Mechanisms of Photochemical Air Pollution

By J. N. Pitts, Jr. and B. J. Finlayson[*]

Dedicated to Professors Philip A. Leighton and Francis E. Blacet

Selected aspects of the chemistry of photochemical air pollution is discussed and some important, unresolved problems dilineated. The reactive species considered include NO_2, O_3, $O(^3P)$, $O(^1D)$, $O_2(^1\Delta_g)$, OH and HO_2. Both the kinetics and mechanisms of the reactions constituting the major tropospheric sources and sinks of these species are treated where available. The application of this information in both computer and smog chamber simulations of photochemical smog is discussed.

1. Introduction

Photochemical air pollution was first overtly recognized in the Los Angeles Basin in the 1940's from the crop damage it caused[1]. This new type of smog was characterized by the formation of oxidants[2] in contrast to the well-known "London Smog" which contained primarily SO_2 and particulates[3]. *Haagen-Smit* and co-workers[4–7] demonstrated that a mixture of cracked gasoline or olefins and ozone acting on crops reproduced the smog damage, and showed that ozone was produced when a mixture of nitrogen dioxide and individual organics (olefins, alkanes, alcohols, carbonyl compounds, acids) or dilute auto exhaust was irradiated.

Since then these experiments have been reproduced under a variety of conditions. Figure 1 shows a typical time dependence[8–10] of the reactants and major products when a mixture of nitrogen oxides and propylene in the part-per-million (ppm) concentration range are irradiated in air with ultraviolet light ($\lambda \gtrsim 290$nm)[3, 11]. Initially, NO is rapidly converted to NO_2. Simultaneously, the olefin concentration decreases and acetaldehyde appears. When the NO concentration is sufficiently low, O_3 and peracetyl nitrate ($CH_3CO_3NO_2$) build up while the NO_2 and C_3H_6 concentrations fall.

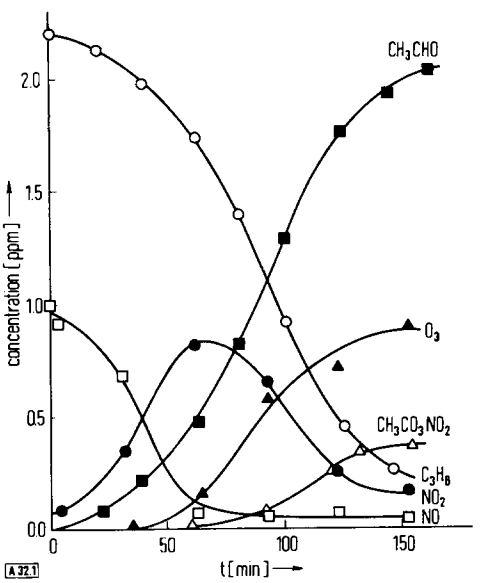

Fig. 1. Typical concentration-time profiles [8—10] for the reactants and major products in the photooxidation of propylene in the presence of NO and NO_2 (after [10]).

In this system NO_2 is the major light-absorbing species[3]. At wavelengths less than 430nm NO_2 dissociates forming NO and ground state oxygen atoms, $O(^3P)$, (see Section 2):

$$NO_2 \xrightarrow{\lambda < 430\,nm} NO + O(^3P) \quad (1)$$

In air this is rapidly followed by:

Fullerton Calif. 92634 (USA)

$O + O_2 + M \rightarrow O_3 + M$ $\quad k_2^{[*]} = 2.1 \times 10^8$ (M = N_2) (2) [12, 13]

$O_3 + NO \rightarrow NO_2 + O_2$ $\quad k_3 = (1.1 \pm 0.2) \times 10^7$ (3) [14]

In the presence of propylene, we should include:

$O + C_3H_6 \rightarrow$ products (4)

$O_3 + C_3H_6 \rightarrow$ products (5)

The behavior shown in Figure 1 has challenged chemists to explain the following apparent anomalies. Starting with large quantities of NO and small amounts of NO_2, we see in the initial stages of the reaction an increase in NO_2, the species which we know is being lost photochemically by reaction (1). Secondly, the rate of olefin disappearance is much greater than that due solely to its reactions with O and O_3, as shown in Figure 2[10]. These anomalies imply that a chain reaction must be involved both in the NO—NO_2 conversion and in the olefin loss.

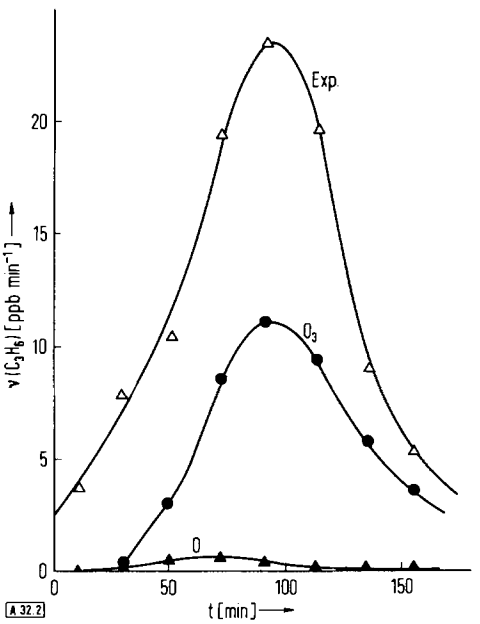

Fig. 2. Comparison of the experimentally determined rate v of propylene loss to that calculated from its reaction with O and O_3 [8—10] (after [10]).

The behavior described above is characteristic of photochemical smog formation involving any reactive hydrocarbon, singly or in complex mixtures such as auto exhaust. In 1961, *Leighton*[3] speculated that radicals such as R, RO_2, RO, OH, HO_2, and H might be involved. Further work since then has strengthened and clarified these ideas. One major contribution was the suggestion[15, 16] that CO, in conjunction with hydroxyl (OH) and hydroperoxyl radicals (HO_2) might participate in the NO to NO_2 conversion:

$OH + CO \rightarrow CO_2 + H$ (6) [17]

$k_6 = 9.8 \times 10^7$

$H + O_2 + M \rightarrow HO_2 + M$ (7) [18]

$k_7 = (2.13 \pm 0.4) \times 10^{10}$ (M = N_2)

$HO_2 + NO \rightarrow NO_2 + OH$ (8) [19]

$k_8 = (1.8 \pm$ factor of 3) $\times 10^8$

Thus, carbon monoxide, which was assumed to be unreactive in photochemical air pollution until the rate of reaction (6) was shown[20] to be fast, may now assume an important role under appropriate conditions. Some organics, such as formaldehyde, may act in a similar manner[21]:

$OH + HCHO \rightarrow H_2O + HCO$ (9) [22]

$k_9 = (8.4 \pm 2.1) \times 10^9$

$HCO + O_2 \rightarrow HO_2 + CO$ (10) [23]

$k_{10} = (3.4 \pm 0.7) \times 10^9$

$HO_2 + NO \rightarrow HO + NO_2$ (8)

Thus, any source of H, HO_2, or OH will contribute to the rapid oxidation of NO to NO_2 and, as we shall see, to the enhanced rate of olefin consumption.

Understanding the detailed course of the reactions involved in complex smog mixtures such as that in Figure 1 is the immediate goal of atmospheric chemists today. This necessitates an intimate knowledge of the kinetics and mechanisms (including intermediates *and* products) of all elementary reactions involved. Only then can we accurately and reliably predict the time dependence of the pollutant concentrations in such simulated smog experiments. Of course, even this mammoth task is only a step towards the ultimate aim—predicting the same time dependence in the real atmosphere where fresh pollutants are constantly being added, meteorology is changing, and some of *yesterday*'s "aged" smog is also present when the sun rises to initiate the reactions *today*. In order to meet even the initial goal, however, we lack kinetic and mechanistic information in many crucial areas, information which must be obtained by careful, quantitative research in a variety of systems ranging from the torr to part-per-billion (ppb) concentration ranges. This provides an unparalleled opportunity for chemists to apply their expertise to a societal problem facing all of us.

In this article, we briefly summarize current knowledge of selected areas of photochemical air pollution, and in doing so, delineate some of the present and future challenges to the chemist. This is not intended to be a comprehensive review but rather an examination of certain interesting aspects of smog chemistry which we hope will put the subject in perspective. We apologize in advance to the many scientists whose work is not included, or discussed in the detail it deserves, due to the limitations of space.

2. Photolysis of Nitrogen Dioxide (NO_2)

NO_2 is the major light-absorbing species in the solar actinic region ($\lambda > 290$ nm) and is an important (but not the sole) initiator of photochemical smog formation. It has been established[3] that the primary process on absorption of wavelengths less than ≈ 398 nm is dissociation, with a primary quantum yield of approximately unity:

$NO_2(X^2A_1) \xrightarrow{h\nu} NO(X^2\pi) + O(^3P)$ (1)

This is consistent with the NO_2 bond dissociation energy of 3.115 eV ($\lambda = 398$ nm)[24]. At wavelengths greater than 430 nm, there is no $O(^3P)$ production[3, 25–28]; only photophysical processes occur.

Bond rupture also occurs, however, at wavelengths between 398 and 430 nm[3, 25, 26, 29], as confirmed by a recent study[28].

[*] Rate constants throughout are given in l-mol-s units at 300 °K.

In this wavelength region the photon is not sufficiently energetic by itself to cause dissociation, and the excess energy must come from the rotational energy[26, 28, 35].

Recently, *Jones* and *Bayes*[28] measured relative quantum yields for NO formation at exciting wavelengths from 295 to 445 nm in 5 or 10 nm intervals using a photoionization mass spectrometer. This technique, which has proven to be powerful and will undoubtedly play a large role in kinetic and mechanistic studies in the future, uses photon absorption to ionize the species entering a quadrupole mass spectrometer. The advantages over ionization by conventional electron impact include (i) the possibility of selective ionization (through the choice of ionizing wavelength) of small quantities of species in the presence of large amounts of compounds which would otherwise interfere, (ii) minimization of fragmentation processes, hence greatly simplifying interpretation of the mass peaks, and (iii) partial confirmation of identification through the use of resonance lamps of varying photon energy[28, 30].

The quantum yields for NO[28] were put on an absolute basis using the results of previous work at 313 and 366 nm. Since reaction (1) is rapidly followed by

$$O + NO_2 \rightarrow NO + O_2 \qquad (11)$$

Φ_{NO} is anticipated to be 2.0 at $\lambda < 398$ nm in the absence of competing processes.

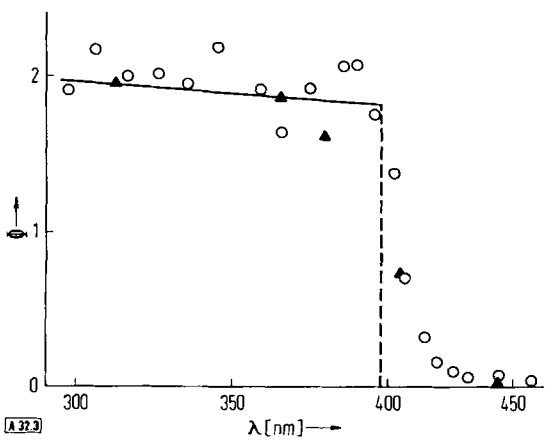

Fig. 3. Wavelength dependence of the quantum yield [28] for NO formation in the photolysis of NO_2; ○ from ref. [28]; ▲ from ref. [3, 26]. Dotted line gives the dissociation energy of NO_2 (3.115 eV) [24]. Solid line is the least squares fit to the data of ref. [28] (after [28]).

Figure 3 gives the results of this investigation[28] as well as those of earlier studies[3, 26]. It is seen that for $295 < \lambda < 398$ nm, Φ is close to 2 but decreases slightly with increasing wavelength. *Jones* and *Bayes*[28] suggested that the competing process which accounts for $\approx 3\%$ of the reaction at 313 nm and $\approx 8\%$ at 366 nm may be energy transfer to O_2. Thus these investigators[31, 32] observed the production of electronically excited $O_2(a^1\Delta_g)$ when mixtures of NO_2 and O_2 were irradiated in the region $330 < \lambda < 590$ nm. *Frankiewicz* and *Berry*[33, 34] also observed the production of small quantities of $O_2(b^1\Sigma_g^+)$ in the same system.

As mentioned above, the observed dissociation of NO_2 at $\lambda > 398$ nm can be qualitatively explained by the contribution of the rotational energy, in agreement with recent spectroscopic studies[35]; quantitatively, however, the calculated NO quantum yields are lower[28] than those determined experimentally. Further studies are necessary in order to resolve this discrepancy between theory and experiment.

3. The Role of Ozone in Photochemical Air Pollution

In air, the ground state oxygen atom, $O(^3P)$, produced in the photolysis of NO_2, is removed primarily by reaction (2) with O_2. At the present time, this is the only reaction known to produce O_3 although alternate reactions such as that of the Criegee diradical (see Section 3.2) with O_2 have been suggested[36].

$$R\dot{C}HOO\cdot + O_2 \rightarrow RCHO + O_3 \qquad (12)$$

3.1. Kinetics of the Ozone-Olefin Reaction

Table 1 gives typical room temperature rate constants for the reactions of O_3 with some species normally present in polluted urban atmospheres. Using these rates and typical ambient pollutant concentrations, one calculates that the only important loss processes of O_3 occur by reaction with olefins, NO, and to a lesser extent, NO_2. The rapid reaction (3) of O_3 with NO is the reason that O_3 does not begin to accumulate (Figure 1) until the NO concentration has decreased to a low value. This may also at least partially explain why oxidant levels in downtown Los Angeles have dropped as the NO emissions have risen; concurrently, ozone concentrations have increased in communities downwind due to the subsequent photolysis of the NO_2 formed by reaction (3)[41–43].

Table 1. Selected room temperature rate constants for some ozone reactions.

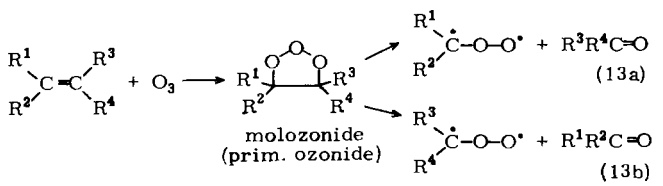
Compound	$k \times 10^{-3}$ [l mol^{-1} s^{-1}]	Ref.
Ethylene	0.93 ± 0.09	[37]
Propylene	7.5 ± 0.6	[37]
Isobutene	8.2	[38]
trans-2-Butene	165 ± 14	[37]
$(CH_3)_2C{=}CHCH_3$	296 ± 10	[38]
$(CH_3)_2C{=}C(CH_3)_2$	906 ± 48	[38]
Toluene	7.2×10^{-3}	[39]
$HC{\equiv}CH$	52×10^{-3}	[39]
CH_3CHO	20×10^{-3}	[39]
CH_4	$\leq 0.72 \times 10^{-3}$	[39]
CO	$\leq 0.6 \times 10^{-3}$	[39]
NO	$(1.1 \pm 0.2) \times 10^{4}$	[14]
NO_2	19 ± 3	[40, 14]

At low NO concentrations O_3 reacts primarily with olefins at rates of $\approx 10^3$—10^5 l mol^{-1} s^{-1}. While the rate constants of Table 1 are generally the most recently determined ones, there are significant disagreements in the literature values, particularly for olefins containing an internal double bond. It now appears that secondary attack of intermediates on the reactants makes the experimentally determined rate constant sensitive to the reaction conditions, particularly the O_2 concentration[38, 44]. Additionally, the rate of formation of the major carbonyl products may be nonlinear[45], at least under certain conditions, and hence those rate studies based solely on product formation may be in error. These factors have only recently come to light and indicate the need for

further kinetic studies over a wide variety of experimental conditions.

3.2. Mechanism of Gas Phase Ozone-Olefin Reactions

Until recently, the mechanism of the ozone-olefin reactions in the gas phase had generally been interpreted in terms of a modified liquid phase Criegee mechanism[46-48]. The initial electrophilic attack of ozone on the olefin is thought to produce a molozonide, or primary ozonide, which cleaves to the Criegee "zwitterion" (more likely a diradical in the gas phase) and a carbonyl compound [reactions (13a) and (13b)]:



(13a)

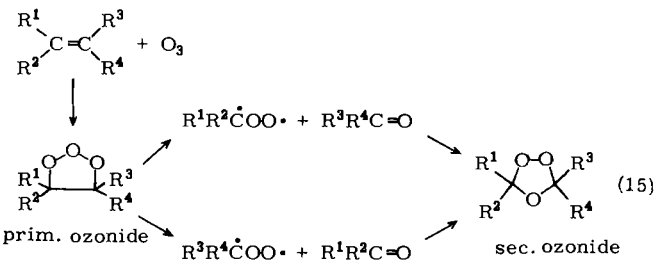
(13b)

According to *Scott*, *Hanst*, and co-workers[49,50], the diradical then decomposes, rearranges or reacts further. The extent of decomposition will be determined primarily by the size of the diradical since larger molecules will have a greater number of vibrational degrees of freedom over which to dissipate the excess energy without decomposing. For example, the Criegee diradical $CH_3\dot{C}HOO\cdot$ from the propylene reaction may decompose[49,50] as follows:

$$CH_3-\dot{C}H-O-O\cdot \xrightarrow{(a)} H_2O + CH_2=C=O$$
$$\xrightarrow{(b)} CH_3OH + CO \qquad (14)$$
$$\xrightarrow{(c)} CH_4 + CO_2$$

All of these products were observed in the propylene-ozone reaction[49,50].

On the other hand, secondary ozonide formation was observed by infrared spectroscopy[50] for the longer chain hydrocarbons (1-hexene, 2-pentene, and 3-heptene) where diradical decomposition is not expected to be extensive. Presumably this arises by recombination of the diradical and carbonyl fragments in a manner analogous to the liquid phase [reaction (15)].

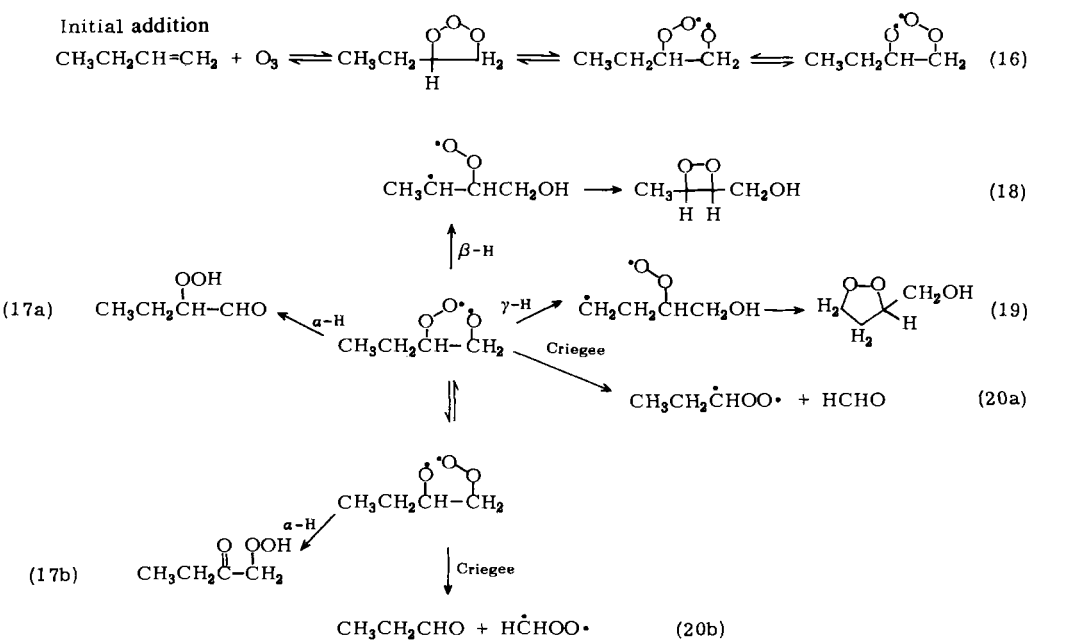


(15)

However, the formation of such ozonides has not been reported using alternate techniques such as GC. Such confirmatory studies are, in the authors' opinion, desirable.

Subsequent studies using a variety of techniques over a wide range of experimental conditions have yielded results which are not easily explained by this mechanism, however. These include (i) the formation of a wide variety of "abnormal" ozonolysis products such as peroxides; aldehydes, and ketones one and two carbons shorter than the major carbonyl product; and carbonyl compounds having the same chain length as the reactant olefin[51-54], (ii) non-unit stoichiometry[38,52,55,56], (iii) the formation of radical intermediates at low pressures[58], including significant yields of H atoms[44,57,59], and (iv) the production of chemiluminescence[44,57,59-63].

In order to explain these observations, *O'Neal* and *Blumstein*[64] have proposed that, in addition to the Criegee path, α, β, and γ abstractions of the primary ozonide can occur. For example, for the 1-butene reaction with O_3, the following series of reactions are postulated; the relative importance of each of these paths under various experimental conditions can be calculated from the thermochemistry and unimolecular theory. The ΔH^0 values are −32.9 for reaction (16), −74.3 for (17a), −65 for (18), −80 for (19), and ≤4.4 kcal/mol for (20a).

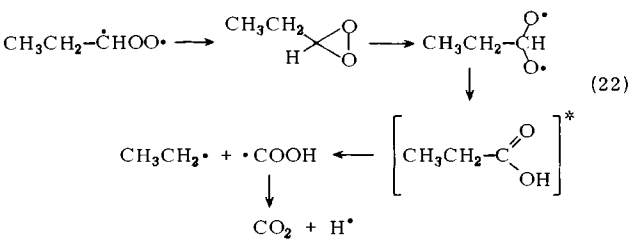


Chemiluminescence is then rationalized by the decomposition of the dioxetanes formed by β-hydrogen abstraction[44, 64, 65], leading to electronically excited species.

Reactions (16)—(20) are highly exothermic and hence will result in the formation of excited products. Decomposition of these energetic species will occur in competition with their collisional stabilization and hence be pressure dependent. For example, excited hydroperoxides formed by α-hydrogen abstraction, as in (17), are known[66] to cleave at the O—OH bond if sufficient energy is available [reaction (21)].

(21)

A novel feature of the *O'Neal-Blumstein* proposal is the postulated rearrangement of the Criegee diradical under certain conditions to the excited acid which may also decompose[64, 67] [reaction (22)].

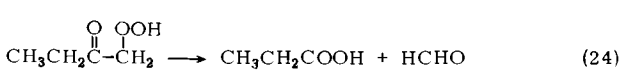


(22)

This may explain the production of H atoms[44, 57, 59] and also be consistent with the proposals of *Scott*, *Hanst*, and coworkers[49, 50] regarding the modes of decomposition of the diradical $CH_3\dot{C}HOO\cdot$ (see above). Acetic acid is known to decompose photochemically to CH_4 and CO_2[68] and thermally to $CH_2{=}C{=}O + H_2O$[69]. Ketene has been observed in significant yields from the reaction of *cis*-2-butene with ozone both at low[58, 70] and at high[70] total pressures, while CH_3COOH was not detected[58, 70].

At high pressures and for long chain diradicals the acid from the Criegee cleavage may be stabilized, in which case the final products are the same as those from the decomposition of the α-carbonyl hydroperoxide [reactions (23) and (24)].

(23)



(24)

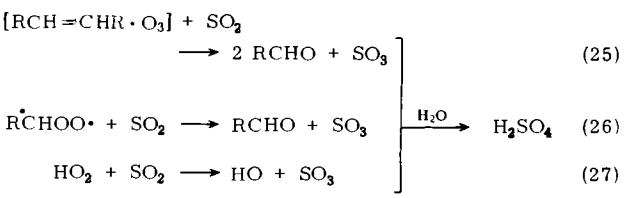
The only means of differentiating between these two paths is identification of the α-carbonyl hydroperoxide which is an intermediate in the α-hydrogen abstraction path but not in the Criegee path.

While this theory of ozone-olefin reactions is attractive, further experimental validation is needed before the theory, or selected aspects thereof, can be accepted. It is evident that much more work is needed on the intermediates (including radical species), stoichiometry, effects of oxygen, total pressure, and reactant concentrations using a variety of techniques in order to establish confidently the mechanisms and the bimolecular rate constants of these complex reactions.

Because of the uncertainties regarding the reaction mechanism, the precise role of ozone-olefin reactions in photochemical smog formation still remains obscure. One possibility is the production of H atoms followed by their reaction with O_2 to form HO_2[44]. Furthermore, if radicals such as HCO which are formed at 2 torr[58] are also produced at atmospheric pressure, they too may participate in the NO to NO_2 conversion by formation of HO_2, by reaction (10). Finally, it is interesting to speculate that the α-carbonyl hydroperoxide may be the phytotoxicant produced in ozone-olefin reactions[71, 72].

3.3. Effect of Sulfur Dioxide on Ozone-Olefin Reactions

When SO_2 is added to a mixture of ozone and olefin in the dark or to dilute auto exhaust which is subsequently irradiated, it is rapidly oxidized by some unidentified reaction intermediate or product to sulfuric acid aerosol[45, 73–75]. An ozone-olefin adduct[45], the Criegee diradical[45], and HO_2[44] have all been suggested as the oxidizing species [reactions (25)—(27)].



(25)

(26)

(27)

While further detailed studies are badly needed, this important finding may explain the high rates of oxidation of SO_2 in areas of photochemical smog[21] and would suggest that the use of high sulfur fuels in such areas be discouraged[43] because of the apparent toxicity of particulate sulfate[163] and its role in visibility reduction.

4. Reactions of $O(^3P)$ with Olefins and Arenes

At typical ambient pollutant levels $O(^3P)$ reacts to a small extent with hydrocarbons, in addition to its primary loss by reaction (2) with O_2.

4.1. Kinetics of Reactions of $O(^3P)$ with Olefins and Arenes

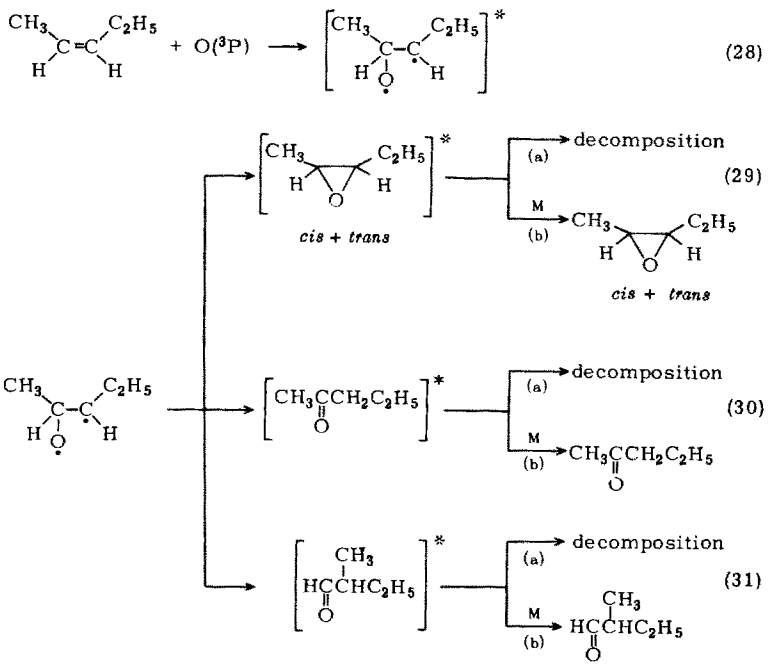
Table 2 gives the values of selected rate constants for the reactions of $O(^3P)$ with some olefins and arenes. These rates, which show an electrophilic trend[76], represent addition to the double bond. While it was suggested[78] that abstraction may occur ≈ 15 % of the time at 300 °K in the $O(^3P)$-1-butene reaction, OH was not detected[79] as an intermediate in this reaction, supporting previous assumptions that hydrogen abstraction is too slow to compete with addition at room temperature.

4.2. Mechanism of the $O(^3P)$-Olefin Reaction

The results of a definitive series of studies of the $O(^3P)$-olefin reactions led *Cvetanovic* and co-workers[76] to postulate the following reaction mechanism, illustrated by the reaction of $O(^3P)$ with *cis*-2-pentene [reactions (28)—(31)].

Table 2. Typical rate constants k at 298°K for the reaction of $O(^3P)$ with olefins [165] and arenes [77].

Olefin	$k \times 10^{-8}$ [l mol^{-1} s^{-1}]	Arene	$k \times 10^{-8}$ [l mol^{-1} s^{-1}]
Ethylene	4.3 ± 0.5	Benzene	0.144 ± 0.02
Propylene	20 ± 1.7	Toluene	0.45 ± 0.045
1-Butene	24 ± 3.7	*o*-Xylene	1.05 ± 1.11
cis-2-Butene	92 ± 15	*m*-Xylene	2.12 ± 0.21
2-Methyl-2-butene	313 ± 30	*p*-Xylene	1.09 ± 0.11
2,3-Dimethyl-2-butene	425 ± 46	1,2,3-Trimethylbenzene	6.9 ± 0.7
		1,2,4-Trimethylbenzene	6.0 ± 0.6
		1,3,5-Trimethylbenzene	16.8 ± 2.0



According to this scheme:

1) $O(^3P)$ adds to the double bond, primarily to the less substituted carbon atom, forming a triplet diradical [reaction (28)].

2) The diradical is sufficiently long-lived that some rotation about the original double bond occurs since both *cis* and *trans* epoxides are formed starting from one geometric isomer of the olefin [reaction (29)].

3) Ring closure to the epoxide must be competitive with rotation since the ratio of *cis* to *trans* epoxides formed is not the same for the reaction of the *cis* and *trans* olefins respectively.

4) The epoxide formed contains ≈90 kcal/mol excess energy and hence will decompose [reaction (29a)] unless first collisionally stabilized [reaction (29b)].

5) The diradical may also undergo an internal migration of an H atom from the carbon to which the oxygen is attached to the adjacent carbon to form methyl *n*-propyl ketone containing ≈115 kcal excess energy; the excited ketone will then decompose [reaction (30a)] if not collisionally stabilized [reaction (30b)].

6) The alkyl group attached to the carbon attacked by the $O(^3P)$ may also migrate to the neighboring carbon, ultimately forming excited 2-methylbutanal which can decompose [reaction (31a)] or be stabilized by collisions [reaction (31b)].

7) The migration of the alkyl group is partly internal and partly external in nature, as indicated by the formation of small amounts of CH_4 and C_2H_6.

8) This splitting off of an alkyl radical from the triplet diradical, its third available reaction mode, is not quenched by increasing pressures and hence is referred to as the "pressure independent fragmentation."

This reaction scheme, postulated on the basis of the observed stable products, has been confirmed recently by the detection of the intermediate radical species using photoionization mass spectrometry[80–83]. These studies have also elucidated minor reaction paths which occur in addition to those described above.

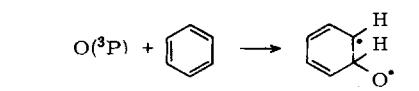
One of the major unsolved mechanistic problems of the $O(^3P)$ reaction with olefins, relevant to photochemical smog, is the effect of excess molecular oxygen at atmospheric pressure. Such studies are hampered by the possibility of ozone formation *via* reaction (2) since ozone also reacts with olefins to produce a wide variety of products including carbonyl compounds.

In one study[84] where NO_2 was used as the source of $O(^3P)$ and increasing amounts of O_2 were added to the *cis*-2-pentene reaction, significant quantities of acetaldehyde and propanal were formed, the epoxide yield decreased and the yields of methyl propyl ketone and 2-methylbutanal remained constant. Under these conditions O_3 formation should be negligible and it therefore appears that O_2 must interact with some of the intermediates. The triplet diradical is probably sufficiently short-lived[76] so that no collisions occur before it undergoes further reaction. Since the yields of the addition

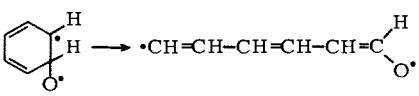
carbonyl compounds are also unaffected by increasing pressures of O_2[84], it appears that the most likely interaction of O_2 is with the excited epoxides. However, until there is much more data available on the effect of O_2 on these reactions and on their intermediates, a detailed mechanistic discussion is not possible. Such studies are particularly important in that some monofunctional epoxides show carcinogenic activity in mice and rats[85]. Such epoxides include 3,4-epoxy-1-butene and styrene oxide which one *might* envision as being formed from oxygen atom reactions with 1,3-butadiene and styrene, respectively. It must be stressed however, that the production of such epoxides under ambient air conditions and their presence in polluted urban atmospheres at detectable levels has not been confirmed.

4.3. Mechanism of the O(^{3}P)-Arene Reaction

In 1961 *Cvetanovic* and co-workers[86,87] reported that the volatile products of the reactions of O(^{3}P) with benzene and toluene are water and CO, and phenol (from C_6H_6) and cresols (from C_7H_8), respectively, with the major product being nonvolatile polymeric compounds which deposited on the walls of the cell. This has recently been confirmed[88,92]. The polymeric material is thought to contain such functional groups as —CHO[86,89], —OH, and C—O—C[89] and to be aliphatic in nature[86]. While the formation of this "polymer" has repeatedly haunted researchers, it is interesting from the point of view of photochemical air pollution in that significant quantities of aliphatic difunctional compounds recently have been observed in ambient air particulate matter[90,91]. Many of these compounds contain five and six



(32)

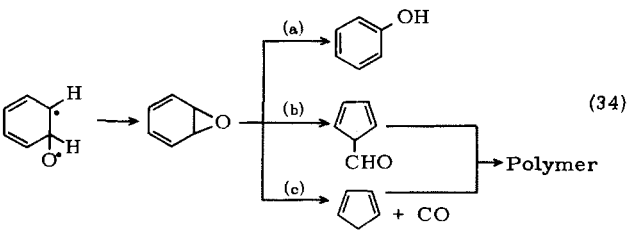


(33)

carbon atoms and hence we feel may arise from the attack of reactive radicals such as O(^{3}P) and OH on an aromatic ring, followed by ring opening and subsequent reactions with O_2, *etc.* For example, following the initial addition of O(^{3}P) to the benzene ring[86] [reaction (32)], ring opening may occur according to reaction (33)[89].

Subsequent reactions of the unsaturated diradical may then produce the nonvolatile products[86].

Alternatively, the following Scheme (34) has been proposed[86] to account for the observed products:



(34)

Such a mechanism cannot be extended to more complex arenes, as shown for example, by the lack of formation of 2,6-dimethylanisole in the 1,2,3-trimethylbenzene reaction[92].

It is obvious that the reaction of O(^{3}P) with arenes is very complex and will require the use of highly sophisticated techniques such as photoionization mass spectrometry in order to clarify the reaction mechanisms. However, with the increasing arene content of gasoline as lead is removed, even higher levels of these compounds in ambient air are anticipated. Hence, these reactions may become increasingly important, particularly if it can be conclusively demonstrated that ring opening to produce unsaturated aliphatic compounds is a major reaction pathway.

Although highly speculative at the present time, another possible route to ring opening in photochemical smog may involve the oxygen-enhanced absorption of light by arenes followed by their photooxidation to difunctional unsaturated compounds. Thus, in solution the irradiation of oxygen-saturated benzene led to the formation of both six and twelve-carbon conjugated dialdehydes[93].

5. Reactions of Electronically Excited O(^{1}D) Atoms

Electronically excited O(^{1}D) atoms containing 45.4 kcal/mol excitation[94] are produced in polluted urban atmospheres by the photolysis of O_3 at wavelengths less than 308 nm[95]. While the major tropospheric removal process of O(^{1}D) is physical quenching to O(^{3}P) primarily by O_2 and N_2, water is typically present at concentrations of ≈ 1—3% and hence can account for chemical quenching of $\approx 9\%$ of the O(^{1}D) atoms formed[96,97]:

$$O(^1D) + H_2O \xrightarrow{(a)} 2OH$$
$$\xrightarrow{(b)} H_2O + O(^3P)$$
$$\xrightarrow{(c)} H_2O_2$$
$$\xrightarrow{(d)} H_2 + O_2 \qquad (35)$$

It is estimated that more than 90% of the reaction produces hydroxyl radicals (path a)[98]. Hence, at high ozone concentrations in severe photochemical smog, this reaction may be an important source of OH radicals (see Section 7.1).

Recently, it has been shown that, in contrast to O(^{3}P) whose rates of reaction with chlorofluoroalkanes are very low[99], O(^{1}D) atoms react at almost collision frequency with a variety of these compounds[100,101]. Thus, the rate constants for its reactions with $CFCl_3$, CF_2Cl_2, CHF_2Cl, and CF_2ClCF_2Cl are 3.5×10^{11}, 3.2×10^{11}, 2.1×10^{11}, and 2.0×10^{11} l mol^{-1} s^{-1}, respectively. Major products with $CFCl_3$ and CF_2Cl_2 are COFCl and COF_2, respectively. Probably, chlorine is also formed either as Cl_2 in a molecular elimination process or as a recombination product of Cl atoms. This is currently being investigated.

Since chlorofluoroalkanes are commonly used as aerosol propellants and are released into the atmosphere in great quantities, their atmospheric sinks are of considerable interest. In the troposphere, the concentration of O(^{1}D) is sufficiently low that reaction with chlorofluoroalkanes is not a significant loss process, and, as indicated above, other tropospheric reactions of these compounds are slow. In the stratosphere, however, the O(^{1}D) concentrations are much higher[102] and reaction with chlorofluoroalkanes that may have undergone vertical transport from the troposphere could prove to be signifi-

cant[100, 101]. This is especially true if either Cl_2 or Cl are formed in the primary attack of $O(^1D)$ or if COFCl (arising from $CFCl_3$) is photolyzed to produce Cl, as seems likely. Thus *Molina* and *Rowland* have recently proposed that chlorine atoms from the photodissociation of chlorofluoroalkanes by short wavelength solar radiation in the stratosphere[103] could lead to a chain destruction of stratospheric O_3[103, 104] in a manner similar to that suggested for nitric oxide.

Whether or not either of these proposed mechanisms for degradation of chlorofluoroalkanes, direct photodissociation or attack by $O(^1D)$ atoms, actually poses a problem depends upon several factors: (i) validation of these mechanisms under simulated stratospheric conditions; (ii) establishment of present and predicted future chlorofluoroalkane concentrations in the stratosphere; and (iii) their importance as chlorine atom sources relative to other precursors to Cl already existing in the stratosphere. Clearly, research in these areas is vitally needed.

6. Singlet Molecular Oxygen, $O_2(^1\Delta_g)$

Leighton[3] first considered the electronically excited states of O_2 as potential atmospheric oxidants, but he concluded that their production by the direct absorption of sunlight was too small to be significant. *Bayes*[105] then showed that if the O_2 absorption coefficients are corrected for collisional line broadening, excited $O_2(^1\Delta_g)$ may be formed in high enough concentrations and have a sufficiently long lifetime to react with simple olefins in the atmosphere, for example, according to reaction (36)[106, 107].

(36)

Subsequently, it was proposed[108, 109] that energy transfer from triplet excited organic pollutants to ground state oxygen might yield significant concentrations of $O_2(^1\Delta_g)$. Additional sources of $O_2(^1\Delta_g)$ in polluted urban atmospheres[110, 111] include energy transfer to O_2 from NO_2[31–34] (see Section 2), photolysis of O_3[112–114], exothermic chemical reactions producing O_2[115], oxygen-enhanced absorption by organics[116], and the hydrolysis of peracetyl nitrate[164].

Quantitative estimates of the yields of $O_2(^1\Delta_g)$ from each of these processes are difficult. However, a recent estimate[31] of the $O_2(^1\Delta_g)$ concentration due to the sum of direct absorption, energy transfer from NO_2^*, and photolysis of O_3 is $\approx 10^{-5}$ ppm.

It was thought[108–111] that $O_2(^1\Delta_g)$ might in part be responsible for the excess rate of consumption of olefins (Fig. 2) and the conversion of NO to NO_2 if its rate constants for reactions with olefins were sufficiently high, a point that was at that time unknown. Subsequently, these rate constants were found to be comparable to those of ozone-olefin reactions, *i.e.*, approximately five orders of magnitude lower than those of the corresponding $O(^3P)$ reactions[111, 117–119]. Since the $O(^3P)$ concentration is estimated[3] to be $\approx 10^{-8}$ ppm and if the $O_2(^1\Delta_g)$ concentration is $\approx 10^{-5}$ ppm[31] the oxidation of olefins by $O_2(^1\Delta_g)$ will not contribute significantly to the bulk consumption of olefins in polluted urban atmosphere [111, 120, 121] (see Table 5).

Recent calculations by *Firestone* and *Calvert*[122], however, indicate that we should be cognizant of possible health problems associated with $O_2(^1\Delta_g)$. They calculate that the half-life for quenching of $O_2(^1\Delta_g)$ by O_2 is sufficiently great (9.0×10^{-4} min) compared to the period for the inhalation cycle (3.5×10^{-2} min), that $O_2(^1\Delta_g)$ may reach the lung unquenched a significant portion of the time. Depending on the nature of the products formed by the interaction of $O_2(^1\Delta_g)$ with the lung tissue, some adverse health effects may arise.

Hence the presence of $O_2(^1\Delta_g)$ in polluted atmospheres is of concern for several reasons: (i) its calculated lifetime is sufficiently great that significant quantities may penetrate into the lung and react to form toxic compounds; (ii) it may react with a variety of olefins and arenes[123–129] and in ambient air form such known toxins as hydroperoxides[85, 129–131] which may then be inhaled; and (iii) it may be formed *in situ* by hydrolysis of air pollutants such as peracetyl nitrate[164].

Further work seems warranted to establish the ambient levels of $O_2(^1\Delta_g)$, to clarify its reactions with organics in ambient air and with biological components, and to establish the effects of the products of these reactions on human organisms.

7. The Hydroxyl Radical (OH): Kinetics and Mechanisms

The suggestion that the OH radical is an important chain carrier in photochemical smog formation[3, 15, 16] has sparked much interest in both its kinetics and reaction mechanisms. This emphasis has been given added impetus recently by the detection of OH in ambient air at daytime concentrations of the order of $10^8/cm^3$ using a tunable UV laser[132].

7.1. Sources of the OH Radical

As mentioned above, $O(^1D)$ atoms formed during ozone photolysis react with water to produce 2 OH radicals [reaction (35a)]. The reaction of HO_2 with NO [reaction (8)], and the photolysis of nitrous acid[133] are also sources of OH in the polluted troposphere.

$$HONO + h\nu \xrightarrow{\lambda < 400\,nm} OH + NO \quad \Phi \approx 1\ [133] \tag{37}$$

The HONO is formed in the reverse of reaction (37) as well as by reaction (38), which may be homogeneous or heterogeneous, or both (see discussion in references [21] and [138]),

$$NO + NO_2 + H_2O \rightarrow 2\,HONO \tag{38}$$

and possibly by reaction (39)[134]:

$$HO_2 + NO_2 \rightarrow HONO + O_2 \tag{39}$$

While HONO has not yet been detected in ambient air, it has been tentatively identified in smog chamber experiments on propylene-NO_x mixtures in moist air using *in situ* analysis by Fourier transform infrared spectroscopy[135]. The reactant concentrations in these experiments were, however, somewhat higher than ambient (7.8 ppm C_3H_6, 6.2 ppm NO, and 3.8 ppm NO_2).

The photolysis of hydrogen peroxide[3, 68, 114] also produces OH:

$$H_2O_2 + h\nu \xrightarrow{\lambda < 370\,nm} 2\,OH \qquad (40)$$

The first detection and measurement of H_2O_2 in ambient air by a wet chemical method was reported several years ago[136] when concentrations as high as 0.18 ppm in Riverside, California, were measured during a severe smog episode. Subsequent studies on a very smoggy day in July 1973 in Pasadena, California, located approximately 40 miles west and upwind of Riverside, using Fourier transform infrared spectroscopy[137], gave inconclusive results on the presence of H_2O_2. Hence further studies on the ambient concentrations and diurnal variations of H_2O_2 are important.

The relative importance of each of the OH-forming reactions changes during the day as discussed in detail by *Demerjian, Kerr,* and *Calvert*[138].

7.2. Kinetics of the Reactions of the OH Radical

Kinetic studies of the reactions of OH with both organics and inorganics indicate that its reaction rates are very fast, as shown in Table 3, and in some cases, *e.g.*, reaction with the higher olefins, are essentially diffusion controlled.

Table 3. Typical rate constants k for some reactions of the OH radical at 300°K.

Compound	Reaction	k[1 mol^{-1} s^{-1}]	Ref.
CO	$OH + CO \rightarrow H + CO_2$	9.8×10^7	[139]
O_3	$OH + O_3 \rightarrow HO_2 + O_2$	$(3.3 \pm 0.9) \times 10^7$	[140]
NO	$OH + NO \xrightarrow{(M)} HONO$	$(\approx 6\text{—}12) \times 10^9$	[141] [a]
NO_2	$OH + NO_2 \xrightarrow{(M)} HNO_3$	7.2×10^9	[141, 142] [a]
CH_4	$OH + CH_4 \rightarrow H_2O + CH_3$	6.2×10^6	[143]
HCHO	$OH + HCHO \rightarrow H_2O + HCO$	$(8.4 \pm 2.1) \times 10^9$	[22]
Ethylene	[c]	$(1.8 + 0.6) \times 10^9$	[144]
Propylene	[c]	$(8.7 \pm 1.3) \times 10^9$	[144]
trans-2-butene	[c]	4.5×10^{10} [b]	[145]
$(CH_3)_2C{=}C(CH_3)_2$	[c]	9.9×10^{10} [b]	[145]
Xylene [d]	[c]	1.1×10^{10} [b]	[145]

[a] Most rate studies done at low pressure; this is the recommended value based on extrapolation of rate data into the second order regime.
[b] Rates measured relative to that for propylene for which $k = 1.0 \times 10^{10}$ l mol^{-1} s^{-1} [146].
[c] See discussion.
[d] Mixture of isomers.

7.3. Mechanism of the Reaction of OH with Alkanes and Aldehydes

The reaction of OH with alkanes and aldehydes proceeds by abstraction to produce H_2O and a reactive radical species such as CH_3• in the case of methane, or HCO• on reaction with formaldehyde. Its rate of reaction with aldehydes is as fast as that with the smaller olefins[22, 144–146] and hence is anticipated to be significant in the atmosphere. The subsequent reactions of the radicals produced may then oxidize NO to NO_2:

$$CH_3 + O_2 \xrightarrow{(M)} CH_3O_2 \qquad (41)$$
$$CH_3O_2 + NO \rightarrow CH_3O + NO_2 \qquad (42)$$
$$CH_3O + O_2 \rightarrow HCHO + HO_2 \qquad (43)$$
$$HO_2 + NO \rightarrow OH + NO_2 \qquad (8)$$
$$HCO + O_2 \rightarrow HO_2 + CO \qquad (10)$$

Recently, there has been some controversy over the products of the important reaction between NO and CH_3O_2, which for many years had been presumed to yield NO_2 and methoxy radicals [reaction (42)]. Thus, recent studies[147] indicated that the reaction of NO with CH_3O_2 occurred by addition rather than as written in equation (42). However, subsequent work[148] has established reaction (42) as the exclusive reaction path. The absolute rate of this reaction has not yet been determined and that of reaction (43)[149] needs further definition.

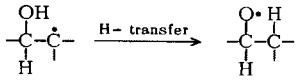
7.4. Mechanism of Reaction of OH with Olefins

The mechanism of the OH-olefin reaction is not known. In principle either abstraction of a hydrogen atom or addition to the double bond may occur. However, since activation energies for abstraction are commonly much higher than those for addition, one anticipates that at room temperature addition is the primary mode of reaction, particularly in view of the very high rate constants (Table 3). This is supported by the absence of a kinetic isotope effect on the rate of reaction of C_3D_6 as compared to C_3H_6[144, 145]. In addition, a mass peak corresponding to the OH-olefin adduct has been observed in the reactions of ethylene and propylene at total pressures of 1—4 torr[146]. These peaks increased with pressure[146] suggesting that collisional stabilization of the excited adduct is competitive with its decomposition under these conditions. The thermochemistry of the addition reaction (44) dictates that the adduct will have ≈ 35 kcal/mol excess energy.

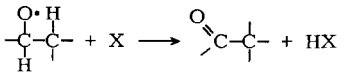
$$OH + \rangle C{=}C\langle \longrightarrow -\overset{OH}{\overset{|}{C}}-\overset{\bullet}{C}- \qquad (44)$$

The corresponding aldehydes are the major stable products, *i.e.*, CH_3CHO and C_2H_5CHO from the C_2H_4 and C_3H_6 reactions, respectively[146]. Isotope studies indicate that the H atom from the OH is retained in the product aldehyde[146], suggesting a series of reactions such as (45) and (46). Our speculations emphasize the need for much more detailed investigations of these reactions under a variety of conditions of total pressure, oxygen concentration, *etc.*

Essentially nothing is known about the kinetics and mechanism of the reactions of OH with arenes, partly because



(45)



(46)

$X = O_2$ etc.

such studies are experimentally difficult. However, this area is also one which is essential to our understanding of the detailed course of the complex reaction sequences in polluted urban air.

8. The Hydroperoxyl (HO_2) Free Radical

8.1. Sources of the HO_2 Radical

The recognized sources of HO_2 in photochemical smog[138] include any sources of H or HCO radicals as in aldehyde photolysis or alkoxy radical oxidations [reaction (43)].

While there have been regrettably few detailed analyses of the concentrations and types of aldehydes in ambient air, formaldehyde appears to constitute a significant portion ($\approx 40\,\%$) of the total aldehydes present[150]. This will of course vary with location and nature of the photochemical smog. For example, *Hanst* and co-workers[137] found in Pasadena, California, on July 25, 1973, a peak O_3 concentration of 0.68 ppm and, remarkably, no formaldehyde (≤ 0.01 ppm) but large quantities (0.05 ppm) of formic acid.

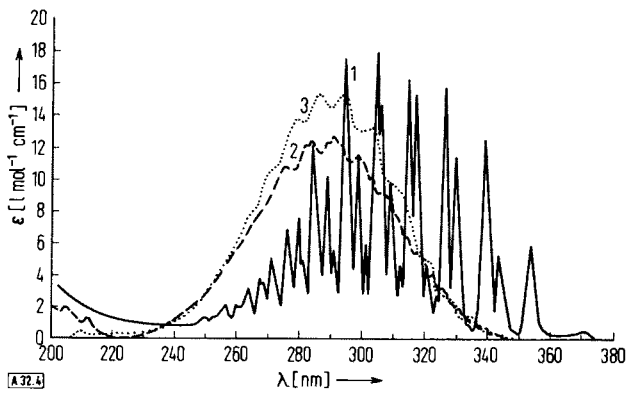


Fig. 4. Absorption spectra [68] for (1) HCHO (≈ 75 °C); (2) CH_3CHO (25 °C); and (3) C_2H_5CHO (25 °C) (after [68]).

The photochemistry of HCHO is particularly important because it absorbs radiation well into the actinic ultraviolet region (Fig. 4) and because the primary process I [reaction (47a)]

$$HCHO + h\nu \rightarrow H + HCO \qquad \text{(I) (47a)}$$

gives two precursors to HO_2 radicals per photon absorbed *via* reactions (7) and (10). Higher aldehydes are also important but they yield only one *direct* precursor of HO_2 in the primary photodissociative act I′ [reaction (48)]

$$RCHO + h\nu \rightarrow R + HCO \qquad \text{(I′) (48)}$$

and do not absorb as far into the actinic UV as does formaldehyde (Fig. 4). The alkyl radicals may also act as a source of HO_2 through a more complex reaction sequence [*e.g.* reactions (41)—(43)].

The importance of aldehyde photolysis in photochemical smog[3, 151, 152] was recently placed on a more quantitative basis by *Calvert* and co-workers[153] who estimated the rates of HO_2 generation from HCHO photolysis as a function of solar zenith angle using the wavelength dependence[154] of the quantum yields, Φ_I and Φ_{II} where process II [reaction (47b)] is

$$HCHO + h\nu \rightarrow H_2 + CO \qquad \text{(II) (47b)}$$

There is presently some controversy about the wavelength dependence of the absolute and relative values of Φ_I and Φ_{II}[155] and clearly, further quantitative photochemical studies on the system are urgently needed.

8.2. Kinetics of the Reactions of HO_2 Radicals

HO_2 reacts with a variety of compounds at rates which are generally several orders of magnitude slower than the corresponding OH reactions. Table 4 gives some typical values of rate constants recommended by *Lloyd*[156]. The errors quoted for these measurements are in many cases quite large due to the paucity of reliable data.

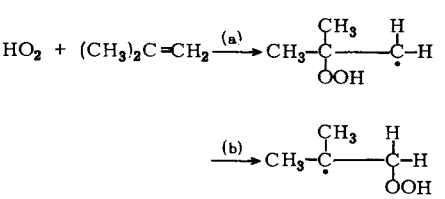
Table 4. Recommended [156] values of the rate constants (300 °K) for some gas phase reactions of the HO_2 radical.

Compound	Reaction	k [l mol^{-1} s^{-1}]
CO	$HO_2 + CO \rightarrow OH + CO_2$	6 ± 2
O_3	$HO_2 + O_3 \rightarrow OH + 2O_2$	$(9 \pm 100\,\%) \times 10^5$
NO	$HO_2 + NO \rightarrow OH + NO_2$	$(2 \pm$ factor of 3$) \times 10^8$ [19]
SO_2	$HO_2 + SO_2 \rightarrow OH + SO_3$	$(5.2 \pm 1.1) \times 10^5$ [19]
C_2H_6	$HO_2 + C_2H_6 \rightarrow H_2O_2 + C_2H_5$	$(0.08 \pm$ factor of 10)
HCHO	$HO_2 + HCHO \rightarrow H_2O_2 + HCO$	$(1.7 \pm$ factor of 10$) \times 10^3$
C_2H_4	$HO_2 + C_2H_4 \rightarrow$? [a]	$\approx 10^4$
i-C_4H_8	$HO_2 + i$-$C_4H_8 \rightarrow$? [a]	$\approx 10^5$

[a] See following discussion.

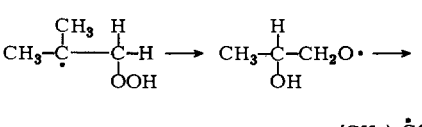
8.3. HO_2-Organic Reaction Mechanisms

If little is known about the kinetics of HO_2 reactions, even less is known about its reaction mechanisms, particularly with olefins and aromatics. *Avramenko* and co-workers[157] have proposed, from their product studies of the C_2H_4, C_3H_6, and i-C_4H_8 reactions with HO_2 in a flow-discharge system at a total pressure of ≈ 60 torr, that the first step involves addition to the double bond [reaction (49)].



(49)

These additions are much less exothermic than the corresponding OH-olefin reactions, with ≈ 10—14 kcal/mol excess energy residing in the adduct. The isomerization and decomposition



(50)

of the adduct [(reaction (50)] and subsequent reactions of the radical fragments were postulated to give the major observed products. However, the authors detected O atoms in the flow system and suggested[157] that the source of the O atoms may be the wall reaction

$$H + O_2 \xrightarrow{\text{wall}} O + OH \qquad (51)$$

Lloyd[156] suggests reaction (52b) may be responsible:

$$\begin{aligned} H + HO_2 &\xrightarrow{(a)} H_2 + O_2 \\ &\xrightarrow{(b)} H_2O + O \\ &\xrightarrow{(c)} 2OH \end{aligned} \qquad (52)$$

In either case, one anticipates that OH will also be produced. Since both $O(^3P)$ and OH react with olefins at rates which exceed that for HO_2 by 4—5 orders of magnitude, very small concentrations of these species may drastically affect the observed products and product distribution.

It is evident that the entire area of HO_2 reaction kinetics and mechanisms warrants extensive investigation. Experiments are most hampered by the problem of producing HO_2 in a manner which is free from interferences by other reactive species such as OH[156]. Wall reactions may also be important and these are often difficult to factor out. One interesting approach is that of *Hendry* and co-workers[158] who have used the radical initiated gas phase oxidation of 1,4-cyclohexadiene at $\approx 100\,^\circ C$ as their source of HO_2 for kinetic studies. This method, however, suffers from the disadvantage that studies must be carried out well above room temperature.

9. Computer and Smog Chamber Simulations of Photochemical Smog

9.1. Computer Kinetic Models

Despite this lack of critical data in many areas, several groups of researchers have made substantial inroads into computer simulation of the complex reaction sequences typified by Figure 1. Ideally, this requires both the detailed reaction mechanisms and accurate rate constants. For those elementary reactions whose rate constants are not known, one can estimate the value by standard methods[159] or else use it as an adjustable parameter which can be varied to give the best fit to time-concentration profiles (Fig. 1). As pointed out by *Calvert* and co-workers[160], the latter approach is "a sophisticated effort in curve fitting", whereas the former is a more demanding test of the validity of the proposed mechanism.

It should be recognized, however, that a good computer fit of the experimental data may be fortuitous and arise from compensating errors in various parts of the overall scheme, or from the insensitivity of the total mechanism to that particular elementary reaction.

A detailed computer simulation by *Calvert* and colleagues[138] illustrates both the utility of this approach and the chemical insights which can be gained. For example, the predicted rates of attack (rate = rate constant × concentration of reactive species) of various reactive species on *trans*-2-butene in a "typical" polluted urban atmosphere are given in Table 5. Using their mechanism and rate constants, it is evident that at short reaction times the rate of attack by OH far exceeds that by all other species combined and hence OH is primarily responsible for the excess rate of olefin consumption (Fig. 2) in the early stages of the reaction. At longer reaction times, O_3 and HO_2 become important. It should be stressed, however, that the validity of these predictions depend on the rate constants and mechanistic details chosen.

Table 5. Rate of attack (ppm min^{-1}) × 10^4 on *trans*-3-butene of some reactive intermediates as predicted by computer simulation of a sunlight irradiated, auto-exhaust polluted atmosphere [138]. Initial reactant mixture contains 0.075 ppm NO; 0.025 ppm NO_2; 0.10 ppm *trans*-2-butene; 10 ppm CO; 0.10 ppm CH_2O; 0.06 ppm CH_3CHO; and 1.5 ppm CH_4; relative humidity 50% at 25 °C; zenith solar angle, 40°.

Time [min]	Reactive species				
	$O(^3P)$	O_3	HO_2	HO	$O_2(^1\Delta_g)$
2	0.13	0.26	1.69	18.1	2.9×10^{-5}
30	0.17	1.58	1.49	5.9	2.0×10^{-5}
90	0.03	1.00	0.49	1.2	0.7×10^{-5}
120	0.01	0.65	0.28	0.7	0.4×10^{-5}

9.2. Airshed Models

Research on the detailed kinetic and mechanistic aspects of photochemical smog such as we have been discussing can be viewed as simply another "academic exercise" unless the results can be translated into a form that can be effectively utilized by public officials charged with the responsibility of actually *controlling* air pollution. Happily this challenge is currently being met by atmospheric scientists, many of whom have been cited earlier in this article, who not only are conducting basic research but also are involved with the development of reliable and operationally useful airshed models. These models can be utilized, for example, to assess the most cost-effective control strategies as well as to predict well in advance severe smog episodes which may threaten the health of the public.

Such total airshed models require as input[161]: (i) a detailed emission inventory for fixed and mobile sources; (ii) an assessment of the meteorological and topographical features of the area and an evaluation of the land use; and (iii) a reliable description of the chemical and physical processes occurring in the polluted atmosphere. Because of the complexity of the smog system in the real world, it is generally considered not feasible to include in (iii) all possible reactions as is done in the so-called "specific mechanism" approach[10, 138, 162] exemplified above by the work of *Calvert* and co-workers[138]. Hence in airshed models, a "lumped parameter"[161, 162] approach to the chemistry is often used, *i.e.*, the reaction of a whole class of compounds, *e.g.* olefins, with one reactive species, *e.g.* OH, is represented by one equation, one rate constant and stoichiometric coefficients for the amounts of products in each step. In these "lumped mechanism" models, some of the rate constants and stoichiometric coefficients are then treated as adjustable parameters. However, this approach suffers from the criticism cited above, *i.e.*, given enough parameters, curves can be drawn to fit any set of experimental data. Hence, a model which accurately reproduces one set of data may not be applicable to ambient air, or indeed, to another smog chamber.

9.3. Smog Chamber Studies

A major problem encountered in validating the chemistry portion of these computer models is the paucity of reliable data taken over a wide range of carefully controlled experimental conditions in the ppm-ppb concentration range of reactants typical of polluted ambient air. This gap is understandable since the technical (and financial) difficulties involved in conducting quantitative mechanistic photochemistry in such complex systems are not inconsiderable[10, 138, 161, 162]. They include, for example, (i) quantitative sampling and analysis of specific trace contaminants in complex and often heterogeneous mixtures in air, (ii) understanding and dealing with the important effects of the surface-to-volume ratio and the nature of the walls of the chamber, (iii) availability of an ample supply of highly purified air (volumes of some chambers run into thousands of liters), and (iv) careful control over a wide range of reaction conditions including temperature, relative humidity and the intensity and spectral distribution of the ultraviolet light to which the synthetic smog is actually exposed.

In order to overcome some of these problems, the chamber shown in Figures 5 and 6 was constructed[166]. Its features include (1) FEP Teflon lining to minimize wall reactions, (2) 20 mm thick fused silica windows which pass $\approx 90\%$ of the 240 nm radiation, (3) the capability of evacuation to 10^{-6} torr by a hydrocarbon-free pumping system, (4) a temperature operation range of $-35°$ to $+100\,°C$, (5) faithful reproduction in both absolute intensity and spectral distribution of the sun's ultraviolet radiation by means of a solar simulator powered by a 25-kilowatt high pressure xenon arc, and (6) an optical system that generates a collimated light beam that fills the cylindrical chamber without touching the walls. With appropriate filters the solar simulator can mimic tropospheric *or* stratospheric radiation. Especially important is the match in intensity in the region 295—330 nm where many important processes occur, such as the photolyses of ozone, aldehydes, and hydrogen peroxide. Previous "conventional" chambers were usually "intensity poor" in this region by virtue of their light sources (usually fluorescent black lamps emitting primarily 366 nm radiation) and the wavelength transmission cutoff of the chamber walls.

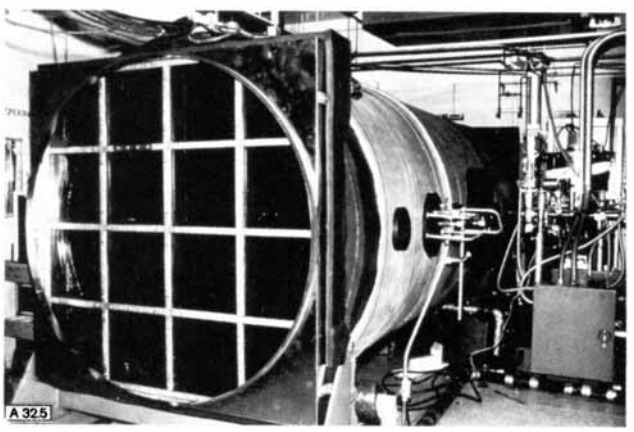


Fig. 5. Evacuable smog chamber at the Statewide Air Pollution Research Center, University of California, Riverside. Length: 3.96 m, diam. 1.52 m, vol. 5500 l.

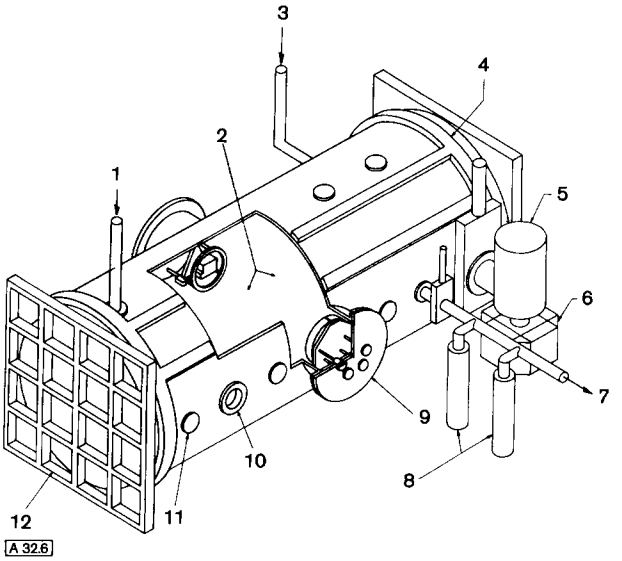

Fig. 6. Schematic diagram of the evacuable smog chamber. 1, ambient air inlet; 2, Teflon coated inner surfaces; 3, pure air inlet; 4, temperature control manifold (partial); 5, titanium sublimation pump; 6, ion pump; 7, liquid ring pump; 8, cryogenic sorption pumps; 9, multiple reflection infrared device; 10, light scattering experiment port; 11, sampling ports; 12, quartz windows.

An additional important feature of this chamber is the incorporation of a White cell multiple pass optical system capable of pathlengths up to 200 meters. When mated to an ultra high resolution ($0.06\,cm^{-1}$) and rapid scan (2.5—15 μm in six seconds) Fourier multiplex infrared spectrometer, one can carry out *in-situ* analysis of highly reactive pollutants down to 10 ppb or less.

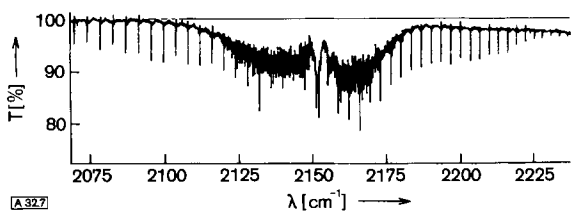

Fig. 7. Infrared spectrum, recorded using Fourier interferometry, of ketene from the reaction of *cis*-2-butene (50 ppm) with O_3 (10 ppm) at a total pressure of 2 torr and a pathlength of 50 m, in the evacuable smog chambers depicted in Figs. 5 and 6. The evenly spaced lines are the rotational lines of CO.

For example, Figure 7 shows the high resolution infrared spectrum of ketene (generated by the reaction of O_3 with *cis*-2-butene)[170] superimposed on the rotational structure of the 4.7 μm band of CO. Ketene has not been detected in ambient air to date perhaps because of the lack of suitable analytical methods. If present in smog, however, it may be amenable to identification by this technique.

10. Concluding Remarks

We hope that this rather brief and necessarily selective discussion has given the chemist who is not an expert in the field some feeling for the problems the air pollution chemist confronts and some of the areas to which he himself can make a significant contribution. The outcome and utility of air pollution simulation studies ultimately rest on the accuracy of the input data generated by a diverse group of scientists and in the long run the validity of the kinetic models reflects

what essentially amounts to the old adage often applied to computer studies, "garbage in ... garbage out". It is the task of we scientists to minimize the "garbage in!"

Umpolung of Amine Reactivity. Nucleophilic α-(Secondary Amino)-alkylation *via* Metalated Nitrosamines[**][***]

New synthetic methods (7)

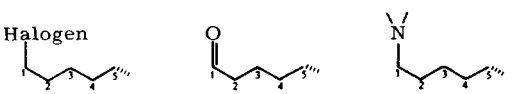
By Dieter Seebach and Dieter Enders[*]

There are basically two kinds of hetero atoms in organic molecules: one kind confers electrophilic character upon the carbon atom to which it is bound, and the other kind turns it into a nucleophilic site. The development of methods permitting transitions between the two resulting categories of reagents has become an important task of modern organic synthesis. The scope of such umpolung of the reactivity of functional groups is discussed for the case of amines as an example. A method of preparing masked α-secondary amino carbanions consists in nitrosation of the secondary amine, followed by metalation of the resulting nitrosamine α to the nitrogen, reaction with electrophiles, and subsequent denitrosation. Many examples are given for each of these steps which illustrate the wide scope of the overall synthetic operation (electrophilic substitution at the α-C atom of the secondary amine). Preliminary applications and a method for avoiding the handling of nitrosamines are presented, and the report concludes with a brief account of the significance of nitrosamines in the study of carcinogenesis and mutagenesis.

1. Introduction

1.1. Concept of Umpolung

We chemists are obliged to conform to certain simple rules dictated by Nature. Thus from the very beginning of our education in organic chemistry we learn—just how explicitly depends on the quality of our teacher—that heteroatoms such as halogen, oxygen, and nitrogen produce a certain reactivity pattern in a carbon skeleton: their electronegativity, being greater than that of carbon (−I effect), and their ability to stabilize an adjacent positive charge (+M effect) lead to the sites shown in Scheme 1 which are susceptible to attack by



sites of $\frac{\text{electrophilic}}{\text{nucleophilic}}$ reactivity are C atoms $\quad \frac{1, 3, 5, \ldots}{2, 4, 6, \ldots}$

attack by $\frac{\text{nucleophiles}}{\text{electrophiles}}$ occurs at C atoms

Scheme 1. Polarity pattern in hetero-substituted carbon chains.

reagents possessing a given "philicity". Nucleophiles attack the odd C atoms ($N^{1,3,\cdots}$ attack)[*] whereas electrophiles attack the even C atoms ($E^{2,4,\cdots}$ attack) of the chain (for examples see Table 1).

In C—C linking reactions of two or more heterosubstituted carbon compounds it is thus established what synthetic opera-

Institut für Organische Chemie der Universität
63 Giessen, Ludwigstrasse 21 (Germany)

[**] This report draws extensively on the Dissertation of *D. E.*

[***] Attempts to find an English equivalent of the term "*Umpolung*" have yielded none so concise as the original German word. Its general adoption into English has therefore been proposed (see Chem. Ind. (London) *1974*, 910).

[*] Wherever there is a danger of confusion with a nitrogen atom the nucleophile will be designated "Nu".

Table 1. Examples for the typical reactivity of halogen compounds, carbonyl compounds, and amines with nucleophiles and electrophiles.

Attack by Nu or E at atom *n*	Halogen compound	Carbonyl compound	Amine
N^1			
	S_N substitution	addition or substitution at carbonyl C	aminoalkylation
E^2			
	HX′ addition	substitution at α-carbonyl C	enamine reactions
N^3				$S_{N'}$ substitution	1,4- or Michael addition	vinylogous Mannich reaction

tions are possible and the *distance* between the functional groups in the product is predetermined. A carbonyl compound is alkylated at position 2 by a halide [eq. (1)]; acylation, the aldol reaction, and the Mannich reaction [eqs. (1)—(3)] afford products having the heteroatoms in a 1,3 arrangement; additions of enamines to α,β-unsaturated carbonyl compounds furnish 1,5-bifunctional compounds [eq. (4)] (*odd* distance!). Any "trick" by which the polarity pattern shown in Scheme 1 is contravened will be termed umpolung of the normal reactivity in the broadest sense. The price to be paid for an umpolung invariably involves a synthetic detour, *i.e.* we must reckon with additional steps such as introduction and removal of protecting and masking groups or with having to perform rearrangements. On the other hand, we are then able to attach a synthon possessing a given reactivity, E or N, at atypical sites of a carbon chain and to synthesize molecules having *even* instead of *odd* distances between the functional groups.

Table 2. Examples for umpolung of carbonyl compounds and amines. Newly formed bonds are shown in bold print.

Attack	Reagent	Equivalent	Product type	Ref.

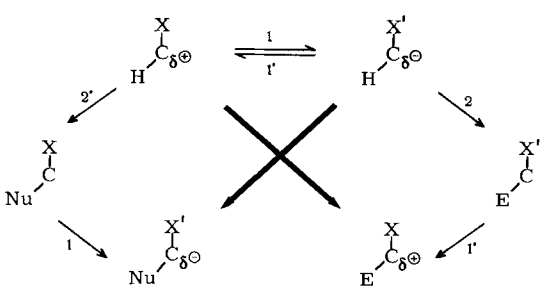
N^4				[3, 12]

Umpolung is as old as organic synthesis itself, as is apparent from the first examples listed in Table 2. However, a systematic search for umpolung methods was only initiated by the enormous advances made in carbanion and carbocation chemistry during the past twenty years. Another contributing factor has been the full realization of the advantages offered by reagents of reversed charge affinity. The lower part of Table 2 gives some examples of carbonyl umpolung which we have described in detail elsewhere[1–3].

1.2. Reversible Umpolung

Of greatest synthetic value is *reversible umpolung*. The concept is shown for a simple $E^1 \rightleftharpoons N^1$ example in Scheme 2. A compound having a C atom rendered positive is transformed,



Scheme 2. General principle of reversible umpolung.

by modification of the heteroatom from X to X′ in step 1, into a derivative in which the originally electrophilic C atom has now become nucleophilic. Reaction with an electrophile in step 2 is followed by reversal of step 1, *i.e.* by reinstitution of the original reactivity in step 1′. The net result (bold arrow from upper left to lower right) is introduction of an *electrophile* at a *positively* charged C atom.

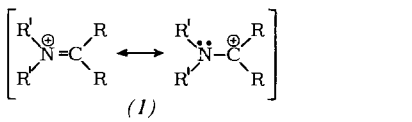
Attack by a nucleophile on a nucleophilic C atom (bold arrow from upper right to lower left) is feasible *via* the sequence 1′, 2′, 1. After temporary umpolung the C atom is in both cases finally available with normal reactivity again. A fre-

quently exploited example of the former case is umpolung of carbonyl compounds with thioacetal derivatives[1-3], and the latter case is illustrated by the masking of α-carbonyl cations by means of chloronitrones[8] (see also Table 2). In the following, the methods available for umpolung of amines will by briefly considered and a new reversible umpolung for secondary amines will be described in detail.

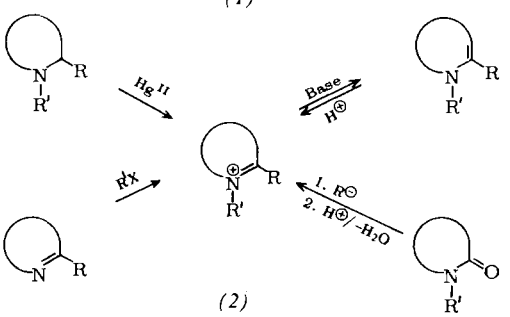
2. Possibilities of Umpolung of Amine Reactivity

2.1. α-Amino Carbocation *versus* α-Amino Carbanion

Amines display a "notorious" electrophilic reactivity at the α-C atom: the Mannich[13-15], Vilsmeier-Haak[16], Bischler-Napieralski, and Pictet-Spengler[17] reactions proceed *via* immonium ions of type *(1)*; salts of *(1)* are isolable[18-21],



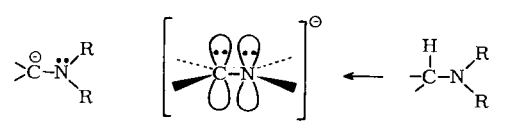
(1)



(2)

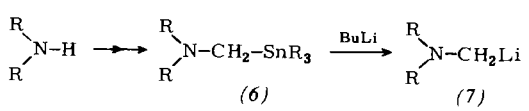
and even commercially available[22], and the dichloro derivative *(1)*, R=Cl[16] and a vinylimmonium ion *(1)*, R—R= $=C(CH_3)_2$[23] have recently been introduced into organic synthesis. Just how easy it is to come by immonium ions is obvious from the four routes shown for formation of the cyclic derivatives *(2)*. *Electrophilic* α-aminoalkylations are thus common events in organic synthesis and in biochemistry.

The situation is completely different with *nucleophilic* α-aminoalkylations, *i.e.* regarding the availability of α-amino carbanionic derivatives *(3)—(5)*; neither the relatively small electronegativity of the amino nitrogen nor the electronic configuration comparable with that in a ketyl[24] or ethylene



(3) *(3a)*

(4) *(5)*



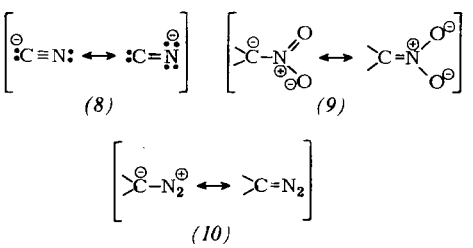
(6) *(7)*

dianion [see *(3a)*] favor the formation of a carbanion derivative, as may be seen from the extremely slow H/D[25] and H/Li exchange[26-28] in tertiary aliphatic amines. Once they have been formed, *e.g.* by transmetalation of the tin compounds *(6)*, α-aminomethyllithium compounds *(7)* display sufficient thermodynamic stability—*e.g.* toward Wittig rearrangement[29]—at 0 °C in hydrocarbons or ethers to act as reagents for nucleophilic α-*tertiary*-aminomethylation[26, 27]. Anions *(4)* and *(5)* of *secondary* and *primary* amines can be envisaged only if strong anion-stabilizing groups are bound to the carbon since tautomerization affording an amide anion would otherwise occur.

Since amines number among the most important classes of substances in organic chemistry and since at most *tertiary* α-aminoalkylating agents such as *(7)* are directly accessible, the use of *masked* synthons of anions *(3)—(5)* with reversed reactivity at the α-N-carbon atom is highly significant. Thus the question arising is: (a) what factors favor formation of a negative charge adjacent to nitrogen? and (b) which of these factors can be exploited in the sense of Scheme 2 for temporary umpolung of reactivity?

2.2. Dipolar and/or Resonance-Stabilized α-N-Carbanions

As is obvious from the "classical" α-N-carbanions *(8)* and *(9)* listed in Table 2, and from the diazo compounds *(10)*, which are likewise nucleophilic at the carbon, there exist bonding states of the nitrogen in which adjacent C atoms bear a negative charge, owing to endowment of the nitrogen



(8) *(9)*

(10)

with a positive charge (inductive effect), hybridization effects at the carbon (stability series $sp\text{-}C^{\ominus} > sp^2\text{-}C^{\ominus} > sp^3\text{-}C^{\ominus}$, increase in electronegativity of the carbon with increasing s character), and/or resonance stabilization of the negative charge.

A literature search reveals that the generation of negative charges on C atoms adjacent to nitrogen in derivatives of types *(11)—(17)* is favored, as can be deduced from H/D exchange, condensation, or metalation reactions. Remarks on the various types and references are given under the relevant formulas in Table 3. It is trivial that any substitution at the negative C atom leading to additional delocalization, such as incorporation of allyl ($\overset{\ominus}{C}$—C=C), benzyl ($\overset{\ominus}{C}$—C_6—H_5, in general $\overset{\ominus}{C}$-aryl or $\overset{\ominus}{C}$-heteroaryl), enolate ($\overset{\ominus}{C}$—C=O), or iminoenolate resonance ($\overset{\ominus}{C}$—C=N, $\overset{\ominus}{C}$—C≡N) will further enhance the stability, and in the ultimate case will suffice to generate an ambident, fully masked α-N anion. Lithiated α-amino ester derivatives *(18)* represent an example[127] which should be termed lithium enolates rather than nucleophilic

Table 3. Structures *(11)*—*(17)* with negative charges on the C atoms adjacent to nitrogen.

(11)

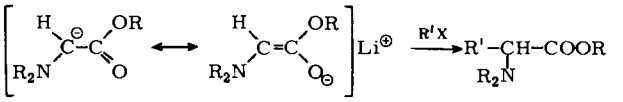
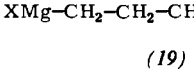
α-aminoalkylating agents. Although they possess considerable preparative significance, these cases will be excluded from the present discussion, as will reagents with E^3-umpolung of the amine skeleton (see Scheme 1 and Tables 1 and 2), such as *(19)*[128-130] and *(20)*[131].

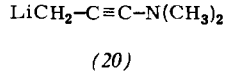
Among the numerous α-N anion systems *(11)*—*(17)* there are several which cannot be utilized as masked amino carb-



(18)



(19)



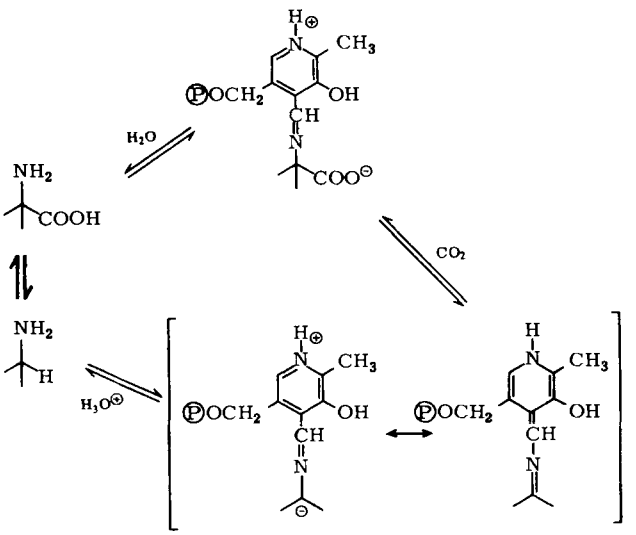
(20)

anions *(3)*—*(5)*; some have long been employed for the umpolung of amines[132] [Table 2 and Systems *(8)*—*(10)*], while others have only recently been exploited for the purpose. However, only very few of them are suitable for reversible umpolung according to the general Scheme 2.

2.3. Reversible Umpolung at the α-Position of Primary, Secondary, and Tertiary Amines

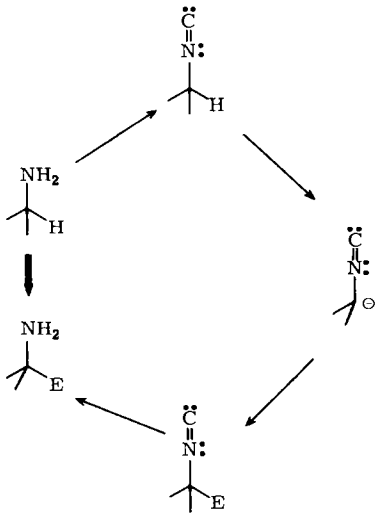
As may be seen from Scheme 2, reversible umpolung essentially involves the following three steps: Masking of the compound exhibiting normal reactivity with umpolung; reaction with "opposite sign"; "demasking".

The elegant way in which Nature has solved this problem for *primary amines* is apparent from Scheme 3 which outlines the interconversion of amino acids and biogenetic amines with the aid of a pyridoxal phosphate derivative[35]; the electrophiles $H^{\oplus}$ and CO_2 undergo mutual exchange at the α-amino C atom.



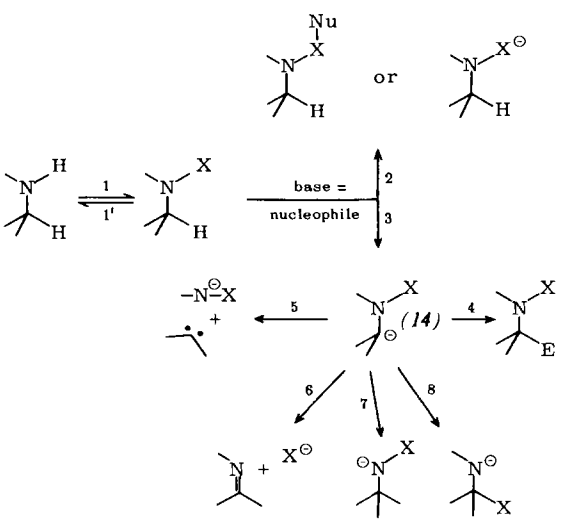
Scheme 3. Reversible umpolung of primary amines in Nature. Ⓟ = phosphate.

Those derivatives *(11)*, which can readily be prepared from primary amines, and nitro compounds of type *(12)* appear to be most suitable for imitation of this process *in vitro*. So far the best solution having a broad scope is probably the isocyanide method developed by *Schöllkopf* and his group[7] (Scheme 4): A variety of mild methods is available for conversion of primary amines into isocyanides; subsequent metalation and reaction with electrophiles proceed excellently and demasking is a hydrolytic step. In comparison, masking *via* nitro compounds (>CH—NH_2 → >CH—NO_2) requires an oxidation[133], the nitro anions (>$\overset{\ominus}{C}$—NO_2) only react with certain electrophiles at the C atom[4, 39, 134], and reductive demasking succeeds only under quite drastic conditions[135].



Scheme 4. Reversible umpolung of primary amines *via* isocyanides.

The derivatives *(14)* suggest themselves for reversible umpolung of *secondary amines*. The following conditions must be



Scheme 5. Conditions for reversible umpolung of secondary amines *via* anions of type *(14)*.

fulfilled (see Scheme 5):

a) X must be readily attached (masking, step 1);

b) X must be removable under mild conditions, *i. e.* replaceable by H (eventual "demasking", step 1');

c) X should neither contain CH acidic groups nor be subject to easy attack by a nucleophile (step 2);

d) X must impart sufficient acidity to the α-amino CH group [step 3, →*(14)*];

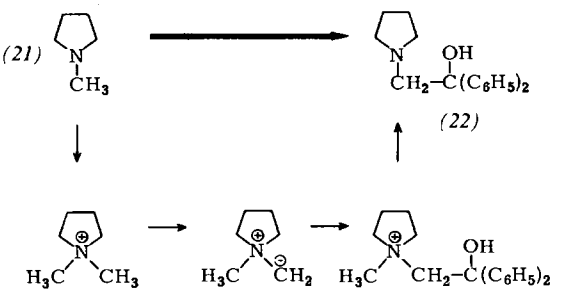
e) *(14)* must be strongly nucleophilic at the $C^{\ominus}$ atom (step 4);

f) *(14)* should not decompose by α- or β-elimination (steps 5 and 6); and

g) *(14)* should not rearrange (steps 7 and 8).

In the course of the last three years we have found only one substituent X which satisfies these requirements: the nitroso group[71, 79–81, 83, 88–90]. Thus we have used it to develop the first practicable method for reversible umpolung of secondary amines. The remaining sections of this progress report are devoted to its detailed description.

No general procedure for reversible α-anionization of *tertiary amines* has yet been developed. Ammonium ylides[46, 47] and amine oxides *(13)*[59, 60] should prove suitable for this purpose, as demonstrated by the—conceptual—conversion of 1-meth-



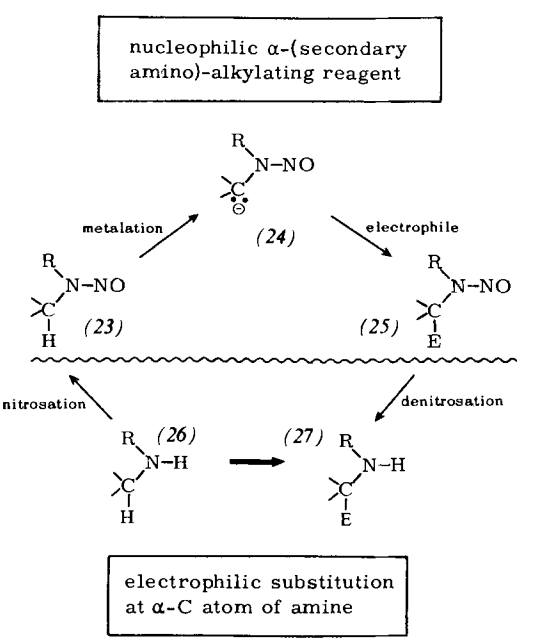
ylpyrrolidine *(21)* into the amino alcohol *(22)*. Of the steps involved, quaternization is trivial, hydroxyalkylation of the ammonium ion with benzophenone *via* the ylide is possible in 52% yield according to *Wittig*[46, 47], and mild and selective methods are nowadays available for removal of the methyl group to give *(22)*[136, 137].

Amines can also be functionalized by free-radical processes[138].

3. Metalated Nitrosamines as Masked Nucleophilic α-(Secondary Amino)alkylating Reagents

3.1. Concept

If it proves possible to convert nitrosamines *(23)* having at least one α-hydrogen atom into metal derivatives of the anion *(24)*, and if *(24)* is stable and sufficiently reactive to give good yields of the substituted nitrosamines *(25)* with



electrophiles, then a secondary amine *(26)* has effectively been subjected to electrophilic substitution at the α-C atom to form *(27)*. Nitrosation of amines, *(26)*→*(23)*, and the denitrosation of nitrosamines, *(25)*→*(27)*, are actually well-

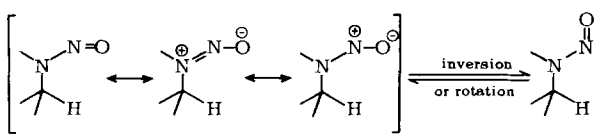
proven methods of organic synthesis. We cannot go into details of these steps here; mention should however be made of the extensive literature on this topic[139-146] and of the fact that we have performed the nitrosations[139, 140] primarily in glacial acetic acid and found either hydrogen chloride in inert solvents (benzene, ether[141]), or Raney nickel[143] in THF, most suitable for removal of the nitroso group[140-146]. In many cases both steps proceed in yields of more than 95%.

The wavy line in the reaction scheme is intended not only to separate the net electrophilic substitution from the individual steps but also to signalize an area of hazard: it is hoped that nitrosamines are generally known to be *carcinogens*. This aspect and the precautions they demand are considered in Section 3.7.

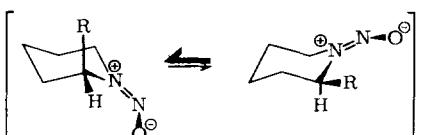
The following sections are devoted to the metalation of nitrosamines, the stability of lithionitrosamines and their reactions with electrophiles, as well as a number of examples of overall reactions *(26)*→*(27)*.

3.2. Metalation of Nitrosamines [Step *(23)*→*(24)*]

On consideration of the three resonance formulas of a nitrosamine *(23a)*↔*(23b)*↔*(23c)*, several analogies with carbonyl compounds become apparent. Besides the "neutral" formula *(23a)*, the dipolar electronic configurations *(23b)* and *(23c)* are very important. This may be deduced form the coplanarity of the nitrosated nitrogen[147], which is compatible with *(23b)*, and from the high ON—N rotational or O—N inversional



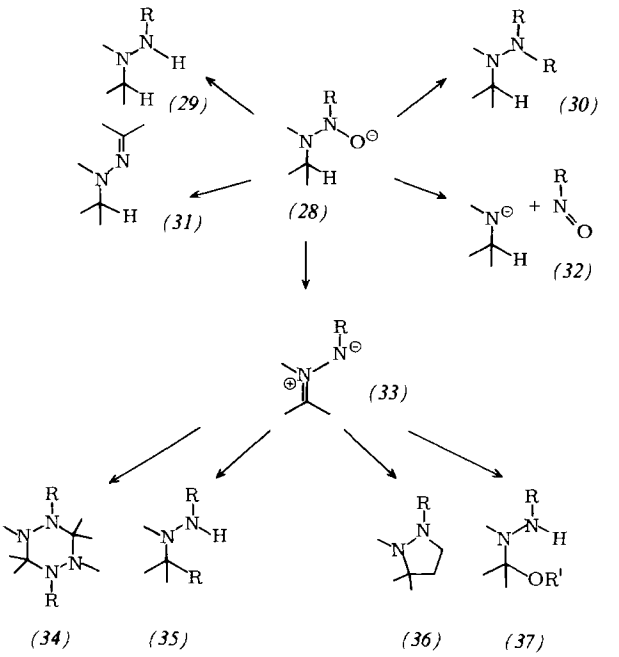
(23a) *(23b)* *(23c)* *(23')*



(23")

barrier *(23)*⇌*(23')*, which amounts to about 23 kcal/mol in dialkylnitrosamines[139, 148-150]. The marked axial preference of the substituent R in 1-nitrosopiperidines *(23")* can also be interpreted in the same way[151-156]. Electron-withdrawing groups or those that can engage in conjugation, such as CF_3 or C_6H_5, considerably lower the N—N rotational barrier when attached to the nitrosated nitrogen[157, 158]. CNDO calculations show the nitroso-N atom to bear a partial positive charge[159]. Hence this atom will be attacked readily by nucleophiles (see also pathway 2 in Scheme 5). Since the H atom adjacent to the positively charged nitrogen can be acidified, as in a carbonyl derivative [cf. *(23b)*], however, each Lewis base reacting with a nitrosamine therefore has a choice of attacking the nitroso nitrogen as a nucleophile or the α-CH group as a base.

Until recently only the former reaction type was known. The primary adduct *(28)* has an unusually large range of secondary reactions from which to choose. All the products isolated



(29) *(30)* *(31)* *(28)* *(32)* *(33)* *(34)* *(35)* *(36)* *(37)*

(29)—*(32)* and *(34)*—*(37)* can be explained in terms of *(28)*. Depending upon the nature of the group R and the conditions of reaction and work-up complicated mixtures[71, 79, 160-163] of these products are sometimes formed in reactions with RMgX and RLi (R=alkyl, aryl, R_2N). The hydrazines *(29)* and *(30)* apparently arise from attack of a second mol of $R^{\ominus}$ with loss or replacement of the oxygen[160-162]. Hydrazones *(31)* can result [160, 161] if R contains an α-hydrogen atom. A transnitrosation product *(32)* may be released by β-elimination[71, 79, 161]. Finally an azomethinimine *(33)*[42, 164] may be formed, either in the reaction mixture or during work-up; this species can dimerize to hexahydrotetrazine *(34)*[79, 161], react with a second $R^{\ominus}$ to yield *(35)*[161], be trapped by dipolarophiles to form *(36)*[162] or be "neutralized" on work-up with alcohols, yielding *(37)*[161, 162].

Unequivocal proof of the acidity of nitrosamines *(23)* not bearing an additional acidifying group[74, 165] was probably first established by *Rademacher* and *Lüttke*[75, 77] by base-cata-

(42)

lyzed perdeuteration of dimethylnitrosamine. In 1970, *Keefer* and *Fodor* succeeded in methylating dimethylnitrosamine *(38a)* with sodium hydride/methyl iodide to give a low yield of ethylmethylnitrosamine. Two years later we reported[79] the quantitative metalation of the same nitrosamine to *(39a)* with lithium diisopropylamide (LDA) in tetrahydrofuran at $-80\,^{\circ}C$ and reactions with various electrophiles. Other metalating agents generally gave poorer yields of *(39a)* owing to competing attack at the nitroso group.

Since metalation of dimethylnitrosamine *(38a)* also succeeds in the presence of excess dimethyl sulfoxide, the pK_a value of *(38a)* must lie below 34[167]. Meanwhile, we have been able to show that other primary, as well as secondary and tertiary, Li derivatives *(39)*, *(40)*, and *(41)* can be produced from nitrosamines and LDA and reacted with a variety of electrophiles (see Sections 3.4 and 3.5). Table 4 reveals the broad scope of metalation of nitrosamines! The examples *(39b)*, *(39c)*, *(39e)*, *(39f)*, and *(40m)* show the acidity to follow the usual series $-CH_3 > -CH_2- > \geqslant CH$. Owing to the enhanced thermodynamic stability of the benzylic Li derivative the series is violated in the case of benzylmethylnitrosamine [*(39g)*, *(40d)*, Table 4].

Table 4. Primary and secondary lithium derivatives *(39)* and *(40)* of nitrosamines [71, 79—81, 83, 88—90] prepared with lithium diisopropylamide (LDA) at $-80\,^{\circ}C$.

[a] The yields given are the highest yet obtained with the Li derivatives *(39)* and *(40)* on reaction with electrophiles (see Tables 5—8). In most cases they have not been optimized.

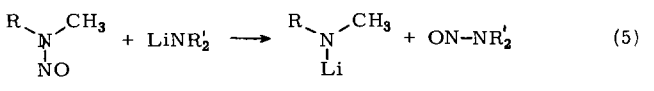
[b] Kinetically controlled metalation (5 min) at CH_3, thermodynamically controlled metalation (> 60 min) at CH_2.

[c] Metalated with cyclohexylisopropylamide at $-110\,^{\circ}C$.

The rate at which the nitrosamines are metalated by LDA at $-80\,^{\circ}C$ is extremely fast: with methylnitrosamines the electrophile can be added a few minutes after the metalating agent; hexamethylphosphoric triamide (HMPA) further accelerates this step, as we were able to show for 1-nitrosopiperidine[88]. According to our experience, its Li derivative *(40j)* is formed the most slowly of all the compounds listed in Table 4; 3—4 h are required. In the presence of four equivalents of HMPA this time can be reduced to 1 h. At the same time HMPA enhances the stability of lithionitrosamines[88] (see Section 3.3).

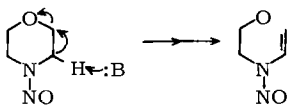
The stereochemistry of nitrosamine deprotonation was established by *Fraser et al.*[78] for the dibenzoazepine derivative *(40s)*: of the four hydrogens present in the precursor, of which two are quasi-axial and two are quasi-equatorial as indicated in *(42)*, the *syn*-axial one, H^4, is preferentially replaced by D on treatment with bases. This is in accord with our findings[88] in the metalation of nitrosopiperidines to yield *(40j)*, *(40m)*, *(40n)*, and *(40o)* (Table 4).

Difficulties arising from the side- and secondary reactions discussed in Scheme 5 occur only in special cases when our metalation procedure is employed. Transnitrosation according to eq. (5) becomes the principal reaction if R has a pronounced anion-stabilizing effect[71], as in nitrosamides and nitrososul-

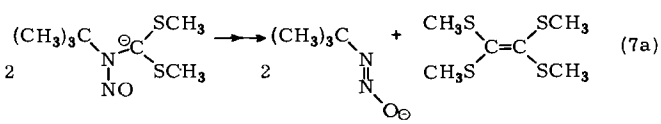


(5)

R = Ar, COR, COOR, Tos

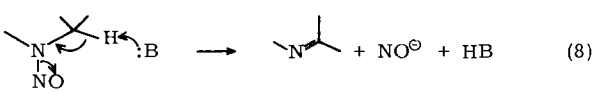


(6)



(7a)

(7b)



(8)

fonamides; with nitrosomorpholine, elimination according to eq. (6) takes place[71]; and the thioacetal derivative[90] shown in eq. (7a) undergoes α-elimination, which is presumably also responsible for the formation of stilbene from metalated dibenzylnitrosamine [eq. (7b)][89]. So far, in our metalation experiments with dialkylnitrosamines, we have not obtained unequivocal evidence for the $NO^{\ominus}$ elimination, described in eq. (8) and also observed with other bases[74, 165].

3.3. Dimerization of Lithionitrosamines to Tetrahydro-*v*-tetrazine Derivatives[71, 79, 83, 88, 89]

Even at −80 °C the lithium derivatives *(39)*—*(41)* are only short-lived reagents. Thus the lithiated dimethylnitrosamine *(39a)* decomposes with a half-life of two hours in HMPA-free THF solution (8 h in the presence of four equivalents of the

(46) *(47)*

amide), as we have shown by trapping with benzaldehyde as electrophile. So far we have isolated up to 55% yields of the tetrazine oxide *(43a)* as the sole decomposition product. Other derivatives *(39)* and *(40)* correspondingly afford compounds *(43b)*—*(43f)*. The structure of these novel heterocycles was confirmed by spectroscopy and by reduction to the oxygen-free tetrahydro-*v*-tetrazines *(44)*, which are meanwhile also accessible in low yield, by oxidation of bis-hydrazines *(45)*[168, 169]. After decomposition of lithiated methylphenylnitrosamine *(39h)* (see Table 4) we isolated the dinitroso derivative *(46)* (15%) and secondary products of the dianilide *(47)* (30%). The products *(43)*, *(46)*, and *(47)* are apparently formed by C—C linkage between the formerly anionic C atoms of the lithionitrosamines; *(43a)*—*(43f)* are

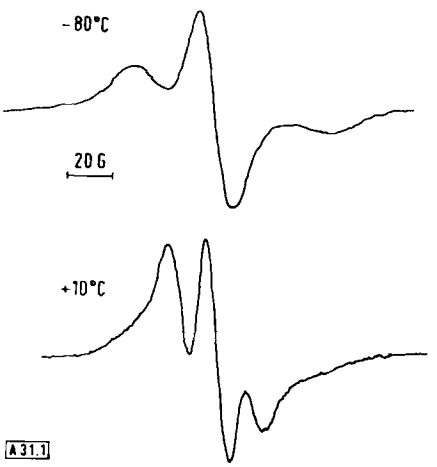

Fig. 1. ESR spectra of a lithiodimethylnitrosamine solution at −80 and +10 °C. The changes occurring on going to the higher temperature are reversible. The metalation mixture (THF/hexane/lithium diisopropylamide) does not give a signal prior to addition of the nitrosamine. Perdeuterated dimethylnitrosamine affords the same spectrum (recorded with a Varian E4 spectrometer).

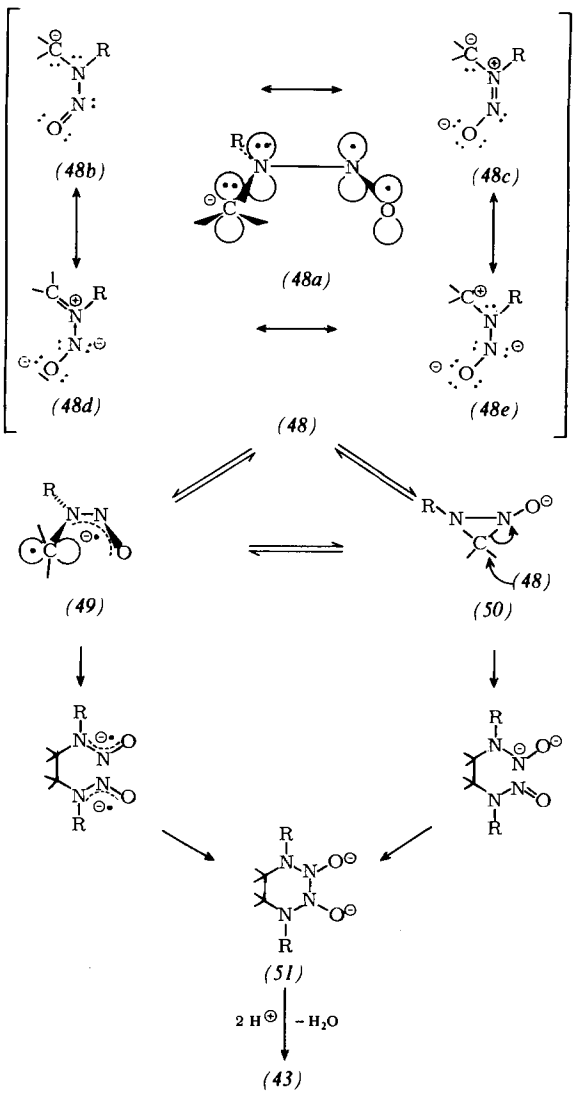
dimers minus H_2O, *(46)* is a dimer minus H_2 of the original nitrosamines.

Concerning the course of this reaction one can indulge at most in interesting speculations, which are closely related to the important question of the structure of the lithionitrosamines *(39)*—*(41)*. If it is deduced from the stereochemistry of deprotonation [see *(42)*][78] that the resulting anion prefers the planar *cis* form *(48)*, then the π-system *(48a)* occupied by six electrons should be present: this system can be described by four resonance formulas *(48b)*—*(48e)*. Dimerization of *(48)* as a 1,3-dipole should not proceed *via* the head-to-head product *(51)* to the observed tetrazine *(43)*. However, a 90° rotation of the C atom with decoupling of the π-system[170]



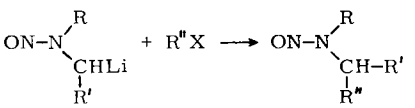
giving *(49)* or a ring closure to *(50)*, for which there is experimental evidence[165], would explain the formation of the tetrazine oxides *(43)*, as may be seen from the flow chart. Nitrosamine radical ions such as are formulated therein are formed very readily by alkali metal reduction[171]. Corroborating evidence for the presence of radicals in solutions of lithionitrosamines comes from ESR spectra of lithiodimethylnitrosamine (Fig. 1). An interpretation of the spectra and a definite mechanistic concept of *v*-triazine formation have not yet been produced.

3.4. Reactions of Lithionitrosamines with Electrophiles [Step (24)→(25)]

It is clear from the foregoing Section that all reactions of nitrosamine lithium derivatives with electrophiles must be carried out at or below −80°C. Only when the reaction of the lithium compounds with the electrophile is faster than their decomposition can good yields of products having the general structure *(25)* be expected. Hence it is hardly surprising that, for instance, epoxides, which are also relatively inert towards other lithium reagents[172], cannot be utilized as electrophiles. In contrast, additions to carbonyl groups proceed exceedingly rapidly (see Section 3.4.2, α-hydroxyalkylations and preparation of aminoethanols) and succeed even at temperatures of about 0°C under conditions of base catalysis (tBuOK)[71,85,88,89] or at even higher temperatures with α-tin-substituted nitrosamines[71] (see Section 3.4.2).

3.4.1. Alkylation

Alkylations of primary and secondary lithionitrosamines *(39)* and *(40)* accomplished so far are summarized in Table 5. The substituted derivatives *(52)* with R′=H [from *(39)*] and R′=alkyl and aryl [from *(40)*] are formed in yields ranging from 60 to 95% and higher. However, the reactions with primary alkyl iodides, especially in the case of the lithiated cyclic nitrosamines *(40i)*, *(40j)*, *(40m)*, *(40n)*, and *(40r)* give yields at the lower limit of this range, while allylation, methoxymethylation, and benzylation proceed almost quantitatively.



(39), R′ = H
(40), R′ ≠ H

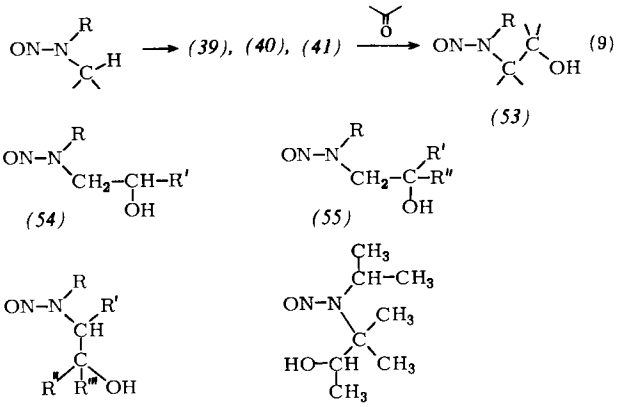
Cyclizations are also possible *via* alkylation with dihaloalkanes and are mentioned in Section 3.5.4.

3.4.2. Reactions with Aldehydes and Ketones (α-Hydroxyalkylation)

There are about 50 examples of this reaction, which corresponds to the aldol addition: it is formulated in general terms in eq. (9). Depending upon the nitrosamine and carbonyl



(53)

(54)

(55)

(56a), R/R′ not linked
(56b), R-R′ cyclic

(57)

components employed, the structure of the products of type *(53)* can vary within wide limits. The primary and secondary lithionitrosamines *(39)* and *(40)* react with aliphatic and aromatic aldehydes, and with aliphatic, cycloaliphatic, and aromatic ketones to give adducts of types *(54)*, *(55)*, and *(56)* listed in Tables 6 and 7 (Section 3.5.3). The α-branched

Table 6. Reactions of primary and secondary lithionitrosamines *(39)* and *(40)* with aldehydes and ketones involving hydroxyalkylation to the products *(54)*—*(56)* [71, 79, 80, 88—90] (further examples will be found in Table 7, Section 3.5.3). The yields refer to distilled or recrystallized products [general type *(25)*].

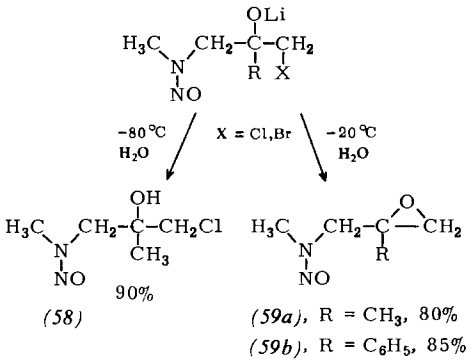
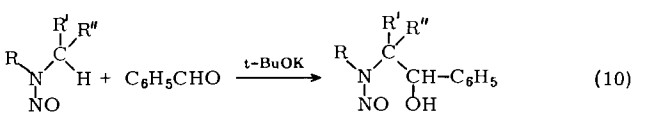
derivatives *(56)* having two chiral centers are obtained as mixtures of diastereomers. Linkage to a methine carbon atom in the nitrosamine moiety leads to the product shown in formula *(57)* [from *(41)* and acetaldehyde]. Enolate formation plays a subordinate role to carbonyl addition, even on reaction with readily enolizable carbonyl compounds like diphenylacetaldehyde, acetone, cyclohexanone, 3β-hydroxy-16α,17α-epoxy-5-pregnen-20-one, and camphor. Carbonyl groups subject to pronounced steric hindrance, such as that of fenchone, react with ease. Halo ketones like chloroacetone and bromoacetophenone are attacked exclusively at the carbonyl; if the initially formed lithium alkoxides are protonated at the reaction temperatures then nitrosaminohalohydrins like *(58)* are obtained. On warming lithium halide elimination occurs, furnishing the epoxynitrosamines *(59)*. Thus the lithionitrosamines can be described as powerful *carbonylophiles* (cf. also acylation, Section 3.4.4).



(58)

(59a), R = CH_3, 80%
(59b), R = C_6H_5, 85%

Examples[85, 88] of *in-situ* generation of nitrosamine anions and addition to a non-enolizable aldehyde are given in eq. (10). The comparison between nitrosamines and carbonyl compounds already mentioned above (see Section 3.2) comes once



(10)

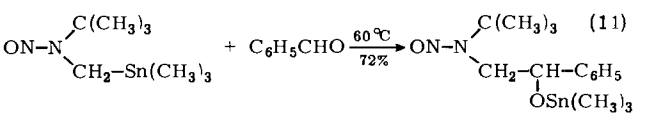
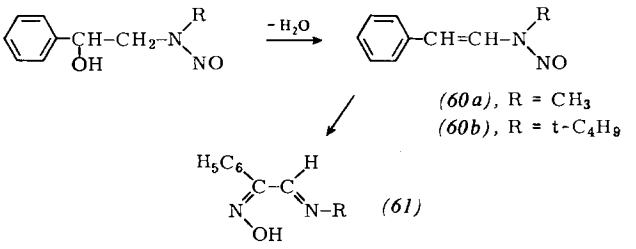
R-R' = -$(CH_2)_4$-, R'' = H 80%



(11)

more to mind on consideration of the carbonyl addition [eq. (11)] accomplished by merely mixing the components and warming to 60 °C[71]. This reaction type has long been known in the case of α-silyl[173] and α-stannyl[174] carbonyl derivatives[175]. Use of this modification should permit nucleophilic aminoalkylation [see *(26)* → *(27)* and Section 3.5] of carbonyl derivatives that are sensitive to aggressive organolithium compounds; moreover, the reactivity of aldehydes, ketones, and esters towards α-stannylnitrosamines should vary widely, thus rendering *selective* reaction with polyfunctional molecules possible.

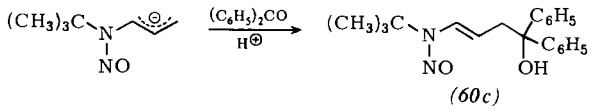


(60a), R = CH_3
(60b), R = t-C_4H_9

(61)

Adducts of type *(54)* with aromatic aldehydes can be dehydrated to the interesting but scarcely known[176, 177] enenitrosamines *(60)*. Compounds *(60a)* and *(60b)*, formed almost quantitatively in the *trans* form, undergo 1,3-nitroso shift to give iminooximes *(61)* on heating, irradiation, or treatment with gaseous hydrogen chloride in benzene[71].

An enenitrosamine *(60c)* is also obtained on reaction of metalated allyl-*tert*-butylnitrosamine with benzophenone. All

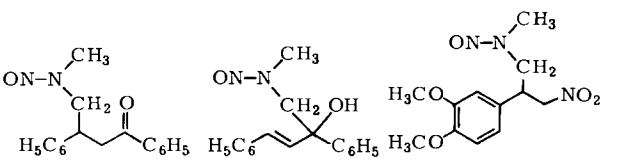


(60c)

other electrophiles we have used so far add to this allyl anion α to the heteroatom[88].

3.4.3. Reaction with α,β-Unsaturated Ketones and with Nitroolefins (Michael Addition)

As can be seen from Table 6, reaction of the lithionitrosamines *(39a)* and *(40f)* with cyclohexenone affords 85 and 80%, respectively, of the 1,2-adduct after hydrolysis[79, 90]. NMR and IR analytical comparison of the starting materials and the crude and pure products rules out the formation of more than traces of the 1,4-adduct. The situation is different with benylideneacetophenone which is even found to yield somewhat more Michael product *(62)* than allyl alcohol *(63)* on reaction with lithiodimethylnitrosamine; the overall yield is almost quantitative. From β-nitro-3,4-dimethoxystyrene and

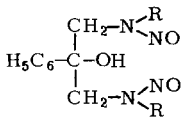


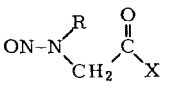
(62), 55% *(63)*, 45% *(64)*

the same nitrosamine we could finally isolate the product *(64)* of conjugated addition in 75% yield[89].

3.4.4. Acylation and Carboxylation (Nitrosated α-Amino Ketones and Amino Acid Derivatives)

The pronounced *carbonylophilic* nature of lithiated nitrosamines can interfere when they are to be acylated with acyl chlorides: 1:1 reaction of benzoyl chloride with lithiodimethylnitrosamine furnished an 80% yield (based on the latter) of the bisadduct *(65a)*[79] [similarly, *(39d)* afforded *(65b)* in 45% yield[71]]. On modification of the reaction conditions





(65a), R = CH_3
(65b), R = t-C_4H_9

(66a), X = OH, R = t-C_4H_9, 80%
(66b), X = OCH_3, R = t-C_4H_9, 95%

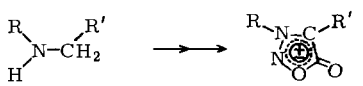
(66d), X = CH_3, R = CH_3
(66e), X = C_6H_5, R = CH_3
(66f), X = C_6H_5, R = t-C_4H_9
} 40-50%

(initial excess of acyl chloride, reverse addition) and use of other acylating agents (methyl carboxylates, carbon dioxide, phenyl isocyanate, phenyl isothiocaynate), however, moderate to very good yields of α-amino acid or α-amino ketone derivatives *(66)*[71] are obtained. Carboxylation with CO_2 has been described for a further series of nitrosamine anions [*(40e)*[78], *(40i)*[80], *(40r)*[78], and *(40s)*[78]]. Removal of the nitroso group[71, 78], which is also employed as a protecting group in peptide synthesis[178], thus provides an entry to *N*-substituted amino acids. This constitutes a first example of electrophilic substitution at a secondary amine, *(26)*→*(27)*, with E=COOH, and an imitation of the biochemical interconversion of amino acids and primary amines according to Scheme 3 (see also applications, Sections 3.5). Since nitroso amino acid derivatives are readily transformed into sydnones[179, 180], the metalated nitrosamine route provides access to this class of compounds from secondary amines [eq. (12)].

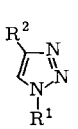


(12)

The esters and ketones *(66)* are formally analogs of 1,3-dicarbonyl compounds and should undergo base-catalyzed condensation reactions at the CH_2 group.

3.4.5. *v*-Triazoles by Reaction with Nitriles[71, 81, 89]

Apart from the carboxylic acid derivatives mentioned in the previous Section, nitriles also represent potential acylating agents. We were unable to react enolizable aliphatic nitriles such as acetonitrile with nitrosamine anions. In contrast, aromatic nitriles afford the *v*-triazoles *(67)* and *(68)* in the yields shown, provided that the metalated nitrosamine is employed



(67a), R^1 = CH_3, R^2 = C_6H_5, 83%
(67b), R^1 = CH_3, R^2 = *p*-CH_3-C_6H_4, 57%

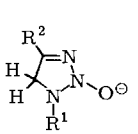
(69)



(70)

in a twofold excess. A 1:1 reaction furnishes only 35—55% of these heterocycles. By analysis of aliquot samples from the reaction mixtures we were able to show that the nitrile reacts sluggishly. If acetic acid is added at −78 °C after 30 min during the preparation of *(67a)*, 25% of triazole and 6% of the acylation product *(66e)* are isolated along with 65% of unreacted benzonitrile. After prolonged reaction only the decomposition products *(43)* and *v*-triazoles are obtained. Hence the triazoles are probably formed *via (69)* and *(70)*. It is still an open question whether the improved yields obtained from the 2:1 reaction are merely a consequence of competitive decomposition (see Section 3.3) or are due to proton abstraction at the CH_2 group of *(70)* by the excess of lithium derivative. This *v*-triazole synthesis is suitable for the preparation of novel triazoles such as *(68)*.

3.4.6. Reactions with Hetero-Electrophiles[71, 90]

A number of hetero-substituted nitrosamines have already been mentioned [see Table 4: *(40f)*, *(40g)*; Tables 5 and 6: reactions of *(40f)*; eqs. (7) and (11)]. We obtained the derivatives *(71)*—*(73)* in high yields by reaction of the corresponding nitrosamine anions with trimethylchlorosilane, trimethylchlorostannane, disulfides, or diselenides. The sulfoxide *(74)* is accessible quantitatively by metaperiodate oxidation of *(73)*. A use of the tin derivative *(71b)* is shown in eq. (11). The sulfur- and selenium-substituted nitrosamines *(72)*—

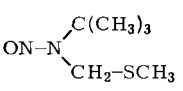
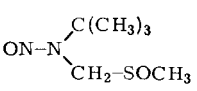
(72c), RX = SeC_6H_5, 70%



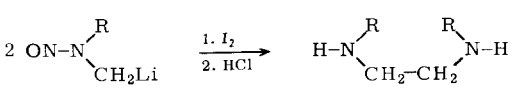
(73), 90%



(74)

(74) may be regarded as *N,S*- and *N,Se*-acetals of formaldehyde. *N,O*-Acetals of this type have recently been prepared by a completely different method[181, 184].

So far we have been unable to isolate α-halo nitrosamines on reaction of metalated nitrosamines with chlorine, bromine, and iodine[71]. Iodine leads to oxidative coupling which can be exploited in the synthesis of ethylene diamines—relevant examples are shown in eq. (13)[71, 79, 89].

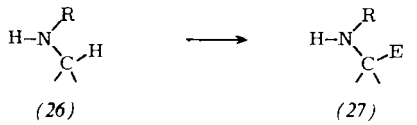


(13)

R = CH_3, 95%
R = t-C_4H_9, 50%

3.5. Applications

The two foregoing Sections (3.3 and 3.4) have demonstrated the feasibility of preparing the nitroso derivatives of higher substituted secondary amines *via* metalated nitrosamines. It has already been mentioned in Section 3.1 that secondary amines and nitrosamines can be readily interconverted. This property opens the way for a simple electrophilic substitution *(26)*→*(27)* [eq. (14)] at the α-C atom of secondary amines.

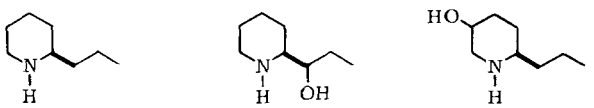


(26) (27) (14)

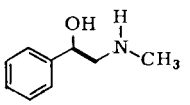
Examples of applications for the synthesis of amino acids and ethylenediamines have already been presented in Section 3.4.4 and in eq. (13).

3.5.1. Denitrosation of Products Listed in Tables 5 and 6 to Yield Simple Alkaloids

Some of the products of alkylation and hydroxyalkylation of lithionitrosamines *(39)* and *(40)* listed in Tables 5 and 6 are nitroso derivatives of simple alkaloids. We have prepared[71,88] the hemlock alkaloids *(75)*[185] and halostahine *(76)*[186] by denitrosation[140-146]. In the formulas, and also



(75a) coniine *(75b)* conhydrine *(75c)* ψ-conhydrine

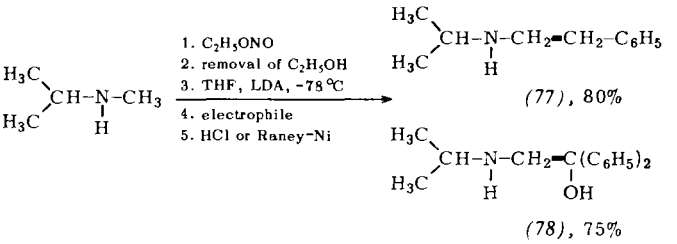


(76) halostahine

in the following discussion, the newly formed C—C bonds are emphasized by bold print. The simplicity of the new method can be demonstrated for compound *(75c)* which we have prepared from the commercially available compounds 3-hydroxypiperidine and *n*-propyl iodide[88] (40% overall yield); synthesis by "classical" methods is far more complicated and less productive[187]. Numerous applications of metalated nitrosamines can be envisaged in the field of alkaloid synthesis (see also Section 3.5.4).

3.5.2. "One-Pot" Substitution According to Equation (14)

Successful application of this method for electrophilic substitution α to the nitrogen of secondary amines requires that the handling of carcinogenic (see Section 3.7) nitrosamines is completely avoided in order to reduce the hazard to a minimum. We have therefore developed a technique by which a secondary amine is weighed into a flask and a substituted secondary amine is isolated on work-up. The method involves preparation of a standard solution of ethyl nitrite in anhydrous tetrahydrofuran, of which an aliquot is added to the amine destined for nitrosation in a flask under an inert gas. Quantitative formation of the nitrosamine is complete within 10—50 h at 20 °C. The co-product ethanol is removed together with solvent under reduced pressure. Dissolution in THF is followed by metalation in the usual manner (Section 3.2; LDA = lithium diisopropylamide), and treatment of the lithium derivative with the electrophile. After warming, the nitrosamine is denitrosated in the reaction mixture, *i.e.* without prior isolation, by gaseous hydrogen chloride or Raney nickel; only then is the product worked up[188]. In this way we have obtained phenethylisopropylamine *(77)* and the amino alcohol *(78)* in high yields from methylisopropylamine and benzyl bromide and benzophenone, respectively.



(77), 80%

(78), 75%

3.5.3. 2-Amino-1-arylethanols from Aromatic Carbonyl Compounds and Secondary Amines

This modification can be employed for preparing numerous 2-amino-1-arylethanols, a class of compounds having an extre-

Table 7. Arylaminoethanols of types *(79)* and *(80)*. The yields given are total yields based on the original amount of carbonyl component and thus include the addition *and* denitrosation steps [71, 88].

Starting components	Product	Yield [%]	M.p. [°C] [a]
benzaldehyde, isopropylmethyl-nitrosamine		74

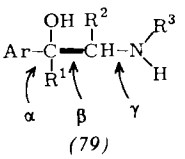
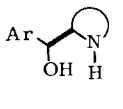
mely wide spectrum of pharmacological activity[189]. On preparation of compounds of type *(79)*, the α-bond to the aromatic ring is normally coupled by acylation; some of the acylating agents used already contain the N-function[191,192]; however, in most cases this function is introduced subsequently by linkage of the γ-C—N bond[193-196]. Compounds of type *(79)* can be produced from metalated nitrosamines and aromatic aldehydes and ketones with formation of the β-C—C bond. Some examples and overall yields, based on the carbonyl component used, are listed in Table 7; this procedure is clearly also suitable for preparing cyclic derivatives *(80)* whose production by other methods is invariably more complicated[197,198].



(79)



(80)

Table 8. Cyclizations *via* metalated nitrosamines according to the general equations (15)—(18).

Starting material	Eq.	Product(s)	Ref.

(15)

(16)

(17)

(18)

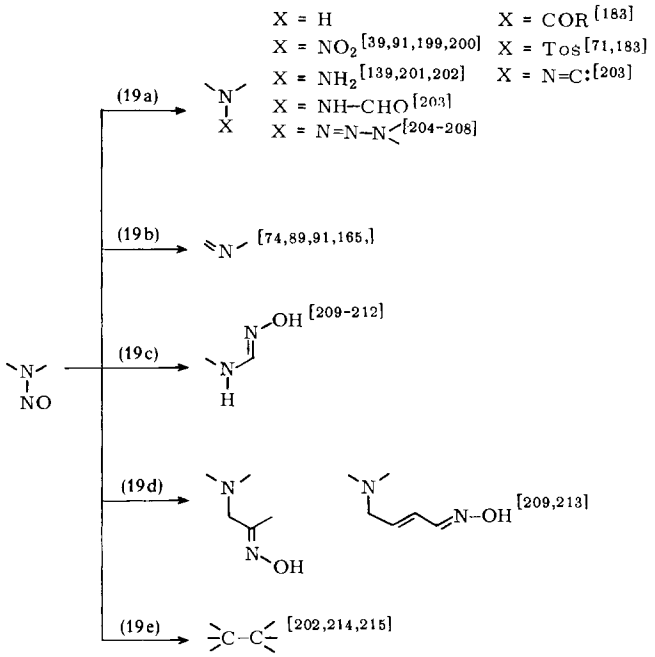
3.5.4. Cyclizations *via* Metalated Nitrosamines

In principle, heterocyclic or nitrogen-substituted carbocyclic compounds should be accessible *via* metalated nitrosamines according to the generalized equations (15)—(18). The boldly printed bonds in the rings are each newly formed. Cyclization as shown in eq. (15) is possible only with electrophilic centers E that survive the metalation conditions applied on removing the CH proton adjacent to the α-nitrogen. The same clearly applies to the cyclization steps in eqs. (17) and (18). Reactions with bifunctional electrophilic compounds according to eqs. (16)—(18) are favored if the two electrophilic centers differ in their reactivity, as for example in the case of 1-chloro-*n*-iodoalkanes or ω-halo aldehydes and ω-halo ketones. In reaction (16) the initial open-chain adduct is denitrosated, whereupon the nitrogen of the secondary amine, which has now become nucleophilic, forms a C—N bond with the electrophilic function in the incorporated side chain and thereby closes the ring.

First examples of the preparation of cyclic compounds with participation of at least one nitrosamine C—C linking step α to the nitrogen are shown in Table 8. The yields, which have not yet been optimized, lie between 30 and 80%.

3.6. Chemistry of Nitrosamines

Not only can nitrosamines be denitrosated to their parent secondary amines [eq. (19a), X=H[139,139-146]]; they also undergo many other reactions. Reactions with bases and nucleophiles have already been mentioned in Section 3.2 [products *(29)*—*(32)* and *(34)*—*(37)*]. Several other conversions of synthetic value[139] are depicted in equations (19a)—(19e). As may be seen from eq. (19a), oxidation leads to nitramines, reduction to hydrazines or their derivatives, replacement of the NO group by COR and RSO_2 gives carboxamides and sulfonamides respectively. Basic elimination of HNO or, after oxidation to the nitramine, of HNO_2 affords azomethines according to eq. (19b); photolysis according to eq. (19c) furnishes hydroximamides; photoaddition to olefins or 1,3-dienes according to eq. (19d) yields amino oximes. Finally, in certain cases it is possible to formally eliminate N_2O as shown in eq. (19e) to give compounds devoid of nitrogen. Thus substitution α to nitrogen in nitrosamines *via* the metal derivatives *(39)*—*(41)* has a preparative significance ranging well beyond the production of amines.

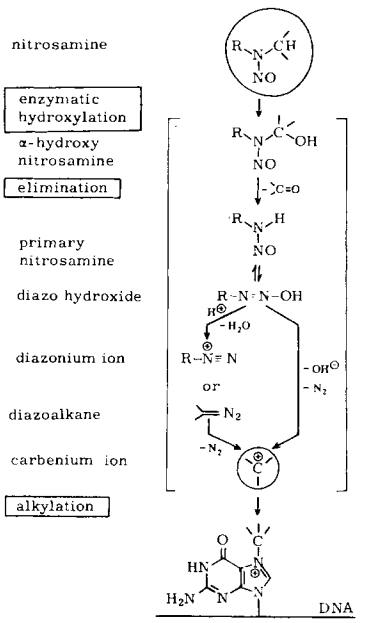


3.7. Carcinogenic and Mutagenic Action of Nitrosamines[216-222]

Most of the nitrosamines tested so far are extremely potent carcinogens and/or mutagens. Their occurrence in the environment[223], *e.g.* in cigarette smoke, in nitrite-preserved meat, and in smoked fish, is well established. Such activity is limited to those nitrosamines which bear at least one hydrogen atom on the carbon situated α to the nitrogen atom. Animal experiments show that, in contrast to other dangerous compounds encountered in everyday laboratory work, nitrosamines have a relatively low toxicity. However, these tests also reveal that in certain cases a single large dose can produce cancer. Tissue changes resulting from a single dose, or on administration over a prolonged period followed by complete cessation, become manifest only after an induction period. In experimental animals having an average life expectancy of about 800 d, the induction period can be as long as several hundred days. Treatment of pregnant animals can lead to their progeny developing carcinomas in later life without ever having been exposed to nitrosamines after birth[224].

Compared with other classes of carcinogens and mutagens, including those of similar activity, nitrosamines are characterized by showing a pronounced organospecific or organotropic effect. Depending upon its structure, a given nitrosamine will give a high "yield" (as the cancer experts say) of carcinoma in a particular organ, irrespective of how it is applied (inhalation, intravenous or subcutaneous injection, oral incorporation, or diffusion through the skin) while even closely proximate tissues remain unaffected. This structure/organ correlation places nitrosamines among the most important reagents of cancer and mutagenesis research. On the one hand they are employed for purely experimental reasons, *i.e.* for the study of morbid changes in a certain type of tissue which can also become cancerous "naturally", this work being important for the development of new methods for early diagnosis and therapy. On the other hand, it is hoped that elucidation of the mechanism underlying the organ specificity of nitrosamines might bring us one step closer to answering the question of how cancer arises. Furthermore, precisely this observed organ specificity suggests that it might be possible to find nitrosamine derivatives which specifically mutate cancerous tissue and thus exert a carcinostatic effect. In fact, nitroso derivatives, especially nitroso-amides, are presently undergoing clinical tests as anti-cancer drugs in several countries.

The currently preferred theory of carcinogenesis and mutagenesis by nitrosamines is outlined in Scheme 6.



Scheme 6. Alkylation theory of carcinogenesis by nitrosamines.

The nitrosamines are assumed to be α-hydroxylated by hydroxylases. The resulting 2-hydroxy nitrosamine decomposes to a carbonyl compound and a diazo hydroxide[225], a precursor of diazo and diazonium derivatives which like all other alkylating agents, even such "everyday" synthetic reagents as methyl iodide and dimethyl sulfate, are carcinogens.

Recent studies on the metabolism of nitrosamines *in vivo* show that the alkyl chains are also subject to ω oxidation yielding alcohols and carboxylic acids, to β-oxidation affording ketones, and to chain shortening[226-229].

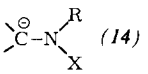
The results of animal experiments cannot be applied *a priori* to humans. After lectures on this topic we have often been approached by older colleagues who enjoy the best of health, although at one time they had worked with large amounts of nitrosamines and nitrosamides without any precautionary measures (for a time low molecular weight nitrosamines were used, *e.g.* as polar solvents on an industrial scale[230]).

What does this mean for the chemist working with nitrosamines? The chemist is accustomed to working with dangerous substances with a minimum of risk, and such work should be part of his training. He must always adapt his techniques to avoid incorporation of chemicals. We cannot even guess how many of the compounds in daily laboratory use might exert dangerous long-term effects. All our work with nitrosamines is performed in a specially reserved fume hood contain-

ing a full complement of equipment and an HBr/glacial acetic acid bath for washing all apparatus[231]. The extractors are fitted with extra-powerful motors. Disposable gloves are worn during all manipulations. Low molecular volatile nitrosamines, which possess only limited synthetic potential, are commercially available and must always be stored in a fume hood[232]. Liquids and solutions are handled with syringes. Whenever possible the "*one-pot*" procedure described above is used (Section 3.5.2).

4. Conclusions

In spite of intense searching, no other acidifying group has yet been found which permits reversible transformation of secondary amines into nucleophilic aminoalkylating agents *via* anions of type *(14)*. It requires little imagination to predict



(14)

that further searching for novel reagents with inverse reactivity will bring in a rich harvest of valuable results and additional knowledge, which might even bring us nearer to the virtuosity of analogous biochemical processes demonstrated in Scheme 3, and show us how to reach our goal in a more intelligent and less brutal way.

Generous support of our work on metalated nitrosamines by the Deutsche Forschungsgemeinschaft (Project SE 158/7), the Fonds der Chemischen Industrie, and the Schunk und Ebe Company, Giessen, is gratefully acknowledged.

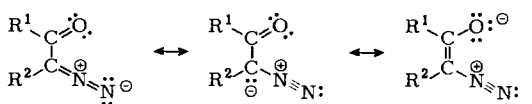
The Wolff Rearrangement of α-Diazo Carbonyl Compounds

By Herbert Meier and Klaus-Peter Zeller[*]

The readily accessible α-diazo carbonyl compounds are distinguished by their high reactivity, which opens up a variety of preparative applications under modified conditions. Wolff rearrangements of these compounds, induced thermally, photochemically, or catalytically, afford ketenes. Free and complexed carbenes, 1,3-dipoles, 1,3-diradicals, and the antiaromatic oxirenes have been considered as intermediates or transition states. The present progress report attempts to integrate preparative and theoretical aspects.

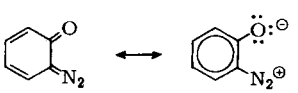
1. Introduction

α-Diazo carbonyl compounds *(1)* contain the CO—CN_2 group, which is capable of resonance, as characteristic structural unit.



(1)

The C—C bond can be part of a carbon chain or of a cyclic system. If it belongs to an aromatic ring then an inner diazonium phenoxide ("*o*-quinone diazide") *(2)* is present.

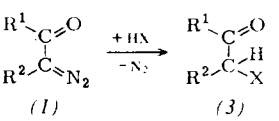


(2)

Key positions in the attached groups may also be occupied by heteroatoms. In this context, the α-diazo carboxylic acid derivatives *(1)*, R^1 = OR, NH_2, NHR, NR_2, *etc.*, warrant special attention.

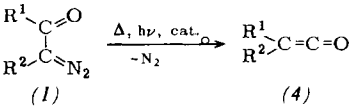
Apart from the CO stretching vibration, a simple analytical feature of the open-chain α-diazo carbonyl structure is the diazo band lying between 2090 and 2190 cm^{-1} (usually at 2130 cm^{-1}) in the IR spectrum. Mutual interaction between the diazo and the carbonyl group lowers the CO frequency and raises the N_2 frequency.

α-Diazo carbonyl compounds are particularly reactive substances. Reactions involving loss of the N_2 group are generally induced thermally, photochemically, catalytically, or by (Lewis) acids. Whereas the decomposition by acids is applic-



(1) *(3)*

able to all diazoalkanes, in the other three processes one observes a rearrangement that is specific for α-diazo carbonyl compounds and is known after its discoverer as the Wolff



(1) *(4)*

rearrangement[1, 2]. The preparative value of the Wolff rearrangement is due to the ready accessibility of the α-diazo carbonyl compounds[3] and to the wide range of reactions of the resulting ketenes *(4)*.

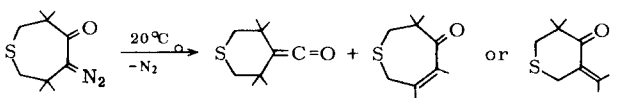
[**] European Science Exchange Program Fellow.

2. Methods of Conducting the Reaction

2.1. Thermolysis

Thermal energy can induce α-diazo carbonyl compounds to lose nitrogen and undergo Wolff rearrangement. The decomposition temperatures range between room temperature and 750 °C in gas phase pyrolysis[4]. Although generally greater than that of common diazoalkanes, the thermal stability of α-diazo carbonyl compounds can be reduced by electronic effects[5, 6] and even more effectively by steric effects[7]. Thus the diazo ketone *(5)*, whose —CO—CN_2— is twisted owing to ring strain, decomposes on formation at room temperature[7].

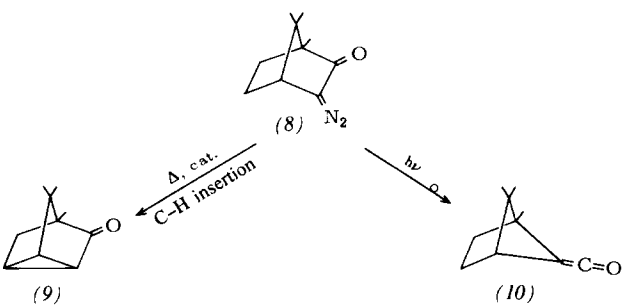


(5) *(6)* 49% *(7)*

The tendency to undergo Wolff rearrangement often shows a marked initial increase at the expense of other competing reactions as the thermolysis temperature is raised. Reaction in boiling aniline or boiling benzyl alcohol with addition of tertiary bases such as collidine, isoquinoline, or *N*,*N*-dimethylaniline has become a proven preparative method.

2.2. Photolysis

The photochemical variant of the Wolff rearrangement discovered by *Horner*[8] is frequently superior to other methods. It also succeeds when the thermal or catalytic approach merely results in a C—H insertion, as with diazocamphor *(8)*[9-11].



(9) *(10)*

The limit of the photochemical method is reached when the desired reaction product is itself photolabile under the irradiation conditions, *e.g.* with 2-diazo-1,3-indandione *(11)*.

The choice of wavelength should be guided by the common photochemical principle: as long as possible, as short as necessary. Decreasing wavelength (increasing energy) of the radiation used leads to increasing amounts of by-products. However, the lowest energy excited singlet state S_1 of diazo ketones, generated by irradiation at the wavelength of a low-intensity forbidden transition in the near UV or visible range, displays only modest reactivity (cf. Section 6).

In the presence of triplet sensitizers, Wolff rearrangement is greatly reduced or completely suppressed in favor of other carbene reactions.

2.3. Catalysis

The decomposition temperature of α-diazo carbonyl compounds can be drastically lowered by metal (ion) catalysts Ag, $Ag^{\oplus}$, Cu, $Cu^{\oplus}$, $Cu^{2\oplus}$, Pt, Pd, Rh, *etc.* Most frequently use is made of freshly precipitated Ag(I) oxide in the presence of alkaline reagents. With the exception of CuI, copper catalysts not only exert an activating effect on nitrogen elimination but also stabilize the resulting carbene (see Section 6.2) by complex formation[3]. The same applies to rhodium[12] and palladium catalysts[13]. As a consequence, Wolff rearrangement no longer occurs or becomes very difficult. Catalysts are sometimes also used during photolysis of α-diazo carbonyl compounds[14] (Table 1).

Table 1. Catalysts for Wolff rearrangement of α-diazo ketones.

Catalyst	Ref.
$Ag_2O/Na_2S_2O_3$	[1]
$Ag_2O/Na_2S_2O_3/Na_2CO_3$	[15]
$AgNO_3$	[16]
$C_6H_5—CO_2Ag$/tertiary base	[17]
$CF_3—CO_2Ag$	[17]
colloidal Ag from $Ag_2O + H_2CO$	[18]
CuO	[19]
CuI/acetonitrile	[20]
Cu/acetonitrile	[19]
platinum	[21]

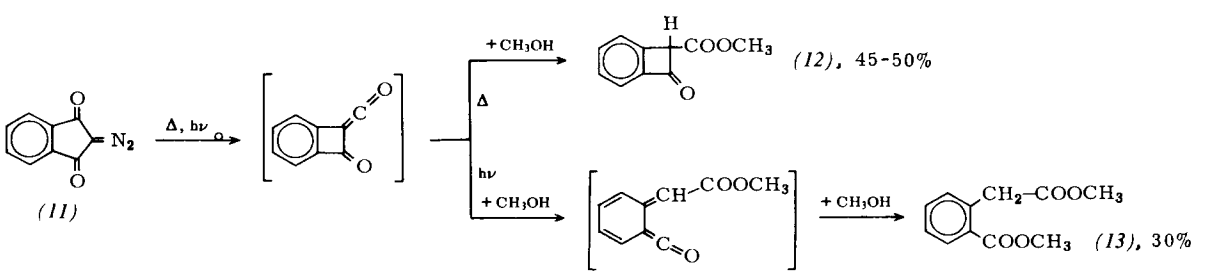
3. Secondary Reactions of Ketene Products

The ketenes *(4)* are generally not isolated after a Wolff rearrangement; instead their reaction products are obtained.

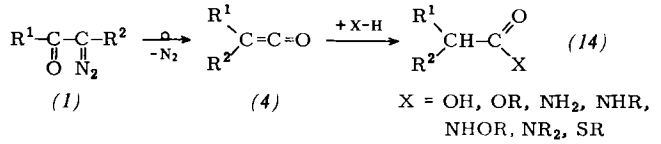
3.1. Addition of Nucleophiles

If the Wolff rearrangement is conducted in the presence of nucleophilic reagents whose proton activity is not excessively high, then the ketene intermediates yield carboxylic acids *(14)* or their derivatives[3, 22, 22a].

This synthesis represents the principal application of the Wolff rearrangement, particularly in connection with the homologization of carboxylic acids[15]. Remarkably, the photochemical



(11) *(12)*, 45-50% *(13)*, 30%



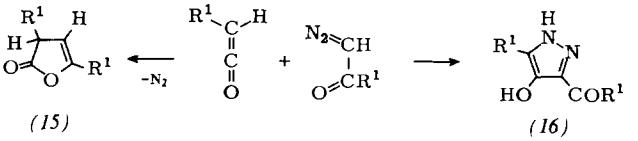
(1) (4) (14)

X = OH, OR, NH_2, NHR, NHOR, NR_2, SR

Wolff rearrangement of 2-diazo 1,3-diketones in the presence of water leads to β-keto carboxylic acids which otherwise prove to be unisolable[151, 151a] (cf. Section 4.5).

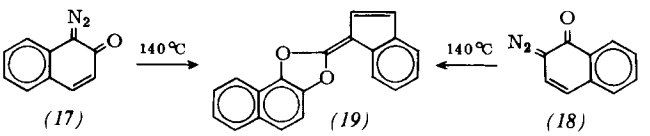
3.2. Intermolecular and Intramolecular Cycloadditions

While the relatively stable ketenes resulting from decomposition of corresponding α-diazo ketones in inert solvents are isolable, neither aldo ketenes nor their dimers can be prepared. In some cases the more labile aldo ketenes react with intact α-diazo ketone to give 3-buten-4-olides *(15)*[23-26] or pyrazoles *(16)*[27].



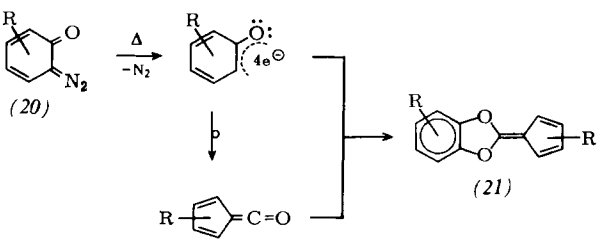
(15) (16)

On thermolysis of 1-diazo-2-oxo- *(17)* and 2-diazo-1-oxo-1,2-dihydronaphthalene *(18)*, *Yates* and *Robb* obtained the same 2-methylene-1,3-dioxole derivative *(19)*[28].



(17) (19) (18)

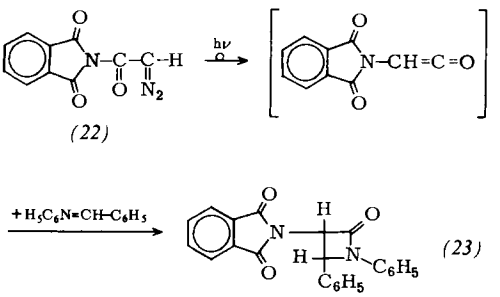
Nearly all *o*-quinone diazides behave in this manner on thermolysis[28a]. The resulting ketene reacts with unrearranged primary fragments (carbenes), yielding compounds of type *(21)*.



(20) (21)

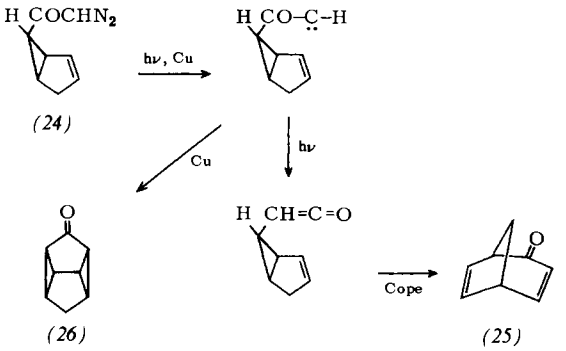
The ketenes formed "*in situ*" in the Wolff rearrangement have frequently been subjected to cycloadditions with C=C, C=N, and N=N double bonds or with *o*-quinones[29-35]. The trapping of an unstable aminoketene to give the α-amino β-lactam *(23)* should be cited as an example[36].

The scope of this cycloaddition is limited above all by reaction of the starting compound itself or its primary fragments (carbenes) prior to rearrangement. The case of the diazo ketone *(24)* is interesting because intramolecular cycloadditions



(22) (23)

occur preferentially at the ketene stage in the photochemical reaction[37] but at the carbene stage in the catalytic process[38].

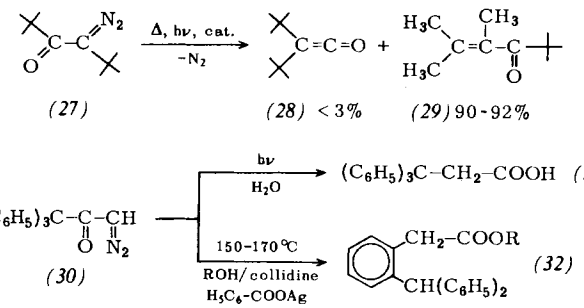


(24) (26) (25)

4. Substrates Capable of Rearrangement

4.1. Open-Chain α-Diazo Ketones

Whereas little is known about the Wolff rearrangement of α-diazo aldehydes[39-41], numerous publications have appeared on the fragmentation of open-chain α-diazo ketones[3]. In principle, alkyl, aryl, and aralkyl groups can migrate. The *tert*-butyl group in *(27)*[42] and the triphenylmethyl group in *(30)*[43] qualify as borderline cases.

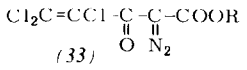


(27) (28) < 3% (29) 90-92%

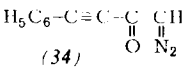
While the *tert*-butyl group of *(27)* invariably displays only a limited proclivity to migrate, the triphenylmethyl group undergoes clean photochemical reaction. In the catalytic process, however, anomalous attack at the *ortho* position of a phenyl ring occurs in compound *(30)*. 9-Diazoacetylfluorene behaves similarly to triphenyldiazoacetylmethane *(30)*[43].

The presence of additional functional groups, particularly in α position to the CO group, can interfere with the Wolff rearrangement or lead to secondary reactions. Studies on the influence of, for example, halo[44-53], substituted hydroxyl[54, 55], free and substituted amino[56-64], cyclopropyl[65],

and cyclopropenyl groups[35, 66-71] have been reported. Incorporation of double or triple bonds into the α-diazo carbonyl compounds, especially in the αβ position to the CO group[78], suppresses the Wolff rearrangement either completely or partially[34, 37, 38, 72-78]. The Wolff rearrangement is known to occur with the α,β-unsaturated diazo carbonyl compounds *(33)*[79] and *(34)*[80].



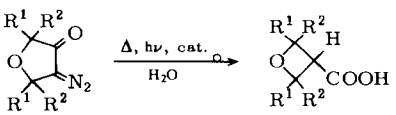
(33)



(34)

4.2. Cyclic α-Diazo Ketones

Apart from the Arndt-Eistert homologization[81, 82], ring contraction is the main application of the Wolff rearrangement. Above all the photochemical variant proves suitable for producing strained systems (bicyclics[10, 83-99], polycyclics[85, 87, 100-103], paracyclophanes[104-106], steroids[107-112]). The formation of the oxetane *(36)* can be considered as an example[113, 114].

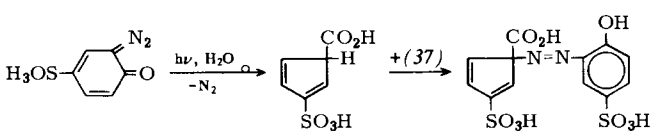


(35) *(36)*

2-Diazo-1-oxoacenaphthene is a negative example—it fails to undergo ring contraction[115].

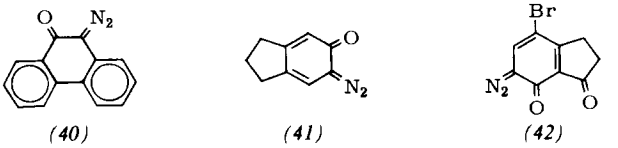
4.3. *o*-Quinone Diazides

As originally demonstrated by *O. Süs*[116, 117, 117a], the Wolff rearrangement can also be implemented with *o*-quinone diazides. In this case the rearrangement involves ring contraction, thus providing access to the cyclopentadiene series (Süs reaction). This reaction is exploited in a photocopying process (Diazotype, offset process)[116-118] in which an increase in pH promotes coupling of rearrangement products with unreacted *o*-quinone diazide, *e.g. (38)* with *(37)*, to yield the azo dye *(39)*.



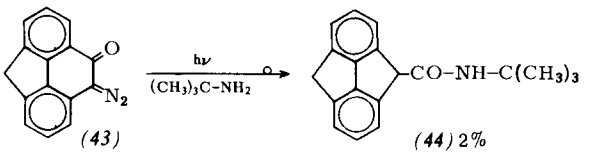
(37) *(38)* *(39)*

Coupling reactions can be avoided by working in acid media. Thus irradiation of derivatives of 1-diazo-2-oxo-1,2-dihydronaphthalene and 2-diazo-1-oxo-1,2-dihydronaphthalene leads to the corresponding derivatives of 1-indenecarboxylic acid[116, 119, 120] [see formula *(19)* in Section 3.2]. Application to the pyridine and quinoline series[119-121] permits synthesis of pyrrole- and indolecarboxylic acids. Photochemical transformation of 3-diazo-2-oxo-2,3-dihydropyridine to 2-pyrrolecarboxylic acid is a remarkable reaction because it involves migration of an sp^2 nitrogen[120]. Whereas *(40)*[122, 123], *(41)*[120], and *(42)*[124] undergo smooth Wolff rearrangement,



(40) *(41)* *(42)*

only 2% ring contraction occurs with *(43)*[125], presumably owing to an increase of *ca.* 50 kcal/mol in strain energy[123].

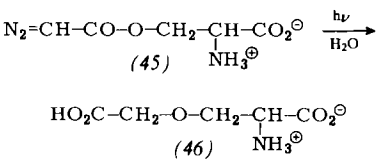


(43) *(44)* 2%

Thermal decomposition of *o*-quinone diazides in inert solvents leads to 1,3-dioxoles, only part of the keto carbene being subject to Wolff rearrangement (cf. Section 3.2).

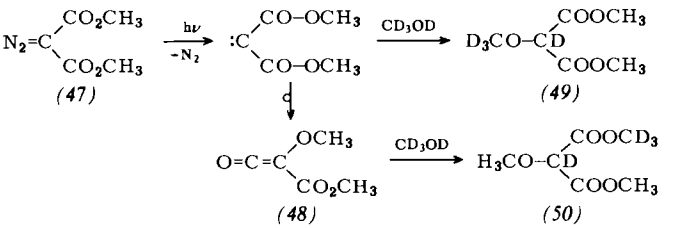
4.4. Derivatives of α-Diazo Carboxylic Acids

The first example of Wolff rearrangement of a functional group bound to a heteroatom was observed in the photolysis of *O*-diazoacetylserine *(45)* in water[126].



(45) *(46)*

Nowadays a series of examples is known for the migration of substituted hydroxyl[127-133], mercapto[134], and amino groups[127, 135-137], which are all usually induced photochemically. Formation of dimethyl methoxymalonate from

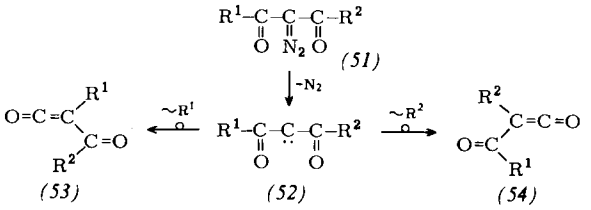


(47) *(48)* *(49)* *(50)*

dimethyl diazomalonate *(47)* involves, for example, about 30% of an intramolecular methoxy group migration since irradiation of *(47)* in perdeuteriomethanol affords an 80% overall yield of the insertion product *(49)* and the rearrangement product *(50)* in the ratio 9:4[130].

4.5. 2-Diazo 1,3-Dicarbonyl Compounds

On rearrangement of unsymmetrically substituted[138] 2-diazo 1,3-dicarbonyl compounds *(51)*, both R^1 and R^2 can migrate, since a diacylcarbene *(52)* is present after loss of N_2. Studies on compounds *(51)* (see Table 2) therefore provide an indication of the relative migration tendencies of various groups (cf. Section 6).



(51)

(53) (52) (54)

Table 2. Wolff rearrangement of unsymmetrically substituted open chain 2-diazo 1,3-dicarbonyl compounds of type (51).

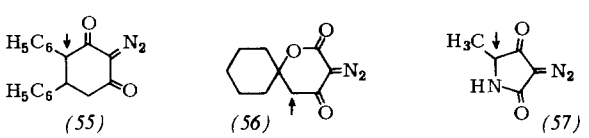
Cyclic 2-diazo 1,3-dicarbonyl compounds can also be included in these investigations. The arrows in formulas (55)[157], (56)[158] and (57)[159] indicate the centers of selective migratory aptitude.

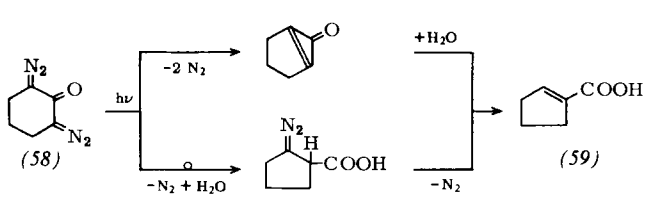


(55) (56) (57)

4.6. Other Diazo Carbonyl Compounds

Thermally[160] or photochemically induced[161, 162] Wolff rearrangement of 1-diazo 2,3-dicarbonyl compounds requires migration of an electron-impoverished carbonyl carbon to a carbenoid center, thus imparting not only preparative but also theoretical interest to the reaction.

Final confirmation of the Wolff rearrangement of 1,3-bisdiazo 2-carbonyl compounds (58)[163-166] is still outstanding.

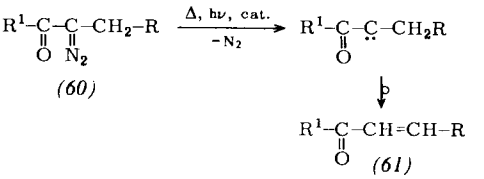


(58) (59)

5. Competing Reactions

5.1. [1.2]-Hydrogen Shifts

α-Diazo ketones of type (60) very frequently react *via* a [1.2]-H shift at the carbene stage, especially under catalytic conditions, to form α,β-unsaturated ketones (61)[167-171].

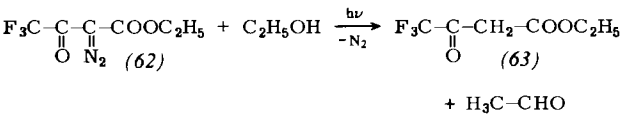


(60) (61)

A [1.2]-methyl shift is the principal reaction route of 4-diazo-2,2,5,5-tetramethyl-3-hexanone (27)[42] (cf. Section 4.1).

5.2. Hydrogen Abstraction

Saturation of the transient carbene by H abstraction from the solvent occasionally accompanies the Wolff rearrangement. In ethyl α-diazotrifluoroacetate (62)[51] it becomes the major reaction:

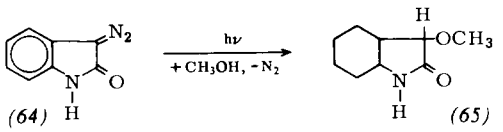


(62) (63)

In the photochemical process, the lowest triplet state (of the diazo ketone) is responsible for H abstraction[140]. The extent of this competing reaction depends upon the wavelength and solvent[140].

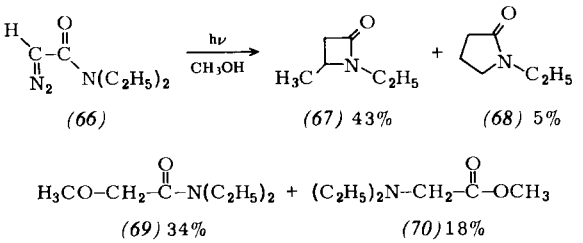
5.3. Intermolecular and Intramolecular Insertions

The α-oxo carbenes arising as intermediates in the Wolff rearrangement frequently insert into C—H, C—C, C—O, C—S, C—N, C—Hal, O—H, N—H, and S—H bonds[3]. Greatest preparative importance attaches to the insertion reactions into the O—H bonds of water, alcohols, phenols, carboxylic acids, *etc.* For instance, *(64)* does not undergo rearrangement but insertion on irradiation[172].



(64) *(65)*

An example of an intramolecular insertion should also be mentioned in this context[135]: only *(70)* is formed by Wolff rearrangement.

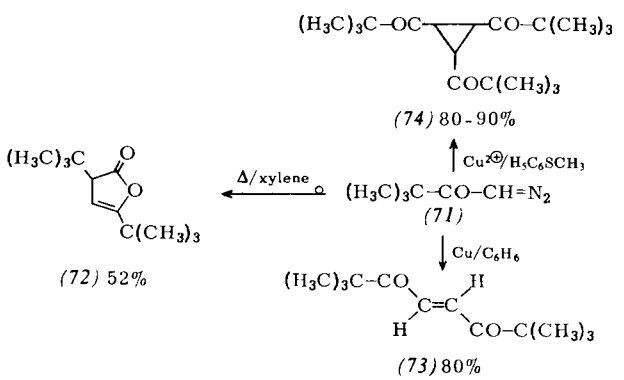


(66) *(67)* 43% *(68)* 5%

(69) 34% *(70)* 18%

5.4. Dimerization and Oligomerizations

Dimerizations and oligomerizations of the stabilized carbenes is often observed in the decomposition of α-diazo carbonyl compounds, especially when performed catalytically—as illustrated by the following example[173]:



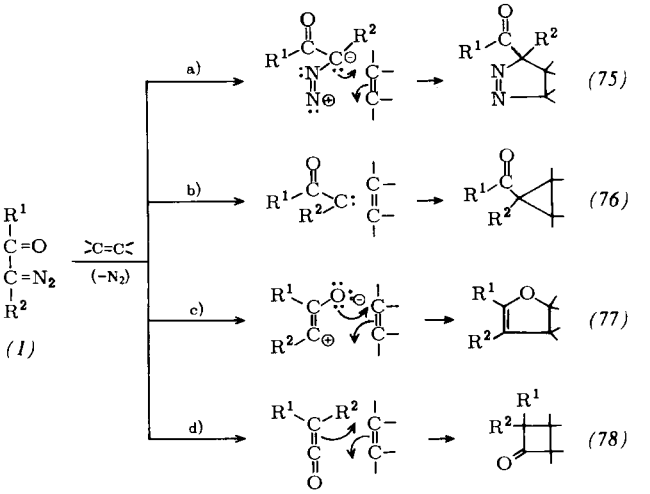
(74) 80-90%

(72) 52% *(71)* *(73)* 80%

5.5. Cycloadditions

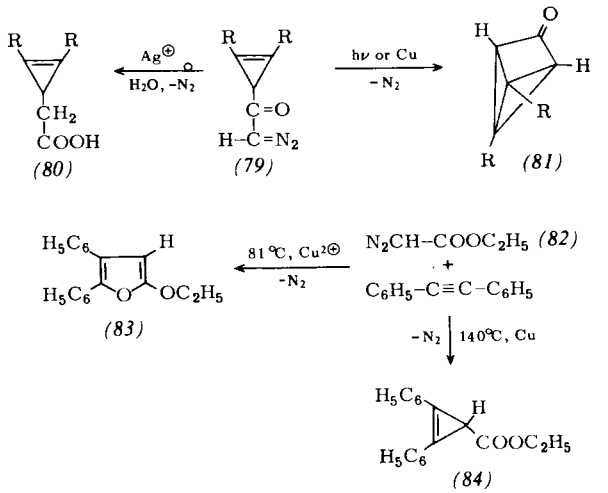
α-Diazo carbonyl compounds are capable of numerous intermolecular and intramolecular cycloadditions to double bonds (C=C, C=O, C=N, C=S, N=N) or triple bonds (C≡C, C≡N)[3]. The possible reactive species are (a) the starting compound itself, (b) a carbene intermediate, (c) a 1,3-dipolar intermediate, and (d) the ketene ensuing from Wolff rearrangement (cf. Section 3.2).

The competing processes (a) and (b) are particularly interesting with regard to the mechanism of the Wolff rearrangement.



(1) *(75)* *(76)* *(77)* *(78)*

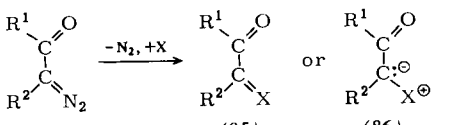
The reactions of *(79)* to give *(81)*[174-176] and of *(82)* to form *(83)*[177, 178] should illustrate this point.



(80) *(79)* *(81)* *(83)* *(84)*

5.6. Other Competing Processes

A wide range of reagents can interfere with the Wolff rearrangement owing to the pronounced reactivity of the diazo compounds and the degradation products[3]. Special mention is made here of additions to the carbene intermediate or to the starting compound itself:



(1) *(85)* *(86)*

X = O[84, 114, 185, 188]
X = N-N=CR$_2$[114, 179-185]
X = C=N-R[186]
X = SR$_2$[187]

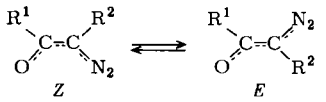
6. Reaction Mechanisms and Intermediates

6.1. Elimination of Nitrogen

6.1.1. Steric Effects

Physicochemical investigations (IR, UV, NMR data, dipole moments) demonstrate that, in solution, α-diazo carbonyl com-

pounds generally exist in *Z/E* equilibrium about the C—C bond having partial double bond character[189-193] ($\Delta G^{\ddagger}_{298} \approx 15$ kcal/mol).

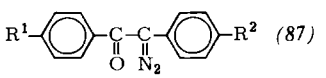


Z *E*

In view of a concerted mechanism of the Wolff rearrangement starting from the *Z*-conformation, the two rotamers have occasionally been assigned differing reactivities[189]. The behavior of compounds *(5)* (*Z*, labile) and *(27)* (*E*, 3% Wolff rearrangement) fits this concept well, but still does not prove its validity. Steric hindrance has been proposed as an alternative explanation for the inertness of *(27)*, and the lack of delocalization energy for the lability of *(5)*. Resonance of the coplanar CO—CN_2 group normally leads to a gain of about 0.7 β in delocalization energy[194]. However, resonance is impossible in the twisted heptacycle *(5)* since the CO and CN_2 are mutually orthogonal. Kinetic studies[195-199] and the finding that substituents have different effects on nitrogen elimination[196, 200] and on migratory aptitude contraindicate a concerted mechanism, regardless of the manner in which the reaction is conducted.

6.1.2. Electronic Effects

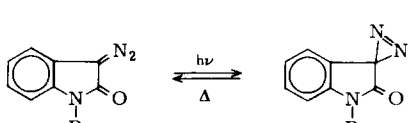
For the case of substituted azibenzils *(87)*, electronic effects occurring on thermal nitrogen elimination can be correlated with the Hammett σ constants[196].



(87)

Electron-withdrawing groups R^2 decelerate the decomposition, while their electron-repelling counterparts have an accelerating action. The effect of groups R^1 is exactly opposite, but less significant[196, 197].

In the photochemical variant, N_2 elimination can be accomplished both by direct irradiation in the entire absorption range of the α-diazo carbonyl compound and on triplet sensitization. The apparent integral quantum yield is always lower than 1[200]. Values of 0.6, 0.5, and 0.07[201] are obtained for diazoacetophenone at 250, 294, and 325 nm. The longest wavelength forbidden transition[193], which leads to the lowest energy singlet excited state S_1, is therefore not very effective. S_1 undergoes mainly radiationless deactivation. Under suitable conditions additional photochromic valence isomerization to diazirines *(89)* is possible[201, 202].



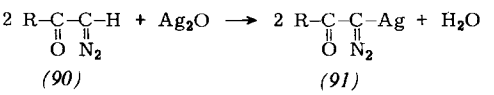
(88) *(89)*

Numerous quantum yield measurements have been performed on substituted diazoacetophenones[200]. Electron-withdrawing and electron-repelling *para* substituents lower the quantum yield. No uniform trend could be established for electronic effects in the catalytic variant[198, 199].

6.1.3. Medium Effects

Elimination of nitrogen is independent of both the rearrangement and also the presence of nucleophilic reagents[195, 196]. It obeys a first-order rate law[196]. This disproves the addition-protonation mechanism discussed by *Eistert*[203], which assumes participation of the nucleophile prior to nitrogen elimination. There remain certain medium effects[195-197, 204] arising from polarity changes and from hydrogen bonding to the carbonyl oxygen or the diazo carbon. The presence of such aggregates in mixed systems of aprotic and protic solvents has also been detected by UV spectroscopy[205]. The resulting barrier to resonance facilitates thermal elimination of N_2. However, the absence of H/D isotope effects[196] demonstrates that complete $H^{\oplus}$ transfer does not take place in the rate-determining step.

Whereas monomolecular decomposition can be assumed in the thermal and photochemical processes, transient participation of the metal or metal ion occurs in the catalytic variant. According to a hypothesis put forward by *Huisgen*[206], the electrophilic $Ag^{\oplus}$ ion adds to the diazo carbon and thus effects nitrogen elimination and migration of the group. Indeed, reaction of diazomethyl ketones *(90)* with silver(I) oxide in tetrahydrofuran at −15 °C affords silver-substituted diazo ketones *(91)*[207].

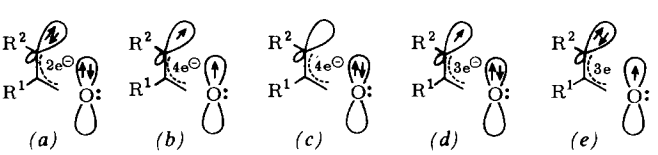


(90) *(91)*

Newman and *Beal*[17], who have developed a homogeneous medium for the $Ag^{\oplus}$ catalyzed rearrangement (methanol in the presence of silver benzoate and triethylamine) assume a radical chain process to occur under these conditions. Triethylamine has a kind of initiating effect as proton transfer agent and $Ag^{\oplus}$ likewise for electron transfer[17]. In recent kinetic studies[198] a complex between the deprotonated diazo ketone and $Ag[N(C_2H_5)_3]_n^{\oplus}$ has been proposed as crucial intermediate.

6.2. Primary Fragments

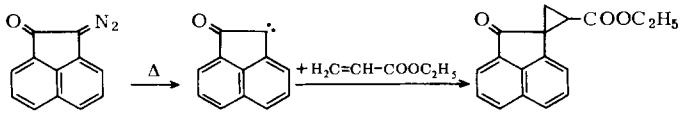
The singlet carbene *(a)*, the 1,3-diradical *(b)*, the 1,3-dipole *(c)*, and the two-spin systems *(d)* and *(e)* are reasonable possibilities for the ground state of the primary fragments left after elimination of nitrogen.



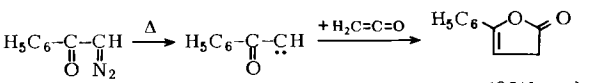
(a) *(b)* *(c)* *(d)* *(e)*

In the plane of the σ bond skeleton there is a p orbital of the oxygen and an sp^2 or p orbital of the "diazo carbon" to be populated; in a plane at right angles there are three

p orbitals comprising an allyl system. *(a)* and *(c)* are singlet states. A scalar and dipolar spin coupling can be assumed in *(b)*, and dipolar spin couplings in *(d)* and *(e)*. This leads to singlet and triplet splitting, so that a total of five singlet and three triplet states will result. If the sp^2/p alternative or antibonding levels are included, then the number of possibilities increases considerably. The energetic proximity of these states makes any theoretical decision difficult. In the thermal case [*e.g. (92), (94)*] an indication of the nature of the primary fragments is provided by trapping- and side reactions (cf. Section 5).

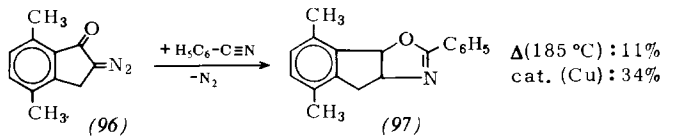


(92) *(93)*[208]



(94) *(95)*[209]

Thus a singlet carbene and 1,3-dipole participation may be assumed. However, in the numerous 1,3-dipolar cycloadditions with C=C, C=O, C=S, C=N, C≡C, and C≡N bonds[210] it is often doubtful whether the primary fragments or the original α-diazo carbonyl compound itself is involved in the reaction. With primary fragments showing a low tendency to undergo rearrangement and additional stabilization by complex formation with copper, trapping reactions, yielding *e.g. (97)* are much more likely[211].

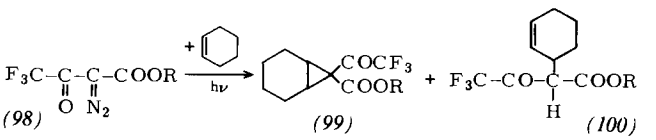


(96) *(97)*

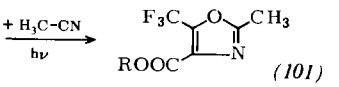
In the $Ag^{\oplus}$-catalyzed Wolff rearrangement the free keto carbene is apparently present after elimination of nitrogen.

The reaction course during direct photolysis was followed by absorption spectrometry (flash photolysis)[212] and by ESR spectroscopy[213, 214]. At 77 K, azibenzil affords a triplet carbene exhibiting hardly any Wolff rearrangement (<3%). Marked deviation from an angle of 180° can be deduced from the ratio of its zero field parameters ($D/hc = 0.3815$, $E/hc = 0.0489\ cm^{-1}$). (The triplet carbene disappears in favor of an oxygen radical when the temperature is raised[214].)

The Wolff rearrangement of azibenzil increases up to a yield of 85–90% at room temperature[214]. In the triplet-sensitized decomposition of α-diazo carbonyl compounds, Wolff rearrangement occurs at most as a minor reaction[152, 215–217]. The major processes are H abstraction and insertions. The most obvious conclusion to be drawn from all these observations is that the photochemical Wolff rearrangement takes place in a singlet state of the primary fragment. Since the relative migratory aptitudes of individual groups differ from those in the thermal variant (cf. Sections 4.7 and 6.4), the process must involve a singlet excited state. For small singlet-triplet splitting, an intersystem crossing of low activation energy in both directions can be assumed so that reactions of the triplet state are also observed on direct photolysis, and the Wolff rearrangement is found to occur in sensitized photolysis. The quantum yield for the transition $S_1 \rightarrow T_1$ increases with the temperature and the energy of the illuminating light[140].



(98) *(99)* *(100)*

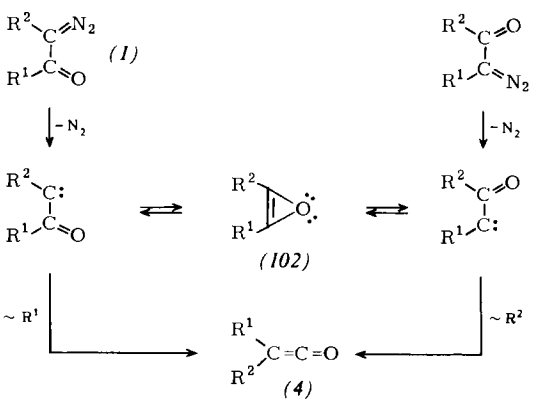


(101)

Photochemically generated primary fragments, *e.g.* from *(98)*, can also be trapped in a kind of carbene reaction or a 1,3-dipolar reaction[218–221].

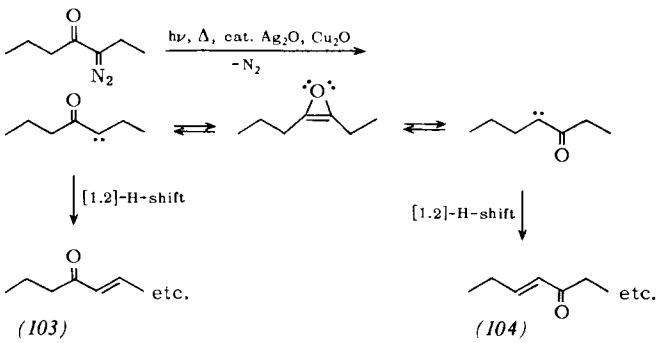
6.3. The Oxirene Intermediate

The oxirenes *(102)*, antiaromatic 4π electron systems, formed by valence isomerization of the primary fragments should possess similar energies to the α-oxo carbenes[222–224]. The true role of the oxirenes in decomposition of α-diazo carbonyl compounds long remained unclear due to a lack of experimental work[225–227]. Conclusive proof of the intermediate appearance of oxirenes during the photochemical Wolff rearrangement has been obtained with the aid of three independent methods employing isotopic labeling.



The extent of oxirene[*] formation depends upon the conditions, *e.g.* on the concentration of water[228]. The carbene-oxirene equilibrium makes it difficult to reach any conclusion regarding the migratory aptitude of the groups R^1 and R^2. In all systems investigated so far[229], however, the initial carbene formed after nitrogen elimination undergoes reaction. Oxirene participation could be ruled out on sensitized photolysis, on catalysis, and on thermolysis in solution[227–231]. Proof of oxirene formation that is completely independent of the Wolff rearrangement was obtained with unsymmetrical α-diazo dialkyl ketones[170] and a number of special aryl-substituted α-diazo ketones[232a].

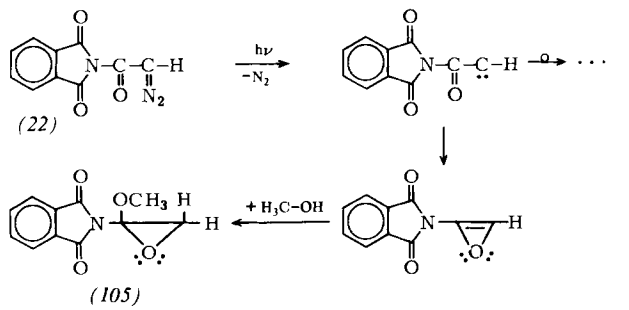
[*] No oxirene could be detected on photolysis of α-diazohomoadamantanone in the presence of water [228a].



(103) *(104)*

hν:	57%	43%
Δ(465 °C):	64%	36%
cat.:	100%	0%

The trapping reaction yielding *(105)* strongly suggests that the oxirenes are true intermediates, and not merely transition states[232].



(22) *(105)*

6.4. Rearrangement of the Primary Fragments

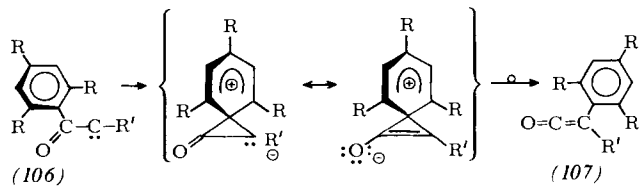
The examples cited in Section 4 demonstrate that hydrogen, alkyl, aryl, substituted hydroxyl, mercapto, and amino groups can all migrate. Thus H, C(sp^3), C(sp^2), C(sp), N(sp^3), N(sp^2), O, or S represent migrating centers. Apart from this absolute migratory disposition, the relative migratory aptitudes of individual groups established primarily with 2-diazo 1,3-dicarbonyl compounds (Section 4.5) also warrant interest. The following series is generally valid for the thermal reaction[152, 155, 156, 137]:

$$H > C_6H_5 > CH_3 > NR_3 > OR$$

In the photochemical variant, phenyl and methyl change places. The electronic effects are similar in both cases[152]:

$$p\text{-}H_3CO{-}C_6H_4 > C_6H_5 > p\text{-}O_2N{-}C_6H_4$$

The mesityl and above all the 2,4,6-tribromophenyl group migrate far more readily than purely electronic effects of methyl and bromo substituents would suggest[154]. This pronounced steric effect is most probably due to restriction of resonance in the keto carbene intermediate *(106)*.



(106) *(107)*

R = CH_3, Br

All these findings show that a high electronegativity at the migrating center and an electron-poor R^1—CO bond tend to favor the relative migratory aptitude of the group R^1 (in accord with classical ideas of an anionotropic migration). In contrast, a partial double bonding character of this bond arising from participation of the CO group in resonance of R^1 have an unfavorable effect, especially in the excited state. The group R^2 also influences the migratory disposition of R^1[233].

Regardless of the way in which the reaction is conducted, the migrating groups are not severed entirely from the molecular framework, thus largely or completely conserving all stereochemical information[234–242]. In particular all intermolecular mechanisms can therefore be discounted.

7. Conclusion

The principles of the above mechanistic and preparative investigations on the Wolff rearrangement show how fresh aspects have repeatedly come to light during the course of work on a 70-year old reaction. A considerable extension of this topic has recently been provided by electron-impact induced Wolff rearrangement[243–246], and by thermal and photolytic rearrangements of related systems such as α-diazo sulfones[247], α-diazo phosphane oxides[248, 249], β-oxo sulfonium ylides[250] and their *S*-oxides[251], 1,2,3-triazoles[252], 1,2,3-thiadiazoles[253–256], and 1,2,3-selenadiazoles[257–259].

Isomerization Polymerization of Lactams

By H. K. Reimschuessel[*]

Isomerization polymerization affords a macromolecule whose repeating unit is derived from an isomer of the original monomer. Thus hexa- and heptacyclic β-carboxymethyllactams yield polymers containing glutarimide units, whereas penta- and hexacyclic β-carboxylactams furnish polymers containing succinimide units. Some dimethyl derivatives of β-carboxylactams isomerize or rearrange, and 5-oxopyrrolidine-3-acetic acid does not react at all. These observations can be explained in terms of a bicyclic intermediate.

1. Introduction

Isomerization polymerization is feasible with substituted lactams containing a carboxylic group capable of interacting with the amide function[1]. Whereas the ordinary ring opening polymerization of lactams yields polyamides, isomerization polymerization affords polyimides. Both processes are characterized by competition between intramolecular cyclization and intermolecular polymerization. In the ordinary ring opening polymerization of lactams the former reaction is part of a polymer-monomer equilibrium, and the product of cyclization is the particular lactam itself. The chemical structure of the repeating unit of the corresponding polymer molecule is in this case identical with that of the opened lactam ring. Of course, this also applies to any cyclic oligomers formed during polymerization. A rather different situation, however, characterizes isomerization polymerization for which no polymer-monomer equilibrium is indicated. The structures of both the propagating species entailed in this polymerization and the product of any cyclization differ from that of the starting lactam. Furthermore, no structural identity exists in this case between the lactam and the repeating unit of the polymer molecule.

[*] Dr. H. K. Reimschuessel

Morristown, N. J. 07960 (USA)

Whether polymerization or cyclization is the dominating reaction depends for either process upon thermodynamic and kinetic factors, and upon the total molecular strain energy of the particular ring structure. This energy is directly related to the sum of all molecular deformations which are usually expressed in terms of:

1) bond stretching or bond compression (a function of the bond length, related to the motion of the bonded nuclei along the internuclear line);

2) bond angle bending (related to the radial scissoring motion of the bond angle—also known as angle strain or Baeyer strain);

3) bond torsion (refers to the rotational motion around the bond axis, related to the dihedral angle—also known as torsional strain, Pitzer strain, bond opposition force);

4) nonbonded interactions (refers to the interaction between substituents on neighboring carbon atoms and depends on the nuclear distance).

The extent to which each type of strain contributes to the total molecular strain depends upon the ring size. In the ordinary ring opening polymerization of lactams it appears that bond angle bending (2) dominates in case of the four-membered rings, whereas torsional forces (3) prevail in the five-, six-, and seven-membered rings, and both torsional forces and nonbonded interactions (4) seem to characterize the larger

rings. In general, the four-, seven-, eight-membered, and larger ring lactams polymerize readily, whereas the five- and six-membered lactams do not polymerize easily. This agrees with results reported by *Dainton et al.*[2], according to which the thermodynamic feasibility with respect to ring-opening polymerization is at a minimum for the five- and six-membered rings. In case of lactams, the six-membered δ-valerolactam (2-piperidone) is the most stable ring and exhibits the least tendency to polymerize.

Regardless of ring size, substituents generally increase both the rate of ring closure and the stability of the ring, and thus decrease the polymerizability of the particular lactam. This is due mainly to conformational effects: both the enthalpy and entropy of reaction are affected by the presence of a substituent. *Cubbon*[3] related the enthalpy of ring closure to the increase in the number of *gauche* interactions between adjacent carbon atoms in lactams. This increase becomes less when a substituent is introduced, *i.e.* the contribution to the enthalpy of ring closure is less than for the unsubstituted lactam. This is reflected in a lower heat of polymerization and a higher monomer equilibrium concentration for lactams such as methyl caprolactam and the respective equilibrium polymers[4].

A substituent has little or no influence on the entropy of the ring compound[2]; however, it has a considerable effect on the entropy of a linear polymer molecule by restricting its rotation. Consequently, introduction of a substituent increases the entropy of ring closure. The magnitude of this entropy increase seems to be directly proportional to both the size and number of the substituents. Thus ring closure of a substituted lactam is characterized by a lower enthalpy and higher entropy than that of the unsubstituted compound. Both effects shift the equilibrium toward the cyclic monomer at the expense of the extent of polymerization.

The above phenomena and rationalizations, however, pertain only to lactams containing substituents that are incapable of reacting with other functions present in the system. If the particular substituent is capable of inter- or intramolecular interaction with the amide function of the lactam such that either a cyclic transition state or a cyclic intermediate results, because the formation of such a cyclic structure is highly favored both geometrically and thermodynamically, then a drastically altered reactivity of the parent ring system could be the consequence.

It is well known that carboxyl groups can react with amide functions. Transamidation and acylation are the main reactions occurring. The present account will therefore consider lactams bearing carboxyl or carboxymethyl groups.

2. Substituted Lactams

The lactams investigated thus far may be divided into three groups: (i) carboxymethyl lactams; (ii) carboxy lactams; (iii) carboxy lactams containing non-reactive substituents. The first group contains 2-oxoperhydroazepine-3- and -4-acetic acid (α- and β-carboxymethylcaprolactam, α-CM7 and CM7 respectively), 2-oxopiperidine-4-acetic acid (4-carboxymethyl-2-piperidone, CM6), and 5-oxopyrrolidine-3-acetic acid (4-carboxymethyl-2-pyrrolidone, CM5). The second group is represented by 2-oxopiperidine-4-carboxylic acid (4-carboxy-2-piperidone, C6) and 5-oxopyrrolidine-3-carboxylic acid (4-carboxy-2-pyrrolidone, C5), and the third group comprises 2,2-dimethyl-6-oxopiperidine-4-carboxylic acid (6,6-dimethyl-4-carboxy-2-piperidone, DMC6), 2,2-dimethyl-5-oxopyrrolidine-3-carboxylic acid (5,5-dimethyl-4-carboxy-2-pyrrolidone, DMC5), 2-methyl-6-oxopiperidine-4-carboxylic acid (6-carboxy-6-methyl-2-piperidone, MC6), the ethyl derivative (EC6), 2-methyl-5-oxopyrrolidine-3-carboxylic acid (4-carboxy-5-methyl-2-pyrrolidone, MC5), and the ethyl derivative (EC5) (see Table 1).

α-CM7 was obtained from α-bromocaprolactam *via* nucleophilic substitution employing sodium diethyl sodiomalonate[5], whereas both CM7 and CM6 were synthesized *via* nucleophilic addition of the malonate anion to the corresponding α,β-unsaturated lactam[6,7]. CM5 was prepared by hydrolysis of its ethyl ester, which was synthesized according to the procedure given by *Henecka et al.*[8,7].

The synthesis of C6 entailed addition of hydrogen cyanide to dialkyl itaconate, and reductive cyclization of the resulting dialkyl cyanomethylsuccinate to alkyl 2-oxopiperidine-4-carboxylate followed by saponification[9]. C5 was obtained from its methyl ester which was synthesized *via* esterification of aminomethylsuccinic acid[10].

DMC6 was synthesized by reductive cyclization of methyl 2-(2-nitroisobutyl)succinate followed by saponification[10]. DMC5 was prepared by the same sequence of reactions[10]. The synthesis of MC6 and EC6 consisted in nucleophilic addition of nitroethane (or 1-nitropropane) to dimethyl itaconate, reductive cyclization of the resulting ester, and subsequent saponification[11]. The synthesis of MC5 and EC5 entailed Michael addition of nitromethane (or 1-nitropropane) to either diethyl maleate or fumarate, reductive cyclization of the resulting ester, and saponification[11].

