Urey[26] was the first to use this principle for calculations on exchange reactions of oxygen derivatives. By elimination of the masses and moments of inertia with the aid of the Teller-Redlich product rule, *Urey* attempted to make the statistical equations simpler and mathematically more elegant. The result of such a transformation is that after all the structural terms have been eliminated, in the main only vibrational frequencies are left in the statistical formulas. However, the frequencies required for the calculation are the frequencies of a harmonic oscillator, since the product rule is valid only for harmonic vibrations. Though this model does not correspond very closely to reality, the simplified calculation procedure has become widely used. *Bigeleisen*[27,28] has applied the Urey method to condensed systems.

An important factor in the investigation of the condensed state is the vapor pressure isotope effect, which is determined either directly as the ratio p_l/p_h of the vapor pressures of the light and heavy pure components or from the difference in the concentrations of the isotopes in the gaseous and in the condensed phases at the natural isotope abundances. The vapor pressure isotope effect for the water species $H_2{}^{16}O$ and $H_2{}^{18}O$ has been measured over the range of temperatures from $+100°C$ ($p_{16}/p_{18}=1.0050$) to $-40°C$ ($p_{16}/p_{18}=1.0228$)[11,29,30].

Table 3. Vapor pressure ratios of isotopic methanol species at 760 torr (according to *Borowitz* [31]).

Isotopic variant	$\frac{p_{16}}{p_{18}}-1$	$\frac{p_{12}}{p_{13}}-1$
CH_3OH	+0.0026	−0.00028
CH_3OD	+0.0022	−0.00029
CD_3OH	+0.0017	−0.00034
CD_3OD	+0.0010	−0.00020

The vapor-pressure ratio of the isotopic methanol species (Table 3) was obtained from the enrichment of the isotopes ^{18}O and ^{13}C in the steady-state countercurrent distillation of natural methanol and its fully deuterated variant[31]. Whereas oxygen gives the normal isotope effect here ($p_l > p_h$), the inverse isotope effect ($p_l < p_h$) is found for carbon under the same conditions. The inversion of the effect is a widespread phenomenon in thermodynamic equilibria. The variation of the ratio of the equilibrium constants with temperature can sometimes be represented by a curve with several minima and maxima, which converges toward a value of unity only at very high temperatures[32].

2.3. Kinetic Isotope Effect

For quantitative predictions of the rate of a chemical reaction it is necessary to know, among other things, the energy states

of the reaction components and of the activated complex. Owing to the difficulty of the problem there is little hope for an absolute calculation of the rate constant k in most cases. A quantitative estimation of the kinetic isotope effect (k_l/k_h) seems more promising[33,34]. For the decarboxylation of malonic acid, for example, the effects of possible transition states of the reaction on the characteristics of the variation of k_l/k_h with temperature can be seen from model calculations[35]. The true kinetic isotope effect is determined either by direct measurement of the absolute reaction rates with isotopically pure substances or by measurement of the fractionation of the isotopes in a mixture of light and heavy components in the course of the reaction (competition method). The absolute method has been used for the investigation of the alkaline methanolysis of aryl benzoates *(1)*[36].

$$CH_3O^{\ominus} + C_6H_5\text{-}C(=\overset{18}{O})\text{-}OAr \longrightarrow C_6H_5\text{-}C(=\overset{18}{O})\text{-}OCH_3 + ArO^{\ominus}$$

(1)

The isotope effect, which is secondary in this case, was found to be $k_{16}/k_{18} = 1.018$ and 1.024 respectively at 30 °C[*]. According to the investigations carried out so far[37-39], the isotope ^{18}O reduces the reaction rate by 1 to 2% in the cleavage and reformation of C—O and O—O bonds. The kinetic isotope effect thus has the same order of magnitude as the $^{13}C/^{12}C$ effect in the cleavage of C—C bonds.

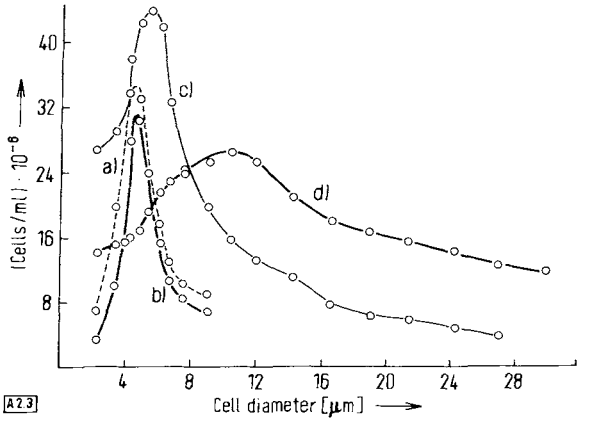

Fig. 3. Isotope effects in the size distribution of *Chlorella* cultures. a) H, ^{16}O, ^{12}C, ^{14}N; b) H, ^{18}O, ^{13}C, ^{15}N; c) D, ^{16}O, ^{13}C, ^{15}N; d) D, ^{18}O, ^{13}C, ^{15}N (from *Katz et al.* [41]).

In plant and animal organisms, there are metabolic processes consisting of large numbers of chemical reactions with steps which must all be correctly timed in relation to one another. The extent to which kinetic isotope effects of oxygen influence or can be used to influence the synchrony of the vital processes is still largely unknown. For bacteria *(Escherichia coli)* grown in $H_2{}^{18}O$, the exponential growth was found to be slower by a factor of 1.5 than the normal growth in natural water ($H_2{}^{16}O$)[40]. For unicellular algae *(Chlorella vulgaris)*, culture in $D_2{}^{18}O$ led to an unusual increase in the average cell size and in the range of variation of the cell size (Fig. 3)[41]. However, no toxic effects of heavy oxygen were observed on replacement of ^{16}O by ^{18}O in the bodies of living mice[42]. The development of the new field of isotopic biology is of great importance to the medical applications of the oxygen isotopes, which have already been put into practice with the use of $C^{18}O$ in lung function tests[43].

[*] An isotope effect is described as secondary if bonds from the isotope are not broken at all or are not broken in the rate-determining step. The value $k_{16}/k_{18} = 1.018$ refers to *p*-bromophenyl benzoate and the value 1.024 to phenyl benzoate.

2.4. Theoretical Evaluation of Isotope Effects

The question of the advantage that can be gained from the measurement of isotope effects in connection with the understanding of natural processes leads to a problem that has recently become increasingly important. The quantitative agreement of the measured isotope effects with the calculated values should be the ultimate criterion for the validity of a theory, whether in the theoretical treatment of anharmonic molecular vibrations or in the model of a liquid structure. Thus the isotope effect in the viscosity of isotopic water species has been studied to check *Eyring*'s theory[13,44].

So far, however, theoretical expectations have only been partly satisfied. The only basis for the evaluation of the isotope effect appeared to be the postulate of the absolute equality of the force fields and electronic structures in isotopic systems. The Born-Oppenheimer approximation, according to which the potential energy of the nuclear motion and the molecular force constants are independent of the isotopic substitution, is regarded as an axiom in particular by *Bigeleisen* and his school[45a]. *Steele*[45b], on the other hand, points out that systems involving polyatomic molecules correspond to complicated many-body problems, in which isotope-dependent potential components of the anharmonic vibrations always occur. According to *Steele*, the physical properties of liquid CH_4 and CD_4 can best be represented by slightly modified potential functions. The "anomalous" isotope effects discovered by *Pinchas*[19-25] for heavy oxygen now satisfactorily show that this assumption of the equality of potentials has no absolute validity. The frequency increases resulting from substitution with ^{18}O in phosphate and borate can only be explained on the basis of changes in potential energy.

New anomalies are also being found in growing numbers for other elements. *Wicke et al.*[46] have reported an unexpected course for the isotope effect in the diffusion of the hydrogen isotopes in palladium. The diffusion coefficient D decreases in the order $D_D > D_H > D_T$. A quantitative analysis of true isotope effects without the use of simplifying basic assumptions is certainly difficult. The Born-Oppenheimer approximation may still be useful, *e.g.* in the form of the Teller-Redlich product rule, if it is used as a reference scale for assessing of the true course of the potential.

The total energy of a molecular system can be resolved into translational, rotational, and vibrational components. If a property of the system is caused primarily by translation processes, the isotope effect depends mainly on the molecular weights, as is found for the vapor pressures and viscosities of the isotopic water species. The anomalous behavior of the molal volume, on the other hand, points to strong vibrational components in the statistical energy distribution of the associated water molecules. The multi-body effect of the molecular vibrations, which should be exaggerated in the condensed phase, is evident even for the isolated single molecule. The anharmonic interaction between the fundamental of the symmetric stretching vibration and the first harmonic

of the deformation vibration leads to a characteristic double line in the Raman spectrum of carbon dioxide, for which *Fermi* was the first to find an explanation. On attempting a quantitative treatment of the isotope effect of the Fermi resonance, one will discover the complete failure of the conventional models[47]. Analysis of the accurately recorded vibrational spectra of the isotopic CO_2 variants in the gas phase showed that the perturbation constant W_0 increases with decreasing mass of the central atom and with increasing mass of the outer atoms:

$$W_0(^{13}C^{16}O_2) < W_0(^{12}C^{16}O_2) < W_0(^{12}C^{18}O_2)$$

In order to establish an empirical law for this mass dependence, it was necessary to assume that the real cause of the isotope effect is not the change in the angle of the CO_2 molecule but the motion of the central atom[47].

3. Fractionation Effects

Because of the differences in the properties of isotopic substances, all transformations or transitions of the substances are accompanied by temperature-dependent fractionations of the isotopes. The elementary effect of this isotope separation is expressed quantitatively by a separation factor α, which is defined for the oxygen isotopes ^{16}O and ^{18}O by

$$\alpha_{18} = \left(\frac{[^{18}O]}{[^{16}O]}\right)_A \Big/ \left(\frac{[^{18}O]}{[^{16}O]}\right)_B$$

and which gives the ratio of the isotope concentrations in the phases or chemical compounds A and B. For simple systems, the separation factor can be correlated with the equilibrium constants and calculated by the methods of statistical mechanics. In the vaporization equilibrium, the distillation separation factor corresponds to the ratio of the vapor pressures of the pure isotopic components, provided that the latter form ideal mixtures and satisfy *Raoult*'s law and *Dalton*'s law of partial pressures. The investigation of the fractionation effects can be used for the determination of "pure" isotope effects, but is more important as a basis for the estimation of paleotemperatures, for the differentiation and characterization of chemically identical substances, and finally for the purification of the isotopes.

The elementary effects of oxygen are attracting increasing interest in physical chemistry. Examples from this field are the investigations on the electrolytic evolution of gaseous oxygen[48] and on the bonding of crystal water in copper sulfate[49]. The fractionation of the oxygen isotopes during the evolution of photosynthetic oxygen in transpiring leaves has recently been studied to explain the anomalously high ^{18}O content of atmospheric oxygen (Dole effect)[50]. The measurement of $^{18}O/^{16}O$ fractionation effects has already become routine in hydrology and geology.

3.1. Fractionation Effects in the Natural Water Balance

The range of variation of the ^{18}O content in natural water is roughly given by the marginal values of 0.199 atom % (ocean bottom water) and 0.189 atom % (polar ice)[51]. Since the isotopic composition of water depends on latitude, elevation, time of year, climate, and other factors, it is a valuable indicator in the study of hydrologic systems. The necessary isotope analyses call for the measurement of minute changes in the ratios $R_{18}=[^{18}O]/[^{16}O]$ and $R_D=[D]/[H]$. The isotope fractionation is expressed internationally by the δ notation as the $^0/_{00}$ deviation in relation to SMOW (Standard Mean Ocean Water):

$$\delta[^0/_{00}] = \left(\frac{R}{R_{SMOW}} - 1\right) \times 1000$$

In mass-spectroscopic analyses using the double-collector technique, one can achieve an accuracy of $\Delta\delta_{18} = \pm 0.1\,^0/_{00}$ or $\Delta[^{18}O] = \pm 0.00002$ atom % and $\Delta\delta_D = \pm 1\,^0/_{00}$ or $\Delta[D] = \pm 0.000015$ atom %[52]. As a result of evaporation and condensation, the water circulating on the terrestrial sphere undergoes a succession of fractionation processes, which are strongly temperature-dependent. In the course of these processes the individual isotopes are fractionated to varying degrees. According to *Craig*[53], the following relation is generally valid for atmospheric precipitation:

$$\delta_D = 8\delta_{18} + 10$$

Under favorable conditions, the evaluation of the δ_D and δ_{18} values of water and ice samples allows the determination of the temperature variation during condensation. Thus the formation and growth of hailstones has been investigated by analysis of the radial distribution of hydrogen and oxygen isotopes (Fig. 4)[52]. The measurement of the δ_{18} and δ_D values is used in ground-water hydrology for the differentiation of bodies of water, and for the elucidation of the relationships between springs, lakes, and ground-water reservoirs, and for the determination of water balances for standing and flowing bodies of water[54].

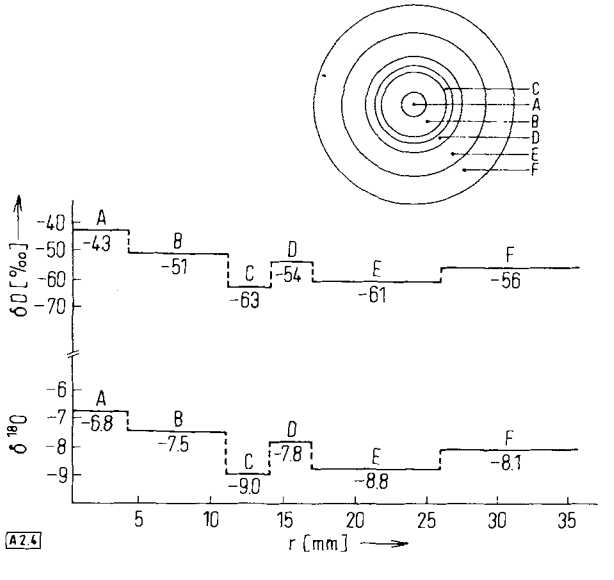

Fig. 4. Radial distribution of deuterium and ^{18}O in a hailstone (from *Majoube et al.* [52]).

3.2. Fractionation Effects in Geochemical and Cosmochemical Processes

Marine deposits of calcium carbonate shells of belemnites, mollusks, and foraminifera exhibit periodic variations of the

$^{18}O/^{16}O$ ratio, which are due to temperature differences at the time of formation of the calcium carbonate. The isotopic composition of the limestone oxygen functions here as a thermometer, which can be calibrated by means of the temperature dependence of the equilibrium constant for the exchange reaction

$$CaC^{16}O_3 + H_2{}^{18}O \rightleftharpoons CaC^{18}O^{16}O_2 + H_2{}^{16}O$$

It is found[55,56] that:

$$T[^\circ C] = 16.5 - 4.3(\delta_{18}^{limestone} - \delta_{18}^{water}) + 0.14(\delta_{18}^{limestone} - \delta_{18}^{water})^2$$

The temperature determination, which can achieve an accuracy of at best $\pm 0.5\,^\circ C$ with an accuracy of $\pm 0.1\,‰$ for δ_{18}, in principle presupposes that the ^{18}O content in the prehistoric oceans is known. By careful elimination of misleading factors, however, absolute paleotemperatures can be extrapolated with an accuracy of 5 °C, the lower time limit being roughly the beginning of the Mesozoic. With this method it has been possible to trace the temperature cycles of the ice ages back over a period of approximately 150 million years (Fig. 5)[57].

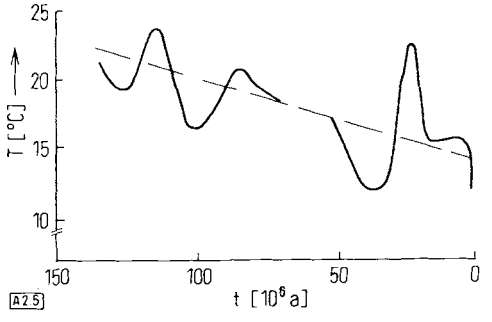

Fig. 5. Temperature variations in middle latitudes during the past 150 million years according to the isotope analysis of marine calcium carbonate [57].

The equilibrium distribution of the isotopes ^{16}O and ^{18}O in the calcite/water system has been the subject of very intensive experimental studies between 0 and 760 °C, and has been used for geothermometry. Other isotope thermometers[55] are based on the $^{18}O/^{16}O$ fractionation effect in the systems quartz/water (250—800 °C), magnetite/water (400—800 °C), and muscovite/water (400—650 °C)[58].

"Internal" thermometers are obtained from the combination of two solid phases after elimination of the aqueous phase. The quartz/magnetite pair has proved to be particularly reliable, whereas no satisfactory establishment of the isotope equilibrium is found for other pairs. Thus if quartz and magnetite or other suitable pairs of minerals are present in a rock, the formation temperature can be determined directly without any information about the gaseous or liquid phase.

Definite systems of substances that can be used for the quantitative evaluation of the fractionation effect are not always present. In general, however, the isotope method is an excellent means for the establishment of genetic relationships between minerals and for determining whether a silicate was formed at high or at low temperatures. The extension of the isotope method to the investigation of meteorites and moon rock[59] leads to the "cosmothermometer", with the aid of which conclusions can be drawn about the formation of planets and moons from interstellar dust and gases[60]. *Clayton et al.* recently found virtually pure ^{16}O in dust particles from the Allende meteorite. This could mean that the solar system is older than is currently believed[61].

3.3. Multiplication of Elementary Fractionation Effects in Technical Isotope Separation Plants

The elementary effect that results in a slight enrichment of an isotopic component in one phase or the other in the thermodynamic equilibrium of two phases is the basis of the method used to obtain the pure oxygen isotopes. The separation processes carried out so far on the technical scale utilize the countercurrent flow between a liquid phase and a gaseous phase, or in the case of thermodiffusion, the countercurrent flow within a gaseous phase (Table 4). With phase reversal at the ends of a separation section, the countercurrent principle leads to multiplication of the elementary fractionation effect, the separating effect of a countercurrent column being measured by the number of theoretical plates.

A theoretical plate, which is defined by a concentration shift corresponding to the elementary separation factor along the separation column, is realized by a column section of a certain height (HETP). Since the elementary effects of the $^{18}O/^{16}O$ and $^{17}O/^{16}O$ separations are very small, the process with the highest separation factor and the smallest HEPT should be the most suitable for the isolation of the oxygen isotopes. The highest separation factor is found in the exchange equilibrium between gaseous CO_2 and water[62]. However, because the exchange proceeds slowly even at high temperatures and in the presence of catalysts, technically acceptable values for the HEPT were not achieved[63]. According to the selection

Table 4. Parameters of the $^{18}O/^{16}O$ and $^{17}O/^{16}O$ separation in technical isotope separation plants. T = working temperature, α = separation factor, HETP = height of a column section corresponding to one theoretical plate.

Process	T [°C]	α_{18}	α_{17}	HETP [cm]	Ref.
H_2O Distillation	+ 77—79	1.0061	1.0032	1.6—2.5	[70]
D_2O Distillation	+ 75	1.0051	1.0026	1.5—2.5	[73]
CO Distillation	−192	1.008	1.004	1.6	[68]
NO Distillation	−152	1.0372	1.0186	1.4—3.8	[64]
$NO/H_2O/HNO_3$ Exchange	+ 25	1.018	1.009	3.7	[66]
CO_2/H_2O Exchange	+ 25	1.042	1.022	*ca.* 600	[63]
	+120	1.024	1.013	*ca.* 17	
O_2 Thermodiffusion	+800/50	1.016	1.008	2.8	[70]

criteria mentioned, therefore, the most favorable process appears to be the countercurrent distillation of nitric oxide, though this calls for an unconventional low-temperature technique. An NO distillation plant with packed columns has recently been set up at Los Alamos; the columns, sunk to a depth of 200m in the ground, are operated at about -150 °C. The plant is designed for an annual isotope output of 12 kg of ^{18}O, 2 kg of ^{17}O, and 18 kg of ^{15}N[64,65].

The possibility of separating oxygen and nitrogen isotopes at the same time also characterizes the Spindel-Taylor process, which is based on the reaction of nitrogen oxides with nitric acid[66]. However, this process seems to be employed for the concentration of ^{18}O only in Tbilisi (USSR)[67]. The low-temperature distillation of carbon monoxide[65,68], which is used for the $^{13}C/^{12}C$ separation, also finds little application for the production of the oxygen isotopes.

The separation process that is of the greatest practical importance at present is the one with the lowest separation factor and the simplest procedure, *i. e.* the countercurrent distillation of water[69]. In this field the Weizmann Institute long held a dominant position. The distillation plant at Rehovot (Israel) has been on stream for several years under steady-state conditions, *i. e.* the input of feed and the removal of product (about 5 kg of ^{18}O with a purity of 98 atom % annually) are performed continuously with constant concentration profiles[70,71]. The ^{17}O intermediate product, which is withdrawn with a ^{17}O concentration of 20 atom %, is partly decomposed by electrolysis and passes in the form of gaseous oxygen into an arrangement of thermodiffusion columns, where it is concentrated up to 96 atom % of ^{17}O. The same principle was used in a ^{17}O separation unit in Oak Ridge[72], which has now been closed down. A particularly promising variant of water distillation is being pursued at the Nuclear Research Center in Karlsruhe. Instead of natural water, the feed material here is the heavy water produced for nuclear reactors, which not only has a high deuterium content but also exhibits a considerable pre-enrichment in ^{18}O and ^{17}O[73,74].

The separation plants being used for the production of pure oxygen isotopes are all experimental plants that have been built by research institutes or research centers and in which economic aspects were of secondary importance. When all these plants have reached full production, a total annual output of 5—6 t of ^{16}O, 20—22 kg of ^{18}O, and 2—3 kg of ^{17}O can be expected. The quantities of oxygen isotopes produced in this way are still very small in comparison with the production of D_2O, but they will allow a more liberal use of these isotopes in research and technical fields than has been possible for a long time.

4. Isotopic Labels

An important class of applications for the oxygen isotopes depends on the possibility of distinguishing between the isotopes of the same chemical element. If a component of a reaction is labeled with an isotope enriched beyond its natural abundance, its behavior in the reaction can be followed qualitatively and quantitatively. The significance of this effect is said to be summed up by *Seaborg* in the following words[75]: "The possibilities for learning that have been offered to science by the discovery of the principle of labeled atoms are comparable in their importance only with the invention of the microscope".

In practice, the principle of labeling with isotopes can be applied in three ways. By the use of *tracers*, it is possible to study the course of a reaction in detail and to elucidate reaction mechanisms. Labeling of selected components and investigation of the *isotope exchange* allows the direct measurement of the formation and decomposition of molecules and the self-diffusion of the atoms of an element. The *dilution method* allows the quantitative determination of components of a reaction mixture without complete separation.

The tracer method utilizes the disequilibrium between both the chemical components and the isotopes, whereas in the isotope exchange reactions the chemical components are in thermodynamic equilibrium, but the isotopes are not. In the dilution method, both chemical equilibrium and equilibrium between the isotopes must be established.

4.1. Stable Tracers

The history of the stable tracer isotope ^{18}O began in 1934, when *Polanyi* and *Szabo*[76] found, in the alkaline hydrolysis of amyl acetate *(2)*, $R=CH_3$, $R'=C_5H_{11}$, in ^{18}O-water, that heavy oxygen had been transferred into the acetic acid, but not into the amyl alcohol. This proof of the alkyl oxygen mechanism[48] for the hydrolysis of esters pointed the way for the development of theoretical organic chemistry (Fig. 6).

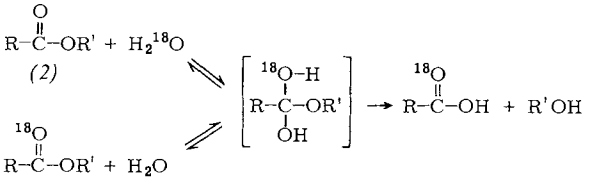

Fig. 6. Mechanism of hydrolysis and oxygen exchange in esters of carboxylic acids.

It was also established by labeling with ^{18}O that the oxygen of the amide in the Beckmann rearrangement of ketoximes comes from the water. There have been so many tracer experiments in inorganic chemistry that we shall merely refer here to the exemplary investigations by *Taube*[48,77], who explained among other things the transfer of oxygen from ozone to SO_2, NO_2^-, Mn^{2+}, and Tl^+, and to *Gordon*'s work[78] on the redox reaction of U^{IV} with Cl^{III}. In the latter case the importance of the tracer is that it enables one to distinguish between $1e^-$ and $2e^-$ transitions.

The application of heavy oxygen in biochemistry precipitated some revolutionary changes in this field[79,80]. The discovery of the oxygenases in 1955 by tracer experiments with labeled oxygen gas marked the end of the Wieland theory, according to which molecular oxygen merely acted as a secondary electron acceptor in the biological oxidation processes. Following the pioneering work of *Mason*[81] and *Hayaishi*[82], an immense number of enzymes capable of transferring atmospheric oxygen directly to the metabolic substrates have been discovered. The inert behavior of molecular oxygen toward exchange reactions proved to be a favorable precondition in these investigations.

In-vivo experiments with oxygen isotopes are often complicated by the fact that the isotopic label is broken down too rapidly by oxygen exchange with the ever-present cell water, which is usually also catalyzed by enzymes. The undesirable isotope exchange is further favored by relaxation effects, which result from the hindrance of mass transfer by the numerous cell membranes and from the ability of the cells to store metabolites. *In-vitro* experiments therefore give more reliable results, but they cannot be carried out in most cases. This problem is particularly evident in plant photosynthesis.

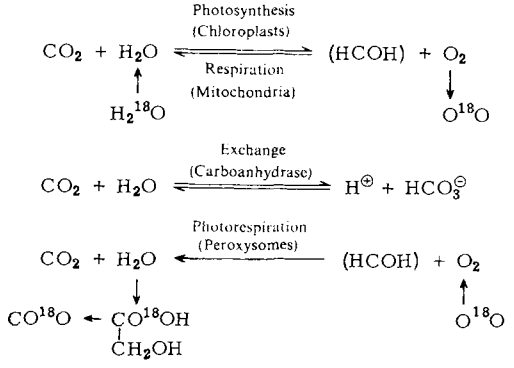

Fig. 7. Fundamental balances of the oxygen turnover in the photosynthesis of plants.

Plants use water and carbon dioxide as starting materials for the biosynthesis of carbohydrates and the production of molecular oxygen (Fig. 7). An attempt to answer the question whether the oxygen formed by photosynthesis comes from the water or from the CO_2 was made as early as 1941 by ^{18}O labeling experiments, which indicated that it comes from the water[83]. Unfortunately it was not taken into account that the oxygen exchange between H_2O and CO_2, additionally accelerated by the enzyme carboanhydrase, leads to very rapid leveling of the ^{18}O concentrations, and that the water, which is present in by far the greater quantity, then determines the ^{18}O level in the evolved oxygen gas. Despite many recent investigations on the photosynthesis mechanism, the source of the photosynthetic oxygen has not yet been established[84,85]. It is certain, however, that if a conclusive answer is possible, it can only be provided by isotope experiments.

Biochemical research is being concentrated at present on special steps in photosynthesis. Thus it has been found with the aid of the tracer technique that the carotenoid pigments in the chloroplasts, particularly the xanthophylls, are involved in the evolution of oxygen[86]. ^{18}O also supplies proof that considerable oxygen absorption occurs during active photosynthesis[87]. The oxygen taken up by the peroxysomes is consumed in the simultaneous photorespiration.

The increasing use of the heavy isotopes of oxygen in the investigation of animal and human metabolism also merits attention. The mechanism of the enzymatic transformation of a carcinogenic substance has been established by an *in-vitro* experiment[88]. The process in question is an isomerization of 2-fluorenyl-*N*-hydroxyacetamide, which is converted into the corresponding *o*-amidophenol by an enzyme system isolated from the microsomes of rat liver.

Samuel et al.[89,90] examined the direct conversion of oxygen gas into CO_2 and water in the brains of living rats. The *in-vivo* isotope analysis was made possible by implanted microprobes. These contained replaceable tantalum wires, which were anodically oxidized by a pulse of current, and the surface oxide was then examined for ^{18}O and ^{16}O by activation analysis (see Section 6.1). The tracer experiments showed that in deep anesthesia the oxygen turnover in the brain cells of the animals decreases by 20% in relation to the normal sleeping value, while it increases by 20% in stress situations. A half-life of about 50 h was found for the water metabolism in rat brain. The respiratory oxygen absorbed by the brain cells maintains several metabolic processes, including the stepwise conversion of phenylalanine into dopamine, which plays an important part in the central nervous system as a neurotransmitter. In order to detect the formation of dopamine in specific regions of the brain, it was necessary to dissect and extract the rat brains. The use of the isotope ^{17}O as a biological tracer was found to be very advantageous for the isotope analysis of the micro quantities of organic material extracted. The ^{17}O, which was administered to the animals in a high concentration in the respiratory oxygen, could be quantitatively determined in the isolated metabolic products by neutron activation.

4.2. Exchange Reactions

The exchange of isotopes between like or unlike molecules is clear proof of the limited lifetimes of chemical bonds. It allows a quantitative determination of reaction kinetics, and particularly the determination of the activation energies of physicochemical processes. The accuracy of such measurements depends to a small extent on the consideration of isotope effects.

Exchange reactions of the oxygen isotopes have been investigated in homogeneous and heterogeneous systems in all aggregation states. The homomolecular oxygen exchange in the gas phase reaches measurable values only above 200 °C[91]. It is accompanied by a heterogeneous exchange between the O_2 gas and the oxide surface of the reaction vessel, which increases rapidly with rising temperature. Far more than 100 publications have been devoted to the heterogeneous exchange between gaseous oxygen and solid oxides[92,93]. It was hoped that the nature of oxide catalysts might be elucidated by this method. Though exchange studies have made important contributions to our understanding of the solid aggregation state, they have not been able to reveal any direct relationship between the exchange rate and activation energy on the one hand and the catalytic activity on the other. The mobility and self-diffusion of oxygen in oxide layers[94,95] on metal surfaces and in oxide ceramics (UO_2)[96] can also be studied with the aid of the stable tracers ^{18}O and ^{17}O.

A focus of great interest in isotope research is the oxygen exchange between organic and inorganic compounds and the solvent water. Since oxygen is an extremely reactive element, there is only a small number of oxygen derivatives that do not exchange oxygen with water under normal conditions[3,97]. These include the anions of the salts $KClO_4$, $KClO_3$, KNO_3, KNO_2, Na_3PO_4, Na_3PO_3, Na_2SeO_4, Na_2SO_4, Na_2SO_3, Na_2CO_3, and CH_3COOK. Acidification of solutions of the salts is enough to induce the exchange process. The only organic oxygen compounds that are resistant to oxygen exchange with water are the normal monohydric or polyhydric alcohols such as methanol and glycerol and the monohydric

and polyhydric phenols. Tertiary alcohols and hydroquinone are again able to undergo the exchange. The resistance of alcohols and phenols has been used for the detection of methoxy groups that had been introduced biosynthetically into the benzene ring[98].

The inability of alcohols to undergo oxygen exchange was also an important part of the argument in the case of the hydrolysis of esters. The acyl-alkoxy cleavage can be demonstrated here beyond any doubt, though isotope exchange between the carbonyl oxygen and the water occurs simultaneously with the hydrolysis of the ester (Fig. 6). Both reactions proceed *via* the same intermediate[97]. Which of the two is faster depends on the pH of the solution and on steric and electronic factors.

The oxygen exchange between carbon dioxide and water, which is due to the formation and decomposition of carbonic acid and of hydrogen carbonate ions, has repeatedly been investigated by the ^{18}O labeling method[99-101]. The kinetic constants of the carbonic acid and hydrogen carbonate reaction as calculated from the exchange rate give a valuable addition to the data obtained by conventional measuring methods, which exhibit considerable divergence. The superiority of the isotope method is seen above all in the measurement of the carboanhydrase activity. Even extremely small quantities of the enzyme can be detected in this way in plant, animal, or human cell tissue[102].

The exchange kinetics with heavy oxygen have also been measured in other systems, *e. g.* in solutions of bromate ions in H_2O and D_2O[103,104]. A photochemically induced oxygen exchange was observed in chemically pure acetone doubly labeled with D and ^{18}O[105].

4.3. Dilution Method

The use of compounds with enriched isotopes for the quantitative chemical analysis of substances that are difficult to isolate is based on a simple principle. A mixture containing a substance A in a molal quantity M with an isotope having the natural abundance c_0 is mixed with a small quantity M' of the same substance A having an isotope concentration c' and allowed to come to general equilibrium. By isolating any fixed quantity of A from the mixture and determining the new isotope content c, one can easily calculate the total quantity M of the substance A with the aid of the mass balance

$$Mc_0 + M'c' = (M + M')c$$

as follows:

$$M = M'(c - c')/(c_0 - c)$$

An example of the application of this principle has been described by *Tamada* and *Furuya*[106]. The oxygen content of steel is usually determined by a vacuum melting technique. It was possible to save a platinum metal bath required for this determination by the use of the isotope method. The exchange of the oxygen in the molten metal with the ^{18}O in a fixed quantity of CO gas led to a measurable decrease in the isotope content, from which it was easy to find the desired oxygen content.

5. Nuclear and Electron Spin Resonance

Among the three stable oxygen isotopes, only the middle one, ^{17}O, has a nuclear spin, which is accompanied by a magnetic moment (nuclear angular momentum quantum number $I = 5/2$). The ^{17}O nucleus also has an electric quadrupole moment. The quantization of the nuclear spin in a magnetic field allows the measurement of characteristic energy states, which provide important information about the embedding of the nucleus in an atomic or molecular structure. The shielding effect of neighboring electrons leads to a "chemical shift" of the ^{17}O resonance line, which, when measured as a relative change in the magnetic field, extends over a range of about 1000 ppm. This effect is about 100 times as large as for proton resonance. The spin-spin coupling between like or unlike nuclei and between nuclei and unpaired electrons causes line splitting, whose multiplicity ($Z = 2NI + 1$) allows conclusions to be drawn about the structure and number of electronically equivalent nuclei. The number, position, and width of the resonance lines are closely related to the mean lifetimes of the molecular states, with the result that the substitution and exchange kinetics can be quantitatively determined.

5.1. Chemical Shift and Structural Problems

The chemical shift of the ^{17}O resonance signal of oxygen compounds is generally measured in relation to the line of $H_2{}^{17}O$. The position of a ^{17}O line in the NMR spectrum is characteristic not only of a certain type of bonding of the oxygen atom but sometimes even of the particular functional group[107]. Thus aldehydes and ketones dissolved in water give ^{17}O shifts from -50 to -70 ppm for the OH groups of the acetal and about -520 to -570 ppm for the double-bonded oxygen in the CO group (Fig. 8).

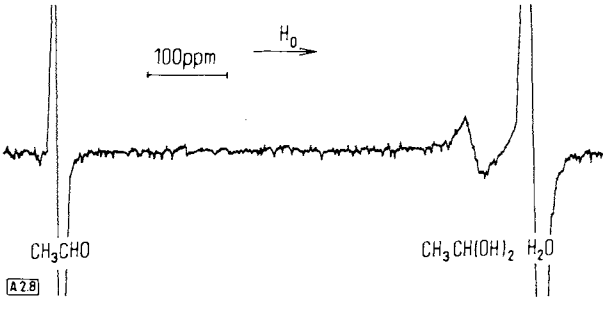

Fig. 8. Chemical shifts of ^{17}O-NMR signals in a solution of acetaldehyde in ^{17}O-water [107].

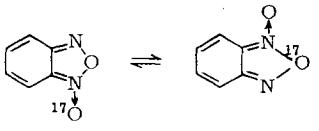
A series of NMR studies have been devoted to the solvation of cations and anions. Provided that the water of hydration is bonded strongly enough to a central ion and undergoes only a slow exchange with the free bulk water, it is represented in the spectrum by a specific signal that stands out from the ^{17}O signal of the solvent. By measurement of the intensities of the separate signals, coordination numbers of 6, 4, and 6 were found for the hydration complexes of the ions Al^{3+}, Be^{2+}, and Ga^{3+} respectively[107]. The above conditions are not satisfied in 1:1 electrolytes. These give only one ^{17}O signal, which results from the superposition of many short-lived solvation states and shows a shift that is proportional to the concentration of the salt[108].

5.2. Reaction Kinetics



There are two ways of following kinetic processes by NMR spectroscopy. Which of these is used in a given case depends on the absolute value of the reaction rate. For processes having a half-life of more than 1 min, the change in the concentration of a ^{17}O-labeled component can be determined directly from the change in the signal intensity. For example, the reversible hydration of aliphatic aldehydes and ketones *(3)*,

$$>C=^{17}O + H_2O \rightleftharpoons >C\begin{matrix}{}^{17}OH\\OH\end{matrix} \rightleftharpoons >C=O + H_2{}^{17}O$$

(3)

which proceeds in accordance with the indicated reaction scheme in the case of ^{17}O-labeled compounds, can be pursued by direct measurement of the CO resonance line. Half-lives of between 6 min and 2 h were found[109,110].

For fast reactions with half-lives of between 1 and 10^{-3} s, the kinetics are determined by analysis of the excess width of the resonance lines. A good example of this technique, which is still little used in ^{17}O measurements, is the intramolecular rearrangement of benzofurazan oxide *(4)*[111].

(4)

The heterocycle has two chemically non-equivalent oxygen atoms, for which two different ^{17}O resonance lines are found at room temperature. With rising temperature these signals become broader and broader until they finally combine to form a new signal, which dominates the spectrum at 100 °C. The intramolecular oxygen exchange is then so fast that the ^{17}O resonance responds only to a mean value of the electron density in the molecule.

5.3. Nuclear Spin/Electron Spin Interaction

In free radicals, coupling occurs between the spins of the unpaired electrons and the nuclear spins. Measurement of the electron spin resonance (ESR) reveals a hyperfine structure of the resonance line in this case. The interaction of an electron with one ^{17}O nucleus leads to six ESR lines, and with two ^{17}O nuclei, as in $^{17}O_2$, to a total of eleven ESR lines. This fine structure is a reliable means for the identification of oxygen atoms in the ESR spectrum and for the selective investigation of their electronic states. The formation of the O_2^- radical in redox processes has been detected by the ESR technique. On oxide surfaces exposed to γ radiation, *Tench et al.*[112-114] obtained the ESR spectra of the species O^-, O_2^-, and O_3^- in the adsorbed oxygen (Fig. 9). It was found that the radical $(O^-)_s$ reacts readily with excess molecular oxygen to form the molecule-ion $(O_3^-)_s$, which changes into $(O_2^-)_s$ above 400 °C. This last species is stable at room temperature and resistant to isotope exchange with the oxide ions of the lattice.

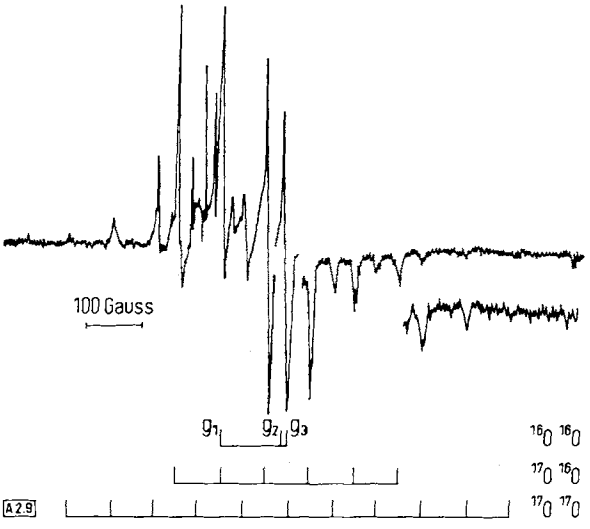


Fig. 9. Fine structure of the ^{17}O electron spin resonance line of molecular oxygen on MgO having a large specific surface area (from *Tench* [114]).

6. Nuclear Reactions

The specific nuclear reactions of the oxygen isotopes proceed regardless of the chemical or physical form in which the oxygen is present. An oxygen isotope may be used as an accelerated projectile or as a stationary target. The nuclear processes with high-energy ^{16}O and ^{18}O ions will not be discussed here because of their small range of applications. Target reactions are important in practice, particularly irradiation experiments with neutrons and with charged elementary particles. Whereas the uncharged neutrons penetrate massive samples of material and cause total activation, projectiles such as the proton, the deuteron, the triton, and the α particle have only a very small penetration depth because of their electric charge, and activation with these particles is confined to surface layers. The transformation and decomposition products formed in the nuclear reactions are also strongly absorbed by the sample if they carry a charge. For this reason, neutron activation is mainly followed by measurement of the γ radiation, which is either emitted promptly or given off by a reaction product after a certain delay.

6.1. Activation Analysis

The conventional isotope analysis of oxygen is carried out in special cases by densimetric methods[115,116], but generally with the mass spectrometer[117,118]. Though quantities of the order of 1 mg to 10 µg can sometimes be determined by direct mass-spectrometric measurement, nuclear activation analysis[119] has definite advantages to offer in trace analysis. A series of nuclear processes, involving a considerable amount of experimental work, is available for use in activation analysis (Table 5).

The (α,n) process[120] has low cross sections, but is relatively simple to use. Unstable isotopes of the elements Ra, Rn, Po, Ac, Am, Pu, *etc.* are used as α sources. In the case of the heavy oxygen isotopes, α capture leads to the formation of stable neon isotopes, and the emitted neutron or γ radiation can be measured. Differentiation between ^{18}O and ^{17}O is possible only by γ spectroscopy. An arrangement for the measurement of neutrons with the aid of BF_3 proportional

Table 5. Nuclear reactions and activation analysis of the stable oxygen isotopes.

Isotope – nuclear reaction —product	Cross-section	Excitation energy	Half-life of product	Decay radiation of product	Detection limit of isotope
$^{18}O(\alpha,n\gamma)^{21}Ne$	60 mb ($\bar{\sigma}$)	5—6 MeV			0.1 mg
$^{17}O(\alpha,n\gamma)^{20}Ne$	60 mb ($\bar{\sigma}$)	5—6 MeV			
$^{18}O(p,n)^{18}F$	200 mb	4 MeV	112 min	$\beta^+ \rightarrow \gamma$	10^{-8} mg
$^{17}O(p,n)^{17}F$		4 MeV	66 min	$\beta^+ \rightarrow \gamma$	
$^{18}O(p,\alpha)^{15}N$	75 mb	0.7 MeV			10^{-9} mg
$^{16}O(d,p)^{17}O$	40 mb	0.9 MeV			10^{-8} mg
$^{18}O(n,\gamma)^{19}O$	0.2 mb	thermal	29 s	β^-, γ	2 mg
$^{17}O(n,\alpha)^{14}C$	235 mb	thermal	5568 a	β^-	
$^{17}O(n,p)^{17}N$	22 mb	14 MeV	4.2 s	β^-, n	
$^{16}O(n,p)^{16}N$	40 mb	14 MeV	7.4 s	β^-, γ	0.2 mg

counters, which has been developed to a patentable stage by the Weizmann Institute, allows continuous measurements on paper chromatograms[121]. However, the detection sensitivity achieved so far is only 40 to 100 µg of ^{18}O, which is unsatisfactory.

With high-energy protons, *e.g.* from the beam of a cyclotron, the heavy oxygen isotopes are converted into the positron emitters ^{18}F and ^{17}F, with simultaneous emission of neutrons. The annihilation radiation of the liberated positrons is used for the ^{18}O analysis. The resulting γ quanta are either measured directly or detected by the blackening of photographic films (autoradiography). Since a high degree of interference is caused by the ^{18}O background of natural oxygen in a paper chromatogram, the chromatograms must be eluted in segments in biochemical tracer analysis, the separated substances then being transferred to tantalum or platinum plates for the proton irradiation[122,123]. Recoil protons formed in nuclear reactors by the action of fast neutrons on substances containing water also initiate a (p,n) reaction on ^{18}O nuclei. This technique has also been used in activation analysis[124].

Amsel et al.[125,126] have developed a special irradiation and measuring apparatus for the microanalysis of oxide films on metal surfaces. This apparatus allows a parallel determination of ^{18}O by means of the (p,α) reaction and of ^{16}O by the (d,p) reaction. To measure the total quantity of an isotope in a surface segment, use is made of plateau regions of the cross-sections for the specific reactions. Thus the target is irradiated in a high vacuum with ≈700 keV protons for the ^{18}O analysis and with 800—900 keV deuterons for the ^{16}O analysis. The prompt α particles or protons are recorded. With isotope standards that can be obtained by anodic oxidation of metallic tantalum in corresponding water samples, it is possible to achieve a relative accuracy of 1% in the measurements. The detection limits is 10^{-12} g of oxygen. This technique was the precondition for the *in-vivo* isotope analysis of cell water in the brains of living rats (see Section 4.1)[90]. In addition to the pure isotope analysis, *Amsel*'s method also allows a quantitative determination of concentration profiles of the oxygen isotopes up to a layer depth of about 1 µm. The measurement of the depth distribution of oxygen is based on the resonance absorption. There is a narrow resonance at 629 keV in the cross section of the (p,α) reaction of ^{18}O (Fig. 10). If a target containing ^{18}O is bombarded with protons having exactly this resonance energy, the α particles are emitted almost exclusively from the first surface layer (50—100 Å). If the energy of the proton is increased to slightly above 629 keV, the resonance zone is displaced into the crystal lattice because of the deceleration effects. The α particles emerging

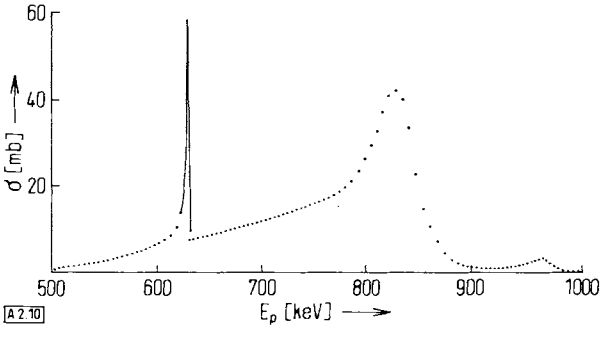

Fig. 10. Cross-section of the (p,α) reaction of the isotope ^{18}O (from *Amsel* [126]).

from the resonance zone provide a measure of the ^{18}O concentration in this zone. Figure 11 shows the ^{18}O profile in a tantalum oxide with a sandwich structure (140 Å—^{18}O/840 Å—^{16}O/420 Å—^{18}O)[126]. The Amsel method of microprofile analysis is extremely suitable for the investigation of diffusion, corrosion, and passivation phenomena in semiconductors and metals[126-128].

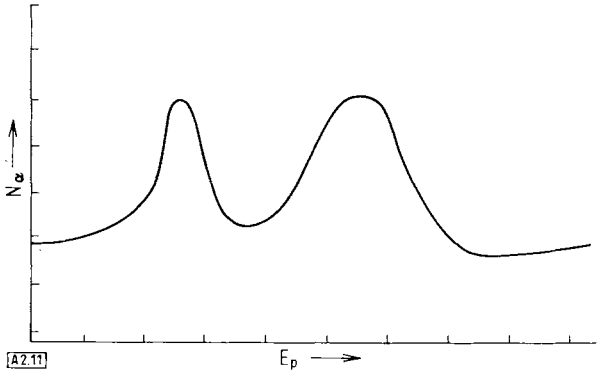

Fig. 11. Depth distribution of ^{18}O in the surface film of an electrolytically oxidized sample of tantalum with ^{18}O—^{16}O—^{18}O layering [126]. E_p = 390 eV/channel, N_α: counts/division.

Nuclear reactors moderated with light or heavy water are excellent neutron sources for activation analyses with thermal

neutrons. The ^{16}O nucleus, with its "magic" number of protons and neutrons (8), is too stable to be activated under these conditions. The ^{18}O nucleus is converted by neutron capture into the unstable ^{19}O, whose γ radiation can be used for the analysis[129]. Because of the very low cross-section, however, fairly large quantities of material are required for an analysis of this type.

The activation of ^{17}O, which has an excellent cross-section[130], seems much more promising. The ^{14}C produced here by an (n,α) reaction is also formed in the thermal neutron flux from natural ^{14}N, and is therefore not specific for the detection of ^{17}O. On the other hand, the prompt α radiation is specific for the ^{17}O process, provided that the presence of the isotopes ^{6}Li, ^{10}B, and ^{21}Ne can be ruled out. This is always so in the biological samples from tracer experiments, with the result that the (n,α) process of ^{17}O is extremely advantageous in biochemistry.

Malmon[131] suggested a microtrack method for the recording of the prompt α particles. If a chromatogram is irradiated while it is in close contact with a metal or plastic foil, the liberated α particles leave deceleration tracks in the foil; these can be counted by means of electron microscopy in gold or platinum foils or under the optical microscope in the case of plastic foils (after amplification by alkaline etching). This simple procedure on the one hand allows the simultaneous irradiation of any number of samples, and on the other it allows the localization of the tracer ^{17}O in biological fine structures. It was experimentally introduced into biochemistry by *Samuel*[90].

Activation analysis with fast neutrons responds to all three isotopes of oxygen. Fast, nondestructive analyses of many stable isotopes are possible with neutron generators that operate with accelerated deutrons and tritium targets and use the nuclear reaction

$$D + T \rightarrow {}^{4}He + n + 14\,MeV$$

for the production of 14 MeV neutrons[132]. Because of the low cross sections, the process again calls for fairly large quantities of substance in the case of the oxygen isotopes. The activation of ^{17}O leads by the reaction sequence[133]

$$^{17}O(n,p)^{17}N \xrightarrow[4.2\,s]{\beta^-} [^{17}O]^* \xrightarrow{n} {}^{16}O$$

to delayed neutrons that are easy to measure. The activation of ^{16}O with 14 MeV neutrons is a method often used for the determination of oxygen in metals, graphite, and other pure substances[134–137]. It is even applied in medicine for blood-flow measurements, in which the heart is irradiated with neutrons for one second and the 6 MeV γ radiation of the reaction product ^{16}N is then monitored in several parts of the body[138].

6.2. Radioactive Energy Sources

The development of heart pacemakers and artificial pumps, which are implanted in the human body to assist the blood circulation, has made significant progress with the use of $^{238}Pu^{16}O_2$ as an energy source. ^{238}Pu, which is produced from ^{237}Np in nuclear reactors, decomposes with a half-life of 87 years with α and γ emission[139]. A spontaneous fission with a half-life of 4.8×10^{10} years occurs at the same time. Since plutonium is used in the oxide form for reasons of chemical stability, two neutron-producing processes take place in PuO_2 containing natural oxygen, *i. e.* the spontaneous fission with a yield of about 2800 n s^{-1} g^{-1} of Pu and the (α,n) reaction of the isotopes ^{18}O and ^{17}O with a total yield of 20000 n s^{-1} g^{-1} of Pu. In addition to these there are also corresponding nuclear reactions with other trace elements, particularly fluorine[140, 141]. These processes are extremely undesirable, since the neutrons liberated pass through the wall of the power pack and activate elements in its immediate vicinity. With isotopically pure ^{16}O, at least the (α,n) process of the heavy oxygen isotopes can be completely eliminated.

Two methods are used for the preparation of $^{238}Pu^{16}O_2$. The PuO_2 obtained from Pu(III) oxalate is allowed to undergo exchange with pure $^{16}O_2$ gas at 850 to 105 °C or with $H_2{}^{16}O$ at 700 °C, and is then sintered at 1200 °C[142]. For the isotope analysis of the PuO_2, a high-temperature reduction was carried out with pure carbon, and the CO formed was determined by mass spectrometry after gas-chromatographic separation in a stream of He[143]. The best $^{238}Pu^{16}O_2$ samples obtained so far gave a neutron emission of 3000 n s^{-1} g^{-1} of Pu.

The world demand for high-purity ^{16}O for biomedical, radiation-medical, and power investigations and applications amounts to 100 to 1000 kg per year[65], and is still increasing. This fact clearly indicates that the isotopy of the material world is by no means a subject merely for investigation in fundamental research. The breakthrough in isotope research to the industrial scale, which was first achieved for deuterium, is now being paralleled by the application of the stable isotopes of the vital element oxygen.

Photochemistry in Interstellar Space and Reactions Generating Interstellar Molecules

By H. D. Breuer[*]

Over 20 different molecules and radicals have so far been detected in interstellar space. The number of such molecules and radicals and their frequently complicated structure raise the question of the processes leading to their formation. Diatomic molecules and radicals could arise in gas-phase reactions. Formation of polyatomic molecules can be explained in terms of reactions proceeding on the surface of dust particles and possibly involving interstellar radiation. The author demonstrates, with the aid of a model, that the molecular abundances and distributions within dust clouds in certain regions can be explained by photocatalytic reactions.

1. The Interstellar Medium

The discovery of over 20 molecules (including polyatomic radicals) in interstellar space by radioastronomy has opened up a new area of study uniting two fundamentally different branches of research, astrophysics and chemistry. To the astrophysicist the molecules are excellent probes for research into the interstellar medium since their spectra yield information about the physical conditions at the location of the molecule which is inaccessible to all other observational techniques applied today. For the chemist the question arises how molecules are formed at all in interstellar space. Any answer to this question requires that we first characterize interstellar space and the interstellar medium and examine what factors can affect the formation and dissociation of molecules.

Interstellar space is occupied by material composed mainly of two components, interstellar gas and interstellar dust. The chemical composition of interstellar gas follows from the relative cosmic abundances of the elements (Table 1). Hydrogen, responsible for 70% by mass, is the most common element, followed by helium (28%). Elements heavier than helium constitute the remaining 2%.

All available evidence indicates that this composition is constant throughout our galactic system. Interstellar dust is amenable to observation only where its density is sufficiently great. The negative photograph of the Orion nebula reproduced in Figure 1 illustrates a concentration of this kind.

The areas appearing dark are regions of intense optical radiation arising from the ionized gaseous component. The contours

Table 1. Relative cosmic abundance of the elements (after [1]).

Element	Abundance relative to H	First ionization potential [eV]
H	1.0	13.6
He	1.0×10^{-1}	24.6
C	2.3×10^{-4}	11.3
N	1.3×10^{-4}	14.5
O	6.0×10^{-4}	13.6
Ne	2.0×10^{-4}	21.6
Na	4.4×10^{-6}	5.1
Mg	4.4×10^{-5}	7.6
Al	2.2×10^{-6}	6.0
Si	4.8×10^{-5}	8.1
S	2.1×10^{-5}	10.4
Ar	7.1×10^{-6}	15.8
Ca	2.5×10^{-6}	6.1
Fe	3.2×10^{-5}	7.9

shown link points of equal radio emission. Towards the center of the radio frequency emission, the optical radiation appears to be blocked over a wide streak, appearing white in the Figure, while the radio frequency emission remains unaffected. This blocking of the optical radiation is due to interstellar dust. The diameter of the dust particles is of the same order of magnitude as the wavelength of optical radiation: hence the latter is strongly attenuated. In contrast, the dust particles have little influence on the longer radio waves.

Whereas extinction and polarization measurements provide comparatively reliable information about the size of the dust particles, only very little is known about their chemical composition. The range of materials suggested extends from ice *via* metals to diamond. However, recent observations[2] suggest that at least some of the regions contain silicates. The Orion nebula is just one example of a cloud made up of gas and dust. Observations show that a whole range of cloud types exist. They differ primarily with regard to density, *i.e.* the concentration of dust, and size[*]. In the extreme case, gravitational forces can arise in very dense clouds which can overcome the internal gas pressure. The cloud then collapses to form the precursor of a new star.

Since the interstellar molecules are observed mainly in dust clouds, and these optically dense clouds are accessible to radioastronomical measurements, it becomes possible to directly observe star formation at this stage.

In the various types of clouds the hydrogen density[**], and thus also the density of the other elements, varies between 10 and $10^7\,cm^{-3}$. The ratio of hydrogen density to the dust density is about 10^{10}. The kinetic gas temperatures are likewise dependent upon the density. Outside the cloud several 10^3 °K are observed at a hydrogen density of $1\,cm^{-3}$ while this temperature can drop to well below 100 °K in dense clouds.

The temperature of the dust particles, which absorb energy in the visible and ultraviolet and radiate in the far infrared, lies between 50 and 20 °K, depending on size and chemical composition, in free interstellar space. In very dense clouds the temperature can be as low as 5 °K.

Further characterization of the interstellar medium also includes the interstellar radiation field, the integrated radiation emitted by the stars into interstellar space. However, only the spectral range above 912Å is of interest since photons having $\lambda \leqslant 912$ Å are able to ionize hydrogen and are therefore absorbed in the immediate vicinity of the emitting star. According to *Habing*[3] the radiation density in dust-free regions has a mean value of $U_\lambda = 4 \times 10^{-17}\,erg\,Å^{-1}\,cm^{-3}$[***]. The

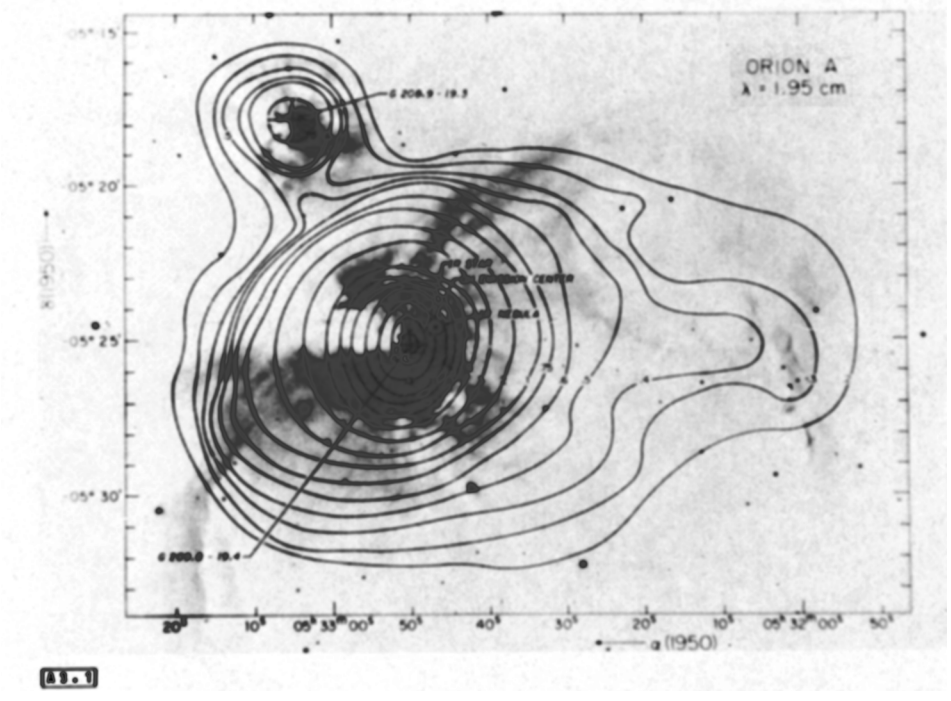

Fig. 1. Negative reproduction of the Orion nebula. Explanations in text. The Orion nebula is situated about 1.6×10^3 light years from the Earth. The photograph was kindly provided by the Max-Planck-Institut für Radioastronomie, Bonn.

[*] The radii of the clouds are in the range 10^{18}—10^{20} cm.

[**] The hydrogen density is defined as $N_H\,cm^{-3}$.

[***] Recent satellite measurements [4] show that the radiation flux rises to about 10×10^{-17} erg Å cm^{-3} in the proximity of the sun.

wavelength-dependent extinction of the radiation by interstellar dust is shown in Figure 2.

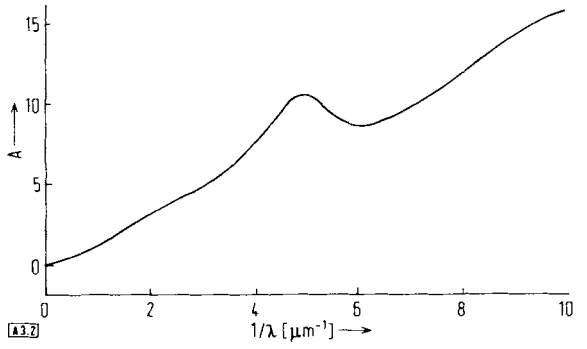

Fig. 2. Extinction A of interstellar radiation by dust as a function of the wavelength (after [1]). The extinction is proportional to the optical depth. $1/\lambda = 2\,\mu m^{-1}$ corresponds to $\lambda = 5000$ Å, $1/\lambda = 10\,\mu m^{-1}$ corresponds to $\lambda = 1000$ Å.

For our further treatment of molecule formation and the lifetimes of interstellar molecules it is of importance that the extinction increases very steeply with decreasing wavelength.

2. Interstellar Molecules

2.1. Interstellar Molecules and Theoretical Models of Molecule Formation

The molecules identified so far in interstellar space are listed in Table 2. Three representatives, namely CN, CH, and CH^+, were detected as long ago as 1940 by their optical spectra[5]. However, the majority of these molecules were found by radioastronomic measurements, generally by observing rotational transitions in the electronic ground state.

Table 2. List of molecules and radicals discovered in interstellar space (after [1]).

Molecule	Spectral region	Column density [cm^{-2}] [a]	Year of discovery
H_2	UV	$\approx 10^{20}$	1970
OH	cm	10^{12}—10^{16}	1963
SiO	mm	$\approx 10^{13}$	1971
H_2O	cm	?	1969
NH_3	cm	?	1968
CH	visible	$\approx 10^{13}$	1937
CH^+	visible	$\approx 10^{13}$	1941
CN	mm, visible	$\approx 10^{15}$	1940
CO	mm, UV	10^{17}—10^{19}	1970
CS	mm	10^{13}—10^{14}	1971
OCS	mm	$\approx 10^{16}$	1971
HCN	mm	10^{14}—10^{15}	1970
H_2CO	cm	10^{12}—10^{16}	1969
HNCO	cm, mm	$\approx 10^{14}$	1971
H_2CS	cm	?	1971
HCOOH	cm	$< 10^{13}$	1970
HC_3N	cm, mm	$\approx 10^{16}$	1970
H_2CNH	cm	$\approx 10^{14}$	1972
CH_3OH	cm, mm	?	1970
CH_3CN	mm	$\approx 10^{14}$	1971
$HCONH_2$	cm	$> 10^{11}$	1971
$HCOCH_3$	cm	$\approx 10^{14}$	1971
CH_3CCH	mm	?	1971

[a] The column density is defined as the volume density integrated over the visual beam and projected onto $1\,cm^2$. The densities given here are mean values.

As more and more interstellar molecules were discovered, increasing attention was focused on the question of possible formation reactions. In view of the varying conditions of density and temperature in interstellar space it would appear unlikely that all the molecules observed are formed by the same type of reactions. For instance, formation of diatomic molecules and radicals can be explained by binary collisions in the gas phase. *Solomon* and *Klemperer*[6] have calculated the densities of diatomic molecules for a particular region of the constellation Ophiuchus for which adequate observational data are available[7]. Assuming a kinetic gas temperature of 20 °K, a hydrogen density of $100\,cm^{-3}$, and the corresponding relative densities of other elements according to Table 1, about 30 simultaneous exothermic reactions were considered.

The most important reaction was found to be

$$C^{\oplus} + H \rightarrow CH^{\oplus} + h\nu$$

The reaction

$$C + H \rightarrow CH + h\nu$$

is of less significance since under the prevailing conditions the interstellar radiation is able to almost completely ionize atomic carbon. The other diatomic molecules and radicals are formed in exchange reactions. Some densities calculated in this way are compared with observed values in Table 3.

Table 3. Comparison of calculated and observed column densities of diatomic molecules and radicals (after [6]).

	Column density [cm^{-2}] obs.	calc.
CH	4.3×10^{13}	1.7×10^{13}
CH^+	2.6×10^{13}	1.3×10^{13}
CN	8.3×10^{12}	6×10^{12}
NH	$< 8 \times 10^{12}$	0
OH	$< 7 \times 10^{13}$	0
CO	—	2.4×10^{14}
$C_2 + C_2^+$	—	7×10^{12}

The discrepancies, which are sometimes of considerable size, arise on the one hand from the lack of precise knowledge of some of the transition probabilities required in calculation of the rate constants, and on the other from the considerable errors that can occur in the column densities determined from radioastronomical observations.

Much greater difficulties are associated with the question of formation of polyatomic molecules. In principle, the presence of the molecules can be explained in two ways: The saturated molecules could have been formed by successive addition of atoms or radicals; alternatively, the observed molecules may have been formed from fragments of larger molecules originating from comets[8] or produced in regions of very high density and temperature[9], for example where a new star is formed, and transported by radiation pressure to the cold clouds. For reasons discussed in Section 2.3, the second explanation is highly improbable.

Dalgarno and *McRay*[10] studied the gas-phase formation of molecules in reactions involving negative ions. Their results show that the rates of formation of OH and H_2O are suffi-

ciently large in clouds of low density. H_2CO can be formed by reactions involving $H^{\ominus}$ or $O^{\ominus}$ according to:

$$H^{\ominus} + HCO \rightarrow H_2CO + e^{\ominus}$$
$$O^{\ominus} + CH_2 \rightarrow H_2CO + e^{\ominus}$$

However, the rates of formation are too small to provide the sole explanation of the observed abundances. Application of this reaction mechanism to more dense clouds assumes the presence of an ionizing radiation source within, or in the close proximity of, the cloud.

For energetic reasons, many of the observed molecules can only be formed by three-body collisions in the gas phase. However, owing to the low densities encountered in interstellar space the probability of three-body collisions is much too low to account for the molecular densities observed. Interstellar dust is therefore now thought to play an essential role in the formation of polyatomic molecules. Since, as already mentioned, the chemical composition of the dust particles is unknown, nothing can be said about their catalytic activity. Merely assuming that atoms or relatively small radicals are adsorbed onto the surface of dust particles, it can be shown that the residence times for all pertinent atoms and radicals are of adequate duration and that, in spite of the low environmental temperatures, the atoms are capable of diffusing over the surface and of undergoing mutual interaction.

Possible reactions of this kind have been examined by *Watson* and *Salpeter* in a theoretical study[11]. Although their investigation indicated adequately fast rates of formation on the surface of dust particles, the proposed model requires photons in the wavelength range between 1000 and 2000 Å for the desorption process. However, this part of the radiation field will experience pronounced attenuation in the more dense clouds in which most of the molecules are observed (see Fig. 2).

2.2. Experimental Studies on Molecule Formation in Surface Reactions

Various experimental studies have indicated that radiation above 2000 Å can have some influence on molecule formation.

In simulation experiments on the formation of organic molecules on the surface of Mars, *Hubbard et al.*[12] obtained $^{14}CO_2$, ^{14}C-formaldehyde, and ^{14}C-acetaldehyde, as well as several other organic compounds containing ^{14}C which could not be uniquely identified. The starting materials were ^{14}CO and water vapor, diluted in $^{12}CO_2$ or nitrogen. Either sterilized and baked soil or ground Vycor glass was employed as substrate. The wavelength region of the radiation used was between 2000 and 3000 Å.

Similar results were previously obtained by *Breuer* and *Moesta*[13] on irradiation of gases adsorbed onto metal surfaces. In these experiments, gases such as hydrogen, nitrogen, oxygen, carbon monoxide, and methane were adsorbed onto ultrapure metal surfaces (tungsten and nickel) under ultrahigh vacuum conditions and irradiated with 2537-Å light (mercury resonance line). It had been established in earlier work[13a] that photoreactions are possible in adsorbed layers in this wavelength range. The gases were chosen so as to include the most common elements found in interstellar gas and to ensure that small molecules, such as CO and hydrocarbon radicals, are present in the adsorbed layer. While the metals used on no account reflect the physical and chemical composition of interstellar dust, they do have the advantage of permitting work on well defined surfaces and the study of the true primary steps of the photoreactions without fear of spurious results due to interfering impurities. The reaction products were detected by mass spectrometry. Moreover, deuterated gases (D_2, CD_4) were used and the natural isotopic abundances $^{12}C/^{13}C$ were observed to guarantee correct identification. The initial reaction consists in electronic excitation of the adsorbed CO molecules, followed by dissociation into C and O atoms. The C and O atoms which may be excited can react further with other adsorbed atoms, molecules, or radicals.

Table 4 lists the molecules identified in the experiments. Owing to the method of detection employed, no final decision can be reached whether the radicals observed are fragmentation products formed in the ion source of the mass spectrometer or whether they are desorbed as radicals from the surface. For some of the molecules, the cross-sections for formation and desorption from the surface are also given. These cross-sections can be calculated from the spatial requirement of the molecules, the quantum yield of the corresponding photoreaction, and from apparatus parameters such as pumping rate, radiant flux, *etc.*

Table 4. Identified radicals and molecules as products of photocatalytic reactions. Substrate: tungsten; $\lambda = 2537$ Å.

Adsorbed gases	Identified products	Cross-section [cm^2]
CO	C_2O, CO_2, C_2O_2, C_3O_2	
CO, CH_4	H_2CO	10^{-16}
CO, H_2, N_2	CN	1.5×10^{-18}
	HCN	5×10^{-19}
	N_2H	
	NO	
	N_2H_2	
	C_2N	
	C_2HN	
	C_2H_2N	
	CH_3CN	1.5×10^{-18}
	HNCO	1×10^{-18}
	N_2O	
	$HCONH_2$	1×10^{-18}
	HC_3N	5×10^{-19}

The order of magnitude of the cross-sections shows that these photoreactions can make a considerable contribution to the production of molecules. It should, however, be borne in mind when applying these results to molecule formation in interstellar space that the desorption probability may be reduced by the low environmental temperature[*], and that the catalytic activity of the dust particles and their surface heterogeneity are unknown.

2.3. Lifetimes of Interstellar Molecules

Whereas considerable uncertainty still surrounds the events occurring in molecule formation, more precise information

[*] Recent experiments have shown that the formation reaction also proceeds at 65 K.

is available about their dissociation, and hence about their lifetimes. *Stief*[14] estimated the lifetimes in clouds of various dust concentrations. The lifetime of a molecule against photodissociation depends upon three factors: the absorption cross-section; the quantum yield; and the radiation field to which the molecule is exposed.

Apart from the "interstellar" molecules CO, H_2O, H_2CO, OCS, and NH_3, the calculations included a number of others whose existence is suspected but not yet confirmed.

In the wavelength region above 912Å the quantum yield Φ for dissociation is about unity for all molecules except CO; this molecule has the highest dissociation energy (11.1 eV ≙ 1115 Å). At higher densities, dissociation can also occur at wavelengths above 1115 Å. However, since dissociation then involves collisions with excited molecules this event is negligible under interstellar conditions. No laboratory studies have been performed in the wavelength range between 1115 and 912 Å so that no adequate answer can be given regarding the dissociation probability of CO in interstellar space.

Stief's calculations show that in dust-free regions the lifetimes of all the molecules studied are less than 100 years. In Figure 3 the lifetimes of several molecules are plotted as functions of the extinction in the cloud, and thus as functions of the dust concentration.

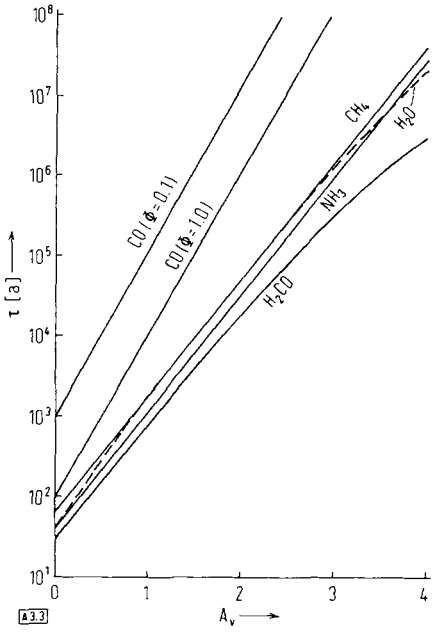

Fig. 3. Calculated lifetimes τ of several molecules as a function of the dust density, expressed as the extinction in the visible region, A_v; Φ = quantum yield (after *Stief* [14]).

Owing to the uncertainty associated with determination of the dissociation quantum yield for carbon monoxide the lifetime is calculated for two different values (Φ = 0.1; Φ = 1.0). The fact that the lifetimes in dust free regions are below 100 years has a direct consequence in molecule formation. In this very short time (on an astronomical scale), the molecules can only travel a distance which is much shorter than that between two clouds. Hence it follows that molecules can only be formed in those clouds in which they are observed. The possibility that the molecules were formed in other regions, mentioned in Section 2.1, is therefore ruled out.

3. Model for Formation and Distribution of Molecules in Dust Clouds

The unknown chemical and physical properties of the dust particles clearly complicate any discussion of concepts pertaining to molecule formation. Lack of precise knowledge of the chemical nature of the adsorption layer presents a further difficulty. Assuming that the original coverage reflects the cosmic abundances of the elements, the composition can change unpredictably as soon as a reaction starts and radicals appear on the surface. If the dust particles also have catalytic properties, certain reactions may proceed preferentially and the composition of the adsorption layer undergoes drastic changes.

However, in order to estimate whether photocatalytic reactions can contribute to molecular densities as observed in interstellar space, in spite of the difficulties mentioned, one can make the following assumption[15]: The surface of the dust particles is completely occupied by "reactive particles". A photon flux which can be calculated from the radiation density impinges on the surface. Compared with the radiation outside the cloud, the photon flux is attenuated by a factor of 10^3 by the dust. This attenuation corresponds to a dust density of 10^{-10} cm^{-3}. The dust particles have a diameter of 0.1 μm. An average value of 10^{-18} cm^2 is adopted for the cross-section for formation and desorption. At an attenuation of 10^3, the mean lifetime τ is about 10^{13} s[13].

For $\approx 10^{15}$ adsorbed particles per cm^2 dust surface and a photon flux (in the range 2000 to 3000 Å) of 1.5×10^5 cm^{-2} s^{-1} we thus obtain a mean steady-state molecular density of about 5×10^{-5} cm^{-3}, or, for a cloud diameter of 10^{19} cm (*ca.* 10 light years), a column density of 5×10^{14} cm^{-2}. Comparison with Table 2 shows that this value roughly corresponds to the mean molecular density of the polyatomic molecules.

Since formation of molecules in photocatalytic reactions occurs at higher wavelengths than photodissociation in the gas phase, the distribution of the molecules in dust clouds can be qualitatively pictured as shown in Figure 4.

A Gaussian distribution is assumed for the dust cloud; however, the same considerations apply to other distributions. Division of the radiation density into $U_\lambda < 2000$ Å and $U_\lambda > 2000$ Å accounts for the fact that the short-wave ultraviolet radiation is much more strongly attenuated than the longer wavelength component. Since molecule formation is directly proportional to the dust density, the greatest molecular densities are expected at the center of the cloud, or at the point of highest dust concentration for irregular dust distributions. This case is shown for the molecules M_1 and M_2.

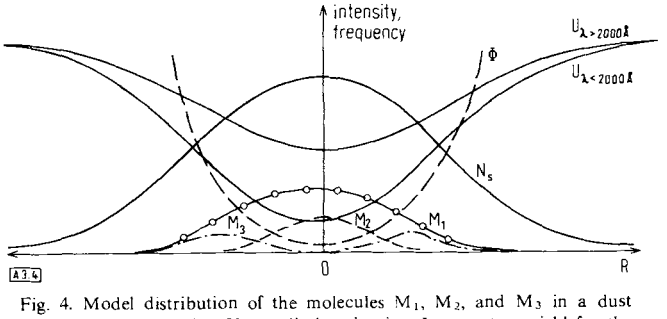

Fig. 4. Model distribution of the molecules M_1, M_2, and M_3 in a dust cloud. N_s = dust density, U_λ = radiation density, Φ = quantum yield for the photodissociation, R = distance from center of cloud.

If $\sigma_1 > \sigma_2$ (formation cross-section for molecules M_1 and M_2, respectively) a greater abundance will result for M_1 than for M_2 for the same wavelength dependence. Should higher photon energies be required for a formation reaction, the maximum shifts to a region into which the corresponding radiation penetrates with sufficient intensity. Owing to the lower dust concentrations and the enhanced dissociation probability, correspondingly reduced molecular densities will then be expected. M_3 reflects this kind of behavior. The size of the molecular clouds is limited by the photodissociation, which, in turn, is a function of the dust density. The curve designated Φ in Figure 4 is the integral quantum yield, which reaches the value 1 in dust-free regions.

Distributions of this kind, where several kinds of molecules are mixed in the interior of the cloud while the individual molecular species occupy regions of differing size, are indeed observed.

4. Summary and Outlook

It is now regarded as certain that polyatomic interstellar molecules are formed on the surface of dust particles. However, uncertainty still surrounds the question of which reactions are responsible for their formation. An attempt has been made in the above model to show that an effective contribution of photocatalytic reactions can be deduced from experimental results such as cross-sections, or from astronomic observations such as radiation densities and dust particle sizes.

Laboratory experiments have shown that many other molecules and radicals are formed in addition to the molecules observed in interstellar space. Thus molecules such as C_2H_2, CH_4, or CO_2, whose detection by radioastronomic methods is extremely difficult if at all possible, are also presumed to occur in interstellar space. Any overall picture of chemical reactions in interstellar space should, of course, also include these molecules. For the same reason, a structural selection, such as could be read off from Table 2, would appear purely accidental.

A deeper understanding of the physical and chemical conditions in interstellar space will require both further extensive radioastronomic studies and laboratory experiments. The latter could represent a valuable supplement to radioastronomical observations, since simulation experiments could, for example, elucidate the chemical structure of interstellar dust or answer the question why NO is not observed as an interstellar molecule.

5. Addendum[*]

Since the observation and study of interstellar molecules is a very young branch of scientific research, it is hardly surprising that a large number of publications in this field have appeared since the completion of this manuscript in May 1973. Two of these papers should not go without mention here. In a review article *McNally*[16] has described the formation and destruction mechanisms currently under discussion. A special model for very dense dust clouds is discussed by *Herbst* and *Klemperer*[17]. In these very dense clouds the hydrogen is present exclusively in molecular form. The density is given as $10^4 cm^{-3} < N_{H_2} < 10^6 cm^{-3}$. Since optical radiation can only penetrate the outermost layers at these densities, cosmic radiation in the 100 MeV range is considered as energy source. In all, about 100 homogeneous gas phase reactions are investigated which explain the formation of molecules such as H_2O, HCN, NH_3, and H_2CO by various routes. The model also permits an estimate of the time required until a steady state is reached for the various molecules. Dust plays an important role in this model because molecular hydrogen participates in the primary step of these reactions. However, the formation of molecular hydrogen can only be explained by means of a surface reaction.

The Chemistry of Hydroxamic Acids and *N*-Hydroxyimides

By Ludwig Bauer and Otto Exner[*]

This progress report is concerned primarily with problems relating to the structure and reactions of hydroxamic acids and *N*-hydroxyimides, and also surveys some of the biological activities of these compounds. Particular significance attaches to the Lossen rearrangement of *O*-acylated hydroxamic acids, which leads to isocyanates or their reaction products.

1. Introduction

The chemistry of hydroxamic acids began in 1869 when *H. Lossen*, working in *W. Lossen*'s laboratory, isolated oxalohydroxamic acid from the reaction products of ethyl oxalate and hydroxylamine[1]. Later, when *W. Lossen* obtained a mixture of mono-, di-, and tribenzoyl derivatives from the reaction of hydroxylamine with benzoyl chloride, an era of tedious structural investigation commenced which was plagued by polymorphism, stereoisomerism, and tautomerism[2]. The pioneering efforts of investigators like *A. Werner*, *Lauder W. Jones*, and *C. D. Hurd* paved the way for a clearer understanding of structure and reactions in hydroxamic acid chemistry. In the absence of spectral data, the structure of the oxo form *(1)* was difficult to establish; many experimentalists believed that the hydroximic acid structure *(2)* represented hydroxamic acids correctly and that *(2)* would also exhibit geometrical isomerism akin to oximes. In his review in 1943, *Yale* brought some order to the state of confusion existing in the literature of hydroxamic acids[3]. Considerable progress was achieved in the last 30 years in understanding the chemistry of acyl derivatives of hydroxylamine[4], particularly with the evolution of spectral methods.

(1) *(2)* *(3)*

(1a), R = C_6H_5

Hydroxamic acids occupy relatively little space in textbooks. A noted exception is the Lossen rearrangement leading to isocyanates, which is usually mentioned as an appendage to the related Hofmann, Curtius, Schmidt, and Tiemann rearrangements[4]. Complexation of metal ions by hydroxamic acids is the basis of a number of analytical determinations[5]. The best known of these complexes is that with Fe^{3+} whose beautiful purple color forms the basis for the sensitive qualitative and quantitative determination of carboxylic acids and their derivatives[6,7].

This quick color test retains some value in the preparative work with hydroxamic acids and is unique for hydroxamic acids of structure *(1)*, although hydroxamic acids possessing either an NH or OH group may exhibit a red color with Fe^{3+} ion.

2. Structure of Hydroxamic Acids

Monoacylation of hydroxylamine should produce *N*- and *O*-derivatives, *(1)* and *(3)*, respectively. Members of both series are known, but thermodynamically controlled reactions usually yield only *(1)*.

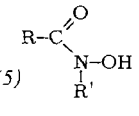
2.1. *O*-Acylhydroxylamines *(3)*

It was shown in 1942 that hydroxylaminolysis of isatoic anhydride produces *O*-(2-aminobenzoyl)hydroxylamine *(3a)*[8], the first identified representative of class *(3)*, although the classical Wöhler synthesis produces both *N*-hydroxyurea *(1)*, R = NH_2, and "isohydroxyurea" *(3)*, R = NH_2. The structure of the latter was proved by chemical methods to be *O*-carbamoylhydroxylamine[9a], and this structure was confirmed recently by X-ray analysis[10].

(3a)

Acylations of hydroxylamines frequently provide the primary kinetically controlled product *(3)*, which rearranges rapidly, particularly under the catalytic effect of hydroxylamine (α-effect)[9,11], to the thermodynamically stable hydroxamic acid *(1)*. Although it is possible to prove the structure of *(3)* by further acylation and subsequent Lossen rearrangements[8,9a], one can now readily distinguish between *(1)* and *(3)* by IR spectroscopy. The carbonyl stretching frequency in *(3)* is considerably higher (1760—1730 cm^{-1}) than that for the more amidic type of C=O in *(1)* (1670—1640 cm^{-1})[9b,12,13c]. Syntheses of *O*-acylhydroxylamines *(3)* are still being investigated and ingenious methods have been devised to prepare these types of compounds[9,13].

2.2. Hydroxamic Acids ("*N*-Acylhydroxylamines") *(1)*

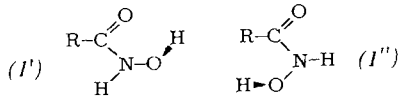


Structure *(1)* represents hydroxamic acids in the solid state, as shown by X-ray analyses of crystalline acetohydroxamic acid hemihydrate[14] and *N*-hydroxyurea[15]. All spectral evidence indicates that *(1)* is the predominant species in solutions. Attempts to detect even minute amounts of the tautomeric oximino form *(2)* in solutions failed. UV studies on hydroxamic acids and the monoalkyl derivatives of type *(4)* and *(5)* support structure *(1)*[16], which is further substantiated by the C=O stretching frequency in their IR spectra[12,17]. Furthermore, ESR[18], mass[19], and NMR[20] spectra of hydroxamic acids agree with structure *(1)*.

(4)

(4a)

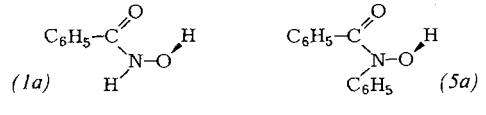
(4b), R = CH_3, R' = Alkyl
(4c), R' = CH_3
(4d), R = C_6H_5, R' = CH_3
(4e), R = C_6H_5, R' = Alkyl



(5)

(5a), R = R' = C_6H_5
(5b), R = CH_3, R' = Alkyl
(5c), R' = CH_3
(5d), R = C_6H_5, R' = CH_3

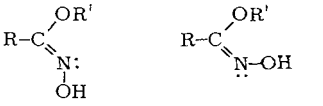
Direct proof for the NH grouping in (1) was obtained only recently[20d] from the NMR spectrum of *p*-nitrobenzohydroxamic[^{15}N] acid in dimethyl sulfoxide, where a large spin-spin coupling constant between ^{15}N and H, $J_{N-H} = 102$ Hz, was observed[20d].



By way of comparison, thiohydroxamic acids are now believed to exist in the thioacylhydroxylamine form, R—CS—NHOH, both in solution and the solid state[20e,g]. Along those lines, it is interesting to note that amidoximes exist primarily as amino-oximino tautomers, R—C(=NOH)NH_2[20h]. All these types of molecules are strongly hydrogen bonded.

In the hydroxamic acid molecule (1) the oxygen, carbon, and nitrogen atoms belonging to the —C(O)—NO grouping are expected, by analogy with amides, to be in one plane; *a priori*, the OH group could assume two different spatial positions with respect to the C=O group: (1') and (1''). The NH—OH grouping is clearly not planar[14,15,21a]; for instance benzohydroxamic acid (1a) in dioxane approaches (1')[21a]. This conclusion was reached by determining the dipole moments of benzohydroxamic acid and suitable derivatives and by calculating dipole moments of these substances from suitable bond moments and angles[21].

(1') (1'')



A similar conformation is postulated for the *N*-phenyl derivative (5a)[23]. No intramolecular hydrogen bond O—H···O is present in the crystal[14], probably due to unfavorable steric conditions, whereas such a bond is detected in dilute solutions by IR spectroscopy. This also explains the low C=O frequency[12,17c].

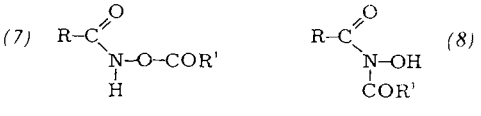
(1a) (5a)

Attempts to detect restricted rotation around the C⋯N bond of (1) due to partial carbon-nitrogen double bond character have not borne fruit. However, slightly restricted rotation about the C⋯N bond is reported for the highly substituted compound (10a) (see Section 3)[20b]. In a more recent report, NMR spectra of formohydroxamates HCO—N(R)OR' at low temperature clearly revealed restricted rotation about the C⋯N bond. The configuration of the rotamers was established by means of long range coupling constants[20g].

In order to study torsion about an N—O bond, the NMR spectra of 1-isopropoxy-2-pyridone (4a), a cyclic hydroxamate, were examined and a certain barrier to rotation was found[22].

(E)-(6) (Z)-(6)

(6a), R = C_6H_5, R' = $C_6H_5CH_2$
(6b), R' = C_2H_5
(6c), R = C_6H_5, R' = C_2H_5



Since neither tautomerism nor partial double bond (C⋯N) character is detected in (1), the configurations of the N—OH group pose no structural problem. A configurational problem arises, however, when fixed C=N bonds are present, as in structure (6): (*E*) and (*Z*) isomers of type (6) have been differentiated by dipole moment measurements[26] which reversed the original literature assignments. These results were confirmed by X-ray analysis[24]. Dipole moment or NMR determinations were also useful in establishing the (*E*) and (*Z*) isomers of related *S*-alkyl thiohydroximates RC(=NOH)-SR'[25a,25b] and *O*-methylarenohydroximoyl chlorides ArC(=$NOCH_3$)Cl[25c].

3. Nomenclature

The hydroxamic or carbohydroxamic acid nomenclature (IUPAC Rule C-451.3) may be used for (1). For example, CH_3CO—NHOH is named acetohydroxamic acid, *cyclo*-$C_6H_{11}CO$—NHOH, cyclohexanecarbohydroxamic acid, and 1,4-$C_{10}H_6(CO—NHOH)_2$ 1,4-naphthalenedicarbohydroxamic acid. Alternatively, compound of type (1) may be named as *N*-hydroxycarboxamides according to Rule C 841.3.

Monoalkyl derivatives (4) and (5) are esters and *N*-substituted hydroxamic acids, respectively; for example (4b), CH_3CO—NHOAlkyl can be designated as alkyl acetohydroxamates (or *N*-alkoxyacetamide) and (5b), CH_3CON(Alkyl)OH, as *N*-alkylacetohydroxamic or *N*-alkyl-*N*-hydroxyacetamide.

Compounds of type (6) are best named as derivatives of hydroximic acids (2). For example, (*Z*)-(6a) would be benzyl (*Z*)-benzohydroximate.

(7) (8)

(7a), R = R' = CH_3
(7b), R = R' = C_6H_5

(8a), R = R' = CH_3

(9)

(9a), R = R' = C_6H_5, M = Na
(9b), R = $(C_6H_5)_3C$, R' = CH_3, M = K

The acyl derivatives (7) and (8) can be named as hydroxamic acid derivatives, *e.g.* (7a) and (8a) as acetohydroxamic acetic anhydride and *N*-acetylacetohydroxamic acid, respectively. This type of name is preferred to those such as *O*,*N*-diacetylhydroxylamine and *N*-hydroxydiacetylamine, which infer that

these compounds are bases. Salts of *(7)* [*viz. (9)*] can then be named as hydroxamates.

(10) *(11)*

(10a), R = C_6H_5, R' = C_6H_5CO, R'' = $C_6H_5CH_2$

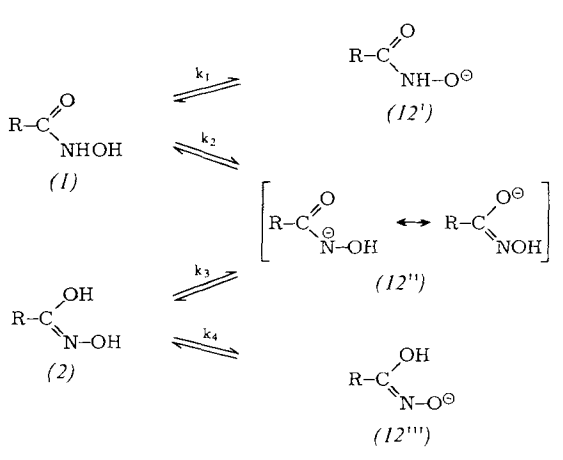
(10b), R = R' = R'' = CH_3

(10c), R = C_6H_5

(11a), R = C_6H_5

Dialkyl derivatives *(10)* are referred to as hydroxamates (*i.e.*, as esters). Therefore, *(10b)* can be named methyl *N*-methylacetohydroxamate; the possible names derived from *N*-hydroxyamides should also be borne in mind.

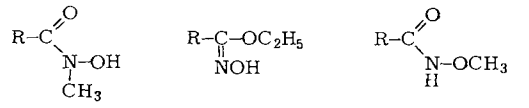
Like *(6)*, compounds *(11)* are derivatives of hydroximic acid; however, they can also be named as *N*-hydroxyimidic acid derivatives in analogy with the *N*-hydroxyamide nomenclature of hydroxamic acid derivatives.



No attempt will be made to include the nomenclature of cyclic hydroxamic acids in which the functional groups become part of a heterocyclic system[4d, 27].

4. Ionization of Hydroxamic Acids *(1)*

4.1. Structure of the Hydroxamate Anion *(12)*

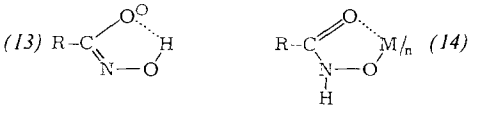


The unexpected relatively high acidity of hydroxamic acids *(1)* is one of their most striking properties. A number of pK_a values for RCO—NHOH are reported in the literature[28, 29] and these are of the order of 9 pK units, *i.e.*, approximately 6 units more acidic than amides $RCONH_2$. It should be noted that the difference between $NH_4^{\oplus}$ and $NH_3OH^{\oplus}$ is of the order of 3 pK units only. In a recent paper, the thermodynamic ionization constants were determined for a number of *p*-substituted benzohydroxamic acids and were found to correlate well with those calculated using Hammett's constants[28g, 29a].

The structure of the anion *(12)* is still the subject of some controversy. *A priori*, three possibilities *(12')*, *(12'')*, and *(12''')* are considered[29], and the ultimate aim is to determine

the four partial dissociation constants k_1 to k_4. At this point it is difficult to generalize beyond one hydroxamic acid and the solvent systems used for the particular study. Another difficulty lies in the detection of minute fractions; this problem also hindered the tautomerism studies alluded to in Section 2.2.

Nevertheless, some evidence has accumulated that *(12'')* best represents the structure of the anion of *(1)*. Measurements of dissociation constants could theoretically yield all the desired values k_1 to k_4 when the experimental pK values of such alkyl derivatives as *(5c)*, *(6b)*, and *(4c)* are considered as approximations of k_1, k_4 and $k_2k_3/(k_2+k_3)$, respectively[29]. This method can only lead to rather crude approximate values since the introduction of alkyl groups on N or O markedly effect these dissociation constants.



(5c) *(6b)* *(4c)*

(5d), R = C_6H_5 *(6c)*, R = C_6H_5 *(4d)*, R = C_6H_5

Although claims are made in the literature[29b, c] that the anions of aceto- and benzohydroxamic acids are composed of a mixture of *(12')* and *(12'')*, the proof based on UV measurements and pK_a values is not altogether convincing[29b, c, 30].

There is great disparity of values in the literature[29] resulting from pK_a determinations on hydroxamic acids *(1)* and their derivatives *(4)*, *(5)*, and *(6)*. For example, it would appear that benzohydroxamic acid *(1a)* and its methyl ester *(4d)* are stronger acids than *(5d)* or *(6c)*[29]. This is not unexpected, since resonance contributions [see *(12'')*] would enhance stabilization of the former, but not the latter two alkyl-substituted derivatives. In any one series, the acidity of either the NH or OH protons are affected to some degree by the nature of the substituents. For example, electron releasing substituents would reduce the relative acidity of the NH protons in *(4)* more than in *(5)*, since the inductive effect would be felt less by the more remote OH proton[5a, 29, 31].

An IR study of a salt of deuterated benzohydroxamic acid[31] in the solid state and in dioxane solution detected the O—D vibration frequency which could point to the presence of *(12'')* or, for that matter, *(12''')*. An intramolecular hydrogen bond, as in *(13)*, may also contribute to the stability of *(12'')*. An intramolecularly hydrogen-bonded species *(13)* could explain the stability of *(12'')* and the fact that nucleophilic reactions seem to take place preferentially on the NOH oxygen atom. The structure of complex salts of hydroxamic

(13) *(14)*

acids may differ from that of simple salts; the formula *(14)*[5] is supported already by the fact that *N*-alkylhydroxamic acids *(5)* form complexes, while *(4)* and *(6)* do not.

To summarize, the exact composition of salts of simple unsubstituted hydroxamic acids is not established with absolute certainty but there is good evidence that hydroxamic acids

bearing electron-attracting substituents dissociate exclusively to the anion *(12″)*, and thus belong to the *N*-acids.

4.2. Structure of the Hydroxamic Acid Cation

The structure of the cations of hydroxamic acids has received little attention, particularly since such salts are seldom isolated. Protonation of the carbonyl oxygen is suggested, by analogy with the behavior of amides; hence the cations are represented by the following formula[32]:

$$RC{=}\overset{\oplus}{O}H(NHOH) \leftrightarrow RC(OH){=}\overset{\oplus}{N}HOH$$

5. Reactions

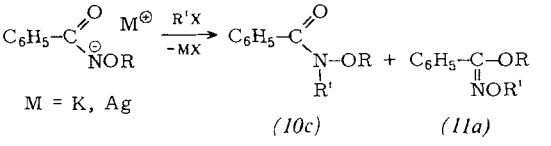
It is not intended to survey all the reactions which have been reported for hydroxamic acids, but rather to restrict this section to recent studies in which the products have been well characterized.

5.1. Hydrolysis

Acid or base-catalyzed hydrolyses of hydroxamic acids *(1)* and their derivatives *(4)* or *(5)* to carboxylic acids and hydroxylamine derivatives proceed readily and it would appear logical to compare these hydrolyses with corresponding reactions of amides[29g, 32b, 32c]. Kinetic studies do indeed suggest that the mechanism of acid and base-catalyzed hydrolyses of benzohydroxamic acid resembles those of amides[32c].

By analogy to the hydrolysis of other carboxylic acid derivatives, the acid-catalyzed reaction is assumed to involve a cation whose structure is discussed in Section 4.2.

Attack by water leads to a tetrahedral intermediate of the kind usually associated with nucleophilic acyl substitution reactions; this intermediate yields the final products. First-order dependence on hydronium ion supports such a mechanism in a kinetic study of the hydrolysis of benzohydroxamic acid[32c]. For the acid-catalyzed hydrolysis of a number of aliphatic hydroxamic acids, polar and steric effects are found to be of comparable magnitude. This contrasts with the acid-catalyzed hydrolysis of amides or esters which show little or no dependence on polar effects. The observed rates correlate well with those calculated from the two-parameter Taft equation and thus support the above mechanism[29g].



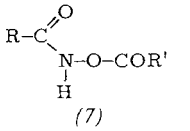
The base-catalyzed reaction is somewhat more complicated since the structure of hydroxamate anion *(12)* has not been settled. The question arises as to whether the unionized hydroxamic acid or its anion is attacked by hydroxide ion or water to produce the acid and hydroxylamine. Both first and second order dependence on hydroxide ion are inferred in the base-catalyzed reaction[32c], and further data are needed to establish these mechanisms.

5.2. Alkylation

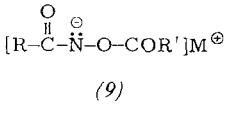
Alkyl hydroxamates *(4)* are the major products resulting from the action of an alkylating agent on the hydroxamate ion *(12)*[33], in spite of the fact that three plausible sites exist for alkylation. One would expect the ambident anion *(12″)* to favor alkylation of the nitrogen or the carbonyl oxygen rather than the OH oxygen. However, the bifurcated anion species might be sufficiently hydrogen-bonded or coordinated to the accompanying cation that the oxygen attached to the nitrogen becomes the most nucleophilic and sterically least encumbered atom [see *(13)* and *(14)*] for attack on an electrophilic center.

The α-effect exerts a tremendous influence in effecting such a facile and selective reaction to form *(4)*. The anion *(12)* is rarely alkylated on the nitrogen to give *(5)*; these compounds are synthesized by another route, *viz.* acylation of R—NHOH[12, 33c–33e].

Further alkylation of *(4)* poses an interesting problem. The anion of *(4)* behaves more like an ambident anion and is subject to all the theories on this subject. The ratios of products are largely dependent upon the solvent, the nature of the accompanying cation, and the electrophilicity of the carbenium ion center in the alkylating agent. Alkylation of the potassium and silver salts of the alkyl esters C_6H_5CO—NHOR *(4e)* afforded a mixture of products from which the esters *(10c)* and the (*Z*) and (*E*) isomers of *(11a)* were isolated[33a]. The



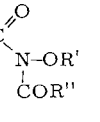
(10c) *(11a)*

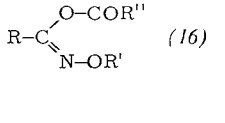


isomer distribution is very much influenced by the alkyl halide R′X, the solvent (DMF/R′OH), the structure of R′ and the nature of the leaving group X. The isomers did not isomerize during work up and were thus formed under kinetically controlled conditions. Although the authors advance theories compatible with current thoughts on S_N reactions involving ambident anions, there are no predictions regarding the major products arising from the alkylations of *(4)*[33a].

5.3. Acylation

The reaction of hydroxamic acids *(1)* with acid halides or anhydrides produces mixed anhydrides ("*O*-acylhydroxamic acids") *(7)*[34]. More reactive acid halides, however such as sulfonyl or phosphoryl halides induce an almost spontaneous Lossen rearrangement of *(1)* presumably *via* *O*-sulfonyl or *O*-phosphoryl derivatives (see Section 6). The mixed anhydrides *(7)* are acids (p*K* in water would be *ca.* 7[29a]); they form



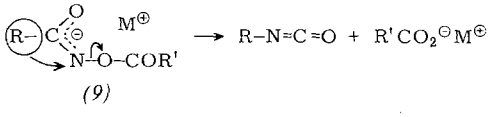


(7)

(9)

(15)

(16)

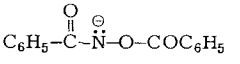


stable salts (in the cold) which rearrange on heating. Alkylation of these salts *(9)* and subsequent hydrolysis of the acyl residue produces either the (*Z*) or the (*E*) isomer of *(6)*[33a]. Acylation of the esters *(4)* yields the trisubstituted compounds *(15)*, and in certain instances also the isomers *(16)*[34c].

6. The Lossen Rearrangement

In 1872 *Lossen* discovered the rearrangement bearing his name when he observed that pyrolysis of the mixed anhydride *(7b)* affords phenyl isocyanate[2, 3]. This rearrangement does not take place with hydroxamic acids RCO—NHOH *(1)*, as is stated erroneously in some textbooks. Preliminary *O*-acylation is essential for a smooth rearrangement. Even then, such acyl derivatives only undergo pyrolytic rearrangement under fairly stringent conditions; *e.g.* *O*-(acetoacetyl)benzohydroxamic acids form isocyanates, acetone, and carbon dioxide only at 300—400 °C[34d].

The usual mode is to convert compounds *(7)* by means of a strong base (preferably in nonhydroxylic solvents) at low temperature into the salt *(9)*, preferably in a medium from which the salt precipitates. Rearrangement of the anion of *(9)* to the isocyanate involves the departure of the carboxylate ion with concomitant migration of the group R from carbon to nitrogen.

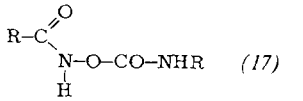


(7b) $C_6H_5-C(=O)-N(H)-O-COC_6H_5$

(9)

The rate of this base-catalyzed Lossen rearrangement depends upon the electronic nature of the groups R and R'. *Hauser*'s kinetic data relate the rate of rearrangement to the strength of the acid $R'CO_2H$[35]. Thus, the rate increases as the departing group $R'CO_2^{\ominus}$ becomes more electron-attracting. This explains why *O*-sulfonyl or *O*-phosphoryl hydroxamic acids cannot be isolated: they rearrange extremely rapidly in a basic milieu (see below).

In another study, it was demonstrated that the rearrangement is facilitated as the electron-releasing power of R in *(9)* increases, provided no undue steric effects enter the picture[36]. The stereospecificity of the Lossen rearrangement supports this concerted mechanism since it is proven that the configuration of R in *(7)* remains unchanged during the rearrangement[37]. All attempts to show that nitrene intermediates are involved in nonphotolytic rearrangements have been unsuccessful. The ionic pathway indicated above with concomitant movement of group R from C to N as the anion departs therefore represents the best picture for the mechanism[34e].

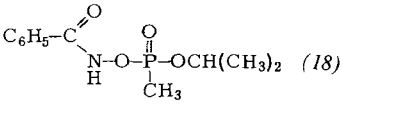


(9a)

(9b)

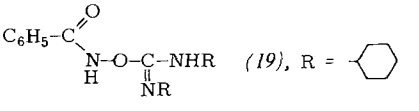
An example of the conventional rearrangement is that of *(9a)* in water at 95 °C to produce *N,N'*-diphenylurea. Presumably, the first product is phenyl isocyanate which hydrolyzes, in part, to aniline. The latter adds to residual isocyanate to produce the urea. As a matter of fact, *(9b)* is known to rearrange in water at room temperature to furnish trityl isocyanate.

Other activating groups inducing Lossen rearrangements have also been explored. 2,4-Dinitrofluorobenzene converts *(1)* into the *O*-2,4-dinitrophenyl derivatives, which rearrange in alkaline media to the amine RNH_2, 2,4-dinitrophenol, and carbon dioxide[38]. Another reagent for activating hydroxamic acids is sulfur trioxide (as the triethylamine complex) which forms the salts $RCO-NHOSO_3^{\ominus}$ $(C_2H_5)_3NH^{\oplus}$, in excellent yield. These derivatives are transformed into isocyanates, ureas, or urethanes under appropriate conditions[39].



(17)

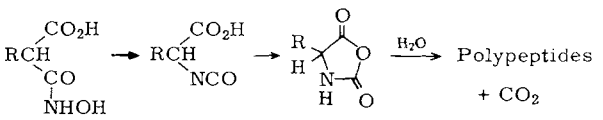
(17a), R = R' = C_6H_5



Unexpectedly, sulfonyl and phosphorus halides react vigorously with hydroxamic acids RCO—NHOH *(1)*. However, the products are not the *O*-sulfonyl or *O*-phosphoryl derivatives, but rather rearrangement products, *e.g.* *O*-carbamoyl hydroxamic acids *(17)*[40]. Thus, potassium benzohydroxamate is rearranged spontaneously by benzenesulfonyl chloride to give *(17a)* in one step.

A similar result is reported when benzohydroxamic acid *(1a)* was treated with the nerve gas "Sarin" (isopropyl methylphosphonofluoridate). In this reaction, the highly reactive intermediate *(18)* rearranges to phenyl isocyanate which in turn adds to unreacted benzohydroxamic acid to form *(17a)*.

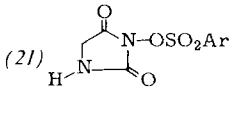
The reaction of benzohydroxamic acid with benzenesulfonyl chloride or diisopropyl phosphofluoridate at pH 7.6 and 25 °C was investigated extensively in oxygen-18 labeled water[41]. The absence of oxygen-18 in any of the products expected from a Lossen rearrangement supports the mechanism involving initial formation of the *O*-sulfonyl- or *O*-phosphoryl hydroxamic acid. These hydroxamic acids then rearrange to phenyl isocyanate with simultaneous departure of the sulfonate *or* phosphate anion from the nitrogen. The isocyanate produced *in situ* now adds benzohydroxamic acid to produce the *O*-(phenylcarbamoyl)benzohydroxamic acid *(17a)*[41].



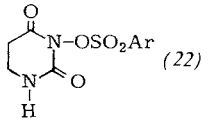
(18)

(19), R =

Interestingly, dicyclohexylcarbodiimide also reacts with benzohydroxamic acid to produce *(17a)*[42a]. The intermediate *(19)* from the addition of the hydroxamic acid to the diimide loses *N,N'*-dicyclohexylurea with concomitant rearrangement to phenyl isocyanate. Again isocyanate then adds a mole of benzohydroxamic acid to furnish the product. The rearrangement of the *anion* of *(17a)* is typical; the resulting carbamate anion loses CO_2 to yield aniline, which adds to phenyl isocyanate affording the isolated product *N,N'*-diphenylurea[42a]. An unusual Lossen rearrangement was observed when benzohydroxamic acid was treated with thionyl chloride, followed by thallium(I) phenoxide. The isolated triphenyl isocyanurate

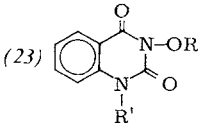


(20)



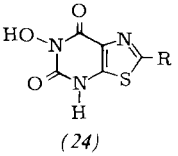
(23%) presumably arises from trimerization of phenyl isocyanate[42b].

Neighboring groups frequently react with an isocyanate group produced during a Lossen rearrangement. The Lossen degradation of half-malonohydroxamic acids *(20)* provides polypeptides, presumably *via* the route shown.

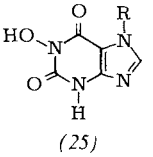


Since such polypeptides are prepared entirely in a basic medium, it becomes possible to synthesize an acid-sensitive polypeptide such as polytryptophan[43]. A hydroxamic acid group adds to a neighboring nitrile group when α-cyano esters react with hydroxylamine to form 5-amino-3-isoxazolones[44a]. Salicyclo- and anthranilohydroxamic acids react with benzenesulfonyl chloride to yield 2-benzoxazolone and 2-benzimidazolone, respectively[44]. Along these lines, a hydroxamic acid group can add to an adjacent isocyanate group to form a cyclic *N*-hydroxyimide. Thus, sulfonyl halides transform malonohydroxamic acids into *(21)*[45], and succino- and phthalohydroxamic acids into *(22)* and *(23a)* respectively[46].

(21)

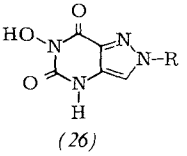


(22)



(23)

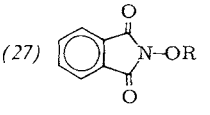
(23a), R = SO_2Ar, R' = H
(23b), R = $SO_2C_6H_5$, R' = H
(23c), R = $SO_2C_6H_5$, R' = CH_3



An extension of this method of fusing an *N*-hydroxyuracil ring onto five- or six-membered heteroaromatic systems resulted in the synthesis of various heterocycles of biochemical interest[47-51]. These include 3-hydroxylumazine, fused pyridopyrimidinediones, thiazolouracils, *e.g. (24)*, 1-hydroxyxanthines, *e.g. (25)*, and a number of *N*-hydroxypyrazolouracils represented by the selected structure *(26)*.

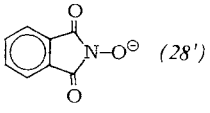
(24)

(25)



(26)

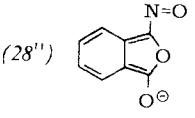
7. The Chemistry of Cyclic *N*-Hydroxyimides



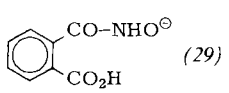
Cyclic *N*-hydroxyimides[52], particularly *N*-hydroxyphthalimide *(27a)*, have been known for a long time. Their synthesis has been discussed in Section 6. They may be formally regarded as *N*-acylhydroxamic acids of type *(8)*.

7.1. Structure and Alkylation

The assumption that *(27a)* exists in a colorless and a yellow modification proved to be erroneous. The yellow hue of the otherwise colorless crystals is caused by a minute amount of the intensely red anion *(28)*. One would expect the anion *(28')* of *N*-hydroxyphthalimide to be colorless [like the anion of *N*-hydroxysuccinimide]. It has therefore been suggested that the contribution of the highly chromophoric isomer *(28'')* is responsible for the intense color. In aqueous medium, the red solution of the salts of *N*-hydroxyphthalimide turns colorless due to their hydrolysis to *(29)*. The identity of *(29)* is established by its deep purple coloration with ferric chloride and by its isolation as the hydroxylammonium salt[52c]. Furthermore, *(29)* can be degraded by benzenesulfonyl chloride to anthranilic acid[52c].



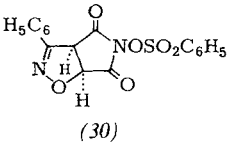
(27)



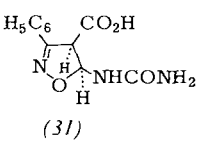
(28')

(27a), R = H
(27b), R = SO_2Ar

(28'')

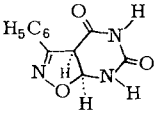


(29)



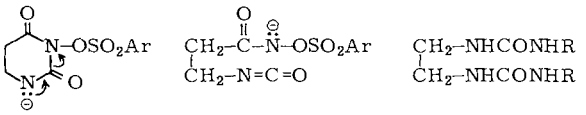
The stable triethylammonium salt of *(28')* can be alkylated in benzene to furnish *N*-alkoxyphthalimides, which readily yield *O*-alkylhydroxylamines on acid hydrolysis[53].

7.2. The Lossen Degradation of *N*-Hydroxyimides



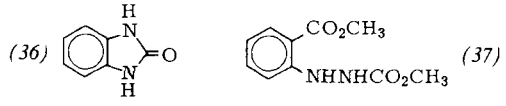
Although hydroxamic acids RCO—NHOH *(1)* fail to form stable *O*-sulfonyl derivatives, *N*-hydroxyimides form isolable *N*-sulfonyloxy and *N*-phosphoryloxy derivatives[52,54]. The Lossen rearrangement of these sulfonates to amino acids has been performed for aliphatic and aromatic systems. Thus reaction of *cis*-*N*-benzenesulfonyloxyhexahydrophthalimide with 10% aqueous NaOH solution produced *cis*-2-aminocyclohexanecarboxylic acid which is isolated as the benzenesulfonate[37c]. *N*-Sulfonyloxyphthalimides *(27b)* are degraded by amines to anthranilic acid derivatives[52,54a]. By a similar mechanism, *N*-benzenesulfonyloxynaphthalimide is converted by hydroxide ion to naphthostyril[55]. In the same vein, *cis*-*N*-benzenesulfonyloxy-3-phenyl-2-isoxazoline-4,5-dicarboximide *(30)* reacts with aqueous ammonia to yield only one ureido acid *(31)* which was further cyclized, in a separate step, by dilute hydrochloric acid to *(32)*[56].

(30)



(31)

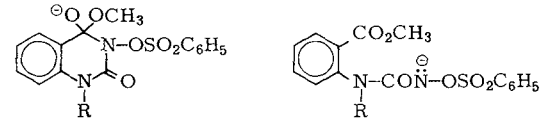
(32)



Interesting Lossen rearrangements are observed with *(22)*: treatment with one equivalent of NaOH produces ethylenediamine[46b], and degradative reduction to *N*,*N'*-dimethylethylenediamine occurs with $LiAlH_4$[57]. Both rearrangements are initiated by formation of *(33)* [the anion of *(22)*] which opens to give the anion *(34)* of *O*-arenesulfonyl-3-isocyanatopropionohydroxamic acid. The latter is the logical precursor for 1,2-ethylenediisocyanate, which can be hydrolyzed to ethyl-

enediamine or reduced to *N,N*-dimethylethylenediamine. The reaction of *(22)* with ammonia or amines produces ureas *(35)*, presumably *via* the diisocyanate[58].

(33) *(34)* *(35)*



In a series of surprising Lossen rearrangements, 3-benzenesulfonyloxy-2,4-quinazolinedione *(23b)* rearranges either to benzimidazolone *(36)* or *o*-hydrazinobenzoic acid derivatives *(37)*[59a].

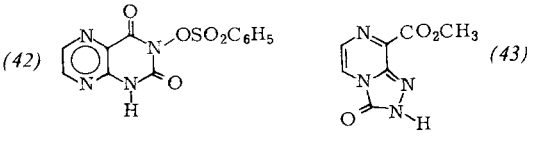
(36) *(37)*

The reaction of *(23b)* with NaH in DMF yields *(36)*. Presumably, neutralization of the acidic ring NH proton forms the anion [cf. *(33)*] which opens to produce *O*-benzenesulfonyl-2-isocyanatobenzohydroxamic acid. The latter rearranges to phenylene diisocyanate, from which *(36)* is created.

Lossen degradation to *(37)* is brought about by sodium methoxide in methanol. Attack by methoxide ion at the highly electrophilic C-4 atom of *(23b)* gives rise to a tetrahedral intermediate *(38a)* which opens to form *(39a)*. This second intermediate then rearranges to give *(40a)* which can add methanol to furnish *(37)*.

(38) *(39)*

(38a), R = H *(39a)*, R = H



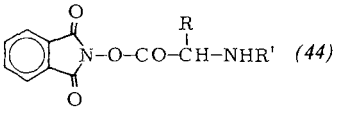
(40) *(41)*

(40a), R = H

It was therefore not surprising that the 1-methyl analog of *(23b)* [*(23c)*] is degraded by methoxide ion to 1-methyl-3-indazolone derivatives *(41)*, R = H or CO_2CH_3[59].

When the *pyridine* analogs of *(23a)* are treated with sodium methoxide, a series of *pyridine* analogs of *(37)* is obtained[59b]. An unusual product is encountered when the *pyrazine* analog *(42)* is exposed to sodium methoxide in methanol: the triazolopyrazine *(43)* is formed.

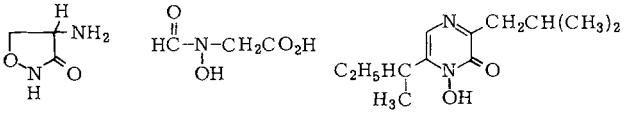
The mechanism of this reaction follows that suggested for the transformation of *(23)* into *(40)*, with the difference that



(42) *(43)*

the isocyanate cyclizes onto the pyrazine ring nitrogen in preference to adding methanol.

7.3. *N*-Hydroxyimides in Peptide Syntheses



A number of investigators have explored the use of *N*-acyloxyimides as precursors for peptide syntheses[60]. The method commences with the preparation of esters of amino acid derivatives *(44)*, followed by attack by another amino acid on the activated ester carbonyl group to form a peptide link, with release of the *N*-hydroxyimide anion.

(44)

8. Brief Survey of Some of the Biological Activities of Hydroxamic Acids

Recent progress in hydroxamic acid chemistry has been stimulated by the isolation of several naturally occurring and the synthesis of a number of medicinally active hydroxylamine derivatives[4d]. Notable among these are the antibiotic cycloserine *(45)*[61], the antitumor antibiotic hadacidin *(46)*[62], and the heteroaromatic antibiotic aspergillic acid *(47)*[63].

(45) *(46)* *(47)*

A wide spectrum of biological activities has been reported and a full recent review exists[4d]. A few recent examples will now be considered. A series of *o*-, *m*-, and *p*-alkoxybenzohydroxamic acids was found to be highly effective against pathogenic fungi[64], while salicohydroxamic acids and derivatives are effective antibacterial and antifungal agents[65]. β-Alkylaminopropionohydroxamic acids show hypotensive properties[66], and a number of hydroxamic acids and *N*-hydroxyureas possess hypocholesteremic activity[67]. *p*-Butoxyphenylacetohydroxamic acid (Bufexamac) is in actual use as an antiinflammatory agent in humans[68]. A series of terephthalohydroxamic and other dicarbohydroxamic acids have been investigated as potential antimalarials[69].

In a quantitative structure-activity relationship study, using the Hansch approach, a series of aliphatic and *m*- and *p*-substituted benzohydroxamic acids were investigated for their relative power to inhibit urease activity[72]. Among the alkylhydroxamic acids, maximum activity was observed with heptanohydroxamic acid *(1)*, R = C_6H_{13}, which the authors attribute to stereospecific "hydrophobic bonding". They concluded that electronic effects do not play a significant role in this activity. However, the steric effect of a bulky substituent becomes very clear in a series of aliphatic hydroxamic acids in which a phenyl group is moved along the fatty acid chain: a remarkable decrease of inhibitory power is observed as the phenyl group approaches the hydroxamic acid group.

Hydroxamic acids number among the few compounds effective as nucleophilic reactivators of sarin-inactivated chymotrypsin[71] or acetylcholine esterase[28d]. *N*-Hydroxyurea has been investigated extensively since it exhibited antileukemic activity in mice and spurred extensive pharmacological screening of many *N*-hydroxyureas and urethans[4d]. Hydroxyurea (Hyd-

rea) is available to the medical profession as an approved drug for the treatment of melanoma, myelocytic leukemia, and carcinoma of the ovary[70].

One of the metabolites of the carcinogenic *N*-(2-fluorenyl)acetamide is *N*-(2-fluorenyl)acetohydroxamic acid[72]. This points to the potentially important biological oxidation of amides by *N*-hydroxylation and it is conceivable that other compounds containing monosubstituted amide groups can form similar metabolites.

9. Conclusions

While tremendous progress has been made over the past 30 years in understanding and applying the chemistry of hydroxamic acids and *N*-hydroxyimides, a number of problems remain to be solved. Although the structures of hydroxamic and hydroximic acids and derivatives are fairly well established, the fine structure of the anion of hydroxamic acid, as well as its hydrolysis and behavior on nucleophilic substitution, remain to be clarified. Perhaps, the greatest endeavor in the next decade will be in the area of the biological evaluation of hydroxamic acid derivatives. In the meantime the study of hydroxamic acids will remain a viable part of chemistry[*].

The authors thank Drs. Charles D. Hurd and Harry L. Yale for their constructive criticisms of this manuscript. Their many comments are deeply appreciated.

Mass Transport in Solids

By Günther Heinz Frischat[*]

Two aspects are especially important in connection with mass transport in solids; these are the phenomenological description of the diffusion process and the discussion of the transport mechanism. In addition to the self-diffusion of the constituent ions or atoms of a solid, which can be followed only with the aid of radioactive or stable isotopes, other known types of diffusion are the diffusion of trace elements, which can in principle be treated in the same way as self-diffusion, and chemical diffusion, in which the diffusion partners differ in their chemical composition. Processes of this type are being increasingly studied with the electron beam microprobe. Regardless of the crystallinity and the type of bonding, problems concerned with diffusion in solids can be discussed from a single standpoint by slight adaptation to suit the particular situation in question.

1. Introduction

Diffusion processes in solids provide information about the mobility of the particles that constitute the solid or that react with it. In the former case, *i.e.* in self-diffusion, the intrinsic mobility of the atoms or ions is determined; an insight into the dynamic structure of solids can be gained from measurements on this process. In the second case, *i.e.* chemical diffusion, one follows true chemical reactions, exchange processes, *etc.* between one solid and another solid, a liquid, or a gas. Chemical diffusion and self-diffusion are uniquely related to each other.

It is not purely on their own account that diffusion processes are interesting. There are many processes in which mass transport of this nature is involved or is even rate-determining. Some examples are crystallization, oxidation or scaling processes, corrosion phenomena on metals or oxides under the

action of melts or gases, and solid-state reactions such as cement formation and sintering, *etc.*

The first step in a diffusion study is the phenomenological description of the diffusion process. This is often very difficult because, except in the case of single crystals, the effects of higher-dimensional crystal imperfections such as dislocations, grain boundaries, and internal surfaces (pores and microcracks), as well as noncrystalline phases, must be taken into account. The next problem is to clarify the mechanism of the mass transport, *i.e.* the individual reaction steps taking place on the atomic scale in conjunction with the structure and the disorder of the solid. The two aspects are comparable in their importance.

It is also necessary to examine how these processes are affected by the bond character in the solid (*e.g.* metal, ionic crystal).

2. General Laws of Diffusion

For the present, diffusion will be regarded here as a process that leads to concentration leveling within a single phase. Since diffusion always involves at least two components, there are at least two diffusion equations to be considered, though in many cases it is sufficient to follow only one component explicitly[1-8].

Fick's laws form the basis for the mathematical description of diffusion processes. Fick's 1st law links the diffusion flux with the concentration gradient as the driving force:

$$\vec{J} = -D \operatorname{grad} c \tag{1}$$

$\vec{J}$ = diffusion flux [g cm^{-2} s^{-1}]; c = concentration [g/cm^3]; D = diffusion coefficient [cm^2/s].

The change in the concentration with time is described by Fick's 2nd law:

$$\frac{\partial c}{\partial t} = \operatorname{div}(D \operatorname{grad} c) \tag{2}$$

t = diffusion time [s].

In many experimentally realizable cases, a one-dimensional treatment in the x direction is sufficient. One then obtains

$$\frac{\partial c}{\partial t} = \frac{\partial (D \cdot \partial c/\partial x)}{\partial x} \tag{2a}$$

and for constant D this gives the usual form

$$\frac{\partial c}{\partial t} = D \cdot \frac{\partial^2 c}{\partial x^2} \tag{2b}$$

The solutions of eq. (2) depend on the particular initial and boundary conditions of the diffusion experiments. We shall first consider the case of a constant diffusion coefficient, *i.e.* eq. (2b). Two of the commonest cases in diffusion studies on solids have a point source and a step source respectively as initial conditions.

In studies with radioactive tracers (cf. Section 3.1), the diffusing substance is concentrated at the point $x=0$ at $t=0$; the initial and boundary conditions (point or instantaneous source) are then:

$$c(x,t) = \begin{cases} c_0 \delta(x) \text{ for } t=0 \\ 0 \text{ for } x \to \infty \text{ and } t \geq 0 \end{cases} \tag{3}$$

c_0 = initial concentration [g/cm^2]; $\delta(x)$ = Dirac's delta function

The solution of eq. (2b) is given under these conditions by the Gaussian function:

$$c(x,t) = \frac{c_0}{2\sqrt{\pi D t}} \exp(-x^2/4Dt) \tag{4}$$

A step source occurs *e.g.* when diffusion processes take place between two solids in contact with each other (cf. Section 3.2). The initial and boundary conditions are

$$c(x,t) = \begin{cases} C_0 \text{ for } x<0 \text{ and } t=0 \\ 0 \text{ for } x>0 \text{ and } t=0 \end{cases} \qquad \frac{\partial c}{\partial x} = 0 \text{ for } x \to \pm\infty \text{ and } t>0 \tag{5}$$

The solution of eq. (2b) is then given by

$$c(x,t) = \frac{C_0}{2}\left[1 - \operatorname{erf}\left(\frac{x}{2\sqrt{Dt}}\right)\right] \tag{6}$$

C_0 = initial concentration [g/cm^3]; erf(y) = Gaussian error function (listed *e.g.* in Ref. [3])

Solutions are also known for other geometric cases[1-8]. The experimenter's problem is initially to design the experiment as far as possible in such a way that one of the known solutions can be applied. It is only when the corresponding conditions cannot be realized that other solutions of the diffusion equations should be sought.

Eq. (2) was solved above on the assumption of a constant diffusion coefficient D. This assumption is never strictly valid, and is approximately valid only in limiting cases. It is particularly important to know the dependence of the diffusion coefficient on the concentration. One must therefore start with the general eq. (2) or (2a) with $D=D(c)$. The Boltzmann-Matano solution method[9,10] then leads, for the initial and boundary conditions in eq. (5) and for $t=$ const., to

$$D(c) = \frac{1}{2t}\frac{dx}{dc}\int_c^{c_0} x\,dc \tag{7}$$

It is physically obvious that all the matter that diffuses out of the half-space $x<0$ must be found later in the half-space $x>0$. The coordinate of the "Matano plane" $x_m=0$ can therefore be calculated from the equation

$$\int_c^{c_0} x\,dc = 0 \tag{8}$$

Only if the molar volume is constant does this coordinate coincide with the value $x=0$ for the original interface at the start of the experiment.

So far we have considered diffusion in a *single* phase. In systems with several phases, diffusion leads to leveling of the chemical potentials μ, or in the case of charged particles to leveling of the electrochemical potentials η. The driving forces, instead of a concentration gradient grad c, are then the potential gradients grad μ or grad η. At equilibrium

the μ or η values for the two phases are equal; no mass transport then occurs, even if the concentrations in the two phases are different. "Uphill diffusion" is therefore formally possible. Further complications in the evaluation of diffusion experiments on solids can arise *e.g.* from inhibitions at the phase boundary. The two phenomena may also occur together (for further information see Refs. [1—8]). *Wagner*[11] gives equations that allow an evaluation for $D(c)$ even when several phases are present.

3. Experimental Methods

In the study of diffusion in solids, the three-dimensional distribution of the diffused substances is usually determined experimentally to allow the calculation of the diffusion coefficient. The detection method to be used depends on the nature of the experiment and the required sensitivity.

Many physical and chemical detection methods have been developed over the years. Examples are X-ray absorption or fluorescence methods, optical methods, chemical methods of various kinds, methods involving the use of radioactive or stable isotopes, microhardness determinations, the use of the electron beam microprobe, and mass spectrometric, autoradiographic, or activation-analytical methods.

Two commonly used methods, one for the determination of self-diffusion and the other for the determination of chemical diffusion, will now be described in some detail.

3.1. Use of Radioactive Isotopes

The use of isotopes is essential for the determination of self-diffusion. There is no concentration gradient in self-diffusion. A large number of suitable isotopes are available, *e.g.* ^{14}C, ^{22}Na, ^{26}Al, ^{45}Ca, ^{59}Fe[12]. These emit γ or/and β rays, which can be followed with the aid of counters. Some α-active isotopes, *e.g.* ^{212}Pb, ^{210m}Bi, and ^{233}U, are also suitable. However, a number of important elements (oxygen, nitrogen, silicon, *etc.*) have no radionuclides that can be used. In such cases, one must turn to stable isotopes (^{18}O, ^{15}N, ^{30}Si, *etc.*) and their detection by relatively demanding activation-analytical (*e.g.* by the reaction $^{18}O(p,n)^{18}F$) or mass-spectrometric methods.

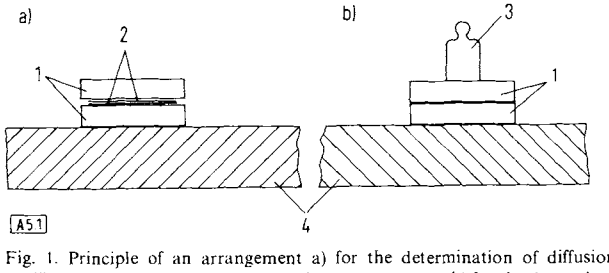

Fig. 1. Principle of an arrangement a) for the determination of diffusion coefficients with radionuclides (sandwich arrangement); b) for the determination of chemical diffusion (contact method). 1 = samples, 2 = tracer layers, 3 = weight, 4 = substrate.

Figure 1a shows the principle of the arrangement for diffusion determinations with radionuclides. The initial condition of a point source in eq. (3) is reasonably well satisfied by the tracer layer (*e.g.* a drop of $^{22}NaCl$ in aqueous solution, total quantity of ^{22}Na about 10^{-9} g), applied before the diffusion experiment, with a thickness of $< 3\,\mu m$. Each sample corresponds to a diffusion system that is unbounded on one side; this condition is satisfied in most cases by samples with a diameter of *e.g.* 2 cm and a thickness of 1 mm.

After the diffusion, *i.e.* the penetration of the radioactive particles into the solid, it is necessary to determine their distribution. This can be done in various ways. In the serial sectioning method, thin layers 50, 5, or 0.5 μm [depending on the penetration depth; special electrolytic microetching techniques even allow the removal of 100 Å layers (cf. *e.g.* Ref. [13])] are removed by grinding, etching, machining *etc.* The radioactivities of the individual layers are then determined. In the case of hard and brittle materials (hard metals, ceramics, glasses, *etc.*), it is preferable to measure the activity of the residual sample[14].

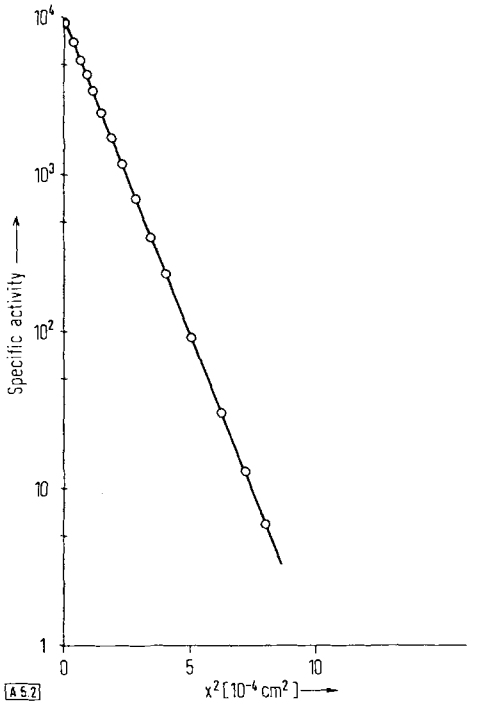

Fig. 2. Profile of the diffusion of ^{103}Pd in Pd single crystals. $T = 1148$ °C, $t = 242$ h [15]. The specific activity is given in arbitrary units. The diffusion coefficient is found to be $D = 3.15 \cdot 10^{-11}$ cm^2/s.

Figure 2 shows an example of the diffusion of ^{103}Pd in metallic Pd[15]. The penetration curve may be evaluated numerically with an automatic computer or graphically as in Figure 2. It can be seen immediately from eq. (4) that a plot of $\log c(x,t) = f(x^2)$ gives a straight line, from whose slope the diffusion coefficient is obtained. An absolute determination of the tracer concentration is unnecessary. This and similar types of plot are known as "diffusion profiles".

By this technique just described or by similar methods, it is possible to determine diffusion coefficients of between about 10^{-4} and 10^{-15} cm^2/s, and even as low as about 10^{-18} cm^2/s with the special microstripping techniques. Values down to 10^{-18} cm^2/s can also be measured when α-active nuclides are used[16]. It is clearly of no importance in this type of diffusion experiment whether the solid investigated is a metal, an ionic crystal, a glass, an organic crystal, *etc.* One simply makes corresponding changes in the preparation techniques.

3.2. Use of the Electron Beam Microprobe

In chemical diffusion, the diffusion partners normally differ in their chemical composition, and *e.g.* a new phase may

be formed on leveling by diffusion. To investigate a solid-state reaction[*] of this type, the two starting materials are pressed together under light pressure by the contact method, sealed together (*e.g.* glasses), *etc.* (cf. Fig. 1b). After a time, a reaction layer has formed between the starting materials, and this layer must be analyzed.

The electron beam microprobe is being increasingly used for the study of this and similar diffusion processes between solids or between melts and solids[17]. This instrument is based on the principle that a finely focused electron beam stimulates the emission of characteristic X-rays by the chemical elements at the point where it strikes the specimen. Both point analysis and line scanning of the samples are possible. This method allows the selection of sample volumes of a few μm^3 from the structure and their qualitative or quantitative analysis. Reference standards, for example, are necessary for quantitative analysis.

The elements between ^{5}B and ^{92}U can be detected; within this range, the nature of the solid (*e.g.* metal, ionic crystal) is of no importance. Diffusion coefficients of between 10^{-4} and 10^{-13} cm^2/s, and in special cases even lower values, can be determined.

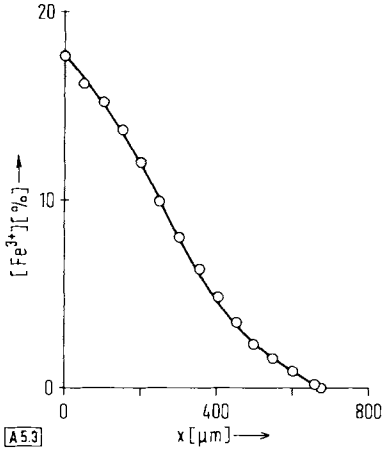

Fig. 3. Profile of the diffusion of Fe^{3+} (from Fe_2O_3) in MgO, $T = 1390$ C, $t = 66.5$ h [18].

Figure 3 shows the profile obtained in this way for the diffusion of Fe^{3+} ions in the binary system MgO—Fe_2O_3[18]. In every case, the evaluation also gives the concentration dependence of the diffusion coefficient (cf. Section 4.2).

4. Examples of Diffusion in Solids[**]

4.1. Self-Diffusion

4.1.1. Single Crystals

Nothing has been said so far about the structure of the substance in which diffusion occurs. We shall deal first with single crystals, which are characterized by a strictly regular structure and by the fact that they contain only zero-dimensional crystal defects (Frenkel or Schottky defects) that are present at thermal equilibrium. Effects due to higher-dimensional defects should be negligible. It has been known for a long time that diffusion processes are brought about by this intrinsic imperfection. This type of diffusion is known as lattice or volume diffusion.

There are numerous known examples of self-diffusion processes in single crystals of all kinds (see *e.g.* Refs. [19—24, 26]). The possibility of description by an unequivocal diffusion coefficient is an important characteristic (see also Fig. 2). In normal single crystals, all the sites that can be occupied by the migrating particles are energetically equivalent. However, if this situation is changed, *e.g.* for structural reasons (type A zeolite[27]), because of traps[*] (Bi[28]), or because of substitution and interstitial sites (SiC[29]), deviations occur.

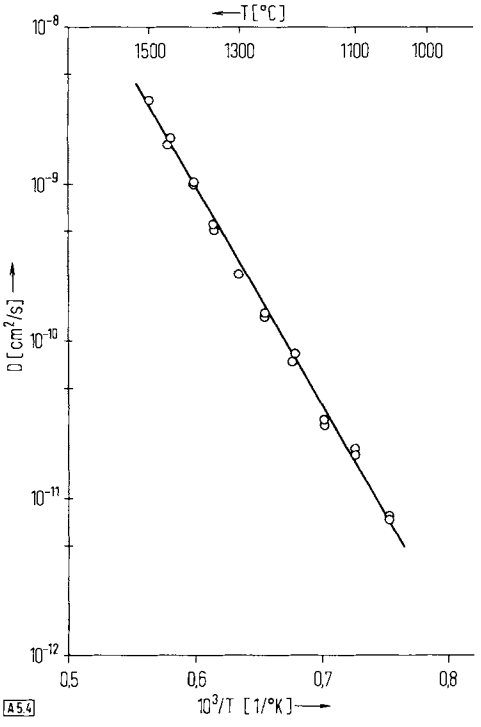

Fig. 4. Temperature dependence of the diffusion of ^{103}Pd in Pd single crystals, $T = 1057$ to 1503 C [15].

Figure 4 shows the temperature dependence of the diffusion of ^{103}Pd in Pd single crystals[15]. The values of the diffusion coefficient D are plotted according to the Arrhenius equation:

$$D = D_0 \exp(-Q/RT) \qquad (9)$$

D_0 = frequency factor [cm^2/s]; Q = activation energy [kcal/mol]; R = general gas constant [cal deg^{-1} $mole^{-1}$]; T = temperature [K].

The numerical values obtained are

$$D_0 = 0.205^{+0.05}_{-0.04}\ cm^2/s \text{ and } Q = 63.60 \pm 0.65\ kcal/mol.$$

The self diffusion coefficient of palladium between 1057 and 1503 °C is unequivocally fixed by these quantities.

[*] The term "solid-state reaction" refers here not only to chemical reactions but also to ion exchange processes.

[**] Values for diffusion in solids can be found *e.g.* in [2—8]. There are also a series of reviews on limited fields, *e.g.* on metals [19], oxides [20], carbides [21], halides [22], inorganic nuclear fuel materials [23], SiO_2 [24], and glasses [25]. Probably the most comprehensive collection of diffusion values is Diffusion Data [26], which started to appear in 1967. This collection contains results for metals, semiconductors, oxides, glasses, halides, refractory materials, organic crystals, *etc.*

[*] Traps are sites in the structure where particles can be enclosed immobile for some time.

Table 1. Examples of self-diffusion and diffusion of trace elements in single crystals. D_0 = frequency factor, Q = activation energy.

Substance	Isotope	Temp. range [°C]	D_0 [cm²/s]	Q [kcal/mol]	Ref.
Palladium	^{103}Pd	1057–1503	$0.205^{+0.05}_{-0.04}$	63.60 ± 0.65	[15]
AgCl	^{110}Ag	140–350	1.46	20.5	[30]
AgCl	^{36}Cl	324–443	$1.33 \cdot 10^2$	47.1	[30]
CoO	^{60}Co	963–1638	$(5.0 \pm 0.4) \cdot 10^{-3}$	38.39 ± 0.23	[31]
Imidazole, a-axis	^{14}C, ^{3}H	80–90	$10^{2.5 \pm 6}$	60 ± 10	[32]
γ-Iron	^{63}Ni	1130–1380	$0.44^{+0.3}_{-0.2}$	66.6 ± 1.6	[33]
AgCl	^{22}Na	180–300	8.81	27.4	[34]

Results for other monocrystalline substances can be obtained in a similar manner. Some examples are given in Table 1. The accuracy of the results naturally depends on the experimental conditions. Values for the diffusion of trace elements in single crystals, *e. g.* the diffusion of Ni in γ-Fe[33] or of Na in AgCl[34], can be treated in a similar manner.

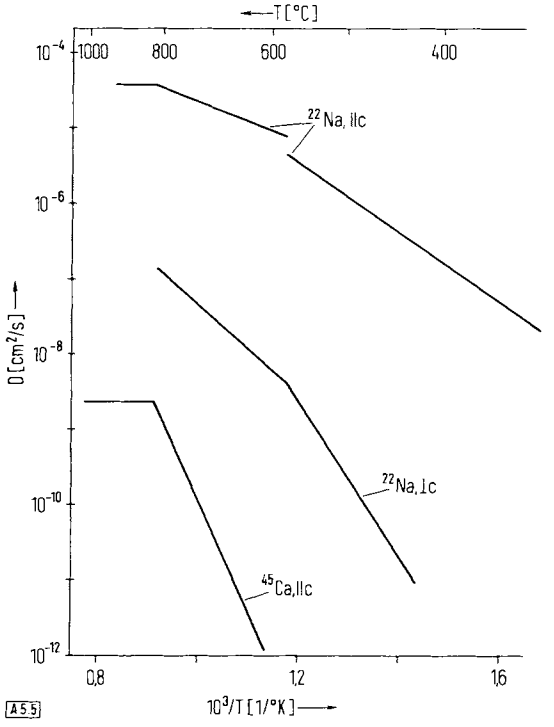

Fig. 5. Temperature dependence of the diffusion of traces of ^{22}Na and ^{45}Ca in quartz single crystals (cf. also Table 2) [35].

Table 2. Diffusion of traces of sodium and calcium in quartz single crystals [35]. D_0 = frequency factor, Q = activation energy.

Type	Temp. range [°C]	D_0 [cm²/s]	Q [kcal/mol]
∥ c, ^{22}Na	300–570	0.68 ± 0.12	20.2 ± 0.3
∥ c, ^{22}Na	600–800	$(7.09 \pm 1.06) \cdot 10^{-3}$	11.5 ± 0.2
⊥c, ^{22}Na	440–570	$(2 \pm 1) \cdot 10^2$	41 ± 1
⊥c, ^{22}Na	600–790	$(4 \pm 2) \cdot 10^{-2}$	27 ± 1
∥ c, ^{45}Ca	600–800	$(1 \pm 0.8) \cdot 10^5$	68 ± 2

The results for the diffusion of Na and of Ca in quartz single crystals reflect special properties of the substance investigated, *e. g.* the α-β transition at 573 °C, the strong anisotropy, and the temperature independence of the diffusion for $T > 800$ °C (cf. Table 2 and Fig. 5[35]). Measurements of this type can therefore be used for the structural characterization of the substances investigated.

4.1.2. Bicrystals and Polycrystals

4.1.2.1. General

The step from a single crystal to a polycrystalline material yields additional energetically favored sites at grain boundaries and other lattice defects. In the general case, therefore, one must expect a superposition of all possible components. If one first considers the coexistence of two processes, *e. g.* volume diffusion and grain-boundary diffusion, whose temperature dependences are described by Arrhenius functions of the type in eq. (9), the following relation is found for a combination of the two processes:

$$D_V/D_K = \text{const.} \exp[-(Q_V - Q_K)/RT] \quad (10)$$

D_V and D_K = diffusion coefficients for volume diffusion and for grain-boundary diffusion respectively [cm²/s]; Q_V and Q_K = activation energies of the corresponding processes [kcal/mol]

Since Q_V is always greater than Q_K, volume diffusion is always favored at higher temperatures, while grain-boundary diffusion is favored at lower temperatures.

According to *Harrison*[36], every diffusion process in a real solid with one-dimensional or two-dimensional crystal imperfections (dislocations or grain boundaries) passes through three successive stages, for which calculation is possible:

1. The mean depth of penetration in the volume is negligible, *i. e.*:

$$2\sqrt{D_V \cdot t} \ll \delta \quad (11)$$

δ = width of the lattice defects [cm]

2. $2\sqrt{D_V \cdot t}$ is large in relation to δ, but is nevertheless always smaller than the mean distance l [cm] between the lattice defects; the relation (12) is therefore valid (see Section 4.1.2.2):

$$2\sqrt{D_V \cdot t} < l \quad (12)$$

3. The mean depth of penetration in the volume is given by the relation (13) (see Section 4.1.2.3);

$$2\sqrt{D_V \cdot t} \gg \text{or at least} > l \quad (13)$$

The relation (11) can only be used for short diffusion times t. This case will therefore not be considered further.

4.1.2.2. Large Crystallites

Diffusion in large crystallites is represented by the model of a bicrystal with a two-dimensional, semi-infinite grain boundary of thickness δ (cf. Fig. 6), which was first proposed by *Fisher*[37].

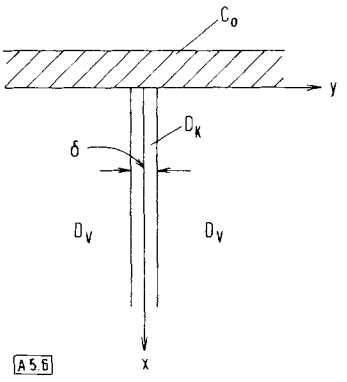

Fig. 6. Fisher model for the calculation of grain-boundary diffusion in bicrystals and polycrystals with large crystallites [37]. For explanation of the symbols, see text.

Diffusion equations must be set up both for the edge of the grain boundary and for the crystal outside the boundary, suitable continuity conditions being taken into account. The concentration within the grain boundary is of no interest, since the grain boundary is normally very narrow. Under the conditions specified by *Fischer*[37] (*i. e.* 1. initial condition corresponding to eq. (5); 2. constancy of δ; 3. $D_K \gg D_V$; and 4. perpendicular diffusion from the boundary into the grain), the following equation is found for the diffusion in the interior of the semi-infinite bicrystal [see also eq. (6)]:

$$c(x,y,t) = C_0 \exp(-\gamma x)\left[1 - \operatorname{erf}\left(\frac{y}{2\sqrt{D_V \cdot t}}\right)\right] \qquad (14)$$

where $\gamma = \sqrt[4]{\frac{4D_V}{\pi t}} \cdot \frac{1}{\sqrt{\delta \cdot D_K}}$

y = coordinate [cm]

If the mean grain size is greater than the maximum depth of penetration as a result of volume diffusion, one can integrate with respect to y, and the quantity that has diffused into a layer of thickness Δx is found to be

$$\bar{c}(x,t) = 4C_0 \sqrt{\frac{D_V \cdot t}{\pi}} \exp(-\gamma x) \qquad (15)$$

If the diffusion is followed by the serial sectioning method (cf. Section 3), γ (and hence the product $\delta \cdot D_K$) can be determined from the slope of the straight line $\log \bar{c}(x,t) = f(x)$ if D_V is known. *Hässner* and *Bergner*[38] were able to show that this simple relation is still valid when the residual activity is measured (see also Fig. 9).

These criteria have been substantially confirmed for many metallic bicrystals or polycrystals with large crystallites, *e.g.* for self-diffusion in Sn[39], γ-Fe[40], Ag[41], and Ni[33], and also for the diffusion of trace elements, *e.g.* of ^{63}Ni in γ-Fe[33]. Figure 7 shows an example of the diffusion of a ^{113}Sn/^{123}Sn mixture in polycrystalline tin having a purity of 99.99%[39]. The linearity demanded by eq. (15) is satisfied over a wide activity range; deviations due to superposition of a volume diffusion component occur only near the surface of the sample.

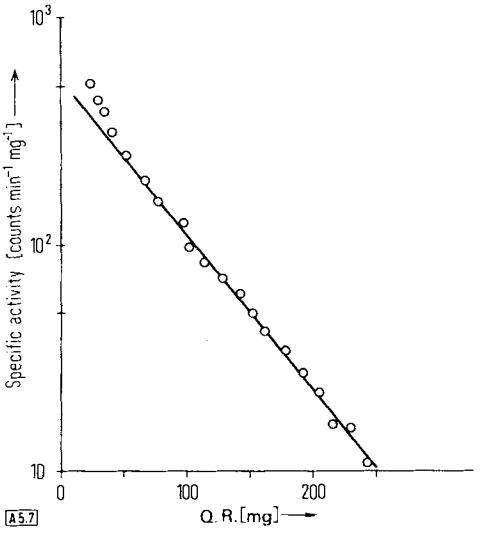

Fig. 7. Profile of the grain-boundary diffusion of ^{113}Sn/^{123}Sn in polycrystalline Sn, $T = 90$ °C, $t = 189$ h [39]. Q.R. = quantity removed. The diffusion coefficient is found to be $D_K = 1.11 \cdot 10^{-7}$ cm^2/s.

To be able to evaluate this diffusion profile for D_K, it is necessary to know D_V and δ, the width of the lattice defects. D_V has been measured between 150 and 225 °C[42] (cf. Table 3). Values for lower temperatures can be obtained from these results by extrapolation. *Fisher*[37] and many later authors (see *e.g.* in Ref. [39]) used a value of δ = 5 Å for metals. The profile shown in Figure 7 for D_K can be evaluated in this way. The temperature dependence of D_K can also be determined; in the case of Sn, one obtains $D_{0K} = (6.44^{+5.9}_{-4.9}) \cdot 10^{-2}$ cm^2/s and $Q_K = 9.55 \pm 0.70$ kcal/mol for the range from 39 to 115 °C. The autoradiogram reproduced in Figure 8 shows that the diffusion is in fact mainly grain-boundary diffusion. The blackening is essentially confined to the grain boundaries.

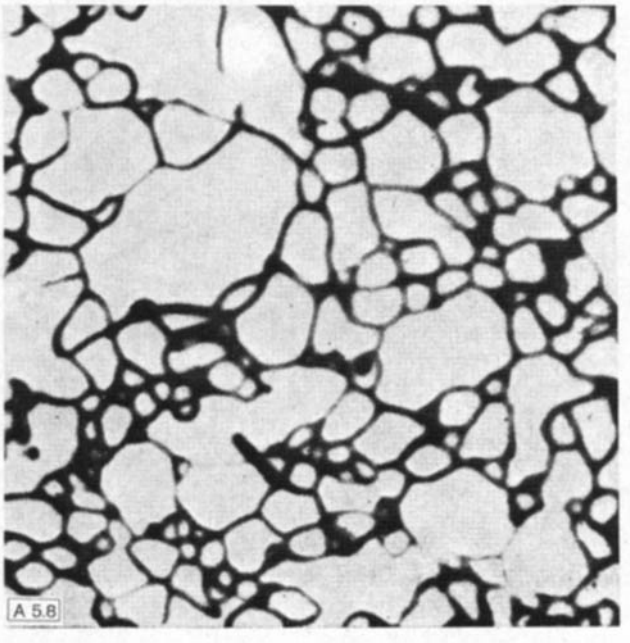

Fig. 8. Autoradiogram of a diffusion sample corresponding to Figure 7 [39], enlarged 15 times.

Table 3 contains other examples. Thus because of the imprecise knowledge of δ for the self-diffusion of Fe in γ-iron, *Lacombe et al.*[40] give only the value of $\delta \cdot D_{0K}$. The self-diffusion of

Table 3. Examples of the relation between volume diffusion, grain boundary diffusion, and dislocation diffusion in metals. D_0 = frequency factor, Q = activation energy.

Substance	Isotope	Temp. range [°C]	D_0 [cm²/s]	Q [kcal/mol]	Type	Ref.
Tin	$^{113}Sn/^{123}Sn$	150–225	$0.78^{+0.54}_{-0.32}$	22.8 ± 0.5	volume	[42]
Tin	$^{113}Sn/^{123}Sn$	39–125	$(6.44^{+5.9}_{-4.9})\cdot10^{-2}$	9.55 ± 0.70	grain boundary	[39]
γ-Iron	^{59}Fe	918–1259	0.58	67.9	volume	[40]
γ-Iron	^{59}Fe	918–1014	$1\cdot10^{7}$ [a]	40.0	grain boundary	[40]
Nickel	^{63}Ni	1149–1390	$1.39^{+0.9}_{-0.6}$	65.9 ± 1.5	volume	[33]
Nickel	^{63}Ni	850–1100	$(1.75^{+2.0}_{-1.0})\cdot10^{-2}$	28.2 ± 2.0	grain boundary	[33]

[a] $\delta\cdot D_{0K}$ in cm³/s

Ni has been studied in volume, along grain boundaries[33], and under the influence of edge dislocations[43] (plastic deformation of Ni single crystals). The diffusion of trace elements in metals, *e.g.* that of ^{63}Ni in γ-Fe, also falls in this category[33]. These examples show that diffusion is strongly accelerated by higher-dimensional lattice defects. As a rough rule, $Q_V/Q_K \approx 2$; a similar ratio is found for dislocation diffusion.

Grain-boundary diffusion also occurs in nonmetals. Some examples are the diffusion of ^{137}Cs in ice[44], of ^{36}Cl and ^{131}I in KCl and KI crystals[45], of ^{22}Na and ^{45}Ca in $Na_2O\cdot2CaO\cdot3SiO_2$[46], and of ^{22}Na in Al_2O_3[47]. *Zaplatynsky*[48] pointed out, however, that for many oxides or halides the ratio D_K/D_V is not of the order of 10^5, as in metals, but is close to 1. This can lead to difficulties in the evaluation based on the Fisher model[37], since one of the conditions for this model is $D_K \gg D_V$.

Curve 1 in Figure 9 shows an example of the diffusion of ^{22}Na in polycrystalline Al_2O_3 having a mean crystallite size of 23 μm[47]. Since the condition $D_K/D_V \gg 1$ is obviously satisfied in this case, the profile can be described according to

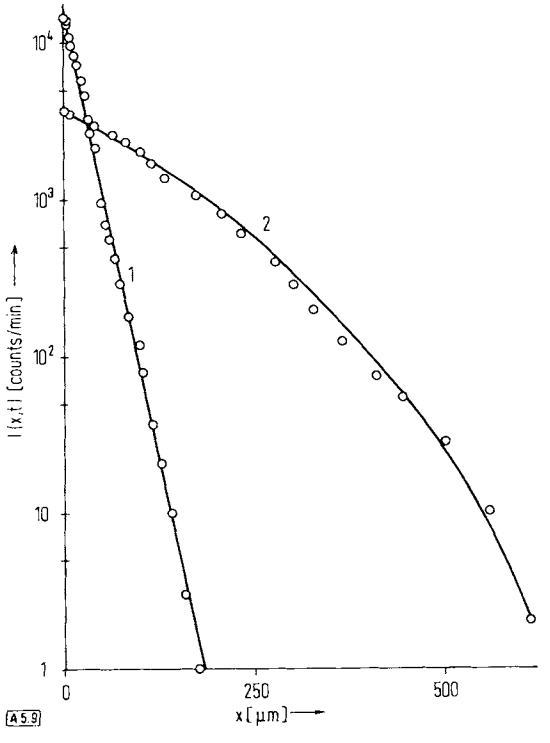

Fig. 9. Profile of the diffusion of ^{22}Na in polycrystalline Al_2O_3. Curve 1: T = 1223 °C, t = 2 h; Curve 2: T = 1750 °C, t = 0.75 h [47]. Plotted as residual activity I; x = thickness of removed layer. The diffusion coefficient is found from Curve 2 to be $D_{eff} = (6.24 \pm 1.20)\cdot10^{-8}$ cm²/s.

eq. (15) over the entire range. However, greater difficulties are encountered in the evaluation of such experiments for ionic crystals than for metals. This is because the effective width of the grain boundaries in ionic crystals is very strongly dependent on the impurities deposited at these boundaries (nature, quantity, valency). Unlike in the case of metals, long-range electric forces must be expected with excess atoms. It is not surprising, therefore, that *e.g.* in the diffusion of MgO, values of a few μm were found for the disturbed zone in the vicinity of grain boundaries[49]. However, if the crystals are extremely pure or if the impurities are distributed in the crystal rather than in the grain boundaries as a result of special heat treatment, the grain-boundary diffusion component (*i.e.* the effective disturbed zone) is much smaller[50].

The diffusion is again strongly dependent on the dislocation density in ionic crystals. As in the case of metals, the different dislocation densities were produced by plastic deformation of single crystals. A dislocation density of up to $3\cdot10^7$ cm/cm³ is obtained by this means in $SrTiO_3$ crystals. ^{18}O diffusion studies[51] show that when the dislocation density is changed by a factor of 2, the D_0 values change from $1.6\cdot10^{-7}$ to $1.2\cdot10^{-5}$ cm²/s, and the Q values change from 15.5 ± 2.0 to 29.3 ± 3.0 kcal/mol. In the diffusion of ^{90}Sr in $SrTiO_3$, the product $(\delta\cdot D_{disloc.})$ can be represented as a function of the dislocation density at 1875 °C by

$$(\delta\cdot D_{disloc.})_{Sr^{2+}} = 3.84\times10^{-19}\cdot\rho^{(0.23\pm0.10)}$$

and the corresponding ratio for ^{44}Ti can be represented[52] by

$$(\delta\cdot D_{disloc.})_{Ti^{4+}} = 2.92\times10^{-19}\cdot\rho^{(0.26\pm0.10)}$$

However, investigations of this type are still very inaccurate. The equations (14) and (15) calculated by *Fisher*[37] are merely approximate solutions. Later publications by *Whipple*[53], *Suzuoka*[54], *Levine* and *MacCallum*[55], and others give mathematically exact solutions for the case of an initial concentration in the form of a step or in the form of a point. *Le Claire*[56] and others found, however, that on the one hand the different initial conditions have only a small influence on the results, while on the other, in the relation

$$\log\bar{c}(x,t) = f(x^m)$$

in which $m = 1$ according to *Fisher*[37], other authors obtained $m = 4/3$[53], $6/5$[54], *etc.*, *i.e.* exponents that are very difficult to distinguish from 1 in this type of experiment.

Examples of the application of these more accurate calculation methods are to be found for the self-diffusion of Cl and I in KCl and KI respectively[57], of Sb in Sb metal[58], of Ti in α-Ti[59] and of Fe in Co[60].

4.1.2.3. Small Crystallites

The relation (13) is normally valid only for long diffusion times and small crystallites. The diffusing particle comes into contact with a very large number of crystal defects in succession as it passes through the crystal (cf. Fig. 10). Because of the frequent change between the possible sites, an effective mean diffusion process containing components of all kinds takes place. An experiment under these conditions should therefore give a diffusion profile similar to that in a single crystal, but with D_V in equations (4) and (6) replaced by D_{eff}. Curve 2 in Figure 9 shows an example of the diffusion of ^{22}Na in α-Al_2O_3[47]. The diffusion coefficient found here is the effective coefficient.

Fig. 10. Model for the occurrence of an effective diffusion process in a polycrystal with small crystallites.

Since grain-boundary diffusion is an effect of the internal surface, its influence should increase with decreasing crystallite size (*i.e.* with increasing surface area of the crystallites in relation to the volume). Measurements by *Laurent* and *Bénard*[45] on alkali metal halides with mean crystallite sizes of between 3000 and 30 μm showed the expected effect only for the (large and hence more strongly polarizable) ions Cs^+, Cl^-, Br^-, and I^-; the results for the ions Na^+ and K^+, on the other hand, agreed with those for single crystals. However, there have even been cases in which reversed dependence on the crystallite size was found[61]. Moreover, the influence of impurities is not yet clear.

Interesting approaches to the calculation of the effective diffusion in a real metallic solid have been described by *Hart*[62] and in particular by *Hässner*[63]. This model crystal is assumed to contain a sufficiently dense three-dimensional arrangement of lattice defects (grain boundaries, dislocations, pores), *i.e.* the relations (16) should be valid:

$$2\sqrt{D_V \cdot t} \gg l$$
$$2\sqrt{D_V \cdot t} \gg d \qquad (16)$$
$$2\sqrt{D_V \cdot t} \gg R_p \text{ or } d_p$$

l = crystallite diameter [cm]; d = distance between dislocations [cm]; R_p = pore radius [cm]; d_p = distance between pores [cm]

On the assumption that the model substance contains crystals in the form of cubes (width of grain boundary $\delta = 5 \cdot 10^{-8}$ cm), tubular dislocations with a radius $r_0 = 10^{-7}$ cm, and a relative pore volume of V_p/V, *Hässner*[63] found the following expression for the effective diffusion:

$$D_{eff} = \left(1 - \frac{3}{2}\frac{V_p}{V}\right) \cdot D_V + \frac{3}{2}\frac{\delta}{l} D_K + \pi \cdot 10^{-14} \rho \cdot D_p + \frac{3\delta'}{R_p} \cdot \frac{V_p}{V} D_0 \qquad (17)$$

δ' = thickness of the disturbed region of the internal surfaces [cm]; D_p = diffusion coefficient in the dislocations [cm^2/s]; D_0 = diffusion coefficient on the surface [cm^2/s]

$D_{0\,eff}$ and Q_{eff}, and hence the temperature dependence of the effective diffusion coefficient, can also be calculated on a similar basis.

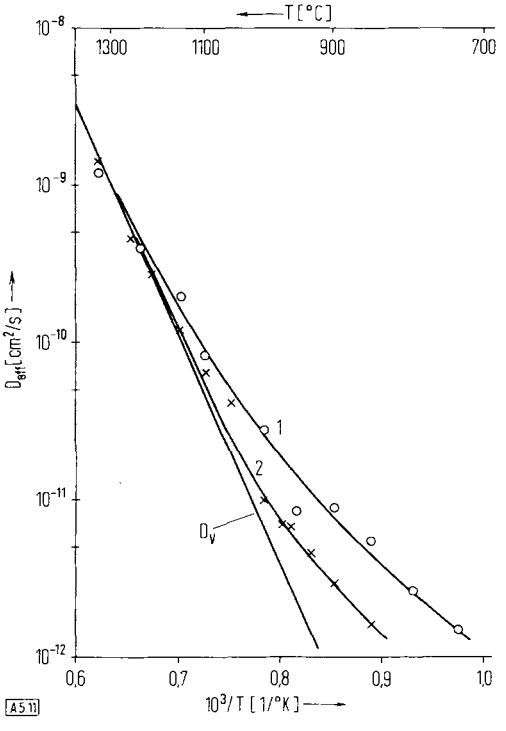

Fig. 11. Comparison of calculated and measured diffusion coefficients D_{eff} for sintered nickel. Series A (○): mean pore volume 8.2%, most frequent pore size 30 μm, most frequent grain size 33 μm; series B (×): mean pore volume 6.1%, most frequent pore size 10 μm, most frequent grain size 100 μm [64]. The Curves 1 and 2 for series A and B respectively were calculated from eq. (17).

Figure 11 shows the results of the experiments carried out by *Hässner et al.*[64] on sintered 99.7% pure nickel to verify these models. In addition to the temperature dependence of D_V (the volume self-diffusion measured on single crystals), Figure 11 shows experimental values for two series with different grain sizes and the corresponding calculated values. The agreement between calculation and experiment is good.

Several authors point out that the relations (16) and also (12) and (13) are sometimes very restrictive[36,63]. The derived models are approximately valid even when *e.g.* the relation $2\sqrt{D_V \cdot t} \approx l$ exists between the depth of penetration in the volume and the size of the lattice defects l. Definite transition states can also be evaluated experimentally. Thus *Lundy* and *Federer*[65] showed that for diffusion in UO_2, even in the

case of the Fisher model[37], a clear differentiation is possible between volume diffusion and grain-boundary diffusion in a concentration curve. The same is true of self-diffusion in tellurium[66] and of the self-diffusion of Na and Ca in $Na_2O \cdot 2CaO \cdot 3SiO_2$[46]. A check on the literature dealing with diffusion measurements on polycrystalline material often reveals deviations from the models, which are themselves clearly formulated.

4.1.3. Crystal Surfaces

The surfaces of solids naturally also provide energetically favored sites for the transport of matter. Experiments for the detection of such processes can be carried out *e.g.* with radioactive isotopes. However, transport on the surface can also be observed in sintering experiments, in the smoothing of surface scratches, *etc.* (for reviews see Refs. [67—69]).

4.1.4. Glasses

Glasses are characterized by the fact that their structure consists of a more or less disordered network. Though the ordering of the individual $SiO_{4/2}$ tetrahedra (if one regards silica glasses or silicate glasses as typical representatives of this class of substances) results in a short-range order, the long-range order typical of crystals is absent because of the different ways in which the individual tetrahedra are linked, *e.g.* to form

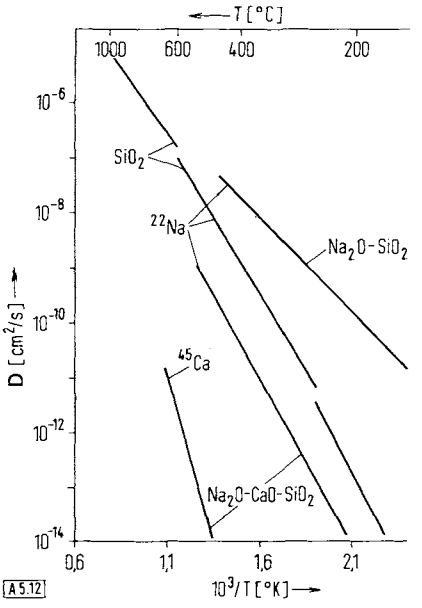

Fig. 12. Temperature dependence of the diffusion of ^{22}Na and ^{45}Ca in silicate glasses (cf. Table 4) [70, 72].

five-membered, six-membered, seven-membered, and larger rings, and because of other types of disorder. A higher degree of order may be produced in certain regions by phase separation processes, but these structures still resemble those of liquids rather than of crystals.

Self-diffusion experiments on a homogeneous glass (*e. g.* with ^{22}Na on a glass from the $Na_2O—SiO_2$ system) lead to the initially surprising result that the diffusion profiles, as in the case of ideal single crystals, can be described by unequivocal values of the diffusion coefficient over the entire activity range. Despite the ill-defined structure of the glass, the sites available to the migrating particles must be structurally and energetically equivalent[70]. Deviations from this simple behavior occur only in special cases, *e. g.* when, as a result of phase separation, the glass has a structure in which clearly different diffusion sites have been produced[71].

Figure 12 shows some typical diffusion results for glasses; the corresponding D_0 and Q values are shown in Table 4. The Na ion is much more mobile in binary $Na_2O—SiO_2$ glasses than in ternary $Na_2O—CaO—SiO_2$ glasses. Silica glass with trace contents in the ppm range assumes an intermediate position in this respect. It can also be seen from Figure 12 that the doubly charged Ca^{2+} ions have a much lower diffusion coefficient and a much higher activation energy than the Na^+ ions in the same ternary glass (for further results on the self-diffusion of other ions or in other glasses, see *e. g.* in Refs. [24-26, 70, 72]).

Table 4. Examples of self-diffusion in glasses [70, 72]. D_0 = frequency factor, Q = activation energy.

Glass	Isotope	Temp. range [°C]	D_0 [cm²/s]	Q [kcal/mol]
SiO_2 [a]	^{22}Na	170–250	2.13 ± 0.29	28.3 ± 0.2
SiO_2 [a]	^{22}Na	250–600	0.374 ± 0.019	25.8 ± 0.1
SiO_2 [a]	^{22}Na	600–1000	$(4.05 \pm 0.24) \cdot 10^{-2}$	21.6 ± 0.1
$Na_2O—SiO_2$	^{22}Na	100–400	$(2.46 \pm 0.13) \cdot 10^{-3}$	15.7 ± 0.1
$Na_2O—CaO—SiO_2$	^{22}Na	200–600	$(3.76 \pm 0.47) \cdot 10^{-2}$	27.3 ± 0.2
$Na_2O—CaO—SiO_2$	^{45}Ca	470–600	$(3.39 \pm 0.49) \cdot 10^{2}$	56.2 ± 0.3

[a] Silica glass with traces of Na.

4.2. Chemical Diffusion

In chemical diffusion, the diffusion partners differ in their chemical composition. Figure 3 showed a concentration curve in the binary system $MgO—Fe_2O_3$. The values obtained by the Boltzmann-Matano evaluation[9, 10] (cf. Section 2) were a little too high, since the molar volume of the spinel phase formed is different from that of MgO. On the other hand, if the curve is evaluated by *Wagner's* method[11], the results in Figure 13 are obtained for D_{Fe}[18]. The diffusion coefficient thus shows a very distinct dependence on the Fe concentration in the substance. The changes in the activation energy (between 49 and 80 kcal/mol) are attributed to the variation of the ratio $Fe^{2+}/Fe_{tot.}$ with the temperature, the oxygen partial pressure, and the total iron content.

The diffusion behavior of two metals that have been brought into contact is shown schematically in Figure 14. Since the two components have different mobilities, different diffusion fluxes occur in the two directions. For each jump of an atom,

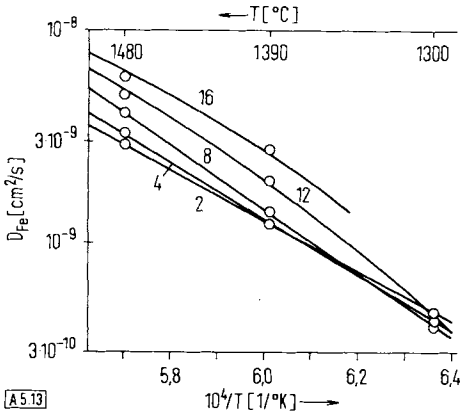

Fig. 13. Temperature dependence of $D_{Fe^{3+}}$ in the binary system $MgO—Fe_2O_3$ [18]. The figures by the curves indicate the Fe content [%].

there is a corresponding migration of a vacancy in the opposite direction. The result is that the vacancies heal in one sample, *i.e.* the sample becomes shorter and possibly thinner, while in the other sample new vacancies are formed, *i.e.* this sample becomes longer and possibly thicker. The changes in the dimensions are manifested in particular in a displacement of the original separation plane and in the formation of a swelling on one side and a constriction on the other, often accompanied by a zone containing holes. This is a zone in which vacancies have united instead of reaching equilibrium with the lattice. This phenomenon is also known as the Kirkendall effect[73] (for further information see *e.g.* in Ref. [74]).

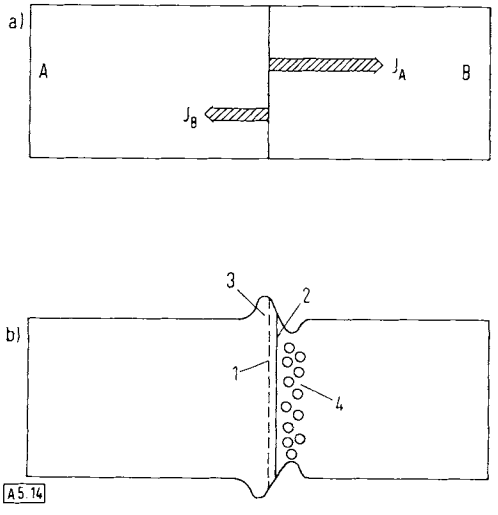

Fig. 14. Diagram illustrating the Kirkendall effect [73]. a) Representation of the mass fluxes J_A and J_B; b) appearance after diffusion; 1 and 2 = welding plane before and after the experiment respectively, 3 = swelling, 4 = holes.

Chemical diffusion in glasses occurs when *e.g.* a solid glass containing Na is introduced into a salt melt containing K and the surface of the glass is modified as a result of an exchange reaction of the type:

$$(Na^+)_{glass} + (K^+)_{melt} \rightleftarrows (Na^+)_{melt} + (K^+)_{glass} \qquad (18)$$

By measurement of the Na and K concentrations in the glass with a microprobe, it can be shown that the Na:K exchange actually occurs in a ratio of 1:1, and that the remainder of the glass structure (consisting *e.g.* of Si, O, Al) is unaffected.

Curve 1 in Figure 15 shows the K—Na interdiffusion coefficient $\tilde{D}$[*] obtained according to Boltzmann-Matano[9,10] as a function of the equivalent fraction of the K^+ ions $N_K = c_K/(c_K + c_{Na})$.

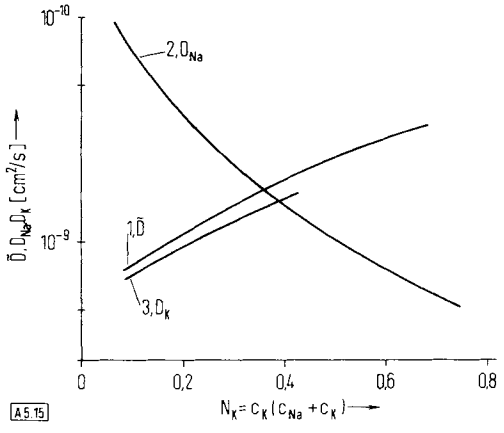

Fig. 15. Relation between chemical diffusion and self-diffusion in glasses. Curve 1: measured interdiffusion coefficient D; Curve 2: measured self-diffusion coefficient D_{Na}; Curve 3: self-diffusion coefficient D_K calculated from eq. (23) [77]. $T = 400$ °C.

If two cations with different mobilities interdiffuse in a rigid network of anionic groups, an electric potential is produced in order to maintain equal ion fluxes, and hence electroneutrality. The flux J_i of the ionic species i in the x direction can be described by the Nernst-Planck equations[75]

$$J_i = \frac{u_i}{F}\left(RT\frac{\partial c_i}{\partial x}\cdot\frac{\partial \ln a_i}{\partial \ln c_i} + z_i c_i F E\right) \qquad (19)$$

u = electrochemical mobility [cm²/Vs]; z = valency; a = thermodynamic activity [g/cm³]; F = Faraday constant [C/mol]; E = electric field strength [V/cm]

From these equations and the condition for electroneutrality, one obtains

$$J_A = -\tilde{D}\cdot\frac{\partial c_A}{\partial x} \quad \text{and} \quad J_B = -\tilde{D}\cdot\frac{\partial c_B}{\partial x} \qquad (20)$$

with the interdiffusion coefficient

$$\tilde{D} = \frac{D_A \cdot D_B}{N_A D_A + N_B D_B}\cdot\frac{\partial \ln a_A}{\partial \ln c_A} \qquad (21)$$

with $N_i = c_i/(c_A + c_B)$, the molar content of the ionic species i. Only for the case of an ideal solution, *i.e.* for $\partial \ln a/\partial \ln c = 1$, does one obtain the generally known form

$$\tilde{D} = \frac{D_A \cdot D_B}{N_A D_A + N_B D_B} \qquad (22)$$

D_A and D_B = self-diffusion coefficients of A and B respectively [cm²/s]

These arguments will now be applied to the example shown in Figure 15. Curve 1 shows the measured interdiffusion coefficient, curve 2 shows the course of the self-diffusion coefficients

[*] "Interdiffusion" is the name given to the special case of binary alkali metal ion exchange with a stable SiO network.

D_{Na}[76], and the course of the self-diffusion coefficient D_K in this system can be calculated from

$$\tilde{D}_K = \frac{\tilde{D} \cdot D_{Na}(1 - N_K)}{D_{Na} - \tilde{D} N_K} \tag{23}$$

(cf. curve 3)[77].

An interesting technical application of ion exchange processes of this type will be briefly mentioned here. If this process is carried out at a temperature that is far enough below the transformation temperature T_g of the glass (*i.e.* the glass structure should be perfectly rigid), the exchange of the smaller Na^+ ion for the much larger K^+ ion (0.96 and 1.33 Å respectively) results in high compressive stresses (up to 7000 kp/cm^2) in the affected surface layer. The stresses are retained only while the structure is rigid. This procedure ("chemical strengthening of glasses") is being used to an increasing extent to increase the strength of glass objects[78, 79].

Investigations on chemical diffusion in ternary systems are much more complicated. No general conclusions can be drawn at present (cf. *e.g.* investigations on the systems MgO—Fe_2O_3—Ce_2O_3[18] and Fe—Si—C[80] and on glasses of the K_2O—SrO—SiO_2 system[81]).

5. Diffusion Mechanisms

5.1. Correlation Effects

Though only one particle in 10^3 to 10^4 is incorrectly arranged in single crystals even close to the melting point[82], this imperfection is of decisive importance to mass transport. Figure 16 illustrates four of the possible diffusion mechanisms for a monatomic crystal. A direct exchange of places between adjacent particles is energetically improbable, particularly in the case of ionic compounds (Fig. 16a). In the direct interstitial mechanism (Fig. 16b) a particle in the interstitial space continues to move in this space, while in the vacancy mechanism (Fig. 16c) a sufficient number of unoccupied positions must

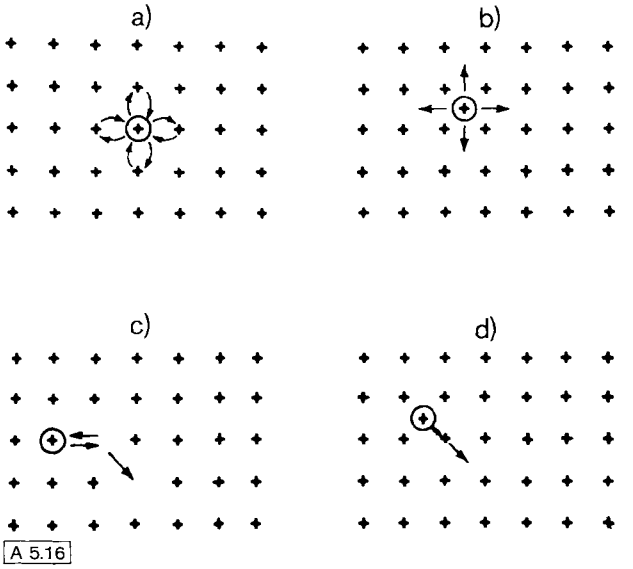

Fig. 16. Diagrams of several possible diffusion mechanisms in a monoatomic crystal. a) Direct exchange mechanism, $f = 1$; b) direct interstitial mechanism, $f = 1$; c) vacancy mechanism, $f = 0$—1; d) interstitialcy mechanism, $f = 0$—1. f = correlation factor (see eq. (24) and Table 5).

be available; in the indirect interstitial mechanism (interstitialcy mechanism) (Fig. 16d), a particle in an interstitial site pushes a particle from the lattice into an interstitial site and occupies the lattice site for itself. All these elementary steps require a particular "threshold energy" U (migration energy), which corresponds to the saddle point of the migrating particle between the initial and final states (cf. Fig. 17).

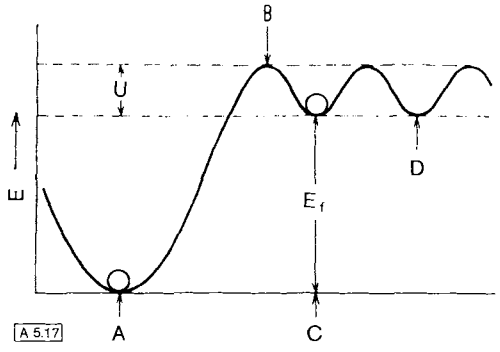

Fig. 17. Potential energy diagram for a particle in various lattice positions. A = occupied normal lattice site, B = saddle point for transfer into interstitial site, C = occupied interstitial site, D = unoccupied interstitial site, E_f = energy of defect formation, U = threshold energy.

Both in the exchange mechanism and in the direct interstitial mechanism, diffusing radioactive particles can execute steps in all directions with equal probability if the substance in which the diffusion occurs is isotropic. In the vacancy mechanism and in the interstitialcy mechanism, on the other hand, all the successive steps of a particle are no longer equally probable. A particle (cf. Fig. 16c) migrates *e. g.* into a vacancy. However, the next step of this particle will be in the forward direction only if a suitable vacancy is again available. In any case there is always a vacancy behind the particle, *i.e.* the vacancy created by the particle itself as it migrated. The same is true of the interstitialcy mechanism (Fig. 16d). Successive steps are therefore no longer independent of one another, and one speaks of a correlation effect of self-diffusion. The correlation factor f describing this effect can be derived from a series expansion from the general diffusion equation, and is found[83, 84] to be as follows:

$$f = 1 + 2\cos\vartheta_1 + 2\cos\vartheta_2 + \cdots \tag{24}$$

ϑ_i = angle between the i-th and the (i+j)-th steps

f can assume values between 0 and 1, depends on the geometry of the lattice and on the diffusion mechanism, and can be calculated from theoretical arguments (cf. Table 5)[85].

Table 5. Calculated correlation factors f for diffusion by a vacancy mechanism (V) and by an interstitialcy mechanism (I) [85].

V		I	
Lattice type	f	Lattice type	f
Diamond	0.5000	AgCl	0.3333
Cubic	0.6531	CaF_2	0.4
Cubic body centered	0.7272	$CdCl_2$	$f_x = f_z = 0.4$
Cubic face centered	0.7815		
Hexagonal close packing	$f_x = f_y = 0.7812$; $f_z = 0.7815$		

5.1.1. Conductivity Methods

There are two methods for the experimental determination of f. The first method can be used only for ionic crystals. According to Nernst-Einstein, the tracer diffusion of the corresponding ionic species and the specific electrical conductivity are related as follows:

$$D_i^* = \frac{\sigma \cdot s_i \cdot k \cdot T}{n_i (z_i e)^2} \cdot f_i \qquad (25)$$

D^* = tracer diffusion coefficient [cm^2/s]; σ = total specific electrical conductivity [$\Omega^{-1}\,cm^{-1}$]; s = transport number; k = Boltzmann's constant [J/°K]; n = number of ions/cm^3; z = valency; e = elementary charge [A.s]

These arguments were first checked on heavy metal halides such as AgBr and AgCl[30, 86-88]. The f values of between 0.4 and 0.6 found experimentally for Ag^+ agree with the calculated values if one assumes an interstitialcy mechanism proceeding in the cation sublattice. This also agrees with the fact that the cation sublattice in heavy metal halides is imperfect because of Frenkel defects. More recent investigations on AgCl suggest that there may even be two slightly different interstitialcy mechanisms for the Ag^+ ions (collinear and noncollinear steps of the two particles involved)[89].

However, if bivalent ions are incorporated into the lattice (*e. g.* $CdBr_2$ into AgBr single crystals), the number of Ag interstitial sites decreases at the cost of the Ag vacancies; the f value of 0.80 that is then found clearly points to a vacancy mechanism. A similar situation was found for $CdBr_2$-doped AgCl crystals, with $f = 0.78$[90].

These arguments have also been applied to glasses, which resemble heavy metal halides, in these respects[91, 70]. Experimental f values of about 0.4 to 0.5 again point to an interstitialcy mechanism, but it must be remembered here that lack of knowledge about the structure of glass introduces an unknown into these considerations.

5.1.2. Isotope Effect Method

The second method for the experimental determination of f involves the measurement of the isotope effect of the self-diffusion by the use of different isotopes of the same element[84]. Since the heavier particle is naturally slower, one obtains eq. (26) on the assumption that not more than one building unit jumps in the mechanism under consideration[*]:

$$f \cdot \Delta K = \frac{1 - D_2/D_1}{1 - \sqrt{m_1/m_2}} \qquad (26)$$

m_1, m_2 = masses of the diffusing particles [g], $\Delta K \leq 1$

Unlike the conductivity method, this method for the determination of f is not confined to ionic compounds. It can be used whenever two suitable isotopes of the same element exist, *e. g.* ^{22}Na and ^{24}Na, ^{55}Fe and ^{59}Fe, ^{55}Co and ^{60}Co, ^{65}Zn and ^{69}Zn, ^{103}Pd and ^{112}Pd, ^{105}Ag and ^{110}Ag, *etc.* Thus vacancy mechanisms have been found in this way *e. g.* for NaCl[84], for Pd[15] and for CoO[31], in agreement with other considerations, according to which vacancy processes should predominate for alkali metal halides, for close-packed metals, and for most oxides.

On the other hand, as in the consideration of the correlation effect, it must be concluded from the isotope effect of $^{105}Ag/^{110}Ag$ in the heavy metal halide AgBr[92] that an interstitialcy mechanism operates here. The $^{22}Na/^{24}Na$ isotope effect has recently also been determined for a glass from the Na_2O—SiO_2 system[93]. Here again, in comparison with the behavior of the Ag^+ ion in AgBr, it is found that the Na^+ ion must be subject to an interstitialcy mechanism. The values found experimentally are shown in Table 6.

Table 6. Results of some isotope effect measurements. f = correlation factor, $\Delta K \leq 1$.

Substance	Isotopes	$f \cdot \Delta K$	Mechanism	Ref.
NaCl	^{22}Na, ^{24}Na	0.78	vacancy mechanism	[84]
Pd	^{103}Pd, ^{112}Pd	0.8134 ± 0.0424	vacancy mechanism	[15]
CoO	^{55}Co, ^{60}Co	0.582 ± 0.009	vacancy mechanism	[31]
AgBr	^{105}Ag, ^{110}Ag	0.29	collinear interstitialcy mechanism	[92]
Na_2O—SiO_2-glass with 17.4 mol-% Na_2O	^{22}Na, ^{24}Na	0.25	similar as in AgBr	[93]

5.2. Thermodynamic-Statistical Considerations

5.2.1. Activation Energy and Frequency Factor

If the diffusion coefficient is determined as a function of the temperature, the characteristic values D_0 (frequency factor) and Q (activation energy) can be determined from the initially empirical Arrhenius equation (9). What do these parameters tell us?

To find the answer, let us again consider Figure 17. For a diffusion step, an arbitrarily selected particle requires the threshold energy U in addition to the defect energy E_f. The activation energy found experimentally thus normally contains two components; in particular, $Q = E_f + U$ for a monatomic substance with Schottky defects and $E_f/2 + U$ for an ionic compound of the type A^+B^-. However, the separate experimental determination of the two energy components is possible only in special cases, in ionic crystals *e. g.* with the aid of electrical conductivity results[82]. This applies *e. g.* to the migration energy if a "frozen" disorder is present or if the substance contains practically no thermally activated defects below a certain temperature. For this extrinsic range $E_f \approx 0$ and hence $Q \approx U$.

[*] If several particles take part, *e. g.* in the interstitialcy mechanism, eq. (26) must be replaced by a rather more complicated formula.

The migration energy U and the vibration frequency $\nu[s^{-1}]$ of the particles in the potential well are related as follows

$$\nu = \frac{1}{2b}\sqrt{U/2m} \tag{27}$$

b = distance of jump [cm]; m = mass of the particle [g]

on the assumption of a sine-shaped diffusion potential that is approximated close to the equilibrium position by a second order parabola. The vibration frequency should be close to ν_D (Debye frequency). A number of comparisons carried out so far show satisfactory agreement in some cases between theory and experiment. Thus the calculated migration energy for rhombic PbO was 21.9—27.7 kcal/mol, while the Q value found from the diffusion was 22.4 kcal/mol[94].

A number of relations have been given for the frequency factor D_0; the following equation was proposed by *Zener*[95]:

$$D_0 = \gamma \cdot f \cdot \nu \cdot b^2 \exp(\Delta S/R) \tag{28}$$

γ = geometric factor; $(\Delta S/R)$ = diffusion entropy factor

ΔS can also be broken down into a component for the migration of the particle and a component for the formation of imperfections. D_0 has been calculated at least approximately for a number of metals with the aid of this or similar equations, and compared with experimental values (cf. Ref. [74]). However, difficulties generally arise in the calculation of the diffusion entropy

$$\Delta S = k \sum_i \ln(\nu_i/\nu_i') \tag{29}$$

since the vibration frequencies ν_i (undistorted lattice) and ν_i (distorted lattice) are unknown.

In most cases, therefore, the entropy has the character of a quantity to be adapted. A tendency has been found experimentally for a vacancy mechanism to exist when $(\Delta S/R) > 0$, and an interstitial mechanism when $(\Delta S/R) < 0$. The negative migration entropy may be due to local density increases in interstitial diffusion, which are associated with an increase in the vibration frequencies, since it follows for $\nu_i' > \nu_i$ that

$$\Delta S = k \sum_i \ln(\nu_i/\nu_i') < 0$$

It may also be of interest in this connection that estimates of this type for glasses give negative entropy factors[70]. This again supports the suggestion of an interstitial process.

All these considerations lead to the conclusion that diffusion in close-packed metals normally proceeds by a vacancy mechanism. Participation of interstitial sites cannot be ruled out in less closely packed semiconductor crystals. A vacancy mechanism also operates in the diffusion of cations in alkali metal halides and in a series of oxides; exceptions are found in the diffusion of anions *e.g.* in UO_2, NiO, and MgO. An interstitial mechanism predominates in these cases. This is to be expected in particular for substances having structures in which there are large interstitial spaces (*e.g.* because of a lamellar, chain, or sheet structure). It has also been established that the diffusion of cations in heavy metal halides takes place by an interstitialcy mechanism. There is evidence that this is also true of the diffusion of alkali metals in silicate glasses.

5.2.2. Influence of Divacancies

There have recently been growing signs that the diffusion in a series of substances cannot be described by a simple Arrhenius function corresponding to eq. (9) over the entire temperature range up to the melting point. The closer one comes to the melting point, the greater are the deviations. Satisfactorily verified values are available for the diffusion of Cl in NaCl[96], the diffusion of Na in AgCl[97], the self-diffusion of Ni[98] and Ag[99], and a number of other cases. All the authors explain these cases by the coexistence of two mechanisms. The normal course is described by a process involving single vacancies, and the abnormal course by a process involving divacancies. Since the two processes have different D_0 and Q values, the resulting function deviates from linearity in the Arrhenius diagram.

5.2.3. Knowledge of the Imperfection

Whereas our knowledge of the imperfection in halides, metals, and simple oxides is relatively good, very little is known about the situation in more complicated substances, *e.g.* the silicates[100]. Also the interpretation of chemical diffusion processes in binary and especially in ternary systems on the basis of imperfection models is still in its infancy[18,101]. The point on which the least is known is the nature of the "defect centers" in glasses, which have a highly distorted structure in any case. When Frenkel's view on the formation of a pair of defects is applied to a glass, the following dissociation process in the structure must be taken into account:

$$[SiO_{3/2}O^-M^+] + [SiO_{4/2}] \rightleftarrows [SiO_{3/2}O^-] + [M^+SiO_{4/2}] \tag{30}$$

The groups on the left-hand side are uncharged; the charged complexes on the right may be formally compared to a vacancy or an interstitial ion in a crystalline substance. The number of these "pairs of defects" can be calculated as a function of temperature in much the same way as *e.g.* for AgBr. According to this model, the measured activation energy Q should contain both formation and migration components.

On the other hand, if one uses a model suggested by *Charles*[102] for the glass structure, in which, because of the loose arrangement, the number of sites that can be occupied by alkali metal ions is greater than the number of alkali metal ions present, Q would merely contain an energy component for migration. According to the arguments of *Lengyel* and *Boksay*[103] this second possibility should exist in glasses.

6. Closing Remarks

One aim of this report was to show that both the experimental and the theoretical principles of mass transport by diffusion are largely independent of the nature of the solid investigated. The measuring procedures must naturally be matched to the material under consideration, and the discussion of the mechanism starts with the structure that is present and its

imperfection; in principle, however, the same questions arise for all materials, regardless of whether they are crystalline or noncrystalline substances, whether the solid is inorganic or organic, or whether the bonding in the substances is metallic, heteropolar, or of some other type.

A focal point for further investigations in the near future will be diffusion in multicomponent systems, both for phenomenological description and for explanation on the basis of imperfection models. Further investigations on the influence of dislocations and grain boundaries on mass transport are also necessary; importance should also be placed here on the question of the mechanism of such processes, since practically nothing is known about this field. Further results for noncrystalline substances would also be desirable; in the case of oxide glasses, the mobility of the particles forming the network (*e.g.* Si) is particularly interesting. Knowledge about diffusion in nonoxide glasses is also lacking at present. Investigations of this nature may also help to provide information about the structures that are not very amenable to direct methods (*e.g.* X-ray diffraction).

Another trend in these investigations will be the reliable measurement and interpretation of small deviations from normal behavior. Increases in measuring accuracy and better characterization of the substances may contribute in this connection.

As was mentioned in the introduction, diffusion also plays an important part in a number of technical processes. To obtain a better theoretical understanding of these processes, and hence to be able to make them more efficient, results from diffusion in solids should be applied in practice to a greater extent than in the past. Since the procedure in these fields is still often very empirical, knowledge about mass transport is not merely of academic interest.

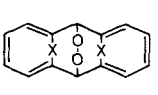
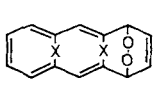
Photooxidation of Annulenes



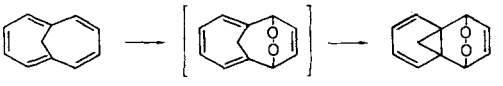
By *Emanuel Vogel, Arnold Alscher*, and *Klaus Wilms*[*]

Dedicated to Professor Hellmut Bredereck on the occasion of his 70th birthday

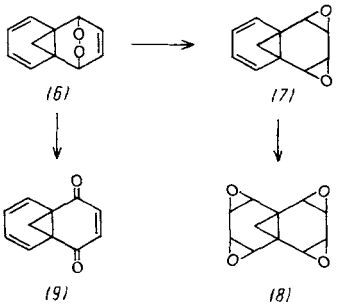


The bridged [4*n*+2]annulenes having a naphthalene[1] or an anthracene perimeter[2] resemble the classical aromatic compounds naphthalene and anthracene *inter alia* in being stable to atmospheric oxygen[3,4] and in exhibiting favorable steric conditions for 1,4-cycloadditions. It therefore seemed reasonable to assume that these annulenes, like certain naphthalenes and anthracene, undergo dye-sensitized photooxidation, *i.e.* reaction with singlet oxygen, to give 1,4-endoperoxides (1,4-epidioxy compounds) [*(1)* and *(2)* and/or *(3)*] or their reaction products[5]. As we have now found, the photooxidation behavior of bridged [10]- and [14]annulenes accords with expectations.

(1)



(2)



(3)

1,6-Methano[10]annulene *(4)*[6], which is remarkably stable to oxygen and is photostable in an inert gas atmosphere, undergoes fairly rapid oxidation on irradiation with a sodium vapor lamp in the presence of methylene blue and oxygen (methylene chloride; 10—15 °C)[7]. If the irradiated mixture is worked up below 15 °C the sole reaction product isolated is a sterically homogeneous 1,4-endoperoxide (*ca.* 25% after 12 h) whose NMR and UV spectra show it to possess the norcaradiene structure *(6)* [concerning the properties of *(6)* and the other photooxidation products mentioned in the text, see Table 1]. The peroxide group in *(6)* is apparently *anti* to the three-membered ring, for the cyclopropane protons of the compound accord well in their chemical shifts with those of the hydrocarbon tricyclo[4.3.1.0^{1,6}]deca-2,4-diene[8]. The 1,4-endoperoxide *(6)* is presumably formed by a [4+2] or [8+2] cycloaddition of singlet oxygen to *(4)* followed by a cycloheptatriene-norcaradiene valence isomerization of the resulting adduct *(5)*; however, the intermediacy of tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene[9] instead of *(5)* cannot be completely ruled out.

(4) *(5)* *(6)*

In parallel to the behavior of related 1,4-endoperoxides[10] compound *(6)* yields the diepoxide *(7)* on gentle heating; *(7)* can be regarded as a trishomobenzene or trishomonaphthalene derivative. Under the photooxidation conditions employed with *(4)*, compound *(7)* is able to take up a further mole of singlet oxygen, albeit slowly, to give the tetraepoxide *(8)* *via* a 1,4-endoperoxide which has hitherto defied attempts at isolation. Since *(8)* exhibits only one AA'BB' system and a singlet in its NMR spectrum the two new epoxide rings are doubtless also *anti* to the cyclopropane ring. On attempted chromatography over alumina, compound *(6)* undergoes

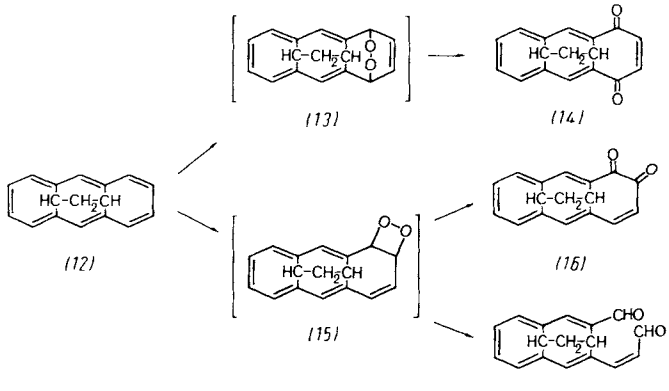
dehydrogenation to give the known compound tricyclo[4.4.1.0^{1,6}]undeca-3,7,9-triene-2,5-dione *(9)*[11].

1,6-Oxido[10]annulene and 1,6-imino[10]annulene can be photooxidized only very slowly, probably because the $-I$ effect of the bridge oxygen and the bridge nitrogen, respectively, lower the tendency of these annulenes to undergo cycloadditions with singlet oxygen.



(10) *(11)*

The 1,4-endoperoxides derived from 1,6-oxido- and 1,6-imino[10]annulene show an even more pronounced tendency to rearrange thermally to diepoxides than *(6)*. Accordingly, attempts to isolate the peroxides have so far invariably afforded the isomers *(10)*[12] and *(11)*[13], respectively. To our knowledge, *(11)* is the first benzeneimine derivative in which the hydrogen on the nitrogen is not replaced by substituents.

The aromatic bridged [14]annulenes having an anthracene perimeter are also amenable to photooxidation, although with these compounds the reaction proceeds less uniformly than in the case of *(4)*. As a representative example we shall consider the behavior of 1,6:8,13-propanediylidene[14]annulene *(12)*. Irradiation of *(12)* in the presence of methylene blue and oxygen (methylene chloride; 10—15 °C) leads to complete reaction of the starting material within only 2—3 h giving a mixture of products which can be separated into the two [14]annulene quinones *(14)* (9%) and *(16)* (8%)[14] and the dialdehyde *(17)* (9%) by chromatography over silica gel.

The structures of the three photooxidation products *(14)*, *(16)*, and *(17)* follow from the NMR spectra in conjunction with the UV spectra and the detection of CO groups. In accord with the C_s symmetry of the molecule, the NMR spectrum of *(14)* (see Table 1) is relatively simple: as expected it shows only an AA'BB' system and two singlets for the perimeter protons. The coupling constants of the protons belonging to the AA'BB' system indicate that *(14)* contains the cycloheptatriene and not the norcaradiene partial structure. In the case of the less transparent spectra of *(16)* and *(17)*, crucial evidence for the structural elucidation was provided by the fact that the spectrum of *(16)* features an AB system among the signals of the perimeter protons, whereas that of *(17)* contains the signals of two (non-equivalent) aldehyde protons.

(13) *(14)* *(12)* *(16)* *(15)* *(17)*

The annulene quinone *(14)* is apparently a subsequent product of the initially formed 1,4-endoperoxide *(13)*. That a peroxide of type *(2)*, which would be the analog of 9,10-dihydro-9,10-epidioxyanthracene[15], or the respective quinone does not occur in detectable amounts among the reaction products is probably due to steric effects. The isomeric annulene quinone *(16)* and the dialdehyde *(17)* must arise from the 1,2-dioxetane *(15)*; however, it remains to be established whether *(15)* is a primary photooxidation product or whether it is formed from *(13)* in the process of isolation[16][**].

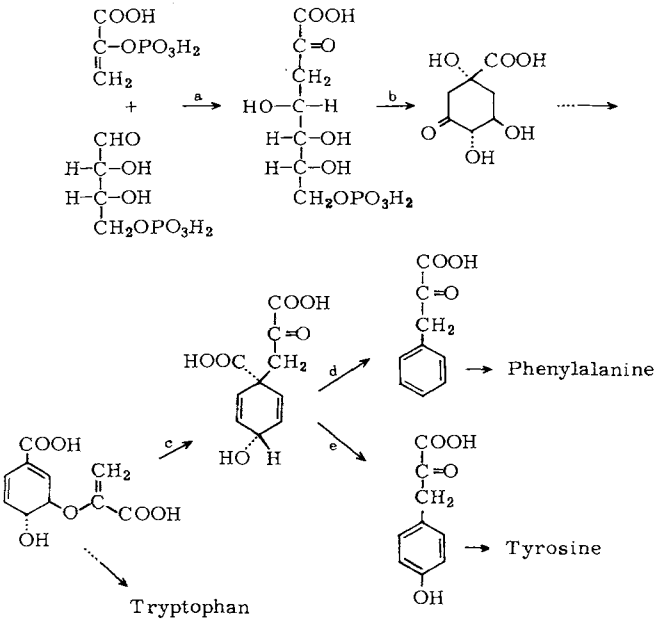
Effect of the Herbicide *N*-Phosphonomethylglycine on the Biosynthesis of Aromatic Amino Acids

By *Uta Roisch* and *Franz Lingens*[*]



Dedicated to Professor Hellmut Bredereck on the occasion of his 70th birthday

The herbicide[1] *N*-phosphonomethylglycine *(1)* has proved particularly promising for destruction of perennial resistant weeds such as couch grass and bindweed.

$H_2O_3PCH_2-NH-CH_2-COOH$ *(1)*

From growth experiments with *Lemna gibba* and *Rhizobium japonicum*, *Jaworski*[2] concluded that the effect of this compound is due to inhibition of the biosynthesis of aromatic amino acids. The inhibitory action of *(1)* could be reversed by addition of aromatic amino acids.

We have studied which metabolic step is influenced by the herbicide (see Scheme 1). *N*-Phosphonomethylglycine *(1)* was synthesized as described by *Crofts* and *Kosolapoff*[3] and by *Edward*[4]. Growth of *Escherichia coli* B is completely inhibited for 16 h by *(1)* at a concentration of 2×10^{-3} M. This inhibitory effect is partially removed by addition of phenylalanine; tyrosine at the same concentration counteracts the inhibition to a lesser extent; the two amino acids have an increased effect if administered in admixture. The effect of

Scheme 1. Biosynthesis of phenylalanine, tyrosine, and tryptophan. Enzymes: a, 3-deoxy-2-oxo-D-arabinoheptonic acid 7-phosphate synthetase (E.C. 4.1.2.15); b, 5-dehydroquinic acid synthetase; c, chorismate mutase (E.C. 5.4.99.5); d, prephenate dehydratase (E.C. 4.2.1.51); e, prephenate dehydrogenase (E.C. 1.3.1.12).

tryptophan was slight, but nevertheless significant. The action of *(1)* can be eliminated completely by addition of a mixture of all three amino acids. No effect was observed with other amino acids (histidine, valine, leucine).

We have found that *(1)* inhibits the enzyme 3-deoxy-2-oxo-D-arabinoheptonic acid 7-phosphate synthetase (E.C. 4.1.2.15, test according to[5]); with 10^{-2} M *(1)* inhibition amounts to 50%. 5-Dehydroquinic acid synthetase (test according to[6]) is also inhibited by *(1)*. Both inhibitory effects are removed by addition of Co^{2+}.

Chorismate mutase (E.C. 5.4.99.5, test according to[7]), prephenate dehydrogenase (E.C. 1.3.1.12, test according to[8]), and prephenate dehydratase (E.C. 4.2.1.51, test according to[7]) are not affected by *(1)*.

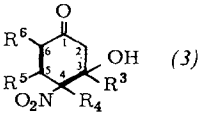
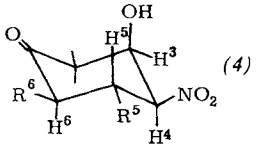
tion of alkaloid precursors, we examined the behavior of the polyanions *(1)* and *(2)*[2]. These species were obtained from 1,3-dicarbonyl derivatives by stepwise metalation.

(1a), R = H
(1b), R = CH_3



(2a), R = CH_3
(2b), R = $H_2C^{\ominus}$



(3g)

Consecutive Michael addition and, after appropriate work-up (see *Experimental*), aldol reaction leads directly to the highly substituted cyclohexanones *(3)*; the synthesis of *(3g)* will serve as an example [for *(3a)—(3i)* see Table 1]. (The newly formed C—C bonds are emphasized by bold print in the formula.) The products *(3)* can readily be obtained pure owing to the pronounced ease with which they crystallize[3]. The spectroscopic data [*e.g.* IR: OH (br.) 3600—3200, C=O 1710, NO_2 1560 cm^{-1}] and elemental analyses are in accord with the proposed structures.

Surprisingly, neither the melting behavior nor the NMR spectra of the crude and pure products *(3)* gave any indication of the formation of diastereoisomers (up to four chiral centers). The configuration of the uniform products can in some cases be deduced from the NMR spectra (in D_6-DMSO or $CDCl_3$, for example see *Experimental*) [cf. formula *(4)*].

(3)

(4)

The typical[4] *gauche* ($J_{3\text{-H},4\text{-H}} = 2.5$ Hz) and *anti* coupling constants ($J_{4\text{-H},5\text{-H}}$, $J_{5\text{-H},6\text{-H}} = 12$ Hz) establish the *cis* relationship of OH and NO_2 in *(3b)* and *(3f)*, the *trans* relationship of NO_2 and R^5 in *(3a)—(3c)* and *(3e)—(3i)*, and the *trans* relationship of R^5 and R^6 in *(3h)*. No decision on the configuration about the C^3—C^4 bond of the ring in *(3a)*, *(3c)—(3e)*, *(3g)—(3i)* can be reached on the basis of the NMR spectrum.

5-(3,4-Dimethoxyphenyl)-3-hydroxy-3-methyl-4-nitrocyclohexanone (3g):

β-Nitro-3,4-dimethoxystyrene (1.16 g, 5.5 mmol) in THF (30 ml) is added to a stirred solution of *(1b)* (12 mmol) [prepared by consecutive metalation of 2,4-pentanedione (1.53 g) with NaH (0 °C) and *n*-butyllithium (−78 °C)] in THF (40 ml)/hexane (7 ml) under argon at −78 °C over 15 min. After 3 h the cold solution (−78 °C) is poured into water (250 ml), neutralized with acetic acid, and extracted with methylene chloride; yield 1.10 g (73%) of *(3g)*, m.p. 156—159 °C (from CH_2Cl_2/ether). IR (KI): 3350 (OH, broad), 1715 (C=O), 1560 and 1365 cm^{-1} (NO_2). NMR ($CDCl_3$): δ = 6.80 (2 aromatic H, s), 6.72 (1 aromatic H, s), 5.00 (H^4, d, 12 Hz), 3.96 (H^5, m), 3.80 ($2OCH_3$, 2 s, 0.015 ppm separation); 3.0 (OH, br. s); 2.4—2.8 ($2H^2$, $2H^6$, m), 1.40 (3H (CH_3), s).

Sulfonylbis(imidosulfur Oxide Difluoride) from Trichlorophosphazosulfonylimidosulfur Oxide Difluoride[**]

By *Christof Jäckh* and *Wolfgang Sundermeyer*[*]

We have already utilized the reaction of mercury bis(imidosulfur oxide difluoride) *(1)*[1] with element halides to prepare numerous imidosulfur oxide difluorides[2,3] not previously accessible by other methods. Compound *(1)* also reacts quantitatively with trichlorophosphazosulfonyl chloride *(2)*[4] to give trichlorophosphazosulfonylimidosulfur oxide difluoride *(3)*.

[*] Prof. Dr. W. Sundermeyer and Dipl.-Chem. C. Jäckh
Anorganisch-chemisches Institut der Universität
69 Heidelberg 1, Im Neuenheimer Feld 7 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The mass spectra crucial for elucidation of the reaction course were kindly recorded by Dr. *R. Geist*.

$$Hg(NSOF_2)_2 + 2Cl{-}SO_2{-}NPCl_3 \rightarrow 2F_2OSN{-}SO_2{-}NPCl_3 + HgCl_2 \quad (1)$$
(1) (2) (3)

Compounds *(1)* (0.1 mol) and *(2)* (0.2 mol) are heated to 70 °C for 9 h in dry carbon tetrachloride (200 ml). After cooling, the mercury chloride is removed (G 3 frit) in the absence of air and the solvent drawn off under vacuum. Pure *(3)* remains as a yellowish viscous liquid which is sensitive to hydrolysis and decomposes above 100 °C during distillation at 0.01 torr. The compound was identified by elemental analysis and its mass spectrum: m/e = 320/318/316/314 molecular ion (rel. int. 0.09/2.7/7.3/6.4 %), 283/281/279 $F_2OSN{-}SO_2{-}NPCl_2$ (0.08/5.5/6.4), 220/218/216/214 $SO_2{-}NPCl_3$ (5.5/34.6/98/100), 164 $F_2OSN{-}SO_2$ (5.5), 150 $NPCl_3$ (5.5), 115 $NPCl_2$ (3.6), 100 $NSOF_2$ (3.7), 80 NPCl (9.1), 67 OSF (10.9), 66 PCl (3.6), 64 SO_2 (9.0), 62 NSO (5.5), 48 SO (7.3), 46 SN (14.5), and 45 NP (5.3). The ^{19}F-NMR spectrum displays a singlet at −45.8 ppm in $CFCl_3$ (external standard), and the IR spectrum bands at 1415, 1365, 1240, 1190, 880, 850, 775, 630, 600, 555, 540, and 510 cm^{-1}.

Neither the reaction of sulfonyl chloride with *(1)* nor that of sulfamide or doubly symmetrically substituted sulfamide, nor that of $F_2OSN{-}SO_2{-}NCO$[3], with sulfur oxide tetrafluoride *(4)*[5] has yet afforded sulfonylbis(imidosulfur oxide difluoride) *(5)*. We have now obtained *(5)* by cleavage of the trichlorophosphazo group in *(3)* by OSF_4.

$$F_2OSN{-}SO_2{-}NPCl_3 + OSF_4 \rightarrow F_2OSN{-}SO_2{-}NSOF_2 + [F_2PCl_3] \quad (2)$$
(3) (4) (5) (6)

The reaction presumably involves formation of *(6)* which, however, reacts further with *(4)*. This course is evidenced by analysis of the by-products.

$$2[F_2PCl_3] + 3OSF_4 \rightarrow 2PF_5 + 3OSF_2 + 3Cl_2 \quad (3)$$
(6) (4)

Accordingly, a corresponding excess of *(4)* should enhance the yield of *(5)*. This is found not to apply in practice.

Heating of a mixture of *(3)* (0.1 mol) and *(4)* (0.1 mol) to 80 °C for 10 h in a 100-ml autoclave, the volatile products being drawn off into a cold trap after the reaction mixture has cooled, followed by distillation of the volatile components together with the liquid residue found in the autoclave affords a low yield (*ca.* 2 g, 7.5 %) of *(5)*, b.p. 49 °C/12 torr. The substance was identified by elemental analysis and its mass spectrum: m/e = 266/264 molecular ion (rel. int. 2.7/14.5 %), 166/164 $F_2OSN{-}SO_2$ (10.9/100), 100 $NSOF_2$ (9.1), 86 OSF_2 (1.8), 83 SO_2F (1.6), 67 SOF (12.8), 64 SO_2 (1.8), 48 SO (2.7), and 46 SN (2.7). The transition 264→164 is confirmed by a metastable peak at 101.9.—The ^{19}F-NMR spectrum contains a singlet at −46.2 ppm in $CFCl_3$ (ext. standard), and the bands of the IR spectrum appear at 1435, 1265, 1090, 880, 815, 730, 708, 695, 550, and 532 cm^{-1}.

An indication that the reaction proceeds according to eq. (2), and for the formation of fluorophosphoranes such as *(6)*, was also provided by the reaction of triphenylphosphazo derivatives such as $(CH_3)_3Si{-}NP(C_6H_5)_3$[6] or $Cl{-}SO_2{-}NP(C_6H_5)_3$ with OSF_4, where triphenyldifluorophosphorane is formed instead of triphenyloxophosphorane. Application of this reaction to trichlorophosphazo derivatives thus opens up an additional method for the preparation of imidosulfur oxide difluorides. For example, compound *(2)* reacts with *(4)* according to

$$Cl{-}SO_2{-}NPCl_3 + OSF_4 \rightarrow F{-}SO_2{-}NSOF_2 + [FPCl_4] \quad (4)$$
(2) (4) (7)

giving fluorosulfonylimidosulfur oxide difluoride *(7)*[7].

Rearrangement of (Trimethylsilyl)methyl Allyl Ethers, A Dyotropic Reaction?

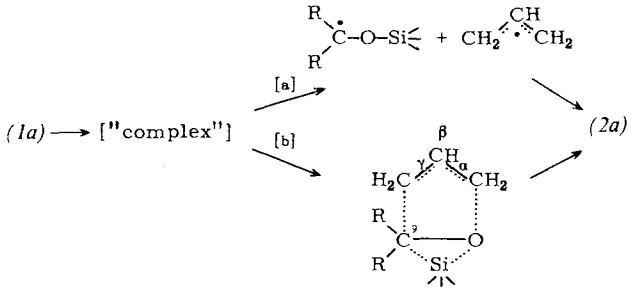
By *Manfred T. Reetz* [*]

Recently dyotropic rearrangements were defined as pericyclic processes in which two σ-bonds interchange their positions[1]. In order to test whether such reactions are feasible, allyl ethers of type *(1)* containing silyl and allyl moieties as potential migrating groups were synthesized[2]. These groups were chosen to ensure that rearrangement should be thermally allowed according to orbital symmetry[3,4].

(1) *(2)*

(a), R + R = *o*, *o'*-biphenylylene
(b), R = phenyl

Heating of *(1)* in inert solvents up to 160—200 °C did indeed afford the silyl ethers *(2)*[5] (yields: *(2a)*, 98 %; *(2b)*, 97 %). Despite the absence of appreciable amounts of side products, the rearrangement does not proceed according to a single mechanism, since the rearrangement of *(1a)* (α,α-D_2) afforded *(2a)* with only 80 % allyl inversion. The origin of the "wrong" isomer was explained by cross-over experiments which revealed that migration of the silyl groups is 100 % intramolecular, while that of the allyl groups is only 72 % intramolecular. In contrast, thermolysis in the presence of a radical trapping agent (benzoquinone) furnished *(2a)* in *ca.* 60 % yield, but *completely intramolecularly with more than 97 % allyl inversion*[6].



The rearrangement of *(1a)* in the absence of a radical trapping agent obeys first order kinetics, and is influenced only slightly by solvent polarity: k_{rel} = 1.0 (decalin): 1.2 (benzene): 2.8 (*o*-dichlorobenzene): 5.1 (propylene carbonate). Thus ions or zwitterions can be ruled out as possible intermediates. The activation parameters (measured in benzene) have the values

[*] Dr. M. T. Reetz
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

$E_a = 32.3 \pm 0.6$ kcal mol^{-1}, $\Delta H^{\neq} = 31.4 \pm 0.6$ kcal mol^{-1}, $\Delta S^{\neq} = -8.9 \pm 0.8$ cal deg^{-1}.

The secondary kinetic deuterium isotope effect of $k_H/k_D = 1.05 \pm 0.03$ measured for *(1a)* (α,α-D_2) (160 °C, benzene) shows that the allyl C—O bond can be stretched only to a slight extent in the transition state. The corresponding effect of $k_H/k_D = 1.00 \pm 0.03$ measured for *(1a)* (γ,γ-D_2) also excludes appreciable bond formation between the allyl C^{γ} atom and the fluorenyl C^9 atom in the transition state.

Although the present results do not permit final conclusions regarding the mechanism, it appears certain that in the rearrangement the initial motion of the silyl group is far more advanced than that of the allyl group. Rate-determining formation of a short-lived complex, in which the silyl moiety coordinates with the O-atom, followed by rapid decomposition into radicals[7] (path [a]) or intramolecular concerted rearrangement (path [b]) is conceivable.

[5] The structure of *(2)* was established spectroscopically, analytically, and by independent syntheses.

[6] Molar ratio benzoquinone: *(1a)* = 0.4 : 1 (in benzene). Even with a ten-fold increase in benzoquinone concentration the yield of *(2a)* remained at 60%.

[7] Path [a] represents a homolysis with neighboring group participation. This rare reaction type is currently being investigated with the benzyl ethers corresponding to *(1)*.

Subhalides of Tellurium: Crystal Structures of α-TeI and β-TeI

By *Rüdiger Kniep*, *Dietrich Mootz*, and *Albrecht Rabenau*[*]

After elucidating the crystal structures of Te_3Cl_2 and Te_2X (X = Cl, Br, or I)[1] we have now completed determination of the structures of the remaining known subhalides of tellurium[1].

Phase studies in the system Te—TeI_4[2] have shown that TeI is the only thermodynamically stable phase of the pseudobinary system. The phase width previously assumed for "Te_xI" could not be confirmed; instead it was proved that this is a further phase of 1:1 stoichiometry which was formed together with Te_2I in the same preparation. The compound that is stable with respect to the phase diagram (TeI in[1]) is now called α-TeI; the compounds β-TeI (Te_xI in[1]) and Te_2I[1] are metastable[2].

The crystals used for structure analysis of β-TeI and α-TeI were prepared hydrothermally in concentrated hydriodic acid[4]; their lattice constants have been given previously[1]. Although according to IR and Raman investigations of α-TeI[5] the crystal structure was not likely to possess an inversion center, the result of our complete structure analysis justifies its description in the centrosymmetric space group $P\bar{1}$. The structure of β-TeI is also centrosymmetric, having space group C2/m.

For determination of the crystal structure of β-TeI the intensities of 779 independent reflections with $Mo_{K\alpha}$ radiation ($\theta_{max} = 30°$) were measured on an automatic single-crystal diffractometer. After corrections for absorption and anisotropic refinement the *R* factor amounts to 5.4%.

Figure 1 represents the macromolecular structural unit of this structure. It consists of a zigzag chain of Te atoms running parallel to the crystallographic *b* axis, the atoms having alternate square-planar and trigonal-pyramidal coordination. Correspondingly, there are two independent I atoms in bridging and terminal positions respectively. Formally the β-TeI building unit is generated by halving the Te_2I unit[6] along its length and occupying the free valences each by one I atom.

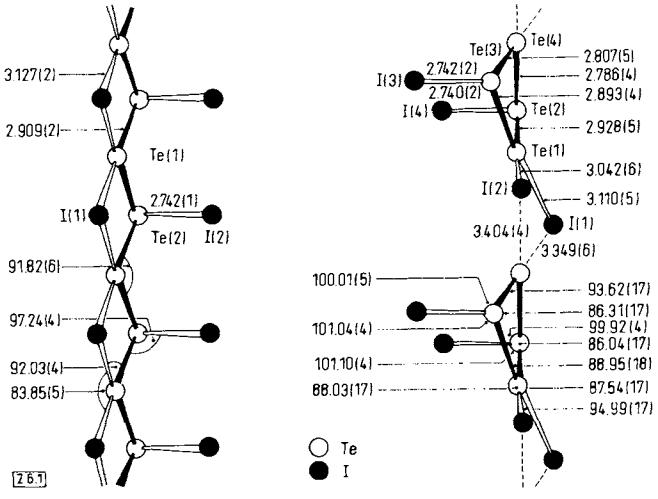

Fig. 1. Structural unit of β-TeI (left) and α-TeI (right): bond lengths (Å) and bond angles (°) with standard deviations in parentheses.

For determination of the crystal structure of α-TeI 3233 reflections were measured with $Mo_{K\alpha}$ radiation ($\theta_{max} = 30°$). After anisotropic refinement the *R* factor amounts to 5.5%.

Figure 1 shows a section of the molecular association in the α-TeI structure parallel to the crystallographic *c*-axis. It is interesting that here the structural unit is not macromolecular but a small molecule Te_4I_4. A Te_4 ring is formed, whose Te atoms are coordinated in three different ways: Te(1) square-planar, Te(2) and Te(3) trigonal-pyramidal, Te(4) only two-fold. The distances between I(1) and I(2) and the bivalent tellurium of the neighboring molecule in the *z*-direction are the shortest intermolecular contacts; they link the molecules into chains along the crystallographic *c*-axis.

That the four-membered ring in α-TeI consists only of Te atoms becomes clear from a comparison of the bond lengths and angles with those of β-TeI and from considerations of

the mechanism of the transformation β→α observed in single crystals[7]. This atomic assignment is also indicated by a qualitative interpretation of the electrical conductivities of all the tellurium subhalides[8, 9]. The concept of modified tellurium structures[1] is useful in such considerations: graded similarities to and differences from the structure of elemental tellurium are reflected in the conductivities.

[6] Te_2I [1] here became the key substance because the differentiation of Te from I followed from the structure determination of the isotypic Te_2Br and also because the results thus achieved could be applied to the interpretation of the β- and α-TeI structures.

[7] The structural course of this topotactic reaction has not yet been completely formulated and experimentally checked. It seems certain, though, that the cohering fragment I(1)-I(1)'-Te(1)-Te(2)-Te(2)'-I(2)-I(2)' ($I \doteq x, 1+y, z$) of the β-TeI building unit already constitutes the α-TeI molecule up to (but not including) the Te(4) atom required for the Te_4 ring closure.

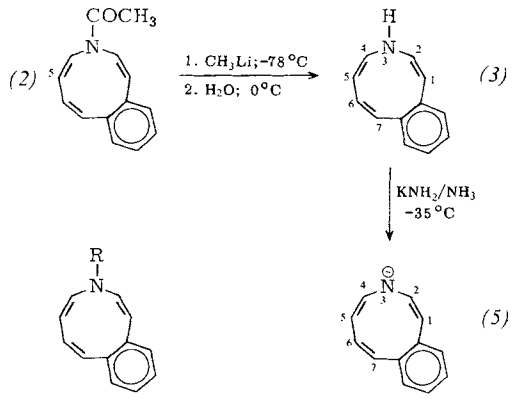
3*H*-3-Benzazonine and the 3-Benzazoninyl Anion[**]

By *A. G. Anastassiou* and *E. Reichmanis*[*]

In the area of nonbenzenoid aromatics direct comparison of a given member with benzene in terms of π-electron delocalization is normally judged to constitute a reliable, albeit demanding, test of "aromatic" character. Recently, we demonstrated[1] that of all known heteronins *(1)*, X = heteroatom, only 1*H*-azonine *(1a)*[2] and the corresponding base, the azoninyl anion *(1b)*[3], may be classified as "aromatic", with the latter slightly more so than the former. Presently, we offer direct comparison between these two species and benzene with a description of the title substances.



(1a), X = NH
(1b), X = $\overset{\ominus}{N}$

3*H*-3-Benzazonine *(3)* was prepared by treatment of the corresponding acetamide *(2)*[4] with methyllithium in THF at −78 °C followed by aqueous quenching at 0 °C. It was isolated as an air-sensitive pale yellow viscous oil displaying the following spectral characteristics: λ_{max} (hexane) = 290 nm ($\varepsilon \approx 2000$); ^{1}H-NMR (60 MHz; D_6-acetone/D_2O): $\tau = 2.71$ (4H, s), 3.55 (d, 1H^7, $J_{7,6} = 11.5$ Hz), 3.90 (d, 1H^6, $J_{6,7} \approx 11.5$ Hz)[5], 3.92 (d, 1H^2, $J_{2,1} = 10.5$ Hz), 4.37 (d, 1H^4, $J_{4,5} = 10.0$ Hz), 4.72 (d, 1H^1, $J_{1,2} = 10.5$ Hz), and 5.71 (d, 1H^5, $J_{5,4} = 10.0$ Hz)[5]; *m/e* 169 (M^+; 43%). Chemically, the structure of *(3)* was confirmed through conversion to the methoxycarbonyl derivative *(4a)*[4] (NMR, IR) on successive treatment with methyllithium and methyl chloroformate.

(4a), R = $COOCH_3$
(4b), R = $CON(CH_3)_2$

The region of NMR resonances associated with the azonine moiety of *(3)* serves to establish the molecule as an unexceptional benzopolyene. It is noted, for example, that the NMR signals due to the α ($\tau = 3.92$ and 4.37) and β protons ($\tau = 4.72$ and 5.71) of *(3)* are significantly displaced to higher field relative to their counterparts in the spectrum of 1*H*-azonine *(1a)* ($\tau = 2.93$ for H^α and 4.00 for H^β)[1, 3]. Moreover, unlike 1*H*-azonine whose NMR spectrum is displaced to lower fields relative to those of its *N*-substituted variants[1], comparison of *(3)* with its *N*-substituted derivatives, *(2)*, *(4a)*, and *(4b)*, in terms of H^5, *i.e.*, the β proton least likely to be influenced by the benzene group, actually reveals an upfield shift in the case of the parent and one which satisfies the linear correlation between $\delta(H_\beta)$ and σ_p^- (*N*-substituent, R = H, $CON(CH_3)_2$, $COOCH_3$, $COCH_3$) recently shown[6] to be characteristic of the isolated

function[7]. The nine-membered segment of *(3)* emerges as polyenic also on the basis of the UV spectrum (290 nm) which shows the type of mild bathochromic shift, by comparison with those of its derivatives *(2)* (275 nm), *(4a)* (267 nm), and *(4b)* (288 nm), one might expect chiefly on the basis of decreased heteroatom electronegativity in the absence of major skeletal changes.

Attention in this project was next directed towards the preparation of the corresponding base of *(3)*, namely the anion *(5)*, in the hope that the attendant reduction in heteroatom electronegativity might provide the necessary driving force for the development of a delocalized heteronin skeleton in spite of the adverse effect of benzannelation.

Exposure of *(3)* to potassium amide in liquid ammonia at *ca.* −35 °C changes the NMR spectrum from that described earlier for *(3)* (see above)[8, 9] to one consisting of absorptions at[10]: $\tau = 2.4$—2.7 (m), 2.8—3.1 (m), 3.38 (d, H^2, $J_{2,1} = 10$ Hz), 3.6—4.1 (m, $H^6 + H^7$), 3.72 (d, H^4, $J_{4,5} = 8.5$ Hz), 5.10 (d, H^1, $J_{1,2} = 10$ Hz), and 6.23 (dd, H^5, $J_{5,4} = 8.5$ Hz, $J_{5,6} = 4.5$ Hz) in relative areas of *ca.* 2:2:1:2:1:1:1. Convincing chemical proof that the species displaying the new spectrum is the benzazoninyl anion *(5)* was obtained by the regeneration of the original spectrum, *i.e.*, that of *(3)*, on rapid addition of a cold (*ca.* −70 °C) ammonia solution of *(5)* to moist ether at 0 °C.

It is immediately obvious from the NMR spectrum of *(5)* that the nine-membered segment of the molecule does not sustain a ring current at the temperatures employed in this

study (< -30 °C)[11]. This is best evidenced by the *upfield* shift of β protons H^1 (by 23 Hz) and H^5 (by 32 Hz) on going from *(3)* to *(5)*, which simply reflects the increased availability of the lone pair for limited delocalization but is clearly inconsistent with the development of the diamagnetic ring current expected of this system.

Obviously, the present findings indicate that neither 3-benzazonine *(3)*, at ambient temperature, nor the corresponding base *(5)*, generated at *ca.* −70 °C and observed at −35 °C[11], are capable of sustaining a ring current, *i.e.*, they are no more than benzopolyenes under the experimental conditions employed here.

(6)   *(7)*

Interestingly the behavior of *(3)* and *(5)* sharply contrasts with that of their iso-π-electronic carbocycle, the benzocyclononatetraenyl anion *(6)* which was recently shown[12] to possess a well delocalized 14π frame exhibiting strong ring diamagnetism over a wide temperature range (−55 to +35 °C).

[5] The signal shows secondary splitting.

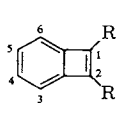
[6] *A. G. Anastassiou* and *R. L. Elliott*, J. C. S. Chem. Commun. *1973*, 601.

[7] In CCl_4 the H^5 resonance shows at $\tau = 5.71$ in *(3)*, 5.22 in *(4b)*, 5.18 in *(4a)*, and 5.10 in *(2)*.

[8] The NMR spectrum of *(3)* in liquid ammonia is very similar to that recorded in D_6-acetone. Most importantly, the chemical shifts of key β protons H^1 and H^5 are the same in the two media.

[9] In the generation of *(5)*, as described here, it is essential that the conversion of potassium to KNH_2 be complete, since potassium metal was found to activate efficient denitrogenation of *(5)* or *(3)* to benzocyclooctatetraenyl dianion *(7)* (NMR). For comparison purposes this dianion was prepared independently on exposure of benzocyclooctatetraene to potassium in liquid ammonia (−40 °C) and was found to possess a well delocalized 14π frame by NMR [$\tau = 2.05$ (2H, dd, $J = 7$ Hz, 3.5 Hz), 3.25 (d, H^5, H^{10}, $J_{5,6} = 11.5$ Hz), and 3.5—4.3 (6H, m)]. Exposure of the dianion prepared by either method to water at 0 °C affords three distinct benzocyclooctatrienes.

[10] The chemical shifts in liquid ammonia were determined by employing dimethoxyethane as internal standard.



[11] If *(5)* is allowed to stand overnight at 0 °C, its NMR spectrum undergoes radical changes. The structural characterization of the compound(s) responsible for the development of the new spectrum is currently under way.

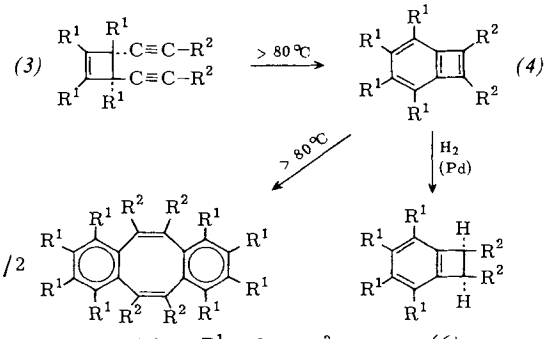
Isolation of 3,4,5,6-Tetramethyl-1,2-diphenylbenzocyclobutadiene

By *Henner Straub*[*]

Apart from metal complexes, no stable derivatives of benzocyclobutadiene *(1a)* are known[1]; only the naphtho[*b*]cyclobutadienes *(2a)* and *(2b)* have been isolated so far. Resonance energy calculations[2] on *(1a)* and *(1b)* indicate such a pronounced stabilizing effect of the two phenyl groups that isolation of compound *(1b)* does not appear to be a futile undertaking[3].



(1a), R = H
(1b), R = C_6H_5

(2a), R^1 = H; R^2 = C_6H_5
(2b), R^1 = C_6H_5; R^2 = Br

We were recently able to show by means of trapping reactions that thermal dimerization of the *trans*-bisacetylene *(3)* in boiling cyclohexane proceeds *via* the permethylated 1,2-diphenylbenzocyclobutadiene *(4)*[4]. Meanwhile we have found that the valence isomerization *(3)* → *(4)* is complete within a few minutes at *ca.* 110 °C, whereas the dimerization of *(4)* to *(5)* still progresses relatively slowly at this temperature. Timely quenching of the reaction mixture to room temperature permits isolation of the benzocyclobutadiene *(4)* in 20% yield[5] in the form of carmine red needles (m. p. 120 °C, dec.). *(4)* undergoes significant decomposition in solution at room temperature, even in the absence of air[6], but is surprisingly stable in crystalline form and transforms to the dimer *(5)*—without melting—only above 80 °C.

(5) R^1 = CH_3, R^2 = C_6H_5 *(6)*

The hydrocarbon *(4)*[7] has remarkable spectroscopic properties: the mass spectrum shows the molecular ion *m/e* 310 and the associated isotopic peak, but no significant fragmentation. The ^{1}H-NMR spectrum (CH_2Cl_2) displays a multiplet at $\delta = 7.15$—7.45 (10H) for the aromatic protons and only *one* singlet at $\delta = 1.93$ (12H) for the four methyl groups. This signal, which appears at relatively high field, has previously been observed for the starting material *(3)*[4] in high temperature measurements. In the IR spectrum (KBr) the $\nu_{C=C}$ stretching modes of the aromatic nuclei are accompanied by two further bands at 1660 and 1475 cm^{-1} which do not appear in the spectrum of the hydrogenation product *(6)*. In the UV region [*n*-hexane, nm (log ε)][6] *(4)* absorbs at 201 (4.66), 218 sh (4.38), 278 (4.60), and less strongly at 468 (3.25). The red compound *(2a)*[8] also absorbs *inter alia* at similarly long wavelengths [436 (371), 455 (3.71) in ethanol]. These long-wave bands are apparently characteristic of condensed 1,2-diphenylcyclobutadiene systems.

Chemical proof of the structure of *(4)* is based, apart from trapping reactions[4], on catalytic hydrogenation with palladium on calcium carbonate in which *(4)* rapidly takes up one mole of hydrogen to form the colorless benzocyclobutene *(6)* (m. p. 159 °C)[7]. The structure of *(6)* is confirmed by mass, IR, UV, and in particular by its ^{1}H-NMR spectrum [2.02 (s, 6H), 2.22 (s, 6H), 4.95 (s, 2H), 6.83 (s, 10H) in CCl_4]. As for the nonmethylated *cis*-1,2-diphenylbenzocyclobutene[9], the *cis* configuration of *(6)* is deduced from the characteristic upfield shift of the phenyl signals.

[*] Dr. H. Straub
Chemisches Institut der Universität
74 Tübingen, Auf der Morgenstelle 18 (Germany)

The extent to which the four methyl groups in *(4)* contribute to stabilization of the skeleton *(1b)* is difficult to estimate. However, the effect cannot be very large since the intermediate 3,4,5,6-tetramethylbenzocyclobutadiene undergoes immediate angular dimerization[10] like *(1a)*.

3,4,5,6-Tetramethyl-1,2-diphenylbenzocyclobutadiene (4)

All operations and measurements have to be performed under nitrogen. A solution of *(3)* (3.1 g, 10 mmol)[4] in light petroleum (b.p. 110—130 °C, 150 ml) is first heated to 110 °C (oil bath 175—180 °C) for 9 min and then immediately cooled in an ice bath. After complete removal of solvent (3—1 torr at room temperature) the residue is rapidly dissolved in light petroleum (b.p. 60—80 °C) and freed from sparingly soluble *(5)* (*ca.* 30%) by filtration. The filtrate is concentrated (14 torr at room temperature) until the onset of crystallization. The mixture is then cooled to −20 °C and the carmine red needles filtered off under suction (m.p. 120 °C, dec.); yield 20%.

[5] If *(4)* is trapped in solution directly with reactive dienophiles, the yields of the adducts exceed 80% in some cases [4].

[6] The UV spectra were each recorded 3 min after dissolution of *(4)*. The extinction coefficients of the bands change when the solution is allowed to stand, ε_{201} and ε_{218} increasing and ε_{278} and ε_{468} decreasing. The decrease in ε_{468} of a *ca.* 0.4 mM solution affords a half-life of *ca.* 23 min for *(4)* at room temperature.

[7] Correct elemental analyses were obtained for *(4)* and *(6)*.

[8] This does not apply to *(2b)*; *M. P. Cava* and *H. Y. Hwang* in ref. [1], p. 246.

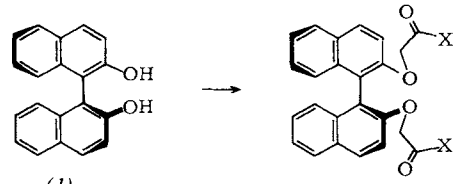
Chiral Macrobicyclic and Macrotricyclic Ligands[**]



By *Bernard Dietrich*, *Jean-Marie Lehn*, and *Jacques Simon*[*]

Complexation of alkali and alkaline-earth cations[1] by macrocyclic[2], macrobicyclic[1,3], and macrotricyclic[4–6] ligands leads to the formation of inclusion complexes of the cryptate[3] type. The design of molecular receptors capable of *molecular recognition* represents the next step in the elaboration of synthetic ligands which may selectively complex a given substrate molecule[5,6]. An interesting special case is the design of optically active substances capable of functioning as *chirospecific molecular receptors; i.e.* substances which display preferential complexation of one optical antipode of a given substrate. Optically active macrocyclic amino-ether[7] and polyether[8,9] ligands have been described recently; the latter display pronounced selectivity of complexation of chiral substrates[9]. Such behavior is also known for the natural macrocyclic polysugars, the cyclodextrins[10].

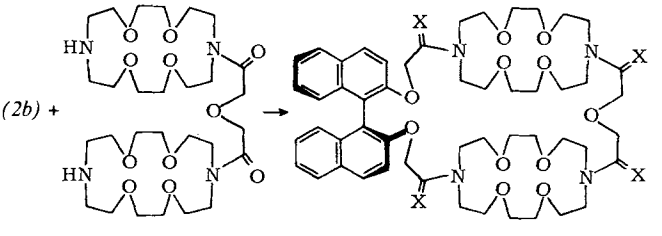
[**] Molecular Receptors, Part 3. Reported in part at the First Fall Organic Chemistry Meeting of the American Chemical Society, October 1—3, 1973, North Falmouth, Massachusetts.—Part 2: ref. [6].

We present here our results on the synthesis and on some properties of the chiral macrobicyclic and macrotricyclic molecules *(4)* and *(6)*, which may function as ligands for metal cations[1,3,6] as well as for molecules[6]. The binaphthyl group has been selected as center of chirality in the recently described chiral macrocyclic polyethers[8,9]. Not only does it introduce marked chirality into a molecule but is also quite easily prepared and resolved[11], and confers increased lipophilicity upon the system. Other chiral groups may be used for similar purposes[12].



(1) *(2a)*, X = OH *(2b)*, X = Cl

Optically active (*S*)-(−)-1,1′-bi-2-naphthol *(1)* [m.p. 206 °C; $[\alpha]_{578}^{25}$ −40° (*c* = 0.5, THF); −39.6° (*c* = 1.05, THF)[11]] has been obtained *via* resolution of its phosphoric acid derivative with cinchonine[11] and recrystallized from toluene. Condensation of *(1)* with bromoacetic acid in refluxing methanol in the presence of potassium carbonate affords the optically active dicarboxylic acid *(2a)* [m.p. (racemic) ≈210 °C; $[\alpha]_D^{25}$ −36° (*c* = 0.22, acetone); yield 95%]. The corresponding dichloride *(2b)* is obtained by treatment with oxalyl chloride in benzene; the yield is quantitative (NMR spectrum) and the oily product is used without further purification; the crystalline racemic dichloride has m.p. 73—75 °C.

(3) *(4a)*, X = O *(4b)*, X = H_2

Condensation of *(2b)* with the macrocyclic diamine *(3)*[3] under high dilution conditions[3] gives the macrobicyclic dicarboxamide *(4a)* [m.p. 190—192 °C; $[\alpha]_D^{25}$ −92° (*c* = 0.41, $CHCl_3$); yield 60%]. Reduction of *(4a)* with diborane in THF[3] leads to the optically active macrobicyclic diamine *(4b)* [oil; $[\alpha]_D^{25}$ −151° (*c* = 0.39, $CHCl_3$); yield 90%].

(5) *(6a)*, X = O *(6b)*, X = H_2

High dilution condensation[3] of *(2b)* with the diamine *(5)*[5] affords the tetracarboxamide *(6a)* [glass; $[\alpha]_D^{25}$ −42° (*c* = 0.23, acetone); yield 50%]. Diborane reduction[3] of *(6a)* gives

the optically active macrotricyclic tetraamine *(6b)* [oil; $[\alpha]_D^{25}$ $-68°$ ($c=0.17$, $CHCl_3$); yield 90%]. Compounds *(4b)* and *(6b)* were further purified by lyophilization in benzene/methanol (9:1). The spectral (NMR; mass) and analytical data of the compounds described are in agreement with the structures *(2)*, *(4)*, and *(6)*. Control experiments were performed to ensure that no detectable racemization occurs in the course of the condensation and reduction steps leading to *(2a)*, *(4b)*, and *(6b)*.

Hydrolysis of the borane-amine adducts formed in the diborane reductions was not effected under reflux (as in ref.[3]); instead the products were treated with a mixture of THF and 9 N HCl (1:1) for one hour at 25°C. The amines *(4b)* and *(6b)* were extracted with toluene after the solution had been rendered basic.

Compounds *(4)* and *(6)* are the first optically active, synthetic macrobicyclic and macrotricyclic substances to be reported. Macrotricyclic systems contain a large intramolecular cavity which should be capable of accommodating substrate molecules[5,6]. Molecular models show that the cavity of compounds *(6)* forms a deep (about 8 Å) chiral pocket. Like their previously described achiral analogs[1,3,5], *(4b)* and *(6b)* complex various metal cations.

Formation of complexes between ligand *(4b)* and the bromides of sodium, potassium, rubidium, and cesium leads to marked changes in the NMR and UV spectra of the ligand. An interesting effect is found for the optical rotation. The element of chirality is the angle between the two naphthalene systems in the binaphthyl fragment. Complexation of a metal cation inside the molecular cavity is expected to affect the optical activity of *(4b)* both by electronic effects and by modification of the chirality angle. The latter factor may be expected to display a gradual variation as the size of the included cation increases from sodium to cesium and deforms the ligand, the charge remaining constant. This is indeed observed: $[\alpha]_D^{25}=+36$, -9, -130, and $-215°$ (in $CHCl_3$) for the cryptate complexes of *(4b)* with NaBr, KBr, RbBr, and CsBr, respectively. Assuming that the value measured for Na^+ contains both the effect of cation charge and that of conformational change on cation inclusion, the variations observed for K^+, Rb^+ and Cs^+ may be related to a progressive opening of the dihedral angle caused by the increase in cation size. Complexation also leads to large changes in the circular dichroism spectra of the ligand.

The macrotricyclic ligand *(6b)* also shows pronounced NMR spectral changes on cation complexation (Na^+, K^+). The specific rotation is -25 and $0°$ for the Na^+ and K^+ complexes respectively. Like the previously described tetraamides[5,6], *(6a)* does not form stable complexes with alkali metal cations. However, it contains amide (like peptides) and ether binding sites and has been found to extract ammonium salts from water solution into chloroform[13]. Both cation and anion properties are expected to affect such ion pair binding. So far only low optical resolution (about 10% optical purity) of racemic substrates has been achieved[13].

Depending on the properties desired, additional structural features may be introduced into these ligands (*e.g.* cationic or anionic sites for substrate-ligand ion pairing and catalytic sites for specific reactions), as has been done for macrocyclic polyethers (carboxylate sites)[8,9] and for macropolycyclic amino-ethers (carboxylate, imidazole, and hydroxamate sites)[14].

A Novel Method for the Stereoselective Synthesis of *trans* Olefins

By *Kiyosi Kondo, Akira Negishi*, and *Daiei Tunemoto*[*]

We report herein a new and useful two-step synthesis of *trans* olefins from alkyl halides R^1—X and γ-substituted allylphosphonates, *e. g.* diethyl 2-butenylphosphonate *(1a)* and diethyl (3-methyl-2-butenyl)phosphonate *(1b)*.

There are several reports in the literature describing electrophilic capture of phosphonate-stabilized carbanions by alkyl halides or ketones[1]. However, those adducts do not appear to be satisfactorily transformed into olefins[2]. We found that lithio derivatives of γ-substituted allylphosphonates such as *(1a)* or *(1b)* were alkylated at the α position exclusively by a variety of alkyl halides. Furthermore, the adducts *(2)* undergo a smooth reductive fission to olefins *(3)* on treatment with $LiAlH_4$ in dry ether at 0°C for a few hours. The IR spectra exhibited a strong absorption at 965 cm^{-1} characteristic of *trans* olefins; their homogeneity was confirmed by gas chromatography using several different columns.

Thus the newly found hydrogenolysis of allylic phosphonates, in conjunction with alkylation as described above, constitutes an excellent and generally applicable method for the stereoselective synthesis of *trans* olefins[3] (Table 1).

A further advantage of the method derives from the fact that even if the starting material *(1)* is not stereochemically

Table 1. Yields of the reaction products from allylphosphonates *(1)* and alkyl halides X—R^1.

(1)	X—R^1	*(2)* Yield [%]	*trans*-Olefin *(3)*	Yield [%]
(1a)	$Br—CH_2C_6H_5$	83	$CH_3CH_2CH=CH—CH_2C_6H_5$	89
(1a)	$Br—(CH_2)_7CH_3$	92	$CH_3CH_2CH=CH—(CH_2)_7CH_3$	56
(1a)		78		82
(1a)	$Br—CH_2CH(OC_2H_5)_2$	35	$CH_3CH_2CH=CH—CH_2CH(OC_2H_5)_2$	40
(1b)	$Cl—CH_2C_6H_5$	55	$(CH_3)_2CHCH=CH—CH_2C_6H_5$	82
(1b)	 [a]	67		77
(1b)	$Br—(CH_2)_7CH_3$	94	$(CH_3)_2CHCH=CH—(CH_2)_7CH_3$	84
(1b)		91		83

[a] THP tetrahydropyran-2-yl.

pure reduction of *(2)* still affords pure *trans* olefin. For example, alkylation of a mixture of *cis*- and *trans*-2-butenylphosphonate *(1a)* with benzyl bromide followed by reduction afforded *trans*-1-phenyl-2-pentene exclusively[4].

(4) *(5)*

Finally, the present method was applied to the synthesis of *trans*-11-tetradecenal, which is the sex attractant of the eastern spruce budworm, *Choristoneura fumiferana Clemens*[5]. Starting with readily available bromide *(4)*[6] and *(1a)*, and using the same procedure as described above, we obtained *trans*-11-tetradecenol *(5)* in 73% yield, which was readily converted into the aldehyde in 95% yield.

trans-1-Phenyl-2-pentene (3), R = H, $R^1 = CH_2C_6H_5$

n-Butyllithium (12 mmol) was added to a stirred solution of *(1a)* (1.92 g, 10 mmol) in THF (20 ml) at −60 °C under a positive pressure of argon and stirred at this temperature for 1 h. Benzyl bromide (1.7 g, 10 mmol) in THF (5 ml) was added dropwise to the solution. After stirring for an additional 30 min at −60 °C, the reaction mixture was allowed to warm to room temperature. The mixture was quenched by the addition of 10% aqueous NH_4Cl and the product was isolated by extraction with ether. Distillation of the crude product afforded 2.33 g (83%) of the adduct *(2)*, R = H, $R^1 = CH_2C_6H_5$ (b. p. 144 °C/0.3 torr). A solution of this adduct (1.4 g, 5 mmol) in dry ether (100 ml) was cooled in an ice bath and $LiAlH_4$ (0.11 g) was added. After stirring for 1 h at 0 °C, a few drops of water were added and the resulting mixture was filtered through celite. The solid was washed with ether and the combined filtrates were evaporated. The resulting crude product was purified by distillation to yield 0.65 g (89%) of *(3)*, R = H, $R^1 = CH_2C_6H_5$ (b. p. 88 °C/14 torr). The overall yield of the olefin did not decrease when the two steps were performed successively without purification of the intermediate.

We have studied the reaction of 1,2,4,6-tetraphenyl-λ⁵-phosphorin-1-yllithium *(5a)* and the corresponding 1-methyl compound *(5b)* with the transition metal salts $AgNO_3$, $Hg(OAc)_2$, and $FeCl_2$.

(6)

(6b), R' = CH_3

R = C_6H_5

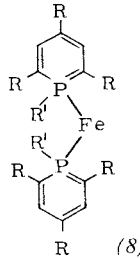
(5a), R' = C_6H_5
(5b), R' = CH_3

$\frac{1}{2}$ $[C_{23}H_{17}P–R']_2Fe$ + LiCl

(7a), R' = C_6H_5
(7b), R' = CH_3

[*] Prof. Dr. G. Märkl and Dipl.-Chem. C. Martin
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

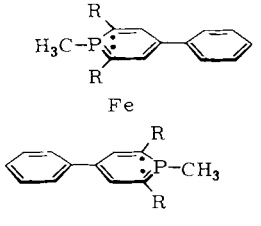
The anions[5] of *(5a)* and *(5b)*, which are sensitive to moisture, can be obtained as deep blue-red solutions by reaction of 2,4,6-triphenylphosphabenzene *(4)* with phenyl- and methyllithium, respectively, in benzene or THF; they can be isolated as relatively stable deep red salts of the tetrabutylammonium ion[6].



(5a) and *(5b)* undergo redox reactions with $AgNO_3$ and $Hg(OAc)_2$; silver or mercury is deposited and the phosphorin *(4)* regenerated. It has yet to be established whether σ-complexes having P—Ag or P—Hg bonds play an intermediate role in these reactions.

Treatment of *(5a)* and *(5b)* with $FeCl_2$ in THF (reaction conditions as for ferrocene formation from cyclopentadienyl anion and $FeCl_2$) affords deep brown solutions from which brownish red neutral compounds *(7a)* and *(7b)* can be isolated by chromatography (SiO_2/light petroleum); they form fine, felted, lustrous needles on crystallization from benzene/light petroleum.

(7a), m.p. 231 °C; mass spectrum (70 eV, T_0 = 180 °C): 858 (M^+, 5%); ^{1}H-NMR: τ = 2.34—3.57 (m, 40H), 4.72 (br. d, 4 phosphorin-H), $^3J_{P\ H}$ = 10 Hz.



(7b), m.p. 192 °C; mass spectrum (70 eV, T_0 = 160 °C): 734 (M^+, 21%); ^{1}H-NMR: τ = 2.15—3.20 (m, 30H), 4.63 (br. d, 4 phosphorin-H), $^3J_{P-H}$ = 8 Hz, 9.96 (d, 6H), $^2J_{P-H}$ = 5 Hz (methyl-H).

The results of elemental analysis, osmometric molecular-weight determination, and mass spectrometry clearly indicate a metathetic reaction yielding $[C_{23}H_{17}P—R']_2Fe$. The ^{1}H-NMR spectrum of *(7b)* permits tentative conclusions regarding structure. Whereas the methyl protons of 1,1-dimethyl-2,4,6-triphenyl-λ^5-phosphorin *(6b)* appear as a doublet at τ = 8.27, the corresponding signal of *(7b)* exhibits a pronounced upfield shift (τ = 9.96).

(8)

R = C_6H_5

(7b)

We consider that this effect is interpretable only by assuming that the P—CH_3 groups are located directly above the phenyl substituents, as depicted, the methyl protons thus experiencing strong diamagnetic shielding. Similar conditions are found in 1,4-poly(methylenebenzenes)[7] and 1,6-methanocyclodecapentaenes[8]. The shift of the phosphorin proton signal from τ = 1.93 in *(4)* to 4.72 in *(7a)* and 4.63 in *(7b)* accords with observations on the π-complex *(1)* (τ = 4.0[11]).

The ^{31}P-NMR signals of *(7a)* lie at +45 ppm (relative to external H_3PO_4) and those of *(7b)* at +55 ppm. Since σ-complexation of phosphanes (PR_3) with carbonylmetal compounds leads to distinctly negative coordination shifts of the ^{31}P resonance [$(C_6H_5)_3P$, $\delta^{31}P$ = +6.0 ppm; $(C_6H_5)_3PCr(CO)_5$, −55.3 ppm; $[(C_6H_5)_3P]_2Ni(CO)_2$, −32.6 ppm[9]], the values for *(7a)* and *(7b)* contraindicate σ-bonded iron in the formally conceivable structure *(8)*.

The large ^{31}P upfield shift in *(7a)* and *(7b)* relative to the λ^5-phosphorins *(6)*, R' = alkyl or aryl [$\delta^{31}P$ = +6.0 ppm] is comparable with the considerable gain in shielding of the P atom on going from the phosphorin *(4)* (−178.2 ppm) to the π-complex *(1)* (−4.3 ppm). These data and the findings of ^{1}H-NMR spectroscopy strongly suggest structure *(7)* with central bonding of the iron over the phosphorin 6π system resembling that in dibenzenechromium and the metallocenes.

Preparation and Reactions of Trifluoromethanesulfonic Arenesulfonic Anhydrides[1][**]

By *Franz Effenberger* and *Klaus Huthmacher*[*]

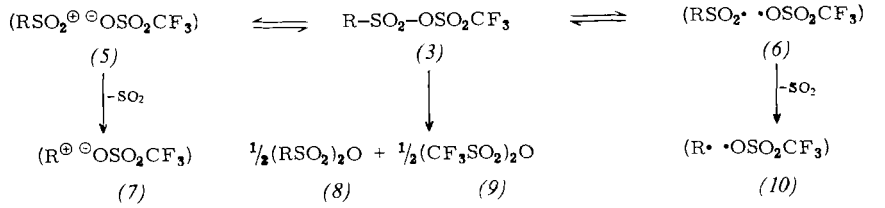
Dedicated to Professor Hellmut Bredereck on the occasion of his 70th birthday

In the course of our investigations on new electrophilic agents, we have reported on the preparation of trifluoromethanesulfonic carboxylic anhydrides and their high acylating potential[2]. We have now succeeded in obtaining the mixed sulfonic anhydrides *(3)* from sulfonyl bromides *(1)* and silver trifluoromethanesulfonate *(2)*.

$$\underset{(1)}{R\text{–}SO_2Br} + \underset{(2)}{AgOSO_2CF_3} \xrightarrow[-AgBr]{} R\text{–}SO_2\text{–}O\text{–}SO_2CF_3 \quad (3)$$

$$(3) \xrightarrow{+Ar\text{–}H,\ HOSO_2CF_3} R\text{–}SO_2\text{–}Ar \quad (4)$$

Since the anhydrides *(3)* are not stable in pure form, exact physical data cannot be given; their structure, however, is established unequivocally by ^{1}H-NMR and by their reaction with arenes, yielding aryl sulfones *(4)* (Table 1).



The extraordinary sulfonylating potential of the anhydrides *(3)* is apparent from the reaction with an arene as unreactive as chlorobenzene, which is sulfonylated in high yield even at 0 °C (see Table 1). With sulfonyl halides, on the other hand, sulfones are formed from arenes only at elevated temperature and in the presence of Friedel-Crafts catalysts[3].

The anhydrides *(3)* are thermolabile; in the absence of arenes which can be sulfonylated they decompose in various ways depending on the nature of R.

[*] Prof. Dr. F. Effenberger and Dipl.-Chem. K. Huthmacher
Institut für Organische Chemie der Universität
7 Stuttgart 80, Pfaffenwaldring 55 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

For R = alkyl, heterolytic dissociation to *(5)* and subsequent loss of SO_2 yielding *(7)* are observed; the decomposition temperature falls as the stabilization of the carbenium ion

$R^{\oplus}$ increases. Radicals *(10)* are formed preferentially from anhydrides with polyalkyl- and polyalkoxyarenesulfonic components, probably by homolysis to *(6)* and loss of SO_2. The anhydrides listed in Table 1 suffer disproportionation into *(8)* and *(9)* upon warming. Since this process already occurs at temperatures slightly above 50 °C, the anhydrides *(3)* cannot be prepared from *(2)* and the less reactive sulfonyl chlorides.

Table 1. Preparation of trifluoromethanesulfonic arenesulfonic anhydrides *(3)* and their reaction with arenes to form sulfones *(4)* [a].

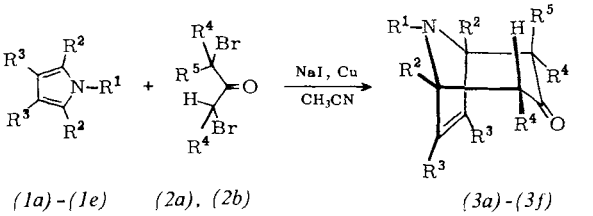
4-CH_3—C_6H_4—	toluene	di-*p*-tolyl [c]	100	
4-CH_3—C_6H_4—	chlorobenzene	4-chloro-4′-methyldiphenyl [d]	80	123—124

[a] The anhydrides *(3)* were prepared from *(1)* and *(2)* at 0 °C in nitromethane, and reacted with a threefold excess of arene (Ar—H) at the same temperature. The yields were determined by GLC. The yields obtained on a preparative scale are only slightly lower.
[b] The melting points of the sulfones *(4)* are in accordance with literature data. Mixed melting points with authentic material show no depression.
[c] Isomer distribution: 2,4′ : 3,4′ : 4,4′ = 42 : 5 : 53.
[d] No other isomers could be detected.

4-Methyldiphenyl sulfone, (4): R = p-tolyl, Ar = phenyl



Compound *(2)* (2.56 g, 0.01 mol) is dissolved in nitromethane (10 ml) at 0 °C, and a solution of *p*-toluenesulfonyl bromide (2.35 g, 0.01 mol) in nitromethane (10 ml) is added. After 30 min stirring, benzene (2.34 g, 0.03 mol) is added. Stirring is continued for another 30 min, chloroform (20 ml) is added, the AgBr precipitate seperated, and the organic phase is washed with sodium carbonate solution and with water. The solvent is stripped off and the residue recrystallized from ethanol: yield 2.15 g (93 %), m. p. 126—127 °C (127—128 °C[4]); mixed m. p. 127 °C.

A New Tropinone Synthesis[**]

By *Gérard Fierz*, *Ross Chidgey*, and *H. M. R. Hoffmann*[*]

We have developed a strikingly simple and versatile synthesis of tropinones which utilizes common starting materials and proceeds under neutral conditions at room temperature. Quite generally, the reductive dehalogenation of α,α′-dibromo ketones *(2a)* and *(2b)* with sodium iodide in the presence of pyrroles *(1a)*—*(1e)* and copper has been found to produce a variety of 6,7-dehydrotropinones *(3a)*—*(3f)*[1]. The adducts *(3)* are sensitive and tend to decompose on prolonged standing, especially when exposed to air, but they can be conveniently stored as hydrochlorides at 0 °C and also be purified in the same way (Table 1).

(1a)-(1e) *(2a), (2b)* *(3a)-(3f)*

Table 1. Dehydrotropinones *(3a)*—*(3f)* from pyrroles *(1a)*—*(1e)* and α,α'-dibromo ketones *(2a)* and *(2b)*.

	(1)				(2)			Dehydrotropinone *(3)* [a]
	R^1	R^2	R^3		R^4	R^5		Yield [%] [b]
(1a)	H	H	H	*(2a)*	CH_3	H	*(3a)*	65 [c]
(1b)	CH_3	H	H	*(2a)*	CH_3	H	*(3b)*	89
(1b)	CH_3	H	H	*(2b)*	CH_3	CH_3	*(3c)*	70
(1c)	H	CH_3	H	*(2a)*	CH_3	H	*(3d)*	66
(1d)	CH_3	CH_3	H	*(2a)*	CH_3	H	*(3e)*	74
(1e)	H	CH_3	CH_3	*(2a)*	CH_3	H	*(3f)*	50

[a] The equatorial methyl protons resonate at δ = 0.90 ppm, axial methyl protons at 1.25 ppm, bridgehead methyls at 1.3 ppm and olefinic methyl protons at 1.61 ppm. The structural assignments are corroborated by comparison with model compounds [1] and by ^{13}C-NMR as well as IR spectra. Excellent microanalytical data were obtained for the crystalline hydrochlorides.

[b] Estimated by ^{1}H-NMR spectroscopy.

[c] The product contains the isomeric 2β,4β-dimethyl-8-azabicyclo[3.2.1]oct-6-en-3-one as the minor product in a ratio of 1:6.

The new route to tropinones complements the classical Robinson-Schöpf reaction[2]. A wide range of alkylated dehydrotropinones and nortropinones has become accessible, which can be converted into tropine analogs by conventional methods[3]. For example, reduction of *(3b)* with $LiAlH_4$ in ether yields 2α,4α-dimethyl-6,7-dehydrotropine *(4a)* and 2α,4α-dimethyl-6,7-dehydropseudotropine *(4b)* in equimolar amounts. In contrast, hydrogenation of the olefinic double bond [*(3b)*→*(5)*]

followed by $LiAlH_4$ reduction furnishes 2α,4α-dimethyltropine *(6)* with little (< 5%), if any of the corresponding pseudotropine isomer.

Experimental

In a typical experiment the dibromo ketone (0.01 mol) and redistilled or recrystallized (substituted) pyrrole (0.012 mol) in anhydrous acetonitrile (20 ml) are added dropwise over a period of *ca.* 30 min to a suspension of finely powdered copper (1.9 g, 0.03 mol) and sodium iodide (6.0 g, 0.04 mol) in acetonitrile (30 ml) under nitrogen. Efficient stirring is maintained at room temperature until all the dibromoketone has disappeared (usually 3 to 4 h). The mother liquor is worked up without delay by addition of dichloromethane (20 ml) and ice-cold water (200 ml), filtration from cuprous iodide and residual copper and washing with a little dichloromethane. After a further extraction of the aqueous filtrate with dichloromethane (50 ml) the combined organic layer is freed from any remaining copper by treatment with dilute ammonia until the blue color of the ammonia complex has completely disappeared. After drying with anhydrous sodium carbonate and removal of the solvent the resulting crude dehydrotropinone is purified by careful extraction with ice-cold dilute hydrochloric acid, neutralization at 0 °C and re-extraction into dichloromethane.

Macromolecular Colloquium

The Macromolecular Colloquium was held at Freiburg (Germany), March 7—9, 1974. It was organized by the Institute for Macromolecular Chemistry of Freiburg University.

From the lectures:

A Contribution to the Thermodynamics of the Structural Transition of Phenylalanine-Specific Transfer Ribonucleic Acid in Solution

By *Th. Ackermann* (lecturer), *D. Bode*, *M. Grubert*, and *U. Schernau*[*]

With the physico-chemical investigation of solutions of a phenylalanine-specific transfer ribonucleic acid ($tRNA^{Phe}$) as an example, it is shown that important clues to the secondary and tertiary structure of dissolved biopolymers can be obtained from the temperature dependence of the thermodynamic variables of state. Conclusions regarding the "cooperativity" of the system can be drawn from the transition curves obtained by calorimetric and spectroscopic methods for a thermal denaturation process that is similar to the helix-coil transition. This cooperativity is strongly dependent on the composition of the solvent. The dependence on the concentration of Mg^{2+} ions is particularly pronounced. The accurate determination of the thermodynamic parameters of the system allows a comparison with the thermal reference values obtained by systematic investigations on nucleic acids and simple polyribonucleotides.

The minimum number of "base pairs" present in the secondary structure of the dissolved $tRNA^{Phe}$ can be estimated on the basis of these results. The result of this estimation is compared with the various models proposed in the literature (*e.g.* cloverleaf structure) for the secondary and tertiary structures of the dissolved phenylalanine-specific transfer ribonucleic acid.

Applications of Neutron Scattering to Polymer Characterization

By *Henri Benoît*[*]

Neutron scattering will become a very important tool for studying polymers in solution and in bulk for two reasons: First, the wavelength of cold neutrons is of the order of 10 Å, thus facilitating determination of radii of gyration and of the whole scattering envelope; secondly, hydrogenated and deuterated samples differ greatly in their scattering intensity. Hence material can be studied in bulk, using normal polymer as the solvent and deuterated molecules as scattering objects.

Present and possible future applications of neutron scattering include: 1) size determinations on macromolecules in the glassy state and 2) in concentrated solutions; 3) effect of orientation and stretching on dimensions; and 4) conformation of copolymers.

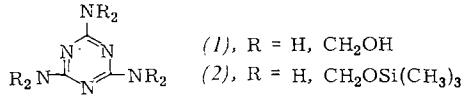
Polypivalolactone

By *Norbert Volkommer* and *Gerhard Bier* (lecturer)[*]

Pivalolactone and its preparation, polymerization, and use in particular as a fiber raw material have been the objects of numerous patents in recent years.



The syntheses of the monomer are briefly discussed. The monomer is advantageously polymerized with anionic initiators. The polymer, an aliphatic polyester with methyl side groups, is highly crystalline and has a melting point above 200 °C. The product can be processed thermoplastically.

Structure of the Reaction Products of Melamine and Formaldehyde

By *D. Braun* (lecturer) and *V. Legradic*[*]

The first stage in the reaction between melamine and formaldehyde in aqueous alkaline medium yields mixtures of mono- to hexakis(hydroxymethyl)melamine *(1)*.

(1), R = H, CH_2OH
(2), R = H, $CH_2OSi(CH_3)_3$

The melamines *(1)* were converted into the silyl ethers *(2)* by reaction with *N,N*-diethyltrimethylsilylamine. By gel-chromatographic fractionation followed by careful hydrolysis, it was possible for the first time to isolate the hydroxymethylmelamines *(1)* preparatively and to establish their structure by analysis and by IR and NMR spectroscopy.

In addition to the hydroxymethylation, the initial phase also involves condensation to form oligomers with several melamine nuclei, which can also be separated by gel chromatography. Since equilibria are always established between bound and free formaldehyde in aqueous reaction solutions of melamine and formaldehyde, the *N*-hydroxymethyl groups of the condensates can be removed by reaction with ammonia to form hexamethylenetetramine; hydroxymethyl-free polynuclear compounds are then left behind. In the condensates prepared in the presence of alkali, the melamine residues are linked mainly *via* methyl ether bridges.

In addition to melamine resin, polyoxymethylene glycols are also formed from formaldehyde in aqueous medium; these can also be detected by gel chromatography and are present in the industrial products.

Synthesis and Some Properties of Star Polymers with more than 100 Branches

By *H. Eschwey*, *M. L. Hallensleben*, and *W. Burchard* (lecturer)[*]

Three fundamental methods, all involving anionic polymerization have been described for the preparation of polymers branched in the shape of a star:

[*] H. Eschwey, Dr. M. L. Hallensleben, and Prof. Dr. W. Burchard
Institut für makromolekulare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

1) Termination method:

Linear living polymers with relatively uniform molecular weight distributions and a carbanion end group are allowed to react with polyfunctional terminators containing halogen, such as $SiCl_4$. In this method the halogen atoms are replaced by the living polymer chains.

2) Propagation method:

The anionic polymerization is initiated with the aid of polyfunctional initiators, which initiate the growth of several polymer chains simultaneously from a common center. Living star polymers are obtained.

3) *Rempp*'s method:

Linear living polymers with a carbanion end group are copolymerized anionically with a small quantity of a bifunctional monomer, *e.g.* living polystyrene with divinylbenzene. The products consist of small, internally crosslinked polydivinylbenzene nuclei with long pendant polystyrene branches.

Methods 1 and 2 have so far been confined to the synthesis of star polymers with 3—6 branches. Star polymers with at most 20 branches can be obtained by method 3.

We have developed another method in order to obtain polymers with more branches and higher molecular weights. In this method, polyfunctional macromolecular initiators (soluble living polydivinylbenzene microgels of different sizes and with different numbers of carbanion groups that are active in the polymerization) were prepared by anionic polymerization. When these initiators were used as initiators for the anionic polymerization of styrene, they allowed the synthesis of star polymers having from 8 to about 400000 branches and molecular weights of 10^3—10^9. The products were characterized by means of light scattering and viscometry. The g' factor showed pronounced deviations from the Zimm-Kilb theory for star polymers. The shape factor of the light scattering is in good agreement with theoretical calculations.

^{1}H and ^{13}C Relaxation Measurements on Homopolymers and Copolymers

By *W. Gronski, R. G. Brüssau,* and *H.-J. Cantow* (lecturer)[*]

Chain movement, steric hindrance, and intramolecular interaction of the phenyl groups were investigated for solutions of polystyrene and copolymers of styrene (ST) with maleic anhydride (MAH), vinyl chloride (VC), and butadiene (BU). These investigations were carried out by determination of the spin-lattice relaxation times of ^{1}H and ^{13}C nuclei having different chemical shifts with the aid of the Fourier transform technique.

The temperature dependence of the ^{13}C relaxation of atactic polystyrene in D_8-dioxane gives an activation energy of 4.5 kcal/mol for the chain motion. The temperature dependence shows no significant difference for atactic and for isotactic polystyrene. The contribution of the intramolecular interaction of the side groups to the relaxation of the phenyl protons can be isolated from ^{1}H relaxation measurements on partly deuterated polystyrenes. By additional use of the correlation time of the chain movement as determined from the ^{13}C relaxation, it is thus possible to establish the conformation of the phenyl rings.

The ^{1}H and ^{13}C relaxation times of the styrene units in alternating ST-MAH copolymers are considerably shorter than in polystyrene; this is a consequence of the reduced mobility of these copolymers. Similar behavior is found for ST-VC copolymers: the relaxation time decreases with increasing length of the VC sequences.

[*] Dr. W. Gronski, Dr. R. G. Brüssau, and Prof. Dr. H.-J. Cantow
Institut für makromolekulare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

On the other hand, the chain mobility of ST-BU copolymers is so great that the ^{13}C relaxation times of the phenyl ring in a concentrated solution (65 wt.-%) of a random copolymer with a styrene content of 25 wt.-% are about five times as long as in a 20% polystyrene solution. The correlation time of the segment motion of styrene units at 52 °C is 1.4×10^{-10} s. The steric hindrance of the side groups is so slight that the rotation of the rings can be detected. The correlation time for the rotation is about 2.5 times as long as that for the segment motion.

Mechanism of the Degradation of Polymers in Solution by Ultrasound

By *A. Basedow* and *K. H. Ebert* (lecturer)[*]

The degradation of polymers in solution by ultrasound has been investigated in the molecular weight range from 30000 to 100000. The degradation products were characterized by determination of the molecular weight distributions with the aid of chromatography on porous glass.

In the discussion of the numerous results, it is not possible to say *a priori* whether the degradation reaction is caused by shock waves or by inhomogeneous flow fields. Investigations on the degradation kinetics of dextran in various solvents and with the addition of third substances show that the nature of the solvent has a considerable influence on the cavitation characteristics, and hence also on the degradation constants, since the cavity implosion energy determines the intensity of the shock waves or inhomogeneous flow fields produced. A quantitative relation has been found between the molar enthalpy of vaporization of the solvent and the degradation constant. The influence of solvation and hence of the solvent-polymer interaction on the degradation reaction is only slight. However, our results indicate that expansion of the polymer coil favors degradation. According to the existing theoretical views this means that the rupture of the molecules is caused mainly by shock waves. The experimental observation that the molecules disintegrate into two parts of approximately equal size suggests that the inhomogeneous flow fields cause stretching of the polymer coils; rupture may occur in this way in the high molecular weight range.

^{13}C-NMR Spectroscopy on Polyethers

By *D. Fleischer* (lecturer) and *R. C. Schulz*[*]

The chemical and physical properties of many copolymers exhibit characteristic variations with the distribution of their monomer units. If this sequence distribution is known, it is possible to draw conclusions regarding the mechanism of the polymerization reaction. The investigations on this point and the determination of the overall composition were carried out by ^{13}C-NMR spectroscopy on polymers that had been obtained by polymerization of oxacyclic monomers (ethylene oxide, 1,3-dioxolane, 1,3,5-trioxane, 1,3,5-trioxepane, and 1,3,6-trioxocane) with ring cleavage and consisted only of methylene oxide (M) and ethylene oxide (E) units.

^{1}H-NMR spectra of these homopolymers and copolymers show triad sequences for the M units, whereas only one practically unresolved signal is observed for the E units in every case. With the aid of the greater chemical shift in the ^{13}C-NMR

[*] Dr. D. Fleischer and Prof. Dr. R. C. Schulz
Institut für Makromolekulare Chemie der Technischen Hochschule
61 Darmstadt, Alexanderstrasse 24 (Germany)

spectrum it is possible to distinguish EE linkages from isolated E units in MEM triads, and the nature of the ring cleavage can thus also be easily determined in this way.

However, greater sequence lengths can also be determined by ^{13}C than by ^{1}H-NMR spectroscopy, and can even be quantitatively determined because of approximately equal relaxation times. Thus pentad sequences have been found both for the M and for the E units. These results enable conclusions to be drawn with regard to the side reactions that accompany the growth reactions.

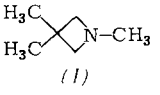
Finally, by the use of europium chelates as shift reagents, it is possible to assign heptad sequences to the resonance lines, and these sequences can also be quantitatively determined.

New Methods for the Preparation of Reactive Microgels and Their Use for the Construction of Inhomogeneous Networks

By *W. Obrecht*, *U. Seitz*, and *W. Funke* (lecturer)[*]

Microgels with pendant reactive vinyl groups were prepared by polymerization and copolymerization of divinyl and dimethacrylic monomers. A new method was developed for the purification of the emulsion polymers; it was possible to isolate the microgel particles in a highly dispersed form by this method.

The size and size distribution of the resulting polymers were determined (by electron microscopy), as well as the number of pendant double bonds (by several addition reactions).



By copolymerization of reactive microgels with bifunctional monomers, networks with a defined inhomogeneous structure could be prepared.

Cationic Polymerization of Azetidines

By *E. J. Goethals* (lecturer) and *E. Schacht*[*]

1,3,3-Trimethylazetidine *(1)* and azetidine *(2)* are quantitatively converted into polymers above 60 °C by cationic initiators. The polymerization of *(1)* was investigated with nitrobenzene as the solvent and triethyloxonium tetrafluoroborate as the initiator.

(1)

(2), R = H

(3), R = $(CH_2)_3NH_2$

Kinetic measurements and investigations by 300-MHz ^{1}H-NMR spectroscopy showed that the growing chains in this polymerization are cyclic quaternary ammonium salts, and that the concentration of the growing chains remains constant in the course of the polymerization. The absence of a termination reaction between growing chains and polymeric amino groups is explained by the fact that the basicity of the monomer is much greater than that of the polymer.

The polymerization of azetidine *(2)* was investigated in methanol with perchloric acid as the initiator. A dimer *(3)* is first formed in a high yield from *(2)*. This dimer polymerizes further to give a polymer in which 20% of the amino groups are tertiary, 60% secondary, and 20% primary.

Proton Resonance Measurements on Polymaleic Anhydride and Maleic Anhydride-Isobutene Copolymers

By *D. O. Hummel* (lecturer) and *J. Bestgen*[*]

The compositions and configurations of a series of maleic anhydride(MA)-isobutene(IB) copolymers (produced by radiation chemistry) and the structure of homopolymeric polymaleic anhydride (PMA) were investigated by ^{1}H-NMR spectroscopy.

The nature and frequency of occurrence of the sequences were determined for the MA-IB copolymer. On the other hand, resolution of the PMA resonance complex into individual lines and hence an assignment to specific *n*-ads is impossible, since PMA is a complicated multispin system with small chemical shifts.

Comparison of spectra of several samples with different monomer concentrations in the starting mixture provided evidence of equimolar alternance of the copolymer.

With the aid of the Karplus theory and on the basis of values of coupling constants for model substances, the determination of the coupling constants of the methine protons led to the result that only *trans* opening of the double bond in MA occurs on addition of the IB monomers; the MA units in the chain consequently have the *threo* configuration. Strong steric hindrance of the *cis* opening is assumed in order to explain this.

A resolution of the methyl resonance led to two doublets with different intensities, which can be assigned to *threo*-diisotactic and *threo*-disyndiotactic linkages of the MA units, the diisotactic orientation being slightly favored over the disyndiotactic.

No differences in configuration were found for samples that had been polymerized at different temperatures and in different solvents.

Macrozwitterions

By *W. Kern* (lecturer), *V. Jaacks* (deceased), and *H. Schnecko*[*]

Macrozwitterions[1] have a positive charge at one end of the linear oligomeric or polymeric molecule and a negative

[*] Prof. Dr. W. Kern and Prof. Dr. H. Schnecko
Organisch-Chemisches Institut der Universität
65 Mainz, Johann-Joachim-Becher-Weg 18—20 (Germany)

charge at the other. They are thus true zwitterions, and can form salts with corresponding counterions.

Macrozwitterions are interesting in two respects:

1) as themselves, because the conformation of the charge carrier can be studied as a function of the distance between the opposite charges and as a function of the medium; and

2) as intermediates in certain ionic polymerizations.

Some strongly polar monomers polymerize cationically with ansolvo acids, and other polar monomers polymerize anionically with ansolvo bases. However, it is not easy to choose the reaction conditions so accurately that one can say that there is no cocatalyst (*e.g.* H_2O) present. Even in very small quantities, water reacts with the Lewis acid or the Lewis base to form a protonic acid that initiates a cationic polymerization or a hydroxide-ion base that initiates an anionic polymerization.

However, if it can be shown that macrozwitterions with provable structures occur in polymerization mixtures where proton-active compounds have been ruled out as far as possible, conclusions can be drawn with regard to the mechanism of this polymerization, *i.e.* a zwitterion mechanism can be deduced. No macrozwitterions can occur in cocatalysis.

Tertiary phosphanes initiate the anionic polymerization of acrylonitrile and are incorporated as phosphonium ions. Some cyclic compounds can also be polymerized with simultaneous ring cleavage by ansolvo compounds to give macrozwitterions, *e.g.* β-lactones with the aid of tertiary amines. Reactions of this type are very suitable for the synthesis of macrozwitterions.

Quasi-Static Glass Temperature and Configuration Entropy

By *H. G. Kilian*[*]

The states at the quasi-static glass temperature of homologous polymer systems apparently have the same free volume. If this limiting state is regarded as a liquid saturated with holes (with a hole size distribution), it can be shown by the thermodynamic description of known measurements on homologs of polystyrene and on polystyrene-solvent mixed systems that regardless of the molecular structure of the liquid, an "iso-excess entropy state" probably exists at T_g'. Holes, polymer molecules, and solvent molecules evidently do not have a random arrangement, but are distributed in such a way that the deviations from the ideal athermic mixture at $T_{g\infty}$ are the same for all the systems investigated.

Structure of Macromolecular Adsorption Layers on Solids

By *E. Killmann* (lecturer), *M. v. Kuzenko, H. J. Strasser,* and *K. Winter*[*]

The elucidation of the conformation of adsorbed macromolecules is the aim of investigations on polymer adsorption from solution on solid surfaces. In addition to the adsorbed amount (obtained from the difference between the concentrations of the polymer solution before and after adsorption) the thickness and concentration of the adsorbed layer (ellipsometrically), the enthalpy of adsorption and of immersion (calorimetrically), and the number of adhesive segments per macromolecule (IR spectrometrically) were determined.

The results obtained by these methods for layers of polyethylene glycol, polystyrene, and polyvinylpyrrolidone adsorbed on Aerosil (SiO_2) and chromium surfaces from various solvents are compared. The dependences of the characteristic parameters on the concentration, the molecular weight and the kind of polymer, on the kind of solvent and on the state of the adsorbent surface lead to conclusions about the structure of the adsorbed layer and its dependence on the degree of coverage, the competing interactions in the polymer-solvent-adsorbent system, and the size and shape of the macromolecule in solution.

Synthesis of Alternating Copolyamides and their Sequence Analysis by ^{1}H- and ^{13}C-NMR Spectroscopy[1]

By *H. R. Kricheldorf* (lecturer), *E. Leppert,* and *G. Schilling*[*]

The monomers *(1)*—*(3)* were synthesized from silylated aromatic or aliphatic ω-amino carboxylic acids. All three classes of monomers can be polycondensed in solution to form copolyamides with alternating sequences. However, temperatures of 180—250 °C are necessary for the condensation of *(1)* and *(2)*, and the best results are therefore obtained by condensation in the melt in these cases.

$$C_6H_5O\text{–}CO\text{–}NH\text{–}A\text{–}CO\text{–}NH\text{–}B\text{–}COOH \quad (1)$$

$$S{=}C{=}N\text{–}A\text{–}CO\text{–}NH\text{–}B\text{–}COOH \quad (2)$$

$$CF_3\text{–}COO^{\ominus}\,[\overset{\oplus}{N}H_3\text{–}A\text{–}CO\text{–}NH\text{–}B\text{–}COOC_6Cl_5] \quad (3)$$

A, B = bivalent aliphatic or aromatic residue

For copolyamides of *p*-aminobenzoic acid and aliphatic ω-amino carboxylic acids, the sequence can be checked with the aid of ^{1}H-NMR spectra, and specifically the signals of the aliphatic protons. The resolution of the ^{1}H-NMR spectra is no longer sufficient in the case of purely aliphatic copolyamides, but homologous and alternating sequences can be distinguished by means of the carbonyl C signals of the ^{13}C-NMR spectra. These sequence analyses have shown that transamidation reactions disturb the alternating sequences at condensation temperatures > +200 °C.

Structural Investigations on Fibrinogen in Solution

By *K. Lederer* (lecturer), *R. Hammel,* and *J. Schurz*[*]

We have investigated solutions of fibrinogen ($c = 3$—20 g/l) by X-ray small angle scattering and viscometry. At very small angles the X-ray small angle scattering showed a strong dependence on the preparation of the sample, while the data normalized to the unit of concentration exhibited very little concen-

[1] *L. Buchmann, W. W. Schmitt-Fumian, R. Hammel,* and *K. Lederer,* to be published.

tration dependence. These disturbances, which were due to aggregates, were largely eliminated on filtration of the solutions. The X-ray small angle scattering measurements on the filtered solutions gave a value of $R = 122$ Å for the radius of gyration, a molecular weight of $M = 335000 \pm 25000$, and $R_q = 24$ Å for the cross section radius of gyration, from which a length of $L = 430$ Å can be deduced on the assumption of a rod-shaped fibrinogen molecule. On the other hand, the viscosity measurements at a rate of shear $q = 10^4$—$5 \times 10^5\ s^{-1}$ gave a very low pseudoplasticity, which, on the basis of the value $D_{Rot} = 40000\ s^{-1}$ for the rotational diffusion constant from flow birefringence measurements, points to an axial ratio $p \leqslant 5$.

These results and earlier results reported by other workers may be compared with the calculated properties of fibrinogen models. The best agreement of all data was obtained on assumption of a sausage shape for the fibrinogen molecule, with a length $L = 450$ Å and a thickness $2R = 90$ Å, as suggested by *Bachmann, Schmitt, Hammel,* and *Lederer*[1] on the basis of electron micrographs of preparations obtained by the spray freeze etching method. The large volume of this model ($V = 3 \times 10^6$ Å^3) gives a hydration of about 5 g of H_2O/g of fibrinogen, which is unusually high for proteins. It is feasible that the highly swollen structure of fibrinogen possesses considerable flexibility.

Matrix Polymerization of Methyl Methacrylate

By *T. Miyamoto* (lecturer), *S. Tomoshige*, and *H. Inagaki*[*]

Recently it has been demonstrated that under some specific conditions, stereospecific polymerization of methyl methacrylate (MMA) may proceed through a reaction mechanism in which the stereocomplex formation plays an essential role. The stereocomplex consists of a mixture of isotactic and syndiotactic polymethyl methacrylate (PMMA), and is contained in the acetone-insoluble fraction.

This report deals with some specific features of PMMA prepared with *n*-butylmagnesium chloride in toluene at -50 °C. For the purpose of experiment, we have developed a new preparative technique to separate the stereocomplexes into components. The principle of this technique consists in competitive adsorption of two different tactic polymers from solution onto the surface of an adsorbent such as silica gel (solvent: chloroform).

The acetone-insoluble fractions of the products obtained by the polymerization in the absence of preformed PMMA (blank polymerization) were separated successfully into isotactic and syndiotactic components on a preparative scale by our technique. The content of isotactic triads in isotactic components was remarkably high (*ca.* 85 %), while the content of syndiotactic triads in syndiotactic components was *ca.* 60—70 %. The molecular weight of syndiotactic components was considerably lower than that of isotactic components. Furthermore a relation was found between the steric structure of whole polymerization products and the conversion of monomer; the products obtained at lower conversions (< 10 %) were predominantly isotactic, and with increasing conversion the isotacticity decreased to a constant value. On the other hand, the acetone-soluble fractions were assigned as "atactic" from their behavior on thin layer chromatography.

The polymers obtained in the presence of preformed isotactic PMMA (matrix polymerization), in sharp contrast with the products obtained by blank polymerization, were predominantly syndiotactic, especially when the ratio of amount of produced polymer to added polymer was lower than *ca.* 2. No exact parallelism between the molecular weights of added and produced polymers could be confirmed.

Synthesis of Macromolecules of Well Defined Properties by Enzymatic Polycondensation

By *B. Pfannemüller*[*]

The kinetics of the phosphorylase-catalyzed polycondensation of glucose-1-phosphate to form α-(1→4)-glucan (amylose) with maltotetraose and higher oligomers as primer are analogous to the kinetics of the anionic polymerization with butyllithium. The primer in the phosphorolytic synthesis corresponds to the initiator in the anionic polymerization. However, the monomer is activated in the enzymatic polycondensation, whereas the growing chain is activated in the anionic polymerization.

As in the anionic polymerization, the linear synthetic product exhibits the following characteristics: 1) regulation of the degree of polymerization by the primer concentration and the conversion ($DP = 4$—approx. 30000); 2) high homogeneity ($P_w/P_n = 1.001$—1.01)[1]. Moreover, the enzymatically synthesized product: 3) is a stereoregular polymer capable of forming a helical structure[2]; and 4) it contains functional groups and can be investigated in *aqueous* media and in organic solvents (as derivatives).

As in the anionic polymerization, block polymers of ABA type can also be obtained by phosphorolytic polycondensation.

Anionic polymerization of macromolecules with more than two *living* ends has only recently been achieved[3], and star-shaped polymers have been synthesized so far mostly by a termination method. However, polymers with numerous growing chains are readily prepared by enzymatic synthesis.

Living comb-shaped polymers are obtained by coupling the primer molecules chemically to side groups of an existing linear chain. Glycoside linkages, alkali-labile ester linkages, and acid-labile hydrazone linkages have been studied for this purpose. Polysaccharides and polyacrylamide are used as carrier molecules. Corresponding experiments have been carried out also with cyclodextrin and polyfunctional benzene derivatives.

Using glycogen and amylopectin as polyfunctional primers star polymers having 15—20 and 10000 chains respectively per molecules are obtained. The problem of determination of the number and lengths of the new chains is discussed.

Amylose in aqueous solution exhibits an association tendency with an unusual chain length dependence. This property appears to be even more pronounced in some branched products. The linear amylose molecules are known to be capable of forming a helical superstructure. It is found by measurements of the ORD and CD spectra that the capability for helix formation persists even in highly branched products.

The fibril formation observed with the linear amylose-iodine complexes on examination in the electron microscope enables the star-shaped structure to be imaged directly.

Structure and Properties of Pharmacologically Active Polymers

By *J. Bartulin, H. G. Batz, G. Franzmann, V. Hofmann, M. Przybylski, H. Ringsdorf* (lecturer), and *H. Ritter*[*]

Pharmacologically active macromolecular compounds, which are still regarded with skepticism for theoretical and practical reasons, have attracted growing interest during recent years because of their polymer-specific properties[1].

For low molecular weight drugs, a change in structure leads in most cases to a loss of specific activities. Vital properties of macromolecular drugs, on the other hand, depend on their polymeric structure, which can be relatively easily influenced *e.g.* by comonomers, polymer-analogous reactions, and crosslinking. A new model for pharmacologically active polymers takes into account *e.g.* possibilities for variation of their solubility and toxicity, the possibility of removal of the active groups (pharmacokinetics, depot effects), and the distribution of the polymers in the body[2]. In this connection, the synthesis[3] of macromolecular drugs and preliminary investigations on their activity are reported.

Mechanism of Cationic Polymerization of Lactams

By *M. Rothe* (lecturer), *G. Bertalan*, and *J. Mazánek*[*]

The kinetics and the mechanism of the cationic polymerization of ε-caprolactam and 8-octanelactam with anhydrous strong acids were investigated. Initiation results in the formation of the salt of the ω-amino acyllactam *(1)*, $n=0$; the chain growth takes place on the ammonium end group of this salt by transamidation with monomeric lactam or with acyllactam end groups. This yields polyamides with N-terminal ammonium groups and C-terminal *N*-acylated lactam rings *(1)*.

(1), m = 5, 7

Above 200 °C, subsequent reactions occur to an increasing extent on both end groups, and these reactions considerably alter the polymerization mechanism and the kinetics. N-Terminal amidine groups and acylamidine groups inside the chains are then formed; the water eliminated hydrolyzes the acyllactam and acylamidine groups to carboxyl groups.

The functional groups were determined in the same sample by potentiometric titration, acyllactam groups after hydrolytic conversion into carboxyl groups, and amidine residues after selective acylation of the amino groups. The concentrations of the groups depend on the polymerization conditions; amidine and carboxyl groups are present to a considerable extent even at the beginning of the polymerization.

Amidine groups initiate the polymerization of lactams much less effectively than amino groups; on the other hand, it is well known that they react very rapidly with carboxyl groups. Reactions of carboxyl groups with ammonium, amidinium, and lactam groups are therefore superimposed on the original growth-reaction.

The kinetic curves with their characteristic points of inflection can be explained by participation of these reactions.

Some Problems and Results in Cellulose Research

By *G. V. Schulz*[*]

The following cellulose problems, which I started to investigate about 30 years ago together with Frau *E. Husemann*[1,2], are still topical today:

1) What is the molecular weight of native cellulose and what is its molecular weight distribution? 2) Does the cellulose molecule contain periodically arranged bonds that are easier to break ("weak points") or regions that are more susceptible to degradation ("weak zones")? 3) How are the chain molecules arranged in the fibrils?

The degree of polymerization of native cellulose appeared to grow continuously over the decades, until it was finally shown by investigations on cellulose from the bolls of cotton plants grown in a glasshouse that there are two kinds of cellulose: the primary wall cellulose, which has a very irregular structure, and a very uniform cellulose of the secondary wall, which has a degree of polymerization of about 14000[3,4]. Celluloses from other plants seem to correspond closely to this "model cellulose".

The other two questions can only be answered together. The earlier investigations indicated "weak points", separated by a regular distance of about 400—500 glucose units, in oxidative and hydrolytic degradation[1,5]. However, the starting materials were not native cellulose, since they had been modified by external influences after their biosynthesis. When we resumed the investigation of the oxidative degradation of native cellulose, we encountered the phenomenon of intramolecular crosslinking; this phenomenon greatly complicated the course of the degradation in time, and the molecular weight distributions[6]. The crosslinking effect shows that the cellulose molecules are folded in the native fiber; *Husemann et al.*[7] were able to show with greater certainty than before that the glucoside chains in the cellulose lattice have an antiparallel arrangement.

The kinetics of the degradation of cellulose can be quantitatively understood by reversal of a theory proposed by *Stockmayer*[8] for the polymerization of trifunctional and tetrafunctional monomers. According to this theory, unchanged native cellulose contains no bonds that are more readily broken by oxidation, and the molecular weight distributions correspond to those expected to result from purely random degradation. However, from the fact that the earlier results have been reproduced many times, it must be concluded that the "weak points", though produced by secondary effects, must be potentially present in the native cellulose molecule in view of their regular arrangement.

The above three questions now seem to be closer to a solution. The elucidation of these questions is an essential condition

Occurrence of Branching Reactions in the Copolymerization of Trioxane with 1,3-Dioxolane

By *K.-H. Burg, H. Leugering*, and *G. Sextro* (lecturer)[*]

The formation of branched molecules *(1)* can be expected in principle in the homopolymerization of trioxane[1].

(1)

The detection of branched structures is particularly difficult because of the thermal instability of trioxane homopolymers; the situation is more favorable in trioxane copolymers. As far as we knew, however, branched structures had never been detected either for the homopolymers or for copolymers.

It is known that the spherulite size in polyoxymethylenes is very sensitive to traces of branched or crosslinked polyoxymethylenes[2], though there are at present no quantitative views on the mechanism of this nucleation process.

On the basis of the experimental findings, we then investigated copolymers of trioxane and 2 wt.-% of 1,3-dioxolane. The products were prepared and isolated under various conditions. On the basis of spherulite size determinations, experiments with model substances, and degradation experiments, it may be assumed that more than 99% of linear molecules are formed at polymerization temperatures of about 110 °C, whereas small quantities of branched chains are also obtained at 70 °C.

Crosslinking Reactions in the Rubber Particles of High-Impact Polystyrene

By *H. Adler, G. Fahrbach*, and *D. J. Stein* (lecturer)[*]

The elasticity of the rubber phase in high-impact polystyrene is determined by the crosslink density, which thus has a decisive influence on the impact strength of the polymer. The rubber dissolved in styrene is crosslinked by reactions of its double bonds and allyl H atoms that take place simultaneously with the homopolymerization and graft polymerization of the styrene.

The suspension polymerization of solutions of rubber in styrene was investigated using several types of rubber, and with di-*tert*-butyl peroxide as the initiator. The following conclusions can be drawn from the results of the experiments: The preferred crosslinking point is the 1,2 configuration of butadiene. 1,4 and 3,4 configurations in butadiene and isoprene units also take part in the crosslinking reactions, but their reactivity is considerably lower. In butadiene-styrene copolymers the 1,2 configuration has roughly the same reactivity as in polybutadiene, but the reactivity appears to be lower in isoprene polymers. With all types of rubber, the crosslinking rate increases with increasing conversion of styrene; this is particularly noticeable at styrene conversions above 98%. This relationship is explained by a crosslinking copolymerization of the styrene with the 1,2 groups of the rubber.

Peculiarities of the Particle Formation in the Emulsion Polymerization of Acrylic Esters

By *N. Sütterlin* (lecturer), *G. Markert*, and *H.-J. Kurth*[*]

Two approaches are generally used for the description of the particle formation in emulsion polymerization. The theory of *Smith* and *Ewart*[1] ascribes the decisive role to the micelles, whereas that of *Roe*[2] is based on a thermodynamic consideration of a dissolution-precipitation equilibrium. Both approaches lead *via* the same selection criteria to the same quantitative relations in the kinetics of the emulsion polymerization.

Practical experience has shown that the views of *Roe* are more probable. It is appropriate in this approach to pay greater attention to the equilibrium concentration of the monomers in the aqueous phase and at the same time to the hydrophilicity of the polymer.

If the mean number of particles per unit volume is plotted as a function of the soap concentration present at the start of the polymerization in logarithmic coordinates, one obtains the well-known S-shaped relations, in which the critical micelle concentration of the emulsifier is not a pronounced point of the curve. The number of particles for a given emulsifier concentration depends on the saturation concentration of the monomer in the aqueous phase.

The fact that the number of particles is substantially independent of the initial concentration of the emulsifier for very low and very high soap concentrations can be explained by agglomeration processes with different causes.

These agglomeration phenomena affect the mean number of particles in particular for the most hydrophilic members of the acrylate and methacrylate series. One reason for this is probably the equilibrium concentration of the emulsifier on the particle surface, which increases with increasing hydrophobicity of the polymer, with the result that more hydrophobic polymers are more effectively stabilized.

X-Ray and Calorimetric Detection of the Formation of Individual Kinks

By *A. Weiss* (lecturer), *G. Lagaly*, and *S. Fitz*[*]

Kinks and gauche blocks are postulated as the most important rotational-isomer forms of alkyl chains in crystalline and paracrystalline solids. We have been able to detect directly the formation of individual kinks on bimolecular layers of long-chain alkyl compounds and to determine the character of the transition and the transition enthalpies and entropies by measurement of the specific heat. In our model systems the kinks arrange themselves into blocks. Beyond a critical concentration, a drastic change in structure takes place with transformation into gauche block structures. The experimentally determined limiting concentrations of kinks for the kink block structures agree very closely with the values estimated by *Pechhold* and *Blasenbrey* from statistical thermodynamics.

Conversions of Bacterial Polysaccharides by the Action of Lysogenic Phages and Their Immunochemical and Biochemical-Genetic Significance

By *O. Westphal*[*]

It is well known that the infection of species of Enterobacteriaceae with lysogenic phages leads to changes in the enzyme system for the biosynthesis of the corresponding specific bacterial (surface) polysaccharide, and hence to definite changes in the polysaccharide structure. The starting strain and the converted strain produce correspondingly different immune responses, *i.e.* antibodies with different specificities, in the animal. Details of the polysaccharide biosynthesis can be discovered by the biochemical study of lysogenic conversions, while immunochemical analysis allows a more precise definition of the polysaccharide structures that are responsible for the specificity, *i.e.* the determinant groups. Numerous enterobacterial species that have been known for a long time can be transformed into one another by lysogenic conversions. A picture of evolution mechanisms within bacterial genera is progressively emerging in this way. Lysogenic conversions exhibit analogies with some malignant transformations of cells in higher animals.

Progress in the Synthesis of Human Proinsulin and of a Proinsulin Model

By *H. Zahn* (lecturer), *H. Berndt*, *J. Föhles*, *D. Brandenburg*, *W. Schermutzki*, and *V. K. Naithani*[*]

The chain of human proinsulin, which consists of 86 amino acid residues, is to be represented in the form of a monomeric cyclic tricystine peptide derivative with three disulfide bridges within the chain (A 6,7, A 11,20, and B 7,19). The thiol protection required for this was achieved by synthesis of the fragments B 1—B 23 with the cystine bridge B 7,19 and A 6—A 21 with the disulfide bridges A 6,7 and A 11,20. The peptide derivatives required from the regions B 24—C 15 and C 16—A 5, as well as the human C peptide, are also available; the condensation of fairly large fragments can thus be taken in hand.

The question (discussed by *Steiner*) whether the C peptide ensures the correct pairing of the cysteine residues by specific interactions with the A and B chains or whether the segment merely serves as a flexible connecting link to allow intramolecular formation of the disulfide bridges has been answered by recombination studies on semisynthetic $N^{\alpha A1}$—$N^{\varepsilon B29}$—bridged insulins, which showed that the second of the above possibilities is correct. The linkage of the α-amino group of the glycine A1 with the ε-amino group of the lysine B29 *via* an L,L-diaminosuberic acid bridge yields a crystallizable "clamp" insulin, which can be recovered again in yields of about 70% after reduction of the three cystine bridges.

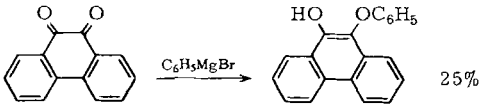
Free Radicals in Grignard Reactions

By *Friedrich Bickelhaupt*[*]

It has been suspected for some time that the formation of Grignard compounds *(1)* from alkyl halides and magnesium in ethers involves free radicals. Observation of the CIDNP effect in a Grignard reagent (*e.g. (1a)*; the relevant nuclei are emphasized in the formulas) has provided fresh direct evidence for the correctness of this assumption.

$$CH_3-CH_2-CH_2-I + Mg \xrightarrow{(n\text{-}C_4H_9)_2O} \underset{(1a)}{CH_3-CH_2-CH_2-MgI} \; (+\underset{(2a)}{CH_3-CH=CH_2} + CH_3-CH_2-CH_3)$$

The absence of a net effect and the occurrence of E/A polarization[**] in *n*-propylmagnesium iodide *(1a)* and of A/E polarization[**] in the side product propene *(2a)* support the following simplified reaction scheme[1]:



Both solvent effects and the behavior of 6-bromo-1-hexene, which readily undergoes cyclization to methylcyclopentane derivatives in the free radical state under the conditions of the Grignard formation reaction, constitute compelling evidence that the major reaction is direct combination of alkyl radical and magnesium(I) halide and that formation of polarized Grignard compound *(1)* via* the radical pair accounts for only a small percentage of the overall reaction.

Under certain conditions the occurrence of free radicals may also be expected in the reactions of Grignard compounds, *e.g.* in the reaction of *o*-quinones such as *(3)* with phenyl-

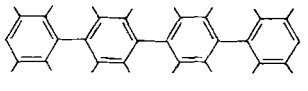
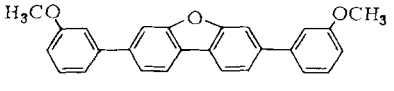
ABSTRACTS



Reviews



Abstracts of selected progress reports and review articles

The uses of chromium(II) salts in preparative organic chemistry are reviewed in an article by *J. R. Hanson.* They are used for the reduction of alkyl chlorides, unsaturated systems, epoxides, acyloxyketones, and nitro compounds. In addition to the chloride, sulfate, and perchlorate, a Cr(II)-ethylenediamine reagent has been found to be a very effective reducing agent. Certain solvents and H donors such as *n*-butanethiol or hypophosphorous acid can influence the course of the reaction. In several cases the use of Cr(II) salts permits selective reductions, *e.g.* the reduction of halides and nitro groups, whereby CO groups remain intact. [Applications of Chromium(II) Salts in Preparative Organic Chemistry. Synthesis *1974,* 1–8; 55 references]

[Rd 694 IE –M]

Novel applications of the Ullmann synthesis of symmetric and asymmetric biarylenes, biphenylenes, and ring compounds are described by *P. E. Fanta.* An arylcopper compound almost certainly functions as an intermediate in the synthesis. The reactivity of an aryl halide is strongly substituent-dependent: electronegative groups such as nitro and methoxycarbonyl groups, particularly in the *ortho* position, activate the halogen atom considerably; amino, hydroxy, and carboxy groups inhibit or impede the reaction, as do bulky groups in the *ortho* position. The Ullmann reaction has been applied to heterocyclic systems and the synthesis of oligoarylenes. The reaction of a large excess of a monofunctional component with a difunctional diiodo compound to give linear polyphenylenes is to be regarded as a cocondensation-Ullmann reaction. This method is particularly suitable for the synthesis of highly substituted and bridged polyphenylenes, such as *e.g. (1)* and *(2).* [The Ullmann Synthesis of Biaryls. Synthesis *1974,* 9–21; 145 references]

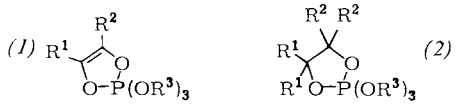
(1)

(2)

[Rd 695 IE –M]

Photodifluoroamination and reactions of fluorine atoms are reviewed by *C. L. Bumgardner* and *E. L. Lawton.* Tetrafluorohydrazine, N_2F_4, reacts with lower alkanes RH on irradiation with replacement of a hydrogen atom by the NF_2 group:

$$N_2F_4 \rightleftharpoons 2\,NF_2$$



$$NF_2 \xrightarrow{h\nu} F + NF$$
$$RH + F \rightarrow R + HF$$
$$R + NF_2 \rightarrow RNF_2$$
$$R + N_2F_4 \rightarrow RNF_2 + NF_2$$
$$2\,NF \rightarrow N_2F_2$$
$$NF + NF_2 \rightarrow N_2F_2 + F$$

Methane yields not only CH_3NF_2 but also HCN, which is formed by unimolecular HF elimination. Both NF_2 and F can add to alkenes, *e.g.* propylene. In this system unimolecular elimination of CH_3 can also take place. On photodifluoroamination of propyne and allene rearrangements occur. Nitriles react in the same way as alkynes. [Photodifluoroamination and Atomic Fluorine Reactions. Accounts Chem. Res. *7,* 14 to 20 (1974); 33 references]

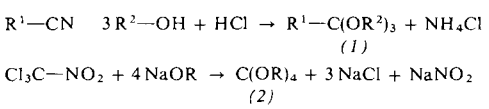
[Rd 697 IE—L]

Structure, syntheses, and reactions of oxyphosphoranes are reviewed by *F. Ramirez.* Oxyphosphoranes are compounds containing pentacoordinate phosphorus bonded to at least one oxygen atom: $(RO)_{5-n}PX_n$, $n = 0$—4. Their synthetic value has been realized during the past decade. Five-membered cyclic oxyphosphoranes are stable. The survey deals in particular with five-membered systems containing two endocyclic O atoms with one or no double bonds, with special reference to the chemical behavior of 2,2,2-trialkoxy-1,3,2λ⁵-dioxaphos-

pholes *(1)* and -phospholanes *(2)*. In addition, brief mention is made of other cyclic oxyphosphoranes, *e. g.* 2,2,2-trialkoxy-1,2λ^5-oxaphospholenes and $-\Delta^4$-1,4,2λ^5-oxazaphospholenes.