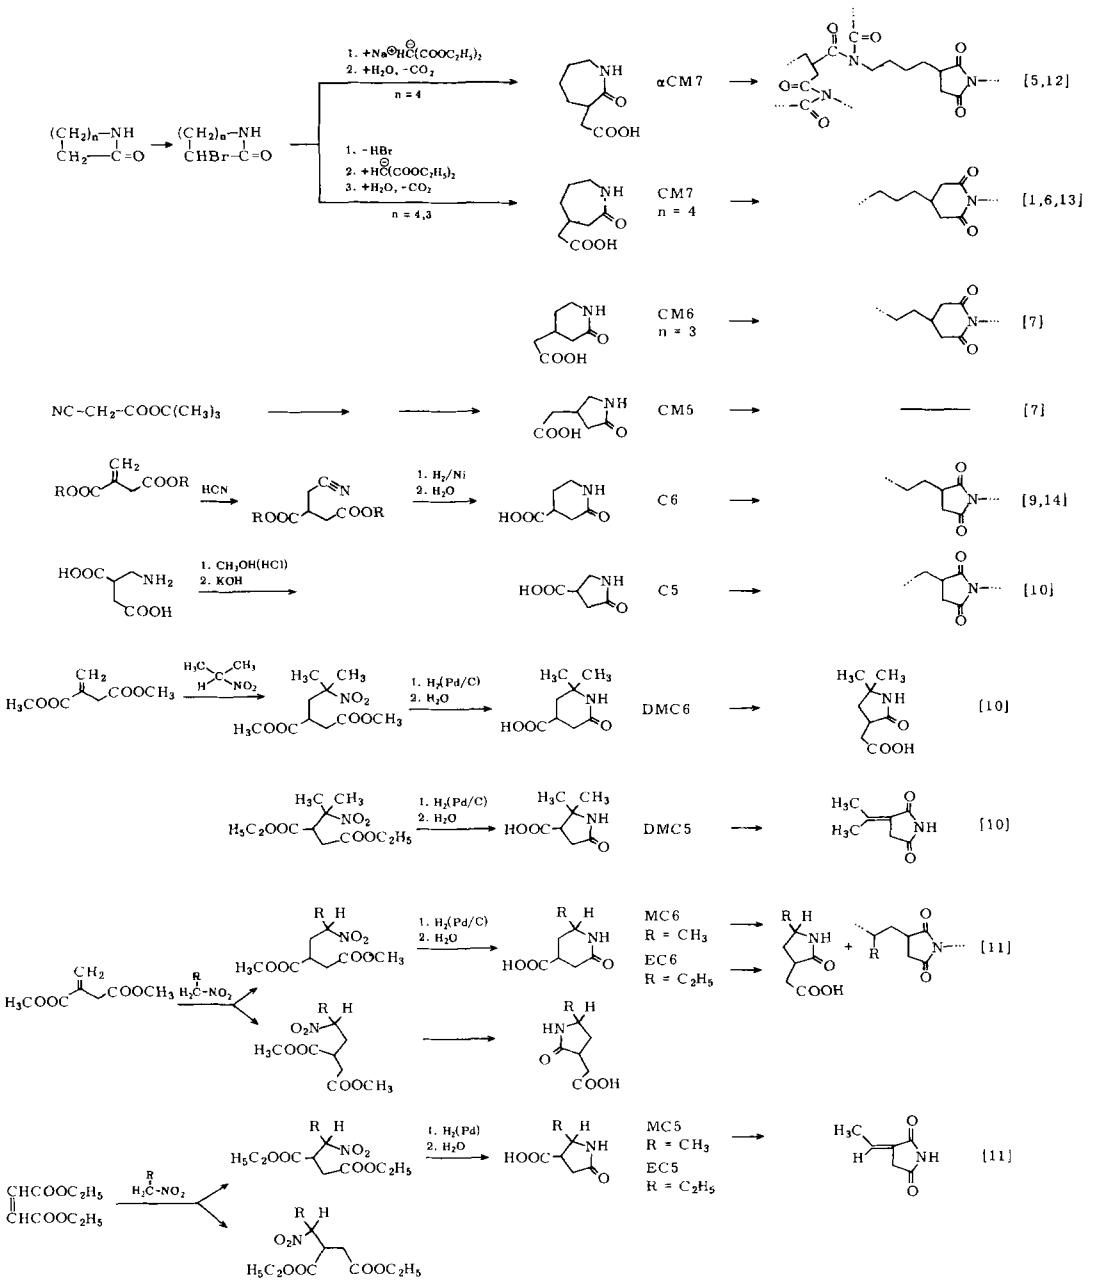
The addition of nitroalkanes to dimethyl itaconate and diethyl maleate (fumarate) yielded in both cases mixtures of diastereoisomers. Thus, in the former case reductive cyclization of the mixtures afforded both MC6 (or EC6) and 5-methyl- (or 5-ethyl)-2-oxopyrrolidine-3-acetic acid, while in the second case MC5 (or EC5) and an appreciable amount of noncrystallizable material were obtained[11]. General reaction schemes are summarized in Table 1.

3. Principal Reactions: Structure and Properties of Reaction Products

Numerous reactions can be envisaged that are peculiar to the functions that characterize the lactams considered. For the present review, however, only those reactions are of interest that are thermally induced by heating a particular lactam in an inert atmosphere to temperatures above its respective melting point. Under these conditions, polymerization and/or rearrangement may occur. Whereas the latter may or may not entail the formation of water, the former always does. CM5 was found to be the only one of four carboxymethyllactams studied that neither polymerized nor rearranged when heated to above its melting point. The others polymerized.

The polymer derived from αCM7 was a colorless transparent material that did not melt or decompose below 300 °C[12]. It was insoluble in all solvents and did not contain soluble

Table 1. Synthesis of carboxy- and carboxymethyl-substituted lactams and structure of their reaction products.



compounds or unreacted monomer. This polymer was obviously highly crosslinked. The polymerization of both CM6 and CM7 resulted in high molecular weight, linear, crystallizable polymers that were soluble in solvents such as formic acid, *m*-cresol, trifluoroethanol, and sulfuric acid, but insoluble in all common organic solvents. The polymer derived from CM6 did not melt below 400 °C but did show signs of decomposition at temperatures above 300 °C. The conversion of monomer into polymer was about 80 to 85 %. Polymerization of CM7 resulted in essentially complete conversion into a polymer that melted at 281 °C and had a glass transition temperature of about 90 °C.

The carboxylactams C6 and C5 polymerized upon heating to temperatures of about 200 °C to form linear amorphous polymers[9, 10] that were soluble in formic acid, *m*-cresol, sulfuric acid, and trifluoroethanol but insoluble in the common organic solvents. Essentially complete conversion of monomer into polymer was also a characteristic of these two cases. The gem-dimethyllactam derivatives did not polymerize but rearranged. Upon heating to temperatures above their respective melting point (232 °C, 206 °C), DMC6 isomerized quantitatively to 5,5-dimethyl-2-oxopyrrolidine-3-acetic acid whereas DMC5 rearranged to isopropylidene succinimide with elimination of water. The occurrence of both polymerization and isomerization upon thermal treatment distinguishes compounds MC6 and EC6. Heating of MC6 or EC6 to 230 °C resulted in both polymerization and the formation of 5-alkyl-2-oxopyrrolidine-3-acetic acid. There was no indication of polymerization when MC5 was heated to temperatures of about 200 °C. The sole reaction product in this case was ethylidenesuccinimide, which was formed with elimination of water.

The structures of both the lactam derivatives and the corresponding reaction products (polymers or/and rearrangement products) are shown in Table 1.

3.1. Spectroscopic Studies

The reaction products were identified by conventional analysis. The chemical structure of the polymers was deduced mainly from the information obtained from infrared and NMR analyses, and solubility characteristics. The infrared spectra of all of the polymers showed strong absorptions related to the imide moiety. Absorptions in the 1675 to 1705 cm^{-1} and 1725 to 1790 cm^{-1} ranges were attributed respectively to asymmetrical and symmetrical carbonyl vibrations, whereas C—N—C antisymmetrical stretching and imide group vibrations accounted for absorptions in the 1350 to 1390 cm^{-1} and 1140 to 1150 cm^{-1} ranges.

A detailed structural analysis has been performed on poly[(2,6-dioxo-1,4-piperidinediyl)trimethylene] (PMC7). This polymer is obtained by thermal polymerization of CM7 (see Table 1)[13]. Depending upon the conditions of polymerization, this polymer could be obtained either as a predominantly crystalline or an essentially amorphous material. Differences observed in the infrared spectra of the crystalline and amorphous polymers have been considered indicative of the existence of two different conformations of the dioxopiperidine ring, which in turn can give rise to two different chain conformations. As indicated in Figure 1a, one is characterized by an equatorial position of the trimethylene moiety with respect to the plane of the imide group, whereas the other (Fig. 1b) pertains to a structural unit in which the trimethylene group is positioned axially to the plane of the ring.

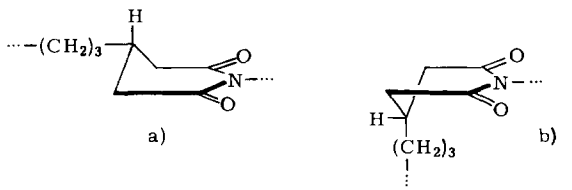


Fig. 1. Conformations of the structural unit in poly[(2,6-dioxo-1,4-piperidinediyl)trimethylene] (PMC7). a) equatorial, b) axial trimethylene group.

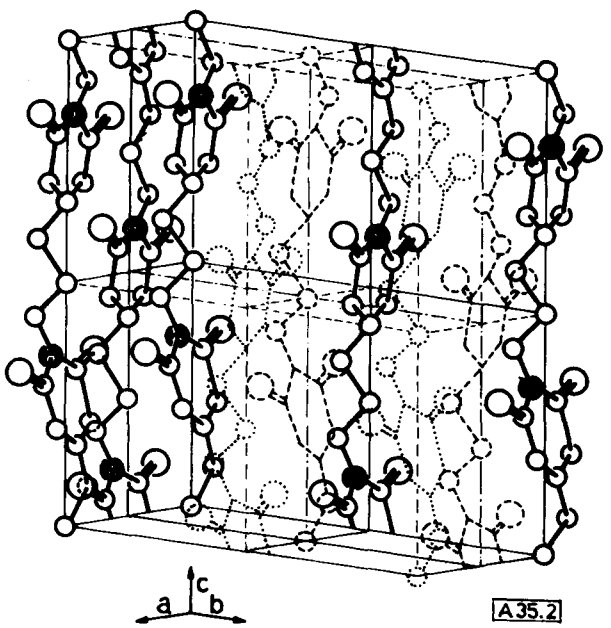

Fig. 2. Configuration of polymer chains in the unit cell of poly[(2,6-dioxo-1,4-piperidinediyl)trimethylene] (PCM7): $a = 9.64$ Å, $b = 11.32$ Å, $c = 15.80$ Å, $\alpha = 98°$, $\beta = 96°$, $\gamma = 114°$.

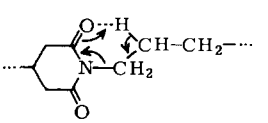
NMR analysis indicated that the axial conformation is the predominant structure of the polymer in formic acid solution. The equatorial conformation has been ascribed to the crystalline modification. This was supported by X-ray analysis, which indicated a triclinic unit cell containing eight structural units (Fig. 2).

The polymer was found to crystallize in positively birefringent spherulites.

The response of the amorphous polymer derived from CM7 to annealing differs from that of polymers such as polyamides and poly(ethylene terephthalate) which readily crystallize when heated above their glass transition temperatures. Even prolonged annealing of the unoriented amorphous polyimide resulted in only insignificant crystallization. Annealing of amorphous polymer which was oriented by cold drawing resulted in rapid and extensive crystallization. However, no crystallization was induced during the orientation process; this is quite different from the behavior of most linear polymers, such as polyamides and polyesters. This phenomenon can be rationalized by assuming that in the glassy state this polyimide contains chain segments of either of the two conformations considered. Crystallization therefore depends, not only upon the mobility of the macromolecules, but also on rate and extent of conformational changes of the dioxopiperidine moiety during the orientation process.

Except for poly[(2,6-dioxo-1,4-piperidinediyl)dimethylene] (PCM6), which is highly crystalline, the other linear polymers of interest (PC6 and PC5) are amorphous. This is readily explained by the presence of an asymmetric center at C^3 of the ring moiety of the repeating unit.

Additional support for the chemical structure of the polymer PCM7 was obtained from mass spectroscopic studies[18]. Subjecting a polymer sample ($\eta_{red} = 2.7$) to 70 eV at 270 °C yielded $[-(CH_2)_3-CH(CH_2CO)_2N-]_2H$, *m/e* 307, as major fragment which corresponds to two repeating units of the polymer. When the monomer was introduced at 270 °C into the preheated source, signals appeared at *m/e* 154, 307, 460, and 613, after unreacted monomer had been flushed off. These values correspond to fragments of the general structure $[-(CH_2)_3-CH(CH_2CO)_2N-]_nH$ where *n* is 1, 2, 3, and 4. A possible mechanism for the formation of these fragments may entail a six-center pyrolysis reaction (see formula) followed by addition of a proton.



3.2 Viscosity-Molecular Weight Relations

The relationship between the viscosities of polymer solutions and polymer molecular weights was studied in detail for poly[(2,6-dioxo-1,4-piperidinediyl)trimethyline] (PCM7) and poly[(2,5-dioxo-1,3-pyrrolidinediyl)dimethylene] (PC6). Intrinsic viscosities were determined in *m*-cresol solutions and evaluated by using the Huggins equation

$$\eta_{sp}/c = [\eta] + k^1[\eta]^2C \qquad (1)$$

The Kuhn-Mark-Houwink-Sakurada equation

$$[\eta] = K_{w(n)} M_{w(n)}^{a} \quad (2)$$

was employed for correlating the viscosities with the molecular weights. The latter were obtained either from light-scattering ($\overline{M}_w$) or osmotic pressure measurements ($\overline{M}_n$). Values for the Huggins constant k^1 and the interaction parameters K and a are listed in Table 2.

Table 2. Values for k^1, $K_{w(n)}$, and a in equations (1) and (2) for PCM7 and PC6.

Polymer	k^1	a	K_w	K_n
PCM7	0.35	0.73	4.5×10^{-4}	7.5×10^{-4}
PC6	0.41	0.65	4.3×10^{-4}	

A Schulz-Flory distribution of molecular weights was indicated by a value of 2 for the ratio $\overline{M}_w/\overline{M}_n$.

The viscosity-molecular weight relations were also derived for these two polymers; the samples exhibited $\overline{M}_w$ values of up to 75000 (PCM7) and 150000 (PC6). However, considerably higher molecular weights are obtainable for these two systems (*e.g.* more than 300000 for PCM7).

3.3. Mechanical Properties

Tensile properties were determined for PCM7 and PC6 according to ASTM D1708 on films obtained by compression molding, and for PCM7 also on monofilaments obtained by melt extrusion and subsequent drawing (draw ratios between 4:1 and 6:1). The values obtained depended upon the molecular weights of the samples and upon the particular conditions of sample preparation. Since no attempts have yet been made to develop optimum processing conditions, the data listed in Table 3 may not be representative of ultimately attainable values. They show, however, that materials of considerable strength are readily obtained.

Table 3. Tensile properties of PCM7 and PC6.

	PCM7 Film	PC6 Film
Tensile strength [kg/mm²]	0.0827—0.124	0.0621—0.110
Elongation [%]	70—90	3—10
Modulus [a] [kg/mm²]	3.103—3.998	2.206—3.585
	PCM7 Monofilament	
Tensile strength [g/denier]	6—8.5	
Elongation [%]	12—16	
Tensile modulus [g/denier]	75—105	

[a] Calculated from the secant at 2% elongation.

The corresponding polymer samples were tested at relative humidities of 0% and 50%. It was found that the moisture content did not significantly affect the tensile properties. This is explained by the rather low equilibrium moisture regain that characterizes these polymers. At relative humidities of 50% and 100%, the moisture content of PCM7 was respectively 0.56 and 1.40%, whereas in case of PC6 it was 3.6 and 11.3%.

3.4. Thermal Characteristics

Differential thermal analysis, loss of stress birefringence, and torsion tests were used to determine the transition temperatures for the linear polyimides. The values are listed in Table 4 together with the main decomposition temperatures as determined by both differential thermal analysis and thermogravimetric analysis at a programmed heating rate of 10°C/min.

Table 4. Thermal analysis data of several polyimides.

	M.p. [°C]	Glass transition [°C]	Main decomposition [°C]
PCM6	>400	168—173	420
PCM7	281	85—91	460
PC6	—	127—135	400
PC5	—	205—210	410

Kinetics and Mechanism

4.1. Kinetic Findings

Information on possible reaction mechanisms was obtained from kinetic studies. The conversions of CM7 into the polyimide PCM7 and of DCM5 into isopropylidene succinimide have been considered as representative examples of the polymerization and rearrangement reactions respectively. In evaluation of experimental polymerization data the extent of reaction

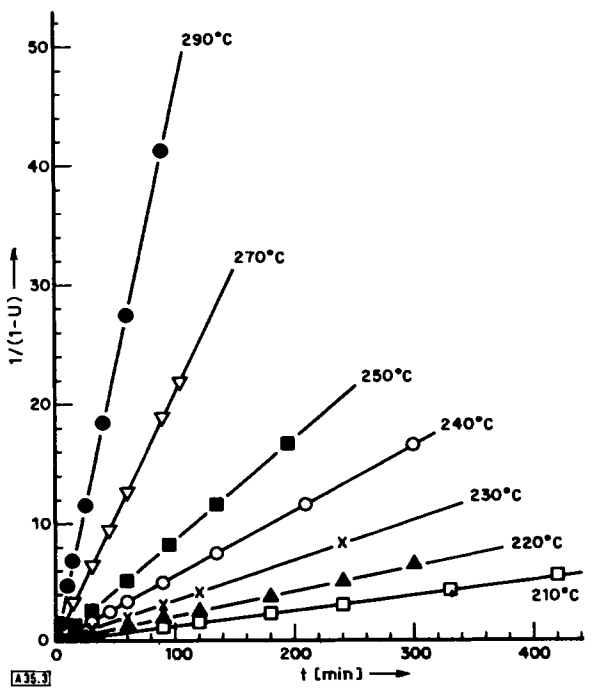


Fig. 3. Second-order rate plot of conversion data for polymerization of CM7 [15].

was assumed to depend upon the momentary concentration of imide groups (I) which is related to the respective concentrations of both unreacted monomer (M) and polymer molecules (c) by the stoichiometric relation:

$$I = M_0 - M - c = U - c \quad (3)$$

Where M_0 is the initial monomer concentration, and U the monomer conversion[15]. From eq. (3) it follows that

$$dI/dt = -dM/dt - dc/dt = dU/dt - dc/dt \quad (4)$$

Experimental data are plotted in Figures 3 and 4. These plots show that both monomer conversion and chain growth

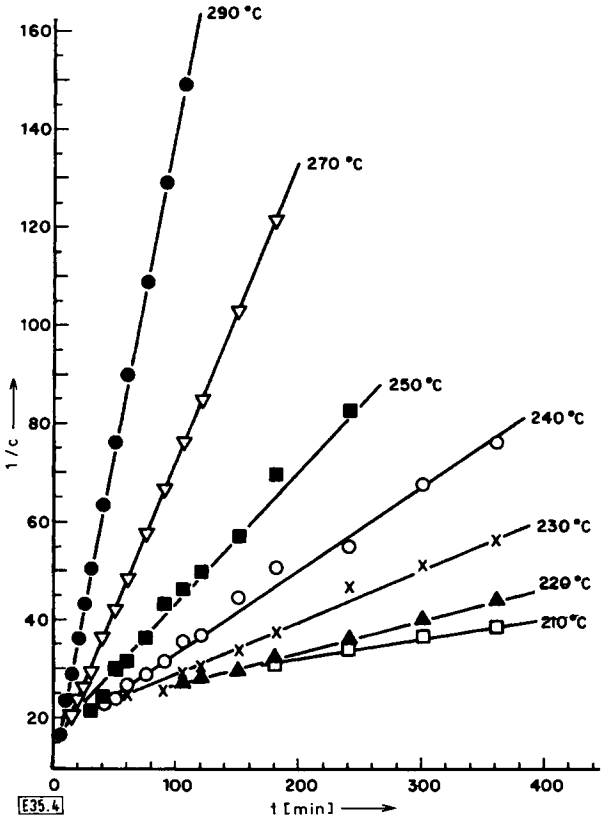

Fig. 4. Second-order rate plot for chain growth on polymerization of CM7 [15].

are second order reactions. For the main phase of the polymerization process considered, the rate of polymerization was found to be adequately represented for the temperature range of 210 to 290 °C by eq. (5):

$$dI/dt = k_p(M^2 + 3.167c^2)$$
$$k_p = 74.9 \times 10^7 \exp(-23800/RT) \quad (5)$$

The conversion of DMC5 into isopropylidene succinimide was studied at the temperatures of 225, 232, and 240 °C[10]. This reaction is also of second order (Fig. 5). The mole fraction x of DMC5 was calculated from the relation $x = a_1/(a_1 + a_2)$ where a_1 and a_2 are the areas of the peaks at $\delta = 1.10$, 1.35 and 1.78, 2.20, respectively, in the corresponding NMR spectrum.

The slopes of the straight lines in Figure 4 represent values for the overall rate constant k_r at the particular temperatures. The temperature dependence of k_r was found to obey the Arrhenius equation, and the activation energy E and the pre-

(the lactam carbonyl function) and a nucleophile (the carboxship

$$\log k_r = \log A - E/(4.574T) \quad (6)$$

to be $A = 25.85 \times 10^{12}$ and $E = 34.346$ kcal/mol.

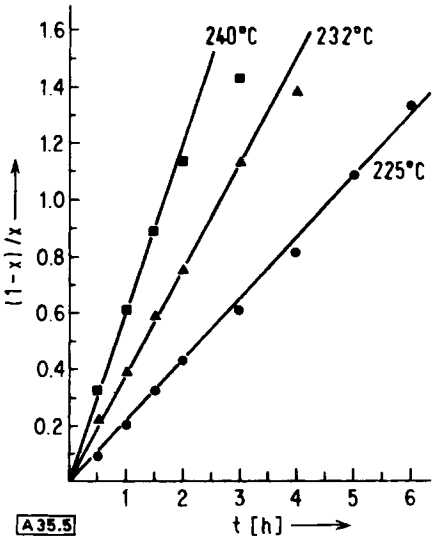

Fig. 5. Conversion of DMC5 into isopropylidene succinimide.

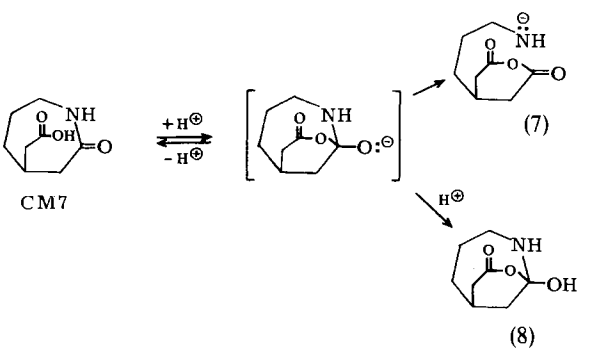
4.2. Mechanism

Comparing the structures of the lactams listed in Table 1 with those of their reaction products indicates that conversion into polymers or transformation into different monomeric ring systems involves isomerization. In the case of CM7, isomerization could be explained in terms of the commonly accepted carbonyl addition-elimination mechanism [eq. (7)][16].

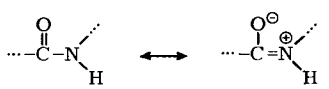


Polymer formation would then consist in polycondensation of the isomerization product *via* an intermolecular reaction between the amino- and anhydride functions of the 3-(3-aminopropyl)glutaric anhydride. Whereas second order kinetics can be readily accommodated for this polycondensation which affects the concentration of the polymer molecules c, a simple isomerization according to eq. (7) should obey first order kinetics. Operation of second order kinetics over fairly large ranges of monomer conversion therefore suggests that the isomerization process may be governed by a more complex mechanism.

On reaction with carboxylic acids, lactams act as nucleophiles of moderate basic power and thus convert acids into their conjugate bases. Since the carboxymethyl- and carboxy lactams under consideration contain both an electrophilic group (the lactam carbonyl function) and a nucleophile (the carboxylate ion) in the same molecule, a bicyclic intermediate of the type shown in eq. (7) will form if the configuration of the particular lactam is conducive to ring formation. The competitive intermolecular reaction is thermodynamically less favored in this case.

It is therefore reasonable to postulate formation of a bicyclic intermediate as the principal initial reaction. Once formed it may undergo any of three fast reactions: (i) elimination of the internal nucleophile from the lactam carbonyl carbon atom; (ii) elimination of the amino moiety; (iii) addition of a proton. The first reaction would be a reversal of the cyclization and thus regenerate the original lactam derivative. The second reaction is the one depicted in eq. (7) for CM7. It is however incompatible with the observed kinetics. Furthermore, this reaction could not participate in the rearrangement of DMC5 to isopropylidenesuccinimide since no opening of the lactam ring was indicated. The third reaction, considered less likely in most of the ordinary addition-elimination reactions involving carboxylic acid derivatives, entails the addition of a proton to the electron pair that stems from the carbon-oxygen double bond of the lactam and has become localized on the oxygen atom.

This addition, as illustrated in eq. (8) for CM7, stabilizes the bicyclic structure by precluding the attainment of coplanarity required for regeneration of the amide moiety.



For the lactam derivatives considered addition of a proton therefore seems to be the most likely reaction. It apparently leads to stable bicyclic structures that have a finite existence and are presumed to be the principal reaction intermediates. The overall kinetics of the conversion of the particular lactam derivatives may thus be determined by reactions involving these species. The second order kinetics observed for the conversion of both the polymerizing lactam derivatives and those that rearrange to monomers may be explained by mechanisms that involve either electrophilic catalysis or interaction between two of the considered protonated species.

Conceivable mechanisms entailing catalysis by ionizable carboxy groups are shown in Figure 6 for the conversion of CM7, rearrangement of DMC5, and isomerization of DMC6.

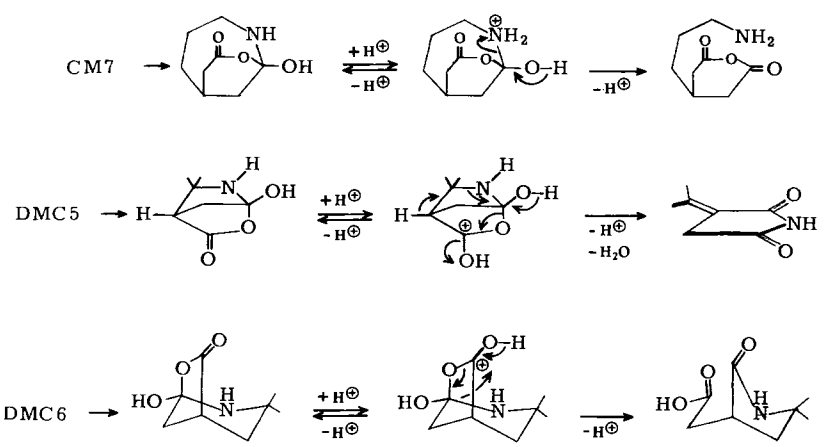


Fig. 6. Electrophilic catalysis in the reaction of carboxy-substituted lactams.

The rate of conversion may be expressed by eq. (9):

$$-dM/dr = k_c[COOH][M] = k_c[M]^2 \qquad (9)$$

according to which the second order kinetic representation can be readily rationalized.

Alternative mechanisms characterized by interactions between intramolecularly protonated species, are illustrated in Figure 7 for the conversion of CM7 and the rearrangement of DMC5. Both involve bimolecular reactions. Whereas the former is an association reaction resulting in the linear dimer of the corresponding polymer, the formulation of the latter corresponds to that of an exchange reaction leading to the succinimide derivative and regeneration of the original pyrrolidone derivative.

Both are multi-center reactions proceeding with elimination of water and rearrangement *via* a six-membered cyclic transition state. In both cases the arrangement yields a coplanar species that has a lower free energy than the strained and highly organized corresponding polycyclic structure. In case of DMC5 the coplanar structure represents the final product, whereas in case of CM7 the coplanar iminolactone rearranges *via* a four-center reaction to the energetically even more favored linear dimer.

Whether it is electrophilic catalysis or a complex bimolecular reaction that constitutes the principal mechanism for the conversion of the particular lactam derivatives cannot be deduced conclusively from presently available information. However, mass spectroscopic examination[18] of low molecular weight polymer which had been obtained from CM7 at temperatures between 200 and 220 °C showed the presence of a *cyclic* dimer. This was not observed in case of high molecular weight samples obtained by polymerization above 280 °C. It could also be shown that this cyclic structure did not result from pyrolysis reactions; it actually disappeared upon prolonged heating at 275 to 300 °C while the linear pyrolysis products $[-(CH_2)_3CH(CH_2CO)_2N-]_nH$ mentioned in Section 3.1 started to appear. This is indicative of the ability of the cyclic dimer to polymerize by ring opening. A possible mechanism for its formation during the initial polymerization reaction is shown in Figure 8.

Molecular models of this cyclic dimer are strain-free.

Detection of the cyclic dimer in the initial reaction products lends some support for the bimolecular reaction mechanism shown in Figure 7. Formation of a bicyclic structure, involving intramolecular nucleophilic addition of the carboxylate ion to the lactam carbonyl group and addition of a proton, appears

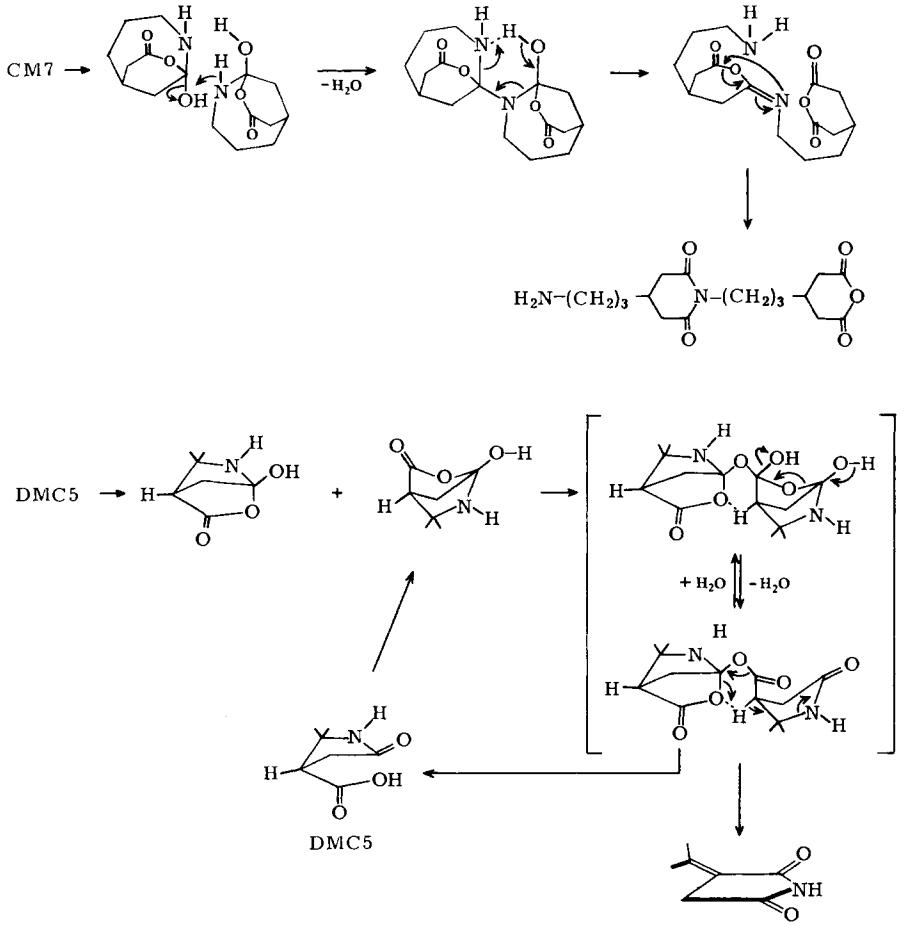

Fig. 7. Bimolecular reactions occurring in the conversions of carboxy-substituted lactams.

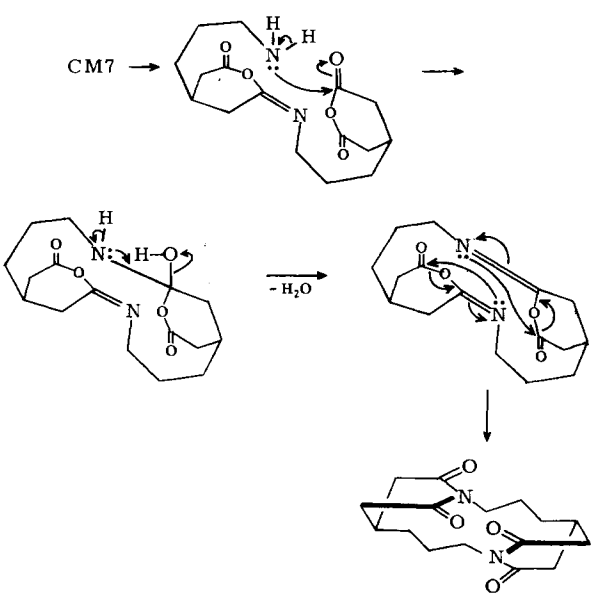

Fig. 8. Formation of cyclic dimer of CM7.

to be the initial reaction in either mechanism. This postulate is further substantiated by the observation that neither polymerization nor rearrangement occurred when the corresponding ester lactams were employed in place of the carboxylactams.

The type of reactions that could be expected in case of the ester lactams was indicated when addition was carried out with 1,5,6,7-tetrahydroazepin-2-one and ethyl phenylacetate. Instead of the expected Michael adduct to the double bond a bicyclic compound was obtained and identified as 6-phenyl-1-azabicyclo[3.2.2]nonane-7,8-dione[17]. As shown in Figure 9, the Michael adduct undergoes cyclization by nucleophilic

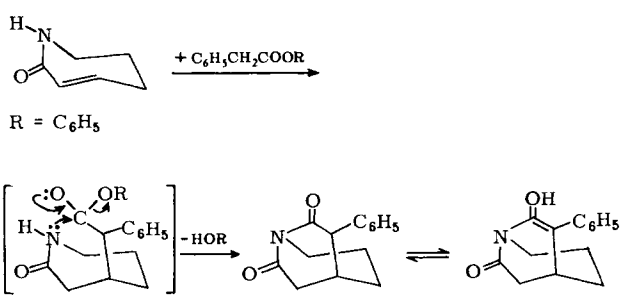

Fig. 9. Formation of 6-phenyl-1-azabicyclo[3.2.2]nonane-7,8-dione.

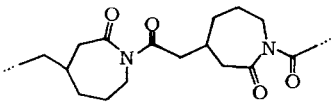
attack of the amide function on the ester carbonyl with subsequent elimination of ethanol. The formation of this compound demonstrates rather clearly the effect of a substituent on the ease of cyclization. Under comparable conditions this particular reaction did not occur when the phenyl group was replaced by a hydrogen atom, neither was there any indication in this case for the occurrence of the corresponding intermolecular reaction which would have resulted in a polymer having seven-membered rings.



Furthermore, with respect to the ring size, it is well known that among the lactams the six-membered 2-piperidones exhibit the least tendency toward ring-opening polymerization, whereas the five-membered 2-pyrrolidones polymerize rather readily. If one were to assume that the phenomena related to the carboxy group containing lactams were merely the result of some type of activation of the amide bond, then the reactivities of the particular derivatives should in any instance parallel those of the corresponding parent lactams. We have seen that this is not the case: CM6 polymerizes fairly easily upon heating, whereas CM5 did not react at all under corresponding conditions. It has therefore been concluded that a bicyclic intermediate (see, *e.g.*, Fig. 10a) is the reactive species in both polymerization and rearrangement, and that the ability to form such a structure is a necessary condition for the conversion of carboxy- and carboxymethyllactams. The nonreactivity of the CM5 thus appears to be a consequence of this compound's inability to form a corresponding bicyclic structure, as it is indicated in Figure 10b and easily demonstrated with molecular models.

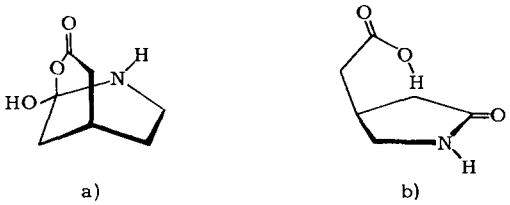


Fig. 10. a) Bicyclic intermediate derived from 2-oxopiperidine-4-acetic acid (CM6); b) structure of 5-oxopyrrolidine-3-acetic acid (CM5).

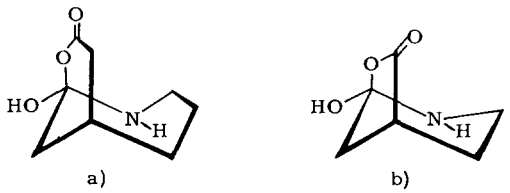

Fig. 11. Bicyclic intermediates derived from a) 2-oxoperhydroazepine-4-acetic acid (CM7) and b) 2-oxopiperidine-4-carboxylic acid (C6).

There appears to be a reciprocal relation between the extent of reaction and the degree of bond angle distortion in the corresponding bicyclic intermediate. Bicyclic structures characterized by essential absence of bond angle bending pertain, as shown in Figure 11, to CM7 and C6. For both compounds the extent of reaction was particularly high with respect to both the monomer conversion and the degree of polymerization. In case of the 6,6-dimethylpiperidone derivative, isomerization to the 5,5-dimethyl-2-oxopyrrolidine-3-acetic acid was essentially quantitative. This is another instance where elimination of nonbonded interactions by introduction of substituents results in a ring formation rather than polymerization.

In contrast, both the conversion in rearrangement reactions and the molecular weights in case of polymerization were low when the attainment of the postulated bicyclic intermediate was accompanied by appreciable bond angle distortion, as indicated for the pyrrolidone derivatives. Whereas CM7, as shown in Figure 11a, can form the bicyclic intermediate with essentially no distortion of bond angles, stereo models indicate that a corresponding structure derived from αCM7 is not favored, though not impossible, since it would be highly strained. It is conceivable that this strain contributes to the observed intermolecular crosslinking occurring upon polymerization, which in this case should result in a polymer structure containing succinic imide units.

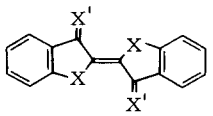
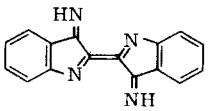
"Indigo Diimine"—A Tautomer with Unsymmetrical Structure[1]

By *Hartmut Sieghold* and *Wolfgang Lüttke*[*]

We have investigated the ways in which the light absorption of the indigo dyes *(1)* is influenced by variation of the electron-acceptor groups X'.

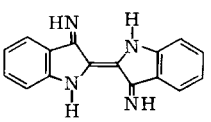


(1a), X = NH, X' = O
(1b), X = X' = NH[≡*(2a)*]
(1c), X = S, X' = NH
(1d), X = S, X' = O

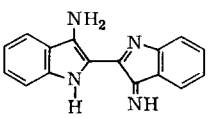


(3)

On spectroscopic characterization of "indigo diimine" *(1b)*[2] we were surprised to find that the substance does not exist in the symmetrical form *(2a)* but in the tautomeric form as 3-amino-2-(3-imino-2-indolyl)-1*H*-indole *(2b)*, both in solution and in the solid state.



(2a) [≡*(1b)*]



(2b)

This structural assignment is based on the following arguments analysis of the IR spectrum (Table 1):

1) The fact that the spectrum is more complex than that of the symmetrical indigo *(1a)* indicates the absence of a center of symmetry.

2) *Four* NH stretching vibrations appear in the IR spectrum of "indigo diimine" both in the solid state and in C_2Cl_4 solution.

3) Partial deuteration[3] proved that the bands at 3441 and 3388 cm^{-1} belong to a primary amino group (appearance of a new NH absorption of the NHD group at 3420 cm^{-1}).

4) The absorption at 3227 cm^{-1} must be assigned to the NH stretching vibration of the ketimino group of *(2b)*[4]. For comparison we synthesized dehydroindigo diimine *(3)* (3219 cm^{-1}) and thioindigo diimine *(1c)*[5] (3234 cm^{-1}).

5) We assign the remaining band at 3286 cm^{-1} to the NH stretching vibration in the indole ring of *(2b)*. [Cf. ν_{NH} of indigo *(1a)*: 3268 cm^{-1}.]

6) ^{15}N labeling of the exocyclic nitrogen atoms shifts the bands at 3441, 3388, and 3227 cm^{-1} strongly, whereas the band at 3286 cm^{-1} exhibits only a small isotope effect. This supports the assignment given in 3–5 above and proves the presence of *(2b)*. The small isotope effect of the band at 3286 cm^{-1} is explained by strong coupling of this stretching vibration with ^{15}N—H vibrations favored by intra- and inter-molecular hydrogen bonding.

7) Four new bands, not present in the indigo spectrum, appear between 1650 and 1500 cm^{-1}; they belong to the complex vibrations of the vinylogous amidine system NH_2—C=C—C=N—.

In addition there are arguments from the ^1H-NMR spectrum in favor of the unsymmetrical structure *(2b)*.

Theory[6] (HMO and PPP calculations) predicts a *hypsochromic shift* of the long-wavelength absorption maximum of the *symmetrical* indigo dye *(1)* when the carbonyl groups (X' = O) are replaced by ketimino groups (X' = NH). We were able to confirm this in the cases of thioindigo *(1d)* which cannot undergo tautomerism and its diimine *(1c)*: their long-wavelength bands (in $CHCl_3$) are at 547 and 518 nm, respectively[6].

Theory also requires that an *unsymmetrical* form such as *(2b)* always absorb at *longer wavelength* than the *symmetrical* one. Experimentally, the absorption maximum of *(2b)* (in $CHCl_3$ solution) is observed at 617 nm, which compares with 604 nm for indigo *(1a)*.

All physical data show, in agreement with theoretical studies, that the unsymmetrical tautomer *(2b)* is the stable form in the solid state and in solution.

Table 1. NH stretching vibration frequencies ν of 3-amino-2-(3-imino-2-indolyl)-1*H*-indole *(2b)* in the associated and monomeric state, together with isotopic shifts Δν on partial deuteration and ^{15}N labeling.

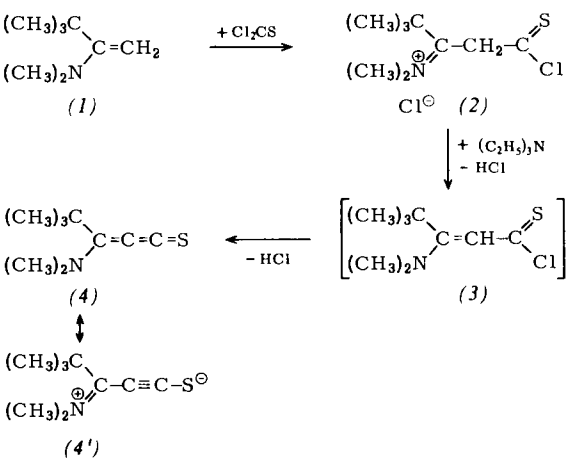
Synthesis of a Stable Substituted Thiacumulene: The Concept of Cumulogy

By *Michel Parmantier, Jean Galloy, Maurice Van Meerssche,* and *Heinz Günter Viehe*[*]

Hetero-trienes and -tetraenes having cumulated double bonds are rare, and expectedly very reactive compounds. We have now synthesized 3-dimethylamino-4,4-dimethyl-1,2-pentadiene-1-thione *(4)*.

Addition of thiophosgene to a solution of 2-dimethylamino-3,3-dimethyl-1-butene *(1)* in ether forms the salt *(2)* which loses HCl on treatment with triethylamine at $-20°C$ to produce *(4)*. The vinylogous thiocarbamoyl chloride *(3)* assumed as intermediate was not isolated.



Compound *(4)* melts at 114°C. Further physical data: IR ($CHCl_3$): 2980, 2035, 1530, 1405, 1370 cm^{-1}; UV ($CHCl_3$): $\lambda_{max} = 380$ nm; ^{1}H-NMR ($CDCl_3$): $\delta = 3.4$ (6H, s); 1.4 ppm (9H, s); mass spectrum: $m/e = 169$ (M^+), 154 ($M - CH_3$), 125 [$M - N(CH_3)_2$], 112 [$M - C(CH_3)_3$]; 68 ($S{=}C{=}C{=}C^+$); relative molecular mass (osmometry in $CHCl_3$): 171.

While the expected resonance form *(4')* does not show up in the IR spectrum, its participation is apparent from the ^{13}C-NMR spectrum [two *N*-methyl signals at 41.1 and 47.6 ppm in C_6D_6; only one *N*-methyl signal at 45.8 ppm for *(1)*] and likewise from the X-ray analysis [mean values of two crystallographically independent molecules are shown in *(4a)*].

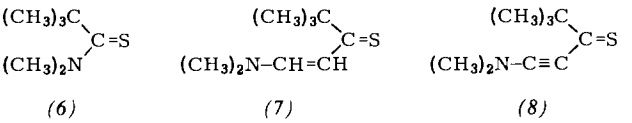
Prof. Dr. M. Van Meerssche and J. Galloy
Laboratoire de Chimie Physique et Cristallographie de l'Université de Louvain

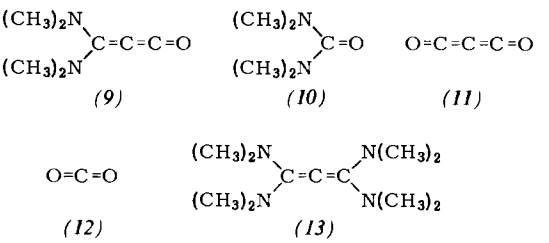
On attempted recrystallization from hexane, *(4)* hydrolyzed and dimerized to *(5)* whose structure was established by X-ray analysis.

We regard compound *(4)* as the "cumulog" of *(6)*, in the same way as *(7)* and *(8)* can be viewed as vinylog and ethynylog of *(6)*, respectively.



(6) *(7)* *(8)*

This cumulogy concept appears heuristically useful in the synthesis of new classes of compounds and in predicting their reactivity. Thus, one might regard the still hypothetical compound *(9)* as the cumulog of tetramethylurea *(10)*, the relatively stable carbon suboxide *(11)* as the cumulog of carbon dioxide *(12)*, and our recently reported[1] allenetetramine *(13)* is the cumulog of methanetetramine. Cumulogous phosphorus ylides are also known[2].



(9) *(10)* *(11)* *(12)* *(13)*

Synthesis of (4):

To a stirred solution of *(1)* (2.5 g, 0.02 mol) and triethylamine (5.6 ml, 0.04 mol) in ether (50 ml) at $-20°C$ is added (during 10 min under nitrogen) thiophosgene (2.3 g, 0.02 mol) dissolved in diethyl ether (20 ml). Stirring is continued until room temperature is attained (*ca.* 30 min). After filtration of the reaction mixture the filtrate is concentrated in vacuum until crystallization occurs. Recrystallization from ether or hexane with traces of dichloromethane affords 0.51 g (15%) of *(4)*.

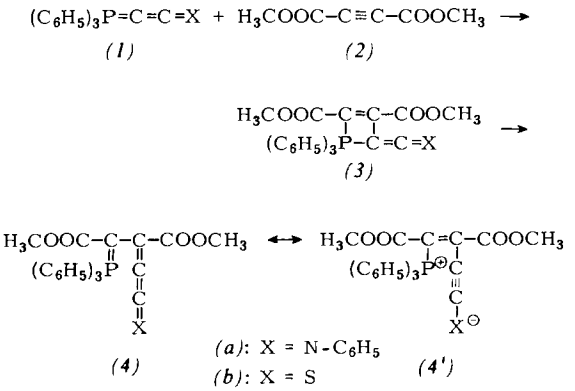
Synthesis of a Stable Alkylideneketenimine and an Alkylidenethioketene

By *Hans Jürgen Bestmann, Günter Schmid,* and *Dieter Sandmeier*[*]

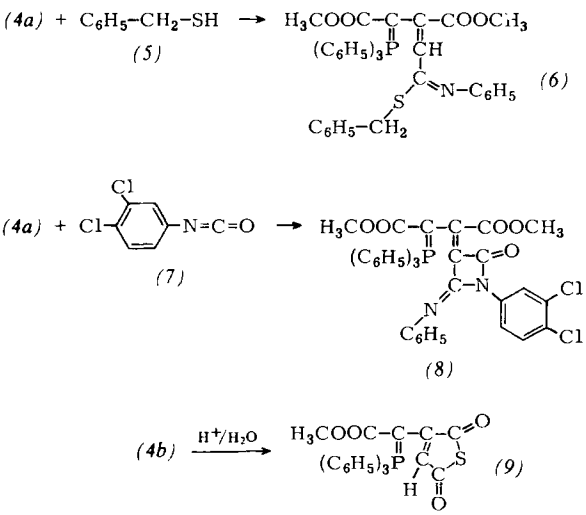
Alkylideneketenimines have previously been known only as unisolable, very reactive intermediates[1], and alkylidenethioketenes have not so far been found at all. We have now synthesized the first stable members of both classes of compounds, by reaction of *N*-phenylketeniminylidenetriphenylphosphorane *(1a)*[2] or thioketenylidenetriphenylphosphorane *(1b)*[2] with dimethyl acetylenedicarboxylate *(2)*.

[*] Prof. Dr. H. J. Bestmann, Dr. G. Schmid, and Dipl.-Chem. D. Sandmeier
Institut für Organische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Henkestrasse 42 (Germany)



We assume that compounds *(1)* and *(2)* first yield 1-λ^5-phospha-2-cyclobutenes *(3)*, which transform into the red *N*-phenylalkylideneketenimine *(4a)* or the ocher-colored alkylidenethioketene *(4b)* by valence isomerization[3].

(4a): Yield 70%; m.p. 179—180°C; IR: 2080 ($\nu_{C=C=C=N}$), 1724, 1667 cm^{-1} (ν_{CO}); ^{1}H-NMR: τ=6.20, 6.76 ($2OCH_3$); ^{31}P-NMR: δ = −16.88 ppm[4]; MS: M^+ 519.—*(4b)*: Yield 74%; m.p. 170—171°C; IR: 2000 ($\nu_{C=C=C=S}$), 1720, 1690 cm^{-1} (ν_{CO}); ^{1}H-NMR: τ=6.21, 6.68 ($2OCH_3$); ^{31}P-NMR: δ = −15.94 ppm[4]; MS: M^+ 460.



The stability of compounds *(4)* can be explained by the possibility of resonance *(4)* ↔ *(4')*. *(4a)* is more reactive than *(4b)*. We attribute this to the preponderance of the resonance structure *(4b')* that results from the low tendency of sulfur to undergo double-bonding. With phenylmethanethiol, *(4a)* reacts to give the phosphorane *(6)* (m.p. 118°C, dec.) and with 3,4-dichlorophenyl isocyanate *(7)* by cycloaddition to give *(8)* (m.p. 215°C, dec.). If aqueous hydrochloric acid is allowed to act on *(4b)* the thioanhydride *(9)* (m.p. 218°C) is formed. All the new compounds give the expected molecular spectroscopic results and correct elemental analyses.

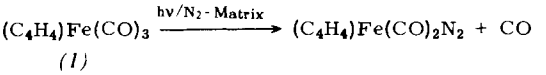
μ-Carbonylbis(cyclobutadienecarbonyliron), a Complex Containing an Iron-Iron Triple Bond—A Model for the Unusual Behavior of $Fe(CO)_4$ in Solution?[**]

By *Ingrid Fischler*, *Knut Hildenbrand*, and *Ernst Koerner von Gustorf*[*]

In continuation of our photochemical studies on dinitrogen complexes of transition metals[1] we have examined whether the photochemical substitution of CO by N_2 in arenetricarbonylchromium complexes discovered by *Sellmann et al.*[2] can also be applied to dienecarbonyliron complexes. Preliminary experiments with cyclohexadienetricarbonyliron and bis(cyclohexadiene)monocarbonyliron[3a] proved unsuccessful. However, parallel studies by *Rest*[3b] showed that in an N_2 matrix at 20°K CO can be replaced photochemically by N_2 in cyclobutadienetricarbonyliron *(1)* and in trimethylenemethanetricarbonyliron.



Irradiation ($\lambda \geq 280$ nm) of *(1)* in tetrahydrofuran (THF) at −40°C with passage of N_2 gave rise to a color change from yellow to orange-red. On removal of the solvent (−20°C, exclusion of light) the reaction mixture turned dark red, and an extremely sensitive dark red product *(2)* containing no nitrogen was isolated from the residue. According to elemental analysis and its mass spectrum, which contained the fragment ions $[M-2CO]$, $[M-3CO]$, and $[M-3CO-C_4H_4]$ in addition to the molecular ion ($M=300$), the composition $(C_4H_4)_2Fe_2(CO)_3$ is indicated for compound *(2)*. Cryoscopy in benzene yielded a molecular weight of 339. According to its IR spectrum (in pentane, −20°C) compound *(2)* contains two terminal CO groups bonded to iron [ν_{CO}: 2051 (s) and 1980 (vs) cm^{-1}] and a bridging CO group [ν_{CO}: 1861 (vs) cm^{-1}].

In the ^{1}H-NMR spectrum (in $C_6D_5CD_3$, −30°C) a sharp singlet is observed at τ = 5.78 ppm (paramagnetic shift of 1.02 ppm relative to *(1)*). The ^{13}C-NMR data of *(1)* and *(2)* are listed in Table 1. The magnetic equivalence of the carbonyl

Table 1. ^{13}C-NMR data of $(C_4H_4)_2Fe_2(CO)_3$ *(2)* and $(C_4H_4)Fe(CO)_3$ *(1)*.

	(2)	*(1)*
$\delta_{C_4H_4}$ [ppm from TMS]	77.8	64.5
δ_{CO}	238.8	214.9

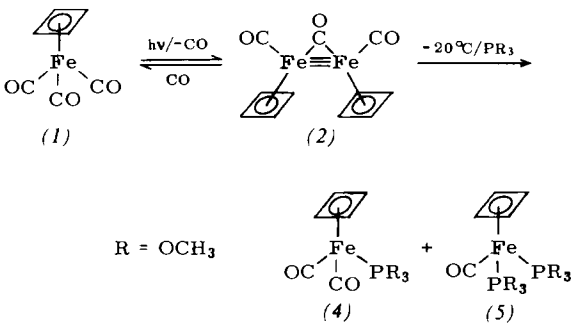
433 Mülheim-Ruhr, Stiftstrasse 34—36 (Germany)

[**] A preliminary report of our findings was presented at the VI. Int. Conf. Organometal. Chem., Amherst, August 1973: *E. Koerner von Gustorf, I. Fischler, F.-W. Grevels, D. Schulz*, and *R. Wagner*, Abstr. p. 46.

C atoms can be attributed to the known fast exchange of such groups[4]; the equivalence of the C atoms linked to protons and the agreement of the ^1H-^{13}C coupling constants of *(1)* and *(2)* suggest that two intact and similar cyclobutadiene units are present in *(2)*[5].

At −20°C, *(2)* reacts quantitatively with CO to give *(1)*. Treatment of *(2)* with an excess of trimethyl phosphite furnishes a 1:1 mixture of the cyclobutadienecarbonyliron complexes *(4)* and *(5)*. For purposes of comparison, compounds *(4)* and *(5)* were prepared by photolysis of *(1)* in the presence of $P(OCH_3)_3$[3a] [*(4)*: ν_{CO}: 1988, 1932 cm^{-1}; $\varepsilon = 2840$, 3930 l mol^{-1} cm^{-1}; *(5)*: ν_{CO}: 1915 cm^{-1}; $\varepsilon = 2030$ l mol^{-1} cm^{-1}].

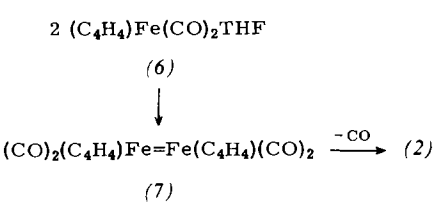
The reactions of *(2)* with CO and $P(OCH_3)_3$ provide additional evidence for intact cyclobutadiene ligands in *(2)*.



All known iron(0) compounds conform to the 18-electron rule[6]. Since *(2)* is diamagnetic we propose that this new complex has a structure containing an Fe—Fe triple bond[15]. The intensity of the CO stretching vibrations indicate the terminal CO groups[7]—and hence also the cyclobutadiene units—to have a *cis* configuration.

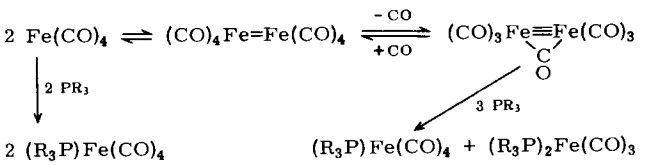
The postulated triple bond between two transition metal atoms is not without its parallels, even though *(2)* apparently represents the first example in the case of iron[8]. We hope that X-ray structure analysis will provide information about the participation of σ-, π-, and δ bonding components. (The necessary low temperature technique is currently being developed by *C. Krüger*.) The coordination in *(2)* corresponds to that in $Fe_2(CO)_9$[9] if it is imagined that two bridging CO groups are replaced by two Fe—Fe bonds.

IR spectroscopy reveals that only one CO is initially lost on photolysis of *(1)* at −40°C in THF; bands at 1975 and 1900 cm^{-1} are to be assigned to the complex $(C_4H_4)Fe(CO)_2THF$ *(6)*. (Confirmatory evidence for the presence of *(6)* comes from reaction with $P(OCH_3)_3$: addition at −40°C affords exclusively compound *(4)*.) The CO stretching vibrations of *(2)* appear on removal of the solvent at −20°C (2051, 1980, 1861 cm^{-1}).



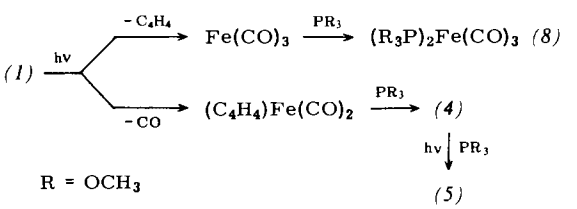
The formation of *(7)* from *(6)* corresponds to that of $Fe_2(CO)_8$ from $Fe(CO)_4$[10]. Transformation of *(7)* into *(2)* with loss of CO apparently proceeds extremely readily since *(7)* could not be observed under our experimental conditions.

The formation of *(2)* from *(6)* *via* *(7)* and the smooth reaction of *(2)* with $P(OCH_3)_3$ may contribute to our understanding of a surprising observation: $Fe(CO)_4$, prepared, for example, by irradiation of $Fe(CO)_5$[10d], from $Fe_2(CO)_9$[11], or from olefintetracarbonyliron[10c, 12], reacts with phosphanes and phosphites to give a mixture of $Fe(CO)_4(PR_3)$ and $Fe(CO)_3(PR_3)_2$ under conditions in which $Fe(CO)_4PR_3$ is not attacked by PR_3. In our opinion this finding can be explained as follows:



Conversion of *(6)*, which can be regarded as substituted $Fe(CO)_4$, into *(2)* provides a model supporting this proposal.

Opposing views have been expressed[13] concerning the primary step of the photolysis of $(C_4H_4)Fe(CO)_3$: whereas *Gunning et al.* favor elimination of cyclobutadiene with formation of $Fe(CO)_3$, *Chapman et al.* were only able to observe the elimination of CO in a matrix. We have therefore examined the photoreaction of *(1)* with trimethyl phosphite (in pentane) which can be expected to afford the following products:



After 40% conversion of *(1)*, only *(4)* could be observed by IR spectroscopy; comparative measurements showed that we would have been able to detect 10% of *(8)* in admixture with *(4)*. Hence it follows that the quantum yield for elimination of CO is at least 10 times higher than that for the loss of cyclobutadiene[14].

Procedure:

Compound *(1)* (8 mmol) was dissolved in dry THF (120 ml) and irradiated at −40°C for 6 h with simultaneous passage of nitrogen in an immersion apparatus with a Philips HPK 125 W high pressure mercury lamp. After removal of solvent at −20°C unreacted *(1)* was also removed by molecular distillation *in vacuo*. Extraction of the black residue with pentane (10 ml) at −20°C and cooling of the solution to −70°C afforded compound *(2)* in approximately 8% yield.

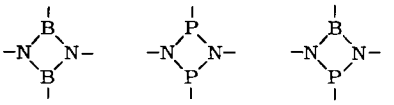
[14] *J. D. Black, J. Boylan, P. S. Braterman*, and *W. J. Wallace*, J. Organometal. Chem. *63*, C 21 (1973). These authors replied to the arguments of *Chapman et al.* by suggesting that loss of the relatively voluminous cyclobutadiene in a matrix defied detection because of rapid reverse reaction in the cage. Our observations indicate that this objection has little, if any, significance.

[15] *Note added in proof*: In the meantime a complex similar to *(2)* has been obtained on photolysis of 1,2-diphenyl-3,4-di-*tert*-butylcyclobutadienetricarbonyliron; however, all CO are bridging in this compound. The Fe-Fe distance of 2.177 Å agrees with a triple bond [*S. Murahashi, T. Mizoguchi, T. Hosokawa, I. Moritani, Y. Kai, M. Kohara, N. Yasuoka*, and *N. Kasai*, J. C. S. Chem. Comm. *1974*, 563].

1,3,2,4-Diazaphosphaboretidines: A Four-Membered Boron-Nitrogen-Phosphorus Heterocycle[**]

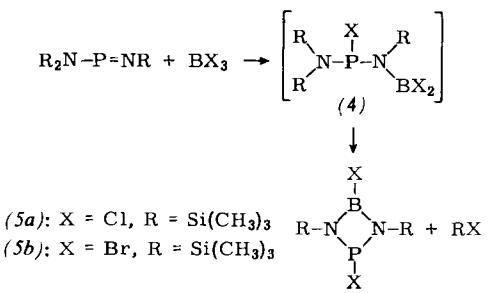
By *Edgar Niecke* and *Wolfhelm Bitter*[*]

Heterocycles of types *(1)* and *(2)* have been known for a long time[1].



(1) *(2)* *(3)*

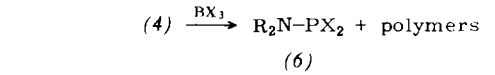
In the context of our studies on "phosphazenes" having phosphorus in an unusual coordination state[2] we have now succeeded in synthesizing cyclic compounds of novel type *(3)* by reaction of bis(trimethylsilyl)aminotrimethylsilyliminophosphane[3] with boron halides.



(4)

(5a): X = Cl, R = $Si(CH_3)_3$
(5b): X = Br, R = $Si(CH_3)_3$

Evidence for the transient formation of an iminophosphane-boron trihalide adduct *(4)* is provided by the appearance of bis(trimethylsilyl)aminodihalophosphanes *(6)*[4] as by-products: they are either formed directly from *(4)* or by the action of boron halide.



(6)

1,3,2,4-Diazaphosphaboretidines *(5)* are stable in the absence of moisture; the corresponding dihalophosphanes *(6)* undergo significant loss of trimethylsilyl halide to form vitreous decomposition products, even at room temperature. The composition and structure of the compounds were established by elemental analysis and mass, vibrational, and NMR (^{1}H, ^{11}B, ^{31}P) spectra.

The mass spectrum [*m/e* (rel. int.)][5] contains the molecular ions M 286 (25%) *(5a)*, M 374 (14%) *(5b)*, and M 261 (20%) *(6a)*, as well as the following characteristic fragments: $M-CH_3$ 271 (100%), M−Cl 251 (12%), $ClPNSi(CH_3)_2$ 138 (49%), $ClBNSi(CH_3)_2$ 118 (35%), $PNSi(CH_3)_3$ 118 (65%), $BNSi(CH_3)_3$ 98 (48%); $M-CH_3$ 359 (15%), M−Br 295 (81%), $BrPNSi(CH_3)_2$ 182 (21%), $BrBNSi(CH_3)_2$ 162 (22%), $PNSi(CH_3)_3$ 118 (100%), $BNSi(CH_3)_3$ 98 (54%); and $M-CH_3$ 246 (20%), M−Cl 226 (25%), $ClPNSi(CH_3)_2$ 138 (100%), $PNSi(CH_3)_3$ 118 (57%).

The stretching vibrations of the skeleton for the heterocycles *(5a)* and *(5b)* (partially with isotopic splittings) are observed at[6]: *(5a)*: 1280 s (1281 m, p), 1224 vs (1223 s, dp), 1064 vs (1065 ss) cm^{-1}; *(5b)* 1279 s (1269 m, p), 1217 vs (1218 s, dp), 1038 vs (1040 ss) cm^{-1}.

The ^{11}B- and ^{31}P-NMR data (50% solution in C_6H_{12}, $F_3B{\cdot}O(C_2H_5)_2$ and 85% H_3PO_4, respectively, as external standard) confirm the coordination number 3 for boron and phosphorus in accord with the structures shown: $\delta_{^{11}B} = -30$ *(5a)*, −27 ppm *(5b)*; $\delta_{^{31}P} = -171.7$ *(5a)*, −191.0 *(5b)*; and −186.1 ppm *(6a)*.

In the ^{1}H-NMR spectrum (30% solution in CH_2Cl_2, TMS internal standard) the trimethylsilyl protons are expectedly observed as a doublet: $\delta_{^1H} = -0.26$ *(5a)*, −0.28 *(5b)*, −0.42 ppm *(6a)*; $^4J_{HP} = 0.68$ *(5a)*, 0.66 *(5b)*, and 2.58 Hz *(6a)*.

Experimental:

(5a) and *(6a):* BCl_3 (15 g, 0.13 mol) is condensed into a solution of $(R_3Si)_2NPNSiR_3$ (28 g, 0.1 mol) in light petroleum (100 ml) contained in a 250-ml two-neck flask fitted with two reflux condensers (−70 °C), moisture being rigorously excluded. The reaction mixture is then stirred for 1 h with cooling (< −10 °C). After removal of the solvent and R_3SiCl in a water-jet vacuum at room temperature, the volatile fraction (up to 90 °C/0.1 torr)[7] is separated from the polymeric component of the reaction mixture. Lower boiling fractions (up to 40 °C/0.1 torr)[7] are collected separately and fractionated over a "slit-tube" column[8] at 1.0 torr. *(5a)*[9] (7 g, 25 %) is obtained at 41–42 °C, and *(6a)*[9] (3 g, 12 %) at 46–47 °C.

(5b): BBr_3 (15 g, 0.06 mol) is added dropwise with stirring to $(R_3Si)_2NPNSiR_3$ (14 g, 0.05 mol) under an inert gas at 0 °C. After 1 h at room temperature most of the R_3SiBr is drawn off and the residue is fractionated in an oil-pump vacuum. Redistillation (Vigreux column) of the fraction obtained at 50–65 °C/0.1 torr affords *(5b)*[9] (13 g, 70 %), b.p. 60–61 °C/0.1 torr.

[4] The formation of bis(trimethylsilyl)aminodibromophosphane *(6b)* could be detected only by NMR spectroscopy: $\delta_{^1H} = -0.44$ ppm, $^4J_{HP} = 2.5$ Hz; $\delta_{^{31}P} = -213$ ppm.

[5] Based on the isotopes ^{11}B, ^{35}Cl, and ^{79}Br.

[6] The missing ring vibration occurs in the range 720–790 cm^{-1}.

[7] The higher boiling component contains a solid, presumably bis(trimethylsilyldichloroborylamino)chlorophosphane, which has not yet been isolated pure.

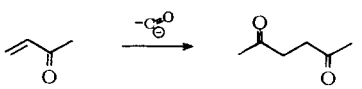
[8] "Spaltrohr" column, Fischer, Labor- und Verfahrenstechnik, Bonn-Bad Godesberg.

[9] *Ca.* 95 % pure. The amount of trimethylsilyl halide present owing to decomposition on distillation is 3–5 %.

Michael Additions of Metalated Thioacetals to Cyclic Enones[**]

By *Dieter Seebach* and *Rainer Bürstinghaus*[*]

The Michael addition of nucleophilic acyl equivalents to α,β-unsaturated carbonyl compounds [eq. (1)] is a reaction of particular synthetic utility[1].



(1)

So far this transformation has succeeded in the case of thioacetals as masked acyl anions only on use of lithium cuprates[1b, 2].

To our surprise, we have now found that the readily accessible[3a] lithiated bis(methylthio)(silyl)- and bis(methylthio)-(stannyl)methanes *(1)* undergo 1,4 addition to cyclic enones *(2)* in good yields—in contrast to the corresponding 1,3-dithiane derivatives which only undergo 1,2 addition[4]. The resulting enolates *(3)* afford the Michael adducts *(4)*, E = H, on aqueous work-up. However, the enolates can be alkylated directly by treatment of the reaction mixture with alkyl iodides to form the α,β-disubstituted ketones *(4)*, E ≠ H, which are isolated predominantly as *trans* isomers. (For examples, see Table 1.)

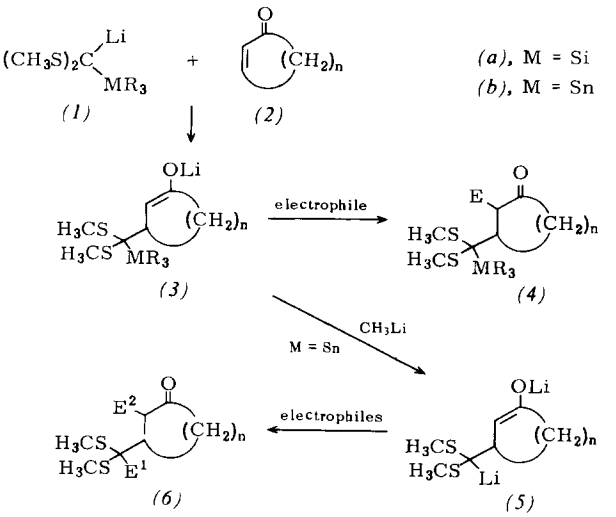


Table 1. Yields of ketones *(4)* prepared from thioacetals *(1)* and enones *(2)*.

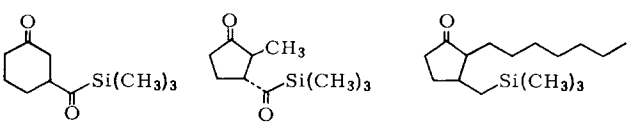
M	*n*	R	E	Yield [%] [a]
Si	2	CH_3	H	73
Sn	2	CH_3	H	70
Si	2	CH_3	CH_3	71
Si	2	CH_3	n-C_7H_{15}	65
Sn	2	CH_3	n-C_5H_{11}	65
Si	3	CH_3	H	78 [b]
Sn	3	CH_3	H	75
Sn	3	n-C_4H_9	H	65
Si	3	CH_3	CH_3	75
Sn	3	C_6H_5	H	60
Si	4	CH_3	H	60

[a] Products isolated by molecular distillation *in vacuo*.
[b] M.p. 56 °C.

Finally, in the case of the adducts *(3b)* it is possible to produce the novel dilithium derivatives *(5)* by transmetalation[3b], as we were able to show, *e.g.*, by hydrolysis to the tin-free product *(6)*, $n = 3$, $E^1 = E^2 = H$ [NMR in CCl_4: *one* SCH_3 singlet at δ = 2.1 ppm, 5-Hz doublet of the $(RS)_2CH$ proton at δ = 3.5 ppm]. Apparently, the carbanionoid center adjacent to the S atoms in *(5)* is more nucleophilic than the enolate system, for after addition of *one* equivalent of methyl iodide and subsequent hydrolysis we isolated *(6)*, $n = 3$, $E^1 = CH_3$, $E^2 = H$ [NMR in CCl_4: two SCH_3 singlets separated by 2 Hz (diastereotopic) at δ = 2.0 ppm, $(RS)_2C{-}CH_3$ as singlet at δ = 1.4 ppm].



To our knowledge, the compounds *(1b)* described above and the corresponding 1,3-dithiane derivatives[4b] are the first

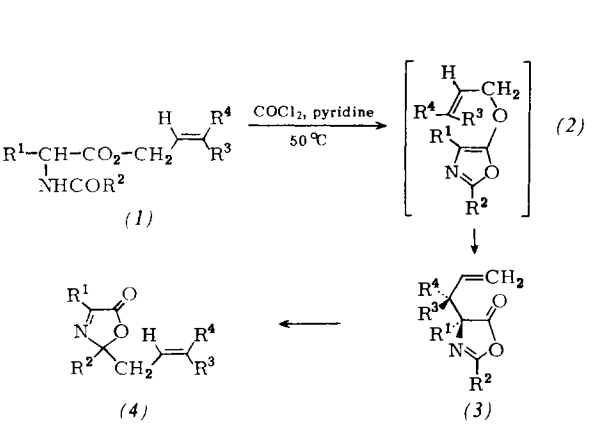
Hetero Cope Rearrangements in the Cyclization of Allyl and Propargyl Esters of *N*-Acyl Amino Acids to Oxazolin-5-ones[**]

By *Börries Kübel*, *Gerhard Höfle*, and *Wolfgang Steglich*[*]

Alkyl esters of *N*-acyl amino acids are converted on treatment with dehydrating agent into 5-alkoxyoxazoles[1, 2]. We have found that 5-allyloxyoxazoles *(2)*, formed from the *N*-acylamino acid allyl esters *(1)*[3], rearrange directly under the reaction conditions to 4-allyloxazolin-5-ones *(3)*. Cyclization is accomplished by dropwise addition of a solution of phosgene (1.5 mol) in toluene to a solution of the ester *(1)* and pyridine (3—6 mol) in chloroform and warming the mixture after 30



(1) *(2)* *(3)* *(4)*

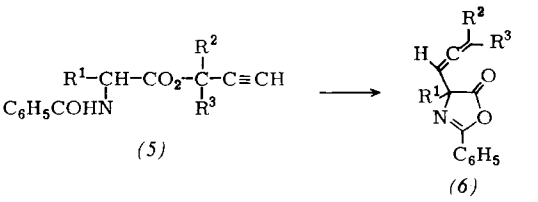
minutes' stirring at 20°C to 50—70°C for 1—3 h[2]. P_2O_5 in chloroform proved to be less satisfactory as reagent since acid-sensitive allyl residues are liberated (see Table 1).

From the ^{1}H-NMR spectra of *(3e)* and *(3f)* it is evident that only one diastereoisomer is formed in each of these cases; this is in agreement with the stereospecific course of the Claisen rearrangement[5].

On prolonged heating, the 2-oxazolin-5-ones *(3)*, R^3, $R^4 \neq H$, obtained from 3,3-disubstituted allyl esters are converted by further hetero Cope rearrangement into 2-allyl-3-oxazolin-5-ones *(4)*. For the preparative synthesis of *(4)* it is recommended that esters *(1)* be used as starting material, without isolating *(3)* (Table 1).

The ease of the secondary reaction *(3)* → *(4)* depends on the spatial requirements of the groups R^1, R^3, R^4. Thus *(3f)* rearranges completely into *(4f)* on boiling in chloroform for 3 h, while 12 hours' boiling in benzene is necessary for the rearrangement *(3e)* → *(4e)*. Under the conditions used for cyclization ($COCl_2$/pyridine, 1.5 h, 50°C), *N*-isobutyryl-2-phenylglycine geranyl ester affords *(4h)* directly—as a result of additional stabilization of the 3-oxazolinone form by conjugation of the C=N double bond with a phenyl residue.

4-Allenyl-2-oxazolin-5-ones *(6)* are accessible in the same way as *(3)* if the propargyl esters of *N*-acyl amino acids *(5)* are cyclized instead of *(1)* (Table 2).



(5) *(6)*

If cyclization of the esters *(1c)* and *(5i)* is carried out with P_4S_{10} in 1,2-dichloroethane (24 h, reflux)[6], the 2-thiazolin-5-ones (m.p. 53 and 59°C resp.)[4] corresponding to *(3c)* and *(6i)* are formed in 40% yield.

4-Isopropyl-4-linalyl-2-phenyl-2-oxazolin-5-one (3f) and 2-geranyl-4-isopropyl-2-phenyl-3-oxazolin-5-one (4f)

Butyllithium (2.5 mmol) followed by 4-isopropyl-2-phenyl-2-oxazolin-5-one (4.0 g, 20 mmol) are added with stirring to a solution of geraniol (3.1 g, 20 mmol) in benzene (30 ml). The mixture is stirred for one day, washed with 0.5 N HCl, dried over $MgSO_4$, and finally concentrated by evaporation under vacuum [yield 6.1 g (86%) *(1f)*, pale yellow oil].—A solution of $COCl_2$ (10.3 mmol) in toluene (3 ml) is now added slowly with stirring to a solution of the ester *(1f)* (2.5 g,

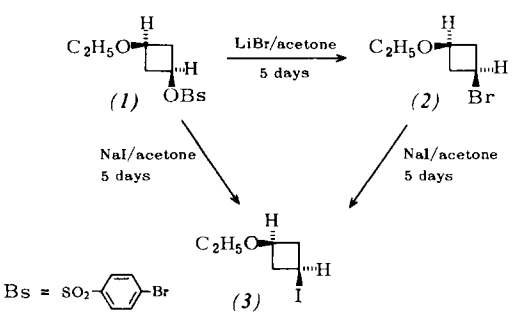
Experimental Evidence for a Novel Limiting Mechanism of Aliphatic Nucleophilic Substitutions[**]

By *Tarek ElGomati, Dieter Lenoir*, and *Ivar Ugi*[*]

Reaction of *cis*-3-ethoxycyclobutyl brosylate *(1)*[1] (7.00 g, 21 mmol) with sodium iodide (11.20 g, 75 mmol) in refluxing acetone (70 ml), *i.e.* under typical S_N2 conditions[2], leads to the formation of a stereochemically uniform iodide *(3)*; according to a ^{1}H-NMR comparison with *(1)*, *(3)* is the *cis*-isomer.

Exchange of the brosylate by iodide *via* a two-step sequence of reactions, including isolation of the bromide *(2)*, affords a product which according to its IR and NMR spectra and refractive index, is identical with the directly formed iodide *(3)*. The yields of the products *(2)* and *(3)* (Scheme 1) were 60—80 % after destillation.



Scheme 1

[**] We thank Dr. *Herbert Eck* of Wacker-Chemie, Burghausen, for 3-ethoxycyclobutanone.—Support is acknowledged from the National Science Foundation, Grant G.P. 28927 X, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.

This result lends itself to the following alternative interpretations:

a) The substitution *(1)*→*(3)* proceeds with retention[3], whereas the others occur with inversion[3,4].

b) Compound *(3)* and its *trans*-isomer equilibrate, with the equilibrium lying predominantly on the side of *(3)*.

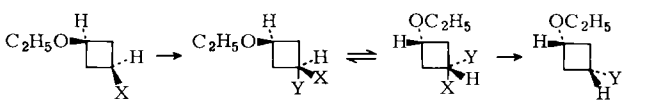
c) All substitutions, *(1)*→*(2)*, *(1)*→*(3)* and *(2)*→*(3)*, are retentive.

Since all reactions have been carried out under the same conditions and belong to the same substitution type[4], interpretation (a) is improbable[5]. Interpretation (b) can be ruled out because *(3)* is obtained in high purity, while, as a rule, in the thermodynamic equilibrium of the *cis*- and *trans*-isomers of 1,3-disubstituted cyclobutane derivatives, the *cis*-isomer predominates to the extent of 70–80 %[6].

Hence the conclusion is that all three substitutions proceed according to (c) with retention.

Considering the reaction conditions, and the fact that the S_N reaction of the brosylate *(1)* in aqueous acetone leads to 98 % inversion, the above reaction cannot involve a mechanism entailing ionic intermediates[7].

The most reasonable explanation is offered by a recently postulated type of bimolecular substitution[7], proceeding *via* the penta-coordinated intermediates *(4)* and *(5)*, which are interconverted by a turnstile rotation (TR)[8], or a resultwise equivalent Berry pseudorotation (BPR)[8]; however, the latter is less likely here because of the presence of the 4-membered ring (Scheme 2). The second order S_N2 limiting mechanism otherwise observed in aliphatic nucleophilic substitutions, with pentacoordinated transition state *(6)* (or pentacoordinated intermediate in the limiting case) having apical leaving and entering groups, and a diequatorial 4-membered ring is at an energetic disadvantage in contrast with *(4)* and *(5)*, because of strain. An S_N1 nucleophilic substitution with "edge attack" can be ruled out; all available experimental and theoretical evidence indicates that in aliphatic second order nucleophilic substitution the formation and decomposition of pentacoordinate transition states, or of intermediates takes place through apical entry of the entering group and apical departure of the leaving group[9].



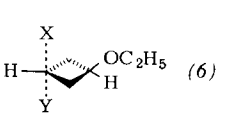
(1), X = OBs
(2), X = Br

(4)
(a), X = OBs, Y = Br
(b), X = OBs, Y = I
(c), X = Br, Y = I

(5)

(2), Y = Br
(3), Y = I

Scheme 2

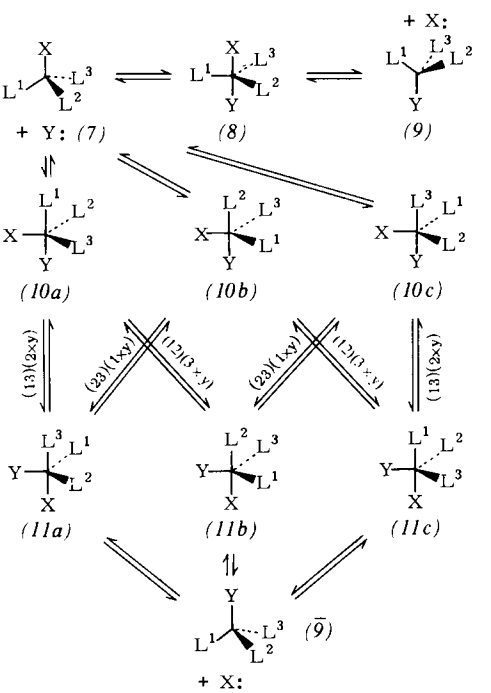


(6)

Thus the reactions of Scheme 1 indicate that there exist S_N with pentacoordinate intermediates, whose lifetime is long enough for permutational isomerization. This is in contrast to the presently accepted belief of the transition state nature of the pentacoordinate species *via* which S_N processes proceed.

From the perspective of apical entry and departure of ligands during the interconversion of tetra- and pentacoordinated configurations, and with due consideration of the present results, one is led to the following view of second order nucleophilic substitutions (Scheme 3): A nucleophile, Y, enters a "tetrahedral free face" of *(7)*, a compound with a tetracoordinate central atom and four ligands L^1, L^2, L^3, X one of which, X, is a leaving group. The entering group Y becomes thus an apical ligand of a pentacoordinate configuration *(8)* or *(10)*.

If the nucleophile enters opposite to X, *(8)* results, with the leaving group X in an apical position, from which it can depart directly giving rise to a "normal" S_N2. Otherwise pentacoordinate species *(10a)*, *(10b)*, or *(10c)*, result, with the leaving group X in an equatorial position. In this case X can only leave from an apical position after rearrangement (by TR, or BPR) into *(11a)*, *(11b)*, or *(11c)*, respectively. The product is $(\bar{9})$, the enantiomer of *(9)*. When there are no constraints that affect the skeletal placement of the ligand set $\{L^1, L^2, L^3, X, Y\}$, a "normal" S_N2 according to *(7)*→*(8)*→*(9)* is observed—with *(8)* as transition state, or intermediate—since *(8)* [or *(10)*] loose X much faster than they undergo the isomerization *(10)*→*(11)* which would be required for a retentive S_N. If, however, the attack on *(7)* by Y to form *(8)* is substantially retarded relative to the formation of *(10)* by constraints originating with the ligand set, then *(7)*→*(10)*→*(11)*→$(\bar{9})$ prevails. Here *(10)* and *(11)* cannot be transition states, but must be intermediates, because of the lifetime requirement for the permutation isomerization *(10)*→*(11)*. Let L^1 and L^2, for example, belong to a 3- or 4-membered ring, or maybe also a 5-membered ring, then the species *(8)*, *(10c)* and *(11a)* with a diequatorial ring are too strained to be S_N intermediates, and *(7)*→*(10a)*→*(11b)*→$(\bar{9})$ and *(7)*→*(10b)*→*(11c)*→$(\bar{9})$ are the fastest S_N reactions.



Scheme 3

A mechanism analogous to that in Scheme 2 may also be responsible for the observed preferential retention encountered in the reduction of gem. dihalocyclopropanes with $LiAlH_4$ and $LiAlD_4$[10] and analogous reactions[11].

According to quantum mechanical calculations[12] cyclopropane derivatives, with pentacoordinate carbon in a geometrical arrangement resembling a TR barrier situation, are energetically more favorable than arrangements corresponding to *(6)*.

The steric course of nucleophilic substitution at a tetracoordinate phosphorus center[13] incorporated in a 4-membered

ring proceeds analogously to the scheme *(1)*→*(3)*→*(2)*. Recently, however, a nucleophilic substitution at phosphorus in a 4-membered ring was observed to involve inversion[14]. Perhaps in this case the permutational isomerization of the pentacoordinate intermediate not only follows the TR mechanism, but also an interconversion by TR2[8]. The retentive nucleophilic substitutions at silicon[15] could also proceed *via* interconverting pentacoordinate intermediates.

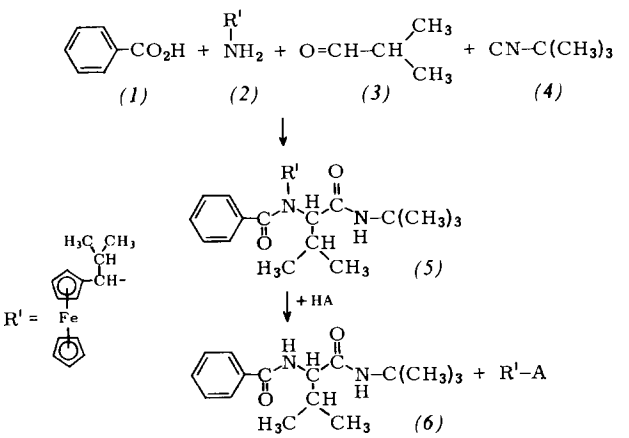
Asymmetrically Induced Four Component Condensation with Extremely High Stereoselectivity and Multiplication of Stereoselectivity[**]

By *Reinhard Urban* and *Ivar Ugi*[*]

In the synthesis of peptide fragments by four component condensations[1] it is essential to form the new α-amino acid unit in the desired configuration with maximum stereoselectivity.

The stereoselectivity of the asymmetrically induced model four component condensation *(1)*+*(2)*+*(3)*+*(4)*→*(5)* reaches $c_{(R,S)\text{-}(5)}$: $c_{(R,R)\text{-}(5)}$ 99.5 : 0.5 under suitably chosen reaction conditions.



No.	Amine *(2)*	T [°C]	C_0 [mol/l] [b]	Q_{pn} $c_{(R,R)\text{-}(5)}$: $c_{(R,S)\text{-}(5)}$	*(5)*, Yield [%]
1	rac.	−30	0.02	26.4 : 73.6	32
2	rac.	0	0.02	38.7 : 61.3	40
3	rac.	20	0.02	51.5 : 48.5	45
4	rac.	−78	0.02	0.5 : 99.5	26
5	*R*(−) [a]	−78	0.05	0.94 : 99.06 [c]	97 [b]
6	*R*(−) [a]	0	0.05	40.9 : 59.1 [c]	77
7 [d]	*S*(+) [a]	−78	0.05	20.0 : 80.0	61

[a] $[\alpha]_D^0 = \pm 79.8°$ ($c = 1$, benzene). Preparation and configurational assignment of *(2)*: *H. Klusacek, D. Marquarding, I. Ugi*, and *R. Urban*, unpublished.
[b] Concentration of all starting materials, except in experiment 5 where a 10% excess of *(1)*, *(2)* and *(3)* was used.
[c] Gravimetric determination.
[d] Addition of 0.02 mol/l triethylammonium benzoate.

The unusually high degree of stereoselectivity is due to the fact that under the conditions of reaction 4 (Table 1)[2a] the rather bulky optically active amine component *(2)* leads to an almost uniform reaction mechanism, a pair of corresponding reactions involving solvent separated immonium ions and nitrilium ions[1–3]; the decrease in stereoselectivity on the addition of triethylammonium benzoate is evidence for this[2b]. The latter pair of corresponding reactions has high intrinsic stereoselectivity[1c], because the bulky groups reduce the number of participating conformations in the selectivity determining pair of transition states, and effect thus the high degree of selectivity which is characteristic for rigid systems[3].

The ratio of the isomers formed, $Q_{pn} = c_{(R,R)\text{-}(5)} : c_{(R,S)\text{-}(5)}$, was determined by high pressure liquid chromatography (Hupe

& Busch, Karlsruhe, UFC 1000) on a Perisorb column (Merck) in cyclohexane/ethyl acetate 100:3.3. The evaluation was based on reference mixtures of the pure isomers.

The products were identified as the (*R,R*) or (*S,S*), and (*R,S*) or (*S,R*) isomers by NMR comparison with the known products of α-phenylethylamine and α-ferrocenylethylamine[4]. The absolute configuration of the condensation product *(5)* was assigned by removal of the α-ferrocenylalkyl group R^1. After the cleavage reaction *(5)* → *(6)* of the predominating product of reaction 5 the optical rotation of the resulting valine derivative was found to correspond to that of *N*-benzoyl-(*S*)-valine *tert*-butylamide[4, 5]. Accordingly, the configuration of the above product *(5)* is: *N*-benzoyl-*N*-[(*R*)-α-ferrocenylisobutyl]-(*S*)-valine *tert*-butylamide.

In this context it is interesting to note that the cleavage by 0.1 M trichloroacetic acid in methanol of (*R,R*)-*(5)* is about 50 times faster than that of (*R,S*)-*(5)*. An accurate determination of the rate ratios has not been carried out yet. This enables a multiplication of stereoselectivities with regard to *(6)*.

Let the cleavage of (*R,R*)-*(5)* be 50 times faster than that of (*R,S*)-*(5)*, and a 1:200 mixture of (*R,R*)-*(5)* and (*R,S*)-*(5)* be subjected to the cleavage reaction for five halflives—which correspond to 1/10 of the halflife time of (*R,S*)-*(5)*—then a 0.03:187 mixture of (*R,R*)-*(5)* and (*R,S*)-*(5)* results. The subsequent complete cleavage of this mixture would yield (*R*)-*(6)* and (*S*)-*(6)* in a ratio 0.016:99.984. In the products of the first cleavage step which were obtained according to such a procedure the presence of (*R,R*)-*(5)* could not be detected by the usual methods (NMR, TLC).

This model experiment with its high primary and subsequent multiplication of selectivity opens the way to highly selective peptide syntheses by four component condensations[1c].

N-Benzoyl-N-[(R)-α-ferrocenyl-isobutyl]-(S)- and -(R)-valine tert-butylamide, (R,S)-(5) and (R,R)-(5)

10 mmol of the aldimine formed from *R*(−)-*(2)* and *(3)* is dissolved in 2/3 of the total amount of methanol and thermostated (see Table 1, reaction 5 and 6).

Solutions of *(4)* (10 mmol) and *(1)* (10 mmol) in the rest of the methanol are added dropwise with stirring and in this sequence to the first mentioned solution during 30 min. After 2—4 days the reaction mixture is poured into water, extracted with ether, and washed with 3% aqueous tartaric acid, 1 N aqueous sodium hydroxide, and finally with water.

The crude product is purified by chromatography on silica gel 60[70—230 mesh ASTM (Merck)]. (*R,S*)-*(5)*: m.p. 155—156 °C, $[\alpha]_D^{20} = -123.5°$, $[\alpha]_{546}^{20} = -242.5°$ (*c* = 1, benzene); (*R,R*)-*(5)*: m.p. 178—180 °C, $[\alpha]_D^{20} = -431.7°$, $[\alpha]_{546}^{20} = -657.0°$ (*c* = 1, benzene).

σ-Complex Intermediates in Acylation and Sulfonylation of 1,3,5-Tripyrrolidinobenzene—Preparation, Reactions, and Structure[1]

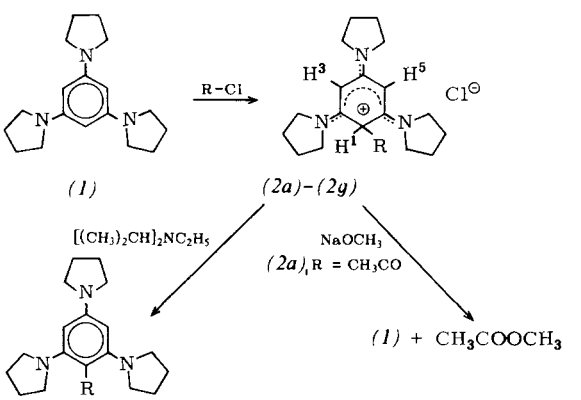
By *Peter Menzel* and *Franz Effenberger*[*]

In the acylation of arenes, σ-complex (Wheland) intermediates have been cited[2] for the formyl fluoride/boron trifluoride reaction of alkylbenzenes; they have received no mention, however, in more recent spectroscopic work[3]. σ-Complex intermediates have been established unequivocally by NMR spectroscopy for the sulfonylation of persubstituted benzenes[4]. With the extremely electron-rich 1,3,5-triaminobenzenes, such complexes have even been isolated in the case of protonation[5], alkylation[6], and halogenation[7]; we now report analogous results for the acylation and sulfonylation of triaminobenzenes.

If 1,3,5-tripyrrolidinobenzene *(1)* is treated with acetyl or benzoyl chloride in anhydrous dichloromethane at 0 °C, the orange-yellow σ-complexes *(2a)* and *(2b)*, respectively, can be precipitated with ether from the brownish yellow reaction solutions. Sulfonylation of *(1)* with tosyl chloride under similar conditions yields *(2d)*, while *(2c)* [formed upon reaction with mesyl chloride in $CDCl_3$] can be identified only by NMR spectroscopy. Compounds *(2e)*, *(2f)*, and *(2g)* which have proved essential for assessing the conformation of Wheland intermediates[8], are prepared analogously (Table 1).

Except for *(2c)*, the σ-complexes *(2)* are stable at room temperature for a reasonable time. The chloride ion may be exchanged with either $AgClO_4$ or $AgBF_4$.

Deprotonation of *(2)* to *(3)* is effected with *N,N*-diisopropylethylamine; no deprotonation but rather cleavage of the acetyl group is observed with sodium methoxide.



Nonplanarity of the cyclohexadienylium ring has been established by X-ray crystallography for σ-complexes of type *(2)* with R = CH_3 and R = Br[10]. If *(2a)*—*(2g)* are also nonplanar only two extreme conformations (*syn* or *anti*) are possible for steric reasons. In case of restricted rotation about the C^1—C^7 or C^1—S bonds these two conformations could be differentiated by NMR spectroscopy. There is no significant change, however, in the NMR signals over a wide temperature range, thus ruling out rotation or an alteration of rotational behavior.

For the acyl σ-complexes *(2a)* and *(2b)*, the olefinic protons $H^{3,5}$ exhibit nearly identical shifts, while H^1 is less shielded by 1.63 ppm in *(2b)* as compared with *(2a)* (Table 1). The acyl complexes must therefore be assigned the *syn* conformation (A *syn*) where H^1 is strongly deshielded if R′ = phenyl.

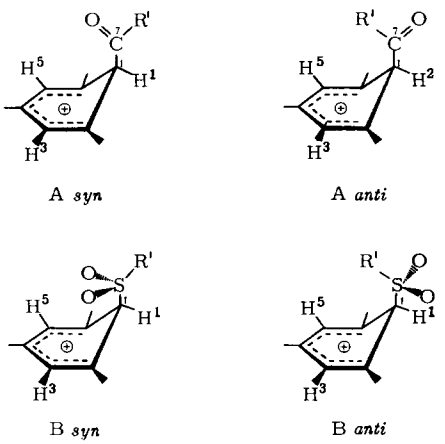
7 Stuttgart 80, Pfaffenwaldring 55 (Germany)

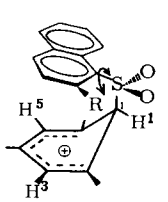
Table 1. σ-Complexes *(2)* prepared.

	R	^{1}H-NMR, δ [ppm] [a] H^1	$H^{3,5}$	IR [cm^{-1}] [b] C=N and C=C
(2a)	CH_3CO	4.86	5.07	1610; 1520; 1435
(2b)	C_6H_5CO	6.49	4.92	1615; 1523; 1430
(2c)	CH_3SO_2	5.66	5.00	
(2d)	p-CH_3—$C_6H_4SO_2$	5.55	4.63	1620; 1540; 1430
(2e)	9-Anthryl-SO_2	5.75	3.84	1620; 1540; 1430
(2f)	1-Naphthyl-SO_2	5.66	4.21	1620; 1545; 1427
(2g)	2-Methyl-1-naphthyl-SO_2	5.58	4.59 3.93	1620; 1545; 1425

[a] 0.1 M in $CDCl_3$, 30°C, internal reference TMS.
[b] KBr pellet. The three intense bands listed are characteristic of 1,3,5-triaminobenzene σ-complexes [9].

In contrast, the analogous sulfonyl complexes *(2c)* and *(2d)* exhibit different shifts for $H^{3,5}$ and almost identical shifts for H^1, and must therefore exist in the *anti* conformation (B *anti*). In this arrangement, the olefinic protons of *(2d)* come to lie within the diamagnetic shielding cone of the tolyl ring, and thus experience an upfield shift as compared with *(2c)*. If this rationalization is correct, the effect should be much more pronounced for an anthracenesulfonyl complex: indeed, $H^{3,5}$ of *(2e)* appear better shielded by another 0.8 ppm while the H^1 signal is shifted slightly downfield. For the naphthalenesulfonyl compound *(2f)* where only one proton experiences additional shielding by the annelated benzene ring, separate resonances are expected for H^3 and H^5. Due to rapid oscillation of the naphthyl moiety about the S-aryl bond, however, the spectrum shows only one singlet of intermediate shift.





(2f), R = H
(2g), R = CH_3

Upon introduction of a methyl group in the β position of *(2)*, this oscillation is no longer possible for steric reasons; accordingly, the $H^{3,5}$ signal of *(2g)* is split into two resonances. Concomitant with the increasing shielding by larger and larger π-systems, the ^{1}H signal shows a systematic downfield shift in the series *(2d)*→*(2f)*→*(2e)*, thus providing further confirmation that the aryl rings are fixed above the cyclohexadienylium system. Differing conformations of acyl and sulfonyl σ-complexes would be impossible in a planar structure; furthermore, the marked influence of the aryl substituents upon the $H^{3,5}$ signal of *(2d)*—*(2g)* would be hard to explain. The σ-complexes, at least of triaminobenzenes, must therefore exist in a nonplanar conformation with the substituent at C^1 in axial position, both in solution and in the solid state.

Stable Solutions of 1-Aza-2-cyclopentadienone Salts in Thionyl Chloride/Antimony Pentachloride[**]

By *Wilhelm Flitsch* and *Klaus Gurke*[*]

The stability of cyclopentadienones is not essentially enhanced by the presence of nitrogen atoms in the ring: unsubstituted azacyclopentadienones are unknown[11]; diazacyclopentadienones are unstable compounds which have only rarely been isolated and readily dimerize[12].

In the salts of azacyclopentadienones dimerization is opposed by intermolecular repulsion between the ions. We have been able to prepare stable solutions of the salts of 1-aza-2-cyclopentadienones (2-oxopyrrolium salts) *(1)* from the hydroxylactams *(2)*[13] with thionyl chloride and antimony pentachloride by mixing the reactants at −80°C and then slowly warming the reaction mixture to room temperature. The known benzoannelated analog *(4)* is formed similarly from the hydroxylactam *(3)*[14].

^{1}H-NMR data of the salts are listed in Table 1. The correlation of the signals was confirmed by double resonance experiments. The chemical shifts and coupling constants were assigned by computer simulation. Comparison with the ^{1}H-NMR spectra of protonated 2*H*-pyrroles, *e.g.* 2*H*-pyrrolium hydrogen sulfate shows that the ring proton signals of the salts *(1)* and *(4)* lie at surprisingly high field. Similar observations were made with substituted cyclopentadienones.

Table 1. ^{1}H-NMR data of the salts *(1)* and *(4)* (δ values in ppm, CH_2Cl_2 as internal standard, δ = 5.28; solvent $SOCl_2/SbCl_5/CH_2Cl_2$). Corresponding signals are placed under one another.

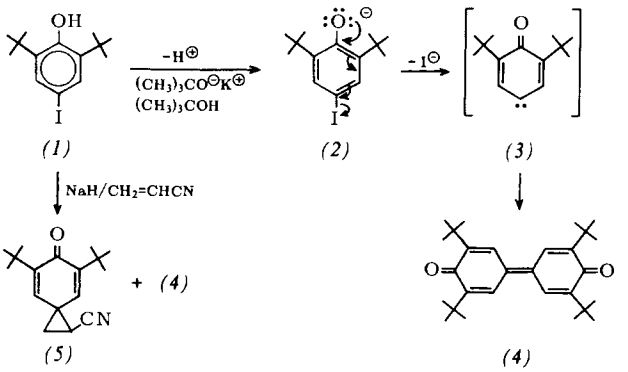
3,5-Di-*tert*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene by 1,5-Elimination[**]

By *Peter Bartholmei* and *Peter Boldt*[*]

On thermolysis or photolysis 4-diazo-2,6-di-*tert*-butyl-2,5-cyclohexadien-1-one decomposes into 3,5-di-*tert*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene *(3)* which dimerizes to the diphenoquinone *(4)*[1] and can be trapped with alkenes to form spirodienones of type *(5)*[2].

We attempted to prepare the keto carbene *(3)* by elimination of hydrogen halide from *p*-halophenols: reaction of 2,6-di-*tert*-butyl-4-iodophenol *(1)* with strong bases such as potassium *tert*-butoxide or sodium hydride afforded the diphenoquinone *(4)* in 95% yield. Use of acrylonitrile as solvent and sodium hydride as base furnished 80% of *(4)* and 18% of *(5)*. Hence it may be deduced that the carbene *(3)* or a corresponding carbenoid had been generated from the initially formed phenoxide *(2)* by extrusion of an iodide ion.



(1) *(2)* *(3)* *(4)* *(5)*

3,3',5,5'-Tetra-tert-butyl-4,4'-diphenoquinone (4)

Potassium *tert*-butoxide (2 g, 18 mmol) in *tert*-butyl alcohol (60 ml) was mixed with compound *(1)* (3.3 g, 10 mmol) in *tert*-butyl alcohol (60 ml). After 14 hours' stirring under nitrogen, the reaction mixture was treated with water (200 ml) and extracted with light petroleum. The evaporation residue *(in vacuo)* of the dried organic phase yielded 1.9 g (95%) of compound *(4)* after recrystallization (methanol/water).

5,7-Di-tert-butyl-6-oxospiro[2.5]octa-4,7-diene-1-carbonitrile (5)

A solution of *(1)* (3.3 g, 10 mmol) in acrylonitrile (100 ml) was added dropwise with stirring to NaH (1 g, 40 mmol) at 0 °C. After 5 hours' stirring under nitrogen the solution was poured into light petroleum (500 ml), any excess NaH destroyed with ethanol, and the mixture washed with water, dried, and evaporated *in vacuo*. The evaporation residue was chromatographed from light petroleum/acetone (9 : 1) on silica gel. The eluates of the first and second zones contained *(4)* (1.6 g, 80%) and *(1)* (0.06 g, 2%), respectively, and that of the third zone *(5)* (0.46 g, 18%) which, after recrystallization from cyclohexane, exhibited m.p. 120 °C (literature value[2]: 118.5—119.5 °C). The NMR, IR, and mass spectra were in accord with formula *(5)*.

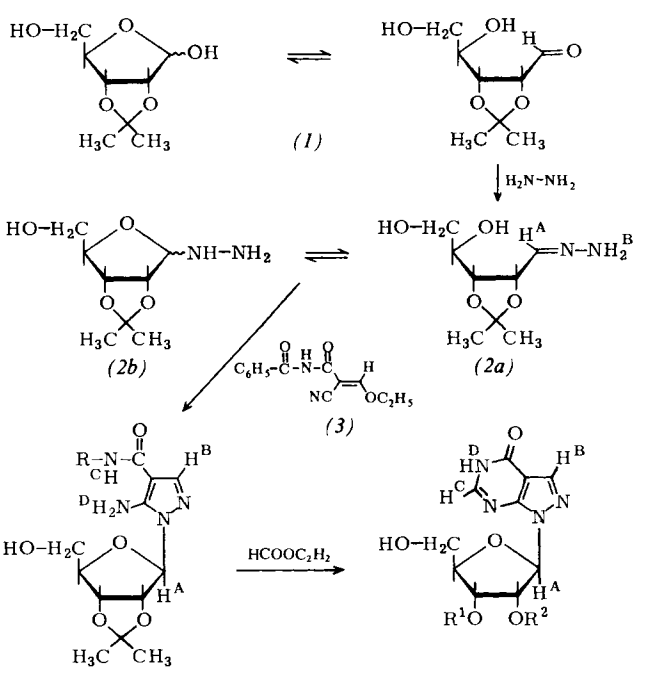
reaction of a protected D-ribofuranose with a heterocyclic compound, its heavy metal salt, or its trimethylsilyl derivative[1]. We now describe a method for the preparation of pyrazole nucleosides and their derivatives which avoids the difficulties of the above methods by stepwise formation of the product starting from the D-ribose, as in the biosynthetic pathway[2]. This technique provides a convenient route to, *e.g.*, the biologically important allopurinol riboside *(5b)*[3].

Protected D-ribose derivatives such as 2,3-*O*-isopropylidene-D-ribose *(1)* can be transformed quantitatively into the hydrazine derivative *(2)* by treatment with hydrazine[4]. NMR observations in D_6-DMSO show that *(2)* comprises an equilibrium mixture of the hydrazone form *(2a)* and the hydrazinofuranose form *(2b)*, in which *(2a)* predominates (≈90%). The configuration of *(2b)* at the anomeric center could not be deduced from the NMR spectrum; it can however be assumed on the basis of consecutive reactions and other findings[4] that the hydrazino group is at least partly β configurated.



(4a), R = C_6H_5-CO

(4b), R = H

(5a), R^1–R^2 = $>C(CH_3)_2$

(5b), R^1 = R^2 = H

Thermodynamically controlled reaction of *(2)* with polyfunctional cyclization reagents such as the ethoxymethyleneacrylamide derivative *(3)*[5], which form the pyrazole system, results in double ring closure and specific β-glycosidic linkage of the furanose and pyrazole ring in a single step to give the pyrazole nucleoside derivative *(4a)* (m.p. 160—161 °C, yield 58%). On reaction of *(3)* with *(2)* the equilibrium *(2a)*⇌*(2b)* apparently shifts towards the furanose form, in which the hydrazino group adopts the β configuration under the influence of three chiral centers.

The action of sodium methoxide on *(4a)* afforded the amide *(4b)* (m.p. 181 °C, yield 72%), which furnished the isopropylidene-protected allopurinol riboside *(5a)* (yield 85%) on treatment with ethyl formate. Compound *(5a)* was converted into the allopurinol riboside *(5b)* (m.p. 204 °C[6], yield 80%) by an acidic ion exchanger (Amberlite IR 120 in the H^+ form).

NMR data of compounds *(2a)*, *(4a)*, *(4b)*, *(5a)*, and *(5b)* are listed in Table 1.

Table 1. NMR data of the ribose derivatives prepared (in δ relative to tetramethylsilane as internal standard).

Synthesis of Novel Anti-inflammatory Steroids

By *Henry Laurent, Erich Gerhards*, and *Rudolf Wiechert*[*]

Fluocortolone *(1)*, developed by *Raspé et al.*[1, 2], was shown to be a strong anti-inflammatory corticoid suitable for local or systemic application. After oral administration of *(1)* there could be isolated a number of metabolites from human urine[3]. One of these was identified as the water-soluble, α-keto acid *(3a)*. We have synthesized this metabolite *(3a)* and a number of ester derivatives in order to investigate the anti-inflammatory activity of these substances.

Reaction[4] of *(1)* with alcohols in the presence of copper(II) acetate and oxygen leads initially to the aldehyde *(4)* which rearranges to a mixture of the epimeric 20-hydroxy esters *(2)* upon prolonged reaction.

Selective oxidation of the 20-hydroxy compounds *(2)* to the α-keto esters *(3b)*—*(3e)* can be accomplished with activated

ester *(3b)*. Replacement of methanol by butanol or isopropyl alcohol yields the corresponding esters *(3c)* and *(3h)*.

In the vasoconstriction test on human skin, these ester derivatives *(3)* were found to possess a local anti-inflammatory activity. However, upon subcutaneous and oral administration to animals in the adjuvant paw edema assay, spleen and thymus assay test and in the eosinophile test, these esters are practically inactive. They are also found to have no effect upon gluconeogenesis or electrolyte excretion in the rat. As a result of these and other findings, the butyl ester *(3c)* is currently undergoing clinical trials for use as a topically-active corticoid without the usual systemic activity.

Other corticosterone derivatives *(5)*, some of which exhibit pronounced corticoid effects, have been transformed into the 21-esters *(6)* by means of the methods developed for fluocortolone *(1)*.

Procedure A:

a) 6α-Fluoro-11β,21-dihydroxy-16α-methyl-1,4-pregnadiene-3,20-dione *(1)* (300 g) in *n*-butanol (4.5 l) is stirred vigorously

	R	Procedure	Yield [%]	M.p. [°C] [a]	$[\alpha]_D^{25}$ [°] [c]	UV Maximum [nm] ε [e]

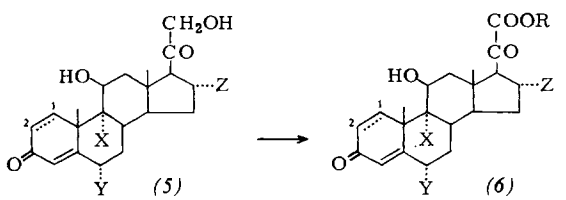
[c] $c = 0.5$ in chloroform.
[d] $c = 0.5$ in pyridine.
[e] In methanol.

The esters *(3f)*—*(3h)* were synthesized by transesterification of the α-keto esters *(3b)* and *(3c)* in the presence of basic catalysts. Using the method described by *Corey et al.*[5] for oxidative esterification of α,β-unsaturated aldehydes with manganese(IV) oxide and methanol in the presence of cyanide ions, the 21-aldehyde *(4)* could be converted into the methyl



with copper(II) acetate (150 g) for 260 h. The solution is evaporated *in vacuo*, the residue dissolved in dichloromethane; the resulting solution is washed several times with 12% ammonium hydroxide solution, then with sodium chloride solution, and finally dried and evaporated to dryness. The residue is chromatographed over silica gel. Elution with 20 to 50% acetone/hexane affords 289.5 g of a mixture of butyl 6α-fluoro-11β,20α- and 6α-fluoro-11β,20β-dihydroxy-16α-methyl-3-oxo-1,4-pregnadien-21-oate *(2c)*. b) The ester *(2c)* (275 g) is stirred vigorously for 3 h with manganese(IV) oxide (3.0 kg) in dichloromethane (2 l). The filtrate obtained from the reaction mixture is evaporated down and the residue chromatographed with hexane/acetone/dichloromethane over silica gel. Recrystallization twice from acetone/hexane gives

[c] In methanol.

112.0 g of butyl 6α-fluoro-11β-hydroxy-16α-methyl-3,20-dioxo-1,4-pregnadien-21-oate *(3c)*.

Procedure B:

A solution of *(3c)* (5.0 g) in *n*-propanol (300 ml) is refluxed with potassium *tert*-butoxide (250 mg) under argon for 1 h. The product is precipitated with 1% acetic acid, filtered off, dried, and recrystallized from acetone/hexane. One obtains 2.07 g of propyl 6α-fluoro-11β-hydroxy-16α-methyl-3,20-dioxo-1,4-pregnadien-21-oate *(3g)*.

Procedure C:

a) To a solution of *(1)* (1.0 g) in methanol (125 ml) is added a solution of cooper(II) acetate (250 mg) in methanol (125 ml). The mixture is stirred for 15 min at room temperature with passage of air. After dilution with dichloromethane, it is washed with 5% ammonium chloride solution and water, dried over sodium sulfate, and the solvent evaporated off *in vacuo*. Yield: 1.05 g of 6α-fluoro-11β-hydroxy-16α-methyl-3,20-dioxo-1,4-pregnadien-21-al *(4)*. b) The aldehyde *(4)* is stirred in methanol (20 ml) with potassium cyanide (1 g), conc. acetic acid (1 ml), and manganese(IV) oxide (10 g) for 10 min at room temperature. The filtrate obtained from the reaction mixture is diluted with dichloromethane, washed with water, dried with sodium sulfate, and evaporated to dryness *in vacuo*. The residue is chromatographed over silica gel. Elution with 18 to 22% acetone/hexane affords 525 mg of methyl 6α-fluoro-11β-hydroxy-16α-methyl-3,20-dioxo-1,4-pregnadien-21-oate *(3b)* after recrystallization from acetone/hexane.

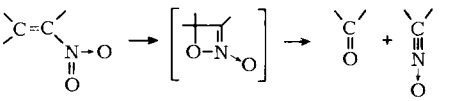
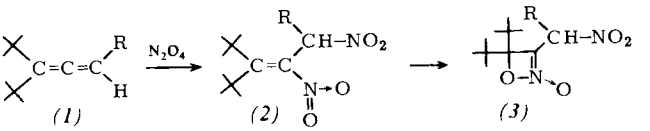
4*H*-1,2-Oxazete *N*-Oxides from 1,1-Di-*tert*-butylallenes [1]

By *Karlheinz Wieser* and *Armin Berndt* [*]

Apart from the sterically stabilized 4*H*-1,2-oxazete *N*-oxide *(6)* [2], derivatives of this heterocycle have hitherto only been reported as reactive intermediates in thermal [3] and photochemical [4] cleavages of α,β-unsaturated nitro compounds to form carbonyl compounds and nitrile oxides. Preparation of other isolable derivatives was precluded by the poor accessibility of sterically hindered nitroalkenes.

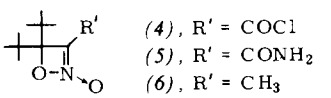


We have now found that the readily accessible 1,1-di-*tert*-butylallenes *(1)* [5] are ideal starting materials for the synthesis of 3-substituted 4,4-di-*tert*-butyl-4*H*-1,2-oxazete *N*-oxides. Addition of N_2O_4 to *(1)* leads directly to the readily crystallizing oxazete *N*-oxides *(3)* after work-up at room temperature. On careful work-up at *ca.* 0 °C the dinitroalkenes *(2)* can be isolated, which undergo smooth first-order reaction to give *(3)* on heating.



(1) *(2)* *(3)*

(a), R = H; *(b)*, R = Br; *(c)*, R = Cl



(4), R′ = COCl
(5), R′ = $CONH_2$
(6), R′ = CH_3

On standing *(3c)* undergoes partial transformation to the acyl chloride *(4)*, from which other derivatives, *e.g. (5)*, can be prepared. All new compounds have been unequivocally characterized by their spectroscopic data (see Table 1), and the oxazete *N*-oxides also by elemental analysis and their mass spectra.

While *(4)* and *(5)* can be stored at room temperature, the derivatives *(3a)*—*(3c)* decompose even at 0 °C to oily mixtures of products from which di-*tert*-butyl ketone could be isolated by gas chromatography.

[a] δ scale, all signals are singlets. [b] Conversion temperature. [c] Diastereotopic, accidently isochronic. [d] In C_6D_6.

Procedure:

Compound *(1)* (0.65 mol) is added dropwise to a stirred solution of N_2O_4 (11 g, 0.13 mol) in dry ether (40 ml) cooled to −10 °C. After 1 hour's stirring at −5 °C, excess N_2O_4 and ether are removed in a vacuum.—Isolation of *(2)*: The precipitate is rapidly filtered off and washed with a small volume of ice-cold ether.—Preparation of *(3)*: The reaction mixture is stirred for 20 min with water (30 ml), then taken up in benzene, and the benzene phase is washed neutral with water, dried with $MgSO_4$, and evaporated in a Rotavapor. The crystalline residue is filtered, washed with a small amount of ice-cold light petroleum, and recrystallized from the same solvent.

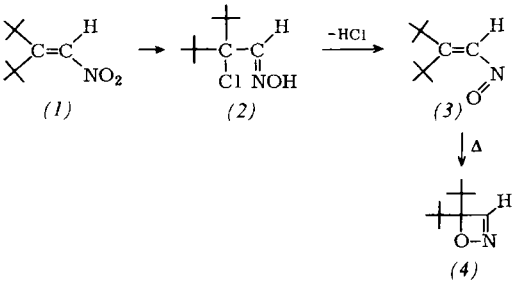
Since reactive molecules can be stabilized by introduction of bulky substituents and nitroalkenes subject to strong steric hindrance cyclize to 4*H*-1,2-oxazete *N*-oxides[4], we have attempted to synthesize stable 4*H*-1,2-oxazetes by thermal cyclization of correspondingly substituted nitrosoalkenes. For this purpose, the α-chloro oxime *(2)* (2-*tert*-butyl-2-chloro-3,3-dimethylbutanal oxime) was prepared from the nitroalkene *(1)*[5, 6]. Compound *(2)* was then converted into 2-*tert*-butyl-3,3-dimethyl-1-nitroso-1-butene *(3)* by elimination of HCl with 1,5-diazabicyclo[4.3.0]non-5-ene[7]. Compound *(3)* is the first nitrosoalkene to be stable at room temperature.



(1) *(2)* *(3)* *(4)*

Brief heating of *(3)* to 220 °C, accomplished by drawing it at 10^{-4} torr through a 90-cm vertical glass tube packed with glass rings at this temperature into a cold trap (−196 °C), furnishes 4,4-di-*tert*-butyl-4*H*-1,2-oxazete *(4)* in 54% crude yield. The by-products of the reaction are di-*tert*-butyl ketone and hydrogen cyanide which are apparently decomposition products of *(4)* since they are formed in low yields at low temperature, in greater yields at higher temperatures, and are the sole products above 240 °C. Below 220 °C the reaction product still contains unreacted *(3)*. Compound *(4)* can be isolated by preparative layer chromatography.

The structure of *(4)* follows from mass-spectrometric elemental analysis, fragmentation to ions of di-*tert*-butyl ketone and hydrogen cyanide[8], and the spectral data listed in Table 1. It is confirmed by degradation of *(4)* to di-*tert*-butyl ketone and sodium cyanide on heating with sodium methoxide in methanol.

Table 1. Compounds *(2)*—*(4)*, *(6)*, and *(7)* prepared.

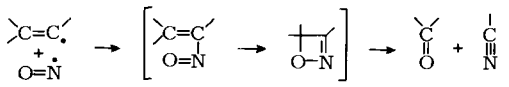
Stable 4*H*-1,2-Oxazetes by Intramolecular Cyclization of α,β-Unsaturated Nitroso Compounds[1]

By *Karlheinz Wieser* and *Armin Berndt*[*]

Derivatives of 4*H*-oxazete have hitherto only[2] been postulated as reactive intermediates in the formation of carbonyl compounds and nitriles from vinyl radicals and NO[3].



To stabilize 4*H*-1,2-oxazetes, we have attempted to synthesize 4*H*-1,2-oxazetes with bulky substituents by intramolecular cyclization of correspondingly substituted nitrosoalkenes. For this purpose, the α-chloro oxime *(2)* (2-*tert*-butyl-2-chloro-3,3-dimethylbutanal oxime) was prepared from the nitroalkene *(1)*[4, 5]. Compound *(2)* was then converted into 2-*tert*-butyl-3,3-dimethyl-1-nitroso-1-butene *(3)* by elimination of HCl with 1,5-diazabicyclo[4.3.0]non-5-ene[6]. Compound *(3)* is the first nitrosoalkene to be stable at room temperature.

(1) *(2)* *(3)* *(4)*

Brief heating of *(3)* to 220 °C, accomplished by drawing it at 10^{-4} torr through a 90-cm vertical glass tube packed with glass rings at this temperature into a cold trap (−196 °C), furnishes 4,4-di-*tert*-butyl-4*H*-1,2-oxazete *(4)* in 54% crude yield. The by-products of the reaction are di-*tert*-butyl ketone and hydrogen cyanide which are apparently decomposition products of *(4)* since they are formed in low yields at low temperature, in greater yields at higher temperatures, and are the sole products above 240 °C. Below 220 °C the reaction product still contains unreacted *(3)*. Compound *(4)* can be isolated by preparative layer chromatography.

The structure of *(4)* follows from mass-spectrometric elemental analysis, fragmentation to ions of di-*tert*-butyl ketone and hydrogen cyanide[7], and the spectral data listed in Table 1. It is confirmed by degradation of *(4)* to di-*tert*-butyl ketone and sodium cyanide on heating with sodium methoxide in methanol.

The starting material for the preparation of another stable 4*H*-1,2-oxazete was obtained by reaction of ammonium 3-*tert*-butyl-4,4-dimethyl-2,3-dinitro-2-pentanide *(5)*[8] with dilute sulfuric acid. Preparative layer chromatography of the product mixture afforded the nitro oxime *(6)* (3-*tert*-butyl-4,4-dimethyl-3-nitropentanone 2-oxime). On reaction of *(6)* with an equivalent amount of sodium methoxide in methanol sodium nitrite is eliminated to give 4,4-di-*tert*-butyl-3-methyl-4*H*-1,2-oxazete *(7)*, whose structure is established unequivocally by elemental analysis, the spectral data listed in Table 1, and its mass-spectrometric fragmentation to ions of di-*tert*-butyl ketone and acetonitrile.

(5) (6) (7)

Since no blue coloration is observed during the transformation *(6)* → *(7)*, we assume that the expected nitrosoalkene cyclizes considerably faster than *(3)*. Attempts to prepare 4*H*-1,2-oxazetes having sterically less demanding substituents were unsuccessful.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

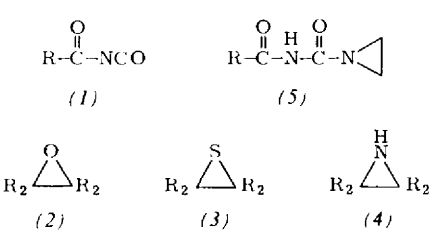
The synthesis of polychloro compounds with chlorinated functional groups such as $-CH_2Cl$, $\geq CCl_2$, $-CCl_3$, *etc.* by direct chlorination of the substrate is unsatisfactory. Addition and telomerization reactions open up new routes for the direct synthesis of a number of types of polychloro compounds. *R. Kh. Freidlina* and *E. C. Chukovskaya* describe such reactions of unsaturated compounds (alkenes, vinyl, alkyl, acryl monomers) with compounds containing a trichloromethyl group, *e.g.* 1,1,1-trichloroethane, 1,1,1,3-tetrachloropropane, 1,1,1,5-tetrachloropentane, pentachloroethane, DDT, 1,1,1-trichloro-2-methyl-2-propanol, trichloroacetates. The reactions are initiated by systems consisting of an iron compound, particularly pentacarbonyliron, in combination with cocatalysts such as acetonitrile, methanol (in large amounts), *N*,*N*-dimethylaniline, DMF, hexamethylphosphoric triamide (in small amounts). The reactions proceed *via* cleavage of the C—Cl bond of the trichloromethyl group and formation of polychloro derivatives having a $R-CCl_2-CH_2-C(Cl)\leq$ group. [Synthesis of Polychloro Derivatives with Various Functional Groups Containing Chlorine. Synthesis *1974*, 477—488; 47 references]

[Rd 736 IE—M]

The synthesis of cyclobutanes from olefins by photochemical cyclodimerization, metal-catalyzed cyclodimerization, and radical-cationically induced dimerization is dealt with in an article by *L. J. Kricka* and *A. Ledwitch*. The photochemical cyclodimerization of simple olefins to cyclobutanes is limited to a few examples, whereas strained cyclic olefins readily cyclodimerize. There are numerous examples for the photochemical cyclization of polycyclic olefins, unconjugated dienes, and vinylarenes. A few examples are known for the metal-catalyzed cyclodimerization of olefins. A number of vinyl-substituted aromatic amines, particularly carbazole derivatives, cyclodimerize in the presence of oxidizing agents such as Fe^{III}, Ce^{IV}, and Cu^{II} and on irradiation with UV and daylight, especially under the action of sensitizers. Linear dimers occur as by-products. The reactions proceed *via* intermediary radical cations. [Cyclobutanes from Photochemical, Metal-Catalyzed, and Cation-Radical Induced Dimerization of Mono-Olefins. Synthesis *1974*, 539—548; 89 references]

[Rd 737 IE—M]

Cycloaddition reactions of aliphatic and aromatic acyl isocyanates *(1)* are summarized in a review by *B. A. Arbuzov* and *N. N. Zobova*. Suitable methods have been found in recent years for the preparation of these compounds (which are more reactive than alkyl and aryl isocyanates) and their thio and seleno analogs. Owing to their double-bond system, acyl isocyanates *(1)* can undergo $[\pi 2+\pi 2]$ and $[\pi 4+\pi 2]$ cycloadditions with numerous unsaturated compounds and thus afford new routes to the synthesis of heterocyclic systems. A description of the physical and chemical properties of *(1)* is followed by an account of their reactions with unsaturated compounds (*e.g.* olefins, enamines, enol ethers, isocyanides, acetylenes, diazo compounds, carbonyl compounds, dialkyl sulfoxides), oxiranes *(2)*, thiiranes *(3)*, and aziridines *(4)*. Reactions of *(1)* with *(2)* or *(3)* usually



(1) (5)

(2) (3) (4)

yields open chain and cyclic derivatives, the latter with ring expansion. Reaction with aziridine leads to the urea derivative *(5)*, whose benzoyl derivative can rearrange to a five-membered ring system, an imidazoline derivative. *N*-Substituted aziridines react in a similar way with benzoyl isocyanate at high temperatures in the presence of LiBr *via* ring expansion to give an imidazolidine derivative. [Cycloaddition Reactions

of Aliphatic and Aromatic Acyl Isocyanates. Synthesis *1974*, 461—476; 70 references]

[Rd 739 IE—M]

Mixed cyanide phosphane complexes of transition metals are reviewed by *P. Rigo* and *A. Turco*. So far complexes of this type are known with metals of the eighth group and the first subgroup of the periodic table. Phosphane ligands stabilize low oxidation numbers of metals and promote the formation of otherwise unstable transition metal compounds as organometallics, hydrides, dinitrogen complexes, *etc.* As cyanide phosphane complexes of a certain metal may occur in different oxidation and coordination numbers, they can play an important role in homogeneous catalysis of organic reactions. This is exemplified in the synthesis of organic nitriles catalyzed by nickel complexes. Bi- and polynuclear cyanide phosphane complexes with cyanide bridges have also been prepared. [Cyanide Phosphine Complexes of Transition Metals. Coord. Chem. Rev. *13*, 133—172 (1974); 151 references]

[Rd 740 IE—H]

The importance of nickel as a trace element in organisms is the subject of a review by *F. H. Nielsen* and *D. A. Ollerich*. The essential function of this element has been long recognized from pharmacological, toxicological, biochemical, and chemical investigations. Recently, it has been possible to induce nickel deficiency in experimental animals. This results in biochemical and morphological changes in the liver. A deficiency of nickel in the organism leads to slower oxidation of α-glycerophosphate and the lipid level increases, while the phospholipid level sinks. Morphological changes can be observed by the increase in volume of cisterna of the rough endoplasmic reticulum and of the mitochondria. [Nickel: A New Essential Trace Element Fed. Proc. *33*, 1767—1772 (1974); 52 references]

[Rd 744 IE—R]

Recent results of hemoglobin research are reported by *E. Antonini*. Since a resolution down to 2.8 Å has been achieved in X-ray structural analyses, it is possible to distinguish quite accurately the individual groups participating in interactions and to recognize changes in conformation. The discovery of further anomalous hemoglobins has led to a better understanding of the relationship between structure and function. The assembly of subunits has been studied in detail since it became possible to isolate α- and β-chains preparatively. The equilibrium and kinetics of the ligand binding have gained new importance, especially as regards the influence of polyanions such as ATP or 2,3-diphosphoglycerate on the addition of oxygen. [Heme Proteins: Hemoglobin FEBS Lett. *40*, S98—S104 (1974); 98 references]

[Rd 746 IE—R]

Lipids and membranes are reviewed in an article by *J. A. Lucy*. Membranes which primarily act as barriers are particularly rich in lipids, whereas in "functional" membranes the protein content predominates. In addition, differences are also found in the cholesterol content, in the degree of unsaturation, and in other chemical criteria. An important function of the lipids is the modification of the activity of membrane-bound enzymes. Membranes have a certain fluidity, the extent of which is determined, *inter alia*, by cholesterol content. At present, particular interest is being shown in the stability of membranes and the role of lipids in membrane fusion. [Lipids and Membranes. FEBS Lett. *40*, S105—S111 (1974); 45 references]

[Rd 747 IE—R]

The specificity of enzymes of D-glucose metabolism toward anomers is discussed in an article by *B. Wurster* and *B. Hess*. The substrates of carbohydrate metabolism generally exist as mixtures of cyclic and open chain substances. In order to make speculations on structure or on metabolic processes it is important to know which form of substrate is the reaction partner of the enzyme. The specificity at high enzyme activity is determined so as to be able to follow the anomerization as the slowest step. There are non-specific (hexokinase), specific (dehydrogenases), and other enzymes with more or less distinct α- or β-specificity (mutases, isomerases). The open-chain form also serves as substrate (aldolase). Some enzymes catalyze the anomerization process. As a rule the enzymes with highest specificity are those which catalyze reactions at, or directly adjacent to, the anomeric carbon atom. [Anomeric Specificity of D-Glucose Metabolism. FEBS Lett. *40*, S112—S118 (1974); 69 references]

[Rd 748 IE—R]

Insect hormones and their bioanalogs as potential insecticides is the subject of a review by *F. Šorm*. This topic has recently commanded a great deal of interest, since it is hoped that methods will be found for the selective control of insects. Distinction is made between activating, molting and juvenile hormones. The latter are potential insecticides since they hinder development to the adult form. Numerous compounds have recently been isolated from plant sources or chemically synthesized, some of which are even species specific. Difficulties are still encountered in the use of these compounds in the open country. [Insect Hormones and Their Bioanalogues as Potential Insecticides. FEBS Lett. *40*, S128—S132 (1974); no references]

[Rd 749 IE—R]

New approaches to immunosuppression is the title of a review authored by *L. R. Lyle* and *C. W. Parker*. Particular emphasis is placed on the potential use of "toxic" antigens. They are synthesized by binding a toxin or a toxin-producing enzyme to an antigen; these conjugates can then destroy antigen-sensitive cells selectively. Another interesting possibility is the use of non-metabolizable antigens. [New Approaches to Immunosuppression. Fed. Proc. *33*, 1889—1893 (1974); 38 references]

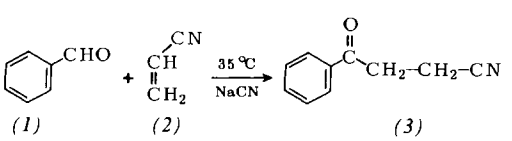
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Ketones are prepared by treatment of aromatic or heterocyclic aldehydes with activated unsaturated compounds in the presence of cyanide ions. Thus, β-benzoylpropionitrile *(3)* is formed in 80% yield from benzaldehyde *(1)* and acrylonitrile *(2)*. The following aldehydes are cited among others as exam-

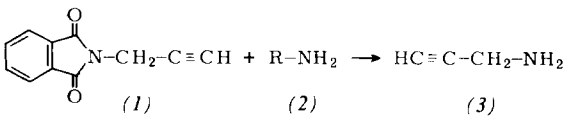


(1) *(2)* *(3)*

ples: *p*-chlorobenzaldehyde, *p*-methoxybenzaldehyde, furfuraldehyde, and 2-pyridinecarbaldehyde. As well as *(2)*, the following unsaturated compounds are suitable components for this reaction: esters of crotonic, maleic, and cinnamic acid, benzylideneacetone, phenyl vinyl ketone, and enamines. [DOS 2262343; Bayer AG, Leverkusen]

[PR 231 IE—G]

Propargylamine *(3)* is obtained in high yield when *N*-propargylphthalimide *(1)* is treated with high-boiling amines *(2)* [b.p. above 130°C, preferably above 170°C; in examples, R = $HO(CH_2)_2$—, benzyl and $(C_2H_5)_2N(CH_2)_3$—] in a solvent



(1) *(2)* *(3)*

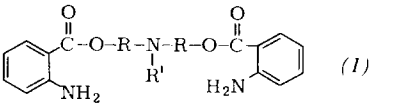
of similar high boiling point [DOS 2405370; Centre d'Études pour l'Industrie Pharmaceutique, Toulouse (France)]

[PR 232 IE—K]

Acetonedicarboxylic acid and its derivatives are formed in high yield when ketene and phosgene react in a suitable organic solvent at −30 to +50°C with molar ratio of total ketene: total phosgene < 2.0 and the product is allowed to react with a compound containing active hydrogen, *e.g.* with an alcohol. The acetonedicarboxylic esters prepared by this process can be converted into citric acid or citrates by a cyanohydrin synthesis and subsequent hydrolysis. [DOS 2409 342; Akzo GmbH, Wuppertal]

[PR 233 IE—D]

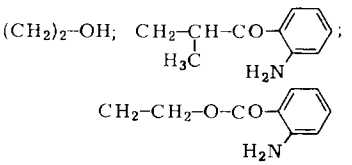
Aromatic polyamines such as *(1)*, **suitable for the production of polyurethane plastics** with improved tensile strength, are obtained by reaction of (i) compounds containing at least one tertiary nitrogen atom and at least two hydroxyl groups and with molecular weights within the range 119 to 1000 with (ii) isotoic anhydride in maximally equivalent amount.



(1)

R = $-(CH_2)_2-$; $-\underset{CH_3}{CH}-CH_2-$; $-(CH_2-CH_2-O)_2-$

R' = CH_3; $n\text{-}C_4H_9$; C_2H_5; $c\text{-}C_6H_{11}$; C_6H_5;



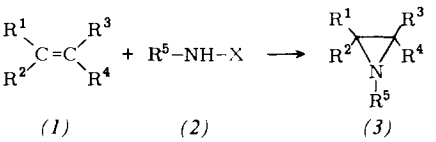
The groups favored for R and R' are given in the formula scheme. [DOS 2160590; Bayer AG, Leverkusen]

[PR 235 IE—W]

Transparent plastics reinforced by glass fibers can be obtained from 5—50 wt.-% of glass fibers or glass beads and 95—50 wt.-% of a mixture of at least two compatible thermoplastic materials whose proportions have been so assigned that the refractive index of the mixed plastics and the glass fibers is less than 0.002. Mixtures with poly(methyl methacrylate) and styrene-maleic anhydride copolymers are described. [DOS 2229129; BASF AG, Ludwigshafen]

[PR 236 IE—W]

Aziridines *(3)* are obtained on reaction of olefins *(1)* with *N*-haloamines *(2)*. R^1 to R^4 represent H, alkyl, cycloalkyl,



(1) *(2)* *(3)*

or aryl; R^5 is H or alkyl; X is Cl or Br. [DOS 2354470; Akademie der Wissenschaften der DDR, Berlin (GDR)]

BOOK REVIEWS

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopedia of Technical Chemistry). Editional board: *E. Bartholomé, E. Biekert, H. Hellmann*, and *H. Ley*. Acaricide bis Antihistaminica (Acaricides to Antihistamines). Verlag Chemie GmbH, Weinheim 1974. 4th Edit., xvi, 720 pp., 208 figures, 211 tables, subscription price DM 345.—; final price *ca.* DM 385.—.

This is the first of the alphabetically arranged volumes constituting the main part of the new (4th) edition, as in previous editions of "Ullmann"[*]. As in the thematic part, the text in the alphabetical volumes has been completely rewritten. However, the general concept has been retained, *i.e.* the main emphasis is on industrial methods of production and related problems. The presentation has become more terse than previously which was a necessity in order to accommodate the increased amount of material relating to new products and processes within a work of reasonable size. At the same time, the new layout (two columns on each page and more pronounced optical subdivision) has improved the clarity of presentation.

Under the various key words the sub-sections on properties, occurrence and raw materials, preparation, quality, storage and transport, uses, economics, toxicology, are accompanied by a special section on the problems of liquid and gaseous effluents. Each entry is followed by a bibliography for further information, divided into surveys and specialized references.

Pharmaceuticals are particularly well represented in the key words in this volume, together with alkaloids (57 pp.), analgetics (25 pp.), antibiotics (60 pp.), and antihistamines (14 pp.). The raw materials include ammonia (70 pp.), acetylene (29 pp.), and acetaldehyde (13 pp.), and of the metals there is aluminum (including alloys and compounds, 112 pp.). Other large entries are for acetone (18 pp.), aliphatic aldehydes (24 pp.), alcohols (including polyhydric ones, 33 pp.), amines (aliphatic 19 pp., aromatic 10 pp., aniline 11 pp.), and anthraquinone dyes (62 pp.). Recognized industrial experts are responsible for the individual key word entries; the sections

[*] Cf. Angew. Chem. internat. Edit. *13*, 423 (1974).

on toxicology are written by *H. Oettel* (Ludwigshafen), and many of those on economics by *L. Franke* (Frankfurt/Main).

With the appearance of this, the first, new alphabetical volume it can be stated that in its new edition "Ullmann" retains its unbeaten record as a handbook of technical chemistry in respect to both the quality of its contents and to its lay-out. Particular credit should go to the editors, who, in spite of the large number of authors, have preserved the pleasant and homogeneous presentation.

Ulfert Onken [NB 236 IE]

Die Struktur der Atome und Moleküle (The Structure of Atoms and Molecules). By *J. Barrett*. Translated by *M. Ziegler*. Verlag Chemie GmbH, Weinheim 1973. 1st Edit., x, 348 pp., 205 figures, 62 tables, paperback, DM 38.—.

The book leads from the particle-wave dualism of photons and electrons to atomic structure and the periodic system. The major part of the work is concerned with bonding in diatomic molecules and gives a detailed treatment of Walsh diagrams and the electron pair repulsion model. The whole is rounded off by a chapter on π-electrons and bonding in solids and transition metal complexes.

The text is intended for first-year students and for teachers who want an introduction to theoretical chemistry that does not involve complicated derivations. Such readers demand a clear text in which simplicity is not achieved at the expense of correctness, and the important point to note is that since most of today's introductory chemistry books contain increasingly longer and better theoretical chapters, a book devoted solely to theory must offer some advantages over the general chemistry textbooks.

Unfortunately, this is not true of the book in question. The observant reader will find so many mistakes that its usefulness for students must often be questioned. For example, already on page 3 the electrostatic nature of nuclear forces leads to serious fears about the stability of our world, whereas the nucleus and the electrons are held together by "nuclear forces". The translation is not particularly careful; for example, we find "*virtuelles Vakuum*", "*degenerierte d-Orbitale*" and "*nicht müssen*" (for "must not"). This type of mistake, whether trivial or grave, could be easily removed, but the language mastery of either the author or the translator seems inadequate for the conceptual difficulties of modern physics; for instance, on page 48 it is interchangeably asserted that the wave nature of electrons should be understood as statistical and non-statistical.

It is true that such mistakes and inaccuracies occur mainly in the first part, but it seems dangerous to burden beginners or other readers with them, particularly as this book may remain the only one on theoretical chemistry that the reader works through.

It should not be overlooked that the chemical part, in particular the last two chapters, is considerably more successful, but the book cannot really be recommended until it has received more careful—and editorial—revision.

Finally, some suggestions may be permissible. In recent years quantum-chemical calculations have been used increasingly in organic chemistry, so that a new edition should contain chapters on the Woodward-Hoffmann rules and on Hückel theory. Also, photoelectron spectroscopy could be used as convincing support for the shell structure of atoms and as an experimental basis for the introduction of the MO model.

International Edition in English

Geochemistry of Stable Isotopes

By Jochen Hoefs[*]

During the past 25 years a new branch of research has developed under the name "stable isotope geochemistry", and its importance within the earth sciences has steadily increased. The present progress report considers the scope, and also the limitations, of this discipline.

1. Introduction

The foundations of isotope geochemistry were laid by *Urey et al.*[1] about 40 years ago with the discovery of the heavy isotope of hydrogen (deuterium). Even the preliminary experimental studies revealed that a partial separation or fractionation of the isotopes is possible by natural processes. The breakthrough to a degree of experimental precision adequate for most of the problems of isotope geochemistry came in the guise of a mass spectrometric technique, known as the "compensation bridge", developed by *Nier et al.*[2] in 1947.

Isotope geochemistry is concerned not so much with absolute isotope ratios but rather with differences in isotopic composition between a sample and a standard, which are expressed as "δ values". The δ value is defined as:

$$\delta[^0/_{00}] = \frac{R_{(sample)} - R_{(standard)}}{R_{(standard)}} \times 1000$$

where R is the isotope ratio of the pertinent element (*e.g.* $^{18}O/^{16}O$). The precision is generally $\pm 0.1\,^0/_{00}$. Positive (negative) δ values signify that the sample contains more heavy (light) isotopes than the standard.

Natural variations in isotopic composition can arise in two fundamentally different ways:

1) By genesis of nuclides on radioactive decay, particularly of the isotopes ^{40}K, ^{87}Rb, ^{232}Th, ^{235}U, and ^{238}U. Decay reactions provide a means of dating minerals and rocks. This discipline is known as geochronology.

2) By processes attributable to differing zero point energies of the isotopes and thus to their differing masses[3–7].

This progress report will be concerned exclusively with processes of the second kind.

2. Isotope Fractionation

The isotopes of an element can be fractionated in the following ways: by isotope exchange reactions in chemical equilibria, by kinetic processes, and by changing the state of aggregation.

Isotope exchange reactions between several phases of a system are generally not accompanied by chemical changes. Such exchange reactions can be described in a similar manner to "true" chemical reactions. Typically:

$$CaC^{16}O_3 + H_2{}^{18}O \rightleftharpoons CaC^{18}O^{16}O_2 + H_2{}^{16}O$$

The equation means that when calcium carbonate and water are present together the heavy isotope ^{18}O becomes enriched in the calcium carbonate. All isotope exchange reactions show temperature-dependent equilibrium constants. The equilibrium constant at 0 °C and 25 °C, respectively, is $K_0 = 1.0326$ and $K_{25} = 1.0286$. In other words: at 0 °C the oxygen in calcium carbonate contains $32.6\,^0/_{00}$ more ^{18}O than the oxygen in the water. With rising temperatures the equilibrium constant tends to unity, *i.e.* the separation effects disappear. This is the principle underlying determinations of "paleotemperatures" for geological objects, which will be considered in greater detail in Section 4.

[*] Doz. Dr. J. Hoefs
Geochemisches Institut der Universität
34 Göttingen, Goldschmidtstrasse 1 (Germany)

Kinetic isotope fractionations are generally due to differing reaction rates of isotopic molecules. These effects can occur in chemical reactions and in physical processes, *e.g.* diffusion of gases. On average the molecules containing the light isotope move faster in the gas phase than those containing the heavy isotope. The relative velocities can be deduced from the square root of the molecular weight ratio. For instance, the following relationship applies to CO_2:

$$\frac{\text{velocity } (^{13}C^{16}O^{16}O)}{\text{velocity } (^{12}C^{16}O^{16}O)} = \sqrt{\frac{45}{44}} = 1.011$$

i.e., the average velocity of $^{12}CO_2$ is $11\,^0/_{00}$ higher than that of $^{13}CO_2$. In Nature, typical examples of kinetic isotope fractionations are found in photosynthesis and bacterial sulfate reduction.

Isotope fractionations also occur during changes of phase, *e.g.* on crystallization and fusion. From the standpoint of isotope geochemistry, the evaporation and condensation of water occupies a position of paramount importance. The molecules H_2O and HDO, and $H_2{}^{16}O$ and $H_2{}^{18}O$, have different vapor pressures; the lighter isotope accumulates in the vapor phase. On evaporation of water, the light hydrogen isotope becomes enriched in the vapor phase more than the light oxygen isotope owing to a greater relative mass difference $\Delta m/m$. However, both undergo proportional fractionation so that in all samples of water that have participated in the atmospheric cycle a correlation exists between δD and $\delta^{18}O$, which is expressed empirically as

$$\delta D = 8\delta^{18}O + 10$$

(see Fig. 1).

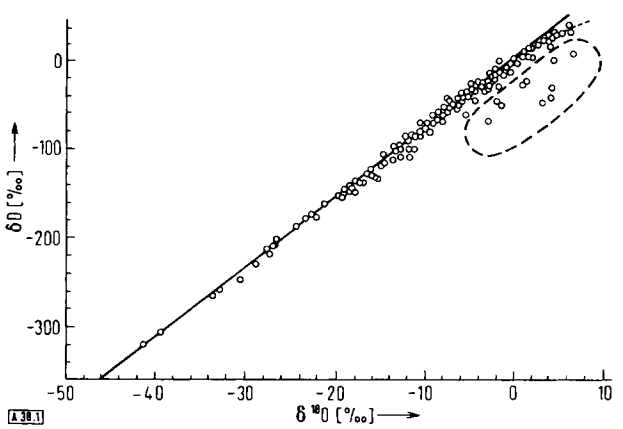

Fig. 1. Isotopic composition of meteoric water samples. The standard employed is SMOW (Standard Mean Ocean Water). The enclosed points apply to samples where evaporation took place under nonequilibrium conditions (after ref. [8]).

The most detailed studies have so far been performed on isotope fractionation for the elements hydrogen, carbon, oxygen, and sulfur; the elements boron, nitrogen, and silicon have been investigated less extensively[9].

The isotopic composition is determined by mass spectrometry, a high precision being attainable only for gaseous samples. Hence it is essential that a suitable gaseous compound of the element to be analyzed should exist, and that the element can be converted into that compound. Furthermore, it is of utmost importance that each step of the chemical preparation procedures should proceed quantitatively. Otherwise the results may be falsified by relatively large fractionation effects.

For elements which do not form suitable gaseous compounds such as potassium, magnesium, and calcium—a mass spectrometric determination of solid substances must be performed, the precision attainable then being about 10 times lower. Since the theoretically predicted fractionation effects for these elements are themselves rather small, the differences measured are of the same order as the experimental error. Precise statements are therefore still impossible for these elements (with the possible exception of potassium for which the differences are somewhat larger).

Prior to a discussion of applications, a number of generally valid rules of isotope geochemistry should be mentioned.

1) Isotopic fractionation is especially pronounced for elements whose isotopic masses differ widely. Hence the greatest isotopic fractionations are encountered with hydrogen. The maximum differences in isotopic composition are of the order of 50% in terrestrial samples and considerably higher in lunar samples owing to the influence of the solar wind (proton current). With carbon-13 and oxygen-18 the natural differences amount to 10—11% in extreme cases, and 15% with sulfur-34. As the atomic number increases, the expected fractionation contributions decrease. Contemporary analytical techniques permit recognition of fractionations up to bromine (atomic number around 35).

2) The elements best suited for geochemical studies are those which form solid, liquid, and gaseous compounds that are stable over a wide temperature range.

3) The heavier isotope is very often incorporated in the more highly oxidized form. Examples: sulfates are "heavier" than sulfides, and carbonates are "heavier" than organic carbon compounds. Exceptions to this rule can provide clues to a special origin.

4) Differences in isotopic composition decrease with rising temperature. Thus isotopic composition is a fundamental indicator of the formation temperature of minerals and rocks.

5) In biochemical reactions, *e.g.* photosynthesis and bacterial sulfate reduction, the light isotope is enriched in the reaction product since kinetic isotope fractionations occur preferentially in biological processes. In other words, biologically formed compounds should tend towards negative δ values.

3. Water

Water plays a crucial role in numerous geological processes. This applies not only to events on the earth's surface, but also to those occurring at greater depths (*e.g.* in the earth's mantle, even though the mantle most probably contains no more than 0.1% of H_2O). In this context, we shall merely consider the question whether the various volcanic phenomena such as hot springs, geysers, *etc.* involve surface water or juvenile water. The relationship shown in Figure 1 provides an unequivocal answer to this question, as is apparent from Figure 2.

The solid circles represent the isotopic composition of rain water in volcanic regions, and the open circles indicate the isotopic composition of the hot water. While the hydrogen

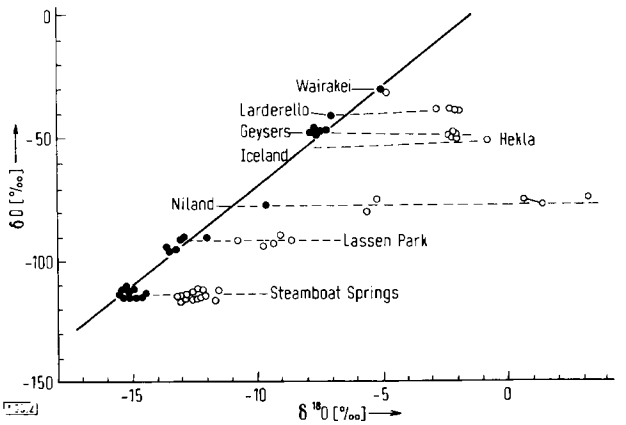

Fig. 2. Isotopic composition of "hot springs". ●, local rainwater; o, "hot springs" (after ref. [10]).

isotope composition of the hot water agrees well with that of the local rainwater, the oxygen isotope composition is always displaced to a greater or lesser extent towards higher values. This shift occurs because at high temperatures the water exchanges its oxygen isotopes with the ^{18}O-enriched silicates and, above all, carbonates in the surrounding rocks to become enriched in ^{18}O itself. Isotope analyses reveal that natural hot spring water are fed to at least 95 % by percolating surface water.

4. Thermometry

The determination of the "temperature of formation" of minerals and rocks can be regarded as one of the central questions in earth sciences. However, most of the "thermometers" so far described suffer from the disadvantage that not only the temperature, but also the pressure, have to be considered in the calculations. This is not the case with thermometers based on the determination of isotopic composition since the volumes of isotopically substituted molecules are independent of pressure. The first and best known thermometer of this kind is connected with the term "paleotemperature". In 1947, *Urey* postulated that the oxygen isotope ratio in calcereous organisms should provide a measure of the water temperature from which the organisms secrete carbonate. Thus the ^{18}O content of fossil chalk shells is measured and the temperature at which the animal lived and built up its shell is derived from the known temperature dependence of the oxygen isotope exchange between water and carbonate. In principle, it should therefore be possible to establish the past temperature of the oceans. Application of this thermometer requires that three prerequisites be fulfilled:

1) The isotopic composition of the seawater in the geological past must be known. Balance calculations strongly suggest that the isotopic composition of the oxygen in the oceans has not changed significantly during the past 400 million years.

2) The secreted carbonate must have been in isotopic equilibrium with the surrounding water. On passage through the calcereous organisms and during the actual secretion metabolic processes occur which can lead to isotopic fractionation. In recent years, evidence has accumulated that very many, if not most, organisms secrete carbonate selectively by metabolic processes[11-14] and therefore no longer reflect the original isotopic composition of the seawater.

3) After secretion of the carbonate, no isotopic exchange should occur between the shell and circulating pore water. However, the question whether recrystallization has occurred in a fossil after its deposition in a sediment cannot always be answered with certainty[15, 16].

Owing to the uncertainties mentioned, the above three prerequisites will certainly not be fulfilled in most cases. It is therefore not surprising that the method of paleotemperatures has recently commanded less interest.

In contrast, the determination of "formation temperatures" from the oxygen isotopic composition in silicates is becoming increasingly important.

Studies on minerals and rocks from widely differing sources have repeatedly shown that silicate, carbonate, and oxide minerals contain varying amounts of ^{18}O[17, 18]. Table 1 lists the most important minerals in the order of their ability to enrich ^{18}O.

Table 1. Important minerals arranged in the order of decreasing ^{18}O content of their oxygen.

Quartz SiO_2
Alkali metal feldspar $KAlSi_3O_8$ or $NaAlSi_3O_8$
Calcite, aragonite $CaCO_3$
Muscovite $KAl_2Si_3AlO_{10}(OH)_2$
Anorthite $CaAl_2Si_2O_8$
Garnet $(Mg,Fe^{II})_3Al_2(SiO_4)_3$
Pyroxenes $(Ca,Mg,Fe)_2Si_2O_6$
Amphiboles $Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$
Biotite $K(Mg,Fe)_3Si_3AlO_{10}(OH)_2$
Olivine $(Mg,Fe)_2SiO_4$
Magnetite Fe_3O_4

That this order is nearly always fulfilled in all rocks can be interpreted as a criterion of equilibration. Failure to comply in isolated cases indicates disequilibrium, at least for the mineral occupying the wrong place. Such disequilibrium can be caused by isotopic exchange with an aqueous solution after crystallization of the mineral; feldspars in particular, and also micas, are susceptible to such processes.

The ^{18}O concentration of the minerals listed in Table 1 have been related to crystallochemical properties[18]. Those silicates containing the most Si—O—Si bonds have the greatest tendency to concentrate ^{18}O. It can be deduced from numerous

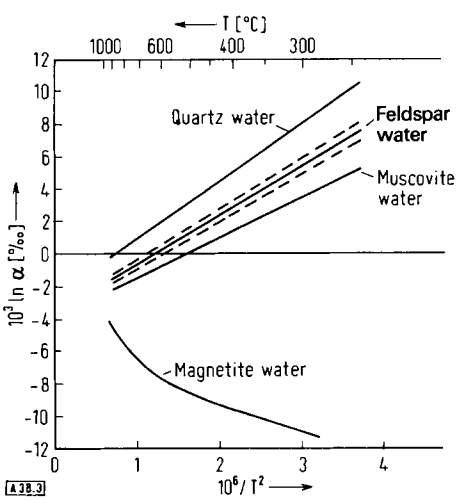

Fig. 3. Experimentally determined ^{18}O fractionation curves for several minerals. Ordinate: Fractionation factor $10^3 \ln\alpha \sim {}^{18}O_{(mineral)} - {}^{18}O_{(water)}$ in ‰ (after ref. [19]).

experimental data that at the temperature of formation of magmatic rocks the Si—O—Al bonds contain about $4\,^0/_{00}$ less ^{18}O then the Si—O—Si bonds, and the Si—O—Mg and Si—O—Fe bonds contain $2\,^0/_{00}$ less again.

Experimentally determined calibration curves (Fig. 3) permit calculation of the "formation temperatures" of rocks. The method requires measurement of the $^{18}O/^{16}O$ ratios of at least two minerals coexisting in the rock sample. The most successful application of this thermometer has been with metamorphic rocks in the temperature range of 250 to 600 °C[17, 20–22]. The value actually determined is the temperature of the last isotope exchange between the minerals and a fluid phase which in many cases can deviate considerably from the true "formation temperature". One may therefore ask what the measured temperatures have to tell us. However, in the most favorable case, particularly against a background of detailed knowledge of geological and petrological data, such a temperature value can certainly be of assistance.

5. Biosphere

The expression biosphere as used here embraces all living organisms—plants, animals, and microorganisms—and their remains in the geological milieu, *e.g.* coal and petroleum. Photosynthesis plays an essential role in fractionations occurring in the biosphere. This applies not only to carbon but also to hydrogen and oxygen. However, we shall restrict our attention to carbon in this article. Photosynthesis entails kinetic fractionation processes which can be divided into two steps[23]:

Step 1: the plant surface preferentially absorbs $^{12}CO_2$;

Step 2: of this CO_2, the $^{12}CO_2$ is preferentially incorporated into the primary photosynthetic product.

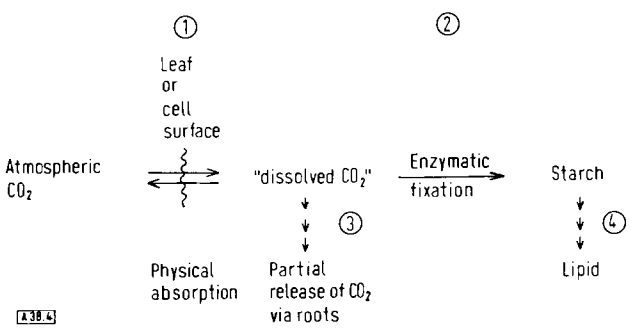

Fig. 4. Model for fractionation of carbon isotopes during photosynthesis. ①—④ are the steps in which fractionation can occur (after ref. [23]).

A fairly detailed model is depicted in Figure 4; four steps are shown in which the isotopes can undergo fractionation. The relative weights and efficiencies of the individual steps differ within species and families so that the isotopic composition can vary widely in plants[24]. Furthermore, numerous studies on plant material have shown that the isotopic composition of the carbon can provide information about the metabolism of organisms. Plants whose photosynthesis involves the enzyme ribulose 1,5-diphosphate carboxylase (RuDPC) can be distinguished from those which require the enzyme phosphoenol pyruvate carboxylase (PEPC) instead[26].

The organic constituents such as proteins, carbohydrates, *etc.* extracted from organisms are characterized by various $^{13}C/^{12}C$ ratios (Table 2). This gives us an opportunity to trace the history of these constituents during and after deposition in sediments. For instance, a decarboxylation is generally associated with a lowering of the ^{13}C content of the residual organic material since the carboxyl group is enriched in ^{13}C[27]. Fossil sediments are enriched in ^{12}C relative to recent sediments because "isotopically heavy" proteins and, to a lesser extent, carbohydrates (see Table 2)—as the most unstable organic compounds in the geological milieu—undergo very fast degradation[28]. Moreover, it can be shown that petroleums arise from the lipid fractions of plants and animal primary products[29].

Table 2. Isotopic composition of organic compounds in marine plankton (after ref. [25]).

	$-\delta^{13}C\ [^0/_{00}]$

6. Sulfide Ore Deposits

The sulfide ore minerals such as FeS_2, $CuFeS_2$, PbS, ZnS, *etc.* belong to the least soluble compounds of the respective elements. How can these relatively insoluble metal sulfides be enriched and transported without enormous volumes of water?

With the advent of "isotope geochemistry" attempts were made—almost inevitably—to find fresh answers to such old questions. Numerous studies have been undertaken (*e.g.*[30–34]) to establish the origin of the sulfur by means of the $^{34}S/^{32}S$ ratio in sulfide mineral ores. In these investigations it was assumed that the sulfides from magmatic-hydrothermal ores, whose sulfur should come from greater depths, exhibit a fairly constant isotopic composition comparable with that of sulfides in meteorites. In contrast, ore deposits whose sulfur has come from surface-near sediments and can often be derived from the action of sulfate reducing bacteria have a highly variable isotopic composition with a predominance of negative ("light") δ values. This is due to kinetic fractionations in bacterial sulfate reduction in which "heavy" sulfate reacts to give "light" hydrogen sulfide[35, 36].

Meanwhile[37, 38], this concept has been proved invalid in the above simple form. Whereas the ore minerals were formerly always assumed to have the same isotopic composition as the ore-transporting solution, *Ohmoto*[38] has shown that the isotopic composition can depend upon the following factors:

1) Isotopic composition of the total sulfur in the ore-forming solution; 2) temperature of the solution; 3) oxygen fugacity of the solution; 4) pH value of the solution.

For instance, at 250 °C a change in the oxygen fugacity by a factor of ten or a change in the pH value by one unit can give rise to a $20\,^0/_{00}$ change in the isotopic composition of the sulfides deposited. However, these considerations are based on the assumption that the dissolved sulfur compounds and the precipitated sulfides are in equilibrium, a condition which certainly may not always be fulfilled in Nature.

7. Extraterrestrial Material

Variations in the isotopic composition of meteorites and lunar samples can provide evidence for differing nuclear syntheses. The fractionation pathways described so far are characterized by a dependence of fractionation upon the relative mass difference $\Delta m/m$. With elements having more than two isotopes, *e.g.* oxygen, the fractionation effect for ^{17}O is therefore only half as great as that for ^{18}O. A plot of $\delta^{17}O$ *versus* $\delta^{18}O$ should therefore be a straight line having a slope of

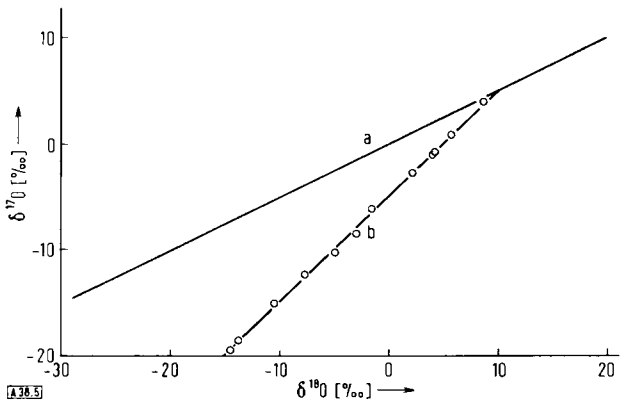

Fig. 5. Relation between ^{17}O and ^{18}O contents in terrestrial samples and lunar samples (a), and in minerals from carbonaceous meteorites (b) [40].

$+\frac{1}{2}$, provided that all samples have arisen *via* the same nuclear synthesis. *Kaplan* and *Hulston*[39] obtained similar results for sulfur in meteorites. In contrast, *Clayton et al.*[40] have obtained a line having a slope of $+1$ (see Fig. 5) for several anhydrous minerals from carbonaceous chondrites. This could be due to the admixture of almost pure ^{16}O, which may not have come from our planetary system.

8. Outlook

In conclusion we might attempt to forecast the future development of isotope geochemistry, neglecting further instrumental and methodological improvements. Our present knowledge of the isotopic composition of the elements present in terrestrial material is good. In order to gain further insight into the origin of minerals, rocks, and other interesting objects it will be necessary, on the one hand, to combine isotopic studies on the various elements and, on the other, to attempt simulations of natural fractionation processes in the laboratory.

Fixation of Atmospheric Nitrogen by Microorganisms

By Diethelm Kleiner[*]

In Memory of Artturi Ilmari Virtanen

Research on the enzymatic assimilation of molecular nitrogen (N_2 fixation) has made decisive advances in recent years. Both the purely scientific aspects of this process and its industrial implications are assuming ever-increasing interest. Some of the results most important from the biochemical point of view have been collected in the present report.

1. Introduction

The fixation of atmospheric nitrogen by microorganisms is a process whose importance is exceeded only by photosynthesis. The pioneering contributions to its study are closely connected with the names of *D. Burk*, *P. W. Wilson*, and *A. I. Virtanen*, but biochemical elucidation of the enzymatic processes involved took a leap forward only when, in 1960, it became possible to prepare cell-free extracts capable of fixing nitrogen[1].

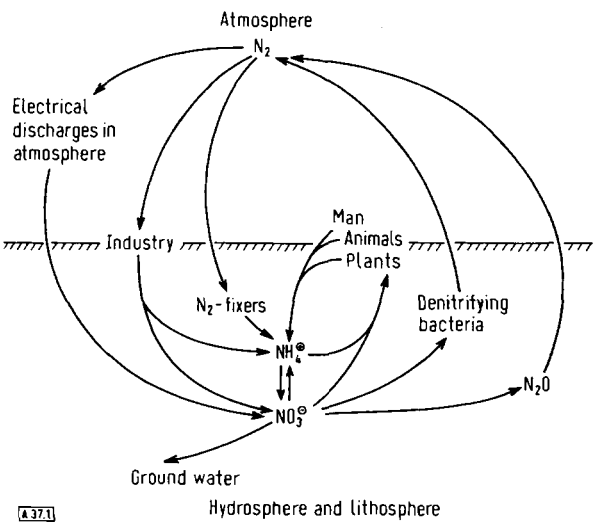

Fig. 1. Nitrogen cycle in Nature (after [2]).

Figure 1 shows the nitrogen cycle existing in nature in which part of the inorganic nitrogen present in the soil is washed out into the ground water and a further part is lost to the air by the action of denitrifying bacteria (reduction of nitrate to N_2). These losses are generally balanced by three processes: formation of nitrogen oxides by atmospheric electrical discharges (a few percent), industrial fertilizer production (*ca.* 30%), and microbial activity (*ca.* 70%)[2].

Many of the microorganisms capable of fixing nitrogen remain to be discovered. Those organisms that are known to have this action—whether existing free or in symbiosis—belong exclusively to the domain of the procaryotes (bacteria and blue-green algae) (Table 1). Of the sporadic reports that continually appear about N_2 fixation by fungi, not one could be confirmed on reinvestigation by means of the very sensitive acetylene-reduction method (see Section 3.2)[3].

[*] Dr. D. Kleiner
Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)

Free-living N_2-fixing agents are widely distributed in nature, being found in many soils[4–8], in lakes and seas[9–13], on Antarctic rocks[14], in hot springs[15], in the wood of dying

Table 1. N_2-fixing organisms.

a)	Free-living
	1. Bacteria (*e.g. Clostridium, Azotobacter*)
	2. Blue-green algae (*e.g. Anabaena, Tolypothrix*)
b)	Symbionts
	1. Blue-green algae in lichens
	2. Blue-green algae or bacteria in leaves (leaf symbionts)
	3. Rhizobia in leguminous plants
	4. Several mainly unknown microorganisms (Actinomycetes?) in the roots of angiosperms

trees[16], and in the gut of termites[17], mammals[18], and man[18]. More important agriculturally and ecologically, however, are the symbionts, particularly the bacteria that occur in nodules on the roots of higher plants.

2. Inertness of the N_2 Molecule

Nitrogen is known to be an unreactive element. Comparison of some of the physical properties and the molecular parameters of the isoelectronic compounds N_2, CO, and C_2H_2 (Table 2) shows that the main reason for this lack of activity lies in the great increase in bond energy occurring on transition from the double to the triple bond[19].

Table 2. Physical properties of the isoelectronic molecules N_2, CO, and C_2H_2 (after [19]).

	:N≡N:	:C≡O:	HC≡CH
Bond length [Å]	1.098	1.128	1.208
Ionization energy [eV]	15.6	14.0	11.4
Dissociation energy [kcal/mol]	225	235	200
Bond energy [kcal/mol] of the			
1st bond	38	84	83
2nd bond	100	170	147
3rd bond	225	235	200

Although the reaction

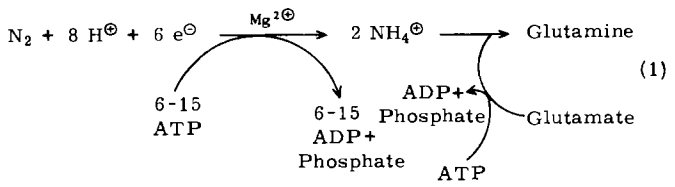
$$3\,H_2 + N_2 = 2\,NH_3$$

is exergonic with $\Delta G_0 = -12$ kcal/mol[19], it is immeasurably slow at room temperature even in the presence of industrial iron catalysts (Haber-Bosch process). In industry temperatures of at least 400 °C and pressures of about 200 atm are necessary to afford worthwhile conversion[20].

3. Biochemistry of Microbial N_2 Fixation

3.1. Reaction Path

In N_2-fixing microorganisms the assimilation is catalyzed by the binary enzyme complex nitrogenase. In this process the nitrogen is reduced according to eq. (1) to ammonium ions[21], which are probably bound to glutamate with the aid of the



(1)

enzyme glutamine synthetase[22]; ferredoxin is presumably responsible for the electron transport[23-27]. As in the Haber-Bosch process, the reaction can be induced only with a considerable expenditure of energy, which is here made available in the form of ATP[28-32]. The number of ATP molecules consumed in conversion of each N_2 molecule is not known exactly; in experiments *in vitro* it changes with the experimental conditions[33-35].

3.2. Determination of the Nitrogenase Activity[36]

In the oldest and most direct method the reaction is followed by means of heavy nitrogen. After incubation the tissue or enzyme preparation is subjected to *Kjeldahl* digestion, the NH_3 is oxidized to N_2, and the ^{15}N content of the nitrogen is determined by mass spectrometry. This method is used mainly for the determination of the activity *in vivo*.

Ammonia can also be measured directly by colorimetry if the enzyme preparations under study cannot induce its further reaction. In such cases the cofactors shown in eq. (1) (Mg^{2+}, ATP, and an electron donor, for which dithionite[37] has proved very suitable) must be added to the (usually cell-free) preparations.

In the simplest and most sensitive method, which is therefore most frequently used, acetylene is reduced to ethylene, this reduction also being catalyzed by nitrogenase (see Section 3.3). The two compounds can be readily determined by gas chromatography. The method is so sensitive that the fixation activity of no more than two blue-green algae colonies can still be determined[38].

3.3. Specificity of Nitrogenase

The active site of nitrogenase is not very substrate specific. To date the compounds listed in Table 3 have been reduced *in vitro* under the influence of the enzyme. If no substrate is added, the enzyme reduces protons and molecular hydrogen is evolved. It is remarkable that the acetylene is reduced only to ethylene[40]. In D_2O *cis*-$C_2H_2D_2$ is formed exclusively[40].

Except for the complicated reactions of cyanides and isocyanides, the relative reaction rates are in approximately inverse proportion to the number of electrons transferred, and it is therefore assumed that activation of the electrons

Table 3. Compounds reduced by nitrogenase (after [39]) n = Number of electrons transferred, V_{rel} = relative reaction rate.

Substrate	Product	n	V_{rel}
N_2	$2\ NH_3$	6	1
$N_3^{\ominus}$	$NH_3 + N_2$	2	3
N_2O	$H_2O + N_2$	2	3
C_2H_2	C_2H_4	2	3—4
HCN	CH_4, C_2H_4, C_2H_6, NH_3	6	0.6
	CH_3NH_2	4	
CH_3CN	C_2H_6, NH_3	6	0.2
CH_3NC	CH_3NH_2, CH_4	6	0.8
	C_2H_4, C_2H_6	8, 10	
	C_3H_6, C_3H_8	12, 14	
$2\ H^{\oplus}$	H_2	2	4

is the rate-determining step. Kinetic analysis of the mutual influence of the substrates has led to the hypothesis of a flexible active site capable of binding substrates with various structures[41]. All the reactions except evolution of hydrogen are inhibited by CO[41, 42]; inhibition of the reaction by the product ADP is of physiological importance[43] (see Section 4), but it is not yet clear whether this is due only to product inhibition or also to a regulatory inhibition of the enzyme[39, 44, 45]. Oxygen denatures the enzyme irreversibly.

3.4. Enzyme Purification

Denaturation by oxygen provides the chief difficulty in the preparation of pure nitrogenase, so that all the procedures must be conducted in oxygen-free atmosphere (under N_2, H_2, or argon).

In 1966 *Bulen* and *Le Comte*[46] discovered that nitrogenase is a complex of two easily separable proteins which, in the absence of systematic names, are designated component I (Mo—Fe-protein, molybdoferredoxin, azofermo) and component II (Fe-protein, azoferredoxin, azofer). A general purification scheme with the following principal steps has evolved in the course of time:

1) Preparation of a crude extract;
2) Preliminary purification (mainly fractional precipitations);
3) Chromatography on diethylaminoethyl cellulose. Elution with solvents of different ionic strengths can lead to separation of the two components in impure form;
4) Further purification of the isolated components (gel filtration, electrophoresis, fractional precipitations, heat denaturation).

This separation of the two components and their purification have been described for several microorganisms. However, in each case it has been shown that neither of the two proteins alone is able to catalyze the reduction of N_2, even in the presence of all the cofactors.

Suggestions that a third protein is necessary for full nitrogenase activity[47, 48] could not be confirmed[49].

3.5. Physicochemical Characterization of the Components

Table 4 shows the physical and chemical properties of the nitrogenase components of several organisms. In spite of the differing origins of the components, their properties are very similar. The occurrence of molybdenum in component I and the cold lability of component II in many organisms are remarkable. In accord with the low isoelectric points the

amino-acid analyses carried out so far on I and II from all the organisms show a predominance of acidic amino acids[54–56, 63, 64]; the absence of tryptophan from II is remarkable. According to *Marchalonis* and *Weltman*[65], the amino-acid composition of components I from *C. pasteurianum*, *K. pneumoniae*, *A. vinelandii*, and *Rh. japonicum* indicates their evolution from a common precursor; similarly, components II from *C. pasteurianum*, *A. vinelandii*, and *K. pneumoniae* may have evolved from a single ancestral protein.

[a] Abbreviations: C.p.—*Clostridium pasteurianum*; A.v.—*Azotobacter vinelandii*; K.p.—*Klebsiella pneumoniae*; Rh.j.—*Rhizobium japonicum*; Chr.—*Chromatium spp.*; M.f.—*Mycobacterium flavum*.

It could be shown by Mössbauer spectroscopy that the Fe atoms in I belong to three distinct groups with differing spectra, while in II they are bound in the same way[66]. The occurrence of iron and sulfide-sulfur in approximately equal amounts, the characteristic EPR signals (see Section 3.7), the absorption spectra in the visible and near UV regions[45], and the evolution of H_2S on acidification classify both nitrogenase components as iron-sulfur proteins[67]. Many members of this class, which is widely distributed among the procaryotes, are characterized by very low electron-transfer potentials.

3.6. Combination of the Components from Different Organisms

Although the nitrogenase components from different organisms are very similar, they cannot be combined at will to give active complexes. In particular, those that are only remotely related taxonomically show little readiness to cooperate[39, 68, 69]. For example, neither the combination of I from *A. vinelandii* (obligately aerobic) with II from *C. pasteurianum* (obligately anaerobic) nor the reciprocal mixture is capable of N_2 fixation[69]. Closer relatives give more positive results; for example, all "cross-reactions" of the nitrogenase proteins from *B. polymyxa* and *K. pneumoniae* (both facultatively anaerobic) are almost as active as the homologous combinations[69]. It is not yet known what causes these differences, because neither the amino-acid sequence nor the tertiary structure of any nitrogenase protein has so far been elucidated.

3.7. Electron Transport and Reaction Mechanism

Only very recently have the roles of the two components in the overall process been established, by means of EPR spectroscopy[70–75]. Fig. 2 shows the EPR spectra of the two components from *C. pasteurianum*, alone and in admixture, at 13 K, with and without cofactors. It is assumed that the signals at $g = 4.29$, 3.77, and 2.01 belong to half-reduced I, whereas reduced I shows no signal. In contrast, oxidized II is assumed not to display any signal but after reduction to show the signals at $g = 4.3$, 2.05, 1.94, and 1.88. Thus, in the presence of dithionite, I exists in the half-reduced form (a) and II in the reduced form (b). The signal of the mixture (c) shows weak interactions between the components, but no electron transfer. Addition of MgATP has no effect on

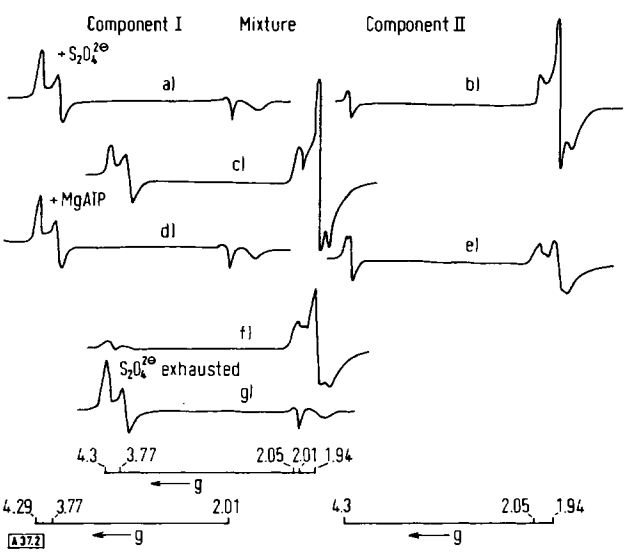

Fig. 2. EPR spectra of nitrogenase components I and II from *C. pasteurianum* under various conditions. a)—g) see text (after [70]).

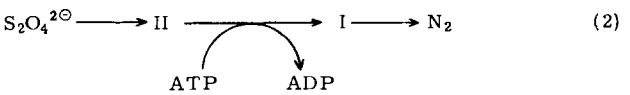
the spectrum of I (d), but changes the spectrum of II (e). Hence it is concluded that MgATP is bound to II, and this finding has been confirmed by binding studies[76, 77] and other experiments[78]. The complex of II with MgATP is now in a position to reduce I completely with hydrolysis of ATP, whereupon the signal of the latter largely disappears (f). ATP can thus effect electron activation or conformational change of II, after which electron transfer can take place.

When the electron source is exhausted, II is oxidized and I is half-reduced, and only the signals of I are observed (g). Accordingly an electron flow as in eq. (2) may be postulated for the enzymatic reduction of N_2.



(2)

Although the electron transport in the enzyme complex has been largely elucidated by these investigations, they provide no information about the composition of the active site or the mechanism of the N_2 reduction. The oldest and most widely accepted proposal[79] assumes reduction of the N_2 in three steps, by way of diimine and hydrazine to ammonia. However, in spite of intensive search neither of these intermediates could be discovered, and furthermore, neither hydrazine nor diimine can be reduced by nitrogenase[80, 81]. In two other proposed mechanisms the ability of Mo^{III} and Mo^{VI} to form stable compounds is emphasized[82, 19]. Also, in analogy to inorganic N_2 complexes[82a], end-on binding of the N_2 has been postulated[82]. However, none of these theories has yet been supported by experimental evidence[*].

4. Regulation of Nitrogenase Activity *in Vivo*

As already mentioned, microbial reduction of N_2 is possible only because energy in the form of ATP is consumed for the activation of the unreactive N_2 molecule, so that this assimilation process is very expensive for the organism. A regulatory system has therefore been developed in many N_2-fixing organisms, in which the nitrogenase synthesis is repressed by $NH_4^{\oplus}$[83–90]. The extracellular $NH_4^{\oplus}$ concentration effecting this repression can be very low for many organisms (*e.g. ca.* 10 µmol/l in *A. vinelandii*[91]). If there is an adequate external supply of $NH_4^{\oplus}$ (and $NO_3^{\ominus}$) ions, this crude regulatory mechanism slows down the expensive N_2 assimilation that is then no longer necessary. Induction of the synthesis by the substrate N_2 probably does not occur; indeed, from the standpoint of evolution it would be useless since there is hardly any biotope on the Earth that is free from N_2[89].

A second and more sensitive regulatory mechanism, also mentioned above, is based on inhibition of the enzyme by ADP[43]. The organism is thus unable to use up its ATP completely for N_2 fixation unless the ADP produced in this reaction is immediately reconverted to ATP. Even though a low level of ATP decreases the rate of the N_2 fixation, ADP amplifies this signal to the nitrogenase. AMP has no inhibitory activity[43].

5. Possible Industrial Applications

Implications of the industrial application of N_2 assimilation abound in agriculture, environmental protection, and food technology.

5.1. Agriculture and the Environment

5.1.1. Symbionts

It has long been known that cultivation of leguminous plants increases the subsequent yield of other crops (green manuring)[92]. This is due to the N_2 assimilation by nodular bacteria (rhizobia), which can impart 80—90% of their nitrogen to the host plants[93]. To *Virtanen* in particular belongs the credit for the development of very active strains of rhizobia, which are used for the inoculation of leguminous seeds and which have led to considerably increased harvests.

However, it is still unclear what factors enable rhizobia to form a symbiotic association with leguminous plants in particular. Extensive investigations are now in progress[94, 95] on the clarification of this problem, in the hope that it will be possible to induce other plants also to undergo symbiosis with rhizobia[95]; the recent discovery of symbiosis between a non-leguminous plant (*Trema aspera*) and a bacterium of the genus *Rhizobium*[96] is encouraging.

In addition to leguminous plants there are other N_2-assimilating symbioses of ecological importance, *e.g.* among the lichens and in the roots of some angiosperms and gymnosperms[97, 98]. In the last case it has not yet been possible to isolate the endophyte (probably an actinomycete[99]). Both groups are extremely important for the colonization of washed out, arid soils, as these are poor in readily soluble nitrates and ammonium salts[92, 93].

5.1.2 Free-Living Microorganisms

The free-living N_2 fixers excrete up to 80%[13] of their assimilated nitrogen in bound forms, *inter alia* as NH_3[100, 101], hydroxylamine derivatives[102], amino acids[103, 104], peptides[105] growth substances[106], and fungicides[106]. These excretions can in turn be taken up and utilized by higher plants[107, 108].

In most soils the number of free-living N_2 fixers is small in comparison with the number of other soil bacteria[109], but it is assumed that, as a result of their wide distribution, the free-living N_2 fixers make a significant, though small, contribution to the fertility of the soil (5—20 kg of N per hectare per year, compared with 100—300 from leguminous plants[39, 94]. This contribution can be increased in two ways:

a) by transfer of the genetic material for N_2 fixation ('nif-genes') to soil bacteria that occur frequently;

b) by optimization of the living conditions of free-living N_2 fixers.

As regards a), it has recently been possible by conjugation to transfer nif-genes from *K. pneumoniae* to *E. coli*[110], which otherwise cannot assimilate atmospheric nitrogen. This success has given rise to great hopes but it has not yet led to large-scale

[*] Editorial comment: *G. N. Schrauzer* will shortly comment upon the most recent views concerning the mechanism of nitrogen reduction in this journal.

application, and the transfer of nif-genes to human hereditary material, envisaged by some journalists, belongs for the present to the realm of science fiction.

As regards b), the number of N_2 fixers can be increased by favorable ecological conditions to such an extent that almost the entire nitrogen demand of a biotope can be met by their activity. This is the case if in nitrogen-poor soils the amount of energy required for the assimilation of N_2 is available. This energy is ultimately provided by sunlight and is conserved in the form of ATP either by photophosphorylation or by photosynthesis (formation of carbohydrates) and oxidative phosphorylation. Bacteria capable of photophosphorylation and blue-green algae find particularly good living conditions in the warm, well-illuminated flooded areas of rice fields[111]; their large contribution to the nitrogen balance has been confirmed by measurements of N_2 fixation *in situ*[112, 113], and it has also been found in numerous experiments that the rice yield can be increased by inoculating the fields with these organisms[114–117].

Other favorable biotopes exist in the root zones of some plants if the roots excrete large amounts of organic compounds. (The reduction of 10 mg of N_2 requires *ca.* 1 g of carbohydrate.) The rhizospheres of cane sugar and bahia grass (*Paspalum*[118, 119]) have been investigated most widely. These plants excrete so much carbohydrate that some cane sugar fields have been cultivated for more than 100 years without nitrogen-manuring, yet without any decrease in yield[119].

Attempts have also been made to increase the yields of other cultivated plants (maize, wheat, oats, potatoes, *etc.*) by inoculating the fields with N_2 fixers, particularly *Azotobacter*[106, 120–123]. In most cases the application of these "bacterial manures" has resulted in a small increase in yield, but ironically this is probably ascribable less to an increase in the N content (because of the energy deficiency) than to the above-mentioned bacterial production of growth substances and fungicides[106, 121]. Becauses of the effort involved, the use of "bacterial manuring" has decreased greatly in recent years[106]. This technology could, however, attract renewed attention if questions of environmental protection and the dependence of agriculture on industry come to the fore. Only a small part of the nitrogen in artificial manures is utilized by the plants, the remainder being washed out into the ground water[109, 124, 125]. This in turn contributes to nutrient enrichment of the water and its eutrophication. However, nitrogen-containing secretions from microorganisms are released continuously and are probably better retained in the soil. The major problem remains the provision of a cheap source of energy. It has already been shown that the nitrogen content of soil can be increased under certain conditions by the addition of straw (cellulose) because of a stimulating interaction between N_2-fixing and cellulose-decomposing bacteria[126, 127].

It should also be noted that, owing to their high carbohydrate consumption, free-living N_2 fixers could be useful in the biotechnological purification of effluents having a high content of organic compounds[128, 129].

5.2. Food Technology

Provision of carbohydrates and proteins for the world's population is one of the most urgent problems of our time. Although this is primarily a political problem[130], yet in the long view new methods of providing food must be developed. Here mention will be made only of two unorthodox solutions of the protein problem.

In New Guinea there is a race of Papuans whose daily food consists almost exclusively of *ca.* 2 kg of sweet potatoes together with leaves, and in spite of the resulting permanent protein deficiency the district is densely populated and the adults can perform heavy work[131]. The solution of this riddle may lie in the significant activity of N_2 fixers recently discovered in the intestinal flora of these people.

When investigating an Indian maize mash ("Pozol"), a group of Mexican research workers[132] found that its nitrogen content increased by 30—60% during the 5 to 10 days fermentation period customary in that area; they attributed this enrichment to the activity of N_2 fixers. This conclusion should be tested by the acetylene-reduction method, but in this connection it is remarkable how widely the fermentation of food is encountered among many non-European peoples[133].

The author is grateful to Prof. K. Wallenfels for critical perusal of the manuscript and for stimulating discussions.

Preparation, Structure, and Reactions of Halomalondialdehydes[1]

New synthetic methods (8)

By Christian Reichardt and Klaus Halbritter[*]

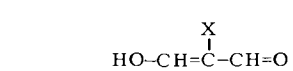
Dedicated to Professor Karl Dimroth

The present progress report provides a survey of the synthesis, structure, and reactions of halomalondialdehydes, including "cyanomalondialdehyde" (diformylacetonitrile), the only pseudohalogen compound so far known in this series. Halomalondialdehydes are reactive compounds, applicable in a variety of ways, and are characterized particularly by their cyclizations with bifunctional compounds. Many of the reactions discussed below can be applied to substituted malondialdehydes other than those specified.

1. Introduction

The chemical properties of saturated aliphatic dialdehydes of the general formula OCH—$(CH_2)_n$—CHO ($n>1$) do not differ fundamentally from those of simple monoaldehydes, for they act as bifunctional monoaldehydes; however, the first two members of this homologous series—glyoxal ($n=0$) and malondialdehyde ($n=1$)—are exceptional, since in the former compound the two carbonyl groups interact conjugatively and in the latter there is a possibility of keto-enol tautomerism. Glyoxal and malondialdehyde can be regarded as the initial members of a homologous series of unsaturated dialdehydes, and it is then useful to distinguish those with an even number of carbons from those with an odd number. Unsaturated aliphatic dialdehydes with an even number of carbons and of general formula OCH—$(CH{=}CH)_m$—CHO, being vinylogs of glyoxal, can be assigned to the series of polyene dyes. Unsaturated dialdehydes of the general formula OCH—$(CH{=}CH)_{m-1}$—CH_2—CHO⇌OCH—$(CH{=}CH)_m$—OH are enolized and are thus vinylogs of formic acid; the anions (and cations) of these dialdehydes belong to the polymethinoxonol class of dyes[2].