The synthesis of *(1)* and *(2)* from trialkyl phosphites is considered in detail; preparative examples are given. [Synthesis *via* Oxyphosphoranes. Synthesis *1974*, 90—113; 108 references]

[Rd 700 IE—M]



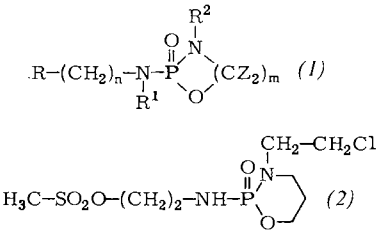
Progress in lithium chemistry in 1972 is surveyed by *W. H. Glaze*. A consideration of questions relating to structure and bonding, kinetics and reaction mechanisms is followed by a treatment of lithium carbenoids and halogen-substituted organolithium compounds. There follow lithiation reactions (H→Li exchange). A series of interesting publications is concerned with the use of lithium compounds as polymerization initiators, and for the after-treatment of polymers in order to modify their properties. Addition reactions of Li compounds to carbonyl compounds, olefins, and similar substrates, as well as reactions with heterocycles and with organometallic compounds close the review. [Lithium Annual Survey Covering the Year 1972. J. Organometal. Chem. *68*, 1—67 (1974); 233 references]

[Rd 705 IE—M]

The photochemical hydroxylation of aromatic compounds, which is, *inter alia*, of biological interest, is considered from a preparative viewpoint by *T. Matsuura* and *K. Omura*. The survey embraces direct hydroxylation with replacement of H by OH, hydroxylation with replacement of a substituent attached to an aromatic ring, and a number of other methods. Direct hydroxylation can be carried out with photochemically generated OH radicals, *e. g.* from Fenton reagent, from water by radiolysis, from dilute aqueous H_2O_2 solution by photolysis, and with atomic O (from N_2O, *N*-oxides of heterocyclic bases) as well as by dye-sensitized photooxygenation (*e. g.* tyrosine→dopa). The photochemical hydrolysis of aromatic diazonium salts, halides, and nitrobenzene derivatives affords phenols, the other substituents exerting a pronounced effect on the reaction course. [Photochemical Hydroxylation of Aromatic Compounds. Synthesis *1974*, 173—184; 63 references]

[Rd 701 IE—M]

Methods for the synthesis of orthocarboxylic esters *(1)* **and orthocarbonic esters** *(2)* are discussed by *R. H. DeWolfe*, paying special attention to the synthesis of acyclic representatives and heterocyclic orthoesters having 1,3-dioxolane, tetrahydrofuran, tetrahydropyran, 2,6,7-trioxabicyclo[2.2.2]octane, or 2,4,10-trioxaadamantane structures and spiro systems. Orthoformates *(1)*, $R^1 = H$, can be synthesized from HCN, formamide, trihalomethane, or halomethyl ethers, other orthoformates, or trithioorthoformates; orthocarboxylates *(1)* are accessible from nitriles, amidoyl chlorides, other orthoesters, ketene acetals, trihalomethyl compounds, and orthocarbonates. Orthocarbonic esters *(2)* are prepared from trihalomethyl compounds or halomethyl ethers, as well as by transesterification of tetramethyl orthocarbonate, and tetraalkyl orthocarbonates from dibutyltin dialkoxides and carbon disulfide.—Orthoesters are widely used in organic synthesis; cyclic orthoesters serve as valuable intermediates for the protection of hydroxy and carboxy groups. [Synthesis of Carboxylic and Carbonic Ortho Esters. Synthesis *1974*, 153—172; 143 references]

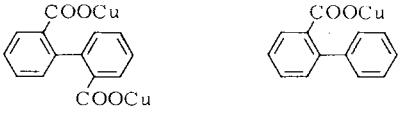


[Rd 702 IE—M]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Esters *(1)* of alkanesulfonic acids and 1,3,2-oxazaphospha cyclic alcohols have an immunosuppressive action and good



R = halogen, lower alkanesulfonyloxy

Z = H, alkyl(C_1—C_4)
n = 2, 3

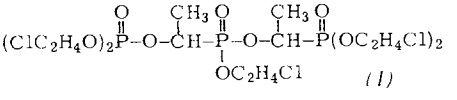
tolerance characteristics. They can be prepared by known methods. A preferred compound is *(2)*. [DOS 2107936; Asta-Werke AG, Brackwede]

[PR 158 IE—K]

In a new process for the production of diphenic acid and 2-phenylbenzoic acid, in which no starting materials obtained from coal tar are required, readily obtainable copper(I) phthalate is heated in a solvent (such as quinoline, pyridine, alkylpyridine) to 110 to 200 °C, and the copper(I) salts *(1)* and *(2)*

(1) *(2)*

are then separated and the free acids isolated. The ratio of *(1)* to *(2)* in the reaction mixture can be adjusted by means of the reaction temperature, higher temperatures giving larger proportions of *(2)*. [DOS 2214690; Aktiebolaget Bofors, (Sweden)]



[PR 169 IE—U]

A process for increasing the molecular weight of high-density polyethylene in the polymerization of ethylene with methylated polysiloxanes, compounds of metals of the IVth subgroup, and aluminum chloride consists in the additional use of organotin compounds having the formula SnR_4. R may be identical or different aliphatic or cycloaliphatic residues. Even small quantities of tetrabutyltin mixed with the three components mentioned above cause a distinct increase in activity

and lead to a narrower molecular weight distribution with a remarkable increase in molecular weight (η_{red} 3—3.6 dl/g as compared with 2.13 dl/g). [DOS 2206386, Wacker-Chemie GmbH, München]

[PR 187 IE—W]

Combustion-resistant acrylic glass based on methyl methacrylate and phosphoric acid or esters of phosphoric acid are obtained by copolymerization with bromophenyl methacrylates (pentabromophenyl, dibromophenyl, and tribromo-

(1)

phenyl methacrylate). The softening point is only slightly depressed (Vicat values between 120 and 133 °C) by this addition. 5 to 10 wt.-% of *(1)*, phosphoric acid, or tris(bromocresyl) phosphate are used as the phosphorus derivative. [DOS 2202791, Röhm GmbH, Darmstadt]

[PR 188 IE—W]

Electrophoretic binders for cationic deposition that crosslink at high temperatures consist of a synthetic resin containing hydroxyl groups, which is partly allowed to react with a polyisocyanate blocked at one end, and also containing amino groups. The resin is dispersed in water by quaternization with lactic acid or acetic acid. As an example, a bisphenol A epoxy resin with an equivalent weight of 910 is allowed to react in *N*-methylpyrrolidine with a 2,4-toluene diisocyanate blocked at one end with 2-ethylhexanol, and dimethylamine is then added to react with the epoxide residues. The resin is dispersed with acetic acid in water. Binders that can be deposited cathodically offer improved protection against corrosion and do not attack phosphate protective films as readily as anionic binders. [DOS 2252536; PPG Industries, Inc., Pittsburgh, Pa. (USA)]

[PR 190 IE—W]

BOOK REVIEWS

Einführung in die Physik (Introduction to Physics). By *R. Fleischmann*. Verlag Chemie GmbH—Physik Verlag, Weinheim/Bergstr. 1973. 1st ed., xviii, 677 pp., 436 figures, 60 tables, bound DM 65.—.

This book, which is based on a series of lectures, resembles *Pohl*'s textbook in that it introduces and explains the essential physical concepts with the aid of briefly described experiments. Care is taken to distinguish clearly between quantities that should be kept conceptually separate, such as the inertial mass and the gravitational mass. This and other similar didactic measures may enable the author to achieve his aim of guarding the beginner (to whom the book is primarily addressed) as far as possible against the usual errors.

Special mention should be made here of the consistent references to the dimensions to be used and to the units, which are listed in a separate section at the end of the book. Here one also finds very useful tables for the conversion of units, for conversion to moving reference systems according to theory of relativity, for the mathematical use of scalars, of vectors and tensors, *etc.*

As far as the choice of subject matter is concerned, the book confines itself mainly to physical processes that can be approximately described and understood in terms of a mental picture. This does not mean, for example, that the wave nature of material particles is ignored, but the predominantly theoretical conclusion from wave and quantum mechanics (Schrödinger equation) play only a minor part in the book. In the field of thermodynamics, one of the concepts that are not easy to grasp and do not lend themselves to mental imagery is entropy; the discussions on this topic are probably not easy for the beginner to understand. On the other hand, there is a brief but nevertheless sufficiently informative description of the areas of physics that are vital to modern investigations in nuclear physics.

The physical laws are examined in the book with the aid of a variety of numerical examples. The examples unfortunately contain a number of discrepancies, which are particularly likely to trouble the student since he will probably assume that the values were obtained by some conversion or other, whereas they are actually simple errors of calculation. Discrepancies of this kind are also to be found in the tables, but these can easily be eliminated in a second edition.

Klaus Schäfer [NB 195 IE]

Boranes in Organic Chemistry. By *H. C. Brown*. Cornell University Press, Ithaca—London 1972, 1st ed., xiv, 462 pp., numerous figures, bound $ 24.50.

The new "H.C.B." is based on a series of lectures given at Cornell University in the autumn of 1969. The book is both more and less than its title suggests. Not only are the "Prolog" and the "Epilog" autobiographical in content, but the "life history" is also reflected by the choice of material and the emphasis in the presentation of all the other chapters. Thus the author's work on free radicals, steric effects, and (how could it be otherwise?) even on the problem of non-classical carbenium ions have been incorporated into the "boron book". Everything is considered from the view-point of the old campaigner. This is naturally also true of the actual "main" chapters, the "Selective Reductions", the "Hydroboration", and the "Organoboranes" and their reactions, among which the reactions with carbon monoxide, the alkylations, and free-radical reactions receive sections to themselves. The author's priorities are illustrated by the following example: The varied reaction of carbon monoxide with organoboranes, which has been dealt with by the author in numerous publications, is given 15 subsections with no fewer than 28 pages. The oxidation of organoboranes with *N*-oxides is not mentioned once in the entire book, though three sections covering 6 pages are devoted to the oxidations of the organoboranes.

The reader will derive special enjoyment and many a smile from numerous passages. The author expresses himself in so many places in his own characteristic manner. The descriptions of the ways in which results were achieved are interesting.

This will be useful to younger readers, particularly since such relationships usually cannot be found in the literature.

The book, which has a subject index and is otherwise excellently presented, is a very good source of information on "H.C.B." chemistry. A broader outlook results from the fact that the author has been practising chemistry for a long time in company with many worthy colleagues. However, the subject indicated by the title of the book is by no means exhaustively discussed. The book can be recommended to any critical reader. No library should be without this excerpt from the contemporary history of chemistry.

Roland Köster [NB 202 E]

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopedia of Industrial Chemistry). Editorial board: *E. Bartholomé, E. Biekert, H. Hellmann*, and *H. Ley*. Edited by *H. Bucholz-Meisenheimer*.

Vol 1: General Principles of Process and Reaction Technology. Verlag Chemie, Weinheim. 4th Edit. 1972. xx, 644 pp., 328 figs., 132 tables, bound DM 315.—. Subscription price DM 285.—.

Vol. 2: Process Technology I (Unit Operations). 1972. xx, 764 pp., 949 figs., 92 tables, bound DM 315.—.

Vol. 3: Process Technology II and Reaction Equipment. 1973. xvi, 592 pp., 630 figs., 104 tables, bound DM 315.—.

Three of the planned six systematic volumes of the new edition of "Ullmann", publication of which was started in 1972, are now available; the first of the eighteen alphabetic volumes has meanwhile also appeared. Despite the change of publisher (the new edition is published by Verlag Chemie), the well-proven basic concept of the third edition has been kept unchanged[1]. The editorial board has wisely decided to revise the work completely instead of continuing it in the form of supplementary volumes. The latter possibility would have had the advantage of giving a more up-to-date result, but the unity and clarity offered by the new edition are probably more important to most of those who use the work, since true up-to-dateness can only be achieved by following the latest original publications.

The present three volumes, together with the fourth volume (Process Development and Plant Design), which has not yet been published, are descended from Volume 1 of the third edition. The enormous development that has taken place in chemical process technology during the past 20 years is clear simply from the greatly increased size of this systematic part. This is true in particular of the theoretical grounding and penetration of the field. For this reason the work as a whole begins with a special volume on scientific principles. This is followed by two volumes dealing with the unit operations of process technology together with the associated equipment, as well as general fields of process technology such as heating and cooling, materials, and pressure and vacuum technology.

The volume on basic principles (Vol. 1) consists of the following sections: Chemical Thermodynamics (53 pp.), Estimation of Physicochemical Properties of Gases and Liquids (28 pp.), Fluid Dynamics (35 pp.), Heat Conduction and Heat Transfer (13 pp.), Diffusion and Mass Transfer (28 pp.), Chemical Kinetics (36 pp.), Dimensional Analysis and Similitude (16 pp.), Principles of Chemical Reaction Engineering (75 pp.), Statistical Methods in the Planning and Evaluation of Experiments (68 pp.), Optimization (58 pp.), Mathematics (194 pp.).

The essential contents of the individual sections are definitions and explanations of the fundamental concepts and derivations of the fundamental relationships. Examples are given to illustrate theoretical methods arising from these discussions; special mention may be made of the mathematical determination of material values and the statistical planning and evaluation of experiments.

The bibliographies at the end of each contribution are designed primarily to enable the reader to obtain further and more advanced information from monographs on the subject. All the contributions (written by a total of ten authors, all but one of whom work at universities) are characterized by clear and impressive presentation; this gives the volume a well-rounded and unified character.

Whereas the first volume had no equivalent in the previous edition, the next two volumes really are a new edition of the previous first volume, *i.e.* a thorough revision.

Volume 2 contains the sections: Size Reduction and Classification (80 pp.), Mineral Dressing (62 pp.), Mechanical Separation Processes for Two-Phase Systems (105 pp.), Mixing (63 pp.), Size Enlargement (31 pp.), Heating and Cooling (143 pp.), Physicochemical Separation Processes (241 pp.).

Volume 3 follows with contributions on: Materials and Noise Prevention (82 pp.), Pressure and Vacuum Technology (47 pp.), Conveying (54 pp.), Refrigeration and Cryogenics (67 pp.), Electrolysis (51 pp.), Photoreactions (15 pp.), Reactors (222 pp.); the contribution on reactors is further divided into the sections: Homogeneous Gas and Liquid Phase Reactions (34 pp.), Liquid-Liquid and Gas-Liquid Reactions (40 pp.), Noncatalytic Reactions with Solids (70 pp.), Reactions on Solid Catalysts (54 pp.), Electrothermal Furnaces (24 pp.).

The contributions are all divided into several subsections, generally written by different authors. For example, the contribution on physico-chemical separation processes (Vol. 2) consists of the parts: Distillation and Rectification, Liquid-Liquid Extraction, Absorption, Adsorption, Diffusion Separation Methods, Evaporators, Sublimation, Crystallization, Fractional Crystallization from the Melt, Separation by Freezing, Drying, Extraction of Solids. The number of authors who have contributed to Volumes 2 and 3 (49 and 35 respectively) is accordingly much greater than for Volume 1; in the established Ullmann tradition, these are all acknowledged experts, mainly from industry.

The contributions describe the particular principles and the practical execution of the procedures for the sector in question. The construction and operation of the equipment are thoroughly explained with the aid of illustrations; methods for the calculation and design of equipment are also dealt with in exemplary fashion.

In view of the extensiveness of the subject matter and its division into individual topics, as occurs in Volumes 2 and 3, and indeed as is necessary for a thorough presentation, overlapping has been unavoidable. One should also bear in mind that the division of the material undoubtedly depended in part on the authors who were available. The reviewer nevertheless feels that a more rigorous subdivision would have been possible in particular in the sections on "Heating and Cooling" and "Reaction Equipment", in the interests of a more unified and better-balanced description of these fields. In the section on Reaction Equipment, for instance, roasting processes are certainly overstressed, above all when one considers that they occupy almost as much space as the contributions on heterogeneously catalyzed gas reactions in fixed beds and in fluidized beds together. Reactors for radiation-chemical reactions, apart from photoreactions, are not discussed; this omission should be corrected in the alphabetic part. This is also to be recommended for the key words "Storage", "Aseptic Production Techniques", "Tabletting": the first as a fundamental operation that is important for all types of chemical plants, and the last two as processes that are used *e.g.* in the packaging of pharmaceuticals.

However, these critical remarks are not intended in any way to belittle the outstanding achievement of the editors and authors. These three general volumes are indisputably the most comprehensive and most up-to-date work in existence on the field of chemical process technology as a whole; this is true even as far as foreign literature is concerned. It is worth mentioning that the new Ullmann also contains lists of contents and indexes in English. The presentation, illustrations, and print are of outstanding quality. Each contribution is followed by a clearly arranged list of references.

As in the previous edition, these general volumes will be of immense assistance to anyone who is concerned with process problems, both as a source of general information and as a source of advice on special problems. The latter case will particularly concern the practical engineer or chemist confronted with the question which process and which equipment are most suitable for a given purpose. This question of the choice of processes and equipment, which is not discussed in the same depth in all the contributions of Volumes 2 and 3, should be treated on a broader basis in Volume 4, which will be available shortly.

Ulfert Onken [NB 199 IE]

[1] Cf. Angew. Chem. internat. Edit. 9, 647 (1970).

MTP International Review of Science. Inorganic Chemistry: Series One. Edited by *H. J. Emeléus*. Volume 4: Organometallic Derivatives of the Main Group Elements. Edited by *B. J. Aylett*. Butterworths, London, and University Park Press, Baltimore, 1972. 1st ed., 424 pp., numerous figures, bound £ 10.—.

The series "Inorganic Chemistry" comprises a total of ten volumes and an index volume. The *first* series contains important progress reports on work published during the period from about 1967 to 1971. The second series, which is of roughly the same size, is scheduled for 1974; it will contain reviews of publications from the period 1971—1973. Further series will follow at roughly equal intervals.

Volume 4 of the first series is divided into nine chapters, which largely embrace the field of the organometallic chemistry of the main group elements. The material is divided as follows: Organoalkali Metal Compounds (author: *P. West*); Organoderivatives of Zinc, Cadmium, and Mercury *(K. C. Bass)*; Organoboron Compounds *(K. Niedenzu)*; Aluminum, Gallium, Indium, and Thallium *(J. B. Farmer* and *K. Wade)*; Silicon, Part 1 *(V. Chvalovsky)*; Silicon, Part 2 *(H. Bürger)*; Germanium *(E. J. Bulten)*; Tin and Lead *(A. J. Bloodworth)*; Organic Compounds of Arsenic, Antimony, and Bismuth *(J. P. Crow* and *W. R. Cullen)*.

In these nine chapters the authors report the most important developments in the various fields during the years 1969 and 1970. The reports are based on 2608 literature references. All earlier review articles and books dealing with the field in question are generally also cited in the various chapters. The result is a very useful literature compilation, which cannot always be complete, owing to the width of the individual fields. This Volume 4 unfortunately does not contain a chapter on organometallic compounds of the elements of the second main group. However, the editor *B. J. Aylett* assures us that a chapter on this topic will be included in the above-mentioned volume in the second series.

The work is not a pure list of highlights, nor does it have the character of a detailed review. It adopts a reasonable intermediate position, and it is pleasing to note that it contains few printing errors. The presentation of the work is very good, and it can be recommended to any organometallic chemist as a literature survey.

Jochen Ellermann [NB 201 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Interpretation of Mass Spectra. By *F. W. McLafferty*. W. A. Benjamin, Reading 1973. 2nd revised and enlarged edition, xix, 278 pp., bound $ 15.00; stitched $ 7.50.

Englisch für Chemiker—English for Chemists. By *F. L. Boschke*, *B. M. Crook*, and *G. N. Tomby*. Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart 1973. viii, 93 pp., stitched DM 12.50.

Environmental Literature. A Bibliography. By *G. F. Bennett* and *J. C. Bennett*. Noyes Data Corporation, Park Ridge 1973. viii, 134 pp., bound $ 18.00.

Drilling Mud and Fluid Additives. By *J. McDermott*. Volume 20 of the series "Chemical Technology Reviews". Noyes Data Corporation, Park Ridge 1973. x, 305 pp., bound $ 36.00.

Photographic Emulsions. Recent Developments. By *R. W. James*. Volume 21 of the series "Chemical Technology Reviews". Noyes Data Corporation, Park Ridge, 1973. x, 303 pp., bound $ 36.00.

Furans. Synthesis and Applications. By *A. Williams*. Volume 18 of the series "Chemical Technology Reviews". Noyes Data Corporation, Park Ridge 1973. x, 301 pp., bound $ 36.00.

Contents: Furan and Substituted Furans; Tetrahydrofurans; Benzofurans and Dibenzofuran; Dihydrobenzofuran; Dihydrofurans, Furanones, and Griseofulvins.

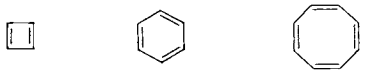
The Cyclobutadiene Problem

By Günther Maier[*]



Dedicated to Professor Karl Winnacker on the occasion of his 70th birthday

Cyclobutadiene has recently become the center of reawakened interest. By use of the matrix isolation technique, cyclobutadienes can now be prepared as monomers frozen in matrices. Thus both the unsubstituted parent compound and its alkyl-substituted derivatives are amenable to study. The present progress report surveys the entire field; however, particular emphasis is placed on the author's own results from investigations concerning this classical problem of organic chemistry.

1. Introduction

About one hundred years have passed since *Kekulé*[1] turned his interest to the preparation of cyclobutadiene ("diacetylene") in his attempts to accomplish a total synthesis of a benzene derivative from aliphatic components. Like *Willstätter*[2], who attempted the first synthesis specifically directed towards cyclobutadiene around the turn of the century, *Kekulé* was unsuccessful.

These failures were unexpected; as vinylogs of benzene *(2)*, cyclobutadiene *(1)* and cyclooctatetraene *(3)* were ascribed "aromatic" properties, and therefore expected to exhibit pronounced stability.

(1) *(2)* *(3)*

The early pioneering studies simply could not lead to positive results because—as we now know—not only the experimental methods but also the theoretical concepts of the day prevented success. Nevertheless, *Willstätter* did actually synthesize cyclooctatetraene *(3)* by a laborious route[3]. The compound behaved in a completely unexpected manner. It had the character of a polyolefin and bore no resemblance whatsoever to benzene. However, all efforts to obtain cyclobutadiene in a similar fashion were in vain.

In view of these bitter disappointments it is understandable why about half a century elapsed until cyclobutadiene chemistry again came into its own during a second ten-year phase beginning in the mid-1950's.

All the attendant successes could not disguise the fact that in spite of enormous efforts—the papers published up to the end of 1965 fill a whole book[4]—nobody had been able to isolate the parent hydrocarbon or simply substituted derivatives, or even detect them as short-lived intermediates. This disappointing situation together with the discouraging pronouncements of theorists account for the delay of several years before a third assault was launched. The events of the most recent epoch provide the subject matter of the present report. It summarizes the author's own work in the field, supplemented by the most significant results from other workers' publications appearing during the past three years[5].

2. Theoretical Predictions

The contrasting behavior of cyclobutadiene and cyclooctatetraene on the one hand and benzene on the other long remained a mystery to the organic chemist. This was only to change

[*] Prof. Dr. G. Maier
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

in about 1930 when *E. Hückel*[6] summarized the results of molecular orbital theory in the rule bearing his name. Accordingly, monocyclic conjugated polyenes having the general composition $(C_2H_2)_n$ ("annulenes") can be divided into two groups, *i.e.* into compounds containing $(4n+2)$ electrons and those with $(4n)$. Benzene is the simplest representative in the series of $(4n+2)$ systems which are stabilized by delocalization, while cyclobutadiene, necessarily being planar, is the prototype of the $(4n)$ class, which exhibits no particular stabilization in spite of the conjugated arrangement of double bonds.

The simple Hückel MO treatment predicts a zero π-delocalization energy for cyclobutadiene. The two nonbonding molecular orbitals are singly occupied; thus a triplet ground state is to be expected (Fig. 1). In contrast, VB theory indicates considerable resonance stabilization of the cyclobutadiene molecule. The gain in energy per electron is forecast to be even greater than that in benzene. A further result deriving from the VB method is that singlet cyclobutadiene may not possess a ground state of maximum symmetry (D_{4h}), but rather prefers an arrangement of lower symmetry (D_{2h}).

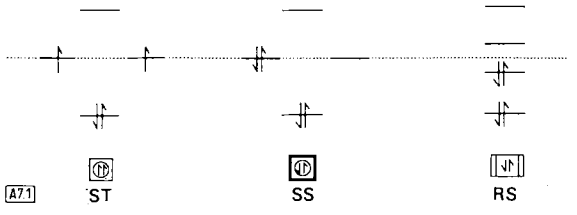


Fig. 1. MO schemes of cyclobutadiene. ST = square triplet, SS = square singlet, and RS = rectangular singlet molecule.

The above discrepancy reflects the difficulties inherent to the theoretical treatment of cyclobutadiene; in principle the two approximations should lead to the same result. Meanwhile[7], theoretical calculations have been refined and supplemented by new approximation methods[8-13]. Regardless of the method employed, the triplet ground state is found to be distinctly favored over a singlet variant for a square structure. The various methods also concur in predicting a square singlet molecule (SS) to be unstable owing to the Jahn-Teller theorem which requires a state of lower symmetry. By undergoing distortion the molecule attempts to achieve a more stable configuration; one possibility is a singlet cyclobutadiene having rectangular geometry (RS). Unlike the $(4n+2)$ annulenes in which bond alternance becomes significant only for a large number of ring members, such alternance is seen to be pronounced even for the parent compound of the $(4n)$ series, cyclobutadiene. However, the approximations are incapable of predicting exactly which of the two possibilities, square triplet (ST) or rectangular singlet cyclobutadiene (RS), should be the more stable. The energy difference between the ST and RS ground states will certainly be small. *Dewar*[12] has predicted a value of 2 kcal/mol (RS more stable than ST). Apart from rectangular distortions, others are also conceivable which likewise avoid the unfavorable SS configuration. The degeneracy of the middle π-MO's would also be resolved on deformation to a rhombus, a trapezium, or a folded structure (Fig. 2). (X-ray studies[14] on a "push-pull" cyclobutadiene of type *(4)* indicate that a rhomboid geometry represents a real possibility.)

Fig. 2. Alternative distortions in cyclobutadiene.

According to modern views, the energy content of cyclobutadiene is greater than that of the corresponding open-chain conjugated diene. Hence cyclobutadiene is characterized by a "negative resonance energy". It possesses antiaromatic character; the molecule is not stabilized by cyclic conjugation but destabilized instead[15-18]. In fact, the calculations would indicate cyclobutadiene to be an antiaromatic *par excellence*. An increase in energy content of 18 kcal/mol—and even about 34 kcal/mol for the SS configuration—has been predicted by *Dewar*[12]. The same method yields a decrease of 20 kcal/mol in the energy content of benzene. In each case, the reference level is the enthalpy of formation of the corresponding classical polyene which can be determined with considerable accuracy. Calculated and measured values are in agreement for the aromatic benzene (adoption of the conjugated polyene as energy reference leads to the value of 20 instead of the usual 36 kcal/mol); experimental proof has yet to be obtained for the antiaromatic cyclobutadiene (Fig. 3).

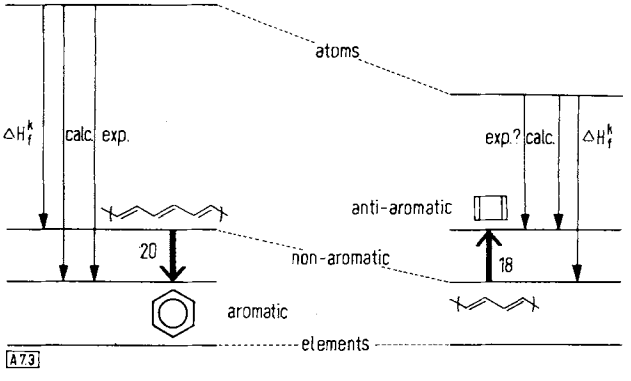

Fig. 3. Distinction between an aromatic and an antiaromatic compound, schematic. Energies are given in kcal/mol.

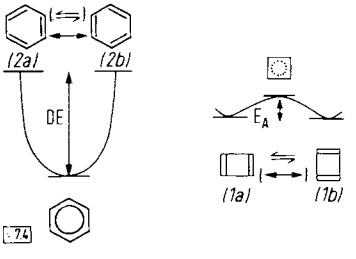
Benzene and cyclobutadiene are worlds apart. The former possesses an ideally delocalized π-electron system. The two Kekulé structures *(2a)* and *(2b)* (Fig. 4) are fictitious resonance structures serving merely to describe the resonance-stabilized molecule. The delocalization energy (DE) is considerable. Completely different conditions are found in cyclobutadiene. Assuming a rectangular singlet ground state, then the two structures *(1a)* and *(1b)* describe two valence isomers, *i.e.* real species in mutual equilibrium: they are separated from each other by an energy barrier (E_A)[19]. The square structure having equal bond lengths describes the transition state of valence isomerization between two forms having



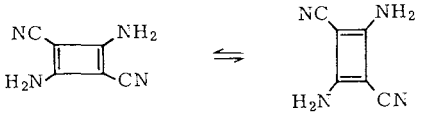


Fig. 4. Distinction between resonance (mesomerism) and valence isomerism (examples: benzene and cyclobutadiene, respectively).

alternating bond lengths (Fig. 4). It is extremely difficult to predict[12] the height of the energy threshold. On the one hand, the geometrical prerequisites for bond transfer are optimally fulfilled and the process could proceed very rapidly; on the other hand, if it is permissible to equate the transition state with SS cyclobutadiene, then an activation barrier of at least $34-18=16$ kcal/mol is to be expected. An essential requirement is that the transition *(1a)*⇌*(1b)* should not be bound up with a change in multiplicity to triplet cyclobutadiene. In other words: it is unclear to what extent the principle of conservation of orbital symmetry will oppose this fluctuation.

A value of about 3 kcal/mol was calculated in the case of the donor-acceptor substituted cyclobutadiene *(4)*[20].

(4a) *(4b)*

3. Statement of Problem

This brief summary shows that the cyclobutadiene problem not only possesses great theoretical interest but also represents a challenge to the experimental organic chemist. Anybody seeking a solution will have to answer the following questions:

1) Are synthetic methods available which permit the generation of cyclobutadienes at very low temperatures?

2) Is it possible to create conditions under which these cyclobutadienes can exist as monomers?

3) What is the multiplicity of cyclobutadienes in the ground state? Is there any relation between multiplicity and substitution pattern?

4) What geometry do cyclobutadienes possess in the ground state? Does this geometry vary depending on the presence of singlet or triplet molecules?

5) Do cyclobutadienes display characteristic spectroscopic properties? Do the spectra provide any information about the electronic situation, and do they permit assignment to a particular electronic configuration?

6) Are there any chemical reactions typical of cyclobutadienes? Can any characteristic differences be observed between singlet and triplet cyclobutadienes?

7) Can an equilibrium be detected between two valence isomeric forms of suitably substituted derivatives? How high is the energy barrier for this process?

8) What is known about the valence-isomeric relationship cyclobutadiene/tetrahedrane?

9) Is cyclobutadiene really the prototype of an antiaromatic compound, as required by theory? How great is the destabilization?

Even if a suitable synthetic route were to be found and the existence of monomer proved, further important points still remain to be established: The multiplicity still has to be elucidated by ESR studies and the geometry by X-ray studies or analysis of IR and Raman spectra. UV and photoelectron spectra will have to be consulted to obtain valid information about the electronic situation in the cyclobutadiene molecule. NMR spectra will be required for observation of a possible coalescence phenomenon and the expected paramagnetic ring current. And finally, experimental determination of the heat of combustion or hydrogenation must be performed in order to establish the energy content.

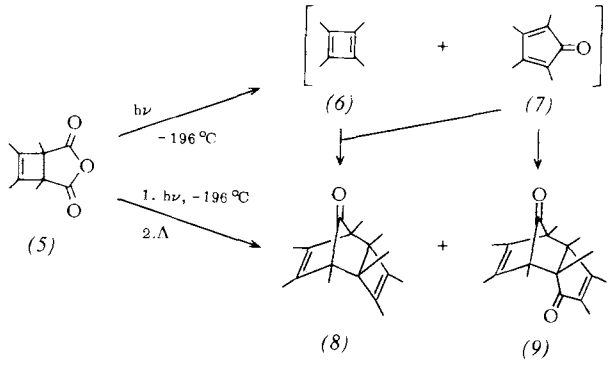
If anything, the earlier experimental observations made one fact very clear: the lifetime of cyclobutadiene—with the exception of cyclobutadienes modified by fusing with aromatic systems[21] or by a "push and pull" effect[22], and of course cyclobutadiene complexes[23], *e.g. (81)*—is certainly so short that isolation appears hopeless. Studies by flash pyrolysis[24–26] and flash photolysis[27–29] had shown the lifetime of the unsubstituted parent to be probably no more than a few ms. If an attempt to isolate cyclobutadienes is not to be condemned to failure from the outset, then conventional thermal preparations are immediately ruled out. Instead, a method must be chosen which permits generation of cyclobutadienes at extremely low temperatures. Hence only a photochemical process comes into question.

We have devoted our efforts to the synthesis of photoprecursors suitable for generating cyclobutadienes in order to fulfill the long-standing wish for a direct spectroscopic observation of cyclobutadiene and its derivatives by means of the matrix isolation technique.

4. Method

In the matrix isolation technique[30, 31] highly reactive species are frozen in a matrix at extremely low temperatures. Organic solvent glasses are employed as matrices in which the species resulting on photofragmentation are capable of existence as monomers owing to the extremely low rate of diffusion, and are thus amenable to direct observation. Hydrocarbons, perfluorinated organic compounds, ethers, and alcohols (particularly multicomponent systems in various mixing ratios) are suitable for use as UV-transparent inert solvents. Liquid nitrogen (77 K) can be used for quenching. After irradiation and melting of the matrix the products are isolated and identified in the usual way. Recently, noble gases, especially argon, have found increased application as guest matrices. The necessary cells and cooling systems—liquid helium (4 K) in open or closed circulation—have recently become commercially available.

5. Methylated Cyclobutadienes

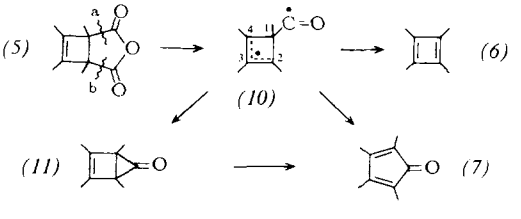


Suitable precursors for photochemical generation of cyclobutadienes are cyclobutenedicarboxylic anhydrides which can be prepared by sensitized photoaddition of correspondingly substituted acetylenes to maleic anhydrides.

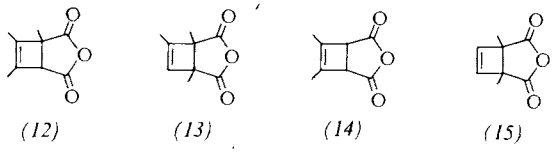
Surprisingly, these anhydrides exhibit pronounced maxima between 228 nm (unsubstituted anhydride) and 241 nm (tetramethylated derivative) owing to homoconjugative interaction of the C=O group with the C=C double bond. The position of the maximum shifts towards longer wavelengths with increasing number of alkyl groups.

Irradiation of tetramethylcyclobutenedicarboxylic anhydride *(5)*[32] affords a complicated mixture of products[33]. The crucial intermediates for formation of the twelve isolated and identified products are the monoketone *(8)* and the diketone

(9). Formation of these two compounds can be regarded as evidencing the intermediacy of tetramethylcyclobutadiene (6) and tetramethylcyclopentadienone (7).



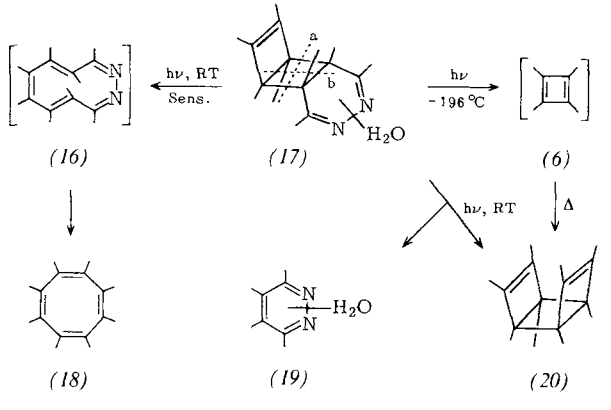
Support for this view comes from the results of low temperature photolysis[34] of (5). On irradiation in a matrix (ethanol/ether/isopentane) at −196 °C a deep yellow coloration is observed which vanishes immediately upon thawing, even before the



glass has completely melted. Only the two adducts (8) and (9) can then be isolated as products. On irradiation in a matrix under the same conditions these adducts give the same product mixture as is found on irradiation of (5) in solution at room temperature. Thus it is clear that on irradiation of (5) no adduct (8) or dimer (9) is present prior to thawing of the matrix and that tetramethylcyclobutadiene (6) and cyclopentadienone (7) must be frozen in the matrix as monomers. Provided that the matrix is kept at −196 °C, the yellow color is retained for several hours after the lamp has been switched off. It may be assumed that the stability of (6) and (7) under these conditions is due less to the low temperature than to the greatly reduced mobility of the molecules in the frozen state.

In order to gain an insight into the mechanism of the fragmentation reaction we have also subjected partially methylated anhydrides to photocleavage. The distribution of the methyl groups in the products can provide an indication of whether cyclobutadienes really do occur as intermediates, for other reactions are conceivable which could also explain the formation of key substances like (8) or (9).

All available evidence suggests that the primary step in photocleavage of, *e. g.* the anhydride (5), is liberation of CO_2. The diradical fragment (10) can then react by one of two possible routes. It can either undergo CO elimination to form the cyclobutadiene (6) or recombination at position 2 or 4 to give a cyclopentadienone. We cannot yet say whether this isomerization proceeds directly or *via* a bicyclopentenone intermediate (11). A number of findings—it is impossible *e. g.* to detect compounds of type (11) in a matrix by IR spectroscopy—appear to favor the one-step reaction of (10) giving (7).



This is supported by studies in the series of anhydrides (12)[32], (13)[35], (14)[32], and (15)[35], and especially by the substitution pattern in the products of room temperature photolysis of (12)[36] and (14)[37]. (When the substituents are different, cf. formula (5), rupture of bonds a and b leads to two different diradicals.) Quantitative determination of the total of 19 known structurally elucidated products resulting on cleavage of the anhydride (14) also permits one to conclude that steric factors exert a certain selectivity in 1,2-dimethylcyclobutadiene[37]. The doubly substituted double bond is less reactive than the unsubstituted one.

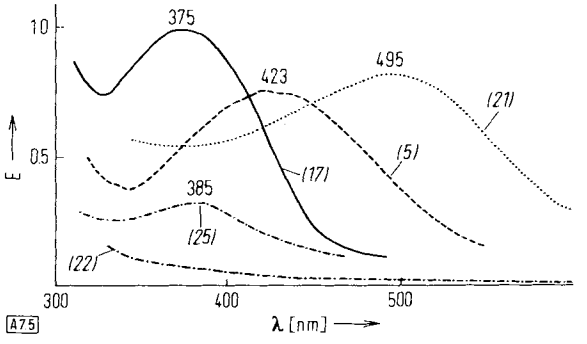
Low temperature photolysis[34, 36] of the partially methylated anhydrides (12)—(15) also displays the expected picture. Both (12) and (14) give a yellow matrix on cleavage at −196 °C. Again, after melting of the glass, only adducts of cyclobutadienes to cyclopentadienones and dimers of the corresponding cyclopentadienones, but no secondary photoproducts of these compounds, are found. In contrast, photofragmentation of monomethylated cyclobutenedicarboxylic anhydrides takes an exceptional course[35].

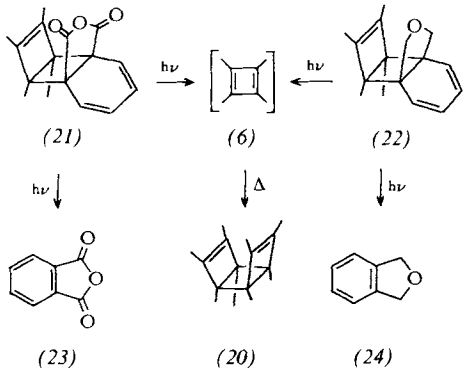
The yellow color observed on cleavage of tetramethylcyclobutenedicarboxylic anhydride (5) at −196 C can be due to both cyclobutadiene (6) and cyclopentadienone (7). Proof that the cyclobutadiene system is capable of existence as the monomer under the conditions applied, and is possibly characterized by a typical UV absorption, is feasible only if an independent synthetic pathway for photochemical generation of cyclobutadiene (6) is available. Formation of cyclopentadienone must be ruled out completely.

As an example of such a method we can consider the photofragmentation of the heterocycle (17). Irradiation of (17)[38] gives an almost quantitative yield of the *syn*-tricycle (20) and tetramethylpyridazine (19). In this context it may be mentioned that octamethylcyclooctatetraene (18) is formed almost exclusively on sensitization with benzophenone[39]. Apparently (17) is cleaved across a on direct irradiation, while ring-opening across b to yield a diaza[10]annulene (16) is preferred on sensitization. The latter product then furnishes the hydrocarbon (18) by elimination of nitrogen. The change

in stereochemistry on going from the *anti*-configurated heterocycle *(17)* to the *syn*-tricycle *(20)* proves the intermediacy of cyclobutadiene *(6)* in the unsensitized irradiation.

It is especially interesting that on irradiation of *(17)* in a matrix at −196 °C a yellow coloration is again observed which is stable only under these severe conditions and disappears on removal of the liquid nitrogen. As products, the hydrocarbon *(20)* and tetramethylpyridazine *(19)* can be detected in more than 90% yield. Since *(19)* absorbs at 258.5 nm it should now be possible to detect tetramethylcyclobutadiene *(6)* directly by UV spectroscopy. Whereas a broad maximum at 423 nm is found on photochemical cleavage of the anhydride *(5)* in a low-temperature cell, a maximum at 375 nm appears in the case of *(17)* when exposed to identical conditions (Fig. 5). This absorption must be asssigned to tetramethylcyclobutadiene *(6)*.





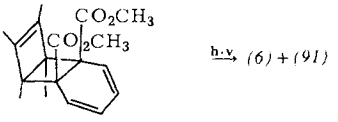


Fig. 5. Low-temperature UV spectra starting from *(5)*, *(17)*, *(21)*, *(22)*, and *(25)*; layer thickness 1 mm. The spectra correspond to tetramethylcyclopentadienone *(7)*, the charge-transfer complexes *(26)*, *(27)*, and *(28)*, and free tetramethylcyclobutadiene *(6)* (see text).

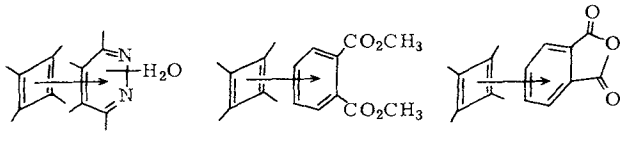
The only possible source of error could arise from the maximum at 375 nm being due not to the "free" cyclobutadiene but to a charge transfer complex between *(6)* and the pyridazine *(19)*. In order to reach a decision in this matter, we have searched for other photoprecursors for an independent generation of *(6)*. The principle employed in cleavage of *(17)*, namely that of forcing formation of *(6)* by elimination of a component stabilized by delocalization, should also be applicable to compounds *(21)* and *(22)*. Indeed, both substances smoothly form the tricycle *(20)* on room-temperature irradiation. Compound *(21)*[40] yields phthalic anhydride as second product; *(22)* eliminates phthalan *(24)*, and *(25)* dimethyl phthalate *(91)*[41]. The same applies to low-temperature photolysis. If the fragmentation is performed in a low-temperature cell at −196 °C, then in the case of *(21)* a deep red coloration is observed which is due to a maximum at 495 nm. On cleavage of *(22)* neither a coloration nor a maximum above 300 nm is observed (Fig. 5). If a very thin layer (0.1 mm) is irradiated, then, in addition to the spectrum of the cleavage product *(24)*, an absorption can be seen which gradually increases from 300 nm towards shorter wavelengths.



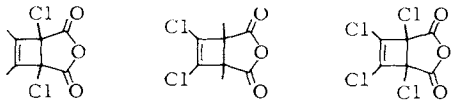
We are now in a position to produce tetramethylcyclobutadiene *(6)* by five independent routes[42], starting from *(5)*, *(17)*, *(21)*, *(22)*, or *(25)*. However, a different UV spectrum is recorded for each one of these fragmentations. How can

(25)

these contradictory results be explained? Presumably tetramethylcyclobutadiene is an excellent electron donor. Should cleavage of *(17)* or *(21)* simultaneously generate an acceptor molecule, a charge-transfer complex can be formed in the matrix. The necessary geometrical arrangement is already provided by the starting materials. This possibility does not exist in the case of the anhydride *(5)* where the donor and acceptor (cyclopentadienone) arise from different starting molecules.

These considerations permit the following assignments: the maximum at 423 nm observed on cleavage of *(5)* is due solely to tetramethylcyclopentadienone *(7)*. The 375-nm band seen in the case of *(17)* comes from the charge-transfer complex *(26)*. The absorption at 385 nm resulting on cleavage of the ester *(25)* indicates the presence of complex *(27)*. Even more pronounced is the interaction in complex *(28)*: hence the band at 495 nm when *(21)* is used as precursor. Only the fragmentation of *(22)* generates free tetramethylcyclobutadiene *(6)* (phthalan does not possess acceptor properties).

(26) *(27)* *(28)*



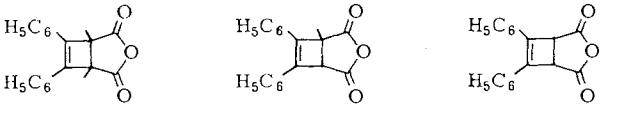
However, the absorption of *(6)* apparently lies below 300 nm, in accord with the theoretical predictions[9] for rectangular singlet cyclobutadiene which should display no further allowed transitions above 197.7 nm ($f = 0.21$).

6. Chlorinated Cyclobutadienes

According to studies by *Cava*[43], halogen atoms can exert a significant stabilizing effect on the naphthocyclobutadiene system. Presumably the halogen atoms have a dual action: by way of their inductive effect (reduction of the charge density in the ring) and their mesomeric effect ("push-pull" interaction between the substituents and the π-system of cyclobutadiene).

Nothing is yet known about the degree of stabilization in simply substituted cyclobutadienes[44-47]. We have therefore irradiated the chlorinated anhydrides *(29)*[48], *(30)*[49], and

(31), hoping to detect these species directly in the matrix by spectroscopy and to glean some information about the extent of stabilization by the chlorine atoms from the behavior of the system on thawing. The experiments[50] not only con-

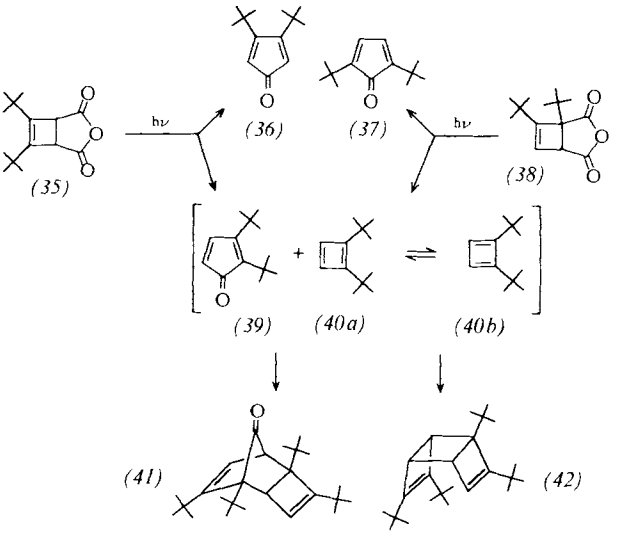


(29) *(30)* *(31)*

firmed the fragmentation mechanism discussed in Section 5 [*(29)* and *(30)* both afford the same adduct of 1,2-dichloro-3,4-dimethylcyclobutadiene to 2,3-dichloro-4,5-dimethylcyclopentadienone as required] but also show that the chlorine atoms at least prolong the lifetime of the cyclopentadienone ring system. However, no unequivocal statement can be made whether the same applies to the cyclobutadiene ring system.

7. Phenylated Cyclobutadienes

By virtue of their mesomeric effect, phenyl groups should have an even more favorable influence on the cyclobutadiene ring system than chlorine atoms. As a supplement to the investigations by *Freedman*[51] and *Pettit*[52], it seemed reasonable to generate phenylated cyclobutadienes in a matrix at −196 °C by photofragmentation of the anhydrides *(32)*, *(33)*, and *(34)*, and to study the degree of interaction with the



(32) *(33)* *(34)*

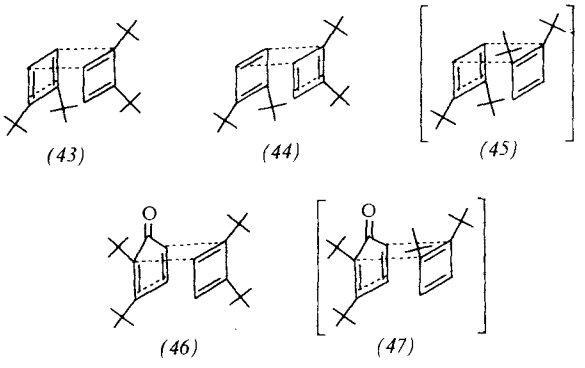
phenyl groups. The anhydrides are readily accessible by photoaddition to tolan[53], but unfortunately turn out to be too photostable. By promoting distribution of the absorbed energy, the phenyl groups preclude photocleavage. Even several hours' irradiation leads to minimal conversions.

8. *tert*-Butylated Cyclobutadienes

The predicted antiaromaticity of cyclobutadiene would lead one to expect a high reactivity, particularly with regard to a Diels-Alder-like dimerization. Introduction of *tert*-butyl groups represents a method of preparing sterically hindered but electronically intact cyclobutadienes[54–58]. We have attempted to apply the photofragmentation reaction to *tert*-butylated anhydrides with the aim of preparing not only stable cyclopentadienones, but possibly even isolable cyclobutadienes.

Low temperature photolysis of 3,4-di-*tert*-butylcyclobutenedicarboxylic anhydride *(35)*[59] affords 3,4-di-*tert*-butylcyclopentadienone *(36)*, which can exist as the monomer, as well as two additional products, the monoketone *(41)* and hydrocarbon *(42)*. Owing to steric hindrance in the transition state, the dienone *(36)* fails to dimerize even at room temperature. It does not even add 1,2-di-*tert*-butylcyclobutadiene *(40)*. The latter is only able to form the adduct *(41)* with the

(35) *(36)* *(37)* *(38)* *(39)* *(40a)* *(40b)* *(41)* *(42)*



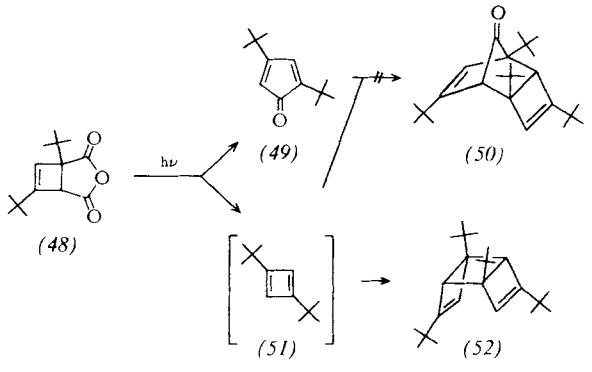
2,3-di-*tert*-butylcyclopentadienone *(39)* likewise present in the matrix. The unconsumed cyclobutadiene dimerizes to the tricycle *(42)*[36].

If the positional isomer *(38)* is irradiated under analogous conditions, compounds *(41)* and *(42)* are again obtained after thawing of the matrix. Instead of the dienone *(36)*, the monomeric 2,5-di-*tert*-butylcyclopentadienone *(37)* can then be isolated.

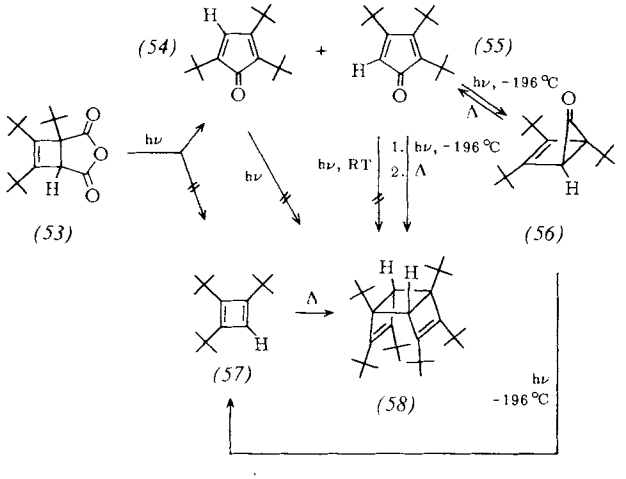
These findings[60] constitute additional proof of the cleavage scheme proposed above. Moreover, it is apparent that two *ortho tert*-butyl groups can stabilize the cyclopentadienone, but not the cyclobutadiene, ring system to such a degree as to render it isolable.

Of greater importance is the fact that the above results can be regarded as evidence for a valence-isomeric equilibrium *(40a)*⇌*(40b)*. The distribution of substituents in *(42)* reveals that either two 1,4-isomers *(40b)* must have reacted according to formula *(43)* or two 1,2-isomers *(40a)* according to *(44)*. Although apparently more likely from statistical considerations, combination *(45)* does not seem to come into play. The substitution pattern in adduct *(41)* results from addition of the 1,4-valence isomer *(40b)* to the dienone *(39)* [transition state *(46)*]. Diels-Alder reaction of *(40a)* [transition state *(47)*] would lead to a different product.

The simplest explanation is the following: the same valence-isomeric system *(40a)*⇌*(40b)* is formed from both *(35)*



(43) *(44)* *(45)* *(46)* *(47)*



and *(36)*; however, the equilibrium lies completely on the side of the 1,4-isomer *(40b)* in which the bulky substituents

are farthest apart. A similar situation is discussed by *Pettit*[52] for "*ortho*"-(1,2- and 1,4-)diphenylcyclobutadiene.

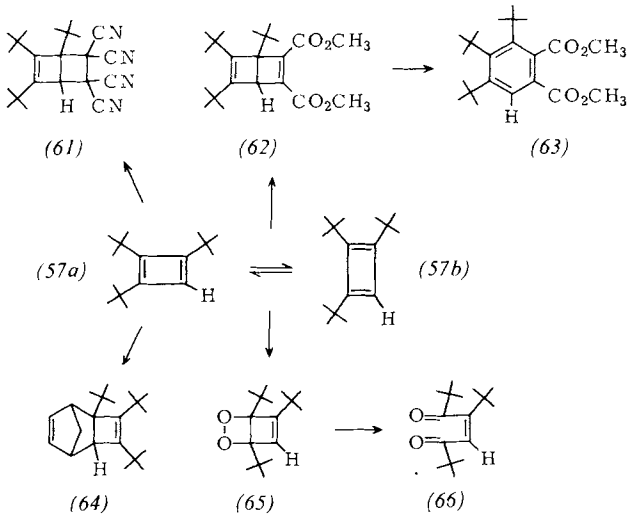
Owing to its greater inherent steric hindrance 1,3-di-*tert*-butylcyclobutadiene *(51)* should be less prone to undergo Diels-Alder reaction than *(40)*. This prediction is confirmed by experiment[60]. Irradiation of the anhydride *(48)*[61] gives only two products, *i.e.* 2,4-di-*tert*-butylcyclopentadienone *(49)* and the dimer *(52)* of 1,3-di-*tert*-butylcyclobutadiene *(51)*. Enclosed in the matrix, *(51)* can no longer undergo Diels-Alder reaction with the dienone *(49)* to give *(50)*. Nevertheless, it is still sufficiently reactive to give *(52)* by self-addition.

The ideal starting material for preparation of tri-*tert*-butylcyclobutadiene, which, according to the above arguments, might be stable enough to be detectable as the monomer in solution, would appear to be the anhydride *(53)*. However, its photocleavage leads exclusively to the two cyclopentadienones *(54)* and *(55)*. Neither cyclobutadiene *(57)* nor its dimer *(58)* is found.

We explain this disappointing reaction course as being due to preferential formation of the former of the two conceivable diradical intermediates *(59)* and *(60)* because in this form the third *tert*-butyl group possesses a staggered orientation. Elimination of CO from *(59)* would necessarily lead to an eclipsed arrangement of all *tert*-butyl groups and is therefore precluded.

Thus the problem arises of finding an alternative path for the synthesis of tri-*tert*-butylcyclobutadiene *(57)*. One possibility that springs to mind is the anodic oxidation of the dianion of the dicarboxylic acid parent of anhydride *(59)*[62]. Performed under the usual conditions, Kolbe electrolysis affords only 1,2-di-*tert*-butyl-3-pivaloylcyclopropene[63] and the diketone *(66)*[63] as defined isolable products; under very mild conditions a low yield of 2,3,5-tri-*tert*-butylfuran[64] is obtained. These results suggest that anodic oxidation of 1,3,4-tri-*tert*-butylcyclobutenedicarboxylic acid does indeed lead to tri-*tert*-butylcyclobutadiene *(57)*, but the sensitivity of this species towards oxygen represents a serious obstacle to its detection.

In spite of all these difficulties we refused to capitulate, and our perseverance was finally rewarded[65]: If the photofragmentation of *(53)* at −196 C is followed by IR spectroscopy, the carbonyl band due to the cyclopentadienones *(54)* and *(55)* is seen to exhibit a partial drop in extinction on prolonged irradiation. A detailed study showed that *(54)* is photostable at all temperatures. The same applies to *(55)* at room temperature. Strangely enough, however, *(55)* undergoes photocleavage at −196 °C. Low-temperature IR spectra betray the formation of CO. Under favorable conditions, the tricyclic hydrocarbon *(58)* is isolated in over 80% yield on thawing of the matrix.



We explain this surprising result in the following way: The three adjacent *tert*-butyl groups in *(55)* induce the molecule to transform into the bicyclic compound *(56)*. The thermal reverse reaction is so fast at room temperature that the steady-state concentration of *(56)* is extremely low. At −196 C, however, the concentration is sufficiently high (although still not high enough for detection by IR spectroscopy) to play a product-forming role in the reaction. Elimination of CO leads to the long-sought tri-*tert*-butylcyclobutadiene *(57)*.

On irradiation for three hours at −196 C in a perdeuterated methylcyclohexane glass (sealed NMR sample tube), *(55)* is converted almost completely into a new species which survives thawing to room temperature and is characterized by three signals in the 100-MHz ^{1}H-NMR spectrum [τ=4.65 (1H), 8.86 (9H), and 8.95 (18H)]. After 24h only the spectrum of the dimer *(58)* can be recorded. Thus there can be no doubt that the intermediate is tri-*tert*-butylcyclobutadiene *(57)*.

We not only accomplished the first preparation of a cyclobutadiene stable at room temperature which bears only alkyl substituents and must consequently have an intact π-electron system, but were also able to determine the chemical shift of a proton attached directly to the cyclobutadiene ring and thus to obtain an indication of the paramagnetic ring current in cyclobutadiene.

The equivalence of the two *tert*-butyl groups of *(57)* which are adjacent to the proton in question can be viewed as an argument favoring a fast valence isomerization *(57a)*$\rightleftharpoons$*(57b)*, provided that *(57)* possesses a singlet ground state with alternating bond lengths.

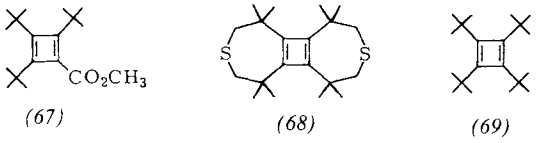
The successful preparation of *(57)* now permits unique characterization of the typical reactions of a cyclobutadiene[66]. In this context, the readiness to undergo Diels-Alder reactions and the ease of autoxidation warrant particular attention. Tri-*tert*-butylcyclobutadiene *(57)* readily forms adducts not only with maleic anhydride[67], but also with tetracyanoethylene and dimethylacetylenedicarboxylate, attack taking place

(61) (62) (63)

(57a) (57b)

(64) (65) (66)

exclusively at the less substituted double bond. It is characteristic for the adduct *(61)* that the bridgehead *tert*-butyl group gives a separate NMR signal for each methyl group owing to hindered rotation, provided that acetone is used as solvent; no splitting is observed in benzene. The Dewar-benzene derivative *(62)* is stable at 100 °C but isomerizes to dimethyl 3,4,5-tri-*tert*-butylphthalate *(63)* at 150 °C. Compound *(63)* can also be obtained by diene synthesis with the cyclopentadienone *(55)*[68].



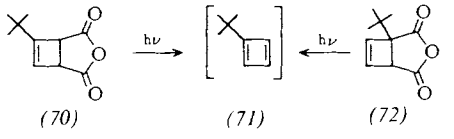
In the examples cited so far, *(57)* reacts as a diene. Its ability to function as a dienophile is manifested in its reaction with cyclopentadiene. The NMR spectrum[69] of the product indicates structure *(64)*.

It is therefore hardly surprising that the dimerization of *(57)*, which is also classified as a Diels-Alder reaction, is relatively fast in spite of pronounced steric hindrance. The activation enthalpy and activation entropy of this reaction may be expected to have highly unusual values. Kinetic studies are in progress[66].

Particular interest attends the reaction of the cyclobutadiene *(57)* with oxygen, on the one hand because a compound is formed to which we are forced to assign the structure of a cyclobutene ring fused to a dioxetane. The NMR and IR spectra, the positive reaction with potassium iodide solution, and the ready conversion into the unsaturated diketone *(66)* constitute structural proof of *(65)*. This latter isomerization occurs even at room temperature. On the other hand, autoxidation occupies a special place in that it occurs specifically at the doubly substituted double bond. The reason could lie in the stepwise nature of the reaction, in contrast to the course of the Diels-Alder reactions.

It is of course very tempting to apply the above method to the synthesis of tetra-*tert*-butylcyclobutadiene *(69)*. Preparation of the starting materials presents a serious obstacle, however. Meanwhile, this gap has largely been closed by the work of *Masamune*[67] and *Krebs*[70]. *Masamune* has not only generated tri-*tert*-butylcyclobutadiene *(57)* and detected it in solution, almost simultaneously with and independently of us, but also isolated the ester *(67)*; the method of choice was also low-temperature irradiation of suitable photoprecursors (cyclopropenyldiazomethane derivatives).

Thermal dimerization of strained cycloalkynes represents another entry to these compounds. Experiments with unsubstituted[71] and tetramethylated cyclohexyne[72] remained unsuccessful; however, by using the corresponding $PdCl_2$ complex *Krebs* has been able to prepare the cyclobutadiene derivative *(68)*, the first example of a cyclobutadiene stabilized by steric

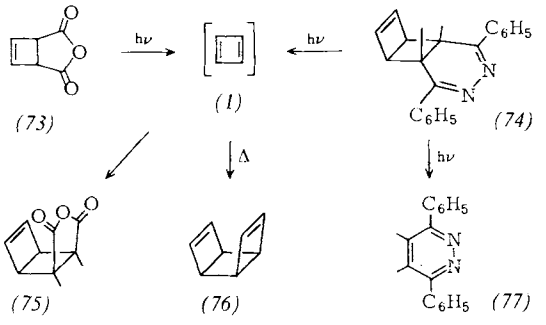


(67) (68) (69)

hindrance. On exclusion of oxygen the crystalline product is completely stable at room temperature. The question as to the extent of possible stabilization by the sulfur atoms has been answered by the photoelectron spectrum[73]: no transannular n/π interaction exists.

9. Unsubstituted Cyclobutadiene

It was our aim to arrive at stable cyclobutadienes by introducing bulky residues. In addition, we had also set ourselves the task of establishing the existence of unsubstituted cyclobutadiene *(1)* with the aid of the matrix method. The photofragmentation of the mono-*tert*-butyl-substituted anhydrides *(70)*[74] and *(72)* leads up to the second kind of problem. Both anhydrides should yield the same cyclobutadiene *(71)*, *i.e.* starting from *(70)* and *(72)* the same UV spectrum should



(70) (71) (72)

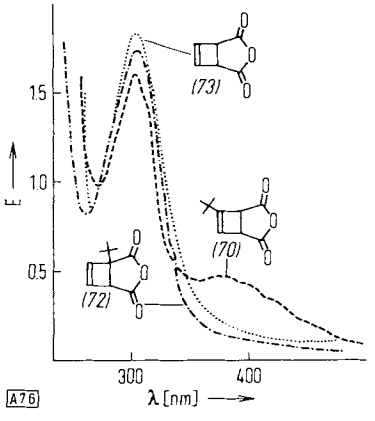
be obtained on low temperature photolysis. This is indeed the case[75] (Fig. 6). During matrix irradiation, a maximum appears between 300 and 305 nm which is presumably due to *tert*-butylcyclobutadiene *(71)*. The assignment is relatively easy since IR analyses have established that only little cyclopentadienone results on photofragmentation of *(70)*, and none at all is formed from the positional isomer *(72)*. It should be emphasized that the absorption maximum recorded here is completely different from that obtained in the case of tetramethylcyclobutadiene (Fig. 5).

What is the situation regarding unsubstituted cyclobutadiene itself? Publications by *Nenitzescu*[76] and *Pettit*[77] convincingly demonstrate that cyclobutadiene *(1)* has to be assumed as an intermediate in the dehalogenation of 3,4-dichlorocyclobutene and oxidative decomposition of the $Fe(CO)_3$ complex *(81)*.

A fitting climax to our experiments would be the generation of the parent compound *(1)* in a matrix starting from the anhydride *(73)*[78,79]. The relatively short-wave absorption maximum of *(73)* at 228 nm with an extinction of only 670 represents an experimental problem. Thus it is difficult to excite the molecule with 253.7 nm light. Irradiation of *(73)* at room temperature in methylene chloride results only in dimerization[80]. If this intermolecular reaction is suppressed by embedding the anhydride in a matrix (ether/tetrahydrofur-

an/isopentane) it is indeed cleaved as desired on irradiation[75], albeit to a limited extent. The IR spectra indicate formation of CO_2 and CO. After eight hours' irradiation a 9% yield of the *syn*-tricyclic compound *(76)* is isolated as sole product on thawing of the matrix[75,80]. Of greater significance is

the reoccurrence of a maximum at 301 nm in the UV spectroscopic record of the fragmentation of *(73)* (Fig. 6). This band vanishes immediately on warming. The position of the maximum corresponds to that observed on irradiation of the anhydrides *(70)* and *(72)*. There is a conspicuous difference between these spectra and those of tetramethylcyclobutadiene reproduced in Figure 5.



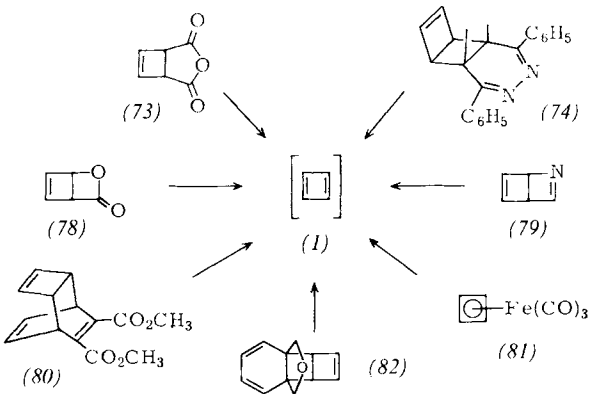


Fig. 6. Low-temperature UV spectra starting from *(70)*, *(72)*, and *(73)*; layer thickness 1 mm. The first two spectra correspond to *tert*-butylcyclobutadiene *(71)*, and the other to cyclobutadiene *(1)*.

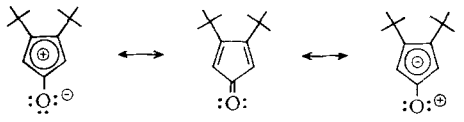
Assignment of the band at 301 nm to unsubstituted cyclobutadiene *(1)* would stand on a firmer footing if the same absorption were to be observed on fragmentation of another photoprecursor. For this reason, we synthesized the heterocycle *(74)*, by analogy with *(17)*, and irradiated it under the same conditions at −196 °C. Although fragmentation to cyclobutadiene and 4,5-dimethyl-3,6-diphenylpyridazine *(77)* does in fact occur, as desired, the conversion is so low (owing to the phenyl groups, cf. Section 7) that the UV maximum of *(1)* cannot be differentiated against the strong absorption of the pyridazine. On heating, the tricyclic compound *(76)* is again formed as sole product from *(1)*. It is not found on room-temperature irradiation of *(74)*. If irradiation is performed in the presence of an excess of dimethylmaleic anhydride, then a small amount of adduct *(75)* can be detected. A crucial breakthrough, at least as far as unsubstituted cyclobutadiene is concerned, was accomplished by two American research groups: both applied the matrix isolation technique to photolysis of the lactone *(78)*. *Corey*[81] first synthesized this compound ten years ago, and remarked at the time that

it should be an ideal precursor for generation of cyclobutadiene. This prediction is confirmed by the observation that irradiation of *(78)* in presence of carbonylmetal compounds yields cyclobutadiene complexes[82]. The photochemical behavior of α-pyrone and its bicyclic isomer *(78)* accordingly remained a center of avid interest[83–85]. Nevertheless, success did not follow immediately. Only very recently, *Chapman*[86] and *Krantz*[87] independently generated cyclobutadiene *(1)* by irradiation of *(78)* in noble gas matrices at temperatures of 8—20 K and characterized it by means of its IR spectrum. Analogous investigations with deuterated[13,88] derivatives of *(78)* leave no doubt that the IR spectrum recorded really is due to cyclobutadiene *(1)*[**].



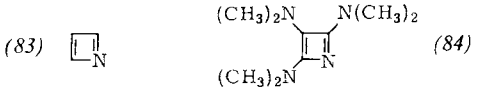
Furthermore, *Masamune*[89] observed a UV maximum at 300—305 nm when he subjected the cyclic ether *(82)* to photocleavage in a matrix at −175 °C. This constitutes independent confirmation of our spectral observations. It may thus be assumed that this absorption behavior is peculiar to cyclobutadiene *(1)*. While such a band contradicts theoretical predictions regarding the electronic spectrum of singlet cyclobutadiene, a certain agreement is found with the calculated[9] absorption ($\lambda_{max} = 380$ nm; $f = 0.2$) for square triplet cyclobutadiene.

Meanwhile, a whole series of precursors has become available for the generation of cyclobutadiene. To the compounds *(73)*, *(74)*, *(78)*, and *(82)* already mentioned, we can add Dewar-pyridine *(79)*[86], the adduct *(80)* between dimethyl acetylenedicarboxylate and cyclooctatetraene[29], as well as the cyclobutadiene complex *(81)*[27,28].

10. Relationship between Cyclobutadiene and Cyclopentadienone

Two *tert*-butyl groups suffice (Section 8) to reduce the reactivity of the cyclopentadienone ring system to such an extent that compounds stable at room temperature are obtained. Since *(36)* and *(37)* have become readily accessible, the properties of these annulenones can now be studied in detail. These investigations are closely related to the cyclobutadiene problem. Any contribution by canonical structure *(36a)* will lead to an antiaromatic destabilization of species *(36)*; if *(36c)* represents the molecule better it will be manifested in a drastic modification of the carbonyl reactivity owing to the reversed polarity of the C=O double bond.

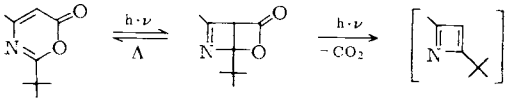
[**] *Note added in proof* (July 8, 1974): Irradiation of anhydride *(73)* in an argon matrix at 8K also results in a clean photocleavage to CO_2, CO, and unsubstituted cyclobutadiene (1237, 653, 573 cm^{-1}) [124].



(36a) (36b) (36c)

Thus the cyclopentadienone molecule[90] poses problems[91] resembling those considered for cyclobutadiene in Section 3. Attempted syntheses have been reported on several occasions[92–94]. It was only in 1971[95] that the parent compound could be synthesized and detected by IR spectroscopy at low temperature. Derivatives *(49)*[96], *(37)*[97a], and *(54)*[97b] have so far remained poorly accessible.

Studies performed hitherto on the available substances indicate that the cyclopentadienone ring system possesses the character of a "normal" unsaturated ketone in the electronic ground state (IR, NMR, photoelectron spectra[98]). (A different situation is found in cyclopropenones where conjugative effects are significant[99].) However, the UV spectra[60] of cyclopentadienones warrant attention. The frequency of the long-wave band is highly dependent upon the number and position of the substituents. From a chemical standpoint (carbonyl reactions) they do not behave in a typical manner (no hydrazone formation, *etc.*). It should also be mentioned that on adduct formation between cyclopentadienones and cyclobutadienes the former always act as dienes and the latter exclusively as dienophiles, although the cyclopentadienone certainly has the lower electron density of the two ring systems. These reactions therefore have to be classified as Diels-Alder reactions with inverse electron demands.



11. Azacyclobutadiene

A compelling analogy exists between azacyclobutadiene *(83)*, the simplest heterocyclobutadiene, and the pure carbocycle *(1)*. Application of the methods discussed so far to the preparation of azacyclobutadienes appears particularly promising since calculations by *Dewar*[100] ascribe a stabilizing effect to the nitrogen [lowering the negative resonance energy from −18 kcal/mol (cyclobutadiene) to −15.5 kcal/mol (azacyclobutadiene); a value of +23.1 kcal/mol is calculated for pyridine]. Additional stabilization is to be expected from donor groups in positions 2 and 4[101]. Hence it becomes clear why *Gompper*[102] was able to isolate the azacyclobutadiene derivative *(84)*.

(83) (84)

Oxazinones of type *(85)*[103] are favorable starting materials for the photochemical generation of the parent compound *(83)* ("azete") or its simply substituted derivatives. We[104] have examined the photochemical behavior of, *inter alia*, compound *(85)* and discovered that irradiation at −78 °C readily yields the bicyclic valence isomer *(86)*[69]. The starting compound *(85)* is regenerated on thawing to room temperature. If the bicyclic lactone is further irradiated at low temperature, elimination of CO_2 can be observed by IR spectroscopy. Since no acetonitrile is formed as cleavage product, it may be concluded that the aza derivative undergoes the desired photocleavage into azacyclobutadiene *(87)* and CO_2, in analogy to the cleavage of the Corey lactone *(78)*. Although structural elucidation of the photoproducts is not yet complete, available evidence would indicate that azacyclobutadienes are amenable to a variety of stabilization reactions. Whereas

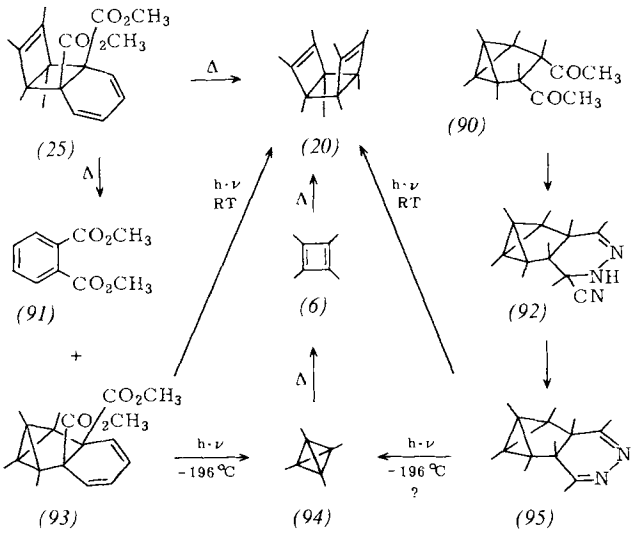
(85) (86) (87)

dimerization plays the dominant role in the carbocyclic systems, the situation is more complex in the aza series, possibly because of the high polarity of the C=N double bond.

12. Cyclobutadiene/Tetrahedrane Valence Isomerism

Only two possible structures are open to a compound having the composition $(CH)_4$ (four methine groups), *viz.* cyclobutadiene *(1)* and tetrahedrane *(88)*. Only photochemical transitions between these two valence isomers are "symmetry-allowed"[105]. The fact that thermal isomerization of tetrahedrane to cyclobutadiene is "symmetry-forbidden" provides a ray of hope that it might just be possible to produce a compound having the tetrahedrane structure. Thermodynamically the chances appear very remote: the energy content of tetrahedrane is calculated[106] to exceed that of cyclobutadiene by 70[106a] or 84 kcal/mol[106b]. Moreover, the alternative pathway, primary cleavage to the diradical *(89)*, is predicted to

(1) (88) (89)



be isothermal[106b]. In other words: this bond rupture must be accompanied by a barrier of more than 20 kcal/mol if tetrahedrane is to be identified as an intermediate trapped in a matrix.

Since theoretical predictions regarding both the energy content of tetrahedrane and the height of the energy barrier for conversion into *(89)* are contradictory[106, 107], only experiments can decide.

There has been no lack of attempts[108]. However, all claims to successful syntheses have so far failed to stand up to scrutiny. The most convincing studies are still those[109–111] in which evidence for the occurrence of a tetrahedrane intermediate is gleaned from the labeling pattern of acetylenes obtained as cleavage products.

It was our objective to gain an indication of whether tetramethyltetrahedrane *(94)* is capable of existence by photocleavage of the bicyclobutane derivatives *(93)* and *(95)*, whose cyclobutene analogs *(25)* and *(17)*, respectively, yield tetramethylcyclobutadiene almost quantitatively on irradiation (Section5). Starting from the diacetyl compound *(90)*[112], the heterocycle *(95)* can be obtained *via* the hydrocyanic acid adduct *(92)*[113]. The second photoprecursor *(93)* results[114] on pyrolysis of the tricyclic compound *(25)*. Unfortunately, the yield of *(93)*

is very low (≈ 1 %). The major products of thermal cleavage are the dimer *(20)* of tetramethylcyclobutadiene and dimethyl phthalate *(91)*, as for photofragmentation.

What can be said about the photochemical behavior of the two potential tetrahedrane precursors *(93)* and *(95)*? Room-temperature irradiation of the heterocycle *(95)* affords[113] a complex product mixture. Apart from octamethylcyclooctatetraene *(18)* and its photoproducts[33], a small amount of the dimer *(20)* can be detected. This finding might be construed as indicating that the reaction does indeed follow the pathway *(95)* → *(94)* → *(6)* → *(20)* to a certain extent.

The results obtained on irradiation of the diester *(93)* are even more exciting[113]. As in the case of the cyclobutene isomer *(25)*, room-temperature irradiation furnishes dimethyl phthalate *(91)* and the dimer *(20)* of tetramethylcyclobutadiene *(6)* almost quantitatively. This observation could indicate that *(93)* initially regenerates *(25)* which then yields the isolated products. Such a conclusion is discounted on the one hand by the failure to detect *(25)* as an intermediate on following irradiation of *(93)*. On the other hand, this possibility is ruled out by the results of matrix irradiation. After irradiation of *(93)* at −196 °C and subsequent warming to room temperature, *(91)* and *(20)* are again the sole products. If *(93)* were to undergo isomerization to the tricycle *(25)* in the initial reaction step, then the maximum corresponding to the charge-transfer complex *(27)* would appear in the low-temperature UV spectrum as discussed in Section 5. However, no such absorption band can be detected.

Thus, in our opinion, it is not tetramethylcyclobutadiene *(6)* which is trapped in the matrix but another species that is readily transformed into *(6)*. It is very tempting to regard this intermediate as tetramethyltetrahedrane *(94)*. If this were the case, then it follows that the tetrahedrane derivative *(94)* is stable in a matrix at −196 °C and undergoes valence isomerization to *(6)* only on thawing to a temperature range in which the matrix is already soft enough to permit dimerization. Since the intermediacy of tetramethylcyclobutadiene *(6)* cannot be detected by spectroscopy, the rate at which the dimer *(20)* is formed must exceed that of valence isomerization *(94)* → *(6)*.

To date we have been unable to decide whether the species frozen into the matrix really is tetramethyltetrahedrane *(94)* or possibly the corresponding bicyclobutanediyl diradical. In any case, we regard the above results as a challenge to defy the theorists' rather gloomy predictions and to persevere in our attempts to solve the tetrahedrane problem too.

13. Summary

What is the current state of our knowledge, *i.e.*, what answers can be given to the questions posed in Section 3?

1) Suitable methods exist for the photochemical generation of cyclobutadiene and its simply substituted derivatives at low temperatures. On irradiation of cyclobutenedicarboxylic anhydrides, cyclopentadienones are formed as coproducts. Heterocyclobutadienes, *e.g.* azacyclobutadiene *(87)*, also appear to be accessible by photofragmentation of suitable precursors.

2) Cyclobutadienes can be obtained as monomers by use of the matrix isolation technique.

3) Evidence exists that cyclobutadienes, and especially higher substituted derivatives, possess a singlet ground state. Thus we have so far been unable to observe the signals expected for a triplet in the ESR spectrum of both the parent system and tetramethylcyclobutadiene. However, this "negative" finding should not be given too much weight. The following chemical argument is perhaps more convincing: Dimerization of cyclobutadienes could, in principle, yield not only *syn* dimers of type *(76)* but also the *anti*-configurated isomers. These stabilization reactions are always strictly stereospecific, however. After thawing of the matrix only one tricycle is found in each case. It may be concluded from the proven *syn* configuration of *(42)*[115] and *(76)*[76] that the other dimers possess an analogous stereochemistry. Assuming that this stereospecificity can only be expected of singlet molecules (*endo* rule of the Diels-Alder reaction), then this finding would also contraindicate a triplet ground state. Nevertheless, it should be mentioned that neither experimental proof nor theoretical explanation can yet be offered. Nobody knows whether a triplet cyclobutadiene might not also be able to form the *syn* adducts in a stereospecific manner. Finally, the photoelectron spectra also point to singlet ground states[73].

4) The IR spectra recorded for unsubstituted cyclobutadiene[13,86-88] are compatible only with a square arrangement. A rectangular geometry or distortions of the kind shown in Figure 2 would lead to a greater number of bands.

5) Cyclobutadienes are characterized by typical UV spectra. Unsubstituted cyclobutadiene and its monosubstituted derivatives display a band at 300—305 nm. In contrast, higher substituted derivatives appear to possess no band above 300 nm. "Free" tetramethylcyclobutadiene displays only a gradual increase from 300 nm towards shorter wavelengths. Tetramethylcyclobutadiene shows an exceptionally pronounced tendency to form charge-transfer complexes with suitable acceptors. Relevant information is available concerning the ionization energies of cyclobutadiene[116] and some of its derivatives[73,117,118]. The good donor properties of tetramethylcyclobutadiene accordingly become understandable.

6) Cyclobutadienes are extremely reactive compounds. Even tri-*tert*-butylcyclobutadiene undergoes relatively rapid trans-

formation into its dimer, even though molecular models indicate considerable steric hindrance in the transition state. Apart from dimerization, autoxidation also appears to be a typical stabilization reaction.

7) Studies on di-*tert*-butyl[36, 60] and diphenylcyclobutadiene[52] provide some evidence for the existence of a valence-isomeric equilibrium. The results available suggest that the energy barrier is not higher than about 8 kcal/mol[12].

8) As required by theory, tetrahedrane is probably even more unstable than its valence isomer. Preliminary studies suggest that tetramethyltetrahedrane is capable of existence when frozen into a matrix, but is transformed extremely readily into tetramethylcyclobutadiene.

9) Quantitative experimental determination of the antiaromatic destabilization of cyclobutadiene has been attempted[15]. It is reported to lie in the range of 12—16 kcal/mol. The extremely high reactivity of cyclobutadienes, exceeding that of cyclopentadienones, for which diffusion-controlled rate constants are discussed, likewise reflects their high energy content. Of course, this argument only applies when the energy of the transition state is not increased to the same extent. However, calculations[12] show that its transition state is considerably less destabilized than cyclobutadiene itself. Reliable information about the π-orbital energies is available from photoelectron spectra. While the ionization potential is estimated as 8.50 eV[25, 116] in unsubstituted cyclobutadiene *(1)*, it amounts to 6.89 eV[73] in the case of *(68)*, and, surprisingly, tri-*tert*-butylcyclobutadiene *(57)* shows a similarly low value of 6.80 eV[117] although it bears only three alkyl substituents.

All these data refer to electroneutral cyclobutadiene. It may be expected that at least the dication[119] or the dianion of cyclobutadiene, the "aromatic" pendants, so to speak, would be more readily preparable than the "antiaromatic" *(1)*. The dications of tetramethylcyclobutadiene[120] and tetraphenylcyclobutadiene[121] have in fact been prepared by *Olah*, and convincing evidence for the existence of cyclobutadiene dianion has been reported by *Pettit*[122].

14. Future Tasks

Questions still remain to be answered. To name but a few: Why does cyclobutadiene react as a singlet molecule although IR spectra prove it to have a square structure, *i.e.* precisely that geometry which theory requires for a triplet ground state? Why do the UV spectra differ from those of more highly substituted derivatives? Is this a consequence of a change in multiplicity depending on the number of substituents? Is it permissible to postulate that the former have a triplet ground state and the latter a singlet ground state on the basis of a comparison with calculated spectra? How can tetramethylcyclobutadiene react as a singlet molecule when generated photochemically at low temperatures, while the same molecule appears to display triplet character at very high temperature[123]?

What kind of barrier determines a valence isomerism of the type *(57a)*$\rightleftharpoons$*(57b)*? What interrelationships describe the cyclobutadiene/tetrahedrane system?

This list could be continued. The points mentioned underline the importance of following the fragmentation of available precursors in noble gas matrices by UV, IR, Raman, and ESR spectroscopy. Correlation of the results obtained should provide unequivocal information. Relevant studies are in progress[124].

Furthermore, gas-phase thermal cleavages of suitable starting materials are necessary in order to determine whether the multiplicity in the ground state changes as a function of temperature. The adducts *(21)*, *(22)*, and *(25)*, which undergo both photochemical and thermal cleavage[41, 114] as already mentioned in Section 12, represent suitable model substances. Fragmentation to tetramethylcyclobutadiene and the corresponding aromatic coproducts already begins at 50 °C. This means that all the prerequisites are now fulfilled for answering the remaining open questions in the near future.

I am indebted to my co-workers Dr. U. Mende, Dr. G. Fritschi, Dr. M. Schneider, Dr. F. Bosslet, Dr. B. Hoppe, Dipl.-Chem. A. Alzérreca, Dipl.-Chem. W. Mayer, Miss G. Kreiling, Dipl.-Chem. U. Schäfer, and Dipl.-Chem. C. Haacke whose willing and skillful efforts culminated in numerous results reported in this article. Financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Equilibrium and Transport Properties of Low-Melting Salts

By Joachim Richter[*]

An understanding of the physical and chemical phenomena and the structure of salt melts calls not only for kinetic and spectroscopic data but also for systematic studies on the equilibrium and transport properties of individual systems. The present article deals with the activity coefficients, transport numbers, and self-diffusion and interdiffusion coefficients of salt melts, and the results of consistent measurements of these quantities are reported.

1. Introduction

The term salt melts (or more generally electrolyte melts) is applied to inorganic salts (or electrolytes) that dissociate into their ionic constituents in the molten state. A distinction is made between pure molten salts that consist of only one component, *e.g.* $NaNO_3$, and salt melts that consist of two or more components, *e.g.* $NaNO_3+Ca(NO_3)_2$.

Nitrate melts are among the most thoroughly investigated low-melting salt melts. The general discussions below are illustrated by results for the systems $NaNO_3+AgNO_3$ and $LiNO_3+AgNO_3$.

Interest in salt melts has increased rapidly in recent years for two reasons:

The first reason is the increasingly rapid development of a wide range of practical applications for salt melts, *e.g.* in reactor construction, in the remelting of electrolyte slags and other applications in metallurgy, and as effective, very fluid heat exchangers at high temperatures, in the electrolytic isolation of metals or in fuel cells; moreover, increasing numbers of chemical reactions can be carried out with high rates and in high yields in salt melts, and so on.

The second reason for the growing interests in salt melts is the great importance that they have attained in fundamental research. The study of the thermodynamic, kinetic, and spectroscopic properties of these liquids is improving our understanding of the physical and chemical phenomena and of the structure of melts. Though the matter is still under discussion, there is good reason to hope that the structure of salt melts will be easier to understand than that of systems such as $NaNO_3$ in water, *i.e.* systems with a neutral solvent, which

[*] Prof. Dr. J. Richter
Lehrstuhl für Physikalische Chemie II der Technischen Hochschule
51 Aachen, Templergraben 59 (Germany)

have much more complicated structures. Fundamental research is being carried out at present in an effort to clarify the structure of salt melts; this necessitates systematic studies on the equilibrium properties and transport phenomena of individual systems.

The modern literature on salt melts dates back to about 1960 (see *e.g.* the monographs[1-5,8], the book of tables[6], and the data collection[7]). The latest findings and results are presented in the series "Advances in Molten Salt Chemistry", the first volume[9] of which appeared in 1971, the second[9] in 1973. The transport properties of salt melts in particular have formed the subject of recent reviews[10,11]. The literature is rounded off by a number of general surveys[12-15].

2. Activity Coefficients

For the thermodynamic description of salt melts, one requires a clear definition of the activity coefficients of all the components present in a system. Proposals have been made by *Temkin*[16], *Forland*[17], and *Flory*[18], but these are not very suitable for a general description because of the models on which they are based. *Haase*[19,20] introduced the general concept of an "ideal electrolyte melt", and defined suitable activity coefficients in *binary* electrolyte melts by means of the equation

$$\ln f_i \equiv \psi_j - \psi_j^{id} \qquad (1)$$

The activity coefficient f_j of the component j is dimensionless, and depends, as usual, on the temperature T, the pressure P, and the composition. ψ_j is an abbreviation for

$$\psi_j \equiv (\mu_j - \mu_{oj})/RT$$

μ_j is the chemical potential of the component j in the mixture, μ_{oj} is the chemical potential of the pure liquid component j, and R is the gas constant. ψ_j^{id} is the corresponding expression for the standardized ideal melt. The standardized ideal mixture is defined by the condition that the melt is completely dissociated, contains no complex ions, and the expression $\psi_i = \ln x_i$ (x_i: true mole fraction of the ionic species i) is valid for every ionic species i. The reference melt can thus be described by measurable quantities such as the stoichiometric mole fractions.

These new activity coefficients have the advantage that they allow the description of the thermodynamic behavior even of complicated melts, *i.e.* melts in which the constituents have different valencies. The logarithms of these activity coefficients can be represented by power series in the mole fraction with *whole-number* exponents, which satisfy the general principles of thermodynamics. The limiting laws for the freezing point depression and for the vapor pressure of salt melts can thus be given in a simple form[21]. Moreover, for a large number of binary systems, the activity coefficients for the two components of these systems (the parameters of their series expansion) can be calculated from the known analytical expression for the additional molar free enthalpy $\bar{G}^E$[22]. The additional functions of the molar free enthalpy, the molar entropy, and the molar enthalpy can also be derived from these series.

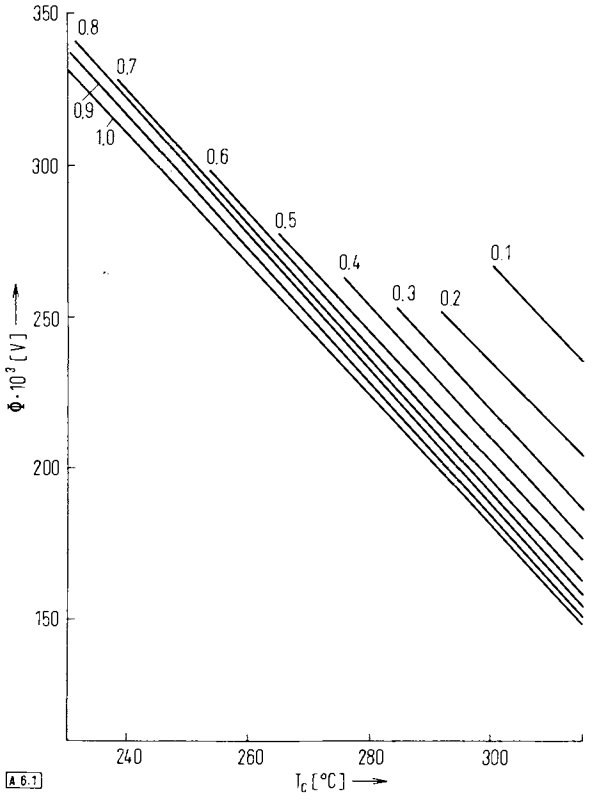

Fig. 1. Emf (Φ) as a function of the temperature T_c for the system $NaNO_3 + AgNO_3$ with the mole fraction x_2 of silver nitrate as the parameter (numbers by the straight lines).

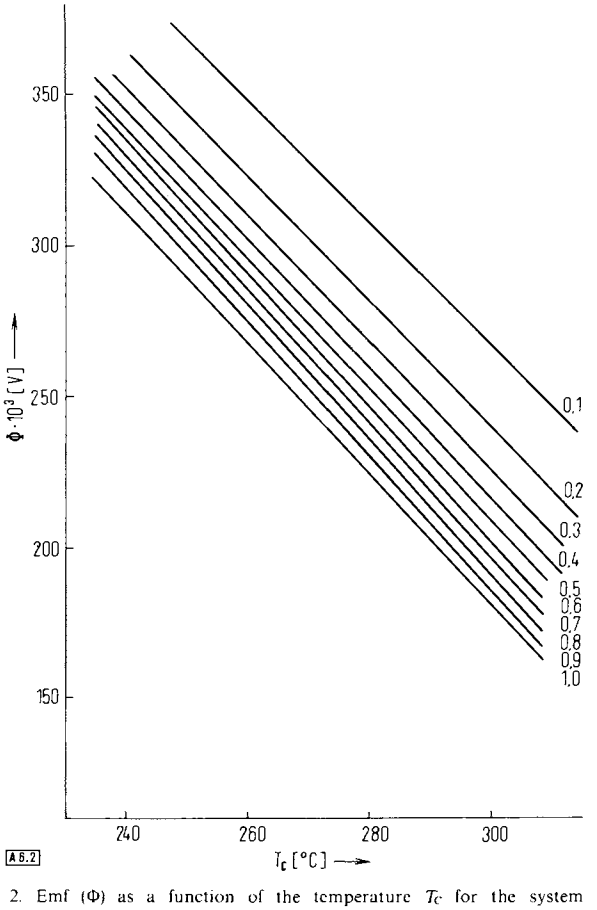

Fig. 2. Emf (Φ) as a function of the temperature T_c for the system $LiNO_3 + AgNO_3$ with the mole fraction x_2 of silver nitrate as the parameter (numbers by the straight lines).

Ketelaar and *Vos*[23] have compared the four definitions of the ideal mixture given by *Temkin*, *Forland*, *Flory*, and *Haase*, and pointed out the differences in the models.

Sehm[24] has recently determined the activity coefficients for the systems $NaNO_3+AgNO_3$ and $LiNO_3+AgNO_3$ in the temperature range 240 to 310 °C over the entire concentration range, as far as the phase diagram allows, by emf measurements on a chemical cell. A nitrate electrode of a form similar to that developed by *Ketelaar* and *Dammers-deKlerk*[25, 26] was used. The measured emf (Φ) is shown as a function of temperature, with the mole fraction of silver nitrate as the parameter, in Figure 1 for the system $NaNO_3+AgNO_3$ and in Figure 2 for the system $LiNO_3+AgNO_3$. Figure 3 shows the activity coefficients calculated from these results for the two systems at fixed temperatures. The interdiffusion coefficients were determined at these temperatures (see Section 5.2 and Fig. 7).

Because of the linear dependence of the emf on the temperature, six constants that are characteristic of the salt melts investigated, and that do not depend either on the composition or on the temperature, can be determined from the analytic presentation of the activity coefficients[27].

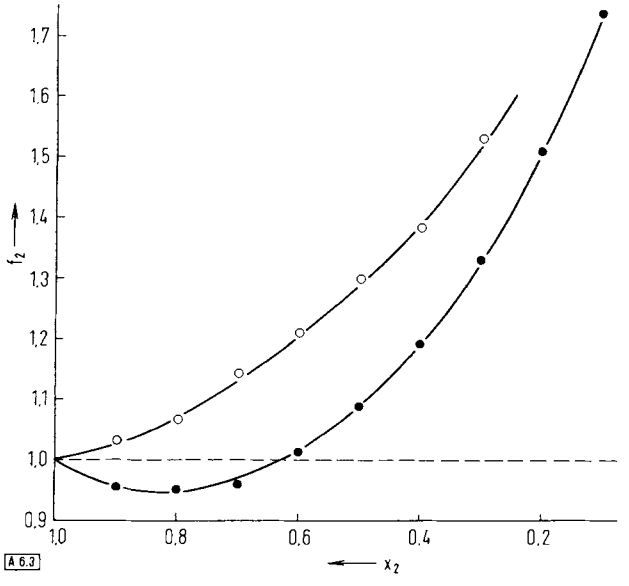

Fig. 3. Activity coefficients f_2 as a function of the mole fraction x_2 of silver nitrate for the system $NaNO_3+AgNO_3$ at 290 °C (o – – o) and for the system $LiNO_3+AgNO_3$ at 260 °C (● — ●).

On the basis of the definition (1), it is possible to derive an expression that enables the activity coefficients of *any* salt melt, regardless of its composition, to be given explicitly. The emf (Φ) of a chemical (isothermally-isobarically reversible) cell obeys the following relation:

$$\ln f_k = \frac{F(\Phi-\Phi_0)}{qRT} - \psi_k^{id} \qquad (2)$$

F is the Faraday constant and Φ_0 is the emf of the cell with the pure component k, for whose ions the electrodes of the cell are reversible. q is the factor that precedes the chemical potential of the component k in the expression for the affinity of the heterogeneous reaction corresponding to k.

The function ψ_j^{id} can now be determined in succession for the individual systems (two components with or without a common ion, *e.g.* $NaNO_3+AgNO_3$ or $NaCl+KBr$, three components with one or two common ions or without a common ion, *e.g.* $NaNO_3+KNO_3+Ca(NO_3)_2$, $NaCl+KCl+KBr$, or $AgCl+TlNO_3+KBr$, *etc.*), and the following rather more complicated expression[28] is found for the general formulation:

$$\psi_j^{id} = \ln \frac{\nu_j^{\nu_j}\prod_{j\alpha}\left[x_j + \sum_{l=1}^{p}(\nu_{l\alpha}/\nu_{j\alpha})x_l\right]^{\nu_{j\alpha}}}{\left(\sum_{i=1}^{n}\nu_i x_i\right)^{\nu_j}} \qquad (3)$$

ν_j is the sum of the dissociation numbers for the component j, x_j is the mole fraction, $\nu_{j\alpha}$ is the dissociation number of the ion α in the component j, and l indicates the components that have an ion in common with the component j. The product in eq. (3) is accordingly taken over the ions of the component j, the summation in l over all p components that have an ion in common with j, and the summation in i over all n components present.

This complicated expression (3) becomes very simple for most of the systems investigated, and together with eq. (2), it allows the determination of activity coefficients from emf measurements for any salt melt, regardless of its composition.

For very simple systems (in which all the components have the same dissociation number and contain a common ion, *e.g.* $KNO_3+AgNO_3+NaNO_3$), this agrees with the usual literature definition, which was taken over from solutions of low molecular weight non-electrolytes:

$$\ln a_j = \ln x_j + \ln \gamma_j$$

In this expression, a_j is the activity and γ_j is the activity coefficient of the component j. The definitions differ in all other cases. The new definition [eqs. (1)—(3)] has the advantage that the logarithm of the activity coefficient for *all* systems can be expanded in series, which are of fundamental importance to all the limiting laws of the salt melts considered.

3. Transport Numbers

The transport numbers are generally determined by three methods, *i.e.* the Hittorf method, the moving boundary method, and emf measurements on concentration cells with transport. The Hittorf method was used for salts melts *e.g.* by *Kawamura* and *Okada*[29], who, like *Duke et al.*[30], used the formula of *Aziz* and *Wetmore*[31] for the evaluation. The question of the external and internal transport numbers (reference systems) and their relation to one another has not yet been clarified here; this problem is being examined at present by *Haase*[32]. The moving boundary method is applied to salt melts only in isolated cases[33], since it is extremely difficult to investigate systems of this type by optical methods. We determined the transport numbers of the systems $NaNO_3+AgNO_3$ and $LiNO_3+AgNO_3$ with the aid of a concentration cell[34].

The concentration cell with transport can be represented for such a system by the following scheme:

$$Cu|Ag|NaNO_3 + AgNO_3(x_I)||NaNO_3 + AgNO_3(x_{II})|Ag|Cu$$

The terminals of the cell, which connect the silver electrodes (Ag) to the measuring instruments, consists of copper. The double line symbolizes the direct liquid contact between the two melts with different concentrations (x_I = mole fraction of silver nitrate in the left half-cell, x_{II} = mole fraction of silver nitrate in the right half-cell). From the emf measured as a function of temperature and composition, the internal transport numbers t_{NA} and t_{Ag} (t_{NO_3} is zero, since the common nitrate ions are reference particles in the sense of the Hittorf reference system) are determined from the following formula[35]:

$$F\Phi = RT\int_{x_I}^{x_{II}} \frac{1}{1-x_2} t_a \, d\ln(x_2/f_2) \qquad (4)$$

x_2 is the mole fraction and f_2 is the activity coefficient of silver nitrate; $t_a = t_{Na}$ or t_{Li}; $t_a + t_{Ag} = 1$. Eq. (4) is evaluated graphically with the aid of the activity coefficients determined by *Sehm*[24] (for further details see[36]). The concentration range in which measurements are possible is $0.7 \leqslant x_2 \leqslant 1.0$ at 240 °C to $0.1 \leqslant x_2 \leqslant 1.0$ at 300 °C for the system $NaNO_3 + AgNO_3$, and $0.1 \leqslant x_2 \leqslant 1.0$ in the same temperature range for the system $LiNO_3 + AgNO_3$. The transport numbers of the systems $NaNO_3 + AgNO_3$ (Fig. 4) and $LiNO_3 + AgNO_3$ (Fig. 5) are shown as examples at the same temperatures as for the activity coefficients (Fig. 3).

Our values are compared in Figure 4 with data found by *Duke et al.*[30] with a Hittorf apparatus. The temperature control was improved in the emf measurements; an analysis *after* the experiment is unnecessary, and the emf apparatus, unlike the Hittorf apparatus used by *Duke et al.*, contains no membrane. The deviation of the transport numbers from the previously found linearity with respect to the mole fraction thus seems to be verified.

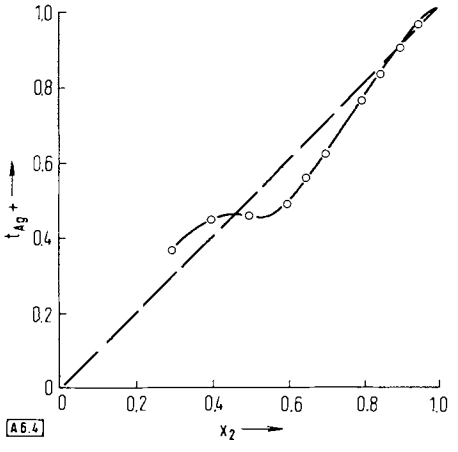

Fig. 4. Transport numbers t_{Ag^+} of the silver ions as a function of the mole fraction x_2 of silver nitrate for the system $NaNO_3 + AgNO_3$. (---): at 305 ± 5 °C (after [30]); (o ··· o): at 290 ± 1 °C.

Figure 5 shows a comparison of the transport numbers for the system $LiNO_3 + AgNO_3$ with the results of Hittorf measurements by *Kawamura* and *Okada*[29], for which the above remark is valid.

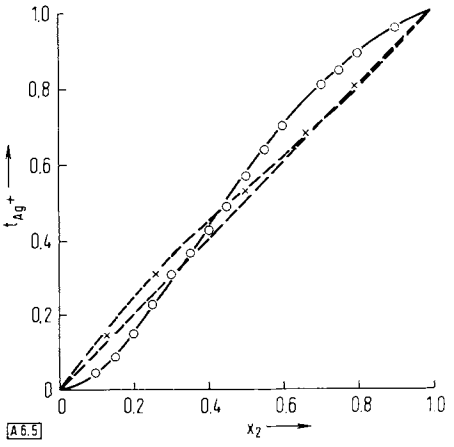

Fig. 5. Transport numbers t_{Ag^+} of the silver ions as a function of the mole fraction x_2 of silver nitrate for the system $LiNO_3 + AgNO_3$. (× ··· ×): at 300 °C (after [29]); (o ··· o): at 260 °C.

From these transport numbers, together with the known densities and electric conductivities of the systems, it is possible to calculate the ion mobilities, equivalent conductivity, and ionic conductivities, as well as their limiting values and values for the ideal melt, as suggested in the papers by *Timmermann* and *Richter*[37] and by *Amkreutz*[36] and calculated for the systems discussed here.

4. Self-Diffusion

4.1. General and Definitions

Investigations on salt melts have so far been confined to the phenomenon of self-diffusion, apart from the few exceptions of interdiffusion (see Section 5). The starting assumption is that the simplest relations between the mobilities and radii of the ions and the structure of the melt are to be expected in self-diffusion, *i.e.* "in the limiting case in which the difference between two diffusing substances in a binary mixture disappears[38]" (the exact definition of self-diffusion is given below), since the measurements are carried out in very simple systems (usually one-component systems) with few assumptions. Moreover, self-diffusion experiments are easier and much faster to carry out than interdiffusion experiments (see Section 5).

The term diffusion is used in general for any mass transport in a mixture that is caused by a concentration gradient. The collective term self-diffusion in particular, which we shall have to differentiate below, is applied to the transport of a labeled ionic species in relation to the same unlabeled ionic species in a salt or in a salt mixture at a concentration gradient close to zero for the labeled particles.

For the definition of self-diffusion, it is necessary to clarify three terms that have been adopted in the literature, *i.e.* tracer diffusion, intradiffusion, and self-diffusion.

Let us first consider a melt that consists of one component, *i.e.* of two ionic constituents, *e.g.* molten sodium chloride with the component NaCl and the two ionic constituents Na and Cl. If we replace some of the Na^+ ions by labeled Na^{+*} ions (experimentally by addition of a radioactive isotope), we have a system for which all three phenomena can be defined.

The diffusion flow density, *i.e.* the quantity of substance passing through a reference surface per unit area and per unit

time, can be defined in any desired reference system. For experimental purposes, we observe the transport of the labeled constituent in relation to the unlabeled constituent. The movements are therefore coupled by the experimental conditions. However, we determine the mean velocity of the ionic constituent with respect to the chosen reference velocity. For simplicity, we consider the one-dimensional case of diffusion (position coordinate z) in the Fick reference system.

In *tracer diffusion*, the reference velocity for the diffusion flow density ${}_w\vec{J}_j^*$ of the labeled ionic component j* (with molarity c_j^*) in the Fick reference system, *i.e.* the mean volume velocity $\vec{w}$, is given by:

$${}_w\vec{J}_j^* = c_j^*(\vec{v}_j^* - \vec{w}) \tag{5}$$

$\vec{v}_j^*$ is the mean velocity of the labeled ionic constituent j*.

Experience shows that each independent diffusion flow is a homogeneous linear function of all the independent concentration gradients if extremely high gradients are ruled out[39]. For the salt melt considered here, it follows that the diffusion flow density defined in eq. (5) is:

$${}_w\vec{J}_j^* = -D_j^* \frac{\partial c_j^*}{\partial z} \tag{6}$$

The tracer diffusion coefficient D_j^* is defined by eq. (6). The operator $\partial/\partial z$ means differentiation with respect to the position coordinate z for a fixed time. The temperature and pressure are the same for all positions (other transport phenomena, such as thermal diffusion, would otherwise occur). Tracer diffusion is thus the diffusion of the labeled ionic constituents in relation to the Fick (or any other chosen) reference system. The tracer diffusion is measured with radioactive isotopes that differ in their physical and chemical behavior from the unlabeled ionic constituents.

If one stipulates that the differences between the chemical properties of the labeled and the unlabeled ionic constituents are negligible, the tracer diffusion will be identical with the *intradiffusion* postulated by *Albright* and *Mills*[40]. These authors introduced the concept of intradiffusion because of the difference between and the ambiguity of the terms tracer diffusion and self-diffusion. However, since intradiffusion cannot be brought about experimentally in the strict sense of its definition, the additional concept of intradiffusion, in my opinion, leads to further confusion. The intradiffusion coefficient is numerically equal to the tracer diffusion coefficient if the differences between the chemical properties of the labeled and of the unlabeled ions disappear.

In tracer diffusion, the concentration of the labeled ions is very low. The labeled ions do not interact directly with one another, or, as formulated by *Bearman*[41], the labeled ions move in an essentially homogeneous environment. The tracer diffusion coefficient nevertheless depends on the concentration of the labeled ions. The hypothetical intradiffusion coefficient, because of the chemical identity of the two ionic species, is independent of the ratio between the concentrations of the labeled and the unlabeled ions, and depends only on the total concentration of the ionic constituent observed.

The *self-diffusion coefficient* D_{ii} of the ionic component i (the same as j, but unlabeled) will be taken here as the limiting value of the tracer diffusion coefficient for a vanishingly small concentration of the labeled ionic constituent j*:

$$D_{ii} \equiv \lim_{c_j^* \to 0} D_j^* = D_{jj} \tag{7}$$

This is found experimentally by measurement of D_j^* as a function of c_j^* and extrapolation to $c_j^* \to 0$. This is the same as saying that the difference in the chemical *and* physical properties disappears.

We can see that self-diffusion does *not* become identical with intradiffusion, since intradiffusion allows differences in the physical properties, *i.e.* in particular in the masses of the isotopes. Analogous isotope effects in the mobilities were carefully investigated by *Lundén* and *Ljubimov*[42] for the system $Li_2SO_4 + K_2SO_4$. These authors defined a mass effect (relative difference in mobility divided by the difference between the masses of the isotopes) and determined its dependence on the composition. It was found that the isotope effects cannot be disregarded.

In the remainder of this discussion, therefore, we shall consider only tracer diffusion and self-diffusion as its limiting value in the sense defined above.

Tracer diffusion and self-diffusion are defined in the same way in aqueous electrolyte solutions and in non-electrolyte solutions[43]. In non-electrolyte solutions, the self-diffusion of the solute at infinite dilution must be physically identical with the interdiffusion (see Section 5). *Bearman*[41] showed that for simple systems of binary non-electrolyte solutions, the interdiffusion coefficient becomes equal to the self-diffusion coefficient at infinite dilution. We were able to show the same result for simple binary salt melts[44].

4.2. Experimental Methods for the Measurement of Self-Diffusion

The most suitable method for the determination of self-diffusion in salt melts is the capillary method, which is the method most commonly used in the investigations. The capillary method exists in two variants. In one case (method 1), a capillary closed at one end and filled with labeled ions is introduced into a bath containing unlabeled salt; in the second variant (method 2), the capillary contains the unlabeled salt, while the bath contains the labeled ions. Method 1 (diffusion out of a capillary) was introduced by *Dworkin et al.*[45] for salt melts; method 2 (diffusion into a capillary) was devised by *Bockris* and *Hooper*[46].

Instead of the capillary, a sintered plate with fine pores may be impregnated with labeled ions and introduced into a bath containing unlabeled salt (method 3). This method (porous frit technique) was devised by *Djordjevic* and *Hills*[47] for salt melts, and developed further by *Sjöblom*[48].

There have been a number of experiments in which a layer of labeled salt was applied over unlabeled salt in a capillary; unlike in methods 1 and 2, therefore, the boundary is situated inside the capillary (method 4). This method, which was introduced by *Angell* and *Bockris*[49] and further developed by *Wallin*[50], is now no longer used.

Finally, *Ketelaar* and *Honig*[51,52] developed the paper electrophoresis method (method 5), in which glass-fiber paper is

Table 1. Self-diffusion coefficients D_{Na^+} in $NaNO_3$ (molten) at 350 C. For methods 1, 2, 3, and 5 see text.

Method	$D_{Na^+} \cdot 10^9$ [$m^2 s^{-1}$]	Ref.
1	2.33 ± 0.04	[45]
1	2.27 ± 0.07	[55]
1	2.27 ± 0.07	[56]
2	2.10 ± 0.09	[57]
2	2.13 ± 0.05	[58]
3	2.44 ± 0.1	[47]
5	2.49 ± 0.1	[52]

impregnated with the salt melt and supported on a glass plate. The tracer diffusion coefficients are then calculated from the Gaussian distribution obtained after a certain time as a result of the diffusion of the radioactive isotopes. In an improvement of this method introduced by *Ketelaar* and *Kwak*[53] in 1967, the glass fiber paper is replaced by quartz glass fibers, and an Al_2O_3 substrate is used as the support. This avoids the exchange of the Na^+ ions in the $NaNO_3$ melt under investigation with the ions in the glass.

As a comparison of the five methods, Table 1 shows the self-diffusion coefficients of Na^+ in $NaNO_3$ at 350 °C as found by seven groups of authors[54]. Method 4 is unsuitable for nitrate melts, and does not therefore appear in Table 1. As has also been observed in measurements on other systems, method 2 gives slightly lower values, and methods 3 and 5 slightly higher values, than method 1. We shall not consider the errors of the individual methods in detail, but merely note that the capillary method has been found to be the best for salt melts.

Another suitable method for the experimental study of self-diffusion is NMR spectroscopy, whose application to salt melts is still in its early stages because of experimental difficulties.

The first investigation on self-diffusion in salt melts was published by *Klemm* and *Berne*[59] in 1953. The authors used the capillary method to investigate the diffusion of radioactive thallium ions in thallium chloride. Very many investigations of self-diffusion in salt melts and above all in metals and metal alloys have now been carried out. (See in particular Refs. [45, 53, 56, 60–64], which are concerned with the nitrate melts discussed here or with their components.)

The most reliable values for the self-diffusion coefficient D_{Na^+} of Na^+ in $NaNO_3$ appear to be those given by *Bockris* and *Nagarajan*[65], which are shown in Table 2 as a function of the temperature T_C.

Table 2. Self-diffusion coefficients D_{Na^+} of Na^+ in $NaNO_3$ as a function of the temperature T_C [65].

T_C [C]	$D_{Na^+} \cdot 10^9$ [$m^2 s^{-1}$]
350	2.14
370	2.38
390	2.61
420	3.04

5. Interdiffusion

5.1. Fundamental Principles

The transport process referred to in normal scientific usage as diffusion will be referred to here as interdiffusion, to distinguish it from self-diffusion. Whereas self-diffusion is investigated mainly in one-component systems, interdiffusion can only occur in systems containing two or more components. Self-diffusion in salt melts has been extensively studied both theoretically and experimentally; on the other hand, the development of experimental methods for the investigation of interdiffusion is still in its early stages.

The theoretical treatment of interdiffusion is particularly simple for salt melts in which two ionic constituents migrate independently of each other in relation to a third. In the following discussion we shall again consider the systems $NaNO_3 + AgNO_3$ and $LiNO_3 + AgNO_3$, which consist of three ionic constituents or of two components in the sense of the Gibbs phase rule with a common anion. In both systems, the cations of the component 1 (Na^+ or Li^+) and the cations of the component 2 (Ag^+) move in relation to the common anion (NO_3^-). This situation is illustrated schematically in Figure 6.

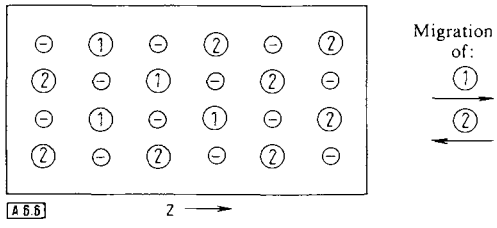

Fig. 6. Schematic representation of a salt melt consisting of two components with a common anion. z = position coordinate. ① denotes the cationic constituent of component 1, ② that of component 2, and ⊖ the common anionic constituent.

In the measurements, the movement of one cation is observed in relation to that of the other. The movements of the two types of cation are thus coupled by the experimental conditions; in this sense, they are not independent of each other. For this reason there is only one interdiffusion coefficient for each system.

This interdiffusion coefficient D can be defined by a generalization of the Fick law[66]:

$$ {}_{\omega}\vec{J}_n = - D \frac{1-\omega_n}{\bar{V}(1-x_n)} \operatorname{grad} x_n \qquad (n=1, 2) \tag{8} $$

${}_{\omega}\vec{J}_n$ is the diffusion flow density of the component n in an arbitrary reference system with the reference velocity $\vec{\omega}$, ω_n are the corresponding weight factors, and $\bar{V}$ is the molar volume of the melt. D is retained in this type of definition in every reference system. As we showed earlier[67], this is possible *only* for salt melts with three ionic constituents. [With this choice of definition, we no longer have the difficulty of converting D^V into D^M (D^V: diffusion coefficient in the Fick reference system, D^M: diffusion coefficient in the barycentric system) *etc.*, which is usually found in the literature.]

The only reference systems of any appreciable importance for diffusion in salt melts are the Fick system and the Hittorf system.

Fick's law[8] in the Fick reference system (index w) has the form:

$$ {}_{w}\vec{J}_2 = - D \frac{V_1}{\bar{V}^2} \operatorname{grad} x_2 \tag{9} $$

V_1 is the partial molar volume of component 1. The corresponding equation in the Hittorf reference system (index $-$), with the mean velocity of the common anionic constituent as the reference velocity, is[67]:

$$-\bar{J}_2 = -\frac{D}{\bar{V}} \frac{1}{x_1 + (\nu_{2-}/\nu_{1-})x_2} \operatorname{grad} x_2 \qquad (10)$$

ν_{1-} and ν_{2-} are the dissociation numbers of the anionic constituents of components 1 and 2.

Fick's second law or a relation corresponding to Fick's second law and following from Fick's first law in the form (9) or (10) is used in the majority of diffusion experiments.

5.2. Experimental Methods for the Measurement of Interdiffusion

Four methods have so far been developed for the investigation of interdiffusion in salt melts. However, all these methods embrace only a very small concentration range, so that they are only suitable for the investigation of the limiting values of the diffusion coefficients for $x_n \rightarrow 0$. *Sjöblom*[63,68] developed a gravimetric method, *Gustafsson et al.*[69,70] an optical method, *Laity* and *Miller*[71] a method that involves the use of a diaphragm cell, and *Thalmayer et al.*[72] a chronopotentiometric technique. *Sjöblom*[73] has now improved the gravimetric method so that measurements are possible over the entire concentration range.

We have modified the method involving the diaphragm cell in such a way that the interdiffusion coefficients of low-melting salt mixtures can be determined relatively accurately over the entire concentration range with the aid of a new evaluation procedure[74]. The results for the system $NaNO_3+AgNO_3$ at 290 °C and for the system $LiNO_3+AgNO_3$ at 260 °C are shown in Figure 7.

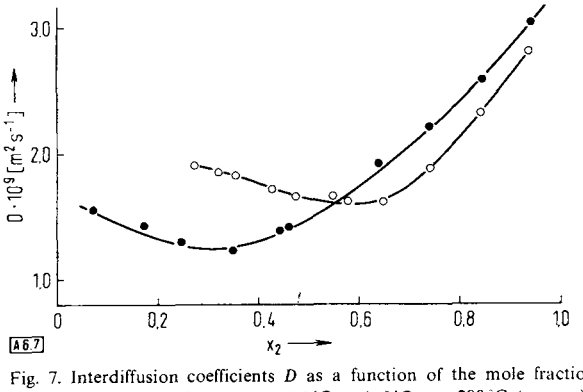

Fig. 7. Interdiffusion coefficients D as a function of the mole fraction x_2 of silver nitrate for the system $NaNO_3+AgNO_3$ at 290 °C (o — o) and for the system $LiNO_3+AgNO_3$ at 260 °C (• — •).

Though the measuring accuracy is relatively good in these investigations, optical methods will probably prove, after further development, to be the best methods for the investigation of diffusion in salt melts, owing to the greater fundamental accuracy of measurement.

6. Closing Remarks

For a deeper understanding of the physical and chemical phenomena and the structure of salt melts, spectroscopic and above all kinetic data are necessary in addition to knowledge of the thermodynamic properties. We confine ourselves here to the thermodynamic data, which include not only those discussed already but also *e.g.* the transport coefficients of the melts in centrifugal and gravity cells[75,76] and in thermopiles[35,77]. The latter are being determined at present in our laboratory for the systems examined here.

A possibility for the unified presentation of the data discussed here is offered by the formalism of the coefficients of friction, as formulated *e.g.* by *Klemm*[78]. This allows one first to calculate the interfriction coefficients, which are a measure of the interactions between different ionic constituents. From these interfriction coefficients, with a very simple assumption about the relationship between self-diffusion and interdiffusion[79], it is possible to calculate the self-friction coefficients, which are a measure of the interactions between similar ionic constituents.

For the binary nitrate melts examined here, therefore, we obtain a total of six friction coefficients for each system.

The transport processes investigated are largely determined by the structure of the salt melt. There are several models for the structure of simple salt melts, which proceed from the experimentally based requirement that a salt melt must contain cavities. The various approaches differ in the interpretation of the size, mode of formation, and distribution of these cavities in the melt, and lead to the quasi-lattice model, to the hole model, to the crystallite or polyhedral hole model, and to the free volume model as described by *Sundheim*[3] for salt melts. These models are rarely discussed nowadays, since they are not very specific and they give a sufficiently good description of the transport properties only with simplifying assumptions.

The models of *Temkin*[16], *Førland*[17], and *Flory*[18] and *Hasse*'s definition[19,20] are based on purely thermodynamic considerations, and formulate the reference melt idealized in some form (ideal behavior of the melt). By themselves, these do not provide evidence of the true structure of a salt melt.

An entirely new development is appearing at present as a result of model calculations using the computer simulation technique, which are yielding the first good results (cf. *e.g.* Ref.[80]).

Optical measurements are necessary in addition to transport and friction coefficients, since the existence of compounds or complexes in the melt cannot be conclusively demonstrated by thermodynamic measurements alone. When the investigations on the transport coefficients of thermal diffusion have been completed, we may obtain a more accurate picture of the structure of low-melting salts.

I am grateful to Prof. Dr. R. Haase for his generous encouragement of my own work in this field. Part of this work was supported by the Deutsche Forschungsgemeinschaft, to which we are also grateful.

Transition to Nonmetallic Behavior in Expanded Liquid and Gaseous Metals

By Friedrich Hensel[*]

At high temperatures and pressures, liquid and gaseous metals exhibit a steady transition from metallic to nonmetallic behavior when the density is sufficiently reduced. All the properties are influenced by this transition, as is shown by measurement (on mercury, cesium, and potassium) of the electric conductivity, the density, the thermoelectric power, and in some cases the Hall effect, as well as the optical absorption. The continuous variation of the density over a wide range is achieved by compression or expansion above the critical temperatures of the metals, *i. e.* 1490 °C for mercury, 1750 °C for cesium, and 1925 °C for potassium.

1. Introduction

In a series of liquid and solid solutions of metals in nonmetallic solvents, the solution exhibits a steady transition to metallic conductivity and metallic optical absorption with increasing metal concentration. Examples that have been known for a long time are solutions of alkali metals in liquid ammonia or amines[1-3], solutions of electropositive metals in their molten halides[4, 5], and highly doped solid semiconductors[6]. All these systems, in which the transition from nonmetallic to metallic behavior is brought about by the increasing proximity of the dissolved metal atoms as their concentration is increased, have the disadvantage that they are multicomponent systems. It is therefore necessary to take into account the influence of the solvent, *i. e.* the main component, in the theoretical and experimental study of the transition.

In recent years, metal-nonmetal transitions have also been studied in single-component systems consisting of compressed metal vapors[7-12]. However, a continuous increase in density to the desired degree is possible only if the compression is carried out above the critical temperature. The situation is therefore very similar to that in the solutions of metal in ammonia, in which the transition is also observed only at relatively high temperatures, *i. e.* above the critical temperature T_c of the miscibility gap. Below T_c, two liquid phases coexist, *i.e.* a blue nonmetallic phase and a bronze-colored metallic phase.

Figure 1 shows the equilibrium diagram found experimentally for liquid and gaseous mercury[8, 9, 13]. Here again, phase separation into a vapor having a low density and a relatively low electric conductivity and a liquid having a high density and a high, possibly metallic conductivity occurs below the critical temperature $T_c = 1490$ °C. This means that in the case of metals, the phase transition from the liquid to the vapor and the transition of the electronic structure from a metallic liquid to a non-conducting vapor must always be considered together. Special emphasis must be placed on the change in the type of chemical bonding that accompanies the phase transition. Whereas metallic bonding, *i. e.* interaction between ions surrounded by a polarizable degenerate electron gas, is present in the liquid, the forces between the atoms or molecules (*e. g.* K, K_2, Cs, Cs_2, or Hg) in the non-conducting vapor phase are of the "van der Waals" type.

[*] Prof. Dr. F. Hensel
Fachbereich Physikalische Chemie der Universität
355 Marburg, Biegenstrasse 12 (Germany)

Above the critical temperature T_c, the homogeneous supercritical phase can be continuously compressed to densities corresponding to those of liquids without phase separation, and the continuous transition from nonmetallic to metallic behavior can thus be achieved. However, as can be seen from the isobars in Figure 1, the unavoidable pressures are relatively high, with values of up to three times the critical pressure of 1510 bars.

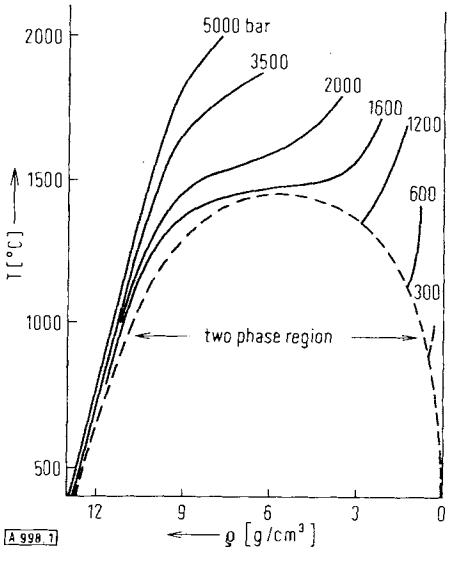

Fig. 1. Equation of state of liquid and gaseous mercury. The broken line shows the liquid-vapor coexistence curve (cf. [8, 9, 13]).

The extremely high temperatures and high pressures are also the reason why little attention was paid to the liquid-vapor phase behavior of metals, and especially to the critical points, until a few years ago, despite the fact that almost 80% of the elements in the periodic system are metals in the solid or liquid states at normal pressure. As can be seen from Table 1, the measured or estimated critical temperatures range from 1490 °C for mercury to 20000 °C for tungsten. The boiling points T_b and the ratios T_c/T_b are also given in the table for comparison. For most nonmetallic substances, such as inert gases or organic liquids, the above ratio is approximately 1.5. The metals deviate from this rule, with values of between 2.1 and 4. Since the critical pressures are also relatively high, the simultaneous use of high temperatures and pressures is always necessary for experiments close to the critical point. The first attempt to determine the critical point of mercury was made by *Bender*[14, 15] in 1915. The densities ρ_V and ρ_L

Table 1. Boiling point at 1 bar, critical temperature, and critical pressure for a number of metals.

Metal	Normal boiling point T_b [K]	Critical temperature T_c [K]	T_c/T_b	Critical pressure p_c [bar]	Ref.
Hg	630	1760	2.54	1510	[8, 9]

[a] Estimated.

of the vapor and of the liquid were measured in fused quartz capillaries under saturation pressure up to 1380 C. It was found that the arithmetic mean of the densities, $0.5\,(\rho_L+\rho_V)$, varies linearly with the temperature in the range covered by the measurements. On the assumption that the linearity is exhibited by all metals up to the critical point, *Grosse*[16, 17] estimated the critical temperatures of many metals from experimental data obtained at low temperatures for the liquid densities and vapor densities of these metals[18]. It was only through the development of a special experimental technique, favored by the rapid advances in the production of high-temperature materials during the past few years, that a number of experiments have been possible on the three metals having the lowest critical temperatures, *i.e.* mercury, cesium, and potassium. The fundamental thermodynamic properties density, vapor pressure, and critical data and the electronic properties electric conductivity, thermoelectric power, Hall effect, and optical absorption have been measured in some cases.

For these investigations, it was necessary to extend the measurements in particular to temperatures of up to 2300 °C and pressures of up to 5000 bars. It is important here to determine *e.g.* the conductivity, the density, or the optical absorption in measuring cells with accurately defined geometries. Materials found to be suitable for such cells are pure tungsten, molybdenum, niobium, the high-temperature alloy tungsten-rhenium, and (only for measurements on mercury) the sintered nonmetals aluminum oxide, thorium oxide, beryllium oxide, and, especially for optical measurements, corundum single crystals. These materials are resistant to the supercritical, compressed metals under investigation. However, cells of this kind cannot be constructed in such a way that they can still withstand a high internal pressure at temperatures of 2000 C. An arrangement was therefore used in which the measuring cells, together with the necessary resistance furnaces, are placed in larger autoclaves, which are filled with pure argon or helium under the same pressure as the fluid metal inside the measuring cell. This avoids any mechanical stress on the tungsten, molybdenum, niobium, or ceramic cells.

2. Investigations on Mercury

The metal that has been most intensively studied is mercury, whose critical temperature is within a range that is experimentally readily accessible. Figure 2 shows the DC electric conductivity (probably the most characteristic metallic property) found by various groups of workers[8, 9, 12, 13, 19, 20] as a function of the pressure for a number of subcritical and supercritical temperatures.

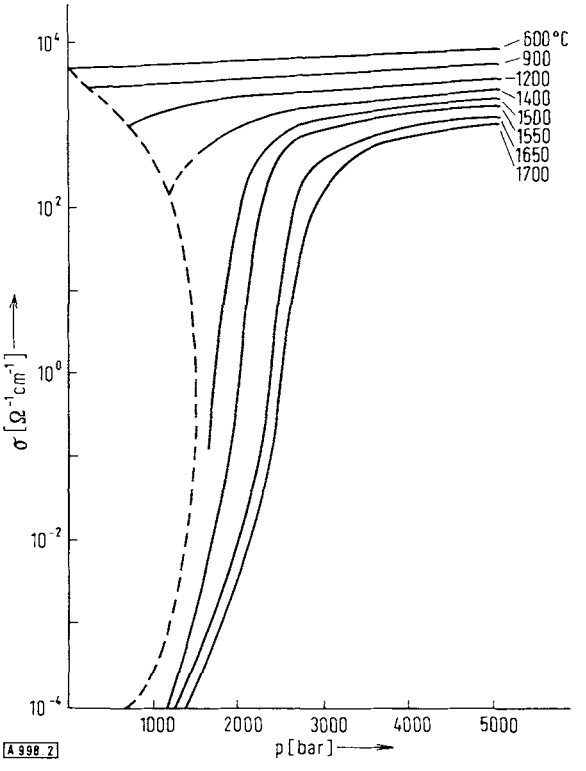

Fig. 2. Specific electric conductivity of mercury at subcritical and supercritical temperatures (in C) as a function of the pressure. The broken line shows the probable course of the conductivity of the coexisting liquid and gaseous phases (cf. [8, 9, 19]).

At subcritical temperatures in the liquid phase, the conductivity σ changes only very slightly with pressure. Thus a pressure increase of 1000 bars at 600 C increases σ by only 6%. A strong dependence on pressure is observed only at supercritical temperatures. A pressure increase of only 500 bars in the vicinity of the critical point can sometimes increase the conductivity by up to five orders of magnitude. This strong pressure dependence, which is also found for the metals cesium[10] and potassium[11], is undoubtedly due to the great decrease in the mean interatomic distance as the pressure is increased in this range. Slightly above the critical point of a pure substance, the compressibility is very high (cf. Fig. 1). An at least partly simple relation is therefore to be expected between the conductivily and the density. This is confirmed by Figure 3, which shows σ as a function of the mean interatomic distance, as measured by the cube root of the reciprocal

number density N[*] of the mercury atoms. The upper scale shows the density in grams per cubic centimeter for comparison.

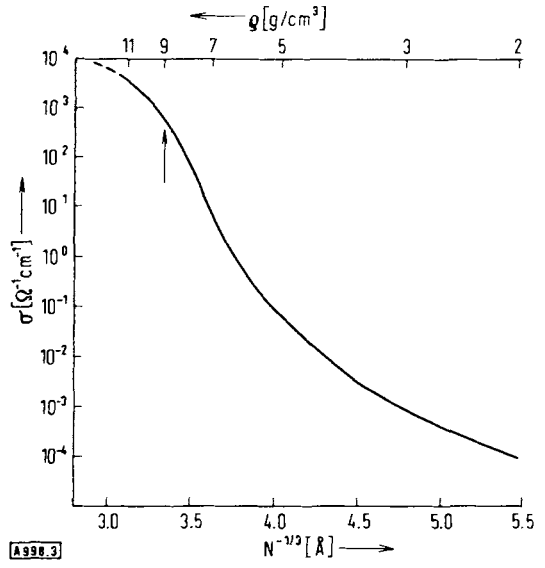

Fig. 3. Specific electric conductivity of mercury at a constant supercritical temperature of 1550 °C as a function of $N^{-1/3}$ (as a function of the density). N = number density of Hg atoms.

Between 3 and 5.5 Å, corresponding to a density change from 13.5 to 2 g/cm^3, the conductivity changes from approximately $10^{+4}\,\Omega^{-1}\,cm^{-1}$, a typical value for metals, to $10^{-4}\,\Omega^{-1}\,cm^{-1}$, a typical value for insulators at high temperatures (*e.g.* quartz: $\approx 10^{-5}\,\Omega^{-1}\,cm^{-1}$ at 1200 °C). This transition from a metallic to a nonmetallic state can best be explained on the basis of the band model[21], which has been known in solid-state chemistry and physics for more than 40 years. The clearest model is the "tight binding approximation"[22], in which a metal is regarded as a collection of atoms that are brought together from an infinite distance apart. Regardless of the arrangement of the atoms, this model fundamentally always leads to the following picture. If the atoms are brought close together by an increase in density, the Coulomb interaction between the atomic cores and the overlapping parts of the atomic orbitals leads to splitting of the energy levels of the entire system and hence to splitting of the levels into energy bands. The energy bands, whose widths depend mainly on overlap of atomic orbitals of nearest neighbors, and hence on the interatomic distance, are derived from the discrete energy levels of the isolated atoms forming the system, and consist of a large number of closely spaced individual levels. A substance is a metal if the states of a band are only partly occupied, or if a fully occupied band overlaps with an empty band having a higher energy. In both cases, there is no forbidden energy zone between the occupied ground states and the empty excited states. Electrons in states close to the highest occupied energy level are thus freely mobile. The second case is found in solid and liquid mercury having high densities (about 13.5 g/cm^3). The 6s band formed from the doubly occupied 6s level of the isolated atom is fully occupied and overlaps sufficiently with the higher 6p band, which forms the conduction band.

The situation to be expected on expansion of a simple, *e.g.* cubic crystal constructed from divalent atoms of this type is shown schematically in Figure 4. It is assumed here that the divalent atoms are arranged in a lattice in which they are all equidistant from one another (interatomic distance a). In an imaginary experiment, this distance can be continuously increased. As a increases, both the occupied valence band α and the unoccupied conduction band β become narrower; *i.e.* the overlap between the two bands is decreased as a result of the expansion, and ultimately, at a distance a_0, an energy gap ΔE is formed between the bands and rapidly increases with increasing a. The expanded crystal is then a semiconductor. An electric current can flow only if electrons pass from the valence band α into the conduction band β as a result of thermal or optical excitation.

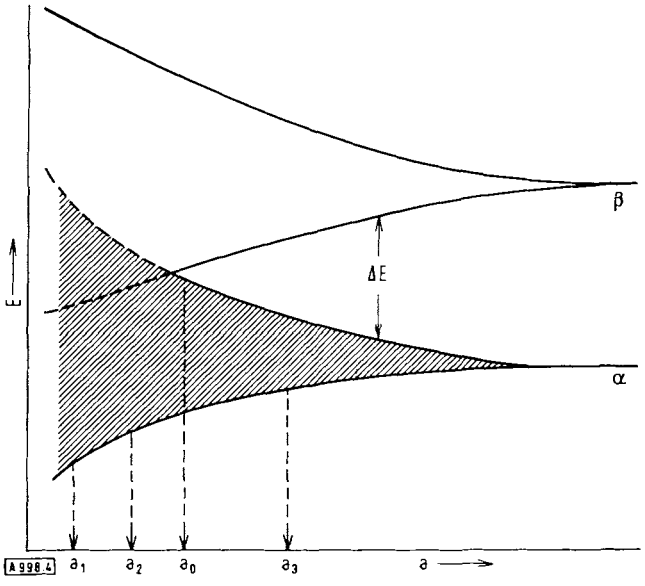

Fig. 4. Schematic representation of the formation of energy bands from the energy levels of the atoms for a divalent solid metal as a function of the interatomic distance a. α = occupied band; β = empty band; ΔE = energy gap.

However, this model cannot be applied to liquid or gaseous systems without substantial modification. In a liquid system or even in a solid at high temperatures with pronounced fluctuations of the density and hence of the interatomic distance, there may not be any sharply bounded forbidden energy zone. The distance variations always lead to a number of allowed energy states within this zone due to the interaction of the electron with the ions in their instantaneous positions. *Mott*[23, 24] has shown that the true energy gap of the crystalline semiconductor is replaced in a noncrystalline system by a minimum in the density of states $N(E)$, which is also called a "pseudogap". The quantity $N(E)\cdot dE$ denotes the number of energy states in the unit volume which is available for an electron with a given spin direction in the energy range between E and $E+dE$. The proposed density of states $N(E)$ for expanded crystalline and liquid mercury is shown schematically in Figure 5 as a function of the energy for various mean interatomic distances a_1, a_2, and a_3 (cf. Fig. 4). In the upper part of the figure, the broken lines indicate the density of states of the separate bands of the solid; the continuous lines show the sum of the two overlapping bands. The lower part of the figure, on the other hand, shows the presumed course of $N(E)$ for liquid mercury. Sharp contours such as are possible in the density of states curve of a solid do not occur

[*] N = number of mercury atoms per cm^3.

here, and the "pseudogap" mentioned above is found in place of the energy gap of the solid. For comparison, the broken line shows the course of the density of states $N(E)_{free}$ calculated for a free degenerate electron gas (formed from the two valence electrons of the mercury atoms). The arrows indicate the most probable position of the Fermi level[*].

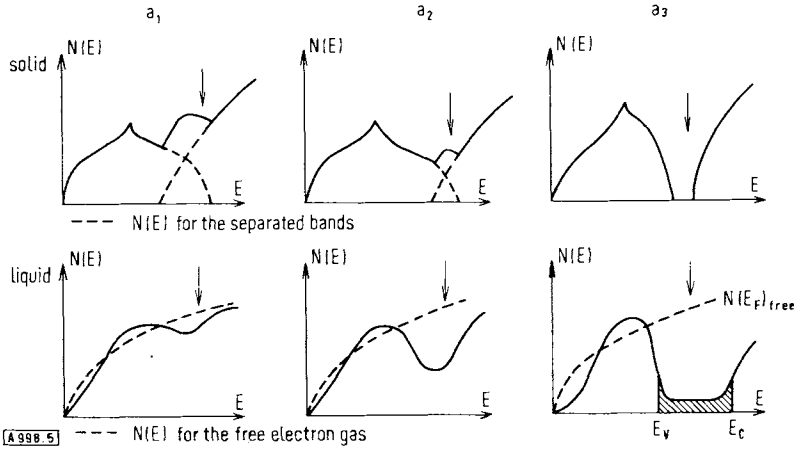

Fig. 5. Schematic representation of the density of the electronic states $N(E)$ in the two bands of Fig. 4 for the three different interatomic distances a_1, a_2, and a_3. The upper part of the figure shows the assumed course of $N(E)$ for a crystal, and the lower part the course for a liquid system. Localized electronic states are indicated by shading. The arrow shows the position of the Fermi energy.

For expanded mercury, the Fermi level, *i.e.* the highest occupied level, is within the "pseudogap". The density of states at the Fermi energy $N(E_F)$ decreases with increasing mean interatomic distance. A particularly interesting case is that shown under a_3. In the discussion of strongly perturbed amorphous or liquid semiconductors, various authors[25-28] have suggested that states may be localized in regions of low density of states. Calculations for a randomly constructed, one-dimensional chain of atoms[24] had shown that unlike in the case of a periodic potential, where waves can travel unhindered through the entire lattice, localized electronic states now occur. This result is applied to three-dimensional systems, for which no exact calculations have been carried out. The idea of such localized states is not new to semiconductor chemists and physicists. Localized donor and acceptor levels arise in crystalline semiconductors as a result of isolated centers of disturbance. The only novelty is the model of a practically continuous distribution of localized states. According to *Mott*[29], there should be exactly defined energies that separate regions with localized states from those with unlocalized states. These energies are indicated in Figure 5 by E_C and E_V (from conduction and valence bands). The region of localized states is shaded. The Fermi energy probably lies in this region in the case of mercury. This model allows the interpretation of the transition from metallic to nonmetallic behavior observed in Figure 3.

However, measurement of the conductivity, which is determined by the nature and concentration of the charge carriers and by their mobility, is not enough for this purpose. Additional measurements of the absolute thermoelectric power and of the Hall effect[*] are necessary for the separate determination of the individual factors. It should be mentioned that the Hall effect can be used only for the metallic region of expanded mercury. The normal theory of the Hall effect for crystalline semiconductors is not valid for liquid or amorphous semiconductors, and no new theory has been produced so far, so that the type or the concentration of the charge carriers cannot be determined from such a measurement.

The findings so far can be interpreted as follows: Between 13.5 and 11 g/cm^3, the course of $N(E)$ is as shown in Figure 5 under a_1. The density of states $N(E_F)$ at the Fermi energy is not very different from the calculated "free density of states" $N(E_F)_{free}$. The conductivity behavior in this region can be explained by the free-electron model. According to this model, the conductivity is σ_{free} and the Hall constant is $R_{H,free}$[30].

$$\sigma_{free} = \frac{e^2 n^{2/3} L}{(3\pi^2)^{1/3}\hbar} \quad (1)$$

$$R_{H,free} = \frac{1}{nec} \quad (2)$$

L is the mean free path of the electrons, n is the electron concentration, and all other symbols have the usual meanings. Figure 6 shows the results obtained by *Even* and *Jortner*[20, 31] for the Hall constant of expanded liquid mercury as a function of the density. The quantity plotted is the ratio of the measured Hall constant R_H and the value calculated for $R_{H,free}$ from eq. (2) on the assumption of two free electrons per atom. No deviation from the "free Hall constant" is observed between 13.5 and 11 g/cm^3. Since the change in n, which is due only to the change in density, is not large, the dependence of the conductivity on the density up to 11 g/cm^3 can only be explained by a decrease in the mean free path. A calculation of the free path of the electrons in mercury as a function

[*] For metals at 0 K, the Fermi level is the highest occupied energy level of the conduction band. For an insulator or an intrinsic semiconductor, the Fermi level lies exactly in the center of the forbidden zone.

[*] When a steady current is flowing in a steady magnetic field electromotive forces are developed which are at right angles both to the magnetic force and to the current and are proportional to the product of the intensity of the current and the magnetic force.

of the density has been carried out by *Evans*[32] on the basis of the Ziman model[33–35] of quasi-free electrons. The resulting volume coefficient for the conductivity $(\partial \ln \sigma / \partial \ln V)_T$ (V = volume), with a value of 6.7 ± 1.0, is in reasonably good agreement with the experimental value of 8.0[1,2]. The differences between the experimental values and those calculated from the free-electron model become distinctly greater for densities of less than 11 g/cm³. At 11 g/cm³, however, the conductivity is already so low that this model can no longer allow a good description. The mean free path of the electrons, formally calculated from eq. (1), is now comparable with the mean distance a between the ions, and the Hall constant begins to deviate considerably from $R_{H,free}$; it increases very rapidly with decreasing density (Fig. 6).

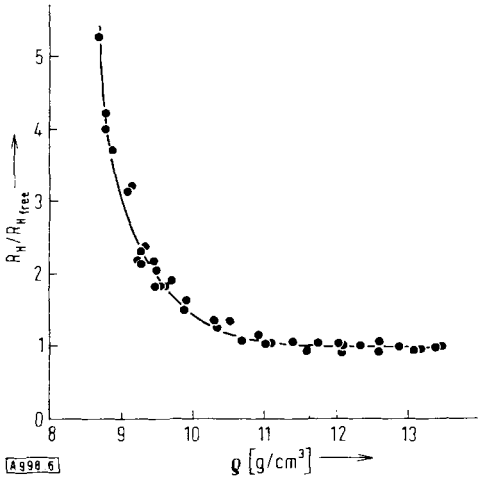

Fig. 6. Ratio of the measured Hall constant R_H and the Hall constant $R_{H,free}$ calculated for a free degenerate electron gas from eq. (2) for liquid mercury as a function of the density of the mercury (cf. [20, 31]).

This suggests that for densities lower than 11 g/cm³, the density of states at the Fermi energy $N(E_F)$ deviates strongly from $N(E_F)_{free}$, *i.e.* that the case is as indicated under a_2 in Figure 5. *Mott*[23,30] and *Friedman*[36] found that σ and R_H then depend on $N(E_F)$.

$$\sigma = \sigma_{free} \times \left(\frac{N(E_F)}{N(E_F)_{free}} \right)^2 \tag{3}$$

$$R_H = R_{H,free} \Big/ \left(\frac{N(E_F)}{N(E_F)_{free}} \right) \tag{4}$$

In the calculation of σ_{free}, L is taken to be equal to the mean interatomic distance a. Eqs. (3) and (4) allow independent calculations of $N(E_F)/N(E_F)_{free}$. The values obtained from the two measured quantities agree perfectly, and are plotted in Figure 7 as a function of the density. $N(E_F)$ decreases very rapidly with the density, and at 9 g/cm³, it is only about 30% of the value for the free electron $N(E_F)_{free}$.

For densities lower than 9 g/cm³, *i.e.* $N(E_F)/N(E_F)_{free} < 0.3$, σ and R_H can no longer be described by eqs. (3) and (4)[31]. Moreover, the dependence of the conductivity on temperature and density shows a pronounced increase with decreasing density in this range. Figure 8 shows the measured volume coefficients $(\partial \ln \sigma / \partial \ln V)_T$ and temperature coefficients $(\partial \ln \sigma / \partial \ln T)_V$[9,12] as functions of the density.

The temperature dependence of the conductivity is always high and positive when the current is produced by thermally

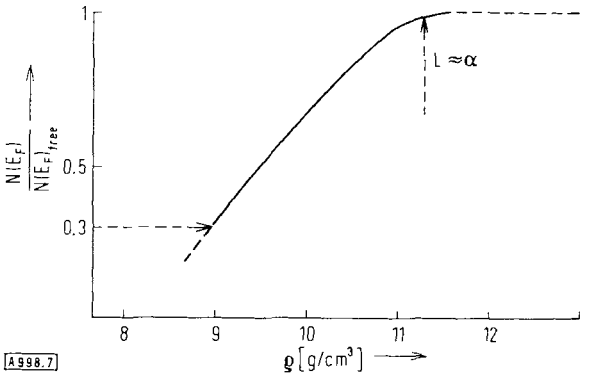

Fig. 7. Density of states at the Fermi energy $N(E_F)$ as calculated from eqs. (4) and (5) for mercury as a function of the density of the mercury. $N(E_F)_{free}$ is the density of states calculated for the free electron gas [21, 22].

activated charge carriers, as *e.g.* in a conventional solid semiconductor, in which the valence and conduction bands are separated by an energy gap. However, by optical absorption measurements[37,38] on compressed gaseous mercury, it has been shown that the 6s and 6p bands in mercury overlap for densities greater than 5 g/cm³, so that there is no true energy gap between the two bands; the density of states at the Fermi energy $N(E_F)$ is finite. It is therefore probable

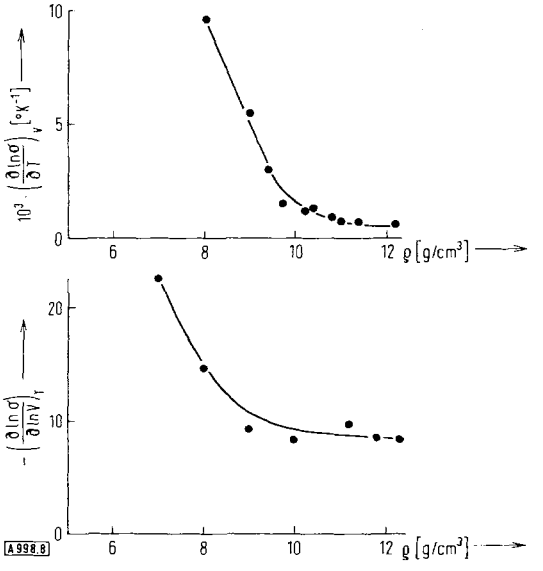

Fig. 8. Temperature and volume coefficients of the specific conductivity σ for liquid mercury as a function of the density of the mercury (cf. [9,12,42]).

that the case indicated in Figure 5 under a_3 is now present. The states in the vicinity of E_F are localized. An electric current can flow only if excitation causes electrons to pass from states close to E_F into mobile states above E_C. The conductivity (and this is in agreement with experiment, Fig. 8) must therefore be strongly dependent on the temperature. The following relation is expected for a constant density:

$$\sigma = \sigma_0 \times \exp - \left(\frac{E_C - E_F}{kT} \right) \tag{5}$$

In eq. (5), $(E_C - E_F)$ should increase with decreasing density; this also corresponds to the pronounced increase in the measured volume coefficients for densities lower than 9 g/cm³.

The validity of eq. (5) unfortunately cannot be checked by conductivity measurements alone, since the shape of the density of states curve $N(E)$, the region of localized states, and hence $(E_C - E_F)$ itself depend on the temperature. Several research groups have therefore investigated the absolute thermoelectric power of liquid and gaseous mercury as a function of pressure and temperature[12, 39-41].

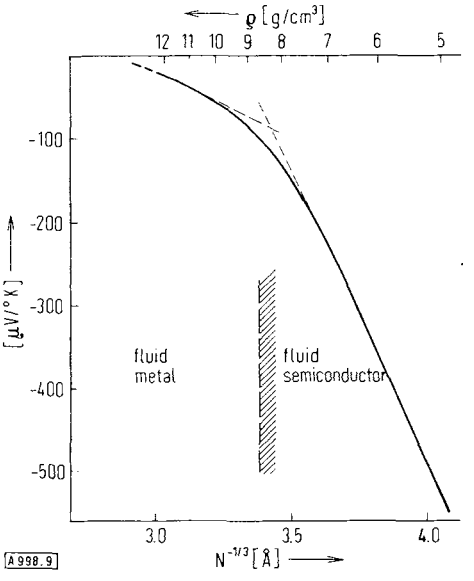

Fig. 9. Absolute thermoelectric power of mercury at a constant supercritical temperature of 1550 °C as a function of $N^{-1/3}$ (as a function of the density).

The experimental data are shown in Figure 9 as a function of the cube root of the reciprocal number density N of the mercury atoms and as a function of the density. Between 13.5 and 9 g/cm³ one finds values of between -5 and $-90\,\mu V/°K$, which are typical of solid and liquid metals. For densities lower than 9 g/cm³, the absolute value of the thermoelectric power very rapidly increases, and finally reaches $550\,\mu V/°K$ at 5 g/cm³; absolute thermoelectric powers as high as this are observed in semiconductors. If, as has been assumed so far, the current in mercury at densities lower than 9 g/cm³, as in a conventional semiconductor, is mainly due to thermally excited electrons[42], the thermoelectric power is given by[12, 30]

$$S = \frac{k}{e} \times \left(\frac{E_C - E_F}{kT} + \text{const.} \right) \qquad (6)$$

k = Boltzmann's constant

Combination of eqs. (5) and (6) gives an experimentally checkable relation between the conductivity σ and the absolute thermoelectric power S[12, 30].

$$\ln \sigma = \frac{eS}{k} + \text{const.} \qquad (7)$$

This relation (7) is found in Figure 10 to be confirmed for mercury densities lower than 8 g/cm³.

The measured slope of the straight line, *i.e.* $1.2 \times 10^{+4}$ (°K/V), agrees satisfactorily with the calculated value of $e/k = 1.16 \times 10^{+4}$ (°K/V). The transition from the liquid or gaseous metal to the liquid or gaseous semiconductor thus seems to occur in the density range between 8 and 9 g/cm³ in the case of mercury. It should be emphasized that this

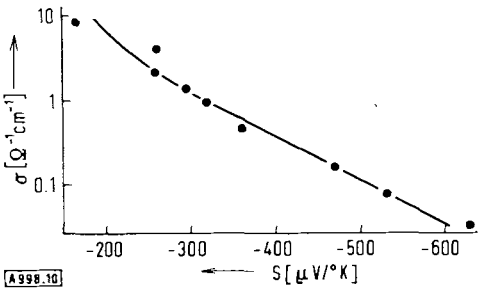

Fig. 10. A plot of the logarithm of the conductivity σ as a function of the thermoelectric power S of expanded liquid mercury gives a straight line with a slope of $1.2 \times 10^{+4}$ [°K/V] for densities lower than 8 g/cm³ (cf. eq. (7)).

transition does not occur at the critical point of mercury. The critical density of 5.3 g/cm³ is much lower. Moreover, liquid mercury expanded to a density of less than 9 g/cm³ then exhibits semiconducting properties instead of metallic properties.

3. Investigations on Alkali Metals

There are far fewer experimental results available for the univalent alkali metals, which have the lowest critical temperatures after mercury. The high chemical reactivity of these metals, particularly the violence of the reactions with nearly all available electrically insulating materials at high temperatures, presents great difficulties. Only the vapor pressure curve, the critical data, and the electric conductivity have been measured for potassium[11, 43], and the vapor pressure curve[10, 44, 45], the densities[46, 47], the critical data[11, 46], the conductivity[10, 48, 49], and the thermoelectric power[49] for cesium. Figure 11a shows conductivity isotherms for potassium at subcritical and supercritical temperatures as functions of the pressure. The behavior observed is qualitatively the same as for the divalent mercury. The pressure dependence is relatively low at subcritical temperatures. Only at temperatures above the critical point does one observe a steady but steep decrease in the conductivity with decreasing pressure, which indicates the transition to nonmetallic behavior. However, one difference from the behavior of mercury should be pointed out. At the critical point, which is the end point of the vapor pressure curve shown in Figure 11b ($p_c = 155$ bars, $T_c = 1925$ °C), a conductivity of $\sigma = 10$ to $100\,\Omega^{-1}\,cm^{-1}$ is recorded. This is relatively high in comparison with the value of only 10^{-1} to $10^{-2}\,\Omega^{-1}\,cm^{-1}$ measured at the critical point of mercury.

By combination of conductivity and density data for cesium, a discussion of the conductivity behavior as a function of the interatomic distance is again possible. Figure 12 shows the conductivity σ at the constant supercritical temperature of 2000 °C as a function of the cube root of the reciprocal number density N of the cesium atoms. Between $N^{-1/3} = 3 \times 10^{-7}$ and 10^{-7} cm, the conductivity increases only slightly with decreasing interatomic distance, whereas in the relatively narrow range between 10^{-7} and 0.5×10^{-7} cm, it increases by three orders of magnitude to values that are typical of liquid metals (for comparison, the conductivity of liquid cesium at 60 °C and 1 bar is $2.4 \times 10^{+4}\,\Omega^{-1}\,cm^{-1}$). In the first case, the region of large interatomic distances, σ is of the order of $1\,\Omega^{-1}\,cm^{-1}$, and is certainly nonmetallic.

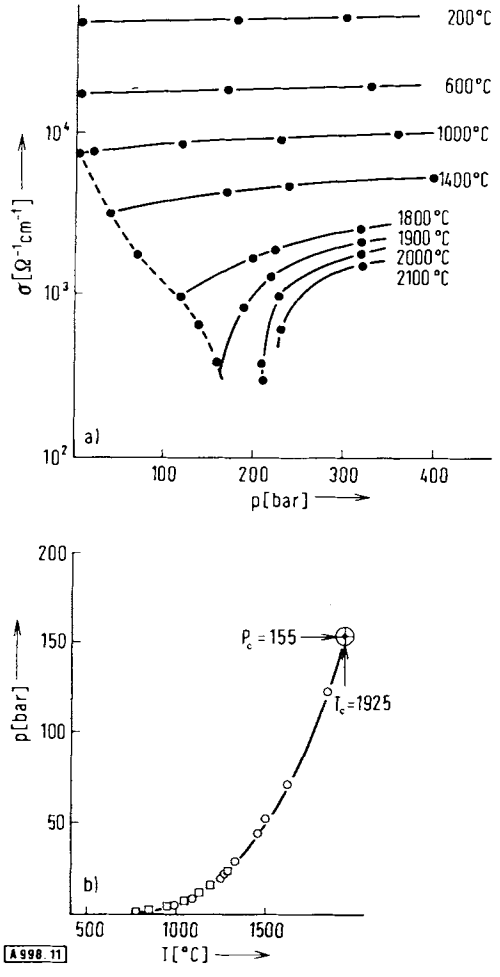

Fig. 11. a) Specific electric conductivity σ at subcritical and supercritical temperatures as a function of the pressure. b) Vapor pressure curve up to the critical point of potassium. The broken line shows the probable conductivity of liquid potassium at the saturation pressure (cf. [11, 43]).

In this range we probably have a dense gas of Cs atoms and Cs_2 molecules, and the conductivity is caused by thermal ionization of the neutral particles. Calculation of σ with the simple Saha equation for the degree of ionization[50] and the Chapman-Enskog theory[51] for charge transport in dilute gases gives a conductivity of $0.7\,\Omega^{-1}\,cm^{-1}$ for $N^{-1/3}=10^{-7}$ cm, in good agreement with experiment. The degree of ionization calculated from the ionization potential of the isolated atom is $\alpha=1.5\times10^{-4}$, and $40\,Å^2$ [52] is used as the mean collision cross section of the neutral cesium atom.

With decreasing distance, the conductivity increases by a factor of about 2 down to 1.5×10^{-7} cm; the only explanation for this is an increase in the thermal ionization. This is probably due to the increasing content of more complex molecular aggregates in the cesium gas with decreasing distance, *i.e.* with increasing pressure. For $N^{-1/3}=1.5\times10^{-7}$ cm, the estimated dimer content based on the molecular data for Cs_2 from spectroscopic measurements[53] is 10%. No accurate measurements of the ionization potential of Cs_2 are known. However, measurements on small clusters of sodium atoms show that there has already been a considerable decrease in the ionization potential[54]. If a similar effect existed for cesium clusters, this would lead to an increase in the degree of ionization, and hence to an increase in the conductivity.

The transition from the thermally activated conductivity of the dilute gas to the metallic conductivity of the compressed gas occurs at interatomic distances $N^{-1/3}$ of less than 10^{-7} cm. This transition cannot be predicted from the usual one-electron approximation of solid-state physics, the band model described in Section 2. According to this model, in a crystalline material consisting of univalent atoms, there is always a half-filled conduction band, whatever the distance between the atoms.

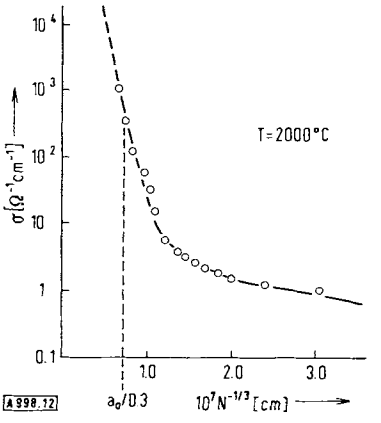

Fig. 12. Specific electric conductivity of cesium at a constant supercritical temperature of 2000 °C as a function of $N^{-1/3}$. N = number density of the Cs atoms, $a_0=2.33$ Å (radius of the neutral Cs atom [55]; cf. [10, 35, 47, 48]).

As was first pointed out by *Mott*[56,57], however, this prediction of the model is wrong, since the Coulomb interaction between the electrons cannot be disregarded at large interatomic distances. *Mott*[56–58], *Kohn*[59], and *Hubbard*[60,61] have carried out theoretical treatments of this electron-electron interaction for crystalline univalent substances. Though their models differ in detail from one another, they all predict nonmetallic behavior for large interatomic distances and metallic behavior for small interatomic distances. The first rough estimate of the critical interatomic distance at which the transition should occur was made by *Mott*. This author found that the activation energy required for the production of charge carriers at large distances tends discontinuously toward zero if the interatomic distance $N^{-1/3}$ and the radius of the neutral atom a_0 are related as follows:

$$N^{-1/3}a_0 \geq 0.3 \qquad (8)$$

The critical value of $N^{-1/3}$ calculated from eq. (8) for the transition from metallic to nonmetallic behavior is in fact situated in the region of the rapid increase in conductivity (Fig. 12). An accurate analysis of the temperature dependence of the conductivity of cesium shows, however, that the change from a negative temperature dependence of the conductivity (typical of liquid univalent metals[62]) to a positive temperature dependence occurs at a distinctly lower interatomic distance than that calculated from eq. (8). Table 2 shows the mean interatomic distance $N^{-1/3}$, the mean free path L of the electrons, and the temperature coefficient $(\partial\ln\sigma/\partial\ln T)_V$ of the conductivity as functions of the density. The change in the sign of $(\partial\ln\sigma/\partial\ln T)_V$ occurs at a density at which $N^{-1/3}=5.9\,Å\approx L$. This is distinctly smaller than the value of 7.8 Å found for $N^{-1/3}$ from eq. (8).

There is at present no satisfactory theory for the metal-nonmetal transition in liquid or gaseous expanded univalent metals,

Table 2. Mean interatomic distance $N^{-1/3}$, mean free path of the electrons L (formally calculated from eq. (1)), and temperature coefficient of the conductivity at constant volume $(\partial \ln \sigma / \partial \ln T)_V$ for cesium as a function of the density ρ. The mean temperature is 1750 °C.

ρ [g/cm³]	$N^{-1/3}$ [Å]	L [Å]	$\left(\frac{\partial \ln \sigma}{\partial \ln T}\right)_V$
1.5	5.16	15.5	− 1.2
1.3	5.41	12.5	− 0.9
1.1	5.72	9.8	− 0.4
0.9	6.11	6.1	+ 1.2
0.7	6.65	2.0	+ 10.4
0.5	7.44	0.5	+ 54.0

which should take into account the effects of thermal motion and of thermal density fluctuations.

4. Outlook

It seems important to point out that despite the considerable number of experimental facts that have been described in this report, the chemical or physical mechanism underlying the metal-nonmetal transition is still largely unknown. Nevertheless, the findings show that, however one may describe the interatomic forces in a liquid metal, the description must change with the density. As the atoms move farther apart on expansion, the metallic bonding changes into nonmetallic bonding. Recent measurements on the viscosity[63] of expanded liquid and gaseous mercury may possibly provide information about the nature of the interatomic forces.

A second unsolved problem is the formation of the "pseudogap" and the occurrence of localized states within this gap. Optical absorption and emission measurements and photoconductivity measurements are expected to yield information about the pseudogap. The part played in the formation of the localized states by the development of large molecular aggregates, which can decisively influence the transport of electrons, is one of the most pressing theoretical questions. Another question that must be examined in this connection is whether a univalent metal (*e.g.* Cs or K) is really univalent in the gaseous state at low densities. Diatomic molecules (Cs_2 and K_2) have a bond energy of more than 10 kcal/mol, so that for the gaseous alkali metals, the metal-nonmetal transition could be initiated by overlap of energy bands of the diatomic molecule. It should be possible to check this hypothesis by magnetic susceptibility measurements.

Very many problems are thus still awaiting clarification. The experiments are difficult and time-consuming, but the result could be a deeper understanding of the metal-nonmetal transition in general. The great similarity between the observations on compressed metal vapors and those on metal-ammonia solutions, solutions of metals in salts, and liquid mixtures *e.g.* of magnesium with bismuth or of thallium with tellurium, in which a transition from metallic to nonmetallic behavior occurs in the vicinity of the composition Mg_3Bi_2 or Tl_2Te[64], suggests that a single theory might be capable of describing all these very different systems.

X-Ray Absorption Spectroscopy on Free Molecules

By W. H. Eugen Schwarz[*]

The most recent spectroscopic method that can be applied to chemical problems is X-ray absorption spectroscopy, in which the excitation of individual core electrons of an atom is studied. The analysis of the spectra with the aid of simple theoretical models yields information both about the core orbitals of the atom and about the unoccupied molecular orbitals, from which various molecular properties can be deduced. These not only include charge distribution, electronic configuration, geometry, and spatial and energy characteristics of orbitals of the molecule under investigation; one can also obtain parameters of radicals (such as stability, bond length, ionization potential, and electronic excitation energy) that differ from the molecule under investigation in that the nuclear charge of one atom is one unit higher.

1. Introduction

An important contribution to scientific progress in chemistry is being made by advances in physical and especially spectroscopic methods. The most recent of the spectroscopic methods that is starting to acquire importance in chemistry is X-ray absorption spectroscopy. This term will be applied to spectroscopy in the energy range that leads to optical excitation of "core electrons". This calls for light quanta with an energy of more than 30—50 eV[**], corresponding to wavelengths λ of less than 400—200 Å. This radiation is known as soft X-rays or XUV.

The discovery that the chemical environment influences the X-ray absorption spectrum of a bonded atom was made in 1920 in the laboratory of *Siegbahn sr.* during the investigation of solids[1]. X-ray absorption spectroscopy was first applied to free molecules during the 1930's[2]. The number of publications, mainly dealing with studies on complex compounds[3], has increased since 1945, but it was only during the last few years that the sensitivity and the resolving power of the spectrometers were increased to such a degree that the line spectra that are now obtainable can be effectively used for more detailed chemical problems. The course of the development was similar to that of X-ray photoelectron spectroscopy (ESCA)[4], which has a history extending back over more than 50 years, but which has only recently become a versatile method for use in chemistry as a result of a spectacular breakthrough. The reason why the underlying ideas took so long to reach maturity lay in experimental difficulties, which were overcome in the case of the ESCA method through the development work of *Siegbahn jr.*

A number of experimental questions of X-ray absorption spectroscopy will first be briefly discussed in Section 2. The principles of X-ray absorption spectra and models for their interpretation are presented in Section 3. In the next section, some specific chemical and physicochemical problems will be discussed with the aid of representative spectra.

2. Experimental[9]

Like any other spectrometer, an X-ray absorption spectrometer consists of four parts: a radiation source; a monochromator; an absorption cell; and a detector.

2.1. Radiation Source

One of the main difficulties of X-ray absorption spectroscopy lies in the light sources. Until recently, the radiation used was mainly the bremsstrahlung from *X-ray tubes*[5–7]. However, the intensity of the soft and ultrasoft component in the wavelength range from a few Å to a few hundred Å is low; furthermore, the radiation is strongly divergent. Through the development of special X-ray tubes, it has been possible to extend the range of the useful radiation down to quantum energies of 50 eV ($\lambda \approx 250$ Å), with an energy resolution of at best a few tenths of an eV. The work of a Leningrad research group deserves special mention in this connection[8].

An important breakthrough was achieved with the aid of synchrotron radiation[9–11]. In a *synchrotron* or storage ring,

53 Bonn, Wegeler Strasse 12 (Germany)

[**] 1 eV (electron volt) corresponds to 23 kcal/mol.

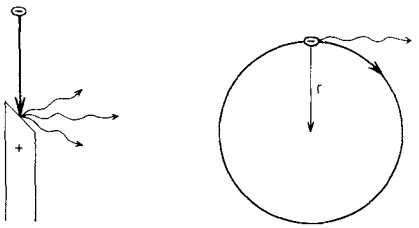

Fig. 1a. X-ray tube (left) and synchrotron (right) as radiation sources (schematic). r = radius vector. ⊖ = electron.

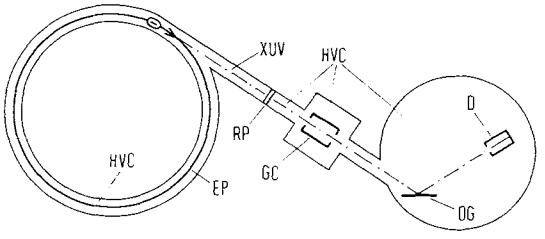

Fig. 1b. Synchrotron radiation absorption spectrometer. DG = diffraction grating, D = detector, EP = circular path of the electrons in the synchrotron, GC = gas absorption cell, HVC = high vacuum channel and vessel, RP = reference probe for measurement of the primary intensity of the radiation, XUV = X-rays.

electrons orbit with almost the velocity of light in a circular path EP (see Fig. 1a and 1b). As a result of the centripetal acceleration, the electrons emit continuous electromagnetic radiation normal to the radius vector r; because of the relativistic velocity of the electrons, the radiation is emitted into a very small solid angle in the forward direction. The high-intensity range of the substantially parallel radiation extends over the entire energy scale in which we are interested. However, the construction and operation of this type of equipment is extremely expensive, partly because of the necessary ultra-high vacuum, so that this radiation can only be used where it occurs, so to speak, as a waste product of high-energy physics or where disused electron accelerators are available. The existing possibilities have so far been used mainly in connection with problems of solid-state physics, whereas there have been relatively few studies on molecules and atoms in the gaseous phase. The latter have been carried out mainly in the installations at Hamburg (DESY), Stoughton (University of Wisconsin), Washington (NBS), and Tokyo.

2.2. Monochromator

Crystal spectrographs, and especially double-crystal spectrographs, are often used as monochromators for medium-soft X-rays ($E > 500\,eV$)[15]. By the use of special organic crystals with large interplanar distances, it has been possible to extend the range of these instruments down to $\lambda = 100\,Å$ ($E \approx 125\,eV$)[19]. *Line gratings* can be used over the entire range of wavelength that are of interest here, especially in the region of the longer-wave ultrasoft X-rays. However, the reflectivities of all materials are so low that it is necessary to use a glancing angle of incidence.

2.3. Absorption Cell

At a gas pressure in the torr range, it is customary to use absorption cells a few cm long with *open entry and exit slits* for the radiation. To maintain the high vacuum in the apparatus, the gas emerging through the slit must be continuously pumped out and replaced by further material flowing into the cell. To overcome this disadvantage, the windows of the cell may be sealed with thin films, *e.g.* of carbon, but one must then be prepared to accept the absorption of the *window films*.

2.4. Detector

The spectra can be recorded on *photographic plates* or, if the intensity of the radiation is sufficiently high, with electronic detectors, particularly open *photomultipliers*. Apart from the improvement of the light sources, it was especially the detector technique that helped to improve the resolution of the instruments, which has been increased to $1 : 10^{-4}$.

The development of the equipment is still proceeding rapidly. Further details and a description of individual instruments can be found in the literature cited.

3. Theoretical Principles

3.1. X-Ray Absorption Spectroscopy in Comparison with Other Spectroscopic Methods

Let us consider a simple molecule (see Fig. 2). The molecular orbitals (MOs) describing the state of the electrons in the molecule can be divided into three classes: 1. *core orbitals*; these are localized close to the nucleus of an atom and describe very strongly bound electrons that are hardly affected by molecule formation; 2. occupied *valence orbitals*; these MOs are derived from the atomic orbitals (AOs) of the valence electron shells, and extend over the entire molecule or at least over several atoms; 3. *virtual MOs*, which are unoccupied in the ground state of the molecule, but can be used for the description of excited electrons.

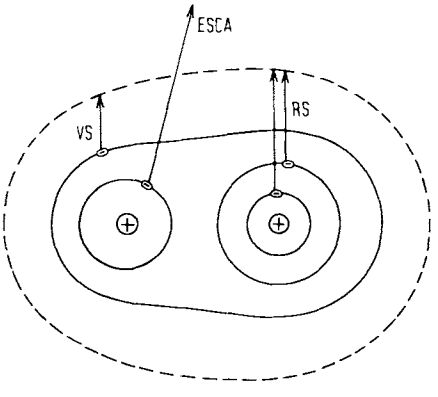

Fig. 2. One-electron excitations in a diatomic molecule on light absorption (VS), X-ray absorption (RS), and ESCA. — — — occupied orbitals, - - - - virtual orbital.

In conventional *absorption spectroscopy with visible and ultraviolet light*, electrons are promoted from the occupied valence MOs into the unoccupied MOs, whereas the more strongly bound core electrons can only be promoted with X-rays, which have much higher energies. Transitions to the virtual MOs are investigated by *X-ray absorption spectroscopy*, and transitions to the continuum by *ESCA* (see Fig. 2). The three methods can therefore compete with and also complement one another.

Since the core MOs are localized on individual atoms and their energy shift essentially depends only on the mean strength of the field of the directly bonded neighboring atoms, X-ray absorption spectroscopy and ESCA are probes for *individual atoms in the molecule*. It should be noted that a higher resolution can generally be achieved in X-ray absorption spectroscopy (0.1—0.01 eV) than in ESCA (1—0.1 eV). In particular, the absolute accuracy of X-ray absorption spectroscopy is usually better, since contact potentials, space charges, and the Fermi level cause displacements of the ESCA values that are difficult to estimate[4]. Moreover, the X-ray absorption spectrum yields information about a whole *series of unoccupied MOs* below (and sometimes also above) the ionization limit, and hence also about the overall structure of the molecule, whereas ESCA gives only the ionization potential *(IP)* of the excited core electron itself. However, ESCA is thus an important complement to X-ray absorption spectroscopy, since knowledge of the ionization potential greatly facilitates the assignment of the X-ray absorption lines corresponding to the unoccupied MOs, which can present considerable difficulties even for molecules of medium size.

Nevertheless, the X-ray absorption spectra are much clearer than the valence electron absorption spectra. There are two reasons for this. Firstly, in the valence electron absorption spectra, the electrons are excited from several valence MOs lying close together, so that several series of lines overlap and interfere with one another. The energies of the core levels, on the other hand, are generally so far apart that two series of lines for different starting levels do not overlap in the X-ray absorption spectrum. Secondly, the interaction of the low-lying hole state (produced by the X-ray excitation) with the excited electron is relatively small, and can be disregarded or taken into account easily by perturbation theory, whereas in the valence electron spectrum, the electron interaction has an extremely strong influence. The *interpretation* of X-ray absorption spectra is therefore much easier, and can often be achieved purely with the aid of simple models, without long quantum-chemical calculations.

The disadvantages of X-ray absorption spectroscopy in comparison with valence electron absorption spectroscopy should not be overlooked. Because of the high excitation energy in X-ray absorption, the absolute energy resolution for the same relative resolution is 1—2 orders of magnitude poorer in the X-ray absorption spectrum than in the valence electron spectrum. The resolving power is also limited by the natural line width, which is frequently 0.1 eV or more owing to the finite lifetime of the highly excited states. Thus in the X-ray absorption spectrum, the vibrational structure can usually be resolved only in the case of small molecules. Finally, the cost of equipment of X-ray absorption spectroscopy is very high, whereas commercial instruments are available for valence electron spectroscopy and ESCA.

3.2. Interpretation Models for X-Ray Absorption Spectra

To be able to use X-ray absorption spectra of molecules for chemical problems, it should be possible to analyze the recorded spectra with the aid of simple qualitative and semi-quantitative principles and without extensive calculations. The models that are important in this connection will now be briefly described.

As was mentioned earlier, the interaction between the electron hole in the atomic core and the excited electron is generally very small, so that to a first approximation the *one-electron model* is sufficient for the interpretation of spectra, *i.e.* the electronic transition energies $h\nu_{ij}$ correspond very closely to the differences in a homogeneous set of one-electron orbital energies ε_i (see Fig. 3):

$$h\nu_{ij} = \varepsilon_j - \varepsilon_i \qquad (1)$$

Simple *MO ideas* about the virtual MOs that form the final levels of the one-electron excitations yield the first indications of the energy and intensity of the absorption bands to be expected. Semiempirical or *ab-initio MO-SCF calculations* must be carried out in more complicated cases.

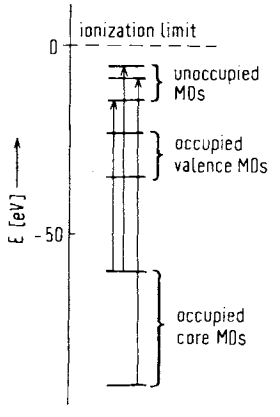

Fig. 3. Electronic excitation by X-ray absorption in the one-electron model.

The virtual MOs can be roughly divided into two classes: 1. MOs derived from the valence electron shells of the atoms, which frequently have antibonding character; 2. MOs lying outside the valence electron shells, so-called Rydberg orbitals with nonbonding character. The valence electron spectra, as indicated above, cannot generally be interpreted in the one-electron MO model. Because of the great distance between the Rydberg MOs and the valence electron shell, however, this can be achieved quite satisfactorily for the optical Rydberg spectra. There is therefore a close *correlation between the Rydberg spectra* of related molecules in the normal optical and X-ray ranges, which can be used for interpretation purposes. In CO, for example, if a 1s electron of carbon is excited, the positive C nucleus will be shielded by only a single 1s electron instead of by two. The effect is the same, to a first approximation, whether a core electron is removed or the nuclear charge on the corresponding atom is increased by 1. On C-1s excitation, therefore, the residual molecular core of CO is similar to the core of the NO molecule, *i.e.* the X-ray spectrum of CO and the valence electron spectrum of NO should have similar structures [$(Z+1)$ *analogy*].

The core electrons to be excited are situated very close to the nucleus. The influence of the chemical environment on this core AO largely depends on the absolute strength and the symmetry of the field produced in the vicinity of the nucleus by the directly bonded atoms. Chemical shifts of the core orbital energy and splitting of p and d AO levels

can therefore be very satisfactorily dealt with in the electrostatic *point charge model* (cf. also[4]) and with the *ligand field theory*[12].

To estimate the transition intensities, we require the behavior only of the unoccupied MOs close to the nucleus. This can be satisfactorily described in a *one-center expansion* by one of the unoccupied AOs of the atom in question. Whereas the energies of the X-ray absorption bands can usually be adequately understood in the one-electron model, the observed intensities sometimes differ considerably from those in this model. The *electron interaction* (and also the spin-orbital coupling in the case of heavier atoms) is clearly in evidence here. In the one-center model, these effects can simply be treated as in atoms[13].

In addition to the MO and ligand field models, the *pseudopotential model*[14] in particular is very helpful for an understanding of the spatial positions and energies of the virtual MOs. According to the Pauli principle, the higher orbitals must be orthogonal to the lower, occupied MOs. This quantum-mechanical phenomenon prevents the excited electron from remaining where the molecule already has an electron. This phenomenon can be described by a potential that strongly repels the excited electron at points of particularly high electron density in the molecule. The potential is known as the occupation exclusion potential or the pseudopotential. (The repulsive effect connected with the Pauli principle, which is proportional to the square of the overlap between two occupied orbitals, has nothing to do with the electrostatic Coulomb interaction, and is generally much more significant than the latter[15].)

As was mentioned above, the main possibilities for the final state of the excited electron are a) antibonding valence MOs and b) nonbonding Rydberg MOs. The core orbitals of the atom, which form the starting levels of the one-electron excitations, are nonbonding in character. In transitions to nonbonding Rydberg MOs (class b), therefore, there is little change in the bonding, so that we expect sharp absorption lines of the 0—0 type. On excitation to antibonding valence MOs (class a), on the other hand, bonds are weakened and lengthened. The shape of the absorption bands is then strongly determined by vibrational effects (*Franck-Condon model*). The *Jahn-Teller effect* must also be taken into account in the case of highly symmetrical molecules[16].

4. Examples of the Application of X-Ray Absorption Spectroscopy

4.1. Energy Standards for ESCA Measurements

As was mentioned earlier, it is difficult to obtain accurate absolute energy values by the ESCA method. It is best to mix the gas under investigation with a reference gas whose ionization potential is accurately known. Suitable gases for this purpose are the inert gases, for which accurate X-ray absorption spectra have been recorded (*e.g.* [17, 18]).

Figure 4 shows an X-ray absorption spectrum of argon at excitation energies in the region of 250 eV[17]. The lines correspond to transitions of a $2p_{1/2}$ and of a $2p_{3/2}$ core electron to the unoccupied *n*s Rydberg AOs[19]. The energies of the

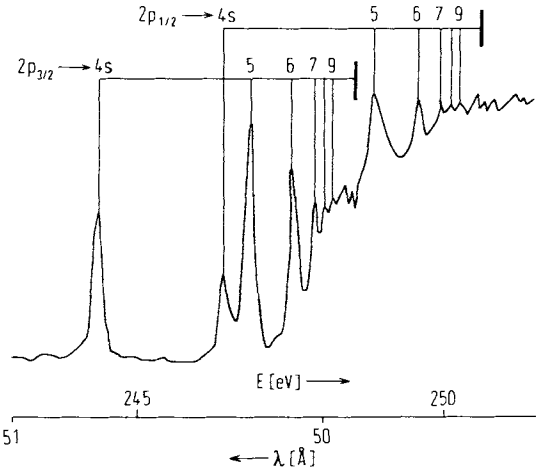

Fig. 4. Ar2p X-ray absorption spectrum [17, 19].

Rydberg orbitals can be represented very accurately by the "Rydberg formula":

$$\varepsilon_n = 13.605/(n - \delta)^2 \text{ [eV]} \quad (2)$$

where δ is an empirical constant. According to eq. (1), the measured energies ΔE_n of the absorption lines should then be given by the formula

$$\Delta E_n = BE_{2p} - \varepsilon_n \quad (2a)$$

if the two parameters δ and BE are suitable chosen. BE_{2p} is the desired ionization energy of a 2p electron, which is also known as the 2p *b*inding *e*nergy. An example is shown in Table 1.

Table 1. 2p excitations in the X-ray absorption spectrum of argon gas. ΔE_n = excitation energy.

Initial level:	$2p_{3/2}$		$2p_{1/2}$	
Final level	ΔE_n [eV]		ΔE_n [eV]	
	exp.	calc. with $\delta = 2.15$ and $BE = 248.53$ eV	exp.	calc. with $\delta = 2.15$ and $BE = 250.57$ eV
4s	244.42	244.55	246.47	246.59
5s	246.89	246.86	248.93	248.90
6s	247.61	247.61	249.65	249.65
7s	247.94	247.95	249.99	249.99
8s	248.13	248.13	250.18	250.17
9s	248.25	248.24	250.28	250.28

It is possible in this way to determine core electron binding energies (= ionization potentials) with an accuracy of about 10^{-3}—10^{-4} by extrapolation of X-ray absorption Rydberg series.

4.2. Core Electron Binding Energies of Molecules. Charge Distributions

The Rydberg spectra of molecules are more complicated than those of atoms, on account of the lower symmetry. A necessary condition for the determination of ionization potentials from X-ray spectra by extrapolation is obviously that it should be possible to assign the measured lines correctly. This presents no difficulty if a $(Z+1)$-analogous valence electron Rydberg

spectrum is known. As an example, Table 2 shows a comparison of the C1s X-ray absorption spectrum of CO[20] with the valence electron Rydberg spectrum of NO[21].

Table 2. C1s excitations of CO and optical Rydberg levels of NO.

XUV spectrum of CO [a], peak energies [eV]	Rydberg orbital	Rydberg spectrum of NO [21], energies [eV]	Energy differences
289.4_3	3s	5.48	283.9_3
289.7_4	3s*	5.77	283.9_7
290.0_5	3s**	6.06	283.9_9
290.3_1	$3p_\pi$	6.49	283.8_2
290.5_7	$3p_\sigma$, $3p_\pi^*$	6.61, 6.79	$283.8_7 \pm 0.09$
290.8_8	$3p_\sigma^*$	6.89	283.9_9
291.6_2	4s	7.55	284.0_7
291.8_8	3d, 4s*	7.78, 7.84	$284.0_5 \pm 0.03$
292.1_0	$4p_{\pi,\sigma}$, 3d*	7.97—8.07	$284.0_8 \pm 0.05$
292.3_9	$4p_{\pi,\sigma}^*$, 5s	8.26—8.33	$284.0_9 \pm 0.04$

[a] The energies were obtained from the spectrum in [20].
[b] * and ** denote respectively single and double vibrational excitation in the final state.

The Rydberg spectra in the X-ray region and in the normal UV thus correspond to within about 0.1 eV. The X-ray absorption Rydberg series assigned in this way can be extrapolated as in the case of the atoms. In this case the C1s binding energy is found to be 293.4 ± 0.2 eV. Addition of the mean energy difference from the last column in Table 2 to the valence electron ionization potential of NO gives practically the same value for the C1s ionization potential, *i.e.* 293.3 ± 0.1 eV. The N1s ionization potential of the N_2 molecule has been found in a similar manner from its X-ray spectrum, the value obtaining being 409.5 ± 0.1 eV[22].

Rydberg lines have also been resolved in the X-ray spectra of a large number of other molecules. However, no $(Z+1)$-analogous valence electron spectra are known in any of these cases. We have nevertheless been able to assign the X-ray absorption Rydberg spectra of most of the molecules (though not always with absolute certainty[23–26]) with the aid of qualitative models, which were partly supported by *ab-initio* SCF calculations[23]. Our assignments of the spectra[23, 26] differ in part from those in the original experimental work, but reassurance is provided by the fact that this has little influence on the *binding energies* obtained by extrapolation. (H_2S is an exception, see[23].)

Even if the Rydberg excitations, which are generally weak, can no longer be resolved or cannot be observed at all, it is still possible to obtain certain information about the core electron binding energies. For example, from the well-resolved S2p spectrum of SF_6, the energies of the two lowest unoccupied valence MOs are found to be -8.5 eV and -3.3 eV[26]. The S1s spectrum shows lines at 2481 eV and 2486 eV, but no Rydberg series[27]. From these data, the S1s binding energy is found to be $2489\,{}^1/_2$ eV.

The core electron binding energies derived by the author in this and similar ways from experimental spectra are shown in Table 3. Some uncertainty always exists in the last decimal place. The results are compared with reliable ESCA data. The agreement is satisfactory except in the cases of CO and GeH_4, where the differences found are 3 and 5 eV respectively, which are well outside the expected accuracy of the methods.

From the chemical shifts of the ionization potentials of atoms in various molecules, it is possible to deduce the *charges* on these atoms; this was discussed in detail by *Siegbahn* and *Nordling*[4]. A simple electrostatic model is generally sufficient. For this purpose we numbered the atoms of an $(N+1)$-atomic molecule, assigning the number 0 to the atom to be ionized. A partial charge of $+q_i$ units on the atom i at a distance R_i (in bohr) from the atom 0, according to *Coulomb*'s law, increases the ionization potentials *(IP)* of the atom 0 by $\Delta IP = e^2 \cdot q_i / R_i$. On grounds of electroneutrality, a partial charge of exactly $\sum_{i=1}^{N} q_i$ must be missing from the valence shell of the atom 0. If the interaction energy between a valence electron v of the atom 0 and the core electron c to be ionized is J_{vc} (in a.u.), therefore, the molecular ionization potential of the atom 0 has a chemical shift of

$$\Delta IP = 27.2\,\text{eV} \times \sum_{i=1}^{N} \left(\frac{1}{R_i} - J_{vc} \right) \times q_i$$

with respect to a free atom.

For example, the ionization potential (Xe $4d_{5/2}$) is 67.55 eV in free xenon but 70.4 eV in XeF_2 (see Table 3), *i.e.* $\Delta IP = 2.85$ eV. With $R_1 = R_2 = \text{Xe—F} = 3.75$ bohr, $J_{4d,5p} = 0.43$, and the assumption that the charges on the two fluorine atoms are equal, one obtains $q_1 = q_2 = -1/3$, *i.e.* the charge distribution in XeF_2 can be described by $F^{-1.3}$—$Xe^{+2.3}$—$F^{-1.3}$[46].

4.3. Properties of Radicals

4.3.1. The CF Radical

In the last section we used the valence electron spectrum of NO to obtain information about the C1s spectrum of CO, in particular with regard to the assignment of the recorded bands. Conversely, we shall now deduce information about the CF radical from the O1s spectrum of CO.

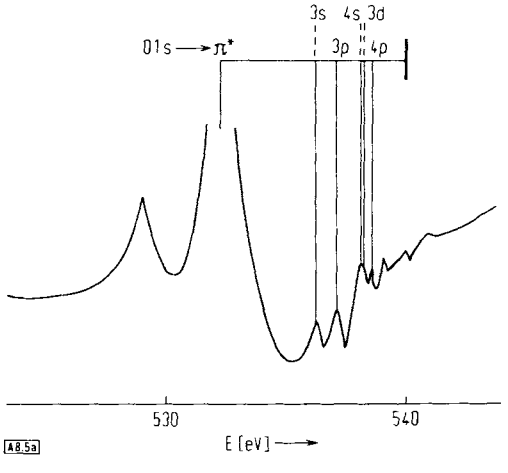

Fig. 5a. O1s X-ray absorption spectrum of CO [20].

The experimental spectrum[20] is shown in Figure 5a, with an assignment by the author[47], while Figure 5b shows a schematic potential curve diagram. The excitation of an O1s electron to Rydberg MOs or to the ionization continuum should cause practically no change in the force constant and the length of the bond. At most, *e.g.* the equilibrium distance in CO^+, as in the $(Z+1)$-analogous CF^+ (because of the

[a] HC = hydrocarbons.
[b] Unsatisfactory agreement between X-ray absorption value and ESCA value, possibly due to inaccurate calibration of the XUV spectrometer.
[c] The more recent ESCA value of *Johansson* [69] of 541.3 eV agrees considerably better with our value.

higher effective nuclear charge of O^+ or F in relation to the O atom), might be a few percent smaller than in CO. The first line[47] in the CO spectrum corresponds to the transition of the O1s electron to the lowest unoccupied MO of the antibonding π^* type. The correspondingly excited CO molecule will therefore have a slightly greater equilibrium internuclear distance and a smaller force constant, as also will the CF molecule in its ground state. The maximum approximately corresponds to the vertical transition (see Fig. 5b), which according to the Franck-Condon model, is displaced by $\varepsilon \approx \Delta^2/5.8h\nu$ toward higher energies in relation to the 0—0 transition (Δ = half-width of the absorption coefficient $\mu(E)$; $h\nu$ = vibrational quantum). Finally, it must also be taken into account that the $^2\Pi$ ground state of the CF molecule corresponds in its energy to the mean of the $^1\Pi$ and $^3\Pi$ states of the (O1s→π^*)-excited CO molecule, and is therefore lower than the observed $^1\Pi$ state of CO by the value of the exchange integral K_{O1s,π^*}. One thus obtains the following information about the CF radical:

1. The ionization potential is 9 eV. This confirms the values given by *Carroll*[48] (8.9 eV) and *Berkowitz*[49] and *Wahl*[51a] (9.2 eV), while the higher values in the range from 9.6 to 13.8 eV found by other authors[50] may be rejected.

2. An equilibrium distance of 1.3 Å and a first excitation energy to the lowest Rydberg state (3s) of 5⅓ eV are in agreement with spectroscopic measurements[48, 51] and theoretical calculations[51a].

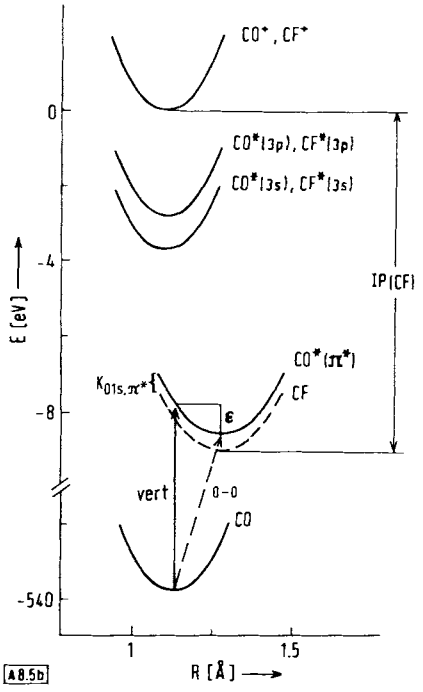

Fig. 5 b. Potential curve diagram (schematic) of CO (on core electron excitation) and CF (on valence electron excitation).

3. Higher Rydberg excitations are predicted at 6.2 eV (3p), 7.2 eV (4s), 7.4 eV (3d), 7.7 eV (4p), *etc.* Recently, *Matthews*[70] measured a band system of CF at 6.4 eV which indeed belongs to the $3p\pi\,^2\Pi$ Rydberg state.

4.3.2. The OF Radical

It should be possible to obtain information about the little-known OF radial from the O1s spectrum of O_2. The spectrum of oxygen is theoretically particularly interesting, since this is the first and so far the only case (with the exception of the homologous Te_2[33]) in which the electron interaction not only influences the intensities of the lines but also has a considerable effect on their positions, so that the spectrum can no longer be interpreted in the one-electron model.

The excited O1s electron has the half-occupied π_g MO and the strongly antibonding σ_u^* MO available in the valence shell of the O_2 molecule. The $(O1s \rightarrow \pi_g)$ excitation leads to the electronic configuration $(1s^1 \ldots \pi_g^3)$, to which the four $^{1,3}\Pi_{g,u}$ molecular states belong; of these however, on the basis of the selection rules, only the $^3\Pi_u$ state is optically attainable from the $^3\Sigma_g^-$ ground state of O_2. Of the 16 states belonging to the configuration $(1s^1 \ldots \pi_g^2 \sigma_u^*)$, only the two $^3\Sigma_u^-$ states, which differ in the coupling of the four electron spins, can be reached. If two-electron excitations did not play any part, the three transitions mentioned would be the only non-Rydberg excitations that should appear in the X-ray absorption spectrum of O_2. In addition to the measured energies, Table 4 shows the corresponding assignment of the lines, which is in agreement with the energies and intensities of the X-ray spectrum[26] and with the ionization potentials from ESCA measurements (see Table 3).

On the basis of these data, a potential curve diagram of O_2 was drawn in Figure 6, and potential curves of OF were then plotted in the diagram. From the figure we obtain an adiabatic ionization potential of 12 eV and a vertical ionization potential of $12^1/_2$ eV. *Wahl et al.*[52] have carried out an *ab-initio*

Table 4. O1s spectrum of O_2.

Peak energies [eV]	Assignment
531.9	$(1s^2 \ldots \pi^2)^3\Sigma_g^- \rightarrow (1s^1 \ldots \pi^3)^3\Pi_u$
534.9	$\rightarrow (1s^1 \ldots [\pi^2\sigma^{*2}\Sigma^-])^3\Sigma_u^-$
536.6$_5$	$\rightarrow (1s^1 \ldots [\pi^2\sigma^{*2}\Sigma^-])^3\Sigma_u^-$
539.7	$\rightarrow (1s^1 \ldots \pi^2 \cdot 3s.p)$
541.9	$\rightarrow (1s^1 \ldots \pi^2 \cdot$ higher Rydberg MOs)

calculation for the CF molecule. From this calculation and the discussion of several experimental results, they propose a value

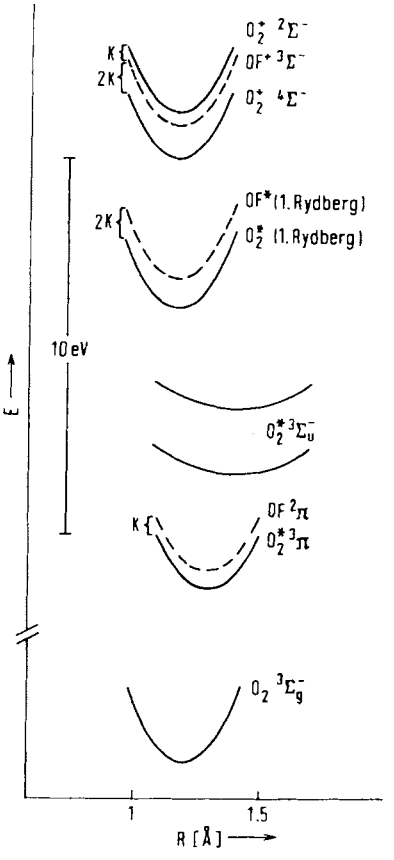

Fig. 6. Potential curve diagram (schematic) of O_2 (— · —) and OF (– – –)

of 13.1 eV for IP_{vert}. This value seems rather high, whereas the estimate of $IP_{ad} = 12.2$ eV by *Price et al.*[53] agrees well with our value. The first Rydberg excitation of CF should appear in the region of $7^2/_3$ eV.

4.3.3. The ArH Radical

Figure 7 shows the Cl 2p absorption spectrum of HCl[37] In addition to the indicated Rydberg lines, there is a very broad band at 200—204 eV, which is due to the transition to the antibonding σ^* MO[23]. If the corresponding potential curve is given by $V(R)$, the absorption coefficient μ can be represented parametrically in the semiclassical Franck-Condon model as a function of the excitation energy E by

$$\mu = \frac{\text{const} \times E}{\exp\left(M\left(\frac{\omega}{\hbar}\right)(R-R_0)^2\right)E'(R)}$$

$$E = V(R) - 0.5\,M\,\omega^2(R-R_0)^2$$

where M, ω, and R_0 are the reduced mass, the vibration frequency, and the equilibrium distance of HCl, and E' is the derivative dE/dR. $V(R)$ can be determined by fitting of μ to the experimental curve.

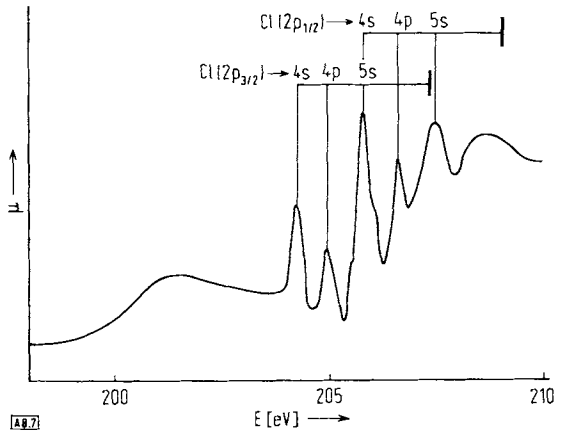

Fig. 7. Cl2p X-ray absorption spectrum of HCl [23, 37].

The result is shown in Figure 8. The $(Z+1)$-analog of this repulsive state is ArH in the ground state, whose potential curve is of interest for the interpretation of molecular collision

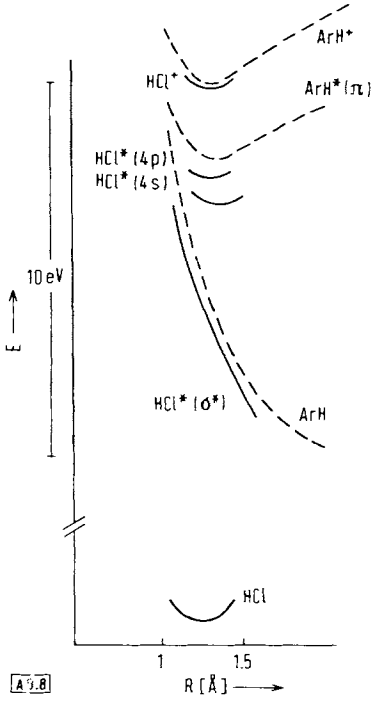

Fig. 8. Energies of HCl on $Cl2p_{3/2}$ excitation from X-ray absorption spectroscopic data (———) and potential curves of ArH obtained by *ab-initio* calculation of *Vasudevan* [23a] (– – – – –).

experiments with H and H_2 in excited states. For comparison, Figure 8 shows several potential curves found by *Vasudevan*[23a] for the ArH system by quantum-chemical *ab-initio* calculations.

4.3.4. The NH_4 and PH_4 Radicals

As a final example we shall discuss the neutral radicals of the onium ions. In contrast with the ions, practically nothing is known about the radicals. For example, it has not yet been possible even to show conclusively that H_3O and NH_4 can exist[54]; PH_4 was recently identified for the first time, though not as the free molecule, but trapped in a krypton matrix[55].

By X-ray absorption spectroscopy on the stable molecules CH_4, SiH_4, NH_3, and PH_3, it is now possible to obtain some information about the $(Z+1)$-analogous radicals NH_4, PH_4, OH_3, and SH_3[23]. According to this, the species mentioned should be thermodynamically unstable by about 1/2 eV toward the removal of H, while ClH_2 is much more unstable.

The fact that PH_4 has nevertheless been detected could be due to an activation barrier of several kcal/mol for the decomposition, as was predicted theoretically for H_3O[65]. According to the X-ray absorption spectrum of SiH_4, the metastable PH_4 with an internuclear distance of ≈ 1.7 Å and an ionization potential of just 5 eV would be expected to give a long-wave electronic absorption band in the IR at 1—1.5 μm and further bands of the Rydberg type in the violet with $\lambda < 450$ nm, which could be used for the further identification of PH_4.

According to earlier X-ray absorption measurements by *Chun*[28] on CH_4, one would have expected a considerable stability (≈ 1 eV) and an ionization potential of about $5\,^1/_2$—6 eV for NH_4, which would also correspond to the view of *Melton* and *Joy*[66]. However, a later measurement by *Chun*[56] on CH_4, which has been confirmed in the meantime by theoretical calculations[67], gives values of almost 2 eV less; NH_4 is thus thermodynamically (*i.e.* not necessarily kinetically) unstable, and the adiabatic ionization potential is approximately 4 eV. This agrees with calculations by *Bishop* for NH_4[54].

4.4. Electronic and Geometric Structure of Molecules

4.4.1. Xenon Hexafluoride

The XeF_6 molecule is an interesting test case for models for the prediction of molecular geometries. As an approximation, XeF_6 can be described by the ionic structure $Xe^{6+}F_6^-$. According to the LCAO-MO model, the two lone valence electrons remaining on the central atom are then in the totally symmetrical configuration $(5s)^2(5p)^0$, and an octahedral O_h geometry is expected for XeF_6 (see Fig. 9a). The electron

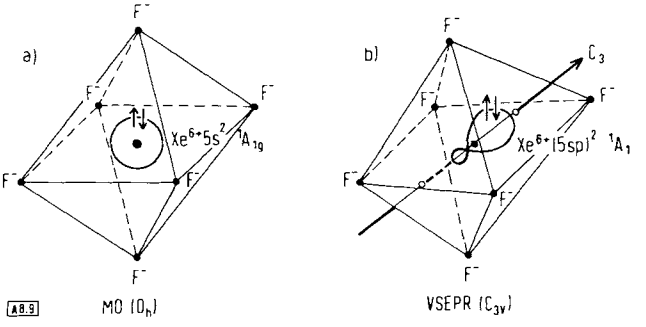

Fig. 9. Geometry and electronic structure of XeF_6. a) according to the MO model and b) according to the electron pair repulsion (VSEPR) model.

pair repulsion model[15b], on the other hand, predicts a very highly distorted geometry, in which the lone pair of electrons would be described by a doubly occupied sp hybrid orbital $(5sp^n)^2$ (see Fig. 9b).

Extensive structural investigations have been carried out on gaseous XeF_6 by electron diffraction[57]. The experimental results are not easy to interpret, but the mean symmetry of XeF_6 certainly cannot be O_h. The two most probable interpretations are as follows:

a) In principle, the electronic configuration is of the type shown in Figure 9a. However, because of the interaction with a configuration of the type shown in Figure 9b with a considerably higher energy, the asymmetric vibration modes of the XeF_6 octahedron are extremely soft, anharmonic, and coupled with one another, with the result that the molecule vibrates around the O_h symmetry, but spends by far the greater part of its time in asymmetrically distorted geometries.

b) The lowest electronically excited state of an Xe^{6+} ion is a $(5s)^1(5p)^1$ triplet. According to the three mutually perpendicular p orbitals, which are equivalent in the O_h symmetry, this state is geometrically triply degenerate. This degeneracy is lost by splitting on distortion of the octahedral geometry, and a splitting term becomes energetically more favorable (Jahn-Teller effect). It might now be possible[58] that this electronic triplet state with highly distorted geometry is situated only about 1 kcal/mol above the octahedral $5s^2$ singlet state (see Fig. 10), so that a thermodynamic equilibrium between two electronic-geometric isomers results.

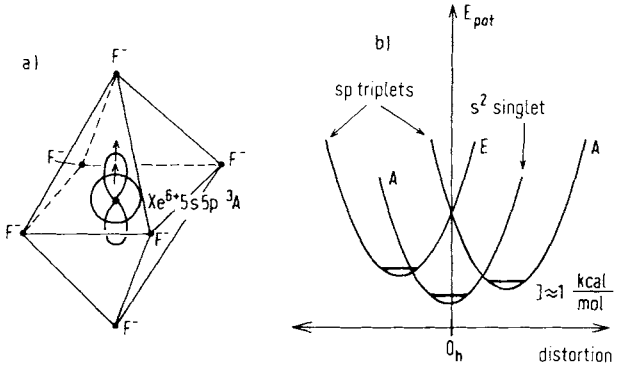

Fig. 10. a) Geometry of XeF_6 in the lowest triplet state; b) schematic potential curve diagram of XeF_6 (after *Goodman et al.*[58]).

Whereas certain hysteresis phenomena in the UV and Raman spectra[58] support possibility b, all the other experimental results (measurement of electric and magnetic moment[59]; IR, Raman, and UV spectra[58]) are compatible with both interpretations[26].

According to interpretation a (see Fig. 9a), the 5s shell is doubly occupied, whereas according to interpretation b (see Fig. 10a) the 5s shell has a vacancy in the thermally populated 5s5p state. Consequently an electronic transition $4p \rightarrow 5s$ should be found in the X-ray spectrum only in case b. Other excitations of a Xe4p electron are fundamentally ruled out; transition to the 5p-AO is forbidden by the spectroscopic selection rules, and transitions to the higher orbitals of the Rydberg type such as 3d, 6s, *etc.* are extremely weak according to the pseudopotential model[44]. To decide between cases a and b, we investigated the X-ray absorption of XeF_6 in the 150 eV region[60], but were unable to find any Xe4p excitation. In our opinion, therefore, it is more likely that XeF_6 is present in the gas phase as a single species with O_h symmetry corresponding to the simple MO model, and undergoes extremely large deformation vibrations toward the geometry predicted by the VSEPR model, rather than that an isomer mixture is present.

4.4.2. Ligand Field Splitting of Core Orbitals

If transition metal atoms are incorporated into molecules, especially complex molecules, the fivefold degeneracy of the d orbitals is eliminated by the ligand field splitting. The same effect should also occur in principle for the d core orbitals of heavy atoms, though it may be expected to be much less than in the case of d valence AOs, since the latter naturally interact much more strongly with the ligands. Whereas the resolving power of the ESCA method has not so far been sufficient for detection of the effect, it was recently detected for the first time by X-ray absorption spectroscopy on the xenon fluorides[25]. Figure 11a shows part of the X-ray absorption spectrum of XeF_2, and Figure 11b shows the one-electron level diagram derived from the spectrum. The measured split-

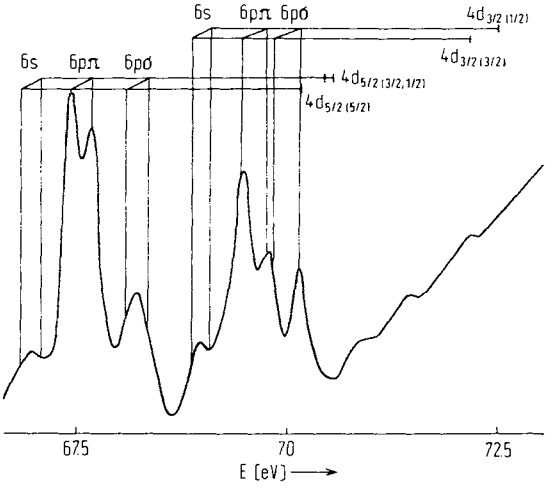

Fig. 11a. Xe4d Rydberg spectrum of XeF_2 [25].

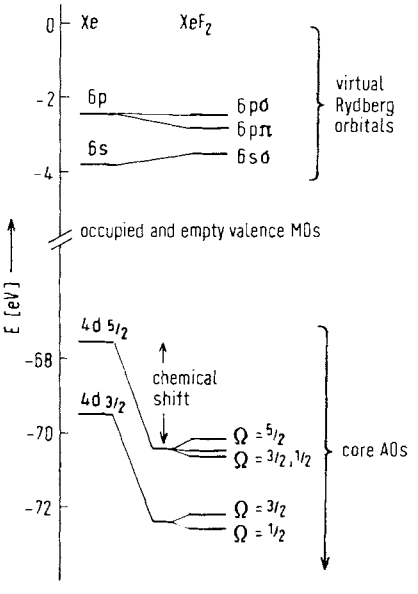

Fig. 11b. One-electron levels of xenon and XeF_2.

tings of 0.24 and 0.35 eV for the two $Xe4d_{5/2}$ and $Xe4d_{3/2}$ levels can be reproduced very satisfactorily in an electrostatic ligand field model using the charge distribution $Xe^{2/3}(F^{1/3-})_2$ as derived in Section 4.2 from the mean chemical shift of the levels. The reason why the electrostatic model is found to be quantitatively much better here than for the transition metal complexes is that overlap and delocalization effects are of practically no importance for core orbitals.

4.4.3. Structure of Virtual Orbitals

From the transitions of a core electron to the ionization continuum that can be recorded by ESCA, primary information is obtainable only for the core orbitals. On the other hand, information can be obtained about the unoccupied orbitals in the ground state, too, from the transitions of the type "core AO → virtual MO" that give rise to the X-ray absorption spectrum. The unoccupied orbitals in the ground state are not only important for excited molecular states, but also allow deductions about the occupied valence MOs and play a part in kinetic transition states.

The occupied and unoccupied MOs of the valence shell are complementary to one another. These ideas were used in Section 4.4.1 to deduce the electronic structure of the ground state of the XeF_6 molecule from its X-ray absorption spectrum. *Sadowski*[61] used a similar principle to determine the polarity of the σ bond in HCl from the X-ray absorption spectrum. The AO mixing coefficients of the MOs were obtained in this case from measured *absorption intensities*. The "experimental" result for the bonding MO was (0.5 H1s + 0.7 Cl3p), which is in satisfactory agreement with the theoretically calculated MO

The antibonding force of a virtual MO can be calculated from the recorded *band shape*. An example of this was given in Section 4.3.3 in the discussion of HCl and ArH, where we were able to deduce a dissociative potential curve from an extremely broad and asymmetric absorption band. The narrower (order of magnitude 1 eV) and nearly symmetrical bands, on the other hand, indicate that the core electron promoted to an unoccupied valence MO causes only a lengthening and weakening of the bond, as in the case of the O1s spectrum of CO discussed above or the xenon fluorides discussed in detail by *Schwarz*[25].

An interesting type of virtual orbital has been discovered in compounds in which a central atom is surrounded by several strongly electronegative ligands in a cage-like manner. The prototype of such molecules is SF_6, whose S2p spectrum is shown in Figure 12. Unusual features of this spectrum are: 1. the extremely low intensity of the Rydberg series and 2. the occurrence of fairly broad and very intense absorption bands above the ionization thresholds. Because of the high electron density in the environment of the fluorine atoms, a repulsive potential acts here on an additional electron, both because of the electrostatic Coulomb repulsion and because of the Pauli principle (pseudopotential effect)[62, 44]. Thus the six F^- ligands form a potential wall around the sulfur atom, as shown schematically in Figure 13. The low intensity of the Rydberg transitions is explained by the fact that the excited core electron of the sulfur must first tunnel through this potential wall in order to reach an outer orbital. In particular, the electron can be excited to states that correspond in their energy to a free, ionized electron, but it initially remains trapped in the interior of the molecule by the potential cage until it tunnels to freedom after a mean lifetime τ. These excitations are actually transitions to "inner" molecular orbitals, as is shown by the fact that the corresponding lines are also observed unchanged in the X-ray spectrum of solid SF_6[64], whereas experience shows that this is not so in the case of transitions to "outer" Rydberg orbitals.

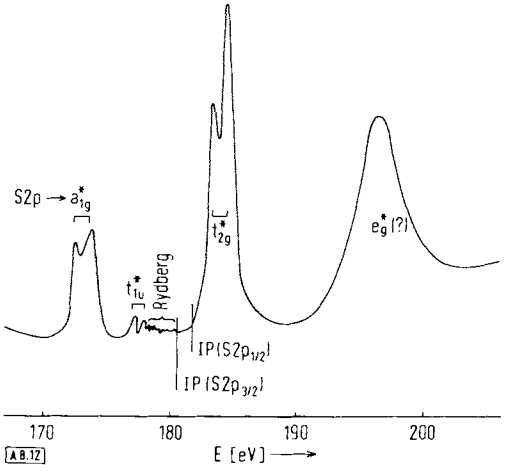

Fig. 12. S2p absorption spectrum of SF_6 [20, 45].

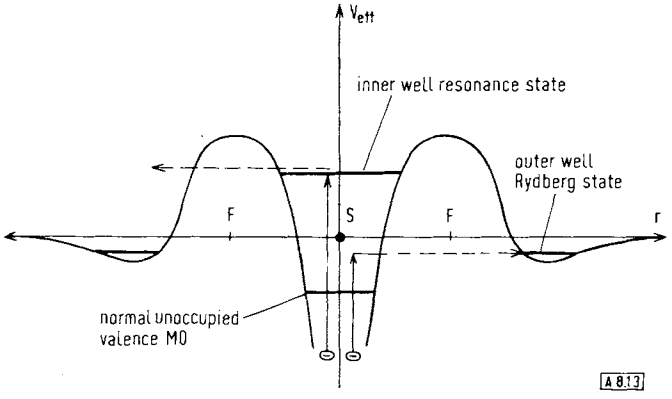

Fig. 13. Effective molecular potential in SF_6 (schematic).

The half-width of the two bands denoted by t_{2g}^* and e_g^* is not due only to the Franck-Condon broadening, but also results from the natural line width ΔE_{nat} caused by the very short lifetime τ of these resonance states in accordance with the formula

$$\Delta E_{nat} \times \tau \approx \hbar$$

A line width of 1 eV corresponds to a mean lifetime of only about 10^{-15} s, whereas the period of molecular vibrations is in the region of 10^{-13} to 10^{-14} s. The existence of the potential cage also leads to the capture of free electrons with low energies by SF_6. In fact, SF_6 has an extremely high electron capture cross section[63], which is also utilized in technical applications.

4.5. Spin-Orbit Coupling Effects

We would like to end our survey of the use of X-ray absorption spectroscopy with a brief word about spin-orbit coupling. Though *spin-orbit splitting of core orbitals* is of interest, knowledge about this splitting is rather scarce at present. Table

5 shows the spin-orbit splittings derived from the X-ray absorption spectra of the molecules mentioned in Table 3.

Table 5. Spin-orbit splitting of core orbitals of bound atoms.

Atom	AO	ΔE [eV]
Si	2p	0.6_2
P	2p	0.9_0
S	2p	1.1_5
Cl	2p	1.6_0
Ge	2p	31.4
	3p	≈ 5
Te	4d	1.48
I	4d	1.68
Xe	4d	1.93

In the case of the 4d orbital of xenon, an accurate X-ray absorption spectroscopic results exists for elementary xenon[18]: 1.97 eV. Though the Xe4d AO is a relatively high core orbital and is already appreciably influenced by the strongly polar bonds in the xenon fluorides (cf. the ligand field splittings indicated in Section 4.4.2), the difference in spin-orbital splitting between free and bound xenon is practically no greater than the experimental uncertainty of a few 10^{-2} eV. The 2% lower value for the molecules at most indicates a very slight delocalization of the Xe4d AOs in the molecule. In any case, it may be assumed in general that spin-orbit splitting of atomic core orbitals is independent of the chemical environment, and this is why the molecule in question has not been indicated in Table 5.

Spin-orbit couplings in the valence orbitals of molecules are naturally much smaller, and they are therefore often disregarded. For example, there have so far been no *ab-initio* calculations for molecules with heavy atoms in which the spin-orbit coupling was explicitly taken into account. The significance of spin-orbit coupling to important chemical problems such as stability, reactivity, and polarity of bonds is not very clear. In this connection, growing interest is being shown in the measurement of the spin-orbit splitting of unoccupied valence MOs. An effect of this type has so far been detected by X-ray absorption spectroscopy only for XeF_4[25] and XeF_6[60]; according to this work, the doubly and triply degenerate unoccupied valence orbital of the e_u or t_{2u} type has a spin-orbital splitting of 0.8 to 0.9 eV, respectively.

Quantitative Cyclotrimerization of 3,3-Dimethylcyclopropene to "Hexamethyl-*trans*-σ-trishomobenzene"[1]

By *Paul Binger, Gerhard Schroth*, and *John McMeeking*[*]

In the course of our studies on the behavior of thermally stable unsaturated three-membered cyclic hydrocarbons in the presence of transition metal complexes[2] we have also investigated the reaction of 3,3-dimethylcyclopropene *(1)*[3] at palladium(0) catalysts. Only the cyclodimerization of 1-methylcyclopropene in the presence of palladium(II) catalysts has hitherto been described[4].

In the presence of catalytic quantities of tetrakis(triphenylphosphane)palladium(0)[5] compound *(1)* undergoes *quantitative* trimerization to crystalline hexamethyl-*trans*-σ-trishomobenzene *(2)*[1], m.p. 38 °C.

(1) *(2)*

Mass spectrometry indicates a molecular weight of 204 for *(2)*. The sharply structured IR spectrum points to a rigid carbocycle and exhibits no C=C stretching vibrations. The precise molecular structure of *(2)* follows from the ^{1}H-NMR spectrum (Fig. 1): the presence of four signals for the eighteen methyl protons in the ratio 3:6:6:3 and three signals for the six three-membered ring protons in the ratio 2:2:2 reveal a *trans* configuration (C_s symmetry). The four "*cis* protons" A,A',B,B' exhibit coupling constants of $J_{AA'} = 10.1$, $J_{AB} = 9.0$, $J_{AB'} = -0.5$, and $J_{BB'} \approx 0$ Hz (determined with the aid of the iteration program LAME; mean error 0.08 Hz). The coupling constant between the "*trans* protons" X,X' and B,B' amounts to only *ca.* 0.5 Hz owing to almost complete orthogonality; in the spectrum this coupling is recognizable only as line broadening of the two pertinent signals. The three-dimensional X-ray structure analysis[6] confirms our ^{1}H-NMR results.

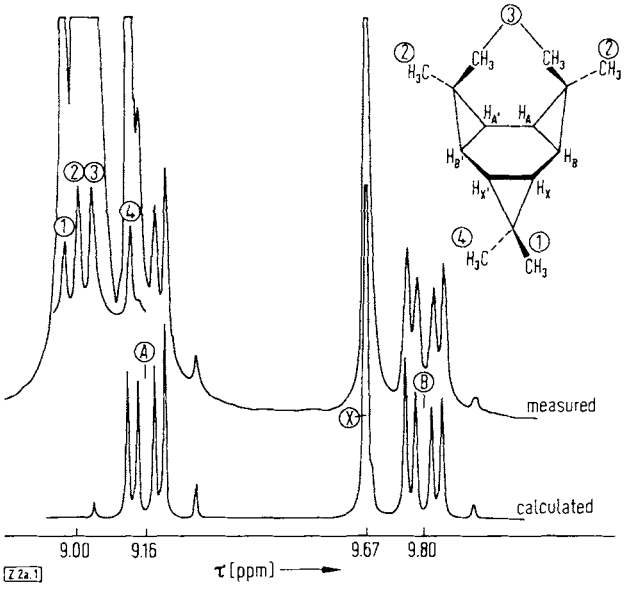

Fig. 1. ^{1}H-NMR spectrum (100 MHz; in benzene, 20 °C) of hexamethyl-*trans*-σ-trishomobenzene *(2)*.

Above *ca.* 120 °C compound *(2)* isomerizes to a homogeneous $C_{15}H_{24}$ hydrocarbon containing one C=C bond whose structure is currently under study.

To our knowledge, the cyclotrimerization of *(1)* to *(2)* is the first example of a smooth cyclohexane ring formation from an alkene and provides a new entry to "σ-trishomobenzene" derivatives[7].

In the presence of triphenylphosphane-modified nickel(0) complexes, compound *(1)* undergoes preferential dimerization

[*] Dr. P. Binger, G. Schroth, and Dr. J. McMeeking
Max-Planck-Institut für Kohlenforschung

to *trans*-3,3,6,6-tetramethyltricyclo[3.1.0.0^{2,4}]hexane; a small amount of *(2)* is also formed.

Procedure:

Compound *(1)* (8 g, 118 mmol) is added dropwise over 2 h to a stirred solution of tetrakis(triphenylphosphane)palladium(0) (0.41 g, *ca.* 0.36 mmol) in benzene (25 ml) with intermittent cooling to 40–45 °C. After stirring for another 2 h all the components that are volatile at 0.1 torr are drawn off and the residue fractionally distilled. Apart from benzene, one obtains 8 g (100%) of *(2)* (99.2% pure according to GC), b.p. 76 °C/0.5 torr, m.p. 38 °C.—The catalyst which is recovered as a brownish yellow powder is still active for further trimerizations.

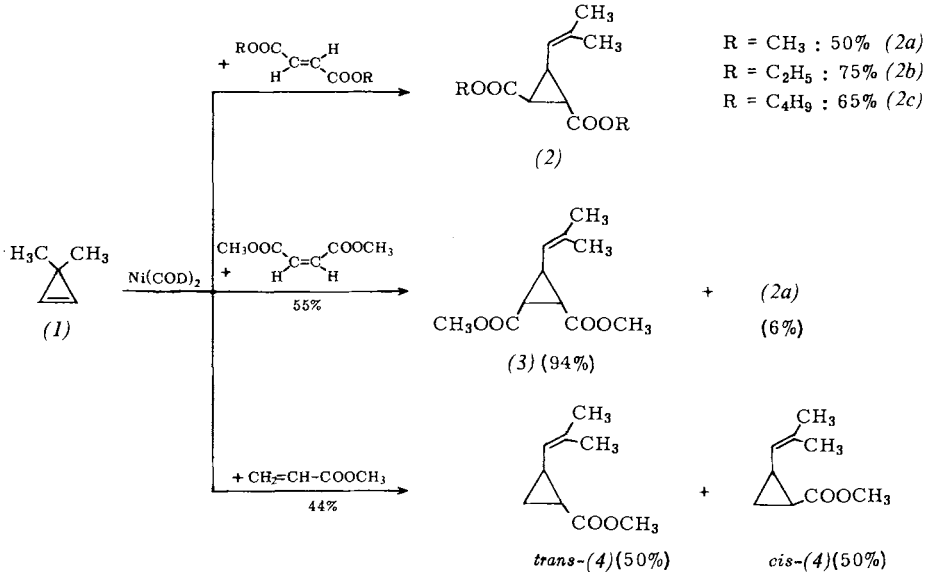
[1] 3,3,6,6,9,9-Hexamethyl-*cis,cis,trans*-tetracyclo[6.1.0.0^{2,4}.0^{5,7}]nonane.



[2] *P. Binger*, Angew. Chem. *84*, 352 (1972); Angew. Chem. internat. Edit. *11*, 309 (1972); Synthesis *1973*, 427; *P. Binger* and *J. McMeeking*, Angew. Chem. *85*, 1053 (1973); *86*, 518 (1974); Angew. Chem. internat. Edit. *12*, 995 (1973); *13*, 466 (1974).

and the cyclotrimerization of *(1)* at palladium(0) complexes[4] have been reported.

We found that with nickel(0) catalyst, *e.g.* Ni(COD)$_2$[5], compound *(1)* affords benzene-soluble oligomers consisting mainly of chains of the type

(^{1}H-NMR). Triphenylphosphane-modified nickel(0) compounds preferentially convert *(1)* into a cyclodimer[4]. On the other hand, reaction of *(1)* with an excess of dialkyl fumarate in the presence of nickel(0) catalysts results in codimerization to give up to 75% yield of pure dialkyl 3-(2-methyl-1-propenyl)cyclopropane-*trans*-1,2-dicarboxylate *(2)*. In contrast, dimethyl maleate and *(1)* afford *ca.* 94% pure dimethyl *trans*-3-(2-methyl-1-propenyl)cyclopropane-*cis*-1,2-dicarboxylate *(3)* in 55% yield together with 6% of *(2a)* which is formed owing to ready C=C isomerization at nickel(0) catalysts.

Codimerization of 3,3-Dimethylcyclopropene with Ethylenecarboxylic Esters at Nickel(0) Catalysts

By *Paul Binger* and *John McMeeking*[*]

After methylenecyclopropane[1], we have now also investigated the behavior of 3,3-dimethylcyclopropene *(1)*[2] in the presence of nickel(0) complexes. So far only the cyclodimerization of 1-methylcyclopropene at palladium(II) catalysts[3] Methyl acrylate and *(1)* react at a nickel(0) catalyst to form a *ca.* 44% yield of an equimolar mixture of methyl *cis*- and *trans*-2-(2-methyl-1-propenyl)cyclopropanecarboxylate *(4)* alongside *ca.* 10% of a 2:1 mixed trimer [exp. MW 240 (MS)] of acrylic ester and *(1)*. Higher molecular weight products are also formed.

The composition and structure of the substituted alkyl cyclopropanecarboxylates *(2)* to *(4)* were deduced from their IR, mass, and above all their ^{1}H-NMR spectra. The *cis* or *trans* orientation of the substituents in *(3)* and *(4)* followed from the position of the vinyl proton signal[6] (*e.g. trans-(4)*: $\tau = 5.40$ ppm; *cis-(4)*: $\tau = 4.92$ ppm) and from the coupling constants of the ring protons[7] (*e.g. (3)*: $J_{cis} = 8.5$ Hz; $J_{trans} = 6.2$ Hz).

The substituted cyclopropane derivatives *(2)* to *(4)* are presumably formed from *(1)* while π-bonded to nickel(0) by cleavage of the C^1—C^3 bond, possibly *via* a transient complex-bonded carbene species.

Diethyl 3-(2-methyl-1-propenyl)cyclopropane-trans-1,2-dicarboxylate (2b):

Compound *(1)* (6.4 g, 94 mmol) is added dropwise over 1.5 h to the red solution of Ni(COD)$_2$ (1.1 g, 4.2 mmol) in diethyl

[*] Dr. P. Binger and Dr. J. McMeeking

433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

fumarate (59.8 g, 347 mmol) at room temperature. During the reaction the temperature of the mixture is kept at 35—40 °C by water cooling. After stirring for 1 h, all the components that are volatile at 115 °C/0.1 torr are distilled off to leave 2.1 g of a black viscous residue. Fractional distillation affords 42.7 g of 96% pure (GC) diethyl fumarate and 17.5 g of 93.8% pure (GC) *(2b)*, b. p. 63—65 °C/0.001 torr, which still contains diethyl fumarate (1.6%) and six other unknown compounds (4.6%).

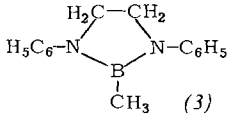
1,3-Diphenyl-2,4,5-trimethyl-1,3,2-diazaboroline

By *Lothar Weber* and *Günter Schmid*[*]



Diazaborolines are derived from pyrroles by formal isosteric replacement of a C=C by a BN group and are isoelectronic with the cyclopentadienide ion. They therefore warrant attention as potential complex ligands. The first representative of this class, 1,3-dimethyl-2-phenyldiazaboroline[1], has been described in a recent publication. We have now found a novel elegant preparation of these heterocycles in the synthesis of 1,3-diphenyl-2,4,5-trimethyl-1,3,2-diazaboroline *(1)*.

Reduction of the boronium salt *(2)* with sodium amalgam in diethyl ether affords *(1)* in about 50% yield.

(2) *(1)*

The starting material *(2)* is obtained as a reddish-brown solid, m. p. 152 °C (dec.) by reaction of *N,N'*-diphenylbiacetyldiimine with methyldibromoborane in ether. The salt is readily soluble in polar solvents; a 1.71×10^{-3} M solution in CH_3CN

(3)

displays a specific conductivity of $2.03 \times 10^{-5}\,\Omega^{-1}\,cm^{-1}$, thus indicating extensive dissociation. The structure of the cation follows from its ^1H- and ^{11}B-NMR spectra and from reduction to *(1)*.

The diazaboroline *(1)* can be isolated as a yellow liquid having the viscosity of honey, b. p. 112—115 °C/0.05 torr. It is soluble in all inert organic solvents and exhibits a pronounced tendency to crystallize; however, complete crystallization has hitherto not been observed. Cryoscopic molecular-weight determination gives a value of 244 (calc. 262.11). Compound *(1)* is extremely sensitive to air (decomposition with dark coloration).

The ^1H-NMR spectrum (C_6D_6, TMS internal standard) contains three sharp signals in the intensity ratio 3:6:10 at −0.57 (B—CH_3), −1.92 (C—CH_3), and −7.20 ppm (C_6H_5). The chemical shift ^{11}B amounts to −28.0 ppm (relative to BF_3 etherate). Comparison of this value with that of the "nonaromatic" compound *(3)*[2], *i.e.* −33.4 ppm, indicates a significantly stronger shielding of the boron atom in the ring system *(1)*.

Boronium salt (2):

CH_3BBr_2 (1.95 g, 10.0 mmol) is dissolved with cooling in anhydrous ether (100 ml) and added dropwise to vigorously stirred ether (500 ml) simultaneously with a solution of biacetyldianil (2.48 g, 10.0 mmol) in ether (100 ml). The sparingly soluble reddish brown product is filtered off, washed with ether, and dried *in vacuo*: 4.13 g of *(2)* (93.3%).

1,3-Diphenyl-2,4,5-trimethyl-1,3,2-diazaboroline (1):

Sodium amalgam (180 g, 1%) is added to a suspension of *(2)* (9.49 g, 22.5 mmol) in ether (150 ml). After stirring for 24 h at room temperature the orange-yellow solution is separated from mercury and NaBr and the ether stripped off *in vacuo*. Distillation of the oily residue at 112—115 °C/0.05 torr yields 3.03 g of *(1)* (51.3%).

Preparation and Properties of Cycloocta[1,2-*b*:4,3-*b'*:5,6-*b''*:8,7-*b'''*]tetrathiophene[1][**]

By *Bernd Greving*, *Annegret Woltermann*, and *Thomas Kauffmann*[*]

Formal linkage of arenes[2] to macrocycles yields cyclopolyarenes. It can hardly be doubted that the heterocyclic representatives of this class will include members exhibiting pronounced nucleophilic or electrophilic activity[3] if the cyclic systems are composed exclusively of nuclei of one category, as in the cyclotetraarenes *(1)* and *(2)*[4]. Wherever this does not apply, a certain degree of compensation of the nucleophilic and electrophilic properties typical of the individual nuclei may be expected[5,6].

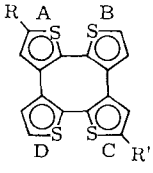
In order to cast some light upon the situation we have synthesized the colorless cyclotetraarene *(1)* [m.p. 254 °C (from chloroform/ether 2:1)] as shown from the dibromides *(3)*[7] (route A) and *(4)*[8] (route B)[9]. The compound *(1)*, which is obtained in 25 and 18% yield, respectively, is shown to be nonplanar by molecular models; instead it has the spatial structure *(1a)*.



(3) *(1a)* *(4)*

According to the ^{1}H-NMR spectrum [($CDCl_3$, TMS, 100 MHz), 2 doublets at $\delta = 6.93$ (H^β) and 7.34 (H^α) (1:1); $J_{\alpha,\beta} = 5.2$ Hz] the nuclei of *(1)* are typical π-electron excess nuclei (thiophene: $\delta = 7.00$ to 7.40). They undergo mutual electronic interaction, for in the UV spectrum (10^{-4} M chloroform solution) the absorption maximum exhibits a bathochromic shift in comparison with thiophene [*(1)*: $\lambda_{max} = 278$ nm ($\varepsilon = 18000$); thiophene: $\lambda_{max} = 239$ nm ($\varepsilon = 5600$)]. Since the absorption maximum lies between that of 2,2'-bithienyl [$\lambda_{max} = 297$ nm ($\varepsilon = 12300$)] and that of 3,3'-bithienyl [$\lambda_{max} = 263$ ($\varepsilon = 19000$)], it may be assumed that the mesomerism is essentially limited to two neighboring nuclei. As in the case of the two bithienyls, the spectrum of *(1)* contains an additional strong band at 242 nm ($\varepsilon = 11000$) indicating a separate electronic transition in the individual thiophene nuclei.

(5)

(6), R = Li, R' = H
(7), R = 4-Pyrimidinyl, R' = H
(8), R = R' = 4-Pyrimidinyl

While hydrogen-lithium exchange has not yet been accomplished in open-chain tetraarene *(5)*[10], compound *(1)* could be smoothly lithiated. The reaction with 1 mol of butyllithium in THF at 0 °C (1/2 h) proceeded almost quantitatively. The monolithium compound *(6)* is probably the major product since subsequent reaction with 1.2 mol of pyrimidine (3 h at 0 °C and then 1 h at 65 °C) and oxidation of the hydrolyzed reaction products with $KMnO_4$ in acetone at 20 °C (part of the product *(7)* can already be detected prior to oxidation) afforded, apart from unchanged *(1)* (52%), the yellow monopyrimidinyl derivative *(7)* [m.p. 245—247 °C (from ethanol/chloroform 1:1); yield 79% based on reacted *(1)*] as the main product, as well as a likewise crystalline dipyrimidinyl derivative [m.p. 205—207 °C (from ethanol); yield 9% based on reacted *(1)*]. It has yet to be decided whether the second substituent in the dipyrimidinyl derivative is bonded to nucleus C as shown in *(8)* or whether it is located in the α position of nucleus B or D. The exceptionally small amounts obtained in the case of two further yellow substances (presumably also dipyrimidinyl derivatives) have so far obstructed their preparation in a pure state.

In the lithium compound *(6)*, in its pyrimidine adduct, and in *(7)*, one of the four thiophene nuclei is modified electronically by the substituent. Since dipyrimidinyl derivatives are apparently formed in much smaller quantities than the monopyrimidinyl derivative, this modification seems to be transmitted electronically to the remaining three thiophene nuclei thus preventing the second substitution.

Apart from the reservation made above for the dipyrimidinyl derivative, the structures of the new compounds are established by their spectra (MS, ^{1}H-NMR, UV) and elemental analysis.

[1] Protophanes and Polyarenes, Part 16.—Part 15: *Th. Kauffmann* and *H.-H. Kniese*, Tetrahedron Lett. *1973*, 4043.

[2] In this communication the term "arene" refers to monocyclic aromatic hydrocarbons and corresponding heterocycles.

[3] The expressions nucleophilic and electrophilic refer here to the predominating behavior taken over the known reactions.

[4] In the cyclic systems formally composed of 2p/2π electron systems [5], the stability and tendency to undergo regeneration (after addition of reagents) strongly depend upon the number of groups used in their construction (Hückel rule). As examples of such groups we may cite —O—, —S—, —N<, >C=C<, >C=N—. In contrast, the properties of cyclopolyarenes should hardly be influenced by the number of units since the units themselves have aromatic character, and, as found for polyphenylenes [cf. *H. A. Staab* and *F. Binnig*, Chem. Ber. *100*, 293 (1967)] will no doubt generally retain it on linkage.

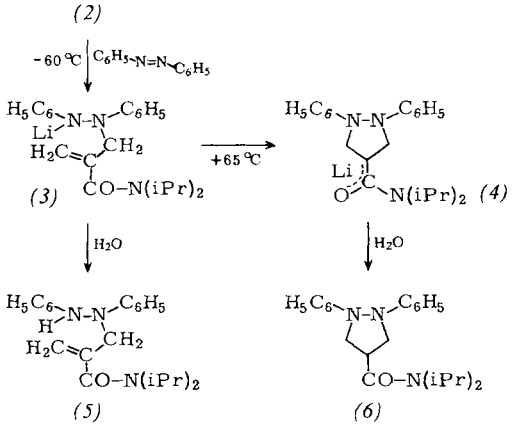
1,3-Anionic Cycloadditions of 2-(N,N-Diisopropylcarbamoyl)allyllithium with a Two-Step Mechanism[1][**]

By *Willi Bannwarth*, *Rudolf Eidenschink*, and *Thomas Kauffmann*[*]

Reaction of a solution of 1 mol of *N,N*-diisopropylmethacrylamide *(1)* (m.p. 47—47.5 °C) and 2 mol of *trans*-azobenzene in THF at −60 °C with 1 mol of lithium diisopropylamide affords 2-(*N,N*-diisopropylcarbamoyl)allyllithium *(2)* for which the structures *(2a)* and *(2b)* would appear most likely. The lithiation of *(1)* presumably proceeds at a temperature as low as −60 °C because hydrogen-metal exchange is promoted by the γ-N atom of the carboxamide group ("γ effect"[2]). Compound *(2)* adds to the azobenzene present, since workup of the reaction mixture after hydrolysis with water gave a 53% yield of 2-(1,2-diphenylhydrazinomethyl)-*N,N*-diisopropylacrylamide *(5)* (m.p. 110—111 °C). If the reaction is carried out at 65 °C, slow formation of the anionic cycloadduct *(4)* occurs *via* a route that can be shown[3] to involve the interme-



[*] Dipl.-Chem. W. Bannwarth, Dr. R. Eidenschink, and Prof. Dr. Th. Kauffmann

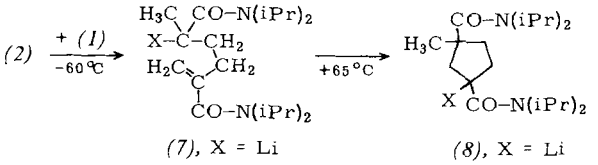
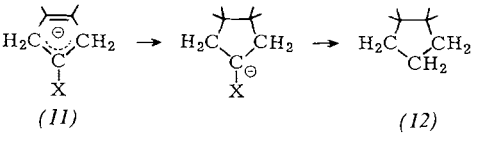
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



(1) *(2a)* *(2b)*

diate *(3)*. After addition of water, a 65% yield of *N,N*-diisopropyl-1,2-diphenylpyrazolidine-4-carboxamide *(6)* (m.p. 140 to 140.5 °C) could be obtained. The same product could be prepared by reaction of *(5)* with 1 mol of lithium diisopropylamide at 65 °C in THF and subsequent hydrolysis with water (92%).



(2) *(3)* *(4)* *(5)* *(6)*

If the above reaction is carried out at −60 °C in the *absence of trans-azobenzene*, Michael addition of *(2)* to *(1)* affords the adduct *(7)*, for a 98% yield of bis(*N,N*-diisopropyl)-2-methyl-5-methylenehexanediamide *(9)* (oil purified by column chromatography; b.p. 135 °C/10 torr, $n_D^{20} = 1.4760$) was obtained after addition of water to the reaction mixture. The corresponding reaction at +65 °C leads—demonstrably *via* the open-chain adduct *(7)*[3]—to the anionic cycloadduct *(8)*, as shown by the isolation of bis(*N,N*-diisopropyl)-1-methylcyclopentane-1,3-dicarboxamide *(10)* (m.p. 114.5—116 °C) in 27% yield.

(7), X = Li *(8)*, X = Li
(9), X = H *(10)*, X = H

We have not yet accomplished cycloaddition of the lithium derivative *(2)* to olefins other than *(1)* to any significant extent. Compound *(2)*, which appears to be favored by having a relatively easily degradable auxiliary group —CON(*i*Pr)$_2$ permitting the cycloaddition process and bears no other substituents[4], therefore cannot be regarded as the reagent we are seeking in order to perform "cyclopentanation" of CC double bonds according to *(11)* → *(12)*. It may, however, represent a milestone on the way to this goal and may prove useful as a reagent in the synthesis of heterocycles.

(11) *(12)*

In the above reaction a 1,3-anionic cycloaddition has been shown for the first time to proceed in a stepwise, *i.e.* nonconcerted, manner.

(6a). The spectra of *(3a)*, *(2a)*, and chlorobutatriene[2] were used for comparison.

The ^{13}C-NMR spectrum confirmed the structural proposal, in particular on comparison with the spectrum of butatriene[4]. The UV spectrum [λ_{max}(ethanol) = 258 nm ($\varepsilon \geq 10^4$) also accords with the structure given. The spectra of butatriene[5] and *(2a)*, PF_6 instead of Cl[6], were used for comparison.

Reaction of the salts *(6)* with nucleophiles proceeds *via* 1,4-addition, formally yielding the monosubstitution products of the salts *(3)*. Cyclopentadiene affords propadienylsulfonium salts[7].

S,S-Dimethyl-S-(4-phenylthio-2-butynyl)sulfonium hexafluorophosphate (8c):

A solution of sodium (0.90 g, 0.039 mol) in anhydrous methanol (50 ml) is added dropwise to a stirred solution of *(3a)* (9.88 g, 0.04 mol) in anhydrous methanol (800 ml) at −40 °C over a period of 30 minutes. The colorless solution containing some unreacted *(3a)* shows pH ≈ 6.5.—Thiophenol (5.51 g, 0.05 mol) is then added and the reaction mixture is allowed to warm to room temperature within 3 hours. The solvent is distilled off and the solid residue is extracted with dichloromethane and freed from sodium chloride and traces of *(3a)* by filtration. Removal of the solvent and drying affords 9.80 g (95 %) of *S,S*-dimethyl-*S*-(4-phenylthio-2-butynyl)sulfonium chloride *(8a)*.—An aqueous solution of *(8a)* (1.00 g) is treated with a slight excess of ammonium hexafluorophosphate. Recrystallization of the precipitate from ethanol yields 1.20 g [80% based on *(3a)*] of colorless crystals decomposing in the range 52—53 °C.

Stable Propadienylsulfonium Salts by Cycloadditions with Butatrienylsulfonium Salts[**]

By *Heinz Braun* and *Gottfried Strobl*[*]

Propadienylsulfonium salts ("allenesulfonium salts") are accessible in equilibrium mixtures by isomerization of 2-propynylsulfonium salts and can be characterized by spectroscopy[1]. The salts undergo highly regiospecific addition with nucleophiles and are interesting intermediates[2, 3]. Propadienylsulfonium salts generated *in situ* have been proposed as reagents for peptide syntheses[1] and postulated as intermediates in fragmentations[4] and rearrangements[5, 6]. To our knowledge, no representative of this class has yet been isolated in pure form. In this communication we wish to report the preparation and characterization of stable propadienylsulfonium salts.

Whereas tetraarylbutatrienes add cyclopentadienones to the central double bond in Diels-Alder reactions[7], the terminal double bond acts as dienophilic component in diene syntheses of butatrienylsulfonium salts *(1)*[8] with cyclopentadiene.

(a), R = CH_3, X = Cl; *(c)*, R = CH_3, X = PF_6;
(b), R = C_2H_5, X = Br; *(d)*, R = C_2H_5, X = PF_6

[4+2] Cycloaddition of cyclopentadiene and *(1)* affords mixtures of the crystalline salts *(2)* (≈ 50 %) and *(3)* (≈ 50 %) in yields of about 90 %.

(2a)/(3a) and *(2b)/(3b)* are soluble in water, alcohols, and chloroform, and can be recrystallized from ethanol/ether. *(2c)/(3c)* (dec. 140—150 °C) and *(2d)/(3d)* (dec. 80—85 °C) are stable at room temperature and yield correct analytical data. Structural assignment of *(2a)/(3a)* is based on the following findings:

1) ^{1}H-NMR spectrum (60 MHz, $CDCl_3$, TMS internal standard): δ = 7.3—7.1 (m, $^+$S—CH=), 6.5—6.0 (m, 5-H + 6-H), 3.6 (mc, 1-H), 3.45 (s) and 3.37 (s, total of 6H, $(CH_3)_2S^+$ of *(2a)* and *(3a)*, respectively), 3.2 (mc, 4-H), 2.7 (mc, 3-H''), 2.1 (mc, 3-H'), 1.6 (mc, 7-H' + 7-H''). Only the signals of the dimethylsulfonio groups can be evaluated separately for *(2a)* and *(3a)*, the other signals of corresponding protons of *(2a)* and *(3a)* appear together in the spectrum of the mixture.

2) UV spectrum (ethanol): Continuous absorption in the range 35000—50000 cm^{-1} with a maximum at 50000 cm^{-1} ($\varepsilon = 3.7 \times 10^4$) preceded by a shoulder at 40000 cm^{-1} ($\varepsilon = 3 \times 10^3$).

3) IR spectrum (KBr): 1960 ($\nu_{C=C=C}$), 1625 cm^{-1} ($\nu_{C=C}$). No absorption in the region 2260—2100 cm^{-1} ($\nu_{C\equiv C}$).

4) The ^{13}C-NMR spectrum confirms the proposed structure (see also ref.[9]). The appearance of separate signals for *(2a)* and *(3a)* demonstrates that both diastereoisomers were formed.

(RS)- and (SR)-S,S-Dimethyl-S-2-(5-norbornen-2-ylidene)-vinylsulfonium chloride (2a) and (3a)

A 1.5 M solution of sodium methoxide (57 ml) is added dropwise to a stirred suspension of *S,S,S',S'*-tetramethyl-2-butynylenedisulfonium chloride[8] (22.2 g, 0.09 mol) in anhydrous methanol (700 ml) at −40 °C over a period of 2 hours. After addition of cyclopentadiene (33.0 g, 0.5 mol) and 15 hours' stirring at −40 °C, the reaction mixture is warmed to room temperature within 8 h. The solvent is distilled off (rotary evaporator, bath temp. 30—40 °C) and the residue extracted with chloroform and freed from sodium chloride by filtration. Removal of the solvent and drying (25 °C at 0.1 torr) afforded 17.5 g (95 %) of a mixture of *(2a)* and *(3a)* which was shown to be pure by NMR spectroscopy. Recrystallization from

Dibenzofurans by Intramolecular Ring Closure Reactions

By *Akinori Shiotani* and *Hiroshi Itatani*[*]

Palladium compounds are very important in the homogeneous catalysis of organic reactions[1]. The oxidative coupling reactions of aromatic compounds were investigated in the presence of palladium acetate under oxygen pressure. The dimerized compounds were obtained in good yield in the absence of solvent[2].

We have now accomplished an intramolecular ring-closure reaction to give 2,8-dimethyldibenzofuran *(1)* in the corresponding reaction of di-*p*-tolyl ether in the presence of palladium acetate and 2,4-pentanedione (for conditions see Table 1).

(1) *(2)*

Compound *(1)* which was isolated by fractional distillation crystallizes as white leaflets (from ethanol), m.p. 62—64 °C (64 °C[3]). Elemental analysis, mass spectrum, and ^{1}H-NMR spectrum are in accord with the structure given. The dimers *(2)* were isolated from the oily fraction (b.p. 125 to 150 °C/0.5 torr) by chromatography (alumina, hexane/benzene, 1 : 1). The gas chromatogram displays three isomers; a molecular peak is observed in the mass spectrum.

Dibenzofuran is known to be formed as a by-product in poor yield when diphenyl ether is heated to 700 °C in a glass tube[4]. The method developed by us is suitable for the preparation of substituted dibenzofurans (see Table 1) which have hitherto only been accessible by laborious multistep syntheses[5]. Substituents on the benzene nucleus favor intramolecular ring closure and suppress dimerization owing to the reduced interaction between the molecules. Solvents have the same effect[6].

The analogous reaction of *m*-tolyl *p*-tolyl ether gave white needles (m.p. 82—83 °C). Elemental analysis and mass spectrum are in accord with the expected structure of a 2,7- or 2,9-dimethyldibenzofuran; the ^{1}H-NMR spectrum showed 2,7-dimethyldibenzofuran *(3)* to be present [(in CCl_4): $\delta = 2.47$ (2 CH_3), 7.02 (H^8), 7.10 (H^3), 7.28 (H^6), 7.35 (H^4), 7.60 (H^1), 7.67 (H^9); $J_{1,3} = 1.5$ Hz, $J_{3,4} = 7.5$ Hz, $J_{1,4} \approx 0.6$ Hz, $J_{6,8} = 1.2$ Hz, $J_{8,9} = 7.5$ Hz, $J_{6,9} \approx 0.5$ Hz].

In the same way, fluorenones are formed from benzophenones, although in low yields (see Table 1). Diphenyl sulfide, diphenyl sulfone, *N,N*-diphenylacetamide, and phenyl benzoate could not be reacted.

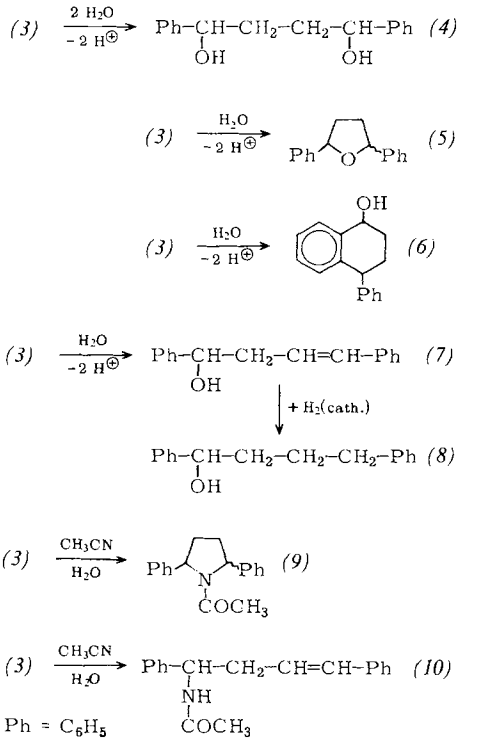
Hydroxylating Dimerization of Styrene at the Anode[1][**]

By *Eberhard Steckhan* and *Hans Schäfer*[*]

The dimerization and functionalization of electron-rich olefins at the graphite anode has hitherto been performed mainly in methanolic solution. The process yields predominantly 1,4-dimethoxylated butane derivatives in good yields[2].

We are currently investigating the introduction of other functional groups by variation of the nucleophile. Electrolysis in aqueous electrolytes should lead to the formation of substituted 1,4-butanediols and tetrahydrofurans.



(1) *(2)*

$\longrightarrow$ 1/2 Ph–CH(⊕)–CH_2–CH_2–CH(⊕)–Ph *(3)*

Ph = C_6H_5

The potential-controlled preparative electrolysis of styrene *(1)* ($E = +1.2$ to $+1.6$ V relative to Ag/AgCl) at graphite electrodes affords the products *(4)* to *(10)* in aqueous acetonitrile or a dichloromethane/water suspension (Table 1). Their formation is readily interpreted as proceeding *via* the intermediate dication *(3)* and its deprotonation or solvolysis.

(3) $\xrightarrow[-2\,H^{\oplus}]{2\,H_2O}$ Ph–CH(OH)–CH_2–CH_2–CH(OH)–Ph *(4)*

of +1.6 V (relative to Ag/AgCl), and a current density of 25 mA/cm² until consumption of 0.1 F. After extraction of the electrolyte with ether and dichloromethane and distillation of the solvent and unreacted styrene there remains 19 g of crude product. The crude product still contains small amounts of olefin and supporting electrolyte. 2.35 g was separated by column chromatography over silica gel (270 g; eluant: light petroleum/ether 3:1, v/v). Compound *(5)* (720 mg), b.p. 190 to 193 °C/12 torr, was eluted as the second fraction.

Table 1. Results of hydroxylating anodic dimerization of styrene in aqueous electrolytes. The compounds *(4)* to *(10)* were characterized by C,H analysis and/or their IR, NMR, and mass spectra, as well as comparison with authentic samples. Conditions: Electrolysis was performed at a potential of +1.2 to +1.6 V relative to Ag/AgCl and a current density between 20 and 30 mA/cm² up to a conversion of 0.1 F.

Reaction of *N*-Phenyl(keteniminylidene)triphenylphosphorane with Carbonyl Compounds

By *Hans Jürgen Bestmann* and *Günter Schmid*[*]

The reaction of *N*-phenyl(keteniminylidene)triphenylphosphorane *(1)*[1] with aromatic aldehydes *(2)*, $R^1 = Ar$, $R^2 = H$, in a molar ratio of 1:1 yields the hitherto unknown, deeply colored 1,3-bis(arylmethylene)-2,4-bis(phenylimino)cyclobutanes *(6)*, $R^1 = Ar$, $R^2 = H$.

It can only be assumed that a Wittig reaction between *(1)* and *(2)* initially gives the arylmethyleneketenimines *(3)*, $R^1 = Ar$, $R^2 = H$, which immediately undergo cycloaddition with *(1)* to form the ylides *(4)*, which themselves react with a second molecule of *(2)* affording *(6)*. After reaction between *(1)* and *(2)* in the molar ratio 2:1, the phosphoranes *(4)* can often be isolated in crystalline form or reacted in the product solution with another carbonyl compound *(5)* to yield *(7)* (Table 1).

molecular-spectroscopic data and elemental analysis were obtained for all the compounds listed in Table 1.

Model Experiments for Peptide Fragment Coupling without Racemization-Prone Activated Amino Acid Derivatives

By *Hasso von Zychlinski*, *Ivar Ugi*, and *Dieter Marquarding*[*]

The fragment strategy is one of the most useful synthetic concepts for peptides and proteins[1]. This involves the stepwise synthesis of peptide fragments with two or more amino acid units, and subsequent coupling of fragments by acylation. Since the latter requires the activation of the C-terminal amino acid unit of a peptide fragment, there is substantial danger of racemization *via* the azlactone which can be formed from the activated intermediate. Even the azide method has recently been shown not to be free from racemization[2, 3]. It is not yet possible to assess whether *Kemp*'s reagent[4] or the combination of dicyclohexylcarbodiimide and *N*-hydroxysuccinimide[5] generally affords racemization-free coupling of peptide fragments.

All coupling methods which are based upon the conventional concept of peptide bond formation by acylation proceed as second order reactions, whereas the concurrent racemization processes correspond to first or pseudo first order kinetics. Accordingly, it can by no means be taken for granted that a method which leads to a negligible degree of racemization in the case of small peptides and relatively high concentrations of reactants will be equally good with larger fragments. However, in fragment coupling by four-component condensation[6] of an N-terminally and a C-terminally protected peptide fragment *(1)* and *(2)* with an isocyanide *(3)* and an aldehyde *(4)*, racemization-prone activated peptide derivatives of conventional type are avoided; formation of the new peptide bond occurs by a first order reaction. The only intermediate which could lead to racemization is *(5)*, but it rearranges spontaneously and immeasurably fast into the stable product *(6)*[6].

The usefulness of such a sequence of reactions as a method of fragment coupling depends in a critical manner upon the cleavage *(6)*→*(7)* which must be accomplished without

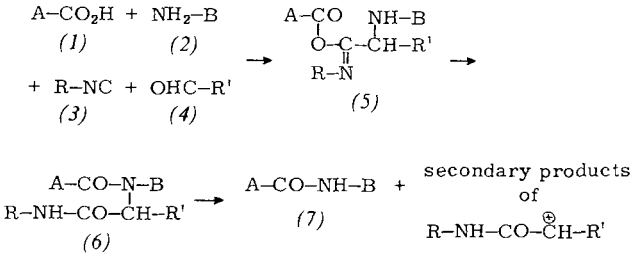

Table 1. Products of type *(4)*, *(6)*, and *(7)*.

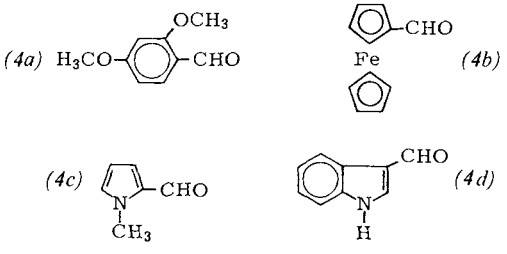
decomposition or racemization of the final product *(7)*. This is only possible if group R' of the aldehyde *(4)* assists the cleavage reaction[7].

We found in model four-component condensations with phenylacetic acid *(1a)*, benzylamine *(2a)*, *tert*-butyl isocyanide, and the aldehydes *(4a)*—*(4d)* that the condensation products *(6)*, $A=B=C_6H_5CH_2$, $R=t\text{-}C_4H_9$ could be cleaved with cold trifluoroacetic acid to yield *N*-(benzyl)phenylacetamide, *(7)*, $A=B=C_6H_5CH_2$ (Table 1).



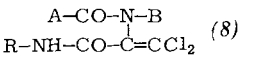


Table 1. Results of model four-component condensations of *(1a)*, *(2a)*, *(3a)* and the aldehydes *(4a)*—*(4d)* (reaction conditions: 20 mmol of each reactant in 30—50 ml of methanol, THF, or dichloromethane at 0—20 °C). The products *(6)*, $A=B=C_6H_5CH_2$, $R=t\text{-}C_4H_9$, were cleaved with cold trifluoroacetic acid to form *(7)*, $A=B=C_6H_5CH_2$.

Aldehyde	*(6)* Yield [%]	m.p. [°C]	*(6)*→*(7)* T [°C]	t [h]	Yield [%]
(4a)	75	167—168	0	20	23
			40	4	38
(4b)	77	175—176	0	20	49
(4c)	68	146—148	20	2	53
			20	4	63
(4d)	62	216—219	20	4	63
			20	18	70

We found also that chloral leads to products of type *(6)* which cannot be isolated [*e.g.* *(6)*, $A=B=C_6H_5CH_2$, $R'=CCl_3$, $R=t\text{-}C_4H_9$] because of their spontaneous decomposition into *(7)* (43—49%), presumably *via* the intermediate *(8)*.

A product of type *(6)*, $A=B=C_6H_5CH_2$, $R=c\text{-}C_6H_{11}$, $R'=2\text{-}NO_2\text{—}C_6H_4$ (72%, m.p. 213—215 °C) is obtained by four-component condensation from *o*-nitrobenzaldehyde. In analogy to the *o*-nitrobenzylurethanes[9], it is photolyzed to form *(7)*, $A=B=C_6H_5CH_2$ (65%).

Model four-component condensations and cleavage experiments with *N*-acylated amino acids and peptides *(1)*, in combination with C-terminally protected amino acid derivatives *(2)* are presently being carried out in order to determine if and under which conditions these peptide coupling reactions proceed without racemization[10].

The 1:1 Intermediate of the "Criss-Cross" Cycloaddition of Isobutylene to Hexafluoroacetone Azine[1][***]

By *Klaus Burger* and *Willy Thenn*[*], together with *Alfred Gieren*[**]

Hexafluoroacetone azine *(1)*[2, 3] reacts with electron-rich olefins to form "criss-cross" cycloadducts (1,3-:2,4-addition)[4] such as 1,5-diazabicyclo[3.3.0]octanes. The 1:1 intermediate

[***] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of the reaction of *(1)* with isobutylene has recently been isolated and assigned the structure of a Diels-Alder adduct *(3)*[5]. However, the proposed structure and the mechanistic interpretations derived therefrom are incorrect. Isobutylene reacts with equimolar amounts of *(1)* on two-days' shaking at room temperature in a sealed tube to give *(2)* which still contains some 2:1 adduct. Separation is feasible by crystallization. The amount of "criss-cross" cycloadduct increases with increasing reaction temperature.

The proposed structure *(3)*[5] is inconsistent with the ^{19}F-NMR spectrum ($CDCl_3$, CF_3COOH as external standard), which contains three signals at -5.1, -12.5, and -26.0 ppm in the ratio 2:1:1, and with mass spectral decomposition (no elimination of N_2), the ^{13}C-NMR spectrum[6], and the reactions[7, 8].

We found that the 1:1 adduct is a stable azomethinimine[9], 2-[5,5-dimethyl-3,3-bis(trifluoromethyl)-1H^+-1-pyrazolinio]-1,1,1,3,3,3-hexafluoro-2-propanide. The structure of *(2)* was proved unequivocally by X-ray structure analysis[10]. This constitutes the first isolation and characterization of the 1,3-dipolar intermediate of "criss-cross" cycloaddition postulated by *Huisgen*[11].

An azomethinimine intermediate *(4)* also readily explains the reaction of *(1)* with cyclopentene and olefins of the type $CHR^1{=}CHR^2$ (R^1 = isopropyl or *tert*-butyl, R^2 = H) to give 3-pyrazolines *(7)*.

A series of intramolecular de- and reprotonations *via* intermediates such as *(5)* and *(6)* provide a plausible mechanistic interpretation. If the final step of the rearrangement were to be a [1.4]-sigmatropic H shift[12], then *(6)* would be expected as sole intermediate.

2-[5,5-Dimethyl-3,3-bis(trifluoromethyl)-1H^+-1-pyrazolinio]-1,1,1,3,3,3-hexafluoro-2-propanide (2)

Isobutylene (2.80 g, 50 mmol) and compound *(1)*[2, 3] (16.40 g, 50 mmol) are shaken together at room temperature in a sealed tube for 2 to 3 days. The resulting crystals are recrystallized from anhydrous hexane; yield 16.35 g (85%) of *(2)*, m.p. 77—78 °C.

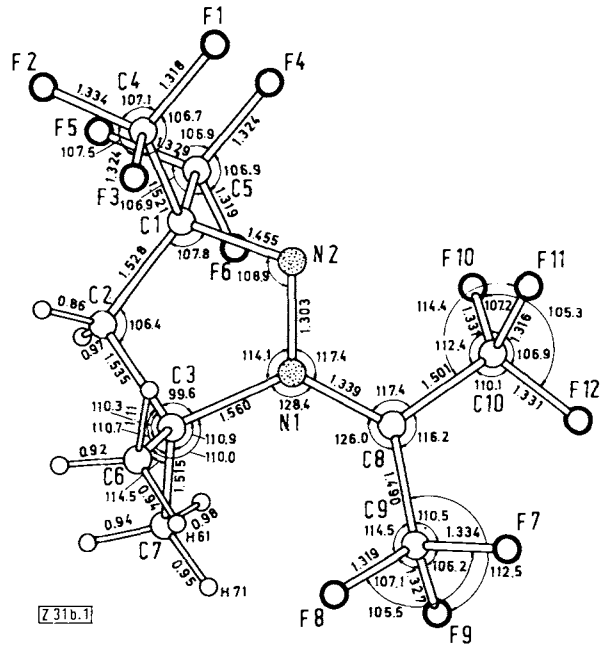
X-Ray Structure Analysis of the 1:1 Intermediate of the "Criss-Cross" Cycloaddition of Isobutylene to Hexafluoroacetone Azine

By *Alfred Gieren* and *Poojappan Narayanan*[*], together with *Klaus Burger* and *Willy Thenn*[**]

The 1:2 "criss-cross" cycloaddition[1] of hexafluoroacetone azine[2, 3] to isobutylene proceeds *via* a 1:1 intermediate[4, 5]. X-Ray structure analysis shows unequivocally that the stable azomethinimine 2-[5,5-dimethyl-3,3-bis(trifluoromethyl)-1H^+-1-pyrazolinio]-1,1,1,3,3,3-hexafluoro-2-propanide *(1)* is formed, thus confirming *Huisgen's* postulate of a 1,3-dipolar intermediate of the "criss-cross" cycloaddition[6].

Monoclinic single crystals of *(1)* were obtained from hexane solution. Space group: $P2_1/a$; $a = 12.67_8$, $b = 11.38_8$, $c = 9.98_6$ Å, $\gamma = 106.4_5°$; $d_{exp} = 1.82\,g\cdot cm^{-3}$; 4 molecules per unit cell; $d_{calc} = 1.84\,g\cdot cm^{-3}$. 2623 independent reflections (403 not observed, $I \leq 2\sigma_I$; $\vartheta/2\vartheta$ scan, five-point measurement, $\vartheta \leq 70°$) were measured with an automatic single crystal diffractometer using $Cu_{K\alpha}$ radiation. The structure was solved with the aid of the direct method program PHASDT[7].



All the atoms (except H) were visible in an *E*-Fourier synthesis with 299 phased reflections. Least-squares refinement, first with isotropic and then with anisotropic temperature factors, was performed up to an *R* factor of 8.7% (observed reflections). A difference Fourier synthesis calculated at this stage showed all the H atoms. Upon inclusion of the H atoms in the refinement, convergence was obtained at $R = 4.4\%$.

The structure of the molecule is shown in Figure 1. The N1—N2 and C8—N1 distances indicate strong double bond components of approximately equal magnitude. The zwitterionic compound is therefore essentially described by the two resonance formulas *(1)*. The mean value of the C—C(sp^3—sp^3)

C4—C1—C5: 111.4°

C1—C5:	1.519 Å	C3—C6:	1.521 Å

Fig. 1. Molecular structure of 2-[5,5-dimethyl-3,3-bis(trifluoromethyl)-1*H*$^+$-1-pyrazolinio]-1,1,1,3,3,3-hexafluoro-2-propanide *(1)*. The mean standard deviations of the given bond lengths and angles amount to: 0.004 Å (except C—H: 0.04 Å) and 0.3 respectively.

bond lengths in the five-membered ring amounts to 1.532 Å, and that of the exocyclic C—C(sp^3—sp^3) bonds is 1.519 Å. Expectedly, the sp^2—sp^3 type bonds originating from C8 (to C9 and C10) are somewhat shorter. The mean value of the C—F bond lengths is 1.326 Å. Like these bond lengths, the C1—N2(sp^3—sp^2) bond also corresponds to the expected value. However, the isotypic C3—N1 bond shows an exceptional degree of lengthening (more than 0.1 Å, see below).

The geometry of the compound reflects the high degree of substitution of the five-membered ring. Thus the elongation of the C3—N1 bond arises because of the strain in the $C6H_3(C7H_3)$—C3—N1—C8—$C9F_3$ system due to the methyl groups on C3 and the $C9F_3$ group. The intramolecular contacts F8···H61 and F8···H71 are only 2.15 and 2.28 (±0.04) Å respectively. Repulsion between the two methyl groups and the $C9F_3$ group is also responsible for the opening of the angles at N1 and C8 lying within this system. Typically, the angles facing the lone pair (on N2) are reduced[8].—This effect is also observed for the angles at C1. The intramolecular interactions also lead to twisting about the N1—C8 bond which displays double bond character: C9—C8—N1—C3: −24.4° and C10—C8—N1—N2: −13.3°. The difference in twisting about the C8—N1 bond causes the sp^2 carbon atom C8 to project out of the plane of its three neighboring atoms by 0.05 Å. N1 is also displaced to some extent from the plane of its three neighbors (Δ = 0.02 Å). Both sp^2 centers display slight rehybridization from sp^2 in favor of sp^3. This is best described in terms of a slight contribution of the 1,3 dipolar resonance formula *(1')*. The C8—N1—N2 resonance system is not only twisted about the C8—N1 bond but also about the N1—N2 bond: dihedral angle C1—N2—N1—C3: −18.2° and C1—N2—N1—C8: 158.8°. The other dihedral angles within the five-membered ring amount to: about N1—C3: 19.0°; about C3—C2: −11.5°; about N2—C1: 9.2°; and about C1—C2: 3.0°. Accordingly, the five-membered ring has a slightly twisted envelope conformation with the flap at N1. The normal conformation would be an envelope with the flap at C2. The prime cause of this special feature is the interaction of the $C4F_3$ and $C6H_3$ groups which are positioned *cis* to each other.

Reactions of Trifluoromethyl-Substituted Azomethinimines with Nucleophiles[1][**]

By *Klaus Burger, Willy Thenn, Helmut Schickaneder*, and *Horst Peuker*[*]

The 1 : 1 intermediate 2-[5,5-dimethyl-3,3-bis(trifluoromethyl)-1*H*$^+$-1-pyrazolinio]-1,1,1,3,3,3-hexafluoro-2-propanide *(1)*, formed by reaction of hexafluoroacetone azine with isobutylene[1, 2] reacts with nucleophiles to form 1 : 1 adducts.

Methanol and ethanol react with *(1)* in a sealed tube at 85 °C to yield 1-(1-methoxy- and 1-(1-ethoxy-2,2,2-trifluoro-1-trifluoromethylethyl)-5,5-dimethyl-3,3-bis(trifluoromethyl)-pyrazolidines *(2a)* and *(2b)* respectively. Their structure follows unequivocally from IR, ^{1}H-NMR, and mass spectra[3]. The reaction *(1)* → *(2)* is reversible on prolonged heating of *(2)* at normal pressure. Methanol adducts have proved of value as a stable storage form and as a convenient neutral source of azomethinimines in the 3,4-dihydroisoquinoline series[4].

On heating for several hours at 80—90 °C or on standing for several weeks at room temperature in a sealed tube, phosphites react with *(1)* to form iminophosphoranes of type

[b] Film.
[c] In KBr.

The ^{1}H-NMR spectra of *(4)* [δ = 1.48–1.57 (s, $2CH_3$), 2.28–2.39 (d, CH_2)] display a P=N–C–C–H coupling constant of 2.5–3.7 Hz (we found $J_{P-O-C-C-H}$ in 5-alkyl-substituted 2,3-dihydro-1,4,2λ^5-oxazaphospholes to be 1 to 2 Hz[6]); $J_{P-N-C-C-H}$ is reported as 0.6–1.2 Hz[7]. The degradation pattern of the mass spectra[3] M^+, $[M-164]^+$, $[M-206]^+$, $[M-220]^+$ supports the proposed structure *(4)*. The ^{31}P-NMR spectra[8] show the values expected for iminophosphoranes[5].

1-(1-Methoxy-2,2,2-trifluoro-1-trifluoromethylethyl)-5,5-dimethyl-3,3-bis(trifluoromethyl)pyrazolidine (2a)

Compound *(1)*[1] (5.7 g, 15 mmol) and anhydrous methanol (0.64 g, 20 mmol) are heated to 85 °C in a sealed tube for 24 h. After cooling, the crude product is purified by chromatography on a silica gel column (eluant: *n*-hexane), yield 4.05 g (65%) of colorless crystals, m.p. 37–38 °C, ν(NH) = 3250 cm^{-1}. Compound *(2b)* can be obtained in analogous fashion, yield 75%, m.p. 42–43 °C, ν(NH) = 3260 cm^{-1}.

7,7,7-Trifluoro-4,4-dimethyl-2,2,6-tris(trifluoromethyl)-1,5-diaza-5-heptenylidenetrimethoxyphosphorane (4a)

Compound *(1)*[1] (7.68 g, 20 mmol) and trimethylphosphite (2.48 g, 20 mmol) are heated to 80–90 °C in a sealed tube for 12 h. The resulting product is fractionated *in vacuo*, yield 9.8 g.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

and a triple bond system in the positions 1,3:2,4 to hexafluoroacetone azine[4, 5]) provides a new general approach to bicyclic heterocycles such as 1,5-diazabicyclo[3.3.0]oct-2-enes *(2)* and 1,5-diazabicyclo[3.3.0]octanes *(3)* (Table 1), as well as their hetero analogs. The intense IR absorption of *(1)* at 1510 cm^{-1} disappears after cycloaddition; it is to be assigned to the azomethinimine system. The first cycloaddition of an azomethinimine to a multiple bond system was reported in 1960 by *Huisgen*[6].

Dimethyl 6,6-dimethyl-4,4,8,8-tetrakis(trifluoromethyl)-1,5-diazabicyclo[3.3.0]oct-2-ene-2,3-dicarboxylate (2b)

Compound *(1)*[2, 3] (3.84 g, 10 mmol) and dimethyl acetylenedicarboxylate (1.42 g, 10 mmol) are heated in anhydrous benzene (40 ml) for 16 h. The crystalline residue obtained on evaporation of the solvent is purified by chromatography (alumina, chloroform) and recrystallized from *n*-hexane, yield 4.72 g.

9,9-Dimethyl-7,7,11,11-tetrakis(trifluoromethyl)-1,8-diazatricyclo[6.3.0.0^{2,6}]undecane (3a)

Compound *(1)* (5.76 g, 15 mmol) and cyclopentene (1.02 g, 15 mmol) are heated to 110 °C in a sealed tube for 3 days. The crude product is purified by column chromatography (alumina, chloroform) and subsequently fractionated *in vacuo*; the colorless fraction of b. p. 50—52 °C/0.05 torr immediately crystallizes, yield 5.25 g.

Two-Step Multicenter Reactions: A System in Which "Forbidden" Processes Occur Faster than the "Allowed" Process[**]

By *Gerd Kaupp* and *Rainer Dyllick-Brenzinger*[*]

Application of the Woodward-Hoffmann rules[1] would appear attractive for the planning of syntheses. In such applications predictions of particularly low activation energies for orbital-symmetry allowed concerted reactions and selection rules for thermally or photochemically allowed or forbidden processes are characteristic[1]. The reaction temperatures for two-step (but not for symmetry-forbidden concerted[2]) multicenter reactions can be determined by thermokinetic increment calculations[3]. In order to reach a more reliable decision regarding which reaction conditions are particularly favorable for specific examples within certain reaction classes, it is therefore desirable to experimentally detect, or possibly rule out (short-lived) intermediates[4]. Quantitative measurements on model systems of the type

$$A + B \rightleftharpoons C \rightleftharpoons D \rightleftharpoons A + B$$

are suitable for this purpose. We here report the kinetic detection of a common intermediate in the thermolyses of the cyclopentadiene-anthracene adducts *(1)* and *(2)*[5], reactions which include suprafacial 1,3 shifts and [4+4] and [4+2] cycloreversions (cf. formula scheme), and compare this with the result of photolysis[5].

Both the rearrangement *(1)* → *(2)* (also ^{1}H-NMR detection in hexachlorobutadiene) as well as the formation of anthracene *(4)* from *(1)* and from *(2)* can be followed by UV spectroscopy when oxygen-free *n*-dodecane solutions (0.3 ml; 10^{-4} M) are heated in evacuated ampoules. The following data were determined in order to carry out kinetic analysis:

1) First order rate constants k_{III} at four different temperatures[6] between 214.2 and 246.5 °C from the quantitative formation of *(4)*.

2) Sums of rate constants ($k_I + k_{II}$) at five different temperatures between 186.3 and 226.2 °C from the consumption of *(1)* taking quantitative account of the slight overlapping of the absorption of *(2)* and *(4)* at 282 nm.

3) Increase in concentration of *(4)* from *(1)* at five different temperatures between 173.2 and 214.5 °C up to quantitative cleavage.

4) First order rate constants k_I and k_{II} by evaluation of the integrated rate expression for parallel consecutive reactions[7].

The activation parameters from the Arrhenius plots for k_I, k_{II}, and k_{III} (cf. formula scheme) require an interpretation based on the principle of microscopic reversibility in terms of a common intermediate *(3)*. This appears surprising since the necessarily suprafacial 1,3 shift *(1)* → *(3)* and the [4+4] cleavage *(1)* → *((4)+(5))* is formally forbidden[1], while the [4+2] cleavage *(2)* → *((4)+(5))* is formally allowed[1]. However, such a conclusion follows compellingly from the observations presented below:

1) The Arrhenius activation energies for the processes I, II, and III are equal (within the limits of error).

2) The retro-Diels-Alder reaction of *(2)* ($k_{III} = 1.70 \times 10^{-}$ s^{-1}; 226.2 °C) is not preferred over the reactions of *(1)* ($k_I = 3.72 \times 10^{-4}$, $k_{II} = 1.55 \times 10^{-3}$ s^{-1}; 226.2 °C) but disfavored instead.

3) In contrast to the formation of *(2)* from *(1)* (at 226.2 °C a maximum of 15% after 23 min) the reverse 1,3 shift *(2)* → *(1)* cannot be detected by UV spectroscopy.

Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)
Dipl.-Chem. R. Dyllick-Brenzinger
Organisch-chemisches Laboratorium der Eidgenössischen Technischen Hochschule
CH-8006 Zürich, Universitätsstrasse 6 (Switzerland)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

4) Thermochemical increment calculations do not reveal any differences in the molar heats of formation ΔH_f^0 of *(1)* and *(2)* even after taking special account of the H/H interactions (staggered or eclipsed).

Since the adducts *(1)* and *(2)* have (almost) equal energy contents it does not appear surprising that the same activation energies are found for the 1,3 shift and cycloreversions (within the limits of error) if the (possibly polar) diradical *(3)* is formed initially without any change in multiplicity. The "allowed" reaction *(2)*→(*(4)*+*(5)*) is not energetically favored, and the differences in the reaction rates are due almost exclusively to the different frequency factors (cf. formula scheme). The symmetry-corrected rate constant $(k_I+k_{II})/2$ is 5.6 times greater than k_{III} (see above). This kinetic disadvantage of the retro-Diels-Alder reaction suggests that the eclipsed arrangement of benzhydrylic and allylic hydrogen atoms in *(1)* (dihedral angle *ca.* 12°[10]; ^{1}H-NMR coupling constant $J=9.0$ Hz[5]) enhances the probability of cleavage of the C—C bond compared to the staggered arrangement in *(2)* (60°[10]; 3.0 Hz[5]).

In both cases the intermediate *(3)* is formed which has the possibility of rotation about the exocyclic C—C bond, and finally the products (*(4)*+*(5)*) and *(2)* are obtained in the ratio $k_{II}/k_I=80.5/19.5$. In addition, molecular models predict that the stabilization route *(3)*→*(1)* must also be operative. This reaction, which cannot be detected by UV spectroscopy mainly because the primary reaction of *(1)* on pyrolysis is *ca.* 11 times faster, would become of preparative significance if the decomposition of the [4+4] adduct *(1)* could be prevented: selective irradiation of anthracene *(4)* in cyclopentadiene *(5)* (0 C) affords a photointermediate[5] which is likewise assumed to have formula *(3)* (presumably in similar rotational and vibrational states). Kinetically controlled reaction then yields *(1)* and *(2)* in the ratio 58/42[5].

The utility of direct comparison of thermal and photochemical two-step reactions is apparent from the results obtained on irradiation of adduct *(1)*[11]. The "allowed" reactions afford 80% of *(4)* and 18% of *(2)* ($\phi=0.26+0.06$; CH_3CN; 20 C)[5]. The measurable deactivation ratio of thermally and photochemically generated *(3)* is thus, as expected, equal (within the limits of error). Hence the conclusion is justified that intermediate *(3)* generated from *(1)* undergoes stabilization to (*(4)*+*(5)*), *(1)*, and *(2)* in the ratios 4.1:1.4:1.0.

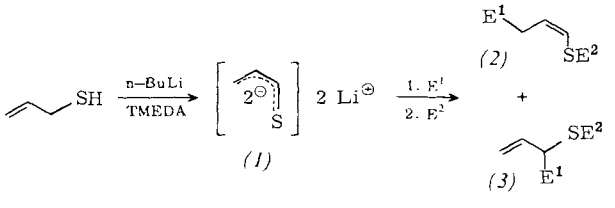
Doubly Metalated 2-Propene-1-thiol Thioacrolein Dianion[1][**]

By *Karlheinz Geiss, Bernhard Seuring, Reimund Pieter*, and *Dieter Seebach*[*]

As exemplified by eq. (1) and (2), carbonyl compounds add electrophiles (E) at the α position (E^2 reaction[2]) and nucleophiles (Nu) at the β position (N^3 reaction[2]). *Umpolung* at C^3 is, in principle, possible with heterosubstituted allylic anions provided that they are susceptible to attack by electrophiles at the γ position to the hetero atom; with X=SR the α position is preferentially attacked [eq. (3)][2, 3]



(1)

(2)

(3)

In this communication we report a novel allylic anion, the doubly metalated 2-propenethiol *(1)*[4, 5], which reacts preferentially in the γ position with a variety of electrophiles, including alkyl and benzyl chlorides and bromides, epoxides, aliphatic, cycloaliphatic, aromatic aldehydes and ketones, and dimethyl disulfide. The dilithio derivative is formed quantitatively by treating a 0.3—0.9 M solution of the thiol in THF with 2.1 equivalents of *n*-butyllithium (1.6 M in *n*-hexane) in the presence of 1—2 equivalents of tetramethylethylenediamine (TMEDA) for four hours at 0 °C. As shown in Table 1, the γ/α ratios[6] in which products *(2)* and *(3)* are formed range from 67:33 to 80:20 (NMR spectrum). The γ adducts

(1)

(2)

(3)

are formed almost exclusively (>95%) in the *cis*-configuration[6]. The isomers *(2)* and *(3)* may be separated by preparative thin-layer, column, or gas chromatography.

The use of *(1)* as synthon in analogy to eq. (3) is demonstrated by the reaction of the products *(4)* and *(8)* of type *(2)* in Scheme 1. We have developed a new procedure for the

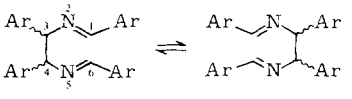
Dynamic Stereochemistry of the Degenerate Diaza-Cope Rearrangement[**]

By *Fritz Vögtle* and *Ernst Goldschmitt*[*]

A further milestone was passed in the theory of valence isomerization when, in 1971, *Dewar*[1] postulated that 3,7-diazasemibullvalene has to be formulated as a nonclassical molecule [bishomopyrazine *(1)*] in the ground state.



(1)

While experimental proof of this prediction is still forthcoming, the recently described thermal valence isomerization of 1,3,4,6-

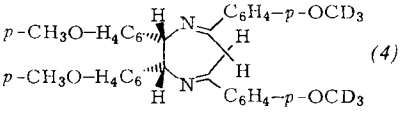
(2) (2')

(a), Ar = phenyl
(b), Ar = 4-methylphenyl
(c), Ar = 4-methoxyphenyl
(d), Ar = 4-cyanophenyl
(e), Ar = 4-pyridyl
(f), Ar = 2-pyridyl



tetraaryl-2,5-diazahexadienes[2], whose *degenerate* variant *(2)*⇌*(2')* is reported in the present communication, permits analogous studies of heteroatom and substituent effects in a nonbridged model system.

At elevated temperatures (above 120 °C in D_6-DMSO) the diaza-Cope rearrangement *(2a)*⇌*(2a')* of *N,N'*-dibenzylidene-1,2-diphenylethylenediamine leads to an equilibrium between *meso*- and *d,l*-valence isomers in the ratio 1 : 1, irrespective of whether the reaction starts from *meso-(2a)* (m. p. 171—173 C; 164—165 C[3]) or *d,l-(2a)* (m. p. 159—160 C). This was established by proton magnetic resonance comparisons with authentic *meso*- and *d,l* compounds (Fig. 1).

Thus the deuterium-labeled azomethine *meso-(3)* obtained on reaction of *meso*-1,2-diphenylethylenediamine with [formyl-D]-benzaldehyde affords a completely equilibrated 1 : 1 : 1 : 1 valence isomer mixture of *meso*- and *d,l-(3)* and *-(3')* whose components can be distinguished by their proton resonance. An analogous equilibration is observed starting from *meso-(4)*.

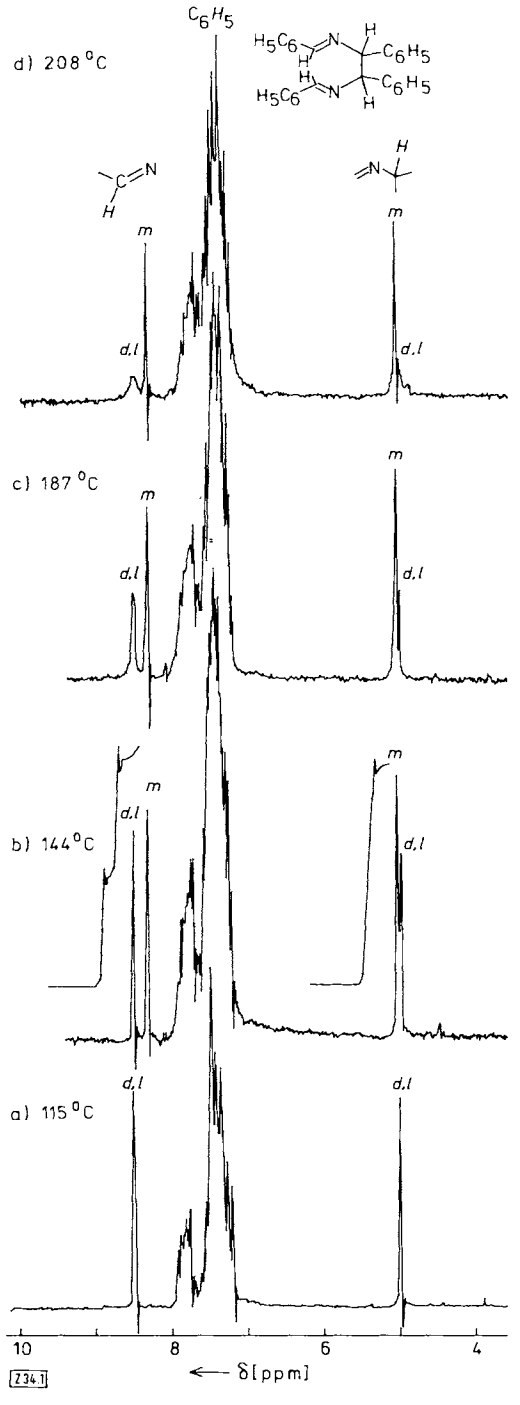
(3) (3')

(4)

Comparison of the ^{1}H-NMR signal intensities at 139, 146, and 152 C as functions of time affords an approximate value of 31 kcal/mol for the free enthalpy of activation $\Delta G^{\neq}$ of the *d,l*→*meso* transition of *(2a)* which is to be regarded as constitutionally but not configuratively degenerate.

It is particularly appealing that the degenerate diaza-Cope rearrangements can be observed directly by dynamic ^{1}H-NMR spectroscopy (Fig. 1): on heating of a sample of *d,l-(2a)* dissolved in D_6-DMSO the initial reaction is the above *d,l*⇌*meso* isomerization, which is readily recognized by appearance of CH=N—CH proton resonances of the *meso* compound. A further increase in temperature leads to increasing broadening of the H^1,H^3- and H^4,H^6 signals of the *d,l* form; they again appear as sharp singlets on cooling of the sample solution. Accordingly, *d,l-(2a)* is a *molecule having a fluctional structure* at elevated temperatures.

The free energy of activation at the extrapolated coalescence temperature ($T_c \approx 220$—230 °C; $\Delta\nu = 209$ Hz) has a value of 23—24 kcal/mol and is thus lower than in open-chain Cope systems (1,5-hexadienes)[1,4]. Remarkably, the signals of *meso-(2a)* remain as sharp singlets in this temperature range (Fig. 1). This finding is in accord with calculations[1,4] and experimental results[5] which indicate that the boat-like six-center transition state—which would have to be traversed in the case of a valence isomerization *meso-(2a)*⇌*meso-(2a')*[2]—requires a higher activation energy than the chair-like four-center transition state which is to be assumed for the *d,l*⇌*d,l* conversion[6]. A further argument for the greater tendency of the *d,l* form to rearrange compared to the *meso* form could lie



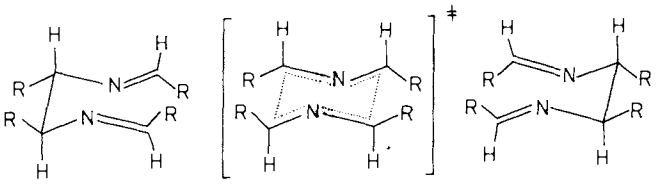


Fig. 1. Temperature-dependent proton resonance (sections) of *d,l-(2a)* (60 MHz in D_6DMSO). *d,l*: signals of the *d,l* compound; *m*: signals of the *meso* form.

in the *d,l* compound being conformationally more favorable for the chair transition state whereas the conformation of the *meso* compound is unfavorable for the boat transition state. This becomes clear on consideration of molecular models.

For kinetic determination of the activation parameters of the *d,l*⇌*d,l* valence isomerization, we resolved racemic 1,2-diphenylethylenediamine into the antipodes with the aid of optically active tartaric acid[7]. (+)-*(2a)* and (−)-*(2a)* were obtained in crystalline form. Their racemization, which is due to a [3.3]-sigmatropic shift, was pursued by polarimetry at several different temperatures. The rate of valence isomerization is already too high for polarimetric measurements at 70 °C. Racemization of the optical antipodes in the course of the diaza-Cope rearrangement is readily understood in

view of the mirror image geometry of the substituents in the transition state (Fig. 2). The rearrangement obeys first order kinetics at all temperatures ($k_{31.8\,°C}=5.23\times10^{-5}$, $k_{41.4\,°C}=1.50\times10^{-4}$, $k_{45.0\,°C}=2.39\times10^{-4}$, $k_{48.6\,°C}=3.53\times10^{-4}$). The activation energy E_A for the degenerate diaza-Cope rearrangement is found to be 21.8 kcal/mol. Interestingly, a value of 23.9 kcal/mol is obtained for $\Delta G^{\neq}$, which agrees with that determined by the coalescence method. As expected, the entropy of activation is strongly negative: $\Delta S^{\neq}=-7.5$ cal deg^{-1} mol^{-1}.

[Z 34 2]

Fig. 2. Racemization (*S,S*)-(*2*)→(*R,R*)-(*2'*) or (*R,R*)-(*2*)→(*S,S*)-(*2'*). The mirror image in the transition state is shown gray.

The degenerate diaza-Cope rearrangement even appears to take place in the solid state: crystals of (−)-(*2a*) lose their optical rotatory power within 24 h.

Introduction of *o*, *m*, or *p* substituents into the four aromatic nuclei of (*2*) leads to further degenerate diaza-Cope systems. The compounds studied hitherto confirm the results obtained with the unsubstituted system (*2a*): only minimal changes are found in the activation parameters of (*2b*) and (*2c*). In the presence of electron-attracting substituents as in (*2d*)—(*2f*) avoidance reactions occur which are possibly attributable to an irreversible cleavage of the weakened allyl σ bond. The considerable influence of the 3,4 phenyl substituents of (*2a*) is underlined by the lack of any tendency of *N,N'*-dibenzylideneethylenediamine to undergo rearrangement at 210 °C.

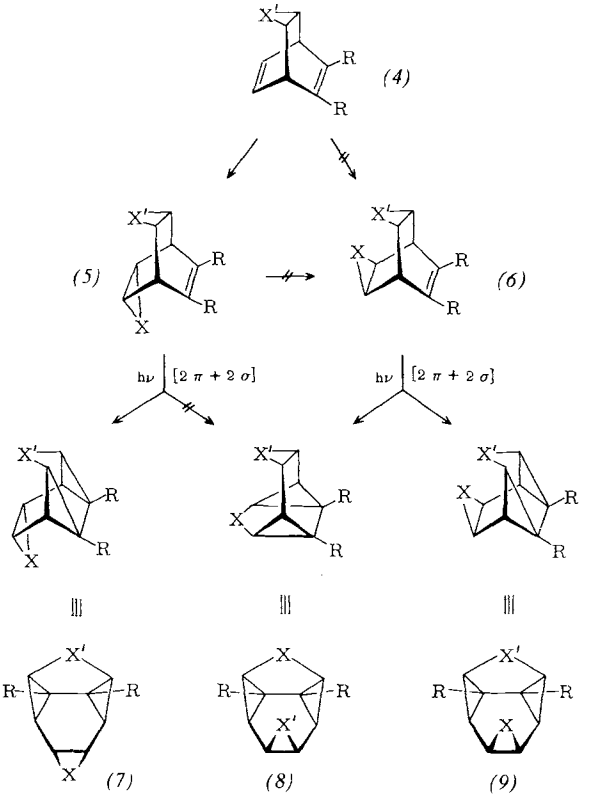
Simple Bridged *cis*-Oxa- and *cis*-Aza-tris-σ-homobenzene Systems; Synthesis and 3σ→3π Isomerization[**]

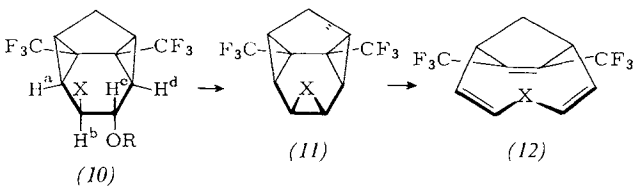
By *Horst Prinzbach, Shinzo Kagabu*, and *Hans Fritz*[*]



The zero-bridged *cis*-tris-σ-homobenzene compounds (*2*) (X = CH_2, $CHCO_2CH_3$, O; R = CO_2CH_3, CF_3, CH_3) occupy a special position in that their thermolysis proceeds not *via* the usual 3σ→3π cleavage to (*3*) (6-electron process) but *via* 2σ→2π cleavage to (*1*) (4-electron process)[1]. The hypothesis that the multiply annelated four-membered ring is responsible for this behavior was to be tested on a model of *cis*-tris-σ-homobenzene systems having a longer bridge, *e.g.* (*8*) or (*9*). [2π+2σ]-photocyclization of the bishomobarrelenes (*5*) or (*6*) appeared a likely method for their preparation.

(*1*) (*2*) (*3*)

These expectations were not fulfilled however; photoreactions with various *endo,exo*-bishomobarrelenes (*5*) (X,X' = CH_2, $CHCO_2CH_3$, O, NR'; R = CO_2CH_3, CF_3, CH_3) afford almost exclusively the *trans*-tris-σ-homobenzene products (*7*), which are incapable of 3σ→3π opening, with participation of the three-membered ring *anti* to the excited chromophore. The *endo,endo*-bishomobarrelenes (*6*)—both possibilities of [2π+2σ]-addition lead to *cis* products [(*8*), (*9*)]—are, however, inaccessible. Regardless of the nature of the three-membered ring in (*4*) (X' = CH_2, CHCN, O), the second three-membered ring is only formed from the *exo* side (X = CH_2, $CHCO_2CH_3$, O, NR') to give (*5*) under a wide variety of conditions[2, 3]. The steric conditions and the proclivity to rearrangement of the tricyclo[3.2.2]nonane skeleton also thwarted attempts to bring about a transition (*5*)→(*6*) by way of known substitution and cyclization steps[3].



This *exo-endo* isomerization is however possible at the stage of (*7*). The "*trans*-oxide" (*7*) (X = O, X' = CH_2, R = CF_3)[3], which is accessible from (*5*) (X = O, X' = CH_2, R = CF_3) on a preparative scale by direct photoexcitation and is highly resistant to attack by nucleophiles, undergoes smooth reaction in a 2 N sulfuric acid solution in DMSO to give the crystalline *trans*-diol (*10a*) (72%; m.p. 112 °C; τ = 5.87 (H^b), 6.26 (H^c); $J_{b,a}=4.2$, $J_{b,c}\approx6$, $J_{c,d}\approx0$ Hz; CD_3COCD_3, 270 MHz). The action of *ca.* 1 equiv. of tosyl chloride (pyridine, 20 °C, 3 d) results in 60% conversion to a mixture of unchanged (*10a*) and the bistosylate (*10c*) (colorless needles, m.p. 127—128 °C;

(e), X = N_3, R = tosyl

(a), X = O
(b), X = NH
(c), X = $NCOCH_3$

ca. 30%; $\tau = 4.91$ (H^b), 5.23 (H^c); $J_{b,a} \approx 6.5$, $J_{b,c} = 3.7$, $J_{c,d} \approx 1$ Hz; $CDCl_3$; 270 MHz) which is also found to contain a monotosylate (colorless needles, m. p. 106—107 °C; *ca.* 20%) on chromatography (silica gel, CH_2Cl_2), shown by the ^{1}H-NMR data ($\tau = 5.55$ (H^b), 5.45 (H^c); $J_{b,a} = 4.5$, $J_{b,c} = 5.3$, $J_{c,d} \approx 0$ Hz; $CDCl_3$, 270 MHz) to be the desired *exo*-ester *(10b)*.

In accord with the conformational mobility in the skeleton *(10)*, evidenced *inter alia* by the substituent-dependent coupling constants, cyclization of *(10b)* to the *cis*-monooxa-tris-σ-homobenzene *(11a)* (colorless crystals, m. p. 50—51 C; 82%) can be performed under conventional conditions (sodium methoxide, ether, 20 C). For preparation of the "*cis*-imine" *(11b)* we resorted to the reaction sequence which has proved its value in the synthesis of *cis*-"benzene triimine" from *cis*-"benzene trioxide"[4]. In the presence of a little concentrated sulfuric acid, *(7)* (X = O, X' = CH_2, R = CF_3) reacts selectively with an excess of sodium azide in DMSO (130 C) to form the *trans*-azido alcohol *(10d)* (colorless crystals, 68%, m.p. 82.5—83 C; $\tau = 5.98$ (H^b), 6.20 (H^c); $J_{a,b} = 4.2$, $J_{b,c} = 7.0$ $J_{c,d} \approx 0$ Hz; $CDCl_3$, 270 MHz). After esterification to give *(10e)* (tosyl chloride, pyridine; colorless needles, 96%, m.p. 105.5—106.5 C), reduction and cyclization to *(11b)* can be accomplished with $NaAlH_4$ in THF (colorless crystals, m. p. 87.5—88.5 °C, 55%). Acetylation in pyridine/acetic anhydride to give *(11c)* (m.p. 75—76 °C) is almost quantitative.

The bis(trifluoromethyl)tris-σ-homobenzene compounds *(11a)*—*(11c)* are more stable thermally than the unbridged oxa- or aza-analogous diesters[1]. Above 160 C and 140 C *(11a)* and *(11c)* respectively—unlike the homologs *(2)*—undergo fast, uniform, irreversible 3σ→3π cleavage to form the bridged heterononatrienes *(12a)* (colorless crystals, m.p. 17—18 C) and *(12c)* (yellowish crystals, m.p. 75—76 C). The structures *(10)*—*(12)* are confirmed by physical data (UV, IR, MS, ^{1}H- and ^{13}C-NMR) and elemental analyses. The characteristic coupling constants used for spectroscopic identification of the *cis-trans* isomers *(11)* and *(7)*, and also the trienes *(12)*, are in good agreement with the values for the unbridged oxa- and aza-σ/π-trishomobenzenes[5].

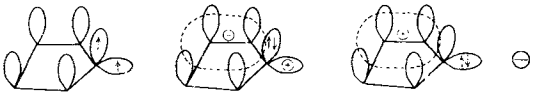
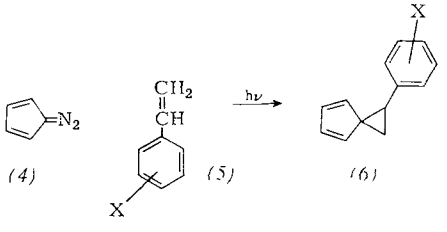
Proof of the Electrophilic Character of Cyclopentadienylidene[**]



By *Heinz Dürr* and *Franz Werndorff*[*]

According to EHT calculations[1] the electrophilic or nucleophilic character ought to alternate[2] in the series of cyclic carbenes *(1)*—*(3)*. Compound *(3)* has recently been shown to exhibit the expected nucleophilic character[3].



(1) *(2)* *(3)*

In the case of the carbene cyclopentadienylidene *(2)* essentially three configurations are possible: the triplet σ_p and the singlets p^2 (aromatic) and σ^2 (antiaromatic). σ^2-*(2)* should participate in nucleophilic additions whereas p^2-*(2)* should participate in electrophilic additions[2]. The ground state of *(2)* at 77 °K is the triplet p-*(2)*[2] (ESR).

$\sigma p(T_1)$ $p^2(S_0)$ $\sigma^2(S_2)$

A criterion for electrophilic or nucleophilic character of a carbene is its rate of addition to variously alkylated olefin pairs. In the case of *(2)*, *Moss*[4] was unable to clarify this

(4) *(5)* *(6)*

Table 1. Phenylspiroheptadienes *(6a)*—*(6e)* obtained by [1+2]cycloaddition of cyclopentadienylidenes *(2)* to the styrenes *(5a)*—*(5e)* [a].

	X	*(6)*, yield [%] [b]	k_{rel} [c]
a	H	18	—
b	*p*-CH_3	12	$1.2_1 \pm 0.1$
c	*p*-CH_3O	17	$1.9_5 \pm 0.3$
d	*p*-Cl	12	$0.6_0 \pm 0.1$
e	*m*-Br	7	$0.5_5 \pm 0.04$

[a] The structure of *(6)* was confirmed spectroscopically; formation of a pyrazoline from *(5)* and *(4)* was ruled out by control experiments.

[b] Obtained by photolysis of *(4)* in the styrenes *(5)* (high-pressure Hg-vapor lamp. GW_v filter: $\lambda > 360$ nm, 20 ± 1 °C. 60—91% of calculated N_2).

[c] For determination of k_{rel} the photolysis of *(4)* was carried out in equimolar mixtures of *(5a)* and one of the other styrenes *(5)* (75% N_2). The spiroheptadiene mixture of *(6a)* and *(6x)* was filtered over silica gel and then analyzed gas chromatographically (2—3 m columns, 20% SE 30 on Chromosorb PAW 30—60 mesh, 160—170 °C); the results (5 measurements) were evaluated using eq. (2).

[*] Prof. Dr. H. Dürr and Dipl.-Chem. F. Werndorff
Fachbereich 14, Organische Chemie der Universität
66 Saarbrücken (Germany)

[**] Cycloalkenecarbenes Part 11.—Part 10: *H. Dürr, B. Ruge*, and *B. Weiss*, Liebigs Ann. Chem., in press.

problem—which can be regarded as a decisive test for *Hoffmann*'s calculation[1]. We now describe the [1+2]-cycloaddition of *(2)* to styrenes *(5)* containing *p* or *m*-substituents of different electronegativity. Unlike in Ref. [4] steric effects are excluded. The singlet character of *(2)* at room temperature, a prerequisite for such studies as these, was proven by its stereospecific cycloaddition to *cis*- or *trans*-olefins[4]. The competition constants k_{rel} (Table 1) for the cycloaddition of *(2)* [from diazocyclopentadiene *(4)*] to styrene pairs should therefore permit conclusions to be drawn regarding the nucleophilic or electrophilic character as well as the electronic configuration of *(2)*. For the determination of k_{rel}, eq. (1) can, under the reaction conditions—twentyfold excess of styrene and equimolar mixture *(5a)*/*(5x)*—be simplified to eq. (2) [*(5x)*=*(5b)* to *(5e)*].

Correlation of k_{rel} with Hammet σ constants[5] yields a reaction constant of $\rho = -0.76 \pm 0.10$ (correlation with the σ^+ values[5]: $\rho = -0.46 \pm 0.05$).

$$k_{rel} = \frac{k_B}{k_A} = \frac{\log([B_0]/[B])}{\log([A_0]/[A])} \quad (1)$$

$$k_{rel} = [(6b)-(6e)]/[(6a)] = k_{(6x)} \cdot k_{(6a)}. \quad (2)$$

k_A and k_B = rates of addition to *(5a)* and *(5x)* resp.

These values confirm quite clearly the electrophilic character of *(2)* and therewith the alternance between electrophilicity and nucleophilicity in the carbene series *(2)* and *(3)*; moreover, the p^2 electronic configuration of the reactive species at room temperature can be regarded as confirmed.

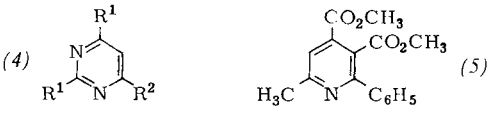
Thermolysis of 1,3-Oxazin-6-ones to 2,4,6-Trisubstituted Pyridines[1]

By *Ernst Buschmann* and *Wolfgang Steglich*[*]

On heating to 270 °C β-acylaminoacrylates afford 1,3-oxazin-6-ones *(1)*[1], which on prolonged heating on a hot-metal bath (300—320 °C) undergo further reaction to give 2,4,6-trisubstituted pyridines *(3)*, nitriles, and CO_2.



(1) *(2)* *(3)*

In the case of *(1a)*—*(1c)* 2,4,6-trisubstituted pyrimidines *(4)* are formed as by-products. They remain in the distillation flask after *(3)* has been distilled off and can be isolated in an analytically pure state by preparative gas chromatography (Table 1).

The trialkyl-substituted pyridines and pyrimidines can be readily distinguished from each other by characteristic IR bands (CCl_4) at 1605, 1570 [*(3a)*—*(3d)*][2] and 1595, 1560 cm^{-1} [*(4a)*—*(4c)*] respectively. The NMR spectra are in accord with the given structures.

The formation of pyridines, nitriles, and CO_2 can be explained in terms of the Diels-Alder dimer *(2)*. As in the reaction

(1e)	C_6H_5	CH_3	2 h, 310 °C	*(3e)*	15	156—158/0.8
(1f)	$(CH_3)_2CH$	C_6H_5	4 h, 300 °C	*(3f)*	22	85—87/0.2

[a] All compounds gave correct elemental analyses (partly as perchlorates and picrates).

[b] Ethyl β-acetaminocrotonate was used for the thermolysis. Here the oxazinone *(1a)* formed along with other compounds reacts further to give *(3a)* and *(4a)* so readily that it can not be isolated.

[c] Along with much unreacted *(1a)*.

with electron-rich multiple bonds, the cycloaddition proceeds regiospecifically[1]. The oxazinones *(1)* cannot be converted into pyrimidines by heating with nitriles, thus ruling out this route for the formation of *(4)*. That 1,3-oxazin-6-ones *(1)* can enter into [4+2] cycloadditions also with electron-poor multiple bonds is demonstrated by the reaction of *(1e)* with dimethyl acetylenedicarboxylate (20 min, 200 °C), which affords the pyridinedicarboxylate *(5)* (m.p. 215—217 °C) in 36% yield.

2-Isopropyl-4,6-dimethylpyridine (3b)

4-Methyl-2-isopropyl-1,3-oxazin-6-one *(1b)*[1] (8.4 g) is heated for 4 h at 320 °C (hot-metal bath). The product of thermolysis is extracted with 1 N HCl. The aqueous phase is neutralized with 1 N KOH, extracted with ether, and dried over $MgSO_4$. After removal of solvent the final product is distilled under water-jet vacuum; yield 2.96 g (73%).

Reviews

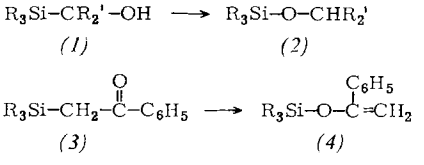
Abstracts of selected progress reports and review articles

Selected partially alkylated boranes have advantages in organic synthesis compared with trialkylboranes, as shown by *E. Negishi* and *H. C. Brown* in a review. Strongly hindered olefins react rapidly to give the monoalkylboranes, of which thexylborane (1,1,2-trimethylpropylborane) *(1)*, prepared from 2,3-dimethyl-2-butene and borane in THF at 0°C, is being used to an increasing extent. Compound *(1)* and olefins react almost quantitatively to form thexylmonoalkylboranes *(2)* which in turn can hydroborate numerous olefins to the mixed trialkylboranes *(3)*. The article considers the use of com-

(1) *(2)* *(3)*

pounds *(3)* for the production of unsymmetrical and cyclic ketones, the coupling of unequal alkyl groups, the synthesis of *trans*-disubstituted olefins, conjugated dienes, diols from dienes, as well as 1,5-diols from monoolefins. Interesting possibilities are presented by selective reduction with *(1)* and with trialkylboranes such as *(3)* which contain the thexyl group. [Thexylborane—A Highly Versatile Reagent for Organic Synthesis *via* Hydroboration. Synthesis *1974*, 77—89; 48 references]

[Rd 703 IE—M]



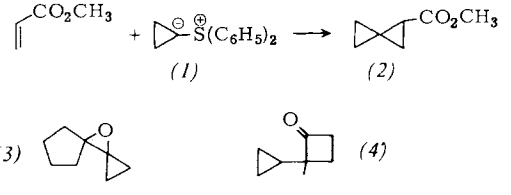
Papers concerning organomagnesium compounds *(1)* which appeared in 1972 are summarized by *C. Blomberg*. The reactions leading to *(1)* are first discussed, followed by the synthesis of halo- and alkoxy-substituted *(1)* and derivatives of *(1)* containing C=C double bonds and other metals; consideration is also given to reactions involving intermediate or "*in-situ*" Grignard compounds. NMR studies on the physical properties, structure, and molecular association of *(1)* are also reported, as are the mechanisms of reactions of *(1)* with *e.g.* carbonyl compounds and free-radical reactions of *(1)*. Many of the papers cited are devoted to reactions between *(1)* and organic compounds, O_2, O_3, peroxides, S, and Te, as well as compounds of B, Si, P, S, and As. [Magnesium. Annual Survey Covering the Year 1972. J. Organometal. Chem. *68*, 69—219 (1974); 368 references]

[Rd 704 IE—M]

Advances in the chemistry of germanium in 1972 are surveyed by *B. C. Pant*. After an overview of the direct syntheses of Ge compounds, the author discusses alkylations and arylations (Grignard method, aryl-Li compounds as intermediates), Ge—H, and Ge-metal compounds (*e.g.* organogermanyl-Hg and -Cd derivatives, germanyl-substituted ferrocenes, and Ge, Ge—N, Ge—P, Ge—As, Ge—O, Ge—S(Se, Te) compounds containing Ti, Zr, Hf) with regard to their synthesis and reactions. Addition of organohydridogermanes to alkynyl derivatives leads to alkenyl and alkynyl compounds. Cyclic Ge compounds can be prepared from multiply unsaturated compounds and organohydridohalogermanes, by addition of $GeCl_2$ to dienes and trienes, and of GeL_2 to alkynes, and *via* silicon compounds. The survey closes with references to Ge-containing polymers and sections on physicochemical and spectroscopic studies and analysis and applications of organogermanium compounds. [Germanium. Annual Survey Covering the Year 1972. J. Organometal. Chem. *68*, 221—293 (1974); 300 references]

[Rd 707 IE—M]

Rearrangements of organosilicon compounds are reviewed by *A. G. Brook*, who devotes particular attention to rearrangements of compounds which have functional groups (OH, C=O, S→O, C=N, *etc.*) attached to the carbon adjacent to silicon. For instance, in the presence of active metals, organometallic compounds, or bases such as pyridine, trialkyl- and triarylsilylmethanols *(1)* undergo intramolecular 1,2 rearrangement to alkoxysilanes *(2)*. The configuration at the Si atom is



(1) *(2)* *(3)* *(4)*

retained. The article also considers thermal decarbonylation of silanecarboxylic acids and their esters, photolysis of acylsilanes in CCl_4 to give halosilanes, and the thermolysis of β-oxosilanes *(3)* to form alkenyloxysilanes *(4)*. [Some Molecular Rearrangements of Organosilicon Compounds. Accounts Chem. Res. *7*, 77—84 (1974); 59 references]

[Rd 708 IE—L]

New methods of alkylation have been compiled by *B. M. Trost*. Sulfur ylides of type *(1)* have proved to be excellent alkylation

(1) *(2)*

(3) *(4)*

reagents. They react with α,β-unsaturated ketones and esters to give spiropentanes *(2)*, and with aldehydes or ketones to yield oxaspiropentanes *(3)* and/or cyclobutanones *(4)*. Further reactions of these products furnish, *e.g.*, four-, five-, and six-membered carbocycles, γ-butyrolactones, and acyclic compounds of numerous types. [New Alkylation Methods. Accounts Chem. Res. *7*, 85—92 (1974); 47 references]

[Rd 709 IE—L]

New applications of periodic acid and periodates in organic chemistry and biochemistry are reported by *A. J. Fatiadi*. A discussion of various properties of H_5IO_6 and $NaIO_4$ and the mechanism of oxidation by these compounds, which has still not been completely elucidated, is followed by an account of their use as oxidants for polycyclic aromatic hydrocarbons (oxidative dimerization, quinone formation, oxidative hydrol-

ysis), non-benzenoid aromatic compounds, cyclopolyenes (azulene, ferrocene), and steroids, as well as the oxidative degradation of bile pigments, heterocyclics (indole and tryptophan type), and terpenes. Examples of arene iodination by H_5IO_6 or I_2/H_5IO_6 are also presented. Periodates with organic cations are valuable agents for oxidations in aqueous and non-aqueous media. Periodate oxidation can be exploited in the synthesis of heterocyclics, and plays a significant role in stereospecific asymmetric syntheses of carbohydrates. Periodate serves as co-oxidant in oxidations with $KMnO_4$, OsO_4, RuO_4, CrO_3, *etc.* Oxidations of hydroxyaromatics are of preparative value. Typical applications in biochemistry include structural analyses of nucleic acids, and the degradation of collagen, glycoproteins, and carbohydrates. Recent analytical applications of periodates are also reported. [New Applications of Periodic Acid and Periodates in Organic and Bio-Organic Chemistry. Synthesis *1974*, 229—272; 592 references]

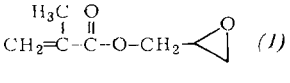
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office



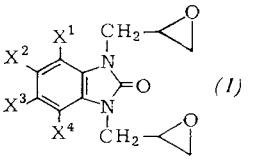
Polyolefin blends with high resistance to low temperatures and to cracking under load consist of a) 20—80 wt.-% of a polypropylene with a viscosity of 4—9 dl/g and b) 80—20 wt.-% of a polyethylene with a viscosity of 0.5—3 dl/g and a density of 0.95—0.97 g/cm³. The component (a) may be modified with 1—20 wt.-% of ethylene, and the component (b) with 1—3 wt.-% of propylene. The blends can be used for injection molding or blow molding. [DOS 2208265; Montecatini Edison S.p.A., Milan]

[PR 162 IE—A]

Non-gelling, water-dispersible cationic epoxy resins for coating compositions that can be deposited electrophoretically on cathodes contain chemically bonded quaternary phosphonium or sulfonium groups. Acids having dissociation constants higher than 1×10^{-5}, such as boric acid or lactic acid, are used as counterions. The resins are prepared *e. g.* from commercial epoxy resins and tributylphosphane in the presence of lactic acid. Coatings formed with these cationic electrophoretic lacquers are more resistant to alkalis and acids than binders that can be deposited anionically. [DOS 2261804; PPG Industries, Inc., Pittsburgh, Pa. (USA)]

[PR 189 IE—W]

High-setting polyacrylate molding powders that can be molded into products having a high elongation at break, tensile strength (1100—2100 kg/cm²), and glass transition temperature (90 °C) consist of a prepolymer of glycidyl methacrylate *(1)*, methyl methacrylate, and methacrylonitrile or acrylonitrile. The readily fusible prepolymers have average molecular



(1)

weights of 2000—10000 (vapor pressure osmometer). The powders are crosslinked for 30 minutes with dibasic acids such as azelaic acid, adipic acid, pentanedicarboxylic acid, sebacic acid, *etc.*[1] at temperatures around 190 C. [DOS 2261314; Ford-Werke AG, Köln]

[PR 191 IE—W]

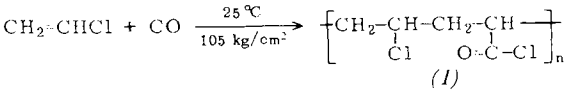
New diglycidylbenzimidazolones that can be used for the production of casting resins, sintered powders, or molding compositions by curing with amines or anhydrides correspond to the formula *(1)*, where X is preferably a methyl group or hydrogen, or X^1 and X^2 together form a fused benzene ring. The starting compounds are benzimidazolones, which

(1)

are converted into the diepoxide by conventional methods with epichlorohydrin. Cured compositions possess outstanding stability to water. [DOS 2300010; Ciba-Geigy, Basel (Switzerland)]

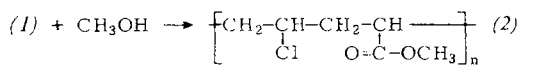
[PR 192 IE—W]

A process for the production of synthetic paper consists in brief initial treatment of a biaxially drawn film of a high-impact styrene resin/elastomer blend of the ABS type with a solvent that has a swelling action on the styrene polymer, followed by passage of the film through a non-solvent. One obtains a synthetic paper that exhibits excellent writability and printability with a smooth surface. The high-impact blend contains 3 to 7 wt.-% of an elastomer of polybutadiene, polybutadiene-styrene, or an ethylene-propylene terpolymer with an average particle diameter of 0.5 to 5 µm. An acrylonitrile-butadiene-styrene polymer, a methyl methacrylate-styrene-butadiene copolymer, or an acrylonitrile-butadiene-styrene-methyl methacrylate copolymer may also be used as the resin phase (styrene polymer). Examples of solvents that have a swelling action are acetates, ketones, aromatic hydrocarbons, and cyclic ethers; non-solvents are alcohols (C_1—C_{10}). [DOS 2240764; Sumitomo Chemical Co. Ltd., Osaka (Japan)]



[PR 193 IE—W]

A continuous process for the carbanionic block polymerization of butadiene and styrene makes use of the influence of thorough mixing or of plug flow on the block structure. The monomers of the butadiene type are first continuously polymerized with butyllithium in toluene, with ideal mixing, up to a conversion of 70 % to form a "living" block; again under steady conditions (ideal mixing), styrene is then added in a second stage with continuous flow-through, whereupon a random butadiene-styrene copolymer grows on the butadiene block. The conversion based on butadiene is now 95 %. In a reactor without appreciable back-mixing with plug flow, the styrene first polymerizes with the remaining 5% of butadiene, and styrene then grows on the chain ends. In a subsequent pin mixer, the molecular weight of the living block copolymer can be doubled by introduction of *e. g.* 1,2-dibromoethane. In the resulting block copolymer, $(B)_x$—$(B/S)_y$—$(B/S)_z$—$(S)_n$ (B = butadiene, S = styrene), the first $(B/S)_y$ block has a random structure, and the second $(B/S)_z$ block is "blurred". [DOS 2111966; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

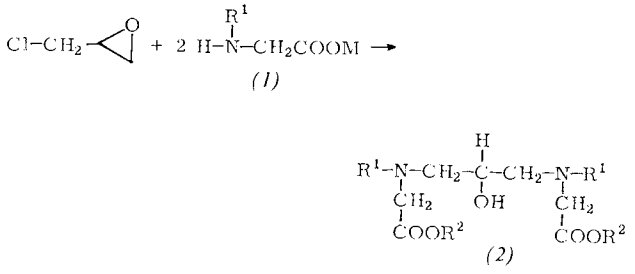


[PR 194 IE—W]

[1] The crosslinking with the corresponding acid (poly)anhydrides is claimed in DOS 2261335 (Ford-Werke AG, Köln).

Copolymers *(2)* **of vinyl chloride and acrylic ester units** can be prepared by free-radical copolymerization of vinyl chloride with carbon monoxide in the presence of an alcohol. A vinyl chloride-acryloyl chloride copolymer *(1)* is first formed, and

(1)

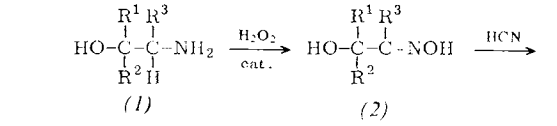


(2)

this reacts further with the alcohol to form *(2)*. [DOS 2211380; Montecatini Edison, S. p. A., Milan (Italy)]

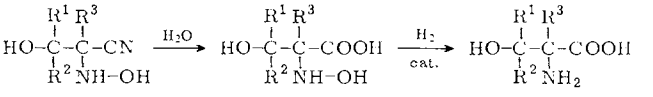
[PR 195 IE—W]

Chelate-forming amino acids having the formula *(2)* are formed as their alkali metal salts from aqueous solutions of amino compounds *(1)* by reaction with epichlorohydrin



(2)

R^1 = alkyl (C_1–C_{20}), H, CH_2CH_2OH, CH_2COOH, or CH_2COOM; R^2 = H or M; M = alkali metal



at pH 6—10.5 and at 65—105 C. The free acids can be obtained by acidification to pH 1.3—2. The alkali metal salts of *(2)* are extremely suitable for the complexing of nickel, copper, zinc, and iron ions. The nickel, copper, and zinc complexes can be used for the control of the metal ion concentration of electroplating baths. Zinc and iron complexes are suitable for the supply of complexed zinc and iron to growing plants. The tetracarboxylic acid *(2)*, $R^1 = CH_2COOH$, $R^2 = H$, can be used as a stabilizer for developers in color photography. [DOS 2234905; W. R. Grace & Co., New York (USA)]

[PR 201 IE—D]

β-Hydroxy-α-amino acids *(5)* can be prepared in a four-step process from the amino alcohols *(1)*. The process can be advantageously used *e.g.* for the synthesis of serine from

(1) *(2)*

(3) *(4)* *(5)*

R^1, R^2, R^3 = H or substituted or unsubstituted aliphatic, aromatic, cycloaliphatic, or heterocyclic residues containing 1—8 C atoms

aminoethanol (yield 58%). [DOS 2326874; Snam Progetti S. p. A., Milan (Italy)].

[PR 202 IE—D]

BOOK REVIEWS

Römpps Chemie-Lexikon (Römpp's Lexicon of Chemistry). By *O.-A. Neumüller*. Franckh'sche Verlagshandlung, W. Keller & Co., Stuttgart 1973. 7th Edit. Vol. 2, D—G, 625 pp. + 18 p. Appendix, 215 figures, bound DM 125.—, ISBN 3-440-03852-1; Vol. 3, H—L, 659 pp. + 19 p. Appendix, 170 figures, bound DM 125.—, ISBN 3.440-03853-X.

The publication of the first volume of the fully revised and expanded "Römpp" (to appear in 6 volumes instead of 4) was announced in October 1972[1]. Volumes 2 and 3 (letters D—G and H—L), which were edited under the direction of *O.-A. Neumüller* with the assistance of *K. Esser* and *K. Siekmann*, have now been published. The editors have set themselves the ambitious target of completing the 7th edition, for which a file of more than 160000 cards will have to be dealt with, by 1975 at the latest. It is their intention that none of the entries from the 6th edition should be incorporated into the 7th edition without revision, and that new terms from the current literature should be included at the same time. On browsing through the volumes, in fact, one finds frequent references to works published in 1972 and even 1973 to allow further reading on the problem in hand. In most cases, however, sufficient information is given in the text under the entries. The explanations of the entries are clear and understandable. Special care has been taken to follow the IUPAC nomenclature in the naming of chemical substances. However, this does not mean that older names that are still in common use, such as *Kaliumsulfhydrat* and *Kaliumsilicofluorid* are omitted.

Many new terms are included in the 7th edition. For example, on leafing through one finds HMO theory, hot melts, INDOR, jogs, and KWIC index. Some entries already found in the 6th edition, such as Insecticides, have been considerably expanded. Valuable references are made to recent commercial products, suggesting that catalogs and brochures have been carefully monitored and sifted. The care with which the volumes published so far have been edited, composed, corrected, and printed is commendable.

There is no doubt that chemists will find the new "Römpp" valuable in their daily work. However, it can also be warmly recommended to workers in neighboring fields.

Christian Weiske [NB 198 IE]

Physikalische Organische Chemie (Physical Organic Chemistry). Reaction Rates, Equilibria, Mechanisms. By *L. P. Hammett*. Verlag Chemie, Weinheim 1973. viii, 413 pp., numerous figures and tables, bound DM 59

More than 30 years ago, *L. P. Hammett* gave an enure field a name and a direction in his book "Physical Organic Chemistry", which has now become a classic. In the present work,

a translation of the 2nd edition, which has little but its name in common with the first, the doyen offers a refreshingly unconventional presentation of the principles underlying the investigation of heterolytic reactions of organic compounds in solution. Established views are very carefully and critically spot-lighted, and their historical development is traced (only apparently loosely) with the intimate familiarity of one who was actually present. At an advanced level (mastery of algebraic details and knowledge of current physicochemical laws are assumed), *Hammett* fills a gap, particularly noticeable in Germany, between textbooks on mechanisms of organic reactions and "pure" physical chemistry.

The work can be broadly divided into three parts. After introductory original remarks on the self-assessment of the chemist, the first part deals with fundamental physicochemical concepts. A self-consistent, very formal and terse description of "Thermodynamics in Solutions" and notes on statistical mechanics are followed by a very useful introduction to the treatment of kinetic data and an excellent account of the theory of the transition state and its direct consequences, such as isotope effects, the Curtin-Hammett principle, *etc.* In the middle part, the author presents a skillful and even exciting illustration of the knowledge that has been acquired, taking as his examples "Nucleophilic Substitution" and "Azo Coupling", and leading the reader naturally to the ion-pair concept, which becomes the central theme in the subsequent chapter "Salt Effects" and "Influence of the Solvent on Reactivity". The final part presents brilliant summaries of fields that are closely associated with the name *Hammett:* acidity functions; acid and base catalysis; linear free energy and isokinetic relations.

This work must inspire all who are interested in the investigation of organic reaction mechanisms. Advanced students should find the chapters on kinetics, theory of the transition state, and linear free energy relations extremely valuable. The layout of the book is very clear, and it contains many excellent graphs. The translation by *Peter Schmid* is good, and a number of technical terms used rather loosely by the author have been discreetly corrected.

Günter Helmchen [NB 200 IE]

Der Umfang des Stoffschutzes für chemische Erfindungen (The Scope of Substance Protection for Chemical Inventions). By *B. Geissler*. Carl Heymans Verlag KG, Cologne—Berlin—Bonn—Munich, 1972. 1st Edit., xxiii, 189 pp., DM 42.

The lifting of the ban on product protection has raised a number of problems, including the question of the scope of product protection for chemical compounds. The subject is discussed systematically and in the light of different legal backgrounds. After an introductory chapter on the history of product protection in Germany, the author deals with the scope of protection provided by product claims for chemical inventions in France, in the USA, and in the Scandinavian countries. After a brief outline of patent theories it is deduced, with a careful weighing up of the arguments for and against absolute product protection, that only a purpose-linked product claim is adequate for chemical inventions. Although this result appears virtually only as a conclusion from the arguments presented, it leaves a certain uneasiness. Perhaps this is because the discussion of the problem of protection for products that have not been prepared chemically, which has long been practiced in the Federal Republic of Germany is a little too brief. Claims of the "agent for..." type that were customary even before the ban on product protection was lifted are purpose-linked (and therefore largely satisfy the author's requirements) but they are incapable of completely satisfying the requirements. If broad product protection is granted to alloys, glasses, and compositions of matter, similar protection should be extended to new chemical substances. The question of whether it is only "apparently" broad would have to be investigated in all cases on the same principles. However, it must not be overlooked that, for example, intermediates cannot be adequately covered by purpose-linked product claims. The "object" problem in the case of new products, with which the author deals, also offers much food for thought: in the discovery of a new substance, does not the essence of the invention after all lie in the provision of this newly constituted substance, as is stated in the Imidazoline Decision of the Federal Supreme Court published after the book went to press? The fact that these new substances must (also) be useful is a legal requirement for patentability. In spite of these misgivings the book can be recommended to anyone who has to deal with the scope of claims: it is a point in favor of a book if it makes the reader think.

Friedrich Rämisch [NB 203]

Dielectric and Related Molecular Processes, Vol. 1. Specialist Periodical Reports. The Chemical Society, London 1972. 1st Edit., xv, 394 pp., several figures and tables, bound £ 8.

In seven chapters the present book contains several up-to-date articles on dielectrics and molecular processes in the substances.

Chapter 1, "The Theory of the Macroscopic Properties of Isotropic Dielectrics" by *B. K. P. Scaife*, presents an introduction from the classical standpoint. Chapter 2, "Dielectric Relaxation and Molecular Correlation" by *G. Wyllie*, deals with the dielectric relaxation processes and the molecular models used for their interpretation. This is probably the most detailed modern review of this field in existence at the moment.

Chapter 3, "Dielectric Polarization in Gases" by *H. G. Sutter*, is concerned with the special problems that arise in the dielectric polarization of gases. Relaxation phenomena are not discussed. Chapter 4, "Time Domain Methods" by *A. Suggett*, gives an excellent, concise (18 pp.) survey of the modern methods in which the pulse technique is used for the determination of dielectric data in liquids, solutions, and polymers.

Chapter 5, "Dielectric Properties of Water and of Aqueous Solutions" by *J. B. Hasted*, deals fairly comprehensively with the phenomena that occur in water or in aqueous solutions, and the structure of water is also discussed. Chapter 6, "Dielectric Polarization Phenomena in Biomolecular Systems" by *G. Schwarz*, presents a brief description (26 pp.) of the use of dielectric methods for the investigation of biopolymers, and the author also deals with his own field, the conformational transitions of biopolymers.

Chapter 7, "General Molecular Theory and Electric Field Effects in Isotropic Dielectrics" by *S. Kielich*, occupies roughly half of the book and gives a detailed account of the electrical and magnetic properties of molecular systems, with special consideration of multipoles and the corresponding potentials. The statistical and electromagnetic properties of dielectrics are then briefly discussed. A very long section is devoted to electro-optical properties, particularly to the Kerr effect, and another section deals with the changes in the electrical properties in strong electric fields.

Despite its heterogeneous content, the book will be of great value to any scientist working in the field of dielectrics. It

is regrettable that apart from the section on biopolymers, the dielectric phenomena of high polymers are not discussed. The book also lacks descriptions of measurements in the microwave and far IR regions. It is to be hoped that these topics will be included in subsequent volumes of this series.

Werner Zeil [NB 204 IE]

Biosynthesis, Vol. 1. Specialist Periodical Reports. The Chemical Society, London 1972. 1st Edit., 149 pp., bound £ 6.50.

The present first volume in a series on the biosynthesis of cell constituents is mainly concerned with methodological studies and results for natural products from plants. The literature discussed is mainly from the years 1970 and 1971, though earlier studies are also included where these are required to clarify relationships and basic principles.

The general principles are presented by *S. A. Brown* in the opening chapter on labeling procedures in living plants and in isolated tissue systems, with mutants and with specific antimetabolites. This chapter also deals with the recent development of differential NMR spectroscopy for following the fate of structural components, which can take the place of isotope studies in favorable cases. The book then continues with the discussion of fields in which particularly fruitful and penetrating developments and results have been achieved in recent years: the biosynthesis of monoterpenes and sesquiterpenes from acetyl coenzyme A (*J. R. Hanson*), the conversion of isopentenyl pyrophosphate into triterpenes, steroids, and carotenoids (*H. H. Rees* and *T. W. Goodwin*), and the biogenesis of phenolic compounds from shikimic acid or from acetate units (*J. B. Harborne*). One still often has to resort to general feeding experiments here to determine the reaction sequence; in the case of the flavonoids, however, it has been possible to establish the individual enzymatic steps, particularly through the work of *Grisebach*, and it is to be expected that the next volume will be able to report similar progress from other synthetic chains of plant materials. The book ends with a mainly tabular summary of the biogenesis of alkaloids (*E. Leete*), a complete account of which is to be given in another series.

The detailed studies on the stereochemical course of the condensations, rearrangements, and oxidoreductions in the polyprene syntheses are conceptionally and experimentally outstanding. The individual chapters are excellently written, and not only give the essential lines of current research but also show the directions that are now becoming important. The careful selection and discussion of the literature makes the volume a strongly commendable guide to these publications on plant physiology, which are often widely scattered and not readily accessible. Those who are working in the field will find this helpful in their own work, and it will also prove an excellent aid to anyone seeking a general survey. These volumes thus really fulfill their intended purpose, and will be welcomed by everyone concerned with the biochemistry of the natural products of plants.

L. Jaenicke [NB 205 IE]

Atom-Absorptions-Spektroskopie (Atomic Absorption Spectroscopy). By *Bernhard Welz*. Verlag Chemie GmbH, Weinheim/Bergstr. 1972. 1st Edit., x, 216 pp., 52 figs., 46 tables, cloth DM 58.—.

Atomic absorption spectroscopy is one of the methods of instrumental analysis whose widespread use is not confined to chemical laboratories. Atomic absorption spectrometers are nowadays to be found in many biological, mineralogical, and clinical laboratories. This spectroscopic method is also one of the standard methods of analysis in the protection of the environment. When an instrumental method of analysis is used in such a wide variety of fields, one often finds that it is not always used to its full advantage, mainly because of the user's training. A particularly welcome feature of the present book, therefore, is that it has been written in such a way that it will also be understandable to biologists, mineralogists, geologists, and clinical chemists.

The book deals with the physical principles of the method without going into special physical and mathematical details, as well as with the component parts of the instrument (light sources, optics, electronics, *etc.*) and the determination of the various elements (in alphabetical order).

A separate chapter is devoted to specific applications in medicine, biochemistry, toxicology, food chemistry, geochemistry, petrochemistry, *etc.* Literature references for further information are given here in tables arranged according to elements for the particular type of test sample in question (*e.g.* serum, urine, fertilizer, *etc.*). The book also contains a short chapter on flame emission spectroscopy and atomic fluorescence spectroscopy, a very comprehensive bibliography (859 references), and an appendix listing the commercially available atomic absorption spectrometers (with tables of technical details).

The book, which may be described as an excellent synthesis of introduction and reference work, will be useful to anyone who is concerned with atomic absorption spectroscopy.

Egon Fahr [NB 207 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Wechselwirkung von π-Elektronensystemen mit Metallhalogeniden. By *H.-H. Perkampus*. From the series "Molekülverbindungen und Koordinationsverbindungen in Einzeldarstellungen". Edited by *G. Briegleb*, *F. Cramer*, and *H. Hartmann*. Springer-Verlag, Berlin 1973. xi, 215 pp., bound DM 68.—.

Contents: Einleitung und Abgrenzung; Donatoren und Acceptoren; Proton-Additions-Komplexe; π-Komplexe; σ-Komplexe.

Free-Radical Chemistry. Structure and Mechanism. By *D. C. Nonhebel* and *J. C. Walton*. Cambridge University Press 1974. xv, 571 pp., bound £ 15.00.

Contents: Production of Free Radicals; Detection; Shapes; Stabilities; Reactions in the Gas Phase; Reactions of Atoms; Alkyl Radicals; Heteroradicals; Oxidations and Reductions; Aromatic Substitution; Fragmentations; Rearrangements; Cyclizations; Displacement Reactions.

An Introduction to Solid State Physics and its Applications. By *R. J. Elliott* and *A. F. Gibson*. Macmillan, London 1974. xxi, 490 pp., bound £ 5.95.

Contents: Crystal Structure; Excitations; Lattice Vibrations; Electrons in Bands; Imperfections in Crystals; Optical Properties of Solids; Optical and Microwave Properties of Free Carriers; Transport; Semiconductor Junction Devices; Magnetism.

Biosynthesis, Vol. 2. Senior Reporter: *T. A. Geissman*. The Chemical Society, London 1973. ix, 308 pp., bound £ 8.00.— A volume in the series "Specialist Periodical Reports".

Carbon Suboxide in Preparative Organic Chemistry

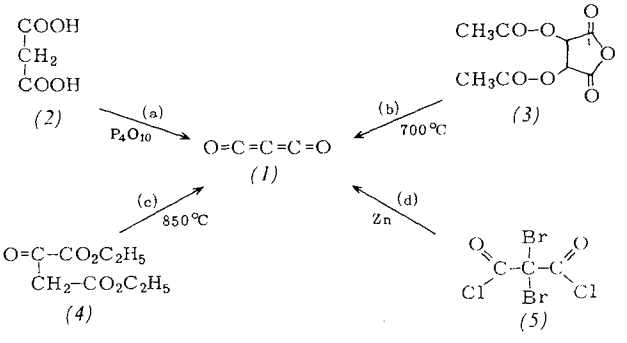
New synthetic methods (1)

By Thomas Kappe and Erich Ziegler[*]

Although it has been known for nearly 70 years, carbon suboxide was used almost exclusively for the preparation of simple malonic acid derivatives until about 1960. Since then, however, the significance of this unusual "bisketene" has steadily increased in synthetic chemistry (especially that of heterocyclic compounds). This progress report surveys the possible applications of C_3O_2 in preparative organic chemistry, including photochemical reactions.

1. Introduction

While studying the action of phosphorus pentoxide on diethyl malonate at 300 °C, *Diels*[1] observed that the generation of ethylene and some CO_2 was accompanied by formation of small quantities of another gas which first caught his attention by virtue of its powerful irritating action on the mucous membranes. He was able to isolate a substance having a boiling point of 6.8 °C, to which he assigned[2] the structure of allenedione *(1)*



O=C=C=C=O *(1)*

on the basis of elemental analysis, molecular-weight determination, and, above all, a series of reactions leading to malonic acid derivatives. He named the compound "carbon suboxide"[3]. The following year *Diels*[4] published another much more productive synthesis from malonic acid and P_4O_{10} which is still used for the preparation of *(1)* in many laboratories.

The name carbon suboxide for *(1)* is somewhat misleading since the compound does not behave as a "normal" oxide of carbon but as a bisketene. Viewed in this way, *(1)* can be considered as a doubly dehydrated malonic acid; most of its reactions furnish derivatives of this acid. Owing to its unusual structure, carbon suboxide has mainly attracted the interest of theoretical and physical chemists since its discovery. Results of such studies have been presented in a recent review[5]. In the following we shall therefore only briefly touch upon the most recent results concerning the structure of C_3O_2. The aim of this progress report is primarily to present recently developed applications of carbon suboxide to preparative organic chemistry, particularly in the synthesis of heterocyclic compounds[6]

2. Preparation of Carbon Suboxide

Of the many reactions known to afford C_3O_2 there are four which lend themselves to laboratory preparations:

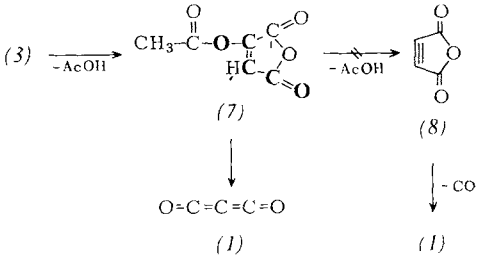
a) Dehydration of malonic acid *(2)* with P_4O_{10} at 140—150 °C, as used by *Diels*[4] (*ca.* 23% yield);

b) Thermolysis of *O,O*-diacetyltartaric anhydride (2,5-dioxotetrahydrofuran-3,4-diyl diacetate) *(3) in vacuo* at 600—700 °C

[*] Prof. Dr. Th. Kappe and Prof. Dr. E. Ziegler
Institut für Organische Chemie der Universität
A-8010 Graz, Heinrichstrasse 28 (Austria)

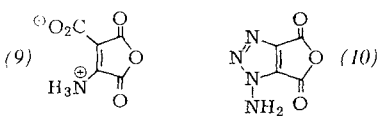
(46—68%) or under normal pressure at 770°C (*ca.* 45% yield)[7];

c) Pyrolysis of diethyl oxaloacetate *(4)* in the presence of acetic anhydride at 850—880°C (48% yield)[9]; and



d) Dehalogenation of dibromomalonyl chloride *(5)* with zinc turnings in boiling ether (*ca.* 80% yield)[10, 11].

These preparations are considered in the available reviews[5, 6], in some cases[6e] with diagrams of apparatus. Thermal decomposition of silver ketenide *(6)*, which is accessible from silver acetate and acetic anhydride in pyridine, is also reported to yield compound *(1)* quantitatively and in high purity[12]:



$$\underset{(6)}{2Ag_2C{=}C{=}O} \xrightarrow[150\,^{\circ}C]{} \underset{(1)}{C_3O_2} + C + 4Ag$$

This route does not yet seem to have been exploited in preparative work, probably owing to the danger of explosion of *(6)*.

The most important preparation of *(1)* is that starting from diacetyltartaric anhydride *(3)*. However, until very recently the formation of *(1)* was interpreted erroneously. *Ott*[13], the discoverer of the reaction, initially formulated elimination of acetic acid to give acetoxymaleic anhydride *(7)*, as was later confirmed; further loss of acetic acid was assumed to give acetylenedicarboxylic anhydride *(8)* which undergoes fragmentation with decarbonylation to form *(1)*. In contrast to the results of *Dashkevich*[9] who, in 1960, deduced the intermediacy of the hetaryne *(8)* in formation of *(1)* from both *(3)* and *(4)* on the basis of ^{14}C-labeling studies, in 1968 *Crombie*, *Gilbert*, and *Houghton*[8] unequivocally ruled out *(8)* (or any other symmetrical derivative) as intermediate by application of five differently ^{14}C-labeled diacetyltartaric anhydrides *(3)* and acetoxymaleic anhydrides *(7)* and of *(3)* bearing an ^{18}O label in the ester oxygen function. Instead, C^1 in *(3)* and *(7)* is eliminated and an O atom of the 2-hydroxy group of the original tartaric acid is retained; *i.e.* C_3O_2 arises from the atoms shown in bold print in formula *(7)*[14].

The question whether the hetaryne *(8)* occurs as an intermediate in the pyrolysis of *(3)*, *(4)*, and *(7)* is of significance since in the case of an affirmative answer other methods

of aryne chemistry could be employed in the preparation of *(1)*: *e.g.* diazotization of the anhydride *(9)* or reaction of the aminotriazole *(10)* with lead tetraacetate.

3. Structure of Carbon Suboxide

The geometrical and electronic structure of carbon suboxide has been a subject of detailed study in recent years[15–17]. The question whether C_3O_2 possesses a linear, angled, or zigzag structure[18] seemed to have been definitely answered in favor of a linear geometry on the basis of exact analysis of the IR spectrum[19–22] when in 1969 *Smith* and *Barrett*[23] put forward the hypothesis that C_3O_2 is only a quasilinear molecule, the frequency of the bending mode at the central C atom being 63 cm^{-1}, on the basis of certain peculiarities in the vibrational spectrum. Deflection experiments on molecular beams of C_3O_2 in inhomogeneous electric fields have recently demonstrated that the angle at the central carbon atom can deviate by at most 9° from the linear configuration. Electron diffraction studies[24] on C_3O_2 lead to a similar result.

Recent *ab initio* calculations with geometrical searching by *Sabin* and *Kim*[17] failed to show a low energy barrier for a bending vibration about the central C atom. Instead, a steep energy gradient is found even for small deviations (1°) from the linear structure. According to this calculation[17], the C=C and C=O distances are 1.332 and 1.243 Å (±0.005 Å) respectively [the measured values are ≈1.29 and 1.17 Å][25]; the resulting π-orbital energies are listed in Table 1, together with the *ab initio* results and values calculated by *Siegbahn*[26] from photoelectron spectra.

Table 1. π-Orbital energies [eV] in carbon suboxide *(1)*.

Method	$^1\Pi_u$	$^1\Pi_g$	$^2\Pi_u$
ab initio [17]	−18.66	−17.69	−11.89
ab initio [26]	−18.72	−17.74	−11.12
from ESCA values [26]	−16.0	−15.0	−10.8±0.2

Table 2 shows the charge distribution in carbon suboxide, which is also of significance in its chemical behavior. The unusually high negative charge on the central atom C^2 is surprising. Noteworthy is the good agreement between the values calculated from experimentally determined ESCA

Table 2. Charge distribution in $O{=}C^1{=}C^2{=}C{=}O$ *(1)*.

	O	C^1	C^2
Calc. from			
ESCA values [26]	−0.28	+0.45	−0.33
CNDO/2 [27]	−0.28	+0.46	−0.36
ab initio [17]	−0.260	+0.419	−0.318
ab initio [26]	−0.25	+0.59	−0.68

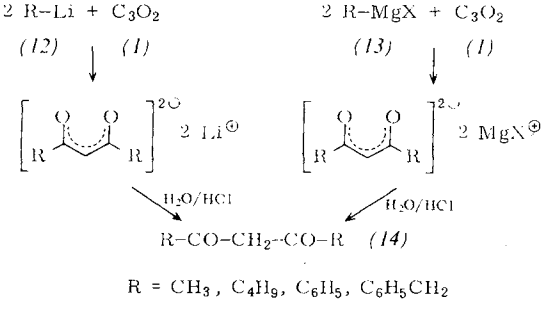
values[26] and those of a CNDO/2 calculation by *Ohlsen* and *Burnelle*[27] and the *ab initio* calculation by *Sabin* and *Kim*[17]; the *ab initio* values obtained by *Siegbahn*[26] predict an even greater polarization.

4. Reactions of Carbon Suboxide

As doubly dehydrated malonic acid, carbon suboxide *(1)* is extremely reactive. It is therefore hardly surprising that C_3O_2 can be used for reactions which give only unsatisfactory

yields, if they proceed at all, when attempted with other malonic acid derivatives. Many reactions of *(1)* even take place below 0 °C. Moreover, C_3O_2 is a "clean" reagent: viewed formally all the reaction products are adducts of *(1)* to the substrate, *i.e.* the reaction gives no by-products like HCl or chlorinated phenols such as are formed with malonyl chloride or reactive malonic esters[28,29]. The advantage of using *(1)* with sensitive substrates or products is clearly seen. Catalysts such as $AlCl_3$, and H_2SO_4 or *p*-toluenesulfonic acid, can considerably enhance the electrophilicity of *(1)*.

4.1. Reactions with Nucleophiles to Give Open-Chain Malonic Acid Derivatives



When present in excess, nucleophiles (NuH) such as aliphatic or aromatic amines[6d,6e], alcohols[6d,6e,30], phenols[6d,6e,30], or thiols[30,31] react smoothly with C_3O_2 to form malonamides, esters, or thioesters.

$$\underset{(1)}{O{=}C{=}C{=}C{=}O} + 2NuH \longrightarrow Nu{-}CO{-}CH_2{-}CO{-}Nu$$

Reaction with water is relatively slow (perdeuteriomalonic acid is formed with D_2O[32]). Hence the reaction with amines[33], anilines[34] amino acids[33,35], and proteins[36] can be carried out in buffered aqueous solution. *Hegar*[37] studied the addition of *e.g.* phenol to *(1)* in aqueous solution in the pH range 1—14 at 0 °C. He obtained diphenyl malonate as sole product; the maximum yield was found at pH 11. Alkyl malonate formation is catalyzed not only by acids[30] (enhanced electrophilicity of C_3O_2), but also by the corresponding Na alkoxides (conversion of substrate into the more nucleophilic anion). The yield of ester then becomes almost quantitative[38]. Oximes[6a,39], hydroxylamine and its *N*-substituted derivatives[40], amide oximes[41] and also some of their ethers[42] generally give linear malonic acid derivatives. In some cases, open-chain *N,N'*-diacylmalonamides *(11)* have also been obtained from carboxamides (but not from thioamides, cf. Section 4.3.2)[43].

$$2R{-}CONH_2 + \underset{(1)}{O{=}C{=}C{=}C{=}O} \longrightarrow \underset{(11)}{R{-}CO{-}NH{-}CO{-}CH_2{-}CO{-}NH{-}CO{-}R}$$

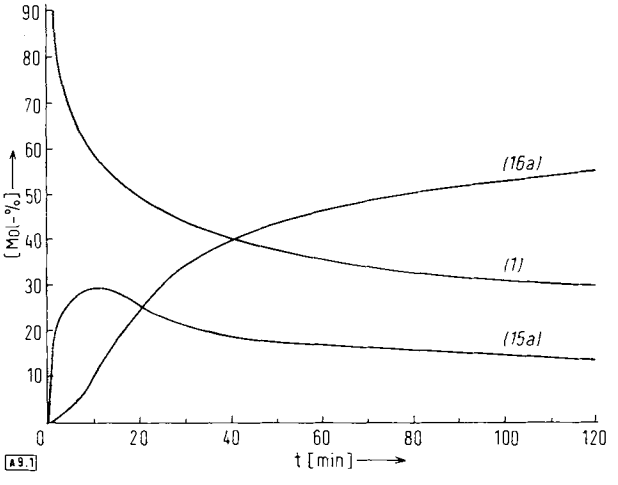
Action of excess organolithium compounds *(12)* or Grignard compounds *(13)* on C_3O_2 in ether followed by hydrolysis likewise furnishes β-diketones *(14)*[44,45], sometimes in enolized form.

4.2. Reactions Affording Ketenecarboxylic Acid Derivatives and Acylketenes

Nucleophiles add to C_3O_2 in a stepwise reaction involving ketenecarboxylic acid derivatives such as *(15)*. *Staudinger*[46] discovered in 1912 that, *e.g.* the non-catalyzed reaction of alcohols with *(1)* is slower than with other ketenes, and that unreacted C_3O_2 is still detectable after several days at low temperatures. Relevant quantitative studies have been performed only very recently with the aid of gas chromatography[47,48]. Remarkably, these investigations show (in contrast to previous assumptions[6f]) that the rate constant of the initial step, *i.e.* formation of the ketenecarboxylic acid derivative [*e.g.* the ester *(15)*] is more than double that of the second step in all the cases considered. A relatively high concentration of intermediate must therefore always be expected in reactions of *(1)* with nucleophiles, even when the latter are present in excess. Figure 1 shows the course of addition of 1-propanol to C_3O_2.

$$\underset{(1)}{C_3O_2} \xrightarrow[k_1]{+R{-}OH} \underset{(15)}{ROCO{-}CH{=}C{=}O}$$

$$\xrightarrow[k_2]{+R{-}OH} \underset{(16)}{ROCO{-}CH_2{-}COOR} \qquad k_1 > 2k_2$$



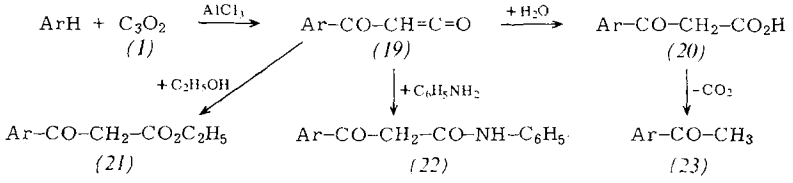


Fig. 1. Plot of reaction of C_3O_2 *(1)* (3.3 mmol) with 1-propanol (10 mmol) in ether (30 ml) at -20 °C (after [48]). Intermediate, *n*-propyl ketenecarboxylate *(15a)*; product, di-*n*-propyl malonate *(16a)*.

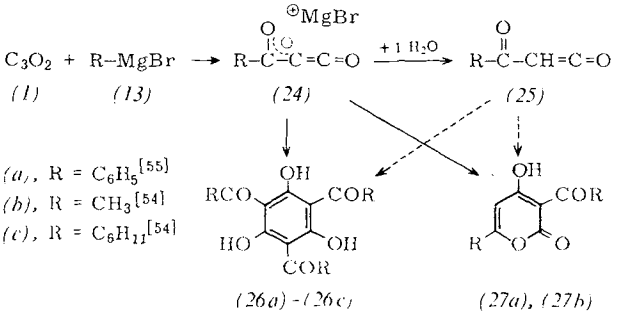
The reverse reaction, formation of such ketenecarboxylic acid derivatives as reactive intermediates on thermolysis of malonic esters [*i.e.* *(16)* → *(15)*] was postulated as early as 1955[49,28]. In 1967 *Ziegler* and *Sterk*[50] were able to show in an IR study that heating of malonyl chloride *(18)* to 80 °C affords the same ketenecarbonyl chloride *(17)* as is formed on mixing of gaseous HCl and C_3O_2. Addition of alcohols to *(1)* with formation of *(15)* can likewise be observed by IR spectroscopy whereas cleavage of aryl malonates to ketenecarboxylic esters can only be detected above *ca.* 250 °C by this method[51].



$$\underset{(1)}{C_3O_2} \xrightarrow{+HCl} \underset{(17)}{Cl{-}CO{-}CH{=}C{=}O} \xleftarrow[80\,^\circ C]{-HCl} \underset{(18)}{Cl{-}CO{-}CH_2{-}CO{-}Cl}$$

The intermediate formation of relatively inert ketenecarboxylic acid derivatives or acylketenes in reactions of *(1)* with nucleophiles can be exploited for preparation of mixed-functional

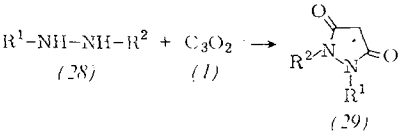
derivatives of malonic acid. Friedel-Crafts acylation of aromatics with C_3O_2 followed by hydrolysis and decarboxylation of the aroylacetic acids *(20)* generally affords only the methyl ketones *(23)*[52]. The existence of the aldoketene *(19)* can however be established by treating the reaction mixture with ethanol or aniline instead of water. In this case, ethyl aroylacetates *(21)* or aroylacetanilides *(22)* are formed[53].

Reaction of the Grignard compounds *(13a)*—*(13c)* with C_3O_2 in the molar ratio 1 : 1 also proceeds *via* the non-isolable acylketenes to yield the 2,4,6-triacylphloroglucinols *(26a)*—*(26c)* as major products; the 4-hydroxy-2-pyrones *(27a)* and *(27b)* can be isolated as side products[54, 55]. In the most thoroughly studied[55] reaction of *(13a)*, formation of acetophenone, β-hydroxy-β,β-diphenylpropionic acid, benzophenone, triphenylmethanol, and biphenyl was also

detected[56]. Most probably, trimerization to the phloroglucinols *(26)* and dimerization to the pyrones *(27)* does not occur *via* the free acylketenes *(25)*, but proceeds directly *via* the corresponding MgBr complexes[55]. While dimerization of acylketenes to 6-substituted 3-acyl-4-hydroxy-2-pyrones of type *(27)* has long been known[57], the trimerization of an aldoketene to a phloroglucinol derivative has hitherto apparently been observed only with benzylketene[58].

4.3. Reactions Yielding Heterocycles

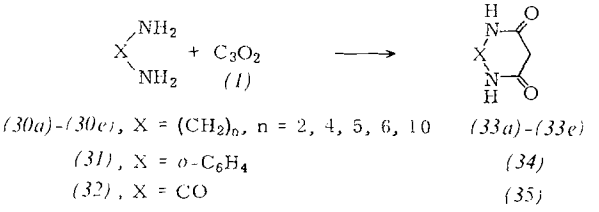
On reaction of C_3O_2 with substances whose molecules possess two nucleophilic centers, ring closures can of course occur *via* the intermediate acylketenes. Prerequisites for such a reaction course are:



a) A favorable mutual spatial orientation of the two nucleophilic atoms (1,2; 1,3; or 1,4 position, the number of six-membered heterocycles resulting from a 1,3-arrangement so far having been found to greatly outweigh the other possibilities), and

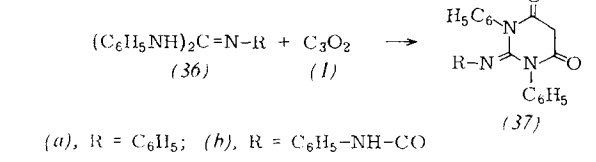
b) approximately comparable nucleophilicity of the two centers (otherwise mainly open-chain products result).

In borderline cases where both open-chain malonic acid derivatives and cyclic products are formed, the yield of the latter should increase on application of the dilution principle (particularly in view of the relatively long lifetimes of the ketenecarboxylic acid intermediates). However, systematic studies on this point have yet to be performed.



4.3.1. Heterocycles Containing Two N Atoms

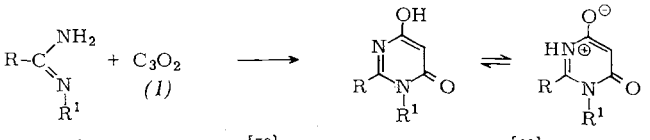
The reaction of C_3O_2 with phenylhydrazine yielding 1-phenylpyrazolidine-3,5-dione *(29a)* was described by *Van Alphen*[59] as long ago as 1924. Later reports[60–62] are concerned with reactions of other substituted hydrazines to form pyrazolidinediones, including that of hydrazobenzene *(28b)* which otherwise tends to resist "malonylation". Unsubstituted hydrazine itself gives only linear polymers[61].



(a), $R^1 = C_6H_5$, $R^2 = H$[59]
(b), $R^1 = R^2 = C_6H_5$[60]
(c), $R^1 = R^2 = CH_3$[61]

Slow introduction of C_3O_2 into dilute ethereal solutions of the aliphatic diamines *(30a)*—*(30e)* furnishes the 7- to 15-membered cyclic malonamides *(33a)*—*(33e)* in quantitative yield[61, 63]. Rapid addition of *(1)* (*e.g.* by shaking of a toluene C_3O_2 solution with an aqueous diamine solution) leads to linear polyamides[37, 64].

(30a)–*(30e)*, X = $(CH_2)_n$, n = 2, 4, 5, 6, 10 — *(33a)*–*(33e)*
(31), X = *o*-C_6H_4 — *(34)*
(32), X = CO — *(35)*



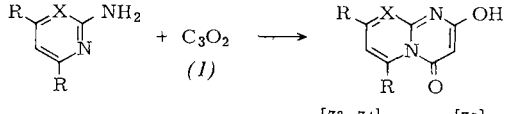
o-Phenylenediamine *(31)* gives 1*H*-1,5-benzodiazepine-2,4(3*H*,5*H*)-dione *(34)*[59], and urea *(32)* smoothly yields barbituric acid *(35)* (75% in acetone + $AlCl_3$[61], 85% in DMF[65]). While reaction of diphenylguanidine affords two isomeric 2-iminobarbituric acids alongside an open-chain malonic acid derivative, the threefold substituted guanidines *(36a)* and *(36b)* give only the 2-iminobarbituric acids *(37a)* and *(37b)* respectively[66].

(a), R = C_6H_5; *(b)*, R = C_6H_5–NH–CO

Amidines *(38)* react with malonic esters in the presence of Na alkoxide[67] or with malonyl chloride[68] to give moderate

yields of hydroxypyrimidones *(39)*[69]; however, as a cyclizing reagent, carbon suboxide leads to almost quantitative conversion even in the cold. Especially good results are obtained with *N*-aryl-substituted benzamidines[70] (cf. also Section 4.3.5.2).

(38), R^1 preferably Ar[70]



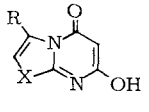
(39)[69]

(40), R = C_6H_5, CH_3; R^1 = OC_2H_5, $OCH_2C_6H_5$[42, 71]

(41)

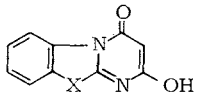
Amide oxime ethers react with malonyl chloride to give exclusively pyranopyrimidinediones[71]. Experiments on acetamide oxime ether and benzamide oxime ether *(40)*, however, showed that the parent compounds, in this case the *N*-alkoxypyrimidones *(41)*, are also accessible by reaction with C_3O_2 at -20 °C[42, 71].

α-Amino-N-heterocycles such as 2-aminopyridines, -pyrimidines, -oxazoles, -thiazoles, *etc.* can be regarded as cyclic amidines. It therefore comes as no surprise that substances of this class undergo exceptionally ready reaction with C_3O_2 to give fused hydroxypyrimidones, some of which are accessible only with difficulty, if at all, by other routes. Thus 2-aminopyridine *(42a)* furnishes "malonyl-α-aminopyridine" *(43a)*[73–75] which was first synthesized by *Chichibabin* in 1924[72]. The 2-aminopyrimidines *(42b)* and *(42c)* likewise afford almost quantitative yields of the pyrimidopyrimidines *(43b)* and *(43c)* respectively[43]. A more complicated reaction course is observed in the cyclization of non-symmetrically substituted 2-aminopyrimidines for which ring closure can adopt two different directions, depending upon the substituent[76].



(42) *(a)*, X = CH, R = H[73, 74]

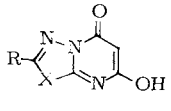
(b), X = N, R = H[43]



(c), X = N, R = CH_3[43]

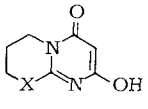
(43)[75]

(44), X = O, R = H (100%)[77]



(45), X = S, R = H (90%)[43]; R = Alk, Ar (53–58%)[78]

(46), X = O (89%)[74, 77]



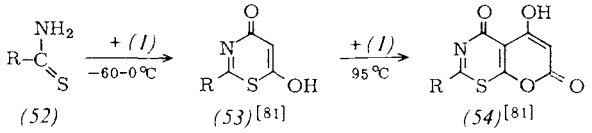
(47), X = S (83%)[74, 78]

2-Aminooxazole and 2-aminothiazole react similarly to form the fused pyrimidines *(44)*[77] and *(45)*[43, 78] respectively. 2-Aminobenzoxazole and 2-aminobenzothiazole yield *(46)*[74] and *(47)*[74, 78], respectively. Reaction of 2-amino-1,3,4-oxadiazole and 2-amino-1,3,4-thiadiazoles with *(1)* gives *(48)*[74]

(48), X = O, R = H (67%)[74]

(49), X = S, R = H, Alk, Ar (87–96%)[74, 79]

(50), X = O (100%)[77]



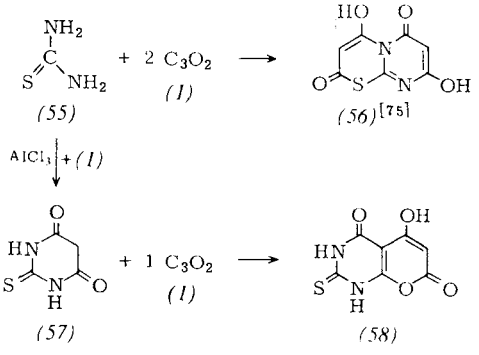
(51), X = S (92%)[77]

and compounds *(49)*[74, 79], respectively. Finally, *(50)* and *(51)* respectively can be obtained from 2-amino-5,6-dihydro-4*H*-1,3-oxazine and -thiazine[77].

4.3.2. Heterocycles Containing One N and One S Atom

As mentioned in Section 4.1, carboxamides yield only open-chain malonic acid derivatives with C_3O_2[43]. Owing to the approximately comparable nucleophilicity of their N and S atoms, thioamides *(52)* behave differently. Thus thiobenzamide[43] and substituted thiobenzamides give almost quantitative yields of 6-hydroxy-1,3-thiazin-4-ones *(53)* at as low a temperature as -60 °C[65, 80–82]. Heterocyclic thioamides like nicotinthioamide, isonicotinthioamide, and picolinthioamide behave similarly[43, 65].

On use of an excess of C_3O_2 and at higher temperatures, further reaction with *(1)* occurs. Pyrone derivatives *(54)* are easily isolated in pure form, whereas higher polypyrones can only be obtained as mixtures (cf. also Section 4.6)[43, 65]. Addition of *ca.* 15 C_3O_2 molecules (statistical average) could be detected with a product that was insoluble in boiling dioxane[43].

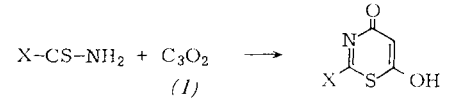


(52) *(53)*[81] *(54)*[81]

R = Phenyl[43], subst. Phenyl[65], 1-, 2-Naphthyl[43], 2-, 3-, 4-Pyridyl[43, 65]

+ *(1)* → etc.

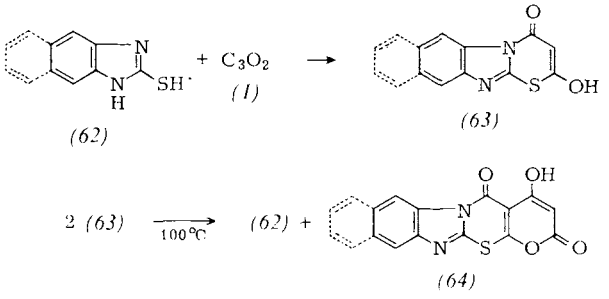
According to *Dashkevich*[61, 83], thiourea *(55)* and *N*-arylthioureas afford thiobarbituric acid *(57)* and its *N*-aryl derivatives in the presence of $AlCl_3$. However, *Ziegler*[43] found that in the absence of $AlCl_3$ thiourea readily adds two moles of C_3O_2. It could recently be demonstrated that the sulfur is incorporated into the bicyclic ring system to form the pyrimidothiazine *(56)*[82]. In contrast, the thioxo group remains intact on reaction of thiobarbituric acid *(57)* with C_3O_2 to give the pyranopyrimidine *(58)*[82]. Hence it follows that



(55) *(56)*[75]

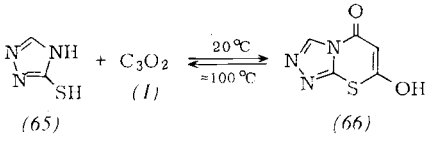
(57) *(58)*

(57) cannot be an intermediate in the formation of *(56)*. Instead, thiourea reacts with C_3O_2 as a "thioamide" to form a reactive 2-aminothiazinone which, as an "amidine", immediately reacts with a second molecule of *(1)* to give *(56)* (see Section 4.3.1).



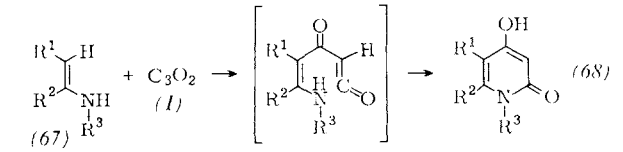
N-Acylthioureas *(59a)* afford 2-acylamino-6-hydroxy-1,3-thiazin-4-ones *(60)*[83] whereas dithiocarbamic esters *(59b)* react with *(1)* in acetonitrile or ethyl acetate to form the corresponding 2-alkylthio derivatives *(61)*[84].

Benzimidazole-2-thiol *(62)* exhibits a remarkable behavior in that it undergoes cycloaddition with C_3O_2 to form a thermolabile 1:1 adduct *(63)*. If this compound is heated for a



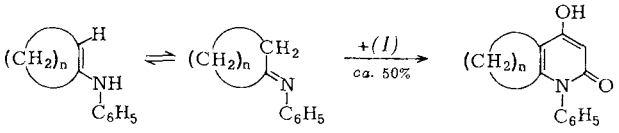
(59a), X = R-CO-NH *(60)*, X = R-CO-NH
(59b), X = R-S *(61)*, X = R-S

few minutes in five times the amount of pyridine, it decomposes to benzimidazole-2-thiol *(62)* and the pyrone derivative *(64)*[74]. Naphthimidazole-2-thiol behaves similarly[74].

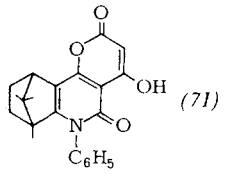


The addition product *(66)* formed from 1,2,4-triazole-3-thiol *(65)* and C_3O_2 is even more labile and decomposes to the starting materials on heating[74] [cf. the retrocleavage of mesomeric thiazine betaines *(121)*—*(123)*].

4.3.3. Heterocycles Containing One N Atom



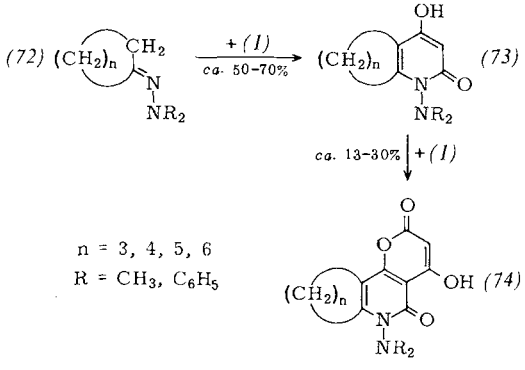
Enamine derivatives *(67)*, which are accessible from β-oxo esters or β-diketones by treatment with ammonia or primary aliphatic or aromatic amines, undergo ready reaction with C_3O_2 at 20 °C to form 4-hydroxy-2-pyridones *(68)*[85].



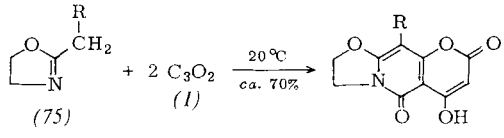
R^1 = $CO_2C_2H_5$, CO-CH_3; R^2 = Alk, Ar; R^3 = H, Alk, Ar

Reaction of the anils *(69a)*—*(69d)* with C_3O_2 *(1)* in ether to give the bicyclic 4-hydroxy-2-pyridones *(70a)*—*(70d)* proceeds somewhat less easily[86]. The anil of camphor proves to be an exception: it reacts with *(1)* only under drastic conditions (100 °C, 4 h) to give a poor yield of the pyranopyridinedione *(71)*[86].

In analogous manner, the hydrazones *(72)* can be converted into *N*-amino-4-hydroxy-2-pyridones in ether at 40—80 °C in an autoclave; the (readily separable) pyrone derivatives *(74)* are invariably formed as side products[87].

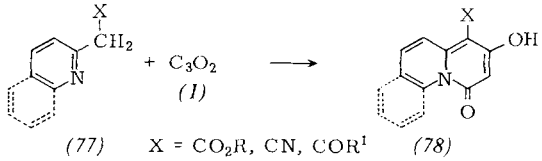


(69a)-*(69d)*, n = 3, 4, 5, 6 *(70a)*-*(70d)*



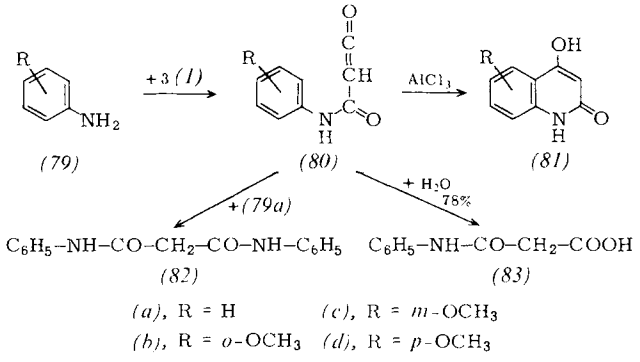
(71)

Another class of compounds containing an active methyl or methylene group α to a C=N double bond is found in the imidic esters. Cyclic imidic esters such as the 2-oxazolines



(75) afford only addition products with 2 mol of C_3O_2 even when the reaction is carried out in ether at 20 °C[88].

(a), R = H; *(b)*, R = CH_3 *(76)*

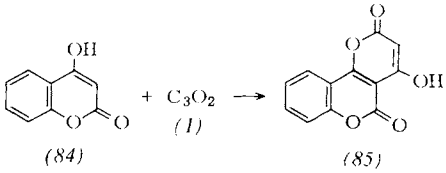


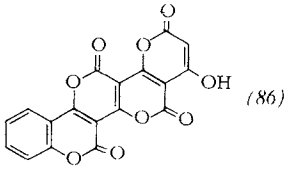
α-Picoline does not react with C_3O_2. However, if the side chain is activated by an ester[29], nitrile[29], or acyl group[89], then *(77)* gives almost quantitative yields of the 2-hydroxy-4-quinolizinones *(78)*. In the same manner, 2-quinolylacetic ester also yields the corresponding benzo derivative[90].

(77) X = CO_2R, CN, COR^1 *(78)*

The reaction of C_3O_2 with an excess of aniline affords malondianilide *(82)* quantitatively. This is frequently utilized in the quantitative determination[6e] of the C_3O_2 content of solutions in a method already employed by *Diels*[39]. However, *Omori*[91] has recently shown that, in the presence of $AlCl_3$ in refluxing benzene, reaction of C_3O_2 and aniline in a molar ratio of 3:1 yields 17% of 4-hydroxyquinolone *(81a)* alongside *(82)*. The transient occurrence of ketenecarboxanilide *(80)* can be demonstrated by formation of malonmonoanilide

(83) (78%) on addition of water to the reaction mixture (prior to heating in benzene). Higher yields (up to 67%) of



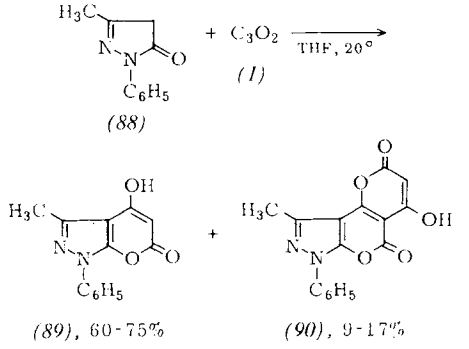


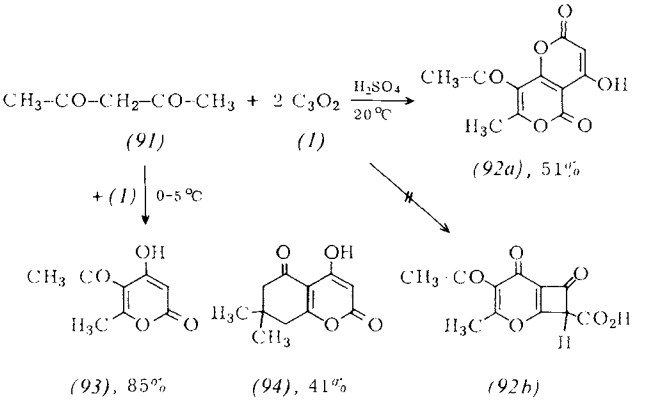
substituted quinolones (81b)—(81d) are obtained on use of methoxyanilines (79b)—(79d). Malondianilide (82) is known to afford 4-hydroxyquinolone (81a) in 93% yield on heating to 245—250 °C in the presence of $AlCl_3$[92]; not even traces of this compound are formed from (82) and $AlCl_3$ in refluxing benzene (80 °C)[93].

4.3.4. Heterocycles Containing One O Atom

Ring closure reactions of C_3O_2 to yield heterocycles containing one O atom as side or subsequent reactions have repeatedly been mentioned in the foregoing Sections; examples included formation of the pyrone derivatives (54), (58), (64), (71), (74), and (76). This property of C_3O_2 to react with heterocycles containing the malonyl grouping and with other electron-rich phenols in a process involving annelation of a 4-hydroxy-2-pyrone system was discovered by *Ziegler*[94] as long ago as 1961. Since 4-hydroxy-2-pyrones again contain a reactive malonyl grouping and can be regarded as an electron-rich phenolic system, this reaction can be induced to yield polypyrone derivatives if conducted in the presence of excess C_3O_2. The structural relationship of this class of compounds to "red coal" is discussed in Section 4.6. In the following we shall consider the reaction of carbon suboxide with phenolic compounds, ketones, and 1,3-diketones.

4-Hydroxycoumarin (84), which is itself a "malonic acid derivative" formed in high yield by self-cyclization of diphenyl malonate (87) at 150 °C in the presence of $AlCl_3$[95], adds one mole of C_3O_2 at 90 °C in THF to give the pyrone derivative (85) (*ca.* 50% yield). The reaction also yields polypyrones such as (86) which formally arises by addition of 4 mol of C_3O_2 to phenol, and which can also be synthesized in stepwise manner *via* reactive malonic esters[94, 96].

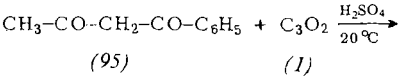




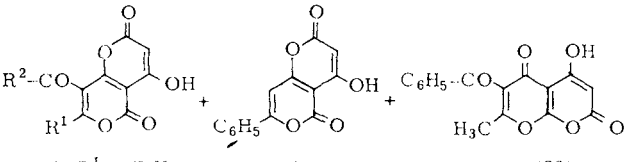
Direct reaction of C_3O_2 with phenol in the presence of $AlCl_3$[97] (*e.g.* in tetrachloroethane) affords 28% of diphenyl malonate (87) as major product, alongside very small amounts of compounds (84) and (85). On use of *o*-, *m*-, and *p*-cresol the yield of 4-hydroxycoumarins rises to *ca.* 10% while that of the pyrone derivatives remains constant at 0.5 to 1.1%. In the presence of H_2SO_4 however, only malonic esters are formed[97].

$$C_6H_5OH + C_3O_2 \xrightarrow[25\,^\circ C]{AlCl_3} 28\%\,CH_2(CO_2C_6H_5)_2 + 0.2\%\,(84) + 0.9\%\quad (85)$$
(1) (87)

Ring closure with (1) to give heterocycles containing one O atom also takes place with methyl(phenyl)pyrazolone (88). Depending upon the reaction conditions, the pyranopyrazolone (89) is accompanied by varying amounts of pyranopyranopyrazoledione (90)[43].



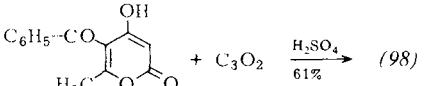
The action of C_3O_2 on β-diketones and β-oxo esters in the presence of H_2SO_4 was first described by *Hegar*[37]. This author showed that, *e.g.*, pentanedione (91) reacts with 2 mol of C_3O_2 in ether, and formulated the product as the cyclobutapyran derivative (92b). However, *Hradetzky* and *Ziegler*[98] were able to demonstrate that the product is actually the isomeric pyranopyrandione (92a) and that the reaction with $2C_3O_2$ can be applied to a series of further β-diketones. *Omori*[99] subsequently found that the 1:1 adduct (93) is also accessible in good yield on reaction of (91) with (1) in equimolar amounts below 5 °C; under analogous conditions he obtained the tetrahydrocoumarin derivative (94) from dimedone[97].



A much more complicated course is taken by the reaction of C_3O_2 with unsymmetrical β-diketones like benzoylacetone (95). A 2:1 addition would be predicted to yield the isomeric pyranopyrandiones (96a) and (96b) owing to the ambifunc-

tional character of *(95)*. In fact, *Omori*[99] isolated two products on reaction of *(95)* with C_3O_2, which he formulated as *(96a)* and *(96b)*, probably being ignorant of an earlier study[100]. According to *Ziegler et al.*[100], however, the major product of prolonged reaction (8 days) between *(1)* and *(95)* in ether and in the presence of H_2SO_4 is the "α,γ-pyronopyrone" *(98)* and the deacylated[101] "α,α-pyronopyrone" *(97)*[102]. Owing to the similarity in the melting points[100,102] and the spectroscopic data[102c], there is good reason for assuming that the substance formulated as *(96a)* by *Omori*[99] is in fact *(97)*[103].

This apparently somewhat obscure behavior of benzoylacetone *(95)* can be explained, not only by the fact that reaction of *(95)* with, *e.g.*, malonyl chloride leads initially to the two isomeric 4-hydroxy-2-pyrones *(99)* and *(100)* (which are undoubtedly intermediates in the reaction with C_3O_2) but above all by the rearrangement of *(100)* to *(99)* at the melting point (168 °C) or on acid catalysis[104]. Hence it is also understandable why the stable substance *(99)* gives exclusively *(98)* in good yield on treatment with C_3O_2 in the presence of H_2SO_4



(95) *(1)*

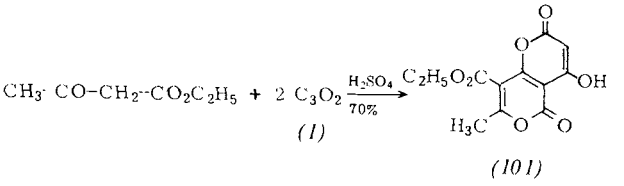
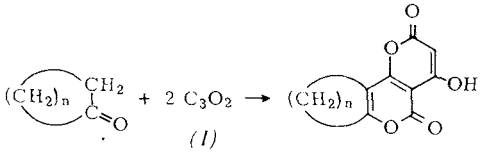
(97) *(98)*

(99) *(1)* *(98)*

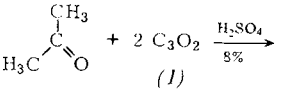


(100) *(1)* *(96a)* + *(97)* + *(98)*



whereas the rearrangeable compound *(100)* furnishes a mixture of *(96a)*, *(97)*, and *(98)* which can only be separated by chromatography[100].

While acetoacetic ester and *(1)* give a 70% yield of the pyranopyrandione *(101)*[99], simple ketones lacking an additional activated methylene group are converted only with difficulty and in unsatisfactory yields into pyranopyrandiones. Thus cyclohexanone *(102a)* and cycloheptanone *(102b)* merely give 10—15% of the pyranopyrandiones *(103a)* and *(103b)* respectively after six to eight weeks' reaction (without H_2SO_4 as catalyst)[43]. Reaction of acetone with C_3O_2 (in ether with H_2SO_4) furnishes only 8% of the pyranopyrandione *(104)*[99]; a somewhat higher yield of *(104)* can be obtained from triacetolactone *(105)* and C_3O_2[98].



It appears remarkable that 1,3-dicarbonyl compounds react with C_3O_2 only in the presence of protic acids. Three explanations have so far been proposed for the catalytic action of H_2SO_4: formation of an electrophilic cation ($O{=}C{=}CH{-}\overset{\oplus}{C}{=}O$) by protonation of C_3O_2[99]; generation of reactive sulfuric malonic anhydrides[98]; and finally rupture of the hydrogen bonds in the enolized dicarbonyl compounds by the mineral acid[98].

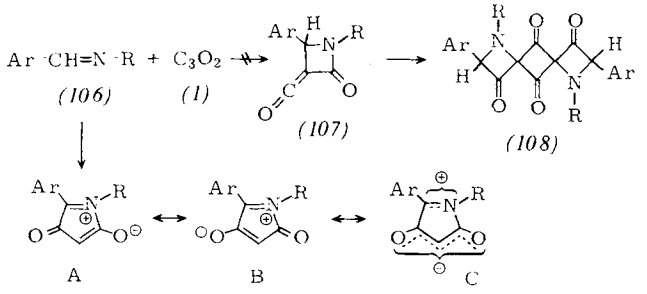
(104) *(1)* *(105)*

All pyranopyrandiones react with ferric salts to give intensely colored 3:1 complexes which can be extracted from aqueous media by chloroform[93].

Particular mention should be made of the following fact: All pyranopyrandiones of the kind considered in this Section are "protected" polyoxocarboxylic acids. The significance of this class of compounds—especially the polypyrones such as compounds of type *(86)*—for the biosynthesis of phenolic natural products is known[105]. The protected β-trioxocarboxylic acid chain is shown in bold print in formula *(104)*. Action of alkalis on this compound under various conditions yields orsellinic acid, orcine, and other phenolic compounds which can themselves act as intermediates for natural products[96,105]. Other synthetic pathways have hitherto been commonly employed for the preparation of such polypyrone compounds. The above results would suggest that C_3O_2 may also be used to advantage for the production of such polypyrones (= polymalonyl compounds) (cf. also Section 4.6).



4.3.5. Reactions Leading to Mesoionic Heterocycles

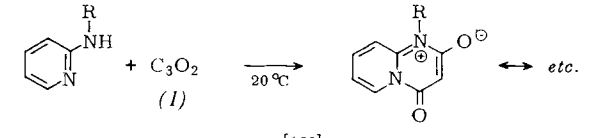
4.3.5.1. Five-Membered Systems

It has been shown in Section 4.3.3 that azomethines with α-methyl or α-methylene groups afford 4-hydroxy-2-pyridones. In the absence of the acylatable group, as in the azomethines *(106)* derived from benzaldehydes, a completely novel reaction takes place with C_3O_2.

The reaction of benzylideneaniline with *(1)* was first reported by *Dashkevich*[106], who assigned the spiro structure *(108)* to the product and assumed a primary [2+2] addition to the β-lactam ketene *(107)* followed by [2+2] dimerization (cf. Section 4.4). In fact, however, the reaction does not afford

a 2:2 adduct but (as can be shown by mass spectrometry) instead a 1:1 adduct. *Sterk et al.*[107] proposed a zwitterionic structure *(109)* describable only in terms of a series of

(106) *(1)* *(107)* *(108)*

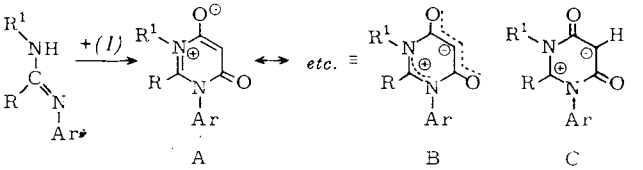


A B C

(109) Ar = C_6H_5; R = C_6H_5; *o*-, *m*-, *p*-C_6H_4Cl; *p*-C_6H_4Br; *p*-$C_6H_4NO_2$; *p*-$C_6H_4CH_3$; CH_3; C_2H_5; i-C_4H_9; C_6H_{11}; $CH_2C_6H_5$

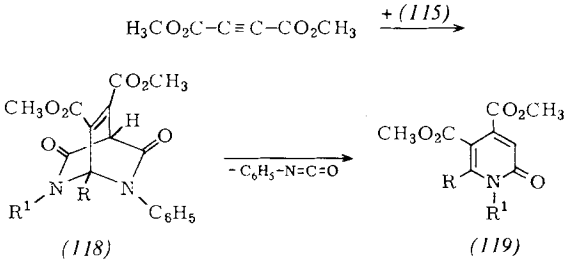
resonance formulas (*e.g.* A↔B). The charge distribution in compounds *(109)* is probably best described by formulation C. Besides benzylideneaniline, a large number of other Schiff bases react similarly with C_3O_2[107,108]. In the preparation of compounds such as *(109)*, carbon suboxide can be successfully replaced by malonyl chloride[107].

4.3.5.2. Six-Membered Systems



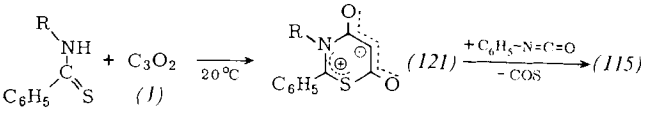
Amidines and monosubstituted amidines react with C_3O_2 to form hydroxypyrimidones (see Section 4.3.1) which exist predominantly in the tautomeric zwitterionic form[69]. *N,N'*-Disubstituted amidines such as *(110)* and *(112)* which contain only one replaceable H atom should accordingly yield "fixed" zwitterionic pyrimidines directly on reaction with *(1)*. That this does in fact occur was demonstrated simultaneously by *Potts*[109] and *Kappe*[110] in 1971 for *N*-substituted 2-aminopyridines *(110)* which afford the betaines *(111)* on reaction in ether.

(110) *(a)*, R = CH_3[109] *(b)*, R = C_6H_5[110] *(111)*



This reaction can also be applied to simple *N,N'*-disubstituted amidines *(112)* (including formamidines, R = H)[112]. In similar fashion, *N*-substituted amide oxime ethers *(113)* can yield *N*-alkoxypyrimidine betaines *(116)*[113]. Finally, further extension of this synthetic principle to *N,N'*-disubstituted *S*-alkylisothioureas *(114)* affords the 2-alkylthiopyrimidine zwitterions *(117)*[114].

Derivatives, *e.g.* of *(115)*, substituted at C-5 can also be prepared from reactive malonic esters and malonyl chlorides[110]; however, satisfactory results are obtained only with carbon suboxide for compounds that bear no substituents in the malonyl moiety. The resulting pyrimidine betaines *(111)* and *(115)*—*(117)* can also be described only by a series of canonical resonance formulas[110]. Formula B best describes the charge distribution, while the "sextet canonical structure" C indicates that these compounds are potential starting materials for 1,4-dipolar cycloadditions. Indeed, compounds *(111)* and *(115)* react very smoothly with reactive acetylenes, *e.g.* *(115)* with dimethyl acetylenedicarboxylate to form the addition compound *(118)*, which is, however, extremely prone to stabilization by loss of phenyl isocyanate, yielding 2-pyridones *(119)*[109,111,112]. This concept of preparing mesoionic heterocycles with the malonyl grouping can be applied to *N*-substituted thioamides (cf. Section 4.3.2); thus thiobenzamides *(120)* react with C_3O_2 in ether to give the mesomeric thiazine betaines *(121)*[115]. Similarly, pyridine- and pyrimi-



A B C

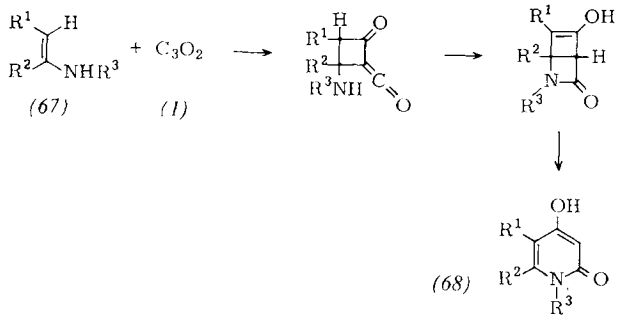
(118) *(119)*

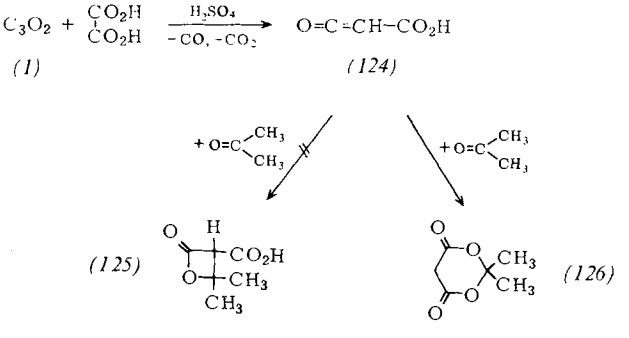
dine-2-thiol furnish the zwitterionic 1,3-thiazines *(122a)* and *(122b)*, respectively, and 2-thiazoline-2-thiol the zwitterion *(123)*[115]. Thiazine betaines also undergo 1,4 dipolar cycload-

(120) *(a)*, R = C_6H_5 *(b)*, R = $CH_2C_6H_5$ *(121)*



(122a), X = CH *(123)*
(122b), X = N

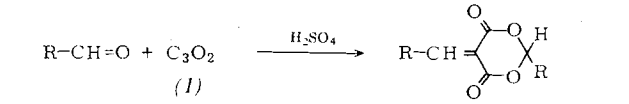
ditions; for instance, reaction with aryl isocyanates proceeds *via* an intermediate analogous to compound *(118)* with elimination of carbon oxide sulfide to give mesoionic pyrimidines, *e.g.* *(121)*→*(115)*[116]. When heated to above their melting point the thiazine betaines *(121)*—*(123)* eliminate C_3O_2. These substance can therefore be used as sources of carbon suboxide[115].



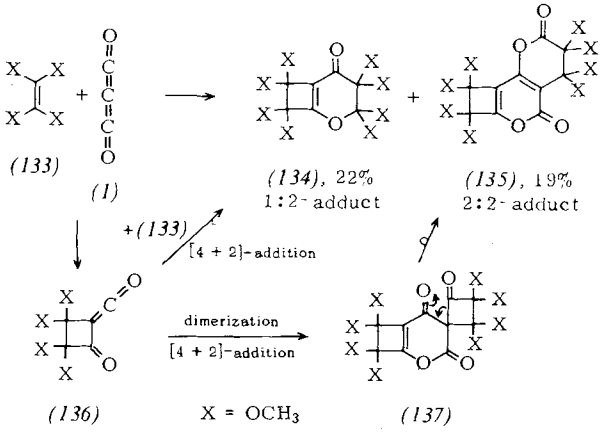
4.4. "Cycloadditions"

As already mentioned, C_3O_2 appears to behave as a "double ketene", and thus as a double electrophile, in all its reactions; hence any substrate is doubly acylated stepwise *via* a ketenecarboxylic derivative to form open-chain or cyclic malonic acid derivatives.

However, the question has repeatedly been raised whether C_3O_2 might not also undergo electrocyclic [2+2]-cycloadditions (*e.g.* $_\pi2_s+_\pi2_a$). For instance, *Ulrich*[6f] formulated the reaction of *(1)* with enamines such as *(67)* and *(69)* as proceeding *via* a bicyclic intermediate by analogy with the behavior of simple ketenes, albeit without experimental evidence.



Assumption of a double [2+2] cycloaddition led *Dashkevich*[106] to (erroneously) assign the structure *(108)* to the reaction product obtained from *(1)* and benzylideneaniline. As early as 1924, *Diels*[39] described the reaction of acetone with *(1)* in the presence of oxalic acid and H_2SO_4 as a [2+2]-cycloaddition of the transient ketenecarboxylic acid *(124)* (the water arises from decomposition of the oxalic acid) to the C=O bond of acetone with formation of the β-lactone *(125)*. This concept of the reaction course has hitherto been incorporated in nearly all reviews[6b, 6c, 6e]. However, the reaction product obtained by *Diels* has been shown[93] to be Meldrum's acid *(126)*[117] and not *(125)*. Remarkably, the ester of the substituted ketenecarboxylic acid can indeed

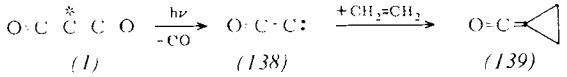


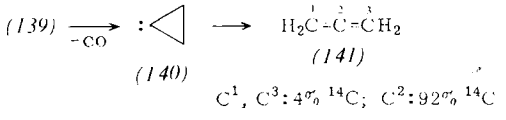
act as a $_\pi2_a$ component in [2+2]-cycloadditions, as *Sterk* recently demonstrated in the case of their dimerization[118]. Furthermore, the addition of ethyl ethylketenecarboxylate to benzylideneaniline yields a β-lactam as [2+2]-adduct; however, the reaction involves an isolable zwitterionic intermediate[119].

Reaction of the benzaldehydes *(127a)*—*(127c)* with *(1)* in ether and in the presence of H_2SO_4 likewise circumvents [2+2]-addition. According to *Hopf* and *Hegar*[120], the products are compounds *(130a)*—*(130c)* having a Meldrum's acid skeleton and not the β-lactones which are usually obtained from ketenes. Cinnamaldehyde *(128)* and thiophene-2-carbaldehyde *(129)* react in an analogous manner. The structure of the products is indicated unequivocally by degradation experiments. Moreover, *Wessely*[121] prepared *(130a)* independently and almost simultaneously by condensation of "phenyl-Meldrum's acid" with benzaldehyde. This synthesis also throws some light on the probable formation of *(130)*—*(132)*: A certain amount of water is inevitably introduced into the reaction system by the sulfuric acid; the resulting malonic acid (or malonic sulfuric anhydride) reacts with the aldehydes affording Meldrum's acids which undergo ready condensation with aldehydes to form unsaturated derivatives[117c] (the water functioning as catalyst being released in the process).

127) (a), R = C_6H_5, *(b)*, R = p-$C_6H_4CH_3$, *(c)*, R = p-C_6H_4Cl *(130)*
128) R = C_6H_5-CH=CH *(131)*
129) R = 2-Thienyl *(132)*

A detectable primary [2+2]-addition of C_3O_2 seems to have been reported only recently by *R. W. Hoffmann*[122] for an electron-rich olefin. After reaction of C_3O_2 with tetramethoxyethylene *(133)* in ether, approximately equal yields of a 1:2 adduct *(134)* and a 2:2 adduct *(135)* can be isolated. Since the structure of these compounds appears to be established, we are compelled to make the following mechanistic assumptions: The primary step is indeed a [2+2]-addition to yield the acylketene *(136)*. This reacts as a typical acylketene[123], either by [4+2]-addition with another molecule of tetramethoxyethylene *(133)* yielding the 1:2 adduct *(134)* or by dimerization to *(137)* which undergoes stabilization by a known type of rearrangement[124] to the pyranopyrandione *(135)*.

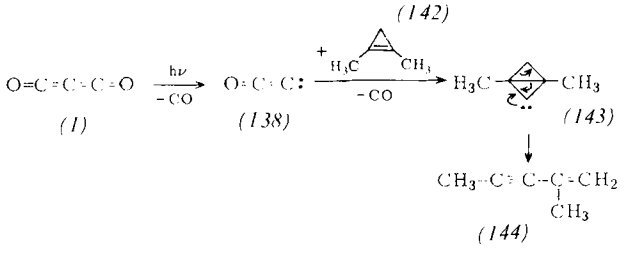




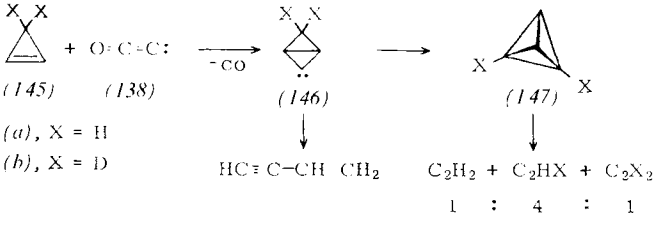
Summarizing, even though the available experimental evidence is still very sparse, the known reactions of *(1)* permit formulation of the following rule: In principle, carbon suboxide avoids the usual ketene addition reactions as long as the substrate contains two (or even only one, see Section 4.3.5) H atoms susceptible to electrophilic displacement.

4.5. Photochemical Reactions

Carbon suboxide undergoes a simple photochemical reaction with olefins[125–129]; a single carbon atom is inserted into the C=C double bond to form allenes and two molecules of CO. Thus ethylene furnishes allene *(141)* as major product alongside a little methylacetylene. By labeling the central C atom of C_3O_2 with ^{14}C it can be shown that this atom mainly provides the central C atom of the allene[126]. This reaction therefore bears a close formal resemblance to the

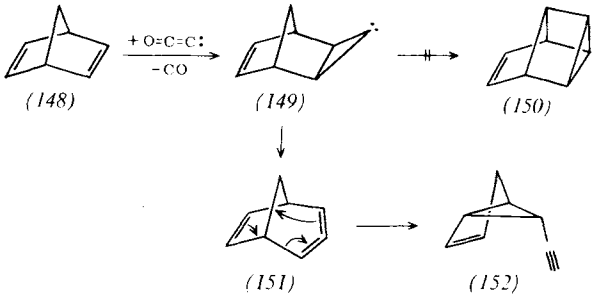


attack of carbon atoms on olefins[127a]. However, decomposition of C_3O_2 into 2 CO and $C(^3P)$ requires 141.5 kcal/mol, whereas the above photochemical reaction occurs already with 3000-Å light (corresponding to 95.3 kcal/einstein)[127b]. The initial photochemical step has therefore always been assumed to be decomposition of C_3O_2 into CO and carbonylcarbene *(138)*[125], which reacts with ethylene (and other alkenes) to give the high-energy ketene *(139)*. Subsequent elimination of another molecule of CO furnishes cyclopropylidene *(140)* which undergoes cyclopropylidene-allene rearrangement in the usual manner[127c].



Studies by *Williamson* and *Bayes*[128] suggest the existence of *(138)* as a triplet and a singlet species. Photolysis of *(1)* at 3000 Å is reported to give C_2O ($X^3\Sigma$), while C_2O ($\tilde{a}\ ^1\Delta$) is generated at 2500 Å. Whereas the singlet carbene reacts fairly unselectively, the triplet species clearly displays electrophilic properties (in contrast to the views held by other authors[129]). This observation accords with the fact that *(138)* reacts faster with ethylene homologs (*e.g.* 40× faster with isobutylene) than with ethylene itself[125, 128].

The reactions with cyclopropene derivatives are also interesting since cyclopropylidene-allene rearrangement would then lead to a highly strained structure. Thus, according to *A. P. Wolf*[130], 1,2-dimethylcyclopropene *(142)* undergoes an alternative reaction *via* the carbene *(143)* to yield 2-methyl-1-penten-3-yne *(144)* as major product. No evidence could be found for the intermediacy of a tetrahedrane in this reaction.



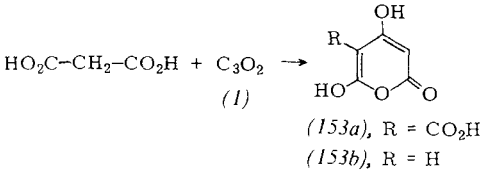
In a later study, however, the same research group[131] were unable to rationalize a reaction of cyclopropene *(145a)* and its 3,3-dideuterated derivative *(145b)* except by assuming a tetrahedrane intermediate. In accord with the above mechanism, cyclopropene and C_3O_2 give a 33% yield of vinylacetylene *via* the bicyclic carbene *(146)*. 24% of acetylene

is also formed (yields based on reacted cyclopropene). 3,3-Dideuteriocyclopropene *(145b)* affords acetylene, monodeuterioacetylene, and dideuterioacetylene in the ratio 1:4:1. This result rules out all plausible mechanisms for acetylene formation except that proceeding *via* the tetrahedrane *(147)*.

Klumpp and *Van Dijk*[132] attempted to synthesize the unknown compound tetracyclo[3.3.0.$0^{2,4}$.$0^{3,6}$]oct-7-ene *(150)* from norbornadiene *(148)* *via* the carbene *(149)* by a C—H insertion reaction. However, photolysis of C_3O_2 in the presence of *(148)* affords only a C_8H_8 compound which is isomeric with *(150)*, namely the alkyne *(152)*. The reaction can proceed *via* the strained allene *(151)* as intermediate[133]; however, other routes are also conceivable[132, 134].

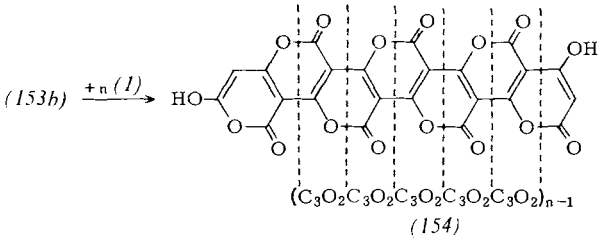
Interestingly, it follows from the above observations that in photochemical reactions C_3O_2 undergoes successive loss of two CO molecules, showing a close resemblance to the reactions of atomic carbon[127d]. Photolysis has so far been studied

in detail only for olefins. It may be expected that the possible applications of :CCO in preparative organic chemistry are much greater.



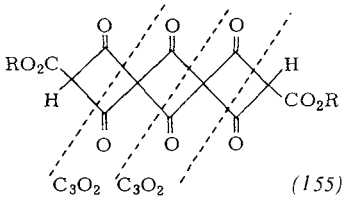
4.6. Polymerization

Since its discovery[1], the polymerization of carbon suboxide has been studied by numerous chemists. Results prior to 1968 are surveyed in "Gmelins Handbuch"[5]. Reference should be made here to a widespread fallacy concerning the ease of polymerization[6a-6c, 6e] of C_3O_2. As early as 1922, *Ott* and *Schmidt*[13] demonstrated that carefully purified C_3O_2 can be kept unchanged for long periods, and this observation has repeatedly been confirmed[5, 48, 94, 135]. Even then, our experience has shown that polymerization only occurs when traces of water or other proton-releasing (or nucleophilic) substances are present. "High-temperature polymerization", as well as polymerizations[5] induced by radiolysis or photolysis, appear to be exceptions.



The intensely colored polymers are usually termed "red carbon" in the earlier literature; this rather inaccurate designation was later[136] changed to "red coal". The similarity between "polymeric C_3O_2" and C_3O_2 addition products with a variety of substrates (*e.g.* phenolic compounds) prompted *Ziegler*[19, 137] in 1960 to postulate a close constitutional relationship between polypyrone compounds—*e.g.* *(86)*—and "red coal". Supporting evidence for these views on the structure of poly-α-pyrones has been gathered by other authors[138-140] from spectroscopic and X-ray studies.

Water-induced[141] polymerization has already been formulated as proceeding *via* an acetonedicarboxylic anhydride intermediate *(153b)*[94], whose formation is simply explained by



addition of *(1)* to malonic acid and decarboxylation of the primary product *(153a)*. This concept received support from IR and UV studies on the induction phase[5] of the "polymerization" of C_3O_2 to "red coal"[135]. In this way it also proved possible to discount structural investigations[142] on "red coal", in which UV spectra were interpreted in a manner supporting the former Diels formulation[6a, 39] as polyspirocyclobutanedione *(155)*.

(153a), R = CO_2H
(153b), R = H

(154)

(155)

The use of C_3O_2 to produce graft polymers represents a recent application. *Bukowski* and *Porejko* have copolymerized "polyamide 6" (polycaprolactam) in toluene with C_3O_2[143a] Grafting of C_3O_2 onto polyethylene films proved possible after initial activation of the polyethylene by UV or γ irradiation or by ozonization[143b]. Cross-linked products having novel properties are obtained in both cases.

State of Development of Atomic Absorption Spectrometry[**]

New analytical methods (1)

By Hans Massmann[*]

Atomic absorption spectrometry has developed extremely rapidly in recent years, and is now used in many analytical laboratories. The purpose of this progress report is to show the present position and to examine critically the possibilities and limitations of atomic absorption methods.

1. The Physical Principle

To be able to measure the atomic absorption, the sample must be converted into atomic vapor. This step is common to all methods of optical atomic spectroscopy, *i.e.* emission spectral analysis, atomic absorption analysis, and atomic fluorescence analysis.

Atomic absorption is based on the ability of free atoms to absorb electromagnetic radiation of the wavelengths that they are also able to emit. Since the atoms can only pass into certain discrete higher energy states on absorption of radiation energy, they can only absorb radiation quanta that have exactly the energy required for the transition. The absorption spectra of free atoms are therefore line spectra. Atomic absorption, like atomic emission and atomic fluorescence, can be observed only at certain wavelengths that are characteristic of each element. This is the reason for the high selectivity and specificity[1] of atomic spectral methods of analysis, and hence also of atomic absorption methods.

Only the most sensitive lines, *i.e.* the resonance lines, can be used in the main for atomic absorption analysis. These lines are based on transitions from the ground state to an excited state. Some elements, such as titanium, offer a wide selection of lines having similar sensitivities. For other elements, however, there is often only one line that can be used. For example, the zinc lines at 2138 Å and 3076 Å differ by a factor of about 5000 in their sensitivity.

A number of elements cannot be determined with the usual atomic absorption methods and instruments. This is because the resonance lines of these elements, which are indicated by a black triangle in the periodic system in Figure 1, lie in the vacuum UV at wavelengths below 2000 Å. Radiation with wavelengths in this range is unable to penetrate the

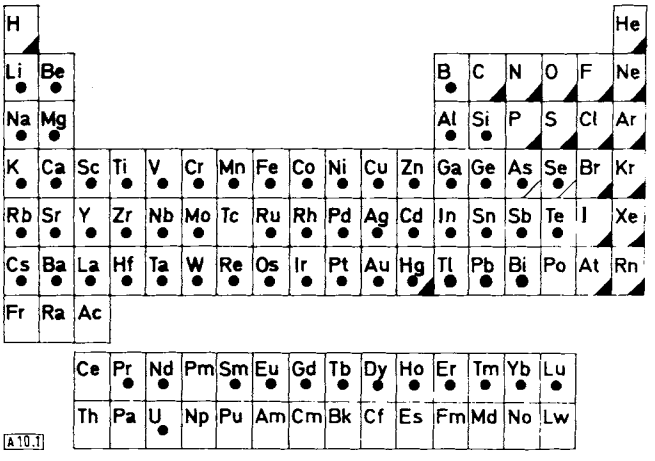

Fig. 1. Periodic system showing the elements that have been determined by atomic absorption with a flame (●), and the elements whose resonance lines lie in the vacuum UV (◢). As and Se are borderline cases.

flame gases and the air. Much more expensive special methods are necessary for the measurement of atomic absorption in this range, but these are not yet of any importance in practical analysis.

However, in the case of mercury, whose most sensitive resonance line is situated at 1850 Å, a less sensitive resonance line at 2537 Å can be used for determination purposes. This

[**] Based on a plenary lecture at the Conference of the "Analytical Chemistry" Group of the GDCh on the subject of "Trace Analysis" in Erlangen on April 2–5, 1973.

line is based on a "forbidden transition", *i.e.* a singlet-triplet transition. The determination of mercury with a flame is not very sensitive in this case, but determinations in a simple absorption cell are particularly suitable for mercury. This forms the basis of a series of sensitive methods with high detection powers, which are described in Section 6.

The elements that can still just be determined with a flame and without a vacuum monochromator, though their resonance lines lie below 2000 Å, include arsenic and selenium. The usual flames absorb more than 70% of the radiation at the wavelength of the arsenic line, 1937 Å. Substantially transparent flames, and particularly flames containing no nitrogen, are therefore used for arsenic determinations.

2. Measuring Arrangement and Measuring Principle

The measuring arrangement for atomic absorption analysis is shown in Figure 2. The essential parts are the primary light source (a), the absorption volume (b), the spectral apparatus (c), and the photoelectric measurement and evaluation system (d). The functions of these parts will now be discussed.

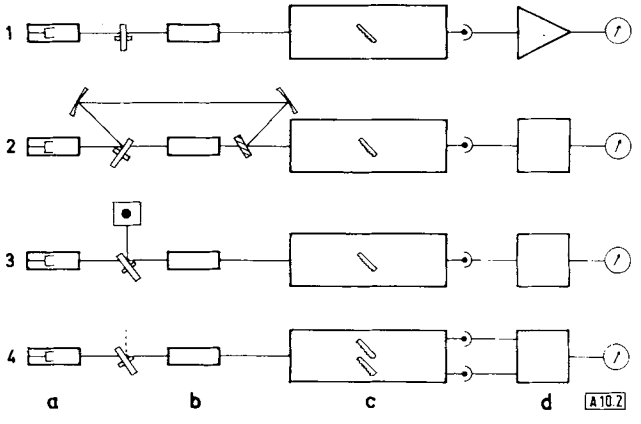

Fig. 2. Diagram of the measuring arrangement of atomic absorption instruments. 1, single-beam instrument; 2, twin-beam instrument; 3, single-beam instrument with automatic background compensator; and 4, twin-channel instrument for simultaneous measurement at two wavelengths. a = primary light source, b = absorption volume, c = spectral apparatus, d = photoelectric measurement and evaluation system (see also Section 2.3).

2.1. Primary Light Sources

To measure the atomic absorption of an element, one must have a primary light source whose emitted radiation has the same wavelength as the resonance line of the element to be analyzed. This requirement is easy to satisfy if one uses a light source that gives a continuous spectrum, *e.g.* an incandescent lamp for resonance lines in the visible region of the spectrum.

However, this is possible only if a spectral apparatus with a very high spectral resolution is used. Normal atomic absorption instruments cannot be used for this purpose, since the width $\Delta\lambda$ of the absorption lines is so small that the lines are extremely difficult or impossible to recognize with moderate spectral resolution. For sensitive measurement, not only should they be recognizable, but it should preferably also be possible to measure the absorption maximum.

As early as 1953—1955, while laying the foundation of atomic absorption spectrometry, *Walsh*[2] showed how very sensitive measurement of atomic absorption could be achieved even with a low spectral resolution, *i.e.* with relatively small instruments; the answer was to use line emitters, particularly hollow

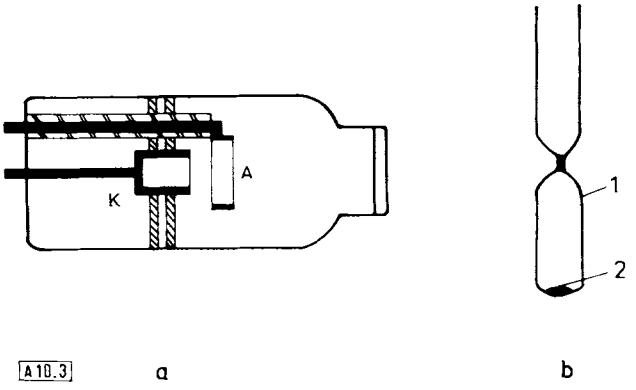

Fig. 3. Primary light sources for atomic absorption spectrometry. a) Hollow-cathode lamp; K = cathode, A = anode. b) Electrodeless quartz lamp for excitation in the high-frequency or microwave range. 1 = Sealed quartz tube, 2 = metal or metal halide.

cathodes (Fig. 3a), as primary light sources. Hollow-cathode lamps emit the line spectrum of the cathode material as well as the line spectrum of the discharge gas.

Under suitable discharge conditions, hollow-cathode lamps emit spectra with very narrow lines, and all that is left to the spectral apparatus is to separate the resonance line from other lines that are not absorbed. It is thus possible to design relatively small, compact atomic absorption instruments. However, interference in the analysis ("spectral interference") is then often unavoidable in the case of spectra containing numerous lines, since the resonance line and the interfering lines cannot be separated completely, if at all.

Another disadvantage is that a different hollow cathode must be used for each element. Though it is possible to construct hollow-cathode lamps (and some are even commercially available) whose cathode material contains several elements, and which therefore emit the spectra of several elements, the number of element combinations that can be used is very limited. Spectra of multielement lamps naturally contain greater numbers of lines, and the danger of spectral interference is therefore increased.

What about the quality of modern hollow-cathode lamps? What other line emitters can be used as primary light sources? Hollow-cathode lamps with a high spectral radiation density at the wavelength of the resonance line have been developed for a large number of elements in recent years. However, they still differ by more than three orders of magnitude in their radiation density. Unfortunately, few reliable measurements have been published[3]. In particular, the hollow cathodes for As, Se, Te, and some rare earth metals are unsatisfactory.

Electrodeless discharge lamps (Fig. 3b) are obtainable for a series of elements. These consist of a sealed quartz tube containing an inert gas at a pressure of a few mbar and some metal or metal halide. The element is vaporized and excited in an alternating electromagnetic field with a high frequency, or in most cases an extremely high (microwave) frequency. These lamps have proved particularly useful in atomic fluorescence analysis.

The requirements for the primary light source are different in fluorescence measurements, since the large solid angle into which these lamps radiate can be utilized in fluorescence excitation. This is not possible in absorption measurements[*]. Practically the only factor that counts in light sources for atomic absorption is the spectral radiation density. However, this is only partly greater for electrodeless discharge lamps than for modern hollow-cathode lamps[3]. In the present state of development, the use of discharge lamps seems worthwhile only for elements for which hollow cathodes with sufficiently high radiation densities are not available, *e.g.* As and Se.

Another important point is the constancy of the radiation emission. The relative standard deviations for the intensity variations are often less than 0.1% for the hollow cathode. This constancy cannot yet be equaled by electrodeless discharge lamps.

Light sources that could become important for atomic absorption spectrometry in the future are variable-frequency lasers[4]. These have high radiation densities and radiate in a very small wavelength range ($\Delta\lambda < 1/100$ Å). There would then be no need for a monochromator. The advantage of these lasers is that the wavelength of their radiation can be varied over a wide range. The same primary light source can therefore be used for the determination of several elements.

However, the tunability is also the weakness of this light source. Since the wavelength is determined by the operating conditions, these conditions must be kept so constant that the variation of the wavelength is considerably less than the width of the emitted wavelength band. This is a great technological problem. Because of the high price of these laser light sources, their use will initially be possible only for special investigations.

2.2. Absorption Volume

For the measurement of the atomic absorption, the sample must be converted as completely as possible into atomic vapor. This is the decisive process. It is this, and not the primary light source, the optics, or the photoelectric measuring technique, that mainly determines the efficiency of the methods.

Flames are used in most cases for the conversion of the sample into atomic vapor, the sample being atomized and introduced continuously into the flame in the form of an aerosol. Very precise concentration determinations are possible by measurement of the atomic absorption with a flame as the absorption volume. Relative standard deviations of 1% can be achieved in many cases. Unfortunately, the detection sensitivity is not high in comparison *e.g.* with that of some methods of emission spectral analysis.

Furnaces are very suitable for use as absorption volumes in microanalyses, and sometimes even for trace analyses. Less common absorption volumes are electric discharges such as DC arcs, high-frequency and microwave plasmas, and hollow cathodes. Unheated or only slightly heated cells are used for mercury determinations.

The special properties of the important absorption volumes will be considered in the discussion of the analytical procedures in later sections.

[*] The relationships for the radiation flux and the optical system are given as an Appendix in the IUPAC Document [13].

2.3. Radiation Selection, Radiation Measurement, and Processing of Experimental Values

In contrast with the methods of emission spectral analysis, whose strength lies especially in the simultaneous determination of several elements (simultaneous analysis with polychromators), the methods used in atomic absorption spectrometry are almost exclusively sequential, *i.e.* the elements are determined one after another. Radiation selection is therefore almost exclusively carried out with monochromators, since the precise determination of several elements with a polychromator would call for a number of conditions that are usually incompatible in practical analytical problems. This will be discussed in Section 4.1.

There are also two-channel atomic absorption spectrometers, which consist of two independent monochromators and measuring systems. However, the importance of these instruments is that the second channel can be used for the measurement of a reference signal rather than to allow the simultaneous determination of two elements. Since the light for both channels is passed through the absorption volume (generally a flame), some types of interference can be almost completely suppressed, while others can be reduced; the types of interference that are affected in this way are those due to processes in the flame.

In all atomic absorption instruments, the radiation of the primary light source is periodically modulated before the absorption volume. This can be achieved by means of a mechanical shutter, *e.g.* by a rotating sector disk (see Fig. 2), or by modulation of the discharge current of the primary light source. This enables the measuring electronics to distinguish between the useful signal coming from the primary light source and the interference signal due to the radiation emission of the flame. This is not entirely possible. In measurements in wavelength ranges in which the flame emits strongly, there is a marked increase in the scatter of the experimental values.

The dark intervals resulting from the modulation of the radiation can be used for the measurement of reference signals to reduce interference. Two such possibilities will be mentioned here.

One possibility is used in twin-beam instruments (Fig. 2, no. 2). On modulation, the beam is not simply interrupted, but is deflected and led around the absorption volume into the monochromator. In this way, lamp fluctuations and fluctuations in the measuring electronics can be reduced, but not fluctuations that arise from the flame, or from the absorption volume in general. After the development of better primary light sources and more stable measuring electronics, however, these more expensive instruments will not necessarily be preferable to single-beam instruments.

A particularly important possibility, on the other hand, is the use of the dark interval for simultaneous background measurement ("background compensation"). During the dark interval of the measuring beam, the light from a second light source, and specificially a source of continuous radiation, *e.g.* a deuterium lamp or an incandescent lamp, is admitted (Fig. 2, no. 3). In this way, the interfering background can be measured and taken into account automatically by electronic means. Since correct measurement of the background is particularly important in atomic absorption spectrometry,

and is also particularly difficult, it will be discussed in Section 4.2.

Modern atomic absorption instruments naturally contain a series of electronic systems designed to allow better and faster collection and processing of the experimental values; these systems will not be discussed here. In any case the necessary critical insight into what happens is not made easier or even superfluous by this.

3. Atomic Absorption Analyses with Flames as Absorption Volumes

3.1. Choice of Flames and Burners

The flames most commonly used in atomic absorption spectrometry are produced with acetylene, propane, or hydrogen as the fuel and air as the oxidizing agent. The acetylene/nitrous oxide flame is also used. Because of their relatively low combustion velocity, these flames can all be produced with an elongated slit burner. This gives a favorable flame shape for absorption measurements. The sample is introduced through a mixing chamber/atomizer. Since the larger droplets of the aerosol (80—90% in most cases) separate out in the mixing chamber, only a very fine aerosol reaches the "laminar" flame. Interference due to incomplete vaporization is therefore less pronounced than in the turbulent flames produced with oxygen as the oxidizing agent and with direct atomizer burners. The properties of some flames are shown in Table 1.

Table 1. Combustion velocities and temperatures of some flames.

Fuel	Oxidizing agent	Combustion velocity [cm/s]	[°C]
Mixing chamber/atomizer and slit burner; laminar flame			
Propane	Air	80	1925
Hydrogen	Air	450	2050
Acetylene	Air	160	2300
Acetylene	Nitrous oxide	180	2900
Direct atomizer burner; turbulent flame			
Hydrogen	Oxygen	3000	2650
Acetylene	Oxygen	2500	3100

The data given (combustion velocities and temperatures) are intended only as a guide. They depend on the conditions under which they were determined[5], *e.g.* on the geometry of the burner and on the fuel gas/oxidizing agent mixture.

Special mention of the acetylene/nitrous oxide flame is appropriate. The introduction of this flame by *Willis* in 1965[6, 7] was probably the most important step in atomic absorption spectroscopy with flames. It allowed the accurate and reliable determination of elements that form very stable compounds (oxides, hydroxides, *etc.*), *i.e.* Al, Be, Ti, B, and rare earth metals. Despite the relatively high temperature of the acetylene/nitrous oxide flame, some elements are converted only very incompletely into atomic vapors. In the case of boron, for example, only 0.3—0.4% of the material is in the atomic form in this flame[8], while in the acetylene/air flame the proportion is less than 0.1%. One disadvantage of the acetylene/nitrous oxide flame is the relatively strong radiation of the flame itself. Because of the very high temperature of the flame, there is a danger of interference due to ionization in the case of readily ionizable elements, since ionized atoms are lost as far as the measurement of the atomic absorption is concerned.

Several, frequently competing requirements must be considered in the choice of flame: high transparency, low intrinsic radiation, high sensitivity, low risk of ionization, low chemical interference (partner effects), *etc.*

An example of a flame with a high transparency, which is particularly important for the determination of elements (such as As and Se) with resonance lines in the short-wave UV, is the argon/hydrogen/diffusion air flame. Air, as the oxidizing agent, diffuses into the flame plasma from outside[9].

3.2. Interference due to Light Scattering and Molecular Absorption[10, 11]

Interference due to light scattering from particles and droplets is particularly noticeable in the short-wave UV. Even if the sample does not contain the element under analysis, this interference may cause an absorption to be recorded on aspiration of the sample. It is then necessary, particularly at low concentrations, to measure the background. This measurement could be carried out with similar samples that contain the element under analysis in an undetectable concentration. If no such samples are available, the background can be determined with a continuous radiation source as the primary light source.

The measurement of the background is much more difficult if it is caused by molecular absorption. Absorption by molecules and free radicals can occur over the entire spectral range. It is caused by molecules and radicals not only from the flame gases but also from the sample matrix. This absorption may occur both in the form of continuous molecular bands and as line-rich electronic excitation spectra. A reliable background measurement free from systematic errors may be impossible in the second case.

3.3. Interference due to Ionization

Interference due to ionization occurs particularly in the determination of elements with low ionization energies, *i.e.* specially in the determination of alkali and alkaline earth metals. As a result of the ionization, some of the atoms are lost as far as the measurement of the atomic absorption is concerned. Some examples showing the content of ionized atoms in some flames are given in Table 2[12]. Varying concentrations of one of these elements may displace the equilibrium between neutral and ionized atoms. If this fact is not taken into account,

Table 2. Content of ionized atoms in relation to the total number of atoms of an element in some flames [12].

Element	Ionization energy	Proportion of ionized atoms [%]		
		Propane/Air	Acetylene/Air	Acetylene/Nitrous oxide
Cs	3.87	28	-	96
Rb	4.16	14	-	90
K	4.32	2.5	-	82
Na	5.12	0.3	-	26
Li	5.37	0.01	-	16
Sr	5.69	-	13	20–80
Ca	6.11	-	3	10–40

the result obtained for the concentration of another element may be wrong. In the determination of easily ionizable elements, therefore, another easily ionizable element, *e.g.* cesium, is generally added as a "spectrochemical buffer"[13] or ionization buffer.

3.4. Chemical Interference

Interference can also occur in the determination of elements because other constituents of the sample form stable compounds with the elements under analysis. An example is the well-known interference due to phosphate in the determination of alkaline earth metals:

$$2CaCl_2 + 2H_3PO_4 + E \rightarrow Ca_2P_2O_7 + 4HCl + H_2O$$

Interference of this kind can be reduced by the addition of *e.g.* an excess of lanthanum chloride:

$$LaCl_3 + H_3PO_4 + E' \rightarrow LaPO_4 + 3HCl$$

where $E' > E$. As a rule, the hotter the flame used, the smaller is the addition required. (In view of the diversity of these interferences, the reader is referred to reviews, particularly in Refs. [14,15].)

3.5. Range of Application of Atomic Absorption Analysis with Flames

It has not yet been possible to determine all the elements whose resonance lines lie in the visible and UV regions of the spectrum. The elements for which this has been possible are indicated in Figure 1. Thus cerium, for example, has not yet been detected by atomic absorption in a flame[16] Cerium oxides, particularly the monoxide, are very stable and do not undergo detectable dissociation even in the fuel-rich reducing acetylene/nitrous oxide flame.

The great sensitivity differences in the determination of the various elements are therefore mainly due to the wide differences in the degree to which the elements can be converted into atomic vapor with the usual flames. Hotter flames, such as electrically produced plasmas[17], may offer important advantages for the determination of some elements.

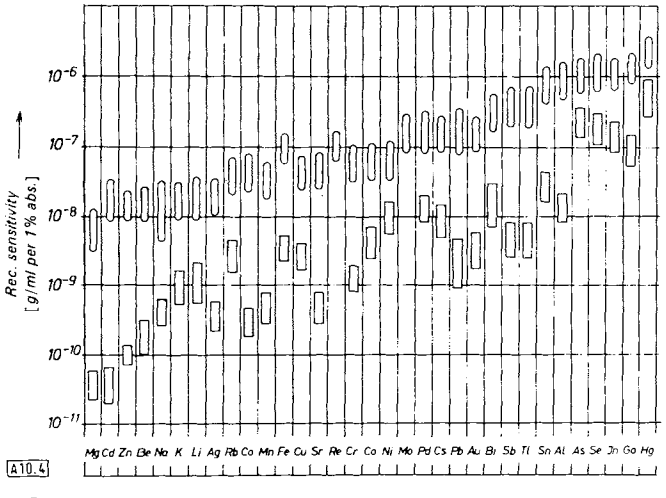

Fig. 4. Approximate ranges for the reciprocal sensitivity in atomic absorption analysis with flames (○) and with graphite tube furnaces (□) (see also Section 5.3).

Figure 4 shows the sensitivities achieved in the determination of a number of elements. The reciprocal sensitivity is plotted in g/ml per 1% absorption[*]. Exact numerical values are meaningless unless the apparatus conditions and the analytical problem are accurately defined; for this reason, the figure shows only ranges. This tells us nothing about the attainable detection limits. These depend not only on the sensitivity but also on the analytical interference level. If the prevailing interferences are due only to the apparatus and the flame, *i.e.* if they are not caused *e.g.* by fluctuating blank values, approximate guide values can be given. Under these (special) conditions, it will be possible to reach detection limits c that are lower than the values indicated for the reciprocal sensitivity c/1% absorption, and in some cases more than an order of magnitude lower.

In addition to the elements indicated in Figure 1 that can be determined directly by atomic absorption, it is also possible to determine other elements by indirect methods. Methods of this kind have been developed *e.g.* for P, S, F, Cl, and I, and also for elements whose direct determination is not sufficiently sensitive, *e.g.* for Ti, V, Nb, Ge, As, and Se. In these methods, use is made of the influence of the element to be determined on another element that can be determined satisfactorily by atomic absorption. For example, fluorine can be determined by measurement of the decrease in the absorption signal of magnesium or the increase in the absorption signal of zirconium[18]. However, special care is necessary in the development of procedures for indirect methods. A survey of these methods is given by *Kirkbright* and *Johnson*[19].

4. Concentration Ranges, Calibration, and Background Measurement in Atomic Absorption Spectrometry

4.1. The Usable Concentration Range

Unlike in the methods of emission spectral analysis, the concentration range in which precise measurements are possible with samples at the same dilution is relatively small in atomic absorption spectrometry. This is true not only of measurements with a flame as the absorption volume, but also for furnace and other methods.

The relative standard deviations for the determination of the concentration of three elements with an acetylene/air flame are plotted against the concentration c in Figure 5. The broken curve shows the effects of fluctuations in the hollow-cathode radiation and in the measuring electronics. These fluctuations are decisive for the large relative standard deviations at low concentrations, but are no longer of any importance at higher concentrations, where the decisive factor is the fluctuations of the concentration of the element under analysis in the flame. However, as can be seen from the standard deviations for absorbance measurements, which are plotted in the same diagram, the relative standard deviations for absorbance measurements are almost constant over a wide absorbance range.

[*] In the literature on atomic absorption spectrometry, data of this type are often referred to as "sensitivity". However, the sensitivity of a method increases as the indicated value in g/ml per 1% absorption decreases. These data are therefore referred to here as "reciprocal sensitivities".

They are about 1% in this case. The rapid increase in the relative standard deviations for the concentration determination at higher concentrations is due not to increasing absorbance fluctuations but to the curvature of the calibration curves. The curvature is particularly pronounced in the case of nickel.

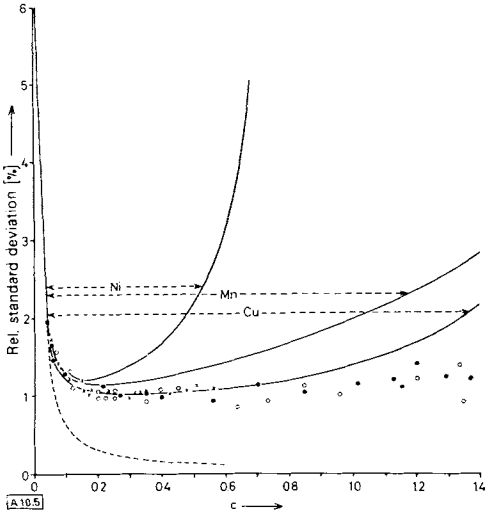

Fig. 5. Usable concentration ranges for the determination of nickel, manganese, and copper by atomic absorption. —·— relative standard deviation for concentration determinations. Relative standard deviation for absorbance measurements of Ni ×, of Mn ○, and of Cu ●. Ni: 2320.0 Å, $F_c = 15$; Mn: 2794.8 Å, $F_c = 35$; Cu: 3247.5 Å, $F_c = 37$. The concentration c is given in arbitrary units.

If one assumes that the relative standard deviation at the limits of the usable range may be twice the value in the most favorable case, the lowest and the highest concentration should differ by a factor of only $F_c = 15$ in the case of nickel, $F_c = 35$ for Mn, and $F_c = 37$ for Cu. The concentration ranges that can be used for precise measurements are therefore only slightly greater than one order of magnitude in atomic absorption measurements.

4.2. Calibration and Background Measurement

As in atomic spectroscopy in general, the calibration must be carried out with "samples of the same type". Calibration samples that have been analyzed by some other method or synthetic samples may be used. Finally, the calibration may also be carried out by the addition method[*]. The choice of calibration method will be decided by the analytical problem.

The condition of calibration with samples of the same type is relatively easy to satisfy if the calibration is carried out by the addition method. However, the results must be regarded particularly critically in this case, since the necessary background measurement can lead to systematic errors in the measurements, even with automatic background compensation.

The problem of the background measurement is to determine the background under the very narrow resonance line, which cannot be resolved by the monochromator. The transmission range of the monochromator is shown as a triangle in Figure 6. The abscissa is the wavelength, and the ordinate is the spectral radiation flux Φ_λ.

The transmission range of the monochromator has a triangular form of this type if the widths of the entry slit and of the exit slit are equal ($s_e = s_a$) and greater than the diffraction width of the monochromator $\lambda f/w$. In this expression λ is the selected wavelength, f is the focal length of the collimator, and w is the size of the beam-limiting diaphragm in the optical system of the monochromator.

In case a (Fig. 6), the radiation flux of the resonance line is decreased by atomic absorption, in case b by continuous background absorption, *e.g.* by the dissociation continuum of molecules, and in case c by a line from the electronic vibrational spectrum of molecules.

If a background measurement is carried out with a source of continuous radiation, the radiation flux will not be measurably reduced in case a, since only atomic absorption occurs. No background absorption will therefore (rightly) be observed. The background measurement also gives the correct value in case b, since the resonance radiation and the continuous radiation are decreased in the same way. In case c, however, the background measurement is wrong, since the resonance line radiation and the continuous radiation are decreased in different ways. This is always so if the background is due to electronic excitation spectra of molecules.

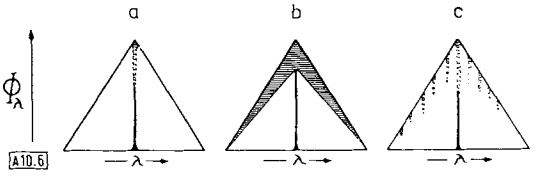

Fig. 6. Decrease in the radiation flux Φ_λ of the resonance line a) by atomic absorption and b) and c) by molecular absorption. The transmission range of the monochromator can be described by $[s_e = s_a \gg \lambda f/w]$. For further details see text.

This is shown in Figure 7 for the background interference of the bismuth line at 3068 Å due to an OH band. The two absorption spectra were recorded with a spectrograph having a very high resolution. In case a, a bismuth solution was

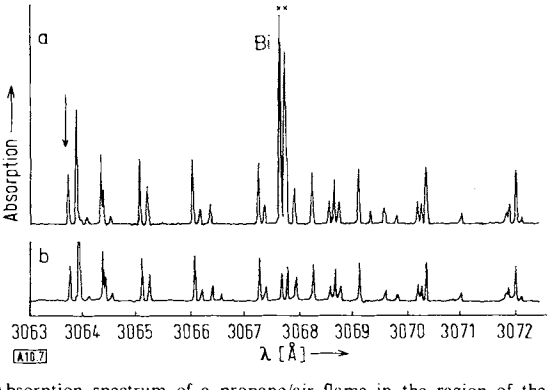

Fig. 7. Absorption spectrum of a propane/air flame in the region of the bismuth line 3067.7 Å. a) With atomic absorption of bismuth, b) without atomic absorption. The arrow indicates the short-wave edge of the OH band. The absorption is given on an arbitrary scale. 3.4 m Ebert spectrograph, grating: 1800 lines/mm, 2nd order spectrum. Practical resolution 250000; photographic recording.

[*] In the addition method (δ calibration [1]), the sample for analysis is divided into portions, and the element to be determined is added to the various portions in stepped known quantities. These samples can then be used as calibration samples for the determination of the course of the analytical curve.

aspirated into a propane/air flame,| while in case b only water was aspirated. As a result of nuclear moment splitting, the bismuth line has two components. It can be seen that two band lines almost exactly coincide with the bismuth lines. The background measurement could be carried out correctly with a spectral apparatus having this resolution. However, this is not possible with the monochromators of moderate resolution that are usual in atomic absorption spectrometry.

5. Atomic Absorption Spectrometry with Furnaces as Absorption Volumes

5.1. Furnace Types and Furnace Methods

The first application of a furnace in atomic absorption spectrometry goes back to *L'vov*. However, the graphite tube furnace developed by this author[20, 21] is very complicated, even after subsequent simplifications[22]. A whole series of simpler furnace types have now become common in analytical practice.

A selection of common furnace types, which differ in the shape and size of the usable absorption volume, is shown in Figure 8. The diagram only shows the main part. Graphite

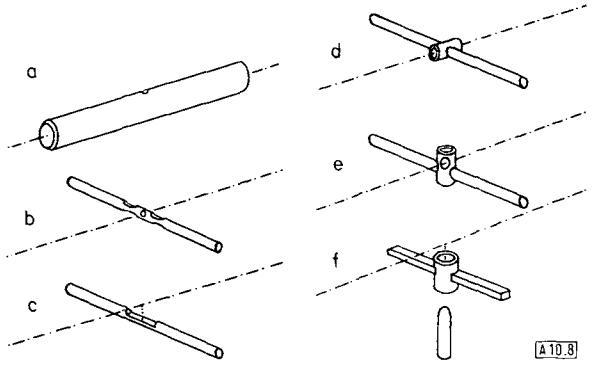

Fig. 8. Furnace types in atomic absorption spectrometry. The optical axis is indicated in each case.

is used as the furnace material. An electric current is passed through the graphite for heating. Temperatures of 2800 °C or higher can be reached in this way within a few seconds.

Electromagnetic high-frequency fields are occasionally used for heating, *e.g.* in the Langmyhr-Thomassen graphite tube furnace[23]. Furnace type f[24] is heated, not by electric resistance heating, but by an arc, which is struck between the lower auxiliary electrode and the graphite crucible.

To prevent combustion of the graphite furnace, it must be used in a chamber filled with inert gas, *e.g.* argon. A chamber of this type is used for the relatively large furnaces of type a[25]. For smaller furnaces, such as types b to e, a stream of inert gas may simply be led over the red-hot graphite[26, 27]

Other materials that are difficult to melt, such as ceramic materials or metals, may naturally also be used as furnace materials. Furnaces with a heatable tantalum strip have proved to be very useful for some analytical problems[28, 29]. A survey was published by *Kirkbright* in 1971[30].

In atomic absorption analyses with flames as absorption volumes, the sample is generally introduced continuously. In spectrochemical terminology, these are known as analyses with "unlimited sample size", The analytical signal is therefore independent of time, and this makes the measurement and averaging very easy. In furnace methods, on the other hand, limited quantities of sample are used in almost every case. A small sample is introduced into the furnace, and the furnace is then heated so that the sample vaporizes as completely as possible. The vapor disappears from the useful absorption volume by diffusion, convection, and possibly by forced flow of protective gas. It is therefore necessary to measure and evaluate a time-dependent signal. Since the magnitude of the analytical signal depends not only on the concentration of the element under analysis but also on the quantity of sample introduced, the quantity of sample must be measured out precisely. This is easy in the case of liquid samples. These generally also satisfy the requirement that the sample introduced should be representative of an initial sample that is usually very much larger.

However, great difficulties often arise in the direct analysis of solid samples, and these may even make the analysis impossible. The division, handling, and introduction of samples that must be smaller (often very much smaller) than 1 mg is difficult, and the danger of contamination is increased. It is also impossible in many cases, *e.g.* in the analysis of geological samples, to ensure that the sample introduced is representative of the larger initial sample[23]. Liquid samples are therefore nearly always used in atomic absorption analyses with furnaces.

5.2. Procedures for Atomic Absorption Analysis with Furnaces

As in all analytical methods, a very carefully devised procedure must be followed in atomic absorption analysis with furnaces. Whereas there have been many investigations on the physical and chemical processes in flames that can be used for this purpose, little is known at present about the decisive processes in atomic absorption furnaces, though systematic studies on this point are in progress at present in several laboratories.

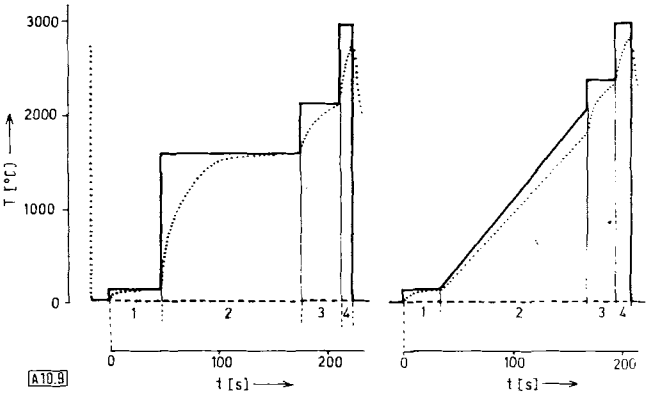

Fig. 9. Heating program for atomic absorption analysis with furnaces. Dotted curves show how the actual temperature follows the set heating program.

In general, the furnace must not be heated immediately to the temperature required to produce the atomic vapor of the element under analysis. Interference due to light scattering and molecular absorption would usually be unavoidable. By trying out suitable heating steps (time) and heating stages (temperature), it is often possible to control the vaporization in such a way that interference due to the sample matrix

is avoided. Figure 9 shows schematic examples of heating programs, which must form an essential part of any procedure.

It is relatively easy to determine the correct heating program for the determination of an element that is difficult to vaporize in a matrix that vaporizes readily. An example is shown in Figure 10. This is the determination of manganese in alkali metal chlorides. The most sensitive resonance line of manganese at 2795 Å lies in a wavelength range in which all alkali metal halides absorb strongly in the vapor phase.

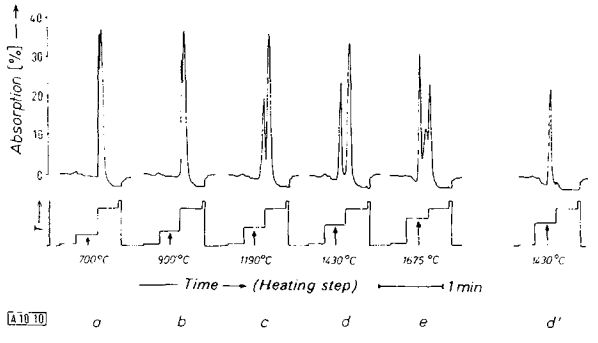

Fig. 10. Experiments for the development of a heating program for the determination of manganese in alkali metal chlorides with a graphite tube furnace (measurements by Dr. Ş. Güçer). For further information see text.

In heating step 1, a final temperature of 110 °C was selected to evaporate the solvent. To establish the temperature that must be selected in heating step 2 to vaporize the alkali metal chlorides without loss of manganese, the temperature was raised in steps from 700 to 1675 °C in experiments a to e. At 1430 °C (experiment d), the background absorption in heating step 2 (1st signal) and the analytical signal in heating step 3 (2nd signal) are clearly separated. A higher temperature in heating step 2 (1675 °C in experiment e) results in loss of manganese at the end of heating step 2.

Experiment d' was carried out under the same conditions as experiment d, but with a deuterium lamp as the primary light source. One therefore sees only the molecular absorption in heating step 2, but not the atomic absorption of manganese in heating step 3.

In many analytical problems it is not so easy to achieve the desired result. A suitable heating program frequently cannot be found. Especially in the trace analysis of organic samples, *e.g.* in biochemical or clinical trace analyses, sample preparation is usually necessary, sometimes at considerable cost. The early hopes of being able to carry out a process equivalent to ashing in the absorption furnace itself have not so far been fulfilled.

It must be pointed out again that the considerations on the background measurement in Section 4.2 also apply to atomic absorption analyses with furnaces. Indeed, automatic background compensation in furnace methods is an important technical aid, without which some analyses would not have been possible. However, its application must be viewed very critically if one is to avoid systematic errors. Unfortunately, there is at present no catalog of interfering molecular spectra and necessary experimental data for atomic absorption analysis with furnaces. A collection of spectra and data of this kind could greatly facilitate the development of reliable procedures.

5.3. Range of Application of Atomic Absorption Analysis with Furnaces

Higher concentrations of atomic vapor are reached in the useful absorption volume of a furnace than in flames. The sensitivity of furnace methods is therefore greater than that of flame methods. A comparison of the reciprocal sensitivities in g/ml per 1% absorption is shown in Figure 4. These were determined with a tube furnace of type a (Fig. 8) having an internal diameter of 8 mm. The sample size was 50 µl. Since the analytical problem cannot be precisely defined here, the diagram once again shows only ranges as a guide to the reciprocal sensitivity.

The furnace methods lose some of their superiority in a comparison of the detection limits. Absorptions lower than 1% can often be measured reliably by flame methods, but only rarely by furnace methods.

This comparison is based on the assumption that sufficient sample material is available for both methods. One advantage of the furnace method, however, is that only small quantities of sample are used (1—100 µl, depending on the type of furnace). The sensitivity and detection power for quantitative analyses of an element are very high. Under favorable conditions, it is possible to determine even 10^{-10}—10^{-11} g of some elements, *e.g.* Mg, Cd, Zn, and Be.

Because of these properties, furnace methods are particularly suitable for the determination of small trace concentrations if a mixed spectrochemical method[31] is used, *e.g.* if a chemical separation or concentration process is carried out first.

How does the detection power compare with that of methods of optical emission spectral analysis? Solid samples were used for this comparison; the concentration data also refer to the mass of the solid substance. A method with a very high detection power was used for comparison[32]; this was emission spectral analysis with a DC arc and a spectrograph whose resolution is so high that the physical width of the lines is resolved.

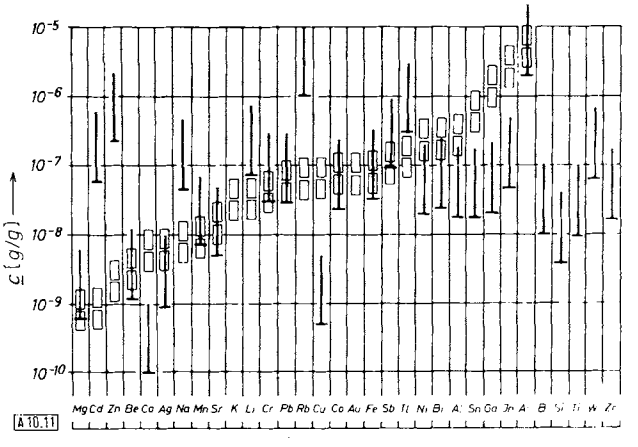

Fig. 11. Approximate ranges for detection limits c in atomic absorption analysis (□) with graphite tube furnace and in emission spectral analysis (⊥) with a DC arc and a high-resolution spectrograph [32].

Here again, naturally, one can only give guiding values unless the analytical problem is accurately defined. Figure 11 therefore shows only ranges. These are valid for cases in which the interference due to the matrix is relatively small. For analyses with the absorption furnace, this means in particular

that only slight interference due to light scattering or molecular absorption occurs in the detection of the element under analysis. As can be seen from Figure 11, by measurement of the atomic absorption in furnaces, it is possible for some elements to reach detection limits of the same order of magnitude as in an emission spectroscopy method with a high detection power, and sometimes, *e.g.* in the case of zinc, to reach even lower limits. This says nothing about whether a particular analytical problem can be solved by one method or by another, but only whether there is any prospect of a solution.

6. Special Methods of Atomic Absorption Spectrometry

In addition to the atomic absorption methods with flames and furnaces, there are a large number of special techniques and methods, which cannot be described in detail here. Some of these are extensions of normal flame methods. Thus the length of the useful absorption volume, and hence the number of free atoms in the absorption volume, can be increased if a flame is allowed to burn in a heated tube through which the radiation passes in the axial direction[33, 34]. This gives a considerably greater detection power for a number of elements[35–38], but the risk of interference is also considerably increased.

The boat method[39] and the method described by *Delves*[40] are also flame methods. In the former, the liquid sample is carefully evaporated to dryness in a metal (*e.g.* tantalum) boat, and the boat is heated rapidly and reproducibly[41] in the flame. As in the furnace methods, a time-dependent absorption signal is then observed. In the Delves method, the sample is evaporated to dryness in a crucible, but its vapor is allowed to flow through a tube that is open in the middle and that is already in the flame. Neither of these methods requires much additional outlay. They are very suitable for a number of analytical problems, *e.g.* for the determination of lead[40] or cadmium[42] in blood. In the simplest case, the sample may even be applied to a sampling loop made from platinum, dried, and vaporized in the flame[43].

Special mention should be made here of the many methods for the determination of mercury[44]. The detection power in the flame is very low, and is inadequate for many analytical problems, particularly for the determination of the element in biological samples and for the checking of environmental pollution.

However, mercury can be determined very satisfactorily in a cold or only slightly heated cell. Methods of this type are now very widely used, and differ mainly in the manner in which the atomic mercury vapor is produced[49, 50].

The method most commonly used at present was developed by *Poluektov*, *Vitkun*, and *Zelyukova*[45]. It is based on the reduction of mercury with $SnCl_2$:

$$Hg^{2+} + Sn^{2+} \rightarrow Hg^{0} + Sn^{4+}$$

The atomic mercury is then transported into the absorption cell in a current of air or nitrogen. A time-dependent signal is generally observed. However, since mercury does not oxidize appreciable in air and condenses only slightly in the concentrations that occur, it is also possible to use closed systems and to measure quasi-stationary absorption signals[46, 47].

This method for the determination of mercury is well suited to automation[48, 49]. However, it is essential that the digestion necessary for the determination in organic samples should be well organized. Since the method for the determination of mercury in the absorption cell has a very high detection power, the practical detection power usually depends on the purity of the reagents required for digestion. *Lindstedt* and *Skare*[49] give a value of 0.5 ng as the detection limit after acid digestion, and 1.5 ng after digestion with permanganate. These detection limits refer to the treatment of ml of urine or 0.3 ml of blood.

7. Closing Remarks—Comparison of the Method of Atomic Absorption Spectrometry with other Spectrochemical Analytical Methods

What do the methods of atomic absorption spectrometry achieve in comparison with other spectrochemical methods of analysis that are also used for the detection of elements and the determination of their concentration? This comparison will be confined to the most important methods of atomic spectroscopy, *i.e.* those of optical emission spectroscopy, X-ray spectroscopy, and mass spectroscopy. Moreover, we can only mention a few very general points that may be important to the assessment or selection of a given method of spectrochemical analysis, since detailed and precise quality figures could be given only if the methods used for the comparison were "complete", *i.e.* if they were defined "by a procedure that is fixed in all its details and by a specific analytical problem"[1].

Let us first consider the state of aggregation of the sample for analysis and the preparation of the sample. For atomic absorption analysis, the samples must be in the liquid form; solid samples must therefore be dissolved. Only a few methods have so far been developed for the atomic absorption analysis of special solid samples.

On the other hand, solid samples are generally used in most other atomic spectrochemical methods, *e.g.* in most methods of optical emission spectral analysis with arcs, sparks, and glow discharges, with those of X-ray spectrometry, and with solid-state mass spectrometry.

If the samples are in the solid form, an analytical method for solid samples can naturally offer considerable advantages. The analysis can sometimes be carried out more rapidly. The monitoring of steel production in a modern oxygen steelworks, for example, is possible only because the steel samples need not be dissolved, but are simply separated and ground after solidification and can then be analyzed, generally with an optical emission spectrometer.

However, the ability to analyze solid samples does not always mean that the sample preparation is simpler and faster. For the geochemical analysis of solid samples, for example, if the analysis is to yield accurate results, a considerable amount of sample preparation is usually necessary, *e.g.* grinding, mixing with additives, melt digestion, *etc.*

Spectral analysis in solution, particularly atomic absorption analysis, may naturally be preferable to solid-state analytical methods purely because the samples are already liquid or because wet-chemical preparations, such as concentration processes, separation processes, *etc.*, are necessary. The form or preparation of the required calibration samples, particularly the preparation of synthetic calibration samples from pure

starting materials, is also much simpler in most cases. The possibility of calibrating an analytical method with synthetic calibration samples (σ calibration[1]) is particularly important in analytical chemistry. With this type of calibration it is possible to obtain analytical results that are free from systematic (but not random) errors, since the true contents are known from the preparation and can be assigned directly to the experimental values. The addition of any necessary additives, such as spectrochemical buffers, is usually also much easier with liquid samples than with solid samples.

Another point that is often of decisive importance in the assessment or selection of spectrochemical analytical methods is the question whether the simultaneous determination of several elements is possible or whether the elements must be determined successively. Simultaneous determinations take less time, at least in photoelectric analytical methods. The quantity of sample required and consumed is generally smaller. It should also be taken into account that in X-ray spectrometric methods of analysis, a certain quantity of sample is necessary, but is not consumed.

Atomic absorption spectrometry is unsuitable for simultaneous determinations of several elements except in very special cases. Most atomic absorption instruments are therefore designed as single-channel instruments. This means that the cost of these instruments is considerably lower than that of optical spectrographs with the accessories for the evaluation of the photographic plate or for spectrometers with photoelectric radiation measurement, *i.e.* instruments that allow the simultaneous determination of several elements.

Provided that a few well-established basic rules are observed, the risk of systematic errors due to interference with the analysis is low. Analyses by atomic absorption spectrometry also have the advantage that they are very precise. Though they frequently do not attain the precision of X-ray spectrometry in the determination of high contents, and sometimes not even that of optical emission spectrometry with photoelectric radiation measurement, the precision is nearly always superior to that of optical emission spectrometry or of mass spectrometry with photographic radiation measurement. The instruments are very simple and flexible. They can be adapted fairly easily for new analytical problems.

These characteristics of atomic absorption spectrometry are the reason why it is used for the analytical problems that call for the precise determination of the concentrations of elements in liquid samples where it is usually necessary to determine only a small number of elements, but possibly in a large number of samples, *e.g.* in medical or biochemical analysis, and where the cost of equipment of such limited problems must be kept low.

However, it is also necessary to point out a disadvantage: the concentrations in liquid samples can be precisely determined only in a relatively small range.

Isopeptide Crosslinks—Their Occurrence and Importance in Protein Structure

R. S. Asquith, M. S. Otterburn, and W. J. Sinclair[*]

Isopeptide links refer to bonds between the ε-amino group of lysine and the side-chain carboxyl groups of glutamic or aspartic acid. Covalent crosslinks of this kind, which undoubtedly occur in protein feedstuffs and reduce their nutritional value, also participate in the fibrinogen→fibrin transformation and play a part in stabilizing the structure of keratins. Isopeptide links also arise on heating of both fibrous and globular proteins, the amount formed depending upon the severity of heat treatment. The mode of formation and the significance of these crosslinks require further elucidation.

1. Introduction

Proteins are biopolymers with a molecular weight arbitrarily defined as greater than 5000. They are responsible for many indispensible functions in cellular structure, catalysis, metabolic regulation, and contractile processes, acting in protective and defensive roles in animals.

Protein chains are built up of α-amino acids linked by amido groups (peptide links) between α-amino and α-carboxyl groups of adjacent residues. Many of their properties are dependent, however, not only on this primary sequence of residues in the polypeptide chain but also on the secondary (shape of chain) and tertiary structures (chain aggregation). Many interchenic forces and crosslinks are responsible for maintaining the tertiary structure. These include salt linkages, which are the result of coulombic interactions between oppositely charged acidic and basic side chains and were first postulated in 1931 by *Speakman* and *Hirst*[1] as well as hydrogen bonds, which have also been recognized as not only playing an important role in stabilizing the secondary structure in the normal form of an α-helix, but also occurring as an interchenic link in the tertiary structure[2, 3]. The importance of the interaction between hydrophobic residues in globular proteins was recognized at an early stage[4]. These findings have now been extended to include fibrous proteins[5, 6].

One major naturally occurring covalent crosslink (found particularly in the keratins) is the amino acid cystine, by which two peptide chains can be linked through the disulfide bridge. Because of its ease of oxidation, reduction, and degradation and the influence of these effects on wool keratin, the reactions of the disulfide bridge have been studied particularly thoroughly[6–8]. As a result of this work other crosslinks have been postulated and subsequently isolated from degraded proteins. Thus lanthionine[9, 10], lysinoalanine[11–13], and ornithinoalanine[14] all occur in alkali-treated proteins which in their native form contain cystine. The mechanism of formation is basically a bimolecular β-elimination of a proton in the β-position to the disulfide bond, yielding the reactive intermediate dehydroalanine (Fig. 1).

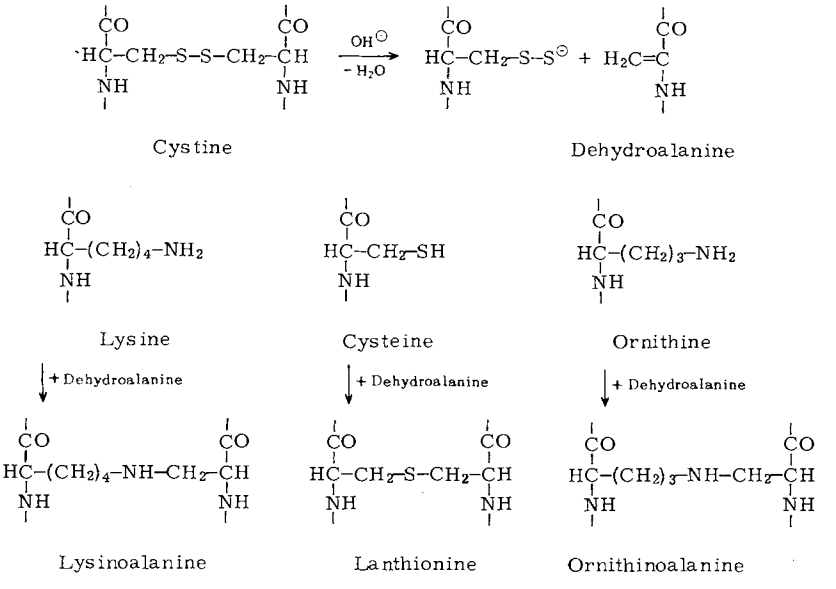

Fig. 1. Formation of dehydroalanine on alkali-treatment of cystine in a protein network; reaction of dehydroalanine to form lysinoalanine, lanthionine, and ornithinoalanine.

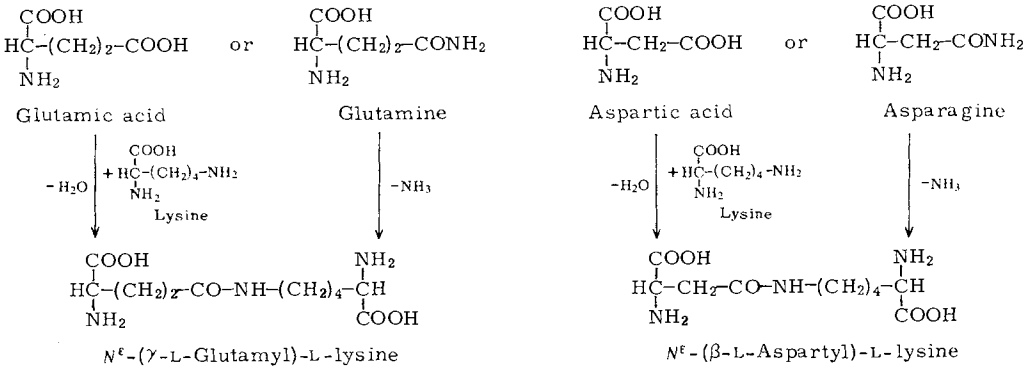
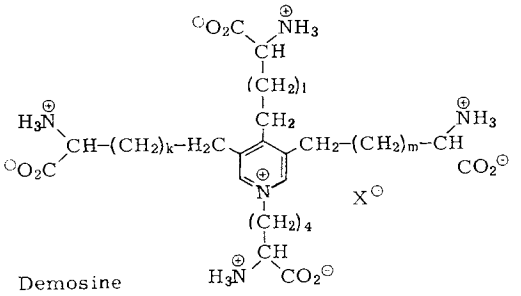
[*] Prof. R. S. Asquith, Dr. M. S. Otterburn, and W. J. Sinclair
Department of Industrial Chemistry
The Queen's University of Belfast
Belfast BT9 5AG (Northern Ireland)

Positive proof of this reaction scheme has recently been obtained by the isolation of the dehydroalanyl peptide: γ-glutamyl-dehydroalanyl-glycine from alkali-treated glutathione[15, 16]. The intermediate so formed can then react with adjacent amino acid residues forming new inter- and intramolecular covalent bonds. Many investigations have shown that increased protein stabilization occurs when such new bonds are formed, and this work has been fully reviewed by *Zahn*[17].

The nature of the crosslinks in collagen and elastin have been presented in a recent review by *Gallop et al.*[18]. Lysine links of dimeric and trimeric tyrosine[20]. The mechanism of formation of the dimer and trimer is believed to be initiated by a peroxidase enzyme. This enzyme catalyzes the oxidative coupling of the tyrosine residues through the position 3 of the aromatic rings. The dimeric and trimeric tyrosines so produced crosslink the polypeptide chain.

Some evidence has recently been put forward by *Raven et al.*[21] that dityrosine occurs in Tussah silk fibroin and wool keratin. No conclusions, however, were drawn by these authors as to whether or not the residue was present as a crosslink.





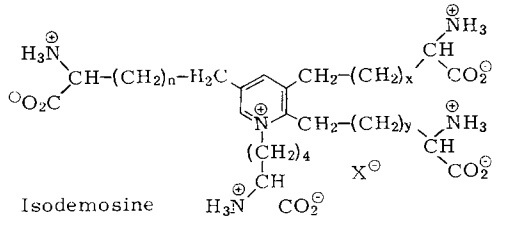


Fig. 2. Postulated reaction schemes for the formation of isopeptides.

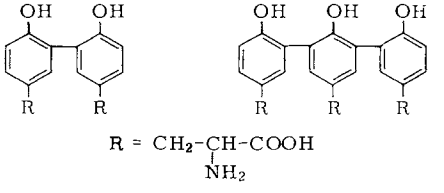
is the amino acid primarily involved in such links. This amino acid undergoes enzymic oxidation and deamination yielding 2-aminoadipinaldehydic acid



This product is a precursor to the relatively simple crosslinks such as those found in collagen and the more complex ones which occur in elastin, *i.e.* demosine and isodemosine.

The elastic protein resilin, which was isolated from the cuticle of insects by *Weis-Fogh*[19], has been shown to contain cross-

An obvious interaction, which would result in a covalent crosslink being formed, is that between the ε-amino group of lysine and the side-chain carboxylic groups of glutamic or aspartic acids. Loss of water would yield an ω-ε-amide link (Fig. 2). Today such a link is termed an isopeptide link to differentiate it from the normal peptide link.

Whilst such links have often been postulated, only recently have they been established as definite chemical moieties, thereby demanding reinvestigation of many proteins in which their possible occurrence had been ignored. The present paper summarizes some of the more recent findings regarding the isopeptide link.

2. History of the Isopeptide Link

The fact that salt linkages were shown to exist between side chain carboxyl and amino residues as early as 1931 suggested that these groups were sufficiently close to one another to permit the formation of a covalent bond. Such a crosslink was first suggested by *Astbury* in 1934[22] as probably occurring in the keratin molecule. This postulate tended to be obscured by the later findings that lysine reacts with cystine degradation products. Nevertheless, *Pauling* and *Niemann*[23] again suggested in 1939 that the isopeptide link could occur. Indirect evidence accumulated for the formation of the isopeptide link from studies of the effect of heat on proteins; thus *Mecham* and *Olcott*[24] subjected a series of proteins to dry heat and observed that the resulting proteins had decreased solubilities and decreased moisture regain. They also showed that the availability of basic and acidic sites in the heated proteins to dyestuffs had decreased as compared with the unheated material, despite the fact that there was no difference in the amounts of acidic or basic amino acids estimated in hydrolyzates of the materials. *Mecham* and *Olcott* interpreted their

results as a loss of some of these polar groups, possibly by internal ester or amide formation.

Undoubtedly the work of *Beuk et al.*[25] supported the postulate that some form of isopeptide crosslinking was occurring. Thus these authors showed that the digestability of the protein by enzymes decreases as the severity of heating is increased. It has also been noted that some samples of gelatin become insoluble when heated—this has been attributed to isopeptide formation[26], as was the insolubility of anhydrous gelatin[27].

3. Availability of Lysine

From nutritional studies lysine has been known for some time to be an essential amino acid. Indeed it is fairly common to add the free amino acid to protein feedstuffs which are naturally deficient in the compound, in order to enhance their nutritional value.

Heat sterilization can reduce the nutritional value without necessarily reducing the total lysine content of the foodstuff. Undoubtedly many feedstuffs contain carbohydrates as well as proteins, and in the presence of reducing sugars the ε-amino group of lysine can undergo a Maillard reaction, *i.e.* the aldehydic groups of the reducing sugars condense with the ε-amino groups of lysine, thus blocking these groups and rendering the lysine unavailable for nutrition. It was generally and correctly assumed that this type of reaction is responsible for the reduction in the nutritional value of heated foods (*e.g.* dried milk), and may be in part responsible for the color changes observed during heating of foodstuffs.

Carpenter[28] and others[29,30] therefore devised a number of methods of determining the proportion of ε-amino lysine groups available for reaction in foodstuffs and hence nutritionally valuable. These methods rely on reacting the available amino groups of lysine with a reagent such as 1-fluoro-2-4-dinitrobenzene (FDNB). By determining the amount of N^{ε}-(2,4-dinitrophenyl)lysine obtained hydrolysis of the protein and subtracting from the total lysine present, the amount of "bound" lysine is obtained, *i.e.* lysine unavailable for reaction with the reagent. Obviously the ε-amino group of lysine may be blocked by reactions whose products hydrolyze during the hydrolysis of the protein, hence returning this lysine as the free amino acid. Alternatively the ε-amino group may be blocked by the formation of acid-stable products, such as lysinoalanine. The latter products are not returned as lysine on hydrolysis of the protein and may be difficult to detect on amino-acid analysis of hydrolyzates.

Whilst any blocking of the ε-amino group may reduce the nutritional value of the protein, it is sometimes desirable to differentiate between acid-labile and acid-stable link formation. *Asquith et al.*[31] designed a method permitting direct estimation of the "bound" lysine involved in hydrolytically labile links. The method relies on recovery of free lysine following chemical blocking of the available lysine and acid hydrolysis of the protein. Such lysine as is recovered must be that bound by acid-labile links in the protein. These latter authors, however, were not investigating nutritional foodstuffs but rather the effect of dry heat on the carbohydrate-free protein, keratin. Application of this method to the analysis of dry-heated keratin showed that the amount of lysine unavailable for reaction with FDNB, but recoverable as free lysine in the protein hydrolyzate, increases progressively as the severity of treatment increased[32], clearly indicating that acid-labile links are formed on heating keratin.

For the keratins[6] it is well known that selective fission of the disulfide crosslinks by oxidation with organic peroxy acids (*e.g.* performic acid) results in a material separable into three fractions by isoionic precipitation. These fractions are termed α-keratose (soluble in alkali, insoluble in acid), β-keratose (insoluble in acid or alkali), γ-keratose (soluble in acid or alkali at all pH values). The fission of the disulfide bonds thus increases the solubility of keratin in suitable aqueous solvents.

Increased solubility by reduction of the degree of interchenic crosslinking is a common phenomenon in polymer chemistry. Even though it has been suggested that these fractions correspond, in untreated wool, to specific histological components of the fiber, decreases in solubility can still be used[33] as a measure of enhanced crosslinking (caused by introduced links stable to peroxy acids). Prior heat treatment of the wool resulted in an increase in the proportion of the insoluble fraction (modified β-keratose), with a corresponding decrease in the more soluble fraction. The more prolonged or intense the heat treatment, the greater is the degree of insolubilization of the protein. This clearly indicates progressive enhancement of crosslinking of some type by the heat treatment.

Examination of the fractions obtained from different wools indicated that the proportion of bound lysine is greatest in the insoluble β-keratose fraction, even in untreated wool. Further, the proportion of bound lysine increases with severity of heat treatment (Fig. 3). The proportion of bound lysine in the more soluble fraction α-keratose remained the same, irrespective of heating conditions[32]. The amount of this fraction decreases as severity of treatment increases, suggesting that when crosslinking through lysine reaches a certain level this fraction becomes insoluble in ammonia solution. The most soluble fraction (γ-keratose) contains a negligible proportion of bound lysine which is unaffected by heat treatment, although the proportion of the fraction changes.

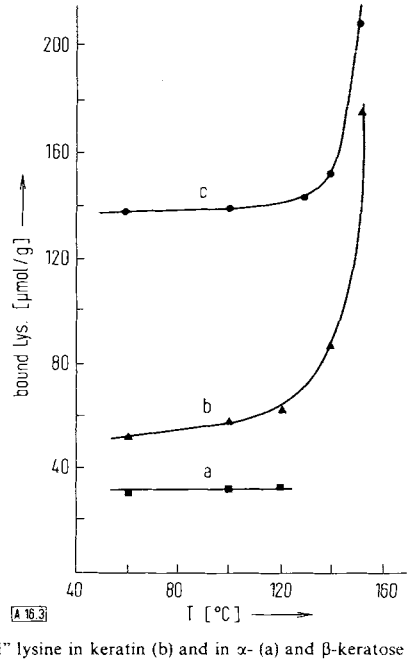


Fig. 3. Amount of "bound" lysine in keratin (b) and in α- (a) and β-keratose (c) *versus* the temperature of heating. The samples were heated for 48 h.

These results not only clearly indicate that interaction of lysine with some other amino acid to yield an acid labile link is occurring in keratin, but also show that the product of this reaction acts as an interchenic crosslink. This was further substantiated in the case of heated keratin by the finding that there is a direct relationship between the proportion of insoluble β-keratose fraction found and the concentration of "bound" lysine present, as shown in Figure 4. Even

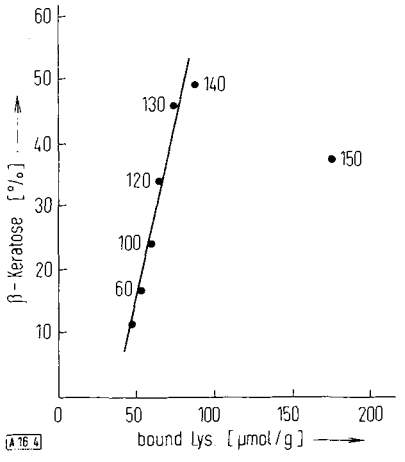

Fig. 4. Amount of insoluble β-keratose *versus* the concentration of bound lysine. The numbers indicate the temperature [°C] at which the samples were heated. The lowest point corresponds to a control sample.

in the β-keratose fraction obtained from virgin wool there is a markedly greater proportion of "bound" lysine than in either of the other fractions from the same source. On the basis of these findings *Asquith* and *Otterburn* postulated the possibility of isopeptide bonds[32] being the acid-labile crosslink formed. Further, *Bjarnason* and *Carpenter*[34, 35] showed that after heat treatment the available lysine decreases in pure nutritional proteins and postulated the occurrence of the isopeptide links as being responsible. Despite these numerous postulates, conclusive proof of the existence of such links was difficult to obtain.

4. The Isopeptide Link in Fibrin

It was in this field of research that the first breakthrough in the identification of an isopeptide link was achieved. Early workers on the fibrinogen→fibrin transformation had suggested the free glycine end groups react with glutamic acid to give γ-glutamyl-glycine links which would lead to the fibrinogen becoming insoluble[36], this reaction being catalyzed by a transglutaminase. In 1966, however, *Lorand*[37] postulated the formation of N^{ε}-(γ-glutamyl)-lysine isopeptide, as did *Fuller* and *Doolittle*[38], to account for the insolubility of fibrin.

The major difference between this work and that on heated proteins was the mechanism proposed for the formation of the isopeptide link. Thus it was assumed that the link in heated proteins results from a condensation reaction between the free carboxyl of glutamic acid and the ε-amino group of lysine with loss of water, whereas in the fibrinogen→fibrin transformation such a dehydration reaction would be less likely *in vivo*. Hence linkage was postulated to occur through an amide exchange between glutamine and an ε-amino group of lysine. Such a reaction would be more probable in enzyme-catalyzed systems.

It was not until 1968 that three groups of workers advanced more definite evidence of the existance of the N^{ε}-(γ-glutamyl)-lysine crosslinks in polymerized fibrin[39–41]. These workers found that crosslink formation in the fibrinogen→fibrin transformation involves a complex series of reactions; firstly thrombin causes the splitting off of fibrinopeptides A and B from fibrinogen, yielding a fibrin gel which is then strengthened by isopeptide crosslinking. The reaction is catalyzed by transglutaminase enzyme *in vivo*. The same authors also examined whether N^{ε}-(β-aspartyl)-lysine isopeptide crosslinks might also be present. However, available evidence suggests that this isopeptide is absent in fibrin.

5. Isopeptides in Virgin Wool

The major difficulty in the identification and isolation of a moiety such as the isopeptide link in keratin is that it cannot be isolated by acid hydrolysis. Enzymic hydrolysis of keratin is also difficult due to the high concentration of cystine residues in the proteins, thus preventing easy penetration of enzymes into the insoluble matrix. Positive identification of isopeptides was therefore impossible until a system of total enzyme hydrolysis suitable for keratin had been devised. In 1969 such a method was developed at WIRA (Wool Industries Research Association)[42]. The method consists of first reducing the cystine residues with tributylphosphane and blocking the thiol groups so formed by reaction with acrylonitrile, to prevent reoxidation. The fibrous protein is therefore opened up to subsequent attack by enzymes and can be hydrolyzed completely to amino acids by treatment with pepsin, pronase, amino peptidase M, and prolidase[43]. These enzymes together catalyze the hydrolysis of all normal peptide links along the chain but do not attack the primary amido groups of asparagine or glutamine, nor are the isopeptide links of N^{ε}-(γ-glutamyl)-lysine or N^{ε}-(β-aspartyl)-lysine affected. Prior to the publication of the hydrolytic system a cooperative study was undertaken by *Asquith* and *Otterburn* and the WIRA group. This work resulted in the identification and isolation of N^{ε}-(γ-glutamyl)-lysine in virgin wool keratin[44].

Whilst in work with other proteins the isopeptide link had been detected by comparison of enzyme hydrolyzates with synthetic N^{ε}-(γ-glutamyl)-lysine, this was the first time that the isopeptide N^{ε}-(γ-glutamyl)-lysine was positively identified. Examination of enzyme hydrolyzates obtained from virgin wool indicated two peaks in the region between leucine and tyrosine—one of which corresponds in mobility to N^{ε}-(γ-glutamyl)-lysine (Fig. 5).

Using a preparative ion-exchange column a wide fraction was collected containing leucine, tyrosine, and the two unknowns. After desalting and concentration, this fraction was separated by paper chromatography. Using synthetic N^{ε}-(γ-glutamyl)-lysine as a marker, the band corresponding in position to the isopeptide was excised and eluted with distilled water. The eluate was split into two portions, the first of which was acid-hydrolyzed and found to contain not only glutamic acid and lysine but also aspartic acid.

The second portion was treated with 5-dimethylamino-1-naphthalenesulfonyl chloride (DNS). On subequent acid hydrolysis

this portion yielded α-DNS-Asp, α-DNS-Glu, and α-DNS-Lys. The presence of α-DNS-Lys indicated that the ε-amino group was blocked in the original peptide material, whilst the presence of α-DNS-Asp and α-DNS-Glu indicated that their α-amino groups were not involved in peptide links. Thus it was possible to conclusively establish the presence of both types of isopeptide links[45].

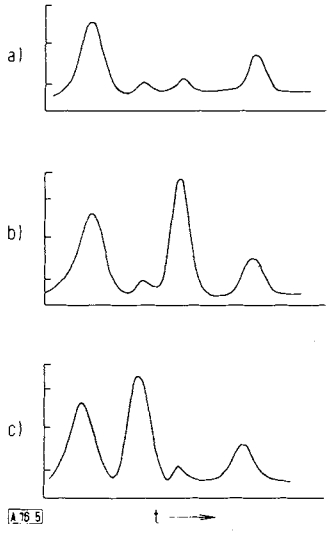

Fig. 5. Chromatograms of a) enzymically hydrolyzed wool keratin, b) with addition of synthetic N^{ε}-(γ-glutamyl)-lysine, and c) with addition of synthetic N^{ε}-(β-aspartyl)-lysine.

In both this work and work by *Milligan et al*[46] the amounts of N^{ε}-(γ-glutamyl)-lysine present in virgin wool were found to be very small. *Harding* and *Rogers*[47] found considerably greater amounts of the isopeptide in the keratin spines of various mammals. *Loewy et al.* reported N^{ε}-(γ-glutamyl)-lysine in the cultures of chicken-breast muscle and L-cell membrane[48]. Examination of oxidized wool keratin by *Asquith et al.*[49] indicated that the insoluble fraction (β-keratose), believed to arise from the inter-cuticular membrane[33], had the highest concentration of isopeptide links. The helix material (α-keratose) contained less whilst the amorphous γ-keratose contained none.

These findings open up fields for discussion on the importance of this link in maintaining the physical properties of structural proteins. Whilst in the fibrinogen→fibrin transformation its function may be to assist in the insolubilization of the fibrin, and it may also assist a similar function in muscle protein, its importance is less well defined in the fibrous proteins. Certainly the keratins after keratinization are well stabilized in their physical form by the disulfide bonds. The isopeptide links present in them may be purely fortuitous as a result of earlier metabolic processes prior to the formation of the fiber. Alternatively, *Otterburn*[50] pointed out that the formation of the disulfide crosslinks (*i. e.* keratinization) of the wool fiber occurs at a relatively late stage in fiber formation and he therefore suggested that the isopeptide links, though few in number, may stabilize the protein prior to keratinization into a less mobile and less soluble form. Their presence may permit an easier alignment of the material during extrusion into the follicle and also aligning the sulfydryl residues in suitable positions for easy oxidation to the disulfide bonds.

Zahn[51], in an excellent summary on the importance of crosslinking in the structure of keratin fibers, drew attention to the slightly different view adopted by *Harding* and *Rodgers*[47]. These authors, in their studies of the isopeptide content of a series of mammalian fibers, of which foetal lamb's wool was one, showed that those fibers exhibiting a high content of medulla tended to have a high isopeptide content. They therefore postulated that the disulfide bond is of prime importance in stabilization of the cortex, but suggested that the isopeptide link may be of more significance in stabilizing the protein of the medulla. Such postulates must at this stage remain very tentative.

6. Isopeptide Formation in Heated Wool

Asquith and *Otterburn* were able to show that on dry heating of wool the concentration of isopeptide links increased considerably (Table 1)[49]. Thus, whilst in virgin wool only very small amounts of N^{ε}-(β-aspartyl)-lysine were found, the quantity virtually doubled after heating for 48 h at 120 °C. Clearly both types of isopeptide links are being formed in the heating process and, since ammonia is lost, this may occur *via* direct dehydration or amide exchange (see Fig. 2). These authors reported that when wool keratin is heated at temperatures above 140 °C for prolonged times the protein remains resistant to enzymatic hydrolysis even after complete reduction of the disulfide bonds. They had previously observed[31] that the bound lysine in such samples, as determined with 1-fluoro-2,4-dinitrobenzene, was high. They could only conclude that considerable isopeptide crosslinking had occurred and this was sufficient to inhibit enzyme-catalyzed hydrolysis.

Table 1. Isopeptide content [μmol/g] of heated wool keratin. The lysine content amounts to 220 μmol/g, the duration of heating 48 h.

T [C]	"Bound" Lys	N^{ε}-(γ-Glu)-Lys	N^{ε}-(β-Asp)-Lys
—	45	15	13
60	50	17	17
100	55	20	20
120	60	25	20
140	90	40	35

Such an inhibition could arise if the protein was becoming more highly crystalline, and hence preventing the penetration of the enzymes. Studies of the changes in the X-ray diffraction pattern of heated wools[52] does not support such a hypothesis. The ordered structure (observed as the α-pattern of keratin) commences to decay in material that has been heated to above 140 °C, the reflections then becoming less discrete until a totally amorphous material is finally abtained. This change, by opening up of the crystalline structure, would be expected to enhance ease of penetration rather than the converse, thus assisting enzyme-catalyzed hydrolysis. It was therefore concluded that the high degree of crosslinking by isopeptide links is responsible for the resistance to hydrolysis. The three-dimensional polymer so produced presumably excludes the approach of the enzyme molecules to the normal labile peptide bonds by a pore-sieve effect.

Such findings are of only academic significance in relation to changes in the structure of wool keratin, precluding as they do an absolute estimation of the amounts of isopeptide

links formed in vigorously heated wool. In relation to digestibility of nutritional proteins, however, such enzyme resistance could be of practical significance. It would seem improbable that a protein changes suddenly from an easily hydrolyzed, slightly crosslinked material to a totally enzyme resistant, highly crosslinked substance. It is more likely that enzyme hydrolysis is progressively retarded as crosslinking increases until a point is reached where no hydrolysis occurs. The possible effects of such factors on nutritional studies are discussed below.

7. Significance of Isopeptides in Nutrition

It is now well established that the nutritional value of protein feedstuffs is reduced on heat sterilization. Since *Carpenter*[53] and other workers[54, 55] have conclusively established that this fall is accompanied by an increase in the binding of the ε-amino group of lysine, as determined by the 1-fluoro-2,4-dinitrobenzene technique, it is clear that this ε-amino group is essential in some way in the metabolism of nutritional proteins. The simple blocking of lysine side chains by acetylation is insufficient to explain the reduction in nutritional properties of lysine-containing protein feedstuffs, for *Bjarnason* and *Carpenter*[34] showed that N^{ε}-acetyl-L-lysine has the growth promoting value of an equivalent quantity of L-lysine when fed to young rats in a lysine-deficient diet. Further, total acetylation of the ε-amino group of lysine in a protein feedstuff does not reduce the growth promoting factor as much as an absence of lysine. Feeding of heated protein foodstuff also leads to a greatly increased amount of fecal lysine.

In a study of the effect of heat damage of proteins *Bjarnason* and *Carpenter*[35] concluded that the reaction of the ε-amino groups of lysine with the γ- and β-carboxyl group of glutamic and aspartic acids respectively could occur under drying conditions encountered in practice. They therefore suggested that lysine may be bound by isopeptide links or by the decomposition products of cystine—the latter would result in the formation of lanthionine and lysinoalanine, as has been shown in other proteins[56].

Recently *Waible* and *Carpenter*[57] investigated the influence of N^{ε}-(γ-glutamyl)-lysine on the growth of chicks and were able to show that the free isopeptide is undoubtedly metabolized and has some growth promoting effect. None of the peptide could be detected in the urine although some occurred in the plasma, indicating absorption of the material through the intestine wall.

Further work has shown the difficulty of this problem. Thus it has been shown with chicken muscle protein that the amount of unavailable lysine increased on sterilization whilst the nutritional value decreased. Further, as the amount of cystine present in chicken muscle is small, it is hardly surprising that neither lysinoalanine nor lanthionine were detected in the acid hydrolyzates. Subsequent analyses for isopeptides have conclusively proven the occurrence of isopeptides in the heated material. The isopeptide was formed in inverse proportion to the amount of available lysine present[58].

Investigation of the amounts of isopeptide links in the feces and urine of rats fed on this sterilized protein show that no compounds having isopeptide links are detectable in the urine or in low molecular weight peptides therein. However, on enzyme hydrolysis the fecal protein has been shown to contain N^{ε}-(γ-glutamyl)-lysine and N^{ε}-(β-aspartyl)-lysine. The amounts present are considerably less than are present in the dietary protein, clearly indicating that breakdown of the isopeptide link can occur in the digestive tract.

The mere chemical fixation of the ε-amino group of lysine in this protein is not, therefore, the sole reason for the loss in nutritional value. It would seem that the formation of these crosslinks (as was found previously with heated wool) is sufficient to retard enzyme degradation of the protein such that at least part of it passes beyond that part in the digestive system where easy absorption into the blood stream is possible. Although analyses have shown that the proportion of isopeptide crosslinks in the feedstuff has decreased by the time the material arrives in the ileum, this decrease is considerably less than that observed when the material passes from the ileum to the colon[58]. This latter degradation of the protein and isopeptide link may occur *via* such processes as fermentation in the hind gut; however, absorption is then reduced to such an extent that an overall loss in nutritional value is still observed. Further elucidation of these theories is being carried out.

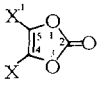
Halovinylene Carbonates in Organic Synthesis

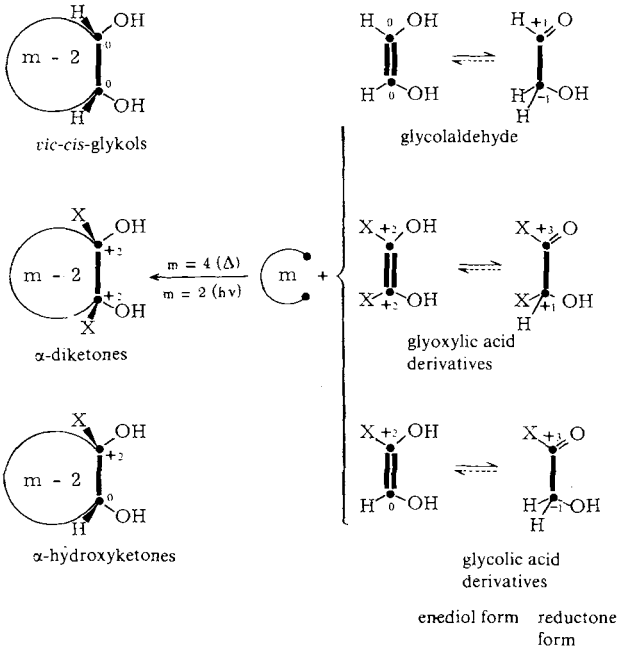


New synthetic methods (2)

By Hans-Dieter Scharf[*]

Monohalo- and dihalovinylene carbonates constitute a new class of cyclophiles which permit simultaneous introduction of masked α-hydroxyketo and α-diketo functions, respectively, into the cycloadducts. Demasking can be performed by simple hydrolysis. Solvolytic opening of the carbonate ring leads to glycolic acid derivatives in the case of the monohalo compounds and to glyoxylic acid derivatives with the dihalo compounds. Preparation of the title compounds, their potential as synthetic reagents, and the chemistry of their simple reaction products are surveyed from a preparative viewpoint.

1. Introduction



Vinylene carbonate (1,3-dioxol-2-one) *(1)*, the parent compound of the class, has been known since 1953[1], and its behavior as a reactant in both thermal[2-9] and photochemical cycloadditions[10-15] has been repeatedly investigated.

(1), X = X' = H
(2), X = X' = Cl
(3), X = Br, X' = H
(4), X = Cl, X' = H
(5), X = X' = Br

Compound *(1)* is the cyclic carbonate of the *cis*-enediol form of glycolaldehyde. The oxidation states of the two carbon atoms, which differ in the reductone form of glycolaldehyde[16] (+1 and −1), become equal in the tautomeric enediol form; cycloaddition to an *m*-centered π-electron system yields an adduct exhibiting the oxidation pattern of a vicinal *cis*-diol.

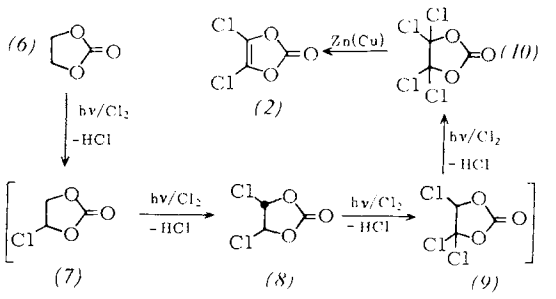
Formal replacement of two hydrogen atoms of glycolaldehyde by halogen X raises the oxidation states of the two C atoms

[*] Prof. Dr. H.-D. Scharf
Institut für Organische Chemie
51 Aachen, Prof.-Pirlet-Strasse 1 (Germany)

by two, both in the reductone form and in the enediol form. Cycloaddition reactions then furnish adducts having the oxidation pattern of an α-diketone. These compounds can be liberated by solvolysis.

Finally, a tautomeric enediol form is also conceivable for corresponding derivatives of glycolic acid with differing oxidation states (+2 and 0) at the two centers, which—being fixed by the carbonate ring as in the other cases—confer the oxidation pattern of an α-hydroxy ketone upon the cycloadduct. This formalism provides a satisfactory description of the chemistry of the vinylene carbonates *(1)*—*(5)*. Two-center attack at positions 4 and 5 in *(1)*—*(5)* leads to derivatives of the enediol form, while nucleophilic attack at position 2 affords derivatives of the reductone form[*].

Hence vinylene carbonates are versatile reagents for the preparation of substances which are accessible only with difficulty, if at all, by other routes.



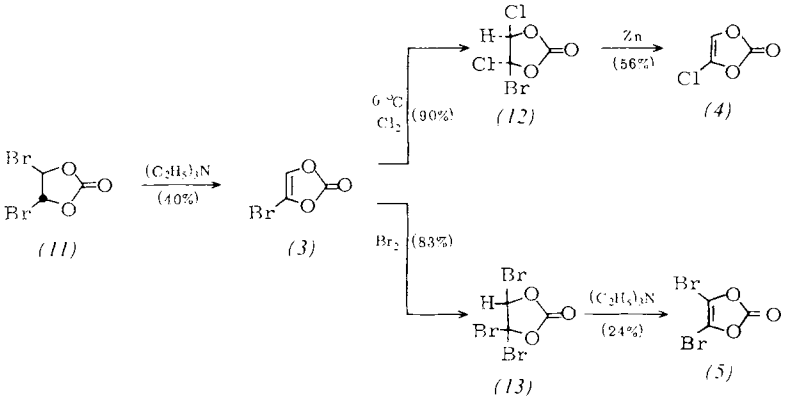
The present progress report surveys the (mainly preparative) results obtained so far with the derivatives *(2)*—*(5)*.

2. Preparation and Properties

2.1. Dichlorovinylene Carbonate *(2)*

The first representative of the halovinylene carbonates *(2)* was prepared from ethylene carbonate *(6)*[17,18]. Photochlorination of *(6)* according to *Ellingboe* and *Melby*[19] leads *via* compounds *(7)*—*(9)* to tetrachloroethylene carbonate *(10)* (82%), which affords dichlorovinylene carbonate *(2)* (85%) on treatment with Zn(Cu) in ether.

The lacrimatory liquid solidifies to crystals (m.p. 19 °C) below room temperature and can then be stored indefinitely in a refrigerator.



reactions. Even at elevated temperatures (b. p. 143 °C/760 torr) the half-life for cleavage is large compared to the reaction time.

In the presence of triphenylphosphane or trimethyl phosphite, however, *(2)* undergoes spontaneous decomposition with elimination of CO at room temperature[18]. This reaction, whose mechanism has not yet been elucidated, is typical of the halovinylene carbonates *(2)*—*(5)*; it is not observed with the parent compound *(1)* or its dialkyl derivative[13] (X=alkyl). Moreover, it is remarkable that tertiary amines do not induce cleavage.

In how far the purely thermal elimination of CO to form oxalyl chloride can be classified as a cheletropic cleavage has been investigated in a theoretical study[21].

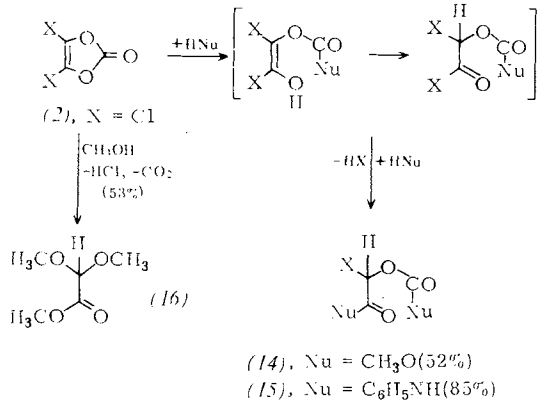
2.2. Monobromovinylene, Monochlorovinylene, and Dibromovinylene Carbonate *(3)*, *(4)*, and *(5)*

Exhaustive free-radical bromination of ethylene carbonate *(6)* in analogy to the chlorination does not lead to a preparatively useful result in the intended sense. Halogen-exchange reactions with compounds *(8)* and *(10)* also prove unsuitable as a

In the liquid state and in dilute aprotic solvents, CO is eliminated to form increasing amounts of oxalyl chloride[18], a fact which has led to erroneous interpretation of UV absorption measurements, especially in the presence of aromatics[20] (see Section 7). The lattice energy apparently contributes to stabilization of the molecule. Experience has shown that small amounts of oxalyl chloride do not interfere in preparative method of preparing the homologous halo derivatives *(3)* and *(5)*. Nor can monochlorovinylene carbonate *(4)* be obtained from *(8)* by elimination of HCl under S_E2 conditions, a result which confirms the *trans* positions of the Cl atoms in *(8)*[22]. In contrast, dibromoethylene carbonate *(11)*, obtained by addition of bromine to *(1)*, eliminates HBr to form *(3)*[23]. Thus *(3)* became the key substance for preparation of *(4)* and *(5)*[24].

Addition of chlorine to *(3)* affords monobromodichloroethylene carbonate *(12)*, which is converted into *(4)* on treatment

[*] The numbering of the ring atoms is based upon that of the 1,3-dioxole system.



with zinc in ether[24]. Furthermore, *(3)* can be transformed into tribromoethylene carbonate *(13)* which yields dibromovinylene carbonate *(5)* on HBr elimination.

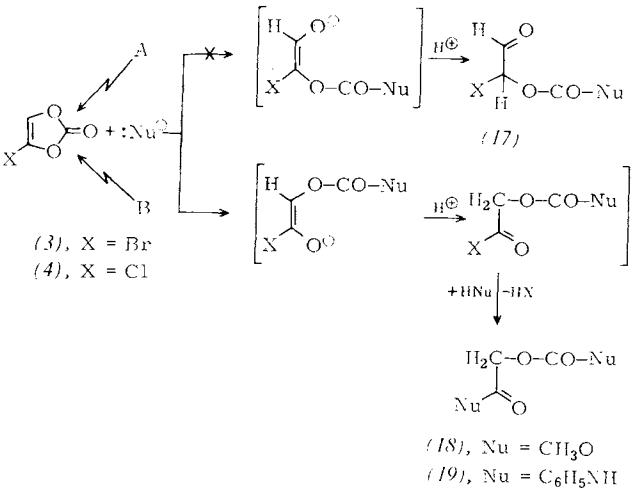
Attempts to prepare diiodovinylene carbonate *(1)*, X = X' = I, by a Finkelstein reaction failed to give any isolable product apart from elemental iodine and CO.

3. Solvolysis Reactions

3.1. Dihalovinylene Carbonates

Methanolysis and aminolysis of *(2)* lead to derivatives of glyoxylic acid. The former reaction initially affords methyl *O*-methoxycarbonylchloroglycolate *(14)*, and the latter the corresponding anilide *(15)*[18].

(2), X = Cl



(14), Nu = CH_3O (52%)
(15), Nu = C_6H_5NH (85%)

Methanolysis of *(2)* under reflux or methanolysis of *(14)* under more drastic conditions finally affords the dimethyl acetal *(16)* of methyl glyoxylate.

3.2. Monohalovinylene Carbonates

There are fundamentally two different reaction routes open to solvolysis of the monohalo derivatives *(3)* and *(4)*, depending upon whether the nucleophile initially cleaves bond A or B. Rupture of bond A would lead to a derivative of α-haloglycolaldehyde *(17)*, whereas cleavage of bond B would yield a glycolic acid derivative.

Both alcoholysis and aminolysis give only products arising *via* route B[24]. Treatment with methanol yields methyl *O*-methoxycarbonylglycolate *(18)*, and aniline forms the anilide *(19)*.

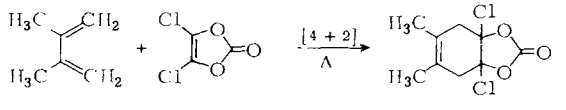
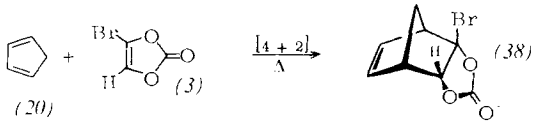
[a] In *o*-dichlorobenzene.
[b] In xylene.
[c] In diethylene glycol diethyl ether.
[d] In a glass autoclave.

While cyclopentadiene *(20)* and 1,3-cyclohexadiene *(21)* give exclusively the corresponding *endo* adducts, *(23)* and *(24)* respectively[25], furan *(22)* is found to give the two stereoisomeric adducts in the ratio *(25)*:*(26)* = 1:2, together with small amounts (1.5%) of a 2:1 adduct *(27)*[26]. In contrast to the adduct of furan and maleic anhydride[27-29] or maleimide[30], attempts at subsequent mutual interconversion of adducts *(25)* and *(26)* at the temperature of formation or above prove unsuccessful, thus justifying the assumption that the *exo* form *(26)* arises on an energetically competitive reaction coordinate with *exo* regioselectivity.

With cycloheptatriene, the three adducts *(29)*–*(31)* are formed. Here too, *exo* preference is observed in contrast to the cycloheptatriene/maleic anhydride adducts[31] which are formed in a ratio of 84:15:1 at 176 C. The structures are analogous to those of *(29)*–*(31)*. Table 1 lists the data for the Diels-Alder adducts formed with *(2)*.



Anthracene *(32)* and its 9,10-dimethyl derivative *(33)* are also suitable as dienes for Diels-Alder reaction with *(2)*[25].

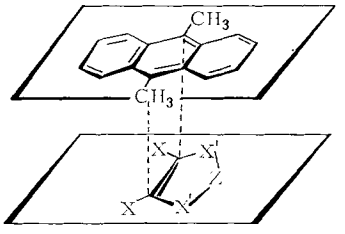


(32), R = H
(33), R = CH_3

(2)

(34), R = H
(35), R = CH_3

(36) *(2)* *(37)*



(20) *(3)* *(38)*

Under the usual conditions, *(2)* fails to react with open-chain 1,3-dienes such as butadiene and isoprene. However, a 15% yield of the adduct *(37)* is formed with 2,3-dimethylbutadiene *(36)*[25]. Monobromovinylene carbonate *(3)* likewise affords a Diels-Alder adduct *(38)* (22% yield) with cyclopentadiene[24] (Table 1).

4.2. Kinetic Results[32, 33]

In order to compare the dienophilic activity of the vinylene carbonates *(1)* and *(2)* with those of the corresponding compounds of the maleic acid series—maleic anhydride *(39)* and dichloromaleic anhydride *(40)*—towards 9,10-dimethylanthracene *(33)*, the activation parameters of the reactions were measured (or taken from the literature[34]) (see Table 2).

(33)

(1), *(2)*, *(39)* *(40)*

Table 2. Kinetic data for the reactions of *(1)*, *(2)*, and *(40)* with the diene *(33)*, and values obtained by *Sauer et al.* [34] for *(39)*/*(33)*. k_2 refers to 130 C.

Dienophile				$10^4\,k_2$	E_A	$\Delta H^{\neq}$	$\Delta S^{\neq}$	$(k_2)_{rel.}$
	X	X'	Z	[l mol^{-1} s^{-1}]	[kcal mol^{-1}]	[kcal mol^{-1}]	[cal mol^{-1} K^{-1}]	
(39)	H	CO	O	14100	10.9	10.2	−33	10071
(40)	Cl	CO	O	145	13.1 ± 0.4	12.4 ± 0.4	−37	104
(2)	Cl	O	CO	8.7	17.2 ± 0.3	16.5 ± 0.3	−32	6.2
(1)	H	O	CO	1.4	22 ± 1.3	21.5 ± 1.3	−23	1

In the case of the maleic acid derivatives *(39)* and *(40)*, chlorine substitution at the double bond of the dienophile raises the activation barrier of the reaction with *(33)*, while in the carbonate series reaction with the dichloro compound *(2)* proceeds slightly more readily than with the parent compound *(1)*. The activation entropies found for reactions with *(39)*, *(40)*, and *(2)* are normal, in agreement with literature values[35], while the reaction with *(1)* displays a surprisingly low value[36].

Assuming that the magnitude of the frontier orbital interaction between the reactants at the start of reaction plays a dominant role in controlling the height of the activation barriers[37, 38] enables us to reach a qualitative understanding of the differing effects of chlorine substitution in the two classes of compounds.

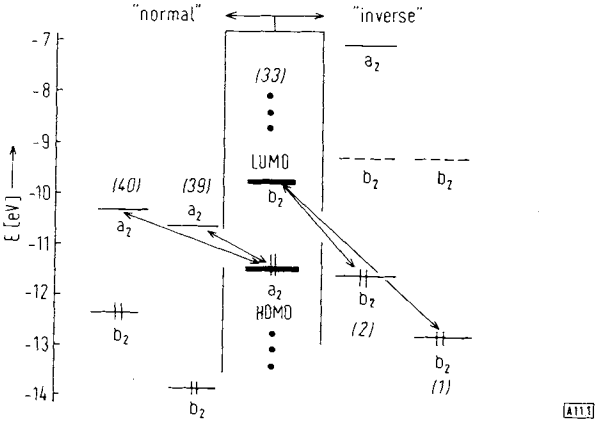


Fig. 1. Comparison of $[4\pi_s + 2\pi_s]$-cycloadditions with "normal" and with "inverse" electron demands. The plot shows the EHT MO energies [39] calculated for compounds *(1)*, *(2)*, *(33)*, *(39)*, and *(40)*. See text for details.

The calculated[39] orbital energies of the reactants are plotted in Figure 1. The symmetry-correct interactions of the HOMO of *(33)* with the pertinent LUMO of *(39)* and *(40)*, which lead to an energy-lowering splitting along the reaction coordinate, show that owing to the greater energy difference in the case of *(40)* the activation energy of this reaction will be higher than in the case of *(39)*.

Since both dienophiles are "electron deficient", *i.e.* possess high ionization energies, whereas the diene *(33)* is "electron rich", these reactions are classified as "normal" Diels-Alder reactions[40]. A different situation is encountered with compounds *(1)* and *(2)*. Here a symmetry-correct interaction can only occur between the respective HOMO of *(1)* and *(2)* and the LUMO of *(33)*, in such a manner that a higher activation barrier is to be expected in the reaction with *(1)* because of the greater difference in energy. Owing to the direction of electronic polarization, these reactions are said to belong to Diels-Alder reactions having "inverse" electron demands[41,35][*].

Application of second order perturbation theory[38,42] also permits rationalization of the regioselectivity of the [4+2]-cycloaddition of *(2)* to furan and estimation of the *exo* preference. For this purpose the EHT MO energies[39] and the corresponding LCAO MO coefficients are shown in Figure 2 for the energy levels of furan and the cyclophile *(2)* which are relevant in a zero-order approximation.

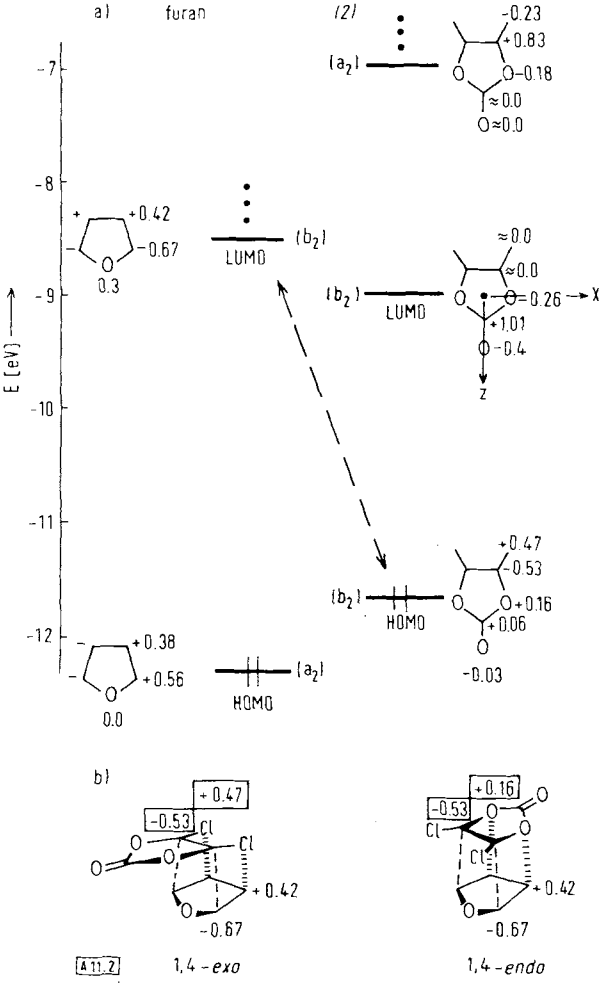

Fig. 2. Explanation of the regioselectivity of the [4+2]-cycloaddition of dichlorovinylene carbonate *(2)* to furan. a) EHT MO energies [39] and LCAO MO coefficients. b) Calculation of the stabilization component ΔE for 1,4-*exo* and 1,4-*endo* addition. For details see text.

$\Delta E_{exo} \approx 2[-0.53][-0.67]+[0.47][0.42])^2/(E_{HOMO(2)}-E_{LUMO(furan)})$

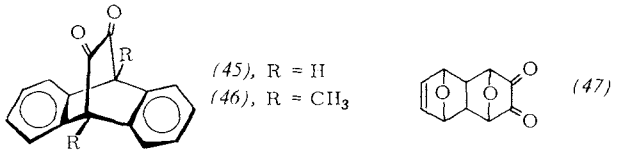
$\Delta E_{endo} \approx 2([-0.53][-0.67]+[0.16][0.42])^2/(E_{HOMO(2)}-E_{LUMO(furan)})$

[*] Experimental ionization energies for *(1)*, 10.3, and for *(2)*, 9.92 eV. *H. Bock* and *K. Wittel*, personal communication.

If it is assumed, in keeping with second-order perturbation theory for cycloaddition with simultaneous bond formation between two or more reaction centers of the reactants[43], that the route-determining stabilization component ΔE of the π-electron energy is primarily proportional to the square of the sum of the coefficient products taken over the interacting centers of the reactants, and inversely proportional to the energy gap between the levels considered [HOMO*(2)* and LUMO(furan)], then the *exo* preference of the reactants can be explained as follows:

The secondary interaction of the Cl atoms of *(2)* with positions 3 and 4 of furan in the *exo* arrangement is greater (+0.47) than the secondary interaction with the oxygen atoms (+0.16) in the *endo* orientation.

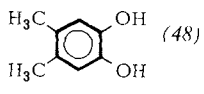
It thus also becomes understandable why the parent compound *(1)* adds mainly *endo*-selectively[2-4,7,8] in the thermal [4+2]-cycloadditions known so far.



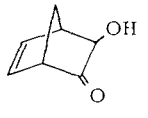
Considerations of this kind are obviously very crude: they can claim no more than to indicate general trends. Nevertheless, regioselectivities can be articulated more precisely in this manner than in terms of the stereochemical rules derived empirically[44].

5. α-Diketones and Simple Derivatives

Hydrolysis of the [4+2]-cycloadducts *(23)*—*(27)*, *(29)*—*(31)*, *(34)*, and *(35)* afford bridged α-diketones, some of which were hitherto unknown. The initial products are condensed hydrate forms from which the α-diketones *(41)*—*(47)*[25,26] can be obtained pure by sublimation (Table 3).



(41) Z = CH_2 *(41a)*
(42) Z = CH_2-CH_2 *(42a)*
(43) Z = O *(43a)*
(44) Z = ▷ *(44a)*



(45), R = H
(46), R = CH_3

(47)

(48)

(49)

Hydrolysis of compound *(37)* expectedly yields 4,5-dimethylpyrocatechol *(48)*, while adducts with monohalovinylene carbonates, *e.g. (38)*, lead to 3-hydroxy-5-norbornen-2-one *(49)* (Table 3). No spectroscopic evidence is obtained for the presence of the enediol form in this substance. The monoketals are readily formed by methanolysis of the cycloadducts in the presence of hydrogen carbonate. The α-diketones *(41)*, *(42)*, and *(44)*—*(46)* are yellow to orange, and the diketones *(43)* and *(47)* are red. This deepening of color is apparently due to interaction between the oxygen p orbital, which is symmetrical with respect to the molecular plane, and the

ψ_1 orbital of the "diene" grouping formed from the two keto groups positioned α to each other. Owing to the ensuing splitting, the energy gap to the lowest unoccupied π* level is reduced.

ketones[56–60]. On irradiation, the ketals *(41a)* and *(43a)* are in photochemical equilibrium with the four-membered cyclic ketals *(41b)* and *(43b)* respectively. The reacting excited state is most probably a singlet. Nevertheless, the reaction

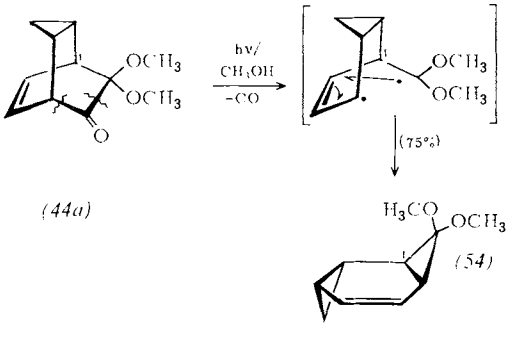
5.1. Photolytic and Thermolytic Studies

The α-diketones *(41)*—*(46)* and the monoketals *(41a)*, *(43a)*, and *(44a)* are formally Diels-Alder adducts of the parent dienes with the hitherto unknown "bisketene" C_2O_2, unsuccessfully sought by *Staudinger*[50], and its monoketal dimethoxyketene *(50)*, respectively. Since both these cyclophiles—provided they exist at all—would be antarafacial reactants, preparation of the above cycloadducts by $[4\pi_s + 2\pi_s]$ Diels-Alder addition is impossible. Once the cycloadducts had become available by the above route, however, it seemed obvious to attempt a preparation of the unknown cyclophiles C_2O_2 and *(50)* by $[4\pi_s + 2\pi_a]$ cycloreversion of the adducts, which should possess a favorable reaction coordinate when performed photochemically. Photolysis of the diketones *(41)*—*(46)* leads almost completely to the dienes and carbon monoxide. No experimental evidence is obtained for the transient occurrence of C_2O_2[51–54].

Photolysis of the monoketals *(41a)*[55] and *(43a)*[26] follows a fairly uniform mechanism resembling that of β,γ-unsaturated

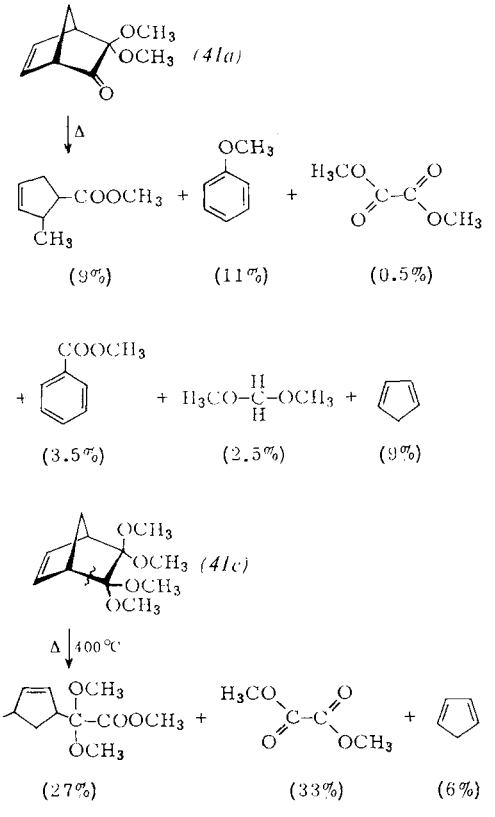


does not involve a concerted sigmatropic $[1,3]_s$ shift; instead, initial formation of a diradical intermediate capable of a variety of further reactions has to be assumed on the basis of temperature dependence.

Isomerization of the diradical intermediate to a cyclic oxycarbene ("oxacarbene") and subsequent addition of methanol leads to the stereoisomers of compounds *(51)* and *(52)*, whose stereochemistry could be established by NMR spectroscopy with aid of paramagnetic shift reagents[61, 26].

Decarbonylation occurs only for $Z = CH_2$ to form the dimethyl ketal of bicyclo[3.1.0]hex-2-en-6-one *(53)*.

When Z = O, the diradical decomposes to furan and dimethoxyketene *(50)* which can be trapped as the dimethyl acetal of the glyoxylic ester *(16)* with methanol[26]. This cleavage, which was formerly observed on photolysis of dehydronorcamphor[56], does not occur with *(41a)* ($Z = CH_2$), thus also confirming the intermediacy of the diradical whose substituent effects depending upon Z are manifested in the varying cleavage pattern.

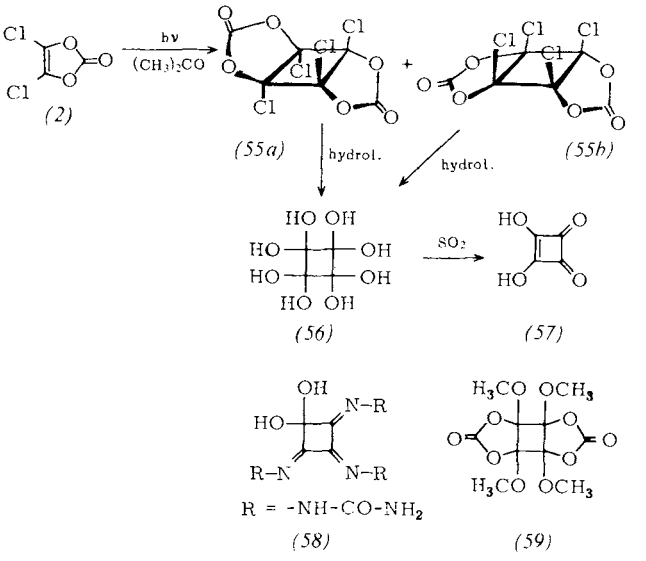


Photolysis of *(44a)* with decarbonylation proceeds in highly uniform manner, and has been utilized in an elegant synthetic route to the σ-bishomobenzene series, *e.g.* to *(54)*[26]. This finding can likewise be rationalized by assuming an intermediate diradical.

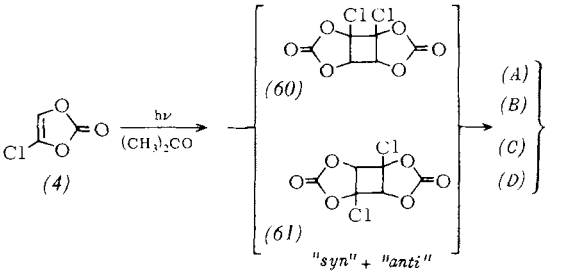
The *trans* conformation of the two cyclopropane rings follows compellingly from the stereochemistry of the original monoketal *(44a)* and is confirmed by ^{1}H-NMR spectroscopy[62].

These results would indicate that—despite participation of singlet states—the fragmentation reactions proceed in a step-

wise manner, *i. e.* the coordinates of the concerted $[4\pi_s+2\pi_a]$ cycloreversion apparently lie at higher energy than would correspond to the energy of the light quantum of the incident radiation. Since the cyclophiles considered are antarafacial components even higher energies are to be expected for $[4\pi_s+2\pi_s]$ cycloreversion. It is therefore not surprising that thermolysis is by no means homogeneous but yields a wealth of fragments whose genetic sequences have not yet been elucidated[63]. The results of thermolysis of compounds *(41a)* and *(41c)* serve as illustrative examples.



The bis(dimethyl ketal) *(41c)* of norbornenedione *(41)* can be formally regarded as the Diels-Alder adduct of tetramethoxyethylene to cyclopentadiene, although it cannot be prepared from the components[64]. In this case too, the $[4\pi_s+2\pi_s]$ cycloreversion coordinate appears to be energetically very high. Hence thermolysis of *(41c)* only affords compounds to be viewed as stabilization products of intermediate radical fragments[65]. These adducts *(41a)* and *(41c)*, which are obtainable *via* cycloaddition of 1,3-dienes to dichlorovinylene carbonate *(2)*, can therefore be termed "pseudo-Diels-Alder adducts".

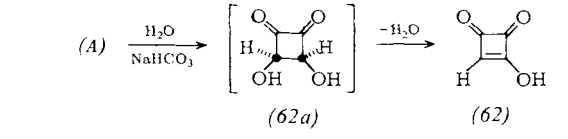


6. [2+2]-Cycloadditions

6.1. Photochemical Cyclodimerization of Di- and Monochlorovinylene Carbonate *(2)* and *(4)*

Dichlorovinylene carbonate *(2)* can be dimerized to form two stereoisomeric cyclobutane derivatives *(55a)* and *(55b)*[66] by irradiation in acetone; both isomers yield octahydrocyclobutane *(56)* which was obtained by *West, Niu,* and *Ito*[67] on oxidation of squaric acid *(57)* with nitric acid. Squaric acid is formed from *(56)* by the action of SO_2. As with other hydrated forms of cyclooligomeric carbon monoxide $(CO)_n$, dehydration always modifies the molecule[68]. However, *(55a)* which is more readily obtained in crystalline form, can be converted into an orange cyclobutanetetrone tris(semicarbazone) monohydrate *(58)* by treatment with semicarbazide hydrogen chloride.

The chlorine atoms of the isomers *(55)* undergo extremely ready nucleophilic replacement prior to solvolytic opening of the carbonate ring. Dissolution in, *e.g.*, methanol leads very rapidly to a homogeneous tetramethoxy compound *(59)* of unknown stereochemistry; no intermediates can be detected by gas chromatography.



Irradiation of 1 : 1 mixtures of monochlorovinylene carbonate *(4)* and acetone with the aid of a high-pressure mercury lamp leads to the formation of four stereoisomeric C_4-cyclodimers *(A)*—*(D)*, one of which [*(A)*] is relatively insoluble and precipitates during irradiation[24]. The stereochemical details have yet to be elucidated.

Table 4. Physical properties of the C_4-dimers of monochlorovinylene carbonate *(4)*.

	(A)	*(B)*	*(C)*	*(D)*
M.p. [°C]	189	191	109	179–80
IR [a]:	1815	1840	1860	1820
$\nu_{C=O}$	1845			1840
^{1}H-NMR [b]: τ [ppm]	6.13 (s)	6.10 (s)	5.91 (s)	6.09 (s)

[a] In KBr.
[b] In [D_6]-acetone.

Hydrolysis of the easily obtainable dimer *(A)* yields the hydroxycyclobutenedione *(62)*[24, 117, 118].

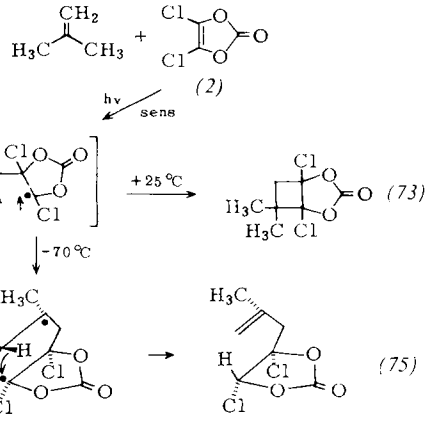
The formation of *(62)* from dimer *(A)* by hydrolysis allows conclusions to be drawn regarding its stereochemistry: The 1,2 arrangement of the CO groups in *(62)* is obviously due to the vicinal arrangement of the Cl atoms in *(A)*, and the ready elimination of water from the intermediate dihydrosquaric acid *(62a)* suggests a *syn* configuration of the carbonate rings with regard to the four-membered ring.

Recently, *Cole et al.*[119] have isolated *(62)* as baceterial toxin from *Fusarium moniliforme* and *Gibberella fujikuroi*, and elucidated the structure of its potassium salt by X-ray analysis[120]. The compound, which has been designated "moniliformin", exhibits biocidal properties.

6.2. Cyclodimerization of Dichlorovinylene Carbonate *(2)* with Olefins

Preparation of cyclobutane derivatives from simple olefins and *(2)* by sensitized photocycloaddition proceeds readily and gives good to very good yields[69, 70]. Experience has shown acetophenone to be a highly effective sensitizer; diethyl ether, dioxane, and diethylene glycol diethyl ether have proved their value as solvents.

As the simplest open-chain olefin, ethylene reacts with *(2)* to give the cyclobutane derivative *(63)*[17] without side-products at room temperature. Cyclic olefins having $n>3$ afford adducts having typical linkage patterns. For instance, cyclohexene *(65)* ($n=4$) gives a *trans* adduct *(71)* as well as the *anti* and *syn* adducts *(70)* and *(68)*. Formation of *(71)* evidences a multi-step reaction course. The stereochemistry was established by ^{1}H-NMR studies[70] (Table 5).



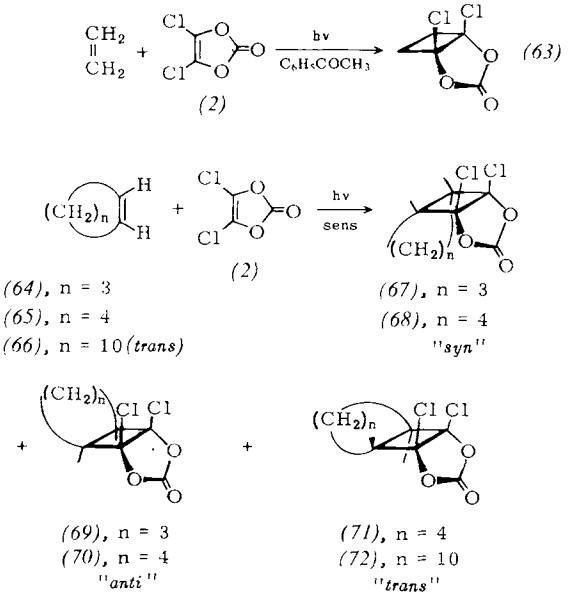


Table 5. Cyclobutane derivatives from *(2)* and olefins. Sensitizer: acetophenone or acetone; solvent: dioxane; light source: HPK 125 Philips UV lamp, Pyrex filter.

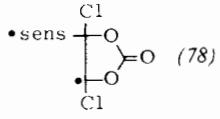
Olefin	Adduct	Yield [%] [a]	Isomeric comp.	M.p. [°C]	Ref.
Ethylene	*(63)*			54	[17, 70]
Isobutylene	*(73)*				[71]
Cyclopentene *(64)*	*(67)*	95	49	99.5	[70]
	(69)		51	58.5	
Cyclohexene *(65)*	*(68)*		23.2	59	[70]
	(70)	95	40.5	74	
	(71)		36.3	43	
trans-Cyclododecene *(66)*	*(72)*	41		97	[69]

[a] The yield is based on the amount of *(2)* in the starting materials (2.5 mol/l solvent); olefin concentration 2.5 mol/l.

Proof of a typical reaction sequence with participation of a diradical intermediate was obtained with *(2)* and isobutylene as reactants[71]. At room temperature, only the cyclobutane derivative *(73)* is obtained. However, at −70 °C compound *(75)* also arises. Its formation doubtless involves intramolecular H abstraction from the diradical *(74)* which appears to be subject to hindrance at low temperature.

6.3. The Question of Photosensitization in Cycloadditions of Dichlorovinylene Carbonate *(2)* to Olefins



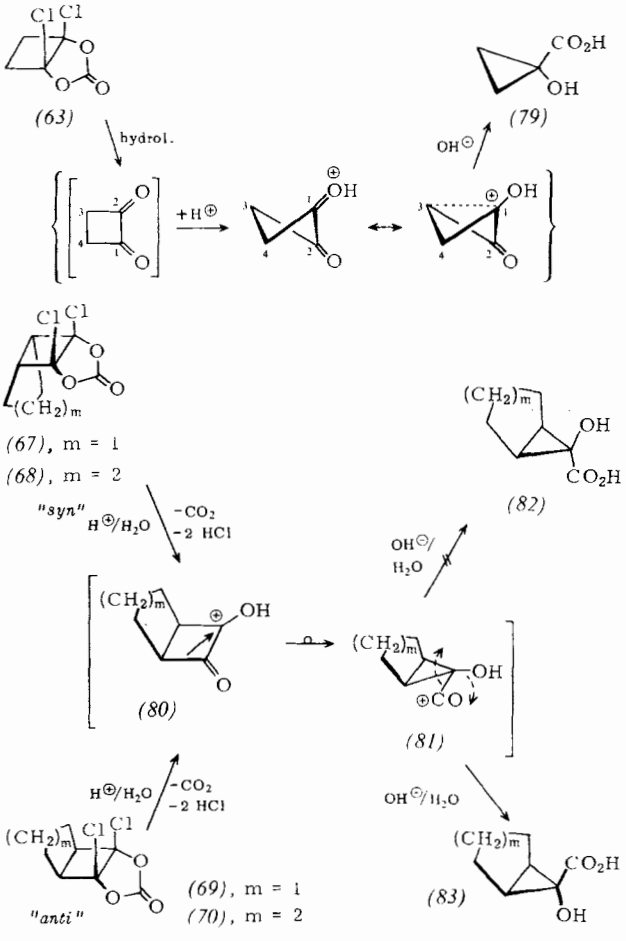
Above 200 nm the UV spectrum of pure *(2)* exhibits no bands other than the end absorption. Spurious bands in the 300—360 nm[120] range are due to oxalylchloride present as impurity[70]. If the excellent sensitizing effect of acetophenone ($E_T=74$ kcal/mol)[72] or acetone ($E_T=79.5$—82 kcal/mol)[73], in cycloadditions of *(2)* with olefins is interpreted as being due to triplet energy transfer, then the energy E_T of the lowest triplet level of *(2)* would have to lie <74 kcal/mol above the ground state.

PPP calculations[74] as well as quantum yield measurements on sensitized cycloaddition reactions with application of sensitizers of decreasing triplet energy[75] reveals that the lowest triplet term of *(2)* is 68—70 kcal/mol above the ground state.

Moreover, the quenching constant for the Norrish Type II cleavage of butyrophenone by *(2)* is found to be $k_q = 5.6 \times 10^8\ l\ m^{-1}\ s^{-1}$[76]. These results suggest that a triplet-energy transfer from the above sensitizers to *(2)* is very likely.

The photoreaction of *(2)* with furan to give *(90)*, *(92)*, and *(94)* (see Section 6.5) again belongs to the class of sensitized photocycloadditions, *i.e.* in the absence of sensitizer, *e.g.* acetophenone, no reaction occurs.

The photopinacolization of acetophenone on irradiation of its ethereal solution, which was observed by *Ciamician* and *Silber*[78], is suppressed only slightly by furan, but strongly in the presence of furan and *(2)*, in favor of photoadduct formation [*(90)*, *(92)*, *(94)*][26].



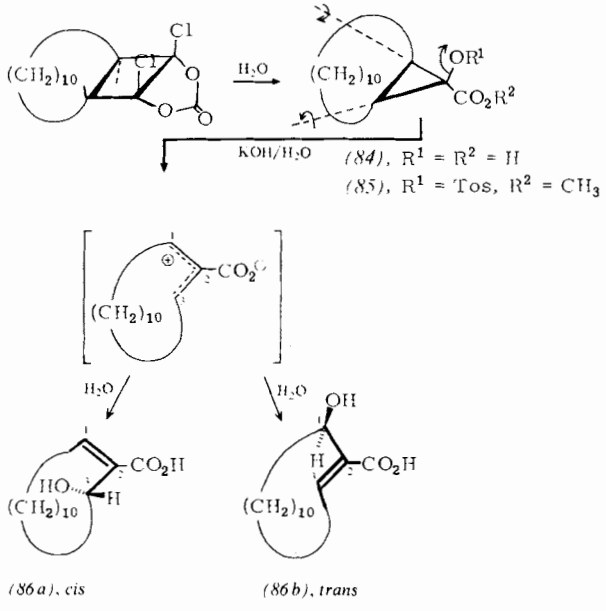
(78)

Although the intermediate existence of a 1,4-biradical such as *(78)* cannot be completely ruled out on the basis of these results, we again favor triplet-energy transfer from ^{3}Sens* to *(2)*.

The same applies to the photosensitized dimerization of *(2)* to *(55a)* and *(55b)* and of *(4)* to *(60)* and *(61)*.

6.4. Synthesis of α-Hydroxycyclopropanecarboxylic Acids

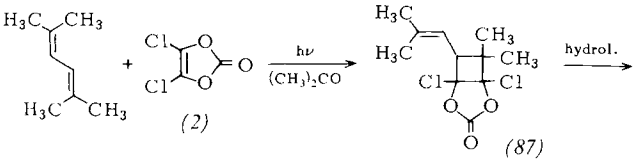
Compounds *(63)* and *(67)—(72)* possessing potential α-diketo functions should transform into α-diketones of the cyclobutane series or their hydrate forms on hydrolysis. It frequently proves possible to briefly observe the typical UV spectra[79,85] of 1,2-cyclobutadiones[80–85] which have meanwhile become accessible by another route. They can also be trapped by phenyl hydrazine, but resist isolation[86]. Instead, they rearrange to α-hydroxycyclopropanecarboxylic acids, *e.g.* *(63)* affords *(79)*, in protic solvents[17,87].



This reaction, which renders the α-hydroxycyclopropanecarboxylic acids readily accessible (Table 6), displays an interesting stereoselection. The stereoisomeric cycloadducts *(67)* and *(69)* should afford the two likewise stereoisomeric 1-hydroxybicyclo[3.1.0]hexanecarboxylic acids *(82)*, $m=1$, and *(83)*, $m=1$, respectively, since the carbenium ion resulting on opening of the cyclic cation *(80)* can escape both "upwards" and "downwards". The same applies to *(68)* and *(70)*. However, isomers of type *(83)* are formed exclusively without any detectable trace of the isomeric compounds *(82)*.

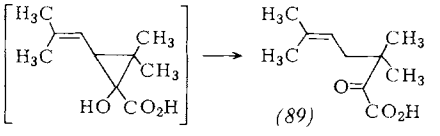
Table 6. α-Hydroxycyclopropane derivatives.

Cpd.	M. p. [°C]	Yield [%]	Ref.
(79)	108	95	[17, 85, 89]
(83), $m=1$	106	85	[86]
(83), $m=2$	129—130	81	[86]
(84)	161	73	[69]



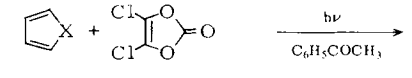
Since similar results are obtained on protonation of bicyclo[*m*.2.0]alkane-(*m*+3), (+4)-diones, which have meanwhile become available[87,88], formulation *via* the intermediates of type *(80)* and *(81)* is justified. The reason behind this stereoselectivity has not yet been elucidated.

Solvolysis of the tosylates of *(83)*, $m=1$ and $m=2$, and of *(84)* proceeds *via* a disrotatory opening of the cyclopropane ring with ring expansion to give β-hydroxycycloalkenecarboxylic acids. Thus equimolar amounts of the β-hydroxycyclotridecenecarboxylic acids *(86a)* and *(86b)* are obtained from *(84)* or *(85)*[69].



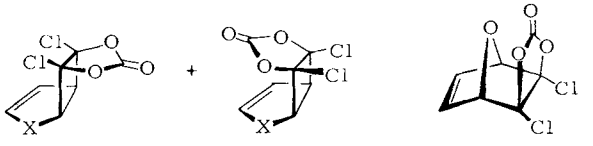
6.5. Dienes as Cycloaddition Components

The photochemical cycloaddition of *(2)* to 1,3-dienes proceeds with a widely varying degree of success. 2,5-Dimethyl-2,4-hexadiene affords two stereoisomeric adducts *(87)* in only moderate yield[71]. The reason most probably lies in the excellent quenching properties of the dienes towards photoexcited ketones, which strongly reduce the sensitizing action.

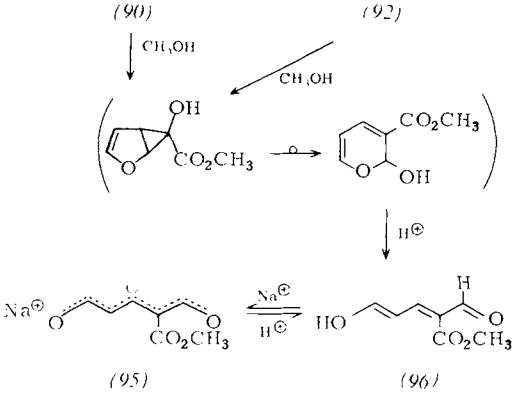


(2) *(87)*

2 isomers



(88) *(89)*



(2)

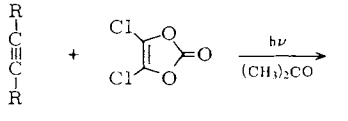
X = O, S

(90), X = O *(92)*, X = O *(94)*
(91), X = S *(93)*, X = S

However, α-hydroxychrysanthemumic acid *(88)* cannot be isolated on hydrolysis: the tautomeric keto form *(89)* appears very readily. Experience shows that the α-hydroxycyclopropanecarboxylic acids having a double bond conjugated with the three-membered ring yield the tautomeric keto forms very rapidly.

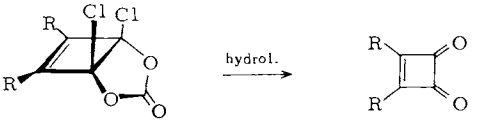
(95) *(96)*

The yields obtainable from heterocyclic dienes such as furan[26] and thiophene[26,90] again vary widely. While furan affords the isomers *(90)*, *(92)*, and *(94)* in the ratio 16:25:9 (60% overall yield), thiophene furnishes only 9.5% of the cyclobutane derivatives *(91)* and *(93)*. A photochemical *exo*-[4+2]-cycloadduct analogous to the furan derivative *(94)* is not observed in the case of thiophene[91].



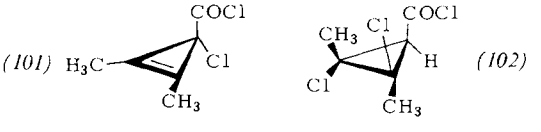
Methanolysis of *(90)* and *(92)* in the presence of sodium carbonate proceeds *via* a series of consecutive reactions to form the sodium salt of the dienologous carboxylic acid *(96)*[26], a derivative of glutaconic dialdehyde. The sodium salt *(95)* is deep red in aqueous solution, whereas the dienologous acid *(96)* is yellow. They co-exist in a pH-dependent reversible equilibrium: the system can therefore be employed as an indicator.

The substance reduces Fehling's solution and gives violet colorations typical for β- and δ-dicarbonyl compounds with Fe^{3+}.



6.6. Alkynes as Cycloaddition Components

Acetylene[92] and 2-butyne[93] are suitable for sensitized [2+2]-cycloaddition to *(2)*. In solution at room temperature, *(97)* is formed in only poor yield from acetylene and *(2)*. The cyclobutenedione *(98)* has nevertheless been prepared in this way by subsequent hydrolysis of *(97)*.



The photoreaction of *(2)* with 2-butyne proceeds less clearly. The product *(99)* is accompanied by *(101)* and *(102)*. However, product analysis and the temperature and solvent dependence of the reaction do provide an insight into the pertinent cycloaddition mechanism. Both *(99)* and *(101)* arise from a common photochemically generated intermediate *(103)* which must possess a strongly polar structure since it is stabilized only in polar solvents such as acetone or acetonitrile. It eliminates CO_2 to form the cyclopropene derivative *(101)*. Intermediate *(103)* is essentially a 1,4-diradical *(103a)* which collapses to a 1,4-dipole *(103b)* in an intramolecular redox reaction; ring closure to the cyclopropene system occurs with loss of CO_2.

(97), R = H *(98)*, R = H
(99), R = CH_3 *(100)*, R = CH_3

An activation barrier must exist between *(103a)* and *(103b)* since only *(99)* is formed at low temperatures. *trans*-2,3-Dichloro-2,3-dimethylcyclopropanecarbonyl chloride *(102)* arises from *(101)* in a dark reaction by the action of hydrogen chloride formed as side-product in the photoreaction. Formation of *(102)* can be rationalized as involving an intermediate

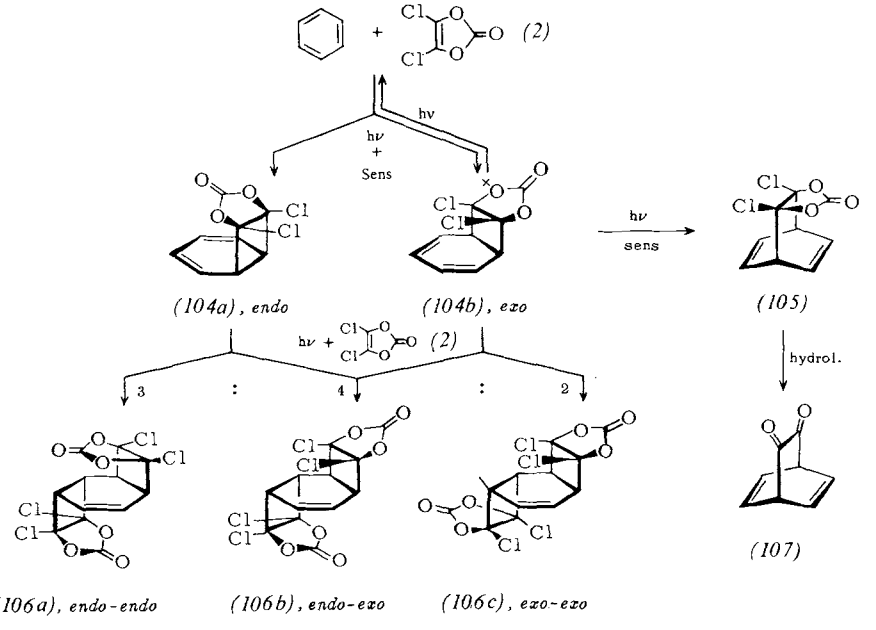
cyclopropenylium ion, and can be accomplished with pure *(101)* and HCl. Hydrolysis of *(99)* yields dimethylcyclobutenedione *(100)* which is identical with the product obtained by *Blomquist* and *Vierling via* an alternative route[94].

In general it may be said that the photocycloadditions of *(22)* to alkynes at room temperature give much lower yields and are usually less selctive than to alkenes. At low temperatures (−30 to −40 °C), however, the adducts *(97)* and *(99)* are obtained exclusively as homogeneous products. Hence the reaction can compete effectively with other more complicated procedures[95].

7. Photochemical Additions to Benzene and Naphthalene

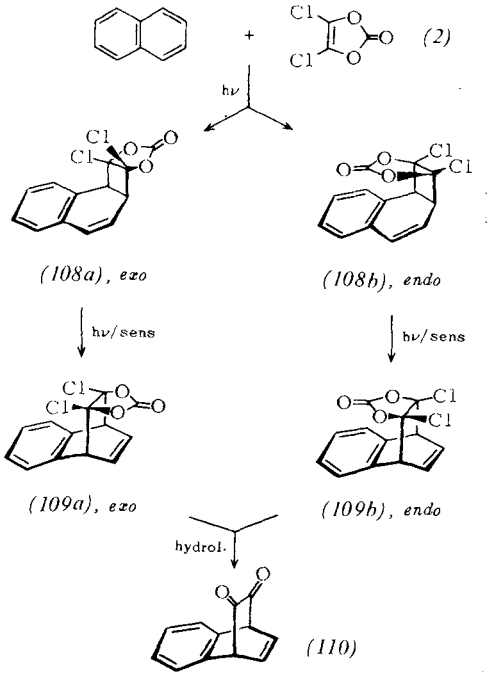
The classical photochemical cycloaddition of maleic anhydride to benzene provided the impetus for an understanding of the use of simple aromatic compounds as cycloaddition partners[96–99].

It was deduced from a large number of studies that the actual reactive species in the case of maleic anhydride and benzene is a charge transfer complex of the reactants[100] which is subject to nucleophilic attack by a further molecule of maleic anhydride in the course of the reaction, leading to stereospecific formation of the known 2:1 adduct[77].



Meanwhile, further experimental results have shown how olefins and dienes undergo photochemical cycloaddition to benzene[101–103] and naphthalene, and *Bryce-Smith* has collected a number of fundamental cases of symmetry-controlled cycloadditions to benzene under photochemical conditions[101, 109].

Accepting this concept, then a concerted 1,2- or 1,4-cycloaddition with retention of configuration at the linkage sites is "allowed" only if the added molecule reacts from the S_1 state with S_0 benzene or if benzene reacts from the $S_2(^1B_{1u})$ state with the S_0 olefin. In contrast, reaction of $S_1(^1B_{2u})$ benzene with the S_0 olefin is symmetry-forbidden so long as no charge transfer complexes or exiplexes of the reactants are involved[101, 103].



The study of the photochemical addition of *(2)* to benzene and naphthalene commanded not only preparative interest, as repeatedly mentioned, but mechanistic interest too, because, in spite of claims to the contrary[20, 110], no charge transfer complex between the reactants could be detected[70].

On photoaddition of *(2)* to benzene[70, 20, 110–113] with acetophenone or 2-butanone as sensitizer, only the 1,2-cycloadduct *(104b)* can initially be isolated from the mixture after brief irradiation since it crystallizes from the reaction mixture[111, 112, 70].

On further irradiation the concentration of *(104b)* steadily decreases in favor of the 1,4-cycloadduct *(105)* and the two stereoisomeric 2:1 adducts *(106b)* and *(106c)*. Since the 2:1 adduct *(106a)* can also be isolated, it has to be assumed that the *endo*-isomeric 1,2-cycloadduct *(104a)* is formed but presumably undergoes very fast reaction and thus escapes detection owing to an insufficient steady-state concentration. In the presence of the sensitizers employed, the isolated *exo* 1,2-adduct is partly cleaved to the starting compounds and partly rearranges to the 1,4-adduct *(105)*. The above time dependence of the concentration of *(104b)* becomes understandable in the light of these observations.

However, the structure and stereochemistry of the products have been established. The 1,4-adduct *(105)* is formally the Diels-Alder adduct of *(2)* to benzene; the adduct cannot be obtained by a thermal route. This compound proved to be a suitable starting material for the preparation of the hitherto unknown bicyclo[2.2.2]octa-5,7-dien-2,3-dione *(107)*[112] which, unlike the non-isolable homologous norbornadien-7-one[113], is fairly stable thermally. However, *(107)* undergoes very ready photochemical decomposition to benzene and carbon monoxide.

On irradiation of naphthalene/*(2)* solutions[115] under conditions ensuring that only naphthalene can absorb light, the primary products, as in the case of benzene, are the isomeric 1,2-adducts *(108a)* and *(108b)*, and after prolonged irradiation the 1,4-adducts *(109a)* and *(109b)*. All compounds have been isolated and their stereochemistry established by ^{1}H-NMR spectroscopy with the aid of lanthanoid shift reagents[61].

On selective irradiation in the longest wavelength absorption band of naphthalene the same reaction course is operative as is observed on irradiation with the unfiltered light of a high pressure mercury lamp. The initial products are the 1,2-cycloadducts *(108)* which then disappear in favor of the 1,4-cycloadducts *(109)*. Preparative isolation of the 1,2-adducts *(108)* from the reaction mixture therefore proved to be more problematical than that of the 1,4-cycloadducts.

The 1,4-adducts *(109)*, which may also be regarded as the thermally inaccessible "Diels-Alder adducts" of naphthalene to *(2)*, can be isolated in good yields by exhaustive irradiation or by use of acetophenone as sensitizer.

Sterically pure *exo* and *endo* 1,2-adducts *(108a)* and *(108b)* regenerate *(2)* and naphthalene quantitatively on direct irradiation. In the presence of sensitizer, however, they undergo >80% stereoselective conversion into the corresponding 1,4-cycloadducts *(109)*. Mechanistic studies reveal the following picture of the naphthalene/*(2)* system:

The 1,2-adducts *(108)* are formed from the S_1 excited state of naphthalene which is trapped by *(2)*. We are therefore dealing with a singlet reaction of naphthalene.

Unlike benzene, naphthalene possesses no degenerate energy levels owing to its lower symmetry. Thus the symmetry disqualification postulated by *Bryce-Smith* for the S_1 state of benzene[101] does not apply to a concerted process from the S_1 state of naphthalene.

Reaction to give the 1,4-cycloadducts *(109)* then takes place from a triplet state of *(108)* which can be occupied either by addition of a sensitizing agent, *e.g.* acetophenone, or by triplet-excited naphthalene itself. (Excited naphthalene has a significant intersystem crossing rate[116] so that 1,4-adducts can also arise in the absence of a sensitizer.) The reason for 1,2-adducts *(108)* not undergoing immediate reversion to naphthalene and *(2)* on direct irradiation is that they absorb at shorter wavelengths than naphthalene and can therefore be largely protected by use of suitable filters.

Hydrolysis of the 1,4-isomer *(109)* affords the diketone *(110)*, which is likewise very stable thermally but is subject to extremely ready photochemical decomposition to naphthalene and carbon monoxide.

8. Conclusion

Observations performed to date on the chemistry of halovinylene carbonates show that this relatively young class of compounds will assume a place among the synthetic reagents of organic chemistry owing to the variety of their possible applications. In spite of the tentative nature of some of the results and a number of unsettled optimization questions, these derivatives have opened the way to molecules whose formation reaction will stimulate further preparative and mechanistic studies.

Work from our laboratory reported in this survey was generously supported by the Deutsche Forschungsgemeinschaft, the Amt für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie. I would like to link my thanks to these institutions with an expression of gratitude to my co-workers for their skill and engagement which made these results possible.

Reaction of 1,3-Oxazin-6-ones with Ynamines and Ketene *N,O*-Acetals

By Wolfgang Steglich, Ernst Buschmann, and *Oswald Hollitzer*[*]

1,3-Oxazin-6-ones *(3)*[1] open up interesting preparative prospects that have hitherto been little explored. We have found that 4-methyl-1,3-oxazin-6-pnes *(3a)—(3c)* (Table 1) can be prepared from 2-(acylamino)crotonic esters *(1)* by heating them in a metal-bath at 270 °C and distilling off the alcohol that is formed[2]; the reaction may occur by way of ketene intermediates *(2)*[3].

(1) *(2)*

(3)

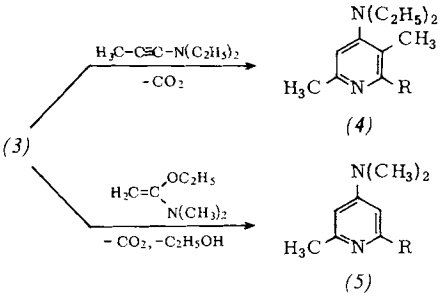

Table 1. 4-Methyl-1,3-oxazin-6-ones *(3)* prepared [a].

Cpd.	R	Yield [%]	B.p. [°C/torr]
(3a)	$(CH_3)_2CH$	65	40—42/0.1
(3b)	$(CH_3)_2CHCH_2$	40	47—49/0.15
(3c)	$(CH_3)_3C$	60	39—41/0.3
(3d) [b]	CF_3	52	66—69/12

[a] All the compounds gave correct elemental analyses.
[b] From *tert*-butyl 3-aminocrotonate and trifluoroacetic anhydride.

The 2-trifluoromethyl derivative *(3d)* was obtained from *tert*-butyl 3-aminocrotonate by the action of trifluoroacetic anhydride at room temperature. The 1,3-oxazinones *(3a)—(3c)* show characteristic bands in the IR spectrum (CCl_4) at 1770, 1632 and 1580 cm^{-1} [*(3d)*: 1795, 1655 and 1595 cm^{-1}] and NMR signals for the methyl group and the vinyl protons at $\delta=2.18$ (d, $J=1$ Hz) and 5.9 (q, $J=1$ Hz), respectively [*(3d)*: $\delta=2.38$ and 6.25].

Reaction of the 1,3-oxazinones with *N,N*-diethyl-1-propynamine affords 2,3,6-trisubstituted 4-(diethylamino)pyridines *(4)*; and 2,6-disubstituted 4-(dimethylamino)pyridines *(5)* are formed on reaction with 1-ethoxy-*N,N*-dimethylvinylamine[4] (Table 2). The reactions of *(3a)—(3c)* in ether are complete within a few hours, but cooling is necessary with *(3d)* because of the strong evolution of heat.

(4) *(5)*

Table 2. 4-(Dialkylamino)pyridines *(4)* and *(5)* prepared [a].

Cpd.	R	Yield [%]	B.p. [°C/torr]	M.p. [°C]
(4a)	$(CH_3)_2CH$	79	64—66/0.2	
(4b)	$(CH_3)_2CHCH_2$	89	77—78/0.2	
(4c)	$(CH_3)_3C$	65	78/0.1	
(4d)	CF_3	67	66—68/0.2	
(5a)	$(CH_3)_2CH$	80	63—64/0.2	
(5b)	$(CH_3)_2CHCH_2$	90	78—79/0.1	
(5c)	$(CH_3)_3C$	94		73
(5d)	CF_3	80		75.5

[a] All the compounds gave correct elemental analyses.

The orientation of the substituents follows from the NMR spectra. Thus *(4d)* shows an H,F coupling of 2.3 Hz between the trifluoromethyl group and the methyl group in position 3. For the *tert*-butyl derivative *(5c)* the aromatic protons appear as an AB quartet at $\delta=6.20$ and 6.37 ($J=2.5$ Hz) but for *(5a)* and *(5b)* as a single signal. The 2-trifluoromethyl group in *(5d)* causes a shift of the AB quartet to $\delta=6.52$ and 6.79.

Their diene character determines the course of reaction of 1,3-oxazinones with electron-rich multiple bonds, whereas with 3,1-benzoxazinones the anhydride system from carboxylic and imidic acids also plays an important part[5]. The regiospecificity observed corresponds to attack by the nucleophile on the C=N group of this system.

2-tert-Butyl-4-methyl-1,3-oxazin-6-one (3c)

Ethyl 3-(pivaloylamino)crotonate (105 g) *(1c)* was heated for 3 h in a metal bath at 270 °C, the ethanol formed distilling off through an air-condenser. Distillation in a high vacuum afforded a colorless oil (49 g, 60%).

Organisch-Chemisches Institut der Technischen Universität
1 Berlin 12, Strasse des 17. Juni Nr. 135 (Germany)

2-tert-Butyl-4-(dimethylamino)-3,6-dimethylpyridine (4)

N,N-Dimethyl-1-propynylamine (2.5 g) in anhydrous ether (10 ml) is dropped into *(3c)* (3.34 g) in ether (20 ml) at room temperature. After 4 hours' stirring, the mixture is extracted with 1 N HCl, the aqueous phase is neutralized with 1 N KOH and extracted with ether, and the extract is dried over $MgSO_4$. After removal of the solvent the residue is distilled in a high vacuum. Yield 3.05 g (65%).

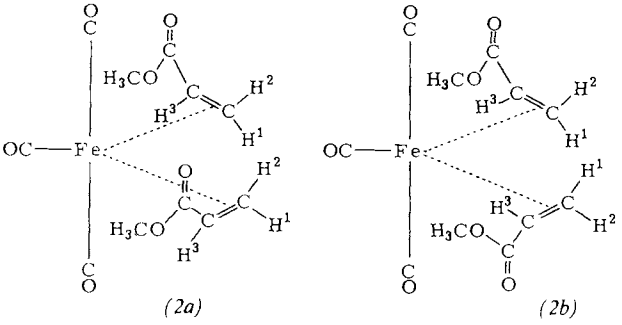
Photochemical Synthesis of Bis(η-methyl acrylate)tricarbonyliron

By *Friedrich-Wilhelm Grevels, Dorothea Schulz*, and *Ernst Koerner von Gustorf*[*]

Electronic excitation of an olefintetracarbonyliron complex can lead both to cleavage of the olefin-iron bond and to elimination of CO[1].

$$LFe(CO)_4 \xrightarrow{h\nu} \begin{cases} \xrightarrow{a)} CO + LFe(CO)_3 \\ \xrightarrow{b)} L + Fe(CO)_4 \end{cases}$$

The coordinatively unsaturated olefintricarbonyliron species formed according to a) should react with an excess of olefin (L) to give the hitherto unknown[2] bis(olefin)tricarbonyliron $L_2Fe(CO)_3$; the tetracarbonyliron formed according to b) reacts with L to regenerate the starting material.



Irradiation of (η-methyl acrylate)tetracarbonyliron *(1)* in the presence of excess methyl acrylate in *n*-hexane at −30 °C thus generates bis(η-methyl acrylate)tricarbonyliron *(2)*, which we were able to isolate as a light yellow solid that is stable for an extended period at −78 C.

$$\underset{(1)}{(CH_2\text{-}CH\text{-}COOCH_3)Fe(CO)_4} + CH_2{=}CH\text{-}COOCH_3 \xrightarrow[\text{hexane}]{h\nu,\ -30\,^\circ C} \underset{(2)}{(CH_2{=}CH\text{-}COOCH_3)_2Fe(CO)_3} + CO \quad (1)$$

The composition of *(2)* follows from elemental analysis and the mass spectrum which shows the molecular ion ($m/e = 312$) and the successive loss of 3 CO ($m/e = 284, 256, 228$) as well as the elimination of one methyl acrylate molecule ($m/e = 226$) and the subsequent loss of 3 CO ($m/e = 198, 170, 142$) at a vaporization temperature of −30 C.

In the IR spectrum (*n*-hexane, −30 C) of *(2)* three bands appear in the metal carbonyl stretching region at 2087 (vw, $A_1^{(1)}$), 2024 (vs, B_1), and 2012 cm^{-1} (s, $A_1^{(2)}$) whose intensity ratio indicates that both olefinic ligands occupy equatorial positions in the trigonal bipyramidal complex (C_{2v} local symmetry)[3].

The ^{1}H-NMR spectrum (Table 1) shows two sets of signals whose intensity ratio depends upon the temperature and work-up conditions, thus indicating the presence of two isomers *(2a)* and *(2b)* in which the corresponding protons of the two methyl acrylate ligands are equivalent. We succeeded in recording the spectrum of pure *(2a)*.

(2a) *(2b)*

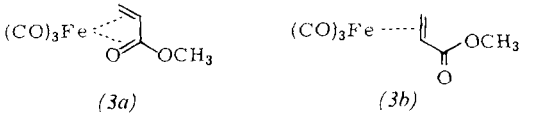
Table 1. ^{1}H-NMR data of the isomeric complexes *(2)* (0.4 M in [D_8]-toluene, −31 C).

	τ [ppm]				Coupling constants [Hz]		
	H^1	H^2	H^3	H^{CH_3}	J_{12}	J_{13}	J_{23}
(2a)	7.58	6.78	6.48	6.59	<1	6.5	12
(2b)	7.38	6.98	6.74	6.62	<1	6.5	12

Assuming rotation to occur about the metal-olefin bond axis[4], then other conceivable isomers are merely conformers of *(2a)* or *(2b)*. Assignment of structures is based on the ^{1}H-NMR spectra: the anisotropic effect of the ester carbonyl groups on the vinyl protons of the other olefin ligand should lead to a downfield shift for H^1 and an upfield shift for H^2 and H^3 on going from *(2a)* to *(2b)* (assuming coplanarity of the C=O and C=C bond planes as indicated in the formulas[5]).

On warming to 0 C pure *(2a)* (0.4 M) undergoes partial conversion into *(2b)*, yielding equal concentrations of the two isomers; this isomerization *(2a)* → *(2b)* requires temporary cleavage of an iron-olefin bond.

On heating of a dilute solution (0.003 M) of *(2)* in *n*-hexane from −30 to −5 °C the IR bands of *(2)* largely disappear and are replaced by three new bands at 2064 (m), 1994 (s), and 1979 cm^{-1} (s). The process can be reversed by addition of methyl acrylate, thus showing that at this temperature the complex *(2)* can reversibly loose an olefin ligand and is in equilibrium with (methyl acrylate)tricarbonyliron *(3)*.



$$\underset{(2)}{} \xrightleftharpoons{-5\,^\circ C} \underset{(3)}{(CH_2{=}CH\text{-}COOCH_3)Fe(CO)_3} + CH_2{=}CH\text{-}COOCH_3 \quad (2)$$

We have not yet been able to isolate *(3)* in pure form. Since its IR spectrum resembles those of tricarbonyliron complexes of α,β-unsaturated ketones[6] with regard to intensity distribution and splitting pattern of the M(C≡O) bands we tend

[*] Dr. F.-W. Grevels, D. Schulz, and Dr. E. Koerner von Gustorf [**]
Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung

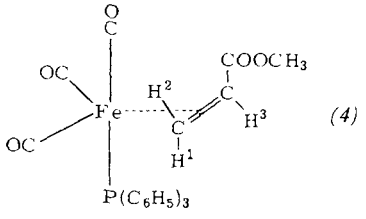
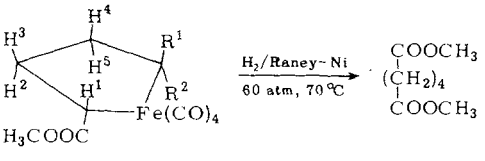
[**] We are grateful to Dr. J. Leitich for his assistance in the discussion of the ^{1}H-NMR spectra.



to favor structure *(3a)* in which the α,β-unsaturated ester is coordinated as a 1-oxabutadiene system[7].

(3a) *(3b)*

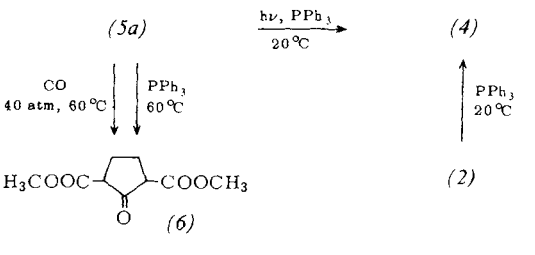
It may be expected that *(3a)* is readily transformed into *(3b)* and behaves *de facto* as a coordinatively unsaturated species since an ester group generally displays little inclination to coordinate to metal(0)[7]. A small amount of *(3b)* might possibly be present in equilibrium with *(3a)*.



On warming to 20 C under a CO atmosphere complex *(2)* regenerates *(1)*; reaction with triphenylphosphane affords (η-methyl acrylate)tricarbonyl(triphenylphosphane)iron *(4)*[8] (cf. equilibrium (2)). X-Ray structure analysis[9] of *(4)* shows that the largely σ-bonded phosphane ligand occupies the axial position[10] and the π-bonded olefin ligand the equatorial position in the trigonal bipyramid.

(4)

(2)⇌*(3)* provides a means of studying the chemistry of L—Fe(CO)$_3$, an important primary photolysis product of L—Fe(CO)$_4$, "in the dark". The formation of LFe(CO)$_3$ as an intermediate in complex photochemical reactions of LFe(CO)$_4$ can be regarded as proven if reaction of a particular substance with *(2)* "in the dark" and with LFe(CO)$_4$ upon irradiation yields the same product[11].



If *(1)* (0.05 M) and methyl acrylate (0.5 M) in hexane are irradiated, not at −30 C, but at +20 C, then instead of 1 mol only 1/3 of a mol of CO is released per mol of *(1)* and the reaction comes to a halt after conversion of about 50% of *(1)*, due to the back reaction of *(2)* with CO. About 20% of the reacted *(1)* affords two isomeric complexes having the composition $(C_4H_6O_2)_2Fe(CO)_4$. IR, ^{1}H-NMR, and mass spectra[12] show them to be dimethyl *trans-* and *cis*-1,1,1,1-tetracarbonylferracyclopentane-2,5-dicarboxylate *(5a)* and *(5b)*, respectively, of which *(5a)* predominates.

(5a), $R^1 = COOCH_3$, $R^2 = H^6$
(5b), $R^1 = H^6$, $R^2 = COOCH_3$

Both compounds can be hydrogenated to dimethyl adipate by H_2/Raney nickel.

Thermal reaction of *(5a)* with CO affords dimethyl cyclopentanone-2,5-dicarboxylate *(6)*, while heating with PPh_3 likewise furnishes *(6)* as well as tricarbonylbis(triphenylphosphane)iron. The C—C bond produced during formation of *(5)* can be ruptured again photochemically. Compound *(4)* results from irradiation of *(5)* in the presence of PPh_3. Dimethyl *trans*-2-hexen-1,6-oate and its Fe(CO)$_4$ complex were also isolated as products of a hydrogen shift.

(5a) *(4)* *(6)* *(2)*

Compounds such as *(2)* and *(5)* have recently been proposed as intermediates in the photochemical formation of cyclopentanones from Fe(CO)$_5$ and cyclic olefins[13]. Indeed, we were able to show that *(5)* is formed thermally from *(2)* and reacts with CO yielding the cyclopentanone derivative *(6)*. These results again demonstrate the value of low temperature photolysis for the elucidation of reaction mechanisms. We shall report separately on the reaction step inducing the C—C linkage formation[14].

Procedure:

A solution of *(1)* (2.54 g, 0.01 mol) and methyl acrylate (8.6 g, 0.10 mol) in hexane (200 ml) was irradiated for 4.5 h at −30 C in an immersed lamp apparatus (Solidex glass, high-pressure mercury lamp Philips HPK 125 W), whereupon 1.02 mol of CO were liberated per mol of *(1)*. Compound *(2)* precipitates as light yellow crystals within 2–3 days at −78 C; the crystals were separated by inverse filtration and dried in an oil-pump vacuum at −30 °C[15]. Yield: 2.72 g (87%).

Structural Analysis by Direct Observation of Atoms by Dark Field Transmission Electronmicroscopy[**]

By *Robert F. Whiting, F. Peter Ottensmeyer*, and *Frederick C. Nachod*[*]

The most desirable method for the determination of chemical structure is the direct visualization of the atoms of a molecule. X-ray diffraction analysis can accurately map the positions of the atoms in a molecule but this technique is not routinely available. Chemical structural analysis usually relies on synthetic and spectrometric procedures which are highly sophisticated but are necessarily indirect. There is always a measure of reasonable doubt in the results obtained.

Recently it has been shown that single heavy atoms can be imaged in the electron microscope by a variety of techniques[1]. In particular, atoms ranging in atomic number from 46 (Pd) to 92 (U) have been directly imaged in a number of compounds by dark field electron microscopy in our laboratory[2]. The resolving power of the electron microscope (Philips EM 300) was shown to be better than 3 Å. Since this is within the range of atomic separations for the larger atoms in molecules, it led us to consider the possibility of structural analysis of some characteristic compounds containing heavy atoms. This communication reports the use of high resolution dark field electron microscopy to confirm the structure of a diiodobenzoic acid derivative.

In an investigation of urographic radiopaques, *Larsen et al.*[3] synthesized a 3,5-bis(acetamido)diiodobenzoic acid which, on the basis of analysis of its synthetic relationships to known compounds, was assigned the structure of the 2,6-diiodo isomer; other data, such as NMR findings, were ambiguous. Along with the diiodobenzoic acid, a sample of 3,5-bis(acetamido)-2,4,6-triiodobenzoic acid was used as a control in the study. For the electron microscopic investigation these acids were converted into the acetatouranyl(VI) salts *(1)* and *(2)*

$UO_2(OOCCH_3)^{\oplus}$

(1), R = H
(2), R = I

respectively, by "staining" the carboxyl group with a uranyl acetate [12 hours stirring, 0.05 N uranyl acetate, 0.05 N HCl (pH 3.5), filtration (0.22 μ Millipore filter)].

The sample solution was applied to a pretreated 10—20 Å thick film of carbon and examined by dark field electron microscopy in a Philips EM 300 (80 kV; magnification $10^5\times$). Dark field illumination was obtained by beam tilt. Details of these techniques have been described elsewhere[2]. The electron micrographs of *(1)* and *(2)* (Figure 1) show the relationship of the position of the iodine atoms (lighter dots) to that of the uranium atom (dark dot). Only the heavier atoms in the molecules are observable. Atoms as light as carbon scatter too few electrons to produce a signal strong enough to stand out above the electron noise and the random structure of the support film. The slight differences in geometry in the images generally observed are thought to be due to small disarrangement of the atoms caused by the intense electron bombardment of the molecule in the microscope at the time of exposure of the image. Nevertheless the numbers, geometry and separations of the spots are entirely consistent with the basic molecular structure (cf. particularly Fig. 1b).

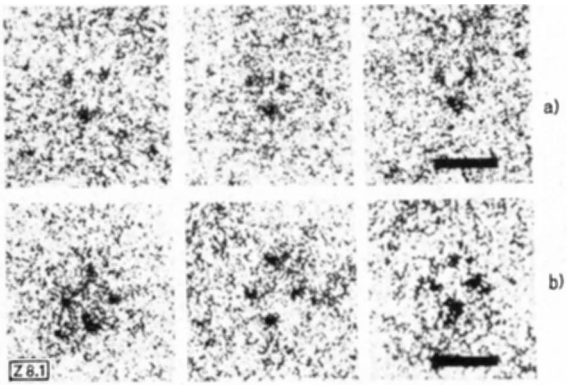

Fig. 1. Dark field electron micrographs of uranyl stained 3,5-bis(acetamido)-2,6-diiodobenzoic acid *(1)*, and uranyl stained 3,5-bis(acetamido)-2,4,6-triiodobenzoic acid *(2)*. In each image only the iodine and uranium atoms are visible. The images have been oriented such that the uranium atom is on the bottom. The bars represent 10 Å.

Thus, a structure derived by chemical analysis has been verified by dark field electron microscopy. The technique is straightforward and, assuming the necessary expertise has been acquired, takes about half a day to complete. At present compounds are restricted to those containing heavy atoms to be used as positional markers, although atoms as light as sulphur have been detected by use of such markers in conjunction with signal averaging of many images[4].

The Contact Contribution in the Lanthanoid-Induced Shift of ^{13}C=O-NMR Signals[**]

By *Horst Kessler* and *Michael Molter*[*]

In principle, the application of lanthanoid shift reagents (LSR) permits NMR spectroscopic determination of the geometry of molecules in solution. Requirements for such a determination are:

a) Separation of the dipolar contribution (pseudocontact contribution, Δ_{dip}) from the contact contribution (Δ_{con}) and from the diamagnetic contribution (Δ_{dia}) of the observed induced shift (Δ_{obs}).

b) Axial symmetry of the complex and a knowledge of its molecular composition.

c) Knowledge of the site of complexation and the position of the principal magnetic axis.

d) Knowledge of the effect of complexation on the conformational equilibrium of flexible molecules.

Having already considered point d) in a previous study[1] we now examine point a) in the present communication.

The information gained from ^1H-NMR measurements on organic molecules with LSR frequently proves to be insufficient for an unambiguous determination of the requirements listed above. ^{13}C-NMR LSR studies provide additional data. Although LSR have occasionally been employed in assignments of ^{13}C signals, quantitative data have rarely been reported[2-4]. We studied the dependence of the contact contribution Δ_{con} (which is more important for carbons than for protons[5]) of the carbonyl carbons in the compounds *(1)*—*(7)* with Ln(fod)$_3$ (Ln = La, Eu, Pr, Yb; see Table 1; fod = 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionate).

Table 1. Observed LSR-induced shift Δ_{obs} of the carbonyl carbon atoms in the compounds *(1)*—*(7)*. The molar ratios substrate: LSR = 20:1 and 10:1 were chosen for the ^{13}C-NMR measurements and the values (in ppm) extrapolated linearly to substrate: LSR = 1:1. The error in the Δ_{obs} values is taken as 1.5 ppm due to the use of a 4K memory NMR computer.

R^1—CO—R^2 *(1)*-*(7)*

The observed shifts Δ_{obs} consist of a diamagnetic (complexation shift, Δ_{dia}) and a paramagnetic term ($\Delta_{dip} + \Delta_{con}$):

$$\Delta_{obs} = \Delta_{dia} + (\Delta_{dip} + \Delta_{con})$$

The diamagnetic term ($\Delta_{dia} = \Delta^{La}_{obs}$), which was determined by measurements with La(fod)$_3$, decreases with increasing donor strength of the substituents in the series *(1)*—*(6)*[6]. This behavior is in accordance with observations on the protonation of carbonyl compounds[7].

The "anomalous" upfield shifts of the ^{13}CO signals in the amide *(7)*, the urethan *(4)*, and the ureas *(5)* and *(6)* after addition of Eu(fod)$_3$ are particularly interesting. This effect, which has been occasionally mentioned[8], can be utilized in the assignment of ^{13}C-NMR signals[9].

The contribution of Δ_{dip} and Δ_{con} can be obtained from the values listed in Table 1. The ratios of Δ_{con} and Δ_{dip} among the different lanthanoids (Eu^{3+}, Pr^{3+}, and Yb^{3+}) can be assumed constant[10] and provide the remaining equations necessary for separation of Δ_{dip} and Δ_{con}. Use of three different paramagnetic ions provides more data than necessary to check the accuracy of this procedure.

The agreement of Δ_{dip} and Δ_{con} as calculated from the experimental shifts Δ^{Eu}_{obs}, Δ^{Pr}_{obs}, and Δ^{Yb}_{obs} was only moderately good when the theoretical values of *Reuben*[10] and *Dobson et al.*[11] were used; it improved, however, when the experimental values of *Dobson et al.*[11] were employed (Fig. 1).

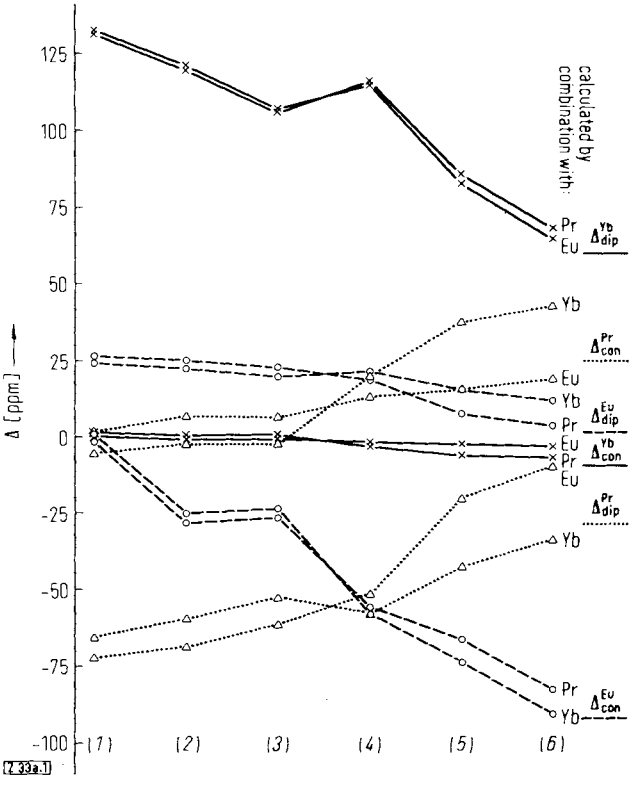

Fig. 1. Contact (Δ_{con}) and pseudocontact shifts (Δ_{dip}) of the carbonyl carbon atoms in *(1)*-*(6)*. The following experimentally determined ratios [11] were used for the separation of the paramagnetic term of the LSR-induced shift ($\Delta_{para} = \Delta_{con} + \Delta_{dip}$):

$\Delta^{Eu}_{dip} : \Delta^{Pr}_{dip} : \Delta^{Yb}_{dip} = (4) : (-11) : (22)$ and

$\Delta^{Eu}_{con} : \Delta^{Pr}_{con} : \Delta^{Yb}_{con} = (-48.1) : (11) : (-1.8)$.

Numerical example:

$\Delta^{Eu}_{para} = \Delta^{Eu}_{con} + \Delta^{Eu}_{dip}$

$\Delta^{Yb}_{para} = \Delta^{Yb}_{con} + \Delta^{Yb}_{dip}$

$\frac{\Delta^{Eu}_{con}}{\Delta^{Yb}_{con}} = \frac{-48.1}{-1.8}$; $\frac{\Delta^{Eu}_{dip}}{\Delta^{Yb}_{dip}} = \frac{4}{22}$

The contribution of the contact term increases rapidly with increasing donor properties of the substituents [*(1)*→*(6)*] and the dipolar term decreases. The increasing basicity of the carbonyl oxygen in the series *(1)*—*(6)*[12] apparently enhances spin delocalization (causing an increase in Δ_{con}) as a result of stronger complexation. The decreasing contribution

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

of the dipolar shift could be rationalized because the spin delocalization causes a decrease in the magnetic field.

The above results support the previous suggestion[10] that the pseudocontact term Δ_{dip} for carbon, which is important for conformational studies, is best determined with Yb(fod)$_3$, whereas Eu(fod)$_3$ is more suitable for measurements in which the contact term is important[9].

Use of the Eu(fod)$_3$-Induced Shift for Determination of the Complexation Site and for Signal Assignment in the ^{13}C-NMR Spectra of Protected Dipeptides[**]

By *Horst Kessler* and *Michael Molter*[*]

Assignment of the signals of the carbonyl carbon atoms in ^{13}C-NMR spectra of peptides frequently proves impossible by conventional methods. In certain cases the use of Eu(fod)$_3$ (tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)-europium) as a shift reagent is useful. With this reagent the contact contribution Δ_{con} is so large that it overcompensates the pseudocontact term Δ_{dip} in the case of urethans, amides, and ureas and leads to an "anomalous" upfield shift of the ^{13}C=O signal[1,2].

In the carbonyl region of its ^{13}C-NMR spectrum a Z- or boc-dipeptide methyl ester shows three signals. The urethan carbonyl carbon peak at 154–156 ppm is distinctly separated from those of the amide and ester carbonyl carbons (169–173 ppm). Only one of the latter signals is shifted upfield after the addition of Eu(fod)$_3$. Upfield shifts of ester carbonyl carbons cannot be observed, whereas such shifts do occur with amide carbonyl carbons due to the large contact term[11]. This allows the assignment of these two signals (Table 1). There are only two carbonyl groups which can complex with the shift reagent in boc-Gly-OCH$_3$. The urethan carbonyl group ($\delta = 156.0$ ppm) shows the above-mentioned "anomalous" upfield shift ($\Delta_{obs} = -9$ ppm[3]), which indicates a considerable degree of complexation. In the protected dipeptides

Table 1. ^{13}C-NMR shifts of dipeptides. The values are given in ppm relative to TMS (solvent CDCl$_3$). The values given in parentheses are the Eu(fod)$_3$-induced shifts (extrapolated to Eu(fod)$_3$:substrate = 1:1). [a] Remaining aromatic signals of Z-Phe-Ala-OCH$_3$: 130.0, 128.7; 128.3; 127.1.

Z-Phe-Ala-OCH$_3$: [a] 136.0; 136.4; CH_2 38.5; CH_3 17.7; CH_2 66.7; 156.0 (+2.6); 55.8 171.2 (−24.1); 47.8 173.0 52.4 (+5.4)

Boc-Phe-Phe-OCH$_3$: 126.5; 128.0; 128.8; 126.5; 136.3; 135.4; CH_2 38.2; CH_2 37.8; $(CH_3)_3C$ 28.1; 76.6 154.7 (+1.7); 55.7 170.9 (−20.7); 53.2 170.5 51.9 (+9.4)

Boc-Gly-Phe-OCH$_3$: 127.0; 128.4; 129.1; 135.8; CH_2 37.8; $(CH_3)_3C$ 28.2; 79.9 156.0 (−1.8); 44.2 169.5 (−11.8); 53.1 171.8 52.1 (+3.7)

Boc-Phe-Gly-OCH$_3$: 126.7; 128.4; 129.3; 137.0; CH_2 38.6; $(CH_3)_3C$ 28.3; 80.1 155.6 (−2.6); 55.8 172.2 (−22.1); 41.2 170.0 52.1 (+3.9)

Boc-Gly-Gly-OCH$_3$: $(CH_3)_3C$ 28.2; 80.0 155.6 (−1.7); 44.1 169.6 (−15.2); 41.0 169.6 52.2 (+3.4)

Trt-Gly-Gly-OCH$_3$: 126.7; 128.0; 128.4; 145.2; 71.1; 52.3 171.8 (−27.3); 40.8 170.3 52.3 (+6.5)

(Table 1) the upfield shift of the urethan CO signal is small compared to that of the amide signal, thus indicating preferred complexation at the amide carbonyl group. However, the weak upfield shift of the urethan CO signal in boc-Phe-Gly-OCH$_3$, boc-Gly-Phe-OCH$_3$, and boc-Gly-Gly-OCH$_3$ demonstrates that this group is partially complexed too[5].

This indicates that in protected dipeptides several complexing sites compete for the lanthanoid shift reagents. Hence their use in conformational analysis of such compounds[6] becomes

Addition of Aliphatic Aldehydes to Activated Double Bonds[1]

By *Hermann Stetter* and *Heinrich Kuhlmann*[*]

Aromatic and heterocyclic aldehydes can be added to α,β-unsaturated nitriles, esters and ketones under catalytic influence of cyanide ions. Aliphatic aldehydes, however, do not add under these conditions because of the strong basicity of the cyanides.

We have found that both aromatic and heterocyclic aldehydes as well as aliphatic aldehydes *(1)* can be added to α,β-unsaturated nitriles, esters, and ketones when thiazolium salts, whose catalytic activity in the formation of acyloins is well known[2], are employed in the presence of bases. γ-Ketonitriles, γ-ketoesters *(4a)*, and γ-diketones *(4b)*, respectively, are formed. The reaction course differs from that mentioned earlier[3] only in the mode of formation of the intermediary carbanion *(3)*.

The reaction can be carried out in polar solvents, *e.g.* alcohols, dimethylformamide, water, and corresponding mixtures. In the case of the examples listed in Table 1, the following reaction conditions were used:

Table 1. Examples for the reaction of aldehydes with α,β-unsaturated carbonyl compounds or nitriles.

Crystal and Molecular Structure of *cis*-Trioxatris-σ-homobenzene (*cis*-"Benzene Trioxide")[**]

By *Walter Littke* and *Ulrich Drück*[*]

The chemistry of carbo- and heterocyclic *cis*-tris-σ-homobenzene compounds raises questions whose answers require a knowledge of exact structural parameters. In the present communication we report the results obtained in an X-ray structure analysis of *cis*-trioxatris-σ-homobenzene[1, 2].

The compound forms orthorhombic crystals from solutions in methanol or acetone. The unit cell, having the dimensions $a = 9.169 \pm 0.004$, $b = 10.325 \pm 0.006$, $c = 10.892 \pm 0.006$ Å, contains eight molecules and belongs to the space group Pbca. The experimentally determined ($d_{exp} = 1.62$ g/cm^3) and calculated density ($d_{calc} = 1.61$ g/cm^3) are in good agreement. This density value, which is relatively high for an organic substance

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

containing no heavy atoms, is attributable to dense packing within the cell.

A single crystal ground to a sphere (0.7 mm diam.) was mounted on a computer-controlled four-circle diffractometer (CAD 4, Enraf-Nonius) and 1319 symmetry-independent reflections

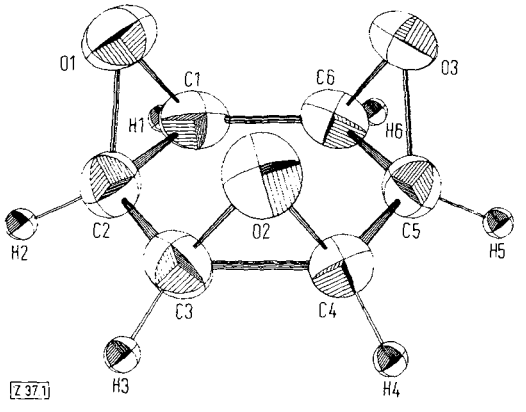

Fig. 1. *cis*-"Benzene trioxide" molecule, computer plot.

were measured with $Mo_{K\gamma}$ radiation. The positional parameters of all the atoms except the hydrogens could be determined by use of the symbolic addition method[3] and subjected to least-squares anisotropic refinement. The hydrogen atoms could then all be localized by Fourier difference synthesis, and further sharpening of all atomic parameters (anisotropic for C and O, isotropic for H) finally led to an R value of 0.056.

Figure 1 shows the highly symmetrical structure of *cis*-"benzene trioxide". The six carbons (cyclohexane ring) are coplanar (maximum deviation ±0.01 Å). Further planes can be constructed 0.42 Å below this ring plane through the six hydrogens (maximum deviation ±0.06 Å) and 1.19 Å above the ring plane through the three oxygens. All three planes are parallel. The three oxirane rings are twisted outwards from the C_6 ring (dihedral angle = 106.9°). The oxygen atoms are located at the apices of an almost equilateral triangle having the edge lengths O1—O2 = 2.86, O2—O3 = 2.80, and O3—O1 = 2.81 Å. These distances very closely resemble normal oxygen contacts (van der Waals radius 1.40 Å); it may therefore be presumed that similar conditions also apply for the two neighboring oxygens in *trans*-"benzene trioxide".

The most important intramolecular distances and bond angles of the molecule are shown schematically in Figure 2.

The carbon atoms bridged by oxygen have slightly shorter bonding distances (average 1.470 Å) than the unbridged ones (mean value 1.487 Å). Overall, the C—C bond lengths (mean value for all six bonds 1.479 Å) correspond to an sp^2—sp^2 single bond (1.48 Å). The mean value of the six CCH angles directed away from the oxirane rings (C6—C1—H1, H2—C2—C3, C2—C3—H3, H4—C4—C5, C4—C5—H5, and H6—C6—C1) amounts to 116.50 .

Table 1. Structural data of ethylene oxide (gaseous, microwave spectroscopy) [4] and *cis*-"benzene trioxide".

Ethylene oxide		Benzene trioxide	
Distances	[Å]	Distances (mean values)	[Å]
C—H	1.082	C—H	0.985
C—C	1.472	C—C (oxirane ring)	1.470
C—O	1.436	C—O	1.437
Angles	[°]	Angles (mean values)	[°]
H—C—H	116.68	C—C—H	116.50
C—O—C	61.40	C—O—C	61.52

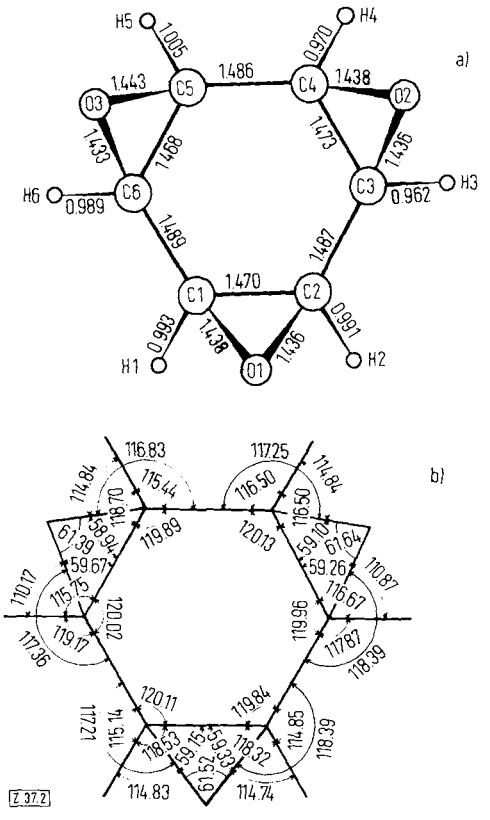

Fig. 2. Molecular geometry of *cis*-"benzene trioxide": a) bond lengths [Å]; b) bond angles [ ].

The extent of agreement of the corresponding structural parameters of *cis*-"benzene trioxide" and ethylene oxide—except for the C—H bond lengths—is remarkable (Table 1). Thus the *cis* arrangement of the three oxirane rings in *cis*-"benzene trioxide" which is favorable for conjugative interaction is without consequence in this respect. Accordingly, good agreement is observed with the values published by *Kitahara et al.*[5] for 9-cyano-*trans*-dioxatris-σ-homobenzene.

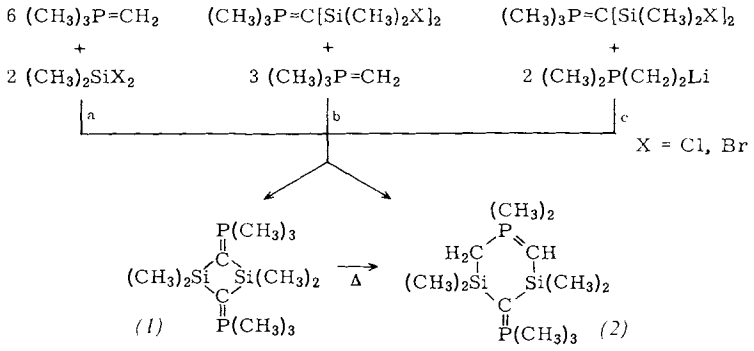
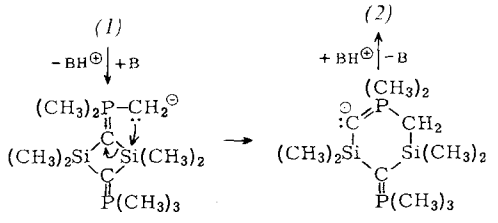
Isomerization by Ring Expansion in Silylated Phosphorus Ylides[1]



By *Wolfgang Malisch* and *Hubert Schmidbaur*[*]

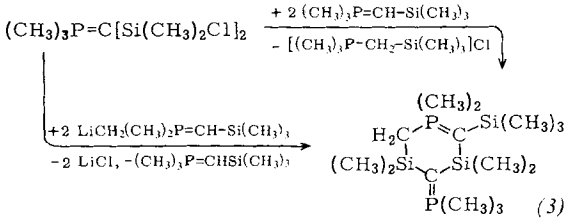
On reaction of alkylidenetrialkylphosphoranes with dialkyldihalosilanes[2], ylidic derivatives of 1,3-disilacyclobutanes of



[*] Dr. W. Malisch and Prof. Dr. H. Schmidbaur
Institut für Anorganische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

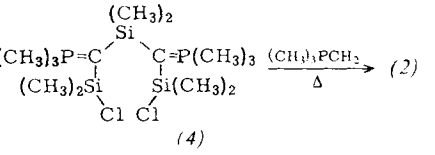
type *(1)* are formed surprisingly readily; their cyclobutane analogs are incapable of existence[3]. It appears that two Si atoms, but not two C atoms, provide sufficient shielding between the two carbanionic centers of the ylide functions[4].

By variation of the reaction conditions and the substituents we have now found, however, that *(1)* is not the thermodynamically most stable product but merely a kinetically favored initial intermediate of such reactions: on prolonged reaction and in the presence of a slight excess of ylide (path a, b) or metalated ylide (path c) as a base the isomeric six-membered cyclic compound *(2)* is formed irreversibly. Moreover, *(1)* also transforms to compound *(2)* slowly at 25 °C, and more rapidly at 120 °C. The process corresponds to a ring expansion involving a formerly exocyclic ylide function.



The isomerization process *(1)* → *(2)* is induced by deprotonation of *(1)* at a PCH_3 group and nucleophilic attack of the resulting carbanion at a silicon atom. Ring opening generates a new carbanion which yields the CH group of *(2)* by concerted abstraction of a proton.

Silacyclobutane ring opening by ylides proceeds similarly[5]. Earlier results obtained on the isomerization of five- and six-membered *disilanyl* ylide ring systems[6] are confirmed and supplemented by this new variant of carbanionic rearrangement[7].



A derivative *(3)* which is substituted on the ylidic C atom of ring *(2)* is formed quantitatively on reaction of bis-(dimethylchlorosilyl)methylenetrimethylphosphorane[2] with trimethylsilylmethylenetrimethylphosphorane[8] or its metalation product[4]. Silylation of the starting ylide prevents formation of a four-membered ring in this case.

The composition of *(2)* (m.p. 32—34 °C, b.p. 113—115 °C/0.1 torr) and *(3)* (m.p. 65—67 °C, b.p. 119—121 °C/0.01 torr) was established by elemental analysis and molecular weight determination. The structure follows from the NMR spectra.

^{1}H-NMR (C_6H_6, TMS int., 35 °C): *(2)*: τ$(CH_3)_3$P 8.92 ppm (d, 9H), *J*(HCP) 11.9 Hz; τ$(CH_3)_2$P 8.88 (d, 6H), *J*(HCP) 11.8; τCH_2 9.22 (dd, 2H), *J*(HCP) 15.0; τCH_3Si 9.59 (d, 6H), *J*(HCSiCP) 0.8; τCH_3Si' 9.72 (s, 6H); τCH 10.40 (ddt[9], 1H).—*(3)*: τ$(CH_3)_3$P 8.90 (d, 9H), *J*(HCP) 11.9; τ$(CH_3)_2$P 8.74 (d, 6H), *J*(HCP) 11.75; τCH_2 9.05 (d, 2H), *J*(HCP) 14.75; τ$(CH_3)_2$Si 9.81 (dd, 6H), *J*(HCSiCP) 0.4, *J*(HCSiCP') 0.3; τ$(CH_3)_2$Si' 9.68 (dd, 6H), *J*(HCSiCP) 0.4, *J*(HCSiCP') 0.8; τ$(CH_3)_3$Si 9.71 (s, 9H).

^{31}P-NMR (C_6H_6, 85% H_3PO_4, 35 °C): *(2)*: δP +1.525 ppm, δP' +1.274, AB, *J*(PP') 6.4 Hz.—*(3)*: δP +2.39, δP' −2.86, AX, *J*(PP') 3.8 (^{1}H-decoupled).

On reaction with $(CH_3)_2SiCl_2$ at −78 °C compound *(1)* undergoes ring cleavage to give *(4)*, m.p. 88—89 °C[10]. Attempted ring closure with $(CH_3)_3P{=}CH_2$ leads to ylide intermediates of higher molecular weight, and presumably also to larger rings. However, distillation again affords *(2)*, which appears to be especially stable.

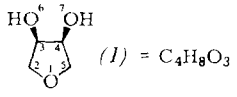
The Crystal Structure of a 1:1 Sodium Perchlorate Complex of 1,4-Anhydroerythritol (*cis*-3,4-Tetrahydrofurandiol)



By *R. E. Ballard*, *A. H. Haines*, *E. K. Norris*, and *A. G. Wells*[*]

There is interest in the complexes of alkali and alkaline earth metals with neutral molecules such as macrocyclic polyethers[1], macrocyclic antibiotics[2], and cryptates[3]. We report the formation of new complexes between 1,4-anhydroerythritol (*cis*-3,4-tetrahydrofurandiol) *(1)*[4] and the iodide, thiocyanate, and perchlorate of sodium which are obtained

[*] Dr. R. E. Ballard, Dr. A. H. Haines, E. K. Norris, and A. G. Wells
School of Chemical Sciences
University of East Anglia
Norwich NOR 88C (Great Britain)

as hygroscopic crystals by concentration of equimolar ethanolic solutions of the two components.

After recrystallization from 2-propanol/ethyl acetate the derivatives analyzed as [2(*1*)·NaI], [(*1*)·NaSCN], and [(*1*)·$NaClO_4$].

(*1*) = $C_4H_8O_3$

Crystal data: $C_4H_8O_3 \cdot NaClO_4$. Orthorhombic; $a = 12.77$, $b = 7.28$, $c = 17.69$ Å; $V = 1644.5$ Å^3; $d_{calc} = 1.83$; $d_{exp} = 1.79$; $Z = 8$; space group $P2_12_12_1$.

Intensities of reflections ($Cu_{K\alpha}$ radiation, Ni-filtered) from a crystal of the perchlorate mounted in a Lindemann tube on a Weissenberg camera were measured visually. The coordinates of the sodium and chlorine ions were found by a direct method program[5]. Application of Fourier technique established the structure with the exception of the hydrogen atoms, and refinement gave $R = 0.129$.

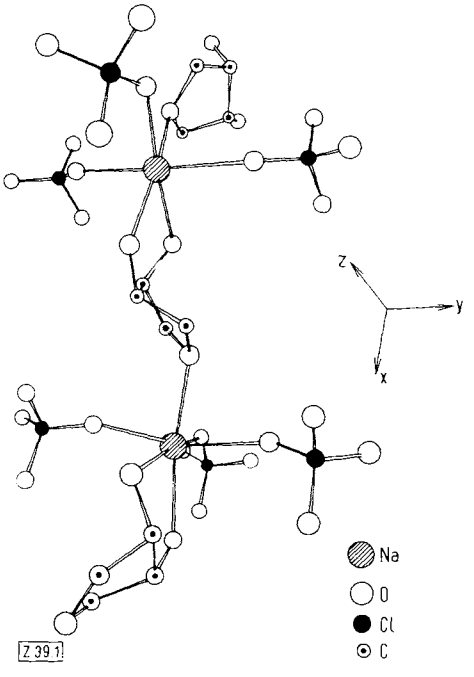


Fig. 1. Perspective section from the crystal structure of the complex [(*1*)·$NaClO_4$].

Figure 1 shows the similar environments of the two types of sodium ion in [(*1*)·$NaClO_4$]. Each is coordinated to six oxygen atoms which lie at the corners of a distorted octahedron. These six atoms comprise three oxygens from three different perchlorate ions, two from the hydroxyl groups of one molecule of (*1*), the remaining one being the tetrahydrofuran oxygen of a second molecule of (*1*). The resulting structure is an infinite network.

Planarity analyses of the two types of tetrahydrofuran ring (see Fig. 1) indicate near envelope conformations. In the one enantiomer C(3) in both rings is displaced 0.57 Å from the least squares plane through the other four atoms; the displacement in both types of ring is to that side from which the numbering (see formula (*1*)) appears anticlockwise. The torsional angles of the rings are listed in Table 1.

Table 1. Torsional angles [ ] in the rings (*1*) in the complex [(*1*)·$NaClO_4$]; standard deviation ≈ 0.8 .

Ring 1		Ring 2	
O(1)—C(2)—C(3)—C(4)	−40.0	O(1')—C(2')—C(3')—C(4')	−40.0
C(2)—C(3)—C(4)—C(5)	35.1	C(2')—C(3')—C(4')—C(5')	33.0
C(3)—C(4)—C(5)—O(1)	−17.7	C(3')—C(4')—C(5')—C(1')	−15.6
C(4)—C(5)—O(1)—C(2)	− 6.5	C(4')—C(5')—O(1')—C(2')	− 9.0
C(5)—O(1)—C(2)—C(3)	28.9	C(5')—O(1')—C(2')—C(3')	30.4
O(6)—C(3)—C(4)—O(7)	41.0	O(6')—C(3')—C(4')—O(7')	40.1

Normal values were found for Na—O separations, which lie in the ranges 2.32—2.59 Å ($OClO_3$), 2.29—2.32 Å (OH), and 2.35—2.36 Å (etheric oxygens). These Na—O distances are smaller than the Na—O (ether) distances found in the complexes of "dibenzo[18]crown-6" with NaBr[6], but similar to those found in the "benzo[15]crown-5"-sodium iodide complex[7].

Stabilization of the Pentacoordination of Phosphorus by Tridentate Ligands[**]

By *Dieter Hellwinkel* and *Wolfgang Krapp*[*]

In general the stabilities of derivatives of pentacoordinated phosphorus increase in the following order: acyclic < monocyclic < spirocyclic[1]. Some phosphoranes with tridentate ligands have recently also been reported and some of these have notable stability[2]. A few years ago we began systematic studies with the object of developing tridentate ligand systems that would also constrain phosphoranes to assume unusual geometries[3]. We now report a type of tridentate ligand that is optimally suited to the trigonal-bipyramidal structures preferred by such compounds[4].

For this purpose we first synthesized 1-bromo-2,6-bis(hydroxymethyl)benzene [2-bromo-*m*-phenylenedimethanol] which can, after double etherification with dihydropyran, be converted smoothly into the 1-lithium derivative. Reaction of this derivative with diphenylchlorophosphane afforded diphenyl[2,6-bis(tetrahydro-2-pyranyloxymethyl)phenyl]-phosphane (*1*), which yielded the phosphorane (*4*) even in attempts merely to remove the tetrahydropyranyl protecting groups (THP) by acid transacetalization in boiling ethanol. This is reasonable only if spontaneous atmospheric oxidation of the phosphane (*1*) is assumed to have occurred. In fact the phosphane oxide (*3*) obtainable from the phosphane (*1*)

[*] Prof. Dr. D. Hellwinkel and Dipl.-Chem. W. Krapp

by means of H_2O_2 is readily converted into 8,8-diphenyl-2*H*,6*H*-1,2-oxaphospholo[4,3,2-*hi*][2,1]benzoxaphosphole *(4)* by HCl. *(4)* is obtained more simply and directly from *(1)* by reaction with 2 equivalents of bromine. The unprotected hydroxylic phosphane oxide *(2)* that is formed on oxidation of *(1)* by H_2O_2 in acid solution can be transformed almost quantitatively into the phosphorane *(4)* by heating it for a short time at *ca.* 200 °C, in complete accord with the facts that the mass spectrum of *(2)* is dominated by the $(M-18)^+$ fragment and that *(2)* melts with evolution of gas.

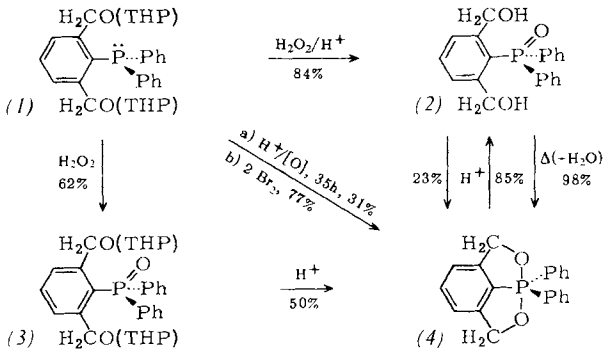

Table 1. Physical properties of the phosphorane *(4)*.

M. p. [°C]	$\delta^{31}P$ [ppm]	$\delta(H_2COP)$	$^3J(H_2COP)$ [Hz]	$^4J(H_2CCCH)$	ν(P—O) [cm^{-1}]	MS *m/e*, *I*
131.4	+22.9	5.02	2.8	0.6	1025 1045	320, 88% 319, 100%

To our knowledge, this is the first case in which a (tetrahedral) triarylphosphane oxide has been "acetalized" by simple loss of water to a (trigonal-bipyramidal) dialkoxytriarylphosphorane[5]. Our studies have also revealed the astonishing thermal stability of the phosphorane *(4)*: the compound survives heating for several hours above 200 °C and sublimes without decomposition even under atmospheric pressure. This unusual stability accords with theoretical views on the possible modes of fragmentation of derivatives of pentacoordinated phosphorus[6]: according to orbital-symmetry considerations only axial-axial and equatorial-equatorial fragmentations (or rearrangements) are thermally allowed[7]; in the case of *(4)*, however, both processes would lead to thermodynamically unfavorable products, namely to an enormously strained peroxide[8] or to a cyclic phosphonous ester with "T"-geometry in addition to biphenyl.

The ligand system that has been so successful in stabilizing the coordination number 5 for phosphorus could also be useful for preparation of hypervalent[9] species of other main-group elements.

Structure of the 1:1-Adduct of Hexafluoroacetone Azine and 4-Ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane

By *Alfred Gieren* and *Poojappan Narayanan*[*], together with *Klaus Burger* and *Willy Thenn*[**]

1,2λ^5-Azaphosphiridine structures *(3)* were recently proposed for the 1:1-adducts formed on reaction of hexafluoroacetone azine *(1)* with phosphites and with tris(dimethylamino)phosphane[1]. An X-ray structure analysis of the 1:1-adduct obtained by the same process from *(1)* and 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane *(2)*[2] shows the structure of a 4-ethyl-1-[5,5,5-trifluoro-2,2,4-tris(trifluoromethyl)-1,3-diaza-3-pentenylidene]-2,6,7-trioxa-1λ^5-phosphabicyclo-[2.2.2]octane *(4)*. The previous compounds[1] are therefore not azaphosphiridines *(3)* but iminophosphoranes of type *(4)*.

The structure analysis was carried out with orthorhombic single crystals of *(4)* obtained from hexane solution: space group $Pna2_1$ or Pnam; $a = 12.19_8$, $b = 15.34_8$, $c = 10.00_0$ Å;

$d_{obs} = 1.71$, $d_{calc} = 1.73\ g \cdot cm^{-3}$; $Z = 4$ (one or half a molecule per asymmetric unit). It is difficult to distinguish between $Pna2_1$ (acentric) and Pnam (centrosymmetric) (see below) because the molecule contains a mirror or pseudomirror plane, whose orientation coincides with the crystallographic mirror

[*] Dr. A. Gieren and Dipl.-Phys. P. Narayanan
Max-Planck-Institut für Biochemie, Abteilung Strukturforschung I

plane in Pnam. 1696 independent reflections were measured with $Cu_{K\alpha}$-radiation up to a Θ value of 65° on an automatic single-crystal diffractometer; two crystals were used for these measurements because the substance decomposed. The intensities of 868 reflections lay below the significance limit ($I \leqslant 2\sigma_I$), which indicates an unusually high temperature factor (mean value for all atoms 15 Å^2) or disorder of molecules in the crystal.

Since the *E*-value statistics indicated an acentric space group we first assumed the space group $Pna2_1$. The structure was solved by direct methods by using the PHASDT program[3]. The solution with the best consistency gave phases for 211 reflections. An *E*-Fourier synthesis calculated therefrom showed the positions of all the atoms (other than H) except the terminal carbon of the C_2H_5 group. This C atom (temperature factor 19 Å^2) was only localized after introduction of anisotropic temperature factors at $R = 14.0\%$ in a difference Fourier synthesis. On refinement by the method of least squares (ORFLS program)[4] the strong parameter correlations caused by the pseudomirror plane led to convergence difficulties, but these were overcome on use of isotropic temperature factors first by alternate refinement of the scaling factor on the one hand and of the remaining parameters on the other and then by splitting into three overlapping partial cycles. Owing to the large number of parameters, the refinement with anisotropic temperature factors was carried out in cycles made up of two overlapping partial cycles. In that work a shift limitation (0.6) proved useful. The *R* factor amounts to 9.0% (observed reflections).

In parallel work the structure was also refined for the centrosymmetric space group Pnam. Here convergence set in at $R = 12.6\%$. The Hamilton test[5] indicated relevance of the *R*-factor difference on refinement in the alternative space groups and thus favored $Pna2_1$. The calculated difference Fourier syntheses for the two space groups and comparison of the temperature factors also favored this space group.

Figure 1 shows the molecular structure after refinement in $Pna2_1$. The significance of the bond lengths suffices for distinction between single and double bonds, but the dispersion of atomic distances and bond angles does not justify detailed discussion, which will therefore not be undertaken here.

The preference for the acentric space group indicates a somewhat staggered conformation for the 2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane system. However, even if the centrosymmetric space group is assumed the staggered conformation is more probable (statistical disorder?) than a fully eclipsed conformation which was published for the same system in $OP(OCH_2)_3CCH_3$[6]. The two conformations were also found for the bicyclo[2.2.2]octane system[7].

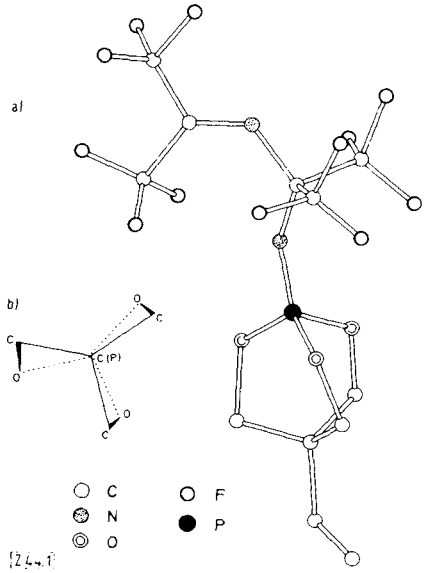

Fig. 1. a) Molecular structure of 4-ethyl-1-[5,5,5-trifluoro-2,2,4-tris(trifluoromethyl-1,3-diaza-3-pentenylidene]-2,6,7-trioxa-1λ^5-phosphabicyclo[2.2.2]-octane (4). b) Conformation of the 2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane system.

Structure and Spin Multiplicity of a [4]Annulene System[1]

By *Günther Lauer, Claus Müller, Karl-Wilhelm Schulte, Armin Schweig*, and *Adolf Krebs*[*]

We have obtained the photoelectron (PE) spectrum (Fig. 1; measured at 110°C) of the cyclobutadiene derivative *(1)*[2]. The assignment of the first two bands follows from the relative intensity (①:② = 1.2:2), shape, and location [for compari-

(1) *(2)* *(3)*

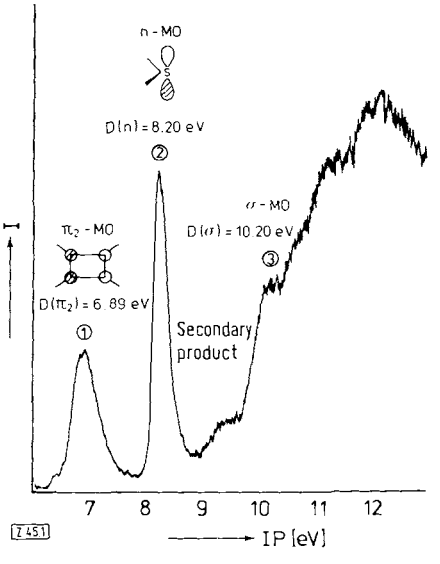

Fig. 1. Photoelectron spectrum of *(1)* with interpretation.

son: 8.19 eV in *(2)* and 8.23 eV in *(3)*] of the band ②. Band ③ is assigned in accord with CNDO/S and MINDO/2 calculations and with the results of a semiempirical LCMO consideration (cf. 1. below) to a σ-ionization.