Because of its low stability, malondialdehyde *(1)*, the parent compound of this homologous series, could not be obtained in crystalline state until 1941 (*Hüttel*[3]), although as early as 1903 *Claisen*[4] had obtained it in aqueous solution by hydrolysis of 3-ethoxyacrolein diethyl acetal[5].



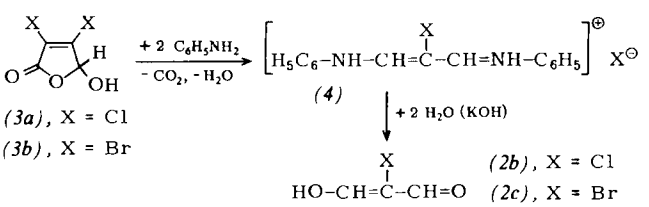
(1), X = H
(2), X = alkyl, cycloalkyl, aryl, heteroaryl, CHO, COR, CO_2R, CN, NH_2, NR_2, $N_2^{\oplus}$, N=N-R, NO_2, OH, OR, OCOR;
(2a), X = F; *(2b)*, X = Cl; *(2c)*, X = Br; *(2d)*, X = I;
(2e), X = CN

On the other hand, some of the substituted malondialdehydes *(2)*, *e.g.* nitro-[6] and bromomalondialdehyde *(2c)*[7, 8], were prepared and studied in depth long ago. Only the halo- and pseudohalomalondialdehydes *(2a)* to *(2e)* are treated in detail below, but they should be regarded as characteristic representatives of a large number of accessible substituted malondialdehydes.

2. Preparation of Monohalomalondialdehydes

2.1. General Methods

Mucochloric acid *(3a)* and mucobromic acid *(3b)* react with aniline to afford, with decarboxylation, the halomalondialdehyde dianil hydrogen halides *(4)*, from which alkaline hydrolysis leads by way of the monoanils and potassium salts to the free halomalondialdehydes *(2b)* and *(2c)*[7, 9]. In this way chloromalondialdehyde *(2b)* was first obtained[9].



(3a), X = Cl
(3b), X = Br
(4)
(2b), X = Cl
(2c), X = Br

Hydrolysis of the 1,2,3,3-tetrahalo-1-propenes *(5a)* and *(5b)* with conc. sulfuric acid leads, according to the nature of the halogen on C-2, to chloro-[10-14] or bromomalondialdehyde[11]. Compounds *(5a)* and *(5b)* are readily accessible by $AlCl_3$-catalyzed addition of chloroform to the 1,2-dihaloethylene followed by dehydrohalogenation.

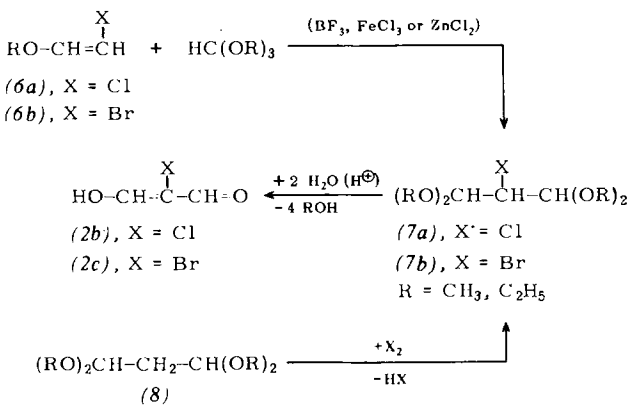
(5b), X = Br
(2b), X = Cl
(2c), X = Br

The electrophilic addition of orthoformic esters to suitably β-substituted enol ethers *(6)* is of particular importance, since

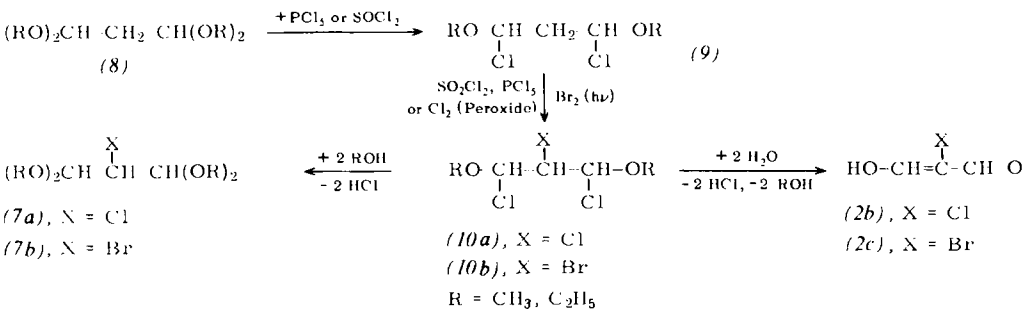
[*] Prof. Dr. C. Reichardt and Doz. Dr. K. Halbritter
Fachbereich Chemie der Universität
335 Marburg, Lahnberge (Germany)

it can be used for the synthesis of many substituted malondialdehydes; in case of *(6a)* and *(6b)* this reaction gives 70—80% yields of the readily hydrolyzable tetraalkyl acetals *(7a)* and *(7b)* of chloro-[15, 16] and bromomalondialdehyde[15–17], respectively. The reaction is catalyzed by Lewis acids and includes the addition of a dialkoxycarbenium ion formed from the orthoester to the double bond of the enol ether[18, 19].



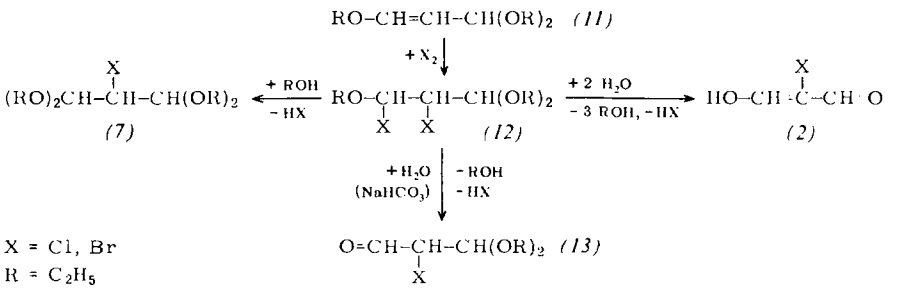
The tetraalkyl acetals *(7a)* and *(7b)* are also accessible by cautious direct halogenation of the malondialdehyde diacetal *(8)*[20–23, 23a].

Although halogens substitute the malondialdehyde diacetals *(8)* directly at C-2, the first product formed on treatment of *(8)* with phosphorus pentachloride or thionyl chloride is 1,3-dialkoxy-1,3-dichloropropane *(9)*, which can then also be halogenated at C-2, thus giving *(10a)* or *(10b)*[24]. These 1,2,3-trihalo compounds can be converted by alcohols into the diacetals *(7a)* and *(7b)* and by water into chloro- *(2b)* and bromomalondialdehyde *(2c)*[24].



(2b) can also be prepared from an intermediate (X=Cl, R=$COCH_3$) similar to *(10a)* which is obtained from trimethylene diacetate by photochemical chlorination[25].

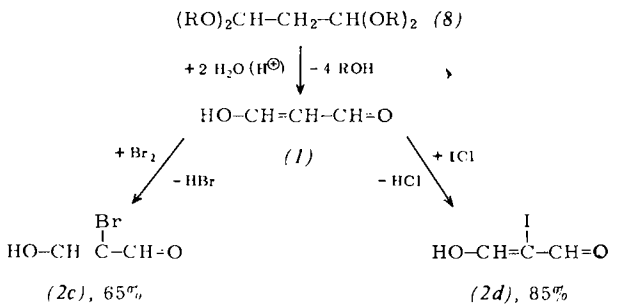
According to the method used, working up the products *(12)* of the addition of chlorine or bromine to 3-ethoxyacrolein



diethyl acetal *(11)*, R=C_2H_5, may yield the halomalondialdehyde *(2b)* or *(2c)* or alternatively their tetraalkyl acetals *(7a)* or *(7b)* or even the 1,1-dialkyl acetals *(13)*[9, 26–30].

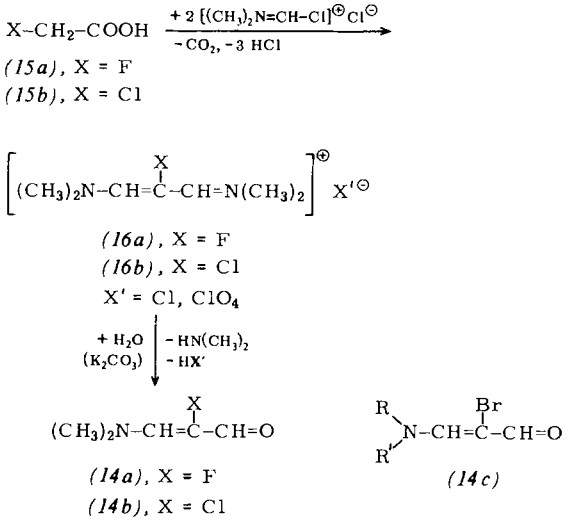
In an essentially similar manner, addition of bromine to 1,3-diethoxy-3-chloro-1-propene leads to bromomalondialdehyde *(2c)*[31].

A further route to halomalondialdehydes is provided by direct substitution of free malondialdehyde *(1)* [prepared by acid-catalyzed hydrolysis of malondialdehyde tetraalkyl diacetals *(8)*] by bromine or iodine(I) chloride. The former reaction is the simplest method of preparing bromomalondialdehyde *(2c)*[32] and the latter is the only route so far known to iodomalondialdehyde *(2d)*[33].



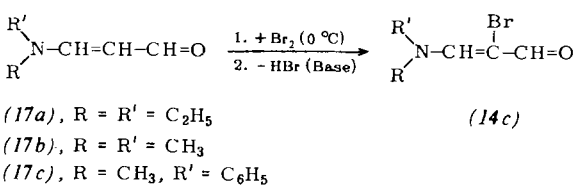
The 3-(dimethylamino)-2-haloacroleins *(14a)*[33–35], *(14b)*[34] and *(14c)*, R=R'=CH_3[36, 37], are important derivatives of the halomalondialdehydes, because as vinylogous formamides they can be readily hydrolyzed to the free halomalondialdehydes. By a process worked out by *Arnold*[34], and also applicable for the synthesis of other substituted malondialdehydes, Vilsmeier formylation of halogenated acetic acids *(15)* affords satisfactory yields of the aminohaloacroleins *(14a)* and *(14b)*. The course of the first reaction step is complicated and not yet fully understood[33, 34].

Fluoromalondialdehyde *(2a)* has only recently become known. Its synthesis by the route *(15a)*→*(14a)* involves a 37% yield of 3-(dimethylamino)-2-fluoroacrolein *(14a)*,



which is hydrolyzed by aqueous sodium hydroxide to the sodium salt of fluoromalondialdehyde, whence the free dialdehyde is obtained by means of ethereal hydrogen chloride[33, 35]. Alkylation of *(14a)* by triethyloxonium tetrafluoroborate followed by treatment with dimethylamine permitted the trimethinium salt *(16a)* to be isolated as tetrafluoroborate[38].

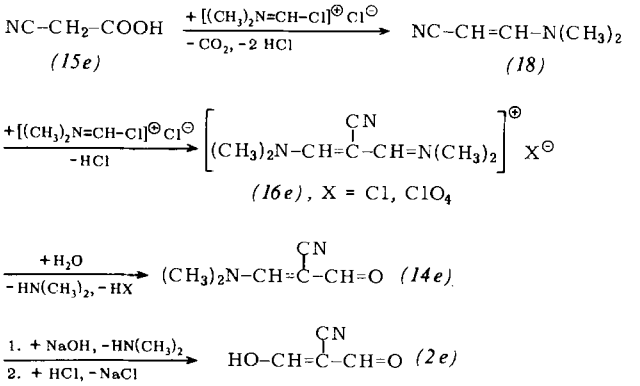
Vilsmeier formylation of bromoacetic acid led, however, not to 2-bromo-3-(dimethylamino)acrolein *(14c)*, but to a derivative of formylmalondialdehyde by the introduction of a third dimethylaminomethylene group[34]. 2-Bromo-3-(dialkylamino)acroleins can nevertheless be obtained by cautious direct bromination of the 3-(dialkylamino)acroleins *(17a)*—*(17c)* in inert solvents (benzene, chloroform, or dichloromethane)[36, 37]; the hydrogen bromides formed initially are converted into *(14c)* by treatment with bases (triethylamine or sodium carbonate solution).



Bromination of *(17b)* in aqueous solution at room temperature and subsequent heating at 100 °C lead directly to bromomalondialdehyde *(2c)*[39]. From the reaction conditions described in ref.[39] it can be deduced that the primary product is not the free malondialdehyde [obtainable by hydrolysis of *(17b)*] but instead the hydrogen bromide of *(14c)*, R = R′ = CH_3, which is hydrolyzed to bromomalondialdehyde *(2c)* at 100 °C.

The 1,3-bis(dimethylamino)-2-halotrimethinium salts *(16)* arising on Vilsmeier formylation of substituted acetic acids are also valuable halomalondialdehyde derivatives and can be obtained either, like *(16b)*, by suitable work up directly from chloroacetic acid[34, 40] or, like the bromine derivative, by bromination of the unsubstituted trimethinium salt with *N*-bromosuccinimide[41].

Vilsmeier formylation of haloacetic acids can be extended to cyanoacetic acid *(15e)*[42, 43]. Reaction of *(15e)* with dimethylformamide/oxalyl chloride in the presence of triethylamine gives, however, a 50% yield of 3-(dimethylamino)acrylonitrile *(18)* which must be again formylated in order to produce the trimethinium salt *(16e)*; according to the mode of work up, the isolated product may be the trimethinium perchlorate[41] (83%) or, after hydrolysis, 3-(dimethylamino)-2-formylacrylonitrile *(14e)* (79%)[43]. Further hydrolysis of *(14e)* is the simplest route so far to cyanomalondialdehyde *(2e)*[43].

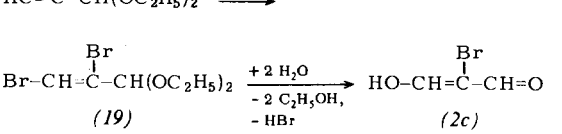


Surprisingly, the carboxyl group of *(15e)* is not needed to activate the CH_2 group in the Vilsmeier formylation: even acetonitrile reacts with dimethylformamide/$POCl_3$ to give *(14e)* in 32% yield[42, 43].

2.2. Special Methods

Whereas the more general methods described in Section 2.1 can all be used for the synthesis of at least two halomalondialdehydes, the present section gives synthetic routes that have not yet been generalized.

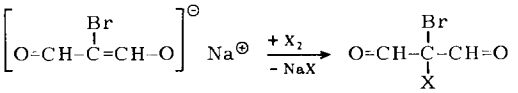
The first synthesis of bromomalondialdehyde *(2c)* was achieved by *Lespieau*[8] by the addition of bromine to 1,2-dibromo-2-methoxy-1-propene. *(2c)* can also be obtained from propargylaldehyde diethyl acetal by the addition of bromine (in chloroform) and hydrolysis of the unisolated intermediate *(19)*[44].



The first synthesis of cyanomalondialdehyde *(2e)* was accomplished by condensation of 3,3-diethoxypropionitrile with ethyl formate and hydrolysis of the intermediate 2-formyl derivative, which yields the sodium salt of *(2e)*[45, 46]. Catalytic hydrogenation of cyanoform (dicyanoketenimine) leads to 3-amino-2-formylacrylonitrile in 50% yield among other products, and alkaline hydrolysis then affords the sodium salt of cyanomalondialdehyde[47, 48].

3. Preparation of Dihalomalondialdehydes

Dibromomalondialdehyde *(20a)* is formed in 76% yield on bromination of the sodium salt of bromomalondialdehyde (in CCl_4)[32]. Chlorination gives bromochloromalondialdehyde *(20b)*[32].



(20a), X = Br
(20b), X = Cl

The tetraethyl diacetal of *(20a)* can be prepared in 60% yield from bromomalondialdehyde tetraethyl diacetal *(7b)*, R = C_2H_5, by reaction with the pyridine-bromine addition compound[28]. Attempted double dehydrohalogenation of this compound to yield carbon suboxide tetraethyl acetal was unsuccessful[28].

4. Fine Structure of Halomalondialdehydes

Halomalondialdehydes can exist as crystals and in solution in one of the three tautomeric forms *(A)* to *(C)*. An X-ray structure analysis of bromomalondialdehyde *(2c)* has been carried out[49, 50], and its results are collected in Figure 1[50]. It is found that, in the crystal, *(2c)* assumes the (*Z*)-enol form *(B)* stabilized by intermolecular hydrogen bonding[51].

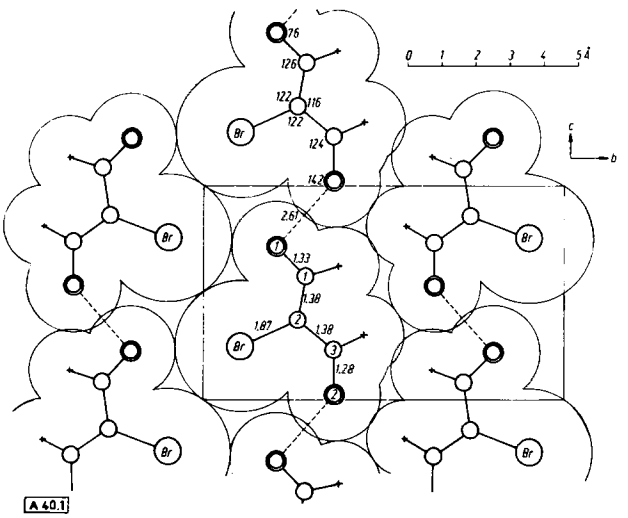


Fig. 1. Bond lengths, bond angles, and packing of the planar molecules of bromomalondialdehyde *(2c)* in the crystal [50]. Cell constants: $a = 6.490(4)$ Å; $b = 10.830(6)$ Å; $c = 6.392(3)$ Å; space group $Cmc2_1$.

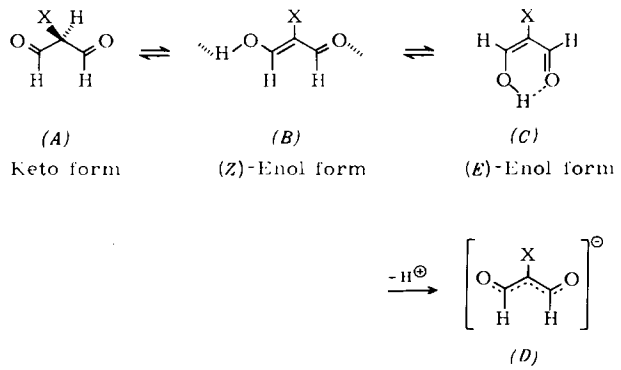
Occurrence of the enol form *(B)* also in solution is indicated by the following chemical and spectroscopic findings: a) With aqueous iron(III) chloride solution, solutions of halomalondialdehydes give the reddish-violet coloration characteristic of enolized 1,3-dicarbonyl compounds. b) Aqueous solutions of halomalondialdehydes are acidic; CO_2 is liberated from sodium carbonate. c) The IR spectra of the various halomalondialdehydes are very similar[33, 43, 52]. A detailed analysis has been carried out for the IR spectrum of bromomalondialdehyde, and this is in accord with the enol form *(B)*[52]. The IR spectrum of the bromomalondialdehyde anion indicates the conformation *(D)* with C_{2v} symmetry[52], which has also been demonstrated for the anion of unsubstituted malondialdehyde *(1)*[53]. d) The ^{1}H-NMR spectra of halomalondialdehydes (measured for *ca.* 0.2 M solutions in trideuterioacetonitrile) contain a singlet for the hydroxyl proton at *ca.* 5.5—9.5 ppm and just one signal for the two other protons at *ca.* 8.1—8.9 ppm, the intensity ratio being 1 : 2[33, 43, 54]. The OH signal is shifted downfield with increasing concentration of the solution measured[33, 43]. Such association shifts are characteristic of intermolecular hydrogen bonding. Because of the rapid exchange of position of the hydroxyl proton the two H atoms on C-1 and C-3 are equivalent and give rise to only one signal, which in the case of fluoromalondialdehyde is split to a doublet by coupling with the fluorine ($^3J_{FH} = 21$ Hz). The size of this coupling is in the region typical of vicinal *trans*-^{19}F-^{1}H couplings in fluoroalkenes[33].



(A) Keto form — *(B)* (*Z*)-Enol form — *(C)* (*E*)-Enol form

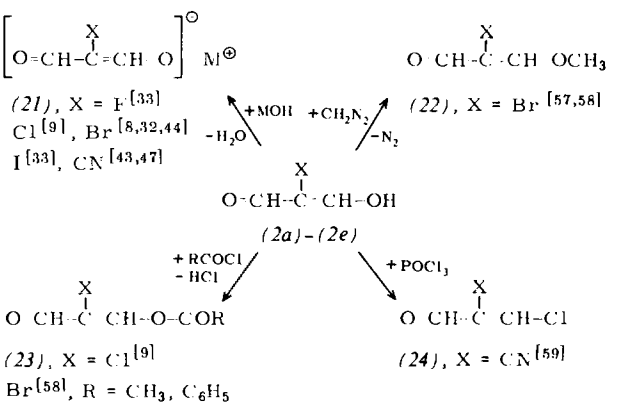
(D)

For malondialdehyde *(1)*, which occurs in the form *(C)* in apolar solvents (CCl_4, $CHCl_3$, CH_2Cl_2) but in form *(B)* in polar solvents (H_2O)[55], CNDO/2 calculations favor form *(C)* with unsymmetrical intramolecular hydrogen bonds as the energetically most favorable state[56].

5. Uses of Halomalondialdehydes in Syntheses

5.1. Preparation of Open-Chain Compounds

The fact that it is not only formally that halomalondialdehydes can be regarded as vinylogous formic acids is shown by their typical carboxylic acid reactions, such as those with metal hydroxides to give salts *(21)*, with diazomethane to give vinylogous esters *(22)*, and with acid halides (in pyridine) or phosphoryl chloride to give vinylogous carboxylic anhydrides *(23)* or formyl chlorides *(24)*, respectively.



(21), X = F[33], Cl[9], Br[8,32,44], I[33], CN[43,47]

(22), X = Br[57,58]

(2a)–(2e)

(23), X = Cl[9], Br[58], R = CH_3, C_6H_5

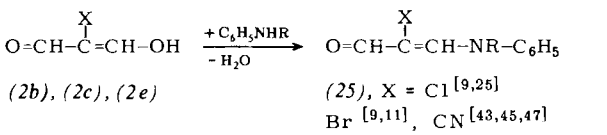
(24), X = CN[59]

However, halomalondialdehydes undergo typical aldehyde reactions such as ready acetalization [*(2b)*[13], *(2c)*[32]] and many of the reactions in the following sections.

5.1.1. Reactions with Amines

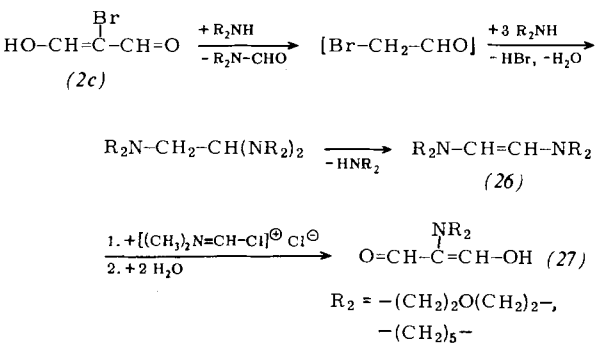
Halomalondialdehydes react with primary or secondary aromatic amines to give, according to the reaction conditions,

either the vinylogous formamides *(25)* (monoanils) or the dianils; the hydrogen halides of the latter are, however, more advantageously prepared from the mucohalic acids *(3)* and aniline (see Section 2.1). Investigation of the fine structure of the potentially tautomeric monoanils (and dianils) of cyanomalondialdehyde in solution shows their exclusive existence in the lactam form *(25)*, R = H, with intramolecular hydrogen bonding[43], in agreement with the results obtained for malondialdehyde anils[60-63].



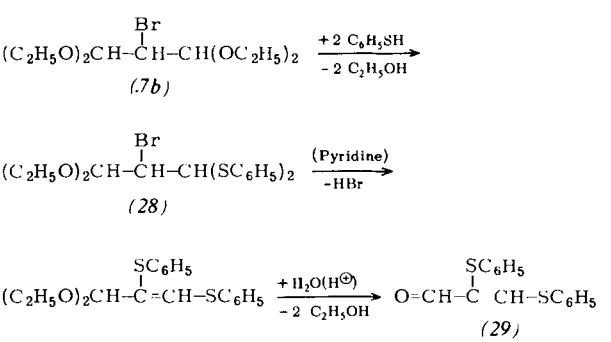
(2b), (2c), (2e) *(25)*, X = Cl[9,25], Br[9,11], CN[43,45,47]; R = H, CH_3

Surprisingly the reaction of bromomalondialdehyde *(2c)* with secondary aliphatic (cyclic) amines (morpholine, pyrrolidine) takes a different course, providing a simple route to vinylenebis(dialkylamines) *(26)*[64] which can be converted, again by Vilsmeier formylation, into the (dialkylamino)malondialdehydes *(27)*[65].

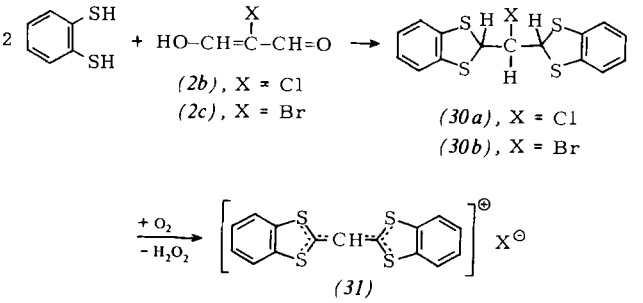


5.1.2. Reactions with Thiols

Interaction of thiophenol with bromomalondialdehyde tetraethyl acetal *(7b)* affords first the acetal-thioacetal *(28)*, which is not converted by pyridine into the ketene dithioketal by normal elimination of HBr[29] but instead gives a derivative *(29)* of (phenylthio)malondialdehyde by migration of a phenylthio group[66].



With sodium *p*-nitrophenyl sulfide chloromalondialdehyde reacts by nucleophilic substitution, yielding (*p*-nitrophenylthio)malondialdehyde[67]. With dithiopyrocatechol chloro- *(2b)* and bromomalondialdehyde *(2c)* give the bis(dithioacetals) *(30a)* and *(30b)*, respectively, both of which afford the methine dye *(31)* when air is passed through their solutions in moist chloroform[68].



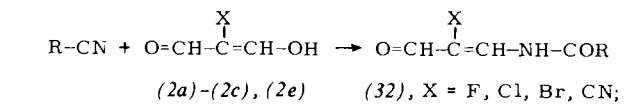
(2b), X = Cl; *(2c)*, X = Br

(30a), X = Cl; *(30b)*, X = Br

(31)

5.1.3. Reactions with Nitriles

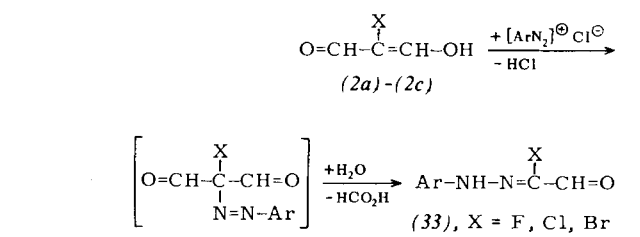
The reaction of aliphatic nitriles with halomalondialdehydes occurs analogously to that of aliphatic carboxylic acids with nitriles[48], thus providing simple access to *N*-(2-formyl-2-halovinyl)carboxamides *(32)*[54].



(2a)-(2c), (2e) *(32)*, X = F, Cl, Br, CN; R = CH_3, C_2H_5

5.1.4. Reactions with Diazonium Salts

When applied to halomalondialdehydes, the Japp-Klingemann reaction, *i.e.*, treatment of 1,3-dicarbonyl compounds with aromatic diazonium salts, leads to 1-haloglyoxal 1-phenylhydrazones *(33)*[69-72], which possess insecticidal and acaricidal properties[70].

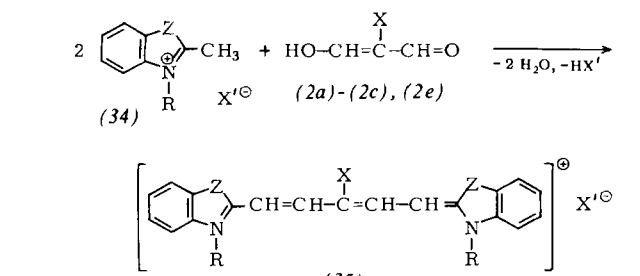


(2a)-(2c) *(33)*, X = F, Cl, Br

The potentially tautomeric compounds *(33)* exist in solution exclusively in the open phenylhydrazone form shown in the formula[72].

5.1.5. Reactions with CH-Acidic Compounds

Condensation of halomalondialdehydes *(2)*, their dianils *(4)*, their sodium salts *(21)*, or their acetals *(7)* with the heterocyclic immonium salts *(34)* customarily used in cyanine chemistry leads to γ-substituted pentamethine cyanine dyes *(35)*[73-81],



(34) *(2a)-(2c), (2e)*

(35)

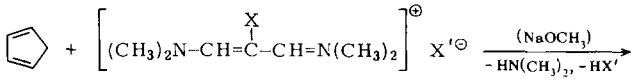
R = CH_3, C_2H_5;

X = F[80], Cl[73,79], Br[74-76,78,79,81], CN[77,79];

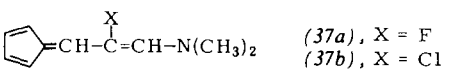
Z = $C(CH_3)_2$, CH=CH, O, S, Se

which have assumed importance as sensitizers of photographic silver halide emulsions[82] and as models for investigating the influence of substituents on the UV and visible spectra of polymethine dyes[79, 80, 83].

In condensations of halomalondialdehydes it is often advantageous to employ the 2-halotrimethinium salts *(16)* instead of the free dialdehydes, since the higher electrophilic potential of the former frequently makes reaction possible even with only weakly CH-acidic reactants. For example, the 6-[2-(dimethylamino)-1-halovinyl]fulvenes *(37)* thus become easily accessible from *(16)* and cyclopentadiene[38, 84].



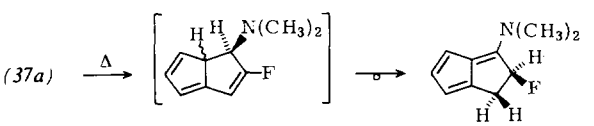
(36) *(16a)*, X = F; *(16b)*, X = Cl



(37a), X = F; *(37b)*, X = Cl

5.2. Preparation of Carbocyclic Compounds

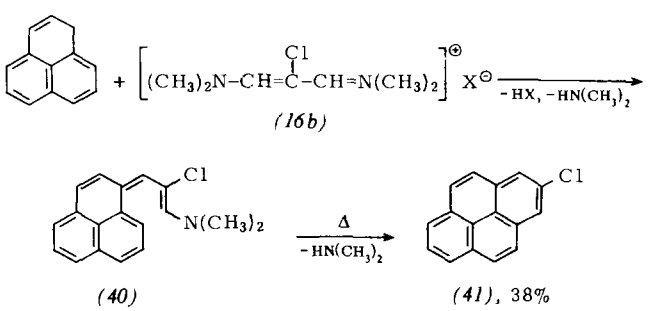
When heated for a short time in piperidine the 6-[2-(dimethylamino)-1-fluorovinyl]fulvene *(37a)* mentioned in Section 5.1.5 undergoes a presumably conrotatory electrocyclic reaction yielding the non-isolable intermediate *(38)*, which then affords 3-(dimethylamino)-2-fluoro-1,2-dihydropentalene *(39)* by a double sigmatropic [1.5]-shift of hydrogen[38, 85].



(37a) *(38)* *(39)*

In the corresponding reaction of the chloro compound *(37b)* nucleophilic replacement of the chlorine leads to the 2-piperidino derivative[54] which, like *(39)*, should be useful for the preparation of simpler pentalenes.

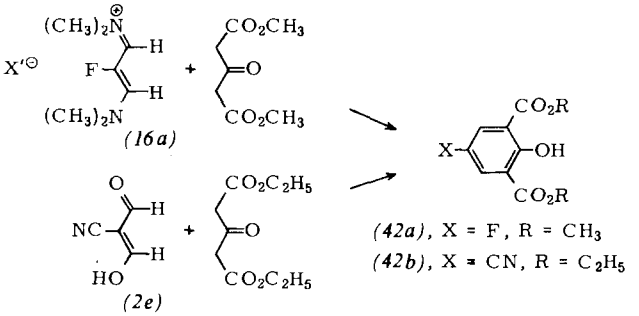
An electrocyclic ring closure with subsequent elimination of dimethylamine leading to the 2-chloropyrene *(41)* has been observed when the intermediate product *(40)* obtained from phenalene and the 2-chlorotrimethinium salt *(16b)* was heated[40]—a reaction that is capable of considerable generalization[86].



(16b) *(40)* *(41)*, 38%

On treatment of 1,2,3,3-tetrachloro-1-propene *(5a)* with anthrone in conc. sulfuric acid the intermediate chloromalondialdehyde formed from *(5a)* (cf. Section 2.1) undergoes ring closure to 2-chlorobenzanthrone[11].

The elegant Hill synthesis of *p*-nitrophenol from nitromalondialdehyde and acetone[6] has been applied to halomalondialdehydes in only two cases: interaction of cyanomalondialdehyde *(2e)* or the 2-fluorotrimethinium salt *(16a)* and acetonedicarboxylic ester gives the phenols *(42a)*[38] and *(42b)*[43], respectively.



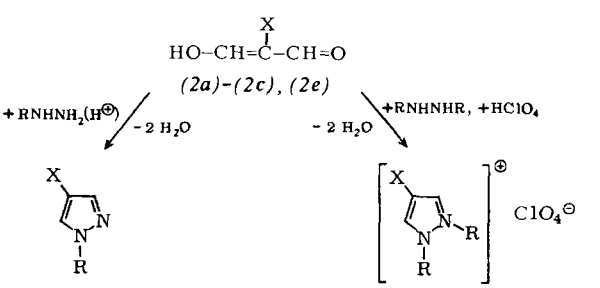
(16a) *(2e)* *(42a)*, X = F, R = CH_3; *(42b)*, X = CN, R = C_2H_5

5.3. Preparation of Heterocyclic Compounds

The synthetic potential of the halomalondialdehydes (and other substituted malondialdehydes), which is by no means yet exhausted, lies particularly in their heterocyclization with bifunctional reactants, such reactions often making it possible to prepare by simple routes pharmacologically valuable halogen-substituted heterocycles that are in many cases difficult to prepare by other methods.

5.3.1. Synthesis of Five-Membered Heterocycles

Interaction of halomalondialdehydes with hydrazine or phenylhydrazine gives good yields of 4-halopyrazoles *(43)*. It is only with iodomalondialdehyde *(2d)* that the use of hydrazine leads to unsubstituted pyrazole; here, as in almost all other cases, reactions of iodomalondialdehyde with nucleophiles are accompanied by an immediate formation of iodine[54].



(43), 50-95%
X = F[38,87], Cl[9,24,25], Br[8,9,24], CN[43,47];
R = H, C_6H_5, 4-NO_2–C_6H_4

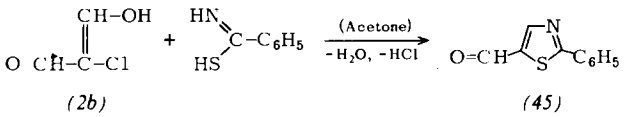
(44), 50-60%
X = F[38,87], Br[54], CN[43];
R = CH_3, $C_6H_5CH_2$

The method discovered by *Elguero et al.*[88] for the preparation of 1,2-dialkyl-substituted pyrazolium salts *(44)* can also be applied to halomalondialdehydes[38, 43, 54, 87]. 1,2-Diphenylpyrazolium salts *(44)*, R = C_6H_5, however, cannot be obtained in this way since in acid solution hydrazobenzene undergoes the benzidine rearrangement. Nevertheless, the 4-bromo-1,2-diphenylpyrazolium salt can be prepared by oxidative ring

closure of bromomalondialdehyde dianil with *N*-bromosuccinimide[89].

With sulfanes H_2S_x ($x=2$ or 3) chloro- and bromomalondialdehyde give 4-halo-1,2-dithiolium salts, analogous to *(44)*, in 10% yield[90].

Although in the preceding reactions the bifunctional nucleophile reacts with both carbonyl groups, treatment of chloromalondialdehyde *(2b)* with thiobenzamide gives an almost quantitative yield of 2-phenyl-5-thiazolecarbaldehyde *(45)*, which arises by the reaction of only one carbonyl group and nucleophilic replacement of the chlorine atom[91].

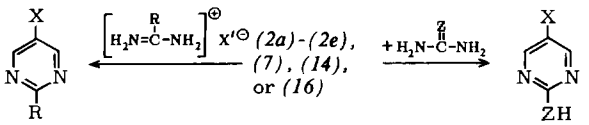


(2b) *(45)*

Similarly, 5-aminoimidazo[1,2-*a*]pyridine-2-carbaldehyde is formed from 2,6-diaminopyridine and chloro- or bromomalondialdehyde in 10 or 17% yield, respectively[92].

5.3.2. Synthesis of Six-Membered Heterocycles

Halomalondialdehydes are of special importance for the synthesis of substituted pyrimidines *(46)* and *(47)*. In condensations with amidinium salts[99] or urea derivatives the free halomalondialdehydes *(2a)—(2e)*[24, 38, 87, 93, 94] or their acetals *(7)*[24] are introduced in an acid reaction medium, or the 3-(dimethylamino)-2-haloacroleins *(14)*[38, 87] or 2-halotrimethinium salts *(16)*[43, 95, 96] are used in a basic reaction medium. The yields vary between 20 and 95%.



(46) *(47)*

X = F[38,87], Cl[95], CN[43];
R = CH_3, C_6H_5

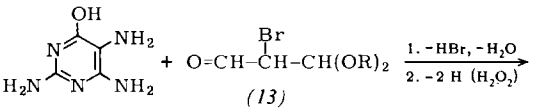
X = F[38,87], Cl[24,93-96], Br[24,96], CN[43,96], I[54];
Z = NH, S, O

By a process described by *Bredereck et al.*[97], 5-halopyrimidines which are unsubstituted at C-2, such as 5-bromo- (63%)[22] and 5-fluoropyrimidine (52%)[38, 87] can also be synthesized from halomalondialdehyde derivatives and formamide.

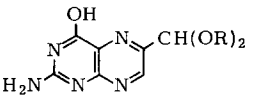
Novel types of heterocycles such as 3-fluoropyrimido[1,2-*b*]indazole[38] and 6-chloroselenazolo[3,2-*a*]pyrimidinium salts[98] are formed from 3-aminoindazole and fluoromalondialdehyde or 2-aminoselenazolium salts and chloromalondialdehyde, respectively.

The pteridine derivative *(48)*, which is formed on reaction of bromomalondialdehyde diethyl acetal *(13)*, X=Br, with 2,5,6-triamino-4-pyrimidinol, is a valuable intermediate for the synthesis of folic acid (pteroylglutamic acid)[27, 30].

The monoanils *(25)*, X=CN, R=H[43, 45, 47] obtainable from aromatic amines and cyanomalondialdehyde *(2e)* can be cyclized under drastic conditions to yield 3-quinolinecarbonitriles[45, 100, 101]; thus, when heated at 300 °C with anhydrous zinc chloride, the monoanil that is readily obtainable from

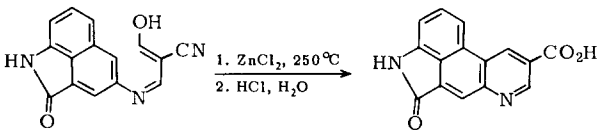


(13)



(48), R = C_2H_5

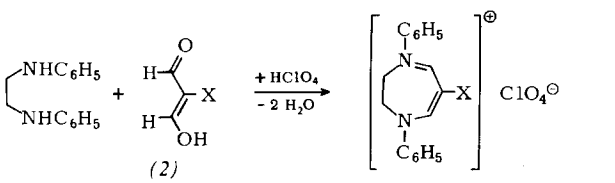
(2e) and aniline affords a mixture of 3-quinoline-carbonitrile and -carbamide[45]. Application of this reaction to the monoanil *(49)* arising from cyanomalondialdehyde and 2-aminonaphthostyril[45] and other complicated amines[100, 101] leads to quinoline derivatives such as *(50)*, which have become important intermediates for the synthesis of some lysergic acid derivatives.



(49) *(50)*

5.3.3. Synthesis of Seven-Membered Heterocycles

When 1,2-dianilinoethane, introduced by *Wanzlick* and *Löchel*[102] as a reagent for the detection of aldehydes, reacts with substituted malondialdehydes, it does not lead, as expected, to imidazolidines; instead, the 2,3-dihydro-1*H*-1,4-diazepinium salts *(51)* are formed (see also ref.[104]).



(2)

(51), X = F[38,87], Cl[54], Br[103], CN[43]

Bromomalondialdehyde reacts analogously with *o*-phenylenediamine, yielding a 3-bromo-1,5-benzodiazepine[105, 106].

The Replacement of Phosphates in Detergents—Possibilities and Limits[**]

By Peter Berth, Günter Jakobi, Edmund Schmadel, Milan J. Schwuger, and Carl Heinrich Krauch[*]

Elimination of phosphates from detergents alone, is insufficient to solve the eutrophication problem. Nevertheless, the endeavors of the detergent industry are aimed at finding phosphate substitutes. Novel approaches for at least a partial replacement of detergent phosphates have been found by using water-soluble organic complexing agents as well as heterogeneous organic or inorganic ion exchangers. So far, a large-scale replacement is not possible. It is not justifiable until all technical requirements are met with and safety with regard to man, animals, plants and drinking water has been established.

1. Introduction

While several years ago, the term "eutrophication" was familiar only to a number of specialists, it now belongs to the vocabulary of the daily press. In connection with phosphate eutrophication, detergents are among the targets of criticism, because of their content of pentasodium triphosphate (STP)[***].

What are the issues?

Undisturbed natural waters are frequently characterized by a stationary state—with regard to their content of biomass—of producers, consumers and decomposers.

The *producers* build up the biomass from minerals (phosphate, *etc.*), CO_2 and light. This is to say that they do not depend on organic carbon as a nutrient. The producers are used up by the *consumers* (mainly fish), forming a food chain up to the species man. The metabolic products are then mineralized and thus recycled by the *decomposers*.

This balance may be disturbed by excessive addition of nutrients or harmful substances: additional matter entering the ecosystem may have different effects on the activity of decomposers and producers.

Organic matter is accumulated, if it cannot be degraded by the decomposers, and a stationary state cannot be achieved. If, however, the additional organic matter is decomposed, more oxygen is withdrawn than in the stationary state.

The presence of additional inorganic matter may lead to excessive fertilization and stimulate growth of the producers, thus contributing to eutrophication. This applies, for instance, to phosphates.

Phosphates are also part of natural waters, as they are released by soil erosion. Furthermore, they find their way into the waters by way of animal and human feces.

The share of phosphates originating from detergents in stagnant or slowly flowing waters—only in these are the high nutrient concentrations achieved which will result in eutrophication—can be estimated on the basis of statistical data on land use and population figures in the affected area, sales figures for detergents and calculation of the amount of phosphate entering domestic sewerage systems by way of metabolic products. These values vary from area to area depending on the density of population, industrial structure, development of canalization and sewage treatment plants, season, amount of rainfall, type of soil and limnological conditions. According to investigations by the joint pollution control commission for Lake Constance in 1972, about 1170 tons of phosphorus found its way into the lake. 470 tons of this amount (40%) came from washing and cleaning products[1]. In the case of the Haltern reservoir, the share of phosphates originating from domestic sewage (detergents and fecal matter) is calculated to amount to 35 to 40%[2]. More than half of the

[**] Based on a paper presented by *P. Berth* during the Detergent Chemistry Meeting of the "Gesellschaft Deutscher Chemiker"—Bamberg, October 11. 1974.

[***] Sodium triphosphate.

phosphate content of the Wahnbachtal impounding reservoir is thought to reach the water by way of soil erosion[3].

The situation is quite different if a large city without surroundings is considered. Investigations in Chicago (USA) showed communal sewage to contain up to 68 % of phosphate originating from washing and cleaning products[4]. The situation may be similar in other conurbation areas, such as, for instance, the Ruhr District.

Many attempts have been made to assess the phosphate load in surface waters. According to *Bucksteeg*, the human excretion of phosphorus is 1.65 g per inhabitant per day[5]. Assuming an average quantity of sewage of 0.374 m^3 per person and day to reach the surface waters *via* the public sewage system[6], then the fecal P-content in waste water is calculated to be about 4.4 mg per liter. Mechanical and biological treatment will eliminate an average of 35 % of this[7–10], so that about 2.86 mg of fecal phosphorus per liter remain in the sewage plant effluent.

Figures for the long-term average of the surface water effluent in the Federal Republic of Germany which is about 68.4×10^9 m^3/a[11], and the total amount of sewage (6.4×10^9 m^3/a in 1969)[6] yield a dilution ratio of 1 : 10.72 (sewage/receiving water).

Thus, the amount of phosphorus in the surface waters, which is of fecal origin, should be *ca.* 0.27 mg P per liter. According to *Nümann*[12] about one third of this, *i. e. ca.* 0.09 mg phosphorus per liter is available for plant growth in the form of soluble phosphate.

Vollenweider[13], on the other hand, gives a threshold value for *oligotrophic* waters of 0.01 mg available phosphorus per liter. This value—an independent determination is presently being carried out at the Ruhrverband, Essen[14]—cannot be met, even if no detergent phosphates at all were to go into the sewage.

Hence, phosphates must be eliminated from *all* sources in order to really solve the problem of phosphate eutrophication[*]. Extensive elimination can be achieved by leading the entire sewage into sewage treatment plants and adding a chemical precipitation step to the mechanical and biological purification. In this way heavy metals and biochemically difficultly degradable organic compounds are eliminated from the sewage together with phosphates.

Here, the bulk of experience has been collected in Sweden, where 90 % of the waters are stagnant or slowly flowing, and where over 500 sewage plants incorporating chemical precipitation have been built since 1968. This measure has resulted in considerable improvement of the quality of surface waters. The phosphorus content of the effluent on leaving the chemical precipitation plant is between 0.02 and 0.5 mg per liter, and is—at an initial concentration of 1.5 to 9 mg per liter—independent of the initial concentration[15]. Considering that the phosphorus is diluted and partially *immobilized* (by precipitation) on entering the receiving water, the threshold value of 0.01 mg per liter demanded by *Vollenweider* is reached.

In spite of these considerations, the detergent industry has been trying for years to find ways to reduce the phosphate content in detergents.

[*] Consensus by experts at the Hearing "Waschmittel/Gewässerschutz" before the Ministry of the Interior of the Federal Republic of Germany, Bonn, February 26–27, 1973.

Before going into the proposition of eliminating phosphates from modern detergents, let us first discuss the function and importance of phosphates as additives in detergents.

2. Functions and Properties of Phosphates in Detergents

Polyphosphates have a specific washing power of their own, which varies according to the type of fiber and the nature of the soil constituents, *i. e.* the washing performance of phosphate solutions is considerably better than that of pure water. In addition to these primary washing effects (effects on single application) phosphates show remarkable secondary washing properties (effects on repeated application of a detergent). The reason for this is that polyphosphates remove alkaline earth ions from the water, the textiles and the dirt; the precipitation of insoluble alkaline earth salts on textiles is prevented and the dirt is dispersed in the wash liquor. Thus—even after many washings—incrustations and graying of the laundered textiles are minimal. In the physicochemical interpretation of these properties, which are the most important properties of phosphates in the washing process, a distinction has to be made between non-specific effects and specific effects. The former can also be achieved with other additives by changing the pH-value or the ionic strength of the wash liquor, while the latter, the specific effects, reveal the chemical characteristics of phosphates.

2.1. Non-Specific Effects

2.1.1. Alkalinity

Pentasodium triphosphate (STP), the most important of the laundry phosphates and the most widely used, shows alkaline reaction in aqueous solutions. An increase in the pH-value of the wash liquor frequently accelerates the chemical degradation of the soil constituents; thus, removal of fatty soils, for example, is facilitated by partial hydrolysis of the ester linkages.

2.1.2. Increased Interfacial Activity of Ionic Surfactants

The increased interfacial activity of ionic surfactants caused by the presence of electrolytes is another non-specific effect. As shown in Fig. 1, STP exhibits the same behavior as other electrolytes: addition of STP lowers the interfacial tension between an aqueous solution of sodium dodecyl sulfate and

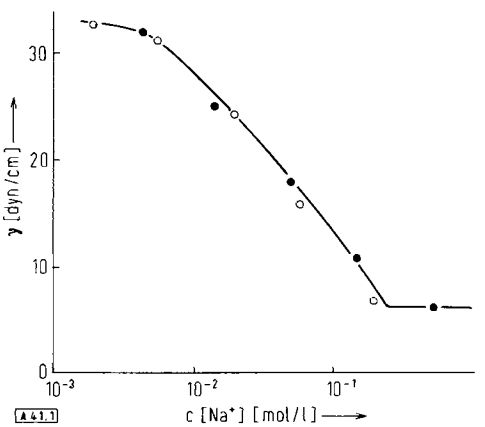

Fig. 1. Interfacial tension γ in the system sodium dodecylsulfate/water/paraffin oil as a function of Na^+-ion concentration, added as Na_2SO_4 (○) or STP (●). The concentration of dodecylsulfate was 1×10^{-3} mol/l.

paraffin oil to the same extent as the addition of an equivalent amount, with respect to the Na^+ concentration, of sodium sulfate.

2.1.3. Non-Specific Development of Electrostatic Surface Charges

Finally, the adsorption of hydroxide ions and other anions leads to the development of an electric potential at the dirt particle and fiber surfaces relative to the aqueous medium[16]. These surface charges lead to electrostatic repulsion between the dirt particles themselves and between dirt particles and fibers.

2.2. Specific Effects

It turns out—especially with cotton as the substrate—that STP shows a washing power which is too large to be explained by these non-specific effects. Furthermore, the specific washing performance of STP is further, and frequently synergistically, increased by combination with anionic surfactants (Fig. 2).

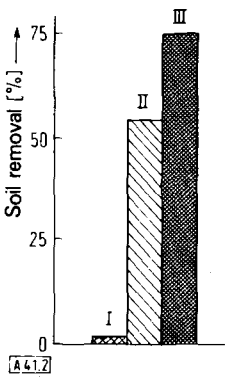

Fig. 2. Primary washing power of anionic surfactants and STP (cotton substrate). Column I: 1.0g anionic surfactant per liter + 2.0g Na_2SO_4 per liter. Column II: 2.0g STP per liter. Column III: 1.0g anionic surfactant per liter + 2.0g STP per liter. Linear alkylbenzenesulfonate as anionic surfactant.

Apparently, this specificity is connected with a specific adsorption of the laundry phosphates on certain types of fibers and soils: electrophoretic studies (determination of zeta-potentials) on soil pigments have shown that STP is strongly adsorbed at surfaces such as those of hematite and γ-Al_2O_3, which show localized concentrations of charge[*], but not at graphite or soot surfaces. Similarly, cotton differs from other fibers in that carboxy groups, which are practically totally ionized in the wash liquor, are present at the surface in addition to hydroxy groups.

The consequences of specific STP-adsorption during the washing process at interfaces with marked concentrations of charge are twofold: interfacial potentials are altered, and anionic surfactants are displaced from solid matter surfaces.

2.2.1. Influences on Interfacial Potentials

The electrostatic repulsions between the individual soil pigment particles and between these and the fibers are increased as a consequence of the increased potential at the pigment particle and fiber surfaces[18]. This effect is also responsible for the distinct ability of STP to disperse hydrophilic soil pigments: clay minerals, *e.g.* are significantly better dispersed by STP than by surfactants (Fig. 3)[18a].

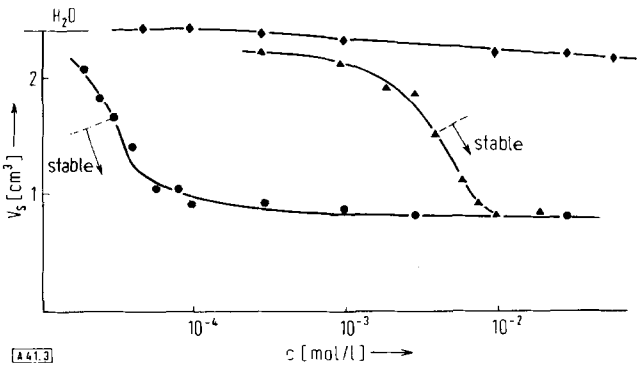

Fig. 3. Sedimentation V_S of kaolin in the presence of anionic surfactants (▲) (example: sodium dodecylsulfate), non-ionic surfactants (♦) (example: dodecyl nonaglycol ether), and STP (●).

2.2.2. Displacement of Anionic Surfactants from Solid Matter Surfaces

Because of specific adsorption, phosphates may reduce the extent of adsorption of anionic surfactants at certain surfaces[17] (Fig. 4). Thus, phosphate adsorption leads to the liberation of adsorbed surfactants "for other duties". The synergy between STP and anionic surfactants observed especially in the case of cotton is probably related to this effect.

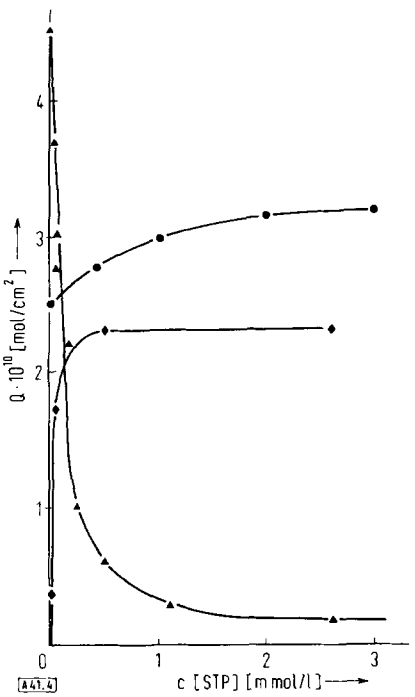

Fig. 4. Competitive adsorption Q of STP and anionic surfactants on soot and γ-Al_2O_3. On soot, STP increases the adsorption of *n*-dodecyl sulfate (●), while on γ-Al_2O_3 adsorption of *n*-decylbenzenesulfonate (▲) is suppressed by STP. The adsorption of STP (♦) on γ-Al_2O_3 is shown for comparison.

In contrast, the adsorption of anionic surfactants is increased in the case of surfaces without marked concentrations of charge, *e.g.* in the case of synthetic fibers or soot. Therefore, surfactant effects prevail in such cases.

[*] Differences encountered in textile fiber and soil pigment interfaces are frequently characterized using the terms 'polar' and 'non-polar'. While the use of these terms is well-established, they do not characterize the chemical differences with sufficient precision.

2.2.3. Binding of Alkaline Earth Ions

A further, very important property of polyphosphates is their binding capacity for alkaline earth ions, the hardening constituents of water. In general, the presence of free alkaline earth ions—introduced with the tap water, and also as constituents of soil—is generally detrimental to the washing process. Removal of the alkaline earth ions prevents precipitation of their compounds with detergent components and the formation of lime deposits in washing equipment and on textiles. Furthermore, polyphosphates remove alkaline earth ions from the soil particle surfaces; thus, the soil is literally "broken up".

In addition, the removal of alkaline earth ions is desirable for another reason: use of the most common types of surfactant at normal dosage levels leads to adsorptive saturation[*] at the interfaces. However, increasing concentration of electrolyte then leads to a decrease in thickness of the electrical double-layer at the interfaces, and thus to decreased electrostatic repulsion between fiber and soil. In principle, increasing the electrolyte concentration by addition of STP has the same effect; it is much more pronounced, however, in the case of the divalent alkaline earth cations than in the case of the monovalent cations, which are freed by the dissociation of STP.

3. Possibilities of Lowering the Phosphate Content in Detergents

As shown in the preceding paragraphs, phosphates are valuable ingredients of laundry detergents. Furthermore, manufacturing, packaging and storage are uncomplicated, and corrosion problems are absent. The environmental behavior of phosphates is particularly impressive: phosphates are toxicologically safe in every respect; there are no adverse effects on sewage or drinking water treatment. A reduction of the phosphate content of laundry detergents—or even a total elimination without replacement—would have the following consequences:

a) a deterioration of the primary washing performance: impact on cleanness and hygiene[19]

b) deterioration of the secondary washing performance: deterioration of wear properties and durability of the laundered textiles because of increasing degree of incrustation[19]

c) formation of lime deposits in the washing machines: reduction of service life[19, 20].

In order to avoid these shortcomings, external measures, such as central water softening, as well as a replacement of detergent phosphates in favor of other compounds have been considered.

3.1. External Measures

The alkaline earth ions present in ordinary tap water may be eliminated by water softening appliances before the washing process. However, alkaline earth ions are also introduced by dirt as well as textile incrustations in amounts that may result in increases of water hardness in the order of 10 to 15° German hardness[21–24]. Therefore, the problem cannot be solved by the use of softened water in the washing machine, but at best be somewhat reduced. Furthermore, there are hygienic objections against the provision of ion exchangers in washing machines: ion exchange resins can become growth media for microorganisms, especially fungi[25–28].

3.2. The Replacement of Detergent Phosphates by Other Substances

The search for phosphate substitutes appears more promising; on a worldwide basis, some 500 million DM has been invested into this particular approach.

There are numerous factors limiting the chances of success: it is not only required that phosphate substitutes take over the functions of detergent phosphates to the greatest possible extent, but also acceptable phosphate substitutes must be toxicologically safe to humans and unobjectionable with regard to sewage biology. Furthermore, they should be biologically degradable—or removable by other means—and should not contribute to eutrophication, nor interfere with the preparation of drinking water *etc.*[29] (Tables 1 and 2).

3.3. Water-Soluble Inorganic Substances

One possibility of phosphate replacement is to use strongly alkaline substances, in order to at least partially compensate for the loss of primary washing power. Among the compounds

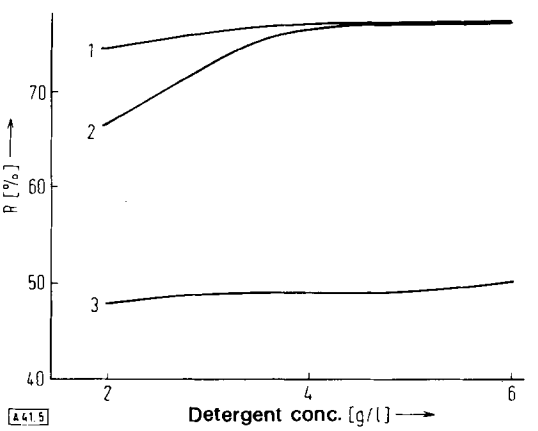

Fig. 5. Primary washing power (quoted as remission R) of STP (1), STP/Na_2SO_4 (2), and Na_2CO_3 (3) in a heavy duty laundry detergent formulation at 90 °C on resin-finished cotton. For definition of R see legend to Fig. 6.

of this class, soda and sodium silicate have been subjected to the most detailed studies. Both compounds contribute to the primary washing performance of a detergent only by their alkalinity, *i.e.* by non-specific effects; the primary washing performance, as shown in Fig. 5, is quite inferior to that of STP. Also the secondary washing behavior is unsatisfactory due to the lack of binding capacity for calcium and magnesium ions: this leads to the formation of incrustations on textiles and lime deposits in the washing machines. Finally, the incorporation of strongly alkaline substances in laundry detergents increases their skin irritancy.

[*] As long as adsorptive saturation has not been reached, increases in the concentration of electrolytes—including hardening constituents of water—lead to increased adsorption and thus to increased washing power of the surfactants. Such conditions may be found, for example at low dosage levels of short-chain surfactants.

3.4. Replacement by Water-Soluble Organic Substances

Because of the difficulties just mentioned, the search for phosphate substitutes has been focused on water-soluble organic complexing agents during the last ten years. Both low molecular weight as well as high molecular weight organic substances have been studied[30–42].

Table 3, which lists only a small selection of the compounds already studied, compares the calcium binding capacity, acute toxicity, and biological degradability of some technologically interesting organic complexing agents with the values for STP.

Figures 6a to 6d show the results obtained with laundry detergents based on these complexing agents at various dosage levels. The primary washing performance has been determined using three different textile substrates, cotton, highly finished cotton and cotton/polyester blends.

3.4.1. Organic Complexing Agents Containing Nitrogen or Phosphorus

At first sight, the consideration of phosphonic acids and compounds containing nitrogen as potential substitutes for laundry detergent phosphates might appear paradoxical: after all, one wishes to avoid the addition of nitrogen, and especially of phosphorus, to stagnant waters. However, it is quite conceivable that nitrogen or phosphorus containing phosphate substitutes can be found which contribute less to eutrophication than STP at the dosage levels required.

Of all the organic phosphonic acids examined—Table 3 lists some examples—hydroxyethanediphosphonic acid (HEDP)

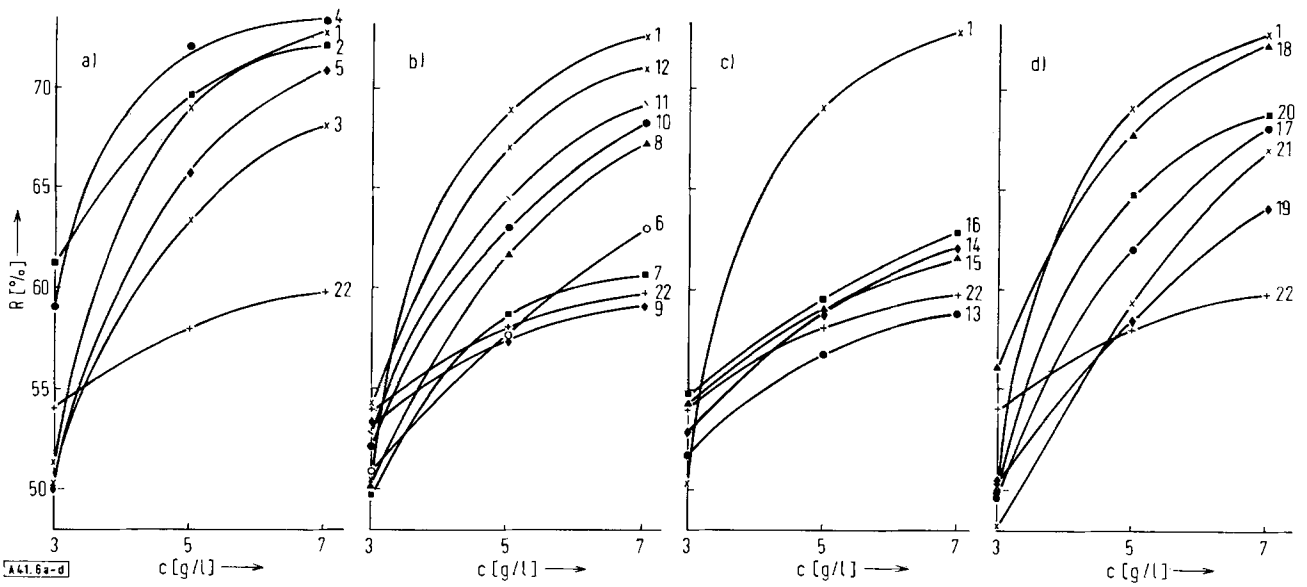

Fig. 6. Primary washing power (quoted as remission R) of water-soluble organic complexing agents in a heavy duty laundry detergent formulation on three textile substrates (cotton, highly finished cotton, cotton/polyester blend) as a function of concentration compared to STP (1) and Na_2SO_4 (22). a) Compounds 2—5; b) compounds 6—12; c) compounds 13—16; d) compounds 17—21. Numbering as in Table 3. The primary washing performance is determined as the (light) remission (R [%]) of standard test cloths which had been soiled and washed under standard conditions. The potential phosphate substitutes were tested in detergent formulations, which closely corresponded to commercially available detergents, the phosphate content (40% STP) being replaced by equal amounts of the substitutes.

Table 3. Calcium-binding capacity, acute toxicity and biodegradability of water-soluble organic complexing agents. For primary washing performance, see Fig. 6.

[a] The numbering corresponds to the numbers in Figures 6a to 6d.
[b] The *calcium binding capacity* is given as mg CaO/g of the potential phosphate substitute at 20 and 90 °C, determined at pH 10.
[c] The acute *toxicity* is given as LD_{50} in g/kg for rats and mice.
[d] The *biological degradability* is given as biochemical oxygen demand (BOD) in percent of theory after 30 days. The biochemical oxygen demand is a quantitative measure of the rate of aerobic microbial degradation of chemical compounds. The theoretical oxygen demand corresponds to complete mineralization [43].
[e] Irrelevant.

(No. 2) gave the best results in the washing tests. At low dosage levels, HEDP is even better than STP.

Among nitrogen containing complexing agents—generally aminopolycarboxylic acids with triply substituted nitrogen—nitrilotriacetic acid (NTA) (No. 4) has turned out to be the most interesting compound. NTA shows a somewhat better primary washing performance than STP on weight for weight replacement; it counts among the best phosphate substitutes studied so far. However, the toxicological and ecological properties of nitrogen-containing complexing agents have not yet been fully elucidated. In any case, it is important that nitrogen-containing complexing agents do not contain secondary amines, for these may be converted into nitrosamines in oxidizing media or in the presence of nitrous acid, and nitrosamines are carcinogenic. Moreover, objections against NTA have been raised with respect to the possible mobilization of heavy metals from river sediments.

As it is still unclear whether the results of extensive toxicological as well as ecological studies will suffice to remove these doubts, present research and development work is focused on phosphorus and nitrogen free complexing agents.

3.4.2. Low Molecular Weight Nitrogen-free and Phosphorus-free Compounds

Some cyclic polycarboxylic acids (Table 3) show pronounced washing performance in addition to high calcium binding capacity. Hydroxypolycarboxylic acids, and the etherpolycarboxylic acids obtainable from them by carboxymethylation of the hydroxy groups, are particularly interesting. *O*-(Carboxymethyl)tartronic acid (No. 12) shows excellent properties in the washing process even at low dosage levels.

While citric acid (No. 14) is toxicologically unobjectionable, its washing properties above 30 °C are poor, since its calcium binding capacity decreases strongly with increasing temperature. Consequently, a replacement of STP by citric acid is out of the question in Europe[*].

[*] There are marked differences between European and American washing processes. Thus, American laundry detergents do not contain perborate, and the US home washer has no heating system, but is connected to a central hot water system. American washing machines are therefore not suited for washing at close to boiling temperatures.

3.4.3. Higher Molecular Weight Nitrogen-free and Phosphorus-free Polycarboxylic Acids

Numerous oligomeric as well as polymeric water-soluble organic complexing agents containing many carboxy groups are accessible by homopolymerization of unsaturated carboxylic acids or carboxylic acid precursors, or by copolymerization with other monomers. Many of these polymeric polycarboxylic acids have outstanding calcium binding capacities, and some—polycarboxylic acids without other substituents as well as polymers with additional hydroxy and/or ether functions—show marked primary washing performances and quite satisfactory secondary washing properties.

The biological degradability of polymeric carboxylic acids is generally poor; under certain conditions, however, these compounds may be eliminated at least partially by sludge adsorption in biological sewage treatment plants. This type of elimination is, for example, observed in the case of poly(α-hydroxyacrylic acid), (No. 18), which corresponds to STP in its washing performance at all dosage levels, and is even somewhat better than STP at very low dosage.

3.4.4. The Mode of Action of Water-soluble Organic Phosphate Substitutes

Mellithic acid as well as HEDP correspond to STP in increasing the zeta-potential of hematite (Fig. 7). Also, in competitive adsorption experiments with organic complexing agents and

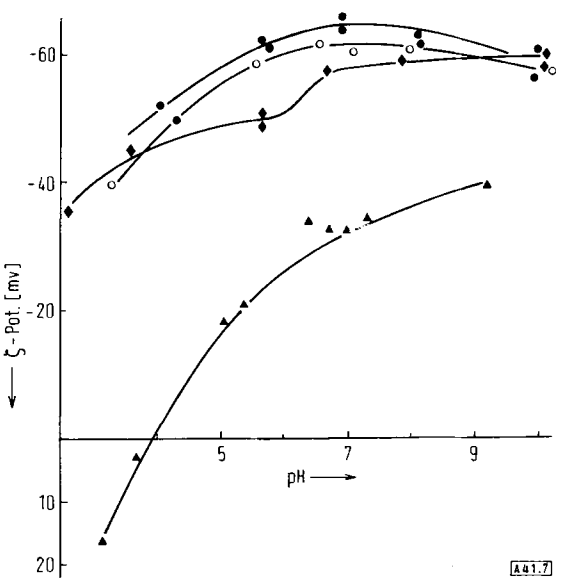

Fig. 7. pH-dependence of the zeta potential of hematite in the presence of STP (●), benzenehexacarboxylic acid (○) 1-hydroxyethane-1,1-diphosphoric acid (◆), and sodium chloride ▲.

anionic surfactants, similar results were obtained as with STP and anionic surfactants, which implies that the organic complexing agents show specific adsorption similar to the one found in the case of STP at interfaces with marked concentrations of charge.

4. Water-insoluble ("Heterogeneous") Systems

The use of water-*in*soluble phosphate substitutes deserves a separate chapter since an entirely different approach from that commonly used is involved. The laundry detergents in common use are water-soluble, so it is not surprising that the search for phosphate substitutes was first focused on water-soluble organic complexing agents. However, any additional organic compounds introduced into the ecosystem water would present a basically undesirable burden. The problem may be circumvented by the use of water-insoluble phosphate substitutes, which may be removed from the wash liquor after the washing process. The concept of removing the constituents of water hardness by means of water-insoluble inorganic ion exchangers is of biblical age[44]. The finely dispersed mineral bentonite, which is capable of ion exchange, has been used as a washing aid for probably thousands of years. In more recent years, bentonite was used in "war soaps" during both world wars because of the shortage of fats and oils. By modern standards, however, the washing performance of bentonite is unsatisfactory[45, 46].

A few years ago, the use of water-insoluble organic ion-exchangers in laundry detergents was proposed. However, neither the standard products nor a special ion-exchanging cotton cloth (phosphorylated cellulose) gave satisfactory results in the washing process[47, 48]. Common organic ion-exchangers tend to form deposits on the laundered textiles and in both cases the washing performance was quite inferior to that of STP, in a weight-to-weight comparison.

On the other hand, poromeric fleeces[49, 50], which contain carboxy groups and are manufactured by a special process show considerable washing power in a weight-by-weight comparison with STP[51, 52]. Such a "washcloth" may be separated from the laundry after the washing process and discarded together with other household refuse. Only CO_2, H_2O and $CaCO_3$ would be formed on incineration of the refuse.

However, not until all refuse is subjected to incineration, will the washcloth approach prove ideal with respect to its environmental impact. Moreover, the washcloth is not perfectly satisfactory because of its expensive petroleum basis (polyacrylate)..

Despite the fact that washing with insoluble inorganic ion-exchangers has so far not gained acceptance, except in times of need, we have reinvestigated this field in recent years.

Alkali-metal aluminum silicates of the following composition were found to be particularly promising[53]:

$$M_{2/n}O : Al_2O_3 : x\,SiO_2 : y\,H_2O$$

$M = Li, Na, K$

$n = 1$

$x \approx 2$

y = variable

In contrast to the behavior of water-soluble complexing agents, the calcium binding capacity of these silicates increases with increasing temperature (Fig. 8), quite a desirable novel feature for washing at higher temperatures. In addition, the calcium binding capacity depends on the duration of the exposure, the pH value of the wash liquor, the particle size of the silicates, and the concentration.

Table 4 compares the washing performances of detergent formulations with normal and low phosphate contents, where part of the normal phosphate content is replaced by a sodium aluminum silicate. Tests were carried out on three different

textile substrates at various temperatures. It can be seen that the laundry detergent containing sodium aluminum silicate is comparable to the laundry detergents commonly used today. A similar finding is observed on comparison of secondary washing properties.

Before any particular phosphate substitute is chosen, not only have hygienic, toxicological and ecological factors to be considered, but also the impact on industrial as well as national economics. In the latter respect, sodium aluminum silicates offer a particularly promising alternative, inasmuch as they

Table 4. Primary washing power of detergents, based on 40% STP, 20% STP+20% sodium aluminum silicate (HAB) and 20% STP, on artificially soiled textiles.

Washing temperature	Fabric	Dosage (g/l)	Primary washing effect in % remission at 460 nm

can be manufactured from domestic raw materials. The extensive study program instituted to test their environmental behavior is outlined in Table 5. In many respects, this program differs from the testing programs used in the evaluation of water-soluble organic phosphate substitutes. While in the case of organic materials the question of biological degradability and the resulting intermediates formed in the process is of prime importance, this question is irrelevant in the case of inorganic substances such as sodium aluminum silicates. Sodium aluminum silicates occur in large quantities in the lithosphere; they are natural constituents of lake and river sediments, and therefore it is hoped that there is very little ecological risk involved. Nevertheless, these risks must be assessed most carefully.

Some preliminary results support our expectations: thus, laundry detergents containing sodium aluminum silicates are comparable to detergents containing phosphates with respect to their toxicological properties. The acute toxicity of sodium

Table 5. Environmental behavior of sodium aluminum silicate—an assessment of individual measures.

aluminum silicates is given as $LD_{50} > 10\,g/kg$ (mouse, oral intake). The toxicity to water organisms (Daphnia: $LC_0 > 100\,mg/l$[*]) and fish (golden orfe: $LC_0 > 250\,mg/l$) is also very low. According to model experiments, the presence of sodium aluminum silicates does not interfere with the biological degradation of linear alkylbenzenesulfonate. Their influence on the various types of mechanical and biological sewage treatments remains to be assessed in extensive experimental studies. Sodium aluminum silicates have a high binding capacity for transition metal ions (copper, cadmium, zinc, nickel, cobalt, manganese). This feature is presently believed to be an advantage; however, the consequences for the various sewage treatment processes must be studied. The same applies to questions of sedimentation. Here, preliminary studies have shown that sodium aluminum silicates tend to form aggregates with other sewage constituents and are largely eliminated in the pre-sedimentation of sewage treatment; thus they do not reach the surface waters.

We are indebted to BASF, Bayer, Hoechst, Chemische Werke Hüls, Gelsenberg, VEBA Chemie, GAF, Monsanto, and Solvay for sample chemicals as well as useful suggestions. The studies concerning the development of suitable sodium aluminum silicates were carried out jointly with Degussa.

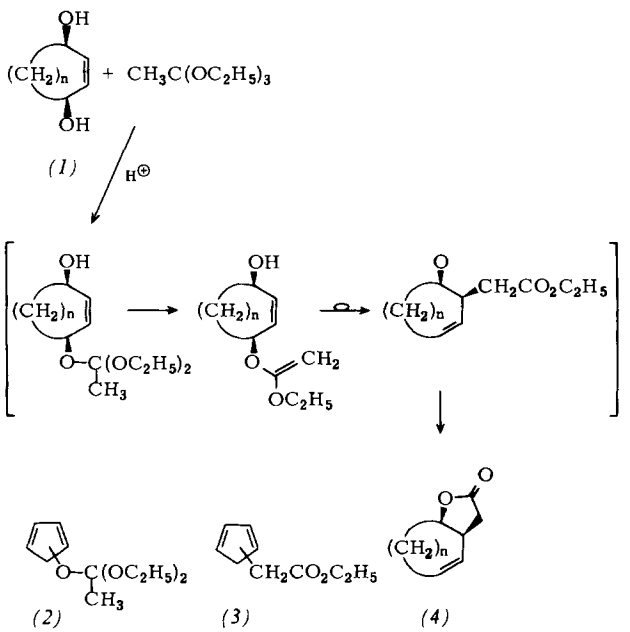
Synthesis of Bicyclic γ-Lactones from 2-Cycloalkene-1,4-diols

By *Kiyosi Kondo*, *Masakatsu Matsumoto*, and *Fumio Mori*[*]

We have recently reported that the condensation of *trans*-2-alkene-1,4-diols with orthocarboxylic esters leads directly to γ-lactones bearing vinylic substituents in the β-position[1]. The reaction has now been extended to cyclic alkenediols *(1)* and found to be a simple and convenient method for the preparation of bicyclic γ-lactones. One of the products is the well-known precursor *(4a)* for the synthesis of prostaglandins and jasmones[2]. The starting 2-cycloalkene-1,4-diols *(1)* can easily be obtained by photosensitized oxygenation of cyclic 1,3-dienes followed by reduction of the resulting 1,4-endoperoxides with thiourea or $LiAlH_4$.

Thermal condensation of the diols *(1a)*—*(1d)* with triethyl orthoacetate in the presence of a catalytic amount of a weak acid, such as hydroquinone or phenol, and distillation of the reaction mixture leads directly to the lactones *(4a)*—*(4d)* (see Table 1). Though the distilled *(4a)* was essentially pure judging from its NMR spectrum, careful analysis by GC-MASS revealed that the cyclopentadienes *(2)* and *(3)* were present as contaminants.



(a), n = 1; *(b)*, n = 2; *(c)*, n = 3; *(d)*, n = 4

Table 1. Bicyclic γ-lactones *(4)* from diols *(1)*. Hydroquinone was used as a catalyst.

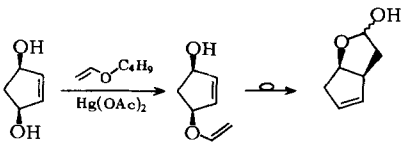
The analogous Claisen rearrangement followed by cyclization can also be performed with the vinyl ether *(5)*[3]. Heating of *(5)* in xylene under an argon atmosphere for 4 h afforded the bicyclic γ-lactol 2-oxabicyclo[3.3.0]oct-6-en-3-ol *(6)* directly in 63% yield; b.p. 49 °C/0.15 torr (44—45 °C/0.01 torr[2c]).



(1a) *(5)* *(6)*

2-Oxabicyclo[3.3.0]oct-6-en-3-one (4a)

A mixture of *cis*-2-cyclopentene-1,4-diol *(1a)* (3.0 g, 30 mmol) and triethyl orthoacetate (11.3 g, 70 mmol) was heated with hydroquinone (0.33 g, 3 mmol) at 140—150 °C for 6 h with continuous removal of the resulting ethanol. The reaction mixture was fractionally distilled under reduced pressure. The first fraction was unreacted orthoester, and the second one was the desired bicyclic γ-lactone *(4a)*; yield 3.08 g (85%); b.p. 74 °C/0.3 torr (70—71 °C/0.2 torr[2c]).

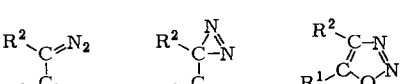
The ether *(5)* could easily be separated by column chromatography on neutral alumina (Woelm, activity grade IV).

Diazirines as Photochromic Valence Isomers of α-Diazo Carbonyl Compounds[**]

By *Erika Voigt* and *Herbert Meier*[*]

As cyclic valence isomers, the diazirines *(2)* and the 1,2,3-oxadiazoles *(3)* should be discussed in the context of the α-diazo carbonyl compounds *(1)*.



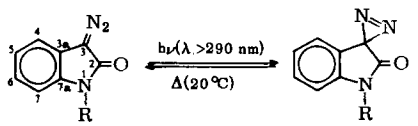
(1) *(2)* *(3)*

[*] Univ.-Doz. Dr. H. Meier and E. Voigt
Chemisches Institut der Universität
74 Tübingen, Auf der Morgenstelle (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

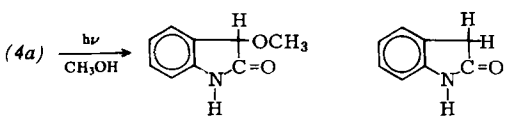
Whereas heterocycles of type *(3)* are so far unknown, numerous alkyl- or aryl-substituted diazirines are known to exist[1]. In contrast to the α-diazo carbonyl compounds, which are generally thermodynamically more stable than aliphatic diazo compounds, the stability of the diazirines is lowered by pseudoconjugation of the three-membered ring with a carbonyl function. Thus the half-life of 1-oxospiro[cyclohexane-2,3'-diazirine] with regard to elimination of nitrogen is found to be about one hour at room temperature[1-3].

The ready thermal or photochemical elimination of nitrogen from *(1)* and *(2)* imposes experimental limitations on the valence isomerization *(1)*⇌*(2)*. We have detected it for the first time in the case of the thermally reversible photochromic system 2-oxo-3-diazoindoline *(4)*/2-oxospiro[indoline-3,3'-diazirine] *(5)*.



(4) *(a)*, R = H; *(b)*, R = CH_3 *(5)*

Irradiation of *(4a)*[4-6] in methanol leads, by nitrogen elimination, *via* the carbene intermediate to the major products 3-methoxyoxindole *(6a)* and oxindole *(7a)*.



(6a) (30 : 25) *(7a)*

If the reaction is prematurely interrupted, a product can be isolated by column chromatography which is itself photolabile. On standing as the pure solid or in solution, the pale yellow to colorless crystals are transformed back to the red starting compound *(4a)*, even at room temperature.

According to cryoscopic molecular weight determination, the crystalline compound must be an isomer of *(4a)*. Spectroscopic data unequivocally indicate the structure *(5a)*. Compound *(4b)* behaves analogously. The UV spectra of *(4a)* and *(5a)* differ primarily in the absence of the longest-wave transition [λ_{max} = 440 nm (ε = 21.3)], responsible for the red color of the diazo compound *(4a)*, from the spectrum of *(5a)*. On complete retro-isomerization *(5a)* → *(4a)*, three isosbestic points can be observed. The characteristic IR bands of *(4a)* and *(5a)* are listed in Table 1.

Table 1. Characteristic stretching vibrations of *(4a)* and *(5a)* $\bar{\nu}$ [cm^{-1}].

The Dimerization of Propylene to Linear Hexenes

By *G. Henrici-Olivé* and *S. Olivé*[*]

A homogeneous catalyst solution made up from pentanedionatopalladium, a tertiary phosphane, and ethylaluminum dichloride, in 1,2-dichloroethane, dimerizes propylene selectively (up to 95%) to linear hexenes, although at relatively low reaction rate (Table 1). Replacement of the phosphane by a phosphite increases the rate, but considerably lowers the selectivity. As in all systems containing a Lewis acid such as $C_2H_5AlCl_2$, special care must be taken to eliminate moisture from the reaction solution. Otherwise highly active cationic species will cause the polymerization of propylene.

Table 1. Dimerization of propylene with Pd/Al catalysts in the presence of phosphorus-containing additives. [$Pd(acac)_2$] = 2 × 10^{-3} mol/l; [$C_2H_5AlCl_2$] = 22 × 10^{-3} mol/l; [P]/[Pd] = 2; [propylene] = 1.3 mol/l; T = 20 °C; t = 3 h

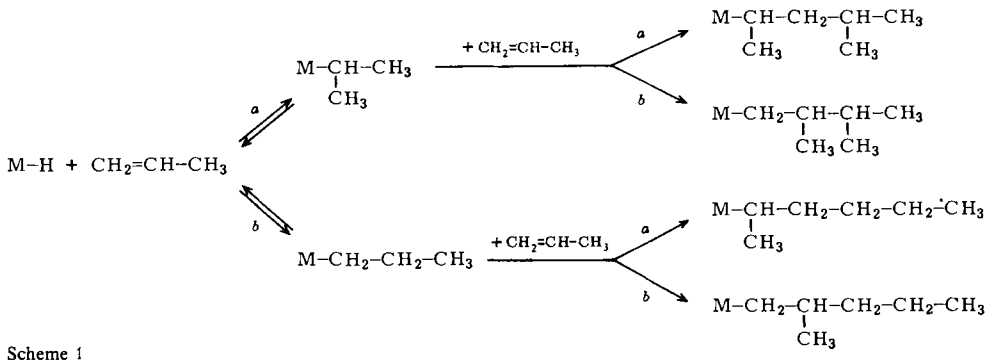
Phosphorus compound	Conversion [%]	Selectivity [%] linear hexenes	methyl-pentenes	dimethyl-butenes
Bu_3P	4	95.1	4.9	-
Ph_3P	4	81.8	18.2	—
$(PhO)_3P$	12	23.6	68.2	8.2

Four reaction modes are conceivable for the dimerization of propylene at a transition metal center M, depending upon the orientation of the monomer in the two insertion steps (Scheme 1).

The first step is reversible, since β-hydrogen abstraction regenerates a metal hydride and propylene. The second step is irreversible; β-hydrogen abstraction at this stage gives the product dimer and a metal hydride, which latter continues the kinetic chain.

[*] Dr. G. Henrici-Olivé and Prof. Dr. S. Olivé
Monsanto Research S.A.
CH-8050 Zürich, Eggbühlstrasse 36 (Switzerland)

The dimerization of propylene with Group VIII metal complexes (in particular those of nickel) in combination with alkylaluminum compounds has repeatedly been reported[1-3]. It appears from these literature data that, in the absence of steric effects, the route *aa* giving 4-methyl-2-pentene is



Scheme 1

by far the predominant one, indicating that the *a* mode of monomer incorporation is electronically favored. *Wilke, Bogdanović, et al.*[2], however, have shown that, in the case of the catalyst system π-allylnickel halide/alkylaluminum compound the addition of bulky phosphane ligands can force the reaction to adopt the route *ab* by steric influences.

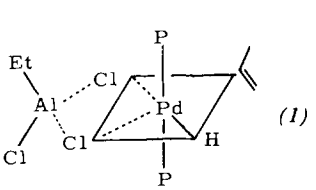
The presently reported formation of linear hexenes, on the other hand, requires the unusual reaction sequence *ba*. Evidently this must be also the consequence of a steric phenomenon, because an electronic tailoring of the catalyst center would influence both steps in the same manner. It is assumed that also in this system the first step occurs predominantly according to the electronically favored *a* mode, but that the combined bulk of the resulting isopropyl group plus the surrounding ligands impedes the second step. Because of the reversibility of the first step the less favorable (slower) *b* mode can then gain importance. The incorporation of the first monomer gives the less bulky *n*-propyl group which permits the second step to proceed according to electronic preferences, *i.e.* by route *a*.

Comparison of the data obtained with tributyl- and triphenylphosphane (Table 1) underlines the steric character of the influence of the phosphane. Differing considerably in the electron donor ability, the two phosphanes have comparable bulkiness. Reaction rate and isomer distribution are similar. The low reaction rate appears to indicate that the catalyst spends most of its time in the inactive form attached to the isopropyl group. The less bulky phosphite ligand, on the other hand, is not able to build up an efficient barrier.

The ratio P/Pd is critical; best results are obtained at P/Pd = 2; at lower ratios black colloidal Pd^0 is formed even at low concentration of alkylaluminum compound. At P/Pd $\geq$ 5 no catalytic activity is observed, presumably due to the blocking of free sites.

Relatively high ratios of Al/Pd are required, indicating that the catalytic species is formed in an equilibrium reaction. Activity is found for $5 \leq$ Al/Pd ≤ 25, with an optimum around 20. In this region an absorption peak at 25600 cm^{-1} is observed, indicating the presence of an alkylaluminum compound in the complex.

Based on these data, and in analogy to other Ziegler type catalyst systems[4, 5], we suggest structure *(1)* for the active site (P = phosphane).



(1)

Evidently the pentanedionate ligands of the palladium have to be displaced by chlorine (from the alkylaluminum chloride, as found formerly for $VO(acac)_2$ and $Cr(acac)_3$[5]). Subsequent exchange of one chlorine with an ethyl group forms an alkyl derivative of Pd which, on β-hydrogen abstraction, produces the hydride. The other chlorine is used for the aluminum bridge. The phosphanes keep the complex in solution[6].

Chemiluminescence of the Exhaust Gases of an Internal Combustion Engine

By *Joachim Stauff* and *Hartmut Fuhr*[*]

Only few publications[1, 2] have so far considered the possibility that atmospheric pollutants are emitted in electronically excited states. On the other hand, studies on "photochemistry without light"[3] describe effects occurring during the action of molecules that have been electronically excited by chemical reactions on other ground state molecules which normally only take place on irradiation of the reaction mixture with

[*] Prof. Dr. J. Stauff and Dr. H. Fuhr
Institut für physikalische Biochemie und Kolloidchemie
6 Frankfurt/M.-Niederrad 1, Sandhofstrasse 3 (Germany)

visible or ultraviolet light. We have now found that the exhaust of an internal combustion engine (Otto motor) contains electronically excited molecules.

We employed an auxiliary electrical generator driven by a Briggs and Stratton four-stroke engine of 164 cm^3 capacity fueled by gasoline having research octane number 90–92. The generator produced current up to 1500 watt. Varying loads could be produced by switching resistors of different sizes into the generator circuit. The exhaust passed first through the muffler fitted to the device and then through an observation system consisting of replaceable ground Pyrex tubes of 5-cm diameter. The chemiluminescence was recorded at right angles to the direction of flow of the gas by red-sensitive photomultiplier (RCA 7265) fitted to a direct current amplifier.

Only slight luminescence was observed directly after starting the engine. Its intensity increased with time as a function of the load. After switching the engine off, an afterglow persisted for 40 min. Flushing the Pyrex tube with N_2 or O_2 had no effect on the intensity and rate of decay. The intensity rises 10- to 20-fold if the exhaust is allowed to impinge on a glass plate positioned at 45° to the directions of flow and observation. The decay curve of the luminescence obeys first order kinetics with a rate constant of about $10^{-3} s^{-1}$ and a lifetime of 10^3 s (16 min). The luminescence intensity initially increases exponentially with the engine load, and then at a somewhat slower rate.

Most probably, the high-energy combustion product is present in the soot particles or tar droplets that precipitate on the walls of the tube or on the glass plate. No luminescence is observed if the exhaust aerosol is passed through a tube having six 90° bends.

A crude determination of the spectral distribution of the luminescence was accomplished with a set of cut-off filters. The emission maximum lies between 420 and 470 nm, thus indicating a remarkably high energy level of the luminescence reaction.

Extraction of the soot or tar deposits on the glass plate with *n*-heptane or benzene yields solutions displaying fluorescence maxima in the same region as those in the luminescence spectrum.

If the exhaust gas is passed through a solution of 9,10-diphenylanthracene in dibutyl phthalate the luminescence is intensified by a factor of 20 to 30. The same effect was observed with chlorophyll a in dibutyl phthalate and with rubrene in benzene.

These observations show that photodynamic effects warrant more attention, especially in view of the known fact that the carcinogenic action of electronically excited molecules is considerably greater than that of the corresponding ground states[4].

Reductive Dehydrohalogenation of β-Halogenated Fatty Acids and Stereoselective Hydrogenation of α-Halogenated α,β-Unsaturated Fatty Acids by *Clostridium kluyveri*[**]

By *Hironobu Hashimoto* and *Helmut Simon*[*]

We recently reported the hydrogenation of structurally very different α,β-unsaturated fatty acids by hydrogen[1] or cofermentation[2] with the aid of *Clostridium kluyveri.* We have now found that α,β-unsaturated β-halocarboxylic acids *(1)* are converted by *C. kluyveri* in presence of crotonate or butyrate, or hydrogen gas, into the halogen-free saturated carboxylic acids (Table 1).

R = H or CH_3; X = F, Cl or Br

Table 1. Reductive dehydrohalogenation of β-halocarboxylic acids of type *(1)* and *(2)* by *Clostridium kluyveri* in presence of hydrogen as reducing agent.

Exp.	Halocarboxylic Acid *(1)* or *(2)*	Product	Yield [%]
1	*E*-β-Chloroacrylic acid *(1a)*	Propionic acid	70
2	*Z*-β-Chloroacrylic acid *(1b)*	Propionic acid	30
3	*E*-β-Bromoacrylic acid *(1c)*	Propionic acid	100
4	*Z*-β-Chlorocrotonic acid *(1d)*	[a]	
5	*Z*-β-Fluorocrotonic acid *(1e)*	[a]	
6	β-Chloropropionic acid *(2a)*	Propionic acid	90
7	D,L-β-Chlorobutyric acid *(2b)*	[a]	
8	*E*-β-Chloroacrylic acid *(1a)* [b]	no reaction	
9	β-Chloropropionic acid *(2a)* [b]	β-Hydroxypropionic acid	100

[a] Quantitative conversion to butyric and acetic acid. Corresponds to the fermentation with crotonic acid.
[b] Without reducing agent.

Saturated β-halocarboxylic acids lead to the same products (Experiments 6 and 7). If incubation is carried out in the absence of reducing agent, the unsaturated acids *(1a)* do not react (Experiment 8), whilst the saturated acids *(2a)* eliminate HX and add water (Experiment 9). Clearly, the crotonases in *C. kluyveri* also facilitate elimination of haloacid instead of water. Particularly surprising is the fact that both enantiomeric forms of β-chlorobutyric acid are converted.

To our knowledge such activities have not previously been described.

$RHC{=}CX{-}COOH$ (3) $\qquad RCH_2{-}CHX{-}COOH$ (4)

R = H or CH_3; X = F, Cl, or Br

The behavior of unsaturated α-halocarboxylic acids is depicted in Table 2. With the exception of α-fluorobutyric acid the absolute configurations of the compounds obtained are known.

Table 2. Hydrogenation of α,β-unsaturated α-halocarboxylic acids *(3)* by *Clostridium kluyveri* in presence of hydrogen to α-halocarboxylic acids *(4)*.

Halocarboxylic acid *(3)*	Amount [mmol]	Product *(4)*	Yield [%]	$[\alpha]_{23}^{D}$ [°] in methanol	*c* [g/100 ml]	$[\alpha]_{23}^{D}$ [°] in methanol [3]
α-Chloroacrylic acid *(3a)*	2.0	(*R*)-α-Chloropropionic acid *(4a)*	91	17.3 ± 1.4	0.51	−13.9
α-Bromoacrylic acid *(3b)*	1.5	(*R*)-α-Bromopropionic acid *(4b)*	86	32.4 ± 3.6	0.49	−27.6
Z-α-Fluorocrotonic acid *(3c)*	2.6	α-Fluorobutyric acid *(4c)*	98	1.2 ± 0.1	2.0	—
Z-α-Chlorocrotonic acid *(3d)*	0.5	(*R*)-α-Chlorobutyric acid *(4d)*	83	12.7 ± 1.4	0.42	− 9.7
Z-α-Bromocrotonic acid *(3e)*	1.0	(*R*)-α-Bromobutyric acid *(4e)*	79	21.6 ± 0.9	1.1	−31.7

The hydrogenation system of *C. kluyveri* affords the *R* configuration. Most of the compounds exhibit a higher rotation than is given in the literature[3]. An exception is α-bromobutyric acid.

As a rule for each mmol of sodium salt of the carboxylic acids, 2.0 g of wet *C. kluyveri* sediment grown on crotonate was incubated in 10 ml 0.1 M phosphate buffer at pH = 7.0 for 10—25 h at 35 °C under hydrogen.

[2.2.2.2](1,2,4,5)Cyclophane[***]

By *Richard Gray* and *V. Boekelheide*[*]

Although cyclophanes with multiple bridges having three or more linking atoms in the bridges are known[1], the tris-bridged cyclophanes having only two linking atoms in the bridges, [2.2.2](1,3,5)cyclophane and [2.2.2](1,2,4)cyclophane, have only been reported recently[2]. Because of the strong transannular interaction between the aromatic π-electron clouds in these molecules, as evidenced from their spectral and chemical properties, it is of interest to examine other, even more highly-bridged cyclophanes. We now report the synthesis of [2.2.2.2](1,2,4,5)cyclophane *(9)*.

Treatment of dimethyl 2,5-dimethylterephthalate *(1)*[3] with *N*-bromosuccinimide gave *(2)* (colorless needles, m. p. 169 to 171 °C; caution! *(2)* is a potent allergen)[4]. The coupling of *(2)* with 1,4-benzenebis(methanethiol) occurred in 59% yield to give *(3)* (colorless prisms, m. p. 158.5—159.5 °C). Irradiation of a solution of *(3)* in trimethyl phosphite, following the usual procedure for expulsion of sulfur from the molecule[5], gave *(4)* (colorless plates, m.p. 144—145 °C) in 69% yield. From the work of *Reich* and *Cram*[6], it is known that carbonyl groups attached to one deck of a [2.2]paracyclophane exert a strong influence directing electrophilic substitution to the pseudogeminal position of the opposite deck. Therefore, as anticipated, chloromethylation of *(4)* using chloromethyl methyl ether and aluminum chloride gave *(5)* (colorless plates, m. p. 189—192 °C) in 72% yield. Reduction of *(5)* with diisobutylaluminum hydride led to *(6)* (colorless powder, m. p. (dec) > 200 °C) in 98% yield. Oxidation of *(6)* with activated manganese dioxide[7] then gave the corresponding dialdehyde *(7)* (fine yellow needles, m.p. (dec) > 240 °C) in 85% yield. Transannular carbenoid insertion reactions of [2.2]paracyclophanes have been observed previously by *Cram*; they provide

an excellent method for the introduction of bridges consisting of two carbon atoms[8]. When *(7)* was converted into the corresponding bis(tosylhydrazone) *(8)* and this was treated with sodium methoxide in THF followed by irradiation with a sun lamp, conversion to the desired hydrocarbon *(9)* occurred in 49% yield.

[2.2.2.2](1,2,4,5)Cyclophane *(9)* sublimes readily at 250°C to give tiny, colorless plates [m. p. 350°C; ^{1}H-NMR ($CDCl_3$): a singlet at $\tau = 4.04$ (4H) and an A_2B_2 pattern at 6.50—7.40 (16H); λ_{max}(cyclohexane) = 248 ($\varepsilon = 3610$), 294 (sh, 660), and 303 nm (1050). The NMR chemical shifts of the aromatic hydrogens of *(9)* are at lower field than those of the symmetrical [2.2.2](1,3,5)cyclophane ($\tau = 4.27$); this would suggest that the aromatic rings of *(9)* are boat-shaped with the —CH groups at the bowsprit positions allowing them to be further apart.

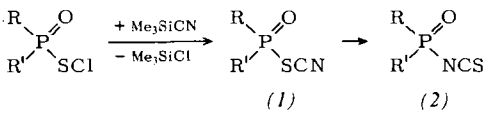
at room temperature to the corresponding isothiocyanatidate[3].

We tried to overcome the difficulties presented by the silver cyanide method by using trimethylsilyl cyanide as reaction partner. This reagent was recently employed in the synthesis of inorganic and organic cyanides[4].

The appropriate sulfenyl chlorides[**] were allowed to react with trimethylsilyl cyanide at −10°C in dichloromethane. Exothermic reaction took place and trimethylsilyl chloride was removed under vacuum at 0°C. The spectroscopic properties of the thiocyanatidates *(1a)*—*(1d)* (Table 1) are identical with those described in our previous papers[3, 5].



(1) *(2)* (1)

Thiocyanatidates synthesized by the trimethylsilyl cyanide method are distinctly more stable than those obtained by the silver cyanide method. It was possible to isolate *tert*-butyl(phenyl)phosphinothiocyanatidate *(1d)* as a crystalline solid (m.p. in sealed tube: 38—42°C; rearrangement). *(1d)* is stable at room temperature under strictly anhydrous conditions for several days. Starting from the optically active *tert*-butyl(phenyl)phosphinothioic acid we succeeded in preparing optically active *(1d)* which isomerized in the reaction mixture to *(2d)*[1] and could be trapped as the optically active *N*-[*tert*-butyl(phenyl)phosphinoyl]-*N'*-cyclohexylthiourea *(4)*[***].

Table 1. Physical data of the phosphorothiocyanatidates *(1a)*—*(1c)* and phosphinothiocyanatidate *(1d)* and their isomerization products, the isothiocyanatidates *(2a)*—*(2c)* and *(2d)*.

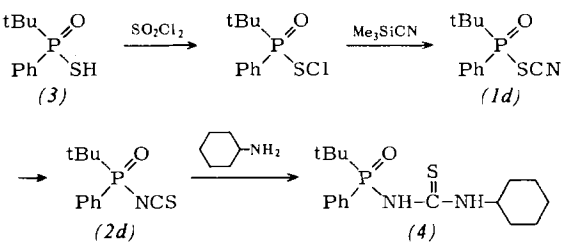
(2d)			−39.0	1210, 1240	2000	97/0.01	1.5750

[a] δ-values, H_3PO_4 as standard.
[b] *(1c)* isomerized to *cis-(2c)* (64%) and *trans-(2c)* (36%) [5].



(3) *(1d)* *(2d)* *(4)* (2)

The reason for the relatively high stability of *(1d)* is, in the light of our earlier findings on the rearrangement of cyclic phosphorothiocyanatidates, due to steric hindrance, which affects the rate of the SCN^--catalyzed $S_N2(P)$ isomerization.

[4] Satisfactory elemental analyses were obtained for all the new compounds reported. Further, the UV, IR, NMR, and Mass spectra of all the new compounds are also in agreement with the given structures.

A New Route to Phosphoro- and Phosphinothiocyanatidates

By *Andrzej Łopusiński*, *Jan Michalski*, and *Wojciech J. Stec*[*]

Although intermediate formation of phosphoro- and phosphinothiocyanatidates *(1)* would appear indispensable to describe many reactions leading to the isomeric isothiocyanatidates *(2)*[1, 2], it was only recently that we were able to report evidence for the formation of a phosphorothiocyanatidate in the reaction of bis(neopentyloxy)phosphorylsulfenyl chloride with silver cyanide. The thiocyanatidate isomerizes rapidly

[**] Prepared from the corresponding monothioacids [6] or their triethylammonium salts [7] by action of sulfuryl chloride in dichloromethane (see also eq. (2)).

[***] Starting from *(3)* [8], $[\alpha]_D^0 = +18.5°$, *(4)* was obtained according to eq. (2). [*(4)*: m.p. 162—164°C (ethanol), $[\alpha]_D^0 = +53.0°$ (benzene)].

The existence of the relatively stable, optically active compound *(1d)* contraindicates the dissociative mechanism.

Determination of the Absolute Configuration of Amines[***]

By *Francisc Kerek* and *Günther Snatzke*[*]

Neutral complexes such as the Cu^{II} complexes $[Cu(im)_2(am)_2]$ *(1)* (im: succinimidato, phthalimidato; am: sterically non-hindered primary or secondary amine)[1] offer a new and particularly simple method for determining the absolute configuration of amines. Contrary to the former assumption[2] that chiral amines as monodentate ligands in copper complexes are incapable of inducing circular dichroism (CD) within the d-d bands, we have observed two Cotton effects of opposite signs for each of the complexes *(1)* between 400 and 800 nm. In addition, further Cotton effects are found at shorter wavelengths. The longer wavelength CD bands (Table 1) are far better suited for stereochemical correlations than those at shorter wavelengths. Only the signs of the Cotton effects are required for determining absolute configurations (see Fig. 1).

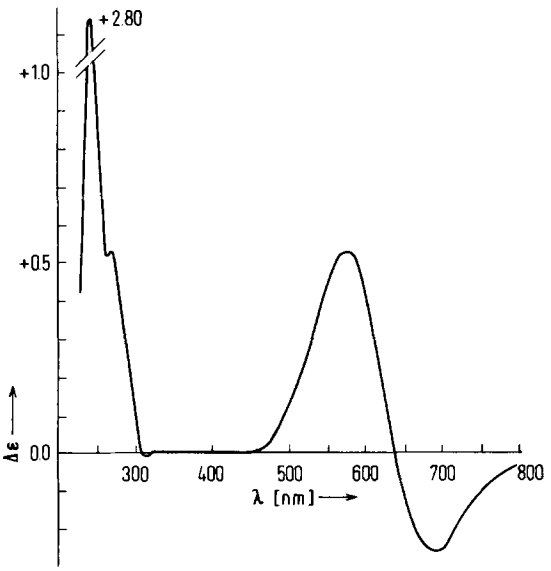

Fig. 1. CD spectrum of $[Cu(su)_2((+)\text{-}sec\text{-}BuNH_2)_2]$, $c = 5 \times 10^{-3}$ mol/l, in CH_2Cl_2.

Table 1. Δε values for several $[Cu(su)_2(am^*)_2]$ complexes *(1)* prepared *in situ* from $[Cu(su)_2(ip)_2]$ or $[Cu(su)_2(py)_2]$ (su = succinimidato; ip = isopropylamine; py = pyridine) in CH_2Cl_2. [Cu] ≈ 0.001–0.01 mol/l, [am*]:[Cu] ≈ 2:1 to 40:1.

[***] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The somewhat involved preparation of the complexes *(1)* according to *Tschugaeff*[1] can be avoided owing to their kinetic lability: thus it suffices to add the optically active amine (am*) to a solution of a "parent complex" (*e.g.* with am = isopropylamine) in dichloromethane, chloroform, or benzene and then to record the CD immediately. Above a molar ratio of about 8 : 1 ([am*] : [Cu]) the CD end values are reached which are also obtained starting from the isolated complexes *(1)*. The signs of the Cotton effects can already be established at much lower am* concentrations. In this way it becomes possible, *e.g.* with as little as 1–2 mg of an amino acid ester, to ascertain whether it belongs to the D or the L series. Rigorous exclusion of moisture is not necessary.

The chiroptical data of bidentate amino acid complexes have been investigated previously (*e.g.* refs.[3–6]). In all cases the proline complexes exhibited the opposite sign to that of all the other amino acid complexes of the same optical series. The CD of the proline complex *(1f)*, however, is in no way exceptional.

Since the complexing constant of amines in *(1)* is far greater than that of other possible ligands, other functional groups do not generally exert interfering effects. Possible chelating with a sterically favorable second amino or hydroxy group can easily be recognized from the appearance of an additional CD band in the region of 530 nm; however, the 700-nm band generally remains informative. Readily oxidizable groups such as —SH (cysteine) destroy the complex.

The above method is much simpler and more reliable than the comparable procedure of reacting amines[7] or amino alcohols[7, 8] with lanthanoid reagents or with pentanedionatonickel complex[8], for which measurements have to be performed in the short-wave range (≈ 300 nm) near the transmission limit of the solutions and the sign of the CD frequently varies with the substrate : complex concentration ratio.

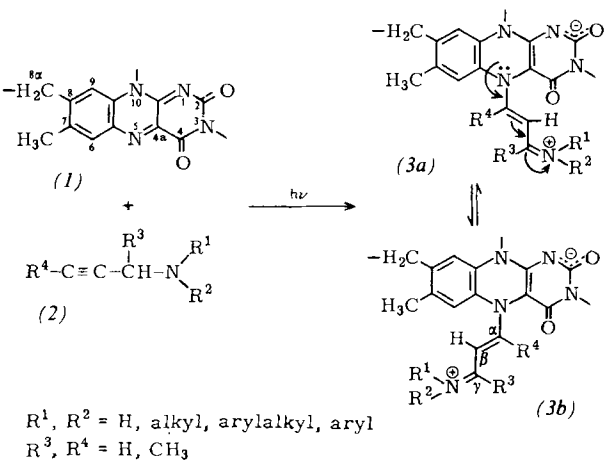
Inhibition of Monoamine Oxidase by Propargylamine: Structure of the Inhibitor Complex[1]

By *Bernd Gärtner* and *Peter Hemmerich*[*]

Mitochondrial monoamine oxidase (MAO) is a key enzyme in the metabolism of biogenic amines[2]. It contains flavin adenine dinucleotide (FAD) as coenzyme and differs characteristically from most common flavoenzymes by the fact that the FAD coenzyme is *covalently* bound to the protein. The structure of this linkage (*via* C-8α of the flavin to a cysteine sulfur of the protein) has been ascertained by *Singer et al.* through enzymatic degradation[3] of the protein and by *Ghisla* and *Hemmerich*[4] who synthesized the modified coenzyme. MAO is irreversibly inhibited[5] by propargylamines *(2)* e.g. pargyline® [*(2)*, $R^1=CH_3$, $R^2=CH_2C_6H_5$, $R^3=R^4=H$].

[*] Prof. Dr. P. Hemmerich and Dr. B. Gärtner
Fachbereich Biologie der Universität
775 Konstanz, Postfach 7733 (Germany)

Chuang et al.[6] first isolated a spectrally pure, soluble preparation of this membrane-fixed flavoprotein with which they also obtained the highly characteristic electronic spectrum of pargyline-enzyme complex. This spectrum has been shown[7] to coincide with the spectrum of a product resulting from photoreduction of flavin with pargyline®. We have elucidated the structure[1] of the product and found it to arise by a novel photo*addition* to N-5 of the flavin nucleus[1] leading to the trimethinecyanine chromophore *(3)*. The terminal groups of this cyanine consist of the now reduced flavin group and the amino group of the photosubstrate.



The "flavocyanines" *(3)* exist in neutral solution in a mesoionic state, where the positive charge is localized in the cyanine part of the molecule and the negative charge in the pyrimidine subnucleus of the flavin. Protonation occurs with p*K* 4—5 at N-1, without essential alteration of the absorption spectrum (approx. 15 nm hypsochromic shift). The cations thus formed are stable towards hydrolysis while reaction of *(3)* with bases results in the characteristic solvolysis of the cyanine system, yielding an aldehyde of type HFl—CH=CH—CH=O as the first intermediate which can be isolated. Further action of base, which proceeds most rapidly with secondary amines, liberates flavin quantitatively as unmodified flavoquinone *(1)*. This chemical reversibility of adduct formation has not yet been verified in the enzymatic system.

According to expectation[8], the trimethine chains possess *trans* configuration throughout (^{1}H-NMR, $J_{CH-CH\,trans}=11.5$—12.0 Hz). Hence, when $R^1=R^2$, *two* and only two *(5)* N÷÷C (α) rotamers *(3a, b)* can be demonstrated directly by ^{1}H-NMR (for each rotameric species *(3a)*, *(3b)* separate signals of α,β,γ 6,9-protons, cf. Experimental). The rotamer population depends on the solvent; equilibration *(3a)*⇌*(3b)* occurs within less than 5 minutes upon dissolution of the crystals at room temperature. The cyanine chromophore is not entirely coplanar with the terminal flavin group, as suggested by molecular models and as supported by the relatively large half width[9] of the longwave band. An additional molecular asymmetry results, leading, in the case of increased steric hindrance by a substituent $R^4=CH_3$, to the ^{1}H-NMR-spectroscopic non-equivalence of prochiral methylene protons ($R^1=CH_2—C\equiv C—CH_3$, ABX_3). We assign the 400 nm band to the lowest energy π-π*-transition of the cyanine chromophore (oscillator strength[10] $f=0.4$—0.6). This transition shows a strong negative solvatochromy (approx. −25 nm upon change from $CHCl_3$ to methanol). This supports the assumption that the 4a,5-azomethine function of the flavocoenzyme is the dehydrogenating enzyme site. One may further conclude that covalent flavin-substrate interactions are relevant in molecular pharma-

cology and, presumably, even in pure enzymology of flavoproteins.

The new synthetic principle can be generally extended to π-electron deficient azaheterocycles.

Experimental:

A well stirred solution of 3-methyllumiflavin[11] (1.50 g, 5.5 mmol) and *N*,*N*-dimethylpropargylamine (4.6 g, 55.0 mmol) in 0.1 M phosphate buffer (600 ml, pH 7.7) was illuminated under argon for 30 hours with a 170 W mercury high-pressure lamp (HERAEUS, Hanau; pyrex cooling jacket). The brown precipitate was filtered off by suction, washed with water (50 ml), dried, and extracted with hot benzene (3 × 50 ml). The residue was reprecipitated from hot chloroform (25 ml) by addition of hot benzene (60 ml), and then from hot methanol (30 ml) by addition of ether (120 ml).

Yield: 600 mg (28%) 5-(γ-dimethyliminiopropenyl)-3-methyl-1,5-dihydrolumiflavin betaine; yellow needles, m.p. 226—227 °C (dec.). UV: λ_{max} (ε) in benzene 430 nm (29650); in chloroform 427 nm (22700); in methanol 402 nm (25500); in H_2O, pH 7.0, 391 nm (25500). ^{1}H-NMR (90 MHz; TMS as internal standard), δ [ppm] in D_6-DMSO: rotamer *(3a)* (82%) α-H 7.85, β-H 5.10, γ-H 7.77; *(3b)* (18%) 8.10, 5.80, 8.01; $J_{\alpha\beta} = J_{\beta\gamma} = 12.0$ Hz; in CF_3COOH: rotamer *(3a)* (73%) 7.68, 5.34, 7.77; *(3b)* (27%) 8.00, 6.12, 7.90; $J_{\alpha\beta} = J_{\beta\gamma} = 12.0$ Hz.

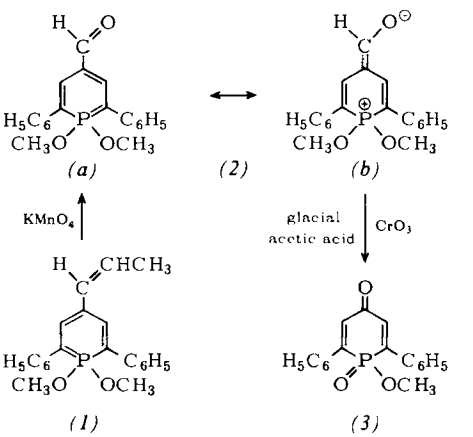
1,1-Dimethoxy-2,6-diphenyl-λ⁵-phosphorin-4-carbaldehyde and -4-carbonitrile[1]

By *Hans Henning Pohl* and *Karl Dimroth*[*]

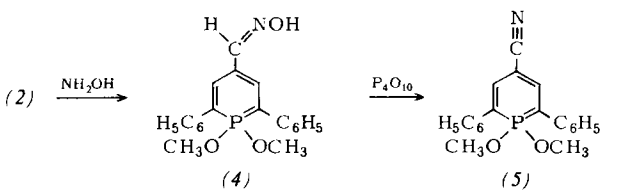
1,1-Heterosubstituted λ⁵-phosphorins *(1)* are characterized by exceptional stability of the λ⁵-phosphorin ring, so that they can be considered as a new type of heteroaromatic compound[2]. In order to study their chemistry we are seeking methods for synthesizing derivatives containing functional groups attached to the phosphorin ring. The starting material for the carbaldehyde *(2)* described in this communication and other compounds accessible therefrom is 1,1-dimethoxy-2,6-diphenyl-4-propenyl-λ⁵-phosphorin *(1)*[3].

On oxidation of *(1)* with potassium permanganate by a phase transfer process[5] in benzene/water containing tetra-*n*-butylammonium bromide[4], the double bond of the side chain is cleaved without destruction of the λ⁵-phosphorin ring. Thin layer chromatography on silica gel permits isolation in more than 60% yield of the carbaldehyde *(2)* which crystallizes in yellowish needles (m.p. 96 °C). It is stable in air, and its solutions have a strong bluish fluorescence.



In the ^{1}H-NMR spectrum ([D_6]-acetone) at room temperature a doublet at δ = 8.63 ppm ($^3J_{P-H} = 38$ Hz) is found for the protons at C-3 and C-5 of the phosphorin ring. At low temperatures this A_2X system passes into an ABX system, which appears well resolved at −60 °C. From the non-equivalence of the protons on C-3 and C-5 it can be concluded that rotation around the axis C(4)—CHO is restricted by delocalization in the sense of the formulas *(2a)* and *(2b)*.

Although the aldehyde is not further oxidized by an excess of potassium permanganate, 1,4-dihydro-1-methoxy-2,6-diphenyl-λ⁵-phosphorin-1,4-dione *(3)* is obtained in about 50% yield on use of chromic acid in glacial acetic acid.



The oxime *(4)*, melting at 141—142 °C (dec.), and the *p*-toluenesulfonylhydrazone, m.p. 160—161 °C, are formed from the aldehyde *(2)* in smooth reactions. Removal of water from *(4)* is effected by P_4O_{10} in benzene, yielding the 4-cyano-substituted λ⁵-phosphorin *(5)* which crystallizes in pale yellowish needles (m.p. 130 °C), and which can be hydrolyzed affording the carboxamide.

4-(Acetylamino)-1,1-dialkoxy-2,6-diphenyl-λ⁵-phosphorins[1]

By *Karl Dimroth* and *Manfred Lückoff*[*]

In the course of work aimed at synthesis of λ⁵-phosphorins containing functional groups attached to the phosphorin ring, we succeeded in preparing the 4-(acetylamino)-1,1-dialkoxy-2,6-diphenyl-λ⁵-phosphorins *(4a)* and *(4c)* as key compounds for further reactions. The starting materials are the 4-(arylazo)-λ⁵-phosphorins *(3)*, which in turn can be prepared by means of electrophilic substitution with arenediazonium salts[2] from λ⁵-phosphorin derivatives containing electrofugal leaving groups at C-4. A new reaction is the ready formation of *(3)* to *(3c)* in 70—90% yield of pure compounds from the readily accessible[3] 4-benzyl-λ⁵-phosphorins *(1a)* to *(1c)* by way of the carbenium tetrafluoroborates *(2a)* to *(2c)*[4] and benzene- or *p*-toluene-diazonium tetrafluoroborate in dimethoxyethane containing sodium hydrogen carbonate and a few drops of water. The reactions *(3)*→*(4)* were effected by zinc dust in glacial acetic acid and acetic anhydride. The crystalline, analytically pure *N*-acetyl derivatives *(4a)* and *(4c)* are sensitive to light and give solutions with yellow-green fluorescence; they were separated from the *N*-acetyl-aniline or -toluidine formed simultaneously and isolated in 64 and 69% yield, respectively.

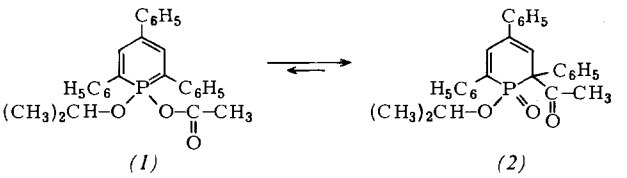
A Rearrangement in the λ⁵-Phosphorin Series Analogous to the Claisen Rearrangement

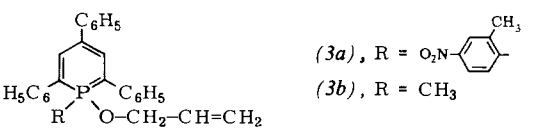
By *Ortwin Schaffer* and *Karl Dimroth*[*]

Dedicated to Professor Eugen Müller

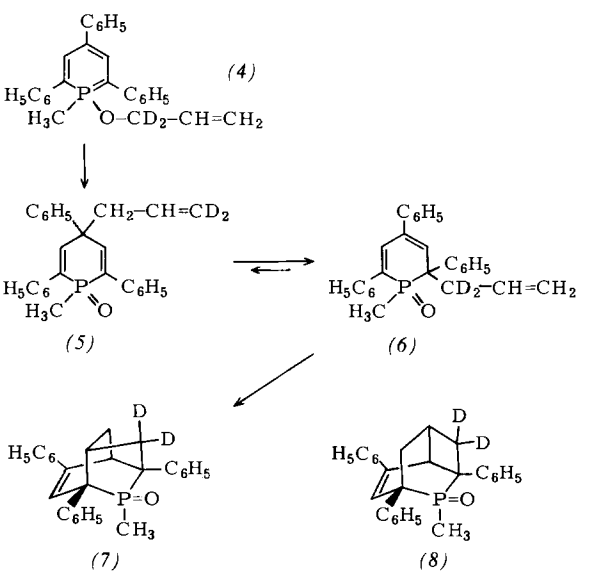
We recently reported[1] a thermal sigmatropic [1,3]-rearrangement analogous to the Fries migration, which leads from 1-acetoxy-1-isopropoxy-2,4,6-triphenyl-λ⁵-phosphorin *(1)* to 2-acetyl-1,2-dihydro-1-isopropoxy-2,4,6-triphenyl-λ⁵-phosphorin-1-one *(2)*. *(1)* exists in reversible equilibrium with *(2)*.

The readily accessible 1-alkoxy-1-aryl-[2] and 1-alkoxy-1-alkyl-2,4,6-triphenyl-λ⁵-phosphorins[3] make it possible to prepare the allyloxy derivatives *(3a)* and *(3b)* and thus to study the thermal rearrangement of the latter compounds.





Both compounds rearrange to isomeric compounds within a few hours when warmed even at *ca.* 110 °C (boiling toluene). Compound *(4)* labeled by means of [1,1-D_2]-allyl alcohol was prepared for a study of the course of the reaction.



Analysis of the ^{1}H-NMR spectra shows that *(4)* first rearranges cleanly to the phosphacyclohexadiene derivative *(5)*

[*] Dr. O. Schaffer and Prof. Dr. Karl Dimroth
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

substituted at C-4. If the rearrangement is prematurely interrupted, *(5)* is obtained analytically pure as a crystalline compound. Heating *(5)* in toluene causes a [3,3]-sigmatropic rearrangement that leads to an equilibrium greatly in favor of *(6)*, this being the reverse reaction of that found in a study of the Claisen rearrangement. However, we found no trace of a reverse rearrangement of *(5)* to *(4)*. On longer heating of *(5)* in toluene, *(6)* is accompanied by a new, stable, excellently crystallizing product which can also be obtained from pure *(6)*. For this compound we propose structure *(7)* [or possibly *(8)*], whose formation is explained by an intramolecular Diels-Alder reaction that is irreversible under the reaction conditions. Proof of the structure is currently being sought by X-ray structure analysis.

As a synchronous thermal $[_3s_5s]$-rearrangement, the reaction *(4)* → *(5)* would be symmetry-forbidden if the orbital symmetry of the λ^5-phosphorin derivative *(4)* is the same as that of a phenyl ether. A synchronous course is not in line with the fact that when *(4)* is warmed in toluene an ESR signal (doublet at 23.5 gauss) appears which can be assigned to the relatively stable phosphacyclohexadienyl radical with five-valent phosphorus[4]. On longer heating, the intensity of this signal decreases. An ESR signal for the allyl radical could not be observed.

The unexpected course of this rearrangement may depend on the geometry of compound *(4)*. The allyl group—unlike that in allyl phenyl ethers—occupies a structural position favorable for attack of the terminal CH_2 group on C-4 of the heterocycle, this being possible due to the tetrahedral structure at the phosphorus atom.

Rearrangement of 1-methyl-1-propargyloxy-2,4,6-triphenylphosphorin, analogous to *(3)*, requires a somewhat higher temperature (*ca.* 140 °C, xylene). Preliminary experiments indicate a course similar to the allyl rearrangement.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The biochemistry of hypoglycine is reviewed in an article by *K. L. Manchester*. This amino acid (β-(methylenecyclopropyl)-alanine), which occurs in the fruits of some plants, is toxic and leads, in small doses, to vomiting; larger doses lead to hypoglycemia and ultimately to death. The synthesis, purification, and chemical reactions of the amino acid are described. Its effect on the metabolism is to inhibit reactions which involve participation of leucine, an amino acid which is physicochemically very similar to hypoglycine. This leads to interferences with the protein synthesis and with the biological degradation of leucine. Hypoglycine also affects the β-oxidation of fatty acids by inhibition of flavin enzymes. Teratogenic effects on rat embryos have also been observed. [Biochemistry of Hypoglycine. FEBS Lett. *40*, S133—S139 (1974); 56 references]

[Rd 750 IE—R]

The chemical and biological functions of membrane-active complexing agents are reviewed by *Yu. A. Ovchinnikov*. This class of substances, whose prototype is valinomycin, form complexes with alkali and alkaline earth metal ions, which, because of the lipophilic regions of the molecules, are ion carriers. The behavior of valinomycin and its analogs and enniatin, which is also a depsipeptide, in lipid double layers and natural membranes is discussed. Spectral investigations on the dependence of complex formation on the solvent are also described. [Membrane Active Complexons. Chemistry and Biological Function. FEBS Lett. *44*, 1—21; 36 references]

[Rd 752 IE—R]

The active ribosome sites in *Escherichia coli* is the subject of a review by *O. Pongs, K. H. Nierhaus, V. A. Erdmann*, and *H. G. Wittmann*. In the course of the last few years numerous experimental results have been obtained regarding the processes of initiation of protein synthesis, elongation of the peptide chain, and termination, which in turn are subdivided into individual steps. These results and further information obtained on the protein factors necessary for the reactions provide a detailed picture of the regulatory processes on ribosomes during the course of the synthesis. [Active Sites in *Escherichia coli* Ribosomes. FEBS Lett. *40*, S28—S37 (1974); 142 references]

[Rd 756 IE—R]

Structural transformations of ribosomes are discussed in an article by *A. S. Spirin*. Dissociation of the ribosome into two unequal parts proves to be a general building principle and appears to be essential for their functioning. Partial functions of the ribosome have been investigated on both fragments. The unfolding at lower magnesium concentrations, which leads to a lowering of the sedimentation coefficients, and an increase in viscosity, made it possible to study the structure of the ribosomal proteins and their relationship to the ribosomal RNA. The reversible dissociation of ribosomal particles at high alkali metal chloride concentrations permitted the selective elimination of certain proteins. Partial ribosomes could be assembled from the fragments by spontaneous reassociation. [Structural Transformations of Ribosomes (Dissociation, Unfolding and Assembly) FEBS Lett. *40*, S38—S47 (1974); 183 references]

[Rd 757 IE—R]

Vibrational structure in electronic spectra of coordination compounds is the subject of a review by *C. D. Flint*. If such vibrational structure is observed, different selection rules may make it possible to identify vibrational frequencies not observ-

able in the IR and Raman spectrum. Thus, the normal coordinate analysis of the respective complexes is simplified, as the number of approximations made in setting up the force field is reduced. [Vibronic Spectra of Coordination Compounds. Coord. Chem. Rev. *14*, 47—66 (1974); 45 references]

[Rd 760 IE—H]

New results of the photochemistry of complexes of the heavier transition metals are discussed by *P. C. Ford, J. D. Petersen,* and *R. E. Hintze.* Most work in this field is concerned with complexes derived from metal ions with the electron configurations $4d^6$ and $5d^6$. Reactions of coordinated ligands, isomerizations, redox, and substitution reactions were observed. The special feature of these metals compared to the first transition row metals is the higher spin-orbit coupling rendering easier interconversion between excited states of different multiplicities. [Photochemistry of Hexacoordinate Complexes of the Heavier Transition Metals. Coord. Chem. Rev. *14*, 67—105 (1974); 109 references]

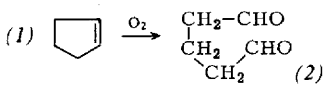
[PR 241 IE—S]

Glutardialdehyde *(2)* is formed on uncatalyzed gas-phase oxidation (1—3 atm, 280—450 °C, 1—30 sec) of cyclopentene *(1)* with a selectivity of 50—70 mol-% and an oxygen consumption

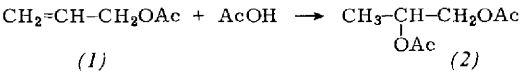


(1) *(2)*

of about 20 %. [DOS 2261657; Bayer AG, Leverkusen (Germany)]

[PR 243 IE—G]

Propylene diacetate ("**propylene glycol diacetate**") *(2)* can be prepared by treating allyl acetate *(1)* with acetic acid on polyphosphoric acid/SiO_2 catalysts (100 atm, 200 °C). Allyl



(1) *(2)*

propionate may be used in place of *(1)*, and propionic or butyric acid in place of acetic acid. [DOS 2219915; Farbwerke Hoechst AG, Frankfurt (Germany)]

[PR 244 IE—G]

Silicate foam materials (water glass foams) are obtained by mixing air into a water glass solution and simultaneously adding a hardening substance such as 1,2-dichloroethyl dichloroisocyanide, benzoyl chloride, *o*-toluenesulfonyl chloride, or dipropyleneglycol bis(chlorofumarate). [DOS 2228359; Bayer AG, Leverkusen (Germany)] [PR 255 IE—W]

Ligandenfeldtheorie (Ligand Field Theory). Chemische Taschenbücher 19. By *P. Schuster*. Verlag Chemie GmbH, Weinheim 1973. 1st Edit., ix, 192 pp., 32 figures, 43 tables, paperback, DM 28.—.

This volume in the "Chemische Taschenbücher" series provides the reader with an introduction to ligand field theory, but it seems doubtful if such relatively short treatment can fulfil the author's intention, stated in the Foreword, *i.e.* to offer an introduction to the beginner or near-beginner and to lead him from there to the stage where he can read and understand original papers "without difficulty".

The book is suited above all—and for this it is suited very well—as a basis for a lecture or seminar on ligand field theory. Without such additional introduction the reader who, as stated in the Foreword, has mastered only the "simplest principles" of quantum mechanics, would hardly be able to follow the necessarily concise expositions. For example, finding the energy levels relating to a many-electron problem would be difficult for such a reader.

Several misprints and blemishes in the setting could certainly be corrected in the next edition: one example is the repeated confusion between v and υ. Superscripts, *e.g.* those characterizing an approximation step, should be placed consistently in parentheses, at least within one and the same formula. The angular momentum quantum number l should not be printed in italics when this is not done with any of the other quantum numbers. The additional problems set are certainly very useful, yet the reviewer doubts whether the reader would be able to solve them after going through this book; they should at least be complemented by provision of the answers.

Karl Hensen [NB 237 IE]

Ionenkristalle, Gitterdefekte und Nichtstöchiometrische Verbindungen (Ionic Crystals, Lattice Defects and Non-stoichiometric Compounds). By *N. N. Greenwood*. Translated by *H.-G. von Schnering* and *B. Kolloch*. Verlag Chemie GmbH, Weinheim 1973. 1st Edit., viii, 185 pp., 60 figures, 26 tables, paperback, DM 28.—.

The declared aim of this book, "to give the first systematic and comprehensive account of modern views on the influence of lattice defects on the properties of ionic solids", is certainly pitched too high, since the first edition of *Kröger*'s "The Chemistry of Imperfect Crystals" appeared as early as 1964, four years before the first edition of the English original of the book reviewed here. The book rather provides an introduction, for the most part intelligibly presented, to the chemistry of imperfect ionic crystals, and its evolution from a lecture manuscript can be recognized, not least by the skilfully selected examples. The first three chapters are devoted to ideal ionic crystals, occupying a relatively large space (about 60 pages), even after taking into account the "chemical" viewpoint that the author intentionally emphasizes. The next three chapters are concerned with lattice defects in "stoichiometric" and "non-stoichiometric" crystals, although in the introduction to Chapter 6 the author himself recognizes this differentiation to be "arbitrary in the narrow sense". The last chapter describes the experimental study of non-stoichiometric phases. Surprisingly, the relation between vacant sites and material transport is handled explicitly in only four pages, and the study of lattice defects by magnetic resonance is merely mentioned (Chapter 4).

Summarizing, it may be stated that this translation, satisfactorily produced and in fluent, almost faultless German, is not exactly good value for money in comparison with the original (DM 16.—), but it is certainly suitable for readers interested in a concise introduction to the chemistry of imperfect ionic crystals.

G. Borchardt [NB 240 IE]

Reaktionsmechanismen der Organischen Chemie. Ein Seminarbuch (Reaction Mechanisms in Organic Chemistry. Seminar Book). By *H. Höver*. Verlag Chemie GmbH, Weinheim and John Wiley & Sons, New York 1973. 1st Edit., 565 pp. 23 figures, 28 tables, paperback, DM 48.—.

Traditional textbooks on reaction mechanisms in organic chemistry generally begin with a section on methods and then treat the various types of reaction. The reader can then test and extend his knowledge by means of the problems set at the end of each section.

The present book turns this arrangement upside down. It begins by setting out the problems on the first pages, and in the 500 pages of the second part accompanies the solution of the specific exercises with a very broad and complete description of the field. The author's intention of presenting a typical seminar book is thus realized.

The 210 problems are presented according to a systematic scheme: Structural formulas are given for the starting materials, but the intermediates and the end products are written as molecular formulas and characterized by IR, UV, and NMR data. Each reaction is studied in detail, so that often more than ten molecular formulas have to be unravelled. Special attention is paid to seeing that the mechanism explains the formation of all the products.

Most of the often very specialized problems are barely soluble by even an advanced student, so that sensible use of this book would be by joint work on the problems within the framework of a seminar. In this way the student would learn in detail all the reaction types in organic chemistry; the greatest emphasis is placed on important research areas such as the Woodward-Hoffmann rules. The chemistry of radicals and photochemistry are treated too sparingly. It is also apparent that the results of kinetic measurements are not sufficiently included in the discussions.

Apart from these criticisms it seems to me that the author has succeeded in producing a comprehensive modern book on reaction mechanism, especially suitable for seminar work with advanced students.

What Do We Know About Nuclear Fission?

By Dieter C. Aumann[*]

Dedicated to Professor H.-J. Born on the occasion of his 65th birthday

Nuclear fission, although a physical phenomenon, is also of interest to the chemist. It was discovered by chemists, and chemists have made a material contribution to our present knowledge in this field. A comprehensive theory of nuclear fission has not, as yet, been developed, despite the volume of experimental data that has amassed in the 35 years since its discovery. In the past few years discoveries have been made which cannot be explained with conventional theoretical models of nuclear fission. The most important discovery was that of shape isomerism, a novel type of nuclear isomerism. It would appear that an accurate calculation of fission barriers is a prerequisite for precise explanation of many experimental findings. Recent results in this connection and an outline of the present state of our knowledge of nuclear fission constitute the main theme of this paper.

1. Introduction

Only few scientific discoveries have proved so important to the fate of mankind as that of nuclear fission. Its utilization for military purposes, in the form of nuclear weapons, could lead to disaster—as a source of energy it could prove a blessing to the human race. In the Federal Republic of Germany nuclear power accounts for about 3% of the electricity contributed to the national grid. It is to be hoped that this contribution will be increased to about 30% by 1980 and to 40% five years later *i.e.* a contribution of 50000 MW by 1985.

Although 35 years have passed since its discovery, nuclear fission still remains a challenging field for research. A complete theory of nuclear fission has yet to be developed which could suitably describe this complicated nuclear reaction and the phenomena associated with it, such as *e.g.* the probability of fission, energy released in fission, the distribution of neutrons and protons among the fission fragments, the angular distribution of fission fragments, the number and energy of neutrons and gamma quanta emitted by the fission fragments *etc.* Several theoretical models of the fissioning nucleus have been developed, each of which describe some of the aforementioned phenomena, but as yet none is capable of satisfying all experimental findings.

In their two classical publications[1, 2] *Hahn* and *Strassmann* showed that radioactive isotopes of elements from the middle of the periodic system having atomic numbers of about half that of uranium are formed when uranium is irradiated with neutrons. *Meitner* and *Frisch*[3] interpreted this finding, quite correctly, as the splitting or cleaving of the excited uranium nucleus into two roughly equal fragments. They coined the term "nuclear fission" for such a nuclear reaction, and recognized that it was accompanied by the release of a considerable amount of energy. *Frisch*[4] demonstrated that most of this energy is imparted to the fission fragments as kinetic energy and that the fragments are forced apart by the Coulomb repulsion of their nuclear charges. He was able to observe these fission fragments as large pulses in an ionization chamber.

Target nucleus in equilibrium deformation

Nuclear reaction: particle capture or direct reaction, *e.g.* (d,p) or (α,α′)

Excited nucleus with equilibrium deformation of target and E MeV of excitation energy, nuclear charge number Z_f, mass A_f and angular momentum J_f.

Transition state nucleus with saddle point deformation and $(E-E_f)$ MeV of excitation energy (E_f=fission barrier). Lifetime depends on $(E-E_f)$ and is *ca.* 10^{-15} s for thermal neutron capture.

Scission configuration: two nuclear potentials; fragments highly deformed with the degree of deformation depending upon fragment stiffness; kinetic energies of fragments small; occasional small particle emitted. The fragments have nuclear charge numbers Z_{l_1} and Z_{h_1}, masses A_{l_1} and A_{h_1}, spins J_{l_1} and J_{h_1}

$Z_f = Z_{l_1} + Z_{h_1}$; $\quad A_f = A_{l_1} + A_{h_1}$

Accelerating primary fragments under Coulomb interaction; approx. 10^{-20} s for fragments to reach 90% of their final kinetic energy K.E.; they thus travel *ca.* 10^{-11} cm.

Accelerated primary fragments of high excitation energy separated by a relatively large distance.

Neutron emission (ν_l, ν_h) in $10^{-18}-10^{-14}$ s.
Distance of fragments: 10^{-5}—10^{-9} cm.

$A_{l_1} = A_{l_2} + \nu_l$; $\quad A_{h_1} = A_{h_2} + \nu_h$

γ-ray emission in 10^{-12}—10^{-10} s
Distance of fragments: 10^{-1}—10^{-3} cm.

Primary fission products (secondary fission fragments) in their ground state with nuclear charge numbers Z_{l_1} and Z_{h_1}, masses A_{l_2} and A_{h_2}, and spins J_{l_2} and J_{h_2}. These nuclei are neutron rich and β^--unstable.

β-Decay (with $\tau > 10^{-2}$ s, slow process) to secondary fission products. Occasionally β-decay populates a neutron unstable level: emission of delayed neutrons. Radiochemists investigate the long-lived nuclei of this decay process.

$Z_{l_1} = Z_{l_2} - n_l$; $\quad Z_{h_1} = Z_{h_2} - n_h$ (n_l, n_h number of β-decays)

Stable end products

Fig. 1. Schematic representation of the successive steps of nuclear fission (after [13]).

The original works on nuclear fission were reviewed by *Turner*[5] in an article which was able to be published just before the use of nuclear fission for military purposes was recognized, and the outbreak of the second world war hampered further publications in this field. It was as late as 1951 before some of the major works that were carried out on nuclear fission during the war years in the USA were able to be published[6]. Radiochemical investigations carried out in Germany on fission products during the first years after the discovery of nuclear fission were reported by *Seelmann-Eggebert* and *Strassmann*[7]. In the following years several review articles and monographs were published, giving detailed accounts of the latest data on nuclear fission and up-to-date developments on the theory of fission[8-14]. Since 1965, the International Atomic Energy Agency (IAEA) has arranged symposia on the physics and chemistry of fission which are held at intervals of four years[15-17].

Although a physical phenomenon, nuclear fission is of great interest to the chemist for it leads to outstanding and important chemical changes. Isotopes of more than 35 elements having about half the nuclear charge of the original element are formed during the fission of a heavy element. The chemist is responsible for the production of highly pure uranium for use as fuel in reactors, and for the processing of burnt fuel elements which are poisoned with fission products and transuranium elements. Nuclear fission was discovered by chemists, and chemists have made a considerable contribution to the present state of our knowledge in this field. Since the middle sixties, however, refined physical methods of measurement, especially coincidence and multiparameter measurements with semiconductor detectors, faster electronics, larger multichannel analyzers and computers, have pushed radiochemical methods more and more into the background. With radiochemical methods one measures the yields of isotopes of one element or a few elements formed in fission. With physical methods the whole range of fission products can often be recorded in a single experiment. Radiochemical techniques are relatively slow and identify fission products only when all intermediates have already decayed (see Fig. 1). Furthermore, the fission products are detected integrally *i. e.* no distinction is made between otherwise like fission products which have been formed with different kinetic energy, or those arising from the fission of various highly excited nuclei, or those formed directly from the fissioning nucleus or by β-decay of another fission product. Physical coincidence techniques, on the other hand, permit simultaneous measurement and correlation of several quantities; *e.g.* the number of neutrons emitted per fragment can be determined as a function of fragment mass.

Radiochemical methods can, however, be used to great advantage if fission products which are formed in very small yields have to be isolated from the complex mixture of fission products. With chemical methods of separation, the mixture is resolved into components according to the atomic number Z; the mass number A is determined by radioactivity measurements on the isolated fission products, so that very small amounts of an atomic nucleus ${}^{A}_{Z}X$ can be isolated and identified from a large excess of several orders of magnitude ($>10^{12}$) of other fission products. Since the chemical methods integrate over longer times, all the atomic nuclei formed during one experiment are collected so long as their half-life is not too short. Thus extremely less-probable processes can be detected. Hence, for many problems radiochemical methods are irreplaceable. With the aid of such methods it was possible *e.g.* to detect the very low-probability fission of heavy nuclei of average excitation energy into three almost equally sized fragments[18-20] or to measure the population of shielded fission product isomers of very small yield[21]. Radiochemical methods are also superior to physical methods when investigating the fission of nuclei having high specific alpha activity, *e.g.* ^{254}Fm. In the present progress report the most recent results and the present state of our knowledge of nuclear fission will be discussed. In the absence of a comprehensive theory this will be done from the standpoint of the experimenter, especially the radiochemist. The volume of experimental material reported in the literature on this topic is so large, however, that a certain amount of selection has had to be made. An attempt is also made to indicate the gaps in our knowledge of nuclear fission and to outline the problems which can be resolved especially with the aid of radiochemical methods.

2. When and How Does an Atomic Nucleus Fission?

An atomic nucleus can split into two or more fragments if sufficient excitation energy is supplied to it to overcome the fission barrier (fission threshold). This excitation energy is provided by nuclear reactions which are initiated by bombarding the nucleus with neutrons, photons or charged particles. The heaviest elements ($Z>90$) might even split "spontaneously", without being externally excited; in this process, the potential barrier is penetrated similarly as in alpha decay, by quantum mechanical tunnelling. The nature of the fission process (Fig. 1) remains the same in many ways, from very low excitation energies (near the fission threshold) up to moderate excitation energies of fissioning nuclei (about 50 MeV).

Shortly after the discovery of nuclear fission, *Bohr* and *Wheeler*[22] tried to interpret the "splitting process" on the basis of the liquid drop model. The atomic nucleus was regarded as a charged liquid drop whose stability is determined by two opposing forces. The short-range nuclear forces hold the nucleus together, analogous to the surface tension of a liquid drop, while the repulsive Coulomb forces between the protons try to split the nucleus apart. The stability and shape of a nucleus depend upon the balance or imbalance between the electrostatic forces and the nuclear forces. If such a drop is deformed its stability decreases. The surface area of the nuclear drop is at the same time enlarged; work is done against the surface tension, and the potential energy of the nucleus increases, at first much more rapidly than the Coulomb energy decreases. If the electrostatic repulsion is finally greater than the surface tension then deformation of the nucleus increases until the latter finally necks and splits into two parts.

Fig. 2 shows the potential energy of the nucleus as a function of its deformation, calculated according to the liquid drop model. The potential barrier is shown over which the nucleus must pass in "prompt" fission induced by external excitation, or tunnel through in the case of spontaneous fission.

If sufficient activation energy is supplied to a heavy nucleus, it can become deformed to such an extent that its potential

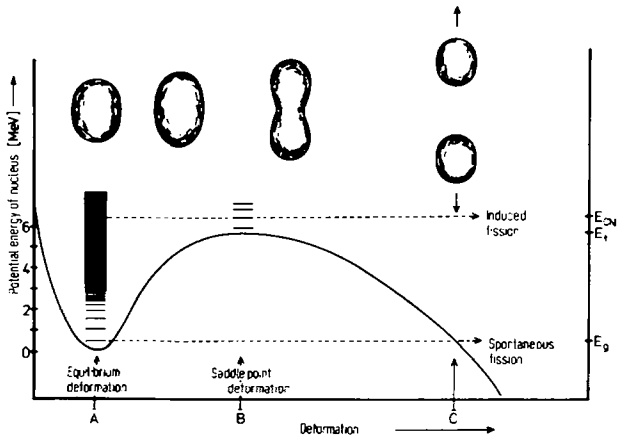

Fig. 2. Schematic representation of the fission barrier according to the traditional liquid drop model. The potential energy of the fissioning nucleus changes with deformation. The energy levels of the nucleus in the ground state and in the saddle point are shown. E_f is the height of the fission barrier; E_{CN} is the excitation energy of the compound nucleus (excited nucleus), which must be higher than E_f for the excited nucleus to fission; and E_g is the ground state of the nucleus from which the spontaneous fission originates. The phases A, B, and C of the fission process are investigated by different experimental methods (see Text).

energy reaches a maximum. This labile equilibrium state between the repulsive Coulomb forces and attractive nuclear forces is referred to as the "saddle point" configuration or "transition" nucleus. The least amount of energy which must be supplied to the nucleus to reach the saddle point is called the critical deformation energy, fission barrier, or fission threshold. The nucleus deformed to the saddle point configuration is expected to have a spectrum of excited states similar to those of a nucleus near its ground state, since the greater part of its excitation energy is present as deformation energy.

The states of the nucleus in the saddle point deformation are called "transition states" or "fission channels". Each fission channel is characterized by a set of quantum numbers and by its saddle point energy.

If the nucleus is deformed beyond the saddle point configuration it is cleaved into two fragments by the Coulomb forces, the nuclear potential of the fissioning nucleus being divided into the nuclear potentials of the two separating fragments. This stage of the deformation is called the "scission configuration". It is at this stage that the distribution of protons and neutrons, excitation energy and angular momentum to the two fission fragments is finally decided. These fission fragments are formed with mass and charge numbers which vary over a wide range, and they contain different amounts of excitation energy. They are accelerated to kinetic energies totalling about 160 MeV by the Coulomb forces, which on their part depend on the proton and neutron composition of the fragments. One thus observes mass, charge and energy distributions in the fission fragments.

If the deformed fission fragments convert into their equilibrium form, their deformation energy is transformed into internal excitation energy. The fragments become heated and neutrons are evaporated off. The fission fragments give up the remainder of their excitation energy in the form of gamma quanta. The fragments are now referred to as secondary fission fragments or primary fission products. These processes are illustrated in Fig. 14 (Section 10).

The secondary fission fragments are formed in the ground state, but they are very neutron rich *i.e.* they are unstable toward β-decay and are thus radioactive. Only at this stage of the fissioning process can radiochemical experiments come to our aid. The radiochemist separates the β-unstable fission products and studies the longer-lived atomic nuclei (> 1 s).

Since a complete theory of the fission process is still lacking, information about this process and its individual steps must be sought by experiment. These experiments ought to answer two questions: 1. When does a nucleus fission? and 2. How does a nucleus fission?

The first question can be answered with experiments in which the fission probability of atomic nuclei and its change with excitation energy is measured. The second question can be studied with experiments which show how mass, charge, energy, and angular momentum of the fissioning nucleus are distributed to the fission fragments and how these distributions change when different types of atomic nuclei are fissioned.

In figure 2 the three phases A, B and C of the fission process are indicated. Phase A involves formation of the compound nucleus, its excitation and its path along the potential barrier, *i.e.* the problem of when a nucleus fissions. The experiments which throw light on the nature of phase A are those in which measurements are made on the lifetimes of spontaneously fissioning nuclei, the fission threshold and fission cross section as a function of mass, charge and energy of the excited nucleus, the competition between fission and other forms of decay of the nucleus such as neutron or gamma quanta emission; in short the probability of fission of nuclei under various conditions.

In phase B saddle point deformation and nuclear states at the saddle point are investigated. Information on this phase is obtained mainly by accurate measurements of the fission cross section as a function of angle and energy. Studies on the angular distribution of the fission fragments and its energy dependence allow characterization of the quantum numbers and energies of the transition states.

The question "How does a nucleus fission?" is answered by experiments in region C which study the descent of the fissioning nucleus from the saddle point deformation to the scission configuration and the formation of the fission fragments. The kinetic energy of the fragments and the number of prompt neutrons and gamma quanta are measured as a function of the excitation energies of the nuclei; it is then possible to determine the distribution of the excitation and deformation energy to the two fragments. Measurements of mass and charge distributions of the fission fragments and the energy dependence of these distributions afford information on the partition of the nucleons of the fissioning nucleus to the two fragments. Determination of the angular momentum of the two fission fragments likewise provides interesting insights into the processes taking place in phase C.

Very frequently it is impossible to measure these quantities for the primary fission fragments, since the time in which they emit neutrons and gamma quanta is very short (see Fig. 1). In addition, these processes lead to new distributions of such quantities in the secondary fission fragments. Attempts must then be made to infer these quantities for the fission fragments from measurements of the corresponding quantities in fission products.

3. The Double-Humped Fission Barrier

In the course of the last 10—15 years more and more experimental findings have indicated that it is too crude to treat an atomic nucleus as an electrically charged drop of incompressible liquid. Admittedly, the liquid drop model describes the average properties of atomic nuclei in the ground state and in the fission process quite conveniently, but it fails in detail.

Thus experimentally determined nuclear masses in the neighborhood of nuclei containing the well-known "magic" number of protons and neutrons, 2, 8, 20, 28, 50, 72 and 126, show a small but clearly systematic deviation from the nuclear masses calculated with the liquid drop model. Although the average deviation of the total binding energy, which lies in the order of $8 \times A$ MeV (A = mass of nucleus), is only a few MeV, the magic nuclei prove to have a binding energy up to 13 MeV higher than would be predicted by the liquid drop model.

The liquid drop model predicts a sharp decrease of the fission barriers as a function of the quantity Z^2/A of the fissioning nucleus. The measured fission thresholds of heavy nuclei, however, decrease much more slowly. Fig. 3 compares experimentally determined fission barriers with those calculated on the basis of the liquid drop model. The barrier heights calculated for elements heavier than thorium are too low and decrease too rapidly with increasing Z. (On the basis of this decrease of the fission barriers predicted by the liquid drop model, it was long ago concluded that there was a theoretical limit to the periodic system at $Z \approx 100$ –110.)

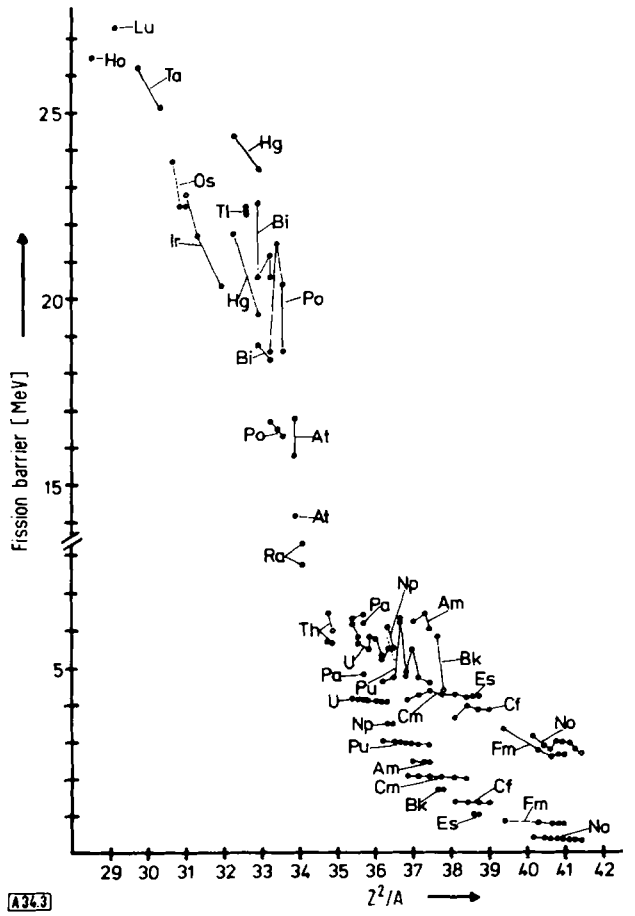

Fig. 3. Fission barriers as a function of Z^2/A of the fissioning nucleus; (○) experimental, (●) calculated with the liquid drop model (values from [23—25]).

The liquid drop model also fails completely when called upon to explain the preferred asymmetric fission of the heavy nuclei into two unequal fragments (see Section 8) and the saw-toothed distribution of the number of neutrons emitted from fission fragments (see Section 13).

These inadequacies of the liquid drop model have always been attributed to "shell effects" originating in the shell structure of the atomic nuclei. The shell model of the atomic nuclei, in which each nucleon is treated as moving independently of the other nucleons in an average potential which is produced by mutual interaction of all nucleons, was able to predict the magic numbers of protons and neutrons which correspond to closed shells. The properties of atomic nuclei in the ground state and in excited states such as spin and parity, magnetic moment, the occurrence of long-lived isomers *etc.* could also be described, firstly for spherical and later also for deformed atomic nuclei after *Nilsson*[26] had extended the shell model to non-spherical nuclei. The experimentally determined deformations of many nuclei in the ground state could be reproduced with the aid of the Nilsson model.

However, the Nilsson model proved unsatisfactory when applied to strongly deformed nuclei, as occur in fission. The binding energy of a nucleus calculated as a function of its deformation did not vary at all in the form of a fission barrier.

Neither of the two nuclear models alone— the liquid drop model nor the shell model—could provide a reliable picture of the strongly deformed fissioning nucleus. It was as late as 1968 before *Strutinsky*[27, 28] was able to amalgamate the liquid drop and the shell model for describing the properties of strongly deformed nuclei quantitatively. The total binding energy of a nucleus is represented as the sum of two quantities: the slowly changing liquid drop energy $E_{LD}(Z,N)$, which is an average value for the uniformly distributed nucleons in the phase-space, and the shell correction $\Delta E_s(Z,N,\beta)$ which oscillates with the deformation β of a nucleus and corresponds to the deviations from this uniform distribution.

$$E(Z,N,\beta) = E_{LD}(Z,N) + \Delta E_s(Z,N,\beta) \qquad (1)$$

The underlying principle is that a macroscopic model, namely the liquid drop model, quantitatively reproduces the smooth trend of the binding energy of the nuclei with respect to their number of nucleons and their deformation, while a microscopic model, namely the single particle or shell model, describes the "local" fluctuations but not the smooth trends. If both models could be united, both the smooth trend and the "local" fluctuations ought to be reproduced[29].

Strutinsky generalized the usual definition of "shells" and regarded them as regions of low density of the single-particle energy levels near the Fermi energy (*i.e.* that energy up to which all single-particle levels in a certain nucleus are occupied). Figure 4 illustrates the effect of a variation of the local level density of single-particle states on the binding energy of a nucleus. In the arrangement shown on the left the binding energy of the nucleus will be greater than in the arrangement shown on the right, since the nucleons occupy the deeper and more bound states because of the lower level density near the Fermi energy.

The variations of the level density not only occur from nucleus to nucleus as a function of the respective number of nucleons, but also in one and the same nucleus, *i.e.* with a constant number of nucleons, as a function of the deformation of the nucleus. It follows, therefore, that shells can occur not only in spherical nuclei but also in deformed nuclei. For a certain

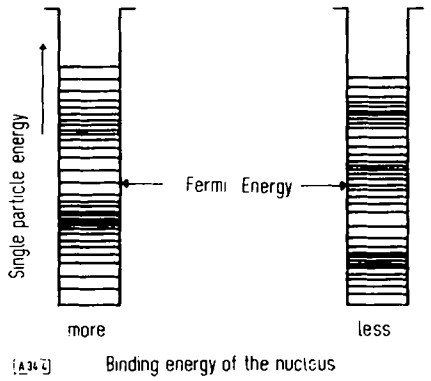

Fig. 4. Effect of local level density of single-particle states on the binding energy of the nucleus (after [30]).

number of nucleons there are quite distinct deformations in which the nucleus is stable. The ^{235}U nucleus is already deformed in the ground state because the most stable arrangement for the number of nucleons of this nucleus results not in a spherical but in a deformed nucleus. Figure 5 gives a qualitative illustration of the distribution of the single-particle states in a nucleus as a function of the deformation.

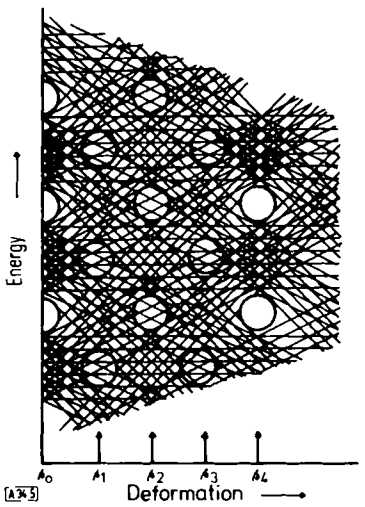

Fig. 5. Schematic representation of the distribution of single-particle states in a deformed nucleus. The low density regions (shells) are shown by circles (after [30]).

The regions of low level density are indicated by circles. They appear at the deformations β_1, β_2, β_3, β_4 *etc.* and correspond to magic numbers of nucleons at specific shapes of the nucleus. If the single-particle levels of a nucleus in a certain deformation are occupied just up to one of these regions then a shell is closed. Such nuclei with this deformation will be exceptionally stable. In Fig. 5, in addition to the well-known shells in spherical nuclei ($\beta=0$), other shells appear at the same energy for deformations β_2 and β_4. Shells likewise appear at deformations β_1 and β_3, while in spherical nuclei regions of high level density are present at the same energy.

The potential energy of a nucleus as a function of its deformation can be calculated in the following five steps[29]:

1. Specification of the shape of the nucleus,
2. Calculation of the "macroscopic" part of the potential energy by means of the liquid drop model,
3. Definition of the single-particle potential "felt" by the nucleons,
4. Solution of the Schrödinger equation to obtain the energies of the single-particle levels, and
5. Calculation of the "microscopic" part of the potential energy, the shell correction, from the single-particle energies.

The total potential energy of a nucleus is then given by the sum of the "macroscopic" energy calculated in Step 2 and the "microscopic" shell correction calculated in Step 5. The magnitude of the shell correction is only a few MeV; the binding energy calculated for heavy nuclei by the liquid drop model is of the order of 1600–2000 MeV. These small corrections, however, are important, since the fission threshold of heavy nuclei is only about 5—6 MeV (see Figures 2 and 7).

Several groups, who have performed such theoretical calculations arrive at qualitatively similar results. They are summarized in review articles by *Nix*[29], *Brack et al.*[31], and *Pauli*[32].

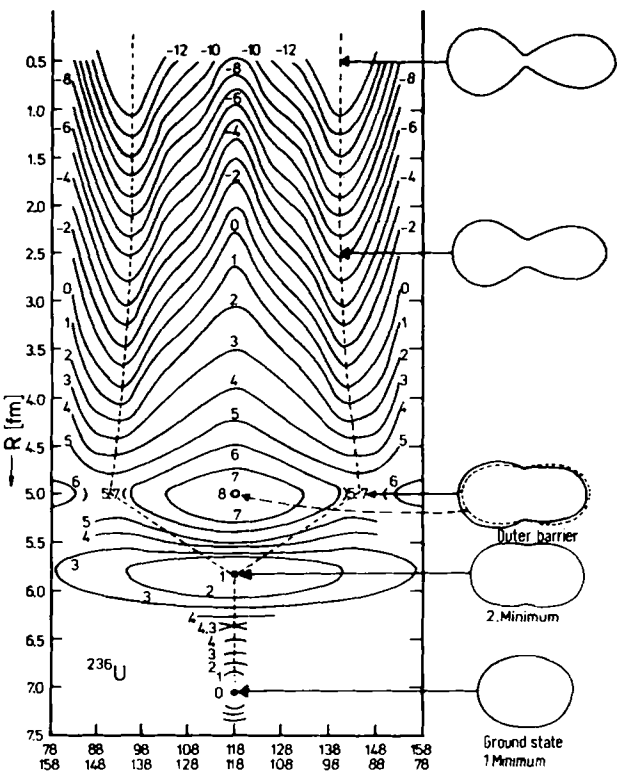

Fig. 6. Potential energy surface for ^{236}U. The sites of equal energy are shown as a function of the shape of the fissioning nucleus. The shape of the nucleus is described by the radius R of the neck and the mass ratio of the portions of the nucleus on either side of the neck plane. The path of minimum potential energy from the ground state, over the inner barrier into the second minimum, over the outer barrier and along a valley to scission is indicated by dotted lines (modified after [33]).

To illustrate the results of such calculations Fig. 6 shows the potential energy surface of the ^{236}U nucleus, *i.e.* its potential energy as a function of its deformation[33]. A vertical cut through such potential energy surfaces along the symmetry axis, *i.e.* along the mass ratio 118/118 yields a trend of the nuclear potential energy which is shown schematically in Fig. 7. The surprising result of these calculations is that the fission barrier in the actinoid nuclei has a double humped shape. The two potential maxima are separated by a second potential minimum, which is located about 2—3 MeV higher than the minimum which represents the ground state of the nucleus. If a nucleus deforms, then its potential energy at first increases with the deformation, reaches a maximum over the first (inner) barrier, then decreases again until the second minimum is reached. In this second minimum the nucleus is two to three times more strongly deformed than in the ground state. Since a nucleus in this second minimum is hindered by the inner and outer potential barriers A and B to decay, it is metastable and relatively long-lived. If the nucleus is deformed further its potential energy increases again. The nucleus then passes over the second barrier, approaches the scission configuration and finally decays into two fragments. The deformations of the nucleus along this path are illustrated in Fig. 7.

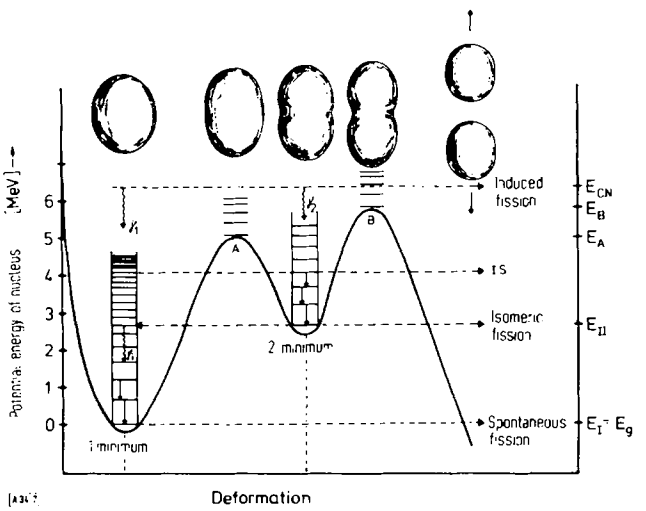

Fig. 7. Schematic representation of the double humped fission barrier as given by amalgamation of liquid drop and shell models. The nuclear states in the first and second minimum are shown together with the excitation states of the nucleus at the barriers A and B. Energy E_I is the ground state of the first minimum, E_{II} is the ground state of the second minimum; E_A and E_B are the heights of the inner and outer barriers, and E_{CN} the excitation energy of the compound nucleus. Spontaneous fission from the ground state and from the isomeric state ensue from the lowest energy level in the first and second minimum, respectively. A nucleus in the second minimum with energy E_{II} is in a metastable state since it lies between two potential barriers. It can tunnel through the potential barrier B and spontaneously fission, or through the potential barrier A and de-excite by gamma emission (γ_i). A compound nucleus formed with an excitation energy E_{CN}, which lies above the potential barrier, can either undergo prompt fission or give up its excitation energy in the form of gamma rays (γ_1 or γ_2) and decay to levels in the first or second minimum. I.S. signifies intermediate structure in sub-barrier fission cross section.

Which experimentally observable events can we expect if the fission barrier has a double humped shape? During the past few years a few phenomena have in fact been discovered which could only be explained with difficulty without the existence of a double humped fission barrier, namely the spontaneously fissionable isomers and the intermediate structures in subthreshold fission cross sections.

4. Spontaneously Fissionable Isomers

The first isomer, which decays by spontaneous fission, was discovered by *Polikanov et al.*[34] in the Joint Institute for Nuclear Research in Dubna (USSR). It was a chance discovery during attempts to synthesize nuclei of the transcurium elements by bombarding isotopes of the actinoids such as ^{235}U, ^{238}U, ^{232}Th with heavy ions such as ^{11}B, ^{16}O, ^{20}Ne, ^{22}Ne. In these experiments a nucleus was formed which decayed by fission with a half-life of 14 ms. This fission activity could subsequently be attributed to the nucleus ^{242}Am. The half-life of 14 ms was shorter by a factor of 10^{19} than that predicted for ^{242}Am on the basis of systematics for ground-state spontaneous fission.

This enormous increase in the probability of fission was difficult to understand. The probability to tunnel through the potential wall, by which the lifetime of the spontaneously fissioning nucleus is determined (see Fig 2), would increase by a factor of 10^{19} if the nucleus had an excitation energy of 2—3 MeV, *i.e.* if it was excited into an excited state in the ground-state minimum of the potential energy curve as shown in Fig. 2. Such an excited state should of course decay in times much shorter than milliseconds to the ground state by emission of gamma quanta.

The transition into the ground state must accordingly be delayed for some reason. Such a delay could be effected by a very high spin of the excited isomeric state, which, however, would have to be 20 ħ and more. And then when it was discovered that the spontaneously fissionable isomer of ^{242}Am is also formed[35] on irradiation of plutonium and americium nuclei with alpha particles, deuterons and neutrons *via* the nuclear reactions $^{239}Pu(\alpha,p)\,^{242mf}Am$, $^{242}Pu(d,2n)\,^{242mf}Am$, $^{243}Am(n,2n)\,^{242mf}Am$, and $^{241}Am(n,\gamma)\,^{242mf}Am$, the puzzle deepened, for the "light" deuterons and neutrons introduce substantially less than 20 ħ of angular momentum into the reaction product. The generation of the high spin *via* gamma cascades, which could occur in the formation of the isomer, also appeared unlikely.

An experiment by *Flerov et al.*[36] also contraindicated a high spin. These authors determined the ratio of the production of the spontaneously fissionable isomer $^{242mf}Am$ to the production of the ground state ^{242}Am, the isomer ratio, as a function of the average angular momentum of the compound nucleus, whose decay leads to formation of the spontaneously fissionable isomer $^{242mf}Am$. The isomeric ratio for a high-spin isomer should increase monotonically with the mean spin of the compound nucleus, a phenomenon which has been confirmed by experiment on other isomeric nuclei. In the production of $^{242mf}Am$ *via* compound nuclei with differing angular momentum, however, it was shown that the isomeric ratio $^{242mf}Am/^{242}Am$ is almost independent of the angular momentum of the compound nuclei. Hence another cause must be responsible for the simultaneous increase in probability of fission and decrease in probability of gamma decay.

Investigations on other heavy nuclei soon showed that the fissionable isomer of ^{242}Am is no exceptional case, but that "fission isomers" occur in many nuclei between Th and Bk. The spontaneously fissionable isomers known to date are shown in Fig. 8[37] together with their half-lives, which lie between 10^{-11} and 10^{2} s.

The first fission isomer to be discovered, ^{242m}Am, is still that with the longest half-life known to-date. Spontaneously fissionable isomers with half-lives in the millisecond range are sought for by an experimental technique which utilizes the momentum which is transferred from the projectile nucleus to the compound nucleus. As target material foils are used which are so thin (*ca.* 20 –50 μg/cm^2) that the reaction products escape from the target because of their momentum. These recoil atoms are allowed to strike a rapidly rotating wheel and the nuclei thus collected out of the accelerator beam are carried past a series of fission-sensitive detectors. Expecially suitable are fission track detectors[38] which are dielectric materials such as mica, glass, plastics (polycarbonates). The structure of these materials is more strongly radiation-damaged along the trail of a charged particle on slowing down heavy ions than on slowing down lighter particles. These "latent" tracks of the heavy ions, *e.g.* of fission products of spontaneously fissionable isomers can be enlarged under certain conditions, by chemical etching in HF or NaOH solutions, so that they become visible under a microscope.

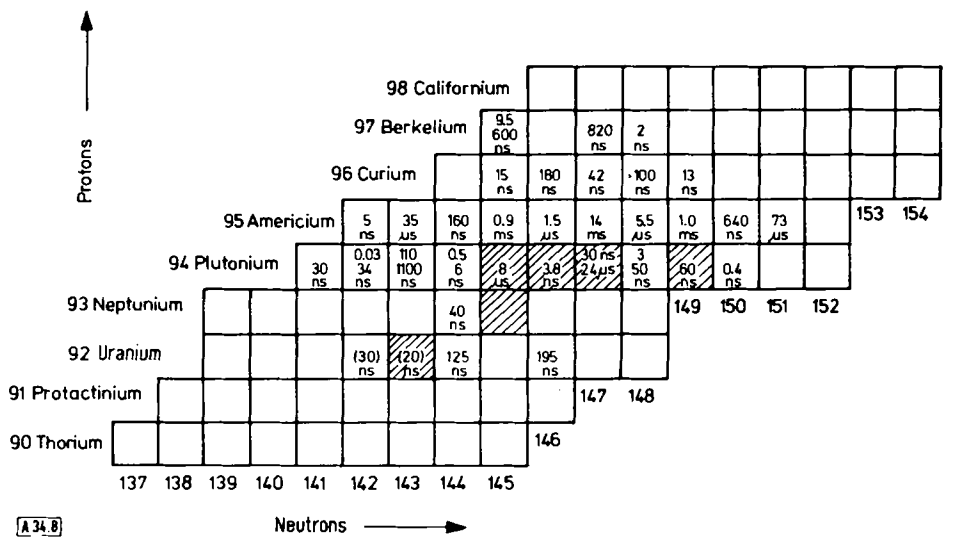

Fig. 8. Section from the chart of nuclides in the region of the actinoids showing the half-lives of all fission isomers known to date. Two numbers in the same field indicates the existence of spin isomers within shape isomers. Shaded fields indicate nuclides for which intermediate structures in the sub-barrier fission cross section have been observed.

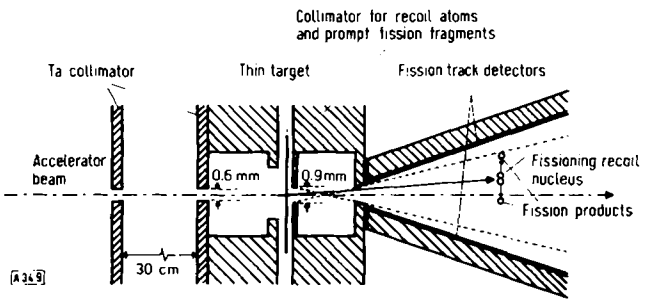

Fig. 9. Experimental arrangement for the measurement of fission isomers with half-lives between 1 microsecond and 5 nanoseconds. The polycarbonate foils used as fission track detectors are arranged to record only delayed fissions from the recoil nuclei flying from the target, not the prompt fissions in the target itself (after [97]).

Such fission track detectors are also used in the method in which the fission isomers with half-lives in the region of microseconds down to about 5 nanoseconds can be measured. Most of the fission isomers discovered to-date have half-lives that lie in this range. The experimental arrangement is illustrated in Fig. 9: A finely collimated beam of protons, deuterons or alpha particles strikes the target from the left. Targets whose thickness lies within the same order of magnitude as the range of the compound nuclei are also used in these experiments; the compound nuclei are driven from the target by transfer of momentum in the direction of the beam. If these nuclei undergo fission during flight between the fission track detectors the fission products will be recorded. The geometrical arrangement hinders direct flight of fission fragments originating from prompt fission from target to fission track detectors. Hence the detectors register only delayed fissions of the fission isomers during the flight of the nuclei. The half-lives are calculated from the velocity of these recoil nuclei and the density of the fission track in the polycarbonate foil as a function of the distance from the target.

The existence of spontaneously fissioning isomers can now be readily explained with the aid of the double-humped fission barrier. If a highly deformed nucleus having an excitation energy which is above the fission barrier (*e.g.* with E_{CN} in Fig. 7) is formed and its excess excitation energy is dissipated in the form of gamma quanta before it fissions, while at the same time the strong deformation of the nucleus is retained, then it can be caught in the ground state of the second minimum of the fission barrier. Since only about 10^{-3}—10^{-2}% of the nuclei reach the second minmum -- the remainder suffer prompt fission—the experimental investigation of these isomeric states is very difficult. They have an excitation energy of 2—3 MeV with respect to the ground state in the first minimum. They are, however, relatively long-lived since the decay is hindered by the inner and outer potential barriers. The nucleus is metastable toward decay by direct radiative transitions to the ground state of the first minimum, *i.e.* the real ground state of the nucleus, for a change in nuclear shape is required prior to gamma decay into the ground state of the first minimum. To do this, the nucleus must

penetrate the potential wall A (see Fig. 7). The enhanced probability of spontaneous fission from the ground state in the second minimum, that is the marked decrease in the half-life of spontaneous fission relative to that from the ground state in the first minimum, is accounted for by the smaller potential barrier B through which the nucleus must tunnel. A nucleus in the ground state of the first minimum, on the other hand, must penetrate the total potential barrier A + B in order to fission spontaneously. The fact that fission isomers have been found only in the case of nuclei between uranium and berkelium is connected with the relative heights of the inner and outer potential barriers. In the case of nuclei above berkelium the outer potential barrier B is so low that the resulting extremely short half-lives have still not been able to be measured. Conversely nuclei below uranium have such a low inner potential barrier that they decay into the first minimum by gamma emission before they can spontaneously fission.

This new type of nuclear isomerism is called shape isomerism so as to emphasize the difference from spin isomerism. Spin isomers are states of one and the same nucleus between which transitions are hindered by gamma emission because their spins differ by several units of ħ. One can compare the shape isomers of atomic nuclei with rotation isomers of molecules, *e.g.* dichloroethane, in which transitions from one configuration to the other are likewise hindered by a potential barrier.

5. Intermediate Structures in the Subthreshold Fission Cross Section

A few years ago the presence of sharp resonances was observed in high resolution measurements of the cross section for induced sub-barrier fission of a few heavy nuclei. These regions of relatively high fission-probability occur in groups separated by wide energy intervals in which no fission takes place. Figure 8 shows those nuclei (shaded) in which intermediate structures have been found in the subthreshold fission cross section[39]. A typical example is shown in Fig. 10[40].

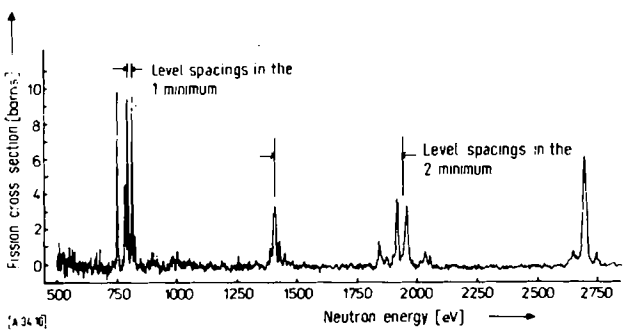

Fig. 10. Subthreshold neutron fission cross section of ^{240}Pu as a function of neutron energy between 500 and *ca.* 3000 eV (after [40]).

In these experiments the compound nucleus formed by penetration of low-energy neutrons into the target nucleus has an excitation energy that lies somewhat below the two potential maxima. In Fig. 7, E_{CN} would lie below E_A. Initially the compound nucleus will have a deformation similar to that of the target nucleus and will be excited to one of the states in the first minimum. The compound nucleus thus formed can only fission by tunneling through the potential barrier. The probability for this at low excitation energies is very small and ought to increase monotonically with neutron energy. The occurrence of some resonance groups is difficult to explain if the fission barrier has only one hump, but is quite understandable if there is a second minimum in the potential energy surface. Then, for a nucleus of the same total excitation energy the average level density in the second minimum must be smaller than in the first minimum because a part of the total excitation energy of a nucleus in the second minimum is bound as deformation energy, so that only a smaller amount is available for other modes of excitation. If the energy of the compound nucleus at a level in the first minimum happens to be approximately equal to the energy of a nuclear state in the second minimum then a coupling of the two states takes place. The nucleus can pass over from the level and deformation of the first minimum into the level and deformation of the second minimum. From this excited state of the shape isomer the probability of fission is increased because of the greater penetrability of the outer barrier B, similarly to the greater probability of fission of the shape isomer compared to that of the nucleus in the ground state. The fine structure in Fig. 10 corresponds, therefore, to the level density of the compound nucleus in the first minimum at an excitation energy of about 5 MeV which originates from the binding energy of the captured neutron. Each group of resonances corresponds to a level in the second minimum.

6. Spectroscopy of Shape Isomers

If the inner potential barrier is not significantly higher than the outer one, a shape isomer can also tunnel through the inner barrier and de-excite by gamma emission to the ground state of the first minimum (γ_i in Fig. 7) instead of spontaneously fissioning. So far such a γ-decay of the shape-isomeric state into the first minimum has been detected only in the case of the 200 ns isomer of ^{238}U[41]. A gamma peak was measured at 2.514 MeV, which is ascribed to a transition from the 0^+ ground state in the second minimum to the lowest 2^+ rotational level at 0.045 MeV in the first minimum. The half-life of this gamma decay agrees with that measured for the spontaneous fission of the shape isomer ^{238mf}U. The branching ratio between gamma decay and spontaneous fission, which has been determined as being about 40, shows that in this case the first barrier is easier to penetrate than the second. This is the first exact measurement to be made of the excitation energy of a shape isomer – which, in this case, amounts to 2.56 MeV.

A group in Munich[42] has recently proved experimentally that fission isomers are indeed strongly deformed nuclei, more strongly deformed than nuclei in the ground state minimum. This being the case, rotational states ought to occur in the excitation spectrum in the second minimum (since a deformed nucleus can rotate and its rotational energy is quantized) built on the shape isomeric state. Since deformation of the nucleus in the second minimum ought to be much greater than that in the ground state it follows that the rotational states must lie closer together than in the rotational band built on the ground state in the first minimum.

By bombarding ^{238}U with 25 MeV alpha particles the Munich team produced the shape isomer $^{240mf}Pu$, whose half-life is 3.8 ns. The compound nucleus ^{240}Pu formed in this nuclear reaction either fissions promptly or decays by emission of gamma quanta into the first minimum (γ_1 in Fig. 7) or, with much lower probability, into the second minimum (γ_2) and there into the isomeric ground state. In the case of even-even nuclei the last transitions (shown by arrows in Fig. 7) ought to be E2 transitions within the rotational band built on the isomeric ground state. These ought to be strongly converted, however, and have lifetimes much shorter than 0.1 ns, *i.e.* short in comparison with the lifetime of the fission isomer. A measurement of coincidences between the conversion electrons from these last transitions and the fission fragments of the isomeric fission from the ground state of the second minimum did in fact show lines in the spectrum of the conversion electrons which could be interpreted as components of three E2 transitions between the states of a rotational band. The rotational constant of 3.33 keV calculated therefrom is considerably smaller than that of the rotational band of the ground state in the first minimum (7.16 keV). It corresponds to the largest moment of inertia, *i.e.* to the largest deformation of an atomic nucleus that has so far been observed. Hence it presents direct evidence that the shape isomer of the ^{240}Pu nucleus is, in fact, connected with a deformation larger than the ground-state deformation.

Attempts to detect the gamma rays alone which are emitted by the compound nucleus when it decays to the ground state of the second minimum have so far been unsuccessful[43].

7. Mass Distribution

A plot of fission fragment or fission product yield as a function of the number of nucleons, *i.e.* mass number, independent of the number of protons, provides a mass distribution or mass yield curve. Radiochemical methods give only the yields of primary and secondary fission products of mass A_{h_2} and A_{l_2}, respectively (see Fig. 1), after emission of prompt neutrons. One determines the cumulative yield of a long-lived fission product at the end of the β-decay chain for as many mass numbers as possible, *i.e.* the sum of the yields of all fission products of a definite mass *e.g.* A_{h_2}. Figure 12 (Section 9) shows the β-decay chain of mass 141. In this chain the yield of ^{141}Ce is determined a few hours after irradiation, *i.e.* after the precursors with short half-lives have already decayed.

The mass distribution of the primary fission fragments before emission of prompt neutrons can be determined by instrumental methods, in which the kinetic energies and/or velocities of the two fragments formed are measured simultaneously. Naturally, these quantities also are determined on the fragments after evaporation of neutrons. The influence of the neutrons emitted by the accelerated fragments on the energies and velocities of the fragments can, however, be taken into consideration, so that the energies and velocities and, because of conservation of momentum and mass, also the masses of the fragments before neutron emission are obtained[44, 45].

The limited mass resolution and low sensitivity of this method are the main reasons for it not having replaced the time-consuming radiochemical method, which only affords the secondary mass distribution, albeit with unequivocal and complete mass (and atomic number) resolution even for very low yield fission products (10^{-8}% and less). The radiochemical method can also be employed in fission systems where the physical method fails, *e.g.* if the specific rate of fission or the ratio of fission to alpha decay rates is very low.

Figure 15 (Section 10) shows the mass distributions of primary and secondary fission fragments of the thermal neutron induced fission of ^{235}U. In the mass distribution curve of the secondary fragments the yield maxima are centered at a mean value of about two mass units lower than the maxima in the curve of the primary fragments. This shift is caused by prompt neutron emission. In fission systems in which the mass distribution of primary and secondary fragments is known, the number of emitted neutrons as a function of the mass of the fission fragments can be obtained indirectly (see Section 12).

The structure of the mass yield curve changes characteristically with the atomic number and mass of the fissioning nucleus and its excitation energy. An overview of the dependence is given in Fig. 11. In the case of the heavier actinoid nuclei (Fig. 11c) asymmetric fission into two different heavy fragments is preferred. The mass distribution curves have two strongly pronounced peaks and a low minimum in the region of symmetric fission. The heavy maximum remains almost constant at mass number 138—140, independent of the mass and atomic number of the fissioning nucleus, while the light maximum is shifted rather linearly to heavy masses. This almost constant position of the heavy maximum is observed in the fission of ^{229}Th with thermal neutrons and other fission systems through to the spontaneous fission of ^{256}Fm[48] (Fig. 11a and 11c). The stable position of this maximum is obviously connected with the closed-proton ($Z = 50$) and closed-neutron ($N = 82$) shells of nuclei, which are found in the mass region of the left flank of the heavy maximum.

Symmetric fission increases with increasing excitation energy of the fissioning nucleus. The valley between the maxima of asymmetric fission tends to rise and the mass distribution tends to become broader. Nuclei whose atomic number and mass are smaller than that of the thorium isotopes have a high fission barrier (see Fig. 3). Fission of such nuclei requires a higher excitation energy than is possible with thermal neutrons, but takes place on bombardment with fast neutrons or charged particles of sufficiently high energy.

In the fission of nuclei of intermediate atomic number ($88 \leqslant Z \leqslant 91$, Fig. 11e) the two asymmetric maxima are accompanied by a third symmetric maximum, since both symmetric and asymmetric fission can occur with similar probability. Only symmetric fission is observed in the case of the lighter nuclei ($Z \leqslant 88$, Fig. 11f), and here also the width of the yield curve increases with increasing excitation energy.

Only recently was it discovered that ^{258}Fm ($^{257}Fm + n_{th}$) fissions symmetrically (Fig. 11a)[49]. This is all the more surprising since the spontaneous fission of the neighboring nuclei ^{256}Fm and ^{257}Fm is asymmetric[49–51]. However, as is shown in Fig. 11, there is a distinct trend toward symmetric fission with increasing mass number of the fermium nucleus.