As a result of our findings some fundamental questions can now be answered concerning the structure (see 1. and 2. below) and spin multiplicity (see 3. and 4. below) of this [4]annulene system:

1. *Unlike the donor-acceptor-substituted cyclobutadienes*[4], *(1) possesses a cyclic-conjugated π-system.* This conclusion is reached by the LCMO method, according to which π_2 is considered as an antibonding and π_1 as a bonding linear combination of two localized olefin-π-basis MO's. The interaction of the two π-basis MO's in *(1)* follows from the measured[5] MO energies [$\pi_2 = -6.89$ eV in *(1)* and $\pi = -9.01$ in *(3)*], which give $H_{\pi\pi} = -2.12$ eV. With $0.72 H_{\pi\pi} = 2c^2\beta_{\pi\pi}$ ($c = 0.7$, where c denotes the $2p_\pi$ AO coefficient in the basis MO and the factor 0.72 takes account of the fact that only 72%[6] of the measured interaction occurs across the newly formed bonds), the resonance integral of the newly formed π-bond results as $\beta_{\pi\pi} = -1.6$ eV (for comparison: $\beta_{\pi\pi}$ of the central C—C bond in butadiene $= -2.4$ eV[7], $\beta_{\pi\pi}$ of an aromatic C—C bond $= -3.0 \pm 0.2$ eV[4]). We therefore expect the π_1 ionization at $9.01 + 2.12 = 11.1$ eV[8]. The energy-rich π_2 MO explains the good donor properties of tetraalkyl-substituted cyclobutadienes[9].

2. *Contrary to a previous hypothesis*[10], *(1) contains a* [4]*annulene system that is not influenced by the sulfur atoms.* This follows from the good agreement between the *n*-sulfur ionizations in *(1)* to *(3)* and the exclusion of transannular *n*/π interactions in *(2)*[3].

3. *(1) exists in the singlet molecular ground state.* This result follows from comparison of the measured ion energies of *(1)* (cf. Fig. 1) with the calculated[11] ion energies on ionization of the cyclobutadiene singlet(S) ground state S_0 on the one hand and of the cyclobutadiene triplet(T) ground state T_0 on the other (Fig. 2).

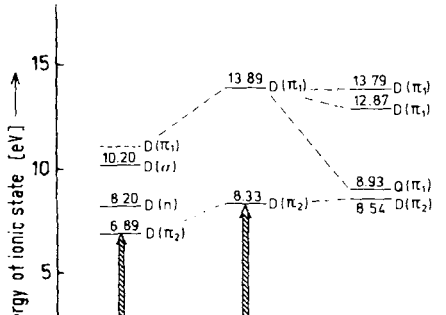

Fig. 2. Ion energies measured for *(1)* and calculated for rectangular (1.495 Å/1.319 Å [12]) singlet(S) and square (1.425 Å [12]) triplet(T) cyclobutadiene relative to the molecular ground state energies. That the $D(\pi_2)$ energy of *(1)* is lower than that of cyclobutadiene (≈ 1.5 eV) is a result of the alkyl-substitution.

For T-cyclobutadiene *two* π-ionizations, corresponding to the doublet(D) and quadruplet(Q) ion states $D(\pi_2)$ and $Q(\pi_1)$, are to be expected in the region of lower ionization potential. Experimentally, only *one* π-ionization [band ①, corresponding to the doublet ion state $D(\pi_2)$] is found in this region, as is to be expected for S-cyclobutadiene. Accordingly *(1)* exists in the singlet molecular ground state. Thus for unsubstituted cyclobutadiene also, PE spectroscopy should be the most suitable method for clarification of the multiplicity problem.

4. *The Triplet state T_0 of (1) is not detectably populated alongside the singlet state S_0 at 110 °C.* This result follows from the absence of a shoulder, corresponding to the $Q(\pi_1)$ ion state, on the flank of higher ionization potentials of band ①.

According to our findings, *(1)* possesses a true alkylated rectangular [4]annulene π-system in the electronic singlet ground state.

[6] The remaining 28% of the measured interaction occurs between the $2p_\pi$ AOs which are located opposite to each other across the diagonals of the cyclobutadiene ring. The calculations which are based on the CNDO/S [11] approximation yielded (for rectangular cyclobutadiene, 1.319 Å/1.495 Å, and F = SCF operator): $\langle\pi|F|\pi\rangle = -3.0$ eV, $\langle 2p_\pi|F|2p_\pi\rangle_{bond} = -2.1$ eV and $\langle 2p_\pi|F|2p_\pi\rangle_{diagonal} = -0.8$ eV. The percentages of the calculated interaction are much independent on the specific choice of the rectangular geometry.

A New Mononuclear Metallo Complex with an Inhomogeneous Second Sphere in Bis(iodomercurio)hydroxomercuriooxonium Perchlorate, $[O(HgI)_2HgOH]ClO_4$[**]

By *Klaus Köhler, Gerhard Thiele*, and *Dietrich Breitinger*[*]

As a part of our studies on mercurioiodonium derivatives[1, 2] we have solved the structure of the compound formulated by *Hayek*[3] as $[Hg(HgI_2)_2](ClO_4)_2$ by X-ray analysis.

This intensely yellow compound crystallizes as trapezoid platelets from solutions of HgO and HgI_2 in 20% $HClO_4$. The crystallographic data were determined using an automatic four-circle diffractometer (Hilger-Watts, Type Y 290; $Mo_{K\alpha}$ radiation, graphite monochromator)[4] [unit cell: $a = 1047.9(4)$, $b = 1302.2(1.1)$, $c = 754.5(5)$ pm; $\beta = 90.31(3)^\circ \triangleq 1.576(1)$ rad; space group $C_{2h}^5 - P2_1/n$; $Z = 4$; $d_{X\text{-ray}} = 6.31$, $d_{pyk} = 6.25$ g cm^{-3}]. The structure was determined from 1135 independent reflections using three-dimensional Fourier methods ($R = 0.062$ after empirical correction for absorption)[2]. This model indicates that the *Hayek*[3] formulation is erroneous, and, in fact,

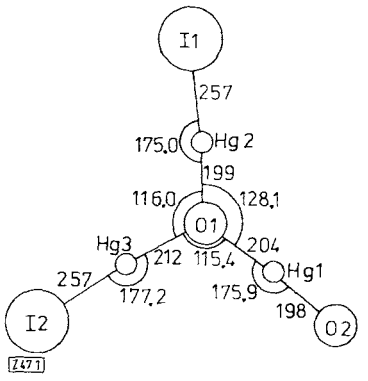

Fig. 1. Structure of the cation $[O(HgI)_2HgOH]^+$; bond lengths [pm] and bond angles [°].

planar bis(iodomercurio)hydroxomercuriooxonium ions $[O(HgI)_2HgOH]^+$ (Fig. 1) and ClO_4^- ions occur in the lattice. To our knowledge this is the first example of a mononuclear metallo complex with an inhomogeneous second sphere to be discovered.

Deviations of the heavy atom skeleton from C_{2v} symmetry are due to varyingly strong additional interactions between ClO_4^- ions and the Hg atoms of the cation; intermolecular contacts perturbing the symmetry also exist between I and Hg atoms.

The mean distance between three-coordinate oxygen and mercury $\bar{R}$(O—Hg) = 205 pm agrees with the bond lengths in $[O(HgCl)_3]^+$ (R(O—Hg) = 205 pm)[5]. The two equal bond lengths R(Hg—I) = 257 pm are significantly shorter than the corresponding values in the yellow modification of HgI_2 (R(Hg—I) = 261 pm)[6]. This effect is attributable to the formal positive charge on the central oxygen atom. Similar short bond lengths between Hg(1) and the hydroxy-oxygen O(2) (R(Hg—O) = 198(3) pm; Fig. 1) are known only for Na_2HgO_2 (R(Hg—O) = 196 pm; standard deviation not reported)[7].

The occurrence of a hydroxyl group, whose proton could not be localized by X-ray study, and which is coordinated in such an unusual way to mercury, and also the formation of weak hydrogen bonds to ClO_4^- ions, were shown by vibrational spectrometry. Vibrational spectra of the isotypic tetrafluoroborate, $[O(HgI)_2HgOH]BF_4$, prepared analogously, show that the hydrogen bonds between the complex cations and the anions are even weaker in the latter, although the spectra are otherwise in full agreement.

Improved Preparation of Monosodium Cyanamide

By *Stefan Weiss* and *Helmut Krommer*[*]

According to an almost hundred years old process, monosodium cyanamide (sodium hydrogencyanamide) *(1)* which is of interest as a starting material for syntheses can be obtained by treating cyanamide with sodium ethanolate in anhydrous ethanol[1]. In a search for an industrially useful method of preparation we have found that cyanamide reacts smoothly at room temperature with sodium hydroxide in an alcoholic suspension, yielding exclusively *(1)* if the reaction medium is an aliphatic alcohol containing three to five C atoms[2]. It is particulary significant that this method affords *pure* monosodium cyanamide in *quantitative yield.*

$$H_2N\text{-}CN + NaOH \xrightarrow{C_3\text{- to }C_5\text{- alkanol}} Na[HN\text{-}C{\equiv}N] + H_2O$$
(1)

Experimental:

Finely powdered sodium hydroxide (80.0 g, 2.00 mol) is added with vigorous stirring to a solution of cyanamide (84.1 g, 2.00 mol) in 2-propanol (500 ml) while the temperature is kept at 25 °C by cooling. After *ca.* 3 h a colorless, loose powder, sensitive to moisture, can be isolated by filtration and drying in a vacuum (40—50 °C): 127 g (99 %) of pure *(1)*, characterized by elemental analysis and argentometric cyanamide determination.

Efficient Synthesis of Sugar 3,2-Enolones[1] from 2-Hydroxyglycals and Their Conversion into 4-Pyrones

By *Eleonore Fischer* and *Frieder W. Lichtenthaler*[*]

Although previously[2] formulated as hypothetical intermediates in the long known conversion of acylated 2-alduloses into kojic acid derivatives[3], sugar 3,2-enolones[1] of type *(2)* have hitherto been obtained only from hexoses in the form of 1-*O*-methyl derivatives[4], and then always by oxidation of difficultly accessible, partially acylated hexosides with subsequent β-elimination. We now describe an efficient synthesis of 1-acylated 3,2-enolones from 2-hydroxyglycal esters *(1)* → *(2)*, which is applicable to hexoses, deoxyhexoses, and pentoses and *via* the 1-halo compounds, also provides ready access to the 1-alkoxy derivatives.

(1) *(2)*

The chlorides *(4)*[6] which are the primary addition products of chlorine[5] to the perbenzoyl-2-hydroxyglycals *(3a)—(3c)* are stable only at low temperature and are extremely sensitive to hydrolysis. In the presence of water the tetrabenzoyl-2-aldosulose *(6a)* or the tribenzoyl derivatives *(6b)* and *(6c)* are obtained, a finding which is readily interpreted by formation of the partially esterified orthoacid derivatives *(5)* and their decomposition. If, however, a benzene solution of *(4)* is heated for a short time in the presence of an acid-acceptor (*e.g.* aqueous $NaHCO_3$), hydrolysis to *(6)* is accompanied by elimination of benzoic acid with formation of the 3,2-enolones *(7a)—(7c)* in yields of 50—60 % [based on *(3a)—(3c)*] (see Table 1).

Subsequent reactions of these benzoyl enolones were investigated mainly for the hexose derivative *(7a)*. With HCl/acetyl

(10)-DNP	*(10)*	68	209–211	– 134	4.36	3.65 (d, 4)

[a] DNP denotes the 2,4-dinitrophenylhydrazone of the corresponding compounds.
[b] In $CHCl_3$.
[c] Coincident with the aromatic protons.

chloride or HBr/glacial acetic acid, *(7a)* underwent smooth exchange of the 1-benzoyloxy group and formation of the α-halo derivatives *(8)* and *(9)* respectively, from which the β-alkyl glycosides *(10)* and *(11)* are accessible in good yield by short heating in an alcohol (see Table 1). At room temperature the enolones *(7a)* and *(10)* and the aldosulose *(6a)* smoothly give 2,4-dinitrophenylhydrazones. However, on heating with, *e.g.*, phenylhydrazine in acetic acid solution for a short time, hydrolysis of the 1-substituent occurs. As a result the aldehyde group participates in the reaction with formation of the same phenylosazone of m.p. 190 °C that is also obtained analogously from the enolones *(8)*, *(9)*, and *(11)* and is assigned structure *(12)* on the basis of these and spectroscopic data. In contrast to *(12a)*, whose rotation ($[\alpha]_D^{20} = -45°$ in pyridine) indicates considerable resistance to racemization of the one remaining center of chirality, the phenylosazone *(12c)*, m.p. 161—163 °C, prepared analogously from the pentose enolone *(7c)*, is optically inactive, as expected.

Not unexpectedly, in view of similar conversions[4b, 7], the enolones *(7)*—*(11)* show a marked tendency to form the 4-pyrone system, a fact which supports previous mechanistic concepts[2]. Thus, when heated for a short time with sodium acetate in glacial acetic acid, the hexose derivatives *(6a)*, *(7a)*, and *(8)*—*(11)* afford dibenzoylkojic acid *(13a)* in yields exceeding 80%, whilst equally smoothly 5-*O*-benzoylallomaltol *(13b)*[8] is obtained from *(7b)*, and the 3-*O*-benzoate of pyromeconic acid, *(13c)*, m.p. 153 °C[9], from the pentose enolone *(7c)*. In aqueous acid or alkali (*e.g.* 50% trifluoroacetic acid or 2 N NaOH) the free 4-pyrone *(13)*, H in place of Bz, is formed.

The structures and configurations of the compounds prepared were proved by NMR spectroscopic and rotatory findings as well as by combustion-analytical data. The β-configuration of *(10)* followed unambiguously from non-identity with the α-anomer which has clearly different physical data[4d] and affords a 2,4-dinitrophenylhydrazone of m.p. 233—234 °C, $[\alpha]_D^{20} = +390°$ ($c = 0.1$, $CHCl_3$). The dinitrophenylhydrazone of *(7a)* shows a correspondingly high positive rotation, whence also the α-configuration can be assigned, and the same configuration follows from the differing 4-H/5-H coupling constants which for the α-anomers always amount to 2 Hz as a result of the H_1^0 conformation, which is notably less than that (3.5 Hz) for the β-anomers *(10)* and *(11)* existing in the H_0^1 conformation. The α-configuration of the aldosuloses *(6a)* and *(6b)* is indicated both by the high positive rotation of *(6a)* and in particular by the chiroptical findings, which can be interpreted on the basis of the exciton chirality rule for enones[10]. Since, however, β-anomers are to be expected on decomposition of the intermediate orthoacid, the loss of HCl from *(5)* must be accompanied by C-1 epimerization—not unusual under in these conditions—leading to the more stable α-anomer.

[5] Addition of chlorine has been studied previously for the case of *(3a)* [3b]. A product which, from its m.p. and rotation, is clearly identical with *(7a)* was, however, assigned the structure of a 2,3,4,6-tetra-*O*-benzoyl-D-glucose 1,2-epoxide (I), and structure (II) was assigned to the 1-halo compounds *(8)* and *(9)* formed by addition of HX thereto [3c]. Hence the preparation of compounds of type (I) and (II) has not yet been accomplished.

1,2-Dichlorides from 2-Hydroxyglycals: Preparation and Assignment of Configuration by the Exciton Chirality Method

By *Frieder W. Lichtenthaler* and *Eleonore Fischer*[*]

Six isomers require discussion for the chlorine-addition products of peracyl-2-hydroxyglycals *(1)*, namely the 1,2-dichlorides with the *manno/lyxo-* *(6)/(7)* or the C-2 epimeric *gluco/xylo*-configuration and the 2,2-dichloro compounds *(5)* in α- and β-form conceivably obtainable by way of 1,2-acyloxonium chloride intermediates. Hitherto it has not been possible to decide unambiguously between these possibilities although this reaction has been much investigated because the chlorine adducts can be hydrolyzed to 2-uloses[1] and some crystalline dichlorides have been characterized[2]. By synthesis of two hexose, 6-deoxyhexose and pentose dichlorides each from the perbenzoyl-2-hydroxyglycals *(1a)—(1c)*, and by the first application of the exciton chirality method[3] to determination of the configuration at a tertiary carbon atom, we have now succeeded in unequivocally assigning structures and configurations to the products and thus in elucidating the steric course of the reaction.

Chlorination of *(1a)—(1c)* in benzene or toluene (5—10 min at 25 °C) gives in each case a pair of dichlorides *(6a)—(6c)* or *(7a)—(7c)* in 1:1 to 3:1 mixtures; these products can be separated without difficulty and unambiguously characterized (cf. Table 1). They are remarkably inert, as is shown by their stability to water, silver carbonate/acetone, silver perchlorate/methanol in the cold, and towards heating with aqueous sodium hydrogen carbonate in benzene.

Compounds containing geminal chlorine substituents can be unambiguously excluded because of the non-identity of *(6a)*

(1) *(2)* *(3)*

(5), R' = Bz

(a), R = CH_2OBz; *(b)*, R = CH_3; *(c)*, R = H

and *(7a)* with the α- and β-tetrabenzoates obtained by benzoylation of 2,2-dichloro-D-arabinohexose *(4)*[4] (cf. Table 1), as well as by mass-spectrometric findings. Since one of the principal modes of fragmentation begins with excision of the C-1 substituent, *(6a)—(6c)* and *(7a)—(7c)* always show (M − 35) mass lines with the isotopic ratio 3:1 (loss of chloride), while the two anomers *(5)* always show a (M − 121) mass line with the isotopic ratio 3:2 owing to loss of the 1-benzoyloxy group.

That the products thus formulated as 1,2-dichlorides are in each case pairs of anomers, *i.e.* have the same stereochemistry at C-2, can be most clearly demonstrated by the reactions occurring on short heating with $TiCl_4$ in chloroform. In the

Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Schlossgartenstrasse 2 (Germany)

case of the 1,2-dichlorohexoses only one of the two isomers is converted into the other, and then quantitatively—specifically *(7a)*→*(6a)* and *(7b)*→*(6b)*. This behavior can be interpreted only as a β→α anomerization[5], the initial compound having the β-configuration, while the α-configuration is to be assigned to the non-anomerizable isomer.

In accord with the above are the distinct differences in position of the 1-H signals: α-anomers *(6a)* and *(6b)* (1-H equatorial): $\tau < 2.6$; β-anomers *(7a)* and *(7b)* (1-H axial): $\tau = 3.02$ or 3.05, respectively. For the two 1,2-dichloropentoses—each isomer affords a 1:1 mixture *(6c)*⇌*(7c)* when heated with $TiCl_4$ in chloroform—the configuration at C-1 is assigned mainly on the basis of NMR data. As can be derived unambiguously from the splitting mode of the ring-CH, *(6c)* exists in the C1 conformation. From the significant correspondence of the position of the 1-H signal with those of *(6a)* and *(6b)* ($\tau < 2.6$ in each case) their equatorial orientation can be assumed and thus the α-configuration. For *(7c)*, however, long range coupling constants $J_{1,3} = 1.5$ and $J_{3,5e} = 1.0$ Hz are observed and indicate W orientation, proving the 1C conformation [cf. formula *(7c)*, Fig. 1]. This indirectly establishes the β-configuration, because only in β-anomers are the steric and energetic conditions present that permit the dipole-dipole interactions—unfavorable on the C1 form—between equatorial C-1 substituents and ring-oxygen to be compensated by transformation into the 1C conformation.

A decision between the *manno/lyxo*- and *gluco/xylo*-configuration for the anomeric pairs can be made on the basis of the chiroptical properties[6]. In its CD spectrum 2,3,4-tri-*O*-benzoyl-α-L-rhamnopyranosyl bromide *(8)* shows, as expected[3], two Cotton effects with opposite signs, the first of which ($\Delta\varepsilon_{234} = +44.6$) accords with the positive chirality of the benzoate chromophores on C-2, C-3, and C-4 (Fig. 1, A). On the contrary, the α-anomers *(6a)*—*(6c)* afford CD curves that are mirror images of that for *(8)* (Fig. 1 and Table 1), whence it can be concluded that they have the all-negative chiral arrangement of the benzoyloxy groups (Fig. 1C), *i.e.* *(6a)* and *(6b)* D-*manno*, and *(6c)* D-*lyxo*[7]. Due to their ready anomerization, *(7a)*—*(7c)* are to be regarded as β-anomers (cf. above), which is confirmed by the CD data—negative sign of the first Cotton effect that specifies the chirality. The effect, however, is much weaker than for the α-anomers, for example, by a factor of 3 for the hexoses, indicating considerable distortion of the C1 chair conformation towards the B1 boat form[8]. For the pentose derivatives *(6c)* and *(7c)*, however, the intensities of the first Cotton effects differ by a power of ten, this being in agreement with the fact that the total chirality derivable from the 1C conformation of *(7c)* is only very small since the rotational contributions from the interacting chromophores largely compensate each other (Fig. 1, B).

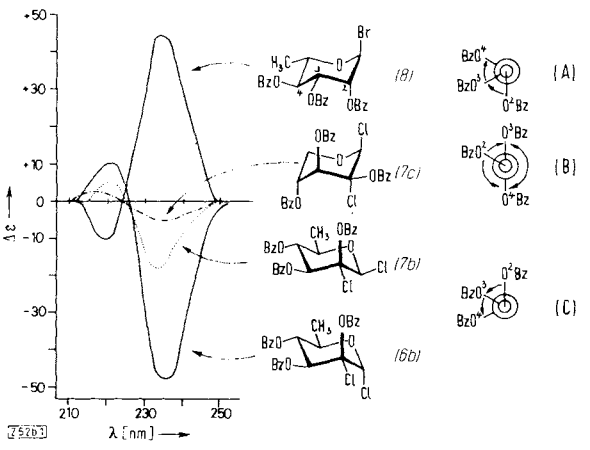

Fig. 1. CD spectra in isooctane of tri-*O*-benzoyl derivatives of α-L-rhamnopyranosyl bromide *(8)*, 2-chloro-β-D-lyxopyranosyl chloride *(7c)*, and of the anomers of 2-chloro-D-rhamnopyranosyl chloride *(6b)* and *(7b)*. The chirality directions of the benzoate chromophores on C-2 to C-4 are shown schematically by the modified Newman projections, (A), (B), and (C).

The stereospecificity of the addition of chlorine at C-2 of the 2-hydroxyglycal ester *(1)* is surprisingly exclusive; it is clearly the result of the anomeric effect on the carbon atom next to the anomeric center. It is doubtless the (in apolar solvents) unfavorable dipole-dipole interactions between the two C—O bonds of the ring-oxygen and a chlorine atom attacking from above that permits only the alternative attack by the electrophile *(1)*→*(2)* in which the electrostatic interations are reduced to a minimum [cf. dipole directions in *(2)*]. Then the dichlorides are formed from the ion pair *(2)*⇌*(3)* by combination with the gegenion; in the presence of water, however, perbenzoyl-2-aldosuloses are formed by hydrolysis[1b].

[7] For the C-2 epimers with *gluco*- or *xylo*-configuration at most a small Cotton effect is to be expected, and then probably [3] only one split into a doublet, for the chiralities between the 2,3- and the 3,4-benzoyloxy groups cancel and interaction between the 2,4-benzoyloxy groups does not contribute.

[8] The intensity is always 30% less for the anomer pair *(6a)*/*(7a)* than for *(6b)*/*(7b)*: this may be ascribed to the positive chirality contribution of the 6-benzoyloxy group which is preferably oriented *gauche* to the C-4 substituents and to the ring oxygen atom.

A Palladium(II) Complex as Hydrogenase Model

By *G. Henrici-Olivé* and *S. Olivé*[*]

A variety of microorganisms activate molecular hydrogen. This ability is ascribed to enzymes named hydrogenases which, in most cases, contain a transition metal center (iron)[1]. We wish to report on a synthetic catalyst, [2,2'-ethylenebis(nitrilomethylidine)diphenolato]palladium(II) (Pd-Salen) which, in several respects, behaves in the same way as a hydrogenase, and which therefore is considered as a suitable model.

Pd-Salen

The catalyst is prepared by reacting $Pd(NO_3)_2 \cdot 2H_2O$ with 2,2'-ethylenebis(nitrilomethylidine)diphenol (Salen) in meth-

[*] Dr. G. Henrici-Olivé and Prof. Dr. S. Olivé

anol. The complex precipitates; after washing with methanol it is analytically pure. It is very poorly soluble in alcohol and in most organic solvents, but fairly soluble in DMF or pyridine. Solutions in either of these two solvents as well as suspensions of the complex in ethanol activate molecular hydrogen.

The hydrogenation of 1-hexene has been studied in DMF solution. The dependence of the reaction rate r_H on the catalyst concentration, [Cat], in the range 3×10^{-3} to 13×10^{-3} mol/l; on the 1-hexene concentration, [Olefin], in the range 0.03 to 0.3 mol/l; and on the hydrogen pressure, P_{H_2}, in the range 50 to 500 torr, is given by eq. (1) to (3):

$$r_H \sim [\mathrm{Cat}]_0 \quad (1)$$

$$1/r_H = a + b/[\mathrm{Olefin}] \quad (2)$$

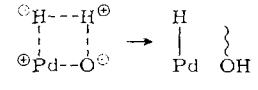
$$1/r_H = a' + b'/P_{H_2} \quad (3)$$

Rate laws of essentially the same type have been reported by *Kleiner* and *Burris*[2] for the hydrogenation of methyl viologen[**] with hydrogenase extracts from *Clostridium pasteurianum*.

The rate of hydrogenation with Pd-Salen goes through a maximum in slightly alkaline solution. *Tamiya* and *Miller*[3] observed a comparable pH dependence of the activity with hydrogenase.

In C_2H_5OD, Pd-Salen catalyzes the formation of HD from H_2. The same observation with hydrogenase was interpreted by a heterolytic splitting of H_2 by the enzyme (E)[1]:

$$E + H_2 \rightleftarrows EH^{\ominus} + H^{\oplus}$$



The proton is assumed to be taken up by a nonidentified "basic site" within the enzyme, where it may readily be exchanged with $D^{\oplus}$ before the backward reaction takes place. A substrate (S) is hydrogenated thus:

$$EH^{\ominus} + H^{\oplus} + S \rightarrow E + SH_2$$

We suggest an analogous mechanism for our synthetic catalyst which, however, includes a definition of the "basic site".

In Pd-Salen, the Pd center is surrounded by two nitrogen and two oxygen atoms of the planar chelating ligand, which occupy the equatorial positions. In the solid state, one of the axial positions of each surface Pd-Salen unit is occupied by the next lower unit (presumably Pd—Pd interaction). A fifth ligand appears to be necessary also in solution, since activity is observed only in coordinating basic solvents (DMF, pyridine). This leaves only one site free for coordination. The hydrogenation process, however, requires at least two vicinal sites, one for the hydrogen molecule and one for the olefin. Hence we have to assume that one or more ligands are removed from the metal in the course of the process.

The first step is presumably the coordination of a hydrogen molecule at the free site. Subsequent heterolytic splitting of the H_2 molecule probably involves a highly polarized four-center transition state; the proton is transferred to one of the oxygen anions of the chelating ligand giving a phenol group which does not occupy a coordination site at the metal.

At this stage H—D exchange between the OH group and C_2H_5OD may easily be visualized.

The new free equatorial coordination site can accommodate an olefin molecule, which is subsequently bound as an alkyl group (Alkyl-Cat-$H^{\oplus}$) by insertion into the Pd—H bond. In an intramolecular process, the proton of the phenol OH group is transferred to the alkyl giving the alkane. The original Pd-Salen complex is reformed after the alkane has left the center:

$$\mathrm{Cat} + H_2 \overset{K_1}{\rightleftarrows} H^{\ominus}\text{—Cat—}H^{\oplus}$$

$$H^{\ominus}\text{—Cat—}H^{\oplus} + \mathrm{Olefin} \overset{K_2}{\rightleftarrows} \mathrm{Alkyl—Cat—}H^{\oplus}$$

$$\mathrm{Alkyl—Cat—}H^{\oplus} \overset{k}{\rightarrow} \mathrm{Cat} + \mathrm{Alkane}$$

The rate law following from this scheme

$$r_H = \frac{k K_2 K_1 [H_2][\mathrm{Olefin}]_0[\mathrm{Cat}]_0}{1 + K_1[H_2] + K_1 K_2 [H_2][\mathrm{Olefin}]_0}$$

is in perfect agreement with the results of the kinetic measurements [eq. (1) to (3)]. The suggested mechanism is further corroborated by the finding that hydrogenation and H—D exchange occur at comparable rates (of the order of 10^{-3} mol of substrate l^{-1} s^{-1} based on 1 mol of Pd-Salen, at $P_{H_2} = 720$ torr).

The diacetyldioxime complexes of Pd and of Ni show the same behavior as Pd-Salen. Since square-planar chelating ligands are relatively frequent in Nature, we suggest that enzymes containing transition metal ions, such as certain hydrogenases, nitrogenases, *etc.* may well function according to a similar mechanism, where the "basic site" is just one anion of a chelating ligand, *e.g.* $S^{\ominus}$, $O^{\ominus}$, $COO^{\ominus}$, or $N^{\ominus}$. The catalytic process would then be characterized by a sequence of availability and non-availability of coordination sites.

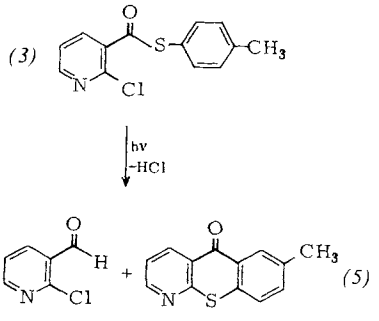
2- and 4-Azathioxanthones by Photorearrangement of *S*-Aryl Thionicotinates[1][**]

By *Gerd Buchholz*, *Jürgen Martens*, and *Klaus Praefcke*[*]

S-Aryl esters of aromatic thiocarboxylic acids containing —I substituents (*e.g.* $CH_3—SO_2—$[2] or $CH_3—SO—$[3]) in the *ortho* position afford thioxanthones on "nucleophilic" photorearrangement[2,3]. No thioxanthone is formed in absence of the acceptor substituent[4].

We have now found that the positive charge on the *o*-C atom required for the photorearrangement can also be induced

(1) *(2)*



by an N atom in the ring. Irradiation[5] of *S*-*p*-tolyl thionicotinate *(1)*[6] affords a mixture of products, from which 25% of di-*p*-tolyl disulfide, 17% of *(1)* and 44% of 7-methyl-2-aza-

thioxanthone *(2)*[7] can be isolated successively on column chromatography (residue: indefinite polymer).

On irradiation[5] of *(3)*[8,9] there are formed the hitherto unknown 2-chloro-3-pyridinecarbaldehyde *(4)*[9,10] (51%), 7-methyl-4-azathioxanthone *(5)*[11] (27%) which is isomeric with *(2)*, and di-*p*-tolyl disulfide (21%); in addition 22% of *(3)* can be isolated.

The two pharmaceutically interesting azathioxanthone systems were thus obtained for the first time by a photochemical route. It is surprising that in each case only one of the two possible isomers is formed.

^{13}C-NMR Spectra of Heptafulvene, Pentafulvene and Sesquifulvalene[1,2][**]

By *Roger Hollenstein, André Mooser, Markus Neuenschwander*, and *Wolfgang von Philipsborn*[*]

For years much interest has been attached to the cyclic, cross-conjugated π-electron systems of heptafulvene *(1)*, pentafulvene *(2)* and sesquifulvalene *(3)* because additional resonance stabilization was expected owing to the possible dipolar resonance structures with six π-electrons[3]. In this connection particular importance is attached to the spectroscopic properties of the unsubstituted compounds which could be compared directly with the numerous quantum-chemical calculations. The ^{1}H-NMR spectra of *(1)*[4,5], *(2)*[6] and *(4)*[7,4] show marked alternation of the vicinal H,H coupling constants, thus indicating largely olefinic character of the parent compounds. The situation does not differ appreciably even for 8,8-dicyanoheptafulvene[8].

In all these cases formation of aromatic structures would be connected with charge separation. Information about the extent of this can be expected from ^{13}C chemical shifts. Experience shows that these shifts are very sensitive to changes in charge density but less affected by diamagnetic ring currents. To find the contribution of possible polarization effects of the π-system to the chemical shift of the olefinic C atoms (δ_C = 112–160 ppm) we first tried to account for the substituent effects by means of additive empirical substituent increments[9,10] and structurally similar model compounds as, *e.g.*, in the case of the pair *(4)* and *(5)*. Calculations by *Savitsky* and *Namikawa*'s method[9] neglect contributions from substituents in the γ-position, but they can be applied unambiguously also to cyclic polyenes. Experimental and calculated δ_C values are collected in Table 1.

Table 1. ^{13}C shifts (±0.2 ppm, $CDCl_3$, TMS = 0) of *(1)* [a], *(2)* [b], *(3)*, *(4)* [a] and *(5)* [b]. Calculated values in parentheses.

	5	141.7	(139.1)
	6	160.2	(140.5)

[a] At −40°C with 5–10 molar excess of triethylamine as stabilizer.
[b] At −5°C.
[c] Assignment uncertain.
[d] C^7: 119.8; C^8, C^9: 125.4 [c], 128.2 [c]; C^{10}: 120.9.

The δ_C value of the exocyclic C atom, which should be most affected by polarization effects, accords very well with the calculated value in the case of heptafulvene *(1)*. The same is true for the ring-carbon atoms C^2, C^5 and C^3, C^4. In the pentafulvenes *(2)* and *(5)*, however, C^6 is shifted by 14.1 and 19.7 ppm, respectively, to higher frequencies. This effect was found with a large number of 6-alkyl-substituted pentafulvenes and interpreted as resulting from a *ca.* 10% contribution of polar structures to the electronic ground

state[6]. The shifts of -5.9 ppm (C^1, C^4) and $+4.6$ ppm (C^2, C^3) for *(2)* also indicate polarization effects in the π-system. Benzofulvene *(3)*[11], however, shows better agreement for C^3, C^4 and C^6. The diene system of *(3)* and the heptafulvene *(1)* can thus be regarded as essentially normal conjugated olefins.

According to the ^{1}H-NMR data[7] and the ^{13}C-NMR data of the five-membered ring, sesquifulvalene *(4)* whose dipolar resonance structure contains an aromatic five-membered and seven-membered ring does not show a more extensive charge separation than is found in *(5)*. The value for C^{12} differs from the calculated value by only $+7.4$ ppm, which may indicate that the excess of positive charge found at the corresponding position in the pentafulvenes is delocalized over several C atoms in the seven-membered ring of *(4)*. In fact the sum of the shifts of C^1, C^2 and C^3 in *(4)* is greater than in *(1)*.

From the ^{13}C-NMR data it can thus also be concluded that pentafulvene *(2)*, heptafulvene *(1)* and sesquifulvalene *(4)* should be regarded as largely olefinic structures. The small extent of charge separation in these compounds is also shown by the relatively small dipole moments[12]. Formation of an aromatic seven-membered ring in *(1)* and *(4)* requires not only charge separation but also overcoming of steric strain, and it seems that the corresponding energies are not sufficiently compensated by the gain in delocalization energy.

X-Ray Structure Analysis of the α-Cyclodextrin-Krypton Inclusion Complex: A Noble Gas in an Organic Matrix[**]

By *Wolfram Saenger* and *Mathias Noltemeyer*[*]

In aqueous solution, α-cyclodextrin (cyclohexaamylose, α-CD), the smallest of the cyclic oligosaccharides obtained by degradation of starch by *Bacillus macerans*, forms inclusion complexes with substances (guest molecules) whose nature extends from hydrophobic to hydrophilic, *e.g.* paraffins, aromatic compounds, fatty acids, amines, halogens, and salts[1,2]. Hydrophobic interactions, hydrogen bridge bonds, van der Waals and dipole-dipole forces have already been discussed as bonding forces that might stabilize these inclusion compounds[2], but not all of these need be considered for all types of inclusion complexes.

X-ray structure analyses of the adducts of α-CD with water[3], iodine[4] and 1-propanol[5] have clarified the nature of the conformational changes that can be observed spectroscopically during the formation of the inclusion[7]. These show that the α-CD molecule in the crystalline water adduct[3] or in "aqueous solution" takes up a strained conformation which is relaxed on formation of an adduct with any guest molecule other than water.

The structure analysis of the krypton adduct reported below was designed to explain how an apolar guest behaves that can use only van der Waals forces and in its dimensions (4 Å) resembles the water molecule (3.8 Å). The α-CD-krypton adduct first prepared by *Cramer* and *Henglein*[6] was crystallized at 3 and at 14 atm of krypton pressure (Table 1). 3900 reflexion intensities were measured for both crystals with a diffractometer, and the structures were solved and refined to a crystallographic reliability index of 8.6% in both cases.

Table 1. Crystallographic data of the α-cyclodextrin-krypton adducts.

Z 55.1 a) b) c)

Fig. 1. Views of the α-CD-krypton adduct formed a) at 3 and b) at 14 atm; c) structure of the α-CD·2H_2O adduct. Hydrogen bonds are denoted by broken lines, the positions of the oxygen atoms of included water molecules are denoted by W and those of the krypton atoms by KR. The numbering used in the text for the six glucose residues is shown in Fig. 1c. ● = Oxygen, ○ = carbon.

α-CD and five molecules of water of crystallization, but they do differ in the krypton contents and in the positions that the noble gas atoms take up (Table 2). As Figures 1a and 1b show, the α-CD molecule exists in an almost hexagonal structure, similar to that observed in the isomorphous adducts with iodine and 1-propanol; the six C(6)—O(6) bonds point radially "outwards" from the center of the molecule. The krypton positions are only statistically occupied (Table 2). The statistical distribution of the krypton over several positions is due to its failure to fill the void in the cyclodextrin with a diameter of 4—5 Å.

For the α-CD·2H_2O adduct (Fig. 1c) the situation is substantially different: The two included water molecules are fixed in definite, fully occupied positions by hydrogen bridge bonds formed to two O(6)—H hydroxy groups that are twisted "inwards". Here, unlike the situation for the krypton adduct, the α-CD molecule fits the relatively small van der Waals radius of the water molecule (3.8 Å) because it contracts its hole by twisting the glucose residues 1 and 5. This conformation[3], which the "empty" α-CD molecule assumes also in aqueous solution before forming an inclusion compound with a molecule other than water, has an increased energy content. When a krypton atom is included, a conformational change of the α-CD molecule occurs together with a decrease in its energy content, whereby the adduct is stabilized. In addition hydrophobic interactions may stabilize the α-CD-krypton adduct, whereas van der Waals forces can hardly be of importance because of the mutually unfavorable space-filling.

Complex formation as a result of energy decrease due to conformation effects may play a general role in biochemistry, *e.g.* in enzyme-substrate interactions[8].

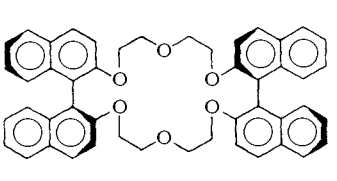
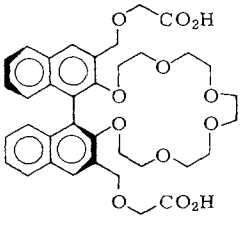
Abstracts of selected progress reports and review articles



Progress in arsenic chemistry reported in 1972 is reviewed by *G. O. Doak* and *L. D. Freedman*. A brief mention of primary and secondary arsanes, including those with As—Si bonds, is followed by a detailed discussion of papers dealing with tertiary arsanes (preparation, spectra, use as ligands, chemistry, physical properties) and amino and halo arsanes. Arsonic acids have been obtained by coupling of diazotized arsanilic acid with chromanones, thiochromanones, and similar compounds, and subsequent decomposition of the coupling products with evolution of N_2. Tertiary arsane oxides can be prepared from enantiomeric tertiary arsanes without racemization by oxidation with N_2O_4. A series of publications are concerned with the reaction of tertiary arsane oxides with alkyl halides. Alkaline cleavage of arsonium salts proceeds with retention of configuration, in contrast to that of phosphonium salts. Further studies have been performed on the reactions of arsenic ylides. Additional sections are devoted to compounds with As—S bonds, cyclic As derivatives, spectroscopic studies, and analytical methods. [Arsenic. Annual Survey Covering the Year 1972. J. Organometal. Chem. *68*, 295—369 (1974); 316 references]

[Rd 706 IE—M]



Nonbenzenoid aromatic π-electron systems is the title of a review by *F. Sondheimer*. After surveying the typical properties of benzene as the prototype of an aromatic molecule, the author examines annulenes, dehydroannulenes, bridged annulenes, ionic systems, and heteroaromatic systems to establish which properties of benzene are found in these systems and which are not. For instance, while [18]annulene, having a $(4n+2)$ π-electron system, undergoes electrophilic substitution, is almost planar, exhibits no alternation of bond lengths and a diamagnetic ring current, it is nevertheless not particularly stable, reacts rapidly with bromine, and is subject to a valence isomerization. However, its "aromatic" character becomes clear on comparison with [16]annulene. [Nonbenzenoid Aromatic π-Electron Systems. Chimia *28*, 163—172 (1974); 80 references]

[Rd 711 IE—L]

The chemistry of inclusion compounds is considered by *D. J. Cram* and *J. M. Cram*. Such complexes of organic molecules command particular interest as models for simulating the substrate selectivity of enzymes. The structure and bonding in molecular complexes of this type are discussed with reference to the crown ethers and their derivatives with the binaphthyl grouping. They can complex and lipophilize alkali metal, ammonium, and alkylammonium ions. An optically active crown ether *(1)* containing two binaphthyl groups preferentially

(SS)-(1)

(S)-(2)

complexes (>2:1) an enantiomeric form of a (1-phenylethyl)-ammonium salt. A dicarboxylic acid *(2)* having a crown ether-binaphthyl skeleton behaves similarly towards enantiomeric amino acids; this property could be utilized in an instrument for resolution of entantiomers. [Host-Guest Chemistry. Science *183*, 803—809 (1974); 22 references]

[Rd 712 IE—L]

Metabolism and function of alkaloids in plants are the topic of a survey by *T. Robinson*. Alkaloids are by no means inert final metabolic products but are degraded and synthesized in some cases at considerable rates. The degradation products and pathways are frequently unknown. Very little proof has so far been obtained for the common view that alkaloids have a protective function. [Metabolism and Function of Alkaloids in Plants. Science *184*, 430—435 (1974); 61 references]

[Rd 713 IE—L]

Base-catalyzed C—C addition reactions of hydrocarbons, in which alkali metals and organoalkali metal compounds, including potassium *tert*-butoxide in isolated cases, serve as catalysts are reviewed—with exclusion of addition reactions leading to macromolecules—in an article by *H. Pines*. The successful oligomerization of simple olefins by alkali metal in the presence of a promotor such as anthracene was first reported in 1956. In this article the author discusses the dimerization of propene, isoprene, styrene, dihydronaphthalene, the reactions of propane with butenes, and olefin ethylation with ethylene. Two or more molecules of a hydrocarbon can react with each or one another with or without hydride elimination with formation of C—C bonds. Intramolecular cyclizations of open-chain and cyclic alkenes and alkynes (*e.g.* 1,3,8,10-cyclododecatetrayne → biphenylene by potassium *tert*-butoxide in *tert*-butanol at room temperature) proceed in like fashion in the presence of strong bases. Alkylarenes containing benzylic hydrogen undergo reaction with lengthening of the alkyl group. Conjugated dienes afford alkenylarenes. Promoters are superfluous if the substrates readily yield alkali metal compounds. [Base-catalyzed Carbon-Carbon Addition Reactions of Hydrocarbons. Synthesis *1974*, 309—327; 48 references]

[Rd 714 IE—M]

Synthesis and preparative use of metal derivatives of primary and secondary arsanes, stibanes and bismuthanes are summarized in a report by *G. O. Doak* and *L. D. Freedman*. Reaction of these arsenides, stibides, and bismuthides with organohalo compounds is an important preparative method for tertiary arsanes, stibanes, and bismuthanes. These metal derivatives are also useful for the synthesis of compounds with covalent bonds between arsenic or antimony and Si, Ge, Sn, or Pb. The report deals, *inter alia*, with the cleavage of triarylarsanes, triarylstibanes, diarsanes, and bis(diarylarsenic) oxides with alkali metals. The metal derivatives are prepared by reaction of secondary arsanes and stibanes with organolithium compounds or alkali metals; primary arsanes react in a similar fashion with Na, K or organolithium reagent. Reactions of haloarsanes, -stibanes and -bismuthanes with alkali metal as well as those of alkali metal arsenides M_3As and $(M_2As)_2$ or alkali metal stibides M_3Sb and $(M_2Sb)_2$ with alkyl halides are also discussed. [Syntheses and Reactions of Arsenides, Stibides, and Bismuthides. Synthesis *1974*, 328—338; 79 references]

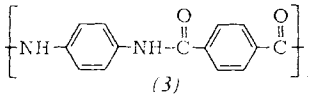
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

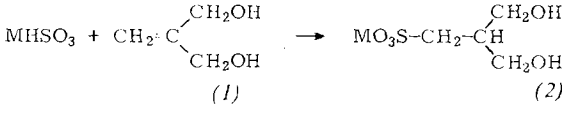


Styrene-acrylonitrile copolymers that can by processed thermoplastically and are particularly suitable for the production of CO_2-impermeable beverage bottles consists essentially of a resin that contains 76—85 wt.-% of polymerized acrylonitrile and 24—15 wt.-% of an aromatic olefin blended with a grafted rubber. The graft component contains 50—70 wt.-% of a rubber, and the grafted fraction 61—85 wt.-% of acrylonitrile and 39—15 wt.-% of aromatically substituted olefins. To enable the composition to be used for the production of impact-resistant bottles, the resin should have a melt viscosity of 2×10^4 to 4×10^5 poises at 220 °C. The polymerizations are carried out in emulsion; accurate feed recipes must be adhered to in this process. [DOS 2256612; E. I. du Pont de Nemours and Co., Wilmington, Del. (USA)]

[PR 197 IE—W]

Polyhydrazide fibers with high elasticity moduli have a content of at least 85% of the repeat units *(1)* to *(3)*. Accurate instructions are given for the composition of the polymer. Thus the maximum contents of these repeat units that may be present are 40 mole-% of *(1)*, 42.5 mole-% of *(2)*, and

(1) *(2)*

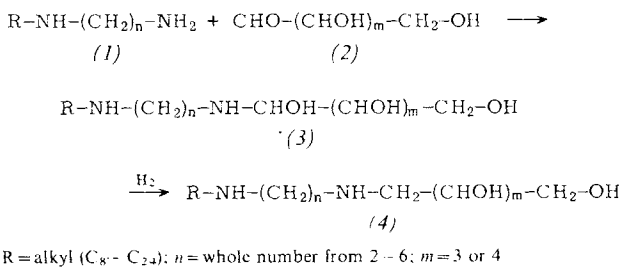


(3)

75 mole-% of *(3)*. For example, terephthalodihydrazide, and *p*-aminobenzohydrazide are dissolved with lithium chloride in hexamethylphosphoric triamide and condensed with terephthaloyl dichloride in the presence of pyridine. The solution is extruded through spinnerets into water. The resulting fibers are drawn at about 370 °C to increase their strength. [DOS 2232504; Toray Industries, Inc., Tokyo (Japan)]

[PR 198 IE—W]

Salts of 3-hydroxy-2-hydroxymethylpropanesulfonic acid *(2)* are obtained by addition of hydrogen sulfites to 2-methylene-1,3-propanediol *(1)* in the presence of oxygen, which acts as a catalyst (M = NH_4, alkali metal). The salts *(2)* are suitable

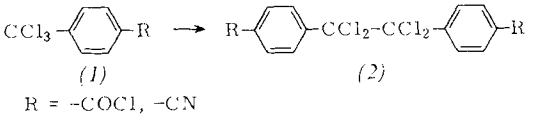


(1) *(2)*

for use as co-condensable compounds *e.g.* for the production of copolyesters for basically dyeable polyester fibers, as monomers for polyurethanes, or as intermediates for organic syntheses. [DOS 2224304; Bayer AG, Leverkusen]

[PR 199 IE—D]

***N*-Alkyl-*N'*-polyhydroxyalkylalkylenediamines** *(4)* can be used as textile-softening additives for washing products and as raw materials for the synthesis of surfactants. They can be obtained by reaction of *N*-alkylalkylenediamines *(1)*, *e.g.*



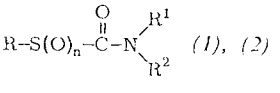
(1) *(2)* *(3)* *(4)*

R = alkyl (C_8 - C_{24}); n = whole number from 2 - 6; m = 3 or 4

N-octyltrimethylenediamine, with aldoses *(2)*, such as glucose, mannose, and arabinose, followed by catalytic hydrogenation of the reaction products *(3)*. [DOS 2226869; Henkel & Cie. GmbH, Düsseldorf]

[PR 200 IE—D]

Derivatives of 4,4'-tetrachloroethylenedibenzoic acid *(2)* are obtained by reductive coupling of the 4-trichloromethylbenzoic acid derivatives *(1)* in the presence of catalytic quantities of Cu powder or Cu ions, with the addition of chlorinatable substances such as acetone or olefins and possibly HCl acceptors to bind the chlorine released. The derivatives *(2)*, preferably the acyl chloride and the nitrile, are suitable for use



(1) *(2)*

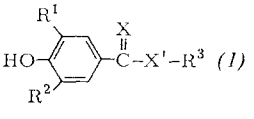
R = -COCl, -CN

as starting materials for polymers, *e.g.* polyesters or polyamides. [DOS 2208398; Dynamit Nobel AG, Troisdorf]

[PR 203 IE—D]

Herbicidal sulfoxides and sulfones having the formulas *(1)* and *(2)* are preferably prepared by oxidation of the corresponding thiolcarbamates with 3-chloroperbenzoic acid. *(1)* and *(2)* are very suitable for use against lawn weeds. It is

(1), *(2)*



n = 1,2

(1), R = halophenyl, phenalkyl; R^1, R^2 = alkyl, cycloalkyl, benzyl, *etc.*
(2), R = alkyl, haloalkyl, alkenyl; R^1, R^2 = alkyl, cycloalkyl, alkenyl, *etc.*

well known that *S*-alkyl and *S*-benzyl *N*,*N*-dialkylthiocarbamates possess herbicidal properties. [*(1)*: DOS 2340517; *(2)*: DOS 2341119; both Stauffer Chem. Co., Westport, Conn. (USA)]

[PR 206 IE—S]

3,5-Dialkyl-4-hydroxy(thio)benzoic esters *(1)* have a morphogenetic hormonomimetic action, and are suitable for use

(1)

X, X' = O or S; R^1, R^2 = alkyl (C_3—C_6), branched; R^3 = alkyl, alkenyl, aralkyl, aryl

against insects, particularly gnats. [DOS 2339137; Chevron Research Co., San Francisco, Calif. (USA)]

[PR 207 IE—S]

The Radiation Chemistry of Macromolecules. Edited by *Malcolm Dole*. Vol. 1. Academic Press, New York—London 1972. 1st Edit., xiv, 369 pp., numerous figures, bound $ 23.—.

The effects of high-energy radiation (electromagnetic radiation, electronic radiation) on macromolecules have attracted both scientific and technical interest. The first 11 of the 14 chapters in this book deal on the one hand with the theoretical principles of radiation chemistry and on the other with the physical and chemical phenomena of the solid state.

The section on radiation chemistry is mainly concerned with the primary processes induced in matter by ionizing radiation and with the reactions of the resulting short-lived species such as ions, excited molecules, and free radicals. Special chapters are therefore devoted to the theory of free radicals and to investigations on trapped electrons in organic glasses and polymers with the aid of optical and ESR spectroscopy. The treatment of molecular mobilities and electrical conductivity in polymers is followed by a discussion of the change in the electrical conductivity in irradiated polymers. Another chapter deals with the phenomenon of thermoluminescence in polymers, which is still in its early stages as a field of research. This is followed by a chapter on the statistical theory of degradation and crosslinking, which are at present the two most important technical processes involving the application of high-energy radiation to polymers.

The last three chapters deal with experimental technique and the results of irradiation experiments on linear polyethylene as the prototype of a simple macromolecule. After the introductory theoretical chapters, this part of the volume will certainly be welcomed, since it discusses practical results of radiation chemistry and tries to correlate them with the complicated morphology of polyethylene.

The book can be recommended to anyone seeking a general picture of the processes that occur on irradiation of macromolecules. The many literature references will also help those who wish background information on the material, which is very difficult in part.

Christel Schneider [NB 206 IE]

Molecular Geometry. By *R. J. Gillespie*. Van Nostrand Reinhold Comp., London 1972. 1st Edit., ix, 228 pp., numerous figures and tables, bound *ca.* DM 38.—

In past monographs, inorganic structural chemistry has been marked by the crystal-chemical approach. It is therefore all the more commendable that the structure of isolated molecules, together with inorganic stereochemistry, is given precedence in the present book.

However, the general title forms a cover for the special approach developed earlier by the author together with *R. S. Nyholm*, the "*valence shell electron pair repulsion theory*" (VSEPRT). This theory assigns spherical spaces around the closed shell of the core electrons to pairs of free and valence electrons as proposed by *Bent*, and derives the molecular geometry from the magnitude of the electron pair repulsion. This concept is presented and extended in the first third of the book. It is remarkable that in a book with this title, neither elements of group theory nor ideas such as orbitals or hybridization are required in the development of a concept of bonding and structure, a concept that will be greatly appreciated by the practical worker; S means sulfur, and never denotes either entropy or an axis of rotation-reflection. At the same time, however, this is a danger of the book, which is undoubtedly intended to appeal mainly to students: alternative views (such as the hypervalent bonding theory) are omitted altogether, or else an attempt is made in an appendix to provide a connection with the MO approach. This becomes particularly clear in examples such as F^-, which should not exist according to p. 38, or in postulates such as that of a second valence shell invoked to explain the paramagnetism of O_2 ($\cdot\{:O\equiv O:\}\cdot$ with a triple bond; pp. 84/85).

The strength of the book lies in the second part, which presents an unusually thorough survey of the structural types of compounds, arranged according to elements of the first, then the second and higher periods of the periodic system and transition metals. Here again molecular structures take precedence over ionic lattices, and a large number of diagrams (not always of uniform quality) are included for greater clarity. The emphasis is clearly placed on non-tetrahedral and non-octahedral structures; polyhedral structures are derived in an understandable manner.

On the whole the book gives a competent subjective account of inorganic stereochemistry, and can be recommended to anyone who is familiar with the limitations of the VSEPRT and with alternative approaches.

Hans Bürger [NB 208 IE]

Metal π-Complexes, Vol. II. Complexes with Mono-Olefinic Ligands. By Max Herberhold. Elsevier Publishing Company, Amsterdam—London—New York. Part I: General Survey, 1972, 1st Edit., xv, 643 pp., 206 figs., 85 tables, bound *ca.* DM 295.—. Part 2: Specific Aspects, 1974, 1st Edit., xvi, 508 pp., 106 figs., 51 tables, bound *ca.* DM 250.—

Hardly any other field has developed so rapidly over the past 20 years as the chemistry of transition metal π-complexes. Until now there has been no general survey of existing knowledge in the field of π-complexes with monoolefinic ligands. The publication of both parts of a detailed monograph on this subject is therefore very welcome. After a historical introduction, the first part deals with general preparative methods. Two long chapters then describe the chemistry of transition metal complexes with olefins, and specifically a) with olefins having no functional groups (the material is arranged here according to the metal) and b) with olefins containing functional groups (arranged according to the functional group).

The second part considers spectroscopic studies, X-ray structures, stability of the olefin complexes, the theory of metal-olefin bonding, and the use of these compounds in industrial processes.

The first part covers the literature comprehensively up to 1968. An appendix lists 210 publications from the years 1969 and 1970; this gives some idea of the annual growth of this field. In the second part, the literature up to 1970 is included, and an appendix lists 239 further references from the period up to the middle of 1972.

The plan of the first part is broad. Physical properties and chemical reactivity are discussed in detail. Clarity is aided by numerous tables and summaries in the form of formula schemes. The overall impression reflects the author's years of experience in this field and his attention to detail.

Opinions may be divided with regard to the arrangement of the material and the classification principle. In the reviewer's opinion, a discussion of the theory of metal-olefin bonding at the beginning of the book would have helped the reader to understand many of the systematic relationships. The brief note on the historical development of bonding theories on

pages 15 to 19 would have been a good starting point for this discussion. The separate treatment of the π-complexes of pure olefins and of olefins containing functional groups makes it more difficult for the reader to trace relationships between the structure of the olefin and the properties of the complexes, particularly as a function of the metal. This arrangement also makes repetitions inevitable (compare *e.g.* pages 88 to 90 and 335 to 336). However, the excellent subject index and the author index are helpful in this respect.

For the specialist particularly this first volume is a real treasure house. It contains an abundance of interesting information that would certainly not appear in normal surveys and reviews, and that will undoubtedly stimulate new investigations. The author could possibly have taken more opportunities to direct the reader's attention to questions that are still unanswered.

Both parts have been carefully produced, and the reviewer has been unable to find any serious printing errors, a point that is particularly pleasing in connection with the references. A missing H in the structural formula of tetracarbonyl(pyrrolidine)iron (Part 1, p. 77) was also missing in the original publication. The author and the publishers are particularly to be commended for their care.

In the second part an attempt by the author to give an interpretative survey is sometimes missed too. An indication of corresponding specialist publications such as Kellers' "NMR-Untersuchungen an Komplex-Verbindungen" would help here. On the other hand there are again numerous excellent tabular summeries and reaction schemes. The completeness of the information can also be relied upon. In the chapter on IR spectroscopy, a short mention of the CO stretching vibrations of the olefin-carbonylmetal complexes would have been useful, since in practice they are often used for characterization and for the detailed study of the bonding in these complexes.

This two-part monograph will be an indispensable aid to anyone working in the field of metal-olefin complexes, regardless of whether he is seeking an introduction or has already had many years' experience. The corresponding hope, expressed in the foreword, is fulfilled in every respect. This monograph should indeed find a wide readership, even though some hearts may sink at the price.

Ernst Koerner von Gustorf [NB 209 IE]

2200 Begriffsbestimmungen nach DIN (Deutsch und Englisch) (2200 DIN Definitions (German and English)). By *H. G. Freeman.* Beuth-Vertrieb GmbH, Berlin—Cologne—Frankfurt/M. 1972. 1st Edit., 352 pp., bound DM 35.50.

This book lists in alphabetical order 2200 keywords selected from approximately 4000 DIN specifications. The keywords belong to the fields of mechanical engineering, electrical engineering, metallurgy of iron and other metals, techniques of welding, soldering, measuring, control devices, X-rays, plastics, adhesives, coatings, the testing of materials, physics, and chemistry. The keywords are explained by definitions laid down by Standards Institutes and, if necessary, by additional annotations. The corresponding English or rather British definition (adapted to British Standards) is supplemented by an explanation corresponding to the meaning of the German text. For each keyword the original DIN specification from which the word stems is listed. Homonyms are listed consecutively. In the second part the English terms are compiled in alphabetical order, without definitions but with the German terms and the field to which the terms belong. The book is supplemented by a list of standard specifications containing translations of technical terms into English and other languages. The standard specifications are classified according to the Standards Institute.

For the first time, a work compiling information scattered over many standard specifications has become available, which can be used even by those not familiar with the standards. This carefully written book will constitute a valuable tool for the specialized translator and is an indispensable addition to the many technical dictionaries already in existence.

Christian Weiske [NB 211 IE]

Interpretation of Mass Spectra of Organic Compounds. By *M. C. Hamming* and *N. G. Foster.* Academic Press, New York—London 1972. 1st Edit., xiv, 694 pp., numerous figures and tables, bound $ 37.50.

The mass spectrometer is still regarded by many organic chemists as a costly but very precise instrument for the determination of molecular weights and empirical formulas and is used accordingly. The utilization of the information contained in a mass spectrum for the determination of molecular structures often fails on account of the complexity of the problem and the lack of simple, comprehensive, and generally applicable principles of interpretation. Many attempts have been made to overcome this problem in countless textbooks and studies, generally with reasonable success; the book in question represents another independently conceived attempt.

The book is intended as an introduction to organic mass spectroscopy, but it opens up interesting possibilities for the specialist on account of its comprehensive literature index and carefully compiled bibliography.

The authors first describe in condensed form the instrumental basis of mass spectroscopy and the general properties of mass spectra, the influence of instrumental and material parameters on spectra, and the types of ions encountered. Sample manipulation and injection techniques are described in great detail. This is followed by a summary of fragmentation reactions. In contrast to many textbooks on this subject, there is not much discussion of the fragmentation pattern of different classes of substances; instead, after discussing the most important breakdown mechanisms (8 types of simple bond cleavage, 5 rearrangement reactions) and their occurrence in relation to the existence of certain structural elements, a strategy is slowly developed, which should allow a step by step integration of the mass spectrum of a substance and lead to its identification. This strategy culminates in a schematic procedure, which requires a specific rectangular arrangement of the mass spectra; the interpretation is then achieved by means of "interpretation maps" (39 interpretation maps are listed in the appendix). This is undoubtedly an interesting and stimulating attempt, but it is based largely on hypothesis, for the method is still far from perfection. Finally, computer processing of mass spectroscopic data assumes an important place in the book.

A few of the book's drawbacks cannot be overlooked. The broad epic style, in addition to lack of accuracy and clarity, does not facilitate reading. The very small number of illustrated mass spectra is remarkable. In comparison with the length of some other chapters, the treatment of metastable transitions and of pertinent modern techniques of measurement is much too short. Nevertheless, the book can be recommended to students and specialists, particularly on account of the wealth of information it contains.

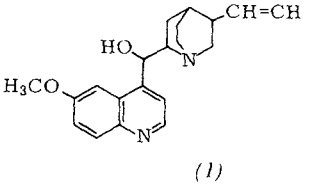
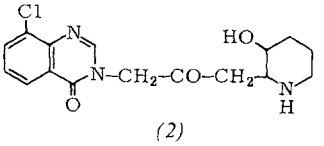
Antimetabolites of Coenzyme Q. Their Potential Application as Antimalarials

By Thomas H. Porter and Karl Folkers[*]



Malaria is transmitted to man by the bite of the female Anopheles mosquito, man acting as the intermediate host, and the mosquito as the definitive host for the plasmodia. Plasmodia are found to have become resistant to certain chemotherapeutic agents. A new fundamental approach to malaria chemotherapy is based on the biochemical rationale of inhibition of the electron transfer mechanism in the metabolism of plasmodia by antimetabolites of coenzyme Q, which is essential for electron transfer. Coenzyme Q refers to 2,3-dimethoxy-5-methyl-1,4-benzoquinones with isoprenoid chains of varying length on C-6. In this progress report a series of synthetic antimetabolites are presented together with a discussion of their action in current pharmacological tests.

1. Malaria—Still a Widespread Disease

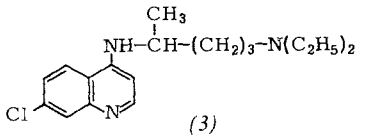


Malaria, a disease of the blood system caused by protozoa of the genus *Plasmodium*, is perhaps the most worldwide of all human diseases. According to a new treatise by *Steck*[1] at least one-tenth of the human race suffers from malarial disease each year despite all attempts both therapeutically and prophylactically to control the disease. It is still the most devastating of the infectious diseases of man. The millions of infections and many hundreds of thousands of deaths that occur each year demonstrate that malaria constitutes a global problem that has not yet been eliminated[1].

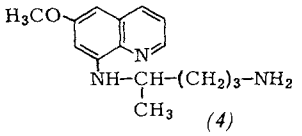
Malaria is transmitted to man by the bite of the female *Anopheles* mosquito, man acting as the intermediate host, and the mosquito as the definitive host for the plasmodia. Control of malaria has been effected by the public health measures of eradication of the mosquito vector by chemical agents and destruction of breeding areas; numerous chemotherapeutic agents have been developed for treatment of the illness.

In chemotherapy, two natural product antimalarials which have withstood the test of time and have proved effective are quinine *(1)* and febrifugin *(2)*. However, because of the threat of restricted quinine supplies during the World Wars, these drugs have gradually been replaced by synthetic chemotherapeutic agents such as chloroquine *(3)*, primaquine *(4)*, amodiaquine *(5)*, proguanil *(6)*, and pyrimethamine *(7)*.

(1)



(2)



Between about 1948 and 1950 the resistance of plasmodia to certain chemotherapeutic agents became a significant problem following the discovery in Malaya of the resistance of *Plasmodium falciparum* and *Plasmodium vivax* to proguanil *(6)* (cf. Ref. [2]). Since then the resistance to other important antimalarials has been reported from many other countries of the world, including Africa and South America.

As certain strains of plasmodia have been found to be resistant to conventional antimalarial drugs, such as chloroquine *(3)* and primaquine *(4)*[3–5] new approaches to malaria chemotherapy have had to be sought by many investigators. One new and fundamental approach is based on the biochemical rationale of an inhibition of the electron transfer mechanism in the metabolism of plasmodia; this approach forms the main theme of the present progress report.

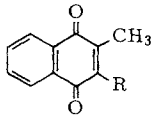
2. Early Research on Naphthoquinones as Antimalarials

As early as 1942, as the result of a screening program in the search for new antimalarial agents, hydrolapachol *(8)* and two structurally similar quinones *(9)* and *(10)* were found to possess antimalarial activity against *P. lophurae* in ducks. These results stemmed largely from the prodigious researches carried out by *Fieser* and *Leffler* and their respective co-workers on quinones, particularly the naphthoquinones[6, 7].

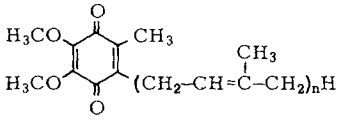
(8), R = $(CH_2)_2$–$CH(CH_3)_2$
(9), R = $(CH_2)_8$–$C(n\text{-}C_5H_{11})_2$ (OH)
(10), R = $(CH_2)_3$–(cyclohexyl)



Emerging from all this effort were, *inter alia*, clinical data on two naphthoquinones *(9)* and *(10)*, which showed antimalarial activity in man[6]. In the case of *(9)*, it was stated that "two patients left the hospital in perfect condition with no parasites in the blood ... or without relapse"[6]. For *(10)*, it was said that the "effect was not satisfactory, but enough to show ... definite antimalarial activity in man"[6].

In 1943, *Bauer* found that some of these 2-alkyl-3-hydroxy-1,4-naphthoquinones were also effective prophylactic agents against malaria in chickens[8–10]. Administration of such quinones, in adequate dosage prior to and for about five days after the inoculation of chickens with sporozoites of *P. gallinaceum*, provided complete protection. In further investigations it was established that these naphthoquinones destroyed the exoerythrocytic forms of the malarial parasite which were in the reticuloendothelial cells of chicks infected with *P. gallinaceum*[9, 10].

Research on the mode of action of these quinone antimalarials was limited during the 1940's, althouth certain data did indicate interference with cell respiration. About 1945, *Wendell*[11] found that 2-alkyl-3-hydroxy-1,4-naphthoquinones were indeed potent inhibitors of respiratory systems. At concentrations of *ca.* 1×10^{-6} mol/l, 2-(3-cyclohexylpropyl)-3-hydroxy-1,4-naphthoquinone *(10)* reduced the respiration of parasitized erythrocytes by about 50% in blood drawn from a duck infected with *P. lophurae*. The results of these studies also indicated that these compounds interfere with carbohydrate metabolism and cause accumulation of lactic acid in the organism.



3. Discovery of Coenzyme Q_8 in Plasmodia

The structural similarity between the compounds *(8)*—*(10)* and vitamin K *(11)* formerly implied that the antimalarial activity of these naphthoquinones was the result of antagonism of vitamin K. Such a concept appeared reasonable, for it was known that vitamin K participates in the metabolism of many microorganisms, although the presence of vitamin K in plasmodia had still not been established, and apparently not even sought for.

(11a), K_1, R = Phytyl

(11b), K_2, R = $(CH_2\text{-}CH{=}C(CH_3)\text{-}CH_2)_nH$

(12), coenzyme Q

Smith et al.[12, 13] reported that 2-(3-cyclohexylpropyl)-3-hydroxy-1,4-naphthoquinone *(10)* produced a hemorrhagic syndrome and hypoprothrombinemia in young rats, and that the development of these symptoms was prevented by simultaneous administration of vitamin K. These authors' data also implied the existence of a form of vitamin K in plasmodia.

It was not until after these studies on naphthoquinone antimalarials that coenzyme Q (ubiquinone) *(12)* was discovered, and its widespread presence in living systems and its role in cell respiration, *e.g.* in succinate-dehydrogenase- and NADH-dehydrogenase-coenzyme Q[*] enzyme systems, was established (cf. Ref. [14]).

Hendlin and *Cook*[15] and *Takemari* and *King*[16] demonstrated the inhibition of succinate-dehydrogenase by certain 2-hydroxy-1,4-naphthoquinones and its reversal by coenzyme Q_{10}[**]. Similarly, *Howland*[17] demonstrated the inhibition of mitochondrial NADH-dehydrogenase by 2-alkyl-3-hydroxy-1,4-naphthoquinones.

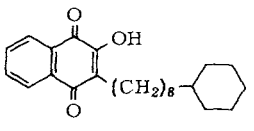
Since 1958, it has been known that microorganisms biosynthesize and apparently use vitamin K and/or coenzyme Q in their oxidative metabolism. Consequently, one could also assume that vitamin K and/or coenzyme Q are present in plasmodia, since the occurrence of mitochondria in plasmodia, particularly in its later stages of development, had already been documented[18, 19].

It was predicted that coenzyme Q could exist in plasmodia as an intrinsic component of metabolism, and that the antimalarial activity of naphthoquinones *(8)*, *(9)*, and *(10)* could, at least in part, be due to inhibition of coenzyme Q in the manner of antimetabolites.

[*] These enzymes are also known as "succinoxidase" and "DPNH-oxidase", respectively.

[**] The subscript denotes the number *n* of isoprene units.

The search for the presence of coenzyme Q in plasmodia was successful; in 1967 *Rietz*, *Skelton*, and *Folkers* reported the occurrence of coenzyme Q_8 and Q_9 in *P. lophurae*[20, 21]. Mass spectral data and reversed-phase paper chromatographic results showed that CoQ_8 and possibly CoQ_9 were present in parasitized duck blood and could be biosynthesized by *P. lophurae*. Vitamin K was not detected in lipid fractions by reversed-phase paper chromatography.



Skelton, *Lunan*, and *Folkers*, in collaboration with *Schnell*, *Siddiqui*, and *Geiman*[22], next demonstrated that the [^{14}C]-coenzymes Q_8, Q_9, and perhaps Q_7 are biosynthesized from [^{14}C]-*p*-hydroxybenzoic acid in parasitized blood; the authors isolated these coenzymes from the blood cells of rhesus monkeys which were parasitized with *P. knowlesi*. It was then shown by *Skelton et al.*[23] that CoQ_8 was biosynthesized in the blood of rhesus monkeys infected with *P. cynomolgi* and in the blood of mice infected with *P. berghei*. Again, the presence of vitamin K in plasmodia could not be detected, neither by reversed-phase paper chromatography nor by mass spectral analysis, nor by a labeling method using *in vitro* cultures of *P. knowlesi* that had been incubated with [^{14}C]-shikimic acid, a precursor in the biosynthesis of vitamin K.

Schnell et al.[24] also demonstrated the biosynthesis of coenzymes Q_8, Q_9, and Q_{10} in *Aotus* blood cultures infected with *P. falciparum*; but only the CoQ_{10} was intrinsic to the mammalian cells.

With the establishment of the presence and biosynthesis of coenzyme Q_8 as the dominant coenzyme Q (compare Ref. [25]) in plasmodia and the apparent absence of vitamin K, it seemed reasonable that such naphthoquinones as *(8)*, *(9)*, and *(10)* could actually exert at least part of their antimalarial activity by interference with the biosynthesis and/or the function of CoQ_8 in the metabolism of plasmodia. Also, it was now clearly evident that the synthesis of new analogs of coenzyme Q, rather than of vitamin K, opened up a biochemically valid and previously unexplored approach to new and effective antimalarials and to other chemotherapeuticals.

4. Synthesis and Antimalarial Activity of Menoctone

In 1967, *Fieser* and *Archer* and their respective associates[26] synthesized additional members of the 2-(ω-cyclohexylalkyl)-3-hydroxy-1,4-naphthoquinone series, including the new naphthoquinone derivative menoctone, 2-(8-cyclohexyloctyl)-3-hydroxy-1,4-naphthoquinone *(13)*, which has since been extensively investigated as an antimalarial agent both curatively and prophylactically.

(13)

In mice infected with *P. berghei*, menoctone showed activity (T − C = 6.2)[*] at 20 mg/kg and 4/5 cures at 160 mg/kg in the routine one-dose (sc) treatment[23]. However, at a dose level of 640 mg/kg, menoctone exhibited toxic effects; this dosage led to only 2/5 cures and 3/5 deaths[27].

[*] (T − C) is defined as the change in survival time (in days) of treated and untreated (control) animals.

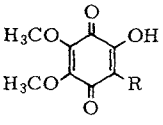
For comparison: chloroquine *(3)*, when it was given orally at a dose of 5 mg/kg once a day for five days to groups of five mice, consistently cleared the blood of parasites in all mice for the entire test period of 28 days[28]. Similar results were obtained with menoctone, but at a daily dose rate of 25 mg/kg for five days[28].

Menoctone was also highly effective prophylactically. In 1968 *Berberian et al.*[29] reported that menoctone afforded mice more protection than primaquine *(4)* when the drugs were administered orally twice daily throughout the course of the preerythrocytic cycle. Two and a half times as much primaquine had to be given to the mice to afford complete protection [(number of parasite-free animals/number of surviving animals on the *n*th day after infection) = 1]. Moreover, oral toxicity data showed that menoctone *(13)* was 1/15 as toxic as primaquine *(4)*.

5. Inhibition of Coenzyme Q Enzymes by Chloroquine *(3)* and Menoctone *(13)*

After having established the presence of CoQ_8 in plasmodia it seemed appropriate to test already known antimalarial drugs and also the extensively studied naphthoquinone, menoctone *(13)*, *in vitro* to see if they actually do have antimetabolite activity for coenzyme Q. Subsequently, both chloroquine *(3)* and menoctone *(13)* were found by *Skelton et al.*[30] to inhibit the NADH-dehydrogenase coenzyme Q system. Chloroquine diphosphate depressed NADH-dehydrogenase activity to 70, 60, 50, and 17% when levels of 25, 50, 100, and 1000 nmoles, respectively, were added to the intact system supplemented with 100 nmoles of exogenous CoQ_{10}. Menoctone proved to be a far much more potent inhibitor in this *in vitro* system; as found by *Szarkowska*[31], at levels of 1, 10, and 25 nmoles in an intact NADH-dehydrogenase system in the presence of 100 nmoles CoQ_{10}, it depressed enzyme activity to 83, 12, and 11%, respectively, of the CoQ_{10}-treated control system[30].

Current research by *Crane et al.*[32] on mitochondrial electron transport indicates that chloroquine *(3)* inhibits oxidation of reduced coenzyme Q_{10} at a site containing a non-heme iron protein (MW ≈ 16000). Chloroquine does not, however, inhibit the oxidation of durohydroquinone; this finding is consistent with chloroquine competition for enzyme sites with CoQ_{10}.



Other important evidence, although indirect, for the inhibition of coenzyme Q systems by antimalarial naphthoquinones was found in a study of the changes in *P. berghei* fine structure induced by menoctone *(13)* and primaquine *(4)*[33]. The initial mitochondrial swelling would appear to be followed by generalized degenerative changes in the plasmodia. This finding suggested an initial action of the drugs on the parasite's mitochondria, the apparent CoQ_8-containing organelle in which oxidative processes are carried out.

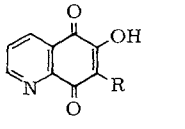
In a study of chloroquine resistance in malaria by *Fitch*[34], the major difference between chloroquine-sensitive and chloroquine-resistant parasites was a deficiency of high affinity binding of chloroquine by cells infected with the chloroquine-resistant parasite. This binding deficiency could explain the reduced ability of chloroquine-resistant parasites to concentrate chloroquine[35, 36] and suggests that chloroquine-resistance is due to a decrease in the number, affinity, or accessibility of chloroquine receptor sites in the malaria parasite.

6. Synthesis of Other Antimetabolites of Coenzyme Q

At this stage of the investigations, the synthesis of new quinones as potential antimalarials could be designed upon new knowledge of the existence and role of coenzyme Q_8 in the metabolism of plasmodia.

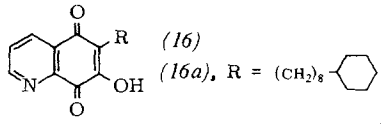
New hydroxybenzoquinones based on the structure of coenzyme Q, the 2-alkyl-3-hydroxy-5,6-dimethoxy-1,4-benzoquinones *(14)*, were synthesized by *Catlin et al.*[37,38] by procedures which permitted considerable structural variation; the alkyl groups were aliphatic (including isoprenoid moieties). *Catlin et al.*[37,38] and *Pardini et al.*[39] found the quinones *(14)* to be potent inhibitors of coenzyme Q enzyme systems. *In vitro* studies showed that some of these hydroxy-1,4-benzoquinones strongly inhibit succinate-dehydrogenase and NADH-

(14)



dehydrogenase in intact mitochondrial systems from bovine heart (Table 1)[37] or in a system which is extracted for removal of coenzyme Q_{10}[37]. Compound *(14c)* was more effective than other phytyl derivatives carrying residues other than OH[39]. The succinate-dehydrogenase system was generally more sensitive to most of the benzoquinones than was the NADH-dehydrogenase system, the influence of the alkyl side chains on the activity being very slight[39].

According to *Castelli et al.*[40] the quinones *(14a)* and *(14c)* are also effective inhibitors of NADH- and succinate-dehydrogenase of intact mitochondria from yeast. CoQ_2 reversed the inhibition in NADH-dehydrogenase, but there was little or no significant reversal in succinate-dehydrogenase. Surprisingly, when CoQ_6-deficient NADH-dehydrogenase was supplemented with 2-hydroxy-5,6-dimethoxy-3-phytyl-1,4-benzoquinone *(14c)* and CoQ_{10}, there was an unexpected increase in enzyme activity, indicating some coenzymatic activity in this particular case[40].



It is important to emphasize that the coenzyme Q_8 of plasmodia is a lipoidal substance; this is largely because of the forty carbon atoms in its isoprenoid side chain. Consequently, one may presume that effective inhibitors of coenzyme Q_8 would, of necessity, also have to be lipoidal in nature. For this reason, the synthesis of several categories of lipoidal quinones has been undertaken as part of our research toward new and effective prophylactic and curative antimalarials. Quinones were designed with long side chains to impart lipoid character and with various ring substituents which could offer differences in oxidation-reduction potentials, hydrogen bonding, and alkylation sites.

6.1. Alkylhydroxyquinolinequinones

Two series of lipoidal quinones which were examined in this connection were the 7-alkyl-6-hydroxy- and 6-alkyl-7-hydroxy-5,8-quinolinequinones *(15)* and *(16)*, respectively, which had previously already been synthesized by *Pratt* and *Drake*[41,42]. In this study, *Porter et al.*[43] synthesized additional new alkylated 5,8-quinolinequinones, namely by alkylation of 6- and 7-hydroxy-5,8-quinolinequinones, with diacyl peroxides.

(15)

(16)

(16a), R = $(CH_2)_8$-⬡

In the 7-alkyl-6-hydroxy-5,8-quinolinequinone series *(15)*, maximum antimalarial activity against blood-induced *P. berghei* in mice, according to the procedure of *Osdene et al.*[44], was displayed by compound *(15a)* with a side chain of 15 carbon atoms. 6-Hydroxy-7-*n*-pentadecyl-5,8-quinolinequinone *(15a)*[43] showed 1/5 cures and an extension of survival time (T − C) = 13.2 days at 640 mg/kg in the routine one-dose treatment (sc) of mice infected with *P. berghei*. In the 6-alkyl-7-hydroxy-5,8-quinolinequinone *(16)* series, 6-(8-cyclohexyloctyl)-7-hydroxy-5,8-quinolinequinone *(16a)* was the most potent antimalarial; it effected 5/5 cures at 640 mg/kg under the same test conditions.

Most of the 7-alkyl-6-hydroxy-5,8-quinolinequinones *(15)* were also tested on NADH-dehydrogenase and succinate-dehydrogenase in bovine heart mitochondria for inhibition of coenzyme Q[45] (see Table 2). The results demonstrated that a reasonably good correlation existed in this series of quinones between the concentration of the inhibitor in the *in vitro* system and the observed *in vivo* antimalarial activity against *P. berghei* in mice. In succinate-dehydrogenase, the greatest inhibitions were found in the case of analogs with 7-*n*-tetradecyl- *(15e)*, 7-*n*-pentadecyl- *(15f)*, 7-*n*-hexadecyl- *(15g)*, 7-(5-cyclohexylpentyl)- *(15k)*, and 7-(8-cyclohexyloctyl)- *(15l)* side chains. NADH-dehydrogenase was less sensitive than succinate-dehydrogenase to these analogs; *(15f)*,

Table 1. *In-vitro* assay of the inhibitory activity of some 2-alkyl-3-hydroxy-5,6-dimethoxy-1,4-benzoquinones *(14)* [a] on NADH-dehydrogenase- and succinate-dehydrogenase-enzyme systems in intact mitochondrial systems. The specific activity (S.A.) is defined as the oxygen uptake in μatoms O_2/min per milligram of mitochondrial protein.

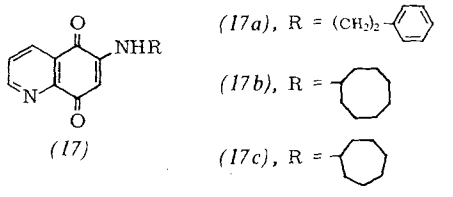
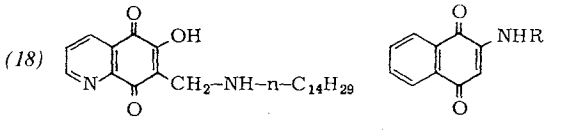
[a] nmol inhibitor/mg mitochondrial protein.
[b] Antimetabolite-CoQ_{10} index: for a definition see Section 7. The average concentration of CoQ_{10} in mitochondria was determined from several preparations of mitochondria and found to be *ca.* 2 nmol/mg mitochondrial protein. This value was assumed for the calculation of AI_{50}.
[c] For 56% inhibition.
[d] For 40% inhibition.



(15g), and *(15k)* analogs were the most inhibitory. For both *in vitro* enzyme systems, the optimum length of the lipoidal straight side chain for maximum inhibition was 15 or 16 carbon atoms.

Skelton et al.[46] found that menoctone *(13)* and a representative of the 5,8-quinolinequinones, 7-(8-cyclohexyloctyl)-6-hydroxy-5,8-quinolinequinone *(15l)*, inhibit succinate-cytochrome c reductase and the succinate-coenzyme Q reductase in bovine heart submitochondrial systems and that coenzyme Q_6 effects reversal of inhibition. The same substances also inhibit the succinate-coenzyme Q reductase of intact mitochondria from the human heart.



In another study, *Skelton et al.*[47] attempted elucidation of the mechanism of action of these quinone antimalarials. Menoctone *(13)* and the quinolinequinone *(15l)* inhibited the NADH-cytochrome c reductase system of yeast submitochondrial particles and the succinate-cytochrome c reductase systems of both yeast and bovine heart submitochondrial fragments[47]. The inhibition could be reversed by addition of exogenous coenzyme Q_6 to the systems containing no added phospholipid[47]. Lineweaver-Burk double reciprocal plots indicated that these two quinones act by competitive inhibition of coenzyme Q enzyme systems[47].

6.2. Alkylamino-quinolinequinones and -naphthoquinones

Other categories of quinones newly synthesized as potential antimalarials are 6-alkylamino-5,8-quinolinequinones *(17)*, 6-hydroxy-7-*n*-tetradecylaminomethyl-5,8-quinolinequinone *(18)*, and the 2-alkylamino-1,4-naphthoquinones *(19)*. Numerous quinones of this type have already been reported[41,42,48–50].

(17)

It was important to design these new quinone types with alkyl side chains, so as to impart greater lipoidal character to the molecule, and with alkyl side chains containing varying types and numbers of heteroatoms. It was hoped that such analogs might be more effective antimetabolites of the highly lipoidal coenzyme Q_8 of plasmodia.

A series of fifteen new 6-alkylamino-5,8-quinolinequinones *(17)* and 6-hydroxy-7-*n*-tetradecylaminomethyl-5,8-quinolinequinone *(18)* were synthesized by *Porter et al.*[51], and representative compounds were evaluated for antimalarial activity against *P. berghei* in mice[44]. Three quinones 6-phenethylamino-5,8-quinolinequinone *(17a)* (T–C = 7.3

at 640 mg/kg), 6-cyclooctylamino-5,8-quinolinequinone *(17b)* (T − C = 6.9 at 640 mg/kg), and 6-cycloheptylamino-5,8-quinolinequinone *(17c)* (T − C = 6.5 at 320 mg/kg)—were declared "active" by the standard criterion of 100% increase or greater in the survival time for antimalarial activity against *P. berghei*; all three derivatives were non-toxic at the dose levels tested.

Representative compounds were tested in mitochondrial NADH-dehydrogenase and succinate-dehydrogenase systems for inhibition of coenzyme Q. The 6-alkylamino-5,8-quinolinequinones *(17)*, represented in the assay by seven of the fifteen compounds, were potent inhibitors in both the NADH-dehydrogenase and succinate-dehydrogenase systems; the inhibition could be completely reversed by CoQ_{10} (see Table 3)[51].

Eight new 2-alkylamino-1,4-naphthoquinones, *(19)*, have also been synthesized by *Porter et al.*[52] and tested for antimalarial activity against *P. berghei* in mice. None of these compounds, however, showed any significant activity in this test. Significantly, the 2-alkylamino-1,4-naphthoquinones, represented in the *in vitro* assay by seven of the eight new compounds and three previously prepared derivatives, likewise showed no important inhibition of either the NADH- or succinate-dehydrogenase enzyme system[52].

Table 4. *In-vivo* assay of antimalarial activity of 7-alkylthio-5,8-quinolinequinones *(20)* [a] on mice infected with *P. berghei* [44]. The figures in brackets denote the dose (in mg/kg) administered in each case.

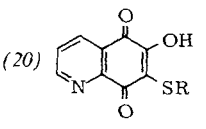
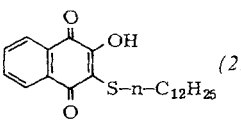
6.3. Alkylthiohydroxyquinolinequinones

One of our most recent series of quinones, the 7-alkylthio-6-hydroxy-5,8-quinolinequinones *(20)* described by *Porter et al.*[53], represent a new structural type of effective antimalarial quinones, which show little or no toxicity in the prophylactic assays, and which most likely function as antimetabolites of the indispensible coenzyme Q_8 of plasmodia. This series of new antimetabolites of coenzyme Q appears to be one of the most promising types of such analogs in our research on the prophylactic and curative treatment of malaria.



(20)



Twelve new 7-alkylthio-6-hydroxy-5,8-quinolinequinones *(20)* were synthesized by *Porter et al.*[53] and *Wan et al.*[54] by 1,4-addition of appropriate alkanethiols to 6-hydroxy-5,8-quinolinequinone and subsequent oxidation of the quinoline-

dose levels of both 320 mg/kg and 640 mg/kg without toxicity in the routine one-dose (sc) treatment of mice.

Prophylactically, this compound cured 3/5 chicks at 160 mg/kg (Table 5) in the sporozoite-induced *P. gallinaceum* test developed by *Rane* and *Rane*[55]. 6-Hydroxy-7-oleylthio-5,8-quinolinequinone *(20h)*, the corresponding C_{18} derivative having one double bond in the side chain, showed increased *in vivo* prophylactic activity with 4/5 cures at 15 mg/kg. In comparison, compound *(20d)* showed only 1/5 cures at 40 mg/kg. Unsaturation in the side chains appears to enhance *in vivo* prophylactic activity. The lower homolog of *(20d)*, 6-hydroxy-7-*n*-tetradecylthio-5,8-quinolinequinone *(20b)*, was totally curative[23], curing 5/5 chicks at a dose of 80 mg/kg. The best compound, 7-*n*-heptadecylthio-6-hydroxy-5,8-quinolinequinone *(20g)*, cured 5/5 chicks at a dose of 10 mg/kg; its effectiveness at

lower dosages is as yet unknown. This quinone showed no toxicity at doses from 10 mg/kg to 320 mg/kg.

The alkylthio-5,8-quinolinequinones *(20a)*, *(20c)*, and *(20d)* and the alkylthio-1,4-naphthoquinone *(21)* showed marked inhibition of both NADH- and succinate-dehydrogenase mitochondrial CoQ-enzyme systems from bovine heart (Table 6).

6-Hydroxy-7-*n*-octadecylthio-5,8-quinolinequinone *(20d)*, the quinolinequinone which exhibited the greatest *in vivo* activity against *P. berghei* in the mouse, showed more inhibitory activity in the NADH-dehydrogenase system than the other two alkylthio-5,8-quinolinequinones *(20a)* and *(20c)* tested in the same assay. Surprisingly, 2-*n*-dodecylthio-3-hydroxy-1,4-naphthoquinone *(21)*, which showed only marginal antimalarial activity in the murine assay, was a potent inhibitor of the mitochondrial NADH- and succinate-dehydrogenase enzyme systems.

The effectiveness of these alkylthio-5,8-quinolinequinones, *in vitro* and *in vivo*, may be due to their having a combination of molecular characteristics for inhibition including electron transport, relative affinities for binding to functional and/or biosynthetic sites of CoQ_8 in plasmodia, and lipoidal character.

The screening results[27] described herein for mice[44] and chicks[55] are generally based on findings which were obtained on treatment of animals with only one dose; this method was chosen for simplicity of routine assay of very large numbers of compounds. It is not known what the dosage and drug

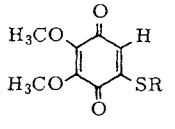
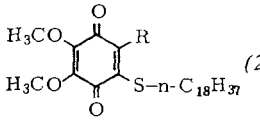
effectiveness would be if the optimum regimen were determined by the traditional procedures of pharmacology in the case of the most promising antimetabolites of coenzyme Q for antimalarial effectiveness.

6.4. Benzodioxinquinones (Ethylenedioxyquinones)

A new series of coenzyme Q analogs, the 6-alkyl-7-hydroxy-2,3-dihydro-1,4-benzodioxin-5,8-quinones (ethylenedioxybenzoquinones) *(22)*, have been synthesized by *Bowman et al.*[56] on the basis of the minor differences in the electronic and rotational nature between the ethylenedioxy group and the two methoxy groups. These differences could fundamentally affect the oxidation-reduction potential of the 1,4-benzoquinone and, in turn, also the inhibitory activity. Appropriate isoprenyl or alkyl groups were inserted at C-6 by alkylation.





(22)   *(14f)*

The succinate-dehydrogenase and NADH-dehydrogenase systems of intact mitochondria from bovine heart were used in tests for inhibition of these quinones *in vitro* (Table 7). In succinate-dehydrogenase the *n*-nonyl *(22a)*, *n*-decyl *(22b)*, *n*-pentadecyl *(22d)*, and farnesyl *(22g)* derivatives showed inhibitions of less than 40%; the phytyl *(22f)*, *n*-heptadecyl *(22e)*, and 5-cyclohexylpentyl *(22c)* analogs showed inhibitions of about 50%. All analogs were less inhibitory in NADH-dehydrogenase.

2-Hydroxy-5,6-dimethoxy-3-*n*-pentadecyl-1,4-benzoquinone *(14f)* and the analogous compound *(22d)* showed about 90% and 35% inhibition, respectively, in succinate-dehydrogenase—the strongest inhibitions in this series of experiments. Apparently, the dimethoxy groups are more favorable than the ethylenedioxy group for the inhibition of enzymes.

6.5. Alkylthio-2,3-dimethoxy-1,4-benzoquinones

Another new category of 2-alkylthio-5,6-dimethoxy-1,4-benzoquinones, compounds *(23)* and *(24)*, have recently been synthesized by *Wikholm et al.*[57] as potential antimetabolites of coenzyme Q.

(23)  *(24)*

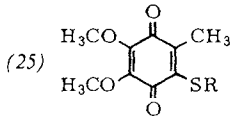
The series of alkylthio-1,4-benzoquinones prepared in this study provided variation in alkyl side chain length; in addition one compound having a branched alkenylthio substituent [*(23c)*] was also prepared. Within the series of 2,3-dimethoxy-5-*n*-octadecylthio-1,4-benzoquinones *(24)* several 6-substituents provided potentially significant variation in redox potential of the new quinones.



In the 6-substituted 2,3-dimethoxy-5-methyl-1,4-benzoquinone *(25)*, lengthening of the alkylthio side chain—from

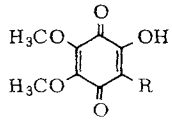
Finally, reductive acetylation of crude 2-alkylthio-3,5,6-trimethoxy-1,4-benzoquinone, another analog in this series, afforded the crystalline diacetoxy derivatives *(26)* of the corresponding hydroquinones.

6.6. Alkylquinoxalinequinones

Recently, *Porter et al.*[58] have initiated the synthesis of a new series of 6-alkyl-5,8-quinoxalinequinones *(27)*, and the alkylthioquinones were investigated as potential inhibitors of

(27a), R = S-n-$C_{12}H_{25}$

(27b), R = $(CH_2)_5$-⬡



coenzyme Q and as antimalarial drugs. The groups introduced as side chains were *n*-dodecylthio- *(27a)* and 5-cyclohexylpentyl- *(27b)*. *(27a)* was inactive against blood-induced *P. berghei* in mice at 640 mg/kg and inactive against sporozoite-induced *P. gallinaceum* in chicks at 80 mg/kg.

(28a) has been tested prophylactically against sporozoite-induced *P. gallinaceum* in the chick and was effective, without toxicity, at dose levels of 30 mg/kg (1/5 cures) and 120 mg/kg (4/5 cures).

7. Comparison of Inhibitory Activity by the Antimetabolite CoQ_{10} Index (AI_{50})

To facilitate comparison of the inhibitory activities of various analogs and derivatives *in vitro*, *Bowman et al.*[45] have defined an "antimetabolite CoQ_{10} index" (AI_{50}); this corresponds to the ratio of nmoles of analog per nmoles of CoQ_{10} in the actual mitochondrial preparation which causes approximately 50% inhibition of enzyme activity. The inhibitory activities of these analogs were measured by their effect on the oxygen uptake of the CoQ enzymes (determined either by the Warburg manometric method or by polarographic measurement of oxygen). For most analogs, inhibition of the CoQ enzymes was determined at several concentrations so that the concentration at which 50% inhibition was effected could be estimated by extrapolation.

The antimetabolite CoQ_{10} indices for some 7-alkyl-6-hydroxy-5,8-quinolinequinones *(15)* in NADH-dehydrogenase and succinate-dehydrogenase are listed in Table 2[45]. The 7-*n*-pentadecyl- and 7-(5-cyclohexylpentyl)-6-hydroxy-5,8-quinolinequinones *(15f)* and *(15k)* were the most effective antimetabolites of this series in NADH- and succinate-dehydrogenase.

(14)

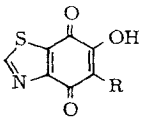


Table 8. Antimetabolite CoQ_{10} indices of 2-alkyl-3-hydroxy-5,6-dimethoxy-1,4-benzoquinones *(14)*.

(14c)	Phytyl	26	50	10	50

[a] Actual 50% inhibitions or approximately 50% inhibitions from extrapolation of experimental values [45].

6.7. Benzothiazolequinones

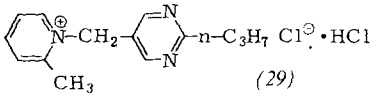
A new series of 5-alkyl-6-hydroxybenzothiazole-4,7-quinones *(28)* have been synthesized by *Friedman et al.*[59] in the continuing program to explore new heterobicyclic quinone systems for potential pharmacological activity. The two new quinones *(28a)* and *(28b)*, containing *n*-undecyl and *n*-pentadecyl side chains, respectively, were prepared by a multistep procedure.

(28a), R = n-$C_{11}H_{21}$

(28b), R = n-$C_{15}H_{31}$

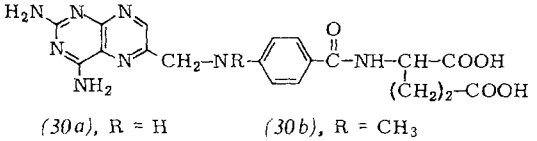
The antimetabolite CoQ_{10} indices of eight 2-alkyl-3-hydroxy-5,6-dimethoxy-1,4-benzoquinones *(14)* have been determined by *Bogentoft, von Klaudy*, and *Folkers*[60] (Table 8). For the CoQ-NADH-dehydrogenase system, a range of antimetabolite indices of 5—32 were obtained for these inhibitors. The 2-(5-cyclohexylpentyl)-analog *(14h)* was the most effective antimetabolite with an index of 5. The farnesyl- and phytyl-analogs *(14a)* and *(14c)* had indices of 17 and 26, respectively. The antimetabolite CoQ_{10} indices for the CoQ-succinate-dehydrogenase system varied from 5.5 to 14 for all eight analogs;

no difference was evident in the case of the farnesyl and phytyl derivatives.



In general, these eight analogs were more effective antimetabolites of CoQ in succinate-dehydrogenase than in NADH-dehydrogenase, but the difference in sensitivity between the two systems was small.

8. Application of Coenzyme Q Antimetabolites in the Therapy of Other Diseases



This demonstrated effectiveness, both curatively and prophylactically, of antimetabolites of coenzyme Q in the treatment of malaria, with little or no toxicity, may be extended to the therapy of other diseases. From the above data it can be concluded that a certain selective toxicity for an antimetabolite of CoQ has been achieved and that further analogs can be synthesized which could exhibit even more effective selective toxicity in chemotherapy. Such selective toxicity can be based on differential inhibition of pathways. The widespread occurrence of coenzyme Q in nature would suggest its presence in a number of potential pathogens such as bacteria, fungi, other protozoa, and helminths. Antimetabolites of coenzyme Q could destroy these organisms or inhibit their growth.

The criticism is frequently encountered that an antimetabolite of a vitamin cannot be useful in man or domestic animals without serious toxicity to the host, which negates the useful aspect. Evidence shows that such toxicity to the host does not necessarily occur. Moreover, the progress described here on antimetabolites of coenzyme Q demonstrates that useful therapeutic activity without toxicity is feasible.

Antimetabolites or other vitamins are already in use in the treatment of diseases. Amprolium *(29)*[61], a thiamine antagonist, is suitable as a coccidiostat in veterinary medicine; it is selectively effective against coccidia of the digestive tract and prevents coccidiosis in chickens without adverse effect upon growth.

(29)

(30a), R = H *(30b)*, R = CH_3

Similarly, antifolates have found widespread application in the treatment of cancer because of their selective toxicities. The folic acid antagonists aminopterin *(30a)* and methotrexate *(30b)*, are both used in the treatment of acute leukemia in children[62].

Appreciation is particularly expressed to Dr. David P. Jacobus for his sympathetic encouragement of the initiation of the basic research which led to the establishment of coenzyme Q_8 as intrinsic to the metabolism of plasmodia. For their subsequent cooperation we wish to thank Dr. Thomas R. Sweeney and Dr. Edgar A. Steck of the U.S. Army Medical Research and Development Command (Contract No. DADA 17-69-C-9067); Contribution No. 1202 from the Army Research Program on malaria. We also wish to express our thanks to the Robert A. Welch Foundation, and Dr. Lewis H. Sarett, Merck Sharp and Dohme Research Laboratories, New Jersey, for their valuable support of this work.

Enzymatic Reduction of Ribonucleotides: Biosynthesis Pathway of Deoxyribonucleotides

By Hartmut Follmann[*]

Ribonucleotide reductases are enzymes that synthesize the deoxyribonucleotides required for the replication of DNA in dividing cells. They thus have a key function for the growth of microorganisms and of all plant and animal tissues. The enzymes reduce all four purine and pyrimidine ribonucleotides (as the 5'-diphosphates or triphosphates) with direct substitution of the 2'-hydroxyl group by hydrogen. The physiological reducing agents are the mercapto groups of thioredoxins, a group of small proteins, which are regenerated from the oxidized form by NADPH-dependent thioredoxin reductases. There are two known types of ribonucleotide reductases (I and II), which catalyze hydrogen transfer with the aid of protein-bound iron ions or of 5'-deoxyadenosylcobalamin (coenzyme B_{12}); free radicals can be detected in both cases. The enzymes are regulated by effector nucleotides. There may exist a homeostatic mechanism, which guarantees the supply of DNA precursors to the cell.

1. Deoxyribonucleotides as Building Units of DNA

In a bacterium or growing cell, before new deoxyribonucleic acid (DNA), the macromolecular carrier of the genetic information in the chromosomes, can be synthesized during cell division, its monomeric building units must be available in the cell as substrates of the replicating enzymes. This condition seems obvious, but among the numerous processes in the synthesis of nucleic acids[1] (Fig. 1), surprisingly little is known about the formation of the four deoxyribonucleotides (step b), in contrast with the very extensively studied biosynthesis of the purine and pyrimidine ribonucleotides (step a). Similarly, the polymerization of deoxyribonucleotides (step c) *in vivo* has not yet been fully elucidated in all important details. Though the 5'-triphosphates of deoxyadenosine, deoxycytidine, deoxyguanosine, and thymidine (dATP, dCTP, dGTP, and dTTP[**]) are generally considered the immediate precursors of DNA, an enzymatic polymerization of the corresponding 5'-diphosphates is also known[2], and a DNA replication at the level of 5'-monophosphates activated in some other way has been suggested[3].

[**] The 5'-phosphates of the ribonucleosides adenosine (A), cytidine (C), guanosine (G), and uridine (U) and of the deoxyribonucleosides deoxyadenosine (dA), deoxycytidine (dC), deoxyguanosine (dG), and thymidine (dT) are denoted in the usual manner by the abbreviations –DP (diphosphate) and –TP (triphosphate); (d)N is an unspecified (deoxy)ribonucleoside. DNA: deoxyribonucleic acid, RNA: ribonucleic acid, FAD: flavin adenine dinucleotide, NADPH and NADP: reduced and oxidized nicotinamide adenine dinucleotide phosphate respectively. For the structures of these compounds cf. *W. Saenger*, Angew. Chem. *85*, 680 (1973); Angew. Chem. internat. Edit. *12*, 591 (1973).

All these deoxyribonucleotides are present in the cell only in minute steady-state concentrations. They can hardly be detected by direct analysis in the presence of the chemically similar ribonucleotides, whose concentrations are higher by

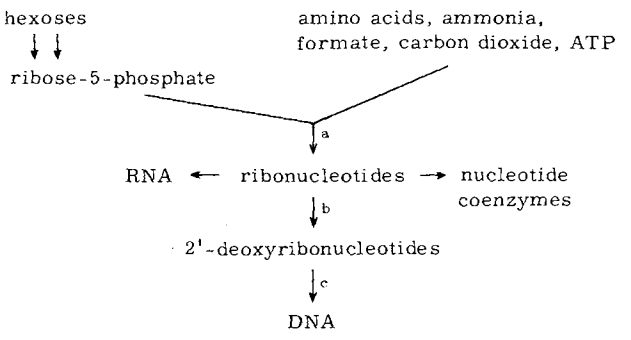

Fig. 1. Dependence of the DNA replication (step c) on the purine and pyrimidine biosynthesis (step a) and the ribonucleotide reduction (step b) in the course of the *de-novo* nucleic acid biosynthesis.

a factor of 10 to 100. It is only recently[4,5] that the deoxyribonucleoside triphosphates present in a tissue extract can be quantitatively determined in amounts of less than 1 pmole with the aid of DNA polymerase I and synthetic polynucleotide templates *in vitro*. Pools of the order of 10–100 pmole of dNTP per 10^6 cells were found in cell cultures of mice[6,7] and of hamsters[8,9] and in ascites tumor cells[10], these quantities being distributed between the cell nucleus and the cytoplasm[11]. They exhibit considerable growth-dependent variations[9,108], but they can only sustain DNA replication for about 1—5 min in any case. Only oocytes such as those of the frog *Xenopus laevis* appear to be better supplied with DNA precursors, since the pool of 12 pmole of dNTP per cell found here[12] is sufficient for the synthesis of the DNA of more than 2000 new cell nuclei.

There are two possible routes for replenishment of the deoxyribonucleotide pools, *i.e.* reutilization of DNA fragments such as thymidine from the catabolic metabolism or supplied from outside, or complete synthesis of new material[13]. The first route ("salvage pathway") is essential for auxotrophic microorganisms; it requires a series of inducible enzymes such as nucleoside deoxyribosyl transferases, nucleoside phosphorylases, and nucleoside kinases, which can separate the bases, sugars, and phosphate residues of the nucleotides from one another and recombine them.

Since all other organisms synthesize DNA without the supply of deoxyribonucleotides and make practically no use of nutritive nucleic acids, they must all be capable of *de-novo* synthesis. The pentose component of the nucleic acids is obtained here from the oxidative and non-oxidative carbohydrate metabolism of the cell, as can be shown *e.g.* by the isotope content of the RNA and DNA when *Escherichia coli* is cultured on ^{18}O-labeled glucose or fructose[14]. In none of these pathways is free 2-deoxyribose formed and then incorporated into nucleotides; the enzyme deoxyribose aldolase that is in principle able to synthesize this sugar from glyceraldehyde-3-phosphate and acetaldehyde[15] probably catalyzes only the degradation of 2-deoxyribose-5-phosphate *in vivo*[16]. The biosynthesis of all nucleotides proceeds instead from ribose-5-phosphate, with construction of the heterocyclic bases (Fig. 1) to form ribonucleotides, from which the deoxyribonucleotides are formed in a further reaction, with retention of the *N*-glycoside linkage between the sugar and the base. This relationship was first demonstrated by *Reichard* in 1950 in the utilization of ^{15}N-labeled cytidine (but not cytosine) for RNA *and* DNA in the metabolism of the living rat[17]. The conversion of ^{14}C-labeled ribonucleosides into deoxyribonucleotides was also detected first in microorganism cultures[18] and later in cell-free extracts (*e.g.* from *E. coli*[19]).

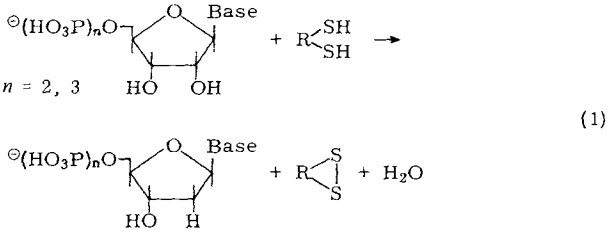
Enzymes that reduce ribonucleoside-5'-phosphates with replacement of the 2'-hydroxyl group by hydrogen to form 2'-deoxyribonucleotides are known as ribonucleotide reductases[20]. The reducing agents in every known case are dithiols, which are converted into the disulfide and regenerated in a further enzyme reaction. There are only few reviews of these reactions[1,13,21,22]. The present report deals with our current knowledge of the occurrence and the structure of ribonucleotide reductases, their reaction mechanism, and their unusual regulation phenomena. Numerous investigations during the past few years have shown that these enzymes, to which little attention had previously been given, are of outstanding importance to the development of all life forms.

2. Ribonucleotide Reductases

2.1. Occurrence, Isolation, and Detection

Ribonucleotide reductases, as inducible enzymes very closely connected with cell proliferation, are most easily found in rapidly growing cell cultures and tissues; great difficulty is encountered in their detection in resting tissues. Bacteriophages, microorganisms in the exponential growth phase, germinating plant seeds, embryonic or regenerating animal organs and tumors are typical materials for the isolation of ribonucleotide reductases (Table 1). The majority of the known enzymes come from bacteria and mammalian tissues, whereas the reduction of ribonucleotides in plants, for example, has not yet been very extensively studied. The reductases of *Escherichia coli*, of *Lactobacillus leichmannii*, and from Novikoff tumors, which have been under investigation for some time by the research groups of *Reichard* (Stockholm), *Blakley* (Iowa City), and *Moore* (Houston), exhibit a number of properties that are typical of all enzymes, but the deoxyribonucleotide synthesis as a whole exhibits many species-specific peculiarities in most organisms.

The very limited knowledge of the reduction of ribonucleotides that existed until recently bears witness to the difficulties of dealing with these enzymes. They always occur in small quantities and are often unstable proteins, so that they are not easy to purify by conventional methods (*e.g.* from yeast[32] or wheat[33]). A successful use of affinity chromatography with insolubilized coenzyme B_{12}[51] or dATP[52] for the purification of the ribonucleotide reductases from *L. leichmannii*, *E. coli*, and the bacteriophage T4 promises progress in this respect.



Ribonucleotide reductases are also much more difficult to determine quantitatively than most other enzymes. There is no fast routine assay for the simple reaction (1) that is catalyzed by them. The most common method makes use of a radioactive substrate such as [5-^3H]CDP, the resulting labeled deoxyribonucleotide being determined after separation by paper, column[53,118], or thin layer chromatography[54]; this test is

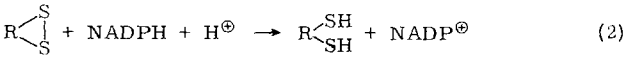


Table 1. Ribonucleotide reductase activity in extracts of various organisms and tissues.

[a] See Sections 2.2.1 and 2.2.2.

subject to interference by other nucleotide-transforming enzymes, particularly in crude extracts. A less sensitive method is the colorimetric determination of deoxyribose with diphenylamine; in this case, the deoxyribonucleotide formed must

first be hydrolyzed with acid[55]. A method that is also suitable for kinetic measurements simulates the physiological process, the reaction (1) being coupled with the regeneration of the dithiol thioredoxin by thioredoxin reductase [reaction (2)], and the NADPH consumption being followed spectrometrically[56]; however, purified enzymes and thioredoxin of suitable specificity are necessary for this enzyme determination. Finally, the coenzyme B_{12}-dependent ribonucleotide reductases (enzymes of type II in Table 1) can be determined by the liberation of tritium from [5′-^{3}H]-5′-deoxyadenosylcobalamin (coenzyme B_{12}, see below) during the reduction. The radioactive water formed is sublimed out of the reaction solution for this determination[26, 57].

2.2. Specificity of the Enzymes

All purified ribonucleotide reductases catalyze the reduction of the four natural ribonucleotides (and also of ribonucleotides with non-natural bases) by the same enzyme protein; there is no indication that the other systems contain several enzymes that are specific for individual nucleotides. All the ribonucleotide reductases are also alike in that they accept low molecular weight dithiols such as dithioerythritol or reduced lipoic acid as reducing agents *in vitro*, and they require the 5′-diphosphates or 5′-triphosphates of the ribonucleosides as substrates. Reduction at the 5′-monophosphate level does not seem to occur, though nucleotide kinases may give the incorrect impression that it does occur in unpurified extracts. However, the ribonucleotide reductases must be divided into two very different groups according to cofactor requirement and protein nature.

2.2.1. Ribonucleoside Diphosphate Reductases (EC 1.17.4.1)

Enzymes of type I (Table 1), represented by that from *E. coli*, are found in microorganisms, plants, and animals as high as man. So far as is known, they always reduce the diphosphates ADP, CDP, GDP, and UDP. A characteristic of this group is that instead of catalyzing the redox reaction (hydrogen transfer) between dithiol and ribose with the aid of one of the conventional coenzymes, they contain protein-bound iron ions, which are essential for the activity of the enzyme. The existence of such an enzyme is therefore often recognized by the fact that reduction of ribonucleotides is

stimulated by low concentrations of iron salts or inhibited by complexing agents for iron. The enzyme reaction is inhibited particulary specifically by hydroxyurea[58] and by 1-formylisoquinoline thiosemicarbazone[59]; however, this inhibition is only partly reversible, and probably also leads to further changes in the proteins. Many of these enzymes also require magnesium ions and ATP (as an effector, and not as an energy source) for their activity. It is not yet possible to say whether this is true of all reductases of type I.

2.2.2. Ribonucleoside Triphosphate Reductases (EC 1.17.4.2)

Type II (Table 1) comprises enzymes whose hydrogen transfer reaction involves 5'-deoxyadenosylcobalamin. This coenzyme form of vitamin B_{12} catalyzes several enzymatic hydrogen shifts *via* the 5'-methylene group of its adenosyl residue (cf. Fig. 3)[60]; its participation in the reduction of ribonucleotides was first detected by *Blakley* and *Barker*[25] in a cell-free extract of *Lactobacillus*. A number of enzymes can evidently also use diphosphates as substrates instead of the triphosphates ATP, CTP, GTP, and UTP. They are not greatly affected by metal ions. Apart from the lower algae *Euglena*, the coenzyme B_{12}-dependent ribonucleotide reductases seem to occur only in prokaryotes (organisms without cell nuclei). Their distribution in many microorganisms has been investigated by the very sensitive test with radioactive coenzyme[28], but there is no regularity of occurrence here, even in closely related species. Many attempts have been made to demonstrate the participation of B_{12}-dependent reductases in the DNA synthesis of mammals, particularly in the unbalanced DNA formation in the megaloblasts of the bone marrow in pernicious anemia, but the action of vitamin B_{12} in these systems is definitely not connected with the reduction of ribonucleotides[44].

2.3. Protein Structure

Only a few of the ribonucleotide reductases listed in Table 1 have been purified sufficiently for detailed analyses of their protein structure and of the bonding of substrates and effectors. No far-reaching comparisons are possible from a glance at Table 2. Nevertheless, it can be seen that several iron-dependent reductases are large proteins with two dissimilar components, each of which is inactive by itself, and which may be regarded as a regulatory subunit and a catalytic subunit. Thus in the case of the separated pure subunits of the enzyme from *E. coli*[61], protein B1 has at least four different kinds of nucleotide binding sites[65], whereas B2 binds two iron atoms, but no nucleotides. Their enzymatically active 1:1 complex is formed in the presence of magnesium ions and the positive effector dTTP; binding of the inhibitor dATP leads to an inactive, aggregated protein. The amino acid analysis and other properties of this enzyme system have been reported[66].

The manner in which the iron atoms are bound is particularly interesting in these proteins. In the *E. coli* protein B2, they are inert to reducing and oxidizing agents and are not bonded to inorganic sulfur (as in other "non-heme iron" compounds); they can be removed from the protein by careful dialysis against 8-hydroxyquinoline 5-sulfonate and imidazole, and can be reconstituted to give a fully functional B2 by treatment of the enzymatically inactive apoprotein with iron(II) ascorbate[67].

The UV absorption spectrum of the metalloprotein, like the Mössbauer spectrum (recorded for the [^{57}Fe]protein B2)[67], points to a close structural relationship with the hemerythrins; in these oxygen-transporting proteins of marine worms and brachiopods, there are two "high-spin" iron(III) ions in an antiferromagnetically coupled (*i. e.* as a whole diamagnetic) binuclear complex, whose protein ligands are unknown. The function of the iron in B2 is evidently not the transport of either oxygen or electrons; it serves for the production and stabilization of an organic radical that is also detectable in the subunit B2 and that is probably involved in the reduction (see Section 3.1.). The T4 phage enzyme[62] is very similar in all these properties to the enzyme from *E. coli*.

The coenzyme B_{12}-dependent reductases seem to have somewhat simpler structures. The relatively small *Lactobacillus* enzyme combines all the catalytic and regulatory binding sites (at least four for the substrate, coenzyme, and effectors) in a single polypeptide chain, which is not unusually long[64]. Its amino acid analysis and initial attempts to prepare large protein fragments have been described; kinetic and mechanistic studies are particularly well advanced for this enzyme.

Table 2. Protein structure of purified ribonucleotide reductases.

Source and purity	M.wt. and/or sedimentation coefficient	Properties	Ref.
Escherichia coli (homogeneous)	245000 9.7–10.1 S	Separable by chromatography into B 1 (m.wt. 160000, 2 peptide chains) and B 2 (m.wt. 78000, 2 peptide chains); B 1 binds nucleotides, B 2 contains 2 atoms of Fe (light abs. 360, 410 nm); B 1 : B 2 complex stabilized by Mg; in presence of dATP inactive dimer	[61]
Phage T4 (homogeneous)	225000	1 Protein having 2 atoms of Fe (light abs. 360, 410 nm), only slightly stabilized by Mg; denaturing electrophoresis yields 2 pairs of peptide chains having m.wt. 80000 and 35000 resp.	[62]
Rat liver (300×)	6.6 S	Aggregated and inactivated in presence of dATP	[42]
Bone marrow (50×)		Separable by chromatography into 2 dissimilar proteins S 1 and S 2, inactive when separated	[45]
Novikoff tumor (150×)		2 Dissimilar proteins P1 and P2	[63]
L. leichmannii (homogeneous)	76000	1 Polypeptide chain (*ca.* 690 amino acids), incapable of dissociation or aggregation	[64]
Thermus X-1	80000	Activity maximum at 70 °C, stable up to 80 °C; effector action only at elevated temperature (change of conformation?)	[30]

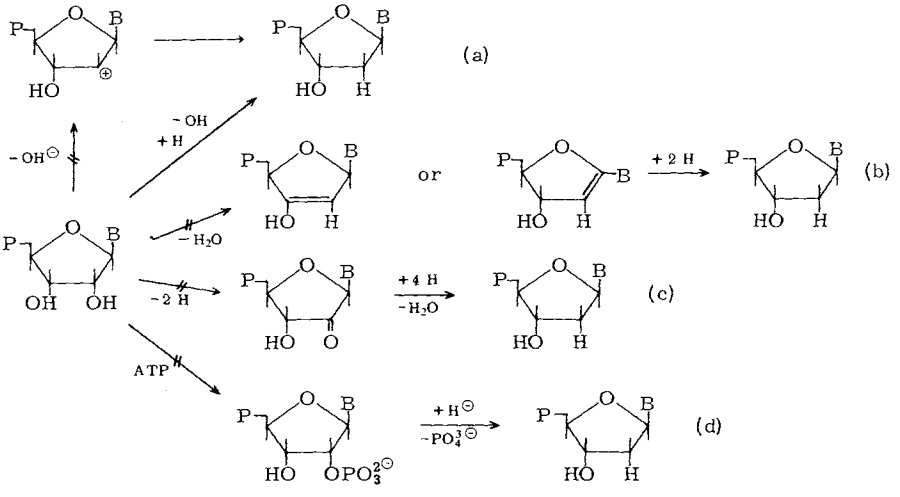
2.4. Subcellular Localization

The localization of the ribonucleotide reductases in the cell has not yet been systematically studied. They are generally thought to be cytoplasmic enzymes, since little or no reductase activity is found in cell nuclei, mitochondria, and microsomes of rat liver[42] or of Novikoff tumors[68]. There have recently been indications that these tissues contain ribonucleotide reductase as an enzyme complex together with other enzymes of the DNA biosynthesis, *i. e.* thymidylate synthetase, thymidylate kinase, and DNA polymerase II[68,69]. These enzyme activities sedimented in the ultracentrifuge with a postmicrosomal membrane fraction of unknown origin, and after breakdown of the membrane fragments they were visible in the electron microscope as particles with a size of 8.5—12 nm. The membrane component does not seem to be essential to the activity and cohesion of the enzymes. Similar material with a high reductase activity has also been isolated from thymus, spleen, and HeLa cells.

body temperature? Deoxygenations at high temperatures or catalytic hydrogenations can hardly be cited as non-enzymatic parallels for nucleotide molecules, and the only known chemical conversion of a ribonucleotide (AMP) into the corresponding deoxyribonucleotide by linkage of the 2'-hydroxyl group and the adenine base followed by removal of sulfur from the intermediate 8,2'-anhydroadenosine thioether [reaction (3)][70] also does not proceed under physiological conditions.

The high specificity of the enzyme reaction for ribonucleotides with an intact 2',3'-*cis*-diol grouping[81] can be interpreted by multiple fixation of the substrates to the protein *via* the phosphate ions, the purine or pyrimidine base, and the 3'-hydroxyl group (cf. Fig. 4), but an explanation of the redox reaction itself presents both chemists and enzymologists with a problem that is as difficult as it is interesting.

The fate of the atoms and groups involved has been so thoroughly studied in the enzymes from *E. coli* and *L. leichmannii* with isotope-substituted model nucleotides and spectroscopic techniques that, despite the very different protein structures



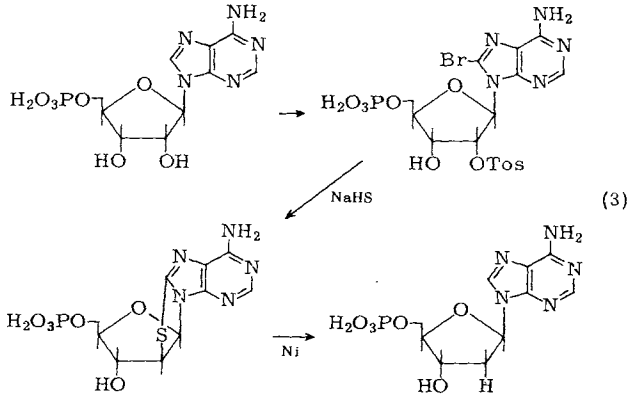


Fig. 2. Possible reaction pathways for the replacement of the 2'-hydroxyl group of ribose by hydrogen: a) direct substitution, b) dehydration-hydrogenation, c) oxidation-reduction, d) activation by ATP. P = phosphate residue, B = purine or pyrimidine base.

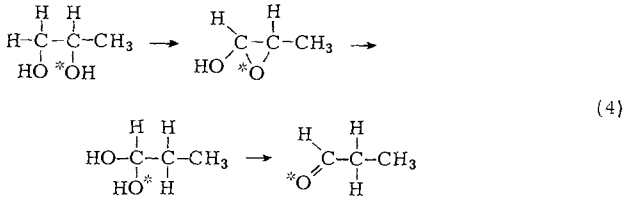
3. Mode of Action and Regulation



3.1. Reduction of the Hydroxyl Group

How is one of the two secondary hydroxyl groups of ribose selectively reduced to a methylene group at pH = 7 and at

and cofactors, it is conceivable that the modes of action of these two bacterial reductases are fundamentally similar. It may be taken as certain that the 2'-hydroxyl group is reduced directly without the existence of intermediate products [Fig. 2(a)]. The experiments mentioned below rule out reaction sequences such as dehydration-hydrogenation (b) or oxidation-reduction (c), and activation of the hydroxyl group by phosphorylation (d) likewise cannot be detected, since synthetic cytidine-2'-phosphate-5'-diphosphate is not a reductase substrate[71]. In both systems, only one new hydrogen atom enters the molecule with retention of configuration at the asymmetric $C^{2'}$. This follows from chemical[72,73] and NMR-spectroscopic analyses[74,75] of the monodeuterated (or monotritiated) 2'-deoxyribonucleotides obtained when the enzymatic reduction is carried out in ^2H_2O or ^3H_2O and hence with deuterated or tritiated dithiols $R(S^*H)_2$ as the reducing agent. The assignment of the enzymatically formed products has also been confirmed by independent synthesis of the two epimeric [2'-(α- or β-)deutero]-2'-deoxycytidines[76]. These results are compatible only with the direct pathway (a), and at the same time refute an S_N2 substitution of the hydroxyl group with inversion, which is improbable in any case at the furanose ring.

The coenzyme B_{12}-dependent enzyme diol dehydrase from *Aerobacter aerogenes* catalyzes an oxidoreduction of propanediol to propionaldehyde, which seems to be related to the reduction of ribonucleotides, and which proceeds with migration of oxygen *via* an epoxide intermediate [reaction (4)][77]. By reaction of specifically ^{18}O-labeled adenosine triphosphates[78] with *Lactobacillus* ribonucleotide reductase, we have

(4)

shown that no intramolecular migration of the oxygen atoms 2′ and 3′ occurs in this system; $O^{2'}$ disappears completely from the molecule, and $O^{3'}$ in [3′-^{18}O]ATP is not affected by the reduction. However, if [2′-^{18}O]ATP is incubated with enzyme and coenzyme in the absence of reducing agent, no equilibration of the isotope content of $O^{2'}$ with $H_2{}^{16}O$ occurs, *i.e.* a conventional S_N1 reaction with ionization at $C^{2'}$ also does not take place by route (a)[79]. The isotope pattern of the RNA and DNA from *E. coli* in a medium containing ^{18}O, which is identical apart from $O^{2'}$[14], shows that here again the 2′-oxygen is eliminated by reduction in the same direct way.

Nucleotides in which the free 2′-OH group is replaced by a phosphate residue[71], by a methoxy[81], amino, azido, or chloro substituent[80], or by an OH group in the *arabino* configuration[81] are not transformed by ribonucleotide reductase; however, 3′-*xylo*nucleotides, 3′-deoxyribonucleotides[82,83] and 3′-*O*-methylribonucleotides are also not reduced[81]. Since most of these compounds are not effective inhibitors, we assume that the 3′-hydroxyl group is a binding site for the enzyme, and that substrate *binding* (on 3′-OH) and substrate *reduction* (on 2′-OH) are concerted. All these findings can be formally compared to an S_Ni reaction, in which the exchange of the hydroxyl group takes place in a prefixed complex with several reaction partners (enzyme groups and reducing agent) with retention of configuration.

There is much less clarity about the hydrogen transfer between thioredoxin or another dithiol and the 2′-position of ribose. There is growing experimental evidence that free-radical intermediates, which are stabilized by the cofactors (iron atoms in *E. coli*, 5′-deoxyadenosylcobalamin in *L. leichmannii*), occur in this process. Thus an organic free radical that is characterized by a light absorption at 410 nm and an ESR signal at $g = 2.0047$, and whose destruction (*e.g.* by hydroxylamine) is exactly paralleled by a loss of the enzyme activity, is observed in the metalloprotein B2[67]. A hydrogen-transferring function of the coenzyme in the *Lactobacillus* reductase system can be detected even more directly. It has been known for some time that this enzyme, in the presence of dithiols and an effector such as dGTP, catalyzes a tritium exchange between synthetic [5′-^{3}H]-5′-deoxyadenosylcobalamin and water (which is used as an activity test) or conversely between ^3H_2O and unlabeled coenzyme, and that this tritium exchange and the substrate reduction are inhibited to the same extent by protein reagents such as *N*-bromosuccinimide[26,57]. The reactive intermediate, in which there must be *three* equivalent hydrogen atoms on $C^{5'}$ of the coenzyme, was recently discovered by fast-reaction techniques[84,85]; with a half-life in the region of 10—100 ms, one observes a change from the spectrum of the coenzyme (with trivalent cobalt as a central atom) to a spectrum of reduced cob(II)alamin and the appearance of an ESR signal at $g = 2.119$, which can be reconciled with an enzyme-fixed complex of the free radicals [$>Co^{2+}<$] and [5′-deoxyadenosyl·]. The concentration of this intermediate rapidly decreases again in the presence of substrate. 5′-Deoxyadenosine and aquocob(II)alamin are also formed in a slow, irreversible reaction, with the appearance of other ESR signals[86]. It may be assumed that the deoxyadenosyl radical formed by reversible homolysis of the Co—C bond in the coenzyme is responsible, in conjunction with one or more thiol groups, both for the hydrogen exchange and for the reduction of the ribose (Fig. 3).

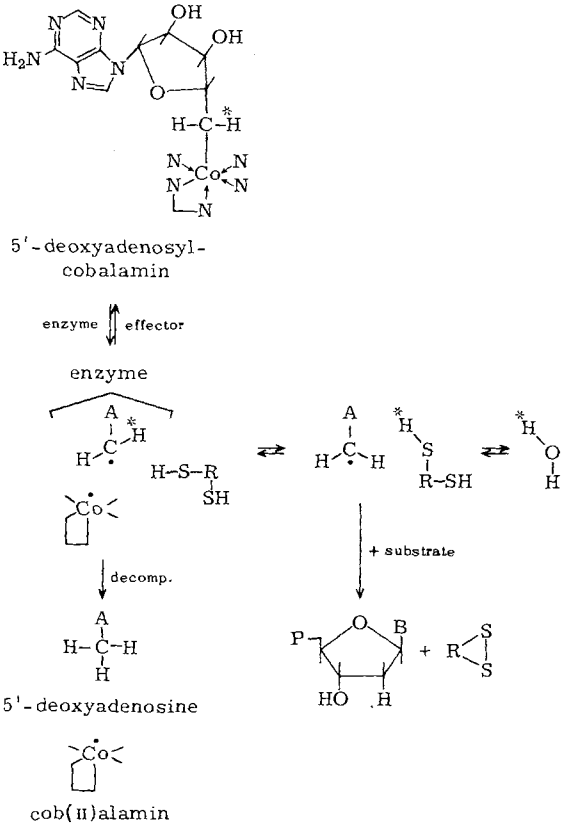


Fig. 3. Structure and function of 5′-deoxyadenosylcobalamin (coenzyme B_{12}) in the ribonucleotide reductase from *L. leichmannii* (modified after [84]). The transfer of a hydrogen isotope (*) from labeled coenzyme to water or from water to the coenzyme or the substrate is shown. A = adenosine – $C^{5'}$, B = purine or pyrimidine base, P = phosphate residues, R = thioredoxin or dithiol. The corrin ring system and the lower axial ligand of the cobalt are only indicated.

A separate analysis of the nature of the hydrogen transfer as the final step of the reduction of substrate in such enzyme-radical-thiol complexes will prove very difficult. No ESR signal that could be assigned to a nucleotide radical has been observed so far. It is therefore impossible at present to say

whether the hydroxyl group is finally replaced by a hydrogen atom or by a hydride ion. An answer to this question would also require a precise knowledge of the amino acid side chains in the catalytic center of the proteins, since the hydroxyl group could, *e.g.*, be specifically protonated by these side chains and removed as a water molecule. (So far it has only been shown that cysteine residues are probably involved in the activity of both bacterial reductases[66, 87].) From all the observations taken together, one may expect a highly ordered transition state from the substrate, amino acid groups of the enzyme, and a reduced species from cofactors and SH groups; Figure 4 is an attempt to describe this transition state in the form of a "snapshot".

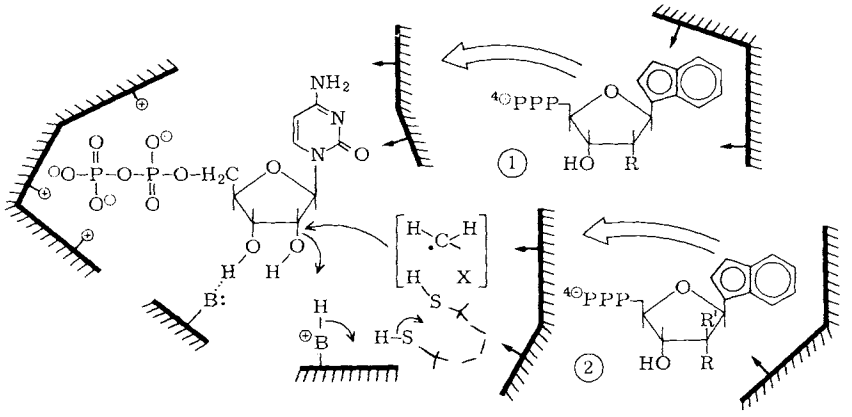

Fig. 4. Hypothetical model of the active site of a ribonucleotide reductase. The substrate (cytidine diphosphate) is fixed to the protein *via* the terminal phosphate residues and the 3'-hydroxyl group; the quality of the bonding to the purine or pyrimidine base depends on an allosteric effector ①. The reduction of $C^{2'}$ is stimulated by other effectors ②, which optimize the bonding of the hydrogen-donating system. X is the iron complex or cob(II)alamin radical of the type I and type II reductases respectively. Arro on the protein symbolize interactions of unknown nature. B = basic ami acid residue, P = phosphate, R,R' = H or OH.

In reality, however, the dynamic situation is even more complicated by the bonding of allosteric effectors to the enzyme.

3.2. Regulation of Enzyme Activity

Regulation of substrate reduction by effectors or modifiers is so characteristic of ribonucleotide reductases that its description would fill many pages[30, 57, 62, 65, 81–83, 88–91]. Primarily, deoxyribonucleoside triphosphates and ATP, and also modified nucleotides[81–83], accelerate or inhibit the catalysis by the enzyme, both the K_m values and the rate constants of the substrates being altered. Table 3 shows that there are similarities in this respect among the type I enzymes, but there are also great species-specific differences. A different picture is found for the regulation pattern in the case of the *Lactobacillus* reductase (Table 4), where in addition to slight product inhibition, a pronounced specific stimulation of the reduction of ATP by dGTP, of CTP by dATP, and of UTP by dCTP is observed[89]; even totally non-natural and slow-reacting nucleotides such such as (*N*-ribofuranosylbenzimidazole)-5'-triphosphate are subject to the stimulation[81].

Little is known about the detailed mode of action of the effectors, as in most cases of this type. A number of observations point to changes in the conformation of the protein, as is required by the model of an allosteric regulation[30, 42, 65, 66]. It is conceivable that the catalytic site of a reductase is thereby particularly well or less well ordered (Fig. 4). Extensive binding studies[21, 65] show that there are two classes of regulatory sites on the *E. coli* subunits, one of which controls the substrate specificity and the other the total activity of the enzyme.

Table 3. Effect of nucleoside triphosphates on the reduction of ribonucleotides: stimulation (+) and inhibition (−).

Effector	*E. coli* [65, 90]				T4 phage [62]				Novikoff tumor [88]			
	UDP	CDP	GDP	ADP	UDP	CDP	GDP	ADP	UDP	CDP	GDP	ADP
dTTP	+	+	+	+	+	+	+	+	−	−	+	+
dCTP					+	+						
dGTP			+	+			+	+	−	−	−	+
dATP	−	−	−	−	+	+	−		−	−	−	−
ATP	+	+			+	+			+	+	+	

Table 4. Relative reaction rates of the reduction of ribonucleotides by *Lactobacillus* reductase [81, 89].

Effector	GTP	ATP	UTP	CTP	ITP [a]	BzTP [b]
none	100	20	14	36	6	0.2
dGTP	86	103				2
dCTP			37	31		
dATP		15		102		
dTTP					38	
araATP		11		36		

[a] Inosine triphosphate.
[b] (*N*-Ribofuranosylbenzimidazole)-5'-triphosphate.

The *Lactobacillus* reductase also reacts to two groups of effector nucleotides, one of which again affects the substrate specificity and the other the enzyme-coenzyme interaction, including the tritium exchange[81]. A regulatory effect of the coenzyme concentration on the binding of substrate and effectors is also observed[89]. From the marked base specificity of all these effects, considerable binding contributions by the amino and keto substituents of the purine and pyrimidine bases can be expected in the catalytic and regulatory centers; these interactions have not yet been analyzed.

From the regulation phenomena listed in Tables 3 and 4, it seems natural to construct a homeostatic mechanism that guarantees a balanced supply of all four deoxyribonucleotides to the cell. If one nucleotide accumulates during DNA synthesis, it stimulates production of the others; on the other hand, if no further DNA is being formed, an accumulation of certain nucleotides inhibits further reduction of ribonucleotides. Detailed models of this kind have been devised[88-91]. The extent to which this regulation is actually achieved *in vivo* is admittedly difficult to estimate from the behavior of the isolated ribonucleotide reductases at partly unphysiological concentrations. Further unknowns are the rate and control of the biosynthetic pathways by which effector nucleotides (particularly dTTP) must first be formed from the primary reduction products (*e.g.* dUDP) before they can exert a feedback control[13]. However, changes in the deoxyribonucleotide pools in tissue cultures under the influence of thymidine and other nucleosides in the medium point to a functioning of allosteric regulation in intact cells[117].

4. The Hydrogen-Donating Thioredoxin System

The hydrogen required for the reduction of ribonucleotides ultimately comes from the cellular NADPH pool that is available for synthetic purposes, but it is used only through the intervention of a specific "redoxin". As was mentioned earlier (Section 2.1), the thioredoxin system, which was first discovered in *E. coli*, consists of the small protein thioredoxin, whose cysteine residues change reversibly between the dithiol and disulfide forms, and the flavoenzyme thioredoxin reductase, which is responsible for the reduction of the oxidized thioredoxin. If one includes the (probable) processes on enzymes and coenzymes, one thus obtains a multi-stage hydrogen and electron transport from NADPH to ribose (Fig. 5).

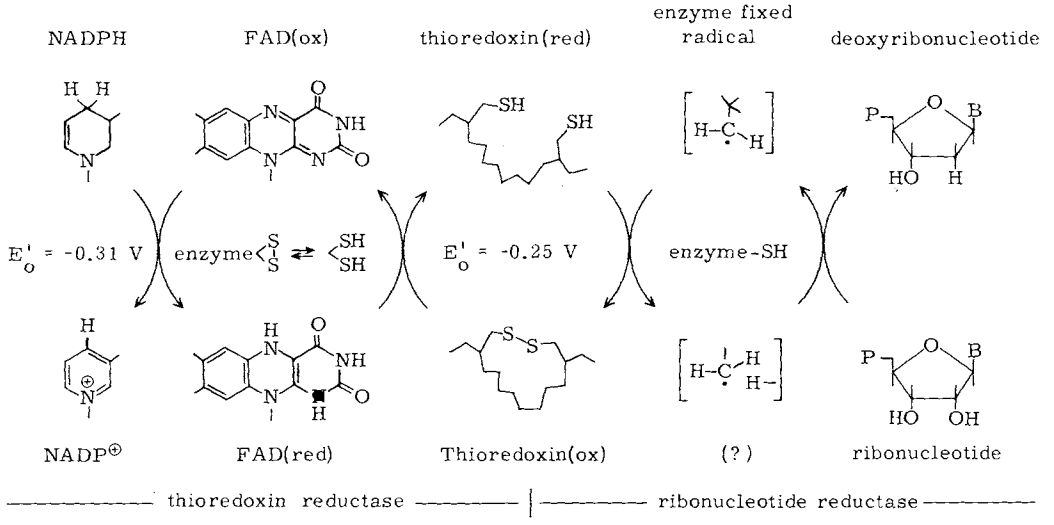

Fig. 5. Intermediate steps of the hydrogen transfer from NADPH to ribonucleotides by thioredoxin reductase and ribonucleotide reductase. In the penultimate stage, the structure of the 5'-deoxyadenosyl residue (type II reductases) is indicated (cf. Fig. 3). P = phosphate residues, B = purine or pyrimidine base.

Thioredoxins are heat-stable polypeptides built up from about 100 amino acids and having a molecular weight of about 12000, which have been isolated from the phage T4, from bacteria, from yeast, and from liver (Table 5). They themselves have no enzyme activity, but as an active site they contain two cysteine residues separated by two other amino acids: the sequence of this region in *E. coli* and yeast[101,102], is -Trp-Cys-Gly-Pro-Cys-Lys-, while the sequence in the T4 phage is -Lys-Cys-Val-Tyr-Cys-Asp-[93]. Oxidation to the disulfide with formation of a 14-membered ring is accompanied by considerable local changes in conformation, which are directly reflected in the changing tryptophan fluorescence of the molecules[103]. Like glutathione reductase, the NADPH-specific thioredoxin reductases, whose existence has also been detected in several tissues (Table 5), contain FAD as the

Table 5. Molecular weights and other properties of thioredoxin and thioredoxin reductases.

Source	Thioredoxin	Thioredoxin reductase	Ref.
Escherichia coli	11657, 108 amino acids, 2 Cys	66000–73000, 2 peptide chains, 2 FAD	[92, 99, 101, 104]
T4 phage	87 amino acids, 2 Cys	not detected	[93]
Lactobacillus leichmannii	12000	55000	[94]
Yeast	12600, *ca.* 120 amino acids, 4 Cys	75000, 2 subunits, 2 FAD	[95, 102, 119]
Rat liver	not yet purified to homogeneity		[96, 100]
Calf liver	12000, 103 amino acids, 4 Cys		[97]
Novikoff tumor	12100, 109 amino acids, 6 Cys	66700	[98]

prosthetic group; a disulfide grouping with the sequence -Ala-Cys-Ala-Thr-Cys-Asp- also takes part in the redox process in the *E. coli* enzyme[104].

Thioredoxins, thioredoxin reductases, and ribonucleotide reductases of different species have varying activities in heterologous mixtures, and no systematic pattern of interchangeability has been recognized so far. The readily obtainable *E. coli* thioredoxin has proved suitable as a hydrogen donor for the *Lactobacillus* and yeast ribonucleotide reductases[105,32], but is inactive toward the reductases of the T4 phage and of wheat[62,33]. Whereas the *E. coli* ribonucleotide reductase accepts all known thioredoxins, the thioredoxin reductase of the same bacterium is strictly specific for its own oxidized thioredoxin and that of T4 phage[93-95,98].

Reductions of ribonucleotides and of thioredoxin show practically no connection with other metabolic pathways in the cell. Only the participation of the thioredoxin system in the reduction of methionine sulfoxide and of sulfate in yeast has been detected[106], and the nitrate reduction and the ribonucleotide reduction in anaerobic microorganisms could have a common hydrogen-donor system[28]. The ribonucleotide reduction, in accordance with Figure 5, is not reversible; from what was said earlier, a general biosynthesis pathway from deoxyribonucleotides to ribonucleotides is not to be expected. However, an enzymatic hydroxylation of thymidine or 2'-deoxyuridine to ribothymidine or uridine occurs as the first step in the oxidative conversion of thymidine into uracil[107]. A pyrimidine-2'-deoxyribonucleoside 2'-hydroxylase isolated from the mold *Neurospora crassa* catalyzes this reaction with oxygen, ketoglutarate, iron(II) ions, and ascorbate as substrates and cofactors.

5. Ribonucleotide Reduction and Growth

Ribonucleotide reductase cannot be detected in dry wheat grains or in unfertilized sea urchin eggs, but within a few hours after the start of germination or after fertilization, extracts of these tissues exhibit the ability to reduce ribonucleotides[33,35]. If part of the liver is removed from rats, the ribonucleotide reductase activity of the regenerating tissue increases to 20 times the normal value between 20 and 50 h after the operation[42,43], and the deoxyribonucleotide pools show a pronounced increase at the same time[108]. In the brains of chick and rat embryos, a pronounced maximum of this enzyme activity roughly coincides in time with the fastest proliferation of neuroblasts[47].

The key function of the ribonucleotide reductase for cell growth becomes even clearer when its activity (or the size of the dNTP pools) is followed during the division cycle and is compared with the DNA synthesis in cultures of synchronized cells. In mouse L cells[41] and (particularly clearly, see Fig. 6) in yeast cells[109], the ribonucleotide reductase reaches its peak shortly before the strongest DNA production during the S phase (*i.e.* the synthesis phase between two cell divisions). The quantity of the four deoxyribonucleotides present in synchronized mammalian cells (mouse, hamster)[6-9] also increases by a factor of 10 only during the S phase and decreases in the early G2 phase, during or shortly after the DNA synthesis reaches its maximum.

From the action of inhibitors of mRNA and protein biosynthesis such as actinomycin[43], puromycin[35], or cycloheximide[41,109] in many of these tissues, it is quite clear that the increase and decrease in the ribonucleotide reduction is in fact due to induction or absence of *de-novo* enzyme synthesis. The early appearance of ribonucleotide reductases in growing cells can be easily reconciled with the stepwise onset of the production of mRNA, protein, and DNA[110]. On the other hand, no pronounced growth-dependent variations of this kind have been observed for preceding and succeeding enzymes such as thioredoxin reductase[100] and DNA polymerase[35,41].

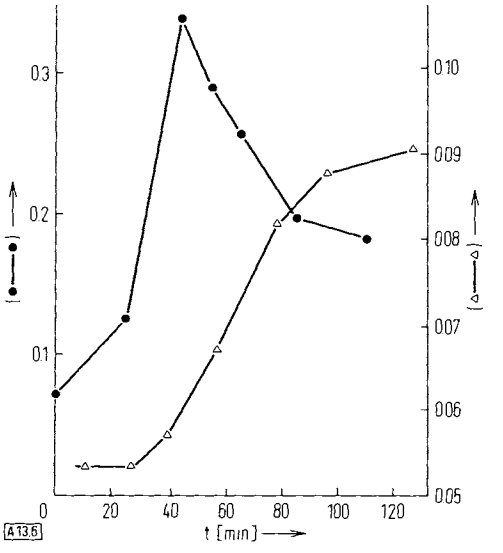

Fig. 6. Ribonucleotide reductase activity (●···●) and DNA production (△ △) in synchronized yeast cells (after [109]). Left-hand ordinate: nmol of substrate reacted per mg of protein per min; right-hand ordinate: mg of DNA per 100 ml of culture; abscissa: incubation time of the yeast culture.

Ribonucleotide reductase is just as essential for the bacterium *Escherichia coli* as for eukaryotic cells. Two mutants E101[111] and LD195[112] in which the proteins B1 and B2 of the reductase exhibit only a small fraction of the activity of the wild type and are temperature-sensitive have recently been isolated. The gene locus *dna*F (one of seven that are responsible for DNA synthesis) was thus identified as the structure gene for ribonucleotide reduetase. These bacteria can multiply at 37 to 42 °C only if deoxyribonucleosides are supplied in the medium, and growth inhibition by hydroxyurea[58] is 20 times as strong as in the case of the wild type. Similarly, coenzyme B_{12} may be limiting for the type II reductases. The nodule bacterium *Rhizobium meliloti* exhibits growth disturbances and a reduced DNA content in the cells if it lacks cobalt, the central metal atom of deoxyadenosylcobalamin[113].

Their significant involvement in the DNA synthesis and in cell proliferation makes the ribonucleotide reductases (and their inhibition) a subject of great current interest in virus-infected tissues and in tumor cells. T4 phages contain three genes *nrd*A, B, and C; phage-specific ribonucleotide reductase and thioredoxin (but not thioredoxin reductase) that have only a remote similarity to the bacterial proteins are formed in the host cell as the products of these genes[23,24,62,114]. Increased specific reductase activities are found in kidney cells infected with polyoma virus[40], in Yaba monkey virus

tumors[49], and in leukemic mice[46], but there are generally no qualitative differences in relation to normal mammalian enzymes. Until pure enzymes from normal and from infected tissues are available, it will therefore not be possible to say for certain whether pathogenic plant and animal viruses, and in particular the oncogenic RNA viruses, have specific ribonucleotide reductases. No obvious differences in the reductase systems have been found in rat tumors and healthy rat livers. Nevertheless, the reduction of ribonucleotides in tumors merits great attention from the diagnostic and chemotherapeutic standpoints, since *Elford* has been able to demonstrate a striking correlation between the rate of growth of numerous rat hepatomas and this enzyme activity[150]: The very rapidly proliferating Novikoff and Walker tumors exhibit reductase activities up to 500 times as high as those of the slowest-growing tumors. Relationships are conceivable between the cytotoxic action of hydroxyurea and arabinonucleosides for malignant and normal tissues *in vivo* and their inhibitory effect on ribonucleotide reductases *in vitro*[136, 58, 81, 115]; both substances most strongly inhibit DNA synthesis and have less effect on the RNA and protein syntheses. On the other hand, it must not be forgotten that the nucleic acid metabolism of a cell involves two dozen nucleotides and not many fewer enzymes, so that the role of an individual enzyme, though important, can hardly be the sole determining factor in a complex process like DNA replication.

6. Outlook

Numerous chemically and biologically interesting aspects of the reduction of ribonucleotides require further elucidation: reaction mechanism, structure of the active sites and mode of action of the effector molecules on the protein, initiation and repression of enzyme biosynthesis. Though the initiating factors of the enzyme induction are still completely unknown, regulatory intervention in normal and in pathological cell growth by means of these key enzymes should be feasible in the future. The existence of two entirely different ribonucleotide reductase systems for the catalysis of a fundamental metabolic reaction is remarkable. We feel that a comprehensive characterization of the ribonucleotide reduction and the thioredoxin system in other organisms at different levels of evolution is of the greatest importance in order to clarify the distribution of the enzyme types and regulation patterns. This may be expected to yield new information about the evolution and phylogenesis of life, since most models of the origin of life take no account of the transition from ribonucleotides or RNA to DNA as self-reproducing material, a step that is scarcely imaginable without enzymes[116]. Finally, the search for new, possibly more easily handled ribonucleotide reductases is of interest from the standpoint of preparative nucleotide chemistry, since it could facilitate access to modified deoxyribonucleotides from the much more readily accessible ribonucleotides. The recent rapidly growing interest in the reduction of ribonucleotides should provide an answer to some of these questions.

Our own work in this field has been supported by the Deutsche Forschungsgemeinschaft. I am also indebted to Harry Hogenkamp and Ray Blakley (Iowa City) for their generous support, and to numerous other colleagues for their kindness in communicating new results.

What Do We Know about the Deeper Layers of the Earth?

By Roland G. Schwab[*]

In the last twenty years modern chemical and physical methods have done much to extend our knowledge of the Earth. Some new questions have been raised, *e.g.* the question of the bonding relationships in the Earth's interior, which make the Earth an interesting object of research to chemists as well. This progress report attempts to give a survey of the Earth's structure as seen at the present day. Naturally, special emphasis has been placed on those aspects which concern the chemist.

1. Introduction[**]

In the first place it seems useful to compare the major physical characteristics of the Earth with those of neighboring celestial bodies: Mercury, Venus, the Earth, and Mars constitute the four inner planets of our solar system. Its mass of 6×10^{27} g and an average radius of 6371 km make the Earth the largest of these planets, as can be seen from Table 1.

Table 1. Relative masses, relative radii, and densities of the four inner planets (as well as of the Moon) (after *Urey* [1]).

Planet	Rel. mass	Rel. radius	Density [g/cm³]
Mercury	0.0543	0.377	5.59
Venus	0.8137	0.957	5.12
Earth	1.0	1.0	5.515
(Moon)	0.0123	0.2728	3.34
Mars	0.1077	*ca.* 0.525	*ca.* 4.1

The ancient Greeks calculated an amazingly accurate value for the Earth's radius, while the Earth's density first became known through Newton's work. However, much time was to pass before it was possible to obtain clues about the structure and composition of the Earth's interior. Apart from a series of other physical and chemical disciplines three fields have done most during this century to advance our knowledge: 1. seismology, 2. geochemistry, and 3. modern high-pressure research (high-pressure petrology).

Seismology allows physical parameters to be measured within the Earth, and high-pressure research enables geochemical material systems existing under the conditions of pressure and temperature (P, T conditions) prevailing in the Earth's interior to be investigated experimentally. Correlation of the geophysical data with the results obtained from geochemistry and high-pressure petrology is one of the main tasks of modern Earth science research. In this connection it may be asked how reliable are statements about the deeper layers of the Earth, because direct sampling and investigation is only possible on the outermost part of the planet, *i.e.* on the crust. Neither do boreholes really help to extend out direct knowledge, as it is hardly possible to drill to depths greater than 10 km. Furthermore, the means of doing so are generally only available for commercial purposes, *e.g.* for the search for oil and gas. This means, in turn, that sedimentary strata are practically the only ones penetrated. Some important clues about regions to a depth of approx. 100 km are provided by volcanic phenomena. However, insofar as science will only take as certain what can be directly observed and examined, such data can only be obtained about the Earth's surface, where there is a possibility of representative sampling.

Similarly to the situation in chemistry and physics, reliable statements may be obtained beyond this point on the basis of indirect measurements. The Earth models developed analogously to the atomic models are basically as certain as the existence of the electron or the atomic nucleus. The important role played by electromagnetic waves in the elucidation of the structure of matter has been taken over by "seismic waves" in investigations into the interior of the Earth.

2. Underlying Principles and Classical Results of Seismology

Seismic measurements concern the transmission of elastic compressions and deformations produced in the Earth by earthquakes or nuclear explosions. Fundamentally two types of oscillations can be distinguished:

1. compression waves (longitudinal oscillations) and
2. shear waves (transverse oscillations).

The velocities v_l and v_t of these three-dimensionally propagating body waves depends on the elastic properties and the density of the medium:

$v_l^2 = (K + \frac{4}{3}\mu)/\rho$ for the longitudinal waves
and
$v_t^2 = \mu/\rho$ for the transverse waves
K = bulk modulus, μ = modulus of rigidity, ρ = density

Both types of waves are produced simultaneously in solid materials; in liquids and gases, which offer no resistance to deformations, the shear waves do not arise. This offers a possibility of recognizing molten regions in the Earth's interior.

According to the above equations the velocity of the longitudinal waves is greater than that of the transverse waves by a factor of 1.7. Therefore, if one records the waves arriving at a given locality a certain distance from an earthquake focus, the longitudinal compression waves arrive as the primary waves (P-waves) and the transverse shear waves as secondary waves (S-waves). Since the density ρ increases with increasing

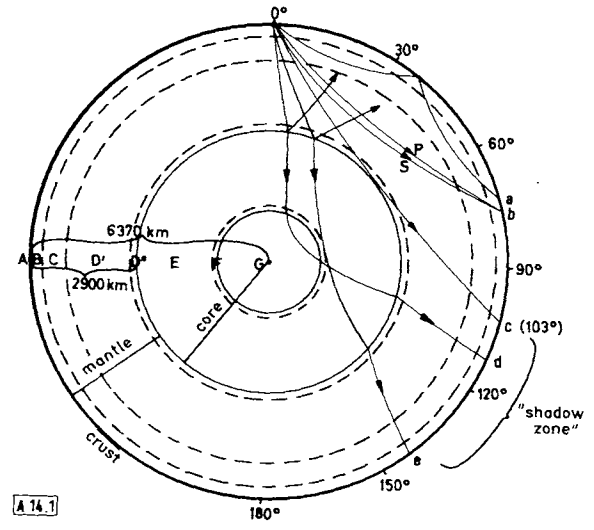

Fig. 1. Course of earthquake waves through the Earth: unless stated to the contrary, these are P waves. Deeper layers are recorded with increasing angular distance between the recording point and the focus; reflection and refraction take place at phase boundaries. The S waves disappear above 103°; P waves can only be observed if they traverse the inner core ("shadow zone" from c to e). The course and the velocity of the seismic waves have led to division of the Earth into crust, mantle, and core, and to the further subdivision of these into zones ("Bullen zones": A—G).

depth on account of rock compaction, the body waves follow a convex path relative to the center of the Earth, *i.e.* they reappear at a fixed distance from the earthquake focus. The greater the distance between the recording point and the earthquake focus, the deeper the layers that have been penetrated (cf. Fig. 1).

If the seismic waves encounter material or phase boundaries during their passage through the Earth, the respective "rays" are split up into P and S waves in addition to being reflected and refracted, so that the seismograms adopt fairly complicated forms. Earthquake waves arriving at the surface are reflected, but they also give rise to surface waves, *i.e.* disturbances which propagate two-dimensionally over the Earth's surface. Surface waves are divided into Rayleigh waves and Love waves, depending on whether their direction of oscillation is perpendicular to the surface, as is the case with water waves, or whether it is along the surface. Both disturbances appear in seismograms with maximum amplitude (M waves). Classical seismic analysis is based on plotting velocity profiles

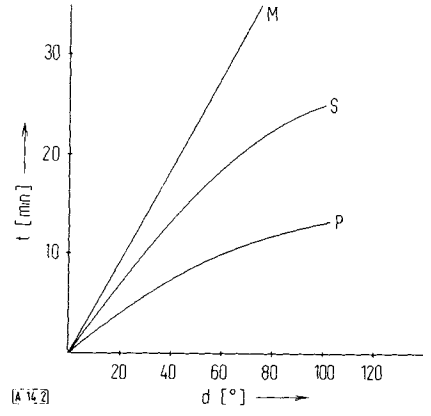

Fig. 2. Schematic representation of travel-time curves for P, S, and M waves. The curves are obtained by recording the arrival times at increasing distances (angular distance d) from the earthquake focus.

through the Earth, which can be obtained by complicated calculations from the travel-time curves. Such curves (Fig. 2) are obtained by relating the arrival times of the respective wave types to the distance from the earthquake focus.

Travel-time curves of this type reveal some characteristic features (Fig. 2):

1. For P and S waves they are curved concavely against the d-axis (d = angular distance), *i.e.* the velocity of propagation of the body waves increases with increasing distance or with increasing depth of penetration.

2. For angular distances greater than 103° P waves are seldom recorded, S waves not at all; the travel-time curve for the S waves stops slightly before 103°, as their course deviates somewhat from that of the P waves.

3. The surface waves (M waves) produce straight lines in the travel-time curves, as they propagate at constant velocity which depends upon their wavelength. Evaluation of surface wave measurements only became possible by the use of computers.

3. The Layered Structure of the Earth—A Result of Classical Seismology

Early on it was found necessary to divide the Earth into crust, mantle and core in order to evaluate the travel-time curves of body waves. The first clues pointing to the existence of a central core were provided in 1906 by *Oldham*[2]. In 1909 *Mohorovičić*[3] drew attention to the sudden increase in the velocity of body waves at a depth of *ca.* 30 km. This discontinuity of "Moho" boundary marks the boundary between the crust and the mantle. Its depth, and consequently the thickness of the solid crust, varies strongly from place to place (Fig. 3).

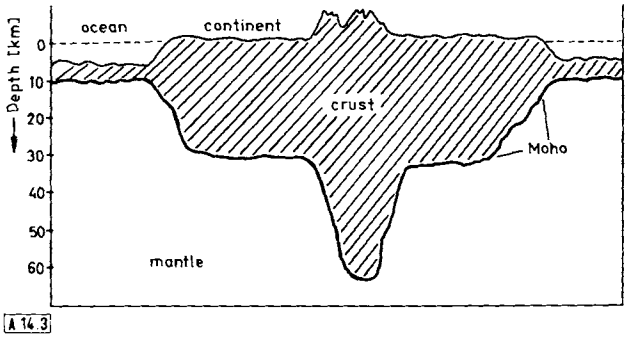

Fig. 3. Schematic representation of the crust thickness of oceanic and continental areas, corresponding to varying depth of the Moho surface. The thickness of the crust in oceanic regions is on average 5 km, rising to 33 km in continental regions. Below high mountain ranges it reaches a thickness of more than 60 km.

According to *Jeffreys*[4], the transition from mantle to core is to be expected at a depth of 2898 ± 3 km. The large central core is distinguished by strikingly different elastic properties. Thus, the P waves are retarded within the outer core, and the seismic rays refracted into it. This results in the "shading effect" of the core at angular distances of 103° to *ca.* 142°. In this area only P waves are encountered, which pass through the inner part of the core and are there strongly bent (Fig. 1). The complete disappearance of the shear waves indicates that the outer core is liquid, while a solid state of aggregation

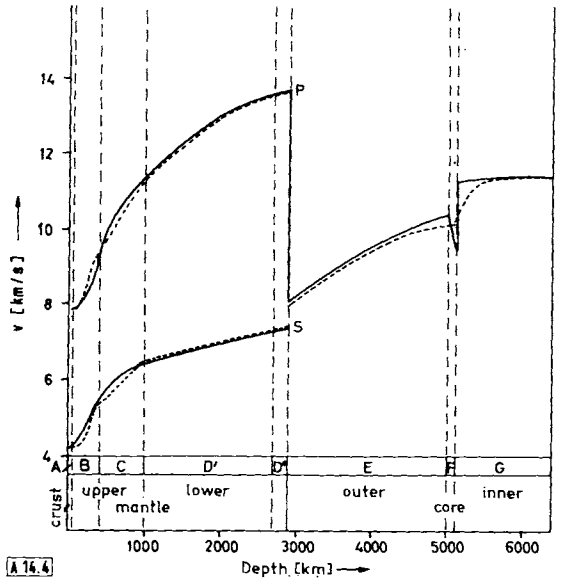

Fig. 4. Seismic profiles according to *Jeffreys* [4] (·····) and *Gutenberg* [8] (– – –). The velocity distribution of the P and S waves (v = velocity) led *Bullen* [7] to a finer subdivision of the Earth into eight characteristic zones.

must again be assumed for its inner part[5-7]. With *ca.* 68.5 wt-% the mantle constitutes the major part of the Earth's mass, followed by the core with *ca.* 31.0 wt-%. The crust accounts for less than 0.5 wt-%.

The division of the Earth into three major zones is also reflected in the classical seismic velocity profile given by *Jeffreys*[4] (Fig. 4).

On the basis of *Jeffreys*' data the Earth is divided into eight Bullen zones[6, 7] (Table 2).

Table 2. The "Bullen zones".

Bullen zone	Depth [km]	Name
A	0--33	Crust
B	33--410	Upper mantle
C	410--1000	
D'	1000--2700	Lower mantle
D''	2700--2900	
E	2900--4980	Outer core
F	4980--5120	Transition zone
G	5120--6371	Inner core

The question now is, by what phases and rocks can one most easily explain the seismic velocities observed in the respective Bullen zones. For this purpose the seismic profiles must be refined and the p,T relationships and the chemical compositions in the interior of the Earth must be studied more closely.

4. Recent Seismic Results

Recent investigations on surface waves and natural oscillations of the Earth, which can be observed during major earthquakes, have produced more reliable information about the density distribution within the Earth and have also led to more refined seismic profiles. In the upper mantle, in particular the classical views have undergone a whole series of important changes. Most authors agree on the following points (Fig. 5): the upper mantle contains a zone in which the velocity of the shear waves (S waves) in particular is markedly reduced. This low-velocity zone (LVZ) appears over the entire world at a depth of *ca.* 100 to 250 km. Its existence was first suggested by *Gutenberg*[9, 10]. It is also agreed that there are at least two clear higher-velocity zones in the upper mantle, located at 300—400 km and at 600—700 km and associated with corresponding density jumps. A further discontinuity is probably situated at a depth of 1050—1150 km. This region of the mantle (400—1050 km) is also described as a "transition zone". The data concerning the velocity and density distributions in the lower mantle are relatively consistent. Essentially, there only remain discrepancies about the nature of the transition zone between the mantle and the core from a depth of approximately 2800 km, and about the exact size of the core. Generally, the core is thought to begin at a depth of 2898 (approx. 2900) km. According to individual authors, however, this depth can be as little as 2821 km.

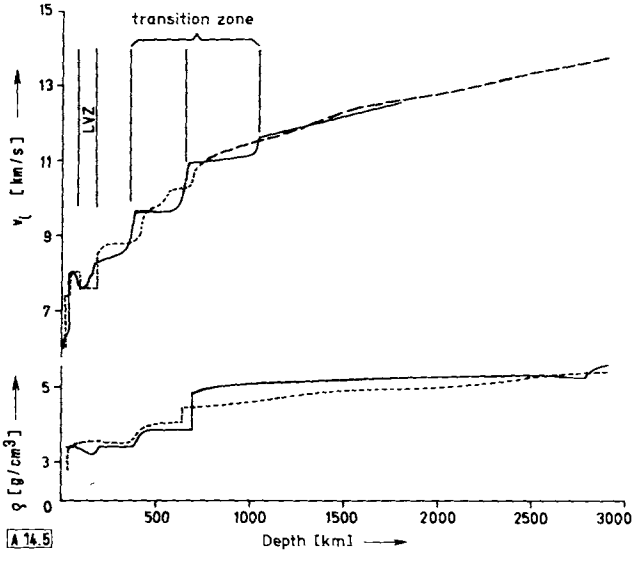

Fig. 5. Velocity of the P waves (v_l) and densities within the mantle. After the increase in the "Moho" (depth 30 km), the characteristic points are the sudden decrease of the seismic velocities in the LVZ and the stepwise velocity increases in the transition zone (according to *Archambeau et al.* [13] (·····), *Helmberger* and *Wiggins* [14] (– – –), and *Vinnik* and *Nikolayev* [15] (·– ·– ·)). The seismic velocities can be relatively well correlated with the densities (according to *Anderson* [11] (——) and *Jordan* and *Anderson* [12] (– – –)).

In the core itself, only the liquid state of the outer core and the solid state of the inner core can be taken for certain. However, it has been suggested that there are up to four layers in the core[16]. The lithostatic pressure at the relevant depth can easily be calculated from the density distribution. The pressure rises from 1 atm at the ground surface to more than 3000 kbar (1 kbar = 1000 bar; 1 bar ≙ 0.99 atm) in the core (see Fig. 6).

5. The Chemical Composition of the Earth

The seismic velocities and the corresponding densities can only be interpreted if we have some indications about the chemical composition of the crust, the mantle, and the core. It is then possible to study the corresponding systems experimentally at the appropriate temperatures and pressures. All the phenomena in the velocity and density distributions that

cannot be ascribed to the effect of compaction of the layer in question must be attributed to changes in phase or in the chemical composition. High-pressure experiments can now be performed under static conditions up to and around 450 kbar at room temperature and up to around 300 kbar at 1200 °C[17]. Under dynamic conditions (shock wave experiments) the entire pressure range prevailing in the Earth can be covered experimentally. It is therefore necessary to know the chemical composition as precisely as possible in each case.

It is generally agreed that the chemical composition of the Earth was determined by the nature of its formation, and that the solar system and the Earth arose jointly from a cloud of gas and dust, the Earth by aggregation of the solid components. There are three indications for the chemical composition of the original substance:

1. distribution of the elements expected from nuclear synthesis;
2. distribution of the elements in the Sun; and
3. the results of chemical investigations on meteorites, if possible on material that may contain still unchanged aggregations from the original dust cloud.

These sources indicate that the Earth had an original composition such as we find in certain stony meteorites (carbonaceous chondrites of type I). The main constituents of these are listed in Table 3.

Table 3. Main constituents of carbonaceous chondrites of type I (after *Wiik* [18]).

Constituent	wt-%	Constituent	wt-%
H_2O	19.29	P_2O_5	0.35
C	3.97	K_2O	0.07
organic matter	5.53	CaO	1.56
Na_2O	0.74	TiO_2	0.07
MgO	15.96	Cr_2O_3	0.34
Al_2O_3	1.64	MnO	0.22
SiO_2	22.63	FeO	10.42
NiO	1.29	FeS	16.73
		CoO	0.06

The original solid material out of which the Earth was formed in the solar system, could therefore be more simply described as silicate-iron oxide dust with relatively high proportions of ice and carbon. It is widely agreed that this original material must have passed through a high-temperature reduction stage during aggregation. The only point on which there is disagreement is whether this occurred in one original body (*Ringwood*'s one-stage theory[19, 20]) or in several smaller bodies (*Urey*'s multistage theory[21–27]). In any event, the result was the reduction of iron oxide to metallic iron. The carbon present in the original material, or the organic substance, is supposed to have acted as the reducing agent. The temperatures necessary for the reduction process are thought to have been provided by the kinetic energy of infalling dust particles and larger fragments.

The reducing conditions at temperatures above 1000 °C led to a selective depletion of the most volatile elements and to a corresponding accumulation of less volatile ones, such as Ca, Mg, Al, Si, Ti (as oxides) and Fe, Co, and Ni (as elements).

The resulting silicate-metal phases, whether in one original body or several, were gravitationally unstable and gradually underwent segregation so that the heavy metal concentrated at the center and formed the planet's core, whereby the gravitational energy was set free. According to this theory, therefore, a mantle composed mainly of Mg and Fe silicates must have been formed in addition to a metallic core composed essentially of iron and a crust whose weight was of no real consequence.

The chemical models of the mantle, which incidentally comprises the major part of the Earth (*ca.* 68 wt-% and 90 vol-%), agree on the following points:

1. More than 90 wt-% of the mantle can be described by the $MgO—FeO—SiO_2$ system; no other oxide amounts to more than 4 wt-%.

2. The constituents $Na_2O—CaO—Al_2O_3$ together form between 5 and 10 wt-%, so that approximately 98 wt-% of the mantle can be covered by the six-component system $MgO—FeO—SiO_2—Na_2O—CaO—Al_2O_3$.

3. No other oxide reaches 0.6 wt-%. Since MgO and FeO are interchangeable in most silicates, and the same holds true to some extent for Na_2O and CaO, the mantle can then be described more simply by the quaternary system $CaO—MgO—Al_2O_3—SiO_2$.

The mean atomic weights found by a seismic equation of state as proposed by *Anderson*[11, 28, 29] are consistent with this picture. This equation is based on the seismic parameter Φ, which is obtained in accordance with

$$\Phi = K/\rho \quad \text{(a)}$$

$$\Phi = \partial p/\partial \rho \quad \text{(b)}$$

$$\Phi = v_l^2 - K(4/3)v_t^2 \quad \text{(c)}$$

(K = modulus of rigidity, ρ = density, p = pressure, v_l = longitudinal-wave velocity, v_t = transverse-wave velocity)

and from seismic data (c), static high-pressure experiments (a and b) and shock-wave experiments (b) (see also Section 2). From this one can estimate the mean atomic weight in the upper and lower mantle to be 22.4. *Birch*[30] arrived at the same result by a different route.

For the outer core the values are between 45.7 and 53.2. For comparison, the atomic weight of iron is 55.85. These considerations, therefore, also indicate an iron core and an Mg, Fe silicate mantle.

Before considering the phases of the crust, mantle, and core in greater detail, we must first discuss another important parameter, *i.e.* the temperature prevailing in the respective zones.

6. Temperatures in the Earth's Interior

While it is possible to obtain precise information about the distribution of pressure within the Earth, the same cannot be done for the temperature. We can only indicate boundary conditions, which essentially are based on measurements of the heat flux through the Earth's surface and on the respective solidus temperatures, as well as on the state of aggregation in the individual layers.

In both oceanic and continental areas the mean heat flux is

$f = 1.5 \times 10^{-6}$ cal cm^{-2} s^{-1}

If we take as a basis an average heat conductivity of the rocks equal to:

$c = 5 \times 10^{-3}$ cal cm^{-1} s^{-1} °C^{-1}

The result is a "geothermal gradient" of 3 °C/100 m. This means that we could expect 3000 °C at a depth of 100 km. However, seismic data indicate that practically the entire mantle must be crystalline, while only the metallic outer core is liquid. So the solidus temperatures of the mantle silicate are generally not exceeded. This leads us to estimate the temperatures at the core-mantle boundary as around 4000 °C. However, as proved by numerous volcanoes ejecting rock melts, the solidus temperatures can be exceeded within the upper mantle, at least locally. In the light of these circumstances, a steep temperature rise is produced in the crust and the upper mantle, followed by a very level course in the rest of the Earth (Fig. 6).

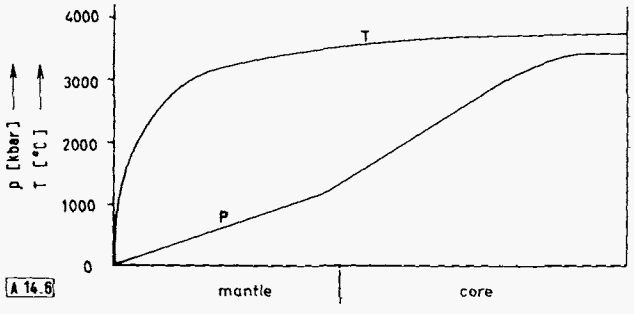

Fig. 6. Pressure and temperature distributions within the Earth

The exact position of the geotherms in the crust and the upper mantle depends upon a number of factors. These include the thermal prehistory of the Earth, the electrical and thermal conductivity of the respective layers, the precise geochemical element distribution, the nature and extent of the heat production, and the mechanism of the heat transfer.

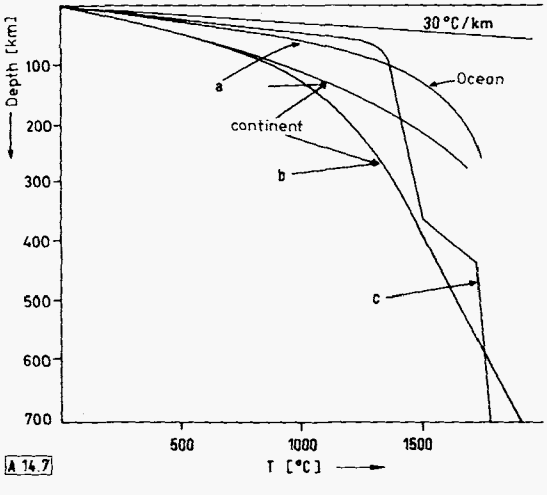

Fig. 7. Course of geotherms in the upper mantle according to *Ringwood* [20] (a), *Clark* and *Ringwood* [31] (b), and *Turcotte* and *Oxburgh* [32] (c). The differences between ocean and continent should be observed, as well as the almost constant temperature relationships as they are assumed to be at a depth of *ca.* 100–400 km on account of convection (c). The theoretical gradient of 30 °C/km is also given; this was found from measurements of the heat flux through the crust.

A further decisive factor is to what extent convection is possible. After all, very different geotherms are given for the upper mantle, which however come markedly closer to one another with increasing depth (Fig. 7).

The course of the geotherms reveals that the greater part of the Earth's heat is produced in the crust and the upper mantle. The reason for this is that the natural radioactive elements are strongly concentrated in the crust and the upper mantle, being almost completely absent in the rest of the Earth. We shall now discuss in greater detail the phases and rocks one can expect to find in the respective zones.

7. The Crust

The chemical and mineralogical composition of the crust with its directly accessible rocks is well known. The oceanic crust consists of a layer of deep sea sediments *ca.* 1 km thick and below it of a dark, magmatic rock, named basalt. Basalt is made up essentially of Ca, Mg, Fe metasilicates (pyroxenes) and Ca, Na aluminosilicates of the $NaAlSi_3O_8$—$CaAl_2Si_2O_8$ system, the plagioclases. Corresponding lavas are also ejected from the majority of the 800 or so volcanoes active at the present time, in both oceanic and continental regions.

On the basis of seismic data and field observations we can assume that the lowest part of the continental crust is also basaltic. The upper part of the continental crust is basically determined by the reactions of the rocks with the atmosphere *i.e.* by weathering and sedimentation. Sinking of the sediments into the *p,T* region of the middle crust produces first consolidation (diagenesis), then solid-state reactions with the formation of new minerals (metamorphosis), and finally partial melting (anatexis).

We know from investigations on these systems that the primary eutectic melt is very water-rich and that it has a granitic composition. In the resulting magma chambers convective flows occur, tearing material off the roof and the walls of the magma chambers. This material is totally or partially melted, while crystallization occurs on the bottom. This process causes the magma chambers to ascend until they finally solidify near the surface as large granite domes. Later they are exposed by erosion and again transformed into sediments. The continental crust therefore reveals a layer structure (Fig. 8). Rock melts can be expected in the middle part of the crust; however, these are very rich in SiO_2 (acidic). The magmas of the crust are granitic and only occur in the continental region.

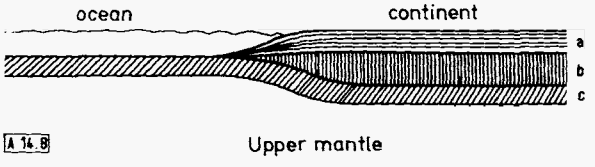

Fig. 8. Schematic representation of the layer structure of the continental crust. Key: a = Sediment, b = granite and gneiss, c = basalt/gabbro.

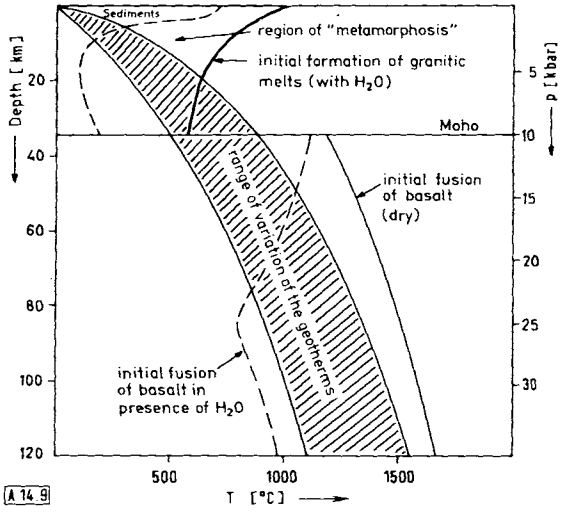
Basaltic melts can not be generated in the crust region, as can easily be seen by comparing the melting ranges of granites and basalts with the *p,T* conditions prevailing in the crust and the upper mantle (Fig. 9). Within the variation range of the geotherms, granitic melts may form from a depth of *ca.* 20 km if appropriate starting material is available. Basaltic melts cannot form either in the crust or in the mantle without

the presence of H_2O. However, if water is present basaltic melts can be generated under the conditions of the upper mantle. Beside the granitic magmatism of the crust, therefore, we have the basaltic magmatism of the upper mantle.

The basalt magmas from the mantle can provide important information about this part of the Earth. However, the chemical composition of the melts may undergo appreciable changes during their ascent on account of fractional crystallization and/or absorption of crust material (assimilation). Oxidation processes and separation of oxidic iron ores may lead to acidic residual melts.

Part of the basaltic melts does not solidify into true basalt at the Earth's surface but rather deeper down, *e.g.* in the lower crust. Under the cooling conditions prevailing here the melts take a long time to crystallize and are of a special texture. The special name of "gabbro" is given to the basaltic magmas solidifying at such greater depths.

It would, therefore, be more correct to describe the lower crust as gabbroid. This raises the question of how to explain the transition from the crust to the mantle in the Moho; is the Moho surface a phase boundary or a chemical boundary?



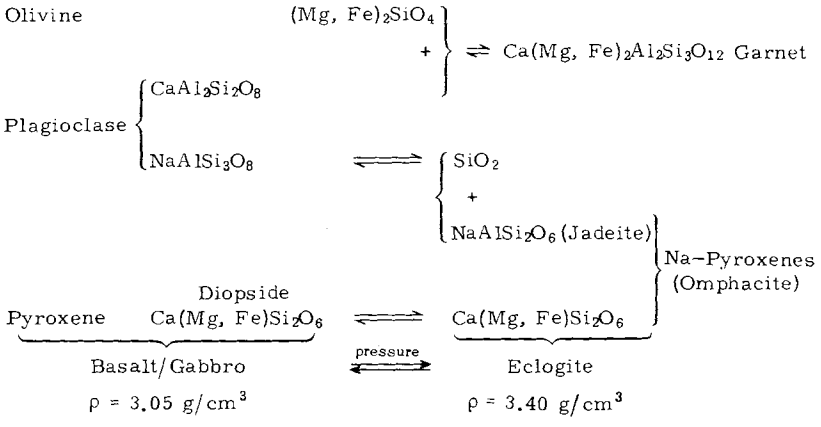


Fig. 9. The possibilities for the formation of rock melts in the crust and upper mantle. Basaltic melts can only be formed in the upper mantle and in the presence of H_2O; granitic magmas are formed in the crust. Metamorphic rocks are also formed here.

8. The Mantle

8.1. The Nature of the Moho Discontinuity

In accordance with the chemical composition of the mantle one can expect to find essentially Mg,Fe silicates below the Moho. It is interesting to find that only two types of rock satisfy the geophysical requirements as regards composition, density, mineral constituents, *etc.* Both rocks consist basically of metasilicates and orthosilicates. The first rock type, eclogite, is formed directly from basalt under a pressure of *ca.* 15 kbar at 1000 °C. It then undergoes an isochemical phase transformation in which the loosely packed framework structures of the feldspars, in particular, change into the denser mineral phases of orthosilicates and metasilicates. The reaction can be formulated in the manner shown in Scheme 1.

Scheme 1

The conversion of basalt or gabbro into eclogite leads to a marked increase in the density, which provides a good explanation for the velocity increase of seismic waves as they reach the Moho discontinuity. However, there exists no general agreement on the course of the transformation region in the p,T diagram, especially at lower temperatures[33,34]. If one assumes the Moho to be a phase boundary between gabbro and eclogite[33,35-39], then the basaltic magmas would be formed by complete melting of this "mantle rock".

Peridotite offers a second possibility of a mantle rock, with olivine as the orthosilicate in place of garnet. Peridotite differs chemically from basalt, so that in this case one should describe the Moho as a chemical boundary. It must be possible for a basaltic magma to form from the peridotite of the upper mantle by fractional melting. *Ringwood*[40] describes such a peridotite as "*pyrolite*". The concept of a peridotite mantle is supported by a series of geological and petrographic observations[41,45,31]. A pyrolite made up of basalt and dunite in a ratio of 1:3 would offer a good explanation for the oceanic heat flux and the seismic velocities; on the other hand, a corresponding chemical composition is also expected on the basis of the "chondritic earth model" (Table 4).

There are several arguments against the Moho being a pure phase boundary. Here we shall only point out that at a phase boundary there ought to be a strong correlation between the heat flux, which naturally depends on the temperature at the respective depth, and the position of the Moho, *i.e.* the crust thickness. But since the heat flow is the same in the oceanic region as in the continental, there is then no

explanation for the great differences between the thickness of oceanic and continental crust. There are also geochemical reasons for regarding an eclogite mantle as an extremely unsatisfactory hypothesis[47], though one can, of course, always

Table 4. Composition of the mantle rock (after *Green* and *Ringwood* [46]) in wt-%, and definitions of some important rock names.

	Derived as pyrolite	Derivation from the "chondritic earth model"
SiO_2	43.06	44.69
MgO	39.32	39.08
FeO	6.66	7.81
Fe_2O_3	1.66	--
Al_2O_3	3.99	4.09
CaO	2.65	3.19
Na_2O	0.61	1.14

Eclogite:	consists mainly of pyroxene (metasilicate) and garnet (orthosilicate); it is the high-pressure equivalent of basalt
Peridotite:	contains more than 90% of pyroxene + olivine (orthosilicate)
Dunite:	contains more than 90% of olivine
Pyrolite:	a special peridotite having the composition dunite: basalt = 3 : 1 (mantle peridotite).

count on eclogite being present in the upper mantle. Basaltic melts resulting from partial fusion of the peridotite mantle are supposedly transported into the p,T range of eclogite formation, particularly in tectonically active regions, and are correspondingly transformed. In this manner mantle regions with eclogite layers in the peridotite rock occur[48]. One can therefore conclude that there is a peridotite mantle of pyrolite composition with eclogite layers showing strong lateral variations. If this assumption is correct, then the seismic discontinuities of the mantle must be capable of correlation with the phase changes of the mantle rock which occur under the corresponding p,T conditions.

8.2. Phase Transformations in Peridotite with Increased Pressure and Temperature

If we assume that the mantle peridotite also contains Na_2O, CaO, and Al_2O_3, then at 1 atm a framework silicate, namely Na-Ca feldspar (plagioclase) appears as an aluminum carrier. The rock is then referred to as plagioclase-peridotite. As is the case with the plagioclase of basalts, the loose framework structure becomes unstable on elevation of pressure and reacts with olivine (formally) in accordance with

$$3Mg_2SiO_4 + 2CaAl_2Si_2O_8 \rightleftharpoons MgAl_2O_4 + \underbrace{MgAl(Si,Al)O_6 + Mg_2Si_2O_6 + 2CaMgSi_2O_6}_{\text{Al-pyroxenes}}$$

olivine — plagioclase — spinel

A spinel peridotite with Al pyroxenes is therefore formed from the plagioclase peridotite. As the pressure is increased further there is another increase in density: a garnet phase is formed through the reaction of the pyroxene with the spinel, formally according to

$$4MgSiO_3 + MgAl_2O_4 \rightleftharpoons Mg_3Al_2Si_3O_{12} + Mg_2SiO_4$$

pyroxene (enstatite) — spinel — garnet (pyrope) — olivine (forsterite)

The spinel-peridotite changes over into garnet-peridotite.

On account of its importance for ground-surface phenomena, the low-velocity zone (LVZ) of the seismic profiles between 100 and 250 km will be dealt with separately later on. We must therefore examine whether the sudden velocity jumps of the seismic waves at depths of *ca.* 400 km and *ca.* 650 km coincide with the density increase reactions of the mantle peridotite in corresponding regions of temperature and pressure. Garnet-peridotite remains stable to a depth of around 400 km. Beyond this depth two densification reactions can be demonstrated experimentally according to *Ringwood*[49]. These are:

1. Conversion of olivine $(Mg, Fe)_2SiO_4$ into a high-pressure phase of the type of spinel, in which, however, the Si^{4+} is still tetracoordinated:

$$(Mg,Fe)_2^{[6]}Si^{[4]}O_4 \xrightarrow{p} \beta(Mg,Fe)_2^{[6]}Si^{[4]}O_4$$

olivine type — spinel type

$\Delta\rho = 8\%$

and

2. Decomposition of the metasilicate (pyroxenes) into complex garnets, in which a quarter of the Si^{4+} present changes over to six-fold coordination, *e.g.*

$$2Mg_2^{[6]}Si_2^{[4]}O_6 \xrightarrow{p} Mg_3^{[6]}(MgSi)^{[6]}Si_3^{[4]}O_{12}$$

pyroxene — garnet

$\Delta\rho = 10\%$

Since olivine constitutes *ca.* 57% of the mantle peridotite, and pyroxene *ca.* 25%, we have an explanation for the density jumps and the associated velocity increases of seismic waves at a depth of *ca.* 400 km. Experimental results indicate the existence of two seismic discontinuities lying close together between 360 and 420 km, and this has been confirmed by more recent measurements[50, 51].

Thermodynamic arguments based on germanate model systems as well as shock-wave experiments suggest that the densification reactions shown in Scheme 2 start in the second and larger seismic discontinuity at a depth of *ca.* 650 km:

1. $(Mg,Fe)_2SiO_4$ (spinel) $\begin{cases} \xrightarrow{p} (Mg,Fe)_2SiO_4 \text{ of the } Sr_2PbO_4 \text{ type} \\ \text{or} \xrightarrow{p} (Mg,Fe)SiO_3 \text{ of the ilmenite type} + (Mg,Fe)O \end{cases}$

2. $M_3(M,Si)Si_3O_{12}$ (garnet) $\begin{cases} \xrightarrow{M=Mg^{2+}} 4MSiO_3 \text{ of the ilmenite type } (FeTiO_3) \\ \left[\xrightarrow{M=Ca^{2+}} 4MSiO_3 \text{ of the perovskite type } (CaTiO_3)\right] \end{cases}$

3. $NaAlSi_2O_6 \longrightarrow NaAlSiO_4$ of the Ca_2FeO_4 type + SiO_2 (stishovite)
jadeite

Scheme 2

These transformations result in hexacoordination of the entire Si^{4+}, which is associated with a considerable density jump. The normal density ρ_0 of the rock formed here lies between 3.99 and 4.03 g/cm^3. It is approximately equal to that of the corresponding isochemical mixture of the free oxides in which $Si^{[6]}O_2$ in the rutile type is present as stishovite. At deeper seismic discontinuities one must therefore assume the possibility of a transformation into still denser phases.

Indeed there is at least one other clear seismic discontinuity at a depth of 1050 km. Beyond that, however, the seismic profiles of the lower mantle permit no major density changes. Even in the case of the discontinuity at 1050 km we had to consider densification reactions of the silicates to compounds with a density 5% above that of the free oxides. Mg^{2+} and Fe^{2+} must then adopt a coordination number higher than 6; a possibility would be, for example, the conversion of $MgSiO_3$ (of the ilmenite type) into a perovskite structure and of Mg_2SiO_4 (of the Sr_2PbO_4 type) into a K_2NiF_4 and/or a Ca_2FeO_4 structure. Here the Si^{4+} is still hexacoordinated but the Mg^{2+}(Fe^{2+}) has a coordination number of 12.

8.3. The Lower Mantle

It is likely that this does not exhaust the possibilities of further phase transformations. The lower mantle is supposed to be "squeezed" at the boundary with the core into a state of densest atomic packing. Up to now a mantle of chemically uniform composition has been assumed, with $X_{FeO} = ca.\ 0.1$[31], an opinion not shared by some geophysicists[38, 51] who regard the lower mantle as having an iron concentration that increases with increasing depth. Recent seismic measurements by *Johnson*[52] (Fig. 10) point to the existence of further phase transformations, which contradict the homogeneity[31, 53, 54] assumed up to now for this region.

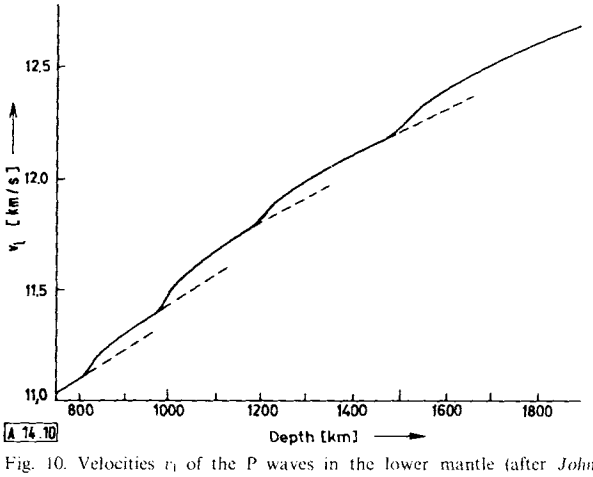

Fig. 10. Velocities v_l of the P waves in the lower mantle (after *Johnson* [52]). The inhomogeneities established can probably be attributed to further phase transformations with smaller density jumps. In any case, the normal density ρ_0 of the lower mantle must clearly be above that of oxide mixtures of peridotite of pyrolite composition.

The experimental interpretation of the phase relationships in the lower mantle is based essentially on shock wave experiments[55, 56]. It can be shown that under the corresponding p,T conditions the densities are higher than those of the free oxides. The experiments also indicate further phase transformations in the lower mantle, although an increase in the iron content cannot in principle be ruled out. On the basis of crystallochemical arguments, essentially minerals of the perovskite and calcium ferrite types can be expected.

9. The Core

The Wiechert-Gutenberg discontinuity defining the core is certainly a chemical boundary. According to an alternative hypothesis proposed by *Ramsay*[57, 58], the boundary between the mantle and the core is an isochemical phase boundary due to pressure degeneration of the mantle silicate, but the existing geophysical and geochemical evidence argues strongly against this view[59].

Thus, the relationships obtained experimentally between the density, pressure, seismic velocities, and mean atomic weights show that a mantle material of Mg, Si, and O in a metallic state could not satisfactorily explain the densities and seismic velocities determined for the core. Furthermore, the transformation of nonmetals into a metallic state under high-pressure conditions is only accompanied by greater volume or density changes (>20%) if the nonmetal has an "open" structure with directional covalent bonding. The density increase then results from the denser packing of the metallic state. It must be assumed, however, that in the lower mantle the silicates are already as densely packed as possible. According to *Ramsay*'s hypothesis, on transition to the metallic state this already highly compressed material must undergo a first-order transformation (as a multicomponent system) accompanied by a density jump of around 65%. However, the experimental and theoretical results to date show this to be impossible.

If the original material of the Earth is assumed to be chondritic then transfer of the entire iron and nickel into the core would produce a central body with a mass of only 26.48% of the total, as compared with the actual figure of around 31%[20]. There must, therefore, be another element that has entered the Earth's core. Further specific evidence for this argument is given below:

If the density of the core is compared with that of iron under the corresponding p,T conditions (shock-wave experiments), it is found that the core density is 10–20% lower than the density of iron. On the other hand, the seismic-wave velocities are considerably higher in the core than in pure iron[30, 59, 60]. Finally, a mean atomic weight of between 45.7 and 53.2 has been estimated for the outer core from seismic equations of state, while the atomic weight of iron is 55.85. An element of lower density and lower atomic weight must therefore have been mixed in a fairly high proportion with iron in the core; at the same time, this would be responsible for the higher seismic velocities.

H, He, C, O, N, Mg, Si, and S have been discussed as possible admixtures. Of these, H, He, C, O, and N can be discounted, since they do not reduce the density of iron; they merely occupy the gaps present in the iron lattice. Mg is an unlikely candidate, since its affinity for oxygen is greater than that of silicon, which is also available in large amounts. Two possibilities remain therefore: admixture of S or of Si (Table 5).

Table 5. Chemical composition of the core in wt.-%.

	after *Mason* [61]	after *Ringwood* [20]
Fe	86	84
Si		11
Mg	6.0	
S	7.4	
Ni		5.3
Co	0.4	

Although no arguments can be presented which totally exclude either of the possibilities, there is strong evidence in favor of silicon as the admixture element. With iron, silicon forms

an extensive series of solid solutions with a clear reduction in density and an increase in seismic velocities. Furthermore, silicon has been proved to be an essential component of the metallic phase of enstatite-chondrites (stony meteorites)[62].

The core is therefore an iron body, which has a liquid outer part and solid inner part, and which contains large amounts of S or Si in solution, the probability being strongly in favor of Si. The Earth's magnetic field has its origin in the liquid outer core. The phases of the whole Earth are compiled in Table 6.

tion of a zone of partial melting (Fig. 11). Basaltic melts with some free H_2O (and CO_2!) are expected here, which can be observed in large quantities during volcanic activity. The top and the bottom of the LVZ prove in this case ($P_{H_2O} < P_{tot}$) to be intersections of the geotherms with the solidus line of the mantle peridotite.

Anderson and *Sammis*[63] assume that at least 1% of melt must be present to permit convective heat transport. It is their opinion that an equilibrium is set up between heating, melting and convective removal of heat by the melt. The

10. Influence of the Deeper Layers on the Geological Phenomena at the Surface

10.1. The Low-Velocity Zone (LVZ) in the Upper Mantle

In recent years special attention has been paid to the zone in the upper mantle in which the velocity of the seismic waves suddenly decreases.

If we consider all the observations and facts available[63, 64] we cannot escape the conclusion that the mantle material in this region must be partly molten. This would mean that the geotherm exceeds the solidus temperature of the mantle peridotite, which is only possible if the mantle material contains water. Even 0.1 wt-% of water leads to a displacement of the liquidus-solidus field, so that the LVZ merits the description of a zone of partial melting (Fig. 11). Basaltic melts with some free H_2O (and CO_2!) are expected here, which can be observed in large quantities during volcanic activity. The top and the bottom of the LVZ prove in this case ($P_{H_2O} < P_{tot}$) to be intersections of the geotherms with the solidus line of the mantle peridotite.

Anderson and *Sammis*[63] assume that at least 1% of melt must be present to permit convective heat transport. It is their opinion that an equilibrium is set up between heating, melting and convective removal of heat by the melt. The critical proportion of melt, leading to rapid convective heat dissipation and the associated magmatic and volcanic activity, is given as 5%. The magmatic phase lasts until the uncritical value of *ca.* 2% of melt is again reached. The ascent of the lighter magma results in the crust being formed as a fractionation product of the mantle.

While the interpretation of the LVZ as a zone containing some melt is basically correct, there are other possible explanations for its sharp boundaries, suggested by recent experimental results.

The fundamental question is, in what concentrations can H_2O and CO_2 be expected in the mantle? The enormous quantities of gas emitted by volcanoes suggest the presence of large quantities of H_2O and CO_2 (>0.1%). The top and the bottom

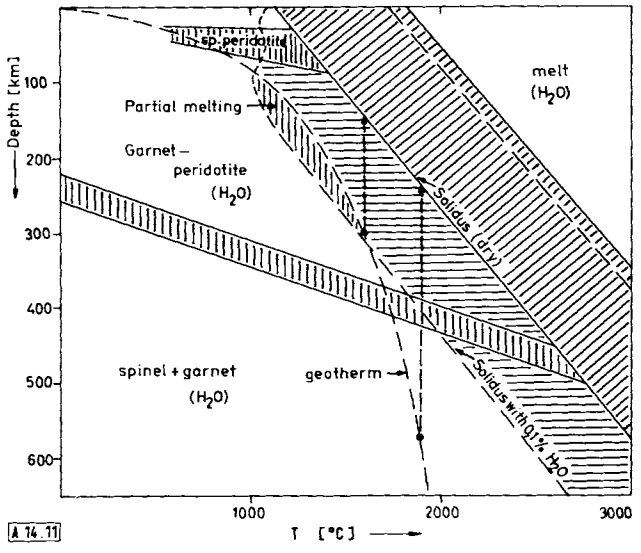

Fig. 11. The liquidus-solidus region of mantle peridotite with and without water in the upper mantle. In the absence of water the geotherm does not reach the solidus; moreover, the liquidus-solidus range is relatively narrow. Melting was only possible by the ascent of material from greater depth (arrows). Even 0.1% of water lowers the solidus temperature so much that partial melting in the LVZ area becomes possible. Since the liquidus line practically does not move at all, the field of melt equilibrium is considerably enlarged.

of the LVZ would in this case be explained by the stability of the compounds formed between the H_2O and the mantle silicates. Under moderate p,T conditions *i.e.* at temperatures up to *ca.* 1000 C and in the pressure range up to *ca.* 20 kbar, water enters the silicate at the Si^{4+} in the form of OH^- ions. Band silicates and layer silicates (amphibole, phlogopite, serpentine) are formed, which decompose into water-free silicates and H_2O at higher temperatures and pressures (Fig. 12). The resulting melting point depression determines the roof of the LVZ.

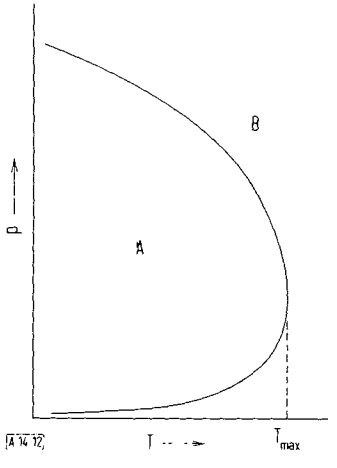

Fig. 12. Schematic representation of the stability field of water-containing silicates with OH^- ions at the Si^{4+} (A). At higher temperatures and pressures these compounds decompose into silicate and H_2O (B).

Sclar[65] was able to demonstrate that free H_2O can be reincorporated into mineral phases under the p,T conditions prevailing at the bottom of the LVZ, though it is then bound in a different manner. For example, at 40 kbar and 1200 C Mg_2SiO_4 reacts with H_2O to form a metasilicate:

$$Mg_2SiO_4 + 2H_2O \rightleftarrows Mg_2SiH_4O_6$$

This is therefore a pyroxene in which every other SiO_4^{4-} tetrahedron of the anionic chain is replaced by an $H_4O_4^{4-}$ tetrahedron. In these "water pyroxenes" we see a crystallochemical possibility of incorporating large amounts of water into the phases of the mantle, and such minerals would then make up the lower boundary of the LVZ.

Investigations on gas inclusions in fragments of mantle peridotite (olivine nodules) transported to the surface in basalt lavas led *Ernst*, *Mages*, and *Schwab*[66,67] to the conclusion that CO_2 as well as H_2O is incorporated into the mantle silicate phase. Solid solutions are presumably formed here, in which SiO_4^{4-} is replaced by CO_4^{4-} and which these authors describe as "carbon silicates".

According to *Neuhaus*[68], tetracoordination of the C^{4+} in orthocarbonate is only to be expected under high-pressure conditions (pressure homologs rule). These are supposed to lead to an adaptation of the cationic and anionic radii, resulting in ever higher coordination numbers and denser packing. Tetracoordination is possible only with a radius ratio $r_{cation}/r_{anion} \gtrsim 0.22$, for example, in the silicates at 1 atm with $r_{Si^{4+}}/r_{O^{2-}} = 0.29$. In carbonates the coordination number is 3 because $r_{C^{4+}}/r_{O^{2-}} = 0.11$. The pressures necessary for the transition to tetracoordination, when the carbonates assume a silicate-like structure *e.g.* according to

$$\underset{\text{magnesite}}{MgC^{[3]}O_3} \xrightarrow{p} \underset{\text{orthocarbonate with anionic chains}}{MgC^{[4]}O_3}$$

are estimated by *Neuhaus* to be ≈ 200 kbar for the pure phases. Markedly lower pressures can however be expected for the isomorphous substitution of Si^{4+} by C^{4+}, depending on the extent of the substitution and on the composition and structure of the silicate. Accordingly, the bottom of the LVZ could be regarded as a "bonding boundary", marking a changeover from the high-pressure chemistry of the mantle, where CO_2 and H_2O are incorporated in the crystalline phases as CO_4^{4-} and $H_4O_4^{4-}$ groups, to "normal chemistry", with the CO_2 and H_2O occurring as free molecules or in lower-coordinated mineral phases.

This interpretation of the LVZ as a zone in which the H_2O and the CO_2 released from the mantle silicates lead to partial melting also offers a possible explanation for the formation of carbonatic, basic, and acidic rock melts from one starting material[69]. The gas richness of the resulting melts would at the same time provide the power for active, sometimes explosive volcanism.

10.2. Tectonic Phenomena Caused by the Partial Melting and by Phase Transformations in the Upper Mantle

The described zone containing molten regions is less dense than the neighboring layers of the mantle and is therefore unstable both from the mechanical and the gravitational point of view. This result in the formation of convection cells in the upper mantle, which exert powerful forces on the higher-lying crust, producing stretching, compression, arching, and subsidence (Fig. 13).

Basaltic melts can ascend through fissures in the expansion zones, while earthquakes occur in the zones of compression. Within the LVZ the more volatile components collect at the "top boundary" and here produce a further reduction in the viscosity. In this way the crust and a part of the upper mantle can slide on the LVZ with relatively low friction. This explains both continental drift and the phenomenon of sea-floor spreading, *i. e.* the formation of new oceanic crust by an ascending convective current emerging from a midoceanic ridge with the resulting lateral displacement of the sea floor on both sides of the ridge[70].

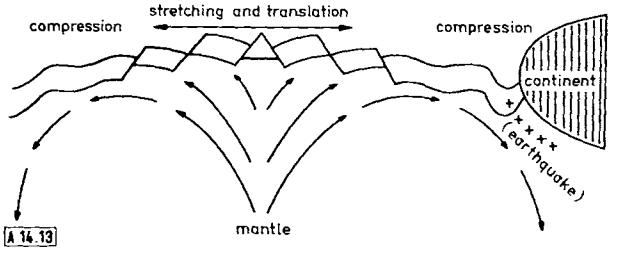

Fig. 13. Schematic representation of the effects of convection in the upper mantle. As well as arching and stretching in the ascending convection current, translation occurs by its side, followed by compression and subsidence.

Convective flows in the upper mantle are also the cause of the formation of domes and depressions, though it must be remembered that these are ultimately caused by displacements of phase boundaries due to the different temperatures in the ascending and descending parts of the convection current. The densification reactions in the upper mantle can also give rise to earthquakes, which have been recorded from depths of 700 km (maximal). The source of the energy of tectonic phenomena observed on the ground surface and the energy required for the formation of the associated crystal structures should thus be sought entirely in the upper mantle. And finally, the crust itself originates from the mantle.

11. Summary

During the last twenty years geochemical, geophysical and petrological investigations have done much to extend our knowledge of the deeper layers of the Earth. It was already known that the Earth is divided into crust, mantle, and core, and that these regions differ in their chemical composition; however, the correlation of seismic data with the results of petrological high-pressure research has provided evidence for a number of phase boundaries, particularly in the upper mantle. These are due to densification reactions occurring continuously with increasing pressure and lead to new types of compounds and structures in the mantle silicate. At the transition to the metallic core, which consists of an Fe, Si, Ni alloy, the mantle silicates are present in densest atomic packing. While the mantle can be regarded as essentially crystalline, the outer core is liquid. Only in the region of the upper mantle do the temperature and pressure conditions result in a zone of partial melting, manifested on seismic profiles by a reduction in seismic velocities. The causes of magmatism, volcanism, and the tectonic phenomena in the crust should be sought in this zone, the mainspring of all geological activity.

The author is indebted to Prof. Dr. Th. Ernst, Dr. G. Mages, and Herr P. Brosch for their assistance in checking this paper.

A Hundred Years of Stereochemistry—The Principal Development Phases in Retrospect

By Jost Weyer[*]

The theory of the arrangement of atoms in space was initiated in 1874 by *van't Hoff* and *Le Bel*. The starting points were mainly in the fields of structural chemistry and optical activity. After early difficulties, stereochemistry gained acceptance in the last quarter of the 19th century and led to many interesting investigations and discoveries: the investigation of geometrical isomerism, the Baeyer strain theory, the stereochemistry of nitrogen, the determination of the configurations of carbohydrates, Walden inversion, and the beginning of inorganic stereochemistry all fall in this period. Theoretical verification of the principal stereochemical hypotheses and the exact determination of the steric arrangement of atoms by physical methods were achieved only in the 20th century.

1. Introduction

A hundred years ago, the foundation stone of stereochemistry was laid by the work of *van't Hoff* and *Le Bel*. In a historical review presented to mark the 25th jubilee of this branch of knowledge[1], *Walden* expressed the view that "there is at present no other theory in modern organic chemistry that is as far-reaching, as rich in problems, and as certain of success as the stereochemical theory". Yet another quarter of a century later, in another review[2a], *Walden* mentioned *Kekulé*'s assertion that most theories do not last longer than 25 years, and expressed surprise that the stereochemical theory was not yet obsolete. Even today, after a hundred years, stereochemistry has lost none of its significance; indeed, during the last 20 years it has undergone an upward swing, whose end is not yet in sight. This is underlined by the award of the 1969 Nobel prize for chemistry to *Barton* and *Hassel*[2b] for their stereochemical work.

[*] Dr. Jost Weyer

The present article clearly cannot present the entire development of stereochemistry, even in a concise form[3]. From the extensive material available, therefore, I have selected and discussed those facts that in my opinion have contributed decisively to the further development of stereochemistry.

2. The Antecedents of Stereochemistry

Like all scientific ideas, hypotheses, and theories, stereochemistry, as the theory of the arrangement of atoms in space, also has its antecedents. There were three main factors that contributed to the genesis of stereochemistry: the atomic theory, the structural theory of the chemical bond, and optical rotation. Among these factors, only the atomic theory (or some other corpuscular theory) was a necessary condition, since stereochemistry is inconceivable without discrete particles of matter of some kind.

The idea that the particles of matter in a substance have an arrangement in space can be traced back to antiquity, and was mentioned even by the two founders of atomism, *Leucippus* and *Democritus*[4]:

"However, these atoms, which were separated from one another in the infinite void and differed in shape (schema), size (megethos), position (thesis), and arrangement (taxis), moved around in empty space, and on meeting one another they collided; and some bounced apart, as often happens, whereas others became entangled with one another as a result of the symmetry of their shapes, size, position, and arrangement, and remained together; this is how the compound bodies were formed."

This rather vague picture of an arrangement of the atoms in space can be followed throughout the history of atomism, but it was only in the 19th century that it took on a more distinct shape as a result of greatly increased knowledge about the composition of substances.

After *Dalton* had conceived the chemical atomic theory in 1803, *Wollaston* was the first to try and extend *Dalton*'s theory to the arrangement of atoms in space. In a publication from the year 1808, he wrote[5]:

"I am inclined to think, that when our views are sufficiently extended, to enable us to reason with precision concerning the proportions of elementary atoms, we shall find the arithmetical relation alone will not be sufficient to explain their mutual action, and that we shall be obliged to acquire a geometrical conception of their relative arrangement in all three dimensions of solid extension".

For the case of four atoms of one kind combined with one atom of another, according to *Wollaston*'s view, a stable arrangement is achieved "if the four particles are situated at the angles of the four equilateral triangles composing a regular tetrahedron[6]".

In the first half of the 19th century, stereochemical ideas of a general nature were widespread, *i. e.* the chemical compounds were pictured not as an indiscriminate aggregation, but as structured three-dimensional arrangements of atoms. However, few attempts were made to investigate the spatial distribution of the atoms, or at least, as *Wollaston* did, to develop clearer concepts of this distribution; in fact, *Dalton*'s atomic theory itself was doubted by leading investigators, mainly on philosophical grounds.

The development of stereochemical ideas entered a new stage in 1858 when *Couper* and *Kekulé* conceived the valency theory (tetravalency of the carbon atom, linking of atoms to form chains) and this was developed by *Butlerow* into a general structural theory of chemical bonding. Though the bonding of the atoms was the focus of interest in the structural theory, stereochemical ideas also became topical once again, since the bonds were mostly pictured in three dimensions. *Butlerow* in 1862, was the first to apply the tetrahedral model specifically to the carbon atom[7]:

"Nehmen wir ein grobes Beispiel und stellen wir uns das Kohlenstoffatom als ein Tetraëder vor, bei welchem jede der 4 Flächen ein Atom Wasserstoff zu binden im Stande ist, ...[*]."

An innovation introduced as part of the structural theory was the graphic representation of valences with bond lines (represented with dotted lines by *Couper* in 1858 and with continuous lines by *Crum Brown* in 1864), *i. e.* the introduction of structural formulas. To avoid any idea of a planar arrangement of the atoms that might be suggested by structural formulas of this type, and also to assist intuition, some chemists used atomic models made from wood and other materials. As early as 1810, *Dalton* had worked with ball and rod models, and it is known that *Hofmann*, *Baeyer*, and *Kekulé*, among others, used models of this type in the 1860s for teaching purposes. In 1867, *Kekulé* proposed an atomic model for the carbon atom that offered an improvement over earlier models:

"wenn man die vier Verwandtschaftseinheiten des Kohlenstoffs, statt sie in eine Ebene zu legen, in der Richtung hexaedrischer Axen so von der Atomkugel auslaufen lässt, dass sie in Tetraederebnen endigen[8][**]."

Similar atomic models of a wide variety of designs later became an important research instrument for the stereochemist, and have remained so up to the present day.

Optical rotation, which, as was mentioned earlier, contributed along with the atomic theory and the structural theory to the birth of stereochemistry, was discovered in 1811 by *Arago* and investigated further by *Biot*. Optical rotation became interesting in chemistry when *Biot* found that the optical activity is not tied to the crystalline state (as it is in the case of quartz), but that organic substances such as oil of turpentine or solutions of camphor, sucrose, or tartaric acid are also optically active[9].

Biot's work was carried on by *Pasteur*, who investigated the crystalline forms of several salts of tartaric acid and found that all tartrates have hemihedral faces. He therefore assumed that a relationship must exist between the hemihedrism (*i. e.* a crystallographic property) and the optical rotation of the tartrates. This hypothesis was confirmed experimentally in 1848 when *Pasteur*, by manual sorting, succeeded in separating the sodium ammonium salt of optically inactive racemic acid into two crystalline forms that were related to each other as object and mirror image[10]. In aqueous solution, one of these modifications turned the plane of plane-polarized light to the left, and the other to the right. The close connection between crystalline form and rotatory power was thus demonstrated in the case of tartrates. At the same time, *Pasteur*'s discovery was the first example of resolution of a racemate, in this case by spontaneous crystallization. During the next few years he discovered two further resolution methods, *i. e.* the reaction of racemic acid with optically active bases (1852) and biochemical resolution (1858).

In an article summarizing his experiments which was published in 1860, *Pasteur* expressed the following views on the arrangement of the atoms in such compounds[11]:

"Nous savons en effet, d'une part, que les arrangements moléculaires des deux acides tartriques sont dissymétriques, et de l'autre, qu'ils sont rigoureusement les mêmes, avec la seule différence d'offrir des dissymétries de sens opposés. Les atomes de l'acide droit sont-ils groupés suivant les spires d'une hélice dextrorsum, ou placés aux sommets d'un tétraédre irrégulier, ou disposés suivant tel ou tel assemblage dissymétrique déterminé? Nous ne saurions répondre à ces questions. Mais ce qui ne peut être l'objet d'un doute, c'est qu'il y a groupement

[*] "As a crude example, let us imagine the carbon atom as a tetrahedron, each of whose 4 faces is able to bond an atom of hydrogen, ..."

[**] "if the four valences of carbon, instead of lying in a single plane, are allowed to radiate from the atomic sphere in the direction of hexahedral axes so that they terminate in tetrahedral planes".

des atomes suivant un ordre dissymétrique à image non superposable. Ce qui n'est pas moins certain, c'est que les atomes de l'acide gauche réalisent précisément le groupement dissymétrique inverse de celui-ci"[*]."

Pasteur himself was unable to solve this problem but others later followed up his results.

The factor that actually triggered the development of stereochemistry was a number of unexplained cases of isomerism. The first four examples in which substances with the same percentage composition exhibited different chemical behavior were discovered in the 1820's: fulminic acid and cyanic acid, ethylene and butene, ammonium cyanate and urea, tartaric acid and racemic acid. In 1830, *Berzelius* had coined the term isomerism for this phenomenon. Most cases of isomerism were later satisfactorily explained by the structural theory. However, some cases defied all attempts at interpretation; these include the isomerism of maleic and fumaric acid, of the tartaric acids, and of the lactic acids. With regard to the lactic acids, *Wislicenus* said the following in 1869[12]:

"Es ist damit der erste sicher constatirte Fall gegeben, dass die Zahl der Isomeren die Structurmöglichkeiten übersteigen kann. Thatsachen wie diese werden dazu zwingen, die Verschiedenheit isomerer Molecule von gleicher Structurformel durch verschiedene Lagerung ihrer Atome im Raum zu erklären und sich nach bestimmten Vorstellungen darüber umzusehen[**]."

The situation that had arisen was thus one that may be regarded as typical in the history of the natural sciences. *T. S. Kuhn*, who, in his work "The Structure of Scientific Revolutions", has dealt with the development of new fundamental scientific ideas or theories (he himself calls them paradigms)[13], characterizes such a situation as follows: in the "normal" science, which is under a certain paradigm, there first arise anomalies that can no longer be explained by the existing theories. If these anomalies are serious enough, they can trigger a crisis within the scientific community concerned. This crisis is settled only when the facts that were regarded as anomalies in the light of the old paradigm can be satisfactorily explained by a new paradigm. Such a crisis situation in Kuhn's sense existed in organic chemistry at the end of the 1860's, though all chemists did not perceive it as such: The anomalies of the acids mentioned above could no longer be explained under the paradigm of the structural theory. The "revolution"[***] later proved to be an extension of the structural theory.

[*] "We know in fact, on the one hand, that the molecular arrangements of the two tartaric acids are dissymmetric, and on the other that they are exactly the same except that they exhibit dissymmetry in opposite directions. Are the atoms of the right-handed acid grouped in the form of a right-handed spiral, or are they situated at the apices of an irregular tetrahedron, or are they fixed in some dissymmetric arrangement or other? We cannot answer these questions. But there can be no doubt that the atoms are grouped in a dissymmetric arrangement that does not coincide with its mirror image. It is no less certain that the atoms of the left-handed acid have exactly the opposite dissymmetric grouping."

[**] This is thus the first definitely verified case in which the number of isomers can exceed the structural possibilities. Facts such as this will force us to explain the difference between isomeric molecules with the same structural formula by different arrangements of their atoms in space, and to look for definite ideas on these arrangements."

[***] *Van't Hoff* spoke more aptly of a "reform of prevailing views".

3. The Fundamental Stereochemical Work of *van't Hoff* and *Le Bel*

The increasingly frequent need to take into account the arrangement of the atoms in space was satisfied in 1874 by two young chemists: *Joseph Achille Le Bel*, 27 years of age, and *Jacobus Henricus van't Hoff*, 22 years old. These two workers made their discoveries independently of each other, possibly a sign that stereochemical ideas were "in the air" around this time. *Le Bel* had studied at the École Polytechnique, and became an assistant to *Wurtz* at the École de Médicine in Paris. *Van't Hoff* had attended the Polytechnic at Delft and spent a few months with *Kekulé* in Bonn, and, as chance would have it, he also came to *Wurtz* in Paris in the middle of 1873. Though *Le Bel* and *van't Hoff* knew each other, they had at that time, on their own assertion, never discussed stereochemical ideas with each other. In the middle of the following year, *van't Hoff* went to Utrecht to start work for his doctorate. Before he started this work, however, at the beginning of 1874, he issued a 12-page pamphlet in his mother tongue entitled: "Suggestion for the Extension to Three Dimensions of the Structural Formulas Currently used in Chemistry"[14].

In the introduction to his pamphlet, *van't Hoff* stated that the structural formulas used at that time were no longer able to explain certain cases of isomerism, and that this might be due to the absence of ideas about the arrangement of the atoms in space. After the introduction of the tetrahedral model for the carbon atom, he made the following central pronouncement[15]:

"Voor het geval de vier affiniteiten van een koolstof-atoom zijn verzadigd door vier onderling verschillende univalente groepen kunnen twee, en niet meer dan twee verschillende tetraëders worden verkregen, die elkaârs spiegelbeelden zijn, doch nooit zoo gedacht kunnen worden, dat ze elkaâr bedekken, d. i. men heeft the doen met twee isomere structuurformules in de ruimte[*]."

Van't Hoff referred to such an atom as an "asymmetrisch koolstof-atoom". He then showed that any optically active carbon compound contains an asymmetric carbon atom, whereas the converse is not always true. He gave numerous examples from the literature to demonstrate this. *Van't Hoff* also applied the tetrahedral model to the carbon-carbon double bond, two tetrahedra being joined by a common edge. For the case where each of the two doubly bonded carbon atoms carries two different groups, *van't Hoff* predicted another type of isomerism, which is now known as geometrical isomerism. He also gave examples to support this hypothesis.

Two months later, in November 1874, *Le Bel* published his stereochemical conception under the title "Sur les relations qui existent entre les formules atomiques des corps organiques et le pouvoir rotatoire de leurs dissolutions" (The relations that exist between the atomic formulas of organic compounds and the rotatory power of their solutions)[16]. *Le Bel* approached the problem from a different direction from *van't*

[*] "In the case where the four affinities of a carbon atom are saturated by four different univalent groups, it is possible to obtain two and not more than two different tetrahedra, one of which is the mirror image of the other, but which can never be imagined in such a way that they can be brought into coincidence, *i.e.* one has two isomeric structural formulas in space."

Hoff. His hypothesis was based neither on the tetrahedral model of the carbon atom nor on the concept of fixed valences between the atoms. He proceeded from purely geometrical considerations, *i.e.* from symmetry arguments; he spoke of the dissymmetry, not of individual atoms, but of the entire molecule, so that his views would nowadays be classed under the heading of molecular dissymmetry.

Le Bel started with the hypothetical molecule MA_4, where M was an atom or group of atoms joined to four univalent atoms A. If three atoms A are replaced by different substituents, geometric considerations lead to the following rule[17]:

"En général si un corps dérive de notre type primitiv MA^4 par la substitution à A de trois atomes ou radicaux distincts, sa molécule sera dissymétrique et il aura le pouvoir rotatoire[*]."

Le Bel considered that exceptions to this rule were possible. Conversely, if optical activity can be detected for an atom M with four different substituents, then according to *Le Bel* the original groups of atoms A were situated at the apices of a regular tetrahedron. He thus regards the tetrahedral grouping, not as a general principle, but as a special case.

Le Bel then considered substances containing a double bond. Since chemical isomers could be obtained in this case by the introduction of only two different substituents, he assumed that the hydrogen atoms of ethylene, as the simplest substance in this series, were situated at the base corners of a square pyramid. He applied similar symmetry considerations to aromatic and hydroaromatic compounds, and cited numerous examples from the literature to support all his hypotheses.

The roots of the two stereochemical concepts are relatively easy to trace. *Van't Hoff* came from *Kekulé*'s school, *i.e.* from the camp of the structural chemists, and he wished his hypothesis to be understood as an extension of the structural theory to spatial relationships. The tetrahedral atomic models used by *Kekulé* in his lectures presumably also prompted his pupil *van't Hoff*, at least unconsciously, in the conception of the asymmetric carbon atom. *Le Bel*, on the other hand, was trained in the tradition of *Pasteur* (whose investigations he also mentioned expressly in his article), *i.e.* he started out from *Pasteur*'s considerations on the connection between optical rotation and molecular structure.

When *van't Hoff* and *Le Bel* published their hypotheses in 1874, there was nothing new, as is shown by the earlier history, in either general speculations about the arrangement of atoms in space or assumed connections between optical activity and dissymetric molecular structure or the tetrahedral model of the carbon atom. The achievement of *Le Bel* and *van't Hoff* lies rather in the fact that they developed concrete ideas about the three-dimensional arrangement of the singly and doubly bonded carbon atoms, they were able to interpret and predict the occurrence of optical activity and they brought their views into a uniform theoretical system. Both can therefore be justifiably regarded as the founders of stereochemistry.

4. The Reaction of Chemists to the New Hypothesis

Van't Hoff's hypothesis, being more readily appreciable and more specific, came closer to satisfying the immediate needs of chemists; hence the first discussions of the new theory were based not on *Le Bel*'s interpretation but on *van't Hoff*'s. However, even *van't Hoff*'s work was practically ignored at first. To make his ideas known to the scientific world, *van't Hoff* published a French translation of the original work[18], a condensed version[19], and an expanded French version, as a separate pamphlet[20]. He sent copies of this last publication, together with home-made cardboard tetrahedral models, to *Baeyer*, *Butlerow*, *Henry*, *Hofmann*, *Kekulé*, *Frankland*, *Wislicenus*, *Wurtz*, *Berthelot*, and others.

The reaction to these publications was slight. *Wurtz* wrote a letter of agreement, *Baeyer* expressed his approval of the new hypothesis to his pupils, and *Berthelot* politely rejected *van't Hoff*'s views at a meeting of the Société Chimique, while *Kekulé* later, on the occasion of his Bonn rectorial address, gave half-hearted approval to the ideas of his former pupil. However, there was no real discussion such as *van't Hoff* had hoped for. A turning point came when *Wislicenus*, at the end of 1875, asked *van't Hoff* if he might have the French pamphlet translated into German by his assistant *Herrmann*. This translation, which appeared in 1877 with a foreword by *Wislicenus*[21], introduced the phase of scientific discussion.

Kolbe reacted unusually violently[22] after the German translation had been brought to his attention. He attacked not only *van't Hoff* but also *Herrmann* and *Wislicenus*, and he did not even refrain from personal abuse. Among other things he wrote[23]:

"Es ist bezeichnend für die heutige kritikarme und Kritik hassende Zeit, dass zwei so gut wie unbekannte Chemiker, der eine von einer Thierarzneischule, der andere von einem landwirthschaftlichen Institute, die höchsten Probleme der Chemie, welche wohl niemals gelöst werden, speciell die Frage nach der räumlichen Lagerung der Atome, mit einer Sicherheit beurtheilen und deren Beantwortung mit einer Dreistigkeit unternehmen, welche den wirklichen Naturforscher geradezu in Staunen setzt[*]."

Irrelevant and defamatory as this criticism was, it nevertheless made a decisive contribution to the dissemination of *van't Hoff*'s views.

In retrospect, one might ask why the stereochemical ideas met with so much indifference and rejection. An only apparently trivial answer is found if the scientists in question are grouped according to their age: *Wislicenus*, *Landolt*, *E. Fischer*, *Wallach*, *Baeyer*, *V. Meyer*, *Auwers*, *Werner*, and *Hantzsch* were all between twenty and fifty years of age when they started their stereochemical work, *i.e.* they belonged to the younger generation (not forgetting *Le Bel* and *van't Hoff* themselves). On the other hand, the advocates of classical organic chemistry, *e.g. Butlerow*, *Kekulé*, *Hofmann*, *Beilstein*, *Pasteur*, *Dumas*, and *Wurtz*, all of whom except *Beilstein* were roughly fifty years of age or older, showed little interest in the expansion of the structural theory toward three-dimensional views. This is thus a case of the validity of *Planck*'s assertion that a new scientific truth usually becomes accepted, not because

[*] "If a substance is derived from our original type MA_4 by substitution of A by three different atoms or radicals, its molecule will generally be dissymmetric and possess rotatory power."

[*] "It is typical of the present time, when there is so little criticism and so much hatred of criticism, that two practically unknown chemists, one from a veterinary college and the other from an agricultural institute, pass judgment on the loftiest problems of chemistry, which will probably never be solved, particularly the question of the position of atoms in space, with an assurance, and undertake to answer these problems with an impudence, that absolutely astonish the true scientist."

its opponents have been convinced, but because the opponents gradually die out and the rising generation has been made familiar with it from the outset[24].

However, there is also a more profound reason for the rejection of stereochemistry by the older generation of chemists. Influenced by the philosophy of *Auguste Comte*, many chemists believed that it was fundamentally impossible to determine the actual structure of compounds. Thus *Berthelot* and *Kolbe* had already rejected the structural theory, and even the type theory. Even *Kekulé*, one of the founders of the structural theory, was doubtful about the reality presented by structural formulas. In his opinion, these were merely reaction formulas and could in no way express the actual arrangement of the atoms in a compound. *Kolbe* repeatedly expressed the view that it would never be possible to determine the arrangement of atoms in space. When two young, inexperienced chemists now believed that they had solved these "loftiest problems of chemistry", this appeared to *Kolbe* as a dangerous reversion to speculative *Naturphilosophie*.

5. The Development of Classical Stereochemistry

After the first, in part philosophically grounded reactions to the stereochemical ideas had died down, stereochemistry entered a phase of objective discussions based on experimental arguments. The chemists had a new paradigm in *Kuhn*'s sense: The problem was to verify or refute the theoretically predicted relationships between the arrangement of atoms in space and optical activity (*e. g.* the number of isomers for a given number of asymmetric carbon atoms). One of the principal pieces of evidence was the resolution of optically inactive compounds containing asymmetric carbon atoms into their optical antipodes, for which *Pasteur* had already developed the methods. In all these investigations, the Le Bel-van't Hoff hypothesis was confirmed time and again, and apparent anomalies later proved to be incorrect interpretations.

The turning point came in the middle of the 1880's, when a number of important chemists incorporated stereochemical questions into their research program: in addition to *Wislicenus*, mainly *Baeyer*, *E. Fischer*, and *V. Meyer* in Germany and *Le Bel* in France. During the first few decades there emerged regular schools of stereochemists, most of whom can be traced back to *Wislicenus* or *Kekulé*. Thus *Werner* was a pupil of *Hantzsch*, who in turn was a pupil of *Wislicenus*; *Fischer* was a pupil of *Baeyer*, and the latter was a pupil of *Kekulé*.

The interest in stereochemistry can also be seen from the numerous editions and translations of *van't Hoff*'s "Lagerung der Atome im Raume" (Arrangement of Atoms in Space)[*] and from the appearance of the first textbooks and handbooks of stereochemistry[3d, 25, 26]. Stereochemistry was also introduced into chemical textbooks. The growth of stereochemistry can be traced out quantitatively too: Whereas 20 optically active compounds were known in 1874, the number in 1904 was more than 900; *van't Hoff*'s Dutch pamphlet covered 12 pages, while *Freudenberg*'s handbook covered 1500. The necessary terminology was also created: in 1880 *V. Meyer* coined the expressions stereochemistry and stereochemical and in 1886 *Wunderlich* proposed the term configuration (stereochemical) as distinct from constitution (structure-chemical).

Of the numerous stereochemical investigations that were started in the last quarter of the 19th century, only a few of the most important can be mentioned here. These include *Baeyer*'s strain theory, which was conceived in 1885 by *Adolf Baeyer*[27], to explain the difference in the ring-forming tendencies of cyclic compounds and the reactivity of compounds containing double or triple bonds. *Baeyer* extended the van't Hoff-Le Bel hypothesis by the assumption that deviations from the tetrahedral angle are possible and that these would lead to "strain" in the bonds. The greater the "distortion" of the tetrahedral angle, the greater the strain should be. On the basis of the model, *Baeyer* calculated the deviations from the ideal tetrahedral angle for carbocyclic systems from cyclopropane to cyclohexane, starting with the tacit assumption that all these rings are planar. He also included the double bond in his considerations by regarding it as a two-membered ring. He came to the conclusion that the five-membered ring should be formed most easily, since the deviation from the tetrahedral angle is least in this case, and that the strain should increase with decreasing and with increasing ring size. Considerable limitation of *Baeyer*'s original strain theory was later found to be necessary, but it proved at the time to be a very fruitful hypothesis.

Whereas the views of *Le Bel* and *van't Hoff* on the stereochemistry of singly bonded carbon became accepted relatively quickly after the early resistance, it took longer for their hypotheses on the steric arrangement of compounds containing carbon-carbon double bonds to gain acceptance. The body of facts available was still small, so that it was still possible to hope that one of the traditional explanations might suffice. The break-through in this area was due to *Johannes Wislicenus*, who investigated the steric relationships in double-bond systems in an extensive study planned on a broad experimental basis[28], and coined the term "geometrical isomerism" for the cases of isomerism found in this study. A new and highly successful feature was the idea that one could often decide, on the basis of the reaction behavior, which of the possible isomers is present or which configuration is favored.

The extension of the tetrahedral model to ring and double-bond systems was associated with a conceptual obstacle. In these two cases one either assumed angled or bent bonds, in which case the bond was no longer the straight line between the centers of two atoms, or else two bonds of the carbon were bent into parallel positions, and one could then no longer speak of a tetrahedron. However, most chemists were not fully aware of this contradiction, and this relativization of the tetrahedral postulate was accepted without rejection of the model as such[29].

A decisive test of the new theory was provided by *Emil Fischer*'s carbohydrate syntheses[30]. In an extensive systematic study, *Fischer* was able to determine the relative configurations of numerous sugars and their relations to one another, and in no single case did he find any contradiction of the predictions of the Le Bel-van't Hoff theory. The foundation stone was thus laid for the countless determinations of the configurations of natural products that are today still a subject of investigation

[*] The German translation appeared in several editions and revisions (1892, 1894, 1908, as also did the French version (1887, 1892). The work was also translated into English (1891, 1898, 1901) and Russian (1911).

by organic chemists. *Fischer*'s work was also important in another respect. He introduced a new two-dimensional notation for the characterization of the relative configurations of optically active compounds; as his reference substance he first chose saccharic acid[31], then tartaric acid[32], and this was later replaced by glyceraldehyde[33]. *Fischer*'s notation for asymmetric carbon atoms, which proved to be valuable in particular for carbohydrates and amino acids, was recently modified by the *R,S* notation of configurations in such a way that it is possible to characterize all classes of substances[34].

There was no immediate need for a stereochemistry of nitrogen until the end of the 1880's, when a number of cases of isomerism were discovered in the oximes, for which the usual structural formulas were no longer adequate. A satisfactory explanation of the number of isomers observed was achieved by *Alfred Werner* and *Arthur Hantzsch* in an article published in 1890[35], which became the foundation of the stereochemistry of trivalent, double-bonded nitrogen. These authors also started with the van't Hoff-Le Bel hypothesis, which they extended by the following assumption[36]:

"Die drei Valenzen des Stickstoffatomes sind bei gewissen Verbindungen nach den Ecken eines (jedenfalls nicht regulären) Tetraëders hin gerichtet, dessen vierte Ecke vom Stickstoffatom selbst eingenommen wird[*]."

Van't Hoff had tried to explain the C—C double bond by two tetrahedra joined by one edge. *Werner* and *Hantzsch* now placed the nitrogen atom and the substituent bonded to the nitrogen at the two free apices of one of the tetrahedra, and they used this to describe the geometric relationships of the C—N double bond. By repeating the process in the second tetrahedron, they obtained the steric arrangement of the N—N double bond. Though the tetrahedral model suffered some rather hard wear here, the analogy with geometrical isomerism of the ethylene type proved to be apt, and *Hantzsch* and *Werner* were able to predict correctly the number of possible isomers and in some cases even the presence of one of the possible forms.

During the 1890's, there were numerous hypotheses regarding the stereochemistry of pentavalent nitrogen, but little experimental material was available. Conclusive proof of the optical activity of asymmetric nitrogen was obtained only in 1899, when independent experiments by *Le Bel*[37] and by *Pope* and *Peachey*[38] resulted in the resolution of quaternary ammonium compounds with four different substituents into their optical antipodes. *Pope* later also prepared optically active compounds of sulfur, selenium, and tin.

Whereas steric considerations had at first been confined to carbon and nitrogen, *Werner* expanded them into a stereochemistry of the chemical elements in general. He laid the foundation stone in 1893 in a classical study, in which he also founded the discipline of coordination chemistry[39]. For cobalt complexes with six ligands he proposed the form of an octahedron, and for platinum complexes with four ligands a square arrangement, the metal atom in each case being situated in the center of the system. With the aid of these steric ideas he was able to explain the number of isomers observed for coordination compounds. In the course of his further investigations, which were carried out mainly in the first decade of the 20th century, *Werner* demonstrated geometrical isomerism and mirror-image isomerism in complexes of cobalt, chromium, platinum, and other metals, discovered cases of optical activity without any asymmetric central atom (confirming *Le Bel*'s views on molecular asymmetry), and proved his hypotheses by the resolution of complex compounds into their optical antipodes.

6. Stereochemistry and Mechanism of Chemical Reactions

Around the turn of the century, there was still a long way to go for a stereochemistry of chemical reactions, but two chance discoveries made in the 1890's steered chemical research in this direction; these discoveries were "steric hindrance" and "Walden inversion".

Victor Meyer found that only very low yields could be achieved in the esterification of mesitylenecarboxylic acid, triphenylacetic acid, and similar compounds. These observations led him to the idea that the hindrance of such reactions was caused mainly by the bulk of neighboring substituents[40], and he therefore called this phenomenon "steric hindrance of chemical reactions".

In 1896, *Paul Walden* discovered an "optical cycle", which led from levorotatory malic acid *via* dextrorotatory chlorosuccinic acid, dextrorotatory malic acid, and levorotatory chlorosuccinic acid back to the starting material[41]. Since two pairs of optical antipodes had been produced in this process, inversion of the configuration on the asymmetric carbon atom must have occurred at two points in the cycle. *Walden*'s discovery, which was soon found to be a widely occurring phenomenon, led to the question of the stability of the four groups bonded to the asymmetric carbon atom and the mechanism of substitution processes. At the same time it raised serious doubts as to the reliability of the determination of configurations in which substitutions on the asymmetric carbon atom had been carried out.

Numerous hypotheses were proposed to explain the Walden inversion, but it was not until forty years later that *Hughes* and *Ingold* found a satisfactory explanation, which also allowed predictions for the first time[42]. On the basis of their extensive studies on the mechanism of substitution reactions, these authors found that Walden inversion generally occurs in bimolecular substitutions (S_N2 and S_E2) on the asymmetric carbon. These substitutions proceed *via* a transition state in which the entering substituent is on one side of the carbon atom, and the original substituent on the other; as the original substituent leaves, the configuration "flips over".

7. Hindered Rotation about Single Bonds and Conformation

In 1877, *van't Hoff* had expressed the supposition that rotation must be possible about the carbon-carbon single bond[43].

[*] "The three valences of the nitrogen atom are directed in certain compounds toward the apices of an (irregular) tetrahedron, whose fourth apex is occupied by the nitrogen atom itself."

Though this view was doubted in some cases, it was found that the experimental results could also be interpreted without the assumption of hindered rotation.

The first considerations of conformation[*] in the narrower sense that did not prove to be incorrect interpretations were concerned with the cyclohexane system. On the basis of model considerations and purely mathematical calculations, *Sachse* found in 1890 that *Baeyer*'s strain theory was invalid for six-membered and higher rings, and that strain-free rings could be constructed with retention of the tetrahedral angle[44]. For cyclohexane he established two forms, which are now known as the chair and boat conformations. *Sachse*'s views were not accepted by his contemporaries, partly because they were unable to prevail against the strain theory of the famous *Baeyer*, and partly because *Sachse* considered the isolation of the two forms as conceivable. Almost thirty years later, *Mohr* adopted *Sachse*'s hypothesis[45] and showed that it has unlimited validity for cyclohexane if one assumes that there is only a low energy barrier between the two forms. He extended *Sachse*'s views to bicyclic and polycyclic six-membered ring systems and to diamond. *Mohr*'s prediction that decalin should have strain-free *cis* and *trans* forms was confirmed experimentally by *W. Hückel*, who isolated the two forms[46]. Similarly, the work of *Böeseken* on the boric acid and isopropylidene derivatives of cyclic diols contributed to the ultimate acceptance of the Sache-Mohr theory[47].

Incentives to conformational considerations were also coming in the meantime from another quarter. In 1922, *Christie* and *Kenner* resolved 4,6-dinitrodiphenic acid and 4,4',6,6'-tetranitrodiphenic acid into their optical antipodes[48]. One of the suggested explanations, *i.e.* that rotation about the common axis is prevented here by the bulk of the *ortho* substituents, with the result that the two benzene rings do not lie in the same plane (later known as atropisomerism), soon proved to be correct. Even ethane, which had previously been regarded as the prototype of a molecule with free rotation, was found to exhibit hindrance of the rotation. *Kemp* and *Pitzer* found, by comparison of calculated and experimental entropy values, that an energy barrier of about 3 kcal/mol must be assumed for the rotation of the methyl groups in ethane[49].

Despite the hindrance of rotation observed in these cases, considerations of conformation were at that time still of minor importance to the organic chemist, since there were practically no experimental aids for the detection of conformational effects. This situation was changed by the physico-chemical investigations carried out in the 30's and 40's by research groups working with *Mizushima*[50], *Hassel*[51], and *Pitzer*[52]. Special mention should be made of an investigation by *Hassel*, in which he showed by electron diffraction experiments on simple cyclohexane derivatives that these are nearly always in the chair form, that it is possible to distinguish between axial and equatorial substituents, and that the chair form with the greater number of equatorial substituents is the more stable[51a].

However, the actual flowering period of conformational analysis did not begin until 1950, when *Barton* showed, in a fundamental study on the conformations of steroids, that important conclusions regarding the stability and reaction behavior of chemical compounds can be drawn from considerations of conformation[53]. The rapid acceptance of conformational ideas in organic chemistry that now began was favored by the improvements in X-ray structural analysis and NMR spectroscopy during the 50's and 60's, as a result of which it was possible for many conformation determinations to be carried out.

[*] The term "conformation" was coined by *Haworth* in 1929.

8. Theoretical and Experimental Confirmation of the Fundamental Stereochemical Postulates

The van't Hoff-Le Bel hypotheses and their extensions, *e.g.* by *Baeyer*'s strain theory, raised a number of questions regarding the nature of the valence and the structure of the atoms. For example, the physical reality underlying the tetrahedral model and the postulate of free rotation around single bonds and a rigid arrangement around double bonds was unknown. It was also uncertain whether the steric phenomena were due to intrinsic properties of the atom and whether directed valences actually existed. Such problems could at first only be treated on a purely speculative basis.

Opinions were divided in particular on the question of directed valences. *Van't Hoff* was of the view that the number and direction of the valences must be connected with the shape of the atoms[54]. *Wislicenus* regarded the atoms as three-dimensional forms with preferred valence sites[55]. He thought it conceivable that the carbon atom was at least approximately tetrahedral in shape, and that the sites of action of the valences were concentrated at the apices of the tetrahedron.

Le Bel belonged to the group that rejected the idea of valences fixed in space[56]. In his view, the fixed position of the atoms in space resulted from an interplay between the spheres of attraction and repulsion of the atoms, a state of equilibrium being reached with a certain steric arrangement. *Werner* too was opposed to directed individual valences, since he regarded the affinity as a force acting uniformly in all directions from the center of the atom[57]. Like *Le Bel*, *Werner* therefore considered the tetrahedral arrangement of the substituents around a carbon atom as a secondary effect, which, in the case of four identical substituents, results purely from the fact that this is how the greatest bond strength can be achieved.

A theoretical interpretation of the main stereochemical postulates that was satisfactory to the chemist was made possible only by the quantum theory. The decisive contribution to the solution of the problem is found in an article published in 1931 by *Linus Pauling*, which provided the foundation for the quantum-mechanical interpretation of the chemical bond[58]. Among other things, *Pauling* calculated the eigenfunctions for an sp^3-hybridized atom and summarized his findings as follows[59]:

"We have thus derived the result that an atom in which only s and p eigenfunctions contribute to bond formation and in which the quantization in polar coordinates is broken can form one, two, three, or four equivalent bonds, which are directed toward the corners of a regular tetrahedron. This calculation provides the quantum mechanical justification of the chemist's tetrahedral carbon atom."

Since the arrangement of these eigenfunctions is cylindrically symmetrical with respect to the direction of the bond, *Pauling*

concluded that there must be free rotation about a single bond, provided that the rotation is not hindered by steric effects.

For the double bond, *Pauling* in the same article and *E. Hückel*[60] independently came to the conclusion that maximum overlap of the eigenfunctions is possible only in two arrangements of the substituents in relation to the double bond, these arrangements differing from each other by 180° (*cis* and *trans* arrangements), and that free rotation is lost in double-bond systems. Thus the fundamental hypotheses of stereochemistry, which chemists had already been using for decades, were now provided with a theoretical foundation.

Experimental proof of *van't Hoff*'s tetrahedral model had become possible after the two *Braggs* had determined the crystal structure of diamond by X-ray structural analysis[61]. *Mohr* proposed two models based on carbon tetrahedra for diamond, and showed that one of these models is identical with the Bragg space lattice[45]. These results were confirmed *inter alia* by *Astbury*, who determined the crystal structure of dextrorotatory tartaric acid[62].

One problem that remained unsolved, even after *Astbury*'s investigations, was the determination of the absolute configuration, *i.e.* the question of the actual arrangement in space of the substituents on an asymmetric carbon atom. This problem was clarified only in 1951, *i.e.* more than 75 years after the fundamental hypotheses of *van't Hoff* and *Le Bel*, when *Bijvoet* determined the absolute configuration of sodium rubidium (+)-tartrate by X-ray structural analysis[63]. It was found that the configuration arbitrarily assigned by *Fischer* to dextrorotatory tartaric acid[32] corresponds to the true arrangement in space.

A New Method for the Preparation of Transition Metal-Carbene Complexes

By *Wolfgang Anton Herrmann*[*]

As a rule the Wolff rearrangement of diazoketones[1] proceeds so rapidly that mostly only the corresponding ketene can be isolated in which intramolecular rearrangement has completely terminated. Only under narrowly defined conditions can the intermediary ketocarbene be intercepted by an intermolecular reaction[2]. Heavy-metal ions, such as Ag^+ or Cu^{2+} have proven effective as stabilizers of the reactive carbenes[3].

Reaction of dicarbonyl(η-methylcyclopentadienyl)(tetrahydrofuran)manganese *(1)* with an excess of α-diazodeoxybenzoin *(2)* in tetrahydrofuran (THF) leads to slow evolution of nitrogen and formation of a brownish-black crude product, which on separation by column chromatography yields an emerald-green crystalline compound that is stable to air and deflagrates when heated in a sealed tube at 90.5 °C. Molecular weight determination and elemental analysis show the new compound to have the composition $C_{22}H_{17}O_3Mn$; physical data and spectroscopic findings prove it to have the structure of a benzoylphenylcarbene complex *(3)* and at the same time rule out formation of the isomeric diphenylketene complex *(4)*[4].

Complex *(3)*, which is readily soluble in polar and apolar organic solvents, shows a strong absorption band in the visible region of the spectrum ($\lambda = 387$ nm; $\varepsilon = 12800$ l/mol·cm) while *(4)* absorbs only below 250 nm.—The IR spectrum of *(3)* exhibits two strong, almost equally intense bands in the stretching region of the terminal carbonyl groups bound to the metal atom (1979 and 1920 cm^{-1}, diethyl ether). The $\nu_{C=O}$ frequency of the benzoyl group of the carbene ligand occurs at 1628 cm^{-1} (KBr; *(2)*: 1631 cm^{-1}).—The ^{1}H-NMR spectrum contains two highly structured multiplets at $\tau \approx 2.4$ and 2.6 ppm which are assigned to the two C_6H_5 groups. The spin system of the C_5H_4-protons likewise appears as a multiplet at $\tau = 5.1$ ppm, and the CH_3 singlet occurs at $\tau = 8.19$ ppm. In the decomposition of *(3)* in the mass spectrometer (70 eV) the two CO groups bound to the central metal are eliminated first; the molecular ion of tolan ($m/e = 178$), which is formed by deoxygenation of the carbene ligand, is also observed.

Dicarbonyl(η-methylcyclopentadienyl)(benzoylphenylcarbene)-manganese (3):

A 1 M solution (8 ml, 8 mmol) of α-diazodeoxybenzoin *(2)*[5] in benzene is added dropwise to a stirred solution of the THF-complex *(1)*—which is formed photochemically from $(CH_3C_5H_4)Mn(CO)_3$ (1.09 g, 5 mmol)—in THF (30 ml). The mixture is stirred for 48 h at room temperature, concentrated in a water-jet vacuum, and the resulting oily, brownish-black residue is then degassed for 5 h in a high vacuum. On chromatographic separation on a silica gel column ($l = 45$, $\varnothing = 2.5$ cm) with benzene the first yellow zone consists of a mixture of $(CH_3C_5H_4)Mn(CO)_3$ and diphenylketene. This is followed by a very short blue zone, which so far has not been characterized. The carbene complex *(3)* is contained in the third brown zone. The eluate is concentrated and the resulting viscous oil is dried in a high vacuum prior to dissolution in the minimum amount of *n*-pentane/diethyl ether (3 : 1). On cooling the brown solution, emerald green *(3)* crystallizes out at −50 °C [yield: 710 mg (37 %)].

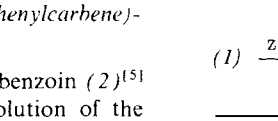
Modes of Reaction of 2- and 3-Hydroxyalkyl Isocyanides with Metal Compounds; Oxazolidinylidene and Perhydrooxazinylidene Complexes of Palladium, Platinum, and Gold[**]

By *Klaus Bartel* and *Wolf Peter Fehlhammer*[*]

Isocyanides are generally stabilized when coordinated to a metallic center. We have found, however, that isocyanides with OH groups at position 2 or 3, which are stable as pure substances, become activated on contact with metal ions and isomerize to *N,O*-heterocycles.



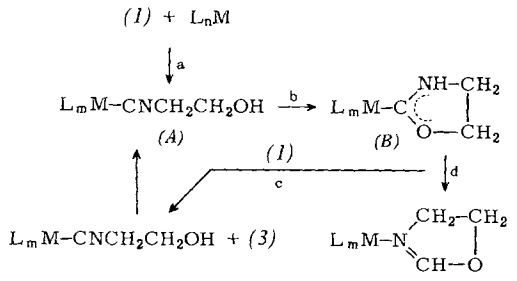
2-Hydroxyethyl isocyanide *(1)* [b. p. 54—55.5 C/10^{-3} torr] and 3-hydroxypropyl isocyanide *(2)* [b. p. 48—50 C/10^{-3} torr] are readily accessible from the corresponding formamides using phosgene as dehydrating agent, according to eq. (1). With an excess of phosgene the crystalline bis(isocyanoalkyl) carbonates are formed[1].

$$HO\text{–}(CH_2)_n\text{–}NHCHO + COCl_2 + 2\ NEt_3 \rightarrow$$

$$HO\text{–}(CH_2)_n\text{–}NC + CO_2 + 2\ [Et_3NH]Cl \qquad (1)$$

(1), n = 2
(2), n = 3

If even a few grains of $ZnSO_4$ or $PdCl_2$ are added to *(1)*, a vigorous exothermic reaction sets in, leading quantitatively to 2-oxazoline *(3)*.



(2)

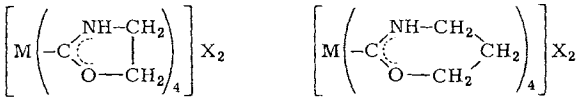
[**] Metal Complexes with Multifunctional Isocyanides, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft.

Complete catalytic cyclization of *(2)* to 5,6-dihydro-4*H*-1,3-oxazine requires warming for several days at 60 °C[2].

The reaction scheme shown in eq. (3) for catalytic isomerization of *(1)* is supported by the isolation and characterization of the isocyanide *(A)* and carbene intermediates *(B)*.

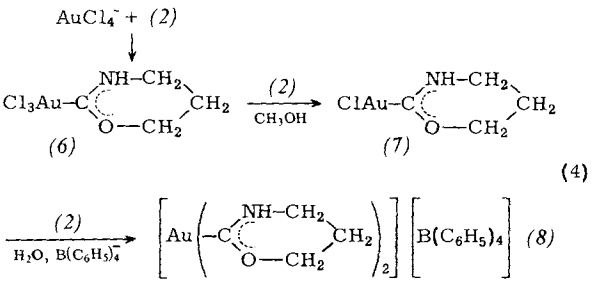


(3)

L_nM = PdI_2, $(C_6H_5CN)_2PdCl_2$, *(4c)*, $PtCl_2$, $AuCl_4^-$, Zn^{2+}

With a stoichiometric ratio of L_nM to isocyanide and suitable metal-complex components L_nM, the reaction can be arrested at stage *(A)* or *(B)*, but this is not possible with catalytic amounts of metal salts because of the substitution step c. In the reaction of the carbonyl compounds $M(CO)_5THF$ or $C_7H_8Mo(CO)_3$ with *(1)* or *(2)* the stable "open-chain" isocyanide complexes of the type corresponding to formula *(A)*, namely $(OC)_5M{-}{-}CN(CH_2)_nOH$ (M = Cr or W; $n = 2$ or 3) or $(OC)_3Mo(CNCH_2CH_2OH)_3$, are formed exclusively.

However, complexes of type *(A)* with $M = Pd^{II}$ or Pt^{II} are extremely unstable and isomerize immediately to oxazolidin-2-ylidene complexes *(4)* of type *(B)*. Only a yellow coloration of the methylene dichloride phase appearing for a short time during treatment of PdI_2 suspended therein with *(1)* shows



(4) *(5)*

(a): X = Cl; M = Pd, Pt
(b): X = Br, M = Pd
(c): X = I, M = Pd

that *(A)* is involved at all. With the appreciably less reactive *(2)* this intermediate is sufficiently long-lived for its IR spectrum to be recorded: the intense absorption at 2240 cm^{-1} is doubtless that of a complexed isocyanide species $\{Pd^{II}{-}CNCH_2CH_2CH_2OH\}$, which exists together with free *(2)* [ν(NC): 2150 vs, 2167 sh cm^{-1}]. A high Δν(or ν)-value, which can be obtained directly from the spectrum, thus correlates also in this case with a high reactivity of the isocyanide ligand towards nucleophilic reagents[3].

Intermolecular addition of alcohols to coordinated isocyanides seldom succeeds and then only under comparatively energetic reaction conditions[4, 5]. However, the salt-like carbene complexes *(4)* and *(5)* not only form very readily but are also extraordinarily stable and decompose only above 160 °C. Acetone-soluble tetraphenylborates are precipitated from their aqueous solutions on addition of $Na[B(C_6H_5)_4]$. The action of an aqueous-acetone solution of *(4c)* on PdI_2 gives orange-red crystals of $[Pd(oxazolidin\text{-}2\text{-}ylidene)_4][PdI_4]$.

Reaction of $Na[AuCl_4]$ in methanol or water with *(1)* or *(2)* instantaneously yields the sparingly soluble, yellow gold(III)-carbene complexes *(6)*, which are slowly reduced by an excess of isocyanide to the gold(I)-complexes *(7)* and *(8)*.

(4)

Finally, interaction of *(1)* and the stoichiometric amount of $ZnCl_2$, where, as expected, the carbene intermediate *(B)* cannot be stabilized, yields dichlorobis(2-oxazoline)zinc(II) quantitatively, in accord with eq. (3, d).

Tetrakis(oxazolidin-2-ylidene)palladium(II) diiodide (4c):

To a stirred suspension of PdI_2 in a little acetone or methylene dichloride the isocyanide *(1)* is added in the molar ratio 1:4. A yellow solution is formed, from which white, analytically pure *(4c)* is precipitated after a few seconds. The product is washed with acetone and ether and dried in a high vacuum. The yield is almost 100%.

Polynuclear Oxofluoro Anions of Molybdenum(V)[**]

By *Rainer Mattes* and *Gerhard Lux*[*]

$MoOF_5^{2-}$ is the only oxofluoro anion of molybdenum so far recorded in oxidation state +5[1]. By treatment of $MoCl_5$, dissolved in tetrahydrofuran or water-alcohol mixtures, with aqueous solutions of NH_3 and NH_4F (or $N(CH_3)_4F$) we have now obtained the new oxofluoromolybdates(V) $(NH_4)_2MoO_2F_3$ *(1)*, $NH_4MoO_2F_2 \cdot H_2O$ *(2)*, and $N(CH_3)_4MoO_2F_2$ *(3)*. Owing to the possibility of formation of metal-metal bonds these compounds should differ structurally from the corresponding molybdenum(VI) compounds in which only coordination polyhedra (octahedra) linked at corners are found[2, 3]. The large number of strongly electronegative ligands leads one to expect particularly strong metal-metal interaction. Also of interest is the extent to which bonding of the ligands lying opposite to the terminal M—O bonds is weakened by the *trans*-effect[4]—an effect that presumably comes into play in biological redox processes involving Mo^V complexes[5].

The IR and Raman spectra of the anions of the salts *(1)* to *(3)* are largely similar, in spite of the differences in composition. For example, Fig. 1 represents the vibrational spectrum of *(2)*.

The bands at 940—980 cm^{-1} show that only one of the oxygen atoms is bound terminally to the molybdenum atom[1]. The

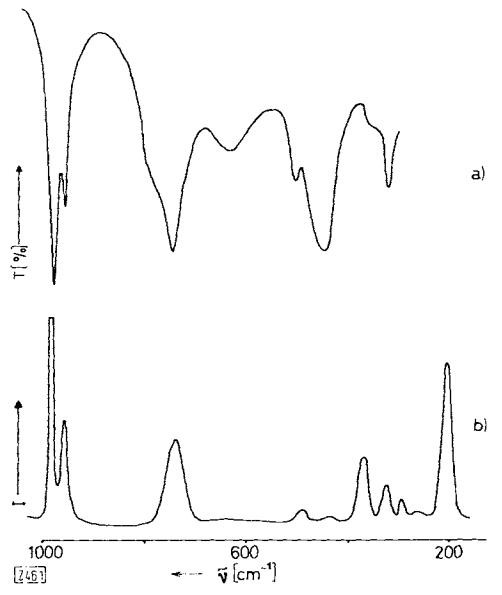

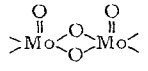

Fig. 1. IR (a) and Raman spectra (b) of $NH_4MoO_2F_2 \cdot H_2O$ (*2*).

broad band at 750cm^{-1} must therefore be due to molybdenum-oxygen bridge bonds[3, 6]. Accordingly all these compounds contain polynuclear complex anions bridged by oxygen atoms. Thus, like $Ba\{[MoO(C_2O_4)H_2O]_2O_2\}$[7], *l*-cysteinato complexes of Mo^{VI}[8] and dilute aqueous Mo^{V} solutions[9], the salts (*1*) to (*3*) very probably contain the binuclear dioxodi-μ-oxodimolybdate(V) groups:

whose residual coordination positions are occupied by F^- and H_2O ligands.

Magnetic investigations gave an effective magnetic moment of 0.58 μ_B for (*1*); (*2*) and (*3*) are diamagnetic. This behavior is explicable by molybdenum-molybdenum interactions where diamagnetism can be achieved by pairing of the two d-electrons with formation of a metal-metal bond[7, 10]. The high intensity band at 200cm^{-1} in the Raman spectrum can be assigned to a metal-metal vibration[11].

Structural investigations are in progress: (*1*) crystallizes orthorhombically with $a=13.60$, $b=7.53$, $c=11.55$ Å, and $Z=8$; (*2*) forms monoclinic crystals with $a=9.33$, $b=13.94$, $c=7.96$ Å, $\beta=113.3°$ and $Z=8$.

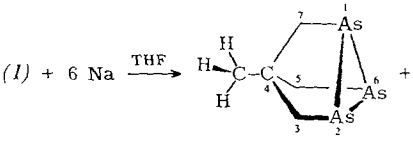
Synthesis of an all-*cis*-Organocyclotriarsane Derivative[**]

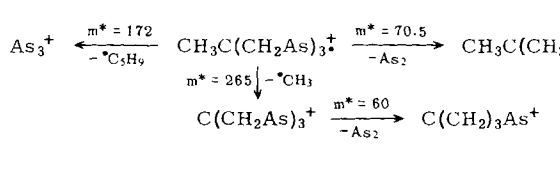
By *Jochen Ellermann* and *Horst Schössner*[*]



Organo-*cyclohexa*-, *-cyclopenta*- and *-cyclotetra*-arsanes, *e.g.* $(C_6H_5As)_6$[1, 2], $(RAs)_5$ (R = CH_3[2], CF_3[3], C_2H_5, *n*-C_3H_7[2], *n*-C_4H_9, iso-C_4H_9[4]) and $(RAs)_4$ (R = CF_3[3], C_6H_5[5], C_6H_{11}, *sec*-C_4H_9, and *tert*-C_4H_9[4]) have been described previously. The organic substituents of the ring systems are generally in *cis- and trans*-positions[2, 6]. We have now been able to synthesize the first all-*cis*-organo*cyclotri*arsane.

Mass-spectroscopic degradation of tetratertiary organoarsenic compounds leads preferentially to fragment ions containing a cyclotriarsane skeleton[7]. Thus *preparative* production of cyclotriarsane derivatives should be particularly easy starting from the corresponding tritertiary organoarsenic compounds. If (*1*), which can be obtained according to eqs. (1) and (2)[8], is treated with sodium in tetrahydrofuran, then crystalline 4-methyl-1,2,6-triarsatricyclo[2.2.1.0^{2,6}]heptane (*2*) is formed as shown in eq. (3).

$$CH_3C(CH_2Br)_3 + 3\ NaAsR_2 \xrightarrow{\text{liq. } NH_3} CH_3C(CH_2AsR_2)_3 + 3\ NaBr \quad (1)$$



$$CH_3C(CH_2AsR_2)_3 + 6\ HI \xrightarrow{CH_2Cl_2} \underset{(1)}{CH_3C(CH_2AsI_2)_3} + 6\ RH \quad (2)$$

(R = C_6H_5)

(*2*)

The composition and structure of (*2*) are proved by elemental analysis and, especially, by the mass spectrum. The molecular ion M^+ occurs at $m/e=294$ with the relative abundance of 100%; in addition the following fragments are observed: 279 $M-CH_3$ (21%), 239 CH_2As_3 (19%), 225 As_3 (68%), 163 $CHAs_2$ (7%), 150 As_2 (10%), 144 $M-As_2$ (67%), 129 $C(CH_2)_3As$ (38%), 116 C_3H_5As (7%), 101 C_2H_2As (10%), 89 CH_2As (22%), 75 As (6%), 69 $CH_3C(CH_2)_3$ (34%). The most important decomposition steps are shown by the metastable transformations m*:

The cyclotriarsane (*2*) can be sublimed and is readily soluble in THF, diethyl ether, $CHCl_3$, and CH_2Cl_2, moderately soluble in CCl_4, CH_3OH, and light petroleum, but insoluble in benzene. In the ^{1}H-NMR spectrum ($CDCl_3$; TMS internal) two singlets are found, at $\delta=1.38$ (CH_2) and 1.50 ppm (CH_3) in

[*] Prof. Dr. J. Ellermann and Dipl.-Chem. H. Schössner

[**] Contributions to the Chemistry of Polyfunctional Ligands, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 28: ref. [7].

the intensity ratio 2:1.04. The strongest band in the Raman spectrum, at 300 vs cm^{-1}, is doubtless to be assigned to the (As—As) stretching vibration (A_1) of the three-membered arsenic ring; further, on the assumption of C_{3v} or C_3 molecular symmetry of *(2)*, the resolved medium-strength bands at 252, 246 sh cm^{-1} in the Raman spectrum of solid *(2)* are tentatively assigned to the expected vibration ν(As—As) (E). In the IR spectrum the characteristic ν(As—C)[7-9] (A_1 + E) are observed at 546 and 522 cm^{-1}.

Experimental:

The tris(diiodoarsane) *(1)* (1.11 g, 1.04 mmol) is added portionwise, with stirring, to sodium pellets (0.7 g, 30 mmol) in THF (20 ml). After initial warming, a vigorous reaction sets in; stirring is continued with cooling for 20 min, then the mixture is filtered from undissolved NaI, excess of sodium and decomposition products. The residue is washed three times each with 15 ml of ether, and the solvent is removed from the filtrate at 20 °C in a vacuum. The dried crude product, which still contains NaI, can be purified by sublimation (80—150 °C/0.5 torr): yield 166 mg (54%) of colorless crystals of *(2)*, m.p. 159 °C.

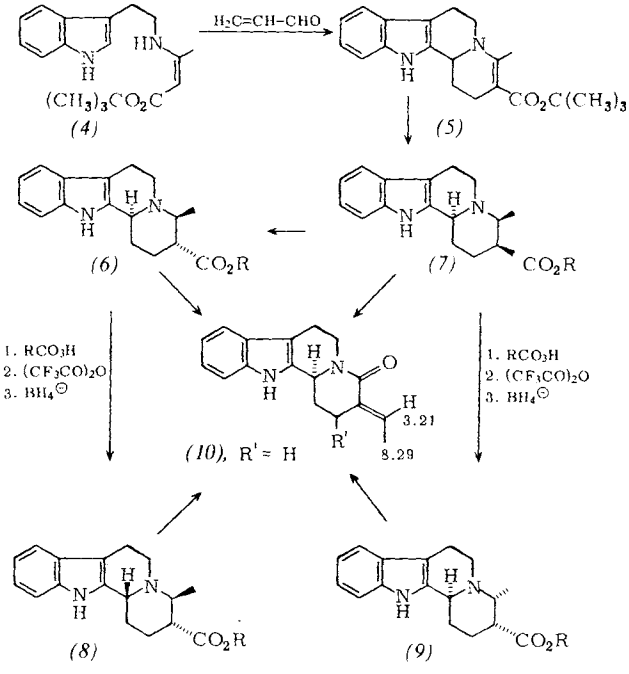
Stereoselective Synthesis of Exocyclic Trisubstituted Double Bonds[1][**]

By *Dietrich Thielke, Joachim Wegener*, and *Ekkehard Winterfeldt*[*]



Exocyclic trisubstituted double bonds as shown in *(1)* occur in many indole alkaloids[2] as a characteristic structural unit.

(1) *(2)* *(3)*

We have attempted to exploit the rearrangement of piperidinecarboxylic acids *(2)* to unsaturated lactams *(3)*[3,4] in the case of substituted indoloquinolizidines as a means of synthesizing compounds of type *(1)*. Publication of the mechanism of the reaction *(2)*→*(3)*, and of successful attempts to rearrange also substituted piperidines of similar kind (which, however, gave both the stereoisomeric olefins), by *Rapoport et al.*[5] has induced us now to release our results, which reveal the high stereoselectivity of the reaction in polycyclic systems.

When the enamine from tryptamine and *tert*-butyl acetoacetate *(4)* is warmed with acrolein and then set aside in glacial acetic acid it affords the vinylogous urethan *(5)*[7]. On reduction thereof with $NaBH_4$ in glacial acetic acid[6], *(7a)* is obtained smoothly and with high stereoselectivity. The configuration follows from spectral data and from the convertibility into *(6a)* on treatment with potassium *tert*-butoxide. *(6a)* and *(7a)* afford the epimers *(8a)* and *(9a)*, respectively, by way of the *N*-oxide, a Polonovski reaction to give the tetrasubstituted immonium salt, and subsequent reduction by $NaBH_4$. All four compounds can be cleaved by trifluoroacetic acid at room temperature to the acids *(6b)* to *(9b)* with retention of configuration (re-esterification regenerates the starting ester of unchanged configuration).

(a), R = $C(CH_3)_3$; *(b)*, R = H

When warmed in acetic anhydride all four acids yield exclusively the same unsaturated lactam *(10)*, R′ = H, in good yield. The configuration at the double bond follows from the NMR data (for τ values see the formula), which are particularly convincing when compared with the values for the isomeric lactam obtained in minute amounts from the mother liquor (vinyl-H: τ = 4.14; methyl-H: τ = 7.96).

Reducing the unsaturated lactam with diisobutylaluminum hydride in monoglyme affords the base *(1)*, R = H. Applicability also to trisubstituted compounds follows from conversion of the enamine of type *(5)* (obtainable from crotonaldehyde) into the unsaturated lactam *(10)*, R′ = CH_3.

It thus appears that during these rearrangements each of the intermediates isomerizes to the thermodynamically stable *trans*-configuration. The unsaturated lactams *(10)*, R′ = H, and *(10)*, R′ = CH_3, are constitutionally and configurationally stable under the conditions of the reaction.

Hexamanganato(VII)manganic(IV) Acid: A "Pseudopermanganic Acid"[**]

By *Bernt Krebs* and *Klaus-Dieter Hasse*[*]

If an aqueous solution of permanganic acid (prepared by reaction of stoichiometric amounts of $Ba(MnO_4)_2$ with H_2SO_4) is concentrated under reduced pressure, one obtains different products, depending upon the experimental conditions: dimanganese heptoxide, water, manganese dioxide phases (with liberation of oxygen), and a new crystalline compound which has not yet been exactly identified[1]. On the basis of chemical analysis and its redox equivalent, the substance was assumed to be a "solid permanganic acid" having the composition $Mn_2O_7 \cdot 2H_2O$[1]. This violet compound is thermally very sensitive and decomposes mainly to Mn_2O_7, oxygen, manganese dioxides, and water above $-4\,^{\circ}C$, reacts vigorously with oxidizable substances, but can be obtained pure as large bipyramidal crystals under optimal reaction conditions (distillation at $-40\,^{\circ}C/10^{-3}$ torr, cf. ref. [1]).

X-Ray structure analysis at $-120\,^{\circ}C$ has now shown that the compound concerned is a complex hexamanganato(VII)-manganic(IV) acid; the redox equivalent per Mn (6.57) corresponding to the exact formula $(H_3O)_2[Mn(MnO_4)_6] \cdot 11H_2O$ *(1)* approaches that of a "true" permanganic acid.

In the $[Mn(MnO_4)_6]^{2-}$ anion, a central Mn^{IV} atom, which is surrounded octahedrally by bridging O atoms, is coordinated with six $Mn^{VII}O_4$ tetrahedra with a trigonal prismatic arrangement of the Mn^{VII} relative to the central Mn^{IV}; the complete anion approximates well to C_2 symmetry. The mean bond lengths amount to Mn^{IV}—O(bridge) 1.90 (individual values between 1.85 and 1.94), Mn^{VII}—O(bridge) 1.74 (1.69 to 1.75), Mn^{VII}—O(terminal) 1.60 Å (1.55 to 1.66 Å).

The hexamanganato(VII)manganate(IV) ion (Fig. 1) represents a new type of a "heteropolyanion" in which both components arise from the same element in different oxidation states. The chemical properties are largely determined by the Mn^{VII} centers present in excess.

The excess protons are clearly present as H_3O^+ ions, which are linked to the other H_2O molecules of the lattice by a hydrogen bond system (O(H)···O distances in the bridges originating from the H_3O^+ groups between 2.48 and 2.60 Å). Crystal data of compound *(1)* (cf. ref. [1]): orthorhombic, C_{2v}^{19}-Fdd2; $a = 17.77(2)$, $b = 63.97(8)$, $c = 10.48(2)$ Å (at $-120\,^{\circ}C$); $Z = 16$; $d_{calc.} = 2.24\,g\,cm^{-3}$. The structure was determined from 1457 film data and refined to $R = 0.092$.

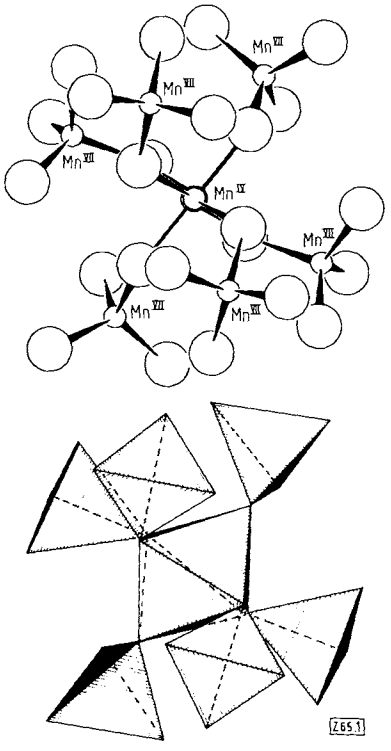

Fig. 1. Structure of the $[Mn(MnO_4)_6]^{2-}$ anion in solid hexamanganato(VII)-manganic(IV) acid $(H_3O)_2[Mn(MnO_4)_6] \cdot 11H_2O$ *(1)*.

The behavior of aqueous permanganic acid solutions on concentration under various conditions will be reported at a later date. The question of the existence of a pure "solid permanganic acid" still remains open. However, results obtained so far, the behavior of Mn_2O_7[2] towards water, and crystallochemical considerations cast doubt upon the stability of a solid phase in the Mn_2O_7—H_2O system (as hydrate $Mn_2O_7 \cdot xH_2O$ or, as formerly postulated, as $HMnO_4$ or as $H_3O^+MnO_4^-$[3]).

Cyclooctasulfur Monoxide from Cyclooctasulfur[1]

By *Ralf Steudel* and *Jörg Latte*[*]

Cyclooctasulfur monoxide was first obtained as a product of the reaction of thionyl chloride with "crude sulfane" H_2S_n[2]. We have now found that cyclooctasulfur can be oxidized directly with trifluoroperacetic acid (molar ratio 1:1) in a simple manner:

$$S_8 + CF_3CO_3H \rightarrow S_8O + CF_3SO_2H$$

The S_8O obtained in *ca.* 45% yield by this method is identical in color, crystal form, decomposition temperature, solubility,

composition, and IR spectrum[3] with the product prepared from $SOCl_2$ and H_2S_n. This new, more productive synthetic route requires much less time and experimental effort than the former preparation.

Procedure:

S_8 (3.76 g, 14.7 mmol) is dissolved in CH_2Cl_2 (800 ml) by refluxing. The homogeneous solution is slowly cooled to 0 °C and protected from light by a black cloth. A freshly prepared solution of trifluoroperacetic acid [obtained by suspension of 50% H_2O_2 (1 g, 14.7 mmol) in CH_2Cl_2 (50 ml) at 0 °C and rapid addition of trifluoroacetic anhydride (5 ml, 36 mmol)] is added dropwise over 1 h to the stirred reaction mixture, which assumes an intense yellow hue. Concentration in a vacuum at 20 °C bath temperature to 1/3 of the original volume leads to precipitation. Further crystallization is induced by cooling to −20 °C. The precipitate is collected on a glass frit, washed with CH_2Cl_2, and dried in a vacuum. The procedure yields 1.8 g of almost pure S_8O which can be isolated analytically pure by recrystallization from CS_2.

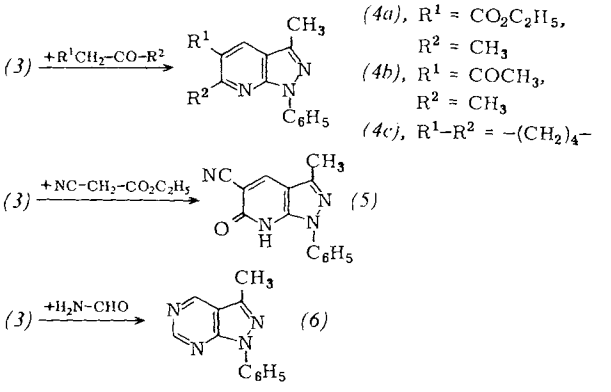
Synthesis of Pyrazolo Heteroaromatic Compounds by Means of 5-Amino-3-methyl-1-phenylpyrazole-4-carbaldehyde

By *Jochen Häufel* and *Eberhard Breitmaier*[*]



5-Amino-3-methyl-1-phenylpyrazole-4-carbaldehyde *(3)* is formed in a modified Vilsmeyer synthesis[1,2]: reaction of 5-amino-3-methyl-1-phenylpyrazole *(1)*[3] with an excess of *N,N*-dimethylformamide (DMF) and phosphorus oxide chloride affords crystalline 5-[(*N,N*-dimethylamino)methyleneamino]-3-methyl-1-phenylpyrazole-4-carbaldehyde *(2)*, which is converted in good yield into *(3)* by acid hydrolysis.

(1) *(2)* *(3)*

This new aldehyde opens a direct route for preparation of condensed heterocycles of the pyrazole series. Thus cyclocondensation of *(3)* with 1,3-dicarbonyl compounds affords the pyrazolo[3,4-*b*]pyridines *(4a)—(4c)*, with ethyl cyanoacetate affords the derivative *(5)* and with formamide the pyrazolo[3,4-*d*]pyrimidine *(6)*. The condensation product of *(3)* with cyclohexanone is identical with 5,6,7,8-tetrahydropyrazolo[3,4-*b*]quinoline *(4c)* prepared from 2-hydroxymethylenecyclohexanone and *(1)*[4]. The compounds prepared were identified by means of spectroscopic data (IR, UV, MS, and ^{1}H- and ^{13}C-NMR).

Chemisches Institut der Universität
74 Tübingen, Auf der Morgenstelle (Germany)

5-Amino-3-methyl-1-phenylpyrazole-4-carbaldehyde (3):

$POCl_3$ (1.5 mol) is added dropwise with cooling to DMF (3.5 mol). Then *(1)* (0.5 mol) is added portionwise, the reaction mixture is stirred for 17 h at 70 °C (oil-bath temperature) and subsequently poured cautiously into an excess of Na_2CO_3 solution (cooling). The crystals that separate after some time [*(2)*] are hydrolyzed by HCl (*ca.* 20 wt.-%). After 50 hours' stirring at 40 °C (oil-bath temperature), neutralization with Na_2CO_3 solution, extraction with ether and removal of the solvent, *(3)* is obtained as a viscous oil. Recrystallization from 2-propanol affords a finely crystalline, pale yellow product: yield 64%, m.p. 97.5 °C.

Pyrazolo[3,4-b]pyridine (4) and 6,7-dihydro-3-methyl-6-oxo-1-phenylpyrazolo[3,4-b]pyridine-5-carbonitrile (5):

The CH-acidic carbonyl compound (0.02 mol) is refluxed with 0.02 mol of *(3)* in glacial acetic acid (30 ml) for *ca.* 30 h. For working-up, the mixture is poured into an excess of Na_2CO_3 solution and extracted with ether. The crude products are recrystallized from ethanol or ethanol/water [*(4a)*, yield 68%, m.p. 79.5 °C; *(4b)*, yield 79%, m.p. 96 °C; *(4c)*[4], yield 46%, m.p. 86 °C; *(5)*, yield 81%, m.p. 316 °C].

3-Methyl-1-phenylpyrazolo[3,4-d]pyrimidine (6):

0.025 mol of *(3)* is heated with 0.1 mol of formamide for 20 h at 140 °C. The cooled reaction mixture is treated with water (10 ml) and extracted with chloroform. The oil remaining on removal of the solvent is crystallized from 2-propanol; yield 60%, m.p. 84 °C.

Conformation of *trans*-Cyclooctene

By *Otto Ermer*[*]

Previous X-ray structural studies have not hitherto given exact structural parameters for *trans*-cyclooctene derivatives[1]

[*] Dr. O. Ermer
Abteilung für Chemie der Universität
463 Bochum, Universitätsstrasse 150 (Germany)

because of unfavorable experimental conditions. In addition, in two of the compounds studied the *trans*-cyclooctene double bond, which is highly non-planar, is coordinated to heavy metal atoms[1], and this complicates conclusions about the structure of *trans*-cyclooctene itself. The X-ray structure analysis of *trans*-2-cyclooctenyl 3',5'-dinitrobenzoate *(1)* (Fig. 1d) described below is free from these disadvantages.

We undertook the X-ray crystal structure investigation in order to test our force-field calculations[2] experimentally, which in the case of *trans*-cyclooctene contradicted the results of a

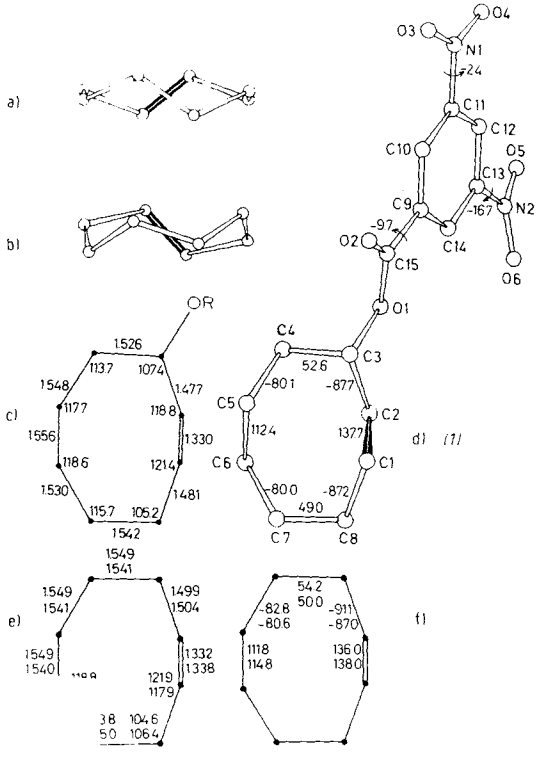

Fig. 1. a) Crown conformation and b) distorted chair conformation of *trans*-cyclooctene (symmetry C_2 in both cases). c) Observed bond lengths [Å] and angles [°] and d) torsion angles [°] (view perpendicular to the best plane through the eight-membered ring of C atoms) of the eight-membered ring in *(1)* (estimated average standard deviations: 0.004 Å, 0.3° and 0.3°, respectively: R = 3,5-dinitrobenzoyl); e) and f) comparison with gas electron diffraction results [4] (upper values) and results of our force field calculations (lower values): ring symmetry C_2.

gas electron diffraction analysis by *Gavin* and *Wang*[3]. From their results these authors deduced a distorted chair conformation (symmetry C_2, Fig. 1b), whereas according to our calculations the crown conformation (symmetry C_2, Fig. 1a) is the more stable by 3.1 kcal mol^{-1}. The data of a gas electron diffraction analysis by *Traetteberg*[4] have been interpreted in favor of the crown conformation (Fig. 1a).

Crystal data of *(1)*[**]: $a = 10.963(2)$, $b = 5.656(1)$, $c = 14.873(2)$ Å; $\alpha = 104.91(1)$, $\beta = 122.75(1)$, $\gamma = 76.18(1)°$; space group $P\bar{1}$; $Z = 2$. The intensities of 2774 reflections were measured (four-circle diffractometer, $\sin\theta/\lambda \leq 0.639$ Å^{-1}, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å). The structure was solved by inspection of a sharpened Patterson function of the crystal. Figures 1 and 2 show the results obtained for the eight-membered ring after refinement [1623 reflections with $F_0 \geq 3\sigma(F_0)$; full matrix; C, N, O anisotropic; H isotropic (one common temperature factor, fixed parameters of the heavier atoms, exclusion of reflections with $\sin\theta/\lambda \geq 0.45$ Å^{-1}); $R = 0.052$].

[**] We thank Dr. *G. H. Whitham*, Oxford, for a sample.

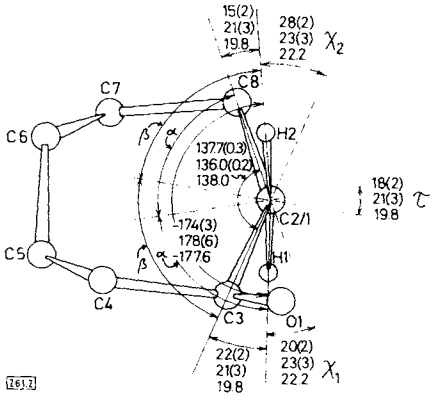

Fig. 2. Torsion and out-of-plane bending angles [°] at the double bond (projection along $C^2{=}C^1$; τ and χ are explained in the text: α and β are auxiliary angles for explanation of the Figure). Upper values: X-ray analysis of *(1)* (estimated standard deviations in parentheses); middle values: gas electron diffraction [4]: lower values: calculated [2].

The carbon skeleton of *trans*-cyclooctene in the crystals of *(1)* possesses the crown conformation with closely approximated C_2 symmetry (Figs. 1c and 1d). Bond lengths, bond angles, and torsion angles agree satisfactorily with *Traetteberg*'s results[4] and our calculations[2] (Figs. 1e and 1f). This holds also for the results of three previous studies[1] insofar as the experimental uncertainties allow comparisons. In particular, and remarkably, the C—C=C—C torsion angle [137(0.3)°; Figs. 1d and 2] and the corresponding angles in the Cu and Pt complexes (134 and 137°, respectively) are very similar. The C—C=C—C torsion angle determined from *Gavin* and *Wang*'s data[3] for the distorted chair conformation amounts to 157°, whereas our calculated value for this conformation is 137.9°; this large discrepancy does not support the view[3] that these older gas electron diffraction data were obtained from a sample of *trans*-cyclooctene possessing the distorted chair conformation, which according to our calculations is less stable, although the energy barrier between the two forms is perhaps large enough to prevent their equilibration[***].

The length of the double bond in the eight-membered ring, being 1.330 Å, is normal in spite of the marked deviation from planarity. Three independent geometric parameters are necessary to describe non-planar distortions of double bonds[2]. We choose the angle of pure twisting τ, which amounts to 18(2)°, and the two out-of-plane bending angles χ_1 and χ_2 [20(2)° at C^1 and 28(2)° at C^2: Fig. 2]. τ is defined as the arithmetical mean of the two H—C=C—C torsion angles, and χ as the supplementary angle of the dihedral angle between the planes of the H—C=C and the C—C=C angles at the same double-bond C atom. The deviation of the C—C=C—C torsion angle from 180° [42.3(0.3)°] is thus composed of 18(2)° pure twisting and of 24(2)° out-of-plane bending (Fig. 2). Obviously the double bond parameters involving H atoms cannot be determined accurately from X-ray data. However, the bending deformations of the double-bond H atoms towards the inner part of the ring are highly significant. All the geometrical details observed for the double bond agree well with the more recent gas electron diffraction results[4] and with our force field calculations (Fig. 2). The essentially harmonic potentials for twisting and out-of-plane

[***] *Note added in proof* (August 19, 1974): We have recently calculated an energy profile for the crown-distorted chair interconversion which does not show an energy barrier large enough to prevent equilibration at room temperature.

bending of a double bond[2] in our olefin force field thus appear to be useful for deformations up to at least 20°.

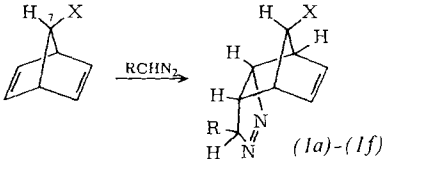
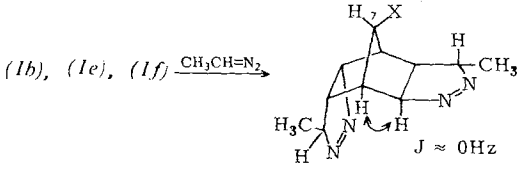
Stereospecific *endo-anti*-Cycloaddition of Diazoalkanes to 7-Substituted Norbornadiene: A π→σ* Effect?

By *Michel Franck-Neumann* and *Madjid Sedrati*[*]



Reaction of diazomethane or diazoethane with *cis*-3,4-dichlorocyclobutene gives *syn*-pyrazolines quantitatively[1] This



R = H, CH_3

astonishing stereospecific cycloaddition induced us to carry out similar investigations with the norbornadiene system.

With diazoalkanes *cis-endo-* and *trans*-dichloronorbornene[2] give only *exo*-adducts[3], as is shown by the very small coupling constants of the bridgehead and pyrazoline protons[4]. The

upfield shift for the C^7 proton in *syn*-position to the azo group is large, being 0.8—1.0 ppm.

The reaction of 7-chloronorbornadiene[5] with diazomethane or diazoethane proceeds differently: the 1-pyrazolines *(1a)* and *(1b)*, respectively [ν(N=N)≈1550 cm^{-1}] which are the sole products (NMR) have *endo*-stereochemistry, as follows from the coupling constants of the bridgehead and pyrazoline protons (≈4.5 Hz)[4]. In the presence of a large excess of diazoethane, *(1b)* then undergoes a further cycloaddition which leads to the *endo-exo*-bispyrazoline *(2b)* [isolated 24%; 75% calculated on the amount of *(1b)* reacting]. Since this barely alters the chemical shift of the C^7 proton [*(1b)*: δ = 3.87 ppm; *(2b)*: 3.78 ppm], it must be assumed that the *exo*-group is *anti* to this proton and consequently that the preceding *endo*-cycloaddition at the double bond occurs *anti* to the 7-chloro substituent (Table 1).

With diazoethane, 7-bromo-[6] and 7-iodo-norbornadiene[7] undergo the same stereospecific *endo-anti*-cycloadditions, affording *(1c)* and *(1d)*, respectively. In the case of norbornadienyl acetate[8] the second cycloaddition occurs approximately as fast as the first, so that a 1:1 mixture of *(1e)* and *(2e)* is formed (56%).

Norbornadien-7-ol[5a] gives, alongside the *endo-anti*-adduct *(1f)*, the bisadduct *(2f)* and the *endo-syn*-pyrazoline *(3)* (m. p. 87 °C; proportions 1.3:1:1; total yield 50%). 7-*tert*-Butoxynorbornadiene[9] and diazoethane, however, afford only an *exo*-adduct—probably the *syn*-isomer.

(3)

These "contrathermodynamic"[10] *endo-anti*-cycloadditions can no longer be explained as being due to an attractive interaction in the transition state between the nitrogens of the diazoalkanes and the chlorine atom[11] or, generally, the C^7-substituent. Now, however, a direct interaction is conceivable between the highest occupied, relatively high-lying π-orbital of the norbornadiene and the low-lying antibonding σ*-orbital of the C—X bond (X electronegative), whereby the *anti*-double bond becomes electron-poor, thus influencing the orientation of the reaction (Fig. 1).

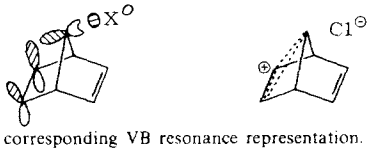

Fig. 1. π→σ* Interaction and corresponding VB resonance representation.

The *endo-syn*-cycloaddition to norbornadien-7-ol can in its turn be explained as involving an intramolecular hydrogen bond[5a, 8], the *syn*-double bond acting in a dative capacity.

Ab initio calculations show that the highest occupied MO of 7-chloronorbornadiene is localized mainly on the chlorine side, but without participation of an antibonding σ*-C—Cl orbital[11]. Since in the frontier orbital model the reactivity in the 1,3-dipolar cycloadditions with diazoalkanes is determined mainly by the HOMO-dipole-LUMO-dipolarophile interaction[12], we consider that a further interaction in this orientation complex with the σ*-orbital provides a better explanation of this *endo-anti*-addition. A formal similarity with anionic hyperconjugation[13] or the anomer effect[14]

can be recognized if one writes a transition state with localized partial charges (Fig. 2).

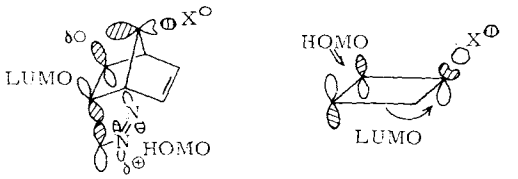

Fig. 2. p→σ* Interactions.

These considerations also apply to additions of diazoalkanes[11] and to the stereospecific Diels-Alder additions to *cis*-3,4-dichlorocyclobutene[15] (Fig. 2). Other stereospecific reactions—mostly cycloadditions—can probably also be explained by interactions with low-lying antibonding orbitals.

1,3,2,4-Diazadistannetidines, the First Four-Membered Cyclostannazanes

By *Dieter Hänssgen* and *Inge Pohl*[*]

The unusual properties of compounds containing the *tert*-butyltin group attached to an inorganic element[1, 2] are shown by, *inter alia*, the action of di-*tert*-butylstannylbis(dimethylamine) *(1)* on an excess of methyl- or benzyl-amine. Unlike other diorganostannylbis(dialkylamines), which react to form cyclotristannazanes[3], *(1)* affords the stannylamine *(2)* which condenses at 100 to 130 °C with loss of alkylamine to yield

$$(t\text{-}C_4H_9)_2Sn[N(CH_3)_2]_2 + 2\ RNH_2 \longrightarrow (t\text{-}C_4H_9)_2Sn(NHR)_2 + 2\ (CH_3)_2NH$$
(1) *(2)*

$$2\ (2) \longrightarrow (t\text{-}C_4H_9)_2Sn\langle N(R)\rangle Sn(t\text{-}C_4H_9)_2 + 2\ R\text{-}NH_2$$
(3)

(a), R = CH_3; *(b)*, R = $C_6H_5CH_2$

the novel 1,3,2,4-diazadistannetidines *(3a)* and *(3b)*, respectively. *(3a)* and *(3b)* form colorless crystals that are sensitive to hydrolysis and dissolve readily in aromatic and aliphatic hydrocarbons.

Whereas the eight-membered heterocycle *(4)* (m.p. 220 °C) is formed from *(3a)* and, *e.g.*, benzonitrile by 1,2-dipolar addition and ring expansion, reaction with sulfur-containing heterocumulenes such as carbon disulfide and phenyl isothiocyanate affords the dithiadistannane *(5)* and isothiocyanate or carbodiimide, respectively.

$$(3a) + 2\ C_6H_5CN \longrightarrow (t\text{-}C_4H_9)_2Sn\langle N(C_6H_5)\text{-}C(=N\text{-}CH_3)\rangle Sn(t\text{-}C_4H_9)_2$$
(4)

$$(3a) + 2\ R'\text{=}C\text{=}S \longrightarrow (t\text{-}C_4H_9)_2Sn\langle S\rangle Sn(t\text{-}C_4H_9)_2 + 2\ R'\text{=}C\text{=}N\text{-}CH_3$$
(5) R' = S or C_6H_5N

The composition and structure of *(3a)*, *(3b)*, and *(4)* were proved by elemental analysis, molecular weight determination (cryoscopic in benzene) and IR, ^{1}H-NMR, and mass spectra. ^{1}H-NMR spectra (measured at 37 °C in C_6D_6, TMS intern., δ values); *(3a)*: *t*-C_4H_9 = −1.07 ($J_{^1H\text{-}C\text{-}^{117,119}Sn}$ = 74/76 Hz); H_3CN = −2.95 ($J_{^1H\text{-}C\text{-}N\text{-}^{117,119}Sn}$ = 49/51 Hz). *(3b)*: *t*-C_4H_9 = −1.22 ($J_{^1H\text{-}C\text{-}^{117,119}Sn}$ = 73.5/77 Hz); H_2C = −4.44 ($J_{^1H\text{-}C\text{-}N\text{-}^{117,119}Sn}$ = 45/47 Hz); C_6H_5 = −7.42 to −7.12 (m). Mass spectra (selection) (*m/e*): *(3a)*: 526 (molecular ion); 469, 412, 355, 298 (rel. int. 100%), corresponding to M − 1, 2, 3, and 4 *t*-C_4H_9, respectively; 269 Sn—$N(CH_3)$—Sn. *(3b)*: 678 (molecular ion); 621, 564 (rel. int. 100%), 507, 450, corresponding to M − 1, 2, 3, and 4 *t*-C_4H_9, respectively; 345 Sn—$N(CH_2C_6H_5)$—Sn. The fragments are given only for ^{120}Sn.

(5) was identified by comparison with a sample prepared in a different way[4].

1,3-Disubstituted 2,4-di-tert-butyl-1,3,2,4-diazadistannetidines (3)

A primary amine (20 mmol) is dropped into *(1)* (3.21 g, 10 mmol) at 0 °C, and the whole is then warmed slowly to 120 °C (3 h). Sublimation of the crude product at 120 °C/0.2 torr affords 2.35 g (94%) of *(3a)* as colorless crystals, m.p. 155 °C.—For isolation of *(3b)* the excess of benzylamine is evaporated at 120 °C/0.1 torr and the solid residue is recrystal-

Stereospecific Hydrogenations with Hydrogen Gas and Microorganisms as Catalysts[**]

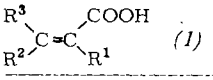
By *Helmut Simon, Bernhard Rambeck, Hironobu Hashimoto, Helmut Günther, Gerhard Nohynek*, and *Helmut Neumann*[*]

There are numerous microorganisms that cause evolution of gaseous hydrogen[1], but there appears to have been no attempt hitherto to carry out hydrogenations with hydrogen gas and microorganisms by reversing the reaction chain that leads to formation of hydrogen. We have used *Clostridium kluyveri*[2] to hydrogenate numerous α,β-unsaturated carboxylic acids, and *Bacillus polymyxa* (NRC-9035)[3] to obtain diols from α-hydroxy ketones, or α-hydroxy ketones and diols from α-oxo acids.

Table 1 shows the relative rates of hydrogenation of, in each case, 0.1 mmol of unsaturated carboxylic acid by means of 80 mg (dry weight) of *Clostridium* in 3 ml of 0.1 M phosphate buffer (pH = 7.0) at 35 °C and 1 atm pressure of hydrogen gas. The absolute rate of hydrogenation amounts to *ca.* 40 μmol/h for tiglate. At 35 C such cells are active for 60–100 h in the presence of tetracycline. The compounds marked [a] in Table 1 were also hydrogenated on a 2 to 10 mmol scale. Insofar as the products were not new it was established that their hydrogenation was completely stereospecific.

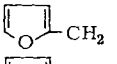
This hydrogenation procedure enables one to obtain on a preparative scale a wide variety of compounds that are chiral only because of stereospecific replacement of H by D and/or T. The [2,3-D_2]-3-phenylpropionic acid obtained in a D_2O buffer has $[\alpha]_{365}^{25} = -7.0$ as sodium salt in water ($c = 0.076$ g/ml).

(3*S*)[3-D,3-T]Propionic acid can be prepared from *cis*-dideuterioacrylic acid[4] in HTO. This procedure is probably the simplest way of obtaining chiral methyl groups on a preparative scale.



Pyruvate and acetoin are intermediates in the fermentation of D-glucose to (2*R*,3*R*)-butanediol by *Bacillus polymyxa*. In view of the overall equation:

$$3CH_3COCOOH + H_2O \rightarrow CH_3CHOHCHOHCH_3 + 3CO_2 + CH_3COOH$$



formation of 2,3-butanediol from pyruvate should also be possible. Pyruvate or 2-oxobutyrate in an atmosphere of nitrogen was, however, almost exclusively decarboxylated oxidatively, with evolution of hydrogen. Nevertheless, under 90 atm pressure of hydrogen the following reactions occur under catalysis by *B. polymyxa* (yields in parentheses):

Pyruvate	→	(2*R*,3*R*)-Butanediol	(65%)
(*R*,*S*)-Acetoin	→	*erythro*- and *threo*-Butanediol	(100%)
2-Hydroxy-3-pentanone	→	Pentanediol	(100%)
(*R*,*S*)-Propionin	→	*erythro*- and *threo*-Hexanediol	(60%)
2-Oxobutyrate	→	Hexanediol	(20%)

Table 1. Examples of acids *(1)* that were hydrogenated by *Clostridium kluyveri* and hydrogen gas.

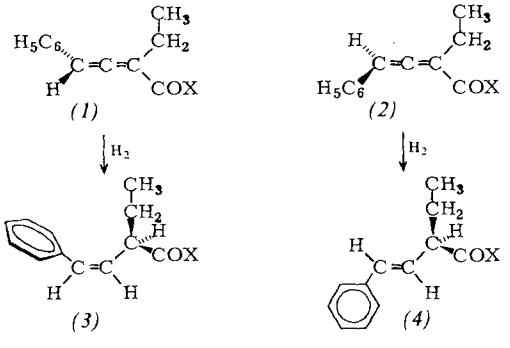
Stereospecific Hydrogenation of (*R*)- or (*S*)-2-Ethyl-4-phenylallenecarboxylic Acid to *cis*- or *trans*-2-Ethyl-4-phenyl-3-butenecarboxylic Acid by Means of *Clostridium kluyveri*

By *Bernhard Rambeck* and *Helmut Simon*[*]



Hydrogenation with hydrogen gas and microorganisms described in[1] can be effected also for 2,4-disubstituted allenecarboxylic acids[2] such as 4-ethyl-2-methyl-, 2-ethyl-4-methyl-, and 2-ethyl-4-phenyl-allenecarboxylic acid. This was studied in detail for (*R*)- and (*S*)-2-ethyl-4-phenylallenecarboxylic acid (2-ethyl-4-phenyl-2,3-butadienoic acids) *(1)* and *(2)*.

Enzymic reactions of enantiomeric molecules not possessing a center of asymmetry have hitherto been investigated hardly at all. If 1.0 mmol of the racemate *(1)*/*(2)* as sodium salt is shaken with 1.2 g (dry weight) of *C. kluyveri* in 25 ml of 0.1 M phosphate buffer (pH = 7.0) at 35 °C under 1 atm of hydrogen gas, two products, *(3)* and *(4)*, are formed, quantitatively and in equal amounts. Hydrogenation of *(1)* and *(2)* in separate experiments proceeds equally fast. The structures *(3)* and *(4)* can be deduced from the results shown in Table 1 together with the fact that hydrogenation of *(4)* or of a 1:1 mixture of *(3)* and *(4)* by chlorotris(triphenylphosphane)rhodium affords the same optically active product. The rotations of the sodium salts of the hydrogenation products *(3)* and *(4)* in water ($c = 0.0038$ and 0.0058, respectively) amount to $[\alpha]_D^{25} = -31°$ and $-29°$, respectively. The optical activity is greatly increased by the chiral twisting of the π-system of *(3)*: at 350 nm the specific rotation is almost $-2500°$.

Whether *(3)* and *(4)* exist in the *R*- or the *S*-configuration cannot yet be stated with certainty: neither *(3)* nor *(4)* has been described in the literature. However, the *R*-configuration appears very probable. For several derivatives of 2-methyl-carboxylic acids, such as 2-methyl-3-butenoate, 2-methylbutyrate, and 2-methyl-3-phenylpropionate, the compound with the negative rotation always has the *R*-configuration. For the first two of these compounds transition from the sodium salt in water to the free acid in chloroform shifts the rotation to more negative values, and this occurs also for *(3)* and *(4)* (cf. Table 1). Since *(1)* gives the *cis*-compound *(3)* whilst *(2)* gives the *trans*-compound *(4)*, and with the assumption that *(3)* and *(4)* have the *R*-configuration, the addition of hydrogen is seen to occur *trans*. This is in accord with the *trans*-addition by means of butyryl-CoA-dehydrogenase[4]. What is surprising is that the two enantiomers are formed at equal rates, particularly in view of the sterically very unfavorable *cis*-configuration of *(3)*.

Table 1. Some data for the products obtained on hydrogenation of *(1)* and *(2)* or the racemate *(1)*/*(2)*.

	(3) from *(1)*	*(4)* from *(2)*	*(3)* and *(4)* from *(1)*/*(2)*

Transition Metal-Carbon Triple Bonds[**]

By *Gottfried Huttner, Hans Lorenz*, and *Wolfgang Gartzke*[*]

E. O. Fischer et al.[1] recently reported a new type of transition metal complex of composition $(CO)_4(Hal)MCR$ and $(CO)_3[P(CH_3)_3](Hal)MCR$ (M = Cr, Mo or W; Hal = Cl, Br or I; R = CH_3, C_6H_5 or C_6H_4R'); their properties indicated

[**] This work was supported by the Leibniz-Rechenzentrum der Bayerischen Akademie der Wissenschaften, by the Deutsche Forschungsgemeinschaft, and by the Fonds der Chemischen Industrie.

a completely novel type of bond between an sp-hybridized carbon atom and a transition-metal atom. In order to prove conclusively the metal-carbon triple bond postulated from valence-electronic considerations and thus the structures proposed for these complexes, we have carried out complete, three-dimensional X-ray structure analyses for $(CO)_4(I)WCC_6H_5$ *(1)*, $(CO)_4(I)CrCCH_3$ *(2)*, and $(CO)_3[P(CH_3)_3](Br)CrCCH_3$ *(3)*[1a].

Table 1. Crystallographic data for *trans*-haloalkyl(aryl)carbyne complexes *(1)* to *(3)*. The figures in parentheses denote standard deviations in units of the last decimal.

	(1)	*(2)*	*(3)*
a [pm]	2010(2)	791.1(9)	683.5(8)

Space group	Pbca	Cmcm	$P2_1$
Z	8	4	4

Reflection data were collected on a Weissenberg diffractometer in the region $0 < \sin\vartheta/\lambda \leq 0.6$ ($Mo_{K\alpha}$ radiation, $\lambda = 71.069$ pm), compounds *(2)* and *(3)* being cooled to the temperature -40 ± 5 C. After Lorentz, polarization, and absorption corrections of the measured intensities all three structures were solved by conventional Patterson and difference-Fourier methods. Partial [for *(1)* and *(3)*] or complete anisotropic [for *(2)*] refinement led to R factors of 0.078 for *(1)* [688 reflections], 0.05 for *(2)* [425 reflections], and 0.07 for *(3)* [1128 reflections].

All three complexes have a slightly distorted pseudooctahedral configuration (Figs. 1—3). In all cases the halogen atom occupies a position *trans* to the "carbyne" group.

$(CO)_4(I)WCC_6H_5$ *(1)* has four equatorial carbonyl groups with W—C_{CO} separations of 207(6) pm (mean value), which correspond to the length of the W—C_{CO} bond in $W(CO)_6$ [205.8 pm][2]. Some of the W—C—O groups appear not to be linear. The W—I separation, at 284.5(5) pm is not unusual in comparison with the sum of the covalent radii of iodine (140 pm) and tungsten (135 pm)[3]. The W—$C_{carbyne}$ separation [190(5) pm] is shorter than the W—C_{CO} bonds and is thus the shortest tungsten-carbon separation found so far in organometallic compounds. The W—C—R group is not linear, as might be expected for an sp-hybridized carbon atom. The plane of the W—C—R angle [162(4)°] is almost perpendicular to that of the phenyl ring.

The molecule $(CO)_4(I)CrCCH_3$ *(2)* possesses two mutually perpendicular mirror planes; the atoms I, Cr, $C_{carbyne}$, and C_{methyl} lie on their line of intersection. Because of this symmetry, only one independent Cr—C_{CO} distance could be determined [194.6(9) pm]. The length of the Cr—I bond at 279.2(2) pm is close to the sum of the covalent radii of chromium and iodine[3]. The Cr—$C_{carbyne}$ bond length [169(1) pm] is the shortest Cr—C distance known so far (cf. Table 2).

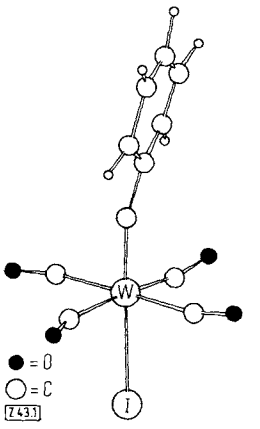

Fig. 1. Molecular structure of $(CO)_4(I)WCC_6H_5$ *(1)*.

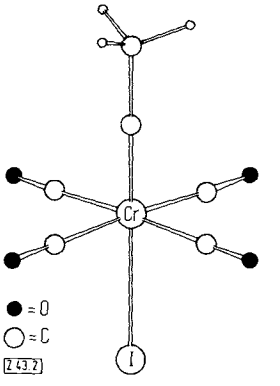

Fig. 2. Molecular structure of $(CO)_4(I)CrCCH_3$ *(2)*.

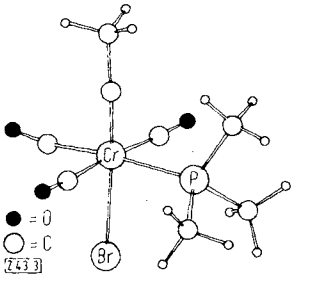

Fig. 3. Molecular structure of $(CO)_3[P(CH_3)_3](Br)CrCCH_3$ *(3)*.

Table 2. Metal-carbon separations in organometallic compounds involving various bond orders. Figures in parentheses denote standard deviations in units of the last decimal.

	σ-Single bonds		"Double bonds" (carbene and carbonyl)		Triple bonds (carbyne)	
	Compound	Separation [pm]	Compound	Separation [pm]	Compound	Separation [pm]
Chromium	$[(o\text{-}CH_3OC_6H_4)_2(bipy)_2Cr]I$ [5]	210(1) [a]	$(CO)_5CrC(OCH_3)C_6H_5$ [10]	204(3)	*(2)*	169(1)
	$(p\text{-}CH_3C_6H_4)CrCl_2 \cdot 3THF$ [6]	201.4(10) [a]	$(CO)_5CrC(NHCH_3)CH_3$ [10]	209(2)	*(3)*	168(3)
	$Li_4Cr_2(CH_3)_8 \cdot 4THF$ [7]	219.9(13)	$(CO)_5CrC(N(CH_3)_2)OC_2H_5$ [10]	213.3(4)		
	$Li_4Cr_2(C_4H_8)_4 \cdot 4THF$ [8]	223.8(22)	$(CO)_5CrC(N(C_2H_5)_2)CH_3$ [10]	216(1)		
			Cr—C_{CO} in $Cr(CO)_6$ [11]	190.9(3)		
Tungsten	$\pi\text{-}C_5H_5(CO)_3WC_6H_5$ [9]	232	W—$C_{Carbene}$	unknown	*(1)*	190(5)
			W—C_{CO} in $W(CO)_6$ [2]	205.8(3)		

[a] Shortened by a π-bonding contribution.

The methyl group is connected to the carbyne-carbon by a normal single bond [149(2) pm]. The Cr—C—CH_3 arrangement appears to be linear, even though F_c calculations with disordered bent molecular models show no influence on the R factor provided that the angular deviation does not exceed 5°.

$(CO)_3[P(CH_3)_3](Br)CrCCH_3$ *(3)* crystallizes with two crystallographically independent molecules in the asymmetric unit of the cell. Both independent molecules have identical geometries within experimental error. Mean values of the bond lengths are: Cr—C_{CO} 193(4), Cr—Br 260.3(5), Cr—P 239.6(9) pm. The Cr—$C_{carbyne}$ separation [168(3) pm] is almost identical with that in *(2)*. The deviation of the Cr—C—CH_3 group from linearity is not significant [177(3)°].

Table 2 shows some bond lengths for chromium and tungsten complexes with metal-carbon single bonds, metal-carbene bonds which can be regarded as partial double bonds, and the new metal-carbyne bonds.

The metal-carbyne carbon bonds are shorter by *ca.* 40 pm than a metal-carbon single bond in the case of tungsten and by *ca.* 50 pm in the case of chromium. For comparison, the shortening in the series alkane, alkene and alkyne is 33 pm (ethane 154, ethylene 134, acetylene 121 pm)[4]. The extremely short metal-carbon separation in the compounds of this study supports the proposition of a metal-carbon triple bond.

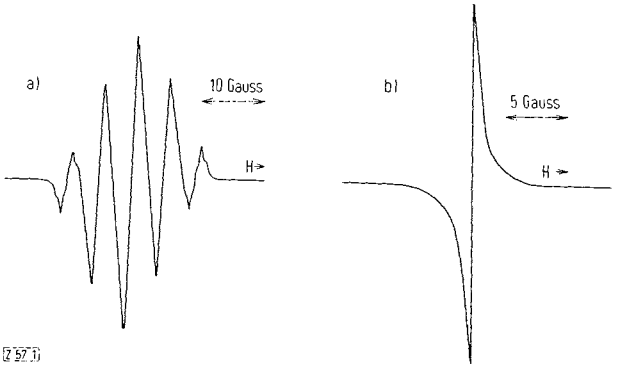
Dissolution of Alkali Metals in Aromatic Hydrocarbon Solvents by Cryptate Formation

By *Bernd Kaempf, Serge Raynal, André Collet, François Schué, Sylvie Boileau*, and *Jean-Marie Lehn*[*]

Macrocyclic and macrobicyclic ligands such as *(1)* and *(2)*, which form stable complexes with alkali metal cations, may be used for dissolving alkali metals in amines or ethers[1-3]. Crown ethers like *(1)* give blue solutions containing mainly the metal anion $M^{\ominus}$ as counter ion of the cation complex. Formation of the more stable alkali cryptate complexes of *(2)* displaces the equilibria towards the generation of solvated electrons[3]. Yellow to red solutions, showing an ESR signal, are obtained when polyethylene oxide in benzene is brought in contact with Na/K alloy. Faintly colored solutions were also obtained with the same system in presence of aromatic hydrocarbons[4].

We wish to report the dissolution of alkali metals in benzene and toluene in presence of *(1)* and *(2)* and some data on the properties of such solutions. All the experiments described employed vacuum line techniques.



When the macrobicyclic cryptand *(2)* (about 15 mg) is added to benzene (about 10 ml) in contact with a film of potassium metal, the film is attacked and dissolves slowly yielding a dark blue solution. Similar results are obtained when potas-

sium is replaced by sodium and/or benzene by toluene. When the macrocyclic crown ether *(1)* is used in place of *(2)*, potassium is also found to dissolve in benzene or toluene. Various other solutions of sodium, potassium, rubidium, or cesium in benzene, toluene, as well as in tetrahydrofuran (see also [1,3]) or tetrahydropyran, have been obtained using *(2)* or other suitable cryptands[5] which form stable complexes with the corresponding cations.

The ESR spectra at −70 °C of the K/*(1)*/benzene or toluene solutions display an intense multiplet with broadened lines. The observed spectra correspond respectively to the radical anion of benzene (seven lines; $a_H \approx 3.8$ G) and of toluene (five lines; see Fig. 1a). In the presence of *(2)* the same systems give an intense single line (see Fig. 1b). In no case was coupling to the metal cation observed.

These results may be interpreted as follows. Dissolution of potassium in benzene or toluene is due to the formation of the stable crown and cryptate complexes of the metal cation. The electron is transferred to a solvent molecule giving a radical anion. When the ligand is a macrocycle like *(1)*, the complexed cation may still be approached by the anion from the top or bottom of the [$K^{\oplus}$, *(1)*] disk, forming a (complexed cation)—(radical anion) ion pair in solvents of

[Z 57 I]

Fig. 1. ESR spectrum at −70 °C of the solution obtained by dissolving a film of potassium metal in toluene using a) the macrocyclic ligand *(1)*, b) the macrobicyclic ligand *(2)*.

low dielectric constant (for a similar pairing with fluorenyl anion, see ref. [6]). The ESR spectrum of potassium naphthalenide in THF displays a very broad signal and a sharp signal, which have been attributed to the coexistence, respectively, of ion pairs undergoing slow electron exchange and free anions with fast electron exchange[7]. Thus the observation of hyperfine structure in the ESR spectra of solutions containing ligand *(1)* indicates that one is indeed dealing with ion pairs undergoing slow electron exchange.

When the ligand is *(2)*, the complexed cation is well hidden inside the three-dimensional molecular cavity so that in effect a sodium or potassium cation is transformed into a very bulky cryptate cation of about 5 Å radius (ionic radius of $Cs^{\oplus} \approx 1.65$ Å). Thus cation-anion interactions are weak and the radical anion is a much less stable, free or weakly paired anion. Consequently the electron transfer reaction is expected to be fast[7] and the radical anion multiplet collapses into a single ESR line.

The UV spectrum of K/*(1)*/benzene contains bands at about 300 and 435 nm, similar to those ascribed to the benzene radical anion in dimethoxyethane (DME) at −70 °C[8]. The spectrum of K/*(2)*/benzene displays only the 435 nm band; the other band might be obscured by the solvent band.

Very intense ESR spectra have been observed for K/*(2)*/toluene solutions on addition of biphenyl, naphthalene, or anthracene. The K/*(2)*/biphenyl system in toluene displays an intense, "exchange-narrowed" single ESR line (about 1.5 G wide) from −70 °C to +38 °C, while the spectrum of the biphenyl radical anion in DME is a complex multiplet extending over about 20 G[9]. The UV spectrum of the solution contains bands at about 400 and 630 nm (intensity ratio 3:1) similar to those reported for the biphenyl radical anion in THF[10]. Although naphthalene-sodium is not soluble in benzene[11], addition of naphthalene to K/*(2)*/toluene immediately produces the characteristic green solution of the naphthalene radical anion. The ESR spectrum at −20 °C is a broad line with some remaining, broadened fine structure, indicating moderately fast electron exchange. Other species, like diamagnetic dianions, may be present to some extent in the solutions described here in addition to the paramagnetic radical anions.

The alkali metal solutions with cryptands *(2)* may present interesting properties and applications in organic chemistry, for instance as reducing agents. Because of the low electron affinity of benzene or toluene and of the weak interactions with the bulky cation, enhanced reducing properties may be expected. It has already been shown that these solutions are efficient initiators for anionic polymerization of various monomers[12].

Structure of Xenon Hexafluoride in Solution: Xe_4F_{24}

By *Herbert Rupp* and *Konrad Seppelt*[*]

The structure of xenon hexafluoride in the solid state has already been determined: the crystal contains tetrameric and hexameric units $[XeF_5^+ F^-]_n$[1]. There are still doubts, however, about the structure of monomeric XeF_6 in the gaseous state—three rapidly interconvertible electronic isomers are under discussion[2]. So far very little has been reported about the structure of XeF_6 in the liquid or dissolved state. We have now investigated this problem by means of ^{19}F- and ^{129}Xe-NMR spectroscopy.

Difficulties were encountered in choosing a suitable solvent; it should be resistant to attack by XeF_6, have high dissolving power, low polarity and low melting point, and favor neither formation of fluorine bridges nor intermolecular fluorine exchange (as *e.g.* HF or BrF_5). It was found that bis(pentafluorosulfur) oxide, $(F_5S)_2O$ (m.p. −115, b.p. 31 °C[3]) satisfies all these requirements.

Xenon hexafluoride dissolves in $(F_5S)_2O$ at room temperature to give a yellowish green solution, thus indicating the presence of monomeric XeF_6 which is also yellowish green in the gaseous state. The ^{19}F- and ^{129}Xe-NMR spectra each show one broad signal ($\delta_F = -118.3$ ppm relative to $CFCl_3$[4], line width ≈200 Hz; $\delta_{Xe} = -5296$ ppm relative to xenon gas[4], dissolved in CF_2Cl_2, line width ≈70 Hz). On lowering the temperature to −45 °C the solution becomes colorless and both spectra are now found to contain sharper signals, in each case shifted slightly upfield ($\delta_F = -109.3$ ppm, line width ≈20 Hz; $\delta_{Xe} = -5292$ ppm, line width ≈40 Hz). Aggregation of monomeric XeF_6 occurs and is complete at −45 °C. At room temperature an equilibrium exists between monomeric and

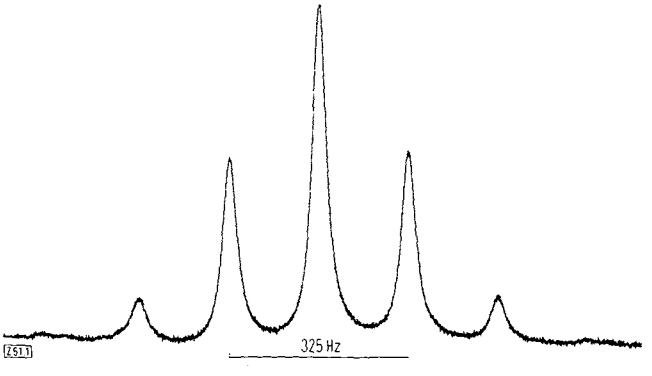

Fig. 1. ^{19}F-NMR spectrum of xenon hexafluoride in $(F_5S)_2O$ at −118 °C.

polymeric species. On lowering the temperature further, both types of NMR signals broaden again without change in the chemical shift, a coalescene point being reached at −75 °C. We interpret these findings in terms of intermolecular fluorine

[*] Dr. K. Seppelt and Dr. H. Rupp
Anorganisch-chemisches Institut der Universität
69 Heidelberg 1, Im Neuenheimer Feld 275 (Germany)

exchange being frozen. At the lowest possible temperature (−118 °C), the multiplets shown in Figures 1 and 2 are observed.

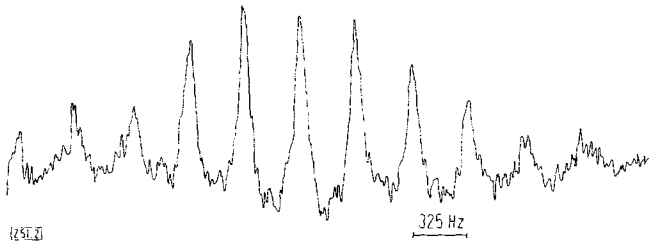

Fig. 2. ^{129}Xe-NMR spectrum of xenon hexafluoride in $(F_5S)_2O$ at −118 °C.

The seven equidistant lines (relative intensities 1.1 : 12.3 : 54.0 : 100 : 55.0 : 12.8 : 1.0) in the ^{19}F-NMR spectrum (Fig. 1) demonstrate that all fluorine atoms are magnetically as well as chemically equivalent. They couple with four equivalent xenon atoms ($J_{^{129}Xe-F} = 325 \pm 3$ Hz). Considering the natural abundance of ^{129}Xe (26.24%, nuclear spin 1/2), one would expect a nine-line spectrum (0.05 : 1.4 : 12.7 : 53.8 : 100 : 53.8 : 12.7 : 1.4 : 0.05). Coupling with ^{131}Xe (nuclear spin 3/2) is not observed because of quadrupole relaxation.

If each fluorine atom couples simultaneously with 4 xenon atoms, then each xenon atom necessarily couples with 24 fluorine atoms(!). Hence the ^{129}Xe-NMR spectrum ought to contain a multiplet of 25 lines, whose relative intensities are given by a binomial distribution of the 24th order. Despite the poor solubility of the compound at such low temperatures, the relatively small isotopic abundance of ^{129}Xe, the moderate specific sensitivity of this nuclear resonance, and the distribution of intensity over so many multiplet lines, a spectrum could still be recorded using the FT technique (Fig. 2). However, only 11–13 equidistant lines of the multiplet were recorded ($J_{Xe-F} = 325 \pm 5$ Hz); measurement of additional lines would have been too time consuming. Thus the intensity of the 6th and 20th line is already as low as 0.3 relative to that of the central 13th line (= 100), while the relative intensity of the 1st and 25th line is only 3.7×10^{-5}. It follows from the intensity distribution that we are dealing with a spectrum of odd multiplicity greater than 19 or 21.

We therefore come to the conclusion that xenon hexafluoride is present in the tetrameric form in solution at −118 °C and that all the xenon atoms and all the fluorine atoms are equivalent. Several structures are conceivable in which the xenon atoms are arranged tetrahedrally. All molecular models demand that intramolecular fluorine exchange occurs within the NMR time-scale, for each fluorine atom "sees" four equal xenon atoms, and each xenon atom 24 equal fluorine atoms. Xe_4F_{24} is thus an extreme—to our knowledge the most extreme—example of a non-rigid molecule.

Bonding between the Xe atoms could be effected by the orbitals not used in Xe—F bonds. Possibly there is a three-center two-electron bond situated on each tetrahedral face. The xenon atoms would then be ninefold coordinated (sp^3d^5) (Fig. 3a). Intramolecular fluorine exchange would be possible *via* the tetrahedral faces (Fig. 3b). This proposed structure resembles

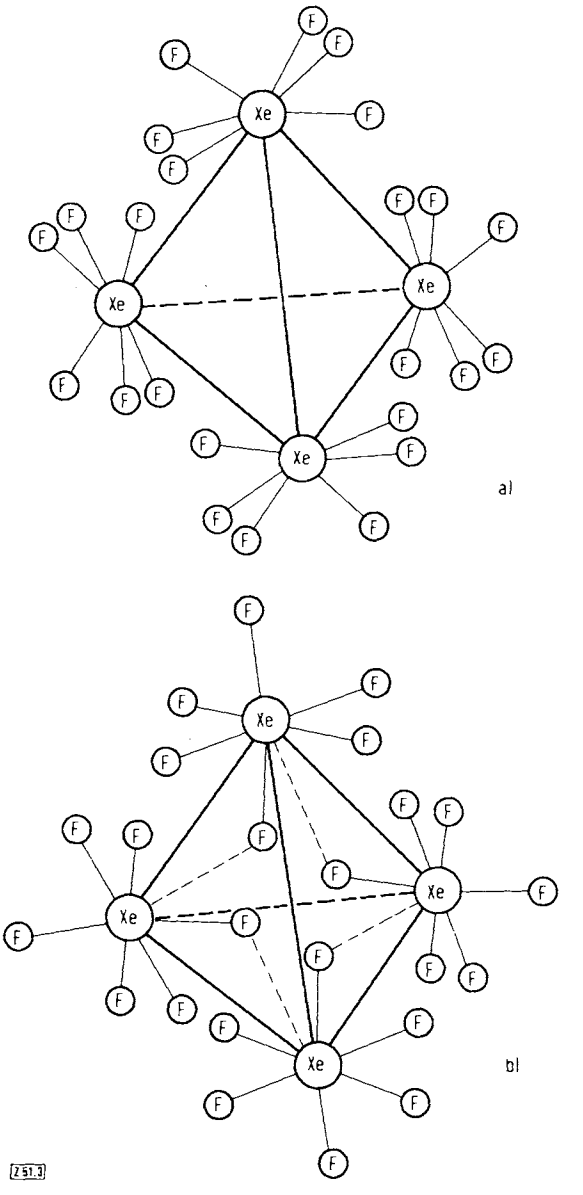

Fig. 3. Two possible structures of Xe_4F_{24} in solution.

in part the structure of crystalline xenon hexafluoride[1]. Fluorine exchange within the Xe_4F_{24} molecule can be regarded as simultaneous pseudorotation of all fluorine atoms (cog-wheel mechanism).

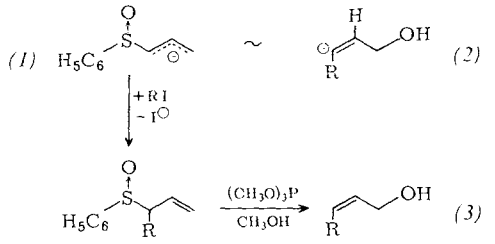
Reviews

Abstracts of selected progress reports and review articles

The higher oxidation states of iron, cobalt, and nickel are reviewed by *W. Levason* and *C. A. McAuliffe*. For iron, the (formal) oxidation states 4—6, for cobalt 3 (only partially) to 5, and for nickel, 3 and 4 are covered. Some halides, oxides, and oxo compounds have been known for a long time; recently, more and more complexes have been found where the higher oxidation states are stabilized by coordination, especially with sulfur, phosphorus, and arsenic donor ligands. In a chapter entitled "oxidation states and bonding", the difficulties of elucidating the true electron distribution in such compounds are stressed. [Higher Oxidation State Chemistry of Iron, Cobalt, and Nickel. Coord. Chem. Rev. *12*, 151—184 (1974); 398 references]

[Rd 716 IE—H]



The stability of fluoride complexes in aqueous solutions is correlated with the sizes and charges of the metal ions by *G. Hefter*. Strong anomalies in the case of complexes of elements in the lower right hand side of the periodic system (Hg^{2+}, Pb^{2+}, Sn^{2+}, Sb^{3+}, Bi^{3+}) are rationalized partially by the fact that d and f orbitals shield the nuclear charge less efficiently than s and p orbitals. Major inexplicable deviations from the electrostatic correlation lead the author to the opinion that some published stability constants might be in error. Enthalpies of complex formation seem to be independent of metal ion charge densities, whereas there is some indication of correlation with entropies of complex formation. [Simple Electrostatic Correlations of Fluoride Complexes in Aqueous Solutions. Coord. Chem. Rev. *12*, 221—239 (1974); 74 references]

[Rd 717 IE—H]

To what extent does perchlorate play the role of a ligand in solution? This question is discussed in a review by *L. Johansson*. Association of kinetically labile hydrated metal ions with perchlorate is insignificant, so that corrections for it are unimportant in equilibrium studies of their strong complexes, where perchlorates are used to maintain constant ionic strength. On the other hand, *e.g.*, Tl^+ forms a stronger complex with ClO_4^- than with F^-, and kinetically inert complex ions, such as cobaltammines, show comparatively stable perchlorate complexes. There is no obvious simple connection between the charge density on a metal ion and its affinity to the perchlorate ion. [The Role of the Perchlorate Ion as Ligand in Solution. Coord. Chem. Rev. *12*, 241—261 (1974); 88 references]

[Rd 718 IE—H]

Allylic sulfoxides—useful intermediates in organic chemistry—are reviewed in an article by *D. A. Evans* and *G. C. Andrews*. In allyl sulfoxides the chemical reactivity has reversed polarity. For example, the sulfoxide stabilized carbanion *(1)* can be regarded as the reversed polarity equivalent of the carbanion *(2)*. Ions of type *(1)* can be converted, *inter alia*, into open chain and cyclic compounds and regioselectively alkylated. Possible applications for the synthesis of cyclic compounds are outlined. [Allylic Sulfoxides: Useful Intermediates in Organic Synthesis. Accounts Chem. Res. 7, 147—155 (1974); 43 references]

[Rd 719 IE—L]

The base-catalyzed addition of hydrocarbons is reported on by *H. Pines*. Such additions are of synthetic interest because they afford hydrocarbons and related compounds by a simple one-step procedure. Hydrocarbons having a benzylic or allylic hydrogen atom are readily converted into carbanions on reaction with bases. These carbanions *e.g. (1)*, can add to olefinic hydrocarbons:

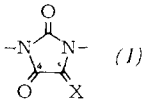
$$\underset{(1)}{C_6H_5CH^{\ominus}Na^{\oplus}} + CH_2{=}CH_2 \rightleftharpoons C_6H_5CH_2{-}CH_2{-}CH^{\ominus}Na^{\oplus}$$

$$C_6H_5CH_2{-}CH_2{-}CH^{\ominus}Na^{\oplus} + C_6H_5CH_3 \rightarrow C_6H_5CH_2CH_2{-}CH_3 + C_6H_5CH^{\ominus}Na^{\oplus}$$

Examples of their uses are the oligomerization of olefins, the addition of alkylarenes or alkylpyridines to olefins, intramolecular cyclizations and the addition of "aprotonic solvents", such as *N*-methyl-2-pyrrolidone, to olefins. [Base-Catalyzed Carbon-Carbon Addition of Hydrocarbons and of Related Compounds. Accounts Chem. Res. 7, 155—162 (1974); 64 references]

[Rd 720 IE—L]

The interaction of proteins with small molecules or ions such as O_2, ATP, amino acids, K^+ or Cu^{2+} has been studied by *I. M. Klotz* with special consideration being given to the stoichiometric and energetic aspects. The distribution of a ligand between solvent and protein in best described in terms of stepwise stoichiometric equilibria. It is shown how an affinity profile, which reveals the nature of the interaction, can be plotted from the measured values. [Protein Interactions with Small Molecules. Accounts Chem. Res. 7, 162—168 (1974); 37 references]



[Rd 721 IE—L]

Einführung in die metallorganische Chemie (Principles of Organometallic Chemistry). By *G. E. Coates, M. L. H. Green, P. Powell,* and *K. Wade.* Translated by *H. P. Becker, T. N. Mitchell, and W. P. Neumann.* Ferdinand Enke Verlag, Stuttgart 1972. 1st Edit., xii, 266 pp., 55 figures, 18 tables, bound DM 29.70.

"Coates" undoubtedly takes the leading place among the textbooks on organometallic chemistry. While the second edition (1960) contained the most important discoveries in this area in one volume, the third edition (1967) was produced in two volumes (together comprising some 950 pages) in spite of a sometimes very terse presentation. The normal size of a student text had surely been exceeded.

A shorter version much more suitable for teaching purposes appeared in English in 1968. Fortunately, a German translation has now been produced. It comprises a rather extensive literature survey, which takes particular account of the recently published monographs and reviews.

The contents of the book are divided into ten chapters. After an introduction in Chapter 1, three chapters deal with organometallic compounds of the main group elements and six with compounds of the transition elements. Emphasis is placed on understanding general and theoretical principles, particularly in the discussion of the transition metal compounds. For example, the reactions and structures of metal-π-complexes with monoolefins, diolefins, and polyolefins, aromatic and heterocyclic compounds, and enyl and dienyl ligands are included under one heading. For the student in the middle of his studies and for chemists not specialized in this field this is surely useful. Chapters 3 and 4 (compounds of the elements of groups 1—5) appear somewhat too detailed to the reviewer; here the limits of an introductory text have been partly exceeded.

The layout (a very sturdy binding) and printing of the German translation are unquestionably commendable. The text is very readable and is supplemented by many structural formulas, tables, and figures, usually very clearly arranged. It would be desirable for as many chemistry students as possible to use this book as a supplement to their instruction in organic and inorganic chemistry.

Helmut Werner [NB 210 IE]

Cephalosporins and Penicillins. Chemistry and Biology. Edited by *E. H. Flynn.* Academic Press, New York—London 1972. 1st Edit., xv, 752 pp., bound $ 25.—

The dominant position of penicillins and cephalosporins among the antibiotics is still unquestioned. Nearly a decade ago the chemistry in this field awoke from temporary quiescence to a surge of surprising activity. Only experts will have been able to keep abreast of the numerous studies since performed on the development of new β-lactam antibiotics; nevertheless, these investigations are frequently of interest to a broader scientific audience. The studies on the younger cephalosporin group have often served as a pacemaker, and hence it is right that the authors have from their own practical experience entitled their book starting with the cephalosporins, reversing the historical order.

The 15 chapters of this book are distinguished by their remarkable homogeneity, pleasing presentation, and easily readable English. First there is a chapter on cephalosporin C by the "father of cephalosporin chemistry" *E. P. Abraham.* Chapters follow on the preparation of 7-aminocephalosporanic acid and 6-aminopenicillanic acid, acylation and alkylation of these compounds, modifications to the dihydrothiazine ring of the cephalosporins, rearrangement of the β-lactam antibiotics, and a survey of total syntheses in this area. Subsequent chapters are concerned with structure determination by physicochemical means and analysis, and with the biology and microbiology as well as the pharmacology and toxicology of β-lactam antibiotics. An appendix contains organic preparative details and UV and NMR data. Spot checks on two rapidly developing areas (chemical deacylation of penicillins and epimerization of the β-lactam ring) underline the up-to-date presentation covering the literature up to 1970/71.

The book, edited by *Flynn*, summarizes in rational form the achievements that have taken place in the chemical and biological fields since the publication of "Chemistry of Penicillin" by *Clark, Johnson,* and *Robinson* in 1945. Like its classical predecessor, it bears the stamp of the authors' enthusiasm and pride in past successes. This topical monograph will be highly valuable to everybody working in the field of β-lactam antibiotics.

Friedrich Moll [NB 213 IE]

Nonaqueous Electrolytes Handbook, Vol. 1. By *G. J. Janz* and *R. P. T. Tomkins.* Academic Press, New York—London 1972. 1st Edit., xii, 1108 pp., bound $ 55.—.

The increasing practical importance of electrochemistry in nonaqueous solutions, *e. g.* for the electrosynthesis of organic and inorganic compounds or for titrations, makes an up-to-date index such as this very welcome. Nine sections give information on: I. The physical properties of pure nonaqueous solvents, II. purification of solvents, III. electrical conductivity of electrolyte solutions in these solvents, as well as IV. their diffusion properties, V. densities, VI. viscosities, and VII. transport numbers. Another volume with emf values, vapor pressures, cryoscopic data, heats of solution, polarographic data, and information on electrical double layers is in preparation.

Section I contains details of the melting and boiling points, dielectric constants, viscosities, densities, and specific conductivities of about 175 solvents, most of them organic, but including important inorganic solvents (among them "water-like" solvents such as DMF, DMSO, the halogens, interhalogen compounds, hydrogen halides, ammonia, *etc.*). In addition 42 binary solvent mixtures, including ones involving water, are listed. The completeness of the bibliography, at least for the last 40 years, claimed in the preface and elsewhere, has not been attained in the case of those solvents with which the reviewer is familiar; for example, the important data of *L. T. Carmichael* and *B. H. Sage* (Ind. Eng. Chem. *44*, 2728 (1952)) on the viscosity of liquid ammonia are missing.

The largest part of the book (about 750 pp.) is devoted to the tabulation of conductivity data in Section III. The solvent, the equivalent conductivity, the corresponding values of concentration and temperature, the equivalent conductivity at infinite dilution, and the literature reference are tabulated according to dissolved electrolytes, but only the solute and the reference are tabulated in the arrangement by solvents. About 650 electrolyte solutions, not only of alkali metal and ammonium salts, but also of amines, quaternary ammonium compounds, and salts of the heavy and transition metals are presented, and in certain cases solutions in mixed solvent systems are included. The authors do not aspire to the comprehensive treatment in the famous "Walden" handbook (Das Leitvermögen der Lösungen. Akademische Verlagsgesellschaft, Leipzig 1924).

It is not clear why there is a Section VIII A, because although the data on DMSO and anhydrous sulfuric acid have already been treated in Sections I—VII they appear here again, though in somewhat greater detail. These details, as well as further literature on the purification of solvents, electrical conductivity, diffusion, density, viscosity, and transport numbers, which are relatively new, are intended as a recent supplement to Sections I—VII. It would be preferable if Section VIII B, in which general references to the larger reference works are given, also contained references to the appropriate German books (*e.g.* Chemie in nichtwäßrigen ionisierenden Lösungsmitteln. Vieweg, Braunschweig 1960, in which electrochemistry is emphasized).

Finally, Section IX contains lists of solvents and solutes, making this very welcome book a more than useful addition to the bookshelf.

Jochen Jander [NB 214 IE]

Lehrbuch der Pharmakognosie. Auf phytochemischer Grundlage. [Textbook of Pharmacognostics. The Phytochemical Basis]. By *E. Steinegger* and *R. Hänsel*. 3rd Edit., Springer Verlag. Berlin—Heidelberg—New York 1972. xii, 557 pp., 5 illustrations, bound DM 78.—.

This is the third edition of a textbook on theoretical pharmacognostics, *i.e.* it contains almost nothing of the traditional approach to practical recognition of drugs, no microscopic morphology, no sections, no plant hairs, *etc.* There are only occasional references to botany and to the distinguishing characteristics of drugs, and what is probably meant by the term "pharmaceutical biology" in the new examination statutes for pharmacists in the German Federal Republic appears to have been neglected. For example, the term "assimilation" does not occur, and in the description of the nucleic acids and ATP the importance of these compounds in the context of genetic information and energy metabolism is not discussed.

By being restricted purely to the phytochemical description of natural products, the 557 pages of text offer, on the other hand, an impressive amount of descriptive matter. The work is a virtual mine of information on natural products, especially on the secondary plant products. The latest results of research are recognized, selected according to pharmaceutical importance, and as far as possible with data on the pharmacology and, when appropriate, on isolation and processing.

A modest plea is made for the inclusion of plant-derived drugs with subtle and, in certain cases undetectable, effects in model tests (these are special areas which are of considerable importance in Europe). Biosynthetic pathways are often given, but, commendably, not taken as proven. The occasional remarks on etymology and history provide pleasant relaxation for the reader. (But *Leonhard Fuchs* is introduced incorrectly as a medical doctor from Frankfurt; he was in fact a professor at Ingolstadt and later at Tübingen.) References to the original literature facilitate the identification of sources. All in all, this is an interesting, valuable, and practical book, well worth the money, and giving complete information on what is of interest to the chemically-oriented pharmacist or physician.

Engelbert Graf [NB 216 IE]

The Biochemistry of the Nucleic Acids. By *J. N. Davidson*. Science Paperbacks. Chapman & Hall, London 1972. 7th Edit., xiv, 396 pp., numerous figures, bound £ 2.25.

Anybody who has long been concerned with nucleic acids will still remember the small book, from which he obtained his first thorough and profound knowledge of this area 20 years ago, and which has remained a constant companion with some updating revisions. In all its editions "Davidson" has been a reliable guide to the increasingly complex field which in other respects was becoming clearer. While formerly the analytical composition and the physical chemistry of the polar sugar phosphate skeleton, the base-pairing laws, and finally the helical molecular structure were the undisputed backbone of the field, now it is the biological functions during the transformation of the genetic code into proteins and enzymes that are in the foreground. The predominant part of the book is therefore devoted to the molecular conformations of ribonucleic and deoxyribonucleic acids, the biosynthetic processes taking place in the replication and transcription, as well as the anabolism and catabolism of nucleic acid components.

From decades of experience the author has mastered the subject, and the most recent literature has been carefully chosen, with a wide selection in each chapter. Clear and informative diagrams in addition to impressive illustrations further assist understanding. The presentation is often simplified, but always balanced and critical. There are no obvious mistakes but, as can be expected, information has accrued or become out of date. The text is clear and lucidly written and does not present difficulties even for beginners, so that this guide can be considered to be the best comprehensive introduction for biologists and chemists to the biochemistry of the nucleic acids and should be read by as many as possible.

L. Jaenicke [NB 218 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Struktur und Bindung – Atome und Moleküle. By *G. Grossmann, J. Fabian*, and *H.-W. Kammer*. Lehrbuch 1 of "Fachstudium Chemie". Verlag Chemie, Weinheim 1973, 232 pp., stitched, DM 25.00.

Struktur und Bindung – Aggregierte Systeme und Stoffsystematik. By *J. Sieler, E. Butter, G. Haucke, G. Kühn, and A. Martin*. Lehrbuch 2 of "Fachstudium Chemie". Verlag Chemie, Weinheim 1973. 212 pp., stitched, DM 25.00.

Controlled Action Drug Forms. By *J. C. Colbert*. Vol. 24 of the series "Chemical Technology Reviews". Noyes Data Corporation, Park Ridge 1974. XII, 337 pp., bound, $ 36.00.

An Introduction to Conservation of Orbital Symmetry. A Programmed Text. By *A. J. Bellamy*. Longman Group Ltd., London 1974. X, 77 pp., stitched, £ 1.50.

Foams. By *J. J. Bikerman*. Vol. 10 of the Series "Applied Physics and Engineering". Springer-Verlag, Berlin 1973. IX, 337 pp., bound, DM 61.60.

Acid Sulphate Soils. 18. Publication of the International Institute for Land Reclamation and Improvement, Wageningen 1973. Vol. I: Introductory Papers and Bibliography, Vol. II: Research Papers. Edited by *H. Dost*. Vol. I: XIV, 295 pp.; Vol. II: 406 pp.—Proceedings of the International Symposium, 13—20 August 1972, Wageningen.

Chemische Carcinogene im Laboratorium. Struktur, Wirkungsweise und Maßnahmen beim Umgang. By *U. Wölcke*. Vol. 3 der Schriftenreihe Arbeitsschutz. Bundesanstalt für Arbeitsschutz und Unfallforschung, Dortmund 1974. 47 pp., stitched, DM 9.80.

Ascorbinometric Titrations. By *L. Erdey* and *G. Svehla*. Akadémiai Kiadó, Budapest 1973. 183 pp., bound, DM 21.20.

Prüfungsfragen Chemie für Mediziner. 100 Multiple-Choice-Fragen mit einer Anleitung zur Bearbeitung. By *K. Beyermann, Ch. Braig, J. Sauer*, and *A. Zeeck*. Vol. 17 of the Series "Taschentext". Verlag Chemie/Physik Verlag Weinheim 1974, 99 pp., stitched, DM 8.80.

Reaktionsverhalten und Syntheseprinzipien. By *E. Uhlig, G. Domschke, S. Engels, B. Heyn*, and *D. Walter*. Lehrbuch 7 of "Fachstudium Chemie". Verlag Chemie, Weinheim 1973. 408 pp., stitched, DM 39.80.

Theory of Unimolecular Reactions. By *W. Forst*. Vol. 30 of the Series "Physical Chemistry". Edited by *E. M. Loebl*. Academic Press New York 1973. XV, 445 pp., bound. $ 29.50.

Polymer Spectroscopy. Edited by *D. O. Hummel*. Vol. 6 of the Series "Monographs in Modern Chemistry". Edited by *H. F. Ebel*. Verlag Chemie, Weinheim 1974. XII, 401 pp., bound, DM 125.—.

Mathematics for Engineers and Scientists. By *A. Jeffrey*. From the Series "Applications of Mathematics". Edited by *A. Jeffrey*. Thomas Nelson & Sons Ltd., London 1971. X, 765 pp., stitched, £ 3.00.

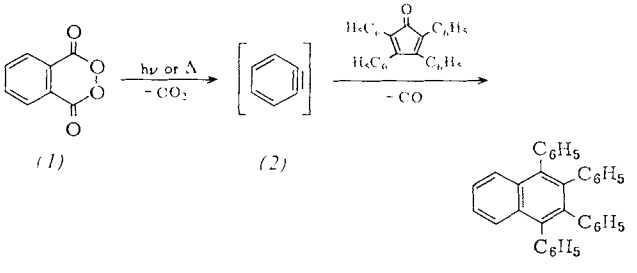
The Synthesis of Unusual Organic Molecules Using Cyclic Peroxides

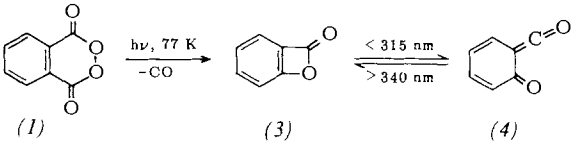
New synthetic methods (3)



By Waldemar Adam[*]

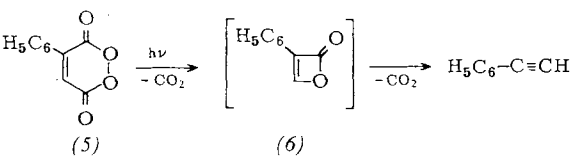
The photodecarboxylation of malonyl peroxides into α-lactones[1] and the thermal conversion of the 1,4-*endo*-peroxide 4,5-epoxy-3,6-epidioxy-1-cyclohexene into the novel benzene trioxide[2] are two recent examples of the potential of cyclic peroxides in the synthesis of unusual organic molecules. The former transformation entails a fragmentation, the latter a rearrangement process. Most reported examples fall into one of these two gross reaction types. Of the numerous examples that have been reported in the literature during the last two decades, only those shall be focused on that lead to unusual compounds or constitute efficient syntheses of known compounds, in order to stress the convenience of cyclic peroxides in the synthesis of organic compounds.

1. Fragmentation Reactions



1.1. Decarboxylations

An early example of the utility of decarboxylative fragmentations of cyclic peroxides was recognized by *Greene*[3] in the attempt to prepare dehydrobenzene *(2)* from phthaloyl peroxide *(1)*. Although thermolysis of *(1)* in solution was complicated due to free radical induced decompositions, on thermolysis in the gas phase *Wittig* and *Ebel*[4] were able to trap the dehydrobenzene *(2)* with tetraphenylcyclopentadienone. Similar observations were made by *Horner* and *Brüggemann*[5] and by *Jones* and *DeCamp*[6].

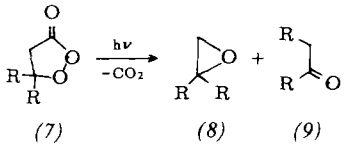


(1) *(2)*

In contrast, photodecarboxylation of *(1)* at 77 K afforded the oxoketene *(4)* employing matrix isolation techniques[7]. In this work the lactone *(3)* was postulated as precursor

(1) *(3)* *(4)*

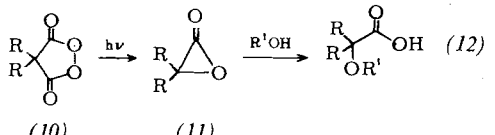
of *(4)*. Indeed, *Chapman et al.*[8] confirmed the presence of the unsaturated β-lactone *(3)* on irradiation of *(1)* in an Argon matrix at 8 K with long wavelength (>340 nm) light. At shorter wavelengths (<315 nm) the lactone *(3)* could be quantitatively converted into its valence tautomer *(4)*, while *(3)* could be regenerated from *(4)* at the longer wavelength. Similarly the lactone *(6)* was proposed as intermediate in



(5) *(6)*

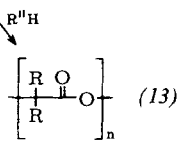
the thermo- and photodecarboxylation of the phenylmaleoyl peroxide *(5)*[9].

[*] Prof. Dr. W. Adam [**]
Department of Chemistry
University of Puerto Rico
Rio Piedras, Puerto Rico 00931 (USA)



[**] A. P. Sloan Fellow 1968–72; J. S. Guggenheim Fellow 1972–1973.

1,2-Dioxolan-3-ones (β-peroxylactones) *(7)* photodecarboxylate[10] into epoxides *(8)*; in addition, minor amounts of ketones *(9)* are formed by rearrangement. In the thermal decarboxylation[11] of compound *(7)* ketones are formed exclusively.



(7) *(8)* *(9)*

Hence, it appeared sensible to photodecarboxylate malonyl peroxides *(10)* in the hope of obtaining the rather difficultly accessible α-lactones *(11)*[12]. Indeed, irradiation[13] of alcoholic solutions of di-*n*-butylmalonyl peroxide *(10a)* afforded high yields (>90%) of the α-alkoxy acid *(12a)*, which was presumably formed by trapping of *(11a)* with alcohol. In

(10) *(11)* *(12)*

(a), R = n-C_4H_9
(b), R = CH_3

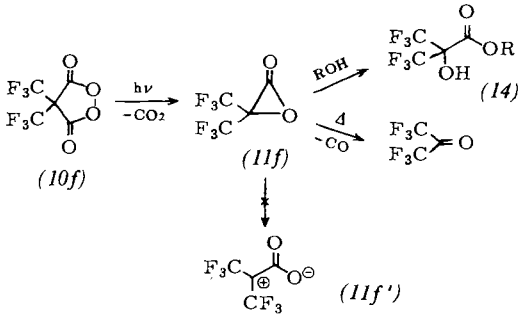
(d), R-R = -$(CH_2)_3$-
(e), R-R = -$(CH_2)_4$-

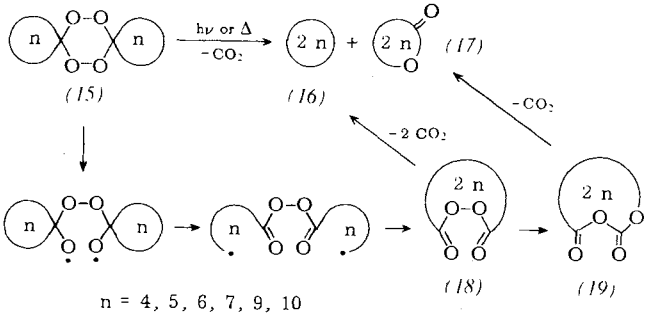


(13)

hydrocarbon solvents R″H the polyester *(13)* was obtained quantitatively.

The formation of α-lactones could be confirmed[1b] by irradiation of malonyl peroxides *(10)* in a matrix at 77 K, whereby the characteristic carbonyl band appeared at 1895 cm^{-1}. On prolonged photolysis, the α-lactones suffered decarbonylation, while on warming to 180 K polymers of type *(13)* were formed.

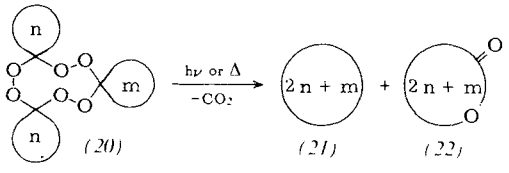
The preparation of an authentic α-lactone, which is stable at room temperature (half-life *ca.* 8 h in the gas phase), has been accomplished recently[1c]. Electronic destabilization of the dipolar valence tautomer *(11f′)* utilizing trifluoromethyl substituents, favored the formation of the cyclic valence tau-



(10f) *(11f)* *(14)* *(11f′)*

tomer *(11f)* in the photolysis of the malonyl peroxide *(10f)*. While α-lactone *(11f)* is stable in nonpolar solvents for weeks at −20 °C, on heating it decarbonylates to give perfluoroacetone. Alcoholysis leads to the α-hydroxy ester *(14)* instead of the usual α-alkoxy acid *(12)*[1a], thus demonstrating very dramatically the "cyclic" chemical behavior of this lactone.

Since malonyl peroxides *(10)* are readily available in high yields from the corresponding malonic acids[13], photodecarboxylation provides the most expedient synthesis so far of the interesting α-lactones *(11)*.

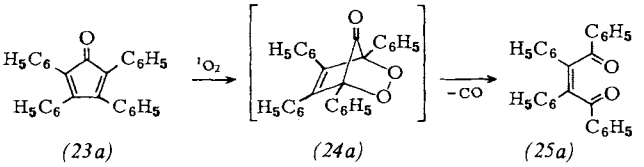


An ingenious decarboxylative fragmentation has been reported by *Story et al.*[14]; it consists in the thermolysis and photolysis of dimeric peroxides of type *(15)*, leading to the carbocycles

(15) *(16)* *(17)* *(18)* *(19)*

n = 4, 5, 6, 7, 9, 10

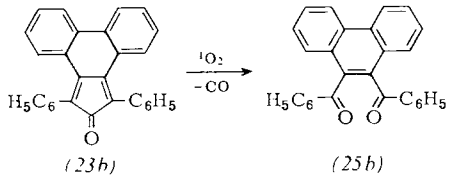
(16) and lactones *(17)*. Here the spirocarbons serve as potential carbon dioxide leaving groups. For example, rupture of the peroxide bond, double β-scission, and finally coupling presumably affords the cyclic diacyl peroxide *(18)*. The latter decarboxylates directly into the carbocycle *(16)* or suffers carboxy inversion[15] to give *(19)*, which subsequently decarboxylates into the lactone *(17)*. Although this mechanism still lacks chemical verification, it is consistent with CIDNP (chemically induced dynamic nuclear polarization) data[16].



(20) *(21)* *(22)*

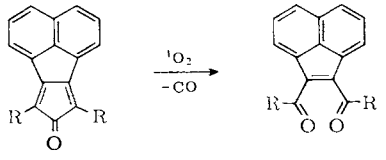
n = 5, 6, 7, 11, 12; m = 5, 6, 7, 9, 11, 12,

The trimeric peroxides *(20)* decarboxylate in a similar way to give carbocycles *(21)* and lactones *(22)*. In view of the ready availability of dimeric and trimeric peroxides, the impressive feature of these decarboxylations is that they provide a simple route to the synthesis of macrocyclic hydrocarbons and esters that are otherwise quite difficult to prepare.



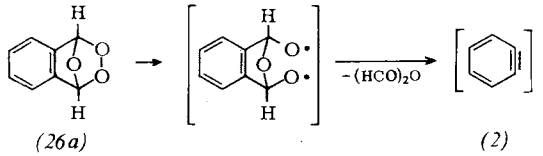
1.2. Decarbonylations

Interesting examples of decarbonylative fragmentation of cyclic peroxides are scarce, but a potentially useful *cis*-diacylation method worthwhile mentioning is the oxidation of cyclopentadienones with singlet oxygen. Thus, addition of photochemically[17] and chemically[18] generated singlet oxygen to tetraphenylcyclopentadienone *(23a)* affords moderate yields (35 to 65%) of *cis*-dibenzoylstilbene *(25a)*, presumably by fragmentation of the intermediary peroxide *(24a)*. Two well known



(23a) *(24a)* *(25a)*

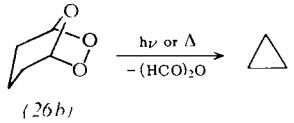
examples are the preparation of 9,10-dibenzoylphenanthrene *(25b)* from *(23b)*[19] and of 1,2-diacylacenaphthylene derivatives *(25c)* and *(25d)* from *(23c)* and *(23d)*[20].



(23b) *(25b)*

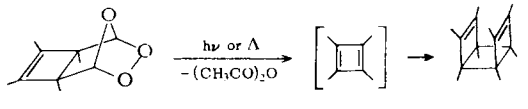
(23c) R = isopropyl *(25c)*
(23d) R-R = $-(CH_2)_{12}-$ *(25d)*

1.3. Fragmentation of Ozonides



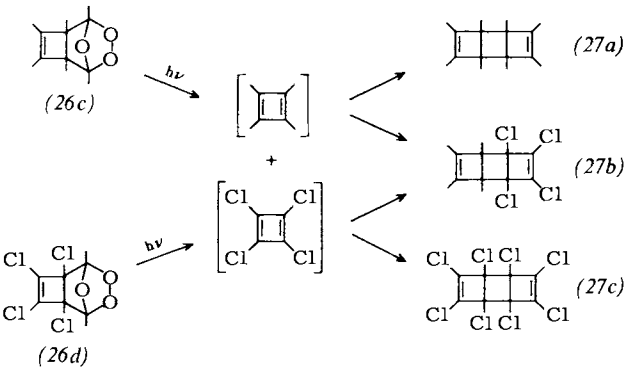
In contrast to 1,2-dioxolanes, such as *(7)* and *(10)*, which are thermally and photochemically converted into epox-

(26a) *(2)*



ides [21], the related 1,2,4-trioxolanes or ozonides *(26)* suffer double β-scission, resulting, in the case of the ozonide *(26a)*, in the formation of dehydrobenzene *(2)*[22]. However, it required almost a decade for this interesting fragmentation to be exploited for synthetic purposes[23].

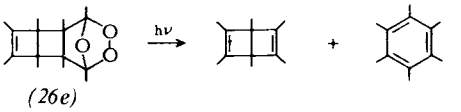
Photochemically, as well as thermally, the ozonide *(26b)* affords a 35—40% yield of cyclopropane as major product.



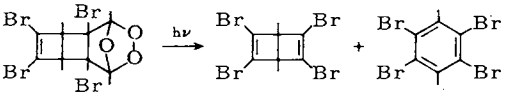
(26b)

Similarly, photolysis of the ozonide *(26c)* derived from hexamethyl(Dewar benzene) gave the *syn*-dimer *(27a)* of tetramethylcyclobutadiene[24].

(26c) *(27a)*

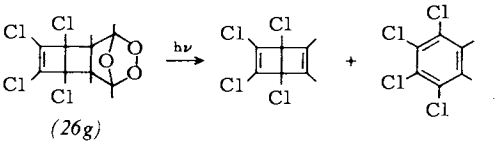


Independently of this work, *Criegee et al.*[25] greatly extended the scope of this novel reaction. They found that the ozonide *(26d)* afforded the *syn*-dimer *(27c)*. This reaction probably proceeds *via* the cyclobutadiene derivative, since the *syn*-dimer *(27b)* is also formed on photolysis of a mixture of ozonides *(26c)* and *(26d)*. This useful olefin synthesis proved to be a highly stereospecific (*ca.* 90%) *cis* reaction, as could be



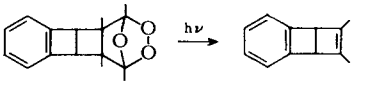
(26c) *(27a)* *(27b)* *(27c)* *(26d)*

demonstrated on using the ozonides derived from *cis*- and *trans*-1,2,3,4-tetramethylcyclobutene[25a].

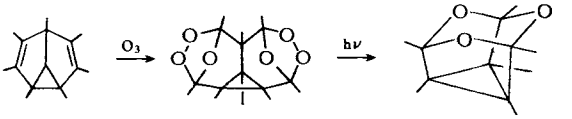


A rather clever utilization of this reaction was the synthesis of hexamethyl(Dewar benzene) from ozonide *(26e)*. The

(26e)

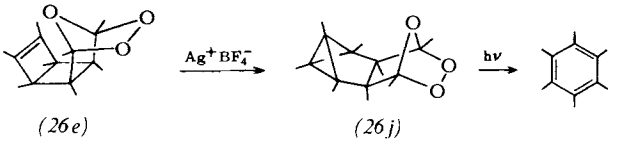


(26f)



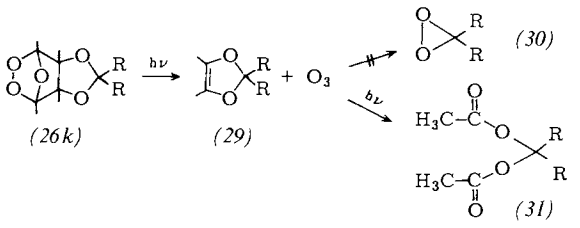
(26g)

ozonides *(26f)* and *(26g)* react analogously. The photolysis of ozonide *(26h)* led, in a similar way, to a Dewar naphthalene derivative[26].



(26h)

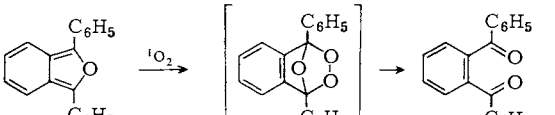
A rather ingenious attempt at preparing tetramethyltetrahedrane utilized the photolysis of the diozonide *(26i)* derived from octamethylsemibullvalene[25a]; in addition to a host of other products, the novel triketal *(28)* was also formed. An



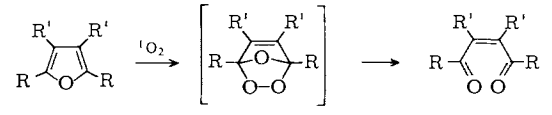
(26i) *(28)*

inventive route to hexamethylbenzvalene *via* photolysis of the ozonide *(26j)* failed, disappointingly yielding only hexamethylbenzene[27].

(26e) *(26j)*



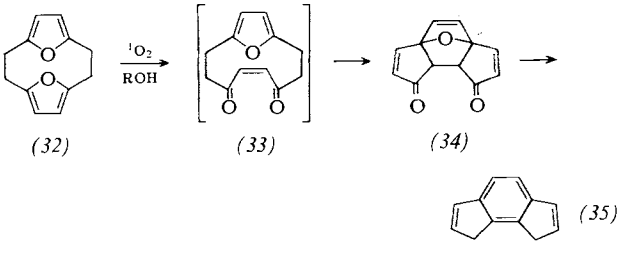
It could also be demonstrated that the photolysis of ozonide *(26k)* constitutes a convenient route to the synthesis (40 to 60% yields) of 1,3-dioxolenes *(29)*[25c]. However, an attempt



(26k) *(29)* *(30)* *(31)*

to prepare the so far unknown 1,2-dioxirane *(30)* by ozonolysis of *(29)* gave the novel acetal *(31)*[25c].

On the other hand, unsaturated ozonides prepared by oxidation of furans with singlet oxygen suffer a completely different fragmentation. A well known example is the oxidation of 2,5-diphenyl-3,4-benzofuran[28] to 1,2-dibenzoylbenzene, which probably proceeds *via* the intermediary ozonide *(261)*; however, the course of the reaction has not as yet been elucidated. This reaction, which is similar to the decarbonylation discussed in Section 1.2, could be utilized for *cis*-diacylations[29], as shown in the cases *(26m)*—*(26p)*. A fascinating example of this reaction was observed by *Wasserman* and

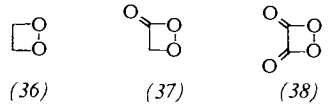


(261)

(26m)-*(26p)*

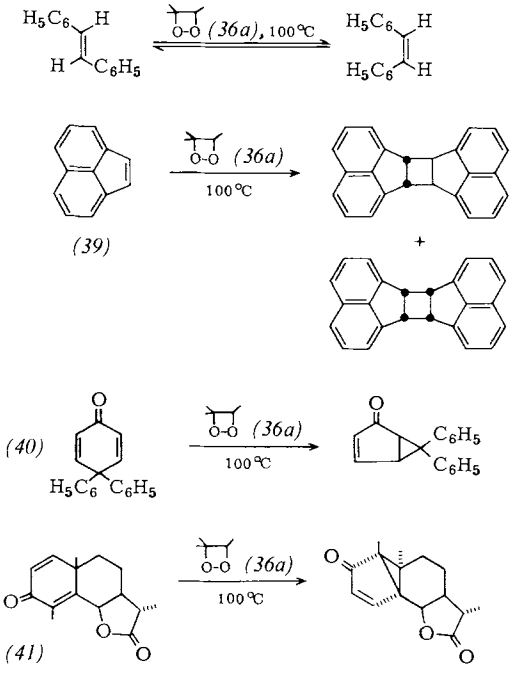
(m), R = R' = H[29b] *(o)*, R = R' = C_6H_5[29a]
(n), R = CH_3, R' = H[29c] *(p)*, R = C_6H_5, R' = H[29a]

Doumaux[30] in the $^1O_2$ oxidation of the furanophane *(32)*, leading to the epoxydiketone *(34)* *via* intramolecular Diels-Alder addition of the intermediary enedione *(33)*. *Katz*



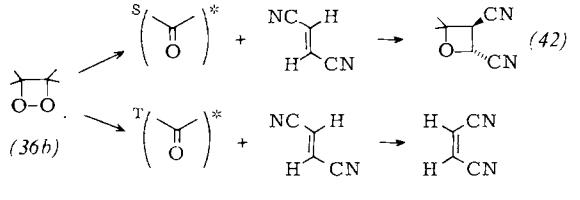
(32) *(33)* *(34)* *(35)*

et al.[31] employed this unusual transformation to obtain dihydro-*as*-indacene *(35)*, the precursor required to prepare *bis*(*as*-indacenyliron).



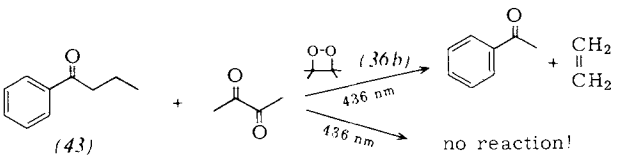
1.4. Chemielectronic Fragmentations

The discovery that four-membered cyclic peroxides such as the 1,2-dioxetanes *(36)*[32], the 1,2-dioxetanones (α-peroxylactones) *(37)*[33], and the carbon dioxide dimer *(38)*[34] lead to triplet energized carbonyl products on fragmentation, opens



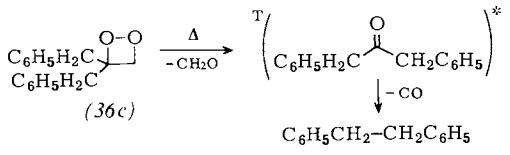
(36) *(37)* *(38)*

up exciting possibilities of performing photoreactions "thermally". By using trimethyl-1,2-dioxetane *(36a)* as energizer it was possible to promote the *cis-trans* isomerization of stilbene, the dimerization of acenaphthene *(39)*, the isomerization of 4,4-diphenyl-2,5-cyclohexadienone *(40)*, and the conversion of santonin *(41)* into lumisantonin *(42)*[35]. Similarly, the di-



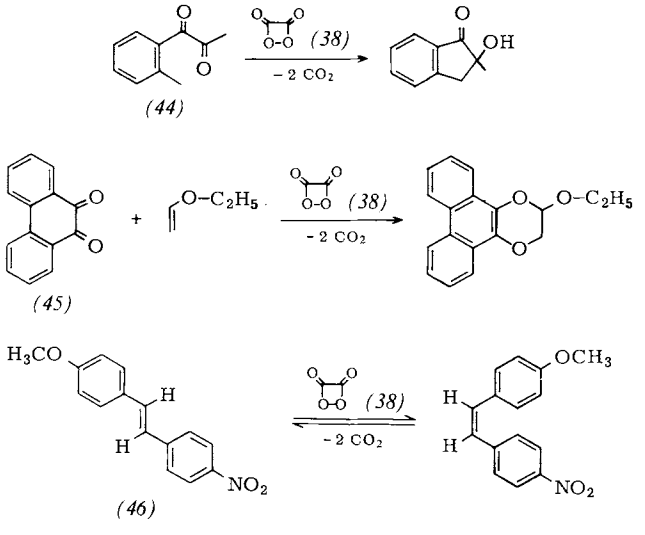
(39) *(40)* *(41)*

merization of pyrimidines in *E. coli* DNA could be chemically energized by 1,2-dioxetanes[36]. *Turro* and *Lechtken*[37] have demonstrated that 1,2-dioxetane *(36b)* fragments into singlet excited acetone, which adds to *cis*-1,2-dicyanoethylene to give oxetane *(42)* and triplet excited acetone which effects *cis-trans* isomerization of the dicyanoethylene. A further important experiment is the biacetyl sensitized fragmentation of *n*-butyro-



(36b) *(42)*

phenone *(43)*, which succeeds only in the presence of 1,2-dioxetane *(36b)*[38]. In another example triplet-excited dibenzyl phenone *(43)*, produced by fragmentation of 1,2-dioxetane *(36c)*, suffered decarbonylation[39]. Finally, by using the car-



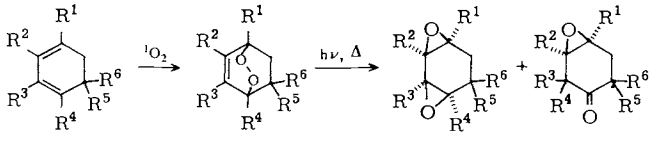
(43)

bon dioxide dimer (38) as energizer, α-diketone (44) could be cyclized[40], ethoxyethylene cycloadded to 9,10-phenanthra-

(36c)

quinone (45), and *p*-methoxy-*p'*-nitrostilbene (46) *cis-trans* isomerized.

(44)



(45)

(46)

2. Rearrangements

2.1. Epidioxides

It has long been known that some epidioxysteroids are thermally and photochemically labile[41], but this knowledge was first exploited for syntheses in 1945 by *Schenck* and *Ziegler*[42]. These authors showed that the diversely substituted peroxides (48), which are readily accessible by oxidation of the 1,3-dienes (47) by singlet oxygen, generally form the diepoxides (49)

(47) (48) (49) (50)

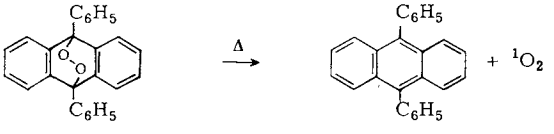
(b), $R^1 - R^6 = H$
(c), $R^1 = R^3 = R^5 = R^6 = CH_3$, $R^2 = R^4 = H$
(d), $R^1 = R^4 = C_6H_5$, $R^2 = R^3 = R^5 = R^6 = H$
(e), $R^1 - R^5 = C_6H_5$, $R^6 = H$
(f), $R^1 = R^3 = R^4 = R^5 = H$, $R^2 = CH_3$, R^6 = Isopropyl

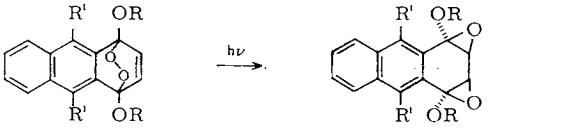
and epoxyketones (50). The latter presumably result from further rearrangement of the diepoxide (49) (cf. Ref. [43]).

(51) (52)



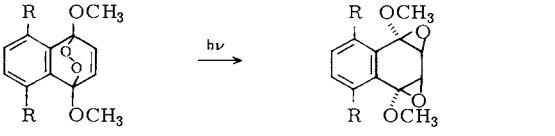
The synthesis of benzene trioxide (52) by thermal rearrangement of epoxyperoxide (51) has already been mentioned[2]. A further example is the thermal conversion of the endoperoxide (48g) into the tetraepoxide (49g)[44]. The prep-

(48g) (49g)



aration of such unusual molecules by conventional synthetic techniques would certainly be cumbersome.

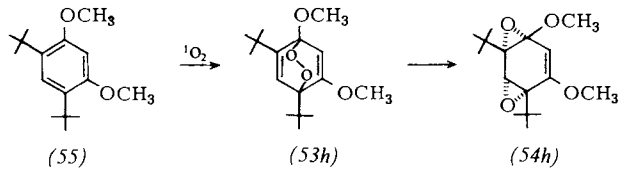
Singlet oxygen is liberated almost quantitatively on refluxing the peroxide (53a) of 9,10-diphenylanthracene (54a) in benzene; this reaction constitutes an excellent chemical source



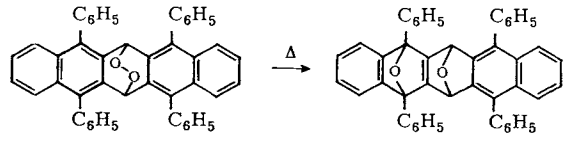
(53a) (54a)

of $^1O_2$[45]. In contrast, peroxides with bridgehead alkoxy groups, such as the anthracene derivatives (53b)—(53e) and the naphthalene derivatives (53f) and (53g), undergo the diepoxide rearrangement[46] mentioned already for the alipha-

(53b)–(53e) (54b)–(54e)



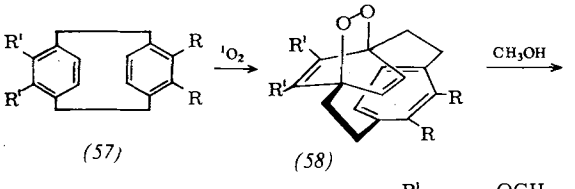
(b), R = CH_3, R' = H
(c), R = C_2H_5, R' = H
(d), R = $CH_2C_6H_5$, R' = H
(e), R' = CH_3, R' = C_6H_5



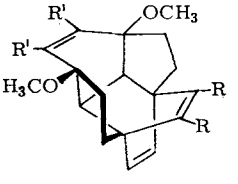
(53f), (53g) (54f), (54g)

(f), R = H
(g), R = C_6H_5

tic systems. Even the resorcinol derivative (55) is sufficiently activated to add singlet oxygen; this affords the peroxide (53h), which also undergoes the diepoxide rearrangement[47], and thus constitutes one of the few examples from the benzene series[48]. The mechanism of the unusual rearrangement of the peroxide (53i) into the diepoxide (56) is still unclear[49].

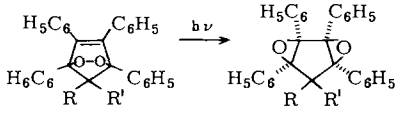


(55) (53h) (54h)



(53i) (56)

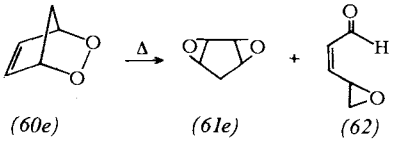
Even more unusual are the paracyclophanes *(57)*. On oxidation with singlet oxygen the intermediary peroxides *(58)* that are formed undergo intramolecular Diels-Alder addition with concomitant methanolysis, resulting in polycyclic molecules *(59)*[50].



(57) (58)

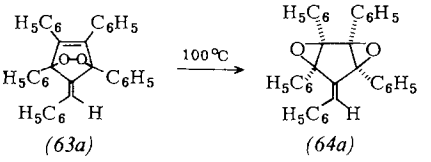
(a), R = H, R' – R' = Benzo
(b), R – R = R' – R' = Benzo

(59)



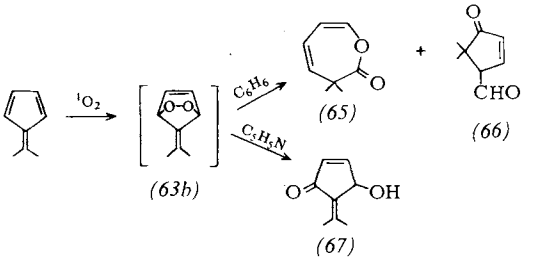
Peroxides *(60)* derived from 1,3-cyclopentadienes are considerably more thermally labile than those from 1,3-cyclohexadienes *(48)* and give rather impure products; but photochemically they undergo the diepoxide rearrangement cleanly and

(60) (61)



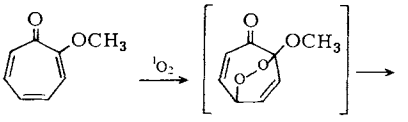
(a), R = R' = H *(c)*, R = H, R' = C_6H_5
(b), R = H, R' = C_2H_5 *(d)*, R = CH_3, R' = C_6H_5

afford *(61)* in good yields (60—95 %)[51]. Thermolysis of the unsubstituted system *(60e)* yields the epoxyaldehyde *(62)* as major product, along with some of the expected diepoxide *(61e)*[52].



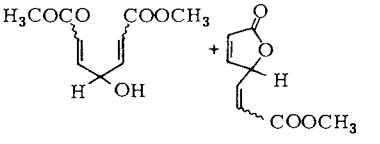
(60e) (61e) (62)

In the thermal rearrangement of epidioxyfulvenes *(63)*[53] in xylene the diepoxide *(64a)* is formed as major product from the pentaphenyl derivative *(63a)*.



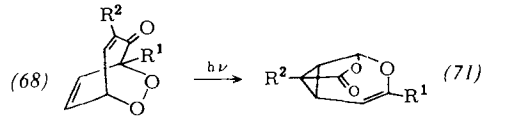
(63a) (64a)

Considerable deoxygenation to the fulvene also occurs. However, photooxidation of dimethyl fulvene[54] in benzene leads to mixtures of the oxepinone *(65)* and the oxocyclopentenecarbaldehyde *(66)* in very good yield. In pyridine as solvent, the hydroxycyclopentenone *(67)* is formed. Both reaction paths were postulated to involve the intermediary epidioxyfulvene *(63b)*. *Uda et al.*[55] have recently shown that the photooxidation of fulvenes provides a convenient route to the oxepinones *(65)* in moderate yields (20—26 %). These compounds are otherwise difficult to prepare.



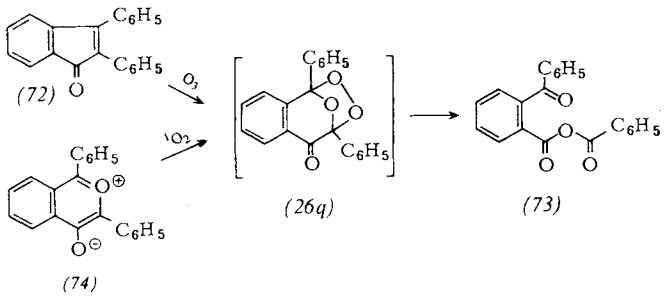
(63b) (65) (66) (67)

In the case of tropones, it has been observed that thermal rearrangement[56] leads to complex mixtures, which derive

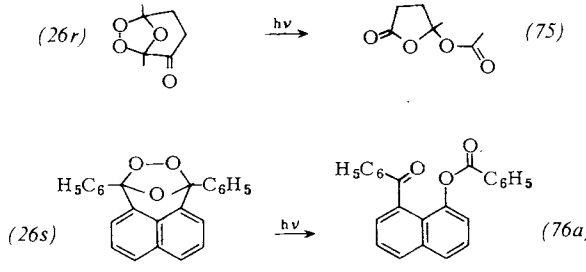


(68a)

(69) (70)

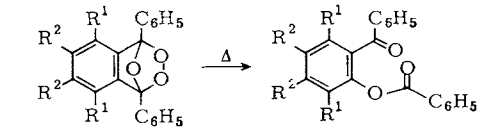


from the labile diester *(69)* and labile lactone ester *(70)*. On the other hand, photolysis of *(68)* yields the bicyclic lactones *(71)*—an interesting synthesis of these novel compounds[57].



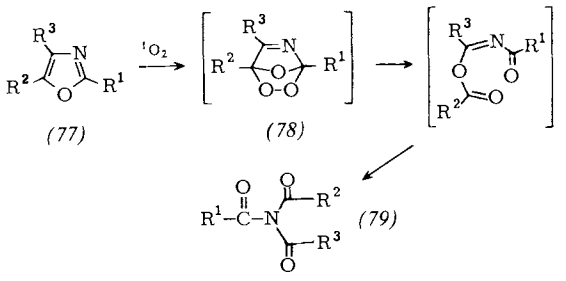
(68) (71)

2.2. Ozonides

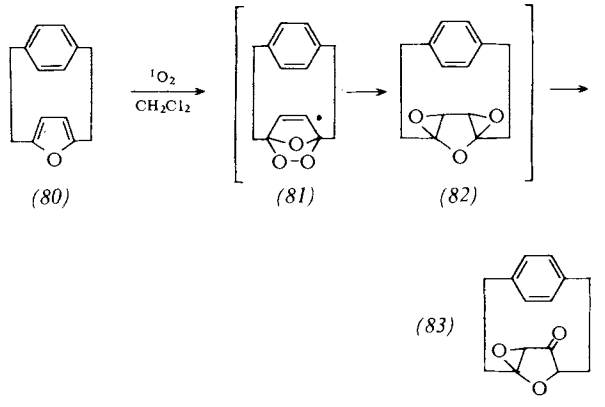


Interesting ozonide rearrangements of synthetic potential are much less numerous. However, *Criegee et al.*[58] have already observed that the ozonide *(26q)*, which is formed in the ozonolysis of indenone *(72)*, undergoes thermal rearrangement into the oxoanhydride *(73)*. The same ozonide *(26q)* could also be prepared by addition of singlet oxygen to the zwitter ion *(74)*[59]. Similarly, an attempt to prepare cyclopro-

panone from ozonide *(26r)* by photoextrusion of acetic anhydride resulted in the rearrangement product *(75)*[25c]. *Story*

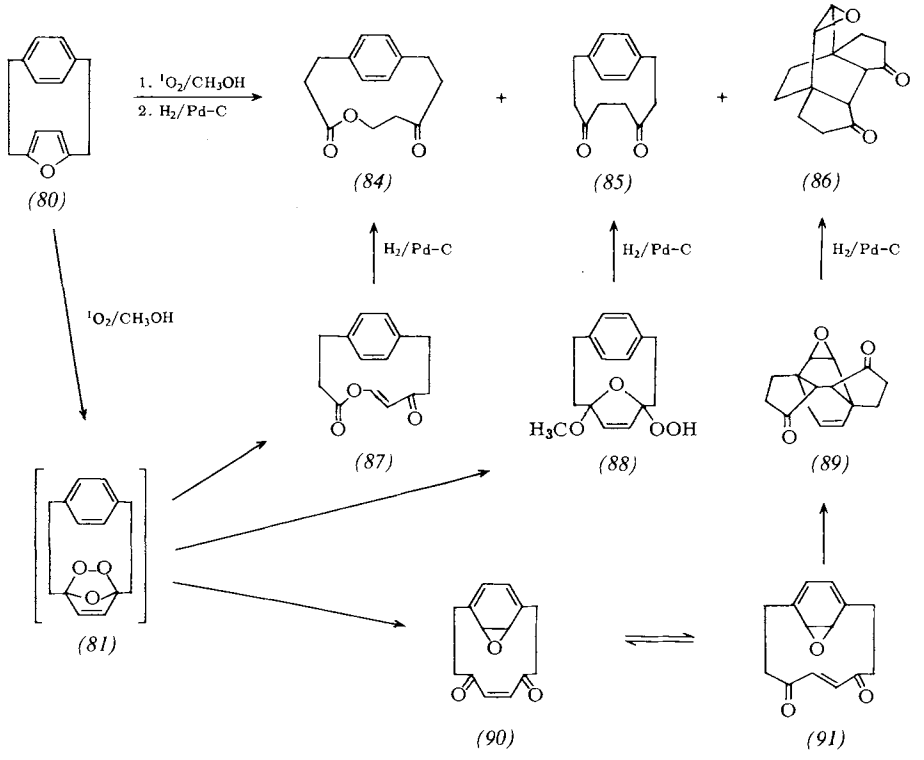


et al.[24] also observed this type of rearrangement in the photolysis of ozonide *(26s)*, a potential source of the diradical 1,8-naphthalenediyl. The oxoester *(76a)* was the major reaction product. Quite related is the recent finding that derivatives of ozonide *(26l)* rearrange into oxoesters *(76b)*[60].

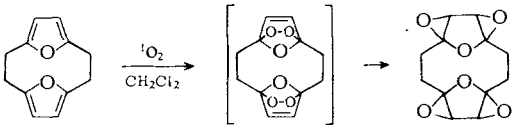


$R^1 = R^2 = H$; $R^1 = C_6H_5$, $R^2 = H$; $R^1 = R^2 = C_6H_5$

The addition of singlet oxygen to oxazoles *(77)*, which leads *via* thermal rearrangement of the intermediary ozonides *(78)*



to the novel triacylamines *(79)* in high yield, should be of unquestionable synthetic value. The mechanism has been established by ^{18}O-labeling experiments[61]



Finally, two interesting rearrangements of ozonides have been observed in the $^1O_2$-oxidation of phanes. For example, the phane *(80)* reacts in dichloromethane to give the epoxyketone

(83), which is thought to arise by rearrangement of the ozonide *(81)* to the diepoxide *(82)*[62].

Still more bewildering is the oxidation of *(80)* in methanol. The catalytic hydrogenation of the photooxidized products led to *(84)*, *(85)*, and *(86)*[62]. The formation of the oxoester *(84)* from ozonide *(81)* is readily understood if one assumes that *(81)* rearranges analogously to *(26s)*; initially, *(87)* is formed. The diketone *(85)* is formed, *via* the hydroperoxide *(88)*, by methanolysis of ozonide *(81)*. However, some rather unusual transformations of ozonide *(81)* must take place to produce the observed polycyclic epoxydiketone *(86)*. For example, transannular epoxidation of the benzene ring in *(81)* gives *(90)*, which *cis-trans* isomerizes into *(91)* and, after subsequent intramolecular Diels-Alder addition, finally affords the compound *(89)*. The second example is the conversion of furanophane *(32)*, *via* the diozonide *(92)*, into the tetraepoxide *(93)*[63].

(32) *(92)* *(93)*

3. Conclusion

The examples collected in this article concerning fragmentations and rearrangements of cyclic peroxides reveal quite effectively the synthetic potential of these compounds. Particularly valuable are the decarboxylations of cyclic diacyl peroxides for the synthesis of strained small rings. On the other hand, the synthesis of macrocycles by the Story fragmentation of spiro ketone peroxides is truly impressive. Also the stereospecific introduction of double bonds *via* the photolytic fragmentation of ozonides will prove to be of unquestionable synthetic value. However, by far the most unique process is the diepoxide rearrangement of epidioxides, providing a beautiful synthetic route to complex organic molecules that are very difficult to synthesize by classical routes. There is little doubt that cyclic peroxides occupy an important place in organic synthesis.

A fellowship from the J. S. Guggenheim Foundation to spend a sabbatical year (1972—73) at the University of Zürich is gratefully appreciated. We thank the National Science Foundation, the Petroleum Research Fund of the American Chemical Society, the Research Corporation, and the University of Puerto Rico for financial support of our work.

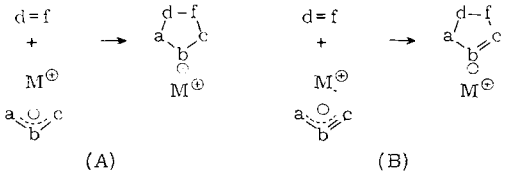
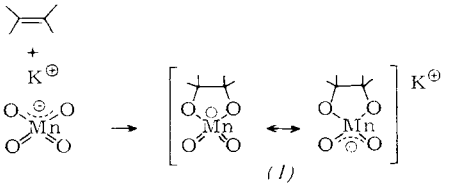
New synthetic methods (4)

1,3-Anionic Cycloadditions of Organolithium Compounds: An Initial Survey[1]



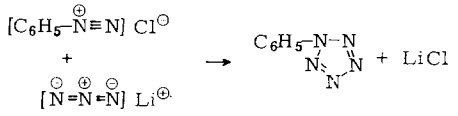
By Thomas Kauffmann[*]



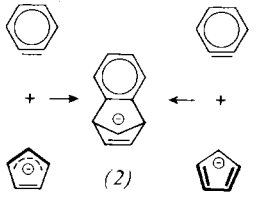
In Memory of Clemens Schöpf

In the field of [3+2]-cycloaddition reactions, 1,3-anionic cycloadditions have now joined 1,3-dipolar cycloadditions as a second reaction type of major general importance. The cycloaddition in question has been found to occur with 2-azaallyllithium compounds, allyllithium compounds (with an electron acceptor located on C^2), and 1,3-diphenylpropargyllithium. Compounds with CC, CN, NN, and CS double bonds and those with CC and CN triple bonds were found to be 1,3-anionophilic. 1,3-Anionic cycloaddition opens new routes to 1-aza-, 1,2-diaza-, 1,3-diaza-, 1,2,4-triaza-, and 1-thia-3-azacyclopentane derivatives, to pyrroles and imidazoles, as well as (and this appears to be of special importance) to cyclopentane derivatives. Currently available data attribute stereospecificity to the 1,3-anionic cycloadditions, which occupy an interesting intermediate position between 1,3-dipolar cycloadditions and transition-metal-catalyzed cyclizations. A two-step mechanism has been demonstrated in one case.

1. Definition and History of Discovery

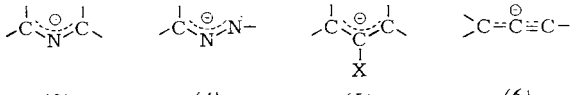


1,3-Anionic cycloadditions[2] are single-step or multiple-step reactions in which "1,3-anions" react with substrates ("1,3-anionophiles") containing a double or a triple bond to yield cycloadducts *via* routes (A) or (B). The reactions differ from the closely related 1,3-dipolar cycloadditions in that the positive charge is separately accommodated at a cation (which may be linked to the anion *via* a partially covalent bond). The first phase of *Baeyer*'s permanganate test, involving the addition of potassium permanganate to a CC double bond with the formation of a cycloadduct of type *(1)*, constitutes a long-known reaction of this kind.

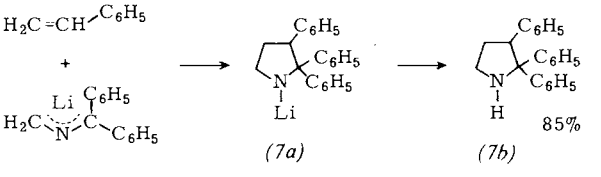


The well known combination of lithium azide with the phenyldiazonium ion to give phenylpentazole[3] is a 1,3-anionic cycloaddition with a cationic 1,3-anionophilic agent.

[*] Prof. Dr. Th. Kauffmann
Organisch-Chemisches Institut der Universität
44 Münster, Orleans-Ring 23 (Germany)



Wittig et al.[4] were able to trap dehydrobenzene in the presence of strong bases by cycloaddition with cyclopentadiene. Since *Ford et al.*[5] have shown that the cyclopentadienyl anion gives an anionic adduct of type *(2)* under such circumstances, the above reactions can therefore also be regarded as 1,3-anionic cycloadditions. However, the following formulas show that they can just as well be regarded as Diels-Alder reactions, since a six-membered ring with an isolated CC-double bond is formed.



(2)

Such ambiguity is absent from our cycloadditions involving open-chain anions of types *(3)*—*(6)*[6]. The first reaction of this kind, *i.e.* formation of 2,2,3-triphenylpyrrolidine *(7b)* (85%) *via* the intermediate *(7a)*, was observed early in 1970[7, 22].

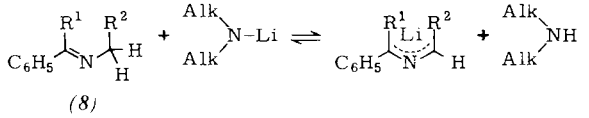
2. Stabilization of the Negative Charge in 1,3-Anionic Cycloadditions and Their Reversal

Some remarks on the significance of charge stabilization in 1,3-anionic cycloadditions with organolithium compounds may perhaps facilitate understanding of the subsequent sections.

Like 1,3-dipolar cycloadditions[8], provided that they proceed in concerted fashion (see, however, Sections 3.2.1 and 4.2) the cycloadditions in question are symmetry-dependent [$_\pi 2_s + _\pi 4_s$] processes. The basic reaction of this type was formulated by *Woodward* and *Hoffmann* (reaction I in Scheme 1)[9]. While a reaction conforming exactly to this basic type has not yet been implemented, this has been achieved in the case of analogous cycloadditions of allyl anions[10] with an electron-attracting substituent on the central carbon (Section 4.2). Available information indicates that the heteroallyl anions best suited for 1,3-anionic cycloaddition are the 2-azaallyl anions[10] (cf. Section 3). Characteristically, a relatively electronegative nitrogen located at the center of the heteroallyl system is flanked by two less electronegative carbons. Prior to the cycloaddition the negative charge is largely located at these peripheral carbons; during the reaction (reaction II in Scheme 1) it migrates to the more electronegative central nitrogen. In contrast to the 2-azaallyl anions, heteroallyl anions which contain electronegative atoms in the peripheral positions and a less electronegative atom at the center like the carboxylate ion are unsuitable for cycloaddition; they are readily formed by 1,3-anionic cycloeliminations (reaction III in Scheme 1; see also Section 5). The 1,2-diazaallyl anions occupy an intermediate position: cycloadditions have been observed only with substrates having strained multiple bonds (cf. Section 4.1).

Thus, apart from the reactions with the extremely labile dehydrobenzene, 1,3-anionic cycloadditions only occur where the negative charge is not extensively destabilized.



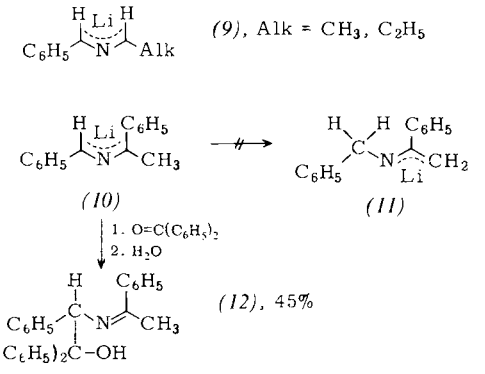
Scheme 1. Charge stabilization as a direction-determining factor. I, II, III, see text. X = O or S.

3. 2-Azaallyllithium Compounds

3.1. Preparation

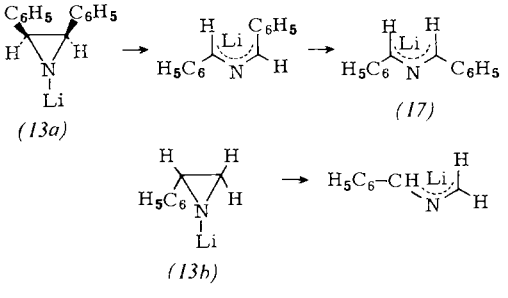
1-Azaallyllithium compounds are well known as reagents for "directed aldol condensations"[11]. In contrast, the isomeric 2-azaallyllithium compounds had not been described in the literature prior to the beginning of our investigations[12]. We were able to prepare them in solution in the following manner.

Hydrogen-lithium exchange in azomethines (method A): Azomethines of type *(8)* are rapidly lithiated[13] with lithium dialkylamides in ether or THF at −70 to −30 °C to give 2-azaallyllithium compounds. Experience gained so far practically rules out any danger of their undergoing undesirable reactions with the azomethine under these conditions.



(8)

$R^1 = R^2 = C_6H_5$; $R^1 = C_6H_5$, $R^2 = H$; $R^1 = H$, $R^2 = C_6H_5$



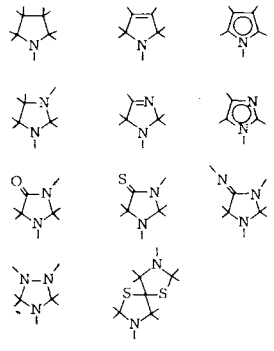
The 2-azaallyllithium solutions thus prepared contain a free secondary amine and its lithium compound owing to equilibration as shown. Consequently, the solutions are unsuitable for reactions with 1,3-anionophilic agents prone to irreversible reaction with amines and lithium amides. With lithium dimeth-

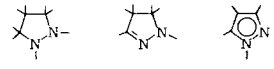
ylamide as the lithiating agent, however, the free amine can be largely evaporated prior to addition of the 1,3-anionophilic agent[14].

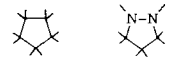
Attempted analogous preparation of 1-alkyl-3-phenyl-2-azaallyllithium compounds *(9)* in significant yield failed because the appropriate azomethines could not be metalated[15]. However, compound *(10)* was prepared. Its reaction with benzophenone to yield exclusively *(12)* shows that the isomerization to the 1-azaallyllithium compound *(11)* (this being associated with a gain in charge-stabilizing electronegativity but loss in conjugation energy) occurs at the most to a slight extent[16].

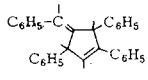
Conrotatory ring opening of N-lithiated aziridines (method B): In this procedure the 2-azaallyllithium compounds are obtained in an amine-free solution. So far, only two examples are known[18,19].

Ring opening of *(13a)* occurs rapidly in THF at 30—40 °C (for detection and configuration of the 2-azaallyllithium compound, see Sections 3.2.1), but that of *(13b)* only proceeds slowly even at 65 °C in the same solvent[19,20].





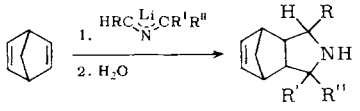




Thermal decomposition of 4-lithio-1,2,4-triazolidines (method C): As shown in Section 5.1, *trans,trans*-1,3-diphenyl-2-azaallyllithium *(17)* is also formed by heating 4-lithio-1,2,3,5-tetraphenyl-1,2,4-triazolidine *(70)*[21]. Other substituted 2-azaallyllithium compounds can probably be obtained similarly.

3.2. Preparative Applications

2-Azaallyllithium compounds can add to unsaturated compounds containing CC, CN, NN, CS, and CO double bonds as well as to those containing CC and CN triple bonds. Whereas addition at the CO double bonds always yields open-chain adducts—at least as the final products (cf. Section 3.2.3)—compounds with other multiple bonds generally give cyclic adducts. The ring systems we have so far obtained by such reactions are listed in Table 1. Information on the individual reactions is presented mainly in Tables 2—8.



Since the 2-azaallyllithium compounds were always prepared using commercial *n*-butyllithium dissolved in *n*-hexane, the reaction mixtures invariably contained 5—10% of *n*-hexane. The *n*-hexane content is not mentioned below unless it exceeded 10%.

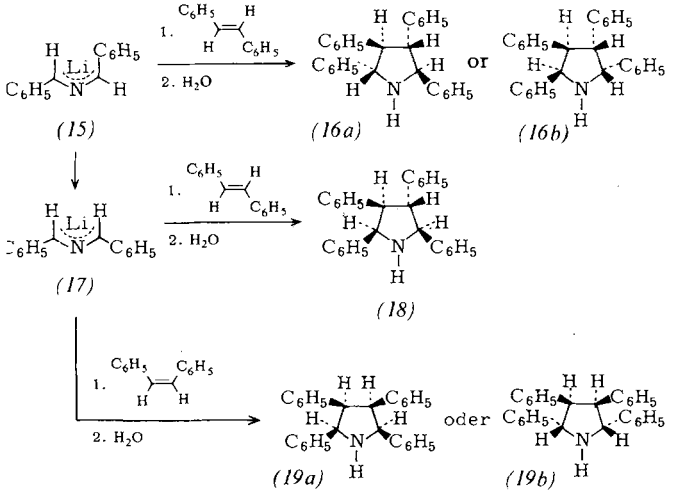
3.2.1. Reactions with Simple Alkenes

The unstrained isolated CC double bond of cyclohexene does not appear to be attacked by 1,1- or 1,3-diphenyl-2-azaallyllithium. The formation of *(14a)* or *(14b)* from norbornadiene in THF at 20 °C[22,23] shows, on the other hand, that strained isolated double bonds can undergo 1,3-anionic cycloaddition with 2-azaallyllithium compounds. Compounds with an olefinic CC double bond conjugated with an aromatic system (Table 2) are better 1,3-anionophiles. Details are given in Sections 3.2.2 to 3.2.7.

(14a), R = H, R' = R'' = C_6H_5 33%
(14b), R = R' = C_6H_5, R'' = H 35%

Regioselectivity: Although 1,3-dipolar cycloadditions generally proceed as concerted processes, the addition of asymmetrically substituted 1,3-dipoles to asymmetrically substituted multiple bonds usually displays a distinct preference for one of the two orientations[8]. The first 1,3-anionic variant we observed (the reaction between 1,1-diphenyl-2-azaallyllithium and styrene formulated at the outset) has showed that 1,3-anionic cycloadditions can also be markedly regioselective. Of the two possible protonated cycloadducts 2,2,3-triphenyl- *(7b)* and 2,2,4-triphenylpyrrolidine, the isomer obtained

Table 2. Cycloaddition of 2-azaallyllithium compounds to simple alkenes.



2-Azaallyl-Li compounds	1,3-Anionophile	T [°C]	t [h]	Products	Yield [%]	Ref.
1,1-Diphenyl-	Styrene	20 [a]	18	2,2,3-Triphenylpyrrolidine *(7b)*	85	[7, 22]

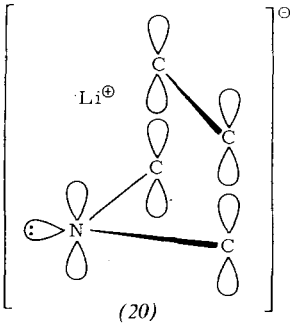
	Acenaphthylene	0 [b]	24	7,9-Diphenyl-7,8,9,9a-tetrahydro-6b*H*-acenaphtho-[1,2-*c*]pyrrole *(22a)* and *(23a)*	40 + 40	[16, 25]

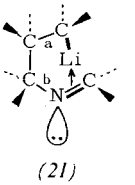
[a] In THF.
[b] In THF/ether (10 : 1).

mainly or exclusively was the sterically less favorable one *(7b)* (85% yield). A distinct regioselectivity of this type has also been observed[2] in cycloadditions of 2-azaallyllithiums to 1,3-dienes (Table 3).

Stereospecificity: The 1,3-anionic cycloadditions investigated here proved to be stereospecific. The best studied reaction is that of 1,3-diphenyl-2-azaallyllithium with *trans*- and *cis*-stilbene. According to the principle of conservation of orbital symmetry[9] thermal opening of the ring of *N*-lithio-*cis*-2,3-diphenylaziridine *(13a)* would give rise to *cis,trans*-1,3-diphenyl-2-azaallyllithium *(15)* in a conrotatory process. Compound *(15)* could be trapped by conducting the ring-opening process (at 40—60 °C) in the presence of 1 mol of *trans*-stilbene. The 2,3,4,5-tetraphenylpyrrolidine having structure *(16a)* or *(16b)* was formed in a 73% yield, *i.e.* a cycloadduct with the two phenyl residues "inherited" from the 2-azaallyl group in the *trans*-position[18].



The *cis,trans* compound *(15)* is unstable, and rapidly rearranges to the more stable *trans,trans* compound *(17)*[18, 24].



(15) *(16a)* *(16b)* *(17)* *(18)* *(19a)* *(19b)*

This reacts in THF at 0 °C with *trans*-stilbene to yield exclusively *(18)* (83% yield), and with *cis*-stilbene at 0 °C to give a product of the constitution *(19a)* or *(19b)* (21% yield). The products of *(17)* thus have the *cis*-configuration in that part originating from the 2-azaallyl and the configuration in the alkene part is retained. The pyrrolidines obtained from *trans*- and *cis*-stilbene exhibited no detectable mutual contamination. Hence, these cycloadditions are stereospecific with respect to the alkene and the 2-azaallyl components (*cis* addition in each case). The cycloaddition of *(17)* to acenaphthylene is also a purely *cis* addition[25].

These findings can be most readily interpreted in terms of symmetry-dependent single-step $[_\pi 4_s + _\pi 2_s]$-cycloaddition processes. Since the 2-azaallyl anions resemble 1,3-dipolar substances in their orbital scheme (*e.g.* azomethine ylides), the MO considerations[26] pertinent to 1,3-dipolar cycloadditions can be extended to the reactions of 2-azaallyl anions. Provided they are one-step processes, these reactions should therefore proceed *via* a "two-plane orientation complex" *(20)*.

(20)

(21)

However, the observed stereospecificity can also be explained in terms of a two-step process with an intermediate of type *(21)*, in which rotation about the *a*- and *b*-axes is blocked by coordination to the CN double bond or to the nitrogen.

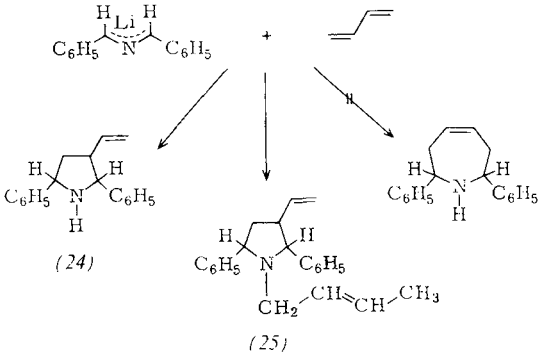
A two-step 1,3-anionic cycloaddition is described in Section 4.2.

In the case of reaction *(17)* → *(18)* the fact that the stereospecificity of this cycloaddition is not in the least impaired (the yield is also virtually unaffected)[21] by the addition of tetramethylethylenediamine, a good complexing agent, may constitute an argument against an intermediate *(21)*.

endo-exo-Isomeric cycloadducts: According to Table 2, the action of 1,3-diphenyl-2-azaallyllithium in THF at 0 °C on acenaphthylene gives rise to two isomeric cycloadducts in approximately equal amounts. By analogy with the structure determinations on *N*-phenylpyrrolidines[27], on the basis of ^{1}H-NMR spectra the *endo*-structure *(22a)* (weaker shielding of the pyrrolidine protons) can be assigned to the higher-melting isomer (m.p. 194 °C), and consequently the *exo*-structure *(23a)* to the lower-melting isomer (m.p. 176 °C)[19, 28].

The lithium compound *(22b)* obtained from *(22a)* by the action of *n*-butyllithium at 0 °C is stable in THF at this temperature, but at 40—50 °C it rearranges quantitatively within 1 h to the thermodynamically more stable *exo*-isomer *(23b)*. There is hardly any doubt that this isomerization proceeds by the formulated cycloelimination-cycloaddition mechanism, especially as acenaphthylene was detectable in small amounts in the reaction mixture.

ing to *(25)*, did not take place when instead of the 2-azaallyllithium compound the corresponding azomethine *(46)* was used in the presence of catalytic amounts of lithium diisopropylamide (cf. Section 3.2.7 and Table 8), which can be plausibly explained by more rapid protonation of the anionic cycloadduct (lithium compound of *(24)*) by the azomethine (*N*-benzylidenebenzylamine) abundantly present in the reaction mixture.



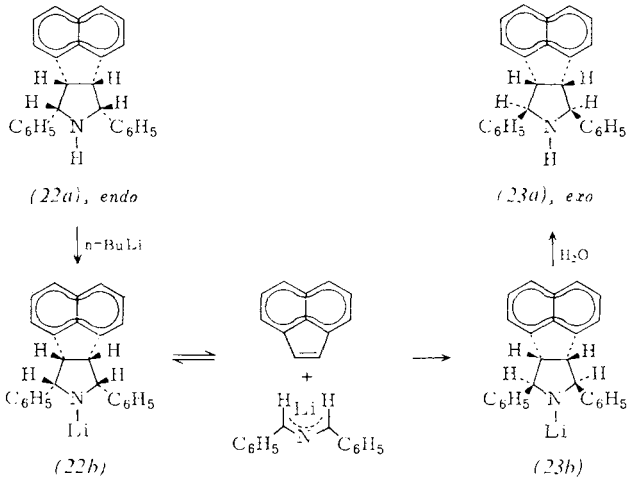


Table 3. Cycloaddition of 2-azaallyllithium compounds to 1,3-dienes in THF at 20 °C (reaction time 16 h) [2, 29].

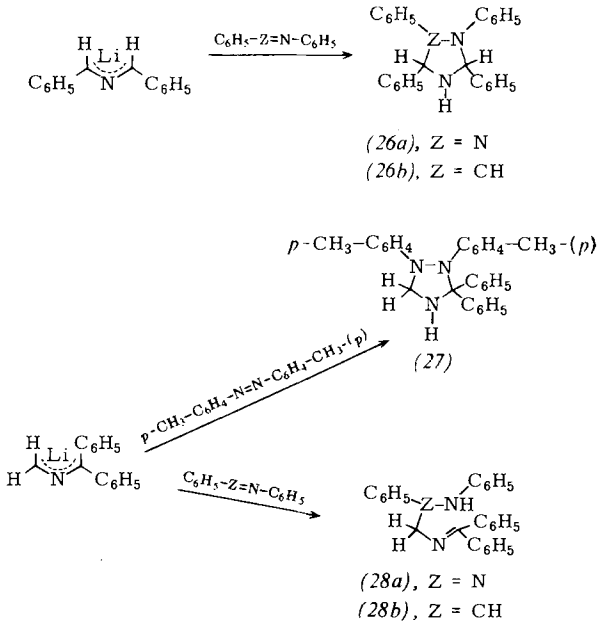
2-Azaallyl-Li compound	1,3-Anionophile	Product	Yield [%]
1,3-Diphenyl-	1,3-Butadiene	2,5-Diphenyl-3-vinylpyrrolidine *(24)*	36
		1-(2-Butenyl)-2,5-diphenyl-3-vinylpyrrolidine *(25)*	47
	Isoprene	3-(1-Methylvinyl)-2,5-diphenylpyrrolidine	92
1,1-Diphenyl-	1,3-Butadiene	2,2-Diphenyl-3-vinylpyrrolidine	91
	Isoprene	3-(1-Methylvinyl)-2,2-diphenylpyrrolidine	35
		3-Methyl-2,2-diphenyl-3-vinylpyrrolidine	13
1,1,3-Triphenyl- [a]	1,3-Butadiene	2,2,5-Triphenyl-3-vinylpyrrolidine	35

[a] In this experiment, the temperature had to be increased to 66 °C.

3.2.2. Reactions with 1,3-Dienes



1,3-Dienes are also convenient 1,3-anionophiles (Tables 3 and 8)[2, 14, 29]. They react with 2-azaallyllithiums to give, apparently exclusively, five-membered cycloadducts; seven-membered ones could not be isolated. In one case the cycloaddition was associated with a secondary reaction. This reaction, leading to *(25)*, did not take place when instead of the 2-azaallyllithium compound the corresponding azomethine *(46)* was used in the presence of catalytic amounts of lithium diisopropylamide (cf. Section 3.2.7 and Table 8), which can be plausibly explained by more rapid protonation of the anionic cycloadduct (lithium compound of *(24)*) by the azomethine (*N*-benzylidenebenzylamine) abundantly present in the reaction mixture.

Table 3 shows that the 1,3- and 1,1-diphenyl-2-azaallyllithium compounds expectedly undergo cycloaddition preferably at the electron-depleted and sterically more readily accessible double bond of isoprene. The 1,3-diphenyl compound shows by far the higher selectivity.

3.2.3. Reactions with Azo Compounds and Azomethines

1,3-Diphenyl-2-azaallyllithium undergoes cycloaddition to the aromatic azo compounds and azomethines listed in Table 4 with the formation of 1,2,4-triazolidines or imidazolidines (*e.g. (26a)* and *(26b)*)[30]. In contrast, no reaction was observed[22, 31] with 4-dimethylaminoazobenzene, 2,2'-azonaphthalene, and 3,3'-azoquinoline under the corresponding conditions. The stereochemistry of the chirality centers of the products has yet to be elucidated.

In contrast, 1,1-diphenyl-2-azaallyllithium, which is generally more prone to form open-chain adducts than the 1,3-isomer (cf. Section 3.2.6), gives the expected cycloadduct *(27)* only with *p,p'*-azotoluene. With azobenzene and azomethines, open-chain adducts of the type *(28a)* or *(28b)* are formed, contrary to previous assumptions based on an erroneous interpretation of the spectra[30, 32].

the 2-azabutadienes (31)[17]. Information on the relevant reactions is given in Table 5. On attempted addition of 1,3-diphenyl-2-azaallyllithium to benzophenone the ketone was recovered largely unaltered[21].

In the benzene/hexamethylphosphoric triamide (1:1) solvent system the yield of (29) $R=R'=C_6H_5$ increased from 42 to 62%; furthermore, the adducts of benzaldehyde and isobutyraldehyde analogous to (29) were prepared in *ca.* 60% yield[35]. The same benzaldehyde adduct was also formed in THF containing diisopropylamine (40%)[21], whereas the action of 1,2-diphenyl-2-azaallyllithium on benzaldehyde and other aldehydes in amine-free THF leads to products [structure (33)?] which regenerate the aldehyde on addition of water[36].

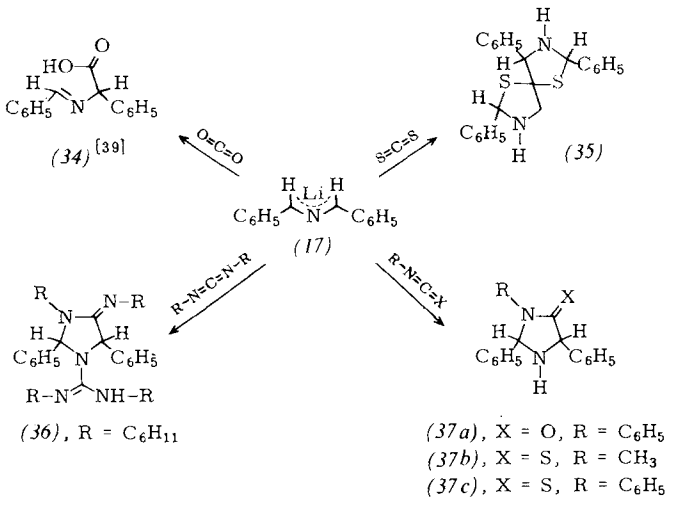
[a] In general the compound was lithiated for 4—5 h at −60 °C, the substrate was added at the same temperature, and the mixture was maintained for several hours at 20 °C. [b] In THF/*n*-hexane (5:1). [c] Heated for 3 h at 65 °C. [d] In THF/ether (9:1).

3.2.4. Reactions with Ketones and Aldehydes

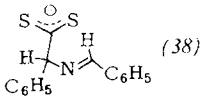
Reactions of 1,1-diphenyl-2-azaallyllithium with ketones and then with water did not yield cyclic products but open-chain compounds of type (29)[13, 17]. It is still unclear whether the reactions involve cyclic intermediates of type (32). The iminomethylation products (29) obtained from 1,1-diphenyl-2-azaallyllithium are of preparative interest since they give rise to β-amino alcohols (30) on hydrolytic cleavage with acids. Both reaction steps thus permit nucleophilic aminomethylation of ketones[13, 34]. Moreover, dehydration of compounds (29) with thionyl chloride/pyridine provides an entry to the hitherto relatively inaccessible class of compounds,

(29)



(30)

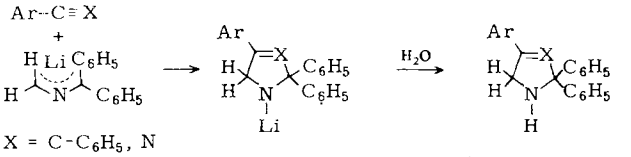
(31)



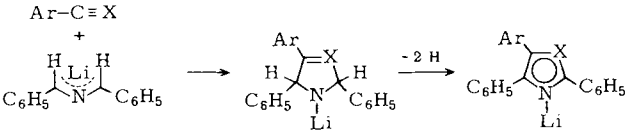
3.2.5. Reactions with Heterocumulenes

The preparation of *trans,trans*-1,3-diphenyl-2-azaallyllithium (17) in solutions containing neither amine nor lithium amide, mentioned in Section 3.1 and 3.2.1, permitted investigations on the behavior of this organolithium compound towards those substrates which, like the oxiranes[37] or heterocumulenes, react irreversibly with amines and lithium amides. Reaction with the heterocumulenes listed in Table 6 and subsequent

hydrolysis with water afforded compounds *(34)*—*(37)*[38] Just these few examples reveal four reaction types.

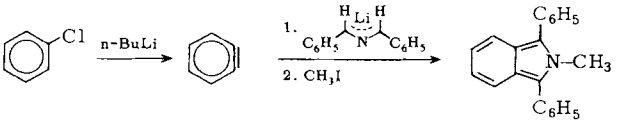


The reaction *(17)* → *(35)* is the first 1,3-anionic cycloaddition to a CS double bond. Attempts to prepare the monocycloadduct of carbon disulfide were unsuccessful. As in the 1,3-dipolar cycloaddition of diphenylnitrilimine to carbon disulfide[8], the first step is clearly slower than the second. This is understandable if the first step of the cycloaddition is assumed to involve a transition state similar to *(38)* with good stabilization of the negative charge.



(38)

The relatively high yield of *(36)* (60 %) permits the conclusion that the dicyclohexylcarbodiimide, although added slowly to the solution of *(17)*, was abundantly available to the anionic cycloadduct for further reaction. Thus the cycloaddition step is again slower than the secondary reaction. Apart from the imidazolidine derivatives *(37)*, no other products could be isolated, implying that the cycloaddition to heterocumulenes with two different double bonds occurs exclusively or predominantly at the CN double bond[40]. Since only one diastereomeric form can be isolated in each case, despite careful chromatographic work-up, all cycloadditions to heterocumulenes are probably stereospecific.



additions, however, limitations appear to be set in this respect by the CH-acidity of many alkynes and nitriles. Thus, it proved impossible, or virtually impossible, to effect cycloaddition of 1,3-diphenyl-2-azaallyllithium to phenylacetylene, 1-phenylpropyne, or aliphatic nitriles (cf. Table 7), which might be due to deactivation of the reagent and substrate by transmetalation. Diphenylacetylene[7] (other non-CH-acid alkynes have still not been tried) and aromatic nitriles nevertheless proved to be 1,3-anionophiles useful for preparative purposes.

Pyrrolines and imidazolines are anticipated as products of the cycloaddition of 2-azaallyllithium compounds to alkynes and nitriles, if side reactions are neglected. The ring systems in question were obtained in the form of the compounds *(39a)* and *(39b)* on use of 1,1-diphenyl-2-azaallyllithium[42].

On the other hand, the corresponding cycloadditions of 1,3-diphenyl-2-azaallyllithium were followed by loss of 2 H atoms, so that pyrroles and imidazoles were formed. This aromatization is presumably initiated by elimination of hydride from *(40)* and concluded by a deprotonation[42].

Stabilization of the primary cycloadduct by loss of hydrogen was also found to occur in the reaction of 1,3-diphenyl-2-azaallyllithium with dehydrobenzene in THF at 20 °C and then with methyl iodide, to give *(41)*[43,44].

Table 6. Cycloaddition and addition of *trans,trans*-1,3-diphenyl-2-azaallyllithium *(17)* to heterocumulenes in THF [38].

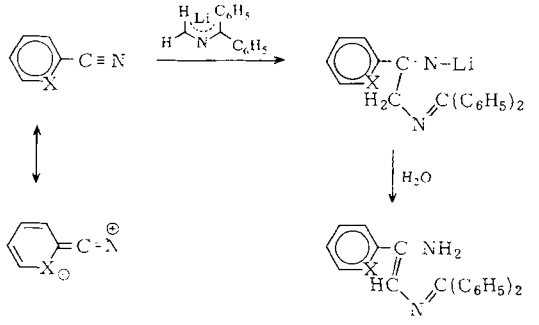
[a] Time of dropwise addition (≈2 min) not included.
[b] No reaction at −40 °C.

3.2.6. Reactions with Alkynes and Nitriles

Alkynes and nitriles of all types are suitable substrates for 1,3-dipolar cycloadditions[8]. In the case of 1,3-anionic cycloadditions, however, limitations appear to be set in this respect by the CH-acidity of many alkynes and nitriles. Thus, it proved impossible, or virtually impossible, to effect cycloaddition of 1,3-diphenyl-2-azaallyllithium to phenylacetylene, 1-phenylpropyne, or aliphatic nitriles (cf. Table 7), which might be due to deactivation of the reagent and substrate by transmetalation. Diphenylacetylene[7] (other non-CH-acid alkynes have still not been tried) and aromatic nitriles nevertheless proved to be 1,3-anionophiles useful for preparative purposes.



According to Table 7, 1,1-diphenyl-2-azaallyllithium reacts with *m*-tolunitrile and with *p*-methoxybenzonitrile to yield cycloadducts. The corresponding reactions with benzonitrile and pyridine-2-carbonitrile were, however, found to lead to the open-chain enamines *(42)*[42]. Therefore, in view of the

Table 7. Cycloaddition of 2-azaallyllithium compounds to organic compounds containing triple bonds [a].

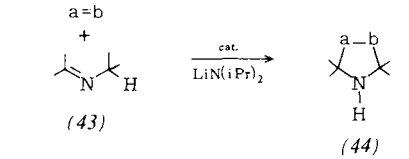
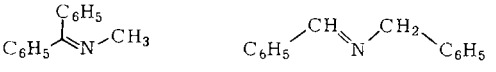
[d] The imidazoles are named as if only the nitrogen arising from azaallyl were protonated.

finding that cycloaddition to the nitrile group occurs only in the presence of electron-supplying substituents on the phenyl nucleus of the aromatic nitriles, a relatively high electron density at the nitrile nitrogen is clearly necessary for closing the CN linkage.



(42), X = CH, N



3.2.7. Cycloadditions with CH-Acid Azomethines and Catalytic Quantities of Lithium Diisopropylamide

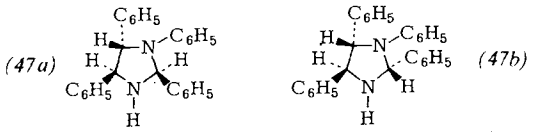
It is of interest whether the cycloadduct of a 2-azaallyllithium compound and a 1,3-anionophile is able to lithiate CH-acid azomethines. Should this be the case, then in accordance with the scheme *(43)* → *(44)*, 1,3-anionic cycloadditions would be possible with catalytic amounts of a lithium amide, *e.g.* lithium diisopropylamide. A series of experiments with azomethines *(45)* and *(46)*, the results of which are presented in Table 8, corroborates this approach[114].

Whereas, for unknown reasons, the use of *(45)* produced satisfactory results in only two cases, the yields obtained with *(46)* were generally good (Table 8). Alkenes with an extended

(43) *(44)*

(45) *(46)*

π-electron system (styrene, *trans*-stilbene) reacted significantly more rapidly than 1,3-butadiene or isoprene. This cannot be accounted for by basicity differences between the *N*-lithiopyrrolidines formed in the course of the cycloaddition, but must be ascribed to differences in 1,3-anionophilic strength of the alkenes. This conclusion is supported by the occurrence of only one cycloadduct. If lithiation were rate-determining, then not only the *trans,trans*-form *(17)* but also the *cis-trans*-form *(15)* of 1,3-diphenyl-2-azaallyllithium, which is likewise formed (cf. ref. [24]) during the lithiation of the azomethine *(46)*, would be trapped. Thus it appears that the latter compound rearranges completely to the *trans,trans*-form *(17)*, which is stable at room temperature, before cycloaddition occurs.

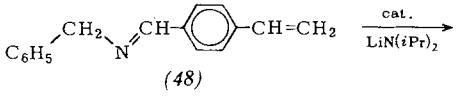


On the other hand, an analogous reaction of *(46)* with *N*-benzylideneaniline gives rise to two isomeric cycloadducts (m. p. 115—117 °C, 44% yield and m.p. 171 °C, 19% yield), the lower-melting isomer being identical with the 2,3,4,5-tetraphenylimidazoline *(26b)* listed in Table 4. The formation of two isomers and the low reaction rate, despite the relatively high 1,3-anionophilicity[46] of *N*-benzylideneaniline, suggest

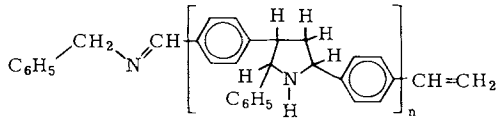
Table 8. Reaction of *N*-(diphenylmethylene)methylamine *(45)* or *N*-benzylidenebenzylamine *(46)* with unsaturated compounds in the presence of *catalytic amounts* (0.02 mole) of lithium diisopropylamide in THF at 22 °C [14].

1,3-Anionophile	*t* [h]	Isolated reaction products	
		reaction with *(45)*	reaction with *(46)*
1,3-Butadiene	16 and 5	2,2-Diphenyl-3-vinylpyrrolidine (73 %)	2,5-Diphenyl-3-pyrrolidine (95 %)
Isoprene	26 and 2	3-(1-Methylvinyl)-2,2-diphenylpyrrolidine (16 %) 3-Methyl-2,2-diphenyl-3-vinylpyrrolidine (7 %)	3-(1-Methylvinyl)-2,5-diphenylpyrrolidine (90 %)
Styrene	16 and 0.5	[a]	2,3,5-Triphenylpyrrolidine (88 %)
trans-Stilbene	28 and 0.1	[a]	2,3,4,5-Tetraphenylpyrrolidine (92 %)
N-Benzylideneaniline	16 and 18	[a]	1,2,4,5-Tetraphenylimidazoles (2 isomers, 44 and 19 %)
Azobenzene	0.3 and 0.2	[a]	[a]

[a] No detectable reaction product.



that in this case the lithiation step and not the cycloaddition step is rate determining, and both *trans,trans (17)* and *cis,trans*-1,3-diphenyl-2-azaallyllithium *(15)* consequently participate in cycloaddition. The configurations of the two isomers could not be established by spectroscopy. However, it seems reasonable to assume that the main product derives from *(17)* and therefore has configuration *(47a)*, implying configuration *(47b)* for the other isomer.

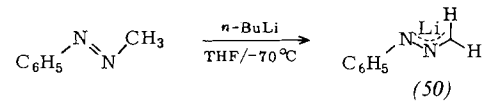


(47a) *(47b)*

The interesting suppression of a side reaction when the reaction of 1,3-butadiene with *(46)* is performed in the presence of catalytic amounts of lithium diisopropylamide, instead of with 1,3-diphenyl-2-azaallyllithium, has already been mentioned in Section 3.2.2.

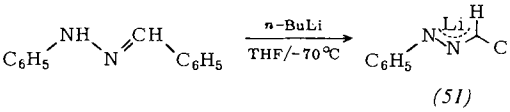
A catalytic amount of the deprotonating base also suffices in the reaction *(48)* → *(49)* (in THF at 20—30 °C)—a novel and presumably stereospecific "ring-forming polymerization"[47]. The colorless, glasshard polymer has a molecular weight of 7500—8000, and thus contains an average of 35—40 monomer units. Since many compounds are conceivable which contain a 1,3-anionophilic group and a potential 1,3-anionic group like *(48)*, numerous analogous 1,3-anionic polycycloadditions should be possible.

(48)



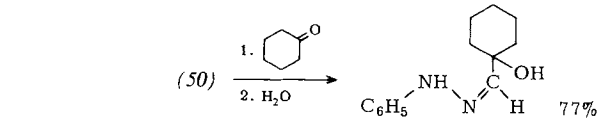
(49)

4. Other Organolithium Compounds Capable of 1,3-Anionic Cycloaddition

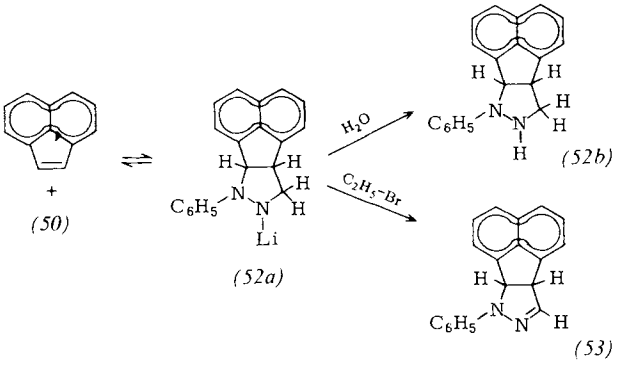


4.1. 1,2-Diazaallyllithium Compounds

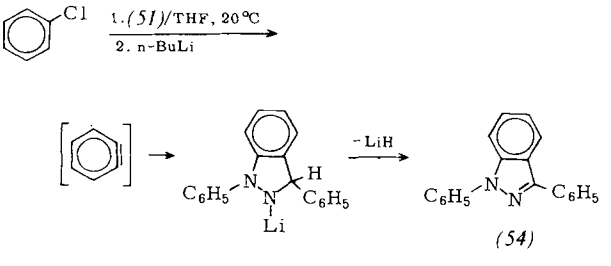
For reasons given in Section 2, 1,2-diazaallyllithium compounds were expected to be less inclined to undergo 1,3-anionic cycloaddition than 2-azaallyllithiums. This has been confirmed. 1-Phenyl-1,2-diazaallyllithium *(50)*[48,49] and 1,3-diphenyl-1,2-diazaallyllithium *(51)*[49,50] were prepared in solution in the specified manner (yield 90—100 %). On reaction of *(50)* with carbonyl compounds the phenylhydrazones of α-hydroxyaldehydes and α-hydroxyketones were formed in average to good yields[49,51].



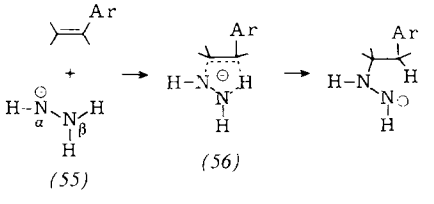
Compound *(50)* reacted with acenaphthylene in THF at 25 °C to give the cycloadduct *(52a)*, which afforded the pyrazolidine *(52b)* (32 %) or the pyrazoline *(53)* (27 %)[49,50], respectively, on addition of water or ethyl bromide. Compound *(52a)*, prepared independently from *(52b)* with *n*-butyllithium, undergoes cycloelimination in THF above 20 °C; after 15 h at 40 °C and hydrolysis with water, 23 % of acenaphthylene and some benzeneazomethane (as one of the hydrolysis products of *(50)*) could be detected[43]. The cycloaddition observed is thus reversible.



(50)



(51)

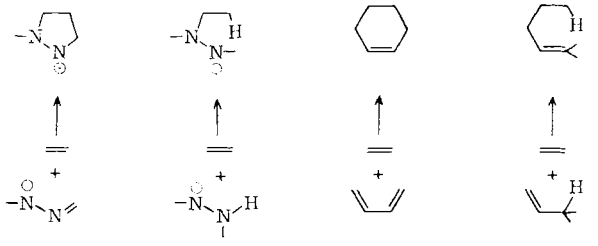


(52a) *(52b)* *(53)*

An analogous cycloaddition of *(51)* to acenaphthylene could not be performed; however, success was achieved in cycloaddition to the more reactive dehydrobenzene, whose preparation from chlorobenzene required addition of *n*-butyllithium. Spontaneous loss of hydride from the cycloadduct led to 1,3-diphenylindazole *(54)* (10 %)[43].

(54)

Attempted cycloaddition of *(50)* and *(51)* to styrene, *trans*-stilbene, or tolane, *i.e.* substrates which, in contrast to acenaphthylene and dehydrobenzene, contain no strained multiple bond, was unsuccessful[50].

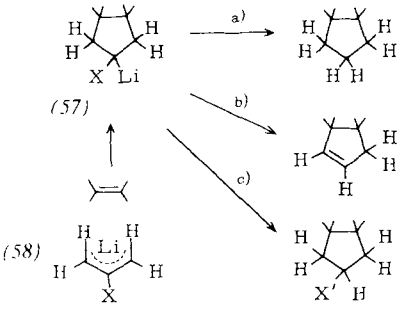


(55) *(56)*

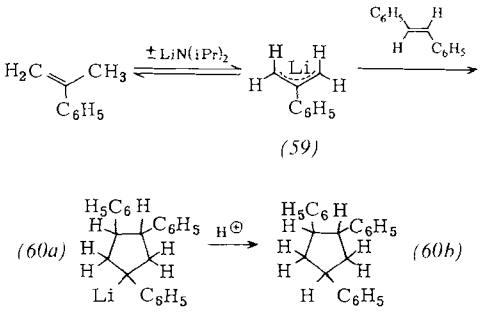
The hydrazide ion *(55)* adds surprisingly easily to multiple bonds[51]. Such marked ability to undergo addition is also observed in the case of the β-monomethylhydrazide ion, but

disappears on replacement of the second H atom on N^{β} by a methyl group. It is therefore assumed that the addition of the hydrazide ion proceeds *via* the cyclic transition state *(56)* with participation of a hydrogen atom[51].

In this connection it is of interest that the addition of hydrazide ion is related to 1,3-anionic cycloaddition in the same way as the "ene reaction" to the Diels-Alder reaction (Scheme 2). In all these four types of reaction, a "quasi-aromatic" transition state[52] is possible.

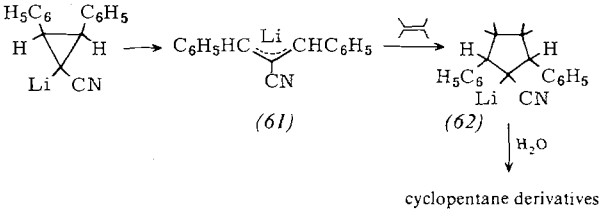


Scheme 2. Comparison of 1,3-anionic cycloaddition of a 1,2-diazaallyl anion with addition of a hydrazide ion, and of the Diels-Alder reaction with the "ene" reaction.



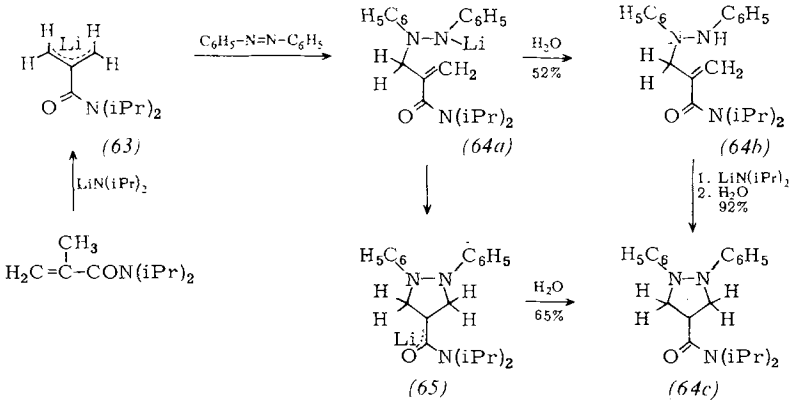
4.2. Allyllithium Compounds

The importance of the Diels-Alder reaction is principally that it provides a convenient way of synthesizing six-membered carbocyclic compounds. A comparably favorable method of preparing five-membered *carbocyclic* compounds would be valuable. The "1,3-dipolar cycloaddition" type of reaction, otherwise so versatile, fails in this respect; as far as we know, only *heterocyclic* compounds could hitherto be synthesized in this way. In contrast, 1,3-anionic cycloadditions are also suitable for the synthesis of carbocyclic compounds[53, 55] and could therefore close a wide gap in the available preparative techniques.



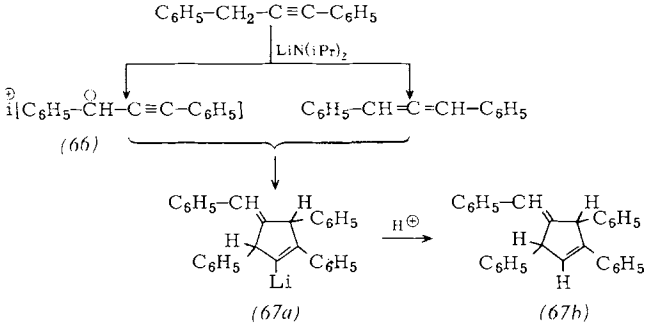
According to the available data, allyllithium compounds undergo cycloaddition to CC double bonds only in cases where an electron-attracting substituent is present on C^2 of the allyl system[14, 54]. A cycloaddition of this kind would only acquire general preparative importance if this substituent [X in *(57)*] could be (a) easily removed by reduction, (b) eliminated together with an α-hydrogen, or (c) exchanged for other substituents after completion of the cycloaddition process. So far this objective has not been achieved.

An allyllithium compound of apparently suitable kind *(58)*, but with substituents not readily removable after the cycloaddition, is 2-phenylallyllithium *(59)*, formed gradually when α-methylstyrene in THF is subjected to the action of lithium diisopropylamide. Reaction of *(59)* with *trans*-stilbene gives the cycloadduct *(60a)*; after addition of water, the cyclopentane derivative *(60b)* could be isolated (41% yield after 130 h at 45 °C)[53, 55].



Following the publication of this synthesis, analogous cycloaddition reactions *(61)* → *(62)* were reported, in which the nitrile group effects charge stabilization in the cycloadduct (18—69% yield). Styrene, *trans*-stilbene, 1,1-diphenylethylene, and acenaphthylene served as 1,3-anionophiles; the organolithium compounds *(61)* and *(62)* were unambiguously detected[56].

The stereochemistry at the chirality centers of cyclopentane derivatives produced by 1,3-anionic cycloaddition have still not been fully elucidated.

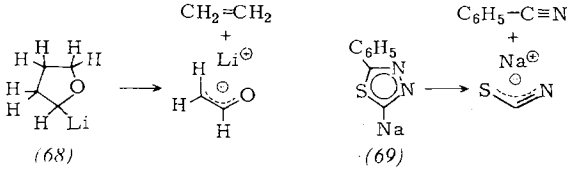


Only the *trans,trans* form of 1,3-diphenyl-2-cyanoallyllithium *(61)* undergoes cycloaddition to activated alkenes, but not the *cis,trans* form[57]. Correspondingly, in spite of the presence of an electron-attracting group at C^2, 1,3-diphenyl-2-(2-pyridyl)allyllithium, which is obtainable in virtually quantitative yield[31] from 1,3-diphenyl-2-(2-pyridyl)propene and lithium diisopropylamide, and which like 1,2,3-triphenylallyllithium[58] occurs not in the *trans,trans*- but in the *cis,trans*- and, above all in the *cis,cis*- form, does not undergo cycloaddition to activated alkenes[54].

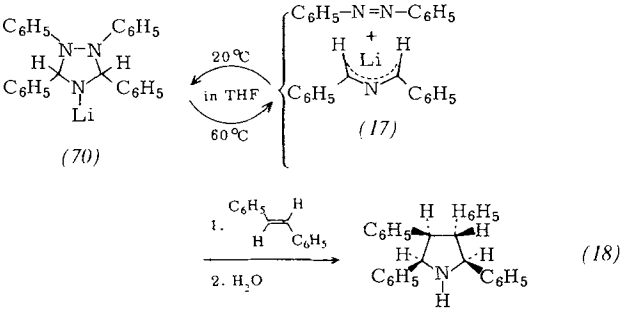
An allyllithium compound of apparently suitable type *(58)*, with *substituents readily removable* after the cycloaddition, is *(63)*. This unstable compound, obtainable at −60 °C in THF, reacts rapidly with azobenzene at −60 °C to give the adduct *(64a)* [detected as *(64b)*], which gives rise to the cycloadduct *(65)* in a second reaction step (at 65 °C) requiring more activation energy[54, 59]. Since in this instance a two-step mechanism has been clearly established, it may be assumed that other 1,3-anionic cycloadditions also proceed in two steps. Compound *(64b)* can be converted into the pyrazolidine *(64c)* by treatment with lithium diisopropylamide in THF at 65 °C and subsequent hydrolysis.

4.3. 1,3-Diphenylpropargyllithium

Owing to its sp-hybridization, the central carbon of the 1,3-diphenylpropargyl anion of *(66)* exhibits relatively high electronegativity. Consequently, it appeared possible that this anion might also enter into 1,3-anionic cycloadditions. In fact, the cycloadduct *(67a)* is formed on reaction of lithium diisopropylamide and 1,3-diphenylpropyne, which in *n*-hexane leads initially to *(66)* (60% yield) and 1,3-diphenylallene[60]; hydrolysis of *(67a)* with water gives its protonation product *(67b)*[53] in 61% yield. The steric arrangement of the substituents in this substance has not yet been established.



5. 1,3-Anionic Cycloeliminations and the Influence of the Metal in 1,3-Anionic Cycloadditions



5.1. Cycloeliminations

A number of cycloeliminations corresponding to a reversal of 1,3-anionic cycloaddition are known:

The elimination of olefins from lithiated 1,3-dioxolanes[61] and 1,3-dithiolanes (see Scheme 1)[61] in a reaction of this type has found preparative application. The analogous scission of lithiated tetrahydrofuran *(68)*[62] not infrequently proves troublesome in the case of organometallic reactions. The cleavage of *(69)* into a nitrile and sodium thiocyanate[63] shows that aromatic systems can also decompose in this fashion. Whereas these and similar[64] cycloeliminations give rise to low-energy anions, which according to currently available information cannot undergo cycloaddition to unsaturated systems, we have observed analogous reactions yielding relatively high-energy anions capable of cycloaddition: The lithiated triazolidine *(70)*, obtained in 73% yield by the cycloaddition of *trans,trans*-1,3-diphenyl-2-azaallyllithium *(17)* to azobenzene in THF at 20 °C, decomposes largely into the components in the same solvent at 65 °C. 51% of azobenzene was set free on heating pure *(70)* to 60 °C in THF for 90 min; the co-product *(17)* could be trapped as the pyrrolidine derivative *(18)* (20%) with *trans*-stilbene[21,28]. This reaction opens up the third route to 2-azaallyllithium compounds (cf. Section 3.1).

An analogous cycloelimination of *(17)*, leading to isomerization, and that of 1-phenyl-1,2-diazaallyllithium *(50)*, have already been mentioned in Sections 3.2.1 and 4.1 respectively.

5.2. Influence of the Metal

In contrast to classical cycloadditions (Diels-Alder reaction, 1,3-dipolar cycloaddition), whose mechanism has been largely elucidated, a new structural element is involved in 1,3-anionic cycloaddition, *i.e.* the positively charged metal atom. Its influence on the cycloaddition and its reversal is therefore of considerable theoretical and practical interest.

We found that lithium and sodium on the one hand, and potassium and magnesium on the other, exert markedly different effects. Whereas 1,3-diphenyl-2-azaallyllithium and -sodium[65] react in THF at 20 °C with *trans*-stilbene to the extent of 80—85 and 60—65%, respectively, yielding 2,3,4,5-tetraphenylpyrrolidinelithium or -sodium, the analogous cycloaddition of 1,3-diphenyl-2-azaallylmagnesium bromide[65] was less than 5% effective, and that of the corresponding potassium compound was less than 10% effective[19,66]. The *reversal* of 1,3-anionic cycloadditions is distinctly favored in

the case of 2,3,4,5-tetraphenylpotassium compared with the corresponding lithium compound[19].

6. Outlook

Priority should be given to the development of a versatile method of synthesizing five-membered *carbocyclic* compounds in accordance with the principle of 1,3-anionic cycloaddition. Several of the reactions outlined in this paper have a direct counterpart in the field of 1,3-dipolar cycloaddition. Future applications of 1,3-anionic cycloaddition to the synthesis of five-membered *heterocycles* will therefore undoubtedly benefit from the experience accumulated for 1,3-dipolar cycloadditions. However, 1,3-anionic cycloadditions also have common features (metal and thus ligand participation, possibility of carbocyclic synthesis and catalytic synthesis, stepwise mechanism, tendency to undergo side reactions) with "transition-metal-catalyzed cyclizations"[67], which could be regarded as a sequence of concerted ring-closure reactions in which the metal constitutes a member of the ring ("metala ring closures"[67]). Approaches to this versatile type of reaction should therefore plainly be investigated through variations in the metal and in the organic components. In mechanistic studies priority should be given to the question whether the mechanism is single-step or two-step, hitherto settled only in one case.

The author wishes to express his sincere gratitude to all those participating in these investigations, and especially to Dr. Edgar Köppelmann and Dr. Rudolf Eidenschink for their individual creative efforts. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie e. V. for effective financial support.

Dinitrogen-Transition Metal Complexes: Synthesis, Properties, and Significance

By Dieter Sellmann[*]

Compared to the large number of CO complexes, N_2 complexes are still rare. In certain cases they may be formed from N_2 gas and metal compounds under physiological conditions, and are therefore frequently considered as possible intermediates in N_2 assimilation. However, despite numerous attempts it has not yet been possible to reduce the N_2 ligand of a fully characterized N_2 complex to NH_3. This negative evidence recently prompted the discoverers of the first dinitrogen complex, the $[Ru(NH_3)_5N_2]^{2\oplus}$ ion isolated in 1965, to express doubt whether such complexes really do play a part in the enzymatic reduction of N_2. The latest findings nevertheless incline toward a somewhat more optimistic view. Thus, the mild partial reduction of the N_2 ligand in metal complexes with inert gas configuration, hitherto considered nonreducible, justifies the hope that a suitable system permitting the catalytic reduction of molecular nitrogen under normal conditions will one day be found. Even apart from any technical potential, the N_2 complexes constitute an interesting chapter of modern inorganic chemistry.

1. Introduction

Under normal conditions molecular nitrogen is usually found to be chemically inert. Thus, reactions involving the N_2 molecule generally require drastic conditions, *e. g.* elevated temperatures and pressures, as in the Haber-Bosch process.

However, nature is capable of converting atmospheric nitrogen enzymatically during N_2 assimilation into ammonia and amino acids under mild physiological conditions (15°C, 0.8 atm. N_2, aqueous medium). In chemistry, only one defined reaction of the N_2 molecule is currently known which also proceeds under physiological conditions: the reaction with metal compounds to yield dinitrogen complexes. This reaction can clearly be considered as a model for the absorption of atmospheric nitrogen by the N_2-assimilating enzymes in nature. Hence the fundamental significance of the reaction and its products.

What features characterize the reaction partner, which allows reduction of the normally inert molecular nitrogen during the course of assimilation?

Biochemists are trying to answer this question by the isolation and study of the nitrogen-assimilating enzymes, the nitrogenases; purely chemical means are employed by chemists attempting to simulate nature *in vitro* by fixing molecular nitrogen to synthetic compounds. Since transition metals—especially molybdenum and iron—are present in the nitrogenases, systems containing these metals are of particular interest. What the chemist wants is a defined system in which he can follow the reduction of the N_2 molecule step by step.

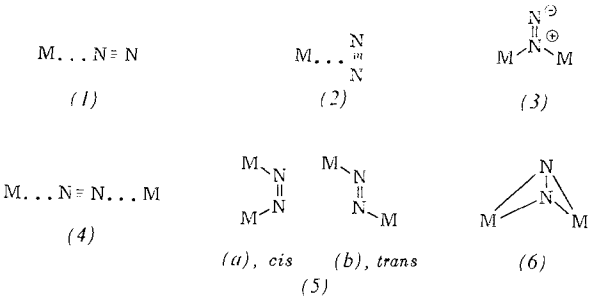
Isolable and unambiguously characterizable model substances thus appear especially important.

N_2-fixing chemical systems can be roughly divided into protic and aprotic. The impetus which led to the investigation of the aprotic group was the observation that Ziegler-Natta catalysts and similar compounds absorb nitrogen and reduce it to nitride-type products. The fundamental difference between these systems and the nitrogenases lies in their aprotic character: the hydrolytic susceptibility of the organometallic components (*e. g.* Grignard reagents, alkylaluminum derivatives, alkali metal naphthalides) makes rigorous exclusion of water essential. The reactions which proceed in such systems are therefore reminiscent of the well-known reaction between nitrogen and lithium to give Li_3N. Coupled with the fact that, with few exceptions, unambiguously characterized compounds could not be isolated, this proved to be a disadvantage compared with the second group, the protic systems. These are capable of existing in aqueous or other proton-containing solvents, and the reaction with molecular nitrogen yields well-defined products, the N_2 complexes, which will be discussed below[1].

2. Definition, Nomenclature, Possible Modes of Bonding



Dinitrogen complexes are coordination compounds which contain the N_2 molecule as ligand. The first example of this class of compounds was discovered by *Allen* and *Senoff* in 1965[2]. The attempted synthesis of ammine complexes from $RuCl_3$ and hydrazine hydrate did not yield the expected $[Ru(NH_3)_6]^{2\oplus}$ ion but the stable complex $[(NH_3)_5RuN_2]Cl_2$ instead.

Long before this discovery, the realization that N_2-assimilating bacteria require molybdenum in order to fix atmospheric nitrogen had led to the hypothesis that dinitrogen-transition metal complexes play a part in this process[3]. However, numerous unsuccessful attempts to prepare such complexes as well as subsequent theoretical considerations led to the assumption that these compounds were not stable.

The isolation of the first stable N_2 complex, and the hope of obtaining information on N_2 assimilation through the study of this new class of compounds, stimulated an intensive search for further examples. The result is a respectable number of new dinitrogen complexes; compared with the hundreds of complexes formed by the isoelectronic carbon monoxide, however, they must still be considered a rarity.

According to the IUPAC rules[4a], the N_2 molecule is named "dinitrogen" when it is a formally uncharged ligand in coordination compounds. Other proposals such as "nitrogenyl" (by analogy with "carbonyl"), "nitrogeno", or "nitrogen" should therefore be avoided.

In principle, several possibilities are conceivable for the linkage between dinitrogen and metals (Scheme 1). These are in particular: terminal ("end-on") bonding [*(1)*], lateral ("side-on", or "edge-on") bonding [*(2)*], bridge bonding *via* one of the N atoms [*(3)*], terminal bridge bonding *via* both N atoms with a metal atom on each nitrogen [*(4)*, *(5)*] or two metal atoms on each nitrogen [*(6)*]. *(1)* and *(3)* correspond to the bonding in terminal and bridged carbonyl complexes respectively, *(2)* is comparable to the bonding in acetylene complexes. In *(1)*, *(2)*, and *(4)* the triple bond in the N_2 molecule is largely retained, but not so in *(3)*, *(5)*, and *(6)*. *(5)* is therefore to be regarded as a complex of the doubly deprotonated diimine HN=NH, and *(6)* as a fully deprotonated hydrazido complex, rather than as dinitrogen complexes.

Scheme 1. Linkage possibilities of the N_2 ligand.

So far, only bonds of types *(1)*, *(4)*, and *(6)* have been unequivocally demonstrated in N_2 complexes; *(2)* has been postulated. The structural unit *(6)* is present in the complex $[\{(PhLi)_3Ni\}_2N_2 \cdot 2Et_2O]_2$[*]. Here the two Ni atoms and the two atoms of the N_2 molecule occupy the corners of a distorted tetrahedron; two such $[Ni_2N_2]$ units are bridged *via* two Li atoms. A side-on π bond between the N_2 molecule and the metal centers is considered as a possibility; accordingly, ethylene readily displaces the N_2 ligand from the complex. The length of the N—N bond was found by X-ray structure analysis to be 1.35 Å, the highest value yet encountered in a N_2 complex. This value approaches that of an N—N single bond (1.47 Å) and points to a considerable activation of the N_2 molecule[4b].

A Pt complex, formed from *cis*-$[PtCl_2(PPh_3)_2]$ and hydrazine, contains the structural unit *(3)* in protonated form[5] (Fig. 1).

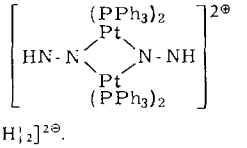


Figure 1. Schematic structure of $[\{Pt(PPh_3)_2N_2H\}_2]^{2\oplus}$.

Molecules related to terminal N_2 complexes include N_2O, HN_3, CH_2N_2, $C_6H_5N_2^{\oplus}X^{\ominus}$, and 1,10-$B_{10}H_8(N_2)_2$, which may be considered as an internal diazonium salt[6]. These nonmetallic compounds containing the N_2 grouping are not discussed here, nor are substances such as azobenzene, Ph—N=N—Ph, which are only formally related to bridged N_2 complexes.

3. Preparation of Nitrogen Complexes

Table 1 summarizes the data on unequivocally characterized N_2 complexes. Apart from chloride and ammonia, phosphanes and hydride ions appear remarkably often as coligands of N_2. It was not until very recently that N_2 complexes were synthesized with arene and CO ligands. In view of the high sulfur content of the nitrogenases, it is surprising that so far only one very unstable and poorly characterized N_2

[*] For abbreviations see Table 1, footnote [a].

complex with a sulfur-containing ligand is known: *trans*-$[Mo(N_2)_2(PMe_2Ph)_2\ (PhSCH_2CH_2SPh)]$.

Table 1 does not include N_2 complexes obtained by matrix isolation at low temperatures (*ca.* −196 °C), *e.g.* CrN_2, NiN_2, PtN_2[7], $Ni(N_2)_n$, $Pd(N_2)_m$[8], and $Ni(CO)_3N_2$[9].

Thus far three possibilities exist for the preparation of N_2 complexes:

1) Direct reaction of N_2 with a metal complex, frequently under strongly reducing conditions.

2) Conversion of a metal complex with ligands containing N—N bonds, *e.g.* N_2H_4 or $N_3^{\ominus}$.

3) Formation of an N_2 triple bond in a metal complex by reaction of ligands such as NH_3 with a nitrogen-containing reagent, *e.g.* HNO_2.

3.1. Direct Methods

A metal complex in the presence of excess ligand is reduced under N_2 by metals, metal amalgams, or hydrides.

$$[WCl_4(PMe_2Ph)_2] + Na/Hg \xrightarrow{N_2} [W(N_2)_2(PMe_2Ph)_4] \quad (1)$$

$$[MoCl_4(PMe_2Ph)_2] + Na \xrightarrow[\text{toluene}]{N_2} [Mo(N_2)_2(PMe_2Ph)_4] \quad (2)$$

$$[FeHCl(depe)_2] + NaBH_4 \xrightarrow[\text{acetone}]{N_2} [FeH(N_2)(depe)_2]BH_4 + NaCl \quad (3)$$

Alkylmetal compounds may also be used as reducing agents. Presumably they introduce an alkyl group into the metal complex; the ensuing olefin elimination produces a hydride complex which then reacts with the N_2. Suitable reactants include $AlEt_2(OEt)$, $AlEt_3$, and $Al(iBu)_3$. $AlMe_3$ yields mainly methyl complexes.

$$[Co(acac)_2] + 3\,PPh_3 + AlEt_2(OEt) \xrightarrow[\text{toluene}]{N_2} [CoN_2(PPh_3)_3] + [CoH(N_2)(PPh_3)_3] \quad (4)$$

$$[Mo(acac)_3] + 2\,\text{diphos} + Al(iBu)_3 \xrightarrow[\text{toluene}]{N_2} \textit{trans}\text{-}[Mo(N_2)_2(\text{diphos})_2] \quad (5)$$

$$[Ni(acac)_2] + PCy_3 + AlMe_3 \xrightarrow{N_2} [\{(PCy_3)_2Ni\}_2N_2] \quad (6)$$

Labile ligands in metal complexes can be displaced by N_2. These are the clearest reactions of molecular nitrogen; they proceed under mild conditions and are frequently reversible.

$$[CoH_3(PPh_3)_3] + N_2 \overset{EtOH}{\rightleftharpoons} [CoH(N_2)(PPh_3)_3] + H_2 \quad (7)$$

$$[Ru(NH_3)_5H_2O]^{2\oplus} + N_2 \overset{H_2O}{\rightleftharpoons} [Ru(NH_3)_5N_2]^{2\oplus} + H_2O \quad (8)$$

$$2[C_5H_5Fe(\text{dmpe})\text{acetone}]^{\oplus} + N_2 \xrightarrow{\text{acetone}} [\{C_5H_5Fe(\text{dmpe})\}_2N_2]^{2\oplus} + 2\,\text{acetone} \quad (9)$$

$$[(hmb)Cr(CO)_3] + THF \xrightarrow{h\nu} [(hmb)Cr(CO)_2THF] + CO \quad (10a)$$

$$2[(hmb)Cr(CO)_2THF] + N_2 \xrightarrow{THF} [\{(hmb)Cr(CO)_2\}_2N_2] + 2THF \quad (10b)$$

In some cases the intermediates cannot be isolated but immediately react further with N_2, as in the reaction according to eqs. (10a) and (10b).

3.2. Conversion of a Ligand with N—N Bonds into N_2

Most systematic syntheses of N_2 complexes were successful by this method.

$$\textit{trans}\text{-}[Ir(CO)Cl(PPh_3)_2] + PhCON_3 \xrightarrow[CHCl_3]{0\,^{\circ}C} \textit{trans}\text{-}[Ir(N_2)Cl(PPh_3)_2] + PhCONCO \quad (11)$$

$$[(PPh_3)_2Cl_2Re(O)N{=}N{-}CPh] + 2\,PPh_3 \xrightarrow{MeOH} \textit{trans}\text{-}[ReCl(N_2)(PPh_3)_4] + HCl + PhCO_2Me \quad (12)$$

$$[C_5H_5Mn(CO)_2N_2H_4] + 2H_2O_2 \xrightarrow[-40\,^{\circ}C]{Cu^{2\oplus}/THF} [C_5H_5Mn(CO)_2N_2] + 4H_2O \quad (13)$$

$$[RuCl(das)_2N_3]PF_6 + NOPF_6 \longrightarrow [RuCl(N_2)(das)_2]PF_6 + \text{by-products} \quad (14)$$

3.3. Formation of an N_2 Ligand from an N_1 Ligand

Ammine complexes can be diazotized with nitrous acid, but this method is of very limited application.

$$[Os(NH_3)_5N_2]^{2\oplus} + HNO_2 \rightarrow \textit{cis}\text{-}[Os(NH_3)_4(N_2)_2]^{2\oplus} + 2H_2O \quad (15)$$

4. Structure of Dinitrogen Complexes

4.1. Molecular Structure

That the metal-N—N or metal-N—N-metal unit in terminal N_2 complexes is approximately linear is apparent from the strong IR absorption of the N_2 stretching vibration; a side-on linkage of the N_2 ligand, as in ethylene or acetylene complexes, would produce only weak IR absorption. Clear evidence for a linear arrangement is provided by X-ray structure analysis (Fig. 2), although accurate determination of bond lengths failed in many cases owing to disorder phenomena.

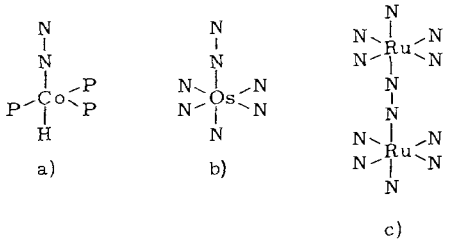

Figure 2. Schematic structures of (a) $[CoH(N_2)(PPh_3)_3]$, (b) $[Os(NH_3)_5N_2]^{2\oplus}$, and (c) $[\{Ru(NH_3)_5\}_2N_2]^{4\oplus}$.

Table 2 summarizes the most important data.

The N—N distances of coordinatively bound dinitrogen are only marginally greater than in the free N_2 molecule. The complex $[\{(PhLi)_3Ni\}_2N_2 \cdot 2Et_2O]_2$[4b], which contains the structural unit *(6)* (Scheme 1) and in which $d_{N-N} = 1.35$ Å, is an exception, as is $[ReCl(PMe_2Ph)_4{-}N_2{-}MoCl_4(OMe)]$ with $d_{N-N} = 1.21$ Å[67b]. For comparison, the length of the NN double bond (in diazomethane) is 1.24 Å and that of the NN single bond (in hydrazine) is 1.47 Å[48].

Since the nitrogenases also reduce acetylene (to ethylene), it should be pointed out that the structures of (end-on) N_2 complexes bear not the slightest resemblance to the acetylene complexes in which the two C atoms of the C_2H_2 are linked to the metal in the same manner. Instead, they are similar to acetylide complexes, *e.g.* $K_2[Cr(CO)_3(C{\equiv}CH)_3]$[56].

4.2. Bonding

The structures of N_2 complexes largely resemble those of the analogous isoelectronic CO complexes, thus revealing similarities in electronic structure. However, while carbon monoxide forms numerous mono- and poly-CO complexes, only a few monocomplexes are known for dinitrogen; among the higher complexes, only bis-N_2 species have been reported. The reason for this, and for the generally greater stability of CO complexes, lies in the electronic differences between N_2 and CO.

The following discussion of the bonding properties of N_2 and CO should throw some light on this aspect. Figure 3 shows the molecular orbital scheme of dinitrogen, as derived

Table 2. Molecular data for some dinitrogen compounds.

from UV[57] an photoelectron spectra[58], as well as from theoretical calculations[59].

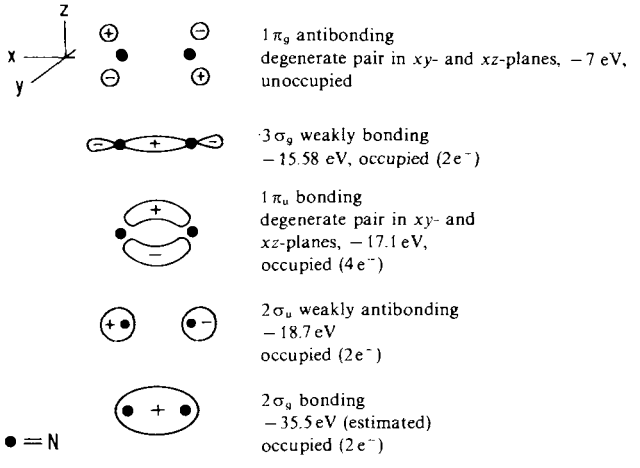

Figure 3. Molecular orbital scheme of dinitrogen.

The exceptional stability of dinitrogen compared to other diatomic molecules is a consequence of its low-lying three highest occupied bonding molecular orbitals. The actual HOMO is a bonding $3\sigma_g$ orbital of very low energy. Hence the ionization energy of N_2 is considerable (15.58 eV), approximating to that of argon (15.75 eV). The LUMO, $1\pi_g$, lies 8.6 eV above the $3\sigma_g$ orbital, *i. e.* so high that it can be occupied at best by electrons from alkali metals and other strongly electropositive metals. The absence of orbitals in the energy range between the two, *i. e.* precisely that range in which the occupied and unoccupied orbitals participating in chemical reactions are located, largely explains the low reactivity of the N_2 molecule.

While the MO scheme of carbon monoxide is very similar to that of dinitrogen, essential differences are noted in the much lower energetic stability of the highest occupied σ and of the lowest unoccupied π^* orbitals (−14.0 and −6 eV respectively) and in the smaller energy difference between these two orbitals, which is lower by 0.6 eV. In addition, the highest occupied σ orbital in CO possesses weak antibonding character; this can be deduced also from the shortening of the C—O bond from 1.128 to 1.115 Å in the ionization $CO \rightarrow CO^{\oplus}$. The ionization $N_2 \rightarrow N_2^{\oplus}$, on the other hand, results in a lengthening of the N—N bond from 1.098 to 1.117 Å[57]. Clearly the electron distribution in CO and N_2 will also differ because carbon and oxygen have different radii, electronegativities, *etc.*, whereas dinitrogen is a homonuclear molecule. CO possesses a small dipole moment ($\mu = 0.2$ D). Calculations of the electron-density distribution also show that the C atom exhibits a greater lone electron pair charge density than the O atom[60].

The metal-dinitrogen bond in N_2 complexes can be described according to the MO method by overlapping of the $3\sigma_g$ and $1\pi_g$ orbitals of the dinitrogen with suitable d orbitals of the metal (Fig. 4).

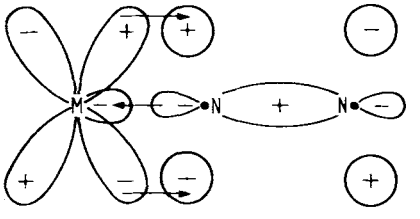

Figure 4. Scheme of the M—N_2 bond.

As in the case of the M—CO bond, a donor bond is postulated involving the $3\sigma_g$ electrons of dinitrogen and an unoccupied metal d orbital. The resulting increased electron density at the metal is reduced by back-bonding from nonbonding occupied metal d orbitals to the antibonding $1\pi_g$ orbital of the dinitrogen. The result is a synergetic σ-π double bond, *i. e.* a strengthening of the σ bonding leads to the simultaneous strengthening of the π bonding.

This type of bonding explains why N_2 complexes are less stable than CO complexes. Most metal complexes possess d orbitals (*e. g.* e_g and t_{2g} orbitals) whose energies correspond better to those of the σ and π^* orbitals of CO than to those of the N_2 molecule. This enhanced interaction increases the stability of the CO complexes.

The bond scheme illustrated in Figure 4 also explains why electronic variations result in largely analogous effects in N_2 and CO complexes.

What physical changes are to be expected in the N_2 molecule as a result of coordination if the above model of the M—N_2 bond is correct?

The N—N bond should become weaker on complex formation, since the electrons of the M—N σ bond come from a bonding orbital of the N_2 and those of the M—N π bond are transferred to an antibonding N_2 orbital. However, this conclusion has recently been disputed. According to theoretical calculations, the removal of electrons from the $3\sigma_g$ orbital should reduce the electron repulsion between the two N atoms and thereby strengthen the N_2 σ bond[61]. The weakening of the N_2 triple bond would then be mainly due to the π back-bonding.

The overall weakening of the N_2 triple bond and consequent activation of the N_2 molecule on complexing are clearly demonstrated by the marked drop in the N_2 stretching frequency, which falls by several hundred wave numbers from the value of 2331 cm^{-1} recorded for the free molecule (Raman spectrum). Furthermore, the N_2 molecule in terminal N_2 complexes is subject to strong electronic polarization, which accounts for the high intensity of the ν_{N_2} absorption in the IR spectrum. This polarization is also confirmed by the ESCA spectra of N_2 complexes. Metal-bound and terminal N atoms exhibit separate N-1s emissions, *e. g.* at 399.9 and 397.9 eV for $[ReCl(N_2)(diphos)_2]$, whereas the emission of the free N_2 molecule is observed at 411 eV. These values afford a charge difference of approximately 0.4 e between the two N atoms, the terminal one bearing the greater negative charge[62,63].

Attempts to determine the properties of the N_2-bonding coordination site in N_2 complexes have been based primarily on comparative studies, and particularly on systematic variation of the coligands of dinitrogen. However, since the stability limits of N_2 complexes are very narrow owing to the unfavorable energy of the N_2 orbitals, only a few examples are available for studying the effect of the variation of coligands on the metal-N_2 bond. Thus the reaction according to eq. (11) can only be effected with triphenylphosphane; tris(*p*-tolyl)phosphane or methyldiphenylphosphane no longer yield isolable complexes[64].

Experience has shown that the central metal of an N_2-bonding complex must exist in a low oxidation state and possess a relatively high electron density. A fitting example is $[Ru(NH_3)_5CO]^{2\oplus}$, the CO analog of $[Ru(NH_3)_5N_2]^{2\oplus}$[65]. Despite the formal double positive charge on the ruthenium, the CO compound exhibits one of the lowest ν_{CO} frequencies (1919 cm^{-1}) ever observed in terminal CO complexes.

The effect of electron density is also apparent from the series $[(benzene)Cr(CO)_2N_2]$ (ν_{N_2} = 2145 cm^{-1}), $[(mesitylene)Cr(CO)_2N_2]$ (ν_{N_2} = 2132 cm^{-1}), and $[(hexamethylbenzene)Cr(CO)_2N_2]$ (ν_{N_2} = 2112 cm^{-1}). Introduction of the "electron-donating" CH_3 substituents into the benzene ring increases the electron density at the chromium. As a result the frequency of the N_2 stretching vibration decreases; the bond scheme in Figure 4 indicates that this phenomenon should be associated with a strengthening of the M—N bond. Accordingly, the stability of the N_2 complexes increases in the above sequence[11].

N_2 and CO ligands influence the central metal in very similar fashion; thus, both exert approximately the same *trans* effect on the Ir—X bond in the complexes *trans*-$[IrX(X')(PPh_3)_2]$ (X = Cl, Br; X' = N_2, CO)[64]. The much-discussed question of the σ-donor and π-acceptor properties of N_2 and CO has not been finally resolved. Mössbauer spectra of *trans*-$[FeH(X)(depe)_2]BPh_4$ (X = N_2, CO) suggest that CO is a better σ-donor and π-acceptor ligand than N_2[22]. The same can be concluded from IR intensity measurements on analogous CO and N_2 complexes[66]. Such behavior can also be deduced from the electronic properties, *i. e.* the energy of the molecular orbitals, of the two molecules. However, for the compounds $[C_5H_5M(CO)_2N_2]$ (M = Mn, Re) and $[ArCr(CO)_2N_2]$ (Ar = benzene, mesitylene, and hexamethylbenzene) it appears from the ^{1}H-NMR and IR spectra that both the cyclic ligands and the CO groups must accommodate a greater electron density in the N_2 complexes than in the corresponding tricarbonylmetal complexes. In these compounds therefore the ratio of σ-donor to π-acceptor strength must be greater for dinitrogen than for carbon monoxide[11,16,17].

Surprisingly, almost the same N_2 stretching vibration frequency is often observed in dinuclear N_2 complexes as in the corresponding mononuclear complexes; examples include $[\{Ru(NH_3)_5\}_2N_2]^{4\oplus}$ (2100 cm^{-1}) and $[Ru(NH_3)_5N_2]^{2\oplus}$ (2130 cm^{-1}). Since the N—N triple bond of the N_2 molecule is weakened by coordination to one transition metal, bonding to two transition metals was expected to result in further weakening. This expectation is fulfilled only in some cases. An explanation for this phenomenon is provided by the bonding scheme of the M—N—N—M bond. If the σ bond component is regarded as largely constant, and the changes in M—N and N—N bonds are attributed mainly to variations in the π system, the scheme shown in Figure 5 applies to the π bonds of complexes with approximate fourfold symmetry, such as the complex $[\{Ru(NH_3)_5\}_2N_2]^{4\oplus}$ or the complex $[(PMe_2Ph)_4ClRe—N_2—CrCl_3(THF)_2]$[55,67a].

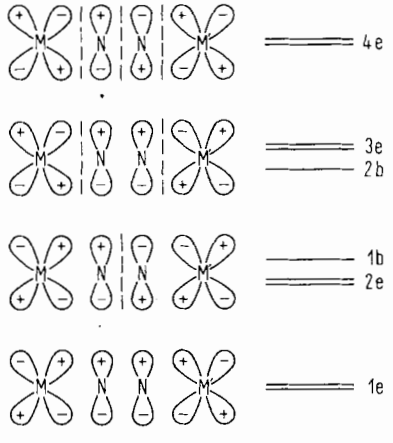

Figure 5. Qualitative molecular orbital scheme for dinuclear N_2 complexes with approximate fourfold symmetry.

The four-center molecular orbitals indicated in Figure 5 are obtained by linear combination of Md_{xz}, Np_x, and $M'd_{xz}$ orbitals. The *z*-axis is determined by the σ bond. A set of energy levels, whose energies increase with increasing nodal number of the molecular orbitals, corresponds to the molecular orbitals. Since, in addition to the orbitals shown, there exists an equivalent set of π molecular orbitals, formed from the Md_{yz}, Np_y, and $M'd_{yz}$ orbitals, the energy levels are degenerate. For the sake of simplicity they are designated as 1e, 2e, *etc.* The δ bonds formed from the Md_{xy} orbitals contribute

practically nothing to the bonding; they correspond to the 1b and 2b levels. For energetic reasons the 1e and 4e levels correspond largely to the bonding and antibonding π molecular orbitals $1\pi_u$ and $1\pi_g$, respectively, of the N_2 molecule in Figure 3. The 2e and 3e levels possess mainly metal character, as do the 1b and 2b levels.

The strengths of the M—N—N—M and of the N—N bonds thus depend chiefly on the occupancy of the e levels. Four electrons of the two N atoms fill the 1e level. This possesses bonding character for the N atoms; owing to its partial metal character, however, a weaker N—N bond results than in the free N_2 molecule. The progressive occupation of higher levels with the 12d electrons of the two $Ru^{2\oplus}$ centers (M = M') leads to a marked weakening of the N—N bond in the 2e level, as the orbitals are antibonding with respect to the N—N bond. The filling of the 1b and 2b levels leaves the N—N bond unaffected, while the occupancy of the 3e level strengthens the N—N bond since the orbitals are bonding with respect to the N atoms. Altogether there are thus five bonding filled orbitals—the bonding character of the filled M—N—N—M σ orbital must of course also be taken into account here—as against two antibonding filled orbitals with respect to the N—N bond: there is therefore hardly any difference between the N_2 bonding in $[\{Ru(NH_3)_5\}_2N_2]^{4\oplus}$ and that in $[Ru(NH_3)_5N_2]^{2\oplus}$. However, if the metal atoms do not possess sufficient electrons to fill the 2b and especially the 3e levels, a much reduced ν_{N_2} frequency is observed compared to the mononuclear complex $[ReCl(N_2)(PMe_2Ph)_4]$ ($\nu_{N_2} = 1925\ cm^{-1}$); examples include $[ReCl(PMe_2Ph)_4—N_2—CrCl_3(THF)_2]$ ($\nu_{N_2} = 1875\ cm^{-1}$), in which the Re^{I} and Cr^{III} centers can contribute a maximum of nine electrons, and $[ReCl(PMe_2Ph)—N_2—TaCl_5]$ ($\nu_{N_2} = 1695$), in which the metal atoms can contribute only six electrons for occupation of the levels.

This effect is particularly well illustrated in $[ReCl(PMe_2Ph)_4—N_2—MoCl_4(OMe)]$. This complex, containing one more electron, exhibits a ν_{N_2} frequency of $1660\ cm^{-1}$. In accordance with the low ν_{N_2} frequency, X-ray structure analysis shows the long N—N distance of 1.21 Å for the Re—N—N—Mo unit[67b].

Figure 5 also illustrates the difficulty of reducing the N_2 unit in such complexes. The electrons taken up first fill the 2b and 3e levels and thereby strengthen the N_2 bond. This is clearly no longer the case when a lowering of the fourfold symmetry resolves the degeneracy of the e levels. Such may be the case in the Fe and Ti complexes mentioned in Section 5.4.

Most of the N_2 complexes isolated so far obey the inert gas rule and are diamagnetic. Exceptions include $[CoN_2(PPh_3)_3]$ and $[\{(C_5H_5)_2Ti\}_2N_2]$, as well as adducts of Lewis acids to $[ReCl(N_2)(PMe_2Ph)_4]$.

5. Chemical Reactions of Dinitrogen Complexes

The discovery of the $[(NH_3)_5RuN_2]^{2\oplus}$ complex nurtured the hope that a pathway for definite reduction of the N_2 molecule under mild conditions had been found, a hope that was not at first fulfilled.

Attempts to reduce the complex-bound N_2 ligand usually results in its liberation. This reaction becomes easier with increasing thermal lability of the N_2 complex; the residual coordinatively unsaturated complexes can be stabilized by the addition of other ligands, *e.g.* H_2O, NH_3, pyridine, PPh_3, or solvent molecules. In the absence of such donors, the resulting complexes are frequently suitable as highly reactive catalysts for the polymerization of olefins. These N_2 complexes thus bear some resemblance to aliphatic diazo compounds which yield the reactive carbenes on loss of N_2.

5.1. Oxidation

N_2 complexes are particularly sensitive to oxidizing agents. Strong oxidizing agents are therefore frequently used for the quantitative determination of N_2[68].

$$[OsCl_2(N_2)(PEt_2Ph)_3] + {}^1/_2Cl_2 \rightarrow [OsCl_3(PEt_2Ph)_3] + N_2 \quad (16)$$

If the N_2 complexes are very stable they can sometimes be oxidized by one unit without loss of the N_2 ligand[69]:

$$[ReCl(N_2)(diphos)_2] + {}^1/_2Cl_2 \rightarrow [ReCl(N_2)(diphos)_2]Cl \quad (17)$$

The oxidized complexes are less stable than the starting compounds, in agreement with the increase of 80—100 cm^{-1} in the ν_{N_2} frequency which indicates a weakened M—N bond. Some complexes undergo reversible electrochemical oxidation, *e.g.* the $[(NH_3)_5Ru—N_2—Os(NH_3)_5]^{4\oplus}$ ion (0.1 V, rotating platinum electrode) to the ion with a fivefold positive charge[70]. Generally, however, the oxidized complexes undergo rapid secondary reactions with loss of the N_2 ligand.

5.2. Displacement or Exchange Reactions

Very stable N_2 complexes can undergo displacement reactions in which the M—N_2 unit is retained. These include the diazotization of the exceptionally stable $[Os(NH_3)_5N_2]^{2\oplus}$ ion to the $[Os(NH_3)_4(N_2)_2]^{2\oplus}$ ion[32]. (The $[Os(NH_3)_5N_2]^{2\oplus}$ ion is so stable that it resists several hours' boiling in conc. HCl.) The Re—N_2 unit in $[ReCl(N_2)(PMe_2Ph)_4]$ is also very stable and is still retained on the displacement of all the phosphane ligands[18].

$$trans\text{-}[ReCl(N_2)(PMe_2Ph)_4] + 2\,diphos \rightarrow trans\text{-}[ReCl(N_2)(diphos)_2] + 4\,PMe_2Ph \quad (18)$$

More numerous, however, are the reactions resulting in displacement of the N_2 ligand. Among them, the reversible exchange reactions of the N_2 ligand with H_2 and water [eqs. (7) and (8) respectively] are of significance for the course of N_2 assimilation. Ammonia too—the final stage of N_2 assimilation—can displace the N_2 group in dinitrogen complexes, sometimes even reversibly:

$$[CoH(N_2)(PPh_3)_3] + NH_3 \rightleftarrows [CoH(NH_3)(PPh_3)_3] + N_2 \quad (19)[70b]$$

$$[Ru(NH_3)_5N_2]^{2\oplus} + NH_3 \rightarrow [Ru(NH_3)_6]^{2\oplus} + N_2 \quad (20)$$

The exchange reactions of the Ru system have been very thoroughly studied, especially by thermochemical methods. The heat of reaction $\Delta H \mp -18.3 \pm 0.9$ kcal/mol found for eq. (8) clearly indicates the strong tendency to form the $[Ru(NH_3)_5N_2]^{2\oplus}$ ion. The greater stability of the analogous CO compound is again evident from the heat of reaction[73]:

$$[Ru(NH_3)_5H_2O]^{2\oplus} + CO \rightarrow [Ru(NH_3)_5CO]^{2\oplus} + H_2O \quad (21)$$
$$\Delta H = -36.1 \pm 1.6 \text{ kcal/mol}$$

Furthermore, the N_2 ligand in $[Ru(NH_3)_5N_2]^{2\oplus}$ can rotate in the complex, the metal-bound and the terminal N atoms interchanging places. This is deduced from the isomerization of $[(NH_3)_5Ru-{}^{14}N\equiv{}^{15}N]^{2\oplus}$ to $[(NH_3)_5Ru-{}^{15}N\equiv{}^{14}N]^{2\oplus}$, which proceeds at 25 °C in aqueous solution with a half-life of *ca.* 2 h and is approximately 45 times faster than the exchange reaction with H_2O according to eq. (8). Thus isomerization proceeds without dissociation of the N_2 ligand; the *dihapto* structure *(2)* of the M—N_2 group in Scheme 1 is postulated as a transition state[71]. However, recent studies of the Ru—N vibrations[72a] cast doubt upon this hypothesis, since the basic assignment of the ν_{Ru-N} vibration to the Ru—N_2 unit could be wrong. *Monohapto-dihapto* bonding isomerism for the N_2 ligand was recently demonstrated by ^{15}N-NMR and IR spectroscopy in $[(C_5Me_5)_2TiN_2]$ at −61 °C[72b].

5.3. Lewis Base Reactions

As explained in Section 4.2, the terminal N atom in the M—N—N unit is probably negatively polarized. Mononuclear N_2 complexes can therefore react as Lewis bases. This leads to symmetrical N_2 complexes

$$[(NH_3)_5RuN_2]^{2\oplus} + [(NH_3)_5Ru(H_2O)]^{2\oplus} \rightarrow [(NH_3)_5Ru-N_2-Ru(NH_3)_5]^{4\oplus} + H_2O \quad (22)$$
$$\Delta H = -6.7 \text{ kcal/mol}$$

as well as asymmetric N_2 complexes:

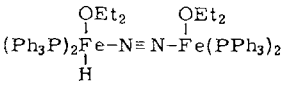
$$[(NH_3)_5RuN_2]^{2\oplus} + [(NH_3)_5Os(H_2O)]^{2\oplus} \rightarrow [(NH_3)_5Ru-N_2-Os(NH_3)_5]^{4\oplus} + H_2O \quad (23)$$

$$[(PMe_2Ph)_4ClReN_2] + [CrCl_3(THF)_3] \rightarrow [(PMe_2Ph)_4ClRe-N_2\cdots CrCl_3(THF)_2] + THF \quad (24)$$

According to eq. (24) a series of asymmetric N_2 complexes can be prepared in which the $CrCl_3(THF)_2$ grouping is replaced by $TiCl_3(THF)_2$, PF_5, $AlEt_3$, $TaCl_5$, $NbCl_5$, and many other Lewis acids[40].

In principle, the same reactions are observed for N_2-bridged complexes as for terminal N_2 complexes. As a further reaction type dissociation can yield terminal N_2 complexes, *e. g.* according to eq. (25):

$$[(PCy_3)_2Ni-N_2-Ni(PCy_3)_2] \rightleftharpoons [(PCy_3)_2NiN_2] + [Ni(PCy_3)_2] \quad (25)$$



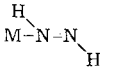
5.4. Reduction

As mentioned at the beginning of Section 5, most attempted reductions of N_2 complexes result in a loss of the N_2 unit. However, this is not always the case: $[CoN_2(PEt_2Ph)_3]$, for instance, can be reduced to an anionic N_2 complex:

$$[CoN_2(PEt_2Ph)_3] + Na/Hg \rightarrow Na[N_2Co(PEt_2Ph)_3] \quad (26)$$

Neither loss nor reduction of the N_2 ligand occur in this reaction.

Greater interest attaches to the reactions of some complexes isolated as solids from nonaqueous systems of the Ziegler-Natta type. Although they have not yet been definitely characterized, they certainly contain an N—N unit. Solvolysis of these complexes results in evolution of N_2 and in partial reduction of the N_2 ligand to hydrazine and ammonia. Thus a red complex isolated from the $(PPh_3)_2FeCl_3$/iso-C_3H_7MgCl/N_2/ether system has been postulated to have the structure:



(If this structure is correct then the complex does not possess fourfold symmetry, in contrast to the Ru and Re complexes discussed in Section 4.2.) Solvolysis of this complex with HCl/ether at −50 °C yields 10% of hydrazine alongside decomposition products and N_2[42].

A deep blue complex of formula $[\{(C_5H_5)_2Ti\}_2N_2]$, for which structure *(5a)* in Scheme 1 is postulated, can be isolated from the $(C_5H_5)_2TiCl/CH_3MgI/N_2$ system. Solvolysis of this complex with methanolic HCl yields mainly dinitrogen; however, hydrazine and ammonia also appear as minor products[39a].

While these experiments show that it is possible in principle to reduce complexed dinitrogen, they have the disadvantage that with the compounds mentioned it is not possible to convert a definite N_2 complex into a definite N_xH_y complex ($x = 1$ or 2, $y = 1$, 2, 3, or 4). This was first accomplished by the reaction of well-defined bis-(dinitrogen) complexes of molybdenum and tungsten with concentrated HCl[74]:

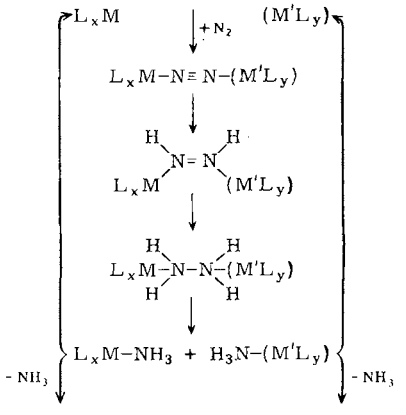
$$[M(N_2)_2(diphos)_2] \xrightarrow{+HCl} [MCl_2(N_2H_2)(diphos)_2] + N_2 \quad (27)$$

One N_2 ligand is eliminated, the central metal is oxidized, and the other N_2 ligand is reduced to an N_2H_2 moiety. The authors favor a diimine complex of the type

for the M—N_2H_2 group. However, IR and ^{1}H-NMR spectroscopic data do not rule out a metal hydrazido structure M=N—NH_2[82].

The formation of N—C bonds in the reaction of N_2 complexes with *e. g.* acyl chlorides had been observed previously[20b-20d].

A metal-hydrazido structure has been confirmed for $[W(N_2H_2)Cl(diphos)_2]BPh_4$ by X-ray structure analysis. The observed relatively short N—N distance of 1.37 Å suggests partial double bond character of the M—N—N bond as in $[W\cdots N\cdots NH_2]^{\oplus}$[83].



6. Dinitrogen Complexes and Other Potential Intermediates of N_2 Assimilation

Coordination of dinitrogen to a metal was suspected to be the decisive step in N_2 assimilation long before the isolation of active nitrogenase extracts from natural sources and the synthesis of stable N_2 complexes. Biochemical studies have contributed greatly to our understanding of N_2 assimilation, but it has not been possible to isolate any intermediates. Even today, all we know for certain is that the process

starts with atmospheric nitrogen and yields ammonia. Recent years have seen the synthesis of model substances which enable the chemist to develop precise and experimentally verifiable concepts concerning the reduction of dinitrogen to ammonia.

It is unlikely that the N_2 molecule takes up six electrons and six protons and decomposes to ammonia in a single step; a stepwise reduction is much more probable. Study of the intermediates therefore acquires considerable significance because such information is indispensable for the simulation of N_2 assimilation *in vitro* and for the development of technical catalysts for reduction of gaseous dinitrogen, *e.g.* to hydrazine under normal conditions.

A series of mechanisms has been proposed in recent years for the reduction of dinitrogen with nitrogenases[75]. In accordance with biochemical data, the most likely alternatives postulate two-electron reduction steps and unaminously assume that the dinitrogen is reduced to ammonia *via* diimine and hydrazine (Scheme 2).

Scheme 2. Intermediates of N_2 reduction, greatly simplified.

According to this scheme, the first step in assimilation involves coordination of dinitrogen to one or two metal centers (the actual number has not yet been established). They may be the same or different (*e. g.* M = M′ = Mo or M = Mo, M′ = Fe) and in the resting phase, *i.e.* in the absence of dinitrogen, they probably exist as aquo complexes. Presumably, the oxidation state of the metal centers changes during reduction of the dinitrogen, *e. g.*

$L_xM^0 \rightarrow L_xM^I$ or L_xM^{II}

the reduced forms of the N_2 molecule possibly existing in deprotonated form, *e.g.* diimine as monoanion $[:\ddot{N}=\ddot{N}H]^{\ominus}$. Which of the steps postulated in the scheme have so far been verified *in vitro*?

1) Coordination of gaseous dinitrogen under physiological conditions is possible [*e.g.* eqs. (7)—(10)]. In the complexes isolated so far the dinitrogen is invariably bound in the end-on and never in the side-on mode.

2) Displacement of the end-product NH_3 by N_2 can be reproduced *e.g.* according to eq. (19).

3) Hydrazine complexes are well known. In addition, hydrazine is formed in the reduction of gaseous nitrogen with $V^{2\oplus}$ salts in alkaline solution[76] and by the hydrolysis of the Fe—N_2 and Ti—N_2 complexes mentioned in Section 5.4. The most conclusive argument for hydrazine as an intermediate, however, is probably the synthesis of the $[MCl_2(N_2H_2)(diphos)_2]$ (M = Mo, W) complexes according to eq. (27).

4) In Scheme 2, diimine complexes are postulated as intermediate stages. Until recently diimine was only known as an unstable intermediate, *e.g.* in organic hydrogenations with hydrazine, or as the decomposition product of HN_3, N_2H_4, or alkali metal tosylhydrazides at low temperatures (*ca.* −196 °C)[77–80]. Lately, however, it has been stabilized under normal conditions by complexation in [*trans*-$N_2H_2\{C_5H_5Mn(CO)_2\}_2$] and [*cis*-$N_2H_2\{Cr(CO)_5\}_2$].

These complexes are formed by the oxidation of hydrazine complexes[81,82]:

$$[C_5H_5Mn(CO)_2N_2H_4] \xrightarrow[-20\,^\circ C]{H_2O_2/Cu^{2\oplus}/THF} [trans\text{-}N_2H_2\{C_5H_5Mn(CO)_2\}_2] + [C_5H_5Mn(CO)_2N_2] + [C_5H_5Mn(CO)_2NH_3] \quad (28)$$

$$[\{(CO)_5Cr\}_2N_2H_4] + H_2O_2 \xrightarrow[Na_2SO_4/0^\circ C]{Cu^{2\oplus}/THF\cdot HCl} [cis\text{-}N_2H_2\{Cr(CO)_5\}_2] \quad (29)$$

The *trans* and *cis* structures of the diimine in the manganese and chromium complexes respectively are readily deduced from their IR spectra. The IR spectrum of [*cis*-$N_2H_2\{Cr(CO)_5\}_2$] is particularly clear. Since the typical absorptions of the $Cr(CO)_5$ groups are confined to the 2100—1800 and 800—350 cm^{-1} regions, bands outside these regions can be safely assigned to the N_2H_2 ligand vibrations. From group theory considerations, three IR-active vibrations ν_{as}(NH), δ_{as}(HNNH), and τ(HNNH) are anticipated for *trans*-N_2H_2, but five IR-active vibrations for *cis*-diimine [ν_{as} and ν_s(NH), δ_{as} and δ_s(HNNH), and ν(N=N)].

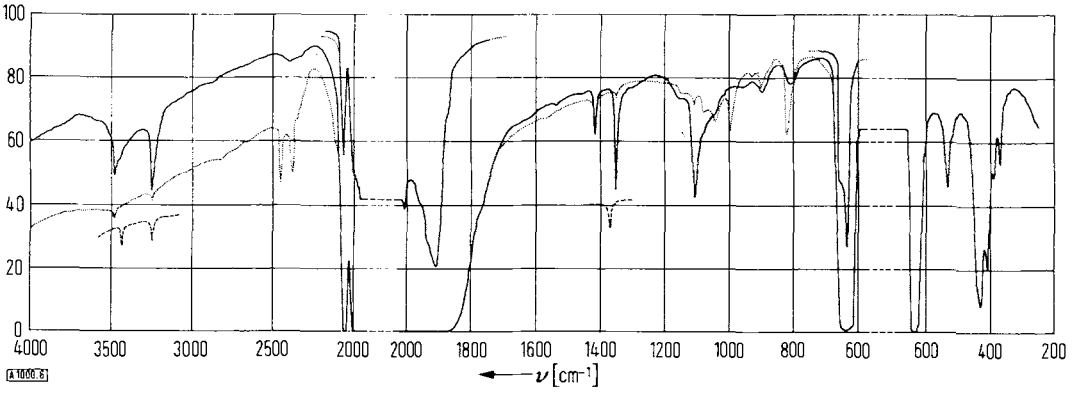


Figure 6. IR spectra (KBr) of $[N_2H_2\{Cr(CO)_5\}_2]$, ... $[N_2D_2\{(Cr(CO)_5\}_2]$, and $[^{15}N_2H_2\{Cr(CO_5\}_2]$ (only those regions that change compared with the spectrum of the N_2H_2 complex).

A glance at the IR spectrum of $[N_2H_2\{Cr(CO)_5\}_2]$ (Fig. 6) immediately shows that in the regions involved (4000—2100 and 1800—800 cm^{-1}) there are five absorptions, which in itself points to a *cis* structure for N_2H_2. Deuterium and ^{15}N-labeling confirm that the absorptions are in fact due to N_2H_2 vibrations and allow assignment of the absorption to vibrational forms of the diimine. Thus, it is seen that *e.g.* the absorption at 1415 cm^{-1} can only be due to the N—N stretching vibration, which, however, might be coupled to the Cr—N stretching vibrations[84].

What is extremely surprising in the synthesis of the diimine complexes is the fact that the tungsten-diimine complex also occurs in the *cis* form, although it is best prepared from the mononuclear hydrazine complex[85]:

$$[(CO)_5WN_2H_4] + H_2O_2 \xrightarrow[Na_2SO_4/0°C]{Cu^{2\oplus}/THF} [cis\text{-}N_2H_2\{W(CO)_5\}_2] + \text{by-products} \quad (30)$$

This could signify that in the complex *cis*-diimine is thermodynamically more stable than *trans*-diimine. A decision as to which of the two isomers is more stable in the free state has so far been impossible, both experimentally and by calculation[86]. The preferential formation of the *cis*-diimine complexes in the case of chromium and tungsten gains importance by the fact that reduction of substrates by nitrogenases most probably also proceeds stereospecifically in the *cis* position; thus, the reduction of C_2D_2 yields exclusively *cis*-deuterioethylene. As, furthermore, the diimine complexes undergo redox reactions under mild conditions in which N_2, N_2H_4, and NH_3 complexes are formed, they are suitable models for studying the intermediate stages in N_2 assimilation; just as the likely synchronous abstraction of two H atoms converts the binuclear chromium-hydrazine complex into the diimine complex, so the synchronous addition of two hydrogen atoms to a binuclear dinitrogen complex could reduce the latter to a *cis*-diimine complex.

7. Outlook for the Future

The first seven years of N_2 complex chemistry were marked by the search for new N_2 complexes and the failure to reduce the dinitrogen bound in them. Very recently a new development has begun to emerge. Now that it has been demonstrated experimentally that complex-bound dinitrogen can be reduced under relatively mild conditions and all the reduction states of the N_2 molecule have been identified, the prospects of finding a catalyst system allowing *in vitro* reproduction of the processes occurring in N_2 assimilation under mild conditions appear brighter than ever before.

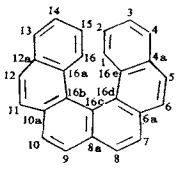
The Helicenes

By Richard Henri Martin[*]

"Helicene" is the name introduced by *Newman* in 1955, to describe the benzologues of phenanthrene in which the extra *ortho*-condensed rings give rise to a (regular) cylindrical helix. The pioneer work of *Newman* in this field cannot be overemphasized; his brillant synthesis and resolution of [6]helicene, achieved eighteen years ago, will remain as a landmark, for it opened the way to the study of a fascinating class of synthetic molecules. In the following review, an attempt is made to summarize the present state of our knowledge in this rapidly expanding field.

1. Introduction



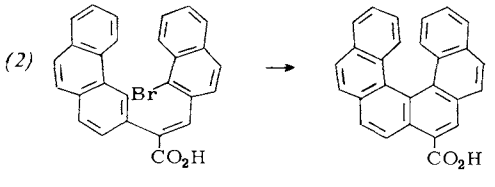
The helicenes are characterized by a helical structure made up of *ortho*-condensed aromatic rings, by the presence of a powerful inherently chiral chromophore, and by the possibility of interactions (*e.g.* electronic interactions) between overlapping aromatic rings. The scientific interest raised by these compounds is due to the unique combination of these three properties in a single molecule.

We shall deal first with the nomenclature of these compounds. The "class name" is "helicene"; "carbohelicenes" contain only carbon atoms in the skeleton, "heterohelicenes" at least one hetero-aromatic ring. In this review helicenes that are made up of benzene rings only are referred to as "all-benzene-helicenes"[**]. "Double helicenes" are helicenes containing

[*] Prof. R. H. Martin D. Phil.
Service de Chimie Organique, Fac. Sc.
Université Libre de Bruxelles
Av. F. D. Roosevelt, 50
B-1050 Bruxelles (Belgium)

[**] *Editorial note*: The expression "benzo-helicenes" is unsuitable, since the prefix "benzo" denotes, according to IUPAC rule A-21.4, the annelation of a benzene ring. The expressions "benzoid helicenes" or "benzenoid helicenes" could be misunderstood for the terms "benzoid" and "benzenoid" are usually used in the sense of "benzene-like" and/or "aromatic".

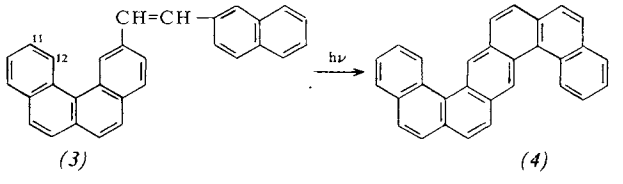
two distinct helicene structures which can be either of the same or of opposite helicity. In "bihelicenyls", two helicenyl residues are coupled by a single bond. For the sake of simplicity we shall adopt *Newman*'s suggestion for the numbering of the helicene skeletons [see formula *(1)*].



(1)

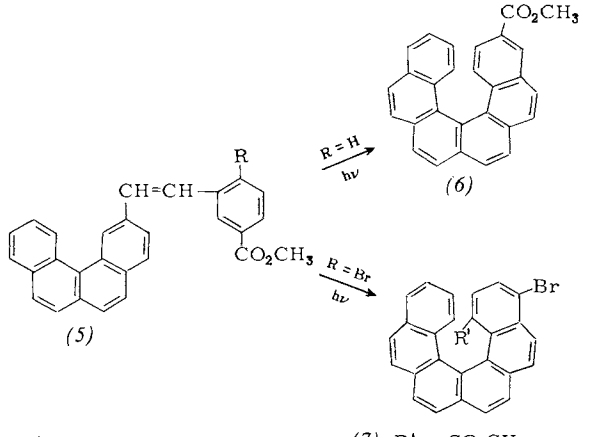
Individual carbo- and hetero-helicenes can be systematically named in accordance with the IUPAC rules A-21 and A-22, and B-3 or B-4, respectively. In the case of all-benzene-helicenes, a frequently used alternative nomenclature indicates the number of rings present in a compound by an arabic numeral (in square brackets) preceding the name "helicene". Thus compound *(1)*, phenanthro[3,4-*c*]phenanthrene, is called [6]helicene. The number of all types of rings can also be designated by multiplying affixes; *e.g.* compounds *(1)* and *(15)* (see below) are hexahelicenes. The name "hexahelicene", however, is frequently used for "[6]helicene".

A large number of heterohelicenes, in which some of the benzene rings are replaced by thiophene rings, have been synthesized and studied at the University of Groningen, Holland. The fundamental contribution of *Wynberg, Groen et al.* in this field (photosyntheses, resolution, rates of racemization, determination of the absolute configuration of these systems and the study of their chiroptical, spectral and chemical properties *etc.*) have been so well described in a concise and stimulating review published by *Wynberg* in 1971[2], that it is felt justifiable here to focus our main attention on the more recent work that has been carried out in this field and, wherever possible, to draw the readers attention to the close similarities or striking differences observed in the properties of the all-benzene- and hetero-helicenes.



2. Synthetic Problems

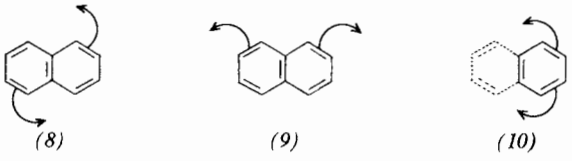
The first synthesis of an all-benzene-helicene, if we exclude [4]- and [5]helicene, is the well known twelve step synthesis of [6]helicene described by *Newman* and *Lednicer*[1]. The main advantage of the very elegant synthetic scheme used by these authors is its unambiguity; it is therefore particularly unfortunate that all attempts to use this scheme for the preparation of the higher benzologue [7]helicene, remained unsuccessful. The second synthesis of [6]helicene was achieved eleven years later by *Bogaert-Verhoogen* and *Martin*[3]. The crucial step of this synthesis is the potash fusion of *(2)* leading to [6]helicene-8-carboxylic acid in 44% yield. This last scheme has recently been used to prepare [7]helicene-7-carboxylic acid,



(2)

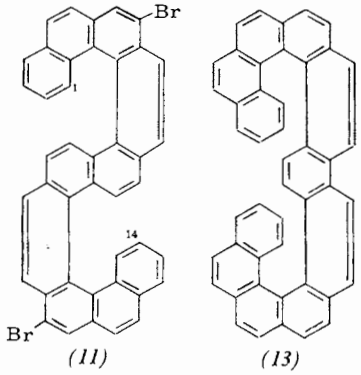
in relatively low yield (*D. Bogaert-Verhoogen*[4]). Both of these schemes suffer from serious limitations[10]; the breakthrough came when it was found that the helicenes could be prepared in fair to excellent yields by the photoinduced cyclodehydrogenation of appropriate 1,2-diarylethylenes[5], following the procedure described by *Wood* and *Malory* in 1964 for the preparative scale photoconversion of stilbene to phenanthrene[6]. It was at the same time surprising and very exciting indeed to discover that the photocyclization process which could give rise to many isomers, in particular to fully planar polycyclic aromatic hydrocarbons, could be of preparative interest for the synthesis of the helicenes! Even more startling is the fact that, in most cases, the helicene is the only cyclized product observed. The photocyclization of *(3)*, which leads preferentially to *(4)*, is one of the most striking exceptions[7]. In such cases, the formation of the undesired product can be either fully or largely prevented by the introduction of a bromine atom as illustrated in Scheme 1. When R = H, methyl [6]helicene-3-carboxylate *(6)* is the major product; on the other hand, when R = Br, the main product is methyl 4-bromo[6]helicene-1-carboxylate *(7)* from which [6]helicene-1-methanol can be prepared in one step by $LiAlH_4$ reduction (*K. Le Van* and *J. Jespers*[4]). In the helicene field, photocyclization has proven exceptionally rewarding. In the course of a few years numerous helicenes of all types, including double helicenes and heterohelicenes, have been prepared, mainly by *Wynberg et al.* (Groningen), by *Laarhoven et al.* (Nijmegen), and in our own laboratory (Brussels)[*]. (For reviews on the photocyclization of stilbene analogs see Refs. [8, 9].)

(3) *(4)*



Scheme 1

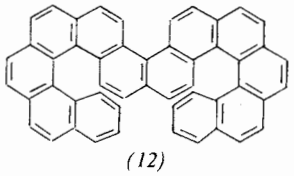
(7), R' = CO_2CH_3



The photocyclization process is extremely simple. The required 1,2-diarylethylenes or bis(arylvinyl)arenes can usually be prepared, in excellent yields, either by the Wittig reaction or

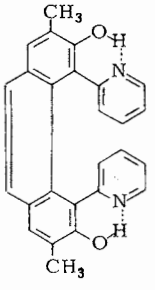
[*] A few problems encountered in the synthesis of all-benzene-helicenes are critically discussed in Ref. [10]. On p. 123 of this review, instead of 1-azahexahelicene, read 3-azahexahelicene.

by the Siegriest reaction[11]. Because of the well known *cis*-⇌*trans* photoequilibrium, the stereochemistry of the starting material is unimportant. Double photocyclizations have proved very useful in many cases, as illustrated by the two-step synthesis of [6]helicene[12], the preparation of [13]-[13], [11]-, [12]-, and [14]helicene (*M. Baes*[4]), and by the synthesis of double helicenes[14] and heterohelicenes[86b]. Substituted all-benzene-helicenes can be prepared without difficulty if the substituent is already present in the molecule to be cyclized; acetyl, dimethylamino and nitro groups are however excluded[9]. An interesting carbohelicene containing a biphenylene system (biphenyleno[2,3-*a*]pentahelicene) has been synthesized recently by *Figeys* and *Vanommeslaeghe*[16]. So far, three types of all-benzene double helicenes, *(8)*, *(9)*, and *(10)*, have been prepared. When the two helicene structures have the same number of rings, *meso* and *dl* pairs are to be expected. If the two helices are up-up (or down-down) in *(11)* and up-down in *(12)* and *(13)*, the corresponding compounds are *dl* pairs. In the case of *(11)*, two stereoisomers have indeed been isolated. The fact that the higher melting isomer was shown to give a positive nuclear Overhauser effect (NOE) between H^1 and H^{14} (proximity effect) proves its *dl* structure[14b].

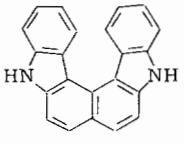


(8) *(9)* *(10)*

(11)



(13)

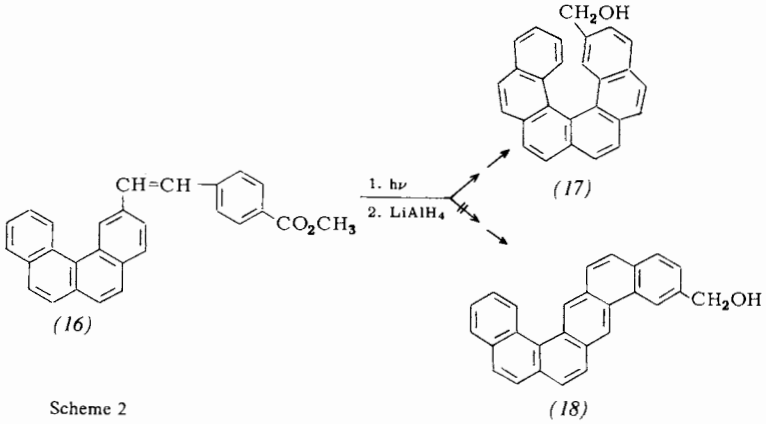


(12)

According to *Laarhoven*[17], the isolated stereoisomer of *(12)* is probably the *dl* pair. In the case of structure *(13)* (*C. Eyndels*[4] and *W. H. Laarhoven*[17]) space-filling models indicate that the *meso* form is sterically very unfavorable. An X-ray diffraction study carried out by *J. Dunitz* (Zurich)[17] on our compound and the partial resolution observed by *Laarhoven* have indeed shown that the only stereoisomer obtained is the *dl* pair. An attempt, by *H. Kagan et al.*[17] to demonstrate the *dl* nature of the higher melting isomer of *(11)* by an absolute asymmetric synthesis using circularly polarized light has unfortunately proven unsuccessful.

4-Aza- *(47c)*[18], 1-aza-, 2-aza- *(47a)* and 3-aza[6]helicene *(47b)*, 2-aza[7]helicene and 2-aza[8]helicene have been prepared by *M. Deblecker* and *F. Geerts-Evrard*[14]. The bromide of 4a-azonia[6]helicene, characterized by NMR spectroscopy but not isolated in a pure state, and the bromides of 4a- and 6a-azonia[4]helicene, have been prepared photochemically by the procedure used by *Bradsher*[19] for the synthesis of azoniaphenanthrenes (*V. Libert* and *H. P. Vanroux*[4]). A number of interesting compounds involving intramolecular hydrogen bonds [*e.g. (14)*], formally related to the azoniahelicenes, have been described recently[15]. As already mentioned, numerous heterohelicenes containing thiophene rings, including a hetero-undecahelicene[51], have been photosynthesized by *Wynberg et al.*[*]. Heterohelicenes containing a furan ring[20] and carbazole systems[21] have been prepared by other methods. Among these, *(15)* is interesting from the historical point of view for, as far as we are aware, this was the first hexahelicene ever synthesized[21b].

(14)



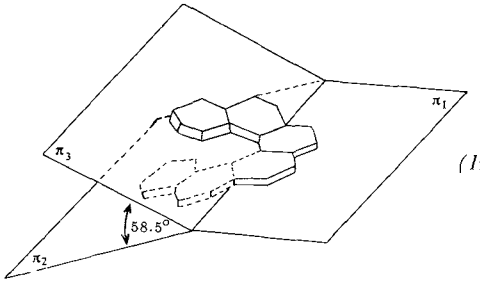
(15)

3. Structural Determinations

As already pointed out, the photocyclization of 1,2-diarylethylenes and bis(arylvinyl)arenes can in principle give rise to many structural isomers. Thus, the double photocyclization used for the synthesis of [13]helicene could give ten cyclized isomers[13]. In contrast, there is usually no ambiguity associated with the photochemical syntheses of heterohelicenes carried out by *Wynberg et al.*

The structural determinations are therefore of crucial importance in the all-benzene-helicene and azahelicene series. How-

(16) *(17)* *(18)*



Scheme 2

[*] The first photosyntheses of all-benzene-helicenes and heterohelicenes were carried out simultaneously and independently in Brussels and in Groningen respectively in 1967.

ever with our increasing knowledge of the properties of the helicenes, this problem can usually be solved without difficulty. NMR spectroscopy has of course been particularly useful in this respect; but other techniques have been applied with success—*e.g.* X-ray diffraction, independent syntheses, specific deuterium labeling[22], GLC[23], study of chiroptical properties, *etc.* The use of a property associated (in this case) with chirality is illustrated in Scheme 2. The structure of the cyclized product was confirmed by the NMR spectrum of the corresponding alcohol [6]helicene-2-methanol *(17)*, which showed an AB system for the diastereotopic protons of the methylene group, thus excluding structure *(18)*.

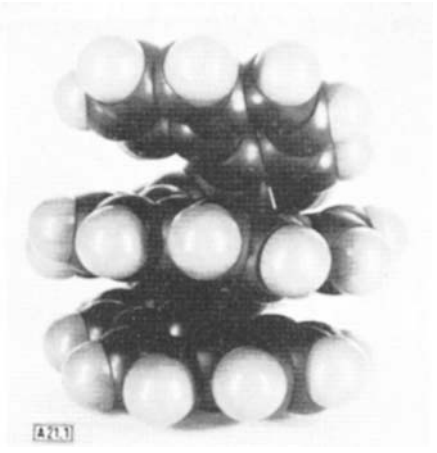
4. Conformations of Helicenes in the Solid State

So far, relatively few X-ray diffraction studies have been carried out in the helicene series. The first X-ray crystal structure analysis of a (hetero)helicene was published by *Stulen* and *Visser* in 1969[24]. Since then, the 1:1 complex [6]helicene/4-bromo-2,5,7-trinitrofluorenone[25], 2-bromo- and 2-methyl[6]helicene[26,27], and [6]helicene itself[28] have been studied by this technique. As already mentioned, the stereochemistry of a double helicene has been elucidated by X-ray diffraction. Of the helicenes in which there is complete overlap of aromatic rings, only 11-bromo[9]helicene (*J. Jespers*[4]) has been examined so far (*G. W. Frank*[17]). [6]Helicene can be roughly depicted by three planes as shown in *(19)*.

(19)

The interplanar angle between the terminal rings is 58.5°. The average bond length for the six inner core carbon-carbon bonds is 1.437 ± 0.004 Å, while the bonds parallel to these on the periphery have an average bond length of 1.334 ± 0.007 Å. The close agreement between the predicted and the observed distortions from coplanarity in [6]helicene, is a welcome tribute to the pioneer work of *Coulson* in this field[29]. Figure 1 gives an idea of the spatial architecture of [13]helicene.

As pointed out by *Lightner et al.*: "... groups no more bulky than a bromine atom or a methyl group when substituted onto carbon 2 and 15 do not significantly alter the geometry of the helix by steric interaction"[27]. The shortest C—C contacts (≈ 3 Å) are always between carbon atoms separated by five bonds *e.g.* C^1 and C^{16a} in 2-methyl[6]helicene and C^1 and C^{22c} in 11-bromo[9]helicene: "This implies that in an infinite helicene molecule there are only $5^1/_2$ benzene rings per helix turn" (*G. W. Frank*[17]). A dramatic change in the shape of the helicene skeleton has however been observed recently by *Laarhoven et al.*[17] in the case of 1,16-dimethyl[6]-helicene. This change is reflected in the much smaller interplanar angle between the terminal rings: 29.6° versus 58.5° in [6]helicene[*]!



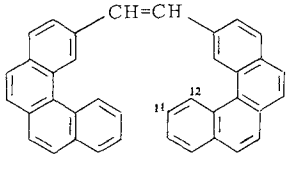


Fig. 1. Space-filling model of [13]helicene.

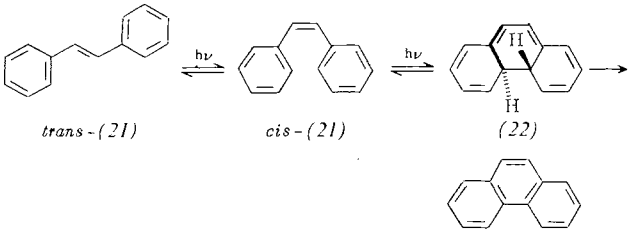
5. Conformation of Helicenes and Helicene Precursors in Solution

Laarhoven et al. have studied the influence of bulky substituents introduced in C^1 and C^2 of [6]helicene, on the UV and NMR spectra[30]. These authors concluded that the helical structure is only appreciably modified by the presence of a large substituent (*e.g. tert*-butyl) in C^1. Polarographic data (half-wave potentials) collected by *Laarhoven* and *Brus*[31] for eight helicenes, including benzo[6]helicenes, indicate that the compounds examined deviate to a similar degree from coplanarity. ^{1}H-NMR studies of the conformation in solution of the *cis*-1,2-diarylethylenes used in the photochemical synthesis of the all-benzene-helicenes, have been carried out independently by *Martin et al.*[32] and by *Laarhoven et al.*[33]. The spectra of these compounds are, in many respects, strongly reminiscent of the spectra of the corresponding all-benzene-helicenes. Thus *e.g.* the strong high field shifts of H^{11} and H^{12} in *cis-(20)* versus *trans-(20)*, the specific solvent effects,

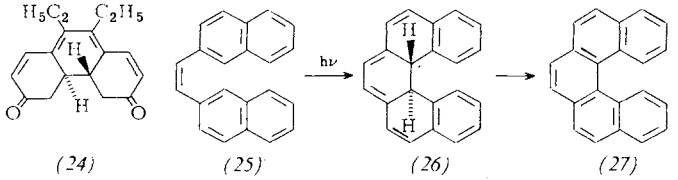


(20)

the influence of tris(2,2,6,6-tetramethyl-3,5-heptanedionato)-praseodymium on the chemical shift of these protons and the temperature dependence of the resonances, clearly indicate the importance of the contribution of "helicene-like" conformations in solution at room temperature. In view of the fact that the geometry in the relaxed excited state may be very different from the geometry in the ground state, there is no obvious correlation between this observation and the ease of photocyclization to the helicene structures. Indeed, *cis-(3)*—whose protons H^{11} and H^{12} show the largest up-field shifts in the unsubstituted series—is one of the few 1,2-diarylethylenes, which does not give the helicene structure ([7]helicene) preferentially!

[*] The conformations in the solid state of a number of *cis*-1,2-diarylethylenes used as precursors in the photosynthesis of all-benzene-helicenes, have been determined by X-ray diffraction (*G. Tsoucaris* [17] and *H. Rabinovich* [17]).

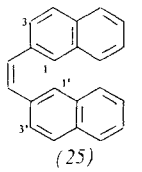
6. The Mechanism of the Photocyclization



The photocyclodehydrogenation in solution of *cis*-stilbene and its analogues is a very complex process which will require further extensive research to be fully understood. Intensive research into this problem has been carried out at the Weizmann Institute (*Fischer, Muszkat, Bromberg et al.*[34]) and at other laboratories[35, 36, 40, 46, 89]. The complexity of the problem is clearly illustrated by the following quotation[34h]: "The common method employed for photocyclodehydrogenation reactions to obtain phenanthrene derivatives involves UV irradiation in the presence of air and iodine. In view of the present results, it appears plausible that under these conditions the DHP's (dihydrophenanthrenes) produced primarily are dehydrogenated by a combination of processes including spontaneous oxidation with molecular oxygen and iodine, oxidation with atomic iodine, and oxidation involving electronically-excited DHP. It is unlikely that singlet oxygen is also involved, in view of the absence of reports on similar dehydrogenation reactions . The recent developments in this field will not be summarized here; however, the stereochemistry of the dihydro intermediates and the regioselectivity will be briefly discussed. The general reaction pathway of the photocyclization of stilbene is outlined in Scheme 3.

trans-(21) *cis*-(21) (22) (23)

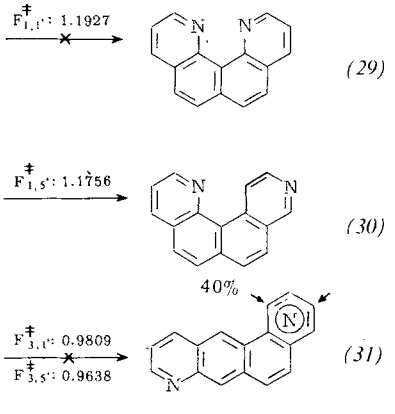
Scheme 3



Until quite recently, no unambiguous proof of the (*trans*-)stereochemistry of the dihydro-intermediates of such reactions was available, the major difficulty arising from the fact that these intermediates could not be isolated. However, in the case of the photocyclization of diethylstilboestrol, *Doyle et al.*[37] have isolated a stable dihydro-tautomer *(24)* of the primary cyclization product. By ozonolysis of this intermediate, *Laarhoven et al.*[38] have isolated *dl*-butane-1,2,3,4-tetracarboxylic acid, thus proving the *trans* configuration of the dihydro-intermediate. This elegant demonstration implies a conrotatory process, as predicted by the Woodward-Hoffmann rules for a concerted photocyclization in the S_1 state. An

(24) (25) (26) (27)

ingenious and decisive proof that the photocyclization of the unsubstituted *cis*-1,2-diarylethylene leading to [5]helicene *(27)* is also a conrotatory process, followed soon after. 1,2-Bis(2-naphthyl)ethylene *(25)* was chosen because of the exceptional thermal stability of the corresponding dihydro[5]helicene *(26)*[39, 34l][*]. By using right and left handed circularly polarized light for the cyclization, *Goedicke* and *Stegemeyer*[40] isolated the optically active (excess (−) and (+), respectively) *trans*-14b,14c-dihydro[5]helicene *(26)*, thus achieving an absolute asymmetric synthesis of this intermediate. As it was already known that the first excited singlet state of the *cis*-1,2-diarylethylene is involved in this type of reaction[41], it followed that the cyclization does not involve "hot" ground state molecules as reactive species.



$F_r^{\ddagger}$
1: 0.630
3': 0.452

$L_{r,s}^{\ddagger}$
1,1' = 2.922
3,1' = 3.281
3,3' = 3.622

(25)

The precise origin of the *regioselectivity* of the photocyclizations is yet another unsettled fundamental problem. In 1967, *Scholz et al.*[42] found that the photocyclizations leading to tetra- and pentacyclic all-benzene-hydrocarbons [*e.g. (25)*] take place almost exclusively between the *(ortho)* carbon atoms showing the highest value of free valence indices in the first excited state ($F_r^{\ddagger}$) or the smallest localization energy ($L_{r,s}^{\ddagger}$)[**]. In the course of the following years, *Laarhoven et al.*, *Timmons et al.*, and *Martin et al.* in collaboration with *Figeys*, made extensive use of this observation either to confirm or to predict the regioselectivity of numerous photocyclizations—including photocyclizations leading to azahelicenes. As shown by *Laarhoven et al.*[43], the photocyclodehydrogenations only take place if the sum of the free-valence indices for the atoms between which cyclization could occur is greater than unity ($\Sigma F_{r,s}^{\ddagger} > 1$). This simple "exclusion-rule" has been further ela-

borated to deal with cases in which more than one $\Sigma F_{r,s}^{\ddagger}$ is greater than unity (products ratio) and to account for steric factors (formation of planar versus non-planar polycyclic aromatic systems)[44]. The usefulness of these empirical rules

[*] Quantum yields [34l] for the following processes have been reported: *cis-(25)*→*(26)*: 0.01; *(26)*→*cis-(25)*: 0.005; *cis*-stilbene→dihydrophenanthrene: 0.1; *(22)*→*cis*-stilbene ≈ 0.7. It is interesting to note that *Fischer* [17] has been unable to observe the photoformation of a dihydro-intermediate by irradiation of 1,2-bis(3-phenanthryl)ethylene.

[**] $L_{r,s}^{\ddagger} = \pi$ electron energy of the starting material in the first excited state minus the π electron energy of the dihydro intermediate in the ground state.

from the synthetic point of view has been demonstrated in a number of publications (see *e.g.* Ref. [45]). It is interesting to note that the photocyclization of *(28)* failed to give 1,12-diaza[4]helicene *(29)*, in spite of the high value of the corresponding $F_{r,s}^{+}$. This result can be ascribed to repulsive interactions between the lone pairs of the nitrogen atoms along the reaction path leading to *(29)* (*F. Geerts-Evrard*[41])[*].

Failure of 1,2-diarylethylenes to cyclize on electron impact (M−2 mass lines of relative abundance smaller than 5%) has also been correlated by *Blackburn* and *Timmons*[46] with the failure of such compounds to photocyclize with aromatization. The converse need not be the case.

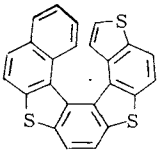
7. Chiroptical Properties

With the exception of the double helicenes and bihelicenyls in their *meso* forms, the helicenes are inherently chiral molecules. The unsubstituted all-benzene-helicenes belong to point group C_2; they are dissymmetric and palindromic[**].

7.1. Optical Resolution

The first experimental proof of the chirality of a helicene was given by *Newman, Lutz,* and *Lednicer*[47] in 1955. Their brilliant resolution of [6]helicene was accomplished using an optically active π-complexing agent (TAPA)[***] specially synthesized for this purpose.

Three monosubstituted [6]helicenes have been resolved so far: the 7-trimethylphosphoniomethyl[6]helicene ion *via* its D(−)hydrogendibenzoyltartrates[48], [6]helicene-2-carboxylic acid by column chromatography of its menthyl ester (*V. Libert*[4]), and 2-bromo[6]helicene with TAPA[26]. One of the heterohelicenes containing carbazole systems has been partially resolved into enantiomers by column chromatography on acetylated cellulose[21c].



In the course of our work on [7]helicene, (the late) *G. M. J. Schmidt* drew our attention to the fact that our specimen of this hydrocarbon had crystallized in the non-centrosymmetric space group $P2_1$. Knowing from the work of *Newman* that [6]helicene has an exceptionally high optical activity ($[\alpha]_D^{24} = 3640°$), it was at once clear that optical activity due to the formation of a conglomerate should be detectable by "hand-picking" of just *one* crystal of [7]helicene.

This proved to be the case. *M. Barbieux*, who had carried out the first synthesis of [7]helicene, grew crystals which were all optically active, one of them being even optically pure: $[\alpha]_D^{20} = 6200 \pm 200°$[7,49]. The formation of optically pure crystals seems to be exceptional in the all-benzene-helicene and heterohelicene series, probably on account of microtwinning.

Since then, [6]-, [8]- and [9]helicene[49], as well as a number of heterohelicenes[50,2] have been "partially resolved" by this technique[*]. On the other hand, we have been unable, so far, to detect the existence of conglomerates in the case of the higher benzologues of [9]helicene and of monosubstituted all-benzene-helicenes[**].

These unsuccessful attempts may have been due to different reasons: the microsize of the crystals, the difficulty to grow single crystals and, last but not least, the failure to find the proper solvent. In this connection, we wish to recall the observation made by *Wynberg et al.*[51] that *dl-(32)* can be "partially resolved" by crystallization from optically active (−)-α-pinene. It has however not been established yet "whether this resolution is thermodynamic in nature or simply due to preferential seeding (kinetic) or to a combination of both".

To our knowledge, the crystallization of *dl-(32)* from the enantiomeric (+)-α-pinene has not yet been attempted. A partial photoinduced destructive kinetic resolution of [6]helicene, using circularly polarized light, has been described by *Kagan et al.*[52] *(vide infra)*. It should be mentioned that optically active all-benzene-helicenes and heterohelicenes can be prepared by homologation of an optically active precursor. Thus, *Wynberg et al.*[51] have obtained a dextrorotatory undecaheterohelicene starting from partially resolved (+)-*(32)*. We are presently working on the synthesis of a series of optically active all-benzene-helicenes, using optically active [6]helicene-2-carboxylic acid as the precursor. This synthetic scheme has already been tested without prior resolution; *dl*-[8][53], [9]-, [10]- and [11]helicene have thus been prepared in 40%, 74%, 79%, and 45% yields, respectively (*V. Libert*[4]). The chirality of the helicene molecule can of course be detected by X-ray crystallography (determination of space group or full crystal structure analysis), ^{1}H-NMR spectroscopy (*e.g.*, diastereotopic protons in [6]helicene-2-methanol *(17)*[53]), ^{13}C-NMR spectroscopy (*e.g.*, diastereotopic $^{13}CH_3$ in 2-isopropyl[6]helicene[30])[***] *etc.* *Oosterhoff*'s attempt to use the "circular polarization of luminescence" technique[54] in the all-benzene-helicenes has unfortunately failed so far[17].

(32)

7.2. Optical Purity

The only helicenes whose $[\alpha]_{max}$ values are presently known are [6]-[11], [7]-, [8]- and [9]helicene[49], 2-bromo[6]helicene[26], and 7-methyl[6]helicene[48]. (Rotation values in chloroform:

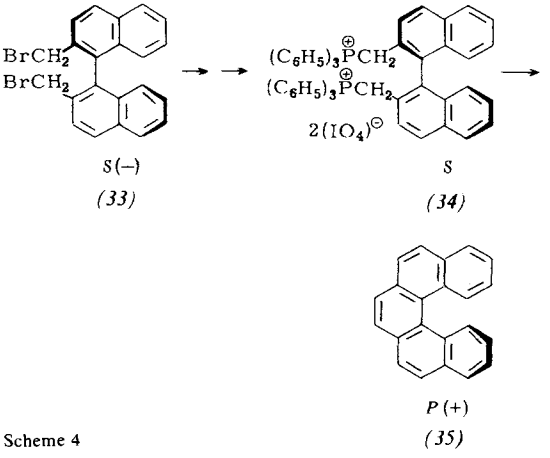
[*] When the yield of the cyclized product(s) is relatively low, no conclusion should be drawn from the study of the $F_{r,s}^{+}$, for it is clear that some of the cyclized isomers, particularly those with an anthracene structure, could be "photodestroyed" selectively.

[**] For a musical palindrome cf. *J. Haydn*: 47th Symphony, 3rd part "Menuet al Roverso" (1772)!

[***] TAPA = 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid.

[*] This "hand-picking" procedure is based, like the famous technique of *Pasteur*, on the formation of conglomerates. However, in the helicene series, because of the very high optical activities, the crystals of the two enantiomers need not be distinguishable. Only the sign of rotation of the solutions of each individual crystal has to be determined; needless to say, this is a time-consuming preparative scale procedure which requires a tremendous amount of perseverance.

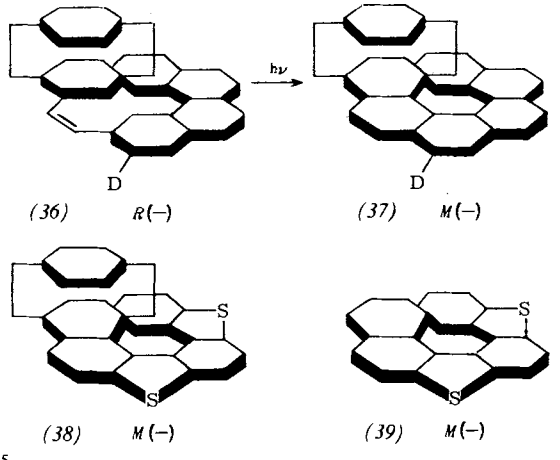
[**] *Frank et al.* [27], however, have observed by X-ray diffraction that crystals of 2-methyl[6]helicene grown from the racemic mixture (benzene-pentane) are optically pure.



[***] The values 55.2 and 55.5 ppm quoted for $\delta^{13}CH_3$ in Ref. [30] are in error and should read 53.7 and 54.0 ppm upfield from $CHCl_3$. We apologize for this mistake which was due to a transitory technical deficiency of our instrument.

$[\alpha]_D^{24} = 3640 \pm 10°$, $[\alpha]_{579}^{25} = 5900 \pm 200°$, $[\alpha]_{579}^{25} = 6900 \pm 200°$, $[\alpha]_{579}^{25} = 8100 \pm 200°$, $[\alpha]_{579}^{25} = 3560°$, and $[\alpha]_D = 3157°$, respectively.) The unsubstituted all-benzene-helicenes were partially resolved by "spontaneous resolution" and further purified by repeated crystallizations under non-equilibrium conditions. The final purification was achieved by two "normal" crystallizations.

7.3. Absolute Configuration

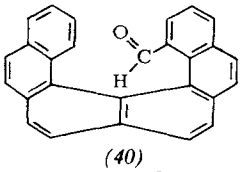


The assignment of the absolute configuration of the helicenes has only been settled recently. Three distinct lines of approach have been used to solve this problem: calculations performed to relate the sign of the long wavelength optical activity to the stereochemistry (helicity) of the molecule, X-ray diffraction studies using Bijvoet's method, and chemical assignments. The most recent and sophisticated treatments (π-SCF orbitals) of the long wavelength optical activity of the all-benzene-helicenes, carried out independently by *Mason et al.*[55] and by *Wagnière et al.*[56], both lead to the conclusion that the dextrorotatory helicenes have the right-handed (*P*) helicity[*]. This conclusion was confirmed a few months later by an X-ray diffraction study (anomalous X-ray scattering) of (−)-2-bromo[6]helicene performed by *Lightner et al.*[26]. The protodebromination of (−)-2-bromo[6]helicene yielded levorotatory [6]helicene. It is appropriate to recall at this point that the first assignment of the absolute configuration of a helicene was achieved by *Wynberg et al.*[58], by X-ray diffraction, on a heterohelicene whose thiophene rings provided the required heavy atom. The results obtained by these authors, namely that (−)-*(39)* has the left-handed helicity, was correctly predicted beforehand by *Groen*[59]. X-ray studies have thus shown that the levorotatory all-benzene-helicenes and heterohelicenes have the same left-handed (*M*) configuration.

The challenge to determine the absolute configuration of helicenes by chemical correlations was tackled simultaneously and independently by *Bestmann et al.*[60] and by *Martin et al.*[62]. *Bestmann*'s elegant and simple method for the determination of the absolute configuration of [5]helicene is shown in Scheme 4[*].

Scheme 4

Tribout and *Martin* used (−)-[2,2]paracyclophane-4-carbaldehyde (Scheme 5) of known absolute configuration as starting material for the synthesis of the levorotatory substituted helicene *(37)* ($[\phi]_{578}^{25} = -12464° \pm 100°$) which, for compelling steric reasons can only have the left-handed (*M*) configuration. The authors then concluded from the close similarity between the ORD and CD curves of this "(−)-[2,2]paracyclophanohelicene" *(37)* and (−)-[6]helicene ($[\phi]_{578}^{25} = -12300°$) that both have the same (*M*) helicity. An application of the above scheme in the heterohelicene series, carried out in collaboration with *Doyle* and *Wynberg*[62], provided a rigorous proof of the validity of the method. Thus the ORD curve of the "(−)-[2,2]paracyclophanoheterohelicene" *(38)* showed overall similarities with the ORD curve of the corresponding (−)-heterohelicene *(39)*, whose left-handed configuration had been determined by X-ray diffraction[59] (Scheme 5).



Scheme 5

7.4. Chemically Induced Asymmetric Syntheses

Only preliminary unpublished results are presently available in this field.

7.4.1. Asymmetric Syntheses Induced by the Helicene Skeleton

We have recently observed that the reduction of *dl*-[6]helicene-1-carbaldehyde (abbreviation: [6]-1-CHO) *(40)* with $LiAlD_4$ gives essentially one *dl* pair of the diastereomeric monodeuteriated alcohols (in the ratio 96:4). The *reversed* ratios of the diastereomeric alcohols is obtained by reduction of the deuteriated aldehyde with $LiAlH_4$. Reoxidation with DDQ[**], of the alcohols resulting from the $LiAlH_4$ reduction gives a 96:4 mixture of 1-CDO- and 1-CHO[6]helicene.

≡ [6]-1-CHO

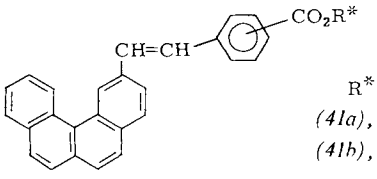
(40)

[6]-1-CHO $\xrightarrow{LiAlH_4}$ [6]-1-CH_AH_BOH

[6]-1-CHO $\xrightarrow{LiAlD_4}$ [6]-1-$\overset{*}{C}H_ADOH$

[6]-1-CDO $\xrightarrow{LiAlH_4}$ [6]-1-$\overset{*}{C}DH_BOH$

[*] As early as 1957, *Moscowitz* [57] using simple Hückel π molecular orbitals arrived at the opposite conclusion. It is important to note in this connection that no sign inversion had inadvertently occurred, as was believed at one time ([58], foot-note 9). The discrepancy is essentially due to the fact that *Moscowitz* could not include configuration interaction among the thirty lowest excited singlets. What is remarkable is that the absolute magnitudes and shapes of his calculated curves so closely approximate the experimental data of *Newman et al.* [74], despite the sign discrepancy (*A. J. Moscowitz*, personal communication).



[*] Bestmann's oxidative coupling of phosphonium salts is the simplest preparative scale procedure yet available for the synthesis of *dl*-[5]helicene [61].

[**] DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

We believe, from NMR evidence, that the most favorable conformation of [6]helicene-1-carbaldehyde is the one shown in *(40)*. If so, the main alcohol resulting from the $LiAlD_4$ reduction of the right-handed (*P*) aldehyde probably has the (*R*) configuration [(*M*)aldehyde→(*S*)alcohol (*J. Jespers*[4]).

7.4.2. Asymmetric Syntheses of All-Benzene-Helicenes Induced by Chiral Substituents[*]

The photocyclizations of the (−)-menthyl esters *(41a)* and *(41b)*, followed by complete reduction ($LiAlH_4$) of the unpurified reaction products, yielded (−)-[6]helicene-3- and -2-methanol respectively.

R* = (−)−Menthyl
(41a), *meta* $-CO_2R^*$
(41b), *para* $-CO_2R^*$

The optical yields of these reactions are not yet known (*J. Jespers* and *V. Libert*[4]); further work is in progress, in collaboration with *K. Mislow*.

7.5. Absolute Asymmetric Synthesis Using Circularly Polarized Light

A century ago, *Le Bel*[63] clearly pointed out that the use of (left- or right-handed) circularly polarized light must, in principle, induce "absolute asymmetric syntheses"[**]. Ever since, numerous attempts have been made to carry out such syntheses, but in no case published before 1971 was there compelling evidence in favor of success; in fact, when the reactions were repeated recently, the claimed asymmetric *syntheses* could not be confirmed. The practical difficulties were such that the possibility of achieving an absolute asymmetric synthesis was even seriously questioned[64]. In order to solve this problem, it was essential to discover a photochemical reaction for which the *g* factor[***] of the chiral precursor (at a given wavelength) and/or the magnitude of the $[\alpha]_{max}$ of the final product are favorable. Such is the case in the photoinduced cyclodehydrogenation of certain 1,2-diarylethylenes leading to all-benzene-helicenes. In this reaction, the relatively small *g* factor of the chiral precursor is well compensated by the exceptionally high optical rotation of the helicene, as was demonstrated by *Kagan et al.*[52,65] and independently by *Calvin et al.*[66]. It is highly satisfactory to note that: a) the optical rotations of the final products are highly significant (no possible ambiguity), b) the helicenes prepared from right and left-handed circularly polarized light show opposite signs of rotation, and c) the photoinduced destructive kinetic resolution of [6]helicene is much slower than its induced photosynthesis and leads to optical activities of opposite signs. The fact that the observed optical activity is not due to an induced asymmetric transformation of the dihydro-intermediate has been confirmed by both schools. *Calvin et al.* have further shown, in the case of [8]helicene, that the optical yield and the sign of rotation of the final product is strongly dependent on the wavelength of the circularly polarized light used for irradiation.

These absolute asymmetric syntheses are only possible because the enantiomers of the helicene precursors (*cis*-1,2-diarylethylenes)—which absorb circularly polarized light of a given chirality to slightly different extents ($\varepsilon_R \neq \varepsilon_S$)—are in *rapid interconversion* at room temperature. Experiments designed to better understand the reason of the large differences observed in the optical yields of closely related helicene syntheses, have been described by *Buchardt et al.*[67]. It is interesting to note in this connection that the double photocyclizations of bis(arylvinyl) arenes of the type Ar′—CH=CH—Ar—CH=CH—Ar′ (Ar′ = or ≠Ar) show in some cases extremely low or undetectable optical yields[*]; such is the case, for example, in the photosyntheses of the double helicene *(11)* (light circularly polarized at 313 nm) and of [13]helicene (light circularly polarized at 313 nm and, in another experiment, at 380 nm). The reason for this observation is not yet clear and further work is in progress. An absolute asymmetric synthesis of 1-aza[6]helicene has been achieved recently by *Kagan*[17].

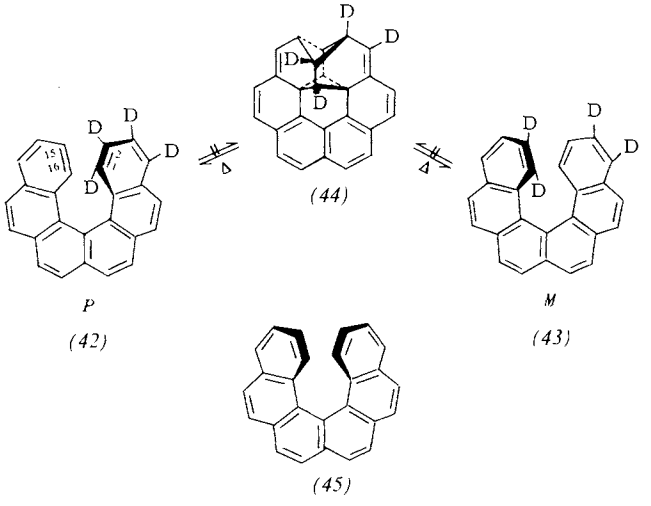
7.6. Thermal Racemizations

If the above "absolute asymmetric syntheses" using circularly polarized light constitute one of the major contributions to the helicene studies, then the thermal racemization of [7]-, [8]- and [9]helicene is undoubtedly the most surprising and intriguing discovery in this field[68,69][**]. Kinetic data of the thermal racemization in solution of [5]-[70], [6]-, [7]-, [8]- and [9]helicene[69] are listed in Table 1.

Table 1. Kinetic data for the thermal racemization of some helicenes in solution.

Helicene	[5]	[6]	[7]	[8]	[9]
$\Delta H^{\neq}$ [kcal mol^{-1}]	22.9	35.0	40.5	41.0	41.7
$\Delta S^{\neq}$ [cal mol^{-1} deg^{-1}]	−4.1	−4.2	−3.9	−4.6	−6.1
$\Delta G^{\neq}$ [kcal mol^{-1}] (27 °C)	24.1	36.2	41.7	42.4	43.5
E_a [kcal mol^{-1}] (27 °C)	23.5	35.6	41.1	41.6	42.3
$t_{1/2}$ (rac.) [min] (T [°C])	62.7 (57)	13.4 (221.7)	13.4 (295)	31 (293.2)	123 (293.5)

[*] The first reported *chemically induced asymmetric synthesis of an all-benzene-helicene skeleton* is the photocyclization of *(36)* leading to *(37)*.



[**] It is common practice to use the expression: "absolute asymmetric syntheses" to describe those asymmetric syntheses which are induced by a chiral *physical* agent instead of by a chiral *chemical* reagent. This distinction, although convenient, is in no way fundamental.

[***] The optical anisotropy factor *g* is defined as the ratio of the circular dichroism $\Delta\varepsilon$ to the extinction coefficient ε.

[*] *H. Kagan et al.* and *R. H. Martin et al.*, unpublished results.

[**] With the exception of [13]helicene, no higher all-benzene-helicene has yet been even partially resolved. Brief accounts or kinetic studies on the thermal racemization of [5]helicene[70], [6]helicene[11], heterohelicenes[71], 2,2′-bi[6]helicenyl[72] and diphenanthro[3,4-*c*:3′,4′-*l*]chrysene[14a] have been published; however, prior to our work, no helicene in which the terminal rings facially overlap had been studied from this point of view.

It should be noted that the $\Delta G^{\neq}$ values for [7]-, [8]- and [9]helicene are remarkably similar. Three reaction pathways have been considered for these racemizations: 1. bond breaking; 2. reaction path involving an internal double Diels-Alder adduct (suggested by *J. Nasielski*); 3. conformational pathway[69]. The first hypothesis, namely the complete rupture of a C—C bond with the formation of a non-stabilized diradical is hardly compatible with the kinetic results. As for the second hypothesis, in the case of [6]- and [7]helicene the occurrence of an internal double Diels-Alder adduct [*(44)* in Scheme 6] has been experimentally discarded by the study of appro-

Scheme 6

priate substituted derivatives. The inversion of the helix by way of an internal double Diels-Alder reaction would be accompanied, in the case of [6]helicene, by a permutation of (D)H—C^1—C^2—H(D) versus H—C^{16}—C^{15}—H. No such permutation was however observed when *dl*-[1,2,3,4-D_4]-[6]helicene *(42)* was submitted to prolonged racemization conditions. The third hypothesis, the "conformational pathway", seems to be the most reasonable one at the present time. The "relatively" low potential barriers for these racemizations can be justified in the conformational process by the fact that the necessary molecular deformations (bond torsion, bond bending *etc.*) are spread over a large number of bonds. This process does not require an achiral conformation along the inversion path; however a non-planar achiral conformation, such as *(45)*, may well occur in the racemization of the unsubstituted all-benzene-helicenes[*].

If, as we believe, the thermal racemization of the helicene is a conformational process, it then follows that the non-planar polycyclic aromatic hydrocarbons in general and the helicenes in particular, are dramatically more flexible than expected. As pointed out earlier by the present author, this erroneous belief is probably largely due to the common use of rigid models, particularly space-filling models... These models which are invaluable in many respects, have however serious shortcomings which may be difficult to assess correctly. Although all-benzene-helicenes are photolabile, they do not racemize photochemically.

[*] In 1968, *Dougherty* [73] stated that the thermal racemization of [6]helicene "requires that the molecule twist through a symmetrical conformation", thus implying a conformational process for the racemization of this hexanuclear helicene.

7.7. ORD, CD and MCD

The CD curve of [5]helicene[70] and the ORD and CD curves of [6]-[74], [7]-, [8]- and [9]helicene[49] and a number of heterohelicenes[75] have been recorded. These curves clearly show that the all-benzene-helicenes of a given series (levo or dextro) have the same helicity. The same is true in the heterohelicene series of *Wynberg*[2]. *Weigang* and *Trouard-Dodson*[76] have studied the CD spectrum of [6]helicene in glasses at liquid nitrogen temperature. The MCD curves of *dl*-[6] to [9]helicene have been recorded by *Djerassi*[17]. It is unfortunate that the ORD and CD curves of the chiral double all-benzene-helicenes are not yet known, for it would be interesting to compare the optical properties of these compounds with the optical properties of the isomeric "normal" all-benzene-helicenes.

8. Spectral Properties

8.1. ^{1}H-NMR Spectroscopy

^{1}H-NMR spectroscopy has played a very important part in the researches carried out on the helicenes in recent years. The structure of practically every all-benzene-helicene, synthesized by the photocyclization process, has been deduced from its ^{1}H-NMR spectrum[*]. The C_2 symmetry of the (unsubstituted) all-benzene-helicenes, has been of great help in this connection, not only in ^{1}H-NMR but also in ^{13}C-NMR spectroscopy[22]. Of particular interest to us was the study of the repercussions of the progressive overlap of benzene rings on the chemical shifts of the protons of the underlying ring(s)[77]. As expected, these protons are shifted to higher fields by the induced diamagnetic ring-current of the overlapping benzene ring(s). The annelation process affects successively the protons of the ABCD four-spin system and of the two-spin systems (EF, GH...) in a rather regular way[**]. This work has now been extended to the higher benzologues, up to [14]helicene (*M. Baes* and *N. Defay*[41])[***].

Some of the protons of the all-benzene-helicenes, from [6]helicene onwards, also show specific solvent effects (C_6D_6 versus $CDCl_3$) which distinguish them from the less distorted isomers which can be formed in the photocyclizations. *Haig* and *Mallion*[78] have carried out a thorough and accurate study of the ^{1}H-NMR spectra of [4]-, [5]- and [6]helicene and have extended the Hückel-London-McWeeny theory of "ring current" effects on proton chemical shifts to non-planar aromatic systems. *Defay*[79], using the very powerful INDOR technique, has not only assigned practically every transition of the ^{1}H-NMR spectrum of [7]helicene, but has also revealed the existence of positive $^5J_{tt}$ (epi) and negative $^4J_{cc}$ (peri) long range cross-ring couplings in this molecule.

Use of the INDOR technique has moreover yielded important information on the double all-benzene-helicene series. *Figeys*

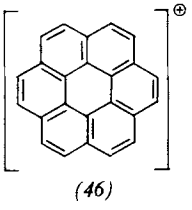
[*] It is a particular pleasure for me to take this opportunity to express my deepest gratitude to a long standing and enthusiast collaborator, Dr. *Nicole Defay*, whose original NMR contributions to our researches in the field of polycyclic aromatic systems, including the helicenes, has been invaluable.

[**] Cf. Figures 7 and 8 in Ref. [77].

[***] The dramatic improvement of the NMR technique in the course of the last 18 years is well illustrated by recalling the conclusion of a study of the NMR spectrum of [6]helicene carried out in 1956: "There does not appear to be any sizable effect due to the 'helical type' overlap of the rings" [1].

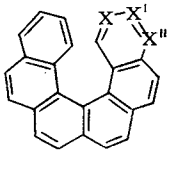
et al., *Wynberg et al.*, and *Laarhoven et al.* have also carried out extensive work on the ^{1}H-NMR spectra of helicenes containing a biphenylene ring system[16], heterohelicenes[2], substituted helicenes[30, 16], benzo[6]helicene[80], double helicenes[14] *etc.*

8.2. ^{13}C-NMR Spectroscopy



The ^{13}C-NMR spectra of [4]- to [7]helicene[81] have been fully assigned as far as the protonated carbon atoms are concerned. Specific deuterium labeling has been used in a few cases by *Martin et al.*[82] for assignment purposes in the all-benzene-helicene series. The observed *ortho* isotope high-field shifts are particularly useful for the specific assignment of the quaternary carbon atoms common to two rings.

Although evidence for the existence of diamagnetic ring current effects on the ^{13}C resonances has been obtained[83], these effects are concealed in most cases by other factors. ^{13}C-NMR spectroscopy is thus less suitable than ^{1}H-NMR spectroscopy as a probe for the magnetic properties of the cyclic π-system of the helicenes.



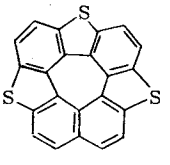
8.3. Mass Spectrometry

The mass spectrum of [6]helicene[73] shows a very intense peak at $m/e=300$ ($M-C_2H_4$) and an intense metastable ion corresponding to the $m/e=328\rightarrow m/e=300$ transition; it also shows peaks for doubly charged ions. There is evidence that the ion with $m/e=300$ is the coronene ion *(47)*[*]. The loss of C_2H_4 has also been observed by *Groen*[84] in the case of heteroheptahelicenes[**]. In order to explain the formation of [coronene]$^+$ from [[6]helicene]$^+$, *Dougherty* has postulated the formation of an internal Diels-Alder adduct, followed by the loss of ethylene. It is interesting to note that the stereochemistry of this adduct (supra-supra on the same side of the aromatic-strip to allow the subsequent loss of ethylene) is different from the stereochemistry of the first internal Diels-Alder adduct (supra-supra on opposite sides of the aromatic-strip) susceptible to lead to the double adduct *(44)* mentioned in our discussion of the racemization of the helicenes (Section 7.6).

The low resolution mass spectrum of 2-aza-[6]helicene *(47a)* has ions at $m/e=300$, 301, and 302; at a resolution of 40000, each of these show two peaks at $m/e=329-C_2H_5$ (10%) and $329-CNH_3$ (90% coronene?), at $329-C_2H_4$ (10%), and $329-CNH_2$ (90%), and at $329-C_2H_3$ (70% azoniacoronene?) and $329-HCN$ (30%); metastable ions are observed for the *m/e* 329→300, 329→301, and 329→302 transitions. Very similar observations have been made in the case of 3-aza- *(47b)* and 4-aza-[6]helicene *(47c)* except that the $M-HCN$ ion is missing (*M. Deblecker*[4]). The occurrence of ions corresponding to the mass of the coronene ion in the last two spectra, suggests that the coronene ion hypothesis should be further scrutinized. An investigation of some potentially pericyclic reactions in the mass spectrometer has been carried out by *Bishop* and *Flemming*[85].

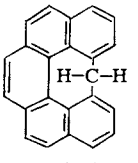
(46)

(47a), X = N, X' = X'' = CH
(47b), X' = N, X = X'' = CH
(47c), X'' = N, X = X' = CH



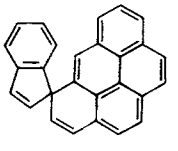
[*] Thermolysis of [6]helicene for 2h at 485°C (10^{-6} torr at 25°C) gives ethylene as the only product volatile at 0°C along with traces of coronene [73].

[**] The heterohexahelicenes of *Wynberg* and *Groen* do not have the right geometry to give the corresponding cyclized ions by loss of C_2H_4.



9. Chemical Reactions and Other Investigations

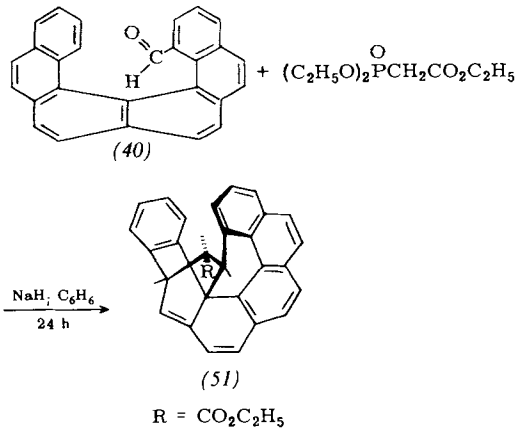
Substitution reactions involving unsubstituted all-benzene-helicenes are as yet unknown. In the case of heterohelicenes, lithiation *ortho* to the S atom of a terminal thiophene ring followed by formylation has been used by *Wynberg et al.*[51] for synthetic purposes.



On treating a heterohexahelicene with $AlCl_3$—NaCl at 140°C *Wynberg et al.*[86] have observed the formation of a new C—C bond between the first carbon atoms of the terminal rings (loss of H_2). The product thus obtained has been used by these authors to synthesize the heterocirculene *(48)*, a member of an interesting new class of compounds. In the all-benzene-helicene series, *Martin et al.* have observed the formation of a methano bridge [cf. *(49)*] between the two end rings of [5]helicene on treatment of [5]helicene-1-methanol in acid medium (*Y. Cochez*[4]). On the other hand, a similar treatment of [6]helicene-1-methanol gave a high yield of product *(50)* (*J. Jespers*[4]). This rearrangement is the first example of a chemically induced modification of an all-benzene-helicene skeleton.

(48)

(49)



(50)

An interesting intramolecular [4+2]cycloaddition [*(40)*→*(51)*], involving the [6]helicene skeleton, has recently been discovered by the school in Brussels (*J. Jespers*[4]).

Only a limited number of further interesting studies carried out in the helicene field can be mentioned in the space available here. The question of σ-π mixing in helicenes has been discussed by *Moscowitz*[57a], *El-Sayed*[87], and, more recently, by *Wagnière*[56a] and *Mason*[55]. Experimental evidence of these interactions is however still lacking. The electron transfer between anion and molecule of [6]helicene and the optical and magnetic properties of anions of hexahelicene have been studied by *Weissman et al.*[88, 89]. The fluorescence of the *cis* and *trans* naphthylethylenes and the helicenes have been examined by *Fischer, Stegemeyer et al.*[90] and *Vander Donckt et al.*[91], respectively.

The study of the helicenes has already yielded important and unexpected results. It is our personal conviction that

(40)

(51)

R = $CO_2C_2H_5$

further work on these unique molecules, whose accessibility is no longer a serious problem, should be highly rewarding in many fields of chemistry.

Never before have I had a better opportunity to give full credit to all my co-workers for their very fine contribution to the study of the helicenes; I sincerely hope that they enjoyed this common venture as much as I did! I also wish to express my deepest gratitude to the Colleagues, in particular Professor H. Kagan and Professor H. Wynberg, and research workers of other laboratories who either collaborated with us or made us benefit from their experience. The financial support of our "helicene program" by the "Fonds de la Recherche Fondamentale Collective" is gratefully acknowledged.

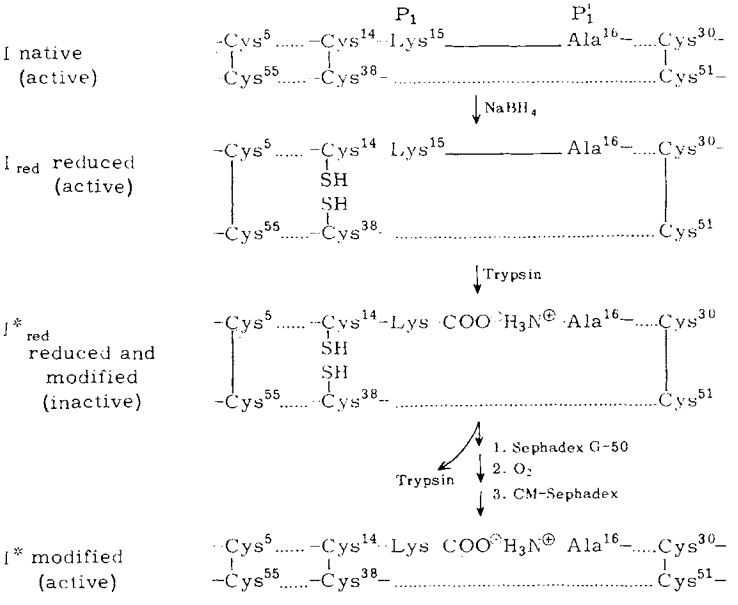
Synthesis of the Active Derivative of Bovine Trypsin-Kallikrein Inhibitor (Kunitz) with Open Peptide Bond in the Reactive Site[**]

By *Helmut Jering* and *Harald Tschesche*[*]

Trypsin-kallikrein inhibitors (type Kunitz)[2, 3] occupy a special place among the natural, low molecular weight proteinase inhibitors I[1, 2]. As a rule, inhibitors suffer partial proteolysis during substrate analogous attachment to the enzyme; the peptide bond $-P_1-P_1'-$ in the reactive site[1, 2] is opened and modified inhibitors I* still possessing full inhibitory activity are formed. So far, this modification could not be established in the case of Kunitz type trypsin-kallikrein inhibitors[1, 2, 4].



We have now succeeded in preparing the modified form I* of an inhibitor of the Kunitz type. The initial step involved selective reduction of one of the three disulfide bridges, the Cys 14—Cys 38 disulfide bridge adjacent to the reactive site, with $NaBH_4$ in aqueous solution[5]. The selectively reduced inhibitor is degraded by trypsin by successive cleavages of the Lys 15—Ala 16, Arg 39—Ala 40 and Arg 17—Ile 18 bonds, the first cleavage of which leads to deactivation of the inhibitor[5]. In order to ensure that cleavage is restricted to the Lys 15—Ala 16 bond, selectively reduced inhibitor was incubated with 20 mol-% trypsin at pH = 3.7 with exclusion of oxygen (to avoid reoxidation of the disulfide bridge Cys 14—Cys 38) just until excess inhibitor was inactivated. Finally, the trypsin was separated from the inhibitor by gel filtration on Sephadex G-50 and the disulfide bridge Cys 14—Cys 38 reoxidized again with O_2 at pH = 8.6 (0.1 M Na-borate). Purification of this modified inhibitor was accomplished by ion-exchange chromatography on CM-Sephadex with a NaCl gradient at pH = 8.6 (see Scheme 1).

The structure of the modified bovine inhibitor I* (Kunitz) can be deduced from the following data[6]: a) same amino acid composition as the starting material I; b) one uniform band on disc electrophoresis at pH = 9.3—because of the additional negative charge I migrates slower (70 % of the migrating distance) than I; c) performic acid oxidation and isolation of the two polypeptide chains that are formed (amino acid residues 1—15 and 16—58); d) complete inactivation of I* by cleavage of Lys 15 with 0.03 mol-% carboxypeptidase B within one hour at room temperature; e) enzymatically catalyzed resynthesis of the peptide bond Lys 15—Ala 16 with regeneration of starting material I[7].

The modified inhibitor I* inhibits the enzymes trypsin and chymotrypsin (from beef), the same complex being formed from enzyme and modified inhibitor as from enzyme and native (unmodified) inhibitor[8]. However, the ratios of the rate constants for complex formation with native (k) or with

Proteinase Catalyzed Resynthesis of the Peptide Bond Lys 15—Ala 16 in the Derivative of Trypsin-Kallikrein Inhibitor (Kunitz) with this Peptide Bond Hydrolyzed[**]

By *Helmut Jering* and *Harald Tschesche*[*]

The open —P_1—P_1'— bond (Lys 15, Ala 16)[1] in modified trypsin-kallikrein inhibitor I* (Kunitz) from bovine organs can be resynthesized with trypsin, chymotrypsin and plasmin. The long reaction times (half-lives corresponding to 17 weeks[2]) due to slow dissociation of the enzyme-inhibitor-complex were shortened by employing equimolar amounts of trypsin (porcine) or chymotrypsin (bovine) at pH = 7.8 (0.2 M tris(2-hydroxyethyl)ammonium chloride/NaOH, 0.01 M $CaCl_2$) and room temp. The complexes were dissociated after 1 h (trypsin) and 48 h (chymotrypsin), respectively, at pH = 1.7 and the enzyme and inhibitor were then separated on Sephadex G-50 at the same pH. In both cases the sole products isolated were the enzyme and the native inhibitor I with intact peptide bond —P_1—P_1'— (kinetically controlled dissociation[3]). A complete resynthesis could also be achieved with catalytic amounts (20 mol-%) of β-trypsin (bovine) at room temperature and pH = 3.7 within 24 h (thermodynamically controlled resynthesis).

The structure of the inhibitor with resynthesized peptide bond was apparent from the following data, which were in accord with those for the native inhibitor: a) amino acid composition; b) migration of the homogeneous inhibitor on disc electrophoresis at pH = 9.3; c) performic acid oxidation yields only one polypeptide chain (amino acids 1–58); d) kinetic constants of the complex formation with enzyme (inhibition curve)[4]; e) difference spectra of the complexes of enzyme with I and I*[4]; f) resistance to inactivation with carboxypeptidase B (2 mol-% in 0.025 M Tris-HCl buffer, pH = 7.2, 24 h at 25 °C). The resynthesis shows that the equilibrium of the enzymatically catalyzed proteolysis of the peptide bond —P_1—P_1'— lies completely on the side of the native inhibitor. This explains the

failure of attempts to prepare the modified inhibitor by direct partial proteolysis of the native protein. Furthermore, the resynthesis of the peptide bond Lys 15—Ala 16 with catalytic amounts of trypsin, chymotrypsin or plasmin proves that the reactive site of the inhibitor for these three enzymes is the same. Thus the trypsin-kallikrein inhibitor (Kunitz) is to be classified as single-headed[5, 6].

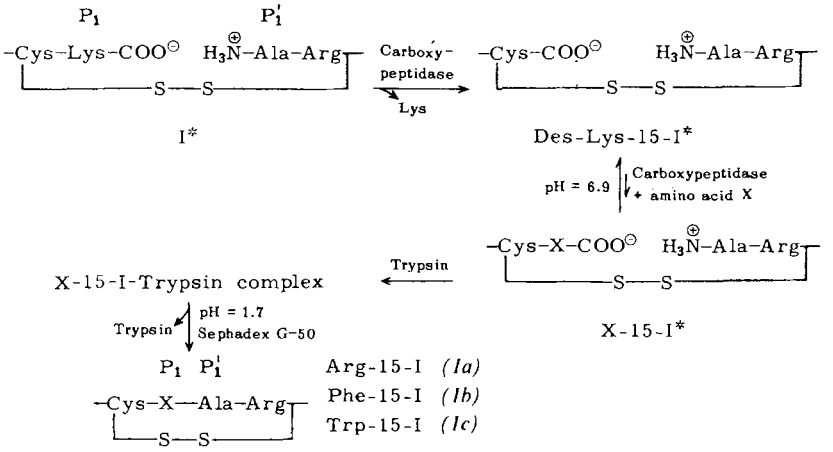
Replacement of Lysine by Arginine, Phenylalanine, and Tryptophan in the Reactive Site of the Trypsin-Kallikrein Inhibitor (Kunitz)[**]



By *Helmut Jering* and *Harald Tschesche*[*]

Cleavage of the P_1 residue from the reactive site of modified proteinase inhibitors I* with carboxypeptidase B inactivates the inhibitors[1]. The cleavage is accompanied by a reduction in the association constant K_{ass} (formation of enzyme-inhibitor complex) of about five to ten orders of magnitude. Reinsertion of a proteinase (*e.g.* trypsin) the high association constant for complex formation ($K_{ass} \approx 10^{10}$—10^{14} mol/l) can be utilized for displacing the equilibrium of the carboxypeptidase-catalyzed reaction, *i.e.* for reincorporation of the residue P_1[2, 3].

We have now used this reaction for insertion of arginine in position 15 of the modified trypsin-kallikrein inhibitor I* (Kunitz)[4] after cleavage of the Lys-15 residue [50 mg I*, 20 units of carboxypeptidase B (Merck) in 1 ml 0.025 M Tris/HCl, pH = 7.2, 0.1 M NaCl, 16 h at room temperature]. The modified des-Lys-15 inhibitor can be isolated by ion-exchange chromatography. It exhibits a single band in the disc electrophoresis and due to a lack of one positive charge it migrates at a slower rate than I*. According to amino acid analysis it contains exactly one lysine less than I*, and when subjected to the usual tests[5] proves to be inactive toward trypsin.

Incorporation of arginine was accomplished by dissolving 1.23 µmol des-Lys-15 inhibitor, 2.46 µmol trypsin (porcine) and 0.02 µmol carboxypeptidase B (Merck) in 2.4 ml buffer (0.1 M tris(2-hydroxyethyl)ammonium chloride/NaOH, 0.15 M KCl, 0.03 M $CaCl_2$ and 0.01 M NaN_3) at pH = 6.9 and incubating the resulting solution with 0.6 ml 0.25 M L-arginine in the same buffer for six days at room temperature. The resulting trypsin-inhibitor complex was then acidified to pH = 1.7 and separated into enzyme and inhibitor fractions by molecular sieve filtration on Sephadex G-50. Ion-exchange on CM-Sephadex C-25 afforded 0.25 µmol unmodified Arg-15-trypsin-kallikrein inhibitor (Kunitz) (Scheme 1).

The Arg-15 inhibitor *(1a)* obtained by enzymatic replacement is characterized by the following data: a) amino acid composition; uniformly migrating band on disc electrophoresis; c) complete resistance to inactivation by carboxypeptidase B (2 mol-% for two days), and d) the same inhibitory activity

Scheme 1. For Arg-insertion with trypsin, carboxypeptidase B was used; for Phe- and Trp-insertion with chymotrypsin, carboxypeptidase A was used. (a), X = Arg; (b), X = Phe; (c), X = Trp.

of the residue P_1, *e.g.* in the reverse reaction of the carboxypeptidase cleavage in the presence of a large excess of free amino acid P_1, increases K_{ass} by the same amount. In the presence of a proteinase (*e.g.* trypsin) the high association constant for complex formation ($K_{ass} \approx 10^{10}$—10^{14} mol/l) can be utilized for displacing the equilibrium of the carboxypeptidase-catalyzed reaction, *i.e.* for reincorporation of the residue P_1[2, 3].

We have now used this reaction for insertion of arginine in position 15 of the modified trypsin-kallikrein inhibitor I* (Kunitz)[4] after cleavage of the Lys-15 residue [50 mg I*, 20 units of carboxypeptidase B (Merck) in 1 ml 0.025 M Tris/HCl, pH = 7.2, 0.1 M NaCl, 16 h at room temperature]. The modified des-Lys-15 inhibitor can be isolated by ion-exchange chromatography. It exhibits a single band in the disc electrophoresis and due to a lack of one positive charge it migrates at a slower rate than I*. According to amino acid analysis it contains exactly one lysine less than I*, and when subjected to the usual tests[5] proves to be inactive toward trypsin.

Incorporation of arginine was accomplished by dissolving 1.23 µmol des-Lys-15 inhibitor, 2.46 µmol trypsin (porcine) and 0.02 µmol carboxypeptidase B (Merck) in 2.4 ml buffer (0.1 M tris(2-hydroxyethyl)ammonium chloride/NaOH, 0.15 M KCl, 0.03 M $CaCl_2$ and 0.01 M NaN_3) at pH = 6.9 and incubating the resulting solution with 0.6 ml 0.25 M L-arginine in the same buffer for six days at room temperature. The resulting trypsin-inhibitor complex was then acidified to pH = 1.7 and separated into enzyme and inhibitor fractions by molecular sieve filtration on Sephadex G-50. Ion-exchange on CM-Sephadex C-25 afforded 0.25 µmol unmodified Arg-15-trypsin-kallikrein inhibitor (Kunitz) (Scheme 1).

The Arg-15 inhibitor *(1a)* obtained by enzymatic replacement is characterized by the following data: a) amino acid composition; uniformly migrating band on disc electrophoresis; c) complete resistance to inactivation by carboxypeptidase B (2 mol-% for two days), and d) the same inhibitory activity towards the enzymes trypsin, chymotrypsin and plasmin as the native lysine inhibitor. Whether differences exist in the rate constants of association to the enzyme-inhibitor complex between native and Arg-15 inhibitor is at present under investigation. In an analogous reaction sequence with carboxypeptidase A and chymotrypsin under corresponding conditions we have been able to incorporate the amino acids phenylalanine and tryptophan as residue P_1. In contrast to the inhibitors with Lys or Arg in the reactive site, the homologous Phe and Trp-inhibitors *(1b)* and *(1c)* are poor trypsin but good chymotrypsin inhibitors. Corresponding results were obtained with the soybean inhibitor (Kunitz)[2, 3].

The Arg-15 inhibitor contains a single-stranded peptide chain and thus corresponds to a protein with the mutation Lys 15 →Arg 15. We have also found this substitution as a natural mutation in the homologous isoinhibitors from snails *(Helix pomatia)*[6].

Inactivation of the Trypsin-Kallikrein Inhibitor (Kunitz) by Cleavage of the Dipeptide Ala 16—Arg 17 in the Reactive Site[**]

By *Helmut Jering* and *Harald Tschesche*[*]

Cleavage of the residue P_1 (Lys 15) from the reactive site of the modified trypsin-kallikrein inhibitor I* (Kunitz)[1] inactivates the inhibitor[2]. The question arises, whether removal of the residue P_1' (Ala 16) likewise inactivates the inhibitor, even though the formation of an acyl-enzyme complex at P_1 is still possible as an intermediate step enroute to the stable enzyme-inhibitor complex C[3].

Cleavage of the residue P_1' (Ala 16) from I* meets with difficulties, since Edman degradation as used for soybean trypsin inhibitor (Kunitz)[4] is not applicable owing to inactivation of the inhibitor (N^{ε}-derivatization), and several aminopeptidases [leucine aminopeptidase from bovine eye lenses (M.W. 300000[5]), aminopeptidase M, *etc.*] do not attack I*. Because of its small molecular weight (19000[6]) aminopeptidase K is effective and cleaves the residues P_1' and P_2' (Ala 16 and Arg 17) within 20 minutes (0.5 µmol I*, 0.2 mol-% aminopeptidase K in 1.5 ml 0.025 M diethyl barbiturate buffer, pH = 8.3) (Scheme 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We wish to thank Fräulein *C. Frank* for carrying out the amino acid analyses. Thanks are also due to Bayer AG, Wuppertal for kindly supplying us with Trasylol® (trypsin-kallikrein® inhibitor (Kunitz) from bovine lung).

The reaction can be so steered that up to 95% modified des-(Ala 16, Arg 17)-inhibitor is formed. Prolonged enzyme reaction cleaves also Ile 18.—The reaction then comes to a standstill.

The modified des-(Ala 16, Arg 17)-inhibitor could be separated from the enzyme by molecular sieve filtration on Sephadex G-50 in 0.1 M acetic acid and was purified by ion-exchange chromatography on CM-Sephadex C-25 in 0.01 M sodium borate buffer, pH = 8.0 (linear NaCl gradient of 0 to 0.3 M). The homogeneous material is characterized by its amino acid composition. Native inhibitor is not attacked at the *N*-terminus (Arg-Pro-Asp-Phe-) by aminopeptidase K.

After cleavage of the residues P_1' and P_2', I* is inactive towards trypsin in the usual test[7], *i.e.* the association constant K_{ass} is reduced by about 8 to 10 orders of magnitude. Whether the acyl-enzyme complex still forms as an intermediate is at present under investigation. Since Arg 17 contributes substantially to the stabilization of the complex[3] a drastic reduction in the association constant K_{ass} had to be reckoned with; however, according to X-ray structural data for the crystallized complex[3] there should still be sufficient interaction for oriented incorporation of des-(Ala 16, Arg 17)-inhibitor into the enzyme.

Photoisomerization of Tricyclo[5.2.1.$0^{4,10}$]deca-2,5,8-triene (Triquinacene)[**]

By *Dieter Bosse* and *Armin de Meijere*[*]

Thermal isomerization of diademane *(1)*[1] leads to triquinacene *(2)*. The reverse reaction is, however, conceivable only as a photochemical two-step process. Because of the di-π-methane system present in the molecule *(2)*[2] a diradical of structure *(3)* should be formed as the first intermediate upon excitation by light. There then arises the interesting question whether an intramolecular cycloaddition of *(3)* to yield *(1)* can occur.

With this in view we irradiated a 0.8 percent pentane solution of *(2)* in a falling-film recycling apparatus at −40°C by

[**] Presented in part at the Chemiedozententagung in Stuttgart on March 31—April 4, 1974 and at the 15th Conference on Reaction Mechanisms at Fort Collins, Colorado (USA) on June 24—28, 1974.—This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

means of a 150-watt Hg medium-pressure lamp (Hanau TQ 150, quartz immersion well). *Ca.* 40—45% of the starting material had reacted after 30—50 h. At least eight new com-

(1) *(2)* *(3)*

ponents could be detected, along with polymeric material, by gas chromatography of the reaction mixture. So far seven of these products have been identified.

First there were the three known $(CH)_{10}$ isomers: bicyclo[4.2.2]decatetraene *(4)* (relative proportion 9%), tricyclo[4.2.2.$0^{2,5}$]deca-3,7,9-triene *(5)* (6%), and bullvalene *(6)* (5%), as well as naphthalene *(7)* (3%) and azulene *(8)* (trace). According to mass-spectrometric molecular weight determinations the two main products were also isomers of molecular formula $C_{10}H_{10}$; on the basis of their spectroscopic and chemical behavior the hitherto unknown structures pentacyclo[4.4.0.0.^{2,4}.$0^{3,10}$.$0^{5,9}$]dec-7-ene *(9)*[3] and hexacyclo-[4.4.0.$0^{2,4}$.$0^{3,10}$.$0^{5,8}$.$0^{7,9}$]decane *(10)*[4] were assigned to them (see Table 1).

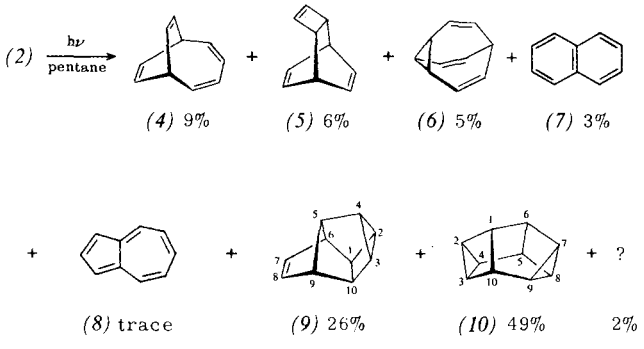

Table 1. NMR spectra of *(9)* and *(10)* [a].

Cpd.	^{1}H-NMR (τ) in CCl_4	^{13}C-NMR (δ) [b] [5]
(9)	4.56 (A_2 part of an A_2X_2 system, H^7, H^8) 7.11 (m, H^5) 7.22 (m, H^6, H^9) 7.84 (dt, H^2, H^3) 7.99 (m, H^1, H^{10}) 8.79 (m, H^4)	
(10)	7.13 (m, H^1, H^6, H^5, H^{10}) 8.11 (m, H^3, H^8) 8.47 (m, H^2, H^7) 9.03 (m, H^4, H^9)	14.39 (d, C^3, C^8; $J_{^{13}C^3-H^3}$ = 179 Hz) 19.10 (d, C^4, C^9; $J_{^{13}C^4-H^4}$ = 163 Hz) 22.24 (d, C^2, C^7; $J_{^{13}C^2-H^2}$ = 183 Hz) 36.83 (d, C^5, C^{10}; $J_{^{13}C^5-H^5}$ = 143 Hz) 52.66 (d, C^1, C^6; $J_{^{13}C^1-H^1}$ = 149 Hz)

[a] The assignment was confirmed by double resonance experiments.
[b] Relative to tetramethylsilane.

Although crystalline *(10)* (m.p. 42 °C) is a highly strained molecule since it contains two bicyclopentyl units, it is nevertheless relatively stable thermally: no rearrangement could be detected after heating a toluene solution for 5 h at 200 °C.

Upon catalytic hydrogenation (10% Pd/C) *(10)* readily took up two moles of hydrogen yielding the known tetracyclo[5.2.1.$0^{2,6}$.$0^{4,8}$]decane (m.p. 158 °C), which was identified by comparison of its characteristic NMR spectrum with that of an authentic sample[6].

Diademane *(1)* is definitely not formed on photolysis of *(2)*. When *(9)* and *(10)* are included, 23 of the 91 theoretically possible $(CH)_{10}$ isomers[7] are now known.

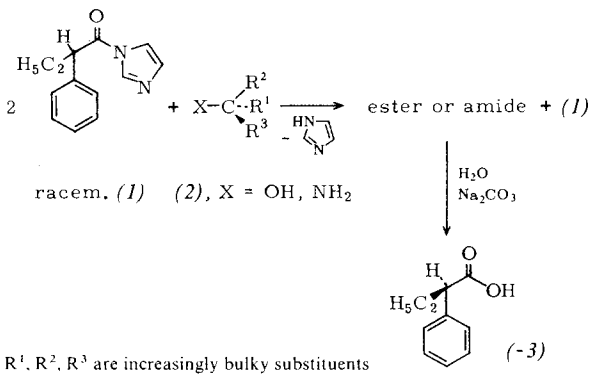
Modified Horeau Analysis for Determination of the Chirality of Amines, Alcohols, and Carboxylic Acids[**]

By *Hans Brockmann Jr.* and *Nikolaus Risch*[*]



Stereospecific reactions can be applied for correlation of configurations of chiral compounds if their course can be predicted on the basis of empirical rules or theoretical considerations. If the absolute configuration of one reactant is known, the chirality of a second can then be derived. Two procedures based on this principle have proved of value for determination of the configuration of secondary alcohols: the asymmetrically induced synthesis of atrolactic esters[1], which can be described by *Ruch* and *Ugi*'s stereochemical analogy model[2], and the method of partial kinetic resolution of bis-(2-phenylbutyric) anhydride developed by *Horeau*[3,4]. Unfortunately Horeau analyses cannot be applied to determine the configuration of amines[5].

We replaced bis-(2-phenylbutyric) anhydride by 1-(2-phenylbutyroyl)imidazole *(1)*, which is easily accessible from 2-phenylbutyric acid and *N,N'*-carbonyldiimidazole, and we then found (Table 1) that its alcoholysis and aminolysis in benzene or THF as solvent occurred with equal stereoselectivity. Although the new procedure—which can be carried out with pure *(1)* or in a single vessel without intermediate isolation—requires longer reaction times for determination of the chirality of alcohols and gives somewhat lower optical yields than the conventional Horeau analysis, the stereoselectivity in aminolyses of *(1)* is generally higher than in aminolyses of bis-(2-phenylbutyric) anhydride (the optical yield in expt. No. 6 of Table 1 amounts to 14 to 36% depending on the reaction temperature[6]).

(1) can be easily prepared in high enantiomeric purity from optically active 2-phenylbutyric acid and then used for partial resolution of racemic alcohols and amides. If *(-1)* is used for this purpose, the chirality *(2a)* of the residual excess of compound *(2)* can be predicted.

(-1) racem. *(2)* *(2a)*

Finally, the imidazole procedure permits determination of the configuration of chiral carboxylic acids: thus if an excess of racemic *(5)* is allowed to act on an optically active 1-acylimidazole *(4)*, the sign of the optical rotation of the residual amine can be used to decide the configuration of the carboxylic acid used, as shown in the formulas (cf. Table 2).

(4) racem. *(5)* *(-5)*

Table 2. Experiments for determination of the absolute configuration of carboxylic acids by way of their imidazolides *(4)*.

Although the reagent *(1)* used by us and also the imidazolides *(4)* of the carboxylic acids listed in Table 2 belong to chirality class A[2], a description of the reaction course by *Ruch* and *Ugi*'s stereochemical analogy model[2] seems to us to meet as many problems as that of conventional Horeau analyses, since the two diastereoisomeric products can be formed through more than two corresponding transition complexes.

Experimental:

The acid *(3)* (328 mg, 2 mmol) is added to a suspension of 1,1'-carbonyldiimidazole (324 mg, 2 mmol) in anhydrous benzene (4 ml) and the mixture is stirred at 22 °C until evolution of CO_2 ceases. Then the base *(+5)* (121 mg, 1 mmol) in anhydrous benzene (1 ml) is added dropwise and the reaction mixture is left for 15 h at 22 °C. The mixture is then separated by repeated shaking between benzene (20 ml) and 10% aqueous NaOH solution (20 ml), the aqueous phase is washed again with benzene, acidified with 5 N HCl, and the *(3)* precipitated is extracted in benzene. Evaporation of this solution after it had been washed twice with water and dried over Na_2SO_4 yielded 140 mg of *(3)*, $[\alpha]_{578}^{22} = 13.4°$ in benzene. Chromatography of the benzene phase on silica gel affords the mixture of diastereoisomeric amides, whose isomer proportions were found by ^{1}H-NMR spectrometry to be 57:43.

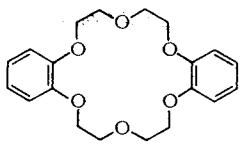
[6] Lowering the reaction temperature lowers the reaction rate but increases the stereoselectivity. The optical yield of 36% is achieved at −22 °C.



Crown Ethers as Catalysts in Reactions of Carbanions and Halocarbenes[1]

By *M. Mąkosza* and *M. Ludwikow*[*]

Catalytic reactions of carbanions and halocarbenes in two-phase liquid systems have become important and versatile tools in organic synthesis in recent years. Suitable catalysts for these reactions are quaternary ammonium[2,3] and phosphonium compounds[4]. The decisive reaction step is the formation of ion-pairs of the type $>\overset{\oplus}{N}<A^{\ominus}$ (where $A^{\ominus}$ = carbanion), which are soluble in the organic phase where they undergo further transformations with simultaneous liberation of the quaternary ammonium ions[5]. The organic "onium" cations can be substituted to some extent in these reactions by inorganic cations ($Na^{\oplus}$ or $K^{\oplus}$) when the latter are strongly solvated or complexed.

Among the most powerful complexing agents for alkali metal ions are the crown ethers[6]. As we have found, many two-phase reactions of carbanions and halocarbenes can be effectively catalyzed by crown ethers, especially dibenzo[18]crown-6 *(1)*. Addition of only a small amount of *(1)* (1 mol-%) to a two-phase system consisting of C—H acid (with or without organic solvent) and concentrated aqueous NaOH solution results in formation of Na[crown ether]$^{\oplus}$ carbanion$^{\ominus}$ ion-pairs, which are soluble in the organic phase where they undergo further transformation.

(1)

$$\text{>C-H} \xrightarrow[\text{NaOH}_{aq}]{(1)} \text{>C}^{\ominus}\ \text{Na}\ (1)^{\oplus}$$

We have studied: a) the alkylation of C—H acids, b) reactions involving trichloromethyl anion and dichlorocarbene, c) reactions of carbanions with aromatic nitro compounds, and d) Darzens condensations in systems containing *(1)*. The following are a few examples.

$$(H_5C_6)_2CH\text{-}CN + BrCH_2\text{-}CH_2Br \xrightarrow[\text{NaOH}_{aq}]{(1)} (H_5C_6)_2C(CN)\text{-}CH_2\text{-}CH_2Br$$

(2) *(3)*

$$CHCl_3 + H_5C_6\text{-}CH{=}CH_2 \xrightarrow[\text{NaOH}_{aq}]{(1)}$$

(4)

(5) $p\text{-}NO_2\text{-}C_6H_4\text{-}C(C_6H_5)(CH_3)\text{-}CN$ $\qquad$ H_5C_6-substituted epoxide *(6)*

a) Addition of 1 mol-% of *(1)* to a stirred mixture of phenylacetonitrile or diphenylacetonitrile *(2)*, alkyl chloride or bromide and 50% aqueous NaOH results in an exothermic reaction. Phenylacetonitrile and ethyl bromide give 2-phenylbutyronitrile[2] (b. p. 120°C/15 torr, yield 85%); *(2)* and 1,2-dibromoethylene give 4-bromo-2,2-diphenylbutyronitrile *(3)*[2] (m. p. 69°C, yield 75%).

b) Mild exothermic reaction of chloroform, styrene, and 50% aqueous NaOH in the presence of 1 mol-% of *(1)* gave 1,1-dichloro-2-phenylcyclopropane *(4)* (b. p. 110°C/15 torr, yield 87%). High yields of dichlorocyclopropane derivatives have also been obtained with other alkenes. Acrylonitrile gave 4,4,4-trichlorobutyronitrile (m. p. 41°C, yield ca. 40%)[7].

c) Reaction of 2-phenylpropionitrile, 1-chloro-4-nitrobenzene and 50% aqueous NaOH in the presence of *(1)* gave 2-(4-nitrophenyl)-2-phenylpropionitrile *(5)* (conditions see Ref.[2b]) (m. p. 76°C, yield 81%). 4-Nitrobenzophenone is converted into 2-(4-benzoylphenyl)-2-phenylpropionitrile[2c] (m. p. 63°C, yield 67%).

d) Darzens condensation of benzaldehyde and chloroacetonitrile in aqueous NaOH in the presence of *(1)* gave 3-phenyloxirane-2-carbonitrile *(6)* as a mixture of isomers (b. p. 137 to 140°C/15 torr, yield 78%) (cf. Ref.[2d]).

Solid Phase Synthesis and Photochemistry of 4,4′-Stilbenedicarbaldehyde[1][**]

By *Jack Y. Wong*, *Carl Manning*, and *Clifford C. Leznoff*[*]

The failure of the photocyclization-oxidation reaction of acetylstilbenes to acetylphenanthrenes is well known and has been rationalized in terms of the intervention of the n-π* excited states of the carbonyl group[2, 3]. In contrast to this previous failure we wish to report the photocyclization-oxidation of the closely related 4,4′-stilbenedicarbaldehyde *(5)* to 3,6-phenanthrenedicarbaldehyde *(6)* in high yield. In addition, the dialdehyde *(5)* has now been synthesized in a unique manner by a multistep synthesis based on our reported solid phase method[4, 5].

Downsview, Ontario M3J 1P3 (Canada)

[**] This work was supported by the National Research Council of Canada.

Terephthalaldehyde was attached exclusively at one aldehyde group through an acetal linkage to an insoluble cross-linked polystyrene polymer as described previously[4]. Reduction of the polymer-bound terephthalaldehyde *(1)* with sodium dihydrobis(2-methoxyethoxy)aluminate in benzene gave polymer-bound *p*-hydroxymethylbenzaldehyde, which was washed under standard washing conditions, but without acid, to ensure retention of the hydroxymethylbenzaldehyde to the polymer[4]. Halogenation with thionyl chloride in pyridine gave polymer-bound *p*-chloromethylbenzaldehyde *(2)*, which on treatment with excess triphenylphosphane gave the polymer-bound *p*-formylbenzyltriphenylphosphonium salt. Reaction of the salt with sodium methoxide in dimethylformamide furnished the polymer-bound ylide *(3)*. Addition of excess terephthalaldehyde to *(3)* ensured that reaction took place at only one aldehyde site of terephthalaldehyde to give polymer-bound 4,4'-stilbenedicarbaldehyde *(4)*. Cleavage of *(4)* with dilute HCl in dioxane gave 4,4'-stilbenedicarbaldehyde *(5)*[6] in 10% overall yield. Thus insoluble polymer supports can be used in multistep organic synthesis as well as in "repetitive sequential-type synthesis"[5].

Irradiation of 4.3×10^{-4} M solutions of the dialdehyde *(5)* in benzene for 2 days gave pure 3,6-phenanthrenecarbaldehyde *(6)* [(40%, m.p. 213—215°C); MS: M^+, 234 (3%), $M^+ - CHO$, 205 (30%), $M^+ - 2CHO$, 176 (100); IR (KBr): $\nu = 2720$, 1695 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 10.30$ (2CHO), 9.22 (H^4, H^5), 8.3—7.8 (H^1, H^8, H^2, H^7, H^9, H^{10}); UV ($CHCl_3$): λ_{max} 258 (35100), 327 nm (11700)]. The structure of *(6)* was supported by the spectral data and elemental analysis.

The ease of photocyclization-oxidation of 4,4'-stilbenedicarbaldehyde *(5)* to 3,6-phenanthrenedicarbaldehyde as compared to the failure of 4-acetylstilbene[2] to photocyclize shows that slight structural modifications (in this case replacement of CH_3 by H and of H by CHO) can have a substantial effect on either the energy levels of the n-π* transition of the carbonyl group or the rate of intersystem crossing. Thus, once again, the danger of predicting the outcome of a chemical reaction on the basis of reactions of similar, but not identical, chemical species has been demonstrated.

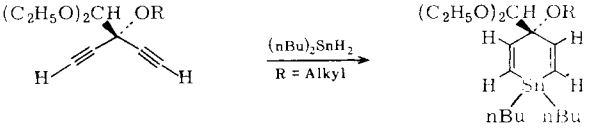
4-Alkoxyarsabenzenes

By *Gottfried Märkl* and *Fritz Kneidl*[*]

Arsabenzenes and phosphabenzenes[1] bearing functional groups have hitherto been unknown. An inquiry into the activity of these groups under the influence of the heteroaromatic ring and *vice versa* would make their synthesis appear particularly desirable.

[*] Prof. Dr. G. Märkl and Dipl.-Chem. F. Kneidl
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)



Our recent preparation[2] of arsa- (and phospha)benzenes *(3)* bearing alkyl and aryl substituents in position 4, from 1,4-

(1) *(2)* *(3)*

dihydrostannabenzenes *(1)* *via* the dihydroarsa(phospha)benzene intermediates *(2)*, should provide an entry to arsa(phospha)benzenes with functional groups at position 4, provided that corresponding precursors *(1)* containing the functional group R can be synthesized.

Ethyl 2,2-diethoxyacetate[3] reacts smoothly with ethynylmagnesium bromide to give 3-(diethoxymethyl)-1,4-pentadiyn-3-ol *(4)*, R = H (Table 1). Etherification of *(4)* with dimethyl or diethyl sulfate by the phase transfer method[4] provides ready access to the alkoxy-substituted pentadiynes *(5a)* and *(5b)* (Table 1).

(4), R = H
(5a), R = CH_3
(5b), R = C_2H_5

(6a), R = CH_3
(6b), R = C_2H_5

The pentadiynes *(5)* undergo smooth cycloaddition with di-*n*-butyltin dihydride, giving 4-(diethoxymethyl)-4-alkoxy-substituted 1,4-dihydrostannabenzenes *(6)* (Table 1). The dihydro compounds *(6)* react with $AsCl_3$ in tetrahydrofuran at 75°C to yield the 1-chloro-1,4-dihydroarsabenzenes *(7)* which can be isolated pure by chromatography with chloroform over silica gel (the dibutyltin dichloride is first eluted with benzene) (Table 1).

Table 1. Compounds of type *(4)*—*(8)* prepared.

(4), R = H, m.p. 57—58°C, light yellow needles, yield 90%; ^{1}H-NMR ($CDCl_3$): $-CH_3$: $\tau = 8.74$ (t), $J = 7$ Hz, 6H; $-OCH_2-$: $\tau = 6.17$ (q), $J = 7$ Hz, 2H; $\tau = 6.20$ (q), $J = 7$ Hz, 2H; ≡CH: $\tau = 7.44$ (s), 2H; ≥CH: $\tau = 5.5$ (s), 1H; IR (cap. layer): $\nu_{C\equiv C}$ 2110 cm^{-1}; $\nu_{\equiv CH}$ 3260 cm^{-1}, ν_{OH} 3400 cm^{-1}

Table 1 *(Continued)*.

(7b), R = C_2H_5, light yellow oil, yield 57 %: same ring proton AB spectrum as for *(7a)*

(8a), R = CH_3, light yellow oil, yield 52 %: ^{1}H-NMR ($CDCl_3$): $-OCH_3$: $\tau = 6.17$ (s); ring protons, A_2X_2 spectrum, H_A: $\tau = 0.37$ (d), H_X: $\tau = 2.40$ (d), $J = 12$ Hz [in 4-methoxypyridine the signals of the ring protons lie at significantly higher field: A_2X_2 spectrum, H_A: $\tau = 1.68$, H_X: $\tau = 3.29$, $J = 6$ Hz; $-OCH_3$: $\tau = 6.27$ (s)]; IR (cap. layer): =CH stretching: 3050, 3020 cm^{-1}; ring stretching: 1550, 1470, 1400 cm^{-1}; C—O stretching: 1245, 1030 cm^{-1} [in 4-methoxypyridine the =CH and C=C stretching bands lie at significantly higher wave numbers: =CH stretching 3070, 3040 cm^{-1}; ring stretching 1590, 1570 cm^{-1}]: UV (ethanol): λ_{max} 223 nm (ε 8900); 287 nm (ε 11000) [significant bathochromic shift compared to unsubstituted arsenin (λ_{max} 219, 268 nm)]; mass spectrum (70 eV): M^+ (C_6H_5AsO) 170 (100 %); $[M-CH_3]^+$ 155 (8 %); $[M-CH_2O]^+$ 140 (13 %); $[155-CO]^+$ 127 (35 %); $[M-As]^+$ 95 (34 %)

(8b), R = C_2H_5, light yellow oil, yield 44 %; ^{1}H-NMR ($CDCl_3$): $-CH_3$: $\tau = 8.60$ (t), $J = 7$ Hz; $-OCH_2-$: $\tau = 5.94$ (q), $J = 7$ Hz; ring protons: A_2X_2 spectrum, H_A: $\tau = 0.34$ (d), H_X: $\tau = 2.60$ (d), $J = 11$ Hz; IR (cap. layer): =CH stretching: 3060, 3020 cm^{-1}; ring stretching: 1540, 1470, 1395 cm^{-1}; C—O stretching: 1230, 1035 cm^{-1}; UV (ethanol): λ_{max}: 226 nm (ε 15100), 291 nm (ε 18000); mass spectrum (70 eV): M^+ (C_8H_9AsO) 184 (91 %); $[M-C_2H_4]^+$ 156 (100 %); $[156-CO]^+$ 128 (38 %); $[156-As]^+$ 81 (93 %)

Thermolysis of the dihydroarsabenzenes *(7)* takes an unexpected course. Whereas thermolysis of the dihydroarsabenzenes *(2)* yields the 4-substituted arsabenzenes *(3)* (it remaining open whether the 1,4-elimination of the methoxy group and the chlorine proceeds *via* a free-radical or an ionic mechanism, and which substituents act as nucleofugal or electrofugal leaving group in the latter case), in the dihydroarsabenzenes *(7)* the formyl acetal group is the better, apparently cationic, leaving group; decomposition at 140 °C affords exclusively the 4-alkoxyarsabenzenes (4-alkoxyarsenins) *(8)* (Table 1).

(7a), R = CH_3; *(7b)*, R = C_2H_5 — *(8a)*, R = CH_3; *(8b)*, R = C_2H_5

The fragmentation patterns apparent from the mass spectra are in complete correspondence with those of phenyl ethers. The 4-hydroxyarsabenzene ("arsaphenol") cation observed in the spectrum of *(8b)* decomposes in the same manner as the phenols with loss of CO. Attempts to convert the 4-alkoxyarsabenzenes *(8)* into the corresponding 4-hydroxyarsabenzene, an "arsaphenol", *via* ether cleavage have so far remained unsuccessful.

Arsabenzene-4-carbaldehyde

By *Gottfried Märkl* and *Fritz Kneidl*[*]

Whereas thermolysis of 1-chloro-4-methoxy-4-alkyl(aryl)-1,4-dihydroarsabenzenes leads *via* loss of the methoxy group and the halogen to 4-substituted arsabenzenes[1], in the case of the 4-alkoxy-1-chloro-4-(diethoxymethyl)-1,4-dihydroarsabenzenes *(1)* the diethoxymethyl group proves to be the better (probably electrofugal) leaving group; thermolysis affords 4-alkoxyarsabenzenes[2].

Reduction of the 1-chloro-1,4-dihydroarsabenzenes *(1)* with trialkyltin hydride to give 1,4-dihydroarsabenzenes *(2)* provides a means of reversing the polarity of the leaving groups. The dihydro compounds *(2)* resist all attempts at detection. Under the conditions of their formation compounds *(2)* undergo 1,4-elimination of ethanol or methanol to form the diethyl acetal of arsabenzene-4-carbaldehyde (4-(diethoxymethylarsabenzene) *(3)* (Table 1).

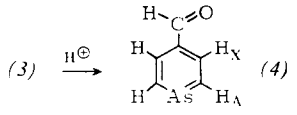
Table 1. Compounds *(3)*, *(4)*, and *(5)* prepared.

(3), light yellow oil, purification by distillation in a bulb tube at 10^{-2} torr, yield 47–52 %: ^{1}H-NMR ($CDCl_3$): $-CH_3$: $\tau = 8.77$ (t), 6H, $J = 7$ Hz; $-OCH_2-$: $\tau = 6.44$ (q), 4H, $J = 7$ Hz; ≡CH: $\tau = 4.54$ (s); ring protons: A_2X_2 spectrum: H_A: $\tau = 0.07$ (d), 2H; H_X: $\tau = 1.94$(d), 2H, $J = 11$ Hz; UV (ethanol): λ_{max} 225 nm (ε 7700), 299 nm (ε 8800); IR (cap. layer): $\nu_{CH(aromatic)}$ 3010 cm^{-1}, $\nu_{C=C}$ 1555 cm^{-1}, $\nu_{CH(aliphatic)}$ 2960, 2920, 2860 cm^{-1}; acetal stretching vibration: 1045, 1085, 1100 cm^{-1}

(4), light yellow oil, yield 70 %: ^{1}H-NMR ($CDCl_3$): ring protons: A_2X_2 spectrum: H_A: $\tau = 0.07$ (d), 2H; H_X: $\tau = 1.67$ (d), 2H, $J = 12$ Hz; —CHO: $\tau = -0.03$ (s), 1H; the aldehyde proton lies in the downfield branch of the H_A doublet; resolution is accomplished in acetone: H_A: $\tau = 0.46$ (d), 2H; H_X: $\tau = 2.10$ (d), 2H, $J = 12$ Hz; —CHO: $\tau = 0.46$ (s), 1H; IR (cap. layer): =CH stretching: 3040, 2970 cm^{-1}, *CHO* stretching: 2840, 2740 cm^{-1}, C=O stretching: 1685, ring stretching: 1560, 1490, 1360 cm^{-1} [4-pyridinecarbaldehyde: =CH stretching: 3060, 3000 cm^{-1}, *CHO* stretching: 2860, 2760 cm^{-1}, C=O stretching: 1710 cm^{-1}, ring stretching: 1600, 1570, 1490, 1415, 1400 cm^{-1}; benzaldehyde: CO stretching: 1700 cm^{-1}]; UV (ethanol): λ_{max} 229 nm (ε 10900), 300 nm (ε 16200) [arsabenzene: λ_{max} 219 nm (ε 15000), 268 nm (ε 11000); 4-pyridinecarbaldehyde: λ_{max} 220 nm (ε 2550 sh), 256 nm (3300)]; mass spectrum: M^+ (C_6H_5AsO) 168 (44 %); $[M-1]^+$ 167 (15 %); $[M-CO]^+$ 140 (62 %); $[(M-1)-CO]^+$ 139 (37 %); $[139-C_2H_2]^+$ 113 (100 %); $[113-1H]^+$ 112 (64 %)



(5), light yellow oil (chromatography on Al_2O_3), which solidifies to a crystalline mass in the cold: ^{1}H-NMR ($CDCl_3$): $-CH_3$: $\tau = 7.83$ (s), 3H; —OH: $\tau = 7.6$ (s), 1H; $-CH_2-$: $\tau = 7.14$ (d), $J = 6$ Hz; ≡CH: $\tau = 4.81$ (t), $J = 6$ Hz; ring protons: A_2X_2 spectrum: H_A: $\tau = 0.17$ (d), H_X: $\tau = 2.1$ (d), $J = 11$ Hz

Under the reaction conditions used for reduction of the 4-methoxy-1,4-dihydroarsabenzene derivative *(1)*, R = CH_3, rapid exchange occurs between the diethyl acetal *(3)* and the methanol formed by 1,4-elimination. According to the ^{1}H-NMR spectrum, the reaction mixture contains only 50 % of the diethyl acetal, alongside 9 % of the dimethyl acetal and 41 % of the ethyl methyl acetal.

The diethyl acetal *(3)* undergoes extremely rapid cleavage, quantitative reaction being complete within 15 min in the presence of an acidic ion exchanger in moist acetone solution.

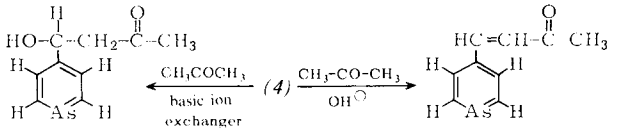
84 Regensburg, Universitätsstrasse 31 (Germany)

Arsabenzene-4-carbaldehyde *(4)* can be obtained pure as a pale yellow oil by bulb tube vacuum distillation (10^{-2} torr). Surprisingly, the product, which is stable under nitrogen, smells strongly and unmistakably of benzaldehyde, thus providing further justification for the trivial name "arsabenzaldehyde"



(3) $\xrightarrow{H^{\oplus}}$ *(4)*

The chemical shift of the aldehydic proton of *(4)* lies almost unchanged in the range corresponding to aromatic aldehydes. In contrast, the signals of the ring protons display a pronounced downfield shift, probably as a result of As anisotropic effects. Benzaldehyde and arsabenzaldehyde *(4)* exhibit an almost identical solvent dependence of the chemical shift.

The mass spectrum of "arsabenzaldehyde" *(4)* shows the characteristic fragments of aromatic aldehydes, the fragmentation pattern being practically identical with that of benzaldehyde[3].

Preliminary experiments reveal a normal electrophilic reactivity of the aldehyde group. In the presence of basic ion exchangers, *(4)* undergoes a normal aldol reaction with acetone to give the alcohol *(5)* (Table 1). Aldol condensations of *(4)* with aldehydes and ketones can also be performed in the presence of strong alkalis. Thus *(4)* reacts with acetone on addition of 20% caustic soda to give arsabenzylideneacetone *(6)* directly.

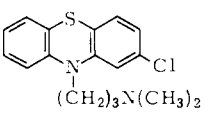
X-Ray Structure Analysis of 6-Thiatetracyclo-[5.4.0.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene



By *Chizuko Kabuto*, *Toshio Tatsuoka*, *Ichiro Murata*, and *Yoshio Kitahara*[*]

We have recently reported on the preparation and reactivity of the novel compound 6-thiatetracyclo[5.4.0.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene *(1)*[1], in which the highly strained bicyclo[1.1.0]butane moiety is incorporated in a sulfur-containing conjugated framework. We have now carried out an X-ray structure analysis of *(1)* in order to establish the geometrical features of the bicyclobutane system[2, 3] and to gain a knowledge of the nature of the CS bonding[4].

(1)

(2)

(1) crystallizes in the orthorhombic space group $P2_12_12_1$ with $a=6.493$, $b=14.690$, $c=8.309$ Å, and $Z=4$. A total of 1110 reflections were measured on a single crystal (*ca.* $0.2\times0.2\times0.3$ mm^3) using an automated Rigaku four-circle diffractometer with $Mo_{K\gamma}$ radiation.

The structure was solved by a heavy atom method and refined by a block-diagonal least-squares method. After several cycles of refinement with anisotropic temperature factors for the C and S atoms and isotropic temperature factors for the hydrogen atoms, which were located from a difference map, the refinement converged to give an *R*-factor of 0.044 for all non-zero reflections.

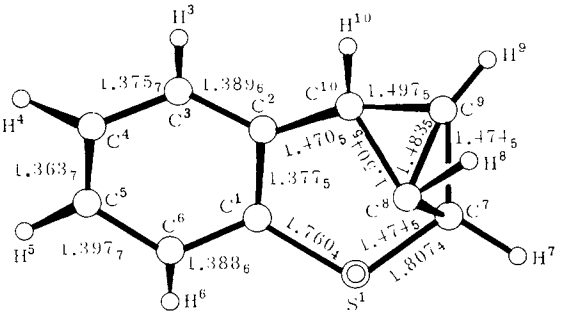

Fig. 1. The molecular structure of *(1)*, viewed along the *c* axis. The bond lengths (Å) and their standard deviations ($\times10^{-3}$ Å) are shown. A few bond angles (°) are as follows:

C^1—S^1—C^7	= 100.3(0.2)	C^8—C^9—C^{10}	= 60.8(0.3)
S^1—C^1—C^2	= 121.2(0.4)	C^7—C^9—C^{10}	= 98.9(0.4)
S^1—C^1—C^6	= 117.5(0.4)	C^2—C^{10}—C^9	= 120.9(0.4)
S^1—C^7—C^8	= 122.3(0.4)	C^2—C^{10}—C^9	= 121.6(0.4)
S^1—C^7—C^9	= 121.3(0.4)	C^8—C^{10}—C^9	= 59.0(0.3)
C^8—C^7—C^9	= 60.3(0.3)	S^1—C^7—H^7	= 105.6(2.6)
C^9—C^8—C^{10}	= 60.2(0.3)	C^2—C^{10}—H^{10}	= 117.1(2.7)
C^7—C^8—C^{10}	= 98.6(0.5)	H^8—C^8—$C^{7,9,10}$ and	
C^7—C^9—C^8	= 59.8(0.3)	H^9—C^9—$C^{7,8,10}$	= 128 to 133(3)

As shown in Fig. 1, the whole molecule is rather rigid and constrained. The benzene ring is planar and S^1, C^{10}, and C^7 atoms lie almost completely on this plane; the maximum deviation from the best plane through the benzene ring and S^1, C^{10}, and C^7 is 0.039 Å for C^7. C^8 and C^9 deviate by 0.74 Å from this plane. The dihedral angle of 122 between the two cyclopropane rings is similar to that in free bicyclobutane[2].

The two C—S bonds differ in length. The length of C^1—S^1 (1.760 Å) agrees well with that for a C(sp^2)—S bond[5]: for example in chloropromazine the length is 1.75 Å, which has been postulated to have 13% double bond character[6]. In contrast, the length of C^7—S^1 (1.808 Å) compares favorably with that for a C(sp^3)—S bond, as found in dimethyl sulfide (1.803 Å)[7]. This bond would be shorter if the carbon atom—as postulated in cyclopropane—were to be sited in an $sp^{2.2}$ hybridization orbital. The length of the C^2—C^{10} bond (1.470 Å), which is about the same as that of the C(sp^2)—C(sp^2) bond (1.48 Å), clearly indicates such an effect.

The bonds C^7—C^8 and C^7—C^9 (both 1.474 Å) are appreciably shorter than the analogous bonds C^8—C^{10} and C^9—C^{10}. For comparison: the corresponding bond to the latter in free bicyclobutane is 1.498 Å[2].

From these findings it may be concluded that the neighboring sulfur atom may change the bonding character in *(1)*, *i.e.*, for example, increase the p-character in the C^7—S^1 bond and correspondingly decrease the p-character in the C^7—C^8 and C^7—C^9 bonds. The bond angle S^1—C^7—H^7 (105.6°) is compatible with such changes in the orbitals.

Photochemical Synthesis of a Tricyclo[5.4.0.0^{1,6}]-undecatetraene in Solution[**]

By *Heinz Dürr, Michael Kausch*, and *Helge Kober*[*]

An explanation of the photolysis of diazocyclopentadienes in benzene requires postulation of an intermediate *(3)* (designated as a "bisnorcaradiene" in ref. [1])[1]. This reaction proceeds *via* the unsaturated spiro compounds *(1)*, which are in equilibrium with their valence isomers, the spiro[cyclopentadienenorcaradienes] *(2)*.

In the present communication we describe the photochemical synthesis of 2,5-diphenyltricyclo[5.4.0.0^{1,6}]undeca-2,4,8,10-tetraene *(3)* in solution.

A 20-mg sample of the valence isomer mixture *(1)*⇌*(2)* in $CDCl_3$/Frigen 11 (1:1, 0.5 ml) was placed in an NMR sample tube and irradiated with a monochromator ($\lambda = 360$ nm) for 2 h at -70 ± 2 °C in a specially constructed Cu low temperature cell. This led to a yellowish solution containing only *(3)* (TLC and NMR indicate no further products). ^{1}H-NMR spectra of this solution were recorded by the PFT method and the CW technique[3]. At −60 °C the spectrum contains a doublet for H^A at $\delta = 2.87$ ppm ($^3J = 9.0$ Hz) and a doublet of doublets for H^B at 4.62 ppm ($^3J = 6.2$ and 9.0 Hz) in the ratio 1:1. The remaining signals are to be assigned to H^C (6.40 ppm), H^F (6.24 ppm), and the $H^{E.D.H.G}$ protons (6.4—7.2 ppm) (7.2—7.6 ppm aromatic H). All signals are broadened by long range coupling. Double resonance experiments show that irradiation at the resonance frequency of H^B leads to a singlet for H^A, while irradiation at the frequency of H^A simplifies the signal of H^B to a doublet. The assignment of H^A and H^B accords well with the δ- and *J*-values for vinylcyclopropane *(8)*[2]. The UV spectrum (*n*-pentane) of *(3)* displays maxima at 288 ($\varepsilon = ca.$ 30000) and 415 ($\varepsilon = ca.$ 7500) nm.

Cooling of the NMR sample from −20 to −90 °C leads to no change in the spectrum of *(3)*. Hence it follows that the equilibrium *(4)*⇌*(3)*⇌*(5)*[4] lies completely on the side of *(3)*. If the solution of *(3)* in $CDCl_3$/Frigen 11 is heated to −10 °C thermal rearrangement occurs to give the benzocycloheptenes *(6)* and *(7)*, which have been previously described in ref. [1]. Valence isomerization first takes place to form *(4)* and *(5)*, which are then transformed by sigmatropic [1.5]H shift to *(6)* and *(7)*. A kinetic study of the thermolysis of *(3)* using UV spectroscopy afforded the activation parameters of the reaction *(3)* → *(6)* + *(7)*: $E_A = 15.8 \pm 0.4$, $\Delta G^{\neq} = 21.5 \pm 0.4$, $\Delta H^{\neq} = 15.2 \pm 0.4$ kcal/mol; $\Delta S^{\neq} = -21 \pm 2$ cal deg^{-1} mol^{-1}. The half-life of *(3)* at 21 °C is 16 min; the reaction *(3)* → *(6)* + *(7)* is of first order.