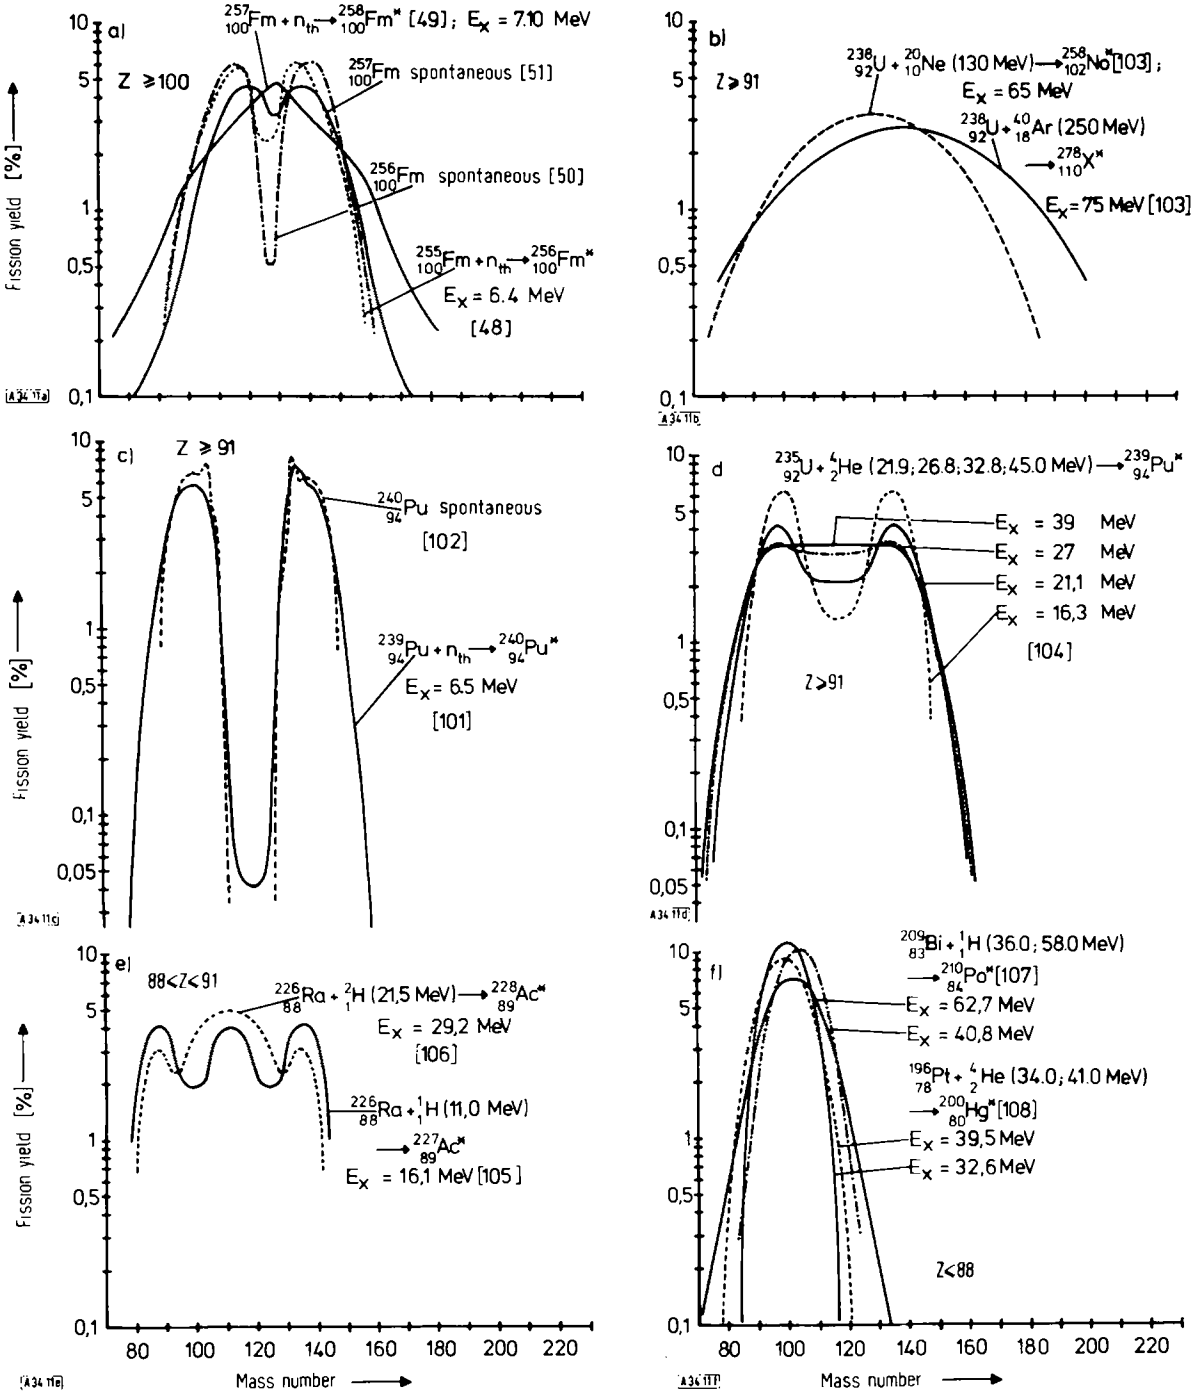

Fig. 11. Mass yield curves as a function of nuclear atomic number Z and mass of the fissioning nucleus, and its excitation energy. The curves, so far as the fission yields were not given in percent, where normalized to a total fission yield of 200%. a) and c) lower excitation energy: $E_x \leq 7$ MeV; spontaneous fission or fission with thermal neutrons. b), d), e) and f): moderate excitation energy: $E_x \leq 75$ MeV; fission with fast neutrons and charged particles (protons, deuterons, alpha particles, heavy ions).

8. Mass Asymmetry of Nuclear Fission

The preferred asymmetric fission of the actinoid nuclei into a smaller and a larger fragment is one of the oldest and still much unsolved puzzles of nuclear fission. The theoretical concepts developed so far have been unable to give a complete and satisfactory qualitative explanation of all the observations made on nuclear fission. True, the liquid drop model describes symmetric fission very well, but it fails in that it predicts symmetric mass distributions for all fissioning nuclei. Asymmetric fission has frequently been explained qualitatively as resulting from shell effects in the fission fragments leading to preferred formation of nuclei with magic or almost magic numbers of nucleons. The mass division in the fissioning nucleus should, according to this concept be determined near to the scission configuration of the nucleus, when the influence of shell effects in the fragments is greatest.

Recently, however, it became clear that the calculations which so successfully describe the double-humped fission barrier (see Sections 3—5) can also explain the asymmetric mass distribution. The calculations show that the ground state in the first minimum, the first fission barrier and the shape

isomeric state in the second minimum have lowest potential energy in deformations which are reflection symmetric with respect to a plane lying in the middle and perpendicular to the longer axis of the fissioning nucleus. The second outer fission barrier, however, is lowered if the nucleus is deformed asymmetrically like a pear[29, 31-33, 53, 54]. This is clearly evident from the potential energy surface of ^{236}U illustrated in Fig. 6 in which the asymmetric and symmetric deformations in various positions are also shown. In the neighborhood of the second fission barrier an asymmetric deformation is accompanied by an energy gain of up to a few MeV. If one assumes that a nucleus prior to fission follows the path of minimum potential energy toward scission, then the route to asymmetric fission passes over the first maximum and through the second minimum along the symmetry axis, but goes around rather than over the symmetric second maximum moving over an asymmetric saddle point left and right of the maximum.

The ground state of a ^{236}U nucleus (Fig. 6) occurs at $R \approx 7.05$ fm. The path of minimum potential energy passes over the first barrier at $R \approx 6.4$ fm, for which the shape of the nucleus is symmetrical. A symmetric deformation is likewise preferred in the second minimum at $R \approx 5.8$ fm. At $R \approx 5.0$ fm, however, the nucleus crosses the second barrier with a strongly asymmetric shape. The deformation corresponds to a mass ratio of 145/91 for the two fragments. This asymmetric saddle point lies *ca.* 2.3 MeV lower than the symmetric maximum. Finally, the asymmetrically deformed, increasingly elongated and necked nucleus moves along a valley to scission. The valley runs out at a mass ratio of *ca.* 140/96, which is in good agreement with that in the fission of ^{236}U at low excitation energy[33].

The transition from asymmetric fission in the light Fm nuclei to symmetric fission in the heavy Fm nuclei (see Fig. 11) is likewise reproduced by these calculations[33]. In the case of the light Fm nuclei the descent to scission follows the path of minimum potential energy over an asymmetric saddle point, and asymmetric deformation is retained up to the point of scission. In the case of heavy Fm nuclei the asymmetric saddle point appears to be only slightly lower or not lower than the symmetric maximum and to occur at low mass asymmetries, so that symmetric shapes are preferred along the whole route to scission. In the heavy Fm isotopes symmetric fission seems to occur when the number of neutrons is $N \approx 158$, *i.e.* when two fragments with approximately double magic numbers of nucleons can be formed, namely nuclei around the double magic nucleus $^{132}_{50}$Sn.

The same single-particle effects responsible for the nuclear deformations in the ground state and a double-humped fission barrier, are also responsible for occurrence of the asymmetric saddle point. As the excitation energy increases, so also increases the probability of symmetric fission, until at high excitation energies a symmetric mass distribution occurs in all nuclei. This transition is probably due to the fact that the influence of single-particle effects at higher energies decreases and the nuclei behave as described by the liquid drop model and fission symmetrically.

If the mass distribution is really determined at the outer barrier then different barriers ought to exist for symmetric and asymmetric fission. Recently, it was in fact found by experiment that in the case of the nuclei ^{227}Ac and ^{228}Ac, the symmetric barrier is higher than the asymmetric barrier by about 1.2 and 2.0 MeV, respectively[55].

In order to test the theoretical concepts on the origin of asymmetric mass distribution, the mass distributions of as great a number of nuclei as possible should be determined as a function of their mass, atomic number, and excitation energy. The "peak-to-valley" ratio, which actually represents the ratio of symmetric to asymmetric fission, must be measured as accurately as possible.

Such investigations are especially necessary on nuclei in the transition region between asymmetric and symmetric fission. The heavy actinoids from Cf to Md have already been the subject of intensive studies in this connection[48, 90]. The other transition region lies between Po and Ra. Unfortunately, there are very few long-lived species of these nuclei which can be prepared in sufficiently large amounts (^{210}Po, ^{226}Ra, ^{228}Ra, ^{227}Ac). Further, the production and handling of these nuclides make special demands on the radiochemist because of their high radioactivity. Nuclei between Po and Ra can also be produced by bombardment of nuclei between Au and Bi with charged particles. However, because of the high Coulomb barrier between target nucleus and projectile, compound nuclei with high excitation energy and high angular momentum are formed. Therefore, phenomena at lower excitation energy cannot be investigated in this way.

A detailed comparison of mass distributions of spontaneous fission from the ground state in the first minimum, of shape isomeric fission from the ground state in the second minimum, and of prompt fission of one and the same nucleus, *e.g.* of ^{240}Pu, can provide information as to whether the route to fission, which starts in the first minimum is exactly the same as that which starts in the second minimum, *i.e.* whether the fragments in the three fission processes are formed in the same region of the potential energy surface.

A number of measurements have been made on mass distributions in the fission of the shape isomers ^{242mf}Am[92], ^{239mf}Am, ^{237mf}Pu, ^{238mf}U, ^{236mf}U[93] and ^{240mf}Pu[94] with semiconductor detectors. According to these measurements the mass distributions in the fission of shape isomers differ little, if at all, from the other two types of fission. However, in these experiments it was impossible to measure the "peak-to-valley" ratios very accurately. This could be accomplished radiochemically if the ratio is not too extreme. But how can fission products of induced prompt fission be distinguished from those of the shape isomers? One makes use of the recoil of either the compound nucleus or the fission product. In the case of long-lived shape isomers (^{240mf}Am, ^{242mf}Am, ^{244mf}Am) a thick target, in which the compound nuclei are stopped, can be transported mechanically from the particle beam after a radiation time of 2–3 half-lives of the shape isomer to a catcher foil. This foil collects the delayed fission products which have a longer range than the compound nuclei of the shape isomer and are able to escape from the target. Alternatively, a thin target is irradiated and the compound nuclei escaping from the target are collected on a wheel (as described in Section 4) and transported in front of a catcher foil on which the fission products of the shape isomers are captured.

The fission products of shape isomers of shorter half-life can be separated from those of induced prompt fission with the experimental setup shown in Fig. 9 if two thin foils are placed in the conical holder instead of the polycarbonate foil. The upper foil must be so thin (*e.g.* 5–6 μm plastic) that it will allow penetration of the fission products formed from the shape isomers during flight with energies of 80–100 MeV. The products of prompt fission flying from the target which do not strike the foils directly because of the collimator but can stray around in the irradiation chamber with thermal energies are, on the other hand, retained by the uppermost foil. The lower foil must be so thick that the fission products of the shape isomer which have penetrated the upper foil are finally retained (15–20 μm aluminum). After irradiation the upper foil is carefully removed and the lower one drawn off and dissolved. The fission products can then be separated from this solution and purified radiochemically[95].

9. Charge Distribution

While the mass distribution indicates the apportioning of the nucleons (neutrons plus protons) of the fissioning nucleus to the two fission fragments, the charge distribution gives a clear indication of how the protons are apportioned. No protons are emitted from the fission fragments. Hence the nuclear charges of the fission fragments and the primary fission products are equal. The nuclear charge does not change until the β-decay of the primary fission products into secondary fission products.

If the yield of fission fragments is plotted as a function of their nuclear charge one obtains a curve that is very similar to the mass distribution curve. Since the protons and neutrons are distributed almost equally within a nucleus, each fission fragment will, to a first approximation, become a share of protons ($Z_{h,l}$ and $Z_{l,l}$) which is proportional to its share of nucleons ($A_{h,l}$ and $A_{l,l}$), *i.e.* $Z_{h,l} \sim A_{h,l}$. The ratio of protons and neutrons in the fission fragments will be about the same as that in the fissioning nucleus. The concept is referred to as the UCD (unchanged charge density) rule ($Z_{h,l}/A_{h,l} = Z_{l,l}/A_{l,l} = Z_f/A_f$).

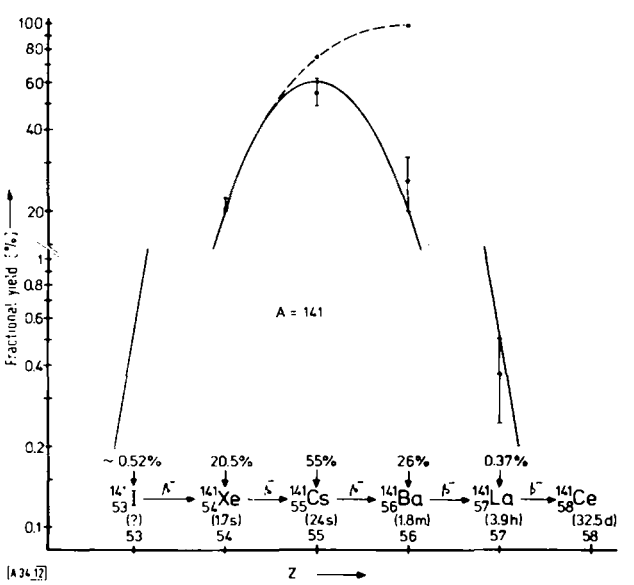

Fig. 12. Charge dispersion for fission products of mass $A = 141$ in the fission of ^{235}U with thermal neutrons. The unbroken curve corresponds to Eq. (2) with $c = 0.80$ and $Z_p = 54.97$. The dashed curve illustrates the cumulative yields (●) (independent yield (○) plus yield from β-decay of precursor). The yield of $^{141}_{53}I$ is estimated from the curve, the yields of the other fission products are measured values [56].

Many experimental investigations have shown, however, that the ratio Z/A is not the same for all fragments, but is greater in the light fragments (index l) than in the heavy fragments (index h) ($Z_{h,l}/A_{h,l} < Z_f/A_f < Z_{l,l}/A_{l,l}$).

To simplify the problem one considers only fission fragments or fission products of the same mass and tries to characterize a most probable nuclear charge Z_p for this mass number, *i.e.* the most probable combination of protons and neutrons for this mass number. The proton-neutron combinations with mass number $A = 141$ (isobaric nuclei) formed in the fission of ^{236}U with thermal neutrons are shown in Fig. 12[56]. A total of 5.70% of the fissions lead to nuclei with mass number 141[91]. Each nucleus of the chain is formed directly as primary fission product from the fissioning nucleus ("independent yield") and by β-decay from its precursor.

If the independent yields of nuclei of the same mass number are plotted against their charge number one obtains the charge dispersion curve, whose maximum represents the most probable charge Z_p (not necessarily an integer) of the mass chain under consideration (Fig. 12). From the Z_p value for fission products of a certain mass number one obtains the Z_p value for the corresponding fission fragments by addition of the number of neutrons evaporated from these fragments to the mass number of the products. Since only the average number of neutrons evaporated from the fragments is known, odd mass numbers are obtained[56].

Charge dispersion curves can be represented by a Gaussian distribution of the nuclear charge within the elements of a mass chain (see Fig. 12). The most probable charge Z_p fixes the position of the dispersion curve within the mass chain, and the parameter c its width.

$$P(Z) = (\pi \cdot c)^{-1/2} \exp[-(Z - Z_p)^2/c] \qquad (2)$$

Up to the present most primary yields of fission products have been measured for the fission of ^{235}U with thermal neutrons[56, 57]. For this fissioning system the most probable charges of those mass chains are shown in Figure 13 for which one or more independent fission yields could be measured. Charge dispersion curves with a width parameter of $c = 0.80$ were fitted to the experimentally determined fractional independent yields.

Most data on charge distribution have until recently been obtained by radiochemically determined independent yields of the individual members of the mass chains. Each determination of an independent fission yield necessitates careful and, in most cases, rapid radiochemical separation of the pertinent fission product, so that the primary distribution is not obscured by the β-decay. Only for a few "shielded" nuclides whose precursors are β-stable can independent yields be determined without being adversely affected by the β-decay (^{86}Rb, ^{96}Nb, ^{126}Sb, ^{128}I, ^{130}I, ^{136}Cs, ^{150}Pm). Very few laboratories are suitably equipped for working with high radioactivities or for carrying out rapid radiochemical separations[58, 59]. The independent yield of many fission products, however, cannot be determined by present day working techniques since their

half-lives or those of their precursors are too short. Hence, primary yields are known for only a few fissioning nuclei and for only a small portion of their fission products.

In the past few years physical methods have been developed for the determination of charge distribution. In one of these methods the fission products are separated in a mass separator; the mean lengths of the β-decay chains of individual masses are determined directly by counting the β-particles with photoemulsions or proportional counters[60-62]. In this method short β-half-lives do not present difficulties since mass separation is achieved within a microsecond; but likewise only the fission products after neutron emission are measured.

A second physical method affords information about charge distribution by simultaneous measurement of the kinetic energy of complementary fission fragments and the characteristic X-rays which they emit and which are associated with the primary charge of the fragments[63]. The nuclear charge of the fragments is determined from the energy of the X-rays. The masses of the fission fragments before neutron emission are obtained from their kinetic energy *via* conservation of mass and momentum (see Section 7).

In this method the charge distribution over the whole mass range, with the exception of low-yield masses in the minimum or on the flanks of the yield curve, is measured in a single experiment. However, owing to limited resolution only the general trend of the most probable charge Z_p can be determined as a function of fragment mass.

In a further method the intensities of the prompt gamma transitions from the 2^+ to the 0^+ level of the ground state rotational band in "even-even" fission product nuclei are measured. From these measurements the independent yields of the fission products, and hence the charge dispersion can be determined in a few mass chains. This method has so far only been used in studies on the spontaneous fission of ^{252}Cf[64].

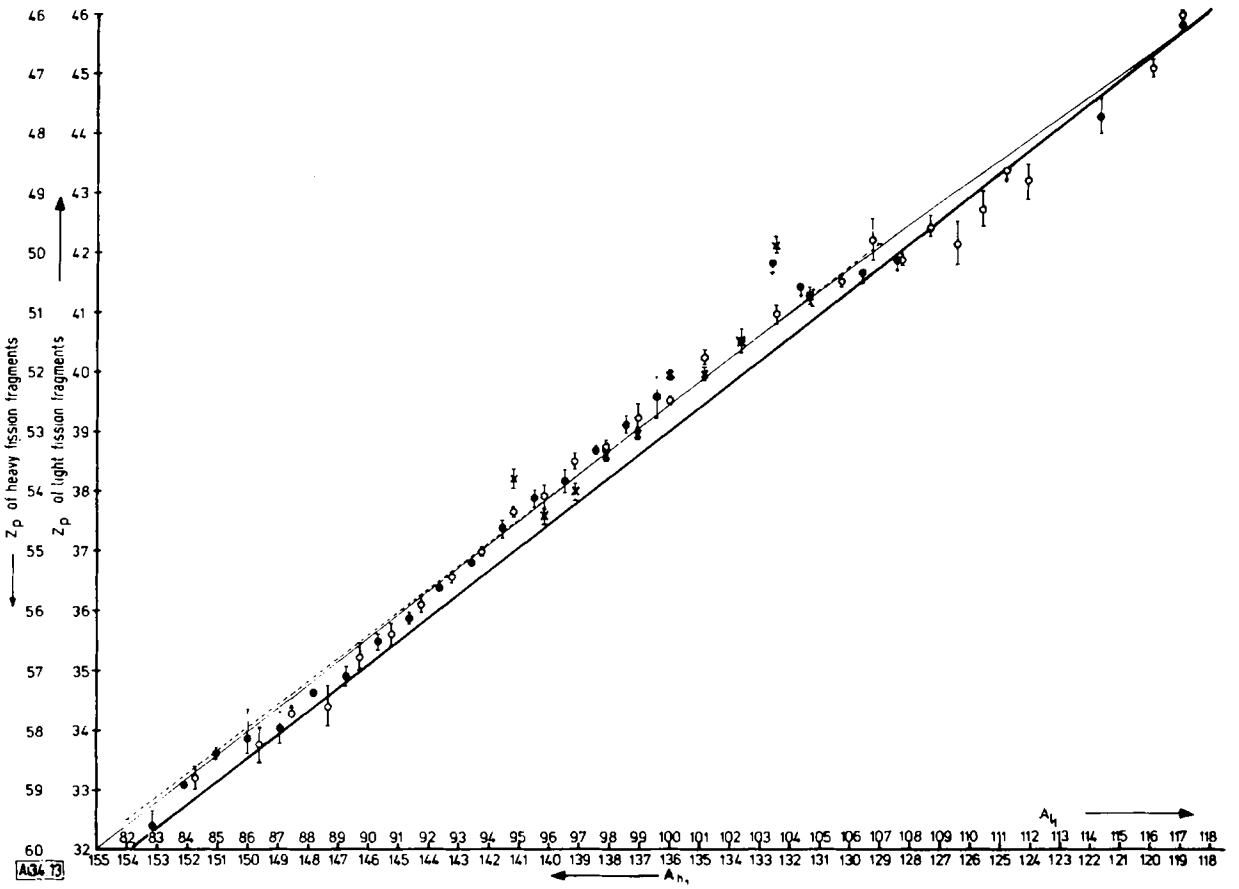

Fig. 13. Most probable nuclear charge Z_p of heavy and light fission fragments as a function of their masses A_h or A_l in the fission of ^{235}U with thermal neutrons. Radiochemical measurements: (●) light fragments, (○) heavy fragments. Physical measurements: a) with mass separator and nuclear emulsion [62]: × heavy fragments, b) measurement of characteristic X-rays [63]: --- line of best fit to the measured values. The thin solid line represents the "normalized" Z_p values of *Wahl* [56]. The charges of the fission fragments would lie on the thick solid line if their charge densities were to correspond to those in the fissioning nucleus. For these lines $Z_{p_h}(UCD) = A_{h_1}(92/236)$ and $Z_{p_l}(UCD) = A_{l_1}(92/236)$.

The most recent Z_p values measured by physical methods have also been plotted in Fig. 13. It can be seen that there is good agreement with the Z_p values determined by radiochemical methods.

From Fig. 13 it is evident that the light fission fragments have a higher and the heavy fission fragments a lower charge density than that of the fissioning nucleus. The average deviation from the UCD rule is about 0.5 charge units. The "normalized" Z_p values by *Wahl*[56], also plotted in Fig. 13, have been calculated for the mass numbers $A_{h_1} > 134$ ($A_{l_1} < 102$) from $Z_p = Z_p(UCD) - (0.45 \pm 0.1)$. This Z_p function was extrapolated to $A_{h_1} = 118$ with the reasonable assumption that the charge division is also symmetric when the mass division is symmetric. These "normalized" Z_p values and $c = 0.80 \pm 0.14$

afford the best reproduction of experimentally determined independent yields.

Considerably fewer measured values are available for the charge distribution in the fission of other nuclei *e.g.* ^{233}U and ^{239}Pu with thermal neutrons or in the spontaneous fission of nuclei such as ^{252}Cf. The values available do, however, confirm the trend found in the case of ^{235}U. The data for charge distribution in the symmetric fission of ^{235}U are also not complete. It can be seen from Fig. 13 that a few Z_p values for masses 120– 130 lie below the Z_p (UCD) straight line. It would be important in this connection to show whether a real effect is involved (influence of the closed-proton shell with 50 protons); in other words, to show that the Z_p curve does not pass smoothly over into the Z_p (UCD) line but first of all crosses it at nuclei around $Z=50$ and then approaches it from the other side. Measurements in this mass region are very difficult owing to the low yield of symmetric fission products. The conception of a new experimental methodology is called for, such as super-rapid chemistry in the gas-phase, rapid chemical separations connected with mass spectrometric measurements, gas-jet recoil-transport method[96].

Much less is known about charge distribution in the fission of nuclei having moderate excitation energy. So far, only radiochemical methods and mass spectrometric methods have been employed in such studies[65–71]. These measurements indicate, that with increasing excitation energy of the fissioning nucleus:

1. the Z_p values are shifted towards those of β-stable nuclei and

2. the width of the charge dispersion curves increases.

Thus in the fission of ^{235}U with thermal neutrons a most probable charge of $Z_p=55$ was measured for the fission products with mass $A=141$ (see Fig. 12 and 13), *i.e.* the yield of $^{141}_{55}Cs$ is the highest of the mass 141 isobars. In this case the excitation energy of the fissioning nucleus ^{235}U is $E_x=6.5$ MeV. In the fission of ^{236}U nuclei with an excitation energy of 39.3 MeV—which are formed on bombardment of ^{232}Th with 44.3 MeV alpha particles—a value of $Z_p=56$ was measured[70]. That is, the most probable charge is shifted about one unit toward that of the β-stable nucleus ($^{141}_{59}Pr$) of mass chain 141; the fission product $^{141}_{56}Ba$ is now formed in highest yield. Radiochemical measurements of independent yields are easier in the case of fission with moderate excitation energy than in fission with low excitation energy. Since the Z_p values shift nearer to those of β-stable nuclei, the independent yields of the fission products which can be measured are higher and consequently easier to determine.

Interpretation of the results of charge distribution measurements in fission of nuclei with moderate excitation energy is difficult since one does not know how many neutrons evaporate before fission and how many are emitted by the fission fragments themselves[72, 73]. In nuclei whose excitation energy is higher than the binding energy of one or more neutrons, neutron emission competes with fission. The nucleus remaining after emission of a neutron can either emit a further neutron, if it still possess sufficient excitation energy, or fission. Hence a mixture of differently fissioning nuclei is formed ("multiple chance fission").

10. Angular Momentum of Fission Fragments

The fissioning compound nucleus formed by a nuclear reaction has an angular momentum $\vec{J}_f$ which is made up of the spin of the bombarding particle $\vec{J}_a$, the spin of the target nucleus $\vec{J}_A$ and their relative orbital angular momentum $\vec{l}_{aA}$. The law of conservation of angular momentum requires that the angular momentum $\vec{J}_f$ in the fission of the compound nucleus remains conserved and be distributed as intrinsic angular momenta $\vec{J}_{h_1}$ and $\vec{J}_{l_1}$ of the two fission fragments and their relative orbital angular momentum $\vec{l}_{h_1}$:

$$\vec{J}_A + \vec{J}_a + \vec{l}_{aA} = \vec{J}_f = \vec{J}_{h_1} + \vec{J}_{l_1} + \vec{l}_{h_1}$$

If the primary fission fragments are formed with a larger angular momentum than that of the fissioning nucleus (*e.g.* spontaneously fissioning ^{252}Cf with spin 0), angular momentum must be "generated" in some way in the fission fragments during the fission process. For example, torques can be generated on each fragment by electrostatic repulsion if the fragment system exhibits a certain asymmetry at the moment of scission[74]. The diagonal component of the Coulomb repulsion between the mutually asymmetrically oriented fission fragments initiates post-scission rotation of the fragments in opposite directions about an axis perpendicular to the fission axis. The spins $\vec{J}_{h_1}$ and $\vec{J}_{l_1}$ of the two complementary fragments can then be greater than the spin of the fissioning nucleus since they are approximately anti-parallel and thus largely cancel each other. Rotational states can also be excited between saddle and scission configuration by interaction of the deformed fragments in their strong Coulomb field; this also results in generation of angular momentum in the separated fragments[75, 52].

Determination of the angular momentum of the primary fission fragments provides us with information about the properties of the fissioning nucleus between the saddle point configuration and the state shortly after the scission configuration. If the fissioning compound nucleus has high angular momentum (*e.g.* the compound nucleus ^{239}Pu, which is formed by bombardment of ^{235}U with 36 MeV ^4_2He particles, has an average angular momentum of 15 h[76]), then part of it will appear as intrinsic angular momentum of the fission fragments. Measurements of the angular distribution of fission fragments in fission with moderate excitation energy show that only a small part of the angular momentum generated in the compound nucleus appears as orbital angular momentum between the fragments[8, 9, 77, 78].

Figure 14 shows a schematic representation of the decay of the primary fission fragment ^{150}Pm. One can imagine the fission fragments rotating with the vectors of the angular momentum lying in a plane that is perpendicular to the symmetry axis of the fissioning nucleus. The spin distribution of the primary fission fragments is modified by the emission of prompt neutrons and gamma rays. The magnitude and orientation of the angular momentum of the fragments have a particular influence on the properties of the gamma emission. Measurement of the number of photons per fission fragment together with a knowledge of the multipolarity of the radiation allow an estimation to be made of the spin of the fragments. Information about the angular momentum of the primary

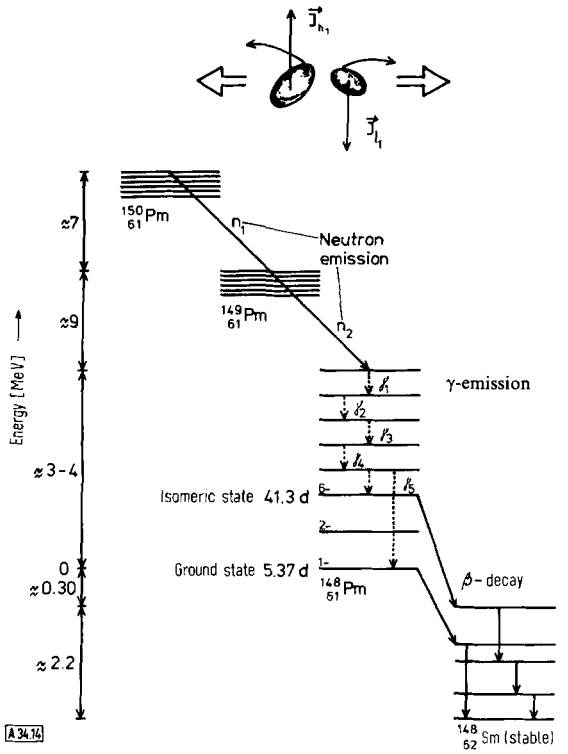

Fig. 14. Schematic representation of the decay of the primary fission fragment $^{150}_{61}$Pm by neutron and gamma emission to the 1^- ground state (half-life: 5.3 d) and isomeric 6^- level (half-life: 41.3 d) of the fission product $^{148}_{61}$Pm and its decay to the stable end product $^{148}_{62}$Sm. One can imagine that after fission, the fission fragments rotate in opposite directions about axes perpendicular to the direction of fission. They have an excitation energy of ca. 20 MeV, which is mainly given up by the emission of neutrons. After evaporation of neutrons the remaining excitation energy is removed by gamma emission. The last gamma transition ends either at the isomer level or at the ground state.

fission fragments can also be obtained by the following measurements on prompt gamma rays[79, 80]:

1. Measurement of the angular distribution of the prompt gamma radiation emitted by the fission fragments.

2. Measurement of the energy and intensity of the prompt gamma transitions of the 2^+, 4^+, 6^+ and 8^+ levels of the ground state rotational band in several "even-even" fission products.

A further method providing information about the angular momentum of primary fission fragments is based on the radiochemical determination of independent isomeric ratios of fission products, *i.e.* of the ratio of the independent yield of a long-lived isomer of a fission product (in Fig. 14 the 6^- state of ^{148}Pm with a half-life of 41.3 d) to the independent fission yield of the ground state of the same fission product (in Fig. 14 the 1^- ground state with a half-life of 5.37 d). The independent portion of fission product yields arises directly from the primary fission fragments by emission of prompt neutrons and gamma rays; hence the relative population of the ground state and isomeric state of a fission product can be related to the initial angular momentum of the fission fragments. The isomeric pair must have a β-stable or long-lived precursor, so that there is either no contribution or, at worst, only a small correctable contribution from β-decay of its precursor[9, 77].

Calculation of the angular momentum of the primary fission fragments from the measured relative yields of isomeric fission products is based on the concepts of the statistical model. The formalism of the calculations was introduced by *Huizenga* and *Vandenbosch*[81] for the calculation of isomeric ratios in

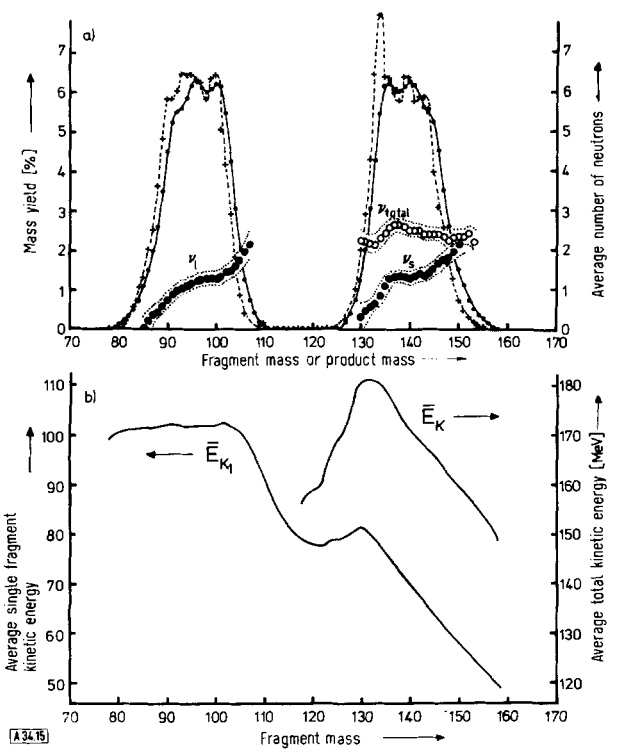

Fig. 15. a) Average number of prompt neutrons emitted from the fission fragments as a function of the fragment mass, obtained by comparison of pre- (●) and post- (+) neutron emission fragment mass distribution for fission of ^{235}U with thermal neutrons. Both mass distributions are shown, ν_l and ν_h represent the number of evaporated prompt neutrons (after [46, 47]). b) Average single fragment kinetic energy and total kinetic energy of the fission fragments as a function of their mass for fission of ^{235}U with thermal neutrons (after [44]).

nuclear reactions such as (n,γ) and (p,n) reactions. In such nuclear reactions the distribution of angular momentum of the compound nuclei can be calculated. The distribution of angular momentum of the compound nucleus in nuclear fission can also be calculated, but then the distribution of the angular momentum to the primary fission fragments cannot be followed accurately. To obtain information about the intrinsic angular momentum of the primary fission fragments from the isomeric ratios of fission products one now asks which distribution of angular momentum must occur in the primary fission fragments in order to explain the observed isomeric ratio. This spin distribution is modified by the neutrons and gamma quanta emitted by the primary fission fragments which remove angular momentum from the system (see Fig. 14). A knowledge of the angular momentum carried away by the neutrons and γ-rays is required.

Table 1 lists the results obtained in some of these studies. A complete compilation of all experimental results obtained so far (apart from those in Refs. [79] and [82]) is given in Ref. [83].

Although still far from being complete, the experimental results obtained todate allow us to draw a few general conclusions[79]:

1. The variation in angular momentum between fission fragments is not large; however,

2. fission fragments in symmetrical fission appear to have a smaller angular momentum than in asymmetrical fission.

3. If the fissioning compound nucleus is formed with higher excitation energy and higher angular momentum *via* nuclear reactions with charged particles (which impart a higher orbital angular momentum than thermal neutrons), a part of this higher angular momentum appears as internal angular momentum of the fission fragments, the remainder as orbital angular momentum between the parting fragments.

11. Kinetic Energy of Fission Fragments

When an excited compound nucleus of mass $M^*(A_f, Z_f)$ fissions into the two fragments $M_h(A_{h_1}, Z_{h_1})$ and $M_l(A_{l_1}, Z_{l_1})$ the total energy E_f released is given by

$$E_f = M^*(A_f,Z_f) - M_h(A_{h_1},Z_{h_1}) - M_l(A_{l_1},Z_{l_1})$$

At the moment of scission of the nucleus the total potential energy of the fission fragments consists of the mutual Coulomb energy E_c and the deformation energy $E_d = E_{d_h} + E_{d_l}$ of the two fragments. The difference between E_f and the potential energy appears in the form of internal energy E'_x and rotational energy E'_{rot}:

$$E_f - (E_c + E_d) = E'_x + E_{rot}$$

As soon as the fragments have separated the Coulomb energy becomes the kinetic energy of the fragments, and the deformation energy of each fragment is transformed into internal excitation energy. When the two fragments are separated by a large distance their total kinetic energy is $E_K = E_c + E'_{rot}$ and the total internal excitation energy $E_x = E_d + E'_x$ *i.e.*,

$$E_f = E_K + E_x$$

The total kinetic energy of all known fissionable nuclei is proportional to $Z_f^2/A_f^{1/3}$. This is to be expected if the kinetic energy of the fission fragments stems mainly from the Coulomb repulsion of the fragments after fission. In symmetric fission ($A_{h_1} = A_{l_1} = A_f/2$, $Z_{h_1} = Z_{l_1} = Z_f/2$) the two fragments, whose charge centers at the moment of scission are separated by a distance D, have a Coulomb energy of

$$E_K = \frac{Z_{h_1} \cdot Z_{l_1} \cdot e^2}{D} = \frac{Z_{h_1} \cdot Z_{l_1} \cdot e^2}{r_0(A_{h_1}^{1/3} + A_{l_1}^{1/3})} = const. \frac{Z_f^2}{A_f^{1/3}}$$

where r_0 is the nuclear radius parameter.

Table 1. Average angular momentum of fission fragments from radiochemical measurements of isomeric ratios and physical studies of the γ-deexcitation of the fission fragments.

[a] RC: Radiochemical determination of the isomeric ratio on the fission products listed; P1 and P2: results of measurements 1 and 2, resp., (see text) of prompt gamma rays.

The average distance D between the charge centers (which almost coincide with the mass centers) of the fission fragments at the moment of scission can be determined by measuring the kinetic energy E_K.

At low and moderate excitation energies of one and the same fissioning nucleus the total kinetic energy is almost independent of the excitation energy; the average distance between the fragments at the point of scission remains nearly constant, even if the excitation energy increases. The increased excitation energy of the fissioning compound nucleus is transformed into excitation energy of the fragments.

If the total kinetic energy of the fission fragments is plotted as a function of the mass of the fragments, then a decrease in kinetic energy is observed in the case of symmetric fission (Fig. 15b). It can be concluded, therefore, that the distance at the scission point for symmetric fission is greater than that for asymmetric fission.

12. Excitation Energy of Fission Products

The excitation energy $E_x = E_{x_h} + E_{x_l}$ is obtained by calculating the total energy released in fission E_f and measuring the total kinetic energy E_K. Thus, fragments formed on symmetric fission have a higher excitation energy than those arising from asymmetric fission. The fission fragments lose their excitation energy by emission of prompt neutrons and gamma rays. A fragment with an excitation energy E_{x_h} can emit an average number ν of neutrons having binding energy E_{Bn} and kinetic energy E_{Kn} and release the energy E_γ in the form of gamma rays.

The total excitation energy of the two fragments formed in a fission process is distributed according to the following equation:

$$E_x = E_{x_h} + E_{x_l} = \nu_h(E_{Bn_h} + E_{Kn_h}) + E_{\gamma_h} + \nu_l(E_{Bn_l} + E_{Kn_l}) + E_{\gamma_l}$$

13. Prompt Neutrons

The number of prompt neutrons as a function of fragment mass can be determined in two ways, either

1. indirectly, from the difference between the initial and final fragment mass distributions (Figure 15a shows the neutron yield determined in this way as a function of fission fragment mass in the fission of ^{235}U with thermal neutrons), or

2. directly; the results of a number of such measurements are shown in Fig. 16 for the fission of ^{235}U with thermal neutrons.

Saw-tooth shaped distribution curves have also been obtained for other fissioning nuclei. It is evident from such curves that light fragments emit more neutrons than heavier fragments in nearly symmetric fission. The reason for this seems to be closely connected with the stiffness or deformability of the fissioning fragments. Fragments with completely or almost completely closed shells ($Z=50$, $N=50$ or 82) are spherical and especially rigid, whereas fragments with only partially filled shells, such as those having masses around 110 or 160, are more readily deformed. If fission leads to formation of two fragments, one of which has a fully closed shell and the other a partially filled shell, the greater portion of the deformation energy on scission will be imparted to the "soft"

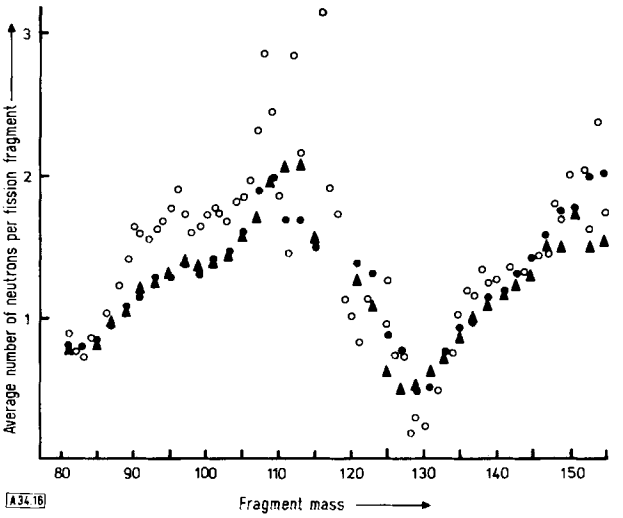

Fig. 16. Average number of prompt neutrons emitted from the fission fragments as a function of the fragment mass, obtained by direct counting of the neutrons in the fission of ^{235}U with thermal neutrons. ○, ▲, and ● represent the results of *Milton* and *Fraser* [109], *Maslin et al.* [110], and *Boldeman et al.* [98], respectively.

fragment and a lesser amount to the "hard" fragment with a completely closed shell. Hence, after fission a higher excitation energy will be contained in the soft fragment, which will then emit more neutrons than the stiff spherical fragment. If both fragments have only partially filled shells, and they readily deform, then a greater amount of deformation energy will be stored in each of them after fission. Moreover, since the distance between the charge centers of highly deformed fragments is greater, their kinetic energy will be smaller (see Section 11). This is the case, for example, in the symmetric fission of ^{235}U with thermal neutrons. Symmetric fragments emit more neutrons (see Fig. 16) and have a smaller average total kinetic energy (see Fig. 15) than asymmetric fragments.

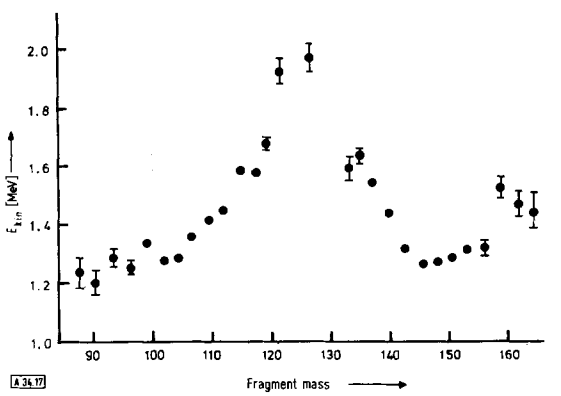

Fig. 17. Average center-of-mass kinetic energy of the prompt neutrons as a function of fragment mass for spontaneous fission of ^{252}Cf (after [99]).

The average energy which prompt neutrons carry away from the fragments, and which consists of binding energy and kinetic energy, does not vary very much from fragment to fragment and lies between 7 and 9 MeV. The average kinetic energy of the prompt neutrons emitted by fission fragments in the spontaneous fission of ^{252}Cf is shown in Fig. 17 as a function of fragment mass.

The amount of excitation energy carried away from the fragments by the neutrons can be calculated from the kinetic

energy of the neutrons, their binding energy—which can be calculated with the aid of a nuclear mass formula, *e.g.* that of *Myers* and *Swiatecki*[24]—and from the neutron yield as a function of fission fragment.

14. Prompt Gamma Rays

After evaporation of prompt neutrons, the remaining excitation energy of the fission fragments is removed by emission of gamma rays (see Fig. 14). Since the time in which the gamma rays are emitted (10^{-10}—10^{-12} s) is considerably longer than the time in which the neutrons are evaporated off ($< 10^{-14}$ s), it can be assumed that emission of gamma quanta takes place after evaporation of neutrons.

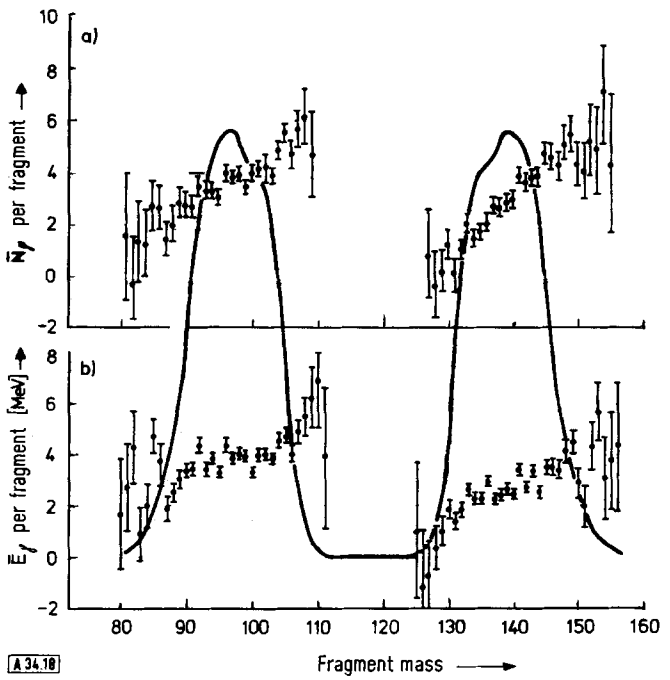

Fig. 18. Average total energy ($\bar{E}_\gamma$) and average number ($\bar{N}_\gamma$) of the gamma quanta emitted from the fission fragments as a function of fragment mass in the fission of ^{235}U with thermal neutrons (after [100]).

Figure 18 shows the average total energy $\bar{E}$ and average number $\bar{N}$ of gamma rays emitted by fission fragments as a function of fragment mass. Both curves are saw-toothed and can be compared with the curve of the average number of neutrons emitted by individual fragments as a function of fragment mass (Fig. 15a and 16).

Fission fragments near those with closed shells $Z = 50$ and $N = 82$, *i.e.* with a mass of about $A_{h_1} = 132$, emit on average only about half as many gamma rays as the complimentary fragments with masses of about $A_{l_1} = 104$. Such a phenomenon would be scarcely expected if the competition between neutron and gamma ray emission is determined merely by the excitation energy. Higher excitation energies would result in increased neutron emission. However, the angular momentum of the fission fragment has a strong influence on the number of gamma quanta emitted by a fragment. The angular momentum is reduced by only a few units by emission of prompt neutrons. If the fragment still possesses a high spin after neutron emission this will be removed by a cascade of gamma quanta, and the emission of gamma quanta will increase relative to that of neutrons. It must be remembered, however, that the gamma cascade is also dependent on the nuclear structure of the fragments. If these have a lower level density, fewer gamma quanta with higher energy will be emitted than by nuclei with larger level densities. Experimental results for the emission of prompt neutrons and gamma quanta have been collected and discussed in detail by *Nifenecker*[89].

15. Conclusion

In this paper only a very limited and concise review of the results and problems of nuclear fission is presented. Many important experimental results have had to be omitted. Thus, important themes such as the probability of fission under the most varied conditions, the spontaneous fission of heavy nuclei from the ground state, the angular distribution of fission fragments, ternary fission, delayed neutrons, and the radioactive decay of fission products, have either not been dealt with at all or have been treated in only a cursory fashion. These themes also include numerous interesting problems for the radiochemist, whose investigations can lead to important conclusions regarding the phenomenon of "nuclear fission".

High Pressure Kinetic Investigations in Organic and Macromolecular Chemistry[**]

By Gérard Jenner[*]

High pressure kinetics appears to be a valuable tool in investigating the mechanism of specific organic reactions. For instance, in pericyclic, Mentshutkin, cage, and polymerization reactions, such studies reveal various features of the transition state, in particular its localization along the reaction coordinate and its nature. However, precise conclusions require separation of the different effects (electrostatic, steric, orbital, *etc.*) which may contribute to the structure of the transition state.

1. Introduction

The rate of chemical reactions in gaseous and condensed phases is influenced by pressure:

1) Compressing the reaction medium increases the concentration of the reacting molecules.

2) Pressure changes the rate of intermolecular diffusion.

3) Pressure compresses the molecules themselves, deforming the "electron clouds" and affecting the collision rate.

In dense liquid phase, the free space required for the formation of the transition state is restricted and the influence of pressure upon the reaction rate overshadows all other effects.

The high pressure thermodynamics of solutions is well known and it is unnecessary to give details in this paper. The fundamental relationships governing the condensed phase equilibria may be written as functions of the activation volume $\Delta V^{\neq}$:

$$\left[\frac{\partial \ln k}{\partial p}\right]_T = -\left[\frac{\partial \Delta G^{\neq}}{RT\partial p}\right]_T = -\frac{\Delta V^{\neq}}{RT} \tag{1}$$

$$\left[\frac{\partial \Delta S^{\neq}}{\partial p}\right]_T = \left[\frac{\partial \Delta V^{\neq}}{\partial T}\right]_p \tag{2}$$

$$\left[\frac{\partial \Delta H^{\neq}}{\partial p}\right]_T = \Delta V^{\neq} - T\left[\frac{\partial \Delta V^{\neq}}{\partial T}\right]_p \tag{3}$$

In these expressions the activation parameters (free energy $\Delta G^{\neq}$, enthalpy $\Delta H^{\neq}$, entropy $\Delta S^{\neq}$) characterizing the transition state have their usual meaning.

Since the activation quantity $\Delta V^{\neq}$ will assume an important place in our investigations of reaction mechanisms, a short outline will be presented here, although the concept has been thoroughly analyzed and discussed elsewhere[1-3].

Rigorously speaking the activation volume is the difference in partial molal volume between the transition state and the initial state. $\Delta V^{\neq}$ often has to be considered as a composite quantity made up essentially of two contributing volumes, the first being related to the structural change during the crossing from the initial to transition state and the second representing the volume change due directly to the modified interaction between the surrounding molecules of solvent and the reacting molecules when they form the transition state (these changes are not only localized in the solvent, but also within the molecules). In principle $\Delta V^{\neq}$ can be calculated exactly by the methods of quantum and statistical mechanics, but in practice the computations for a liquid phase reaction are too involved to be worthwhile.

Expressed on the molar scale (rate constant k_c) and molal scale (rate constant k_x), the Evans-Polanyi relationship is written:

$$\Delta V^{\neq} = -RT\left(\frac{\partial \ln k}{\partial p}c - \beta \Sigma \gamma_i\right) \tag{4}$$

$$\Delta V^{\neq} = -RT\left(\frac{\partial \ln k}{\partial p}x\right) \tag{5}$$

$\Sigma \gamma_i$: stoichiometric change between the transition state and the initial state
β: isothermal compressibility of the solution

As shown by these expressions, to obtain the value of $\Delta V^{\neq}$ at zero pressure it is necessary to write k_c or k_x as a function of p. Unfortunately, no exact function is known for this purpose, and many analytical expressions must be considered according to the magnitude of $\Delta V^{\neq}$ and the pressure range. Simple power series[4] and other empirical relations[5-8] have been proposed:

$$\ln k = a_0 + a_1 p + a_2 p^2 \tag{6}$$

$$\ln k = \frac{a+bp}{1+cp} \tag{7}$$

$$\frac{\ln (k/k_0)}{p} = A + Bp^{0.523} \quad (\textit{Benson-Berson}[8]) \tag{8}$$

$$\frac{\ln(k_{n+1}/k_n)}{p_{n+1}-p_n} = A' + B'\frac{(p_{n+1}+p_n)}{2} \quad (\text{incremental}[7]) \tag{9}$$

These relations obviously imply different pressure dependencies of $\Delta V^{\neq}$ (*e.g.* the quadratic polynomial (6) which is widely used imposes a linear relationship between $\Delta V^{\neq}$ and p). Analytical expressions should be regarded simply as mathematical tools allowing a fitting of experimental results but not as physical models. Caution is required when using several of these methods simultaneously. In any case the best solution is to collect as many experimental kinetic points as possible in the low pressure region and to compare the mathematical values of $\Delta V^{\neq}$ with the value obtained experimentally from the slope of the curve $\ln k = f(p)$.

The various procedures for an accurate determination of $\Delta V^{\neq}$ have been reviewed and commented upon recently[9], particularly the semi-empirical approach of *Benson* and *Berson*[8]

[**] Based upon a lecture delivered at the 12th Meeting of the European High Pressure Research Group, Marburg/Lahn (Germany), March 1974.

which has given rise to some criticism; despite its very poor theoretical basis, however, the method seems to give reasonable approximate values of the activation volume (Table 1).

Table 1. Comparison of several methods for determining $\Delta V^{\neq}$ in Diels-Alder reactions involving isoprene ($\Delta V^{\neq}$ in cm^3/mol).

Method / Dienophile	Graphic	Power series (quadratic)	*Benson-Berson* [8]	Incremental
acrylonitrile [10] (21 °C)	−35.4	−33.1	−34.7	−33.7
methyl acrylate [10] (21 °C)	−31.5	−30.8	−32.8	—
methyl vinyl ketone [10] (20 °C)	−38.1	−36.9	—	—
isoprene [11] (70 °C)	−42.0	−41.3	−43.6	−41.8
maleic anhydride [12] (35 °C)	−37.4	−39.0	−36.5	—

The calculation of the activation volume of an organic reaction permits choice of optimal experimental conditions for a proposed synthesis. Moreover, a knowledge of $\Delta V^{\neq}$ leads to a better understanding of the transition state in relation to the initial and final states, and provides useful information about its structure and properties which is essential for establishing the mechanism of organic reactions. An interpretation usually requires that the activation volume can be resolved into components whose values are known at least approximately. For apolar reactions (such as Diels-Alder reactions), the electrostatic contribution is negligibly small, so that the measured activation volume is related directly to the geometric changes incurred on going from the initial to the transition state.

Reactions in the liquid phase can be crudely classified into three groups:

1) Decompositions and neutralization of ionic charges, which are hardly affected by pressure or show a negative pressure effect ($\Delta V^{\neq} > 0$);

2) Reactions with weak pressure effect ($\Delta V^{\neq}$ close to zero) represented by nonpolar reactions consuming and regenerating a radical or a molecule;

3) Ionization and bimolecular reactions which are generally subject to a strong pressure acceleration ($\Delta V^{\neq} < 0$)[13].

Depending upon the sign and the magnitude of $\Delta V^{\neq}$, the volume balances of organic reactions show different profiles. As is apparent from Figure 1, four kinds of behavior may be distinguished, two displaying a monotonous volume change along the reaction coordinate and two others with volume extrema for the transition state (the case with $\Delta V^{\neq} > 0$ and a volume maximum is very rare[14]).

Table 2. Activation volumes for some classes of reactions.

Reaction type	$\Delta V^{\neq}$ [cm^3/mol]
radical decompositions [15]	0 to +15
rearrangement reactions (Cope, Claisen)	− 8 to −15
radical polymerizations	−10 to −25
Mentshutkin reactions	−20 to −40
ionization reactions	−15 to −45
Diels-Alder reactions	−25 to −50

This report considers the particular pressure effect upon the kinetics of four reaction groups: thermal pericyclic reactions;

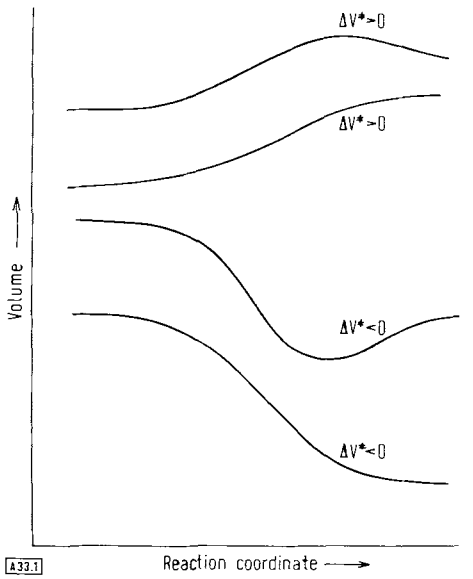

Fig. 1. Various volume profiles of organic reactions.

Mentshutkin reactions; cage reactions; and polymerization reactions.

2. Pericyclic Reactions

According to the terminology of *Woodward* and *Hoffmann*[16, 17] pericyclic reactions are concerted reactions characterized by a quasi-cyclic transition state; moreover the stereochemistry depends solely upon the number of electrons and not the number of participating carbon atoms (or centers). These reactions exhibit large negative activation volumes and provide an example of transition states with few localized charges. Among these reactions, the most thoroughly investigated are the Diels-Alder and the Cope reactions.

2.1. Diels-Alder Reactions

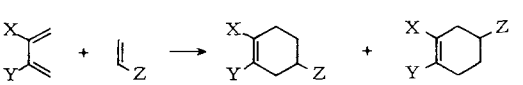
It is obvious that the Diels-Alder reaction is strongly pressure accelerated since the adduct always constitutes the most condensed phase. Besides, the use of pressure avoids the retrodienic reaction whose activation volume is positive (about $+10\,cm^3/mol$). On the other hand, pressure favors not only the Diels-Alder reaction but also the polymerization reactions, and sometimes also decomposition of the dienophile[18, 19].

Use of a very efficient radical polymerization inhibitor and observation of optimal pressure and temperature conditions ensure that the reaction proceeds solely in the direction of diene-dienophile addition[18].

Two aspects of the Diels-Alder reaction may be considered separately with regard to their pressure effect: stereospecificity on the one hand and the kinetics on the other.

2.1.1. Regioselectivity in High Pressure Diels-Alder Reactions

The thermal condensation of a diene and a dienophile generally leads only to cyclohexene derivatives, especially at low temperatures[20].



If the diene is asymmetric, both isomers are obtained (*e.g.* in reactions involving isoprene).

With the aid of NMR spectroscopy, *Brun*[18, 21] was able to determine the percentage of both isomers in the mixture of adducts formed by reaction of isoprene with crotonaldehyde.

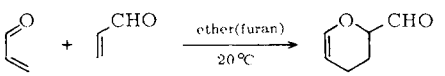
Table 3. Bulk condensation of isoprene and crotonaldehyde (5.5 mol/l each). Reaction time 20 h, temperature 22 °C.

Pressure [bar]	Yield of adduct [%]	Isomer "*para*"	Isomer "*meta*"
1	0	—	—
6000	3.1	60	40
8000	16.8	64	36
10000	31.7	72	28

These results can be explained to a first approximation by electrostatic arguments. The "*para*" isomer is the most polar compound, and it is known that the compression of a reaction mixture induces a volume contraction favoring the formation of polar substances[22, 23]. In fact, pressure increases the polarity of the medium and hence also the electrostatic interactions between the solvent and the polar reaction products. However, as the stereochemistry of the Diels-Alder reactions is little affected by changing the solvent[24], electrostatic effects should play a minor role[25, 26]. A more plausible explanation involves a perturbational view of orbital effects[27].

Gonikberg, Elyanov, et al.[28, 29] have studied the reaction between 1-vinylcyclopentene and methyl acrylate at 80 °C under 1 and 6000 bar, as well as the addition of *trans*-piperylene to methyl acrylate at somewhat higher temperatures and pressures. The variation of the composition of the adduct mixture is explained by steric considerations since models of cyclic transition states for the 1-*cis* isomer have the most compact structure.

Thermal dimerization of acrolein is a limiting case of the Diels-Alder reaction in which the dienophile also behaves as a diene. Surprisingly only the "*meta*" isomer is ever obtained[18] regardless of pressure.



This reaction is highly selective and at room temperature seems to proceed only under high pressure. Once again the stereochemistry can be predicted by a perturbation method[27].

Table 4. Dimerization of acrolein (2.30 mol/l) at 20 °C in furan. Reaction time 8 h.

Pressure [bar]	Adduct [%]
1	0
2000	0.7
3000	1.0
6000	1.3
> 6000	[a]

[a] Explosive decomposition of acrolein.

2.1.2. Pressure Effect upon the Kinetics of Diels-Alder Reactions

As shown by Table 5, pressure strongly affects the kinetics of diene cycloadditions.

Table 5. Values of the ratio k_p/k_o for some isoprene cycloadditions [10]. Diene/dienophile = 1/1; room temperature; solvent 1-bromobutane.

Pressure [bar]	Dienophile acrylonitrile (21 °C)	Dienophile methyl acrylate (21 °C)	Dienophile methyl vinyl ketone (20 °C)
1	1	1	1
1000	3.4	3.0	4.1
1500	7.0	4.6	—
2000	10.5	8.3	12.3
3000	24.4	17.5	19.5
5000	74.4	57.3	—
8000	561	438	—
10000	1650	1530	—

The activation volumes of some recently studied Diels-Alder reactions are given in Table 6.

Table 6. Activation volumes for some Diels-Alder reactions involving isoprene as diene carried out in 1-bromobutane.

Dienophile	T (°C)	$\Delta V^{\neq}$ [cm³/mol]	ΔV [cm³/mol] [a]
acrylonitrile [10]	21	−35.0	−37.0
methyl acrylate [10]	21	−31.5	−36.9
methyl vinyl ketone [10]	20	−38.0	−37.1
isoprene [11]	40	−35.0	−41.9
	50	−40.0	−44.1
	60	−41.0	−45.9
	70	−42.0	−47.8
DMB [b] [30]	70	−37.0	−45.3

[a] Overall volume change between the final state and the initial state.
[b] 2,3-Dimethyl-1,3-butadiene (also the diene in this reaction).

Two mechanisms are conceivable for Diels-Alder reactions: either a concerted (4 + 2) center electrocyclic reaction involving synchronous formation of two σ bonds in the transition state, or a two-step process involving formation of a delocalized bond and crossing through an intermediate diradical. The reported values for $\Delta V^{\neq}$ (Table 6) strongly suggests the simultaneous formation of two bonds in the activation process, *i. e.* the concerted one-step mechanism. Moreover, the highly ordered transition state is confirmed by the high negative activation entropies[11].

The results of *Grieger* and *Eckert et al.*[12, 31–36] are also in very good agreement with this conclusion. In some cases the activation volume was more negative than the volume change on reaction, giving a minimum in the volume profile along the reaction coordinate. This was attributed by *Eckert* to additional contraction as a result of secondary interactions between non-bonding atoms in the transition state which do not occur in the cyclohexene compound.

Nevertheless, caution should be exercised before generalizing these conclusions to include all thermal Diels-Alder reactions because a two-step mechanism cannot always be formally excluded if a compound readily forms a relatively stable diradical. For example, *Stewart*[37] has measured the pressure effect on the cyclodimerization of chloroprene and has observed competing mechanisms. Even though the values of the cited activation volumes are probably not exact owing to the excessive pressure interval employed, he could show that the reaction yields not only vinylcyclohexenes, but also an appreciable amount of divinylcyclobutanes, so that the transition state corresponding to the intermediate diradical is about 10 cm³/mol less compact than the transition state of the one-step case.

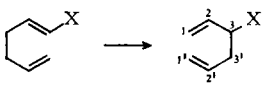
Table 7. Activation volumes for some Diels-Alder reactions studied by *Grieger* and *Eckert* [12,31—36].

Diene	Dienophile [a]	T [°C]	Solvent	$\Delta V^{\neq}$ [cm³/mol]	$\overline{\Delta V}$[b] [cm³/mol]
isoprene	MA	35	acetone	−39.0	−35.9
1-methoxy-butadiene	MA	35	1-chloro-butane	−43.9	−30.4
cyclohexa-diene	MA	35	dichloro-methane	−39.6	−30.3
cyclopenta-diene	DMAC	10	ethyl acetate	−30.2	−33.6
DMB [a]	BA	10	none	−28.6	−32.4

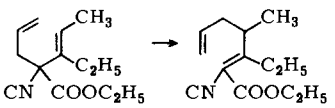
[a] MA, maleic anhydride; DMAC, dimethyl acetylenedicarboxylate; BA, *n*-butyl acrylate; DMB, 2,3-dimethyl-1,3-butadiene.
[b] Overall volume change calculated from partial molar volumes.

2.2. Cope Reactions

The Cope reaction is another pericyclic reaction. If we consider a σ bond adjacent to one or more π systems, then the migration of this σ bond to a new position in a noncatalyzed intramolecular reaction is termed a sigmatropic transposition of order [*n*, *m*] by *Woodward* and *Hoffmann*[16, 17]. For instance the Cope rearrangement is a sigmatropic [3,3]-shift.



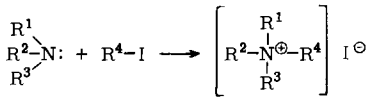
Walling and *Naiman*[38] studied the following Cope reaction at 119 °C at pressures up to 6000 bar



Their results show that the nature of the solvent has very little influence on the reaction rate and that the activation volume is close to $-10\,cm^3/mol$, indicating a cyclic transition state with marked bonding between fragments of the rearranging molecules.

3. Mentshutkin Reactions

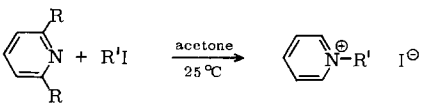
These reactions consist in the addition of an organyl iodide to a tertiary amine.



The process may serve as a model reaction because it is a typical simple bimolecular polar reaction and is sufficiently sensitive to the size and disposition of the substituents attached to nitrogen.

Such reactions are of course pressure accelerated. However, the major source of interest in these investigations is the effect of pressure on sterically hindered Mentshutkin reactions. Since highly substituted compounds are usually more compact than their less hindered counterparts, hindered transition states would seem to have smaller volume requirements than unhindered ones. As a consequence hindered reactions should be accelerated more by pressure than their unhindered analogs. This implies that $\Delta V^{\neq}$ generally becomes more negative when the reactional centers are more sterically crowded. Hence it becomes plausible that the expression suggested for $\Delta V^{\neq}$ in eq. (1) contains a negative term $\Delta V^{\neq}_{steric}$ arising from the overlap of interacting orbitals of the two reacting molecules; the pathway to the transition state entails an interpenetration of the steric groups with a consequent diminution in volume which is roughly proportional to the size of the overlapping groups.

This question has been widely investigated[39–45]. An interesting study by *Le Noble* and *Ogo*[46] on the Mentshutkin reactions



afforded the values for the activation volume given in Table 8.

Table 8. Activation volumes for some hindered Mentshutkin reactions at 25 °C in acetone.

Iodide R′	Amine R	$\Delta V^{\neq}$ [cm³/mol]
CH_3	H	−21.9
	CH_3	−24.4
	C_2H_5	−27.3
	$CH(CH_3)_2$	−30.2
C_2H_5	H	−23.3
	CH_3	−23.9
	C_2H_5	−28.9
	$CH(CH_3)_2$	−35.0 [a]
$CH(CH_3)_2$	H	−26.5
	CH_3	−28.2

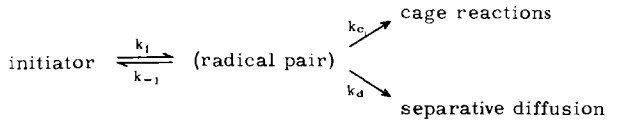
[a] Estimated.

The results show that the activation volume becomes more negative with increasing substitution, either of the amine or of the iodide.

Two explanations have been proposed for the effect of pressure on steric hindrance. *Gonikberg*[40, 41] regards the transition state as rigid and the substituents as compressible spheres; in calculating the magnitude of $\Delta V^{\neq}$ he arrives at values very close to those observed, although he neglects electrostriction arising from strong interaction of the polar transition state with neighboring molecules. This procedure of estimating $\Delta V^{\neq}$ has been criticized[3, 42], and *Weale*[42] proposes another method of calculation based both on covalent and ionic radii of the N and I atoms. The results of *Le Noble et al.* (Table 8) help to clarify these explanations: there really does exist a correlation between steric hindrance and rate accelerations at high pressures. However, although it is permissible to neglect solvation in comparative studies on pressure effects on the rate constants at various pressures ($\Delta\Delta V^{\neq}/\Delta p$), it must be taken into account in estimating the absolute value of $\Delta V^{\neq}$.

4. Cage Reactions

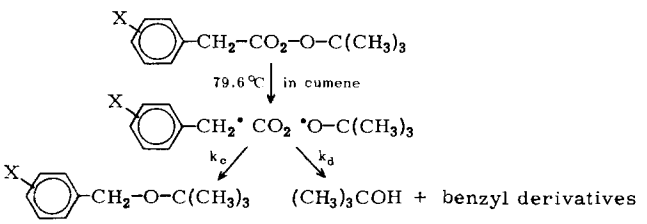
Radical reactions which occur only over short distances and in which geminate radical pairs recombine are regarded as cage reactions. The general scheme is indicated as:



The pressure dependence of the decomposition of two-bond initiators has been investigated by *Neumann et al.*[47-54], who pointed out that the $\Delta V^{\neq}$ values determined for these decompositions do not necessarily reflect the volume change during homolytic scission. The observed rate constant is in fact written as a composite quantity:

$$k_{obs} = k_1\left[\frac{k_d+k_c}{k_{-1}+k_d+k_c}\right] \qquad (10)$$

In the following reaction, only combination and diffusion compete[51].



Partitioning of the initial cages from ring-substituted *tert*-butyl phenylperacetate decomposition gives ethers *via* combination and benzyl radical products and *tert*-butyl alcohol subsequent to diffusion. In this reaction the ratio $k_c/(k_c+k_d)$ increases while separative diffusion is retarded with increasing pressure; the overall activation volume has an apparently low positive value (about $+4\,cm^3/mol$). In other cage reactions, anomalous pressure dependences may be found for geminate radicals, for example in the decomposition of azocumene[53].

These reactions provide an example of the difficulties which often arise in the interpretation of mechanisms on the basis of activation volume values.

5. Addition Polymerization Reactions

Almost the entire quantitative work on high pressure polymerizations has centered on reactions proceeding by a free radical mechanism, and very little attention has been devoted to ionic polymerizations at high pressures. Although radical polymerization reactions are sometimes complex, many of them are well understood under pressure[3, 55-63]. This section will deal with a few aspects of high pressure polymerizations which have hitherto received little attention or none at all.

5.1. Radical Copolymerizations

In radical copolymerization processes, pressure affects the competitive kinetics of homopropagation and crosspropagation. Pressure can modify the reactivity of each monomer and its corresponding radical according to the Evans-Polanyi equation:

$$\frac{\partial(\ln r_A)}{\partial p} = \frac{\Delta V_{AA}^{\neq} - \Delta V_{AB}^{\neq}}{RT} \qquad (11)$$

r_A is the reactivity ratio of the comonomer A at pressures 0 and p.

The quantity $\Delta V_{AA}^{\neq} - \Delta V_{AB}^{\neq}$ measures the influence of pressure on the competitivity between homopropagation ($\sim\!\sim A^{\bullet} + A$) and crosspropagation ($\sim\!\sim A^{\bullet} + B$).

Reference to the literature reveals that in high pressure copolymerizations the reactivity ratios are generally little affected by pressure. However, it must be pointed out that these ratios are often rather imprecise and in some cases the pressure range is so small that no generally valid conclusion can yet be drawn. The most useful results have been obtained for systems in which one of the monomers is acrylonitrile or vinyl acetate. The activation volumes calculated from the pressure dependence of the reactivity ratios are listed in Table 9.

Table 9. Activation volumes for some radical copolymerizations.

System	Ref.	Solvent	T [°C]	$\Delta V_{AA}^{\neq} - \Delta V_{AB}^{\neq}$ [cm³/mol]	$\Delta V_{BB}^{\neq} - \Delta V_{BA}^{\neq}$ [cm³/mol]
acrylonitrile (A) ethyl cinnamate (B)	[64]	bulk	60	−4.7	−7.5
acrylonitrile (A) styrene (B)	[65]	toluene	70	[a]	−9.8

[a] Not calculated.

The transition state in the propagation reaction is mainly affected by the last unit of the macroradical. *Asai* and *Imoto*[66] noted that the pressure dependence of monomer reactivity is also related to the resonance stabilization of the activated complex and the resultant radical. The more pronounced pressure effect is observed for that monomer whose radical exhibits the greater resonance stabilization energy, although steric effects also play an important role. *Yala-Lutokanu*[19] found an interpretation based on the "*Q-e* scheme" to give satisfactory agreement between calculated and observed reactivity ratios.

5.2. Pseudocationic Polymerization

Abdi-Oskoui[67, 68] investigated the high pressure polymerizations of isoprene initiated by iodine or hydrogen iodide.

Iodine participates in many polymerizations as the cation I^+ and thus initiates a cationic mechanism. The iodine-initiated polymerization of isoprene at high pressures is characterized by the complex character of the iodine molecule[67]. In this case, proof has been obtained for a radical mechanism; but even if a cationic mechanism must be excluded, it is still possible to imagine a pseudocationic one involving an organic iodide as propagation agent.

This seems to be the case in the polymerization of isoprene in presence of hydrogen iodide[68]. When a solution of isoprene in dichloromethane is subjected to very high pressures (above

10 kbar) at room temperature a fast reaction takes place in the presence of catalytic amounts of HI which simultaneously gives a cyclic dimer of isoprene (limonene) and a polymer with mainly 1,4 *trans* structure. In the absence of water only cyclodimerization occurs.

Progressive addition of water to the reaction medium increases the polymer yield, but not so much as expected. Moreover, the water concentration has very little effect on the yield of dimer (Table 10).

Table 10. Polymerization of isoprene (5.35 mol/l) with aqueous HI (2.79×10^{-2} mol/l) in CH_2Cl_2 at room temperature. Pressure 12500 bar; reaction time 15 h.

Added water [mol/l]	Total yield [%]	Cyclic dimer [%]
0	16.2	14.6
0.67	19.4	12.1
1.34	20.0	12.2
1.68	28.3	14.1
6.70	34.7	15.3

The activation volume is about $-10\,cm^3$/mol, for any solvent. The radical polymerization of isoprene exhibits a more negative ΔV^* value (about $-20\,cm^3$/mol). The absence of a radical mechanism is confirmed by experiments with a radical inhibitor (no change in kinetics). That water is necessary to initiate the polymerization supports a cationic mechanism; however, the water concentration is so high that carbonium ions will hardly be able to exist in such a medium. Moreover, once the polymerization has been initiated, the further reaction is little affected by an increase in water concentration. These observations lead us to consider a pseudocationic mechanism in which a small amount of HI reacts with isoprene to give an organic iodide through which the propagation would take place.

Another characteristic of this reaction consists in the structural change of the polymer induced by pressure. With increasing pressure the 1,4 *cis* addition (17 % at 1 bar) diminishes, then vanishes above 12 kbar, whereas the amount of 1,4 *trans* units varies from 65 to 78 % in the same pressure interval.

5.3. Anionic Polymerization at High Pressures

Anionic polymerization is a reaction in which the growing end of the macromolecule carries a negative charge or is negatively polarized.

It is well known that the circumstances of a reaction exert a profound effect upon the structure of the anionic polymer, especially for polydienes. For instance the nature of the solvent plays a very important role, but other parameters may also influence the microstructure, *e.g.* pressure. In our laboratory we have spent several years on investigating[69-71] the influence of pressure on the butyllithium-initiated anionic polymerization of isoprene. We noted that the structure of the polymer obtained in a hydrocarbon solvent is very sensitive to pressure changes.

Analysis of the ionic factors shows that the mechanism is chiefly determined by the degree of interaction between the initiating anionic species and the growing chain, leading to three possible propagation forms[72]: contact ion pairs, solvent-separated contact ion pairs (loose ion pairs), and free ions[73,74]. In hydrocarbons, organic lithium compounds readily associate so that the polymer structure would result from associates of the growing chain in which the C—Li bond is strongly polarized[75]. The addition of a polar solvent destroys the associates to produce selectively solvated species and leading to intermediary structures with progressive enrichment in 3,4 units. The presence of the methyl group in the molecule of isoprene can also play an important role in changing the configuration of either the anion or the attacking monomer.

The pressure effect on the concentration of 1,4 *cis* and 3,4 units according to the polymerization solvent is shown in Table 11.

Table 11. Pressure effect upon the ratio (in %) of the 1,4 *cis* and 3,4 structures in the anionic polymerization of isoprene at room temperature in various solvents [*n*-butyllithium] = 0.02 to 0.10 mol/l.

Solvent / Pressure [bar]	*n*-Heptane		Anisole		1,4-Dioxane	
	1,4 *cis*	3,4	1,4 *cis*	3,4	1,4 *cis*	3,4
1	78	5	48	20	0	65
1000	62	8	—	—	0	65
6000	54	12	40	28	0	65
9000	50	13	38	27	0	65
14000	44	14	—	—	—	—

In weakly solvating solvents such as heptane, pressure induces far-reaching transformations by significantly reducing the percentage of the 1,4 *cis* units. In an "intermediary" solvent (anisole), the decrease is less pronounced. In the case of dioxane, the 1,4 *cis* units are absent in the whole pressure range. The pressure effect thus appears to resemble that of a solvent such as dioxane in which contact ion pairs are produced[74], probably by intervention in the association equilibria of the growing chain. Obviously, in the presence of ionic species such as occur in anionic polymerizations, the major contribution to ΔV^* comes from electrostatic effects. Pressure seems to intensify the electric field and its role would ultimately resemble that of a solvent favoring the appearance of an electric dipole between the gegenion and the end of the growing chain[76]. Nevertheless, a steric effect must also be taken into account such as was illustrated in Section 5.2 for the pseudocationic polymerization of isoprene. In that case the electrostatic contribution is not very important and so the structure change is determined mainly by steric effects.

6. Conclusion

This article does not aim at providing an exhaustive review. Instead, selected examples are presented to illustrate the role of high-pressure kinetic studies in elucidating the mechanism of organic reactions. In order to obtain valuable information from high pressure studies it is necessary to resolve the overall activation volume into its component effects and to investigate them separately.

^{13}C Spin-Lattice Relaxation Times and the Mobility of Organic Molecules in Solution

By Eberhard Breitmaier, Karl-Heinz Spohn, and Stefan Berger[*]

While the chemical shifts and coupling constants of ^{13}C NMR belong to the most powerful tools available to the organic chemist for the solution of structural problems, increasing interest is being shown in ^{13}C spin-lattice relaxation times T_1 as structural parameters. Together with the nuclear Overhauser effects arising by proton decoupling of ^{13}C NMR spectra, the T_1 values of ^{13}C nuclei in a molecule permit conclusions to be drawn with regard to relaxation mechanisms. They reflect the inter- and intramolecular mobility of a molecule, and thus complement the results of temperature-dependent NMR spectroscopy. The T_1 differences within a molecule show, for instance, whether the molecular motion is anisotropic in solution, whether the internal motion of groups is subject to steric hindrance, the extent to which strong intermolecular or interionic interactions affect the flexibility of the molecule, and which parts of the molecule are rigid and which are flexible. Finally, differences between the T_1 values measured for the ^{13}C nuclei of a molecule frequently provide a reliable aid in the assignment of ^{13}C NMR spectra, particularly in cases of signal crowding and multiplet overlapping.

1. Introduction[1, 2]

1.1. Nuclear Precession

Only nuclei possessing mechanical angular momentum p (nuclear spin) are suitable probes for nuclear magnetic resonance spectroscopy. The angular momentum imparts a magnetic moment $\mu = \gamma p$ to these nuclei. The ratio γ between the magnetic moment and the mechanical angular momentum is designated as the gyromagnetic constant.

If a nucleus possessing a spin is placed in a static magnetic field, then its magnetic vector $\boldsymbol{\mu}$ precesses about the direction of the field vector $\mathbf{H}_0$. Figure 1 depicts the nuclear precession in a perpendicular x,y,z coordinate system in which the z axis is defined as the direction of the field vector $\mathbf{H}_0$. According to the Larmor equation (1) the frequency of precession ν_0 is proportional to the magnetic field strength H_0 and lies in the radiofrequency range.

$$\nu_0 = \frac{\gamma}{2\pi} H_0 \qquad (1)$$

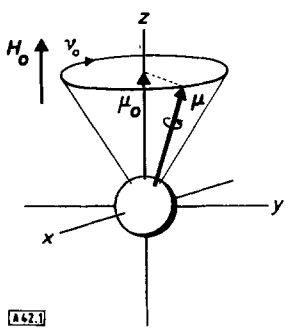

Fig. 1. Nuclear precession.

1.2. Equilibrium Magnetization

The magnetic vector $\boldsymbol{\mu}$ cannot precess randomly but only at certain angles to the vector $\mathbf{H}_0$ of an external magnetic field. The number m of such orientations is determined by the spin quantum number I of the nucleus, according to the quantum mechanical relation

$$m = 2I + 1 \qquad (2)$$

Nuclei having $I = 1/2$, *e.g.* ^1H and ^{13}C, can therefore adopt two possible modes of precession, *i.e.* about the direction of the field vector $\mathbf{H}_0$ ("$+1/2$") and in the opposite direction ("$-1/2$"). Precession about $\mathbf{H}_0$ is the energetically more stable alternative (Fig. 2). An assembly of nuclei in a magnetic field

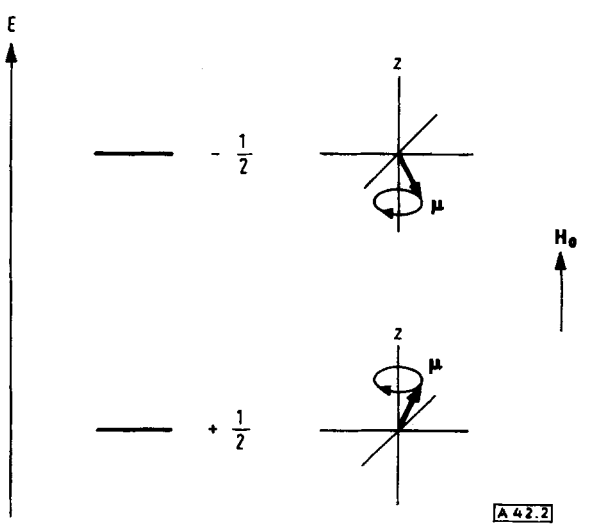

Fig. 2. Nuclear magnetic energy levels (for nuclei with $I = 1/2$).

$\mathbf{H}_0$ will therefore tend towards a Boltzmann equilibrium distribution in which more magnetic vectors precess about the $\mathbf{H}_0$ direction (Fig. 3a) than about the opposite direction. This excess gives rise to the equilibrium magnetization $\mathbf{M}_0$ along the direction of the field vector $\mathbf{H}_0$ (Fig. 3a).

1.3. Nuclear Magnetic Resonance

Continuous or pulsed radiation of radio frequency can induce transitions between nuclear magnetic energy levels (Fig. 2) provided that two conditions are met: the radio frequency ν_1 and the Larmor frequency ν_0 must be equal (resonance), and the vector $\mathbf{H}_1$ of the radio frequency must rotate perpendicular to the field vector $\mathbf{H}_0$. In this way the magnetic vectors are compelled to precess in phase (Fig. 3b), which in turn favors flipping of the magnetic vectors (Figs. 3c and 3d), such that population differences between the nuclear spin levels are balanced. The resultant magnetization $\mathbf{M}_y$ is then not only perpendicular to the standing vector $\mathbf{H}_0$ of the static field but also perpendicular to the rotating vector $\mathbf{H}_1$ of the alternating field (Fig. 3d). This transverse magnetization $\mathbf{M}_y$ thus rotates in the xy plane. In so doing it induces an alternating potential in the receiver coil of an NMR spectrometer (nuclear induction) whose frequency is the difference between the applied radio frequency and the Larmor frequency of the excited nucleus (NMR signal).

The nuclear magnetic resonance process can be represented more simply if the x,y,z coordinate system is allowed to rotate at the Larmor frequency ν_0 about the z axis (x',y',z coordinate system)[2-4]. One thus produces a standing picture in which the magnetization $\mathbf{M}_0$ is directed along the z axis at equilibrium (Fig. 4a). The radio frequency, whose vector $\mathbf{H}_1$ now rotates with the x' axis, deflects the $\mathbf{M}_0$ vector (Fig. 4b) and thus builds up the transverse magnetization $\mathbf{M}_{y'}$. The angle of deflection Θ of $\mathbf{M}_0$ (twist, flip, or pulse angle) depends upon the duration of radio-frequency irradiation in pulsed nuclear magnetic resonance. This radiation time, which lies in the μs range, is called the pulse width. If the radio frequency remains switched on just until $\mathbf{M}_0$ is deflected by 90° or $\pi/2$ (as in Fig. 4c), then the term 90° pulse or $\pi/2$ pulse is employed. Twice that time leads to a 180° or π pulse which inverts the vector $\mathbf{M}_0$ and hence also the Boltzmann distribution of the nuclear spin in Fig. 3a.

1.4. Spin-Spin and Spin-Lattice Relaxation

During nuclear resonance and thereafter, recovery processes regenerate the nuclear spin equilibrium which is characterized by the equilibrium magnetization $\mathbf{M}_0$ and the complete absence of transverse magnetization ($\mathbf{M}_{y'}=0$). These relaxation processes can be readily appreciated in the rotating coordinate system x',y',z (Fig. 5).

Spin-spin relaxation (Fig. 5b—5e) is a decay of the transverse magnetization $M_{y'}$ produced in an NMR experiment. It is assumed to occur continuously as a single exponential. The precessing magnetic vectors lose their phase coherence and once again adopt a regular distribution over the precession cone, regardless of whether their Boltzmann distribution over the nuclear magnetic energy levels (Fig. 3a) has already been reestablished or not. This process can be registered by the receiver of an NMR spectrometer as an exponential decay of the nuclear induction current with time constant T_2 (free induction decay, abbreviated to FID; cf. Figs. 6d and 6e). The spin-spin relaxation time T_2 indicates the time after which the nuclear induction current has dropped to 1/e of its original value.

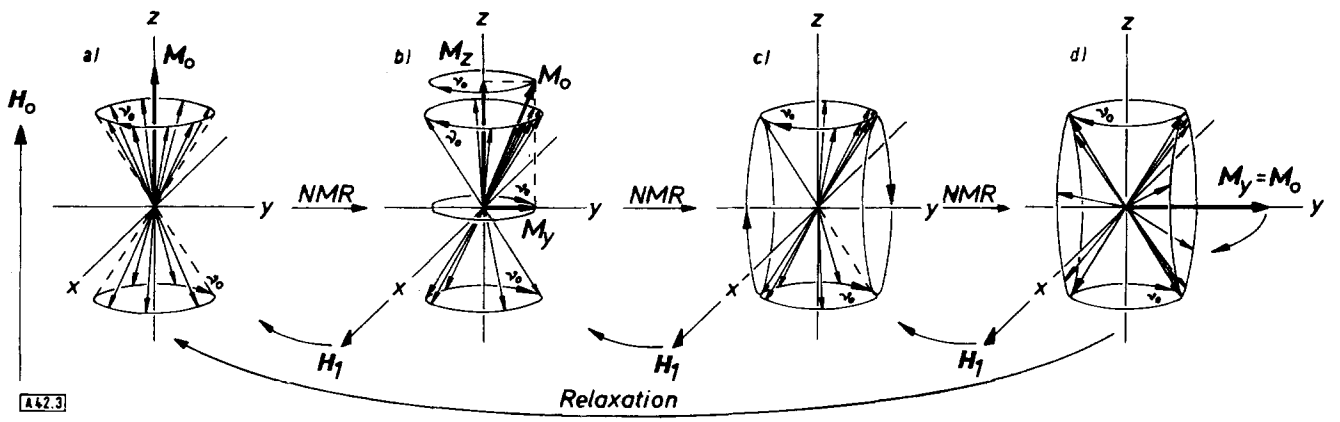

Fig. 3. a) Equilibrium magnetization in the field $\mathbf{H}_0$; b)—d) effect of the alternating field $\mathbf{H}_1$ on the magnetic vectors.

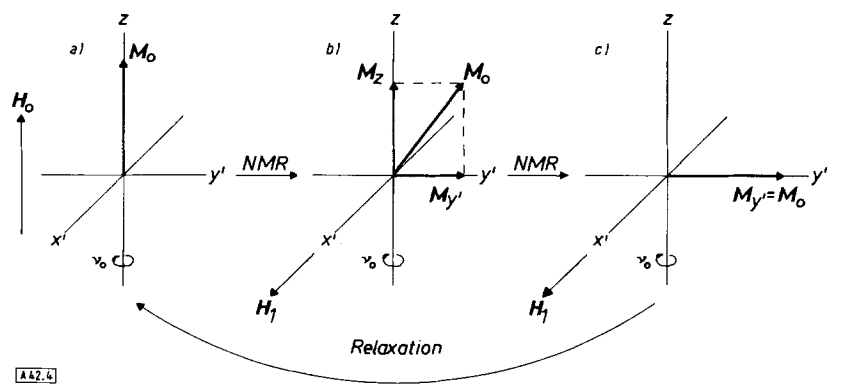

Fig. 4. Motion of the magnetization vector $\mathbf{M}_0$ in a rotating coordinate system under the influence of the alternating field $\mathbf{H}_1$. a) Equilibrium; b) start of deflection; c) deflection by 90° ($\pi/2$ pulse).

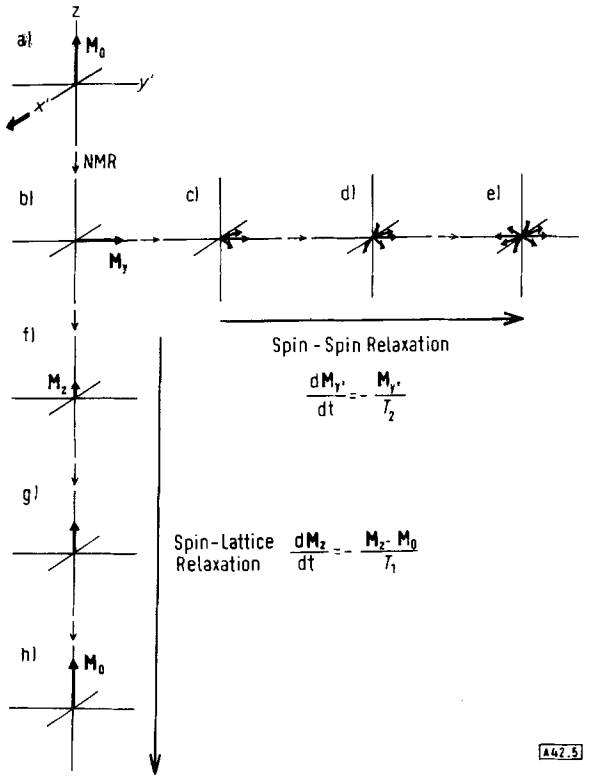

Fig. 5. a) Equilibrium; b) transverse magnetization produced in an NMR experiment; b)—e) decay of transverse magnetization (spin-spin relaxation); f)—h) reestablishment of equilibrium magnetization (spin-lattice relaxation). Shown in a rotating coordinate system.

Fourier transformation $F(t)$ of the FID leads to the frequency function $f(\nu)$, *i.e.* the nuclear magnetic resonance spectrum. This is the basis of pulse Fourier transform (PFT) NMR spectroscopy, shown schematically in Figure 6[2, 5, 6].

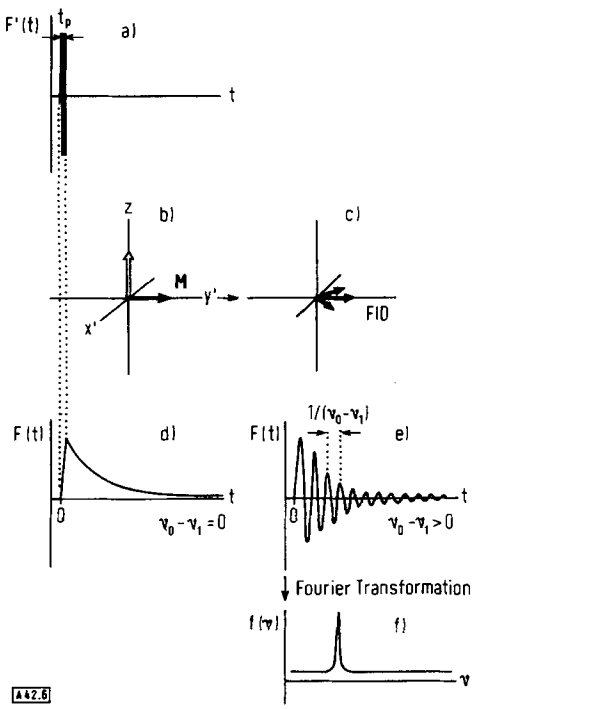

Fig. 6. Pulse Fourier transform (PFT) NMR spectroscopy. a) Radio frequency pulse as input signal; b) and c) rotation of sample magnetization by a 90° pulse and subsequent free induction decay (FID); d) FID signal registered by receiver in case of resonance, e) in case of "off-resonance"; f) Fourier transformed FID signal.

During spin-lattice relaxation, the nuclear spins excited by nuclear resonance return from the more labile to the more stable state (Fig. 2). The Boltzmann spin distribution over the nuclear magnetic energy levels which was disrupted by excitation is reestablished, and the amount of magnetization M_z along the z axis therefore approaches its equilibrium value M_0. This process, which is sketched in Figs. 5f—5h, can be described by eq. (3)[2-4]: spin-lattice relaxation is assumed to be a continuous increase in the longitudinal magnetization M_z to the equilibrium value with a time constant T_1, the spin-lattice relaxation time. T_1 is the time after which M_z has risen to 1/e of the equilibrium value M_0.

$$\frac{dM_z}{dt} = -\frac{M_z - M_0}{T_1} \tag{3}$$

Spin-lattice relaxation liberates energy, which is transferred to the environment of the nuclei. The environment, *e.g.* neighboring or solvating solvent molecules, is designated here as the lattice.

Spin-spin relaxation (decay of transverse magnetization to zero) and spin-lattice relaxation (reestablishment of the equilibrium magnetization $\mathbf{M}_0$) can proceed at different rates for a given kind of nuclei. For instance, spin-lattice relaxation is slower than spin-spin relaxation in the solid state or with macromolecules in solution so that $T_1 > T_2$. In this case, the transverse magnetization has dropped to zero and redistribution of the magnetic vectors over the precession cones is complete before the Boltzmann distribution of the spins between both levels is reached, *i.e.* before the equilibrium magnetization has been restored. With small and medium-sized molecules in the liquid or dissolved state, the relaxation processes often proceed at the same rate, so that $T_1 \approx T_2$. Since the equilibrium magnetization $M_z = M_0$ cannot be attained by a certain number of spins before the transverse magnetization $M_{y'}$ has fallen to zero ($\mathbf{M}_0 = \mathbf{M}_{y'} + \mathbf{M}_z$!), spin-lattice relaxation can proceed slower, but never faster, than spin-spin relaxation. Therefore, in general

$$T_1 \geqslant T_2 \tag{4}$$

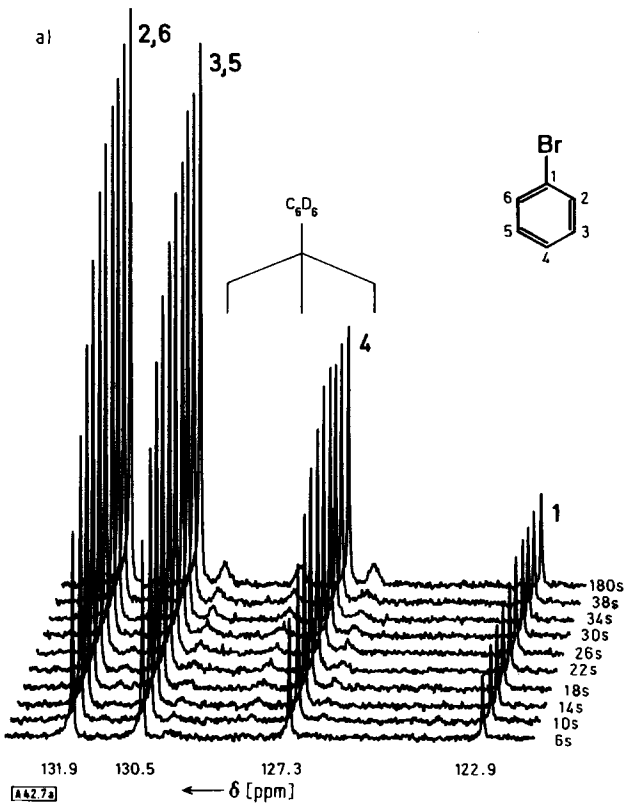
2. Measurement of Spin-Lattice Relaxation Times T_1

Several methods are available for measuring T_1[6-11]. The most important routine methods of Fourier ^{13}C NMR spectroscopy in present use are the "progressive saturation" and "inversion recovery" methods.

The procedure adopted in the "progressive saturation" technique[7] resembles that of Fourier ^{13}C NMR spectroscopy[6]. The signal sequence following a sequence of several 90° pulses is accumulated, and the procedure repeated a number of times for different pulse intervals τ. It is essential that signal summation be undertaken only after a steady-state regime has been obtained where excitation and relaxation balance each other. Therefore, signal accumulation is started for each interval only after the fifth to the tenth pulse. Fourier transformation of the accumulated signals and sequential plotting of the Fourier spectra yield a series of spectra such as that shown in Figure 7a: The signal intensity A_τ asymptotically approaches an equilibrium value A_∞ as the interval τ increases.

T_1 is obtained as the reciprocal slope of a regression line resulting from a semi-logarithmic plot of $A_\infty - A_\tau$ *versus* τ (see *e.g.* Fig. 7b). The signal intensity A is a measure for the amount of the magnetization M.

It is not absolutely necessary to measure the equilibrium value A_∞. Determination of T_1 is already possible with the aid of the averaged signal intensities A_1 and A_2 of only two FT NMR spectra resulting from two sequences of 90° pulses having different intervals τ_1 and τ_2[7b].



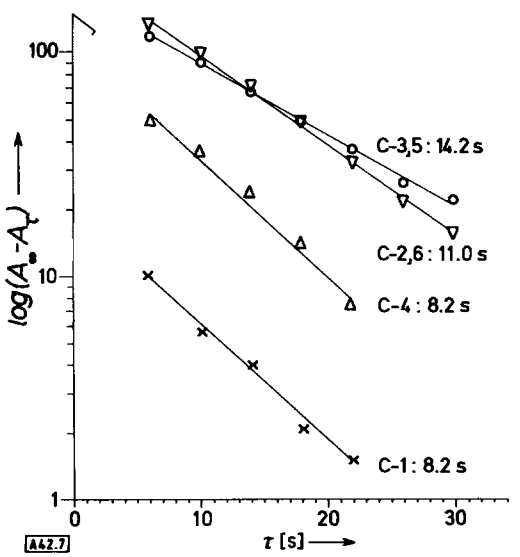


Fig. 7. Measurement of spin-lattice relaxation times T_1 of the ^{13}C atoms of bromobenzene, 85% solution in hexadeuteriobenzene at 28°C and 15.08 MHz. a) Series of measurements (progressive saturation; b) evaluation. T_1 is the reciprocal slope of the straight line.

In the "inversion recovery method" (Fig. 8)[6, 8–11], spin-lattice relaxation is initiated by a 180° pulse, which inverts the Boltzmann distribution of nuclear spins and hence the magnetization vector $\mathbf{M}_0$ (Fig. 8b). After a variable time τ, which determines the extent of spin-lattice relaxation, a 90° pulse is applied to initiate a nuclear induction signal F(t) which affords the NMR spectrum f(ν) on Fourier transformation.

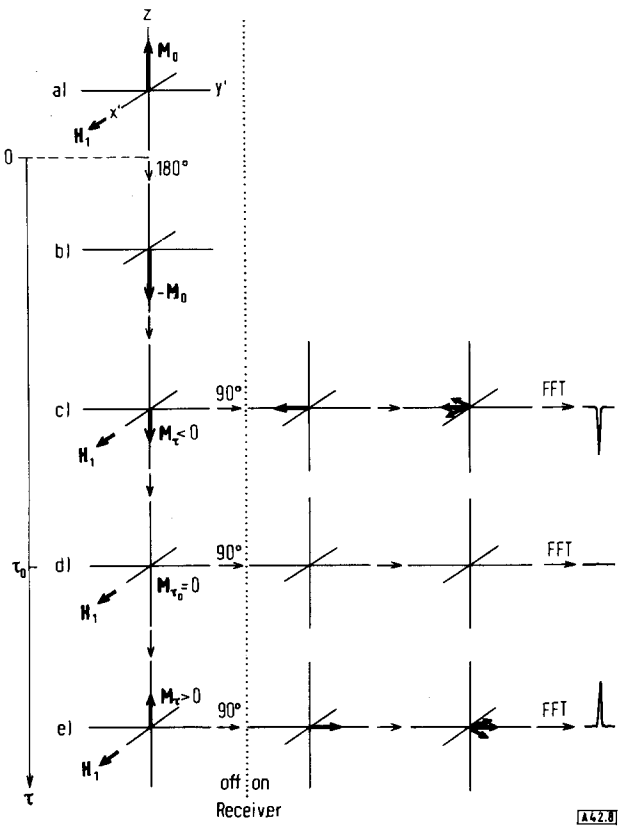

Fig. 8. Inversion recovery or 180°, τ, 90° method: pulse-controlled motion of the magnetization vector in a rotating coordinate system. FFT = fast Fourier transformation. a)–e), see text.

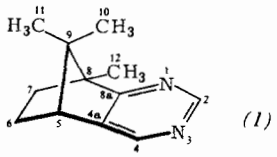
If it follows immediately upon the 180° pulse, the 90° pulse generates an inverted signal (Figs. 8c and 9). This becomes weaker and weaker with increasing interval τ owing to spin-lattice relaxation (Fig. 9). After passing through zero (at τ_0, Figs. 8d and 9), the intensity becomes positive and asymptotically approaches the equilibrium intensity A_∞ as τ increases (Figs. 8e and 9). The resulting series of spectra (Figs. 9a and 9b) are evaluated as for "progressive saturation" (*e.g.* in Fig. 7b), or more simply but less accurately from the interval τ_0, for which the intensity goes through zero, according to eq. (5).

$$T_1 = \tau_0/\ln 2 \qquad (5)$$

The signals following the 180°, τ, 90° pulse sequences usually have to be accumulated in order to increase the sensitivity of the method. One then has to wait after each sequence until all nuclei of the molecule have relaxed.

3. Mechanisms of ^{13}C Spin-Lattice Relaxation[2, 11–13]

In spin-lattice relaxation, the excited nuclei transfer their excitation energy to their environment. They do so *via* interaction of their magnetic vectors with fluctuating local fields of suffi-



(1)

acetylene, and carbonyl compounds (chemical shift anisotropy). The shielding constant σ[1] then possesses spatially oriented components, which can change with time if the molecule moves relative to the field $\mathbf{H}_0$. There arise fluctuating local fields which permit spin-lattice relaxation of the aniso-

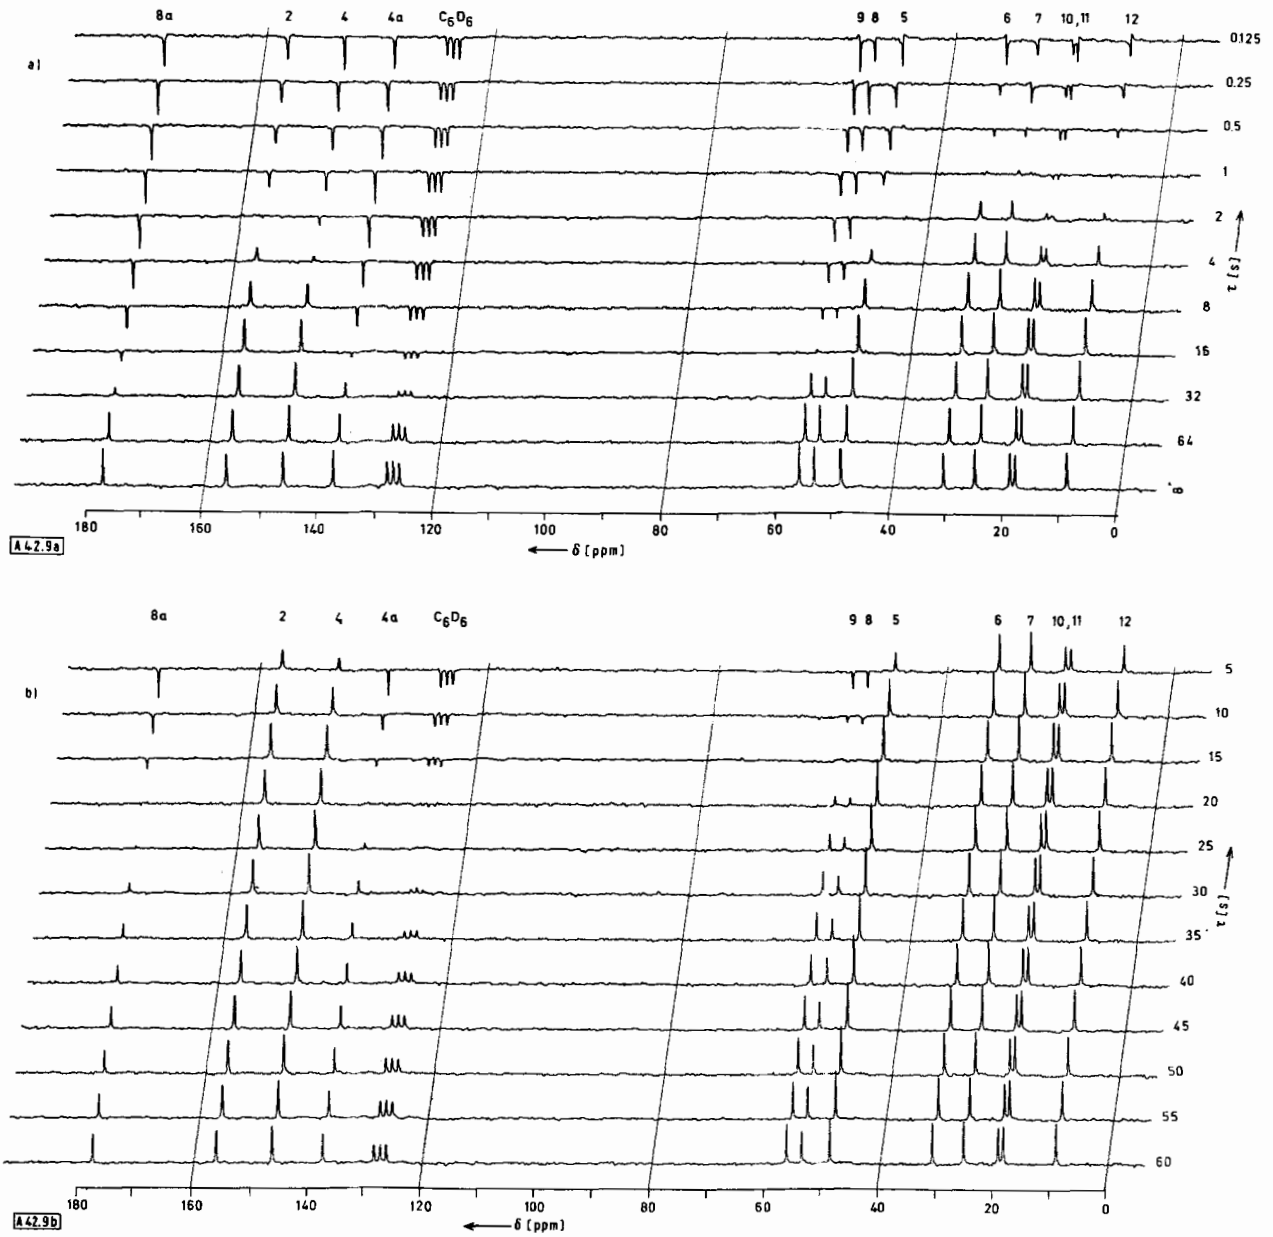


Fig. 9. Measurement of the spin-lattice relaxation times T_1 of the ^{13}C nuclei of 8,9,9-trimethyl-5,8-methano-5,6,7,8-tetrahydroquinazoline *(1)* in hexadeuteriobenzene at 40°C and 22.63 MHz: a) series of measurements with halved intervals; b) series of measurements with subtracted intervals. The series of measurements were evaluated by semilogarithmic plotting of $A_\infty - A_\tau$ *versus* τ (by analogy with Fig. 7b). The T_1 values obtained are given in Section 5.4.1.

cient strength and a fluctuation frequency of the order of the Larmor frequency of the nuclear spin type. Depending upon the atomic and electronic environment of a nucleus in a molecule and the motion of that molecule, there are four potential mechanisms (see Sections 3.1—3.4) contributing to spin-lattice relaxation of the nucleus.

3.1. Relaxation Resulting from Chemical Shift Anisotropy (CSA Mechanism)

The magnetic shielding of a nucleus arising from the surrounding electrons can be anisotropic, *e.g.* in derivatives of benzene, tropically shielded nucleus. A contribution of the CSA mechanism is apparent from a proportionality of the T_1 values measured to the square of the magnetic field strength H_0 applied. This contribution is usually negligible for the ^{13}C nuclei of organic molecules.

3.2. Relaxation by Scalar Coupling (SC Mechanism)

The spins of two proximate nuclei A and X in a molecule undergo coupling, *i.e.* the signals of A and X are split, but only if the lifetime of these nuclei in their nuclear magnetic energy levels (Fig. 2) is sufficiently large (scalar coupling).

If nucleus X relaxes very much faster than nucleus A then no signal splitting is observed. However, the fast relaxation of X generates fluctuating fields which in turn contribute to the relaxation of nucleus A. Quadrupole nuclei having $I \geqslant 1$, *i.e.* nuclei whose charge distribution is not spherically symmetrical, relax so fast, for instance, that they accelerate the relaxation of neighboring nuclei. The contribution of the SC mechanism, which can be recognized from a frequency and temperature dependence of T_1 is particularly large when the coupling nuclei precess with similar Larmor frequencies. This applies to ^{13}C and the quadrupole ^{79}Br. As a consequence ^{13}C nuclei bound to Br relax relatively fast ($CHCl_3$: $T_1 = 32.4$ s; $CHBr_3$: $T_1 = 1.65$ s)[12].

3.3. Relaxation by Spin Rotation (SR Mechanism)

If a molecule or molecular segment rotates, then the magnetic vectors of the bonding electron spins will also rotate. This gives rise to fluctuating local fields which can contribute to spin-lattice relaxation of the nuclei of a rotating molecule or a rotating alkyl group. This SR mechanism plays an important role in small symmetrical molecules (methane, cyclopropane) or in small segments of larger molecules (methyl groups). If the ^{13}C nuclei are not protonated (as in CS_2), spin rotation can even become the predominant relaxation mechanism. In such cases T_1 is found to decrease significantly with increasing temperature[12].

3.4. Relaxation by Internuclear Dipole-Dipole Interaction (DD Mechanism)

Each nuclear spin generates a local magnetic field. If two magnetic nuclei such as ^{13}C and ^{1}H are linked by a bond, then each of the nuclei will "feel" not only the external field $\mathbf{H}_0$, but also the local field of the other nuclear spin (internuclear dipole-dipole interaction). Now molecular motion is very rapid in liquids. Rotations of C—H bonds are correspondingly fast in dissolved organic molecules, and the orientations of ^{1}H and ^{13}C relative to $\mathbf{H}_0$ will be constantly changing. The resulting constantly imposed magnetic reorientation of the two nuclear spins generates fluctuating local fields which contribute to the relaxation of the nuclei. Most of the ^{13}C nuclei in organic molecules, especially those linked to hydrogen (CH, CH_2, CH_3) are relaxed predominantly by internuclear dipole-dipole interaction.

T_1 values of ^{13}C are usually measured with proton noise decoupling[6]. Thus, just one signal, not a multiplet, and consequently only one T_1 value results for each C atom of a molecule. During this decoupling, the protons transfer their excitation energy to the "lattice" primarily by internuclear DD interaction with ^{13}C and consequently forced ^{13}C relaxation. As a result, the population of the energetically more favorable ^{13}C spin states (Fig. 2) increases, and the ^{13}C signal intensities are enhanced on proton-decoupling more than would be expected from the multiplet intensities in the spectra recorded without decoupling (nuclear Overhauser enhancement, NOE[14]).

If ^{13}C relaxation proceeds exclusively by the DD mechanism, the NOE factor η_C, indicating the enhancement of the ^{13}C signal intensity on decoupling, is determined by the gyromagnetic ratios of ^{1}H and ^{13}C according to eq. (6)[14].

$$\eta_C = \frac{\gamma_H}{2\gamma_C} = 1.988 \tag{6}$$

NOE factors of this magnitude are indeed measured for numerous ^{13}C signals of organic molecules, especially for signals of CH and CH_2 carbon atoms, as shown for formic acid in Figure 10[15].

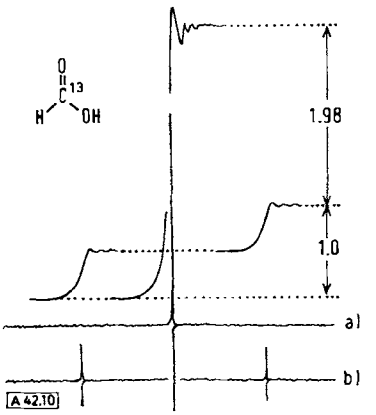

Fig. 10. Nuclear Overhauser enhancement on proton decoupling in the ^{13}C NMR spectrum of ^{13}C-enriched formic acid; a) decoupled, b) coupled (see ref. [15]).

NOE factors smaller than 1.988 indicate participation of other mechanisms in the spin-lattice relaxation of protonated ^{13}C nuclei. The percentage contribution of the DD mechanism can be ascertained from the measured NOE factor according to eq. (7).

$$\%\ \mathrm{DD} = \frac{\eta_C}{1.988} \times 100 \tag{7}$$

Accordingly, the time constant $T_{1(DD)}$ of the DD mechanism can be calculated from the measured η_C and T_1 values [eq. (8)].

$$T_{1(DD)} = T_1 \frac{1.988}{\eta_C} \tag{8}$$

Since the relaxation rates $1/T_1$ on cooperation of several relaxation mechanisms can be assumed to be additive, as shown in eq. (9),

$$\frac{1}{T_1} = \frac{1}{T_{1(DD)}} + \frac{1}{T_{1(SR)}} + \frac{1}{T_{1(SC)}} + \frac{1}{T_{1(CSA)}} + \cdots \tag{9}$$

the measured T_1 value and the value of $T_{1(DD)}$, accessible from the NOE factor η_C *via* eq. (8), can be used to calculate the time constant of a second relaxation mechanism, provided that no further mechanisms are operative. For instance, in benzene the DD mechanism is accompanied only by the SR mechanism. Benzene contains no quadrupole nucleus, and the contribution of the CSA mechanism to ^{13}C relaxation of liquid benzene is so small that the T_1 value can be shown to be independent of the magnetic field strength[16]. Then $T_{1(DD)}$ and $T_{1(SR)}$ can be determined from the experimental values of T_1 and η_C according to Scheme 1[11, 17–19].

Experimental data: Spin-lattice relaxation time $T_1 = 29.3$ s

NOE factor $\eta_C = 1.6$

Percentage of DD relaxation:

$\%\ DD = \eta_C \times 100/1.988 = 80\ \%$

Contribution of DD mechanism:

$T_{1(DD)} = T_1 \times 1.988/\eta_C = 29.3 \times 1.988/1.6 = 36.4$ s

Contribution of SR mechanism:

from $\frac{1}{T_1} = \frac{1}{T_{1(DD)}} + \frac{1}{T_{1(SR)}}$

it follows

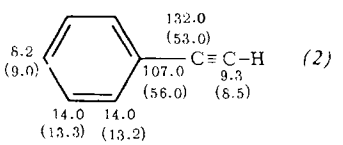
$$T_{1(SR)} = \frac{T_1\, T_{1(DD)}}{T_{1(DD)} - T_1} = \frac{29.3 \times 36.4}{36.4 - 29.3} = 150\ \text{s}$$

Scheme 1. Determination of $T_{1(DD)}$ and $T_{1(SR)}$ from T_1 and η_C measured for benzene.

3.5. Electron Spin-Nucleus Interactions and Consequences

During molecular motion, unpaired electrons generate much stronger fluctuating local fields than the nuclear spins, owing to their considerably greater magnetic moment. As a result, relaxation in the presence of unpaired electrons is dominated by electron spin-nucleus dipole-dipole interactions analogous to internuclear dipole-dipole interactions, especially for non-protonated ^{13}C nuclei. Thus smaller T_1 values are observed for paramagnetic compounds themselves, or in their presence, *e.g.* in solvents containing oxygen. Paramagnetic contaminants, including the oxygen nearly always dissolved in liquids, must therefore be removed if characteristic and reproducible T_1 values are to be measured.

Acceleration of relaxation of a nuclear spin by paramagnetic compounds is the greater the slower the nucleus relaxes. For example, the non-protonated carbon nuclei of phenylacetylene *(2)* in a normally prepared sample (20% in $(CD_3)_2CO$ as solvent) display T_1 values lower by a factor of two (numbers in parentheses)[*] than those for a degassed, *i.e.* largely oxygen-free, solution[18]. In contrast, the faster-relaxing protonated carbon atoms ($T_1 < 20$ s) are affected much less.



(2)

The pronounced relaxation acceleration observed for slowly relaxing nuclei in the presence of paramagnetic compounds is exploited in Fourier transform ^{13}C NMR spectroscopy. On use of the fast pulse sequences that are frequently necessary, the spin-lattice relaxation of "slow" ^{13}C nuclei can no longer follow excitation and the pertinent ^{13}C signals have low intensities. In such cases, addition of small amounts of relaxation accelerators such as radicals or transition metal salts to the sample amplify these signals[20].

It ist quite reasonable that a paramagnetic central ion should accelerate the relaxation of the C atoms of a ligand, and that the magnitude of the acceleration should depend upon the distance between the ion and the C atom being observed.

[*] Unless otherwise stated, the T_1 values in the formulas are given in s.

In such cases, T_1 measurements provide information about the distances between the paramagnetic ion and the ligand. Thus the spin-lattice relaxation times of the ^{13}C nuclei in α- and β-methyl D-glucopyranoside become selectively smaller on binding to the Mn^{2+} complex of the protein concanavalin A[21]. The experimental T_1 values show that the two glucopyranoside anomers retain their C1 chair conformation, but adopt different orientations on binding to the protein complex[21]. The non-reducing end of the α-anomer (C-3, C-4) approaches the Mn^{2+} ion most closely (average separation approx. 10 Å)[21].

4. Influence of Molecular Motion on Dipole-Dipole Relaxation

The majority of ^{13}C NMR measurements are performed with solutions or liquid samples with proton decoupling. Under these conditions, the ^{13}C spin-lattice relaxation times T_1 depend mainly upon the speed of molecular motion relative to ^{13}C Larmor precession. The overall tumbling of molecules in liquids cannot easily be resolved into components such as rotation, vibration, or translation. In order to derive a useful relation with the spin-lattice relaxation, the average time required by a molecule between two reorientations is taken as a measure of molecular motion. This time is referred to the unit circle, *i.e.* divided by 2π, and then designated the effective molecular correlation time τ_C[2, 13, 22–24]. If the molecules are rotating or vibrating, then one revolution or vibration per second (1 Hz) is equal to 2π rad/s. τ_C then corresponds to the average time required by the molecules to rotate through 1 radian.

Only those molecular motions whose "frequencies" lie in the region of the ^{13}C Larmor precession lead to rapid ^{13}C dipolar relaxation. The ^{13}C nuclei are known to precess with a frequency of $\nu_0 \approx 2.26 \times 10^7$ Hz or $\omega_0 = 2\pi\nu_0 \approx 1.42 \times 10^8$ rad/s at a field strength of $H_0 \approx 21$ kG. Most effective DD relaxation then becomes possible owing to molecular motions having correlation times of

$$\tau_C \approx \frac{1}{1.42 \times 10^8} \approx 7 \times 10^{-9}\ \text{s}$$

The correlation function $T_1 = f(\tau_C)$ shown in Figure 11 gives a minimum for such motion; however, this is true only for a field strength of 21 kG. At higher fields the minimum lies at shorter correlation times, *i.e.* the fastest DD relaxation requires even faster motion (Fig. 11).

Very slow molecular motion ($\tau_C > 10^{-9}$ s at $H_0 \approx 21$ kG) leads to an increase in T_1, while T_2 decreases (Fig. 11). The signals then broaden (line width at half-maximum intensity $\Delta\nu_{1/2} \sim 1/T_2$). Therefore the more sluggish macromolecules usually give poorly resolved ^{13}C NMR spectra having a band-like structure.

If the viscosity is sufficiently low, small and medium-sized molecules tumble very fast. The "frequencies" of their motion often even exceed the Larmor frequency $\omega_0 = 2\pi\nu_0$, and the correlation time consequently becomes shorter than the value $\tau_{C(min)}$ leading to the most effective DD relaxation ($\omega_0\tau_C \ll 1$). This situation corresponds to the declining branch of the correlation function (Fig. 11): T_1 and T_2 increase, are approximately equal, and the signals become sharper owing to $\Delta\nu_{1/2} \sim 1/T_2$ (motional narrowing). Under these circumstances

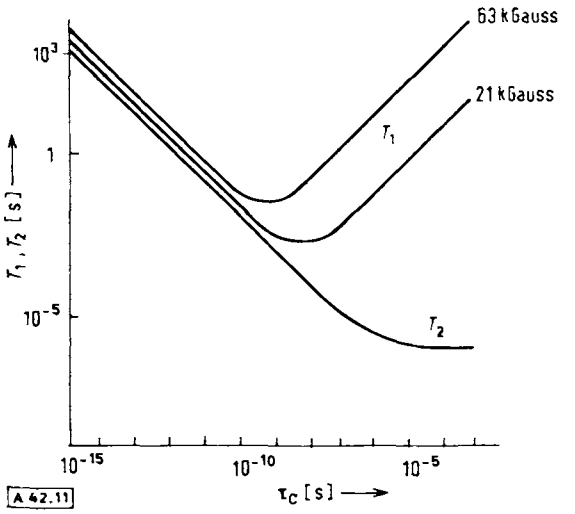


Fig. 11. Relation between the relaxation times T_1 and T_2 and the effective correlation time τ_C. In stronger magnetic fields the T_1 minimum shifts towards smaller correlation times, *i.e.* higher "frequencies" of molecular motion.

the dipolar relaxation time $T_{1(DD)}$ of a ^{13}C nucleus is shown in eq. (10) to be inversely proportional to the number N of directly adjacent protons and to the effective correlation time τ_C[10-13, 22-24].

$$\frac{1}{T_{1(DD)}} = \hbar^2 \gamma_C^2 \gamma_H^2 r_{CH}^{-6} N \tau_C \qquad (10)$$

$\hbar \equiv h/2\pi$; h is Planck's constant; γ_C and γ_H are the gyromagnetic ratios of ^{13}C and ^1H respectively; r_{CH} is C—H internuclear distance, usually about 1.09 Å.

5. Information Content of ^{13}C Spin-Lattice Relaxation Times

5.1. Degree of Alkylation and Substitution of C Atoms

Within rigid molecules the correlation time τ_C is equal for all carbon atoms. Moreover, the C—H bond lengths in nearly all organic compounds are approximately 1.09 Å, except for acetylenes ($r_{CH} \approx 1.06$ Å). Under these conditions, the spin-lattice relaxation time T_1 of a ^{13}C nucleus relaxing by the DD mechanism is shown by eq. (10) to depend solely upon the number N of directly bonded H atoms:

$$T_{1(DD)} = \text{const.}/N \qquad (11)$$

Neglecting the methyl carbons, which do not belong to the rigid skeleton of a molecule owing to internal rotation of the CH_3 groups (Section 5.4.1), the T_1 values for the CH and CH_2 groups of the same molecule give a ratio of 2:1; quaternary C atoms having $N = 0$ relax much more slowly:

$$T_{1(C)} \gg T_{1(CH)} > T_{1(CH_2)} \text{ and } T_{1(CH)} : T_{1(CH_2)} = 2:1 \qquad (12)$$

This relation (12) can be demonstrated for simple rigid molecules, *e.g.* for adamantane having $T_{1(CH)} = 17.0$ s and $T_{1(CH_2)} = 7.8$ s[25]. It is a valuable aid in the assignment of the ^{13}C NMR spectra of large molecules, particularly when signal crowding precludes clear distinction between singlets, doublets, and triplets in coupled or proton off-resonance decoupled ^{13}C NMR spectra[6].

5.2. Molecular Size and Relaxation Mechanisms

The T_1 values of the ^{13}C nuclei generally decrease with increasing molecular size if the molecules are rigid. Thus values in the ms or ns range are observed for the ^{13}C nuclei of the rigid backbone of macromolecules. Medium size molecules (C_{10}—C_{50}) typically show T_1 values between 0.1 s and 20 s. For very small molecules of high symmetry (dumbbells, tetrahedra, pyramids, small regular polyhedra), however, values of up to 100 s and beyond are possible. This applies, *e.g.* to methane derivatives except for bromides (effective SC relaxation, cf. Section 3.2), especially when the molecule contains no H atoms ($^{13}CCl_4$: $T_1 \approx 160$ s[6]). The reason is that the ^{13}C nuclei of very mobile small molecules relax partly, and sometimes even predominantly, by the less effective spin-rotation mechanism. The considerable contribution of SR mechanism to ^{13}C spin-lattice relaxation has already been demonstrated for benzene (Section 3.4).

The relation between molecular size, T_1, and the relaxation mechanisms is apparent from the homologous series of the cycloalkanes. T_1 and NOE data as well as the contributions of the DD and SR mechanisms accessible from these experimental values *via* eqs. (8) and (9) are listed in Table 1. The ^{13}C nuclei of cyclopropane relax almost as fast by spin-rotation as by the DD mechanism ($T_{1(SR)} \approx T_{1(DD)}$). However, in cyclobutane the DD mechanism predominates ($T_{1(DD)} < T_{1(SR)}$), and the carbon atoms of cyclohexane and its higher homologs relax exclusively by the DD mechanism ($T_{1(DD)} \ll T_{1(SR)}$)[26]. The $T_{1(DD)}$ values themselves decrease fairly regularly with increasing ring size (Table 1).

Table 1. Spin-lattice relaxation times T_1 and NOE factors η_C of the ^{13}C nuclei of cycloalkanes containing n carbon atoms [26].

n	T_1 [s]	η_C	DD [%]	$T_{1(DD)}$ [s]	$T_{1(SR)}$ [s]
3	36.7	1.0	50.2	72.2	74.6
4	35.7	1.4	70.5	50.7	121
5	29.2	1.52	76.5	38.2	124
6	19.6	1.9	95.5	20.5	447
7	16.2	1.96	98.5	16.4	> 1000
8	10.3	2.0	100	10.3	> 1000
10	4.7	2.0	100	4.7	> 1000

5.3. Anisotropy of Molecular Motion

Eq. (10) discussed in Section 4 is only valid if the motion of the molecules under study has no preferential orientation, *i.e.* is not anisotropic. Strictly speaking, this applies only for approximately spherical bodies such as adamantane. Even an ellipsoidal molecule like *trans*-decalin performs anisotropic motion in solution: it will preferentially undergo rotation and translation such that it displaces as few as possible of the other molecules present. This anisotropic rotation during translation is accounted for by the three diagonal components R_1, R_2, and R_3 of the rotational diffusion tensor. If the principal axes of this tensor coincide with those of the moment of inertia—as can frequently be assumed in practice—then R_1, R_2, and R_3 indicate the speed at which the molecule rotates about its three principal axes.

The connection between anisotropic molecular motion and nuclear relaxation was derived by *Woessner* as early as 1962[27]. Accordingly, the dipole-dipole relaxation time of a carbon

nucleus is a function of the diagonal components R_1, R_2, and R_3 of the rotational diffusion tensor and the cosines λ, μ, and ν of the angles assumed by the C—H bonds relative to the principal axes of this tensor.

$$1/T_{1(DD)} = f(R_1, R_2, R_3, \lambda, \mu, \nu) \quad (13)$$

If the position of the principal axes of the rotational diffusion tensor were known with respect to the molecular coordinates, then the motion of the molecule could be calculated from the measured relaxation times. With simple molecules, however, it is possible to interpret the T_1 values qualitatively in the sense of an anisotropic motion.

Thus the C—H nuclei in the *para* position of monosubstituted benzene derivatives relax faster than those in the *ortho* or *meta* positions (Table 2[18]). The reason for this behavior probably lies in a preferred rotation about the molecular axis passing through the substituent X and the *p*-carbon. In this motion, the *para* C—H bond does not change its direction relative to the field $\mathbf{H}_0$; fluctuating local fields can only arise at the *p*-C nucleus by rotations of the molecule perpendicular to the preferred axis. However, these less preferred rotations still have sufficiently large frequencies to effectively relax the *p*-C atom. The preferred rotation itself continuously changes the orientation of the *ortho* and *meta* C—H bonds with respect to $\mathbf{H}_0$, but too fast for effective dipolar relaxation of the *ortho* and *meta* carbon nuclei.

Table 2. Spin-lattice relaxation times T_1 of the ^{13}C atoms in benzene derivatives *(3)*

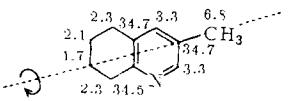
[a] Degassed.

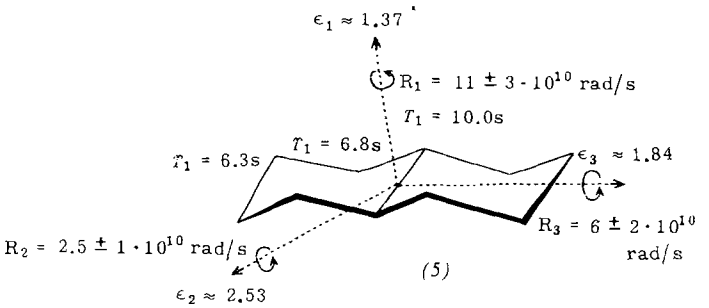
Preferred rotation is also conceivable in 3-methyl-5,6,7,8-tetrahydroquinoline *(4)*, *i. e.* about the axis passing through C-7, C-3, and the methyl group[29]. Accordingly, the C-7 methylene group exhibits a smaller T_1 value than all the other CH_2 groups of this molecule.



(4)

The first quantitative estimate of the rotational diffusion tensor for simple molecules was accomplished by *Grant et al.*[30]. By solving the Woessner equations, they were able to show, *e.g.* for *trans*-decalin *(5)* that the molecule rotates preferentially like a propeller, *i.e.* about the axis perpendicular to the plane of the molecule. The values given as a measure of the rotational frequencies do not correlate with the moments of inertia, but instead with the "ellipticities" of the molecule as defined by *Grant*. They are accessible from the ratios of the interatomic distances perpendicular to the axes of rotation, and can be adopted as a measure of the number of solvent molecules that have to be displaced on rotation about each of the three axes.

The greater the differences between the interatomic distances perpendicular to an axis, the greater will be the ellipticity ε, and the more slowly will the molecule rotate about that axis.

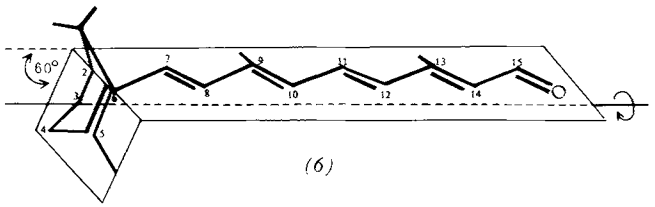


(5)

For less symmetric molecules one has to resort to computer programs[31] to solve the Woessner equations. The orientation of the rotational diffusion tensor is usually defined by assuming that its principal axes coincide with those of the moment of inertia tensor. This assumption is probably a good approximation for molecules of low polarity containing no heavy atoms, since under these conditions the moment of inertia tensor roughly represents the shape of the molecule.

The hitherto most sophisticated application of *Woessner*'s theory has been accomplished for all-*trans*-retinal *(6)* and its isomers[32]. After determination of the components of the rotational diffusion tensor in retinal *(6)* for various dihedral angles between the olefinic chain and the cyclohexene ring, the T_1 values could be calculated for each one of these conformations. The best agreement between experimental and calculated ^{13}C T_1 values results when the 5,6—7,8 dihedral angle

is 60°, in other words when the cyclohexene ring is bent by 60° towards the plane of the olefinic chain[32]. This is the first example of a conformation being determined by measurement of ^{13}C relaxation times.



(6)

Woessner's equations thus permit prediction of spin-lattice relaxation times for the dipole-dipole mechanism, which can be of help in the assignment of ^{13}C NMR spectra. Moreover, the calculations described can be applied to the problem of internal molecular motion.

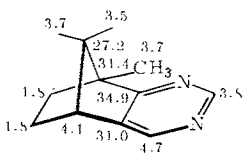
5.4. Internal Molecular Motion

5.4.1. Rotation of Methyl Groups

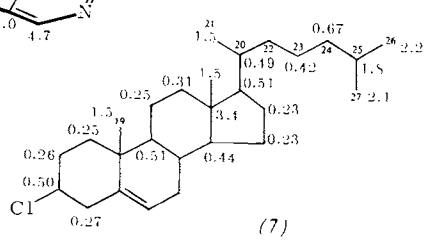
While the skeleton of large molecules is often relatively rigid, the methyl groups bonded to the backbone are highly mobile. Their rotation is thus much faster than the overall motion of the molecule ($\tau_{C(CH_3)} \ll \tau_{C(skeleton)}$). The methyl groups in proton-decoupled ^{13}C NMR spectra therefore exhibit NOE factors that are smaller than the typical value for pure dipolar relaxation (1.988), *i.e.* the signals are relatively weak. At the same time, the spin-lattice relaxation times of the methyl carbon nuclei are usually much longer than permitted by the ratio expected for the DD mechanism according to eq. (10), *i.e.*

$$T_{1(CH)} : T_{1(CH_2)} : T_{1(CH_3)} = 6:3:2$$

The experimental values found for all the methyl carbons in 3-methyl-5,6,7,8-tetrahydroquinoline *(4)*[29], 8,9,9-trimethyl-5,8-methano-5,6,7,8-tetrahydroquinazoline *(1)*[29], and cholesteryl chloride *(7)*[10] may be cited as examples. Lower intensities and longer T_1 values relative to the methylene and methine carbon nuclei thus frequently facilitate detection of methyl resonances in ^{13}C NMR spectra.



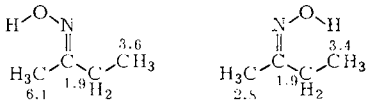
(1)



(7)

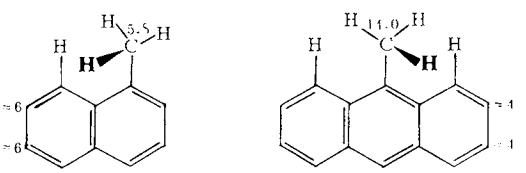
5.4.2. Intramolecular Steric Interactions

Steric interactions can hinder the rotation of methyl groups and thus accelerate methyl relaxation. It can be deduced, *e.g.* from the T_1 values of 2-butanone oxime *(8)*, that the CH_3 group *syn* to the OH group in the more stable *anti* isomer rotates faster ($T_1 = 6.1$ s) than that *anti* to the OH group in the more labile *syn* isomer ($T_1 = 2.8$ s)[33]. As an explanation it is assumed that the van der Waals interactions between the methyl and hydroxyimino groups, and between the methyl and methylene groups are of the same order of magnitude in the *anti* isomer. In contrast, the methyl group in the *syn* isomer adopts an energetically more favorable conformation involving one-sided interaction with the methylene group, with the result that its rotation is hindered[33].



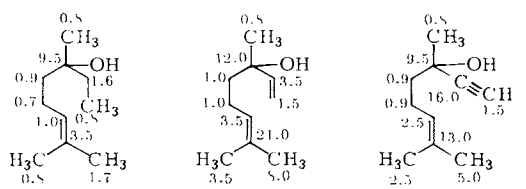
anti (8) *syn*

The T_1 values of the methyl carbon nucleus in 1-methylnaphthalene *(9)* and 9-methylanthracene *(10)* are interpreted accordingly: in *(9)* the *peri* proton forces a preferred conformation of the methyl group and thereby inhibits its rotation. On the other hand, in *(10)* two energetically equivalent *peri* H—CH_3 interactions occur, so that methyl rotation is less hindered because there is no preferred conformation[11].



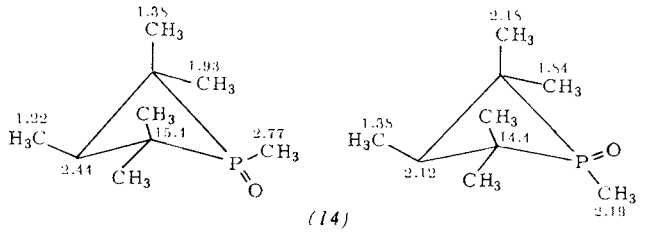
(9) (10)

In the series 6,7-dihydrolinalool *(11)*, linalool *(12)*, and 6,7-dehydrolinalool *(13)* the methyl C atoms of the terminal 1,1-dimethylvinyl group which are located *trans* to the alkyl group show widely differing absolute values of T_1; however, the ratio $T_{1(trans)} : T_{1(cis)}$ is always about 2:1. The rotation of the *trans* methyl groups therefore appears to be less hindered than that of the *cis* methyl groups[28].



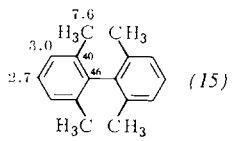
(11) (12) (13)

The T_1 values of the methyl carbon atoms of methylated phosphetanes *(14)* (in s) reveal that the methyl groups attached to C-2 and C-4, as well as to C-3, are subject to greater rotational hindrance than the P—CH_3 group[34]. Surprisingly, the pseudoaxial methyl groups sometimes relax more slowly than their pseudoequatorial counterparts, in spite of the stronger van der Waals repulsion expected for the former[34]. Shorter ^{13}C spin-lattice relaxation times thus do not always constitute proof of hindered rotation. Instead, the effects of methyl mobility found from relaxation time measurements must always be considered in relation to the motion of the entire molecule, which can vary markedly during a change of configuration.



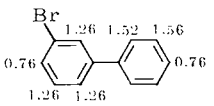
(14)

A more quantitative interpretation of methyl relaxation requires a knowledge of the motional anisotropy of the entire molecule. Thus the activation energy of methyl rotation can be estimated from T_1 data if the rotational diffusion tensor of the molecule, mentioned in Section 5.3, is known[31].

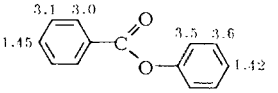


(15)

In biphenyl derivatives and related compounds, substituents can hinder rotation of the phenyl groups. Since phenyl rotation is anisotropic (Section 5.3, $T_{1(o,m)} > T_{1(p)}$), the ratio $T_{1(o,m)} : T_{1(p)}$ of the phenyl carbon nuclei will decrease on rotational hindrance. Hence, a smaller ratio, $T_{1(m)} : T_{1(p)}$ is found in 2,2',6,6'-tetramethylbiphenyl (15)[35] than in biphenyl itself owing to the methyl groups in the *o*- and *o'*-positions (Table 2). In 3-bromobiphenyl (16) and phenyl benzoate (17), the ratio $T_{1(o,m)} : T_{1(p)}$ is significantly larger for the unsubstituted phenyl and phenoxy ring than for the 3-bromophenyl and benzoyl ring[11].



(16)



(17)

5.4.3. Molecular Flexibility

Differing T_1 values for CH_3, CH_2, and CH carbon nuclei within a molecule can arise not only by methyl rotation or anisotropic molecular motion, but also from the segmental mobility of partial structures, even when the dipolar mechanism predominates. Thus the spin-lattice relaxation times of methylene carbon atoms in long alkane chains pass through a minimum at the middle of the chain. In the presence of heavy nonassociating substituents, the minimum is displaced somewhat towards the heavier end of the molecule, as is apparent for decane (18)[36] and 1-bromodecane (19)[37]. The molecular periphery is accordingly more flexible than the center.

(18)

(19)

The same behavior of C atoms having the same number of protons is also observed in the side chain of cholesteryl chloride (7)[10]: the methyl carbon atoms C-26 and C-27 relax more slowly than C-21, the methylene carbon C-24 slower than C-23, and the methine carbon atom C-25 slower than C-20. The mobility of the side chain thus increases with increasing distance from the steroidal skeleton.

In the case of such flexible molecules the correlation time τ_C can be different for each C atom. NT_1 is then no longer a constant as for rigid molecules according to eq. (11), but inversely proportional to the correlation time, as can be seen from eq. (10) (N is the number of protons bonded to a carbon atom).

$$NT_1 \propto 1/\tau_C \qquad (14)$$

The product NT_1 can therefore be interpreted as an internal molecular mobility parameter, although only qualitatively and with a certain amount of caution, as was apparent for a correlation of carbon-13 T_1 values with diffusion coefficients[36]. The increase in T_1 or NT_1 with increasing internal mobility is not only a valuable aid in the signal assignment of carbons having the same degree of substitution, but also offers the possibility of determining the geometry and internal dynamics in the liquid and dissolved states, particularly in the case of large molecules. ^{13}C-T_1 measurements with this aim have been performed on phospholipids, peptides, proteins, and synthetic polymers.

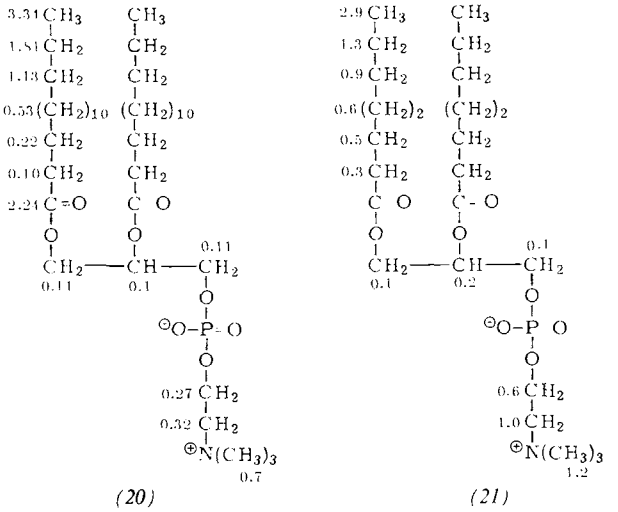
In dipalmitoyllecithin (20) the carbon nuclei relax increasingly slowly going from the central glycerol group to the ends of the two fatty acids, and thence to the tetraalkylammonium end of the choline group[38]. Thus the mobility becomes higher and higher starting from the glycerol skeleton, and proceeding along the fatty acid and choline chains to the molecular periphery. The terminal propyl groups of the fatty acid chains appear to undergo particularly rapid motion. If the fatty acid is shortened or a double bond is introduced, the chain assumes more internal flexibility. This may be seen from a comparison of data for dipalmitoyl-, dioctanoyl-, and dioleyllecithin (20), (21), and (22)[*]: the "central" methylene carbon atoms in (21) and (22) not only relax more slowly than in (20); their T_1 values also differ to a greater degree[39].

Together with proteins, phospholipids are the most important structural components of biological membranes. Since mobility of the lipid segments favors molecular transport through a membrane and thereby increases its permeability, a marked increase in T_1 along a lipid-fatty acid chain also reflects a more efficient molecular diffusion through the lipid layer of a membrane[40].

In methanol, all the α carbons of the cyclic decapeptide antibiotic gramicidin S relax at about the same rate ($T_1 \approx 135$ to 150 ms)[41]. Thus it follows that this molecule undergoes approximately isotropic motion in solution, and that the motion of the α carbons within the peptide ring is slower than the overall molecular motion itself. The mobility parameters NT_1 increase significantly in the order C-α, C-β, C-γ. Thus the side chains become increasingly mobile with increasing length. It is only in the case of the relatively rigid proline skeleton that all carbon nuclei have similar T_1 values. The phenylalanine side chain displays the anisotropy of rotation ($T_{1(o,m)} > T_{1(p)}$) usually encountered in phenyl derivatives. Since the axis of rotation passes through C-β and C-*p*, these

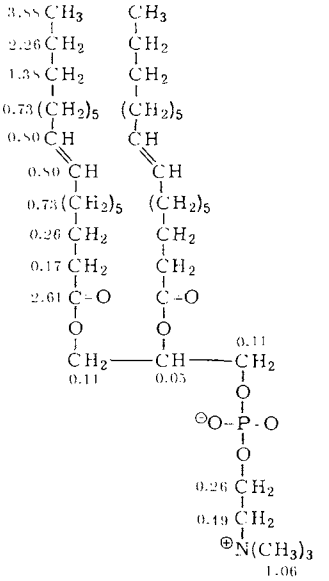
[*] Measured at 52 °C in D_2O solutions that had been treated with ultrasound.

C nuclei should show the same NT_1 values. The differences measured in practice ($NT_{1(\beta)} > NT_{1(p)}$) are possibly due to somewhat different C—H bond lengths (C-β: sp^3 C—H bond; C-p: sp^2 C—H bond)[41].



(20) (21)

η_C are independent of tacticity. These results indicate that internuclear dipole-dipole interaction predominates in the ^{13}C relaxation of polystyrene, but that the polymer chain is also relatively flexible[46].



(22)

In ribonuclease A ^{13}C spin-lattice relaxation of the carbonyl and α and β carbon atoms is slower in the denatured protein than in the native sample[42]. Apparently, the skeleton of this macromolecule becomes more flexible on denaturation, probably owing to conformational changes. However, the ε carbons of lysine in the native protein exhibit relatively large T_1 values which change only insignificantly on denaturation[42]. This behavior is attributed to a considerable segmental mobility of the lysine side chain (Table 3[42]).

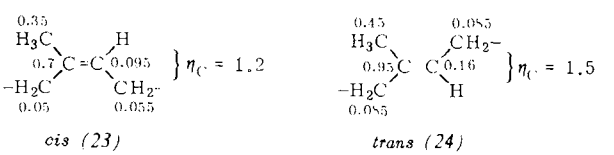
Table 3. ^{13}C spin-lattice relaxation times T_1 of ribonuclease A in aqueous solutions (conc. 0.019 M; 45 °C; 15.08 MHz; maximum deviation ±30 % [42]).

C Atoms	Native T_1 [s]	Denatured T_1 [s]
Carbonyl	0.416	0.539
α-C	0.042	0.120
β-C (Thr)	0.040	0.099
ε-C (Lys)	0.330	0.306

Indeed, ^{13}C spin-lattice relaxation times can also reflect conformational changes of a protein, *i. e.* helix-random coil transitions. This was demonstrated with models of polyamino acids[43–45], in which definite conformations can be generated, *e. g.* by addition of chemicals or by changes in temperature. Thus effective molecular correlation times τ_C of 24—32 ns were ascertained for the α carbons of poly(β-benzyl L-glutamate) in the more rigid helical form and about 0.8 ms for the more flexible "random coil" form[45], from spin-lattice relaxation times and the NOE factors.

A certain segmental mobility of the chains can also be deduced from ^{13}C-relaxation measurements on synthetic polymers. For instance, the ratio of the spin-lattice relaxation times for the methine and methylene carbon atoms of polystyrene is $T_{1(CH)} : T_{1(CH_2)} = 2:1$. The NOE factors η_C lie between 0.8 and 1.1, depending upon the solvent. Both parameters T_1 and

The carbons in amorphous *trans*-polyisoprene (*24*) relax more slowly and display larger NOE factors than the corresponding atoms of amorphous *cis*-polyisoprene (*23*)[47]. Apparently, the "frequency" of internal motion of these molecules lies in the region of the minimum of the correlation function (Fig. 11): the *trans* chain shows slightly shorter and the *cis* chain slightly longer correlation times τ_C; hence the *trans* isomer is more flexible[47]. If carbon black is added as filler to *cis*-polyisoprene (natural rubber), then no significant decrease in T_1 is observed; however, individual line broadening occurs for each carbon atom. The filler therefore appears to impair the mobility of some carbon atoms in the *cis* chain[47]. A situation can then be reached in which segmental motion in the chain becomes so slow that T_1 increases again while the spin-spin relaxation time T_2 continues to decrease (Fig. 11, to right of minimum) so that the signals become broader ($\Delta\nu_{1/2} \propto 1/T_2$).



cis (*23*) *trans* (*24*)

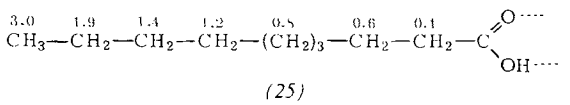
5.5. Association and Solvation of Molecules and Ions

Strong intermolecular interactions such as hydrogen bonds or ion-dipole pairs restrict the motion of molecules and pertinent molecular segments. These interactions increase the correlation time τ_C and accelerate the ^{13}C spin-lattice relaxation. Shorter ^{13}C relaxation times can therefore also indicate that such interactions are operative. The T_1 values of the C atoms of carboxylic acids, phenols, alcohols, and solvated molecular ions behave in this way.

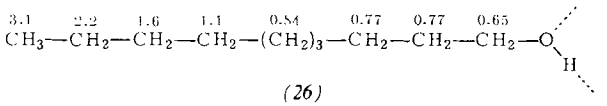
The ^{13}C nuclei in formic and acetic acid relax faster and show larger nuclear Overhauser enhancements than the ^{13}C

Table 4. T_1 and η_C values of ^{13}C nuclei in formic and acetic acid, and their methyl esters[48].

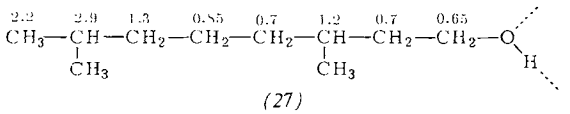
		T_1 [s] at 15 MHz	T_1 [s] at 25 MHz	η_C
Formic acid	—CH=O	10.3±1	10.1±1	2.0 ±0.15
Methyl formate	—CH=O	15.1±2	14.5±1.5	1.55±0.15
	—OCH_3	16.8±2	18.0±2	0.8 ±0.1
Acetic acid	>C=O	29.1±2.2	30.0±3.5	1.08±0.04
	—CH_3	10.5±0.5	9.8±0.6	1.4 ±0.13
Methyl acetate	>C=O	35.0±5	29.0±5	0.25±0.08
	—CH_3	16.3±1.3	17.4±1.5	0.63±0.08
	—OCH_3	17.0±1.5	18.3±2.1	0.93±0.04



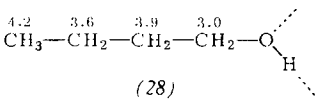
(25)



(26)

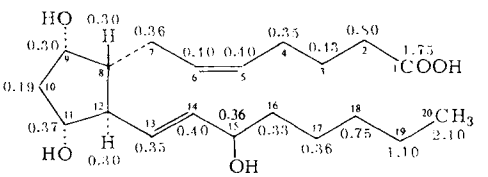


(27)

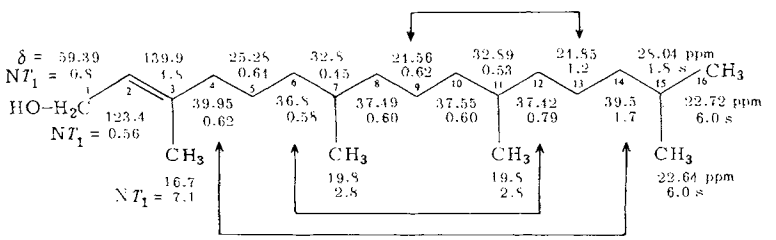


(28)

nuclei of the methyl esters (Table 4)[48]. Hence a methyl ester is more mobile than its parent carboxylic acid, which is dimerized *via* hydrogen bonding. It may also be seen that a pure DD mechanism operates in formic acid, owing to the directly bonded proton ($\eta_C = 2.0$), whereas spin rotation also contributes to ^{13}C relaxation in methyl formate ($\eta_C = 1.55$).



(29)



(30)

Owing to hydrogen bonding, the ^{13}C nuclei of phenol relax faster than the corresponding nuclei of nonassociating benzenes (Table 2). – In decanoic acid *(25)*[37] and 1-decanol *(26)*[37, 49], ^{13}C spin-lattice relaxation becomes progressively slower on going from the associating COOH or CH_2OH group to the hydrophobic end of the molecule. Whereas the hydrocarbon part becomes increasingly mobile towards the exterior, the polar end is rooted by hydrogen bonding. This behavior is also observed in branched alcohols and those having shorter chains such as 3,7-dimethyl-1-octanol *(27)*[28] and 1-butanol *(28)*[11], although it is less pronounced in such cases. In very small alcohols like methanol[50] relaxation is considerably slower ($T_1 = 17.5$ s) as a result of the much faster molecular motion.

In prostaglandin $F_{2\alpha}$ *(29)*, the T_1 values of ^{13}C nuclei in the alkyl side chain increase more significantly towards the periphery than in the associating carboxylic acid chain, thus confirming the assignment of the closely crowded CH_2 signals of the chains in the ^{13}C NMR spectrum[37]. Generally, the increased mobility on going from the associating end of the molecule, and the concomitant increase in T_1 or NT_1 [eq. (14)] can be utilized in signal assignment. Thus in phytol *(30)*, the diterpene alcohol component of chlorophyll, the signals of the carbon atom pairs 4 and 14, 6 and 12, and 9 and 13 defy unequivocal assignment, owing to very similar shifts and equal multiplicities (CH_2 groups). However, the C atoms 12, 13, and 14, which are more removed relative to the associating end of the molecule, undergo faster motion, and the NT_1 values are therefore larger. Signal assignment then follows readily[51].

In weakly solvating solvents interionic interactions between organic molecular ions can lead to fixation of the ionic end of the molecule. The T_1 values of pertinent and neighboring ^{13}C nuclei become smaller. In contrast, strongly solvating solvents such as water and alcohols inhibit interionic interaction and lead to an enhanced mobility of the ions solvated by ion-dipole interactions, and ^{13}C spin-lattice relaxation is consequently slower in such solvents. Thus the T_1 values of *n*-butylammonium trifluoroacetate increase with the polarity of the solvent, as shown in Table 5[11].

Table 5. Solvent dependence of spin-lattice relaxation times of the ^{13}C atoms in *n*-butylammonium trifluoroacetate [11].

Solvent	Conc. [wt.-%]	T_1 [s] CH_3—	—CH_2—	—CH_2—	—$\overset{\oplus}{N}H_3$ $CF_3COO^{\ominus}$
1,4-Dioxane	20	3.35	1.95	1.54	0.88
CH_2Cl_2/acetone	24	3.90	2.41	1.67	0.91
CF_3COOH	15.4	3.98	3.12	2.30	1.54
	28.2	3.46	2.13	1.50	0.97
CD_3OD	20	6.00	5.35	4.52	3.10
D_2O	20	5.00	5.00	4.26	3.75

5.6. Determination of Quadrupole Relaxation Times and Coupling Constants from ^{13}C Spin-Lattice Relaxation Times

While the nuclei ^1H and ^{13}C relax predominantly by the DD mechanism, relaxation of a quadrupole nucleus such as deuterium essentially involves fluctuating fields arising from interaction between the quadrupole moment and the electrical field gradient at the quadrupole nucleus[52]. If the molecular motion is sufficiently fast (decreasing branch of the correlation function, Fig. 11), the ^2H spin-lattice relaxation time is inversely proportional to the square of the quadrupole coupling constant $e^2qQ/\hbar$ of deuterium and the effective correlation time[52]:

$$\frac{1}{T_1} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_C \qquad (15)$$

Since ^{13}C and ^2H relaxation are the consequence of intramolecular interactions, the relaxation times T_1 of ^{13}C and ^2H within a given molecule can be subjected to direct comparison according to eqs. (10) and (15):

$$\frac{T_1(^{13}C)}{T_1(^2H)} = \frac{3}{8}\frac{r^6(e^2qQ/\hbar)^2}{N\hbar^2\gamma_C^2\gamma_H^2} \qquad (16)$$

By using the numerical values for the constants (*e.g.* $r_{CH} \approx 1.09$ Å and $e^2qQ/\hbar \approx 170$ kHz for an sp^3 C—H bond) a simple linear relation between the ^{13}C and ^2H relaxation times is obtained:

$$T_1(^{13}C)/T_1(^2H) = 19.9/N \quad (N = 1, 2, 3 \text{ for } CD, CD_2, CD_3) \qquad (17)$$

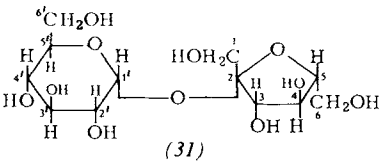
Knowledge of the T_1 values for deuterium thus allows prediction of the ^{13}C relaxation times and *vice versa*[53]. On the other hand, if these data are known the deuterium quadrupole coupling constants can be determined according to eq. (16). Agreement between calculated and experimental quadrupole coupling constants is good, any pronounced deviations indicating that alternative relaxation mechanisms are operative. For instance the quadrupole coupling constant calculated for the terminal acetylene deuteron of phenylacetylene according to eq. (16) is much too large (calc. 254 kHz; exp. 215 ± 5 kHz). This is explained in terms of the chemical shift anisotropy in phenylacetylene[53].

6. Medium and Temperature Effects

Any change in the medium, *i.e.* the solvent, the concentration, the pH value, and the temperature will affect the mobility of the molecules and hence also the spin-lattice relaxation. However, few systematic studies have so far been performed on the concentration dependence or on the precise influence of the macroscopic viscosity, the main reason in the case of ^{13}C lying in the need for highly protracted measurements in concentration studies. Moreover, little is known about the pH dependence of ^{13}C relaxation[54]. Nevertheless, the concentration dependence of ^{13}C relaxation is apparent in the case of saccharose (Table 6)[10], and intramolecular hydrogen bonds can be detected by measuring the concentration dependence of T_1[55]. Solvating solvents appear to facilitate molecular motion, as has already been shown for *n*-butylammonium trifluoroacetate (Table 5)[11].

The ^{13}C nuclei of molecules whose protons undergo exchange relax at different rates in H_2O and D_2O solution. Thus T_1 for the carbonyl carbon of acetamide is 72 s in D_2O, but only 37 s in H_2O[55]. In this context, the influence of paramagnetic impurities should again be mentioned. Traces of paramagnetic ions (*e.g.* Cu^{2+}) no longer detectable by the usual analytical techniques can drastically lower the ^{13}C relaxation times of complexing substrates (*e.g.* amino acids).

Table 6. ^{13}C spin-lattice relaxation times T_1 [s] of saccharose *(31)* in H_2O and D_2O at 42 °C [10].



(31)

	C Atom	0.5 M D_2O	0.5 M H_2O	2.0 M H_2O
C	2	6.0	7.8	2.6
CH	1′	0.54	0.69	0.16
	3	0.51	0.64	0.16
	4	0.52	0.49	0.16
	5	0.58	0.61	0.16
	3′	0.61	0.73	0.15
	2′	0.53	0.69	0.17
	5′	0.60	0.70	0.16
	4′	0.59	0.60	0.17
CH_2	1	0.48	0.40	0.12
	6	0.35	0.30	0.15
	6′	0.34	0.37	0.13

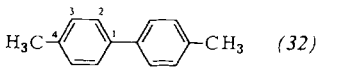
Most previous publications on the temperature dependence of ^{13}C relaxation[56–65] are concerned with simple molecules such as carbon disulfide, iodomethane, and acetonitrile[56–60,63,64]. Any interpretation of the temperature dependence of relaxation times requires a knowledge of the relative contributions of dipole-dipole and spin-rotation relaxation, as the former becomes progressively slower and the latter steadily faster with increasing temperature. In special cases, such as that of cyclopropane[66], the effects of both contributions can almost cancel each other.

The temperature dependence of dipole-dipole relaxation is that of the correlation time, which is usually written in the form of an Arrhenius equation (18):

$$\tau_C = \tau_{C_0} \times e^{\frac{\Delta E}{RT}} \qquad (18)$$

Plotting the logarithm of the dipole-dipole relaxation time $T_{1(DD)}$ *versus* the reciprocal temperature therefore gives an activation energy ΔE for molecular reorientation, which is of the order of 2 kcal/mol for most of the molecules hitherto studied. In the case of 4,4′-dimethylbiphenyl (32) a value of 4 kcal/mol was found from the temperature dependence of T_1 for C-2 and C-3 (Fig. 12)[35]. For T_1 of the methyl carbon atom the Arrhenius plot is curved at lower temperatures since the internal rotation of this group is then probably faster than the overall motion of the molecule.

The temperature dependence of the SR component is more complicated. An Arrhenius relation can again be formulated for the correlation time of spin rotation; however, this function additionally contains a linear temperature term.



(32)

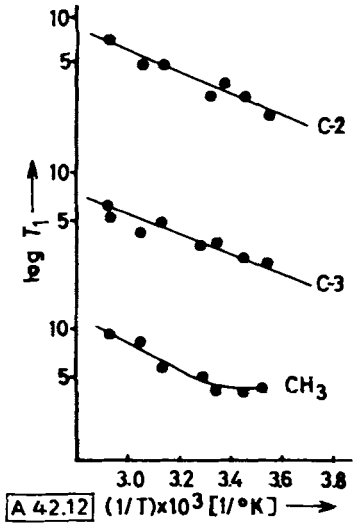


Fig. 12. Temperature dependence of spin-lattice relaxation times T_1 of protonated ^{13}C nuclei in 4,4'-dimethylbiphenyl (32) [35].

7. Outlook

^{13}C relaxation measurements will assume a firm place in the methodology of nuclear magnetic resonance. The principles of the measuring technique have been established[6, 67] and the specific sources of error recognized[67]. On the other hand, the relevant theory is still in a state of flux[68], particularly with regard to the interpretation of T_1 values in terms of the anisotropy of molecular motion and segmental mobility. The organic chemist will profit from relaxation time measurements as a tool for assigning ^{13}C NMR spectra whenever decoupling experiments and shift comparisons fail owing to signal overcrowding. The study of events involving intermolecular motion, such as complexation[69] and micelle formation[70] can now utilize the ^{13}C spin-lattice relaxation time as a new probe. Temperature dependent measurement of T_1 will certainly also be developed into an additional method for the elucidation of internal dynamic processes of molecules. Finally, such measurements will find wide application in biochemistry, for example in active site determination in biomacromolecules[21], the study of lipid double layers[39], or the determination of peptide conformations[71]. Literature for further study is cited in references[72–114].

Investigation of Enzyme Mechanisms with Nucleoside Phosphorothioates

By Fritz Eckstein[*]

Nucleoside phosphorothioates are modified nucleotides in which an oxygen atom bound to a phosphorus atom has been replaced by a sulfur atom. These compounds are suitable for the investigation of enzyme mechanisms because, although they are bound by enzymes in many cases just as well as the natural substrate, the enzymatic reactions very often proceed considerably more slowly. Since nucleoside thiophosphate *O*-esters exist as diastereomers these compounds can be used in suitable cases for information about the stereochemistry of enzymatic reactions.

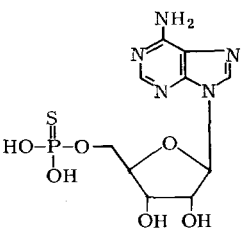
1. Introduction

The rapid development of molecular biology has led, *inter alia*, to the isolation of an ever increasing number of enzymes. Although the functions of these enzymes are known, the understanding of the underlying reactions is often at best fragmentary. It is, therefore, not surprising that many groups are engaged in investigations of enzyme mechanisms.

When the influence of the natural substrate on the enzyme is to be investigated, difficulties can arise from the fact that the enzyme turns over the substrate. Although one can find conditions, *e. g.* by changing the pH and lowering the temperature, under which the rate of reaction is greatly reduced and for the time of the observation very small, one can never completely exclude the possibility that the properties of the enzyme such as its conformation have been drastically affected and that the information thus gained can only be applied with reservation to the proteins' behavior under optimal conditions.

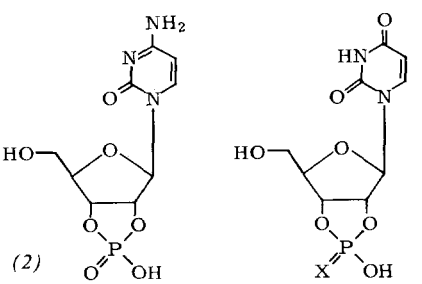
In such cases analogs of the substrate which can be recognized by the enzyme, *i. e.* which can be bound at the substrate binding site, but which cannot be turned over, have been very useful as competitive inhibitors. Using these it has been possible for instance to determine the number of substrate binding sites or conformational changes of an enzyme during the binding of the substrate or an analog as well as to interrupt enzymatic multiple substrate reactions at certain steps. An example for the latter is the utilization of the β,γ-CH_2-analog of guanosine triphosphate (GTP) in protein biosynthesis[1]. As components of the crystalline complex, competitive inhibitors can also be of great value for the determination of the substrate binding site of an enzyme in its crystalline form[2].

Investigations with such competitive inhibitors can always be criticized on the grounds that transformation of the substrate into a non-reactive analog represents such a modification that the experimental results obtained cannot be necessarily extrapolated to the natural substrate-enzyme system. Such investigations will, therefore, be of more value when the alteration in the substrate molecule is small, *i. e.* when the inhibitor is as similar to the substrate as possible. The following discussion will be restricted to a selection of enzyme systems which use nucleotides either as substrates or effectors. It will demonstrate to what extent a class of nucleotide analogs, namely nucleoside phosphorothioates (nucleoside thiophosphates), can be of help in investigations of enzymes. In these analogs an oxygen atom bound to a phosphorus atom is replaced by a sulfur atom; this review will concern itself primarily with analogs in which the oxygen atom that is replaced is not part of an ester bond. The analog of adenosine 5'-phosphate has the structural formula *(1)*.



(1), AMPS

The replacement of such an oxygen atom by a sulfur atom represents a minimal structural change in the natural nucleotide. The base and sugar components as well as the number of negative charges remain completely unchanged. The first dissociation constant is slightly reduced[3]—by about 0.5 p*K* units—from about 5.20 to about 4.70 so that there are no differences to normal nucleotides when working in the neutral pH region or above. The small structural change between nucleoside phosphates and the corresponding nucleoside phosphorothioates is best demonstrated by comparing (Table 1) cytidine 2',3'-cyclic phosphate *(2)*[4] and uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3)*[5] (see Section 3.1) whose structures have been determined by X-ray analysis. Similar values for distances and angles have also been found for a Mg^{2+}-pyridine complex of *O*,*O*-diethylphosphorothioate[6].



(2)

(3), X = S
(4), X = O

X-ray structural analysis of the phosphorothioates shows that the negative charge is localized on the oxygen and not on

the sulfur. The electronegativities of oxygen and sulfur are 3.5 and 2.5, and the van-der-Waals radii 1.40 and 1.85, respectively[7]. The difference in chemical reactivity can be seen from a comparison of the apparent first order rate constants of the hydrolysis of uridine 2',3'-cyclic phosphate *(4)* and uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3)*[8] with uridine 2'(3')-phosphate and uridine 2'(3')-phosphorothioate, respectively (Table 2).

Table 2. Apparent first order rate constants k [$10^{-3}s^{-1}$] of uridine 2',3'-cyclic phosphate *(4)* and uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3)*.

	k in 0.15 N $HClO_4$	k in 0.25 N KOH
Cyclicphosphate *(4)*	2.3	1.2
Cyclicphosphorothioate *(3)*	0.011	0.2

The comparatively large change in chemical reactivity makes these compounds interesting for the investigation of nucleotide dependent enzymes. Nucleoside phosphorothioates meet the condition stipulated above for the smallest possible structural difference between substrate analog and substrate. Nucleoside phosphorothioates also appear attractive from another point of view. *O*-Esters of such compounds where the ester group differs from the nucleoside exist as diastereomers. The investigation of the interaction of separate diastereomers with an enzyme should give some insight into the binding of the nucleotide and, in favorable cases, a detailed description of the mechanism of the enzymatic reaction.

Another advantage is that thiophosphate analogs can be synthesized not only of nucleoside monophosphates but also of nucleoside di- and triphosphates with the sulfur localized on the α-, β- or γ-phosphorus atom. Such analogs should be suitable for the investigation of ATP-dependent enzymes.

In this article nucleoside phosphorothioates, -thiodiphosphates and -thiotriphosphates will be discussed separately. In a thorough and excellent review article on ATP-analogs[9] *Yount* has summarized the results of studies with other ATP analogs.

2. Nucleoside Phosphorothioates

The original synthetic preparation of nucleoside 5'-phosphorothioates, the reaction of nucleosides with tris(1-imidazolyl)-phosphane sulfide[10], has been replaced by the reaction of nucleosides with $PSCl_3$[11]. Purine nucleoside 5'-phosphorothioates can be isolated by precipitation as the barium salts which require no further purification over an ion exchanger[12]. ^{35}S-labeled compounds can also be synthesized in this way.

While nucleoside 5'-phosphorothioates are not or are only extremely slowly degraded by phosphatases, they are competitive inhibitors for these enzymes[3], *i.e.* they bind to the substrate binding site. It was this observation which led to the further development of this class of compounds. [^{32}P]AMP is degraded about 2000 times faster than [^{35}S]AMPS by alkaline phosphatase from calf intestine and *E. coli* [see *(1)*][12]. It is known that the rate of hydrolysis of a phosphate ester by alkaline phosphatase is independent of the ester group; esters of alcohols or nucleosides are degraded just as fast as those of phenols[13]. This does not seem to be the case for esters of thiophosphoric acid.

Nucleoside 5'-phosphorothioates are degraded 2000 times more slowly than the corresponding phosphate[12]. However, *p*-nitrophenyl-[14], 4-methylumbelliferyl-[15] and *p*-phenylazophenylphosphorothioate[16] are degraded 100 times, about 300 times and about 200 times, respectively, more slowly than the corresponding phosphate esters, which themselves are all hydrolyzed at similar rates.

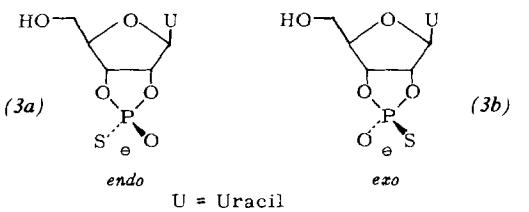
This large difference between phenolic esters of thiophosphoric acid and nucleoside phosphorothioates suggests that the rate determining steps of hydrolysis are possibly different. On hydrolysis of phosphate esters a phosphorylated enzyme intermediate is formed. Whether the formation or the subsequent hydrolysis of this phosphorylated intermediate is rate determining is still in dispute. Investigations on the mechanism of hydrolysis of phosphorothioates might therefore provide clues to enlarge our understanding of this enzyme.

The interactions of adenosine 5'-phosphorothioate *(1)* with enzymes other than phosphatases have been described by *Murray* and *Atkinson*[11]. Also in enzyme reactions where no cleavage of the ester bond occurs, the analog often reacts more slowly than the natural substrate. Thus, adenosine 5'-phosphorothioate is only a poor substrate for myokinase and adenylate desaminase. In the latter system the K_m values for the analog and for AMP are quite similar but the V_{max} values differ by a factor of about 10. Adenosine 5'-phosphorothioate is as active as AMP as an activator for phosphorylase b.

3. Cyclic Nucleoside Phosphorothioates

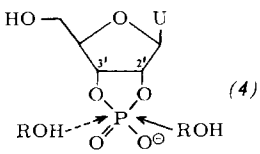
3.1. Uridine 2',3'-*O*,*O*-Cyclic Phosphorothioate *(3)*

Because of the chiral phosphorus this compound exists as the two diastereomers *(3a)* and *(3b)*. Their triethylam-



monium salts can be separated by crystallization[5]. The *endo* (with respect to the ribose ring and sulfur) isomer can be crystallized. Its structure and configuration were determined by X-ray structural analysis. Both isomers are cleaved by RNase A but have different affinities for this enzyme (K_m-*endo* = 6.2×10^{-3} mol/l; K_m-*exo* = 50×10^{-3} mol/l)[8].

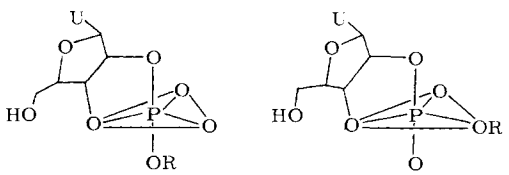
These isomers seemed to be suitable for the elucidation of a disputed step in the hydrolysis catalyzed by RNase A. RNase A hydrolyzes simple esters and polymers of pyrimidine nucleoside 3'-phosphoric acid by a two-step mechanism[2]. In the first, easily reversible step a pyrimidine nucleoside 2',3'-cyclic phosphate is formed by attack of the 2'-OH group on phosphorus (transesterification); in the second step the cyclic ester is hydrolyzed to a pyrimidine nucleoside 3'-phosphate by attack of a water molecule (hydrolysis). The alcoholysis or hydrolysis of uridine 2',3'-cyclic phosphate *(4)* can serve as an example to demonstrate that in principle the alcohol or the water can attack from the opposite side of the leaving group (2'-OH) (in-line, broken arrow) as well as from the same side (adjacent) (solid arrow)[17].



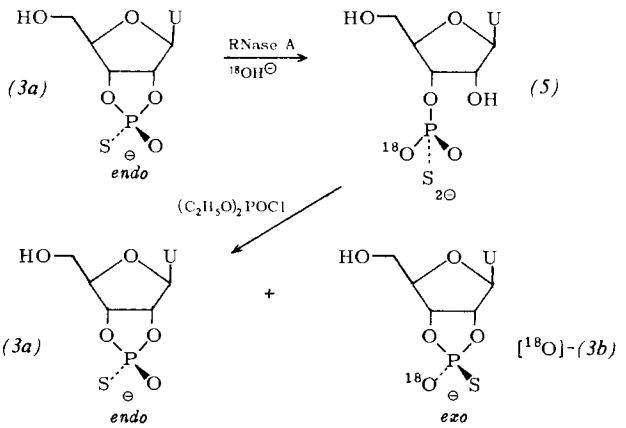
(4)

U = Uracil

Generally it is assumed that the hydrolysis of a five-membered cyclic phosphate ester proceeds *via* a pentacoordinated phosphorus intermediate where the incoming nucleophile as well as the leaving group are in the apical positions of a trigonal bipyramid[18]. The five-membered ring must occupy an apical and an equatorial position, so that the leaving group can always be in an apical position, although this sometimes requires a prior pseudorotation. The adjacent mechanism requires pseudorotation of the pentacoordinated phosphorus intermediate whereas the in-line mechanism does not[19].



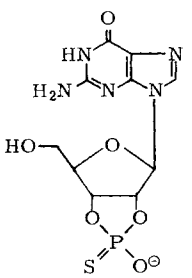
With the known absolute configuration of the diastereomers of uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3)* it should be possible to decide which of the two mechanisms operates. Evidence for the hydrolytic step was obtained by reaction of the *endo* isomer *(3a)* with the enzyme in ^{18}O-containing water. The hydrolysis product, [^{18}O]uridine 3'-phosphorothioate *(5)*, was chemically recyclized to uridine cyclic phosphorothioate (in-line mechanism) and the diastereomers *(3a)* and *(3b)* separated by crystallization and analyzed for their ^{18}O-content[19]. In an in-line mechanism the ^{18}O should be in the *exo* isomer *(3b)*, in an adjacent mechanism in the *endo* isomer *(3a)*. In fact, all the ^{18}O was contained in the *exo* isomer *(3b)*. The second step of the enzymatic hydrolysis can therefore be explained by an in-line mechanism. For investigation of the transesterification step the *endo* isomer *(3a)* was allowed to react with 20% aqueous methanol in the presence of the enzyme to give methyl uridine 3'-thiophosphate. The absolute configuration of this crystallized ester was determined by X-ray structural analysis[20, 21]. In an in-line mechanism this methyl ester should have the *R* configuration, whereas in an adjacent mechanism it should have the *S* configuration. The substance isolated from the enzymatic reaction had the *R* configuration. *Usher* investigated the transesterification reaction of *endo*-uridine 2',3'-cyclic phosphorothioate *(3a)* with cytidine. The product was cleaved under alkaline conditions (in-line), the uridine 3'-phosphorothioate *(5)* thus obtained again undergoing cyclization to uridine cyclic phosphorothioate; the configuration of the isomer obtained was established by crystallization and NMR spectroscopy. This result is also compatible with an in-line mechanism[22].



To what extent can results obtained with phosphorothioates be used to draw conclusions about the mechanism of hydrolysis of the natural substrate, the phosphate? Since the K_m value of the analog is identical with that of the phosphate and the V_{max} value of the analog differs only by a factor of five from that of the phosphate (since the lower value is also to be found on alkaline hydrolysis of the phosphate, it can therefore be explained simply by the phosphorothioates' lower chemical reactivity), there is no reason to believe that the cleavage of both compounds does not follow the same mechanism.

3.2. Guanosine 2',3'-*O*,*O*-Cyclic Phosphorothioate

In analogy to uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3a)*, *(3b)*, guanosine 2',3'-*O*,*O*-cyclic phosphorothioate *(6)* also exists as the *endo* and *exo* isomers[23]. However, attempts to separate the isomers have so far failed.



(6)

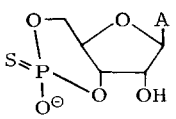
Identification of the isomers was accomplished by comparison of their ^{31}P-NMR spectra with those of the uridine derivatives *(3a)* and *(3b)*, where an assignment of the configuration to the signals was possible. In the reaction of the mixture of diastereomers of *(6)* with RNase T1 in water and methanol only the *endo* isomer undergoes reaction. The chemical shift ($\Delta\delta$) of the methyl guanosine 3'-thiophosphate obtained during the transesterification is just as large as that of the methyl uridine 3'-thiophosphate of the *R* configuration which was

obtained from the reaction of *endo*-uridine 2',3'-*O*,*O*-cyclic phosphorothioate *(3a)* and RNase in aqueous methanol. One can therefore conclude that RNase T1 also follows the in-line mechanism, at least for the transesterification step. Since the chemical shift of the isomeric methyl esters differs only very little, however, this result is not quite as satisfactory as that obtained with RNase A.

3.3. Adenosine 3',5'-*O*,*O*-Cyclic Phosphorothioate

Adenosine 3',5'-cyclic phosphate (cAMP) is apparently one of the most versatile low molecular weight compounds in biology[24]. Apart from the numerous regulatory functions which it exerts and which are of importance for the biochemist, this compound is also of interest for the mechanistically oriented chemist. It is rather stable against alkaline and acid hydrolysis but is degraded in the cell by a specific phosphodiesterase. The mechanism of this enzymatic hydrolysis is of particular interest.

As discussed in connection with uridine cyclic phosphorothioate *(3)* (Section 3.1) the hydrolysis of cyclic phosphate esters proceeds *via* a pentacoordinated phosphorus intermediate where the incoming nucleophile as well as the leaving group are in apical positions[17]. By way of contrast, in six-membered cyclic phosphate esters, a di-equatorial positioning of the ring is preferred for steric reasons[25]. What might be the mechanism of enzymatic hydrolysis of such a structure? Is the structure forced by the enzyme into an apical-equatorial position, possibly involving a pseudorotation process? Here also, the diastereomers of adenosine 3',5'-*O*,*O*-cyclic phosphorothioate *(7)* might be of help.



(7)

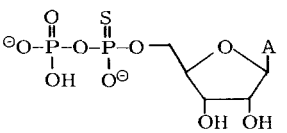
A = Adenine

Judging from the ^{31}P-NMR spectrum both diastereomers are present in a ratio of approx. 1:1. A satisfactory separation by crystallization has not as yet been achieved[26]; however, since the isomers can easily be crystallized this separation should be possible in principle. The results of the hydrolysis of the mixture of isomers with the phosphodiesterases from beef heart and *Dictyostelium discoideum*[27] indicate only a small difference, if any, in rate of hydrolysis of both isomers. The total rate is slower by a factor of about 50—100 than that of adenosine 3',5'-cyclic phosphate.

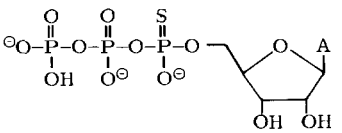
It is also of interest, of course, to see which functions of cAMP the analog can exert. One would hope to be able to differentiate the different cyclic AMP activities in biological systems with the aid of the analog. Analogs which are hydrolyzed slowly enzymatically but which at the same time still undergo reaction are particularly important. Adenosine 3',5'-cyclic phosphorothioate *(7)* belongs to this class of analogs since it is degraded more slowly than cAMP but stimulates for instance protein-kinase almost as well as does cAMP[26] and is also chemotactically as active as cAMP in *Dictyostelium discoideum*[28].

4. Adenosine 5'-*O*-(1-Thiodiphosphate) (ADPαS) and Adenosine 5'-*O*-(1-Thiotriphosphate) (ATPαS)

ADPαS *(8)* and ATPαS *(9)* can be synthesized, contrary to our earlier results[29], without lost of sulfur from adenosine 5'-phosphorothioate by activation with diphenylphosphorochloridate and reaction with pyrophosphate or phosphate[30]. *(8)* and *(9)* also exist as two diastereomers which differ in their reactivity with some kinases[30] and which one can separate analytically by high pressure liquid chromatography[31, 32].



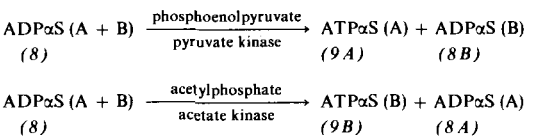
(8), ADPαS



(9), ATPαS

A = Adenine

The reaction of the chemically synthesized mixture of diastereomers A and B of ADPαS *(8)* with phosphoenolpyruvate and pyruvate-kinase leads



to the formation of ATPαS *(9A)*, with about 50% conversion. ATPαS synthesized in this way is readily cleaved to ADPαS by nucleoside diphosphate kinase—in the presence of a nucleoside diphosphate—and by myokinase—in the presence of AMP. Phosphorylation of ADPαS in the presence of acetate kinase and acetyl phosphate leads preferentially to ATPαS *(9B)*, which is only slowly cleaved by nucleoside diphosphate kinase and myokinase. This difference in reactivity of the two ATPαS preparations suggests that they represent the two postulated diastereomers. Indeed only 50% of the chemically synthesized ATPαS *(9)* is cleaved by myokinase and nucleoside diphosphate kinase; in the chemically synthesized ATPαS one can further demonstrate two isomers by high pressure liquid chromatography, but in the enzymatic preparations only one isomer[30-32]. The isomer obtained with pyruvate kinase is designated as isomer A, that obtained with acetate kinase as isomer B. Both isomers of ATPαS exhibit rather similar K_m values with hexokinase but isomer A has a V_{max} value about 100 times larger than that of isomer B[31].

The preferential synthesis of one isomer by different kinases suggests that the substrate binding sites of these kinases have different geometries. By comparison of a series of kinases one can study in this way the similarity of the substrate binding sites. Not only kinases exhibit this stereospecificity. Also phenylalanyl-tRNA synthetase from baker's yeast[33] accepts only isomer A of ATPαS as substrate. DNA-dependent RNA polymerase from *E. coli*[34, 35] and the tRNA-nucleotidyl transferase from baker's yeast[36, 37] however, seem to have a less pronounced stereospecificity towards the isomers of ATPαS. On polymerization of ATPαS and UTPαS with DNA-dependent RNA-polymerase from *E. coli* in presence of poly-d(A-T), one can isolate a double-stranded poly-r(A-U) analog,

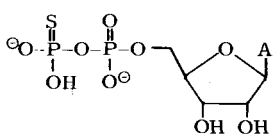
where each phosphate group contains a sulfur atom [poly-r($_S$A$_S$U)][34]. This double-helix is thermally just as stable as the unmodified polymer. It is degraded more slowly by nucleases. Poly-r($_S$A$_S$U) is superior to poly-r(A-U) in the induction of interferon in cell cultures of human fibroblasts and in the rabbit[38]. This also applies to the analog of poly-r(I-C)[39]. It is conceivable that this higher activity is due to the presumably longer lifetime of the modified polymer in cell culture or the animal. However, it cannot be ruled out that other effects, for instance higher affinity of the analog to a receptor, are responsible for it. The toxicity of polynucleotides seems to parallel their ability to induce interferon[40]. The analogs dATPαS and dTTPαS can also be used for the replication of ϕ X174-DNA in ether-treated permeabilized *E. coli cells*[41]. This DNA can be closed by ligase to RFI-particles (circular double strands). It can be demonstrated in spheroblasts that the modified RF-material is apparently also infectious.

The mixture of isomers of ATPαS *(9)* as well as of ATPβS *(11)* (see Section 5) are bound to mitochondrial membranes from rat liver in the absence as well as in the presence of atractyloside[42]. The corresponding diphosphate analogs ADPαS *(8)* and ADPβS *(10)* can not be oxidatively phosphorylated in this system. They are competitive inhibitors for this process.

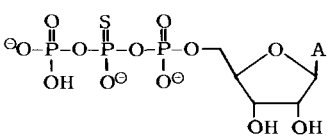
The analogs ADPαS, CDPαS and ADPβS are substrates for the *E. coli* ribonucleotide reductase with similar K_m values to the corresponding natural diphosphates, but strongly decreased rates[43]. This means that the modified substrates are bound just as well as the natural substrates but the reaction proceeds much more slowly even though it occurs on the unmodified part of the molecule. This reduced reaction rate might be due to an incorrect binding which prevents the optimal positioning of the reactive groups.

5. Adenosine 5′-*O*-(2-Thiotriphosphate) (ATPβS)

ATPβS *(11)* also exists as diastereomers A and B which can be synthesized from adenosine 5′-*O*-(2-thiodiphosphate)



(10), ADPβS



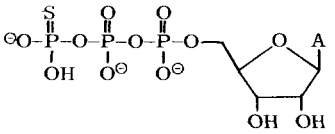
(11), ATPβS

A = Adenine

(ADPβS) *(10)* with pyruvate kinase (isomer A) and creatine kinase (isomer B)[30]. These two isomers differ mainly in their reaction with myosin. Isomer A is cleaved rather rapidly, isomer B extremely slowly. The interaction with other ATPases has not yet been investigated.