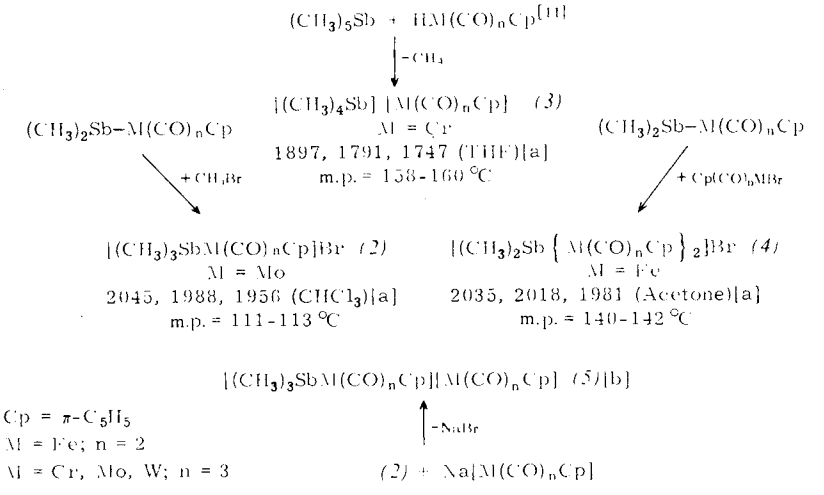
Antimony(V)-Transition Metal Compounds with Covalent and Ionic Character

By *Wolfgang Malisch* and *Peter Panster*[*]



During our studies on the reactivity of dialkylarsenido- and dialkylantimonido-transition metal compounds, which are capable of existence as mononuclear complexes[1, 2], we have found that the action of halogen, *e.g.* bromine, leads to oxidative addition of agent with formation of metal-substituted element(V) dihalides, and not, as in comparable systems, to the cleavage of the element-metal or element-carbon bond[3]. Complexes of this type have previously been postulated only as short-lived intermediate compounds[4].

The antimony(V) derivatives *(1)* of metals of the VIth subgroup are particularly readily accessible; they are generally obtained directly under mild reaction conditions (20 °C, cyclo-

The complexes *(1)* are monomeric in solution, and, according to conductivity measurements, only insignificantly dissociated [*e.g. (1c)*: mol.wt. (cryoscopically in $CHBr_3$) 639 (calc. 644.6); $\Lambda = 1.29\ \Omega^{-1}\ mol^{-1}\ cm^2$ (0.02 M in acetone)[6]]. Their chemical behavior, like that of the trimethylantimony dihalides[7], is determined by the tendency of the central atom to acquire tricoordination *via* ligand elimination.

$$Br_2(CH_3)_2Sb\text{–}Mo(CO)_3\pi\text{-}C_5H_5 \longrightarrow \quad (2)$$
(1b)

$$(CH_3)_2SbBr + \pi\text{-}C_5H_5(CO)_3MoBr$$

This reaction occurs under solvolytic and thermal conditions as well as under mass spectroscopic conditions, and, together with the reaction of formation (1), shows that the halogen-cleavage in such element-transition metal compounds must be regarded as an addition-elimination process. The observed dependence of the rate of decomposition on the nature of the metal and element atoms (Fe≫Mo>Cr>W; As≫Sb) precludes complete characterization of the adducts in critical cases (Fe—Sb or M—As).

Such a reaction behavior confirms the pentacoordination of the central atom and, together with spectral data[8], would strongly suggest a covalent structure of trigonal-bipyramidal geometry for this type of compound, as has already been demonstrated for molecules having the composition $(CH_3)_3SbX_2$[9]. The proposed ligand arrangement is in agreement with the polarity rules applicable to such coordination polyhedra[10]. A prerequisite for realization of covalency in antimony(v)-metal complexes is the incorporation of at least two halogen atoms per molecule. Their successive replacement by methyl [*(2)*, *(3)*] or metal groups [*(4)*, *(5)*] yields exclusively purely ionic products (Scheme 1).

Coordination in Bis(thiooxomolybdato)metalate(II) Complexes of Type $[M(MoOS_3)_2]^{2-}$ and $[M(MoO_2S_2)_2]^{2-}$

By *E. Königer-Ahlborn* and *Achim Müller*[*]

Complex anions of the type $[M(WS_4)_2]^{2-}$ [1, 2] and $[M(MoS_4)_2]^{2-}$ [3] contain the structural unit *(1)* (M^{II} = transition metal; M' = Mo^{VI}, W^{VI}; X = S).

(1)

We have now looked into the question of whether thiooxomolybdates also form the corresponding complexes and whether coordination is preferred *via* oxygen *or* sulfur or an isomeric mixture is formed, as in the case of thiosulfato complexes[4]. Using *Pearson*'s theory the type of coordination is not predictable for complexes with Ni or Co as central atom M.

We have now succeeded in isolating and characterizing the following complexes as tetraphenylphosphonium salts by elemental analysis, IR spectra, electron absorption spectra, and magnetic measurements: $[Zn(MoOS_3)_2]^{2-}$ *(2)*, $[Ni(MoOS_3)_2]^{2-}$ *(3)*, $[Ni(MoO_2S_2)_2]^{2-}$ *(4)*, and $[Co(MoO_2S_2)_2]^{2-}$ *(5)*.

(2), *(3)*, and *(4)* are diamagnetic, while *(5)* has a magnetic moment of 4.0 μ_B (at 295 °K). This suggests the likelihood of a square-planar coordination for the niccolates *(3)* and *(4)* and a tetrahedral coordination for the cobaltate *(5)*.

The electron absorption spectra show d→d transitions along with ligand internal charge transfer bands of the type π(S)→d(Mo) and charge transfer bands π(S)→d(M) (M = Ni, Co). Assignment of the bands is possible only if one assumes negligible interactions between the ligand internal MOs and the AOs of the central atom M. The spectra of *(3)* and *(4)* show the spin-allowed transitions expected for a square-planar NiS_4 chromophore (d^8)[5, 6]; the position of the d→d transition $\nu_1(^1A_{1g} \rightarrow {}^1A_{2g})$ suggests that the ligand field strengths of $MoOS_3^{2-}$ and $MoO_2S_2^{2-}$ are of the same order of magnitude as that of the diethyldithiophosphinate ion[6]. The spectrum of *(5)* exhibits a d→d transition at 14900 cm^{-1}, which lies at about the same energy as in compounds having a tetrahedral CoS_4 chromophore[7].

In tetrathiomolybdato complexes the terminal stretching vibrations $\nu(MoS)_t$ appear at ≈500 cm^{-1} and the bridge stretching vibrations at ≈450 cm^{-1}. Interpretation of the spectra of the corresponding metal-isotope substituted compounds ($^{58/62}Ni$) shows that $\nu(MoS)_t$ is practically not coupled with $\nu(MoS)_{br}$[8]. Thus it follows that bands at ≈500 and ≈450 cm^{-1} may be regarded as an indication of the presence of terminal and bridge MoS bonds respectively. The measured frequencies of the stretching vibrations of *(2)*, *(3)*, *(4)*, and *(5)* are listed in Table 1.

Our investigations show, therefore, that, if oxygen and sulfur atoms are present in complexes of the type $[M(MX_nY_m)_2]^{2-}$ (X = O, Y = S; n = 1 or 2, m = 3 or 2) only the sulfur atoms are used for coordination to the central atom M.

Table 1. Stretching vibrations in the IR spectra of the bis(thiooxomolybdato)-metalates *(2)*—*(5)* (in cm^{-1}).

Complex	$\nu(MoO)$	$\nu(MoS)_t$	$\nu(MoS)_{br}$	$\nu(MS)$ [b]
$[Zn(MoOS_3)_2]^{2-}$ *(2)*	898	502	456, 437	288
$[Ni(MoOS_3)_2]^{2-}$ *(3)*	896	500	458	326
	884	492	446	
$[Ni(MoO_2S_2)_2]^{2-}$ *(4)*	896	— [a]	463	325
	880		453	
$[Co(MoO_2S_2)_2]^{2-}$ *(5)*	903	—	453	289
	884		447	

[a] Very weak band at 498 cm^{-1}.
[b] M = Zn, Ni or Co.

Experimental:

(2) and *(3)*: An aqueous solution of $ZnSO_4 \cdot 7H_2O$ (150 mg) or $Ni(NO_3)_2 \cdot 6H_2O$ (140 mg) and tetraphenylphosphonium chloride (370 mg) is added rapidly to a freshly prepared solution of Cs_2MoOS_3 (470 mg)[9] in H_2O (110 ml).

(4) and *(5)*: An aqueous solution of $Ni(NO_3)_2 \cdot 6H_2O$ (140 mg) or $CoSO_4 \cdot 7H_2O$ (140 mg) and tetraphenylphosphonium chloride (370 mg) is added to a solution of $(NH_4)_2MoO_2S_2$ (230 mg)[10] in H_2O (60 ml).

In each case, the precipitate that is formed is immediately filtered under nitrogen and dried over P_4O_{10} in a vacuum. *(2)* is orange, *(3)* and *(4)* are brown, and *(5)* is green.

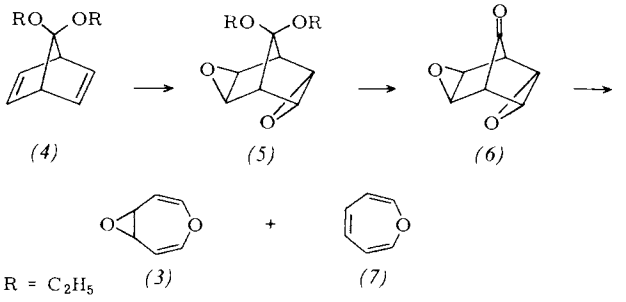
4,8-Dioxabicyclo[5.1.0]octa-2,5-diene

By *Helmut Klein* and *Wolfram Grimme*[*]

The rapid reversible Cope rearrangement of bicyclo[5.1.0]octa-2,5-diene (homotropilidene) *(1)*[11] is retarded on replacement of one methylene group by oxygen, but the "fluxional structure" is retained in 8-oxabicyclo[5.1.0]octa-2,5-diene (epoxydihydrotropilidene) *(2)*[12]. It remained to be seen whether replacement of the second methylene group is also tolerated and this dynamic behavior is retained in 4,8-dioxabicyclo-[5.1.0]octa-2,5-diene (epoxydihydrooxepin) *(3)*.

We have synthesized *(3)*, starting with the double epoxidation of 7,7-diethoxynorbornadiene *(4)*[13] with *m*-chloroperbenzoic acid in benzene at room temperature. The *as*-diepoxyacetal *(5)* (70 %; b.p. 63—65 °C/3 × 10^{-3} torr) thus obtained, gave,



[*] Dipl.-Chem. H. Klein and Prof. Dr. W. Grimme
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

on hydrolysis in 80% aqueous acetic acid, the corresponding ketone *(6)* [50%; m.p. 142°C, from ethanol; NMR ($CDCl_3$, TMS internal): $\tau = 6.30$ (AA'XX' half spectrum, $J + J' = 4$ Hz)

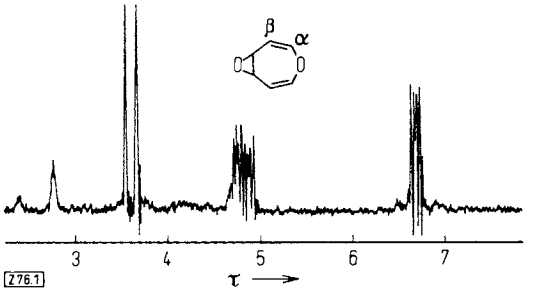
(1), X = CH_2, Y = CH_2
(2), X = O, Y = CH_2
(3), X = O, Y = O

(epoxide *exo*-H), 6.61 (AA'XX' half spectrum, $J + J' = 3$ Hz) (epoxide *endo*-H), 7.00 ppm (m) (bridgehead-H); IR (KBr): $\nu_{C=O} = 1768\ cm^{-1}$].

(4) *(5)* *(6)* *(3)* *(7)*

R = C_2H_5

On sublimation in a stream of nitrogen (17 ml/min) through a capillary (45 cm, 0.3 cm diameter) heated to 420°C, *(6)* fragments in two ways: the main reaction is the expected decarbonylation leading to 4,8-dioxabicyclo[5.1.0]octa-2,5-diene *(3)* (*ca.* 80%); this is accompanied by formation of oxepin *(7)*[5] (*ca.* 20%) with loss of CO_2. Separation of the products is achieved by dissolving the pyrolyzate in pyridine and converting the oxepin into the Diels-Alder adduct[6] (m.p. 217°C, from ethyl acetate) by addition of *N*-phenylmaleimide. On subsequent distillation (room temperature/10^{-3} torr), *(3)* is collected together with solvent in a receiver cooled to −78°C.



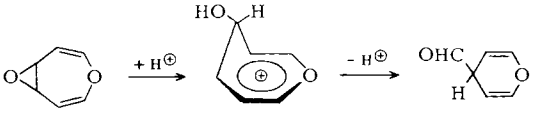


Fig. 1. ^{1}H-NMR spectrum of 4,8-dioxabicyclo[5.1.0]octa-2,5-diene *(3)* (60 MHz, C_5D_5N, TMS internal). The signals at $\tau = 2.38$ and 2.76 ppm are due to the residual ^{1}H of the solvent.

The ^{1}H-NMR spectrum of *(3)* (Fig. 1) contains three groups of signals of equal intensity [(C_5D_5N, TMS internal): $\tau = 3.63$ (d, $J = 7.5$ Hz) (α-olefin H), 4.83 (doubletted AA'XX' half spectrum) (β-olefin H), 6.70 ppm (AA'XX' half spectrum, $J + J' = 6$ Hz) (epoxide-H)]; no line-broading occurs up to 90°C. This clearly indicates that the compound does not undergo a rapid Cope rearrangement, which would render the α-olefin and epoxide protons magnetically equivalent. Loss of "fluxional structure" does not necessarily signify that compound *(3)* is statically present; rather, its mean residence time as one of the two automeric structures at room temperature can be extrapolated to 10^2—10^4 s from the Free enthalpies of activation of *(1)* (14.4 kcal/mol[7]) and *(2)* (*ca.* 17 kcal/mol[2]). The different rates of rearrangement of *(1)* to *(3)* clearly indicate that the cyclic bishomoconjugation in the transition state proceeds more readily *via* methylene bridges than *via* the oxygen bridges. The insulatory effect of the oxygen is not due to any contribution of its lone electron pair in the conjugation—this would lead, in the case of *(2)* to formation of a destabilized $4n$ Hückel system, in the case of *(3)*, however, to a stabilized $(4n + 2)$ Hückel system—but to deformation of its neighboring carbon orbitals *via* which the homoconjugation takes place[8].

As a vinylogous epoxy ether[9] compound *(3)* is sensitive to acids, in the presence of which it rearranges to the 4*H*-pyran-4-carbaldehyde *(9)* [NMR ($CDCl_3$, TMS internal): $\tau = 0.54$ (d, $J = 2.5$ Hz) (aldehyde-H), 3.54 (doublet of triplets) (α-olefin-H), 5.14 (m) (β-olefin-H), 6.44 ppm (m) (tertiary-H)]. The aldehyde *(9)*, which, like its parent compound[10] is unstable towards air, can be catalytically hydrogenated (5% Pd on $CaCO_3$, methanol) to tetrahydropyran-4-carbaldehyde (m.p. 135°C; oxime: m.p. 224°C), which is also readily accessible from tetrahydropyran-4-carboxylic acid[11] by Rosenmund reduction.

(3) *(8)* *(9)*

4,8-Dioxabicyclo[5.1.0]octa-2.5-diene *(3)*, in substance or in benzene solution, immediately rearranges on coming into contact with a glass surface that has not been treated with alkali. The ease and uniformity of rearrangement might best be explained in terms of the homopyrylium ion *(8)* as intermediate.

[2.2](2,5)Benzoquinonophane: Structure and Photochemistry[1]

By *Hermann Irngartinger, Rolf-Dieter Acker, Walter Rebafka,* and *Heinz A. Staab*[*]

In the context of their investigations on the synthesis of "intramolecular quinhydrones", *Rebafka* and *Staab*[2] recently described two diastereomeric[2.2](2,5)benzoquinonophanes which, on the basis of their syntheses, could be assigned the achiral "pseudogeminal" and chiral "pseudo-ortho" structures *(1)* and *(2)*, respectively. X-ray structure analyses were not only of interest for confirmation of these assignments but also for establishing how the molecular deformation observed in [2.2]paracyclophane[3] is changed on replacing the benzene rings by non-aromatic *p*-benzoquinone moieties, and for examining the differences in the photochemical behavior of *(1)* and *(2)*.

(1)   *(2)*

(1) crystallizes from dioxane in the monoclinic space group $P2_1/n$ with two molecules in the unit cell [$a=7.930(2)$, $b=9.280(2)$, $c=8.024(2)$ Å; $\beta=93.30(2)°$; $d_{calc}=1.51\,g\cdot cm^{-3}$]. For the structure determination, 1440 (incl. 420 "unobserved") reflections were measured by the difference filter method up to $\sin\theta/\lambda=0.66$ on a computer-controlled Siemens single-crystal diffractometer using Mo Kα radiation. The structure could be solved on the basis of 120 *E* (*hkl*) values by direct methods[4] and refined by least squares procedures with inclusion of anisotropic temperature factors for the C and O atoms and isotropic temperature factors for the H atoms. The final *R* value after several cycles was 5.1 %.

The molecule *(1)* (Fig. 1) in the crystal has $\bar{1}$ (C_i) symmetry; deviation from 2/m (C_{2h}) symmetry is essentially due to a parallel shift of the two quinone rings of about 0.24 Å perpendicular to $C^3...C^{6'}$. While the bond lengths and angles within the quinone rings of *(1)* are in good agreement with the values for 2,5-dimethyl-1,4-benzoquinone[5], the $C^7—C^8$ bond, which runs parallel to the repulsive forces within the molecule, is stretched to 1.581 Å. There is also considerable boat-shape deformation of the quinone rings (Fig. 2) due to transannular repulsion. The planes E2 through C^1, C^5 and C^6 and through C^2, C^3 and C^4 are inclined at an average of 16° to the plane E1 through C^1, C^2, C^4 and C^5 (the corresponding deformation in [2.2]paracyclophane is 12.6°[3b]). The carbon-oxygen bonds deviate in opposite directions from E1 by 5.5° ($O^1...O^{2'}$: 3.37 Å). Particularly short distances of 2.73 Å and 3.11 Å are found for $C^3...C^{6'}$ and $C^2...C^{5'}$, *i.e.* for the opposite pairs of carbon-carbon double bonds of the two *p*-benzoquinone systems. Since these double bonds lie parallel to each other in the projection onto E1 (in the plane through them they form an angle of 16.5°), favorable conditions prevail for intramolecular photochemical [2+2]-cycloadditions.

On the other hand, the conditions are particularly unfavorable for an intermolecular photocycloaddition which is normally observed in *p*-benzoquinones: although a center point distance between the $C^2—C^3$ double bond of one molecule and the $C^5—C^6$ double bond of a neighboring molecule is found to be 3.80 Å, *i.e.* shorter than the topochemical maximum distance of 4.2 Å[6], these two double bonds are inclined to each other at an angle of 53.3°.

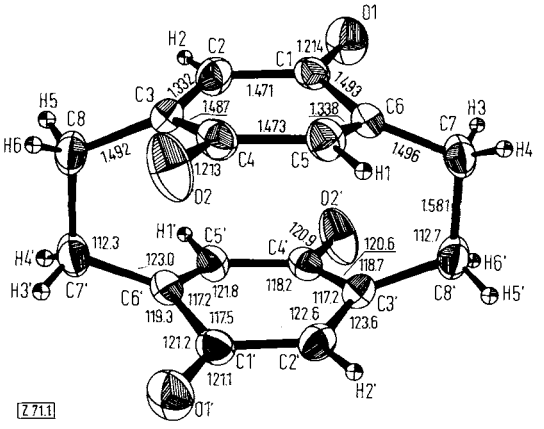

Fig. 1. Bond lengths (Å, standard deviation 0.002 Å) and bond angles (°, standard deviation 0.1—0.2°) of *(1)*, ORTEP drawing: the vibration ellipsoids are drawn at the 50 % probability level for C and O atoms; the H atoms are fixed at 0.1 Å.

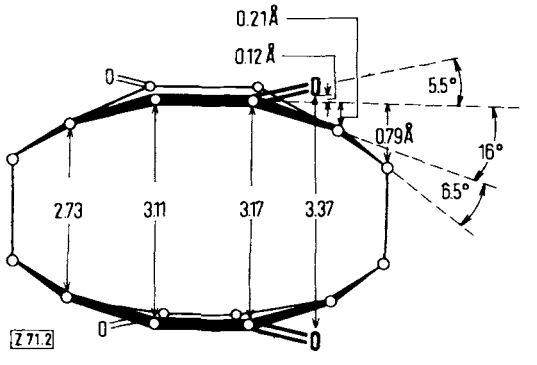

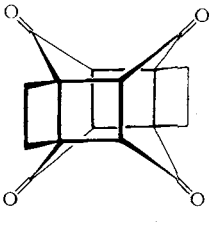

Fig. 2. Transannular distances (Å) and mean deviations from the plane E1 through C^1, C^2, C^4 and C^5 in *(1)*.

Irradiation of *(1)* (900 W Hg high-pressure lamp, Duran filter, 24 h) in the solid state does in fact lead to double intramolecular cycloaddition and formation of a colorless compound (≈90 % yield; dec. >230 °C, from dioxane) having the cage structure *(3)*: ^{1}H-NMR (PFT, 3540 scans, in D_2O): $\delta=2.0—3.6$ (m, 8 methylene-H), 3.76 (s, 4 methine-H); IR: $\nu_{C=O}=1710\,cm^{-1}$ (in dioxane); UV: no maximum above 200 nm; MS: M^+ calc. for $C_{16}H_{12}O_4$ 268.0734, obs. 268.0736. Typical of the mass spectrometric fragmentation is the successive cleavage of the four carbonyl groups down to $C_{12}H_{12}$ and the corresponding cleavage in the (M−1H) series; other important fragment ions are $m/e=214$ (80 %), 201 (100 %), 115 (43 %). Similarly to the structurally related cage compounds obtained by photodimerization of dimethylbenzoquinones[7], compound *(1)* takes up water to give a dihydrate.

 *(3)*

As expected, in contrast to *(1)* no intramolecular cycloaddition of the *p*-benzoquinone units can be observed on irradiation of diastereomeric *(2)* under the same conditions or for longer radiation times. Rather, a considerably slower intermolecular photoreaction takes place to give a high molecular weight

[*] Priv.-Doz. Dr. H. Irngartinger, Dipl.-Chem. R.-D. Acker, Dr. W. Rebafka, and Prof. Dr. H. A. Staab
Institut für Organische Chemie der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

product (40 % yield after 73 h). A topochemical interpretation of this photoreaction is not yet possible, since changes are also observed during collection of the X-ray data of *(2)* [$a = 9.09$, $b = 23.65$, $c = 11.44$ Å; $\beta = 90.9°$; space groups: $P2_1/c$, $Z = 8$; $D_{calc.} = 1.45$].

Reaction of a Vinyl Fluoride with Antimony Pentafluoride. Spectroscopic Evidence for a Stable Vinyl Cation[1][**]

By *Hans-Ullrich Siehl*, *James C. Carnahan Jr.*, *Lothar Eckes*, and *Michael Hanack*[*]

Vinyl cations have been shown to be reactive intermediates in many solvolytic, addition, and rearrangement reactions[2]. However, all previous attempts to produce and spectroscopically detect long-lived vinyl cations have so far failed[3].

In the present communication we report the first attempt to apply the methods formerly used for the generation of trisubstituted carbenium ions[4] to the reaction of vinyl halides and to record the ^{1}H- and ^{13}C-NMR spectra of the resulting solutions at low temperatures.

Table 1. ^{1}H-NMR spectrum of *(1)* in CCl_4 at 22 °C, and of [*(1)* + SbF_5] in SO_2ClF at −73 °C. Chemical shifts in ppm from external TMS = 0.

tube[5] and frozen in liquid nitrogen until the spectra were recorded.

In contrast to the ^{1}H-NMR spectrum of *(1)*, that of the reaction product of *(1)* with SbF_5 $[(1) + SbF_5]$ shows downfield shifts (Table 1). At -73 °C the aromatic region of the spectrum of $[(1) + SbF_5]$ is similar to that of the *p*-methoxybenzyl cation investigated under the same conditions by *Olah*[6], as regards both the chemical shift of the protons as well as the non-equivalence of the two *o*- and *m*-protons (H^c, H^e and H^d, H^f, respectively).

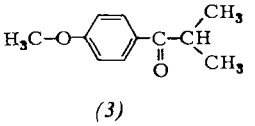

Figure 1 shows the ^{13}C-NMR spectra of *(1)* (Fig. 1a) and $[(1) + SbF_5]$ (Fig. 1b). In the spectrum of $[(1) + SbF_5]$ the methyl groups (C^{10}, C^{11}) that are shifted only slightly downfield appear as a single signal. The C—F couplings are no longer visible. An especially large downfield shift is observed in the case of the signal at 187.5 ppm, which according to the "off-resonance" spectrum corresponds to a quaternary C atom. This signal can be assigned to C^4, since it is shifted downfield by about the same amount as the corresponding signal in the spectrum of the *p*-methoxybenzyl cation[6]. In the "off-resonance" spectrum, the signals at 148.6 and 144.2 ppm and 126.8 and 119.6 ppm, respectively, form doublets and can analogously be assigned to the *ortho* (C^2, C^6) and *meta* (C^3, C^5) positions. The non-equivalence of C^2 and C^6 and of C^3 and C^5 is presumably due to the frozen rotation of the CH_3O group at low temperatures[6]. The assignment of the signals should be regarded as tentative.

That the two methyl C atoms (C^{10}, C^{11}) in $[(1) + SbF_5]$ give rise to only one signal is consistent with the expected symmetry of a substituted linear vinyl cation. A complexation of *(1)* with SbF_5 at the *p*-methoxy group can be ruled out as the sole cause of the observed downfield shift by comparison of the spectra of *(1)* and *(2)* with SbF_5. Protonation of *(1)* and *(2)* with HSO_3F/SbF_5 (1:1) produced the spectroscopically identified aryl(fluoro)isopropylcarbenium ions.

Preliminary ^{13}C-NMR measurements on *(1)* with specific ^{13}C-enrichment at the functional C-atom (C^8)[7] show two intense signals at 174.9 and 189.7 ppm in SbF_5/SO_2ClF. Consequently, the presence of a second species or occurrence of an exchange process cannot yet be ruled out with certainty. All ^{13}C-NMR spectra of $[(1) + SbF_5]$ were accurately reproducible to at least 0.9 ppm.

(2)

(3)

A solution of $[(1) + SbF_5]$ (with specifically ^{13}C-enriched *(1)*) in SO_2ClF was added dropwise to a cooled suspension of K_2CO_3 in methanol and (after work-up with pentane) investigated by gas-chromatography. The sole product found was the ketone *(3)*, which, after isolation, was identified by its NMR, IR and mass spectra[8]. The absolute yield of ketone *(3)* ranged between 20 and 40%; the fluoride *(1)* is stable under the experimental conditions used. Quantitative mass spectrometric investigations on *(3)* showed no changes in the position of the labeled C atom.

Within the limits mentioned above, we interpret the spectroscopic data reported here as the first evidence for the occurrence of a stable long-lived vinyl cation in the reaction of a vinyl halide with antimony pentafluoride. This is supported by the observed downfields shifts of the ^{1}H and ^{13}C-NMR signals, and especially by the similarity between the spectrum of $[(1) + SbF_5]$ and that of the *p*-methoxybenzyl cation regarding the signals in the aromatic region and the shift of the methoxy group.

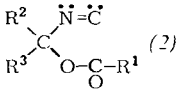
α-Acyloxy Isocyanides ("*O*-Acyl Isocyanohydrins")

By *Gerhard Höfle*[*]



While the formation and transformation of the cyanohydrins have been investigated in detail, to our knowledge no reference has as yet been made to isomers with the isocyanide structure. In the present communication we report on the *O*-acyl derivatives of this type of compound.

Thus, reaction of benzoyl bromide with silver cyanide in acetone leads to formation of α-benzoyloxy isocyanide *(2a)* (1-isocyano-1-methylethyl benzoate) and no trimeric benzoyl isocyanide[1, 2]. The structure of *(2a)* follows unambiguously from the spectroscopic data (cf. Table 2). Presumably the α-acyloxy bromide *(1a)*, which is present in low equilibrium concentration along with acyl bromide and ketone[3], reacts according to a classical isocyanide synthesis more rapidly than acyl bromide with silver cyanide.

X = Br, I

(1)

(2)

As expected, the isolable α-acyloxy bromides *(1c)* and *(1d)*[5] also afford the isocyanides *(2c)* and *(2d)* in high yields. Experiments have shown that the S_N1 reactivity of *(1)* plays a decisive role in the reaction. Despite the levelling influence of the acyloxy group, it depends strongly on the nature of the α-substituents R^2 and R^3 and the leaving group X. Thus, in the case of R^2, R^3 = alkyl and R^2 = phenyl, R^3 = H, the

[*] Dr. G. Höfle
Organisch-Chemisches Institut der Technischen Universität
1 Berlin 12, Strasse des 17. Juni 135 (Germany)

bromide affords the best results, while in the case of R^2 = alkyl, R^3 = H the iodide is to be preferred[4]. *(1f)* also reacts only slowly with X = iodine[4]. No reaction takes place in the case of the chlorides *(1)*.

An overview of the isocyanides *(2)* prepared, and their characteristic spectroscopic data, is presented in Tables 1 and 2. The compounds are colorless crystals or liquids, which become dark and resinous at room temperature and in the presence of air.

The isocyanides *(2)* are relatively stable toward alkaline hydrolysis; thus, in their isolation, removal of silver salts[7] is accomplished by shaking with *ca.* 20% potassium cyanide solution. On the other hand, momentary hydrolysis takes place in 1 N HCl/acetone to give carbonyl compounds, hydrogen cyanide, and carboxylic acids, and, in the case of *(2c)*, smaller amounts of *N*-(α-hydroxybenzyl)formamide. Whether acid hydrolysis proceeds *via* the isocyanohydrin, has still to be investigated.

Table 1. Isocyanides *(2)* prepared [6].

[a] $J_{HCN^{13}C}$ is not determined.

Experimental:

Method A: Acyl bromide (20 mmol) is added with cooling to a stirred suspension of silver cyanide (22 mmol) in ketone (0.2 mol). After 30 minutes the ice-bath is removed and stirring is continued for a further 3—5 h. The excess of ketone is then removed by evaporation in a vacuum and chloroform and 20% potassium cyanide solution are added until all salts are dissolved. The organic phase is dried over $MgSO_4$ and the solvent evaporated off in a vacuum. The residue is distilled or recrystallized from petroleum ether.

Method B: α-Acyloxy bromide *(1)*[5] (20 mmol) is added to a suspension of silver cyanide (42 mmol) in chloroform (30 ml). After 3—5 hour's stirring, the same procedure as in Method A is followed.

Method C: α-Acyloxy iodide *(1)*[4] (20 mmol) is added to a suspension of silver cyanide (44 mmol) in chloroform (20 ml) and stirred, in the case of *(2e)* for 1—2 h, in the case of *(2f)* for 24 h. Thereafter the same method as in A and B is followed.

[2] Thanks are due to Professor *H. A. Staab* for drawing our attention to the publication by *H. Dounchis*.

[3] Mixtures of benzoyl bromide and acetone do not show any new signals in the NMR spectrum; independently prepared iodide *(1a)* decomposes at room temperature into benzoyl iodide and acetone [4].

[4] *G. Wittig* and *M. Jautelat*, Liebigs Ann. Chem. *702*, 24 (1967).

[5] The bromides *(1c)* and *(1d)* are formed quantitatively if the corresponding benzaldehyde is mixed with 2—3 mol acyl bromide and the excess of the latter is removed by distillation under vacuum at room temperature immediately before further use.

[6] All compounds gave correct elemental analyses.

[7] The silver can be recovered quantitatively from the aqueous solution by reduction with zinc dust.

Reviews

Abstracts of selected progress reports and review articles

Applications of X-ray photoelectron spectroscopy (ESCA) in inorganic chemistry are discussed in a review by *W. L. Jolly*. The main value of this method for chemists lies in the fact that core electron binding energies are a function of the chemical environment of the atoms, *i.e.* they are subject to a "chemical shift". This chemical shift is correlated with atomic charge. Thus, it is possible to identify oxidation states, even if they are non-integral. This is important for the proof of valence electron delocalization, especially in coordination compounds. Similarly, π back-bonding, pπ→dπ bonding, and ligand structure and orientation can be investigated with the aid of this method. [The Application of X-Ray Photoelectron Spectroscopy to Inorganic Chemistry. Coord. Chem. Rev. *13*, 47—81 (1974); 119 references]

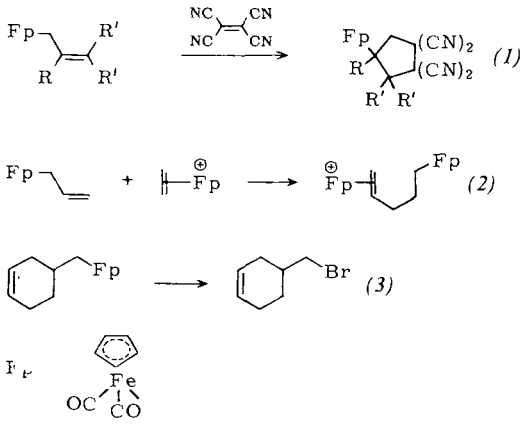
The synthesis of carbocyclic spiro compounds containing skeletal units such as *(1)* ***via* intramolecular alkylation routes** is reviewed in an article by *A. P. Krapcho*. There are six different types of reaction: 1) Intramolecular dehydrohalogenations, dehydrotosylations, and related reactions *e.g.* the cyclization of 2-(ω-bromoalkyl)cycloalkanones and 9-(ω-haloalkyl)fluorenes and the intramolecular dehydration of 2-(2-hydroxyethyl)-cyclohexanones lead to *(1)*. 2) Di- and tetraalkylations of ketones with α,ω-dihaloalkanes and subsequent dehalogenation yields spiroketones in one step; dispiro- and polyspiroketones can also be synthesized in this way. The reaction of



(1)

malonic esters with α,ω-dihaloalkanes, and especially with ditosylates, permits formation of spiro- and polyspiro-linkages. 3) Reductive intramolecular dehalogenation leads to spiropentanes and spirocyclopropane systems and their ketones. 4) Free radical cyclization, such as oxidative coupling of phenol to double bonds and photochemical dehydrobrominations also yield *(1)*. 5) Acid-catalyzed cyclizations (cyclodehydration of alcohols with suitably placed double bond or aromatic ring, cyclization of *ene-ene* or *ene*-aromatic systems) open up further synthetic routes. 6) Thermal cyclizations which yield *(1)* are, *e.g.*, those of cyclic ketones containing a 1-butenyl residue. The thermal or photochemical decomposition of spiropyrazoline adducts (addition of diazo compounds to unsaturated substrates) permit the synthesis of further compounds *(1)*. [Synthesis of Carbocyclic Spiro Compounds *via* Intramolecular Alkylation Routes. Synthesis *1974*, 383—419; 372 references]

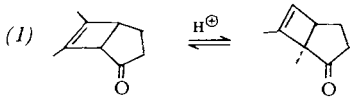
Organoiron complexes as potential reagents in organic synthesis is the title of a paper by *M. Rosenblum*. A simple example for a metal-assisted [3+2]-cycloaddition is the reaction of σ-allyl derivatives of dicarbonyl(η-cyclopentadienyl)iron with tetracyanoethylene to give the cyclopentane derivatives of type *(1)*. With cyclic allyl compound, bicyclenes are obtained. Such cycloaddition reaction may also be effected *e.g.* with

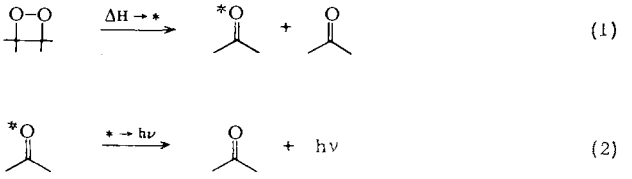


(1) *(2)* *(3)*

the corresponding propargyl-, allenyl-, and cyclopropylmethyl complexes. Other sections of the review are devoted to the synthesis of cationic dicarbonyl(η-cyclopentadienyl)iron-olefin complexes, their reactions with nucleophiles, organometal condensations, *e.g.* to give *(2)*, and demetalation, *e.g.* to give *(3)*. [Organoiron Complexes as Potential Reagents in Organic Synthesis. Accounts Chem. Res. 7, 122—128 (1974); 45 references]

[Rd 724 IE—L]

Acid-catalyzed rearrangements of β,γ-unsaturated ketones, especially in molecules with high ring strain, are reviewed in an article by *R. L. Cargill, T. E. Jackson, N. P. Peet,* and *D. M. Pond*. An example is the almost quantitative isomerization *(1)*→*(2)*. Electron donation from the double bond to the electron deficient carbonyl carbon is the first step



(1)

of the reaction (after protonation of the carbonyl carbon). Usually either 1,3-acyl or 1,2-vinyl shifts are encountered. Numerous applications are forseen for these rearrangements in syntheses. [Acid-Catalyzed Rearrangements of β,γ-Unsaturated Ketones. Accounts. Chem. Res. 7, 106—113 (1974); 49 references]

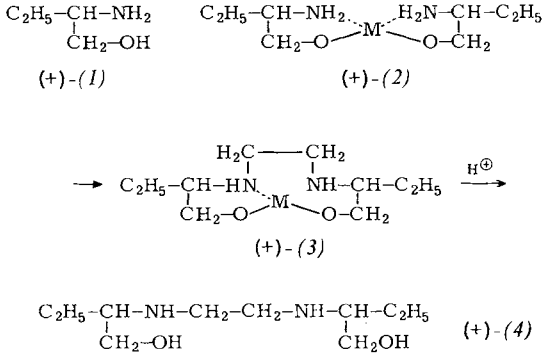
[Rd 725 IE—L]

Tetramethyl-1,2-dioxetane *(1)*, and its use in chemiexcitation, chemiluminescence, photochemistry, chemical dynamics, and spectroscopy are reported on by *N. J. Turro, P. Lechtken, N. E. Schore, G. Schuster, H-Ch. Steinmetzer,* and *A. Yetka*. *(1)* can serve as a source of excited acetone molecules. Its

(1)

(2)

suitability for fundamental investigations in the fields quoted stems from the appropriate coupling of the high selectivity of the chemiexcitation step [Eq. (1)] with the experimental



simplicity and sensitivity of the luminescence step [Eq. (2)]. [Tetramethyl-1,2-dioxetane. Experiments in Chemiexcitation, Chemiluminescence, Photochemistry, Chemical Dynamics, and Spectroscopy. Accounts Chem. Res. 7, 97—105 (1974); 38 references]

Entropy. The Devil on the Pillion. A Popular Exposition. By *J. Zernike*. Kluwer, Deventer 1972, 1st Edit., 150 pp., numerous figures, bound hfl. 34.75.

The title of this book can lead to misunderstandings: apart from the *Maxwell* and *Arrhenius* demons, which in the last chapter are taken to absurdity, everything is very down-to-earth and reasonable. It is doubtful whether the consistent omission of differential derivatives and integrals will prove popular, no matter how skilfully done, for a follower of the creed that school mathematics are the work of the devil will hardly have the ambition to achieve statistical understanding of thermodynamics.

The book offers some valuable advantages. In the first chapter the author presents a very interesting history of the development of thermodynamics without succumbing to the obvious temptation of using unclear expressions. Unfortunately, the history of thermodynamics as a didactic method has been rather overlooked, an unjustifiable trend as *Zernike* shows.

The avoidance of differential and integral calculus necessitates, in the second chapter, derivation of the Clausius-Clapeyron equation by a cycle. Nevertheless, the term "function of state" is explained.

Chapters 3 and 4 are the best part of the book because they contain at last statistical thermodynamics which any chemist can understand. This fills a sorely-felt gap, for in otherwise good thermodynamics textbooks a more than primitive statistical treatment of entropy is usually missing.

The last two chapters are merely an appendage. *Auerbach*'s "ectropism" and *Arrhenius*' demon were wrong approaches and present an unnecessary burden for the reader. Instead the author could have made better use of his didactic skill by presenting some modern developments in irreversible thermodynamics, as the works of *Prigogine*, *Glansdorff*, *Monod*, and *Eigen* permit a less defeatist opposition to the philosophers' criticism of the concept of a heat death of the Universe.

Arno Höpfner [NB 215 IE]

Identification and Analysis of Plastics. By *J. Haslam*, *H. Willis*, and *D. Squirrell*. Butterworth, London 1972. 2nd ed., 748 pp., numerous figures, bound £ 18.00.

Among the more recent guides to the analysis of plastics this book deserves a special place, as it treats together both qualitative and quantitative procedures with chemical and physical methods.

The first part deals with instrumental methods such as UV, IR, NMR, and gas chromatography (including pyrolysis), the methods being illustrated with some practical examples. Then follows qualitative analysis, not only by simple chemical tests, but also by appropriate physical techniques. Subsequent chapters are devoted to vinyl polymers, polyesters, polyamides, polyolefins, fluorinated plastics, rubber-like materials, thermosetting resins, and natural polymers like cellulose and some other classes of plastics. The last part presents details of the analysis of plasticizers, fillers, and solvents. Finally, the book contains a collection of IR spectra of important plastics, although their number and quality of reproduction cannot be compared with the well-known tables by *Hummel*.

For expert analysts the book presents a plentiful source of valuable information from the authors' practical experience; this will undoubtedly be its principal use. The beginner may be overwhelmed by the abundance of material, especially as the layout is not at all clear and the index covers only the 11 main chapters. The next edition really must be more clearly subdivided, so that the reader can find what he needs more rapidly and is not limited to the short index. About 350 bibliographic citations supplement the work, but these have been chosen rather arbitrarily; they usually refer to the authors' own work and are largely limited to publications in English. Thus, the book is a valuable collection of information but it does not always come up to its ambitious title. Any new edition should introduce a more rigorous arrangement of subject matter and a more careful selection of the many methods and details.

Dietrich Braun [NB 217 IE]

Deuterium Labeling in Organic Chemistry. By *A. F. Thomas*. Appleton-Century-Crofts Educational Div./Meredith Corp., New York 1972. 1st edit., xiii, 518 pp., numerous figures, bound, DM 101.80.

Hydrogen atoms in the "stable" bonds of organic compounds are frequently responsible for much more than we are normally aware of or consider. It is therefore far from easy to prepare a compound deuterated in a specific position. The author is well aware of this and has written a truly useful book, but deuterium labeling and its application range into so many specialized fields that the subject is almost too taxing for a single author. It is not surprising, therefore, that chapters which do not deal with the preparative aspect are not entirely satisfactory and that some of the propositions are not quite correct. To mention but two examples: there is no negative isotope effect (p. 38), and an starved yeast is quite different from a denatured yeast (p. 424).

Eight chapters of the book deal with methods of deuteration. The classification is based on the mechanisms and processes which lead to the compounds. These chapters contain an abundance of interesting chemistry. One chapter is devoted to biochemical deuteration, but the many possibilities of stereospecific deuteration are insufficiently appreciated. Another chapter finally deals with isotope effects and analytical procedures. A list 33 pages long of molecular formulas of deuterated compounds, with a brief outline of the method of preparation, is really useful. What makes this book, which contains almost 2000 references, particularly valuable and worthy of recommendation is that the author has the courage and the necessary experience to make critical evaluations. He draws attention to the advantages and weaknesses of individual methods, and gives many practical guidelines.

Helmut Simon [NB 222 IE]

Grundlagen der Stereochemie (Elements of Stereochemistry). By *E. L. Eliel*. UTB, Verlag Birkhäuser Basel—Stuttgart 1972. 108 pp., numerous figures, bound, DM 9.80.

A chemist who has left University ten years ago frequently finds difficulty in reading recent articles on stereochemistry. He encounters many concepts which were never raised during his studies, and many of the notations have acquired different meanings. This is due to the fact that during the last few years stereochemistry has undergone drastic changes with regard to problem formulation, applied experimental methods, and conceptual definition and classification of stereochemical phenomena.

This book will assist those for whom the transition from the earlier, mainly experimentally oriented mode of thinking to the current, more abstract approach is too abrupt.

The didactic arrangement and flowing style make the book a pleasure to read. The descriptions of experimental results and the theoretical discussion are well balanced. Even the untrained reader will find little difficulty in understanding the material and will not have to resort to additional reading (only in the application of the Cahn-Ingold-Prelog rules to multiple bond systems would some additional remarks have been useful). Exercises (with answers) round off the positive impression made by the book.

The book is recommended not only to all students after their preliminary examinations but to all who want to brush up their knowledge and would like a readable introduction to modern stereochemistry.

Günther Maier [NB 224 IE]

Comprehensive Chemical Kinetics. Vol. 4. Decomposition of Inorganic and Organometallic Compounds. By *C. H. Bamford* and *C. F. Tipper*. Elsevier Publishing Company, Amsterdam—London—New York 1972. 1st edit., xii, 272 pp., numerous figures and tables, bound, $ 27.25.

This volume, together with volume 5, constitutes Section 2 "Homogeneous Decomposition and Isomerization Reactions" of the above work. As suggested by the title, all those reactions are discussed which proceed, if not necessarily unimolecularly, at least in the absence of a foreign reactant. Major attention is always paid to the primary reaction (in the true sense), and secondary reactions between reactant molecules and decomposition products are in general only dealt with when they have been shown to contribute significantly to reactant consumption. Photolytic and radiolytic processes are only raised in special cases.

The subdivision of the volume into chapters is substance-oriented, which occasionally results in apparently arbitrary sections; this procedure does, however, ensure maximal clarity and fits in well with the reference nature of the work.

The first chapter *(K. H. Homann* and *A. Haas)* deals with the homogeneous decomposition of hydrides of oxygen, sulfur, nitrogen, silicon, germanium, and boron; The subject of the second *(K. F. Preston* and *R. J. Cvetanović)* is the kinetics of the decomposition of inorganic oxides (especially those of carbon, nitrogen, sulfur, fluorine, and chlorine), of sulfides and selenides (or carbon), of ozone, of certain acids of nitrogen, and of perchloric acid. The following section *(D. A. Armstrong* and *J. L. Homes)* merits particular attention; this is devoted to the decomposition of halogen compounds, especially hydrogen halides, and commendably takes account of the recent findings so important in this field. The concluding chapter *(S. J. W. Price)* deals with the decomposition of alkyl, aryl, carbonyl, and nitrosyl metal compounds. The decomposition of homonuclear diatomic molecules will be discussed in one of the subsequent volumes.

All sections are provided with extensive and instructive tables and figures, and do ample justice to the rigorous demands that may be made on the work.

O. F. Olaj [NB 225a IE]

Comprehensive Chemical Kinetics. Vol. 5. Decomposition and Isomerization of Organic Compounds. By *C. H. Bamford* and *C. F. Tipper*. Elsevier Publishing Company, Amsterdam—London—New York 1972. 1st edit., xvi, 779 pp., numerous figures, bound $ 65.75.

This volume completes Section 2 of the above work. Subdivision according to chemical classes has again been adopted throughout, which allows rapid orientation and almost entirely eliminates overlap.

Many of the homogeneous gas reactions dealt with are considered as models of unimolecular processes; the associated experimental data were (and still are) of the greatest significance for the theory of these reactions. Furthermore, reactions in homogeneous solutions as well as pyrolytic, photolytic, photosensitized, and radiolytic processes are extensively discussed, even where the reaction course is determined by secondary reactions.

The first chapter *(K. J. Laidler* and *L. F. Loucks)* is devoted to the decomposition and isomerization reactions of hydrocarbons, the second *(E. S. Swinbourne)* to the thermal and radiation- and particle-induced decomposition of halogen compounds. The following sections deal with the thermal and photochemical decomposition of aldehydes and ketones *(T. Bérces)*, as well as the decomposition and isomerization reactions of other oxygen-containing compounds such as esters, anhydrides, ethers, alcohols, carboxylic acids, and especially peroxides *(W. H. Richardson* and *H. E. O'Neal)*. The next chapter is concerned with the unimolecular reactions of nitrogen compounds *(O. P. Strausz, H. E. Gunning,* and *J. W. Lown)*; apart from diazo compounds and azides, most attention is understandably paid to azo compounds. These last two chapters thus also contain all the important information on the two major groups of radical formers, namely peroxides and aliphatic azo compounds. The volume concludes with a chapter on the unimolecular reactions of sulfur compounds *(O. P. Strausz, H. E. Gunning,* and *J. W. Lown)*.

The positive aspects of the book again include the uniformly liberal provision of clear tables and figures and an abundance of numerical data; the delayed publication in one case deserves criticism, however. All in all, each chapter indicates that the volume is a worthy member of the series.

O. F. Olaj [NB 225b]

Analysis of Triglycerides. By *C. Litchfield*. Academic Press, New York—London 1972. xvii, 395 pp., numerous figures and tables, bound, $ 19.50.

Until 1955 the only methods available for the analysis of triglycerides were essentially fractional crystallization (*Chevreul*, 1815) and oxidative degradation (*Hilditch*, 1927—1950). Bearing in mind the number of triglyceride isomers which occur in natural fats (approximately 40—1000 in vegetable fats), these methods were quite inadequate; it was only in simple cases that the triglyceride composition could be elucidated. After 1955 a burst of activity resulted in the development of new chemical and physical methods; this subsequently drew to a close in certain areas, but some methods, *e.g.* the application of mass spectrometry to the analysis of triglycerides, are still in their infancy. It is therefore highly welcome that *Litchfield*, who has personally contributed much to the development of analytical techniques in this field, has produced a review in which the current state of knowledge is summarized in concise but unusually informative manner.

Following a brief introduction to the stereochemistry and nomenclature of triglycerides and a short historical review, the extraction of lipids and isolation of triglycerides are first described; in this context the identification of fatty acids by gas chromatography is also touched upon. The following chapters deal with methods of preparation of glyceride derivatives and with the chemical and physical processes currently available for the separation and structure elucidation of triglycerides (chromatography on Ag^+-containing carrier material;

liquid-liquid distribution; gas chromatography; fractional crystallization; chromatographic separation using Kieselgel, Florisil, Al_2O_3, and ion exchangers; partial deacylation with specific and stereospecific lipases; mass spectrometry; DTA, NMR, and IR methods). This is followed by a discussion of the chemical structure and distribution models of natural triglycerides, including the biosynthesis of fats. The last chapter contains indications on the optimal combination of known analytical methods.

In conformity with the reference nature of the work (978 literature references), the individual chapters are kept short; thanks to a very clear and critical presentation which restricts itself to essentials, they nevertheless provide not only an excellent insight into the possibilities and limitations of the different methods, but also many practical hints and suggestions.

113 figures and 62 tables, as well as meticulously produced subject, name, and literature indexes, contribute significantly to the value of the book, which belongs on the shelf of every chemist active in the lipid field.

Modern Methods for the Study of Electrode Processes

By Joachim Heitbaum and Wolf Vielstich[*]

The investigation of electrode processes calls for the use of methods that yield information on the reaction mechanism and the reaction rate, on the nature and stability of intermediates, and on adsorption processes at the electrode. It is no longer enough to record current-voltage curves or charging curves. In addition to the potentiostatic scan method, other methods that have proved useful for the investigation of electrode kinetics are the rotating disc electrode in particular, and to a smaller extent AC polarography. Intermediates can be identified with rotating double electrodes and by ESR spectroscopy or mass spectrometry. Adsorption processes on electrode surfaces can be studied by optical methods or by radioactive tracer methods.

1. Introduction

In the study of electrode processes, there are three phenomena in particular that are of interest to the scientist. These are the electrode kinetics (mechanism and rate of an electrochemical process), the occurrence of intermediates (free radicals, radical-ions), and adsorption (of the starting substance and of intermediates) on the electrode surface.

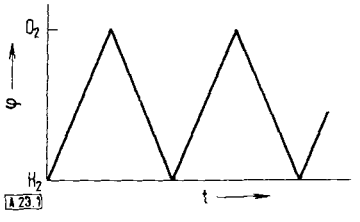
For experimental investigations, various methods are available, depending on the nature of the effect to be studied. Apart from potentiostatic and galvanostatic pulse methods, other methods that have proved useful for the study of electrode kinetics are primarily the potential scan method, the rotating disc method, and modern polarographic methods (AC polarography); intermediates of an electrochemical reaction can be detected and identified with the rotating double electrode (ring-disc or ring-ring) and by optical methods (reflection spectroscopy, electroluminescence). Free-radical intermediates, particularly in organic reactions, can be studied by ESR spectroscopy. Adsorption on the electrode surface or in the electrolytic double layer can be investigated by optical methods (absorption and reflection spectroscopy) and by tracer methods (use of radioactively labeled substances), as well as by the conventional AC measurement.

These methods and their possible combinations will be discussed below. Experimental details and results will be described only in so far as this seems necessary for an understanding of the measuring principle and of the scope of the methods.

2. The Potentiostatic Scan Method

2.1. Measuring Principle

The essential feature of the potentiostatic scan method is a linear variation of the potential of the working electrode between two reversal points (Fig. 1). For most investigations the reversal points chosen should preferably be the potentials



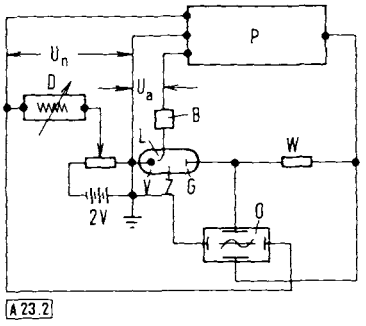


Fig. 1. Variation of potential with time on the measuring electrode in the potentiostatic scan method; potential scanning rate between a few mV/s and 1 V/s. φ = potential, t = time.

of anodic oxygen and cathodic hydrogen evolution, respectively. Electrode poisons are thus constantly removed by oxidation or reduction and the electrode is reproducibly activated.

Institut für Physikalische Chemie der Universität
53 Bonn, Wegelerstrasse 12 (Germany)

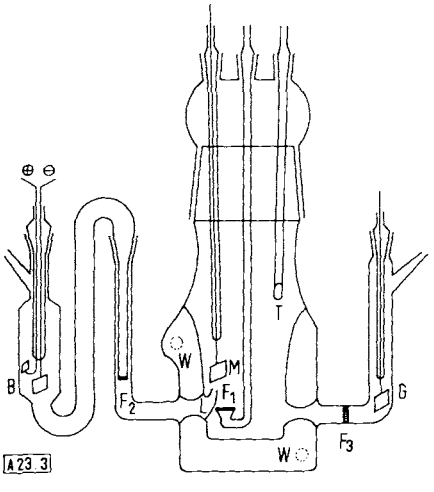

Figure 2 shows the block circuit diagram for the application of the potentiostatic scan method. To achieve a strictly linear variation of the potential of the test electrode, the potential difference between the working electrode and a reference elec-

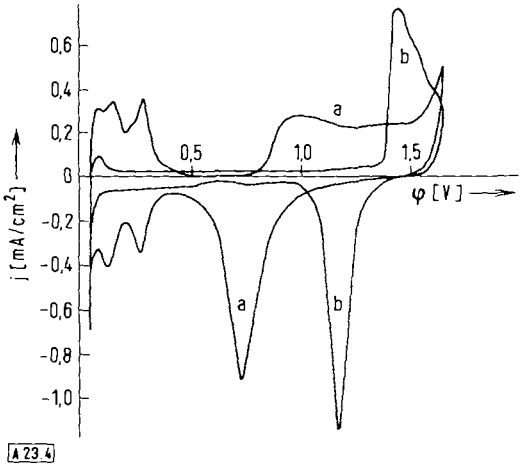
A 23.2

Fig. 2. Experimental device for the potentiostatic scan method. Z = electrolysis cell, V = test electrode, G = counter electrode, B = reference electrode, D = triangular potential wave generator, P = potentiostat, O = oscillograph, W = resistance, L = Luggin capillary. $U_n = U_{nominal}$, $U_a = U_{actual}$.

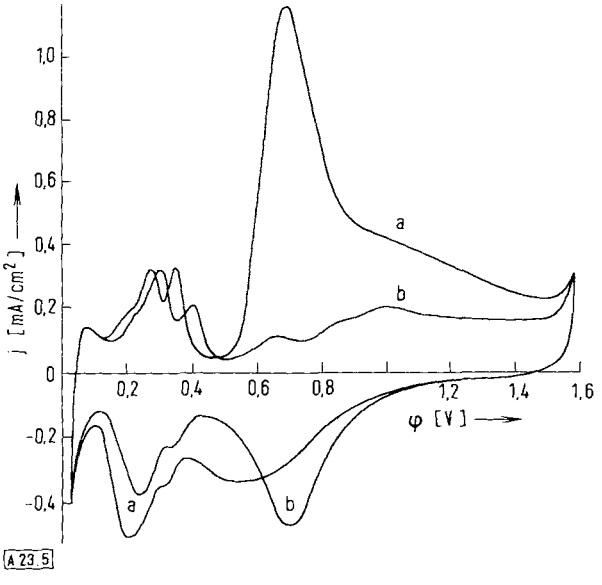
trode (U_{actual}) must be constantly compared, by means of an electronic potentiostat, with the voltage produced by a triangular potential wave generator ($U_{nominal}$). With a time constant of $\tau < 10^{-5}$ s, the potentiostat equalizes the actual voltage and the nominal voltage by passing a current through the working electrode and the counterelectrode. This current is measured as a function of the electrode potential. The potential scanning rate of the triangular voltage generator can be varied between a few mV/s and 1 V/s. An experimental arrangement of this type was first used by *Knorr* and *Will*[1], for investigation of hydrogen and oxygen films on noble metals.



A 23.3

Fig. 3. Electrochemical cell for the application of the potential scan method. M = working electrode, G = counter electrode, B = hydrogen reference electrode, F_1, F_2, F_3 = sintered glass plates, L = Luggin capillary, T = thermometer, W = water ducts to thermostat jacket.

Figure 3 shows an example of a thermostatically controllable electrolysis cell. The working electrode M can be flushed with gas through a sintered glass plate F_1. The counterelectrode and the hydrogen reference electrode B are separated from the working-electrode electrolyte compartment by sintered glass separators F_3 and F_2 respectively. (For further details of the electrolysis cell see [2].)



At smooth platinum in pure sulfuric acid, if the potential of the working electrode is allowed to sweep the range between the start of hydrogen evolution and the start of oxygen evolution, one obtains the current-potential diagram shown in Figure 4, curve a. Since there are no electrochemically active substances in the electrolyte, one observes the build-up and breakdown of chemisorbed hydrogen and oxygen films, the "surface-layer diagram". The nature of the surface-layer diagram depends very strongly on the electrode material used, and to a smaller extent on the electrolyte solution[3]. The surface-layer diagram for a smooth gold electrode in H_2SO_4 (Fig. 4, curve b) shows that the coverage of gold with hydrogen, unlike that of platinum, is very low, and that coverage with oxygen begins sharply only at +1250 mV. Investigations on gold can therefore be carried out over a wide range of potentials without interference from surface-layer currents. (For detailed discussions of surface-layer diagrams see [1–3].)

A 23.4

Fig. 4. Surface-layer diagrams in 1 N H_2SO_4 at room temperature, 100 mV s. N_2 flushing a) on platinum, b) on gold. φ = potential, j = current density.

If an electrochemically active substance is added to the electrolyte, the surface-layer currents and the current-potential characteristics are superimposed. This is shown in Figure 5 for the anodic oxidation of NH_3 in 1 M KOH on platinum. The surface-layer currents can often be eliminated by a suitable choice of the potential scanning rate. With slow potential

A 23.5

Fig. 5. Current-potential diagram a) on smooth platinum in 1 M KOH with 10^{-3} M NH_4OH, 20 °C, 100 mV/s. N_2 flushing; for comparison b) surface-layer diagram on smooth platinum in 1 M KOH. φ = potential, j = current density.

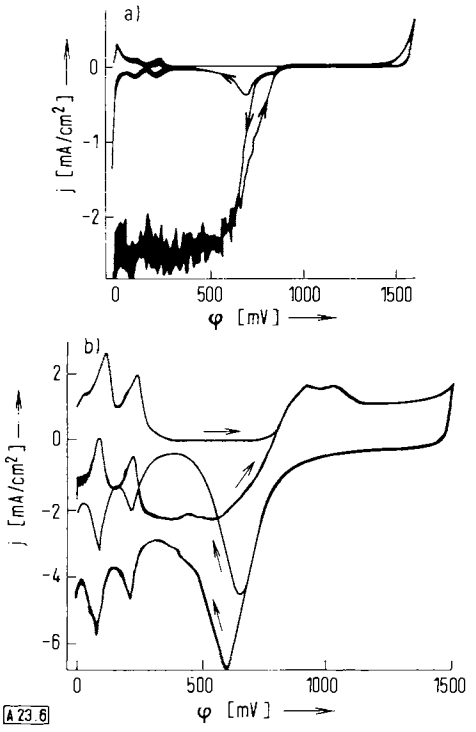


Fig. 6. Current-potential diagram on smooth platinum with O_2 flushing. a) Development of an O_2 diffusion limiting current with slow potential scanning (30 mV/s); top: electrode flushed with N_2; bottom: electrode flushed with O_2. b) Fast scanning (1 V/s); top: electrode flushed with N_2; bottom: electrode flushed with O_2. φ = potential, j = current density.

scanning and a high rate of the electrode reaction, the surface-layer current makes only a negligible contribution to the total current. This is illustrated in Figure 6a for the reduction of oxygen on smooth platinum in H_2SO_4. A cathodic diffusion limiting current develops. With fast potential scanning the surface-layer current is no longer negligible (Figure 6b). The build-up and breakdown of the hydrogen layer and the reduction of oxygen overlap. It can be seen from the diagram that the two processes proceed independently of each other[4, 5].

In many cases the addition of an electrochemically active substance to the electrolyte leads, not simply to a limiting current as in Figure 6a, but to a series of anodic or cathodic current maxima, *i.e.* to an electrochemical spectrum. As an example, Figure 7 shows the current potential diagram of ethanol in H_2SO_4 on smooth platinum. There are three anodic current maxima. Since the electrode was flushed with nitrogen during the recording of this spectrum, the current maxima are not due to a decrease of the electrochemically active substance on the electrode, but result from the inhibiting adsorption of reactants and/or intermediates or, as in the present case, from the inhibiting effect of two kinds of chemisorbed oxygen.

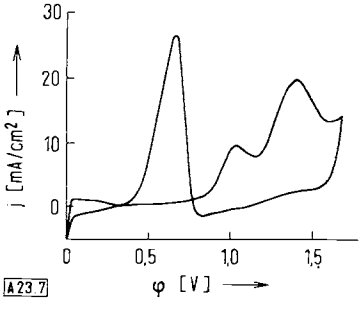

Fig. 7. Current-potential diagram of ethanol on smooth platinum in 1 N H_2SO_4, 350 mV/s, N_2 flushing. φ = potential, j = current density.

2.2. Net Diagrams

Experimental separation of the surface-layer currents from the current potential characteristic of an electrochemically active substance is impossible if the part of the current due to the electrochemical reaction of the active substance is low. As was shown in Figure 5, the interpretation of the electrochemical spectrum is very difficult in such a case, since it is very hard to distinguish between the influence of the surface layer formation and the electrochemical reaction. In cases of this type it seems reasonable to determine the point-by-point difference between the current potential curves obtained in the presence and in the absence of the electrochemically active substance.

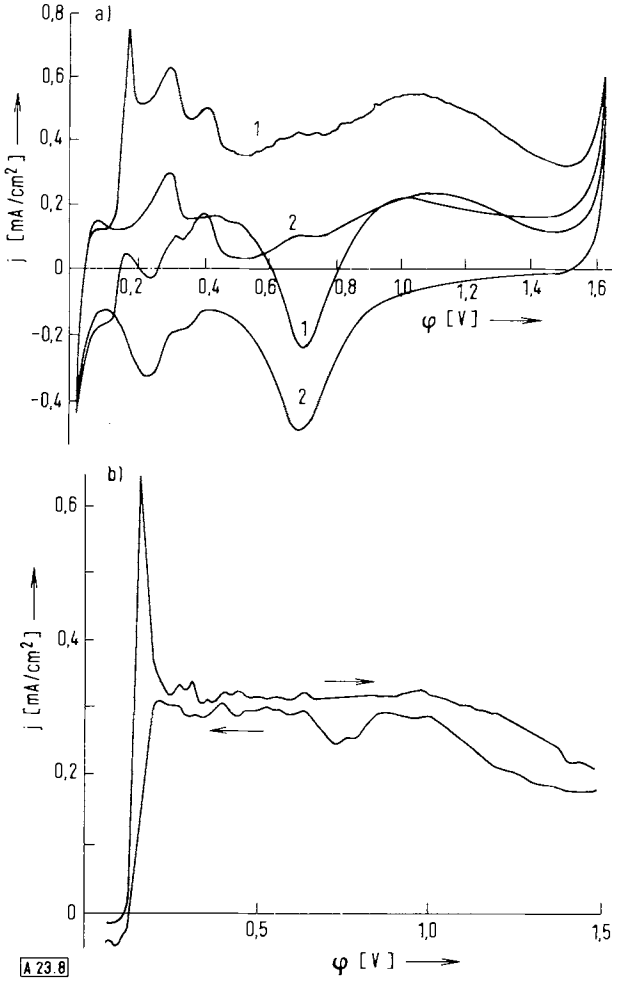

Fig. 8. a) Current-potential diagram on smooth platinum in 1 M KOH + 10^{-4} M N_2H_4, 20 °C, 100 mV/s. N_2 flushing (curve 1); for comparison the surface-layer diagram in 1 M KOH (curve 2). b) Net diagram on smooth platinum in 1 M KOH + 10^{-4} M N_2H_4; the diagram was plotted from the point-by-point differences between curve 1 and curve 2 in a). φ = potential, j = current density.

To illustrate this, Figure 8a shows the current potential curve on smooth platinum in pure KOH (curve 2) and in KOH + 10^{-4} M hydrazine (curve 1). Subtraction of one curve from the other gives the net diagram shown in Figure 8b for the anodic oxidation of hydrazine on platinum[6]. After an initial elimination of hydrogen (the sharp current peak in the anodic sweep

is due to nascent hydrogen), a diffusion limiting current is established at the electrode. A slight decrease in the current is observed at potentials above 1 V, due to the inhibitory effect of the adsorbed oxygen.

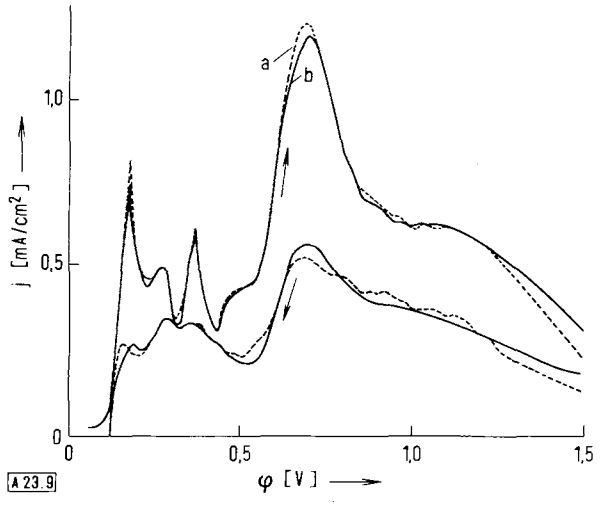

Fig. 9. Net diagram for the superposition of the oxidation of ammonia and of hydrazine on smooth platinum in 1 M KOH + 10^{-3} M NH_4OH + 10^{-4} M N_2H_4, 20 °C, 100 mV/s, N_2 flushing; a) mathematical summation of the net curves for N_2H_4 and NH_4OH; b) experimental sum curve for the simultaneous presence of both substances in the electrolyte. φ = potential, j = current density.

This technique of deriving net diagrams is very suitable for the investigation of the mutual effects of simultaneous electrode reactions. This will be illustrated for the superimposed oxidation of ammonia and of hydrazine on smooth platinum[6]. The net diagrams for hydrazine and for ammonia are first constructed separately by the procedure described above, and the calculated sum curve is obtained. This calculated sum curve corresponds to the case where the two electrochemical processes take place together without inhibition. The experimental sum curve is obtained by recording the current potential diagram for the simultaneous oxidation of NH_3 and N_2H_4. Figure 9 shows both the calculated and the experimental sum curves. The close agreement between curves a and b shows that hydrazine and ammonia are oxidized independently of each other over the entire range of potentials.

2.3. Special Applications of the Potentiostatic Scan Method

Since the surface layer diagrams on different electrode metals are very different from one another, the potentiostatic method can be used for the identification of electrode metals. In particular, the composition of the electrode surface can be determined in the case of alloys[7]. This is particularly successful when the potentials of the oxygen reduction peaks of the alloy components are as far apart as possible. Figure 10 shows the surface layer diagram of a platinum gold alloy. The oxygen chemisorbed on gold is clearly reduced more readily than that chemisorbed on platinum.

By recording current potential diagrams on rotating electrodes, it is very easy to detect whether intermediates involved in the charge transfer reaction pass into solution. On a rotating electrode the intermediates formed are transported more rapidly into the bulk of the solution by the flow on the electrode surface; a smaller current should therefore be

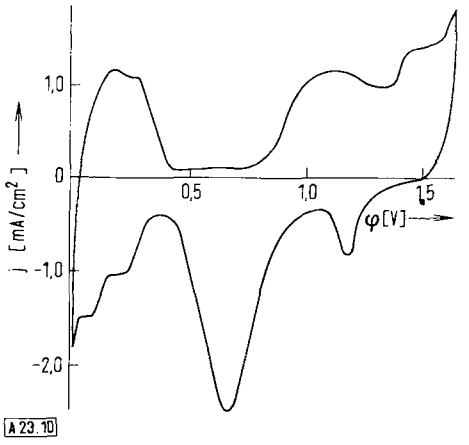

Fig. 10. Surface-layer diagram of a platinum-gold alloy (Pt:Au = 40:60) in 1 N H_2SO_4, 100 mV/s, N_2 flushing. φ = potential, j = current density.

obtained with rotation than without in such a case. This is shown in Figure 11 for the oxidation of methanol in H_2SO_4 on smooth platinum.

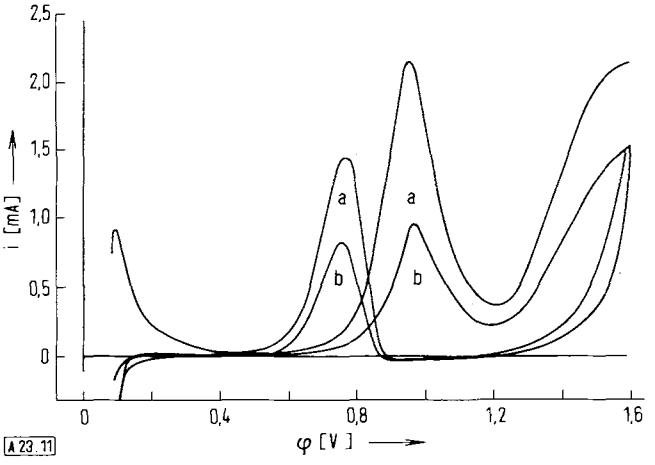

Fig. 11. Current-potential diagram on smooth platinum in 1 N H_2SO_4 + 1 M CH_3OH recorded a) on a rotating electrode (75 Hz); b) without rotation; 100 mV/s. φ = potential; i = current.

The current maxima are distinctly higher without rotation of the electrode (curve a) than on the rotating electrode (curve b). The soluble intermediates are formaldehyde and formic acid. The magnitude of the effect depends on the potential scanning rate. A fast potential variation accelerates the electrode reaction so strongly that only small quantities of the intermediates are transported away into the solution. In this case there is only a slight difference between the diagrams with and without rotation.

3. Rotating Electrodes

3.1. Measuring Principle

The problem in studies on electrode kinetics often lies in the elimination of transport phenomena. *Levich*[8] in 1942 therefore suggested the use of a rotating disc as the measuring electrode. In a practical device it consists of a metal disc sunk into the center of the front area of a plastic cylinder (Figure 12) which rotates in the electrolyte solution. As the cylinder rotates, the solution is sucked along its axis of rotation and thrown radially across the front area, as illustrated in

Figure 13. This leads to the establishment of a constant Prandtl flow boundary layer δ_{Pr} over the entire front area of the cylinder, and hence, according to the equation

$$\delta_N = \left(\frac{D}{\nu}\right)^{1/3} \delta_{Pr}$$

to a concentration profile that is independent of the radius of the electrode (δ_N = Nernst diffusion layer, D = diffusion coefficient, ν = kinematic viscosity). Since

$$j = zFD \frac{c^0}{\delta_N}$$

one obtains a uniform current density j over the disc electrode (z = charge number, F = Faraday constant, c^0 = concentration). Pure mass transport leads to the establishment of a diffusion limiting current j_{gr}, whose magnitude depends on the speed of rotation ω of the electrode. According to *Levich*[9] and *Gregory* and *Riddiford*[10], the equation

$$j_{gr} = \frac{zFD^{2/3}\nu^{-1.6}c^0}{1.6126 + \left(\frac{D}{\nu}\right)^{0.36} \times 0.5704}\omega^{1/2} \qquad (1)$$

is valid in this case.

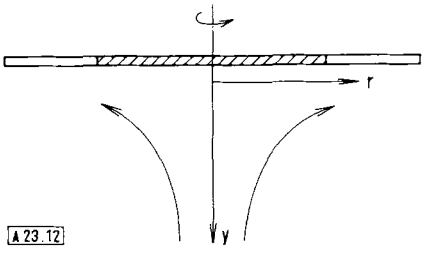

Fig. 12. Flow on the front area of a rotating cylinder with inset disc electrode (shaded); y = axis of rotation, r = radius.

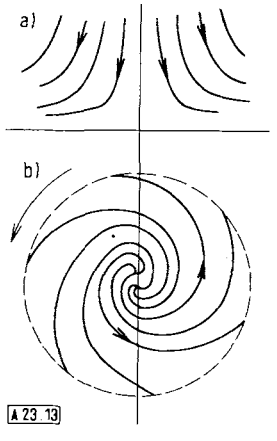

Fig. 13. Flow lines on the front area of a rotating cylinder; a) section, b) elevation.

Figure 14 shows a section through the apparatus, with the electrolysis cell[11]. The motor connected to the cylinder allows rotation speeds of between a few Hz and a few hundred Hz. The rotation speed is recorded by means of a light beam and a perforated disc, and is adjustable with an accuracy of 0.1 Hz.

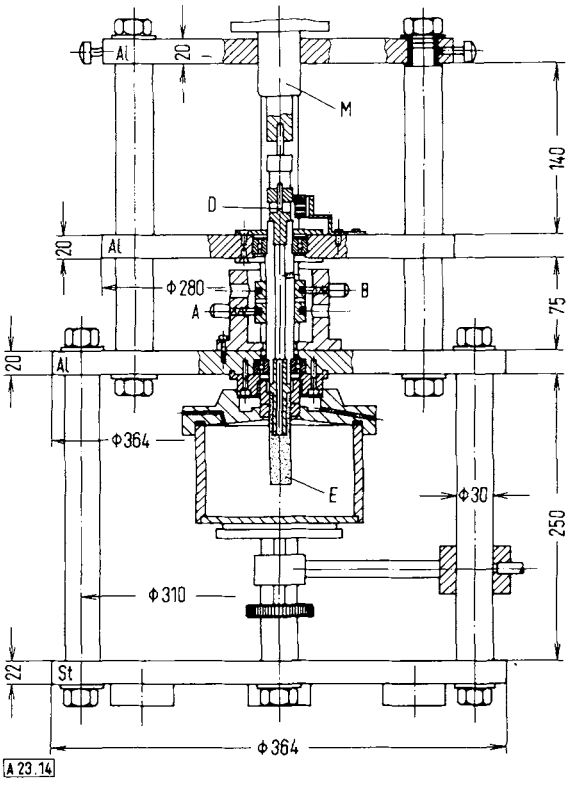

Fig. 14. Measuring apparatus with rotating electrode, in cross section. A, B = current collectors for disc and ring electrode, respectively, D = revolution counter, E = electrode, M = motor, St = steel plate, Al = aluminum discs.

3.2. Possible Applications of the Rotating Disc Electrode

3.2.1. Precision Determination of Diffusion Coefficients

If the rate of an electrochemical reaction is determined exclusively by mass transport (the discharge step is extremely fast) a diffusion current is set up at the electrode and increases, according to eq. (1), in proportion to $\sqrt{\omega}$. According to eq. (1), therefore, the diffusion coefficient D can be determined if the concentration c^0 is known, or the concentration c^0 can be determined if the diffusion coefficient is known, from a plot of j against $\sqrt{\omega}$.

Gostiša-Michelčič, *Vielstich*, and *Heindrichs*[12] have used this method for the precision determination of the trace diffusion coefficient of the proton in KCl. This involves, not the diffusion of the proton, but the rate of charge transfer in protonic solution (hopping mechanism *via* hydrogen bonds). Figure 15 shows the measured diffusion limiting currents for several rotation speeds between 31 and 183 Hz with a smooth platinum disc electrode. The slope of the straight lines in the plot of j_{gr} against $\sqrt{\omega}$ gives the apparent diffusion coefficient of the proton with an accuracy of $\pm 0.3\,\%$. The value found for 25 °C was $D_{H^+} = 74.6 \times 10^{-6} \pm 0.3\,\%$. The accuracy of the method is therefore better by a factor of 5 to 10 than that of the usual methods (polarography, diffusion after *Cottrel*).

3.2.2. Determination of the Characteristic Data of a Charge-Transfer Reaction

Before the current potential curve passes over into the limiting current determined purely by mass transport, both the convective diffusion and the charge-transfer are rate-determining for the reaction. Measurement of the current as a function of the rotation speed ω in this potential range yields informa-

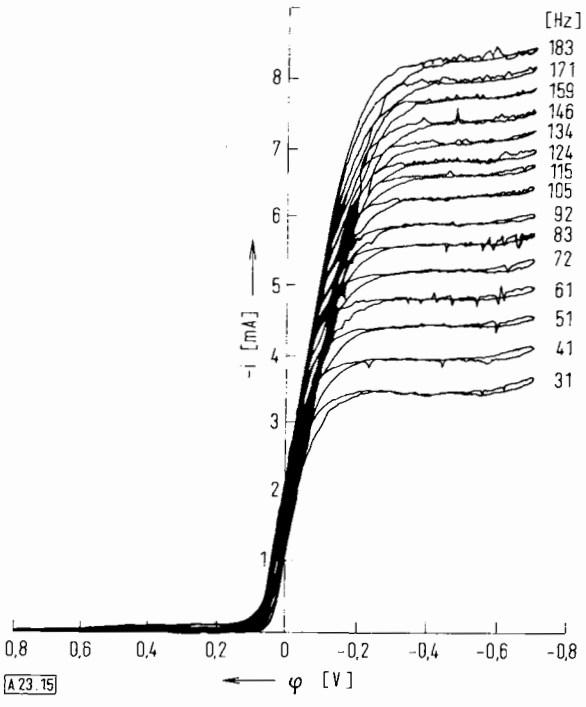

Fig. 15. Current-potential curves (diffusion limiting currents) on a rotating platinum electrode as a function of the speed of rotation in 1 M KCl + 3×10^{-3} M HCl. φ = potential, i = current.

tion about the rate of the electrode reaction if the influence of mass transport is eliminated by extrapolation to $\omega \rightarrow \infty$. *Jahn* and *Vielstich*[13] have derived the following equation for this case:

$$\frac{1}{j} = \frac{1}{j_D} + \frac{1}{j_D} K \frac{1}{\sqrt{\omega}} \tag{2}$$

where j_D is the pure charge-transfer current corresponding to a given overpotential η. j_D can be determined from the intercept on the axis in a plot of $1/j$ *against* $1/\sqrt{\omega}$ for a fixed η (Fig. 16). A series of pairs of values (j_D, η) then yields the pure charge-transfer current potential curve, from which the transfer coefficient α and the exchange current density j_0 can be deduced.

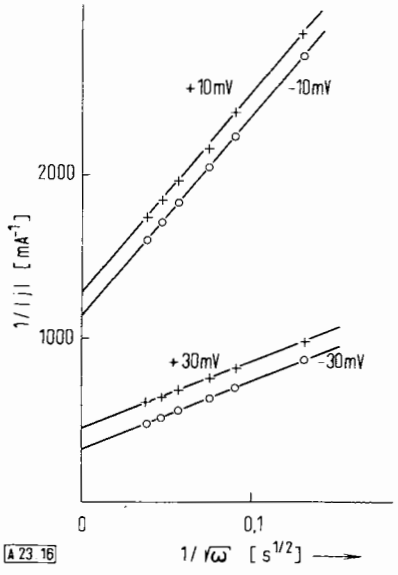

Fig. 16. Plot of $1/|j|$ against $1/\sqrt{\omega}$ for the determination of the charge transfer current density j_D (the parameter is the overpotential η) for the system 10^{-2} M $Fe^{2+}/10^{-2}$ M Fe^{3+} in 1 M $HClO_4$ on smooth platinum. ω = speed of rotation, j = current density.

Jahn and *Vielstich*[13] have tested this method on the system Fe^{2+}/Fe^{3+} in $HClO_4$. The good fit of the experimental points with the connecting straight lines in Figure 16 is a measure of the accuracy of the method. They found a value of 0.23 A/cm² for the standard exchange current density of the system indicated; the transfer coefficient was 0.63.

3.2.3. Determination of the Rate Constants of a Preceding Chemical Reaction

It was explained on the basis of eq. (1) that for pure mass transport the diffusion limiting current on the rotating electrode increases in proportion to $\sqrt{\omega}$. However, if the electrochemical reaction is preceded by an inhibited reaction step (adsorption on the electrode, chemical reaction), derivations from linearity are found at high rotation speeds, as indicated in Figure 17a.

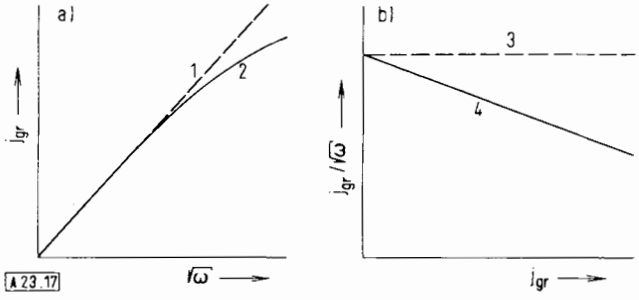

Fig. 17. a) Limiting currents on a rotating electrode plotted against $\sqrt{\omega}$; curve 1, with pure mass transport; curve 2, deviation with kinetic inhibition. b) $j_{gr}/\sqrt{\omega}$ against j_{gr}; curve 3, with pure mass transport; curve 4, with kinetic inhibition. ω = speed of rotation, j_{gr} = reaction limiting current density.

A typical example is the evolution of hydrogen from a weak acid HA, where the protons that react in the charge-transfer reaction are formed by a preceding dissociation on the electrode surface:

$$\begin{aligned} &HA \underset{k_r}{\overset{k_d}{\rightleftharpoons}} H^{\oplus} + A^{\ominus} \\ &H^{\oplus} + e^{\ominus} \rightarrow \tfrac{1}{2} H_2 \end{aligned} \tag{3}$$

The rate of the preceding reaction (*i.e.* the dissociation rate of the weak acid in the above example) can be found from the deviation of the current from the proportionality to $\sqrt{\omega}$ that would exist without reaction inhibition.

According to *Koutecki* and *Levich*[14] and to *Vielstich* and *Jahn*[13], the following relation is valid in this case:

$$\frac{j_{gr}}{\sqrt{\omega}} = \frac{j_{gr,diff}}{\sqrt{\omega}} - \frac{D^{1/6} c_{A^{\ominus}}^{1,2} j_{gr}}{1.61 \cdot \nu^{1/6} (k_d/k_r) \sqrt{k_r}} \tag{4}$$

where j_{gr} is the measured reaction limiting current density and $j_{gr,diff}$ is the limiting current density due to the mass transport. According to eq. (4), a plot of $j_{gr}/\sqrt{\omega}$ against j_{gr}, as in Figure 17b, gives a horizontal straight line for pure mass transport. In the case of reaction inhibition one obtains a straight line with a negative gradient, from which the dissociation rate constant k_d can be calculated according to eq. (4). D, ν, $c_{A^{\ominus}}$, and the equilibrium constant k_d/k_r must naturally be known from thermodynamic measurements or conductivity measurements.

Gostiša-Mihelčič and *Vielstich*[15] have used this method to determine the dissociation constants of acetic and formic acids. Figure 18 shows $j_{gr}/\sqrt{\omega}$ as a function of j_{gr} for the system

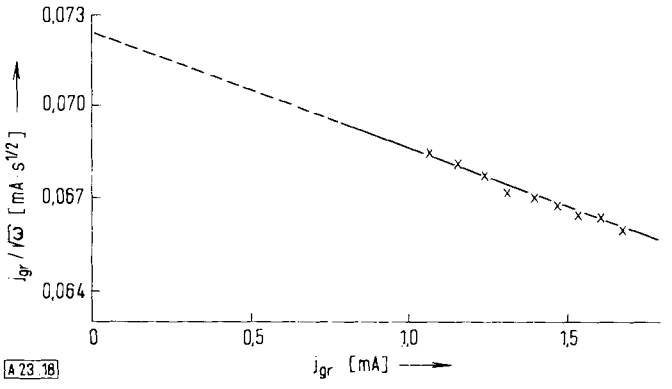

Fig. 18. $j_{gr}/\sqrt{\omega}$ *vs.* j_{gr} plotted for the system acetic acid/sodium acetate; 2.73×10^{-3} M HAc + 3×10^{-2} M NaAc + 1 M KCl, measured on a rotating platinum disc electrode. pH = 5.66. j_{gr} = reaction limiting current density. ω = speed of rotation.

acetic acid/sodium acetate from measurements on a smooth platinum disc electrode. The value found for the dissociation rate constant from the slope of the straight line is $k_d = 5.4 \times 10^5\,s^{-1}$. The diffusion coefficient of acetic acid, $D = 1.2 \times 10^5\,cm^2/s$, can also be found from the intercept of the straight line on the ordinate. A similar experiment gave a dissociation rate constant $k_d = 4.9 \times 10^6\,s^{-1}$ for formic acid. Owing to the higher rate of dissociation of formic acid, this constant was obtainable only by the use of rotation speeds of a few hundred Hz.

3.2.4. Separation of Kinetic and Transport-Controlled Reactions

If two electrochemical reactions proceed simultaneously in the potential range studied, the current components can be separated if one of the reactions is transport-controlled while the rate of the other is kinetically controlled.

According to eq. (1), to a change $\Delta\omega^{1/2}$ in the speed of rotation of a rotating electrode there corresponds a current signal Δi, which is determined exclusively by the transport-controlled component of the current. *Miller*[16] has therefore suggested the superposition of a periodic change $\Delta\omega^{1/2}$ (*e.g.* sinusoidal or rectangular) on a fixed value $\omega_0^{1/2}$, this periodic change

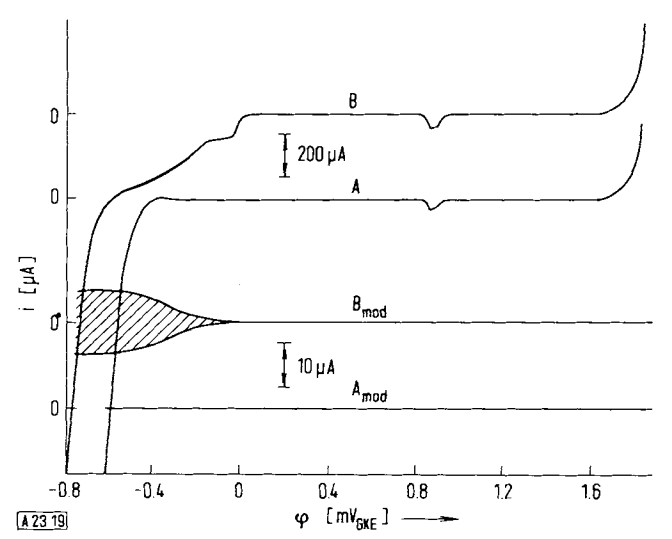

Fig. 19. Cathodic current potential diagram on gold at 26.6 Hz, potential scanning rate 5 mV/s (after [16]). a) in 1 M H_2SO_4; $a_{mod.}$) as a with superimposed sinusoidal frequency modulation; b) in 1 M H_2SO_4 + 2 M $CuSO_4$; $b_{mod.}$) as b with superimposed frequency modulation. φ = potential, i = current.

being so slow that the condition for eq. (1), *i.e.* the establishment of a steady state hydrodynamic flow, is not violated. In this case

$$\frac{\Delta i}{\Delta\omega^{1/2}} = \frac{i_{transp.}}{\omega_0^{1/2}}$$

For given $\omega_0^{1/2}$ and $\Delta\omega^{1/2}$ and measured Δi, it is possible to calculate the pure transport component $i_{transp.}$ and to compare it with the current i found without modulation.

As an example, Figure 19 shows the superposition of a copper deposition controlled by convective diffusion and the evolution of hydrogen, the kinetics of which are rate-determining at gold electrodes in particular. The splitting of the current signal by Δi in the case of the copper deposition can be seen in curve $b_{mod.}$. No Δi corresponding to the frequency modulation is observed in the evolution of hydrogen only (curve $a_{mod.}$).

3.3. The Rotating Double Electrode and Its Applications

The possibilities of a rotating system can be considerably extended if instead of a single electrode one uses several concentric electrodes (disc-ring, ring-ring). A substance formed on the inner electrode is then transported by the radial flow to the outer electrode, where it may undergo a further electrochemical reaction. The narrower the electrodes and the thinner the insulating layer between them, the greater is the sensitivity. Thus with a double ring electrode having a diameter of 10 mm, an electrode width of 1 mm, and an interelectrode distance of 0.1 mm, intermediates having a lifetime of 10^{-5} s can be detected at 400 Hz.

With the aid of this method, *Hamann* and *Vielstich*[17] were able to show that formate is formed as an intermediate in the alkaline electrolyte during the anodic oxidation of carbon monoxide to carbonate. It was not possible to show this directly with a double electrode, since CO and formate react in the same potential range on most electrodes and the oxidation of formate is blocked by carbon monoxide. The detection of formate as an intermediate in the oxidation of CO was made possible only by the use of an outer electrode ring of palladium, an electrocatalyst that is substantially selective for formate.

It can be seen from the foregoing that the double electrode is particularly suitable for the study of short-lived intermediates. However, a measuring arrangement of this type also allows the detection of homogeneous chemical reactions placed between two electrochemical steps. For example, if Fe^{3+} is reduced to Fe^{2+} on the inner electrode the Fe^{2+} can be reoxidized on the outer electrode if the potential chosen is correspondingly positive. The ratio of the reduction current to the oxidation current is known as the collection efficiency N. It gives the percentage of the substance formed on the inner electrode that reaches the outer electrode. N depends only on the electrode geometry selected[18].

If an oxidizing agent, *e.g.* H_2O_2, is added to the electrolyte, part of the Fe^{2+} formed on the inner electrode is oxidized by the H_2O_2 in a homogeneous chemical reaction and is lost with regard to detection on the outer electrode, and the collection efficiency accordingly decreases. The longer the time spent by the Fe^{2+} between the two electrodes, the greater is the decrease. One thus obtains a collection efficiency that

depends on the rotation speed. The rate constant of the homogeneous chemical reaction can be calculated from the variation of N with ω at a given H_2O_2 concentration[19].

4. AC Polarography

In conventional AC polarography, which was developed 30 years ago, the impedance of an electrochemical cell is measured under polarographic conditions, a low-amplitude (< 10 mV) sinusoidal alternating current being superimposed on the direct current, which increases linearly with time (saw-tooth). As a function of the linearly increasing electrode potential one obtains an AC signal that corresponds, to a first approximation, to the first derivative of the normal polarographic wave (Fig. 20), *i.e.* the potential of the current maximum agrees with the half-wave potential of the DC polarogram. This is not, in fact, a simple derivative of the DC curve, as is shown, *e.g.*, by the fact that the irregularities of the polarogram (drop peaks, maxima) are not differentiated at the same time.

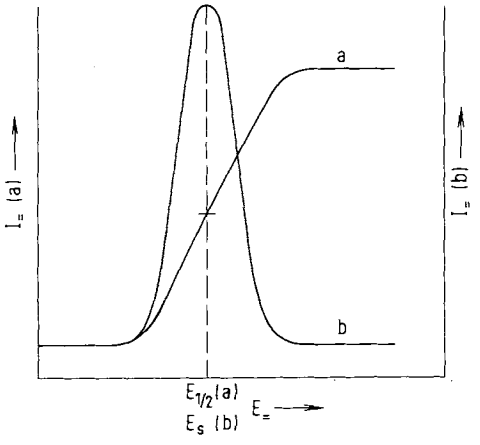

Fig. 20. Schematic representation a) of a polarographic DC step and b) the corresponding AC peak. $E_=$ = DC potential, $I_=$ and $I_\sim$ = DC and AC currents respectively; $E_{1/2}$ = half-wave potential, E_s = potential at current maximum.

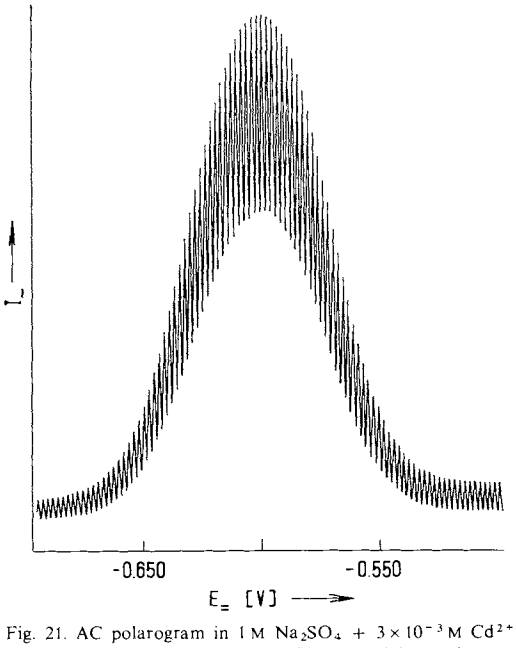

Fig. 21. AC polarogram in 1 M Na_2SO_4 + 3×10^{-3} M Cd^{2+} (after [24]), AC amplitude 5 mV, frequency 320 Hz. Potential scanning rate 25 mV/min. $E_=$ = DC potential, $I_\sim$ = alternating current.

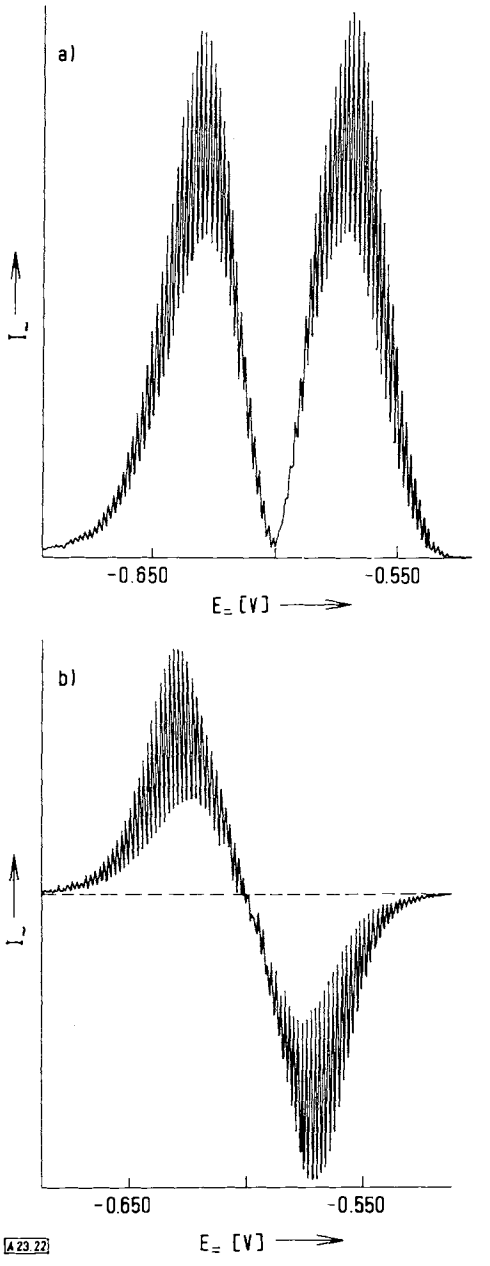

Fig. 22. Second harmonic of an AC polarogram in 1 M Na_2SO_4 + 3×10^{-3} M Cd^{2+} (after [24]), amplitude 5 mV, frequency 80 Hz, potential scanning rate 25 mV/min; a) "conventional" harmonic of an AC polarogram, b) harmonic with phase-selective recording. $E_=$ = DC potential, $I_\sim$ = alternating current.

Theoretical considerations by *Bauer et al.*[20] and by *Breyer* and *Bauer*[21] have shown that the observed AC amplitude and the corresponding real and imaginary impedance components depend on the rate constants and transfer coefficients of the reaction steps. An analysis of the AC polarogram should therefore yield information about the kinetics of the electrode reaction.

The accuracy of the measuring method is limited by the ohmic resistance of the cell and by the capacitive resistance of the double layer. The ohmic voltage drop can be largely eliminated by the introduction of a reference electrode (cf. the potential scan method), which is not usual in conventional polarography. The capacitive impedance component, on the other hand, can be reduced only by the use of a low AC frequency. In any case, the capacitive impedance is greater in AC polarography than in DC polarography, and the sensitivity is accordingly poorer in the AC method. Conventional AC polarography

has therefore never really gained acceptance for kinetic investigations.

Since the early 1960's, a new AC polarographic method has been developed, in which instead of the fundamental curve (Fig. 21), the second (or a higher) harmonic is measured with the aid of a frequency filter[22]. The capacitive current of the charge reversal of the double layer is largely free from harmonics, and the capacitive impedance is significantly lower in this type of measurement than in conventional AC polarography.

The second harmonic of an AC polarogram generally has two current maxima (Fig. 22a), which, with phase-selective measurement, have quantitatively the appearance of the second derivative of the DC polarogram (Fig. 22b). The principle of the phase-selective detector is based on a vectorial comparison of the measured voltage with a control voltage of the same frequency. The detector may be, *e. g.*, a phase-dependent rectifier[23] that passes only the component of the measured voltage that is in phase with the control voltage. The real and imaginary components of an alternating current can thus be measured directly with such an arrangement, and can then be used to find the impedance components. The phase-selective measurement therefore yields additional information about the nature of the measured (ohmic or frequency-dependent) resistance components, so that a double-layer capacity component that is still present in the second harmonic can also be eliminated.

$$X \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Ox + ne^{\ominus} \rightleftharpoons R$$

(— —): $K = k_1/k_2 = \infty$, (- - -): $K = 1$, $k_1 = 1 \times 10^3\,s^{-1}$, (— · —): $K = 0.1$, $k_1 = 1 \times 10^3\,s^{-1}$. $E_= - E_{1/2}$ = difference between DC potential and half-wave potential, $I(2\omega t)$ = alternating current.

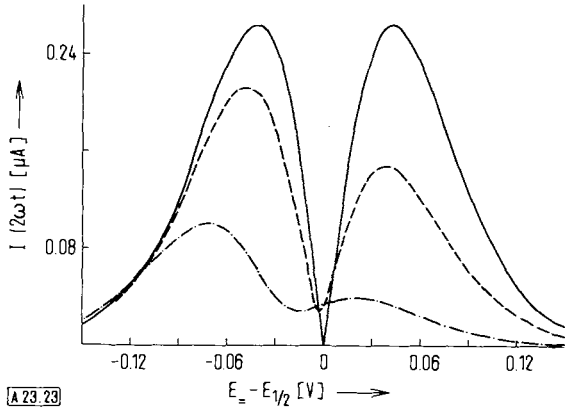

Fig. 23. Calculated second harmonic of an AC polarogram (after [24]) for the system

The shape of the first harmonic of an AC polarogram is very strongly dependent on the kinetics of the charge transfer and of the chemical reaction steps. Figure 23 shows this for the case in which a preceding chemical reaction influences the shape of the second harmonic[24].

5. Optical Methods

5.1. Absorption Spectroscopy

Optical methods are among the most promising *in-situ* techniques (measurement on the electrode surface during the electrochemical reaction) for the study of the electrochemical double layer and of the formation and consumption of reactants, intermediates, and products on or in the vicinity of the electrode surface. In absorption spectroscopy, visible or UV light is allowed to pass through a transparent electrode into the electrolyte compartment, and the quantity of light absorbed is determined. The light absorption is proportional to the concentration of the absorbing substance in the electrolyte. By varying the thickness of the layer of electrolyte, therefore, one can determine the change in the concentration of the absorbing substance as a function of distance from the electrode. Homogeneous chemical reactions that precede or follow the electrode reaction and that proceed at some distance from the electrode are thus also accessible to direct observation.

Conclusions regarding the electrode kinetics can be drawn from the change in the absorption with time during an electrode reaction. In the simple case of an electrochemical reaction $R \rightarrow Ox + ne^{\ominus}$, resulting in the formation of the light-absorbing species Ox which was not initially present in the electrolyte, the absorption M can be calculated for the case of a diffusion-inhibited reaction[25]:

$$M = \mu_0 \int_{x=0}^{x=\infty} [c_{Ox}(x)]\,dx = 2\mu_0 c_R^0 \left(\frac{D_R t}{\pi}\right)^{1/2} \qquad (5)$$

In this equation, μ_0 is the molar absorption of the substance Ox, x is the distance from the electrode, c_R^0 is the initial concentration of the substance R, and D_R is the diffusion constant of R. Eq. (5) states that in a diffusion-controlled electrode reaction, the absorption increases in proportion to $\sqrt{t}$. However, if chemical reactions are coupled with the discharge step, one finds deviations from the $\sqrt{t}$-dependence of eq. (5). The rate constant of the chemical reaction can be determined from this deviation.

Strojek and *Kuwana*[25] used this method in their studies on the oxidation of *o*-toluidine in aqueous solutions. They were able to show that the oxidation proceeds in accordance with the scheme

$$\begin{aligned} R &\longrightarrow S + e^{\ominus} \\ S &\longrightarrow Ox + e^{\ominus} \\ R + Ox &\underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2S \end{aligned}$$

via an intermediate S and a subsequent synproportionation. With the aid of absorption spectroscopy, *Strojek* and *Kuwana* were able to determine the rate constants of this subsequent chemical reaction with an accuracy of about 10%.

5.2. Reflection Spectroscopy

Two fundamentally different methods are known in reflection spectroscopy. In one case the light beam is allowed to reflect several times (to increase the sensitivity) in the interior of a plane-parallel ground transparent electrode, as illustrated in Figure 24. If the angle of incidence of the light is greater than the critical angle, the light is totally reflected, provided

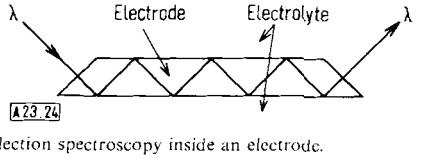

Fig. 24. Beam path in reflection spectroscopy inside an electrode.

that no substances that influence the beam path are adsorbed on the electrode surface. Theoretical considerations and practical experiments have shown that even with total reflection, the reflected beam penetrates for a distance of a fraction of a wavelength into the solution. The reflection coefficient consequently depends on the nature of the substances absorbed on the electrode.

The method has already been repeatedly used, both with visible[26, 27] and with IR light[28]. IR light appears to be particularly suitable for investigations on the surface state of semiconductor electrodes. The conditions for the use of the method in electrochemical studies are, on the one hand, that apart from the substance under investigation there are no other species (solvent, supporting electrolyte) in the solution that influence the beam path and, on the other hand, that the absorption by the adsorbed molecules is sufficiently strong. The latter condition restricts the method to investigations on fairly large organic molecules; for smaller molecules the sensitivity is insufficient for quantitative measurements[29].

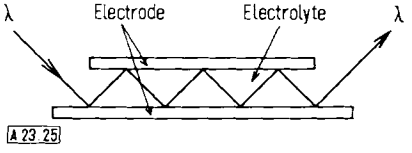

Fig. 25. Beam path in reflection spectroscopy between two electrodes.

The second method of reflection spectroscopy is used more often. In this case the light beam is allowed to reflect several times between two or more plane-parallel electrodes in the interior of the solution, as indicated in Figure 25. *Plieth*[30] recently described the theory and the possibilities of this method.

Takamura et al.[31] used a reflection cell of this type to study the oxide formation and the adsorption of foreign metal ions on gold electrodes. They used visible light and an electrode arrangement that allowed 10—15 reflections. From the dependence of the reflection on the wavelength and on the electrode potential, they were able to conclude that the change in the reflectivity depends on effects of the electric field in the double layer, on the concentration and the photoactivity of the adsorbed substances, and on the structure of the metal surface.

The method thus seems very suitable for *in-situ* studies on substances adsorbed on electrodes with visible and UV light (IR light is strongly absorbed by water and other polar solvents, and is therefore ruled out). If the wavelength dependence of the adsorbed substance can be measured, information about the nature of the specific adsorption is often obtainable (*e.g.* d-orbital interactions).

5.3. Ellipsometry

For ellipsometry one uses only a single electrode, which is irradiated with polarized light. From the change in the phase and amplitude of the polarized light it is possible not only to obtain general information about the adsorption on the electrode surface but also, in particular, to determine the thickness of a surface layer.

Figure 26 shows the principal device for ellipsometry. If one starts, for example, with a plane, homogeneous metal surface and electrochemically produces an oxide film on this electrode by means of a suitable potential, the resulting change in the refractive index of the surface layer very strongly influences the polarization of the incident light wave. This polarization change can be detected by adjusting the analyzer system ($\lambda/4$ plate and analyzer) to complete extinction (or minimum light transmission) for the pure metal electrode and measuring the quantity of light transmitted for the oxide-coated electrode with the aid of a photomultiplier. (For further details see, *e.g.*, [32].)

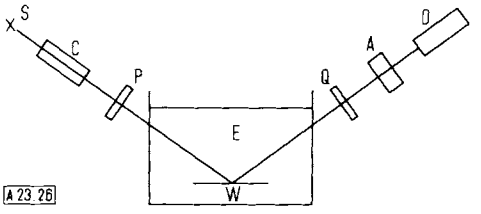

Fig. 26. Principal device of an apparatus for ellipsometry. S = light source, C = collimator, P = polarizer, Q = $\lambda/4$ plate, A = analyzer, D = detector, W = electrode, E = electrolyte.

The ellipsometric method has been used, *e.g.*, for studies of oxide formation on platinum[33] and of the passivation of nickel[34] and iron[35]. In the case of oxide formation on platinum, the coating of the electrode with oxygen, with a mean thickness of 0.2 Å, begins at 0.98 V against the normal hydrogen electrode. The thickness of the oxide layer increases linearly with the potential, and reaches a value of 6 Å at about 1.6 V, the potential at which the evolution of oxygen begins. The mean layer thickness of 0.2 Å is interpreted as being due to a partly formed monolayer.

Ellipsometric studies on the double layer have so far been carried out in most cases at only one wavelength, and consequently yield only rather unspecific information about the nature of the adsorbate layer. Measurements over a wide range of wavelengths should provide information about the interactions (nature of the bonding) that occur in the formation of monolayers on electrode surfaces.

All the optical methods described so far can be used to detect the existence of an adsorbate and to measure its film thickness and the kinetics of the adsorption, but do not allow the identification of an unknown adsorbate.

5.4. Photoelectrochemistry and Electroluminescence

Photoelectrochemistry is based on the Becquerel effect, which was discovered in 1839. *Becquerel* found that a current flows between two unequally illuminated platinum electrodes in an acidic electrolyte. The different levels of illumination of the electrodes evidently lead to the development of a potential difference, which causes the current to flow. It therefore seems reasonable to assign a "photopotential" to an electrode, this being defined simply as the potential of the illuminated electrode with respect to the potential of the unilluminated electrode:

$$\varphi^* = \varphi_L - \varphi_D$$

φ^* is the photopotential, φ_L is the potential of the illuminated electrode, and φ_D is the potential of the unilluminated electrode. The change in the potential of the electrode may be due to a series of primary and secondary effects.

Primary effects: 1, Production of excited molecules by light absorption; 2, photodissociation as a result of light absorption;

3, absorption of light by the metal, non-metal, or semiconductor, with consequent photoionization, photoemission, or change in the population of valence and conduction bands.

Secondary effects: 1, Fluorescence or phosphorescence; 2, photochemical reactions; 3, energy-transfer reactions; 4, other non-radiative de-excitation modes (inelastic collisions); 5, thermal effects (rise in temperature of the illuminated electrode).

This list shows that photoelectrochemistry allows the investigation of numerous effects by measurement of the photopotential or the photocurrent as a function of the exposure to light. The method seems promising in particular for the study of excited molecules and free radicals in organic electrode reactions and for investigations on the oxide film on solid electrodes (for discussion see [36]).

If a molecule or free radical in an excited state is formed in an electrochemical process, it may pass to the ground state with emission of light. This effect, which is known as electroluminescence, is shown in particular by aromatic hydrocarbons[36]. In certain circumstances it allows the identification of an intermediate, and is thus an important addition to the range of methods for the investigation of reaction mechanisms.

6. ESR Spectroscopy

The measuring principle of electron spin resonance spectroscopy is based on the fact that free radicals do not have saturated electron spins and are therefore paramagnetic. In a homogeneous magnetic field, the electron spin has two possible states (parallel or antiparallel to the magnetic field), whose energies are slightly different. The number of radicals in the lower energy state is slightly greater than the number in the higher state (Boltzmann distribution). If energy is supplied to the system in the form of electromagnetic radiation (microwaves) whose energy is exactly equal to the energy difference between the two states, radicals pass from the lower energy level to the higher. This is opposed, however, by the fact that radicals from the higher energy level relax to the lower level as a result of interaction with the environment (spin-lattice interaction). In the resonance case (injected energy = energy difference between the states) this leads to a continuous measurable absorption of the microwave radiation.

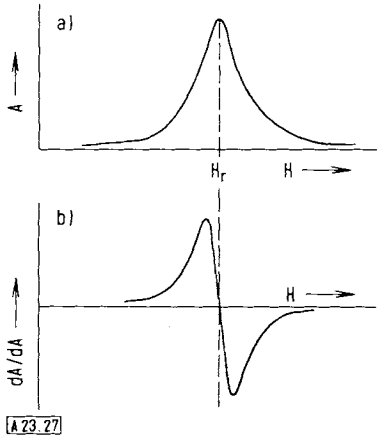

Fig. 27. a) Absorption A as a function of the field strength H. b) First derivative of the absorption curve dA/dH (H_r = resonance field strength).

In the measurements, the strength of the homogeneous magnetic field is varied linearly and the energy absorbed is measured. This gives an absorption curve as shown in Figure 27a, with a maximum at the point of resonance. However, the first derivative is recorded in most cases (Fig. 27b). Interaction of the electron spins with the magnetic moments of the atomic nuclei of the molecules (protons and nitrogen in the case of organic substances; ^{12}C and ^{16}O have no magnetic moment) leads to a splitting of the resonance line (hyperfine structure). The number of hyperfine structure lines can be considerable in the case of organic molecules. As an example, Figure 28 shows the ESR spectrum of the nitrobenzene radical-anion, with 54 hyperfine structure lines.

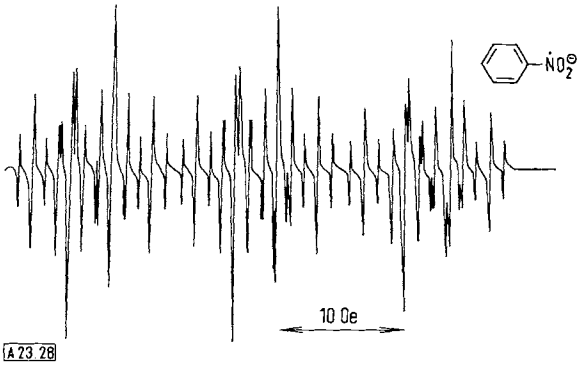

Fig. 28. ESR spectrum of the nitrobenzene radical-anion in aqueous alkali solution (after [37]). The 54 lines observed correspond to the splitting due to the ^{14}N nucleus, one proton (*para*), and two groups of two equivalent protons each (*ortho* and *meta*).

Analysis of the hyperfine structure splitting of the ESR spectrum with regard to the number, intensity, and spacing of the lines yields information on the number and nature (H or N) of atomic nuclei that influence the electron spin. In many cases the molecular structure of the radical can be deduced, *i.e.* the radical can be identified.

The microwaves are injected by means of a cavity resonator inside which the radicals either flow through a thin capillary (external production of free radicals, Fig. 29a), or are directly produced in a shallow cell (internal production of free radicals, Fig. 29b). In the former case, not only is it possible to identify

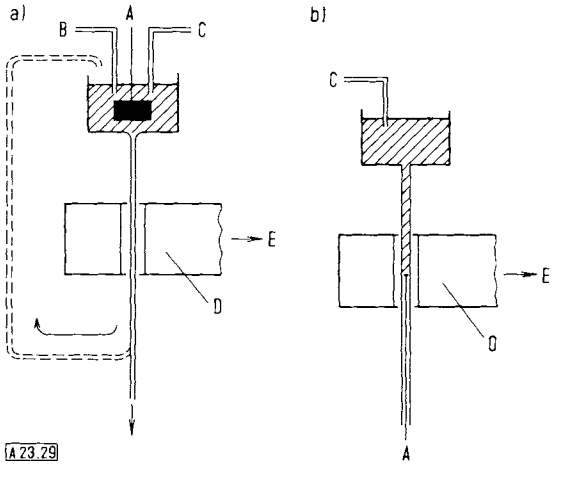

Fig. 29. Scheme of an apparatus for ESR measurements (after [37]) with a) external generation of free radicals, b) internal generation of free radicals. A = working electrode, B, C = connections to reference electrode and counter-electrode, D = microwave resonator, E = hollow conductor connection; magnetic field normal to the plane of the drawing.

the radical-ion, but its lifetime can also be determined by variation of the distance from the point at which it is formed to the measuring position. Moreover, if the flow capillary is branched, a reagent solution may be added, and free-radical reactions can thus also be studied (Fig. 30). The method with internal production of the free radicals can be used for the study of short-lived intermediates.

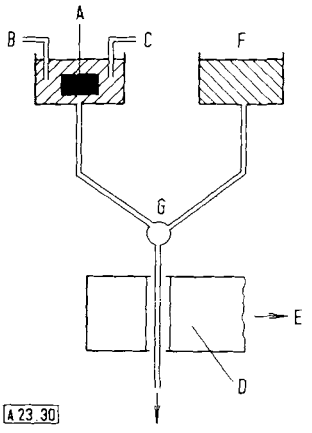

Fig. 30. Scheme of an apparatus with external production of free radicals and mixing with a reagent solution before the ESR measurement (after [37]). A to E as in Fig. 29. F = storage vessel for reagent solution, G = mixing chamber.

As far as electrochemical investigations are concerned, the most important results of ESR measurements are the proof of the presence of free radicals and the determination of their molecular structure. It is also possible to determine absolute or relative concentrations; this is important for kinetics. Further information can be obtained from the hyperfine structure splitting (energies of molecular orbitals) and from the line width (solvation processes, ion-pair formation). ESR spectroscopy thus provides numerous data for electrochemical investigations (for examples see [37]).

7. Radioactive Tracer Methods

In addition to the foregoing methods for the investigation of the electrolytic double layer and the specific adsorption of ions, intermediates, *etc.* on the electrode surface, radioactively labeled substances have frequently also been used for this purpose in recent years. However, the radioactive tracer method did not attain any importance until radioactive isotopes of practically all elements became available *e.g.* as products from nuclear reactors.

The following is an example of a procedure that can be used for the study of the adsorption of organic molecules on metal electrodes. The electrode is immersed in an electrolyte containing the radioactively labeled form of the molecules to be investigated. The adsorption begins immediately after the immersion of the electrode, and an equilibrium is reached after a time. The time taken to reach equilibrium depends *e.g.* on the nature of the adsorbate and of the adsorbent, the temperature the electrolyte concentration, the surface condition of the metal electrode, and its potential. By varying one parameter and keeping the others constant, one can obtain information about the nature and the kinetics of the adsorption[38].

The radioactive tracer method has become a valuable aid to the study of adsorption processes in organic electrochemistry. Thus *Hackermann et al.*[39] studied the adsorption of ^{14}C-labeled organic inhibitors in the corrosion of iron under stationary conditions. *Bockris et al.* have published investigations on the adsorption of organic substances (aldehydes, benzene, naphthalene, and *n*-decylamine) on platinum and partly also on gold and nickel[40]. They interpreted their results by a model of competitive adsorption of organic substances and of water.

8. Identification of Electrochemical Products by Mass Spectrometry

Any investigation of the kinetics of an electrode reaction must necessarily be incomplete until the intermediates and products have been definitely identified. The measuring methods described in the foregoing sections allow this identification only in exceptional cases, when the substances under investigation are present in the dissolved state (double-ring electrodes, electroluminescence, ESR spectroscopy). However, the reaction products are often adsorbed on the electrode. Their existence can be detected by optical methods, but identification has not been possible in the past.

Attempts have recently been made, therefore, to analyze adsorbed products of an electrode reaction in the mass spectrometer. *Bruckenstein*[41] used a microporous non-wetting electrode which is fitted as a cell wall with its hydrophobic side directly on the inlet part of a mass spectrometer (Fig. 31). Low molecular weight, readily volatizable reaction products are extracted from the electrode by the vacuum on the mass spectrometer side, and after ionization by electron impact they are subjected to mass analysis. Since the electrochemical cell is connected directly to the mass spectrometer, the product distribution can be measured as a function of the electrode potential, and the *m/e* signal can be measured as a function of time at a constant potential. Detailed information about the dependence of the reaction mechanism on the potential and about the strength of the adsorptive bond can be obtained in this way.

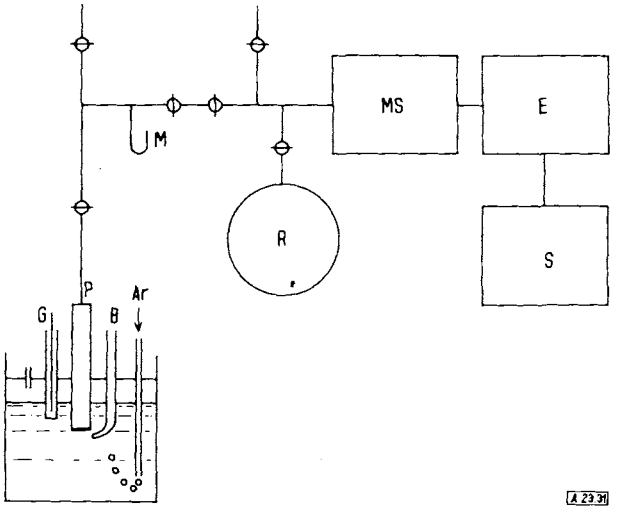

Fig. 31. Schematic representation of an apparatus for the direct analysis of electrochemical reaction products with the mass spectrometer (after [41]). B = reference electrode, E = electronics, G = counterelectrode, M = manometer, MS = mass spectrometer, P = porous electrode, R = reservoir, S = pen recorder.

Another mass-spectrometric method for the identification of adsorbed reaction products has been proposed by the present authors[42]. The electrode in this case is a metal foil 7 µm thick, which is etched at its lower edge. After the electrochemical reaction, this foil is placed in a mass spectrometer; the adsorbate is ionized by application of a very high electric field strength and detected in the mass analyzer. The field desorption method developed by *Beckey et al.*[43] has the special advantage that the molecular peak is normally the base peak. Since the starting substance and the reaction product are present together on the electrode, there is consequently only a slight overlap of the mass spectra, so that a definite identification of the desired substance is generally possible.

To demonstrate the applicability of the suggested method, the reaction product formed on anodic oxidation of 1-butanol in alkaline electrolyte at 700 mV_{RHE} was investigated.

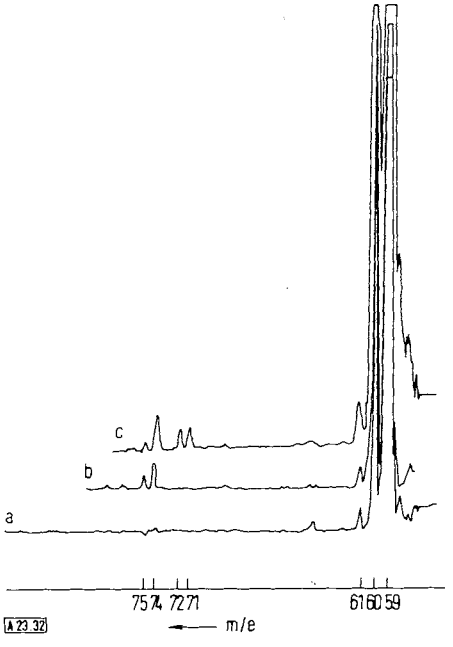

Fig. 32. Mass-spectrometric detection of the oxidation product of 1-butanol adsorbed on the electrode: a) Background spectrum and calibration spectrum of the platinum emitter used (calibrated with acetone, mass numbers 59, 60, and 61); b) mass spectrum of a solution of 0.473 M 1-butanol in 1 M KOH. The mass number 74 corresponds to the molecular peak of butanol (molecular weight 74.12); c) mass spectrum of the same solution as for b) after electrochemical oxidation of the butanol at +700 mV_{RHE}. The mass numbers 71 and 72 correspond to the oxidation product in question.

The results are shown in Fig. 32. Curve a shows the background spectrum of the mass spectrometer with the platinum foil described above as the emitter. The spectrum of acetone, which was used for calibration of the emitter in the mass spectrometer, can be seen at the right-hand edge of the diagram.

Curve b shows the same mass range as curve a. In this case the platinum foil was immersed in a solution of 1 M KOH + 0.473 M 1-butanol without application of a potential before it was placed in the mass spectrometer. The mass numbers 74 and 75 appear in the mass spectrum, 74 being the molecular peak of butanol (molecular wight 74.12).

Finally, before curve c was recorded, the butanol was electrochemically oxidized for about 30 s at a potential of 700 mV_{RHE}. In this case the mass spectrum contains the additional mass numbers 71 and 72, which correspond to the adsorbed oxidation product formed from the butanol by the elimination of hydrogen.

9. Outlook

Modern electrochemical methods nowadays make it possible to obtain accurate information about the kinetics of an electrode process. The rate-determining step of a reaction sequence can often be indicated, and the rate constants of preceding or subsequent chemical reactions can be measured with good accuracy. In establishing a reaction mechanism, however, the investigator must often resort to plausibility considerations, since the identification of the intermediates and frequently even of the end products of a reaction is possible only in exceptional cases.

It is not surprising, therefore, that the efforts of many electrochemists are being concentrated at present on the detection of intermediates. This progress report has shown the successes that have been achieved so far by the use of ESR spectroscopy and mass spectroscopy. It should be remembered, however, that ESR spectroscopy is confined to measurements on relatively long-lived free radicals in solution, mainly in organic solvents, and that mass spectroscopy can be used for the analysis only of practically stable products. There is as yet no sensitive *in-situ* method for the determination of short-lived intermediates on or in the vicinity of the electrode surface that would allow a rapid identification without influencing the course of the reaction.

It is clear that optical methods really offer the only possibility of further assistance here, and the first steps in this direction have already been taken. In the discussion of reflection spectroscopy and ellipsometry it was pointed out that variation of the wavelength of the incident light could yield information about the nature of the adsorbed substance. *Fleischmann et al.*[44] were recently able to identify surface layers by Raman spectroscopy with laser light sources. *Siegbahn et al.*[45] proposed the use of X-rays and electron diffraction.

The examples show that the development of optical methods into analytical procedures for electrochemically produced intermediates is being vigorously pursued at present. New impetus for the study of electrode kinetics may be expected from this quarter in the near future.

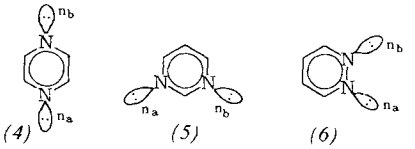
Effects of Through-Bond Interaction

By Rolf Gleiter[*]

The effect of through-bond interaction is derived for 1,4-butanediyl as an example, and changes caused by this effect in the ground state of the system are demonstrated. Spectroscopic methods for the detection of the effect are discussed, and its chemical consequences are illustrated by a number of examples.

1. Introduction

Until a few years ago the interaction of lone pairs of electrons and of π orbitals situated more than 3 Å apart was assumed to be very small. Examples of this situation are found in 1,4-diazabicyclo[2.2.2]octane *(1)*, *p*-benzoquinone *(2)*, *anti*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene *(3)*, and pyrazine *(4)*. The



(1) *(2)* *(3)* *(4)*

assumption that these interactions are very small became the subject of critical examination following calculations by *Hoffmann et al.* for the three isomeric diazabenzenes[1] and didehydrobenzenes[2]. These calculations were stimulated by experiments by *Rees* and *Storr*[3] on cycloadditions to 1,8-didehydronaphthalene (1,8-naphthalenediyl) and by investigations by *McKinney* and *Geske*[4] on the radical-cation $(1)^+$.

[*] Prof. Dr. R. Gleiter
Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Petersenstrasse 15 (Germany)

The results of these calculations will be illustrated for the three diazabenzenes (diazines) pyrazine *(4)*, pyrimidine *(5)*, and pyridazine *(6)*. If the two orbitals indicated on the nitrogen

(4) *(5)* *(6)*

atoms in *(4)*, *(5)*, and *(6)* are denoted by n_a and n_b, we can write down the two non-normalized, but symmetry-adapted linear combinations

$$n_+ = (n_a + n_b)$$
$$n_- = (n_a - n_b)$$

which are shown schematically in Figure 1. The n_+ linear combination is symmetric (S) and the n_- linear combination antisymmetric (A) with respect to the mirror plane m.

If the interaction between n_a and n_b is very small, n_+ and n_- should have approximately equal energies (Fig. 2, center). If the interaction is large, on the other hand, the energy

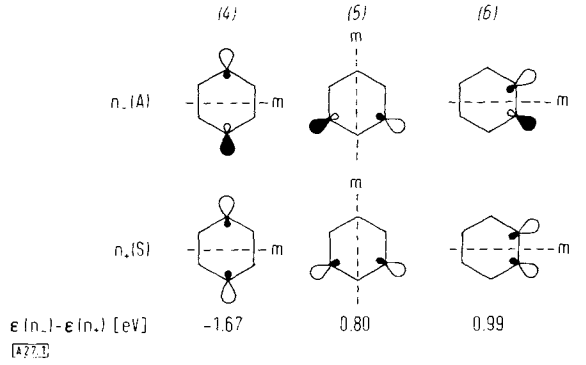


Fig. 1. Schematic representation of the linear combinations of the non-bonding orbitals n_a and n_b for the diazabenzenes *(4)*–*(6)*.

levels belonging to n_+ and n_- should be very different (Fig. 2, right and left). In the latter case there are two conceivable possibilities: Either n_+ is lower on the energy scale than n_- (Fig. 2, right) or *vice versa* (Fig. 2, left).

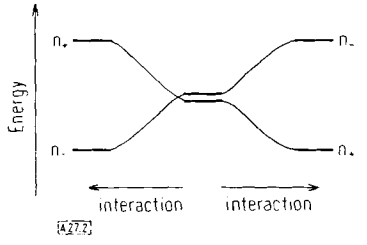

Fig. 2. Variation of the energy levels of n_+ and n_- as a function of the interaction between n_a and n_b.

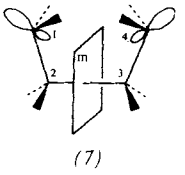
Surprisingly, the EH (extended Hückel) calculations[5] for the diazabenzenes and the didehydrobenzenes not only indicated a large difference (about 1.5 eV) for the compounds of the type *(4)*, but also showed that n_+ is above n_- in this case, whereas n_+ is below n_- for compounds of the types *(5)* and *(6)*. The calculated orbital energy differences $\varepsilon(n_-)-\varepsilon(n_+)$ are given at the bottom of Figure 1.

The discovery that the n_+ level can be either lower or higher than the n_- level suggested the existence of two interaction mechanisms, *i.e.* a purely spatial interaction[*] (through space), in which the n_+ level falls below the n_- level, and an interaction mechanism in which the σ skeleton (through bond) leads, under certain conditions[**], to a reversal of this "normal" sequence.

2. Theory of Through-Bond Interaction



The purely spatial interaction is described in detail in textbooks on chemical bonding. The effect of through-bond interaction will be discussed below for the case of 1,4-butanediyl *(7)*. For a detailed theoretical treatment the reader is referred to the literature[2a].

Just as for the n orbitals of the diazabenzenes *(4)*, *(5)*, and *(6)*, we can form the two symmetry-adapted linear combinations $n_+(S)=(n_1+n_4)$ and $n_-(A)=(n_1-n_4)$ for the orbitals n_1 and n_4 shown on the centers C^1 and C^4 in *(7)*. If one considers only the spatial interaction, the energy difference between n_+ and n_- in *(7)* should be small (Fig. 3, left).

[*] The simplest interaction of this type is that of two H(1s) orbitals leading to the MOs of hydrogen [6, 7].

[**] For a through-bond interaction *via* an odd number of σ bonds, the n_- level is always below the n_+ level [2a].

This energy difference depends on the overlap integral $\langle n_1|n_4\rangle$, which is small because of the spatial separation of the two centers (about 3 Å).

(7)

However, relatively strong splitting can be achieved for n_+ and n_- through the interaction with the σ and σ^* orbitals of the C^2—C^3 bond. As can be seen from Figure 3, the σ orbital is symmetric (S) and the σ^* orbital antisymmetric (A) with respect to the mirror plane m in *(7)*. The interaction of the other orbitals in *(7)* with n_+ and n_- may be disregarded to a first approximation[2a][*].

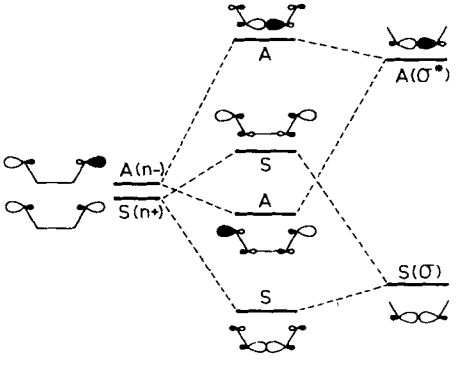


Fig. 3. Interaction diagram for the orbitals of the centers C^1 and C^4 and of the C^2—C^3 σ bond in 1,4-butanediyl *(7)*.

Qualitative rules derived from perturbation theory[7][**] were used to construct the interaction diagram shown in Figure 3 for the σ and n levels.

It can be seen from Figure 3 that n_+ is destabilized by the interaction with the σ orbital, whereas n_- is stabilized by the interaction with the σ^* orbital.

Figure 4 shows a comparison of the one-electron orbitals from an EH calculation for 1,4-butanediyl with and without through-bond interaction; the MO scheme for a through-bond interaction is also compared with the π-MO scheme of 1,3-butadiene.

This diagram leads to three conclusions for a system in which only the two lowest MOs are occupied:

1) The through-bond interaction leads to the reversal of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) compared with a system in which this interaction is absent (Fig. 4, left).

2) The system with through-bond interaction is more stable than the system without this interaction[***].

[*] Apart from the C^2—C^3 bond, all other bonds (*e.g.* C^1—C^2 and C^3—C^4) give symmetric *and* antisymmetric combinations of σ orbitals and σ^* orbitals. It may be assumed to a first approximation that the position *e.g.* of the n_- level does not change if one symmetric orbital is lower (σ) and one is higher (σ^*).

[**] These rules are:
Only orbitals of the same symmetry interact with one another. Interacting non-degenerate orbitals "repel" each other, *i.e.* the lower orbital on the energy scale is stabilized, while the higher one is destabilized.

[***] In our example the total energy of the system is $E=\Sigma n_i\varepsilon_i$. n_i is the occupancy and ε_i is the orbital energy. In the dianion of *(7)*, 1,4-butanediide $(7)^{2-}$, the through-bond interaction would lead to less stabilization than in *(7)*.

3) The C^2—C^3 bond in *(7)* is weakened by a through-bond interaction.

The first two conclusions require no further explanation, but the third will be briefly interpreted. The predicted bond alternance (bonds C^1—C^2 and C^3—C^4 stronger than C^2—C^3) can be best understood by comparison of the MO scheme for *(7)* (Fig. 4, center) with the π-MO scheme for 1,3-butadiene (Fig. 4, right). The one-electron MO schemes are identical as to the symmetry of the orbitals with respect to the mirror plane m. In both cases an S orbital and an A orbital are

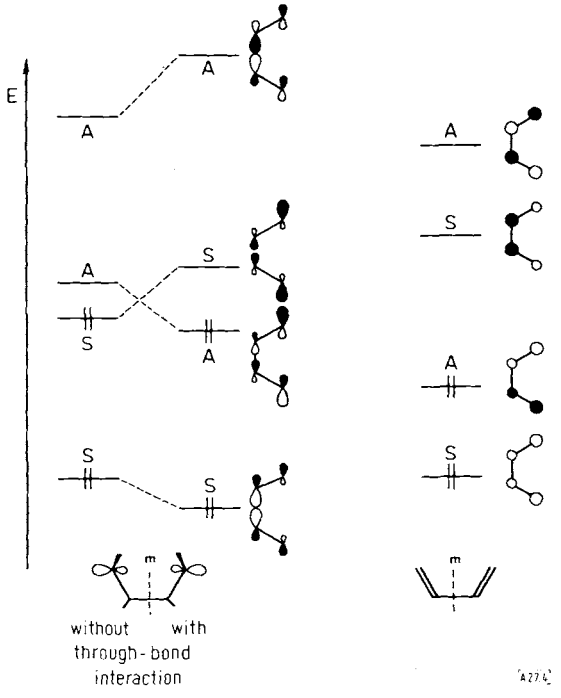

Fig. 4. Comparison of the orbital energies of a system with and without through-bond interaction with the π-MOs of 1,3-butadiene.

each occupied by two electrons. Because of the occupation of the lowest A orbital, which has a node between the centers C^2 and C^3, the contribution of the lowest occupied S orbital to the bond order is roughly cancelled out. In 1,3-butadiene the result is a weakening of the π bonding between the centers C^2 and C^3 (single bond) and a strengthening of the π bonding between the centers C^1 and C^2 and between C^3 and C^4 (double bond).

The same is true of *(7)*, since here again only one S orbital and one A orbital are occupied. These qualitative deductions

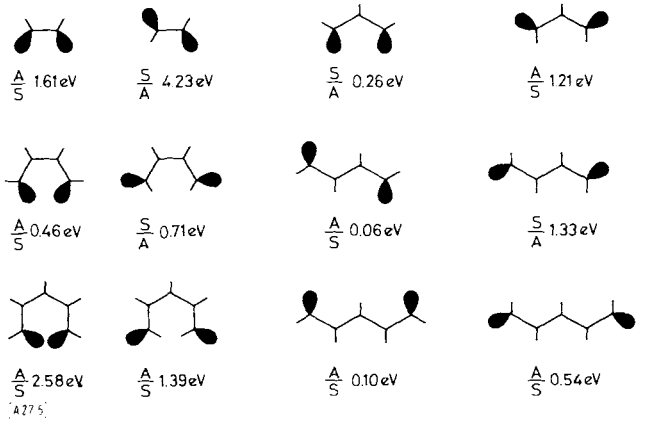

Fig. 5. Model arrangements of lone pairs of electrons und σ bonds. The symmetry of LUMO and HOMO and the calculated energy difference between these two orbitals are indicated under each formula.

have been confirmed by EH calculations[8, 9]. Thus as soon as through-bond interaction predominates, *i.e.* A is lower than S, the C^2—C^3 bond is distinctly weakened in comparison with C^1—C^2 and C^3—C^4.

Conclusions 2 and 3 disappear for a system in which the three lowest orbitals are occupied. Examples of such systems would be 1,4-butanediide $(7)^{2-}$ and 1,2-diaminoethane.

The model calculations by *Hoffmann et al.*[2a] that were mentioned in the introduction have also been carried out for other systems (Fig. 5). The order LUMO-HOMO and the energy difference between the two orbitals are indicated under the corresponding formulas in Figure 5.

3. Methods of Detecting Through-Bond Interaction

Among the many possible MO descriptions of the bonding in 1,4-butanediide $(7)^{2+}$ and in the isoelectronic 1,2-diaminoethane *(8)*, two are outstanding; these are the canonical MOs shown schematically in Figures 3 and 4 and the equivalent MOs. The latter are approximately localized in the bonds or lone pairs of electrons (see below). The two descriptions give the same total energy for the system, but different orbital energies[6][*].

$$^{\ominus}\ddot{C}H_2-CH_2-CH_2-\ddot{C}H_2^{\ominus} \qquad (7)^{2-}$$

$$H_2\ddot{N}-CH_2-CH_2-\ddot{N}H_2 \qquad (8)$$

In the case of ionization (*e.g.* $(8)^+$) or excitation (*e.g.* $(8)^*$) or interaction with another system (X) (*e.g.* $(8)\cdots X$), localized MOs are no longer suitable for their description.

If we wish to "detect" the orbital sequence as expected for the canonical MO description, therefore, we must introduce a perturbation in the manner indicated above. An indication of the correctness of the derived orbital schemes should be obtainable from photoelectron (PE) spectra, ESR spectra, charge transfer spectra, pK_a values, *etc.*

3.1. PE Spectroscopy[10][**]

n-Orbital splitting of 2.13[11] and 1.72 eV[12] is in fact found for the compounds *(1)* and *(4)* respectively; this agrees well with semiempirical[1, 12, 14–16] and *ab-initio* calculations[13]. By analysis of the vibrational fine structure of the first two bands in the PE spectrum of *(1)*, it has been shown[17] that the level corresponding to the first band on ionization belongs to the n_+ orbital, and that of the second band to the n_- orbital. The PE spectrum of *(4)* also showed[18] that the n_+ level is higher than the n_- level. As in the case of the diazines, through-bond interaction effects can also be detected for the diazanaphthalenes[19].

The prediction[20] of a through-bond interaction between the 2p orbitals of α,β-dicarbonyl compounds has also been confirmed by PE spectroscopy[21, 22]. As in the examples considered above, it is found experimentally here again that the n_+ linear combination is above the n_- combination (cf. Fig. 6). Another point that seems interesting is that the splitting $\Delta n = |n_+ - n_-|$ is practically independent of the dihedral angle

[*] The total energy is an observable, whereas the orbital energy is not.

[**] Photoelectron spectroscopy measures transition from the ground state to the ionized state. Measurements of this type therefore only provide information about how the system reacts to the removal of an electron.

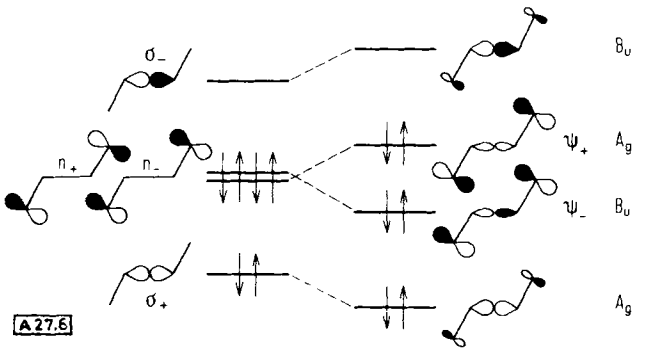

Fig. 6. Schematic representation of through-bond interaction between the linear combinations n_+ and n_- in *trans*-glyoxal (symmetry C_{2h}).

θ of the two carbonyl groups. Thus the splitting is 1.9 eV for biacetyl (θ = 180 °C) and 1.6 eV for camphorquinone (θ = 0°). The through-bond interaction between π orbitals in γ,δ-unsaturated ketones[23] and 1,4-dienes has been demonstrated by many examples[24–27]. In *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene[25] and in hypostrophene (tetracyclo[5.3.0.0^{2,6}.0^{3,10}]-deca-4,8-diene)[26], for example, it leads to reversal of the orbital sequence (A below S) from the through-space interaction[*].

3.2. Electronic Spectroscopy

From what has been said so far it is easy to understand that through-bond interaction can also be detected by electronic spectroscopy. The electronic spectra of γ,δ-unsaturated ketones and amines show the existence of an interaction between the two chromophores when the conformation of the molecule allows an interaction *via* the σ skeleton[28]. The electronic spectra of the diazanaphthalenes[29], of pyrazine[29, 30], and of dimethylpyrazine[30, 31] can be plausibly interpreted by the concept of through-bond interaction. Without this interaction, no splitting would be expected for $\pi^* \leftarrow n_A$ and $\pi^* \leftarrow n_S$ in pyrazine and 1,4-diazanaphthalene, whereas values between 0.2 and 0.5 eV are found. This interpretation of the spectra is supported by *ab-initio*[32] and semiempirical calculations[16, 30, 33, 34].

Similar conclusions can be drawn for the α,β-dicarbonyl compounds. The observed splitting of the two $\pi^* \leftarrow n$ transitions for biacetyl is 1.36 eV[35, 36], and the energy difference between n_S and n_A as found from the PE spectra is 1.9 eV[21][**].

3.3. Other Investigations

One important result of the through-bond interaction concept is the prediction that n_+ is strongly delocalized. This prediction is confirmed by susceptibility measurements on the three diazabenzenes[37]. H—D exchange reactions on pyridine, the diazabenzenes, and the diazanaphthalenes[38], on the other hand, give no indication of a through-bond interaction. This is also true of basicity measurements on 1-azabicyclo[2.2.2]octane and *(1)*[39] and of the diazabenzene-catalyzed hydrolysis of 2,4-dinitrophenyl acetate[40][***].

[*] This orbital sequence could be the reason why the compounds do not undergo intramolecular cyclization on irradiation.

[**] The splitting ΔE of the two $\pi^* \leftarrow n$ transitions as calculated from the ionization potential of biacetyl and an estimation [30] of the Coulomb and exchange integrals by the CNDO/2 method is − 1.6 eV.

[***] The systems investigated are all derived from $(7)^{2-}$ or *(8)*. The perturbation introduced is very slight in comparison with electronic excitation or ionization.

4. Consequences for the Ground State and for Reactivity

4.1. Fragmentation

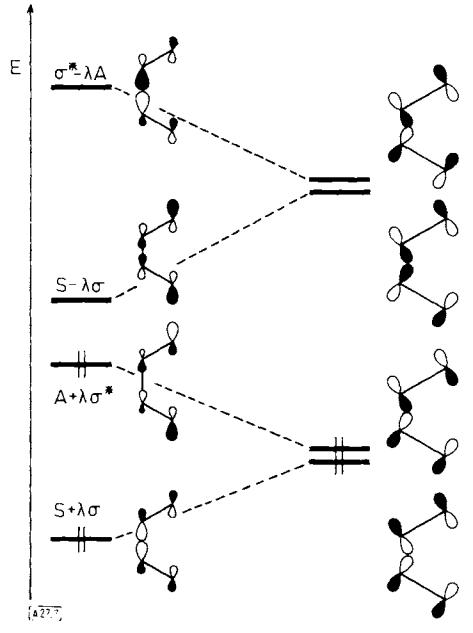
A typical result of the bond weakening predicted as the third conclusion in Section 2 is heterolytic fragmentation, which was studied in detail by *Grob et al.*[41].

$$a\text{–}b\text{–}c\text{–}d\text{–}x \longrightarrow a\text{–}b + c{=}d + x: \qquad (1)$$

An example of this is the fragmentation of γ-amino-halo compounds into olefins and imonium salts.

$$R_2N\text{–}C^3H_2\text{–}C^2H_2\text{–}C^1H_2\text{–}X \longrightarrow R_2\overset{\oplus}{N}{=}CH_2 + CH_2{=}CH_2 + X^{\ominus} \qquad (2)$$

This reaction can proceed either by a concerted mechanism or as a two-step process. In the concerted mechanism the C^2—C^3 and C^1—X bonds are broken simultaneously. In the two-step process the C^1—X bond first heterolyzes, with formation of the cation $R_2\overset{\oplus}{N}$—CH_2—CH_2—$\overset{\oplus}{C}H_2$, which is isoelectronic with *(7)*.



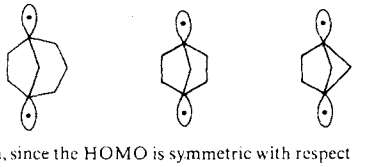


Fig. 7. Correlation diagram for the fragmentation of 1,4-butanediyl *(7)* into two ethylene molecules.

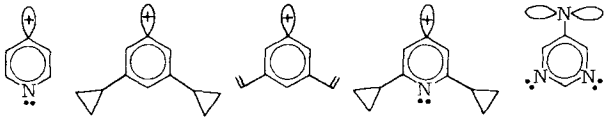
As soon as the through-bond interaction dominates in this cation, the C^2—C^3 bond should be weakened, and the species can undergo fragmentation. A necessary condition[9] for a fragmentation is that the orbital A (HOMO) should be lower than S (LUMO); then and only then is the fragmentation allowed[43] (cf. Fig. 7). The steric condition[41] for this is generally[*] the antiperiplanar arrangement of the lone pair, the C^2—C^3 σ bond, and the unoccupied 2p orbital on C^1.

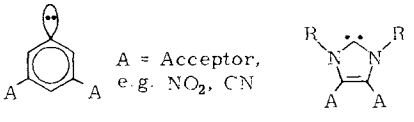


[*] According to an EH calculation [42], the biradicals

should *not* undergo fragmentation, since the HOMO is symmetric with respect to the plane of symmetry. However, the steric condition [41] for a fragmentation is satisfied.

4.2. Possibilities of Stabilization

It follows from the second conclusion in Section 2 that the effect of the through-bond interaction can be used for stabilization. This can be illustrated by predictions on the stabilization of the phenyl cation[44]. According to EH calculations, the aryl cations *(9)*—*(12)*, for example, should be 0.1—0.5 eV more stable than the phenyl cation.



(9) *(10)* *(11)* *(12)* *(13)*

In these compounds an interaction between the positive center (low unoccupied orbital) and the lone pair on the nitrogen (*(9)*, *(12)*), the Walsh orbitals of the three-membered rings (*(10)*, *(12)*), or the π orbitals of the double bonds (*(11)*), which are perpendicular to the plane of the ring, should lead to stabilization.

In 5-pyrimidinylnitrene *(13)*, the singlet state (π^2) should be stabilized in relation to the triplet state by the through-bond interaction between the lone pairs on the ring nitrogen atoms and the empty 2p orbital on the nitrene nitrogen.

Just as a positive charge can be stabilized by donor groups (high occupied orbitals), so acceptor groups (low unoccupied orbitals) can stabilize a carbanion. Examples of this are the *m*-nitrophenyl anion *(14)*[45] and the carbene *(15)*. In the latter compound, the singlet state (σ^2) should be stabilized in relation to the triplet state (σp) by a through-bond interaction.

(14) *(15)*

4.3. Other Examples

An example of the course of a reaction being influenced by through-bond interaction is provided by the photolysis of four-membered ring ketones[46]. In this reaction the light-induced ring expansion to form the isomeric tetrahydro-2-furylidene, which is not observed for homologous cycloalkanones, has been explained by through-bond interaction.

The high stereospecificity of the cycloaddition of enol ethers to tetracyanoethylene *via* 1,4-dipoles[47] is also attributable to the domination of a through-bond interaction in the 1,4-dipole[48].

5. Outlook

The concept of through-bond interaction was recognized six years ago by *Hoffmann et al.*[2a]. Apart from theoretical investigations, which demonstrated the consequences of this new concept for chemical reactions, it has been mainly photoelectron spectroscopy that has shown that through-bond interaction effects can be very considerable. Besides further examples of the existence of a through-bond interaction in formal 1,4-diradicals and 1,4-dipoles, in electronic transitions, and in ionization, further investigations on systems derived from $(7)^{2-}$, but in which the perturbation does not lead to ionization or electronic excitation, appear to be particularly interesting. On the theoretical side, the study of the interactions that were disregarded as a first approximation in the model *(7)* could lead to new results.

I am very grateful to Professor Roald Hoffmann and Professor Edgar Heilbronner, with whom I had the pleasure of working on through-bond interaction effects.

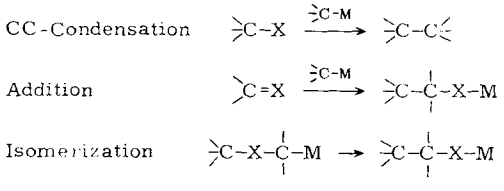
Prescriptions and Ingredients for Controlled CC Bond Formation with Organometallic Reagents

New synthetic methods (5)

By Manfred Schlosser[*]



Merits and drawbacks of known carbon-carbon linking procedures are outlined. Two novel methods are discussed in some detail: the copper-catalyzed alkylation of Grignard reagents and reactions with allylpotassium compounds. Both methods provide a very efficient access to saturated, unsaturated, as well as functionally substituted hydrocarbons and moreover permit an astonishing degree of regio- and stereoselective control of olefin synthesis.

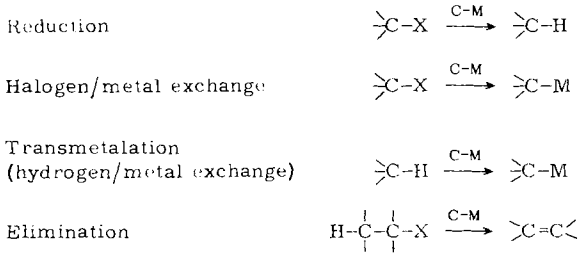
1. Introduction

"The synthesis of most organic molecules can be broken down into the problems of preparing the carbon framework and that of the introduction, modification and (or) removal of various functional groups"[1]. If we accept this approach, then the formation of the carbon skeleton is generally the more demanding part of the task. Fortunately, we can draw on a large repertoire of diverse methods for its accomplishment, though very few are without complications or of universal application. The development of new methods and the improvement of known ones, and the extension of their scope, will continue to tax the ingenuity of the synthetic chemist for a long time to come.

2. Possibilities of CC Bond Formation with Organometallic Reagents

As in the past, organometallic chemistry will continue to play an important role in the further evolution of developments in this field. How can its contribution be defined, and what inherent advantages does it offer? Let us first consider the various types of pertinent reactions. They can be roughly divided into three groups[2, 3]:

Rearrangements offer a most convenient, but insufficiently exploited route for linking two carbon atoms. Numerous syntheses of cyclic[4, 5] and open-chain[6] compounds have utilized this principle.

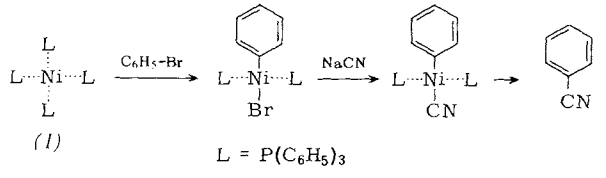


Examples of *additions* of carbanionic species to aldehydes, ketones, and carbon dioxide are too numerous to list. Generally trouble-free, these reactions are nevertheless occasionally accompanied by side reactions, especially reduction of the CO double bond by hydrogenation, particularly when there is massive steric hindrance of the carbonyl group. In contrast, carbon monoxide combines only reluctantly with organo-alkali (and alkaline earth) metals to form a mixture of products[2]; however, its fixation to acetylenes, olefins, or allyl halides can be readily

[*] Prof. Dr. M. Schlosser
Institut de Chimie Organique de l'Université
CH-1005 Lausanne, Rue de la Barre 2 (Switzerland)

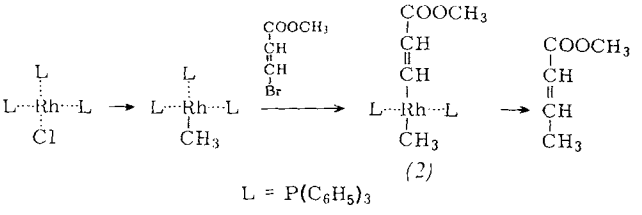
effected with transition element complexes[7]. The most popular and versatile method for the directed formation of CC double bonds, the Wittig reaction[8-9], also belongs to this class of carbonyl additions.

Organometallic additions to CC double and triple bonds that proceed smoothly are less common. A refreshing exception is found in the highly predictable copper-catalyzed additions of organomagnesium compounds to the vinylogous position of an α,β-unsaturated ketone or ester (1,4 additions; cf. ref.[21]), which are of immense preparative value. However, other variants are too readily overshadowed by competitive reactions (*e.g.* metalations), or they continuously recur and thus evolve into polymerizations. These undesirable effects can frequently be avoided by base-catalyzed formation of the organometallic compound *in situ* from a suitable hydrocarbon in the presence of an olefin[10].



The picture is even less clear-cut when we turn to the many methods for CC bond-formation *via condensation reactions*. Based on the analogy of nucleophilic substitution these condensations should take place without difficulty when an organometallic reagent is allowed to react with an alkyl halide (or alkyl *p*-toluenesulfonate). However, the reaction is notoriously prone to go off course. In a radical process the halogen may get lost and be replaced by hydrogen; alternatively, the halogen and the metal in the reactant can exchange places; unless the organometallic compound prefers to exchange metal for hydrogen, that is to metalate an acidic CH bond of the electrophilic substrate; finally, hydrogen and halogen may be lost simultaneously by β-elimination[2,3]:

Attempts to force the desired condensation by employing a stronger reagent are doomed to failure. Any predominance of secondary reactions with Grignard reagents is merely enhanced on use of lithium derivatives and even more so with potassium derivatives, for an increase in the carbanion character of an organometallic species—whether caused by a more electropositive metal or by a solvent with higher solvating power—will invariably promote hydrogen/metal exchange at the expense of other possible reactions[3]. The reagents of choice are therefore organometallic compounds with high nucleophilicity but low basicity. Such properties are available in two cases: either in compounds of transition elements, or in resonance-stabilized alkali metal derivatives. The following two sections contain typical examples illustrating both approaches.

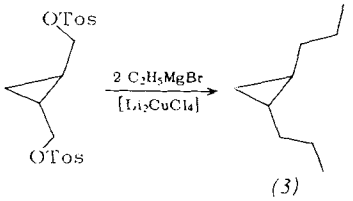


3. Organocopper Reagents

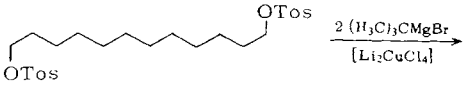
Compounds of transition elements, such as the Ni^0 complex *(1)*[11], resemble the carbenes or, more precisely, carbene precursors (carbenoids *etc.*) in certain respects. Since the weakly bound ligands are easily removed, the central atom displays markedly electrophilic character. On the other hand it also possesses lone pairs in an outer shell[*]. Like carbenes, they can therefore exhibit both electron-donor and electron-acceptor properties, *e.g.* on insertion into carbon-halogen bonds. If a nucleophilic carbon component then also approaches the metal, the unstable intermediate complex can rapidly decompose[12]. Without abandoning contact with the metal, the valences of the two carbon atoms directed toward the central atom glide toward one another until the new CC bond is completely formed. It is thus possible to largely retain the structure[13] and the configuration[14] of the condensation partners.

(1)

In the majority of reaction sequences of this type, however, the nucleophilic component is first fixed to the transition metal (*e.g.* rhodium)[15], and the electrophilic reactant brought into action later. This reversibility of order may point to the transient existence of nonisolable metal complexes (*e.g. (2)*) with two or more organic ligands.

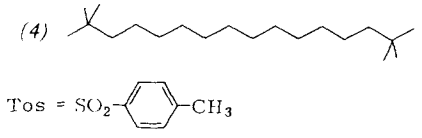


(2)

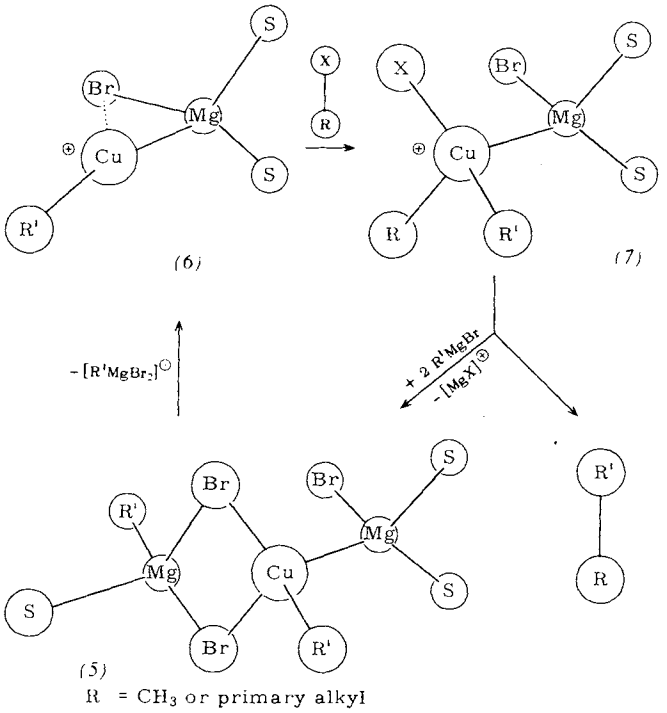


Organic synthesis readily exploits the coordination properties of copper[16]. Important fields of application include aryl-aryl (alkenyl, alkynyl, cyanide) bond formation (Ullmann reaction[17]), oxidative alkenyl-alkenyl bond formation[18-20], the vinylogous addition of Grignard compounds to α,β-unsaturated ketones[21,22], as well as alkyl-alkyl (alkenyl) linkage using lithium organocuprates[23]. The last-mentioned group of CC linkages was considerably simplified when Grignard reagents in the presence of catalytic amounts of a copper salt were found to be equivalent to lithium diorganocuprates[20] (or lithium haloorganocuprates[16] or lithium alkoxyorganocuprates[24]). A subsequent modification—"incubation" of the copper catalyst and reaction with *p*-toluenesulfonates instead of alkyl iodides—has further improved the method and gives excellent yields even in twofold reactions (examples *(3)* and *(4)*; 79% and 99% respectively)[25].

It is suggested that copper(I) becomes part of a mixed association compound *(5)*. A reactive species *(6)* containing formally divalent copper could separate and undergo insertion between carbon and the heteroelement of the electrophilic reactant (alkyl iodide or *p*-toluenesulfonate). The intermediate complex *(7)* then breaks down, with liberation of a hydrocarbon and regeneration of the mixed association compound *(5)*.

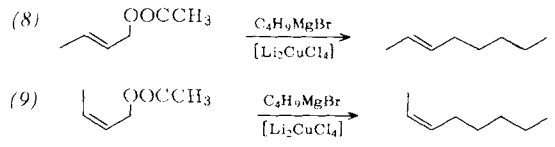


[*] Generally speaking, the 3d orbitals of an Ni^0 complex—occupied by nonbonding electrons—project into the same peripheral outer regions as its $4s4p^3$ hybrid orbitals, which cause the interaction with the ligands. This follows from the greater eccentricity of the d orbitals and is confirmed by their involvement in resonance operations ("back donation"). Ligand loss, which may generate hypovalent complexes—*e.g.* L_2Ni^0—makes the d electrons even more readily accessible.



(3)

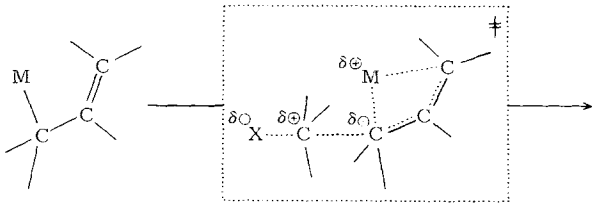
(4)



This mechanism[25,26] explains why copper-catalyzed CC bond formation is unsuccessful with *secondary* and especially with *tertiary* halides or *p*-toluenesulfonates RX. Steric hindrance makes the insertion step more difficult or suppresses it entirely. On the other hand, *p*-toluenesulfonates should be superior to alkyl iodides since they envelop the copper atom by chelation and thus facilitate the insertion. In fact, even acetoxy groups, insofar as they are "mobile" when linked

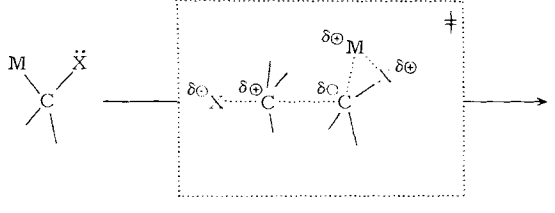
R = CH_3 or primary alkyl
R' = Alkyl, aryl etc.
X = OTos, I
S = Solvent (diethyl ether, tetrahydrofuran)

in the allyl position, undergo the copper-catalyzed displacement reaction, apparently because they also exert a chelating action. The original structure and configuration of the substrate are retained on incorporation into the new olefin formed by reaction of a primary allyl acetate (*e.g. (8)* or *(9)*; 88% and 50% respectively)[25].



Secondary and tertiary allyl acetates, on the other hand, behave differently—no doubt as a result of greater steric hindrance. Reaction with Grignard reagents in the presence of a copper

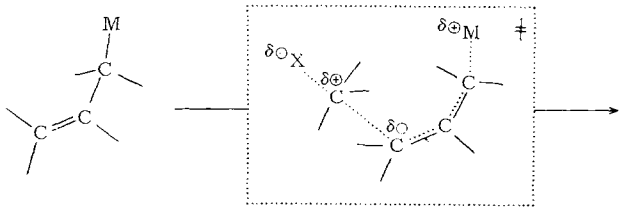
catalyst[26] and with lithium diorganocuprates[27,28] results in substitution in the vinylogous position accompanied by a shift of the double bond.



4. Allyl-Alkali Metal Reagents

As long as transition metals were involved the organometallic reactivity was largely shifted towards the metal. The central atom acts as a template to which the reactants are fixed, paves the way for bond formation and eventually awaits a new reaction cycle. Alkali metals and alkaline earth metals may frequently also intervene in the reaction and leave their individual imprint upon the course[3]. However, if they are derivatives of the allyl, propargyl, or benzyl type—in short, if they occupy a resonance-stabilizable position—they often play no more than a passive role. Acting as an auxiliary reaction center the π-bonding system can then involve the metal in the transition state *(10)* and "distract" it, and thereby endow the carbon atom initially carrying the metal with an almost undiminished nucleophilic reactivity.

(10)



Metalated ethers[29] and thioethers (transition state *(11)*), and especially thioacetals[30-32] as well as ylides (internal carbanion salts!) and amides (free electron pair!) may well owe their unusually high nucleophilicity to this type of exposure of the anionic reaction center.

(11)

For organometallic compounds of the allyl, propargyl, and benzyl type there is of course a second possibility. They can attack the electrophilic reactant with the vinylogous end of the unsaturated system (the γ-position) and continuously replenish the electron density "consumed" from the organometallic bond (transition state *(12)*) during formation of the new CC bond.

It appears reasonable that allylmagnesium and allyllithium compounds should prefer vinylogous attack (S_E2'; *(12)*) to direct substitution (S_E2; *(10)*) since on the one hand small metal atoms hardly "feel" the presence of the π-system as

(12)

long as they are in the proximity of their original position, and on the other hand, direct substitution needs more activation in the initial stages, as cleavage of the CM bond considerably anticipates the formation of a new CC bond (or, in other words, (10) is "less concerted" than (12)). In contrast, allylpotassium compounds should tend rather toward direct substitution on account of their larger and more weakly bound metal atom.

Fortunately, efficient methods exist for the preparation of 2-alken-1-yllithium and -potassium compounds[33, 34], making them readily accessible for systematic investigations.

In the presence of potassium *tert*-butoxide, *n*-butyllithium readily metalates propene at −45 C. Apart from allylpotassium (63 %), the reaction mixture—a pale yellow suspension in hexane—also contains lithium *tert*-butoxide; however, the latter is soluble in benzene or toluene and can thus be removed if desired. The potassium can further be exchanged by a less electropositive metal[34].

Aliphatic, olefinic, or heterofunctionally substituted derivatives of propene (especially substrates of type (13)—(15)) raise new problems: where, and how fast, does hydrogen/metal exchange take place, at which end of the allylic system does the resulting organometallic compound combine with an electrophilic reagent, and what is the configuration of the product?

X–CH=CH–CH$_3$	CH_2=CX–CH_3	CH_2=CH–CH_2X
(13) [(Z) or (E)]	(14)	(15)

4.1. Reactivity

Substituents X subject to p- or d-resonance and able to stabilize carbanions and their organometallic "derivatives" expectedly accelerate hydrogen/metal exchange in the allylic position. Conversely, electron-donating substituents such as alkyl groups, LiO, LiS, and frequently also alkoxy groups, reduce the rate of metalation. Table 1 summarizes these findings.

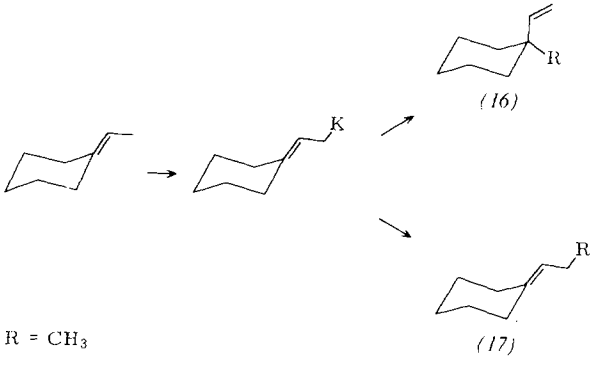


Table 1. Metalation tendency of substrates (13)–(15) according to type of substituent X [a].

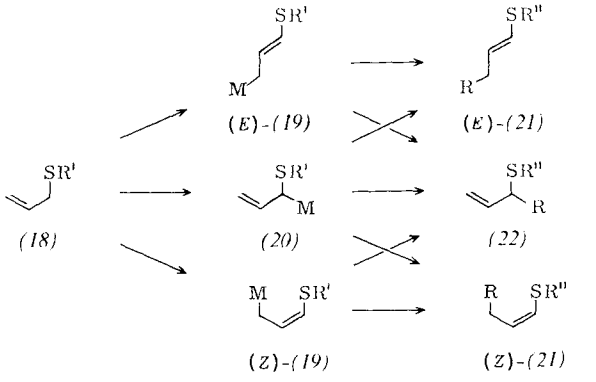
X	(13)	(14)	(15)
CH_3 [b]			− −
CH=CH_2 [c]	[d]	[d]	+ +
OR		[e]	±
OLi	[f]	[f]	− −
SR	[e]	[e]	+ +
SLi	[e]	[e]	±

[a] Explanation: Metalation compared to propene:
+ + much faster
+ faster
± unchanged
− slower
− − much slower.
[b] Or another alkyl group.
[c] Or C_6H_5.
[d] Not observable, due to rapid polymerization.
[e] Not yet examined.
[f] The substrates are enolates; experiments are still in progress.

4.2. Regioselectivity



Experience has shown that the preferred bond position selected by the metal is a primary rather than a secondary or, even worse a tertiary carbon atom. Nevertheless, the action of an electrophilic reactant can result in the formation of a more strongly branched product since—as mentioned earlier—attack at the vinylogous position accompanied by a double bond shift proceeds much more readily. While Grignard reagents predominantly or exclusively undergo this vinylog *i. e.* γ-substitution (S_E2'), the behavior of organopotassium compounds is governed by the solvent: in a nonpolar medium (light petroleum) the branched product is formed in considerable amounts (*e. g.* (16); up to 20 %), in tetrahydrofuran or even more basic solvents (tetraglyme, hexamethylphosphoric triamide) the predominant reaction definitely takes place directly at the organometallic bond (S_E2; leading *e. g.*, almost exclusively to (17))[35][*].

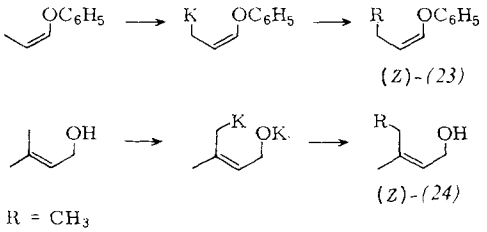
(16)

R = CH_3 (17)

It is frequently more difficult to decide which "metalotrope" ("metalomer") predominates in a tautomeric equilibrium. Thus, in the metalation of allylsulfur compounds (18) (*e. g.* allyl phenyl sulfide (18a)) there is only indirect evidence for the assumption that intermediates (20), in which the metal is located on the hetero-substituted carbon, are formed predominantly. (The alternative possibility, a preferred location of the metal at the other end of the allylic system—metalomers (Z)-

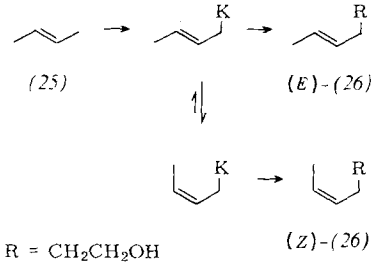
(a): R = CH_3; R' = R'' = C_6H_5; M = K
(b): R = $CH_2CH{=}CH_2$; R' = Li; R'' = $CH_2CH{=}CH_2$; M = Li

[*] The fewer bulky alkyl substituents there are hindering access to the vinylogous position, the more effectively γ attack can compete with direct metal exchange (at the α position). In the case of unbranched alkenylpotassium compounds, the two substitution mechanisms are almost equally favored—at least in nonpolar reaction media (cf. Section 4.3). Extending this argument, it is estimated that allylpotassium itself should accept the electrophilic reactant to an overwhelming extent (>85:15) at the metal-free end of the molecule, thereby undergoing a double-bond shift.



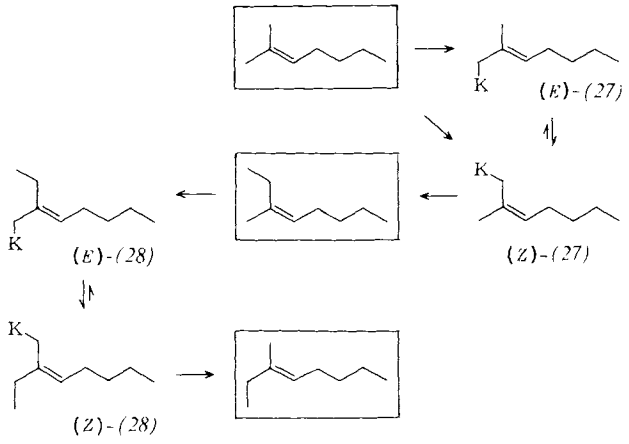
and (*E*)-(*19*)—cannot however be entirely ruled out at this time).

By varying the solvent it is possible to modify the proportions of γ- and α-substituted secondary products (straight-chain or branched derivatives (*21a*) and (*21b*)) within wide limits[36].



4.3. Stereoselectivity

2-Propene-1-thiolates (*e.g.* (*18*), R′ = Li) can also be metalated with *n*-butyllithium (tetramethylethylenediamine is superior to potassium *tert*-butoxide as the "activator" in this particular case). Although the action of allyl bromide on the organometallic intermediate again yields both γ- and α-substituted products, the thioenol-ether component ((*21b*); 42%) now exists exclusively in the (Z)-configuration[36].



Other substrates also show a marked preference for a particular configuration. Thus, (*Z*)-1-propenyl phenyl ether and 3-methyl-2-buten-1-ol (prenol) are readily converted into isomerically pure homologs (*Z*)-(*23*) (84%) and (*Z*)-(*24*) (7%, accompanied by considerable K_2O elimination to isoprene)[36].

Simple alkenylpotassium compounds lacking any functional groups surprisingly also follow this "*cis*-trend". Whether, and to what extent, this stereochemical peculiarity manifests itself, however, largely depends on the reaction conditions. For short reaction times it is possible to conserve the original configuration of the olefin even after metalation and to "propagate" it. Thus (*E*)-2-butene (*25*) is readily enlarged to (*E*)-4-hexen-1-ol ((*E*)-(*26*); 50%)[37]. Over a period of a few hours, however, the butenylpotassium is almost completely converted from the (*E*)-configuration into its (*Z*) torsional isomer, from which (*Z*)-(*26*) (78%) is readily obtained. A carbon atom carrying a metal thus obviously seeks the proximity of alkyl groups, and these therefore change over to the inner side of the alkenyl system in the course of metalotropy and conformational motion[37].

As a result of this behavior pure (*Z*)-3-methyl-3-octene (45%) may be prepared from 2-methyl-2-heptene and can subsequently be entirely converted into its (*E*)-isomer (60%); hydrogen/metal exchange in the starting material leads to an isomeric mixture of the organometallic compound [(*Z*)- and (*E*)-(*27*)], which exclusively affords the (*Z*)-form after a while. Renewed metalation of the homologous hydrocarbon produced by the action of methyl iodide yields first the alkenylpotassium compound (*E*)-(*28*); this is then isomerized to (*Z*)-(*28*) and liberates (*E*)-3-methyl-3-octene on protolysis[35, 37].

The stereoselectivity attainable by adjusting the equilibrium is approximately 1000:1 in both cases [(*Z*)-(*27*) ⇌ (*E*)-(*27*) and (*Z*)-(*28*) ⇌ (*E*)-(*28*)].

The many cooks who did not spoil the broth are V. David, Dr. G. Fouquet, E. Hammer, Dr. J. Hartmann, Dr. R. Muthukrishnan, and P. Schneider. The ingredients were mainly provided by the Schweizerischer Nationalfonds zur Förderung wissenschaftlicher Forschung, Bern.

Biochemistry of the Peroxisome in the Liver Cell

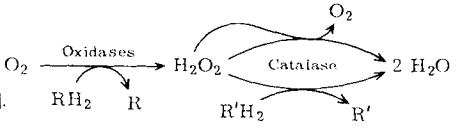
By Helmut Sies[*]

The marker enzyme of the peroxisome—a phylogenetically old yet only recently discovered cell organelle—is catalase, a hemoprotein which decomposes hydrogen peroxide catalatically as well as peroxidatically. In the peroxisomes, catalase is associated with H_2O_2-producing oxidases and other enzymes. Also in parenchymal cells such as liver and kidney cells part of the reduction of oxygen occurs *via* formation of H_2O_2. A central role in peroxisomal H_2O_2-metabolism is played by the active intermediate, catalase-Fe^{3+}-H_2O_2 (Compound I), which is distinguished from free catalase by specific absorption bands. Organ photometry on intact hemoglobin-free perfused rat liver in order to measure Compound I selectively provides a direct insight into the dynamics of the H_2O_2 metabolism which takes place in the range of nanomolar concentrations. Endogenously, 1 g of liver forms approximately 50 nmol of H_2O_2 per min. The turnover number, which in the steady state is $<10\,min^{-1}$ in the cell as compared to $>10^8\,min^{-1}$ for the isolated enzyme with an excess of substrate, can be increased to approximately $10^2\,min^{-1}$ by intracellular stimulation of the H_2O_2 production (*e.g.* by glycolate or urate). The peroxidatic oxidation of hydrogen donors (*e.g.* methanol and ethanol), favored relative to the catalase pathway at low turnover numbers, is of importance in normal metabolism and in pathological conditions.

1. Introduction

As follows from Table 1, the subject of this report has a history going back approximately 150 years.

Research on the biological and chemical aspects of catalase and of hydrogen peroxide metabolism strongly revived in recent years. It received an essential impetus from cell biology. In 1954 *Rhodin* observed electron-optically cytoplasmic inclusions, "microbodies"[1], in the renal tubule cells of the mouse, which also occur in the liver cells[2] and in many other cell types of aerobic organisms. Little was known about the biochemical function of these cell organelles; in the beginning they were regarded as precursors of the mitochondria or as forms of lysosomes. As revealed in studies on homogenates and cell fractions, some oxidases as well as catalase are "particulate"[3-6]; however, they could not be related to the mitochondria, microsomes, or lysosomes. From the behavior of these enzyme activities during the isopyknic density-gradient centrifugation of cell fractions, and from morphological studies, *de Duve* and his co-workers concluded that these were associated with the "microbodies"[7-12]. The presence of H_2O_2-producing oxidases together with H_2O_2-decomposing catalase led to the concept of these cell organelles acting as a functional unit in H_2O_2 metabolism, "peroxisomes"[11,12].



While at the beginning of this century interest in research on the nature of cell respiration was focused on the hemoprotein catalase, it became almost forgotten after the discovery of the "Atmungsferment" cytochrome oxidase. Only in the last few years has it become clear that catalase plays an important part in its domain of biological oxidation, the key position being occupied by the active intermediate catalase-Fe^{3+}-H_2O_2 (Compound I), discovered by *Chance* in 1947[13] (Scheme 1a and 1b).

The function of the peroxisome in intracellular peroxidatic and catalatic reactions can only be partially understood in studies with isolated peroxisomes; rather, the system must be investigated in intact cells or organs. Spectrophotometry of intact organs, developed in recent years, affords a direct

insight into cellular metabolism. The possibilities that organ photometry offers for research on the dynamics of intracellular compartmented processes can be demonstrated by the example of catalase Compound I in isolated perfused rat liver.

In spite of the efforts of many research groups, the manifold functions of the peroxisomes in animal cells are at present incompletely understood (cf. reviews on the cell biology of peroxisomes[12, 14–17], and on the enzymology of catalase[18–20]).

2. The Peroxisome

The peroxisome consists of a matrix surrounded by a unit membrane, and it contains a central core region called the crystalloid (Fig. 1).

Rat liver cells contain approximately 350—400 of these organelles. Table 2 gives a list of enzymes in rat liver peroxisomes, from which it follows that only about half of the peroxisomal protein is accounted for by the known enzyme activities. The nature of the remaining proteins is still unknown. Peroxisomes can be separated from other cell organelles by isopyknic density gradient centrifugation. In Figure 2 this is demonstrated by the localization of the activities of the marker enzymes of the peroxisomes, the mitochondria, microsomes, and lysosomes in the density gradient.

Table 2. Enzyme activities [a] found in rat liver peroxisomes (after [24–28]).

EC number	Enzyme (trivial name)	Fraction of peroxisomal protein [25] [%]
1.1.1.8	Glycerol-3-phosphate dehydrogenase	n. d. [b]
1.1.1.26	Glyoxylate reductase [NAD]	n. d.
1.1.1.29	Glycerate dehydrogenase [NAD]	n. d.
1.1.1.42	Isocitrate dehydrogenase [NADP]	≤25
1.1.1.–	Glyoxylate reductase [NADP]	n. d.
1.1.1.–	Glycerate dehydrogenase [NADP]	n. d.
1.1.3.1	Glycolate oxidase	n. d.
1.1.3.α	L-α-Hydroxy acid oxidase	≤ 3
1.4.3.3	D-Amino acid oxidase	≤ 2
1.7.3.3	Urate oxidase	≤10
1.11.1.6	Catalase	≤16
2.3.1.7	Carnitine acetyltransferase	n. d.

[b] n. d. = not determined.

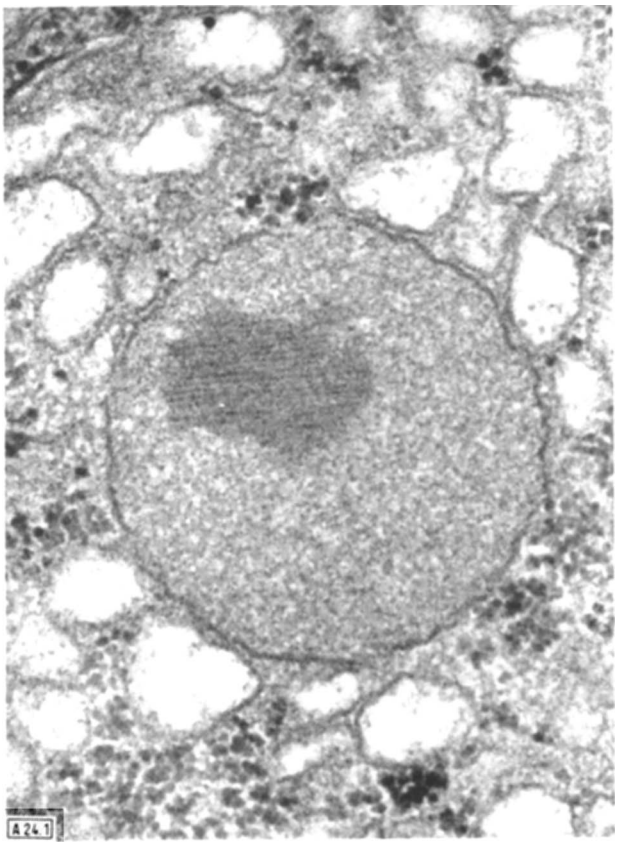

Fig. 1. Peroxisome from rat liver. The central region shows the urate oxidase present in the form of tubuli [21]. Magnification 82000 ×. The electron micrograph was obtained by courtesy of Prof. *F. Miller*.

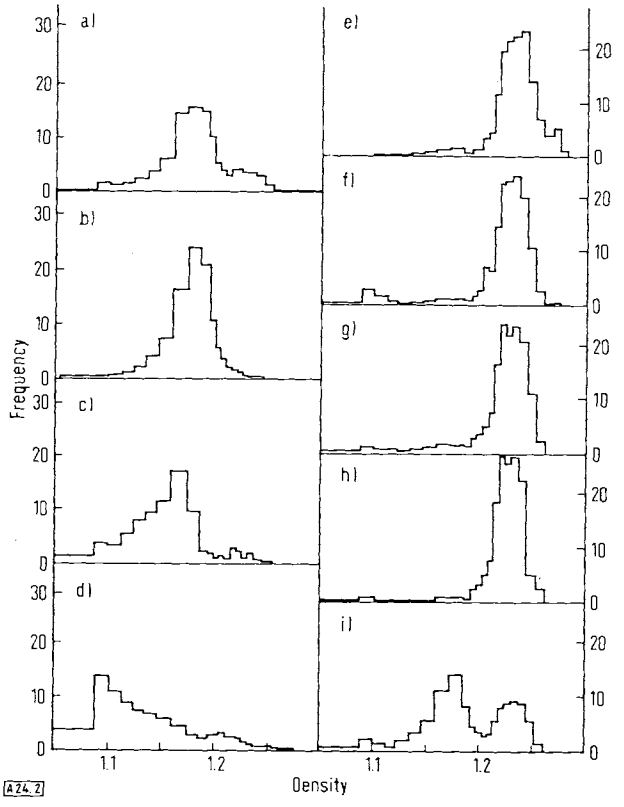

Fig. 2. Equilibrium density distribution of marker enzyme activities in a λ-fraction [10] from rat liver in a sucrose gradient. a) Total protein; below: marker enzymes for b) mitochondria (cytochrome oxidase), c) microsomes (glucose-6-phosphatase), and d) lysosomes (acid phosphatase); right: peroxisome enzymes: e) urate oxidase, f) catalase, g) D-amino acid oxidase, h) L-α-hydroxy acid oxidase, i) isocitrate dehydrogenase (at the density of 1.23 to 1.24). The $NADP^+$-dependent isocitrate dehydrogenase has a bimodal distribution. After treatment of the rat with Triton W-1339 [22] the lysosomes have a particularly low density (from [23]).

With respect to the functional morphology of the peroxisome, it may be mentioned that the organelle is freely permeable to low-molecular-weight solutes (zero osmotic space). Little

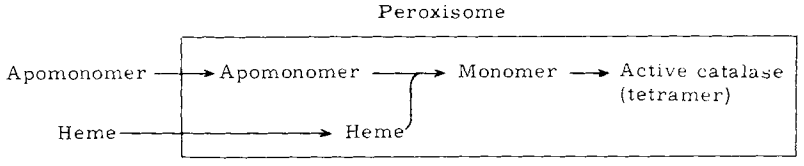

Table 3. Cell biology and cell chemistry of rat liver organelles with oxygen-activating systems.

Parameter	Peroxisomes	Mitochondria	Microsomes	Ref.
Volume fraction in the liver [%]	1.16	18.1	12.8	[30]
Number [ml^{-1}]	62×10^9	280×10^9	—	[30]
Equilibrium density in sucrose gradient [g/ml]	1.23	1.18

Inducibility of components	Hypolipidemic substances [a] salicylates	Thyroxine	Barbiturates, alicyclic hydrocarbons	
Marker enzyme	Catalase	Cytochrome oxidase, succinate dehydrogenase	Glucose 6-phosphatase, cytochrome P-450	
Half-life	1.5—2 d	Proteins of the inner membrane 12—13 d, those of the outer membrane 4 d	Proteins in rough and smooth reticulum 4 d	[32—36]

[a] Example: Clofibrate (ethyl 2-(*p*-chlorophenoxy)isobutyrate).

is known about specific permeability properties of the peroxisomal membrane, which resembles the microsomal membrane in its phospholipid composition[29]. Some properties of peroxisomes are compared in Table 3 with the properties of two other cell organelles with oxygen-activating systems, the mitochondria and the endoplasmic reticulum (microsomes).

mental evidence[56] (cf. also [57,58]). The apomonomer, with a half-life of 14 min is brought into the peroxisome as such in a still unknown manner and there receives the heme group. The apomonomer and the monomer amount respectively to 1.6% and 0.5% of the total amount of catalase; their half-life is less than 1 h (Scheme 2).

Scheme 2. Biosynthesis of catalase (according to [56]).

2.1. Cytochemistry of Peroxisomal Catalase

Cytochemically, catalase is regarded as the marker enzyme of peroxisomes[37], on the basis of the 3,3',4,4'-biphenyltetramine (diaminobenzidine) oxidase activity of catalase[38-41]. This peroxidatic activity of catalase is only observed after fixation of the enzyme, *e. g.* with glutaraldehyde. This applies both to catalase within the peroxisome in the cell[42] and to the isolated enzyme[43], and probably depends on a conformational change of the protein. This is also supported by the increase in reactivity for peroxidatic substrates if the enzyme has been subjected to trypsin degradation under mild conditions or to denaturation by alkali[44].

The question whether an appreciable amount of catalase exists extraperoxisomally *in vivo*[45] and whether this is demonstrable cytochemically[41], cannot yet be answered due to methodological reasons.

2.2. Turnover and Biogenesis of the Peroxisome

The organelle is subject to relatively rapid turnover *in toto*; its measured half-life is approximately 1.5—2 days[32,33].

The stationary content of peroxisomes in the liver cell depends on numerous hormonal, nutritional, and pharmacological influences (cf.[15,46]). For example, ethyl 2-(*p*-chlorophenoxy)-isobutyrate (Clofibrate) causes an increase in the number of peroxisomes[47], which increases the proportion of peroxisomes in the total volume of the liver cell from about 2% to about 17%[48]. This increase is related to an increase in the content of antigen reacting with anticatalase serum[49], *i. e.* the amount of catalase is also increased. The activity of the peroxisomal oxidases given in Table 2 remains unchanged[50], while the activity of the glycerol-3-phosphate dehydrogenase also increases[51]. Similar effects are observed *e. g.* with acetylsalicylic acid[52]. The increase in the number of peroxisomes by Clofibrate does not depend on catalase synthesis, since it also occurs when the formation of catalase is inhibited by allylisopropylacetamide[53].

The biogenesis of the organelle is still in dispute. Close morphological and biochemical relationships to the endoplasmic reticulum have been described repeatedly[54,55]. Investigations on catalase biosynthesis are of special importance in this context. The hypothesis that catalase is first formed essentially within the peroxisomes from extraperoxisomally synthesized precursors has been supported by experi-

Histochemical attempts to establish the passage of active catalase through the free cytoplasm prior to incorporation into the peroxisome[41] led to equivocal results owing to methodological problems[59,60]. In addition, the question whether catalase protein is synthesized *in vivo* on free and/or membrane-bound polysomes, has not been answered unambiguously[61-64]. *Redman et al.*[64] did not find catalase in the rough endoplasmic reticulum. Export proteins such as albumin and intracellular proteins such as catalase could therefore be synthesized at separate sites. *In vitro*, however, membrane-bound as well as free ribosomes can incorporate ^{14}C-leucine into enzymatically active catalase[62,65].

3. Enzymology of Catalase

Catalase is a tetrameric enzyme with four probably identical subunits and four heme groups; the iron in the heme is trivalent. In contrast to hemoglobin, there are no indications of cooperativity between the subunits. Its molecular weight is about 240000 dalton. The methods of its isolation and crystallization, as well as its structural properties and the amino-acid composition, have been reviewed by *Deisseroth* and *Dounce*[20]. The catalatic action of catalase [equations (1a) and (1b), cf. Section 3.1] was one of the first enzymatic functions discovered. At the discovery of hydrogen peroxide in 1818 *Thénard* already observed that this substance is decomposed in the presence of animal tissues with evolution of oxygen[66], a reaction which also occurs on platinum surfaces. Catalase was at the center of intensive discussions concerning the nature of enzyme action[68,69], in particular the heavy metal catalysis in enzymes[70-73], and after its crystallization[74] served as the object of numerous studies[18-20,75,76] on the biocatalysis by hemoproteins.

3.1. Catalase Complexes

Using rapid mixing methods, *Chance*[13] discovered spectrophotometrically an active intermediate, "Compound I", in the reaction of catalase with H_2O_2. Compound I is characterized by a decreased absorbance at 405 nm and an increased absorbance at 665 nm (Fig. 3). On the addition of alcohols to Compound I the absorbance again increases rapidly, *i. e.* free catalase is regenerated through the peroxidatic reaction discovered by *Keilin* and *Hartree*[77,78] (eqs. (1a) and (1c)):

$$\text{Catalase-Fe}^{3+} + H_2O_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{Catalase-Fe}^{3+}\text{-}H_2O_2 \quad (1a)$$
(free catalase; e) (x) (Compound I; p)

$$\text{Catalase-Fe}^{3+}\text{-}H_2O_2 + H_2O_2 \xrightarrow{k_4'} \text{Catalase-Fe}^{3+} + 2H_2O + O_2 \quad (1b)$$

$$\text{Catalase-Fe}^{3+}\text{-}H_2O_2 + C_2H_5OH \xrightarrow{k_4} \text{Catalase-Fe}^{3+} + 2H_2O + CH_3CHO \quad (1c)$$
(hydrogen donor; a)

e, x, p, a, see Section 3.2.

The notation "catalase-Fe^{3+}-H_2O_2" for Compound I should indicate that the heme is occupied by H_2O_2 ("heme occupancy"). It is noteworthy that one mole of catalase does not simultaneously bind four moles of H_2O_2—*i.e.* one molecule per heme—but only approximately 1 to 1.6 moles of H_2O_2[79]. The other heme groups remain free. However, if an alkyl hydroperoxide, *e. g.* methyl or ethyl hydroperoxide, is used instead of H_2O_2, all four catalase subunits can be transformed into Compound I ([80], cf. [81]).

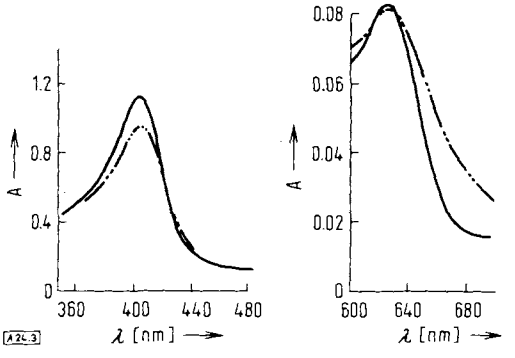

Fig. 3. Absorption spectra of purified catalase (----) from rat liver (catalase heme 9.3 μmol/l). Compound I (–·–·–) was obtained with H_2O_2 (23.5 μmol^{-1} min^{-1}) from the glucose oxidase reaction (after [82]).

The chemical structure of Compound I is still unknown[20]. Recent experiments with peracids indicate a reaction of the type:

$$\text{Enzyme} + H_2O_2 \rightarrow \text{Enzyme} = O + H_2O$$

which is probably followed by peroxidase[83–86].

The other catalase complexes (Compound II and Compound III) are catalatically inactive. Compound II has a low peroxidatic activity with respect to phenols. Indications of the occurrence of these compounds in normal intact liver are lacking[87], and therefore the compounds will not be discussed further here. Compound II is formed by the reduction of Compound I with H_2O_2, with phenols, or with ascorbate[88]. The relationships between Compounds I, II, and III and the donors have been reviewed by *Nicholls* and *Schonbaum*[18].

In the catalase-HCN complex[89, 90], which has a dissociation constant of 10^{-6} to 10^{-5} mol/l, each of the four heme groups carries one HCN molecule. The complex is characterized spectrophotometrically, *e. g.* by a minimum of 624 nm as compared to free catalase.

In the reaction between azide and Compound I the iron is reduced and catalase-Fe^{2+}-NO is formed[91–93].

A covalent complex is produced in an irreversible reaction between 3-amino-1,2,4-triazole[94, 95] and catalase in which a histidine group is involved[96]. The heme is then no longer[97] or almost not[98] capable of binding peroxides or ligands such as HCN.

3.2. Steady State Kinetics of Catalase

The kinetic constants k_1, k_4, and k_4' of eqs. (1a)—(1c) were determined for the isolated enzyme (Table 4). For the kinetic analysis of the steady state of the catalase system it has been found, using *Chance*'s nomenclature[79, 103]:

Table 4. Kinetic constants of catalase [see eqs. (1a)—(1c)]. Some of the values were not measured directly but were calculated from indirect measurements. They indicate the order of magnitude of the values at 20—22 °C. More recent calculations [102] lead to slightly lower values of k_1 and k_4'.

Constant		Preparation	Ref.
k_1	1.7×10^7 l mol^{-1} s^{-1}	Rat liver	[79]
k_4'	2.6×10^7 l mol^{-1} s^{-1}	Rat liver	[79, 99] [a]
k_4	$(0.2—1.0) \times 10^3$ l mol^{-1} s^{-1}	Horse erythrocytes	[13, 79, 100] [b]
k_2	$(0—7.5) \times 10^{-3}$ s^{-1}	*M. lysodeikticus*	[101, 86]

[a] Calcd. by eq. (5a) with $p_M/e = 0.4$.
[b] For ethanol and methanol.

$$\frac{dp}{dt} = k_1 x(e-p) - k_4' x p - (k_2 + k_4 a)p \quad (2)$$

$$\frac{dx}{dt} = \frac{dx_n}{dt} - k_1 x(e-p) - k_4' x p + k_2 p \quad (3)$$

$$\frac{da}{dt} = -k_4 a p \quad (4)$$

e = concentration of the total catalase heme
p = concentration of Compound I
x = H_2O_2 concentration
dx_n/dt = steady state rate of H_2O_2 formation
a = hydrogen donor concentration.

In the case of a steady state of Compound I ($dp/dt = 0$) and the rate of H_2O_2 formation (dx_n/dt = const.), and for the condition $k_2 = 0$, the result for the fraction of the total catalase heme e existing as Compound I (p) (*i.e.* for the heme occupancy) is:

$$\frac{p_m}{e} = \left(1 + \frac{k_4'}{k_1} + \frac{k_4 a_0}{k_1 x_m}\right)^{-1} \quad (5)$$

where the subscript m denotes the steady state. As $x_m \rightarrow \infty$, or $a_0 = 0$ and $x_m \neq 0$, $p_m \rightarrow p_M$; thus

$$\frac{p_M}{e} = \left(1 + \frac{k_4'}{k_1}\right)^{-1} \quad (5a)$$

Equation (5a) demonstrates a simple relationship between the maximal heme occupancy p_M/e existing at the maximal rate of H_2O_2 formation and the second-order rate constants for the formation and catalatic degradation of Compound I.

Another useful relationship describes the catalase reaction for the condition that the hydrogen donor concentration a

is chosen so that $p_m = p_M/2$. In the steady state the donor concentration for half-maximal heme occupancy is directly proportional to the steady state rate of H_2O_2 formation dx_n/dt and inversely proportional to the total heme concentration e[103]:

$$a_{p_m = p_M/2} = \left(\frac{\left(3\frac{k'_4}{k_1} + 1\right)k_4}{2\left(\frac{k'_4}{k_1} + 1\right)} \right)^2 \times \frac{1}{e}\frac{dx_n}{dt} \qquad (6)$$

$\frac{1}{e}\frac{dx_n}{dt}$ = steady state turnover number

From eq. (6) it follows that the catalase system does not have a "Michaelis constant" for H_2O_2 or for the hydrogen donor a. Rather, the ratio of the H_2O_2-formation rate and the concentration of the catalase heme (steady state turnover number) plays a role in the steady state concentration of compound I and hence in the donor concentration required for half-maximal decomposition of Complex I. As will be shown below, these relationships are important for the evaluation of the catalatic and peroxidatic reactions in biological systems.

In order to illustrate this point, two examples of experiments with isolated rat liver catalase are given. Figure 4 shows how the steady state heme occupancy p_m/e depends on the steady state turnover number. Both the H_2O_2 formation rate

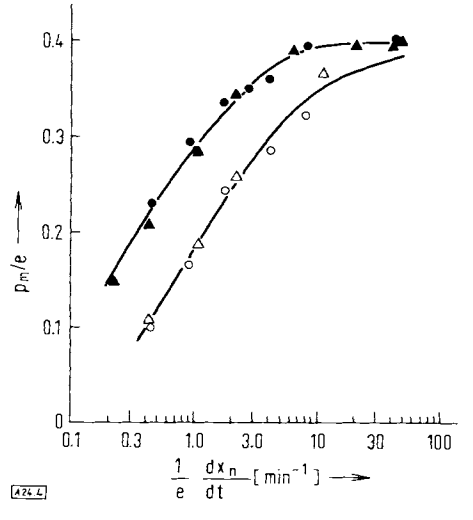

Fig. 4. Dependence of steady state heme occupancy of catalase (p_m/e) on the steady state turnover number (H_2O_2 formation rate/catalase heme concentration), measured with isolated rat liver catalase. The H_2O_2-formation rate (●, ○) was varied from 0.3 to 100 μmol l^{-1} min^{-1} and the catalase heme concentration (▲, △) from 0.1 to 12 μmol/l. Stimulation of the peroxidatic pathway by addition of ethanol (0.1 mmol/l) lowers the steady state heme occupancy (right-hand curve, open symbols). After [82].

(by varying the glucose plus glucose oxidase system) and the catalase heme concentration are varied. As expected, the curve shifts to the right when the peroxidatic pathway competes (by the addition of ethanol).

Figure 5 demonstrates how the partition into peroxidatic and catalatic reactions depends on the rate of H_2O_2 formation and on the concentration of hydrogen donor, in this case ethanol. An exclusively peroxidatic reaction can only be achieved at extremely high donor concentrations and at low turnover numbers[104, 105].

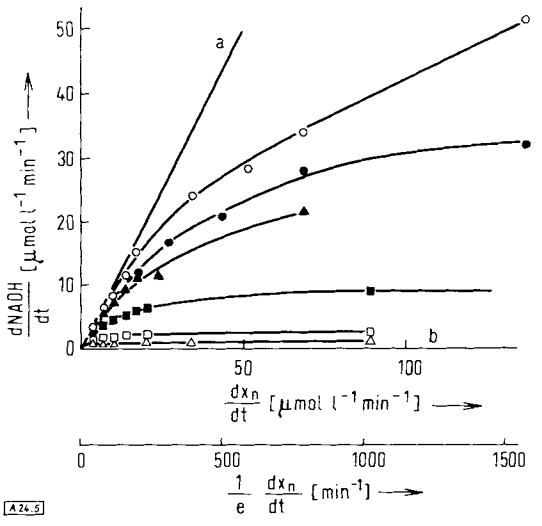

Fig. 5. Distribution of H_2O_2 decomposition between "peroxidatic" and "catalatic" pathways; a, 100% "peroxidatic"; b, 100% "catalatic" reaction. The oxidation rate of ethanol (given as the rate of formation of NADH) is illustrated graphically at several steady state H_2O_2 formation rates dx_n/dt for the following ethanol concentrations: ○, 100; ●, 50; ▲, 25; ■, 5; □, 1; △, 0.33 mmol/l (after [105]).

4. State of Catalase in Hemoglobin-Free Perfused Rat Liver

4.1. Organ Photometry of Catalase Compound I

Since it can be assumed that the H_2O_2 present in peroxisomes is indicated in the form of Compound I, the photometry of this complex allows a direct insight into the metabolism of H_2O_2 and its reaction partners. If the rat liver is perfused with a perfusion fluid free from hemoglobin, optical methods can be used without major difficulty[106–108]; the metabolism of the catalase-containing erythrocytes does not interfere. *Brauser*[109] used the light passing through the lobe of the perfused liver for absorbance measurements (photometry in transmitted light as opposed to reflection photometry), a method that was also used successfully on isolated tissues such as muscle preparations[110–112]. Changes in the steady state content of catalase Compound I in the liver can be detected in the blue (*e.g.* at 405 nm) and in the red spectral regions (*e.g.* at 660 nm).

The problem in the photometry of an organ, a multi-component system, of assigning the measured signals to transitions of specific components, is largely solved by the use of the dual wavelength technique[109–113] and of difference absorption spectra[114, 115]. Since other hemoproteins hardly interfere at the absorbance peak in the red region, the absorbance difference 660—640 nm proves to be best suited with the perfused liver for specific detection of the transition between catalase Compound I and catalase[116, 117].

As Figure 6 shows, the absorbance difference increases upon withdrawal of oxygen (causing an interruption of H_2O_2 formation) and upon the addition of an excess of methanol (causing peroxidatic degradation of Compound I). The two effects are not additive. They are two independent metabolic transitions in which catalase is regenerated from Compound I. The figure shows further that the absorbance difference decreases upon infusion of glycolate. This reflects the increase in intracellular

H_2O_2 production by the flavin enzyme, glycolate oxidase. When catalase is irreversibly inhibited by 3-amino-1,2,4-triazole, both the methanol effect and the effect of withdrawal of oxygen are almost completely lacking[116].

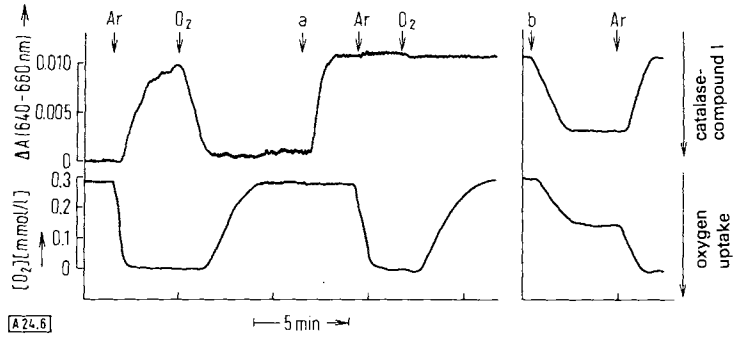

Fig. 6. Upper trace: Left: Recording of the absorbance difference ΔA (640–660 nm) of a perfused liver lobe. The decrease in the catalase Compound I by withdrawal of oxygen or by infusion of methanol (2.5 mmol/l at a) results in a rise of ΔA. Right: Re-formation of Compound I due to H_2O_2 formation from infused sodium glycolate (2mmol/l at b in the presence of 1mmol/l of methanol).
Lower trace: Oxygen concentration in effluent perfusate (after [116]).

4.2. Heme Occupancy of Catalase

Since a continuous endogenous H_2O_2 production in the liver (Figure 6) has been demonstrated, a system of measurement can be devised on the basis of the relationships obtained from the isolated enzyme, which provides information on the state of the enzyme in the intact organ. The heme occupancy $p_m/e=0$ is obtained by an excess of methanol, the maximal heme occupancy $p_m/e=p_M/e$ by an excess of glycolate, and under the same conditions in the perfused organ the catalase-HCN complex is used as a measure of the total catalase heme.

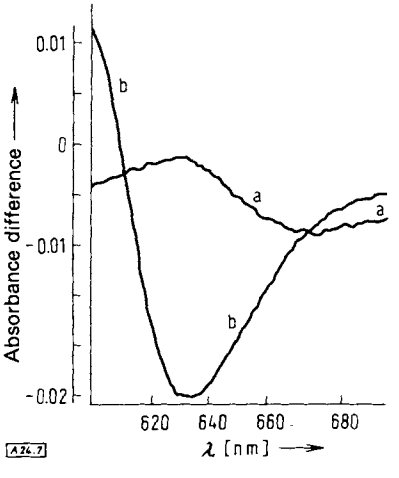

Fig. 7. Absorbance difference spectra of hemoglobin-free perfused rat liver. a) Catalase Compound I, b) HCN-catalase (as a measure of catalase heme). The reference spectrum is that of free catalase in the liver. The spectra correspond to metabolic steady states (see text); they were recorded with a Rapidspektroskop [118]. An instrument computer was used for signal averaging and subsequent digital subtraction according to the method of *Brauser et al.* [114] (after [82]).

Figure 7 shows two absorbance difference spectra. Sodium glycolate (2 mmol/l), methanol (4.8 mmol/l), and methanol (4.8 mmol/l) *plus* sodium cyanide (0.05 mmol/l) were successively infused into the perfusate entering the liver, for 2 to 3 min each. During each of the steady states corresponding to these three conditions 256 absorption spectra of a lobe of the liver were taken within 12 s in the range 600—700 nm and stored. Spectrum a corresponds to the absorbance difference of the liver, obtained by digital subtraction, between the state in the presence of methanol and that in the presence of glycolate, *i.e.* it shows the decrease of the maximal heme occupancy of catalase Compound I to zero heme occupancy. Spectrum b corresponds to the absorbance difference of the liver between the state in the presence of methanol plus cyanide and that in the presence of methanol, *i.e.* it shows the formation of HCN-catalase from free catalase (in the range around 610 nm there is a small contribution by cytochrome oxidase).

With the aid of the difference extinction coefficients[82] determined for catalase isolated from rat liver, a maximal heme occupancy $p_M/e=0.38$ can be calculated from ΔA (640—660 nm) of spectra a and b. Hence the maximal heme occupancy of rat liver catalase *in vitro* (Fig. 4) and *in situ* (Fig. 7) are similar. According to eq. (5a), this means that the catalase molecule has a comparable rate constant ratio k'_4/k_1 at the dilution employed *in vitro* (approximately 10^{-6} mol/l with respect to heme) and with the concentration occurring within the peroxisome *in situ* (approximately 10^{-3} mol/l with respect to heme, see below).

The endogenous steady state of the heme occupancy can be measured by determining the extreme states with methanol and glycolate. In Figure 8 it is 3/4 of the maximal value.

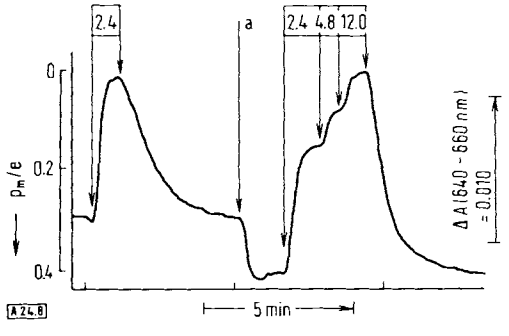

Fig. 8. Recording of the absorbance difference ΔA (640—660 nm) of a perfused liver lobe. Higher methanol concentrations are necessary (see eq. (6) and Fig. 4) for decomposition of Compound I during the stimulation of H_2O_2 formation by glycolate (addition of 2 mmol/l at a). The endogenous heme occupancy is 3/4 of the maximum value. The relevant methanol concentrations (in mmol/l) are given in the upper panel (after [82]).

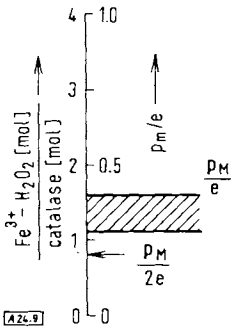

Fig. 9. Schematic representation of the heme occupancy p_m/e of catalase. The shaded region corresponds to the heme occupancy observed in the liver in the endogenous steady state. The maximum value p_M/e is produced by glycolate, urate, *etc.*, and the heme occupancy of zero by withdrawal of oxygen, or by methanol, ethanol, *etc.*

In addition, it can be seen that with increasing the rate of H_2O_2 formation the methanol concentration required for the decomposition of Compound I increases (cf. eq. (6)). The findings and definitions are summarized in Figure 9.

4.3. Catalase Content

Enzyme contents per gram of organ are usually determined from the activity measured in the homogenate and from the specific activity of the isolated enzyme, or by quantitative immunological methods. In another method, which does not require destruction of the tissue, the enzyme content is determined by photometric comparison with components of known content in the intact organ. A suitable reference component for catalase is cytochrome oxidase, the content of which in the liver is 18 nmol/g; the transition from normoxia to anoxia can be established by measuring the band at 607 nm[119]. The catalase content determined in this manner amounts to 1/3 of the content of cytochrome oxidase, *i.e.* 6 nmol/g or 24 nmol/g with respect to catalase heme (approximately 1.5 mg catalase protein per g of liver). From the data of *Price et al.*[33] and *Higashi* and *Peters*[34] results of 1 and 1.5 mg/g have been obtained. This corresponds to a catalase concentration in the peroxisome of approximately 0.5 mmol/l or 120 mg/ml.

For illustrative purposes a determination of the relative tissue content is shown in Figure 10. Here the catalase/cytochrome oxidase ratio increased from 0.33 to 1.1 because the number of peroxisomes was increased by prior treatment with ethyl 2-(*p*-chlorophenoxy)isobutyrate. This also follows from the electron micrograph of the perfused liver.

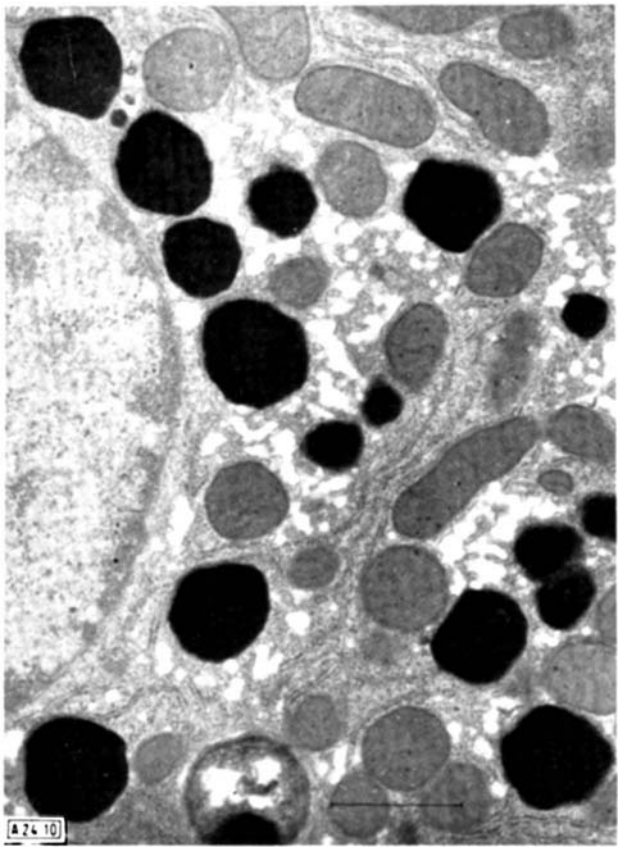

Fig. 10. Perfused liver of a rat pretreated with ethyl 2-(*p*-chlorophenoxy)isobutyrate. Bottom: Absorbance difference spectra, a) catalase minus catalase Compound I (cf. Fig. 7), b) cytochrome oxidase (through subsequent anoxia). The ratio of the catalase and cytochrome oxidase contents is 1.1 (as opposed to 0.33 for an untreated rat). Top: Electron micrograph of this liver after 1 h of perfusion. The number of peroxisomes (contrasted by the DAB reaction after [41]) has increased, while the number of mitochondria has remained unchanged (after [42]). The distance marker corresponds to 1 μm.

5. H_2O_2 Metabolism of the Liver Cell

5.1. H_2O_2 Formation

Identification of the substrates which form H_2O_2 in the liver in the endogenous steady state has not yet been performed. For example, uric acid is continuously formed from purine degradation, its concentration in rat liver amounting to 70 μmol/l[120]. In addition to urate oxidase, flavin-dependent enzyme systems come into consideration for H_2O_2 production[121], either directly or by means of the superoxide radical $O_2^{\cdot-}$[122, 123] through superoxide dismutase[124a–c]. However, the autoxidizability of flavin enzymes is quite variable, as is indicated by the distinction between flavin oxidases and flavin dehydrogenases (cf. reviews on acceptor specificities[125a, b]). In the case of xanthine oxidase a shift between oxidase and dehydrogenase activities was described[126].

Increments of H_2O_2 formation by the addition of H_2O_2-producing substrates can be determined directly by an increase in the methanol concentration required for the half-maximal decomposition of Compound I (cf. eq. (6)). The H_2O_2 formation of approximately 50 nmol min^{-1} g^{-1} determined in this

manner in the intact liver increases 10-fold in the presence of glycolate, and 15-fold in the presence of urate (Table 5). Hence it is in the order of magnitude of 1/100 to 1/10 of the total O_2 uptake. *Portwich* and *Aebi*[128] found comparable rates of H_2O_2 formation in liver slices and liver homogenates by measurement of the peroxidatic oxidation of ^{14}C-formate. The H_2O_2 concentration in the endogenous steady state is 10^{-9} mol/l and increases to 10^{-7} mol/l with maximal stimulation of the H_2O_2 formation by the substrates added[127]. Low steady state turnover numbers of $< 10\,min^{-1}$ to approximately $100\,min^{-1}$ at maximal stimulation are characteristic for the *in situ* condition. Isolated catalase is well-known for particularly high maximal turnover numbers of $> 10^8$ min^{-1}[129]. Hence catalase *in situ* operates in a region that favors the peroxidatic reaction relative to the catalatic reaction. However, this does not mean to say that at high turnover numbers the peroxidatic pathway would be inhibited. Some H_2O_2-producing enzymes of the liver are given in Table 6.

Table 5. Rate of H_2O_2 production in isolated hemoglobin-free perfused rat liver in several metabolic states. Determination by measurement of the heme occupancy [see eq. (6)] (after [127]). $\frac{1}{e} \cdot \frac{dx_n}{dt}$ = steady state turnover number, $dx_n/dt \approx H_2O_2$-formation rate.

Substrate or inhibitor	$[CH_3OH]$ at $p_M/2e$ [mmol/l]	$\frac{1}{e}\frac{dx_n}{dt}$ [min^{-1}]	$\frac{dx_n}{dt}$ [nmol/min][a]
L-Lactate 2 mmol/l, pyruvate 0.3 mmol/l	0.12 (0.09–0.16)	3.8	49
+ Antimycin A 8 µmol/l	0.18	5.8	75
+ Octanoate 0.3 mmol/l and Antimycin A 8 µmol/l	0.40	13.0	170
+ Oleate 0.1 mmol/l	0.16	5.1	66
+ Urate 1 mmol/l	—	54 [b]	750
+ Glycolate 3 mmol/l	—	34 [b]	490

[a] Per gram of liver.
[b] Titration in the presence of 0.6 mmol/l of methanol.

The question widely discussed at the beginning of this century, "Does hydrogen peroxide play any role in the living cell?" (cf. [130]), can be answered by stating that the production of H_2O_2 (as well as O_2^- and organic hydroperoxides) is a normal attribute of aerobic metabolism. A survey of the detection of H_2O_2 formation in living cells and cell fractions is given in Table 7.

The above-mentioned H_2O_2 formation rates may be regarded as the lower limits of the *in vivo* rates, because in the extraperoxisomal space other peroxidases, *e.g.* glutathione peroxidase[143, 144], can compete with catalase for H_2O_2[145]. For example, oxidized glutathione appears in the effluent perfusate after infusion of H_2O_2[146], indicating the activity of glutathione peroxidase. About 1/3 of this enzyme is localized in the mitochondrial matrix and about 2/3 in the cytosol[147].

Table 6. H_2O_2-(or O_2^--)producing enzymes of the liver and their subcellular localization.

EC number	Enzyme (trivial name)	Localization
1.1.3.1	Glycolate oxidase	Peroxisome
1.1.3.α	L-α-Hydroxy acid oxidase	Peroxisome
1.1.3.8	L-Gulonolactone oxidase	
1.2.3.1	Aldehyde oxidase	
1.2.3.2	Xanthine oxidase	Cytosol
1.4.3.3	D-Amino acid oxidase	Peroxisome
1.4.3.4	Monoamine oxidase	Mitochondrial outer membrane
1.4.3.5	Pyridoxamine oxidase	
1.4.3.6	Diamine oxidase	Endoplasmic reticulum
1.6.99.1	NADPH cytochrome c reductase	Endoplasmic reticulum
1.6.99.3	NADH cytochrome c reductase	
1.7.3.3	Urate oxidase	Peroxisome, "core"
1.15.1.1	Superoxide dismutase	Cytosol, mitochondrial matrix

Under certain experimental conditions intraperoxisomally formed H_2O_2 can also leave the peroxisomes and be detected *e.g.* by the complex with cytochrome c peroxidase from yeast.

Table 7. Detection of H_2O_2 formation in living cells and subcellular fractions.

Source	Example	Detection by	Ref.
Bacteria	*Micrococcus lysodeikticus*	Catalase Compound I	[131]
Worms	*Ascaris lumbricoides*	Polarography	[132, 133]
Blood cells	Leukocytes	Diacetyldichlorofluorescein	[134]
Liver	Liver slices and homogenates	^{14}C-Formate → $^{14}CO_2$	[128]
	Isolated perfused rat liver	Catalase Compound I	[113]
Cell fractions			
Mitochondria	Liver (rat)	Catalase Compound I	[103]
		Cytochrome c peroxidase	[137]
	Heart (pigeon)	Scopoletin, horseradish peroxidase	[135]
		Cytochrome c peroxidase	[136]
	Yeast (*S. cerevisiae*)	Cytochrome c peroxidase	[138]
	Protozoa (*C. fasciculata*)	Cytochrome c peroxidase	[139]
Microsomes	Liver (rat)	Scopoletin, horseradish peroxidase	[140]
		Cytochrome c peroxidase	[137]
Peroxisomes	Liver (rat)	Cytochrome c peroxidase	[137]
Cytosol	Liver (rat)	Cytochrome c peroxidase	[137]
Submitochondrial particles	Liver (rat)	Diacetyldichlorofluorescein	[141]
		Polarography	[142]

The increase in heme occupancy of catalase upon infusion of octanoate and antimycin A (Table 5), which is attributed to increments of mitochondrial H_2O_2 production in the liver[127], is therefore particularly striking.

From experiments conducted so far on subcellular fractions[141,99,135-137] it follows that the mitochondrial H_2O_2 production depends on the control state[99] and is greatest[99,135] in the state of respiratory control by the availability of phosphate acceptor ("State 4"[148]). The segment succinate-cytochrome b_{566} as well as the system of energy conservation are postulated to play a role in H_2O_2 formation[149,136]. Since in this segment of the respiratory chain the transition from two-electron transfer to one-electron transfer takes place, the primary product could also be the superoxide radical O_2^-, which then dismutates into H_2O_2 and O_2. Experimental support for this possibility has been provided by *Loschen et al.*[150].

An increase in the oxygen pressure from atmospheric to 1.92 MPa (19 atm) increases the rate of H_2O_2 formation fourfold in pigeon heart mitochondria and 15- to 20-fold in rat liver mitochondria[136]. Thus, considerable differences should exist in the oxygen affinity of the H_2O_2-producing systems. Recently *Oshino et al.*[151a] were able to demonstrate *in situ* on anesthetized rats a fourfold increase of H_2O_2 production in the liver in the presence of glycolate when the animal was exposed to oxygen pressures of 1 atm.

A source of H_2O_2 that is normally negligible but which is worth mentioning is high-energy radiation. X-irradiation of neutral aqueous solutions produces H_2O_2 as a stable product in a concentration of approximately 3—4 $\mu mol\,l^{-1}\,kR^{-1}$[152,153].

5.2. Hydrogen Donors for the Peroxidatic Reaction

The peroxidatic reaction, the "coupled oxidation" of *Keilin* and *Hartree*[77,78], *i.e.* the combination of reactions (1a) and (1c), is important for the metabolism of a number of hydrogen donors in the liver, and thus for methanol[13,154-157], ethanol[158], nitrite[159], and formate[160]. From the reaction sequence it follows that the rate of the oxidation of the hydrogen donors in the steady state cannot be greater than the rate of formation of hydrogen peroxide. With the exception of extremely high hydrogen donor concentrations, however, this value is not reached, as the catalase reaction competes with the peroxidatic reaction (cf. Figure 5)[105]. It should be mentioned that high donor concentrations can be obtained by exogenous supply (50 mmol of ethanol/l ≙ 2.3 ‰).

The titration curves of the steady heme occupancy of catalase in the perfused liver are different for the two primary alcohols methanol and ethanol (Figure 11). On the addition of 4-methylpyrazole the difference disappears; hence, this difference must be attributed to the activity of the alcohol dehydrogenase[127]. The titration curve for methanol remains unchanged on the addition of 4-methylpyrazole—an indication of the lack of reactivity of methanol with the dehydrogenase. These observations are in accord with the similarity of the rate constants k_4 in the reaction of catalase with methanol and ethanol[13].

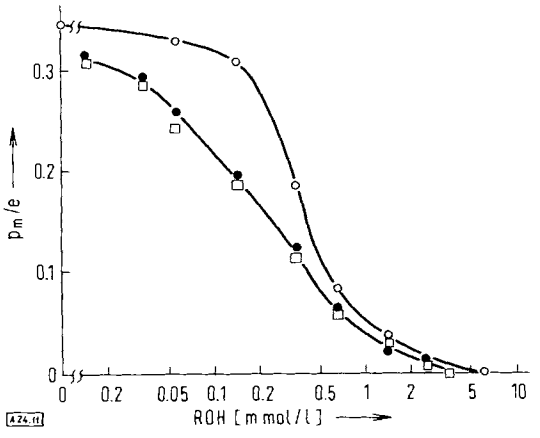

Fig. 11. Dependence of the heme occupancy of catalase (p_m/e) on methanol (□) and ethanol concentration in the perfusate (ROH). The ethanol titration was carried out in the presence (●) and in the absence (○) of 0.1 mmol/l of 4-methylpyrazole (after [127]).

The oxidation of ethanol *via* the catalase pathway is stimulated by increased H_2O_2 formation, as shown in Figure 12. By glycolate addition in the presence of methylpyrazole, the oxidation of ethanol per g of liver increases by approximately

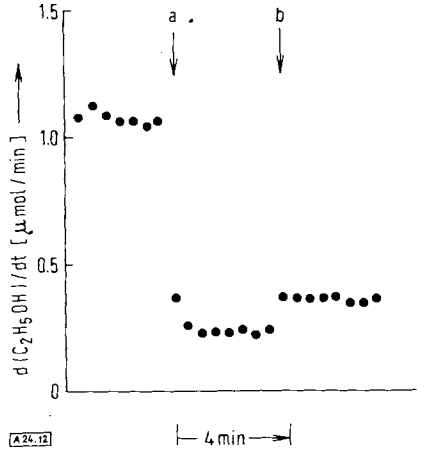

Fig. 12. Ethanol uptake by perfused rat liver, per g of liver [2 mmol of ethanol per l of influent perfusate]. Ethanol uptake in the presence of 90 µmol/l of 4-methylpyrazole (added at point a) is 22% of the control value and increases after the addition of 3.8 mmol/l of glycolate (at point b) to 34%. This increase corresponds, per g of liver, to about 150 nmol/min (after [161]).

150 nmol/min. The stimulation of H_2O_2 production per g liver under these conditions is approximately 400 nmol/min, so that about 35—40% of the H_2O_2 additionally produced is used for the peroxidatic reaction. As expected, this proportion increases at higher ethanol concentrations[162]. The rate of the oxidation of methanol also increases on addition of glycolate[163]. Since the peroxidatic oxidation of ethanol is not connected with NAD^+ reduction, this pathway can be of use[116,164] for avoiding the negative shift caused by the alcohol dehydrogenase in the redox potential of the cytosolic free NAD^+ system[165-169].

Currently, the possibility is being considered whether this could be utilized to influence liver metabolism in alcoholism. *Blomstrand* and *Kager*[170] demonstrated on human subjects that the inhibition of fatty acid oxidation and the accumulation of triglycerides by ethanol can be largely suppressed by the addition of 4-methylpyrazole. Therefore, the use of pyrazole

derivatives concomitant with a stimulation of the peroxidatic pathway of ethanol oxidation opens interesting perspectives. According to recent studies, the peroxidatic oxidation of ethanol by catalase should be responsible[105,137,140,174] for the activity of a special "microsomal ethanol-oxidizing system" (MEOS)[171-173]. The NADPH-specificity of the microsomal activity is attributed in this case to the coenzyme specificity of an autoxidizable microsomal flavoprotein[137,175]. Should this explanation be correct, the oxidation of ethanol in intact endoplasmic reticulum without catalase should not play a physiologically important role (for discussion, see [176]).

Of the aldehydes, catalase only acts on formaldehyde; acetaldehyde is not oxidized[177]. Hence, by measuring catalase Compound I one can follow the formation of ethanol from acetaldehyde[178] in the liver[171].

The question of the nature of the endogenous hydrogen donors is still largely unsettled. Only for ethanol has a continuous supply from the intestinal tract of rats been verified by determinations in portal and in caval blood[179]. Methanol can be formed continuously with the help of pectase by hydrolytic cleavage from pectins; in this manner in human subjects approximately 10–20 mmol of methanol are set free per day[180].

deDuve and *Baudhuin*[12] postulated that the peroxidatic oxidation of α-hydroxy acids plays a role in gluconeogenesis since it might be linked to an oxidation of extramitochondrial reducing equivalents (NADH). Experimental proof of this hypothesis is still lacking.

The possible function of catalase in lipid metabolism of the liver, as already postulated by *Novikoff* and *Shin*[54] and also suggested by the effects of the hypolipidemically active drugs, also remains obscure. Acatalasemic strains of mice as compared to wild strains contain a diminished serum concentration of triglycerides and cholesterol[181]. A possible reason for this observation could reside in a higher content of catalase degradation products within the peroxisomes. It is known that acatalasemia in mice can be attributed to a thermolabile variant of catalase[182], possibly resulting in an increased level of degradation products (*e.g.* subunits). A fall in the blood lipids was produced experimentally by injection of catalase subunits with peroxidatic activity[183-185]. Recently, the lack of peroxisomes in the liver, which contained considerable lipid deposits, was described in a human patient with a fatal cerebro-hepato-renal syndrome (Zellweger's disease)[186].

6. Outlook

The methods of acquiring biochemical information on intracellular processes in intact surviving organs allow insight into the metabolism of hydrogen peroxide taking place in the range of nanomolar concentrations. Constant production of H_2O_2 is a normal feature of liver metabolism. Exogenous influences, *e.g.* the effects of radiation[187,188] or oxygen and ozone poisoning[189,190], could not be discussed here in detail.

Corresponding to our still limited knowledge of the metabolism of endogenous H_2O_2-producing substrates and the endogenous hydrogen donors, we are still at the beginning of a full comprehension of the function of liver catalase (cf.[12,18,20]). Also, phenomena such as the decreased activity of catalase in tumor cells[191] and the inhibition of catalase activity by tumor extracts[192], which is reported to be based upon formation of Compound II[193,194], still require clarification. In contrast, for the plant variants of peroxisomes, *e.g.* the glyoxysomes, clear concepts already exist regarding their function in fat and carbohydrate metabolism (glyoxylate cycle), as well as in photorespiration and photosynthesis (reviews in [17,195]). In particular, the implication attached to the term peroxisome requires further elucidation for animal tissue cells. With the steadily increasing number of known enzyme activities in peroxisomes and peroxisome-containing cell types with biphenyltetramine oxidase activity (cf. the peroxisomes in the small intestine[196] and the myocardium[197,198], in steroid-secreting cells such as the interstitial cells (Leydig cells) of the testes[199] and the adrenal cortex[200]) and with the rapid development of biochemical and cytological methods, further aspects are expected in the near future on the cell biology of catalase, which was once described as a "fossil enzyme"[18].

The author is indebted to Prof. B. Chance and Dr. N. Oshino for stimulating discussions during the course of a fruitful cooperation, to Prof. Th. Bücher for constant support of the studies and valuable discussions during preparation of this manuscript, to Dr. B. Brauser for his help and discussions regarding the application of organ spectrophotometry, and to Prof. F. Miller and Dr. V. Herzog for cooperation on cytochemical problems. The author's own work referred to in the text was supported by the Deutsche Forschungsgemeinschaft, Sonderforschungsbereich 51, Medizinische Molekularbiologie und Biochemie, Teilprojekt D/8, and by NATO Research Grant No. 416.

Specific Interactions. Intermolecular Forces, Steric Requirements, and Molecular Size

By Zeno Simon[*]

Specific interactions or recognition processes are extremely important in many fields of chemistry and biology: typical examples are the enzyme-substrate and the antigen-antibody reactions. Quantitative predictions require a knowledge of steric fit, intermolecular forces, and molecular size. These considerations should facilitate design of new drugs.

1. Introduction

The specificity problem was probably first encountered by the analytical chemist searching for a reagent to precipitate a particular cation out of a mixture. It became a matter of everyday concern to the biochemist, and especially the medicinal chemist, with the advent of *Emil Fischer*'s[1] "lock-and-key" theory of enzyme-substrate interaction, *Paul Ehrlich*'s search for "magic bullets" to kill bacteria without harming the organism, and the study of immune reactions[2].

The specificity or recognition problem is concerned with the fact that a certain molecule A_0—let us term it recognizer—combines with or precipitates only a certain molecular "effector" B_0 out of a sometimes very large number N of such possible effectors B_i. For example, an antibody usually recognizes only the antigenic determinant by which it was elicited, but not the antigenic determinants of the organism's proteins. Likewise an enzyme catalyzes the reaction of only one molecule (*i. e.* its substrate) out of several similar available molecules.

Such specific interactions imply a high affinity of A_0 for B_0 and a sufficiently lowered one for the "false partners" B_i; this idea was implicit in the first attempts to obtain specific reagents, and as early as 1907 *Arrhenius* described immune reactions in terms of chemical equilibria[3]. Thereafter, systematic searches for steric fit requirements and types of forces involved seem to have been conducted mostly by chemists concerned with immune reactions (see, *e. g.*, ref.[4]) and catalysts[5], although much experimental work was also performed in the fields of medicinal chemistry, enzymology, and analytical chemistry. The chemotherapeutic arsenal, industrial catalysts, and the complexons of analytical chemistry are some of the results of this work.

The link between molecular size and specificity may have been recognized less clearly during this work. The earliest reagents used in analytical chemistry—the sulfide ion (S^{2-}) and the carbonate ion (CO_3^{2-})—have low molecular weights and precipitate about half of the several hundred known cations; hence separation of a given cation requires several successive "selection" procedures. Ethylenediaminetetraacetic acid, *Paul Ehrlich*'s Salvarsan, and the sulfonamides, have molecular weights of several hundred. Antibiotics reach molecular weights near 1000, while repressors like the lac repressor, which binds specifically at a certain nucleotide sequence in the *E. coli* genome[6], are proteins (see Fig. 1).

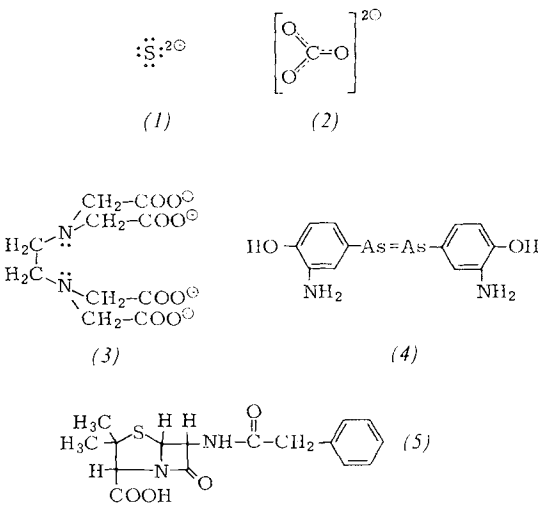

Fig. 1. Molecules of various size and specificity: sulfide ion, *(1)*; carbonate ion, *(2)*; ethylenediaminetetraacetate ion, *(3)*; Salvarsan, *(4)*; penicillin G, *(5)*.

Attempts to characterize quantitatively specific interactions, to relate specificity to affinity differences and molecular size are confined to the last few years. The probability of false base incorporation in DNA replication and transcription was related to affinity differences by *Volkenshtein* and *Eliashevich*[7], specificity-molecular size relations were discussed in relation to DNA-RNA hybridization competition experiments by *Thomas*[8a] and *Conaughy* and *McCarthy*[8b], and a quantitative characterization of specificity in interactions between biological macromolecules has been presented by the author[9].

This report is intended as a general survey of the specific interaction problem. Quantitative data concerning specificity, as well as the relation of specificity to structural requirements and molecular size, will be discussed. Moreover, an attempt will be made to test some of the relations obtained for various chemical and molecular biology processes, and the possibility of predicting structures of compounds having a certain type of biological activity will also be considered.

2. Quantitative Characterization of Interaction Specificity

The requirements placed on a recognition process may be stated as follows[9a, 9b]: The "recognizer" A_0 should be able to complex with or precipitate only a certain molecular species B_0, *i. e.* the "correct" effector, out of N species $B_0, B_1, \ldots, B_{N-1}$ present in various concentrations. Also, the probability of all false recognitions should not exceed a threshold p_f. The degree of specificity of the recognition process may thus be

characterized by the number N of possible effectors, among which A_0 recognizes the correct one, and the probability p_f of false recognitions.

Suppose that "recognition" consists in formation of a 1:1 complex from A_0 and B_0 in a simple chemical equilibrium reaction. This may be the case in cation binding by complexons like EDTA, or in enzymatic reactions in which an enzyme (A_0)-substrate (B_0) activated complex is formed (in the sense of absolute reaction rate theory). The reactions and equilibria for this case are

$$A_0 + B_i \rightleftarrows A_0B_i;$$

$$\frac{[A_0B_i]}{[A_0][B_i]} = K_{0i} \equiv e^{-\frac{G_{0i}}{RT}}; \qquad i = 0,1,\ldots,N-1 \tag{1}$$

The probability p_f of false recognition will be equal to the quotient

$$p_f = \frac{\sum_{i=1}^{N-1}[A_0B_i]}{[A_0B_0] + \sum_{i=1}^{N-1}[A_0B_i]} \approx \frac{\sum_{i=1}^{N-1}[B_i]K_{0i}}{[B_0]K_{00} + \sum_{i=1}^{N-1}[B_i]K_{0i}} \tag{2}$$

If the concentrations of all molecules B_i are appreciably higher than that of the "recognizer" A_0, the quantities of B_i bound in A_0B_i complexes will be negligible, even for B_0, and the B_i concentrations of eq. (2) are practically equal to the total B_i concentration. The specificity of the recognition process will be the higher the greater the quotients K_{00}/K_{0i} of the binding constants for the correct and false partners respectively, *i. e.* the higher the difference

$$\Delta G_i \equiv G_{0i} - G_{00} \tag{3}$$

between the affinity $-G_{00}$ of A_0 for the correct partner B_0 and those for the false ones $-G_{0i}$.

The precision of such a recognition process will decrease, *i. e.* p_f increase, if the total amount of B_i (and especially B_0) is comparable with or smaller than the quantity of the recognizer A_0[10]. In the extreme case when the quantity of A_0 surpasses the sum of quantities of B_i and all binding constants K_{0i} are great enough, practically the whole B_i quantities will be bound in A_0B_i complexes and the error probability p_f will reach a value of about 1.

The A_0-B_i interactions may have cooperative character. In the extreme case recognition implies precipitation of A_0 only by B_0, as in that of cation precipitation by a specific reagent or in antigen-antibody precipitation. For the simple case of 1:1 stoichiometry the solubility product relations required for correct recognition will be:

$$[A_0][B_0] \geq P_{00} \equiv e^{\frac{G_{00}}{RT}} \tag{4a}$$

$$[A_0][B_i] < P_{0i} \equiv e^{\frac{G_{0i}}{RT}}; \qquad i = 1,2,\ldots,N-1 \tag{4b}$$

If coprecipitation is neglected, the error probability p_f will be zero in this case.

The A_0B_i complexes may certainly also have more complicated stoichiometries, but it is unlikely that this will lead to any essential changes in the results of eq. (2) and (4).

A highly specific recognition thus requires a sufficiently high difference ΔG_i between the affinity G_{00} of A_0 for the correct B_0 effector and the affinity G_{0i} for false ones, as well as a sufficient excess of B_0 over A_0. With sufficiently high affinity differences ΔG_i the recognizer A_0 must be able to discern one effector, *i. e.* B_0, from N other effectors B_i. Small structural differences on the B_i regions which come into contact with A_0 will usually lead to only small affinity differences ΔG_i. Therefore the contact region between A_0 and the effectors B_i must be large enough to yield sufficiently large affinity differences ΔG_i for all the N different contact regions on the false effectors B_i.

Let us term these contact regions on A_0 and B_i "recognition sites". One can now understand why a high specificity—large values of N and ΔG_i (possibly as result of unfavorable B_i concentrations) and a small p_f—require large recognition sites. If the A_0 recognition site is to be left unchanged by the interactions with the different molecules B_i, a supplementary part of the A_0 molecule will be required to rigidize the recognition site. The molecule of A_0 must therefore consist of more than just its recognition site.

The situations described above refer to selection (recognition) processes proceeding in a single step. If the selectivity (specificity) of the recognizing agent is low, the separation of a certain component (B_0) out of the mixture ($B_0, B_1, \ldots, B_N$) can be performed by several selection steps with different selecting (recognizing) agents. This is the way ore analysis is performed by the methods of classical analytical chemistry. *Scherer*[11] proposed a similar way—"cascade regulation"—as a hypothetical cell regulation mechanism: restriction of cell protein synthesis to only those coded by a few genes (for example hemoglobin in erythrocytes) may proceed first as a restriction of transcription by repressors, secondly as a restriction in the passage of messenger RNA through the nuclear membrane, and thirdly as a selection by ribosomes of only some of the messenger RNAs available in the cytoplasm.

3. Structure and Interaction Affinity

According to the "lock-and-key" theory, a high interaction affinity ($-G_{0i}$) should require a steric complementarity between a certain part of the recognizer (lock, A_0) and the recognized molecule (key, B_0) and also a complementarity in intermolecular forces between the atoms of A_0 and B_0 which come into direct contact. If recognition means not only complex formation but also reaction (catalysis, enzymatic reactions), *i. e.* G_{00} is the lowest free enthalpy of activation, the tendency of B_0 to react, *i. e.* its reactivity, should also be a determining factor. What importance attaches to reactivity, steric complementarity, and intermolecular force complementarity, and how can these three factors be characterized?

In the catalysis of inorganic reactions, reactivity is the determining factor. The "recognizer" is the catalyst—an ion or, for heterogeneous catalysis, a constellation of atoms on the microcrystalline surface that is not larger than the elementary cell[5]. Ionic precipitate and complex formation[12] implies rigid sites, partition between different solvents[13] non-rigid sites, but here also the sites and molecules implied are small. One should not expect a particularly large specificity for such cases.

We shall be concerned mainly with interactions involving biomacromolecules, where the most interesting specificity problems appear. This is the domain of the lock-and-key effect, with macromolecules having large and sufficiently rigid cavities requiring various complementarity effects.

3.1. Reactivity Parameters

Correlations between various reactivity parameters of substrate molecules (B_i) and enzymatic reaction rates have been studied by the HMO method since the early fifties[14, 15]. The action of drugs was related to various reactivity parameters, and especially electronic charge on various atoms, *via* a perturbation theory by *Cammarata*[16]. This theory assumes the formation of a drug-receptor complex as the determining step in the biological response to the drug. The biological activity, expressed as the logarithm of the rate constant ($\log k$), or of the concentration for semimaximal biological effect, correlates well ($r > 0.95$) with parameters such as π- or total electron charge order at certain atoms (q_i) *via* linear or quadratic equations, but the correlation is valid only in series of similar molecules that do not differ too widely with regard to steric and general chemical structure. As a typical example, the relative phosphorylation rate ($\log V$) of 15 substituted purine nucleosides catalyzed by adenosine kinase correlates satisfactorily ($r = 0.9$) with the frontier electron density f_3^e at the N^3 atom of the base moiety, as calculated by the semiempirical SCF-MO method of *Pariser* and *Parr*. The correlation equation given by *Kaneti*[17] is

$$\log V = -23.9 f_3^e + 2.1; \quad \text{for adenosine, } V = 1 \qquad (5)$$

These 15 purine nucleosides have various substituents in the 1, 2, and 6 positions or some CH groups of the cycle substituted by N atoms. The $\log V - f_3^e$ correlation disappears if substitutions are performed in the sugar moiety (which do not affect f_3^e). Thus adenosine arabinoside or 2'-deoxyadenosine are phosphorylated very slowly ($V = 0.0$—-0.09), as are adenosines with large substituents on C-2 ($V = 0.0$ for CH_3, CH_3O, $(CH_3)_2N$, Cl, Br; however, the correlation applies for F and NH_2). This accords with the assumption that purine moiety is involved in binding of the ribosides to adenosine kinase by chelation[17].

3.2. Steric Fit

The importance of steric fit as compared to the chemical nature of the reacting groups follows from the fact that the reactions of similar substrates of the same chirality are also catalyzed, albeit at different rates. However, the enantiomers do not usually react at all, not even that of the most active substrate. In antigen-antibody interactions, polypeptide antigenic determinants have more "conformational" than "sequential" character, as remarked by *Sela*[18].

One could try to use *Taft*'s[19] steric constants E_s to characterize steric fit, but they reflect only a general screening effect of various substituents on a reaction center in a micromolecular reaction. An attempt by *Dupaix*, *Bechet*, and *Roucous*[20] to correlate α-chymotrypsin-catalyzed hydrolysis rates of acyl substituted *p*-nitrophenyl amino acid esters succeeded only for 9 compounds out of a series of 42 studied.

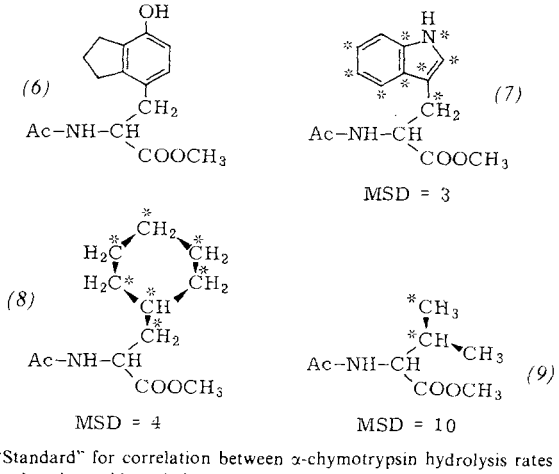
To correlate dissimilarities in steric fit with binding affinity decrease one should have a measure for these steric dissimilarities. However, no well established method seems to exist for this purpose. One could adopt the procedure used by *Rao* and *Rossmann*[21] in comparing suprasecondary structures in proteins: the two similar structures are superposed by a geometric technique so as to minimize the sum of the squares of the distances between all atoms assumed to be equivalent. This sum is then a measure for steric dissimilarity.

A more direct, although more approximative method is that of minimal steric differences (MSDs) of *Simon* and *Szabadai*[22]. The method consists in superposing the two molecules to be compared within limits allowed by bond lengths, bond angles, and free rotations (degrees of allowed variations: ≈ 0.2 Å for bond lengths; $\approx 20°$ for bond angles) and to count the second row atoms which do not superpose. Hydrogen atoms are hereby neglected. This MSD method was used in attempts to correlate the α-chymotrypsin hydrolysis rates of *N*-acetyl amino acid methyl esters listed by *Knowles*[23] and the decrease in biological activity produced by amino acid substitutions in hormonal oligopeptides (data listed in ref.[22]; 92 points). All MSDs were calculated relative to the hypothetical standard molecule *(6)* (Fig. 2). A satisfactory correlation was obtained for the α-chymotrypsin hydrolysis rates ($r = 0.93$) where correlation with Tanford hydrophobicities (HP)[24] of the amino acid side chains R is also obtained ($r = 0.80$; see Table 1). The best correlation equations are:

$$\log V = 0.70\,\text{MSD} + 2.10; \quad s = 0.82,\ r = 0.93,\ n = 14^{[*]} \qquad (6a)$$

$$\log V = 1.57\,\text{HP} - 6.3; \quad s = 1.35,\ r = 0.80,\ n = 14 \qquad (6b)$$

For 92 substituted oligopeptides, the correlation of biological activity *vs.* MSD (with respect to the unmodified oligopeptide) yielded $r = 0.55$. A mean affinity decrease of about 0.5 kcal per second row atom can be inferred[22].



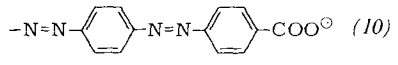


Fig. 2. "Standard" for correlation between α-chymotrypsin hydrolysis rates of *N*-acetyl amino acid methyl esters and minimal steric difference (MSD) of these molecules, and examples of MSD calculations. Hypothetical standard molecule *(6)*. Tryptophan side chain, *(7)*, MSD = 3. The difference between superposed pentacycles and hexacycles is taken as 1. The OH group of the standard is superposed on neither group of the tryptophan side chain. Cyclohexylalanine side chain, *(8)*, MSD = 4. The MSD is given by three atoms of the pentacycle and the OH group of the standard. Valine side chain, *(9)*, MSD = 10. Only two atoms are superposable on the standard. The atoms marked by an asterisk in *(7)*, *(8)*, and *(9)* are assumed to be superposable on atoms or groups of the standard *(6)*.

[*] s = standard deviation, r = correlation coefficient, n = number of derivatives.

Table 1. Kinetic parameters for the hydrolysis of *N*-acetyl amino acid methyl esters by α-chymotrypsin. V = second order rate constant at low substrate concentration; MSD = minimal steric difference; HP = Tanford hydrophobicity (ΔG_i for transfer of an amino acid side chain from water to *n*-octanol). For explanations see text.

$H_2NCHRCOOH$ in $AcNHCHRCOOCH_3$	log V	MSD	HP [kcal]
Trp	0.00	3	3.00
Tyr	−0.07	3	2.97
Cyclohexyl-Ala	−0.71	4	4.0
Phe	−1.00	4	2.65
α-NH_2-Heptanoic acid	−1.71	6	3.1
Met	−2.25	7.5	1.3
α-NH_2-Octanoic acid	−2.28	5	3.8
Leu	−2.43	7	2.49
Nor-Leu	−2.50	7	2.5
Nor-Val	−3.21	8	1.7
α-NH_2-Butyric acid	−4.35	9	1.1
Ala	−5.35	10	0.73
Val	−5.50	10	1.69
Gly	−8.65	11	0

The sparse success of biological activity—MSD correlations indicates that steric fit (complementarity) alone is insufficient for a high interaction affinity. Moreover, it is not the whole biologically active molecule that enters the "lock": the affinity of the antibody elicited by protein-bound *p*-(*p'*-azophenylazo)-benzoate towards benzoate ions substituted in different posi-

(10)

tions indicates a stringent steric fit requirement for the benzoate benzene ring (affinity increases of about 1.0 kcal/mol for *para* substitutions), but much looser steric requirements for the second benzene ring and for the second azo group (ref.[14], pp. 56—61). Thus it would appear that only the *p*-azobenzoate moiety of the antigen enters a "lock" in the elicited antibody.

3.3. Intermolecular Forces

Most reactions in the living cell take place in aqueous solution at a pH of about 7 and temperatures of about 30 °C. The formation of an A_0B_i complex often involves the passage of B_i from water to a more hydrophobic medium. One may thus expect to find correlations between biological activity of B_i and its hydrophobicity π_i, defined as:

$$\pi_i \equiv \log P_{i,\,oct} \tag{7a}$$

where $P_{i,oct}$ the partition coefficient of substance between a hydrophobic solvent (usually octanol) and water. Some ΔG_i values given by *Tanford*[24] are listed in Table 1 under the heading HP.

The use of the hydrophobicity constants π_i is demonstrated by the possibility of calculating the partition coefficient between a given solvent and water, $P_{i,solv}$, by means of two linear equations of the type:

$$\log P_{i,\,solv} = a_{solv} \log P_{i,\,oct} + b_{solv} \tag{7b}$$

One such equation is employed for solutes with a marked hydrogen donor character, and another for solutes with hydrogen acceptor character[13]. For example, partition coefficients for H donors and H acceptors in benzene can be calculated by means of eq. (7c) and (7d), respectively[25]:

$$\log P_{i,\,bz} = 1.019 \log P_{i,\,oct} - 1.401 \tag{7c}$$
$$n = 40,\ r = 0.948,\ s = 0.252$$

$$\log P_{i,\,bz} = 1.441 \log P_{i,\,oct} - 0.794 \tag{7d}$$
$$n = 20,\ r = 0.966,\ s = 0.254$$

These equations have been tested for large numbers n of solutes and give good correlation coefficients r. The hydrophobicity of a given molecule can be calculated from the hydrophobicities π_X of the groups of atoms which comprise the molecule and some increments for branching, ring closure, conjugation, *etc.*[13]. The hydrophobicity of a group X can be evaluated from the differences between partition constants of RX substitution derivatives and those of the unsubstituted parent molecule RH:

$$\pi_X = \log P_{RX,\,oct} - \log P_{RH,\,oct} \tag{7e}$$

Hydrophobicity constants were used especially by *Hansch et al.* for structure-activity correlations in the extrathermodynamic model[26a]. For example the inhibition of adenosine deaminase by various 9-benzyladenines can be described by:

$$-\log I_i = 0.453\,\pi_i - 1.194;\quad n = 8,\ r = 0.992 \tag{8a}$$

(I = inhibition constant)[26b], and the inhibition of the Hill reaction by *N*-phenylethyl carbamates by:

$$-\log C_i = 0.967\,\pi_i + 3.318;\quad n = 7,\ r = 0.982 \tag{8b}$$

(C = concentrations which give 50% inhibition)[26c]. Terms in π^2, σ^2 (Hammett constants), or reactivity indices should be also taken into account for some cases, according to the extrathermodynamic model. As example, for malate dehydrogenase inhibition by phenols (*meta* derivates are not included)[26d]:

$$-\log I_i = 0.73\,\sigma_i^2 - 0.65\,\sigma_i - 0.77\,\pi_i^2 + 2.44\,\pi_i + 3.47; \tag{8c}$$
$$r = 0.952$$

The correlational equations of *Hansch*[26] as well as those of *Cammarata* are valid only for classes of compounds with similar structure. This is not surprising since the configuration of the molecules, and hence the possibility of a steric fit into a "lock", is not accounted for by the reactivity parameters or by the hydrophobicity constants. One may nevertheless ask if a more complete consideration of intermolecular forces would not lead to correlation equations valid for compounds with a more extended domain of structural variation. Thus, the free energy required to transfer phenylalanine (side chain $-CH_2C_6H_5$) from aromatic solvents to water is + 1.8 kcal/mol (for equal concentrations), while for the same transfer from aliphatic solvents the corresponding value is only +0.3 kcal/mol[27]: aromatic rings should prefer aromatic to aliphatic environments. This preference is partly a steric effect—stacking of planar aromatic rings— and partly due to large perpendicular polarizabilities of aromatic rings; the van der Waals interaction energy is proportional to the product of the two polarizabilities.

We proposed a system of six types of intermolecular forces to characterize amino acid side chains[28a, 28b]: 1, hydrophobicity (HP, Tanford values); 2, special aromatic character (AR,

for Phe and Tyr 1.5 kcal/mol, as cited by *Némethy*[27] for the difference between aromatic-aromatic and aromatic-aliphatic interactions, 2.5 for Trp, 1.0 kcal/mol for His); 3, hydrogen bonding character, proton donor (HBD) or proton acceptor (HBA); 4, electrostatic charge at pH 7 (EC^+, EC^-); 5, electron accepting (ACT) or donating character (DCT) in charge transfer complexes (only Trp has donor character, the others are not active in charge transfer); 6, marked dipole moment not due to hydrogen bonds, directed towards the peptide backbone or the other end of the residue (μ^+, μ^- as an approximative characterization of uneven charge distribution, for Trp and Tyr).

These types of intermolecular forces were used in an attempt to correlate the relative decrease in biological activity produced in oligopeptides (antigenic determinants, hormones; most data taken from *Sneath*[29]) by amino acid substitutions with the sums of changes ΔHP, ΔAR, *etc.* in these types of intermolecular forces by the amino acid substitutions. The relative (as compared to the standard oligopeptides) decreased biological activity A, is given by following linear optimized equation[28b]:

$$-\log A_{calc} = 0.45 + 0.12\,\Delta HP + 0.69\,\Delta AR + 0.35\,\Delta HB + 0.004\,\Delta EC + 1.1\,\Delta DCT + 0.77\,\Delta\mu \quad (9)$$

$n = 92,\ r = 0.75,\ s = 0.84$

$-\log A_{exp}$ ranges from 0.00 to 4.65. The partial correlation coefficients for each of the six types of intermolecular forces are respectively 0.26, 0.53, 0.42, 0.22, 0.25, and 0.48, all being above the 95 % confidence limit. The linear correlation coefficient r is small, but the equation is valid for a large number n of substituted oligopeptides. All acceptor sites are proteins. Taking into account the widely varying decreases in activity produced by the same substitution at different positions in the peptide chain of the standard oligopeptide or in other standard compounds, this equation may be one of the best available to describe the effect of amino acid substitutions on oligopeptide-protein interactions, without considering interactions between amino acids on the peptide chain. The importance of the aromatic character (AR) and of the charge transfer interactions (DCT) is remarkable, as is the practically zero coefficient for changes in the electrostatic charge of the oligopeptide; possibly the charged groups of the oligopeptides are always directed towards the aqueous medium, even in complexes with proteins. Table 2 lists calculated [according to eq. (9)] and experimental $\log A$ values for derivatives of oxytocin substituted in positions 3, 4, and 8 (experimental data taken from *Sneath*[29]).

These types of intermolecular forces were adapted for an attempt to correlate the toxicity for mice and rats (molar LD_{50} values) with structure for organophosphorus compounds of the Schrader type[30a, 30b] $R^1R^2P(O)OR^3$. R^3 is here the most acidic group which is eliminated when the compound phosphorylates the acetylcholinesterase (the probable mechanism of action of these compound)[30c]. Modified Hammett constants σ of the substituents R^1, R^2, R^3 were also used in correlation. The optimized equation [similar to eq. (9)]—eight adjustable parameters, 71 compounds—yields a linear correlation coefficient $r = 0.70$. The coefficients for the hydrophobic, aromatic, and hydrogen bond parameters are similar to those of eq. (9) in absolute magnitude. The r value obtained here is also low, but the equation encompasses a wide range of different chemical structures (*i.e.* the substituents R^1, R^2, R^3) much broader than the range for which correlation equations of the type used by *Cammarata* and *Hansch* are valid.

Table 2. Experimental and calculated values, $\log A_{exp}$ [29] and $\log A_{calc}$ respectively, for the reduced biological activity A of oxytocins having substituted amino acid residues as compared with that of oxytocin itself; experiments on rats. $r = 0.95$, $n = 21$, $s = 0.62$.

Oxytocin: Cys-Tyr-Ile[3]-Gln[4]-Asn-Cys-Pro-Leu[8]-Gly

3.4. Molecular Size

As mentioned in Section 1, a certain relation should exist between specificity and molecular size. A procedure will now be outlined for evaluation of the size of the recognition site (contact site between A_0 and the effectors B_i) required for a certain degree of specificity. The "recognizer" A_0 will be larger than the recognition site itself in order to ensure a certain rigidity of this site and possibly to allow for functions other than recognition *per se* (for example complement binding by antibodies).

The simplest reasoning is that adopted by *Thomas*[8a] and *McCarthy*[8b] in discussing the minimum number n of nucleosides in RNA oligonucleotides which can be recognized by absorbed DNA (viral, bacterial *etc.*) as self or alien in hybridization-competition experiments. These oligonucleotides are recognized by complementary base pair formation with DNA segments. If the DNA has N nucleotides there are also (approximately) N overlapping oligonucleotidic sequences on this DNA; if their primary sequences have a sufficiently random distribution, too short oligonucleotides of RNA coded by alien DNA may by chance have a sequence complementary to one on the absorbed DNA. If this is not to happen, n should be so large that the number 4^n of possible "words" in an "alphabet" of $\alpha = 4$ letters should be much higher than N. Thus:

$$\alpha^n \gg N;\quad n > \frac{\lg N}{\lg \alpha} \quad (10)$$

It is important that a "word" having a single changed "letter" as compared to the correct "word" (*i.e.* B_0) may be recognized by A_0, especially if the concentration of B_0 is low and that

of several false effectors B_i high. A highly simplified model for evaluating n in the general case by means of eqs. (2) or (4) is based on the following assumptions[9]:

i) All recognition sites of the effectors B_i have the same number n of monomeric units or atoms;

ii) The decrease in affinity ΔG_i (on going from A_0B_0 to A_0B_i) is proportional to the number ν_i of modifications by which the B_i recognition site differs from that on B_0 (Δg is the mean decrease per modification):

$$\Delta G_i = \nu_i \Delta g \tag{11}$$

iii) The false effectors B_i differ from B_0 by the same number ν of modifications within the combining site.

We must remember that N is the number of B_i types, which are all supposed to have different recognition sites, and α is the number of monomer units (or atoms) from which the B_i molecules are formed.

Going back to eqs. (2) and (1), with $\Delta G_i = G_{0i} - G_{00} = \nu \Delta g$ and $p_f \ll 1$:

$$p_f \cong \sum_{i=1}^{N-1} \frac{[B_i]K_{0i}}{[B_0]K_{00}} = \frac{\sum_1^{N-1}[B_i]}{[B_0]} e^{\frac{\bar{\nu}\Delta g}{RT}}; \quad \bar{\nu} = \frac{2.3RT}{\Delta g} \log \frac{[B_{tot}]}{p_f[B_0]} \tag{12}$$

In order that there are no accidental "false" recognitions a sufficiently low value must be obtained for the probability that the recognition site of any of the N false effectors B_i should differ by less than ν substitutions from that of B_0. Probability and combinatorial calculation techniques yield:

$$N C_n^{n-\nu+1} \cdot \alpha^{-(n-\bar{\nu}+1)} \ll 1 \tag{13}$$

which for $\nu = 1$ is identical with relation (10). Further calculations and use of the Stirling approximation for $x!$ furnishes the approximative result (see ref.[31], for $\log(ne/\nu - 1) \approx 1$):

$$n \gtrsim \bar{\nu} - 1 + \frac{(\bar{\nu}-1) + \log N}{\log \alpha} \tag{14}$$

If recognition leads to precipitation, and not to complex formation, the same results are valid, but the (mean) number ν of substitutions by which the false effectors B_i must differ from B_0 is to be calculated from eq. (15):

$$\bar{\nu} = \frac{2.3RT}{\Delta g} \log \frac{[B_{mx}]}{[B_0]} \tag{15}$$

with B_{mx} as the highest concentration of B_i which should be discerned (not precipitated) by A_0 from B_0.

4. Specificity in Some Chemical and Biochemical Processes

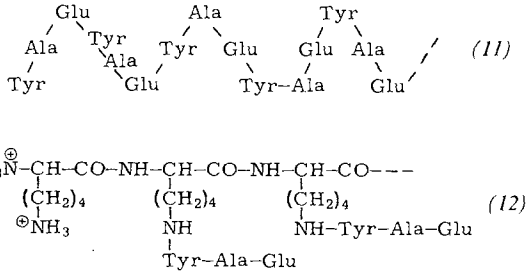
4.1. Antibody Elicitation by Nonself Antigens

The specificity of this process was analyzed on the basis of the assumption that elicitation of (primary) antibody production is triggered by precipitation of the foreign antigen (B_0) on the antibody combining sites (A_0) found on the surface of the respective immunocyte; "self" antigenic determinants (B_i) should thus not precipitate on these "self" antibody combining sites[31].

The lowest concentrations of foreign antigens ($[B_0]$ of eq. (15)) eliciting a primary response are about 10^{-6} mol/l for "weak" antigens and even 10^{-10} mol/l for "strong" ones. The maximal concentration of "self" antigenic determinants $[B_{mx}]$ may be about 10^{-3} mol/l, corresponding to serum globulin concentrations (see ref.[31]). Most antigenic determinants are peptide sequences made of $\alpha = 20$ amino acids. One amino acid substitution in the peptidic antigen produces a mean affinity decrease $\Delta g = 2.0$ kcal/mol. Equation (15) yields $\nu \approx 2$–5 for the concentration range between weak and strong antigens. The maximum possible number of "self" antigenic determinants would be equal to the number of overlapping short peptide sequences on all the proteins which may be coded by the haploid mammalian genome, *i.e.* $N \approx 10^9$; the real number may be perhaps $N \approx 10^7$, due to repetitions in the genome, nonavailability of some sequences, *etc.* For $N = 10^7$, $\alpha = 20$, $\nu = 2$–5, eq. (14) yields a number of $n \gtrsim 9$–13 amino acid residues for antigenic determinants which must be "sensed" by the antibody combining sites. Most antibody combining sites seem to accommodate 6–12 amino acid residues[32]. The smallest antigenic determinant is trialanine attached to a carrier protein[32d]; however, contributions from a more distant part of the carrier protein (not directly bound to the trialanine) to the antigenic determinant cannot be ruled out.

If foreign nucleic acids are to be discerned from endogenous ones containing only four monomeric units, the number of antigenic determinants should be approximately twice as large, *i.e.* $n \gtrsim 18$–25 monomeric units. Alternatively, the organism should not develop antibodies against nucleic acids made up of the usual four bases, which in fact seems to be the case.

Structure-affinity relationships concerning antibody eliciting haptens and similar molecules are discussed in great detail by *Pressman* and *Grossberg*[4]. The importance of conformation for antigen-antibody interaction was demonstrated by *Sela*[18]. Thus the α-helical polypeptide $(Tyr\text{-}Ala\text{-}Glu)_n$ elicits an antibody which gives no cross reaction with polylysine acylated at the ε-amino groups with the Tyr-Ala-Glu tripeptide



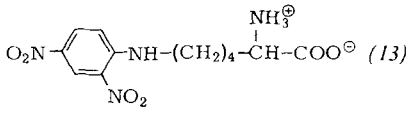


Fig. 3. α-Helical polypeptide $(Tyr\text{-}Ala\text{-}Glu)_n$ *(11)* and the antigen *(12)* obtained by coupling Tyr-Ala-Glu residues to ε-amino groups of poly-L-lysine (schematic).

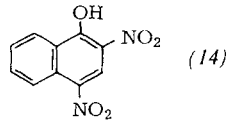
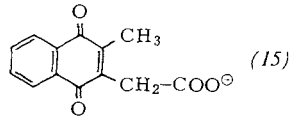


which is nonhelical under these conditions (Fig. 3). Reciprocal non-cross reactivity was also demonstrated. The oligopeptide $(Ala\text{-}Tyr\text{-}Glu)_n$ begins to react with the above mentioned anti-α-helical antibody at $n = 7$, although the peptide as such is not α-helical in solution. The antibody probably forces the antigen into an α-helical conformation[33a]. The reciprocal rela-

tion between the net charge of the immunogenic macromolecules and that of the elicited antibodies was also demonstrated by *Sela*[33b].



Completely synthetic antigens were also obtained[33c]. It appears that a minimum molecular weight is required for antigenicity: dinitrophenyl-(L-Lys)$_n$ becomes antigenic for guinea pigs only for $n \geq 7$.

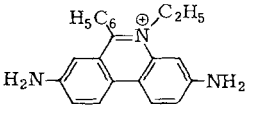
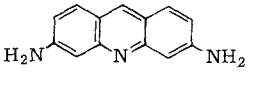
Fig. 4. Molecules which bind to the MOPC-460 myeloma protein: N^{ϵ}-(2,4-dinitrophenyl)lysine, *(13)*; 2,4-dinitronaphthol, *(14)*; Menadione, *(15)*. Molecules which do not bind to the protein: 8-anilino-1-naphthalenesulfonate, *(16)*; N^{ϵ}-(*p*-toluenesulfonyl)lysine, *(17)*.



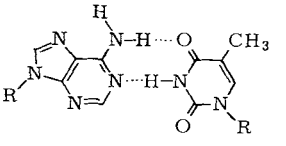
For oligopeptidic haptens and their derivatives obtained by amino acid substitutions, correlation of affinity decrease (towards the elicited antibody) with differences in intermolecular force parameters [in the sense of eq. (9)], yields a correlation coefficient $r \approx -0.75$[28]. An interesting example of specificity determined by intermolecular forces is provided by the affinity of the mouse myeloma proteins MOPC-460 and MOPC-315 for various small molecules (Fig. 4). The former protein strongly binds ($K \approx 10^{-4}$ mol/l) various aromatic nitro derivatives and quinones, *i.e.* molecules with an electron accepting character in charge transfer complexes (ACT); no detectable binding occurs with other aromatic molecules having similar steric structure but lacking this property (for example aromatic amines[34a-34c]). Spectral studies suggest that the combining sites of these immunoglobulins contain two tryptophan residues which form charge transfer complexes with aromatic nitro derivatives[34d].

4.2. Repressor-Operator Interactions



The best studied system in the field is the *Escherichia coli* lac operon. The repressor-operator binding is a simple association equilibrium with the dissociation constant $K \approx 10^{-13}$ mol/l[35a]. The *E. coli* chromosome consists of $N = 4.5 \times 10^6$ base pairs, or about the same number of short overlapping oligonucleotide sequences. An 300-fold excess of *E. coli* DNA without operator gene does not compete detectably with the operator for the repressor[35b], *i.e.* $p_f \approx 10^{-3}$. Point mutations in the lac operator decrease the affinity for the repressor by a factor of 8 to 1000[35d]. The mean affinity decrease per base pair substitution is thus $\Delta g \approx 2.0$ kcal/mol; from eq. (12) $\nabla \approx 7$. As there are $\alpha = 4$ types of base pairs, eq. (14) requires $n \gtrsim 27$ base pairs for the lac operator gene[36]. A calculation by *Sadler* and *Smith*[35e] based upon an assumed binomial distribution of oligonucleotides as compared to the operator segment gives $n = 18$ base pairs. According to an experimental study by *Gilbert* and *Maxam*[37], the lac operator gene comprises about 27 base pairs. *Maniatis* and *Ptashne*[38] indicate a length of about $n = 35$ base pairs for the λ-bacteriophage operator gene unit. Six such identical units are present in the complete operator gene, and the specificity requirements must be the same as for the lac repressor-operator system: the λ-bacteriophage repressor is coded by a permanent gene of the *E. coli* genome.

Binding of the *E. coli* lac repressor to the operator does not imply an unwinding of the DNA. Its dependence upon the ionic strength indicates an charge product of -6 electronic units for the interaction of the two partners[35c]. The primary structure of the lac operator gene, which was deciphered by *Sadler* and *Smith*[35] and by *Gilbert* and *Maxam*[37], presents some interesting symmetries. The primary structure of the lac repressor was also sequenced by *Müller-Hill et al.* and *Beyreuther et al.*[39]. A structural model was proposed for the specific interaction of the double helix DNA of the operator and the sequence of the amino end of the repressor, which presumably has an α-helical structure[39]. This space filling model is based on specific hydrogen bonds between amino acid residues and corresponding groups on the bases and phosphate groups in the deep groove of the DNA. However, according to *Weber et al.*[40], a mutated repressor, whose hydrogen bonding ability for the operator should be lowered according to the model, does not display a markedly decreased affinity.



Aromatic molecules are intercalated fairly easily in the DNA double helix by stacking according to the principle of maximum overlap[41a]. Ethidium bromide or proflavin are readily incorporated into the DNA double helix with an uncoiling of only 12° per intercalation[41b] (Fig. 5). Polyadenine binds very readily to tryptophan which contains an aromatic ring of the same shape and size as purine, less so phenylalanine and histidine[41c]. Poly-dAT binds L-Lys-L-X—NH_2 dipeptides with increasing affinity in the series X = leucine < tyrosine < phenylalanine < tryptophan[41d]. Aromatic amino acid

(18)

(19)

(20)

Fig. 5. Ethidium ion *(18)* and proflavin *(19)* and their similarity to the AT base pair *(20)* in DNA.

residues of the repressor may be bonded by stacking in the operator DNA double helix and some preferences may appear due to reciprocal orientations of dipole moments of the aromatic amino acid rings and the neighboring nucleic acid bases[42].

4.3. Specificity in Reactions with Small Molecules

The case of inorganic analytical reagents has already been mentioned. A typical reagent for cations is ethylenediaminetetraacetic acid (EDTA, Fig. 1). It can specifically complex Ca^{2+} ions in a mixture of alkali metal and alkaline earth ions and is thus suitable for titrimetric determinations. The dissociation constant of $[CaEDTA]^{2-}$ is 2.58×10^{-11} mol/l, and that of $[MgEDTA]^{2-}$ 2.04×10^{-9} mol/l[13,43]; hence a hundredfold excess of Mg^{2+} ions must be present to compete successfully for this complexon. Compared with repressor-operator or antigen-antibody interactions, this specificity is low although sufficient for analytical chemistry.

The substrate specificity of catalytic reactions is also low compared with interactions between biological macromolecules. For example, the activation energies for dehydration of various alcohols over Al_2O_3 at 350 °C are 20.2, 18.3, and 16.4 kcal/mol for ethanol, 1-propanol, and isobutanol respectively[43]. The specificity of a catalyst may be higher: the relative rates of hydrogenation of the ethylenic double bond over Rh, Pd, Pt, and Fe catalysts are approximately 1000:100:10:1 although the interatomic distances increase by less than 0.1 Å in this series of catalysts[43].

The structural features bearing upon substrate-inhibitor-enzyme interactions in enzymatic reactions have been discussed at length by *Webb*[44]. We shall first consider the binding affinity to the catalytic site of the enzyme and the transformation rate of the bound molecule. Molecules exhibiting high affinity and low transformation rate will be competitive inhibitors. In enzymatic elimination of the *p*-nitrophenyl group from the series of amino acid derivatives

$$C_6H_5{-}CH_2{-}O{-}CO{-}NH{-}CHR{-}CO{-}O{-}C_6H_4{-}NO_2$$

by hydrolysis with chymotrypsin, the D-phenylalanine derivative has the highest binding constant ($K = 3.8 \times 10^{-7}$ mol/l; L-Phe derivative $K = 4.5 \times 10^{-7}$ mol/l), the L-phenylalanine derivative the highest transformation rate ($k_3 = 39\,s^{-1}$; D-Phe derivative $k_3 = 0.18\,s^{-1}$). The second order rates V at low substrate concentration are 8.1×10^6 l mol^{-1} s^{-1} for the L-derivative and only 4.8×10^4 l mol^{-1} s^{-1} for the D derivative. Some other L amino acid derivatives give $V = 3.5 \times 10^6$ for the Trp derivative, 2.5×10^4 for the Asn derivative, and 3.1×10^4 l mol^{-1} s^{-1} for the norvaline derivative[20].

The specificity of enzymatic reactions is also low in comparison with the interactions between macromolecules. Thus iodoacetate (ICH_2COO^-), considered as a specific inhibitor of glyceraldehyde dehydrogenase, also inhibits at least 55 other enzymes and a 10^{-3} M concentration of trivalent arsenic compounds—specific inhibitors of keto acid oxidation—also inhibits another 52 enzymes[44]. The specificity requirements placed upon enzymatic reactions within the cell are likewise much lower than those found for antigen-antibody or repressor-operator interactions: the number of small molecules within the cell from which an enzyme must recognize the correct partner is certainly not higher than $n = 10^3$, while an error threshold $p_f = 0.01$ is probably also sufficient[9c].

A very low error threshold is required in DNA replication: the frequency of point mutations (false base incorporation) is 10^{-8}—10^{-11} per base pair and replication[45]; but the DNA-replicase system only has to discern the correct partner among the $N = 4$ deoxyribonucleotides available. The replicase system can be easy "tricked" by base analogs as bromouridine or azaguanine, which are incorporated with high frequency in replicating DNA. According to eq. (12), an error threshold $p_f = 10^{-8}$—10^{-11} and $N = 4$ requires an affinity difference of $\Delta G \approx 11$—16 kcal/mol, which cannot be explained solely by differences in complementary hydrogen bonding in base pairs. A hypothetical explanation for the high precision of replication was proposed by *Kubitscheck* and *Henderson*[46]: the molecular region implied in recognition is larger than the complementary hydrogen bond forming groups of the base pair. The replicase should also sense the groups in positions 5 and 6 of pyrimidine and 6 and 7 of purine.

5. Conclusions. Forecasting of Structures with Particular Biological Activity

The search for substances possessing a desired biological activity is as old as medicine itself. The extensive systematic work performed in our century has been very successful although the theoretical basis may have been rather sparse. *Ehrlich*'s Salvarsan (Fig. 1) was the result of a search on several hundred substances; the idea was probably based on the observation of specific staining of bacteria by certain azo dyes and that the introduction of arsenic renders substances toxic (for other examples see ref.[47]).

Examples may also be given of very extensive but not very successful searches, *e.g.* the testing of the perhaps hundreds of thousands of compounds listed in "Cancer Screening Data", and the not very impressive results of cancer chemotherapy. Principles for guiding such research, even if only of probabilistic value, are thus badly needed. The studies by *Cammarata*[16] and *Hansch*[26] already mentioned are on these lines.

A principle which does not seem to be very widely recognized is the need for a minimum molecular size for a high specificity. Drugs such as sulfonamides block some enzymes of bacteria which differ significantly from their mammalian counterparts; even if these drugs combine with several proteins of the mammalian cell, this may have no dramatic biologic effect. Cancer—as suggested especially by the viral theories—resides in some defect within the genome, perhaps in some viral oncogens incorporated in the host genome. Drugs against various cancers should thus have a specificity comparable with the repressor proteins[48], and it is rather hopeless to search for some simple molecule which could adequately fulfill this task. With macromolecules, the number of possible combinations reaches astronomical figures and it will certainly be very difficult to develop a strategy for search in this case. Problems of strategy also appear in searches for structures with a given biological activity in the area of antibacterial drugs, pesticides, plant growth stimulators, *etc.* Equations of the type (5)—(9) may indicate, for the given class of compounds, what sort of substitution (hydrophobic groups, electron attracting groups, *etc.*) favors the desired type of biological activity. If second power terms are included, one can also indicate optimal values for the corresponding structural parameters (optimal hydrophobicity, optimal electronegativity, *etc.*).

Another search strategy is based on the *Free* and *Wilson* model[49]. In this model, the biological activity is considered as the sum of contributions from molecular segments which may contain different substituents. Taking a certain minimum number of biological activities, the effects of the substituents in the different segments are calculated and one can predict, within the given set of segments and substituents, which molecule should be the most active.

Several classes of desired biological effects can be achieved with a large number of compounds which often vary considerably in their chemical structure. The amount of calculation involved in using such large series of data in forecasting the optimal chemical structure may impose computerization. Pertinent search strategies recently proposed by *Hiller et al.*[50] are based either on a perceptronic, a logico-structural, or a topographic algorithm. Some tests on different sets of chemical compounds give an average reliability of 75—80% in predicting active and non-active compounds, respectively. One problem of such computerized search methods is that of finding an adequate "catalog" of structural parameters for characterizing the compounds.

At present the methods of forecasting structures with a desired biological activity give satisfactory results only within classes of compounds possessing similar chemical structures. The high requirements of specificity in certain cases impose the use of molecules of increasing size and complexity, as illustrated by the last decade's antibiotics. This leads to an enormous increase in the number of compounds be tested; their synthesis would also be extemely time consuming. Hence more knowledge about structural parameters determining biological activity and specificity is badly needed.

trans-Benzocyclononatetraenyl Anion[**]

By *A. G. Anastassiou* and *E. Reichmanis*[*]

The benzocyclononatetraenyl anion *(1)* was recently prepared in our laboratories and was shown to be strongly diatropic by NMR[1]. Despite its obvious aromatic character however, the molecule *(1)* is thermally labile, undergoing clean thermal isomerization on prolonged standing at ambient temperature. Presently, we should like to relate out experience along these lines.

On warming at 56 °C, in liquid ammonia, *(1)* undergoes clean unidirectional isomerization with $k=(2.56\pm0.22)\times10^{-5}\,s^{-1}$, ($\Delta G^{\neq}=26.2$ kcal/mol). The thermolysis product was securely characterized as *(2)* by careful analysis of its nuclear magnetic resonance spectrum[2] featuring, in particular, a high-field ($\tau=12.35$) strongly coupled ($J=16.0$ Hz) doublet. This key resonance unmistakably implicates the presence of a strongly shielded "inner" proton bound to a *trans* bond and located adjacent to the ring juncture. The remainder of the spectrum is also seen to be consistent with structure *(2)*. Specifically, we draw attention to the relatively small coupling constants associated with the C—H bond directly linked to the *trans* function, *i.e.*, $J_{9,10}=5.0$ Hz and $J_{9,8}=8.5$ Hz, which clearly reflect the regional reduction of effective ring size due to the presence of the *trans* bond. By contrast, *all* nonbenzylic protons in the spectrum of the all-*cis* counterpart *(1)* are associated with the same large coupling constant ($J=12$ Hz)[3] whose magnitude is clearly reflective of the wide frame angles expected of a planar all-*cis* nine-membered ring.

Chemically, the molecule was shown to be a benzocyclononatetraenyl anion through its conversion to 5*H*-benzocyclononatetraene *(3)* on exposure to moist ether. It is interesting to note in this connection that *(3)* is the only benzocyclononatetraene formed (>90%) from *(2)* irrespective of whether quenching was effected under conditions of thermodynamic or kinetic control. Very likely the high regioselectivity of this protonation results largely from the molecule's tendency to rid itself of the added strain introduced by the *trans* function.

(1) *(2)* *(3)*

The question now arises as to why the anion *(1)* undergoes *cis*→*trans* isomerization. At first glance, this transformation emerges as all the more puzzling in light of the well documented affinity of the parent, *i.e.*, the cyclononatetraenyl anion, to undergo the reverse process, *i.e.*, *trans*→*cis* isomerization, when warmed to ambient temperature[4]. Closer scrutiny does however reward one with a rational explanation for the *(1)* to *(2)* isomerization. Briefly, it is seen that *(1)*, unlike its parent, is plagued by a pair of *peri* H—H interactions about the juncture which ought to be quite severe for a molecule of its size[5] and thus potentially damaging to the preservation of planarity. Obviously, the molecule may relieve the steric congestion introduced by the *peri* interaction in one of two ways, (i) it may distort, thus *partially* relieving both sets of H—H repulsions and (ii) it may undergo *cis*→*trans* isomerization of a double bond carrying one of the *peri* hydrogens, thus *completely* removing one set of H—H repulsions while preserving the other. Not unexpectedly, the molecule shows preference for the second alternative since only in this manner is it able to preserve its planarity and thus its aromaticity.

Conformational Studies on Aza and Thia Derivatives of 12,13-Dihydro-11*H*-dibenzo[*a*,*e*]cyclononene

By *W. David Ollis* and *J. Fraser Stoddart*[*]

The recognition[1,2] that many heterocyclic "6, 8, 6" systems *(1)* exist in solution in diastereomeric Chair[3] and Boat[3] conformations has encouraged us to examine related "6, 9, 6" systems *(2)*.

(1)

(2a), X = CH_2
(2b), X = NCH_3
(2c), X = $NCH_2C_6H_5$
(2d), X = S

The *N*-benzyl derivative 12-benzyl-12,13-dihydro-11*H*-12-azadibenzo[*a*,*e*]cyclononene *(2c)* (m.p. 109—111 °C) was prepared following the known route[4] to the *N*-methyl derivative *(2b)* using a Stevens rearrangement followed by a Hofmann elimination. The thia derivative *(2d)* (m.p. 101—103 °C) was synthesized by the sequence: (i) photochemical transformation of *trans*-2,2'-stilbenedimethanol[5] into the *cis*-isomer (m.p. 113—114 °C), (ii) conversion with PBr_3 into the *cis*-2,2'-bis(bromomethyl)stilbene (m.p. 125—127 °C), and (iii) ring closure with Na_2S—MeOH to *(2d)* (m.p. 101—103 °C).

The temperature-dependent ^{1}H-NMR spectra (Table 1) shown by the aza derivative *(2b)* are typical for this class of substances

		+40	6.16 (AB1)	A1⇌B1	15.5	C⇌C*		

[a] Sites are designated (A) and (B) for uncoupled two-site systems; sites that represent two time-averaged signals are designated (AB). Sites are designated (A1), (B1), (A2), and (B2) for four-site systems where there is coupling in the form of two AB systems. Sites that represent two time-averaged signals are designated (AB1) [average of (A1) and (B1)] and (A12) [average of (A1) and (A2)] *etc.*

and demonstrate that two diastereomeric conformations are populated in solution. At low temperatures the 11-CH_2 and 13-CH_2 protons give (i) an AB system assignable to a relatively rigid conformation and (ii) a singlet associated with a rapidly inverting conformation. Increase in temperature results first of all in a coalescence of the AB system and the singlet followed by further coalescence finally yielding a sharp singlet. The two processes [*(2b)*, see Table 1; $\Delta G^{\neq}$ = 15.4—15.9, and 16.3 kcal/mol, respectively] have been subjected to line shape analysis[1].

Conformational analysis and strain energy calculations direct attention to five particular conformations: (1) A relatively rigid chair conformation [C, *(3)*, C_s symmetry], (2) a boat conformation [B, *(4)*, C_s symmetry], (3) a twist-boat conformation [TB, *(5)*, C_2 symmetry], (4) asymmetric distorted-boat conformation [DB, *(6)* and *(7)*], and (5) a transition state conformation [TS, *(8)*, C_s symmetry]. Strain energy calculations demonstrate that the C *(3)* and DB conformations [*(6)* and *(7)*] correspond to ground state conformations. The conformational itinerary associates the ground state conformations (C, DB1, DB2 and their enantiomeric or degenerate partners C*, DB1*, DB2*) with the transition states (B, TB, TS, and B*, TB*, TS*). This is the general situation for compounds *(2b)*—*(2d)* (Fig. 1).

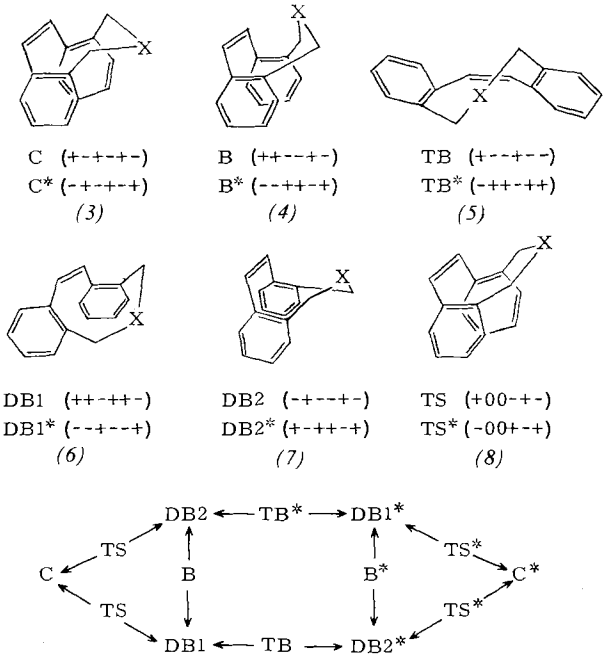

Fig. 1. Conformational changes in the hetero derivatives *(2b)*—*(2d)* of 12,13-dihydro-11*H*-dibenzo[*a*,*e*]cyclononene *(2a)*. The notation [1] for torsional angles refers in turn to the 13a-13, 13-12, 12-11, 11-10a, 6a-6, and 5-4a bonds.

Strain energy calculations show that the DB conformations [*(6)* and *(7)*] lie between[6] the B *(4)* and TB *(5)* conformations on the pseudorotational itinerary associated with all the Boat[3] conformations of the flexible boat family. The identification of the two ground state conformations [observed in the low temperature ^{1}H-NMR spectra of the aza derivatives *(2b)* and *(2c)*] as C and DB illustrates the importance of evaluating temperature-dependent ^{1}H-NMR spectra with collateral strain energy calculations. There is a satisfying correlation between the results observed for the two aza derivatives [*(2b)* and *(2c)*]. The *N*-methyl protons in *(2b)* and the α-protons of the *N*-benzyl groups in *(2c)* provide additional NMR probes and good agreement (Table 1) is attained for the C→Boat interconversions using two independent means of measurement.

Conformational analysis of the thia derivative *(2d)* in association with strain energy calculations showed that the nonbonded interactions between —S— and —CH=CH— would destabilize the DB conformation with respect to the C conformation *(3)* by 4.8 kcal/mol. Its ^{1}H-NMR spectrum showed (Table 1) that only the C conformation *(3)* was observably populated. The observed free energy of activation ($\Delta G^{\neq}$ = 15.5 kcal/mol) for C⇌C* inversion is in very satisfying agreement with the calculated strain energy difference (16.1 kcal/mol) between the C *(3)* and TS *(8)* conformations.

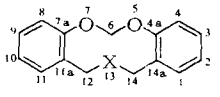
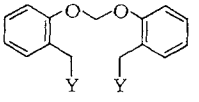
Conformational Studies on Aza and Thia Derivatives of 6,11,12,13-Tetrahydro-5*H*-dibenzo[*a*,*e*]cyclononene and 5,6,7,12,13,14-Hexahydrodibenzo[*a*,*f*]cyclodecene

By *W. David Ollis* and *J. Fraser Stoddart*[*]



The examination[1] of the conformational behavior of the nine-membered ring olefins *(1)* has been extended to include the corresponding "6,9,6" systems *(2)* and "6,10,6" systems *(3)*. In comparison with compounds of type *(1)*, compounds *(2)* and *(3)* show a completely different kind of behavior.



(1a), X = NCH_3
(1b), X = $NCH_2C_6H_5$
(1c), X = S

(2a), X = NH
(2b), X = NCH_3
(2c), X = $NCH_2C_6H_5$
(2d), X = $NCOCH_3$
(2e), X = S
(2f), X = SO_2

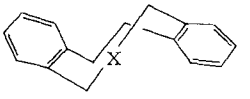
(3a), X = NCH_3
(3b), X = $NCH_2C_6H_5$
(3c), X = S
(3d), X = SO_2

(4a), Y = Br
(4b), Y = OH

The compounds *(2a)*—*(2f)* were prepared by standard methods (cf. Ref. [2]) from 1,2-bis(bromomethyldiphenyl)ethane[3]. Similarly, the dibromide *(4a)* (m.p. 125—127 °C), prepared (PBr_3) from the diol *(4b)*[4] gave the compounds *(3a)*—*(3d)*. It has been stated[2] that the room temperature ^{1}H-NMR spectrum of the secondary amine *(2a)* indicates that this compound has "a freely rotating ring system". We can be rather more explicit in our description of the conformational properties of the "6,9,6" systems *(2)* on the basis of the following results (Table 1).

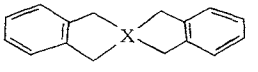
Table 1. Properties, ^{1}H-NMR spectral parameters (100 MHz) in $CDCl_3$—CS_2 (1:1), and free energies of activation for ring inversion (C_2 chair $\rightleftarrows$ C_2 chair*) in the compounds of type *(2)* and *(3)* (T_c = coalescence temperature, $\nu_A - \nu_B$ = difference of the chemical shifts of H^A and H^B protons).

Compound	M.p. [°C]	Group	$\nu_A - \nu_B$ [Hz]	J_{AB} [Hz]	T_c [K]	ΔG^* at T_c [kcal/mol]
(2b)	63—65	11-CH_2, 13-CH_2	20.5	13.5	214	9.8
(2c)	108—110	*N*-α-benzyl	68.0 [a]	12.5 [a]	217 [a]	10.4 [a]
(2d) [b]	143—145	11-CH_2, 13-CH_2 [c]	230.0	13.5	215	9.8
			76.0	14.5	208	9.9
(2e)	110—111	11-CH_2, 13-CH_2	25.8	13.5	231	11.3
(2f)	220—221	11-CH_2, 13-CH_2	23.1	13.8	288	13.7
(3a)	oil [d]	12-CH_2, 14-CH_2	75.4	13.5	227	10.8
(3b)	95—97	*N*-α-benzyl	53.6	12.5	231	11.1
		12-CH_2, 14-CH_2	68.6	13.7	237	11.3
(3c)	103—104	12-CH_2, 14-CH_2	74.0	14.8	223	10.6
(3d)	239—240	12-CH_2, 14-CH_2	112.0	14.3	277	13.1



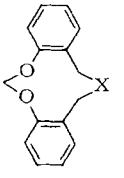
[a] Spectral parameters for the 11,11,13,13-tetradeuterio derivative since the protons H^{11} and H^{13} resonate with almost the same chemical shift as the *N*-α-benzyl protons.

[b] In CS_2.



[c] The 11-CH_2 and 13-CH_2 groups in the amide are diastereotopic [5], and hence give rise to two AB systems, because of slow amide bond rotation in the temperature range where ring inversion is observed (cf. Ref. [10]).

[d] B.p. 120—130 °C at 0.05 torr.



At low temperatures, the ^{1}H-NMR spectra of the compounds *(2b)*, *(2c)*, *(2e)*, and *(2f)* show a *single* AB system associated with either homotopic or enantiotopic[5] 11-CH_2 and 13-CH_2 groups. This requires that the observable ground state conformation must have either C_2 or C_s symmetry. A decision between these two possibilities is provided by the ^{1}H-NMR spectrum of the *N*-benzyl derivative *(2c)*, where below −50 °C, the α-benzyl protons are demonstrably diastereotopic[5]. Clearly, the ground state conformation must have C_2 symmetry leading to either a C_2 chair *(5)* or a C_2 twist-boat *(6)* as the only two possibilities[6]. Discrimination in favor of the C_2 chair *(5)* as the preferred conformation for the "6,9,6" systems *(2)* was shown by strain energy calculations on the sulfide *(2e)*[7]. Extrapolation to the other cases is justifiable.

C_2-chair (+−−+−+−)
C_2-chair* (−++−+−+)
(5)

C_2-boat (+−−++−+)
C_2-boat* (−++−−+−)
(6)

C_2-chair (−++−+−−+)
C_2-chair* (+−−+−++−)
(7)

We conclude that the magnitudes ($\Delta G^* = 9.8$—11.3 kcal/mol) of the free energies of activation for the ring inversion process (C_2 chair $\rightleftarrows$ C_2 chair*) for *(2b)*—*(2e)* are entirely in accord with a process involving torsion about single bonds. This is in contrast with the much higher values[1] ($\Delta G^* = 15.5$—16.3 kcal/mol) for the olefinic "6,9,6" systems *(1a)*—*(1c)* where angle strain is undoubtedly an important contributor in the transition state. The relatively high value ($\Delta G^* = 13.7$ kcal/mol) for the sulfone *(2f)* is mainly due to the much larger steric requirements of the SO_2 group in a torsional process.

The "6,10,6" systems *(3)* show entirely analogous behavior (Table 1). Compounds *(3a)*, *(3c)*, and *(3d)* all exhibit sharp singlets for their dioxymethylene protons at low temperatures.

[*] Prof. Dr. W. D. Ollis and Dr. J. F. Stoddart
Department of Chemistry, The University
Sheffield S3 7HF (England)

This observation is consistent with conformations having C_2 symmetry. For the *N*-benzyl derivative *(3b)* two AB systems, one for the 12-CH_2 and 14-CH_2 ring protons, and the other for the α-benzyl protons, are observed at low temperatures. Thus, the ground state conformation must have C_2 symmetry. The ^{1}H-NMR spectral changes (Table 1) indicate that inversion involving one observable conformation is clearly taking place and the ground state conformation which has been selected is the C_2 chair *(7)*[8]. Strain energy calculations have not been carried out because of the problems presented by several heteroatoms. However, the C_2 chair conformation *(7)* matches that selected by conformational analysis for monocyclic *cis-cis*-1,6-cyclodecadiene derivatives[9].

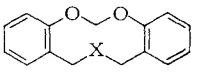
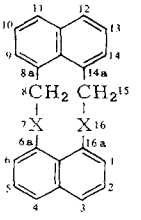
Conformational Studies on Oxa, Thia, and Aza Derivatives of 7,8,13,14-Tetrahydrobenzo[1,2]cyclononа[5,6,7-*de*]naphthalene and 8*H*, 15*H*-7,16-Dioxacyclodeca[1,2,3-*de*:6,7,8-*d'e'*]dinaphthalene

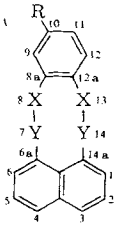
By *David J. Brickwood, W. David Ollis*, and *J. Fraser Stoddart*[*]



Recent results on the definition of the conformational behavior of hydrocarbons and heterocycles belonging to the "6,8,6" *(1)*[1,2], "6,9,6" *(2)*[3,4], and "6,10,6" *(3)*[4] systems by variable temperature ^{1}H-NMR studies and collateral strain energy calculations have encouraged the development of various complementary studies. These include the synthesis and examination of compounds *(4)* and *(5)*, in which an *ortho*-annelated benzene ring of *(2)* [cf. also *(1)* and *(3)*] is replaced by a *peri*-annelated naphthalene residue.



(1)



(2)

(3)

(6a), X = CH_2
(6b), X = O

(4a), R = H; X = CH_2; Y = CH_2
(4b), R = H; X = O; Y = CH_2
(4c), R = Me; X = O; Y = CH_2
(4d), R = H; X = S; Y = CH_2
(4e), R = Me; X = S; Y = CH_2
(4f), R = H; X = NMe; Y = CH_2
(4g), R = H; X = NTs; Y = CH_2

(5), R = H; X = CH_2; Y = O

In the heterocycles *(4b)*, *(4c)*, *(4f)*, *(4g)*, and *(5)*, we have observed (Table 1) an AB system at low temperatures for the ring methylene protons which coalesces to a sharp singlet at higher temperatures. This observation may be interpreted (Fig. 1) in terms of a ring inversion process involving conformations in which the methylene groups are related either by C_s symmetry [chair C *(7)* or boat B *(8)*] or by C_2 symmetry [twist-boat TB *(9)*]. Conformational analysis indicates that the *peri*-interaction between the methylene groups of the ring in the C *(7)* and B *(8)* conformations in compounds *(4b)*—*(4g)* is particularly large. This steric interaction is partially relieved in the TB conformation *(9)*; the principal nonbonded interactions in *(4b)*, *(4c)*, *(4f)*, and *(4g)* are between the methylene groups of the ring and the heteroatoms (X = O, NR'). We therefore propose that the TB conformation *(9)* is the ground state conformation observed and that ring inversion involves a TB⇌TB* pseudorotational process (Fig. 1). Three observations support this proposal: *(i)* The magnitude of the chemical shift differences ($\nu_A - \nu_B$) for the 7-CH_2 and 14-CH_2 protons is found (Tables 1 and 2) to depend significantly upon the nature of the ring heteroatoms. There are a number of examples[5] of van der Waals interactions between heteroatoms and proximate protons which lead to deshielding of the proton involved. The expectation[6] that the deshielding

Table 1. ^{1}H-NMR spectral parameters (100 MHz) and free energies of activation for ring inversion (TB⇌TB*) in compounds *(4b)*, *(4f)*, *(4g)*, *(5)*, and *(6b)* (T_c = coalescence temperature).

Compound	M.p. [°C]	Solvent	Prochiral group	$\nu_A - \nu_B$ [Hz]	J_{AB} [Hz]	T_c [K]	$\Delta G^{\neq}$ at T_c [kcal/mol]

[a] Sites are designated (A) and (B) for uncoupled two-site systems; sites that represent two time-averaged signals are designated (AB). Sites are (A1), (B1), (A2), and (B2) for four-site systems where there is coupling in the form of two AB systems. Sites that represent two time-averaged signals are designated (AB1) [average of (A1) and (B1)] and A12 [average of (A1) and (A2)] *etc.*

[b] $\nu_{A1} - \nu_{B1} = 121$ Hz.

influence of heteroatoms will be related to their polarizabilities is also fulfilled by the data recorded in Tables 1 and 2; *(ii)* when the heteroatoms are both sulfur as in *(4d)* and *(4e)*, then transannular nonbonded interactions with the methylene groups of the ring destabilize the TB conformation *(9)* sufficiently to permit the observation of approximately 20% of a second conformation at low temperatures (Table 2). This minor conformation is presumably the C conformation *(7)*; *(iii)* the fact that the free energies of activation for the dithionins [*(4d)* and *(4e)*] and diazonins [*(4f)* and *(4g)*] are larger than those for the dioxonins [*(4b)* and *(4c)*] is consistent with the pseudorotational process shown in Figure 1, where the folded-boat (FB) conformations [*(10)* and *(11)*] correspond to the transition states. The main component of strain in these FB transition states must arise from nonbonded interactions between the methylene groups of the ring and the heteroatoms (X = O, S, NR').

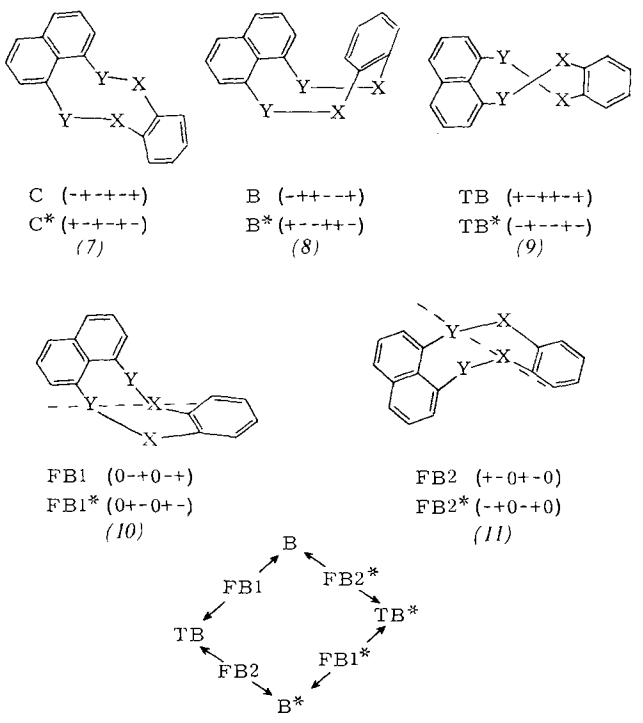

Fig. 1. Conformational changes in compounds *(4b)*, *(4c)*, *(4f)*, *(4g)*, and *(5)*. The notation [1] for torsional angles refers in turn to the 6a-7, 7-8, 8a-8, 12a-13, 13-14, and 14-14a bonds.

Similar considerations of chemical shift differences between the diastereotopic methylene protons (H^A and H^B) and the values of the free energies of activation for ring inversion (Table 1) in the dioxonin *(5)*, and in the dioxecin *(6b)*, also lead to very similar conclusions. The conformational itinerary of compounds *(5)* and *(6b)* also involve ring inversion (TB⇌TB*) between enantiomeric twist-boat conformations.

A Heptalene Synthesis from 1,6-Methano[10]annulene; Evidence for a Fast π-Bond Shift

By *Emanuel Vogel, Heinrich Königshofen, Jürgen Wassen, Klaus Müllen*, and *Jean F. M. Oth*[*]

Heptalene *(1)*, which like its homolog pentalene[1] has long been the subject of theoretical study, was synthesized by *Dauben* and *Bertelli*[2] in 1961. However, it remained poorly accessible and to this day the bonding of the hydrocarbon has still not been thoroughly characterized by experimental means. Recent quantum mechanical calculations[3] indicate that the heptalene structure having delocalized π-bonds (D_{2h} molecular symmetry) is destabilized by comparison with the structure possessing alternating bonds (C_s symmetry). By ana-

logy with the situation observed in [4*n*]annulenes[4], *(1)* was therefore expected to display the phenomenon of a fast π-bond shift.

(1) *(2)*

Our latest studies on the [4*n*]annulene 1,7-methano[12]annulene *(2)*[5], which is derived from heptalene by insertion of a CH_2 group into the 1,7-bond, prompted us to reconsider the question of the bonding in *(1)* and to undertake detailed chemical and spectral comparisons between the two 12π-electron systems. We have now found an improved entry to *(1)* and succeeded in detecting the fast π-bond shift postulated for *(1)*.

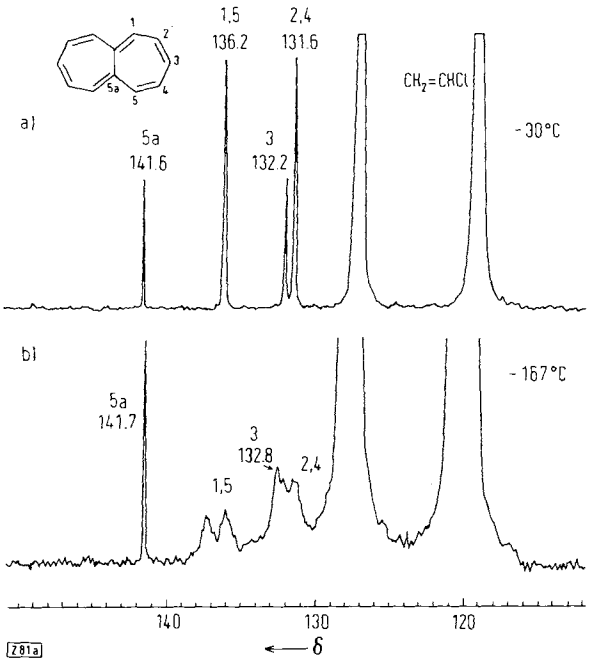
The new heptalene synthesis starts from 1,6-methano[10]annulene *(3)*[6]. As already reported[7], $(CuCl)_2$-catalyzed reaction of *(3)* with diazomethane affords bicyclo[5.4.1]-dodeca-1(11),2,4,7,9-pentaene *(4)*, a product of isomerization of the cyclopropane hydrocarbon formed by CH_2 addition to the 1,2-bond of *(3)*, alongside tetracyclo[5.4.1.0.$0^{2,4}$]dodeca-5,8,10-triene[8]. If *(4)* is subjected to pyrolysis at 400 °C *(in vacuo)* in a pyrex tube filled with quartz chips, a mixture of dihydroheptalenes is formed which contains *(5)* and its C_{2h}-symmetry isomer as principal components. Tetracyclo[5.4.1.0.$0^{2,4}$]dodeca-5,8,10-triene, too, furnishes dihydroheptalenes under the above pyrolysis conditions. Thermal isomerization of the two hydrocarbons clearly proceeds *via* a Berson-Willcott rearrangement[9]. The dihydroheptalene mixture cleanly affords heptalene *(1)* on Dauben dehydrogenation[2]. The hydrocarbon, which displays a pronounced tendency to undergo polymerization and for which no physical constants were previously known, was obtained as brownish red crystals having m.p. 10—12 °C (platelets from methanol).