6. Adenosine 5′-*O*-(3-Thiotriphosphate) (ATPγS)

ATPγS belongs to the most versatile nucleoside phosphorothioates *(12)*[44]. This ATP-analog is only extremely slowly cleaved by phosphatases. The difference in rate to ATP is about 3 orders of magnitude and is thus similar to the difference in hydrolysis between AMP and adenosine 5′-phosphoro-



(12), ATPγS

A = Adenine

thioate *(1)*. Originally it was hoped that also ATPases would cleave ATPγS extremely slowly and that this analog could therefore be used instead of adenylylimidodiphosphate (AMPPNP) in biological systems where such ATPases interfere. It was found, however, that the ratio of rates of degradation of ATPγS and those of ATP differ for each ATPase. A system in which ATPases notoriously interfere is the ATP-cyclase system. In this reaction ATP is cyclized to cAMP. The ATPases obviously destroy the substrate. ATPγS is also a good substrate in this system of rat brain[45]. However, it is degraded rather rapidly so that it does not offer any decisive advantage over the stable AMPPNP although it is a better substrate apparently in some other cyclase systems. ATPγS is also rapidly cleaved by the ATPase of the sarcoplasmatic reticulum[46].

In contrast ATPγS is hydrolyzed extremely slowly, if at all, by the microsomal Na^+/K^+-ATPase[47]. Of this ATPase it is known that the enzyme is phosphorylated in an initial step and that the phosphorylated enzyme is dephosphorylated in the second step. It should be possible to show with the aid of [^{35}S]ATPγS whether this enzyme is also thiophosphorylated. This would open the possibility to freeze the enzyme in the intermediate stage of thiophosphorylation and to investigate in which ways this differs from the non-phosphorylated enzyme.

This freezing of the phosphorylated intermediate stage has been demonstrated in another system with the aid of ATPγS[46]. Rabbit muscle phosphorylase is phosphorylated by ATP with participation of a phosphorylase kinase to phosphorylase a which then can cleave glycogen. The enzyme is again dephosphorylated to phosphorylase b by a phosphorase a-phosphatase and thus inactivated, *i.e.* its activity is regulated by this mechanism in the cell. The enzymatic transfer of the thiophosphate residue onto phosphorylase can be carried out with ATPγS to obtain a thio-analog of phosphorylase a[46]. This analog is as active as phosphatase a in the cleavage of glycogen but is only extremely slowly degraded if at all by the phosphatase. In addition, the phosphorylase-kinase can be activated by a cAMP-dependent protein kinase through phosphorylation with ATP. Also in this reaction ATP can be replaced by ATPγS. One obtains an activated phosphorylase kinase which presumably cannot be hydrolyzed by the corresponding phosphatase. These are cases in which the thiophosphorylated active enzyme can be investigated separately which is of interest particularly in biological systems such as glycogen particles. Since a series of enzymes is regulated through the cycle of phosphorylation-dephosphorylation one can foresee here interesting applications for ATPγS.

The availability of [^{35}S]ATPγS is important for investigations where the thiophosphate residue is being transferred. The enzymatic method which has been developed for the γ-phosphate exchange of ATP with phosphoglycerate kinase[48] can also be applied to ATPγS. Through changes in the experimental conditions it is possible to introduce [^{35}S]-thiophosphate

into ATPγS in this way[12]. [^{14}C]- or [^{3}H]ATPγS can be synthesized from the correspondingly labeled ADP by thiophosphate transfer with myokinase or nucleoside diphosphate kinase[49]. It should be mentioned here that thiophosphate does not form a blue ammonium molybdate complex like phosphate and that in contrast to phosphate it is adsorbed by charcoal. These methods, therefore, are not available for the determination of data of hydrolysis for ATPγS.

Another system in which the properties of ATPγS have been thoroughly investigated are isolated muscle fibers and the proteins actin and myosin which participate in muscle contraction. Interest is concentrated on this system by many groups at the moment in an effort to establish the relationship between chemical reaction (hydrolysis of ATP by myosin) and mechanical work (contraction of muscle). *Lymn* and *Taylor* have developed a model (Fig. 1)[50], in which actin dissociates

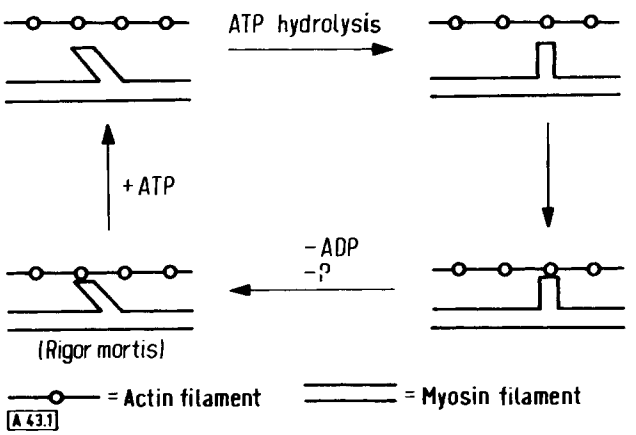


Fig. 1. Lymn-Taylor model for the actin-myosin system. For details see text (after [50]).

from myosin on binding of ATP to the myosin heads without the angles of the heads to the myosin (45°) being changed. The hydrolysis of ATP to ADP and phosphate leads to an extension of the heads and myosin and actin can again combine. In this step the hydrolysis products dissociate and the actual mechanical work—movement of the actin relative to the myosin filament—*i.e.* the contraction occurs. In absence of ATP the muscle returns to the rigor-mortis state. In the presence of ATP the cycle can again start from the beginning, *i.e.* the muscle is in a state of active contraction. The model demands that in this cycle the binding of ATP to the myosin heads causes only dissociation of the actin filament but no extension of the myosin heads. It should be possible to test this idea with ATP analogs which cannot or can only slowly be cleaved by myosin, under the condition that they are being bound similarly to ATP and that the kinetics of the single steps during the hydrolysis of the analogs are known. Moreover a method has to be available to observe such changes in muscle fibers. The latter is possible with X-ray diffraction methods. Of the ATP analogs AMPPNP, $AMPCH_2PP$ and ATPγS, which can be used in principle for such investigations, only ATPγS will be discussed here. In the presence of ATPγS muscle fibers relax (*i.e.* actomyosin dissociation) but cannot contract any more after addition of Ca^{2+} (the physiological contraction stimulator)[51]. As judged from the rates by which ATPγS is being bound to myosin or the myosin subfragment 1 it seems to be more similar to ATP than the other two analogs[52]. Thorough kinetic investigations in *Trentham*'s laboratory in Bristol have shown that the basic difference between ATP and ATPγS is that the actual hydrolysis step of ATPγS is about 1000 times slower than that of ATP. The effect of this is that the dissociation of product is no longer the rate determining step, as it is with ATP itself, but rather the hydrolysis step[53]. In the steady state the complex ATPγS·myosin and not ADP·myosin should be predominant, as in the case of ATP. As discussed above this should allow determination of the orientation of the myosin heads during ATP binding. Such X-ray structural studies are in progress in *Holmes*' laboratory in Heidelberg[54]. Their results[55] are consistent with a 90°-position of the myosin heads and thus would fit only in a modified Lymn-Taylor scheme.

The scheme mentioned above has been refined by *Trentham* and will only be mentioned here in as much as ATPγS was used in this study. On binding of ATP onto the myosin-subfragment 1 the protein fluorescence increases. To decide whether this change of fluorescence is due to the binding of the nucleotide onto the protein or to the conformational change of the binary complex protein-nucleotide or to the hydrolysis of ATP, the slow rate of the hydrolysis step of ATPγS ($k=0.2\,s^{-1}$) in contrast to that of ATP (*ca.* $160\,s^{-1}$) was of help. Since the rates of change of fluorescence ($400\,s^{-1}$) were found to be the same for both substances, while the rates of hydrolysis are largely different, the change of fluorescence could be ascribed to a change of conformation of the binary complex[52]. This can also be of significance for the positioning of the myosin heads as discussed above and thus for the relationship between chemical reaction and mechanical work.

7. Conclusions

These discussions show that nucleoside phosphorothioates exhibit varying properties in their interaction with enzymes. They can be competitive inhibitors but also substrates, in many cases with considerably reduced reaction rates in comparison with normal substrates. This also applies when the actual chemical reaction does not occur on the thiophosphate residue. It seems to be common to all systems studied so far that the affinities of the nucleoside phosphorothioates and of the natural substrates to a given enzyme are rather similar if not identical. Furthermore, in all systems the rate constants of the chemical step seem to be more or less reduced (this has nowhere been shown as unequivocally as in myosin, since with other enzymes only the (steady-state) V_{max} values have been measured) with differences varying from enzyme to enzyme. A prediction about the behavior of nucleoside phosphorothioates towards an enzyme system which has not yet been studied seem to be rather risky at present. This is probably a reflection of our limited understanding of most enzyme systems. The advantage of nucleoside phosphorothioates over other phosphate modified nucleotide analogs is probably that they are not competitive inhibitors in many cases but rather substrates with often reduced reaction rates. These properties, the existance of diastereomers, the ability to transfer the thiophosphate residue of the ATP analog and the possibility of modifying nucleoside mono-, di- and -triphos-

phates open a wide area of application for this group of analogs—as this review hopefully has demonstrated. It remains to be seen whether they can prove as useful in investigations of more complicated systems such as membranes or cell cultures.

I am grateful to many friends and colleagues in this and many other institutes in Germany and abroad for suggestions, criticism, methodical help and the willingness for cooperation without which nucleoside phosphorothioates would never have found such wide distribution and importance. In addition I would like to thank all collaborators for their enthusiastic research which made this work possible. I thank the Deutsche Forschungsgemeinschaft for financial support.

Fluorination of Cyanogen Chloride and *N*-Chlorodichloromethyleneamine

By *J. D. Cameron* and *B. W. Tattershall*[*]

Fluorination of cyanogen chloride with potassium fluoride, suspended in tetramethylene sulfone, or in the absence of solvent, yields *N*,*N*-bis(trifluoromethyl)cyanamide *(1)*, along with trifluoromethyl(difluoromethylene)amine *(2)* and cyanuric trifluoride, under mild conditions.

[*] J. D. Cameron and Dr. B. W. Tattershall
Department of Inorganic Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU (England)

The mechanism for increase of the carbon to nitrogen ratio in the formation of *(1)* or *(2)* from ClCN is unknown, but a yield of *(1)* of up to 25% based on carbon of cyanogen chloride can be obtained.

$(CF_3)_2N{-}C{\equiv}N$ *(1)* $CF_3N{=}CF_2$ *(2)* $CF_3N{=}CCl_2$ *(3)*

Compound *(1)* is a colorless gas [vapor pressure (−80° to +10°C) represented by: $\log_{10} p_{(torr)} = 7.267 - 1246/T$; extrapolated b.p. 11°C] identified by its molecular weight and by chemical and spectroscopic analysis. It is thermostable (70 h in Pyrex at 180°C) and stable toward hydrolysis by

water (70 h at 60 °C). The $(CF_3)_2N$ group was diagnosed by ^{19}F-NMR (single peak 58.3 ppm upfield from internal CCl_3F) and by characteristic infrared absorption at 990 cm^{-1} and mass spectral fragment at $m/e = 114$ ($C_2F_4N^+$). The C≡N stretching frequency occurs at 2260 cm^{-1}; further IR bands appear at 1360 vs, 1270 vs, 1230 vs, 1180 s, 1155 s, 990 s, and 728 s cm^{-1}. The mass spectrum shows the molecular ion at $m/e = 177.9971$, and other fragments at 159, 133, 90 (CF_2NCN^+), 69, and 50. Two isomers of *(1)*, $CF_2{=}NCF_2N{=}CF_2$ and $CF_3N{=}C{=}NCF_3$, have been previously reported[1].

Cyanogen chloride reacts with chlorine to give $ClN{\equiv}CCl_2$[2], but the reaction appears to be easily reversed.

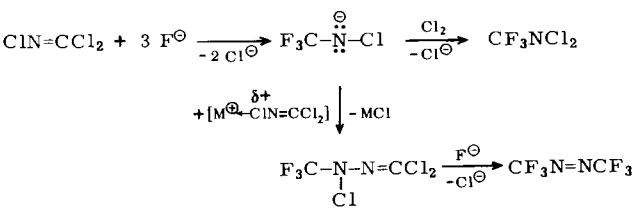
$$ClCN + Cl_2 \rightleftharpoons ClN{=}CCl_2$$

Consequently, reaction of $ClN{=}CCl_2$ with KF in tetramethylene sulfone gives some *(1)*, but the major products are CF_3NCl_2 and $CF_3N{=}NCF_3$, as previously reported for the reaction of ClCN with AgF and chlorine under conditions more conducive to a radical mechanism[3].

$$2\ ClN{=}CCl_2 + 3\ MF \longrightarrow CF_3NCl_2 + ClCN + 3\ MCl$$

$$2\ ClN{=}CCl_2 + 6MF \longrightarrow CF_3N{=}NCF_3 + 6\ MCl$$

We have found that use of KF favors formation of CF_3NCl_2, while AgF favors $CF_3N{=}NCF_3$, suggesting the following scheme which does not involve radicals:



Reaction of $ClN{=}CCl_2$ with SbF_3 gives mainly non-volatile products, but inclusion of CCl_4, CCl_3H, or CCl_3F in the mixture leads to $CF_3N{=}CCl_2$ *(3)*. In contrast to the formation of *(1)* in the basic reactions, the source of the extra carbon atom in *(3)* is clearly the added chloromethane. An acid-catalyzed reaction of $ClN{=}CCl_2$ with CCl_4 has been independently reported[4].

N,N-Bis(trifluoromethyl)cyanamide (1)

KF (20 mmol) is dried in a Pyrex tube at 120 °C in vacuum, then dry tetramethylene sulfone (2 g) is added, and the mixture degassed. ClCN (4.5 mmol) is condensed in from the vacuum system, and the tube is sealed and heated to 60 °C for 60 h. Vacuum fractionation yields *(1)*, which at *ca.* 10^{-3} torr is passed by a trap at −96 °C and stopped at −112 °C. Yield 0.35 mmol (23 %).

Fluorination of N-Chlorodichloromethyleneamine

KF (19 mmol), tetramethylene sulfone (1.8 g), and $ClN{=}CCl_2$ (5.8 mmol) are sealed together in a Pyrex ampoule under the conditions described above, and heated to 60 °C for 70 h. Unreacted $ClN{=}CCl_2$ (0.13 mmol) and ClCN (1.95 mmol) are separated by vacuum fractionation, to yield a mixture of CF_3NCl_2 (1.98 mmol) and $CF_3N{=}NCF_3$ (0.42 mmol) which may be further separated by gas chromatography.

Disilylmercury and Digermylmercury

By *Stephen Cradock, E. A. V. Ebsworth, Narayan S. Hosmane*, and *Kenneth M. Mackay*[*]

We have recently prepared trimethylsilylsilane by the reaction between silyl bromide and bis(trimethylsilyl)mercury. This reaction is very slow in solution. If, however, an excess of *solid* mercurial is treated with silyl bromide, trimethylsilyl bromide is rapidly formed in almost quantitative yield. Trimethylsilylsilane is evolved over a period of days:

$$H_3SiBr + (Me_2Si)_2Hg \rightarrow Me_3SiBr + \underset{(1)}{[Me_3SiHgSiH_3]} \rightarrow Me_3SiSiH_3$$

The solid *(1)* is soluble in benzene. The NMR spectrum of the solution showed new peaks at $\tau \approx 5$ (associated with Si*H*) and $\tau = 10$ (associated with SiC*H*). Each peak had associated ^{199}Hg satellites, and both sets of satellites were collapsed by irradiation at the same ^{199}Hg frequency, showing that the two resonances were due to the same molecular species.

Table 1. NMR data of trimethylsilyl(silyl)mercury and disilylmercury, and of trimethylsilyl(germyl)mercury and digermylmercury. Chemical shifts in ppm, coupling constants in Hz.

	$Me_3SiHgSiH_3$	$(H_3Si)_2Hg$	$Me_3SiHgGeH_3$	$(H_3Ge)_2Hg$
$\tau(SiH_3/GeH_3)$	4.98	5.46	4.54	5.16
$\tau(Me_3Si)$	9.90	—	9.86	—
$\delta(^{199}Hg)$ [a]	+327.1	+196.0	+159.0	−147.45
$\delta(^{29}Si)$ [b] Me_3Si	+ 63.7	—	+ 41.1	—
H_3Si	− 22.1	− 10.3	—	—
$^1J(H^{29}Si)$	178.0	185.0	—	—
$^2J(H^{29}Si)$	6.0	—	6.8	—
$^2J(H^{199}Hg)$	66.0	84.0	92.0	147.0
$^3J(H^{199}Hg)$	54.0	—	62.0	—

[a] In ppm relative to Me_2Hg (positive to high frequency); in $(Me_3Si)_2Hg$ the value is +481.0 ppm.
[b] In ppm relative to Me_4Si (positive to high frequency); in $(Me_3Si)_2Hg$ the value is +64.0 ppm.

Hamilton (New Zealand)

When equimolar proportions of reactants were taken initially, the species could be obtained virtually free of SiH_3Br or $(Me_3Si)_2Hg$; the relative intensities of the Si*H* and the SiC*H* peaks were roughly 1:3, and the ^{29}Si and ^{199}Hg INDOR spectra confirmed the identification of the compound as $Me_3SiHgSiH_3$. Treatment of solid $(Me_3Si)_2Hg$ with excess of SiH_3Br gives Si_2H_6, but if SiH_3Br is added to a solution of $Me_3SiHgSiH_3$ and the solution kept at 50°C for some days, the yellow color fades; trimethylsilyl bromide is formed and the ^1H-NMR spectrum shows a new resonance at $\tau \approx 5$ with ^{29}Si and ^{199}Hg satellites. The ^{199}Hg INDOR spectrum shows the seven-line pattern expected for $(H_3Si)_2Hg$. Both $(CH_3)_3SiHgSiH_3$ and $(H_3Si)_2Hg$ are stable for a matter of days at room temperature in solution, but the compounds are exceedingly reactive as solids towards traces of air and moisture. The NMR parameters for both compounds are given in Table 1.

Treatment of bis(trimethylsilyl)mercury with germyl bromide leads similarly to the formation of $(CH_3)_3SiHgGeH_3$ and $(H_3Ge)_2Hg$; these two compounds were identified by their ^{199}Hg INDOR spectra (Table 1). The germyl compounds are much less sensitive than are their silyl analogs to traces of air and moisture, but are somewhat less stable over extended periods in solution.

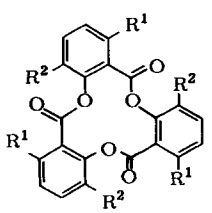
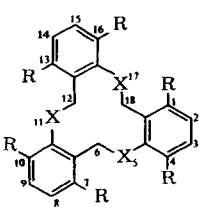
The Conformational Behavior of 6*H*,12*H*,18*H*-5,11,17-Trithiatribenzo[*a*,*e*,*i*]cyclododecene

By *W. David Ollis*, *J. Fraser Stoddart*, and *Michael Nógrádi*[*]

The trisalicylides *(1)*—*(3)*[1], the hydrocarbon *(4)*[2], and its hexamethyl derivative *(5)*[2] are conformationally mobile in solution. Studies[1, 2] on these compounds suggest that the barrier heights for conformational changes in the twelve-membered rings depend on the nature of the substituent atoms or groups at the *ortho* positions of the aromatic rings. Since the hydrocarbon *(4)* is a rather inconvenient molecule to study by NMR line shape methods due to the complexity of the ^1H-NMR spectrum of its CH_2—CH_2 groups, we have prepared the trithia analog *(6)*, m. p. 197—198 °C, by reaction of 2-(chloromethyl)thiophenol[3] with sodium hydroxide in methanol, in order to investigate a molecule where the *ortho* substituents are hydrogen atoms.

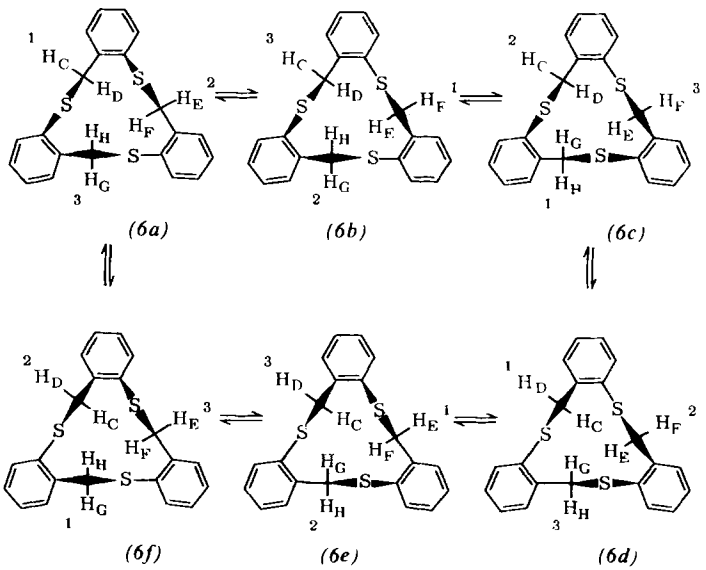




(1), $R^1 = R^2 = CH_3$
(2), $R^1 = CH_3$; $R^2 = CH(CH_3)_2$
(3), $R^1 = CH(CH_3)_2$; $R^2 = CH_3$

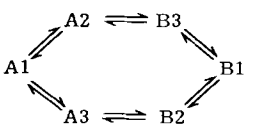
(4), R = H; X = CH_2
(5), R = CH_3; X = CH_2
(6), R = H; X = S

The ^1H-NMR spectrum of this heterocyclic compound *(6)* in CS_2 showed temperature dependence. Three AB systems ($\tau_{A1} = 4.43$, $\tau_{B1} = 6.02$, $\tau_{A2} = 4.61$, $\tau_{B2} = 6.18$, $\tau_{A3} = 5.53$, and $\tau_{B3} = 5.99$; $J_{A1B1} = J_{A2B2} = J_{A3B3} = 9.0$ Hz) for the methylene groups at −106 °C were identified by homonuclear INDOR spectroscopy[4]. They coalesced to a sharp singlet ($\tau = 5.51$) at −36 °C. This observation indicates that the ground state conformation has C_1 symmetry and examination of models suggests that the molecule *(6)* adopts the helical conformation (Scheme 1).



Scheme 1. Helix ⇌ Helix* inversions required to exchange the six methylene protons with six different sites. If *(6a)*, *(6c)*, and *(6e)* correspond to Helix then *(6b)*, *(6d)*, and *(6f)* correspond to Helix*.

The rate constants for Helix ⇌ Helix* inversion at different temperatures were determined by comparing the observed ^1H-NMR spectra with theoretical spectra generated by line shape equations suitable for a six-site exchange process between H_C, H_D, H_E, H_F, H_G, and H_H. Inspection reveals that there are four ways in which three AB systems can be assigned to the pairs of sites represented by 1, 2, and 3. The density matrix approach[5] was used to examine the exchange process *(7)*. Attempts to perform line shape analyses indicated that only the program constructed on the basis of the depicted exchange process provides good matches between computed and experimental spectra over the entire temperature range.



(7)

Thus, like the hydrocarbon *(5)*[2], the trithia compound *(6)* exists in the helical conformation in solution. However, the

Helix⇌Helix* inversion barrier is very much lower for *(6)* ($\Delta G^{\ddagger}_{H\rightleftharpoons H^*}=9.3\pm0.2$ kcal mol^{-1}) than for *(5)* ($\Delta G^{\ddagger}_{H\rightleftharpoons H^*}=17.1$ kcal mol^{-1}). We believe there are two principal reasons for this difference: (i) the absence of methyl substituents in the *ortho* positions of the aromatic rings, and (ii) conjugative stabilization between the lone pairs on sulfur and the π system of the benzene rings in the inversion transition state.

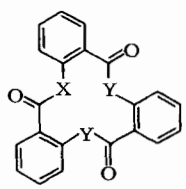
The Synthesis and Conformational Behavior of *N,N',N''*-Trimethyltrianthranilide

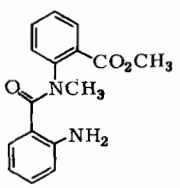
By *W. David Ollis, Jennifer A. Price, Julia Stephanidou Stephanatou*, and *J. Fraser Stoddart*[*]

Although dehydration of salicylic acid and its alkyl-substituted derivatives has been known[1] for over twenty years to yield both disalicylide and trisalicylide derivatives *(1)*, the only anhydro derivative of anthranilic acid which has been reported[2] is dianthranilide. We now wish to report the synthesis of *N,N',N''*-trimethyltrianthranilide *(3)* and discuss its conformational behavior in solution.

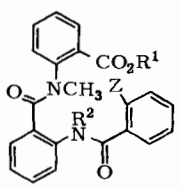
Treatment of a suspension of methyl *N*-anthraniloyl-*N*-methylanthranilate *(4)*[3], m.p. 104—105 °C (88—89 °C[3]) in lithium hydroxide solution with *o*-nitrobenzoyl chloride in benzene afforded the *o*-nitrobenzoyl derivative *(5)* (74%, needles, m.p. 182—184 °C). Conversion into the *N,N'*-dimethyl derivative *(6)* (87%, m.p. 204—206 °C) with methyl iodide and sodium hydride in dimethyl sulfoxide was followed by titanous chloride reduction[4] of the aromatic nitro group. De-esterification was effected by LiOH; the free acid *(7)* (78%) polymerizes on heating.



(1), X = Y = O
(2), X = NH; Y = NCH_3
(3), X = Y = NCH_3



(4)

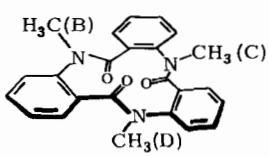


(5), R^1 = CH_3; R^2 = H; Z = NO_2
(6), R^1 = R^2 = CH_3; Z = NO_2
(7), R^1 = H; R^2 = CH_3 Z = NH_2

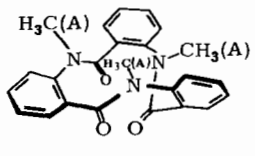
Cyclization was achieved by treatment with dicyclohexylcarbodiimide in dichloromethane to give isomer X (54%, m.p. 182—184 °C; $\tau_{CH_3(A)}=6.90$ and $\tau_{CH_3(B)}=7.29$ in $CDCl_3$) of *N,N'*-dimethyltrianthranilide *(2)*. Quantitative conversion into a second isomer Y (m.p. 251—254 °C; $\tau_{CH_3(A)}=6.73$ and $\tau_{CH_3(B)}=6.83$ in $CDCl_3$) of *(2)* was observed on heating isomer X under reflux in ethanol (3 h). Methylation (CH_3I; NaH; CH_3SOCH_3) of both isomers (X and Y) gave the same compound, *N,N',N''*-trimethyltrianthranilide *(3)* (m.p. >320 °C) on recrystallization from chloroform/ether/light petroleum (b.p. 60—80 °C), in 57% and 76% yields, respectively.

[*] Prof. Dr. W. D. Ollis, J. A. Price, J. S. Stephanatou, and Dr. J. F. Stoddart
Department of Chemistry, The University
Sheffield S3 7HF (England)

When a ^{1}H-NMR spectrum of compound *(3)* was recorded *immediately* after the crystals had dissolved in $CDCl_3$, three equal intensity singlets integrating for three protons each were observed at τ = 6.67, 6.79, and 6.87. After a few minutes a fourth singlet began to appear at τ = 6.51. At equilibrium, the ratio of the peak areas for these singlets was 0.055 : 0.315 : 0.315 : 0.315 (CH_3(A), CH_3(B), CH_3(C), CH_3(D)).



(8), Helix



(9), Propeller

On examination of molecular models, and by analogy with the conformational behavior[5, 6] of the trisalicylides, the spectra of compound *(3)* can be rationalized in terms of two non-planar conformations, the helix (H) *(8)* with C_1 symmetry and the propeller (P) *(9)* with C_3 symmetry, which retain *trans*-amide linkages between the three aromatic rings and which are interconverted by torsion about the Ar—N(CH_3) and Ar—CO single bonds. The interconversion between the H and P conformations, *(8)* and *(9)*, and their enantiomers (denoted by H* and P*) involves the following equilibrium: P⇌H⇌H*⇌P*.

Thus, it may be concluded that *N,N',N''*-trimethyltrianthranilide *(3)* crystallizes in the helical conformation *(8)*. In solution, this conformation is in equilibrium with a small amount (5.5%) of the propeller conformation *(9)*. This finding is to be compared with (i) the observation[5, 6] that tri-*o*-thymotide exists in a propeller conformation in its crystalline clathrate compounds, and with (ii) the observation[5, 6] that in all of the trisalicylides examined to date the propeller conformation is energetically preferred in solution.

The ^{1}H-NMR spectrum of *(3)* in nitrobenzene showed temperature dependence; the four singlets coalesced to a broad singlet at +215 °C. Comparison of the observed ^{1}H-NMR spectra with the theoretical spectra generated by line shape equations[6] based upon a four-site exchange process between CH_3(A), CH_3(B), CH_3(C), and CH_3(D) gave $\Delta G^{\ddagger}_{P\rightarrow H}=21.6$ kcal mol^{-1} and $\Delta G^{\ddagger}_{H\rightarrow H^*}=24.4$ kcal mol^{-1}. The difference in free energy of 1.9 kcal mol^{-1} between the two conformations at +63 °C indicates that the transition states for P⇌H interconversion and H⇌H* inversion must be very similar in their energetic demands.

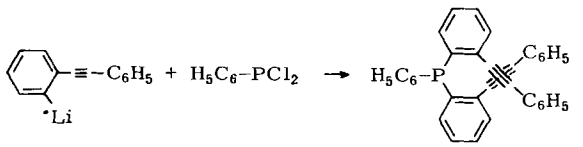
A Novel Cyclobutadiene-Rhodium(I) Complex

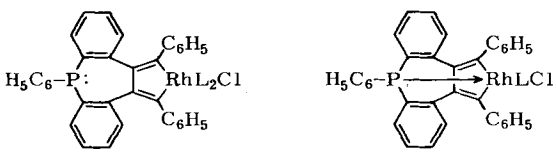
By *Werner Winter*[*]

Alkynylphosphanes of type $R_2P-C\equiv C-R$ behave ambivalently toward transition metals. Thus, reaction of the bis-acetylene compound *(1)* with *e.g.* RhL_3Cl (L = triphenylphosphane) could give, not only a P—Rh-coordination or an acetylene π-complex, but also the compounds *(2)*—*(5)*. Molecular models, however, show that formation of *(3)* can be ruled out, since the length of the bond from the P atom in the angled phosphepin ring would have to be about 5—6 Å.

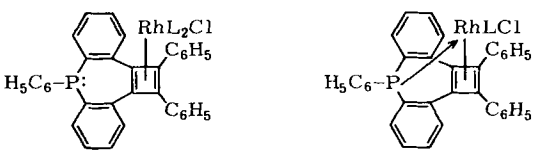


(1)

o,o'-Bis(phenylethynyl)triphenylphosphane *(1)* can be prepared by dropwise addition of dichloro(phenyl)phosphane to *o*-lithiotolan[1] in boiling anhydrous ether under N_2 [*(1)*: 42% yield, m. p. 150—151 °C (xylene); IR (KBr): (C≡C) 2210 cm^{-1} (weak); FT-$^{13}C\{^1H\}$-NMR (in $^{12}CDCl_3$), TMS internal, δ = 96.3 ppm, d, J_{CP} = 5 Hz; δ = 88.7 ppm, d, J_{CP} = 7 Hz (—C≡C); FT-$^{31}P\{^1H\}$-NMR (in $CHCl_3$), H_3PO_4 external, δ = +11.9 ppm; MS = 462].

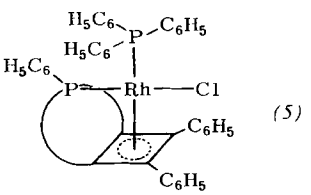


(2) *(3)*



(4) L = $P(C_6H_5)_3$ *(5)*

Heating equimolar quantities of *(1)* and RhL_3Cl in benzene for 15 min under reflux in a nitrogen atmosphere led to almost quantitative precipitation of a fine crystalline, blackish-violet complex (dec. point 211 °C) which is absolutely stable at room temperature. Two triphenylphosphane groups could be detected in the filtrate. Vapor pressure osmometric molecular weight determinations and elemental analysis carried out on the precipitate give the empirical formula $C_{52}H_{38}P_2RhCl \cdot C_6H_6$. No vibrations of the free or of the complexed C≡C groupings could be observed in the IR spectrum.



(5)

[*] Dr. W. Winter
Chemisches Institut der Universität
74 Tübingen, Auf der Morgenstelle 18 (Germany)

The above findings are consistent only with the cyclobutadiene structure *(5)*. Models show that if the Rh—P distance is *ca.* 2.3 Å, the transition metal atom lies almost above the center of the cyclobutadiene ring.

The FT-$^{31}P\{^1H\}$-NMR spectrum of (1,2,7-triphenyl-7*H*-dibenzo[*b,f*]-η-cyclobuta[*d*]phosphepin)(triphenylphosphane)-rhodium(I) chloride *(5)* [in $CH_2Cl_2(N_2)$; 0.1 M H_3PO_4 in D_2O, external; 36.43 MHz] shows an ABX system. Absence of a signal at higher field (δ > 0) clearly indicates that the phosphepin P atom is bound coordinatively to Rh. The δ_1 and δ_2 values are consistent with an Rh^I complex (for comparison: RhL_3Cl, δ = −31.5 and −48.0 ppm; $Rh^{III}L_3Cl_3$, δ = +0.5 and −15.1 ppm[2]). Rh^{III} complexes having a rhodacyclopentadiene structure analogous to *(2)* have δ values between −22 and −27 ppm[3].

The non-equivalent atoms P^1 and P^2 couple with ^{103}Rh (J_{RhP^1} = 158 Hz, J_{RhP^2} = 173 Hz). In contrast, Rh^{III} complexes are found to have coupling constants of 84—115 Hz[2] and 120 Hz (rhodacyclopentadiene complexes)[3].

The coupling constant $^2J_{P^1P^2}$ = 36 Hz is comparable with values for Rh^I complexes (36—38 Hz) (values for Rh^{III} complexes are about 23 Hz)[2]. Assignment of the δ and J_{RhP} values to P^1 and P^2 results from the fact that the signals of the P atoms *trans* to Cl generally lie at lower field than those of the P atoms *cis* to Cl, and that the coupling constants J_{RhP} of the P atom *cis* to Cl is larger than that of the P atom *cis* to Cl[2] (cf. also the "*trans*-effect" in the case of Pt-PR_3 complexes[4]). The *cis* orientation of the two P atoms in *(5)* is also proven by the fact that non-equivalent, *trans* phosphane ligands exhibit $^2J_{PP'}$ values of 300—500 Hz.

Synthesis and Properties of Azuleno[1,2,3-*cd*]phenalene[1]

By *Ichiro Murata*, *Kazuhiro Nakasuji*, *Kagetoshi Yamamoto*, *Tomoo Nakazawa*, *Yutaka Kayane*, *Akira Kimura*, and *Osamu Hara*[*]

Systems composed of azulene and phenalene rings, *e.g. (1)* and *(2)*, are very interesting, not only because of their unique electronic structures but also because of their expected carcinogenic activities as in the case of the related benzo[*a*]pyrene. The stable, crystalline moss green azuleno[5,6,7-*cd*]phenalene *(1)*[2] exhibits considerable carcinogenic activity[3]. We report here on the synthesis and properties of azuleno[1,2,3-*cd*]phenalene *(2)*.

We have synthesized *(2)* from 2*H*-8,9-dihydrocyclopenta[*cd*]-phenalene *(8)* after the well-known *Ziegler-Hafner* azulene

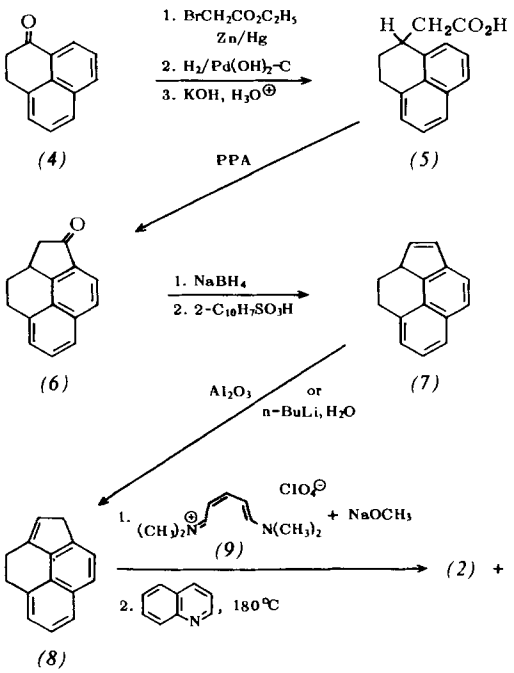
(1) (2), X = H; D_5-(2), X = D (3)

synthesis[4] and its application to the synthesis of dicyclopenta[*ef*,*kl*]heptalene (azupyrene)[5].

Reformatsky reaction of dihydrophenalenone (4)[6] with ethyl bromoacetate followed by hydrogenolysis and hydrolysis led to the carboxylic acid (5)[7], m.p. 90—91.5°C, which was subjected to cyclization with polyphosphoric acid (PPA) to give the tetracyclic ketone (6)[7], m.p. 143—144°C, $\nu_{C=O}$ (KBr) 1695 cm^{-1}, in 40% overall yield. The ketone (6) was converted by reduction with sodium borohydride into the alcohol[7], m.p. 130—131°C, ν_{O-H} (KBr) 3150 cm^{-1}, in 95% yield; the alcohol was then dehydrated with 2-naphthalenesulfonic acid to give 9a*H*-8,9-dihydrocyclopenta[*cd*]phenalene (7)[7] [colorless crystals, m.p. 93—94°C (from *n*-hexane); *m/e* = 192 (M^+, 100%); ^{1}H-NMR: δ ($CDCl_3$) = 1.0—1.7 (m, 1H), 2.4—2.8 (m, 1H), 3.1—3.7 (m, 3H), 6.70 (dd, *J* = 5.3, 1.7 Hz, 1H), 7.03 (dd, *J* = 5.3, 2.1 Hz, 1H) and 7.2—7.9 (m, 5H).



(4) (5) (6) (7) (8) (9) (2) + (3)

On being passed through an alumina column or treated with *n*-butyllithium in tetrahydrofuran followed by water quenching, the compound (7) was found to convert quantitatively into the isomeric hydrocarbon (8)[7] [colorless crystals, m.p. 101—103°C; *m/e* = 192 (M^+, 100%); ^{1}H-NMR: δ ($CDCl_3$) = 2.8—3.4 (m, 4H), 3.4—3.6 (m, 2H), 6.1—6.3 (m, 1H) and 7.1—7.9 (m, 5H)]. Treatment of (8) (in THF) and dimethyl(5-dimethylamino-2,4-pentadienylidene)ammonium-perchlorate (9) with one equivalent of sodium methoxide in methanol at room temperature gave an intermediate fulvene which was not isolated. To effect the cyclization of the fulvene the solvent was replaced by quinoline and the solution was heated at 180°C for 2h. After usual work-up the crude product was purified by column chromatography (Al_2O_3, benzene/*n*-hexane). The desired azuleno[1,2,3-*cd*]phenalene (2) was eluted from the column as a green band and formed stable dark red plates with metallic luster (yield: 62%; m.p. 183—184°C (benzene)), which showed a green color in solution. 4,5-Dihydroazuleno[1,2,3-*cd*]phenalene (3)[8] (green plates, m.p. 158.0—159.5°C (*n*-hexane)), was also isolated as a minor product in 6% yield.

The unusual electronic spectrum of (2) accords with quantum mechanical calculations by *Zahradnik*[10]. In contrast to the electronic spectrum of (1) which shows the longest wavelength absorption maximum at 739 nm ($\log\varepsilon = 3.26$)[2, 11], the longest wavelength absorption of compound (2) is found at 1010 nm; λ_{max} (cyclohexane) = 1010 nm ($\log\varepsilon = 1.99$), 855 (2.49), 760 (2.52), 694 (2.34), 624 (sh, 2.03), 477 (4.69), 471 (4.34), 465 (4.11), 452 (sh, 4.21), 447 (4.35), 425 (sh, 3.87), 421 (3.90), 390 (3.85), 386 (3.37), 351 (4.85), 284.5 (3.96), 261.5 (4.21), 255.5 (4.16), 249.5 (4.12), 244 (4.12), and 226 (4.21). The ^{1}H-NMR spectrum ($CDCl_3$, 100 MHz) showed a 2H doublet with further small splittings at δ = 9.14 (*J* = 9.5 Hz, H-6,10), an AB-quartet at 8.36 (*J* = 9.0 Hz, 2H, H-5,11 or 4,12) and 7.85 (*J* = 9.0 Hz, 2H, H-4,12 or 5,11), a triplet at 7.50 (*J* = 9.5 Hz, H-7,9), and a multiplet at 7.8—8.1 (H-1,2,3 and 8). Complete assignment of the full ^{1}H-NMR spectrum of (2) could be achieved by comparison with the spectrum D_5-(2), which was prepared by using D_5-pyridine as starting material for (9). Thus, an A_2B-system of H-1,3 and H-2 was found at δ = 7.99 and 7.88 with $J_{1,2} = J_{2,3} = 7.8$ Hz

The structure of (2) was established from these spectral data together with the mass spectrum [*m/e* = 252 (M^+, 100%)] and results of elemental analysis[7]. The ease of dehydrogenation during the preparation of (2) is noteworthy and suggestive of the substantial thermodynamic stability of this compound. The diamagnetic susceptibility (measured with a Cahn balance) is χ_M/χ_M(benzene) = 2.7[12]. The foregoing observations furnish convincing evidence for a definite degree of aromaticity of (2).

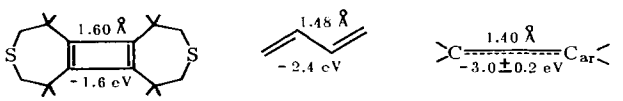
Photoelectron Spectrum and Structure of Tri-*tert*-butylcyclobutadiene[1]

By *Günther Lauer, Claus Müller, Karl-Wilhelm Schulte, Armin Schweig, Günther Maier*, and *Arnaldo Alzérreca*[*]

It has recently been shown[2] that the cyclobutadiene derivative *(1)* has a rectangular structure. This was deduced from a comparison of the resonance integrals determined by PE spectroscopy[3] (lower figures in the following formula) with the known bond lengths[4] (upper figures in the following formula) in *trans*-butadiene and benzene. The rectangular structure of *(1)* has meanwhile been confirmed by X-ray analysis[5]. In the present communication we wish to report that the first cyclobutadiene *(2)* capable of existence at room temperature, which bears only alkyl substituents and is not fixed by rings like *(1)*, is likewise rectangular in structure.



(1)

Since tri-*tert*-butylcyclobutadiene *(2)* was not available as a pure solid owing to its fast dimerization at room temperature our studies were carried out on a mixture of about 2—5% of tri-*tert*-butylcyclopentadienone *(3)*—a by-product of photosynthesis[6] of *(2)*—with *(2)* and its dimeric reaction product *(4)* in a specially constructed glass inlet system. Comparison of the photoelectron (PE) spectrum thus obtained with those of the pure compounds *(3)* and *(4)* showed that band ① (at 6.83 eV, Fig. 1), which precedes all the other bands in the PE spectrum, is a pure cyclobutadiene band. This is in full accord with its complete disappearance within about 60—90 minutes in the course of a series of measurements, although the sample mixture was cooled with liquid air during all intermediate operations connected with the recording of the spectra (such as instrumental adjustment and calibration of the spectra). Previous investigations[2] on *(1)* indicate that band ① must be assigned to the $D(\pi_2)$ ionic state (Fig. 1) of *(2)*.

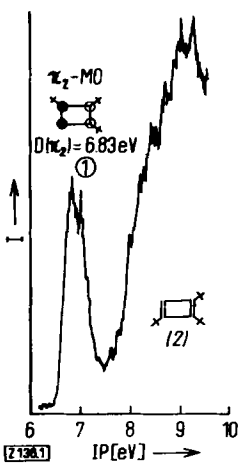


Fig. 1. Photoelectron spectrum of tri-*tert*-butylcyclobutadiene *(2)* in admixture with *(3)* and *(4)* (see text).

The $D(\pi_2)$ ionic states of *(1)* (at 6.89 eV[2]) and of *(2)* (at 6.83 eV) are of virtually *equal energy*. CNDO/S[7] calculations on *(1)* with the experimentally determined geometry[5], and on *(2)* with the same rectangular geometry (1.600 Å/1.344 Å) largely concur in yielding *equal* $D(\pi_2)$ Koopmans ion energies[8] (Fig. 2). A corresponding calculation for square (1.425 Å[9]) *(2)* expectedly predicts a considerably (0.7 eV) more stable $D(\pi_2)$ Koopmans ion[8]. Rectangular tetra-*tert*-butylcyclobutadiene *(5)* should be more readily ionized (by 0.2 eV) than its rectangular relations *(1)* and *(2)*. These results suggest that *(2)*—just like *(1)*—has a rectangular structure.

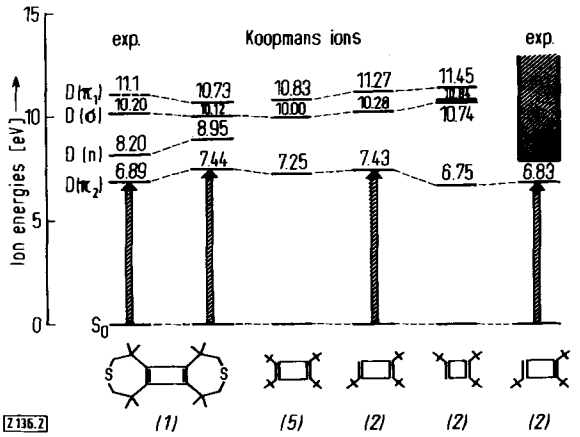

Fig. 2. Comparison of measured and/or calculated ion energies of the cyclobutadiene derivatives *(1)*, *(2)*, and *(5)*.

These findings are confirmed by a semiempirical LCMO estimate according to which π_2 is to be regarded as an antibonding linear combination of a localized *tert*-butylethylene πMO (energy = −9.7 eV[10]) and the corresponding *cis*-di-*tert*-butylethylene πMO (energy = −8.80 eV[11]). The interaction $H_{\pi\pi}$ between the two basis MOs is given by

$$H_{\pi\pi} = \sqrt{\delta E(\delta E + \Delta E)}$$

where ΔE is the energy difference between the two MOs, and δE is the destabilization of the higher-energy MO. If $\Delta E = 0.9$ eV and $\delta E = 1.97$ eV, and it is borne in mind that only 72%[2] of the interaction $H_{\pi\pi}$ can take place by way of the newly formed bonds, we calculate from $0.72\,H_{\pi\pi} = 2c^2\beta_{\pi\pi}$ ($c = 0.7$, where c denotes the $2p_\pi$ AO coefficient in the basis MO) that the resonance integral $\beta_{\pi\pi}$ of these bonds is −1.7 eV, which agrees well with the value of −1.6 eV determined for *(1)*. Accordingly, tri-*tert*-butylcyclobutadiene is rectangular and probably has a geometry resembling that of *(1)*.

[8] According to preliminary estimates of the Koopmans defects for rectangular (1.600 Å/1.344 Å) and square (1.425 Å) unsubstituted cyclobutadiene, Koopmans' theorem is fulfilled satisfactorily in the former case and less well in the latter case. As a consequence, the difference between the $D(\pi_2)$ ion energies (0.7 eV) of rectangular and square *(2)* given in the text will be somewhat smaller.

[10] *U. Weidner* and *A. Schweig*, J. Organometal. Chem. *39*, 261 (1972).

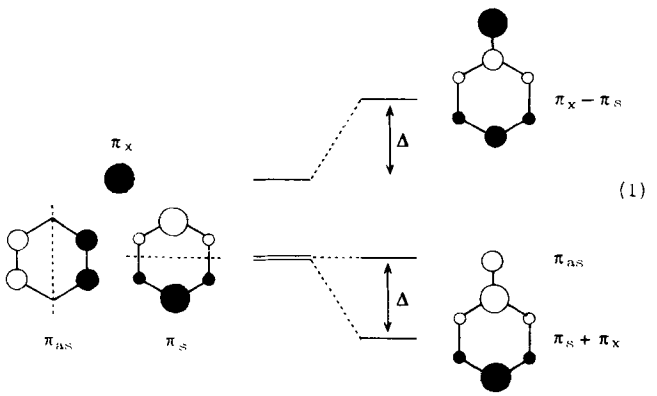
[11] In the case of *trans*-1,2-di-*tert*-butylethylene = 8.85 eV [*W. Schäfer* and *A. Schweig* unpublished]. According to *P. Masclet, D. Grosjean, G. Mouvier*, and *J. Dubois* [J. Electron Spectr. *2*, 225 (1973)] the difference between the adiabatic ionization potentials of *cis*- and *trans*-di-*tert*-butylethylene amounts to 0.05 eV. We therefore assume the vertical IP of the *cis* isomer to be 8.80 eV.

Extreme Perturbation of π-Systems by Ylidic Substituents[1,2]

By *Karl-Heinz A. Ostoja Starzewski, Hans Bock*, and *Heindirk tom Dieck*[*]

The simplest phosphorus ylide $(H_3C)_3P{=}CH_2$[3] reacts with explosive violence when exposed to air or water, in accord with the low-lying first ionization energy of 6.81 eV[2] and the high-field $^{13}CH_2$ NMR signal[4]. These exceptional properties prompted us to examine the interactions between the ylidic π_{PC} bond and the π-system of benzene.

Benzene derivatives are particularly suitable for characterization of substituent effects since the highest occupied π levels π_s and π_{as}, degenerate in benzene itself, are affected to different extents[5]:



(1)

While π_s can undergo mixing with a substituent orbital π_X os like symmetry, π_{as} remains unperturbed (1), since its nodal plane passes through the substitution site, and thus permits the splitting Δ to be read off[5a,b].

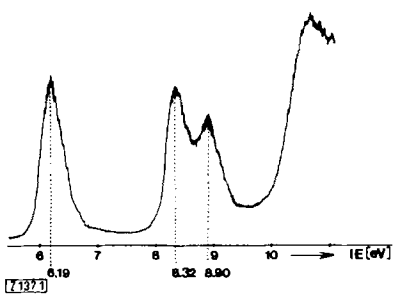


Fig. 1. PE spectrum (5–12 eV) of benzylidenetrimethylphosphorane, calibrated with the $^2P_{3/2}Xe$ band at 12.13 eV.

Although the first ionization energy of benzene is known to be 9.24 eV[5], no band is observed between 9.0 and 10.5 eV in the photoelectron (PE) spectrum of benzylidenetrimethylphosphorane (Fig. 1), contrary to what would be expected from (1).

Various approaches were adopted to solve the riddle of the "missing" benzene π-ionizations, and simultaneously to assign the benzylidene PE spectrum: calculations with a modified CNDO/2 program, reparametrized to achieve an optimum fit with PE data[6], reveal the compositions shown in Figure 2 for the three highest occupied molecular orbitals ψ_{30}, ψ_{29}, ψ_{28}.

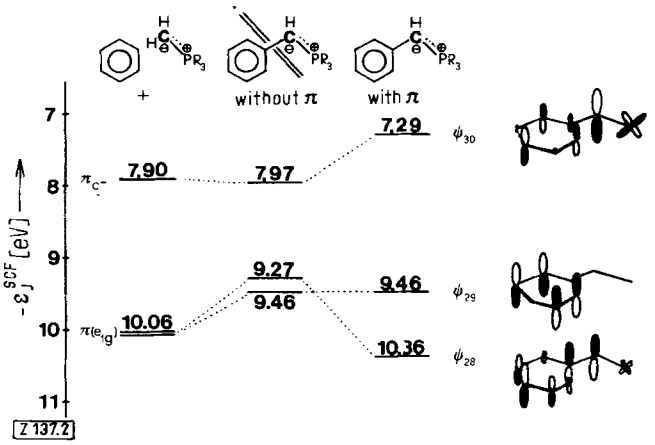

Fig. 2. CNDO correlation diagram for the highest occupied π-orbitals of benzene and methylenetrimethylphosphorane, and of benzylidenetrimethylphosphorane with and without π-interactions.

The calculated orbital sequence is also expected from qualitative perturbation arguments, as is apparent from (1). Particular attention should be directed to ψ_{29} (Fig. 2), which resembles the unperturbed benzene orbital π_{as} in (1). Furthermore, the correlation diagram (Fig. 2) shows how the individual orbitals move on stepwise coupling of the partial systems: if π-interactions are initially neglected[7] then the different inductive raising of the two benzene orbitals is clearly to be seen. Inclusion of π-interactions in a further calculation shows that mixing occurs almost exclusively between π_s and the "carbanion" orbital $\pi_{C\ominus\cdots P\oplus}$. Thus the π_{as} orbital which is raised by about 1 eV relative to benzene reflects the extreme inductive perturbation[5c] by the "carbanion" center.

Since the quality of semiempirical calculations is frequently rather modest, the CNDO/2 eigenvalues $-\varepsilon_j^{SCF}$ (Fig. 2) can be regarded as correlating satisfactorily *via* Koopmans'

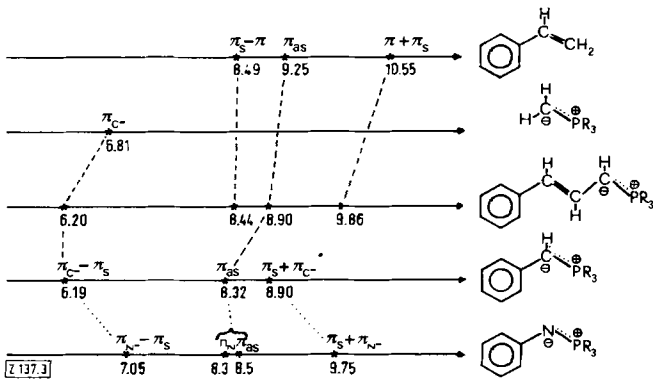

Fig. 3. Ionization energy correlation diagram for the highest occupied π-levels of benzylidenetrimethylphosphorane and appropriate model compounds.

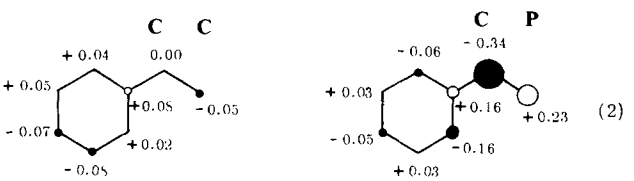
[*] Dipl.-Chem. K. A. Ostoja Starzewski, Prof. Dr. H. Bock, and Prof. Dr. H. tom Dieck
Institut für Anorganische Chemie der Universität
6 Frankfurt am Main 70, Theodor-Stern-Kai 7 (Germany)

theorem $-\varepsilon_n^{SCF} = IE_n$[8] with the PE ionization energies IE_n (Fig. 1). However, since Koopmans' theorem can fail in cases of extreme charge redistribution in the resulting cation radical[8], as is conceivable for ylides, it was important to accomplish an independent assignment by comparing the PE spectra of related compounds (Fig. 3).

The starting points for the comparison are styrene[5b, 9], whose π-orbital sequence having a constant $\pi_{as} = 9.25$ eV is to be derived by mixing $\pi_s \pm \pi_X$ (X:C=C) according to (1), and the simplest ylide with $IE_1 = 6.81$ eV. Even in cinnamylidenephosphorane, where the phenyl ring and the ylide site are separated by three bonds, the π_{as} ionization energy is lowered by 0.35 eV owing to the relatively high charge density in the neighboring "allyl anion". The π-interaction with the ylide system is manifested in the lowered first ionization energy, $\Delta IE_1 = -0.6$ eV. However, the most important feature of the cinnamylidene comparison substance is that there is no steric reason for any change in styrene geometry. Finally, in benzylidenephosphorane, charge concentration at the ylidic carbon leads to a further shift of π_{as} to 8.32 eV.

Figure 3 also shows the ionization energies of the isoelectronic phenyliminophosphorane: the π_{as} destabilization once again indicates a high negative charge on the neighboring nitrogen; the much greater π-splitting shifts π_s to 9.75 eV, and thus beyond the corresponding ionization energy of the unperturbed benzene system.

Summarizing, replacement of the terminal CH_2 group of styrene by the $(CH_3)_3P$ unit drastically perturbs the original charge distribution and confers considerable benzyl anion character. This is readily seen from the CNDO total atomic charges:



(2)

Comparable charge shifts are also calculated for all the other ylide systems mentioned—in full accord with measured ^{13}C-NMR shifts[10].

[Bis(diphenylphosphino-η-benzene)chromium]tetracarbonylmetal Complexes of Chromium, Molybdenum, and Tungsten[1][**]

By *Christoph Elschenbroich* and *Felix Stohler*[*]

Bidentate phosphane chelate ligands are considered to be a well-studied class of compounds[3]. However, a new aspect of their chemistry consists in the transformation of such a ligand into a paramagnetic form. In the case of bis(diphenylphosphino-η-benzene)chromium(0)[2] (bdpc), this transformation can be accomplished by prolonged air-oxidation and renders the behavior of this "ligand" in substitution and solvolysis reactions accessible to study by ESR spectroscopy.

We now report the synthesis of dinuclear bis(arene)chromium-tetracarbonylmetal complexes which are obtained according to eq. (1) as reddish brown crystals displaying only little

$$[(C_6H_5)_2P\text{-}\eta\text{-}C_6H_5]_2Cr^0 + M(CO)_6 \xrightarrow{-2\,CO} \{[(C_6H_5)_2P\text{-}\eta\text{-}C_6H_5]_2Cr^0\}M(CO)_4 \quad (1)$$

(bdpc)

M = Cr, Mo, W

sensitivity to air exposure. Their composition was confirmed by elemental analysis and molecular weight determination; spectroscopic data are listed in Table 1.

In the range of CO stretching vibrations the IR spectra of the dissolved complexes (bdpc)$M(CO)_4$ exhibit four bands that are characteristic of C_{2v} local symmetry of the $M(CO)_4$ group in compounds of type *cis*-$L_2M(CO)_4$[4]. Hence (and also on the basis of ESR data, see below) it is possible to distinguish between the alternative structures *(1a)*[5] and *(1b)*, and to ascribe structure *(1b)* to the new complexes.

(1a) R = C_6H_5 *(1b)*

M = Cr, Mo, W

π-Coordination of Cr^0 to one phenyl group each of the triphenylphosphane ligands in *cis*-$[(C_6H_5)_3P]_2Mo(CO)_4$ (ν(CO): 2022, 1929, 1911, 1899 cm^{-1}[4]) has virtually no effect on the CO stretching frequencies (cf. Table 1), although it raises the electron density in the aromatic rings[6, 7]. However, the ν(CO) frequencies undergo considerable shifts ($+10$ to $+30$ cm^{-1}) if the chelate ligand is oxidized to its cation radical. This increase in CO bond order connected with the oxidation (bdpc)$M(CO)_4 \rightarrow [(bdpc)M(CO)_4]^{\ddagger}$ can be explained in terms of reduced σ-donor and increased π-acceptor character of the cationic ligand relative to neutral bdpc. The green cation radicals $[(bdpc)M(CO)_4]^{\ddagger}$ obtained by passage of O_2 for several hours through solutions of the corresponding neutral complexes reveal, *via* ESR spectroscopy, that oxidation entails removal of an electron from the bis(arene)chromium part of the molecule, and the spin density is largely localized in this part of the molecule. Thus the ESR spectra of the species

[a] Solution in methylcyclohexane; assignment as for *cis*-[(C$_6$H$_5$)$_3$P]$_2$Mo(CO)$_4$ [8].
[b] KBr disc; counterion I$^-$
[c] In [D$_8$]THF, TMS as internal standard. In order to avoid line broadening and contact shifts caused by the presence of small amounts of isostructural cation radicals [9], the sample solutions were reduced on a K mirror until the ESR signal had disappeared prior to recording the ^{1}H-NMR spectra.
[d] In THF at +25°C.
[e] Equivalent within the limits of resolution (protons attached to π-bonded phenyl groups).
[f] Splitting due to intermolecular interactions.

[(bdpc)M(CO)$_4$]$^{+}$ closely resemble that of the ligand cation radical bdpc^{+}, and no coupling is observed with ^{53}Cr, ^{95,97}Mo, or ^{183}W of the M(CO)$_4$ group. In contrast, replacement of an H atom in each of the π-bonded benzene rings by a P(C$_6$H$_5$)$_2$ group leads to a triplet splitting (2 ^{31}P, $I = 1/2$) of each ^{1}H hyperfine component.

Coordination of a M(CO)$_4$ group to bdpc modifies the latter's properties in a characteristic manner: whereas bdpc exhibits considerable thermal stability[2] (can be melted and sublimed without decomposition), (bdpc)M(CO)$_4$ begins to lose triphenylphosphane at 140°C/10^{-3} torr; the M(CO)$_4$ group in (bdpc)M(CO)$_4$ therefore weakens the Cr—arene π bond. On the other hand, the resistance of the C(η-arene)—P bond to solvolysis is enhanced when bdpc^{+} assumes the role of a chelating ligand on M(CO)$_4$.

$$[(C_6H_5)_2P\text{-}\eta\text{-}C_6H_5]_2Cr^{+} \xrightarrow[50\,^\circ C]{THF/5\%\ H_2O} (C_6H_6)_2Cr^{+} + 2\ (C_6H_5)_2PHO \qquad (2)$$

$$\{[(C_6H_5)_2P\text{-}\eta\text{-}C_6H_5]_2Cr\}M(CO)_4^{+} \xrightarrow[50\,^\circ C]{THF/5\%\ H_2O} \text{no reaction}$$

Reaction *(2)* can be conveniently followed by observing the change in ESR hyperfine structure—transition from 10 to 12 equivalent protons with a different coupling constant (a^1H = 3.25 G, bdpc^{+}, and 3.46 G, (C$_6$H$_6$)$_2$Cr^{+} resp.). The differing reactivity of bdpc^{+} and (bdpc)M(CO)$_4^{+}$ in solvolyses of the C(η-arene)—P bond is probably attributable to the forced *syn* orientation of the two C(η-arene)—P bonds in (bdpc)M(CO)$_4$. While *endo* attack by solvent molecules is clearly impossible in this form, an *exo* attack would require the P-containing fragment to depart in the *endo* direction, which would be opposed by the presence of the second C(η-arene)—P(C$_6$H$_5$)$_2$ group.

Procedure:

All reactions are carried out with dry, air-free solvents under inert gas (N$_2$). [(C$_6$H$_5$)$_2$P-η-C$_6$H$_5$]$_2$Cr^0[2] (600 mg, 1.04 mmol) and Mo(CO)$_6$ (317 mg, 1.20 mmol) are refluxed for 2 h in diglyme (25 ml) at 170°C with mechanical re-introduction of sublimed carbonylmetal. After removal of solvent by distillation at oil-pump vacuum, the residue is extracted with a boiling mixture of methylcyclohexane and tetrahydrofuran (2:1, 75 ml). Reddish brown {[(C$_6$H$_5$)$_2$P-η-C$_6$H$_5$]$_2$Cr^0}-Mo(CO)$_4$ crystallizes from the extract, yield 410 mg (51%).

The corresponding Cr and W complexes are prepared in similar manner although in somewhat lower yields, despite prolonged reaction (4 h).

Optical Activity of Oriented Molecules[**]

By *Hans-Georg Kuball* and *Ties Karstens*[*]

Measurement of the optical rotatory dispersion (ORD) and the circular dichroism (CD) of isotropic solutions has proved to be valuable in structural elucidation. Since it follows from the theory[1] of optical activity that ORD and CD depend upon the direction of radiation of the light in the molecule, investigations on oriented molecules should yield additional structural information. So far, this effect has only been detected in flowing media or in electrical fields with oriented molecules of high polymers[2].

Small molecules cannot be oriented sufficiently by these methods[3, 4]. However, a very high degree of orientation can be achieved by their inclusion in liquid crystals—especially in nematic phases—and orientation of the nematic phase in electrical or magnetic fields. Incorporated optically active molecules convert nematic phases into cholesteric phases[5], and the optical activity of the solution is then determined by the liquid crystal and no longer by the included molecule[3, 4] (induced optical activity).

However, this optical activity induced in solution can be compensated by a further optically active component. For this purpose a solvent mixture of two compounds is used which on their own give cholesteric phases of opposite helicity. At a certain temperature (T_{nem}), this mixture, which normally forms a cholesteric phase, behaves as a nematic phase[6] (compensated nematic phase). T_{nem} is a function of the mixing ratio (in present case cholesteryl chloride and cholesteryl laurate in weight ratio 1.8:1; $T_{nem} \approx 36$ °C, depending upon additive). If the optically active substance is dissolved then the nematic phase is transformed into a cholesteric phase owing to the induced optical activity. A change in temperature to T'_{nem} compensates this effect, *i.e.* the nematic phase is restored ($|T_{nem} - T'_{nem}| \approx 3$—4 °C). After orientation of the molecules of this nematic phase in an electrical field (20—30 kV/cm) the optical activity can be measured with a light ray that propagates along the optical axis[7].

Investigations were performed on the steroids 4-cholesten-3-one *(1)* and 3β-acetoxy-5-cholesten-7-one *(2)* in the nematic phase at T'_{nem} and at a temperature ($T = 80$ °C) at which the mixture is isotropic (Figs. 1 and 2). From the degree of polarization $P \neq 0$ (Figs. 1a, 2a) it follows that the molecules in the liquid crystal do not display an isotropic distribution. Since P is larger for *(1)* than for *(2)*, either the orientation must be greater for *(1)* than for *(2)* or, as is more likely, the direction of the transition moment describes a smaller angle with respect to the orientation axis in the case of *(1)* than in the case of *(2)*. The orientation axis is the longest molecular axis, since in this case the dissolved molecules are included in the liquid crystals in similar manner to the molecules of the liquid crystals themselves.

[**] Optical Activity of Oriented Molecules, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

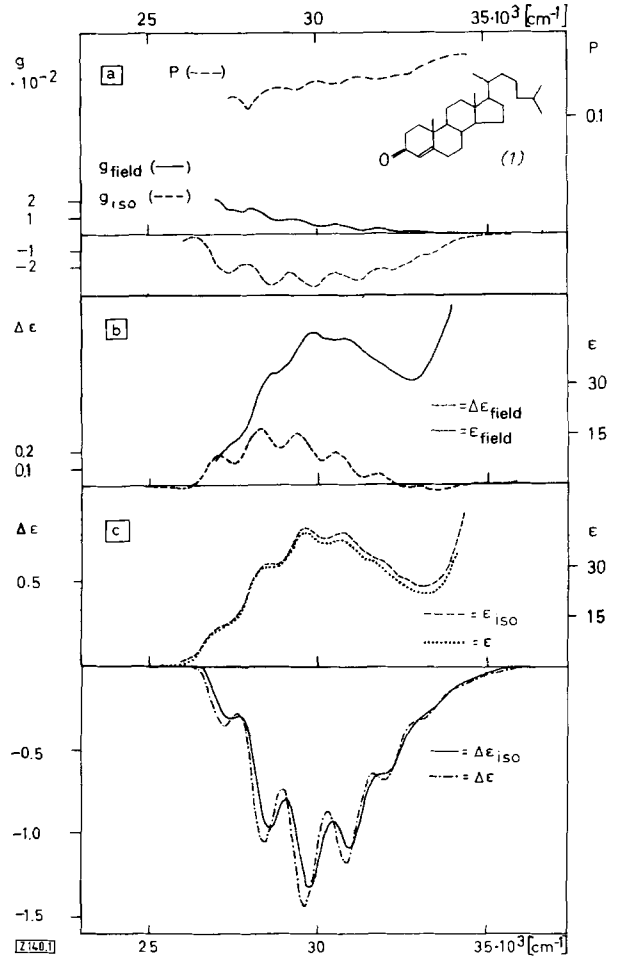

Fig. 1. 4-Cholesten-3-one *(1)*, dissolved in cholesteryl chloride/cholesteryl laurate (cf. text).—a) Degree of polarization $P = (\varepsilon_{\parallel} - \varepsilon_{\perp})/(\varepsilon_{\parallel} + \varepsilon_{\perp})$; $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ are the molar decadic absorption coefficients of the sample for light polarized parallel and perpendicular, respectively, to the optical axis. $g_{field} = \Delta\varepsilon_{field}/\varepsilon_{field}$ and $g_{iso} = \Delta\varepsilon_{iso}/\varepsilon_{iso}$ are the dissymmetry factors.—b) Circular dichroism $\Delta\varepsilon_{field}$ and molar decadic absorption coefficient $\varepsilon_{field} = 1/3\,(\varepsilon_{\parallel} + 2\varepsilon_{\perp})$, measured at T_{nem}.—c) Circular dichroism $\Delta\varepsilon_{iso}$ and $\Delta\varepsilon$ and molar decadic absorption coefficient ε_{iso} and ε, measured in the mixture in the isotropic state ($T = 80$ °C) and in *n*-heptane ($T = 20$ °C).

In all cases, the $\Delta\varepsilon$ and ε spectra (Figs. 1c, 2c) are practically identical in the isotropic mixture and in *n*-heptane ($T = 20$ °C), *i.e.* the mixture displays no anomalous solvent effects. Moreover, the absorption spectrum ε_{field} does not deviate significantly from the spectrum in the isotropic medium. In contrast, the CD is completely different when recorded for the solution in the field. Whereas the CD signal is merely enhanced for *(2)* and its frequency dependence remains the same (Fig. 2b), the sign and the frequency dependence change for *(1)* (Fig. 1b). This effect can be seen clearly from the dissymmetry factors (Figs. 1a, 2a).

The optical activity of *(1)* and *(2)* is largely determined by the chromophore C=C—C=O. Since this group has approximately mirror symmetry in *(1)* and *(2)*[8], the circular dichroism of isotropic solutions will differ in sign. On the basis of these assumptions, the difference between $\Delta\varepsilon_{field}$ in *(1)* and *(2)* should arise from the differing arrangement of the chromophore in the molecule. When measurements are performed in the oriented state, the direction of the light ray runs parallel to the longest molecular axis. However, the chromophore is arranged differently relative to the longest molecular axis in *(1)* and *(2)*, and is therefore traversed differently by the light ray.

The results described here indicate that measurement of optical activity on oriented systems yields not only information about absolute configurations but also provides further structural

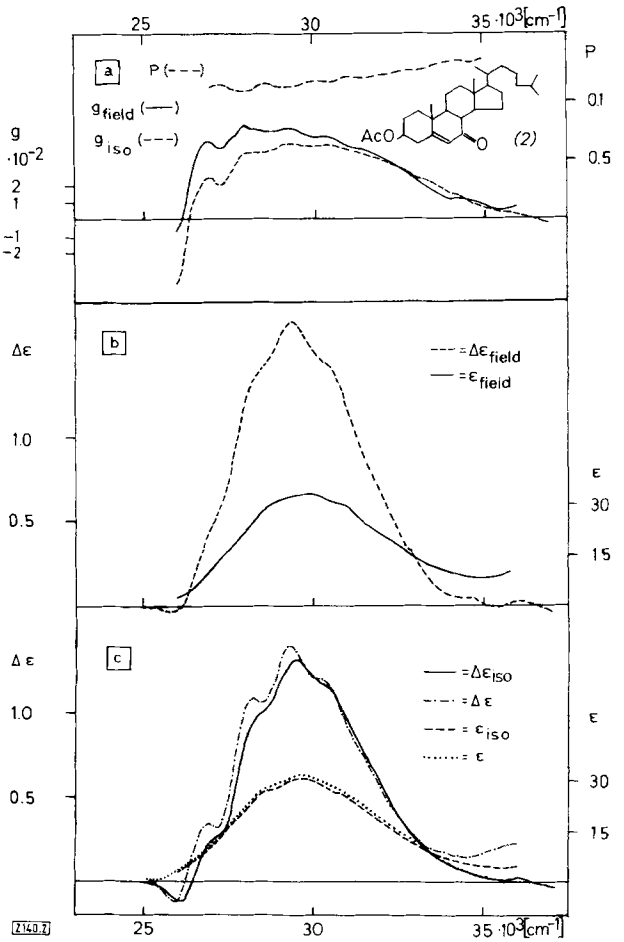

Fig. 2. 3β-Acetoxy-5-cholesten-7-one *(2)*, dissolved in cholesteryl chloride/-cholesteryl laurate (cf. text and legend to Fig. 1).

information, *e.g.* regarding the arrangement of the chromophore relative to the molecular axis. Theoretical evaluation and the consequences of applying the sector rules, *etc.*, will be reported later.

Isolation of Tetrazene, N_4H_4[1]

By *Nils Wiberg, Heiner Bayer*, and *Heinz Bachhuber*[*]

The only hydrogen compounds of nitrogen that have previously been unambiguously characterized are ammonia (NH_3), hydrazine (N_2H_4), diimine (N_2H_2)[2] and hydrogen azide (N_3H). We have now succeeded in preparing a further nitrogen hydride, namely tetrazene (N_4H_4), which, unlike the previously known compounds containing a one-, two- or three-membered nitrogen chain, is based on a skeleton of four nitrogen atoms.

For *synthesis* of this compound, tetrakis(trimethylsilyl)tetrazene[4] which is readily accessible by acid-catalyzed dimerization of bis(trimethylsilyl)diimine[3] is treated with trifluoroacetic acid in methylene dichloride at −78 °C. The tetrazene, being only sparingly soluble in methylene dichloride, is thus precipitated as a colorless solid; it can be purified by sublimation.

$$(Me_3Si)_2N{-}N{=}N{-}N(SiMe_3)_2 \xrightarrow[-4\ F_3C{-}COOSiMe_3]{+4\ F_3C{-}COOH} H_2N{-}N{=}N{-}NH_2$$

The following facts indicate that the nitrogen hydride isolated has the structure of a *trans*-2-tetrazene: 1. Quantitative analysis of the thermolysis products (see below) yields a nitrogen/hydrogen ratio of 1 : 1, *i.e.* the nitrogen hydride has the molecular formula $(NH)_x$.—2. The mass spectrum obtained for the isolated compound at an ionization energy of 70 eV in the gas phase at 5×10^{-7} torr shows the molecular ion $N_4H_4^+$ as an intense line at $m/e = 60$. If the ionization energy is lowered from 70 to 10 eV, then, as expected, the mass groups of ionic fragments $N_mH_n^+$ with one, two or three nitrogen atoms disappear almost completely and there remains only the signal of the molecular ion. Thus x in the molecular formula $(NH)_x$ that follows from the analytical investigations must be replaced by the number 4.—3. By germylation with *N,N*-diethyl(trimethylgermyl)amine the nitrogen hydride N_4H_4 can be converted by the reaction (E = Ge)

$$N_4H_4 \xrightarrow[-4\ H{-}NEt_2]{+4\ Me_3E{-}NEt_2} (Me_3E)_2N{-}N{=}N{-}N(EMe_3)_2$$

into the derivative, tetrakis(trimethylgermyl)-2-tetrazene which could be synthesized by an independent route[5]. N_4H_4 also reacts analogously with *N,N*-diethyl(trimethylstannyl)-amine (E = Sn). Thence we conclude that N_4H_4 has the structure 2-tetrazene.—4. The synthetic route leading to tetrazene consists of protolysis of tetrakis(trimethylsilyl)-2-tetrazene which according to X-ray structure analysis[6] has the *trans*-configuration; and, since a change of configuration during protolysis is unlikely, the 2-tetrazene prepared in this way probably also has the *trans*-configuration[7].

Thermolysis of tetrazene

$$H_2N{-}N{=}N{-}NH_2 \longrightarrow N{\equiv}N + H_2N{-}NH_2$$
$$\qquad\qquad\qquad\qquad\quad \longrightarrow NH_4^{\oplus}\ N{=}N{=}N$$

[*] Prof. Dr. N. Wiberg, Dipl.-Chem. H. Bayer, and Dr. H. Bachhuber
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstr. 1 (Germany)

leads by decomposition to nitrogen and hydrazine and by isomerization to ammonium azide[8]. If pure tetrazene is thus decomposed, the decomposition and isomerization products are formed in about 75 and 25% yields, respectively (*e.g.* found: 1.18 mmol of N_2, 1.18 mmol of N_2H_4, 0.39 mmol of NH_3, 0.38 mmol of HN_3). However, decomposition and isomerization of tetrazene in methanol affords about 40 and 60%, respectively. Thermolysis of solid tetrazene begins only at *ca.* 0 °C (gaseous tetrazene is metastable even at room temperature); *trans*-2-tetrazene is thus unexpectedly thermostable.

Experimental:

Trifluoroacetic acid (6.00 mmol) in methylene dichloride (15 ml) is dropped very slowly into a well-stirred solution of tetrakis(trimethylsilyl)tetrazene[3] in methylene dichloride (25 ml) cooled to −78 °C. The tetrazene is isolated by condensation: the reaction mixture is warmed slowly to 0 °C and the vapor is passed in a high vacuum through a glass trap cooled to −78 °C into one cooled to −196 °C. All the methylene dichloride then collects in the second trap (−196 °C) together with trimethylsilyl acetate; the 2-tetrazene remaining in the first trap (−78 °C) is purified by repeated sublimation in a high vacuum from −15 °C into a tube cooled to −78 °C (yield 90%).

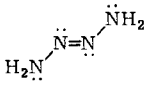
Photoelectron Spectrum of Tetrazene[1]

By *Jürgen Kroner, Nils Wiberg*, and *Heiner Bayer*[*]

The nitrogen hydride N_4H_4 recently isolated for the first time has the geometrical structure of a *trans*-2-tetrazene[1].



To obtain the first preliminary information about its electronic structure we have measured the photoelectron (PE) spectrum of tetrazene[2]. In the energy range up to 21.21 eV it shows eight bands (Fig. 1), which can be assigned by qualitative MO considerations (Fig. 2).

[*] Dr. J. Kroner, Prof. Dr. N. Wiberg, and Dipl.-Chem. H. Bayer
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstr. 1 (Germany)

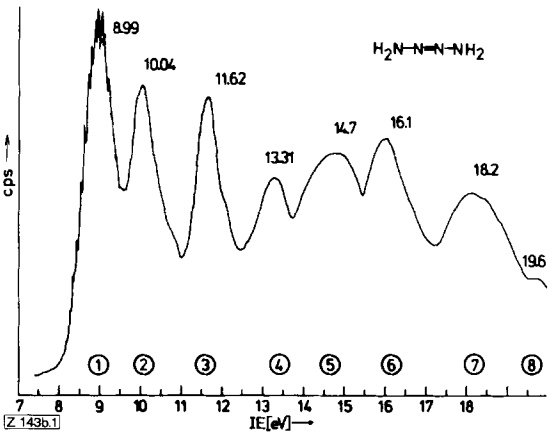


Fig. 1. Photoelectron spectrum of *trans*-2-tetrazene.

Derivation of the orbital sequence of tetrazene (Fig. 2) is based on the vertical ionization energies of *trans*-azomethane[3a] and ammonia[3b] together with consideration of the inductive effects of azo ($-I$) and amino groups ($+I$).

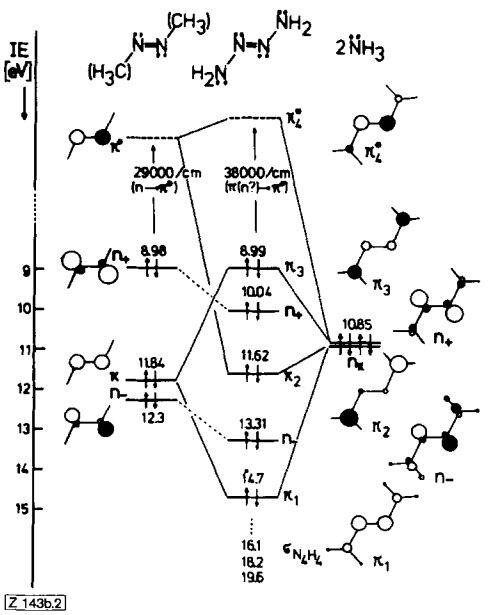

Fig. 2. MO scheme of n- and π-interactions in *trans*-2-tetrazene (vertical ionization energies in eV).

The first PE bands of tetrazene is undoubtedly to be assigned to ionization of the π_3-orbital because of its shape and vibrational fine structure ($\nu^{\oplus} = 650\ cm^{-1}$, *ca.* 15 progressions; cf. also ammonia[3b] and cyanamide[3c]). In view of the inductive effect ($CH_3 \rightarrow NH_2$) and of a small interaction effect between the n-orbital of the azo group and the energetically low-lying σ-orbitals of the amino group ($IE_{\sigma}^{NH_3} = 15.8$ eV[3b]), the second band should refer to ionization of the n_+-orbital of the azo group. If as an approximation one assumes an equal inductive decrease in n_+ and n_- on going from azomethane to tetrazene (≈ 1 eV), the fourth band can be assigned to ionization of the corresponding n_- combination[4]. Thus the third PE band must be assigned to π_2 which mixes symmetry-correctly with the π*-orbital of the azo group. For π_1 there remains the fifth PE band.

The qualitatively derived interaction diagram (Fig. 2) has been confirmed by CNDO/S calculations[5] on the assumption of "pyramidal" amino-nitrogen atoms: π_3 (8.51), n_+ (10.13), π_2 (11.67), n_- (13.92), π_1 (14.44 eV); it was impossible to

obtain comparable agreement between orbital and ionization energies for "planar" amino-nitrogen. The utility of the model used for calculations is further shown by prediction of the three σ-orbital ionizations of the tetrazene [σ_{NNNN} (15.50), σ_{NH_2} (19.88, 19.89 eV)], which correlate satisfactorily with the vertical ionization energies (Fig. 1).

The following, *inter alia*, can be derived from the photoelectron spectrum and the molecular orbital scheme:

1. A tetrazene orbital of π-type advances to the highest occupied orbital owing to π-interaction of π-orbitals of the azo group and n_π-orbitals of the amino groups. This finding is in contrast with previous findings that in compounds of type X—N=N—X the positions of the n- and π-orbitals are indeed appreciably influenced by electronic interactions of the azo group and substituents X but that the highest occupied orbital is always of n_σ-type. Thus the orbital sequence derived by PE spectroscopy for tetrazene contributes also to understanding of the UV spectra of amino-substituted π-electron systems: whereas n→π* transitions of low intensity occur in azo compounds X—N=N—X ($X \neq NR_2$)[6], the low ionization energies of the highest occupied π-orbitals of substituted tetrazenes[7] and triazenes[7] cause coincidence of π→π* and n→π* bands. Corresponding results are valid for azobenzene/aminoazobenzenes[7, 8] and quinone/aminoquinones[3b, 6b, 9].

2. The surprisingly great π-conjugation along the nitrogen chain of the tetrazene (cf. Fig. 2)[10] need not necessarily produce a marked shortening of the N—N single bonds or a lengthening of the N=N double bonds, since the equally strong delocalization of the electron pair in the π_3-orbital opposes this change in the bond lengths. A tetrazene cation $N_4H_4^{\oplus}$ should, however, show appreciably shorter single and longer NN double bonds[11] and should thus be more stable than tetrazene towards radical decomposition. The opposite is to be expected for a tetrazene anion $N_4H_4^{\ominus}$.

3. The structuring of the first PE band of the tetrazene (Fig. 1) and the finding that no satisfactory agreement can be achieved between calculation and experiment for an sp^2-hybridized amino-nitrogen atom can be regarded as showing the occurrence of sp^3-hybridized nitrogen atoms in the amino groups of the tetrazene.

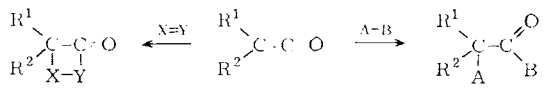
Additions to the C=O Group of Ketenes: β-Substituted α-Trimethylsiloxyacrylonitriles[**]

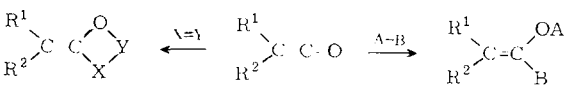
By *Ulrich Hertenstein* and *Siegfried Hünig*[*]

The numerous additions to the cumulated double bond system of the ketenes *(2)* take place almost without exception at the C=C bond with formation of acyl derivatives *(3)* or of four-membered *(1)* or six-membered cycloadducts having a carbonyl function[1]. A—B = R_3^1Si—NR^2R^3 is also added to *(2)* with formation of a Si—C bond[2].



(1) *(2)* *(3)*

In contrast, there are very few additions to the C=O function of ketenes yielding *(4)* or *(5) with retention of the C=C*



(4) *(2)* *(5)*

bond[3]. The dimerization of aldoketenes to *(4)* is well known (X=Y is the CO function of the ketene)[1]. Compounds of type *(5)* are formed on thermal addition of oxiranes (= A—B) to ketene acetals: however, this reaction has only been investigated in the case of diphenylketene[4].

Looking for a reaction *(2)*→*(5)* of maximum generality we found that trimethylsilyl cyanide[5] *(6)* adds cleanly to the C=O bond of ketenes to give β-substituted α-trimethylsiloxyacrylonitriles *(7)*. Thus compound *(7)* does not follow the

scheme *(2)*→*(3)* like trialkylsilylamines, but behaves as in additions to aldehydes and ketones[6–8], and to certain acyl chlorides[6, 9].

Adducts *(7)* are produced both from free ketenes and from those formed *in situ*. Generation of ketene intermediates from acyl chlorides with tertiary amines in the presence of *(6)* seems to be a particularly versatile approach. The adducts *(7)* are apparently formed very rapidly since many ketenes are known to undergo fast dimerization under these conditions[1]. Good yields are even obtained with dichloroketene, which polymerizes so fast in the presence of ammonium salts that it can only be trapped with highly reactive enes[10]. The significance of the ketene intermediate is clear from the finding that no adduct *(7)* is obtained from cyclopropanecarbonyl chloride, which forms no ketene with tertiary amines[11].

Table 1 illustrates the versatility of the reaction, whose scope is limited practically only by the existence of ketene intermediates. The colorless compounds *(7)* can be distilled without decomposition up to ≈120 °C. The stretching vibration of the nitrile function appears largely independent of R^1 and R^2 at 2220–2210 cm^{-1}, and that of the C=C bond at 1645–1620 cm^{-1}.

According to the NMR spectra, mixtures are formed in the cases of unequal β-substitution. Surprisingly however, *(7f)* is homogeneous, the phenyl group probably being *cis* to the nitrile group.

We are presently examining whether the reactivity of the cycloadducts *(7)* more closely resembles that of enol silyl ethers or that of acrylonitriles. Apart from the reactions with cycloaddends and nucleophiles known for other α-substituted acrylonitriles[12], a directed attack at the trimethylsiloxy group and at the nitrile group appears to be of interest.

2-Trimethylsiloxyacrylonitrile (7) from acyl chlorides:

A solution of acyl chloride (0.10 mol) in anhydrous ether (20 ml) is added dropwise under N_2 to a mixture of *(6)* (0.11 mol), triethylamine (0.30 mol), and ether (60 ml) at 0 °C in a carefully dried apparatus over 1.5 h. The reaction mixture is then stirred for 1 h at room temperature and for 1 h at 50 °C. The precipitated ammonium salt is filtered off under suction and washed thoroughly with ether. After removal of the solvent the residue is distilled.

2-Trimethylsiloxyacrylonitrile (7) from free ketenes:

Hexafluorodimethylketene[13] or pyrolytically generated ketene is passed into *(6)* (*e.g.* 10—40 g) at room temperature until the IR band of *(6)* at 2190 cm^{-1} has largely disappeared. The crude product is purified by distillation.

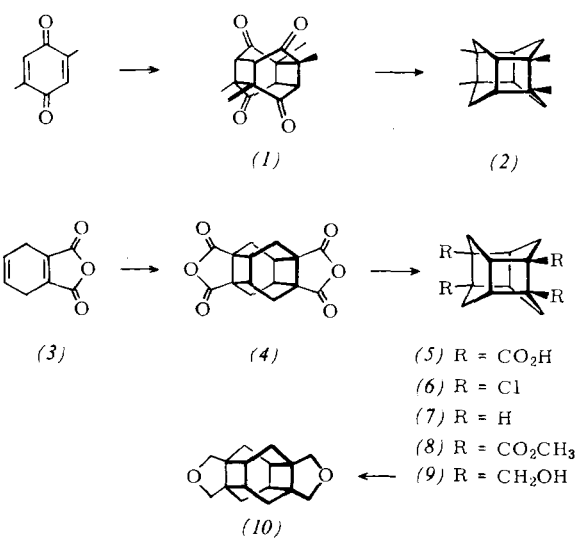
Tetraasterane, Pentacyclo[6.4.0.0^{2,7}.0^{4,11}.0^{5,10}]-dodecane[1][**]

By *Hans-Martin Hutmacher*, *Hans-Günter Fritz*, and *Hans Musso*[*]

The cage dimers of dimethyl-*p*-benzoquinones, *e.g.* *(1)*[2], can be converted into tetramethyltetraasteranes, *e.g.* *(2)*[3, 4], by Wolff-Kishner reduction. We now report the synthesis of the parent hydrocarbon *(7)*, which was first conceived in 1965[3]; all former attempts met with failure[4, 5].

The sparingly soluble cage dimer anhydride *(4)* is accessible in 9–10 % yield in addition to other products by irradiation of 3,6-dihydrophthalic anhydride *(3)* in dioxane[6]. Degradation of the tetracarboxylic acid *(5)* obtainable from *(4)* in 86 % yield initially ran into difficulties. Finally, repeated application of lead tetraacetate and *N*-chlorosuccinimide in dimethylformamide/glacial acetic acid (5 : 1) according to *Grob*[7] gave *ca.* 20 % of tetrachlorotetraasterane (1,2,5,10-tetrachloropentacyclo[6.4.0.0^{2,7}.0^{4,11}.0^{5,10}]dodecane) *(6)*, which is reduced to tetraasterane *(7)* in 74 % yield by sodium in boiling alcohol. The composition and structure of *(6)* and *(7)* can be deduced unequivocally from their spectra (Table 1).



As expected, *(7)* is thermally quite stable. It is unchanged on heating at 500 °C *in vacuo* for 1 h, and only begins to decompose to three major products, which are presently being investigated, above 530 °C. The proximity of the 1,2- and 5,10-substituents on the tetraasterane skeleton accounts for the extreme ease with which *(5)* regenerates *(4)* on heating or on treatment with $SOCl_2$, and with which the tetraalcohol *(9)* [accessible from the tetramethyl ester *(8)* (m.p. 221 °C) with $LiAlH_4$ in ether] reacts with tosyl chloride in pyridine to form "astera-propellane" (6,17-dioxaheptacyclo-

Fatal Accident During Work with 2-(Perfluoroalkyl)-ethyl Iodides

By *Klaus Ulm* and *Walter Weigand*[*]

During the isolation of 2-(perfluoroalkyl)ethyl iodides *(1)* prepared by known procedures[1-3] a fatal accident occurred following circulatory collapse by pulmonary edema.

The cause of the accident was most probably inhalation of toxic substances appearing on isolation of *(1)* from the crude product.

$$RI + C_2H_4 \xrightarrow{1\%\ \text{radical catalysts}} R{-}CH_2{-}CH_2{-}I \quad (1)$$

$R = C_2F_5, C_4F_9, C_6F_{13}, C_8F_{17}, C_{10}F_{21}$

[*] Dr. K. Ulm and Dr. W. Weigand
Hoechst AG
8261 Gendorf/Obb., Werk Gendorf (Germany)

A screening test of acute inhalation toxicity in mice (one hour's exposure) afforded an LC_{50} of 400 to 500 ppm for *(1)*, $R = C_2F_5$, and an LC_{50} of about 4000 ppm for *(1)*, $R = C_4F_9$. Formation of perfluoroisobutylene on isolation of *(1)* could not be detected, even in trace amounts. Perfluoroalkylethylenes prepared from *(1)* are not significantly toxic.

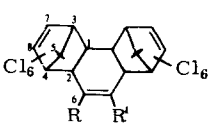
Benzene as Dienophile in the Diels-Alder Reaction[1]

By *Wolfgang Jarre, Dieter Bieniek*, and *Friedhelm Korte*[*]

Furan, thiophene and naphthalene behave towards hexachlorocyclopentadiene as dienophile components in the Diels-Alder reaction[2]. No similar reaction with benzene has previously been described.

Since the course of the Diels-Alder reaction is strongly influenced by pressure, we have tried to cause benzene, chlorobenzene and *o*-dichlorobenzene to react with hexachlorocyclopentadiene at 10 kbar (1 kbar = 987 atm) and 220—240°C (reaction time 20 h). Along with the cage dimer of hexachlorocyclopentadiene, namely dodecachloropentacyclo-[5.3.0.0^{2,6}.0^{3,9}.0^{4,8}]decane[3], we obtained the Diels-Alder adducts *(1)*, always in the ratio 1:1.



(1a): R = R' = H
(1b): R = H, R' = Cl
(1c): R = R' = Cl

On the basis of physical data (UV, IR, MS, ^{1}H-NMR, ^{13}C-NMR) and elemental analyses the new compounds have structures *(1a)*, *(1b)* and *(1c)*. As a representative example, the characteristic data of compound *(1a)* may be cited: m.p. 237—238°C (from methanol). Mass spectrum (70 eV): M^+ 618, rel. int. 0.03%; $[M-Cl]^+$ 583, 0.27%; $[C_5Cl_6]^+$ 270, 100%; $[C_5Cl_5]^+$ 235, 19.4%; $[C_6H_6]^+$ 78, 18.8%. IR spectrum ($CHCl_3$): 1600, 1320, 1250, 1170, 1070, 915, 850 cm^{-1}. ^{1}H-NMR ($CDCl_3$): $\tau = 4.15$ (br), 2H; 6.85 (s), 4H. ^{13}C-NMR ($CDCl_3$, TMS int.): $\delta = 40.11, 44.99$ (C-1,2), 82.44, 82.78 (C-3,4), 101.34 (C-5), 124.88 (C-6), 128.86, 133.19 ppm (C-7,8)[4].

The physical data for compounds *(1b)* (m.p. 212—213°C) and *(1c)* (m.p. 225—227°C) accord with the structures proposed.

Addition of a third molecule of hexachlorocyclopentadiene is impossible because of steric hindrance.

The relative shift of orbital energies occasioned by high pressure, which often leads to a new molecular ground state, may be responsible for the increased reactivity of benzene in the reactions described here[5].

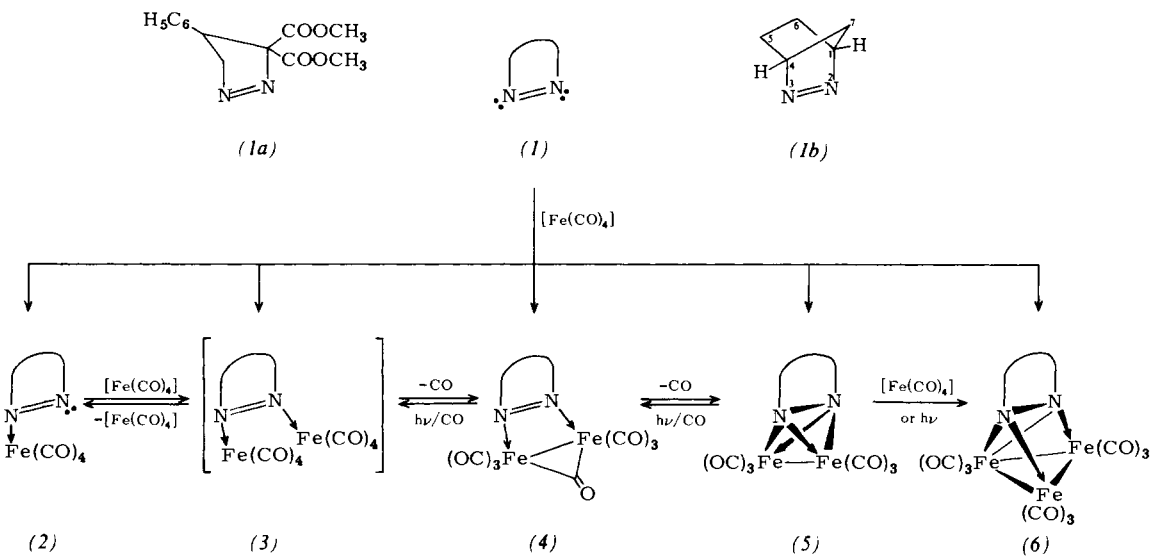
$(C_5H_8N_2)Fe_3(CO)_9$—An Iron Cluster Containing a *cis*-Diimine Unit[1]

By *Angelo Albini* and *Horst Kisch*[*]

Cyclic azoalkanes of medium ring size *(1)* are more suitable than open-chain azoalkanes for study of the complex-chemical behavior of the *cis*-azo group because they contain the isolated N=N double bond always in the *cis*-configuration. We recently showed that on irradiation of a mixture of $Fe(CO)_5$ and *(1a)* the mononuclear complex *(2a)* is formed in the first step of the reaction and that this combines with further carbonyliron fragments to afford the more stable binuclear complex *(5a)*[1]. To find whether the observation on this system is of general importance we have now investigated the reaction of iron carbonyls with 2,3-diazabornene *(1b)* and then isolated, besides the previously known $Fe_2(CO)_6$ complex *(5b)*[2,3], also an $Fe(CO)_4$ complex of type *(2)* and a trinuclear compound of the previously unknown structural type *(6)*.



(6b) crystallizes from acetone/*n*-hexane in shiny black prisms which sublime unchanged at 60 °C/0.04 torr. The mass spectrum, oxidative degradation and elemental analysis lead to the molecular formula $(C_5H_8N_2)Fe_3(CO)_9$. In the ^{1}H-NMR spectrum (C_7D_8) the bridgehead-protons appear as an apparent singlet with about the same chemical shift (7.0 τ) as for *(5b)* (7.2 τ); further, the ^{13}C-NMR spectrum ($CDCl_3$, TMS = 0 ppm) gives for C^1, C^4 and C^5, C^6 only one signal for each pair, at 66.6 and 31.5 ppm, respectively, whose positions again agree well with the data for *(5b)* (62.8 and 30.3 ppm, respectively). *(6b)* can be converted by dilute nitric acid into *(5b)*, in which the presence of an N—N bond is proved by X-ray structure analysis[4]. The IR spectrum (*n*-hexane) contains absorptions of the terminal CO groups at 2072 (s), 2021 (vs), 2012 (vs), 1993 (s), 1976 (s) and 1949 (vw) cm^{-1} and indicates C_{3v} local symmetry of the $Fe_3(CO)_9$ skeleton. On the basis of this finding the novel structure *(6b)* is proposed for the complex, with the *cis*-azo group bound to an $Fe_3(CO)_9$ cluster[5].

The mononuclear compound *(2b)* forms yellow-brown crystals that melt at 38—40 °C without decomposition. The mass spectrum contains the molecular ion and fragment ions that indicate successive removal of CO. The CO stretching vibrations (*n*-hexane) at 2055 (s), 1977 (vs), 1958 (vs) and 1940 (vs) cm^{-1} are largely the same as those of *(2a)* whose structure is proved by X-ray structure analysis[6]. The ^{1}H-NMR spectrum (C_7D_8) shows two broad apparent singlets at 5.65 and 5.45 τ for H^1, H^4 and confirm the unsymmetrical coordination of the ligand; further, for C^1, C^4 and C^5, C^6 the ^{13}C-NMR spectrum (C_7D_8) shows two signals for each pair, at δ = 89.3, 79.0 and 23.6, 22.4 ppm, respectively. When the temperature is lowered to −60 °C the bridgehead-protons yield only a single signal, at 5.8 τ, while the chemical shift for the carbon atoms and the IR absorptions of the CO groups remain unchanged[7]. We presume that rotation around the Fe—N bond is hindered and that at −60 °C a mixture of conformations exists whose ^{1}H-NMR spectrum appears fortuitously to indicate a symmetrical coordination of the ligand; the dependence of the UV spectra of *(2a)* and *(2b)* on temperature and on solvent provide indications in the same direction[8].

The mononuclear complex *(2b)* reacts with further carbonyliron, presumably by way of intermediates of type *(3)* that have not yet been isolated[11], thus giving the stable end products *(5b)* and *(6b)*. Irradiation of *(5b)* ($\lambda \geq 300$ nm) also provides *(6b)*, which is stable under these conditions. Recently a further binuclear complex was reported, for which structure *(4b)* is proposed; decarbonylation at room temperature affords *(5b)*, whence *(4b)* is regenerated on UV-irradiation in presence of CO[9]. IR spectroscopic investigation of this irradiation of *(5b)* shows that it yields also *(2b)* and *(6b)*.

The variety of the complexes isolated reflects the ability of the *cis*-azo group to function as a 2-, 4- or 6-electron donor. Preliminary study of the chemical reactivity of the Fe—N bond in these compounds was carried out with alkynes and

[**] A. A. thanks the Humboldt-Stiftung for a grant.

both *(5a)* and *(5b)*; alkyne is inserted, yielding three new types of complexes, which in the case of diphenylacetylene can be converted into tricarbonyl(tetraphenylcyclobutadiene)iron[10].

Experimental:

(2b): (1b) (6 g, 0.063 mol) and $Fe_2(CO)_9$ (6 g, 0.016 mol) are stirred in *n*-hexane (120 ml) until all the $Fe_2(CO)_9$ is consumed. Column chromatography at −10 °C (silica gel Serva 100—200 nm; *n*-hexane/toluene) and crystallization from ether/*n*-hexane afford analytically pure *(2b)* (1.4 g, 32%), m.p. 38—40 °C.—*(6b)*: Analogous to the preparation[2] of *(5b)*; chromatographic separation (neutral Al_2O_3; *n*-hexane/benzene) affords *(5b)*, and further elution with benzene affords *(6b)* in 20% yield; sublimes at 130 °C in a closed tube.

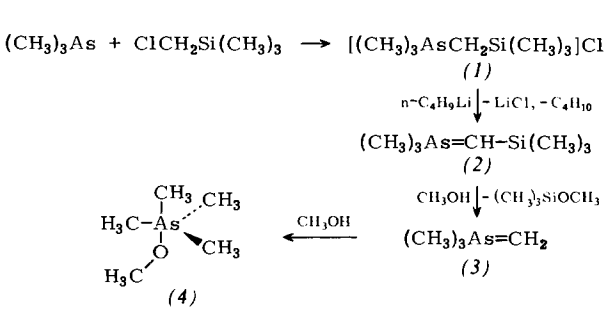
Methoxytetramethylarsorane, $(CH_3)_4AsOCH_3$

By *Hubert Schmidbaur* and *Wolfgang Richter*[*]

Compounds of formula R_4AsX are usually arsonium salts of strictly ionic structure, $R_4As^+X^-$[1]. Methoxytetramethylarsorane *(4)*, however, has now been found to be one of the few compounds of five-coordinate arsenic with covalent bonding, and thus the gap between methoxytetramethyl-phosphorane[2], $(CH_3)_4POCH_3$, and -stiborane[3], $(CH_3)_4SbOCH_3$, is closed.

For the synthesis[10] we used the method of desilylation[4] of the corresponding silyl-substituted arsenic ylide *(2)*[5] with



[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. W. Richter

8 München 2, Arcisstr. 21 (Germany)

subsequent addition of methanol to the free trimethylmethylenearsorane *(3)*[6].

As in the corresponding phosphorus system[2, 4] the reactions *(2)* → *(3)* → *(4)* can be carried out either stepwise or as a "single pot" reaction, in both cases at −20 °C in diethyl ether as a solvent. *(4)* is formed as a colorless distillable liquid (b.p. 38 °C/17 torr) of high chemical reactivity. The compound fumes in air and, when finely divided, is self-inflammable. Its aqueous and alcoholic solutions react strongly alkaline since tetramethylarsonium hydroxide is immediately formed[7].

The ^{1}H- and ^{13}C-NMR spectra of toluene (or benzene) solutions of *(4)* at room temperature show virtual structural equivalence of the four methyl groups bound to arsenic. Only at very low temperatures, however, as with phosphorus analogs, is a splitting of the corresponding lines into two singlet signals (area ratio 3:1) observed. This proves also that *(4)* has a fluctuating trigonal-pyramidal structure[8] (Table 1). Here, for the first time with arsenic, it is possible to distinguish alkyl groups bound axially (a) and equatorially (e) in the same molecule; this has not yet been found for the homologous antimony compound[3].

Table 1. ^{1}H- and ^{13}C-NMR data for $(CH_3)_4AsOCH_3$ *(4)* in [D_8]-toluene, measured against TMS int. [ppm].

	T [°C]	δ(H_3CO)	δ(H_3CAs)
^{1}H	35	3.49	1.27
	−100	3.50	1.45 (e)
			0.00 (a)
^{13}C	0	51.6	20.9
	−105	52.4	17.0 (e)
			26.0 (a)

As with $(CH_3)_4POCH_3$, there is the surprising discovery that the resonance of the axial C atoms lies at lower field than that of the three equatorial C atoms, whereas the H atoms show the reverse relation. This phenomenon is presumably based on the *trans*-influence of the methoxy group.

The ^{13}C resonances of the ylidic C atoms of *(2)* and *(3)* are, however, as expected, recorded at high field and confirm the carbanionic nature of this structural unit[9].

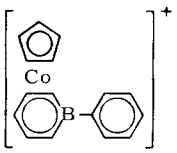
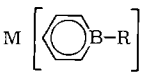
A New Route to Alkali-metal Borinates and to Complex Derivatives of Borabenzene[1]

By *Gerhard E. Herberich* and *Hans Jürgen Becker*[*]

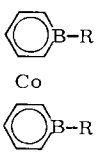
The history of borabenzene derivatives begins with the discovery of the cyclopentadienyl(1-phenylborinato)cobalt cation *(1)*[2] and the independent synthesis of a solution of lithium 1-phenylborinate *(2a)*, M = Li, in tetrahydrofuran[3].



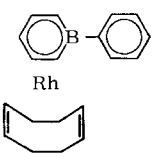
(1)



(2a), R = C_6H_5
(2b), R = CH_3



(3a), R = C_6H_5
(3b), R = CH_3



(4)

Because of their unusual electron configuration, bis(borinato)-cobalt complexes *(3)*, which like the cation *(1)* are accessible from $Co(C_5H_5)_2$ by ring expansion with organylboron dihalides[2b], tend to undergo reactions in which the destabilized metal-ligand bonds are cleaved. We have made use of this tendency previously in ligand-transfer and ligand-substitution reactions[4]. Synthetic possibilities leading much further are now opening up by liberation of alkali-metal borinates from the complexes *(3)*.

When heated with KCN or NaCN in acetonitrile[5], the compounds *(3)* are quantitatively degraded with formation of the corresponding alkali-metal borinates *(2)*, which, after removal of the sparingly soluble cyanides[6], can be used in the solution directly for further reactions or can be isolated as crude powdery products by removal of the solvent.

$$\underset{(3)}{Co(C_5H_5B{-}R)_2} \xrightarrow[(M = Na,\ K)]{MCN} \underset{(2)}{2\ M[C_5H_5B{-}R]}$$

In the case of potassium (1-phenylborinate) *(2a)*, M = K, we obtained, without further purification, ^{1}H-NMR spectra (in [D_8]-THF) that agreed almost completely with the recorded data for the lithium salt[3]; no by-product was recognizable. Thus solutions of alkali-metal borinates *(2)* have now become accessible in only two steps from $Co(C_5H_5)_2$ or in three steps from cyclopentadiene.

The borinates *(2)* can, analogously to the alkali-metal cyclopentadienides[7], be used for a large variety of complexation reactions. For example, from the potassium salt *(2a)*, M = K, and di-μ-chlorodi(1,5-cyclooctadiene)dirhodium[8] we have obtained the first complex borabenzene derivative of rhodium, namely (1-phenylborinato)-(1,5-cyclooctadiene)rhodium *(4)*[9].

$$[Rh(C_8H_{12})Cl]_2 + 2\ K[C_5H_5B{-}C_6H_5] \longrightarrow 2\ Rh(C_8H_{12})(C_5H_5B{-}C_6H_5) + 2\ KCl$$

(4)

Table 1. Data for (1-phenylborinato)-(1,5-cyclooctadiene)rhodium *(4)*.

MS (50 eV): *m/e* (I_{rel} [%]) 364 (100; M^+), 334 (9; $M^+ - C_2H_6 = Rh(C_6H_6)L^+$ with $L = C_5H_5B{-}C_6H_5$), 284 (9; $M^+ - C_4H_6 - C_2H_2$), 256 (35; RhL^+), 254 (30: $RhL^+ - H_2$), 230 (8; $RhL^+ - C_2H_2$), 228 (11; $RhL^+ - C_2H_2 - H_2$), 182 (9; $RhC_6H_7^+$), 180 (11; $RhC_6H_5^+$), 168 (11; $RhC_5H_5^+$); m* = 306.5 (364→334)

^{11}B-NMR (δ[ppm]); measured against external $(C_2H_5)_2O{\cdot}BF_3$ in [D_6]-benzene (100 MHz, room temperature):
-20.9 ± 0.5

^{1}H-NMR (τ[ppm]); measured against internal TMS in $CDCl_3$ [a] (60 MHz, room temperature):

C_6H_5		2.3 m (2H), 2.8 m (3H)	
C_5H_5B:	H^3, H^5	3.68 dd (2H)	$J_{23} = 9.0$ Hz
	H^2, H^6	4.04 d (2H)	$J_{34} = 6.0$ Hz
	H^4	5.02 t (1H)	
C_8H_{12}		6.09 m (4H), 8.05 m (8H)	

[a] In [D_6]-benzene H^2 and H^6 are accidentally isochronous with H^3 and H^5 and appear as a doublet, whereas H^4 is seen as a quintet.

Experimental:

a) *(3a)*[2b] (267 mg, 0.73 mmol) and KCN (1 g, 15 mmol) are heated in acetonitrile (15 ml) for 12 h under reflux with exclusion of air and moisture. After cooling and filtration from the sparingly soluble cyanides removal of the solvent affords $K[C_5H_5B{-}C_6H_5]$ *(2a)*, M = K, as a pale brown, powdery crude product, which is stable under N_2, readily soluble in CH_3CN or THF, but sensitive to water and slowly decomposed in methanol.

b) This crude product is heated with $[Rh(1,5\text{-}C_8H_{12})Cl]_2$[8] (630 mg. 1.28 mmol) in THF (15 ml) for 16 h under reflux. Chromatography on Al_2O_3 (air-free, deactivated by 4% of H_2O) with CH_2Cl_2 gives a pale yellow, rapidly moving first zone. The eluate from this is concentrated to a small volume, covered with pentane and left for crystallization on stepwise cooling to −78 °C. *(3a)* is obtained in 65% yield (347 mg), with m.p. 161—162 °C: it is stable in air; it crystallizes from CH_2Cl_2/pentane in pale yellow, square leaflets, readily soluble in benzene or CH_2Cl_2 but sparingly so in pentane.

Preparation and Structure of Novel Binuclear Palladium Complexes Containing a Metal-Metal Bond: μ-(η-C_5H_5)-μ-(η-C_4H_7)Pd_2L_2[1]

By *Helmut Werner*, *David Tune*, *Graham Parker*, *Carl Krüger*, and *David John Brauer*[*]

The sandwich-like complexes (all)PdC_5H_5 react with Lewis bases L (molar ratio 1:4) with loss of the π-bonded ligands and formation of PdL_4[2, 3].

$$(all)PdC_5H_5 + 4\ L \longrightarrow PdL_4 + C_5H_5(all) \qquad (1)$$

all = C_3H_5, 2-$CH_3C_3H_4$, 2-ClC_3H_4, 1,1,2-$(CH_3)_3C_3H_2$, C_6H_9

L = $P(OCH_3)_3$, $P(OC_6H_5)_3$, $P(C_6H_5)_3$

The first step in the ligand replacement consists of attack by L on the metal and simultaneous π-σ rearrangement of the allylic group[4]. The further reaction steps are in general very fast with formation of the products indicated in eq. (1).

Reaction of (2-$CH_3C_3H_4$)PdC_5H_5 *(1)* and L in an *exact 1:1 molar ratio*, instead of 1:4, leads to formation of binuclear complexes (C_4H_7)(C_5H_5)Pd_2L_2 (with palladium formally in oxidation state +1) [eq. (2)]. Analogous compounds (C_3H_5)(C_5H_5)Pd_2L_2 can be detected by NMR spectroscopy in the system $C_3H_5PdC_5H_5$/L.

$$2\ (2\text{-}CH_3C_3H_4)PdC_5H_5 + 2\ L \longrightarrow \underset{(1)}{} \qquad (2)$$

$$(C_4H_7)(C_5H_5)Pd_2L_2 + C_5H_5(2\text{-}CH_3C_3H_4)$$

(2a), L = $P(C_6H_5)_3$
(2b), L = $P(OC_6H_5)_3$
(2c), L = $P(OCH_3)_3$

The product *(2a)* forms air-stable orange-yellow crystals, readily soluble in benzene or toluene but insoluble in pentane or hexane. The solutions decompose slowly at room temperature. Compounds *(2b)* and *(2c)* decompose rapidly in the solid state under N_2 at 25°C, but are stable for long periods at −30°C.

[*] Prof. Dr. H. Werner, Dr. D. Tune, and Dr. G. Parker

CH-8001 Zürich, Rämistrasse 76 (Switzerland)
Dr. C. Krüger and Dr. D. J. Brauer
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr 1, Kaiser-Wilhelm-Platz 1 (Germany)

C_4H_7 = 
Surprisingly, the coupling constant J_{PH^1} is greater than J_{PH^2} (see Table 1). This result contradicts the order of values for mononuclear π-allylpalladium complexes[5] and is probably due to the unusual position of the $CH_3C_3H_4$ group with respect to the Pd_2L_2 unit. Furthermore, the signal of the 2-methyl protons is a triplet owing to PH coupling; no corresponding splitting was observed for other 2-$CH_3C_3H_4$-palladium-phosphane complexes such as, *e.g.*, $C_4H_7PdCl(PR_3)$.

The crystal structure[6, 7] of *(2a)* is reproduced in Figure 1[8]. The compound contains an almost linear P—Pd—Pd—P group (P—Pd—Pd = 176.6°) with bond lengths Pd—Pd = 2.679 and Pd—P = 2.296 Å[9]. As expected from the NMR data, the cyclopentadienyl and also the methylallyl ligand are coordinated to *both* the palladium atoms. The C_5H_5 and the C_4H_7 planes are parallel to one another and these groups "sandwich" the metal-metal bond. An analogous coordination is probably also present in $(C_6H_6)_2Pd_2(Al_2Cl_7)_2$ (Pd—Pd bond length = 2.58 Å)[11].

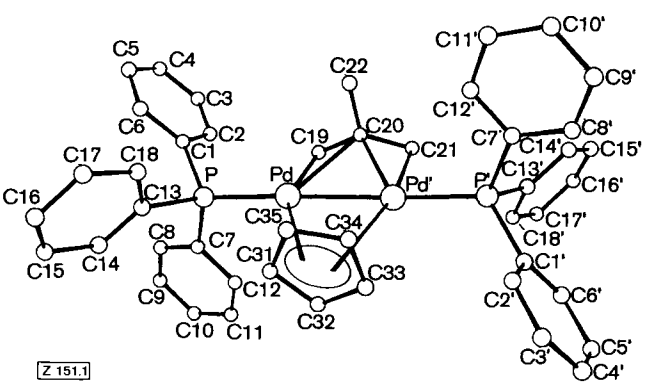

Fig. 1. Structure of the binuclear complex *(2a)* in the crystal; cf. Refs. [6–8].

To the best of our knowledge, *(2a)*—*(2c)* are the first examples of binuclear cyclopentadienyl-metal complexes in which a *five-membered ring spans an M_2 fragment exhibiting a metal-metal bond.* The new compounds react with Lewis acids and with Lewis bases.

μ-(η-Cyclopentadienyl)-μ-[1-3-η-(2-methylallyl)]bis(triphenylphosphanepalladium) (2a)

Triphenylphosphane (141 mg, 0.54 mmol) in toluene (5 ml) was added to a solution of $C_4H_7PdC_5H_5$ (122 mg, 0.54 mmol) in toluene (10 ml) under nitrogen. The mixture was stirred for 3 h at room temperature, the color changing from deep red to orange. After removal of half the solvent and addition of pentane (10 ml) the mixture was kept at −30 °C for 24 h. Orange-yellow crystals were formed; they were filtered, washed with pentane and dried in high vacuum. Yield 85%.

NSF_3 as Ligand in Transition Metal Complexes: (Thiazyl Trifluoride)pentacarbonylrhenium Hexafluoroarsenate[**]

By *Rüdiger Mews* and *Oskar Glemser*[*]

We recently reported the preparation of the first transition metal complexes containing nitrogen-sulfur-fluorine ligands[1, 2].

$$M(CO)_5Br + AgN(SO_2F)_2 \xrightarrow{-AgBr} M(CO)_5N(SO_2F)_2$$

(1), M = Mn, Re

$$M(CO)_5Br + AgNSOF_2 \xrightarrow{-AgBr} M(CO)_5NSOF_2$$

$M(CO)_5NSOF_2$ $\xrightarrow{-CO}$ *(2)*, M = Re

$M(CO)_5Br$ $\xrightarrow{-AgBr,\ -CO}$ $[M(CO)_4NSOF_2]_2$

(3), M = Mn, Re

[*] Prof. Dr. O. Glemser and Dr. R. Mews
Anorganisch-chemisches Institut der Universität
34 Göttingen, Tammannstr. 4 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Structural investigations[3] on the complexes *(2)* and *(3)* show a great similarity of the sulfur oxide difluoride imide group with the isoelectronic thiazyl trifluoride[4]. It was already known that NSF_3 can function as a base toward very strong Lewis acids[5, 6].

$$NSF_3 + MF_5 \longrightarrow F_5M \cdot NSF_3 \quad (M = As, Sb)$$

$$NSF_3 + BF_3 \longrightarrow F_3B \cdot NSF_3$$

$Ag^+AsF_6^-$ can react quantitatively with $Re(CO)_5Br$ under pressure in NSF_3 as solvent at room temperature in accordance with the following equation:

$$\underset{(4)}{Ag^+AsF_6^-} + \underset{(5)}{Re(CO)_5Br} \xrightarrow[-AgBr]{NSF_3} \underset{(6)}{[Re(CO)_5NSF_3]^+[AsF_6]^-}$$

Reaction of *(4)* and *(5)* gives rise to the coordinatively unsaturated cation $Re(CO)_5^+$ as intermediate; this reacts as acid with the weakly basic solvent to give *(6)*.

The thiazyl trifluoride complex *(6)* is a colorless, crystalline solid which is stable at room temperature (decomposition at 123 °C); it has been characterized by elemental analysis and ^{19}F-NMR and IR spectra. The ^{19}F-NMR spectrum (solution in SO_2, $CFCl_3$ int., room temperature) shows a singlet at −60.8 ppm (NSF_3); the expected 1:1:1:1 quartet ($\delta_F = +59.5$ ppm, $J_{AsF} = 916$ Hz) is found for AsF_6^-. The structure of compound *(6)* follows unequivocally from the IR spectrum. The three absorptions [A_1 2175 (m), E(2084 sh) 2057 (vs), A_1 2010 cm^{-1} (s)] to be expected for C_{4v} symmetry of the central atom are observed in the CO region; these are accompanied by the IR-forbidden B_1 at 2108 cm^{-1} (vw). Because of the positive charge in *(6)* all bands are shifted to higher wave numbers compared to the isoelectronic $Re(CO_5)NSOF_2$[2]. The frequencies of the NSF_3 ligands in transition metal complexes are almost constant (cf. Table 1).

Table 1. IR data [cm^{-1}] of thiazyl trifluoride and a few of its coordination compounds.

	NSF_3	$F_5As \cdot NSF_3$	$F_5Sb \cdot NSF_3$	*(6)*	*(7)* [a]	*(8)* [a]
ν_{SN}	1515 m	1650	1650	1636 m	1637 m	1632 m
ν_{SF}	811 vs	950	955	900 sh	882 s	888 sh
				889 s		876 s
	775 s	889	900	846 s	838 s	830 s

[a] *(7)*: $[Mn(CO)_5NSF_3]^+AsF_6^-$; *(8)*: $[\pi\text{-}CpFe(CO)_2NSF_3]^+AsF_6^-$; preparation, properties, and structure of these compounds will be published in Chem. Ber.

Compared with the free ligands the bands in the transition metal complexes suffer less shift to higher wave numbers than in the adducts with arsenic or antimony pentafluoride—which seems reasonable in view of the acid strength. This

CONFERENCE REPORTS

Systems of Carbohydrate Utilization in Bacteria

By *Kurt Wallenfels*[*]

Utilization of carbohydrates of the nutrient medium as a source of carbon for bacterial growth is subjected to gene-dependent regulation. Control loops exist for autocatalytic enhancement of active transport, *i.e.* enrichment against a concentration gradient, chemotaxis, and primary conversion into metabolizable monosaccharides or their derivatives, depending upon the signal emitted by the nutrient medium. The best studied example is the lac system of *E. coli* which optimizes utilization of natural β-galactosides—lactose or 2-*R*-β-galactosylglycerol.

Galactosylglycerol has a chemotactic action on *E. coli*, and is transported independently of the lac operon into the cell where it induces the lac operon by interaction with the lac repressor, so that synthesis of its dependent proteins is enhanced 10^3 to 10^4-fold.—Lactose must first be converted into allolactose (6-β-galactosylglucose) by the basal activity of β-galactosidase; allolactose forms the inducer. Lactose is then transported by lac permease, which is dependent upon the lac operon.

The control loop can be split up, and the growth behavior of the culture modified, by mutation in one of the genes coding for repressor formation, for lac permease, for β-galactosidase, or for galactosylglycerol permease (studies with *B. Müller-Hill* and *W. Boos*).

With *Aerobacter aerogenes*, utilization of macromolecules such as starch or pullulan is dependent upon an enzyme (pullulanase) which hydrolyzes the 1,6 bonds in these substrates. This enzyme is localized on the exterior of the cell wall and serves for the formation of α-1,4-linked maltosaccharides which migrate into the cell, presumably by active transport. Their conversion into metabolizable monomers is accomplished by phosphorolysis or hydrolysis. Aerobacter phosphorylase has been isolated as a homogeneous protein and its close relationship to the phosphorylases of eucaryotes established by determinations of molecular weight, pH optimum, amino acid composition, and pyridoxal phosphate content. The bacterial phosphorylase also degrades the reserve polysaccharide of the bacteria (aerobacter glycogen) but hardly affects mammalian glycogen. Hydrolysis of the maltooligosaccharides and -polysaccharides and of the 1,6 branching of the limit dextrins of the bacterial glycogen is effected by two amylases and a 1,4- and 1,6-specific glucosidase, which can be separated by the trick of "substrate alienation". The two amylases can be distinguished in that one fraction (230000 dalton) cleaves *o*-nitro-α-phenyl glucoside, while the other (35000 dalton) cleaves *o*-nitrophenyl α-maltoside. The third enzyme (86000 dalton) accepts maltose, isomaltose, saccharose, maltotriose, and presumably other α-glucosyl oligosaccharides resulting from amylopectin and pullulan degradation, as substrates. The regulatory system for the bacterial utilization of starch and similar polysaccharides as a source of carbon from the external medium or from the internal reserves is considerably more complex than the lac system, in keeping with the larger number of enzymes involved (studies with *H. Bender*, *P. Földi*, *G. Kurz*, *D. Linder*).

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Chemotaxis as a model for sensory systems is discussed in an article by *D. E. Koshland Jr.* Bacteria, the simplest objects of study, do not respond to absolute concentrations of stimulating substances, but to changes of concentration with time. A specific receptor protein is responsible for the primary binding of each stimulant; further transmission of the various primary stimuli to a common system is still a subject of hypothesis. The duration of the "memory" for *Salmonella* has been calculated as 1—10 s. [Chemotaxis as a Model for Sensory Systems. FEBS Lett. *40*, S3—S9 (1974); 28 references] [Rd 753 IE—R]

The life cycle of RNA phages is reported on by *C. Weissmann*. Because of their smallness these phages are ideal model systems suitable for the study of fundamental biological processes at a molecular level. The article deals with the process of

infection of the bacterial cell by the phages, insertion of the phage RNA into the ribosomes of the host, synthesis of the virus, and the lysis of the bacterial cell, in which the new phage generation is set free. [The Making of a Phage. FEBS Lett. *40*, S10—S18 (1974); 102 references]

[Rd 754 IE—R]

The control of gene expression at the transcription level is reviewed in an article by *F. Gros*. The validity of the classical operon model could be demonstrated by refined biochemical techniques. Nevertheless, it turned out that many of the original hypotheses contain excessive simplifications. This applies to the complexity of the repressor molecules and their multifarious functions, the expiration of the gene expression with time in developing organisms, and the crucial significance of the conformation of the DNA for its function. [Control of Gene Expression in Prokaryotic Systems. FEBS Lett. *40*, S19—S27 (1974); 168 references]

[Rd 755 IE—R]

Progress in the field of antiviral agents is reviewed by *D. Shugar*. Only a few substances of this type have so far gained a firm foothold in therapy. A particularly interesting aspect is the connection between antiviral activity and antitumor activity which has been observed in some cases. The specificity and mode of action of purine and pyrimidine derivatives and of nucleoside and nucleotide derivatives and their analogs are discussed; the potential dangers in the therapeutic use of these substances and the possible enhancement of the activity on simultaneous utilization of several agents are demonstrated. [Progress with Antiviral Agents. FEBS Lett. *40*, S48—S62 (1974); 144 references]

[Rd 758 IE—R]

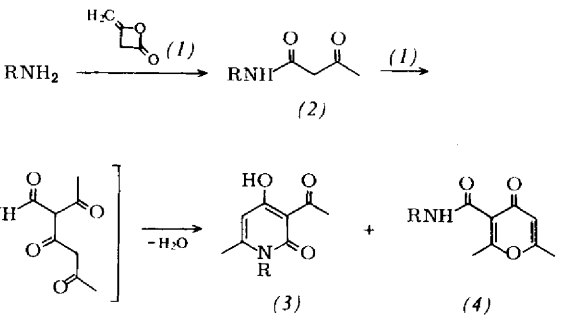
Inhibitors of protein synthesis form the theme of a review article by *D. Vazquez*. The author discusses the results of research over the past ten years regarding the mode of action, selectivity, and specificity of inhibitors. The process of protein biosynthesis is appropriately subdivided into the stage prior to translation, and translation proper. The inhibitors can suppress formation of aminoacyl t-RNA and f-Met t-RNA_F before translation, and the processes of initiation, elongation, and termination during translation. [Inhibitors of Protein Synthesis FEBS Lett. *40*, S63—S84 (1974); 410 references]

[Rd 759 IE—R]

The synthesis of heterocycles with organophosphorus compounds is dealt with in a review by *E. Zbiral*. Tetrahydropyrans, thiacyclohexanes, dibenzo[*b*,*f*]oxepins, coumarins, acridinium betaines, *etc.* are obtained *via* carbonyl-olefination with alkylidenephosphoranes; with 2-oxoalkylidenephosphoranes and a second component, 1,3-dipolar cycloaddition affords 1,2,3-triazoles, pyrazoles, 1,2-oxazoles, and azirines. Iminophosphoranes (P—N ylides) can be used for the synthesis of tetrazoles, pyrazines, 1,2,4,5-tetrazines, 1,2,4-benzotriazines, 1,3-oxazoles, *etc.* Vinylphosphonium salts, *e.g.* triphenylvinylphosphonium bromide, afford pyrrolizines, furan derivatives, chromenes, quinoline derivatives, pyrroles, and pyrazole derivatives; 3-oxo-1-alkenylphosphonium salts (β-acylvinylphosphonium salts) lead to 1,2,3-triazoles, pyrazoles, 1,3-thiazoles, pyrroles, imidazoles, and heterocyclic condensed imidazoles. With vinylphosphane oxides, phosphorus-containing derivatives of dihydro-1,2-oxazoles, dihydropyrazoles, and pyrazoles are formed. [Synthesen von Heterocyclen mit Hilfe von Alkylidenphosphanen, Phosphin-imiden, Vinylphosphonium-salzen und Vinylphosphin-oxiden. Synthesis *1974*, 775—797; 87 references]

[Rd 764 IE—M]

Novel reactions of diketene *(1)* with nitrogen compounds are reported by *T. Kato*. With amines, acetoacetamides *(2)* are formed which in the presence of triethylamine undergo cyclization with elimination of water to give 2-pyridones *(3)* and 4-pyrones *(4)*. Enamines and compounds with C=N double bonds can react with diketene to give 2- and 4-pyridones as well as 1,3-oxazinones. They can annelate further



rings to nitrogen heterocycles, *e.g.* pyridine, quinoline, and acridine derivatives, *via* acetoacetamide intermediates. Spiro compounds can be obtained by cycloaddition to the C=C double bond of diketene. [Recent Synthetic Studies Using Diketenes. Accounts Chem. Res. 7, 265—271 (1974); 59 references]

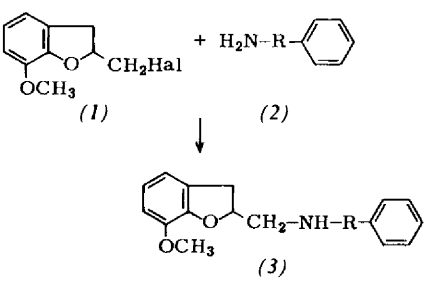
Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

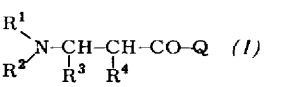
2,3-Dihydro-7-methoxybenzofuran derivatives *(3)* have very good analgetic properties and low toxicity. They are prepared



from the halo compounds *(1)* and the amines *(2)*. R is a bivalent saturated or unsaturated aliphatic group (C_1 to C_4). [DOS 2263093; Eisai Co., Tokyo (Japan)]

[PR 240 IE—K]

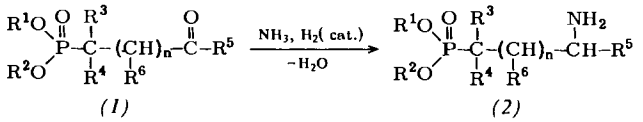
Catalysts with only slight odor for the preparation of polyurethane foam materials, in particular highly elastic soft foam materials, can be selected from among β-amino carbonyl compounds of formula *(1)*, where NR^1R^2 represents a dialkylamino, mor-



pholino, or substituted piperazinyl group, R^3 and R^4 are H or a lower alkyl group, and Q is a C_1 to C_8 alkoxy, *N,N*-dialkylaminoethoxy, or *N,N*-dimethylamino group. [DOS 2358861; Union Carbide Corp., New York (USA)]

[PR 245 IE—D]

Aminoalkylphosphonic esters *(2)* are interesting intermediates for the synthesis of flame-retarding and surface-active materials. They can be prepared from the oxoalkylphosphonic esters



(1) *(2)*

R^1, R^2 = alkyl or R^1—R^2 = alkylene; R^3 = H or alkyl; R^4 = H, alkyl, (subst.) aryl, or furyl; R^5 = H or alkyl or R^4—R^5 = alkylene; R^6 = H or alkyl; n = 0 or 1

(1) by aminating hydrogenation. Compounds *(1)* are accessible by *e.g.*, base-catalyzed addition of vinyl ketones to dialkyl phosphites. [DOS 2358836; Ciba-Geigy AG, Basel (Switzerland)]

[PR 246 IE—D]

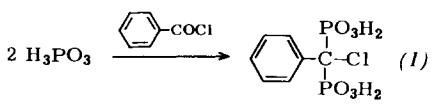
For the preparation of foams from aqueous silicate solution, hydrogen peroxide and a reducing agent, *e.g.* paraformaldehyde or hydrazine, are added. The mixture foams with considerable evolution of heat and becomes hard. [DOS 2227640; Bayer AG, Leverkusen (Germany)]

[PR 256 IE—W]

Copolymerization of ethylene oxide or propylene oxide with carbon dioxide, to give polyethylene carbonates or polypropylene carbonates, can be effected with a catalyst produced from diethylzinc, diethylmagnesium, or triethylaluminum chloride together with water or magnesium sulfate heptahydrate as cocatalyst at 5 to 50 atm and 100 to 200 °C. [DOS 2336854; Nippon Oil Seal Industry Co., Ltd., Fujisawa, Kanagawa (Japan)]

[PR 254 IE—W]

α-Chlorobenzylidenediphosphonic acid (chloro(phenyl)methane-1,1-diphosphonic acid) *(1)*, suitable as a complexing agent, is obtained by heating phosphorous acid with benzoyl chloride at 110—140 °C, preferably in the molar ratio of 1:1.5. *(1)* can be isolated as the sodium salt after separation of the by-products. Because of its good ability to form complexes

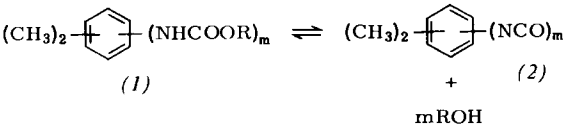


(1)

with multivalent metal ions, its stability against compounds containing active chlorine, and its resistance to hydrolysis at relatively high temperatures, *(1)* and its salts are useful for numerous industrial applications such as industrial cleansers or for water softening processes. [DOS 2310451; Henkel & Cie, Düsseldorf (Germany)]

[PR 247 IE—D]

Thermal dissociation of urethanes *(1)* leads almost quantitatively to the isocyanates *(2)* if conducted as an uncatalyzed process with a short contact time. The urethanes *(1)* are preferably pyrolyzed in the temperature region 350—550 °C at a preferred total pressure within the range 4—105 torr and a residence time of less than 15 s. To avoid the reverse reaction the fission products must be cooled rapidly under



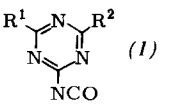
(1) *(2)*

R = CH_3, C_2H_5, *n*-C_3H_7, or *n*-C_4H_9; m = 1, 2, or 3

conditions such that the isocyanate condenses but at least 95 % of the alcohol remains in the vapor form. [DOS 2410505; Air Products and Chemicals, Inc., Allentown, Pa. (USA)]

[PR 248 IE—D]

For the preparation of mono- or diisocyanato-*s*-triazines *(1)* the corresponding *s*-triazinylamines are treated in solution at 150 °C (minimum) with phosgene, if necessary in the presence of a catalyst such as dimethylformamide. 3-Alkoxypropioni-



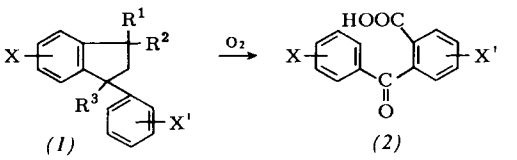
(1)

R^1 = —NCO, halogen, OR', SR', or NR'R"; R^2 = halogen, C_6H_5, R', OR', or NR'R"; R' and R" = alkyl

triles with 1—4 C atoms in the alkoxy group, nitrobenzene, tetrahydrothiophene 1,1-dioxide, and *o*-dichlorobenzene are suitable solvents. [DOS 2409084; Ciba-Geigy AG, Basel (Switzerland)]

[PR 249 IE—D]

Halogenated *o*-benzoylbenzoic acids *(2)* are obtained by liquid-phase oxidation (25—30 atm, 160 °C, 3—4 h) of halogenated indans *(1)* by oxygen in the presence of heavy-metal salts



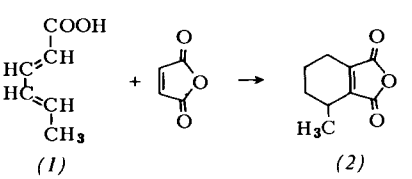
(1) *(2)*

R^1, R^2, R^3 = H or alkyl; X, X' = halogen

and a compound that affords bromide ions. Cobalt and manganese salts are suitable heavy-metal compounds. [DOS 2259681; BASF AG, Ludwigshafen (Germany)]

[PR 242 IE—G]

Isomer-free 3,4,5,6-tetrahydro-3-methylphthalic anhydride *(2)*, a hardener for epoxy resins, is obtained by the addition of sorbic acid *(1)* to maleic anhydride at 80—200 °C, decarboxy-

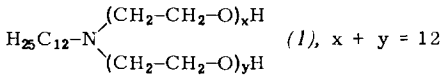


(1) *(2)*

lation occurring simultaneously. [DOS 2315040; Ciba-Geigy AG, Basel (Switzerland)]

[PR 252 IE—W]

For the preparation of flowing powder, filler-containing rubber mixes, a rubber solution is emulsified in water in the presence



(1), x + y = 12

of compounds *(1)*. A solid filler, *e.g.* carbon black, is introduced and the mixture is precipitated in aqueous sodium silicate (water glass) at 90—95 °C and a pH of preferably 1.0 to 3.5. The solvent, *e.g.* hexane, is distilled off continuously. [DOS 2214121; Chemische Werke Hüls AG, Marl (Germany)]

[PR 250 IE—W]

BOOK REVIEWS

Buffers for pH and Metal Ion Control. By *D. D. Perrin* and *B. Dempsey*. Chapman and Hall, London 1974. 1st Edit., vii, 176 pp., numerous tables, bound £3.50

Many chemical and biological systems are governed by acid-base equilibria and are therefore critically dependent on the pH of the solution. The pH conditions can be altered by addition of a buffer, a pair consisting of a Lowry-Brönsted acid and its conjugate base. In practice the question arises again and again as to the buffer system most suitable for the individual case, and in this respect the present laboratory primer will be welcomed by all biologists and chemists who have to deal with pH and metal ion buffers in aqueous and nonaqueous media. The theoretical fundamentals are first discussed, briefly and strictly from the standpoint of practical use, this being followed by collections of data about buffers scattered throughout the literature: zwitterion buffers, particularly those for biochemical work and separations, for biological and medical applications, and for physicochemical measurements, as well as metal ion buffers and standards for ion-selective electrodes are tabulated in complete detail, partly in appendices. The limitations and pitfalls in working with buffers are discussed, as are the disturbances to be borne in mind on a particular choice of buffer, but here unfortunately without always referring to the literature. The competition of structurally similar sugars with Tris buffers could have been added. The construction of pH-buffer tables from the thermodynamic p*K* values is explained: the appended programs are in FOCAL instead of the BASIC that is understood by the usual desk-top computers, but transposition is not difficult. The experimentalist will also welcome the description of the purification of buffers and the introduction to the preparation of standard solutions. The book thus constitutes both a useful and a reliable and convenient aid in every chemical, biochemical, or biological laboratory.

L. Jaenicke [NB 246 IE]

Mathematik für Naturwissenschaftler und Ingenieure (Mathematics for Scientists and Engineers). Vol. 1. Vector, differential and integral calculus. By *A. Jeffrey*. Translated by *R. Janoschek*. Verlag Chemie GmbH, Weinheim 1973. 1st Edit, viii, 385 pp., 86 figures, 18 tables, paperback, DM 39.—.

This book is based on an introductory course in mathematics for engineering students, corresponding roughly to the material of Analysis I and II used at German universities. The original English edition, comprising one volume, has been divided into two volumes in the translation. The eight chapters of Volume 1 deal with the material of Analysis I, *i.e.* with differential and integral calculus. Chapter 1 begins with a short introduction to the elementary theory of sets and describes the basic properties of the real number system; the modern notation is used. After this concession to modern trends in current mathematics the author remains for the rest of the book within the usual "classical" framework of analysis.

The following three chapters deal with the concept of a function, numerical series, and complex numbers, and then lead on to elementary vector calculus. Chapter 5 is concerned with differentiation, including partial derivatives. A special chapter on exponential functions, hyperbolic functions, and logarithms is followed by the two final chapters on integral calculus with a detailed description of integration procedures.

A remarkable feature of this book is that it is an attempt—otherwise rarely undertaken—to combine rigorous mathematical methods of proof with opportunity to practice the calculation techniques. The author has certainly succeeded in attaining this aim, by apt selection of the material.

The mathematical proofs provided with every important statement are simple and clear and are thus easily understood. Moreover, the text contains many examples with detailed descriptions of the approach to the solution, which makes it easy for the reader to learn how to handle formulas and relationships. Numerous practice exercises at the end of each chapter contribute to this aim; hints on how to arrive at the solution are given in the Appendix. The examples and practice problems are taken from scientific and technical fields wherever possible, in order to demonstrate the range of application of the mathematical apparatus. The systematic division into text, definitions, propositions, and examples increases the clarity of the work.

The book may be highly recommended to all students of scientific and technical disciplines in the first few terms and also for private study.

Theo Ankel NB 245 IE]

Comprehensive Biochemistry. Vol. 29 A. Comparative Biochemistry, Molecular Evolution. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier Scientific Publ. Comp., Amsterdam 1974. 1st Edit., xii, 328 pp., 67 figures, 20 tables, bound Dfl. 90.—.

The present volume in this still continuing series of texts[*] contains two chapters, both dealing with evolution: "Concepts of Molecular Biosemiotics and of Molecular Evolution" by *M. Florkin* and "Biochemical Evolution in Plants" by *T. Swain*. The first of these titles will convey little even to a fairly sophisticated reader. A glossary provides help, in which he finds, *e.g.* "Bioseme. Minimal configuration aspect, carrier

[*] Cf. Angew. Chem. internat. Edit. *13*, 825 (1974).

(significator) of the molecular signification (signified) either sequential, structural, *etc.*"—but also: "Allomones. Coactones (q.v.), ...; Coactones. Ecomones (q.v.), ...; Ecomones ...."; etc. All 110 pages are loaded with this kind of freight, which makes severe demands on the reader. The intention is to bring systematic order into the presentation of phylogenetic development, in which the evolution of life is assumed to be from simple biomolecules by asymmetric, autocatalytic, and aggregating forces. The molecular processes occurring during phylogenesis of organisms ("diachronic molecular epigenesis") are mostly considered on the basis of cellular chain molecules ("metabolic catenary biosyntagmas") which become better suited to their structure, function, or regulation, and more versatile, by lengthening or shortening, branching and ramification. The causes are point mutations, feedback, selection, gene duplication, *etc.* Useable biomolecules thus function after self-aggregation into structures of higher order on the physiological and ecological plane. The author's phenomenal knowledge of the facts and historical perspectives and his intellectual insight into his material can only be marvelled at—only the preparation of the dish makes it hard to digest.

The subsequent vegetarian fare is simpler and more heart-warming, the more so since it is spiced with anecdotal asides. Plants and animals are of the same age on the evolutionary time-scale, but the former have adapted themselves much more intelligently—being bound to one place—in order to come to grips with their living space. While animals differ little in their fundamental biochemical capacities—but all the more so in their controlled types of behavior—plants produce a highly diverse range of materials that make their survival possible. The development and the distribution of cellular macromolecules, the primary and secondary constituents of the plant kingdom, are discussed and it is brought out how the various secondary biosynthetic routes determine which niche the given plant will adopt in the ecosystem. Change is the mother of evolution and woe betide him who attempts to confine biochemical evolution in a procrustean bed! In this volume the promised standard of content and production is maintained; it is announced that the second sub-volume will deal with the molecular evolution of bacteria and animals; after that there will still be seven further volumes before the whole series is complete.

L. Jaenicke [NB 247 IE]

Absorption Spectroscopy of Organic Molecules. By *V. M. Parikh*. Addison-Wesley Publishing Co., Reading, Mass 1974. 1st Edit., x, 325 pp., paperback $ 10.75.

Since the intrusion of modern spectroscopic methods into all subdisciplines of chemistry, and thus into general training programs for chemists, there has been no lack of attempts to write books presenting these techniques in a simple manner. We have noted a total of about 20 titles intended as an introduction to these methods for students.

V. M. Parikh has now written a further book of this kind. Following upon a general introduction to spectroscopy he deals with UV, IR, and NMR spectroscopy, and mass spectrometry in four sections, dividing the material into general/-theory, instrumental and evaluation of spectra. Then come a section on the identification of organic compounds with examples and an appendix of tabular surveys (IR and NMR assignment tables *etc.*). Each chapter closes with test questions and a bibliography which is quite extensive in some cases.

Unfortunately, the book which is clearly intended for students, contains a number of failings likely to confuse the beginner but unlikely to distract the expert. Thus some of the IR spectra exhibit precisely those mistakes which are symptomatic of the beginner and whose elimination can be regarded as the primary task of such introductory books ("negative absorptions", excessive amounts of sample, *etc.*). Moreover, the NMR spectra are poorly reproduced (very dark background, poor plotting). In some of the spectra the integration can only be recognized with difficulty. In addition, references to journals unlikely to be found in college libraries (*e.g.* Phil. Mag., Sov. Phys. Tech. Phys., Vacuum, J. Sci. Instrum.) will be of little to help to students. Hence the book has to be pigeon-holed somewhere between an introduction and a monograph and can only really be recommended to those concerned with the teaching of instrumental analysis. Such readers may indeed profit from a variety of ideas found in the book.

Egon Fahr [NB 242 IE]

Orbitale organischer Moleküle (Orbitals of organic molecules). By *W. L. Jørgensen* and *L. Salem*. Translated by *E. König*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., x, 294 pp., 1180 figures, bound DM 32.—.

The authors intend this book (original edition: The Organic Chemist's Book of Orbitals, 1973) for "a new generation of chemists eager to understand molecular structure at the electronic level". They begin with an introduction (44 pages) to the qualitative construction of σ- and π-type molecular orbitals from group and bond orbitals, while assuming their "reality" and practical "utility", ask for chemical applications, and cite references for further reading (76 titles) including such topics as the frontier orbital and the relaxability methods.

The comparison of qualitative orbitals with the perspective computer plots of contours of eigenfunctions obtained by extended Hückel or open-shell MINDO/2 calculations presented on 226 pages is impressive. Clarity is enhanced by suitable normalization, avoidance of changes of perspective, and the use of solid and dashed contours. Skillful arrangement of the very complicated drawings permits combination of the sets of orbitals to give projectable pictures and supplementation by the tabulated occupations. Details concerning the calculation are given for all examples of 104 conformers of 95 molecules (14 containing no carbon atom) with 2 (hydrogen) to 36 (cyclohexane, norbornadiene) valence electrons, and new molecular geometries are cited. In all except four cases, all occupied and several unoccupied (2.4 on average) orbitals are depicted, with group-theoretical and, wherever sensible, orbital type designations, and assignments to known *ab initio* orbital energies. It is accepted that the various methods of calculation may also differ with regard to the geometric parameters. This fact alone should induce one to compare the orbital sequences thus defined with results or interpretations of photoelectron spectroscopy.

Notwithstanding a number of unclear points in the translation and the occasional rather unfortunate choice of terms (*e.g.* "Äthyl-Radical, halbiert" or "Benzol, Dewar-Form") the book is eminently suitable for the illustration of semi-empirical wave functions in the teaching of quantum chemistry.

Gerd Kaupp [NB 244 IE]

Lehrbuch der Organischen Chemie. (Textbook of organic chemistry). By *R. T. Morrison* and *R. N. Boyd*. Translated by *I. Mayer-Ruthardt*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., xxxiii, 1392 pp., 225 figures, 46 tables, bound DM 78.—.

The present German translation of the third edition of "Organic Chemistry" will be of great value to chemistry stu-

dents, and to those requiring a source of readily accessible information, in German speaking countries.

The work is divided into three main sections. Part 1 deals with fundamentals (881 pages), and part 2 treats specialist fields (251 pages). Biomolecules is the collective term for the material presented in part 3. (139 pages). From the entire field of organic chemistry and a number of bordering areas an excellent choice of material has been made, and the subject matter is presented in a didactically skilled manner.

Apart from the most important classes of substances, part 1 contains individual chapters on structure and properties, stereochemistry (subdivided into stereochemistry and structure and stereochemistry and reactions), spectroscopy, and carbanions. In keeping with the material part 2 has a more heterogeneous structure. A chapter on aryl halides and nucleophilic aromatic substitution is followed by chapters on reactions of carbonyl compounds, rearrangements and neighboring group effects, the Woodward-Hoffmann rules (explained with the aid of HOMO-LUMO relationships), polycyclic aromatic compounds, heterocyclic compounds, and macromolecules. In part 3 the main emphasis is placed on fats, carbohydrates, amino acids, and proteins, and an introduction to biochemical processes is also given. Recent trends receive mention in all parts of the book.

The optical presentation of the subject matter is clear; preparations and reactions of compounds are collected in tabular form.

Exercises and problems included in the various chapters help the student to check his progress, and also provide ideas for conducting lectures and seminars. Some of the problems serve to take the reader beyond the actual text of the book. Solutions are given at the end of the volume. References for further reading intended to extend and deepen the students knowledge cover 7 pages.

In the reviewer's opinion, the present work is a welcome alternative to existing German-language textbooks and should find a wide readership.

Jörg Daub [NB 243 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Lehrprogramm Orbitalsymmetrie. By *A. J. Bellamy*. Vol. 28 of the series "taschentext". Verlag Chemie/Physik-Verlag, Weinheim 1974. VI, 107 pp., stitched, DM 17.80.

Handbook of Moisture Determination and Control. Principles, Techniques, Applications. Vol. 1. By *A. Pande*. Marcel Dekker, New York 1974. XI, 266 pp., bound, $ 28.50.

Elektroorganische Chemie. Grundlagen und Anwendungen. By *F. Beck*. Verlag Chemie, Weinheim 1974. XVI, 391 pp., bound DM 88.—.

Kinetics & Mechanisms of Polymerization Reactions. Applications of Physico-chemical Principles. By *P. E. M. Allen* and *C. R. Patrick*. From the series "Ellis Horwood Series in Physical Chemistry". Edited by *T. M. Sugden*. Ellis Horwood, Chichester/John Wiley & Sons, New York 1974. XV, 596 pp., bound, £ 18.00.

Relationships between the Chemistry of Dispersed Metals and Chemical Syntheses with Metal Atoms[**]

By Hans Wolfgang Kohlschütter[*]

An interesting and topical question in modern inorganic chemistry is: To what extent are the well-known chemistry of dispersed metals and the new technique of chemical synthesis with free metal atoms interrelated? Or in other words: Where, do these two facets of metal chemistry meet? In an attempt to glean an answer to this question three important aspects are considered: metal sols, activated metals as powders, and deposits in vacuum processes (evaporation and cathodic sputtering of metals).

1. Metal Sols

The classic example is the well-known red gold sol obtained by reduction of gold chloride ($HAuCl_4$)[1]. Between 1925 and 1972 the following observations were made[2]: The first step of the gold precipitation involved formation of elementary nuclei with a small number of gold atoms (30—300). These then form simple or complicated twins; *i.e.* in the second stage complex nuclei are formed by crystallographic interactions between elementary nuclei. In the third step, growth of complex nuclei to particles containing large numbers of gold atoms (≈ 5000, ≈ 70000, ≈ 124000) takes place. The number of atoms in the particles depends on the reduction processes used. In 1925 *R. Zsigmondy* received a Nobel prize for his work on gold nuclei and their growth. In 1972, crystallographic twinning in complex nuclei was discovered by means of high resolution electron microscopy[3].

The particles of red gold sols are negatively charged[4]. A theoretical and experimental interpretation of the reasons for these charges is sought for by investigations on the formation of ionic gold compounds at the surface of gold particles as well as on the physical chemistry of gold (metal)/electrolyte (solution) interfaces[5]. The charges contribute to the stabilization of the gold sols in a dynamic equilibrium according to[7]

$$V = V_R + V_A$$

where V_R = repulsion potential between neighboring particles
V_A = attraction potential
V = resulting potential

Because of these electric charges gold particles can be fixed to the surfaces of solids, as has been shown in an elegant experiment by *Thiessen*[6]. On thin leaf-shaped crystals of kaolin adsorption of negatively charged gold particles occurred

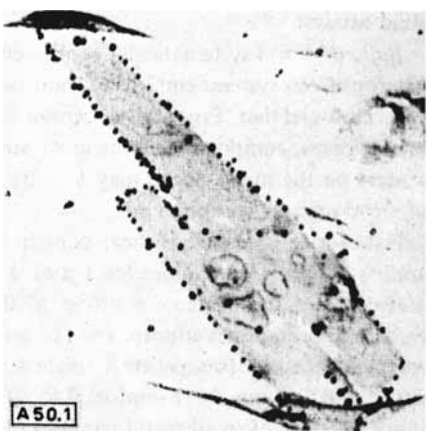

Fig. 1. Adsorption of gold particles on kaolin [6].

only at the edges where the crystal lattice of the kaolin is broken. Here the positive potential of its cations in the interior of the lattice can overlap the negative potential of the gold particles. The large basal faces of the kaolin crystal, on the other hand, remain empty since these faces are the sites of negative OH ions in the lattice of kaolin.

Particles in gold- and silver sols exhibit special physical properties due not only to processes taking place at the interface between metal and solution but also to the slight extension of the metallic phase in the interior of the particle. Thus, the free path of the electrons can play an important role in measurements of dielectric constants[8].

2. Activated Metals in Powder Form

Activated metals are frequently the products of topochemical reactions. They are prepared by reduction of finely divided metal oxides with hydrogen at the lowest possible temperatures[9]. Grains of metal are formed from the grains of metal oxides. These contain aggregates of primary particles. Such a primary particle is a small section of the crystal lattice which coherently diffracts X rays, and which has been found to contain 10^4—10^5 atoms in the case of *e.g.* Au, Cu, Fe, Ni[10]. The heat content of such highly dispersed metals has been found to be only 1 to 3 kcal/mol higher than that of compact metals. This difference is small compared to the evaporation enthalpy of free atoms, which in the case of Au, Cu, Fe, Ni is *ca.* 100 kcal/mol. These small calorimetric effects are due to enlargement of the specific surface area and, in part, to lattice defects. Activated metals of this type are used as starting materials for syntheses and as catalysts, as for example in

1) The Mond-process[11]

$$NiO \xrightarrow[400\,^{\circ}C]{CO} Ni_{active}$$

$$Ni_{active} \xrightarrow[80\,^{\circ}C]{CO} Ni(CO)_4$$

2) Hydroformulation

$$2\ RCH{=}CH_2 \xrightarrow{CO + H_2} RCH_2{-}CH_2{-}CHO + RCH(CHO)CH_3$$

in *homogeneous* systems with the soluble catalyst $(CO)_3CoH$[12], in *heterogeneous* systems with metallic cobalt as solid catalyst.

Ballard[13] has systematically compared homogeneous and heterogeneous systems employing transition elements as catalysts. He found that "Probably we cannot expect stoichiometric metal organic compounds on the metal surface. But the active centers on the metal phase may already have the character of metal organic compounds."

Data for the increase in heat content of activated metals are merely lump sum values for 1 mol. They were originally derived from the heats of solution of the metals in acids. Further information is afforded by: 1) calculation of the energy which is necessary to separate a single atom from the crystal lattice (carried out for cadmium)[14]; 2) calculation of the vapor pressure of small metal particles (carried out for silver spherocolloids)[15].

3. Deposits in Metal Evaporation and Cathodic Sputtering in Vacuum

The deposition of metals by evaporation processes and by cathodic sputtering also involves formation and growth of nuclei. Not only physicists but also chemists have already carried out a great deal of experimental work in this field. At first, however, dispersed metals produced in this way were not pure owing to the presence of residual gases in inefficiently evacuated systems. The progress made in physical technology and the improved equipment that is now available have opened the way to a more detailed understanding of the elementary processes in nucleus formation and nuclear growth, and consequently to the development of methods for the production of high grade purity metals. The production of high-purity substances is of fundamental significance[16].

4. Conclusion

that the chemistry of dispersed metals falls between that of compact metal phases and that of free metal atoms. Indeed the production of free metal atoms and the aggregation of a few metal atoms can be seen as partial problems in chemical syntheses with metal atoms. Looking at it this way we immediately recognize the striking interrelationship between two facets of metal chemistry. Even with the small number of examples selected here we recognize that between the chemistry of dispersed metals and syntheses with metal atoms there is some kind of demarcation line with bridgeheads on both sides. This is readily demonstrated by comparing chemical synthesis with *free* metal atoms (produced by evaporation or cathodic sputtering processes) and chemical synthesis with *partially* free metal atoms (in the active centers of metal surfaces).

Special features in chemical syntheses with metal atoms are: 1) free metal atoms approach the reaction centers with high kinetic energy or in excited states; 2) substances which are present during the evaporation or sputtering of metals in closed systems are no longer "impurities", they are "reaction partners"—chosen on the basis of modern theories of chemical bonding.

Our rough survey illustrates that chemists from *quite different scientific backrounds* are turning their attention to the study of relationships between the chemistry of dispersed metals and metal atom synthesis. Progress in this sector is based on results of *experimental* work in chemistry and physics[17].

Reactions of Transition Metal Atoms with Organic Substrates[***]

By Philip S. Skell and Michael J. McGlinchey[*]

1. Introduction

The foundations of atom chemistry were laid five or six decades ago with the investigation of hydrogen, oxygen, and nitrogen atoms using methods such as discharges through gases, and continued with the researches into the alkali metal atoms by pioneers such as *Michael Polanyi* in the 1920's. Free radical chemistry was gradually evolving and chain reaction processes involving halogen atoms were eventually elucidated. However, by the 1950's the chemistry of probably less than a dozen atomic species was well documented and the higher boiling (and potentially more interesting) elements were virtually ignored, presumably due to the lack of a convenient experimental method.

The development of atomic carbon chemistry in the 1960's was a natural consequence of our own interests in carbenes and other short-lived species. A major contributor was *Lyle Wescott* who solved the problem of producing and reacting carbon atoms[1]. Carbon was vaporized either by use of an arc or by resistive heating, and the hot species was then transferred to a cold zone across a vacuum which insulated the hot source from the site of reaction. The residual pressure (10^{-5} torr) and the dimensions of the container were chosen such that the mean free path was much greater than the distance from the hot source to the cold reaction zone, thus avoiding gas phase reactions; it was anticipated that exothermic reactions occurring at low pressure in the gas phase would result in formation of "hot" molecules which would fragment faster than they could be cooled. Since then many modifications have been introduced, such as laser evaporation of metals and rotating cryostats, but the basic principles are the same although the scope of the experiments has been greatly extended. Mention should also be made of the early advances accomplished by *Margrave, Timms, et al.* with the most interesting high temperature species SiF_2 which has a remarkably long lifetime[2].

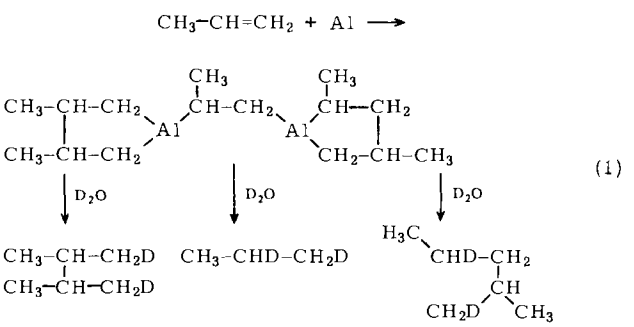
One might dispel initially the illusion that the high temperature origin of the atoms would result in "hot atom" chemistry as a consequence of high kinetic energy. The kinetic energy of a species derived from a 3000 °C source is approximately 6 kcal/mol (≈0.25 eV) which is a trivial contribution to the overall energy of reaction. However, these atoms are of course more reactive than the atoms in the usual condensed phase form of the element since their binding to other like atoms has been overcome.

After several years surveying the field of metal atom chemistry we now feel that it is possible to describe a reasonable number of reactions of a wide variety of atomic species. These range from main group elements such as Mg, B, Al, C, and Si through typical transition elements, *viz.*, Cr, Mn, Fe, Co, and Ni, to the very high boiling elements such as Mo, W, Re, and Pt.

The broadest survey of metal atom reactions was carried out by cocondensing the atoms with propene. With few exceptions propene reacts with metal atoms to form organometallic compounds. No two elements behave identically but there was a noticeable trend from σ to π character for the organometallic products on progressing from left to right across the Periodic Table.

2. Aluminum Atoms and Alkenes

Aluminum, for instance, gave no simple isolable compounds directly and the yellow viscous residue was analyzed by hydrolysis with D_2O to mark each carbon aluminum bond with a deuterium atom[3]. The major products upon hydrolysis were deuterated propane, 2,3-dimethylbutane, 2-methylpentane, and traces of *n*-hexane. A reasonable organoaluminum intermediate, which accounts not only for the products but also for the deuterium distribution observed, is shown in Scheme 1.



(1)

A question which immediately arises is the mechanism of the dimerization of the olefin, *i.e.*, is an aluminacyclopropane initially formed which then opens to a diradical and adds to a second molecule of propene to produce the aluminacyclopentane system? A preliminary indication was provided by

[***] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e.V. at Darmstadt (May 12–15, 1974).

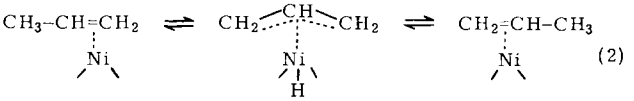
the reaction of 1,3-butadiene with aluminum atoms followed by hydrolysis with D_2O to produce almost exclusively 1-butene and very little 2-butene. The magnesium butadiene adduct hydrolyzes to a 1:1 mixture of 1-butene and *cis*-2-butene[3a]. The preference for 1,2- rather than 1,4-addition might imply an aluminacyclopropane intermediate but it is not a necessary conclusion.

The reaction with *cis*- or *trans*-2-butene to produce the *meso*- and *d,l*-2,3-dideuteriobutanes shows that the reaction is not stereospecific; there is almost no memory of the configuration of the original olefin. However, introduction of a Lewis base such as dimethyl ether or trimethylamine either to the cold matrix or even as a cocondensate with the aluminum and 2-butene yields, after D_2O treatment, 95% of the *cis* addition product; that is *trans*-2-butene yields *d,l*-2,3-dideuteriobutane and *cis*-2-butene produces the *meso*-compound[4]. This provides much more compelling evidence for initial production of an aluminacyclopropane whose rate of ring opening is greatly reduced by the presence of the complexing ligand. It is difficult to rationalize such a retention of stereochemistry on the basis of two aluminum atoms per double bond. Furthermore, at the vaporization temperature, aluminum is predominantly in the ^2P electronic ground state and thus bears some resemblance to singlet carbenes which are known to add stereospecifically to olefins.

In the aluminum-propene reaction the number of deuterium atoms incorporated in solvolysis products per mole of metal reacted accounts for about 2.7 of the 3 valences of aluminum. However, in the aluminum-2-butene reaction the stoichiometry is very different. A ratio of Al : H_2 : butane = 2 : 1 : 2 is found in the hydrolysis products. Furthermore, hydrolysis with D_2O affords D_2 instead instead of H_2; thus no Al-H bonds were originally present since they would have given rise to HD. A probable explanation is the presence of aluminum-aluminum bonds, a previously unreported phenomenon in organoaluminum chemistry. As yet, a molecule such as bis(2,3-dimethylaluminacyclopropane) has not been isolated; such a purification would be fraught with experimental difficulties. Nevertheless, it is possible to titrate out with iodine (1 mole of I_2) that portion of the aluminum-butene system which is responsible for D_2 formation on deuterolysis, while leaving the aluminum to butane ratio unchanged[4a].

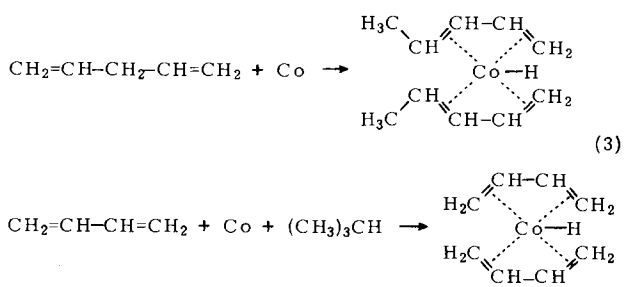
3. Cobalt or Nickel Atoms and Alkenes

It is clear from Section 2 that aluminum forms σ-bonded organometallics. In complete contrast, cobalt and nickel liberate unlabeled propene when the residue from the metal-propene reaction is treated with D_2O[5]. However, the products are not just simple π-complexes, because the cocondensate of nickel (or cobalt) and 1-butene, when allowed to warm up, catalytically isomerizes the substrate to a mixture of *cis*- and *trans*-2-butenes. This process might occur *via* a π-allylmetal hydride intermediate such as has been elegantly demonstrated by *Bönnemann* in the case of propene(trifluorophosphane)nickel[6] or by addition of a Ni-H compound to the alkene to give alkylnickel intermediates and subsequent elimination. The former could be shown to apply. Nickel vapor was cocondensed in separate experiments with 2-deuteriopropene and 3-deuteriopropene. The latter gave a mixture which also contained 1-deuteriopropene, whereas 2-deuteriopropene apparently remained unscrambled. Furthermore, 3-deuteriopropene led to both undeuterated and dideuterated propenes demonstrating that both inter- and intramolecular exchange occurs[7]. This evidence is consistent with a π-allylmetal hydride intermediate which permits a 1,3-hydrogen shift (Scheme 2).



(2)

The successful isomerization of terminal olefins to nonterminal olefins suggested the possibility of isomerizing nonconjugated to conjugated dienes. However, such reactions, *e.g.*, with 1,4-pentadiene and Co atoms are exceedingly complex. Among the early reaction products are linear pentenes and C_5H_6 compounds which polymerize. These disproportionation reactions are not the only problem, however, since the conjugated dienes which eventually appear form stable complexes with the metal (*e.g.*, cobalt) and stop the catalytic process. This is, nevertheless, a route to the novel bis(diene)cobalt hydride complexes (Scheme 3) which can also be synthesized by cocondensing the appropriate conjugated diene with cobalt vapor and a molecule possessing a readily abstractable hydrogen atom[8].



(3)

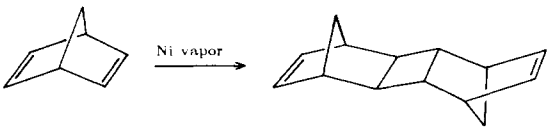
The ^1H-NMR data for these complexes are similar to those reported by *Pettit* for the reaction product of dienes and carbonyliron compounds[9].

The reaction of 1,3-butadiene with nickel vapor gives as the major product a gray residue, which may contain bridging butadiene ligands[5]. This gray residue reacts with more butadiene to produce the blood-red 2,6,10-dodecatrienylenenickel which *Wilke et al.*[10] had previously obtained by other routes in their masterful elucidation of the nickel-catalyzed cyclotrimerization of butadiene. It is also possible to isolate from the reaction of nickel vapor and 1,3-butadiene traces of a volatile yellow material which has been tentatively claimed to contain bis(butadiene)nickel but which certainly contains bis(crotyl)nickel.

4. Metal Atoms and Arenes or Cyclic Dienes

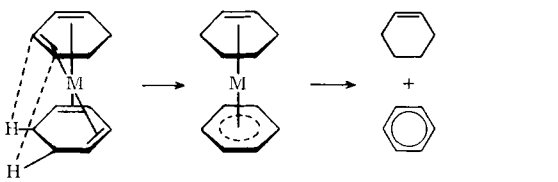
A variety of reactions of metal vapors with cyclic dienes have been observed. Foe example, nickel vapor and 1,5-cyclooctadiene react to yield bis(1,5-cyclooctadiene)nickel directly[5]. However, this route is unlikely to oust the more conventional method which utilizes ethoxydiethylaluminum to reduce bis(pentanedionato)nickel in the presence of 1,5-cyclooctadiene and which is more amenable to relatively large

scale work[11]. In contrast, nickel vapor and norbornadiene yielded no isolable organometallic product but gave predominantly the *exo-trans-exo* dimer of norbornadiene (Scheme 4)[5].



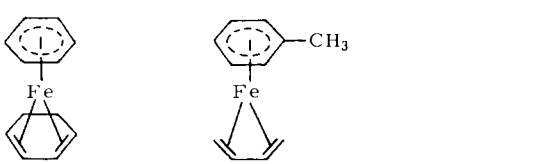
(4)

In yet another type of reaction with cyclic dienes, metal vapors such as Cr, Fe, Co, and Ni bring about rapid, catalytic disproportionation of 1,3- or 1,4-cyclohexadiene to cyclohexene and benzene when the whole cocondensate is allowed to warm to 0 °C. It is tempting to postulate initial formation of a bis(diene)metal complex which then undergoes hydrogen transfer possibly *via* a metal hydride intermediate (Scheme 5).



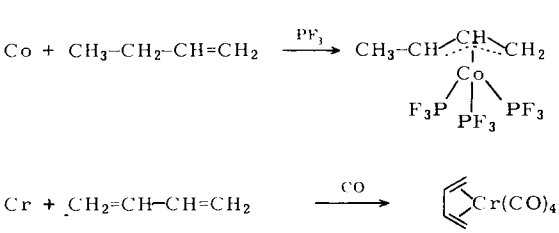
(5)

Although we have not isolated such a diene complex in this case it is possible when using iron vapor to obtain (η-benzene)[1—4-η-(1,4-cyclohexadiene)]iron(0). This type of arene-(diene)metal complex is also synthesizable by cocondensing iron vapor with an arene and then adding a suitable diene to the cold matrix. Thus, one can readily prepare (η-butadiene)-(η-toluene)iron(0) and other analogous species (Scheme 6)[12].



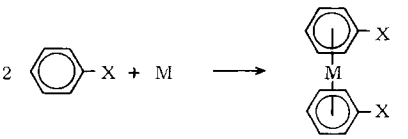
(6)

Another synthetic use of this technique of adding a stabilizing ligand to a reaction matrix is the addition of PF_3[13a] or CO to metal-olefin cocondensates (Scheme 7)[13].



(7)

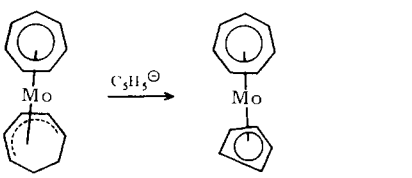
It was first shown by *Timms* in 1969 that the cocondensation method is a viable route to the bis(cyclopentadienyl)metal sandwich compounds, and also that bis(benzene)chromium is synthesizable directly[14]. This provides the cue to the realization that bis(arene) compounds of chromium, molybdenum, and tungsten should be capable of being synthesized even when the arene contains functional groups possessing lone pairs of electrons. Such compounds had previously defied attempts at synthesis because the conventional Fischer-Hafner technique[15] required the use of $AlCl_3$ and this Lewis acid complexed with the substituted arenes and stopped the reaction sequence. Now, however, using the direct synthesis, it has proven possible to make bis(arene)metal compounds of Cr, Mo, and W with the arenes substituted by fluoro, chloro, amino, methoxy, methoxycarbonyl and other functional groups (Scheme 8)[16, 17].



(8)

This has clearly opened up new areas of interest to the organometallic chemist since bis(arene)chromium chemistry was formerly limited to metalation and hydrogen exchange reactions.

An interesting extension of this is the reaction of molybdenum atoms with cycloheptatriene to produce the cycloheptatrienyl(cycloheptadienyl)molybdenum sandwich. The cycloheptadienyl unit is labile and easily replaced by cyclopentadienyl anion (Scheme 9)[17a].



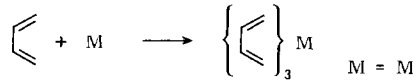
(9)

In contrast to the reaction with nickel atoms[5], norbornadiene is not just dimerized by molybdenum and tungsten atoms but instead a catalytic polymerization occurs in which one ring is opened[20b]. It has been suggested that this process might occur *via* a series of olefin dismutation processes which are so prevalent in molybdenum chemistry[21].

An amusing corollary to this reaction promises to be that of Mo with azulene; however, the product has not yet been unambiguously identified.

5. Tris(butadiene)molybdenum

Yet another novel reaction has been discovered using Mo or W vapors to produce tris(butadiene)molybdenum (or -tungsten) by direct reaction with 1,3-butadiene in the condensed phase (Scheme 10)[18]. The only comparable previously known system is tris(methyl vinyl ketone)tungsten[19] which adopts the relatively unusual trigonal prismatic structure[20].

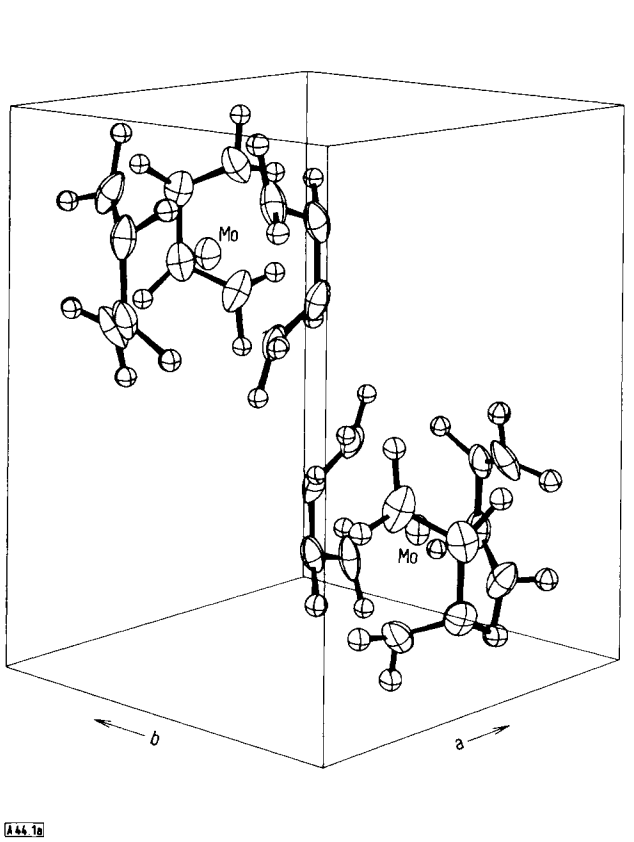


(10)

The new tris(butadiene)molybdenum is sublimable and air-stable, and its X-ray structure shows that the central molybdenum is equidistant from all the carbon atoms[20a]. The butadienes are all *cisoid* and in a trigonal prismatic arrangement in a girdle around the Mo such that they are aligned in the same direction. There is a small distortion in the planarity

of the butadiene system and the C_2—C_3 bond is longer than in free 1,3-butadiene.

of some of the types of reaction possible is presented in Table 1.



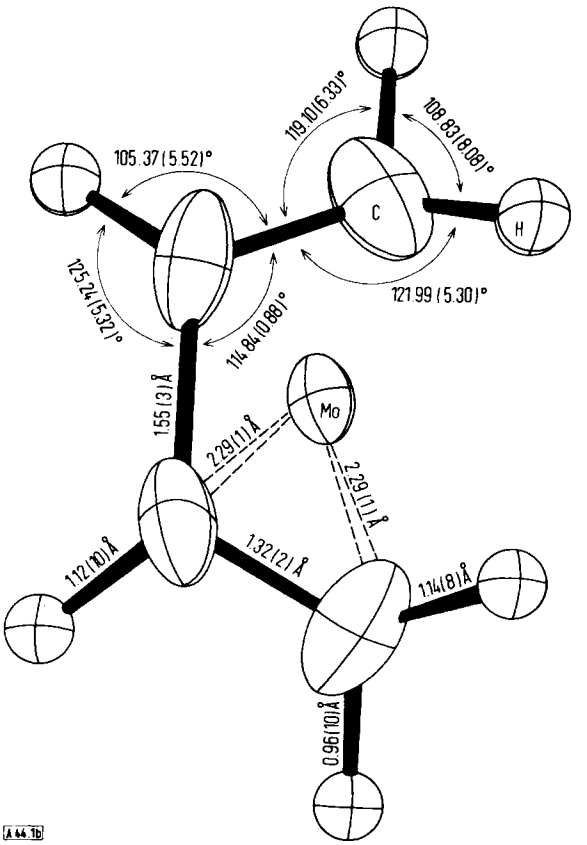


Fig. 1. Crystal structure of tris(butadiene)molybdenum. Space group $P6_3/m$, C_{6h}^2; $a=b=7.208(11)$, $c=11.829(24)$ Å; $Z=2$; $\rho_{calc.}=1.61$ g/cm³ [20a].

6. Metal Atoms and Water

A surprisingly interesting substrate is water, which shows some unexpected reactions with metal vapors. Thus, although chromium and hydrogen chloride react at −196 °C to release one mole of hydrogen per mole of chromium, reaction with water yields half a mole of hydrogen at −196 °C and the other half a mole on warming up. Methanol behaves in a similar manner to water, finally producing dimethoxychromium(II)[21a]. The two hydrogen-producing processes occurring at liquid nitrogen temperature and on warming up show remarkably different isotope effects, as revealed using mixtures of H_2O and D_2O; some of these processes look like free electron reactions while others do not, and these systems obviously merit further investigation. Mo and W show no reaction with H_2O at −196 °C, yet do so on warming up.

Table 1. Possible reactions of metal atoms with organic compounds.

Reaction types	Examples
a) Synthesis of sandwich compounds	$(C_6H_5-OCH_3)_2Cr$ $(C_7H_7)Mo(C_5H_5)$
b) Synthesis of olefin complexes	(1,5-cyclooctadiene)$_2$Pt (1,5-cyclooctadiene)$_2$Ni (1,3-butadiene)$_3$W
c) Indirect synthesis by addition of a stabilizing ligand	$(C_6H_5-CH_3)Fe(PF_3)_2$ (C_5H_5)Co(isoprene)
d) Synthesis of involatile products; analyzed by hydrolysis	$R_2Al-AlR_2$
e) Catalytic isomerizations	1-butene → 2-butene 1,4-pentadiene → 1,3-pentadiene
f) Catalytic hydrogenations	olefin/Pd + H_2 → alkane
g) Acetylene trimerizations	propyne → 1,2,4- and 1,3,5-trimethylbenzenes
h) Catalytic disproportionations	1,3-cyclohexadiene → benzene and cyclohexene

7. Reactions of Metal Atoms in Excited States

We have so far discussed some reactions of metal atoms with organic substrates in an attempt to go some way towards bridging the gap between the conventional electronic picture of an atom and the reactions of a conglomeration of these atoms such as is usually presented in chemical texts. Clearly the reactions of elements in a monoatomic form differ dramatically from the reactions of the bulk metal and a classification

One final point to consider is that not only ground state atom chemistry can be studied by this technique but also atoms in electronically excited states. This is nicely exemplified by our earlier work with carbon atoms which are produced in a ^3P ground state by resistive heating but which contain a sizeable percentage of ^1S and ^1D excited states when produced in an arc[22]. Of course a large number of excited states may be populated by arcing but the time required for the flight of the high temperature species to the walls ($\approx 10^{-5}$ s) allows sufficient time for optically allowed transitions to occur so that only a limited number of metastable

states are going to survive the trip and be able to exhibit some chemistry. The chemistry of the electronically excited state(s) can differ dramatically from that of the ground state, and one such system which nicely demonstrates this is the reaction of magnesium which alkyl halides (Scheme 11).

$$CH_3-CH_2-CH_2-Cl + Mg(^1S) \xrightarrow{-196\,^\circ C} CH_3-CH_2-CH_2-Cl/Mg$$

deeply colored

$$\xrightarrow{-120\,^\circ C} CH_3-CH_2-CH_2-Mg-Cl \quad (75\%) \qquad (11)$$

colorless

$$CH_3-CH_2-CH_2-Cl + Mg(^3P) \longrightarrow CH_3-CH_2-CH_2^{\bullet} + \overset{\bullet}{M}gCl \longrightarrow$$

$$CH_3-CH{=}CH_2 + CH_3-CH_2-CH_3 + n\text{-hexane}$$

(35%) (34%) (traces)

Magnesium vapor produced thermally (by resistive heating of a crucible) is essentially ^1S ground state magnesium which reacts with alkyl halides to give good yields of non-solvated Grignard reagents. Magnesium vapor produced by arcing contains 65–70% of the electronically excited ^3P state which reacts with alkyl halides to yield radicals[23].

The apparent triviality of these excited state reactions should not obscure the underlying principle that by techniques such as arcing it should be possible to elucidate the chemistry of the electronically excited states of many atoms, and this is one direction in which the field of atomic reactions will be heading in the not too distant future.

Isolation and Reactions of Metal Atoms in Matrices[**]

By George C. Pimentel[*]

1. Introduction

The matrix isolation technique was devised to permit the leisurely spectroscopic study of extremely reactive molecular species[1–4]. In this method, normally transient molecular species are embedded (trapped) at high dilution and at very low temperature in an inert solid environment. Anyone involved today in metal atom synthesis will see the similarity of this diagnostic process to the low temperature reaction conditions that have proven so successful in metal atom synthetic chemistry. Hence, it is not surprising that the matrix isolation technique has already contributed significantly to the study of chemical synthesis with metal atoms. The course of metal atom reactions can be interrupted so that the reaction mechanisms can be examined. Not only the chemical identity, but also the molecular structure of reaction intermediates can often be obtained. Sometimes undesired side reactions can be eliminated and kinetic barriers can be revealed. These valuable potentialities imply that workers in metal atom chemistry will wish to become familiar with matrix isolation, first, to be able to evaluate the interesting work of this sort now appearing in the literature and, second, to be able to put the method to use when applicable.

In this review, experimental methods will be described and then the potentialities of matrix isolation will be illustrated by specific examples.

Fortunately, the matrix isolation technique has been the subject of several books and numerous recent and authoritative reviews[5–11]. The book by *Meyer*[6] takes a comprehensive and coherent look at the spectroscopy of low temperature samples, including electronic spectroscopy. It has a valuable

chapter on experiment details, and a tabular survey of over 800 substances that had been studied by matrix methods through 1969. The book edited by *Hallam*[7] focuses on vibrational spectroscopy and its chapters are authoritatively written by active workers in the field. Of particular interest here are the chapters by *Andrews* (Ch. 5) and by *Ozin* (Ch. 9) because these two authors have themselves made important contributions to metal atom chemistry.

2. Spectroscopic Techniques

Each of the spectroscopic fields, visible-ultraviolet, electron spin resonance (ESR), infrared, and Raman spectroscopy has its place in matrix isolation work. In each spectral region, commercial spectrometers can be and are usually used. Because low temperature matrix samples display rather sharp spectral features (infrared line widths are usually about $1\,cm^{-1}$ and sometimes as narrow as a few tenths of a wave number), spectral resolution of 0.3—0.5 cm^{-1} is adequate, a performance readily available in commercial instruments. It is important to note, however, that this level of spectral resolution is usually *needed* to derive full benefit from the matrix method. Through isotopic substitution, the number of equivalent atoms of the type substituted can often be determined, provided the isotopic shifts are resolved. Since the limit of this diagnostic information is fixed by the line widths, valuable information can be lost if spectral slit widths exceed the natural line widths.

detectable Raman signals without excessive matrix heating by the light source. The concentrated beam provided by a laser source circumvents these difficulties provided proper attention is paid to the fact that only momentary excessive heating of a matrix sample can cause diffusion and abort the entire experiment.

In this early stage of experience with matrix Raman spectroscopy, it is probably too early to define the optimum experimental parameters. Instead, it may be more informative to list the conditions that have been successfully used by some of the pioneers, with attention to the laser power, the wavelengths used, and to the sample support and optical geometry.

Table 1 shows that matrix isolation Raman spectra were first successfully recorded and reported in the literature almost simultaneously in four different laboratories. *Shirk* and *Claassen*[12] first reported matrix-isolated Raman spectra of SF_6 and of $CHCl_3$. Their laser beam was dispersed to a 4 mm long line focus with a cylindrical lens to reduce local heating. They deposited the sample on a platinum mirror surface and illuminated at an angle of about 30° from grazing incidence. They were able to observe all three Raman active frequencies of SF_6 and seven of chloroform with spectral resolution near $10\,cm^{-1}$.

Nibler and *Coe*[13] described in detail the technique they developed and the important parameters for successful matrix spectroscopy. They deposited onto a polished aluminum surface and illuminated at 10 to 30° from grazing incidence, this

[a] Angle of incidence measured from surface.

The recent advent of laser Raman spectroscopy warrants somewhat more attention to this type of instrumentation. Raman spectra were conspicuously absent in the first decade of matrix isolation because it was not possible to record Raman spectra of matrix samples with conventional Raman light sources. The extremely high matrix scattering that always accompanies good isolation made it impossible to obtain

angle being optimized for maximum signal. The N_2 matrix Raman signal was found to be proportional to laser power up to 750 mW, using a focused beam. The temperature rise in the mirror sample support was also proportional to power and gave a 3 °C temperature rise at 750 mW. These authors verified the equivalence of support temperature and sample temperature by observing the $\alpha \rightarrow \beta$ phase transition of pure,

solid PD_3. While Rayleigh scattering was not a problem (*Nibler* and *Coe* used a Cary triple monochromator), fluorescence was found to be troublesome. A tiny bit of stopcock grease or pump oil condensed on the metal tip could cause excessive interference from fluorescence. They were able to detect the Raman spectrum of CS_2 in a CO_2 matrix at a dilution of $1:10^4$, though matrix ratios between 100 to 500 are more usually required. Finally, they demonstrated the feasibility of measuring depolarization ratios and showed that the results are somewhat but not strongly dependent on the excitation geometry and the glassy or frosty character of the sample.

Ozin et al. published three brief reports[14–16] in the period encompassed by references [12] and [13]. These concise papers displayed the first matrix-isolation spectra of transient species (SeO_2, $PbCl_2$, $SnBr_2$, Br_3), but they were relatively devoid of description of the special experimental techniques and problems involved in the excitation and recording of matrix Raman spectra. However, the following year, *Ozin* and *VanderVoet*[17] reported some of their experimental procedures. They found that highly polished mirror support surfaces made of Cu, Ag, Pt, and Al give lowest background scattering and are particularly suited for depolarization measurements. They maximized signal intensities by optimizing the N_2-shifted Raman line provided by the matrix, using a three-axis universal stage for movement of the cryostat. Because of matrix warming (it is not indicated whether their laser beam was focused), they emphasize the importance of recording spectra first at the lowest possible laser energy. These spectra aid in recognizing diffusion from local heating at higher powers. They found that 10 to 125 mW laser powers were adequate for obtaining spectra without local heating and diffusion effects.

Hatzenbühler and *Andrews*[18, 19] were also early pioneers in the matrix Raman technique and perhaps the first to apply it to transient species generated through metal atom reactions. They deposited their samples on an oxygen-free hard copper wedge (8:1 slope) to obtain the highest possible thermal conductivity in their sample support. They found only 0.3 °C temperature rise in the support wedge using 1 watt of laser power at 4880 Å. They obtained 5 cm^{-1} resolution while scanning at 10—20 cm^{-1}/min.

3. Cells and Cryostats

The matrix method was developed with the use of liquid refrigerants—liquid hydrogen and helium being needed for most of the truly inert matrix materials. This inhibited to some extent the entry of new workers to the field, because of the difficulties in handling these cryogenic liquids, the expense, the sometimes limited availability of helium and because of safety considerations. *Meyer*[6] devotes eight well-deserved pages to safety precautions, enough to cause a novice to think twice about his interest in the hoped-for results.

All of these obstacles have been essentially removed within the last four or five years because of commercial instrumental developments. Reliable and compact cryogenic optical cells are now sold and even more important, closed cycle cryostats that provide temperatures in the range of 10 to 30 °K without the need to handle either liquid helium, liquid hydrogen, or ultrapure, high pressure gases. With an investment of only about $ 10000 (plus spectrometer) a novice can readily undertake matrix isolation experiments like those to be described. Both *Meyer*[6] and *Hallam*[7] include whole chapters devoted to the design of optical cells and to cryogenic systems, so it is considered unnecessary to repeat them here. It is worth noting however, that among the excellent closed cycle cryostats now available, the "Displex" unit by Air Products Ltd. and the "Cryodyne" unit by Cryogenic Technology Inc. are well suited to matrix isolation studies. Their performance characteristics are similar to those of other devices: Cool-down times between 30 and 60 min are routine to temperatures in the range 16 to 20 °K and these operating temperatures can be maintained with total heat loads of one watt. Larger capacity and somewhat more expensive units will reach temperatures of 11—12 °K with heat load capacities of 1.5 watts. For argon and the heavier inert gases, a temperature of 20 °K or lower is needed and during sample deposition, the heat load requires one watt capacity or greater to prevent local warming of the sample. For neon matrices, 4 °K, hence liquid helium coolant, is needed.

4. Deposition Temperature

The incubation period that was required for the fruition of the matrix isolation technique was connected with the development of low temperature cryostats (see Section 3) and with the discovery of the important parameters involved in successful sample preparation. In the earliest systematic studies of isolation efficiency[3], it was found that diffusion of the reactive constituent, R, (whose isolation is desired) was far more difficult to avoid than had been anticipated. Ultimately, a rule of thumb evolved: diffusion would be too rapid to permit isolation of a triatomic molecule if the matrix temperature even momentarily rose to a temperature above about half the melting point[20]. For the important matrices of N_2 and Ar, diffusion of water is liable to occur if the temperature reaches 35 °K and isolation will be lost if it exceeds 40 °K. Diatomic molecules diffuse more readily; for example, NO diffuses in N_2 in the range 12 to 18 °K[21] while single atoms are even more mobile. All of these remarks refer, of course, to the temperature of the matrix itself, which can be several degrees higher than the supporting substrate during periods of high heat load (*e.g.*, during deposition, during photolysis of a deposited sample, and, especially during operation of a high temperature Knudsen cell or hot wire near the substrate). These observations led to the early recognition of the importance of monitoring the sample substrate temperature in addition to that of the cold metal block to which it is thermally connected. During periods of high heat load, the substrate temperature may rise a few degrees above that of the surrounding copper block—CsI and CsBr are two popular substrates and they have poor thermal conductivities at very low temperatures. It can be added that the temperature *difference* between the copper block temperature and the CsI "window" temperature helpfully indicates the maintenance of thermal contact between the two. This is a crucial property of the cold cell that occasionally changes capriciously from experiment to experiment. A convenient habit is to measure during "cool-down" the lag between the time the copper block temperature passes, say, 30 °K and the time that the window reaches that same temperature. This time lag is an individual characteristic of each cold cell, but if it noticeably exceeds its norm (which should be less than 5 to 10 minutes), then

thermal contact is suspect. Experience proves that time is lost if depositions are carried on with fluctuating thermal behavior in the cold cell.

The window temperature can be measured with a thermocouple pushed into a hole drilled in the salt window; indium sheet wrapped around the thermocouple or Wood's metal poured into the hole provides adequate thermal connection. A suitable thermocouple composition is gold/gold-cobalt alloy (2.1% Co), which retains a useful temperature coefficient even down to 4°K. By comparison, copper/constantan has a lower dE/dT by a factor of 2.5 at 20°K and by a factor of 4 at 4°K, making it almost useless at the lower temperatures.

A highly reflecting metallic substrate can be used in laser Raman studies[12, 13, 17, 18] which eliminates the thermal contact problem and brings the sample significantly closer to coolant temperature[13]. The same advantage can be gained in infrared absorption work by focusing the spectrometer beam onto the sample deposited on a reflecting surface. The reflected beam passes through the sample twice, and the necessary extra spectrometer optics are not an expensive addition, nor are they troublesome to focus.

5. Sample Preparation

A matrix suspension of a reactive species may be prepared by slow deposition of a gas mixture of the matrix and a suitable photosensitive precursor. Then photolysis, either after or during deposition, gives the desired species *in situ* in the matrix environment. If vacuum ultraviolet photolysis is needed, it is almost essential to photolyze during deposition because matrix scattering is so severe at the shorter wavelengths that it will not penetrate the matrix. Of course, photolysis during deposition increases the heat load at this crucial time and it prevents recording the matrix spectrum before photolysis and then again at various photolysis times.

More important to the study of metal atom chemistry are depositions involving high temperature atom sources. *Linevsky* was an early pioneer in the use of a Knudsen cell in his classic matrix study of molecular lithium fluoride[22]. Simultaneous deposition of argon (or other inert gas) in excess from another jet provided the matrix environment. The Knudsen cell temperature was varied to change the matrix/-LiF = M/R ratio so that monomers and dimers could be distinguished.

For evaporation temperatures up to 500°K, a small Knudsen cell no more than one centimeter in diameter can be incorporated in the base of the cold cell. A simple design is described by *Andrews* and *Pimentel*[23] which they used to evaporate atomic lithium in a matrix study of its reaction with nitric oxide. The stainless steel Knudsen cell was wound with heating wires, and slipped into a Pt-mirrored quartz sleeve. A chrome-plated copper radiation shield with a suitable orifice minimized radiation heating of the cold window placed only 4 cm away.

A comparably simple Knudsen cell was described by *Weltner et al.*[24] for evaporation temperatures as high as 2700°K. A cell one inch long and 1/8 inch in outside diameter was made of 0.010 inch tungsten sheet and heated resistively. The sample effused through a 0.050 inch hole in the cell wall. *Weltner* and *McLeod*[25] designed another resistance-heated furnace made to evaporate expensive or rare samples. A cylinder 1/2 inch long and 3/16 inch diameter was made from .005—.010 inch tantalum sheet. After the sample was placed inside, the cylinder was closed with tantalum caps crimped in place, and heated through water-cooled copper electrodes with an AC current of 150 amps at 6 volts. Temperatures of 2700°C were accessible. This cell was used, for example, to evaporate carbon atoms (C_2, C_3, *etc.*) from a 50 mg sample of ^{13}C-enriched graphite. The design is potentially an important one for evaporating expensive, isotopically enriched metal samples or for rare and specially pure metals.

Induction heating can also be used to advantage as again can be typified by the work of *Weltner*[26]. To evaporate carbon vapor at 2300—2600°K, a small sample (5/8 by 1/2 inch) of graphite was supported by tungsten rods at the center of an induction coil of 3/16 inch diameter.

For some purposes, much more complicated double oven evaporation cells are needed. Metals often evaporate as a mixture of monomeric, dimeric and polymeric species. The relative amount of these species can be varied by changing the temperature, a significant aid in the identification of spectral signatures. Unfortunately, in most matrix work, the rate of deposition must be controlled by the oven temperature. Hence, a double oven, with separate temperature control, is needed. The rate of deposition is determined by the first oven temperature. The gas effuses into a second oven chamber at a higher and variable temperature to alter the degree of aggregation prior to entrapment in the matrix material. A recent example of such a double oven Knudsen cell has been reported by *Frey et al.*[27] for use up to 800°K.

A simpler but effective evaporation technique for metal atoms is to use a heated filament of the desired metal instead of the Knudsen cell. The efficacy has been demonstrated by *Kündig et al.*[28a]. Typical filament dimensions were $1.75 \times 0.375 \times 0.008$ inches through which would be passed 80—150 amps at 1—1.5 volts. Of course, suitable baffles must be provided to avoid excessive heating, but high evaporation temperatures are much more readily obtained than with a Knudsen cell. Unfortunately, the hot filament loses two useful features of the Knudsen cell approach. First, from a Knudsen cell, the amount of metal deposited per unit time can be at least roughly calculated by assuming that the inside vapor pressure remains near equilibrium. This estimate, coupled with the argon deposition rate, provides at least a crude estimate of the concentration of the evaporated species. Second, the equilibrium assumption also permits deliberate variation of the monomer to dimer ratio through temperature control.

Two methods for direct determination of the deposition rate can be mentioned. *Andrews* and *Pimentel* calibrated their Knudsen cell evaporation rate *versus* temperature by evaporating onto the cold window for a measured time followed by chemical analysis of the deposited metal[23]. *Ozin et al.* have adopted an elegant method commonly used in monitoring evaporation rates in thin film preparation[28b]. A quartz crystal that serves to tune an RF oscillator is placed near the evaporating filament in geometry equivalent to that of the deposition surface. As evaporation coats the surface of the quartz crystal, the mechanical loading alters the RF oscillator frequency. A deposit of 10^{-8} g can be detected. Continuous monitoring with a frequency counter measures the deposition rate (once the device is calibrated) during each experiment. This does not, of course, provide any information at all about the

monomer to polymer ratio which is determined by little-understood kinetic processes rather than by equilibrium.

This uncertainty about the various metallic species (monomers, dimers, trimers, *etc.*) that are directed to the matrix surface is even further aggravated in electron-beam evaporative techniques. This method has the advantage that very high temperatures can be reached easily, facilitating evaporation of even the more refractory metals. *Shirk* and *Bass* have also shown that metal atoms can be "evaporated" by bombarding a metal surface with positive ions (*e.g.* Ar^+, Kr^+, Xe^+) produced by passing a gas through a glow discharge[29]. They refer to the technique as "sputtering", and for good reason—electron and ion bombardment are known to eject aggregates as well as single atoms.

6. Isolation Efficiency: M/R and Deposition Rate

The last experimental parameters that deserve discussion are those that determine isolation efficiency. Of course, if diffusion occurs during sample preparation, the experimenter will not be confident that he is studying the reactions of single metal atoms. Hence, when diffusion occurs, the matrix isolation technique has been compromised.

The variables at the experimenter's disposal are the "window" temperature, the choice of matrix material, the concentration ratio (M/R), and the deposition rate. These variables can be explored by reference to the paper by *Andrews* and *Pimentel*[30] on the isolation of lithium atoms in inert gas matrices. Lithium atom is undoubtedly the most difficult atom to isolate except for H atom and since both monomeric Li and dimeric Li_2 were measured by these authors[30], quantitative statements about isolation efficiency can be made. The example displays the effects and it can be taken as a "worst case" (except for H).

As mentioned in Section 4, the window temperature must be *well below* half the melting point of the matrix or there is no possibility of isolation. For nitrogen and argon, temperatures between 15 to 20°K (0.2 to 0.3 of the melting point) are quite satisfactory for diatomic and triatomic molecules, but lower temperatures are needed for atoms. This effect is displayed for Li by the first four lines of Table 2. The data taken from *Andrews* and *Pimentel*, show more than a ten-fold improvement in isolation efficiency for argon under the rather poor isolation conditions used and a two-fold improvement for krypton when T_W was lowered from 15°K to 4°K. Obviously, the lower the deposition temperature, the better, but, unfortunately, experimental difficulties of other sorts limit the use of this advantage. Liquid helium is expensive, liquid hydrogen does not conveniently offer a temperature below its triple point, 15°K, and commercial, closed cycle coolers usually furnish temperatures no lower than about 10 to 15°K. Furthermore, scattering by the matrix becomes more and more serious as the deposition temperature is lowered below the "diffusion temperature" (about 1/2 T_M). A good compromise between isolation efficiency and scattering is to place the window temperature in the range (0.2—0.3) T_M (where T_M is the matrix melting point).

Table 2. Effect of experimental parameters on the isolation efficiency of lithium atoms [a] (data from [30]). T_W = window temperature, M/R = ratio matrix/sample.

Parameter	Matrix	M/R	T_W[°K]	[Li]/[Li_2]
T_W	Ar	3300:1	15	0.0006:1
	Ar	3300:1	4	0.0096:1
	Kr	3300:1	15	0.0069:1
	Kr	3300:1	4	0.019:1
Matrix material	Kr [b]	18000:1	4	0.037:1
	Xe [b]	18000:1	4	0.30:1
M/R	Ar	3300:1	4	0.0096:1
	Ar	18000:1	4	0.035:1
	Kr	3300:1	4	0.019:1
	Kr	18000:1	4	0.037:1
	Xe	18000:1	4	0.30:1
	Xe	170000:1	4	[c]

[a] Deposition rate 4.5 mmol/h unless otherwise specified.
[b] Deposition rate 1—1.6 mmol/h.
[c] No Li_2 detected.

The above discussion implies that isolation can be improved at fixed deposition temperature by choosing a matrix with a higher melting point. Table 2 shows the magnitude of the improvement for lithium isolation for the matrix materials Kr and Xe under otherwise identical experimental conditions. Unfortunately, this considerable improvement can be lost because of "frosty", highly scattering matrices formed by the matrix of higher T_M and better isolation efficiency.

Concentration, or M/R, is the third parameter at the experimenter's disposal. Table 2 displays the effectiveness of M/R in this respect for each of the inert gases, Ar, Kr, and Xe. Of course, lower values of M/R suffice for isolating diatomics and larger molecules, which diffuse less readily. In general, M/R must exceed 100 and, for N_2 or Ar matrices at 15°K, ratios exceeding 500 will isolate triatomic molecules very effectively. Of course, if reaction between two deposited species if desired, then concentration ratios may desirably be lower. For example, if reaction between a metal atom and a reaction partner is intended, M/R must be low enough to give a reasonable likelihood of encounter in the matrix but high enough to prevent secondary reactions. *Pimentel et al.*[31-33] usually fix the more concentrated reactant concentration near $M/R = 300$. In some applications, the ease of diffusion of metal atoms relative to the reaction partner might be used to advantage.

Finally, the deposition rate is extremely important in determining isolation. Inert gas and nitrogen matrices have very poor thermal conductivity, so they warm significantly during deposition. Of course, the room temperature matrix gas carries a significant heat capacity and it releases, as well, its heat of sublimation during solidification. As the deposit thickness increases, this heat release at the surface can produce a significant thermal gradient through the sample. If this thermal gradient becomes too large, diffusion occurs, and the isolation function of the matrix is subverted. Under any circumstances, at a given M/R and deposition rate, isolation efficiency is found to decrease as the sample thickness increases. These effects were quantitatively displayed by *Leroi et al.*[34] in their study of the infrared spectrum of CO in argon.

The obvious reply to this difficulty is to control the heat input by lowering the deposition rate as far as practical. To ensure optimum isolation, very slow deposition rates are used by most experienced users of the matrix technique. For example, in the Berkeley laboratories, the matrix sample might be deposited at a rate of 2—3 mmol/h for a deposition time as long as 10 to 48 h.

Apparently in contradiction to this dictum are experiments recently published concerning "pulsed deposition". This deposition technique was pioneered by *Rochkind*[35] with specific application to quantitative analytical use where isolation was not important. *Perutz* and *Turner*[36] then found that under some conditions, effective isolation could also be achieved with pulsed deposition, which offers the hope that deposition times can be shortened significantly. Here in the Berkeley laboratories, *Louis Allamandola*[37] has made a systematic study of pulsed deposition and, indeed, there are advantages to be gained. A sample of CH_3OH in $N_2(M/R=100)$ was deposited at a rate of 3 mmol/h, first in continuous flow and then at the same *average* rate, but in pulses of 30 ms duration at two pulses/min. There was a slight loss of isolation efficiency; perhaps 25% less monomer was obtained. However, there was a significant sharpening of the absorption features of the monomer that made the pulsed sample spectra more readily interpretable. *Rochkind*[35] first noticed this spectral improvement and we join him in attributing it to a local annealing of the matrix cage due to the pulse. Thus our experience is that pulsed deposition is desireable and that judicious choice of pulse size and spacing might decrease deposition times but not by more than a factor of two or three.

7. Metal Atom Reactions by Matrix Isolation

The study of metal atom reactions through matrix isolation spectroscopy can be said to be founded in the matrix study of metal atoms themselves. This implies electronic spectroscopy, of course, and it reaches back to the early work by *McCarty* and *Robinson* (Hg, Na in Ar, Kr, Xe[38]), *Schnepp* (Mg, Mn in Ar, Kr, Xe[39]), *Roncin* and *Damany* (Hg in Ar[40]), and *Brewer*, *Meyer et al.* (Hg in Ar, Kr, Xe[41], Na, K in Ar, Kr, Xe[42]). Today, spectra of atoms in inert gas matrices have been reported for almost half of the elements, as well summarized by *Meyer*[6]. Typical of recent work is the spectrum of tantalum atoms isolated in argon by *Graham* and *Weltner*[43]. The evaporation and isolation of this refractory element suggests that any desired element in the Periodic Table is accessible for this type of study. Furthermore, the spectroscopy furnishes an elegant model: more than 40 sharp absorptions were resolved between 2200 and 5100 Å and, with few exceptions, these features were connected with gas phase counterparts, a significant aid in the interpretation of the latter.

The more direct interest of the present review is, of course, matrix study of reactions of metal atoms with other molecules. A number of laboratories are now beginning work of this sort, mainly using infrared and/or Raman spectroscopy, but also using ESR. This current work will be surveyed briefly, considering first reactions of metal atoms with inorganic molecules and then their reactions with organic molecules.

7.1. Inorganic Substances

Andrews and *Pimentel*[23] may have been the first to attempt deliberate use of the matrix technique to study the reaction of a metal atom with another molecule. They wished to compare the structure and bonding of the then-unknown triatomic molecule LiNO to the counterpart molecules HNO and FNO. Their infrared spectra display the power of isotopic substitution in matrix spectroscopy; absorption frequencies from six different isotopic molecules involving ^6Li and ^7Li, ^{14}N and ^{15}N, and ^{16}O and ^{18}O provided enough information to show that the lithium atom cannot be bonded to the nitrogen atom in the bent triatomic structure known for HNO.

This pioneering study has been fruitfully and productively pursued by *Andrews et al.*, as exemplified by their detailed study of lithium (and the other alkali metals) with O_2[44, 18, 45]. These infrared and Raman spectra again exploit the full potentialities of isotopic substitution and they show unequivocally that the molecule LiO_2 is a symmetric isosceles triangular molecule which *Andrews* finds to be interpretable in terms of ionic bonding between Li^+ and O_2^-.

Table 3 lists other studies of this type now appearing from *Andrews'* laboratory which already include alkali metal atom reactions with F_2O, N_2O and O_3.

Table 3. Some matrix isolation studies of metal atom reactions with inorganic compounds. IR and R = investigation by IR-Raman spectroscopy, respectively.

Metal atom	Reaction partner	Product	Method	Ref.
Li	NO	LiON	IR	[23]
Li	O_2	LiO_2	IR/R	[18, 44, 45]; cf. [46]
K, Rb	O_2	KO_2, RbO_2	IR	[47]
Na, K	O_2	NaO_2, KO_2	R	[48]
Cs	O_2	CsO_2, CsO_4	IR	[49, 50]
Li	F_2O	LiOF, OF	IR/R	[51, 19]
M = Li to Cs	N_2O	MO, M_2O	IR	[52]
M = Li to Cs	O_3	MO_3	IR/R	[53]
Ni	N_2	$Ni(N_2)$, $Ni(N_2)_2$	IR	[54—56]
Pd	N_2	$Pd(N_2)_3$	IR/R	[57]
Pt, Pd	CO	$M(CO)_n$ $n=1,2,3,4$	IR/R	[58—60]
Ni	O_2	$Ni(O_2)$, $Ni(O_2)_2$	IR	[61]

In 1971, *Burdett* and *Turner*[54] carried out codepositions of nickel atoms and nitrogen in argon matrices. They identified certain spectral features with $Ni(N_2)$ and $Ni(N_2)_2$ complexes. This work, while later repeated and reinterpreted[55], forecast and perhaps stimulated a significant series of studies by *Ozin et al.* As shown in Table 3, in *Ozin's* laboratory a number of transition metal complexes have now been studied with N_2, CO and O_2. Current work, by both *Turner*[54] and *Ozin*[57–61] extends studies to other transition metals and to mixed com-

plexes of these molecules. Again, isotopic substitutions are used to elucidate the molecular geometries ("end-on" or "sideways").

Obviously, much is to be learned about the early reaction steps in metal atom reactions and about the bonding in reaction intermediates. Indeed, there is already much information available from these pioneering studies, some of it not yet assessed. For example, the mere finding that alkali metals react with O_2, N_2O and F_2O under matrix deposition conditions implies that there cannot be large activation energy barriers to reaction. While the temperature at which reaction occurs is ill-defined, the time required for cooling from room temperature to below 20°K is surely a small fraction of a second. As a guess, an activation energy of 2 or 3 kcal might be sufficient to prevent reaction. Such arguments have been broached by *Pimentel*[62] but much remains to be considered.

Turning to bonding, the reactions of alkali metals with oxygen forecast enlightening developments concerning transient species. The unequivocal determination of a symmetrical triangular geometry and the change of the oxygen-oxygen stretching frequency from 1600 cm^{-1} to 1100 cm^{-1} surely denotes electron transfer, as concluded by *Andrews et al.*[45, 49]. The Li-O_2 result probably explains why *Andrews* and *Pimentel*[23] had difficulty in their normal coordinate analyses—the only geometries explored were linear or bent but oblique angled MNO and MON structures. No doubt the lithium atom is placed beside and between the nitrogen and oxygen atoms and bonded to both, undoubtedly with substantial charge transfer.

These conclusions contrast with the findings of *Ozin et al.* on the simplest transition metal complexes with N_2 and O_2. Accepting *Ozin*'s assignments, Table 4 shows the O—O or the N—N stretching frequencies and their shifts from that of the uncomplexed diatomic parent. Approximate bond orders can be assigned[63] on the assumption that transfer of a full electron charge to any of these diatomics places an electron in an antibonding orbital and reduces the bond order by 1/2. Clearly both the geometries and the bond orders of the transition metal "complexes" with O_2 are similar to those of the molecules formed by the alkali metal atoms with O_2. In contrast, the transition metal complexes with N_2 are of "end-on" geometry, they are much more weakly bound, and they apparently involve much lower charge transfer. It is noteworthy that the implied charge transfers in the metal-oxygen molecules do not anticorrelate (as might be expected) with the metal atom ionization energies, which range from 90 kcal/mol for cesium to 207 kcal/mol for platinum.

Table 4. Frequencies, bond orders, and charge transfers in metal atom complexes with O_2 and N_2. Matrix material: Ar.

Complex [a]	Frequency ν_c [cm^{-1}]	Shift $\nu_0 - \nu_c$ [b]	Bond order	Charge transfer	Geometry	Ref.
CsO_2	1114	435	1.52	0.96	"side-on"	[49]
LiO_2	1097	452	1.51	0.99	"side-on"	[45]
PdO_2	1024	525	1.44	1.12	"side-on"	
NiO_2	966.6	583	1.40	1.21	"side-on"	
PtO_2	926.6	622	1.36	1.27	"side-on"	
PdN_2	2212	118	2.88	0.24	"end-on"	
PtN_2	2170	160	2.84	0.32	"end-on"	
NiN_2	2088	242	2.76	0.48	"end-on"	

[a] Unless otherwise stated, the frequencies are taken from Ch. 9 of Ref. [7].
[b] ν_0 is the frequency of the pure compound in the matrix: 2330 cm^{-1} for N_2 [54] and 1549 cm^{-1} for O_2 [64].

7.2. Organic Substances

Again, *Andrews* and *Pimentel*[65] were probably the first to attempt a deliberate matrix reaction between a metal atom and an organic molecule. They were trying to produce the methyl radical, CH_3, by codepositing lithium atoms and methyl iodide. Indeed, the desired abstraction reaction occurred, producing CH_3 in the same matrix cage with LiI. An absorption at 730 cm^{-1} was definitively shown to be due to a CH_3 group.

Subsequent matrix studies by *Milligan* and *Jacox*[66] based on *in situ* vacuum ultraviolet photolysis of methane provided another spectrum equally well attributable to the methyl radical, but now absorbing at 611 cm^{-1}. *Tan* and *Pimentel*[67] were able to clarify the discrepancy and show that the absorption at 730 cm^{-1} was due to a methyl group strongly perturbed by or, more likely, bonded to the adjacent lithium halide molecule. This conclusion was bolstered by the spectra of reaction products between sodium atoms and potassium atoms with methyl iodide and methyl bromide. Regarding the CH_3MX cluster as a molecule, it has some possible relationship to a Grignard reagent, although the alkali metal atom does not find itself in a conventional bonding situation.

Once more, *Andrews* went on to exploit these leads. With interest focused on the vibrational frequencies of the halogen-substituted methyl counterpart, *Andrews et al.* have reacted lithium atoms with CCl_4[68], CBr_4[69], CHX_3(X=Cl, Br)[70], $CHBrF_2$[71], $CH_2X^1X^2$(X^1 = Cl, Br, X^2 = F, Cl, Br, I)[72], and CH_2I_2[73]. These authors interpret their spectra as those of essentially free halogen-substituted methyl radicals, in contrast to the findings for CH_3 when prepared by matrix reaction between alkali metal atoms and a methyl halide.

Whatever the significance of the spectra, there is no question that *Andrews et al.* were able to obtain reaction and new, normally transient species when alkali metal atoms and substituted methanes are codeposited under matrix conditions. The work of *Andrews* eloquently demonstrates a rich future for the matrix isolation study of metal atom reactions with organic molecules.

8. Conclusions

The ever increasing use of metal atoms in the synthesis of new metal-organic compounds enhances the significance

of the matrix isolation studies described here. While matrix experiments are relatively tedious, they can be extremely informative about bonding, molecular geometry and reaction pathway. There seems no doubt that metal atom synthetic chemistry will benefit from careful matrix study of prototype reactions. Fortunately, these results can be confidently expected, as attested by the productivity of the laboratories of *L. Andrews* (University of Virginia), *G. A. Ozin* (Toronto University), *J.J. Turner* (University of Newcastle upon Tyne), and others.

Reactions between Metal Atoms and Gases during the Production of Thin Films in High Vacuum[**]

By Max Auwärter[*]

1. Introduction

Production of thin films by reaction of one element with another or with several partners can be achieved in many ways.

In the case of aluminum, oxidation in air at room temperature will lead to a layer of 20 Å Al_2O_3 after 20 minutes; this is sufficient for passivation of the metal. Anodic oxidation is considerably faster and therefore more suitable for obtaining thicker layers. In appropriate electrolytes aluminum can be oxidized at a rate of 11 Å/s, resulting in layers of some 1000 Å of Al_2O_3; this is almost 1000 times faster than natural oxidation. Technical exploitation of this process is of great significance.

The production of thin films from the gaseous phase is a shape forming process which has found little attention so far in industrial chemistry. In the most recent edition of Ullmanns Encyklopädie der technischen Chemie 1973[1a] only flame spraying and pebble bed sintering are mentioned as coating methods from the gaseous phase. In both cases the coating material is in a fine-to-rough dispersed state, mainly in the form of an aerosol.

Although chemical vapor deposition has long been used as a method for the production of thin films, it was not until recent years that it gained increasing commercial importance. Typical reactions are:

$$\underset{(g)}{SiCl_4} + \underset{(g)}{2H_2} \rightarrow \underset{(s)}{Si} + \underset{(g)}{4HCl}$$

$$\underset{(g)}{2GeI_2} \rightarrow \underset{(s)}{Ge} + \underset{(g)}{GeI_4}$$

These reactions are used for the production of pure germanium and silicon.

Very interesting are gas decomposition processes at high substrate temperature:

$$\underset{(g)}{TiCl_4} + \underset{(g)}{2H_2O} \rightarrow \underset{(s)}{TiO_2} + \underset{(g)}{4HCl}$$

$AlCl_3$, $TaCl_5$, and $SnCl_4$ react analogously.

Chemical vapor deposition reactions, for instance pyrolytic reactions, take place mainly at atmospheric pressure or at best in slight vacuum, that is between 1 bar and 1 mbar; very often a carrier gas (hydrogen) is used. In this case only those variables controlling the reaction are of decisive importance for the process; hence even geometrically complex objects, for instance carbon fibers, can be coated uniformly at a growth rate of 100 Å/s at 1000 °C.

Coating processes based on condensation, that is transition from the gaseous to the solid state, take place mainly in high vacuum (10^{-3} to 10^{-7} mbar). (This process is determined by those variables controlling the mass transport.) In this range the film growth and the sequence of reaction can be controlled quite precisely. On geometrically simple objects a film thickness of some 1000 Å can be kept within tolerances of a few Å. The microroughness lies, depending on the material, between 10 to 100 Å; the film growth ranges, in the case of reactive evaporation, between 1 and 5 Å/s.

We can see that the growth rate is slower by almost one order of magnitude compared to that in the previously mentioned methods. In contrast to pyrolytic methods, of particular importance is the possibility of maintaining the temperature of the substrates and thus of the growing film as low as desired. For this reason, and because of the excellent controllability, this process is of particular importance for coating of temperature sensitive and high quality substrates in optics and electronics. Since a number of physical and chemical effects are strongly dependent on the state of the boundary layer and the surface layer of a solid, the application of reactive evaporation may become of growing importance in the next few years.

2. Processes in High Vacuum

According to the kinetic theory of gases, the number of collisions, Z_{volume}, of gas atoms in volume V assuming two-body collisions is

$$Z_{volume} = \bar{v} n V/2l$$

where V = volume in cm^3, $\bar{v}$ = mean molecular velocity in cm/sec, n = number of molecules in one cm^3, l = mean free path in cm.

The impingement rate on the wall Z_{wall} is

$$Z_{wall} = \bar{v} n F/4$$

where F = surface area in cm^2.

Thus we obtain for the ratio of the impingement rate and number of collisions in unit volume, the impact ratio

$$Z_{wall}/Z_{volume} = lF/2V$$

Examples are given in Table 1.

Table 1. Impact ratio Z_{wall}/Z_{volume} for oxygen in a cubic reaction space with 10 cm sides. l = mean free path.

Pressure [mbar]	l [cm]	Z_{wall}/Z_{volume}
1	6.5×10^{-3}	0.3×10^{-3}
10^{-3}	6.5	0.3
10^{-6}	6.5×10^{3}	0.3×10^{3}

At 10^{-3} mbar the impingement rate is almost equal to the number of collisions in unit volume, whereas at 10^{-6} mbar the number of collisions can be neglected as compared

[*] Prof. Dr. M. Auwärter
Balzers Aktiengesellschaft für Hochvakuumtechnik und Dünne Schichten
FL-9496 Balzers (Liechtenstein)

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12—15, 1974).

to the number of impingements on the wall. At 10^{-6} mbar the impingement rate (Z_{wall}) on one square centimeter is 10^{14}. Since in the case of monomolecular coverage 1 cm^2 is covered by approximately 10^{15} molecules, a clean surface will be covered with one monolayer of the residual gas within a few seconds, if the condensation coefficient equals 1. Its value is dependent on the gas, the type and state of the substrate, and also on the temperature. This example shows that the inclusions of residual gas in a thin film which condenses at a rate of 2 Å/s are quite substantial and that one would have to use considerably lower pressures in order to eliminate them.

In the high-vacuum range the dominant residual gas is water vapor. This results in the presence of relatively strong van der Waals bonds with most substrates. In order to break these and subsequently remove the water molecules with a vacuum pump, the reaction vessel has to be heated for many hours at 400 °C.

Figure 1 shows the mass spectrum of the surface of a carefully cleaned stainless steel target before and after heating[14]. Figure 2 is another example for the almost always undefined chemical state of the surface of a solid; it shows the positive secondary ions measured on the surface of a supposedly clean Si-surface with a secondary ion mass spectrometer[15].

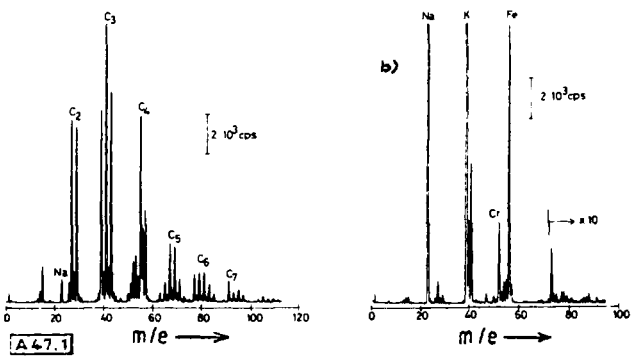

Fig. 1. Mass spectrum of the surface of stainless steel a) before and b) after bakeout [14].

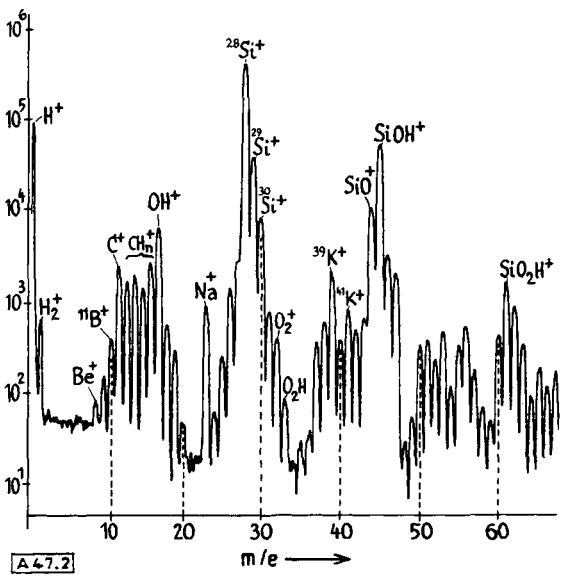

Fig. 2. Mass spectrum of positive secondary ions of the surface of a silicon disk [15].

We may assume that condensation of atoms of metals and insulators on a substrate surface will be substantially influenced by adsorbed gases. Many properties of substrates, as for example the adhesion of the condensed layer, will be changed in a way which is in most cases not easily predictable.

Of prime importance is the bonding of the adsorptive to the adsorbent. In the case of pure physisorption, desorption can be obtained rather easily. Atomic adsorption, however, very often involves several different adsorption states. Besides water, oxygen is also particularly strongly bound. Its heat of adsorption corresponds to the heat of formation of oxides, so that chemisorption approximates to chemical bonding. When coating substrates, as for instance glass, oxygen generally plays a less important role. This is quite different, however, in the case of transition metals, where an oxide-boundary layer is formed because of the incompletely filled d-shell due to diffusion of oxygen.

The bonds with hydrogen are considerably weaker; consequently desorption can be achieved relatively easily.

Nitrogen is almost always adsorbed molecularly and therefore exhibits the bonding character of a physisorption. There are however substrates at which the molecule dissociates, resulting in chemisorption due to atomic adsorption. This happens in the case of refractory metals like Zr, Ti, Mo, Ta, and W.

Hydrocarbons, which are frequently present in vacuum systems, are cracked, particularly at metallic substrates.

In order to remove adsorbed layers, the substrate is exposed to a glow discharge. In this process sputtering also occurs so that atoms from the electrode condense on the substrate and form nucleation centers. In contrast to the rather short mean residence time of a physisorbed gas molecule, the residence time of a condensed atom or molecule at the surface of a substrate is considerably longer; this means however that during this residence time of the single molecule other condensing molecules must interact with it. Nuclei are particularly suited for this interaction. *Hass*[1b] has investigated this interaction on silver and observed the formation of droplets by means of electron micrographs. *Zinsmeister*[2] recently made a significant contribution to the nucleation theory. *Zehnder*[3] has found that condensation of Zn—Cd atoms on paper becomes possible only after prenucleation, for instance with silver atoms.

Originally, thin films produced by evaporation of suitable materials in high vacuum were mainly applied in optics. The substrate material was therefore generally glass. Other substrate materials, for instance metals, first came into use after the development of microelectronics.

3. Reactive Evaporation

The equipment for manufacturing of thin films is simple. A crucible is heated electrically in a chamber evacuated to high vacuum. Preferred materials are refractories, such as molybdenum, tantalum and tungsten; others are pyrolytic graphite and ceramic materials of high thermal stability, such as ThO_2, BeO, ZrO_2, Al_2O_3 and MgO. For evaporation of aluminum, boron nitride/titanium boride crucibles have been used successfully. Electrically nonconducting crucibles have to be heated indirectly. Fig. 3 shows several types of evaporation sources.

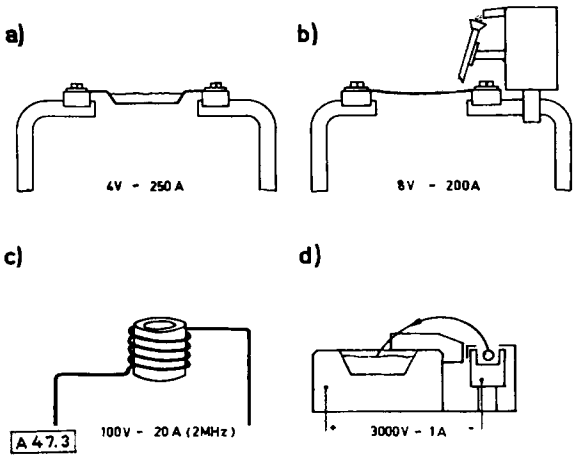

Fig. 3. Examples of evaporation sources: a) Boat evaporation, b) Flash evaporation, c) Inductive heating, d) Electron beam evaporation.

When SiO_2 is heated at 1500 K in a crucible made of material that has reducing properties, sublimation of the reaction product SiO will occur according to

$$M + SiO_2 \rightarrow MO + SiO.$$

The physical properties of SiO are quite different from those of SiO_2. The suboxide SiO has a higher index of refraction n, and higher optical absorption, which is disturbing for most applications in the visible and ultraviolet range; but it is easier to evaporate. If reaction with the crucible material is avoided, then evaporation of SiO_2 as such is possible without dissociation. Highly energetic electron beams are particularly suitable in this case. On penetrating the quartz glass, the beam is retarded and dissipates its energy.

TiO_2 is not only reduced to TiO by reactive crucible materials, but may also dissociate thermally at the high evaporation temperatures. The free oxygen will be removed by the pumping system. The oxygen deficiency can be compensated for by maintaining a partial pressure of oxygen. If at least a partial back reaction, in this case reoxidation, can be maintained in this way, we speak of *reactive evaporation.*

Atoms and molecules evaporating from the crucible are allowed to condense onto a substrate which is mounted at a suitable distance from the crucible.

In reactive evaporation the total pressure of permanent gases and water vapor, which is always present in high vacuum, is so chosen as to avoid collisions occurring between evaporated particles and the residual gas.

Hence, the mean free path l must be at least equal to the distance between crucible and substrate:

$$l = \frac{kT}{\sqrt{2}[\pi(r_1+r_2)^2 P]}$$

where P = total pressure, r_1 and r_2 = radii of gas molecules and evaporating substance, respectively, k = Boltzmann constant, T = absolute temperature.

The total pressure P has to be adjusted to the geometry of the system. The distance between crucible and substrate will range between 20 cm and 2 m, depending on the equipment.

The molecular beam leaving the crucible has a cosine distribution. Its particle density (per volume unit) decreases with the distance R from the crucible approximately according to Lambert's law with $1/R^2$.

For simplification let us call the molecules of the condensing substance A and those of the residual gas B. Because of collisions with the wall, B molecules will impinge on the substrate with arbitrary angle distribution in contrast to A molecules, which impinge with directed angle distribution. Since we exclude collisions between the A molecules, the B molecules, and between A and B molecules, the maximum pressure of B molecules is given. Thus the impingement rate of B molecules (*e.g.* oxygen) on the substrate as a function of the geometry can be calculated from $Z_{wall} = n\bar{v}F/4$. For a crucible-substrate distance of 64 cm and an equal mean free path, the partial pressure of oxygen, which equals the total pressure by displacing the other gases, may be 10^{-4} mbar at most. The corresponding impingement rate Z_{wall} on the substrate is $\approx 10^{16}$ cm^{-2} s^{-1} for $\bar{v} = 4 \cdot 10^4$ cm/s.

Ritter[4] as well as *Kerner* and *Mutschler*[5] have determined the condensation coefficient for B molecules, by investigating the reaction between A and B molecules. Whereas A particles have a condensation coefficient of 1, that of the B particles is ≈ 0.1. To initiate the reaction approximately 10^{15} particles cm^{-2} s^{-1} of A molecules must impinge on the substrate. The kinetic energy $m\bar{v}^2/2 = 3kT/2$ of an A molecule is considerably greater than that of a B molecule. Collisions of A with B molecules would reduce the kinetic energy through interaction: this would lead to soft layers on condensation. We now understand why the required mean free path of the B molecules must be maintained. The allowed margin in choosing the oxygen pressure of the B molecules is very narrow. For a chosen crucible—substrate distance of 64 cm, it will range between 3×10^{-4} and 7×10^{-5} mbar. Control of pressure, for example to 1×10^{-4} mbar, has to be done automatically, because manual control would not be precise enough. Fig. 4 illustrates the above mentioned example of TiO evaporation; it shows the refractive index n of TiO_2 films—prepared by reactive evaporation of TiO—as a function of oxygen pressure. Very similar results are obtained with Ti.

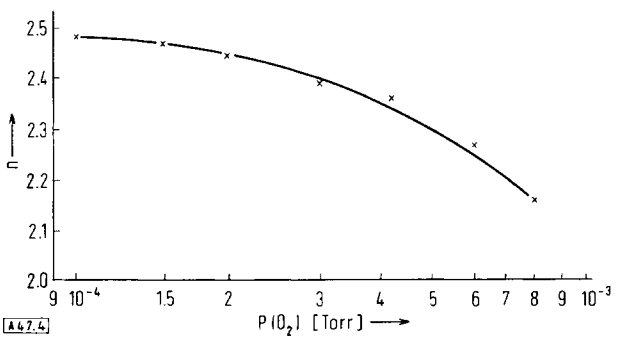

Fig. 4. Refractive index n ($\lambda = 550$ nm) of TiO_2 films as a function of the oxygen pressure during reactive evaporation. $P(O_2)$ = oxygen pressure [4].

Let us briefly study the phenomena of condensation of the A particles and adsorption of B particles on the substrate. The A molecules have a longer mean residence time on the surface of the substrate than the B molecules. In addition, similarly to B molecules in a way, they form a two-dimensional gas with a surface mobility that will depend on the nature of the substrate and the A and B molecules respectively. Thus there is the possibility that small A-aggregates are formed as droplets.

According to *Thomson* the following expression holds for the vapor pressure of a droplet:

$$P_r = P_\infty \exp. \frac{2\sigma V_A}{rkT}$$

where P_r = vapor pressure of the droplet, r = radius of droplet, V_A = volume of an A molecule, P_∞ = equilibrium pressure at the temperature T[K], σ = surface tension.

The smaller r is, the greater will be the vapor pressure P_r of the A molecules in the droplet. Therefore extremely small droplets disappear through desorption of the A molecules or combine with larger already existing droplets. To obtain a stable nucleus, that is a sufficiently large droplet, a critical nucleus size must be exceeded. For nucleation, there must be an oversaturation of A molecules on the surface of the substrate. In order that an A particle condenses, it must impart its excess kinetic energy to the substrate during the mean residence time, which happens after a few lattice vibrations. A measure of the energy exchange is the accommodation coefficient

$$\gamma = (T_g - T_g')/(T_g - T_0)$$

where T_0 = temperature of the surface, T_g and T_g' = the temperature of the A molecule before and after reflection.

After condensation is completed $T_g' = T_0$, *i. e.* $\gamma = 1$.

If, due to surface migration, one adsorbed atom starts interacting with another, the strength of bonding is increased. Upon further growth, the stable nuclei expand parallel to the surface. Thus at first a two-dimensional colloid-dispersed state is generated, which proceeds until the droplets growing by coalescence combine. In many substances the thickness follows the growth structure at the surface; thus, for instance, MgF_2, ZnS and other compounds, on glass substrates exhibit a columnar growth. Fig. 6 shows the columnar growth of a 1800 Å thick ZnS film[6].

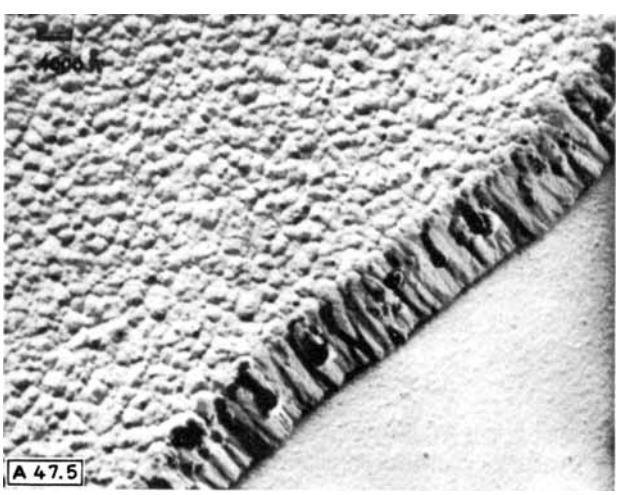

Fig. 5. Electron micrographic cross-section of a 1800 Å thick ZnS film [6].

The competition between cluster formation and the desired reaction

$$2SiO + O_2 \rightarrow 2SiO_2$$

leads to an inhibited reaction in which in addition to Si—O—Si bonds, Si—Si bonds are also formed. The latter are not oxidized completely in the course of film growth, especially at higher substrate temperatures.

Oxidation is also not complete at lower temperatures, even though no Si—Si bonds seem to be formed[7]. Indeed, in a reactive evaporation experiment with non-excited O_2 molecules, *Cremer*, *Kraus*, and *Ritter* found layers of composition Si_2O_3[8]. Reaction of SiO with oxygen requires practically no activation energy. The same is true for the reactive evaporation of Al_2O_3.

In the case of the more reactive Ti, TiO_2 is formed from TiO with O_2 as reactive gas; the TiO_2 is present in the form of a mixture of anatase and rutile.

Fig. 6 shows the growth of reactively deposited TiO_2 films as a function of substrate temperature[9].

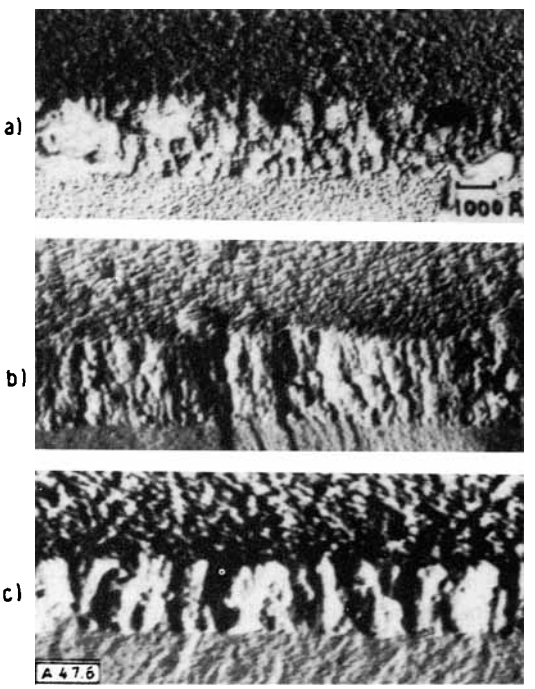

Fig. 6. Electron micrographic cross-section of TiO_2 films, deposited at different substrate temperatures: a) 30 °C, b) 150 °C, c) 400 °C [9].

An interesting reaction is shown by ZnS and other II—VI compounds when evaporated in high vacuum:

$$\underset{(s)}{ZnS} \rightarrow \underset{(g)}{Zn} + \underset{(g)}{{}^1/_2 S_2}$$

i. e., in the gaseous phase, there exist only Zn atoms and S_2 molecules due to dissociation. No condensation of Zn and only a partial condensation of S_2 takes place on the substrate. Only after interaction of Zn and S_2 at the surface is ZnS formed again, *i. e.* ZnS with a small surplus of sulfur.

The temperature dependence of this process and of the oxidation of SiO and TiO is negative, *i. e.* less oxide or sulfide is formed at higher substrate temperatures, since the chemisorption of oxygen or sulfur decreases with increasing substrate temperature[10].

The author first introduced reactive evaporation in 1952 and proposed the activation of B molecules with a gas dis-

charge in order to obtain increased interaction between A and B particles during condensation[11]. Recently, similar experiments have been performed on a laboratory scale by *Heitmann*[12], using a plasma discharge, and by *Zollinger*, with an arrangement that allows the process to be carried out on an industrial scale[13]. The ions, which are generated in small concentrations only, and the excited states result in accelerated reaction between A particles and B particles; an example is

$$2SiO + O_{2\,excited} \rightarrow 2SiO_2$$

With this method the less reactive nitrogen leads to formation of nitride. Furthermore, the generation of carbides is possible. Using reactive evaporation with activated gas, higher condensation rates can be obtained, thus increasing the economics of the method somewhat compared to classic "reactive evaporation".

Among the methods of film production at low pressures, cathode sputtering is the oldest. The underlying physical principles of sputtering using gas discharges will not be dealt with in detail here. Two electrically insulated electrodes are mounted opposite each other in a vacuum chamber, which is evacuated to 1×10^{-2}—5×10^{-2} mbar. On applying a direct voltage of 1—5 kV a self-sustained gas discharge is initiated. Because of the electrical field the positive ions of the sputter gas formed in this way strike the cathode with high energy, most of them penetrating it and imparting their energy, *e.g.*, to dislocations in the lattice. Thus focused collision cascades are generated in atomic arrangements that favor such generation; subsequently atoms of the very last surface layer of the cathode are ejected into the gas phase. If the sputter gas possesses a chemical affinity for the cathode material, they react with each other.

If the cathode consists of two or more components, then, in contrast to thermal evaporation, fractional distillation does not occur, even if the vapor pressures of the components differ. The thin film deposited on the substrate will have the same composition as the starting material.

Oxides, carbides, nitrides and sulfides can be produced with reactive sputtering. The growth rates are somewhat smaller than in the case of reactive evaporation. Nevertheless this process has found broad application in electronics due to many advantages it offers.

The question whether the processes described are suitable for the production of materials in large quantities can only be answered when the mass transport of the reaction partners is compared with that of other processes. Since vacuum equipment can be manufactured with dimensions of only a few meters without being too expensive, the quantity of material that can be deposited by condensation is limited because of the limited size of the substrate. Obviously the condensation area may be increased by suitable attachments, for instance by an unrolling band. Thin films possess great internal stresses because of the extremely high disorder; this may cause peeling off from the substrate at film thicknesses of a few thousand nanometers. This would not cause any limitation to the production of material, since, in this way, a new substrate surface is always being regenerated for condensation. For comparison purposes the determining factor is always the growth rate.

The output of distillates of a molecular evaporator is, on the average, 1.5×10^{-4}—4×10^{-4} g/cm^2 s. For a density of $\rho = 1$ (g/cm^3) the resulting growth rate is 1.5×10^{-4}—4×10^{-4} cm/s.

We have quoted the growth rate in reactive evaporation as being 1—5 Å/s, or 1×10^{-8}—5×10^{-8} cm/s. In reactive sputtering, the mass transport is even smaller. Thus the possible output of molecular evaporators per cm^2 and second is 10^4 times greater. The evaporator surface is almost the same size as the condenser surface, and the vapors escape from a very thin liquid film. In this way it is possible to preserve sensitive products to the greatest extent by using the shortest possible residence time and the lowest possible temperature.

In comparison to the condensation surface, we have in reactive evaporation a point-shaped vapor source, the output of which is therefore considerably limited. The vacuum processes described are obviously used in those cases, where one aims at obtaining an increased value of the product by refining the substrate or by utilizing physical effects. They therefore also differ from processes in which materials are evaporated under high vacuum without chemical reaction.

The method of reactive evaporation is therefore limited to those applications in which one wishes to modify properties of solids in some particular way by extremely thin films. Surface-dependent effects are: corrosion, friction, electrical properties such as *e.g.* electron emission, reflection and absorption. For those interested in reaction kinetics, the vital question is whether thin films of this type can be employed to advantage in the area of heterogeneous catalysis. It is conceivable that thin films may be useful at least for test purposes. Thus, for example, a bolometer strip of minimal heat capacity, which is protected by an inactive thin film and whose electrical resistance is temperature-sensitive, could be coated with an additional thin and catalytically effective film. A reaction will always be exothermic or endothermic, *i.e.* the temperature will change, and this will be indicated by a change in the resistance of the bolometer.

It is difficult to predict to what extent thin films may become of importance in chemical processes. One thing is sure, however: neither reactive evaporation nor reactive sputtering is suitable for the production of large quantities of materials.

Formation of Ad-Layers and Clusters on Condensation of Metal Vapors on Solid Surfaces[**]

By Rolf Niedermayer[*]

Synthesis of organometallic materials can be accomplished in many cases by cocondensation of metal atoms and organic molecules at low temperatures. The reaction kinetics is determined by the competition between metal cluster growth and formation of the organometallic compound. Interesting compounds may contain one or more metal atoms; the latter type could be obtained by reaction between a cluster containing the desired number of metal atoms and an organic molecule. A precise knowledge of the events occurring on condensation of metal atoms and cluster formation can therefore be of value in the control of chemical synthesis. These phenomena have been investigated in connection with the study of the growth of thin metallic films, both experimentally and theoretically. Direct observation of the formation of very small clusters is difficult. The good agreement between experimental results and recent calculations for the development of large clusters, however, allows reliable theoretical conclusions for the first stages of adsorption and cluster formation. The present contribution describes experimental work on film growth and relevant theoretical concepts, and an attempt is made to develop applications to organometallic synthesis.

1. Introduction

The common point of interest between the physics of thin films and low temperature condensation as a synthetic method[1] is the fate of a single atom on a solid surface. Only one method provides a direct answer to this question: field ion microscopy. It can conveniently be used for the direct observation of condensation, as well as subsequent diffusion, desorption, or possible cluster formation. However, the conditions of observation are severely restricted and the utility of the method consequently restricted. We therefore have to rely on more indirect methods if we wish to vary the experimental conditions over a wide range.

Those stages of condensation, in which coherent layers or extended clusters have already been formed, can easily be observed by electron microscopy or electron diffraction under a great variety of conditions[2-4], and it has become possible to analyze these experiments quantitatively[4, 5]. Examples of the experimental and theoretical results cited in this report will give an impression of the state of the art. The quality of these results for later growth stages permits conclusions to be drawn for the early stages, and thus provides an insight into the history of the individual condensed atom. This insight can be summarized by a number of simple mathematical expressions which conclude the present discussion.

2. Two-Dimensional Growth

An understanding of condensation phenomena requires that a distinction be made between a number of binding energies: Λ_0 the evaporation energy of the adsorbate, for example of the adsorbed metal, characterizes the binding of the metal atoms to one another. The energy required to separate a metal atom from a surface is known as the desorption energy (E_{des}). Finally, a certain activation energy has to be expended to move an adsorbed atom from one binding site to another, *i.e.* the migration or diffusion energy (E_{diff}).

Metal atoms condensed onto other metal atoms or onto semiconductors are often bound with a high desorption energy of the order of magnitude existing between the metal atoms. The desorption energy on ionic crystals, *e.g.* alkali halides, is somewhat lower, approximately 20 kcal/mol, while the binding of metal atoms to graphite or similar substrates, and probably to noble gases, is weaker, the desorption energy being about $\leqslant 10$ kcal/mol[6-9].

These differences in binding energy essentially determine the mode of film growth. It can in fact be shown that three-dimensional cluster formation is preferred if the binding between the metal atoms themselves is much stronger than their binding to substrate. Theoretical considerations[3, 10] lead to the following condition for three-dimensional cluster formation:

$$\Lambda_0 \geqslant 3 \cdot E_{des} \tag{1}$$

while two-dimensional clusters form if

$$\Lambda_0 \leqslant 3 \cdot (E_{des} - E_{diff}) \tag{2}$$

In intermediate cases the growth will be two-dimensional or three-dimensional, depending on the geometry of the lattices of substrate and film.

These general rules predict that metals on metals or semiconductors have an initial tendency to grow in two dimensions. In some instances this two-dimensional growth continues to form thicker films, but in most cases growth changes to the three-dimensional mode after completion of the first few monolayers.

An example of purely two-dimensional growth up to 80 ML (monolayers) currently being investigated by *Mlynczak*[6] will now be discussed. Ultrahigh vacuum and cleanliness of the substrate are absolutely essential if reliable conclusions are to result from investigations of this kind. In this experiment sodium is evaporated slowly onto a tungsten (100) surface.

[*] Prof. Dr. R. Niedermayer
Institut für Experimentalphysik IV der Universität

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices onf the Merck'sche Gesellschaft für Kunst und Wissenschaft e.V. at Darmstadt (May 12—15, 1974).

The number of condensed atoms, the structure of the film, the desorption energy, and the frequency constant of desorption can be determined independently in each individual experiment. Under certain conditions the diffusion energy can also been measured. All these data are necessary for analysis of a growth experiment, but in most cases they are not available at the same time.

Condensation of sodium at a rate of 10^{12} atoms/cm^{2}s onto tungsten at 370°K leads to saturation after deposition of 5×10^{14} atoms/cm^2 (Fig. 1). The structure of this film has been investigated *in situ* by grazing incidence high energy

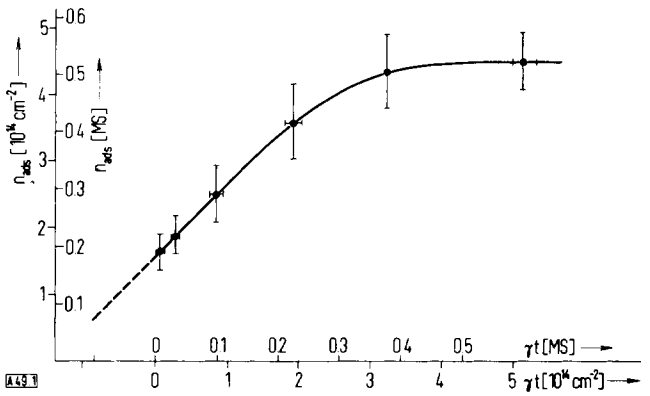

Fig. 1. Dependence of the number of sodium atoms n_{ads} adsorbed on a W(100) surface upon the number $\gamma \cdot t$ of atoms presented to the substrate. Impingement rate $\gamma = 9 \times 10^{11}$ atoms cm^{-2}s^{-1} (0.06 ML min^{-1}); substrate temperature, 370°K.

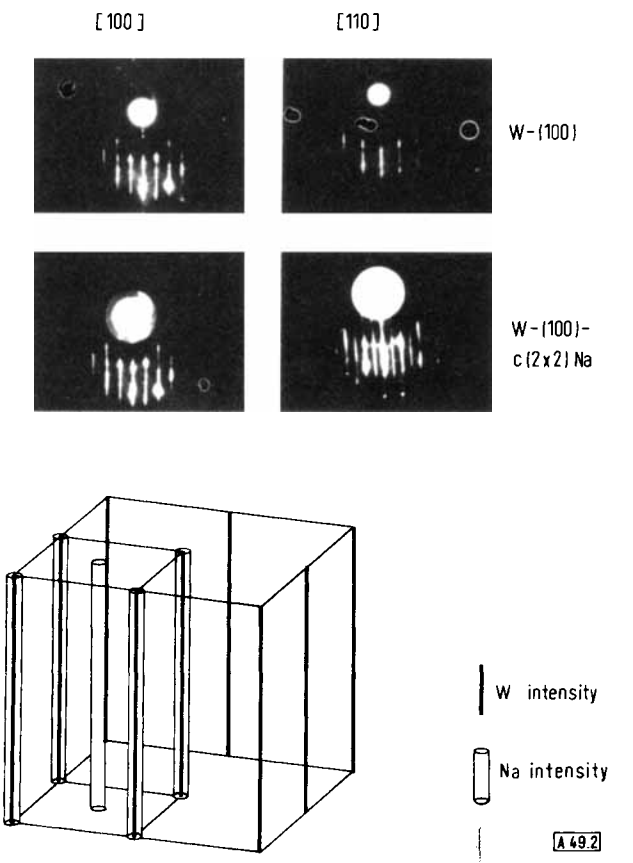

Fig. 2. Diffraction pictures of a clean W(100) surface in the [100] and the [110] azimuths, and of a W surface covered by 5×10^{14} Na atoms cm^{-2}. The lower part of the figure shows a drawing of the reciprocal mesh of the sodium-covered surface.

electron diffraction (RHEED) which affords diffraction patterns like that in Figure 2.

Both the diffraction pictures of the substrate and those of the film show elongated streaks perpendicular to the substrate and are characteristic of diffraction by two-dimensional structures. The Na-covered surfaces show additional streaks in the [110] azimuth. This provides an indication of the positions of the Na atoms, as shown in Figure 3.

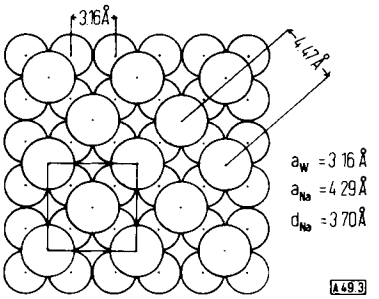

Fig. 3. Model of the sodium-covered tungsten surface as derived from the diffraction pictures.

The sodium atoms are seen to form a superlattice on W(100), which consists of a centered square mesh whose edge is exactly twice as long as that of the underlying tungsten surface. This means that the distance between the sodium atoms is about 4% greater than in the lattice of the compact material. The number of atoms per cm^2 in this configuration is precisely 5×10^{14} atoms. Comparison with the deposition experiment of Figure 1 shows that saturation occurs after completion of the above structure, *i.e.* that the desorption energy then falls. Similar observations are made in many other cases of metal film growth[2]. The energy of desorption is $E_{des} = 2.5 \pm 0.2$ eV, while the heat of evaporation of sodium is only 1.09 eV. According to eq. (2), this ratio of binding energies must lead to two-dimensional growth. At lower temperatures, *e.g.* 310°K, further growth proceeds linearly with time and remains two dimensional. The diffraction pictures still show streaks and remarkably, indicate no relaxation of the lattice constant to its bulk value up to 80 ML. Corresponding diffraction patterns are shown for 20 and 80 ML in Figure 4. The distortion of the lattice of the film up to relatively large thicknesses, *i.e.* real pseudomorphic growth, is a rather singular result of this investigation. It can be understood from the plot of the desorption energy as a function of thickness, shown in Figure 5. We have already stated that the first monolayer

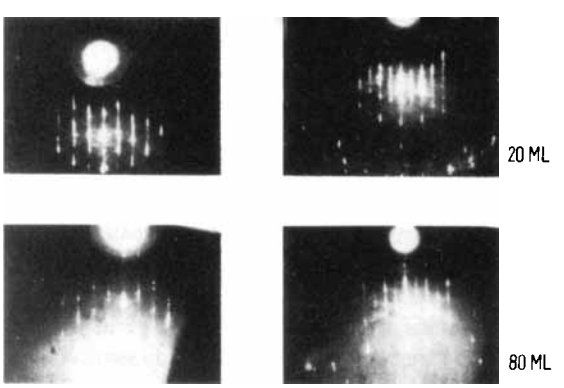

Fig. 4. Diffraction pictures of a W(100) surface covered by 2×10^{16} and 8×10^{16} Na atoms cm^{-2} ($T = 310$°K).

is adsorbed with a binding energy of 2.5 eV. The next layer is bound with 1.27 eV—as is apparent from Figure 5—and then the binding energy decreases monotonously to 1.06 eV, which is attained after 4 monolayers and corresponds approximately to the bulk evaporation energy of sodium. A layer of minimum binding energy would permit lattice relaxation *via* two-dimensional dislocations. However, no such layer is present in our example, and so relaxation must be severely impeded[11, 12]. The Na layer therefore remains strained, like a sheet of rubber stuck under tension to a piece of wood.

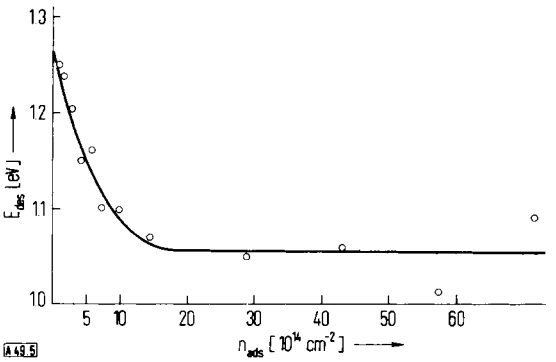

Fig. 5. Dependence of the desorption energy of sodium from tungsten on the number of deposited sodium atoms.

3. Three-Dimensional Growth

To our knowledge the example of extreme two-dimensional growth in Section 2 is the only known case of extended pseudomorphism, and should be considered as a limiting case of film growth. Incorporation of two-dimensional dislocations in an intermediate layer usually ensures early relaxation of the layer lattice. However, early transition to three-dimensional growth is more common, and can be particularly well demonstrated for an example studied by *Steinhage*[7]. *Steinhage* also investigated growth of an alkali metal, *i.e.* potassium, on W(100), using the same equipment but somewhat less refined. The potassium films start to grow two dimensionally in exactly the same way as Na films. The binding energy of the first monolayer is higher than that of the second. The structure of both layers corresponds to Figure 3. However, the third monolayer has a different structure and is much more weakly bound. The desorption energy falls to about 10% of the bulk evaporation energy of potassium after completion of the third monolayer, and further growth proceeds *via* three-dimensional clusters. The lattice parameters of these clusters agree with the bulk lattice constants. The diffraction pictures of the final structure are shown in Figure 6; the appearance of spots instead of streaks indicates three-dimensional diffraction, *i.e.* clusters. Compensation between the first two strained layers and the unstrained clusters must take place *via* an arrangement of two-dimensional dislocations in the interface. It appears significant that the change in the mode of growth occurs precisely when the binding energy has a minimum value.

Very similar results can be obtained in experiments on the growth of many metals on other metals or on semiconductors. However, these systems do not permit accurate determination of the number of clusters, and recourse is generally taken to the growth of metals on alkali halides for

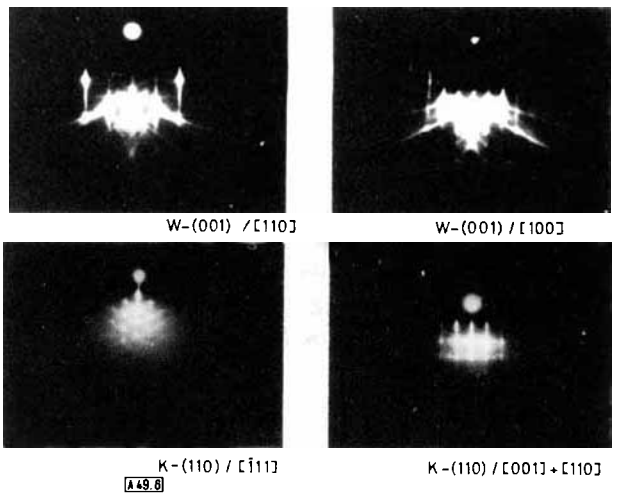

Fig. 6. Diffraction pictures of a clean W(100) surface and of three-dimensional potassium clusters grown on this surface.

investigations on cluster formation and nucleation. In these experiments the cluster layer is fixed in a thin amorphous carbon film and the substrate then dissolved. The carbon films are subsequently investigated by transmission electron microscopy to measure of the number and size of nuclei. Typical examples are the growth experiments for Au on NaCl conducted by *Robins et al.*[13, 14]. Figure 7 shows a series of electron micrographs of the nucleation and coalescence of gold clusters on a (100) rock salt face at a condensation rate of 10^{13} cm^{-2}s^{-1} and a substrate temperature of 250 °C. Nucleation is homogeneous, apart from a few steps of the substrate. The nuclei are partly oriented in preferential directions; their number passes through a maximum and then decreases slowly owing to coalescence. The particles are approximately 150 Å in diameter at the time of maximum nucleus density. Evaluation of such micrographs reveals the dependence of the number of nuclei upon time (Fig. 8). The

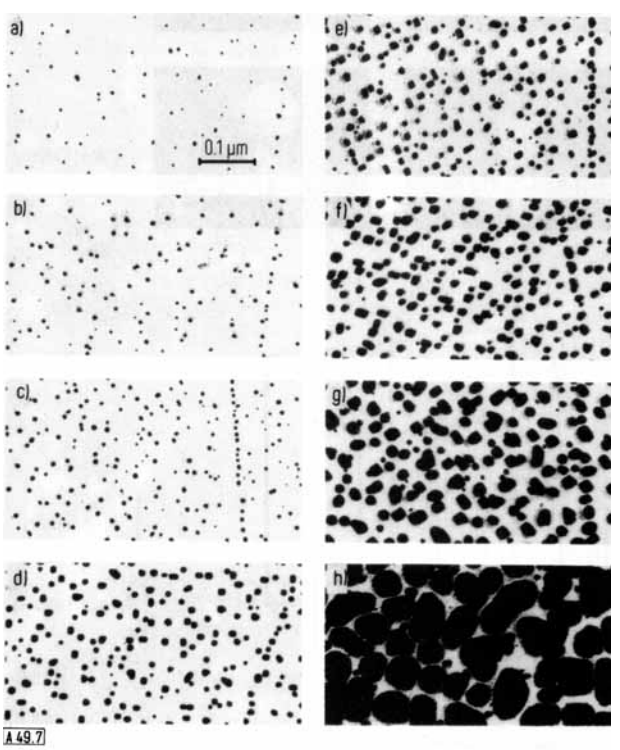

Fig. 7. Electron micrographs of clusters in various growth phases (Au on NaCl (100) surface).

increasing curve (short time scale) corresponds to the end of the nucleation stage while the decreasing curve (long time scale) represents the coalescence stage.

Thus the nucleation rate $\dot{N}_c$, the saturation concentration $N_{c(sat)}$, and the cluster size can be measured as a function of time t, substrate temperature T, and impingement rate J_{imp}. These results can be understood quite well in terms of a kinetic theory of cluster growth, and lead to conclusions about the initial stages of growth.

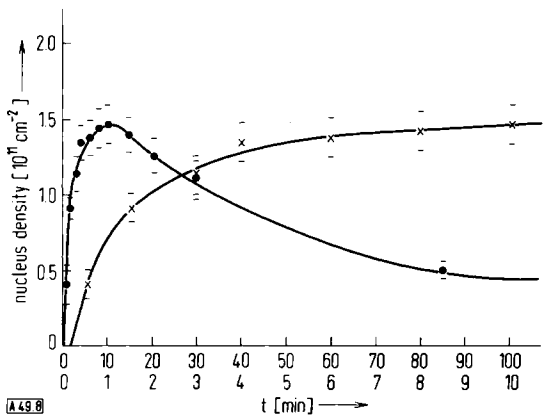

Fig. 8. Evaluation of the growth experiment of Fig. 7. Dependence of nucleus density upon deposition time (×, short time scale; , long time scale). Impingement rate $\gamma = 10^{13}$ atoms $cm^{-2} s^{-1}$; substrate temperature, $T = 523$°K.

4. Kinetic Theory of Cluster Growth

Cluster growth can be analyzed with the aid of a fundamentally simple kinetic theory. A brief account of this theory will be followed by a discussion of the results obtained for the growth of gold on rock salt, which permits a comparison with experiment (Section 3).

Cluster growth has attracted much theoretical attention during the last decade[4, 5], most of the work being based on a model of a sequence of molecular reactions. Monomers B_1 react with i-atomic polymers B_i.

$$B_i + B_1 \underset{J_i}{\overset{\alpha_{i+1}}{\rightleftharpoons}} B_{i+1} \tag{3}$$

The decay probabilities α_{i+1} can be calculated from thermodynamics, and the growth probabilities J_i by solution of the diffusion problem[15, 16]. The complete polymerization process can be described by a set of differential equations:

$$\dot{n}_i = J_{i-1} n_{i-1} - (J_i + \alpha_i) n_i + \alpha_{i+1} n_{i+1} \tag{4}$$

The growth probabilities depend on all polymer concentrations and the size of the growing polymer, while the decay probabilities depend on the properties of the decaying polymer and on temperature only. In connection with this theory a polymer will be called a "cluster". If the set of equations (4) can be solved then all experimentally important quantities can be easily derived. These quantities are: the total number of stable clusters

$$N_c = \sum_{i=i^*+1}^{\infty} n_i \tag{5}$$

where B_{i^*+1} is the smallest stable cluster;
the number of atoms condensed in the stable clusters

$$N_a = \sum_{i=i^*+1}^{\infty} i \cdot n_i \tag{6}$$

and the mean cluster size

$$\langle i \rangle = N_a / N_c \tag{7}$$

from which the mean cluster radius can easily be derived.

Numerical solution of eqs. (4) is in fact possible. The only data required for such calculations are the binding energies, the lattice parameters, substrate temperature, and impingement rate. Figure 9 shows the detailed results for the case of gold on a rock salt substrate at 573 °K and an impingement rate of 10^{13} $cm^{-2} s^{-1}$. The desorption energy ($E_{des} = 20$ kcal/mol) and the diffusion energy ($E_{diff} = 8.5$ kcal/mol) have been chosen for best agreement with a wide range of measurements. Under such conditions the growth process is governed by the equilibrium between impingement and desorption, which is indicated by a constant value of monomer concentration for a considerable time interval. The stationary value determined by impingement rate J_{imp} and desorption probability α_{des} is

$$n_{1(sat)} = J_{imp}/\alpha_{des} \tag{8}$$

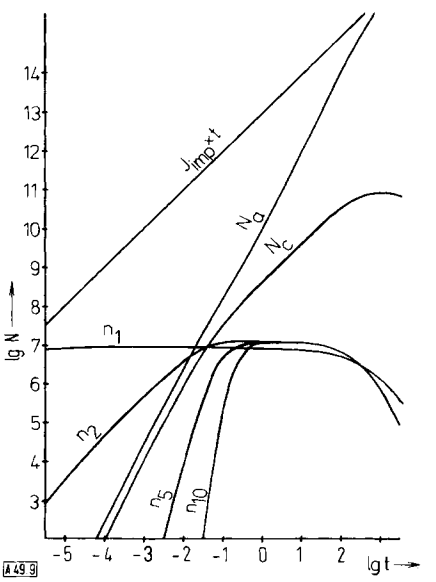

Fig. 9. Calculated dependence of some cluster concentrations n_i, the total number of stable clusters N_c, and the number of condensed atoms N_a on deposition time. Number of atoms presented to the substrate $J_{imp} \cdot t$ at deposition rate J_{imp} is also shown.

The induction period before the start of nucleation is 10^{-2} s and the nucleation ends by coalescence after 100 s; the maximum number $N_{c(sat)}$ of clusters is reached after 1000 s. The nucleation period is characterized by a linear increase in the number of clusters N_c. Another result that can be obtained from the theory concerns the size of the critical nucleus, *i.e.* of that cluster which is just more likely to grow than to decay under the conditions of the experiment. In this case the first stable cluster is a trimer. Each class of clusters has its own induction period; the rise of the cluster concentrations is steeper the larger the cluster. The number N_a of condensed

atoms increases with t^2 during the nucleation period, and then becomes linear. This is in general agreement with experiments on retarded condensation[17].

Unfortunately, the observation of the time dependence of film growth is limited to the final stages of the nucleation period (Fig. 8). This makes a direct comparison of experiments with the theoretical results (Fig. 9) difficult. However, the dependence of nucleation rate, saturation concentration, and mean radius at saturation upon temperature and impingement rate permits comparison of the properties of cluster growth with experiment over a wide range of conditions. Figure 10 shows the influence of the impingement rate on the above parameters. The plots of the nucleation rate $\dot{N}_c$ are almost linear over a wide range of impingement rates, and the slope is $2<\mathrm{d}(\ln N_c)/\mathrm{d}(\ln J_{imp})<2.5$. The size of the critical clusters is given alongside the curve plotted for 834 °K. The influence of the critical cluster size on $\dot{N}_c$ is much less pronounced than, *e.g.*, on nucleation of mist droplets because nucleation in film growth is determined by surface diffusion to a far greater extent than by the decay equilibrium. The dependence of the saturation concentration and the mean radius upon impingement rate is much weaker than that of the nucleation rate. Figure 11 shows the temperature dependence of film growth. At high temperatures the saturation concentrations of clusters decrease and the mean cluster size increases. This is of practical importance for the reduction of crystal defects in thin films. A comparison of experimental data obtained by *Robins et al.*[13] with theoretical results is shown in Figure 12. The dependences of nucleation rate and saturation concentration upon impingement rate (at 300 °C) and substrate temperature (at 10^{13} cm^{-2} s^{-1}) agree within the experimental scatter of data.

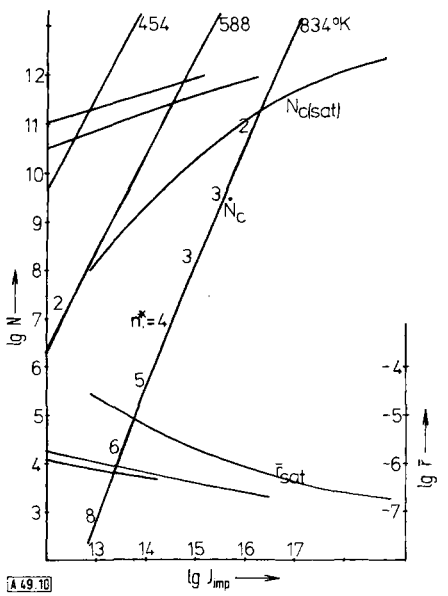

Fig. 10. Logarithmic dependence of characteristic film parameters on impingement rate J_{imp} for some temperatures. N_{cisat} is the saturation nucleus concentration, $\dot{N}_c$ the nucleation rate, $\bar{r}_{sat}$ the mean cluster radius at the time of saturation (in cm). n^* is the size of the critical nucleus at the points indicated.

This indicates that numerous growth experiments can be described by a kinetic theory. Extrapolations to experimentally unobservable regions therefore seem justified.

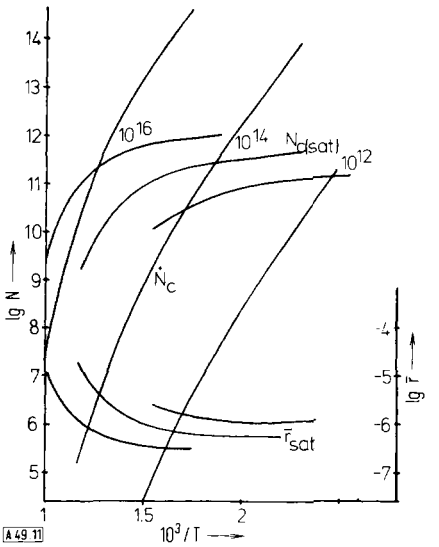

Fig. 11. Logarithmic dependence of characteristic film parameters on substrate temperature T for some impingement rates. Legend as in Fig. 10.

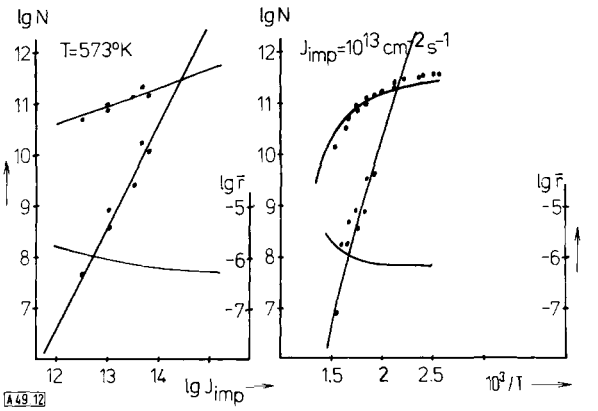

Fig. 12. Comparison between theoretical results for the growth of gold on a substrate with $E_{des}=20$ and $E_{diff}=8.5$ kcal/mol and experimental growth data for gold on rock salt (points from [13, 14]).

5. Low Temperature Condensation

Two examples of low temperature condensation will be presented: condensation of gold at 80 °K and an impingement rate of 10^{16} cm^{-2} s^{-1} on substrates characterized by (i) $E_{des}=5$ and $E_{diff}=2$ kcal/mol and (ii) $E_{des}=10$ and $E_{diff}=4$ kcal/mol. These substrate data might be representative for physical adsorption of a metal on a solid noble gas surface. Accurate experimental data are not yet available.

The low binding energy case is shown in Figure 13. The desorption equilibrium described by eq. (8) is not attained. Instead the monomer concentration is limited by twin formation before significant desorption can occur. The cluster concentrations and nucleus concentrations rise very steeply. No nucleation period, $N_c \sim t$, is observed. The growth under such conditions can be described by an induction period of 10^{-5} s, twin formation until 10^{-3} s, growth of the almost constant number of nuclei until 10^{-1} s, then coalescence. Diffusion is the governing feature of this mode of growth.

Both cases together are shown in Figure 14. In the high binding energy case diffusion of the monomers is largely restricted and film formation occurs directly by coalescence without involving clusters. The induction period is 10^{-2} s. This mode

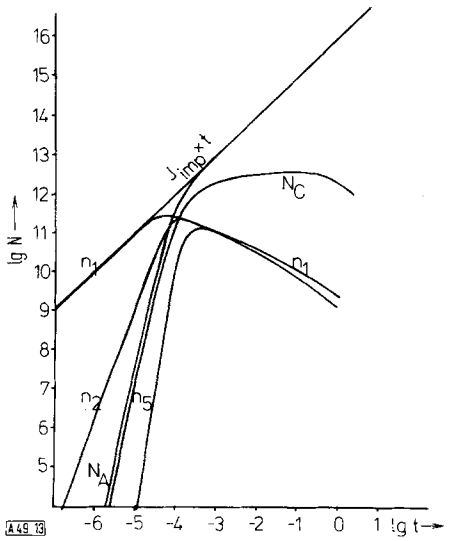

Fig. 13. Calculated dependence of cluster concentrations on deposition time. Legend as in Fig. 9. The calculations are for the case of weakly bound gold ($E_{des}=5$, $E_{diff}=2$ kcal/mol) on a substrate at 80°K.

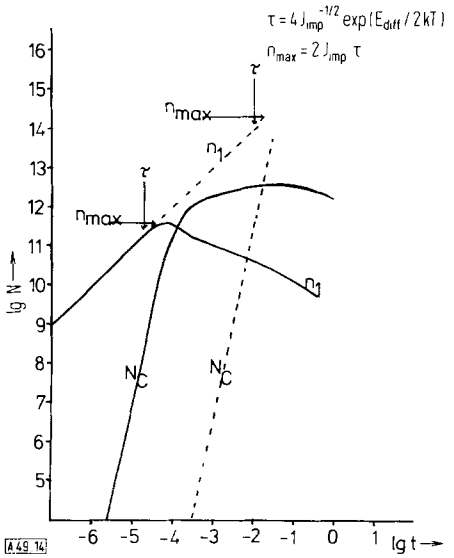

Fig. 14. Calculated dependence of cluster concentrations on deposition time for two different cases of binding. ——, binding as in Fig. 13; – – –, binding with $E_{des}=10$ and $E_{diff}=4$ kcal/mol. The induction time τ and the maximum monomer concentration as calculated from eqs. (9) and (11) are also indicated for the two cases.

of growth also gives two-dimensional layers, which are however strongly disordered compared to those described above.

The foregoing example of low temperature condensation may be of interest for chemical synthesis, especially in the case of reduced surface migration. Simple formulas permitting rapid assessment of growth can be derived from the general theory for the low temperature case, *i.e.* the case where twin formation dominates over desorption. Thus the induction time is

$$\tau = \sqrt{1/(8a\cdot s\cdot \nu_{diff})}\cdot J_{imp}^{-\frac{1}{2}}\cdot\exp(E_{diff}/2kT) \qquad (9)$$

The square root generally lies between 1 and 10 $cm^{-1}\,s^{1/2}$. The concentrations of monomers and twins at the end of the induction period are

$$n_1 = J_{imp}\cdot\tau = \sqrt{1/(8a\cdot s\cdot \nu_{diff})}\cdot J_{imp}^{\frac{1}{2}}\exp(E_{diff}/2kT) \qquad (10)$$
$$n_2 \approx 0.04\cdot J_{imp}\cdot\tau$$

The maximum concentration of monomers is attained at $t_{max}\approx 3\cdot\tau$, and its value is

$$n_{1max} \approx 2J_{imp}\cdot\tau \qquad (11)$$

At this time the numbers of twins and monomers are approximately equal. These formulas can be used as guidelines for the choice of rates, temperatures, and substrates for the attainment of a certain monomer concentration at a given time.

6. Final Remarks

A systematic experimental and theoretical investigation of cocondensation of metals and noble gases and organic materials at low temperatures is still unavailable. Extensions of theoretical considerations delineated above should, however, not be too difficult.

Meanwhile some conclusions can be derived from the simple one-component condensation theory. If the metal atoms react with the cocondensing atoms, a new substrate will be formed, generally with a new diffusion energy. Whatever this may be, a suitable surface temperature and rate of impingement can always adjust the induction time τ and the monomer concentration at this time to optimum values for a reaction with single metal atoms:

$$J_{imp} = n_1/\tau$$
$$T = (E_{diff}/k)/\ln(8a\,s\,\nu_{diff}\cdot n_1\cdot\tau) \qquad (12)$$

Whether reproducible reactions with dimers, trimers, or higher polymers can be achieved experimentally or whether the conditions for such reactions can be deduced theoretically must remain the object of future investigations.

List of symbols

Λ_0,	energy of sublimation
E_{des},	energy of desorption
E_{diff},	energy of diffusion
T,	substrate temperature
k,	Boltzmann constant
γ, J_{imp},	impingement rate
α_{des},	desorption probability
t,	time
B_i,	symbol for a cluster of i atoms
n_i,	concentration of clusters B_i
J_i,	growth probability of a cluster B_i
α_i,	decay probability of a cluster B_i
N_c,	total concentration of stable clusters
N_a,	number of condensed atoms
$\dot{N}_c$,	nucleation rate
i^*,	critical cluster size
$\langle i\rangle$,	mean cluster size
$N_{c(sat)}$,	saturation concentration of stable clusters
$\bar{r}$,	mean cluster radius
$\bar{r}_{sat}$,	mean cluster radius at saturation
$n_{1(stat)}$,	stationary monomer concentration at desorption equilibrium
$n_{1(max)}$,	maximum monomer concentration
τ,	induction time
a,	distance between adsorption sites
ν_{diff},	diffusion frequency
s,	cross-section for twin formation

Production and Condensation of Metal Vapors in Large Quantities[**]

By Walter Reichelt[*]

1. Introduction

Anybody working with evaporation or sputtering of metals under reduced pressure knows that chemical reactions can occur between the vaporized metals and organic components present in the residual gases. Such vapors arising from paraffin oils for instance may enter the working chamber if baffeling between diffusion pump and chamber is poor. The products can often be recognized by their smell.

Reactions of this kind have their uses, however, and when performed on a production scale they require efficient sources of metal vapors. Some aspects of these sources will be considered in the present report.

2. Binding Energy and Evaporation Rates

Many practical applications require a knowledge of the evaporation rate, a quantity deriving from the binding energy of the metal. Macroscopic material constants depending upon the binding energy include the melting point and the heat of evaporation. If we have reliable values of the heat of evaporation of a metal, then vapor pressures can be calculated for any desired temperature. The vapor pressure values yield evaporation rates *via* the expression due to *Hertz:*

$$G = \alpha \cdot p_s \sqrt{M/(2\pi RT)}$$

G: evaporation rate [g cm^{-2} s^{-1}]; p_s: saturation vapor pressure; α: Langmuir coefficient (approximately unity for most of the metals encountered in practice when evaporated from the melt)

Vapor pressure values reported in the literature sometimes show considerable variations. An estimation of the errors can draw upon the theory of metal binding energies. Table 1 lists the temperatures at which the vapor pressure of a number of metals warranting interest in this connection amounts to 1 torr; the melting points and heats of sublimation are given in Figures 1 and 2.

Pt	2646	2600	2531

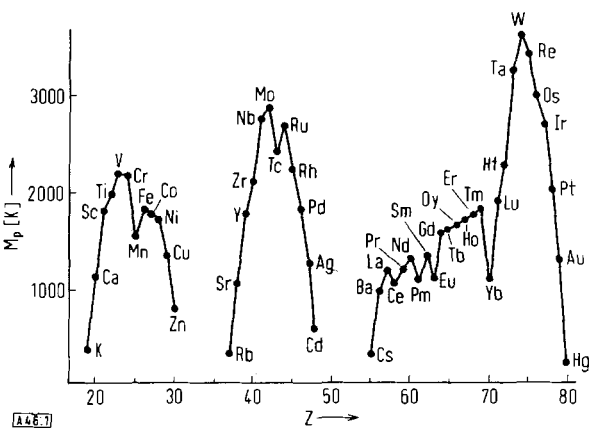

Fig. 1. Melting points m.p. *versus* atomic number Z.

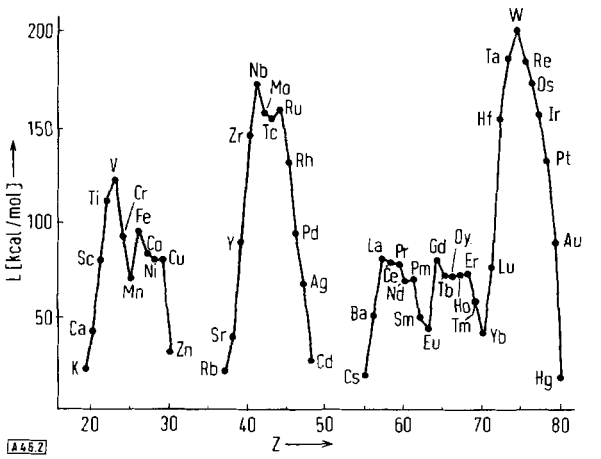

Fig. 2. Heats of sublimation *versus* atomic number Z.

3. Electron-Beam Evaporation

3.1. Crucible Material

The process that gives highest evaporation rates is electron-beam evaporation. Since evaporation is generally from the liquid phase the choice of crucible material is of great importance. Although a water-cooled copper crucible can be used in all cases, cooling must be extremely effective for some metals, *e.g.*, aluminum, in spite of the high thermal conductivity of copper; otherwise intermetallic compounds may be formed. Moreover, water-cooled copper crucibles lead to high energy losses because of the extremely high temperature gradient at the boundary between liquid metal and solid copper and the very low temperature gradient that can be maintained in solid copper. Experience shows that the heat loss is 10 to 30 times higher for a water-cooled copper crucible than for ceramic crucibles.

The ceramic crucible material has to be chosen so that the reaction between the molten metal and the oxide is limited to the surface. Considerable differences are observed in this respect. For example, molten aluminum reacts with quartz within the first few hours of operation to form a layer of solid compound several mm thick. This compound affords excellent protection against further attack.

Satisfactory solutions exist for the metals Cr, Nb, Mo, W, Fe, Co, Ni, Cu, Ag, Au, and the Pt metals. Some of the rare earth oxides are very resistant to molten metals. Molten oxides of mullite and sillimanite can also be used successfully.

3.2. Power Density of the Electron Beam

On use of an electron beam of high power density energy transfer can be restricted to a very small volume of the substance to be vaporized, thus resulting in higher efficiency. Too high a power intensity must be avoided, however, because it would cause spitting of molten metal particles owing to an excessive vapor pressure along the electron beam.

3.3. Energy Balance

Evaporation of 1 cm^3 of nickel in one second (8.9 g/s or 32 kg/h) requires 13.6 kcal/s or 57 kW of sublimation power. In practice the total power that has to be raised for evaporation of 32 kg of nickel per hour is approximately 164 kW and can be supplied for instance by four electron guns of 40 kW each. An approximate analysis of the total power consumption is given in Table 2. The efficiency is about 35%.

Table 2. Breakdown of power requirements for evaporation of nickel with an electron gun.

High tension rectifiers	9%
Electron guns (cathode heating, magnetic fields for beam deflection)	6%
Ionization and X-rays	4%
Thermal conduction through crucible (using a ceramic crucible)	18%
Thermal radiation from melt surface	10%
Electron backscattering	18%
Total power losses	65%
Evaporation	35%

Comparable results are obtained for metals having sublimation energies in the range 70 to 120 kcal/mol. (see Fig. 2; the heat of sublimation of nickel is 81 kcal/mol). With the refractory metals, *e.g.* W, Ta, Re, heat losses by conduction, radiation, and backscattering are higher. The dependence on angle of incidence, atomic number, primary energy, and the phase state has been investigated by *Sommerkamp*[4]. Figure 3 shows the power losses by electron backscattering as a function of atomic number. For the refractory metals Hf, Ta, W, Re the backscattered intensity is as high as 38%.

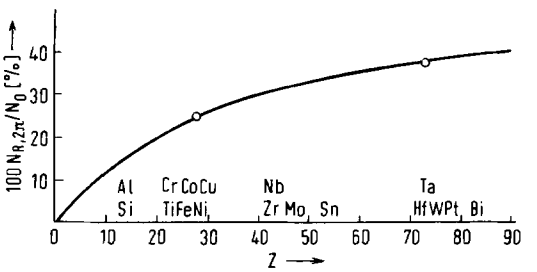

Fig. 3. Power loss by electron backscattering (power ratio $N_{R,2\pi}/N_0$) *versus* atomic number Z. $E_0 = 10$ keV, normal incidence of electron beam.

3.4. Interference

Parasitic electrons and X-rays produced by impact of the electrons on the metal in the crucible can lead to interference if the liberated metal atoms are to be reacted with various substrates.

Parasitic electrons can be eliminated by supplementary magnetic fields or by a negatively charged mesh of metal wire. The most effective method, however, is to chose the polarity such that the crucible is at a positive potential relative to the condensation surface.

X-rays can be largely avoided by reducing the accelerating voltage to a level below the threshold potential for the generation of characteristic X-rays. On reducing the voltage the current must be increased in order to maintain the power density of the electron beam. This can be accomplished by using a cathode of larger area.

3.5. Types of Electron Guns

A high power electron gun (Fig. 4) is generally equipped with an indirectly heated cathode of the block type and an auxiliary cathode of the spiral type.

The gun shown is designed for a power of 250 kW at an accelerating voltage of 22 kV; the maximum current is 11 A. The perveance, a quantity derived from the space charge law which characterizes the performance of a gun, is 3.4×10^{-6}. The beam generating space is evacuated by an auxiliary diffusion pump. Beam-forming is accomplished with two focusing coils; a third coil at the lower end of the gun serves for deflection of the beam.

Figure 5 shows a gun of more modest power (35—50 kW at 20 kV). A water-cooled crucible is connected directly to the gun.

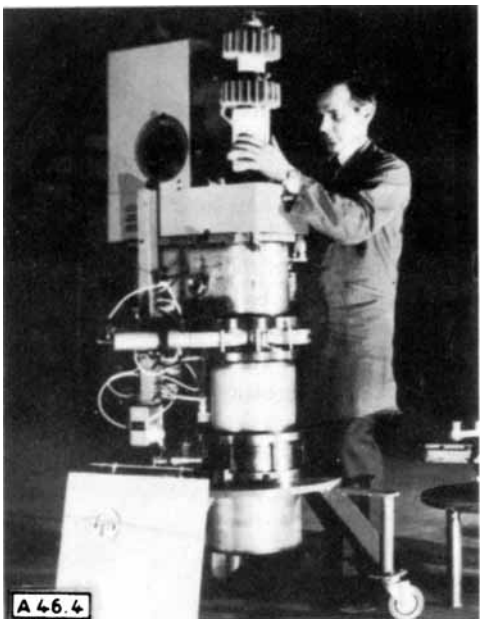

Fig. 4. High power electron gun (250 kW).

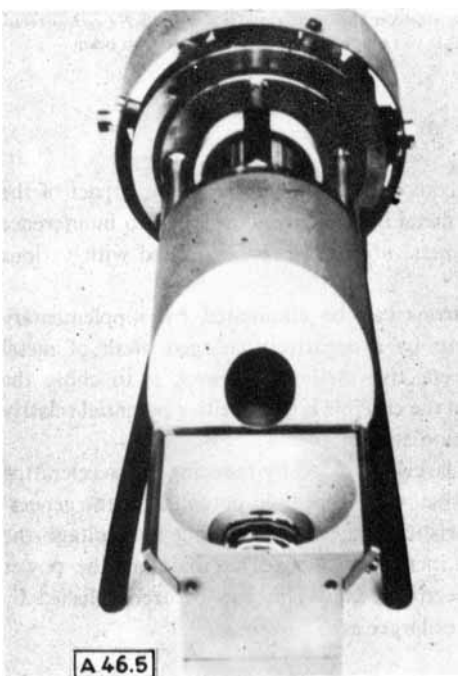

Fig. 5. 30 kW electron gun.

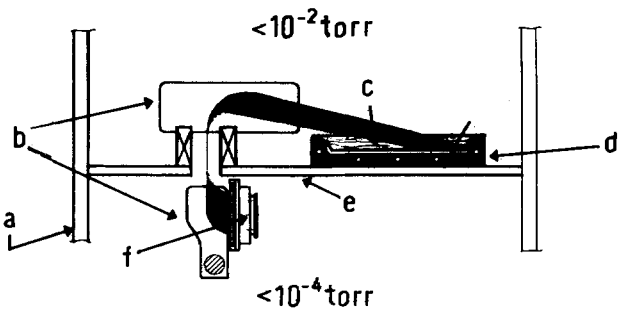

Fig. 6. Scheme of electron gun with linear cathode. a, vacuum tank walls; b, beam deflection system; c, molten material; d, water-cooled support; e, vacuum-tight barrier; f, electron gun.

In contrast to this circular gun concept there are modifications (Fig. 6) in which the cathode is a linear wire that can be of considerable length. The gun consists of a Wehnelt-type linear electrode and a parallel linear anode. In order to protect the cathode against ions and spitting particles the beam is deflected through 270°. With this concept, the beam generating space can also be kept under a higher vacuum than the crucible.

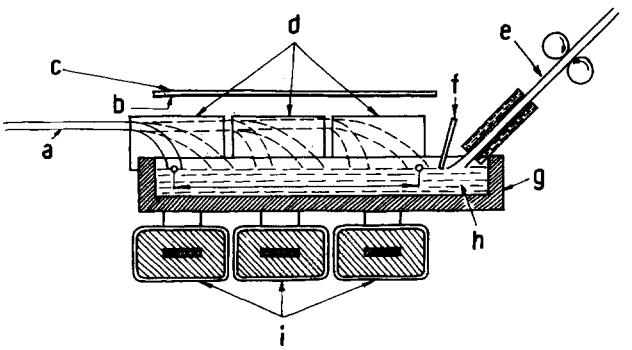

Fig. 7. Electron-beam evaporation unit with one electron gun. a, electron beam; b, deposited layer; c, steel strip; d, pole pieces of deflection magnets; e, feeding system for material; f, shielding; g, crucible; h, evaporation material; i, magnet coils (System: *M. v. Ardenne*).

The life-time for a cathode ranges between 50 and 200 h of operation, where the smaller value holds for spiral type cathodes and the larger one for block type cathodes.

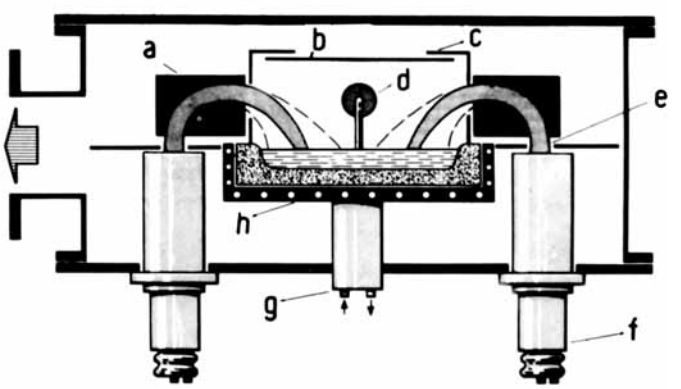

Fig. 8. Electron-beam evaporation unit with two electron guns. a, pole pieces of deflection system; b, steel strip; c, shielding; d, feeding system for material; e, electron beam; f, separately pumped Pierce gun; g, water-cooled crucible support; h, ceramic crucible.

The circular as well as the linear-beam guns are used in connection with either of the two following applications: In Figure 7 only one electron gun is present at the left; the beam is sequentially deflected down to the bath by operating the three magnet coils in turn. Material in solid form is fed on the right into the melt. Figure 8 shows an arrangement where the beams are laterally deflected by magnetic fields, but to a smaller extent. Fig. 9 depicts a 120 kW electron beam evaporation unit with four separately pumped guns; the wire feeding is carried out from an atmospheric environment.

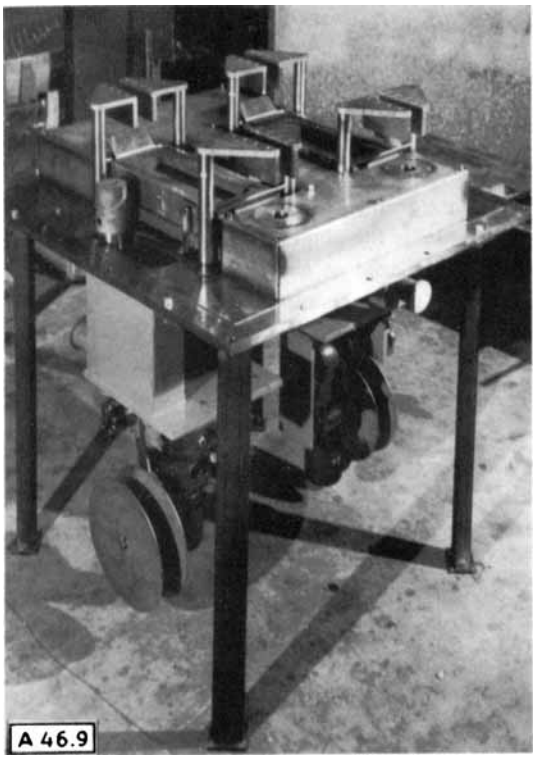

Fig. 9. Electron-beam evaporation unit with four electron guns.

4. Sputter Processes

Timms detailed paper[5] includes the remark that sputter processes have not yet been used in metal-atom syntheses.

For a long time the low sputtering rates precluded use of these processes, and significant advances have only recently been registered. A process that is well suited for sputtering of large quantities of metals (Ta, Mo, W, Re) is plasma sputtering at pressures from 10^{-2} to 10^{-4} torr. The plasma is generated by a high frequency (5 to 30 MHz) electromagnetic field.

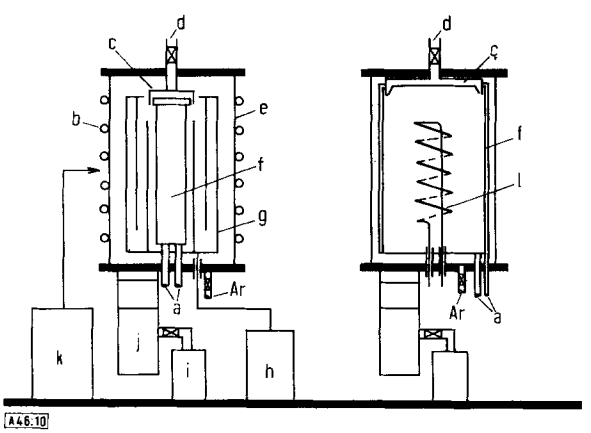

Fig. 10. Arrangement for RF frequency sputtering of metals. a, cooling circuit; b, high frequency coil; c, diffusor; d, reactive gas; e, glass vessel; f, condensed film; g, target of material to be sputtered; h, DC power supply; i, mechanical pump; j, diffusion pump; k, RF frequency generator; l, RF frequency coil made of metal to be sputtered.

There are two possible arrangements: Figure 10 (left) shows an apparatus in which the HF coil for electrodeless plasma generation is located on the outside of a glass cylinder, and a negatively charged target on the inside is bombarded by argon ions. The sputtered material is condensed on coaxially arranged substrates. Higher plasma densities are possible with the apparatus on the right of Fig. 10, where the HF coil is inside the working chamber and consists of the material to be sputtered. For low melting point metals the coil must be water-cooled. The coil need not be cylindrical, but may be composed of linear elements, so that almost all interesting metals, transition metals for instance, can be sputtered by this method.

The present state of the art permits sputtering rates of about 500 g/h with the equipment shown.

The main disadvantage of all sputtering processes is their low power efficiency of only 5—10%, compared with the 35% of electron-beam evaporation (see Section 3.3).

Another difficulty also has to be taken into account. If the metal atoms produced by sputtering are to be reacted with organic compounds then the equipment should be constructed so as to avoid their entering the central region of the plasma where they will easily be decomposed.

5. Condensation and Cooling

The evaporated metal atoms transport energy, *viz.* kinetic energy and heat of sublimation, which has to be removed from the condensation surface by a convenient cooling system. The contribution of the kinetic energy is usually less than 10%. At 2100 K, for instance, iron vapor has a kinetic energy of 6.7 kcal/mol and a heat of sublimation of 97 kcal/mol.

In order to estimate the condensation power we shall consider the example of chromium. For condensation of 1 kg of chromium per hour at 80 K it amounts to approximately 1700 kcal/h or 2 kW. Allowance must also be made for heat radiation from the walls. Since refrigerators employing liquid nitrogen have an efficiency of only about 20%, approximately 10 kW are necessary for removal of the heat liberated.

If the evaporated metals do not unite to form metal lattices on the condensation surface but undergo chemical reactions with various compounds then the cooling power will also change.

6. Evaporation Plants and Their Modification for Chemical Synthesis

Low temperature reactions of metal atoms with organic compounds can be carried out as batch or continuous pro-

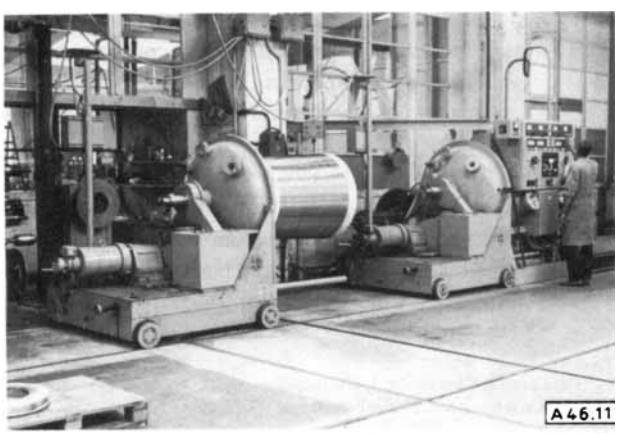

Fig. 11. Evaporation plant used in batchwise metal cladding.

cesses. At present no specially designed equipment for such reactions is commercially available.

Apparatus for a batch process will resemble that already used in metal cladding by evaporation.

Figure 11 shows a large rotating and refrigerated drum which can be introduced into an evacuated chamber. Vaporized compounds can be carefully distributed from above on the cooled surface and reacted with the metal vapor coming from sources located below the drum. The condensation surface may be as large as several square meters. In order to ensure uniform deposition several electron guns situated along a line parallel to the axis of the drum must be used.

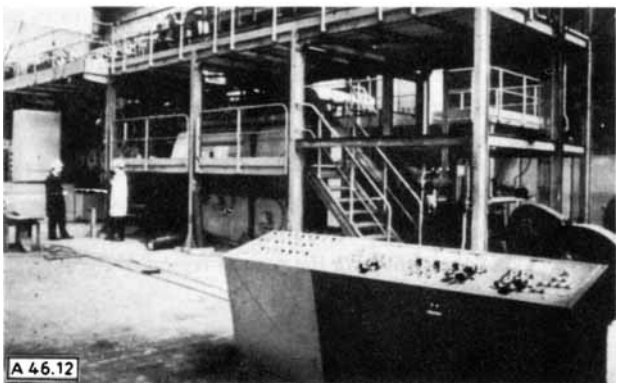

Fig. 12. Evaporation plant for continuous coating of steel strip.

Apparatus for the continuous process could be derived from the continuous band coaters used for coating steel strip with metals (Fig. 12). The strip would pass through a set of seals on entering and leaving the machine. When used for chemical synthesis the plant would have to be equipped with cooling rolls instead of heating rolls and with devices for distributing the gaseous compound over the moving strip. The reaction products could be scraped or brushed from the strip either inside the machine or outside in the atmosphere; the strip might also take the form of a closed loop.

New synthetic methods (9)

Chemistry of Phosphorylcarbenes[1][**]

By Manfred Regitz[*]

Phosphorylcarbenes, which have become known only recently during synthetic experiments in the field of phosphoryldiazoalkanes, have twofold preparative value. In the first place, they can be used to introduce phosphoryl groups into organic compounds, as in the phosphorylcyclopropanation of alkenes or arenes and in the phosphorylcyclopropenation of alkynes. Secondly, phosphorylcarbenes readily undergo rearrangements; hydride, alkyl, aryl, or acyl shifts lead to phosphorylated alkenes. The phosphorylcarbene/methylenephosphane oxide rearrangement provides access to the short-lived P analogs of the ketenes. Finally, the vinylcarbene/allene rearrangement was first discovered in this connection; it competes with ring closure to the cyclopropene.

1. Introduction

Progress in the synthesis of aliphatic diazo compounds leads almost of necessity to corresponding developments in carbene chemistry, since photochemical decomposition of diazoalkanes ensures universal access to carbenes. Thus, investigations into the synthesis of phosphoryldiazoalkanes, begun in our school several years ago, led us to study the reactivity of phosphorylcarbenes. The preparation of organophosphorus compounds by carbene reactions was of interest mainly from the point of view of whether, and in relevant cases to what extent, phosphorylcarbenes differ from their carbonyl analogs, which have been investigated very thoroughly.

2. Preparation of Phosphoryldiazoalkanes

The simplest of the compounds considered in this section, namely the α-diazophosphonate *(1)*, α-diazophosphane oxide *(2)*, and α-diazophosphinate *(3)*, are accessible by diazotization of amines[2] (method A); the only other application of this method was for preparation of the α-diazophosphane oxide *(4)* (Table 1).

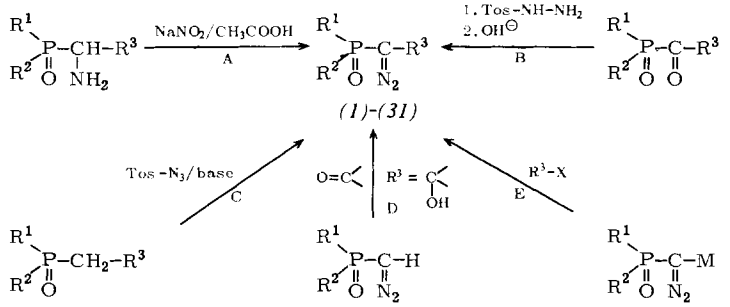
The Bamford-Stevens reaction[2] (method B) has a very wide scope, as shown by examples *(5)*—*(15)* (Table 1). The starting materials in this method are α-oxophosphoryl compounds, whose preparation involves the Michaelis-Arbusov reaction[3] between methoxyphosphanes and acyl chlorides

[*] Prof. Dr. M. Regitz
Fachbereich Chemie der Universität
675 Kaiserslautern, Pfaffenbergstrasse (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

as an essential step; however, failure of the latter reaction has hitherto precluded synthesis of diazomethylphosphane oxides by method B. Only in the case of dimethyl cyclopropyldiazomethylphosphonate *(12)*, R^3 = cyclopropyl, was isolation of the diazo compound impossible for the compound decomposes spontaneously (see Section 4.1).

The phosphoryldiazoalkanes *(16)*—*(20)* containing a carbonyl group or a strongly proton-activating aryl group as a second substituent are obtained only by diazo group transfer[2, 4, 5] (method C) (Table 1). The active methylene compounds serving as starting materials can again be produced by the Michaelis-Arbusov reaction[3].



phenylphosphane oxide *(2)* by carbonyl compounds (Table 1). This aldol-like addition[2, 5] (method D) is generally straightforward when catalyzed by triethylamine [the addition of OH^- is necessary only for *(22)*] and is applicable to aldehydes, dicarbonyl, and tricarbonyl compounds. In the last of these cases the high carbonyl reactivity makes addition of base superfluous.

Reaction of metal derivatives of *(2)* with S_N1-active halides[2, 5] (method E) represents a further variant of the alkylation (Table 1). With benzyl iodide, *(2)*, M = Ag, affords the diazo compound *(30)*; compound *(31)* is obtained from *(2)*, M = Hg—CN_2—$PO(C_6H_5)_2$ and triphenylmethyl bromide. These two metal derivatives are readily accessible from *(2)* and the metal oxides in chloroform[7].

With few exceptions the phosphoryldiazoalkanes are unusually stable thermally, and in this respect they are far superior to the respective carbonyl analogs[19, 20]. If the temperature at which the decomposition constant k_1 amounts to 0.1 min^{-1} is chosen as a measure of comparison, this behavior can be pinpointed by the examples in Table 2. From these data consequences regarding the temperature and the duration of thermolysis can be drawn for thermal generation of phosphorylcarbenes from diazo compounds.

Table 1. Syntheses of the phosphoryldiazoalkanes *(1)*—*(31)*. Method A: Diazotization of amines, B: Bamford-Stevens reaction, C: Transfer of diazo groups, D: Aldol addition, E: Nucleophilic substitution.

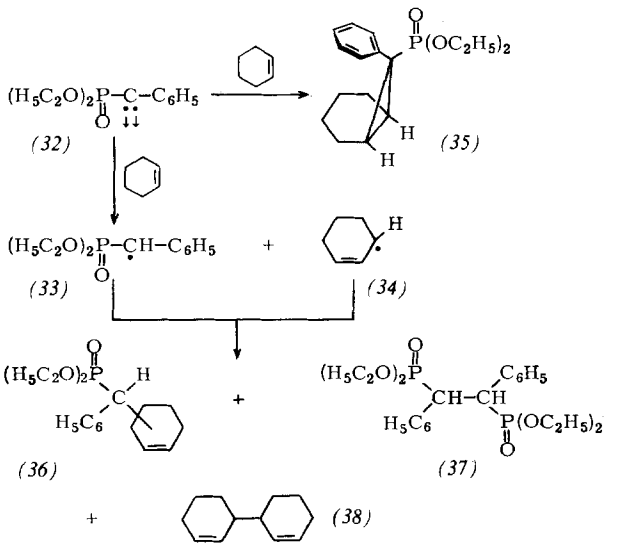
3. Intermolecular Reactions[21]

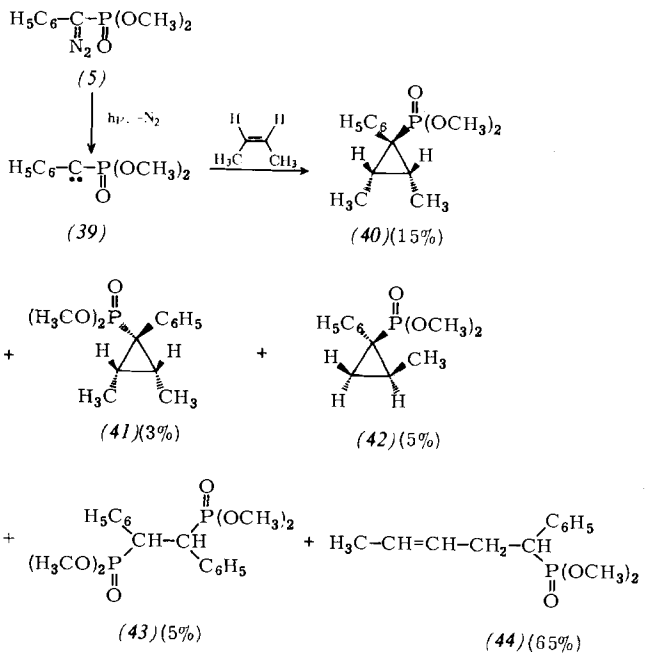
3.1. Phosphorylcyclopropanation of Alkenes

(Diethoxyphosphoryl)phenylcarbene *(32)* produced photolytically from *(7)* adds stereoselectively to cyclohexene, giving the norcarane derivative *(35)* with an *endo*-phenyl and an *exo*-phosphoryl group. The configuration at C-7 is the same as in 7-phenylnorcaradien-7-yl phosphonates *(51)*[10, 22]. At the same time, as an indication of its triplet character, *(32)* abstracts hydrogen from the cyclohexene with the formation of the two radicals *(33)* and *(34)*, the three possible products *(36)*—*(38)* of their combination also being isolated.



The fact that (dimethoxyphosphoryl)phenylcarbene *(39)* is also distinguished by triplet character follows from its reactions with *cis*- and *trans*-2-butene at −20 to −25 °C[23]. The *cis*-olefin undergoes stereospecific [2+1]-cycloaddition to give the diastereoisomers *(40)* and *(41)* alongside non-specific cycloaddition yielding *(42)*; the H-abstraction products *(43)* and *(44)* are also formed[24]. The last-mentioned compound could not be isolated but was determined quantitatively by NMR spectroscopy and coulometric titration with bromine. *trans*-2-Butene affords only two of the three possible cyclopropanes, namely *(40)* and *(42)*, the product picture being otherwise the same[23].

A decision whether the triplet behavior of *(32)* and *(39)* should be assigned specifically to the PO group will have to wait for conclusion of relevant experiments with (dialkoxyphosphoryl)carbenes.



Cyclopropanations with phosphoryldiazoalkanes by the carbenoid route are more clear-cut and usually give a very high yield (Table 3); the H-abstraction that dominates on photochemical production of the carbenes is wholly suppressed. Usually the diazo compounds are decomposed on catalysis by copper [*(46)*—*(49)*]; it is surprising that cyclopropanation of 3-(trimethylsilyl)propene with *(1)*, to yield *(45)*, occurs already at 0—20 °C. The stereochemistry at the phosphoryl-carbon atom of the cyclopropanes is known only for *(46)*[10].

3.2. Phosphorylcyclopropanation of Arenes

Numerous examples are known of the preparation of 7-phosphorylnorcaradienes *(51)* by cyclopropanation of arenes with phosphorylcarbenes *(50)* (Table 4). In the case of the crystalline arenes (*p*-dichlorobenzene, naphthalene), the photolysis of the diazo compounds is carried out in the melt; their thermal stability guarantees photochemical generation of carbenes even under such conditions.

With *p*-xylene H-abstraction by *(50a)* completely swamps cyclopropanation, leading to the typical product picture of radical dimers[10]; in other cases further reaction of *(51)* is frequently observed, yielding tricyclo[5.1.0.0^{2,4}]oct-5-enes *(52)* (Table 4). Both reactions occur stereoselectively; the PO groups are always *exo*[10, 14]. This configuration follows from the *cis*-coupling of the phosphorus with β-cyclopropane protons (*ca.* 17 Hz), which differs distinctly from the corresponding *trans*-coupling (*ca.* 1—2 Hz)[10, 28]. The reference standard for this assignment is the cyclopropane derivative *(46)* (Table 3), for which the two possibilities have been verified. X-Ray structure analyses of *(51a)* and *(51f)* confirm the stereochemistry[29, 30].

Table 3. Phosphorylcyclopropanes *(45)*—*(49)* from olefins and the phosphoryldiazo compound *(1)* or *(5)* with copper catalysis.

Reactants	Cyclopropane	Yield [%]	Ref.

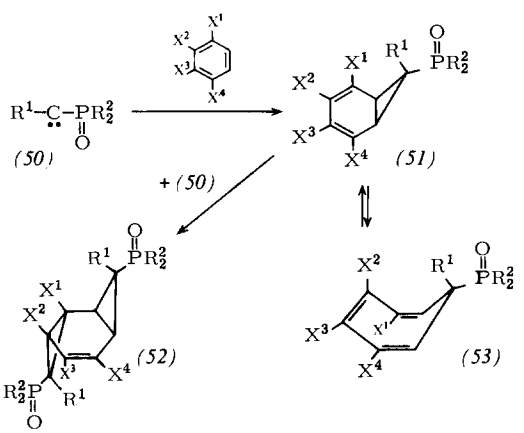
	 *(46)*	8 [b]	[10]
	 *(47)*	73 [c]	[6]
	 *(48)*	90 [c]	[6]
	 *(49)*	96 [c]	[6, 26]

[a] Dichloromethane, 0—20 °C.
[b] Dichloromethane, reflux.
[c] Without solvent, reflux temperature of the olefin.

In some cases, *e.g. (51a)*, valence-tautomeric equilibria with 7-phosphorylcycloheptatrienes exist in solution[28, 31]. From temperature-dependent NMR spectra the equilibrium constants *(51)*⇌*(53)* in CS_2 are found to be 3.78 at −34 °C and 9.95 at −99 °C; at −116 °C the spectrum of the pure norcaradiene is observed[28].



Irradiation of *(1)* in *m*-bis(trifluoromethyl)benzene leads to two cyclopropanation products *(54)* and *(55)*, which in $CDCl_3$ occur in valence-tautomeric equilibrium with the cycloheptatrienes *(56)* and *(57)*, respectively, the trienes being dominant[14, 32]. On prolonged irradiation the *(54)*/*(56)* system is favored; it is possible that cycloelimination from *(55)* leads to (dimethoxyphosphoryl)carbene[33], which adds further to *m*-bis(trifluoromethyl)benzene. However, this is no longer a kinetically but now a thermodynamically controlled reaction.

The same reaction can be brought about thermally; it can thus be regarded as a Berson-Wilcott rearrangement[34], *i.e.* as a sigmatropic [1,5]-carbon shift[35].

(Dimethoxyphosphoryl)(methoxycarbonyl)carbene *(58)* and benzene afford products that depend on the duration of the irradiation[14]. If the photolysis of *(16)* is interrupted before the reaction is complete, the norcaradiene *(59)* or the equilibrium system *(59)*⇌*(60)*, respectively, is produced (NMR spectroscopy in $CDCl_3$). More prolonged irradiation leads next to a not precisely determinable sequence of sigmatropic [1,5]- or [1,7]-shifts of ester groups or H atoms, producing the cycloheptatriene *(62)*. On still further irradiation

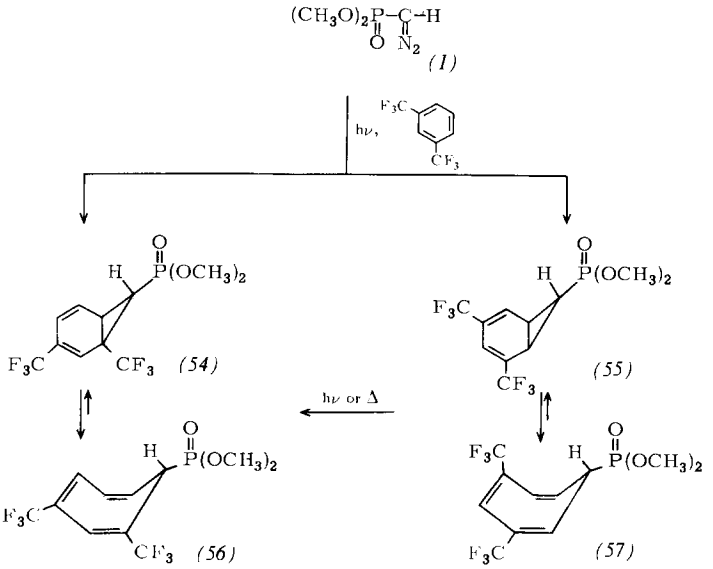
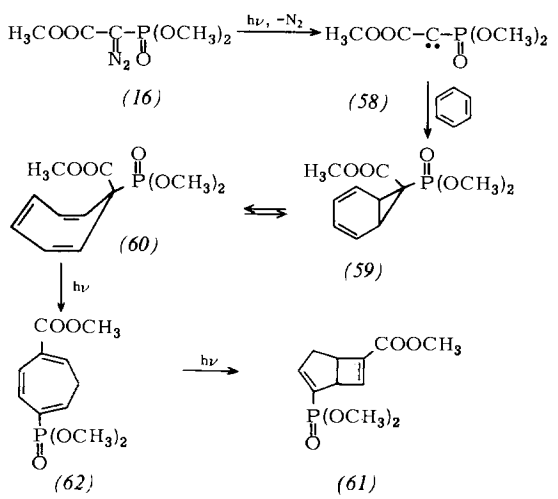
[a] On sensitization with cyclohexanone.

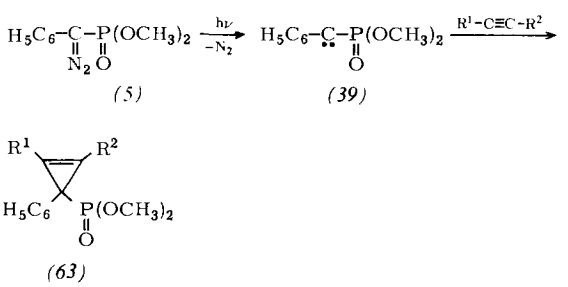


the photostable bicyclo[3.2.0]heptadiene *(61)* is formed from *(62)* by electrocyclic ring closure[36].



3.3. Phosphorylcyclopropenation of Alkynes

(Dimethoxyphosphoryl)phenylcarbene *(39)*, produced photolytically from *(5)*, reacts with alkynes to give satisfactory yields of dimethyl 1-phenyl-2-cyclopropenylphosphonates *(63)* (Table 5) if [3+2]-cycloaddition of *(5)* does not become operative[13].



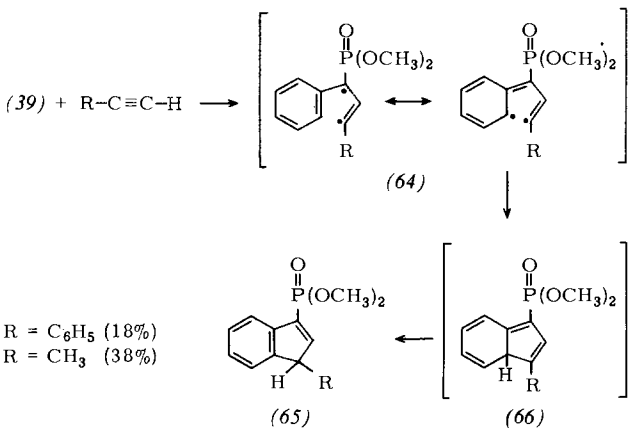
An interesting alternative is provided by monosubstituted alkynes, where ring closure to dimethyl 3-indenylphosphonates

Table 5. Dimethyl 1-phenyl-2-cyclopropenylphosphonates *(63)* from alkynes and (dimethoxyphosphoryl)phenylcarbenes *(39)* [13].

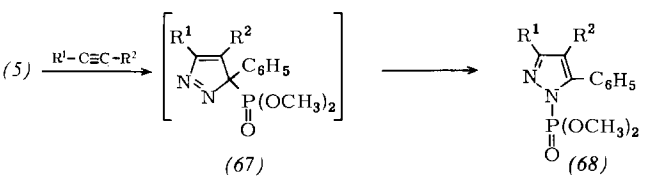
R^1	R^2	Yield [%]
C_6H_5	C_6H_5	61
CH_3	CH_3	55
C_6H_5	CH_3	41
C_6H_5	$COOCH_3$	39
C_6H_5	H	3
CH_3	H	59

(65) competes with the phosphorylcyclopropenation that yields *(63)*[13].

The carbene *(39)* apparently attacks the unsubstituted alkyne-carbon atom with formation of the diradical *(64)*, which cyclizes to *(66)*. Re-aromatization with a sigmatropic [1,5]-hydrogen shift leads to *(65)*[37].



Activated alkynes such as methyl propiolate, dimethyl acetylenedicarboxylate, acetylenedicarbonitrile, or hexafluoro-2-butyne do not undergo the carbene reaction at all, since photolytic carbene generation *(5)* → *(39)* occurs much more slowly than [3+2]-cycloaddition. The 3*H*-pyrazoles *(67)* that are undoubtedly formed initially cannot be isolated but are transformed, in a very rapid sigmatropic [1,5]-shift of the dimethoxyphosphoryl group, into the isomeric pyrazolides *(68)*[38].

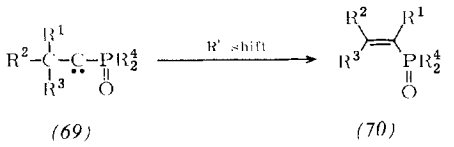


R^1 = $COOCH_3$, R^2 = H (100%) R^1 = R^2 = CN (63%)
R^1 = R^2 = $COOCH_3$ (100%) R^1 = R^2 = CF_3 (100%)

4. Intramolecular Reactions[21]

4.1. Hydride, Alkyl, Aryl, and Acyl Shifts

Phosphorylcarbenes with suitable substituents on the α-carbon, *e.g. (69)*, react extremely readily with migration of a substituent to the carbene center; phosphorylalkenes *(70)* are formed (Table 6).



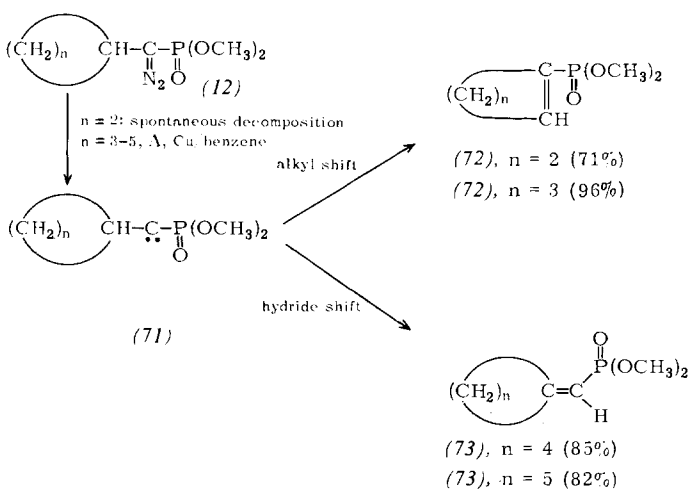
(69) (70)

Table 6. Phosphorylalkenes (70) prepared. Cu(acac)$_2$ = bis(2,4-pentanedionato)copper(II).

R^1	R^2	R^3	R^4	Reaction conditions	Yield [%]	Ref.
H	H	H	OCH_3	*hv*, benzene	22	[39]
H	CH_3	CH_3	OCH_3	Δ, Cu/benzene	87	[12]
				hv, benzene	55	[39]
CH_3	CH_3	CH_3	OCH_3	Δ, Cu/benzene	81	[12]
C_6H_5	H	H	C_6H_5	Δ, Cu(acac)$_2$/benzene	100	[17]
C_6H_5	C_6H_5	C_6H_5	C_6H_5	Δ, Cu(acac)$_2$/benzene	71	[17]

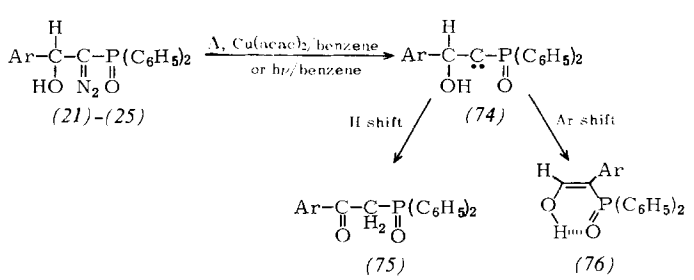
For these reactions the copper-catalyzed thermal decompositions of the diazo compounds corresponding to (69) always give higher yields of the olefin. If the carbenes are generated photolytically (Table 6), carbene dimerization and addition of carbene to solvent benzene also occur, though the latter is completely suppressed on copper catalysis[39].

The kind of substituent shift undergone by cycloalkyl(dimethoxyphosphoryl)carbenes (71) is controlled by the ring size. Cyclopropylcarbene (71), $n=2$, and cyclobutylcarbene (71), $n=3$, apparently prefer the alkyl shift to form cycloalkenes (72), because of ring strain, whereas cyclopentylcarbene (71), $n=4$, and cyclohexylcarbene (71), $n=5$, undergo a 5-hydride shift yielding the methylenecycloalkanes (73)[12].



(12) (71) (72), n = 2 (71%) (72), n = 3 (96%) (73), n = 4 (85%) (73), n = 5 (82%)

True competition between hydride and aryl shifts occurs with the [(arylhydroxymethyl)phosphoryl]carbenes (74) generated from (21)—(25). In the first case the enols that are undoubtedly formed initially are transformed into the ketones [(β-oxoethyl)phosphane oxides] (75), whereas in the second the (β-hydroxyvinyl)phosphane oxides (76) are isolated without any sign of ketone formation (Table 7)[16]. The hydride shift always predominates, irrespective of the mode of carbene generation (Table 7). Here too cyclopropanation of benzene is completely circumvented.



(21)–(25) (74) (75) (76)

An aryl shift associated with ring expansion occurs in the reaction (27) → (77). Reactions of this type are mostly induced by acid catalysis (carbenium ion mechanism)[18]. The shift

Table 7. Competing H- and Ar shifts in (arylhydroxymethylphosphoryl)carbenes (74) [16].

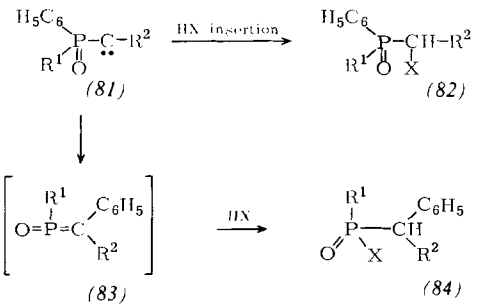
of a benzoyl group to the carbene-carbon atom is responsible for the formation of (78) from (26)[17]. If this reaction is applied to cyclic systems, phosphorylated ring systems can be prepared in high yields, as is illustrated by the selected examples (28) → (79)[17] and (29) → (80)[17].

4.2. Phosphorylcarbene/Methylenephosphane Oxide Rearrangement

In a study of the reactivity of phosphorylcarbenes the question whether these compounds can afford the ketene analogs, methylenephosphane oxides such as *(83)*, in a reaction corresponding to the Wolff rearrangement is of particular interest. Methylenephosphane oxides are interesting in connection with the question whether compounds of pentavalent phosphorus with a coordination number of 3 can exist[40].



(81) *(82)* *(83)* *(84)*

When carbenes of type *(81)* are generated photolytically from diazo compounds in the presence of protic nucleophiles (water, methanol, aniline, or morpholine), they react in two ways: by one route the phosphane oxides *(82)* are formed with HX-insertion, by the other the phosphinic acid derivatives *(84)* are obtained, *i.e.* the carbenes *(81)* partly undergo P/C-phenyl shift to give the methylenephosphane oxides *(83)*[43] which add the nucleophile very rapidly, yielding *(84)* (Table 8).

Irradiation of *(19)* in methanol leads to much more complicated reactions. Competition occurs between the phosphorylcarbene/methylenephosphane oxide rearrangement *(85)* → *(86)*[43] → *(90)* and the equally possible classical Wolff rearrangement *(85)* → *(89)* → *(93)*; the methyl esters *(90)* and *(93)* are formed in the ratio of approximately 4:1. It is possible, however, to reverse this ratio by introducing a *p*-dimethylamino group into the benzoyl group of *(19)* (phosphinic ester: carboxylic ester ≈ 1:2)[41].

Furthermore, *(85)* reacts with methanol by OH insertion, although the phosphane oxide *(87)* cannot be isolated; it undergoes intramolecular, photochemical reduction of the CO group to form the diradical *(91)*, which then cyclizes to the oxetane *(92)*[41]. Finally, reductive elimination of the diazonitrogen[44] also occurs, with formation of *(88)*[44].

Table 8. Phosphane oxides *(82)* and/or phosphinic acid derivatives *(84)* from phosphorylcarbenes *(81)*.

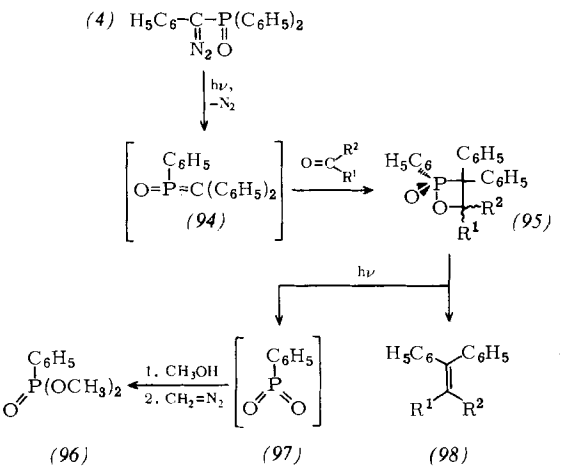
C_6H_5	$COOC_2H_5$	OCH_3	22	61	[22, 41]
H_3CO	C_6H_5	OCH_3	87	—	[42]

Yet another possibility of detecting the short-lived methylenephosphane oxide consists in trapping by carbonyl compounds. If *(4)* is irradiated in benzene in the presence of an aldehyde or a ketone, the latter undergoes orientation-specific [2+2]-cycloaddition to the methylenephosphane oxide, yielding the 1,2-oxaphosphetanes *(95)*. These products can be isolated if, like the adducts of aromatic aldehydes (Table 9), they are photostable (no absorption at $\lambda \geq 280$ nm). Photounstable 1,2-oxaphosphetanes fragment in whole or in part into butadienes or hexatrienes *(98)* (Table 9) and dioxophenylphosphorane *(97)*[45], which was detected in a model experiment.



(4) *(94)* *(95)* *(96)* *(97)* *(98)*

k	CH=CH—C_6H_4—OCH_3-(*p*)	CH=CH—C_6H_4—OCH_3-(*p*)	—	10	[9, 27]
l	—CH_2—CH_2—	CH_2—CH=CH—	—	7	[9, 27]

Irradiation of *(95i)* (Table 9) in methanol afforded the butadiene *(98)* together with the methyl benzenephosphonate formed by addition of methanol to *(97)*; this was esterified to *(96)* by diazomethane and identified[9]. In all cases the rearrangement of *(4)* in benzene was accompanied by cyclopropanation of the benzene which yields the norcaradiene *(51e)* (Table 4). The reaction sequence *(94)* → *(95)* → *(97)* + *(98)* is reminiscent of Wittig carbonyl olefination.

Methylenephosphane oxide *(94)* produced thermally from *(4)* initially reacts with benzylideneacetophenone as in the photoreaction, *i.e.* by [2+2]-cycloaddition to give *(95h)* and partial fragmentation of the adduct to *(98h)*. Additionally, *(94)* and the α,β-unsaturated ketone undergo Diels-Alder reaction giving the 1,2-oxaphosphorin *(99)*. An analogous product picture has been found for diphenylketene and the same ketone[47]. It is not yet clear why the other carbonyl compounds (R^1R^2CO in Table 9) do not react thermally by [4+2]-cycloaddition.

(α-Benzoylbenzylidene)phenylphosphane oxide *(86)* can also be trapped by cycloaddition to carbonyl compounds if the diazo compound *(19)* is irradiated in a *p*-dichlorobenzene melt. If, as is permissible because of the different electronegativities of oxygen and phosphorus, one regards the heterocumulenes as 1,4-dipoles, it becomes understandable why *(86)* undergoes [4+2]-cycloaddition to aldehydes and ketones[48].

If the groups R^1 and R^2 are not identical, the 1,5,2-dioxaphosphorins are produced as diastereoisomers *(100)* and *(101)*, which can often be separated (Table 10).

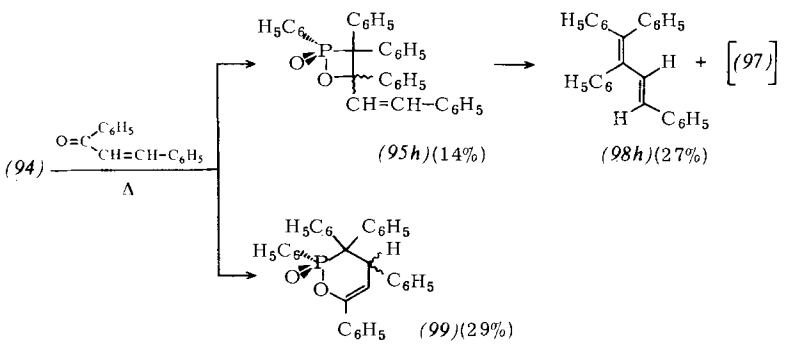
Table 10. 2*H*-1,5,2-Dioxaphosphorins *(100)* and *(101)* from (α-benzoylbenzylidene)phenylphosphane oxide *(86)* and carbonyl compounds [46, 48].

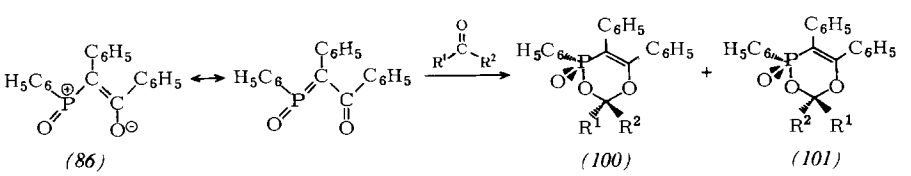
R^1	R^2	Yield [%] *(100)* + *(101)*
C_6H_5	H	28 [a]
C_6H_5	CH_3	22 [b]
C_6H_5	C_6H_5	14
CH_3	H	27 [c]
CH_3	CH_3	45
CH_3	$C(CH_3)_3$	26 [d]
—CH_2—	CH_2—CH_2—CH_2—CH_2—	32

[a] *(100)* and *(101)* can be separated.
[b] *(100)* and *(101)* cannot be separated; ratio ≈ 2:1 (NMR-spectroscopy).
[c] *(100)* and *(101)* can be separated; ratio ≈ 1:1.
[d] *(100)* and *(101)* can be separated; ratio ≈ 20:1.

Thermal fragmentation (215 °C, 5×10^{-3} torr) of *(100)*, $R^1 = R^2 = C_6H_5$, to diphenylacetylene, benzophenone, and the hypothetical *(97)* is in accord with the proposed structure, as is its alkaline hydrolysis to (α-benzoylbenzyl)phenylphosphinic acid and benzophenone[46].

Four dimers of *(86)* are obtained in all the trapping reactions. Their structures are currently being elucidated.

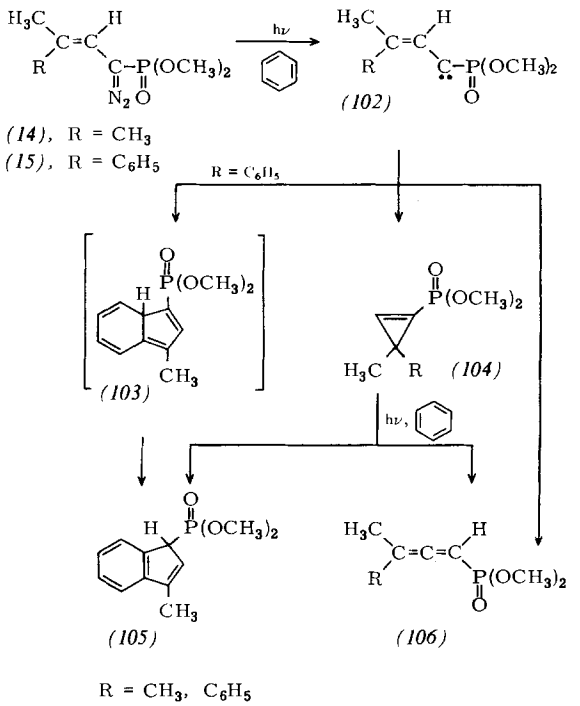




4.3. Vinylcarbene/Cyclopropene Ring Closure and Vinylcarbene/Allene Rearrangement

The carbenes *(102)* produced photolytically from the vinyl diazomethanephosphonates *(14)* and *(15)* in benzene initially avoid the possible formation of norcaradiene in favor of intramolecular reactions. The cyclopropene ring closure giving *(104)* (33 or 45 %, respectively) is preferred, but is accompanied to a minor extent by the hitherto unknown rearrangement to the propadienylphosphonates *(106)* (4 or 7%, respectively)[49].

The carbene *(105)*, R = C_6H_5, cyclizes to dimethyl 1-indenylphosphonate *(105)* (5%). *(103)* should be an intermediate along this route, arising by intramolecular insertion



of the carbene-carbon atom into the *ortho*-CH bond of the phenyl residue; the subsequent sigmatropic [1,5]-shift *(103)*→*(105)* is thermally allowed[49]. The cyclopropenylphosphonates *(104)* are also converted into *(105)* and *(106)* on irradiation[49], the most obvious explanation for this being ring opening of *(104)* to give *(102)*[50], followed by the reactions mentioned above.

A further route to phosphorylvinylcarbenes starts from phosphorylalkynes *(107)*. These alkynes add disubstituted diazoalkanes such as 2-diazopropane or diazodiphenylmethane with the usual orientation, giving 5-phosphoryl-3*H*-pyrazoles *(108)* of considerable stability.

On irradiation in benzene these pyrazoles isomerize with ring opening to yield the diazo compounds *(109)*[51], as can be readily observed by IR spectroscopy. Formation of the carbene *(112)* with loss of N_2 is followed by the reactions already discussed for *(102)*, giving the cyclopropenes *(110)* and the allenes *(111)* (Table 11)[52].

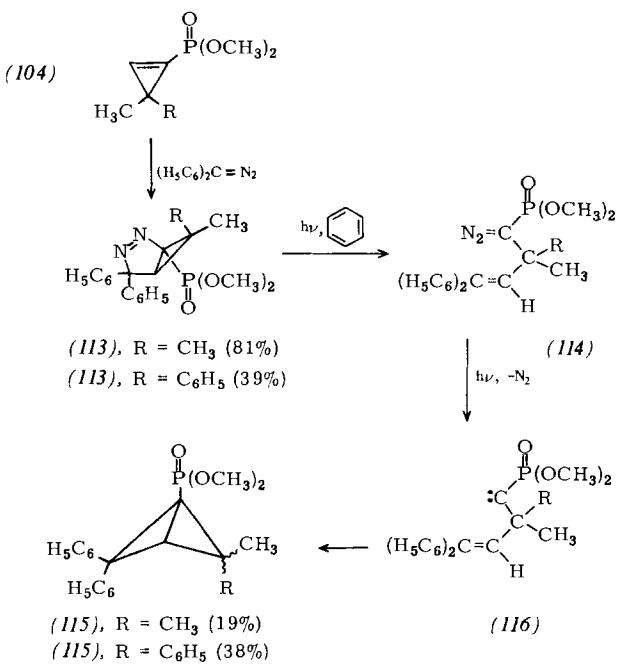
Table 11. 1-Cyclopropenylphosphane oxides *(110)* and propadienylphosphane oxides *(111)* from phosphorylvinylcarbenes *(112)* [52].

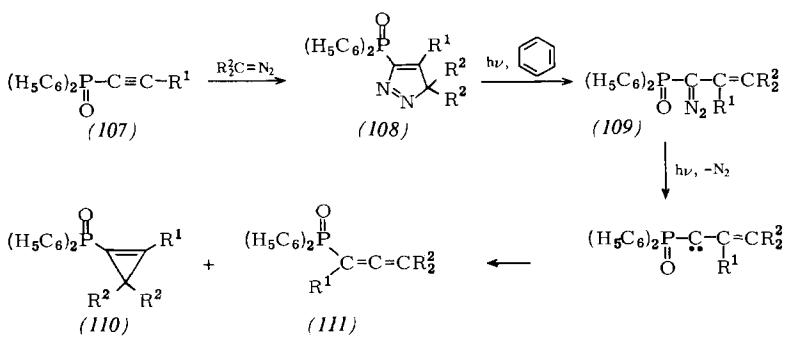
R^1	R^2	Yield [%] *(110)*	Yield [%] *(112)*
C_6H_5	CH_3	77	—
$(C_6H_5)_2P(O)$	CH_3	21	12
$(C_6H_5)_2P(O)$	C_6H_5	60	3

It should be noted that in these cases the shift of the diphenylphosphoryl group in *(112)* must precede allene formation and that the cyclopropene *(110)*, $R^1=(C_6H_5)_2PO$, $R^2=C_6H_5$, can be rearranged photochemically and quantitatively to the allene *(111)*, *(112)* again being a probable intermediate[52].

4.4. Vinylcarbene/Allylcarbene Homologation

This homologation is an extension of cyclization of phosphorylvinylcarbenes to phosphorylcyclopropenes, *e.g.*





(102) → *(104)*. From the latter, by cycloaddition of disubstituted diazoalkanes such as diazodiphenylmethane, one obtains the diazabicyclo[3.1.0]hexenes *(113)*, which on irradiation are converted into the allylcarbenes *(116)* in a photochemical two-step reaction[49].

Ring opening of *(113)* to *(114)* (detectable by IR spectroscopy)[53], which can be interpreted as a [3+2]-cycloreversion, is followed by loss of N_2 to give *(116)*. These carbenes *(116)* undergo intramolecular cyclopropanation to yield the 1-phosphorylbicyclo[1.1.0]butanes *(115)*[49].

Numerous co-workers participated in obtaining the results recorded from our own school. To them I offer my heartfelt thanks for the preparative opening up of phosphorylcarbene chemistry.

New Element-Carbon (p-p)π Bonds

By Peter Jutzi[*]

Recent years have seen the preparation of π systems containing novel (p-p)π bonds between carbon and elements from the third, fourth, and fifth Main Groups of the Periodic Table; most of these compounds are predicted to be incapable of existence according to the classical concepts of the double bond. (p-p)π Bonds between carbon and phosphorus, arsenic, and antimony have been successfully stabilized in resonance-stabilized colored compounds of the cyanine and triphenylmethane type, and also in aromatic systems deriving from benzene, naphthalene, and anthracene. Bismuth-carbon and boron-carbon (p-p)π bonds have likewise been confirmed in aromatic systems. Silicon-carbon and germanium-carbon (p-p)π bonds have been detected in extremely reactive derivatives of silaethylene and germaethylene, respectively. The present report describes characteristic reactions of the new π systems. Their bonding follows from X-ray structure analysis, from photoelectron, UV, and NMR spectra, and from calculations. Criteria for the existence of π systems which are not allowed by the classical double bond rule are discussed; these criteria remain valid on generalization.

1. Introduction

Of the Main Group elements, boron, carbon, nitrogen, and oxygen occupy a special position, being able to form stable (p-p)π bonds. Such bonds are virtually unknown for all other elements with few exceptions. This becomes very clear on comparing element modifications (C-Si, N_2-P_4, O_2-S_8) and also on observation of the structures of comparable compounds (NO_3^--PO_3^-, CO_2-SiO_2, *etc.*).

Experimental failures in attempts to form such π bonds and theoretical work instigated by *Pitzer*[1] and *Mulliken*[2] led to formulation of the so-called "classical double bond rule" which states that elements having a principal quantum number greater than 2 should not be able to form (p-p)π bonds with themselves or with other elements. In strict accord with this rule, relevant compounds possessing El=El bonds were classed as "non-existent compounds".

The highly attractive task of disproving a theory by experiment has recently prompted a number of research groups to undertake renewed studies in this area. As a result, several exceptions to the classical double bond rule have become known.

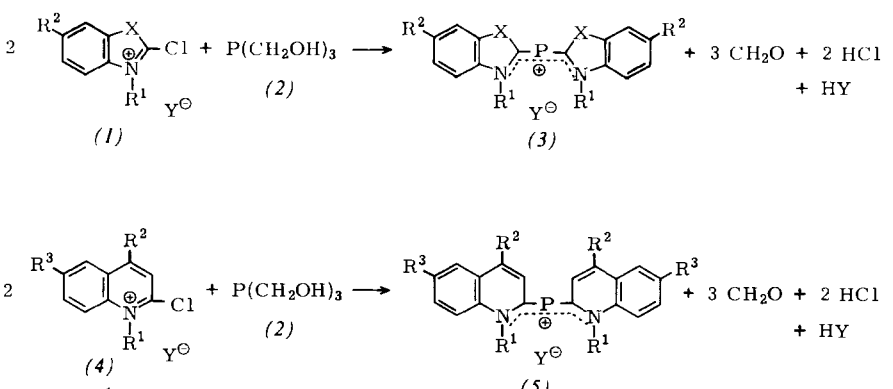
This progress report will present a series of compounds in which (p-p)π bonding has been accomplished for the first time between P, As, Sb, Bi, Si, or Ge on the one hand and carbon on the other. Moreover, bond systems having a B=C double bond will also be described. Although such bonds do not contravene the classical double bond rule, they were also unknown until very recently.

2. P=C, As=C, Sb=C, Bi=C Bonds

2.1. Dyes Having P=C, As=C, and Sb=C Bonds

2.1.1. Phospha- and Arsamethine Cyanines

After *Gier*[3] had demonstrated the existence of P≡C π bonds in 1961 by detection of HC≡P, a species which polymerizes at −130 °C, the first preparation of a stable compound containing a phosphorus-carbon (3p-2p)π bond was accomplished by *Dimroth*'s research school in 1964[4]. Reaction of 2-chlorobenzothiazolium and 2-chloroquinolinium salts [*(1)* and *(4)*, respectively] with tris(hydroxymethyl)phosphane yields resonance-stabilized phosphamethine cyanines *(3)* and *(5)* as stable, yellow to dark red crystalline compounds.



X = S, NR^1

Y = BF_4, ClO_4

R^1 = CH_3, C_2H_5; R^2 = H, Br, OCH_3, CH_3, C_2H_5, $CH(CH_3)_2$; R^3 = H, Br, OCH_3

This synthetic principle was later modified by *Märkl et al.*[5], who used tris(trimethylsilyl)phosphane in place of *(2)*.

[*] Doz. Dr. P. Jutzi
Institut für Anorganische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

The presence of divalent phosphorus having the coordination number 3 could be unequivocally demonstrated by studies on crystal structure[6, 7]. Thus "bis[*N*-ethyl-2-benzothiazole]-monophosphamethine cyanine perchlorate"[6] (Fig. 1) is in complete accord with the structure postulated by *Dimroth et al.* The two P—C bond lengths of 1.76 Å are significantly shorter than P—C single bonds [for comparison: $(CH_3)_3P$, 1.87 Å; $(C_6H_5)_3P$, 1.83 Å]. The CPC angle is 105° [$(CH_3)_3P$, 100°; $(C_6H_5)_3P$, 103°].

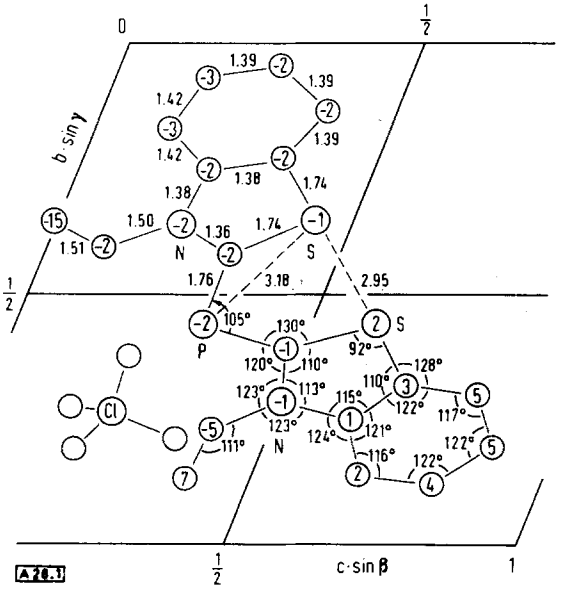


Fig. 1. *y,z* Projection of a perchlorate anion and a phosphacyanine cation with averaged bond lengths [Å] and angles. Deviations from the $2x+y+2z=2$ plane in 1/10 Å are given in the circles.

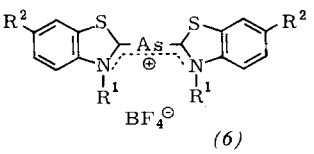
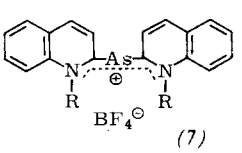
Spectroscopic and chemical investigations on phosphamethine cyanines have recently been reviewed by *Dimroth*[9].

The existence of stable arsenic-carbon (4p-2p)π bonds was first proved by *Märkl*[5] when he synthesized arsamethine cyanines. As in the above synthesis of phosphamethine cyanines, reaction with tris(trimethylsilyl)arsane affords dyes of type *(6)* and *(7)* which are stable in bulk but slowly decompose in solution.



(6)

$R^1 = CH_3, C_2H_5$; $R^2 = H, OCH_3$



(7)

$R = CH_3, C_2H_5$

The ultraviolet/visible spectra of phospha- and arsamethine cyanines closely resemble those of methine- and azamethine cyanines. In accord with the perturbation of the cyanine π-electron system discussed by *Kuhn*[8], decreasing electronegativity of the hetero atom is paralleled by a bathochromic shift of the long-wave absorption maxima (Fig. 2)[5, 9].

2.1.2. Resonance-Stabilized Triarylarsenic(v) and Triarylantimony(v) Cations

Pronounced delocalization extending over the central carbenium ion is assumed to occur in purely organic triphenylmethane dyes. The synthesis of analogous compounds having

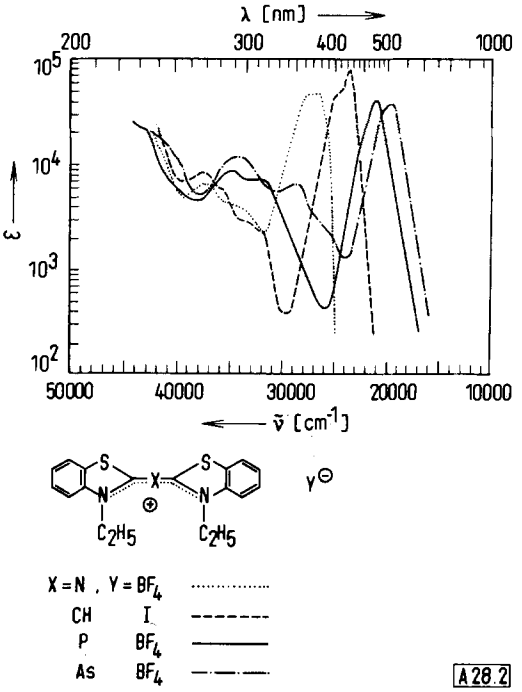


Fig. 2. Ultraviolet/visible spectra of comparable cyanine systems having N, C, P, or As as central atom.

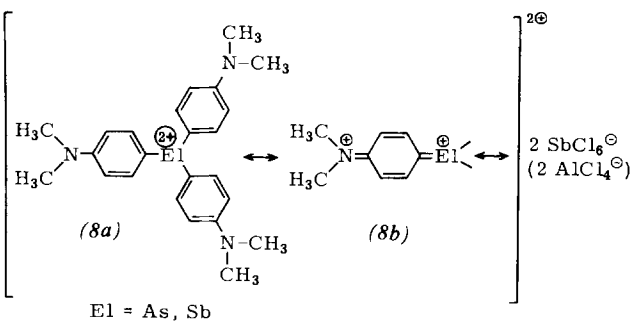
a central arsenic or antimony atom was recently reported by *Klar et al.*[10]. Heating of tris(4-dimethylaminophenyl)arsenic dichloride or -antimony dichloride with antimony pentachloride or aluminum trichloride yields the air- and moisture-sensitive, highly insoluble salts of type *(8)* displaying an intense blue color.



(8a) *(8b)*

El = As, Sb

The UV and ^{1}H-NMR spectra suggest the possibility of resonance *(8a)*⇌*(8b)* and hence a certain degree of double bond character for the element-carbon bonds. (p-p)π Interaction is facilitated in these systems because the higher effective nuclear charge of the central atoms renders the pertinent p orbitals less diffuse and therefore better able to overlap with the C_{2p} π orbitals.

2.2. Phospha-, Arsa-, Stiba-, and Bismutaarenes

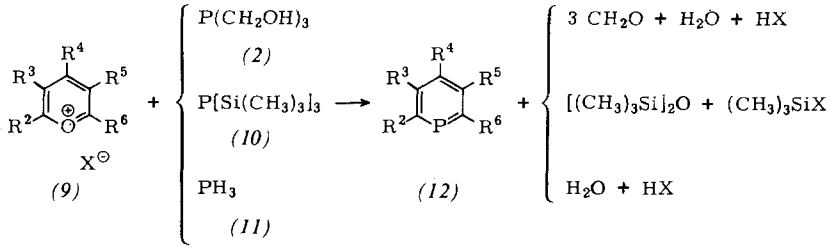
2.2.1. Preparation and Structure of Phosphaarenes

A phosphorus-carbon (3p-2p)π bond was first stabilized in a Hückel π system by *Märkl*[11] in 1966. Reaction of 2,4,6-triphenylpyranylium tetrafluoroborate *(9)* with tris(hydroxymethyl)phosphane *(2)* leads to the surprisingly stable yellow 2,4,6-triphenyl-1-phosphabenzene (2,4,6-triphenyl-λ^3-phosphorin) *(12)*, $R^{2,4,6} = C_6H_5$, $R^{3,5} = H$. Meanwhile more than

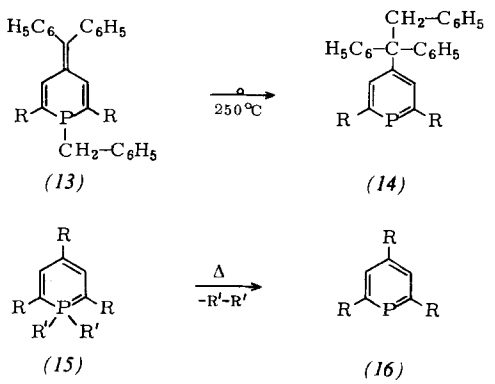
50 aryl-substituted phosphabenzenes have been prepared employing the same synthetic principle[9] under modified conditions. Thus *(9)* and tris(trimethylsilyl)phosphane *(10)* likewise afford compounds of type *(12)*[12], and acid-catalyzed reaction with unsubstituted phosphane itself *(11)* constituted the first preparation of mono-, di-, and trialkyl-substituted phosphabenzenes[13].

In analogous fashion, 4-substituted phosphabenzene derivatives are accessible from corresponding compounds of type *(17)*[19a, 30d].

Benzo-fused phosphabenzenes form much less readily than substituted phosphabenzenes. Thus although the pale-yellow, air-stable crystalline compound 2-phenyl-1-phosphanaphthalene *(21)*[19] is formed on thermolysis of 1-benzyl-2-phenyl-

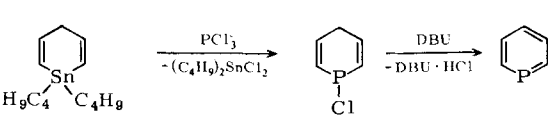


Further synthetic possibilities are provided by thermal rearrangement and elimination reactions. Intermolecular rearrangement of methylenephosphacyclohexadienes to phosphabenzenes *(13)*→*(14)*[14] and the transformation of "non-classical" phosphabenzene derivatives *(15)* into "classical" phosphabenzenes *(16)*[15] may be cited as examples. The reader is referred to the surveys by *Dimroth*[9] and *Märkl*[16] for a discussion of reaction mechanisms and for more detailed information.



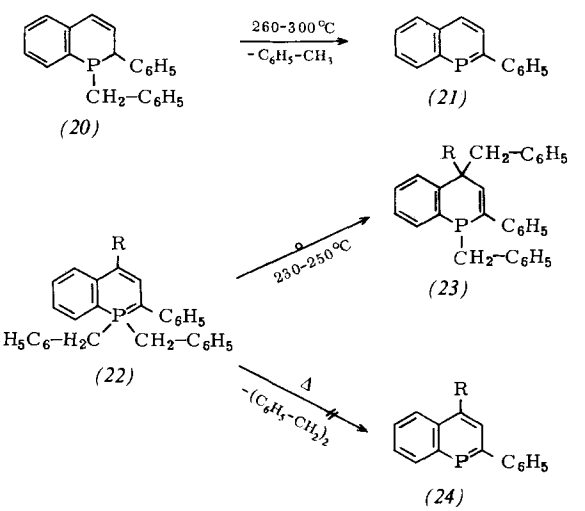
The unsubstituted parent compound of the phosphabenzene series was first prepared by *Ashe*[17] using a completely different approach. 1-Chloro-1-phospha-2,5-cyclohexadiene *(18)* (accessible from 1,1-dibutyl-1-stanna-2,5-cyclohexadiene *(17)* and PCl_3) readily eliminates hydrogen chloride on treatment with bases to give phosphabenzene *(19)* in good yield.

Phosphabenzene, a colorless volatile liquid, is highly reactive compared to its substituted derivatives. It proves to be extremely air- and moisture-sensitive and can only be stored for extended periods under an inert gas. Its structure has been confirmed by ^{1}H-NMR, ^{31}P-NMR, UV, IR, and mass spectra[17] and dipole moment determinations[18].

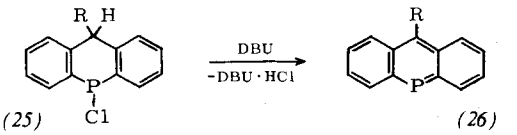


DBU = 1,5-Diazabicyclo[5.4.0]undec-5-ene

1,2-dihydro-1-phosphanaphthalene *(20)*, 1,1-dibenzyl-1-phosphanaphthalene *(22)* no longer reacts like *(15)* but rearranges instead with benzyl migration to form 1,4-dibenzyl-1,4-dihydro-1-phosphanaphthalenes *(23)*[20]. As tertiary phosphanes, these products are energetically favored over phosphanaphthalenes.

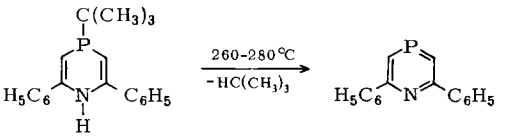


The dibenzo-fused derivative 9-phosphaanthracene (dibenzo[*b*,*e*]phosphorin) is already so unstable—corresponding to the reactivity of positions 9 and 10 of anthracene itself resulting from the π-electron density distribution—that it cannot be isolated. The 9-phosphaanthracene *(26a)* formed on reaction of 9-chloro-9,10-dihydro-9-phosphaanthracene *(25a)* with auxiliary bases can only be detected in solution by UV spectroscopy[21]. Only upon introduction of a phenyl group in position 10 is the reactivity reduced by steric shielding: 10-phenyl-9-phosphaanthracene *(26b)* is an isolable, crystalline, but extremely air-sensitive compound[22].



(a): R = H
(b): R = C_6H_5

The preparative route leading to phosphanaphthalene *(21)* also provides an entry to derivatives of 1-aza-4-phosphabenzene, a new type of aromatic compound with a P=C bond. Thus thermolysis of 2,6-diphenyl-4-*tert*-butyl-1,4-dihydro-1-aza-4-phosphabenzene *(27)* yields 2,6-diphenyl-1-aza-4-phosphabenzene *(28)* as a pale yellow viscous oil[23].



(27) *(28)*

Information concerning the aromatic character and the precise nature of the bonding in phosphabenzenes is provided by spectroscopic and crystal structure studies[24, 25]. The result of an X-ray structure analysis[24] of 2,6-dimethyl-4-phenyl-1-phosphabenzene is depicted in Figure 3. The particularly informative C—P—C distance of 1.74 Å is intermediate between the value for the P—C bond in triphenylphosphane (1.83 Å) and that for the P=C bond in triphenylmethylenephosphorane (1.65 Å). The larger angle in the heterocycle relative to benzene is due to the longer P—C bond. The phosphabenzene ring is almost planar.

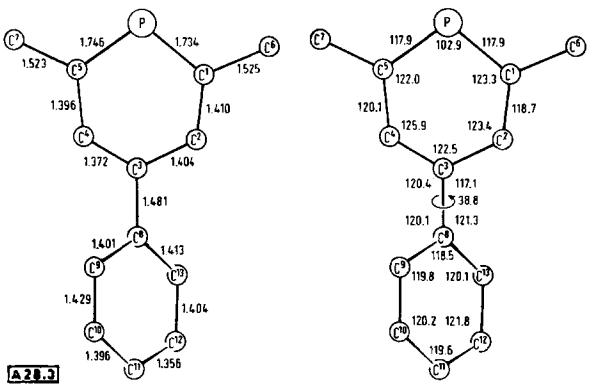


Fig. 3. Projection of a 2,6-dimethyl-4-phenyl-1-phosphabenzene molecule along *a*. Left-hand side: bond lengths [Å]; maximum standard deviation ±0.012 Å. Right-hand side: bond angles [°]; maximum standard deviation ±0.8°.

The ^{1}H-NMR spectra of all phosphabenzenes confirm their aromatic character. The π-electron delocalization follows from the ring current effect which causes the ring proton signals to appear at relatively low field strengths (cf. Section 2.2.4).

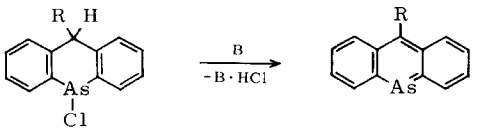
The unusual electronic situation at the phosphorus atom in compounds containing trivalent phosphorus of coordination number 2 is clearly seen in their ^{31}P-NMR spectra. In phosphabenzenes the phosphorus nucleus experiences only slight shielding; the ^{31}P resonance signals appear between $\delta = -170$ and -180 ppm [relative to 85% H_3PO_4, external standard], as against 0 to -60 ppm in normal tertiary phosphanes[9].

The UV spectra of phosphabenzene derivatives are very similar to those of corresponding pyridine and benzene derivatives (cf. Section 2.2.4).

2.2.2. Preparation of Arsa-, Stiba-, and Bismutaarenes

The first indication that it might be possible to stabilize an arsenic-carbon (4p-2p)π bond in a Hückel aromatic compound was obtained when we[26], and almost simultaneously *Bickelhaupt et al.*[27] too, examined the reaction of 9-chloro-9,10-dihydro-9-arsaanthracene *(29a)* with auxiliary bases such as DBU or triethylamine. The product is yellow 9-arsaanthracene *(30a)*, which is however only stable in solution and polymerizes on attempted isolation.

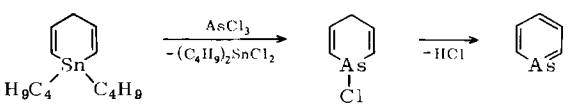
Meanwhile, 10-substituted 9-arsaanthracene derivatives *(30b)—(30e)* have also been prepared; the stability of these heteroarenes shows a significant increase on introduction of a phenyl group[28].



(29) *(30)*

	(a)	*(b)*	*(c)*	*(d)*	*(e)*
R	H	C_6H_5	Cl	Br	OCH_3

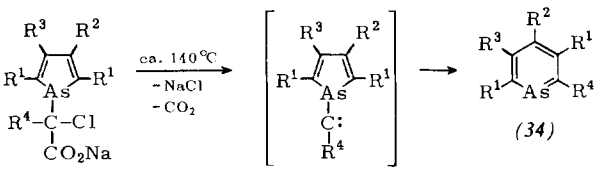
Synthesis of unsubstituted arsabenzene was accomplished by *Ashe* by the same method as was successfully employed for phosphabenzene[17]. Reaction of 1,1-dibutyl-1-stanna-2,5-cyclohexadiene *(17)* with arsenic trichloride to give *(31)* and subsequent elimination of HCl lead to arsabenzene *(32)* as a colorless, highly reactive compound.



(17) *(31)* *(32)*

The ^{1}H-NMR and UV spectra of *(32)* indicate aromatic character (cf. Section 2.2.4).

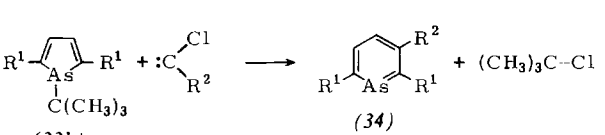
Aryl-substituted arsabenzenes *(34)*, obtained on thermolysis of arsoles *(33a)* by intramolecular carbene insertion[29, 30], are much more stable compounds.



(33a) *(34)*

R^1 = C_6H_5, Naphthyl, *p*-Tolyl
$R^{2,3}$ = C_6H_5, H
R^4 = C_6H_5, Cl, H

Substituted arsabenzenes *(34)* are also accessible by reaction of arsoles of type *(33b)* with phenylchlorocarbene or dichlorocarbene. This synthesis is analogous to the classical pyridine synthesis by ring expansion of pyrroles[30a, b].



(33b) *(34)*

R^1 = C_6H_5
R^2 = C_6H_5, Cl

Further arsabenzenes, some of which bear interesting functional substituents in position 4 ($R = C_6H_5$, *c*-C_6H_{11}, *tert*-C_4H_9, OCH_3, OC_2H_5, CHO, $COOC_2H_5$, $Si(CH_3)_3$, $Ge(CH_3)_3$) can be prepared starting from corresponding stannacyclohexadienes *(17)*[30c, d]. The formyl group in "arsabenzaldehyde", which smells strongly of benzaldehyde, displays a perfectly normal electrophilic reactivity (aldol reaction and aldol condensation with acetone)[30e].

An X-ray structure analysis[31] of 2,3,6-triphenyl-1-arsabenzene (Fig. 4) shows the heterocycle to be planar within the limits of experimental error (C_{2v} symmetry). The As—C bond length of 1.872 Å is shorter than a standard As—C σ bond (1.96 Å). Deviations from 120° in the ring are again a consequence of unequal As—C and C—C bond lengths.

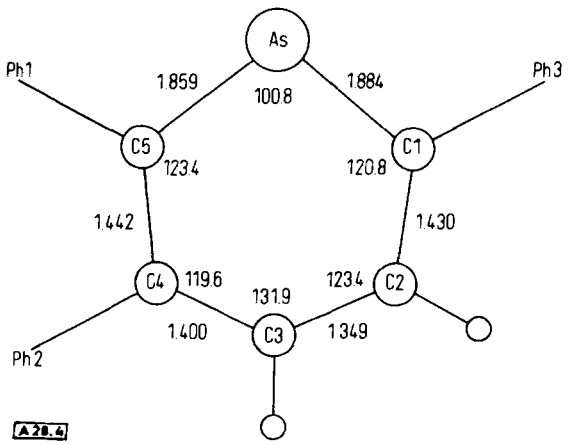


Fig. 4. Bond lengths [Å] and angles [°] in the C_5As ring of 2,3,6-triphenylarsenin. Standard deviations: As—C 0.014, C—C 0.02 Å; C—As—C 0.6, As—C—C 1.0, C—C—C 1.3°.

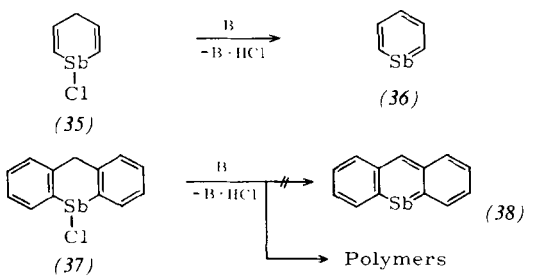
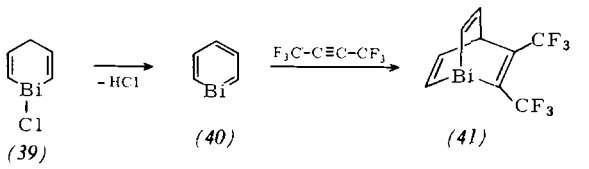
In the light of previous experience, it must be considered highly surprising that even compounds with (5p-2p)π orbital overlapping should be stable under certain conditions. Nevertheless, *Ashe*[32] succeeded in preparing stibabenzene *(36)* by elimination of HCl from 1-chloro-1-stiba-2,5-cyclohexadiene *(35)* and in its unequivocal characterization. The compound is stable only at low temperature ($\lesssim -80$ °C) in bulk and polymerizes on warming. It can, however, be conveniently handled in solution under an inert atmosphere.

Attempts to prepare 9-stibaanthracene *(38)* by the method employed in the synthesis of *(30)* were unsuccessful[33]. Although HCl can be eliminated quantitatively from 9-chloro-9,10-dihydro-9-stibaanthracene *(37)* with auxiliary bases, the reaction only yields polymeric products even at low temperature. The lower gain in resonance energy in the anthracene system no longer suffices to stabilize an Sb=C bond.

It is even possible to detect a (6p-2p)π bond by trapping reactions at low temperature. On elimination of HCl from 1-chloro-1-bismuta-2,5-cyclohexadiene *(39)* *Ashe*[34] obtained



bismutabenzene *(40)*, which is only stable in solution. The compound was characterized as the Diels-Alder adduct *(41)* formed on reaction with hexafluoro-2-butyne.

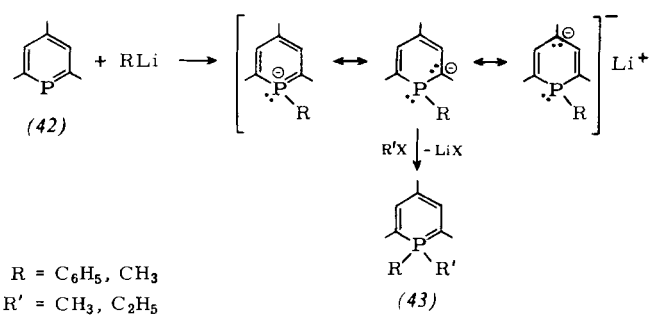


2.2.3 Reactions of Phospha-, Arsa-, Stiba-, and Bismutaarenes

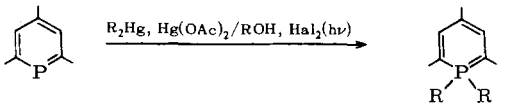
Among the new heteroaromatic compounds the chemistry of substituted phosphabenzenes has been investigated particularly thoroughly and already described in reviews by *Dimroth*[9] and *Märkl*[16]. The most interesting results will be summarized briefly and supplemented in this Section.

In comparison with pyridine, the very slight nucleophilic character of phosphabenzenes is rather striking. According to *Pearson*'s acid-base concept[35] they are classed as "soft" bases, and fail to react with "hard" acids. Attempted protonation, alkylation, and acylation gave negative results. The calculated pK_a value (≈ -10) of phosphabenzenium salts differs considerably from that of the pyridinium ion (≈ 5)[36]. In contrast, reactions with "soft" acids are feasible: 2,4,6-triphenyl-1-phosphabenzene *(12)* ($R^{2,4,6} = C_6H_5$) forms σ complexes with transition metals such as tantalum[37], chromium[38], molybdenum[38], tungsten[38], ruthenium[37], rhodium[37], palladium[37], copper[37], and gold[39]. Of these complexes, those containing Cr, Mo, W, and Au have been unequivocally confirmed by spectroscopic and structural studies. Thus the crystal structure of pentacarbonyl(2,4,6-triphenyl-1-phosphabenzene)chromium(0)[40] shows that all the bond lengths in the heteroaromatic ring of the σ complex correspond to those in the free ligand. The geometry of the complexed phosphabenzene is best described by assuming sp^2 hybridization of the phosphorus atom.

Substituted phosphabenzenes *(42)* display marked electrophilic behavior in numerous reactions. Thus they react with organolithium or organomagnesium compounds to give intensely colored anions which are attacked by electrophiles either at the P atom or at C-2 or C-4[41]; with S_N1-reactive alkyl halides the thermodynamically most stable products are 1,1-disubstituted "non-classical" phosphabenzenes *(43)*, deeply colored, generally strongly fluorescing compounds with phosphorus-carbon (d-p)π bonds.



Oxidation of "classical" to "non-classical" phosphabenzenes can also be achieved by radical reactions, as demonstrated by reactions with mercurials and with halogens[9].

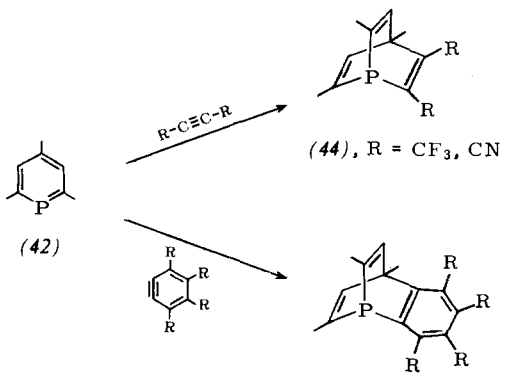


(42) (43)

R = CH_3, C_2H_5, C_6H_5, CH_3–C_6H_4, $CH_3OC_6H_4$, $(CH_3)_2N$–C_6H_4, C_6H_5–CH_2, 2,2'-Biphenyldiyl, OCH_3, OC_2H_5, Cl, Br

Oxidizing agents such as oxygen, halogen, nitric acid, or hydrogen peroxide lead to attack at various ring positions, depending upon how the reaction is conducted. The products are either 1,1-disubstituted λ^5-phosphabenzenes or phosphinic acid derivatives and other oxidation products formed by degradation of the 6π system[9].

The diene character of phosphabenzenes is only slight. As in the case of benzene, Diels-Alder $[\pi 4_s + \pi 2_s]$ cycloadditions occur only with highly reactive dienophiles such as hexafluoro-2-butyne, dicyanoacetylene, or arynes, to form compounds *(44)* and *(45)*, respectively[42–44].

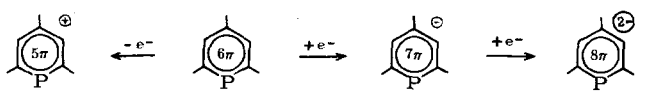


(42) (44), R = CF_3, CN

(45), R = H, Cl

Substituted phosphabenzenes react all the more readily the greater their "electron richness". Retro-Diels-Alder reactions are not observed.

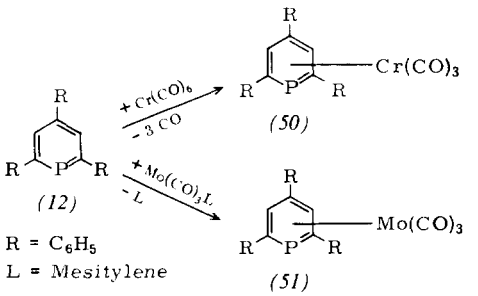
Electron transfer reactions in the π system of phosphabenzenes have led to interesting results. Thus substituted phosphabenzenes can be oxidized very easily to air-stable cation radicals *(46)* which are also highly stable in solution. ESR studies show that these radicals contain an intact phosphabenzene ring. The phosphabenzene anions *(47)* and *(48)* formed on electron addition are much less stable.



(46) (42) (47) (48)

ESR experiments and redox reactions evidence a stepwise reduction *via* the paramagnetic monoanion *(47)* to the diamagnetic dianion *(48)*[9]. Ready formation of anions *(47)* and *(48)* is in accord with the lower half-wave reduction potentials of phosphabenzenes relative to pyridine.

In their complexes with transition metals, phosphaarenes act not only as σ-bonded but also as π-bonded ligands. Thus reaction of 2,4,6-triphenyl-1-phosphabenzene *(12)* with $Cr(CO)_6$ in boiling dibutyl ether leads to tricarbonyl(2,4,6-triphenyl-η^6-1-phosphabenzene)chromium(0) *(50)*, and with tricarbonyl(mesitylene)molybdenum(0) at room temperature to the analogous molybdenum compound *(51)*[45].

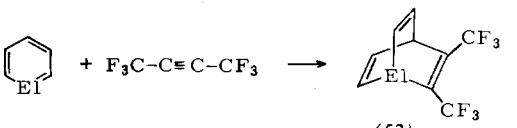


(12) (50) (51)

R = C_6H_5
L = Mesitylene

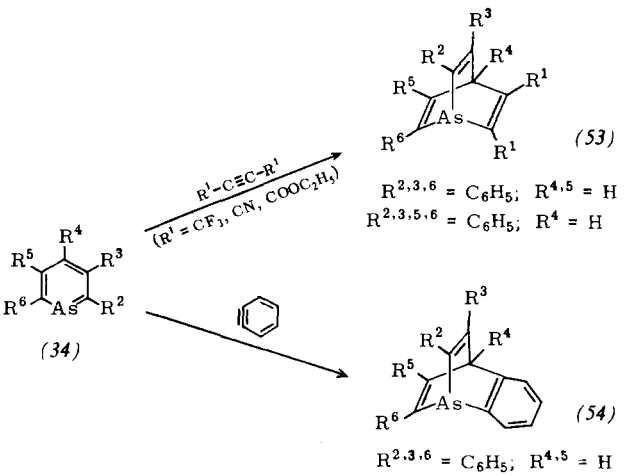
X-Ray structure analysis[46] of *(50)* confirms the presence of a true π-arene complex, the $Cr(CO)_3$ group being bound centrically to the phosphabenzene ring.

In contrast, little is known about the properties of arsa-, stiba-, and bismutaarenes. Only their Diels-Alder reactions have so far been described. For instance, arsabenzene, stibabenzene, and—as already mentioned—bismutabenzene afford corresponding cycloadducts *(52)* with hexafluoro-2-butyne[44].