(3) *(4)* *(5)*

(1) *(1')*

The ^{1}H-NMR spectrum of *(1)*, not formerly investigated for temperature dependence[10], displays an AA'BB'C system corresponding to a heptalene structure with D_{2h} molecular symmetry[11]. No decision can be reached from the observed spectral type whether the π-bonds of *(1)* are delocalized or localized and subject to fast fluctuation.

The ^{13}C-NMR spectrum of *(1)* recorded at −30 °C (Fig. 1a) contains four signals of relative intensity 2:4:2:4, thus demonstrating D_{2h} symmetry in accord with the ^{1}H-NMR spectrum. Signal assignment followed from the ^{13}C—H coupling constants and from the way in which the spectrum changes with temperature. The existence of a fast π-bond shift in *(1)* should be manifested in a splitting of the C^1/C^5 and C^2/C^4 signals into two peaks each on lowering of the temperature, *i.e.* by a change from the 4-line to a 6-line spectrum. The pertinent signals do indeed exhibit gradual broadening below −120 °C, but a further drop in temperature to −160 °C (coalescence) is required for the expected splitting to occur. Remarkably, even at −167 °C, the lowest temperature reached, a certain exchange broadening is still to be observed (Fig. 1b). This ^{13}C-NMR finding constitutes the first experimental proof of the theoretically required bond alternation in heptalene and of a fast π-bond shift corresponding to *(1)*⇌*(1')*.



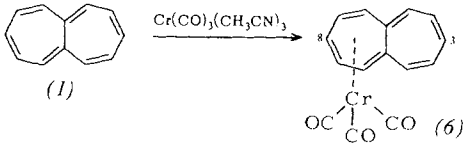


Fig. 1. ^{1}H broad band decoupled ^{13}C-NMR spectra of heptalene *(1)* at a) −30 °C and b) −167 °C [in vinyl chloride/dichloromethane (5:1) with TMS as internal standard].

An activation energy of about 3.5 kcal/mol could be established for the π-bond shift by line shape analysis of the spectra in the temperature range −130 to −167 °C and evaluation of the resulting rate constants according to the Arrhenius equation. Surprisingly, this value is considerably lower than would be expected from the destabilization energy of 12 kcal/mol[3] calculated for heptalene with D_{2h} symmetry[12].

(1) *(6)*

Treatment of heptalene *(1)* with tris(acetonitrile)tricarbonylchromium in tetrahydrofuran (room temperature; 1 h) affords the tricarbonylchromium complex *(6)*[13] [blackish brown platelets from hexane; m.p. 110 °C (dec.); yield 70%] which is stable in the crystalline state; treatment with bis(2-aminoethyl)amine regenerates the hydrocarbon. Although the ^{1}H-NMR spectrum of *(6)* is relatively complicated, double resonance experiments[14] clearly indicate a proton ratio of 1:2:2:2:2:1. Hence the complex must possess C_s symmetry (plane of symmetry through C^3, C^8, and Cr). Nothing can yet be said about the way in which this symmetry arises, particularly since no evidence has yet been found for temperature dependence of the NMR spectrum.

Reduction of *(1)* with lithium in tetrahydrofuran leads to the aromatic heptalene dianion[15] [NMR (D_8-THF): doublet at τ = 2.6 (H^1, H^5), triplet at τ = 4.4 (H^2, H^4), and triplet at τ = 3.9 (H^3)], which can be regarded as the 14π analog of the pentalene dianion[16].

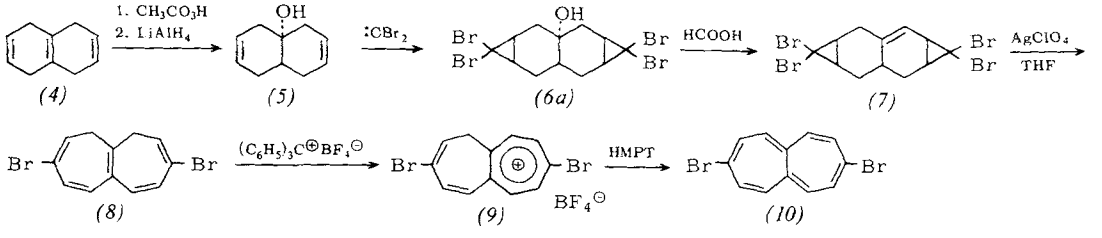
Stable Heptalenes—3,8-Dibromoheptalene

By *Emanuel Vogel* and *Joachim Ippen*[*]

Heptalene [*(1)*, X=H][1,2] and the structurally closely related 1,7-methano[12]annulene [*(2)*, X=H][3] are low-melting polyene hydrocarbons displaying a pronounced tendency to undergo polymerization. For projected X-ray structural investigations on the heptalene and 1,7-methano[12]annulene systems it appeared desirable to have stable crystalline derivatives of the two hydrocarbons at our disposal. Experience from annulene chemistry suggested that little more than symmetrical disubstitution (by halogen, carboxyl, or *tert*-butyl), preferably in positions 3,8 or 4,10, would suffice in the case of heptalene and 1,7-methano[12]annulene to afford compounds having the desired properties. Whereas attempts to prepare symmetrically substituted heptalenes and 1,7-methano[12]annulenes from the parent hydrocarbons have so far remained unsuccessful, compounds of structural type *(1)* and *(2)*[4] have now been obtained by directed syntheses. We shall here describe the preparation of 3,8-dibromoheptalene *(10)*.

(1)

(2)



Our synthetic concept for *(10)* invoked the bis-adducts *(3a)* and *(3b)* of dibromocarbene to the outer double bonds of isotetralin *(4)*, which are inaccessible by direct methods, as key intermediates. It therefore became necessary to protect the central double bond of *(4)* which is more reactive toward dibromocarbene. This was accomplished by converting *(4)* into the known 4a,8a-epoxy-1,4,4a,5,8,8a-hexahydronaphthalene by peracetic acid, and reducing it to the alcohol *(5)* with $LiAlH_4$. Reaction of *(5)* with bromoform (fivefold excess) and 50% aqueous sodium hydroxide by *Mąkosza*'s method[5] yielded a mixture of stereoisomeric bis-adducts from which *(6a)* [m.p. 168—169 °C (dec.); yield 40%] and *(6b)* [m.p. 185—187 °C (dec.); yield 13%] having their three-membered rings oriented *trans-trans* and *cis-trans*[6], respectively, to the OH group could be isolated by fractional crystallization. On heating with anhydrous formic acid, *(6a)* furnished an olefinic product almost quantitatively; the NMR spectrum showed this product to contain 39% of *(3a)* and 61% of *(7)*[7]. Since separation of the two isomers ran into difficulties, the mixture was treated with silver perchlorate in anhydrous tetrahydrofuran (70 °C; 2 h). *(7)* reacted to form dibromodihydroheptalene *(8)*, while *(3a)* surprisingly remained practically unchanged. Isolation of *(8)* [m.p. 118—120 °C (dec.); yield 32%] and *(3a)* [m.p. 180—181 °C (dec.)] was accomplished by chromatography on silica gel (elution with pentane). The ^{13}C-NMR spectrum shows unequivocally, from the non-equivalence of the C atoms of the central double bond, that the dibromodihydroheptalene is *(8)* and not the isomer having through-conjugated double bonds.

Dehydrogenation of *(8)* with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, which has proved of value in the synthesis of 1,7-methano[12]annulene[13], was unsatisfactory. We therefore resorted to *Dauben*'s method[1,8] and converted *(8)* first into

(3a) cis
(3b) trans

the tropylium salt *(9)* (yield 96%) by treatment with triphenylmethyl tetrafluoroborate in dichloromethane (room temperature; 45 min). The best results in the subsequent deprotonation of *(9)* to *(10)* have so far been achieved by stirring the salt at room temperature in hexamethylphosphoric amide (HMPT) for 30 min. After recrystallization from ether, compound *(10)* was obtained as beautiful dark brown crystals (needles) having m.p. 100 °C (dec.) (yield 56%) and which are completely stable to atmospheric oxygen at room temperature.

(4) *(5)* *(6a)* *(7)* *(8)* *(9)* *(10)*

In accord with structure *(10)*, the ^{1}H-NMR spectrum of the compound displays only an AB system at $\tau = 3.74$ and 4.89 ($J = 9.5$ Hz). Since proof of a fast π-bond shift has recently

[*] Prof. Dr. E. Vogel and Dipl.-Chem. J. Ippen
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

been provided by ^{13}C-NMR spectroscopy for heptalene[2], there can be no doubt that the simplicity of the ^{1}H-NMR spectrum of *(10)* is likewise due to a dynamic process of this kind and not to delocalization of the 12π system. The UV spectrum of *(10)* [λ_{max} (cyclohexane) = 250 (ε = 23400 sh), 266 (26350), 356 nm (7200)] shows a slight red shift compared to that of the parent compound, as would be expected from the influence of the bromine substituents.—Detailed studies on *(10)* and other heptalenes derivable therefrom are in progress.

Dimethyl 3,8-Heptalenedicarboxylate

By *Emanuel Vogel* and *Frank Hogrefe*[*]

The synthesis of 3,8-dibromoheptalene[1] suggests that bis-outer adducts of carbenes to isotetralin *(1)*, *i.e.* tetracyclo[5.5.0.0^{3,5}.0^{9,11}]dodec-1(7)-enes, might be generally applicable as starting compounds for preparing heptalenes. While use of dihalocarbenes as carbene components necessitates blocking of the electron-rich central double bond of *(1)*, such a measure is not required on use of the alkoxycarbonylcarbenes which are more reactive and therefore preferentially attack the outer double bonds of *(1)*[2, 3]. From these considerations results a relatively simple entry to dimethyl 3,8-heptalenedicarboxylate.

The reaction of isotetralin *(1)* (0.75 mol) with ethyl diazoacetate (2 mol) in the presence of copper powder (5 g), performed by slow dropwise addition (96 h) of the diazo compound to the isotetralin/copper mixture at 100 °C, afforded a complex product from which a fairly pure 2:1 adduct crystallized after 24 hours' standing; recrystallization from ethanol led to a sterically uniform diethyl tetracyclo[5.5.0.0^{3,5}.0^{9,11}]dodec-1(7)-ene-4,10-dicarboxylate having m.p. 196—197 °C (yield 18 %)[4]. The diethyl ester is readily transformed into the dimethyl ester *(2)* [m.p. 171—172 °C (from methanol); yield 84 %] by alkaline hydrolysis and subsequent esterification of the crude acid with diazomethane. The stereochemistry of *(2)* has not yet been elucidated with regard to the arrangement of the three-membered rings; however, several analogous cases[5] strongly indicate both methoxycarbonyl groups to be in the *exo* position.

Reaction of *(2)* with a 4.5-fold molar amount of *N*-bromosuccinimide (NBS) with addition of azobutyronitrile in boiling carbon tetrachloride (reaction duration 45 min) furnishes a bromination product consisting mainly of the tetrabromide *(3)* (presumably a mixture of stereoisomers), yield *ca.* 55 %. Compound *(3)*, which was not isolated pure, can be smoothly dehalogenated to *(4)* by refluxing with activated zinc dust in tetrahydrofuran. Work-up of *(4)* was by chromatography on a short alumina column (dichloromethane) and recrystallization from *n*-hexane [m.p. 130—132 °C (dec.); yield 60%; UV (cyclohexane): λ_{max} = 230 (ε = 36700), 235 (38600), 296 nm (6100)]. After an initial unsuccessful attempt to dehydrogenate *(4)* to *(5)* *via* the tropylium ion[1, 6], reaction with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in benzene at 160 °C (ampoule; 15 min)[7] led to the desired result. The product *(5)* could be readily isolated by chromatography (silica gel; dichloromethane) and precipitated as brownish red needles on recrystallization from ether; m.p. 142—143 °C (yield 29%). Remarkably, *(5)* is stable to air at room temperature.

The spectral properties of *(5)* largely resemble those of 3,8-dibromoheptalene [60 MHz ^{1}H-NMR spectrum ($CDCl_3$): AB system at τ = 3.30 and 4.82 with J = 10.5 Hz (vinylic protons), singlet at τ = 6.25 (—$COOCH_3$ protons) (intensity ratio 4:3); UV spectrum (cyclohexane) λ_{max} = 262 (ε = 24800), 398 (9700), 547 nm (270, sh)].

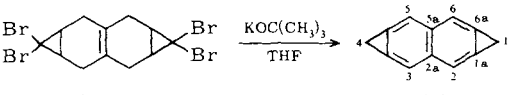
1,4-Dihydrodicyclopropa[*b*,*g*]naphthalene



By *Joachim Ippen* and *Emanuel Vogel*[*]

The cyclopropa-arenes cyclopropabenzene[1-3] and cyclopropa[*b*]naphthalene[4] are relatively stable compounds without pronounced bond fixation, although the presence of the three-membered ring gives rise to extensive strain and distortion of the benzene rings[5,6]. It therefore appeared conceivable that cyclopropa-arenes having more than one three-membered ring might also be capable of existence, *e. g.* 1,3-dihydrodicyclopropa[*a*,*d*]benzene *(1)* and 1,4-dihydrodicyclopropa[*b*,*g*]naphthalene *(2)*. As we found, at least compound *(2)* is isolable.

(1) *(2)*

The *cis-trans* isomeric 4,4,10,10-tetrabromotetracyclo[5.5.0.0^{3,5}.0^{9,11}]dodec-1(7)-enes [*(3a)* and *(3b)* respectively] which we encountered in the synthesis of heptalenes[7] provided us with an opportunity of directly obtaining compound *(2)* by the action of strong bases (*Billups'* method[2]). On treatment of *(3a)* or *(3b)* with a tenfold excess of potassium *tert*-butoxide in tetrahydrofuran (room temperature, 4h), clean dehydrohalogenation does in fact take place, forming the desired compound *(2)* in both cases. The new cyclopropa-arene was obtained after chromatography on alumina (elution with pentane) and subsequent recrystallization from ether as slightly yellow tinted rhombic crystals (yield 30 and 33%, respectively) which undergo explosive decomposition at 132—133 °C. Since the crystals are also sensitive to shock their handling requires caution.

(3a), *cis*
(3b), *trans*

(2)

Proof of the structure of 1,4-dihydrodicyclopropa[*b*,*g*]naphthalene *(2)* follows from the spectra and chemical properties of the compound. The ^{1}H-NMR spectrum shows only two signals at $\tau = 2.41$ and 6.48 (intensity ratio 1:1) and thus corresponds in shape and position of the signals to that expected for aromatic *(2)*. The ^{13}C-NMR spectrum [$CCl_4/CDCl_3$; TMS: $\delta(C^{1a}/C^{6a}) = 122.8$, $\delta(C^2/C^6) = 113.5$, $\delta(C^{2a}/C^{5a}) = 140.1$, $\delta(C^1) = 19.9$ ppm] is informative since it largely accords with that of cyclopropabenzene[8] with regard to the resonance frequencies of C^{1a}/C^{6a}, C^2/C^6, and C^1, and the coupling constant $^1J(1, H) = 170$ Hz. Justification for regarding *(2)* and cyclopropa[*b*]naphthalene as true naphthalene derivatives is provided by the UV spectrum [λ_{max} (cyclohexane) = 226 ($\varepsilon = 74200$), 273 (7050), and 326 nm (6000) (B_b, L_a, L_b bands)[9]]; the only significant difference from that of naphthalene lies in the enhanced intensity of the L_b band. The IR spectrum [CCl_4: 1622 cm^{-1} (aromatic double bond)] and the mass spectrum are likewise in excellent accord with the structure assumed.

Like cyclopropabenzene and cyclopropa[*b*]naphthalene, *(2)* is sensitive to acidic reagents[10]. As an example we cite the extremely fast reaction of *(2)* with acetic acid in the presence of $Ag^{\oplus}$ ion, which leads expectedly to a mixture of 2,6- and 2,7-naphthalenedimethyl diacetate.

According to thermochemical studies by *Billups et al.*, cyclopropa[*b*]naphthalene is destabilized by 67.8 kcal/mol (sum of strain energy and resonance loss) compared with the strain-free aromatic model[6]. Hence it can be reasonably assumed that the corresponding destabilization energy will considerably exceed 100 kcal/mol in the case of *(2)*. Since *(2)* itself already tends to undergo explosive decomposition, it may well be that the limit of existence at room temperature has been reached in *(1)*, where the possibility of a certain internal equalization of strain is even less favorable than in *(2)*.

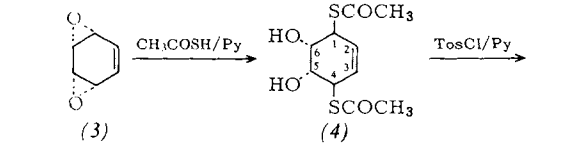
syn-Benzene Bisepisulfide (*syn*-3,4:5,6-Bis(epithio)-1-cyclohexene)[**]

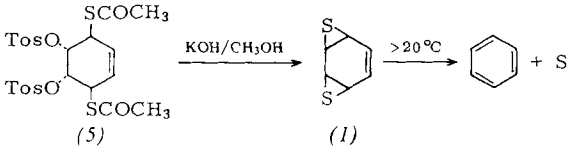
By *Emanuel Vogel, Erich Schmidbauer*, and *Hans-Josef Altenbach*[*]

The still unknown 10π-heterocycle 1,4-dithiocin *(2)*, which is to be regarded as a potential aromatic compound according to the Hückel rule, has been the goal of several synthetic attempts[1,2] and the subject of quantum mechanical calculations[3,4] during recent years. Whereas the experimental work on *(2)* is not very informative with regard to its π-electron structure, Hückel calculations—employing Coulomb and resonance integrals derived from thermodynamic data for divalent sulfur—predict, contrary to expectations, that *(2)* will not possess pronounced electronic stability[4]. As already discussed previously[5,6], symmetry-allowed valence isomerization ($_\pi 2_s + _\sigma 2_s + _\sigma 2_s$ process) of *syn*-benzene bisepisulfide *(1)* constitutes an apparently compelling synthetic route to *(2)*, provided that the eight-membered heterocycle is aromatic. In the present communication we report about compound *(1)*, the first arene episulfide to have been prepared, and its thermal behavior.



(1) *(2)*

A suitable starting material for attempted synthesis of *(1)* was *syn*-benzene dioxide *(3)*, which we described in a recent



[*] Prof. Dr. E. Vogel, Dipl.-Chem. E. Schmidbauer, and Dr. H.-J. Altenbach
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

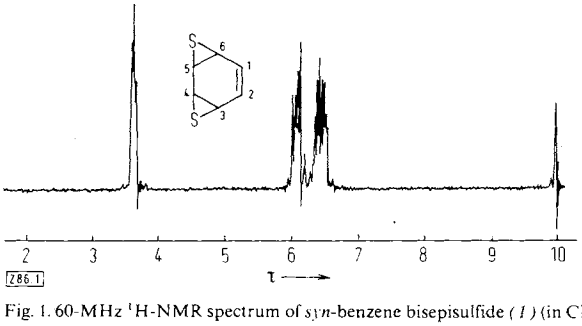
[**] This work was supported by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

publication[7]. Reaction of a solution of *(3)* in pyridine at 0°C with thioacetic acid affords *S,S*-(5,6-dihydroxy-2-cyclohexen-1,4-ylene) bis(thioacetate) [colorless crystals from diisopropyl ether, m.p. 117°C, yield 13%] whose NMR spectrum [($CDCl_3$): $\tau = 4.32$ (d, H-2, H-3), 5.65 (dd, H-1, H-4), 6.05 (d, H-5, H-6), 7.6 (s, CH_3)] shows the *1r,4c,5t,6t* compound analogous to conduritol A[8] to be present. On reaction with *p*-toluenesulfonyl chloride in pyridine (0°C), compound *(4)* gives the ditosylate *(5)* [needles from dichloromethane/pentane, m.p. 172—173°C (dec.), yield 60%]. Subsequent treatment of *(5)* in dichloromethane at −20°C with a fivefold excess of KOH in methanol leads smoothly to the desired *syn*-benzene bisepisulfide (*syn*-3,4 : 5,6-bis(epithio)-1-cyclohexene) *(1)* which is obtained as a crystalline mass after filtration of the reaction solution over a 10-cm alumina column at −20°C and evaporation of the solvent at 0°C. Recrystallization from ether at low temperature afforded colorless needles [m.p. 34—36°C (dec.), yield 80%; mass spectrum: $m/e = 142$ (M^+), 110 ($M^+ - S$), 78 ($M^+ - 2S$, 100%)].

(3) *(4)*

(5) *(1)*

The ^{1}H-NMR spectrum ($CDCl_3$) of *(1)* reproduced in Figure 1 shows a triplet at $\tau = 3.66$ (H-1, H-2) and multiplets at $\tau = 6.11$ (H-4, H-5) and 6.46 (H-3, H-6). Assignment of the episulfide protons, according to which the upfield multiplet is due to the allylic protons H-3 and H-6, is based on double resonance experiments such as have been described previously for *(3)*[7]. In order to determine the coupling constants of the episulfide protons the sample was irradiated at the resonance frequency of the olefinic protons and the resulting AA'BB' system analyzed; the values obtained were $J_{3,4} = 5.94$ Hz, $J_{3,5} = 0.49$ Hz, $J_{3,6} = 0.23$ Hz, and $J_{4,5} = 6.14$ Hz. The high value of $J_{4,5}$ appears significant because it supports the *syn* configuration of the benzene bisepisulfide which so far follows solely from the synthetic pathway[9].



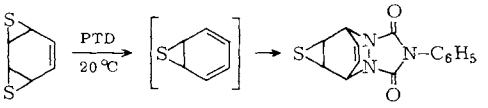


Fig. 1. 60-MHz ^{1}H-NMR spectrum of *syn*-benzene bisepisulfide *(1)* (in $CDCl_3$ at −20°C; TMS as internal standard).

syn-Benzene bisepisulfide is thermolabile. Its solutions in carbon disulfide or chloroform decompose at 20°C with a half-life of about 30 min (determined by NMR spectroscopy) to form benzene and sulfur as final products. Decomposition in the presence of 4-phenyl-1,2,4-triazoline-3,5-dione (PTD) gave a 10% yield of the Diels-Alder adduct *(7)* of benzene episulfide *(6)* [m.p. 157—158°C (dec.) from CCl_4/pentane; NMR ($CDCl_3$): $\tau = 2.5$ (m, 5 aromatic H), 3.9 (t, 2 olefinic H), 4.6 (m, 2 tertiary H), 6.62 (t, 2 episulfide H)[10]]. No evidence has yet accrued for the formation of *(2)* and of thiepin[11] on thermolysis of *(1)*.

(1) *(6)* *(7)*

The thermal properties of *(1)* support the theoretically based prediction that *(2)* is not a 10π-aromatic compound.

Very recently, *Eggelte* and *Bickelhaupt*[12] have synthesized the obviously nonaromatic 1,4-dithiocin-6-yl acetate which fragments—*via* its hitherto undetected *syn*-benzene bisepisulfide valence tautomer—to phenyl acetate and sulfur.

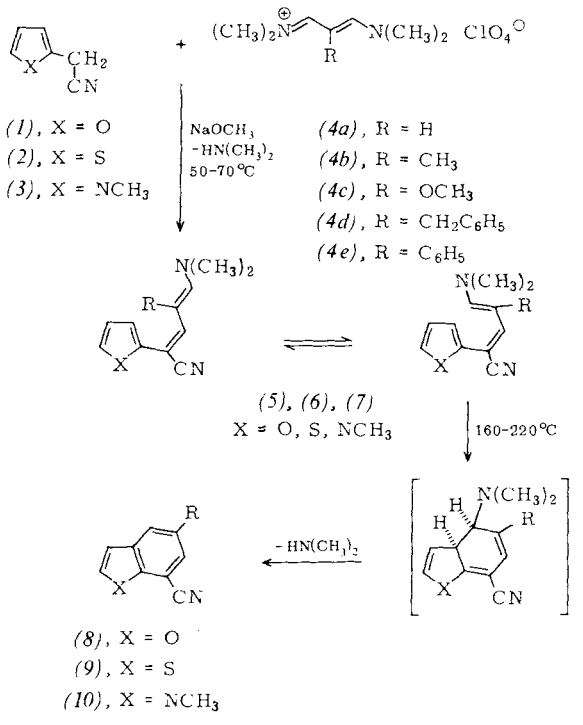
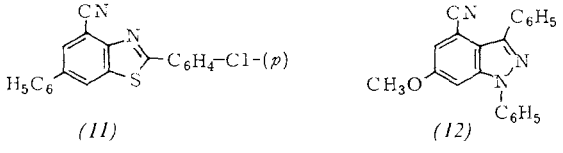
A New Synthesis of Indolizines[**]



By *Christian Jutz, Rudolf M. Wagner,* and *Hans-G. Löbering*[*]

1,3,5-Hexatrienes bearing terminal dialkylamino groups undergo a 6π-electrocyclic reaction with elimination to form benzene derivatives. If a double bond of the hexatriene moiety is part of an aromatic π-system, then benzo-fused compounds are obtained[1-3].



Benzo-annelation of furan, thiophene, and *N*-methylpyrrole can be accomplished particularly smoothly by thermolysis of the 5-dimethylamino-2-(2-hetaryl)-2,4-pentadienonitriles *(5)*, *(6)*, and *(7)*. At 160—220°C they cyclize with loss of

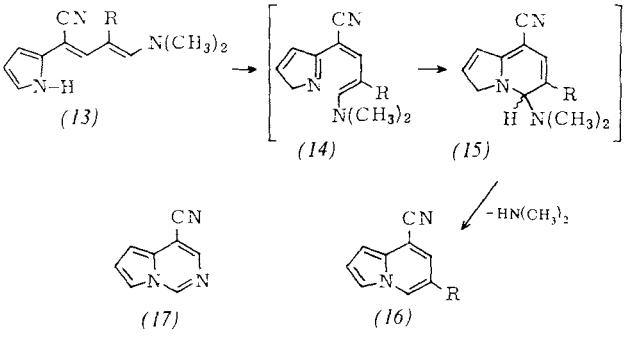
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

dimethylamine to the 1-benzohetarene-7-carbonitriles *(8)*, *(9)*, and *(10)* (Table 1). The precursors *(5)*, *(6)*, and *(7)* are obtained in high yield by condensation of the hetarene-2-acetonitriles *(1)*, *(2)*, and *(3)* with the trimethinimium perchlorates *(4a)* to *(4e)* in pyridine or quinoline after addition of one equivalent of sodium methoxide and heating to 50—70 °C. Condensation and cyclization can also be performed to advantage in quinoline as a single vessel reaction without intermediate isolation. Determination of the dimethylamine eliminated affords a measure of the progress of the reaction. The steric effect of a substituent R on the rotamer equilibrium of *(5)*, *(6)*, and *(7)* can enhance the rate of cyclization or lower the temperature of thermolysis.

(11) *(12)*



In like manner, 2-(4-chlorophenyl)thiazole-4-acetonitrile and *(4e)* afford 2-(4-chlorophenyl)-6-phenylbenzothiazole-4-carbonitrile *(11)* (98 %), m.p. 171—173 °C, while 1,3-diphenylpyrazole-4-acetonitrile and *(4c)* furnish 6-methoxy-1,3-diphenylindazole-4-carbonitrile *(12)* (84%), m.p. 151—158 °C.

Table 1. Examples of compounds of type *(8)*, *(9)*, *(10)*, and *(16)*. All compounds give correct elemental analyses and are substantiated by ^{1}H-NMR spectra.

[a] Obtained from the isolated intermediates.

N-Unsubstituted pyrrole-2-acetonitrile also condenses like *(1)* to *(3)* with the salts *(4a)* to *(4e)* to form orange-yellow 5-dimethylamino-2-(2-pyrrolyl)-2,4-pentadienonitriles *(13a)* to *(13e)*. Contrary to our expectation, thermolysis does not lead to indole-7-carbonitriles, but exclusively to—characteristically lemon yellow—volatile indolizine-8-carbonitriles *(16a)* to *(16e)* (Table 1). The cyclization step must be accompanied by a [1.5]sigmatropic H migration *via* the two non-isolable intermediates *(14)* and *(15)*, if the postulate of an electrocyclic mechanism is to be upheld.

The hitherto unknown "6-azaindolizine", pyrrolo[1,2-*c*]pyrimidine-4-carbonitrile *(17)*, was prepared in analogous fashion by condensation and cyclization of pyrrole-2-acetonitrile with *N*,*N*-dimethyl-(3-dimethylamino-2-azaallylidene)ammonium perchlorate[5] in 55 % yield (yellow needles of m.p. 124 °C).

5-Dimethylamino-2-(2-pyrrolyl)-2,4-pentadienonitrile (13a)

Pyrrole-2-acetonitrile[6] (2.65 g, 25 mmol) and *(4a)* (5.70 g, 25 mmol) in anhydrous pyridine (20 ml) are reacted with an equivalent amount of $NaOCH_3$ in methanol (10 ml) and stirred for 2 h at 70 °C. After vacuum distillation of the pyridine, crystalline *(13a)* is rubbed with water, suction filtered, and chromatographed over alumina (activity III, basic) in CH_2Cl_2; 4.25 g (91 %) of yellow needles (from CH_2Cl_2/hexane), m.p. 147—148 °C.

Indolizine-8-carbonitrile (16a)

Compound *(13a)* (1.87 g, 10 mmol) in quinoline (3 ml) is heated to 200—220 °C for 3 h in a weak current of nitrogen (cessation of dimethylamine liberation); the contents of the flask are then rubbed with 50 ml of 1 N HCl, the precipitated *(16a)* dissolved in benzene, and the benzene solution subsequently washed once more with HCl and water. After sublimation of residue left on evaporation and chromatography on a small amount of alumina (activity III, neutral) one obtains 1.13 g (80%) of fine, lemon-yellow needles having a penetrating odor, m.p. 74—75 °C. ^{1}H-NMR (60 MHz, $CDCl_3$): $\tau = 1.92$ (dd, 1H^5, $J_{5,6} = 7.0$ Hz, $J_{5,7} = 1.0$ Hz); 2.56 (dd, 1H^1, $J_{1,2} = 2.8$ Hz, $J_{1,3} = 1.2$ Hz); 2.88 (dd, 1H^7, $J_{6,7} = 7.0$ Hz); 3.05 (dd, 1H^2, $J_{2,3} = 4.0$ Hz); 3.28 (dd, 1H^3); 3.50 (t, 1H^6). UV (CH_2Cl_2): λ_{max} (log ε) = 251 nm (4.51), 282 (sh, 3.32), 289 (3.49), 311 (3.46), 390 (3.32).

Stable Di- and Tetrabromo-2*H*-isoindoles[1]

By *Richard Kreher* and *Karl Josef Herd*[*]

Proof of the intermediary formation of the 1*H*-isoindole ("isoindolenine") *(1)*, X = H, has been obtained by independent synthesis, and of the existence of the tautomeric 2*H*-isoindole[3] *(2)*, X = H, by transformation reactions[4]. We have now concentrated our studies both on the fixation of the 1*H*- and 2*H*-isoindole structures by substituents on the heterocyclic system[1] and on their stabilization by halogen substituents on the carbocyclic system[2].

For the synthesis of the symmetrically substituted di- and tetrabromo-2*H*-isoindoles *(2a)*—*(2c)*, the relevant 1,2-bis-(bromomethyl)benzenes are converted by reaction with methanesulfonamide in basic solution into the readily isolable *N*-methanesulfonylisoindolines. Elimination of methanesulfinic acid is achieved with potassium *tert*-butoxide in dimethyl sulfoxide (1 h at room temperature) and leads *via* the intermediary 1*H*-isoindole *(1)* to the astonishingly thermostable 2*H*-isoindoles *(2)*, which are isolable in crystalline form and can be characterized by spectroscopical methods. According to the IR spectra ($\nu_{NH} \approx 3380$—$3420\,cm^{-1}$) and the ^{1}H-NMR spectra ($\tau_{CH} \approx 2.2$—2.9) the tautomeric equilibrium lies almost exclusively on the side of the 2*H*-isoindole form *(2)*, both in the solid state and in solution.

(a), $X^1 = X^2 = X^3 = X^4 = Br$
(b), $X^1 = X^4 = Br$, $X^2 = X^3 = H$
(c), $X^1 = X^4 = H$, $X^2 = X^3 = Br$
(d), $X^2 = X^3 = H$, $X^1 = OCH_3$, $X^4 = Br$

On reaction with trifluoroacetic acid, the 2*H*-isoindoles *(2a)*—*(2d)* are protonated in the α-position to give the 1*H*-isoindolium ions *(3)* whose formation clearly profits from the resonance stabilization of the benzenoid system and is thus energetically more favorable than the *N*-protonation. The reversibility of the *C*-protonation in acid medium (deuteriotrifluoroacetic acid) is detectable by complete H/D exchange in the pyrroloid system, whereas NH-deprotonation occurs in deuterium oxide/pentadeuteriopyridine. An exception is 5,6-dibromo-2*H*-isoindole *(2c)*, whose protonated form undergoes irreversible secondary reactions. Consequently, in contrast to the parent compound *(2)*, X = H, which spontaneously polymerize or polycondense in acid medium, the bromine-substituted 1*H*-isoindolium salts *(3)* generally have a spectroscopically detectable lifetime.

Table 1. 2*H*-Isoindoles *(2)* and 1*H*-isoindolium trifluoroacetates *(3)* [a].

(2a), Yield 72%, m.p. > 130 °C (decomp.) (ethyl acetate); ^{1}H-NMR (hexadeuterioacetone): $\tau = -3.0$ to -2.0 (s, broad, NH); 2.58 (d, $J = 3$ Hz, H^1, H^3); *(3a)*, ^{1}H-NMR (trifluoroacetic acid): $\tau = 0.72$ (t, $J = 2.5$ Hz, H^3); 4.70 (d, $J = 2.5$ Hz, $2H^1$)

(2b), Yield 86%, m.p. 55—56 °C (ether/petroleum ether, yield ≈40%); ^{1}H-NMR (hexadeuterioacetone): $\tau = -2.7$ to -1.1 (s, broad, NH); 2.58 (d, $J = 3$ Hz, H^1, H^3); 3.00 (s, H^5, H^6); *(3b)*, ^{1}H-NMR (trifluoroacetic acid): $\tau = 0.38$ (t, $J = 2.5$ Hz, H^3); 1.98 (d, $J = 8.5$ Hz, H^5 or H^6); 2.17 (d, $J = 8.5$ Hz, H^5 or H^6); 4.55 (d, $J = 2.5$ Hz, $2H^1$)

(2c), Yield 82%, m.p. > 120 °C (decomp.) (adsorptive filtration, yield 65%); ^{1}H-NMR (hexadeuterioacetone): $\tau = -3.0$ to -2.0 (s, broad, NH); 2.23 (s, H^4, H^7); 2.85 (d, $J = 3$ Hz, H^1, H^3); *(3c)*, ^{1}H-NMR (trifluoroacetic acid): $\tau = 0.47$ (t, $J = 2.5$ Hz, H^3); 1.3 to 2.5 (m, xH); 4.62 (d, $J = 2.5$ Hz, $2H^1$); 4.80 (m, xH), 5.2 to 5.6 (m, xH).

[a] The isolated isoindoles *(2a)* to *(2d)* give correct analyses and the expected molecular ions in the mass spectrum.

The deactivation of the *o*-quinonoid 10π-electron system of *(2)* is also apparent from the chemical behavior towards dienophiles. No Diels-Alder reaction is detectable on treatment with maleic anhydride under the usual conditions[5], whereas reaction with the more reactive dimethyl acetylenedicarboxylate leads to the 1 : 2 adducts *(4)*, whose formation is explained by 1,3-cycloaddition of the 2*H*-isoindoles *(2)* as well as by Michael addition of the NH group to the activated triple bond of the dienophile.

Table 2. 1 : 2-Adducts *(4)* of 2*H*-isoindoles *(2)*.

(4a), Yield 30%, m.p. 222 °C (methanol); ^{1}H-NMR ($CDCl_3$): $\tau = 4.47$ (s, 2 bridgehead H); 5.07 (s, 1 vinyl H); 6.18 (s, OCH_3); 6.22 (s, $2\,OCH_3$); 6.43 (s, OCH_3)

(4b), Yield 40%, m.p. 196—198 °C (methanol); ^{1}H-NMR ($CDCl_3$): $\tau = 2.92$ (s, 2 aromat. H); 4.35 (s, 2 bridgehead H); 4.94 (s, 1 vinyl H); 6.09 (s, OCH_3); 6.13 (s, $2\,OCH_3$); 6.35 (s, OCH_3)

(4d), Yield 49%, m.p. 191 °C; ^{1}H-NMR ($CDCl_3$): $\tau = 2.87$ (d, $J = 9$ Hz, 1 aromat. H); 3.43 (d, $J = 9$ Hz, 1 aromat. H); 4.27 (d, $J = 2.5$ Hz, 1 bridgehead H); 4.46 (d, $J = 2.5$ Hz, 1 bridgehead H); 4.98 (s, 1 vinyl H); 6.15 (s, OCH_3); 6.10 (s, OCH_3); 6.17 (s, $2\,OCH_3$); 6.37 (s, OCH_3).

In this case, the 5,6-dibromo-2*H*-isoindole *(2c)* also displays irregular behavior; 1,3-cycloaddition leads similarly to intermediary formation of the 1 : 2 adduct, which, however, isomerizes to tetramethyl 7,8-dibromo-3a,9b-dihydrobenzo[*g*]indole-2,3,3a,4-tetracarboxylate. Structurally analogous 1 : 2 adducts are formed on reaction of *N*-alkylisoindoles with the same dienophile[6, 7].

According to the above results, halogen atoms on the benzene ring effect a significant thermal stabilization of the heterocyclic 10π-electron system and a chemical deactivation toward electrophilic and dienophilic components. Reactivity studies[8]

The Structure of a Rectangular Cyclobutadiene[**]

By *Hermann Irngartinger* and *Hans Rodewald*[*]

The geometry of the cyclobutadiene derivative 3,3,7,7,10,10,14,14-octamethyl-5,12-dithiatricyclo[7.5.0.0^{2,8}]-tetradeca-1(9),2(8)-diene *(1)*[1], whose isolation was first reported by *Kimling* and *Krebs*[2], has been established by X-ray structural analysis.

(1)

(2)

Intensity measurements were carried out on a single crystal[3] of *(1)*, which was sealed in a glass capillary under nitrogen. The yellow crystals decompose at 240 °C. The crystallographic data are: $a = 14.925(4)$, $b = 10.457(1)$, $c = 6.397(4)$ Å; $\alpha = 101.11(2)°$, $\beta = 103.77(4)°$, $\gamma = 90.86(2)°$; space group: $P\bar{1}$; $Z = 2$; $D_{calc.} = 1.18$ g cm^{-3}. A total of 4615 reflections (including 1504 that were regarded as unobserved) were measured by the balance filter method on a computer-controlled diffractometer using MoKα radiation. The structure could be solved by the heavy atom method. Refinement by the least-squares technique using anisotropic thermal parameters for the C and S atoms and isotropic thermal parameters for the H atoms yielded a conventional *R* factor of 0.044.

The unit cell contains two independent molecules the centers of which coincide with crystallographic centers of symmetry. The conformation and molecular parameters of the two independent halves of the molecule are almost indentical. Bond lengths and angles of chemically equivalent atoms were averaged (Fig. 1).

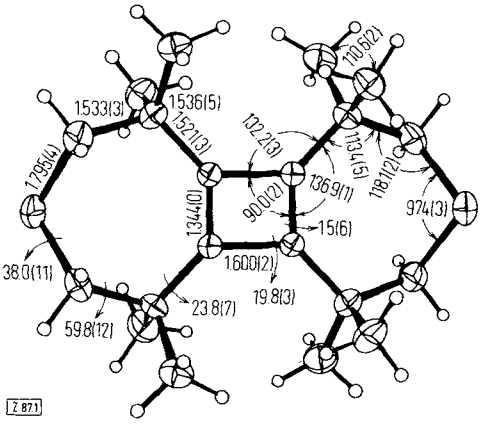

Fig. 1. Averaged bond lengths [Å] and angles [°] of *(1)* with the scatter of the last decimal place in brackets (standard deviation: 0.002 Å and 0.1° resp.). Values next to arrow heads refer to the mean absolute value of the torsional angle [°] [4].

In the crystal the four-membered ring of *(1)* clearly has a planar, rectangular structure, with sidelengths of 1.344 Å and 1.600 Å at an angle of 90°. The shorter bond is approximately the same length as a cyclobutene double bond (1.32—1.36 Å[5]).

The bonds of the four-membered ring which couple the seven-membered rings together are exceptionally longer than the C_{sp^2}—C_{sp^2} single bonds in 3,4-bis(methylene)cyclobutene (1.488 and 1.516 Å[6]). The elongation of these bonds in *(1)* (Fig. 2) might be due, in part, to the repulsive interactions of the methyl groups parallel to C(a)—C(a)'; elongations of 0.02—0.06 Å have been found for the corresponding bonds in aromatic five- and six-membered ring systems having two *tert*-butyl groups in the *ortho* position[7]. Hence, the structural formula *(1)* is favored over that of *(2)*. The results of an electron density difference calculation with $F_{obs.}$—$F_{calc.}$ indicate the presence of bent bonds in the four-membered ring.

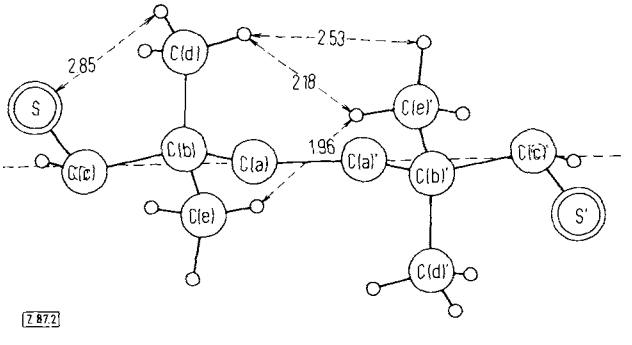

Fig. 2. Conformation of *(1)* viewed along the short edge of the cyclobutadiene. The H···H contacts (Å) are shown with broken lines.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Stiftung Volkswagenwerk.

The C(b) atoms attached directly to the cyclobutadiene ring deviate by 0.19 Å from the plane of the ring, C(b1) and C(b2) being inclined in one direction and C(b1)' and C(b2)' in the opposite direction, thus resulting in a step-like conformation (see Fig. 2). The atoms C(b)—C(a)—C(a)—C(b) in a seven-membered ring lie almost in a plane inclined at about 10.6° to the plane of the cyclobutadiene ring. Transannular interaction between the MOs of the electrons in the lone pairs on sulfur and the π electrons of the C(a)=C(a) bond in the thiacycloheptene ring of *(1)* may be ruled out, since no similar interaction could be established[9] in 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne, which has an analogous conformation with even shorter contacts ($S\cdots C_{sp}=2.94$ Å)[8].

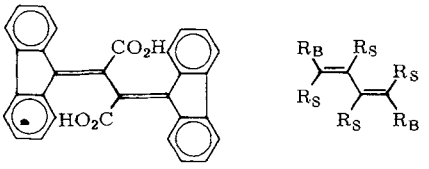
Partial Enantiomerization of an Atropisomeric Butadiene[1]

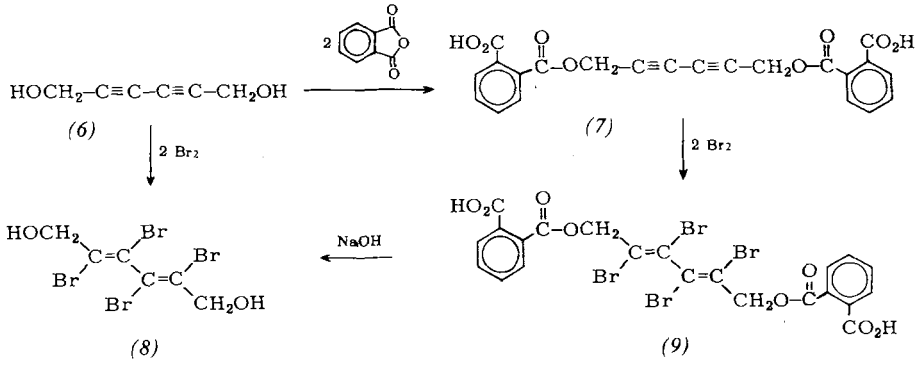
By *Manfred Rösner* and *Gert Köbrich* (deceased)[*]



If formation of the *cisoid*- and *transoid*-coplanar conformations in butadienes is hindered by bulky substituents, occurrence of the atropisomers *(1)* is to be expected. The situation resembles that in the atropisomeric biphenyls *(2)*[3] and highly substituted styrenes *(3)*[4].

A characteristic difference exists between the symmetry of the biphenyl- *(2)* and butadiene systems *(1)*: owing to their dihedral symmetry, atropisomeric biphenyls require definite substitution patterns [*e.g.* $R^1 \neq R^2$ in *(2)*] in order to be chiral, and hence resolvable into optical enantiomers, whereas non-planar butadienes *(1)* belong to the point group C_2 or C_1 and are always chiral.

(1) *(2)* *(3)*



As early as 1957, *St. Goldschmidt et al.* succeeded in paving the way to partial enantiomerization of fulgenic acid *(4)*[5]; however, the enantiomers proved to be sterically very unstable (complete racemization in 22 min at 20 °C).

(4) *(5)*

The chirality of non-planar butadienes was conceptually introduced[6] in previous studies of this series and was demonstrated ^{1}H-NMR-spectroscopically on the basis of the anisochronism of prochiral substituents[6–8]. An independent demonstration of this chirality could recently be made by the signal splitting in the ^{1}H-NMR spectrum of certain butadienes in the presence of an optically active shift reagent[2]. The bulkiness of the four "blocking" substituents R_S in *(5)* *directly* hinder the coplanar orientation of the two double bonds. In addition, the two substituents R_B exert a buttressing effect in that they render a valence angle deformation of the groups R_S very difficult and thus *indirectly* hinder coplanar orientation of both halves of the molecule[7, 9].

We report here on the synthesis and partial resolution of the butadienes 2,3,4,5-tetrabromo-2,4-hexadiene-1,6-diol *(8)* and 2,2'-[2,3,4,5-tetrabromo-2,4-hexadienylenebis(oxycarbonyl)]dibenzoic acid *(9)*. 2,4-Hexadiyne-1,6-diol *(6)*, which is accessible in 90% yield by Glaser coupling of propargyl alcohol[10], was converted by reaction with 2 equivalents of phthalic anhydride in pyridine into the bis(phthalic half ester) *(7)* (yield 95%)[11], which, on bromination in acetone (initially at −45 °C, then at 0 °C) gave the tetrabromide *(9)* (colorless crystals; m.p. 177—178 °C, from chloroform) in 30 to 50% yield[12]. Reaction of *(9)* with 2 equivalents of D-(+)-α-phenylethylamine in acetone afforded a crystalline ammonium salt, whose diastereoisomers could be separated after several digestions with hot acetone.

(6) *(7)* *(8)* *(9)*

[*] Dipl.-Chem. M. Rösner and Prof. Dr. G. Köbrich (deceased)
Institut für Organische Chemie der Technischen Universität
3 Hannover, Schneiderberg 1 B (Germany)

There remained a product having a specific rotation of $[\alpha]_{546}^{20} = -9.5°$ (methanol), from which optically active (−)-*(9)* with $[\alpha]_{546}^{20} = -16.0°$ (in acetone) could be separated by treatment with dilute H_2SO_4. Treatment of (−)-*(9)* with dilute NaOH at room temperature afforded (−)-(*E*,*E*)-*(8)* with $[\alpha]_D^{20} = -14.3°$ (in acetone), which was identical (except for optical activity) with a product obtained by bromination of *(6)* (m.p. 100—101 °C, from chloroform)[13].

The optically active butadienes (−)-*(8)* and (−)-*(9)* are optically stable in the solid state; however, they gradually racemize in solution at room temperature. We have measured the kinetics of the racemization polarimetrically[14] and determined: for (−)-*(9)* [the values for (−)-*(8)* are given in brackets], an activation energy of $E_{exp} = 20.7 \pm 0.3$ kcal/mol (21.7 ± 0.3), $\Delta H^{\neq} = 20.1 \pm 0.3$ kcal/mol (21.1 ± 0.3), $\Delta S^{\neq} = -10.2 \pm 1.0$ cal mol^{-1} K^{-1} (−8.8 ± 1.0). This data provides a free enthalpy of activation $\Delta G^{\neq}$ (at 20 °C) of 23.1 ± 0.3 kcal/mol for (−)-*(9)* and 23.7 ± 0.3 kcal/mol for (−)-*(8)*.

From these results it would appear that stable enantiomers of chiral butadienes having *monoatomic* substituents R_S as blocking groups cannot exist in solution at room temperature (I can be ruled out as substituent because of the decomposability of the corresponding butadienes). We are at present attempting the synthesis of butadienes containing bulky *polyatomic* substituents R_S (*e.g. tert*-butyl). If the buttressing effect of the substituents R_B is sufficiently large[15], (*E*,*E*)-1,2,3,4-tetrabromobutadienes should also be able to form stable atropisomers in solution at room temperature.

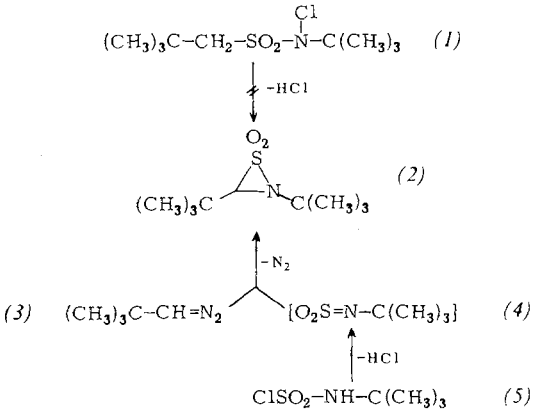
[9] *H.-O. Bödecker, V. Jonas, B. Kolb, A. Mannschreck*, and *G. Köbrich*, Chem. Ber., in press.

[10] Following the procedure described by *A. S. Hay*, J. Org. Chem. *27*, 3320 (1962).

[11] Compound *(7)* had already been prepared *via* another route: *M. D. Cameron* and *G. E. Bennett*, J. Org. Chem. *22*, 557 (1957) (m.p. 145.5—147 °C); it gradually decomposes with violet discoloration (cf. *G. Wegner*, Z. Naturforsch. *24b*, 824 (1969)). The disodium salt is stable.

[12] The empirical formula of *(9)* is confirmed by elemental analysis and MS. ^{1}H-NMR (100 MHz, D_6-acetone): δ = 7.85 (m, 2H aromat.), 7.65 (m, 6H aromat.), 9—10 ppm (broad, 2OH); δ = 5.25 ppm (AB system, 2 × CH_2, $\delta_A - \delta_B = 5.3$ Hz, $J_{AB} = 13.5$ Hz).

[13] ^{1}H-NMR of *(8)* (100 MHz, D_6-DMSO): AB system at δ = 4.3 ppm with $\delta_A - \delta_B = 4.8$ Hz, $J_{AB} = 14$ Hz. Since the signals at 145 °C do not show any coalescence, the energy barrier to rotation about the central single bond of the butadiene system of *(8)* must be $\Delta G_c^{\neq} \geq 21.1$ kcal/mol; cf. Ref. [6, 7]. *(8)* has already been mentioned but not characterized: Jap. Pat. 7036428 and 7235409; Chem. Abstr. 75, P141752g (1971); 78, P4748h (1973).

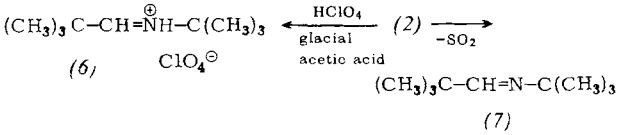


[14] Double determinations at 546 nm and 365 nm in each case at seven different temperatures between 15 and 47 °C [for (−)-*(9)*] and at five different temperatures between 20 and 47 °C [for (−)-*(8)*].

[15] For example, in the case of (*E*,*E*)-1,2,3,4-tetrachlorobutadiene a $(CH_3)_2COH$ group as R_B with 8.3 kcal/mol has more than double the buttressing effect than the CH_2OH (3.7 kcal/mol) or the CH_3OCH_2 group (4.0 kcal/mol) [2, 9].

2,3-Di-*tert*-butylthiaziridine 1,1-Dioxide[**]

By *Helmut Quast* and *Frieder Kees*[*]



The first thiadiaziridines have recently been prepared in the form of their 1,1-dioxides[1, 2]. We have now synthesized the first thiaziridine 1,1-dioxide *(2)*. Thiaziridine 1,1-dioxides have formerly only occasionally been postulated as intermediates[3].

While 1,3 elimination of HCl was unsuccessful when attempted with the *N*-chlorosulfonamide *(1)*[5], which is readily accessible from neopentylsulfonyl chloride[4], we were able to apply the reaction of diazo compounds with sulfenes[6], which has proved of value in the preparation of thiirane 1,1-dioxides, to the *N*-sulfonylamine *(4)*[8] prepared *in situ* from *(5)*[7]. *(2)* crystallizes as colorless needles from pentane at −78 °C. Proof of structure rests on S analysis[10], the base equivalent, mass spectra[11], and reactions.

The molecular peak expected for $C_9H_{19}NO_2S$ could not even be detected in the 16 eV mass spectrum. Instead the spectrum merely shows products of thermal decomposition, *i.e. (7)* and SO_2. In contrast, determination of the base equivalent mass by titration with 0.1 N perchloric acid in glacial acetic acid was surprisingly straightforward[12]. A 91% yield of *(6)*[13] crystallized out.

Pyrolysis without solvent for 10 min at 60—80 °C gave 91 to 95% of SO_2 which was determined successively by gas volumetry and gravimetry[15]. In CCl_4 the SO_2 is accompanied by a quantitative amount of the azomethine *(7)*, as established by spectroscopic comparison (IR, NMR) with an authentic sample[14].

Following the formation of SO_2 in 2.5×10^{-4} M *n*-hexane solution by UV spectroscopy at 288.5 nm shows first-order

Synthesis of α-Functional Nitrosamines

By *Manfred Wiessler*[*]

Addition of nitrosyl chloride to olefins leads to vicinal chloro nitroso compounds or their dimers[11]. If the reaction proceeds in the same manner, the addition of nitrosyl chloride to Schiff bases[2] could lead to α-chloro *N*-nitroso compounds— ideal intermediates for the synthesis of α-functional nitrosamines. In this context, particular interest attaches to the synthesis of α-hydroxy nitrosamines or their esters for they are of special significance for the elucidation of the metabolism of nitrosamines and for studying the carcinogenic action of this class of compounds. The present communication briefly reports the addition of nitrosyl chloride to Schiff bases.

(1)-(5) *(6)-(10)*

(a), X = CH_3O; *(b)*, X = CH_3CO_2;
(c), X = p-NO_2-$C_6H_4CO_2$; *(d)*, X = Cl

If the Schiff base *(1)*[3] is reacted at $-30\,^{\circ}C$ with the stoichiometric amount of NOCl, rapid decoloration occurs. After addition of $CH_3OH/(C_2H_5)_3N$, $CH_3CO_2H/(C_2H_5)_3N$, or p-NO_2—$C_6H_4CO_2H/(C_2H_5)_3N$ at the same temperature and subsequent work-up, the compound *(6a)*, *(6b)*, or *(6c)* can be isolated. All the compounds of type *(7)*—*(10)* listed in Table 1 could be synthesized in the same way. Their structures are confirmed by analytical and spectroscopic data.

In an attempt to prepare compound *(9a)* only the starting materials were isolated. The methyl ether was apparently formed at $-30\,^{\circ}C$ but liberated methyl nitrite with regeneration of the double bond during work-up. The isolation of *(10a)* demonstrates the feasibility of preparing tertiary methyl ethers.

Table 1. α-Functional *N*-nitrosamines of type *(6)*—*(10)* prepared.

Reactant	Product	R^1	R^2	R^3	X	M.p. [°C] B.p. [°C/torr]	Yield [%]

[b] See text.
[c] Not distilled.

It may be assumed that the chlorides *(6d)*—*(10d)* are formed on addition of NOCl to the Schiff bases *(1)*—*(5)*. Confirmation of this course is provided by the isolation of *(6d)* [NMR ($CDCl_3$): $\tau = 4.90$ (2H, s), 8.35 (9H, s)]. The chloride decomposes already at room temperature. Since the secondary chlorides should be even more reactive we have not attempted to isolate them. So far, *N*-chloromethyl-*N*-nitrosomethyl-

The First Oxoniobate(III): $LiNbO_2$[1]

By *Gerd Meyer* and *Rudolf Hoppe*[*]

During attempts to prepare $Li_4Nb_3^{IV}O_8$, whose existence appears to be inadequately substantiated[2], we unexpectedly obtained inhomogeneous wine-red reaction products [$2Li_2O + 3NbO_2$; 900 °C, 35 d, small nickel bomb, under argon]. Apart from *hexagonal platelets* having a *bluish-black* luster (garnet red when viewed by transmitted light) the reaction mixture contained $LiNbO_3$[3] and some Li_3NbO_4[4], which are both colorless.

The same substance was obtained almost pure as a black powder (streak: wine-red) from corresponding mixtures of $Li_2O + NbO + NbO_2$ [700 °C, 3 d, small nickel bomb, under argon]. Debye-Scherrer powder photographs show the single crystals to be identical with the powder, which also contained a little $LiNbO_3$.

The Nb content [70.4 % (exp.); calc. 70.4$_6$ % ($LiNbO_2$), 60.0$_2$ (Li_2NbO_3), and 64.1$_5$ % ($Li_4Nb_3O_8$), respectively] and the increase in weight on careful oxidation [O_2, 700 °C, 12 h: Δ = +11.3 % (exp.); calc. +12.1$_4$ ($LiNbO_2$), +5.1$_7$ (Li_2NbO_3), and +5.5$_2$ % ($Li_4Nb_3O_8$)] as well as structural determination confirm the presence of $LiNbO_2$.

Rotating crystal (above [10.0]), Weissenberg (0*k.l*—2*k.l*), and precession diagrams (*hk*.0, *hk*.1 and *h*0.*l* and *h*1.*l*) indicate a hexagonal unit cell having $a = 2.90_5$ Å, $c = 10.46$ Å, $c/a = 3.60$; $Z = 2$.

Structural determination [128 0*k.l*—2*k.l*, I_0 data recorded with a two-circle diffractometer (Stadi 2 manufactured by Stoe, Darmstadt), $Mo_{K\alpha}$ radiation] ruled out the space groups $P6_3mc$ and $P\bar{6}2c$, which were also compatible with the extinctions, and confirmed the space group $P6_3/mmc$. Interpretation of the Patterson synthesis followed by Fourier difference syntheses and subsequent least-squares refinement led to the parameters listed in Table 1; $R = R' = 5.2_3$ %.

Table 1. Atomic parameters for $LiNbO_2$ (standard deviations in units of the last decimal place are given in parentheses).

Particle	Equiv. posn.	*x*	*y*	*z*	*B* [Å^2]
Li	2a	0	0	0	1.4(7)
Nb	2d	$0.\bar{6}$	$0.\bar{3}$	0.25	0.33(2)
O	4f	$0.\bar{3}$	$0.\bar{6}$	0.1263(4)	0.13(11)

According to these results the compound has a "filled" layer structure of MoS_2 type, which also occurs in NbS_2[5]. Nb^{3+} is in a trigonal-prismatic environment of 6 O^{2-} (distance 2.11$_8$ Å, 6×), which is surprising in view of its "diagonal relationship" to Ti^{2+}. Li^+ occupies octahedral sites between the NbO_2 layers (Li—O = 2.13$_5$ Å, 6×). The I_0 data discount any occupation of the corresponding tetrahedral sites, as shown by *R* values and especially *B* values resulting from test calculations.

Between 3 and 300 K $LiNbO_2$ exhibits temperature-independent magnetism with marked dependence upon field strength, and resembles NbO_2[6] to such a degree that, as with VO_2, it is presumably antiferromagnetic[7] (with $T_N > 300$ K).

The agreement between the Madelung part of the lattice energy

Table 2. Madelung part of the lattice energy (MAPLE) of $LiNbO_2$ [kcal/mol].

	from	binary	×		ternary	Δ	ΣΔ
Li^+	Li_2O	146.2	1	146.2	215.1	+ 68.9	+68.9
Nb^{3+}	NbO	1067.0	0.5	533.5	985.7	− 81.3	−40.7
Nb^{3+}	α′-NbO_2	1112.2	0.5	556.1		−126.5	−63.3
O^{2-}	Li_2O	543.5	0.5	271.8	543.5	0	0
O^{2-}	NbO	474.2	0.75	355.7	(2×)	+ 69.3	+51.9
O^{2-}	α′-NbO_2	575.9	0.75	431.9		− 32.4	−24.3
				Σ: 2295.2	2287.8		− 7.5 (0.3 %)

Dinitrogen(octaethylporphinato)tetrahydrofuranosmium(II): A Nitrogen-Carrying Metalloporphyrin[**]

By *Johann Walter Buchler* and *Paul David Smith*[*]

Iron(II) porphins are known to bind a variety of small molecules, *e.g.* O_2, CO, NO, CH_3NC[1], but hitherto only a single dinitrogen complex, namely dinitrogen(protoporphyrin IX-diethylesterato)pyridineiron(II), has been mentioned[2]. The formation and chemical behavior of this compound as known to the authors[3] are quite amazing in view of well-accepted experience pertinent to the coordination chemistry of dinitrogen complexes. Therefore, the preparation and chemical characterization of other porphinatometal dinitrogen complexes is of interest inasmuch as hemoglobin effects O_2 uptake from N_2-containing air. The previously reported carbonyl(octaethylporphinato)tetrahydrofuranosmium(II) *(1)*[4] has a relatively low IR stretching frequency for the coordinated carbonyl group ($\tilde{\nu} = 1897\,cm^{-1}$). It was therefore expected from a rule expressed by *Chatt*[5] that the isosteric dinitrogen complex should exist.

Cpd.	Os"	X	X'
(1)	Os^{II}	CO	THF
(2)	Os^{VI}	O	O
(3)	Os^{II}	N_2	THF
(4)	Os^{IV}	OCH_3	OCH_3
(5)	Os^{II}	py	py
(6)	Os^{II}	THF	THF

When a drop of hydrazine hydrate is added to a solution of 0.13 mmol octaethylporphinatodioxoosmium(VI) *(2)*[6] in 20 ml tetrahydrofuran (THF) refluxing under N_2, the color of the solution changes within a minute from olive-green to red-violet (λ_{max} 525, 495, and 391 nm). After cooling and removing the volatile components under vacuum at 20 °C a crystalline dark violet residue is obtained. According to its IR spectrum [$\nu(N_2) = 2030\,cm^{-1}$; Fig. 1] and elemental analysis, this substance represents the desired dinitrogen(octaethylporphinato)tetrahydrofuranosmium(II) *(3)*. Like $[Os(NH_3)_5N_2]Br_2$ [$\nu(N_2) = 2028\,cm^{-1}$][7], *(3)* can be kept in air for some time, but is thermolabile and very air-sensitive in solution.

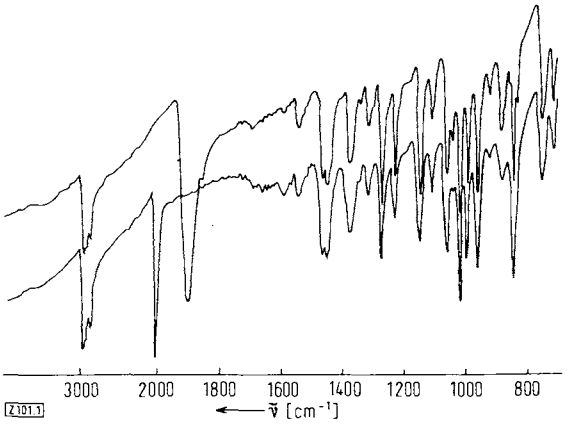

Fig. 1: Comparison of the IR spectra of carbonyl- *(1)* and dinitrogen-(octaethylporphinato)tetrahydrofuranosmium(II) *(3)* (lower trace); Perkin-Elmer 157, KBr.

N_2 and THF are liberated from *(3)* on heating to temperatures between 50 and 180 °C. This is evident from thermogravimetric[8] and IR spectroscopic investigation of the remaining solid as well as from mass spectrometric and vapor-phase chromatographic analysis of the gas phase liberated.

In THF solution at 20 °C, *(3)* shows the following reactions: 1. Autoxidation largely affords *(2)*; in the presence of CH_3OH the methoxide *(4)*[6] is formed.—2. Bubbling CO through the solution yields the carbonyl complex *(1)*.—3. Addition of pyridine furnishes the complex *(5)*[6] by replacement of the THF- and the N_2-ligand; however, in *(1)* at 20 °C only the THF ligand is substituted by pyridine[4].

When the dioxo complex *(2)* is reduced with diisobutylaluminum hydride in THF under argon, a red solution ($\lambda_{max} \approx 510$ nm), presumably containing *(6)*, is obtained. Under N_2, *(6)* is slowly transformed to *(3)*. *(3)* may react in this solution in the same manner as in the above mentioned reactions to give *(1)*, *(4)* or *(5)*.

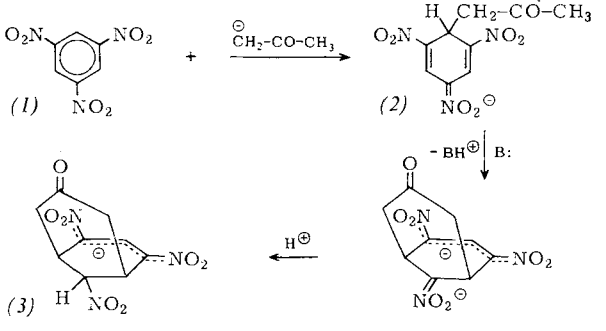
Erratum

In the fifth line of the communication "Trialkoxycyclopropenylium Ions" by *Eckehard V. Dehmlow*, Volume 13, page 209, March 1974, the following correction should be made: "pyrolysis" should read "photolysis".



Reviews

Abstracts of selected progress reports and review articles

The aggregation of dissolved alkane chain molecules is reported on by *G. W. Brady*. X-ray scattering measurements on 1-iodoalkanes showed that spherical aggregates are formed in decalin as solvent. This is not the case in solvents with alkyl chains. Special attention is paid to the aggregation in decalin solutions which contain mixtures of molecules having chain lengths of C_m and C_n where $m+n=22$. The molecules arrange themselves in spherical formation with the iodine atoms on the outside and the alkyl chains on the inside. In mixtures containing molecules with shorter chains the iodine atoms also occupy positions at the periphery of the aggregate. [On the Aggregation of Dissolved Alkane Chain Molecules. Accounts. Chem. Res. 7, 174—180 (1974); 17 references]

[Rd 727 IE—L]

Anionic σ-complexes *(2)* have been studied by *M. J. Strauss*. The complexes are formed by addition of carbanions to electron-deficient arenes *(1)*; multiple additions have also been observed. Cyclizations with *meta* bridging may be regarded as intramolecular analogs of this reaction which, in the pres-

ence of bases (B:) lead, *e.g.*, to the bicycle *(3)*. [Carbanion Additions and Cyclizations Involving Anionic σ Complexes. Meta Bridging Reactions of Aromatics. Accounts Chem. Res. 7, 181—188 (1974); 63 references]

[Rd 728 IE—L]

Stable homoleptic alkylmetal compounds are reviewed in an article by *P. J. Davidson, M. F. Lappert*, and *R. Pearce*. "Homoleptic" compounds are those in which the metal is bonded only to ligands of the same type, *e.g.* $Ti(CH_3)_4$[$(CH_3)_3TiCl$, on the other hand, is referred to as "heteroleptic"]. The authors concern themselves especially with compounds of Si, Ge, Sn, Pb, Sc, Y, Ti, Zr, Hf, V, Cr, Mo, W, Cu, Zn, and Hg with bulky ligands which have no β hydrogen atom, such as *e.g.* $(CH_3)_3SiCH_2$, $[(CH_3)_3Si]_2CH$, $(CH_3)_3CCH_2$, and $(CH_3)_3SnCH_2$. The article contains a tabulated set of data on the synthesis, structure, bonding, and decomposition of several examples. [Stable Homoleptic Metal Alkyls. Accounts Chem. Res. 7, 209—217 (1974); 67 references]

[Rd 729 IE—L]

8α-Substituted flavins of biological importance are described in an article by *T. P. Singer* and *D. E. Edmondson*. Covalently bound flavin has been detected in a series of enzymes. The reactive 8α-methyl group of the isoalloxazine system in these enzymes is coupled with an amino acid side chain, either of histidine or of cysteine. The article deals with the methods for localization of the bond between amino acid residue and flavin, with the change in spectra and redox potentials of the flavin peptides relative to those of the free flavins, and with the chemical properties of histidyl- and cysteinylflavins. According to the results obtained so far, the amino acid sequence distant from the flavin residue also appear to influence the physicochemical properties of the flavin peptide. [8α-Substituted Flavins of Biological Importance. FEBS Lett. *42*, 1—14 (1974); 67 references]

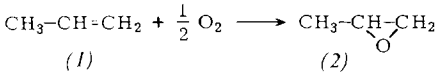
[Rd 731 IE—R]

The regulation of iron absorption, which is discussed by *D. van Campen*, is still an essentially unknown process. It is known that a series of factors influence the absorption of iron, presumably *via* a primary control process that takes place at the cells of the mucous membrane of the small intestine. It is still unknown, however, how the cells receive information about the amounts of iron present. Transmission by humoral factors circulating in the blood and characterization of the cells during their formation are discussed as transfer mechanisms. [Regulation of Iron Absorption. Fed. Proc. *33*, 100—105 (1974); 67 references]

[Rd 732 IE—R]

The biochemical properties of microtubules are reviewed by *J. Bryan*. These cell organelles of the eukaryotes, whose main function, along with microfilaments, is motion in its broadest sense, contain tubulin, a globular protein. This consists of two chemically different protomers, the α- and β-tubulins. During evolution, both protomers have remained remarkably conservative in their chemical composition and, consequently, in their physical properties. This may be due to steric requirements. From the αβ-heterodimers a structure of higher order can be built which can serve as model for the microtubules. [Biochemical Properties of Microtubules. Fed. Proc. *33*, 152—157 (1974); 77 references]

[Rd 733 IE—R]



The interaction of drugs with microtubule proteins is discussed by *L. Wilson, J. R. Bamburg, S. B. Mizel, L. M. Grisham*, and *K. M. Creswell*. The main theme of the article centers on the reaction between tubulin, the protein of the microtubules and the receptors of several "spindle poisons", and the mitosis inhibitor colchicin. The binding of this inhibitor to the protein hinders polymerization of tubulin and thus leads to destruction of the microtubulus structure. Other substances such as the Vinca alkaloids or griseofulvin, bind to other sites of tubulin or inhibit mitosis *via* other mechanisms. [Interaction of Drugs with Microtubule Proteins. Fed. Proc. *33*, 158—166 (1974); 34 references]

BOOK REVIEWS

MTP International Review of Science. Physical Chemistry: Series One. Edited by *A. Maccoll*. Vol. 5: Mass Spectrometry. Butterworths, London, and University Park Press, Baltimore, 1972. 1st edit., iii, 300 pp., 19 figures, bound, £ 10.00.

The title "Mass Spectrometry", even in combination with the series name "Physical Chemistry", appears to be too broad and misleading. The book consists of a collection—unquestionably well selected—of eight separate and unconnected review-type chapters on different types of ionization and ion-molecule reactions within mass spectrometry, which are not even linked by a common keyword index. Nor do the individual chapters attempt to be comprehensive as a rule: "This review aims to be selective rather than exhaustive" (*Robertson*, p. 107). "This review attempts to cover only a fraction of the subject implied by its title" (*Wahrhaftig*, p. 1). The common element consists in the authors' devoting their primary interest to the examination of reaction kinetics; unlike many others, they do not dwell on descriptions of the instrumentation or methods of measurement, as is evident from the small number of illustrations. A more precise title, such as "Selected Chapters on Ionization and Reaction Kinetics in Mass Spectrometry" would therefore have been preferable.

The numerous references, which go up to 1971, will be particularly valuable for the reader who purchases the volume as a result of coincidental interest in several of the chapters. In some cases they are of vital importance; thus, the "Theory of Mass Spectra" (Chapter 1, *A. L. Wahrhaftig*, 114 references) on 24 pages can be no more than sketchy, and for more detailed work the reader must be directed to "existing review articles". The author excuses his favored treatment of quasi-equilibrium theory: "The reviewer admits his bias, but does hope it has not unduly affected his judgment".

The three chapters on the formation of ions, on the other hand, are considerably more meaningful and detailed: "Ionization and Appearance Potentials" (Chapter 2, *J. D. Morrison*, 30 pp., 212 references), which deals with ionization by electron impact, "Field Ionization" (Chapter 4, *A. J. B. Robertson*, 31 pp., 142 references), and "Chemical Ionization Mass Spectrometry" (Chapter 5, *F. H. Field*, 49 pp., 56 references). Chapter 3, "Recent Advances in Electron Spectroscopy", appears out of place in the series but gives a clear description, accompanied by many references, of photoelectron spectroscopy and spectroscopy with electrons which originate from electron impact, Auger, autoionization, and Penning processes (*C. E. Brion*, 48 pp., 448 references). This is followed by chapters on two separate techniques for the investigation of ion-molecule reactions, "Ion Cyclotron Resonance Mass Spectrometry" (Chapter 6, *C. J. Drewery, G. C. Goode, K. R. Jennings*, 35 pp., 98 references) and "Time-of-flight Mass-Spectrometry" (Chapter 7, *R. S. Lehrle* and *J. E. Parker*, 40 pp., 337 references), and finally on "Metastable Ions in Mass Spectrometry" (Chapter 8, *J. L. Holmes* and *F. M. Benoit*, 42 pp., 173 references).

In general, most of the chapters appear to give a useful survey of the topic under discussion, but the book will only truly benefit the reader prepared to go single-mindedly through the original literature.

Jochen Franzen [NB 219 IE]

Chromatography of Environmental Hazards. Vol. 1. Carcinogens, Mutagens, and Teratogens. By *L. Fishbein*. Elsevier Publishing Company, Amsterdam—London—New York 1972, 1st edit., vii, 490 pp., 210 tables, bound $ 42.25.

This volume, the first of a planned three-volume series on the analytical detection of toxic substances in the human environment, concentrates on those chemicals which cause cancer, mutations, and malformations. They include alkylating agents (nitrosamines, aziridines, epoxides, aldehydes, lactones, phosphoric esters, and pyrrolizidine alkaloids), pesticides (not DDT!), pharmaceuticals, food impurities and additives, and several other toxins such as hydrazines, naphthylamines, urethanes, and peroxides. The analytical methods of detection are limited to paper, thin-layer, and gas chromatography for separation, and corresponding methods of identification. The material is presented very clearly and with the requisite degree of detail, with the result that in most cases supplementary reading of the original literature (partially included up to 1971) does not appear necessary. (Unfortunately, references are given only in the text, and not in the many tables.)

The classification of individual substances as carcinogens, mutagens, and/or teratogens appears somewhat questionable. No indication is given of the criteria for this classification in the form of tables, though there are copious literature references. However, a clear definition of such criteria is just what the chemist needs; for example, reference should have been made to the ambiguity of mutagenicity tests in microorganisms. Formaldehyde is thus classified as a carcinogen, which will hardly be subscribed to by an expert in chemical carcinogenesis. The cytostatic Endoxan, on the other hand, though undoubtedly carcinogenic, appears only as a mutagen and teratogen. Nor does it seem consistent to exclude from this volume the important class of carcinogenic polycyclic hydrocarbons of the 3,4-benzpyrene type; these were left for Volume 2.

Despite these minor defects the publication of this book should be welcomed, since it makes the chemist familiar with toxic pollutants and gives the biologist and the doctor an introduction to and directions for the determination of these substances. It is therefore hoped that the work will find widespread distribution.

Rudolf Preussmann [NB 223]

Bindung, Struktur und Reaktionsmechanismen in der organischen Chemie (Bonding, Structure and Reaction Mechanisms in Organic Chemistry). By *Ivan Ernest*. Springer-Verlag, Vienna—New York 1972. 1st edit., x, 389 pp., 6 figures, bound DM 98.—.

This work represents an attempt at summarizing the ever-growing field of physical organic chemistry. As a result of its limited size some of the aspects are discussed in insufficient detail, but each chapter gives numerous references to original papers, review articles, and monographs.

The book contains a brief introduction to the fundamental concepts of molecular orbital theory, of the types of bonds and stereochemistry, as well as a discussion of the characteristics and classification of organic reactions. Current methods of investigation are cited. The core of the book consists of the treatment of polar, radical, and orbital symmetry-controlled reactions; particularly the first two are discussed critically and in great detail. Recent views on reaction mechanisms, *e.g.* on S_N2 reactions, are also included. The chapter on multicenter reactions was deliberately kept brief by the author, since several monographs have recently appeared on this subject.

The reviewer considers this to be a clear and didactically well-written work. Only a few errors or obscurities have crept in, as *e.g.* in the discussion on the resonance forms of *cis* and *trans*-butadiene (p. 22). Its study is specially recommended to undergraduates. In view of its high price, an inexpensive paperback edition would be welcome.

M. T. Reetz [NB 226 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Methoden der Analytischen Chemie. Eine Einführung. Vol. 1: Trennungsmethoden. By *R. Bock*. Verlag Chemie, Weinheim 1974. 362 pp., bound, DM 42.—.

Separation and Purification Methods, Vol. 2. Edited by *E. S. Perry, C. J. van Oss*, and *E. Grushka*. Marcel Dekker, New York 1974. xi, 466 pp., bound, $ 22.50.

The Theory of Pericyclic Reactions

By Nicoloas D. Epiotis[*]

Pericyclic reactions include thermal and photochemical cycloadditions and cycloreversions, electrocyclic reactions and sigmatropic shifts. Configuration interaction analysis can be used for making predictions about preferred reaction pathways, about reaction rates, about the nature of possible intermediate steps, and above all about the stereochemistry of such reactions.

1. Introduction

In 1965, in a series of preliminary communications, *Woodward* and *Hoffmann*[1] first enunciated the principle of the conservation of orbital symmetry in concerted reactions. Since the initial Woodward-Hoffmann contribution, there have been three major developments in the theory of pericyclic reactions:

The first development has been the publication of alternative theoretical schemes for the discussion of pericyclic reactions[2–9], all leading, with minor exceptions, to the same conclusions as the original Woodward-Hoffmann formulation. Of course, all these additional theoretical approaches differ in rigor, general applicability and conceptual simplicity but have served to sharpen our intuition in dealing with the intricate electronic factors which determine the outcome of a pericyclic reaction.

The second development has been the realization that the Woodward-Hoffmann rules can be modified depending on the electronic nature of the reactants, if one recognizes the importance of electronic configurations other than the lowest energy one in describing transition state complexes. In recent publications, we have discussed the importance of charge transfer configurations in thermal and photochemical cycloadditions[10] as well as the importance of doubly excited configurations in thermal pericyclic reactions of various types[11]. The discovery of the importance of configuration interaction in determining the electronic properties of transition states seems, in retrospect, to have been an inevitable discovery. Indeed, many years ago spectroscopists realized that the electronic transitions of molecules could be completely understood only on the basis of a theory which included configuration interaction as a key element[12]. In recent years, *Bader*[13], *Salem*[14], and *Pearson*[15] discussed the importance of excited states in determining the electronic properties of molecules and transition states. Thus, the development of new stereoselection rules based on configuration interaction theory was an inescapable step in the development of the original ideas of *Woodward* and *Hoffmann*. In addition to our work, one should mention the interesting contributions of *Baldwin*[16], *Michl*[17], and *Schmidt*[18] and the theoretical work of *Buenker* and *Peyerimhoff*[19], *Dewar*[20], *Trindle*[21], *Jackson*[22a], and *Raff* and *Porter*[22b] towards understanding how configuration interaction can modify our one configuration view of molecules and reactions.

The third development has been the realization that certain types of orbital interactions, other than frontier orbital interactions, can have some influence on the outcome of certain concerted reactions[23]. The last two developments are bound to stimulate further theoretical and experimental work in the area of pericyclic reactions and may lead to systematization of an enormous number of chemical facts.

In this progress report, a formal configuration interaction theory which can be used in either a semiquantitative or a qualitative sense for making predictions about preferred reaction pathways is presented. The emphasis has been placed on qualitative applications of the theory to stereochemical and rate aspects of pericyclic reactions and the aim has been the development of a general predictive scheme which can be readily put into test in the laboratory.

Seattle, Washington 98195 (USA)

2. Theory

In this work, we shall focus our attention on three general types of reactions:

a) Intermolecular cycloadditions.
b) Electrocyclic reactions.
c) Sigmatropic shifts.

A typical example of an intermolecular cycloaddition is the union of two ethylenes to form cyclobutane. The transition state of such a reaction involves the interaction of two molecules, namely, two ethylene molecules. A typical example of an electrocyclic reaction is the butadiene → cyclobutene transformation and the transition state of such a reaction involves the interaction of two formal molecular fragments, namely, the two ethylenic bonds of butadiene. Finally, a typical example of a sigmatropic shift is the 1,3 migration of carbon in 1-butene; the transition state of such a rearrangement involves the interaction of two formal radical fragments, namely, the migration framework (allyl radical) and the migrating group (methyl radical). In a general sense, most reactions involve the interaction of two fragments at the transition state and these fragments can be real or formal molecules. Unless the two fragments are identical, we can define one as the donor fragment D and the other as the acceptor fragment A[10]. The electronic states of the transition state complex DA involved in an intermolecular cycloaddition, an electrocyclic reaction, or, a sigmatropic shift can be described in terms of linear combinations of wavefunctions appropriate to the fragments D and A. In order to maximize the simplicity of the theory and yet retain the important features of our analysis, we may choose a minimal basis set of zero order configuration wavefunctions. The zero order configuration wavefunctions forming our basis set are:

1. The no bond configuration DA.
2. The locally excited configurations D*A and DA*.
3. The charge transfer configurations $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$.

For brevity, we shall use the term configuration as an alternative term for zero order configuration wavefunction.

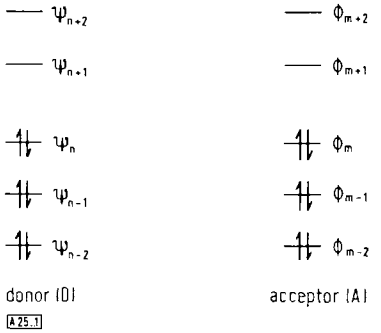

Fig. 1. Molecular orbitals of the donor (D) and acceptor (A) fragments.

The occupied and unoccupied MOs of the D and A fragments are shown in Fig. 1. By employing familiar quantum mechanical notation, we can write each configuration of the basis set in terms of the spin MOs of the two fragments.

In the above equations, A is the antisymmetrization operator. The presence of a dash above ψ or ϕ denotes a spin MO of α spin and the absence of a dash above ψ or ϕ denotes a spin MO of β spin. All five configurations are singlet configurations conforming to the Pauli Exclusion Principle. The energies associated with the five configurations can be written as follows:

$$E(DA) = 0 \quad (1)$$
$$E(D^{\oplus}A^{\ominus}) = -\varepsilon_n + \varepsilon_{m+1} - C = I_D - A_A - C \quad (2)$$
$$E(D^{\ominus}A^{\oplus}) = -\varepsilon_n + \varepsilon_{n+1} - C' = I_A - A_D - C' \quad (3)$$
$$E(D^*A) = -\varepsilon_n + \varepsilon_{n-1} \approx h\nu(n \rightarrow n+1) \quad (4)$$
$$E(DA^*) = -\varepsilon_m + \varepsilon_{m-1} \approx h\nu(m \rightarrow m+1) \quad (5)$$

In the above equations, ε is the SCF-MO energy, I_D is the lowest ionization potential of the donor, I_A is the lowest ionization potential of the acceptor, A_D is the electron affinity of the donor, A_A is the electron affinity of the acceptor, and C and C' are the electrostatic attractive interactions of the excess electron of one fragment with the electron hole of the other fragment and the rest of the symbols have their usual meaning.

We note at this point that, when the two fragments become identical, the charge transfer configurations and the locally excited configurations will have to be replaced by charge-resonance and excitation-resonance configurations[24], respectively. In such a case, the energies of the charge-resonance configurations will still be given by equations (2) and (3), while the energies of the excitation-resonance configurations will be given by equations (4) and (5) corrected for exciton type interaction[25] of the two fragments.

Inspection of equations (1)—(5) reveals that the quantities I_D, I_A, A_D, A_A, $h\nu\,(n \rightarrow n+1)$ and $h\nu\,(m \rightarrow m+1)$ can be extracted from experimental data and only C and C' need to be calculated explicitly[26]. Thus, we are in a position to rank the various configurations according to their relative energies as determined by reference to experimental data. These config-

urations represent the electronic states of the transition state complex in the hypothetical case of zero configuration interaction. Obviously, the real electronic states of the transition state complex result from the interaction between the various configurations and the difference in energy between a configuration and the corresponding electronic state arising from configuration interaction can be thought of as the stabilization or destabilization energy due to configuration interaction.

We can now consider explicitly how configurations interact to produce electronic states. Our first task is to define the Hamiltonian operator, remembering that we are dealing with reactions which involve simultaneous formation of more than one bond in the transition state.

$$H = H_D + H_A + H' \qquad (6)$$

In order to simplify our analysis, we adopt a Hamiltonian which consists of only one electron terms and we set out to develop electronic states which arise from one electron configuration mixing. In equation (6), H_D operates only on fragment D, H_A operates only on fragment A and H′ operates along the two or more forming bonds. Now, we can assume that the MOs of fragment D are orthogonal with respect to H_D and the MOs of fragment A are orthogonal with respect to H_A. Hence, H′ will be solely responsible for configuration mixing. A quantitative determination of the electronic states of a transition state complex DA can then be easily accomplished. Specifically, we can construct the energy matrix, where the diagonal elements are the energies of the zero order configurations and the off diagonal elements are the interaction terms between the zero order configurations. The important thing is that many of these matrix elements can be empirically evaluated by reference to experimental data. We can solve the corresponding secular determinant and get the eigenvalues and eigenvectors of the electronic state wavefunctions. The availability of high speed computers and the existence of ionization potential and spectroscopic data which can serve as empirical input make such configuration interaction calculations possible for systems of chemical interest.

While the theoretician might be interested in the subtle features of a problem which can only be revealed by explicit computation, the organic chemist is more interested in a general qualitative theory which can be directly applicable to problems of interest without the need of computer assistance. Hence, we should reduce the quantitative scheme for the determination of electronic states to a qualitative scheme which can still retain the important features of the theory. The various steps which one has to follow in attempting a qualitative configuration interaction analysis of chemical reactivity are given below:

Step 1. Rank the basis set configurations according to their relative energy. This can be implemented by means of equations (1) to (5).

Step 2. Construct the interaction matrix for the basis set configurations.

Step 3. Generate the electronic states of a given transition state complex by noting that the energy change of any two nondegenerate basis set configurations arising from their interaction will be inversely proportional to the energy difference between the two basis set configurations and directly proportional to the square of their interaction matrix element. The analogy between MO splitting, which is familiar to the organic chemist[27], and configuration splitting as a result of interaction is shown in Fig. 2.

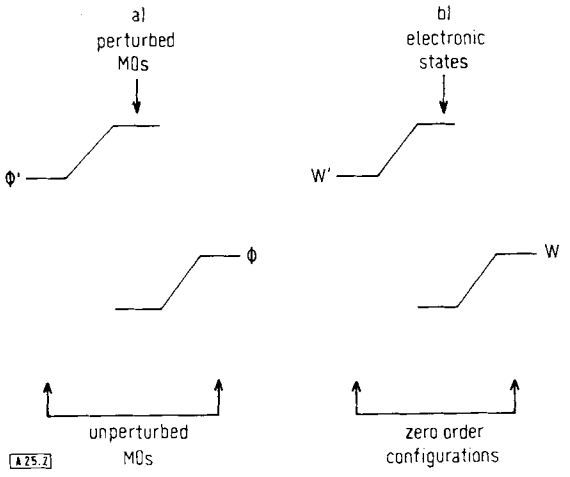

Fig. 2. a) MO interaction diagram, b) configuration interaction diagram. W and W′ are configurations.

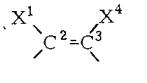

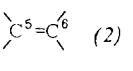

After these steps are completed, one can determine the preferred stereochemical course of a thermal reaction by comparing the relative energies of the lowest electronic states of the transition state complexes corresponding to different stereochemical modes of reaction. Similarly, one can determine the preferred stereochemistry of a photochemical reaction by comparing the relative energies of the first electronically excited states of the transition complexes corresponding to different stereochemical modes of reaction. Other reaction features can be determined in a similar manner[28].

We shall now consider how qualitative configuration interaction theory can be applied to $4n$ and $4n+2$ electron cycloadditions, electrocyclic reactions, and sigmatropic shifts. We shall try to determine the preferred stereochemistry of such reactions under the assumption that they are concerted and involve continuous bonding around the uniting atomic centers in the transition state. Such a transition state will be referred to as "pericyclic".

3. Intermolecular [2+2] Cycloadditions

3.1. Nonpolar Intermolecular [2+2] Cycloadditions

We first examine the case of nonpolar cycloadditions (AD) of *(1)* and *(2)*, where *(1)* is assumed to be the donor partner and *(2)* the acceptor partner. X is assumed to be a heteroatom with a lone pair of electrons in the p_z orbital.

(1)  *(2)* 

D A

In order to simplify the discussion, we assume that equal bond making between C^2 and C^5 and between C^3 and C^6 has taken place at the transition state. The one electron Hamiltonian is written as follows:

$$H = H_{(1)} + H_{(2)} + H'$$

where

$$H' = H_{25} + H_{36}$$

The basis set configurations for the [2+2] cycloaddition transition state complex are shown in Fig. 3. The corresponding wavefunctions can be written as Slater determinants in the manner illustrated in Section 2. The energy of the no bond configuration DA is the zero point on the energy scale. The next configuration in order of increasing energy is the charge transfer configuration $D^{\oplus}A^{\ominus}$. This configuration will necessarily have lower energy than the locally excited configurations D*A and DA* because the promotional energy $\varepsilon_3 - \varepsilon'_2$ in the $D^{\oplus}A^{\ominus}$ configuration is less than the promotional energies $\varepsilon_3 - \varepsilon_4$ and $\varepsilon'_1 - \varepsilon'_2$ in the D*A and DA* configurations respectively and also because the energy of the $D^{\oplus}A^{\ominus}$ configuration is further lowered on account of the coulombic attraction C of the two fragments. The relative energy of the locally excited configurations D*A and DA* will depend to a large extent on the energy difference between ϕ_3 and ϕ_4 in the donor partner and the energy difference between ψ_1 and ψ_2 in the acceptor partner. Finally, the charge transfer configuration $D^{\ominus}A^{\oplus}$ can have either higher or lower energy than one or both of the locally excited configurations D*A and DA* depending on the magnitude of the attractive coulombic term C' relative to the promotional energy term $\varepsilon'_1 - \varepsilon_4$.

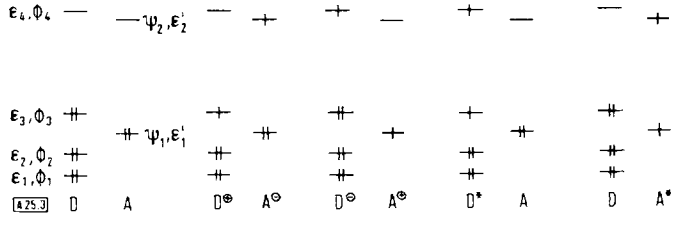

Fig. 3. Basis set configurations for a nonpolar [2+2] cycloaddition. D is the donor and A the acceptor fragment.

The next step is to construct the interaction matrix. This involves computing matrix elements between determinantal wave functions which can be easily accomplished by adhering to simple rules[29]. The interaction matrix is shown in Scheme 1[30].

	DA	D*A	DA*	$D^{\oplus}A^{\ominus}$	$D^{\ominus}A^{\oplus}$
DA	X				
D*A	0	X			
DA*	0	0	X		
$D^{\oplus}A^{\ominus}$	$\langle\phi_3\|H'\|\psi_2\rangle$	$\langle\phi_4\|H'\|\psi_2\rangle$	$\langle\phi_3\|H'\|\psi_1\rangle$	X	
$D^{\ominus}A^{\oplus}$	$\langle\phi_4\|H'\|\psi_1\rangle$	$\langle\phi_3\|H'\|\psi_1\rangle$	$\langle\phi_4\|H'\|\psi_2\rangle$	0	X

Scheme 1. Interaction matrix for a nonpolar [2+2] cycloaddition [30].

At this point, a brief digression would seem justifiable in order to consider the physical significance of matrix elements. In all cases of interest to us, the one electron operator H' responsible for configuration mixing operates along the two pairs of uniting atoms, say pair A and pair B. One can write H' as a sum of two one-electron operators, one (H_A) operating along pair A and another (H_B) operating along pair B.

$$H' = H_A + H_B$$

The matrix element of two configurations W_1 and W_2 with respect to H' can be written as

$$\langle W_1|H'|W_2\rangle = \langle W_1|H_A|W_2\rangle + \langle W_1|H_B|W_2\rangle$$

We distinguish the following cases of interest:

a) $\langle W_1|H_A|W_2\rangle$ and $\langle W_1|H_B|W_2\rangle$ are finite and have the same sign. In such a case $\langle W_1|H'|W_2\rangle$ in absolute magnitude is large, the two configurations mix strongly and there is pericyclic bonding, *e.g.* the resultant electronic state involves bonding interactions along both pairs of atoms.

b) $\langle W_1|H_A|W_2\rangle$ and $\langle W_1|H_B|W_2\rangle$ are finite but have opposite signs. In such a case $\langle W_1|H'|W_2\rangle$ is very small or zero, the two configurations mix slightly or not at all and there is no pericyclic bonding, *e.g.* the resultant electronic state involves a bonding and an antibonding interaction along the two pairs of atoms.

c) $\langle W_1|H_A|W_2\rangle$ is finite but $\langle W_1|H_B|W_2\rangle$ is zero. In such a case $\langle W_1|H'|W_2\rangle$ is still apreciable, the two configurations mix but there is no pericyclic bonding, *e.g.* the resultant electronic state involves a bonding and a nonbonding interaction along the two pairs of atoms. In all subsequent discussions, the matrix elements are evaluated with respect to H' and the resultant electronic states are designated pericyclic or nonpericyclic.

The π MOs of *(1)* and *(2)* are of the general form:

$$\phi_1 = C_{11}p_1 + C_{12}p_2 + C_{13}p_3 + C_{14}p_4$$
$$\phi_2 = C_{21}p_1 + C_{22}p_2 - C_{23}p_3 - C_{24}p_4$$
$$\phi_3 = C_{31}p_1 - C_{32}p_2 - C_{33}p_3 + C_{34}p_4$$
$$\phi_4 = C_{41}p_1 - C_{42}p_2 + C_{43}p_3 - C_{44}p_4$$

where

$$C_{11} = C_{14};\ C_{12} = C_{13}$$
$$C_{21} = C_{24};\ C_{22} = C_{23}$$
$$C_{31} = C_{34};\ C_{32} = C_{33}$$
$$C_{41} = C_{44};\ C_{42} = C_{43}$$

and

$$\psi_1 = C_{15}p_5 + C_{16}p_6$$
$$\psi_2 = C_{25}p_5 - C_{26}p_6$$

where

$$C_{15} = C_{16};\ C_{25} = C_{26}$$

In the above equations, $C_{\mu\nu}$ is the 2p AO coefficient of the νth atom of the μth MO and p_ν is the 2p AO of the νth atom. Because of the symmetry of *(1)* and *(2)*, one has the general relationships

$$C_{\mu 1} = C_{\mu 4}$$
$$C_{\mu 2} = C_{\mu 3}$$

and

$$C_{\mu 5} = C_{\mu 6}$$

The MO integrals of the half interaction matrix can be expanded into AO integrals. In this and all subsequent cases, the sign of the matrix element will not concern us since we shall be dealing with interactions of nondegenerate basis set configurations where the energy change is proportional to the square of the matrix element. Hence, we establish the convention of writing

all interaction matrix elements as positive quantities. In the case of a [2s+2s] cycloaddition (s=suprafacial), the MO integrals become:

$$\langle\phi_3|H'|\psi_2\rangle = 0$$
$$\langle\phi_4|H'|\psi_1\rangle = 0$$
$$\langle\phi_4|H'|\psi_2\rangle = 2C_{42}C_{25}\gamma_{25}$$
$$\langle\phi_3|H'|\psi_1\rangle = 2C_{32}C_{15}\gamma_{25}$$

where

$$\gamma_{25} = \langle p_2|H'|p_5\rangle;$$
$$\gamma_{36} = \langle p_3|H'|p_6\rangle$$

These resonance integrals are appropriate to [2s+2s] union so we can define:

$$\gamma_{25} = \gamma_{36} = \gamma_S$$

In the case of a [2s+2a] cycloaddition (a=antarafacial), the MO integrals become:

$$\langle\phi_3|H'|\psi_2\rangle = 2C_{32}C_{25}\gamma'_{25}$$
$$\langle\phi_4|H'|\psi_1\rangle = 2C_{42}C_{15}\gamma'_{25}$$
$$\langle\phi_4|H'|\psi_2\rangle = 0$$
$$\langle\phi_3|H'|\psi_1\rangle = 0$$

where

$$\gamma'_{25} = \langle p_2|H'|p_5\rangle;$$
$$\gamma'_{36} = \langle p_3|H'|p_6\rangle$$

These resonance integrals are appropriate to [2s+2a] union so we define:

$$\gamma'_{25} = \gamma'_{36} = \gamma_A$$

Accordingly, the half interaction matrices for [2s+2s] and [2s+2a] cycloadditions can be written as shown in Scheme 2.

a) [2s+2s]	DA	D*A	DA*	$D^{\oplus}A^{\ominus}$	$D^{\ominus}A^{\oplus}$
DA	X				
D*A	0	X			
DA*	0	0	X		
$D^{\oplus}A^{\ominus}$	0	$2C_{42}C_{25}\gamma_S$	$2C_{32}C_{15}\gamma_S$	X	
$D^{\ominus}A^{\oplus}$	0	$2C_{32}C_{15}\gamma_S$	$2C_{42}C_{25}\gamma_S$	0	X

b) [2s+2a]	DA	D*A	DA*	$D^{\oplus}A^{\ominus}$	$D^{\ominus}A^{\oplus}$
DA	X				
D*A	0	X			
DA*	0	0	X		
$D^{\oplus}A^{\ominus}$	$2C_{32}C_{25}\gamma_A$	0	0	X	
$D^{\ominus}A^{\oplus}$	$2C_{42}C_{15}\gamma_A$	0	0	0	X

Scheme 2. Half interaction matrices for [2s+2s] and [2s+2a] cycloadditions.

Examination of the two interaction matrices leads to the following conclusions:

1. In the case of [2s+2s] union, the locally excited configurations D*A and DA* can interact strongly with the charge transfer configurations $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ in order to produce the electronic states S_1, S_2, S_3 and S_4 which involve pericyclic bonding of the two cycloaddition partners. In contrast, the remaining electronic state S_0 is a single configuration state without pericyclic bonding. This last electronic state S_0 is a non-bonding state.

2. In the case of [2s+2a] union, the ground state configuration DA can interact weakly with the charge transfer configurations $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ in order to produce the electronic states A_0, A_1 and A_4 with pericyclic bonding of the two cycloaddition partners. In contrast, the remaining electronic states A_2 and A_3 are single configuration states without pericyclic bonding. A_2 and A_3 are non-bonding electronic states.

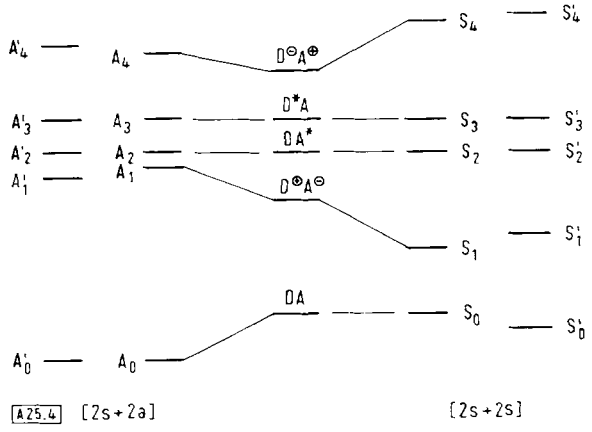

Fig. 4. Configuration interaction diagram for a nonpolar [2+2] cycloaddition. The S and A states refer to symmetrical cases and the S' and A' states to unsymmetrical cases.

These considerations can be simply understood by reference to Fig. 4 which illustrates how the basis set configurations interact to form the final electronic states of the [2s+2s] and [2s+2a] transition state complexes[31]. The configuration interaction diagram (Fig. 4) is constructed under the assumption that the resonance integrals for the [2s+2s] and the [2s+2a] union have the same magnitude.

$$\gamma_S = \gamma_A$$

This assumption simplifies the construction of the configuration interaction diagram and helps focusing our attention on the electronic factors responsible for configuration mixing. However, in addition to the configuration interaction diagram, we have to consider the steric features of [2s+2s] and [2s+2a] transition state complexes in order to assess reliably the relative energy of the corresponding electronic states.

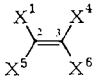
The chemical implications of the configuration interaction diagram are straightforward:

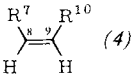
1. A concerted nonpolar [2+2] cycloaddition will proceed thermally in a [2s+2a] manner because the lowest electronic state A_0 involves pericyclic bonding and has lower energy than the lowest electronic state S_0 which does not involve pericyclic bonding. The electronic stabilization of the [2s+2s] and [2s+2a] transition state complexes due to configuration interaction are:

$$SE(2s+2a) = E(A_0) - E(DA) > 0$$
$$SE(2s+2s) = E(S_0) - E(DA) = 0$$

Now, the magnitude of the electronic stabilization of the [2s+2a] transition state complex is small because the energy difference between the DA, $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ configurations is large. Furthermore, the [2s+2a] transition state complex is sterically destabilized. Accordingly, *one may expect that*

a diradical mechanism can dominate a concerted [2s+2a] union of the cycloaddends in thermal nonpolar [2+2] cycloadditions.





2. A concerted nonpolar [2+2] cycloaddition will proceed photochemically in a [2s+2s] manner because the first excited electronic state S_1 is of lower energy than the first electronic state A_1 and both states involve pericyclic bonding. Furthermore, steric destabilization of the excited electronic states of the [2s+2a] transition state complex, if any, can only serve to accentuate the preference for [2s+2s] over [2s+2a] union. The S_1 state has excimer character[32] since it is a mixture of charge transfer and locally excited configurations, while the A_1 state has charge transfer character[33] since it is a mixture of no bond and charge transfer configurations. Finally, we note that S_1 involves strong pericyclic bonding and A_1 involves weak pericyclic bonding. This arises because S_1 is the product of strong configuration mixing, while A_1 is not.

The theoretical analysis presented above is appropriate for nonpolar cycloadditions of two symmetrical molecules involving equal bond formation at the transition state. In practice, one or both cycloaddends can be unsymmetrically substituted and the cycloaddition may involve unequal bond making at the transition state. Under these circumstances, certain MO integrals can become nonzero, albeit small in magnitude. The result is that additional configuration mixing can take place and this is illustrated in Fig. 4. Calculations show that in most cases the asymmetry induced configuration mixing is small and can be neglected when one aims at qualitative generalizations[34]. Inspection of Fig. 4 reveals that the asymmetry induced configuration mixing does not alter our qualitative conclusions.

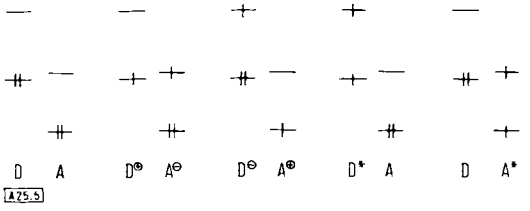
There is a subtle feature involved in asymmetry induced configuration mixing which can be best understood by reference to a specific case. For example, in the case of nonpolar [2s+2s] cycloaddition the no bond configuration DA cannot mix with any of the other configurations when the transition state complex has high symmetry. Now, the absence of symmetry allows DA to mix to a small extent with $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ and generate the electronic state S'_0. In most cases, such induced mixing does not result in pericyclic bonding. Instead, there is a bonding interaction between two centers and an antibonding interaction between the other two centers, the former being stronger than the latter. As a result, asymmetry induced configuration mixing serves to lower the energy of S'_0 relative to S_0 but does not result in pericyclic bonding. To put it crudely, asymmetry induced mixing transforms a nonbonding state into a slightly bonding state but not into a pericyclic state. This discussion is applicable to all other subsequent cases where asymmetry induced mixing is a realistic possibility.

3.2. Polar Intermolecular [2+2] Cycloadditions

We now proceed to examine the case of polar (AX) cycloaddition of *(3)* and *(4)*, where *(3)* is assumed to be the donor partner and *(4)* the acceptor partner. X is a heteroatom with a lone pair in the p_z orbital and R is an electron acceptor substituent.

(3)  *(4)* 

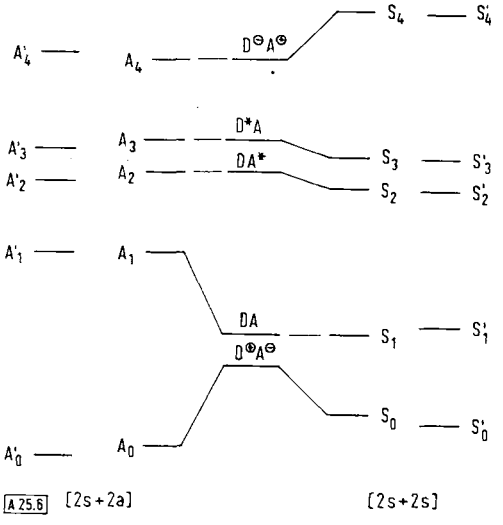
D A



Again, in order to simplify the discussion, we assume that equal bond making between C^2 and C^8 and between C^3 and C^9 has taken place at the transition state. The one electron Hamiltonian is written as follows:

$$H = H_{(3)} + H_{(4)} + H'$$

where

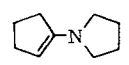


$$H' = H_{28} + H_{39}$$

Our analysis proceeds in exactly the same manner as in the case of nonpolar cycloadditions. The basis set configurations for the [2+2] cycloaddition transition state complex are shown in Fig. 5. The corresponding wave functions can be written as Slater determinant wave functions. The relative energies of the basis set configurations are shown in Fig. 6. The situation is similar to that encountered in nonpolar [2+2] cycloadditions, with one important difference: *in polar [2+2] cycloadditions, the charge transfer configuration $D^{\oplus}A^{\ominus}$ can be the configuration of lowest energy, e.g.* there is a reversal in the relative energy ordering of the $D^{\oplus}A^{\ominus}$ and DA configurations. In general, as one goes from a nonpolar to a polar [2+2] cycloaddition, the energy of the $D^{\oplus}A^{\ominus}$ configuration decreases. At the limit of a very polar cycloaddition, the energy of the $D^{\oplus}A^{\ominus}$ configuration can be lower than the energy of the DA configuration.

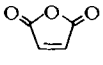
A 25.5

Fig. 5. Basis set configurations for a polar [2+2] cycloaddition. D is the donor and A the acceptor fragment. Only the HOMO and LUMO of the donor and acceptor fragments are shown.



A 25.6

Fig. 6. Configuration interaction diagram for a polar [2+2] cycloaddition. The S and A states refer to symmetrical cases and the S' and A' states to unsymmetrical cases.



It is interesting to investigate the conditions for energy equality between the $D^{\oplus}A^{\ominus}$ and DA configurations. In typical [2+2]

cycloadditions, the magnitude of the coulombic term C ranges between three and six electron volts[35]. Hence, one can qualitatively expect that the energy of the $D^{\oplus}A^{\ominus}$ configuration can be lower than the energy of the DA configuration whenever the quantity $I_D - A_A$ has a value between three and six electron volts. This latter condition is met when the two cycloaddends are a good donor olefin and a good acceptor olefin. For example, the ionization potential I_D of a good donor[36] and the electron affinity A_A of a good acceptor olefin[37] are shown below. The quantity $I_D - A_A$ is calculated to be 4.44 eV. Even lower values are expected for better donors and acceptors.

(5)

I_D = 7.33 eV

(6)

A_A = 2.89 eV

The possibility that the charge transfer configuration $D^{\oplus}A^{\ominus}$ can have higher, equal, or lower energy than the no-bond DA configuration has been emphasized by *Kosower* in his discussion of charge transfer complexes[38].

We wish to emphasize that the estimates of the energy of the $D^{\oplus}A^{\ominus}$, $D^{\ominus}A^{\oplus}$, DA* and D*A configurations are conservative. At the transition state, the olefinic bonds are stretched in the process of forming the cyclobutane adduct. Bond stretch gives rise to increased HOMO energy and decreased LUMO energy, *e.g. at the transition state a molecule is a better donor and acceptor relative to the same molecule in its equilibrium state.* As a result, the $D^{\oplus}A^{\ominus}$, $D^{\ominus}A^{\oplus}$, D*A and DA* configurations will have even lower energy than the ones calculated on the basis of data pertaining to the two cycloaddends in their equilibrium state[39].

We can now proceed to examine how the basis set configurations interact in order to form the final electronic states. By following the same procedure as in the case of nonpolar [2+2] cycloaddition, we can construct the general interaction matrix, expand the molecular orbital integrals into atomic orbital integrals and arrive at the interaction matrices for [2s+2s] and [2s+2a] union of the two cycloaddends. The resultant electronic states are shown in Fig. 6. Once more, the configuration interaction diagrams (Fig. 6) are constructed under the assumption that $\gamma_S = \gamma_A$. It can be seen that the states A_0, A_1, A_4, S_0, S_2, S_3, and S_4 involve pericyclic bonding, while the states A_2, A_3, S_1 do not involve pericyclic bonding. An examination of the configuration interaction diagram leads to the following conclusions:

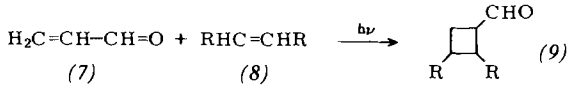
1. Unlike a concerted nonpolar [2+2] cycloaddition, a concerted polar [2+2] cycloaddition can proceed thermally in a [2s+2s] manner because both S_0 and A_0 electronic states involve pericyclic bonding. The electronic stabilization of the [2s+2s] and [2s+2a] transition state complexes due to configuration interaction are:

$$SE(2s+2a) = E(A_0) - E(D^{\oplus}A^{\ominus}) > 0$$
$$SE(2s+2s) = E(S_0) - E(D^{\oplus}A^{\ominus}) > 0$$

Now, the magnitude of the electronic stabilization of the [2s+2a] transition state complex is greater than the magnitude of the electronic stabilization of the [2s+2s] transition state complex due to configuration interaction. This is primarily due to a small energy separation of the DA and $D^{\oplus}A^{\ominus}$ configurations and a larger energy separation of the $D^{\oplus}A^{\ominus}$ and D*A and DA* configurations. On the other hand, the [2s+2a] transition state complex is sterically destabilized to a very large extent relative to the [2s+2s] transition state complex. Hence, a combination of the two effects is almost certain to lead to S_0 having a lower energy than A_0. The electronic stabilization of concerted [2s+2s] union and its favorable steric features lead one to expect that *polar [2+2] cycloadditions will occur thermally in a concerted [2s+2s] manner.*

2. A concerted polar [2+2] cycloaddition will proceed photochemically in a [2s+2a] manner because the first excited electronic state A_1 involves pericyclic bonding while the first excited electronic state S_1 does not; *e.g.* S_1 is a non-bonding state. Furthermore, A_1, the lowest excited state involving [2s+2a] pericyclic bonding, has lower electronic energy than S_2, the lowest excited state involving [2s+2s] pericyclic bonding. Whenever steric destabilization of the excited electronic states of the [2s+2a] transition state complex is small, A_1 will have lower energy than S_2. Once again, we note that S_2, the lowest excited state of the [2s+2s] transition state complex, has excimer character, while A_1, the lowest excited state of the [2s+2a] transition state complex, has charge transfer character. Finally, we note that A_1 involves strong pericyclic bonding and S_2 involves weak pericyclic bonding.

Asymmetry induced mixing can be present in polar [2+2] cycloaddition. In the case that one or both cycloaddends are unsymmetrically substituted or the cycloaddition involves unequal bond making at the transition state, certain integrals can become nonzero, albeit small in magnitude. The result is that additional configuration mixing can take place; this is illustrated in Fig. 6. Again, this effect is small in magnitude and can be neglected when one aims at qualitative generalizations. Inspection of Fig. 6 reveals that the asymmetry induced configuration mixing does not alter our qualitative conclusions.



There are two important classes of photochemical [2+2] nonpolar cycloadditions which merit special attention:

1. Nonpolar [2+2] photocycloadditions involving $n\pi^*$ excitation of one cycloaddend.

2. Nonpolar [2+2] photocycloadditions involving a photoexcited carbonyl group.

We shall examine these two cases in some detail.

A nonpolar [2+2] photocycloaddition involving $n\pi^*$ excitation of one cycloaddend is typified by the reaction of *(7)* and *(8)* to give *(9)*.

(7) *(8)* *(9)*

R = CN, CHO, COOR', etc.

In such a reaction, the $n\pi^*$ excited enone *(7)* attacks an electron poor olefin *(8)* in its ground state. In this reaction, the singly occupied nonbonding orbital of the photoexcited enone does not participate in the reaction; *e.g.* it is only the olefinic bond of the photoexcited enone which is involved

in the photocycloaddition. Hence, the excited electronic states of the transition state complex can only be constructed from zero order configurations which have a singly occupied nonbonding orbital in the enone. The important configurations of this type are shown in Fig. 7 and the corresponding configuration interaction diagram is shown in Fig. 8. It is clear that such photoreactions must be [2s+2s] stereoselective.

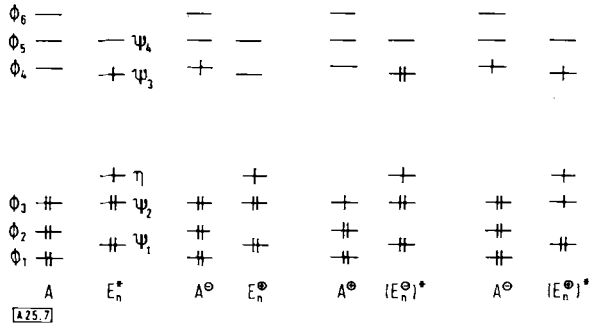


Fig. 7. Basis set configurations for a nonpolar [2+2] photocycloaddition of an nπ* excited enone to an electron acceptor olefin. E denotes the enone fragment and A the acceptor olefin fragment.

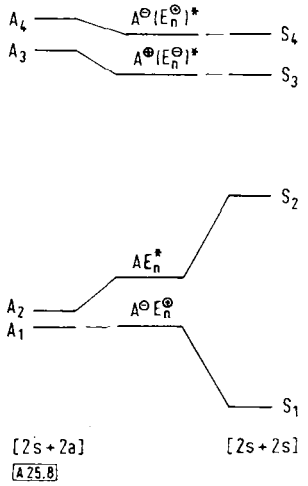

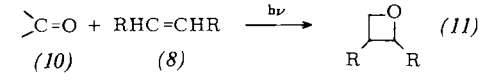

Fig. 8. Configuration interaction diagram for a nonpolar [2+2] photocycloaddition of an nπ* excited enone to an acceptor olefin.

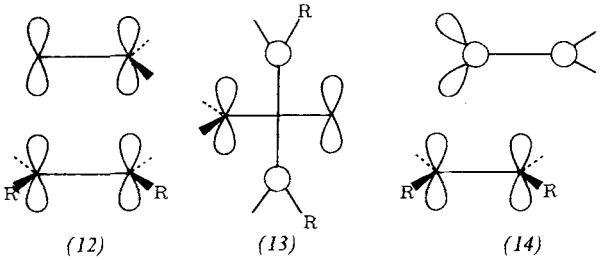

A nonpolar [2+2] photocycloaddition of a photoexcited carbonyl is typified by the reaction *(10)* + *(8)* → *(11)*.

(10) *(8)* *(11)*

R = CN, CHO, COOR', etc.

In this reaction, either the n or π electrons of the carbonyl group can be involved in the photocycloaddition. As a result, there are three possible transition state geometries: *(12)*, *(13)*, and *(14)*.

(12) *(13)* *(14)*

The basis set configurations (Fig. 9) include both nπ* and ππ* excited configurations.

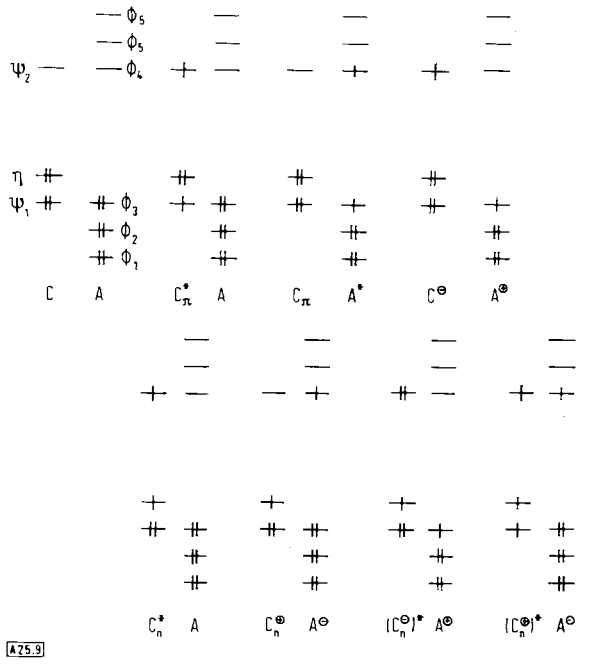

Fig. 9. Basis set configurations for a nonpolar [2+2] photocycloaddition involving a carbonyl group. C denotes the carbonyl fragment and A the acceptor olefin fragment.

Now, if the photocycloaddition is initiated by nπ* excitation of the carbonyl group, then the appropriate excited states of the photocycloaddition transition state complex are constructed from the zero order configurations which mix with the C_n^*A configuration (C signifies carbonyl group). The corresponding general interaction matrix is shown in Scheme 3.

	CA	C_n^*A	$C_n^{\oplus}A^{\ominus}$	$(C_n^{\ominus})^*A^{\oplus}$	$(C_n^{\oplus})^*A^{\ominus}$	$C^{\ominus}A^{\oplus}$
CA	X					
C_n^*A	0	X				
$C_n^{\oplus}A^{\ominus}$	$\langle n\|H\|\phi_4\rangle$	$\langle\psi_2\|H\|\phi_4\rangle$	X			
$(C_n^{\ominus})^*A^{\oplus}$	0	$\langle\psi_2\|H\|\phi_3\rangle$	0	X		
$(C_n^{\oplus})^*A^{\ominus}$	0	$\langle\psi_1\|H\|\phi_4\rangle$	0	0	X	
$C^{\ominus}A^{\oplus}$	$\langle\phi_3\|H\|\psi_2\rangle$	$\langle n\|H\|\phi_3\rangle$	0	0	0	X

Scheme 3. General interaction matrix for a nonpolar [2+2] photocycloaddition involving a carbonyl group.

The resulting configuration interaction diagram is shown in Fig. 10. In this case, as in Fig. 12 and Fig. 13, the $C^{\ominus}A^{\oplus}$ ($C^{\ominus}D^{\oplus}$) configuration does not take part in the formation of the [2s+2s] and [2s+2a] states, since it cannot mix with the other configurations and would represent a high nonbonding state. It follows that nonpolar [2+2] photocycloadditions involving the carbonyl group will be [2s+2s] stereoselective[40]. On the other hand, if the photocycloaddition is initiated by ππ* excitation of the carbonyl group or the olefin, then the appropriate excited states of the photocycloaddition transition state complex are constructed from the zero order configurations which mix with the C_n^*A or $C_\pi A^*$ configurations. The latter two cases are identical to the case of nonpolar [2+2] photocycloaddition of two simple olefins which was discussed before. An important aspect of these photocycloadditions is that asymmetry at the transition state can intermix nπ* and ππ* excited configurations. If such an

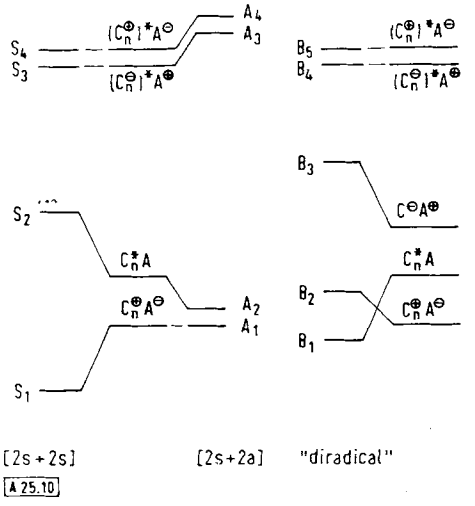

Fig. 10. Configuration interaction diagram for a nonpolar [2+2] photocycloaddition of an nπ* excited carbonyl to an acceptor olefin. The states B_0—B_5 refer to a pseudodiradical.

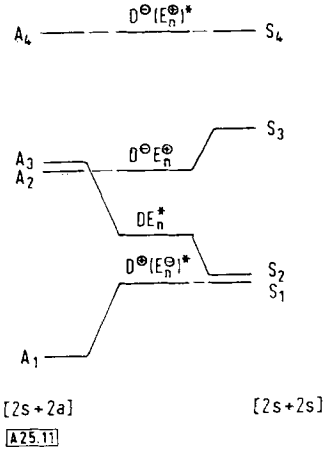

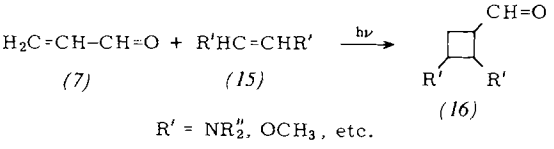

Fig. 11. Configuration interaction diagram for polar [2+2] photocycloaddition of a donor olefin (D) to an nπ* excited enone (E).

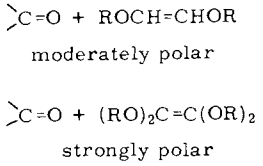

asymmetry induced configuration mixing is present to a large extent, either nπ* or ππ* photoexcitation can lead to similar products by proceeding through the same excited transition state complex. However, it should be pointed out that such asymmetry induced mixing still leads to the prediction that nonpolar cycloadditions of excited carbonyl will be [2s+2s] stereoselective.

Finally, we examine the interesting cases of polar [2+2] photocycloadditions involving nπ* excitation of one cycloaddend and polar [2+2] cycloadditions involving an excited carbonyl group. A typical reaction of the former type is the reaction of *(7)* with *(15)* to give *(16)*.

Here, the nπ* excited enone *(7)* attacks the electron rich olefin *(15)* in its ground state. Again, the excited electronic states of the transition state complex can only be constructed from zero order configurations which have a singly occupied nonbonding orbital in the enone. The configuration interaction diagram (Fig. 11) indicates that, unless steric prohibitions are great, such reactions will be [2s+2a] stereoselective.

An interesting situation arises in the case of polar [2+2] photocycloaddition of an excited carbonyl group. Specifically, one can distinguish modestly polar and extremely polar photoreactions which, as we shall see, are associated with different stereoselectivities.

The basis set configurations are constructed in the usual manner and include both nπ* and ππ* excited configurations. Subsequently, the general interaction matrix is developed and, if the photocycloaddition is initiated by nπ* excitation of the carbonyl group, the appropriate excited states of the photocycloaddition transition state complex are constructed from zero order configurations which mix with the C_n^*D configuration. The resulting configuration interaction diagrams (Fig. 12 and 13) indicate that modestly polar [2+2] photocycloadditions involving nπ* excitation of the carbonyl group will occur *via* a pseudodiradical[40], while extremely polar reactions of the same type will be [2s+2a] stereoselective. On the

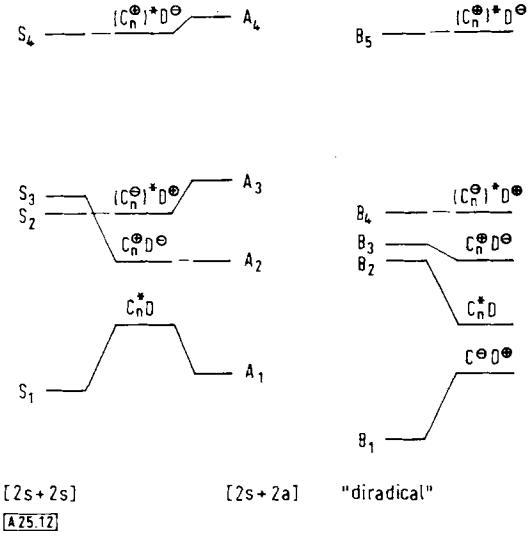

Fig. 12. Configuration interaction diagram for a modestly polar [2+2] photocycloaddition of a donor olefin (D) to an nπ* excited carbonyl group (C). The states B_0—B_5 refer to a pseudodiradical.

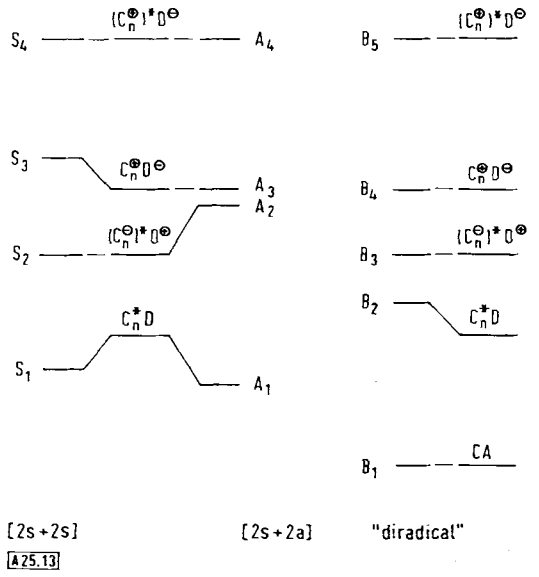
other hand, if the photocycloadditions are initiated by ππ* excitation of the carbonyl group or the olefin, then the appropriate excited states of the photocycloaddition transition state complex are constructed from zero order configurations which mix with the C_π^*D or $C_\pi D^*$ configurations. These latter two cases are identical to the case of polar [2+2] photocycloaddi-



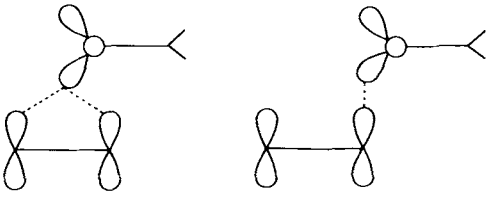


Fig. 13. Configuration interaction diagram for a highly polar [2+2] photocycloaddition of a donor olefin (D) to an $n\pi^*$ excited carbonyl group (C).

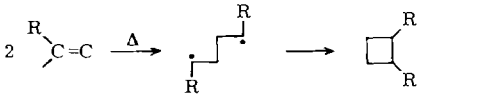
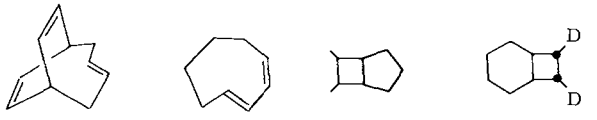
tion of two simple olefins which was discussed before. Once again, the reader is reminded that asymmetry induced mixing can be important in the photoreactions of the carbonyl group. Such mixing will give rise to a diradical mechanism in modestly polar photocycloadditions and to a [2s+2a] mechanism in highly polar photocycloadditions.



A final point remains to be made. In the theoretical discussion, we have assumed an unsymmetric pseudodiradical geometry because it corresponds to the most general case in terms of configuration mixing. However, in modestly [2+2] photocycloadditions involving a carbonyl group the pseudodiradical geometry can be either of the symmetric or unsymmetric type.

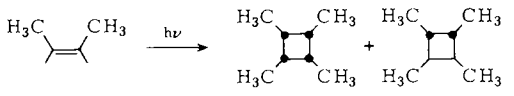


Now, B_1 is the product of the mixing of configurations C_n^*D and $C^{\ominus}D^{\oplus}$. The matrix element of these two configurations is greater for the symmetric geometry and, hence, B_1 corresponding to such geometry has lower energy than B_1 corresponding to the unsymmetric geometry. Consequently, in modestly polar [2+2] photocycloadditions involving a carbonyl group, the "diradical" involves appreciable three center bonding.

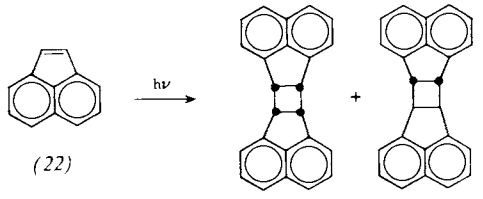
3.3. Applications

We are now prepared to compare our predictions with actual experimental data. Thermal [2+2] cyclodimerizations (AA cycloadditions) are examples of [2+2] cycloadditions which fall in the extreme nonpolar end of the reactivity spectrum. In such reactions, the concerted [2s+2a] pathway is minimally stabilized, while the [2s+2s] concerted pathway is not stabilized, and, as a result, a two-step reaction mechanism becomes highly probable. The regioselectivity of [2+2] thermal cyclodimerizations is consistent with a diradical mechanism and not a concerted [2s+2a] mechanism[41]. A diradical mechanism leads in most cases, but not all, to head-to-head cyclobutane derivatives and a [2s+2a] mechanism to head-to-tail cyclobutane products. Hence, the observed head-to-head regioselectivity of [2+2] thermal cyclodimerizations argues for a diradical mechanism.

The stereochemistry of thermal [2+2] cyclodimerizations has been extensively studied. The thermal [2+2] cyclodimerization of the bicyclic *(17)* has been thought to occur in a concerted [2s+2a] manner[42]. However, the thermal [2+2] cyclodimerization of *(18)* has been studied by *Padwa et al.* and been found to proceed *via* the intermediacy of diradicals[43,44].



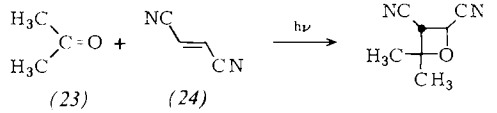
(17) *(18)* *(19)* *(20)*



The stereochemistry of extremely nonpolar [2+2] cycloadditions and cycloreversions has been studied by various workers; in most cases the results are consistent with a diradical mechanism. Thus, the decomposition of the *cis* and *trans* isomers of 6,7-dimethylbicyclo[3.2.0]heptane *(19)* occurs *via* a diradical mechanism[45] and the experimental results are quite similar to those obtained for the decomposition of the *cis* and *trans* isomers of 1,2-dimethylcyclobutane[46]. The cycloaddition of tetrafluoroethylene and 1,2-dideuterioethylene was found to yield cyclobutane products and the observed stereochemistry is consistent with a diradical mechanism[47]. Finally, the pyrolysis of *(20)* yields *trans*-1,2-dideuterioethylene as the major isomer and the proportion of the *trans* isomer formed is larger than would be expected in a thermodynamically controlled reaction[48]. These last results indicate that a [2s+2a] concerted mechanism and a stepwise mechanism involving diradical intermediates are probably in competition.

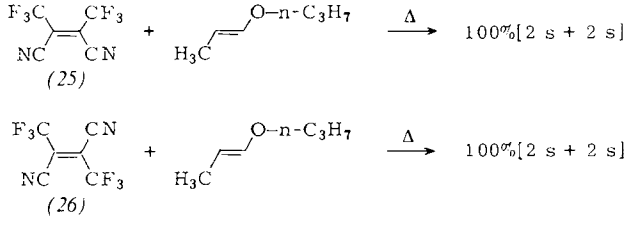
In addition, it should be mentioned that the kinetic parameters of cyclobutane decomposition were shown to be both qualitatively and quantitatively consistent with the diradical mechanism[49,50]. In short, it appears that regiochemical, stereochemical and kinetic criteria favor a two-step mechanism for most thermal [2+2] cycloadditions which are found at the *extremely* nonpolar end of the reactivity spectrum.

Photochemical [2+2] cycloadimerizations which occur *via* the first excited singlet state of the reaction complex are expected to be [2s+2s] stereoselective. Available experimental results confirm these predictions[51-53]. The reactions of *(21)* and *(22)* are examples.



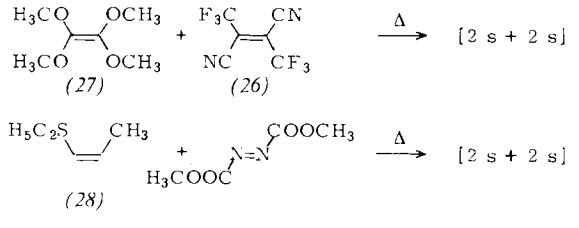
(21) major product

(22) major product



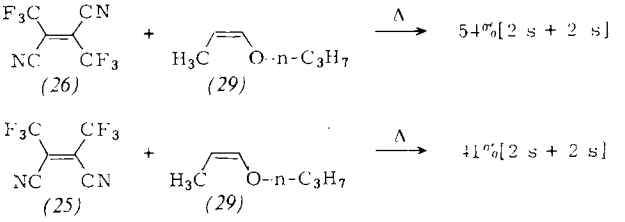
It is very important to note that the regioselectivity of these two photodimerizations has been shown to be consistent with a concerted [2s+2s] mechanism[41]. A large number of [2+2] photodimerizations known to yield products consistent with a concerted [2s+2s] mechanism can be found in recent reviews[54].

Nonpolar [2+2] photocycloadditions involving an excited carbonyl group are predicted to be [2s+2s] stereoselective. Experimental results, *e.g.* in the reaction of *(23)* with *(24)*, have confirmed these expectations[55].



(23) (24)

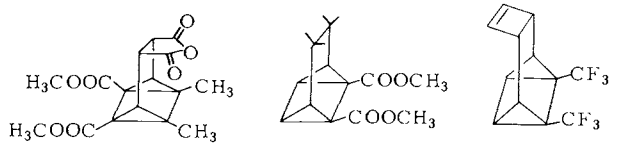
Polar [2+2] cycloadditions have been studied extensively. In such reactions, both the [2s+2a] and the [2s+2s] concerted pathways are stabilized electronically but the unfavorable steric features of the [2s+2a] transition state lead to the prediction that polar [2+2] cycloadditions will occur in a concerted [2s+2s] manner. We believe that the experimental data strongly indicate that this prediction is, in most cases, correct. The reactions of *(25)* and *(26)* are examples of stereospecific [2s+2s] cycloadditions[56].



The polar cycloadditions of *(27)* and *(28)* are [2s+2s] stereospecific with respect to the stereochemically labeled acceptor or donor partner, which is a strong indication that the overall reaction is a concerted [2s+2s] process[57,58]. Many other such reactions are known[56,59].

(27) (26)

(28)

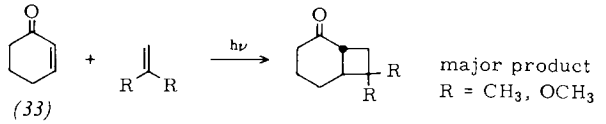


The exceptions to the rule are also interesting. For example, the following reactions of *cis-n*-propoxy-1-propene *(29)* with *(26)* and with *(25)* are nonstereospecific and the products can be thought to arise from a dipolar intermediate. However, an alternative interpretation is that the products arise from competing [2s+2s] and [2s+2a] mechanisms. The latter interpretation becomes even more credible on account of the observation that in the formal [2s+2a] products rotation has only occurred in the acceptor partner. Indeed, a dipolar intermediate would have led to rotation of either donor or acceptor partner.

(26) (29)

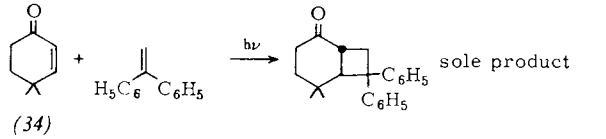
(25) (29)

Kinetic evidence in favor of polar [2s+2s] concerted cycloadditions is also available. Specifically, polar [2+2] cycloadditions are very facile reactions and can occur even at room temperature. The intramolecular cycloreversions of the molecules *(30)*—*(32)* have been studied and in all cases the product was the corresponding norbornadiene derivative.



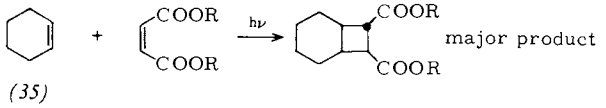
(30) (31) (32)

It was found that *(32)* decomposes slowly at 80°C[60], *(31)* has a half life of 12 min at 19°C[61], and *(30)* has a half life of 3 min at 20°C[62]. In other words, increasing polar character of the cycloreversion leads to faster decomposition rates. An even more impressive result was the determination of the kinetic parameters[62]. It was found that ΔH^{+} for the reaction of *(30)* to the norbornadiene derivative was very much lower than ΔH^{+} for the reaction of quadricyclane to norbornadiene. Yet more impressive was the finding that ΔS^{+} for reaction of *(30)* was very similar to ΔS^{+} for the rearrangement of *cis*-divinylcyclobutane, a concerted reaction. Other examples of facile intramolecular polar [2+2] cycloadditions can be found in the literature[62].



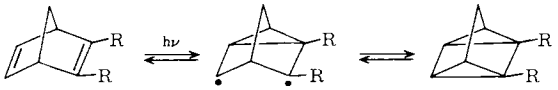
In the past, the stereoselectivity of thermal [2+2] cycloadditions has been rationalized by assuming formation of a diradical or dipolar intermediate. By invoking such intermediates, one can rationalize any set of chemical data. On the other hand, the diradical or dipolar intermediate concept is uniquely poor in leading to predictions. In short, we believe that the wide acceptance of such molecular species as intermediates in thermal [2+2] cycloadditions has been a matter of convenience. In general, diradical intermediates are expected to be important in extremely nonpolar cases where *both one electron and two electron configuration mixing is poor*. Semipolar and polar cycloadditions can involve appreciable pericyclic bonding at the transition state and may not be two-step reac-

tions in the classical sense. The stereoselectivity of [2+2] cycloadditions of substituted butadienes to substituted olefins can be explained by a predominant concerted [2s+2a] mechanism[110]. Such reactions are located near the middle of the cycloaddition reactivity spectrum and stabilization of the [2s+2a] transition state can be appreciable. The stereospecificity of polar [2+2] cycloadditions can be explained by a predominant [2s+2s] mechanism.

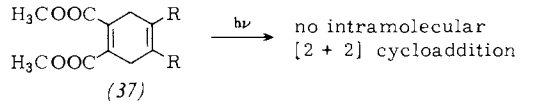


Polar [2+2] photocycloadditions *occurring via the first excited singlet state of the reaction complex* are expected to be [2s+2a] stereoselective, unless steric interactions raise the energy of the lowest excited [2s+2a] pericyclic state. In general, polar [2s+2a] photocycloadditions are expected when at least one partner is a *cis*-disubstituted ethylene molecule. In such cases, the two cycloaddends can approach each other in a [2s+2a] manner and significant orbital overlap can take place. Furthermore, antarafacial union can be facilitated by a twisted geometry of the photoexcited partner, The reactions of the cyclohexenes *(33)—(35)* are examples of polar stereoselective [2s+2a] photocycloadditions[63-66].

(33)

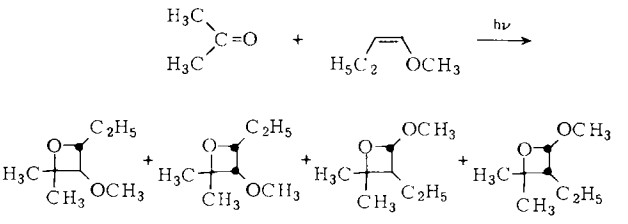


(34)



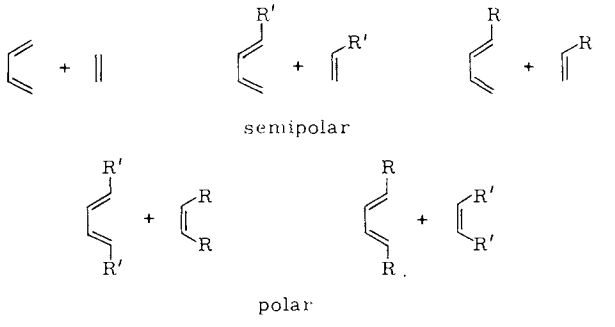
(35)

A most interesting situation obtains when one attempts a polar [2+2] photocycloaddition which is sterically prohibited from occurring in a [2s+2a] manner. In the systems *(36)* and *(37)* intramolecular [2+2] photocycloaddition can only occur in the lowest excited [2s+2s] pericyclic state which, as we have seen, *involves only weak pericyclic bonding because of poor configuration mixing*. As a result, the intramolecular [2+2] photocycloaddition may either occur *via* a stepwise mechanism or not at all. These expectations have been confirmed by experiment[67].



(36)

(37)



R = C_6H_5

Polar photocycloadditions involving the carbonyl group are also known. Modestly polar [2+2] photocycloadditions of carbonyl groups are predicted to occur *via* a "diradical" mechanism. This expectation has been confirmed by *Turro*[68]. On the other hand, extremely polar [2+2] photocycloadditions of carbonyl groups are predicted to be [2s+2a] stereoselective, but such reactions have not yet been studied.

4. Intermolecular [4+2] Cycloadditions

In the case of intermolecular [2+2] cycloadditions, we can distinguish nonpolar (AD) and polar (AX) reactions; the intermolecular [4+2] cycloadditions can be divided into semipolar (AM) and polar (AX) reactions. In the typical examples of semipolar and polar [4+2] cycloadditions shown below, R' is the donor and R the acceptor substituent.

The stereoselectivity of semipolar and polar [4+2] cycloadditions is analyzed in the same way as the stereoselectivity of nonpolar and polar [2+2] cycloadditions. Specifically, one of the cycloaddends is defined as the donor and the other as the acceptor, the basis set configurations and the corresponding Slater determinant wavefunctions are constructed, and the general interaction matrix is built. Expansion of the MO integrals into AO integrals leads to the interaction matrices for [s+s] and [s+a] union and ultimately to the construction of the corresponding electron states. Figure 14 shows the electronic states for semipolar [4s+2s] and [4s+2a] union and Fig. 15 the electronic states for polar [4s+2s] and [4s+2a] union. The effect of asymmetry induced configuration mixing is included in these diagrams. One is led to the following conclusions:

a) A concerted semipolar [4+2] cycloaddition will proceed thermally in a [4s+2s] manner because the lowest electronic state S_0 involves pericyclic bonding and is of lower energy than the lowest electronic state A_0 (which is not pericyclic). The electronic stabilization of the [4s+2s] and [4s+2a] transition state complexes due to configuration interaction are:

$$SE(4s+2s) = E(S_0) - E(DA) > 0$$
$$SE(4s+2a) = E(A_0) - E(DA) = 0$$

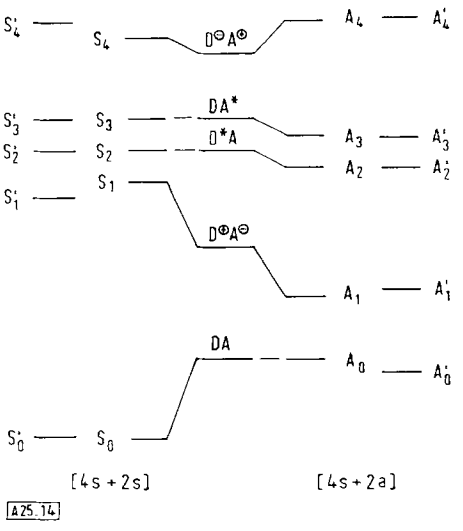


Fig. 14. Configuration interaction diagram for a semipolar [4+2] cycloaddition. The S and A states refer to symmetrical cases and the S' and A' states to unsymmetrical cases.

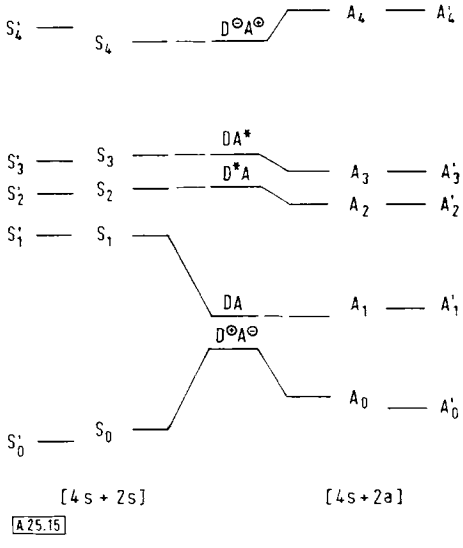

Fig. 15. Configuration interaction diagram for polar [4+2] cycloaddition. The S and A states refer to symmetrical cases and the S' and A' states to unsymmetrical cases.

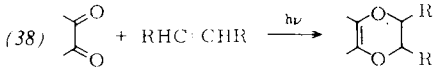
The magnitude of the electronic stabilization of the [4s+2s] transition state complex is moderate and there is no steric destabilization. Hence, a concerted [4s+2s] mechanism can compete effectively with a stepwise mechanism involving diradical intermediates. Nonetheless, we emphasize that the stabilization $SE(4s+2s)$ is at a minimum at the extreme semipolar end of the [4+2] cycloaddition reactivity spectrum.

b) A concerted semipolar [4+2] cycloaddition will proceed photochemically in a [4s+2a] manner because A_1 has lower energy than S_1 and both states involve pericyclic bonding. Whenever steric destabilization of the excited electronic states of the [4s+2a] transition state complex is small, A_1 will have lower energy than S_1. It should be pointed out, however, that such photochemical reactions will be dominated by the competing [2s+2s] photochemical reaction involving one olefinic bond of the diene and one olefinic bond of the dienophile. Finally, we note that A_1 has excimeric character and involves strong pericyclic bonding and S_1 has charge transfer character and involves weak pericyclic bonding.

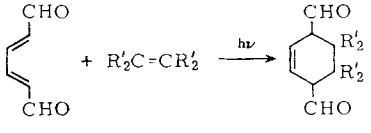


c) A concerted polar [4+2] cycloaddition will proceed thermally in a [4s+2s] manner because both S_0 and A_0 electronic states involve pericyclic bonding. The electronic stabilization of the [2s+2s] and [4s+2a] transition state complexes due to configuration interaction are

$$SE(4s+2s) = E(S_0) - E(D\ A\ ) > 0$$
$$SE(4s+2a) = E(A_0) - E(D\ A\ ) > 0$$

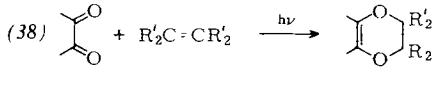
The magnitude of the electronic stabilization of the [4s+2s] transition state complex is greater than the electronic stabilization of the [4s+2a] transition state complex due to configuration interaction. Furthermore, steric effects favor the former over the latter to a great extent. Hence, thermal polar [4+2] cycloadditions are expected to occur in a concerted [4s+2s] manner on account of strong electronic stabilization and favorable geometry. A stepwise mechanism is considered unlikely because the overall stabilization of the [4s+2s] transition state complex is at a maximum at the extreme polar end of the [4+2] cycloaddition reactivity spectrum.

d) A concerted polar [4+2] cycloaddition will proceed photochemically in a [4s+2s] manner because the first excited electronic state S_1 involves pericyclic bonding, while the first excited electronic state A_1 does not; A_1 is a nonbonding state. Furthermore, S_1, the lowest excited state involving [4s+2s] pericyclic bonding, has lower energy than A_2, the lowest excited state involving [4s+2a] pericyclic bonding. Steric effects can only accentuate the energy difference between S_1 and A_2. Finally, we note that S_1 has charge transfer character and involves strong pericyclic bonding, while A_2 has excimer character and involves weak pericyclic bonding.



An important class of semipolar [4+2] photocycloadditions involves the electronically excited carbonyl group of diketones

such as *(38)*. These reactions can be analyzed in the same manner as were the nonpolar [2+2] photocycloadditions involving an excited carbonyl group. The conclusion is that such reactions will tend to be [4s+2a] stereoselective; however, the alternative mode of [2s+2s] union will probably dominate.

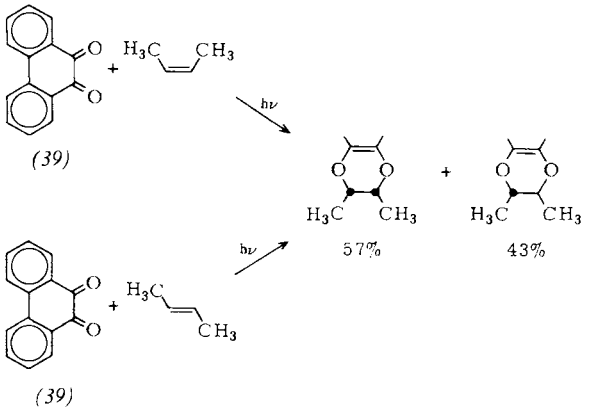


There are two classes of polar [4+2] photocycloadditions which are of special interest to the organic chemist:

a) Polar [4+2] photocycloadditions involving nπ* excitation of one cycloaddend:

R' = $N(CH_3)_2$, OCH_3, etc.

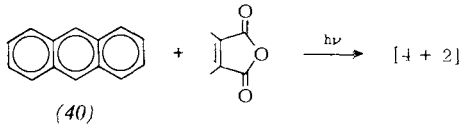
b) Polar [4+2] cycloadditions involving an excited carbonyl group:



R' = $N(CH_3)_2$, OCH_3, etc.

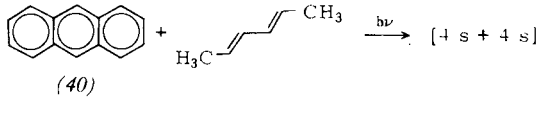
By following the same analysis as in the case of the corresponding [2+2] photocycloadditions, we conclude that a polar photocycloaddition involving $n\pi^*$ excitation of one cycloaddend will be [4s+2s] stereoselective. On the other hand, a modestly polar photocycloaddition involving an $n\pi^*$ excited carbonyl group will occur *via* a diradical mechanism, while a very polar reaction of the same type will be [4s+2s] stereoselective[69].

In thermal semipolar [4+2] cycloadditions, the concerted pathway *via* a [4s+2s] mechanism is electronically stabilized and the concerted [4s+2a] pathway is not. Hence, these reactions are expected to be concerted because the [4s+2s] pathway is sterically unencumbered. However, the electronic stabilization of the [4s+2s] pathway is only modest in the case of semipolar [4+2] cycloadditions. As a result, the transition state for the reaction can be highly unsymmetrical and almost resemble a diradical. These arguments are supported by experimental evidence[71] and theoretical considerations. Thus, it has been found that the observed regioselectivity of semipolar [4+2] cycloadditions is consistent with a highly unsymmetrical, diradical-like transition state[41]. Furthermore, kinetic analysis has implicated a diradical mechanism in certain semipolar [4+2] cycloadditions[70]. An interesting observation: the stereochemistry of extremely semipolar [4+2] cycloadditions has not yet been studied. Such experiments could provide important information about the mechanism of these reactions.



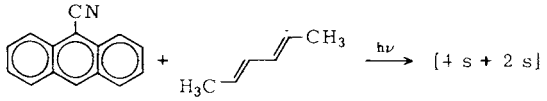
Semipolar [4+2] photocycloadditions occurring *via* the first excited singlet state of the reaction complex are expected to be [4s+2a] stereoselective. However, this sterically unfavorable reaction will probably be dominated by the sterically unhindered [2s+2s] reaction. The mechanism of nonpolar [4+2] photocycloadditions is difficult to study.

Semipolar [4+2] photocycloadditions involving carbonyl groups are likewise difficult to study. The same problem is met with in these reactions as in the corresponding reactions of normal unsaturated systems: the [2s+2s] reaction dominates over the [4s+2a] photocycloaddition. Modestly polar [4+2] reactions of this type are predicted to occur by a pseudodiradical mechanism. Typical experimental results for reactions of the latter type—*e.g.* the reaction of phenanthraquinone *(39)* with *cis*- and *trans*-2-butene—are given below[72].



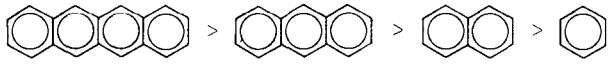
(39)

The kinetics[10,73], regiochemistry[41,74] and stereochemistry[75] of polar, thermal [4+2] cycloadditions are consistent with a concerted [4s+2s] mechanism. These reactions have been studied extensively and there is common agreement that most of them are concerted reactions. Polar [4+2] photocycloadditions occurring *via* the first excited state of the reaction complex are expected to be [4s+2s] stereoselective. Such reactions have been known for a long time[76].



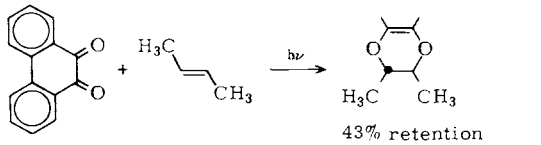
(40)

A most impressive example of a [4s+2s] stereoselective polar [4+2] photocycloaddition was recently reported by *Yang et al.*[77]. Two typical findings from their investigations on anthracene *(40)* and 9-anthracenecarbonitrile *(41)* are shown below. It is clear that increasing the polarity of the reactants shifts the stereoselectivity from [4s+4s] to [4s+2s]. Other stereoselective [4s+2s] polar photocycloadditions are also known to occur[78].

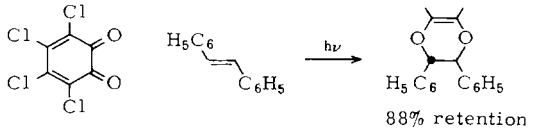


(40)

(41)



It is interesting to point out that Hückel calculations as well as experimental ionization potentials (I.P.) and electron affinities[79] indicate that the electron donating and electron accepting ability of polynuclear arenes varies in the order:



I. P. [eV]	7.15	7.55–7.66	8.12	9.25

It is known that benzene, a poor donor, reacts photochemically with maleic anhydride to yield a [2+2] photoadduct[80], while, as we have already seen, anthracene, a good donor, reacts photochemically with maleic anhydride to yield a [4+2] photoadduct. This contrasting behavior can be readily explained in terms of our analysis.

Highly polar [4+2] cycloadditions involving the carbonyl group are known to be [4s+2s] stereoselective. The results obtained with phenanthraquinone *(39)* and tetrachloro-*o*-

(39)

(42)

benzoquinone *(42)* show that an increase in the electron donating ability of one partner and the electron accepting ability of the other is paralleled by an increase in the [4s+2s] stereoselectivity of the reaction[81,82].

5. Electrocyclic Reactions

As we have discussed already, electrocyclic ring closures are concerted intramolecular cycloadditions and electrocyclic ring openings are concerted intramolecular cycloreversions. In general, an intramolecular [2s+2a] cycloaddition or cycloreversion corresponds to a conrotatory ring closure or ring opening and an intramolecular [2s+2s] cycloaddition or cycloreversion corresponds to a disrotatory ring closure or ring opening. Accordingly, one expects that the stereoselectivity patterns of electrocyclic reactions will resemble the stereoselectivity patterns of concerted intermolecular cycloadditions. In view of these expected similarities, we have chosen to develop the one electron configuration interaction theory of electrocyclic reactions by omitting details which can be found in Section 3.

We first examine the nonpolar ring closure (AD) of butadiene *(43)*.

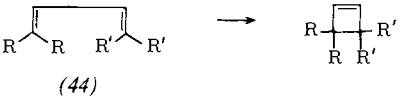
(43)

This reaction is formally equivalent to an intramolecular [2+2] cycloaddition of *(1)* and *(2)*, where *(1)* is assumed to be the donor partner and *(2)* the acceptor partner (see Section 3.1). Unlike intermolecular [2+2] cycloadditions, there can only be unequal bond making between C^2 and C^5 and between C^3 and C^6 in the transition state. The one electron Hamiltonian, the basis set configurations, and the corresponding Slater determinant wave functions, are the same as in the case of the intermolecular nonpolar cycloaddition of *(1)* and *(2)*. However, expansion of the MO integrals of the general interaction matrix into AO integrals yields different results because of the unequal bonding. Thus, in the case of disrotatory ring closure, the MO integrals become:

$$\langle\phi_3|H'|\psi_2\rangle = C_{32}C_{25}(\beta-\gamma)$$
$$\langle\phi_4|H'|\psi_1\rangle = C_{42}C_{15}(\beta-\gamma)$$
$$\langle\phi_4|H'|\psi_2\rangle = C_{42}C_{25}(\beta+\gamma)$$
$$\langle\phi_3|H'|\psi_1\rangle = C_{32}C_{15}(\beta+\gamma)$$

where

$$\beta = \langle p_2|H'|p_5\rangle \quad |\beta|>|\gamma|$$
$$\gamma = \langle p_3|H'|p_6\rangle$$



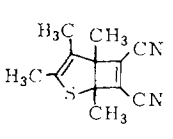
In the case of conrotatory ring closure, *i.e.* intramolecular [2s+2a] cycloaddition, the MO integrals become:

$$\langle\phi_3|H'|\psi_2\rangle = C_{32}C_{25}(\beta+\gamma)$$
$$\langle\phi_4|H'|\psi_1\rangle = C_{42}C_{15}(\beta+\gamma)$$
$$\langle\phi_4|H'|\psi_2\rangle = C_{42}C_{25}(\beta-\gamma)$$
$$\langle\phi_3|H'|\psi_1\rangle = C_{32}C_{25}(\beta-\gamma)$$

Construction of the interaction matrices for disrotatory and conrotatory ring closure leads to the configuration interaction diagrams which show how the electronic states for the two modes of ring closure are derived from the basis set configurations. These diagrams are qualitatively similar to those for unsymmetric intermolecular [2+2] nonpolar cycloadditions (Fig. 4). In this case, A'_n are the electronic states for conrotation and S'_n are the electronic states for disrotation. In the absence of special constraints, steric effects are comparable for disrotation and conrotation. Hence, the relative energy of the electronic states corresponding to disrotation and conrotation can be assessed from consideration of the configuration interaction diagrams alone. An examination of Fig. 4 reveals that thermal ring closure of a nonpolar butadiene will occur in a conrotatory manner because the lowest electronic state A'_0 involves pericyclic bonding and has a much lower energy than the lowest electronic state S'_0. In other words, the conrotatory transition state is stabilized by configuration interaction to a great extent whereas stabilization of the disrotatory transition state is negligibly small.

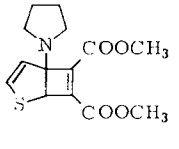
In contrast, concerted ring closure of a nonpolar butadiene will occur photochemically in a disrotatory manner because the first excited electronic state S'_1 has lower energy than the first electronic state A'_1 although both states involve pericyclic bonding. It is important to note that the first excited state for disrotation has excimer character and involves strong pericyclic bonding, while the first excited state for conrotation has charge transfer character and involves weak pericyclic bonding.

We now proceed to examine the polar (AX) ring closure of butadienes of the type *(44)*. This reaction is formally equivalent to an intramolecular [2+2] cycloaddition. Again, unlike intermolecular [2+2] cycloadditions, there can only be unequal bond making between the uniting centers. Our analysis proceeds in exactly the same manner as in the case of ring closure of nonpolar butadiene. The basis set configurations for the ring closure transition state are constructed in the usual manner; the corresponding wavefunctions are written as Slater determinant wave functions. Subsequent expansion of the MO integrals of the general interaction matrix into AO integrals leads to the interaction matrices for disrotatory and conrotatory ring closure. The configuration interaction diagrams are qualitatively similar to those for unsymmetric intermolecular [2+2] polar cycloadditions (Fig. 6). In this case, A'_n are the electronic states for conrotation and S'_n are those for disrotation. Unlike the case of nonpolar ring closure, both A'_0 and S'_0 electronic states involve pericyclic bonding; A'_0 has lower energy than S'_0. Thus, we conclude that, in the absence of steric constraints, A'_0 will remain lower in energy than S'_0 and the ring closure will proceed in a conrotatory manner. In other words, both disrotation and conrotation transition states are stabilized by configuration interaction, but, in the absence of steric constraints, the conrotation transition state will have lower energy than the disrotation transition state, at least in most cases. A'_1 is, however, pericyclic whereas



(44)

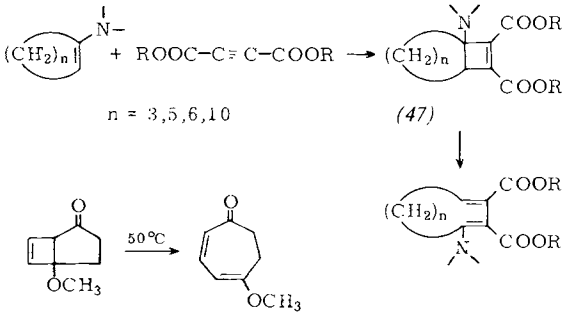
R = CN, CHO, $COOCH_3$, etc.
R' = $N(CH_3)_2$, OCH_3, etc.



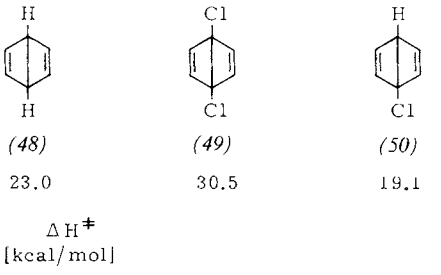
S'_1 does not involve pericyclic bonding to any substantial degree. Furthermore, A'_1, the lowest excited state involving pericyclic bonding appropriate to conrotatory ring closure, has lower energy than S'_2, the lowest excited state involving pericyclic bonding appropriate to disrotatory ring closure. Hence, a photochemical ring closure of butadiene will occur in a conrotatory manner. Again, it is important to note that the first excited state for conrotation has charge transfer character and involves strong pericyclic bonding, while the first pericyclic excited state for disrotation has excimer character and involves weak pericyclic bonding.

According to our analysis, thermal ring closures of butadienes should occur in a conrotatory fashion regardless of whether the two double bonds bear substituents of similar or opposite electronic nature. Indeed, the butadiene → cyclobutene and cyclobutene → butadiene transformations have been shown to occur in a conrotatory manner when the two reaction fragments carry identical substituents[83]. However, there have not been any studies on such systems in which the substrates bear substituents of opposite electronic nature.

While conrotation is expected to dominate over disrotation throughout the entire reactivity spectrum, both the barrier to conrotation and the barrier to disrotation decrease as the reactant becomes unsymmetrically substituted. Thus, if ring opening or ring closure is sterically constrained to occur in a disrotatory manner, asymmetric substitution of the cyclobutene or the diene will tend to reduce the activation energy for disrotation. There are many examples which indicate that these predictions are correct. Thus, it was found that *(45)* is thermally stable, whereas *(46)* opens to the seven-membered ring upon heating[84].



(45)

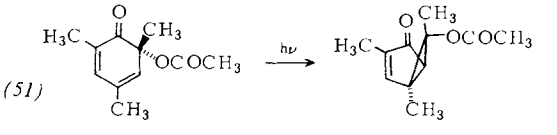


(46)

A host of reactions, which are thought to proceed *via* unsymmetrically substituted cyclobutenes, yield products with an opened cyclobutene ring. This occurs despite the fact that the cyclobutene intermediate, *e.g. (47)*, can open only by disrotation[85,86].

n = 3,5,6,10 *(47)*

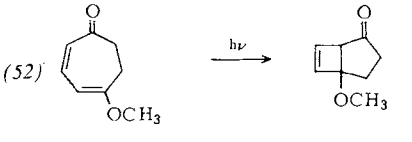
Finally, a most remarkable illustration of the effect of asymmetric substitution on the barrier to disrotation has been presented by *Breslow et al.*[87]. They determined the enthalpies of activation for disrotatory ring opening of three typical Dewar-benzenes *(48)*—*(50)*.



(48) *(49)* *(50)*

23.0 30.5 19.1

$\Delta H^{\neq}$ [kcal/mol]



Other examples are known[88].

Photochemical ring openings and ring closures of symmetrically substituted reactants should occur in a disrotatory manner, if one assumes that the first excited state of the reacting complex is involved. Experimental evidence is in accord with these predictions[89]. The interesting prediction that photochemical ring closures and ring openings of unsymmetrically substituted reactants should occur in a conrotatory manner has not yet been tested. However, it is noteworthy that 2,4-cyclohexadienones such as *(51)*, which are constrained to undergo photochemical ring closure only by disrotation, have been found to yield no ring closure products upon irradiation[90].

(51)

The more flexible 2,4 cycloheptadienones, on the other hand, are known to yield ring closure products upon irradiation[91]. It would be very interesting to investigate whether a transient *trans* fused bicyclic product, arising from conrotatory ring closure, is at all involved in these reactions[92].

(52)

As in the case of butadiene ring closure, we can distinguish semipolar (AM) and polar (AX) hexatriene ring closures. Our configuration interaction analysis proceeds in the same manner as in the case of butadiene ring closures. The configuration interaction diagrams for semipolar conrotatory and disrotatory ring closure are similar to those in Fig. 14 and the configuration interaction diagrams for conrotatory and disrotatory polar ring closure are similar to those in Fig. 15. In both figures, A'_n correspond to the electronic states for conrotation and S'_n to the electronic states for disrotation. The following conclusions are reached:

a) A concerted semipolar hexatriene ring closure will occur thermally in a disrotatory manner because the lowest electronic state S'_0 involves pericyclic bonding and has lower energy than the lowest electronic state A'_0.

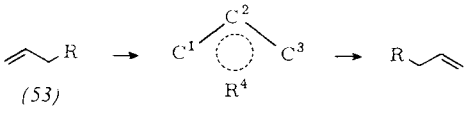
b) A concerted semipolar hexatriene ring closure will occur photochemically in a conrotatory manner because the first excited electronic state A'_1 has lower energy than the first excited electronic state S'_1 although both states involve pericyclic bonding.

c) A concerted polar hexatriene ring closure will occur thermally in a disrotatory manner because the lowest electronic state S_0' has lower energy than the lowest electronic state A_0'; both states involve pericyclic bonding.

d) A concerted polar hexatriene ring closure will occur photochemically in a disrotatory manner because S_1' involves strong pericyclic bonding but A_1' does not, *i. e.* A_1' is nearly a nonbonding state. Furthermore, S_1', the lowest excited state involving pericyclic bonding in a disrotatory mode, has lower energy than A_2', the lowest excited state involving pericyclic bonding in the conrotatory mode.

Thermal and photochemical electrocyclic reactions of symmetrically substituted hexatrienes and cyclohexadienes have been found to occur by disrotation and conrotation, respectively[93]. The effect of asymmetric substitution on the barrier to thermal conrotatory ring closure and ring opening has not been studied. The prediction that asymmetrically substituted hexatrienes and cyclohexadienes should undergo photochemical ring closure and ring opening, respectively, by disrotation has also not yet been tested.

6. Sigmatropic Shifts



6.1. [1,3]-Shifts

We first examine the case of nonpolar (AD) [1,3] sigmatropic shifts. There can be two types:

a) Type I: nonpolar [1,3] sigmatropic shifts, where the migration framework is the donor fragment and the migrating group the acceptor fragment, but the difference in the electron donating and electron accepting ability of the two fragments is small; *i. e.* the ionization potential of the migration framework is slightly less than that of the migrating group.

b) Type II: nonpolar [1,3] sigmatropic shifts, where the migration framework is the acceptor fragment and the migrating group the donor fragment, but the difference in the electron donating and electron accepting ability of the two fragments is small; *i.e.* the ionization potential of the migration framework is slightly greater than that of the migrating group.

We shall examine in detail a type I nonpolar [1,3] sigmatropic shift.

(53)

In the reaction shown above, the migration framework in *(53)* is the allyl radical and the migrating group is the R radical. The former constitutes the donor fragment and the latter constitutes the acceptor fragment. In order to simplify the discussion, we assume that equal bond making between R and C_1 and between R and C_3 has taken place at the transition state. The one electron Hamiltonian is written as follows:

$$H = H(\text{Allyl}) + H_R + H'$$
$$H' = H_{41} + H_{43}$$

The basis set configurations for the type I nonpolar [1,3] sigmatropic shift are shown in Fig. 16 and the corresponding wavefunctions can be written as Slater determinant wavefunctions in the manner illustrated in Section 2. In this case, we have used a more extensive basis set of six zero order configurations because we deal with the special problem of the interaction of two open shell systems.

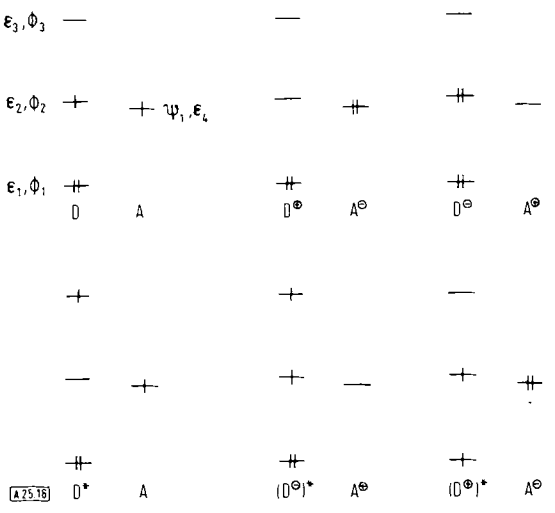


Fig. 16. Basis set configurations for a nonpolar [1,3] sigmatropic shift. D is the donor fragment and A the acceptor fragment.

In the case of the interaction of two closed shell fragments D and A, the quantity $I_D - A_A$ is satisfactorily approximated in simple Hückel theory by the energy difference between the HOMO of the donor and the LUMO of the acceptor. In contrast, in the case of the interaction of two open shell systems D and A, the quantity $I_D - A_A$ cannot be approximated by the energy difference between the singly occupied, nonbonding MOs of the two fragments. In such cases, one has to use the experimentally determined values of I_D and A_A.

The specific example of a nonpolar [1,3] sigmatropic shift of a methyl radical across an allyl radical migration framework can be used to illustrate these considerations. The various zero order configurations of the migration transition state are qualitatively similar to those in Fig. 16. The total energies of DA, $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ can be obtained by the Hückel theory by summing over all occupied one electron MOs and correcting for coulombic interactions in the case of the $D^{\ominus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ configurations:

$$E(\text{DA}) = 2\varepsilon_1 + \varepsilon_2 + \varepsilon_4$$
$$E(\text{D}^{\ominus}\text{A}^{\ominus}) = 2\varepsilon_1 + 2\varepsilon_4 - C'$$
$$E(\text{D}^{\ominus}\text{A}^{\oplus}) = 2\varepsilon_1 + 2\varepsilon_2 - C'$$

For reasonable distances of the two fragments in the transition state, C and C' range between 3 and 6 eV. Hence, it is predicted that the two charge transfer configurations will have much lower energy than the no bond configuration. The relative stability of these configurations is predicted to be: $D^{\oplus}A^{\ominus} > D^{\ominus}A^{\oplus} > DA$.

We can now estimate the relative energies of DA, $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ by reference to experimental results, *e. g.* the ionization potentials[94] and electron affinities[95] of the methyl and allyl moieties.

$$E(\text{DA}) = 0$$
$$E(\text{D}^{\oplus}\text{A}^{\ominus}) = 8.16 - 1.1 - C$$
$$E(\text{D}^{\ominus}\text{A}^{\oplus}) = 9.84 - 2.1 - C'$$

Unlike the previous calculations and under the assumption that C and C' range between 3 and 6 eV, the relative stability of these configurations is predicted to be $DA > D^{\oplus}A^{\ominus} > D^{\ominus}A^{\oplus}$.

This latter conclusion must be the correct one, since the experimental values of the ionization potentials and electron affinities reflect interelectronic repulsive effects which are not accounted for in the simple Hückel theory. In all subsequent discussions of sigmatropic shifts, the relative energies of the zero order configurations are obtained by reference to experimental results and in accordance with equations (1)–(5).

The relative energies of the basis set configurations for nonpolar [1,3] sigmatropic shifts are shown in Fig. 17 and the general interaction matrix is shown in Scheme 4.

The πMOs of the allyl radical and the radical R are of the general form:

$$\phi_1 = C_{11}p_1 + C_{12}p_2 + C_{13}p_3$$
$$\phi_2 = C_{21}p_1 - C_{23}p_3$$
$$\phi_3 = C_{31}p_1 - C_{32}p_2 + C_{33}p_3$$

and

$$\psi_1 = p_4$$

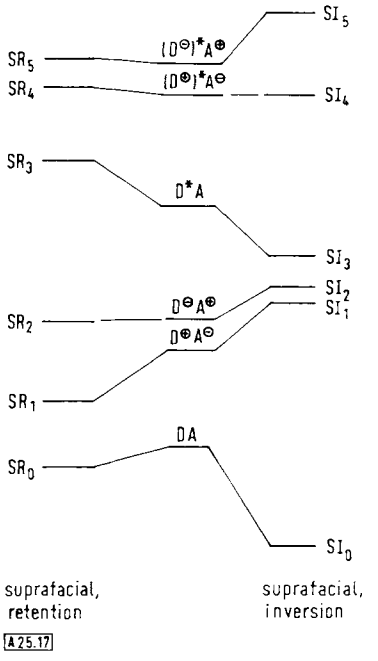

Fig. 17. Configuration interaction diagram for a nonpolar [1,3] sigmatropic shift.

The MO integrals of the general interaction matrix can be expanded into AO integrals; the interaction matrices for suprafacial migration with retention and for suprafacial migrations with inversions can be written as in Schemes 5 and 6. Examination of the interaction matrices leads to the following conclusions:

1. In the case of suprafacial migration with retention, configuration interaction produces five electronic states, SR_0, SR_1, SR_3, SR_4, SR_5 which have pericyclic character and one (SR_2) which does not. The SR_2 electronic state is nonbonding in character.

2. In the case of suprafacial migration with inversion, configuration interaction produces five electronic states, SI_0, SI_1, SI_2, SI_3, SI_5 which have pericyclic character and one (SI_4) which does not. The SI_4 electronic state is nonbonding in character.

Scheme 6. Interaction matrix for a suprafacial [1,3] sigmatropic shift with retention.

These considerations can be simply understood by reference to Fig. 17 which illustrates how the basis set configurations interact to form the final electronic states for the retention and inversion transition state complexes. The configuration interaction diagram of Fig. 17 is constructed under the assumption that the resonance integrals for migration with retention (γ') and migration with inversion (γ) have the same magnitude:

$$\gamma'_{14} = \gamma_{14}$$
$$\gamma'_{34} = \gamma_{34}$$

This assumption serves the dual purpose of simplifying the construction of the configuration interaction diagram and focusing our attention on the electronic factors responsible for configuration mixing. Once again, in addition to the configuration interaction diagram, we have to consider the steric features of migration with inversion in order to assess reliably the relative energy of the corresponding electronic states.

The chemical implications of Fig. 17 can be understood easily and can be stated as follows:

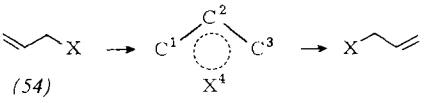
1. A concerted nonpolar [1,3] sigmatropic shift can proceed thermally by either of the following two stereochemical modes:

a) Inversion of configuration at the migrating group, if such a migration mode is not sterically prohibited.

b) Retention of configuration of the migrating group, if migration by inversion of the migrating group is sterically prohibited. This arises because the electronic state SI_0 and the electronic state SR_0 are pericyclic. The electronic stabilization of the two migratory modes due to configuration interaction are:

$$SE(\text{retention}) = E(SR_0) - E(D^{\oplus}A^{\ominus}) > 0$$
$$SE(\text{inversion}) = E(SI_0) - E(D^{\oplus}A^{\ominus}) > 0$$

The magnitude of the electronic stabilization of inversion is much greater than the magnitude of the electronic stabilization of retention. However, the important point is that both inversion and retention are stabilized. The [1,3] shift with inversion is, however, less sterically favored than the [1,3] shift with retention. Hence, the relative net stabilization of the two migration modes involves a very fine balance of opposing electronic and steric effects. Perhaps the most important conclusion is that, when the migration by inversion is sterically prohibited, migration by retention can proceed in a concerted manner. Using a different approach, *Berson* and *Salem* have arrived at the same conclusion[23]. Unlike the case of nonpolar intermolecular cycloadditions and electrocyclic reactions, nonpolar [1,3] sigmatropic shifts have the option of two concerted pathways. Accordingly, stepwise mechanisms are unlikely in the case of such reactions.



2. A concerted nonpolar [1,3] sigmatropic shift will proceed photochemically with retention of configuration of the migrating group because the lowest excited state for retention (SR_1) has lower energy than the lowest excited state for inversion (SI_1). It is important to note that SR_1 has excimer character, while SI_1 has charge transfer character.

Again, in real situations the migration framework can be unsymmetrically substituted and the migration may involve unequal bond formation at the transition state. Under these circumstances certain MO integrals can become nonzero, albeit small in magnitude. Again, calculations show that in most cases the asymmetry induced configuration mixing is small and can be neglected without altering our qualitative conclusions.

We now come to the case of polar (AX) [1,3] sigmatropic shifts. As in the previous case, there can be two types of polar [1,3] sigmatropic shifts:

a) Type I: polar [1,3] sigmatropic shifts, where the migration framework is the donor fragment and the migrating group is the acceptor fragment, and the electron donating and electron accepting ability of the two fragments differ greatly, *i.e.* the ionization potential of the migration framework is much smaller than the ionization potential of the migrating group.

b) Type II: polar [1,3] sigmatropic shifts, where the migration framework is the acceptor fragment and the migrating group is the donor fragment and the electron donating and electron accepting ability of the two fragments differ greatly, *i.e.* the ionization potential of the migration framework is much greater than the ionization potential of the migrating group. We shall examine a type I polar [1,3] sigmatropic shift in detail. In *(54)*, the migration group is the allyl radical and

(54)

the migrating group is the highly electrophilic residue X. The former is the donor and the latter is the acceptor fragment. Again, it is assumed that equal bond making between X and C_1 and between X and C_3 takes place in the transition state. Our analysis proceeds exactly in the same manner as in the case of nonpolar [1,3] sigmatropic shifts. The one electron Hamiltonian is written as follows:

$$H = H(\text{allyl}) + H_X + H'$$
$$H' = H_{41} + H_{43}$$

The basis set configurations for the [1,3] sigmatropic shift transition state complex are shown in Fig. 18; the corresponding wave functions can be written as Slater determinants. The relative energies of the basis set configurations are shown in Fig. 19. The situation is quite different from that encountered in the case of nonpolar [1,3] sigmatropic shifts. The reason

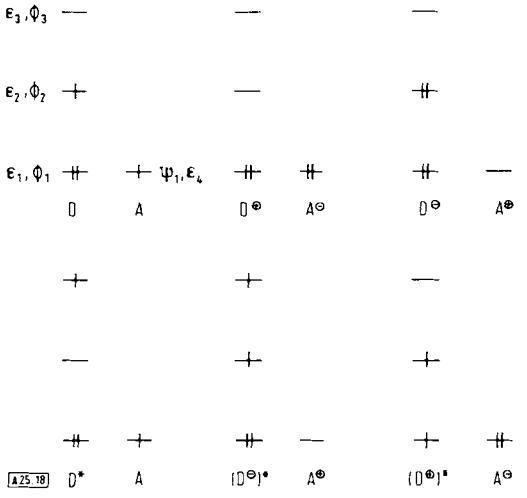


Fig. 18. Basis set configurations for a polar [1,3] sigmatropic shift. D is the donor fragment and A the acceptor fragment.

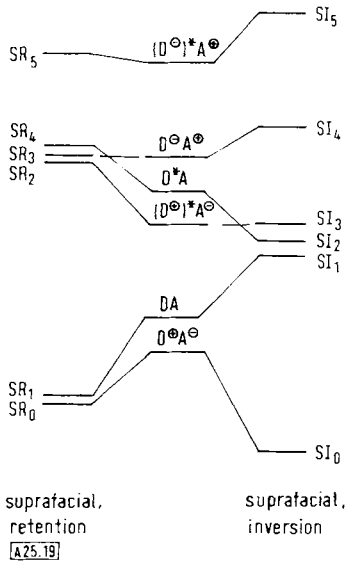

Fig. 19. Configuration interaction diagram for a polar [1,3] sigmatropic shift.

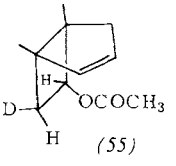
for this is as follows: on going from a nonpolar to a polar sigmatropic shift the energies of the charge transfer configurations $D^{\oplus}A^{\ominus}$ and $(D^{\oplus})^*A^{\ominus}$ progressively diminish, whereas the energies of the charge transfer configurations $D^{\ominus}A^{\oplus}$ and $(D^{\ominus})^*A^{\oplus}$ progressively increase.

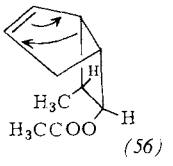
We can now examine how the basis set configurations interact in order to form electronic states. We can construct the general interaction matrix, expand the MO integrals into AO integrals, and arrive at the interaction matrices for migration with retention and migration with inversion. The resultant electronic states are shown in Fig. 19. It can be seen that all states except SR_3 and SI_1 involve pericyclic bonding. The following conclusions can be drawn:

1. Polar [1,3] sigmatropic shifts can proceed thermally by retention of configuration of the migrating group. This arises because both the SR_0 and SI_0 electronic states involve pericyclic bonding. Furthermore, the electronic stabilization of the two migratory modes due to configuration interaction are:



$$SE(\text{Retention}) = E(SR_0) - E(D^{\oplus}A^{\ominus}) > 0$$
$$SE(\text{Inversion}) = E(SI_0) - E(D^{\oplus}A^{\ominus}) > 0$$

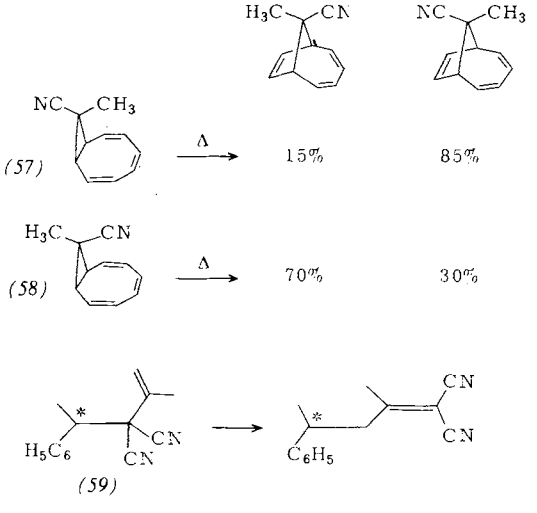
As in the case of nonpolar [1,3] sigmatropic shifts, the electronic stabilization of migration by retention cannot be all that extensive. Now, even in the absence of special steric constraints, inversion is sterically destabilized relative to migration by retention. As a result, in polar [1,3] sigmatropic shifts the concerted migration by retention can dominate concerted migration by inversion. The availability of two concerted pathways makes a stepwise mechanism unlikely.



2. A concerted polar [1,3] sigmatropic shift will proceed photochemically with inversion of configuration of the migrating group if SR_0 and SR_1 are degenerate or almost degenerate, since the lowest excited state for concerted migration with inversion (SI_1) has lower energy than the lowest excited state for concerted migration with retention (SR_2). If SR_0 and SR_1 are not degenerate, however, a polar [1,3] sigmatropic shift will proceed photochemically with retention, since SR_1 will have a lower energy than SI_1. It is important to note that in photochemical polar [1,3] sigmatropic shifts, the lowest possible excited state for concerted migration with retention (SR_1) has excimer character, while the lowest possible excited state for concerted migration with inversion (SI_1) has charge transfer character.

Once more, additional configuration mixing can take place when the migration framework is unsymmetrically substituted or there is unequal bond making in the transition state. The effect is small, however, and does not influence our qualitative conclusions.

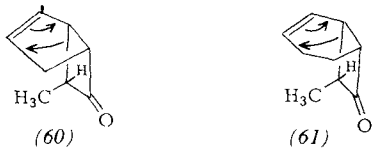
In the case of thermal nonpolar [1,3] sigmatropic shifts, both the retention and inversion concerted pathways are stabilized, the latter, however, to a greater extent than the former. Hence, in the absence of steric prohibitions, one expects that the inversion pathway can dominate. Experimental findings are consistent with this expectation. Indeed, thermolysis of compound *(55)* has provided an example of a suprafacial sigmatropic shift proceeding by inversion[96].



(55)

(56)

On the other hand, when migration by inversion is sterically prohibited, the reaction can occur by retention of the migrating center and still be concerted. Such examples [cf. *(56)*] are now known[97].



Photochemical nonpolar [1,3] sigmatropic shifts are predicted to occur by retention. However, if such a reaction mode is made sterically unfavorable, migration can occur *via* the higher electronic state by inversion. Obviously, in most cases, retention is sterically favored over inversion. In the case of thermal polar [1,3] sigmatropic shifts, both the retention and inversion concerted pathways are stabilized. However, due to a combination of electronic and steric effects, the former can be stabilized more than the latter. Thus, in the absence of steric prohibition of migration by inversion, one expects that the retention pathway can even dominate; and this has been found to be the case experimentally[98,99]. Examples are the reactions of *(57)*—*(59)*.

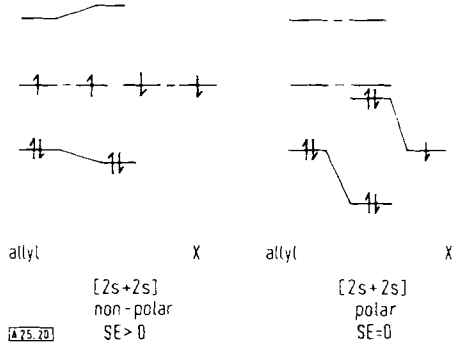
(59)

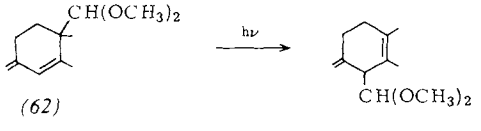
Of course, the same results are expected when the inversion pathway is sterically blocked. Some of the examples described by *Berson et al.* of concerted [1,3] sigmatropic shifts that

proceed by retention can be regarded as moderately polar sigmatropic shifts; such systems are, *e.g.* *(60)* and *(61)*[100].

(60) *(61)*

An important point remains to be explained. In the case of nonpolar [1,3] sigmatropic shifts both our configuration interaction approach and the subjacent orbital control one-configuration analysis predict that suprafacial migration by retention is stabilized. On the other hand, in the case of polar [1,3] sigmatropic shifts configuration interaction stabilizes suprafacial migration by retention but the subjacent orbital control effect is most likely nonexistent. The difference in the nonpolar and polar sigmatropic shifts in terms of subjacent orbital control can be understood by reference to the two interaction diagrams shown in Fig. 20. In the case of nonpolar shifts, orbital interactions lead to a pericyclic complex, whereas in the case of polar shifts they lead to an ion pair.





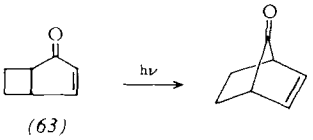


Fig. 20. Orbital interactions for nonpolar and polar [1,3] shifts.

Photochemical polar [1,3] sigmatropic shifts proceed either with inversion or with retention. Intramolecular polar [1,3] sigmatropic shifts—*e.g.* in *(62)*—have been observed photochemically but their stereochemistry is unknown[101,102].

(62)

Cookson has reported a photochemical polar [1,3] sigmatropic shift which proceeds with retention[102], while the following reaction of *(63)* was found to be nonstereoselective; a diradical mechanism was proposed[103].

(63)

In the latter reaction, nonstereoselectivity may reflect competing concerted mechanisms *via* SR_2 (or SR_1) and SI_1. Additional investigations of these reactions may clarify the situation.

6.2. [1,5] Shifts

We now turn our attention to [1,5] sigmatropic shifts. As in the case of [1,3] sigmatropic shifts, we can have two types of nonpolar and two types of polar rearrangements. We can analyze the case of nonpolar and polar [1,5] sigmatropic shifts where the migration framework is the donor and the migrating group is the acceptor fragment in the same manner in which we analyzed the [1,3] nonpolar and polar [1,3] sigmatropic shifts of the same type. The electronic states for nonpolar [1,5] sigmatropic shifts occurring by inversion and retention are shown in Fig. 21. Similarly, the electronic states for polar [1,5] sigmatropic shifts occurring by inversion and retention are shown in Fig. 22. Examination of these figures leads to the following conclusions:

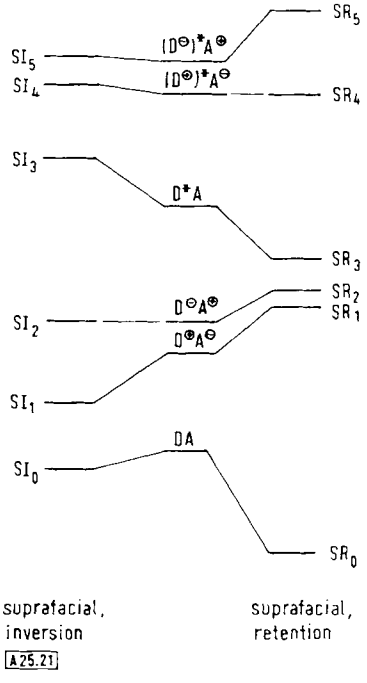

Fig. 21. Configuration interaction diagram for a nonpolar [1,5] sigmatropic shift.

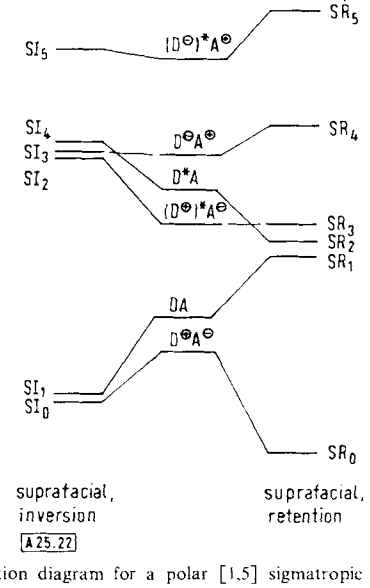

Fig. 22. Configuration interaction diagram for a polar [1,5] sigmatropic shift.

a) A concerted nonpolar [1,5] sigmatropic shift will proceed thermally by retention because the electronic state SR_0 involves pericyclic bonding and has much lower energy than the electronic state SI_0 which also involves pericyclic bonding. The electronic stabilization of the retention and inversion transition state complexes due to configuration interaction are:

$$S\,E(\text{Retention}) = E(SR_0) - E(D^{\oplus}A^{\ominus}) > 0$$
$$S\,E(\text{Inversion}) = E(SI_0) - E(D^{\oplus}A^{\ominus}) > 0$$

The electronic stabilization of retention is large and there is no steric destabilization. On the other hand, the electronic

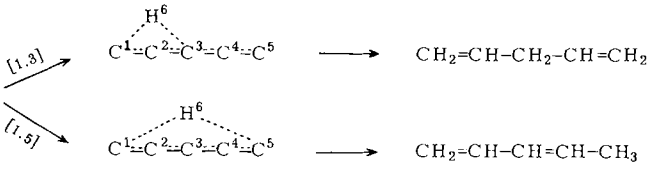
$$CH_3\text{-}CH{=}CH\text{-}CH{=}CH_2$$

stabilization of inversion is small and there is steric destabilization. Hence, migration by retention is expected to dominate over the alternative concerted mechanism or any stepwise mechanism.

b) A concerted nonpolar [1,5] sigmatropic shift will proceed photochemically by inversion because the lowest excited state for concerted migration by inversion (SI_1) has lower energy than the lowest excited state for concerted migration by retention (SR_1).

c) A concerted polar [1,5] sigmatropic shift will proceed thermally by retention because SI_0 and SR_0 involve pericyclic bonding. The electronic stabilization of the two migration modes due to configuration interaction are:

$$S\,E(\text{Retention}) = E(SR_0) - E(D^{\oplus}A^{\ominus}) > 0$$
$$S\,E(\text{Inversion}) = E(SI_0) - E(D^{\oplus}A^{\ominus}) > 0$$



Now, the reaction path with retention is electronically and sterically stabilized to a large extent relative to that with inversion. Hence, electronic and steric factors favor concerted migration by retention over concerted migration by inversion.

d) A concerted polar [1,5] sigmatropic shift will proceed photochemically by retention if SI_0 and SI_1 are degenerate or almost degenerate, because the lowest excited state for concerted migration by retention (SR_1) has lower energy than the lowest excited state for concerted migration by inversion (SI_2). If SI_0 and SI_1 are not degenerate then rearrangement with inversion results.

7. Hydrogen Shifts

Sigmatropic hydrogen shifts are nonpolar sigmatropic shifts where hydrogen uses its 1s orbital in the course of the migration. A [1,3] hydrogen sigmatropic shift can be analyzed exactly like a nonpolar carbon shift. The migration framework is the allyl residue and the migrating group is the hydrogen atom. If we assume that only a suprafacial migration is a viable possibility, we are led to the conclusion that a thermal suprafacial shift is stabilized to a small degree by configuration interaction and that a manifold of excited, strongly pericyclic states exist *via* which a photochemical suprafacial shift can proceed. Both thermal and photochemical [1,3] hydrogen shifts are known and one can reliably assume that such reactions are concerted.

We now come to the case of the [1,5] hydrogen shift. We shall discuss this case in some detail since it leads to interesting conclusions and has pedagogical value. Now, a [1,5] hydrogen shift will necessarily compete with a [1,3] hydrogen shift and an operationally useful analysis involves comparing the relative stabilization of the [1,3] and [1,5] suprafacial migration pathways. In both cases, the migration framework is the pentadienyl residue and the migrating group the hydrogen atom.

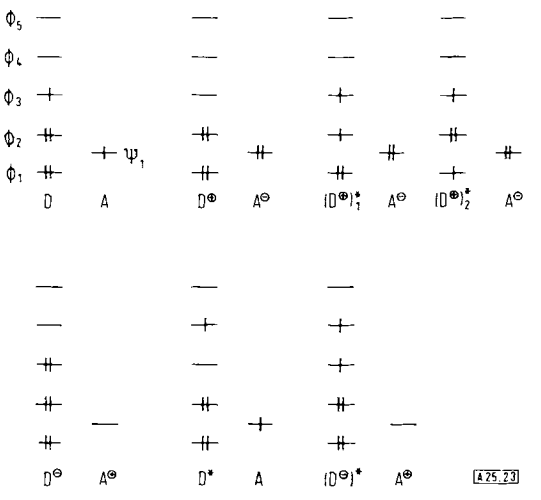


Fig. 23. Basis set configurations for a [1,5] hydrogen sigmatropic shift.

The basis set configurations are shown in Fig. 23. The MOs of the two fragments are:

$$\phi_1 = C_{11}p_1 + C_{12}p_2 + C_{13}p_3 + C_{14}p_4 + C_{15}p_5$$
$$\phi_2 = C_{21}p_1 + C_{22}p_2 - C_{24}p_4 - C_{25}p_5$$
$$\phi_3 = C_{31}p_1 - C_{33}p_3 + C_{35}p_5$$
$$\phi_4 = C_{41}p_1 - C_{42}p_2 + C_{44}p_4 - C_{45}p_5$$
$$\phi_5 = C_{51}p_1 - C_{52}p_2 + C_{53}p_3 - C_{54}p_4 + C_{55}p_5$$
$$\psi_1 = S$$

The general interaction matrix is shown in Scheme 7.

We now wish to explicitly evaluate the MO integrals of the interaction matrix in suprafacial [1,3] and [1,5] hydrogen migration.

Suprafacial [1,3] hydrogen shift

$$\langle\phi_1|H'|\psi_1\rangle = \langle\phi_1|H_{16}|\psi_1\rangle + \langle\phi_1|H_{36}|\psi_1\rangle = C_{11}\gamma_{16} + C_{13}\gamma_{36}$$
$$\langle\phi_2|H'|\psi_1\rangle = \langle\phi_2|H_{16}|\psi_1\rangle + \langle\phi_2|H_{36}|\psi_1\rangle = C_{21}\gamma_{16} + 0$$
$$\langle\phi_3|H'|\psi_1\rangle = \langle\phi_3|H_{16}|\psi_1\rangle + \langle\phi_3|H_{36}|\psi_1\rangle = C_{31}\gamma_{16} + 0$$
$$\langle\phi_4|H'|\psi_1\rangle = \langle\phi_4|H_{16}|\psi_1\rangle + \langle\phi_4|H_{36}|\psi_1\rangle = C_{41}\gamma_{16} + 0$$

Suprafacial [1,5] hydrogen shift

$$\langle\phi_1|H'|\psi_1\rangle = \langle\phi_1|H_{16}|\psi_1\rangle + \langle\phi_1|H_{56}|\psi_1\rangle = C_{11}\gamma_{16} + C_{15}\gamma_{56}$$
$$\langle\phi_2|H'|\psi_1\rangle = \langle\phi_2|H_{16}|\psi_1\rangle + \langle\phi_2|H_{56}|\psi_1\rangle = 0$$
$$\langle\phi_3|H'|\psi_1\rangle = \langle\phi_3|H_{16}|\psi_1\rangle + \langle\phi_3|H_{56}|\psi_1\rangle = C_{31}\gamma_{16} + C_{35}\gamma_{56}$$
$$\langle\phi_4|H'|\psi_1\rangle = \langle\phi_4|H_{16}|\psi_1\rangle + \langle\phi_4|H_{56}|\psi_1\rangle = 0$$

	DA	$D^{\oplus}A^{\ominus}$	$(D^{\oplus})^{\dagger}A^{\ominus}$	$(D^{\oplus})^{\ddagger}A^{\ominus}$	$D^{\ominus}A^{\oplus}$	D*A	$(D^{\ominus})^{*}A^{\oplus}$

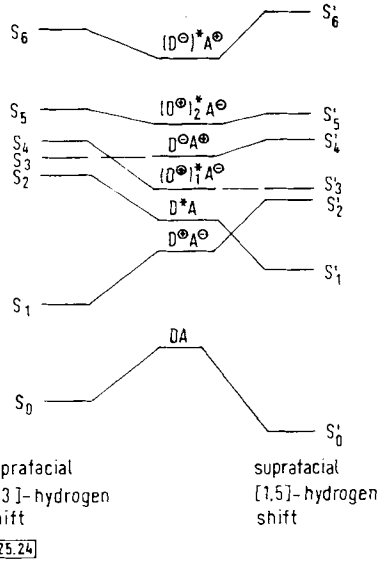


Scheme 7. General interaction matrix for a [1,5] hydrogen shift.

It is quite apparent that we have three kinds of matrix elements of the form $\langle\phi|H_A|\psi\rangle+\langle\phi|H_B|\psi\rangle$:

a) A matrix element where both MO integrals are finite. This leads to mixing of the respective configurations and to pericyclic bonding.

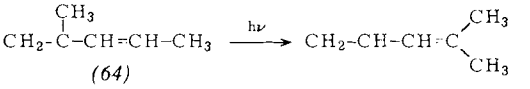
b) A matrix element where the two MO integrals have equal magnitudes but opposite signs. This leads to zero mixing of the respective configurations.

c) A matrix element where one MO integral is finite but the other is zero. This leads to mixing of the respective configurations but *not to pericyclic bonding*. In other words, there is bonding between H and only one of the two migration centers.

A 25.24

Fig. 24. Configuration interaction diagram for competitive suprafacial [1,3] and [1,5] hydrogen sigmatropic shifts.

The configuration interaction diagram for competing [1,5] and [1,3] hydrogen shifts is shown in Fig. 24. The most interesting revelation is that only two of the seven states for [1,3] migration (S_0 and S_5) involve pericyclic bonding. On the other hand, six of the seven states for [1,5] migration involve pericyclic bonding, and only one (S'_3) is a non bonding state. An examination of the configuration interaction diagram leads to the following conclusions:



a) A thermal concerted [1,5] shift will dominate over a competitive [1,3] shift.

b) A photochemical *concerted* [1,5] shift will also dominate over a competitive concerted [1,3] shift because S'_1 has lower energy than S_5.

The first conclusion is an expected one and evidence in its support is plenty[104]. However, the second conclusion is novel and the direct consequence of nodal surfaces through C_3 in ϕ_2, ϕ_3, ϕ_4 of the pentadienyl radical, the migration framework for the two competitive sigmatropic shifts.

The previous discussion was concerned only with suprafacial hydrogen shifts. Now, an antarafacial [1,5] hydrogen shift can be a viable alternative[105]. By going through the same analysis as before, we can show that such a shift will be stabilized less than the suprafacial one in thermal cases. An antarafacial [1,5] hydrogen shift, on the other hand, can proceed *via* an excited pericyclic state, which has lower energy than the excited states responsible for photochemical suprafacial [1,3] and [1,5] hydrogen migration. To put it crudely, a [1,5] shift will dominate over a competitive [1,3] shift in both thermal and photochemical reactions.

Thermal preference for [1,5] over [1,3] hydrogen shifts has been amply demonstrated. The novel conclusion that a photochemical [1,5] hydrogen shift (suprafacial or antarafacial) will dominate over a competitive suprafacial [1,3] sigmatropic shift is supported experimentally, *e.g.* by the reactions of *(64)* and *(65)*[106]. Other examples are known[107].

(64)

(65)

A note of caution: When a photochemical [1,5] sigmatropic shift is impossible because of the geometric constraints of the system, a photochemical [1,3] sigmatropic shift of hydrogen can be observed. The latter may be a concerted reaction proceeding *via* S_5. Such examples have been reported in the literature[108].

8. The Nature of Thermal and Photochemical Pericyclic Reactions

Our configuration interaction treatment can serve as the basis for understanding not only the stereoselectivity of thermal pericyclic reactions, but also for understanding the effect of substituents on the rates of such reactions, which proceed either *via* a least motion path or a nonleast motion path[109]. Table 1 illustrates the relative stabilization of typical pericyclic reactions at the nonpolar and polar ends of the reactivity spectrum. Examination of Table 1 leads to formulation of the following general rule: the rate of a concerted pericyclic reaction will increase, irrespective of its stereochemistry, as the polarity of the reaction increases. Or to put it simply, the more polar a reaction is the faster it will be. Experimental data which illustrate this generalization are given below.

1. Cycloadditions. It is well known that the rates of [2+2] cycloadditions increase as the polarity of the reaction increases. Furthermore, the effect of substituents on the rates of the Diels-Alder reactions (Table 2) is well known and in accord with our predictions.

Table 1. Electronic stabilization of the transition states of polar and nonpolar pericyclic reactions.

Pericyclic Reaction	Nonpolar	Polar
1. Cycloadditions		
[2s + 2s]	Zero	Intermediate
[2s + 2a]	Small	Large
[4s + 2s]	Small	Large
[4s + 2a]	Zero	Intermediate
2. Ring Closures		
4*n* Conrotatory	Small	Large
4*n* Disrotatory	Zero	Intermediate
4*n* + 2 Conrotatory	Zero	Intermediate
4*n* + 2 Disrotatory	Small	Large
3. Sigmatropic Shifts		
[1,3] Suprafacial-Inversion	Intermediate	Large
[1,3] Suprafacial-Retention	[a]	[a]
[1,5] Suprafacial-Inversion	[a]	[a]
[1,5] Suprafacial-Retention	Intermediate	Large

[a] The difference between the electronic stabilization of the polar and the nonpolar reactions is small.

Table 2. Reaction of dienophiles with cyclopentadiene and 9,10-dimethylanthracene in dioxane.

Dienophile	Cyclopentadiene $10^5 k_2$ at 20 °C [l mol^{-1} s^{-1}]	9,10-Dimethylanthracene $10^6 k_2$ at 20 °C [l mol^{-1} s^{-1}]
Tetracyanoethylene	≈43000000	≈13000000000
Tricyanoethylene	483000	5880000
1,1-Dicyanoethylene	45500	127000
Fumaronitrile	81	139
Maleonitrile	91	131
Acrylonitrile	1.04	0.89

2. Electrocyclic reactions. The relative rates of the ring opening of *(66)* and *(67)* are given under the formulas. Increased electron acceptor ability of one of the two fragments in *(67)* is accompanied by enhanced reaction rates[110].

(66) 

$k_{rel}(25\,°C) = 1$

 *(67)*

$k_{rel}(25\,°C) = 10^7$

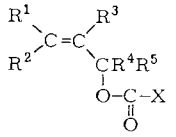
3. Sigmatropic shifts. The rate of a Cope rearrangement increases as the two reaction fragments—formal allyl radicals—aquire opposite polarity[111]. Examples are compounds *(68)*—*(71)*.

(68) 

E_a = 35.3 kcal/mol

 *(69)*

E_a = 28.6 kcal/mol

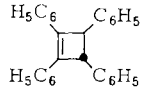


(70) 

E_a = 34.2 kcal/mol

 *(71)*

E_a = 27.9 kcal/mol



Furthermore, the rates of sigmatropic rearrangements of molecules such as *(72)* increase as the substituents R^1—R^5 become more electron releasing and the X substituent becomes more electronegative[112].

 *(72)*

It should be emphasized that our approach can be readily extended to cases where both reaction fragments act as good electron acceptors and electron donors simultaneously. This occurs when the two fragments are highly conjugated systems having a high lying HOMO and a low lying LUMO. As a result, increasing the conjugation of the two reaction fragments is expected to lead to increasing reaction rates. This is nicely illustrated by the cycloreversions of the cyclobutenes *(73)* and *(74)*[113].

(73) 

E_a = 32.5 kcal/mol

 *(74)*

E_a = 21.0 kcal/mol

At this point, it should be mentioned that ring opening of cyclobutenes might involve two separate phases: a phase involving rotation followed by a phase involving bond formation[19]. Hence substituents can affect the energetics of both phases of the mechanism; our approach is pertinent to the rotation part of the aforementioned mechanism only.

We hope that this discussion of the rates of pericyclic reactions will put to rest such obscure ideas as "substituent effects on concerted reactions are expected to be small" or "the rate of a concerted reaction borrows from the rate of the corresponding nonconcerted process", *etc.*

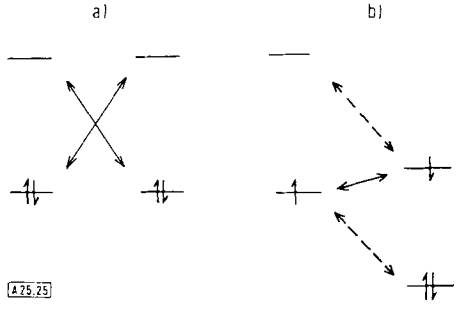


Fig. 25. Configuration interaction diagram for a) nonpolar [2+2] cyclodimerization and b) polar [2+2] cycloaddition. Solid arrows indicate the dominant MO interactions stabilizing [2s+2a] union and broken line arrows indicate those which stabilize [2s+2s] union. Only the HOMOs and LUMOs of the cycloaddends are shown.

A correct and general theoretical treatment of any organic chemistry problem should lend itself to simplification. Figure 25 illustrates how our detailed configuration interaction analysis of thermal [2+2] cycloaddition can be briefly summarized by means of interaction diagrams. This simple approach was initially described by us[10], and constitutes an easy way

for visualizing how reversal of the Woodward-Hoffmann rules can occur in thermal reactions. In the case of nonpolar cycloadditions, the major contributor to the resonance hybrid of the transition complex is the no bond configuration DA. On the other hand, in the case of polar cycloadditions, the charge transfer configuration $D^{\oplus}A^{\ominus}$ is the major contributor. Accordingly, the stereoselectivity of nonpolar cycloadditions will depend on the orbital interactions which obtain in DA, while the stereoselectivity of polar cycloadditions will depend on the orbital interactions which obtain in $D^{\oplus}A^{\ominus}$. In nonpolar [2+2] cycloadditions orbital interactions in DA can only stabilize the [2s+2a] transition state complex, whereas in polar [2+2] cycloadditions orbital interactions can stabilize both [2s+2a] and [2s+2s] transition state complexes. We can analyze in a similar manner the stereoselectivity of semipolar and polar [4+2] cycloadditions.

The nature of the transition state complex in Woodward-Hoffmann allowed and forbidden pericyclic reactions is different, as revealed by our configuration interaction approach. In short, reversal of the Woodward-Hoffmann rules in polar thermal reactions can be traced to the existence of a low energy charge transfer configuration $D^{\oplus}A^{\ominus}$ as well as to the existence of an appropriate excited state which can mix with $D^{\oplus}A^{\ominus}$ and give rise to pericyclic bonding.

The rates of pericyclic photochemical reactions cannot be discussed in any reliable qualitative manner, unless more is known theoretically and experimentally about the process of internal energy conversion[114]. However, our configuration interaction analysis can provide interesting insights into the nature of the transition state complexes involved in photochemical reactions. According to such analysis there are two types of pericyclic photochemical reactions described by the following equations:

$$D + A^* \longrightarrow [\text{excimer complex}]^* \begin{array}{l} \xrightarrow{a} P \\ \xrightarrow{b} P^* \longrightarrow P \end{array} \qquad (7)$$

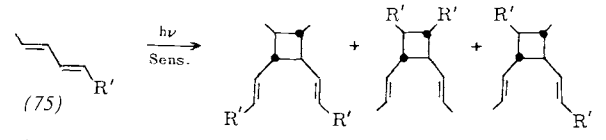
$$D + A^* \longrightarrow [\text{charge-transfer complex}]^* \begin{array}{l} \xrightarrow{a} P \\ \xrightarrow{b} P^* \longrightarrow P \end{array} \qquad (8)$$

The Woodward-Hoffmann allowed reactions proceed according to the first mechanism. In the case of polar photochemical reactions, the Woodward-Hoffmann rules are reversed because there is an excited charge transfer state which has lower energy than the corresponding excimer state.

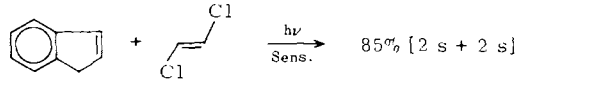
At this point, we wish to digress, and point out that the two mechanistic schemes proposed on the basis of our analysis have been justified, in an entirely different context, by spectroscopic studies. The first mechanism [cf. eq. (7)] involves the transformation of D and A* (or D* and A) to an excimer complex which is primarily made up of the charge transfer configurations $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ as well as the locally excited configurations D*A and DA*. Hence, this transformation is an allowed one. Decay of the excimer to P* (P=product) is most likely because the excimer contains the locally excited configurations D*A and DA*. On the other hand, decay of the excimer to P is also possible because the excimer contains a small amount of the no bond configuration DA as a result of vibrationally induced mixing. This vibrationally induced mixing, which is bound to be significant in the transition state, is nothing else but a form of asymmetry induced mixing which we have previously discussed. Hence, both paths a and b can be followed. The second mechanism [eq. (8)] involves the transformation of D and A* (or D* and A) to an excited charge transfer complex which is primarily made up of the charge transfer configurations $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ as well as the no bond configuration DA. Now, vibrationally induced mixing, which is expected to be significant in the transition state, can endow the excited charge transfer with substantial D*A and DA* character and render the transformation allowed. This vibration induced mixing is, once again, nothing else but a form of asymmetry induced mixing which we have previously discussed. Spectroscopic results support this argument[115]. Laser experiments have shown that the following excitations are possible:

$$(D^{\ominus}A^{\ominus})^* \xrightarrow{h\nu} (A^*D)$$

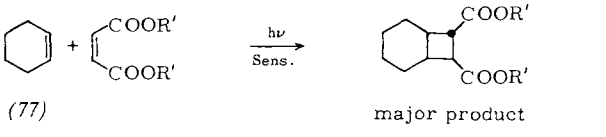
$$(D^{\oplus}A^{\ominus})^* \xrightarrow{h\nu} (AD^*)$$



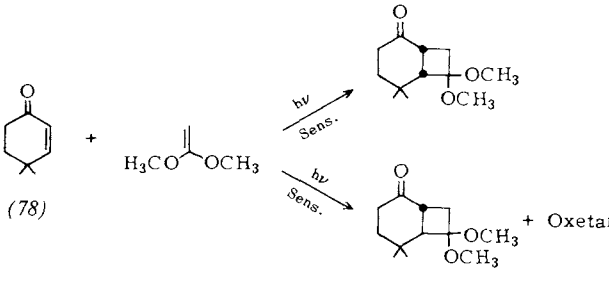
These are "reverse charge transfer transitions", which are allowed because of the presence of locally excited configurations in $(D^{\oplus}A^{\ominus})^*$. This allowedness is bound to be even more marked in photochemical reactions. Decay of the excited charge transfer complex to P is most likely because the former contains principally the no bond configuration DA. Once again, both paths a and b can be followed.



Finally, a satisfying reactivity pattern remains to be pointed out. Photochemical reactions proceeding *via* excimeric states will be electronically predisposed to have opposite stereoselectivity to those proceeding thermally because in the former case stereoselectivity is mainly determined by the mixing of $D^{\oplus}A^{\ominus}$, $D^{\ominus}A^{\ominus}$, D*A and DA* while in the latter it is determined by the mixing of $D^{\oplus}A^{\ominus}$, $D^{\ominus}A^{\oplus}$ and DA. In contrast, photochemical reactions proceeding *via* charge transfer states will be electronically predisposed to have the same stereoselectivity as those proceeding thermally because in both cases stereoselectivity is mainly determined by the mixing of $D^{\oplus}A^{\ominus}$, $D^{\ominus}A^{\oplus}$ and DA.

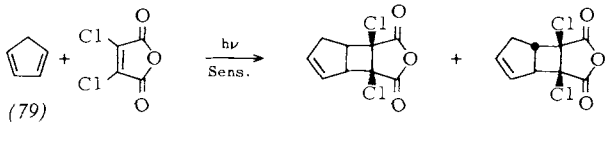


Our detailed configuration interaction analysis of photochemical cycloadditions can be conveniently summarized by means of MO interaction diagrams. The transition state complex of the photoreaction can be assumed to be a resonance hybrid of the D*A (or, DA*) and $D^{\oplus}A^{\ominus}$ contributors. The stereoselectivity of nonpolar cycloadditions will depend on the orbital interactions which obtain in D*A and that of polar cycloadditions on the orbital interactions in $D^{\oplus}A^{\ominus}$. In most cases, one is led to similar conclusions by simply examining the dominant interactions of energy-close orbitals in D*A in both nonpolar and polar cycloadditions. These simple approaches, leading to the same conclusions as the present more detailed approach, have been discussed in a series of papers[110].

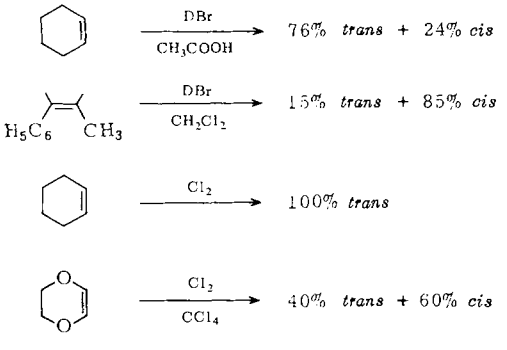


Our analysis of photochemical reactions is formally applicable to singlet reactions. However, one can envision situations where spin orbit coupling could render triplet reactions effectively equivalent to singlet reactions. Spin orbit coupling is facilitated by charge transfer complexation of the triplet excited molecule[116] and, as we have seen, all transition states of photochemical pericyclic reactions have charge transfer contributions which vary from strong (excimer type transition states) to extremely strong (charge transfer type transition states).

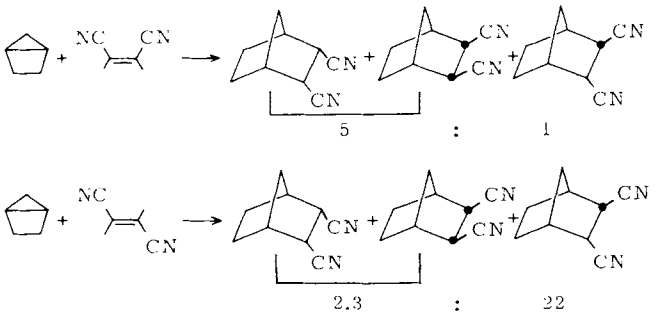
Accordingly, *the fact that a singlet and a triplet reaction have the same stereoselectivity does not necessarily mean that both reactions occur via a common intermediate.* It may very well mean that both reactions are concerted and spin orbit coupling is strong. On the other hand, if a singlet and a triplet reaction exhibit different stereoselectivity and product distribution, this can be taken to be a strong indication of mechanistic duality. A survey of the experimental results reported on sensitized photocycloadditions reveals that many triplet photocycloadditions occur with a stereoselectivity which is expected for concerted singlet photocycloadditions[117]. In our opinion, this could indicate that spin orbit coupling can give rise to rapid spin flipping and the triplet photocycloadditions can thus exhibit the stereoselectivity expected from singlet concerted photocycloadditions. Examples are the nonpolar sensitized [2s+2s] photocycloadditions of compounds *(75)* and *(76)*[118,119] and the polar sensitized [2s+2a] photocycloadditions of compounds *(77)* and *(78)*[120].



In the reaction of *(78)*, the two stereoisomeric states arise from two different triplet states: a triplet reaction can be stereospecific! The amazing stereoisomerism exhibited by the products of the polar, sensitized photocycloaddition of *(79)* is a strong indication that a [2s+2a] reaction is competing with a [2s+2s] reaction, despite the unfavorable steric features of the former type of union[121].

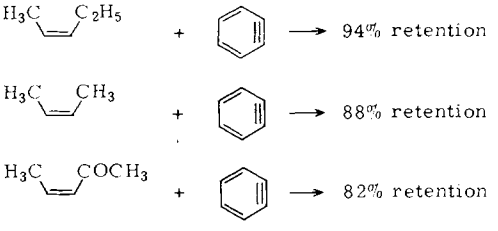


It should be pointed out that in some of the above reactions, the presence of a heavy atom substituent can additionally enhance spin orbit coupling. Here, we should like to bring the reader's attention to an interesting paper by *Ross* and *George*[8] in which the formal inapplicability of the Wigner-Wittmer spin rules to chemical reactions are discussed.



A final point remains to be made: We have derived stereoselection rules for photochemical reactions under the assumption that these reactions occur *via* the lowest excited state of the "transition state complex". We can designate this entity as the photoreaction complex. Our approach predicts that there are two types of photoreaction complexes, one resembling an excited charge transfer complex and another resembling an excimer. In each reaction, these two types of complexes lead to different stereoselectivities. This simple picture seems to be reasonable for reactions where the reactants and the photoreaction complex have similar degrees of conjugation, as is the case in photocycloadditions and photochemical cyclizations. On the other hand, when the reactants are less conjugated than the photoreaction complex, as in the case of photochemical cycloreversions, ring openings, sigmatropic rearrangements, *etc.*, it is possible that a different situation may exist. The photoexcitation of the reactant may involve sufficient energy so that a higher excited state of the photoreaction complex is reached. This higher state can either decay directly to the ground state product or yield an excited product which can subsequently decay to its ground state[122]. Our configuration interaction analysis describes the multitude of higher excited states of the photoreaction complex for each stereochemical mode. Hence, there is a hope that the stereoselectivities of photochemical reactions which proceed *via* a higher excited state can be eventually unterstood in terms of our approach.

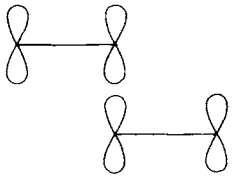
In this work, we have examined the stereoselectivity and rates of concerted cycloadditions and cycloreversions, electrocyclic reactions and sigmatropic rearrangements[123]. Naturally, the same concepts can be applied to other general types of reactions, such as electrophilic additions to double bonds, additions of strained bicyclics to olefins, additions of benzynes to olefins, exchange reactions, ionic rearrangements, *etc.* In these cases, the experimental evidence seems to support strongly our qualitative conclusions. For example, the following trends are observed:



1. In the case of electrophilic additions to double bonds, increasing the electron donating ability of the olefin leads to increased *cis* stereoselectivity[124–127].

2. Strained bicyclic molecules can add to electron acceptor olefins with a high degree of *cis* stereoselectivity[128].

3. Benzyne adds to electron rich *cis* olefins with a high degree of *cis* stereoselectivity[129].



9. The Question of the Intermediate

We now wish to take a closer look at the concept of diradical and dipolar intermediates[130]. Such intermediates can be operationally definable in cycloaddition reactions. Hence, we shall restrict our attention to such reactions and, in particular, discuss the case of [2+2] cycloaddition. Many workers seem to neglect the important fact that diradical or dipolar intermediates must be formed in a transoid geometry so that the two ends do not overlap. Assymmetric overlap of all uniting centers would lead to a variant of a concerted reaction. For example, consider the case of a [2+2] cycloaddition proceeding *via* a stepwise mechanism:

The rate determining step of the reaction can be step 1 or step 2. In the former case, our configuration interaction analysis can lead to an insight as to whether a stepwise or a concerted mechanism will be operative in [2+2] cycloaddition. The electronic states of the transition complexes of [2s+2s] and [2s+2a] concerted reactions, as well as the electronic states for the diradicaloid[131] transition state *(80)*, can be derived in the same manner as before, so that their relative energies can be compared.

(80)

Maximum configuration mixing can take place in the case of this diradicaloid transition state, but the matrix elements will be roughly half the size compared to the nonzero matrix elements of the [2s+2s] and [2s+2a] transition states. Construction of the appropriate configuration interaction diagrams and consideration of the steric features of the various transition states leads to the following conclusions:

a) In nonpolar [2+2] cycloadditions, the transition states of the thermal [2s+2a] and the photochemical [2s+2s] reactions are electronically stabilized. The transition state of the stepwise reaction is also stabilized, though less so than the transition states of the concerted reactions. However, steric effects can destabilize the thermal [2s+2a] pathway but not the photochemical [2s+2s] pathway. As a result, a stepwise mechanism involving diradical intermediates can dominate over the thermal [2s+2a] mechanism but cannot dominate over the photochemical [2s+2s] mechanism, unless the photoexcited cycloaddend reacts in a nearly perpendicular geometry.

b) In polar [2+2] cycloadditions, the thermal [2s+2a] reaction is stabilized to a greater extent electronically than either the [2s+2s] or the stepwise reaction. The latter two are stabilized electronically to comparable extents. The unfavorable steric features of the [2s+2a] transition state render the [2s+2s] and stepwise pathways more favorable, so that polar thermal [2+2] cycloadditions are expected to occur *via* competitive converted ([2s+2s]) and stepwise mechanisms. The photochemical reaction, however, is predicted to proceed preferably *via* an excited intermediate and this pathway is expected to dominate over the concerted ([2s+2a]) reaction. According to these conclusions, one expects that polar thermal [2+2] cycloadditions and, even more so, polar [2+2] photocycloadditions will be nonstereoselective because they involve a transoid intermediate which can exhibit free bond rotation before ring closure. As we have already seen, the experimental results are in disagreement with such inferences.

The above considerations are valid only if the transition state for a stepwise reaction occurs between the reactants and the transoid intermediate. This hypothesis is of dubious validity in the case of nonpolar reactions and is probably incorrect in the case of polar reactions. Conversion of the transoid intermediate into the product requires some activation energy for rotation about the C^2—C^3 bond to yield the cisoid intermediate, and further activation energy for ring closure of the latter to product. Now, ring closures of diradical intermediates could be associated with substantial barriers, which, according to thermochemical calculations by *Benson* and *O'Neal*[132], amount to approximately 6 kcal/mol. Furthermore, barriers to rotation about the C^2—C^3 bond can be substantial when C^1 and C^4 bear substituent groups. If we assume that the activation energy for the decomposition of a diradical back to reactants is of the order of magnitude of 6 kcal/mol, the approximate activation energy for the decomposition of the tetramethylene diradical, we are led to the conclusion that the transition state for nonpolar [2+2] cycloadditions most likely lies between the intermediate transoid diradical and the products. In polar [2+2] cycloadditions, there is an additional factor which has to be considered—the solvation energy of the two ends of the dipolar intermediate which is lost as a result of ring formation and which can be very large[133]. Hence, in polar [2+2] cycloadditions the transition state of the stepwise process is fully expected to lie between the transoid dipolar intermediate and the product.

The following conclusion is reached: in polar cycloadditions, and possibly in nonpolar cycloadditions, one cannot use a

transoid diradicaloid transition state model in order to draw quantum mechanical inferences about the stereochemistry, rate, *etc.* of such reactions[1,3,4]. If the energy of a transoid diradicaloid transition state is calculated by a quantum mechanical method, then one has to add the energy difference between the transition state for step 1 and the transition state for step 2 in order to assess correctly the energy of the transition state of the stepwise reaction.

We can now return to our configuration interaction analysis of the electronic states of diradicaloid transition states. If step 2, and not step 1 as we previously assumed, is rate determining, one has to correct the energies of the transoid diradicaloid states to higher energies. Thus, in nonpolar thermal cycloadditions the stepwise mechanism and the concerted [2s+2a] mechanism will become competitive, while in nonpolar photochemical cycloadditions the [2s+2s] mechanism will dominate over the stepwise mechanism, unless the photoexcited cycloaddend reacts from a nearly perpendicular geometry. Furthermore, in polar thermal cycloadditions the [2s+2s] mechanism will dominate over the stepwise mechanism, while in polar photochemical cycloadditions the [2s+2a] mechanism will compete with, and may even dominate over, the stepwise mechanism.

In short, we believe that there are qualitative reasons for expecting concerted reactions to dominate over their stepwise alternatives, with the exception of nonpolar thermal [2+2] and, possibly, semipolar thermal [4+2] cycloadditions. In addition, experimental results show that the expected stereorandomness of reactions proceeding *via* diradical or dipolar intermediates does not obtain in most cases. Hence, predominantly, although not necessarily exclusively, concerted reactions seem to be good candidates for a plausible interpretation of the origin of stereoselectivity.

10. Conclusion

In this work, we described a simple configuration interaction approach for the treatment of pericyclic reactions. We utilized a Hamiltonian which contained only one-electron parts and, hence, allowed the mixing only of configuration wave functions which differed at most by one spin orbital. Inclusion of two-electron parts in our Hamiltonian will allow mixing of configuration wave functions which differ at most by two spin orbitals. Ultimately, inclusion of one-electron and two-electron terms along with an expanded configuration basis set can produce a computational scheme of sufficient quantitative accuracy. The effect of two-electron mixing on the stereoselectivity of thermal pericyclic reactions has been discussed by us in a series of papers and has been shown to parallel quite closely the effect of one-electron mixing. Accordingly, we believe that the dichotomy between nonpolar and polar pericyclic reactions is a real one and further experimental studies will most likely bear this point out. We now would like to make some remarks pertaining to the Woodward-Hoffmann rules:

a) In the case of thermal reactions the electronically preferred stereochemical mode of union of two cycloaddends or fragments is predicted to be the same by both the Woodward-Hoffmann rules and the configuration interaction treatment. However, the configuration interaction treatment reveals that in polar reactions, an alternative stereochemical mode of union can also be electronically stabilized.

b) In the case of thermal reactions, the Woodward-Hoffmann orbital symmetry approach can provide the framework for discussing two-electron configuration interaction effects. As we have discussed before, diexcitation is energetically inexpensive in polar reactions and can lead to congruence of the orbital symmetry characteristics of the transition state complex and the products in Woodward-Hoffmann forbidden reactions.

c) In polar photochemical cycloadditions, the configuration interaction treatment leads to stereochemical predictions which are opposite to the ones of Woodward and Hoffmann because the importance of charge transfer excitation is paramount. However, even in this instance the orbital symmetry approach rises to the occasion. Thus, the opposite stereoselectivities of a nonpolar and a polar photochemical [4+2] cycloaddition can be predicted by using orbital symmetry arguments. Figure 26 shows the orbital symmetry correlation diagrams for a nonpolar and a polar suprafacial [4+2] photocycloaddition. In the semipolar case there is no congruence between the orbital symmetry characteristics of the lowest excited state of the reactants (a locally excited state) and either the lowest excited state or the ground state of the product. By contrast, in polar [4+2] photocycloadditions, the lowest excited state of the reactants (a charge transfer state) correlates with a higher excited state of the product or *directly with the ground state of the product*. Here, we have a case where orbital symmetry can dictate the mechanism of the reaction, as well as its stereoselectivity. Polar [4+2] cycloadditions are [4s+2s] stereoselective and proceed by the following mechanism:

$$D^* + A \rightarrow (D^{\delta+} \cdots A^{\delta-})^*_{CT} \rightarrow DA$$

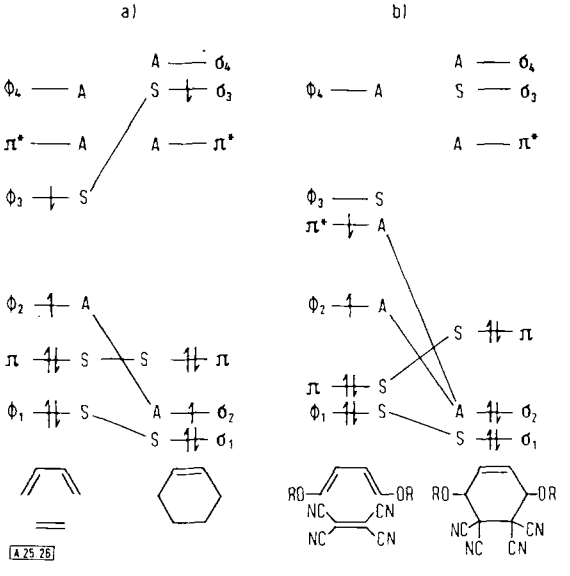


Fig. 26. Correlation diagram for a) a semipolar and b) a polar, suprafacial [4+2] cycloaddition. ϕ_1, ϕ_2, ϕ_3, and ϕ_4 are the π MOs of the unperturbed or perturbed butadiene and π and π^* are the π MOs of the unperturbed or perturbed ethylene. The MO correlations are to be considered as "intended" correlations.

In short, the principle of conservation of orbital symmetry provides a convenient theoretical framework for exploring the stereoselectivity of both nonpolar and polar pericyclic reactions, if one wishes to do so. However, the configuration

interaction approach is simple enough, able to reveal reactivity trends, and can be used to analyze problems where symmetry is totally absent.

The fundamental ideas and the theoretical approach reported in this work have been stimulated by past important contributions of able theorists. The work of *Mulliken* on molecular complexes[135] provided the initial stimulus for this work. The configuration interaction approach discussed in this paper was put forward by *Mulliken* and also by *Longuet-Higgins* and *Murrell*[136] in their studies of the electronic states of unsaturated molecules[137]. Finally, it would have been an unforgivable oversight not to emphasize that the concepts outlined here are the indirect result of countless experimental contributions of able investigators.

[28] For example, the regioselectivity of a reaction can be determined by such a method.

[29] These simple rules are to be found in most textbooks on quantum chemistry. See *e.g.*: *L. Salem*: The Molecular Orbital Theory of Conjugated Systems. Benjamin, New York 1966.

[30] Proportionality constants which precede the MO integrals are omitted for conservation of space.

[31] The magnitudes of the coulombic terms C and C in the energy expressions for $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ depend on the geometry of approach of the two cycloaddends. Hence, the energies of $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ will be slightly different for [s+s] and [s+a] union. In order to simplify the construction of the configuration interaction diagrams for cycloadditions, we have assumed that the energies of $D^{\oplus}A^{\ominus}$ and $D^{\ominus}A^{\oplus}$ configurations are the same for both [s+s] and [s+a] union.

Kinetics and Mechanism of Radical Polymerization

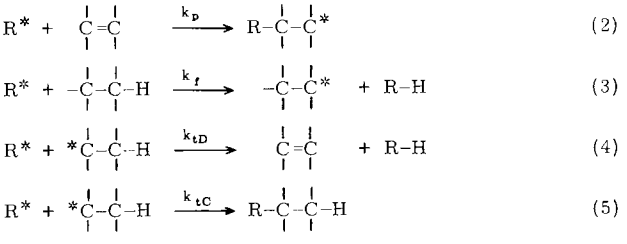
By Peter Mehnert[*]

Low molecular reactions are frequently accompanied by side reactions producing a whole spectrum of by-products whose removal in purification operations generally causes little difficulty because the major and side products usually differ sufficiently in their properties. Hence detailed kinetic studies in low molecular chemistry can claim industrial interest only insofar as they aim to reduce the rate of formation of side products. The situation is completely different in polymer chemistry, where the terms major and side product no longer apply. Instead, one obtains mixtures of similar and/or isomeric molecules which differ so little with regard to molecular weight and structure that resolution into pure substances or isolation of pure substances becomes practically impossible. However, since all partial reactions exert a direct influence on the product spread, *i.e.* the composition and properties of a product mixture are modified by any change in operating conditions, detailed kinetic analyses embracing all relevant partial reactions are an essential prerequisite for the production of defined polymeric products on any scale. This progress report illustrates the importance of kinetics for radical polymerization with the aid of selected examples.

1. Introduction

A series of industrial processes affording products of various qualities are available for radical polymerization, *viz.* solution polymerization, emulsion polymerization, suspension polymerization, and bulk polymerization. The present report deals exclusively with bulk polymerization, whose industrial importance has increased enormously in recent years.

Apart from the case of styrene, which undergoes spontaneous transformation into high molecular compounds, bulk polymerization requires only very small amounts of an auxiliary compound to initiate the polyreaction. This advantage of bulk polymerization, which requires no further additives (such as solvents, controllers, emulsifiers *etc.*) and consequently yields exceptionally pure polymeric products, is counterbalanced by the particularly difficult technical problem of removing the extremely high heats of polymerization amounting to about 100 kJ per mol of monomer.



Those substances which trigger off a polyreaction are termed initiators. The initiators generally used in radical polymerization are peroxides or azo compounds, *e.g.* azodiisobutyronitrile AIBN whose fragments become components of the macromolecules [eq. (1)]. The initiators can fragment thermolytically

$$NC{-}C(CH_3)_2{-}N{=}N{-}C(CH_3)_2{-}CN \xrightarrow{k_i} 2\,{}^*C(CH_3)_2{-}CN + N_2 \quad (1)$$

(thermally induced polymerization) or photolytically (photosensitized polymerization).

Radical polymerization is characterized by the high reactivity of the active polymeric radicals combined with a pronounced non-specificity of reaction: they react both with molecules and with other radicals, by addition and by substitution. In polymer chemistry these reactions are known as: chain propagation (2), chain transfer (3), disproportionating termination (4), and combinational termination (5); R* corresponds to a polymer radical, *e.g.* $^*CHX{-}CH_2{+}CHX{-}CH_2{\rightarrow}_n H$.

$$R^* + \text{C=C} \xrightarrow{k_p} R{-}C{-}C^* \quad (2)$$

$$R^* + {-}C{-}C{-}H \xrightarrow{k_f} {-}C{-}C^* + R{-}H \quad (3)$$

$$R^* + {}^*C{-}C{-}H \xrightarrow{k_{tD}} C{=}C + R{-}H \quad (4)$$

$$R^* + {}^*C{-}C{-}H \xrightarrow{k_{tC}} R{-}C{-}C{-}H \quad (5)$$

Since the starting materials (saturated molecules, radicals, olefins) are partly regenerated in these reactions, the events occurring are extremely complex and finer details still elude description, especially since material factors play a considerable role. Some principle features of importance in the bulk polymerization of vinylic and acrylic compounds in the liquid phase are reported below.

2. Chain Propagation

By far the most important reaction mentioned in Section 1 is the addition of monomer molecules to polymer radicals [eq. (2)] for it determines the microstructure of the polymer chain. This reaction is uniform in that, in the case of monosubstituted and geminally disubstituted olefins, practically only head-to-tail linkages occur which lead to a C—C chain comprising planar zig-zag sections and helical sections of various lengths and joined together in some kind of statistical sequence.

Each linkage step, however, also generates a new center of asymmetry and thus determines the configuration (D or L) of a further asymmetrical C atom. If an irregular D-L sequence is obtained, as in radical polymerization, then the number of possible stereoisomers for a fairly long molecule is greater than the number of molecules of this chain length that can ever be synthesized! Given a mean degree of polymerization of $\bar{P}_n = 10^3$, a production figure of 10^7 t/a corresponds to about 10^{32} macromolecules per year; however, just the vinyl polymer molecules having 1000 basic units amount to 2^{1000} ($= 10^{301}$) stereoisomers.

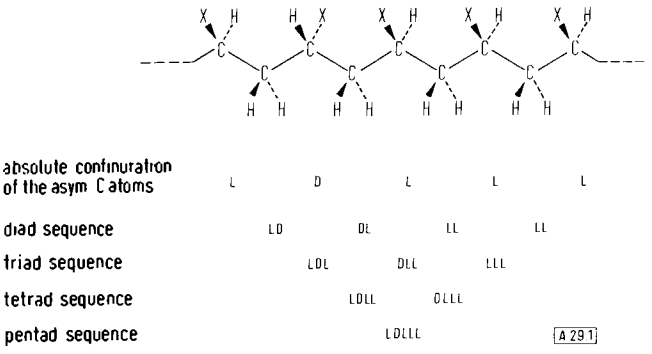

Fig. 1. Section of a head-to-tail linked vinyl polymer bearing the substituent X; its tacticity is denoted by the relative frequency of individual sequences.

For this reason, structural information pertaining to high polymers is usually restricted to the relative frequency of the various stereochemical arrangements in individual sequences (Fig. 1): stipulation of the relative frequency of the three diad sequences (DD), (DL), and (LL), the six triad sequences [eqs. (6)—(8)], the ten tetrad sequences, *etc.* *Natta* coined the term tacticity for this stereoisomerism, and *e.g.* (mm), (mr), and (rr) also designate the relative frequencies

$$(mm) = (DDD) + (LLL) \quad (6)$$

$$(mr) = (DDL) + (DLL) \quad (7)$$

$$(rr) = (DLD) + (LDL) \quad (8)$$

of the isotactic [eq. (6)], the heterotactic [eq. (7)], and the syndiotactic triads [eq. (8)], the symbols m and r being taken from the terms "meso" and "racemic". The significance of the tacticity becomes clear from the following example: whereas polystyrene of tacticity (mm)=1; (mr)=(rr)=0 has a melting point of 230 °C, this value drops to 100 °C for a polystyrene of tacticity (mr)=0.5; (mm)=(rr)=0.25.

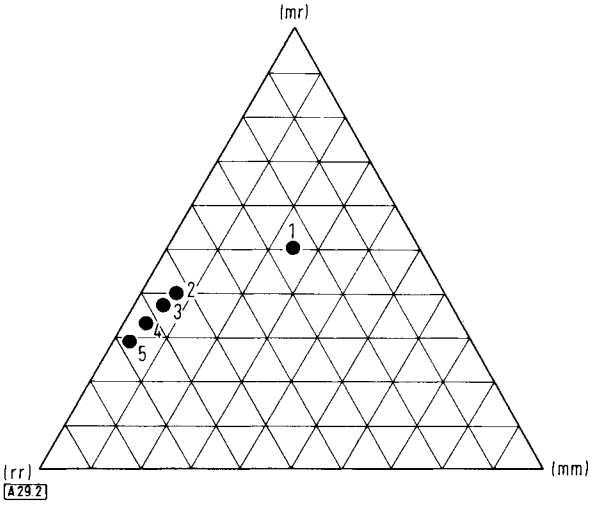

Fig. 2. Tacticity of polymers prepared by radical methods at 50 °C; (mm), (mr), and (rr) denote the relative frequencies of iso-, hetero-, and syndiotactic triads, respectively. 1 = poly(vinyl acetate) [3], poly(methyl acrylate) [4], polyacrylonitrile [5], poly(vinyl bromide) [6], poly(vinyl formate) [7], poly(vinyl chloride) [6, 8, 9]; 2 = poly(methyl methacrylate) [7, 10—12]; 3 = poly(methyl α-chloroacrylate) [13]; 4 = poly(*n*-butyl methacrylate) [14]; 5 = poly(glycidyl methacrylate) [15].

The frequency of the arrangements can best be established by high resolution nuclear magnetic resonance spectroscopy[1].

Figure 2 illustrates the tacticity of several polymers prepared by radical methods[2]. Vinyl polymers are seen to possess a highly regular structure; the relative frequencies of the triad sequences are in the ratio (mm) : (mr) : (rr) = 0.25 : 0.50 : 0.25, whereas polymers obtained from geminally disubstituted olefins exhibit a considerably higher syndiotactic component (rr). The size of substituents apparently also plays a role in methacrylic polymers.

Apart from this pronounced effect of substituent size on the tacticity of polymers produced by radical methods, a minor influence of the polymerization temperature has also been ascertained, which can be expressed in an Arrhenius equation [eq. (9)]. However, this influence is unimportant [E in eq.

$$((DD) + (LL))/(DL) = k\exp(-E/RT) \quad (9)$$

(9) is at most 4 kJ mol^{-1}] so that the polymerization temperature cannot be employed to significantly modify the tacticity of a polymeric product. Whether an Arrhenius representation of the temperature effect is in fact at all justified cannot generally be decided on the basis of a few measurements since it is absolutely essential to investigate a very large temperature range in the case of such small temperature gradients. *Kador* and *Mehnert*[3] have carried out measurements in the range −60... +200 °C and were unable to detect any influence of the polymerization temperature on the tacticity of, *e.g.*, poly(vinyl acetate).

Determination of the relationship between the frequencies and kinetic reaction parameters proves to be fairly complicated since it must be assumed that the addition reaction is influenced both by directly preceding linkages and by the various conformational states of the radical chain end. One therefore proceeds by setting up several reaction models and examining each one by comparison with the experimentally determined sequences. Agreement indicates that the model may be correct, while non-agreement definitely rules it out.

As an example, let us examine a reaction model which accounts for the two immediately preceding additions (...DD, ...DL, ...LD, or LL) and three conformational states ($i = 1, 2, 3$) of the radical chain end, *i.e.* for which a total of twelve different forms of the polymer radical are to be considered. Since each form offers two possible addition modes (D or L), the tacticity is determined by eqs. (10)—(12)[2].

$$(mm) = \Sigma\rho_{DD,i}\cdot\psi_{DD,D} + \Sigma\rho_{LL,i}\cdot\psi_{LL,L} \quad (10)$$

$$(rr) = \Sigma\rho_{DL,i}\cdot\psi_{DL,D} + \Sigma\rho_{LD,i}\cdot\psi_{LD,L} \quad (11)$$

$$(mr) = 1 - (mm) - (rr) \quad (12)$$

$\rho_{DD,i} = [R_{DD,i}]/[R]$ = relative concentration of the polymer radicals present in DD form *etc.*; $\psi_{DD,D} = (k_p(DD_iD)/(k_p(DD_iD) + k_p(DD_iL))$ = probability of formation of an asymmetric C atom of configuration D on addition of a monomer molecule to a polymer radical having the form DD_i, *etc.*

The manner in which these equations can be simplified, *i.e.* which terms can be neglected, which forms are present in equal concentrations, and which reaction probabilities are equal, as well as the question whether a high syndiotactic content is due primarily to differences in conformational state populations or differing reaction probabilities will be discussed later[16-18]. Solution of this problem will require further highly precise NMR studies in order to better understand the statistical relationship between the frequencies of the sequences, as well as extensive ESR investigations to provide information

about the the conformational states of the end of the radical chain.

Attempts have also been made to glean information about tacticity from polymer transition reactions. Thus *Messmer* and *Mehnert*[19,20] observed the intramolecular cyclization tendency of neighboring substituents to form hexacyclic systems and compared radical-polymerized polyisopentenone and polybutenone with purely syndiotactic 1,2-polybutadiene produced by an ionic process.

3. Polymer-Forming Reactions

At low conversions the reaction scheme (1)—(5) of initiated homogeneous polymerization becomes eqs. (13)—(17), which are presented in conventional abbreviated form. R_r and P_r represent specified polymer radicals R* and polymer molecules P. The subscript r indicates the number of monomeric units (fundamental units, structural units) which each of the particles contains, M signifies a monomer molecule. The rate constants

$$S \xrightarrow{k_i} 2R_1 \tag{13}$$

$$R_r + M \xrightarrow{k_p} R_{r+1} \tag{14}$$

$$R_r + M \xrightarrow{k_f} P_r + R_1 \tag{15}$$

$$R_r + R_{r'} \xrightarrow{k_{tD}} P_r + P_{r'} \tag{16}$$

$$R_r + R_{r'} \xrightarrow{k_{tC}} P_{r+r'} \tag{17}$$

at 20 °C are generally of the order of $k_i(\text{AIBN}) = 10^{-7}\,s^{-1}$; $k_p = 10^{+2}$, k_f 10^{-2}, $k_t = 10^{+7}$ mol^{-1} l s^{-1}. The polymer formation reactions are represented by eq. (15)—(17). Eq. (18) for the polymerization rate v_p can be derived from eq. (14). The change in radical concentration is given by eq. (19) or its integrated form [eq. (20)]. As seen from eq. (20), after a short reaction time the function $\tanh(2k_i[S](k_{tD}+k_{tC}))^{0.5}t \simeq 1$; hence the initial rate after this short induction period is given by eq. (21).

$$v_p \equiv k_p[M]\Sigma[R_r] \tag{18}$$

$$d\Sigma[R_r]/dt = 2k_i[S] - (k_{tD} + k_{tC})(\Sigma[R_r])^2 \tag{19}$$

$$\Sigma[R_r] = (2k_i[S]/(k_{tD} + k_{tC}))^{0.5} \tanh(2k_i[S](k_{tD} + k_{tC}))^{0.5}t \tag{20}$$

$$v_i \equiv 2k_i[S] = (k_{tD} + k_{tC})(\Sigma[R_r])^2 = ((k_{tD} + k_{tC})/k_p^2)(v_p/[M])^2 \tag{21}$$

Although the scheme (13)—(17) is fairly simple, the time-dependent expressions for the concentrations $[R_1]$, $[R_r]$, and $[P_r]$ are fairly complicated. Introduction of the symbols H and K [eqs. (25) and (26)] into eqs. (21)—(24) yields eqs. (27) and (28), and hence, after summation over all r, the general rate equation (29) for formation of the polymeric products

$$d[R_1]/dt = 2k_i[S] + k_f[M]\sum[R_r] - k_f[M][R_1] - k_p[M][R_1] - (k_{tD} + k_{tC})[R_1]\sum[R_r] \simeq 0 \tag{22}$$

$$d[R_r]/dt = k_p[M][R_{r-1}] - k_f[M][R_r] - k_p[M][R_r] - (k_{tD} + k_{tC})[R_r]\sum[R_r] \simeq 0 \tag{23}$$

$$d[P_r]/dt = k_f[M][R_r] + k_{tD}[R_r]\sum[R_r] + 0.5k_{tC}\sum_{h=1}^{h=r-1}[R_h][R_{r-h}] \tag{24}$$

$$H \equiv k_f/k_p + ((k_{tD} + k_{tC})/k_p^2)(v_p/[M]^2) \tag{25}$$

$$K \equiv 0.5(k_{tC}/k_p^2)(v_p/[M]^2) \tag{26}$$

$$[R_r] = H\cdot(1+H)^{-r}\Sigma[R_r] = H\cdot e^{rH}\cdot\Sigma[R_r] \tag{27}$$

$$d[P_r]/dt = v_p\cdot H\cdot e^{-rH}\cdot(H - K(2 - rH)) \tag{28}$$

$$d\Sigma r^i[P_r]/dt = v_p\cdot H^{-i}\cdot(H - K(1-i))\cdot\Gamma(1+i) \tag{29}$$

and the Poisson distributions [eqs. (30) and (31)] representing the molecular weight distributions of the polymer molecules and polymer radicals (i,j = positive real numbers including zero). Equations (30) and (31) are likewise generally valid[21], *i.e.* for all distributions (including fractional values of i) and in the presence of all three polymer formation reactions, $i=0$ corresponds to the frequency distribution and $i=1$ to the mass distribution of the polymer particles.

$$\frac{r^i[P_r]}{\sum r^i[P_r]} \approx \frac{d\,r^i[P_r]/dt}{d\sum r^i[P_r]/dt} = \frac{H}{\Gamma(1+i)}\,\frac{(rH)^i}{e^{rH}}\cdot\frac{H - K(2-rH)}{H - K(1-i)} \tag{30}$$

$$\frac{r^i[R_r]}{\sum r^i[R_r]} = \frac{H}{\Gamma(1+i)}\cdot\frac{(rH)^i}{e^{rH}} \tag{31}$$

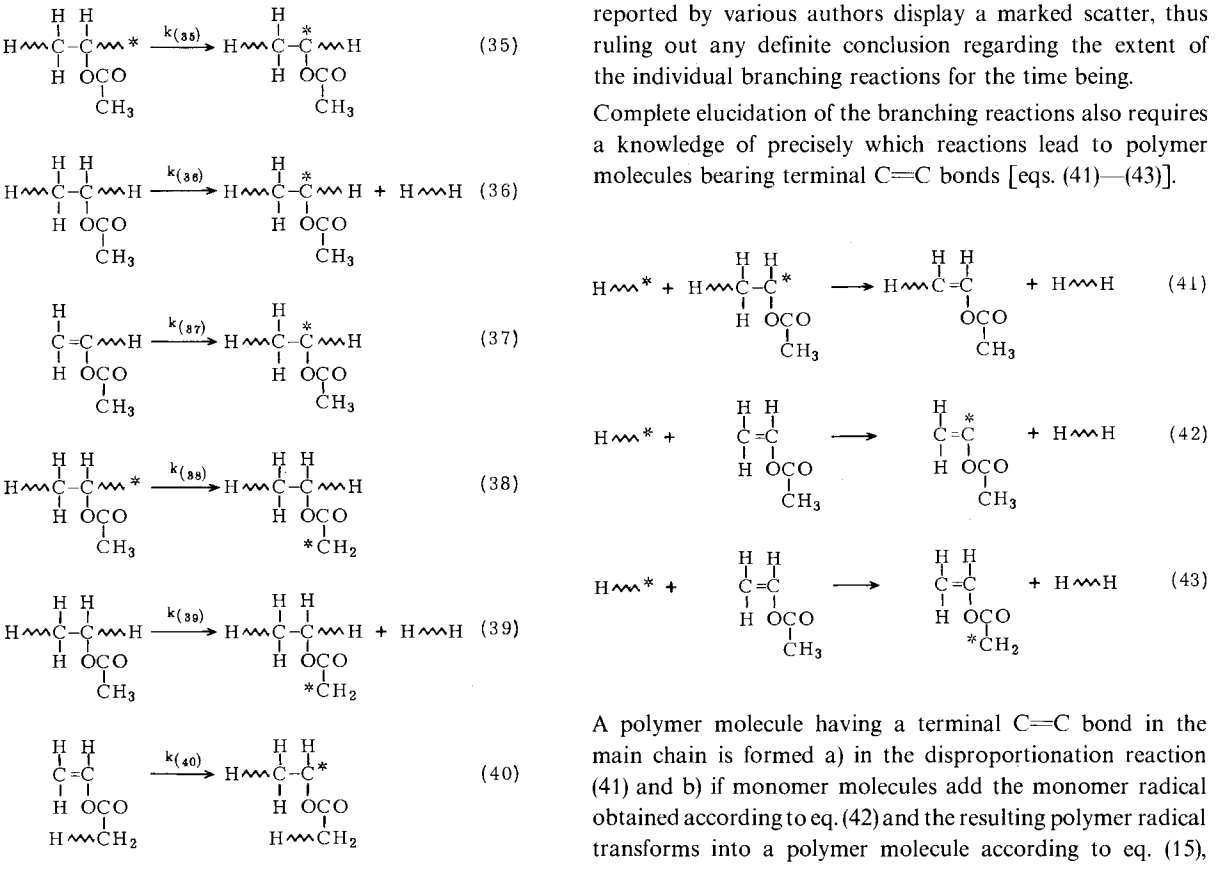
Frequent use of made of the mean degrees of polymerization [eq. (32)], which are much more readily accessible experimentally, and $\bar{P}$ is designated as number average $\bar{P}_n$ for $i=1$; $j=0$, as weight average $\bar{P}_w$ for $i=2$; $j=1$, as z-average P_z for $i=3$; $j=1$, and as viscosity average $\bar{P}_\eta$, which is related to the Staudinger index $[\eta] = K_\eta(\bar{P}_\eta)^\alpha$, for $i = 1+\alpha$; $j=1$. The non-uniformity NU is sometimes also used as parameter for the molecular weight distribution of a polymeric product [eq. (33)]; it lies between 0.5 and 1.0, provided that the reaction course corresponds to eqs. (13)—(17).

$$(\bar{P})^{i-j} \equiv \frac{\sum r^i[P_r]}{\sum r^j[P_r]} \approx \frac{d\sum r^i[P_r]/dt}{d\sum r^j[P_r]/dt} = \frac{H - K(1-i)}{H - K(1-j)}\cdot\frac{\Gamma(1+i)}{\Gamma(1+j)}\cdot H^{j-i} \tag{32}$$

$$NU \equiv (\bar{P}_w/\bar{P}_n) - 1 = 1 - 2(K/H)^2 \tag{33}$$

Equations (27)—(33), which are each written in a general manner[21], clearly show that not only the yield, reaction rate, *etc.* but also the properties of polymers (*i.e.*, in particular, the mean degree of polymerization and molecular weight distribution) are determined by the reaction conditions (primarily temperature, and concentration of initiator and monomer). The experimentally accessible quantities v_p (from conversion/time curves determined by gravimetry or dilatometry) and $\bar{P}$ (from molecular weight determinations by osmometric, light scattering, viscosity, terminal group methods or with an ultracentrifuge) and v_i (from initiator decomposition) always yield only the ratios k_f/k_p and k_t/k_p^2, as is underlined by eqs. (21), (25), and (26). Individual determinations of rate constants can be performed using a method developed by *Chapman et al.*[22] and introduced into polymerization kinetics by *Melville*[23], *viz.* the method of intermittent irradiation in which a thermally induced polymerization is reinforced at equidistant intervals by photosensitized polymerization. Three separate experiments furnish one polymerization rate each: in the dark $(v_p)_{dark}$; on continuous irradiation $(v_p)_{cont}$; on intermittent irradiation $(v_p)_{int}$. If t_l and t_d represent the length of the light and dark period respectively, then the expression due to *Mehnert*[24] (34) affords the ratio k_t/k_p, and it then proves possible to determine k_f, k_p, and k_t.

$$\cosh\frac{k_t A}{k_p[M]} = G^2\cdot\cosh\frac{k_t(B+C)}{k_p[M]} + (1-G^2)\cdot\cosh\frac{k_t(B-C)}{k_p[M]} \tag{34}$$



$$A \equiv (t_l + t_d)(v_p)_{int};\ B \equiv t_l(v_p)_{cont};\ C \equiv t_d(v_p)_{dark};\ G \equiv \cosh\ln\sqrt{(v_p)_{cont}/(v_p)_{dark}}$$

4. Polymer Branching Reactions

The relationships (22)—(23) apply strictly only to the starting conditions, *i.e.* for conversions $C \rightarrow 0\,\%$, since both the falling radical concentration (due to initiator consumption) and the falling monomer concentration have an increasing effect on the molecular weight distribution (and derived quantities) as conversion progresses. Moreover, the very slight, and generally negligible, dependence of the rate constants upon chain length leads to a minor shift in the molecular weight distribution, shorter molecules being disfavored.

However, polymer branching reactions exert a far greater effect upon these functions, and thus upon the properties of the products. Polymer branching reactions are secondary reactions through which polymer radicals and polymer molecules participate in the reaction course such that branched polymer particles are formed; initiated vinyl acetate polymerization is a typical example [eqs. (35)—(40)].

Polymer radicals react a) intramolecularly by substitution [eqs. (35) and (38)], b) with polymer molecules by substitution [eqs. (36) and (39)], and c) with polymer molecules bearing

terminal C=C bonds by addition [eqs. (37) and (40)]; since numerous monomer molecules add to the branching points, there arise main-chain-branched [eqs. (35)—(37)] and ester-branched [eqs. (38)—(40)] polymer radicals which subsequently furnish correspondingly branched polymer molecules according to eq. (15), (16), or (17). Polymer branching thus illustrates the case of a reactant yielding the same product *via* several different pathways. The reaction sequences can only be resolved with the aid of kinetic measurements and comparison with simplifying models.

Experimental study of polymer branching[25-32] has been limited almost exclusively to poly(vinyl acetate); generally speaking the rise in the mean degree of polymerization was determined as a function of the conversion for a given initial polymerization rate. Some researchers have also hydrolyzed the polymeric product to poly(vinyl alcohol) and subsequently reacetylated it to poly(vinyl acetate). This procedure cleaved the ester-branched polymer molecules and thus reduced the mean degree of polymerization. The results are summarized in Table 1. As seen from the Table the relative rate constants

Table 1. Relative rate constants of polymer branching reactions in vinyl acetate polymerization; the rate constants of the substitution reactions (36) and (39) were based on k_t, and those of the addition reactions (37) and (40) on k_p.

T[°C]	$\frac{k_{(36)}}{k_t}$	$\frac{k_{(39)}}{k_t}$	$\frac{k_{(37)}}{k_p}$	$\frac{k_{(40)}}{k_p}$	Ref.
70	0.6	0.3	0	1.0	[25]
60	0.93		0.8		[26]
60	0.63		0.8		[29]
60	1.0		0.66		[30]
60	1.4	0.6	0	0.75	[32]

reported by various authors display a marked scatter, thus ruling out any definite conclusion regarding the extent of the individual branching reactions for the time being.

Complete elucidation of the branching reactions also requires a knowledge of precisely which reactions lead to polymer molecules bearing terminal C=C bonds [eqs. (41)—(43)].

A polymer molecule having a terminal C=C bond in the main chain is formed a) in the disproportionation reaction (41) and b) if monomer molecules add the monomer radical obtained according to eq. (42) and the resulting polymer radical transforms into a polymer molecule according to eq. (15), (16), or (17); a polymer molecule having a terminal C=C bound to the principal chain *via* an ester bridge if the monomer radical formed as shown in eq. (43) reacts in the manner just described.

While the occurrence of reaction (43) and its secondary reactions is beyond dispute, *Nozakura et al.*[32] assume that reaction (42) can be neglected in comparison with the competing reaction (43). The reaction sequence (41), (37) was first proposed by *Mehnert*[31,33,34], who found for poly(vinyl acetate) that the extent of ester branching (which accounts for at most 75—80 % of the total branching[35]) falls with decreasing

degree of polymerization, whereas the mean degree of overall branching $\bar{Z}$ ($\bar{Z}$ = number of branches per monomer unit) increases.

As seen from eqs. (25) and (32), the mean degree of polymerization $\bar{P}$ decreases when H, and thus the polymerization rate v_p, increases. In other words, at a low degree of polymerization the proportion of termination reactions in polymer formation increases, and hence also the rate of formation of terminal C=C in the principal chain according to eq. (41) (termination by disproportionation). Consequently, at high conversions the rate of formation of main-chain-branched polymer molecules according to eq. (37) will also be higher. Since this branching cannot be determined by hydrolysis/reacetylation, the interpretation is in accord with experimental findings. That termination of vinyl acetate polymerization occurs by disproportionation had already been established by *Funt* and *Pasika*[36]. Thus, contrary to previous thinking, the overall degree of branching $\bar{Z}$ increases with decreasing degree of polymerization in polymers whose formation reaction is predominantly disproportionating termination [see eqs. (4) and (16)]; according to eq. (44) $\bar{P}_n$ and $\bar{Z}$ depend only upon the conversion C and upon k_{tC}/k_{tD} and k_f/k_p.

$$(\bar{P}_n)^{-1} = (k_f/k_p)(\ln(1-C))(1-(1/C)-N)-(N\bar{Z}) \quad (44)$$
$$N \equiv (C-(1+(k_{tC}/k_{tD}))\ln(1-C))/(C+\ln(1-C))$$

5. Spontaneous Polymerization

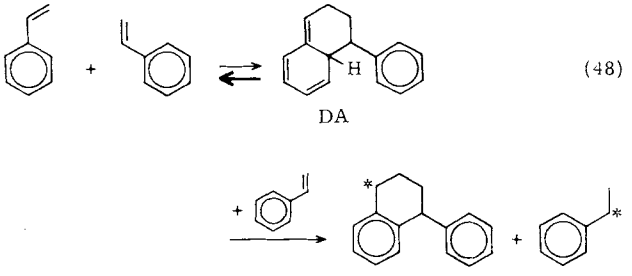
Some monomers, especially styrene and its derivatives, form polymers without addition of initiators; they polymerize spontaneously and can only be stabilized by addition of inhibitors. The mechanism of this spontaneous transformation is likewise of a radical kind and has only recently been elucidated.

Let us first consider the question whether a purely "molecular mechanism" [eqs. (45) and (46)], a series of Diels-Alder additions without reverse reactions, can actually give rise to polymers. Integration of the differential equation (47) derived from eqs. (45) and (46) and insertion of various numerical values into the integrated equation yields the values listed

$$M + M \xrightarrow{k_{(45)}} P_2 \quad (45)$$

$$P_r + M \xrightarrow{k_{(46)}} P_{r+1} \quad (46)$$

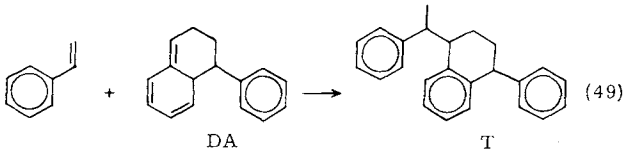
$$-d[M]/d\textstyle\sum[P_r] = 2 + 2(k_{(46)}/k_{(45)})(\sum[P_r]/[M]) \quad (47)$$



in Table 2[37]. It is immediately apparent from the figures that the initiation and propagation reactions must be completely different in character ($k_{(46)} \gg k_{(45)}$) if macromolecules

Table 2. Mean degrees of polymerization $\bar{P}_n = C[M]_0/\sum[P_r]$ calculated from eqs. (45)–(47) ("molecular mechanism") for various conversions $C \equiv 1-([M]/[M]_0)$ and ratios $k_{(46)}/k_{(45)}$. The subscript 0 indicates concentration at time $t = 0$.

C [%]	$k_{(46)}/k_{(45)}$	$\bar{P}_n$
100	10^8	1.4×10^4
1	10^8	1.0×10^3
100	10^4	1.4×10^2
1	10^4	1.1×10^1
100	1	3.1



are to result, such as occurs even at very low conversions in the spontaneous polymerization of styrene.

Mayo[38] was the first to provide a satisfactory interpretation of the initial step occurring in the spontaneous polymerization of styrene. He formulated a Diels-Alder equilibrium between two styrene molecules and a trimolecular secondary reaction as the primary radical-generating reaction (48).

(48)

Kirchner[39] was able to confirm this two-step reaction; he found a significant isotope effect with regard to the rate and degree of polymerization of 2,4,6-trideuteriostyrene, which indicates that the angular hydrogen atom of the Diels-Alder adduct (DA) plays a key role in eq. (48). Moreover, *Buchholz* and *Kirchner*[40] demonstrated that the principal reaction of the Diels-Alder adduct is not regeneration of two monomer molecules but formation of the trimer (T) [eq. (49)] discovered by *Stein et al.*[41,42] in the spontaneous polymerization of styrene; four different stereoisomers are formed.

(49)

Quantitative elucidation of spontaneous styrene polymerization was accomplished by *Wiesner* and *Mehnert*[43,44]. They first performed a gas-chromatographic product analysis of all stable oligomers [*cis*- and *trans*-diphenylcyclobutane (CB), phenyltetralin (PhT), methylbenzyl(phenyltetralin) (T), phenyldihydronaphthalene (PhN)] arising during styrene polymerization and determined the kinetics of their formation. The same authors also completed a kinetic study on the inhibition of spontaneous polymerization with the 1,1-diphenyl-2-picrylhydrazyl radical[45,46] whose property of mild dehydrogenation fit it particularly well for the elucidation of radical mechanisms. The resulting conversion/time plots provided a basis for the first analog computer simulation of the overall reaction course; the initiation mechanism corresponds to the reaction scheme shown in Figure 3, and the Arrhenius equations (52) and (53) were obtained for the generation of the primary radicals [eqs. (50) and (51)].

$$M + M \xrightarrow{k_{DA}} DA \quad (50)$$

$$DA + M \xrightarrow{0.02 \cdot k_R} R_1 + R_2 \quad (51)$$

$$k_{DA} = 3 \times k_{CR} = 1.6 \times 10^6 \text{ mol}^{-1}\text{l s}^{-1} \exp(-102\text{ kJ mol}^{-1}/RT) \quad (52)$$

$$k_R = 25 \text{ mol}^{-1}\text{l s}^{-1} \exp(-40\text{ kJ mol}^{-1}/RT) \quad (53)$$

Once again the highly non-specific reactivity of the radicals becomes apparent: The "cage" radicals can both combine and dis-

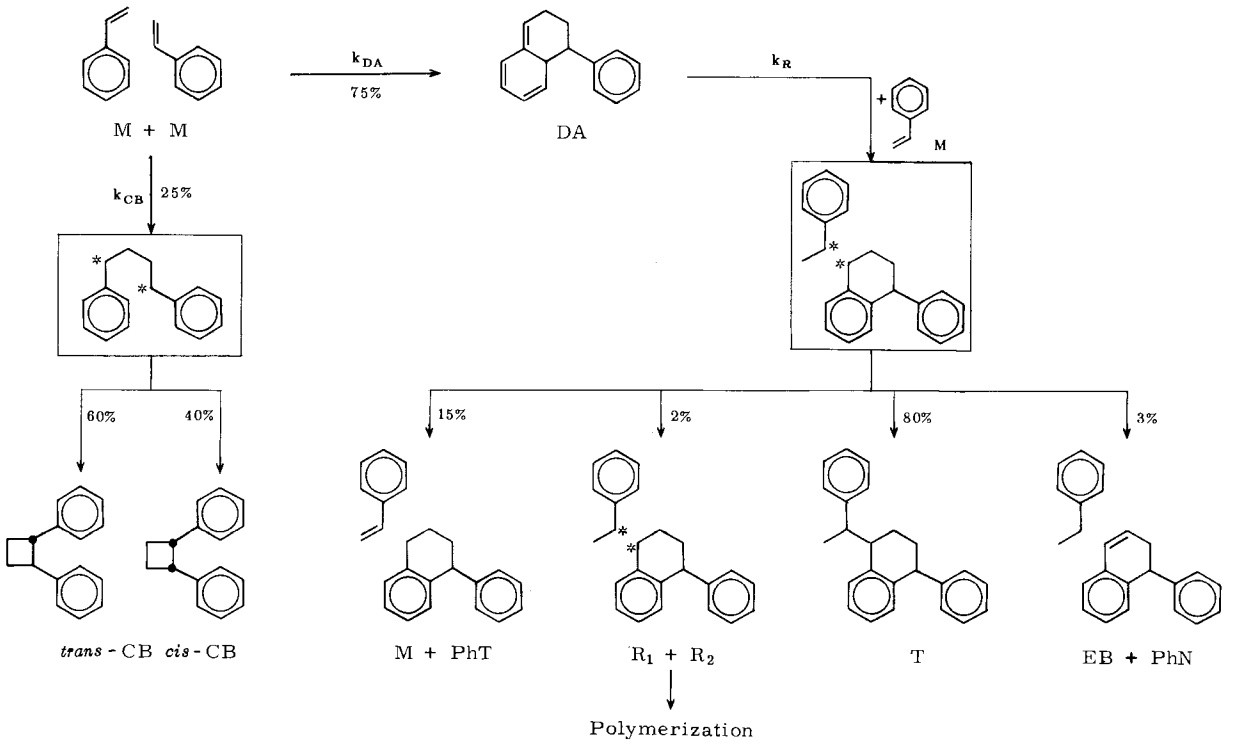


Fig. 3. Initiation mechanism of spontaneous styrene polymerization [44] EB = ethylbenzene; see text for other abbreviations.

proportionate (in two different ways), while some of them diffuse out of the "cage" and initiate the polyreaction. Reverse reactions and additional reaction steps postulated by other authors could not be detected by *Wiesner* and *Mehnert*. Moreover, all reactions obeyed the Woodward-Hoffmann rules.

In contrast to the initiation mechanism and its many side reactions, the polymerization process itself is surprisingly simple [eq. (54)—(56)]. As shown by *Wiesner* and *Mehnert*[47] on the basis of ultracentrifuge measurements, the non-uniformity of polystyrene is $NU = 0.5$ (at 30 °C), which according to eq. (33) is indicative of pure combination termination and

$$R_r + M \xrightarrow{k_p} R_{r+1} \tag{54}$$

$$R_r + R_{r'} \xrightarrow{k_{tC}} P_{r+r'} \tag{55}$$

$$k_{tC}/k_p^2 = 8.4 \times 10^{-8}\,\text{mol l}^{-1}\,\text{s}\exp(+68\,\text{kJ mol}^{-1}/RT) \tag{56}$$

rules out chain transfer to the oligomers. The overall scheme [eqs. (50), (51), (54), and (55)] shows the reaction to be second order with regard to monomer concentration [M] [eqs. (57) to (59)] once quasi-steady state concentrations have been established of R_r and DA; this result accords with the empirical rate law $v_p \sim [M]^2$ proposed by *Suess et al.*[48] and *Schulz et al.*[49] and confirmed by *Kirchner*[50].

$$d[DA]/dt = 0.5 \times k_{DA}[M]^2 - k_R[DA][M] \simeq 0 \tag{57}$$

$$d\Sigma[R_r]/dt = 2(0.02 \times k_R)[DA][M] - k_{tC}(\Sigma[R_r])^2 \simeq 0 \tag{58}$$

$$v_p \equiv k_p[M]\Sigma[R_r] = k_p \times (0.02 \times k_{DA}/k_{tC})^{0.5}[M]^2 \tag{59}$$

The induction period characterizing commencement of the spontaneous polymerization which was first reported by *Benoit*[51] and which affects both the rate and the degree of polymerization, comes about because the concentration of the Diels-Alder adduct, *i.e.* the "initiator of spontaneous polymerization", initially rises and only then assumes a quasi-steady value—in contrast to initiated polymerization where the initiator concentration is constant. At 30 °C the induction period amounts to 10^4 s[44] and the quasi-steady Diels-Alder adduct concentration $[DA]_{quas} = 5 \times 10^{-6}\,\text{mol l}^{-1}$[44]. Whereas $[DA]_{quas}$ is determined by the ratio k_{DA}/k_R, the length of the induction period depends solely upon k_R. Equation (60) shows the way in which the concentration of DA varies with time during the induction period.

$$[DA] = 0.5(k_{DA}/k_R)[M](1 - \exp(-k_R[M]t)) \tag{60}$$

As in initiated polymerization, the first step of spontaneous polymerization is rate determining. The rate constants of the subsequent reactions are considerably higher; the following ratios (61) apply at 30 °C:

$$k_{DA} : k_R : k_p : k_{tC} = 1 : 10^6 : 10^{13} : 10^{19} \tag{61}$$

6. Heterogeneous Polymerization

Some polymers are insoluble in their own monomers with the result that granular or gel-like precipitates are formed during bulk polymerization. This kind of polymerization, in which the monomer acts as precipitant for its own polymer is therefore designated heterogeneous polymerization. However, this phenomenological observation is not the only point in which such processes differ from homogeneous polymerization: the reaction kinetics also vary. Thus the conversion/time curves of heterogeneous polymerization resemble those of autocatalytic reactions with their marked accelerations at the commencement of reaction. Figure 4 compares the conversion/time curves for various kinds of polymerization. Disregarding the induction phase, the following experimentally confirmed rate laws are obtained for the rate of polymerization:

$$v_p \sim [M]\cdot[S]^{0.5}\cdot(k + [S]^{0.5}t) \quad (62)$$
$$v_p \sim [M]\cdot[S]^{0.5} \quad (63)$$
$$v_p \sim [M]^2 \quad (64)$$

for heterogeneously initiated bulk polymerization[52] eq. (62) from eqs. (73), (75), and (76); for homogeneously initiated bulk polymerization eq. (63) from eq. (21); and for homogeneous spontaneous bulk polymerization eq. (64) from eqs. (59).

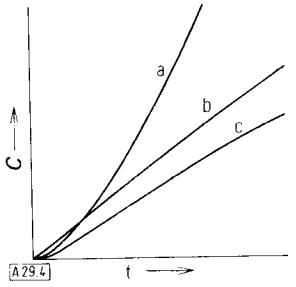

Fig. 4. Conversion/time curves (qualitative) for: a) heterogeneously initiated bulk polymerization of acrylonitrile; b) homogeneously initiated bulk polymerization of vinyl acetate; c) homogeneous spontaneous bulk polymerization of styrene.

The kinetics of heterogeneous polymerization of acrylonitrile were first studied by *Bamford* and *Jenkins*[53-55]. The empirical rate law $v_p \sim [S]^{0.9}$ found by these authors and since confirmed by other invcstigators (most recently by *Lewis* and *King*[56]) was derived qualitatively from the concept that a homogeneously generated polymer radical does not form polymer molecules according to eqs. (15)—(17) but first precipitates and continues to grow in a heterogeneous state at the same rate as monomer molecules can diffuse to the radical site incorporated in the polymer coil, a process subject to steadily increasing hindrance (radical inclusion theory[53-55]). Thus, bimolecular formation of polymer molecules does not occur, but instead chain propagation of a heterogeneous polymer radical gradually stagnates owing to the drop in the rate constant $k_{p(het)}$ with increasing chain length. Indeed, *Bamford* and *Jenkins* have demonstrated radical properties of the isolated polymeric product by ESR measurements[57] and decoloration tests with reddish-violet 1,1-diphenyl-2-picrylhydrazyl[58].

A comprehensive and quantitative kinetic analysis of bulk polymerization of acrylonitrile was first conducted by *Marquardt* and *Mehnert*[52,59-62], who were unable to confirm the rate law $v_p \sim [S]^{0.9}$ but found the expression (62) to apply. They developed an improved dilatometric technique for determining conversion/time curves of heterogeneous polymeriza-

$$S \xrightarrow{v_i} 2R\cdot \quad (65)$$
$$R_r(hom) + M \xrightarrow{k_p(hom)} R_{r+1}(hom) \quad (66)$$
$$R_r(hom) + R_s(hom) \xrightarrow{k_t} P_{r+s} \text{ or } P_r + P_s \quad (67)$$
$$R_r(hom) \xrightarrow{f\cdot v_i} R_r(het) \quad (68)$$
$$R_r(het) + M \xrightarrow{k_p(het)} R_{r+1}(het) \quad (69)$$

tion and employed a new method of evaluation. The result of their studies is summarized in the reaction scheme (65)—(69) for acrylonitrile.

This mechanism is based on the concept that chain propagation (66) is presumably considerably faster (the time τ between two additions is only $\tau = (k_p[M])^{-1} \approx 10^{-4}$ s) than the precipitation process (68) of polymer radicals initially growing in the homogeneous state, *i.e.* that by far the greater part of the polymer radicals R_r (hom) is transformed into polymer molecules in bimolecular termination reactions (67) which then precipitate, and that only a very small fraction f (f = polymer radical precipitation factor) of the polymer radicals becomes heterogeneous [eq. (68)]. The heterogeneous polymer radicals R_r (het) then continue to grow with a steady rate constant k_p (het) [eq. (69)] but do not participate significantly in termination reactions owing to their immobility. Presumably the branching reactions (35) and (36) take place. This simple interpretation has been backed up in several respects by *Marquardt* and *Mehnert*[52]. There result: eqs. (70) and (71) from eq. (65); eqs. (72) and (73) from eqs. (65), (67), and (71), taking account of eqs. (20) and (21); and eqs. (74) and (75) from eqs. (68) and (71). If eqs. (73) and (75) are inserted into eq. (76) and eq. (76) is then integrated, one obtains eq. (77) for $C = 1 - ([M]/[M]_0)$. This integrated rate equation (77) permits a very good description of the experimental results.

$$-d[S]/dt \equiv 0.5 \times v_i = k_i[S] \quad (70)$$
$$[S] = [S]_0 \exp(-k_i t) \quad (71)$$
$$d\Sigma[R_r(hom)]/dt = 2k_i[S](1-f) - k_t(\Sigma[R_r(hom)])^2 \quad (72)$$
$$\Sigma[R_r(hom)] \sim [S]^{0.5} \sim [S]_0^{0.5}\exp(-0.5 \times k_i t) \quad (73)$$
$$d\Sigma[R_r(het)]/dt \equiv fv_i = 2fk_i[S] = 2fk_i[S]_0 \times \exp(-k_i t) \quad (74)$$
$$\Sigma[R_r(het)] \sim [S]_0\cdot(1 - \exp(-k_i t)) \quad (75)$$

Y versus t plots of the experimental data are straight lines whose intersections with the ordinate are proportional to $[S]_0^{0.5}$ and whose slopes are proportional to $[S]_0^{1.0}$ (the subscript 0 signifies the concentration at $t = 0$). The first term in eq. (77) corresponds to chain growth of polymer radicals present in homogeneous form and the second to that of polymer radicals present in heterogeneous form. Since the

$$-d[M]/dt \sim v_p \equiv k_p(hom)[M]\sum[R_r(hom)] + k_p(het)[M]\sum[R_r(het)] \quad (76)$$

$$Y \equiv \frac{-\ln(1-C)}{1-\exp(-0.5 \times k_i t)} = k'[S]_0^{0.5} + k''[S]_0 t \quad (77)$$

latter are not subject to termination, their concentration increases with the reaction time t. The rate constants of steps (65)—(69) present in the constants k' and k'' in eq. (77) were found to be given by eqs. (78) and (79). The polymer radical precipitation factor f lies between 10^{-2} and 10^{-3} at 50 °C, and the rate constant k_p(het) predictably between 10^2 and 10^3 mol^{-1} l s^{-1}, *i.e.* in the same range as the values given for k_p(hom) in the literature. Further support for reactions (65)—(69) comes from work by *Bamford et al.*[63] who obtained a value for k_t/k_p^2 in the homogeneous solution polymerization of acrylonitrile at 60 °C which lies only 40 % above that determined by *Marquardt* and *Mehnert*[52] for bulk polymerization by a greatly improved method.

$$k_t/k_p^2(hom) = 7 \times 10^{-8} \text{ mol l}^{-1} \text{ s} \exp(+60 \text{ kJ mol}^{-1}/RT) \quad (78)$$
$$f\cdot k_p(het) = 3 \times 10^{+12} \text{ mol}^{-1} \text{ l s}^{-1} \exp(-80 \text{ kJ mol}^{-1}/RT) \quad (79)$$

Similar to the situation in spontaneous polymerization induction periods are measurable; here the length of the induction periods t_{IP} observed in heterogeneously induced polymeriza-

tion depends upon the initiator concentration: $t_{IP} \sim [S]_0^{-0.5}$. This experimental finding[52] also accords with the concept that the course of events at the commencement of reaction is determined solely by the contribution of homogeneous polymerization. *Marquardt* and *Mehnert*[52] derived this proportionality from scheme (13)—(17).

7. Precipitation Polymerization

On polymerization, methacrylonitrile behaves completely differently from acrylonitrile[65, 66]. In a well stirred reactor the conversion/time curves follow the same course as with homogeneously initiated bulk polymerization, except that induction periods occur whose length is proportional to $[S]_0^{-0.5}$.

This suggests that the bulk polymerization of methacrylonitrile is a homogeneous polymerization and no polymer radicals precipitate. Corroborating evidence is provided by the empirical rate law (63) found by several different authors[65–68]. The value of k_t/k_p^2 determined for the bulk polymerization is of the same order of magnitude as that for solution polymerization. The only justification for calling this kind of polymerization precipitation polymerization lies in the successive precipitation of "finished" polymer molecules owing to their limited solubility.

8. Two-Phase Polymerization

As shown by *Marquardt* and *Mehnert*[64, 65], a completely different picture results when the bulk polymerization of methacrylonitrile is carried out without stirring. Under such conditions a second AIBN/monomer/polymer phase II appears in which a homogeneous polymerization also occurs. Hence combination of eq. (80) and eq. (21) affords eq. (81) in which the total volume $V = V_I + V_{II}$.

$$v_p \equiv (V_I/V) \times k_{pI}[M]_I \Sigma[R_r]_I + (V_{II}/V) \times k_{pII}[M]_{II} \Sigma[R_r]_{II} \quad (80)$$

$$v_p = (V_I/V) \times (v_i k_p^2/k_t)_I^{0.5}[M]_I + (V_{II}/V) \times (v_i k_p^2/k_t)_{II}^{0.5}[M]_{II} \quad (81)$$

Indeed, on separation of the polymeric products by gel chromatography and ultracentrifugation, *Engel* and *Mehnert*[69] found a bimodal molecular weight distribution providing direct confirmation of the two-phase polymerization concept. If the reactor contents are well stirred no such bimodal distribution occurs[65]. Surprisingly, an acceleration is observed for polymerization without stirring. However, this phenomenon[65] can also be interpreted qualitatively in terms of eq. (81): with increasing time V_I decreases in favor of V_{II} and since $k_{tII} < k_{tI}$ an increase in v_p occurs which manifests itself as an acceleration of the reaction in the experiment. The termination constant k_t in radical polymerization is a diffusion-controlled quantity and thus roughly inversely proportional to the viscosity. Since the viscosity of phase II is considerably higher than that of phase I it follows that $k_{tII} < k_{tI}$.

9. Outlook

Investigation of polymer kinetics requires sophisticated experimental techniques. The monomer must be subjected to extremely thorough purification and above all freed from all traces of oxygen, which clearly has a profound effect on radical polymerization. Operations such as rectification and degassing generally prove inadequate; the monomer must be subjected to some degree of prepolymerization by addition of initiator. The monomer distilled from this prepolymer in high vacuum is then sufficiently pure for studies of polymer kinetics. Owing to the considerable difference in density between monomer and polymer, the decrease in reaction volume observed during reaction can be used as a measure for the conversion (dilatometry), provided a calibration between volume contraction and conversion is first established by gravimetric determinations. This greatly facilitates the plotting of conversion/time curves. However, the dilatometric method requires modification for heterogeneous polymerization[59]. It should be borne in mind when calculating the rate of polymerization that the rate of decrease in monomer concentration differs drastically (up to 56% in the case of acrylonitrile polymerization) from the polymerization rate owing to the volume change accompanying the reaction[59].

The analytical methods available for determining mean degrees of polymerization have already been mentioned. Molecular weight distributions can be ascertained by means of the ultracentrifuge, gel permeation chromatography, and fractional precipitation. Further development and refinement of the methods for characterization of polymeric products should provide access to additional information required for improvements in polymerization technology and in the quality of industrial products, and also complete our knowledge of the course of radical polymerization. In particular we still lack detailed knowledge of polymerizations proceeding in non-homogeneous manner (*e.g.* about vinyl chloride polymerization) and the effect of mixing on the mechanism of polymerization reactions occurring in disperse two-phase systems, which has only been treated qualitatively in the present progress report.

The author is indebted to Prof. Dr. Franz Patat for constant encouragement. Support of some of the investigations mentioned by the Deutsche Forschungsgemeinschaft, the Federal Ministry of Economics (through the AIF and Dechema), the Fonds der Chemischen Industrie, and the Dr.-Otto-Röhm-Gedächtnisstiftung is gratefully acknowledged.

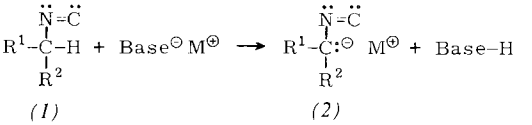
α-Metalated Isocyanides in Organic Synthesis

New synthetic methods (6)



By Dieter Hoppe[*]

α-Alkali-metalated isocyanides, which can be obtained from isocyanides and bases, can be used for nucleophilic introduction of (masked) α-aminoalkyl groups. Intramolecular ring-closure may then follow if a nucleophile combines at the electron sextet of the isocyanide carbon. Treatment of α-alkali-metalated isocyanides with electrophilic agents permits rapid and efficient synthesis of, *inter alia*, 2- and 3-amino alcohols, straight-chain, branched, and β-functional α-amino acids, olefins, vinyl isocyanides, and of a large number of mainly five-, but also six- and seven-membered aza-, diaza-, oxa-aza-, and thia-aza heterocycles.

1. Introduction

Although the activating action of the cyano group[1] has been known for almost a hundred years it was only in 1968 that *Schöllkopf* and *Gerhart*[2] found that the isocyano group also makes hydrogen in the α-position acidic.

α-Metalated isocyanides *(2)* have proved to be valuable organic reagents within the few years since their discovery[3],

(1) *(2)*

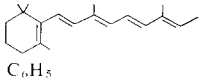
and it is conceivable that in future they will become as preparatively useful as the metalated cyanides. The importance of compounds *(2)* for organic synthesis rests partly on the metalated (*i.e.* anionized) carbon atom, to which electrophilic centers can become attached, and partly on the fact that the "bivalent" isocyanide carbon[4, 5] makes subsequent heterocyclization possible. Since the isocyano group is hydrolyzed

[*] Dr. D. Hoppe
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

to an amino group under acidic conditions, the metalated isocyanides *(2)* are masked α-amino carbanions and enable α-aminoalkyl groups to be introduced nucleophilically into organic and inorganic molecules.

Alkyl isocyanides *(1)* are obtained conveniently and in high yield by dehydration of formamides[5, 4] by means of phosgene[6], phosphorus oxide trichloride[7], toluenesulfonyl chloride[8], triphenylphosphane/tetrachloromethane[9], or thionyl chloride/dimethylformamide[10] in the presence of bases. Isocyanides that are not sensitive to alkali can be prepared by the Mąkosza variant[11] of the Hofmann carbylamine reaction[12].

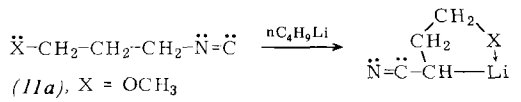
2. Metalation of Isocyanides



Isocyanides *(1)* that do not carry an α-hydrogen atom add Grignard reagents[13] and lithium compounds[14] to the isocyanide group, yielding metalated aldimines; the lithium derivatives have been used as acyl anion equivalents[15]. The reaction of, for example, methyl isocyanide *(3a)* (see Table 1) with *n*-butyllithium in tetrahydrofuran at −70 °C takes quite a different course—the α-hydrogen is replaced by lithium[2]. The formation of isocyanomethyllithium *(4a)*[16] was proved by reactions with carbonyl compounds[17] (cf. Section 4). It has subsequently been found that *n*-butyllithium also smoothly metalates other alkyl isocyanides such as allyl *(5)*[2], benzyl *(7)*[2], and cyclopropyl isocyanide *(9)*[18], *i.e.* those whose parent hydrocarbons are as acid as or more acid than methane on the Cram acidity scale[19].

Isocyanides containing powerfully electron-withdrawing substituents in the α-position, such as α-isocyanoalkanoic esters *(15)*, α-isocyanoalkanonitriles *(17)*, arenesulfonylmethyl isocyanides *(23)*, and α-isocyanomethanephosphonic esters *(25)*, can be completely or partially anionized by weaker bases such as potassium *tert*-butoxide, sodium hydride, sodium ethoxide, or even tertiary amines. Table 1 illustrates the main compound types[128, 129] that have been metalated so far, as well as the reaction conditions.

The cause of the acidifying action of the isocyano group is not yet quite clear, but dipole stabilization of the anion[20] is suspected[127].



This reaction with *n*-butyllithium fails with less acidic α-alkyl-substituted isocyanides such as cyclohexyl[21] and *n*-butyl isocyanide[22], even in the presence of *N,N,N',N'*-tetramethylethylenediamine or hexamethylphosphoric triamide[23], since in these cases α-addition gains the upper hand. Metalation can, however, be forced for these isocyanides too by using strong, weakly nucleophilic bases, such as lithium 2,2,6,6-tetramethylpiperidide[24] *in situ*[25]. A special position is occupied by isocyanides *(11)*, where C-3 carries a donor group such as

Table 1. Main types of isocyanides metalated so far.

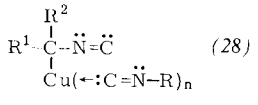
alkoxy or dialkylamino, since now the formation of a chelate has a considerable and favorable influence on lithiation[26].

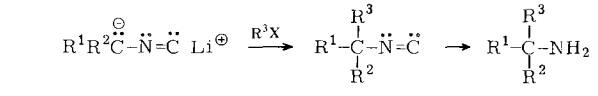


(11a), X = OCH_3
(11b), X = $N(CH_3)_2$

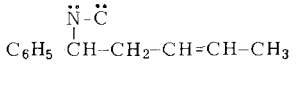
If the isocyanide is of type *(27)*, carrying a nucleofugal leaving group in the β-position, *e.g.* 3-isocyanopropionitrile *(27a)*[27], 2-methoxyethyl isocyanide *(27b)*[28], or 2,2,2-trifluoroethyl isocyanide *(27c)*[29], olefins are obtained when metalation is attempted.

(27a), X = CN
(27b), X = OCH_3
(27c)

The metalated isocyanides are thermolabile and decompose between −60 and 0 °C depending on their structure. If, therefore, higher temperatures are needed for their reaction it is advisable to produce them *in situ*. According to *Saegusa et al.*[31-33], benzyl *(7)* and allyl isocyanides *(5)*, as well as α-isocyanoalkanoic esters *(15)*, undergo reactions characteristic of metalated isocyanides if they are heated with carbonyl compounds or activated olefins in the presence of 1—5 mol-% of copper(I) oxide; a copper-isocyanide complex of type *(28)* with metal-carbon bonds, but of as yet incompletely elucidated structure[33], functions as a crucial intermediate.

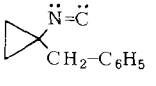


(28)



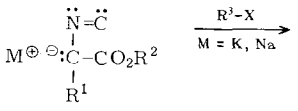
3. Alkylation of Metalated Isocyanides

3.1. Chain Extension of Amines

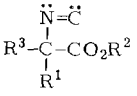


Starting from the lithiated isocyanides *(4a)*, *(6a)*, and *(8a)*, the monoalkylation products *(29)* are obtained by using alkyl bromides or iodides; *(10a)* gave *(30)*. The yields are between 30 and 90 %[54, 18]. Since isocyanides are obtained from amines and are reconverted into amines by acid hydrolysis[55], this sequence constitutes a method for α-alkylating primary amines. Homoallyl- and tertiary cyclopropylamines that are otherwise difficult to prepare, can be synthesized conveniently by this method, *e.g. via (29a)* or *(30a)*.

(4a), *(6a)*, *(8a)*, *(10a)* *(29)*, *(30)*



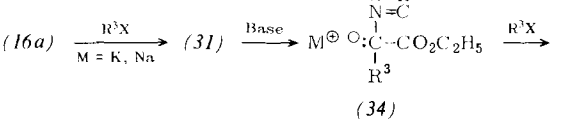
(29a), 89% [54]



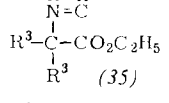
(30a), 76% [18]

3.2. Alkylation of Metalated α-Isocyanoalkanoic Esters; Synthesis of Amino Acids

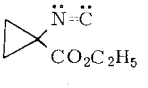
Alkylation of α-metalated α-isocyanoalkanoic esters *(16)* is of interest because its overall effect is the production of longer-chain or α-branched amino acids[39]. For this purpose an alkyl halide R^3X was brought into reaction with a solution of the potassium compound *(16)*, M = K, in tetrahydrofuran, prepared from *(15)* and potassium *tert*-butoxide, or of the sodium compound *(16)*, M = Na, produced *in situ* by sodium hydride in dimethyl sulfoxide/ether. Alkylation of ethyl α-isocyanopropionate *(15c)* is unambiguous, leading to 2-isocyano-2-methylalkanoic esters *(33)*.



(16a), R^1 = H, R^2 = C_2H_5
(16b), R^1 = H, R^2 = tC_4H_9
(16c), R^1 = CH_3, R^2 = C_2H_5

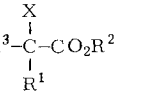


(31), R^1 = H, R^2 = C_2H_5, R^3 = Alkyl
(32a), R^1 = H, R^2 = tC_4H_9, R^3 = $(CH_3)_2CH$: 60% [39]
(33a), R^1 = CH_3, R^2 = C_2H_5, R^3 = $CH_2C_6H_5$: 79% [39]



From ethyl isocyanoacetate *(15a)*, however, mainly the dialkylation product *(35)* is isolated, along with *(31)* and unchanged starting material; this accords with experience gained with other CH-acidic compounds[56]. 1,2-Dibromoethane and 2-chloroethyl toluenesulfonate give respectively 58 and 30 % of ethyl 1-isocyano-1-cyclopropanecarboxylate *(36a)*[39, 76]. The cycloalkylation cannot be applied to secondary or tertiary dihaloalkanes—these react mainly with elimination—so that ring-substituted esters of this type are better prepared by methylenation of 2-isocyanoacrylic esters *(74)* (cf. Section 4.3.1).

(34)

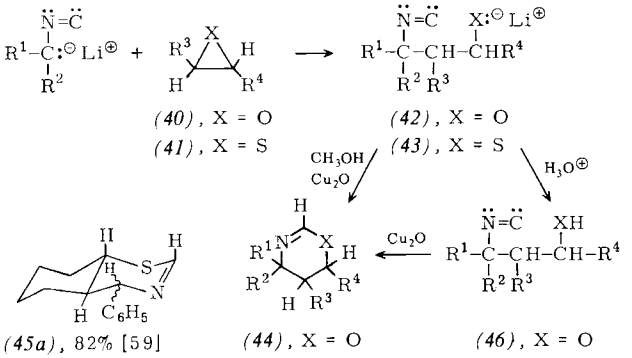


(35a), R^3 = nC_4H_9 : 71% [39]

(36a), 58% [39, 76]

Monoalkylation to give *(32)* is, however, successful with *tert*-butyl isocyanoacetate *(15b)*, since here the bulky ester group prevents attack by a second alkyl halide molecule[39].

2-Isocyanoalkanoic esters of types *(31)*—*(33)*, *(35)*, and *(36)* are convertible by ethereal hydrogen chloride at −10 to 0 °C into *N*-formylamino acid esters *(37)*, by ethanolic hydrogen chloride at room temperature into amino acid ester hydrochlorides *(38)*, and by hot aqueous hydrochloric acid into the amino acids themselves *(39)*[39].



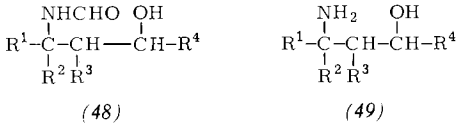
(37), X = NHCHO, R^2 = Alkyl
(38), X = $NH_3^{\oplus}Cl^{\ominus}$, R^2 = Alkyl
(39), X = NH_2, R^2 = H

Attempts at asymmetrically induced synthesis of L-(−)-α-methyl-3,4-dihydroxyphenylalanine (α-methyldopa) by alkylation of (−)-menthyl or (+)-bornyl α-isocyanopropionate gave optical yields of around 10%[57]. *van Leusen et al.*[49] have reported base-induced alkylation of arenesulfonylmethyl isocyanides *(23)*; here too monoalkylation encountered difficulties.

3.3. Alkylation by Epoxides, Episulfides, and Oxetanes

Metalated isocyanides attack epoxides *(40)* at −70 to 0°C at the less substituted carbon atom. The lithium salts *(42)* can be either protonated to give 3-isocyano alcohols *(46)* or cyclized[30,59] to 5,6-dihydro-4*H*-1,3-oxazines *(44)* by warming with methanol or, better, copper(I) oxide[58].

(40), X = O; *(41)*, X = S



(42), X = O; *(43)*, X = S

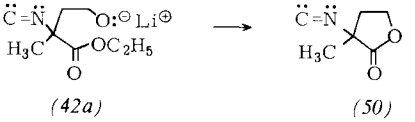
(45a), 82% [59]

(44), X = O; *(45)*, X = S

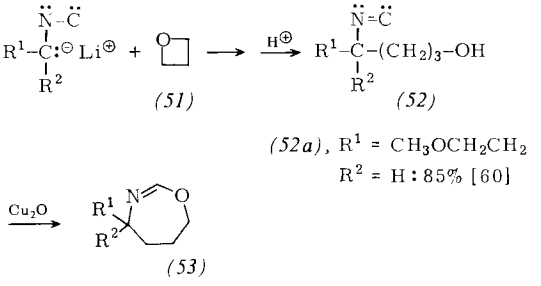
(46), X = O; *(47)*, X = S



(48) *(49)*

The isocyanides *(46)* can be converted quantitatively into (3-hydroxyalkyl)formamides *(48)* or 3-amino alcohols *(49)*[30].

3-Isocyanoalkanethiols *(47)* can be obtained from the lithiated isocyanides *(4)*, *(6)*, and *(8)* and episulfides *(41)*, these products being partially converted into 5,6-dihydro-4*H*-1,3-thiazines *(45)* even at room temperature[60,59].



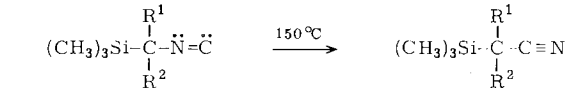
Episulfides that are derived from conjugated olefins do not undergo nucleophilic ring opening of the thiirane ring, because in their case desulfuration occurs with the formation of olefin[61,59].

The (less nucleophilic) α-metalated ethyl isocyanoacetate *(16a)* attacks neither epoxides nor episulfides. Here, as in an inert medium, "self-condensation" (cf. Section 6.1) is dominant. However, lithiated ethyl α-isocyanopropionate *(16c)* with ethylene oxide affords a 51% yield of 2-isocyanobutyrolactone *(50)*, whose formation can be explained by lactonization of the adduct *(42a)*. When warmed with an excess of ethoxide, the lactone *(50)* rearranges (*via* the open-chain ester) to the dihydrooxazine *(44)*[30].

(42a) *(50)*

Oxetanes *(51)* react only above 0°C with metalated isocyanides[60]. For that reason only the less thermolabile compounds with sufficient nucleophilicity, *e.g.* lithiated benzyl *(8a)* or 3-methoxypropyl isocyanide *(12a)*, afford the 4-isocyano alcohols *(52)* in satisfactory yield. Their cyclization to 4,5,6,7-tetrahydro-1,3-oxazepines *(53)* with catalysis by copper also occurs in only moderate yield, since intermolecular polyaddition predominates[60].

(51) *(52)*



(52a), $R^1 = CH_3OCH_2CH_2$, $R^2 = H$: 85% [60]

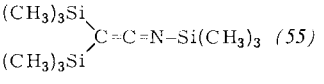
Cu_2O

(53)

3.4. Silylation

Lithiomethyl isocyanide *(4a)* reacts with trimethylchlorosilane even at −78°C, yielding (trimethylsilyl)methyl isocyanide *(19a)*[45]; stepwise lithiation and renewed silylation afford bis- and tris(trimethylsilyl)methyl isocyanide [*(19b)* and *(19c)*].

(19a), $R^1 = R^2 = H$



(19b), $R^1 = (CH_3)_3Si$, $R^2 = H$

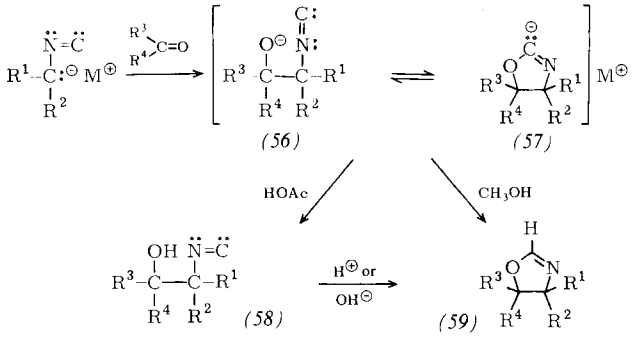
(19c), $R^1 = R^2 = (CH_3)_3Si$

150°C

(54a), $R^1 = R^2 = H$

(54b), $R^1 = (CH_3)_3Si$, $R^2 = H$

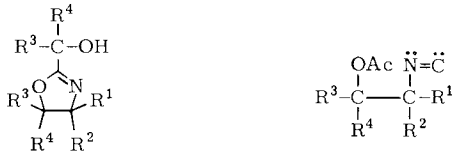
(55)



When warmed to 150°C, *(19a)* rearranges to (trimethylsilyl)-acetonitrile *(54a)*, whereas *(19c)* isomerizes to tris(trimethylsilyl)ketene imine *(55)*. Thermolysis of bis(trimethylsilyl)methyl isocyanide *(19b)* affords a mixture of *(54a)*, *(54b)*, and *(55)*.