El = As, Sb, Bi (52)

Unlike aryl-substituted phosphabenzenes, aryl-substituted arsabenzenes can also add to less reactive dienophiles to yield compounds of type *(53)*, and thus exhibit a more pronounced diene reactivity; cycloadditions with arynes lead to arsabarrelenes *(54)*[47].



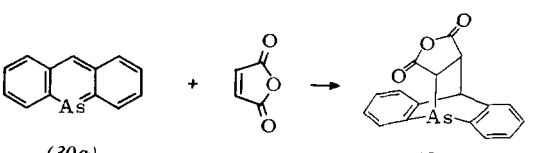
(34) (53)

$R^{2,3,6}$ = C_6H_5; $R^{4,5}$ = H
$R^{2,3,5,6}$ = C_6H_5; R^4 = H

(54)

$R^{2,3,6}$ = C_6H_5; $R^{4,5}$ = H

Expectedly, the anthracene system is also susceptible to Diels-Alder reactions with weak dienophiles under very mild conditions: *e.g.*, 9-arsaanthracene adds maleic anhydride to form *(55)*[26].



(30a) (55)

2.2.4. Photoelectron, UV, and ^{1}H-NMR Spectra

Photoelectron (PE) Spectra

The highest occupied molecular orbitals (HOMO) are of fundamental significance for the properties and reactivity of

a compound. Information about their assignment and energy is provided by PE spectra. Of the series of new heterocycles, photoelectron spectra have been published for phospha-, arsa-, and stibabenzene, for 2,4,6-tri-*tert*-butyl-1-phosphabenzene, 10-phenyl-9-phosphaanthracene, and 10-phenyl-9-arsaanthracene, and compared with previously recorded spectra of benzene and pyridine derivatives[48-50].

Table 1 lists the vertical ionization potentials of benzene, pyridine, and phospha-, arsa-, and stibabenzene. Assignment of the individual bands to π and n/σ ionization processes is based on both characteristic band shapes and on model calculations.

Table 1. Vertical ionization energies for benzene, pyridine, and phospha-, arsa-, and stibabenzene and their assignments.

PE Band		I_v [eV]		I_v [eV]		I_v [eV]		I_v [eV]		I_v [eV]
1	$a_1\ \sigma, n$	9.7	$b_1\ \pi$	9.2	$b_1\ \pi$	8.8	$b_1\ \pi$	8.3	$e_{1g}\ \pi$	9.24
2	$a_2\ \pi$	9.8	$a_2\ \pi$	9.8	$a_2\ \pi$	9.6	$a_2\ \pi$	9.4	$e_{2g}\ \pi$	11.24
3	$b_1\ \pi$	10.5	$a_1\ \sigma, n$	10.0	$a_1\ \sigma, n$	9.9	$a_1\ \sigma, n$	9.6	$a_{2u}\ \pi$	12.19
4	$b_2\ \sigma$	12.5	$b_2\ \sigma$	11.5	$b_2\ \sigma$	11.0	$b_2\ \sigma$	10.4		
5	$b_1\ \pi$	12.6	$b_1\ \pi$	12.1	$b_1\ \pi$	11.8	$b_1\ \pi$	11.7		

Decreasing electronegativity of the heteroatom is accompanied by a decrease in ionization energy. The sequence of MOs determined by *ab initio*[48] and CNDO/2[36] calculations is confirmed most convincingly by the PE data, especially by the sequence reversal of the two highest MOs first observed for these heteroaromatic compounds: while the $a_2(\pi)$ orbital [node at hetero atom] of pyridine is expectedly of higher energy than the $b_1(\pi)$ orbital [lobe at hetero atom], the situation is completely reversed in phospha-, arsa-, and stibabenzene, where the $b_1(\pi)$ orbital is always the HOMO. This reversal is understandable in view of the calculated electron density distribution[36,48]: the hetero atom nitrogen has an overall electron acceptor effect and stabilizes the $b_1(\pi)$ orbital; phosphorus, arsenic, and antimony have the opposite effect and thus stabilize the $a_2(\pi)$ orbital.

Unequivocal proof for this unusual sequence of the two highest occupied π-MOs is provided by comparison of the PE spectra of 9-phenylanthracene, 9-phenylacridine, 10-phenyl-9-phospha- and 10-phenyl-9-arsaanthracene[50] since, in contrast to the benzene system, the highest π-MO in anthracene is not degenerate.

The energies of the free electron pairs on the hetero atoms [$a_1\sigma$/n] are qualitatively of the same order owing to varying mixing of s and p atomic orbitals. Analogous effects are observed on comparison of NH_3 with PH_3, AsH_3, and SbH_3[51].

Estimates of the influence of hetero atom d orbitals on the bonding in the new aromatic compounds tend to vary: according to calculations by *Heilbronner et al.*[48] the effects of d orbitals can be neglected for all molecular orbitals, whereas *Schweig et al.*[36] consider the individual MOs to be stabilized to differing degrees by interaction with d orbitals.

Ultraviolet/visible Spectra

Comparison of the UV/vis spectra of analogous derivatives of benzene, pyridine, and phospha-, arsa-, and stibabenzene clearly reveals structural similarities in the band shapes and a systematic trend with regard to the longest wave absorption maxima. The influence of the hetero atom is manifested in a bathochromic shift of the π-π* transitions. A decreasing π-π* excitation energy runs parallel to the fall in electronegativity of the hetero atom and the likewise decreasing bond strength of corresponding El=C bonds.

Table 2. Longest-wave UV absorption of benzene, pyridine, and phospha-arsa-, and stibabenzene.

λ_{max} [Å]	256	250	246	268	312
	200	192	213	219	236
	180	175			

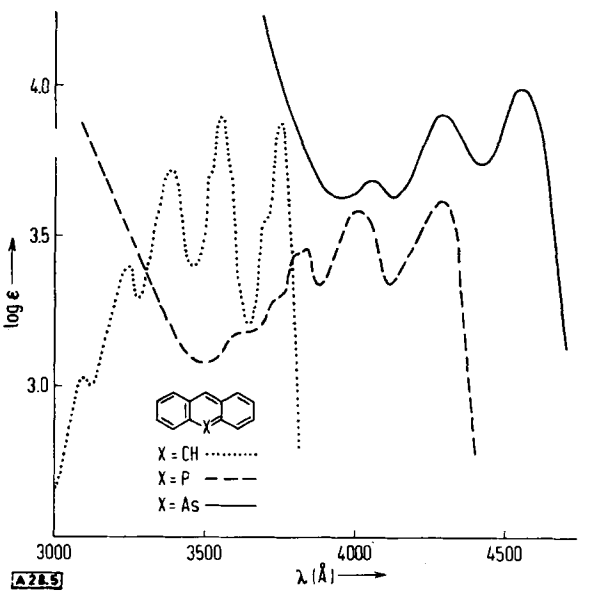


Fig. 5. UV spectra of anthracene (in cyclohexane), 9-phosphaanthracene (in toluene), and 9-arsaanthracene (in THF).

Table 2 shows a comparison of the longest wave absorptions of benzene, pyridine, and phospha-[17], arsa-[17], and stibabenzene[32] (the extinction values are not comparable owing to changes in selection rules). Figure 5 reproduces the long wave regions of the anthracene and phospha- and arsaanthracene spectra[26]; the almost superposable structure of the longest wave absorption bands of phospha- and arsaanthracene and their close similarity to the $1/L_A$ band of anthracene are striking.

^{1}H-NMR Spectra

According to their ^{1}H-NMR spectra, the new heterocycles are aromatic in so far as they display a pronounced ring current effect[9, 16, 17, 32]. The resonances of the ring protons lie at fairly low field. On comparison of the ^{1}H-NMR spectra of pyridine and phospha-, arsa-, and stibabenzene, the progres-

sive downfield shift for the CH protons α to the hetero atom is particularly striking (Table 3).

In molecules with strongly polar groups the electrical dipole moment may be expected to lead to a change in the charge density on certain protons. The dipole moment in pyridine causes deshielding of the α-protons. On going from pyridine to phospha-, arsa-, and stibabenzene this effect should be reduced and an upfield shift occurs in the α-proton signals.

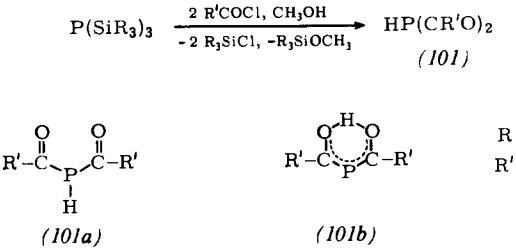

Table 3. Chemical shifts [ppm], coupling constants [Hz] in the ^{1}H-NMR spectra of pyridine [104] and phospha-, arsa-, and stibabenzene [105].

	$\delta_{2\text{-H}}$	$\delta_{3\text{-H}}$	$\delta_{4\text{-H}}$	J_{23}	J_{34}	J_{24}	J_{35}	J_{25}	J_{26}	J_{PCH}
	8.29	7.38	7.75	5.5	7.5	1.9	1.6	0.9	0.4	
	8.61	7.72	7.38	10.0	9.1	1.25	1.80	1.25	−1.90	38
	9.11	7.83	7.53	10.2	8.1	1.05	2.45	1.06	−1.3	
	10.94	8.24	7.78	9.0	11.5	1.0	1.0	4.0	−4.0	

The downfield shift actually observed is therefore attributed to the dominating influence of the magnetic anisotropy of the increasingly large hetero atom[32].

2.3. Other P=C Systems

As early as 1967, Russian authors described an astonishingly simple route to compounds having a phosphorus-carbon (3p-2p)π bond. Reaction of the phenylhydrazones of dimethyl, methyl ethyl, methyl propyl, and methyl butyl ketone with phosphorus trichloride affords isomeric mixtures of 1,2,3-diazaphospholes of type *(100)*[106].

	(a)	(b)	(c)	(d)
R^1	H	H	H	H
R^2	H	CH_3	C_2H_5	C_3H_7

(100)

The structures of these compounds have been confirmed by ^{1}H- and ^{31}P-NMR, IR, and UV spectra, as well as by electron diffraction experiments[107]. Comparison of the UV spectra of *(100)* with those of corresponding 1,2,3-triazoles reveals a slight bathochromic shift, such as is also observed on going from pyridines to phosphabenzenes. The P=C bond length of 1.75 Å also agrees with expectations.

A keto-enol tautomerism involving a P=C bond system has recently been reported for the first time[108]. Stepwise reaction of tris(trimethylsilyl)phosphane with pivaloyl chloride and methanol affords dipivaloylphosphane *(101)*, shown by spectroscopic findings to exist in the keto *(101a)* and in the enol form *(101b)*. Increasing solvent polarity favors the keto form.

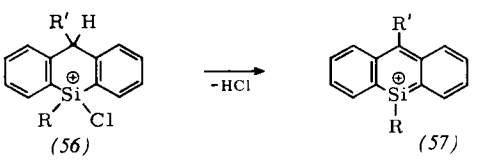
An X-ray structure analysis performed at −80 °C shows that *(101)* assumes the enol form in the solid state (*R* value, 7.4 %; P=C, 1.79 Å).

3. Si=C and Ge=C Bonds

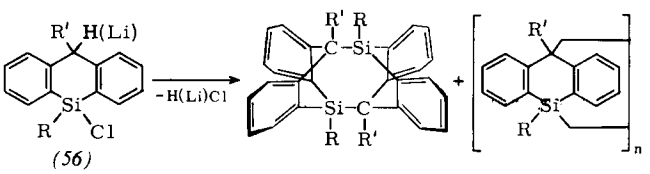
3.1. Experiments on Synthesis of Resonance-Stabilized π-Systems

The reactions described in Section 2 which lead to novel (p-p)π bonds between carbon and elements of the fifth Main Group have sometimes been applied to the formation of such bonds with elements of the fourth Main Group—so far without success.

Thus 9-R-10-R'-9-silaanthracenes cannot be obtained from 9-R-9-chloro-10-R'-9,10-dihydro-9-silaanthracenes *(56)* by elimination of HCl, or of LiCl after prior metalation. Although the desired silaarenes *(57)* appear at remarkable intensities in the mass spectrum[52, 53], the necessary elimination fails to occur in a chemical experiment and reaction proceeds *via* intermolecular substitution leading to dimeric or polymeric products[53–55].



(56) *(57)*



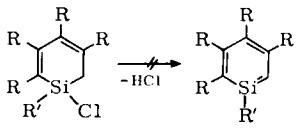
(56)

R = C_6H_5, $C_6H_2(CH_3)_3$, Cl, F, OC_2H_5, C_4H_9, CH_3

R' = $Si(CH_3)_3$, Cl, Br, $COOCH_3$

Analogous results are obtained with 9,10-dihydro-9-germaanthracene derivatives[54].

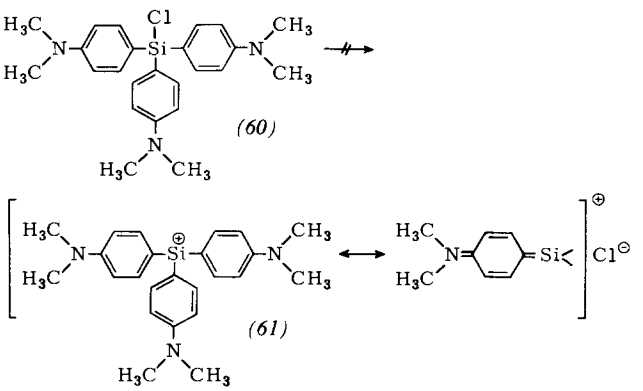
Even the greater gain in resonance energy in the benzene system compared with the anthracene system is not sufficient to stabilize a Si=C bond: although HCl can be eliminated quantitatively from 1-R'-1-chloro-1-sila-2,4-cyclohexadiene *(58)*, no silabenzene *(59)* can be detected, not even as intermediate[56–58].



(58) (59)

R = C_6H_5, H
R' = C_6H_5, CH_3

Attempts to synthesize dyes having a resonance-stabilized Si=C bond have also been described. Tris(4-dimethylaminophenyl)chlorosilane *(60)*, prepared by *Wannagat et al.*[59] in 1955, admittedly corresponds to a "silicocrystalviolet" in composition, but is not ionic in structure and therefore color-

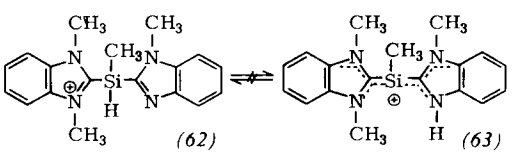


(60)

(61)

less. In this case (p→d)π interactions have such a pronounced stabilizing effect that ionization with resonance stabilization of cation *(61)* is energetically disfavored[59, 10].

Attempted preparations of silamethine cyanine dyes led as far as the successful synthesis of apparently suitable precursors of type *(62)*, but proton migration leading to a resonance stabilized Si=C bond as in *(63)* failed to occur. The proton attached to silicon is still bound as hydride in spite of electron withdrawal by the heterocycles[60].



(62) *(63)*

The first indication of a resonance-stabilized Ge=C bond was obtained by *Curtis*[103] on synthesis of 1-lithio-1,2,3,4,5-pentaphenyl-1-germacyclopentadiene. Investigations on the ionic character of this compound and on resonance stabilization in the anionic 6π system have yet to be performed.

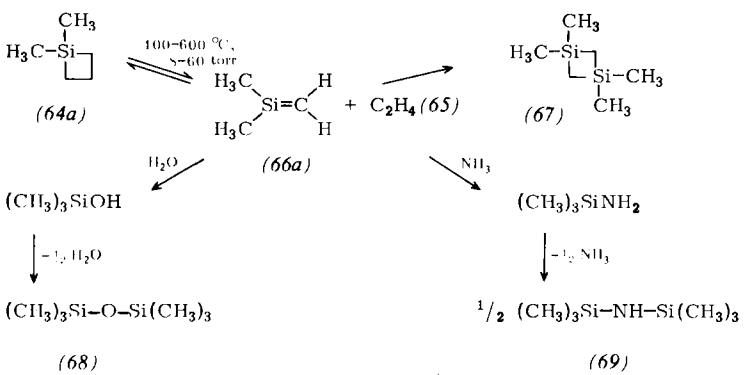
3.2. Silaalkenes and Germaalkenes

Alkene-analogous compounds containing Si=C or Ge=C bonds have frequently been postulated to explain reaction mechanisms[61], but definite proof of these short-lived species was obtained only recently from pyrolysis reactions and photochemical experiments.

3.2.1. Thermolysis Reactions

Studies performed by *Gusel'nikov et al.*[62-64] on 1,1-dimethyl-1-silacyclobutane *(64a)* showed the thermal behavior of this compound to differ in the liquid and gaseous states. Whereas *(64a)* decomposes at about 150°C under normal pressure to give polymeric products, in the gaseous phase it undergoes cleavage in clearly defined manner when heated above 400°C at pressures between 8 and 60 torr; the sole products are ethylene *(65)* and the highly reactive species 2-methyl-2-silapropene *(66a)*, which can only be kept for a short time. Compound *(66a)* dimerizes very rapidly to 1,1,3,3-tetramethyl-1,3-disilacyclobutane *(67)*, but can be trapped by water or ammonia to form hexamethyldisiloxane *(68)* or hexamethyldisilazane *(69)*, respectively.

Kinetic data[64] show the cleavage of *(64a)* to *(65)* and *(66a)*, like that of octafluorocyclobutane to tetrafluoroethylene[65], to be a reversible first order reaction with Arrhenius parameters resembling those for the thermal degradation of alkylcyclobutanes. A triplet ground state is ruled out for *(66a)*. The trapping reactions affording *(68)* and *(69)* are faster than the reverse reaction leading back to *(64a)* and dimerization to *(67)*.

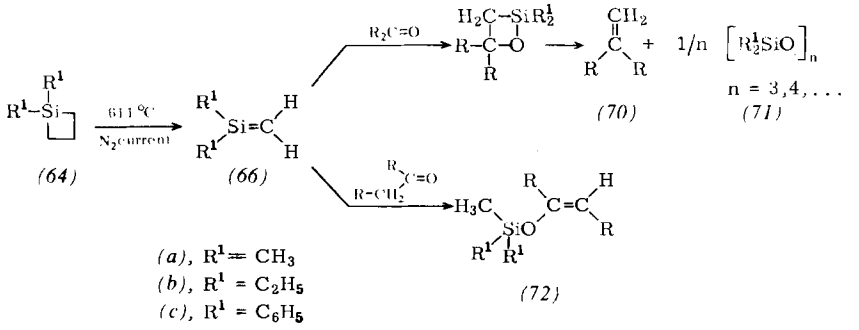


(64a) *(66a)* *(67)* *(68)* *(69)*

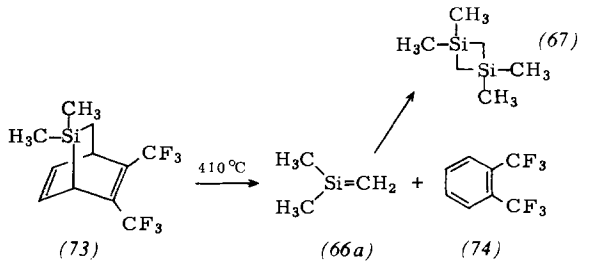
In similar manner, *Sommer et al.*[66a, b] prepared the silaalkenes *(66b)* and *(66c)*, and investigated their reactivity towards various trapping reagents. They undergo a kind of "Wittig reaction" with non-enolizable ketones to give olefins *(70)* and cyclic siloxanes *(71)*, while siloxyalkenes *(72)* are formed with enolizable ketones.

Trapping reactions with halosilanes provide arguments in favor of strongly polar Si=C double bonds[66c].

Another method of preparing silaalkenes has been developed by *Barton et al.*[67-69]. Thermal decomposition of 2,3-bis(trifluoromethyl)-7,7-dimethyl-7-silabicyclo[2.2.2]octa-2,5-diene *(73)* furnishes *o*-bis(trifluoromethyl)benzene *(74)* and 2-methyl-2-silapropene *(66a)*, which can be isolated in a matrix and characterized by its IR spectrum. The very intense band at 1407 cm^{-1} is assigned to the C=Si stretching vibration. This band disappears on heating, when *(66a)* dimerizes to disilacyclobutane *(67)*.

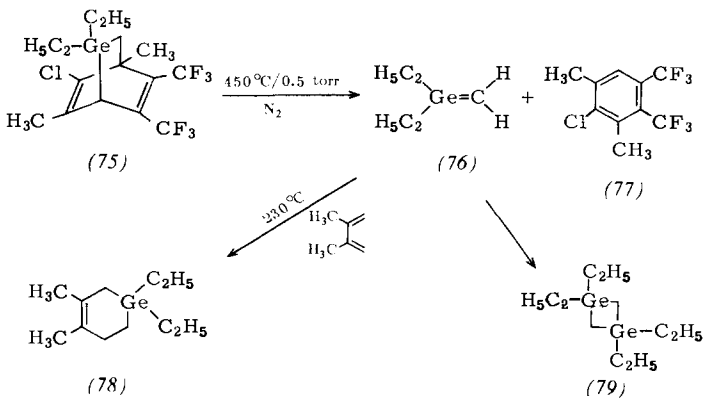


(a), $R^1 = CH_3$
(b), $R^1 = C_2H_5$
(c), $R^1 = C_6H_5$



Further evidence for the occurrence of short-lived silaalkenes was obtained from kinetic studies on the pyrolysis of tetramethylsilane[70]. The pyrolysis products of trimethylsilane can also be easily explained in terms of silaalkene intermediates[71, 72].

Analogous experiments were performed with the aim of forming germanium-carbon (4p-2p)π bonds. While pyrolysis reactions of germacyclobutane derivatives have not yet afforded unambiguous proof for the existence of a germaalkene[73], the decomposition products of 2,3-bis(trifluoromethyl-4,6-dimethyl-5-chloro-7,7-diethyl-7-germabicyclo[2.2.2]octa-2,5-diene *(75)* at 450°C/0.5 torr indicated formation of a short-lived 2-ethyl-2-germabutene *(76)*[74]. It can either be trapped with 2,3-dimethylbutadiene to give *(78)* or be detected as the dimerization product *(79)*.

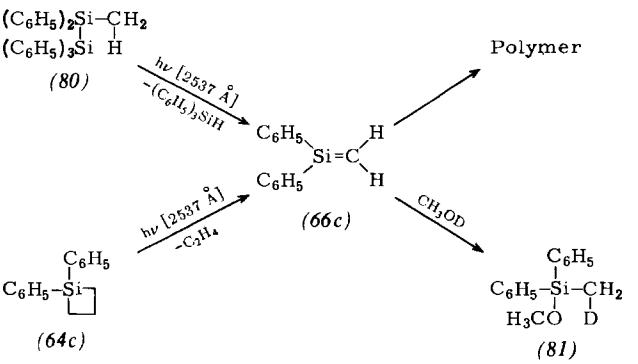


The above thermolytic studies show that sila- and germaalkenes can indeed exist in the gaseous phase at suitable dilutions but decompose very fast in the condensed state and in the usual solvents owing to their kinetic lability. Detection of these compounds by gas phase kinetic studies has been particularly successful.

3.2.2. Photochemical Reactions

Synthesis of extremely short-lived silaalkenes can be accomplished not only by thermal but also by photochemically induced homolysis. Thus irradiation ($\lambda = 2537$ nm) of pure 1,1-dimethyl-1-silacyclobutane *(64a)* at 28 and 77 K yields 2-methyl-2-silapropene *(66a)* which can be characterized by its uniform dimerization to 1,3-disilacyclobutane *(67)*. In cyclohexane solution the same reaction becomes very complicated and *(67)* is formed in only very small yield[67].

Nevertheless, *Sommer et al.* were also able to detect a transient silaalkene in photochemical reactions conducted in solution. Photolysis of both pentaphenylmethyldisilane *(80)*[75] and 1,1-diphenyl-1-silacyclobutane *(64c)*[76] yields 1,1-diphenyl-1-silaethylene *(66c)* which can be trapped as *(81)* with deuteriomethanol.



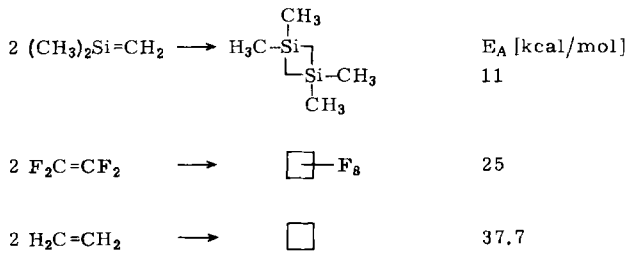
Although the dark reaction of *(64c)* with CH_3OD also entails ring cleavage it leads to different products. It is still unclear whether intermediates having paired electron spins or diradical species are formed in these photochemical experiments.

Intermediates having a Si=C bond have recently also been detected in photochemical and thermal isomerizations. Thus 1-sila-1,3,5-hexatrienes[109] appear transiently during photoisomerization of 1-sila-2,4-cyclohexadiene derivatives; thermally induced *cis-trans* isomerization of propenylallyldimethylsilane proceeds after the manner of a reversible Cope rearrangement *via* a 1,1,3-trimethyl-1-sila-1,5-hexadiene[110].

3.3. Bond Energies and Calculations of Molecules

The π-bond energy in silaalkenes has been crudely estimated from thermodynamic and kinetic data gained for the pyrolysis of 1,1-dimethyl-1-silacyclobutane and of trimethylsilane[77]. It lies between 29 and 45 kcal/mol for 2-methyl-2-silapropene and between 29 and 37 kcal/mol for 2-silapropene. The difference between the dissociation energies of the Si—C bonds in silicon carbide and tetramethylsilane gave a value of about 28 kcal/mol for the π-bond energy in silaethylene[78]. Hence a Si=C π bond is roughly half as strong as a C=C π bond.

EHMO and CNDO calculations[79] on the silaethylene bond system show that interaction between 2pπ(C) and 3pπ(Si) electrons is not particularly effective. This is due less to inadequate orbital overlapping than to the considerable energy difference between the participating C 2p and Si 3p orbitals, which is manifested in a very high polarity, especially in the readily polarizable π system: $H_2C{=}SiH_2 \leftrightarrow H_2\overset{\ominus}{C}{-}\overset{\oplus}{S}iH_2$. The dipole moment of 2.9 D obtained by CNDO calculations[79] for silaethylene is correspondingly high. Of course, the polarity of the C=Si bond facilitates cyclodimerization reactions, as is clearly seen from the low activation energies relative to C=C bond systems[64, 79].



Thus it becomes understandable that silaalkenes can only exist in the gas phase and at low pressures, and can most readily be detected under these conditions which are not nearly so conducive to dimerization as they are in the liquid phase. According to recent CNDO/2 calculations, however, suitable substitution should lead to Si=C bonds that are stable even under normal conditions[79].

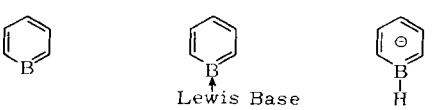
4. B=C Bonds

4.1. Preparation of Boraarenes

The pertinent literature contains several hints that the element boron is fundamentally capable of forming (p-p)π bonds[80]. Thus investigations in boron-nitrogen chemistry show that replacement of a C=C unit in benzene by the isoelectronic $\overset{\ominus}{B}{=}\overset{\oplus}{N}$ grouping leads to systems displaying aromatic properties. Stable bonds to the boron atom can also be deduced from overlap integrals[81, 82]. It is therefore astonishing that no aromatic compound having boron as sole hetero atom was known until very recently. In such compounds a (—CH=) unit in a Hückel π system is replaced by the isoelectronic $(-\overset{\ominus}{B}H{=})$ unit[83].

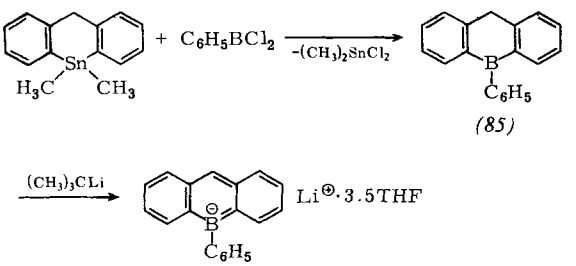
Even if it can exist at all, borabenzene will certainly be extremely unstable owing to its Lewis acidity and its inherent ring strain arising from the hybridization of the boron atom. However, it should be stabilized in compounds of type *(83)* by adduct formation with Lewis bases and attendant rehybridization to sp^2. Anions of type *(84)* isoelectronic with benzene are likewise conceivable.

During the past few years derivatives of *(83)* and *(84)* have been synthesized for the first time and studied with regard to their aromatic properties.

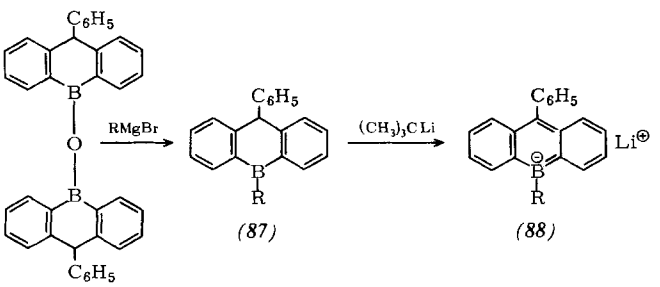


(82) *(83)* *(84)*

For example, metalation of 9-phenyl-9,10-dihydro-9-boraanthracene *(85)* in THF/pentane at −78 °C afforded the 9-phenyl-9-boraanthracene anion, which could be isolated as the solvent-separated ion pair *(86)*[84].



The same kind of reaction gives solvent-free 9-mesityl-10-phenyl-9-boraanthracene anion *(88)*[85] from 9-mesityl-10-phenyl-9,10-dihydro-9-boraanthracene *(87)*, and spectroscopic evidence has also been obtained for the 9-mesityl-9-boraanthracene anion[86].



R = Mesityl

The structure of the boraarene *(86)* is confirmed by its ^{1}H-NMR, ^{11}B-NMR, and UV spectra, and that of *(88)* by its UV spectrum and analytical and spectroscopic data of its deuterolysis product. Thus the proton resonance signals of *(86)* are compatible with a ring current and/or reduced negative charge on C^{10}; in the ^{11}B spectrum the π bond to boron and the consequently enhanced electron density on the boron atom shift the resonance signal upfield. The ultraviolet-visible spectra of *(86)* and *(88)* are especially characteristic of aromatic systems, and closely resemble those of 9-phospha- and 9-arsaanthracene [*(26a)* and *(30a)*] in structure. The longest wave absorption bands are almost identical, thus indicating comparable π-electron systems (Fig. 6).

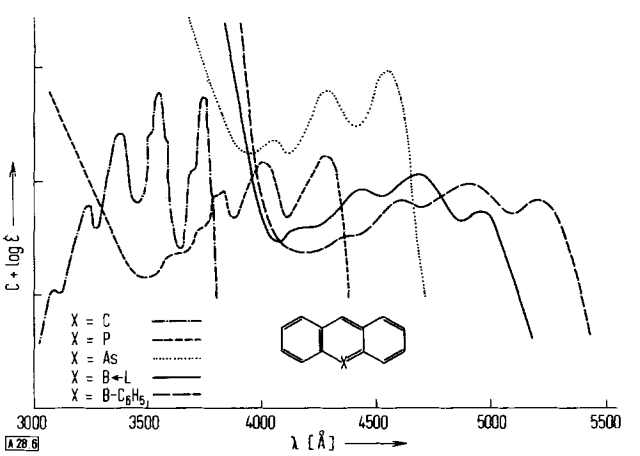


Fig. 6. Ultraviolet-visible spectra of anthracene, *(26a)*, *(30a)*, *(90)*, and *(86)*; measured in THF.

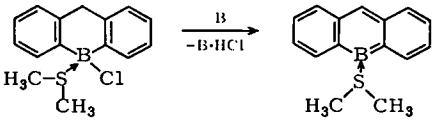
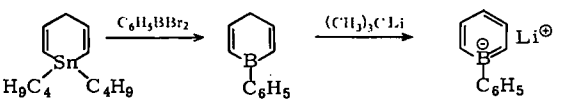
The bathochromic shift of the long-wave absorption maxima occurring on going from *(26a)* to *(30a)*, *(86)*, and *(88)* is attributable to the parallel drop in electronegativity of the hetero atoms in position 9 and the associated decrease in π-π^* excitation energy.

A donor-acceptor complex of type *(83)* has been detected by spectroscopy, but not yet isolated. For instance, reaction of the adduct *(89)* of 9-chloro-9,10-dihydro-9-boraanthracene and dimethylsulfane with auxiliary bases produces a low yield of the extremely unstable dimethylsulfane adduct of 9-boraanthracene *(90)*. Its ultraviolet-visible spectrum is expectedly almost identical with that of *(86)* (Fig. 6).



(89) *(90)*

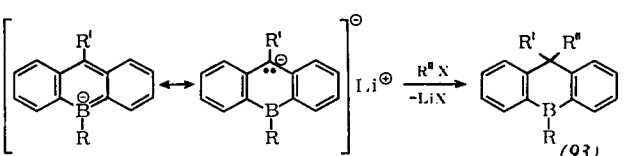
Ashe et al. have detected a non-fused derivative of the borabenzene anion *(84)* from NMR data[88]. 1-Phenyl-1-bora-2,5-cyclohexadiene *(91)* reacts with *tert*-butyllithium to form 1-phenyl-1-borabenzene anion *(92)*.



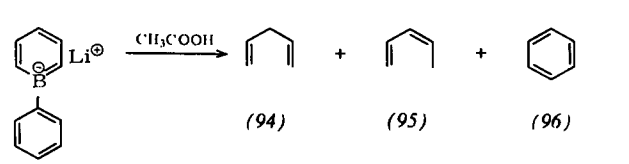
(17) *(91)* *(92)*

The resonance signals of *(92)* in the ^{1}H-NMR spectrum indicate a ring current and/or reduced negative charge on C^4, while a characteristic upfield shift is observed for *(92)* in the ^{11}B-NMR spectrum.

All boraarenes reported so far are extremely sensitive to atmospheric oxygen and moisture. The anionic aromatic compounds *(86)*, *(88)*, and *(92)* react as a resonance structure having a carbanionic center at C-10, C-2, or C-4 and a tervalent Lewis-acid boron atom: hence electrophilic and nucleophilic reactions are possible. Accordingly, reaction of *(86)* and *(88)* with electrophiles leads to 10-substituted 9,10-dihydro-9-boraanthracene *(93)* whereas reaction of *(92)* with an excess of glacial acetic acid involves degradation of the heterocyclic system; the pentadienes *(94)* and *(95)* and benzene *(96)* could all be detected.



(86), *(88)* *(93)*

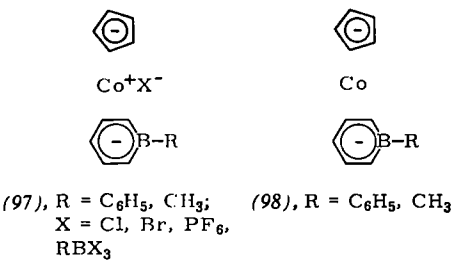


(92) *(94)* *(95)* *(96)*

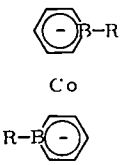
Only one case is known of a reaction retaining the aromatic system: *(92)* reacts with $FeCl_2$ to give the bis(borinato)iron complex[105].

4.2. π Complexes with Borabenzene Anions

Herberich et al. successfully stabilized derivatives of borabenzene anion by ring expansion reactions of complexed cyclopentadienyl anion. Reaction of bis(cyclopentadienyl)cobalt with boron halides is accompanied by complicated redox reactions; the diamagnetic salts of type *(97)* and paramagnetic neutral complexes *(98)* and *(99)* could be isolated as products[89-91].



(97), R = C_6H_5, CH_3; X = Cl, Br, PF_6, RBX_3 *(98)*, R = C_6H_5, CH_3



(99), R = C_6H_5, CH_3, Br, OH, OCH_3

The suspected bonding of the borabenzene anions (borinate ions) as η^6 ligands to the metal in *(97)*, *(98)*, and *(99)*, supported by ^{1}H- and ^{11}B-NMR data, has been confirmed by crystal structure studies on bis(1-methoxyborinato)cobalt *(99)* (R = OCH_3) and on bis(1-methylborinato)cobalt *(99)* (R = CH_3)[92].

These compounds possess a typical centrosymmetric sandwich structure with almost planar borinate ligands. The bonding closely resembles that in π-cyclopentadienyl- and π-benzene complexes. In both complexes, the B—C bond lengths are 1.52 Å and suggest a low double bond participation. The Co—B bonds are the longest metal-ring distances, leading to unsymmetrical bonding of the borinate ligands to the metal. Responsibility for this effect is attributed to the electron in excess of the noble gas configuration at the cobalt atom.

The ionization energies found for compounds of type *(98)* and *(99)* by mass spectrometry are remarkably low (6.5 to 7.1 eV)[91]. Comparison with the ionization energy of bis(cyclopentadienyl)cobalt (6.2 eV)[93] shows that the C_5H_5BR radical acts as a better electron acceptor in its bond to the metal than the C_5H_5 radical.

Borabenzene anions linked to cobalt by a π bond can be transferred to other transition metals[94, 95]. Thus reaction of *(99)* (R = C_6H_5) with $Mn_2(CO)_{10}$ yields 1-phenylborinato-tricarbonylmanganese, while *(99)* (R = C_6H_5, CH_3) and $Fe_2(CO)_9$ afford violet bis(borinato)tetracarbonyldiiron derivatives which can be thermolyzed to orange bis(borinato)iron complexes. These are the first diamagnetic neutral complexes to contain an η^6-borabenzene anion.

5. Conclusion

With the exception of B=C bonds, the novel element-carbon (p-p)π bonds should be incapable of existence according

to the classical double bond rule. This rule, which has been a topic of frequent discussion[96–99], is based in part on the fact that σ bonds between elements of the second long row are relatively long and the increasingly diffuse nature of p orbitals with increasing principal quantum number makes for poor overlap to form π bonds. This has received support from theoretical studies by *Pitzer*[1] and *Mulliken*[2].

However, these cannot be the sole criteria in the case of El=C (p-p)π bonds: π systems based on relatively long σ bonds and involving highly diffuse p orbitals (Table 4) certainly exist. Stable compounds containing S=C (3p-2p)π and Te=C (5p-2p)π bonds have long been known[96, 102], and compounds with Sb=C (5p-2p)π and even Bi=C (6p-2p)π bonds have been mentioned in this progress report.

Table 4. El—C σ bond lengths [Å] (cf. ref. [101]).

1.58	1.54	1.51	1.51
B—C	C—C	N—C	O—C
	1.94	1.87	1.81
	Si—C	P—C	S—C
	1.99	1.98	1.94
	Ge—C	As—C	Se—C
		2.18	2.14
		Sb—C	Te—C

Table 5. Electronegativities according to Pauling [101].

B	C	N	O
2.0	2.5	3.0	3.5
	Si	P	S
	1.8	2.1	2.5
	Ge	As	Se
	1.8	2.0	2.4
		Sb	Te
		1.9	2.1
		Bi	
		1.9	

The stability of these bonds might be explicable by participation of pd hybrids *(b)* as well as pure p orbitals *(a)* in π bonding between carbon and elements of the second long row and higher[79]. This would lead to significant improvement in overlap in spite of unfavorable bond lengths.

(a) *(b)*

Questions concerning the existence of El=C (p-p)π bonds must also take account of bond polarities which can be very great in some cases. They arise from electronegativity differences between the participating elements (Table 5) and lead to unequal electron distributions especially in the readily polarizable π system[79]. Thus varying contributions of the resonance hybrid *(B)* to the ground state of the π-bonded molecules must be expected, depending upon the element concerned.

(A) *(B)*

The elements sulfur, selenium, and carbon exhibit only slight electronegativity differences; corresponding El=C systems therefore exist predominantly as resonance structure *(A)* and some of them are remarkably stable[102]. The greatest electronegativity difference is found between carbon and the elements silicon and germanium; compounds with Si=C and Ge=C bonds contain a considerable proportion of the resonance hybrid *(B)* and therefore display a pronounced kinetic lability. The reactivity of these systems is presumably further affected by the d-orbital contraction resulting from the positive charge on the Si and Ge atom and the associated enhancement of electrophilic character[100]. Similar considerations also apply to B=C systems. Here the pronounced Lewis acid character of the boron atom precludes the formation of π bonds with sp hybridized boron and hence an unoccupied p orbital on the boron atom.

Experience gained so far with El=C bonds can also be applied to other π systems. New element-element (p-p)π bonds should then become available if it proves possible to prepare resonance-stabilized π-systems, to reduce the polarity in the π systems by appropriate substitution, and to avoid oligomerization reactions by steric effects.

I am indebted to J. Baumgärtner, H. Fetz, H. J. Hoffmann, and W. Sakriss for obtaining many of the above results. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Dialkylstannanediyls (Dialkylstannylenes)

By *Ulrich Schröer* and *Wilhelm P. Neumann*[*]

The tin analogs of the carbenes, the stannanediyls (stannylenes) R_2Sn, have long been sought after—ever since the beginning of organotin chemistry. We first came across this problem during our investigations on poly- and cyclostannanes when we observed that the growing poly-tin chain is always lengthened by only one chain link at a time[1], and that the substituted distannanes *(1)* readily undergo decomposition[2]. We have now found, for example, that tetrabutyl-1,2-dichlorostannane *(1a)* disproportionates quantitatively into Bu_2SnCl_2 and a (inhomogeneous) red Bu_2Sn polymer on heating in a sealed glass tube at 120—130 °C for 7 hours.

$$n\ XR_2Sn\text{–}SnR_2X \xrightarrow{\Delta} n\ R_2SnX_2 + (R_2Sn)_n$$

(1a), R = n-C_4H_9, X = Cl
(1b), R = n-C_4H_9, X = H

The assumption that the stannanediyl Bu_2Sn is present as intermediate during this heating—either in the free state or in a transition state complex[3]—finds support in the fact that addition of methyl iodide leads to almost quantitative trapping with insertion into the C—I bond.

$$(1a) \xrightarrow[-\,Bu_2SnCl_2]{\Delta} Bu_2Sn \xrightarrow{MeI} Bu_2Sn\begin{matrix}Me\\ \diagup\\ \diagdown\\ I\end{matrix}$$

A following reaction involving decomposition of initially formed polystannanes can be ruled out—as control experiments have shown[4]: $Bu_2Sn(Cl)Me$ and $Bu_2Sn(Cl)I$ are absent.

Radical chain reactions can also be ruled out, since trapping agents such as hydroquinone remain ineffective. Furthermore, the reaction proceeds no more rapidly than the spontaneous decomposition of *(1a)*. This is accelerated by UV light (high pressure mercury vapor lamp), and is then rapid even at room temperature.

The yield of insertion product (thermal reaction) with alkyl iodides R'I decreases in the series R' = CH_3 (85%), C_2H_5 (70%), n-C_3H_7 (50%), n-C_4H_9 (40%), n-C_5H_{11} (30%); once again, polystannane is formed at the same time. The decrease in yield along this series is doubtless due to the decreasing concentration of c_{C-I} and can also be achieved by dilution with an inert solvent. From this, and the independence of the rate of disproportionation on the presence of a trapping agent, we conclude the intermediary occurrence of free, short-lived dibutylstannanediyl.

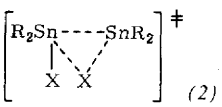
Alkyl iodides afford higher yields of insertion products than bromides, which, under the same conditions afford higher yields than the chlorides (for R' = n-C_3H_7: 50, 30, 20%). In the case of iodides the yields decrease in the series *n*-butyl > *iso*-butyl > *sec*-butyl (40, 35, 25%). Both the ease of bond cleavage and concentration of trapping reagent as well as steric effects thus influence capture of the short-lived stannanediyl.

Other alkyl halides, as well as Sn—Sn groups, are also suitable as R_2Sn trapping reagents (molar ratio 6:1, 120 to 130 °C):

$$\left.\begin{matrix}C_6H_5\text{–}CH_2Cl\\ H_2C{=}C{=}CHI\\ HC{\equiv}C\text{–}CH_2I\\ HC{\equiv}C\text{–}CH_2Br\\ H_2C{=}CH\text{–}CH_2Br\\ Me_3Sn\text{–}SnMe_3\end{matrix}\right\} + (1a) \xrightarrow[-\,Bu_2SnCl_2]{\Delta} \left\{\begin{matrix}C_6H_5\text{–}CH_2\text{–}Sn(Cl)Bu_2 & (15\%)\\ H_2C{=}C{=}CH\text{–}Sn(I)Bu_2 & (25\%)\\ H_2C{=}C{=}CH\text{–}Sn(Br)Bu_2 & (20\%)\\ H_2C{=}CH\text{–}CH_2\text{–}Sn(Br)Bu_2 & (15\%)\\ Me_3Sn\text{–}Bu_2Sn\text{–}SnMe_3\,[5] & (20\%)\end{matrix}\right.$$

Tolan, 1,4-diphenyl-, 2,3-dimethyl- and 1,2,3,4-tetraphenylbutadiene, however, do not react with the stannanediyl; only polystannane is formed. On using organotin hydrides as trapping reagents we obtained complex mixtures, as can be expected as a result of H—X exchange[2].

Other substituents X in *(1)*, as well as Cl and H, have proved useful as leaving groups. Thus, the thermal reaction with CH_3I is complete after 7—8 h at 120—130 °C for X = Cl, at 90—100 °C for X = Br, at 75—85 °C for X = I[6], and at 80—90 °C for X = $OCOCH_3$. For commencement of reaction (at *ca.* 60 °C) a loosening of X is essential; the simplest transition state would be *(2)*.



(2)

This reaction is probably more complicated, since *(1a)* is present as dimer even at 0.05—0.1 M in benzene (vapor pressure-osmometric measurements) bridged *via* Cl atoms (splitting of the Sn—Cl Raman lines at 250 cm^{-1}). A loosening of X in *(1a)*, even at room temperature, has been achieved with the aid of butyllithium; R_3SnX, LiX and the expected secondary products of R_2Sn, with distannane as trapping reagent, *e. g.* the corresponding tristannane[5, 7] are formed.

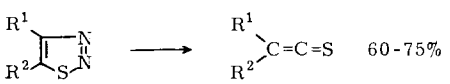
Flash Thermolysis of 1,2,3-Thiadiazoles: A Simple Route to Thioketenes[**]

By *Günther Seybold* and *Christian Heibl*[*]

Thioketenes *(2)* were until now either difficultly accessible or only detectable indirectly as intermediates[2]. It is not surprising therefore that this class of compounds has been little studied and their synthetic potential rarely utilized.

We have now found that the flash thermolysis of 1,2,3-thiadiazoles *(1)* at 580 °C/10^{-4} torr constitutes a simple, convenient, and generally applicable method for the synthesis of thioketenes in good yields—simple, not least because the starting compounds are readily accessible from aldehydes and ketones[3].



(1a)-(1f) *(2a)-(2f)* 60-75%

(a), $R^1 = R^2 = p$-Cl-C_6H_4; *(b)*, $R^1 = R^2 = C_6H_5$;
(c), $R^1 = C_6H_5$, $R^2 = H$; *(d)*, $R^1 = C(CH_3)_3$, $R^2 = H$;
(e), $R^1 = CH_3$, $R^2 = C_6H_5$; *(f)*, $R^1 + R^2 =$

The idea to prepare thioketenes from thiadiazoles is not new. As long ago as 1916 *Staudinger* made attempts to obtain diphenylthioketenes by thermolysis of *(1)* in boiling naphthalene[4]. However, he was able to isolate only tetraphenylthiophene and a compound which was later identified as a 1,3-dithiol derivative[5].

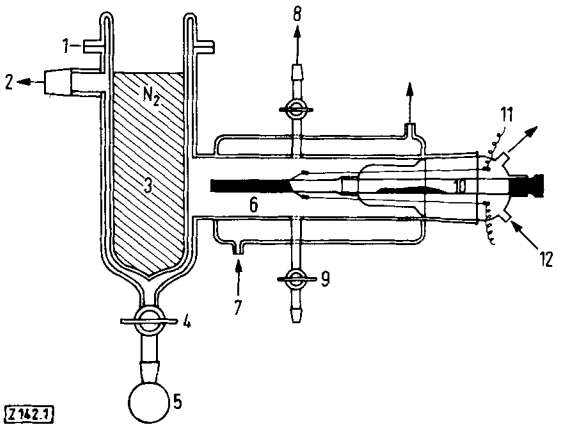


Fig. 1. Apparatus for flash thermolysis. 1: ground joint; 2: to pump; 3: cold finger; 4: coolable tap; 5: receiver; 6: heated quartz tube; 7: cooling water; 8: to manometer; 9: tap; 10: reservoir; 11: current supply; 12: thermostat.

The flash thermolysis was carried out with the apparatus illustrated in Fig. 1[6]. The thiadiazole *(1)* to be pyrolyzed is placed in the reservoir 10 whose temperature is regulated by a thermostat such that a slow but constant stream of substance into the electrically heated quartz tube 6 takes place. Immediately after leaving the hot zone—the residence time is of the order of 10^{-3} s—the pyrolyzate is chilled to −196 °C on the cold finger 3. During the pyrolysis a low-boiling solvent (*e.g.* CH_2Cl_2 or $CFCl_3$) is distilled into the vessel *via* tap 9. In this way dimerizations and oligomerizations are largely avoided when the cold finger is thawed off and dilute thioketene solutions are formed which drip through the coolable tap 4 into the receiver 5. The thioketene solutions obtained in this way are 0.1—0.4 molar and do not contain any by-products; they can be used directly for further reactions or spectroscopic investigations.

The yield of thioketene reached its maximum between 500 and 580 °C (temperature of the quartz tube 6). Above 600 °C decomposition into nitrogen, sulfur, and acetylene derivatives occurred as side reaction. The products found by *Staudinger* could not be detected. This is understandable since the flash thermolysis was carried out at 10^{-4} torr, so subsequent second order reactions of the particles initially formed can be ruled out.

As a rule, we worked at the gram level; however, if the cold finger is made rotatable by means of a ground joint

Table 1. Yields and physical properties of some thioketenes *(2)*.

Cpd.	Yield [%] [a]	IR [cm^{-1}] [b]	^{1}H-NMR δ	λ_{max} [nm] lg ε	Halflife [c]
(2a)	70	1725	—	627 2.31 in CH_2Cl_2	in CH_2Cl_2 at 40 °C: 6.10 h
(2b)	73	1725	—	624 2.51 in CH_2Cl_2	in CH_2Cl_2 at 30 °C: 6.13 h; 40 °C: 3.80 h
(2d)	65—75	1758	1.17 (s, 9H) 4.35 (s, 1H) in $CFCl_3$	575 1.00 in $CFCl_3$	in $CFCl_3$ at 22 °C: 0.98h

[a] Determined by trapping with dimethylamine. The structures of the thioamides were confirmed by elemental analysis, ^{1}H-NMR and IR spectra, and by comparison with authentic samples.
[b] Recorded at −50 °C in a low-temperature cuvette in CH_2Cl_2.

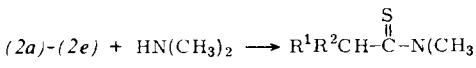
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] Flash Thermolysis of Organic Compounds, Part 3.—Part 2: [1].

1, amounts of up to 10 g can be reacted because of the increased cooling surface.

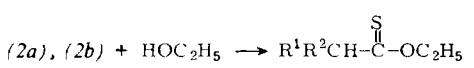
The yields and physical properties of a few thioketenes *(2)* which we have prepared by this method are listed in Table 1.

The structure of the reaction products *(1)* follows unequivocally from the IR bands between 1700 and 1800 cm^{-1} [1, 2, 7, 8] which are characteristic for thioketenes, from NMR, UV and mass spectra, and from chemical behavior. Reaction of *(2a)* to *(2e)* with dimethylamine at −80 °C leads to immediate and quantitative formation of the thioamide *(3)*. Since neither starting compounds nor secondary products of thioketenes react with dimethylamine in this way, this reaction is suitable for the quantitative determination of thioketene in solution. Thioketenes *(2a)* and *(2b)* react with alcohols at room temperature to give the *O*-alkylthiocarboxylic esters *(4)*.



(2a)-(2e) + $HN(CH_3)_2$ → $R^1R^2CH-\overset{S}{\overset{\|}{C}}-N(CH_3)_2$

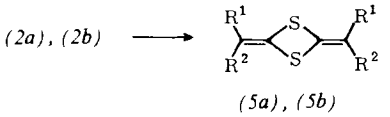
(3a)-(3e)



(2a), (2b) + HOC_2H_5 → $R^1R^2CH-\overset{S}{\overset{\|}{C}}-OC_2H_5$

(4a), (4b)

On warming (30 °C), the diarylthioketenes *(2a)* and *(2b)* dimerize to bismethylenedithietanes *(5)*, which have already been described by *Schönberg*[10].



(2a), (2b) → *(5a), (5b)*

In contrast, the thioketenes *(2c)*—*(2e)* oligomerize at room temperature to complex mixtures. *(2f)* already begins to polymerize at −120 °C and could therefore only be detected indirectly.

The dimerization or oligomerization of the thioketenes *(2a)*, *(2b)* and *(2d)* proceeds strictly according to a second order rate law. The halflives (Table 1) and ^{13}C-NMR spectra[11] of the thioketenes show that both electronic as well as steric effects are responsible for their different kinetic stabilities.

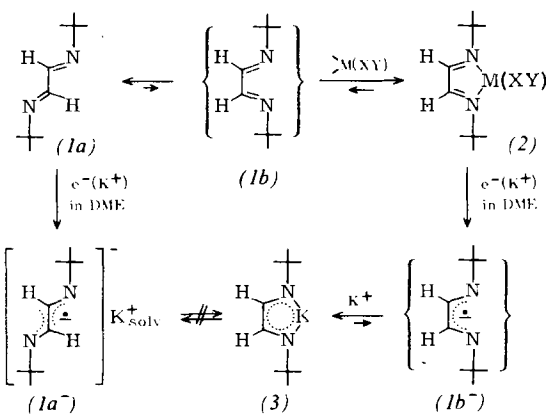
Reductive Fixation of *cis*- and *trans*-1,4-Diazabutadienes[1]

By *Heindirk tom Dieck* and *Klaus-Dieter Franz*[*]

Like butadiene itself in the free state, simple 1,4-dialkyl-1,4-diazabutadienes such as *(1)* exist in the *(E)* conformation *(1a)*. No interaction between lone pairs (as expected for *(1b)*) is observed in the photoelectron spectra, and the IR and Raman spectra indicate the presence of a center of inversion[2]. *(1a)* is readily reduced to the paramagnetic anion *($1a^-$)* by potassium in dimethoxyethane (DME)[3]. The anion *($1a^-$)* displays a highly resolved ESR spectrum in which, at line widths below 0.1 G, not only the splitting by the two H and N atoms of the glyoxal bis(diimine) system (15 lines) but also the hyperfine structure of the 18 equivalent *tert*-butyl protons is visible (a_N 5.62, a_H 4.37, a_H (tBu) 0.15 G)[4, 5].

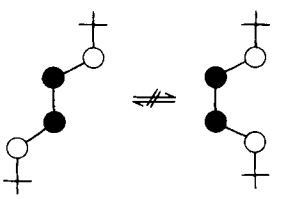


(1a) *(1b)* *(2)* *($1a^-$)* *(3)* *($1b^-$)*

The neutral (*Z*) conformer *(1b)* is not present in measurable concentration in solution; however, the conformational transition *(1a)*⇌*(1b)* occurs readily, as can be demonstrated by rapid formation of numerous chelate complexes *(2)*[6].

Some of the complexes *(2)* are sensitive to reduction (*e.g.* M(XY) = copper(I) halide[7] or π-allylbromodicarbonylmolybdenum[8]). In the course of cleavage by potassium or solvated electrons in DME the (*Z*) conformer of the ligand is reduced; the *cis* anion radical *($1b^-$)* corresponding to *($1a^-$)*, which is probably formed initially, rapidly complexes potassium ions to form the conformationally stable neutral potassium complex *(3)*.

With the reduced compounds of type *(1)* the (*Z*) or the (*E*) conformation can thus be fixed at will. No transition *($1a^-$)*⇌*(3)* is observed in the ESR spectrum at temperatures up to +30 °C; this is reasonable since reduction involves occupation of a molecular orbital with bonding interactions between the centers 2 and 3.



The potassium complex *(3)* displays an ESR spectrum which can be "built up" by superposition of four spectra of the

[*] Prof. Dr. H. tom Dieck and Dipl.-Chem. K.-D. Franz
Institut für Anorganische Chemie der Universität
6 Frankfurt am Main 70, Theodor-Stern-Kai 7 (Germany)

radical *(1a⁻)*. The number four arises from the nuclear spin of the commonest potassium isotope ^{39}K (*ca.* 93%, $I=3/2$).

The large K coupling constant (a_K 1.5 G) and the high resolution prove the conformational rigidity and also the presence of this unusual type of complex[9]. In general, potassium has a preference for a regular coordination sphere of oxygen ligands; in the present case, however, the ligand which is bonded only *via* nitrogen is not replaced by the chelating ether dimethoxyethane present in large excess. Hence specific potassium complexing agents are also conceivable with N ligands.

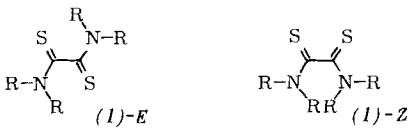
C—N Twisted Ethanedithioamides in Electron-Rich Complexes[1]

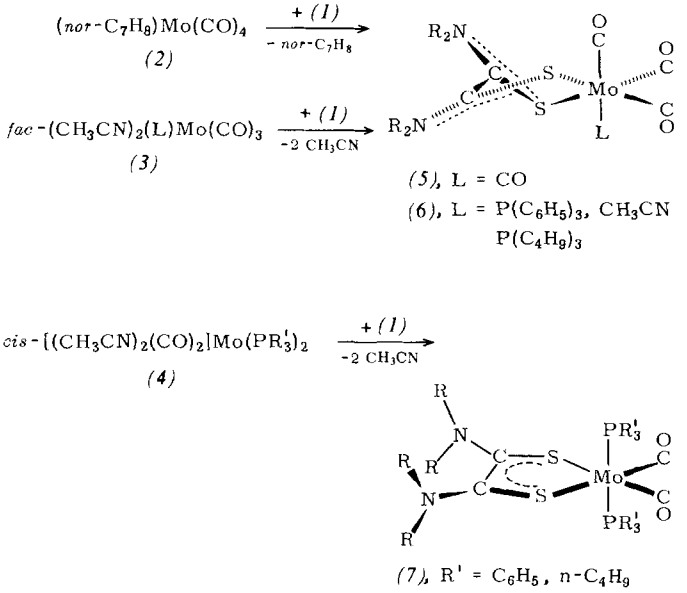
By *Heindirk tom Dieck* and *Michael Form*[*]

We have studied the reactions of carbonylmolybdenum complexes with ethanedithioamides ("dithiooxamides"), the only compounds possessing a S=C—C=S structure to be stable in the free state. Our choice fell upon the *N,N'*-tetraalkyl derivatives *(1)* in order to avoid side reactions (with R=H involving proton loss to give rubeanates).

Compounds *(1)* are not directly comparable with α-dithiones, the extremely readily reducible ligand systems in the so-called dithiolene complexes[2], since they are not planar in the (*E*) conformation but, according to UV[3] and NMR data[4], are twisted about the central C—C bond. A planar (*Z*) conformer of *(1)* is inconceivable owing to steric interactions; *(1)* should therefore be a poor *S,S*-chelating ligand.

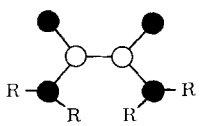


Reaction of *(1)* with the tetracarbonyl- *(2)* or the tricarbonylmolybdenum complexes *(3)* in ether affords moderately stable red ethanedithioamide complexes *(5)* and *(6)*; reaction with the dicarbonylmolybdenum derivatives *(4)* yields the fairly oxidation-resistant violet complexes *(7)*. (All reactions performed at 10—25 °C with the amides *(1)*, R=CH_3, C_2H_5; R_2=$-(CH_2)_4-$, $-(CH_2)_5-$.)



The CO stretching frequencies of *(5)* are low (R=CH_3: 2015, 1906, 1880, 1830 cm^{-1}) and fall even further in the case of *(6)* (R=CH_3, L=CH_3CN: 1910, 1780 cm^{-1}) as is generally observed on replacement of CO by stronger donors. On going to *(7)*, however, the CO frequencies increase markedly in spite of the replacement of CO by, *e.g.*, tributylphosphane (R=CH_3: 1930, 1850 cm^{-1}). This can only be explained by a significant change in the donor-acceptor properties of the *S,S*-coordinated ligands in the transition from *(5)* to *(7)*.

MO calculations show that twisting of *(1)* about C—C with retention of two planar thioamide systems is definitely favored over twisting about N—C, in accord with experiment[3, 4]. Formal reduction leads, however, to occupation of a molecular orbital that has bonding character between C—C and antibonding properties between N—C. Thus the dithiocarbonyl system with twisted R_2N groups becomes energetically more favorable.



The better a metal group is able to release electrons, the more the tetraalkylthioamide will prefer a planar S···C···C···S skeleton and form a "dithiolene" type complex with formally oxidized metal[5].

The NMR non-equivalence[6] of the R groups in *(1)*, well established for the carboxamides, has actually disappeared in the complexes *(7)* and a sharp signal is observed for the tetramethyl compound (R=CH_3: *(1)*, δ=3.25, 3.46 ppm in $CDCl_3$; *(7)*, δ=2.90 ppm in C_6D_6). All the experimental findings can therefore be explained by a conformational change in the ligand that is caused by electronic factors[7]. Complexes of divalent transition metals with *(1)* have been described previously[8, 9]. The preparation under highly acidic conditions described by *Peyronal et al.* presumably also involves a weakening of the thioamide interaction by protonation of the amide nitrogen.

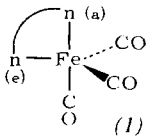
Unsymmetrical Coordination of a Symmetrical 1,4-Diazabutadiene to Iron(0)[1]

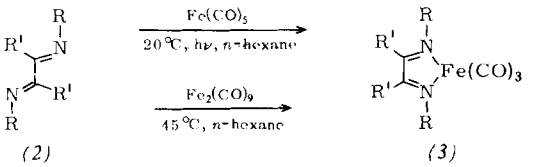
By *Heindirk tom Dieck* and *Alexander Orlopp*[*]

Pentacarbonyliron possesses a trigonal-bipyramidal structure and thus has two fundamentally distinguishable ligand sites. Olefins are known from experience to prefer the equatorial position (e), and n-donors the axial position (a) on substitution[2]. Bidentate n-donors should therefore form an a⌒e chelate *(1)*; however, coordinational asymmetry has never yet been detected with *a priori* symmetrical chelate ligands. Moreover, numerous trigonal-bipyramidal Fe^0 compounds display fluxional behavior[3].



(1)

We have studied the reaction of carbonyliron complexes with 1,4-diazabutadienes *(2a)–(2i)*. The air-sensitive violet [*(3a)*, *(3b)*] or red [*(3c)–(3i)*] tricarbonyl complexes are easily obtained photolytically from $Fe(CO)_5$ or thermally from $Fe_2(CO)_9$.



(2) *(3)*

The readily soluble complexes *(3c)–(3i)* closely resemble one another, and do not show any coordinational differences in the two half-ligands R—N=C(R') in their NMR spectra, in spite of the potentially different coordination sites (a,e). In contrast, the complexes *(3a)* and *(3b)*, having tertiary *N*-substituents, which were studied in detail because of their deviating solvatochromism, display some remarkable features. Both are monomeric compounds that can be sublimed or distilled in high vacuum. Apart from the usual CO frequencies, their IR spectra contain an intense band in the double bond region (1680—1690 cm^{-1}); the other complexes *(3)* exhibit no bands down to 1500 cm^{-1} or only those that are typical of aromatic compounds, like the molybdenum(0) complexes of these ligands[4]. In the ^{1}H-NMR spectrum of *(3a)* and *(3b)* all signal groups of the free ligands are doubled, thus indicating that the two halves must have become different as a result of coordination. In particular, the marked upfield shift of one of the two glyoxalic protons is reminiscent of the shift shown by olefinic protons on π-complex formation [*(2a)* in C_6H_6: δ = 1.2 and 7.9 ppm (9:1); *(3a)* in C_6D_6: δ = 1.44, 1.65, 6.35, and 8.01 ppm (9:9:1:1)].

The extreme difference between the glyoxalic C atoms in the ^{13}C-NMR spectrum of *(3a)* (Δδ = 36.4 ppm) also demonstrates the coordination induced non-equivalence of the two molecular halves originally identical in the free ligands[5].

The spectroscopic data suggest a structure with a C—C twisted ligand in *(3a)* and *(3b)*.

An axial n_N bond and an equatorial $\pi_{C=N}$ donor bond are in accord with the occurrence of an isolated C=N double bond (IR) and the olefin complex-type shielding of a proton (NMR).

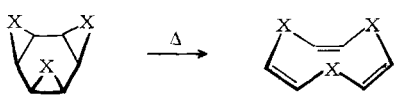
cis-Trithiatris-σ-homobenzene (*cis*-"Benzene Trisulfide")[**]

By *Shinzo Kagabu* and *Horst Prinzbach*[*]

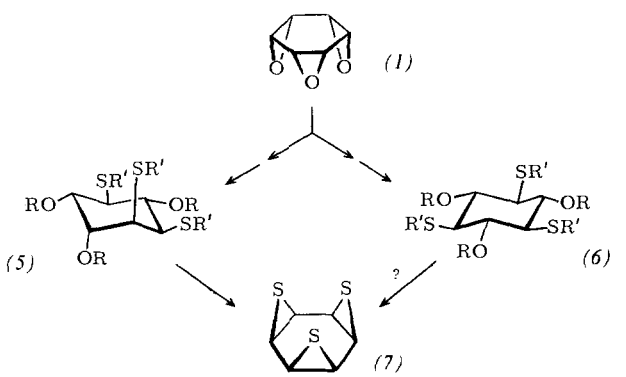
cis-Trioxatris-σ-homobenzene *(1)* and *cis*-triazatris-σ-homobenzene *(2)*[1] have gained significance as synthetic intermediates. Thus thermolysis affords the heterocyclic systems *(3)* and *(4)*[2] and substitution reactions give numerous inositol derivatives which were formerly accessible only *via* more complicated routes, if at all. A very simple and productive synthesis of streptamine may be cited as example[3]. The *cis*-trithiatris-σ-homobenzene (*cis*-"benzene trisulfide") *(7)* should open up further preparative possibilities, while $3\sigma \rightarrow 3\pi$ isomerization to 1,4,7-trithiacyclononatriene *(8)* appeared unlikely from the outset[4].



(1), X = O — *(3)*, X = O
(2), X = NR — *(4)*, X = NR

An obvious synthetic route to *(7)*, which has proved its value in the case of the *cis*-triimine *(2)*, started from *(1)* and proceeded *via* the threefold-cleavage products *(5)* with *chiro* configuration. The *scyllo* derivatives *(6)*, having an all-equatorial arrangement of substituents, which, in principle, are also possible alongside *(5)*, should not be suitable for cyclization. We therefore first established whether the selectivity [>90% *(5a)*; triacetate *(5b)*: m.p. 92°C] observed for thiobenzyl alcohol (methanol, sodium methoxide, 60°C) is retained with other S-nucleophiles[5] that can be utilized for episulfide formation. Compound *(1)* reacts quantitatively with an excess of thioacetic acid at 60°C (24 h). Chromatography (silica gel/chloroform) of the oily reaction product, which was immediately esterified with acetic anhydride because of the known tendency of 2-hydroxythioacetates to undergo rearrangement, affords a mixture of *chiro (5c)* and *scyllo*-trithiohexaacetate *(6c)* (40%; *ca.* 1:1). Reaction with an excess of KSCN (methanol, 20°C) or HSCN (methanol/ether, 20°C) is complicated and poorly understood, probably due in part to the instability of the 2-hydroxythiocyanates and the *trans* diaxial eliminations occurring in the 1,2-disubstituted intermediates and in *(5a)* as a result of the relatively high basicity of the medium.

High yields and the desired stereoselectivity are achieved with an excess of thiourea in the presence of concentrated sulfuric acid. A trisisothiouronium salt is obtained [m.p. 161 to 162°C (dec.), yield >90%] which is shown by spectral comparison with *(5a)*–*(5c)*, and particularly by the ^{13}C data [δ = 171.9; 170.5; 168.6 ppm ($\overset{\oplus}{C}(NH_2)_2$); 72.6; 72.4; 68.7 (C—OH); 55.9; 51.9; 51.1 (C—SR); dioxane/water] to be the *chiro* product *(5e)*. The pathway *via (5e)* has the additional advantage that very mild conditions suffice for the liberation of *(7)*. Thus sodium carbonate is added to an aqueous solution (pH *ca.* 8) of *(5e)*, and the emulsion immediately extracted with chloroform. After recrystallization of the chloroform residue from tetrahydrofuran (−20°C), compound *(7)* can be isolated as fine colorless needles (40%). The *cis* orientation of the three episulfide rings deduced from the stereochemistry of the epoxide → episulfide transformation is confirmed by the ^1H [sharp signal at τ = 6.28 ($CDCl_3$), 6.90 (C_6H_6)] and ^{13}C data [δ = 35.7 ppm ($CDCl_3$)].



(a), R = H, R' = CH_2-C_6H_5
(b), R = $COCH_3$, R' = CH_2-C_6H_5
(c), R = R' = $COCH_3$
(d), R = H, R' = CN
(e), R = H, R' = $\overset{\oplus}{C}(NH_2)_2\ HSO_4^{\ominus}$

The thermal properties of *(7)* are characterized by a pronounced trend to undergo polymerization in the solid state and in solution. In the crystalline state, decomposition with yellow coloration starts slowly as low as 20°C and proceeds rapidly above 100°C. In highly dilute $CHCl_3$ solution, *(7)* remains unchanged for some time; on heating to 100°C it decomposes with liberation of benzene (up to 70%). It follows from the concentration dependence of benzene formation, however, that intermolecular processes are involved. In accord with earlier findings[4], $3\sigma \rightarrow 3\pi$ isomerization of *(7)* to *(8)* is consequently unattainable. Sulfur elimination with

trimethyl phosphite (in THF) to form benzene is fast at 20 °C; nevertheless, neither the disulfide nor the monosulfide can be identified as intermediates (^{1}H-NMR) under a variety of conditions (*e.g.* equimolar ratio; 20 °C). Apparently, elimination of the first sulfur atom has the highest activation energy[6].

The difference between trioxide *(1)*/triimine *(2)* and trisulfide *(7)* apparent from the course of thermolysis is also clear from the mass spectrum: the peaks (inlet temp. 50—70 °C) at *m/e* 174 (M^+), 141 ($M^+ - SH$), 110 ($M^+ - 2S$), 78 ($M^+ - 3S$, 100 %), 64 (S_2) are typical of the fragmentation pattern arising because of preferential loss of sulfur.

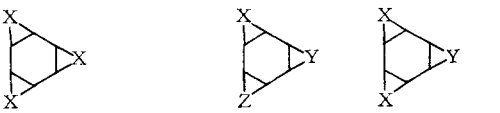
Chemistry of *cis*-Trioxatris-σ-homobenzene. α,α-Dioxa-β-thia- and β-Oxa-α,α-dithiatris-σ-homobenzene[**]

By *Horst Prinzbach, Clemens Kaiser*, and *Hans Fritz*[*]

Our work on the chemistry of *cis*- and *trans*-trisheterotris-σ-homobenzenes *(1a)*–*(1c)*[1] has raised various questions concerned, for example, with the rates and stereochemistries of the individual substitution steps, which have prompted us to undertake comparative studies on systems with differing combinations of hetero atoms, as in *(2)*. We shall now report the preparation of α,α-dioxa-β-thia- *(8)* and β-oxa-α,α-dithiatris-σ-homobenzene *(9)* (the first representatives of the X,X,Y type *(3)*) from *cis*-"benzene trioxide" *(1a)*[2].

The basic problem posed by the synthesis of *(8)* and *(9)* from *(1a)* lay in the synthesis of mono- *(4)* or di-substituted



(1) *(2)* *(3)*

(a), X = O
(b), X = NR
(c), X = S

X, Y, Z = O, NR, S, PR

products *(5)* or *(6)* suitable for directed episulfide formation; previous experience with the *cis*-trisulfide *(1c)*[1] indicated the potential usefulness of isothiouronium salts *(4a)* and *(5a)*–*(7a)*.

Under conditions for the opening of one oxirane ring (equimolar proportions, 20 °C), no detectable amounts of *(4a)* can be found alongside residual *(1a)* and the bisadduct *(5a)* after reaction of *(1a)* with thiourea/sulfuric acid. This kinetic advantage of the second substitution is also observed on use of thioacetic acid; opening of the second oxirane ring is again faster than that of the first, and the yield of *(4b)* (colorless crystals, m.p. 99—100 °C) correspondingly low (5—10%)[3]. The desired selectivity [>75% *(4c)*, colorless crystals, m.p. 80 °C] can be achieved with thiobenzyl alcohol in methanol (sodium methoxide); however, *(4c)* is unsuitable for episulfide formation. These difficulties can be circumvented by use of KSCN: at a 1:1 molar ratio (20 °C, methanol, 30% conversion) *ca.* 95% of the dioxathia product *(8)* are formed alongside polymeric material *via* the unstable compound *(4d)*. Product *(8)*, which is freed from *(1a)* by addition of $LiClO_4$ (1:2 complex insoluble in benzene[4]) and from traces of *(9)* by recrystallization from benzene, is obtained as colorless needles, m.p. 140—141 °C (subliming above 120 °C) which can be kept for some time at −20 °C [^{1}H-NMR: τ = 6.58 (br. s) ($CDCl_3$); 7.15 (br. s 5(6)-H); 7.05—7.25 (AA', 1(4)−H); 7.25—7.45 (BB', 2(3)−H) (C_6D_6); ^{13}C-NMR ($CDCl_3$): δ = 48.4 ppm (1(4)−C), 47.3 (2(3)−C), 32.6 (5(6)−C); MS: *m/e* = 142 (M^+), 113 ($M^+ - CHO$), 97 ($M^+ - CHS$), 68 ($M^+ - CHO, -CHS$), 45 (CHS, 100%)]. The α,α,β arrangement of the hetero three-membered rings established by the synthetic pathway leading

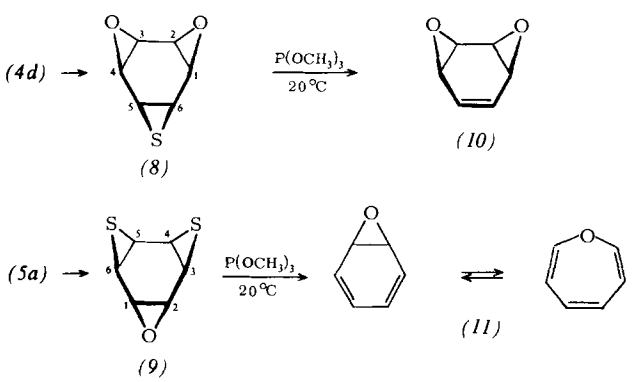
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are also indebted to Prof. Dr. *H. Achenbach* for recording some of the mass spectra.

The KSCN method cannot be used for the synthesis of *(9)*. Even under a variety of conditions only very small amounts of *(9)* are detected alongside *(8)* (up to 30%) by spectroscopy of the complex reaction mixture. The method of choice is the reaction with thiourea/sulfuric acid which has proved its value in the case of *(1c)*. Under controlled conditions (1:2 molar ratio, water/2 eq. H_2SO_4, 10d, 20°C) the yield of the 1,2-bisisothiouronium salt *(5a)* [colorless powder, >160°C (dec.)] amounts to *ca.* 80%; residual *(1a)*, *chiro*-tris-isothiouronium salt[1]—small concentrations of *(6a)* and/or *(7a)* cannot be excluded—are removed by reprecipitation in ethanol/water. This regioselectivity of disubstitution[5] also observed with other nucleophiles, likewise applies, albeit less markedly, to the reaction with thiobenzyl alcohol. With a 1:2 molar mixture (methanol/sodium methoxide, 60°C, 2h) mono- *(4c)* and *chiro* tris-adduct[5] are accompanied by *ca.* 30% of *(5c)* (colorless crystals, m.p. 142°C), *ca.* 20% of *(6c)* (colorless crystals, m.p. 107—108°C), and *ca.* 5% of *(7c)*.

Compound *(9)* is obtained in proven manner (addition of Na_2CO_3 to aqueous solution up to pH 8)[1] from *(5a)* in addition to polymeric components; colorless needles [THF, 50—60%, m.p. 119°C (dec.)] which can be sublimed at 60°C/0.01 torr but gradually decompose on standing (−20°C) [^{1}H-NMR: τ = 6.40 (br. s, 1(2)−H); 6.35—6.55 (AA', 3(6)−H); 6.55—6.75 (BB', 4(5)−H) ($CDCl_3$); 6.85—7.05 (AA', 3(6)−H); 7.15—7.35 (BB', 4(5)−H); 7.23 (br. s, 1(2)−H) (C_6D_6); ^{13}C-NMR ($CDCl_3$): δ = 53.1 ppm (1(2)−C), 33.2; 30.6 (3(6)−C), 4(5)−C; MS: *m/e* = 158 (M^+), 129 (M^+−CHO), 94 (M^+-S_2, 100%), 78 (M^+-S_2, −O), 66 (M^+-S_2, −CO), 45 (CHS); metastable peaks at 56.2 (158→94) and 46.5 (94→66)].

As for *(8)* the *trans* arrangements of episulfide and epoxide rings are shown by very small values of the vicinal coupling constants, $J_{1,6} = J_{2,3} < 2$ Hz. Being incapable of 3σ→3π isomerization as *trans*-tris-σ-homobenzenes[6], *(8)* and *(9)* undergo rapid decomposition by an obscure route above 160°C and *ca.* 120°C, respectively. Elimination of sulfur with trimethyl phosphite (20°C) to give benzene dioxide *(10)*[7] and benzene oxide/oxepin *(11)*[8] proceeds readily in both cases. In connection with the differing fragmentation patterns of *cis*-trioxide *(1a)* and *cis*-trisulfide *(1c)*[1] in the mass spectrometer the metastable peak at *m/e* = 56.2 recorded for *(9)*, possibly indicative of S_2 elimination, warrants attention.



The structural elucidation of substitution products *(4)*–*(7)* based on elemental analysis and spectral comparison (IR, ^{1}H-, ^{13}C-NMR, MS) was considerably facilitated by the fact that the ^{1}H-NMR spectra recorded at 270 or 360 MHz could be extensively analyzed. With regard to the conformational properties, the coupling constants for *(4a)*–*(4c)* [*e.g. (4c)*: $J_{1,2} = J_{2,3} = 5$; $J_{3,4} = J_{4,6} = 3$; $J_{2,OH} = 10$ Hz] evidence an equilibrium between the quasi-e,e and the quasi-a,a conformers, and the coupling constants for *(5)*, *(6)*, and *(7)* [*e.g. (5c)*: $J_{1,6} + J_{1,5} = 3$; $J_{2,3} + J_{3,5} = 5$; $J_{2,OH} = 7$ Hz; *(6c)*: $J_{1,2} = 1.5$; $J_{1,6} = 4$; $J_{2,3} = J_{3,4} = 10$; $J_{4,5} = 9$; $J_{2,OH} = J_{4,OH} = 2$ Hz] the expected quasi-a,a,e,e and e,e,e,e preferred conformations.

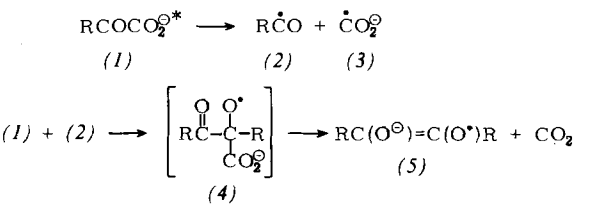
Formation of *cis*- and *trans*-Semidione Radical Anions by Addition of Acyl Radicals to α-Oxo Carboxylic Acids

By *Steen Steenken* and *Dietrich Schulte-Frohlinde*[*]

During *in situ* EPR photolysis[1] of aqueous solutions of α-oxo carboxylic acids $RCOCO_2H$ above pH 5 we have observed *cis* and *trans* isomers of semidione radical anions of type *(5)*. On simultaneous photolysis of two different α-oxo carboxylic acids $RCOCO_2H$ and $R'COCO_2H$ "mixed" radicals *(6)* containing both R and R' were detected in addition. The stationary concentration of the radicals *(6)* was often found to exceed that of *(5)*.

We explain these results by assuming that in the absence of H donors the electronically excited α-oxocarboxylates *(1)* undergo α-cleavage to yield acyl radicals *(2)* and the carboxyl radical *(3)*. It is suggested that the acyl radicals *(2)* are scavenged by *(1) via* addition of *(2)* to the C=O bond of *(1)* followed by decarboxylation of the intermediate adduct *(4)*. CO_2, which was identified by gas chromatography, could be isolated from photolyzed solutions of *(1)*.



$RC(O^{\ominus})=C(O^{\bullet})R'$ *(6)*

R = H, CH_3, C_2H_5, $(CH_3)_2CHCH_2$, $HO_2CCH_2CH_2$

This mechanism was tested by producing acyl radicals *(2)* independently and reacting them with α-oxo carboxylic acids.

According to *Paul* and *Fischer*[2] electronically excited ketones R'COR", where R" designates the bulkier substituent,

[*] Dr. S. Steenken and Prof. Dr. D. Schulte-Frohlinde
Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung
433 Mülheim (Ruhr), Stiftstrasse 34—36 (Germany)

fragment to yield acyl radicals ($R'\dot{C}O$) and alkyl radicals ($\dot{R}''$). On photolysis of ketones of this type in the presence of glyoxylic acid ($HCOCO_2H$) in aqueous solution at pH 7 under conditions where more than 99% of the light was absorbed by the ketones, only the "mixed" semidione radical anions $R'C(O^{\ominus})=C(O^{\bullet})H$ were found, in agreement with the proposed mechanism. With acetone, on the other hand, $HC(O^{\ominus})=C(O^{\bullet})H$ was formed. This finding is rationalized in terms of energy transfer from electronically excited acetone to nonhydrated glyoxylic acid followed by its decomposition according to the scheme *(1)*→→*(5)*. In the case of acetone this energy transfer can be observed since acetone undergoes α-cleavage with much lower yield than the ketones R'COR"[2].

The expected "mixed" semidione radical anions $R'C(O^{\bullet})=C(O^{\ominus})R$ were also formed predominantly when the ketones R'COR" were photolyzed in the presence of the acids $RCOCO_2H$ ($R=CH_3$, CH_3CH_2, $HO_2CCH_2CH_2$), provided the molar ratio [R'COR"]/[$RCOCO_2H$] was not lower than ≈50:1.

The mechanism presented is similar to the reactions proposed[3, 4] to account for the production of the semidione of biacetyl observed on free-radical H-abstraction from acetaldehyde. However, *Paul* and *Fischer*[2] were able to show that in this case the semidione is produced by reduction of biacetyl formed by combination of acetyl radicals.

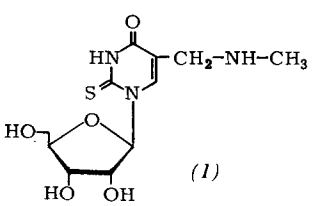
Synthesis of 5-Methylaminomethyl-2-thiouridine, a Rare Nucleoside from t-RNA[1]

By *Helmut Vorbrüggen* and *Konrad Krolikiewicz*[*]

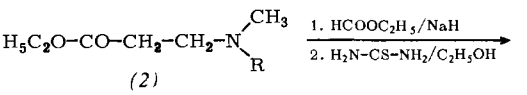
Carbon[2] isolated 5-methylaminomethyl-2-thiouridine *(1)* from *E. coli*-t-RNA and elucidated its structure, while *Nishimura*[3] detected *(1)* in the anticodon of *E. coli*-t-RNA^{Glu} We have now accomplished the first synthesis of *(1)*.



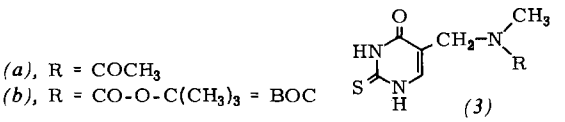
(1)

[*] Dr. H. Vorbrüggen and K. Krolikiewicz
Forschungslaboratorien der Schering AG, Berlin/Bergkamen
1 Berlin 65, Müllerstrasse 170—178 (Germany)

Acylation of ethyl 3-methylaminopropionate[4] with acetic anhydride/pyridine or with *tert*-butoxycarbonyl azide/pyridine gave *(2a)* and *(2b)* in practically quantitative yield. Formylation with ethyl formate/NaH in 1,2-dimethoxyethane and subsequent condensation *in situ* with thiourea and ethanol[5] afforded the thiouracils *(3a)*, m.p. 274—276 °C, and *(3b)*, m.p. 192—194 °C, in 55—60% yield.



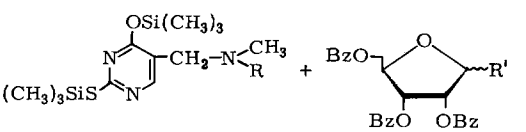
(2)



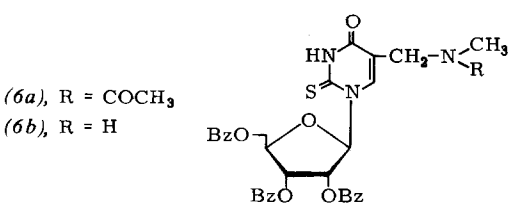
(3)

Silylation of *(3a)* and *(3b)* with hexamethyldisilazane gave the bis-silylated 2-thiouracils *(4a)* and *(4b)* almost quantitatively.

On reaction of *(4a)* with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose *(5a)*/$SnCl_4$[6] in 1,2-dichloroethane a *ca.* 70% yield of the protected nucleoside *(6a)* was obtained. However, the *N*-acetyl group in *(6a)* could not be removed by subsequent treatment with either CH_3OH/NH_3 and $NaOCH_3/CH_3OH$[5] or with 2 N HCl at 80 °C[7].



(4a), R = $COCH_3$ *(5a)*, R' = β-OAc
(4b), R = BOC *(5b)*, R' = Cl



Reaction of *(4b)* with *(5a)*/$SnCl_4$ in 1,2-dichloroethane as well as *(5b)*/$AgClO_4$[5] in benzene resulted in a *ca.* 70% yield of *(6b)* (m.p. 171—173 °C) with concomitant loss[8] of the *tert*-butoxycarbonyl group. After the reaction of *(4b)* with *(5b)*/$AgClO_4$, *(6b)* was isolated after removal of AgCl by filtration as amorphous, ether-insoluble perchlorate.

Saponification of *(6b)* with CH_3OH/NH_3 gave a 80% yield of the desired nucleoside *(1)*, which crystallized from CH_3OH/5% H_2O; m.p. 137—139 °C. $[\alpha]_D = +26.1°$ ($c=1$; H_2O); NMR (D_5-pyridine): $\delta = 2.34$ ($NH—CH_3$); 7.38 (H^1, $J = 1.5$ Hz).

On TLC comparison *(1)* was identical with an authentic sample[2, 9] in i-PrOH/NH_3/H_2O = 7:1:2 ($R_f = 0.67$) as well as in *n*-BuOH/AcOH/H_2O = 5:1:4 (upper phase, $R_f = 0.37$) on cellulose plates (F, Merck Darmstadt).

Synthesis of Sulfinato-*O,S* Complexes of Palladium(II)[**]

By *Ingo-Peter Lorenz, Ekkehard Lindner* and *Wolfgang Reuther*[*]

Because of their typical ambivalence, sulfinato complexes are particularly suitable as model substances for detection of various isomerization phenomena[1]. Bonding through one O (sulfinato-*O*) or one S atom (sulfinato-*S*) as well as through two O atoms (sulfinato-*O,O'*) has already been recorded[2]. There has not previously been any unambiguously proved example for the fourth type of bonding in which oxygen and sulfur are simultaneously coordinated (sulfinato-*O,S*)[3].

We have now succeeded in the first directed synthesis of sulfinato-*O,S* complexes *(2)*, by removing water from aquo complexes of palladium(II) *(1)*[4] by means of 2,2-dimethoxypropane.

$$(RS(O)_2)_2Pd(OH_2)_2 \rightleftharpoons (R(O)OS)_2Pd + 2\ H_2O \qquad (1)$$

(1)

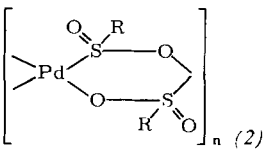
(2a), R = C_6H_5

(2b), R = p-$CH_3C_6H_4$

The compounds *(2a)* and *(2b)* form golden-yellow *diamagnetic* crystals that decompose at 90 and 120 °C, respectively; their composition and structure are proved by elemental analysis and their mass and IR spectra. The mass spectra of the hygroscopic crystals, which decompose even under nitrogen at room temperature, provide R^+, SO_2^+ and SO^+ as the relevant fission products.

In the region between 1220 and 970 cm^{-1} the IR spectra (in Nujol) show two intense absorptions (as doublets), which correspond to ν(SO) and the pseudoasymmetric SOPd stretching vibration: *(2a)*: ν(SO) = 1214 vs, 1203 vs; ν_{as}(SOPd) = 992 vs, 978 sh; *(2b)*: ν(SO) = 1212 vs, 1203 vs; ν_{as}(SOPd) = 994 vs, 975 sh. A striking feature is the unusually large frequency difference, which excludes coordination only through sulfur *or* oxygen[1a] and is characteristic of simultaneous O,S bonding.

A monomeric structure is excluded for *(2)* because the very strained three-membered ring would be unavoidable in that case. The IR spectrum and chemical behavior indicate a polymeric structure.



(2)

The RSO_2^- ligand is always bonded through sulfur to noble metals such as palladium(II) because of their "soft" character[4, 5]. If, for example, the coordinately bound water is removed from the complexes *(1)*, the coordination number 4 favored by Pd^{2+} can be achieved only if an additional Pd—O bond is provided. This is naturally very weak, as is shown in particular by the behavior of the complexes *(2)* with polar solvents. Thus reaction *(1)* is reversible and *(2)* also readily undergoes reversible addition of methanol or acetonitrile with fission of the Pd—O bond; the complexes $(RS(O)_2)_2PdL_2$ with L = CH_3OH or CH_3CN cannot be isolated, but the IR spectra, in solution, show the bands characteristic of a sulfinato-*S* linkage (*e.g.* L = CH_3CN, R = C_6H_5: $\nu_{as}(SO_2) = 1243$, $\nu_s(SO_2) = 1057\ cm^{-1}$). The Pd—O bond in *(2a)* and *(2b)* can be cleaved irreversibly by uni- or bi-dentate ligands such as $P(C_6H_5)_3$, pyridine or 2,2'-bipyridyl, with formation of the known compounds $(RS(O)_2)_2PdL_n$ (n = 1 or 2)[4].

In general, formation of sulfinato-*O,S* complexes is to be expected only in cases when a preponderatingly "soft" central atom is present which favors sulfinato-*S* bonding but undergoes an additional O-bonding in order to reach its favored coordination number (in this case 4) in the absence of a competing ligand.

Experimental:

(1a) or *(1b)* (1 mmol) is stirred with 2,2-dimethoxypropane (3 ml) and acetylacetone (3 ml) at 20 °C for 10 min under N_2, light petroleum (30 ml) is added and the crystalline product is filtered off (D3), washed with ether and dried in a vacuum. Yield: 93% of *(2a)* or 98% of *(2b)*.

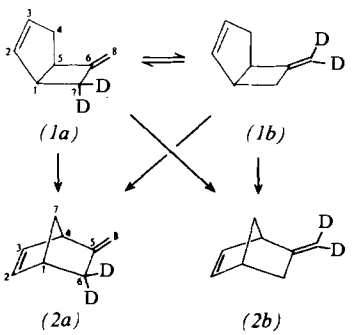
Non-equilibrating Diradicals[1]: Stereochemistry of the Thermal Reorganization of Methyl-substituted 6-Methylenebicyclo[3.2.0]hept-2-enes

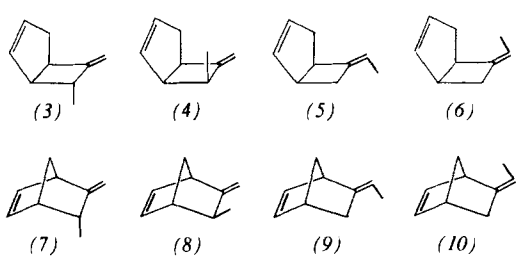
By *Dieter Hasselmann*[*]

Sigmatropic carbon migrations in bisallylic systems are the subject of intense mechanistic investigations[2]. Thermolysis of specifically deuteriated 6-methylenebicyclo[3.2.0]hept-2-enes leads, alongside a relatively slow automerization *(1a)*⇌*(1b)*, to the 5-methylenebicyclo[2.2.1]hept-2-enes *(2a)* and *(2b)*, the product of a formal [1,3]-sigmatropic rearrangement always preponderating slightly[1]. Automerization of the rearrangement products *(2a)*⇌*(2b)* occurs only at appreciably higher temperature[3].



(1a) *(1b)* *(2a)* *(2b)*

The experiments thus far performed, however, do not permit any statement with regard to the stereochemistry of the migrating carbon C^7 (or C^8). The report below concerns the thermal rearrangement of the specifically *methyl*-substituted hydrocarbons *(3)* to *(6)*.



(3) *(4)* *(5)* *(6)*

(7) *(8)* *(9)* *(10)*

At *ca.* 190°C the isomers *(3)* to *(6)* rearrange, both in solution and in the gas phase[4], in each case into one another and into the four methylated 5-methylenebicyclo[2.2.1]hept-2-enes *(7)* to *(10)*[5]. *(7)* to *(10)* can be regarded as stable under the reaction conditions since they rearrange at least 65 times more slowly than the starting material that has the lowest rearrangement rate. The isomerization rates of *(3)* to *(6)* and the product compositions in the gas phase were independent of pressure in the range studied (0.5–6 torr). Added propene or allene exerted no influence on the reaction. At any one temperature the proportions of the stable reaction products proved largely independent of time, although a change in the temperature of thermolysis did effect a change in these product ratios. These results are consistent with the assumption of a set of concurrent, uncatalyzed, unimolecular rearrangements.

Because of the interrelated rearrangements of the starting materials *(3)* to *(6)* the thermolyses follow a complex kinetic scheme of first-order reactions, which can, however, be solved numerically. Starting in each case from pure *(3)*, *(4)*, *(5)*, or *(6)* and using low conversions, we determined approximate values for all the rate constants according to the law for irreversible first-order reactions. These values were improved by extrapolation to zero time. By using these k values educt and product concentrations were calculated with numerical integration by the *Runge-Kutta* method[6] and agreed well with the concentrations found experimentally, so that even a small variation in the experimental k values led to excellent agreement. Table 1 reproduces the rate constants after improvement in this way.

For interpretation of the results three mechanistic alternatives in particular must be taken into account: 1. Competing concerted [3,3]-(Cope) and [1,3]-sigmatropic rearrangements; 2. A two-step mechanism with participation of equilibrated diradicals as intermediates; 3. A course involving non-equilibrating diradicals or diradical transition states of comparable energy ("continuous diradical"[7]).

Table 1. Rate constants [a] of thermolysis of *(3)* to *(6)* (gas phase, 189.0°C).

Educt \ Product	*(3)*	*(4)*	*(5)*	*(6)*	*(7)*	*(8)*	*(9)*	*(10)*
(3)	535.7 [b]	18.3	15.8	0.67	44.7	334.0	120.0	2.20
(4)	16.5	188.9 [b]	10.2	0.48	11.1	16.9	133.0	0.75
(5)	6.7	4.6	59.7 [b]	≈0	6.4	4.8	37.2	≈0
(6)	0.50	0.72	≈0	45.1 [b]	0.20	0.14	≈0	43.5

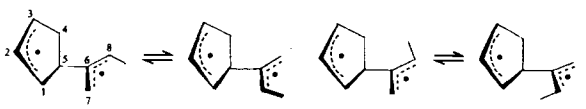
[a] $k \times 10^7 [s^{-1}]$; [b] Total decrease of the educt.

Since stereospecificity cannot be considered as a sufficient criterion[8] for orbital symmetry control[9] of a reaction, an energy gain by resonance stabilization of the aromatic transition state[10] must be demanded in addition as an essential factor. The activation energies for the decrease in amounts of *(3)* to *(6)* can be estimated from the k values (Table 1) with $\lg A = 13.5$—14 to 38—41 kcal/mol (exp. *(1)*→*(2)*: $\lg A = 13.7$, $E_a = 39.6$ kcal/mol[3]). For a hypothetical diradical process a comparable activation energy would be expected[11]. Therefore, according to this model, orbital symmetry controlled energetic assistance can be to a large extent excluded both in the framework of the Frontier Orbital Theory of *Woodward* and *Hoffman*[9] and of the *Berson-Salem* concept[14] of a "subjacent orbital" participation.

Even for thermolysis of *(1)* a significant participation of the [3,3]-sigmatropic (Cope) rearrangement could be excluded on geometrical grounds (C^3—C^8 separation >4 Å)[1]. This prediction is confirmed in this work by the finding that *(9)* is formed at comparable rates from *(3)* and *(4)*; only the reaction *(4)*→*(9)* follows formally the stereochemical course of a Cope rearrangement; and further it is precisely in the case of *(4)*, in contrast to *(3)*, *(5)* and *(6)*, that the *endo*-methyl group should make the transition state for the Cope rearrangement more difficult to reach.

[*] Dr. D. Hasselmann
Abteilung für Chemie der Universität
463 Bochum, Postfach 2148 (Germany)

The sigmatropic [1,3]-migrations *(3)*→*(7)*+*(8)*, and *(4)*→*(7)*+*(8)*, do not occur stereospecifically. This too contraindicates worthwhile resonance stabilization of an aromatic transition state in the [1,3]-rearrangement. The formally orbital symmetry forbidden product *(8)* is actually formed from *(4)* faster than is the allowed product *(7)*[15].



(11a) *(11b)* *(12a)* *(12b)*

The epimerization *(3)*⇌*(4)* requires, in one phase of the reaction, an orthogonal non-bonding relation between C^1 and C^7 and can therefore be regarded as non-concerted. Formal cleavage of the C^1—C^7 bond in *(3)* to *(6)* leads to the resonance-stabilized *cis*- and *trans*-substituted bisallyl diradicals *(11)* and *(12)*. From the product ratio *(7)*/*(8)*, as an example, one can test whether *(11a)*⇌*(11b)* and *(12a)*⇌*(12b)* are equilibrated intermediates: *(5)*→*(7)*/*(8)* = 1.33; *(6)*→*(7)*/*(8)* = 1.43. Then, independently of whatever the *cis*/*trans* ratio *(11)*/*(12)* may be, the values for *(7)*/*(8)* from *(3)* and *(4)* should be found to be between 1.33 and 1.43; however: *(3)*→*(7)*/*(8)* = 0.134; *(4)*→*(7)*/*(8)* = 0.657. The discrepancy between these product ratios is in conflict with equilibrated diradicals as intermediates, in spite of the high energetic stabilization in *(11)* and *(12)*.

Non-equilibrating diradicals offer an explanation for the experimental findings. Even in our more complex system such diradicals appear to behave as individual transition states in the sense of the "continuous diradicals" postulated by *Doering* and *Sachdev*[7]. The hypothesis is supported by the individual rate constants of the rearrangements of *(3)* to *(6)*. The diradical character of the transition states is supported by extensive utilization of the resonance stabilization of both allyl triads and by the gradual change of the rate constants for the total decrease of *(3)* to *(6)*, which reflects only a substituent effect of the methyl group (cf. Table 1). The methyl-free compound *(1)*, with $k_{-(1)} = 100.8 \times 10^{-7}\,s^{-1}$[3] fits in the middle of the series. An alternative that cannot be excluded is the existence of intermediates in flat energy troughs, where product formation competes successfully with rotation around the C^5—C^6 bond in *(11)* and *(12)*. Since the stereochemical course of the rearrangements of *(3)* to *(6)* appears to be severely influenced by the methyl substituents, investigations are in progress with substrates that a) exclude this steric factor and b) increase the flexibility of the system by ring expansion.

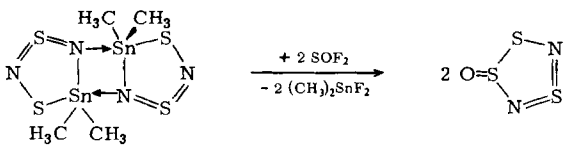
N_2S_3O—The First Oxide of a Five-Membered Sulfur-Nitrogen Ring[**]

By *Herbert W. Roesky* and *Hartmut Wiezer*[*]

The recent synthesis of $N_4S_4O_4$[1] has raised the question whether oxides of cyclic SN compounds containing less than six ring members can be prepared.

$(CH_3)_4Sn_2N_4S_4$ *(1)*[2,4], prepared from S_4N_4 and $[(CH_3)_3Sn]_3N$ by reaction in a molar ratio of 1:1, reacts with SOF_2 with elimination of $(CH_3)_2SnF_2$ according to



(1) *(2)*

The reaction product having the composition N_2S_3O *(2)* is isolated as a red liquid which can be vacuum-distilled without decomposition (b.p. 50 °C/0.01 torr); it does not wet glass. No signs of decomposition were observed, even after storage for several weeks at room temperature. In contrast, the previously known isomer formulated as $(S{=}N)_2SO$ is readily decomposable[4].

The structure of the new compound was elucidated by elemental analysis, IR spectrum, and mass spectrum.

The molecular ion is observed at *m/e* 140 with a relative intensity of 11%, accompanied by the following fragments *m/e* 94 NS_2O (4%), 92 N_2S_2 (4%), 80 S_2O (10%), 78 S_2N (28%), 76 N_2SO (12%), 64 $S_2(SO_2)$ (50%), 60 N_2S (8%), 48 SO (46%), and 46 NS (100%).

In the IR spectrum (cm^{-1}) the band at 1125 vs could be assigned to the SO stretching mode, and those at 981 s, 910 s, and 734 s to the ring skeleton. Further absorptions were registered at 1181 m, 663 s, and 583 m.

Procedure:

An excess of SOF_2 is passed into a suspension of *(1)* (9.9 g) in CH_2Cl_2 (600 ml). The mixture is then stirred for 3 h, the

Vinyllithium and 1,4-Dilithiobutane from Ethylene and Lithium

By *Valentin Rautenstrauch*[*]

Procedure:

A solution of biphenyl (70 mg, 0.45 mmol) and naphthalene (10 mg, 0.08 mmol) in dimethoxymethane (DMM) (2 ml) is stirred at room temperature (RT) in a Schlenk tube under argon with lithium pieces (*ca.* 500 mg, 72 mmol) until the solution turns dark brown (2—10 min). The stirred mixture (RT) is then diluted with DMM (18 ml) over a period of *ca.* 1 h, and stirring is continued for another 30 min. A 2 l flask containing ethylene (normal pressure, *ca.* 90 mmol) is fitted to the Schlenk tube, ethylene is condensed into the solution by cooling it to *ca.* −110 °C, and the system is brought to normal pressure by introduction of argon. The solution is then stirred with the lithium for *ca.* 20 h at −10 °C. The Schlenk tube and the 2 l flask form a closed system; the gas mixture over the cooled solution remains at RT. The solution then contains 3.0 mmol of vinyllithium *(3)*, 1.2 mmol of 1,4-dilithiobutane *(5)*, 0.04 mmol of 1,6-dilithiohexane *(6)*, 0.04 mmol of 3-butenyllithium *(7)*, 0.07 mmol of butyllithium *(8)*, and probably at least 3.3 mmol of lithium hydride *(4)* (along with biphenyl, naphthalene, products derived therefrom, and unreacted lithium).

None of these products is formed at lower temperatures (below −30 °C); *(5)* is not stable at higher temperatures (RT and above).

The organolithium compounds were identified by the usual derivatizations, with ketones, CO_2, and chlorosilanes. Definite proof for the presence of lithium hydride *(4)* is still lacking. After reaction with phenyldimethylchlorosilane *(9)*, phenyldimethylsilane *(10)* can be isolated; *(10)* is probably formed by reaction of *(4)* with *(9)*[1].

Interpretation and Discussion:

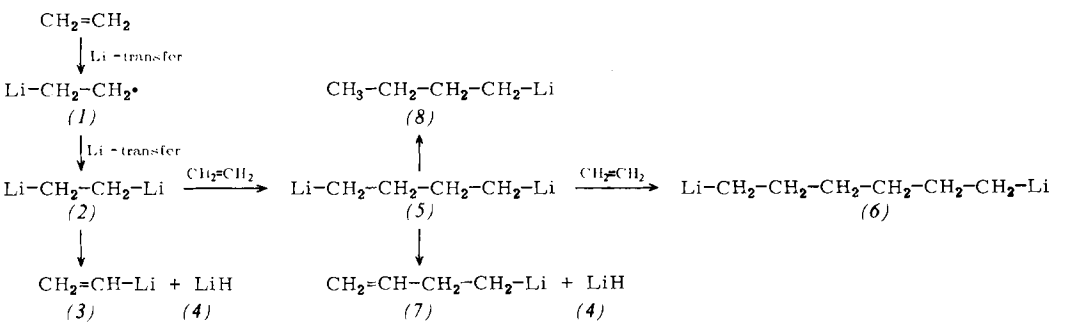
A transfer of lithium to ethylene takes place. This leads to the formation of one or several reactive short-lived intermediates. These react to give vinyllithium *(3)*, lithium hydride *(4)*, and 1,4-dilithiobutane *(5)*. Two parallel overall reactions (1) and (2) can be formulated.

$$\underset{}{CH_2{=}CH_2} + 2\,Li \longrightarrow \underset{(3)}{CH_2{=}CH{-}Li} + \underset{(4)}{LiH} \qquad (1)$$

$$2\,CH_2{=}CH_2 + 2\,Li \longrightarrow \underset{(5)}{Li{-}CH_2{-}CH_2{-}CH_2{-}CH_2{-}Li} \qquad (2)$$

The structures and mechanisms which play a role in these reactions are largely unknown. In particular, it is not known in what way the system biphenyl/naphthalene/lithium is involved in the transfer process[2].

Transfer of lithium to ethylene should lead to an "ethylene anion radical with lithium cation as the counterion" *(1)*[3] and perhaps also to a "1,2-dilithioethane" *(2)*[3]. An obvious hypothesis is that *(1)* and/or *(2)* are intermediates in our reactions (see scheme). It is striking that both a decomposition[4] of *(2)* into vinyllithium *(3)* and lithium hydride *(4)* and an addition of ethylene[5] to *(2)*, which would give 1,4-dilithiobutane *(5)*, would have direct analogies in the behavior of "normal" alkyllithium compounds. Both reactions would bring about a separation of the neighboring charges in *(2)*, and would therefore be especially favored.



Precisely this "normal" behavior is observed in the slow further reactions of 1,4-dilithiobutane *(5)* (scheme). Addition of ethylene leads to the next higher homolog[6], 1,6-dilithiohexane *(6)*, and loss of lithium hydride gives 3-butenyllithium *(7)*; in addition, *(5)* metalates the solvent with formation of butyllithium *(8)*.

To our knowledge, compounds of type *(1)* are unknown, and compounds of type *(2)* have not been identified conclusively[7]; no theoretical studies have been carried out on *(1)* and *(2)*. The overall reaction (1) has parallels in known reactions[8]; reaction (2) is novel.

The postulated formation of *(1)* and *(2)* is plausible. Lithium is a very powerful reducing agent in donor solvents and can form electron-deficient multicenter bonds with carbon; *(2)* would entail two bonds to primary carbon atoms.

German version: Angew. Chem. *87*, 254 (1975)

CAS Registry numbers:
$CH_2{=}CH_2$, 74-85-1; Li, 7439-93-2; *(2)*, 13067-82-8; *(3)*, 917-57-7; *(5)*, 2123-72-0; *(6)*, 2223-57-6; *(7)*, 14660-39-0; *(8)*, 109-72-8

[1] Authentic *(4)*, which is certainly less finely divided and covered by a hydroxide layer, does not react with *(9)* under these conditions.

[2] Biphenyl *(11)* appears to be the active "carrier". The reactions described proceed approximately as fast in the presence of *(11)* alone under otherwise identical conditions; however, reaction of lithium with *(11)* alone does not start easily in DMM. They also seem to occur in the presence of naphthalene alone, but are then much slower (small amounts of stable *(3)* can be detected). In the absence of *(11)* and of naphthalene no detectable reaction takes place. Action of Li on *(11)* in aprotic donor solvents such as DMM affords solutions containing equilibrium mixtures of biphenyllithium *(12)*, and possibly also biphenyldilithium *(13)* with *(11)* and lithium. [Reviews: *V. Kalyanaraman* and *M. V. George*, J. Organometal. Chem. *47*, 225 (1973); *N. L. Holy*, Chem. Rev. *74*, 243 (1974); see also: *D. F. Lindow*, *C. N. Cortez*, and *R. G. Harvey*, J. Amer. Chem. Soc. *94*, 5406 (1972)]. At present we consider two mechanisms (formulated for *(11)* as the carrier): 1) *(12)* and/or *(13)* transfer electrons and lithium cations to ethylene [see *M. Szwarc*: Carbanions, Living Polymers, and Electron Transfer Processes. Wiley-Interscience, New York 1968]. 2) Lithium which reacts directly with ethylene is formed (surface activation, transport into solution) in the reaction system $2\,Li + (11) \rightleftarrows Li + (12) \rightleftarrows (13)$. Transfer activity of the carriers [*(11)* is active, naphthalene weakly active, anthracene inactive] and the energy of their lowest antibonding molecular orbital [see *A. Streitwieser*, Jr.: Molecular Orbital Theory for Organic Chemists. Wiley-Interscience, New York 1968, p. 425] would seem to be related.

[3] As usual in this field we use names and formulas which symbolize the true structures, all of which are unknown. In the case of *(1)* the choice is particularly arbitrary. Possible structures are: *(1)*: ion pair, 2-lithioethyl radical and aggregated structures derived from both; *(2)*: monomeric covalent *(2)* and a cluster structure; *(5)*: cluster structure.

[4] *K. Ziegler* and *H.-G. Gellert*, Liebigs Ann. Chem. *567*, 179 (1950); *R. A. Finnegan* and *H. W. Kutta*, J. Org. Chem. *30*, 4138 (1965).

[5] *P. D. Bartlett*, *C. V. Goebel*, and *W. P. Weber*, J. Amer. Chem. Soc. *91*, 7425 (1969); *A. Maercker* and *W. Theysohn*, Liebigs Ann. Chem. *747*, 70 (1971).

[6] We have indications that higher homologs are also formed in decreasing amounts, *i. e.* we observe the initial steps of a "polymerization" of ethylene [see *K. Clusius* and *H. Mollet*, Helv. Chim. Acta *39*, 363 (1956)]. The first insertion $(2) \rightarrow (5)$ is faster than subsequent ones: the homologs undergo partial decomposition by loss of lithium hydride and by reaction with the solvent (scheme).

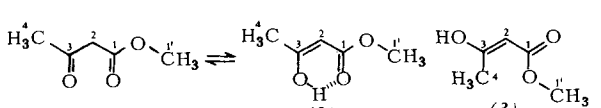
[7] *H. Kuus*, Uch. Zap. Tartu Gos. Univ. *1966*, 133 [Chem. Abstr. *69*, 67443 (1968)]; *1968*, 245 [Chem. Abstr. *71*, 49155 (1969)].

[8] In the absence of solvent certain 1-alkenes react at 20—120 °C with lithium suspension to form *(4)* and the corresponding 1-lithio-1-alkynes and 1-lithio-1-alkenes can be detected as unstable intermediates: *D. L. Skinner*, *D. J. Peterson*, and *T. J. Logan*, J. Org. Chem. *32*, 105 (1967).

Detection of the *trans*-Enol in Methyl Acetoacetate by ^1H- and ^{13}C-NMR Spectroscopy

By *Rudolf Matusch*[*]

The keto-enol tautomerism of methyl acetoacetate $(1) \rightleftarrows (2)$ has been thoroughly studied and the position of the equilibrium determined in numerous ways[1]. However, the *trans*-enol form *(3)*, which should exist alongside the keto form *(1)* and the hydrogen-bonded *cis*-enol form *(2)*, has not hitherto been detected. Since energy values of up to 10 kcal/mol are reported[2] for the hydrogen bond in *(2)*, the form *(3)* would appear to be at a considerable disadvantage.



(1) *(2)* *(3)*

Nevertheless, *(3)* can be enriched in yields of up to 15% very simply by distillation of acetoacetic ester at normal pressure; the rest of the distillate consists of *(1)* and *(2)*. If distillation is performed at reduced pressure no *trans*-enol *(3)* can be detected. Attempted photochemical *cis-trans* isomerization of *(2)* to *(3)* was unsuccessful.

Form *(3)* can be detected by neither UV nor IR spectroscopy[4]. Even with the aid of ^1H-NMR spectroscopy *(3)* can only be recognized on use of anisotropic solvents (Table 1).

Table 1. ^1H-NMR data (δ(TMS) = 0 ppm, coupling constants in Hz), [5] and ^{13}C-NMR data (TMS = 0 ppm) [7] of acetoacetic ester *(1)*, the *cis*-enol form *(2)*, and the *trans*-enol form *(3)*.

	^1H-NMR				
	CH_3	CH_2	OCH_3	Vinyl-H	OH
(1)	1.93 t $J = 0.50$	3.16 m	3.46 t $J = 0.18$		
(2)	1.69 d $J = 0.74$		3.49 s	4.91 q $J = 0.74$	12.60 s
(3)	2.28 d $J = 0.60$		3.26 d $J = 0.46$	4.99 qq $J = 0.60$, $J = 0.46$	
	^{13}C-NMR				
	C-1	C-2	C-3	C-4	C-1′
(1)	167.89	49.72	200.25	29.70	51.91
(2)	173.19	89.73	176.33	20.89	55.29
(3)	168.11	91.03	173.46	18.78	50.52

Support for the conformation proposed for *(3)* comes from a comparison of the coupling constants in *(2)* and *(3)*. The decrease in the allyl coupling constant can be regarded as indicative of isomerization about the double bond; the increase in the coupling constant between the ester methyl group and the vinylic proton from an unmeasurable value to 0.46 Hz can be explained by the W arrangement of the bonds involved in the coupling in form *(3)*.

Unequivocal confirmation of the existence of forms *(1)*, *(2)*, and *(3)*[6] is further provided by the ^{13}C-NMR spectrum[7] (Table 1).

Since changes in the charge density at the carbon atom are known from experience to cause marked shifts of the ^{13}C resonance frequencies, we have here a particularly impressive demonstration of the difference in the electron-withdrawing effect of the hydroxy group with [*(2)*] and without [*(3)*] hydrogen bonding.

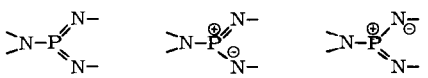
Phosphorus(V) Having Trigonal Planar Coordination

By *Siegfried Pohl, Edgar Niecke*, and *Bernt Krebs*[*]

The σ-bond skeletons of four- to six-coordinate phosphorus can generally be described with the aid of tetrahedra, trigonal bipyramids, and octahedra[1]. Occupation of only three coordination sites leading to planar coordination has hitherto only been postulated for unstable intermediates on the basis of stereochemical and kinetic studies[2].

The synthesis[3] of a phosphorus(V) derivative stabilized by $p_\pi-p_\pi$ bonds and having the composition $(R_3Si)_2NP(NSiR_3)_2$ with $R=CH_3$ has now provided an opportunity to establish, by complete X-ray structural analysis, whether trigonal planar coordination of phosphorus exists in a stable compound. We also wished to examine to what extent the polar resonance structures *(2a)* and *(2b)* should feature alongside *(1)* in descriptions of the bonding in aminodiiminophosphorane.



(1) *(2a)* *(2b)*

Bis(trimethylsilyl)aminobis(trimethylsilylimino)phosphorane[3], m.p. 46 °C, forms monoclinic crystals of space group C2/c having the lattice constants (at 18 °C) $a=17.905$, $b=10.654$, $c=13.236$ Å; $\beta=109.27°$; $V=2383$ Å^3; $Z=4$.

The structure was solved from diffractometer data by the direct method of symbolic addition. Least squares refinement with the structure factors of 1045 reflections observed at 18 °C converged to an R value of 4.3%.

In the solid state the molecule has C2 symmetry. The central phosphorus atom exhibits a planar threefold coordination to nitrogen atoms. The uncorrected P—N bond lengths are 1.503 and 1.646 Å (Fig. 1). The P—N_{imine} distances, which

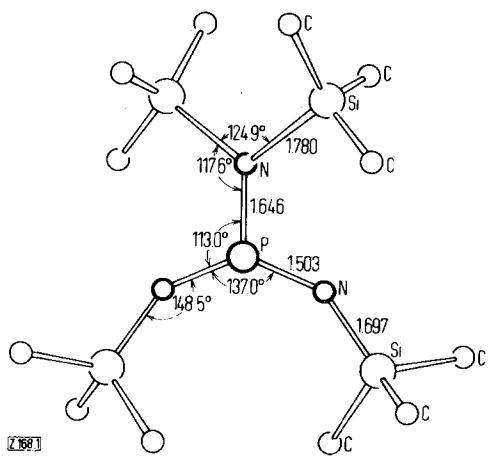


Fig. 1. Molecular structure of bis(trimethylsilyl)aminobis(trimethylsilylimino)-phosphorane in the crystal (bond lenghts in Å).

correspond formally to double bonds, lie at the lower limit of all known values for PN bonds[4]. Apparently, planarity favors particularly strong π bonds which probably also contribute to the stabilization of the coordinatively unsaturated phosphorus. Thus any significant weight of the polar resonance structures can be ruled out.

The P—N_{amine} bond is significantly shorter than a single bond (1.77 Å in $NaPO_3NH_3$[5]). The strengthening of this bond can be explained by $d_\pi-p_\pi$ interaction between phosphorus and amine nitrogen. Although the $N(SiR_3)_2$ group is twisted by about 32° out of the PN_3 plane the participation of d orbitals still permits this kind of overlapping. Similar effects are probably responsible for the shortening of the Si—N_{imine} bonds (1.697 Å) whereas the amine nitrogen is linked to silicon by a normal single bond (1.780 Å). The strengthening of the Si—N_{imine} π bond is in accord with the increase in the PNSi angle to 148.5°.

The Si—C bond lengths average about 1.871 Å. Successful localization of all the H atoms shows that the methyl groups are sterically fixed.

A supplementary low temperature study is in progress.

Lithium Tetraphenyl- and Tetramethylniccolate(II)

By *Rudolf Taube* and *Gerd Honymus*[*]

Simple binary σ-organylnickel(II) compounds NiR_2 generally display pronounced thermal lability. Thus $Ni(CH_3)_2$ already decomposes below −100 °C[1]. The only stable compounds capable of isolation have so far proved to be those containing bulky carbanions devoid of β-hydrogens, such as $Ni[C(C_6H_5)_3]_2$[2] and $Ni[C_6H_2(CH_3)_3]_2$[3].

A considerable stabilization, regardless of the organyl group, is known to occur on complexation, and numerous σ-organyl complexes of the general type NiR_2L_n, $NiR(X)L_n$, and $cpNiRL_n$ have been described[4].

Our attempts to prepare chelate complex-stabilized monoorganylnickel compounds led us to the tetraorganyl complexes $Li_2[Ni(C_2C_6H_5)_4]\cdot 4$ THF *(1)*, $Li_2[Ni(C_6H_5)_4]\cdot 4$ THF *(2)*, and $Li_2[Ni(CH_3)_4]\cdot 2$ THF *(3)*, of which *(2)* and *(3)* represent the hitherto unisolable pure phenyl- and methylnickel(II) combinations stabilized by "ate" complex formation.

For their synthesis, $Ni(dpi)_2$[5] (dpi = anion of 1,3-bis(2-pyridylimino)isoindoline) was added at −78 °C to a solution of $LiC_2C_6H_5$ in THF/hexane or of LiC_6H_5 or $LiCH_3$ in THF/ether and the mixture shaken with warming to room temperature until reaction was complete (*ca.* 1—2 h). Compounds *(1)*, *(2)*, and *(3)* are deposited as small lustrous crystals from the brown solutions; they are filtered off, washed, and recrystallized from THF/hexane [*(1)*] or from THF [*(2)* and *(3)*] by hot extraction[8]. Yield: *(1)*, 65%; *(2)*, 60%; and *(3)*, 56%.

Properties of *(1)*: beige crystals, decomposition with dark discoloration above 90 °C, soluble in THF. *(2)*: yellowish crystals, decomposition at 102—103 °C, moderately soluble in THF. Protolysis with cyclohexanol affords (alongside THF) benzene and biphenyl, and reaction with iodine in THF, with consumption of 4.15 I/Ni, exclusively biphenyl. *(3)*: golden-yellow lustrous crystals, decomposition at 129—130 °C, soluble in ether, more so in THF. Protolysis with butanol affords CH_4 (94%). Reaction with iodine in THF with consumption of 4.1 I/Ni gives CH_4 (35%), C_2H_6 (64%), and C_2H_4 (1%).

The strongly air- and moisture-sensitive new complexes are diamagnetic and therefore have planar coordination. Compared with the previously known solvate-free potassium salt[6], complex *(1)* is characterized by its better solubility and enhanced stability. Complexes *(2)* and *(3)* demonstrate that planar NiC_4 coordination can be achieved not only with sp but also with sp^2 and sp^3 hybridized carbon. The relatively high thermal stability, particularly of the methyl compound, contradicts the frequently cited Chatt-Shaw "π-bonding effect"[7], whose significance for the stability of the transition metal-carbon bond is frequently overestimated. The choice of a suitable nickel(II) chelate complex as starting compound is of essential importance in the preparation of *(2)* and *(3)*. When $NiBr_2 \cdot 2$ THF was used only about 2% of *(3)* could be isolated alongside metallic nickel. This demonstrates the great importance of the synthetic pathway for organo-transition-metallic compounds, the success of the present method apparently resting upon adequate complex-chemical stabilization of the nickel-carbon bond in all the intermediates of organylation.

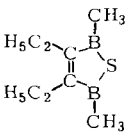
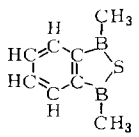
1-5-η-Benzothiadiborolenetricarbonyliron—A Complex Having a Fixed π-Electron System in the Benzene Ring[1]

By *Walter Siebert, Gunther Augustin, Roland Full, Carl Krüger*, and *Yi-Hung Tsay*[*]

1,2,5-Thiadiborolenes have both Lewis-acid and Lewis-base character. *(1)*[2] and *(2)*[3] react with $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ to give red thiadiborolenecarbonyliron complexes formulated as tricarbonyl derivatives *(1)*·$Fe(CO)_3$ and *(2)*·$Fe(CO)_3$ on the basis of analytical and mass-spectrometric data. However, for *(2)*·$Fe(CO)_3$ this implies that the "aromatic" acts as an unusual two-electron donor, which should lead to a loss of π-electron delocalization and fixation of the π bonds in the annelated benzene ring.



(1)



(2)

Spectroscopic findings (Table 1) confirm the participation of two π electrons of the benzene ring in complexation. It follows from the marked upfield shift of the ^{11}B-NMR signal by 51 ppm that the boron atoms interact with the $Fe(CO)_3$ group to a greater extent than in the previously known thiaborane-metal complexes $B(SCH_3)_3 \cdot Cr(CO)_3$ (41 ppm)[4] and $(CH_3)_2BSCH_3 \cdot Cr(CO)_5$ (21 ppm)[5].

Table 1. Spectroscopic data of *(1)* and *(1)*·$Fe(CO)_3$, and *(2)* and *(2)*·$Fe(CO)_3$.

(1)	*(1)*·$Fe(CO)_3$	*(2)*	*(2)*·$Fe(CO)_3$
^{1}H-NMR, δ [ppm] rel. to TMS			
(in CCl_4)		(in $CDCl_3$)	
−0.95 (s, 6)	−0.83 (s, 6)	−1.31 (s, 6)	−1.14 (s, 6)
−0.90 (tr, 6)	−1.17 (tr, 6)	−7.46 (m, 2)	−7.12 (m, 2)
−2.20 (qu, 4)	−2.10 (m, 4)	−7.63 (m, 2)	−7.33 (m, 2)
(J = 7.6 Hz)	(J = 7.6 Hz)		
^{11}B-NMR, δ [ppm] rel. to $(C_2H_5)_2O \cdot BF_3$			
(in CCl_4)		(in $CDCl_3$)	
−66.2	−27.8	−77.2	−26.4
IR, ν(CO) [cm^{-1}] in CCl_4			
	2060 (s)		2060 (s)
	1990 (vs)		1990 (vs)

The IR spectra show two bands for the $Fe(CO)_3$ group in the ν(CO) region, and changes in the region of C=C vibrations, on going from the free ligand to the complex. In the ^{1}H-NMR spectrum all signals are shifted upfield, thus indicating an enhanced electron density on boron and a weakening of the aromatic character of the benzene ring. Owing to relaxation effects, the two C atoms engaged in complex bonding and the CH_3—B group cannot be observed in the ^{13}C-NMR spectrum. The remaining signals undergo a slight upfield shift; the ^{13}C resonances coincide to give just one signal: −211.1 and −210.4 ppm for *(2)*·$Fe(CO)_3$ and *(1)*·$Fe(CO)_3$ respectively (relative to TMS in $CDCl_3$).

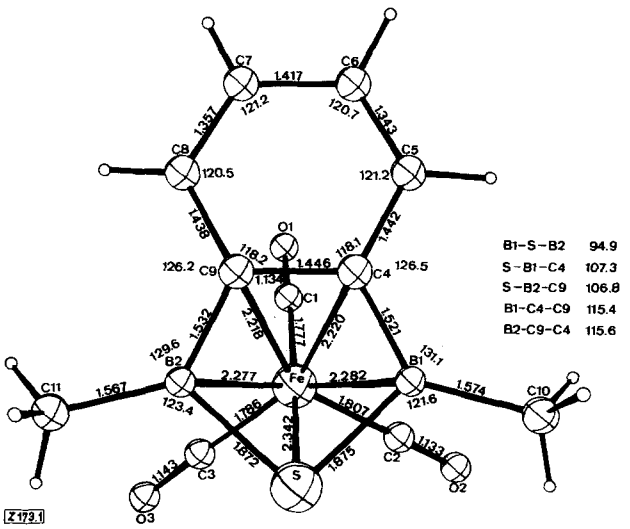


Fig. 1. Molecular structure of benzo-1,2,5-thiadiborolenetricarbonyliron. Maximum error ± 0.004 Å and ± 0.02°.

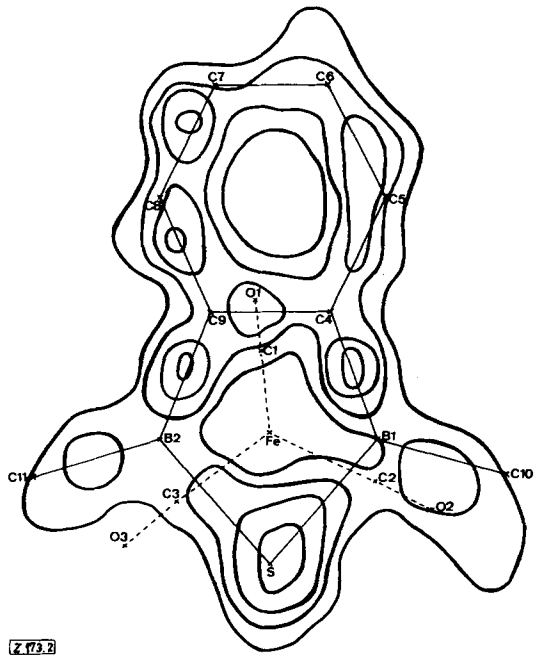
The structure of a *pentahapto*-thiadiborolenetricarbonyliron complex deduced from the spectroscopic data is confirmed by X-ray structure analysis of *(2)*·$Fe(CO)_3$ (Fig. 1).

Crystal data: $a=9.221(3)$, $b=9.322(2)$, $c=9.529(2)$ Å; $\alpha=69.66(2)$, $\beta=72.08(2)$, $\gamma=60.71(3)°$; $Z=2$; $d_{calc}=1.507$ g cm^{-3}; space group $P\bar{1}$. Refined from 2848 measured structural amplitudes (763 unobserved; Nonius CAD 4 diffractometer) including hydrogen atoms to an R value of 0.0262 ($R_w=0.0364$)[6].



Z 173.2

Fig. 2. π-Electron density in benzo-1,2,5-thiadiborolenetricarbonyliron. Contours in 0.1 e Å^{-3}.

The bond lengths in the ring system unequivocally establish the fixation of the π-electron system as cyclohexatriene with formation of a long π bond to the iron. Figure 2 shows a difference Fourier synthesis through the best plane (±0.02 Å) of the thiadiborolene ring; the Fourier coefficients were obtained on refinement of all atoms except hydrogen with 1468 reflections ($\sin\theta/\lambda=0.5$, $R=0.0305$, $\lambda_{Mo}=0.71069$ Å) The π-electron densities accord with the bond lengths found. The appearance of π-electron density in the B1—C4 and B2—C9 bonds warrants particular attention. The relatively long B—S bonds (1.874 Å) exceed those in trithiaborolanes[7] (1.803 Å) and thiaborins[8] (1.807 Å). Expectedly, a CO group on the iron is positioned *trans* to the sulfur.

Procedure:

Compound *(2)* is reacted with dodecacarbonyltriiron (molar ratio 1:1) in boiling toluene (1.5 h). After removal of solvent the dark red product is sublimed at 50 °C/0.01 torr and recrystallized from pentane at −10 °C. Yield 67%, m. p. 82—84 °C (dec.).

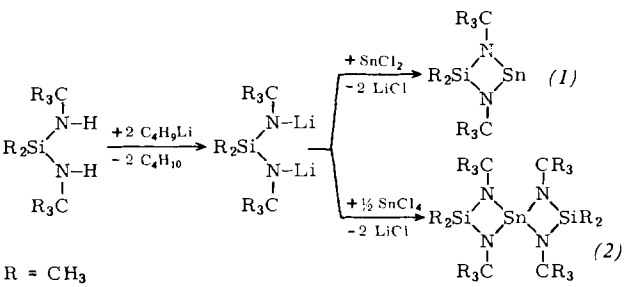
Cyclic Nitrogen Derivatives of Tetra- and Divalent Tin

By *Michael Veith*[*]

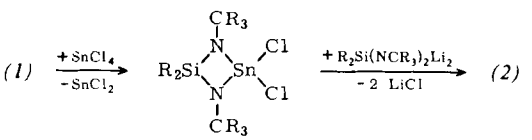
Whereas four-membered silicon-nitrogen rings (cyclodisilazanes) have been known for some time[1,2], corresponding tin-nitrogen rings (cyclodistannazanes) were synthesized only recently[3]. The present communication reports the preparation and characterization of four-membered heterocycles containing tin atoms having a valency of 4 or 2, in addition to silicon and nitrogen atoms. In the latter case the product constitutes the first cyclic nitrogen derivative of a Group IVB element in the divalent state[7].

Preparation of 1,3-di-*tert*-butyl-2,2-dimethyl-1,3,2,4λ^2-diazasilastannetidine *(1)* and the spiro compound *(2)* is accomplished by reaction of dimethyl-*N*,*N'*-bis(*tert*-butyl)silazane[4] according to the following reaction scheme:



The structure of the resulting heterocycles follows from the ^{1}H-NMR spectra, which contain only two signals each in the intensity ratio 3:1 for *(1)* and *(2)*, from the physical data, and from the molecular weights and molecular formulas determined by high-resolution mass spectrometry (Table 1).

Of the many possible *reactions*, that leading to *(2)* is cited as chemical proof for compound *(1)*.



The reaction affords *(2)* almost quantitatively, and also offers the opportunity of preparing spiro compounds of type *(2)* having different kinds of ligands.

X-Ray structure analysis of compound *(2)*[5] confirms the spiro structure expected from chemical arguments. In the crystal the molecule has $2(C_2)$ symmetry; in addition it also

possesses approximate 4 2 m (D_{2d}) symmetry. The four-membered rings are oriented perpendicular to each other, the rings themselves being largely planar. The N—C bonds are inclined only slightly to the ring planes so that the nitrogen has a planar environment. A remarkable feature of the bond lengths and angles (a selection is given in Table 2) is the very small angle at the tin atom. The NSiN′ and SiNSn angles are consequently larger than in the comparable structure of tetramethyl-*N*,*N*′-bis(trimethylsilyl)cyclodisilazane[6] (∢ NSiN′ = 88°, ∢ SiNSi = 92°).

Table 2. Characteristic bond lengths and angles in the molecule *(2)* (the values given are the average values of chemically equivalent bond lengths, the deviations listed in parentheses are in units of the last decimal place).

Sn—N	2.033 (5) Å	∢ SiNSn	95.2°
Si—N	1.727 (7) Å	∢ NSiN	93.4°
C—N	1.469 (7) Å	∢ NSnN	76.3°

Procedure:

A solution of the dilithium salt of dimethyl-*N*,*N*′-bis(*tert*-butyl)silazane (0.05 mol) in hexane is added dropwise over 1 h to a suspension of $SnCl_2$ (0.05 mol) or a solution of $SnCl_4$ (0.025 mol), prepared with cooling, in diethyl ether (50 ml). The mixture warms up slightly and turns red ($SnCl_2$) or yellowish ($SnCl_4$). After 4 hours' stirring the LiCl is filtered off and the solvents removed under reduced pressure. In the case of compound *(1)* the residue is fractionally distilled, and for isolation of compound *(2)* the residue is taken up in ether and crystallized out at −20 °C. Yields: *(1)* 12.0 g (74%), *(2)* 9.9 g (76%).

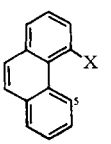
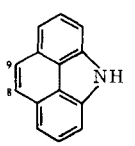
A New Route to 4*H*-Benzo[*def*]carbazole[1]

By *Richard Kreher* and *Wilfried Köhler*[*]

4*H*-Benzo[*def*]carbazole *(2)*, as a tetracyclic hetarene with an integrated isoindole system, exhibits remarkable thermal stability[3]. A versatile synthetic method has been developed[4] in order to facilitate a systematic study of the chemical properties and structure of the homologous [*def*]-annelated carbazoles.



(1)



(2)

Table 1. Prepared compounds *(1a)*—*(1d)* and *(2)*.

(1a), X = CN: m.p. 106—108 °C (methanol); yield 70%; ^{1}H-NMR ($CDCl_3$): τ = 0.1—0.5 (*m*, H^5), 1.9—2.8 (*m*, 8 aromat. H); cf. [6]

(1b), X = $CONH_2$: m.p. 266—267 °C (ethanol); yield 95%; ^{1}H-NMR (hexadeuteriodimethyl sulfoxide): τ = 1.0—1.3 (m, H^5), 1.7—2.7 (aromat. H and NH_2)

(1c), X = NH_2: m. p. 64—65 °C (petroleum ether); yield 70%; ^{1}H-NMR (CS_2): τ = 0.8—1.2 (m, H^5), 2.0—3.0 (m, 7 aromat. H), 3.2—3.6 (m, 1 aromat. H), 6.02 (s, NH_2); cf. [7]

(1d), X = N_3: m.p. 95—96 °C (*n*-hexane); yield 66%; ^{1}H-NMR (CS_2): τ = 0.5—0.9 (m, H^5), 2.4—3.3 (m, 8 aromat. H); MS (70 eV/20 °C): M^+ 219 (18%), $[M-N_2]^+$ 191 (100%), $[M-N_2H]^+$ 190 (48%)

(2): m.p. 174—175 °C (sublimation) ([3]: 173—174 °C); yield 63%; ^{1}H-NMR (hexadeuteriodimethyl sulfoxide): τ = −1.38 (s, NH), 1.9 (s, H^8, H^9), 2.1—2.5 (m, 6 aromat. H); UV (*n*-hexane): λ_{max} = 234 nm (log ε = 4.80), 270 (4.35), 327 (4.11); MS (70 eV/50 °C): $[M+H]^+$ 192 (16%), M^+ 191 (100%), $[M-H]^+$ 190 (30%), $[M-HCN]^+$ 164 (7%)

The essential step consists in the synthesis of the carbazole ring by cyclization[5] of 4-azidophenanthrene *(1d)*, which is obtained from 4-phenanthrenecarbonitrile *(1a)* (Table 1). This is readily and conveniently accessible from 1-naphthylacetonitrile and 1,3-bis(dimethylamino)trimethinium perchlorate by condensation and electrocyclic rearrangement[6]. Under optimized reaction conditions (25 h/80 °C and 110 h/220—225 °C) yields of up to 70% are achieved on a preparative scale. The partial hydrolysis of the carbonitrile *(1a)* to the 4-phenanthrenecarboxamide *(1b)* with conc. KOH solution and glycol monomethyl ether (2.5 h/120 °C) is almost quantitative.

Hofmann degradation to 4-aminophenanthrene *(1c)* cannot be achieved under the usual conditions. This was successfully carried out by reaction with excess hypochlorite solution and dioxane; optimal yields are obtained only with gradual temperature adjustment (5 h/45 °C and 2.5 h/80 °C).

The primary amine *(1c)*[7] is diazotized with sodium nitrite and dilute hydrochloric acid (2 h/0 °C) in a dioxane suspension, and after addition of urea is subsequently converted by reaction with excess sodium azide solution into *(1d)*, which can be isolated by adsorptive filtration.

Of the known ring closing reactions[5, 8], thermolysis of the azide *(1d)* in diphenyl ether (20 min/240 °C) proved to be the best. While the thermally induced N_2-elimination under

[*] Prof. Dr. R. Kreher and Dipl.-Ing. W. Köhler
Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Petersenstrasse 15 (Germany)

these conditions does in fact lead to the 4*H*-benzo[*def*]carbazole *(2)*, formation of *(1c)* by hydrogen abstraction predominates (yield 71%) in xylene. N_2-elimination also occurs under mass spectrometric conditions. The molecular peak is accompanied by the same fragmentation pattern as observed in the case of *(2)*, but with different distribution of intensities.

The above synthetic method might be generally suited for the synthesis of [*def*]-annelated carbazoles and thus extend the scope of bifunctional cyclization of 4,5-disubstituted carbazoles[9].

Synthesis of 5*H*-Dibenz[*c*,*e*]azepine by Elimination of Methanesulfinic Acid[1]

By *Richard Kreher* and *Werner Gerhardt*[*]

Heterocycles containing a cyclic CN double bond are generally prepared by cyclization of α,ω-bifunctional compounds[3]. An attractive alternative is the introduction of the cyclic CN double bond by elimination[4]. In this way halogen-substituted 2*H*-isoindoles are accessible in good yields from *N*-methanesulfonylisoindolines by base-catalyzed cleavage of methanesulfinic acid[2].

We have found a further preparatively interesting application of this method, namely the synthesis of the 5*H*-dibenz[*c*,*e*]azepine *(2)*[5]. The *N*-methanesulfonyl-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine *(1)*[6] required as starting compound is readily accessible from 2,2-bis(bromomethyl)biphenyl and methanesulfonamide. In the reaction with potassium *tert*-butoxide/dimethyl sulfoxide, methanesulfinic acid is eliminated under mild conditions and the cyclic azomethine *(2)* is obtained in remarkably good yields.

(1) *(2)*

Analytical and spectroscopic findings substantiate the existence of the cyclic azomethine structure *(2)*. Further supporting evidence is provided by the formation of cyclic imonium salts on reaction of *(2)* with methyl iodide or trimethyloxonium tetrafluoroborate. Reaction with 2 N sodium hydroxide solution does not result in deprotonation to give *N*-methyl-6*H*-dibenz[*c*,*e*]azepine but in nucleophilic addition of the hydroxide ion to the positively charged CN double bond[7].

Isomerization of the 5*H*-dibenz[*c*,*e*]azepine *(2)* to the tautomeric 6*H*-dibenz[*c*,*e*]azepine with *o*-quinonoid structure has not been observed, either spectroscopically or chemically. A similar behavior is exhibited by the thermally stable 5*H*-dibenz[*c*,*e*]azepine *N*-oxide, which likewise shows no tendency to rearrange[8].

5*H*-Dibenz[*c*,*e*]azepine *(2)*

A mixture of *(1)* (50 mmol) in anhydrous dimethyl sulfoxide (160 ml) and potassium *tert*-butoxide (165 mmol) is stirred for 45 min at room temperature under N_2. More alkoxide (25 mmol) is added to the mixture and stirring is continued for a further 45 min. The final mixture is subjected to two-phase solvolysis with water/ether. The ethereal layer, after separation, drying over calcium chloride, and concentration by evaporation yields an oil, which on distillation (b.p. 124 to 126 °C/0.01 torr) affords *(2)* as colorless crystals (m.p. 83 to 85 °C) in 85% yield [m.p. after sublimation (70 °C/0.2 torr) 84–85 °C]: ^{1}H-NMR ($CDCl_3$): $\tau = 1.62$ (s, H^7); 2.21–2.73 (m, 8 aromat. H); 5.66 (s, CH_2); ^{1}H-NMR (trifluoroacetic acid): $\tau = 0.93$ (d, $J = 9.5$ Hz, H^7); 1.82–2.46 (m, 8 aromat. H); 5.24 (d, $J = 5.5$ Hz, CH_2); ^{1}H-NMR (deuteriotrifluoroacetic acid): $\tau = 0.85$ (s, H^7); 1.77–2.39 (m, 8 aromat. H); 5.18 (s, CH_2).— ^{13}C-NMR ($CDCl_3$): $\delta_{TMS} = 161.9$ (C^7), 139.5, 139.1, 137.4, 132.8, 129.6, 129.0, 128.3, 128.0, 127.7, 127.6, 126.9, 55.0 (C^5).

Reviews

Abstracts of selected progress reports and review articles

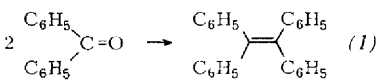
Induced autoimmune diseases are reviewed in an article by *E. M. Tan*. Several drugs (hydralazine, procainamide) generate an autoimmune disease similar to Lupus erythematosus but apparently *via* a different mechanism than the spontaneously occurring disease. It could be shown that a hydralazine-DNA-protein complex is formed *in vitro* whose antigenicity is more stable toward trypsin than that of the original nucleoprotein. *In vivo*, the immunological potential of the nucleoprotein is possibly increased by complex formation. Furthermore, the appearance of the disease is coupled with a decrease in the acetyl transferase level. [Drug-Induced Autoimmune Disease. Fed. Proc. *33*, 1894—1897 (1974); 13 references]

[Rd 763 IE—R]

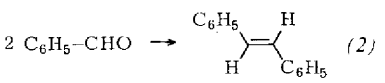
Vibrational spectra of transition metal chalcogen compounds are the subject of a review by *K. H. Schmidt* and *A. Müller*. Especially highly symmetrical molecules and ions are reviewed with spectra that can be totally assigned. Furthermore, the paper contains data of transition metal chalcogen compounds measured with special methods (intensities and band contours, Resonance Raman Effect, matrix spectra). It is shown how conclusions can be drawn from vibrational spectra about the nature of M—O, M—S, and M—Se bonds. [Schwingungsspektren von Übergangsmetall-Chalkogen-Verbindungen. Coord. Chem. Rev. *14*, 115—179 (1974); 326 references]

[Rd 765 IE—H]

The use of low-valent titanium compounds in organic chemistry is discussed in a report by *J. E. McMurry*. Thus in aqueous solution $TiCl_3$ is a versatile reducing agent, which, depending on the reaction conditions, can convert *e.g.* oximes into imines, haloketones into ketones, and nitro compounds into ketones. Noteworthy is the reductive coupling of carbonyl



(1)

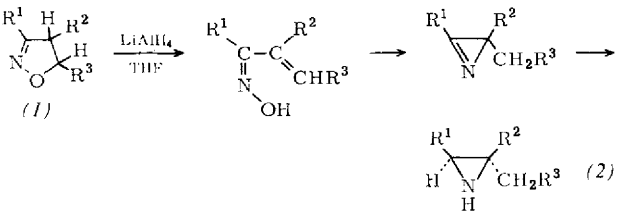


(2)

compounds such as benzophenone or benzaldehyde to tetraphenylethylene *(1)* and *trans*-stilbene *(2)*, respectively, by $LiAlH_4$—$TiCl_3$. Of special interest is the use of $TiCl_3$ for the deoxygenation of sulfoxides and for the reduction of enedicarbonyl compounds. [Organic Chemistry of Low-Valent Titanium. Accounts Chem. Res. *7*, 281—286 (1974); 29 references]

[Rd 768 IE—L]

The synthesis of heterocycles by ring transformation reactions of isooxazoles is reviewed by *T. Nishiwaki*. Aziridines *(2)* and azirines can be obtained by reduction of 2,5-dihydroisooxazoles *(1)* and by thermolysis and photolysis of isoxazoles, respectively. While there are only a few examples for the transformation to four-membered ring azetidines, numerous cases can be cited for the preparation of pyrrole, indole, isothiazole, and pyrazole derivatives thermally or by hydrogenation.



(1) *(2)*

Pyridine, quinoline, isoquinoline, acridine, and pyran derivatives can be prepared by reduction, photolysis or cycloaddition. Diazine, oxazine, and triazine rings can likewise be synthesized by hydrogenation, treatment with alkali or photolysis of the corresponding isoxazole. Seven- and eight-membered heterocycles can be obtained from isoxazoles by hydrogenation or by photolysis. [Synthesis of Heterocycles by Means of the Ring Transformation Reactions of Monocyclic and Condensed 1,2-Oxazoles (Isoxazoles); Synthesis *1975*, 20—37; 115 references]

[Rd 769 IE—M]

Applications of diffuse reflectance spectroscopy to the chemistry of transition metal coordination compounds are reviewed by *E. L. Simmons*. Theories of diffuse reflectance and the problems encountered in reflectance measurements are outlined. The method has been applied to studies of, *e.g.*, thermal decompositions of ammine, oxalate, halogen, and aquo complexes and solid state photochemical reactions. Quantitative analysis is also possible. [The Application of Diffuse Reflectance Spectroscopy to the Chemistry of Transition Metal Coordination Compounds. Coord. Chem. Rev. *14*, 181—196 (1974); 81 references]

[Rd 766 IE—H]

Selected highlights in immunological research in the last decade is the title of a review article by *M. Sela*. During this period the structure and conformation of antibodies have been elucidated and the constant and variable regions of their protein chains have been discovered. Further important progress has been made in the elucidation of antigenicity on a molecular level, of the relation between antibodies, their synthesis and immunologically active cells, as well as of the genetic control of the immune response. Immunology is playing an ever-increasing role as an experimental technique in other branches of science. [Selected Highlights in Immunological Research in the Last Decade. FEBS Lett. *40*, 85—97 (1974); 237 references]

BOOK REVIEWS

Atlas der Kunststoff-Analyse (Atlas of Plastics Analysis). By *D. O. Hummel* and *P. Scholl*. Vol. II Zusatzstoffe und Verarbeitungshilfsmittel (Additives and Processing Aids). Carl Hanser Verlag, Munich and Verlag Chemie GmbH, Weinheim 1973. 1st Edit., xix, 663 pp., 30 figs. 86 tables and 1151 spectra, bound, DM 268.—

This volume deals with the isolation and determination of admixtures and processing aids for plastics. It provides the long-expected supplement to the first volume[*] which dealt with the identification of high polymers and resins and has meanwhile proved its value.

The present volume begins with an outline of the most important experimental analytical methods, which could be kept quite short in view of the explanations in the first volume; finding the experimental details for a given case is made easier by the large number of references to the extensive literature. Then follows a description of the methods of detection of additives and processing aids: solvents, softeners, antiaging materials, stabilizers, vulcanization agents, fillers, pigments, antioxidants, antistatics, biocides, and flame-retardants are considered.

[*] Cf. Angew. Chem. internat. Edit. *10*, 204 (1971).

The following spectral section forms the largest part of the book. In some 1100 IR and 50 UV spectra the user has at his disposal an invaluable store of comparative material on the above-mentioned auxiliary additives. The excellent graphical presentation, linear in wave number, permits unambiguous comparison with his own spectra.

It should also be mentioned that, besides the extensive spectral section, there are abundant data on thin-layer chromatography, gas chromatography, and mass spectrography, as well as information about solvents and an extensive bibliography.

This second volume of the Atlas is an aid for the analytically active polymer chemist and, after short use, will become indispensible.

Wolfgang Brendlein [NB 248 IE]

Ullmanns Encyklopädie der Technischen Chemie (Ullmann's Encyclopedia of Technical Chemistry). Editorial board: *E. Bartholomé, E. Biekert, H. Hellmann*, and *H. Ley* (deceased). Vol. 8: Antimon und Antimon-Verbindungen bis Brot und andere Backwaren (Antimony and Antimony Compounds to Bread and Bakery Products). Verlag Chemie GmbH, Weinheim 1974, 4th Edit., XVI, 730 pp., 160 figures, 294 tables, subscription price DM 345.—; final price *ca.* DM 385.—.

The present volume 8 of the new edition of "Ullmann"[*] is the second in the alphabetical part which, treating the whole field of technical chemistry under alphabetically arranged keywords, forms the major part of the encyclopedia. Here are found not only inorganic and organic starting materials, intermediates and chemicals, raw materials, metals, and polymers, but also application-oriented areas such as dyestuffs, fibers, pharmaceuticals, cosmetics, pesticides, and foodstuffs.

An impression of the range of materials covered by Ullmann can be obtained from a brief look at the more important keywords in the present volume: from inorganic chemistry there are the elements antimony, arsenic, barium, beryllium, lead (Blei), boron, bromine, and their industrially interesting compounds; from the field of organic intermediates there are ethanol, aliphatic ethers, ethylene and several of its derivatives such as ethylene oxide, ethylene glycol, ethylene chlorohydrin, ethanolamine, and ethyleneimine, as well as benzene and some of its derivatives; to these must be added the keywords for materials with special applications, namely antioxidants, asbestos, building materials, bitumen, bleaches, and dyes of the azine and azo series; finally, in the range of biological products and processes we have the keywords biotechnology, bread and other bakery products, beer, and blood—blood needed in medicine not only in the fresh or preserved state for transfusions but also as a raw material for the proteins that are fractionated out of it for special therapeutic applications.

The entry on ethanol also includes drinks obtained by distillation from the products of alcoholic fermentation. Of general interest under this keyword is the section "Physiology and Toxicology": there we learn, *inter alia*, that in flying accidents with a lethal outcome 35—40% of the pilots were ethanol-positive, and that alcohol increases, and sometimes even potentiates, the action of all the old and new depressant psychopharmaceuticals, especially barbiturates.

The entry on biotechnology deserves special attention. Its inclusion shows that the present state of knowledge is kept in mind not only in the content of the entries but also in the conception of the work as a whole. This entry shows particularly well how clarity in subdivision and presentation, in places by tabulated reviews, can lead to a compressed but nevertheless very easily apprehended summary of an extensive subarea of chemical technology. Here as elsewhere in Ullmann, the large number of references to important literature sources contributes to the large content of information.

Summarizing, it remains only to state that in its new form too Ullmann is an essential source of information for all concerned with chemical-industrial problems. In addition, the work will be a valuable tool for the scientist engaged in pure research, for instance when he is interested in the purity and composition of industrial products or in their toxicity.

Ulfert Onken [NB 249 IE]

[*] Cf. Angew. Chem. internat. Edit. *14*, 73 (1975).

Methods of Enzymatic Analysis. Edited by *H. U. Bergmeyer*. 4 Volumes. Verlag Chemie GmbH, Weinheim/Academic Press, New York 1974. 2nd English Edition. Total of 2626 pp., numerous figures and tables. Individual price $ 56 per volume. Set price $ 198 for all four volumes.

Eleven years after the first English edition we have the second edition of "Methods of Enzymatic Analysis" by *H. U. Bergmeyer*, this time in collaboration with *K. Gawehn*. This reference book with its participation of 240 authors has long since become the standard work, and the editor has used the opportunity provided by the need for a new edition to bring it completely up to date. The general subdivision of the book and the clear presentation of its contents remain unchanged. The introduction of additional chapters has increased its size, but not very greatly; tautening the text in many places and omission of outdated material have prevented unnecessary bulk. The expansion of the references listed, almost throughout the work and including publications of very recent date, is most welcome.

The general introduction to the fundamentals of enzyme analysis has been considerably expanded and improved. There are new chapters on reaction kinetics in general and on the kinetics of enzymatic reactions in particular, as well as a chapter on methods of determining Michaelis and inhibitor constants. The text has been kept concise and is very well suited for recapitulation by the advanced student and as an introduction to practical work by the beginner. Moreover, the "Experimental" chapter in the general introduction has been revised and somewhat expanded. New experimental directions, description of a rapid automatic analyser, and new values for the extinction coefficients of reduced pyridine nucleotides (they are a few percent higher then previously) are examples of careful work performed by the authors and editors.

Section B of the book, devoted to biochemical reagents, has been rearranged. It begins with a new chapter in which the nomenclature and problems of standardization, concepts of quality of biochemical reagents, and their sources of supply, are discussed; these are followed by descriptions of enzymes, coenzymes, and substrates and by final collation of the reagents in the approved way.

Section C is concerned with methods of measuring enzyme activities and Section D deals with methods of determining metabolites. These two are only slightly altered, for example by transposing individual enzymes so that they correspond to the new arrangement in the IUB Enzyme Catalog 1973, or by replacing some old methods of determination by improved processes.

Summarizing, it can be stated that in its present form the book needs hardly any fundamental improvement, only that it maintain its high quality.

Dieter Oesterhelt [NB 250 IE]

Magnetochemie. Grundlagen und Anwendungen. (Magnetochemistry. Fundamentals and Applications). By *A. Weiss* and *H. Witte*. Verlag Chemie GmbH, Weinheim 1973. 1st

Edit., ix, 281 pp., 120 figs., 78 tables, bound, DM 59.—.

Thirty-six years after the appearance of *Wilhelm Klemm*'s monograph now comes the first further book on magnetochemistry in the German language. In plan it corresponds largely to its predecessor. The authors first direct their attention to chemists, using simple mathematical formulations. After a short chapter on physical fundamentals the methods of measurement are described, including that for single crystals. Not only the well-known procedures based on field forces but also susceptibility measurements by induction methods and those with the aid of nuclear magnetic resonance are discussed. There follows a chapter on diamagnetism, which treats classical theory and the results of quantum mechanics, the semiempirical and the incremental methods, as well as ion-diamagnetism. The chapter on "Paramagnetism" contains sections on the magnetic properties of free atoms and ions, influences of ligands, spin-path coupling, *Van Vleck*'s paramagnetism, complexes with 4d- and 5d-metal ions, and rare-earth compounds. The conclusion is provided by cooperative effects (antiferromagnetism, ferrimagnetism, and ferromagnetism, electrons in metals and alloys) and examples of the use of magnetochemistry in chemical problems. The dimensions and units for electrical and magnetic magnitudes are collected in an Appendix.

The book is intended as an introduction to the performance and interpretation of magnetic measurements, and its value lies in its first part. Thus, the methods of measurement, their physical foundations, and the sources of error (in particular ferromagnetic impurities) and methods of overcoming them are described simply and clearly. The theory of transition-metal compounds, the chief of interest to the magnetochemist, is important for the interpretation of the experimental data, and this part, as also the presentation of cooperative effects (except for the section on "Electrons in Metals and Alloys") is kept too short. Important concepts, like the Jahn-Teller effect and metamagnetism, are missing and the tables are incomplete (pages 182, 187). In contrast, in many places the authors could have been more concise: thus, *Pauling*'s views on the structure of complexes are now of only historical interest; the incremental methods of determining diamagnetic susceptibility could have been restricted to the *Haberditzl* method. There are also some repetitions (derivation of the Van Vleck formula, magnetic properties of closed electron shells).

If one disregards these shortcomings, the book provides much useful practical information for the magnetochemist by virtue of its extensive bibliography and the numerous examples of applications.

Heiko Lucken [NB 251 IE]

Methoden der Analytischen Chemie (Methods of Analytical Chemistry). Vol. 1. Trennungsmethoden (Methods of Separation). By *R. Bock*. Verlag Chemie GmbH, Weinheim 1974. 362 pp., 236 figs., 79 tables, bound, DM 42.—.

The task of presenting the confusing multiplicity of separation methods used in today's analytical chemistry clearly and systematically is as necessary as it is difficult. It is therefore very pleasing to find that an author as competent as *Rudolph Bock* has undertaken this task in the first volume of his monograph series "Methoden der Analytischen Chemie".

The division of separation methods adopted here, essentially into two large groups (separations by different distributions between two immiscible phases and separations by different migration rates in one phase) at first appears disconcerting, but becomes intelligible on closer attention to the book. Nevertheless, it would have been better to designate the first group as "Separation by establishment of different phase equilibria" (cf. *B. L. Karger, L. R. Snyder*, and *C. Horvath*: An Introduction to Separation Science, Wiley, New York 1973), since natural incorporation of processes such as distillation and sublimation is then possible. Unfortunately, strict adherence to the system resulting from the author's classification leads here and there to statements that could be misunderstood; these arise mainly from insufficient differentiation between separation principles (such as distribution), physical phenomena (such as adsorption), and experimental techniques (such as chromatography).

In a few matters of detail the reviewer does not agree with the author's views. For example, isotope dilution analysis is treated relatively extensively, whereas for detectors in gas chromatography, the reader is referred to Volume 2 of this series; a distribution ratio (in extractions involving the establishment of chemical equilibria) is called a distribution coefficient (in the sense of a Nernst distribution); the term "extraction" is reserved exclusively for dissolution of specific substances out of a solid mixture, whereas the widely used liquid-liquid extraction is referred to as "shaking out".

Nevertheless, the volume as a whole can be regarded as a successful review of methods of separation and thus as a valuable source of information. The didactically skilful method of presentation, which characterizes the experienced college lecturer, makes it easy to become familiar with the problems discussed, and the large number of carefully chosen and collected references makes it easy to search deeper into the material. The keyword subdivisions placed at the head of individual chapters provide rapid information on the contents and are very helpful for tracing detail; this method of presenting material should find increasing application in textbooks.

Dieter Klockow [NB 253 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Synthetic Reactions of Metal Atoms at Temperatures of 10 to 273 °K[**]

By Peter L. Timms[*]

Metal atoms, easily formed by vaporizing metals at high temperatures under vacuum, are reacted with inorganic and organic compounds in solution at 80 to 273 °K or by co-condensing the atoms and substrate vapors at 10 to 80 °K. Gram quantities of products containing metals in low valency states can be isolated in many cases, and some of the compounds formed are inaccessible by conventional synthetic routes.

1. Evaporation of Metals

Much is known about the evaporation of metals because of the scientific and commercial importance of forming metal films by condensation of vapors. The wide range of volatilities among metals is shown in Table 1. The temperatures given are those at which the metal has a vapor pressure of 0.01 to 0.1 torr, sufficient to give rapid evaporation under high vacuum.

Table 1. Evaporation temperature of metals under vacuum.

T[°C]	<1000	1000—1400	1400—1700	1700—2000	2000—2500	>2500
ΔH_{vap} [kJ]	<200	200—360	360—430	430—520	520—600	>600
	Li	Be				
	Na Mg	Mn Cu	Cr Fe Co Ni	Ti V		
	K Ca Zn	Ag Sn	Pd		Zr Ru Rh	Nb Mo
	Rb Sr Cd	Au		U	Pt	Hf Ta W Re Os Ir
		Pr, Nd, Gd, Tb,	La, Ce, Lu			
	Sm, Eu	Dy, Ho, Er, Tm				

Main Group metals are more volatile than most transition metals. With the transition metals, volatility usually decreases down the Groups as the binding energy of the metals increases. Although the lanthanoids are chemically very similar, the volatilities of the metals show surprisingly large variations.

The practical difficulties of vaporizing a metal depend partly on how high a temperature is required and partly on the corrosiveness of the liquid metal. A greater variety of evaporation techniques can be used for the volatile metals than for the very refractory ones. We favor two methods of vaporization of metals for atom synthesis on a preparative scale. The first is evaporation from an alumina crucible wound with molybdenum or tungsten wire which is heated resistively. This is very satisfactory for the transition metals Cr, Mn, Fe, Co, Ni, Pd, Cu, Ag, and Au. We use crucibles of varying sizes giving evaporation rates of 1 to 50 g per hour of these metals. For more refractory metals, or metals which attack alumina, we use electron bombardment vaporization. Our electron gun (Fig. 1) has a heated tungsten filament from which electrons flow to the metal charge maintained at a high positive potential.

[*] Prof. Dr. P. L. Timms
School of Chemistry, University of Bristol
Cantock's Close, Bristol, BS8 1TS (England)

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12—15, 1974).

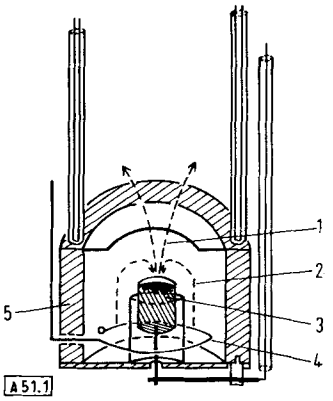

Fig. 1. Electron beam evaporation source. 1, metal vapor; 2, electron beam; 3, crucible (+ve); 4, hot filament (grounded); 5, water-cooled copper block.

This arrangement seems to overcome some of the problems due to stray electrons experienced with electron guns in which the heated charge is at ground potential. Although it is possible to use a water-cooled copper container for the liquid metal, much greater efficiency is achieved by using uncooled tungsten, tantalum, or graphite containers. On a small scale, little contamination of the evaporating metal by the crucible material is observed because the electrons are focused on to the surface of the liquid metal which is thus much hotter than the crucible.

The method of metal atom synthesis requires that the metal vapor is condensed on a cooled surface. The heat radiation which is liberated while a metal is being evaporated has to be absorbed by the refrigerant. The amount of cooling required increases rapidly with the evaporation temperature of the metal. For example, Cr, Mo, and W each vaporize at a rate of 1 g cm^{-2} h^{-1} at a temperature of about 1460, 2760, and 3400 °C respectively. The radiant heat emission from each metal at the given temperature is about 13, 120, and 260 W cm^{-2} h^{-1} respectively. The extra cost of cooling required when vaporizing the refractory metals may be trivial on a laboratory scale, but it will be significant if metal atom syntheses are adopted commercially.

2. Techniques for Reacting Metal Vapors

Much preparative work has been carried out by condensing a metal vapor and the vapors of other compounds on a liquid nitrogen cooled surface under high vacuum[1, 2]. We originally used stainless steel vacuum apparatus[3], and this is undoubtedly very safe and convenient for large scale work. However, largely as a result of success with a glass apparatus built for teaching undergraduates[2], some of our research apparatus is now made of glass and is of a simple and versatile design. Figure 2 shows the type of vessel, set up for vaporization of 2—5 g of a metal from an alumina crucible. The sample inlet system can be heated to aid volatilization of slightly volatile compounds.

After co-condensing the metal vapor with one or more compounds at −196 °C, highly volatile products can be pumped on to the vacuum line when the vessel is warmed. Alternatively, the vessel can be filled with gaseous nitrogen or argon and the furnace and inlet assembly can be lifted out. A variety of fittings can then be put on the top flange of the vessel to facilitate recovery of products by solution techniques in the absence of air and, if necessary, at low temperatures.

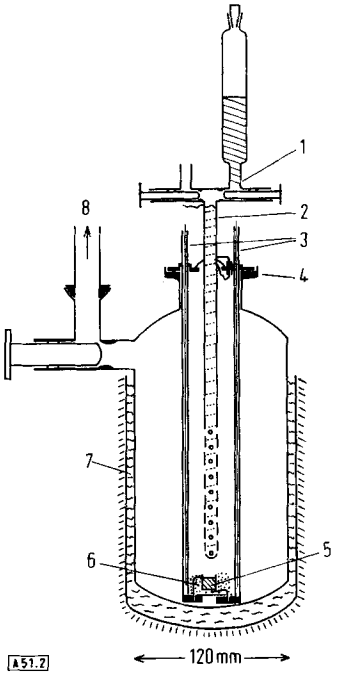

Fig. 2. Apparatus for co-condensation of metal atoms and ligand substrates at −196 °C. 1, inlet for liquids or gases; 2, inlet heating wires; 3, water cooling and electricity; 4, O-ring flange; 5, heated metal; 6, Mo-wire-wound Al_2O_3 crucible; 7, liquid nitrogen; 8, high vacuum.

Recently, we have used a new type of apparatus in which the metal vapor is condensed into a solution of a compound in an inert solvent contained in a rotating evacuated flask (Fig. 3). The solution must be kept at a temperature where its vapor pressure is less than about 10^{-3} torr otherwise the pressure in the flask may be too high to give efficient vaporization of the metal.

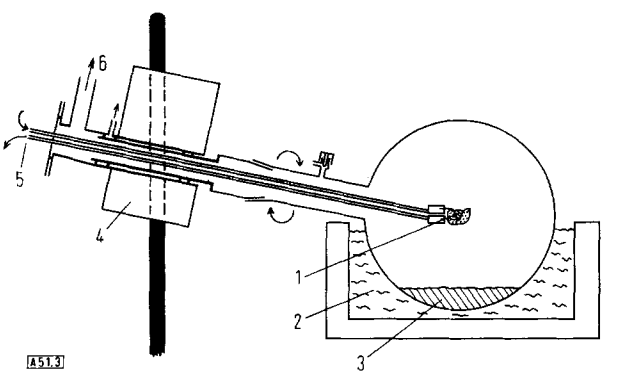

Fig. 3. Rotary apparatus for reacting metal atoms with cooled solutions. 1, evaporating metal; 2, cooling bath; 3, substrate solution; 4, rotary drive mechanism; 5, water and electrical power; 6, high vacuum.

Provided that the solvent and solute are both of low volatility, it is possible to condense metal atoms into solutions at room temperature, although low temperatures are used more commonly to reduce the vapor pressure and to stabilize the reaction products.

In addition to the higher temperature of operation, the procedure has several other advantages over the co-condensation method:

1) Substrates which are too involatile or too unstable to be volatilized can be reacted with metal atoms, provided that they are soluble in an inert solvent.

2) The products are obtained in a convenient form for isolation by conventional solution techniques or for further reaction with other compounds added to the rotary reactor.

3) The apparatus is easily scaled-up or made continuous in operation. For example, a cooled, evacuated, rotating drum 100 cm in diameter and 150 cm long, containing 150 l of a reactant solution, could house one of the metal evaporation sources described by *Reichelt*[14] for producing metal vapor at the rate of 3 kg h^{-1}. On this scale, continuous renewal of the solution and of the metal charge would be practicable.

The main problem with the solution technique is to find an inert solvent which will dissolve at least 2% of the reactant compound at a temperature at which the vapor pressure of the solution is below 10^{-3} torr. Table 2 shows a range of useful solvents and some of their physical properties. The compounds given are not too viscous at their operating temperature to give rapid mixing of the solution as the flask rotates.

Table 2. Solvents for the rotating solution reactor.

Solvent	Operating temp. [a]	M.p. [°C]	B.p. [°C]
Propane	−185	−187	− 42
Isopentane	−145 to −160	−160	+ 28
Methylcyclohexane	−110 to −125	−126	+101
Pet. ether (120—160)	− 80 to − 90	*ca.* −90	
m-Diisopropylbenzene	− 60 to −100	−105	+202
Bis(ethylhexyl) ether	− 10 to − 60	*ca.* −80	+280
Light liquid paraffin	+ 20 to 0	− 20	> +300
Silicone 704 (phenylmethylsiloxane)	+ 50 to − 20	− 20	> +350

[a] Vapor pressure of solution $< 10^{-3}$ torr [°C].

We also have done some work on the reactions of metal atoms with compounds under matrix isolation conditions at 10—40°K. For this, we prefer to form the metal vapors and other high temperature species from tiny alumina tube furnaces with resistively heated tungsten wire windings, but in most respects our apparatus is conventional[4].

3. Results

Much of our most recent work has been on the reactions of transition metal atoms with potential ligands to form complexes containing the metal in a zerovalent or a low valent state. These reactions are conveniently considered according to the number of electrons donated by the ligands. We have also studied dehalogenation reactions of copper, silver, and gold which will be discussed later.

3.1. Reactions with Some 2-Electron Donors

Early work on trifluorophosphane[3] showed that this is a very useful ligand in metal atom co-condensation reactions. It resembles carbon monoxide in its properties as a ligand, but it can be condensed at −196°C unlike carbon monoxide. We have continued to use trifluorophosphane mixed with other ligands in a variety of metal atom reactions.

Trimethylphosphane reacts on condensation with Co, Ni, and Pd atoms to form the known tetrakis(trimethylphosphane)metal(0) complexes in modest yields (5—15%). Iron vapor and trimethylphosphane give the previously unknown $Fe[P(CH_3)_3]_5$, a yellowish-red intensely reactive solid, which can be sublimed at room temperature. The yield of the compound is higher if the trimethylphosphane is diluted with pentane. The co-condensate at −196°C is green-colored, suggesting that $Fe[P(CH_3)_3]_5$ results from secondary reactions on warm-up. Hexane does not have the same effect as pentane and seems to inhibit complex formation. The reason for this striking difference in behavior between two chemically inert diluents is not yet understood.

We have reacted triphenylphosphane with nickel atoms in the rotary apparatus, using a solution in methylcyclohexane at −120°C or a solution in Silicone 704 at 0°C. In both cases, the yield of tetrakis(triphenylphosphane)nickel(0) was very high. Recovery of the pure crystalline solid was easier from the volatile hydrocarbon than from the oily Silicone.

The diatomic molecule PN is generated by heating P_3N_5 at 850°C under high vacuum.

$$P_3N_5 \longrightarrow 3\ PN + N_2 \qquad (1)$$

We have condensed PN and metal atoms with a very large excess of krypton on to a CsI window at 10°K, and we have observed the formation of metal complexes by changes in the infrared spectra on warming the matrix to 20—30°K. With Ni atoms, we see the formation of nickel-N_2 and nickel-PN complexes, and complexes in which both N_2 and PN are coordinated to the nickel. The Ni—N_2 system has been previously studied by *Ozin et al.*[5]. Ag atoms complex preferentially with PN and the species AgPN and $(AgPN)_2$ are formed. Studies with $P^{14}N$ and $P^{15}N$ suggest that PN coordinates through the phosphorus atom to transition metals.

We have attempted to make $Ni(N_2)_4$ by condensing nickel vapor on a surface cooled by liquid nitrogen in the presence of 1 torr pressure of gaseous nitrogen. Subsequent addition of other ligands such as 1,5-cyclooctadiene which would be expected to displace coordinated N_2 and form complexes, gave no evidence that any $Ni(N_2)_4$ was present. In a related experiment, palladium was condensed at −196°C in the presence of 1 torr pressure of CO. Addition of PF_3 did result in the formation of $Pd(PF_3)_4$, suggesting that $Pd(CO)_4$ may have been present on the cold surface. Tetracarbonylpalladium has previously only been prepared in matrix isolation studies by *Ogden et al.*[6]. The matrix isolation method permits the formation of metal complexes which may be endothermic with respect to the solid metal and the ligand. The possibility of obtaining these compounds free of the matrix environment depends critically on their kinetic stability. Our results indicate that $Ni(N_2)_4$ is not kinetically stable at −196°C but that $Pd(CO)_4$ may be stable.

3.2. Reactions with 3-Electron Donors

Apart from work on reactions of nitric oxide with metal atoms[7], our work with 3-electron donors has been confined to studies of allyl compounds. Using tetraallyltin as a source of allyl groups in a co-condensation with Ni atoms at −196 °C gives fair yields (20—30%) of bis(η-allyl)nickel. We could not isolate tris(η-allyl)iron from a similar co-condensation of Fe atoms amd tetraallyltin. However, condensation of Fe atoms with a mixture of tetraallyltin and trifluorophosphane forms $(\eta^3\text{-}C_3H_5)Fe(PF_3)_3$, a paramagnetic, purple compound, stable for short periods at 20 °C. Only a trace of $(\eta^3\text{-}C_3H_5)_2Fe(PF_3)_2$ is formed although this is an 18-electron compound and the observed product is a 17-electron compound.

The reaction of Co atoms with trifluorophosphane and either propene or cycloheptatriene gives an allyl derivative: in each case, the hydrogen loss from the organic reactant must be facilitated by the formation of the tetrakis(trifluorophosphane)cobalt hydride (eq. (2)).

$$\begin{aligned} Co(g) + C_3H_6(g) + PF_3(g) &\xrightarrow[-196\,^\circ C]{\text{condensed}} (\eta^3\text{-}C_3H_5)Co(PF_3)_3 \\ &\quad + HCo(PF_3)_4 \\ Co(g) + C_7H_8(g) + PF_3(g) &\xrightarrow[-196\,^\circ C]{\text{condensed}} (\eta^3\text{-}C_7H_7)Co(PF_3)_3 \\ &\quad + HCo(PF_3)_4 \end{aligned} \qquad (2)$$

3.3. Reactions with 4-Electron Donors

We have prepared bis(1,5-cyclooctadiene)iron(0) by condensing iron vapor into a 10% solution of 1,5-cyclooctadiene in methylcyclohexane at −120 °C in the rotary reactor[15]. This is believed to be the first synthesis of the iron analog of the well-know bis(1,5-COD)nickel(0). Typically, we condensed 2 g to 5 g of iron vapor into 200 ml of the ligand solution in an hour. The product crystallizes from the solution during the preparation and is carried around the rotating flask as a slurry. At the end of the condensation, the compound is dissolved and recrystallized using low temperature solution techniques (yield 30—40%). The pyrophoric, brown crystals decompose with deposition of iron above −40 °C. Green solutions of the compound in hexane quickly deposit an iron mirror above −30 °C, but solutions in 1,5-COD are stable up to 0 °C. Solutions of the compound give no ^{1}H-NMR signal indicating that the compound is paramagnetic, but NMR, ESR, and magnetic balance measurements have all been rendered uncertain by the very facile decomposition of the compound to metallic iron. If the compound is paramagnetic, this would indicate a tetrahedral arrangement of the double bonds in the ligand around the metal, but diamagnetism would indicate a square planar structure.

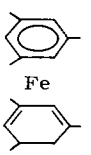
Many other ligands displace cyclooctadiene from $(COD)_2Fe$, including phosphanes, cyclooctatetraene, cycloheptatriene, and butadiene. Since gram quantities of the compound can be made it is a useful reagent for synthesizing other iron compounds. In many cases, it is unnecessary to isolate the pure compound but merely to add a reactant to the crude product in the rotary reactor. Co-condensation of iron vapor and a mixture of cyclooctatetraene and trifluorophosphane at −196 °C gives a low yield of cyclooctatetraene-tris(trifluorophosphane)iron(0). It seems that COT is readily polymerized in metal atom reactions and this accounts for the poor yield of the complex.

3.4. Reactions with 5- and 6-Electron Donors

Nickel vapor reacts on co-condensation with the *closo*-carborane $C_2B_9H_{11}$ to give the known complex $(C_2B_9H_{11})_2Ni$. This compound is a derivative of the *nido*-carborane anion $[C_2B_9H_{11}]^{2-}$. Thus the metal atom forces the carborane to undergo a cage opening reaction from a *closo*- to a *nido*-structure. It is hoped that this will prove to be a general method for making metallo-carborane complexes.

Unlike the neighboring elements in the first transition series, manganese vapor does not react on condensation with cyclopentadiene at −196 °C. However, a mixture of cyclopentadiene and benzene, toluene, or mesitylene condensed with manganese vapor gives a low yield of the corresponding (arene)$Mn(C_5H_5)$ compound. Hydrogen is evolved only on warming the condensate to about −120 °C showing that cyclopentadienyl derivatives are not primary products. The results imply that an arene-manganese complex is better able to coordinate to cyclopentadiene than are manganese atoms. Using different experimental methods, *Koerner von Gustorf*[16] reported similar reactions of manganese vapor.

The formation of arene-iron complexes in co-condensation reactions has already been reported[7–10]. However, we have found that condensation of iron vapor with mesitylene gives modest yields of *(1)* as the only isolable product. It is not clear how one of the diene ligands can gain two additional hydrogen atoms, although the product is then a stable 18-electron compound whereas bis(mesitylene)iron would be a 20-electron compound.



(1)

The reactions of chromium atoms with aromatic compounds has been studied more extensively than any other type of metal atom reaction[2, 8, 10, 11]. We can now report a few additional recent observations: we have prepared two complexes of chromium with hexafluorobenzene, $(C_6F_6)Cr(PF_3)_3$ and $(C_6F_6)Cr(C_6H_6)$ by condensing chromium vapor and C_6F_6 with PF_3 and C_6H_6, respectively. The yields are very poor, 1—2% at the most. The competing reaction seems to be defluorination of the C_6F_6 by chromium. However, each of the C_6F_6 complexes is quite stable in air and can be heated to 100 °C without decomposition.

Work by *Skell et al.*[11] has shown that the yields of arene-chromium complexes from atom reactions are higher for some halobenzenes than for benzene itself. To study this effect further, we took an equimolar mixture of C_6H_6, C_6H_5F, 1,4-$C_6H_4F_2$, 1,3,5-$C_6H_3F_3$, 1,2,3,5-$C_6H_2F_2$, C_6HF_5, and C_6F_6, along with excess trifluorophosphane, and condensed it with chromium vapor. The yield of (arene)$Cr(PF_3)_3$ was a maximum with 1,4-$C_6H_4F_2$ and fell to a minimum with C_6F_6. The decrease in yield from difluoro- to hexafluorobenzene must be due to the increasing tendency for a defluorination reaction to occur. It seems that kinetic factors determine the high

yield of the difluorobenzene complex relative to the benzene complex, as the benzene complex is more stable thermodynamically.

Condensation of Cr atoms with a mixture of pyridine and trifluorophosphane gives two volatile products, $(\sigma\text{-}C_5H_5N)Cr(PF_3)_5$ and $(\pi\text{-}C_5H_5N)Cr(PF_3)_3$. The latter appears to be the first authentic π-pyridine complex. The ^{1}H-NMR spectra of the two molecules are very similar but the resonances in the π-complex are about 2 ppm upfield of those in the σ-complex. Although $(\pi\text{-}C_5H_5N)Cr(PF_3)_3$ is stable in air for short periods, moisture eventually promotes base attack by the pyridine on coordinated trifluorophosphane and an involatile white solid is formed.

3.5. Dehalogenation Reactions of Copper, Silver, and Gold

The dehalogenation of boron trichloride by Cu atoms was the first reaction of a transition metal vapor to be reported[12]. The reaction provides one of the best ways of making diboron tetrachloride or alkyl-substituted diboron chlorides as the yields are high (40—70%) and copper can be vaporized in large quantities. The corresponding reaction of Cu or Ag atoms with phosphorus trichloride gives a 15% yield of diphosphorus tetrachloride, but much of the reduced phosphorus trichloride remains coordinated to the metal halide.

Copper and silver atoms are more selective dehalogenating reagents towards organic compounds than are atoms of the alkali metals. We have condensed Cu and Ag atoms with *R*(−)-*sec*-butyl chloride at −196°C and in each case the product is *S,S*(−)-3,4-dimethylhexane in about 70% optical purity. The reaction of *R*(−)-*sec*-butyl chloride with sodium vapor at −196°C gives an optically inactive 3,4-dimethylhexane.

Gold atoms react on co-condensation with ethyl bromide at −196°C to give butane, ethylene, ethane, and gold(I) bromide. However, ethyl chloride does not react with Au atoms. This observation has important implications. Using available thermodynamic information, it can be calculated that the hypothetical reaction between solid gold and ethyl bromide would be just exothermic, whereas a reaction between solid gold and ethyl chloride would be endothermic. Despite the high heat of formation of Au atoms, it seems that in this case the only advantage in using atomic instead of solid gold is kinetic rather than thermodynamic.

4. Final Comments and Conclusions

Although we have been so successful with a variety of metal atom reactions, not all reactions we attempt go as planned for several reasons. Some metal vapors, notably manganese and tin, are very much less reactive than expected. As discussed by *Ozin*[13], this may be due to more rapid aggregation of these atoms on the cold surface than for other metal atoms. Furthermore, the metal atoms occasionally cause unwanted chemical changes such as dehalogenations, deoxygenations, or catalytic polymerization of organic compounds. Finally, the finely divided metal formed by aggregation of some of the metal atoms sometimes catalyzes the decomposition of the reaction products. We are learning when to expect these types of behavior, but metal atom reactions nevertheless continue to provide surprises.

It must be predicted that many more chemists will soon be using metal atoms in chemical synthesis because useful and exciting compounds can thus be made simply. The apparatus need not be expensive or elaborate to give excellent results. Static apparatus for co-condensations at −196°C and rotary solution apparatus for reactions at higher temperatures should become standard items of equipment to be found in those laboratories synthesizing metal compounds. Probably much more use will be made of the atoms of metals which can be easily vaporized at moderate temperatures on a 2—10 g scale than of the very refractory elements.

The experiments described in this paper have been carried out by Dr. R. Mackenzie, Dr. T. Turney, Dr. R. Middleton, and R. Atkins, and by M. Anthony, M. Baxter, and P. Taylor. R. Porter has given technical assistance and the work has been generously supported by the Science Research Council.

The Laser-Evaporation of Metals and Its Application to Organometallic Synthesis[**]

By Ernst A. Koerner von Gustorf, Ottmar Jaenicke, Otto Wolfbeis, and Colin R. Eady[*]

1. Introduction

In recent years reactions with metal atoms have become an important synthetic method in the area of inorganic and organometallic chemistry[1-3]. The high reactivity of completely "naked" metal atoms often allows reactions at liquid nitrogen temperatures or even lower as a result of the missing interactions in the metal assembly of the condensed phase. Furthermore, steric shielding is also absent. The differences in reactivity between the isolated atoms and the condensed phase increase with the heat of atom formation[2].

Metal atoms are produced by evaporation of metals in high vacuum[4]. Several procedures exist for metal evaporation: Electrical resistive heating; bombardment with electrons of a few kV; cathodic sputtering; inductive heating; and evaporation by arcing.

The first four of these procedures are industrially applied to the production of thin layers[5]. All procedures have different advantages and disadvantages for chemical synthesis with metal atoms.

Since continuous lasers with high output have become available, and since further developments in this area can be expected, we have investigated the possibilities of metal evaporation with lasers and the application of this method to chemical synthesis[6].

2. Laser-Evaporation of Metals

2.1. Selection of Suitable Lasers

Lasers systems currently available are listed in Table 1[7]. It is seen that only gas and solid state lasers can be considered for metal evaporation when operating in the continuous wave mode.

Commercially available high powered lasers are the technically sound CO_2 and YAG lasers. CO_2 lasers can give an output of several kW while a YAG laser can produce several hundred watts. The CO_2 laser functions by transfer of vibrational energy from N_2, excited by gas discharge, to CO_2, the stimulated emission of which is at 10.6 μm. However, to achieve laser action a resonator is needed of at least 3 m in length, and even when folded it still requires a great deal of space. Since the CO_2 laser is very robust and reliable under conditions of continuous operation, it has found many applications in *e.g.* welding and cutting.

Table 1. Laser systems with typical data [7].

Laser system	Active medium	Excitation	Typical lengths [cm]	Output [watt] continuous/pulsed operation	
Gas laser	Noble gases, molecular gases, metal vapors	Gas discharge, chemical excitation	50	10^{-3}—10^{4}	10^{3}—10^{11}
Liquid laser	Organic dyes in solvents	Light from flash or laser	5	10^{-1}	10^{6}
Semiconductor laser	Semiconductor elements doped with Zn or Se	Electric current	0.1	10^{-1}	10^{4}
Solid-state laser	Crystals and glasses doped with metal atoms or rare earths	Flash lamps, continuous gas discharge lamps, tungsten-band lamps.	5	10^{-2}—10^{2}	10^{4}—10^{9}

The YAG laser consists of Yttrium-Aluminum-Garnet doped with Nd^{3+}. On optical excitation, a metastable doublet state of Nd^{3+} is populated which emits at 1.06 μm. A special advantage of a YAG crystal is its high thermal conductivity, allowing large excitational energies. The krypton lamps which are commonly used for the optical excitation have an average life span of 50 hours and can be easily exchanged.

A decision between these two types of lasers should be guided by two points. Firstly, a YAG laser is two to three times more expensive than a CO_2 laser with the same output. Secondly, the wavelength-dependent reflectivity of metals is of special importance. Figure 1 shows the reflectivity of some selected metals as a function of the wavelength[8] and in relation to the emission of a CO_2, a YAG, and a ruby laser.

Iron, for example, is seen to absorb approximately seven times as much energy at 1.06 μm (YAG) as at 10.6 μm (CO_2), which means that in this case preference is to be given to the YAG laser, also in view of the output/price ratio. It further

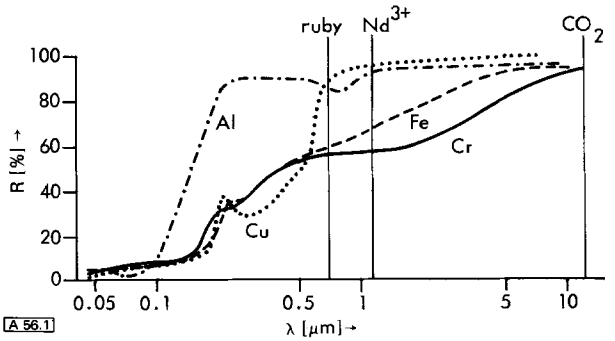

Fig. 1. Reflectivity R of metals as a function of wavelength, λ [8].

becomes clear that highly reflecting metals like aluminum can only be evaporated with great difficulty using an IR laser.