4. Reaction with Aldehydes and Ketones in an Aprotic Medium

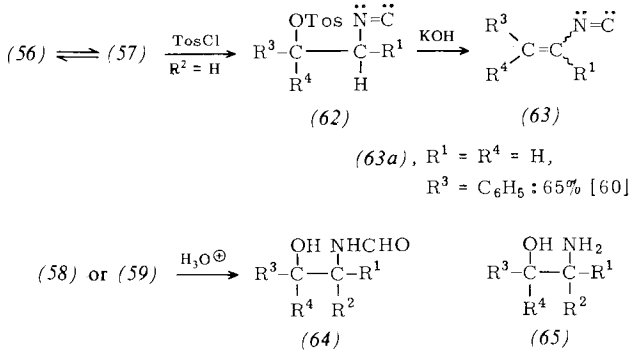
4.1. Synthesis of 2-Oxazolines; 2-Isocyano Alcohols and 2-Amino Alcohols



Lithioalkyl isocyanides of types *(4)*, *(6)*, *(8)*, *(10)*, *(12)*, and *(22)* (prepared by means of *n*-butyllithium in tetrahydrofuran at −70°C) add to aldehydes and ketones at −70°C, yielding 2-isocyano alkoxides *(56)* which exist in mobile equilibrium[62,92] with the 2-oxazolinyl anions *(57)*. Protonation with water at room temperature[17] or, better, with methanol at −70°C[32] affords 2-oxazolines *(59)* in 60—90% yield. However, neutralization by glacial acetic acid at *ca.* −70°C and working up under mild conditions permit isolation of the 2-isocyano alcohols *(58)*[26], which equally cyclize to *(59)* on treatment with (anhydrous) acid or base. If $R^1 \neq R^2$ and

$R^3 \neq R^4$, diastereoisomeric mixtures are obtained, *e.g. (59a)* in the *cis/trans* ratio 1 : 3[32, 63]. 2-(Hydroxyalkyl)-2-oxazolines *(60)* are found as by-products, particularly when aromatic aldehydes or ketones are used. Control experiments have shown[32] that these are formed from the oxazolinyl anion *(57)* and the carbonyl compound: for instance, if 4,5-diphenyl-2-oxazoline is metalated with *n*-butyllithium at −70 °C to the 2-lithio derivative (proved by deuteriolysis) and benzaldehyde is added, then 2-(α-hydroxybenzyl)-2-oxazoline *(60b)* can be isolated in 60% yield[32]. However, the anion *(56)* can be trapped almost quantitatively by acyl chlorides as the 2-isocyanoalkyl ester of a carboxylic acid *(61)*[26, 32].

(58a), $R^1 = R^2 = H$, $R^3 = CH_3$, $R^4 = C_6H_5$: 75% [26]

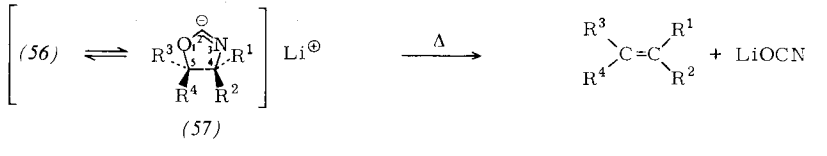


(59a), $R^1 = R^3 = C_6H_5$, $R^2 = R^4 = CH_3$: 87% [32]

(60a), $R^1 = R^2 = R^3 = R^4 = C_6H_5$: 95% [17]

(60b), $R^1 = R^3 = H$, $R^2 = R^4 = C_6H_5$

(61)



(63a), $R^1 = R^4 = H$, $R^3 = C_6H_5$: 65% [60]

mina[27, 32], whereas 2-amino alcohols *(65)* are formed with the use of aqueous or alcoholic hydrochloric acid[66]. This sequence [with *(4)*], combined with a Tiffeneau-Demyanov rearrangement, has been recommended[66] for the homologation of cyclic ketones. 2-Oxazolines *(59)* are formed also on heating sufficiently acidic isocyanides, *e.g.* types *(5)*, *(7)*, and *(15)*, with an excess of the carbonyl compound in the presence of 1—5 mol-% of copper(I) oxide[31, 33]; the course of the reaction is not yet clear in detail.

4.2. Carbonyl Olefination by Metalated Isocyanides

If the adduct formed from, for instance, α-isocyanobenzhydryllithium and benzaldehyde, *i.e. (56a)*⇌*(57a)*, is warmed to room temperature, the product isolated is not the oxazoline *(59)* but, together with lithium cyanate, a 74% yield of 1,1,2-triphenylethylene *(66a)*, which is the result of a carbonyl olefination[2].

This fragmentation can be formulated as a [4+2]-cycloreversion[67, 68] of a (hetero)cyclopentenyl anion, for which theory requires suprafacial removal of the cyanate ion in a concerted thermal reaction. Experimentally it could be shown that the fragmentation occurs stereospecifically, since *cis*-stilbene

(57a), $R^1 = R^2 = R^3 = C_6H_5$, $R^4 = H$

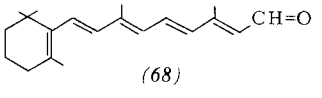
(66a), $R^1 = R^2 = R^3 = C_6H_5$, $R^4 = H$



(66b), $R^1 = R^3 = C_6H_5$, $R^2 = R^4 = H$

(66d), $R^1 = CH{=}CH_2$, $R^2 = R^3 = H$, $R^4 = C_6H_5$

(66e), 60% [18]

(67)

(68)

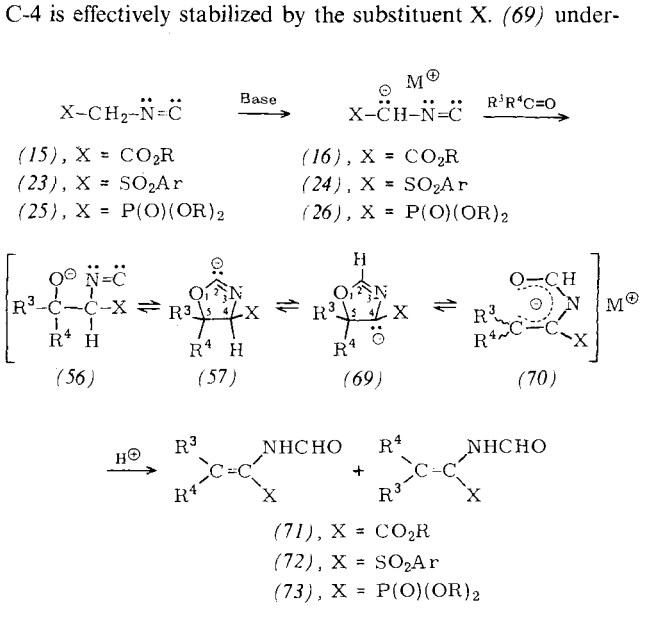
An "*Eintopf*"[*] synthesis[60] of vinyl isocyanides *(63)*, which are difficultly accessible by conventional routes[10, 64, 65], is provided by treatment of *(56)*⇌*(57)* with *p*-toluenesulfonyl chloride, to yield *(62)*, followed by elimination of toluenesulfonic acid.

2-(Hydroxyalkyl)formamides *(64)* are obtained from either the oxazolines *(59)* or the isocyano alcohols *(58)* by mild hydrolysis, *e.g.* with methanol in the presence of basic alu-

(66b) was obtained on decomposition of *cis*-2-lithio-4,5-diphenyl-2-oxazoline *(57b)*[69]. On the basis of very different reaction rates of oxazolinyl anions *(57)* that are inversely substituted on C-4 and C-5, it is presumed that fission of the C^4—N and the C^5—O bond will not have progressed equally in the transition stage. Carbonyl olefination occurs only when the oxazolinyl anion *(57)* carries one or more groups at C-4 and/or C-5 such as phenyl or vinyl that are capable of resonance. Presumably formation of the (energy-poor) lithium cyanate plays no part as a driving force in

[*] From the German term for a stew, being prepared in a single vessel.

this transition state, perhaps because the cyanate ion must be split off from the olefin as an angled particle and can pass into the energetically favorable sp-hybrid only after the bond has broken.



Accumulation of substituents on the oxazoline ring, as in *(57c)*, also hinders carbonyl olefination. Two factors seem to be responsible for this: First, *(57)* must occur in sufficiently high proportion in the equilibrium *(56)*⇌*(57)*; increasing substitution will worsen the position of the equilibrium since vicinal substituents on a five-membered ring are almost eclipsed. As second factor, the substituents hinder the optimal planar arrangement of neighboring sp^2-centers; in these cases there is a predominance of side reactions such as reversion of *(56)* to the starting compounds and their irreversible subsequent reactions[69].

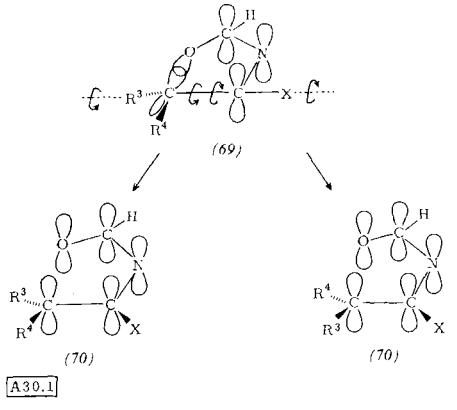
Even though the isocyanide olefination thus cannot compete in its range of application with the universal Wittig reaction[70], it nevertheless deserves attention in some cases: for example, isomer-free (*E*)-1-phenyl-1,3-butadiene *(66d)* is formed from lithioallyl isocyanide and benzaldehyde[28, 2]; all-*trans*-retinyl isocyanide *(67)* and all-*trans*-retinal *(68)* afford 60% of equally isomer-free (all-*trans*-)β-carotene[28].

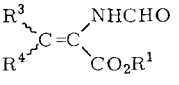
Carbonyl olefination by metalated isocyanides can complement the Wittig reaction in cases where the latter fails owing to increased stabilization of the phosphonium ylide; for instance, α-lithiobenzhydryl isocyanide and benzaldehyde afford *(66a)*, whereas triphenylphosphonium diphenylmethylide does not react with aldehydes[70].

4.3. Metalated Isocyanides of Types *(16)*, *(24)*, and *(26)*; Formylaminomethylenations

Surprisingly, the reactions of metalated isocyanides *(16)*, *(24)*, and *(26)*[11, 29] with aldehydes and ketones occur in aprotic media. In these reagents the carbon atom attached to the metal carries, besides one hydrogen atom, a strongly acidifying substituent (CO_2R, SO_2Ar, or $P(O)(OR)_2$). It is true that these add also to the carbonyl compounds to yield the adducts *(56)*⇌*(57)* (cf. Section 4.1), but now *(57)* tautomerizes to the oxazolinyl anion *(69)* because the negative charge on C-4 is effectively stabilized by the substituent X. *(69)* undergoes rapid ring fission[71], usually occurring between −70 and 0 °C and leading to the "pentadienyl anion" *(70)* which can be obtained by protonation in the form of the isomeric alkenylformamide *(71)* or *(72)*. In these reactions the end effect is that an oxo-oxygen atom is replaced by a formylaminomethylene group, and therefore the designation "formylaminomethylenation" has been proposed[3].

For comparison, the anions *(69)* were prepared from *(59)* by means of, for example, potassium *tert*-butoxide. Experimentally ring opening to give *(70)* was observed, which proves the reaction course postulated above[36, 53]. Two directions of rotation are possible for the change *(69)*→*(70)*. It has also been found that even when the substituents R^3 and R^4 have widely different space-filling capacity the two isomers of *(71)* and *(72)* are formed in comparable amounts[36]. Surprisingly, similar high activation barriers thus have to be overcome for both directions of rotation (cf. Fig. 1).





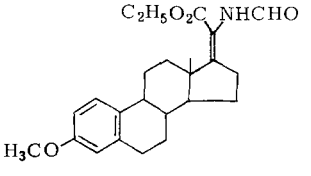


Fig. 1. Stereochemistry of formylaminomethylenation.

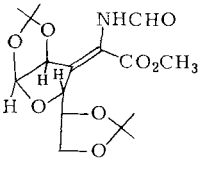
4.3.1. α-(Formylamino)acrylic Esters; Amino Acid Syntheses



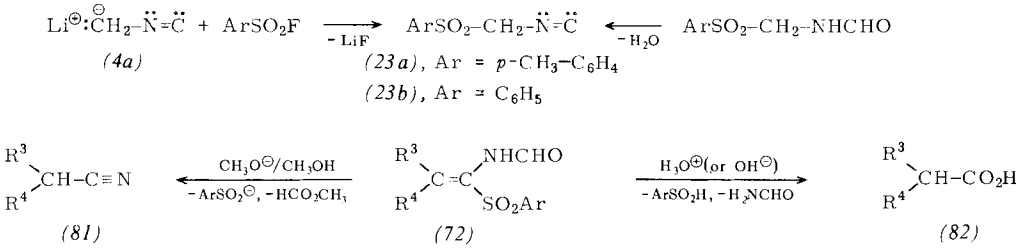
α-(Formylamino)acrylic esters *(71)* are conveniently obtained by the formylaminomethylenation of aldehydes and ketones with potassium or sodium compounds *(16)*[35, 36, 72]. Two standard procedures are to be recommended. Ethyl isocyanoacetate *(15a)* is metalated by potassium *tert*-butoxide in tetrahydrofuran at −70 °C and after addition of the carbonyl compound and warming to room temperature the mixture is worked up as usual[35, 36]. Estrone methyl ether, with its sterically hindered carbonyl group, must however be boiled in THF under reflux[73]; *(71c)* is formed. If sodium hydride

(71a), $R^1 = C_2H_5$, $R^3 = R^4 = CH_3$: 76% [35, 36]
(71b), $R^1 = tC_4H_9$, $R^3 = CH_3$, $R^4 = C_6H_5$: 85% [72, 36]

(71c), 80% [73]

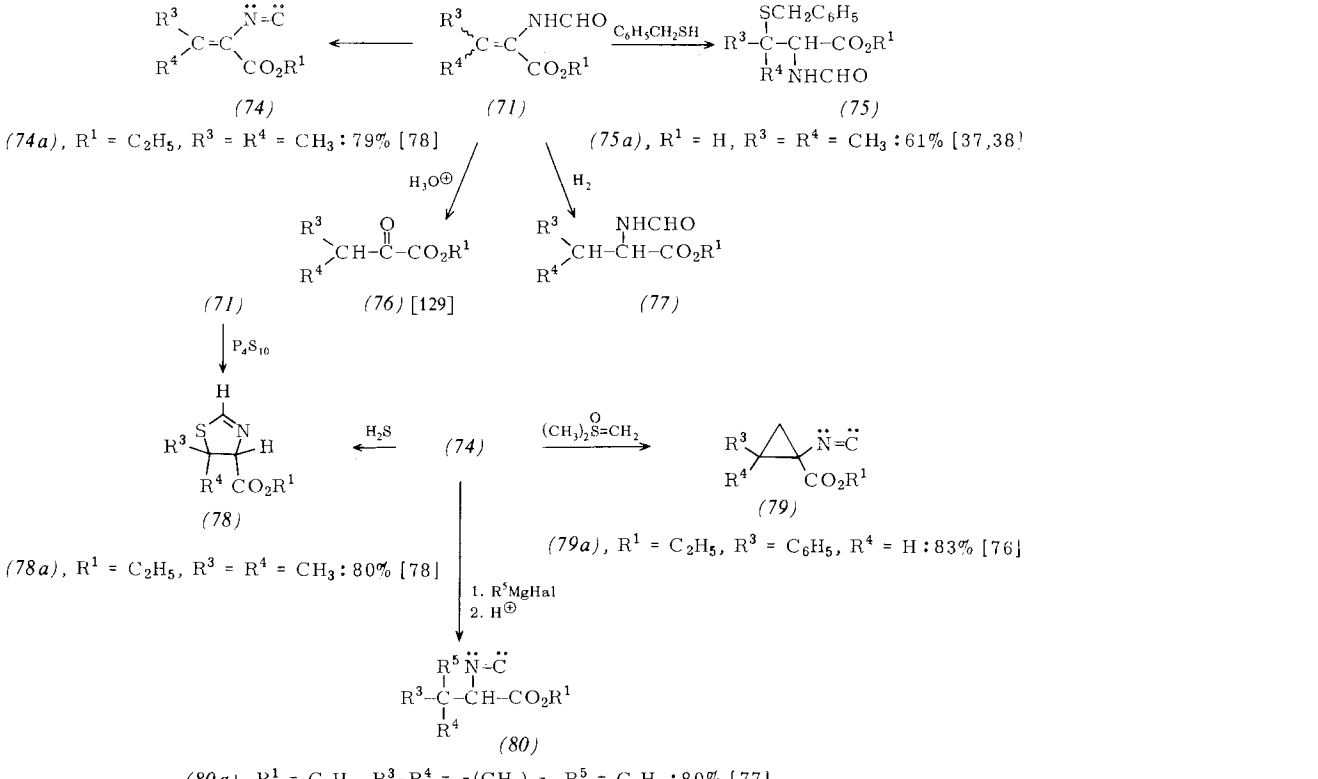
(71d), 70% [80]

(in THF) is used as base, then *(16a)* is produced *in situ*, as *(15a)* and the carbonyl compound are dropped in simultaneously at 20°C[36,38].



Formylaminomethylenation has some advantages over the classical Erlenmeyer azlactone process[74]: it usually occurs under mild conditions and gives good yields, even with carbonyl compounds that otherwise react with difficulty. Furthermore, it affords not the acids but esters, which are more useful for further reactions. The ready and selective removability of the formyl group constitutes yet another advantage[55].

Scheme 1 below shows some of the variations that are possible with the esters *(71)*. Hydrogenation, which can also be effected asymmetrically[75], gives *N*-formylamino esters *(77)*. Cysteine derivatives *(75)* are accessible by the addition of thiols[37,38]; *S*-benzyl-*N*-formylpenicillamine *(75a)*, for instance, can thus be obtained from ethyl isocyanoacetate in an "*Eintopf*" process. Conversion into α-isocyanoacrylic esters *(74)* offers further preparative possibilities[76]: with dimethylsulfoxonium methylide esters *(74)* afford 1-isocyano-1-cyclopropanecarboxylic esters *(79)*[76], which are precursors of 1-aminocyclopropanecarboxylic acids, a procedure that complements their synthesis by cycloalkylation (cf. Section 3.2). Grignard reagents add to *(74)*, yielding *(80)*[77], which permits the synthesis of β-tertiary amino acids. Finally, base-catalyzed reaction with hydrogen sulfide leads almost quantitatively to 5-substituted 2-thiazoline-4-carboxylic esters *(78)*[78], which can also be obtained by direct sulfuration of the acrylic esters *(71)* by tetraphosphorus decasulfide[78]. Thiazolines of type *(78)* have found application in the synthesis of modified penicillins[79].



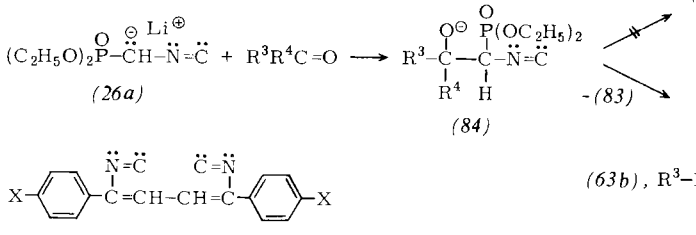
4.3.2. *N*-(1-Arenesulfonyl-1-alkenyl)formamides; Conversion of an Oxo Group into a Cyano or Carboxy Group

Arenesulfonylmethyl isocyanides *(23)* can be obtained from *(4a)* and arenesulfonyl fluorides[48,49] or, better, the formamides[48,49,82] (prepared by aminomethylation of arenesulfinic acids with hydroxymethylformamide[81]). Their potassium salts *(24)* react with aldehydes and ketones at −10°C in tetrahydrofuran, yielding *N*-(1-arenesulfonyl-1-alkenyl) formamides *(72)*.

These formamides can be converted almost quantitatively into carboxylic acids *(82)* by aqueous acid or base[47,48] or into nitriles *(81)* by sodium methoxide[83,84]. This reaction sequence thus allows conversion of a carbonyl compound into the next higher carboxylic acid or nitrile.

(81a), R^3–R^4 = -$(CH_2)_5$-: 85% [83] *(72a)*, R^3 = R^4 = H, Ar = *p*-CH_3-C_6H_4: 81% [95] *(82a)*, R^3 = $C(CH_3)_3$, R^4 = H: 90% [48]

(74a), R^1 = C_2H_5, R^3 = R^4 = CH_3: 79% [78] *(75a)*, R^1 = H, R^3 = R^4 = CH_3: 61% [37,38]

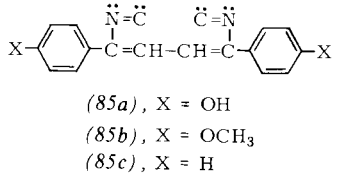


(78a), R^1 = C_2H_5, R^3 = R^4 = CH_3: 80% [78] *(79a)*, R^1 = C_2H_5, R^3 = C_6H_5, R^4 = H: 83% [76]

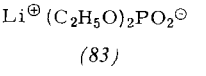
(80a), R^1 = C_2H_5, R^3-R^4 = -$(CH_2)_5$-, R^5 = C_2H_5: 80% [77]

Scheme 1

4.3.3. Vinyl Isocyanides and Dialkyl 1-(Formylamino)-1-alkenephosphonates



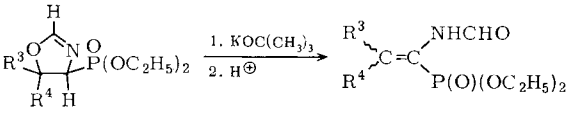
The lithium compound *(26a)* can be prepared from diethyl isocyanomethanephosphonate *(25a)* by *n*-butyllithium[52]; its reaction with carbonyl compounds does not involve formylaminomethylenation but affords *ca.* 80% of vinyl isocyanides *(63)*[52,53], which is the result of Wittig olefination. Apparently the reversible cyclization of *(84)* to the oxazolinyl anions *(57)* and *(69)*, which could then lead to formylaminomethylenation, is a non-occurring variant: decomposition of the adduct *(84)* into lithium diethyl phosphate *(83)* and vinyl isocyanide *(63)* determines the course of the reaction.



(26a) *(84)* *(63)*

(63b), R^3–R^4 = -$(CH_2)_5$- : 84% [53]

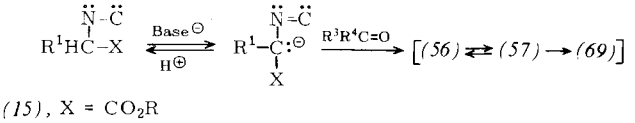
(57) ⇄ *(69)* → *(73)*



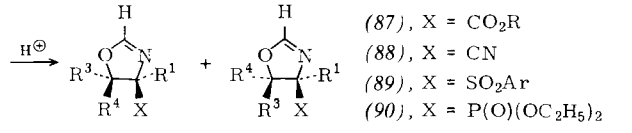
(85a), X = OH
(85b), X = OCH_3
(85c), X = H

(83)

As a preliminary study for the synthesis of isoxanthocillin *(85a)* the diisocyanide *(85c)* was synthesized from diethyl α-isocyanophenylmethanephosphonate and glyoxal[53].



(90) *(73)*

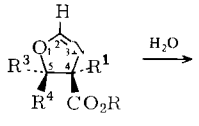


1-(Formylamino)-1-alkenephosphonic esters *(73)* can, however, be obtained by base-induced ring opening of the oxazoline-4-phosphonic esters *(90)* (cf. Section 5.3)[52,53]

5. Base-catalyzed Reaction of Relatively Acidic Isocyanides with Aldehydes and Ketones in Protic Media; Synthesis of Oxazolines

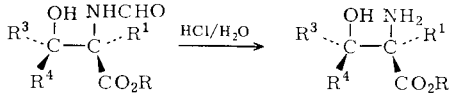
In order that the isocyanides *(15)*, *(17)*, *(23)*, and *(25)* with especially marked CH-acidity may afford oxazolines, *(87)*, *(88)*, *(89)*, and *(90)* respectively, all with R^1=H, on reacting with carbonyl compounds the reaction medium must be weakly basic and protic; otherwise competing and/or subsequent reactions predominate (cf. Section 4.3).

(15), X = CO_2R
(17), X = C≡N
(23), X = SO_2Ar
(25), X = $P(O)(OC_2H_5)_2$



(87), X = CO_2R
(88), X = CN
(89), X = SO_2Ar
(90), X = $P(O)(OC_2H_5)_2$

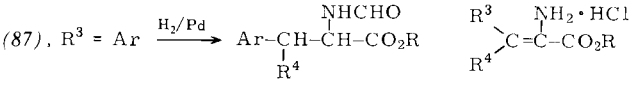
Ethanol has proved useful as the solvent, and sodium cyanide (5—10 mol-%) as the catalyst[40,41] which provides a weakly basic medium as a result of its partial alcoholysis; sodium ethoxide (*ca.* 5 mol-%) in ethanol has also been recommended[35,36]. Triethylamine in dichloromethane[44] proved optimal for α-isocyanoalkanonitriles *(17)*. *Saegusa*'s copper oxide method[31,33] seems to be generally applicable. Whereas diastereoisomeric 2-oxazolines ($R^3 \neq R^4$) having a hydrogen atom on C-4 equilibrate in the basic medium by way of the anion *(69)* to give the thermodynamically favored (*trans*)-isomers, the copper-catalyzed reaction gives mixed diastereoisomers also in these cases[33].



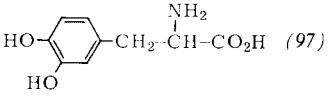
5.1. Alkyl 2-Oxazoline-4-carboxylates and Serine

50—90% yields of ethyl 2-oxazoline-4-carboxylates *(87)* can be obtained from ethyl isocyanoacetate *(15a)* and carbonyl compounds by the "cyanide process"[40,41], the 5-monosubstituted esters R^1=R^3=H) being isolated to more than 95%

(87) [85]



(87a), R^1 = R^4 = H, R^3 = CH_3
R = C_2H_5



(91), R = Alkyl
(92), R^3 = Ar, R = H

(93), R = CH_3, R^1 = Alkyl, R^3, R^4 = Ar, H

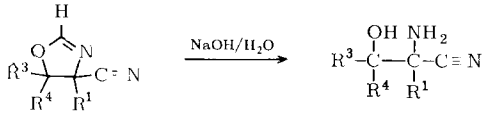
(94), R = H

(95), R = Alkyl *(96)*

(97)

as the *trans*-forms. α-Isocyanoalkanoic esters such as α-isocyanopropionic esters *(15c)*, R^1=CH_3, similarly afford 4-alkyl-2-oxazoline-4-carboxylic esters.

As imidic esters, the oxazolines *(87)*[86] can be hydrolyzed to *N*-formylserine esters *(91)*[41,87]. In neutral to weakly basic medium the hydrolysis occurs with retention of the configuration at C-4 and C-5. Using 6 N hydrochloric acid (*ca.* 100 °C; 1—2 h) one thus obtains the serine derivatives *(94)*; ethyl *trans*-5-methyl-2-oxazoline-4-carboxylate *(87a)*, for example, yields exclusively D,L-threonine. *Matsumoto et al.*[88] prepared ring-methoxylated, α-alkylated phenylserine methyl esters *(93)* by treating methyl α-isocyanoalkanoates *(15)*, R^1 = alkyl, with aromatic aldehydes (sodium hydride in tetrahydrofuran, 20 °C) and hydrolyzing the oxazoline *(87)* *in situ* with methanolic hydrochloric acid (2 h, 50 °C). The proportion of *threo*-*(93)* increases with increasing bulk of the alkyl group.



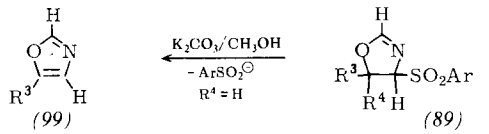
Difficulty is experienced in acid deformylation of β-branched and β-alkoxyphenyl-substituted *N*-formylserine esters *(91)*, $R^1 = H$[89], which are readily dehydrated to α-aminoacrylic ester hydrochlorides *(96)*. *Damico et al.*[90] used this effect for a synthesis of D,L-dopa *(97)* from methyl isocyanoacetate and 3,4-dibenzyloxybenzaldehyde; hydrogenation of the hydrochloride of type *(96)* simultaneously removed the benzyl groups. Hydrogenolysis of 5-aryl-substituted oxazolines *(87)*[91] provides a route to *N*-formylphenylalanine esters *(95)*.

(−)-α-Methylserine *(94)*, $R^1 = CH_3$, $R = R^3 = R^4 = H$, is obtained by the reaction of (−)-menthyl α-isocyanopropionate with formaldehyde and subsequent hydrolysis, although the optical yield in this asymmetric synthesis amounts to only 20 %[93].

Treatment of isocyanoacetic esters *(15a)* with aromatic aldehydes or ketones and an excess of sodium hydroxide in tetrahydrofuran[35,36] affords *N*-formyl-β-arylserines *(92)*; the active base is probably not the alkali metal hydroxide but the alkoxide formed by hydrolysis (cf. Section 8.1).

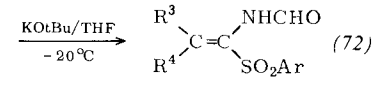
5.2. 2-Oxazoline-4-carbonitriles

1-Isocyanoalkyl cyanides *(17)*[44] are prepared by dehydration of *N*-(1-cyano-1-alkyl)formamides[94] and react with aldehydes or ketones in dichloromethane in the presence of triethylamine even at room temperature to yield 2-oxazoline-4-carbonitriles *(88)*[44], the hydrolysis of which by aqueous sodium hydroxide at 20 °C affords 2-amino-3-hydroxyalkanonitriles *(98)*[44].



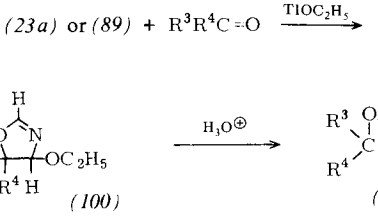
(88) *(98)*

(88a), $R^1 = (CH_3)_2CH$, $R^3 = H$, $R^4 = CH{=}CH{-}C_6H_5$: 93% [44]



5.3. 4-Arenesulfonyl-2-oxazolines and Dialkyl 2-Oxazoline-4-phosphonates

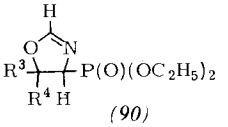
p-Toluenesulfonylmethyl *(23a)* and benzenesulfonylmethyl isocyanide react with carbonyl compounds by the "cyanide process"[48] (at 15—30 °C) or in methanolic potassium carbonate (at 20 °C)[50] to give 60—95 % yields of 4-arenesulfonyl-2-oxazolines *(89)*.



(99) *(89)*

(99a), $R^3 = C_6H_5$: 94% [50] *(89a)*, $R^3 = C_6H_5$, $R^4 = H$, $Ar = p\text{-}CH_3\text{-}C_6H_4$: 94% [48]

(72)



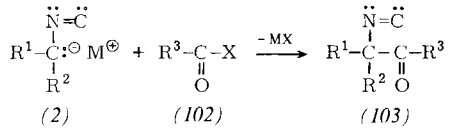
Although these products *(89)* undergo ring opening to vinylformamides *(72)* in an aprotic medium (*ca.* −20 °C) in the presence of strong bases (cf. Section 4.3.2), yet if there is a proton in position 5 they eliminate toluenesulfinic acid almost quantitatively, giving 5-monosubstituted oxazoles *(99)*, when warmed with a base in methanol[50]. When thallium(I) ethoxide is used the sulfonyl group is replaced by an ethoxy group[96]; the 4-ethoxy-2-oxazolines *(100)* thus obtained can be converted into the monomeric 2-hydroxy aldehydes *(101)*[97].

(100) *(101)*

(100a), R^3–R^4 =  : 62% [97]

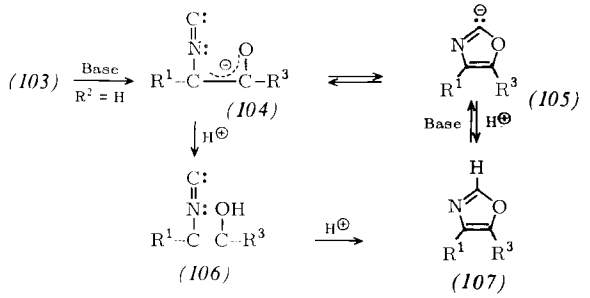
(101a), R^3–R^4 =  : 78% [98]

(90)



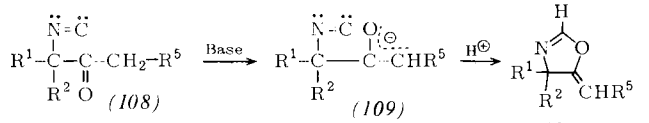
(90a), $R^3 = C_6H_5$, $R^4 = H$: 71% [53]

Diethyl 2-oxazoline-4-phosphonates *(90)* are obtained from diethyl isocyanomethanephosphonate and aldehydes or ketones in 50—70 % yield by either the "cyanide" or the "copper oxide" process[53].



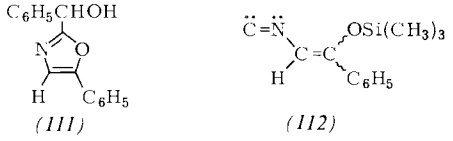
6. Reaction with Acylating Agents

Acylation of metalated isocyanides gives α-isocyano ketones *(103)* [and *(108)*] which undergo various subsequent reactions depending on the nature of the substituents R^1, R^2, and R^3. Suitable acylating agents *(102)* are acid chlorides, anhydrides, esters, and dimethylamides, and especially ethyl chloroformate and diethyl carbonate.



If R^1 or R^2 is hydrogen, the relatively acidic isocyano ketone *(103)* is deprotonated by a base, *e.g.* by unchanged metalated isocyanide. The enolate *(104)* is either further acylated (cf. Section 6.2) or is cyclized to the oxazolyl anion *(105)*. Protonation leads to the oxazole *(107)*, perhaps by way of *(106)*[98]. That the anions *(104)* and *(105)* exist in mobile equilibrium can be shown by metalating 5-phenyloxazole *(107)*, $R^1 = H$, $R^3 = C_6H_5$, with *n*-butyllithium[34]: the anion *(105)* was

(2) (102) (103)

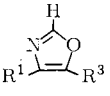


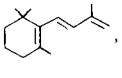
(104) (105) (106) (107)

(108) (109) (110)

R^1, $R^2 \neq H$

(110a), $R^1 = CO_2C_2H_5$, $R^2 = R^5 = CH_3$: 68% [99]

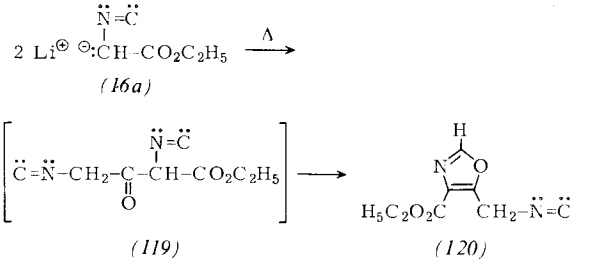




(111) (112)

trapped [as oxazole (111)] by benzaldehyde, and the anion (104) [as the enol ether (112)] by trimethylchlorosilane[34]. If the α-position is blocked by alkyl or aryl groups as in (108) and R^3 is capable of enolization, then the 5-alkylidene-2-oxazoline (110) can be formed by way of the enolate (109)[99].

6.1. Syntheses of Oxazoles

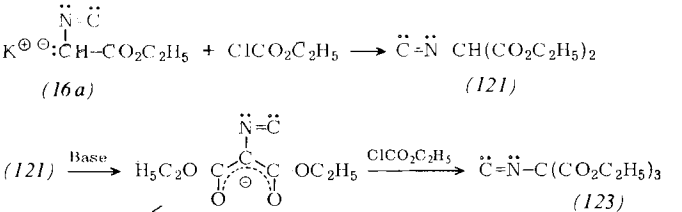


In oxazole synthesis it should be noted that additional metalated isocyanide (2) is often consumed (cf. Section 6); in the reaction with acid chlorides or anhydrides (102) double the stoichiometric amount of metalated isocyanide is used and the excess of isocyanide is either distilled off during working-up or is destroyed by aqueous acid. The utilization of (2) is improved by acylation with esters of *N,N*-dialkylamides (102), for the liberated alkoxide or dialkylamide ($X^{\ominus} = RO^{\ominus}$ or $R_2N^{\ominus}$, respectively) takes over the deprotonation of the isocyano ketone (103)[100]. According to *Matsumoto et al.*[42,43], in the presence of an excess of tertiary amine or sodium hydride the isocyanoacetic esters (15) condense with aroyl chlorides also in the proportion of 1 : 1, yielding 5-aryloxazole-4-carboxylic esters (107), $R^1 = COOR$, $R^3 = Ar$, almost quantitatively.

(107), R^1 = H, C_6H_5, CO_2R; R^3 = Alkyl, Aryl
(113), $R^1 = CO_2C_2H_5$, R^3 = OAlkyl
(114), $R^1 = SC_6H_5$, R^3 = H
(115), $R^1 = SO_2Ar$, R^3 = Aryl
(116), R^1 = H, C_6H_5; $R^3 = C{\equiv}C{-}R$ [101]
(117), $R^1 = CO_2R$, C_6H_5; $R^3 = -CH{-}CH{-}C_6H_5$ [59]
(118), R^1 =  , $R^3 = CH_3$ [28]

Metalated isocyanides (2) have so far been used for the synthesis of oxazoles with a free position 4 and their 4-alkoxycarbonyl, 5-alkyl, and 5-aryl derivatives (107)[34,100,42,43], as well as 5-arylthio- (114)[53,34] and 5-arenesulfonyloxazoles (115)[50] by the use of (21) and (23), respectively[131]. The reaction of chloroformic esters or diethyl carbonate with (16a) gives 5-alkoxyoxazole-4-carboxylic esters (113)[100].

The "decomposition" of lithiated ethyl isocyanoacetate (16a) that begins above 0 °C occurs as an ester condensation, proceeding by way of ethyl 2,4-diisocyanoacetoacetate (119)[102] and leading to the oxazole (120)[60]. Alongside this reaction there occurs an intramolecular cyclization to 5-ethoxyoxazole, a reaction that is observed to a small extent even on distillation of other α-isocyanoalkanoic esters[103].

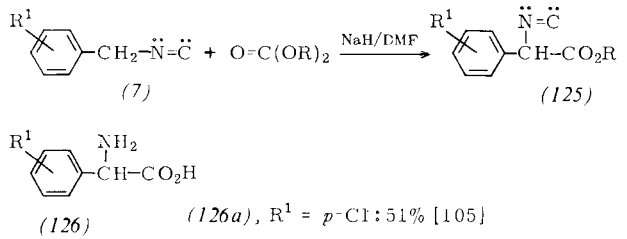


(16a) (119) (120)

Ethyl chloroformate[99] and (16a) always give rise to ethyl 5-ethoxyoxazole-4-carboxylate (113)[104]; the isocyanomalonic ester anion (122) can, however, be trapped by alkyl halides (cf. Section 6.2).

6.2. 2-Isocyanoalkanoic and 2-Isocyano-3-oxoalkanoic Esters; Synthesis of Amino Acids

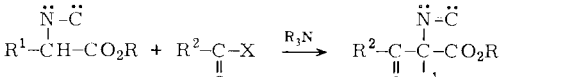
The potassium salt of (122), produced *in situ* from potassium isocyanoacetate (16a) and ethyl chloroformate[99], reacts with alkyl bromides and iodides in boiling tetrahydrofuran to give the esters (124) and thus, like the alkali metal salts of *N*-formylaminomalonic esters, can be used for amino acid synthesis. Further reaction of (122) with the chloroformic ester gave triethyl isocyanomethanetricarboxylate (123)[99] (60% yield).



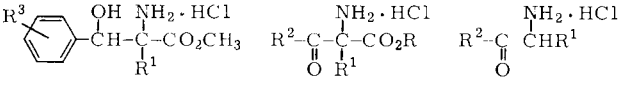
(16a) (121) (123) (122) (113) (124)

(124a), $R^2 = CH_2{-}CH{=}CH_2$: 75% [99]

Ring-substituted α-isocyanophenylacetic esters (125) have been synthesized from benzyl isocyanides (7) and dialkyl carbonate (dimethylformamide/sodium hydride, 20 °C)[22,105]



and hydrolyzed to phenylglycines *(126)* in 50—60% overall yield.

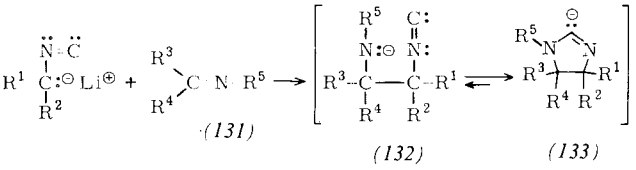


(7) *(125)*

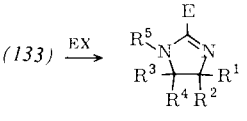
(126) *(126a)*, R^1 = p-Cl: 51% [105]

By acylation of α-monoalkyl-substituted α-isocyanoalkanoic esters *(15)* with aroyl chlorides, *Matsumoto et al.*[42,43] prepared the 2-isocyano-3-oxoalkanoic esters *(127)*, which on hydrogenation and acid alcoholysis were converted stereoselectively into ring-substituted *erythro*-phenylserine methyl ester by hydrochloride *(128)*[88]. With methanolic hydrochloric acid the esters *(127)* give methyl 2-amino-3-oxoalkanoate hydrochlorides *(129)*, which when heated with aqueous hydrochloric acid are hydrolyzed and decarboxylated to 2-amino ketone hydrochlorides *(130)*[42,43].

(15) *(127)*



(128) *(129)* *(130)*



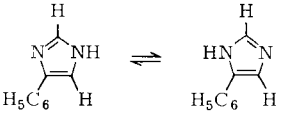
7. Reactions with Heteroanalogous Carbonyl Compounds

7.1. Reaction with Azomethines; Pyrroline Synthesis

So far as has yet been studied, only particularly nucleophilic lithioalkyl isocyanides add to azomethines *(131)*; examples are lithiomethyl *(4a)* and lithiobenzyl isocyanide *(8a)*[106]. The as yet untrapped adduct *(132)* cyclizes to the imidazolinyl anion *(133)*, which on protonation by acids affords a 2-imidazoline *(134)*; or the anion can be further substituted, in position 2, by other electrophiles such as carbonyl compounds or alkylating agents, to give compounds *(135)* or *(136)* respectively[106].

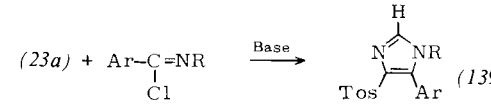
(131) *(132)* *(133)*

(134), E = H



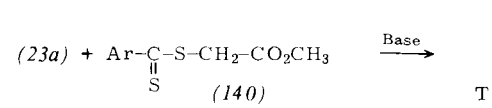
(134a), E = R^1 = R^2 = R^3 = H, R^4 = C_6H_5, R^5 =  : 77% [106]

(135), E = R^6R^7COH



(136), E = Alkyl

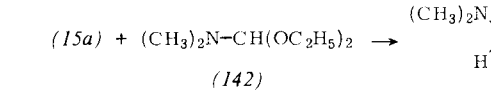
7.2. Reactions with Nitriles, Imidoyl Chlorides, and Dithio Acid Esters; Synthesis of Imidazoles and Thiazoles



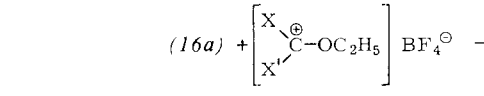
Reaction of metalated isocyanides with nitrogen or sulfur derivatives of carboxylic acids gives imidazoles and thiazoles, analogously to the formation of oxazoles (cf. Section 6.1). 4(5)-Phenylimidazole *(137)* was obtained in 40% yield from lithiomethyl isocyanide *(4a)* and benzonitrile[107]. *van Leusen et al.* synthesized 5-toluenesulfonylimidazole *(139)*[108] and 4-toluenesulfonylthiazole *(141)*[109] from toluenesulfonylmethyl isocyanide *(23a)* and, respectively, areneimidoyl chlorides *(138)* and arenecarbodithioates *(140)*.

(137)

(138) *(139a)*, Ar = C_6H_5, R =  : 80% [108]



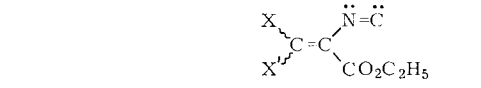
(140) *(141)*



(141a), Ar = C_6H_5 : 53% [109]

7.3. Reaction with Amide Acetals; Synthesis of 3-Hetero-substituted 2-Isocyanoacrylic Esters

Ethyl isocyanoacetate *(15a)* reacts with *N,N*-dimethylformamide acetal *(142)*[110] at room temperature even without the addition of a base to yield 78% of ethyl 3-dimethylamino-2-isocyanoacrylate *(143)*[111] (presumably in the (*Z*)-configuration).

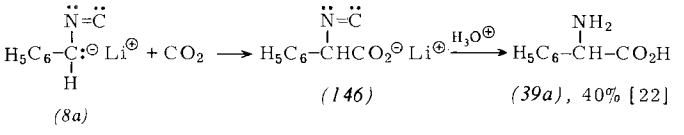


(142) *(143)*

(144a), X = X' = $N(CH_3)_2$

(144b), X = $N(CH_3)_2$, X' = OC_2H_5

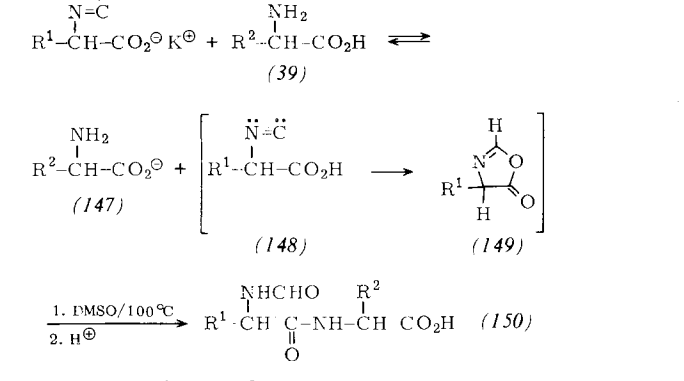
(145a), X = X' = $N(CH_3)_2$; 26% [111]



(145b), X = $N(CH_3)_2$, X' = OC_2H_5 : 14% [111]

3,3-Bishetero-substituted 2-isocyanoacrylic esters *(145a)* and *(145b)* are products of the reaction of ethyl isocyanopotassioacetate *(16a)* with the resonance-stabilized carbenium tetrafluoroborates *(144a)* and *(144b)*, respectively[111], although in poor yields.

8. Reaction with Heterocumulenes

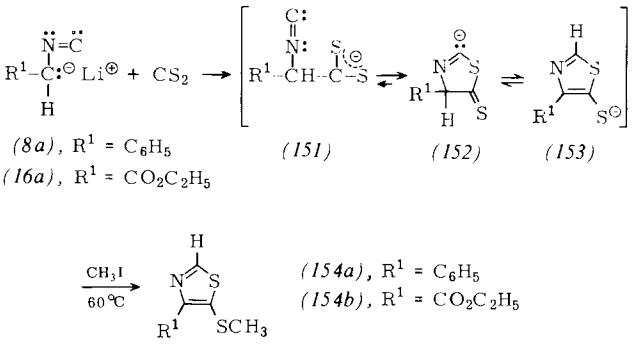


8.1. Reaction with Carbon Dioxide; α-Isocyanoalkanecarboxylates

Isocyanobenzyllithium *(8a)* gave on carboxylation[112] the isocyano carboxylate *(146)*[113, 22], which without isolation was hydrolyzed by acid to phenylglycine (yield 40%). No preparative importance attaches to this reaction, however, as alkoxycarbonylation with carbonic esters (cf. Section 6.2) is preferable for the preparation of amino acids. Salts of the type *(146)* are more simply obtained by alkaline hydrolysis of ethyl[114, 76], methyl, or trimethylsilyl esters[115] under mild conditions. Careful acidification in the absence of moisture leads to the free isocyanoalkanoic acids *(148)*, which on being warmed above 30°C pass into the 2-oxazolin-5-ones *(149)*, which are extremely sensitive to hydrolysis[114].

(8a) *(146)* *(39a)*, 40% [22]

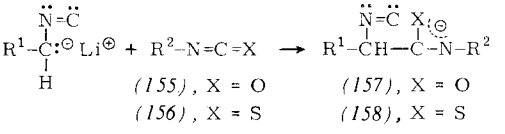
When equimolar amounts of potassium isocyanoacetate or α-isocyanopropionate and amino acids are heated in dimethyl sulfoxide (2—5 h, 100°C), the potassium salts of *N*-formyldipeptides *(150)* are formed[114]; these can be converted into the acids by acidic ion-exchangers. The essential intermediate for this reaction is the oxazolinone *(149)*, which acylates the amino acid anion *(147)*.



(39) *(147)* *(148)* *(149)*

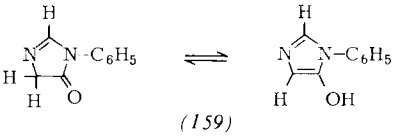
(150a), R^1 = H, R^2 = $-CH_2-CH_2-S-CH_3$: 80% [114]

8.2. Reactions with Carbon Disulfide, Isocyanates, and Isothiocyanates



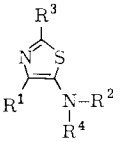
Lithiated benzyl isocyanide *(8a)* and ethyl isocyanoacetate *(16a)* add to carbon disulfide already at −60°C, giving α-isocyanoalkanedithioates *(151)*[111]. However, unlike the carboxylates of type *(146)*, these products are unstable; they cyclize and tautomerize to 5-thiazolethiolates *(153)*, which have been trapped with alkyl halides. For example, after reaction with methyl iodide, the 5-methylthiothiazoles *(154a)* and *(154b)* have been isolated, in 24 and 49% yields respectively.

(8a), R^1 = C_6H_5 *(151)* *(152)* *(153)*
(16a), R^1 = $CO_2C_2H_5$



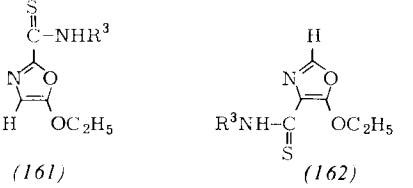
(154a), R^1 = C_6H_5
(154b), R^1 = $CO_2C_2H_5$

The interaction of lithiated isocyanides and isocyanates *(155)* or isothiocyanates *(156)* also begins with 1,2-addition to the heterocumulene system, giving rise to resonance-stabilized carboxamide *(157)* or carbothioamide anions *(158)*, respectively[111]. According to whether the free electron pair of (a)



(155), X = O *(157)*, X = O
(156), X = S *(158)*, X = S

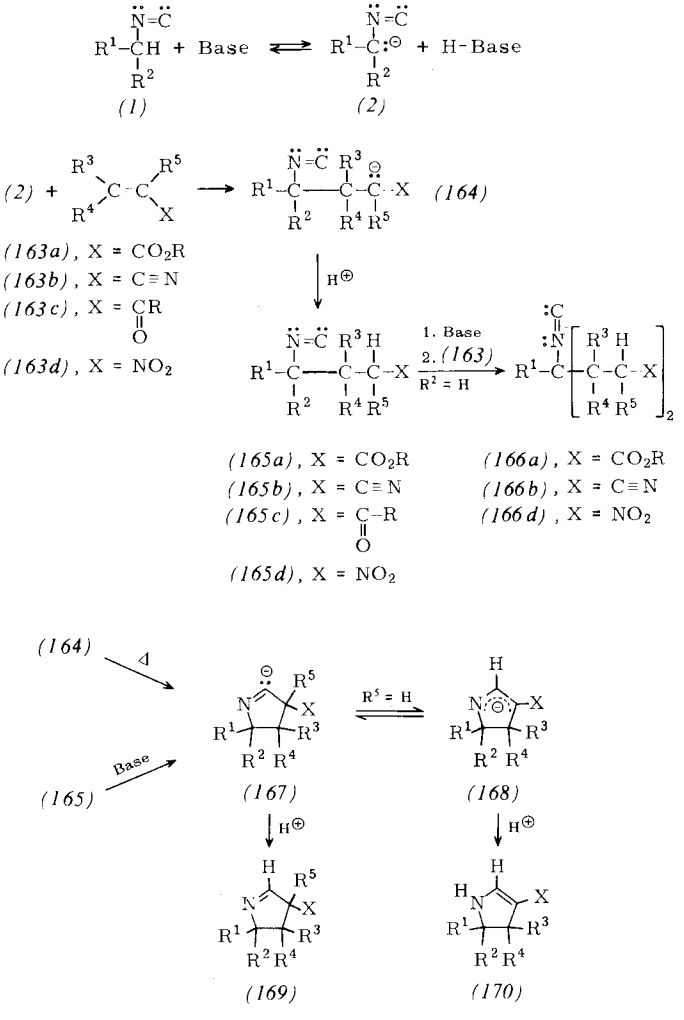
the nitrogen or (b) the oxygen or sulfur combines at the electron sextet of the isocyanide-carbon atoms, there result (a) imidazoles or (b) oxazoles or thiazoles. For example, 3-phenyl-1-imidazolin-4-one *(159)* is obtained in 30% yield from lithiomethyl isocyanide *(4a)* and phenyl isocyanate *(155)*, R^2=C_6H_5[107], whereas the corresponding adduct



(159)

(160a), R^1 = H, R^2 = C_6H_5,
R^3 = R^4 = H : 31% [111]
(160b), R^1 = R^2 = C_6H_5,
R^3 = R^4 = H : 44% [111]
(160c), R^1 = H, R^2 = CH_3,
R^3 = R^4 = $-\overset{\overset{S}{\|}}{C}-NHCH_3$: 24% [111]
(160d), R^1 = C_6H_5, R^2 = CH_3,
R^3 = H, R^4 = $-\overset{\overset{S}{\|}}{C}-NHCH_3$: 11% [111]

(160)

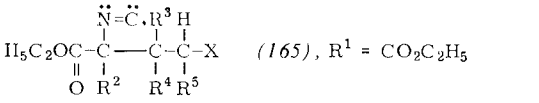


(158) from *(4a)* and phenyl isothiocyanate *(156)*, R^2=C_6H_5, cyclizes on sulfur and gives the 5-aminothiazole *(160a)*. Methyl isothiocyanate, which is more prone to addition, reacts inhomogeneously: it yields mainly more highly thiocarbamoylated thiazoles *(160c)* and *(160d)*. Surprisingly, the reaction of ethyl isocyanolithioacetate *(16a)* with isothiocyanates gives not thiazoles but oxazolethiocarbamides of structures *(161)* or *(162)*[111].

(161) *(162)*

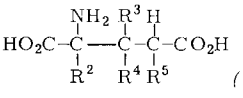
9. Addition to Activated Olefins

In protic media, under base catalysis, isocyanides that have relatively acidic α-protons undergo Michael addition[116] to activated olefins *(163)* such as acrylic esters and nitriles *(163a)* and *(163b)*, α,β-unsaturated ketones *(163c)*, and nitroolefins *(163d)*. On protonation the adducts *(164)* give isocyanides with extended chains; when heated, the adducts cyclize to 1-pyrrolinyl anions *(167)* which, when $R^5 = H$, tautomerize to 2-pyrrolinyl anions *(168)* and thence on protonation afford 1- or 2-pyrrolines *(169)* or *(170)*.

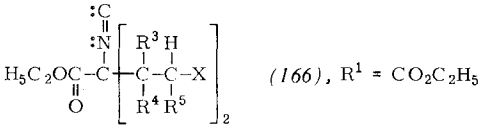


If the monoadduct *(165)* carries a hydrogen α to the isocyanide group it is able to take up a second olefin molecule to give the bisadduct *(166)*, but the resulting proportions of *(165)* to *(166)* can be controlled within only narrow limits by varying the molar ratio of the isocyanide to the olefin.

Particularly reactive Michael components, *e.g.* acrylonitrile and ethyl acrylate, favor the formation of the bisadducts; olefins that are monosubstituted in the β-position can be converted into mono- or bisadducts at will by varying the molar ratio of the reactants, α,β- and β,β-disubstituted olefins and those that are stabilized by a conjugated phenyl group react only to the monoadduct stage.



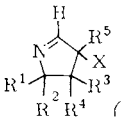
Pyrrolines *(169)* and *(170)* are obtained directly if copper(I) oxide is added as a catalyst[33], but under these conditions the direction of the reaction also can only be slightly controlled.



9.1. Open-chain Adducts of Types *(165)* and *(166)*; Glutamic Acid Synthesis

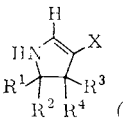
With α,β-unsaturated carboxylic esters *(163a)* ethyl isocyanoacetate *(15a)* or α-isocyanopropionate *(15c)* in ethanol (10—20 mol-% of sodium ethoxide) at 20—50 °C give, respectively, 30—65 % of the (chain branched) 2-isocyanoglutaric ester *(165a)*[117,118] and up to over 70 % of the bisadduct *(166a)*. Hydrolysis leads to the glutamic acid derivatives *(171)*. Analogous cyanoethylation of α,β-unsaturated nitriles *(163b)* gave products *(165b)* and *(166b)*[119,120]. Ethyl 2-isocyano-2-methyl-5-oxohexanoate is formed from *(15c)* and methyl vinyl ketone[121]. For the synthesis of 2-isocyano-4-nitroalkanoic esters *(165d)*, nitroolefins *(163d)* which polymerize rapidly in alkaline media are best brought into reaction with equimolar amounts of lithiated α-isocyanoalkanoic esters *(16)* at −78 °C[122].

$X = CO_2C_2H_5$, $R^2 = R^4 = R^5 = H$, $R^3 = CH_3$: 63% [117,118]
$X = C{\equiv}N$, $R^2 = R^5 = CH_3$, $R^3 = R^4 = H$: 86% [119,120]
$X = C(=O)-CH_3$, $R^2 = CH_3$, $R^3 = R^4 = R^5 = H$: 45% [121]
$X = NO_2$, $R^2 = R^5 = H$, $R^3 = R^4 = CH_3$: 48% [122]



$X = CO_2C_2H_5$, $R^3 = R^4 = H$, $R^5 = CH_3$: 75% [117,118]
$X = C{\equiv}N$, $R^3 = R^4 = R^5 = H$: 55% [119,120]

9.2. Cyclization Products; Synthesis of Pyrrolines and Pyrroles



When heated with sodium ethoxide at 70—110 °C, monoadducts of type *(165)* (*in situ* or after isolation) cyclize to 1- or 2-pyrrolines *(169)* or *(170)*, respectively.

In this connection the behavior of monoadducts of types *(165a)* and *(165b)* is remarkable when there is a hydrogen atom next to the isocyanate group: their cyclization occurs by way of the ester enolate and leads to 5-alkoxyoxazoles *(172a)* and *(172b)*, respectively[118,120] (cf. Section 6.1). Nevertheless, pyrrolines result when copper(I) oxide catalysts are used[33]: *Saegusa* used benzyl isocyanide *(7a)*[33] and allyl isocyanide *(5a)*[31] as well as isocyanoalkanoic esters *(15)* to obtain pyrrolines of types *(170)*, *(173)*, and *(169)*.

If the pyrroline ring contains substituents that can be eliminated, aromatization to the pyrrole may also be achieved. Thus, *van Leusen et al.*[123] synthesized 3,4-disubstituted pyrroles *(176)* from toluenesulfonylmethyl isocyanide *(23a)* and activated olefins with sodium hydride as the base.

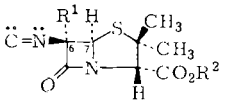
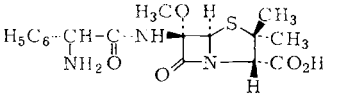
Formation of pyrroles with elimination of nitrite was observed on base-catalyzed cyclization of the adducts *(165d)* obtained from nitroolefins and isocyanoacetic esters; ethyl 3,4-dialkylpyrrole-2-carboxylates *(177)* were isolated[122].

(177)



(178)

(177a), R^2 = R^3 = CH_3 71% [122]



Diethyl 3-methyl-2-pyrroline-2,4-dicarboxylate was found to be a by-product in formylaminomethylenation (cf. Section 4.3.1) of acetaldehyde with ethyl isocyanolithioacetate *(16a)*[35, 36]; control experiments confirmed[62] that here ethyl 2-formylaminocrotonates of type *(71)* function as Michael components[130] for *(16a)*; the adduct cyclizes and then eliminates lithium formamide to yield *(178)*.

10. Modification of Penicillin

6- and 7-substituted penicillins and cephalosporins have aroused considerable biological interest recently[124]. *Bentley* and *Clayton*[125] started from (epimeric) 6-isocyanopenicillin benzyl ester *(179a)*, converted this *in situ* into the anion by potassium carbonate in dimethylformamide, and introduced a 6-methylthio group by means of methoxycarbonyl methyl disulfide; conversion of the sulfur group in the resulting *(179b)* into a methoxy group[126] and introduction of a D-phenylglycyl residue into the amide side chain afforded biologically active ampicillin *(180)*. The isocyanide *(179a)* reacts under the influence of bases with reactive alkyl halides (cf. Section 3.2), with acrylic esters (cf. Section 9), and with ketones (cf. Sections 4 and 5) to yield 6-alkyl-6-isocyanopenicillinic

(179a), R^1 = H (mixture of α and β), R^2 = CH_2–C_6H_5
(179b), R^1 = SCH_3
(179c), R^1 = CH_2 C_6H_5
(179d), R^1 = CH_2–CH_2–$CO_2CH_2C_6H_5$
(179e), R^1 = $C(CH_3)_2$(OH)

(180)

esters *(179c)*, *(179d)*, and *(179e)* in the α-configuration. Aqueous *p*-toluenesulfonic acid has proved valuable for converting the isocyano group into an amino group[125].

I am indebted to Professor U. Schöllkopf for many stimulating discussions and for disclosure of unpublished results. The work was supported by a grant from the Deutsche Forschungsgemeinschaft.

[131] A synthesis of 3-amino-4-hydroxycumarins from *(15)* *via* oxazoles is reported by: *K. Matsumoto, M. Suzuki, M. Miyoshi*, and *K. Okumura*, Synthesis *1974*, 500.

COMMUNICATIONS

Cleavage of Selenium Compounds by Butyllithium. A New, Regiospecific, Allyl Alcohol Synthon

By *Willy Dumont, Pierre Bayet*, and *A. Krief*[*]

In this paper, we describe the ready cleavage of selenonium salts *(1)*[1] and selenides *(6)*[2] by *n*-butyllithium; subsequent addition of a carbonyl compound to the reaction mixture affords alcohols resulting mainly from the migration of one of the substituents originally attached to the selenium.

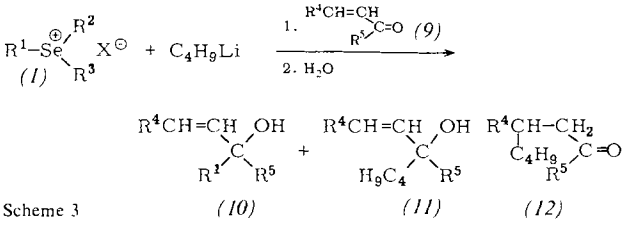
(1a)	CH_3	C_6H_5	H	54	16
(1a)	CH_3	C_6H_5	CH_3	75	—
(1a)	CH_3	n-C_6H_{13}	H	45	28
(1a)	CH_3	C_6H_5	C_6H_5	54	12
(1a)	CH_3	$-(CH_2)_2CH(t\text{-}C_4H_9)(CH_2)_2-$		40	25
(1b)	C_6H_5	C_6H_5	H	40	—
				32 [a]	
(1b)	C_6H_5	C_6H_5	CH_3	70	—
(1b)	C_6H_5	n-C_6H_{13}	H	49	
				7 [a]	—
(1c)	C_6H_5 [b]	C_6H_5	H	56	—

[a] Isolated as methyl ether.
[b] 1-Phenylethanol was also isolated in 24% yield.

In some cases, butylated alcohols were also observed, especially when trimethylselenonium iodide *(1a)* or dimethyl selenide *(6a)* were used (Tables 1 and 2).



Scheme 2

Table 2. Alcohols *(8)* prepared according to Scheme 2 [3b].

(6)	R^1	R^2	R^4	R^5	*(8)*, Yield [%]
(6a)	CH_3	CH_3	C_6H_5	H	32 [a]
(6b)	C_6H_5	CH_3	C_6H_5	H	93
(6b)	C_6H_5	CH_3	n-C_6H_{13}	H	68
(6b)	C_6H_5	CH_3	C_6H_5	CH_3	27
(6c)	C_6H_5	C_6H_5	n-C_6H_{13}	H	85
(6c)	C_6H_5	C_6H_5	C_6H_5	CH_3	74
(6c)	C_6H_5	C_6H_5	C_6H_5	H	72
(6d)	C_6H_5	$C_6H_5CH_2$	C_6H_5	H	75
(6e)	$C_6H_5CH_2$	CH_3	n-C_6H_{13}	H	30 [b]
(6f)	C_6H_5	CH_2=CH−CH_2	C_6H_5	H	60

[a] 1-Phenyl-1-pentanol was also isolated in 44% yield.
[b] 2-Octanol was also detected (1–2%).

Surprisingly, the use of α,β-unsaturated carbonyl compounds *(9)* increased the proportion of butylation products (Table 3).

Scheme 3

Table 3. Allyl alcohols *(10)* and *(11)* and ketones *(12)* prepared according to Scheme 3 [3a]. *(1a)*, $R^1=R^2=R^3=CH_3$, X = I; *(1b)*, $R^1=R^2=C_6H_5$, $R^3=CH_3$, $X=BF_4$.

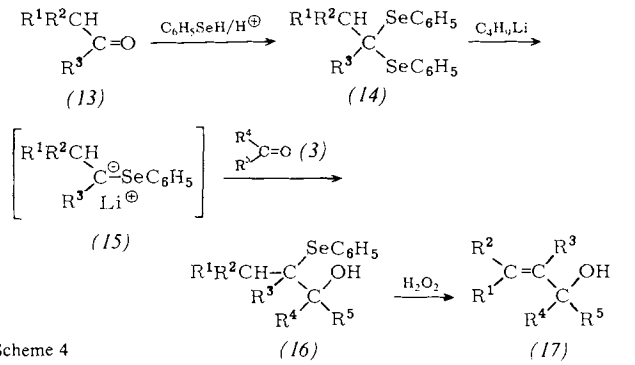
(1a)	CH_3	C_6H_5	C_6H_5	26.5	31.5	40.5
(1a)	CH_3	C_6H_5	H	20	42	–
(1b)	C_6H_5	C_6H_5	C_6H_5	47.5	17	–
				7 [a]		



[a] Isolated as methyl ether.

Typically in *(1b)*, *(1c)* and *(6b)*, the phenyl group is transferred preferentially to the methyl group.

To account for our results, we assume that addition of butyllithium to the selenium compound *(1)* or *(6)* leads to a tetra- *(2)* or tri-substituted intermediate *(7)*[4]; subsequent migration of one of the substituents to the carbonyl compound gives rise to the alcohol.

As a synthetic application of this Se—C cleavage, we describe a new regiospecific synthesis of allyl alcohols *(17)* starting formally from two carbonyl compounds [*(13)* and *(3)*]. The key step of this synthesis is the facile cleavage of selenoacetals *(14)*[5] by *n*-butyllithium in THF (−78 °C) to give carbanions *(15)* which add a variety of aldehydes and ketones *(3)* to form β-hydroxyselenides *(16)* in good yields (Table 4).

While β-hydroxyselenides have already been obtained by the ring opening of epoxides with selenophenolate[6], cleavage of unsymmetrically substituted epoxides can furnish two different β-hydroxyselenides. Such ambiguity is avoided by our method. The exact position and nature of all of the substituents (R^1—R^5) are strictly dependent on the choice of the two carbonyl compounds.

Scheme 4

Table 4. β-Hydroxyselenides *(16)* und allyl alcohols *(17)* prepared according to Scheme 4. Yields refer to purified products [7].

	R^1	R^2	R^3	R^4	R^5	*(16)* Yield [%]	*(17)* Yield [%]
a	H	H	CH_3	C_6H_5	CH_3	67	80
b	H	H	CH_3	H	n-C_6H_{13}	70	80
c	H	H	CH_3	−$(CH_2)_5$−		78	93
d	H	H	H	H	n-C_6H_{13}	49	78
e	H	CH_3	H	H	n-C_6H_{13}	60	74 [a]

[a] We presume that the stereochemistry of the carbon-carbon double bond is mainly *trans* ($J_{H-H}=15$ Hz).

Finally, using *Sharpless*' procedure[6] the hydroxyselenides *(16a)*—*(16e)* are readily oxidized with hydrogen peroxide (THF, 1h, 25 °C) to give allyl alcohols *(17)* in high yield (Table 4). We are currently investigating the scope and stereochemistry of these reactions, as well as the use of Se—C cleavage to generate carbanions which are difficult to obtain by usual methods.

[1] Unstabilized selenonium ylides can be generated by reaction of suitable bases with selenonium salts: *W. Dumont, P. Bayet,* and *A. Krief,* Angew. Chem. *86*, 308 (1974); Angew. Chem. internat. Edit. *13*, 274 (1974).

[2] Similar cleavage of some selenides has been described: a) *H. Gilman* and *R. L. Bebb,* J. Amer. Chem. Soc. *61*, 1110 (1939); b) *H. Gilman* and *F. J. Webb,* J. Amer. Chem. Soc. *71*, 4064 (1949); c) *D. Seebach* and *N. Peleties,* Angew. Chem. *81*, 465 (1969); Angew. Chem. internat. Edit. *8*, 450 (1969); d) *D. Seebach* and *N. Peleties,* Chem. Ber. *105*, 511 (1972). However, no systematic study was performed.

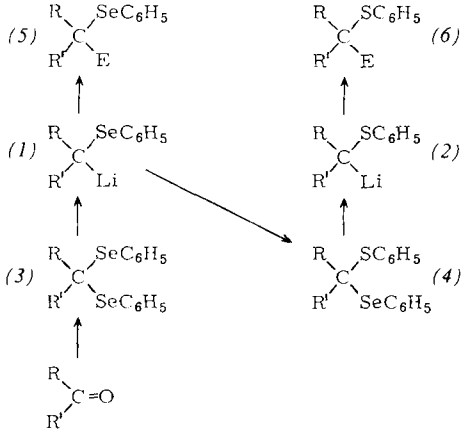
[3] Reaction conditions: a) To a suspension of 6 mmol of *(1)* in THF (10 ml) was added (at −78 °C, under N_2) 5.5 mmol of *n*-butyllithium in hexane (2.75 ml). After 10 min, the carbonyl compound (5 mmol in 5 ml THF) was introduced and the mixture was allowed to react for 2 h at −78 °C and 1 h at 20 °C. b) To a solution of 6 mmol of *(6)* in THF (10 ml) was added (at 0 °C, under N_2) 5.5 mmol of *n*-butyllithium in hexane (2.75 ml). After 15 min at 0 °C and 30 min at 20 °C, the carbonyl compound (5 mmol in 5 ml THF) was introduced and the mixture was allowed to react for 2 h at 20 °C.

[4] See a) *G. Wittig* and *H. Fritz,* Liebigs Ann. Chem. *577*, 41 (1962); b) *D. Hellwinkel* and *G. Farbach, ibid. 715*, 68 (1968).

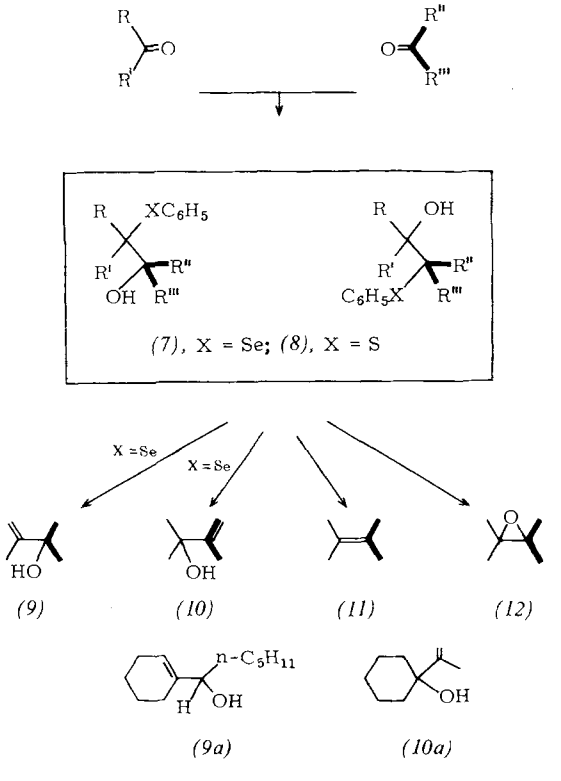
[5] *D. Seebach* [2c, 2d] reported one example of this type: cleavage of bis(phenylseleno)methane with *n*-butyllithium to give phenylselenomethyllithium which was trapped by reaction with benzophenone.

[6] *K. B. Sharpless* and *R. F. Lauer,* J. Amer. Chem. Soc. *95*, 2697 (1973).

[7] Reaction conditions: To a solution of selenoketal *(14)* (5.2 mmol) in THF (10 ml) was added a solution of *n*-butyllithium (5.2 mmol) at −78 °C under N_2. After stirring for a further 1.5 h (not optimized), *(3)* (5 mmol) in THF (5 ml) was slowly introduced. The mixture was allowed to react for 2 h at −78 °C and 2 h (15 h with acetophenone) at 25 °C, hydrolyzed and worked up in the usual manner.



Secondary and Tertiary Phenylthio- and Phenylseleno-alkyllithium Compounds as Novel Reagents for the Formation of C—C Bonds[***]



By *Dieter Seebach* and *Albert K. Beck*[*]

Because of its pronounced nucleophilic character, phenylthiomethyllithium *(2)*, R = R′ = H, which is readily accessible by metalation of thioanisol[1], has acquired considerable preparative significance as a CH_2 synthon in methylenations of carbonyl compounds to give olefins[2a] and epoxides[2b] and for the homologization of primary halides[2c]. However, a wide range of variation of the transfer group seemed to be precluded[2b] by the tendency of alkyl aryl sulfides containing higher alkyl groups to undergo *o*-metalation on reaction with *n*-butyllithium. (Ring metalation is favored thermodynamically by a factor of at least 50[3].)

We have now found C_6H_5Se/Li exchange[4], which is comparable with Br/Li exchange, to offer a kinetically controlled method for the preparation of secondary and tertiary phenylseleno- *(1)* and phenylthio-alkyllithium compounds *(2)*. The selenoacetals *(3)* obtained from aldehydes or ketones or by alkylation of *(1)*, $R=SeC_6H_5$, $R'=H$[4b] are converted into the selenium-substituted derivatives *(1)* within 15 min on treatment with *n*- or *tert*-butyllithium in THF at −80 °C. The products can be transformed by thiolation into the S, Se acetals *(4)* which yield the sulfur-substituted derivatives *(2)* on renewed transmetalation. Reaction of the organolithium compounds *(1)* or *(2)* with electrophiles furnishes the products *(5)* and *(6)* respectively (Table 1).

As can be seen from Scheme 1, the phenylseleno- *(7)* and phenylthio-alkyl alcohols *(8)* prepared with aldehydes and ketones as electrophiles are actually formed by coupling of the carbonyl C atoms of *two* aldehydes or ketones. The selenium derivatives *(7)* can be oxidized[5] to yield allyl alcohols *(9)* or *(10)*, *e.g. (9a)* from cyclohexanone and hexanal (overall yield 50%) or *(10a)* from cyclohexanone and acetone (overall yield 65%). Hence compounds of type *(1)* can be regarded as masked *vinyllithium compounds.*

Scheme 1. Transformations possible with the organolithium compounds *(1)* and *(2)* and ketones and aldehydes as electrophiles.

The olefins *(11)* and epoxides *(12)* should likewise be accessible from the selenium- *(7)*[6] or sulfur-containing alcohols *(8)*[2a, 2b] by known methods.

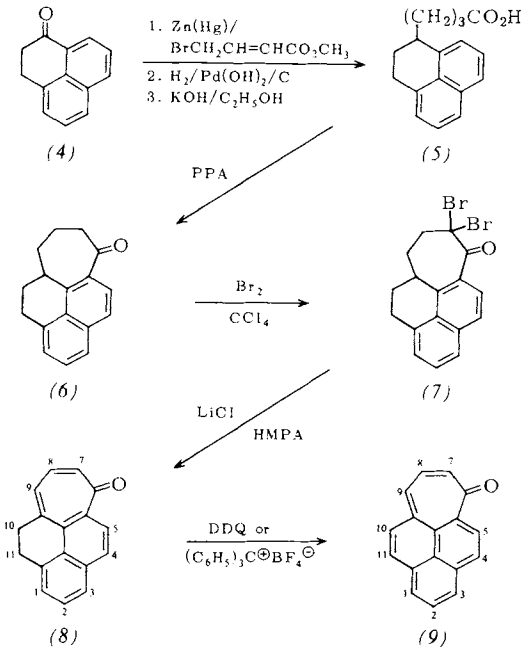
Cyclohepta[*cd*]phenalen-6-one[1]

By *Ichiro Murata*, *Kagetoshi Yamamoto*, and *Yutaka Kayane*[*]

In connection with current interest in the peripheral conjugation in *peri*-condensed polyarenes, we have recently reported the synthesis and properties of the phenalenones *(1)*–*(3)*[2–4]. We have proposed that compounds *(1)* and *(2)* can be regarded as perturbed [13]-annulenones and compound *(3)* as a perturbed [15]-annulenone. In this communication we report the synthesis and properties of a further example of this type of compound, a novel tropone derivative, cyclohepta[*cd*]phenalen-6-one *(9)*.



(1) *(2)* *(3)*

Reformatsky reaction of dihydrophenalenone *(4)*[5] with methyl 4-bromocrotonate afforded the hydroxy ester, which, on hydrogenation with palladium hydroxide on charcoal followed by hydrolysis with potassium hydroxide in ethanol gave the carboxylic acid *(5)*[6], m.p. = 90 °C, in 48% yield [referred to *(4)*]. Cyclization of *(5)* with polyphosphoric acid (PPA) at 90 °C for 1 h afforded the tetracyclic ketone *(6)*[6] in 75% yield: m.p. = 97.5–98 °C; IR (KBr): 1665 cm^{-1}; ^1H-NMR ($CDCl_3$): δ = 1.6–2.2 (m, 6H), 2.5–2.7 (m, 2H), 2.9–3.5 (m, 3H) and 7.0–7.7 (m, 5H). The ketone *(6)* was converted by treatment with bromine in dry carbon tetrachloride into the α,α-dibromoketone *(7)* in quantitative yield: viscous oil; IR (neat): 1695 cm^{-1}; ^1H-NMR: δ = 1.5–2.7 (m,

[*] Prof. Dr. I. Murata, Dr. K. Yamamoto, and Y. Kayane
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

6H), 2.8—3.3 (m, 3H) and 7.0—7.7 (m, 5H). Dehydrobromination of *(7)* to give the tropone *(8)*[6] (in 66% yield) was accomplished by heating in hexamethylphosphoric triamide (HMPA) with LiCl for 1 h at 95—100°C; *(8)*: yellow plates, m.p. = 90.0—90.5°C; *m/e* = 232 (M^+, 64%), 204 ($M^+ - CO$, 100%), 203 (93%) and 202 (pyrene ion, 82%); IR (KBr): 1625, 1590, 1580 cm^{-1}. The absorption bands of the UV spectrum of

(4) *(5)* *(6)* *(7)* *(8)* *(9)*

(8) (λ_{max} (ethanol) = 243 ($\log\varepsilon = 4.38$), 287 (4.33) and 344 nm (3.91)] are in good agreement with those of cyclohepta[*a*]naphthalen-7-one[7].

The conversion of *(8)* into the desired fully conjugated ketone *(9)*[6] was effected by treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in benzene solution in a sealed tube at 120°C for 20 h (yield 21%). The compound *(9)* was found to be more readily accessible by treatment of *(8)* with triphenylmethyl tetrafluoroborate in refluxing acetic acid under nitrogen for 2 h (33% yield): orange scales, m.p. = 144—146°C; *m/e* = 230 (M^+, 27%) and 202 ($M^+ - CO$, 100%); IR (KBr): 1600, 1590 and 1560 cm^{-1}; UV: λ_{max} (ethanol) = 249 ($\log\varepsilon = 4.48$), 311 (4.07), 321 (4.08) and 430 nm (4.23); λ_{max} (cyclohexane) = 246 (4.47), 311 (4.10) and 430 nm (4.19).

Table 1. 100-MHz-^{1}H-NMR data of *(8)* and *(9)* (δ values; TMS internal).

	in $CDCl_3$		in CF_3COOH	
	(8)	*(9)*	*(8)*	*(9)*
H-1,2,3	7.30—7.78	7.68—8.02	7.82—8.21	8.63—9.16
H-7,8,9	6.73—7.10	7.20—7.56	8.24—8.62	
H-10,11	2.88—3.35		3.48—3.82	
H-4	7.96	8.18	8.62	9.23
H-5	8.24	8.77	9.05	9.74
$J_{4,5}$	9.0 Hz	9.0 Hz	9.2 Hz	9.2 Hz

The NMR chemical shifts and coupling constants of *(8)* and *(9)* are summarized in Table 1. It is apparent that in the transition from the dihydroketone *(8)* to the fully conjugated ketone *(9)*, all the vinyl protons move downfield by 0.22 to 0.53 ppm. The most plausible explanation suggests that these downfield shifts arise from deshielding due to the existence of a diamagnetic ring current induced in the periphery of *(9)*. The diatropic effect is enhanced when *(9)* is protonated. Differences in the chemical shifts between the neutral and protonated species of *(9)* are even larger than those observed in the case of *(8)*; this also underlines the significance of the peripheral conjugation in *(9)*.

The Cyclohepta[*cd*]phenalenium Ion[**]

By *Ichiro Murata, Kagetoshi Yamamoto*, and *Yutaka Kayane*[*]

Although there has been considerable interest in the neutral nonalternant isomers of pyrene, the ionic 14π perimeter species which are isoelectronic with pyrene have received little attention. According to theoretical predictions by *Zahradnik*[2] the cyclohepta[*cd*]phenalenium ion *(4)* ought to be quite stable.

[**] The Chemistry of the Phenalenium System, Part 19.—Part 18: [1].

Here we describe the synthesis of *(4)* as the first example of a 14π perimeter cationic system.

Reduction of cyclohepta[*cd*]phenalen-6-one *(1)*[1] with $LiAlH_4$—$AlCl_3$ complex in ether at −50 °C for 2 h led to a mixture of isomeric hydrocarbons, 6*H*- *(2)* and 7*H*-cyclohepta[*cd*]phenalene *(3)* (in a ratio of about 9 : 13). The mixture was isolated in 56% yield after chromatography (hexane) on alumina deactivated with 10% water. All manipulations during the reaction and work-up have to be carried out under nitrogen in order to avoid decomposition of the products. Although compounds *(2)* and *(3)* could not be separated due to their pronounced sensitivity toward air and heat, their structural assignments were readily borne out by 100-MHz ^{1}H-NMR and double resonance experiments. The mixture showed signals for *(2)* at δ = 2.71 (2H-6, d, $J_{6,7}$ = 6.7 Hz), 5.51 (H-7, dt, $J_{7,6}$ = 6.7, $J_{7,8}$ = 9.2 Hz), 6.33 (H-8, dd, $J_{8,7}$ = 9.2, $J_{8,9}$ = 6.5 Hz), 6.84 (H-9, d, $J_{9,8}$ = 6.5 Hz), and for *(3)* at δ = 1.66 (2H-7, dd, $J_{7,6}$ = 7.3, $J_{7,8}$ = 6.5 Hz), 4.82 (H-8, dtd, $J_{8,7}$ = 6.5, $J_{8,9}$ = 8.5, $J_{8,6}$ = 2.4 Hz), 5.27 (H-6, td, $J_{6,7}$ = 7.3, $J_{6,8}$ = 2.4 Hz), and 6.66 (H-9, d, $J_{9,8}$ = 8.5 Hz) along with signals for the aromatic protons at 7.02—8.07 ppm. Irradiation at δ = 2.71 [H-6 of *(2)*] simplified the multiplet at δ = 5.51 attributed to H-7 of *(2)* into a clean doublet with J = 9.2 Hz. Another irradiation at δ = 1.66 [H-7 of *(3)*] changed the multiplets at δ = 5.27 and δ = 4.82 into a broad singlet and a broad doublet, respectively. The mass spectrum of a mixture of *(2)* and *(3)* exhibits peaks at *m/e* = 216 (M^+, 100%), 215 ($M^+ - H$, 73%) and 202 (pyrene ion, 21%).

Hydride abstraction from the freshly prepared mixture of *(2)* and *(3)* with triphenylmethyl tetrafluoroborate in chloroform at room temperature gave the desired cation *(4)*[3] in 79% yield [reddish brown crystals, which sinter at 199—201 °C and show no definite m.p.; IR (KBr): 1040 cm^{-1} (strong, broad, BF_4^-); UV (acetonitrile): λ_{max} = 224 (log ε = 4.40), 257 (3.99), 291 (4.37), 307 (4.37, sh), 316 (4.40), 334 (4.18, sh) and 475 nm (4.49)][4]. The 100-MHz ^{1}H-NMR spectrum of *(1)* in CF_3COOD consists of superimposed signals of AA'XX', 2AB and A_2B spin systems at δ = 9.08 (H-7,8 or H-6,9), 9.66 (H-6,9 or H-7,8), 9.16 (H-5,10)[5], 9.50 (H-4,11)[5], 9.40 (H-1,3) and 9.00 (H-2) with coupling constants of $J_{6,7} = J_{8,9}$ = 10.9, $J_{7,8}$ = 9.0, $J_{6,8} = J_{7,9}$ = 1.4, $J_{6,9}$ = 0, $J_{4,5} = J_{10,11}$ = 8.9 and $J_{1,2} = J_{2,3}$ = 7.7 Hz. Both the appreciable downfield chemical shift with rather narrow range (δ = 9.00—9.66 ppm) and the symmetrical pattern of the signals show the species to have fully delocalized structure with C_{2v}-symmetry.

Despite the fact that a unit positive charge resides over the fifteen peripheral carbon atoms, the ^{1}H-NMR signals of *(4)* are comparable to those of the tropylium ion (δ = 9.20 in CH_3CN)[6] and of the phenalenium ion (δ = 9.30 and 8.48 in $AsCl_3$)[7]. This proves the existence of a strong induced diamagnetic ring current associated with the 14π perimeter of *(4)*. These findings suggest that the ion *(4)* can be regarded as a perturbed [15]annulenium ion weakly coupled with a localized central vinyl crosslink.

In accord with theoretical prediction[2], the ion *(4)* is extremely stable. *(4)* (as tetrafluoroborate) can be stored without any change under atmospheric conditions. Furthermore, *(4)* shows essentially the same UV spectrum in water as in acetonitrile. The pK_{R^+} value of *(4)* was found to be ≥ 8.4[8]; this is about 1pK unit larger than of the 8-cycloheptatrienylheptafulvenyl cation (pK_{R^+} = 7.1[9], 7.49[10]). To our knowledge, *(4)* is the most stable hydrocarbon cation so far reported.

[7] *H. Prinzbach, V. Freudenberger*, and *U. Scheidegger*, Helv. Chim. Acta, *50*, 1087 (1967).

[8] Standard spectrophotometric methods were used for the pK_{R^+} determination in 20% aqueous acetonitrile solution. Each absorbance of 475 nm at various pH values was measured 90 s after preparation of the solution. The pK_{R^+} value of 8.4 thus obtained is the lower limit, since the intensity of absorbance decreases with elapse of time in the pH range near pK_{R^+}. Thus, the measurement at 180 s after preparation of the solution yields a somewhat small value of 8.1 for the pK_{R^+} of *(4)*.

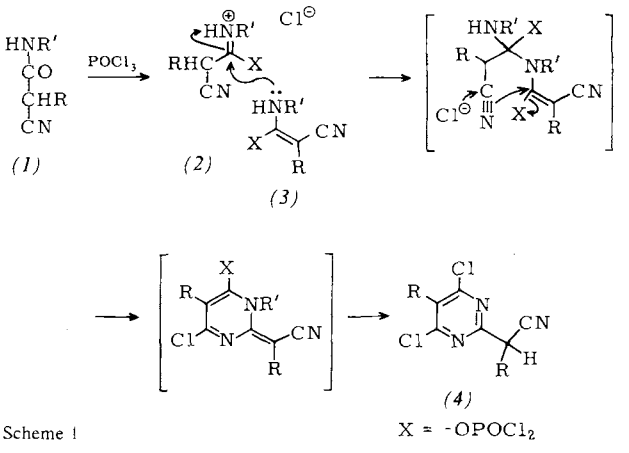
Synthesis of Pyrimidines from 2,*N*-Dialkylcyanoacetamides[1]



By *A. L. Cossey, R. L. N. Harris, J. L. Huppatz*, and *J. N. Phillips*[*]

We have previously reported on novel syntheses of pyridines and pyridinium salts from variously substituted cyanoacetamides[2]. We now describe a further extension of this reaction to the synthesis of pyrimidine derivatives.

When 2-cyano-*N*-methylpropionamide *(1a)* was heated with phosphorus oxide trichloride at 100 °C for 16 h a product was isolated to which the structure *(4a)* was assigned on the basis of the following findings: microanalysis and high resolution mass spectral data indicated the formula $C_8H_7N_3Cl_2$; the IR band at 2258 cm^{-1} is consistent with an unconjugated nitrile, and the NMR spectrum (D_6-DMSO) showed signals at δ = 2.43 (s, 1 ring CH_3), 1.65 (d, 1 side chain CH_3, J = 3.5 Hz), and 4.6 (q, 1 methine H, J = 3.5 Hz). On deuteration the methine proton exchanged, and the signal due to the adjacent methyl group collapsed to a singlet at

CSRIO, Division of Plant Industry
Canberra, A.C.T. 2601 (Australia)

$\delta = 1.7$. Furthermore, when *N*-ethyl-2-cyanopropionamide *(1b)* was similarly treated, the product was identical to that described above, confirming that one alkylamino group and an *N*-alkyl group were lost during the self-condensation.

Scheme 1

We believe that the pyrimidine derivatives *(4)* are formed *via* the route shown in Scheme 1 (cf. Ref. [2]) in which the key step is the formation of a C—N bond in the condensation of the salt *(2)* with its corresponding base *(3)*.

(For further examples of this reaction see Table 1.)

Table 1. Pyrimidines *(4)* from the reaction of 2,*N*-dialkylcyanoacetamides *(1)* and $POCl_3$ [3].

Educt	R	R'	Product	Yield [%]	M.p. [°C]
(1a)	CH_3	CH_3	*(4a)*	26	83—84
(1b)	CH_3	C_2H_5	*(4a)*	23	83—84
(1c)	C_2H_5	CH_3	*(4b)*	37	39—40
(1d)	C_2H_5	C_2H_5	*(4b)*	40	39—40
(1e)	i-C_3H_7	CH_3	*(4c)*	44	43—45

2-(4,6-Dichloro-5-methylpyrimidinyl)propionitrile (4a)

(1a) (5.6 g, 0.05 mol) and $POCl_3$ (16 g, 0.11 mol) are heated on a steam bath under reflux in absence of moisture for 16 h. The reaction mixture is then cooled, cautiously poured into icewater and rendered alkaline with 20% NaOH. The crude product is extracted into chloroform (3 × 50 ml) and the combined extracts washed and dried over Na_2SO_4. The solvent is removed and the residue chromatographed on a silica gel column (30 × 4 cm). Elution with chloroform/petroleum ether (b. p. 40—60 °C (2:1)) affords *(4a)* as a colorless oil (1.4 g, 26%), which solidifies and can be crystallized from ethanol as colorless prisms (m.p. 83—84 °C).

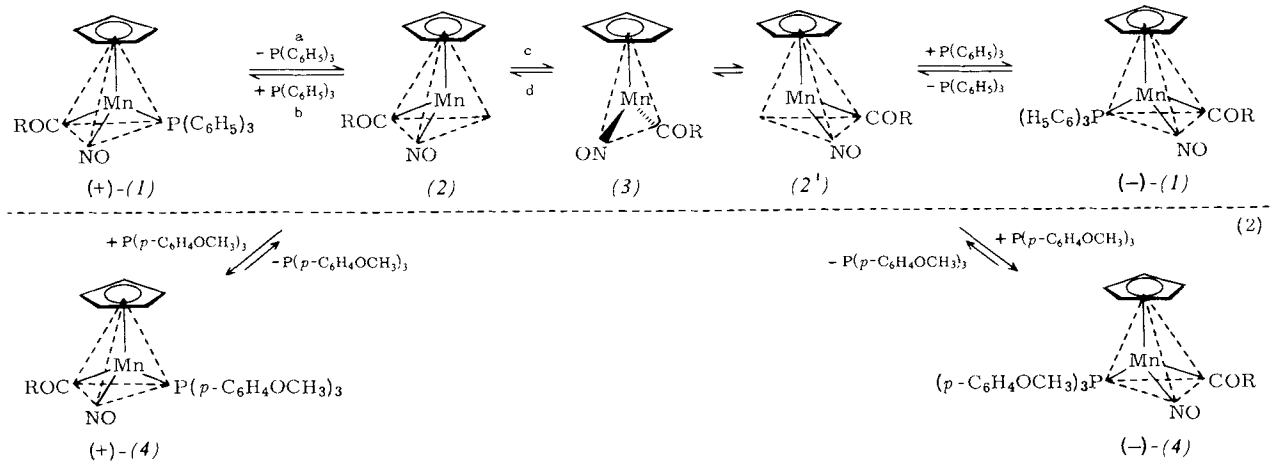
Evidence for a Chiral Intermediate on Phosphane Substitution in the Complex $(+)$-$C_5H_5Mn(NO)(COC_6H_5)P(C_6H_5)_3$[1]

By *Henri Brunner, Jean Aclasis, Manfred Langer*, and *Wolfgang Steger*[*]

Racemization of the species (+)- and (−)-$C_5H_5Mn(NO)(COOCH_3)P(C_6H_5)_3$ in benzene or tetrahydrofuran solution is a first order reaction with respect to the complex concentration; it is independent of the concentration of added triphenylphosphane[2]. In the presence of $P(C_6D_5)_3$ the deuterated triphenylphosphane is incorporated into the complex[3], the rate constants for racemization and phosphane exchange proving to be identical. These findings are consonant with the simple dissociative racemization mechanism (1) whose rate-determining step is cleavage of the Mn—P bond[2, 3].

(1)



The newly found benzoyl complex (+)-$C_5H_5Mn(NO)(COC_6H_5)P(C_6H_5)_3$ (+)-*(1)* also undergoes first order racemization in solution. In contrast to the ester (+)-$C_5H_5Mn(NO)(COOCH_3)P(C_6H_5)_3$, however, this racemization is concentration dependent; it proceeds slightly faster in dilute solution than in concentrated solution. Moreover, the racemization of (+)-*(1)* is retarded by addition of $P(C_6H_5)_3$ (Table 1). Since the phosphane concentration does not change during polarimetric measurement the change in rotation with time can be evaluated according to first order kinetics for each addition of phosphane.

This dependence upon concentration and triphenylphosphane can be interpreted by an extension of the simple dissociation mechanism (1) [cf. (2)].

The three-coordinate chiral intermediate *(2)* arising on dissociation of (+)-*(1)* (reaction step a) can either revert to (+)-*(1)* with retention of configuration in the presence of $P(C_6H_5)_3$ (step b) or achieve planarity with loss of chirality (step c). Promotion of reaction b compared to c explains the retardation of racemization at higher concentrations and on addition of $P(C_6H_5)_3$.

It remains to be established whether *(3)* is an intermediate or a transition state. Assumption of the chiral intermediates *(2)* and *(2')*, on the other hand, is supported by kinetic and stereochemical arguments. Similar intermediates have been postulated in the reaction of $C_5H_5Fe(CO)_2R$ with nucleophiles L[5].

Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

(2)

Applying the Bodenstein steady state concept to Scheme 2 and appropriate simplification affords the expression

$$\frac{k_c}{k_b} = \frac{k_{with} \times [P(C_6H_5)_3]}{k_{without} - k_{with}}$$

where k_b and k_c are the rate constants for steps b and c in (2) and k_{with} and $k_{without}$ are the rate constants for racemization of (+)-(1) with and without addition of $P(C_6H_5)_3$. Table 1 reveals that the competition constant k_c/k_b remains constant on variation of the complex to triphenylphosphane concentration ratio from 1:1 to 1:20. Hence the observed $P(C_6H_5)_3$ dependence of racemization is also quantitatively compatible with Scheme (2).

Table 1. Racemization of (+)-(1) in toluene, $c = 3.86 \times 10^{-3}$ mol/l, at 25 °C with addition of $P(C_6H_5)_3$ in the molar ratio 1:x.

x	$\tau_{1/2}$ [min]	$k_{with} \times 10^4$ [s^{-1}]	$k_c/k_b \times 10^2$ [mol/l]
1	22.1	5.23	7.5
2	23.7	4.87	6.0
3	25.2	4.58	5.8
4	26.5	4.36	5.9
5	28.0	4.13	5.8
6	29.0	3.98	6.1
7	30.6	3.78	5.9
8	32.0	3.61	5.9
10	34.5	3.35	6.0
20	45.0	2.57	6.8
0	21.0	$k_{without} = 5.50 \times 10^{-4}$ [s^{-1}]	

In solutions of (1) the triphenylphosphane ligand can be replaced by tri-*p*-anisylphosphane. Optically active (4) ($\tau_{1/2}$ 337 min, toluene, 20 °C) racemizes much more slowly than optically active (1) ($\tau_{1/2}$ 50 min, toluene, 20 °C).

If racemization of (+)-(1) ($[\alpha]_{546}^{25}$ +255°; $[\alpha]_{436}^{25}$ −1680°; 2 mg/ml toluene) is performed in toluene at 20 °C in the presence of a fivefold excess of tri-*p*-anisylphosphane and interrupted after 50 min, chromatography of the reaction mixture over SiO_2 at −25 °C affords approximately equal amounts of unchanged (+)-(1) ($[\alpha]_{546}^{25}$ +210°; $[\alpha]_{436}^{25}$ −1620°) as the first zone (toluene/ether 10:1) and the optically active substitution product (+)-(4) ($[\alpha]_{546}^{25}$ +130°; $[\alpha]_{436}^{25}$ −815°) as the second zone (toluene/ether 5:1). The latter compound is ascribed the same configuration as (+)-(1) on the basis of its chiroptical properties.

Thus according to Scheme (2) substitution of triphenylphosphane by other ligands with retention of configuration is possible, although the mechanism is dissociative. Racemization of the esters (+)- and (−)-$C_5H_5Mn(NO)(COOCH_3)P(C_6H_5)_3$ probably also follows mechanism (2) even though the chiral intermediates defy detection in this case owing to the far greater competition constant. Formation of a chiral intermediate on dissociation of (+)-(1) appears significant with regard to the stereochemistry, rearrangement, and reactions of photochemically generated carbonylmetal fragments[4].

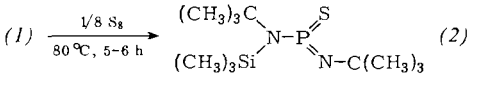
Trimethylsilyl(*tert*-butyl)amino(*tert*-butyl)iminothiophosphorane—A Derivative of Monomeric Metathiophosphoric Acid

By *Otto J. Scherer* and *Norbert Kuhn*[*]

Attempts to isolate the λ^5-phosphorus compounds having coordination number 3 (*e.g.* metaphosphoric acid derivatives) which have repeatedly been postulated[1] as intermediates have so far only succeeded in a single case, that of a completely *N*-silylated aminobis(imino)phosphorane[2]. It has now been found that P^{III} and P^{V} having the unusual coordination number 2 and 3, respectively, are apparently stabilized to an even greater extent by *N*-*tert*-butyl groups than by *N*-trimethylsilyl groups.

(1)

[*] Prof. Dr. O. J. Scherer and Dipl.-Chem. N. Kuhn
Fachbereich Chemie der Universität
675 Kaiserslautern, Postfach 3049 (Germany)



Reaction of phosphorus tribromide with lithium (*tert*-butyl)-(trimethylsilyl)amide in the molar ratio 1:2 furnishes a *ca.* 30% yield of trimethylsilyl(*tert*-butyl)amino(*tert*-butyl)iminophosphane *(1)*.

Compound *(1)* is a distillable yellowish green liquid, m.p. 17—19 °C. In its stability, the compound differs considerably from the trisilylated analog[2], the only known phospha(III)azene[3]. Whereas the latter reacts already at room temperature with carbon tetrachloride, trimethylsilyl azide, or sulfur[4], *(1)* requires elevated temperatures for such reactions[5]. A solution of *(1)* undergoes *ca.* 10% decomposition on exposure to air (open NMR sample tube) for 20 h; the analogous persilylated compound undergoes quantitative conversion within *ca.* 2 h. Hydrolysis of *(1)* in the presence of oxygen affords good yields of $[(CH_3)_3CNH]_2P(O)—O—P(O)[HNC(CH_3)_3]_2$, a diphosphoric tetraamide.

^{1}H-NMR spectrum (10% solution in C_6H_6; TMS internal; 37 °C): $\delta CH_3Si = -0.43$ ppm (d), $^4J_{PH} = 0.5$ Hz; $\delta CH_3C = -1.38$ ppm (d), $^4J_{PH} = 2.1$ Hz. The temperature dependence of the spectrum (at −30 °C: $\delta(CH_3)_3C$ = doublet; $^4J_{PH} = 1.9$ and 2.4 Hz, $\Delta\nu = 6.0$ Hz; coalescence temperature = 0 °C; $\Delta G_c^{\ddagger} = 14.5$ kcal/mol[6]) reveals that the $(CH_3)_3Si$ group fluctuates at room temperature[7].—^{31}P-NMR spectrum (20% solution in C_6H_{12}; H_3PO_4 external): $\delta = -327.5$ ppm (greatest downfield shift yet observed[8]).

UV spectrum[9] (*n*-heptane): $\lambda_{max} = 278$ (log ε = 3.40, probably $\pi\rightarrow\pi^*$ transition), 345 nm (2.00, probably $n\rightarrow\pi^*$ transition). Mass spectrum (20 eV): *m/e* = 246 (21%, M^+), 231 (8), 190 (100), 175 (26), 135 (26), 73 (9), 57 (5).

Compound *(1)* is oxidized by sulfur at 80 °C in *ca.* 80% yield to trimethylsilyl(*tert*-butyl)amino(*tert*-butyl)iminothiophosphorane *(2)*, the first isolable monomeric metathiophosphoric acid derivative.

Compound *(2)* is a distillable yellowish green liquid, m.p. 1—3 °C, which is stable to at least 100 °C. At room temperature, no exchange of the $(CH_3)_3Si$ group is observed in the ^{1}H-NMR spectrum (10% solution in CCl_4, TMS internal): $\delta CH_3Si = -0.45$ ppm (s); $\delta CH_3C(N=) = -1.35$ ppm (d), $^4J_{PH} = 1.5$ Hz; $\delta CH_3CN(Si) = -1.57$ ppm (s).—^{31}P-NMR spectrum (30% solution in C_6H_{12}; H_3PO_4 external): $\delta = -136.0$ ppm.—Mass spectrum (22 eV): *m/e* = 278 (5%, M^+), 263 (41), 246 (47), 223 (25), 207 (100), 190 (16), 73 (33), 57 (19). Unlike *(1)*, compound *(2)*, which readily dissolves in aprotic organic solvents, is extremely sensitive to hydrolysis.

Experimental:

(1): A solution of $(CH_3)_3CNHSi(CH_3)_3$ (22.2 g, 153.1 mmol) in ether (100 ml) is metalated with a *n*-C_4H_9Li/hexane solution (92 ml, 153.1 mmol) and refluxed for 2 h. The resulting solution is added dropwise over 2 h to a solution of PBr_3[10] (20.7 g, 76.5 mmol) in ether (250 ml) at −78 °C, the reaction mixture stirred for *ca.* 12 h and evaporated down in a water pump vacuum. The product is taken up in pentane (30 ml) and filtered through a G3 frit. Fractional distillation (b.p. 60—90 °C/0.2 torr; bath temperature up to 130 °C) and redistillation (Vigreux column) affords *(1)* (b.p. 38—40 °C/0.1 torr; yield 6.0 g, 32%).

(2): A solution of *(1)* (3.5 g, 14.2 mmol) in benzene (15 ml) is refluxed with sulfur (480 mg, 15 mmol) for 5—6 h. Fractional distillation furnishes *(2)* (b.p. 56—58 °C/0.01 torr; yield 3.1 g, 78%).

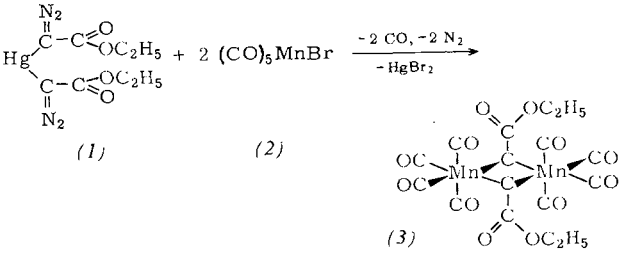
[9] Compound *(1)*, which can formally be regarded as a triazene derivative in which one N atom is replaced by P, differs markedly in color from comparable colorless $(CH_3)_3Si(CH_3)N—N=N—CH_3$: *F. E. Brinckman, H. S. Haiss,* and *R. A. Robb,* Inorg. Chem. *4*, 936 (1965).



[10] On use of equimolar amounts of PCl_3, *(1)* is formed in *ca.* 20% yield.

Pentacarbonylmanganese Bromide—An Organometallic Trapping Reagent for Ethoxycarbonylcarbyne[1]

By *Wolfgang Anton Herrmann*[*]

On UV photolysis in cyclohexene, bis(ethoxycarbonyldiazomethyl)mercury *(1)* affords products whose formation can be attributed to the intermediacy of ethoxycarbonylcarbyne (ethoxycarbonylmethylidine)[2]. We have now been able to trap this extremely reactive intermediate directly for the first time.

If the diazo compound *(1)* is allowed to react with pentacarbonylmanganese bromide *(2)* in the molar ratio 1:2, work-up of the crude product by column chromatography yields a pale yellow readily crystallizing neutral compound which is stable up to about 130 °C; total elemental analysis and osmometric molecular weight determination indicate the composi-

[*] Dr. W. A. Herrmann
Fachbereich Chemie der Universität
84 Regensburg 1, Universitätsstrasse 31 (Germany)

tion $C_{16}H_{10}O_{12}Mn_2$. On the basis of analytical data and the following arguments the new complex is assigned the structure *(3)* in which two tetracarbonylmanganese fragments are symmetrically bridged by two ethoxycarbonylcarbyne ligands.

1) In the ^{1}H-NMR spectrum (60 MHz; 33 °C) the methylene protons appear as a quartet at $\tau = 5.64$, the methyl protons as a triplet at $\tau = 8.65$ in the intensity ratio 2:3 (CD_2Cl_2; internal TMS). No hindrance to free rotation of the ester groups about the C—C axes can be observed in the ^{1}H-NMR spectrum down to −70 °C.

2) In the mass spectrum (70 eV; direct sample injection at 120 °C; $T_0 = 40$—60 °C) the molecular ion M (*m/e* = 504) is accompanied, *inter alia*, by the complete fragmentation sequence $M - nCO$ ($n = 1$ to 8). Hence *(3)* contains eight carbonyl groups bound to the metal.

3) In accord with group-theoretical predictions for a molecule of point group D_{2h}, the IR spectrum (*n*-hexane) contains four bands in the range of the ν_{CO} fundamental vibration (B_{3u}(a), 2076 m; B_{1u}, 2004 vs; B_{3u}(b), 1993 w-s; B_{2u}, 1956 cm^{-1} vs) whose positions and intensities resemble those of the IR absorptions of the isostructural complexes $[(CO)_4MX]_2$ (M = Mn, Tc, Re; X = Cl, Br, I)[3].

4) The numbers of calculated and observed Raman active ν_{CO} fundamental vibrations agree: The four emission bands (B_{2g}, 2090 vs; B_{1g}, 1999 vs; A_g(a), 1954 m; A_g(b), 1935 cm^{-1} m) are not coincident with the IR absorptions owing to the selection rule applicable to *(3)* owing to centrosymmetry.

5) The highly symmetric charge distribution resulting for the proposed structure is confirmed by the virtual absence of a dipole moment in *(3)* ($\mu = 0.18 \pm 0.15$ Debye; cyclohexane, 25 °C).

6) The experimentally detected diamagnetism corresponds to the noble gas configuration in *(3)*. Each one of the ethoxycarbonylcarbyne bridges acts as a three-electron ligand and thus resembles the monodentate (aryl)alkylcarbyne ligands[4].

Di-μ-ethoxycarbonylcarbynebis(tetracarbonylmanganese) (3):

All operations are performed in an inert atmosphere (N_2) using dry (Na/K) nitrogen-saturated solvents. Compounds *(1)* (1.28 g, 3 mmol)[5] and *(2)* (1.65 g, 6 mmol)[6] are refluxed in diethyl ether (200 ml) for 10 h. After removal of the solvent, the benzene-soluble portion of the crude product is filtered (G4 frit). The filtrate is concentrated by evaporation and then chromatographed on silica gel (Merck 7734, activity grade I; water-cooled column). Elution with *n*-hexane affords a little *(2)* as light yellow zone. With *n*-hexane/benzene (5:1) an orange-yellow zone migrates which affords fine needles of *(3)* on concentration and repeated crystallization (*n*-pentane, −85 °C); yield 570 mg (38 %).

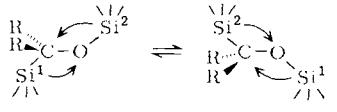
Dyotropic Rearrangement of (Silyl)methyl Silyl Ethers[1][**]



By *Manfred T. Reetz, Miroslav Kliment*, and *Michael Plachky*[*]

Dyotropic rearrangements of the type *(1)* ⇌ *(2)* are thermally forbidden pericyclic $[_\sigma 2_s + _\sigma 2_s]$ processes[2]. However, if the migrating groups possess low-lying unoccupied orbitals of proper symmetry then the constraints imposed by orbital symmetry can be lifted[3].

(1) *(2)*

In order to test this hypothesis we synthesized compounds of type *(3)*[4], expecting the silyl groups having empty d orbitals to undergo positional exchange on thermolysis.

(3) *(4)*

(a): R + R = biphenyl-2,2'-ylene
Si^1 = trimethylsilyl
Si^2 = [D_9]-trimethylsilyl

(b): R + R = biphenyl-2,2'-ylene
Si^1 = trimethylsilyl
Si^2 = dimethylphenylsilyl

If compounds *(3)* are heated to 140 to 175 °C in inert solvents (*e.g.* benzene) the rearrangement products are indeed formed, the reaction leading to an equilibrium: *(3a)*:*(4a)* = 1.0 (164 °C); *(3b)*:*(4b)* = 0.9 (164 °C). Thermolysis of compounds *(4)* prepared by an independent route[4] led to the same equilibrium. No by-products were formed.

Mechanistic evidence resulted from the following findings:

1) Crossover experiments showed the reaction to be strictly *intramolecular*.

2) The rate of rearrangement depends only slightly on the polarity of the solvent: k_{rel} for *(3b)* → *(4b)*: 1.0 (benzene): 1.8 (*o*-dichlorobenzene): 3.5 (propylene carbonate).

3) Activation parameters for *(3b)* → *(4b)*, measured in benzene, are: $E_a = 31.1 \pm 0.6$ kcal mol^{-1}; $\Delta H^{\neq} = 30.3 \pm 0.6$ kcal mol^{-1}; $\Delta S^{\neq} = -8.6 \pm 0.8$ cal mol^{-1} deg^{-1}.

4) Stereochemical investigations show that a chiral silyl group[5] migrates from the C to the O atom with >95 % *retention* of configuration. The same applies to the reverse reaction from the O to the C atom.

The results fail to support the occurrence of ions, zwitterions, or radicals. They are best compatible with a dyotropic mechanism in which both silyl groups undergo migration. Whether a symmetrical transition state is involved, or whether one of the silyl groups migrates faster than the other, cannot be deduced from the information available. However, the similarity between the present activation parameters and those for the related rearrangement of (silyl)methyl allyl ethers[1],

Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

in which a silyl and an allyl group migrate, can be regarded as evidence in favor of an asymmetrical transition state. In any case, the silyl group shift brings about a kind of Walden inversion of the substituents attached to the stationary C atom. This prediction is currently under investigation[6].

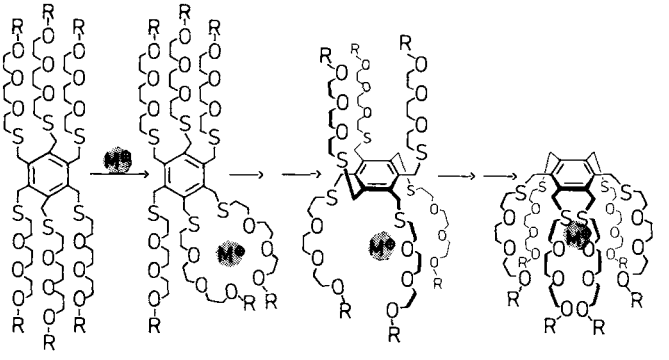
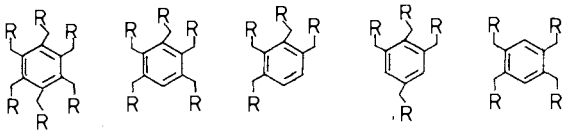
Octopus Molecules[**]

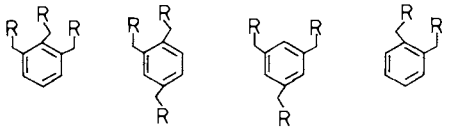


By *Fritz Vögtle* and *Edwin Weber*[*]



Knowledge gained about "coronates"[1], catapinates, and cryptates[2] has induced us to synthesize acyclic but "many-armed" polyether, complex-forming ligands of type *(1a)*, in which each "arm" is fitted with numerous donor atoms. Here we not only report about the unusual complexing tendency of such ligands but also show how their conformational mobility is impeded by spatial crowding.

The hexasubstituted benzene derivative *(1a)* containing 18 oxygen atoms is obtained as a yellowish, viscous oil ($\delta = 4.10$)[3], which is *insoluble in water*, on reaction of benzenehexakis(methanethiol) and 1-bromo-3,6,9-trioxatridecane ("1-bromotriethyleneglycol ω-butyl ether"). It is a remarkably powerful complex ligand for cations since a solution of *(1a)* in dichloromethane removes a great part of the picrate from 10^{-4} N aqueous alkaline-earth picrate solutions (Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}) and almost the entire salt from alkali-metal picrate solutions (Li^+, Na^+, K^+, Rb^+, Cs^+) from the aqueous into the organic phase[4].



This occurs faster and more completely than can be achieved with known crown ethers[5]; only cryptate ligands such as "[2.2.2]" and "[2.2.1]" are equally effective. The usual oligoethers, glycols, and comparative substances such as 1-bromotriethyleneglycol ω-butyl ether and triethyleneglycol butyl ether have no such action under analogous conditions.

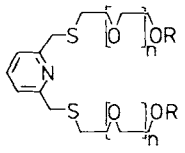
According to a study with space-filling models the unexpectedly strong complex formation by *(1a)* (which invites a study of polyfunctional acyclic biomolecules) must be accompanied by considerable conformational changes. It shows remarkable phenomenological parallelisms to the mode of food capture by an octopus using its suction pads[6].

(1) *(2)* *(3)* *(4)* *(5)*

(6) *(7)* *(8)* *(9)*

	R
(a)	S O O O C_4H_9
(b)	S O O CH_3
(c)	S-α-C_5H_5N
(d)	SCH_3
(e)	$SCH(CH_3)_2$
(f)	S-n-C_4H_9
(g)	S-n-$C_{12}H_{25}$
(h)	S-⬡
(i)	S-⬡
(k)	SO_2CH_3

Picric acid itself can also be easily extracted from aqueous solution by dichloromethane that contains an "octopus molecule" such as *(1a)*. Also remarkable is the, admittedly weak, complexing of cobalt thiocyanate by *(1a)* and its partial transfer into the dichloromethane phase. Heavy-metal salts such as $CuCl_2$, $NiCl_2$, $Ce(SO_4)_2$, $Pr(NO_3)_3$, and $Nd(NO_3)_3$ could not be extracted from water by dichloromethane solutions of *(1a)* or by crown ethers and "[2.2.2]" (under comparable conditions).



A distinct fall in complexing tendency occurs if the number of donor positions is decreased, either by shortening of the arms as in *(1b)* (colorless viscous oil; $\delta = 4.11$) or by successive diminution of their number. Among position isomers with equal numbers of arms the 1,3,5-isomer *(8)* and, on presence of only two substituents, the 1,2-disubstituted system *(9)* stand out for powerful ligand properties. *(8a)* is certainly less efficient than *(1a)* having three more arms, but it is more effective than *(6a)* and even than *(4a)*; here steric factors (see below), lipophilic character, and solubility properties of the ligand seem to be important[2].

Complex-formation by the crystalline potential ligand *(1c)* (m.p. 262 °C, dec.; $\delta = 4.54$, in pyridine) that contains six pyridine rings is hard to establish because of the sparing solubility. The *water-insoluble* pyridine derivatives *(10)* and *(11)* (colorless viscous liquids; $\delta = 3.97$ and 3.85, respectively) have special phase-transfer properties: although alkaline-earth- and alkali-metal picrates cannot be thereby extracted from aqueous solution, picric acid dissolved in water is rapidly and completely transferred into the organic phase (dichloromethane). This does not occur with comparable substances such as pyridine under analogous conditions. Further, in methanol *(10)* forms

a deep-green copper(II) complex, but no interaction is observable with other heavy-metal ions such as Co^{2+} or Ni^{2+}.

(10), n=1, R = CH_3
(11), n=2, R = C_4H_9

Oxygen-free hexasubstituted benzene derivatives *(1d)*—*(1f)*, *(1h)*[7] as well as *(1g)*, *(1i)*, and the hexasulfone *(1k)* were investigated for comparison and naturally have no complex-ligand properties.

The free ligand molecule *(1a)* gives an unexpected ^{1}H-NMR spectrum (Fig. 1), from which conclusions can be drawn about intramolecular mobility phenomena that are slow on the NMR time scale: the signals of the α- and γ-methylene protons are considerably broadened at room temperature. Increase in temperature sharpens all the signals, cooling broadens them further. Clearly there is steric overcrowding in the hexasubstituted system *(1)*[8].

shorter chains, as is shown by the very marked broadening of the signals of the α-methylene protons.

Whereas *(1h)* shows a barely broadened benzyl singlet (δ = 4.29) in spite of the six space-filling phenyl substituents, the sulfone *(1k)* (m.p. >350 °C, dec; δ = 5.13) exhibits somewhat broadened CH_2 signals even at room temperature. Remarkable also is the finding that introduction of six sterically demanding 2,6-dimetbylphenyl groups as in *(1i)* (m.p. 248 to 251 °C; δ = 3.76)[3] does not notably increase the steric crowding over *(1h)*; the 36 CH_3 protons appear as a sharp singlet [δ(CH_3) = 2.30 in $CDCl_3$].

As the number of side chains decreases, the signal broadening becomes less; the steric interactions presently appear to be in the order *(1a)* > *(2a)* (δ = 3.59—4.18) > *(3a)* (δ = 4.02, 4.23) > *(4a)* (δ = 3.77, 3.92, 4.10) > *(5a)* (δ = 4.2); and with *(6a)* (δ = 4.17, 3.98), *(7a)* (δ = 3.98), *(8a)* (δ = 3.83), and *(9a)* (δ = 4.02) interaction is no longer unequivocally detectable. Replacing a benzene-hydrogen atom that is not contiguous to the interacting substituents, as in the change from *(6a)* to *(4a)* or from *(7a)* to *(5a)*, may increase the hindrance to rotation, and this can be interpreted as a steric buttressing effect[11].

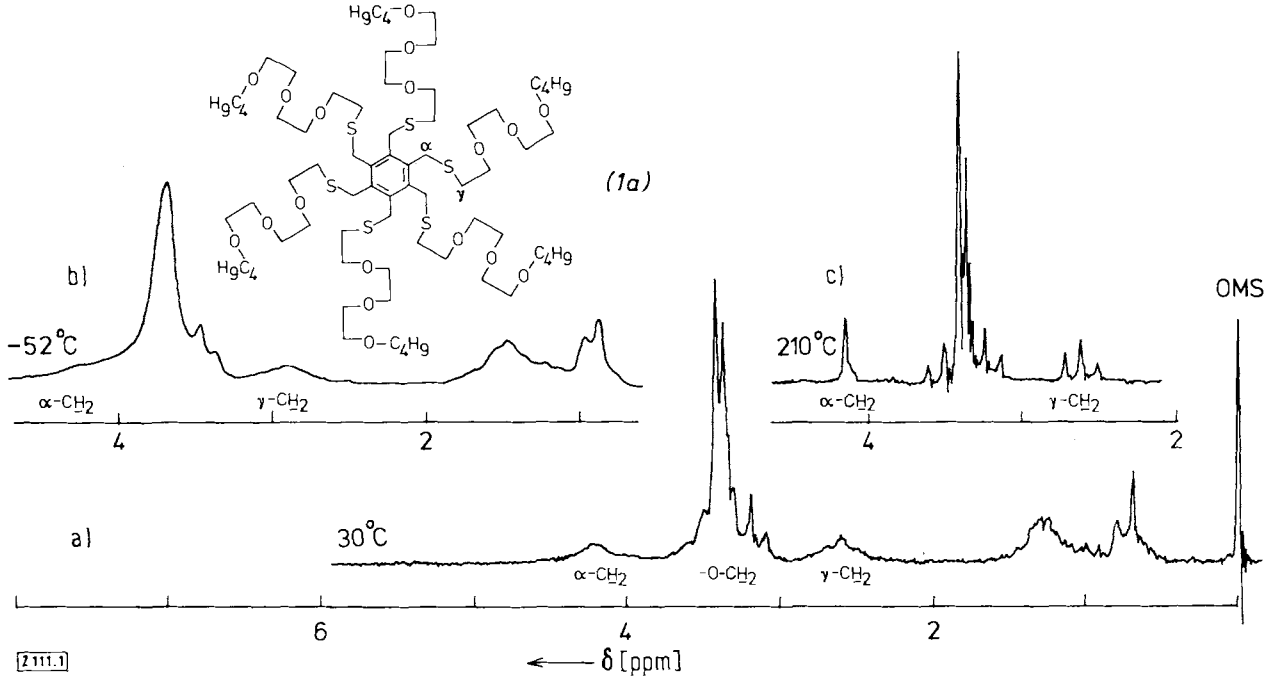

Fig. 1. ^{1}H-NMR spectrum of *(1a)* at several temperatures. a) and c) in diphenyl ether, b) in $CDCl_3$; 60 MHz. OMS = octamethylcyclotetrasiloxane.

We wished to discover whether this steric effect (a) was a characteristic of the polyoxa compounds *(1a)* and *(1b)* for which the heteroatoms or coiling of the arms would be responsible, or (b) was to be ascribed in general to steric overcrowding in the persubstituted benzene ring; so we studied the proton resonance of the hexaorganothio compounds *(1d)*—*(1i)* which contain substituent chains of different lengths and different branching, as well as the hexasulfone *(1k)*. It transpired that here too broadening of the benzylic CH_2 signals could occur: whereas no steric hindrance of rotation could be detected in *(1d)* (δ = 4.12) or in hexakis(bromomethyl)benzene[9] (δ = 4.71 in $CHBr_3$ at 158 °C)[10] by ^{1}H-NMR spectroscopy, we found somewhat broadened signals of the α- and γ-methylene-protons already for *n*-butyl substitution *(1f)* (δ = 4.14). The longer alkyl chains of, particularly, *(1g)* (m.p. 38—39 °C; δ = 4.16) with their greater effective steric requirements, cause steric overcrowding that is greater than for the

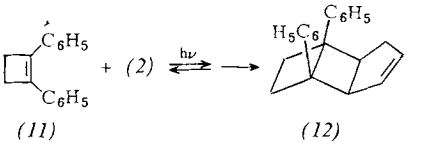
1,4-Diphenylbicyclo[2.2.0]hexanes from 1,2-Diphenylcyclobutenes[**]

By *Gerd Kaupp, Christoph Küchel*, and *Inge Zimmermann*[*]

All previously reported [2π+2π] photocycloadditions of diphenylacetylene to isolated or conjugated double bonds have led only to 1,2-diphenylcyclobutene derivatives or to the valence isomers derivable from them[1]. We now report intermolecular consecutive additions and preparatively interesting quantum yields of the photosynthesis of 1,4-diphenylbicyclo[2.2.0]hexanes from 1,2-diphenylcyclobutenes. Because of the longer lifetime of the fluorescent excited states and, presumably, substantial chromophore leveling, the conditions for such additions are much more favorable than in the case of open-chain *cis*-stilbenes, which do not undergo photocycloadditions[2].



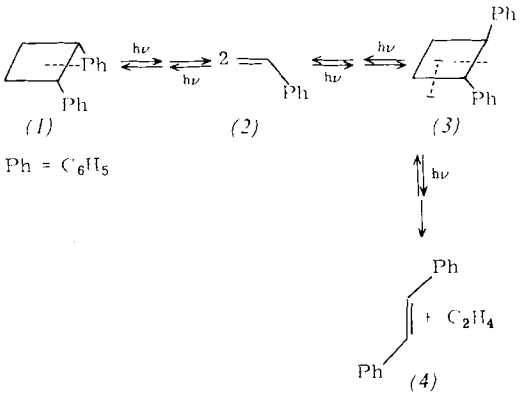
The photolysis of diphenyl acetylene *(1)* in cyclopentadiene *(2)* (pyrex filter, −30°C) leads—undoubtedly *via (3)* (m.p. 82—83°C)—to *(6)* (m.p. 132.5—134°C) and *(7)* (m.p. 110°C) in 32% and 11% yields, respectively[2]. Other products formed include *(5)*, which is formed in 10% yield *via* the photo-Diels-Alder adduct *(4)*[3], some polymers, and alteration products formed during the chromatographic separation.

On catalytic hydrogenation, *(6)* and *(7)* both afford *(8)* (m.p. 113—114°C). They can, however, be readily distinguished by their ^{1}H-NMR spectra: All conceivable isomers of structure *(6)* possess a twofold axis of symmetry, and the resonances H^6/H^{12} give rise to a 7-line spectrum, degenerate in the center (100 MHz; τ = 6.75 ppm; $\Delta\nu_{1/2}$ = 1.8; J = 9.0, 6.5, 2.5 Hz). In contrast, H^6 and H^8 in *(7)* are subject to different anisotropic effects owing to the asymmetrically arranged phenyl groups, and their resonances at τ = 6.45—6.85 ppm give rise to three broad absorptions ($\Delta\nu_{1/2}$ = 3.0, 4.5, and 3.0 Hz). In all cases the sterically more favorable *exo*-arrangement of the two five-membered rings is confirmed by the symmetry properties of the non-superposed ^{1}H-NMR multiplets.

Characteristically structured UV-spectra (O/O transitions at 271 nm; ε = 370, 400, 435) and fluorescence spectra (ϕ_{fl} = 0.0049, 0.0086, 0.0049) serve for the detection of non-conjugated phenyl groups in *(6)*, *(7)*, and *(8)*, respectively.

The primary product *(3)* [λ_{max} = 280 (sh, 8800); 304 (15000); 311 (15000); 327 (sh, 9300)] is obtained uniformly by irradiation (253.7 nm) of *(6)* and *(7)* at −190°C[2]. Correspondingly, irradiation of *(8)* affords *(9)*. *(6)*, *(7)*, and *(8)* photolyze without phosphorescence in the rate ratio 5.4 : 1 : 1.1. In agreement with the two-step mechanism for the photocleavage of four-membered rings[3,4], there is no quantitative correlation between fluorescence intensity (see above) and photoreactivity. Thus it should not be expected that different benzylic C—C bonds will be cleaved with the same probability, nor that the resulting different diradicals[3,4] will be stabilized to reactant and product in the same proportion.

The isolation of *(3)* and *(9)* permits a check on the mechanistic considerations. Both fluoresce intensely (ϕ_{fl} = 0.66 and 0.69, respectively; cyclohexane) and photoadd to undiluted cyclopentadiene *(2)* (λ > 315 nm; −10°C) to give *(6)* and *(7)* (in the ratio 3 : 1)[5], and probably *exo,exo*-1.7-diphenyltetracyclo[5.5.0.0^{2,6}.0^{8,12}]dodeca-3-ene [*i.e.*, *(6)* or *(7)* with one hydrogenated double bond]. A preparative application consists in the corresponding reaction of *(11)*[6] to give *(12)* (m.p. 77°C; yield: 59%)[2]. The fluorescence intensities of *(3)*, *(9)*, and *(11)* (also no phosphorescence at −196°C) in cyclopentadiene are reduced to 1/6, 1/5, 1/10, respectively, compared to those in cyclohexane.



The considerable UV quantum yields[3] for the consumption of the *cis*-stilbene components *(3)*, *(9)*, and *(11)* (φ = 0.50, 0.44, and 0.57, respectively; 0—90% reaction) underline the

potential usefulness of such singlet reactions in the synthesis of other 1,4-diphenylbicyclo[2.2.0]hexanes[7], even though *(1)*, together with other byproducts that are more difficult to characterise and are easily decomposed, and some polymers are also formed in preparative experiments.

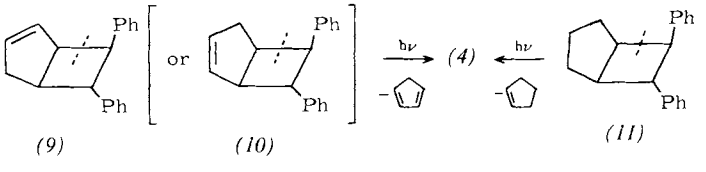
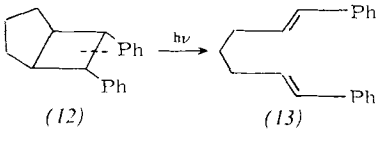
In shortened form: August 13, 1974
German version: Angew. Chem. 86, 740 (1974)



This "*cis*-effect" can be demonstrated quite clearly, for example, with the stilbene photodimers *(5)* and *(8)*, which are obtainable with self-quenching in yields of 47% and 23%, respectively[1a]. *(5)* ($\phi_{fl} = 0.0072$; $\lambda_{fl}^{corr} = 275$ sh, 282, 287, 295 sh nm; cyclohexane; 20°C) decomposes 3 times faster than *(8)*



($\phi_{fl} = 0.024$) into two molecules of *(4)* (no side-reactions at −190°C; no phosphorescence); once again there is a higher probability for cleavage of a *cis* disubstituted bond.

Since no principle of microscopic reversibility of forward and reverse reactions is involved, it is not yet possible to calculate the stabilization ratios of *(6)* and *(7)* (cleavage and ring formation) which determine the quantum yields. The product-determining action of the *cis*-effect in the primary cleavages (diradical formation) is however sufficient for an understanding of the orientation selectivities. Thus *(9)* [or *(10)*?] like *(11)*[1a,7] photolyzes (253.7 nm; −190°C) with release of stilbene *(4)*, even though the less delocalized diradicals are formed in these processes [cf. *(3)*].

In contrast, under the same conditions *(12)* expectedly undergoes a valence isomerization to give *(13)* [cf. *(1)* and *(5)*].

Condensed four-membered rings with planar cyclic chromophores necessarily decompose into two components as in *(14)*[3], *(15)*[3], and *(16)*[9], since rupture of the central σ bonds would not lead to steric relief. As is to be expected,

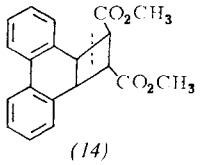
Orientation in Photochemical Cyclobutane Cleavages: *cis*-Effect[**]

By *Gerd Kaupp*[*]

The well-known [2σ→2π] photocleavage of cyclobutane derivatives[1] reveals some interesting orientation selectivities, in spite of the generally large excess of energy in the electronically excited state. We now report on the results of photolysis of phenyl-substituted cyclobutanes which explain these orientations on the basis of empirical-experimental mechanisms with intermediate products without calculation and without postulation of energetically most favorable reactionpaths[1b,2,3,4].



Irradiation of *(1)* or *(3)* (λ = 253.7 or 250 nm) affords *(2)* together with polymers and products that absorb at long wavelengths[5]. Only irradiation of *(3)* leads also to formation of *(4)* *via* the less stabilized diradical[2] (1% at −190°C and 10% conversion). *(3)* fluoresces three times more intensely[6] and photolyzes at −190°C five times more slowly than *(1)* (with uniform cyclobutane cleavages).

Cleavage of the *cis*-disubstituted bond in *(1)* is particularly favored, for this leads to relief of a large part of the steric strain.

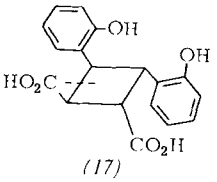
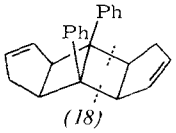
(14) photolyzes faster than *(15)* (*cis*-effect) and with partial formation of *(15)*[2,3]. Similarly clear are the differences in mode of cleavage in the case of *(16)*[9] and its product of hydrolysis *(17)*[10].

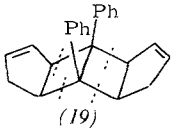


(14)

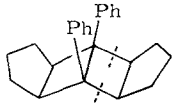
(15)



(16)



(17)



In the photolysis of cyclobutanes with four substituents in *cis*-positions no high selectivity of orientation can be expected. *(18)*, *(19)*, and *(20)*, which photochemically (at −190 °C) uniformly lose one of the five-membered rings[8], are conformationally fixed special cases.

(18)

(19)

(20)

In contrast to the primary cleavages indicated in the formula diagram, steric hindrance between phenyl and methylene groups would, according to molecular models, increase in the first place through stretching of the central four-membered ring-bonds.

It is not certain whether such processes nevertheless occur, being quantum-consuming but chemically unsuccessful[11].

Temperature-Induced Change in Helicity of the Inherently Dissymmetrical Disulfide Group in Cyclocystine[**]

By *Günther Jung* and *Michael Ottnad*[*]

Particular importance attaches to cyclo-L-cystine (3,4-dithia-7,9-diazabicyclo[4.2.2]decane-8,10-dione) *(1)* as a test case for demonstrating the validity of theoretical concepts on the chiroptical properties of the disulfides. *(1)* contains a boat-shaped dioxopiperazine ring which is bridged by a disulfide group having an angle of twist of $\phi = 90°$[1]. Theoretically, a molecule containing a disulfide group twisted at such an angle should not exhibit any optical activity in the region of the longwave disulfide absorption at 245 nm[2]. This prediction has been substantiated (Fig. 1). The negative Cotton effect corresponds to the n-π* transition of *cis*-amides. The octet rule for carbonyl compounds can explain the presence of a *P*-helical disulfide bridge [as in *(1a)*][1]. The Cotton effect at 194 nm corresponds to a superposition of the π-π* transition of the amide groups and a disulfide transition.

P (1a)

M (1b)

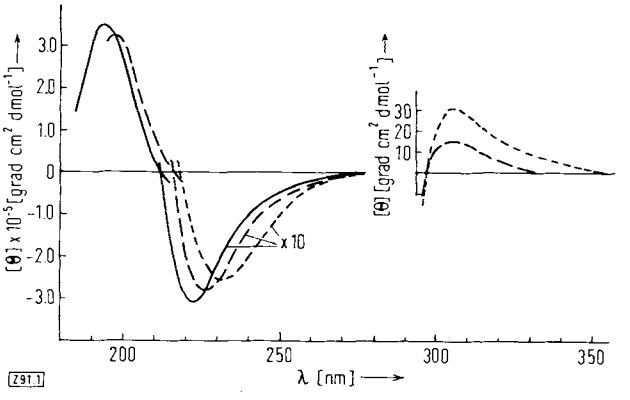

Fig. 1. CD spectra of *(1)* in trifluoroethanol (——), methanol (– –), and dioxane (– – – –).

The high rotatory power can be due to the conformational rigidity of *(1)* and to the favorable geometrical arrangement of the *cis*-amide groups for electrical dipole-dipole interactions. We have found, as expected, that *(1)* has a less temperature-dependent CD (Fig. 2) than other cystine compounds[3]; the change of CD with temperature is characteristic for diastereoisomers which interconvert. Below 40 °C the more stable *P*-helical diastereoisomer *(1a)* predominates, while above 40 °C the population of the *M*-helical form *(1b)*, with its less negative Cotton effect, increases. The temperature dependence in ethanol and in 0.1 N HCl differs considerably from that in trifluoroethanol. The stronger hydrogen-bonding tri-

[*] Prof. Dr. G. Jung and Dr. M. Ottnad
Chemisches Institut der Universität
74 Tübingen, Auf der Morgenstelle (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—We thank Dr. *K. P. Hartter* for supplying the compounds.

fluoroethanol stabilizes mainly the conformation *(1a)*. As expected, the Cotton effect of the n-π^* amide transition is shifted hypsochromically with increasing polarity of the solvent.

In contrast, the Cotton effect at 305 nm is less temperature dependent and not to be ascribed to the disulfide group; a dependence of its position and/or ellipticity on the solvent can hardly be established. This previously unobserved Cotton effect can certainly not arise from an impurity, for highly pure crystals were employed in the investigations. It is conceivable that a positive Cotton effect above 300 nm (possibly a CT transition analogous to that in epidithiopiperazinediones[4]) is superimposed by the negative amide Cotton effect such that it gives an apparent positive maximum above 300 nm.

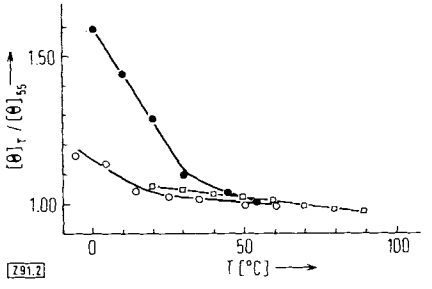

Fig. 2. Temperature dependence of the Cotton effect at about 225 nm in trifluoroethanol (● --●), ethanol (96 %) (○—○), and 0.1 N HCl (□ --□).

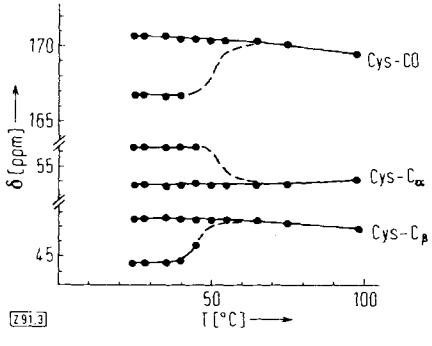
The ^{13}C-NMR spectrum of *(1)* in D_6-DMSO at temperatures below 45 °C shows three weak signals besides the three intense peaks (Fig. 3). The stronger signal of the carbonyl carbon lies at low field, which, independently of the CD, indicates the *P*-conformation for the disulfide bridge in which the sulfur atoms and the carbonyl group are closely proximate[5], the carbonyl carbon atom being more strongly deshielded than that in the *M*-helical molecule, whose ^{13}C signal was previously not observed[11].



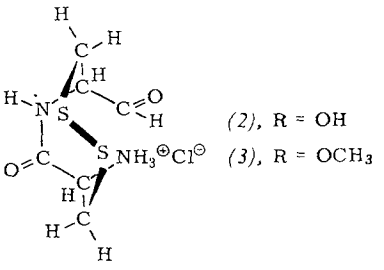


Fig. 3. Temperature dependence of the ^{13}C-NMR signals of *(1)* in D_6-DMSO.

Despite the weakness of the coalescence-point method in the determination of energy barriers from ^{13}C-NMR spectra[6], the lower limit of $\Delta G^{\neq}$ for rearrangement of the *P*-helical conformation of the disulfide bridge into the *M*-helical form can be estimated. Values of 15.6—16.0 kcal/mol are obtained. The highest previously observed rotation barriers about the disulfide group, which were measured on sterically very hindered diaryl disulfides, amounted to 15.7 kcal/mol[7] and likewise can only be considered as a lower limit value for this process. The intensities of the ^{13}C-NMR signals of *(1a)* and *(1b)* give the proportion of the less stable *M*-helical conformers *(1b)* at 25 °C as 15—20 %. Since the relaxation times of the aliphatic C atoms of *(1a)* and *(1b)* are comparable, this estimation is acceptable.

(2), R = OH
(3), R = OCH_3

Conformational calculations on L-cysteinylcysteine disulfide indicate a slightly nonplanar *cis*-amide group and give similar bond lengths and angles as in open chain cystine peptides. The total energies of the *P*- and *M*-conformations should differ only slightly (0.6 kcal/mol)[8]. In contrast to the CD spectrum of *(1)*, the spectra of L-cysteinylcysteine disulfide hydrochloride *(2)* and its methyl ester *(3)* show strongly reduced ellipticities and a reversal of sign, thus indicating lack of interaction between the amide groups and an increased flexibility of the disulfide group[9]. Hence, together with *(1)*, compounds *(2)* and *(3)* are the only examples known so far of compounds with inherent dissymmetrical disulfide groups without optical activity in the region of the longwave disulfide absorption.

Intracrystalline Reactivity of Phyllodisilicic Acid $(H_2Si_2O_5)_x$

By *Gerhard Lagaly, K. Beneke, P. Dietz*, and *Armin Weiss*[*]

It is generally difficult to characterize solid silicic acids. The ≥Si—OH groups are often of low thermal stability, so that even slight heating causes the structure to change by condensation to siloxane groups ≥Si—O—Si≤. Their acidity is low; in attempts to determine the amount of ≥Si—OH groups in aqueous media cleavage of siloxane groups cannot always be excluded with certainty and many reagents do not yield the correct value if the density of silanol groups is high.

[*] Prof. Dr. G. Lagaly and K. Beneke
Institut für Anorganische Chemie der Universität

Dipl.-Chem. P. Dietz and Prof. Dr. Armin Weiss
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1—3 (Germany)

An exception is provided by the crystalline phyllosilicic acids which form characteristic intercalation complexes. This property is shown most markedly by the natural and synthetic silicic acid "H-magadiite" ($H_2Si_{14}O_{29}\cdot 5.4\,H_2O$)[1].

We report below about "phyllodisilicic acid" $(H_2Si_2O_5)_x$. According to X-ray diagrams three forms can be distinguished[2–5], but we investigated mainly form II. This is obtained by reaction of 80% sulfuric acid at 0°C with powdered α-$Na_2Si_2O_5$[2].

After refinement the relatively sharp powder diagram of form II has the axes (cf.[13]) $a_0 = 5.6_4$, $b_0 = 14.6_3$, and $c_0 = 29.7_1$ Å. According to the structure determination by *Liebau*, the SiO_4 tetrahedra are linked to form layers in such a way that twelve-membered siloxane rings are obtained. But unlike the "tetrahedral layers" in clay minerals, the free corners of the tetrahedrons (≥Si—OH groups) project alternately above and below the layer. In the free acid the layers are folded; the basal spacing $d_L = b/2$ is 7.3 Å.

The phyllodisilicic acids are considerably less reactive than H-magadiite. They do not form intercalation complexes by direct reaction with formamide, acetamide, urea, pyridine, pyridine *N*-oxide, or their methyl or ethyl derivatives. It is impossible to distinguish whether simple intercalation complexes have been formed or whether new silicates have arisen by acid-base reactions with retention of the layer structure. Reaction with aqueous hydrazine solutions increases the basal spacing d_L, from 7.3 Å to 9.8—10.5 Å, depending on the water content (Table 1). The increase in the basal spacing is of the same order of magnitude as in kaolinite (from 7.1_5 to 10.4 Å[6]). By washing with water the phyllodisilicic acid is reformed. Methylhydrazine ($pK_B = 7.9$) increases the basal spacing to 10.0 Å, but with *N*,*N'*-dimethylhydrazine ($pK_B = 7.5$) there is no reaction. This makes it clear that base strength is not alone decisive, and that steric effects play an appreciable role.

Table 1. Basal spacings d_L and methods of preparation of intercalation compounds of phyllodisilicic acid $(H_2Si_2O_5)_x$.

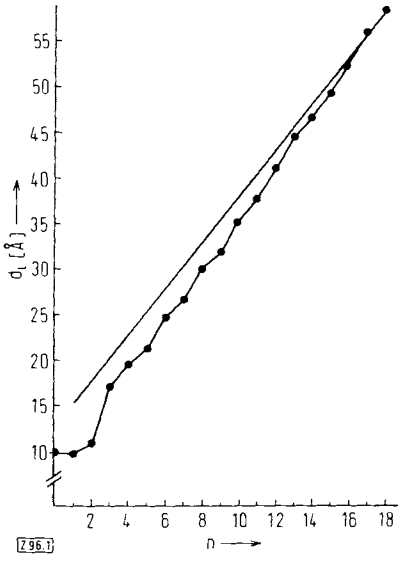
Aniline	22.0	Butylamine	9.4

[a] Aqueous solution

Aqueous NH_3, methylamine, and ethylamine react with expansion of the basal spacing to 9.8, 10.0, and 10.9 Å, respectively. Amines with longer chains do not react directly. If an excess of propylamine is allowed to react with the ethylamine compound, the ethylamine is displaced from the interlayer spaces and the propylamine compound is formed, the basal spacing increasing from 10.9 to 17.1 Å. The butylamine compound can be obtained analogously from the propylamine compound, and therefrom the pentylamine compound, *etc.* ("propping open"[7]). The displacement reactions are reversible.



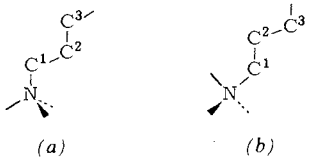


Fig. 1. Basal spacings d_L of intercalation compounds of phyllodisilicic acid with primary *n*-alkylamines as dependent on the number *n* of C atoms in the alkyl chain; -●- experimental values; ——— calculated for bimolecular layers of alkyl chains arranged perpendicularly to the layers according to the relation $d_L = 9.8 + 2 \times 1.26 \times n + 3$ [Å] (9.8 = basal spacing of the NH_3 compound; 1.26 = projection of the C—C bond on the chain long axis; 3 = van der Waals radius of the methyl terminal group).

Figure 1 shows the basal spacings of the *n*-alkylamine compounds with $n = 1$ to 18 C atoms in the alkyl chain. For $n > 2$ they increase linearly with chain length. The average increase is 2.8 Å/CH_2; this value is distinctly greater than the maximal value 2.5 Å that would be expected for a bimolecular arrangement of the alkylamine molecules in the interlayer spaces with their long axes standing perpendicular to the silicate layers. It must be assumed that the chains are tilted at an angle to the silicate layers and that the tilting angle increases with chain length up to 90°. This is shown also in the absolute values: Starting from the NH_3 compound ($d_L = 9.8$ Å) one calculates for perpendicularly arranged chains values of 33.0 and 58.2 Å for, respectively, 8 and 18 C atoms in the alkyl chain; observed values are 30.0 and 58.4 Å. Fitting the NH_2 groups to the puckered silicate layer probably forces an inclined orientation on the shorter alkyl chains. Increasing van der Waals energy with increasing chain length cause the tilting angle to approach 90°. A similar change in orientation was found in the complexes of transition-metal disulfides with alkylamines[8]. The inclination of the shorter alkyl chains is indicated also by the alternation of the basal spacings: the increase $\Delta d_L = d_L(n+1) - d_L(n)$ is larger for odd than for even *n*; and this hints to a specific orientation *(b)* of the NH_2 groups with respect to the silicate layer[9].

(a) *(b)*

Shortening of the shorter alkyl chains by formation of *gauche* bonds is presumably excluded, since this effect is normally favored with long alkyl chains[10].

The ethylamine or butylamine compound can be converted into other amine complexes (Table 1) too.

The amine can be washed out of *n*-alkylamine compounds by anhydrous ethanol, which is an indication in favor of existence of true intercalation compounds and against formation of *n*-alkylammonium silicates by direct acid-base reaction. The free d-orbitals of the Si atoms probably function as acceptors for the intercalated Lewis bases. It is possible that intercalation compounds of crystalline silicic acids may come to be used as models of adsorption systems with amorphous SiO_2 preparations.

The majority of the intercalation compounds are well ordered and the original silicic acid can be reformed in more or less well ordered state by cautious evaporation of the intercalated component or by its extraction with an inert solvent.

In some cases, *e. g.* with dimethyl sulfoxide, formation of intercalation compounds of phyllodisilicic acid is accompanied by large broadening of the (0*k*0) interferences, sometimes even by production of amorphous materials. Presumably the strong interactions between the intercalated molecules and the silicic acid layers change the folding and destroy the parallel orientation over large areas; if the intercalated molecules are removed the original order cannot be restored and hitherto unknown paracrystalline silicic acids result.

The intracrystalline reactivity of phyllodisilicic acid and the structural stability during the intercalation processes proved to be strongly dependent on the mode of preparation of the disilicic acid. Disilicic acid can be prepared not only by reaction of α-$Na_2Si_2O_5$ with 80% H_2SO_4 at 0°C[12], but also with 40% H_2SO_4, 1 N HCl, or H^+-ion exchangers at room temperature. The preparations at room temperature give nearly identical X-ray diagrams with only minor differences in the sharpness of the reflections in comparison with preparations at 0°C, but amorphous products with hydrazine hydrate. Probably at room temperature the folding of the layers becomes less regular and the regions of equal folding direction less extended. Aging phenomena[3, 4] connected with condensation of silanol groups play an important role.

Crystal Structure of $(HgI)_2TiF_6$[**]

By *Klaus Köhler, Dietrich Breitinger,* and *Gerhard Thiele*[*]

Mercurioiodonium complexes of the composition $(HgI)_n^{n+}X^{n-}$ are formed as reaction products in the systems $Hg^{2+}/I^-/X^{n-}$ ($X^{n-} = TiF_6^{2-}$, ZrF_6^{2-}, SnF_6^{2-}, NO_3^-, and BF_4^-)[1]. Vibrational spectrometric investigations of the crystalline solids suggest a structure for the $(HgI)^+$ cation[2] consisting of planar chains with angular bonding at the iodine atom, as has been found for the isoelectronic AuI[3, 4].

The determination of the crystal structure of $(HgI)_2TiF_6$—$(HgI)_2ZrF_6$ and $(HgI)_2SnF_6$ are isotypic—was based on 490 independent reflections (255 with $I<3\sigma$) measured with a four circle diffractometer ($Mo_{K\alpha}$ radiation, graphite monochromator) in the range $0° < \vartheta \leq 22°$[5]. Refinement of the structural model obtained by Fourier methods led, after absorption correction[6], and with anisotropic temperature factors, to a final *R* factor of 0.083 (coordinates in Table 1).

Table 1. Atomic coordinates of $(HgI)_2TiF_6$.

have a distorted octahedral environment. As a result of these interactions the bond angle at mercury deviates from the ideal value of 180° for sp or ds hybridization.

The bond angles at iodine determined from the vibrational spectra are in satisfactory agreement with the values determined by X-ray crystallography[8].

Structure of Diimine: X-ray Diffraction Analysis of $N_2H_2[Cr(CO)_5]_2 \cdot 2THF$[**]

By *Gottfried Huttner*, *Wolfgang Gartzke*, and *Kurt Allinger*[*]

Investigations on the structure and properties of diimine, HN=NH, the simplest azo compound, have so far not been fully satisfactory owing to the instability of the compound. *Wiberg et al.*[1] have recently found a preparative method which provides access to practicable amounts of free diimine, but its ready decomposition (which in the solid state begins at −180 °C), considerably hampers detailed structural investigations[2].

In contrast, the crystalline transition-metal complexes of diimine synthesized by *Sellmann et al.*[3] are sufficiently stable for X-ray diffraction analysis. Structural analysis of the complex $N_2H_2[Cr(CO)_5]_2$ *(1)* was undertaken to provide definite structural parameters of diimine, which presumably is also of biological importance.

Diiminebis(pentacarbonylchromium) *(1)* crystallizes from tetrahydrofuran (THF) solution as dark red needles[4], which rapidly transform into shiny—X-ray amorphous—needles of *(1)* on reduction of the THF partial pressure. According to structural analysis, the red needles obtained initially are crystals of the solvated complex $N_2H_2[Cr(CO_5)]_2 \cdot 2THF$ *(2)*; they can be stored for several weeks in a nitrogen atmosphere at −50 °C under THF vapor pressure.

The addition compound *(2)* crystallizes in the triclinic space group P$\bar{1}$ with $a = 1903$, $b = 1027$, $c = 637$ pm; $\alpha = 97.3$, $\beta = 97.9$, $\gamma = 95.9°$; $Z = 2$; d_{calc} 1.528 g cm^{-3} (1310 measured diffraction intensities, agreement factor $R_1 = 0.068$).

In agreement with the results of earlier investigations by *Sellmann et al.*[3], compound *(2)* contains two pentacarbonyl units bridged by a diimine ligand. The molecule has a crystallographically determined center of inversion in the middle of the N=N bond. The diimine ligand therefore has *trans*-configuration[5].

Each of the hydrogen atoms of the diimine ligand forms a bridge bond to the oxygen atom of a THF solvate molecule.

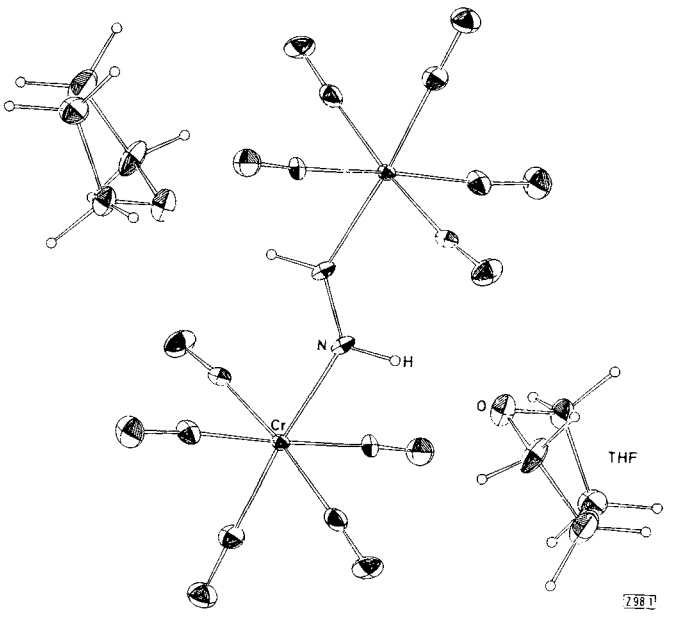

Fig. 1. Structure of the diimine complex $N_2H_2[Cr(CO)_5]_2 \cdot 2THF$ *(2)*.

The $N-O_{THF}$ distances, with a value of 290±1 pm, are in the range typical for N—H—O bridge bonds. The angles N—N—O_{THF} and N—N—Cr are 122.3 and 130.5° respectively. The N=N distance, with a value of 125 pm, corresponds in length to that of a N=N double bond observed for organic azo compounds[6].

The chromium atoms have an almost octahedral surrounding. The $Cr-C_{CO}$ distances have a mean value of 190 pm; the carbonyl groups *trans* to the nitrogen atoms of the diimine appear to be somewhat more tightly bound ($Cr-C_{CO}$ 186 pm). The $Cr-N_{sp^2}$ distance is 207.6±1 pm; it is considerably shorter than the $Cr-N_{sp^3}$ distance in tricarbonyldiethylenetriaminochromium (218.5 pm)[7]; this may be indicative of a small amount of π bonding in the Cr—N bond[8]. The amount of π bonding must be small, since otherwise lengthening of the N=N distance would be expected, such as is observed in dimeric nitroso compounds (*trans*-$(O_2NCH_2CH_2NO)_2$, $d_{N\,N} = 130.4$ pm[9]; *cis*-$(C_6H_5NO)_2$, $d_{N\,N} = 132.3$ pm[10]).

The structure analysis of *(2)* constitutes the first X-ray crystallographic evidence for the existence of diimine[11]. Diimine is present in the solvated complex *(2)* in the *trans* form. The extraordinarily labile free HN=NH is stabilized in *(2)* as a bridge ligand between two $Cr(CO)_5$ units.

A. Heath, R. Mason*, and *K. M. Thomas*, J. Amer. Chem. Soc. *96*, 259 (1974).

Anionic Structure of the So-called Ammonium Dimolybdate $(NH_4)_2Mo_2O_7$

By *Imme Knöpnadel, Hans Hartl, Wolf-Dietrich Hunnius*, and *Joachim Fuchs*[*]

$(NH_4)_2Mo_2O_7$ crystallizes as colorless platelets from a warm concentrated solution (60 °C) of ammonium heptamolybdate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, to which ammonia and ammonium chloride have been added[1].

The triclinic unit cell of space group $P\bar{1}$ contains two formula units. Its lattice constants are: $a = 7.261 \pm 0.001$, $b = 7.961 \pm 0.001$, $c = 7.326 \pm 0.001$ Å; $\alpha = 82.63 \pm 0.05$, $\beta = 94.47 \pm 0.05$, $\gamma = 114.64 \pm 0.05°$.

The structure was elucidated on the basis of three-dimensional diffraction data with evaluation of 3607 independent reflections and refinement to an R value of 5.4 %.

The salt does not contain a dimeric, but rather a *polymeric* anion, in which the MoO_6 octahedra and MoO_4 tetrahedra are linked to form chains (Fig. 1). The coupling is of a completely different type from that in $Na_2Mo_2O_7$ prepared from melts, which likewise contains tetrahedral and octahedral building units[2].

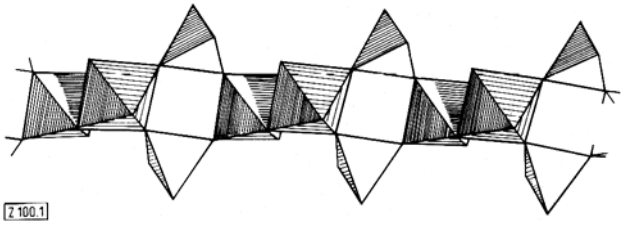

Fig. 1. Anionic structure of $(NH_4)_2Mo_2O_7$.

Two MoO_6 octahedra are bound *via* a common edge [oxygen atoms O^6 and $O^{6'}$; cf. Fig. 2] across a symmetry center to give a Mo_2O_{10} unit. Each of the Mo_2O_{10} units are linked stepwise by two MoO_4 tetrahedra *via* common oxygen atoms [O^3 and O^7] to give infinite chains. The distances between the molybdenum atoms are 3.158 [Mo^1—Mo^2] and 3.169 Å [Mo^2—$Mo^{2'}$]. The molybdenum-oxygen distances are shown in Fig. 2. The anion chains are crosslinked *via* a system of hydrogen bonds through ammonium ions. The distances between the nitrogen atoms and their nearest neighboring oxygen atoms are 2.79 to 2.99 Å.

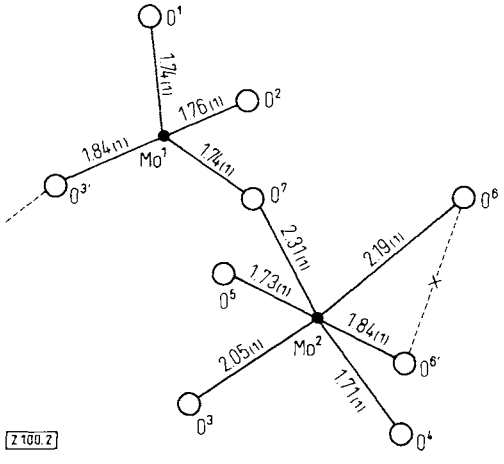

Fig. 2. Molybdenum-oxygen distances [Å] in $(Mo_2O_7^{2-})_\infty$; standard deviations in units of the last decimal place are given in parentheses.

The compound is conveniently named according to the "base-acid ratio", $(NH_4)_2O{:}MoO_3 = 1{:}2$, as ammonium (1:2)-molybdate. Knowledge of its structure is of interest for understanding the formation of polyanions in aqueous solution.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The characterization of chain molecules by their dipole moments is the subject of a review by *J. E. Mark*. Theoretical analysis of the measured dipole moments of randomly coiled chain molecules can provide valuable information on the conformational energies and spatial configurations of such molecules. Examples are "stereochemical copolymers", *e.g.* polyvinyl chloride and poly(*p*-chlorostyrene) and "chemical copolymers", *e.g.* poly(*p*-chlorostyrene-*p*-methylstyrene) copolymer. [The Use of Dipole Moments to Characterize Configurations of Chain Molecules. Accounts Chem. Res. *7*, 218—225 (1974); 63 references]

[Rd 730 IE—L]

The biosynthesis of collagen is described by *E. J. Miller* and *V. J. Matukas*. Five genetically different α-chains of collagen are known which aggregate to give four types of trimers. The distribution of the aggregate types is in part organ-specific. The messenger RNA for the synthesis of the α-chains stems from one cistron; the hydroxylation of prolyl and lysyl residues takes place simultaneously or immediately after the translation. The chains aggregate and form helices as they are still growing on the polysomes, while glycosylation to procollagen takes place later. Procollagen is finally converted by proteolysis into collagen. The findings are discussed in connection with the concepts of cell morphology, localization, transport and

secretion of collagen. [Biosynthesis of Collagen. Fed. Proc. *33*, 1197—1204 (1974); 97 references]

[Rd 735 IE—R]

The azide method for peptide bond synthesis introduced by *Curtius* is still an important coupling method, since the starting compounds are readily accessible, little racemization takes place, and long peptide fragments can be synthesized with minimal protection of amino acid side chains. A review by *Y. S. Klausner* and *M. Bodansky* starts with a description of hydrazide and azide formation and a discussion of the side reactions occurring in such formations and in coupling processes (*e.g.* in the Curtius rearrangement, azide→isocyanate). Modifications of the azide method, especially those which should repress amide formation during preparation of the azides, are exemplified by preparative methods (Honzl-Rudinger and Medzihradszky method). The formation of small amounts of dispiro isomers in the azide coupling cannot be completely ruled out, but is much less likely than, *e.g.* in the case of the dicyclohexylcarbodiimide method. The article deals with the use of the azide method in the solid phase synthesis of peptides, the cyclization of peptides, and the polymerization of peptide azides. The use of cyclocarbodiimides for the synthesis of peptides is briefly touched on. [The Azide Method in Peptide Synthesis. Its Scope and Limitations. Synthesis *1974*, 549—559; 153 references]

[Rd 738 IE—M]

ESR spectra of binuclear transition metal complexes are the subject of a review by *T. D. Smith* and *J. R. Pilbrow*. The theory of magnetic interaction between pairs of similar and dissimilar ions of spin 1/2 is treated extensively. A compilation of interpreted ESR spectra of binuclear complexes with the central ions Cu^{2+}, VO^{2+}, and Ti^{3+} follows. Some denaturization products of naturally occurring Cu^{2+} compounds are also considered. [The Determination of Structural Properties of Dimeric Transition Metal Ion Complexes from EPR Spectra. Coord. Chem. Rev. *13*, 173—278 (1974); 186 references]

[Rd 741 IE—H]

Recent results in the search for trace elements in nutrition are discussed in an article by *K. Schwarz*. Such investigations necessitate very effective isolating systems and feeding of animals with highly pure substances. The severe damages caused by selenium deficiency have been known for a long time. In the meantime it has also been established that this element is present in higher organisms in glutathione peroxidase and in a special cytochrome. The organism requires very small trace amounts of tin and vanadium; the exact biochemical function of these two elements, however, is still unknown. The same applies to fluorine, which appears to have other, more general biochemical effects in addition to being an effective anticaries agent. Silicon, one of the most abundant elements in the earth's crust, is necessary for bone formation and growth of connective tissue. A review is given of other elements which could play a role as trace elements in organisms. [Recent Dietary Trace Element Research, Exemplified by Tin, Fluorine, and Silicon. Fed. Proc. *33*, 1748—1757 (1974); 53 references]

[Rd 742 IE—R]

Silicon as trace element in organisms is reviewed by *E. M. Carlisle*. Lack of this element in higher animals leads to general irregularities in growth. In calcification of young bones, calcium interacts with silicon; silicon is also found in articular cartilage and connective tissue, where it probably plays a role in the crosslinking of protein-mucopolysaccharide complexes. It is also assumed to participate in the biosynthesis of mucopolysaccharides. Many tissues are more silicon-deficient in older individuals than in younger ones. [Silicon as an Essential Element. Fed. Proc. *33*, 1758—1766 (1974); 66 references]

[Rd 743 IE—R]

Vanadium as an essential nutrient is the title of a review authored by *L. L. Hopkins* and *H. E. Mohr*. Animals fed on a vanadium-free diet remain stunted—bodily development and growth of hair and feathers are retarded. The growth of teeth, bone formation, reproduction, and the survival rate of young animals are also adversely affected. Moreover, erythrocyte formation and iron metabolism are far from normal. Studies on the nutritional requirement would suggest that normal food does not contain more vanadium than is absolutely necessary, but rather that there is a general deficiency of this essential element. [Vanadium as an Essential Nutrient. Fed. Proc. *33*, 1733—1775 (1974); 14 references]

BOOK REVIEWS

Carbon-13 NMR Spectroscopy. By *J. B. Stothers*. Organic Chemistry—A Series of Monographs, Vol. 24. Academic Press, New York—London 1972. 1st edit., xi, 559 pp., Numerous tables, bound $ 24.—.

The present monograph represents a summary of almost all the papers on ^{13}C-NMR spectroscopy published to the end of 1970. Following a short introduction on the theory (Chapter 1) and methods (Chapter 2) of NMR spectroscopy, Part II (Chapters 3—8) describes the ^{13}C-chemical shifts of hydrocarbons and their substituted derivatives, organometallic compounds and carbenium ions, heterocyclics, carbonyl compounds, and nitriles. Part III is devoted to ^{13}C coupling constants. A general introduction to the theory of ^{13}C coupling in Chapter 9 is followed by detailed treatment of the ^{13}C-^{1}H coupling constants in Chapter 10 and a review of the ^{13}C-^{19}F and ^{13}C-^{13}C coupling constants and other heteronuclear couplings. Applications of ^{13}C resonance to the solution of structural or stereochemical problems in organic compounds, polymers, and natural products are briefly dealt with in Part IV (Chapter 11). Examples of the elucidation of reaction mechanisms and biosynthetic pathways by ^{13}C resonance and a brief treatment of solvent effects complete the work.

The monograph is well arranged and intelligibly written. Its perusal will present no great difficulty even to the beginner in NMR. The ^{13}C chemical shifts are uniformly converted or given against tetramethylsilane as standard, which greatly facilitates comparison with recent measurements. It is true that new routine methods in ^{13}C resonance, *e.g.* pulse Fourier transform spectroscopy, are but briefly alluded to, although the significance of such methods for ^{13}C resonance was recognized already in 1970. In relation to the scope of the book, and compared to other NMR monographs, the illustrations are also somewhat scanty. The provision of comprehensive author and subject indices, as well as of an index of compounds whose ^{13}C parameters are discussed, tabulated, or illustrated in the figures, will greatly facilitate the reader's

task. For this reason the monograph, composed by one of the pioneers of ^{13}C resonance, is not only a comprehensive reference work (at least until 1970) but, by virtue of its clear arrangement, a pleasure to use. It will thus be a valuable aid to all concerned with or interested in NMR spectroscopy.

Eberhard Breitmaier [NB 220 IE]

Electrochemistry of Cleaner Environments. Edited by *J. O'M. Bockris*. Plenum Press, New York—London 1972. 1st Edit., xiii, 296 pp., numerous figures, bound $ 26.—.

It is well known that protection of the environment is a problem of growing concern to our modern industrial society. What is probably less well known is that it has been recognized for some years that a solution to practically all these problems is to be expected primarily from electrochemistry. The present book is thus very topical, and its readership should extend far beyond the narrow field of electrochemistry.

The replacement of combustion-engined cars by electric cars is unthinkable without electrochemical fuel cells or accumulators. Development is being concentrated on accumulators at present. The contribution by *E. H. Hietbrink et al.* presents a concise survey of this development, covering all the most important points in full. It is not yet certain which of the battery systems, *e.g.* the Pb/PbO_2, Zn/MnO_2, Fe/air, Li/chlorine, or Na/sulfur battery, will one day become the current source of choice for electric cars. One thing that is certain, however, is that the production of electrical energy is not itself a limiting factor.

The electrochemical treatment of effluents *(A. T. Kuhn)*, whether by electrolysis, electroflotation, or electrodialysis, and the electrofiltration of gases *(E. C. Potter)* are methods that have been in industrial use for a long time and that will certainly become more important in the future.

The contribution by *T. A. Henrie* and *R. E. Lindstrom* points out the possibility of digesting sulfide ores by treatment with electrolytically produced hypochlorous acid. Instead of SO_2, which pollutes the atmosphere, this yields an aqueous solution of the corresponding metal sulfate, which can be refined directly by electrolysis. Electrochemistry also provides many methods for continuous trace analysis (CO, SO_2, NO_x, *etc.*), which are discussed by *B. D. Epstein*.

R. P. Hammond and *D. P. Gregory et al.*, in their very detailed, forward-looking contributions, finally examine how the rapidly growing demand for electrical energy can be met and distributed. It is thought that the former can be achieved by fission or fusion power stations of the order of 10000 MW, floating on artificial islands in the ocean. For distances greater than 800 km, the transport of hydrogen, produced on the spot by electrolysis of water, is found to be more economical than the conduction of current. The pipe system filled with hydrogen also serves as a welcome energy store for use as a buffer. In the case of this "hydrogen economy", the consumer burns the hydrogen to produce heat without harmful exhaust gases, while part of it is used to produce current in fuel cells. A superabundance of electrical energy in the future would also lead to an immense resurgence of electrochemistry, *i.e.* the electrosynthesis of inorganic and organic compounds. This point is unfortunately not discussed in the book, an omission that is all the more surprising in view of the space devoted to relatively obscure topics such as the increase in the CO_2 content of the atmosphere (a brilliantly written contribution by *G. N. Plass*). Several references are made to the extensive use of hydrazine as a fuel in fuel cells, though in all probability, even after the production costs have been reduced, this fuel will be banned because of its toxicity (max. permissible conc. = 0.1 ppm). The metal-selective electrolytic processing of whole scrapped cars, which the editor seriously discussed in his introduction, is another idea that will probably never be realized.

These minor faults and imbalances in the distribution of topics in no way detract from the solid overall impression made by this work. It can be recommended to electrochemists and environmental specialists, and also to all those who are interested in learning about forward-looking technical problems.

Fritz Beck [NB 228 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 30. A History of Biochemistry. Part I: Proto-Biochemistry; Part II: From Proto-Biochemistry to Biochemistry. Elsevier Publishing Company, Amsterdam—London—New York 1972. 1st Edit., xvii, 343 pp., 64 figs., 4 tables, bound $ 25.00.

As a reward, so to speak, after 29 volumes of exact biochemistry[*] (not yet published in full), this volume reads like a novel. The shrewd, globe-trotting, broadly educated, and independently thinking editor *Florkin* has taken it upon himself to write the history of biochemistry. Apart from his international personal connections, his own historical studies qualify him to deal with the history of medicine at the crossroads of European intellectual history, the Belgian contact zone of many traditions since the middle ages. Here he presents the first part of a history of development that shows how the relationships between the philosophical concepts of the observation of nature and the empirically reproducible physical laws interacted and molded one another from the pre-Socratics up to the vitalists, and how inductive research finally overcame the dominance of *a-priori*, often esthetically motivated thought patterns and developed from *Occam*'s razor to the scalpel of cell biology. However, the scientist, now freed from the constraints of prejudice, readily falls once again into new fetters of authority, and the chapters in which *Florkin* deals with the cellular concept and *Liebig*'s theories of metabolism are particularly interesting and stimulating. This is especially true for the partisan-minded reader, who is provided here with a detached overview. Outstandingly descriptive and critically argumentative, the book is one of the most worthwhile and most generally instructive that could be found in a scientific library. The author never yields to the cheap temptation to present unconventional views without foundation, or to provoke by iconoclasm or *vice versa*.

One thus obtains new and reflectively inclining insights into the relationships of the history of thought and the relativity of our historical views. It is merely mentioned in passing that the presentation of the book is also excellent. Thus it is with great suspense, hopefully soon to be relieved, that we await the two further volumes, which will set the keystone that holds the arch of biochemistry together.

L. Jaenicke [NB 230 IE]

Kunststoff-Handbuch. Band 8. Polyester (Plastics Handbook, Vol. 8. Polyesters). Edited by *R. Vieweg* and *L. Goerden*. Carl Hanser Verlag, München 1973. 1st Edit., xxvii, 775 pp., 498 figs., 152 tables, bound DM 275.—.

The present volume deals with three important plastics, *i.e.* polycarbonates, polyalkylene terephthalates, and unsaturated polyesters (UP resins), of which the first and last might well have merited a special volume each. Nevertheless, it is justifiable to combine them in a single volume, since the polymers in these three plastics are all built up *via* ester groups. On the other hand the UP resins, as thermosets, have entirely

[*] Cf. Angew. Chem. internat. Edit. *10*, 361 (1971).

different processing characteristics and applications from the thermoplastic polycarbonates and polyalkylene terephthalates.

The basic division of the earlier volumes[*] into constitution, preparation, structure and properties, and processing and use is retained for these three plastics. Special sections on cutting agents, accelerators, inhibitors, glass-fiber reinforcement, and fillers are added in the case of the UP resins, corresponding to their different processing. It would have been interesting to learn more about the use of polycarbonates and UP resins, *e.g.* in the USA. The reason why the section on polyalkylene terephthalates is rather short is probably that this plastic was still in the development stage during the preparation of this volume. One should expect more in a new edition.

It is pleasing to note that a relatively large amount of space has been given to processing and use in the case of the polycarbonates, though the scientific side has not been neglected as a consequence. This is also true of the UP resins, but the sections on aids and fillers, glass fibers, *etc.* are also very informative.

The editors have managed to obtain the services of an outstanding specialist for each chapter, and the volume can therefore be regarded as very successful. Access to the original literature and to patents is facilitated by the extensive bibliography following each chapter. The volume will prove to be a good, fast source of instruction for processers, engineers, architects, and electrical engineers, as well as for chemists and physicists, and can be warmly recommended.

Otto Horn [NB 231 IE]

Die räumliche Struktur organischer Moleküle (The Steric Structure of Organic Molecules). By *Charles C. Price*. "taschentext" Vol. 10. Verlag Chemie, GmbH—Physik-Verlag, Weinheim 1973. 1st Edit., x, 102 pp., 38 figs., 18 tables, bound DM 12.80.

The aim of the "taschentext" series for chemistry and biology students, "to find means for the more effective presentation of fields, in which several disciplines are involved", and the purpose of this book, to familiarize these students with the fundamental factors that determine the principal properties of materials made from natural or synthetic polymers, are very commendable.

However, the title (original edition: Geometry of Molecules, 1971) may mislead the beginner into thinking that the whole of organic stereochemistry is dealt with here. The different use of the term "structure" in this connection can be seen from a comparison of the contents with those of books having related titles, *e.g. Coulson* (The Shape and Structure of Molecules), *Barrett* (Die Struktur der Atome und Moleküle [The Structure of Atoms and Molecules]), *Barry/Barry* (Die Struktur biologisch wichtiger Moleküle [The Structure of Biologically Important Molecules]), *Allinger/Allinger* (Strukturen organischer Moleküle [Structures of Organic Molecules]).

The material is divided in a logical manner into five chapters: The Geometry of Small Molecules (19 pp.); Intermolecular Forces (9 pp.); Dynamic Aspects of Molecular Geometry (23 pp.); Properties of Polymers (26 pp.); and Properties of Biopolymers (15 pp.).

The number of printing errors (pp. 15, 45, 55; 46, 52, 53, 84) is within normal limits. More objectionable are a number of weak points that could have been avoided: A pair of electrons, for example, spends "more time" in the neighborhood of the chlorine atom (p. 14). The title of the section "Asymmetric (Chiral) Molecules", which is too short (1 1/2 pp.) and also tedious (compare the lively chapter "Molecular Dissymmetry" in *Barry/Barry*, see above), is didactically by no means the best, nor are the unusual arrangement of the lactic acid formulas (p. 17) and the representation of inversion at the amine nitrogen (p. 18). The name Perlon should at least be mentioned in the discussion of 6,6-nylon (p. 69). The designation *trans* should not be applied to single bonds (p. 52). A note about the non-drop-like shape of p-orbitals would have been useful on p. 15. In the drawings of molecular models (pp. 16, 17), the bonds lying in the same plane should have been drawn as lines of equal thickness; the striped bonds are disturbing. The word "gefaltet" (folded) should have been used instead of "gebuckelt" (buckled) (cyclopentane ring, p. 45). On p. 47, orbital and molecular models are twisted in relation to each other, though they are placed together for comparison. On the same page there are formulas and corresponding projections that are rather disordered in space.

However, these weaknesses in a few details are more than outweighed by the convincing explanations in the text, which arouse understanding of and above all interest in the "giant molecules".

On the whole, the book fills a gap. The combination of elementary stereochemistry, polymer chemistry, and biochemistry in such a small space may be regarded as successful. This introduction can be recommended not only to those addressed in the foreword, but also to those who are fully trained in neighboring disciplines. *Fritz Vögtle* [NB 232 IE]

Elektrotauchlackierung (Electropainting). By *W. Machu*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., x, 338 pp., 133 figures, 32 tables, bound DM 98.—.

It has not taken many years for electropainting to find wide application as an economic process. Numerous publications have appeared during this time, dealing with the development of coating materials and the latest situation regarding plant and engineering. In the present book *W. Machu* has evaluated a considerable part of this literature and worked it up into a comprehensive review of this modern technique. He deals here with the physical and chemical principles of anodic deposition of paint, the importance of voltage and current strength, the throwing power, pretreatment of the metal, the composition and testing of the varnish materials, special fields of application, plant and procedures, and economic considerations. In conclusion, there is an extensive review of patents. Thus, the book is of equal interest to users and to manufacturers of paints and plants.

The mechanism of film formation by means of electropainting and the influence of the various paint and deposition parameters on the resulting coating are not yet fully understood. The section of the book dealing with this subject adds nothing to existing knowledge: the sometimes inadmissible generalizations of experimental results on specialized varnish systems that are found in the literature cited are here reported without discussion.

The chapters about pretreatment of the metal before electrodeposition varnishing are very detailed. The author's extensive experience with metal cleaning and phosphatizing makes this part of the book a valuable source of information for both users and paint manufacturers. It is disturbing that the pretreatment process of only one supplier is cited. The chapters about paint formulation and supervision of the immersion bath are brief, and are necessarily incomplete for a process whose further development is still under active study.

The descriptions of plant and procedure in electropainting with their numerous illustrations and examples of application, provide a good review of possible applications of the process. Many technical details of the plants are of interest to

[*] Cf. Angew. Chem. internat. Edit. *11*, 947 (1972).

the user. Perhaps some of the misprints, which sometimes distort the sense, could be avoided in a new edition of the book.

Dietrich Saatweber [NB 233 IE]

Spurenelemente in Wein und anderen Getränken (Trace Elements in Wine and Other Beverages). By *H. Eschnauer*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., viii, 220 pp., 7 figures, 129 tables, bound DM 78.—.

In this book information concerning the trace elements of wine and other beverages is presented fully systematically and for the first time. The first part of the book deals with the general problems of trace analysis, namely separation processes, methods of determination, and the reliability of the results, together with the development of the analysis of wine. Particular attention is paid to modern analytical procedures which first made trace element analysis possible.

This is followed by presentation of the actual results, arranged according to the elements. In each case the most important properties of the elements are mentioned and these are followed by their contents in alcoholic beverages, their raw materials, and their intermediate products. Here the distinction between primary and secondary components deserves close attention. Fundamental relationships between these components and, *inter alia*, the soil properties, climatic conditions, and ecological processes are described. A survey of the most common and the most recommended analytical methods is included. Each chapter is supplemented by an extensive bibliography.

A summary of the mineral and trace element content of alcoholic beverages and of German mineral waters is provided in the last section. Nutritional, biological, biochemical, fermentational, and plant-physiological aspects are discussed.

This book deserves special mention because of the wealth of material collected, the clear arrangement of the text, the comprehensive, in part tabular, presentation, and not least the large number of references. As a reference work it constitutes a valuable tool for all the specialists concerned.

W. Thieme [NB 234 IE]

Polymer Spectroscopy. Edited by *D. O. Hummel*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., xii, 401 pp., 262 figures, 76 tables, bound DM 125.—.

This monograph contains a review of the present state of the theory and applications of vibration spectroscopy (IR, Raman), magnetic resonance (NMR, ESR) and mass spectroscopy of synthetic polymers. Several other extremely important spectroscopic methods, such as UV, X-ray structure analysis, and neutron diffraction, have purposely been omitted, and the same applies to discussion of biopolymers.

In the first section of Chapter 2, *H. Tadokoro* and *M. Kobayashi* undertake the difficult task of presenting, briefly and with special reference to polymers, the procedure in the analysis of an IR spectrum and the theoretical prediction of vibrational frequencies by group-theory treatment of the problem. The application of the procedure described is demonstrated on selected polymers.

In Section 2 of Chapter 2, by *D. O. Hummel*, the polymer spectroscopist who is not so familiar with this very complicated subject will find the empirical method of IR spectroscopy of polymers described for many examples.

P. J. Hendra records very clearly, in Section 3 of Chapter 2, the methods, scope, and examples of Raman spectroscopy of polymers now that lasers are used as radiation sources.

Chapter 3, by *E. Klesper* and *G. Sielaff*, has as its main theme the statistics of chain-polymerization of synthetic homo- and copolymers, with NMR spectroscopy providing the analytical method. For a few examples the systematic analytical procedure for NMR spectra and comparison of the theoretical-statistical with the experimental results are demonstrated in full detail. Unfortunately, the possible introduction of ^{13}C-NMR spectroscopy is rarely taken into account. A detailed collection of references to all the synthetic polymers examined by NMR spectroscopy up to 1972 closes this chapter.

In Chapter 4, *H. Fischer* and *D. O. Hummel* introduce ESR Spectroscopy, and not exclusively for polymers. The examples treated give a very good survey of the ESR spectra of polymer radicals that are formed by irradiation, on radical polymerization or on mechanical treatment.

D. O. Hummel, H.-D. Schlüddemage, and *K. Rübenacker* describe in Chapter 5 the limited possibilities for mass spectrometry in the field of high polymers, with a good selection of examples.

With its many thoroughly treated examples, this book will provide a very good insight into this material and a great many valuable suggestions to the polymer chemist interested in empirical spectroscopy; for the theoretically oriented polymer chemist, the necessarily very brief and in part highly specialized theoretical treatments will hardly suffice, although the extensive bibliography will be of great help in further study of the subject. Some hints for chemists interested in biopolymers would have been welcome.

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
PR = Patent abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ACETAMIDES, Synthesis of pyrimidines from 2,N-dialkylcyano ~ (SC) 809 [G.E. *86*, 898 (1974)]

Acetonyl acetate (PR) 615

Acrylic esters, Peculiarities of particle formation in their emulsion polymerization (CR) 418 [G.E. *86*, 455 (1974)]
Copolymers with vinyl chloride (PR) 487

Acrylic glass, Combustion-resistant ~ based on methyl methacrylate (PR) 422

Acrylonitrile, Copolymers with styrene that can be processed thermoplastically (PR) 555

Acylations, Structures of intermediate complexes in Friedel-Crafts ~ (FP) 1 [G.E. *86*, 12 (1974)]

Adsorption layers, Structure of macromolecular ~ on solids (CR) 415 [G.E. *86*, 451 (1974)]

Aggregation of dissolved alkane chain molecules (LA) 746

Air pollution (Book Review) 215

Alcohols, Reactions of λ^3-phosphorins with diazoalkanes in presence of ~ and phenols (SC) 148 [G.E. *86*, 129 (1974)]
Modified Horeau analysis for determination of chirality of amines, ~, and carboxylic acids (SC) 664 [G.E. *86*, 707 (1974)]

Aldehydes, Addition of aliphatic ~ to activated double bonds (SC) 539 [G.E. *86*, 589 (1974)]
Convenient method for conversion into nitriles (CR) 351 [G.E. *86*, 317 (1974)]

Aldol condensations, Cobalt(II) complexes as catalysts (PR) 152

Algae, Cytological chemistry and physiology of blue-green ~ (LA) 152

Alkali metals, Novel ligand systems for complexing ~ (SC) 149 [G.E. *86*, 126 (1974)]
Dissolution in aromatic hydrocarbon solvents by cryptate formation (SC) 611 [G.E. *86*, 670 (1974)]

Alkaloids, Stereoselective synthesis of exocyclic trisubstituted double bonds (SC) 602 [G.E. *86*, 646 (1974)]
Metabolism and function in plants (LA) 554

Alkane, The aggregation of dissolved ~ chain molecules (LA) 746

Alkylation, New methods (LA) 485

Alkylmetal compounds, Stable homoleptic ~ (LA) 746

Allenecarboxylic acid, Stereospecific hydrogenation of (R)- or (S)-2-ethyl-4-phenyl-~ to cis- or trans-2-ethyl-4-phenyl-3-butenecarboxylic acid by means of Clostridium kluyveri (SC) 609 [G.E. *86*, 675 (1974)]

Allenes, Dimerization of "push-pull"-substituted ~ (SC) 143 [G.E. *86*, 162 (1974)]

Allyl alcohol, Cleavage of selenium compounds by butyllithium. A new, regiospecific, ~ synthon (SC) 804 [G.E. *86*, 857 (1974)]

Allyl ethers, Rearrangement of (trimethylsilyl)-methyl ~. A dyotropic reaction (SC) 402 [G.E. *86*, 416 (1974)]

Allylic sulfoxides (LA) 614

Allyllithium, 1,3-Anionic cycloadditions of 2-(N,N-diisopropylcarbamoyl)-~ with a two-step mechanism (SC) 468 [G.E. *86*, 476 (1974)]

Allyl radical, Homohyperconjugation in a perpendicular ~ (SC) 145 [G.E. *86*, 132 (1974)]

Amides, NMR spectroscopic studies on hindered rotation in primary ~ and thio-~ (CR) 350 [G.E. *86*, 316 (1974)]
Polycondensation of N-silylated bis-~ and bis-imides (CR) 414 [G.E. *86*, 450 (1974)]

3'-Amido-3'-deoxyadenosine 3',5'-cyclophosphate, Synthesis (SC) 280 [G.E. *86*, 308 (1974)]

Amines, Tri-tert-butylstannylamine and tri-tert-butylstannyl-N-deuterioamine: the first primary stannyl-~ (SC) 88 [G.E. *86*, 104 (1974)]
1,2-Photoaddition of primary and secondary ~ to benzene (SC) 341 [G.E. *86*, 350 (1974)]
Modified Horeau analysis for determination of chirality of ~, alcohols, and carboxylic acids (SC) 664 [G.E. *86*, 707 (1974)]

Amino acids, Effect of the herbicide N-phosphonomethylglycine on the biosynthesis of aromatic ~ (SC) 400 [G.E. *86*, 408 (1974)]
Iodinated N-acyl derivatives of aromatic ~ (PR) 212
Chelate-forming ~ (PR) 487
β-Hydroxy-α-~ (PR) 487

1-Aminoanthraquinone (PR) 615

Amino ketones, Phenolic ~ (PR) 93

3(5)-Aminopyrazole, Simple synthesis (SC) 206 [G.E. *86*, 237 (1974)]

Ammonoxidation of olefins (PR) 154

Analysis, ~ of herbicides (FP) 217 [G.E. *86*, 244 (1974)]
Trace ~ of organic compounds (FP) 224 [G.E. *86*, 251 (1974)]

Anhydrides, Preparation and reactions of trifluoromethanesulfonic arenesulfonic ~ (SC) 409 [G.E. *86*, 409 (1974)]

1,4-Anhydroerythritol, Crystal structure of a 1:1 sodium perchlorate complex of ~ (cis-3,4-tetrahydrofurandiol) (SC) 541 [G.E. *86*, 555 (1974)]

Anionic σ-complexes (LA) 746

Anions, Reaction between electrophiles and electrolytically generated ~ (CR) 349 [G.E. *86*, 314 (1974)]

Annulenes, Synthesis of tetradehydrocyclotetradeca[c]furans ("didehydro[14]annuleno-[c]furans"), 18π-electron analogs of isobenzofuran (SC) 138 [G.E. *86*, 163 (1974)]
Synthesis of 1,3,5,7,9-cyclodecapentaene-11,13-diynes ("1,3-didehydro[14]-~"). Interconversion between nonequivalent conformers of diatropic dehydroannulenes (SC) 139 [G.E. *86*, 165 (1974)]
Synthesis of tetradehydrobenzocyclotetradecenes ("benzodidehydro[14]-~"). Effect of benzoannelation on the diamagnetic ring current of macrocyclic (4n+2) π-electron systems (SC) 141 [G.E. *86*, 167 (1974)]
An aza[13]- and an aza[17]annulenyl anion (SC) 205 [G.E. *86*, 237 (1974)]
1,7-Methano[12]annulene—the 12π analog of 1,6-methano[10]annulene (SC) 281 [G.E. *86*, 229 (1974)]
1,6-Methano[12]annulene (SC) 283 [G.E. *86*, 231 (1974)]
Dianions of 1,7- and 1,6-methano[12]-~ — novel aromatic 14π electron systems (SC) 284 [G.E. *86*, 232 (1974)]
Synthesis of bridged "didehydrooxa-" and "-thia[17]-~", diatropic homologs of furan and thiophene (SC) 337 [G.E. *86*, 346 (1974)]
Synthesis of bridged "didehydrothia[17]annulene" S-oxides. Dependence of ring current on geometry in stereoisomeric sulfoxides (SC) 339 [G.E. *86*, 348 (1974)]
Photooxidation (SC) 398 [G.E. *86*, 407 (1974)]
Structure and spin multiplicity of a [4]annulene system (SC) 544 [G.E. *86*, 597 (1974)]
A heptalene synthesis from 1,6-methano[10]annulene; Evidence for a fast π-bond shift (SC) 732 [G.E. *86*, 777 (1974)]

Antiaromaticity (LA) 352

Antigen receptors, Nature of ~ on the surfaces of lymphocytes (LA) 152

Antimalarials, Antimetabolites of coenzyme Q. Their potential application as ~ (FP) 559 [G.E. *86*, 635 (1974)]

Antimetabolites of coenzyme Q. Their potential application as antimalarials (FP) 559 [G.E. *86*, 635 (1974)]

Antimony compounds, Antimony(V)-transition metal compounds with covalent and ionic character (SC) 670 [G.E. *86*, 708 (1974)]

Antimony pentafluoride, Reaction with vinyl fluoride. Spectroscopic evidence for a stable vinyl cation (SC) 675 [G.E. *86*, 677 (1974)]

Arenediazonium ions, Reactivity and stability (LA) 210

Aromatic π-electron systems, Nonbenzenoid ~ (LA) 554

Aromaticity, Synthesis and trapping reactions of the spiro[2.3]hexadienylium system: ring strain versus ~ (SC) 271 [G.E. *86*, 276 (1974)]

Arsabenzene-4-carbaldehyde (SC) 668 [G.E. *86*, 746 (1974)]

Arsabenzenes, 4-Alkoxy-~ (SC) 667 [G.E. *86*, 745 (1974)]

Arsanes, Synthesis and preparative use of metal derivatives of primary and secondary ~, stibanes, and bismuthanes (LA) 554

Arsenic compounds, Dimethylarsenido-transition metal complexes—stable organometallic Lewis bases (SC) 84 [G.E. *86*, 51 (1974)]
Synthesis of an all-cis-organocyclotriarsane derivative (SC) 601 [G.E. *86*, 646 (1974)]
Progress in arsenic chemistry (LA) 554

Arylation, Synthesis of homophthalic acids by copper-catalyzed direct ~ of β-dicarbonyl compounds with 2-bromobenzoic acids (SC) 340 [G.E. *86*, 349 (1974)]

Asymmetric synthesis, Photochemistry with circularly polarized light (FP) 179 [G.E. *86*, 222 (1974)]
Synthesis of (±)-pestalotin and (±)-epipestalotin and of optically pure (−)-pestalotin (SC) 77 [G.E. *86*, 40 (1974)]

Atomic absorption spectrometry, State of development (FP) 504 [G.E. *86*, 542 (1974)]
Atom-Absorptions-Spektroskopie (~) (Book Review) 489

Atoms, Structural analysis by direct observation of ~ by dark field transmission electron microscopy (SC) 536 [G.E. *86*, 587 (1974)]

Azaannulenes, An aza[13]- and an aza[17]annulenyl anion (SC) 205 [G.E. *86*, 237 (1974)]

Azabenzo[1,2]cyclonona[5,6,7-de]naphthalene, Conformational studies on oxa, thia, and aza derivatives of 7,8,13,14-tetrahydrobenzo[1,2]cyclonona[5,6,7-de]naphthalene and 8H,15H-7,16-dioxacyclodeca[1,2,3-de:6,7,8-d'e']dinaphthalene (SC) 731 [G.E. *86*, 814 (1974)]

Azadibenzo[a,f]cyclodecene, Conformational studies on aza, and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]

Aza-dibenzo[a,e]cyclononene, Conformational studies on aza and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]
12-~, Conformational studies on aza and thia derivatives of 12,13-dihydro-11H-dibenzo[a,e]cyclononene (SC) 728 [G.E. *86*, 812 (1974)]

Azathioxanthones, 2- and 4-~ by photorearrangement of S-aryl thionicotinates (SC) 550 [G.E. *86*, 562 (1974)]

cis-Aza-tris-σ-homobenzene, Simple bridged cis-oxa-tris-σ-homobenzene and ~ systems: synthesis and $3\sigma \rightarrow 3\pi$ isomerization (SC) 482 [G.E. *86*, 522 (1974)]

Azetidines, Cationic polymerization (CR) 414 [G.E. *86*, 450 (1974)]

2-Azetidinones, General method for synthesis of ~ and 2-azetidinylideneammonium salts (SC) 267 [G.E. *86*, 272 (1974)]

2-Azetidinylideneammonium salts, General method for synthesis of 2-azetidinones and ~ (SC) 267 [G.E. *86*, 272 (1974)]

Azide method for peptide bond synthesis (LA) 824

Aziridines, Lactones and lactams by light-induced reaction of 2-vinyloxiranes and 2-vinyl-~ with pentacarbonyliron—insertion of carbon monoxide into an iron-nitrogen σ-bond (SC) 275 [G.E. *86*, 309 (1974)]
Highly potent reagent for regioselective and stereospecific synthesis of polyenes bearing terminal aziridine groups (SC) 279 [G.E. *86*, 311 (1974)]
New reagent for stereospecific synthesis of ~ from olefins (SC) 279 [G.E. *86*, 311 (1974)]
2-Lithiated 1-tert-butyl-3-methyleneaziridine and its reaction products (SC) 342 [G.E. *86*, 380 (1974)]

Azomethinimine, The 1:1 intermediate of the "criss-cross" cycloaddition of isobutylene to hexafluoroacetone azine (SC) 474 [G.E. *86*, 481 (1974)]
X-Ray structure analysis of the 1:1 intermediate of the "criss-cross" cycloaddition of isobutylene to hexafluoroacetone azine (SC) 475 [G.E. *86*, 482 (1974)]
Reactions of trifluoromethyl-substituted ~ with nucleophiles (SC) 476 [G.E. *86*, 483 (1974)]
[3+2]-Cycloadditions to trifluoromethyl-substituted ~ (SC) 477 [G.E. *86*, 484 (1974)]

Azo compounds, Photochemistry of aliphatic ~ in solution (LA) 93

Azobenzenes, Low melting liquid crystalline o-hydroxy ~ and azoxybenzenes (SC) 344 [G.E. *86*, 378 (1974)]

Azolium salts, Reactions with nucleophilic reagents (CR) 347 [G.E. *86*, 313 (1974)]

Azoxybenzenes, Low melting liquid crystalline o-hydroxy azobenzenes and ~ (SC) 344 [G.E. *86*, 378 (1974)]

Azulene, Cyclopent[cd]-~ and 1,2-dihydrodicyclopent[cd,ij]-~ (SC) 204 [G.E. *86*, 235 (1974)]

3H-3-BENZAZONINE and the 3-benzazoninyl anion (SC) 404 [G.E. *86*, 410 (1974)]

Benzene, Simple synthesis of bicyclo[3.2.2]nona-6,8-dien-3-ones from arenes (SC) 136 [G.E. *86*, 127 (1974)]
1,2-Photoaddition with primary and secondary amines (SC) 341 [G.E. *86*, 350 (1974)]
~ (PR) 747

syn-Benzene bisepisulfide, ~ (syn-3,4:5,6-bis(epithio)-1-cyclohexene) (SC) 736 [G.E. *86*, 818 (1974)]

Benzene trioxide, Crystal and molecular structure of cis-trioxatris-σ-homobenzene(cis-~) (SC) 539 [G.E. *86*, 557 (1974)]

Benzimidazolones, New diglycidyl-~ (PR) 486

Benzocyclobutadiene, Isolation of 3,4,5,6-tetramethyl-1,2-diphenyl-~ (SC) 405 [G.E. *86*, 412 (1974)]

Benzo[1,2]cyclonona[5,6,7-de]naphthalene, Conformational Studies on oxa, thia, and aza derivatives of ~ and 8H,15H-7,16-dioxacyclodeca[1,2,3-de:6,7,8-d'e']dinaphthalene (SC) 731 [G.E. *86*, 814 (1974)]

trans-Benzocyclononatetraenyl anion (SC) 728 [G.E. *86*, 784 (1974)]

Benzocyclopropene, ^{12}C-labeling for the elucidation of reaction mechanisms—~ formation (SC) 276 [G.E. *86*, 278 (1974)]

Benzofuroxans, Photochromism of 4-substituted ~ (SC) 86 [G.E. *86*, 52 (1974)]

Benzoic acid, Derivatives of 4,4'-tetrachloroethylenedi-~ (PR) 555

Benzoic esters, 3,5-Dialkyl-4-hydroxy(thio)-~ (PR) 555

1,4-Benzoquinonetetracarboxylic acid, Polyimides of ~ (PR) 211

Benzoquinonophane, [2,2](2,5)-~: Structure and photochemistry (SC) 674 [G.E. *86*, 705 (1974)]

1-Benzothiepin, Synthesis and reactions (SC) 142 [G.E. *86*, 161 (1974)]

Benzyl radical, ESR spectrum of a perpendicular ~ (SC) 144 [G.E. *86*, 131 (1974)]

Beverages, Spurenelemente in Wein und anderen Getränken (Book Review) 827

Bicyclo[1.1.0]butane, X-Ray structure analysis of 6-thiatetracyclo[5.4.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene (SC) 669 [G.E. *86*, 738 (1974)]

Bicyclo[2.2.0]hexanes, 1,4-Diphenyl-~ from 1,2-diphenylcyclobutanes (SC) 816 [G.E. *86*, 740 (1974)]

Bicyclo[3.2.2]nona-6,8-dien-3-one, Simple synthesis from arenes (SC) 136 [G.E. *86*, 127 (1974)]

Bicyclo[6.1.0]nona-2,4,6-triene, Reaction with tetracyanoethylene (SC) 207 [G.E. *86*, 238 (1974)]

Binaphthylylenephosphoric acids, Optical isomers (PR) 153

Biochemistry, Comprehensive ~ (Book Review) 825

Biopolymers: origin, chemistry, and biology (FP) 121 [G.E. *86*, 111 (1974)]

Biosynthesis (Book Review) 489

1,4-Bis(4,4'-dihydroxytriphenylmethyl)benzene (PR) 212

Block polymerization, Continuous process for ~ (PR) 486

Blood platelets, Inhibition of aggregation by substituted quinazolines (LA) 211

Bonds, Effects of through-bond interaction (FP) 696 [G.E. *86*, 770 (1974)]

Boranes, Partially alkylated ~ (LA) 485
~ in organic chemistry (Book Review) 418, 422

Boron compounds, Rearrangements in organoboron chemistry (LA) 286

Branching reactions, Occurrence in the copolymerization of trioxane with 1,3-dioxolane (CR) 418 [G.E. *86*, 454 (1974)]

2-Bromobenzoic acids, Synthesis of homophthalic acids by copper-catalyzed direct arylation of β-dicarbonyl compounds with ~ (SC) 340 [G.E. *86*, 349 (1974)]

Butadiene, Partial enantiomerization of an atropisomeric butadiene (SC) 741 [G.E. *86*, 775 (1974)]

Butatrienylsulfonium salts, ~ in solution (SC) 469 [G.E. *86*, 477 (1974)]
Stable propadienylsulfonium salts by cycloadditions with ~ (SC) 470 [G.E. *86*, 477 (1974)]

CANDLE material, Transparent ~ (PR) 94

Carbamic acids, Esters of N,N'-ethylenedi-~ and ethylenedithio-~ (PR) 354

Carbanions, Crown ethers as catalysts in reactions of ~ and halocarbenes (SC) 665 [G.E. *86*, 744 (1974)]

Carbene complexes, New method for preparation of transition metal-~ (SC) 599 [G.E. *86*, 556 (1974)]

Carbenes, Crown ethers as catalysts in reactions of carbanions and halo-~ (SC) 665 [G.E. *86*, 744 (1974)]

Carbohydrates, Results and problems of O-glycoside synthesis (FP) 157 [G.E. *86*, 173 (1974)]
Carbohydrate components of surface glycoproteins (LA) 211

Carbon-carbon bonds, Prescriptions and ingredients for controlled CC bond formation with organometallic reagents (FP) 701 [G.E. *86*, 751 (1974)]

Carbon-carbon linking, Improved ~ by controlled copper catalysis (SC) 82 [G.E. *86*, 50 (1974)]

Carbon fibers having cation exchange properties (PR) 353

Carbon monoxide, Lactones and lactams by light-induced reaction of 2-vinyloxiranes and 2-vinylaziridines with pentacarbonyliron—insertion of ~ into an iron-nitrogen σ-bond (SC) 275 [G.E. *86*, 309 (1974)]

Carbon suboxide in preparative organic chemistry (FP) 491 [G.E. *86*, 529 (1974)]

Carbonyl groups, Correlation of ^{13}C-NMR chemical shifts of ~ and thio-~ (SC) 90 [G.E. *86*, 43 (1974)]

Carboxylic acids, Modified Horeau analysis for determination of the chirality of amines, alcohols, and ~ (SC) 664 [G.E. *86*, 707 (1974)]
Aromatic ~ (PR) 747

Carbynes, Pentacarbonylmanganese bromide—An organometallic trapping reagent for ethoxycarbonyl-~ (SC) 812 [G.E. *86*, 895 (1974)]

Catalase, Biochemistry of the peroxisome in the liver cell (FP) 706 [G.E. *86*, 789 (1974)]

Catalysis, Phase-transfer catalyzed two-phase reactions in preparative organic chemistry (FP) 170 [G.E. *86*, 187 (1974)]

Catalysts, Stereospecific hydrogenations with hydrogen gas and microorganisms as ~ (SC) 608 [G.E. *86*, 675 (1974)]

Crown ethers as ~ in reactions of carbanions and halocarbenes (SC) 665 [G.E. *86*, 744 (1974)]
Cobalt(II) complexes as ~ for aldol condensations (PR) 152
Cationic deposition, Electrophoretic binders for ~ that crosslink at high temperatures (PR) 422
Cells, Surface of mammalian ~ (LA) 152
Cellulose, Problems and results in ~ research (CR) 417 [G.E. *86*, 454 (1974)]
Cephalosporin, New synthesis for ~ intermediates (PR) 286
~-s and penicillins (Book Review) 616
Chain molecules, The characterization of ~ by their dipole moments (LA) 823
Chalones (LA) 210
Chemical shifts, Correlation of ^{13}C-NMR ~ of carbonyl and thiocarbonyl groups (SC) 90 [G.E. *86*, 43 (1974)]
Chirality, Modified Horeau analysis for determination of ~ of amines, alcohols, and carboxylic acids (SC) 664 [G.E. *86*, 707 (1974)]
Chiral ligands, Macrobicyclic and macrotricyclic ~ (SC) 406 [G.E. *86*, 443 (1974)]
Chlorinated systems, Highly ~ by ring closure reactions (CR) 210 [G.E. *86*, 134 (1974)]
Chlorine compounds, Unsaturated ~ (PR) 152
Chromatography of environmental hazards (Book Review) 748
Chromium(II) salts, Uses in preparative organic chemistry (LA) 420
Cobalt(I) complexes, 2,3-Dimethyl-1,3-butadienehydridobis(triphenylphosphane)-cobalt(I) (SC) 336 [G.E. *86*, 351 (1974)]
Cobalt(II) complexes as catalysts for aldol condensations (PR) 152
Cobalt compounds, Higher oxidation states of iron, cobalt, and nickel (LA) 614
Coenzyme Q, Antimetabolites of ~. Their potential application as antimalarials (FP) 559 [G.E. *86*, 635 (1974)]
Collagen, The biosynthesis of ~ (LA) 823
Complexes, Structures of the intermediate ~ in Friedel-Crafts acylations (FP) 1 [G.E. *86*, 12 (1974)]
Square planar transition metal ~ with a bidentate ligand spanning trans-positions (SC) 133 [G.E. *86*, 133 (1974)]
Chiral macrobicyclic and macrotricyclic ligands (SC) 406 [G.E. *86*, 443 (1974)]
Evidence for a chiral intermediate on phosphane substitution in complex (+)-$C_5H_5Mn(NO)(COC_6H_5)P(C_6H_5)_3$ (SC) 810 [G.E. *86*, 864 (1974)]
Anionic σ-~ (LA) 746
ESR spectra of binuclear transition metal ~ (LA) 824
Metal π-~, Vol. II. ~ with mono-olefinic ligands (Book Review) 556
Configuration entropy, Quasi-static glass temperature and ~ (CR) 415 [G.E. *86*, 451 (1974)]
Conformational studies on aza and thia derivatives of 12,13-dihydro-11H-dibenzo[a,e]-cyclononene (SC) 728 [G.E. *86*, 812 (1974)]
Conformational studies on aza, and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]
Conformational studies on oxa, thia, and aza derivatives of 7,8,13,14-tetrahydrobenzo[1,2]cyclonona[5,6,7-de]naphthalene and 8H,15H,7,16-dioxacyclodeca[1,2,3-de:6,7,-8-d'e']dinaphthalene (SC) 731 [G.E. *86*, 814 (1974)]
Conformations, ~ of trans-cyclooctene (SC) 604 [G.E. *86*, 672 (1974)]
Conjugative effects, Method for evaluation of inductive effects and ~—application to tropone (SC) 273 [G.E. *86*, 275 (1974)]
Coordination in bis(thiooxomolybdato)metalate(II) complexes of type $[M(MoOS_3)_2]^{2-}$ and $[M(MoO_2S_2)]^{2-}$ (SC) 672 [G.E. *86*, 709 (1974)]
Coordination compounds, Koordinationsverbindungen (Book Review) 354
Cope rearrangement, Dynamic stereochemistry of the degenerate diaza-~ (SC) 480 [G.E. *86*, 520 (1974)]
4,8-Dioxabicyclo[5.1.0]octa-2,5-diene (SC) 672 [G.E. *86*, 742 (1974)]
Copper catalysis, Improved carbon-carbon linking by controlled ~ (SC) 82 [G.E. *86*, 50 (1974)]
Copper compounds, Oxidative coupling via organo-~ (FP) 291 [G.E. *86*, 321 (1974)]
Prescriptions and ingredients for controlled CC bond formation with organometallic reagents (FP) 701 [G.E. *86*, 751 (1974)]
Criss-cross cycloaddition, 1:1 intermediate of ~ of isobutylene to hexafluoroacetone azine (SC) 474 [G.E. *86*, 482 (1974)]
X-Ray structure analysis of 1:1 intermediate of ~ of isobutylene to hexafluoroacetone azine (SC) 475 [G.E. *86*, 482 (1974)]
Crosslinking reactions in the rubber particles of high-impact polystyrene (CR) 418 [G.E. *86*, 454 (1974)]
Crown ethers as catalysts in reactions of carbanions and halocarbenes (SC) 665 [G.E. *86*, 744 (1974)]
Cryptate, Dissolution of alkali metals in aromatic hydrocarbon solvents by ~ formation (SC) 611 [G.E. *86*, 670 (1974)]
Crystals, Intracrystalline reactivity of phyllodisilicic acid $(H_2Si_2O_5)_\infty$ (SC) 819 [G.E. *86*, 893 (1974)]
Crystal structure, Subhalides of tellurium: ~ of α-TeI and β-TeI (SC) 403 [G.E. *86*, 411 (1974)]
~ and molecular structure of cis-trioxatris-σ-homobenzene (cis-benzene trioxide) (SC) 539 [G.E. *86*, 557 (1974)]
~ of a 1:1 sodium perchlorate complex of 1,4-anhydroerythritol (cis-3,4-tetrahydrofurandiol) (SC) 541 [G.E. *86*, 555 (1974)]
~ of $(HgI)_2TiF_6$ (SC) 821 [G.E. *86*, 863 (1974)]
Anionic structure of the so-called ammonium dimolybdate $(NH_4)_2Mo_2O_7$ (SC) 823 [G.E. *86*, 894 (1974)]
Crystalline state of macromolecular substances (FP) 244 [G.E. *86*, 283 (1974)]
Cubacine, a methoxyheteroyohimbine derivative having sympatholytic properties (PR) 353
Cyanamide, Improved preparation of monosodium ~ (SC) 546 [G.E. *86*, 590 (1974)]
Cycloaddition, 1,3-Anionic ~-s of organolithium compounds: an initial survey (FP) 627 [G.E. *86*, 715 (1974)]
Trapping of the 1,4-dipole formed in the [2+2]-~ of tetracyanoethylene to enol ethers (SC) 80 [G.E. *86*, 47 (1974)]
1,3-Anionic ~-s of 2-(N,N-diisopropylcarbamoyl)allyllithium with a two-step mechanism (SC) 468 [G.E. *86*, 476 (1974)]
Stereospecific endo-anti-~-s of diazoalkanes to 7-substituted norbornadiene: A $\pi\rightarrow\sigma$ effect? (SC) 606 [G.E. *86*, 673 (1974)]
~-s of o-quinonoid compounds (CR) 348 [G.E. *86*, 313 (1974)]
Cyclobutadiene, The ~ problem (FP) 425 [G.E. *86*, 491 (1974)]
Isolation of 3,4,5,6-tetramethyl-1,2-diphenylbenzo-~ (SC) 405 [G.E. *86*, 412 (1974)]
The structure of a rectangular ~ (SC) 740 [G.E. *86*, 783 (1974)]
Cyclobutanes, Reaction of N-phenyl(ketenimin ylidene)triphenylphosphorane with carbonyl compounds (SC) 473 [G.E. *86*, 479 (1974)]
Orientation on photochemical ~ cleavages: cis-effect (SC) 817 [G.E. *86*, 741 (1974)]
Cyclobutanone, Stereospecificity as an argument against the intermediacy of 1,4-alkyl/acyl diradicals in the light-induced ~-tetrahydrofurylidene isomerization in condensed phase (SC) 197 [G.E. *86*, 197 (1974)]
Low temperature electronic spectroscopic observations on light-induced ~-tetrahydrofurylidene rearrangement (SC) 198 [G.E. *86*, 198 (1974)]
Peculiar behavior of electronically excited ~-s: A photochemical example of the consequence of through-bond interaction (SC) 199 [G.E. *86*, 199 (1974)]
Simple EH Model for photochemical ~-tetrahydrofurylidene isomerization (SC) 200 [G.E. *86*, 200 (1974)]
Convenient synthesis of ~-s (SC) 267 [G.E. *86*, 272 (1974)]
~-s from 1-bromo-1-lithiocyclopropanes and ketones (SC) 277 [G.E. *86*, 279 (1974)]
Cyclobutenes, 1,4-Diphenylbicyclo[2.2.0]hexanes from 1,2-diphenyl-~ (SC) 816 [G.E. *86*, 740 (1974)]
Cyclocystine, Temperature-induced change in helicity of the inherently dissymmetrical disulfide group in ~ (SC) 818 [G.E. *86*, 856 (1974)]
Cyclodextrin, X-Ray structure analysis of the krypton inclusion complex: A noble gas in an organic matrix (SC) 552 [G.E. *86*, 594 (1974)]
Cyclohepta[cd]phenalen-6-one (SC) 807 [G.E. *86*, 861 (1974)]
Cyclohepta[cd]phenalenium ion (SC) 808 [G.E. *86*, 862 (1974)]
Cycloheptatriene, Novel isomers of ~: tricyclo[4.1.0.$0^{2,7}$]hept-3-ene and tetracyclo-[4.1.0.$0^{2,4}$.$0^{3,5}$]heptane (SC) 208 [G.E. *86*, 197 (1974)]
Cyclohexanones, Addition of oxoalkane polyanions to nitroolefins. New synthesis of ~ (SC) 400 [G.E. *86*, 446 (1974)]
Cyclooctasulfur monoxide from cyclooctasulfur (SC) 603 [G.E. *86*, 648 (1974)]
Cycloocta[1,2-b:4,3-b:5,6-b:8,7-b]tetrathiophene, Preparation and properties (SC) 467 [G.E. *86*, 475 (1974)]
trans-Cyclooctene, Conformations (SC) 604 [G.E. *86*, 672 (1974)]
Cyclopentadienylidene, Proof of electrophilic character (SC) 483 [G.E. *86*, 413 (1974)]
Cyclopent[cd]azulene and 1,2-dihydrodicyclopent[cd,ij]azulene (SC) 204 [G.E. *86*, 235 (1974)]
Cyclophanes, The pseudogeminal "quinhydrone" of the [2.2]paracyclophane series (SC) 203 [G.E. *86*, 234 (1974)]
Cyclopropanes, Stable 1,1-diiodo- and 1-chloro-1-iodo-~ (SC) 132 [G.E. *86*, 42 (1974)]
Cyclopropene, Quantitative cyclotrimerization of 3,3-dimethylcyclopropene to "hexamethyl-trans-σ-trishomobenzene" (SC) 465 [G.E. *86*, 518 (1974)]
Codimerization of 3,3-dimethyl-~ with ethylenecarboxylic esters at nickel(0) catalysts (SC) 466 [G.E. *86*, 518 (1974)]
Cyclopropenylium ions, Trialkoxy-~ (SC) 209 [G.E. *86*, 203 (1974)]

Cyclostannazanes, 1,3,2,4-Diazadistannetidines, the first four-membered ~ (SC) 607 [G.E. *86*, 676 (1974)]

1,3,5,7,9-Cyclotetradecapentaene-11,13-diynes, Synthesis of ~ ("1,3-didehydro[14]annulenes"). Interconversion between nonequivalent conformers of diatropic dehydroannulenes (SC) 139 [G.E. *86*, 165 (1974)]

Cyclotriarsane, Synthesis of an all-cis-organo-~ derivative (SC) 601 [G.E. *86*, 646 (1974)]

DECARBONYLATION, Oxidative ~ of octaethyl-α-hydroxyporphinatozinc(II) (SC) 150 [G.E. *86*, 125 (1974)]

Degradation, Mechanism of polymer ~ in solution by ultrasound (CR) 413 [G.E. *86*, 449 (1974)]

Dehydrogenation, Enzymic ~ of lactate and ethanol (LA) 152

5'-Deoxy-5'-adenosineacetic acid, New type of model nucleotide: ~ (SC) 77 [G.E. *86*, 41 (1974)]

Deoxyribonucleotides, Enzymatic reduction of ribonucleotides: Biosynthesis pathway of ~ (FP) 569 [G.E. *86*, 624 (1974)]

Deuterium labeling in organic chemistry (Book Review) 680

3,5-Dialkyl-4-hydroxy(thio)benzoic esters (PR) 555

1,3,2-Diazaboroline, 1,3-Diphenyl-2,4,5-trimethyl-~ (SC) 467 [G.E. *86*, 519 (1974)]

Diaza-Cope rearrangement, Dynamic stereochemistry of the degenerate ~ (SC) 480 [G.E. *86*, 520 (1974)]

1,3,2,4-Diazadistannetidines, the first four-membered cyclostannazanes (SC) 607 [G.E. *86*, 676 (1974)]

Diazoalkanes, Reactions with λ^3-phosphorins in presence of alcohols and phenols (SC) 148 [G.E. *86*, 129 (1974)]
^{13}C-NMR spectra (SC) 270 [G.E. *86*, 274 (1974)]
Stereospecific endo-anti-cycloadditions to 7-substituted norbornadiene: A π→σ effect? (SC) 606 [G.E. *86*, 673 (1974)]

Diazonium ions, Reactivity and stability of arene-~ (LA) 210

Dibenzo[a,f]cyclodecene, Conformational studies on aza and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydro-~ (SC) 730 [G.E. *86*, 813 (1974)]

Dibenzo[a,e]cyclononene, Conformational studies on aza and thia derivatives of 6,11,12,13-tetrahydro-5H-~ and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]

Dibenzofurans by intramolecular ring closure reactions (SC) 471 [G.E. *86*, 478 (1974)]

Dichloromaleimides (PR) 213

Dictionaries, Wörterbuch der Chemie und der chemischen Verfahrenstechnik (Book Review) 94
2200 Begriffsbestimmungen nach DIN (Deutsch und Englisch) (Book Review) 557

2,4-Dicyano-3,5-dimethylaniline (PR) 287

Dicyclopent[cd,ij]azulene, Cyclopent[cd]azulene and 1,2-dihydro-~ (SC) 204 [G.E. *86*, 235 (1974)]

Dicyclopropa[b,g]naphthalene, 1,4-Dihydro-~ (SC) 736 [G.E. *86*, 780 (1974)]

Dielectrics, Dielectric and Related Molecular Processes (Book Review) 488

Diethyl ketone (PR) 212

Diffusion, Mass transport in solids (FP) 384 [G.E. *86*, 428 (1974)]
Equilibrium and transport properties of low-melting salts (FP) 438 [G.E. *86*, 467 (1974)]

Digestion methods, Aufschlussmethoden der anorganischen und organischen Chemie (Book Review) 289

Diglycidylbenzimidazolones (PR) 486

Diglycolic acid (PR) 486

Diimine, Structure of ~: X-ray diffraction analysis of $N_2H_2[Cr(CO)_5]_2 \cdot 2THF$ (SC) 822 [G.E. *86*, 860 (1974)]

1,1-Diiodocyclopropanes, Stable ~ and 1-chloro-1-iodocyclopropanes (SC) 132 [G.E. *86*, 42 (1974)]

Diols, Steric effects in the mass spectra of monocyclic and bicyclic ~ and their derivatives (CR) 348 [G.E. *86*, 314 (1974)]

4,8-Dioxabicyclo[5.1.0]octa-2,5-diene (SC) 672 [G.E. *86*, 742 (1974)]

Dioxacyclodeca[1,2,3-de:6,7,8-d'e']dinaphthalene, Conformational studies on oxa, thia, and aza derivatives of 7,8,13,14-tetrahydrobenzo[1,2]cyclonona[5,6,7-de]naphthalene and 8H,15H-7,16-~ (SC) 731 [G.E. *86*, 814 (1974)]

1,2-Dioxetane, Tetramethyl-~ (LA) 678

1,3-Dioxolane, Occurrence of branching reactions in copolymerization of trioxane with ~ (CR) 418 [G.E. *86*, 454 (1974)]

Diphenic acid, New process for production of ~ and 2-phenylbenzoic acid (PR) 421

Diphenylketene, First π-~-carbonyl-transition metal complexes (SC) 335 [G.E. *86*, 345 (1974)]

Dipole moments, The characterization of chain molecules by their ~ (LA) 823

Dipoles, Trapping of the 1,4-dipole formed in the 2+2-cycloaddition of tetracyanoethylene to enol ethers (SC) 80 [G.E. *86*, 47 (1974)]

Disulfide group, Temperature-induced change in helicity of the inherently dissymmetrical ~ in cyclocystine (SC) 818 [G.E. *86*, 856 (1974)]

1,4-Dithiocin-6-yl acetate (SC) 345 [G.E. *86*, 381 (1974)]

1,2-Dithioles, New aspects of 1,2-dithiole chemistry (CR) 349 [G.E. *86*, 315 (1974)]

Double bonds, Addition of aliphatic aldehydes to activated ~ (SC) 539 [G.E. *86*, 589 (1974)]
Stereoselective synthesis of exocyclic trisubstituted ~ (SC) 602 [G.E. *86*, 646 (1974)]

Drugs, Metabolism of hormones, ~, and other substances by the gut (LA) 151
The interaction of ~ with microtubule proteins (LA) 746

Dyotropic reaction, Rearrangement of (trimethylsilyl)methyl allyl ethers. A ~ (SC) 402 [G.E. *86*, 416 (1974)]

ELASTOMERS, Mixed accelerator for vulcanization of EPDM ~ (PR) 93

Electrochemistry, Hydroxylating dimerization of styrene at the anode (SC) 472 [G.E. *86*, 480 (1974)]
~ (Book Review) 154
Techniques of ~ (Book Review) 355
~ of cleaner environments (Book Review) 824

Electrocyclic reactions, Perturbed ~: A three-membered ring example (CR) 351 [G.E. *86*, 317 (1974)]

Electrode processes, Modern methods for the study of ~ (FP) 683 [G.E. *86*, 756 (1974)]

Electrolytes, Nonaqueous ~ Handbook (Book Review) 616

Electronic effect of phosphorus and its preparative consequences (CR) 351 [G.E. *86*, 316 (1974)]

Electronic transitions in transition metal compounds at high pressure (FP) 39 [G.E. *86*, 61 (1974)]

Electron microscopy, Structural analysis by direct observation of atoms by dark field transmission ~ (SC) 536 [G.E. *86*, 587 (1974)]

Electropainting, Elektrotauchlackierung (Book Review) 826

Electrophiles, Reaction with electrolytically generated anions (CR) 349 [G.E. *86*, 314 (1974)]

Electrophilic character, Proof of ~ of cyclopentadienylidene (SC) 483 [G.E. *86*, 413 (1974)]

Electrophoretic binders for cationic deposition that crosslink at high temperatures (PR) 422

Emulsifiers, Biodegradable ~ for polychloroprene (PR) 153

Emulsion polymerization, Peculiarities of particle formation in ~ of acrylic esters (CR) 418 [G.E. *86*, 455 (1974)]

Enantiomerization, Partial ~ of an atropisomeric butadiene (SC) 741 [G.E. *86*, 775 (1974)]

Enol ethers, Conformations of the zwitterionic intermediates from tetracyanoethylene and alkyl propenyl ethers (SC) 81 [G.E. *86*, 48 (1974)]

Entropy. The devil on the pillion. A popular exposition (Book Review) 680

Environment, Electrochemistry of cleaner ~ (Book Review) 824

Enzyme levels, Effects of hormones on ~ in the mammalian organism (LA) 152

Epipestalotin, Synthesis of (±)-pestalotin and (±)-~ and of optically pure (−)-pestalotin by asymmetric synthesis (SC) 77 [G.E. *86*, 40 (1974)]

Episulfides, Organic ~ (PR) 213

2,3-Epoxybiphenylene—a new arene oxide (SC) 277 [G.E. *86*, 278 (1974)]

Epoxy resins, Non-gelling, water-dispersible cationic ~ (PR) 486

Equilibrium and transport properties of low-melting salts (FP) 438 [G.E. *86*, 467 (1974)]

ESR spectra of binuclear transition metal complexes (LA) 824

ESR spectroscopy, ESR spectrum of a perpendicular benzyl radical (SC) 144 [G.E. *86*, 131 (1974)]

Ethanol, Enzymic dehydrogenation of lactate and ~ (LA) 152

Ethylenecarboxylic esters, Codimerization of 3,3-dimethylcyclopropene with ~ at nickel(0) catalysts (SC) 466 [G.E. *86*, 518 (1974)]

(+)-2,2'-(Ethylenediimino)di-1-butanol, An improved preparation (PR) 679

Evolution, Recent discoveries in ~ of proteins (FP) 186 [G.E. *86*, 209 (1974)]

Excited states, Chemically produced ~ (FP) 229 [G.E. *86*, 292 (1974)]

FEATHERS, Pigments of reddish hair and ~ (FP) 305 [G.E. *86*, 355 (1974)]

Fibrinogen, Structural investigations on ~ in solution (CR) 415 [G.E. *86*, 452 (1974)]

Flavins, 8α-Substituted ~ of biological importance (LA) 746

Fluoride complexes, Stability in aqueous solutions (LA) 614

Fluorides, Sulfonylbis(imidosulfur oxide difluoride) from trichlorophosphazosulfonylimidosulfur oxide difluoride (SC) 401 [G.E. *86*, 442 (1974)]

Fluorination, Catalytic ~ of vinyl chloride (PR) 212

Fluorine atoms, Photodifluoroamination (LA) 420

Fluorine compounds, Polynuclear oxofluoro anions of molybdenum (SC) 600 [G.E. *86*, 598 (1974)]

Formaldehyde, Structure of reaction products of melamine and ~ (CR) 412 [G.E. *86*, 448 (1974)]

Formaldehyde oxime, Constitution of the polymers and the coordination compounds of ~ (CR) 348 [G.E. *86*, 314 (1974)]

Friedel-Crafts acylations, Structures of intermediate complexes (FP) 1 [G.E. *86*, 12 (1974)]

Functional groups, Mass spectral interaction between the ~ of multiply substituted alkanes (FP) 252 [G.E. *86*, 256 (1974)]

Furan, Synthesis of tetradehydrocyclotetradeca[c]-~-s ("didehydro[14]annuleno[c]-~-s"), 18π-electron analogs of isobenzo-~ (SC) 138 [G.E. *86*, 163 (1974)]
Synthesis of bridged "didehydrooxa"- and "-thia[17]annulenes", diatropic homologs of ~ and thiophene (SC) 337 [G.E. *86*, 346 (1974)]

Furoxans, Thermal decomposition of ~ (PR) 747

GENETICS, Bakterien-, Phagen- und Molekulargenetik (Book Review) 354

Geochemistry, What do we know about the deeper layers of the Earth? (FP) 580 [G.E. *86*, 612 (1974)]

Germanium compounds, Advances in the chemistry of germanium (LA) 485

Glass temperature, Quasi-static ~ and configuration entropy (CR) 415 [G.E. *86*, 451 (1974)]

Glutaraldehyde (PR) 352

Glycoproteins, Carbohydrate components of surface ~ (LA) 211
~. Their composition, structure, and function (Book Review) 215

O-Glycosides, Results and problems of synthesis (FP) 157 [G.E. *86*, 173 (1974)]

Gold complexes, Modes of reaction of 2- and 3-hydroxyalkyl isocyanides with metal compounds; oxazolidinylidene and perhydrooxazinylidene complexes of palladium, platinum, and gold (SC) 599 [G.E. *86*, 588 (1974)]

Grignard reactions, Free radicals in ~ (CR) 419 [G.E. *86*, 382 (1974)]

Growth regulators, New ~ for plants (PR) 615
(Hydrogenated) phthalimidoacetic acid derivatives (ER) 615

HAIR, Pigments of reddish ~ and feathers (FP) 305 [G.E. *86*, 355 (1974)]

Halovinyl carbonates in organic synthesis (FP) 520 [G.E. *86*, 567 (1974)]

Harries' tetraketone, Synthesis of 2,6,10,14-pentadecanetetrones. A δ-tetraketone (~) (SC) 136 [G.E. *86*, 160 (1974)]

Heptafulvene, ^{13}C-NMR spectra of ~, pentafulvene, and sesquifulvalene (SC) 551 [G.E. *86*, 595 (1974)]

Heptalene, Synthesis from 1,6-methano[10]annulene; Evidence for a fast π-bond shift (SC) 732 [G.E. *86*, 777 (1974)]
Stable ~.—3,8-Dibromo-~ (SC) 734 [G.E. *86*, 778 (1974)]

3,8-Heptalenedicarboxylate, Dimethyl ~ (SC) 735 [G.E. *86*, 779 (1974)]

Helicenes (FP) 649 [G.E. *86*, 627 (1974)]

Herbicides, Analysis (FP) 217 [G.E. *86*, 244 (1974)]
Effect of the herbicide N-phosphonomethylglycine on the biosynthesis of aromatic amino acids (SC) 400 [G.E. *86*, 408 (1974)]
Herbicidal sulfoxides and sulfones (PR) 555

Heterocyclic polymers, New ~ (PR) 614

Hexafluoroacetone azine, 1:1 intermediate of criss-cross cycloaddition of isobutylene to ~ (SC) 474 [G.E. *86*, 482 (1974)]
X-Ray structure analysis of 1:1 intermediate of criss-cross cycloaddition of isobutylene to ~ (SC) 475 [G.E. *86*, 482 (1974)]
Structure of 1:1-adduct of ~ and 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane (SC) 543 [G.E. *86*, 560 (1974)]

Hexamanganato(VII)manganic(IV) acid: A "pseudopermanganic acid" (SC) 603 [G.E. *86*, 647 (1974)]

Homohyperconjugation in a perpendicular allyl radical (SC) 145 [G.E. *86*, 132 (1974)]

Homophthalic acids, Synthesis of ~ by copper-catalyzed direct arylation of β-dicarbonyl compounds with 2-bromobenzoic acids (SC) 340 [G.E. *86*, 349 (1974)]

Hormones, cis-trans-Isomerism of thyrotropin releasing hormone (TRH) in aqueous solution (SC) 131 [G.E. *86*, 46 (1974)]
Metabolism of ~, drugs, and other substances by the gut (LA) 151
Effects on enzyme levels in the mammalian organism (LA) 152

Hydrazones, Substituted 5-dialkylaminopyrazoles from ~ and phosgeneimonium salts (SC) 79 [G.E. *86*, 45 (1974)]
~ (PR) 153

Hydrocarbons, Base-catalyzed C—C addition reactions (LA) 554
Base-catalyzed additions (LA) 614

Hydrocarbon solvents, Dissolution of alkali metals in aromatic ~ by cryptate formation (SC) 611 [G.E. *86*, 670 (1974)]

Hydrogenase model, A palladium(II) complex as ~ (SC) 549 [G.E. *86*, 561 (1974)]

Hydrogenations, Stereospecific ~ with hydrogen gas and microorganisms as catalysts (SC) 608 [G.E. *86*, 675 (1974)]
Stereospecific ~ of (R)- or (S)-2-ethyl-4-phenylallenecarboxylic acid to cis- or trans-2-ethyl-4-phenyl-3-butenecarboxylic acid by means of Clostridium kluyveri (SC) 609 [G.E. *86*, 675 (1974)]

Hydroxamic acids, Chemistry of ~ and N-hydroxyimides (FP) 376 [G.E. *86*, 419 (1974)]

β-Hydroxy-α-amino acids (PR) 487

4-(2-hydroxybutoxy)-2-butanol (PR) 353

2-Hydroxyglycals, Efficient synthesis of sugar 3,2-enolones from ~ and their conversion into 4-pyrones (SC) 546 [G.E. *86*, 590 (1974)]
1,2-Dichlorides from ~: Preparation and assignment of configuration by the exciton chirality method (SC) 548 [G.E. *86*, 592 (1974)]

3-Hydroxy-2-hydroxymethyl propanesulfonic acid, Salts (PR) 555

N-Hydroxyimides, Chemistry of hydroxamic acids and ~ (FP) 376 [G.E. *86*, 419 (1974)]

Hydroxylation, Photochemical ~ of aromatic compounds (LA) 421

Hydroxylating dimerization of styrene at the anode (SC) 472 [G.E. *86*, 480 (1974)]

IMIDAZO[4,5-b]QUINOXALINES (PR) 615

Imides, Polycondensation of N-silylated bisamides and bis-~ (CR) 414 [G.E. *86*, 450 (1974)]

α-Imino nitriles, New preparation (PR) 287

Immunoglobulin receptors (LA) 211

Inclusion compounds, Chemistry (LA) 554

1,3-Indandione, Pyridinium ylide of ~ (SC) 343 [G.E. *86*, 380 (1974)]

Indole alkaloids, Stereoselective synthesis of exocyclic trisubstituted double bonds (CR) 602 [G.E. *86*, 646 (1974)]

Indolizines, A new synthesis of ~ (SC) 737 [G.E. *86*, 781 (1974)]

Inductive effects, Method for evaluation of ~ and conjugative effects—application to tropone (SC) 273 [G.E. *86*, 275 (1974)]

Industrial chemistry, Ullmanns Encyklopädie der technischen Chemie (Book Review) 423

Inositolphosphatide metabolism in externally stimulated cells (LA) 286

Infrared spectroscopy, Laboratory methods in ~ (Book Review) 95

Insecticidal substances, New groups of ~ (PR) 287

Insulin, Progress in the synthesis of human pro-~ and of a pro-~ model (CR) 419 [G.E. *86*, 455 (1974)]

Interactions, Specific ~, intermolecular forces, steric requirements, and molecular size (FP) 719 [G.E. *86*, 802 (1974)]

Intermolecular forces, Specific interactions, ~, steric requirements, and molecular size (FP) 719 [G.E. *86*, 802 (1974)]

Interstellar space, Photochemistry in ~ and reactions generating interstellar molecules (FP) 370 [G.E. *86*, 401 (1974)]

Iodine compounds, Iodinated N-acyl derivatives of aromatic amino acids (PR) 212

Ion exchange, Carbon fibers having cation exchange properties (PR) 353

Iron absorption, The regulation of ~ (LA) 746

Iron complexes, Lactones and lactams by light-induced reaction of 2-vinyloxiranes and 2-vinylaziridines with pentacarbonyliron—insertion of carbon monoxide into an iron-nitrogen σ bond (SC) 275 [G.E. *86*, 309 (1974)]
Bis(1,2,4,6-tetraphenyl- and bis(1-methyl-2,4,6-triphenyl-λ^5-phosphorinyl)iron (SC) 408 [G.E. *86*, 445 (1974)]
Photochemical synthesis of bis(η-methyl acrylate)tricarbonyliron (SC) 534 [G.E. *86*, 558 (1974)]
Present knowledge about dinuclear oxo-bridged iron(III) complexes (LA) 352
Organo-~ as potential reagents in organic synthesis (LA) 678

Iron compounds, Higher oxidation states of iron, cobalt, and nickel (LA) 614

Isobutene, Proton resonance measurements on polymaleic anhydride and maleic anhydride-~ copolymers (CR) 414 [G.E. *86*, 450 (1974)]

Isobutylene, 1:1 intermediate of the criss-cross cycloaddition of ~ to hexafluoroacetone azine (SC) 474 [G.E. *86*, 482 (1974)]
X-Ray structure analysis of the 1:1 intermediate of the criss-cross cycloaddition of ~ to hexafluoroacetone azine (SC) 475 [G.E. *86*, 482 (1974)]

Isocyanates, Chemistry of hydroxamic acids and N-hydroxyimides (FP) 376 [G.E. *86*, 419 (1974)]
New route to copolymers containing isocyanate groups (PR) 287
Continuous production of organic ~ (PR) 353
1-Alkenyl ~ (PR) 747
Sulfonylaminosulfonyl ~ (PR) 748

Isocyanides, Metalated ~ in organic synthesis (FP) 789 [G.E. *86*, 878 (1974)]
Modes of reaction of 2- and 3-hydroxyalkyl ~ with metal compounds; oxazolidinylidene and perhydrooxazinylidene complexes of palladium, platinum, and gold (SC) 599 [G.E. *86*, 588 (1974)]
α-Acyloxy ~ ("O-acyl ~") (SC) 676 [G.E. *86*, 679 (1974)]

2H-Isoindoles, Stable di- and tetrabromo-~ (SC) 739 [G.E. *86*, 782 (1974)]

Isomerization, ~ by ring expansion in silylated phosphorus ylides (SC) 540 [G.E. *86*, 554 (1974)]
Selective ~ of long-chain 1-olefins (PR) 154
Isopeptide crosslinks—their occurrence and importance in protein structure (FP) 514 [G.E. *86*, 580 (1974)]
Isoprene (PR) 679
Isotope labeling, ^{13}C-labeling for elucidation of reaction mechanisms—benzocyclopropene formation (SC) 276 [G.E. *86*, 278 (1974)]
Isotopes, Stable ~ of oxygen in research and technical applications (FP) 357 [G.E. *86*, 387 (1974)]
Use of lasers in separation of ~ (LA) 93
Isoxazolinone derivatives (PR) 679

KALLIKREIN inhibitor, Synthesis of active derivative of bovine trypsin-~ (Kunitz) with open peptide bond in the reactive site (SC) 660 [G.E. *86*, 702 (1974)]
Proteinase catalyzed resynthesis of the peptide bond lys 15—ala 16 in the derivative of trypsin-~ (Kunitz) with this peptide bond hydrolyzed (SC) 661 [G.E. *86*, 703 (1974)]
Replacement of lysine by arginine, phenylalanine, and tryptophan in the reactive site of the trypsin-~ (Kunitz) (SC) 662 [G.E. *86*, 704 (1974)]
Inactivation of the trypsin-~ (Kunitz) by cleavage of the dipeptide ala 16—arg 17 in the reactive site (SC) 663 [G.E. *86*, 705 (1974)]
Ketene N,O-acetals, 1,3-Oxazin-6-ones with ynamines and ~ (SC) 533 [G.E. *86*, 596 (1974)]
Ketenes, New synthesis of keteniminylidenetriphenylphosphoranes and thioketenylidenetriphenylphosphorane (SC) 273 [G.E. *86*, 274 (1974)]
Ketenimines, Reaction of N-phenyl(keteniminylidene)triphenylphosphorane with carbonyl compounds (SC) 473 [G.E. *86*, 479 (1974)]
δ-Ketocarboxylic acid esters (PR) 748
Ketones, Synthesis of 2,6,10,14-pentadecanetetrones: A δ-tetraketone ("Harries' tetraketone") (SC) 136 [G.E. *86*, 160 (1974)]
Addition of oxoalkane polyanions to nitroolefins. A new synthesis of cyclohexanones (SC) 400 [G.E. *86*, 446 (1974)]
Acid-catalyzed rearrangements of β,γ-unsaturated ~ (LA) 678
Phenolic amino ~ (PR) 93
Poly-~ with favorable processing properties (PR) 93
Tricyclic ~ (PR) 615
Ketone synthesis, Convenient synthesis of vinylsilanes and their use in ~ (SC) 83 [G.E. *86*, 102 (1974)]
Kinetics, Kinetic investigation of peptide coupling (SC) 149 [G.E. *86*, 163 (1974)]
Comprehensive chemical ~ (Book Review) 681
Kinks, X-ray and calorimetric detection of formation of individual ~ (CR) 419 [G.E. *86*, 455 (1974)]
Krypton, X-Ray structure analysis of the α-cyclodextrin-~ inclusion complex: A noble gas in an organic matrix (SC) 552 [G.E. *86*, 594 (1974)]

LABELED compounds, Preparation of organic compounds containing labeled atoms (PR) 94
Lactams, Lactones and ~ by light-induced reaction of 2-vinyloxiranes and 2-vinylaziridines with pentacarbonyliron—insertion of carbon monoxide into an iron-nitrogen σ bond (SC) 275 [G.E. *86*, 309 (1974)]
Mechanism of cationic polymerization (CR) 417 [G.E. *86*, 453 (1974)]
Unsaturated γ-~ (PR) 679
Lactate, Enzymic dehydrogenation of ~ and ethanol (LA) 152
Lactones and lactams by light-induced reaction of 2-vinyloxiranes and 2-vinylaziridines with pentacarbonyliron—insertion of carbon monoxide into an iron-nitrogen σ bond (SC) 275 [G.E. *86*, 309 (1974)]
Lanthanoid compounds, Contact contribution in the lanthanoid-induced shift of ^{13}C=O-NMR signals (SC) 537 [G.E. *86*, 552 (1974)]
Lasers, Use in separation of isotopes (LA) 93
Laser-Grundlagen und Anwendungen (Book Review) 214
Lewis bases, Dimethylarsenido-transition metal complexes—stable organometallic ~ (SC) 84 [G.E. *86*, 51 (1974)]
Lexicon of Chemistry, Römpps Chemie-Lexikon (Book Review) 487
Ligands, Chiral macrobicyclic and macrotricyclic ~ (SC) 406 [G.E. *86*, 443 (1974)]
To what extent does perchlorate play the role of a ligand in solution? (LA) 614
Lignin, Beech ~—proposal of a constitutional scheme (FP) 313 [G.E. *86*, 336 (1974)]
Liquid crystals, Low melting o-hydroxy azo- and azoxybenzene ~ (SC) 344 [G.E. *86*, 378 (1974)]
Liquid-phase peptide synthesis, Rapid procedure: the crystallization method (SC) 88 [G.E. *86*, 101 (1974)]
Lithium compounds, 1,3-Anionic cycloadditions of organo-~: An initial survey (FP) 627 [G.E. *86*, 715 (1974)]
Cyclobutanones from 1-bromo-1-lithiocyclopropanes and ketones (SC) 277 [G.E. *86*, 279 (1974)]
2-Lithiated 1-tert-butyl-3-methyleneaziridine and its reaction products (SC) 342 [G.E. *86*, 380 (1974)]
1,3-Anionic cycloadditions of 2-(N,N-Diisopropylcarbamoyl)allyllithium with a two-step mechanism (SC) 468 [G.E. *86*, 476 (1974)]
Cleavage of selenium compounds by butyllithium. A new, regiospecific allyl alcohol synthon (SC) 804 [G.E. *86*, 857 (1974)]
Secondary and tertiary phenylthio- and phenylselenoalkyllithium compounds as novel reagents for the formation of C—C bonds (SC) 806 [G.E. *86*, 859 (1974)]
Progress in lithium chemistry (LA) 421
Lymphocytes, Nature of antigen receptors on surfaces of ~ (LA) 152

MACROMOLECULAR colloquium (CR) 412 [G.E. *86*, 448 (1974)]
Macromolecular science, The challenge to ~ (FP) 97 [G.E. *86*, 109 (1974)]
Crystalline state of macromolecular substances (FP) 244 [G.E. *86*, 283 (1974)]
Macromolecules, Ultracentrifugation (Book Review) 154
Radiation chemistry (Book Review) 556
Macrozwitterions (CR) 414 [G.E. *86*, 451 (1974)]
Magnesium compounds, Papers concerning ~ (LA) 485
Magnetic data supports (PR) 94
Magnetic resonance (Book Review) 289
Malaria, Antimetabolites of coenzyme Q. Their potential application as antimalarials (FP) 559 [G.E. *86*, 635 (1974)]
Maleic anhydride, Proton resonance measurements on poly-~ and ~-isobutene copolymers (CR) 414 [G.E. *86*, 450 (1974)]
Mannich bases, Advances in chemistry (LA) 286
Manganese compounds, Evidence for a chiral intermediate on phosphane substitution in the complex (+)-$C_5H_5Mn(NO)(COC_6H_5)P(C_6H_5)_3$ (SC) 810 [G.E. *86*, 864 (1974)]
Pentacarbonylmanganese bromide—An organometallic trapping reagent for ethoxycarbonylcarbyne (SC) 812 [G.E. *86*, 895 (1974)]
Mass spectroscopy, Mass spectral interaction between the functional groups of multiply substituted alkanes (FP) 252 [G.E. *86*, 256 (1974)]
Steric effects in the mass spectra of monocyclic and bicyclic diols and their derivatives (CR) 348 [G.E. *86*, 314 (1974)]
Interpretation of mass spectra of organic compounds (Book Review) 557
MTP International review of science. Physical chemistry: Series one (Book Review) 748
Mass transport in solids (FP) 384 [G.E. *86*, 428 (1974)]
Matrix polymerization of methyl methacrylate (CR) 416 [G.E. *86*, 452 (1974)]
Medicine, Polymers in ~ (FP) 108 [G.E. *86*, 145 (1974)]
Melamine, Structure of the reaction products of ~ and formaldehyde (CR) 412 [G.E. *86*, 448 (1974)]
Mercury compounds, New mononuclear metallo complex with an inhomogeneous second sphere in bis(iodomercurio)hydroxomercuriooxonium perchlorate $[O(HgI)_2Hg-OH]ClO_4$ (SC) 545 [G.E. *86*, 589 (1974)]
Crystal structure of $(HgI)_2TiF_6$ (SC) 821 [G.E. *86*, 863 (1974)]
Metals, Transition to nonmetallic behavior in expanded liquid and gaseous ~ (FP) 446 [G.E. *86*, 459 (1974)]
Metathiophosphoric acid, Trimethylsilyl(tert-yl)amino(tert-butyl)iminothiophosphorane —A derivative of monomeric ~ (SC) 811 [G.E. *86*, 899 (1974)]
Methacrylate, Matrix polymerization of methyl ~ (CR) 416 [G.E. *86*, 452 (1974)]
Combustion-resistant acrylic glass based on methyl ~ (PR) 422
Methodicum Chimicum (Book Review) 213
2-Methoxyallyl bromide, Simple synthesis of bicyclo[3.2.2]nona-6,8-dien-3-ones from arenes (SC) 136 [G.E. *86*, 127 (1974)]
Methyl acrylate, Photochemical synthesis of bis(η-~)-tricarbonyliron (SC) 534 [G.E. *86*, 558 (1974)]
3-Methyl-3,4,5,6-tetrahydrophthalic anhydride, Isomer-free ~ (PR) 286
Microgels, New methods for preparation of reactive ~ and their use for the construction of inhomogeneous networks (CR) 414 [G.E. *86*, 450 (1974)]
Microorganisms, Stereospecific hydrogenations with hydrogen gas and ~ as catalysts (SC) 608 [G.E. *86*, 675 (1974)]
Stereospecific hydrogenation of (R)- or (S)-2-ethyl-4-phenylallenecarboxylic acid to cis- or trans-2-ethyl-4-phenyl-3-butenecarboxylic acid by means of Clostridium kluyveri (SC) 609 [G.E. *86*, 675 (1974)]
Microtubule proteins, Interaction with drugs (LA) 746
Microtubules, Biochemical properties (LA) 746
MO calculations, Problem of ~ for inorganic systems (LA) 352
Molding powders, High-setting polyacrylate ~ (PR) 486
Molecular geometry (Book Review) 556

Molybdate, Anionic structure of the so-called ammonium di-~ $(NH_4)_2Mo_2O_7$ (SC) 823 [G.E. *86*, 894 (1974)]

Molybdenum compounds, Polynuclear oxofluoro anions of molybdenum (SC) 600 [G.E. *86*, 598 (1974)]
Coordination in bis(thiooxomolybdato)metalate(II) complexes of type $[M(MoOS_3)_2]^{2-}$ and $[M(MoO_2S)_2]^{2-}$ (SC) 672 [G.E. *86*, 709 (1974)]

Multicenter reactions, Two-step ~: A system in which "forbidden" processes occur faster than the "allowed" process (SC) 478 [G.E. *86*, 523 (1974)]

NERVOUS system, Chemical transmission in invertebrate central ~ (LA) 152

Nickel(0) catalysts, Codimerization of 3,3-dimethylcyclopropene with ethylenecarboxylic esters at ~ (SC) 466 [G.E. *86*, 518 (1974)]

Nickel compounds, X-Ray structure analysis of the triple-decker sandwich complex tris(η-cyclopentadienyl)dinickel tetrafluoroborate (SC) 135 [G.E. *86*, 125 (1974)]
Higher oxidation states of iron, cobalt, and nickel (LA) 614

Niobium compounds, The first oxoniobate(III): $LiNbO_2$ (SC) 744 [G.E. *86*, 819 (1974)]

Nitriles, Convenient conversion of aldehydes into ~ (CR) 351 [G.E. *86*, 317 (1974)]

Nitrogen complexes, Dinitrogen-transition metal complexes: synthesis, properties, and significance (FP) 639 [G.E. *86*, 692 (1974)]
Dinitrogen(octaethylporphinato)tetrahydrofuranosmium(II): A nitrogen-carrying metalloporphyrin (SC) 745 [G.E. *86*, 820 (1974)]

Nitrogen compounds, Bis(N,N-methylsilanetriyl)tris(sulfur diimide)—a bicyclic derivative of S_4N_4 (SC) 146 [G.E. *86*, 130 (1974)]

Nitroolefins, Addition of oxoalkane polyanions to ~. New synthesis of cyclohexanones (SC) 400 [G.E. *86*, 446 (1974)]

Nitrosamines, Synthesis of α-functional ~ (SC) 743 [G.E. *86*, 817 (1974)]

NMR Spectroscopy, Correlation of the ^{13}C-NMR chemical shifts of carbonyl and thiocarbonyl groups (SC) 90 [G.E. *86*, 43 (1974)]
^{13}C-NMR spectra of diazoalkanes (SC) 270 [G.E. *86*, 274 (1974)]
Contact contribution in lanthanoid-induced shift of ^{13}C-NMR signals (SC) 537 [G.E. *86*, 552 (1974)]
Use of the $Eu(fod)_3$-induced shift for determination of complexation site and for signal assignment in the ^{13}C-NMR spectra of protected dipeptides (SC) 538 [G.E. *86*, 553 (1974)]
^{13}C-NMR spectra of heptafulvene, pentafulvene, and sesquifulvalence (SC) 551 [G.E. *86*, 595 (1974)]
^1H and ^{13}C relaxation measurements on homopolymers and copolymers (CR) 413 [G.E. *86*, 449 (1974)]
^{13}C-NMR spectroscopy on polyethers (CR) 413 [G.E. *86*, 450 (1974)]
Proton resonance measurements on polymaleic anhydride and maleic anhydride-isobutene copolymers (CR) 414 [G.E. *86*, 450 (1974)]
Synthesis of alternating copolyamides and their sequence analysis by ^1H- and ^{13}C-~ (CR) 415 [G.E. *86*, 451 (1974)]
Carbon-13 ~ (Book Review) 824

Norbornadiene, Stereospecific endo-anti-cycloaddition of diazoalkanes to 7-substituted ~: A π→σ effect? (SC) 606 [G.E. *86*, 673 (1974)]

2,4-Norcaradienes, Stereochemical control by secondary through-space interaction: exo/endo-stability of 7-acceptor-substituted ~ (SC) 86 [G.E. *86*, 54 (1974)]

Neutron scattering, Applications to polymer characterization (CR) 412 [G.E. *86*, 448 (1974)]

Norcaradiene rearrangement, Stereochemistry of the degenerate ~: A stereospecific symmetry-forbidden process (SC) 268 [G.E. *86*, 270 (1974)]

Nucleic acids, Biochemistry of ~ (Book Review) 617

Nucleotides, Enzymatic reduction of ribo-~ biosynthesis pathway of deoxyribo-~ (FP) 569 [G.E. *86*, 624 (1974)]
New type of model nucleotide: 5'-deoxy-5'-adenosineacetic acid (SC) 77 [G.E. *86*, 41 (1974)]
Synthetic ~ (Book Review) 96

Nutrition, Recent results in the search for trace elements in ~ (LA) 824
Silicon as trace element in organisms (LA) 824
Vanadium as an essential nutrient (LA) 824

OCTOPUS molecules (SC) 814 [G.E. *86*, 896 (1974)]

Olefin copolymers, Elastomeric ~ (PR) 211

Olefins, New reagent for stereospecific synthesis of aziridines from ~ (SC) 279 [G.E. *86*, 311 (1974)]
Novel method for the stereoselective synthesis of trans ~ (SC) 407 [G.E. *86*, 415 (1974)]
Ammonoxidation of ~ (PR) 154
Selective isomerization of long-chain 1-~ (PR) 154

Optical activity, Photochemistry with circularly polarized light (FP) 179 [G.E. *86*, 222 (1974)]

Organocopper compounds, Oxidative coupling via ~ (FP) 291 [G.E. *86*, 321 (1974)]

Organometallic chemistry, Einführung in die metallorganische Chemie (Book Review) 616

Organometallic compounds, Struktur und Reaktivität polarer Organometalle (Book Review) 355
MTP International review of science. Inorganic chemistry: Series one. (Book Review) 424

Organometallic reagents, Prescriptions and ingredients for controlled CC bond formation with ~ (FP) 701 [G.E. *86*, 751 (1974)]

Orthocarbonic esters, Methods for the synthesis of orthocarboxylic esters and ~ (LA) 421

Orthocarboxylic esters, Methods for synthesis of ~ and orthocarbonic esters (LA) 421

Osmium compounds, Octaethylporphinatodioxoosmium(VI): An extreme metal oxidation state within a porphin system (SC) 341 [G.E. *86*, 378 (1974)]
Dinitrogen(octaethylporphinato)tetrahydrofuranosmium(II): A nitrogen-carrying metalloporphyrin (SC) 745 [G.E. *86*, 820 (1974)]

Oxabenzo[1,2]cyclonona[5,6,7-de]naphthalene, Conformational studies on oxa, thia and aza derivatives of 7,8,13,14-tetrahydrobenzo[1,2]cyclonona[5,6,7-de]naphthalene and 8H,15H-7,16-dioxacyclodeca[1,2,3-de:6,7,8-d'e']dinaphthalene (SC) 731 [G.E. *86*, 814 (1974)]

Oxalic acid and its esters (PR) 286

cis-Oxa-tris-σ-homobenzene, Simple bridged ~ and cis-aza-tris-σ-homobenzene systems; synthesis and 3σ→3π isomerization (SC) 482 [G.E. *86*, 522 (1974)]

1,3-Oxazin-6-ones, Thermolysis to 2,4,6-trisubstituted pyridines (SC) 484 [G.E. *86*, 414 (1974)]
~ with ynamines and ketene N,O-acetals (SC) 533 [G.E. *86*, 596 (1974)]

Oxazolidines, Polyfunctional esters of N-hydroxazolidines (PR) 287

Oxidation states, Higher ~ of iron, cobalt, and nickel (LA) 614

Oxidative coupling via organocopper compounds (FP) 291 [G.E. *86*, 321 (1974)]

Oxidative decarbonylation of octaethyl-α-hydroxyprophinatozinc(II) (SC) 150 [G.E. *86*, 125 (1974)]

Oxiranes, Lactones and lactams by light-induced reaction of 2-vinyl-~ and 2-vinylaziridines with pentacarbonyliron—insertion of carbon monoxide into an iron-nitrogen σ bond (SC) 275 [G.E. *86*, 309 (1974)]

Oxoniobate(III), The first ~: $LiNbO_2$ (SC) 744 [G.E. *86*, 819 (1974)]

Oxygen, Activation of molecular ~ (FP) 29 [G.E. *86*, 1 (1974)]
Stable isotopes of ~ in research and technical applications (FP) 357 [G.E. *86*, 387 (1974)]

Oxyphosphoranes, Structure, syntheses, and reactions (LA) 420

PALLADIUM(0) catalysts, Quantitative cyclotrimerization of 3,3-dimethylcyclopropene to hexamethyl-trans-σ-trishomobenzene (SC) 465 [G.E. *86*, 518 (1974)]

Palladium complexes, A palladium(II) complex as hydrogenase model (SC) 549 [G.E. *86*, 561 (1974)]
Modes of reaction of 2- and 5-hydroxyalkyl isocyanides with metal compounds; oxazolidinylidene and perhydrooxazinylidene complexes of palladium, platinum, and gold (SC) 599 [G.E. *86*, 588 (1974)]

Paper, Production of synthetic ~ (PR) 486

Penicillins and cephalosporins (Book Review) 616

Pentaborane(9), Chemistry (LA) 286

Pentacoordination, Stabilization of ~ of phosphorus by tridentate ligands (SC) 542 [G.E. *86*, 524 (1974)]

2,6,10,14-Pentadecanetetrones, Synthesis of ~. A δ-tetraketone ("Harries' tetraketone") (SC) 136 [G.E. *86*, 160 (1974)]

Pentafulvene, ^{13}C-NMR spectra of heptafulvene, ~, and sesquifulvalene (SC) 551 [G.E. *86*, 595 (1974)]

Peptide coupling, Kinetic investigation (SC) 149 [G.E. *86*, 163 (1974)]
Model experiments for ~ without racemization-prone activated amino acid derivatives (SC) 473 [G.E. *86*, 517 (1974)]
Azide method for peptide bond synthesis (LA) 824

Peptides, Use of $Eu(fod)_3$-induced shift for determination of complexation site and for signal assignment in the ^{13}C-NMR spectra of protected di-~ (SC) 538 [G.E. *86*, 553 (1974)]

Peptide synthesis, Rapid procedure for liquid-phase ~: The crystallization method (SC) 88 [G.E. *86*, 101 (1974)]

Perchlorate, To what extent does ~ play the role of a ligand in solution? (LA) 614

Perfluorination, Continuous ~ (PR) 153

Pericyclic reactions, The variety of thermal ~ (FP) 47 [G.E. *86*, 71 (1974)]
Theory of ~ (FP) 751 [G.E. *86*, 825 (1974)]

Periodates, New applications of periodic acid and ~ (LA) 485

Periodic acid, New applications of ~ and periodates (LA) 485

Peroxides, Synthesis of unusual organic molecules using cyclic ~ (FP) 619 [G.E. *86*, 683 (1974)]

Peroxysome, Biochemistry of the ~ in the liver cell (FP) 706 [G.E. *86*, 789 (1974)]

Pestalotin, Synthesis of (±)-~ and (±)-epi-~ and of optically pure (−)-~ by asymmetric synthesis (SC) 77 [G.E. *86*, 40 (1974)]

Pharmacognostics, Lehrbuch der Pharmakognosie. Auf phytochemischer Grundlage (Book Review) 617

Pharmacologically active polymers, Structure and properties (CR) 417 [G.E. *86*, 453 (1974)]

Phase-transfer catalysis, Phase-transfer catalyzed two-phase reactions in preparative organic chemistry (FP) 170 [G.E. *86*, 187 (1974)]

Phenols, Phenolic amino ketones (PR) 93

2-Phenylbenzoic acid, New process for production of diphenic acid and ~ (PR) 421

Phosgeneimonium salts, Substituted 5-dialkylaminopyrazoles from hydrazones and ~ (SC) 79 [G.E. *86*, 45 (1974)]

Phosphanes, Square planar transition metal complexes with a bidentate ligand spanning trans-positions (SC) 133 [G.E. *86*, 133 (1974)]
Triphenylcyclotriphosphane as a new ligand in transition metal complexes (SC) 147 [G.E. *86*, 124 (1974)]
Hexakis(trifluorophosphane)vanadium hydride (SC) 201 [G.E. *86*, 233 (1974)]
Evidence for a chiral intermediate on phosphane substitution in the complex (+)-$C_5H_5Mn(NO)(COC_6H_5)P(C_6H_5)_3$ (SC) 810 [G.E. *86*, 864 (1974)]

Phosphides, Rb_4P_6, a phosphide with planar six-membered phosphorus rings (SC) 345 [G.E. *86*, 379 (1974)]

Phosphonic acids, 1-Ureidoalkane-1,1-di-~ (PR) 747

Phosphonic esters, Dialkylaminomethane-tri-~ (PR) 747

Phosphonoacetic acid and its salts and amides (PR) 353

N-Phosphonomethylglycine, Effect of the herbicide ~ on the biosynthesis of aromatic amino acids (SC) 400 [G.E. *86*, 408 (1974)]

Phosphoranes, A phosphorus(V) derivative having coordination number 3: Bis(trimethylsilyl)aminobis(trimethylsilylimino-phosphorane) (SC) 134 [G.E. *86*, 128 (1974)]
New synthesis of keteniminylidenetriphenyl-~ and thioketenylidenetriphenylphosphorane (SC) 273 [G.E. *86*, 274 (1974)]
Reaction of N-phenyl(keteniminylidene)-triphenylphosphorane with carbonyl compounds (SC) 473 [G.E. *86*, 479 (1974)]
Trimethylsilyl(tert-butyl)amino(tert-butyl)-iminothiophosphorane—A derivative of monomeric metathiophosphoric acid (SC) 811 [G.E. *86*, 899 (1974)]
Structure, syntheses, and reactions of oxy-~ (LA) 420

Phosphoric acid esters, Improved production of ~ (PR) 94

Phosphorins, Reactions of λ^3-~ with diazoalkanes in presence of alcohols and phenols (SC) 148 [G.E. *86*, 129 (1974)]

Phosphorus compounds, Sulfonylbis(imidosulfur oxide difluoride) from trichlorophosphazosulfonylimidosulfur oxide difluoride (SC) 401 [G.E. *86*, 442 (1974)]
Bis(1,2,4,6-tetraphenyl- and bis(1-methyl-2,4,6-triphenyl-λ^5-phosphorinyl)iron (SC) 408 [G.E. *86*, 445 (1974)]
Structure of 1:1-adduct of hexafluoroacetone azine and 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane (SC) 543 [G.E. *86*, 560 (1974)]
Stabilization of pentacoordination of phosphorus by tridentate ligands (SC) 542 [G.E. *86*, 524 (1974)]
Electronic effect of phosphorus and its preparative consequences (CR) 351 [G.E. *86*, 316 (1974)]
Esters (PR) 421
Analytical chemistry of ~ (Book Review) 154

Phosphorus ylides, Isomerization by ring expansion in silylated ~ (SC) 540 [G.E. *86*, 554 (1974)]

Photoaddition, 1,2-~ of primary and secondary amines to benzene (SC) 341 [G.E. *86*, 350 (1974)]

Photochemistry, ~ with circularly polarized light (FP) 179 [G.E. *86*, 222 (1974)]
~ in interstellar space and reactions generating interstellar molecules (FP) 370 [G.E. *86*, 401 (1974)]
Stereospecificity as an argument against the intermediacy of 1,4-alkyl/acyl diradicals in the light-induced cyclobutanone-tetrahydrofurylidene isomerization in condensed phase (SC) 197 [G.E. *86*, 197 (1974)]
Low temperature electronic spectroscopic observations on light-induced cyclobutanone-tetrahydrofurylidene rearrangement (SC) 198 [G.E. *86*, 198 (1974)]
Peculiar behavior of electronically excited cyclobutanones: A photochemical example of the consequence of through-bond interaction (SC) 199 [G.E. *86*, 199 (1974)]
Simple EH Model for the photochemical cyclobutanone-tetrahydrofurylidene isomerization (SC) 200 [G.E. *86*, 200 (1974)]
Photochemical synthesis of bis(η-methyl acrylate)tricarbonyliron (SC) 534 [G.E. *86*, 558 (1974)]
2- and 4-Azathioxanthones by photorearrangement of S-aryl thionicotinates (SC) 550 [G.E. *86*, 562 (1974)]
Solid phase synthesis and ~ of 4,4′-stilbenedicarbaldehyde (SC) 666 [G.E. *86*, 743 (1974)]
Photochemical synthesis of a tricyclo[5.4.0.$0^{1,5}$]undecatetraene in solution (SC) 670 [G.E. *86*, 739 (1974)]
Orientation in photochemical cyclobutane cleavages: cis-effect (SC) 817 [G.E. *86*, 741 (1974)]
~ of aliphatic azo compounds in solution (LA) 93
Photochemical hydroxylation of aromatic compounds (LA) 421

Photochromism of 4-substituted benzofuroxans (SC) 86 [G.E. *86*, 52 (1974)]

Photodifluoroamination (LA) 420

Photoelectron spectroscopy, Structure and spin multiplicity of a [4]annulene system (SC) 544 [G.E. *86*, 597 (1974)]

Photoisomerization of tricyclo[5.2.1.$0^{4,10}$]deca-2,5,8-triene (triquinacene) (SC) 663 [G.E. *86*, 706 (1974)]

Photooxidation of annulenes (SC) 398 [G.E. *86*, 407 (1974)]

Photosynthesis inhibitors, Powerful ~ suitable for use as weedkillers (PR) 679

Phthalimidoacetic acid, (Hydrogenated) derivatives (PR) 615

Phyllodisilicic acid, Intracrystalline reactivity $(H_2Si_2O_5)_x$ (SC) 819 [G.E. *86*, 893 (1974)]

Physical organic chemistry, Physikalische Organische Chemie (Book Review) 487

Physics, Physik griffbereit (Book Review) 95
Einführung in die Physik (Book Review) 422

3-Picoline and pyridine (PR) 353

Pigments of reddish hair and feathers (FP) 305 [G.E. *86*, 355 (1974)]

Plastics, Inorganic-organic ~ (PR) 747
Identification and analysis (Book Review) 680
Kunststoff-Handbuch (Book Review) 825

Platinum complexes, Modes of reaction of 2- and 3-hydroxyalkyl isocyanides with metal compounds; oxazolidinylidene and perhydrooxazinylidene complexes of palladium, platinum, and gold (SC) 599 [G.E. *86*, 588 (1974)]

Polarized light, Photochemistry with circularly ~ (FP) 179 [G.E. *86*, 222 (1974)]

Polyacrylates, High-setting polyacrylate molding powders (PR) 486

Polyamide imides (PR) 213

Polyamides, Synthesis of alternating ~ and their sequence analysis by ^{1}H- and ^{13}C-NMR spectroscopy (CR) 415 [G.E. *86*, 451 (1974)]
Transparent candle material (PR) 94
Heat-resistant polyimide or polyamide imide films (PR) 153

Polychloroprene, Biodegradable emulsifiers for ~ (PR) 153

Polycondensation, Synthesis of macromolecules of well defined properties by enzymatic ~ (CR) 416 [G.E. *86*, 452 (1974)]

Polyenes, Highly potent reagent for regioselective and stereospecific synthesis of ~ bearing terminal aziridine groups (SC) 279 [G.E. *86*, 311 (1974)]

Polyesters, Heat-resistant thermoplastic ~ (PR) 353

Polyethers, Novel ligand systems for complexing alkali metal ions (SC) 149 [G.E. *86*, 126 (1974)]
Octopus molecules (SC) 814 [G.E. *86*, 896 (1974)]
^{13}C-NMR spectroscopy on ~ (CR) 413 [G.E. *86*, 450 (1974)]

Polyethylene, Process for increasing molecular weight of high-density ~ (PR) 421

Polyethylene glycols, Rapid procedure for liquid-phase peptide synthesis: The crystallization method (SC) 88 [G.E. *86*, 101 (1974)]

Polyhydrazide fibers with high elasticity moduli (PR) 555

Polyimides, Heat-resistant polyimide or polyamide imide films (PR) 153
Laminar composite structure (PR) 211
~ of 1,4-benzoquinonetetracarboxylic acid (PR) 211

Polyketones with favorable processing properties (PR) 93

Polymer, Structure-property relationships in a ~ (FP) 113 [G.E. *86*, 151 (1974)]

Polymer characterization, Applications of neutron scattering to ~ (CR) 412 [G.E. *86*, 448 (1974)]

Polymer powders as binders for the electric powderspraying process (PR) 153

Polymerization, Kinetics and mechanism of radical polymerization (FP) 781 [G.E. *86*, 869 (1974)]
Cationic ~ of azetidines (CR) 414 [G.E. *86*, 450 (1974)]
Matrix ~ of methyl methacrylate (CR) 416 [G.E. *86*, 452 (1974)]
Mechanism of cationic ~ of lactams (CR) 417 [G.E. *86*, 453 (1974)]
Occurrence of branching reactions in co-~ of trioxane with 1,3-dioxolane (CR) 418 [G.E. *86*, 454 (1974)]
Peculiarities of the particle formation in the emulsion ~ of acrylic esters (CR) 418 [G.E. *86*, 455 (1974)]

Polymers, ~ as reagents in organic synthesis (FP) 99 [G.E. *86*, 139 (1974)]

Mechanical fabrication of thermoplastic ~ (FP) 105 [G.E. *86*, 121 (1974)]
~ in medicine (FP) 108 [G.E. *86*, 145 (1974)]
Bio-~: Origin, chemistry, and biology (FP) 121 [G.E. *86*, 111 (1974)]
Crystalline state of macromolecular substances (FP) 244 [G.E. *86*, 283 (1974)]
Constitution of ~ and coordination compounds of formaldehyde oxime (CR) 348 [G.E. *86*, 314 (1974)]
Synthesis and some properties of star ~ with more than 100 branches (CR) 412 [G.E. *86*, 449 (1974)]
^1H and ^{13}C relaxation measurements on homo-~ and co-~ (CR) 413 [G.E. *86*, 449 (1974)]
Mechanism of degradation of ~ in solution by ultrasound (CR) 413 [G.E. *86*, 449 (1974)]
Proton resonance measurements on polymaleic anhydride and maleic anhydride-isobutene co-~ (CR) 414 [G.E. *86*, 450 (1974)]
Polycondensation on N-silylated bis-amides and bis-imides (CR) 414 [G.E. *86*, 450 (1974)]
New preparations of reactive microgels and their use for construction of inhomogeneous networks (CR) 414 [G.E. *86*, 450 (1974)]
Structure of macromolecular adsorption layers on solids (CR) 415 [G.E. *86*, 451 (1974)]
Synthesis of macromolecules of well defined properties by enzymatic polycondensation (CR) 416 [G.E. *86*, 452 (1974)]
Structure and properties of pharmacologically active ~ (CR) 417 [G.E. *86*, 453 (1974)]
Elastomeric olefin co-~ (PR) 211
New route to co-~ containing isocyanate groups (PR) 287
Co-~ of vinyl chloride and acrylic ester units (PR) 487
New heterocyclic ~ (PR) 614
Polymer spectroscopy (Book Review) 827
Polyolefin blends (PR) 486
Polyolefins, Self-extinguishing fiber-reinforced ~ (PR) 212
Polyoxazolidones (PR) 212
Polypeptides, Membrane-active ~ from snake venom (LA) 352
Polypivalolactone (CR) 412 [G.E. *86*, 448 (1974)]
Polysaccharides, Conversions of bacterial ~ by the action of lysogenic phages and their immunochemical and biochemical-genetic significance (CR) 419 [G.E. *86*, 455 (1974)]
Polystyrene, Crosslinking reactions in the rubber particles of high-impact ~ (CR) 418 [G.E. *86*, 454 (1974)]
Porphin, Octaethylprophinatodioxoosmium(VI): An extreme metal oxidation state within a ~ system (SC) 341 [G.E. *86*, 378 (1974)]
Porphyrins, Reactivity of the porphyrin ligand (FP) 321 [G.E. *86*, 363 (1974)]
Oxidative decarbonylation of octaethyl-α-hydroxyporphinatozinc(II) (SC) 150 [G.E. *86*, 125 (1974)]
Dinitrogen(octaethylporphinato)tetrahydrofuranosmium(II): A nitrogen-carrying metalloporphyrin (SC) 745 [G.E. *86*, 820 (1974)]
Potassium compounds, Prescriptions and ingredients for controlled CC bond formation with organometallic reagents (FP) 701 [G.E. *86*, 751 (1974)]
Pressure, Electronic transitions in transition metal compounds at high ~ (FP) 39 [G.E. *86*, 61 (1974)]
Proinsulin, Progress in synthesis of human ~ and of a ~ model (CR) 419 [G.E. *86*, 455 (1974)]
Propadienylsulfonium salts, Stable ~ by cycloadditions with butatrienylsulfonium salts (SC) 470 [G.E. *86*, 477 (1974)]
2-Propene-1-thiol, Doubly metalated ~: Thioacrolein dianion (SC) 479 [G.E. *86*, 484 (1974)]
Propylene oxide (PR) 747
Proteinase inhibitors, Biochemistry of natural ~ (FP) 10 [G.E. *86*, 21 (1974)]
Synthesis of the active derivative of bovine trypsin-kallikrein inhibitor (Kunitz) with open peptide bond in the reactive site (SC) 660 [G.E. *86*, 702 (1974)]
Proteinase catalyzed resynthesis of the peptide bond lys 15—ala 16 in the derivative of trypsin-kallikrein inhibitor (Kunitz) with this peptide bond hydrolyzed (SC) 661 [G.E. *86*, 703 (1974)]
Replacement of lysine by arginine, phenylalanine, and tryptophan in the reactive site of the trypsin-kallikrein inhibitor (Kunitz) (SC) 662 [G.E. *86*, 704 (1974)]
Inactivation of the trypsin-kallikrein inhibitor (Kunitz) by cleavage of the dipeptide ala 16—arg 17 in the reactive site (SC) 663 [G.E. *86*, 705 (1974)]
Proteins, Recent discoveries in the evolution of ~ (FP) 186 [G.E. *86*, 209 (1974)]
Isopeptide crosslinks—their occurrence and importance in protein structure (FP) 514 [G.E. *86*, 580 (1974)]
Interaction with small molecules or ions (LA) 614
Interaction of drugs with microtubule ~ (LA) 746
Protein synthesis, Role of soluble protein factors in translational control of ~ in eukaryotic cells (LA) 210
Pseudopermanganic acid, Hexamanganato(VII)manganic(IV) acid: A "~" (SC) 603 [G.E. *86*, 647 (1974)]
Pyran-2,4-diones, 3-(N-Alkoxyaminoalkylidene)-~ (PR) 679
Pyrazoles, Substituted 5-dialkylamino-~ from hydrazones and phosgeneimonium salts (SC) 79 [G.E. *86*, 45 (1974)]
Pyrazolo heteroaromatic compounds, Synthesis by means of 5-amino-3-methyl-1-phenylpyrazole-4-carbaldehyde (SC) 604 [G.E. *86*, 671 (1974)]
Pyridine and 3-picoline (PR) 353
Pyridine compounds, 1-Aryl-2-phenyl-1-(2-pyridyl)alkanols (PR) 93
Pyridines, Thermolysis of 1,3-oxazin-6-ones to 2,4,6-trisubstituted ~ (SC) 484 [G.E. *86*, 414 (1974)]
Pyridinium ylide of 1,3-indandione (SC) 343 [G.E. *86*, 380 (1974)]
Pyridopyrimidinones, 2-Substituted pyrido[2,3-d]-, -[3,4-d]-, and -[4,3-d]pyrimidin-4(3H)-one (PR) 679
Pyrimidines, Synthesis from 2,N-dialkylcyanoacetamides (SC) 809 [G.E. *86*, 898 (1974)]
4-Pyrones, Efficient synthesis of sugar 3,2-enolones from 2-hydroxyglycals and their conversion into ~ (SC) 546 [G.E. *86*, 590 (1974)]
QUANTUM biochemistry, Quantenbiochemie für Chemiker und Biologen (Book Review) 155
Quinazolines, Inhibition of blood platelet aggregation by substituted ~ (LA) 211
Quinhydrones, Pseudogeminal "quinhydrone" of the [2.2]paracyclophane series (SC) 203 [G.E. *86*, 234 (1974)]
Quinone derivatives (PR) 212
o-Quinonoid compounds, Cycloaddition reactions (CR) 348 [G.E. *86*, 313 (1974)]
RADIATION chemistry of macromolecules (Book Review) 556
Radical polymerization, Kinetics and mechanism (FP) 781 [G.E. *86*, 869 (1974)]
Radicals, Stereospecificity as an argument against the intermediacy of 1,4-alkyl/acyl di-~ in the light-induced cyclobutanone-tetrahydrofurylidene isomerization in condensed phase (SC) 197 [G.E. *86*, 197 (1974)]
Free ~ in Grignard reactions (CR) 419 [G.E. *86*, 382 (1974)]
Reaction mechanisms, ^{12}C-labeling for elucidation of ~—benzocyclopropene formation (SC) 276 [G.E. *86*, 278 (1974)]
Mechanisms—An introduction to the study of organic reactions (Book Review) 214
Bindung, Struktur und Reaktionsmechanismen in der organischen Chemie (Book Review) 749
Rearrangement, Stereochemistry of degenerate norcaradiene ~: A stereospecific symmetry-forbidden process (SC) 268 [G.E. *86*, 270 (1974)]
Sulfonamide-aminosulfone ~: A ~ induced anionically, cationically, and thermally (SC) 270 [G.E. *86*, 273 (1974)]
~ of (trimethylsilyl)methyl allyl ethers. A dyotropic reaction (SC) 402 [G.E. *86*, 416 (1974)]
Dyotropic ~ of (silyl)methyl silyl ethers (SC) 813 [G.E. *86*, 899 (1974)]
~ in organoboron chemistry (LA) 286
~ of organosilicon compounds (LA) 485
Acid-catalyzed ~ of β,γ-unsaturated ketones (LA) 678
Ribonucleic acid, Thermodynamics of the structural transition of phenylalanine-specific transfer ~ in solution (CR) 412 [G.E. *86*, 448 (1974)]
Ribonucleotide reductases, Enzymatic reduction of ribonucleotides: biosynthesis, pathway of deoxyribonucleotides (FP) 569 [G.E. *86*, 624 (1974)]
Ring closure reactions, Highly chlorinated systems by ~ (CR) 210 [G.E. *86*, 134 (1974)]
Ring current, Synthesis of bridged "didehydrothia[17]annulene" S-oxides. Dependence of ~ on geometry in stereoisomeric sulfoxides (SC) 339 [G.E. *86*, 348 (1974)]
Ring expansion, Isomerization by ~ in silylated phosphorus ylides (SC) 540 [G.E. *86*, 554 (1974)]
Ring strain, Synthesis and trapping reactions of the spiro[2.3]hexadienylium system: ~ versus aromaticity (SC) 271 [G.E. *86*, 276 (1974)]
Römpps Chemie-Lexikon (Book Review) 487
Rotation, NMR spectroscopic studies on hindered ~ in primary amides and thioamides (CR) 350 [G.E. *86*, 316 (1974)]
Rubber, Crosslinking reactions in the ~ particles of high-impact polystyrene (CR) 418 [G.E. *86*, 454 (1974)]
Vulcanization of synthetic ~-s with high-energy radiation (PR) 153
Rubidium compounds, Rb_4P_6, a phosphide with planar six-membered phosphorus rings (SC) 345 [G.E. *86*, 379 (1974)]
SALICYLAMIDES, N-Triazolyl- ~ and N-triazolylbenzo-~ (PR) 212
Salt melts, Equilibrium and transport properties of low-melting salts (FP) 438 [G.E. *86*, 467 (1974)]
Selenium, Biological action of vitamin E and ~ (LA) 211
Selenium compounds, Diselenium dioxide octafluoride and ditellurium dioxide octafluoride (SC) 92 [G.E. *86*, 104 (1974)]
Cleavage by butyllithium. A new, regiospecific, allyl alcohol synthon (SC) 804 [G.E. *86*, 857 (1974)]
Secondary and tertiary phenylthio- and phenylseleno-alkyllithium compounds as

novel reagents for the formation of C—C bonds (SC) 806 [G.E. *86*, 859 (1974)]

Selenium oxide tetrafluoride (SC) 91 [G.E. *86*, 103 (1974)]

α-Selenonio alkylides, Synthesis and reactions of unstabilized ~ (SC) 274 [G.E. *86*, 308 (1974)]

Sesquifulvalene, ^{13}C-NMR spectra of heptafulvene, pentafulvene, and ~ (SC) 551 [G.E. *86*, 595 (1974)]

Shift reagents, Contact contribution in the lanthanoid-induced shift of ^{13}C-NMR signals (SC) 537 [G.E. *86*, 552 (1974)]
Use of the Eu(fod)$_3$-induced shift for determination of the complexation site and for signal assignment in the ^{13}C-NMR spectra of protected dipeptides (SC) 538 [G.E. *86*, 553 (1974)]

Silanes, Convenient synthesis of vinyl-~ and their use in ketone synthesis (SC) 83 [G.E. *86*, 102 (1974)]

Silicic acid, Intracrystalline reactivity of phyllodi-~ $(H_2Si_2O_5)_x$ (SC) 819 [G.E. *86*, 893 (1974)]

Silicon as trace element in organisms (LA) 824

Silicon compounds, Bis(N,N-methylsilanetriyl)tris(sulfur diimide)—a bicyclic derivative of S_4N_4 (SC) 146 [G.E. *86*, 130 (1974)]
Rearrangements of organo-~ (LA) 485

Silyl compounds, A phosphorus(V) derivative having coordination number 3: Bis(trimethylsilyl)aminobis(trimethylsilyl)iminophosphorane (SC) 134 [g.E. *86*, 128 (1974)

Silyl ethers, Dyotropic rearrangement of (silyl)methyl ~ (SC) 813 [G.E. *86*, 899 (1974)]

Snake venom, Membrane-active polypeptide from ~ (LA) 352

Sodium cyanamide, Improved preparation (SC) 546 [G.E. *86*, 590 (1974)]

Solid phase synthesis and photochemistry of 4,4'-stilbenedicarbaldehyde (SC) 666 [G.E. *86*, 743 (1974)]

Solids, Mass transport in ~ (FP) 384 [G.E. *86*, 428 (1974)]
Structure of macromolecular adsorption layers on ~ (CR) 415 [G.E. *86*, 451 (1974)]
Vibrational spectroscopy of ~ (Book Review) 155
Surface and defect properties of ~ (Book Review) 214

L-Sorbose, New growth regulators for plants (PR) 615

Space, Photochemistry in interstellar ~ and reactions generating interstellar molecules (FP) 370 [G.E. *86*, 401 (1974)]

Spectrometry, State of development of atomic absorption ~ (FP) 504 [G.E. *86*, 542 (1974)]

Spectroscopy, X-ray absorption ~ on free molecules (FP) 454 [G.E. *86*, 505 (1974)]
Vibrational ~ of solids (Book Review) 155
Atom-Absorptions-Spektroskopie (Book Review) 489
Polymer ~ (Book Review) 827

Spiro compounds, Synthesis of carbocyclic ~ via intramolecular alkylation routes (LA) 678

Spiro[2.3]hexadienylium system, Synthesis and trapping reactions: Ring strain versus aromaticity (SC) 271 [G.E. *86*, 276 (1974)]

Stannylamines, Tri-tert-butylstannylamine and tri-tert-butylstannyl-N-deuterioamine: The first primary ~ (SC) 88 [G.E. *86*, 104 (1974)]

Star polymers, Synthesis and properties of ~ with more than 100 branches (CR) 412 [G.E. *86*, 449 (1974)]

Stereochemistry, Hundred years of ~—Principal development phases in retrospect (FP) 591 [G.E. *86*, 604 (1974)]
Specific interactions, intermolecular forces, steric requirements, and molecular size (FP) 719 [G.E. *86*, 802 (1974)]
Stereochemical control by secondary through-space interaction: exo/endo-stability of 7-acceptor-substituted 2,4-norcaradienes (SC) 86 [G.E. *86*, 54 (1974)]
~ of degenerate norcaradiene rearrangement: A stereospecific symmetry-forbidden process (SC) 268 [G.E. *86*, 270 (1974)]
Dynamic ~ of degenerate diaza-Cope rearrangement (SC) 480 [G.E. *86*, 520 (1974)]
Temperature-induced change in helicity of the inherently dissymmetrical disulfide group in cyclocystine (SC) 818 [G.E. *86*, 856 (1974)]
Molecular Geometry (Book Review) 556
Grundlagen der Stereochemie (Book Review) 680
Die räumliche Struktur organischer Moleküle (Book Review) 826

Stereoselective synthesis, Novel ~ of trans olefins (SC) 407 [G.E. *86*, 415 (1974)]

Stibanes, Synthesis and preparative use of metal derivatives of primary and secondary arsanes, ~, and bismuthanes (LA) 554

Stilbene compounds, Bis-~ (PR) 94

4,4'-Stilbenedicarbaldehyde, Solid phase synthesis and photochemistry (SC) 666 [G.E. *86*, 743 (1974)]

Structure-property relationships in a polymer (FP) 113 [G.E. *86*, 151 (1974)]

Styrene, Hydroxylating dimerization of ~ at the anode (SC) 472 [G.E. *86*, 480 (1974)]
~-acrylonitrile copolymers that can be processed thermoplastically (PR) 555

Substance protection, Der Umfang des Stoffschutzes für chemische Erfindungen (Book Review) 488

Sugar 3,2-enolones, Efficient synthesis from 2-hydroxyglycals and their conversion into 4-pyrones (SC) 546 [G.E. *86*, 590 (1974)]

Sulfonamide-aminosulfone rearrangement: A rearrangement induced anionically, cationically, and thermally (SC) 270 [G.E. *86*, 273 (1974)]

Sulfones, Herbicidal sulfoxides and ~ (PR) 555

Sulfonic acid, Salts of 3-hydroxy-2-hydroxymethylpropane ~ (PR) 555

Sulfonic anhydrides, Preparation and reactions of trifluoromethane sulfonic arenesulfonic anhydride (SC) 409 [G.E. *86*, 409 (1974)]

Sulfonium salts, Butatrienyl-~ in solution (SC) 469 [G.E. *86*, 477 (1974)]
Stable Propadienyl-~ by cycloadditions with butatrienyl-~ (SC) 470 [G.E. *86*, 477 (1974)]

Sulfoxides, Synthesis of bridged "didehydrothia[17]annulene" S-oxides. Dependence of ring current on geometry in stereoisomeric ~ (SC) 339 [G.E. *86*, 348 (1974)]
Herbicidal ~ and sulfones (PR) 555
Allylic ~ (LA) 614

Sulfoximides and their derivatives as reagents for organic syntheses (LA) 152

Sulfur compounds, Bis(N,N-methylsilanotriyl)tris(sulfur diimide)—a bicyclic derivative of S_4N_4 (SC) 146 [G.E. *86*, 130 (1974)]
Sulfonylbis(imidosulfur oxide difluoride) from trichlorophosphazosulfonylimidosulfur oxide difluoride (SC) 401 [G.E. *86*, 442 (1974)]
Cyclooctasulfur monoxide from cyclooctasulfur (SC) 603 [G.E. *86*, 648 (1974)]

Surface, ~ of mammalian cells (LA) 152
~ and defect properties of solids (Book Review) 214

Synthesis, Annual reports—1971 (Book Review) 95
Azide method for peptide bond ~ (LA) 824

Synthetic methods, 1,3-Anionic cycloadditions of organolithium compounds: An initial survey (FP) 627 [G.E. *86*, 715 (1974)]
Synthesis of unusual organic molecules using cyclic peroxides (FP) 619 [G.E. *86*, 683 (1974)]
Prescriptions and ingredients for controlled CC bond formation with organometallic reagents (FP) 701 [G.E. *86*, 751 (1974)]
Metalated isocyanides in organic synthesis (FP) 789 [G.E. *86*, 878 (1974)]

Synthetic paper, Production (PR) 486

TELLURIUM compounds, Diselenium dioxide octafluoride and ditellurium dioxide octafluoride (SC) 92 [G.E. *86*, 104 (1974)]

Tellurium subhalides: Crystal structures of α-TeI and β-TeI (SC) 403 [G.E. *86*, 411 (1974)]

4,4-Tetrachloroethylenedibenzoic acid, Derivatives (PR) 555

Tetracyanoethylene, Trapping of the 1,4-dipole formed in the 2+2-cycloaddition of ~ to enol ethers (SC) 80 [G.E. *86*, 47 (1974)]
Conformations of the zwitterionic intermediates from ~ and alkyl propenyl ethers (SC) 81 [G.E. *86*, 48 (1974)]
Reaction with cis-bicyclo[6.1.0]nona-2,4,6-triene (SC) 207 [G.E. *86*, 238 (1974)]

Tetracycloheptane, Novel isomers of cycloheptatriene: Tricyclo[4.1.0.$0^{2,7}$]hept-3-ene and tetracyclo[4.1.0.$0^{2,4}$.$0^{3,5}$]heptane (SC) 208 [G.E. *86*, 197 (1974)]

Tetradehydrobenzocyclotetradecenes, Synthesis of ~ ("benzodidehydro[14]annulenes"). Effect of benzoannelation on the diamagnetic ring current of macrocyclic (4n+2) π-electron systems (SC) 141 [G.E. *86*, 167 (1974)]

Tetradehydrocyclotetradeca[c]furans, Synthesis of ~ ("didehydro[14]annuleno[c]furans"), 18π-electron analogs of isobenzofuran (SC) 138 [G.E. *86*, 163 (1974)]

cis-3,4-Tetrahydrofurandiol, Crystal structure of a 1:1 sodium perchlorate complex of 1,4-anhydroerythritol (~) (SC) 541 [G.E. *86*, 555 (1974)]

Tetrahydrofurylidene, Stereospecificity as an argument against the intermediacy of 1,4-alkyl/acyl diradicals in the light-induced cyclobutanone-~ isomerization in condensed phase (SC) 197 [G.E. *86*, 197 (1974)]
Low temperature electronic spectroscopic observations on light-induced cyclobutanone-~ rearrangement (SC) 198 [G.E. *86*, 198 (1974)]
Simple EH model for photochemical cyclobutanone ~ isomerization (SC) 200 [G.E. *86*, 200 (1974)]

1,2,3,6-Tetrahydrophthalic anhydride, Isomerization (PR) 353

Tetraoxorhenate(VI), Preparation and properties of tetraoxotechnetate(VI) and ~ (SC) 346 [G.E. *86*, 350 (1974)]

Tetraoxotechnetate(VI), Preparation and properties of ~ and tetraoxorhenate(VI) (SC) 346 [G.E. *86*, 350 (1974)]

Tetrathiophene, Preparation and properties of cycloocta[1,2-b:4,3-b:5,6-b:8,7-b]-~ (SC) 467 [G.E. *86*, 475 (1974)]

Theoretical chemistry, MTP International review of science. ~ (Book Review) 288

Thermoplastic polymers, Mechanical fabrication (FP) 105 [G.E. *86*, 121 (1974)]

Thiabenzo[1,2]cyclononona[5,6,7-de]naphthalene, Conformational studies on oxa, thia, and aza derivatives of 7,8,13,14-tetrahydrobenzo[1,2]cyclononona[5,6,7-de]naphthalene and 8H,15H-7,16-dioxacyclodeca[1,2,3-de:6,7,8-d'e']dinaphthalene (SC) 731 [G.E. *86*, 814 (1974)]

Thiadibenzo[a,f]cyclodecene, Conformational studies on aza, and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]

Thiadibenzo[a,e]cyclononene, Conformational studies on aza and thia derivatives of 6,11,12,13-tetrahydro-5H-dibenzo[a,e]cyclononene and 5,6,7,12,13,14-hexahydrodibenzo[a,f]cyclodecene (SC) 730 [G.E. *86*, 813 (1974)]

6-Thiatetracyclo[5.4.0.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene, X-Ray structure analysis (SC) 669 [G.E. *86*, 738 (1974)]

Thiaziridine, 2,3-Di-tert-butyl-~ 1,1-dioxide (SC) 742 [G.E. *86*, 816 (1974)]

Thioacrolein dianion, Doubly metalated 2-propene-1-thiol: ~ (SC) 479 [G.E. *86*, 484 (1974)]

Thioamides, NMR spectroscopic studies on hindered rotation in primary amides and ~ (CR) 350 [G.E. *86*, 316 (1974)]

Thiobenzaldehyde dianion, Doubly metalated thiobenzyl alcohol—~ (SC) 202 [G.E. *86*, 202 (1974)]

(Thio)benzoic esters, 3,5-Dialkyl-4-hydroxy-~ (PR) 555

Thiobenzyl alcohol, Doubly metalated ~—thiobenzaldehyde dianion (SC) 202 [G.E. *86*, 202 (1974)]

Thiocarbamic acids, Esters of N,N'-ethylenedicarbamic and ethylenedi-~ (PR) 354

Thiocarbonyl groups, Correlation of ^{13}C-NMR chemical shifts of carbonyl and ~ (SC) 90 [G.E. *86*, 43 (1974)]

Thionicotinates, 2- and 4-azathioxanthones by photorearrangement of S-aryl ~ (SC) 550 [G.E. *86*, 562 (1974)]

Thiooxomolybdates, Coordination in bis-(thiooxomolybdato)metalate(II) complexes of type [M(MoOS$_3$)$_2$]$^{2-}$ and [M(MoO$_2$S)$_2$]$^{2-}$ (SC) 672 [G.E. *86*, 709 (1974)]

Thiophene, Synthesis of bridged "didehydrooxa"- and "-thia[17]annulenes", diatropic homologs of furan and ~ (SC) 337 [G.E. *86*, 346 (1974)]
Preparation and properties of cycloocta[1,2-b:4,3-b:5,6-b:8,7-b]-tetra-~ (SC) 467 [G.E. *86*, 475 (1974)]

Through-bond interaction, Effects (FP) 696 [G.E. *86*, 770 (1974)]

Through-space interaction, Stereochemical control by secondary ~: exo/endo-stability of 7-acceptor-substituted 2,4-norcaradienes (SC) 86 [G.E. *86*, 54 (1974)]

Thyrotropin releasing hormone, cis-trans-Isomerism of ~ (TRH) in aqueous solution (SC) 131 [G.E. *86*, 46 (1974)]

Tin compounds, 1,3,2,4-Diazadistannetidines, the first four-membered cyclostannazanes (SC) 607 [G.E. *86*, 676 (1974)]

Toluene (PR) 747

Toxicology, Gesundheitsschädliche Arbeitsstoffe. Toxikologisch-arbeitsmedizinische Begründung von MAK-Werten (Book Review) 288

Trace analysis of organic compounds (FP) 224 [G.E. *86*, 251 (1974)]

Trace elements, Recent results in search for ~ in nutrition (LA) 824
Silicon in organisms (LA) 824
Vanadium as an essential nutrient (LA) 824
Spurenelemente in Wein und anderen Getränken (Book Review) 827

Transfer ribonucleic acid, Thermodynamics of the structural transition of phenylalanine-specific ~ in solution (CR) 412 [G.E. *86*, 448 (1974)]

Transition metal complexes, Dimethylarsenido-~—stable organometallic Lewis bases (SC) 84 [G.E. *86*, 51 (1974)]
Square planar ~ with a bidentate ligand spanning trans-positions (SC) 133 [G.E. *86*, 133 (1974)]
Triphenylcyclotriphosphane as a new ligand in ~ (SC) 147 [G.E. *86*, 124 (1974)]
First π-diphenylketene-carbonyl-~ (SC) 335 [G.E. *86*, 345 (1974)]

Transition metal compounds, Electronic transitions in ~ at high pressure (FP) 39 [G.E. *86*, 61 (1974)]

Transition metals, Transition metal-carbon triple bonds (SC) 609 [G.E. *86*, 667 (1974)]

Transport, Mass ~ in solids (FP) 384 [G.E. *86*, 428 (1974)]
Equilibrium and ~ properties of low-melting salts (FP) 438 [G.E. *86*, 467 (1974)]

Trialkoxycyclopropenylium ions (SC) 209, 745 [G.E. *86*, 203 (1974)]

1,2,3-Triazolines (CR) 349 [G.E. *86*, 315 (1974)]

Tricyclo[5.2.1.0^{4,10}]deca-2,5,8-triene, Photoisomerization (SC) 663 [G.E. *86*, 706 (1974)]

Tricyclo[5.4.0.0.^{1,6}]undecatetraene, Photochemical synthesis in solution (SC) 670 [G.E. *86*, 739 (1974)]

Trifluoromethanesulfonic arenesulfonic anhydrides, Preparation and reactions (SC) 409 [G.E. *86*, 409 (1974)]

Triglycerides, Analysis (Book Review) 681

Trioxane, Branching reactions in the copolymerization of ~ with 1,3-dioxolane (CR) 418 [G.E. *86*, 454 (1974)]
2,6,7-Trioxa-1-phosphabicyclo[2.2.2]octane, Structure of 1:1-adduct of hexafluoroacetone azine and 4-ethyl-~ (SC) 543 [G.E. *86*, 560 (1974)]

cis-Trioxatris-σ-homobenzene, Crystal and molecular structure of ~ (cis-benzene trioxide) (SC) 539 [G.E. *86*, 557 (1974)]

Triphenylcyclotriphosphane as a new ligand in transition metal complexes (SC) 147 [G.E. *86*, 124 (1974)]

Triple bonds, Transition metal-carbon ~ (SC) 609 [G.E. *86*, 667 (1974)]

Triple-decker sandwich complex, X-ray structure analysis of the ~ tris(η-cyclopentadienyl)dinickel tetrafluoroborate (SC) 135 [G.E. *86*, 125 (1974)]

Triquinacene, Photoisomerization of tricyclo-[5.2.1.0^{4,10}]deca-2,5,8-triene (~) (SC) 663 [G.E. *86*, 706 (1974)]

trans-σ-Trishomobenzene, Quantitative cyclotrimerization of 3,3-dimethylcyclopropene to "hexamethyl-~" (SC) 465 [G.E. *86*, 518 (1974)]

Tris-σ-homobenzene, Simple bridged cis-oxa- and cis-aza-~ systems: Synthesis and 3σ→3π isomerization (SC) 482 [G.E. *86*, 522 (1974)]

Tropinone, New synthesis (SC) 410 [G.E. *86*, 444 (1974)]

Tropone, Method for evaluation of inductive and conjugative effects—application to ~ (SC) 273 [G.E. *86*, 275 (1974)]

Tuberculostatics, Improved preparation (PR) 679

Tumor viruses, Transformation of mammalian cells by two DNA ~ (LA) 151

ULLMANNS Encyklopädie der technischen Chemie (Book Review) 423

Ullmann synthesis, Novel applications (LA) 420

Ultracentrifugation of macromolecules (Book Review) 154

Ultrasound, Mechanism of degradation of polymers in solution by ~ (CR) 413 [G.E. *86*, 449 (1974)]

VANADIUM as an essential nutrient (LA) 824

Vanadium compounds, Hexakis(trifluorophosphane)vanadium hydride (SC) 201 [G.E. *86*, 233 (1974)]

Vinyl cation, Reaction of a vinyl fluoride with antimony pentafluoride. Spectroscopic evidence for a stable ~ (SC) 675 [G.E. *86*, 677 (1974)]

Vinyl carbonates, Halo-~ in organic synthesis (FP) 520 [G.E. *86*, 567 (1974)]

Vinyl chloride, Catalytic fluorination (PR) 212
Copolymers of ~ and acrylic ester units (PR) 487

Vinyl fluoride, Reaction with antimony pentafluoride. Spectroscopic evidence for a stable vinyl cation (SC) 675 [G.E. *86*, 677 (1974)]

Vinylsilanes, Convenient synthesis of ~ and their use in ketone synthesis (SC) 83 [G.E. *86*, 102 (1974)]

Vitamin D, Metabolism and function (LA) 151

Vitamin E, Biological action of ~ and selenium (LA) 211

Vulcanization, Mixed accelerator for ~ of EPDM elastomers (PR) 93
~ of synthetic rubbers with high-energy radiation (PR) 153

WATER, Die Analyse der organischen Verunreinigungen in Trink-, Brauch- und Abwässern (Book Review) 355

Wine, Spurenelemente in Wein und anderen Getränken (Book Review) 827

Woodward-Hoffmann rules, Theory of pericyclic reactions (FP) 751 [G.E. *86*, 825 (1974)]
Die Woodward-Hoffmann-Regeln und ihre Anwendung (Book Review) 288

XENON hexafluoride, Structure in solution: Xe_4F_{24} (SC) 612 [G.E. *86*, 669 (1974)]

X-ray absorption spectroscopy on free molecules (FP) 454]G.E. *86*, 505 (1974)]

X-ray photoelectron spectroscopy, Applications (ESCA) (LA) 678

X-ray structure analysis, ~ of 1:1 intermediate of criss-cross cycloaddition of isobutylene to hexafluoroacetone azine (SC) 475 [G.E. *86*, 482 (1974)]
~ of the α-cyclodextrin-krypton inclusion complex: A noble gas in an organic matrix (SC) 552 [G.E. *86*, 594 (1974)]
~ of 6-thiatetracyclo[5.4.0.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene (SC) 669 [G.E. *86*, 738 (1974)]
[2,2](2,5)Benzoquinonophane: Structure and photochemistry (SC) 674 [G.E. *86*, 705 (1974)]
Structure of a rectangular cyclobutadiene (SC) 740 [G.E. *86*, 783 (1974)]
Structure of diimine: ~ of $N_2H_2[Cr(CO)_5]_2 \cdot 2$ THF (SC) 822 [G.E. *86*, 860 (1974)]

Xylene, Benzene (PR) 747

YNAMINES, 1,3-Oxazin-6-ones with ~ and ketene N,O-acetals (SC) 533 [G.E. *86*, 596 (1974)]

ZWITTERIONS, Conformations of zwitterionic intermediates from tetracyanoethylene and alkyl propenyl ethers (SC) 81 [G.E. *86*, 48 (1974)]