However, two points should be considered in this connection:

a) Many materials absorb like gray bodies[9] in the melting point region, which means that the reflectivity in this temperature range can change to higher energy absorption.

b) As can be seen from Figure 2, the reflectivity at 1.06 μm decreases with increasing energy flux density due to non-linear interaction between light and irradiated material[10]. This effect is significant above 10^8 W/cm^2.

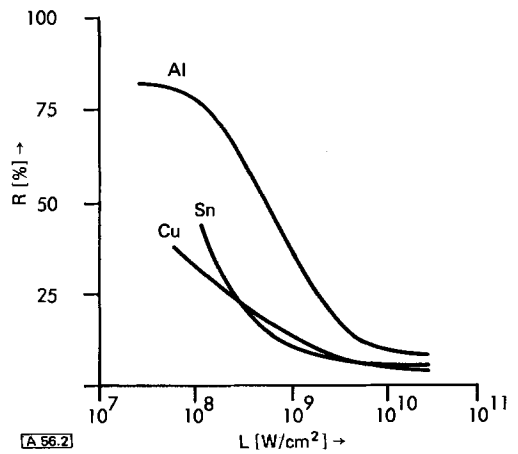

Fig. 2. Reflectivity R at 1.06 μm of aluminum, tin, and copper as a function of energy flux density [10].

Typical values for the diameter of focused laser beams lie in the range of 0.1—2 mm. A 200 W YAG laser in continuous operation and with a beam diameter of approximately 1 mm, produces a power density of 2×10^4 W/cm^2. Hence a region of decreasing reflectivity can only be reached by pulsing (see Table 1).

2.2. The "Window Problem"

While conventional methods of metal evaporation permit location of the energy source inside the high vacuum system, a window is needed when using a laser in order to allow the beam to enter the system from outside. According to our experience[11], germanium is well suited as a window material at 10.6 μm. The window can also be shaped as a lens for the purpose of focusing the beam. Quartz is a suitable window material for 1.06 μm. It is important that the evaporated material does not coat the window. If the window is no longer transparent energy absorption will result in rapid destruction. *Timms*[12] judges this problem as follows: "Heating methods such as a laser beam or focused energy from the sun or from an arc are not easily used for continuous vaporization under vacuum, as vaporized material tends to coat the window through which energy passes into the vacuum system."

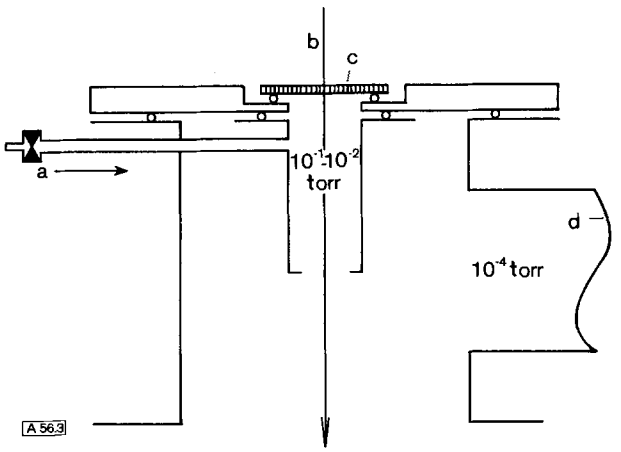

Fig. 3. Principle of a "gas window" which prevents the coating of the laser beam window. a, gas flow control valve; b, laser beam; c, quartz lens; d, vacuum port.

A simple solution of this technical problem is shown in Figure 3. Underneath the quartz lens a gas "window" is mounted on the high vacuum side. This is a piece of tubing into which one can admit gas (*e. g.* argon) through a controlled leak (gas flow control needle valve). Thus the pressure can be increased in this area so that the mean free path is reduced to a few mm. The metal atoms which are moving vertically upwards from the evaporating material are deviated in this chamber by collision. They hit the inner wall of the tubing, remain there, and can therefore no longer reach the window. The window remained completely uncoated when this device was tested by evaporating metals for several hours at a rate of approximately 10 g/h in the apparatus shown in Figures 6 and 7.

Under certain circumstances it is necessary to refocus the laser beam in close proximity to the evaporating material. The lens has to be mounted completely inside the apparatus. Coating of the lens under these conditions can be avoided by using the device depicted in Figure 4.

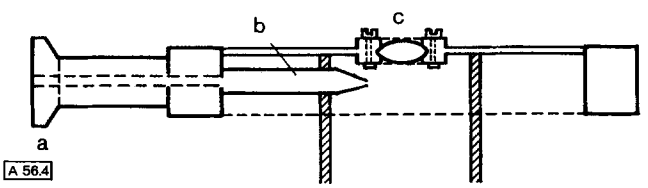

Fig. 4. Ring-shaped lens support with slit jet (to avoid coating of lenses). a, flange for gas flow control valve; b, slit jet; c, lens.

A slit jet is attached to the ring-shaped support of the lens. This slit jet is fed with *e. g.* argon through a gas flow control needle valve. The gas stream flows out of the slit jet across that surface of the lens which has to be kept clear. A sufficient gas dosage will deflect evaporating material away from the lens area. Thus, it can be seen that the "window problem" can easily be controlled in practice.

2.3. Advantages of Laser Application

After a discussion of the problems connected with the application of lasers to metal evaporation, it appears appropriate to point out briefly the specific advantages of this method.

a) No other evaporation method allows the production of comparable energy flux densities. With a focused laser beam it is possible to heat very small areas of material, *e.g.* the tip of a wire. This helps to avoid undesired reactions of extensive hot surfaces with a substrate which is to be co-condensed with the metal atoms. We have developed a device for the continuous evaporation of metal wire using a laser beam. This is depicted in Figure 5.

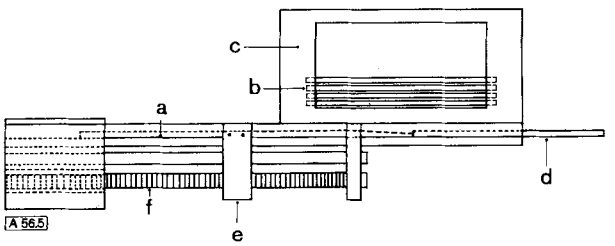

Fig. 5. Device for the automatic feeding of pieces of metal wire into the focal point of a laser beam. a, loading bolt; b, wire cartridge; c, wire magazine; d, cartridge pushed forward; e, threaded guide; f, worm.

Wire pieces of 8 cm length and 1—2 mm diameter are placed in the magazine of the wire feeding mechanism. The lowest wire is pushed forward by a loading bolt out of the magazine into the focal point of the laser beam. The loading bolt is connected by a threaded guide to a worm which is driven by an electric motor. The feed is regulated with a gear box, and adjusted to the speed of melting and evaporation. When the loading bolt is retracted a new piece of wire automatically falls into the slit and is pushed forward with the next forward movement of the bolt.

b) The process of evaporation reacts with little inertia to the switching on and off of the laser, since only small amounts of the material to be evaporated are heated. By fitting a rapid electromechanical shutter into the laser cavity, we are able to chop our YAG laser "mechanically" and thus evaporate metals intermittently.

In principle the possibility of optically deviating the beam allows the alternating evaporation of different metals in the same apparatus.

c) Metal evaporation by the use of laser beams allows the application of the so-called "containerless" method. The metal itself, if necessary cooled from the outside, serves as a container for the molten and evaporating portion. In this way, contamination resulting from a reaction of the container with the molten metal is avoided.

d) The supply of energy by a laser beam from outside provides the possibility of combining several apparatus of different geometry with one laser.

e) There is a special advantage of laser beams in the IR region. Scattered radiation cannot cause any changes of the substrate. This could be of importance for the preparation of radiation-sensitive chemical compounds and is the key problem in the technology of semiconductors for which the application of electron beam evaporation appears to be problematical due to the associated radiation damage.

2.4. Apparatus for Chemical Syntheses with Metal Atoms by Metal Evaporation with a YAG Laser

The aspects discussed in Sections 2.1 to 2.3 have been considered in the construction of the apparatus shown schematically in Figure 6[13]. The reactor, which is 36 cm in diameter and 40 cm high, is made from stainless steel, and can be evacuated to 10^{-4}—10^{-5} torr with a diffusion pump of 1000 l/s suction. The walls of the reactor can be cooled from the outside with liquid nitrogen. The metal to be evaporated is either brought into the focal point of the laser beam using the wire feeding mechanism attached to the side of apparatus, or is put as granules or powder on the bottom of the reactor in a water-cooled copper block to be bombarded there by the laser beam. An alumina crucible which can be heated electrically with a tungsten coil (1.5 mm diameter, 100 A, 10 V) can be placed in this copper block so that our apparatus can also be applied to the evaporation of those metals which cannot be satisfactorily evaporated with a laser beam owing to their high reflectivity. The top of the reactor carries the support for the lens-shaped quartz window, underneath which the gas window described in Figure 3 is located. Attached to the top are also two substrate inlet tubes which can be controlled by magnetic valves. Through these tubes is admitted

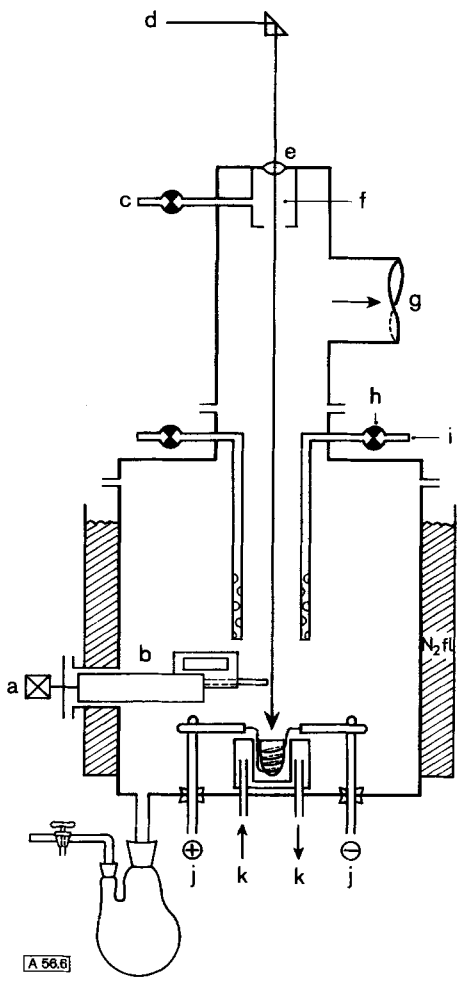

Fig. 6. Diagram of an apparatus for the evaporation (by laser and resistive heating) and co-condensation of metals with organic substrates. a, motor and gearbox; b, wire feeding mechanism; c, gas flow, control valve; d, laser beam; e, lens; f, gas window; g, to vacuum pump; h, magnetic valve; i, substrate inlet; j, current feedthroughs for crucible heating; k, cooling water.—Scale 1 :9 (see Fig. 7). N_2fl = liquid nitrogen.

the material which is to be co-condensed with the metal atoms onto the wall of the reactor. An inspection glass in the top of the reactor allows direct observation of evaporation. Figure 7 shows the apparatus in our laboratory.

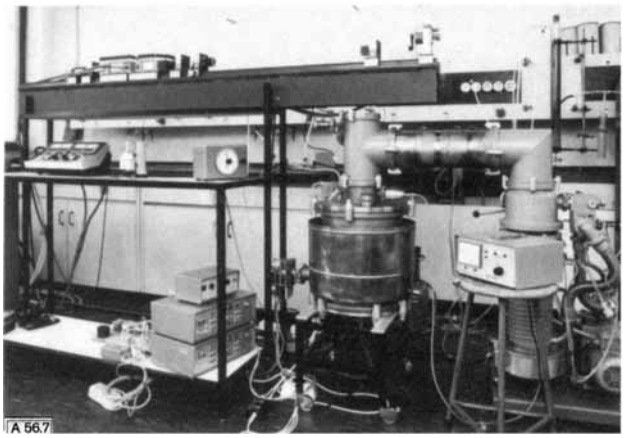

Fig. 7. Apparatus for chemical syntheses with metal atoms in the Mülheim laboratory (see Fig. 6).

The laser used by us is a 200 W cw YAG laser manufactured by Holobeam, and consists of two YAG rods of 7 cm length and 0.7 cm diameter, which are pumped by two krypton lamps each of 5 kW input. The two laser heads together with the mirrors occupy a volume of 60 × 10 × 10 cm, and are mounted on an optical bench. The laser beam is guided by a 90° reflecting prism through the window (lens) into the reactor.

The wire feeding mechanism, the magnetic inlet valves for substrate introduction, and the electromagnetic rapid shutter in the laser cavity, can all be controlled by digital timers.

With the apparatus described we have been able to evaporate chromium, manganese, iron, nickel, copper, erbium, dysprosium, holmium, zinc, tin, lead, and aluminum in amounts of approximately 0.5 to 10 g/h. In the cases of high reflectivity we worked with additional electrical resistive heating. For co-condensation several hundred grams of organic substrate can be used.

Prior to an experiment, the wall of the reactor is first coated with pentane, and thus the co-condensation of metal atoms and reactive substrate takes place on this film. When warming up at the end of an experiment the melting pentane will remove the product mixture from the walls, and everything will be collected in a flask attached to the bottom of the reactor. In many cases it is of advantage to add further reactive compounds during the warming up process. This applies especially to gases which cannot (or only with difficulty) be condensed or frozen at liquid nitrogen temperatures. Reactive primary products can very often be converted into stable compounds by such an after-treatment.

3. Chemical Syntheses with Metal Atoms

The following point of view has been of importance to us for the selection of reactions in order to test the scope and possibilities of our method. Most synthetic procedures in organometallic chemistry can be related *cum grano salis* to the principle of *addition* and *substitution*[14].

Successive addition of ligands to metal atoms allows, in principle, the stepwise formation of a compound:

$$M + xL \rightarrow L_xM \xrightarrow{+yL'} L_xML'_y \quad (1)$$

Complementary to this reaction is the corresponding transformation of a given metal compound by successive steps of substitution:

$$ML_{x+y} \xrightarrow{+yL'} L_xML'_y + yL \quad (2)$$

The photochemical cleavage of the M—L bond is especially suitable[16, 17] for carrying out substitution reactions with dissociative activation[15] according to eq. (3) and (4) (for instance L = CO, PR_3, olefins, dienes).

$$L_nM \xrightarrow{h\nu} L_{n-1}M + L \quad (3)$$

$$L_{n-1}M + L' \rightarrow L_{n-1}ML' \quad (4)$$

Metal atom reactions and photosubstitution can be carried out at very low temperatures, *i.e.* under "extreme" conditions. In many cases they should lead to the same final product (*e.g.* $L_xML'_y$) *via* the same intermediates (*e.g.* L_xM).

Our investigations have been directed towards an analysis of the complementary character of these two methods in order to find out under which circumstances the two methods support each other (*e.g.* for the identification of intermediates), and under which circumstances they supplement each other by showing specific advantages in preparative applications.

3.1. Syntheses of Metal Carbonyls

It was shown by *De Kock*[18] in 1971 that nickel atoms form $Ni(CO)_n$ ($n = 1$—4) in a CO doped argon matrix at 4 K. The stepwise formation of metal carbonyls has also been demonstrated by using matrix spectroscopy in the chromium atom and CO system[19, 20], and for several other metals (see, for instance[3, 21]). With respect to the preparative importance of metal carbonyls which are widely used as starting materials, and considering the relatively high price[22] of current synthetic procedures[23], we have considered the possibility of the synthetic use of the co-condensation of Cr, Mn, and Fe atoms with CO[24]. Since carbon monoxide (m.p. −207 °C) cannot be directly condensed at the temperature of liquid nitrogen and at 10^{-4} torr, we have tried to "getter" it with an excess of tetrahydrofuran. The procedure of warming-up the tetrahydrofuran matrix after finishing the evaporation was also carried out under a CO atmosphere.

As can be seen from Table 2, the yields of $Cr(CO)_6$, $Mn_2(CO)_{10}$, and $Fe(CO)_5$ under these conditions are rather poor. Furthermore, higher evaporation rates did not show any improvement.

According to the work of *Ozin*[25], the binuclear manganese carbonyl results from a diatomic metal species which is formed by the combination of two metal atoms *via* diffusion on the surface of the matrix. In the case of iron it cannot be decided offhand whether a similar mechanism is operative or whether a reactive tetracarbonyl(tetrahydrofuran)iron complex[26] yields $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ on warming up the matrix. By irradiation of $Fe(CO)_5$ in tetrahydrofuran we have prepared the corresponding complex and submitted it to the same work-up conditions. $Fe_3(CO)_{12}$ is also formed in this case[27].

Table 2. Direct synthesis of metal carbonyls from metal atoms using tetrahydrofuran (THF) as a "getter" system.

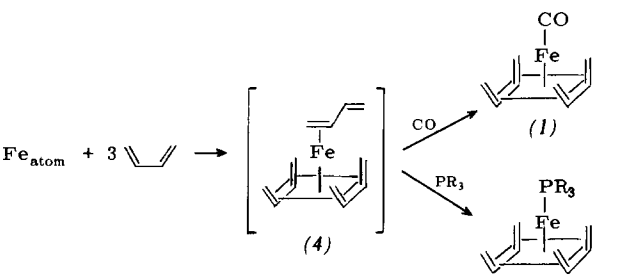
Evaporated metal	[mmol]	THF [ml]	CO [mmol] [a]	Products	Yield [%] [b]
Cr	18	250	45	$Cr(CO)_6$	2.3
Mn	9	140	45	$Mn_2(CO)_{10}$	1.0
Fe	2	220	27	$Fe(CO)_5$	0.4
				$Fe_3(CO)_{12}$	0.2
				$Fe_2(CO)_9$	traces

[a] Addition during evaporation; warming up of the THF matrix in the presence of 3 mol CO.
[b] Yields based on evaporated metal.

3.2. Butadiene Complexes of Iron and Chromium

The smooth photochemical substitution of 4CO groups by 2 butadiene molecules in pentacarbonyliron yielding bis(butadiene)monocarbonyliron *(1)*[28] suggested that we explore the successive addition of butadiene and CO to iron atoms. Co-condensation of butadiene with iron atoms and subsequent warming-up of the matrix under a CO atmosphere, produced *(1)* in a yield of 31%[11]. We suggest that CO interacts with the reactive co-ordinatively saturated intermediate *(4)*. Formation of *(1)* was observed at the same time, and independently of us, by *Skell*[29].

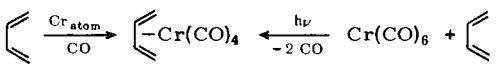
While the photochemical substitution of the last CO in *(1)*, by *e. g.* phosphanes, can only be achieved by irradiation at rather short wavelengths (254 nm)[30], *(2)* can be produced in 17% yield by warming up the *(4)*-containing matrix with PF_3[11]. The corresponding reaction with $P(OCH_3)_3$ gives *(3)*[24].



Bis(butadiene)phosphaneiron complexes are easily accessible by this "one pot" procedure and internal light filter problems[30] which can complicate their photochemical preparations from *(1)*, are avoided.

Bis(diene)monocarbonyliron complexes like *(1)* at *ca.* 100 °C in the presence of triphenylphosphane are catalysts for the dimerization of dienes, *e. g.* of butadiene to 4-vinylcyclohexene and 1,5-cyclooctadiene[28, 31], and are especially suitable for the mixed dimerization of dienes with acrylates yielding heptadienoates[30]. The direction and amount of catalytic activity are strongly affected in *(1)* by replacing CO with phosphanes (see Fig. 8). This example shows that the tailoring of organometallic catalysts is possible using metal atom reactions.

In contrast to iron, the co-condensation of chromium atoms with butadiene and subsequent treatment with CO results in a 4% yield of tetracarbonyl(butadiene)chromium *(5)* which represents the first example of a 1,3-dienetetracarbonylchromium complex[11]. *(5)* decomposes above 0 °C.

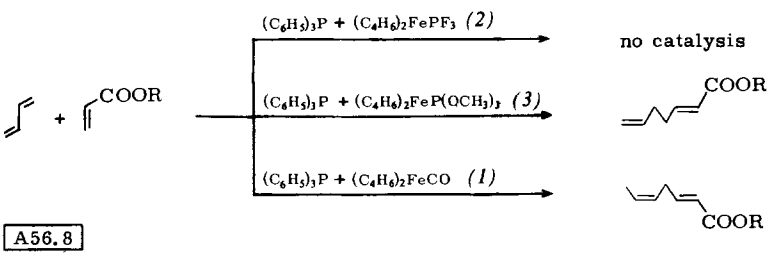


(5)

Compounds like *(5)* are postulated, but not yet isolated intermediates[32] in the photochemically initiated hydrogenation of dienes with $Cr(CO)_6/H_2$[33, 34]. Having established the unstable nature of *(5)* its photochemical synthesis was achieved by irradiation of $Cr(CO)_6$ in the presence of excess butadiene at −40 °C[35]; this represents another example of the complementary nature of metal atom reactions and photosubstitution.

3.3. Cyclooctadiene Chromium Complexes

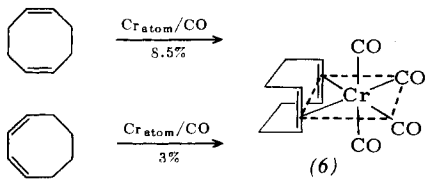
1,5-Cyclooctadiene (1,5-COD) forms a variety of well defined transition metal complexes, the stability of which, *inter alia*, has been ascribed to the chelating character of this ligand[36]. In contrast, complexes with 1,3-COD which can be isolated are quite rare[37, 38]. Cr(0) complexes of 1,3-COD are unknown[39], whereas with 1,5-COD a tetracarbonylchromium complex has been reported, which was formed in 2% yield by the thermal reaction of $Cr(CO)_6$ with 1,5-COD. Attempts to substitute CO in 1,5-COD-$Cr(CO)_4$ have been unsuccessful since 1,5-COD is very easily eliminated[41]; the synthesis of arene- and cyclotrienetricarbonylchromium compounds has been a preparative application of this facile elimination[42].



A56.8

Fig. 8. Effect of axial ligands in bis(butadiene)iron complexes *(1)* to *(3)* on their catalytic activity in the mixed dimerization of acrylate and butadiene. (Besides the main products shown in this figure, further isomeric heptadienoates are formed [30].)

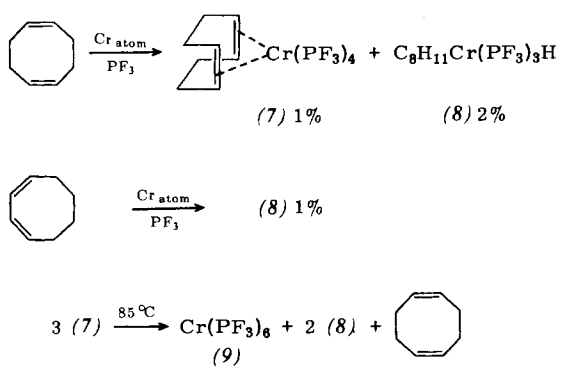
We have therefore investigated the co-condensation of 1,3- and 1,5-COD with chromium atoms with subsequent exposure to CO and PF_3.



(6)

From the reaction of either 1,3- or 1,5-cyclooctadiene with chromium atoms and CO, 1,5-COD-$Cr(CO)_4$ *(6)*[24] is produced. As expected, *(6)* shows 4 IR active CO stretching vibrations (in pentane)[43][*]. A corresponding isomerization with H-shift has also been observed in the thermal reaction of 1,3-COD with $Mo(CO)_6$ and $W(CO)_6$ leading to the 1,5-COD complexes[40]. Apparently this rearrangement cannot be avoided even under our mild conditions.

The co-condensation of 1,5-COD with chromium and PF_3 leads, in addition to the expected 1,5-cyclooctadienetetrakis-(trifluorophosphane)chromium *(7)*, to a red compound *(8)*[24], which is also formed on reaction of 1,3-COD with chromium atoms and PF_3. Heating of *(7)* to 85 °C provided another route to *(8)*, which in this case is formed together with hexakis-(trifluorophosphane)chromium *(9)* and 1,5-COD.



X-ray structural analysis[44] shows *(8)* to be (1—5-η-cyclooctadienyl)hydridotris(trifluorophosphane)chromium (see Fig. 9). The hydridic hydrogen could not be localized. However, in Figure 9 one can recognize the "hole" at the chromium in which it should be situated. Evidence for a hydrido proton is provided by a signal in the ^{1}H-NMR spectrum at $\tau = 22.4$ (at −50 °C in D_8-toluene). With the isolation of *(8)* we have simply captured an intermediate in the transformation of the two cyclooctadienes into each other according to the π-allylhydrido mechanism[45] which was postulated some time ago.

From the ^{1}H- and ^{19}F-NMR spectra[46] solid *(8)* when dissolved rearranges by hydrogen migration into *(8"L')* [most probably *via* the intermediate *(10)*], and appears to be a fluxional molecule at room temperature.

There are parallels in the literature for the hydride addition to the central C atom of a dienyl system[47], as well as for the structural type *(8"L')*[48]. The oxidation of *(8"L')* with Ce^{IV} leads exclusively to 1,3-COD.

[*] ν_{CO}: 2030 w, 1956 m, 1940 vs, 1911 cm^{-1} s.

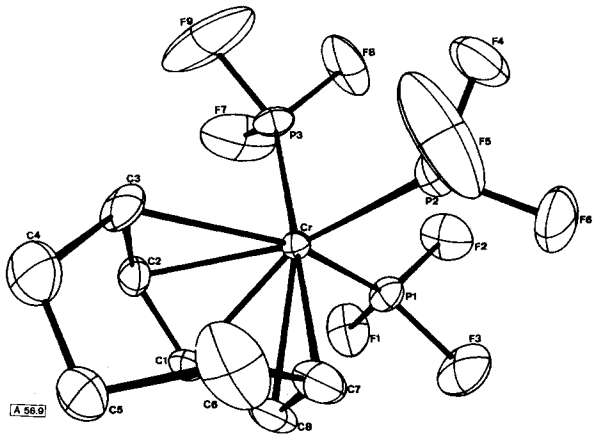


Fig. 9. X-ray structure [44] of (1—5-η-cyclooctadienyl)hydridotris(trifluorophosphane)chromium ($C_8H_{11}Cr(PF_3)_3H$) *(8)*. The hydridic H on chromium was not localized.

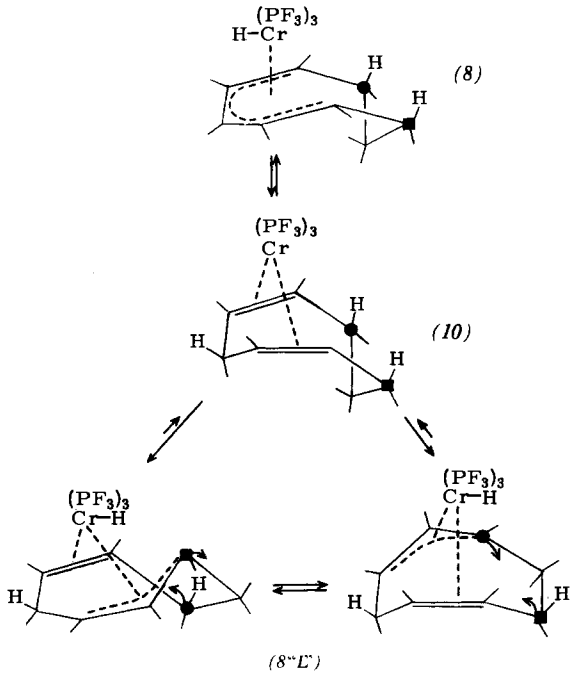
In parallel photochemical investigations we have succeeded in synthesizing *(6)* in yields of 20% by the substitution of



(8"L')

CO in $Cr(CO)_6$[35]. Whether *(7)* can be obtained analogously from *(6)* still needs further clarification.

3.4. Reaction of Cycloheptatriene with Chromium and Iron Atoms

In tricarbonyl(cycloheptatriene)chromium the cycloheptatriene moiety can be replaced thermally by other ligand systems, *e.g.* phosphanes[49]; attempts to substitute the CO fail. CO substitution can however be achieved photochemically; one CO can be replaced by $P(C_6H_5)_3$ and $P(OC_6H_5)_3$[50], as well as by $P(OCH_3)_3$[51]; with $P(OCH_3)_3$ even two CO groups can be replaced but with some complication and small yields.

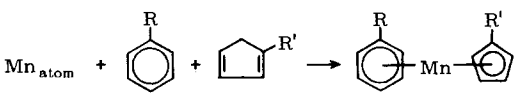
In this case the usefulness of metal atom synthesis as a complementary procedure can be demonstrated again. Co-condensation of chromium atoms with cycloheptatriene and PF_3 yields, after chromatographic work-up, 1% of yellow (1—6-

η-cycloheptatriene)tris(trifluorophosphane)chromium[24].
Work-up without subsequent treatment with PF_3 leads to a mixture of products[52] which contains, besides components of higher molecular weight, a compound according to its mass spectrum of composition $C_{14}H_{17}Cr$, the fragmentation pattern of which corresponds to that of (1—4-η-cycloheptadiene)(η-cycloheptatrienyl)chromium(−1) reported by *E. O. Fischer et al.*[53]. In some fractions a compound $(C_7H_8)_2Cr$ can be observed as reported by *Skell et al.*[54].

The reaction of iron atoms with cycloheptatriene is much smoother and gives good yields of red $(C_7H_9)Fe(C_7H_7)$, in which a cycloheptadienyl system and a valence isomer of the tropylium system are coordinated to iron[52].

3.5. Co-condensation of Manganese Atoms with Arenes and Cyclopentadiene

Timms[1] achieved the synthesis of ferrocene (from Fe and cyclopentadiene) and dibenzenechromium (from Cr and benzene). These findings suggest an investigation for an alternative route to the synthesis of benzene(cyclopentadienyl)manganese(I) *(11)*[55, 56] by the co-condensation of manganese atoms with a mixture of benzene and cyclopentadiene. Indeed pure *(11)* could be produced in this way[24, 57] in yields of 0.5% (with respect to evaporated manganese).



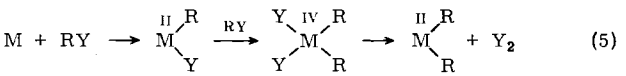
(11), R = R' = H
(12), R = CH_3, R' = H
(13), R = R' = CH_3

The fate of the hydrogen which has to be abstracted from the cyclopentadiene in this reaction is still not clear. The corresponding reactions of manganese atoms with a mixture of toluene and cyclopentadiene give 0.7% of *(12)*. With toluene and methylcyclopentadiene *(13)* actually could only be detected in admixture with components of higher molecular weight. The yields are very unsatisfactory. However, if one considers the yields of *(11)* which are 2—3% for the reaction of C_5H_5Na with $MnCl_2$ and C_6H_5MgBr[55] or 0.4% for the reaction of C_6H_5MgBr with C_5H_6 and $MnCl_2$[56], respectively, then the co-condensation procedure is not so unsatisfactory after all.

D'Aniello and *Barefield*[58] have recently shown that in the reaction of cyclopentadiene with molybdenum and tungsten atoms, the dihydrides $(C_5H_5)_2MH_2$ (M = Mo, W) are formed according to the principle of oxidative addition. Most probably the formation of *(11)* involves a similar intermediate.

3.6. Synthesis of Metal Acetylacetonates

In oxidative addition reactions[59] as briefly mentioned in Section 3.5, according to the general eq. (5) a formal transfer of electrons occurs from the metal to the reacting substrate (in most cases involving bond cleavage), as for instance in the formation of Grignard reagent from magnesium atoms and alkyl halides[60]. Metals which are capable of existing in higher oxidation states can undergo several steps of oxidative addition. Sometimes reductive elimination, *e.g.* of Y_2 in eq. (5), can follow. The detailed mechanism of oxidative addition reactions is a matter of current discussion[61] and is represented schematically in eq. (5).



(5)

We have applied this reaction principle to synthesizing anhydrous metal acetylacetonates by the co-condensation of metal atoms with 2,4-pentanedione (acetylacetone), Y = H[62, 63]. Collective properties of the condensed phase such as overvoltage and passivation do not exist for the isolated metal atoms. The reactions proceed very smoothly and, as shown in Table 3, in acceptable yields[64]. According to preliminary experiments with rare earth metals, erbium, dysprosium, and holmium, can also be converted into the corresponding tris(acetylacetonates) by the co-condensation procedure[52].

Table 3. Synthesis of metal acetylacetonates [M(acac)$_n$] by co-condensation of metal atoms with 2,4-pentanedione (acetylacetone, acacH). Yields are based on evaporated metal.

M	*n*	Yield [%]
Mn	2	30
Cr	3 [a]	32
Fe	2	25
Fe	3 [a]	24
Ni	2	36
Cu	2	10
Zn	2	28
Al	3	14
Sn	2	11
Pb	2	10

[a] Work-up in presence of oxygen.

Amongst the classical procedures of synthesizing metal acetylacetonates, the reaction of metal salts, metal oxides, and hydroxides with 2,4-pentanedione or its metal salts (mostly in water), plays a special role[65, 66]. This method is not without problems for the preparation of the anhydrous compounds and moreover the separation of starting material from the product can also cause difficulties[67]. It was only in 1973 that the sensitive bis(pentanedionato)tin(II) was reported[68]. The direct reaction of the metals themselves with 2,4-pentanedione, which is important for the synthesis of anhydrous metal acetylacetonates in low oxidation states, has long been restricted to the alkali and alkaline earth metals, to aluminum (as an amalgam), and to lead and copper (in the presence of oxygen)[65]. It was only recently that this principle was applied to the transition metals manganese, iron, cobalt, and nickel, which were converted electrochemically into the anhydrous metal acetylacetonates[69].

Complementary to the metal atom synthesis is the preparation of acetylacetonates and their carbonyl derivatives by reaction of 2,4-pentanedione with carbonylmetal derivatives[66] which, for instance, in the case of $Fe(CO)_5$, can be accomplished most efficiently by photolysis[70].

3.7. Reaction of Chromium Atoms with Methanol and Acetic Acid

We have co-condensed chromium atoms with methanol in order to find out whether the reaction of 2,4-pentanedione

with metal atoms can also be applied to other OH-acidic compounds. In a 28% yield we obtained gray/green $Cr(OCH_3)_3$ (oxygen was not excluded during the work-up procedure); its elemental analysis deviated by several percent from the required values[62]. However, the same is observed for the products described in the literature[71].

It was found that isopropanol and *tert*-butanol also react with chromium atoms. However, we were not successful in the purification of the products due to their poor solubility[62].

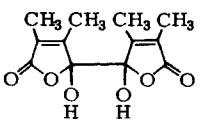
With acetic acid mixtures of chromium(II) and chromium(III) acetate were obtained in approximately 30% yield; the composition of these mixtures was dependent on the work-up conditions.

The atom synthesis of $Cr(OCH_3)_3$ is again paralleled by its photochemical formation from benzene(tricarbonyl)chromium in methanol[71].

3.8. Reductive Coupling of Dimethylmaleic Anhydride with Iron

Our success in the reactions of iron and chromium with dienes to form π-complexes (see Section 3.2) suggested that the corresponding synthesis of olefin complexes should be investigated. It was expected that, in the case of iron, subsequent treatment with CO should lead to the formation of tetracarbonyl(olefin)iron[72] and tricarbonyl[bis(olefin)]iron or ferracyclopentane derivatives as secondary products of the latter[73].

However, the pyrophoric product of the co-condensation of dimethylmaleic anhydride and iron atoms (yield 10—15%) did not react with CO. It was identified as a paramagnetic material of composition Fe(dimethylmaleic anhydride)$_2$[52]. Hydrolysis with hydrochloric acid produced dimethylmaleic anhydride (30%), some as yet unidentified organic material, and in a yield of 50% the novel[74] coupling product *(14)*. Its formation results from a transfer of two electrons from iron to two dimethylmaleic anhydride molecules[75].



(14)

It is worth mentioning that the photoreaction of dimethylmaleic anhydride with $[(C_6H_5)_2PC_2H_5]_3FeH_2N_2$ (which easily loses all ligands on electronic excitation[76]) leads to the same products as in the reaction with "naked" iron[75].

4. Closing Remarks

One can expect that in the future the evaporation of metals with lasers will acquire special importance in the processing of materials since it provides the advantages of evaporation with electron beams without the disadvantage of radiation damage to a sensitive substrate. It should be remembered that the increasing general trend of using lasers in technology will result in a considerable reduction in initial outlay.

In the production of metal atoms for chemical reactions, the laser method provides special advantages. Due to the high energy flux density, heating of very small areas of material, as well as the "containerless" method, are possible. Furthermore the laser evaporation can be pulsed because of the low inertia of the method. The special importance of these advantages in comparison with other methods can only be evaluated in connection with a specific problem.

Chemical syntheses with metal atoms already have a permanent position in the arsenal of the chemists' methods. Now that complete sets of apparatus have become commercially available[77], a rapid increase in the application of this method can be expected. The syntheses of organometallic compounds, of metal complexes and clusters, (especially those with catalytic properties) and of rare inorganic chemicals, should remain in the focal point of the general interest for some time. It is important that the reaction of non-volatile substrates with metal atoms is now possible by using metal evaporation in a rotary reactor, a procedure which is based on the work of *Green*[78] and *Timms*[79]. Experimental studies on the controlled incorporation of metals into macromolecules have therefore become possible. This advance into substrates of low volatility allows higher temperatures for the co-condensation and thus reduces cooling problems which could interfere with an industrial application of chemical syntheses with "naked" atoms. Here one can only say "a man at work in the fields must not go back home to fetch his clothes"[80].

C. R. E. is indebted to The Royal Society, London, for a European Fellowship.—The construction of our metal evaporation apparatus would have been impossible without the enthusiastic co-operation of Messrs Friedhelm Hahn, Wolfgang Köster, and Eckhardt Steinhoff from the Workshop, and of Mr. Wolfgang Küpper from the Electronics Section of the Institute für Strahlenchemie.—Dr. Richard J. Blackborow, Mrs. Marion Budzwait, Dr. Ingrid Fischler, and Dr. Alberto Scrivanti have carried out the quoted current work. We are most grateful to all of them. The kind support of our "venture" by Prof. Dr. O. E. Polansky is gratefully acknowledged.

Reactions of Metal Atoms with Fluorocarbons[**]

By Kenneth J. Klabunde[*]

1. Introduction[***]

With the advent of *Skell*'s carbon vapor reactor[1], interest in the use of high temperature species as reagents for carrying out syntheses has increased greatly, as recently pointed out by *Timms*' excellent review[2]. The most advantageous use of this technique has been in organotransition metal chemistry. Thus, high temperature transition metal atoms are condensed at low temperature (usually −196°C) simultaneously with vapors of organic substrates. The high temperature atoms are formed by vaporizing metals from resistively heated crucibles, by arcing[3] or by laser heating[4]. These atoms have a high chemical potential, and react at low temperature with the organic substrates to form many unusual compounds. Thus, the method can be termed the "metal atom technique" or "freeze-fry chemistry."

Our main interest has been in using the metal atom technique as a way of making some rather unusual and interesting organometallic species. To do this we have assembled a simple metal atom reactor (see Section 6), in which all of the first row transition metals (excepting scandium) as well as Pd, Pt, Zn, and Ag have been studied.

We have been most interested in the metals V(123), Cr(95), Ni(103), Pd(89), and Pt(135). Shown in parentheses are the heats of formation (kcal/mol) of these metals which indicates the amount of energy needed for vaporization, and thus gives a rough idea of the high reactivity of these species.

Three main areas have interested us: (1) the synthesis of polyhalogenated π-complexes of the transition metals; (2) oxidative insertion of metal atoms into carbon-halogen, carbon-carbon, and carbon-oxygen bonds; and (3) preparation of clean, finely-divided active metals.

2. Polyhalogenated π-Complexes

Normal solution techniques have not been successful in preparations of most polyhalogenated π-complexes of the transition metals. Thus, polyhalogenated bis(arene)-complexes of V and Cr, and π-allyl complexes of Co, Ni, Pd, Pt have not been prepared by classical methods. There are several possible reasons for the failure of such procedures, but probably the most important reasons are the presence in solution of nucleophiles (*e.g.* fluoride ions) and/or solvent that can cause facile rearrangements, decompositions, or competitions for open sites on the metal. The metal atom technique avoids these problems. In the case of bis(arene) complexes, the metal atom technique has been quite useful, as has been previously shown by *Timms*[5], *Skell*[6], *Green*[7], and their co-workers. We have been mainly concerned with F, Cl, and CF_3 substitution on bis(arene)vanadium and bis(arene)chromium complexes as well as a hexafluorobenzene nickel complex[8].

The bis(arene)vanadium complexes shown in Table 1 can be synthesized using the metal atom technique. The yields are not high, and when more than one electron withdrawing substituent on the arene (F or CF_3) are present very low yields are obtained. However, the presence of one CF_3 group/arene is acceptable, and imparts considerably increased air stability to the complexes. Substituents F and Cl do not impart much added air stability to these vanadium complexes.

Table 1. Synthesis of bis(arene)vanadium(0) and bis(arene)chromium(0) complexes employing the metal atom technique.

Compound	Yield [%] [a]	Properties
$(C_6H_5F)_2V$	13	red, air sensitive, sublimes 50—70°C/10^{-3} torr
$(C_6H_5Cl)_2V$	7	orange-red, air sensitive, sublimes 50—60°C/10^{-3} torr
$(p\text{-}F_2C_6H_4)_2V$	1	red, air sensitive, sublimes 25°C/10^{-3} torr, odor of organic sulfide
$(C_6H_5CF_3)_2V$	22	orange, moderately air sensitive, sublimes 25°C/10^{-3} torr (80—90°C decomp.)
$(C_6H_5CF_3)_2Cr$	26	yellow, m.p. 91—91.5°C, decomp. 170°C, slightly air sensitive
$[m\text{-}(CF_3)_2C_6H_4]_2Cr$	17	yellow-green, m.p. 91.5—92.5°C, decomp. 200°C, sublimes rapidly at 100°C/10^{-2} torr, very air stable
$[p\text{-}(CF_3)_2C_6H_4]_2Cr$	38	amber, m.p. 150—152°C, decomp. 266°C, sublimes rapidly at 100°C/10^{-2} torr, very air stable
$(o\text{-}ClC_6H_4CF_3)_2Cr$	33	yellow-green, m.p. 81—82.5°C, decomp. 165°C, sublimes rapidly at 100°C/10^{-2} torr, very air stable

[a] Based on metal vaporized.

The bis(arene)chromium complexes (Table 1) are formed readily using the metal atom technique. The presence of two CF_3 groups/arene is acceptable, and imparts remarkable air stability to the materials. The $[m\text{-}(CF_3)_2C_6H_4]Cr$ and $[p\text{-}(CF_3)_2C_6H_4]Cr$ complexes are indefinitely stable in air at room temperature, and are even stable for short periods of time at over 200°C in air. Good, but less air stability was found for the $(CF_3C_6H_5)Cr$ and $(o\text{-}ClC_6H_4CF_3)Cr$ complexes. Chlorinated solvents such as CCl_4, $CHCl_3$, and CH_2Cl_2, however, accelerate the decomposition.

The unusual air stability of these complexes possessing highly electronegative substituents might have been predicted since the first step in the facile oxidative decomposition of dibenzenechromium(0) is probably the one electron oxidation of Cr yielding a Cr^+ complex. This process would be disfavored by the arenes possessing electronegative substituents.

Examination of the IR spectra of $(C_6H_6)_2Cr(0)$ *vs* $(p\text{-}(CF_3)_2C_6H_4)_2Cr(0)$ yielded some information concerning the metal-ring bonding. *Yamada*, *Nakamura*, and *Tsuchida*[9] showed that the 1500 cm^{-1} band in benzene shifts to 1428 cm^{-1} upon complexation with Cr ($\Delta\nu_{C=C}=72$ cm^{-1}). In $[p\text{-}(CF_3)_2C_6H_4]Cr$ the analogous band at 1529 cm^{-1} shifts to

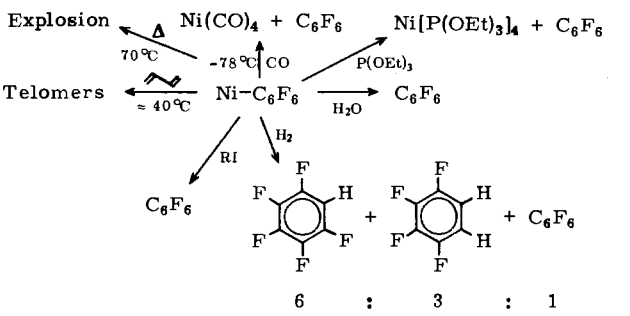
[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12—15, 1974).

[***] Abbreviations used: Alk = (halo)alkyl; Ar = (halo)aryl; Et = ethyl; R = (halo)alkyl and (halo)aryl; R_f = perfluoroalkyl and perfluoroaryl.

1480 cm^{-1} upon complexation ($\Delta\nu_{C\equiv C} = 49\ cm^{-1}$). Thus, there is less C=C bond weakening upon complexation in the *p*-(CF_3) complex, which would in turn suggest a slightly weaker ring-metal bond in this complex than in dibenzenechromium.

Thus, we find that CF_3 substitution on these Cr(0) complexes has the most advantageous effect on air stability, still allows good thermal stability, and we have not found them to possess any explosive character as has been found for monofluorobenzene-[10] and polyfluorobenzenechromium(0) complexes and the corresponding vanadium(0)complexes[8, 10]. Thus the hexafluorobenzene complexes of vanadium, chromium, and nickel formed by the metal atom technique, were found to be extremely sensitive and explosive[8]. The novel C_6F_6—Ni complex could not be isolated in a pure state[8].



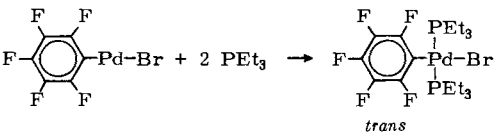
3. Oxidative Insertion of Metal Atoms

Oxidative insertion of metal atoms into carbon-halogen bonds (alternatively termed "oxidative addition" of carbon-halogen bonds to metal atoms) provides a rare opportunity for production and study of non-solvated non-ligand stabilized RMX compounds at low temperature under inert conditions. In the case of transition metals, highly coordinatively unsaturated species can be produced. We have previously reported on a number of reactions of this type:

Zn atoms + $CF_3I \rightarrow CF_3ZnI$	Ref. [11]
Ca atoms + $C_6F_6 \rightarrow C_6F_5CaF$	Ref. [12]
Pd atoms + $C_6F_5Br \rightarrow C_6F_5PdBr$	Ref. [13]
Pd atoms + *n*-$C_3F_7COCl \rightarrow C_3F_7COPdCl$	Ref. [14]

There are good reasons for carrying out these types of studies. Species such as RPdCl (no other ligands) have been proposed as reaction intermediates in palladium promoted olefin arylations, alkylations, carboalkylations, *etc.*[15]. Similarly, RCOPdCl has been discussed as a likely short lived species in palladium catalyzed CO insertion reactions, olefin carbonylations, and reaction mechanisms relating to the Rosenmund reduction[15, 16].

We have concentrated our efforts on the Ni, Pd, Pt triad because of the importance of the corresponding RMX species. Also, we have employed fluorinated alkyl and aryl halides extensively as substrates because it is well known that stronger carbon-metal bonds are formed with these fluorinated systems. Thus, probably higher stability of the non-ligand stabilized R_fMX over the RMX species would result. Considering only the Ni and Pd compounds, the ideal case for highest predicted stability would be C_6F_5PdX. In fact we have produced the very coordinatively unsaturated organometallic species C_6F_5PdBr, and it has exhibited remarkable stability even at room temperature in acetone or the dry state (no ligands). In benzene as solvent it slowly decomposes to C_6F_5—C_6F_5, Pd, and $PdBr_2$ (1 : 1 : 1)[13]. $(C_6F_5PdBr)_n$ is extremely reactive with donating ligands (sulfides, phosphanes, *etc.*) and immedi-



ately takes up two molecules of triethylphosphane to form the bis(phosphane) adduct. This complex is very stable and was shown by NMR data to have *trans* geometry; other phosphanes react similarly[14].

A wide ranging series of Ar_fMX and RMX (M = Ni, Pd) compounds have now been produced in our laboratory. Many of these species are not stable at room temperature, and we have used phosphane trapping techniques in order to determine their thermal stabilities. That is, first the metal atom reaction was carried out at −196 °C, then the matrix warmed from −196 °C to some desired temperature and held there about $^1/_2$ hour, and then triethylphosphane added in order to trap the RMX intermediate as a stable, isolable compound. The results of trapping experiments at a series of different temperatures are collected in Table 2. They will be discussed in sections:

1. (Halo)aryl halides and palladium: Reaction efficiencies for the halides C_6F_5X decrease in the series $C_6F_5I > C_6F_5Br \gtrsim C_6F_5Cl$. All of the resultant compounds C_6F_5PdX were found to be stable at room temperature, soluble in organic solvents, and extremely reactive with phosphane ligands. In the C_6H_5X system, the bromide is more reactive than the chloride. C_6H_5PdBr could not be trapped at 25 or −78 °C, but could at −116 °C. At −78 °C, biphenyl, Pd, and $PdBr_2$ are formed. Thus, the C_6H_5 compounds are thermally far less stable than the C_6F_5 analogs.

2. (Halo)alkyl halides and palladium: CF_3PdBr was generated and trapped by triethylphosphane at either 25 or −70 °C. Both experiments yielded about the same amount of $(Et_3P)_2PdBr(CF_3)$. CF_3PdBr could be washed out of the reactor with acetone while open to the atmosphere, filtered at room temperature, and then triethylphosphane added; about the same amount of adduct was still obtained. Thus, the CF_3PdBr species was stable at room temperature in the air in the dry or dissolved (acetone) state. The yield was low (about 4 %), but only a trace of $PdBr_2$ was formed, and no other products could be detected. Thus, we do not have a very efficient formation of CF_3PdBr at the low temperatures involved; the main competing reaction is Pd—Pd recombination to the bulk metal.

Some R_fPdI compounds are also stable at room temperature; $(CF_3)_2CFPdI$, however, could not even be trapped at −78 °C. Apparently at least two α-fluorine substituents are necessary to impart good thermal stability. In these R_fI reactions (but not R_fBr) large amounts of PdI_2 were always formed, which indicates either free radical abstraction reactions by Pd were important, or the R_fPdI species were formed in vibrationally excited and labile states. R_fBr behaves differently. Trapping experiments were not successful with halides such as CCl_3Br or CF_2Br_2 which shows that the presence of α-halogen other than fluorine (*e.g.* $CF_2BrPdBr$) imparts poor

Table 2. Reactions of alkyl or aryl halides with palladium or nickel atoms followed by trapping of RMX with triethylphosphane:

M atom + R—X → R—M—X $\xrightarrow{2Et_3P}$ $(Et_3P)_2MX(R)$

[c] Decomposition to ethane, ethylene, and *n*-butane.
[d] Methane cleavage during co-condensation, later decomposition to ethylene.

stability to the RPdX species. Also, non-fluorinated alkylpalladium halides could only be trapped in very small amounts, and decomposition products resulted that can be rationalized in terms of free radicals being formed at very low temperatures:

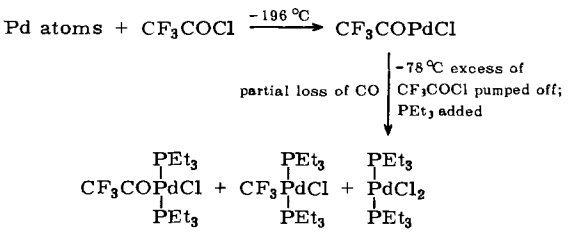
Pd atoms + CH_3CH_2I → (CH_3CH_2PdI) → $CH_3CH_2^{\bullet}$

$CH_3CH_2^{\bullet}$ → $CH_2{=}CH_2$ + CH_3CH_3 + $CH_3CH_2CH_2CH_3$

Overall, the thermal stabilities of the RPdX species vary greatly, and are in the order $C_6F_5 > CF_3 \approx C_2F_5 \approx n\text{-}C_3F_7 > C_6H_5 > CH_3 \approx C_2H_5 \approx CF_2Br \approx i\text{-}C_3F_7$.

3. (Halo)aryl and (halo)alkyl halides and nickel: Nickel atoms yield RNiX compounds that are much less thermally stable than the corresponding Pd species. For example, C_6F_5NiCl was shown to decompose at about −80 °C to perfluorobiphenyl, Ni, and $NiCl_2$. The trapping experiments showed that hardly any insertion products are formed at −45 °C or higher, whereas the yield of decomposition products is high. At −131 °C the opposite is the case. Similar results were found for C_6F_5NiBr. C_6H_5NiX could not be trapped, and only small amounts of CF_3NiBr could be trapped at −78 °C. With non-fluorinated alkyl halides, extremely unstable organometallic species are formed. Free radicals were apparently formed at very low temperatures. In fact, in the case of CH_3I + Ni atoms, methane was given off even during the cocondensation reaction at −196 °C. Overall, stability orders for the nickel system approximate $C_6F_5 > CF_3 > C_6H_5 > CH_3 \approx C_2H_5$.

Acyl halides also react with Pd and Ni atoms (Table 3). The product of insertion of Pd in heptafluorobutyl chloride can be trapped as fairly pure $(Et_3P)_2PdCl(COCF_2CF_2CF_3)$ at −78 °C. Trapping at higher temperatures yields mainly $(Et_3P)_2PdCl_2$. Thus, the primary insertion product was stable at −78 °C. With CF_3COCl and Pd, three products were formed in a trapping experiment at −78 °C.



A similar but more striking result was found in the C_6F_5COCl—Pd reaction where *only* the C_6F_5PdCl was trapped by triethylphosphane (CO completely lost). When non-fluorinated acyl chlorides were reacted with Pd, neither

Table 3. Reaction of acyl halides with palladium or nickel; trapping of product with triethylphosphane:

			$(Et_3P)_2NiCl_2$	20
$CH_3CONiCl$	< −100 (—CO)	−78	$(Et_3P)_2NiCl_2$	10

[a] Based on vaporized metal.

RCOPdCl or RPdCl could be trapped, and CO was released at very low temperatures.

$$\text{Pd atoms} + C_6H_5COCl \rightarrow (C_6H_5COPdCl) \xrightarrow[-CO\ <-50\,°C]{} C_6H_5\text{–}C_6H_5 + C_6H_5Cl + PdCl_2$$

Nickel reacted with CF_3COCl, and CO was released below −78 °C. At this temperature the excess acyl chloride was pumped out, triethylphosphane added, and CF_3NiCl trapped in low yield.

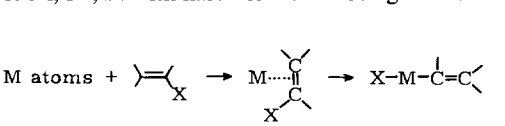
Summarizing the oxidative insertion reactions of Pd and Ni with ArX and RX it can be said: (1) the existence of these coordinatively unsaturated ArMX, AlkMX species has been demonstrated; (2) the effects of Ar or Alk on thermal stability have been determined by means of trapping experiments; (3) we have learned something about the modes of decomposition of ArMX and AlkMX; (4) aryl halides are better than alkyl halides in terms of efficiency of insertion and resultant stability of the intermediates; (5) these reactions have been useful for the preparation of a large number of new bis(phosphane)palladium halide complexes. (Our main interest was in the ArMX and RMX species rather than the phosphane adducts; therefore, not much effort was made toward optimizing the yields of the adducts, although we know the yields go up greatly when the phosphane is deposited simultaneously with ArX and metal atoms[14].) Triethylphosphane has been the most convenient trapping ligand to use due to its high volatility for vacuum transfers. This property also lends volatility to the metal complexes, and nearly all of the phosphane adducts could be studied conveniently by mass spectrometry. In fact the mass spectra are extremely characteristic due to isotopic distribution patterns for Ni and Pd.

Recently some new and very interesting RMX species have been generated. For Pt, the C_6F_5PtBr species has been prepared, has good stability, and reacts with triethylphosphane to yield both *cis* and *trans* phosphane adducts, whereas the Ni- and Pd-analogs yield only the *trans* complexes.

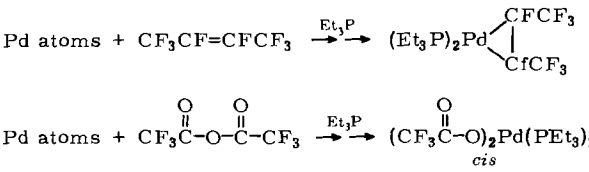
A stable non-fluorinated RMX species, $C_6H_5CH_2PdCl$, has been synthesized from benzyl chloride and Pd atoms. This material is air sensitive, but, surprisingly, does not decompose on warming to room temperature. This result is quite different from other alkylpalladium chlorides (AlkPdCl), and has important implications concerning the question of why some RPdX species are thermally stable and others are thermally very labile. It seems likely to us that bridging aromatic π-systems may be important in coordinating with the open sites on these RPdX species; possibly even more important than the electronegativity of the R group involved.

Reaction of titanium atoms with C_6F_5Br yielded a very unstable material of unknown structure. This unknown material is capable of polymerizing butadiene almost explosively at −78 °C. We have not been successful at trapping or characterizing a species of the type C_6F_5TiBr.

Future efforts in this area should be directed toward learning more about the structural and chemical properties of the more interesting RMX species, and toward learning more about the C—X insertion reaction. Stereochemical aspects of the insertion are being studied with the aid of optically active 1,1,1-trifluoro-2-chloro-2-phenylethane. Also, π and/or σ complexes of Ni, Pd, Pt with halo-olefins are being studied.



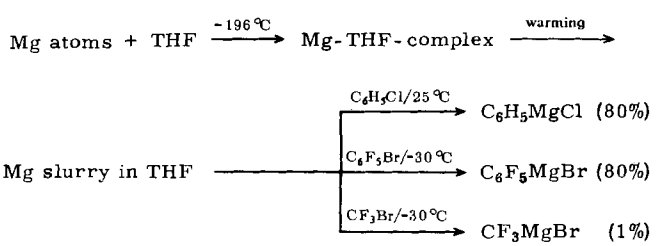
Besides C—X insertions, many other oxidative insertion studies can be envisioned (*i.e.*, Si—X, S—X, N—X, C—C, C—O, O—O, S—S, *etc.*). We have indeed been successful at carrying out C—C and C—O insertions[14]. We have attempted insertion reactions in C—CN bonds with C_6H_5CN and $C_6H_5CH_2CN$, but have not been successful.



4. Production of Clean, Finely-divided Active Metals

Recent literature indicates an intense interest in the production and chemistry of clean, finely-divided metals. Active Mg[17], Zn[18], Ni[19], U[20], and Cr[21] are usually prepared by reduction of metal salts in solution with a reducing agent such as potassium metal.

We have approached the production of active, finely-divided metals using the metal atom technique: metal vapors are co-condensed with solvent, such as tetrahydrofuran (THF) or hexane at −196 °C. On warming, the metal atoms agglomerate, but only to a small degree, and a metal slurry is formed. This slurry can be removed and used as a reagent in normal synthetic procedures. Thus, a Mg-THF slurry has been produced and was very reactive with aryl and alkyl halides that are normally considered unreactive with magnesium. The Mg-THF slurry is useful for the preparation of Grignard reagents at low temperature with no problems of reaction initiation. Both C_6F_5Br and CF_3Br reacted completely at −30 °C. (However, the resultant CF_3MgBr reagent was not very stable at that temperature, and only 1% could be trapped with iodine.)



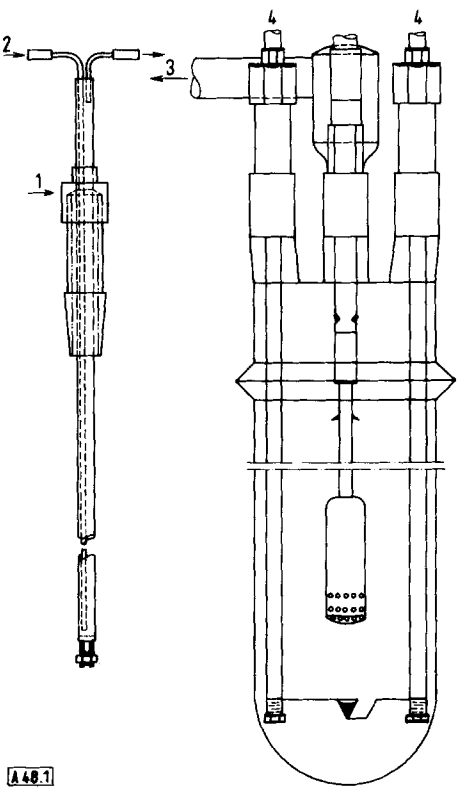
Active nickel, produced by cocondensing Ni vapor with THF followed by warming, serves as a good reagent for coupling alkyl halides such as allyl bromide or benzyl chloride at 40 °C.

5. Practical Considerations

The metal atom technique allows us to produce some unusual compounds and reagents. Our work has shown that highly coordinatively unsaturated organometallic compounds RMX can be produced this way, and these materials may teach us much about catalysis intermediates, especially the homogeneous type. Similarly, active metal slurries produced using this technique may serve as or teach us more about heterogeneous catalysis. Moreover, our interest in polyhalogenated π-complexes of the transition metals stems partly from the fact that some of these compounds can be considered "high energy materials" since there is always the possibility of highly favorable (thermodynamically) decompositions by M—X bond forming processes. Lastly, the metal atom technique in many cases serves as the best (or the only) method for production of new as well as known stable organometallic compounds. Although the yields of these compounds are often quite low (based on metal vaporized), metal wastage can be tolerated since bulk metals are very cheap chemical reagents compared with classical metal complexes as starting materials (*e.g.* $Pd(PR_3)_4$). In most cases even the low yield products are formed in reasonable purity since the main competing reaction is metal atom polymerization to form metal film, which can readily be separated from organometallic compounds.

6. The Reactor

We have succeeded in keeping our metal atom apparatus as simple as possible for reasons of expense as well as to make it attractive to workers in other laboratories. Our present setup can be assembled almost completely from commercially available parts (including crucibles and glass reactor chamber), and can be connected to any normal vacuum line by means of a 24/40 ground glass joint. Usually about 0.3 g of metal



A 48.1

Fig. 1. Reactor (right) and electrode (left) for metal atom reactions. 1, current supply; 2, cooling water; 3, to vacuum line; 4, electrodes.

is vaporized in a typical experiment, although we can readily vaporize 3 g if desirable. Liquid nitrogen is usually used as a coolant for the reactor (about 10 liters is used in a typical experiment) although Dry-Ice cooling has also been employed.

I would like to acknowledge the outstanding work of the graduate students who have been involved in these projects: Dr. James Y. F. Low, Mr. Howard F. Efner, John S. Roberts, Bruce Anderson, and Thomas Murdock. Also, the support of

the National Science Foundation (GP-34493 and GP-42376), and Research Corporation is greatly appreciated.

Transition Metal Atoms in the Synthesis of Binuclear Complexes

By E. P. Kündig, M. Moskovits, and G. A. Ozin[*]

1. Introduction

The vapors above the liquid transition metals scandium through to zinc have been extensively studied using a combination of high temperature Knudsen cell and mass spectrometric techniques[1]. Without exception, small concentrations of the transition metal diatomic molecules M_2 could be detected in the presence of the respective monatomic species M which formed more than 99% of the vapour[1-4]. It is because of this state of affairs that the chemistry of transition metal diatomic molecules has not previously been exploited although considerable information regarding their physical properties has been reported[5].

In searching the literature one finds scattered reports on the diffusion and aggregation properties of monatomic metal species frozen in rare gas solids at cryogenic temperatures. Electronic spectroscopy[5-13] and more recently Mössbauer spectroscopy[3,7] have proven to be of considerable value in this respect as it is sometimes possible to observe the spectra of the monatomic, diatomic and higher aggregate metal species in the presence of each other[5-13]. In this paper we wish to consider the factors which determine the aggregation of metal atoms in matrices to form dimers and binuclear complexes.

Mainly as a result of the elegant work of *Kant et al.*[1] it has proven possible to study the temperature dependence of the M/M_2 ratio using mass spectrometric techniques. These data have been analyzed and yield bond dissociation energies for M_2. They show an interesting "double hump" dependence on atomic weight (Fig. 1).

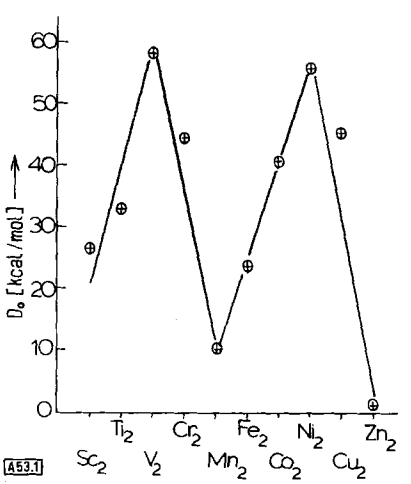

Fig. 1. Dissociation energies of the transition metal diatomic molecules Sc_2 through to Zn_2.

Semiempirical molecular orbital calculations have been reported for the M_2 molecules[14a] and Mulliken overlap population analyses at r_e indicate that σ-bonding predominates in the metal-metal bond, mainly from the 4s orbital. This has recently been confirmed by an *ab initio* SCF-MO calculation on Cu_2[14b]. The valence state electronic configurations for the metal atoms in M_2 are agreed to be $4s3d^{n+1}$. It is interesting to note that when the bond dissociation energy

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12—15, 1974).

D_0 is corrected for the promotion energy term from the electronic ground state $4s^23d^n$ using $D_{vs}=D_0+2E_{vs}$, the valence state dissociation energies D_{vs} are all found to lie in the range 56 ± 10 kcal/mol[1a]. The extremely low D_0 value for Mn_2 is attributed to the high E_{vs} for manganese, and for Zn_2, due to the presence of filled $4s^2$ and $3d^{10}$ valence shells. Aside from Mn_2 and Zn_2, the transition metal diatomic molecules have substantial bond dissociation energies and would be expected to have an independent and interesting matrix chemistry. In Fig. 2 we have presented a tabulation in 'periodic table form' of the known diatomic molecules of the elements.

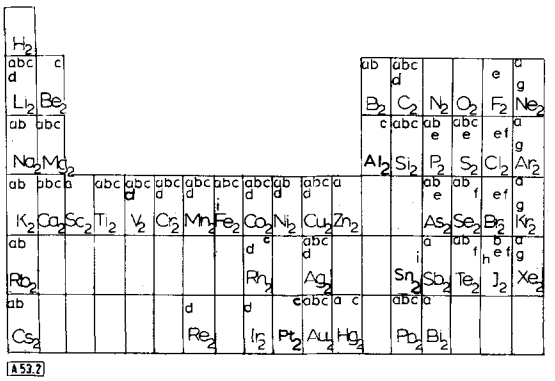

Fig. 2. Periodic table of the known homonuclear diatomic molecules. Detection by a) mass spectroscopy, b) UV-VIS spectroscopy in the gas phase, c) UV-VIS spectroscopy in the matrix, d) matrix chemistry, e) Raman spectroscopy in the gas phase or in the matrix, f) laser-induced resonance fluorescence in the gas phase, g) microwave spectroscopy in the gas phase, h) resonance-Raman effect, i) matrix Mössbauer.

It is generally accepted by matrix spectroscopists that diffusion of atoms or molecules occurs continually in all systems at all temperatures[15]. At very low temperatures (4.2—10°K) the mobilities of matrix isolated species are very small and diffusion is insignificant. However, warming the matrix in order to induce diffusion can be a very powerful tool in the hands of a skillful experimentalist in order, for example, to induce the sharpening of spectral lines, to monitor diffusion controlled chemical reactions, to study *in situ* matrix photolyses, and, of central interest here, to control the aggregation processes of metal atoms.

Even though diffusion in the crystalline solid state is a well-known phenomenon, details of the process are difficult to define or predict quantitatively in matrices owing to their non-uniform nature. Diffusion processes occurring during matrix annealing are complex and numerous. However, only low energy mechanisms such as vacancy migration and diffusion along grain boundaries need be considered[15]. On the other hand, the diffusion processes that can occur in the liquid-like interface formed on quenching gas beams onto a cold target are by no means well understood.

Several authors have reported on the electronic spectra of atoms trapped in matrices which generally show multiplets the centers of which are usually shifted to higher energies than the energy of the gaseous atom (blue shift). A number of explanations have been offered to explain the origin of the multiplet structures of the spectral lines, such as removal of orbital degeneracy by low site symmetries in the host lattice, Jahn-Teller effects, interactions between pairs of trapped atoms on non-nearest neighbour sites in the host lattice, *etc.* The generally-accepted rationale of the matrix shifts is in terms of a van der Waals interaction between the trapped atom and its matrix host[8-11].

Other spectral features, usually an order of magnitude less intense than the atomic lines, which escaped reasonable assignments to atomic lines, have usually been attributed to dimeric or higher metal aggregates.

Recently, some detailed investigations[10, 12, 37] of the experimental parameters which contribute to the formation of these "aggregates" have begun to appear in the literature and are of vital importance to the following discussions.

2. Isolation of Metal Atoms

In order to establish spectroscopically the relative proportion of metal monomer to dimer in a matrix it is necessary to know the extinction coefficients of the metal atom M and the corresponding M_2 molecule. This can be achieved from a careful study of the electronic spectra of the metal atom deposited in a solid inert matrix as a function of metal : matrix concentration. From the data that have previously been reported[7-13] the general consensus is that isolation improves as the metal and matrix atomic weights increase and as the metal concentration and temperature of deposition decrease. Since the M_2 molecules account for less than 1% of the metal vapor during deposition, at very low metal concentrations only metal atoms should be isolated. From the areas of the atomic absorption lines, the atom extinction coefficient ε_M can be deduced. Once ε_M is established, the quantity of isolated M atoms can be calculated in higher concentration runs. The remainder of the metal deposited can be assumed to be present as M_2 from which the M_2 molecule extinction coefficient ε_{M_2} can be deduced.

Andrews and *Pimentel*[12] have reported, for instance, such data for lithium in inert gas matrices from which they calculated a lower limit of about 300:1 for the $\varepsilon_{Li}/\varepsilon_{Li_2}$. More recently, similar experiments have been performed in our laboratories on a number of transition metals[18]. In all cases studied so far, the oscillator strengths of the M_2 molecules are considerably smaller than those of the corresponding atoms. Thus weak, broad M_2 absorptions often observed in the presence of extremely intense atomic absorptions could well reflect the presence of *substantial* concentrations of M_2 molecules and not of well isolated M atoms as has often been proposed[7-13]. This idea received convincing support from recent studies in our laboratories of the effect of metal concentration on the nature of the products of transition metal atom-carbon monoxide matrix reactions. These experiments show quite unambiguously that under certain matrix co-condensation conditions, many transition metals can be induced to react partly or wholly as diatomic molecules.

3. Diffusion of Metal Atoms in Matrices

A number of metals have been isolated as atoms in inert matrices in order to gain an insight into the effect of the matrix upon the spectra of trapped species and in order to study the formation of dimers, higher polymers and the diffusion mechanism of metal atoms in low temperature matrices. Extremely light atoms such as Li[12] and Be[16] have been

observed to diffuse readily in rare gas solids below 40°K, whereas heavier atoms such as Mg[9], Ca[17], Pb[10], Cu[11], Ag[7, 8, 11], Au[11] etc. have less tendency to diffuse and aggregate *after* the deposition has been completed. Matrix annealing with heavier atoms has little effect other than causing the sharpening and/or shifting of spectral lines usually attributable to the increasing regularity and/or phase changes in the host matrix. The low diffusion coefficients of most metal atoms in rare gas solids can be attributed, either or both, to their large masses and/or to van der Waals interaction of M with the matrix. At matrix temperatures the van der Waals energy between large atoms can be several times larger than kT. This essentially increases the size of the diffusing species, it now being a van der Waals molecule which diffuses.

4. Origin of M_2 Molecules and M_2L_n Complexes

The origin of M_2 molecules is of central concern in investigations of the diffusion properties of metal atoms in inert gas matrices. A detailed knowledge of the aggregation process is also vital to our understanding of the formation of binuclear complexes in metal atom-ligand matrix co-condensation reactions. Experiments have been designed which can give a detailed insight into both the origin of M_2 molecules and their respective M_2L_n complexes. For example, when manganese vapor effusing from a tantalum Knudsen cell was condensed with pure $^{12}C^{16}O$ onto a CsI plate cooled to 6—10°K (using Mn deposition rates arranged so that the probability of a Mn atom having another Mn atom as nearest neighbor in the f.c.c. lattice of CO was approximately 1 in 10^3), the matrix infrared spectrum[19] was identical with that obtained from $Mn_2(CO)_{10}$ deposited in an argon matrix (Fig. 3).

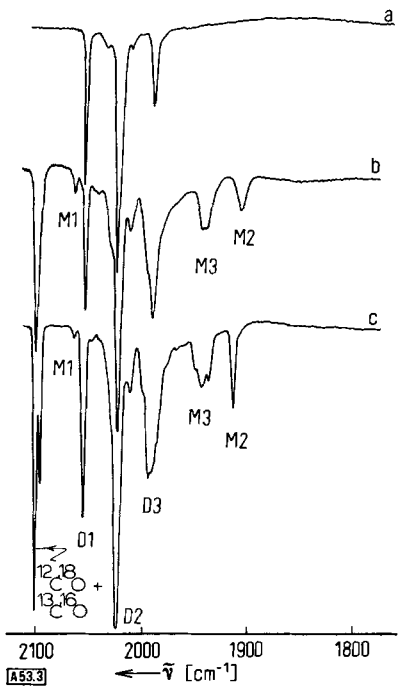

Fig. 3. IR spectra of a) $Mn_2(CO)_{10}$ isolated in Ar (approximately $1:10^3$), b) and c) the products of the matrix co-condensation reaction of Mn atoms with CO/Ar ≃ 1/5 and pure CO respectively showing $Mn_2(CO)_{10}$ (D) and $Mn(CO)_5$ (M) (the splitting of M_3, the E mode of $Mn(CO)_5$, was most pronounced in pure CO and is assigned to a matrix site effect).

These results were thought to be somewhat disquieting in that the mass-spectroscopic data[1c] for manganese vapor effusing from a Knudsen cell establishes a vapor composition of about 99% *atomic* manganese. In addition *Schnepp*[13] and *Mann*[6] have studied the electronic spectrum of manganese vapor deposited into pure Ar at 4.2°K and obtained data consistent with the presence of matrix isolated Mn atoms with very little evidence for molecular Mn_n species. Furthermore, at the high Mn:CO dilutions employed, one would expect the almost exclusive formation of mononuclear carbonyl species $Mn(CO)_n$. However, the data show the "exclusive" formation of the binuclear decacarbonyldimanganese, $Mn_2(CO)_{10}$.

The three possible sources of $Mn_2(CO)_{10}$ were considered to be (i) diffusion and dimerization of a $Mn(CO)_5$ species in the matrix, (ii) high concentrations of Mn_2 effusing from the Knudsen cell, and (iii) surface diffusion and dimerization of Mn atoms or reaction of a Mn atom with a $M(CO)_n$ fragment during deposition. We will consider each of these possibilities in turn.

In the light of *Rest* and *Crichton*'s[20] recent matrix photolysis experiments for $Mn_2(CO)_{10}$ in Ar, the diffusion of $Mn(CO)_5$ in Ar seems an unlikely source of $Mn_2(CO)_{10}$. Their results indicate that mononuclear carbonyl species are *not* formed on mercury arc photolysis of polynuclear carbonyl complexes in argon matrices, but instead $Mn_2(CO)_n$ species are favored. Although the $Mn_2(CO)_n$ products could not be characterized, the data strongly suggested that either the Mn—Mn bond is retained or that the bond is broken during photolysis but the $Mn(CO)_n$ fragments are too bulky to diffuse in argon and remain as nearest neighbors within the argon cage. On terminating the photolysis the dimer species will reform.

In a number of different experiments in which the orifice size of the Knudsen cell was varied between 0.1—1.0 mm, the results with pure $^{12}C^{16}O$ showed only the formation of $Mn_2(CO)_{10}$[19]. Thus the possibility that Mn_2 dimers were being formed in supersonic molecular beams[21] of manganese, effusing from the Knudsen cell with very small orifice diameters (0.1 mm), was considered to be most unlikely, as the results were identical with those with large diameter orifices (1.0 mm). Furthermore, at the low pressures employed (10^{-6}—10^{-7} torr), dimerization in flight is most unlikely as a source of Mn_2.

Double oven Knudsen cell techniques were used to superheat the manganese vapors effusing from the Knudsen cell[19]. In these experiments, designed to dissociate any dimanganese to monatomic manganese, the results were found to be *identical* with those of the single Knudsen cell experiments, showing only the formation of $Mn_2(CO)_{10}$, indicating the unlikelihood of Mn_2 being a major constituent of the effusing vapor.

However, when the Mn:CO ratio was reduced to $1:10^4$ or less, it was found that in addition to the main $Mn_2(CO)_{10}$ carbonyl absorptions (see Fig. 3) three new carbonyl absorptions grew in at 1938 ms, 1911 w and *ca.* 2060 vw cm^{-1}. These new lines always appeared with approximately the same relative intensities after deposition, implying that they are all associated with one species. Extensive experimental and theoretical studies have shown this species to be the square pyramidal $Mn(CO)_5$ radical[19]. $Mn(CO)_5$ was reluctant to diffuse at temperatures as high as 40—45°K (where argon is slowly

boiling off), again implying that matrix diffusion and dimerization of $Mn(CO)_5$ is an unlikely source of $Mn_2(CO)_{10}$.

These results are analogous in many respects to the data for the Co/CO and Cu/CO reactions[22, 23] which yield $Co(CO)_4$ and $Cu(CO)_3$ respectively under conditions of slow metal deposition, yet exclusively $Co_2(CO)_8$ and $Cu_2(CO)_6$ with high metal deposition rates. Furthermore, neither $Co(CO)_4$ nor $Cu(CO)_3$ was observed to dimerize readily during matrix warm-up experiments. It would therefore appear that the relative concentration of binuclear to mononuclear species (whether M_2 molecules or M_2L_n complexes) depends on the metal concentration in the matrix, the mononuclear species being favored at very low metal concentrations.

The dimerization process can therefore be specified to take place during matrix condensation and probably involves surface diffusion of highly mobile atoms in the quasi-liquid phase before they are frozen into the solid matrix.

5. The Effect of the Atomic Weight of M on the Dimerization Process

The data collected for the first row transition metals indicate quite clearly that dimerization of the atoms occurs readily during matrix condensation at metal-matrix ratios greater than 1:1000 and can be attributed to a surface diffusion process occurring during deposition. One would have anticipated from these data that on proceeding to the heavier transition metals, dimerization would be less facile (under comparable conditions) on at least two accounts. First, the rate of diffusion of a metal atom under matrix conditions has a mass dependence of between $M^{-1/2}$ to M^{-1}, depending on whether the diffusion layer is more closely approximated by a gas-like or a liquid-like region, which would reduce the tendency of the heavier transition metal atoms to dimerize, compared to the first row metals. Second, as the heavier metals are more polarizable, van der Waals type interaction

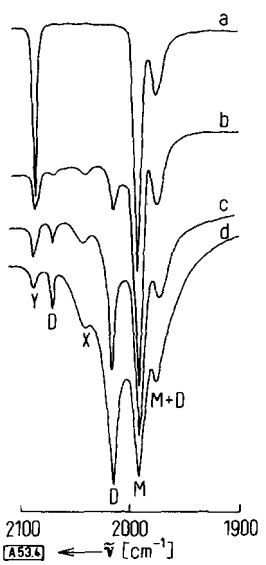

Fig. 4. IR spectra of the products of the matrix cocondensation reaction of Re atoms with CO at 10—15°K. a) Re:CO≃1:10⁵, b) Re:CO≃1:10⁴, c) Re:CO≃1:10³ and d) Re:CO≃1:10², showing the reactions of both Re atoms to yield $Re(CO)_5$ and $Re_2(CO)_{10}$ (M=$Re(CO)_5$; D=$Re_2(CO)_{10}$; X=unidentified, higher aggregate species; Y=$^{13}C^{16}O$, $^{12}C^{18}O$ in natural abundance).

with the matrix material will increase, thereby tending to stabilize atoms rather than M_2 molecules.

That dimerization is far less pronounced with the heavier transition metals is borne out by recent experiments with Re[24], Rh[25] and Ir[25]. For example, using Re/CO flow conditions comparable to those used in the Mn/CO reaction which yielded exclusively $Mn_2(CO)_{10}$, it is found that the only observable reaction product is the mononuclear $Re(CO)_5$ radical[24] (Fig. 4). Reasonable quantities of the binuclear species $Re_2(CO)_{10}$ could be induced to form only by increasing the Re concentration by a factor of at least 100 (see Fig. 4c). Similarly, with Rh/CO and Ir/CO flow conditions comparable to those used in the Co/CO reaction, which yielded exclusively $Co_2(CO)_8$[23], the matrix infrared spectra showed the presence of only $Rh(CO)_4$ and $Ir(CO)_4$[26]. It was found necessary to increase the Rh and Ir metal concentration by a factor of 100 to produce reasonable concentrations of the binuclear complexes $Rh_2(CO)_8$[25] and $Ir_2(CO)_8$[25] analogous to the bridge-bonded form of $Co_2(CO)_8$.

These data support the proposal that the heavier metals form M_2 molecules and M_2L_n complexes in their matrix reactions far less readily than their first row transition metal congeners.

6. The Effect of the Matrix Material on the Dimerization Process

Aside from the prerequisite of high guest to host dilutions for efficient isolation of a chemical species, one must deposit the sample at a temperature lower than $\frac{1}{2}\ T_{m.p.}$ of the matrix host material[27]. At these temperatures the matrix is sufficiently rigid to prevent long-range diffusion and subsequent unwanted reactions of the matrix guest. The degree of isolation of the guest is often very sensitive to the rate at which the matrix is laid down. Thus one can envisage a situation in which the latent heat of condensation of the matrix host on deposition is sufficiently high to cause warming of the matrix and hence diffusion of guest species. This phenomenon, originally discussed by *Bent* and *Fately*[28] is referred to as the "internal blanket effect" and sets an upper limit on the rate at which a matrix can be deposited to ensure efficient isolation.

The parameters that control the degree of isolation of unstable (or stable) molecules, free radicals and molecular ions are well documented. Less well understood, however, are the properties of the matrix which influence the isolation of metal atoms and diatoms. From the limited amount of experimental data presently available for Li/Li_2[12] and Pb/Pb_2[10] and Cr/Cr_2[46] it would appear that for the inert gases the efficiency of isolation of atoms generally increases in the order Xe > Kr > Ar > Ne. This order cannot be explained in terms of a thermal conductivity effect as Ar, which is the most thermally conductive, would be predicted to be most effective at trapping atoms. This is not found to be the case. However, the order is consistent with a rationale in terms of either atomic polarizability and/or rigidity effects. Thus xenon being the most polarizable would interact more strongly in a van der Waals sense with the metal atom (during the deposition) than would argon, thus tending to favor the isolation of metal atoms. Xenon can therefore be thought to be competing with the metal in the dimerization process. Moreover, the most rigid matrix

material, at deposition temperature T°K, would tend to quench metal atoms more efficiently, again consistent with the order of isolating efficiency, Xe > Kr > Ar > Ne. Few other matrix supports have been investigated from this point of view although preliminary studies with SF_6[10] show that it is ideal for isolating Pb_2 molecules, implying that the polarizability of the fluorine atoms in SF_6 is very small. SF_6 has also been used as a matrix for studies of the electronic spectra of Cu, Ag and Au atoms[11], where the degree of isolation of atoms appears to be greatest for Au, which is not unexpected in the light of our earlier discussions of metal atom diffusion as a function of its atomic weight and polarizability.

7. Chemical Evidence for Reactions Leading to Binuclear Transition Metal Complexes

Most of the information concerning matrix reactions leading to binuclear transition metal complexes has been derived from metal atom-carbon monoxide co-condensation reactions. Evidence for the formation of binuclear products comes from the following sources: i) observations of known binuclear carbonyl complexes; ii) synthesis of new binuclear complexes; iii) observation of bridging CO stretching modes; iv) observation of a mononuclear carbonyl complex in the presence of its binuclear counterpart; v) ligand and metal concentration studies; vi) ligand and mixed metal isotope substitution studies; vii) co-deposition of two different metals.

Let us formalize the chemical evidence for the matrix formation of binuclear complexes by discussing each of the above experiments in turn, with reference to selected examples from work performed in our own laboratories.

7.1. Observation of Known Binuclear Complexes

When Mn or Co atoms were deposited with pure $^{12}C^{16}O$ at M/CO ratios of about 1/1000, the matrix infrared spectra

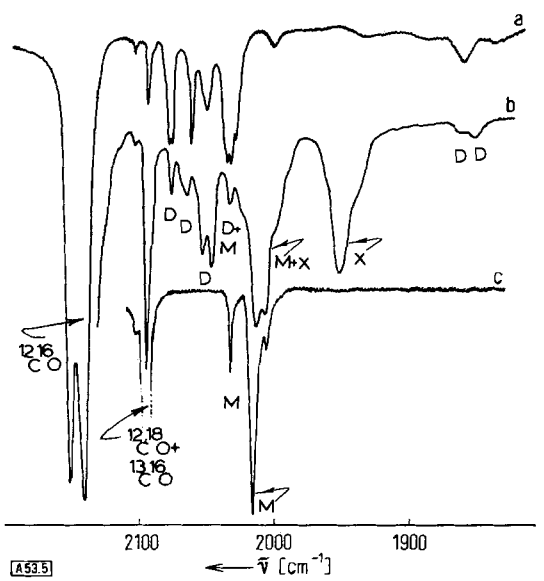

Fig. 5. IR spectra of a) $Co_2(CO)_8$ in Ar (approximately $1:10^3$), b) and c), the products of the matrix co-condensation reaction of Co atoms with CO at $Co:CO \simeq 1:10^3$ and $Co:CO \simeq 1:10^4$ showing the presence of $Co(CO)_4$ (M) and $Co_2(CO)_8$ (D) respectively (the lines marked X belong to cobalt cluster compounds $Co_x(CO)_n$ [22, 26]).

showed the presence of mainly $Mn_2(CO)_{10}$[19] and $Co_2(CO)_8$[22]. The identification of these reaction products was established by comparing the spectra with those obtained by depositing $Mn_2(CO)_{10}$ and $Co_2(CO)_8$ in Ar matrices using gas flow Knudsen cell techniques (Fig. 3 and 5). The similarity of the two sets of data proves, therefore, that manganese and cobalt, under the conditions of a matrix co-condensation experiment, can be induced to yield exclusively binuclear compounds.

7.2. Synthesis of New Binuclear Complexes

The matrix reactions of transition metal atoms can in principle provide chemical pathways to the synthesis of new binuclear complexes which cannot be prepared by conventional methods of chemical synthesis. The carbonyl complexes of the Co, Rh, Ir group of metals can be used to illustrate the potential usefulness of the method.

Until very recently, octacarbonyldicobalt, in its bridged and non-bridged forms, was the only well-defined "parent" binuclear carbonyl complex of the Co, Rh, Ir group of metals[29], although the tetranuclear $M_4(CO)_{12}$ and hexanuclear $M_6(CO)_{16}$ cluster complexes have been well characterized for all three metals. In brief, the synthesis of $Rh_2(CO)_8$ and $Ir_2(CO)_8$ was first claimed in 1940—43 by *Hieber* and *Lagally*[30] by the action of CO on the freshly prepared metal at high CO pressures and temperatures (*ca.* 450 atm, 200 °C). Since then many groups of workers[31] have tried various different approaches, without success, to substantiate the authenticity of $Rh_2(CO)_8$ and $Ir_2(CO)_8$. However, in 1970 *Whyman*[32] reported infrared spectroscopic data for the solution equilibrium of $Rh_4(CO)_{12}$ under conditions of high CO pressure (*ca.* 430 atm) and low temperatures (*ca.* −19 °C). Aside from the CO absorptions associated with $Rh_4(CO)_{12}$, new absorptions were observed which by comparison with the bridge bonded form of $Co_2(CO)_8$ were assigned to the bridge bonded form of $Rh_2(CO)_8$ (Table 1), presumably arising from the disproportionation equilibrium:

$$Rh_4(CO)_{12} + 4CO \rightleftharpoons 2Rh_2(CO)_8$$

The only criticism of this study is that one cannot eliminate the possibility that the spectral changes might have simply arisen from the freezing out of one or more unstable isomers of $Rh_4(CO)_{12}$ (see for example the fluxional behavior of $Rh_4(CO)_{12}$ in solution[33]).

Table 1. IR spectra of $M_2(CO)_8$ (M = Co, Rh or Ir).

$Co_2(CO)_8$ bridged	$Co_2(CO)_8$ non-bridged	$Rh_2(CO)_8$ bridged	$Ir_2(CO)_8$ bridged	$Rh_2(CO)_8$ [32] bridged

[a] Appears as a doublet or a singlet (2040 cm^{-1}) depending on the deposition conditions.

Whyman[31b] has more recently tried a number of similar approaches to substantiate the existence of $Ir_2(CO)_8$, but as yet without success, and prior to metal vapor experiments to be described, the parent binuclear complex $Ir_2(CO)_8$ remained elusive.

Previously, the radicals $Rh(CO)_4$ and $Ir(CO)_4$ had been synthesized from the matrix reactions of Rh and Ir atoms with pure CO[26]. The complexes were characterized using $^{12}C^{16}O/^{13}C^{16}O$ mixed isotope experiments.

Using high Rh atom concentrations which favor the matrix formation of binuclear complexes, the infrared spectra of the products in pure CO show, in addition to the absorptions

[a] Recorded under dynamic vacuum (10^{-6} torr).
[b] The reported infrared spectrum of $Rh_4(CO)_{12}$ shows CO absorptions at 2076, 2071 vs, 2045 s, 1886 s cm^{-1} (in solution; Ref. [32]).
[c] The reported infrared spectrum of $Rh_6(CO)_{16}$ shows CO absorptions at 2070 s, 2043 w, 2021 mw and 1798 s cm^{-1} (in solution; Ref. [31a]) and 2077, 2074 s, 2041 m, 2016 m and 1770 s (solid; Ref. [34]).
[d] Appears as a doublet (2043, 2038 cm^{-1}) depending on the deposition conditions.

assigned to $Rh(CO)_4$, four new CO absorptions which were proven to belong to a single species. Inspection of Tables 1 and 2 shows that the new absorptions are very similar, in terms of frequency and intensity, to the infrared absorptions of the bridged form of $Co_2(CO)_8$ as well as *Whyman*'s bridged form of $Rh_2(CO)_8$. The close correspondence of these sets of data is quite striking, and serves to authenticate the existence of $Rh_2(CO)_8$ in its bridge-bonded form.

Table 3. IR spectra of $Ir(CO)_4$, $Ir_2(CO)_8$ and $Ir_4(CO)_{12}$ [a].

	1845 wsh	
	1822 m	

[a] Recorded under dynamic vacuum conditions.
[b] Assigned to bridged form of $Ir_4(CO)_{12}$ by analogy with $Rh_4(CO)_{12}$. The non-bridged form of $Ir_4(CO)_{12}$ shows CO absorptions at 2072 s and 2032 s cm^{-1} (Ref. [31b]). At room temperature, the strongest lines of $Ir_6(CO)_{16}$ are just beginning to grow in (by comparison with the spectra of Reference [31a]).

Entirely analogous results were obtained with the iridium-carbon monoxide system. These are summarized in Tables 1 and 3. The close correspondence between the sets of data for Co, Rh and Ir shown in Table 1 is quite striking and serves to authenticate the existence of $Ir_2(CO)_8$ in a low temperature bridge-bonded form.

When $Rh_2(CO)_8$ and $Ir_2(CO)_8$ were allowed to warm up on the optical plate under conditions of dynamic vacuum, the infrared spectra showed that a transformation occurred at about $-48\,^{\circ}C$ for $Rh_2(CO)_8$ and about $-58\,^{\circ}C$ for $Ir_2(CO)_8$ to yield the bridge-bonded forms of $Rh_4(CO)_{12}$ and $Ir_4(CO)_{12}$, presumably by loss of CO through the disproportionation reaction.

$$2M_2(CO)_8 \rightarrow M_4(CO)_{12} + 4CO \quad \text{(where M = Rh or Ir)}$$

A further disproportionation of $Rh_4(CO)_{12}$ to $Rh_6(CO)_{16}$ was observed at room temperature (Table 2). The onset of the analogous disproportionation of $Ir_4(CO)_{12}$ to $Ir_6(CO)_{12}$ (Table 3) can just be observed. By comparing the temperatures at which $Rh_2(CO)_8$ and $Ir_2(CO)_8$ disproportionate to the respective bridge forms of $Rh_4(CO)_{12}$ and $Ir_4(CO)_{12}$, one is led to believe that under comparable conditions $Ir_2(CO)_8$ is slightly less stable than $Rh_2(CO)_8$ although it is not possible to estimate the magnitude of this difference from the present data. The instability of $Ir_2(CO)_8$ and $Rh_2(CO)_8$ with respect to disproportionation to $Ir_4(CO)_{12}$ and $Rh_4(CO)_{12}$ above $-48\,^{\circ}C$ is certainly consistent with the fact that the non-bridged forms of the complexes have not been observed and with the difficulties previously experienced by various groups of workers in attempting to synthesize and characterize $Rh_2(CO)_8$ and $Ir_2(CO)_8$.

7.3. Observation of Bridging CO Stretching Modes

The bonding in a bridging carbonyl ligand can be pictured as ketonic which in a valence bond sense would imply a formal oxidation state of +1 for each bridgehead metal. Alternatively the bonding can be discussed in a more flexible generalized way in which a 3-center molecular orbital scheme is considered, involving the 5σ orbital of the CO ligand and the symmetry allowed σ type orbital on each metal atom. A similar 3-center scheme can be envisaged for the π-bonding description of the molecule in order to correlate the CO stretching frequencies (or CO bond stretching force constants) with the extent of π- and σ-bonding. When part of the same complex, bridging carbonyl groups characteristically absorb at lower infrared frequencies than terminal carbonyl groups. Thus the observation of CO bridge stretching modes is indicative of binuclear complex formation and hence matrix reactions of M_2 molecules.

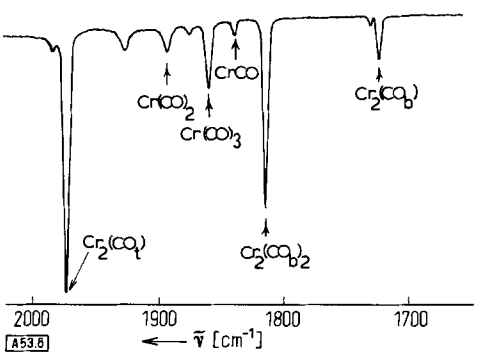

Fig. 6. Infrared spectra of the products of the matrix co-condensation reaction of Cr vapor with CO/Ar = 1/100 (Cr : Ar ≃ 1 : 10^3).

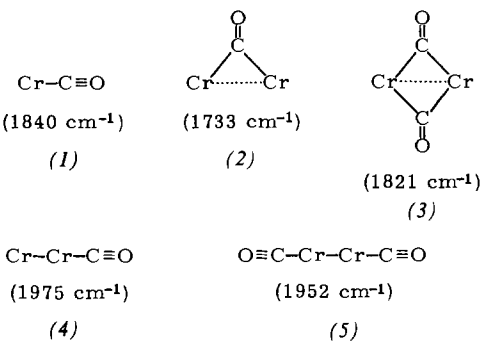
An example of this comes from the Cr/CO/Ar matrix reaction[35] which at high CO concentrations (CO:Ar = 1:20) shows the presence of mainly binary mononuclear $Cr(CO)_n$ complexes (where $n = 6$, 5 and 4). However, on reducing the CO concentration below 1:20 the formation of binuclear complexes become favored and molecules such as $Cr_2(CO_t)$, $Cr_2(CO_b)$ and $Cr_2(CO_b)_2$ (where t = terminal CO and b = bridge CO ligands) are observed (Fig. 6) in the presence of the mononuclear complexes $Cr(CO)_2$ and $Cr(CO)_3$. The stoichiometry with respect to the carbon monoxide ligand, in all cases, was established from $^{12}C^{16}O/^{13}C^{16}O$/Ar mixed isotope experiments (see Section 7.6). The binuclear and mononuclear complexes could be distinguished by retaining the gas flow constant and varying the rate of Cr metal deposition. Details of this technique are discussed in a later section. Experiments of this type served to define the molecules *(1)* to *(5)*.



The monotonic rise to higher frequencies on passing from $Cr_2(CO_b)$ to $Cr_2(CO_b)_2$ is consistent with a decrease in the charge delocalization of the Cr_2 electrons into the π^* orbitals of the CO bridge ligand(s) concomitant with the monotonic increase in the formal oxidation state of the Cr from Cr^I to Cr^{II}. The rise to higher frequencies on passing from Cr(CO) to $Cr_2(CO_t)$ can be rationalized using an inductive argument, in which the charge density associated with the electron used in the Cr—Cr bond of $Cr_2(CO_t)$ spends in CrCO relatively more of its time within the Cr electron core, so shielding the outer d-electrons more from the nucleus and allowing better Cr—CO back bonding which results in a higher CO stretching frequency for $Cr_2(CO_t)$ compared to CrCO.

7.4. Observation of a Mononuclear Carbonyl Complex in the Presence of its Binuclear Counterpart

7.4.1. Comparison of Mononuclear and Binuclear Complexes with Known Species

The Co/CO matrix reaction[22] exemplifies the above situation. Under $Co:CO \simeq 1:10^3$ concentration conditions, $Co_2(CO)_8$ can be identified (Fig. 5). In addition a doublet at 2029 and 2011 cm^{-1} is observed[22]. *Rest* and *Crichton*[36] have independently investigated the matrix photolysis reaction of $Co(CO)_3(NO)$ in argon matrices doped with CO:

$$Co(CO)_3NO \xrightarrow[Ar/CO]{} Co(CO)_4$$

The product of this reaction also shows a doublet at 2029 and 2011 cm^{-1} with an identical intensity ratio to the similar lines observed in the Co/CO reaction. Mixed $^{12}C^{16}O/^{13}C^{16}O$ isotope experiments proved that the product giving rise to the 2029/2011 cm^{-1} doublet in both the matrix photolysis[36] and the Co/CO reactions[22] is one and the same species, namely the C_{3v} $Co(CO)_4$ radical. Further confirmation that both mononuclear and binuclear cobalt carbonyls can result from the matrix reaction of Co atoms with pure CO stems from experiments at *high* Co atom concentrations ($Co:CO \simeq 1:100$) and very *low* Co atom concentrations ($Co:CO \simeq 1:10^5$), the infrared spectra of which show mainly $Co_2(CO)_8$ and mainly $Co(CO)_4$ respectively[22, 26].

7.4.2. Assignment of the Mononuclear Species by Inference

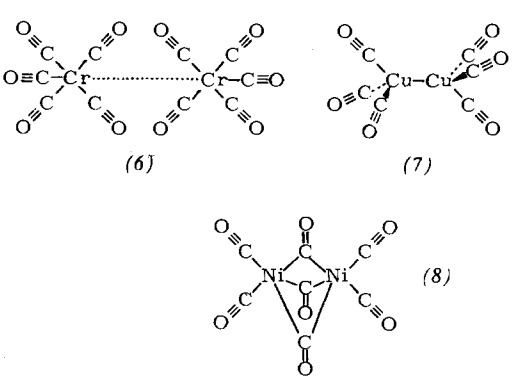
When the mononuclear species has not previously been detected, one has to resort to comparative methods of identification, using isostructural and isoelectronic species (or mixed isotope experiments whenever possible).

For example, when Mn atoms are co-condensed with pure CO at very low concentrations $Mn:CO \simeq 1:10^4$, aside from the absorptions assigned to $Mn_2(CO)_{10}$, *three* new carbonyl absorptions are observed (see Section 4)[19]. This species is assigned to a C_{4v} pentacarbonylmanganese radical, based on the numbers, frequencies and relative intensities of the observed infrared active carbonyl stretching modes. The assignment is further strengthened by comparison of the infrared data with those for other known C_{4v} square pyramidal complexes, for example, $Cr(CO)_5$[38] and $Cr(CO)_5^-$[39] or indeed any $Mn(CO)_5X$ species (X = H, Cl, Br, I or CH_3) containing the C_{4v} $Mn(CO)_5$ residue[40].

7.4.3. Assignment of Bands to M_2L_n Type Molecules

Although it is possible, in principle, to detect the metal-metal stretching vibration belonging to molecules of the type M_2L_n using matrix Raman spectroscopy, distinguishing that band from metal ligand vibrations would be difficult. It is therefore more expeditious to try to discover ways of identifying which bands in the ligand-stretching portion of the spectrum belong to binuclear metal species.

One technique that has been used successfully by us is to investigate the relative absorbances of bands as a function of metal/matrix gas ratio (see Section 7.5).



Using these methods, several binuclear complexes have been prepared and identified, among them being the van der Waals dimer $[Cr(CO)_5]_2$ *(6)*[41], the metal-metal bonded dimer $Cu_2(CO)_6$ *(7)*[23] and a dimeric nickel carbonyl species $Ni_2(CO)_7$ *(8)*[42].

7.5. The Dependence of the Concentration of Binuclear Species on Metal/Matrix Gas Ratio

As indicated earlier, binuclear species can arise in the matrix in two ways. The first is statistical, that is, metal dimers arising from the finite and calculable probability that in one of the nearest neighbor sites about a metal atom there resides another metal atom, while the second is due to reactions in the surface region of the matrix during the first few moments following deposition and before the kinetic energy of the reagents has been accommodated, hence, while the molecules are still fairly mobile.

We will now show that both of these mechanisms give rise, at least in the case of metal atoms deposited into a "reactive matrix" and under such circumstances that mononuclear species still predominate, to binuclear species whose concentration is proportional to the square of the metal/matrix gas ratio, while the concentration of mononuclear species is directly proportional to that ratio. In fact our experience to date indicates that at least in the case of first row transition metals, the surface reaction mechanism far exceeds in importance the statistical generation of dimers.

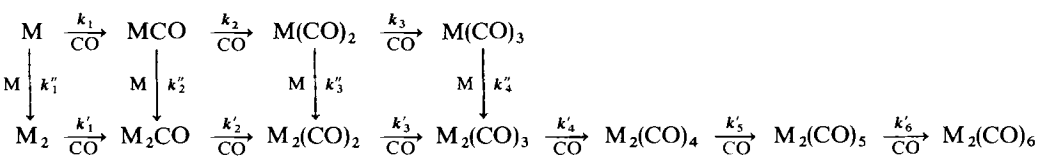
Consider the matrix reaction between a metal atom M and CO which gives rise to mononuclear carbonyls $M(CO)_n$ where $n=1$, 2, or 3 and binuclear species $M_2(CO)_m$ where, for example, $m=1$ to 6 as in the case of the Cu/CO system. Species containing higher aggregates of metal are in general also possible. We will assume, however, that the matrix ratio, [M], never becomes high enough to result in the formation of appreciable quantities of these. Let us now consider the surface reaction and the statistical factor separately.

7.5.1. Surface Reaction

We assume that only CO and M are mobile species. Accordingly only those reactions which involve at least one mobile species will be admitted. This implies that reactions of the form

$$M(CO)_n + M(CO)_{n'} \rightarrow M_2(CO)_{n+n'}$$

are admissible. The total reaction scheme for the formation of $M(CO)_3$ and $M_2(CO)_6$ is therefore as follows.



The backward steps in these reactions are assumed to be negligible slow and are thus not considered.

Mononuclear Species: The rate equations for formation of mononuclear species can be written directly:

$$\frac{d[MCO]}{dt} = k_1[M][CO] - k_2[MCO][CO] - k_2''[MCO][M] \quad (1)$$

$$\frac{d[M(CO)_2]}{dt} = k_2[MCO][CO] - k_3[M(CO)_2][CO] - k_3''[M(CO)_2][M] \quad (2)$$

$$\frac{d[M(CO)_3]}{dt} = k_3[M(CO)_2] - k_4''[M(CO)_3][M] \quad (3)$$

Since the reaction is carried out in pure CO all species of the form $M(CO)_n$ will become $M(CO)_3$ upon quenching, hence the final concentration of $M(CO)_3$ is given by

$$[M(CO)_3] = \int_0^{\tau_q} \left\{ \frac{d[MCO]}{dt} + \frac{d[M(CO)_2]}{dt} + \frac{d[M(CO)_3]}{dt} \right\} dt + [M]_{\tau_q} \quad (4)$$

where τ_q is the average quenching time, *i. e.*, the average lifetime of a species before it is immobilized within the matrix.

Substituting from equations (1), (2) and (3) into (4) one obtains

$$[M(CO)_3] = [M]_{\tau_q} + \int_0^{\tau_q} [M]\{k_1[CO] - (k_2''[MCO] + k_3''[M(CO)_2] + k_4''[M(CO)_3])\} dt \quad (5)$$

where $k_2'' \simeq k_3'' \simeq k_4''$ if the reactions are assumed to be diffusion limited. Integral (5) can therefore be written

$$[M(CO)_3] = [M]_{\tau_q} + \int_0^{\tau_q} [M]\{k_1[CO] - k_2''([M(CO)] + [M(CO)_2] + [M(CO)_3])\} dt$$

Under the experimental conditions considered the CO concentration far exceeds the sum of concentrations of all mononuclear species. Moreover, k_2'' is not expected to be markedly different from k_1. Accordingly integral (5) reduces to

$$[M(CO)_3] \simeq \int_0^{\tau_q} k_1[M][CO]dt + [M]_{\tau_q} \quad (6)$$

The rate of change of concentration of metal can also be written as

$$\frac{-d[M]}{dt} = k_1[M][CO] + k_1''[M]^2$$

which reduces, for the same reasons stated above, to

$$\frac{-d[M]}{dt} \simeq k_1[M][CO]$$

which has the following solution

$$M = [M]_0 e^{-k_1[CO]t} \quad (7)$$

in which [CO] being in great excess is taken to be a constant and where $[M]_0$ is the initial metal concentration, hence proportional to the metal/CO ratio.

Substituting equation (7) into equation (6) and integrating, one obtains

$$[M(CO)_3] \simeq [M]_0$$

Binuclear Species: The kinetic equations governing the production of binuclear species may also be written down as follows:

$$\frac{d[M_2]}{dt} = \tfrac{1}{2}k_1''[M]^2 - k_1'[M_2][CO] \quad (8)$$

together with six other equations of the form

$$\frac{d[M_2(CO)_n]}{dt} = k_n'[M_2(CO)_{n-1}][CO] + k_{n+1}''[M][M(CO)_n] - k_{n+1}'[M_2(CO)_n][CO] \quad (9)$$

for $n \leq 3$ and deleting the term in k'' for $n > 3$.

Using similar arguments as those stated for production of mononuclears the concentration of $M_2(CO)_6$ is given by

$$[M_2(CO)_6] = \tfrac{1}{2}k_1'' \int_0^{\tau_q} [M]^2 dt + k_2'' \int_0^{\tau_q} [M] \left(\sum_{n=1}^{3} M(CO)_n \right) dt \quad (10)$$

We have assumed throughout that the concentration of binuclear species is always smaller than that of mononuclears, consequently the quantity

$$\sum_{n=1}^{3} M(CO)_n \simeq [M]_0 - [M] \quad (11)$$

Substituting (11) into (10) and (7) into the resulting expression and integrating, we obtain

$$[M_2(CO)_6] = K_2[M]_0^2$$

where

$$K_2 = \frac{k_1''}{4k_1[CO]}(1 - e^{-2k_1[CO]\tau_q}) + \frac{k_2''}{2k_1[CO]}[1 + e^{-2k_1[CO]\tau_q} - 2e^{-k_1[CO]\tau_q}]$$

which is $\simeq \tfrac{1}{2}k_1''\tau_q$ to first order in τ_q.

The result of this analysis indicates, therefore, that the ratio of the concentration of binuclear species to that of mononuclear should increase proportionally to the matrix ratio $[M]_0$. A similar analysis for metal trimers indicates that the analogous ratio involving trinuclears increases as the square of the metal-to-CO ratio.

7.5.2. Statistical Concentrations of Dimers

Assuming that aggregates larger than dimers are in negligible abundance and that there are 12 nearest neighbor sites associated with every substitutional site in the CO matrix one can write down the metal dimer and metal monomer concentrations directly.

$$[M_2(CO)_6] = 12([M]_0^2)(1 - [M]_0)^{11}$$

and $[M(CO)_3] = [M]_0(1 - [M]_0)^{12}$

$$[M_2(CO)_6]/[M(CO)_3] = 12[M]_0/(1 - [M]_0)$$

which reduces to approximately $12[M]_0$ for $[M]_0$ not too large.

We see therefore that both the statistical and surface reaction pathways lead to binuclear/mononuclear concentration ratios which are proportional to the matrix ratio while the appropriate ratios related to species containing larger metal aggregates vary as some higher power of the matrix ratio. It is therefore apparent that one can distinguish binuclear species from both higher aggregates and mononuclears by observing the effect of varying the matrix ratio on the relative absorbances of the appropriate spectral bands.

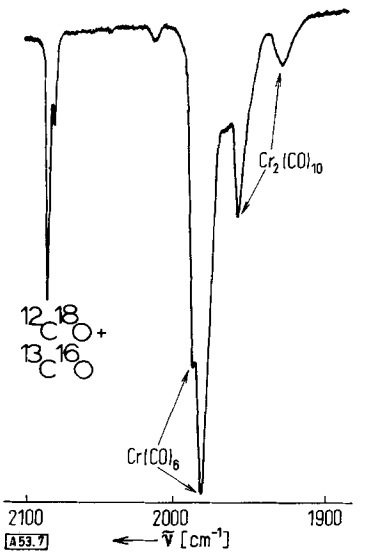


Fig. 7. Infrared spectrum of the products of the matrix co-condensation reaction of Cr vapor with CO at 10—15°K with Cr:CO ≃ 1:10³.

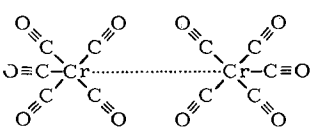
Let us illustrate this by considering the results for the Cr/CO reaction in more detail.

When Cr atoms are co-condensed with pure $^{12}C^{16}O$ at 10—15°K, the major product of the reaction is seen to be $Cr(CO)_6$ (Fig. 7). However, *two* other intense carbonyl absorptions at 1962 and 1933 cm^{-1} always accompanied the hexacarbonylchromium. These two new lines appeared with the *same* relative intensities in a number of different runs, and are ascribed to a species X. The intense carbonyl absorptions have very similar frequencies and relative intensities (approximately 3:1) to those of *Turner*'s pentacarbonylchromium[38] produced by photolyzing $Cr(CO)_6$ in Ar ma rices. Furthermore, annealing of the CO matrix at 40—45°K had essentially *no* effect on the spectrum, a result which parallels the annealing behavior of *Turner*'s pentacarbonylchromium in Ar/CO matrices[38].

If X is indeed a coordinatively unsaturated square pyramidal pentacarbonylchromium, its reluctance to react with CO is most unusual, especially in a "pure" CO matrix, which leads one to believe that the vacant coordination site in the C_{4v} $Cr(CO)_5$ fragment is blocked.

One explanation is that the lines belong to a weakly interacting dimer *(9)*.



(9)

That the weakly interacting dimer $Cr_2(CO)_{10}$ *(9)* is indeed a likely formulation for complex X in keeping with the results of a careful study of the dependence of the absorbance ratio $A_X/A_{Cr(CO)_6}$ on the Cr/CO ratio: The absorbance ratio is observed to increase proportionally with increasing Cr concentration.

The Cu/CO co-condensation reaction in pure CO and in dilute CO/Ar matrices provides another example of the use of this method to determine metal stoichiometry[23].

On the basis of known first row mononuclear and binuclear binary carbonyl complexes $V_2(CO)_{12}$, $Cr(CO)_6$, $Mn_2(CO)_{10}$, $Fe(CO)_5$, $Co_2(CO)_8$, $Ni(CO)_4$, all of which conform to the 18 electron formalism, one would have predicted the existence of $Cu_2(CO)_6$ as the next member of the series. However, binary carbonylcopper complexes long sought after by conventional methods of chemical synthesis[43] have so far remained elusive, their instability being a reflection of the presence of a very stable filled 3d valence shell, a situation not conducive to $d\pi$-π^* back bonding.

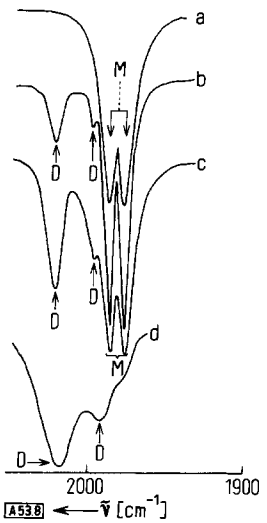


Fig. 8. IR spectra of the products of the matrix cocondensation reaction of copper vapor with pure CO. a) Cu:CO≃1:10^5, b) Cu:CO≃1:10^4, c) Cu:CO≃1:10^3 and d) Cu:CO≃1:10^2. The spectra show the gradual progression from $Cu(CO)_3$ (M) to $Cu_2(CO)_6$ (D) formed from the matrix reactions of CO with Cu atoms.

The infrared spectrum of the product of the reaction of Cu atoms with pure CO at Cu:CO concentrations in the range 1:10^5 (Fig. 8a) shows a doublet at 1990, 1977 cm^{-1}[23]. The $^{12}C^{16}O/^{13}C^{16}O$ mixed isotope experiments define the product as a tricarbonyl complex (M). At the low Cu concentrations used, the product is best assigned to $Cu(CO)_3$. (This formulation is confirmed by mixed metal studies.)

By retaining the CO flow constant and studying the spectrum as a function of the rate of Cu atom deposition, two new CO lines (D) at higher frequencies than those of $Cu(CO)_3$ are seen to grow in as the Cu concentration increases (Figure 8b—8d). A proportional increase in the absorbance ratio D/M is observed with increasing Cu concentrations. At Cu:CO concentrations of 1:100, $Cu(CO)_3$ is not observed, the only detectable product being the new carbonyl species. In addition, the new carbonylcopper species (D) grows in when CO/Ar matrices containing only $Cu(CO)_3$ are allowed to warm up to 40—45 °K (at which temperature the Ar matrix is slowly boiling off).

The infrared spectra, the Cu concentration dependence, and the formation of the new copper carbonyl species on allowing $Cu(CO)_3$ to diffuse, suggest a dimerization process with the formation of a binuclear $Cu_2(CO)_6$ complex having a structure containing a copper-copper bond[23a].

The results in dilute CO/Ar (1/100) matrices also present an intriguing problem, showing in addition to small concentrations of $Cu(CO)_3$, *two* new species absorbing at 2010 and 1890 cm^{-1}. Mixed $^{12}C^{16}O/^{13}C^{16}O$ isotope experiments prove these to be a mono and dicarbonyl respectively (Fig. 9). By studying the absorbance of these compounds as a function of Cu concentration, retaining the CO/Ar concentration constant (but with the ligand in excess for reasons delineated earlier), one discovers that the absorbance ratio $A_{Cu(CO)_3}$: $A_{Cu_X(CO)_2}$: $A_{Cu_Y(CO)}$ remains constant over a 300-fold change in Cu concentration, proving the new complexes to be mononuclear with respect to copper, namely, $Cu(CO)_2$ and Cu(CO).

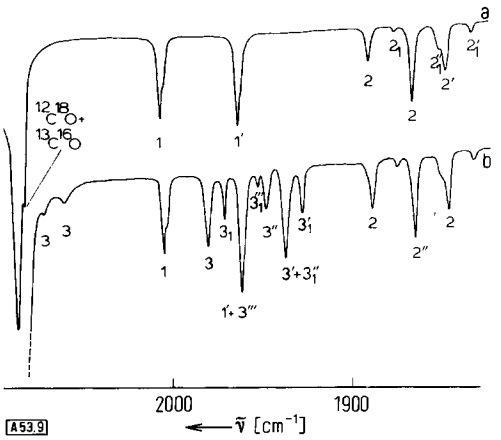

Fig. 9. IR spectra of the products of the matrix cocondensation reaction of copper atoms with a) $^{12}C^{16}O:^{13}C^{16}O:Ar \simeq 1:1:100$ after deposition at 6—10 °K showing the presence of $Cu(^{12}C^{16}O)$, (1); $Cu(^{13}C^{16}O)$, (1'); $Cu(^{12}C^{16}O)_2$, (2); $Cu(^{13}C^{16}O)_2$, (2'); $Cu(^{12}C^{16}O)(^{13}C^{16}O)$, (2'') (where 2_1, $2'_1$ and $2''_1$ represent a matrix splitting of the respective isotopic dicarbonyl complexes $Cu(^{12}C^{16}O)_n(^{13}C^{16}O)_{2-n}$); b) after warm-up to 30 °K, showing the growth of the CO stretching modes of the isotopic tricarbonyls $Cu(^{12}C^{16}O)_n(^{13}C^{16}O)_{3-n}$ (where $n=0$—3) ($3/3_1$ notation refers to a matrix splitting of the tricarbonyl complex).

7.6. Mixed Isotopic Substitution

It is well established that mixed isotopic substitution experiments provide a useful method for determining the stoichiometry and structure of a matrix isolated species. Two distinct situations can be considered. On the one hand one can co-condense an isotopically *pure* metal atom with a *mixture* of isotopic ligands such as $^nX_2/^mX_2$; alternatively one can co-condense a *mixture* of metal atom isotopes $^pM/^qM$ with a *pure* ligand. Barring an isotope effect in the kinetics of formation, the product distribution can be expected to be statistical and an analysis of the number, frequencies and infrared and Raman intensities of the isotopic components can, in principle, determine the product stoichiometry with respect to both ligand and metal, the molecular structure of the product, the vibrational assignments and force fields. Studies of this type are fundamental to almost any matrix isolation experiment.

An outline will now be given of how this method has been applied in determining the binuclear complexes formed in matrix co-condensation reactions. When manganese atoms are co-condensed with $^{12}C^{16}O:Ar = 1:250$, using Mn deposition rates which favor the formation of Mn_2 (Fig. 10a), two prominent low frequency CO absorptions are observed at 1835.4 and 1688.2/1680.0 cm^{-1}[19] (the latter was shown to

be a matrix site splitting), together with a high frequency weak absorption at 1964.4 cm^{-1}. Using an isotopic mixture $^{12}C^{16}O : {}^{13}C^{16}O : Ar \simeq 1 : 1 : 500$, the matrix infrared spectrum shown in Fig. 10b was obtained in which a characteristic isotope pattern of a symmetrical dicarbonyl and a low and high frequency monocarbonyl are easily discernible (Table 4). Matrix warm-up experiments at about 25—30 °K showed the dicarbonyl to grow at the expense of the low frequency monocarbonyl.

$Mn_2(CO_t)$: $f_r = 15.58$

[b] Matrix splitting.

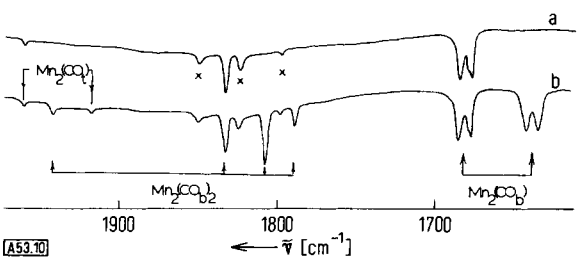

Fig. 10. IR spectra of the products of the matrix co-condensation reaction of Mn atoms with a) $^{12}C^{16}O : Ar \simeq 1 : 250$; b) $^{12}C^{16}O : {}^{13}C^{16}O : Ar \simeq 1 : 1 : 500$ at 6—10 °K at $Mn : CO \simeq 1 : 1000$ (x refers to Mn trace impurities).

On the basis of the frequencies of the observed carbonyl stretching modes when compared to $Mn_2(CO)_{10}$ or $Mn(CO)_5$, together with the prior knowledge that Mn_2 should constitute a major proportion of the reacting metal species in the matrix under the experimental conditions used, the low frequency CO stretching modes are best assigned to a binuclear bridged monocarbonyl species *(10)* and a binuclear bis-carbonyl bridged species *(11)*. Whether or not a Mn—Mn bond should be included in a description of their bonding will be elucidated using ESR experiments. The monocarbonyl absorbing at high CO stretching frequencies is assigned to the binuclear species *(12)* by analogy with $Cr_2(CO_t)$ described earlier.

7.7. Co-deposition of Two Different Metals

If the product of a matrix co-condensation reaction is suspected to contain more than a single metal atom then, in principle, simultaneous deposition of *two* different metals (chosen usually from the same group in order to maintain similar chemical properties and to avoid major structural changes in the trapped product) with the reacting gas can verify the molecular composition and aid the vibrational assignments.

This technique is particularly useful for monoisotopic metals or when isotopes of the metal are *not* readily accessible. Few examples using mixed metals can be referred to in the literature other than *Andrews'* studies of alkali metal peroxides[44] Na_2O_2, K_2O_2, Rb_2O_2 and Cs_2O_2 formed by secondary reactions of the alkali metal atom M with the respective superoxide MO_2 in the matrix.

Brewer used metal co-deposition studies (for example, Pb/Ag, Cu/Ag, Cu/Au, Ag/Au) in order to investigate the origin of the multiplet splitting in the electronic spectra of Pb, Cu, Ag and Au atoms in inert matrices[10, 11]. He discovered that even at one atom percent of metal, the atomic spectra remained essentially unperturbed, indicating that the fine structure was not due to nearest neighbor M—M interactions but, rather, site symmetry lattice perturbations. However, detailed investigations of the electronic spectra of the diatomic species present in these mixed metal experiments were not feasible, presumably because of the low absorption intensities associated with the diatomic molecules. In the infrared the situation is quite different, as dimeric carbonyl reaction products usually have high extinction coefficients and are easily observed and in principle the mixed metal experiment is an ideal way by which one can ascertain the stoichiometry of the products with respect to the metal. For example, when Cu and Ag atoms were simultaneously co-condensed with pure CO[23a] the spectrum obtained was essentially a superposition of the spectra of the respective Cu/CO and Ag/CO reaction products, consistent with our earlier conclusions of a mononuclear formulation, namely, $Cu(CO)_3$ and $Ag(CO)_3$[23, 45].

8. Conclusion

The information presented in this paper demonstrates that the diffusion properties of metal atoms may be probed and their aggregation processes, at least to dimeric molecules, controlled by utilizing matrix isolation techniques. The chemistry of the transition metal diatomic molecules, their spectroscopy and the characterization of the reaction products should prove very fruitful indeed in providing a large number of new molecules and in helping to understand the chemical nature of diatomic molecules. Moreover, the possibility exists for tailor-making new polynuclear molecules with features of interest to those interested in compounds containing metal-

metal bonds, the reactivity and selectivity of transition metal based catalysts or the relationship of the binuclear complex M_2L_n to L chemisorbed on bulk metal M. Finally, a great deal of knowledge concerning the energetics of metal formation might be obtained by carefully studying metal atom aggregation processes using matrix isolation infrared, laser Raman, UV-visible and ESR spectroscopy.

We would like to thank Mr. H. Huber, Mr. J. Hulse, Miss L. Hanlan and Mr. D. McIntosh for invaluable technical assistance and for many stimulating discussions. We also gratefully acknowledge the financial assistance of the Research Corporation and the National Research Council of Canada.

Photochemistry in Matrices and Its Relevance to Atom Synthesis[**]

By James J. Turner[*]

1. Introduction

In the matrix isolation technique, developed largely by *Pimentel*[1] the object is to isolate a reactive species in a large excess of an inert rigid matrix, usually at very low temperatures. The species can then be spectroscopically examined at leisure.

Several techniques have been used, mostly vibrational, electronic, and ESR spectroscopy, but also including Mössbauer, and magnetic circular dichroism. There is always the assumption that the appropriate spectroscopic energy levels of a trapped species are only slightly perturbed by the matrix environment. Comparison of gas-phase and matrix-isolated vibrational spectra of *stable* molecules suggests that the assumption is reasonably valid and hence that structures of *unstable* species deduced from matrix vibrational data are unlikely to be grossly misleading.

Reactive species may be trapped in matrices by a variety of techniques, summarized below:

1) *In situ photolysis of a stable parent, e.g.*

$$OF_2/Ar \xrightarrow{h\nu} OF + F$$

The parent gas mixture, OF_2 diluted in argon, is deposited on a cold window (4K) and then irradiated with UV light[2].

2) *Deposition from the gas phase, e.g.*

$$Xe + Cl_2 \xrightarrow[\text{discharge}]{\text{electric}} XeCl_2 \text{ in Xe}$$

The gas leaving the discharge is condensed on a window at 20K and the $XeCl_2$ identified by both infrared[3] and Raman[4] spectra.

$$BH_3CO/Ar \xrightarrow{\Delta} BH_3$$

The carbon monoxide-borane in argon passes through a hot tube and a very carefully designed nozzle. The detection of BH_3 by thermal decomposition is something of a triumph[5] in view of the number of attempts to isolate the species.

$$SiO_2/Ar \xrightarrow{\Delta} SiO, Si_2O_2, Si_3O_3$$

The silicon-oxygen species effusing from a Knudsen cell are co-condensed with a large excess of inert gas[6].

Atom synthesis, e.g.

$$Li + NO/Ar \longrightarrow LiON$$

$$Ni + (N_2)/Ar \longrightarrow Ni(N_2)_x \quad (x = 1\text{-}4)$$

$$Li + OF_2/Ar \longrightarrow \text{'LiF'} + OF$$

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12—15, 1974).

The first mentioned reaction was the first matrix synthesis using metal atoms[7]. As is evident from this symposium program, there have been major strides since then. The second example also involves direct addition[8], whereas the third is an "abstraction" reaction[9] and it is noteworthy that the infrared spectrum of the OF radical confirms the original photochemical generation by *Arkell et al.*[2].

However, this paper is concerned with *photochemical* generation of unstable species in a matrix and particularly the relevance to atom synthesis.

2. Photochemical Generation of Unstable Species

The major problem with matrix photochemistry is the "cage effect". The matrix atoms surrounding an isolated species are in general impermeable to all species except the smallest atoms such as C, N, O, and F. Photochemistry will therefore only lead to isolation if one or both of the following conditions is met:

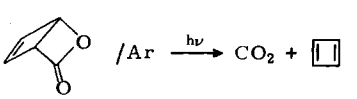
1) the species produced are stable with respect to recombination, in which case it will not matter if the photochemically generated fragments are adjacent;

2) one of the photochemically generated products can escape from the cage.

The following brief sections illustrate the principle ways in which matrix photochemistry can be promoted.

2.1. Photochemical Fission

Two examples will serve to illustrate this technique:



$$OF_2/Ar \xrightarrow{h\nu} OF + F \xrightarrow{\Delta} OF_2 + [O_2F_2]$$

The first of them shows the generation of the long-sought cyclobutadiene[10]; although neither CO_2 nor cyclobutadiene escape from the cage, the two species are stable with respect to the reverse reaction.

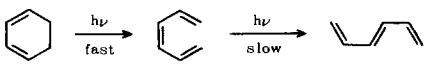
In the second example, already mentioned briefly in Section 1, gas phase[11] studies indicate that F and OF will combine with almost zero activation energy; hence they are not stable when adjacent in the matrix. Although gaseous OF_2 can be photodissociated up to 580 nm, *Arkell et al.*[2] showed that no OF was observed in the matrix unless $\lambda < 365$ nm. Thus the F atom needs a thermal "kick" to eject it from the surrounding argon cage. Softening of the argon matrix by warming allows F and OF to diffuse and they recombine; there is also some production of O_2F_2 due to OF/OF combination.

Two examples where the cage prevents isolation involve diazomethane (CH_2N_2) and chromyl chloride (CrO_2Cl_2). Contrary to expectations based on gas phase studies, photolysis of these in matrices shows no production of CH_2 and CrO_2Cl, respectively. The CH_2 and N_2 recombine, as can

be shown by photolysis in a $^{15}N_2$ matrix[12]; presumably also CrO_2Cl and Cl recombine[13]. The cage effect can however be turned to advantage. For example, vacuum UV photolysis of $CHCl_3$ in argon leads to the isolation of CCl_3[14]; presumably the photochemically produced H atoms readily diffuse away, whereas any Cl atoms produced cannot escape.

2.2. Photoisomerization

There is little reported evidence for this in matrices, but it is clear that conclusions must be treated with considerable caution. For example, in solid argon, the reaction



differs from the photochemical behavior in solution[15].

2.3. Bimolecular Reactions

These can be conveniently divided into two categories—"reactive matrix" and "tunneling". In the first category the matrix technique is inverted in the sense that a matrix is chosen because of its reactivity rather than inertness. It is often not convenient or possible to use a pure reactive matrix but a ratio of reactive to inactive matrix of about 5:100 to 10:100 is usually enough to ensure that photochemically generated fragments are in direct contact with the reactive matrix. Two examples will illustrate this technique[16, 17]:

$$HI + CO \xrightarrow{h\nu} HCO + I$$

$$Ni(CO)_4 + N_2 \xrightarrow{h\nu} Ni(CO)_3N_2 + CO$$

The term "tunneling" simply means that at least one of the photochemically generated species has to travel through the matrix to react with the substrate. For example:

$$F_2 + O_2/Ar \xrightarrow{h\nu} \underset{\text{(very dilute)}}{2\,F + O_2} \longrightarrow O_2F + F$$

where the F atom travels through the argon till it encounters an O_2 molecule[18].

2.4. Electron Transfer

Kasai et al.[19] was the first to use this technique, in the generation of the radical anion $B_2H_6^-$:

$$B_2H_6 + Na/Ar \xrightarrow{h\nu} B_2H_6^- + Na^+$$

The loss of Na and production of $B_2H_6^-$ was followed by ESR spectroscopy. It should be noted that this is a concerted process since the light used is of much lower energy than that required for the ionization of sodium. Ions can also be generated by vacuum UV photolysis[20, 21] or electron bombardment of the condensing parent molecule[22].

$$C_2H_2/Ar \xrightarrow[UV]{\text{Vacuum-}} C_2^-$$

$$Ni(CO)_4/Ar \xrightarrow[UV]{\text{Vacuum-}} Ni(CO)_3^-$$

$$Cr(CO)_6/Ar \xrightarrow[e^{\ominus}]{\substack{+Na,\ h\nu(vis) \\ \text{Vacuum-UV}}} Cr(CO)_5^-$$

3. Relevance of Photochemistry to Atom Synthesis

Two examples will serve to illustrate some of the difficulties. Some years ago *Andrews* and *Pimentel*[23] obtained IR evidence for CH_3 by co-condensing Li atoms with CH_3I/Ar. However, the spectrum of CH_3 obtained on vacuum UV photolysis of CH_4/Ar was different[24]. It was subsequently shown that *Pimentel et al.* had in fact stabilized $CH_3 \cdots LiX$ rather than CH_3 itself[25].

Rest and *Turner*[26] described the generation of $Ni(CO)_3$ by photolysis of $Ni(CO)_4$ in various matrices and assigned the two CO stretching vibrations to a pyramidal (C_{3v}) fragment. *DeKock*[27] synthesized all the species $Ni(CO)_x$ ($x = 1$—4) by co-condensation of nickel atoms with CO; however, the IR spectrum of the $Ni(CO)_3$ showed only one band. It has subsequently been shown[28] that the weaker of the two bands in *Rest* and *Turner*'s spectrum was due to dimeric species whose formation is attributed to use of $Ni(CO)_4$ at too high a concentration in the inert matrix gas.

Thus considerable care is needed in the detailed interpretation of results obtained by either technique. However, generally each has its own advantages and disadvantages as considered below.

Isolation

A major problem of atom synthesis is that it is very difficult to ensure that the species formed contain only one metal atom—diffusion on the cold surface can lead to the formation of fairly high polymers[29]. Provided high dilution is used, photochemical generation eliminates this problem. However, it has been shown[30] that even at dilutions as high as 1:20000 there is some evidence for the photolytic production of dimers.

UV/Visible Spectroscopy

Matrices produced by atom condensation are often highly scattering and even if not so, frequently contain excess metal atoms. In either case it is extremely difficult to obtain UV/visible spectra of trapped species. In contrast, such spectra are generally easily obtained for photochemically generated fragments. It is also worth mentioning that the photochemical generation of species is of considerable relevance to the study of intermediates in solution chemistry.

Stable Starting Compound

Clearly the generation of a reactive species by photochemical methods requires a starting compound that is moderately stable and easily handled. The atom technique suffers no such restriction.

Cage Effect

This has been considered above but it is worth emphasizing that it will be unusual for large fragments to sit adjacent

to each other without reacting back to starting material. For example it is well known[31] that $Fe_2(CO)_9$ acts as a source of $Fe(CO)_4$, but photolysis of $Fe_2(CO)_9$ in low temperature matrices[32] leads only to the formation of $Fe_2(CO)_8$ (bridged and unbridged). In atom synthesis, the cage effect is of little relevance, since the initial formation of reactive species occurs at the cooling but instantaneously fluid surface. Subsequent controlled annealing will of course permit diffusion of smaller species at a lower temperature than that for larger species.

Structure

Hints have already been given that the matrix can have some effect on the behavior of trapped species. A fundamental question therefore is whether species generated photochemically in a matrix will have a geometrical structure radically different from that expected in say the vapor phase. After all, photolysis of a large molecule may lead to fragmentation in such a way that the fragments are held in a vice-like grip by the matrix and cannot relax to their preferred equilibrium geometry. There is however no evidence that species generated photochemically in a matrix have a structure different from that generated by atom synthesis. In the following Sections we shall consider, in detail, some specific examples.

4. OF, $Ni(CO)_3$, and $Co(CO)_4$

We have already considered OF and $Ni(CO)_3$, where the photochemical and atom techniques, with suitable allowance for mistakes (!), give the same answer. *Crichton et al.*[33] have generated $Co(CO)_4$ by photolysis of $Co(CO)_3NO$ in a CO matrix and analyzed the ^{13}CO isotopic spectra, concluding that the complex, has C_{3v} symmetry. *Ozin et al.*[34] have generated the species by co-condensation of Co atoms and CO and have assigned the Raman spectra to a D_{2d} structure. Figure 1 compares the IR and Raman spectra from which it is clear that the basic frequencies are the same.

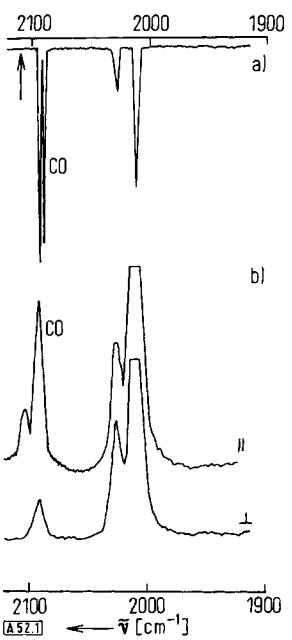


Fig. 1. a) IR spectrum of $Co(CO)_4$ obtained by photolysis of $Co(CO)_3NO$ in a CO matrix [33]; the arrow ↑ indicates position of the very weak A_1 band calculated for C_{3v} symmetry. b) Polarized Raman spectrum of $Co(CO)_4$ from co-condensation of Co atoms and CO [34].

Hence the molecule is clearly distorted from T_d; whether it is C_{3v} or D_{2d} is something of a minor point.

5. Photochemical Fragmentation of Hexacarbonyls of Cr, Mo, W

In 1962 *Sheline et al.*[35] photolyzed the hexacarbonyl compounds $M(CO)_6$, M = Cr, Mo, W in hydrocarbon glasses at 77 K and obtained preliminary infrared evidence for the formation of the pentacarbonyls with C_{4v} symmetry. We have since then performed an extensive study of these carbonyls and several others in inert gas matrices at low temperature.

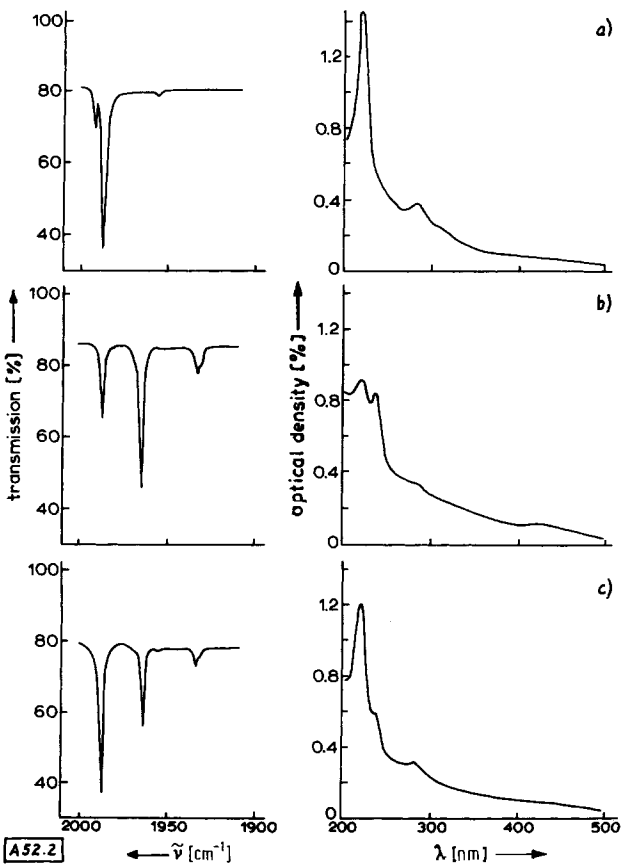

Fig. 2. IR (left) and UV/visible spectra (right) of $W(CO)_6$ in argon: a) after pulsing on to a KBr window at 20 K; b) after 30 s photolysis through a quartz window with an unfiltered medium pressure mercury arc; c) after 1.5 min irradiation through a soda glass filter ($\lambda > 330$ nm) [36].

Figure 2 shows one of our early experiments[36]. It is clear from this that UV photolysis generates a lower carbonyl fragment, which interestingly can be converted back to $W(CO)_6$ by irradiation in the visible. In fact, using a monochromator[37] with the Hg arc it can be shown that irradiation in either of the UV bands of $W(CO)_6$ produces $W(CO)_5$ and irradiation in either the UV or visible band of $W(CO)_5$ converts it back to $W(CO)_6$:

$$W(CO)_6/Ar \underset{h\nu'}{\overset{h\nu}{\rightleftharpoons}} W(CO)_5 + CO$$

The mechanism of this photoreaction has been discussed elsewhere[37].

That the primary photochemical product is $M(CO)_5$ with a C_{4v} structure is demonstrated in Figure 3, from which it will be seen that whereas a C_{4v} structure fits both the frequen-

cies and intensities of the isotopic data, a D_{3h} structure cannot be made to fit[38].

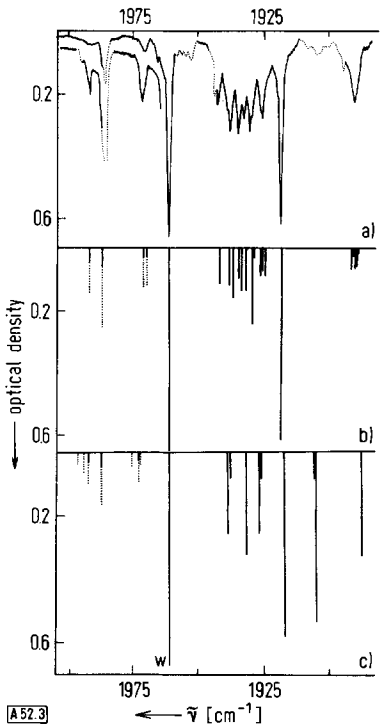

Fig. 3. a) IR spectrum of ^{13}CO-enriched $Cr(CO)_5$ in CH_4 at 20 K; b) calculated spectrum of $Cr(CO)_5$ with C_{4v} symmetry; c) calculated spectrum for D_{3h} symmetry (see ref. [38]).

It has been suggested that the photolysis simply produces an isocarbonyl:

$$M(CO)_6/Ar \xrightarrow{h\nu} (OC)_5MOC$$

This is certainly not the case for the following reasons:

1) No band assignable to an isocarbonyl structure is seen, whereas photolysis leads to production of molecular CO, with frequency virtually identical to that of matrix-isolated CO in argon.

2) Photolysis in a matrix doped with ^{13}CO leads to exchange and generation of $M(^{12}CO)_x(^{13}CO)_{6-x}$ and $M(^{12}CO)_y(^{13}CO)_{5-y}$.

3) The visible absorption of $Cr(CO)_5$ is extremely sensitive to the matrix[39]; corresponding bands appear at 480 nm in xenon and 624 nm in neon. On the other hand the visible band of $Cr(CO)_5NH_3$ is virtually unchanged from matrix to matrix[39]. Thus the inescapable conclusion is that the matrix species blocks the coordination site[*]. It is worth commenting that the sensitivity of $Cr(CO)_5$ to matrix is of considerable relevance to solution photochemistry, suggesting that in a hydrocarbon solvent $Cr(CO)_5$ forms a weak complex with the solvent[30].

Prolonged UV photolysis of $M(CO)_6$ in a matrix effects extensive fragmentation[40] (Fig. 4).

Labels on the bands indicate those that grow and decay together. It is a reasonable assumption that the lower carbonyls will be generated successively.

[*] $Cr(CO)_5$ can also be generated in a CO matrix, in which case an isocarbonyl may be formed but there is still no sign of an isocarbonyl infrared band [39].

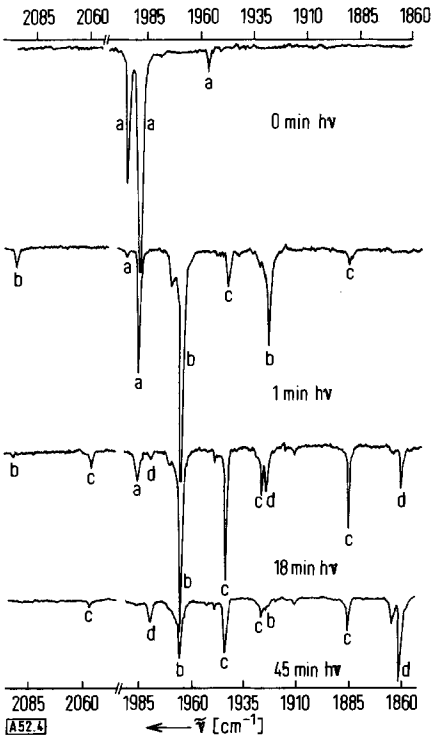

Fig. 4. IR spectra carbonylmolybdenum fragments produced by prolonged photolysis of $Mo(CO)_6$ in a methane matrix; a = $Mo(CO)_6$, b = $Mo(CO)_5$, c = $Mo(CO)_4$, d = $Mo(CO)_3$ (see ref. [40]).

$$Mo(CO)_6 \xrightarrow{h\nu} Mo(CO)_5 \xrightarrow{h\nu} Mo(CO)_4 \quad \text{etc.}$$

The bands are assigned on this basis. Assuming a CO-factored force field, detailed isotopic studies show that the structure of these species are as shown in Figure 5.

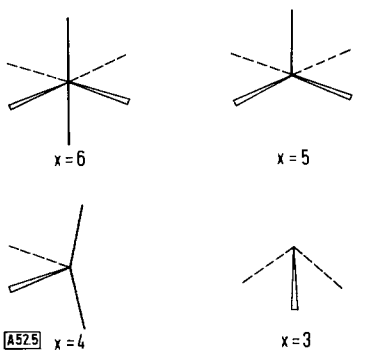

Fig. 5. Schematic structures of $Mo(CO)_x$ fragments deduced from detailed ^{13}CO isotopic studies.

It might be argued that these structures are forced on the fragments by the particular matrix environment (see above). However, polarization[41] studies demonstrate that the fragments can rotate when irradiated. In particular, the $Cr(CO)_5$ C_{4v} fragment changes orientation, probably *via* a D_{3h} intermediate. It is unlikely, therefore, that the matrix acts as a "clamp". Moreover, recent calculations by *Burdett*[42] on carbonyl fragments match remarkably well with those observed experimentally. Perhaps the most convincing argument however is that, although much broader, spectra obtained on M/CO/Ar co-condensation[40] reactions match those of the photolysis products. It is interesting to note that synthesis adds successive CO units to M whereas photolysis removes successive CO units from $M(CO)_6$.

6. Photochemical Synthesis

The fact that photolysis at one frequency removes CO and at another frequency puts it back suggests that it should be possible to substitute CO by another ligand in either a one-step or a two-step process. In practice this is relatively easy to do with small ligands. For example[17]:

$$Ni(CO)_4 + N_2 \xrightarrow{h\nu} Ni(CO)_3N_2 + CO$$

The observed IR frequencies correspond closely to those obtained on co-condensation of $Ni/CO/N_2$[43].

$$Cr(CO)_6 + N_2 \longrightarrow Cr(CO)_5N_2,\ Cr(CO)_4N_2 \quad [40,44]$$

$$\left.\begin{aligned} Fe(CO)_5 + N_2 &\xrightarrow{h\nu} Fe(CO)_4N_2 \\ + Xe &\xrightarrow{h\nu} Fe(CO)_4Xe \\ + CH_4 &\xrightarrow{h\nu} Fe(CO)_4CH_4 \end{aligned}\right\} [45]$$

In the latter two examples there is firm spectroscopic evidence that both "naked" and "complexed" $Fe(CO)_4$ are obtained. The photochemical pattern can be summarized thus[45]:

$$Fe(CO)_5 \underset{\lambda > 320\ nm}{\overset{UV}{\rightleftharpoons}} Fe(CO)_4 + CO \underset{\lambda > 320\ nm}{\overset{UV}{\rightleftharpoons}} Fe(CO)_3 + 2\ CO$$

$$Fe(CO)_4 \underset{\lambda > 375\ nm}{\overset{+Xe,\ \lambda > 320\ nm}{\rightleftharpoons}} Fe(CO)_4Xe$$

In conclusion, therefore, we suggest that photochemical techniques in matrices are of considerable relevance to matrix atom synthesis and that both methods still have a big future.

I should like to acknowledge many hours of discussion with my colleagues and their permission to quote unpublished work in this report.

Spectral Evidence for Lanthanoid and Actinoid Carbonyl Compounds[**]

By Raymond K. Sheline and James L. Slater[*]

The co-condensation of actinoid or lanthanoid atoms and a mixture of argon containing small amounts carbon monoxide on a surface cooled with liquid helium leads, after annealing of the argon matrix, to a series of new binary actinoid and lanthanoid carbonyl compounds. Evidence for these new carbonyls is obtained using infrared spectroscopy. Preliminary interpretation of the IR spectra suggests that at least six complexes, $M(CO)_{1-6}$, have been observed for each metal. A distinct difference in the infrared spectra is observed for the ytterbium derivative, probably associated with the fact that ytterbium lacks one electron from having entirely filled 4f orbitals. A brief description of the possible bond hybridization and its effect on the M—C—O bonding, which may explain the difference between ytterbium and the other lanthanoids, is presented.

1. Introduction

Recently, a large number of new binary "metal carbonyls" have been synthesized using two rather different experimental techniques, both of which employ matrix isolation of relatively unstable species.

In the first of these procedures, a stable binary metal carbonyl compound is incorporated in a matrix. Subsequent photolysis results in the expulsion of one or more molecules of CO and the production of a number of less substituted metal carbonyls whose presence is detected using infrared spectroscopy. Initially, our research group[1] prepared a series of pentacarbonyl derivatives $M(CO)_5$ (where M = Cr, Mo, and W) by the photolysis of the appropriate hexacarbonyl compounds in rigid hydrocarbon matrices at temperatures of *ca.* 77 °K. An extensive series of experiments carried out by *Turner et al.*[2] led to the observation of a large number of lower metal carbonyls and their derivatives. In particular, they have observed $M(CO)_{2-5}$ (where M = Cr, Mo, and W). Other starting compounds photolyzed by this group included $Ni(CO)_4$[3], $HMn(CO)_5$[4], and $Fe_2(CO)_9$[5].

In the second technique involving matrix isolation, metal atoms and argon containing small amounts of CO are condensed on a liquid helium cooled surface followed by controlled annealing of the resulting argon matrix. Once again, the compounds formed can be identified spectroscopically. In the first of these studies *DeKock*[6] prepared $Ni(CO)_{1-4}$ and tentatively identified $Ta(CO)_{1-6}$. Using the same apparatus as *DeKock*, *Slater* of our laboratory[7] succeeded in preparing $U(CO)_{1-6}$. Since that time, large numbers of metal carbonyls have been prepared using the co-condensation technique. These include $Cu(CO)_x$[8], $Ag(CO)_x$[8], $Pd(CO)_4$[9], $Pt(CO)_4$[10], $Al_x(CO)_2$[11], $Ge(CO)_x$[12] and $Sn(CO)_x$[12]. Indeed, it seems to be a safe assumption that the co-condensation technique can be used to prepare binary carbonyl compounds of most (and probably all) metals.

This paper represents a status report on the binary carbonyls of the actinoids and lanthanoids[7, 13, 14].

The preparation of uranium carbonyl has historical interest. Volatile uranium compounds were required by the Manhattan Project for the separation of the isotopes ^{235}U and ^{238}U by gas-phase diffusion. It was thought that uranium carbonyl might be particularly suitable since metal carbonyls are generally volatile and would be far less corrosive than the volatile uranium hexafluoride. Most, if not all, of the tested methods for preparing metal carbonyls were tried. These standard methods involve the reaction of uranium metal, hydride, or halide with carbon monoxide and a reducing agent. The reaction conditions were varied but most were carried out at high temperatures in pressurized bombs. No uranium carbonyl was synthesized[15].

2. New Experimental Findings

The route which finally led to the fulfillment of our aim—namely the preparation of binary uranium carbonyls—will be described in some detail, for it is exemplary for the synthesis of other actinoids as well as lanthanoids. The main contribution to the success was an apparatus designed and built by *Weltner*[16] (Fig. 1).

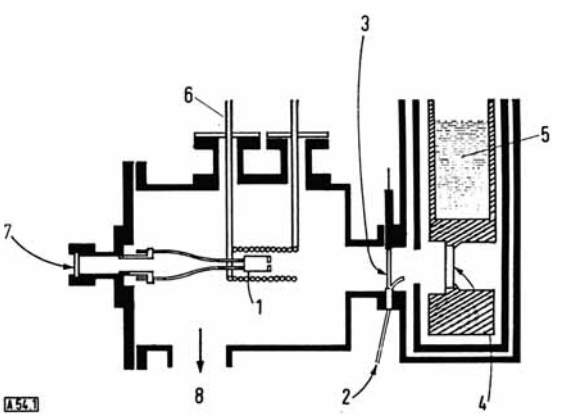

Fig. 1. Apparatus for the preparation of actinoid and lanthanoid carbonyls by matrix isolation [16]. 1: Sample cell for metal evaporation; 2: gas inlet; 3: movable shutter; 4: cooled window; 5: liquid helium; 6: induction heater; 7: window for temperature measurement; 8: high vacuum.

The powdered uranium metal, with a purity of 99.8%, was packed in a sample cell and placed in the induction heater under high vacuum. The sample cells were made of

[**] Based on a lecture delivered at the Symposium "Metall-Atome in der chemischen Synthese" of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. Darmstadt, Germany (12—15 May 1974). This work supported in part by the U.S. Atomic Energy Commission (Contract No. AT-(40-1)-2434).

either tantalum or tungsten and were baked at high temperature prior to deposition of the matrix. A temperature of about 1950 °K was used for the vaporization of the uranium so that the vapor pressure of the metal was about 10^{-5} torr. This insured that only monoatomic species were present in the vapor. All trapping was done at liquid helium temperature. The metal atoms and the argon-CO mixture were allowed to condense onto the cold CsI window for 30 to 50 min. After the matrix has been deposited on the CsI window, the entire system (Dewar window and copper block) was rotated 90° allowing infrared spectra to be taken without interfering with the furnace. It is possible to control the temperature on the window by varying the flow of liquid helium to the copper block.

At 4 °K the argon forms a rigid matrix. At 16 °K the matrix loses its rigidity and the CO molecules begin to diffuse through the solid argon matrix. The diffusion was controlled by careful "annealing" of the matrix. As soon as the temperature had reached the desired level, the matrix was immediately quenched to 4 °K by opening the valve that controls the helium flow to the copper block. Infrared spectra were taken at 4 °K after annealing and the matrix was allowed to warm to higher temperatures on each successive anneal.

The basis of the matrix isolation technique is that high dilution ratios exist between the lattice and the trapped atoms or molecules, so that there are no interactions between the reactive species within the rigid lattice. It is assumed that activation energies are low enough so that the rate of formation of the metal carbonyls will be controlled by diffusion processes within the matrix.

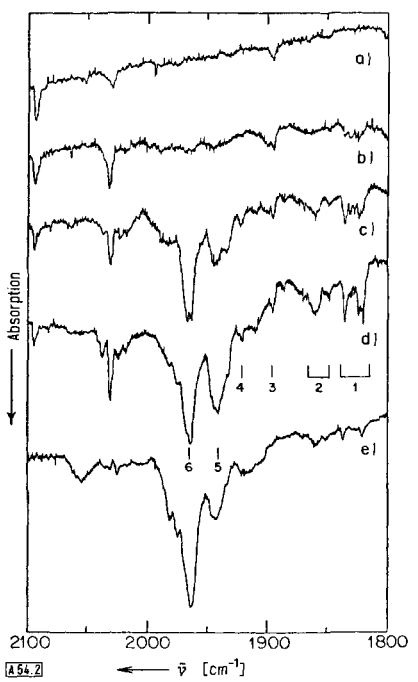

Fig. 2. IR spectra of an Ar-CO matrix (300:1) containing uranium atoms: a) no annealing; b) 17 °K; c) 19 °K; d) 20 °K; e) 30 °K. The arabic numerals refer to the tentative assignment of intermediate carbonyls—*n* in $U(CO)_n$.

Figure 2 shows the infrared spectra in the 1800—2100 cm^{-1} range taken at various stages in the annealing process with a matrix prepared with a 300:1 dilution ratio of carbon monoxide in argon and uranium atoms. The strong ^{12}CO band is present at 2138 cm^{-1} in all spectra but is not shown in the figure. Spectrum a shows the matrix prior to an annealing. The carbon-oxygen stretching frequencies at 2092 cm^{-1} (for natural abundance ^{13}CO) and three very weak bands at 2029, 1893, and 1800 cm^{-1} are found in the spectrum. In spectra b and c, a large number of IR bands are growing into the spectrum as a result of annealing. Spectra d and e, following annealing to higher temperature, show the dominance of higher frequency bands at 1961, 1938 and the broad band around 1920 cm^{-1}.

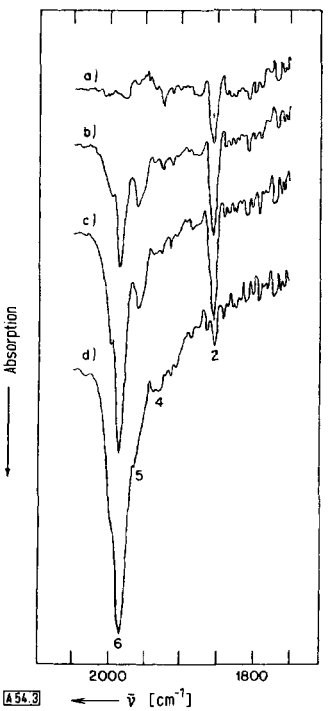

Fig. 3. IR spectra of $Pr(CO)_n$ in an argon matrix with 2 mol-% CO: a) before annealing; b)—d) after various stages of annealing. Cf. Table 1.

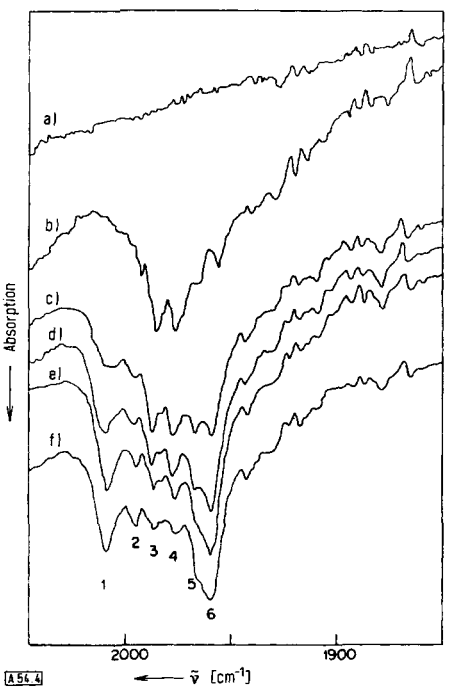

Fig. 4. IR spectra of $Yb(CO)_n$ in an argon matrix with 1 mol-% CO: a) no annealing; b) 32 °K; c) 36 °K; d) 39 °K (2 min); e) 39 °K (35 min); f) 39 °K (80 min). Cf. Table 2.

Similar sets of infrared spectra are available at a variety of controlled annealing stages for argon-carbon monoxide matrices containing a lanthanoid (Pr, Nd, Gd, Ho or Yb) instead of uranium atoms (cf. Figures 3 and 4).

It is immediately obvious that the spectra including the systematic changes resulting from annealing are very similar for uranium, praseodynium, neodymium, gadolinium and holmium carbonyls (Table 1). On the other hand, the spectra of the ytterbium carbonyls differ markedly; the frequencies of their infrared active bands are presented in Table 2. These differences are not unexpected. U, Pr, Nd, Gd and Ho are typical actinoids and lanthanoids in that they have a +3 normal oxidation state. Yb, on the other hand, tends to be more like Sr or Ba in physical properties and has a +2 normal oxidation state[17]. This sudden change in properties results because Yb, which would normally be expected to lack one electron from having filled 4f orbitals, promotes the 5d electron to achieve this more stable filled 4f configuration.

Yb	1958	1966	1976	1986	1995	2008

The difficulties in assigning IR frequencies to specific carbonyl compounds are compounded by the fact that we do not even know which carbonyl species, and in particular which coordinations, are to be expected. The tentative assignment shown in Table 1 is supported by the following findings: firstly, the lowest frequency bands were observed with little or no annealing, in each of the metal-carbonyl systems considered; secondly, these bands grew and disappeared with progressively higher frequencies occurring in a startlingly similar way as annealing to higher and higher temperatures continued; and thirdly, the observed relationship between carbonyl stretching frequency and the tentatively assigned coordination number. This is shown in Fig. 5 where in the upper part of the diagram the carbonyls produced by matrix photolysis of known hexacarbonyl metal complexes are compared with the actinoid and lanthanoid carbonyls of this study; in the lower part the relationship between coordination number and the CO stretching frequency for the tentatively assigned carbonyl derivative is presented. This relationship is quite linear for the lanthanoid carbonyls, and, analogously, for the uranium carbonyls, with a slightly greater slope. The correlation between $Ta(CO)_{1-6}$ and the lanthanoid and actinoid carbonyls is particularly striking.

There are, however, a number of experimental and theoretical problems with these assignments. In the first place, only mononuclear compounds were considered. In view of the

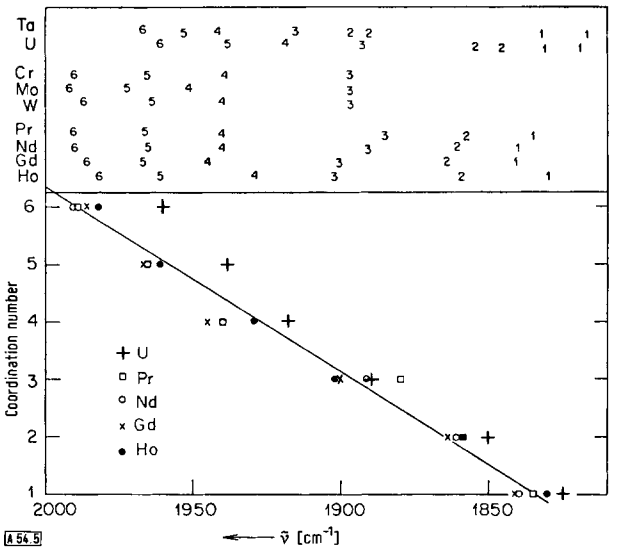

Fig. 5. Relationship between tentative coordination number and CO stretching frequency for metal carbonyl compounds (cf. text).

considerable dilution of the metal and the fact that the lowest frequencies, which were more nearly in the frequency range of bridge-forming CO ligands, formed first, this assumption appears to be borne out by experiment. However, there are a number of weaker bands which appear in the IR spectra of (cf. Figs. 2—4) whose origin is difficult to establish. Most of the coordination numbers tentatively assigned have more than one IR active species. This is shown in Table 3 where the IR activity is presented for a variety of different molecular symmetries of metal carbonyls with coordination numbers from 1 to 8. In order to decide this issue, the molecular configuration as well as the coordination number must be determined. In view of the complexity and quality of the spectra, this is not possible with the present data.

Table 3. Some possible symmetries and the corresponding IR-active C—O stretching modes for $M(CO)_{1-8}$.

Molecule	Symmetry (Geometry)	CO Stretching Mode
M(CO)	$C_{\infty v}$ (linear)	$1\Sigma^+$
$M(CO)_2$	$D_{\infty h}$ (linear)	$1\Sigma_\mu^+$
$M(CO)_2$	C_{2v} (angular)	$1A_1+1B_1$
$M(CO)_3$	D_{3h} (trigonal planar)	$1E'$
$M(CO)_3$	C_{3v} (trigonal pyramidal)	$1A_1+1E$
$M(CO)_4$	T_d (tetrahedral)	$1T_2$
$M(CO)_4$	D_{4h} (tetragonal planar)	$1E_\mu$

$M(CO)_5$	D_{3h} (trigonal bipyramidal)	$1A_2''+1E'$
$M(CO)_5$	C_{4v} (tetragonal pyramidal)	$2A_1+1E$
$M(CO)_6$	O_h (octahedral)	$1T_{1\mu}$
$M(CO)_6$	D_{3h} (trigonal prismatic)	$1A_2''+1E$
$M(CO)_7$	D_{5h} (pentagonal bipyramidal)	$1E_1'+1A_2''$
$M(CO)_7$	C_{2v} (TaF_7^{2-}—structure [a])	$3A_1+1B_1+2B_2$
$M(CO)_8$	C_{2v} (trigonal dodecahedral)	$4A_1+2B_1+2B_2$

[a] Trigonal prism with extra group in one rectangular face.

Another explanation for the "excess" IR bands may be the existence of crystal splitting in the argon matrix (cf. Ref. [6]).

No attempt is made to describe the coordination number or the structure of the ytterbium carbonyls, although it appears that the structures and/or the coordination numbers are quite different from those of the carbonyls of typical lanthanoids or actinoids. It is, however, obvious that a number of mononuclear carbonyl compounds are formed. Indeed, the complexity of the

spectra appears to suggest even more compounds and higher coordination numbers than for the normal f-orbital element carbonyls.

3. Structural Considerations on the Basis of Orbital Hybridization

The considerations of basic identity and possible coordination numbers in the last section are developed from purely experimental reasoning. We are led irrevocably to the existence in each of the spectra of a number of new binary carbonyls with possible coordination numbers from 1 to at least 6. In this section we will attempt to use theoretical arguments for band hybridization of the orbitals of the lanthanoid and actinoid central atom to make some predictions about possible structures.

It should first be noted that the spectra of the normal lanthanoid and actinoid carbonyls (all of these except the ytterbium carbonyls) are remarkably similar. Since the number of f electrons in these species differs, while the spectra indicate the species are the same, we are led to assume that the f electrons, and therefore the f orbitals, do not participate significantly in the bonding. This conclusion is reinforced by the fact that just in those cases where there is a rearrangement of the electrons from the 5d orbital to entirely fill the 4f orbitals in ytterbium, the spectra indicate quite different species. We will operate then with the assumption that the 5d, 6s and 6p, and for uranium the 6d, 7s and 7p, metal orbitals are primarily involved in bonding and in that order in energy. Using these orbitals and assuming that each carbon monoxide molecule brings two electrons to a coordinate covalent bond, it is possible, according to *Kimball*, to predict the structures

[a] Hybridization of the orbitals assuming the f electrons do not participate. The "typical" actinoids and lanthanoids include U, Pr, Nd, Gd, and Ho.
[b] Parentheses indicate that there is a choice of more than one orbital, only one of which may be chosen.

that would arise[18]. The possible structures and coordination numbers from 1 to 8 are presented in Table 4. Assuming that the electron configuration utilized in hybridization for the "typical" lanthanoids and actinoids is $5d^36s^06p^0$ and $6d^37s^07p^0$, respectively, one arrives at the hybridizations and structures shown in column 4 of Table 4 for the appropriate coordination numbers. In a similar way, assuming for ytterbium the electron configuration $5d^26s^06p^0$ for hybridization, one arrives at the hybridizations and structures shown in column 5 of Table 4 for the appropriate coordination numbers.

It is immediately obvious that these simple hybridization considerations imply that the typical lanthanoid and actinoid carbonyls should have coordination numbers from 1 to 7, rather than 1 to 6 as was suggested by the experimental data. In the case of ytterbium, coordinations from 1 to 8 are expected.

We are now left with the difficult task of trying to reconcile experimental and theoretical results. Actually, the difference may be less than we might initially suppose. Indeed, on the high wave number side of each of the strong bands in the region of $\approx 2000\,cm^{-1}$, an additional infrared band is observed which could easily represent the sevenfold coordinated metal carbonyl. Furthermore, a number of additional bands are observed which have not been interpreted. Thus, one possibility is that the theoretical suggestions may ultimately be borne out by a more complete experimental interpretation. On the other hand, the considerably lower symmetry of the sevenfold coordinated system may mean that it is not formed—in spite of the expected additional energy available—when the rare gas structure of electrons is obtained.

Two clarifications do come from the theoretical studies. They point very clearly to a mechanism for explaining the widely different spectra of the typical lanthanoid and actinoid carbonyls on the one hand and those of ytterbium on the other. Not only are the maximum coordination numbers different, but also the structures expected for coordination numbers >3. Furthermore, the π back-bonding between metal atoms and CO tend to be weaker with increasing coordination number (cf. column 6 and 7 of Table 4). This effect is enhanced when the decreased π back-bonding is divided among increasing numbers of bonds. The decreased π back-bonding between metal and CO implies increasing C—O bond order and C—O stretching frequency with increasing coordination number, as first pointed out by *DeKock*. Exactly the same behavior was observed in our experiments (see Table 1).

In view of the presence of at least one odd electron in each of the hybridized carbonyl species of the typical lanthanoids and actinoids, the simple symmetrical structures predicted in Table 4 are not allowed by the Jahn-Teller effect. However, the simplicity of the infrared spectra observed in the case of $V(CO)_6$, and the failure to observe P, Q, and R branches in the gas spectrum[19], implies that there is a dynamic Jahn-Teller effect which involves no static distortion of the octahedral (O_h) symmetry in this molecule. In a similar way, it seems probable that the simple symmetries of Table 4 are to be expected for the typical lanthanoid and actinoid carbonyls because of a dynamic Jahn-Teller effect. With the promotion of the d electron in ytterbium, the structures of the carbonyl species of this diamagnetic metal predicted in Table 4 should not be influenced since no Jahn-Teller effect is expected for this molecule.

4. Conclusion

A large number of new actinoid and lanthanoid carbonyls have been observed involving many coordination numbers. It is, however, clear that a great deal of additional experimental and theoretical work is required to understand the complex details of spectra and structure of these new compounds.

One of the most useful experiments would utilize ESR to determine whether the theoretical hybridizations suggested here are consistent with experiment. In particular, it would be of considerable interest to see if the carbonyls of ytterbium are diamagnetic in contrast to the expected paramagnetism of the other lanthanoid or actinoid carbonyls.

It would also be of considerable practical interest to study the stability of these carbonyls at higher temperatures. In view of the extremely small amounts of carbonyls generated in these experiments, it would probably be advisable to use the method of *Timms*[20] to attempt the preparation of macro quantities. Despite the fact that it has not been possible to prepare uranium carbonyls at room temperature, it is by no means certain that uranium carbonyls are unstable at room temperature as shown by *Timms* for other compounds. This possibility might have significance in the separation of uranium isotopes.

We wish to thank Professor William Weltner of the University of Florida for his cooperation and the use of his equipment in the studies of the uranium carbonyls, and Professor V. Calder and Mr. T. C. DeVore of Iowa State University for their cooperation with one of us (JLS) in the study of the lanthanoid carbonyls.

The Flipping of CO Ligand Groups in Metal Carbonyl Compounds and its Frequency in $Fe(CO)_5$[**]

By Raymond K. Sheline and Harald Mahnke[*]

It has been proven qualitatively by a number of authors using variable temperature NMR experiments that most metal carbonyl complexes are nonrigid. A quantitative determination of the ligand exchange frequency ν_e is often achieved by a line shape analysis or by measurement of the transverse relaxation time T_2 using the Carr-Purcell method. In the case of a "very fast" exchange, however, both methods prove unsuccessful. It is shown in this study that a simultaneous fit of IR or Raman spectra on the one hand and NMR spectra on the other can make possible the determination of ν_e for the "very fast" exchange and can also facilitate the determination of ν_e in "slow" and "medium" exchange cases considerably. The ligand exchange frequency thus found for $Fe(CO)_5$, $1.1 \times 10^{10} s^{-1}$, is unexpectedly high; comparison with variable temperature measurements on solid $Fe(CO)_5$, yields similar energy barriers. A mechanism of exchange closely related to the "Berry mechanism" is proposed. Finally the consequences of this surprisingly large ligand exchange rate are discussed with respect to IR band assignments for molecular "fragments" $M(CO)_x$ (where x = coordination number, and M is a transition metal, typically lanthanoid or actinoid).

1. Introduction

Many physical changes occur in molecules extremely rapidly. These include bond switching such as that which occurs in hydrogen bonding, molecular association, internal rotation or pseudorotation and conformational motions of stereoisomers. If these processes occur between distinguishable sites on a time scale which affects the shape of the NMR resonance lines, it is possible to obtain an estimate of the time required for the physical change.

The shape, Y, of the observed lines in the NMR spectrum can usually be described by[1]

$$Y(\omega-\omega_0) = f(\nu_e, \delta\sigma^0, P_a, P_b) \quad (1)$$

where ω and ω_0 are the variable frequency and the frequency at the absorption maximum, ν_e is the frequency of ligand exchange, $\delta\sigma^0$ is the chemical shift difference between the exchanging sites a and b and P_a, P_b are the populations of these sites. If the populations P_a, P_b are treated as constant the shape of the spectrum depends on ν_e and $\delta\sigma^0$. Three cases can be distinguished.

1. ν_e is at least five times smaller than the line separation, $\Delta\nu$, corresponding to $\delta\sigma^0$ in Eq. (1) in the absence of exchange.
2. ν_e and $\Delta\nu$ have the same order of magnitude.
3. ν_e is at least five times larger than $\Delta\nu$.

In the first case a sharp spectrum corresponding to a rigid structure is observed. The second case results in a very broad unresolved spectrum. Sometimes these broad signals disappear in the background noise. A sharp time-averaged spectrum is observed in the third case. Its appearance is much simpler than in the first case and information like spin-spin coupling constants is lost due to the time averaging.

[**] Based on a lecture delivered at the symposium "Metal Atoms in Chemical Synthesis" held under the auspices of the Merck'sche Gesellschaft für Kunst und Wissenschaft e. V. at Darmstadt (May 12–15, 1974). This work was supported in part by the U.S. Atomic Energy Commission under Contract No. AT-(40-1)-2434.

For the temperature dependence of the exchange frequency ν_e, we can write an Arrhenius-type equation

$$\nu_e = \nu_e^0 \exp(-E_a/kT) \quad (2)$$

where E_a is the activation energy. If E_a is large enough the rate of exchange can be slowed down sufficiently by cooling the compounds so that all three of the above discussed cases can be observed. Such effects have often been observed in the nonrigid metal carbonyls.

To evaluate ν_e quantitatively, it is necessary to do careful line shape analysis involving the functional dependences described in Eq. (1). This analysis is usually more complicated than discussed here because P_a and P_b are also temperature dependent. This difficulty can be overcome using a separate variable temperature IR or Raman study which yields the mole fractions and the populations, P_a and P_b[2]. Unfortunately, most of the examples studied so far by NMR techniques fail to utilize these complementary parallel techniques[3–5]

However, line shape analysis as a tool for the determination of ν_e breaks down if the energy barrier hindering the exchange becomes too small and/or if ν_e becomes too large. The most well known example is $Fe(CO)_5$. As one of the first nonrigid structures to be postulated and established, it stands as the prototype of a number of such molecules with trigonal bipyramidal structure[6, 7]. In these compounds cooling within the experimentally accessible temperature range (+80 °C to −150 °C) does not affect the NMR spectrum, thus entirely ruling out line shape analysis.

In the following we are concerned with ν_e for $Fe(CO)_5$ and therefore with a case not susceptible to line shape analysis. In this fast exchange case the line shape analysis is replaced by a measurement of the transverse relaxation time T_2. In Eq. (1), T_2 and the absorption $Y(\omega-\omega_0)$ are both functions of the same variables. The measurement of T_2 by pulse techniques, however, allows the study of much faster exchange processes than is possible with the analysis of line shape[8]. In view of the close relationship between T_2 measurements and line shape analysis, the same ideas (discussed above) apply. Both are influenced by populations and thus by mole fractions.

If populations are determined independently by variable temperature IR studies, $\delta\sigma^0$ can usually also be determined independently. Thus ν_e, the only unknown which influences T_2 or the NMR line shape, can easily be determined.

X-ray and electron diffraction studies on $Fe(CO)_5$ reveal its structure to be a trigonal bipyramid belonging to the D_{3h} point group with axial and equatorial bond lengths of 1.79 Å and 1.842 Å, respectively[9]. Although the two different M—C bond distances indicate a different electronic environment for the axial C-atoms compared to the equatorially bonded carbon atoms, high resolution ^{13}C NMR studies reveal that all five carbons appear to be equivalent[6, 7]. Such an equivalence would be expected if nonequivalent ligand groups exchange their molecular sites (presumably by an intramolecular process) at a rate which is fast compared to the frequency difference between the chemical shifts of the exchanging nuclei. This situation corresponds to the third case discussed above. The observed chemical shift $\langle\sigma(K)\rangle$ of the K^{th} nucleus in $Fe(CO)_5$ is therefore time-averaged and must be accounted for by an equation of the type,

$$\langle\delta(K)\rangle = \sum_i a_i\sigma_i^0 \qquad (3)$$

where the σ_i^0 are the chemical shifts of the exchanging sites, which are not directly observable in the fast exchange case, and the a_i are statistical populations. For $Fe(CO)_5$ the subscript i can best be denoted as ax and eq and σ_{ax}^0, σ_{eq}^0 are the ^{13}C chemical shifts of the axial and equatorial positions, respectively. Since a trigonal bipyramid has two axial and three equatorial positions, a_{ax} and a_{eq} have the values of 0.4 and 0.6, respectively.

2. A Method for the Determination of $\delta\sigma^0$ and the Populations P_a and P_b

T_2-measurements are well described for the fast exchange case by the equation

$$\frac{1}{T_2} - \frac{1}{T_2^0} \geq P_a P_b (\delta\sigma^0)^2 \tau_e \qquad (4)$$

Here, $1/T_2$ is the total transverse relaxation rate, $1/T_2^0$ is the transverse relaxation rate in the absence of exchange and $\delta\sigma^0 = |\sigma_{ax}^0 - \sigma_{eq}^0|$ and τ_e are the chemical shift difference between the exchanging sites and the mean lifetime of the D_{3h} configuration, respectively. The measurement was performed at 61 MHz and −20°C and gave for $Fe(CO)_5$[10]

$$10^{-3}\,s^{-1} \geq 6/25\,(\delta\sigma^0)^2\tau_e \qquad (5)$$

The product of the populations P_aP_b is in this case determined by the symmetry of the molecule as 6/25. In order to determine the rate of exchange, ν_e, the ^{13}C chemical shift difference $\delta\sigma^0$ between axial and equatorial sites must be determined by an independent measurement.

Using equation (3), it is possible to calculate $\delta\sigma^0 = |\sigma_{ax}^0 - \sigma_{eq}^0|$, if an independent equation in the two unknowns σ_{ax}^0 and σ_{eq}^0 can be obtained. This can only be accomplished by changing the weighting factors, a_{ax} and a_{eq}. Although the weighting factors of $Fe(CO)_5$ cannot be influenced, those of a "pseudo-isotope" do change.

For this purpose the series of compounds $Fe(CO)_x(PF_3)_{5-x}$ has been studied. CO force constants are not significantly influenced by increasing degree of PF_3 substitution for CO in the molecule. This has been interpreted to result from the very similar amount of π-bonding ability of both ligands[11]. The same ought to also apply for the ^{13}C chemical shifts. Since only one additional independent equation is needed in order to determine σ_{ax}^0 and σ_{eq}^0 with Eq. (3) and since this series of compounds runs from $x=1$ up to $x=5$, we can test this assumption by means of an overdetermined system of equations.

The best test for the pseudo-isotope character of the compounds $Fe(CO)_x(PF_3)_{5-x}$, however, is based on spin-spin coupling constants. Isotopic substitution of Y for X changes the spin-spin coupling constant J_{AX} to J_{AY}. The ratio of J_{AX} to J_{AY} is equal to the ratio of the gyromagnetic ratios of the X and Y nuclei. This ratio can be replaced by the ratio of the magnetic moments of nuclei if both isotopes have the same total spin I. This simple relationship holds because all electronic terms which usually influence the spin-spin coupling constant cancel. Real isotopes have very nearly identical electronic environments. Thus, real isotopes certainly show the same σ_i^0's in Eq. (3) since the a_i's are not influenced by isotopic substitution. Pseudoisotopes, on the other hand, have different ligand populations between axial and equatorial positions and therefore have different a_i's. Moreover, these a_i's usually change with temperature. Hence, the electronic environment of the carbon nuclei is certainly influenced by pseudo-isotopic substitution, as are also the ratios of the coupling constants. If the assumption of pseudo-isotopes is warranted, the ratio of the $^{13}C-{}^{31}P$ to the $^{31}P-{}^{31}P$ spin-spin coupling constants should be approximately equal to the ratio of the magnetic moments of the ^{13}C and ^{31}P nuclei.

$$\frac{J_{^{13}C\text{-}^{31}P}}{J_{^{31}P\text{-}^{31}P}} = \frac{\mu_{^{13}C}}{\mu_{^{31}P}} \qquad (6)$$

This relationship has been tested and proven accurate for the *cis*-coupling constants $J_{^{13}C-^{31}P}^{cis}$ and $J_{^{31}P-^{31}P}^{cis}$ for the compound $Fe(CO)_3(PF_3)_2$. The relationship also applies for the *vic*(120°) and *trans*(180°) spin-spin coupling constants. These compounds are therefore well suited as pseudo-isotopes for our purpose. Figure 1 shows the possible stereoisomers for $x=3$ and their symmetry classifications.

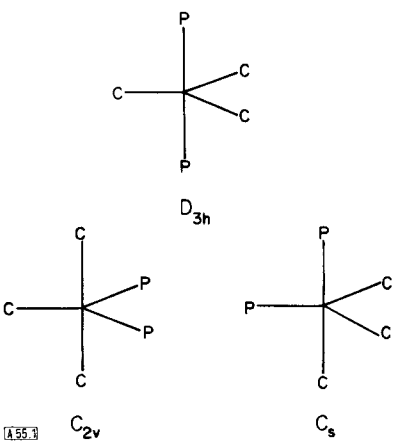

Fig. 1. Stereoisomers of $Fe(CO)_3(PF_3)_2$ and their symmetry classifications.

These stereoisomers cannot be separated due to the fast intramolecular isomerization process. However, the infrared spectra show bands due to the various stereoisomers, thus

setting an upper limit on the frequency of exchange. *Haas* and *Sheline*[11] made a band assignment for the CP stretching region based on force constant calculations (Table 1) and computed the mole fractions x_i of the isomers which are present at room temperature. The statistical populations a_{ax} and a_{eq} from Eq. (3) can easily be expressed in terms of these mole fractions. For $Fe(CO)_3(PF_3)_2$, *e.g.*, we obtain[*]

$$a_{ax} = 0.67\,X_{C_{2v}} + 0.33\,X_{C_s}$$
$$a_{eq} = X_{D_{3h}} + 0.33\,X_{C_{2v}} + 0.67\,X_{C_s} \qquad (7)$$

By measuring variable temperature infrared spectra for the compounds with $x=1$ up to $x=4$, a whole set of weighting factors a_{ax} and a_{eq} can be calculated. If time-averaged chemical shifts are determined for corresponding temperatures and compounds, a heavily overdetermined system of equations is obtained.

the NMR parameters, the chemical shifts as well as the spin-spin coupling constants, are time averaged and an overdetermined system of equations results which yields the true coupling constants and chemical shifts of the system which it would display in the absence of exchange.

The weighting factors are usually given by the mole fractions (or functions of the mole fractions) of the various possible stereoisomers. They are easily deduced from Fig. 1. So far we have only discussed variable temperature IR spectroscopy for the determination of the mole fractions x_i. This proves suitable as long as the exchange frequency is much slower than the IR line splitting $\Delta\nu$. Under these conditions the IR spectra display distinct species "in the absence of exchange". An alternative would be to study the Raman spectra. The selection rules of IR and Raman spectroscopy are different; consequently, the observation of both spectra offers an additional independent way for the determination of the x_i.

Table 1. Mole fractions for the different isomers of $Fe(CO)_5$ and $Fe(CO)_x(PF_3)_{5-x}$ at 25 °C.

Compound	Symmetry	Mole Fraction [%]	Frequency [cm^{-1}]
$Fe(CO)_5$	D_{3h}	100	2000

eq-$Fe(CO)(PF_3)_4$	C_{2v}	50	2008

The observed coupling constants $\langle J_{CP}\rangle$ can be explained by using the experimentally determined mole fractions together with a set of coupling constants, J_{CP}^{trans}, J_{CP}^{vic} and J_{CP}^{cis}. For example, we would write for the compound with $x=3$ (cf. Fig. 1):

$$\langle J_{CP}\rangle = \tfrac{1}{6}[6\,X_{D_{3h}}J_{CP}^{cis} + X_{C_{2v}}(4J_{CP}^{cis} + 2J_{CP}^{vic}) + X_{C_s}(J_{CP}^{trans} + 2J_{CP}^{vic} + 3J_{CP}^{cis})] \qquad (8)$$

Likewise, we write for the phosphorus-phosphorus spin-spin coupling constants $\langle J_{PP}\rangle$ of the compound $Fe(CO)_3(PF_3)_2$ (Fig. 1):

$$\langle J_{PP'}\rangle = X_{D_{3h}}J_{PP'}^{trans} + X_{C_{2v}}J_{PP'}^{vic} + X_{C_s}J_{PP'}^{cis} \qquad (9)$$

Similar relationships can be written for all compounds with $x=1$—4 and all observed coupling constants. The $\langle J_{CP}\rangle$ coupling constants are obtained from ^{13}C-NMR spectra, whereas the $\langle J_{PP'}\rangle$, $\langle J_{FF'}\rangle$, $\langle J_{PF'}\rangle$ and $\langle J_{PF}\rangle$ coupling constants are obtained from ^{31}P- or ^{19}F-NMR spectra[12]. All

The observed ^{13}C chemical shifts are shown in Figure 2 as a function of temperature. A strong temperature effect is observed for both $Fe(CO)_3(PF_3)_2$ and $Fe(CO)_2(PF_3)_3$,

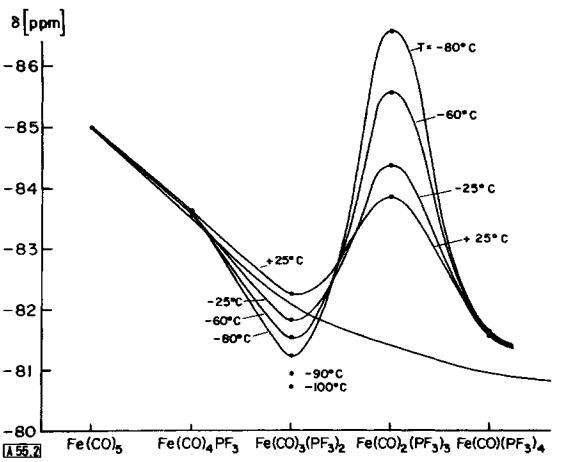

Fig. 2. ^{13}C chemical shift for the compounds $Fe(CO)_x(PF_3)_{5-x}$ as a function of temperature.

[*] It should be noted that, here, point groups are obtained by regarding the PF_3 groups as a single point. Thus, one structure of $Fe(CO)_3(PF_3)_2$ is the trigonal bipyramidal with point group D_{3h}. Obviously, the actual point group is "pseudo D_{3h}". This same simplification applies to other structures but does not affect the symmetry arguments.

whereas the remaining compounds of the series show at most a very small temperature dependence.

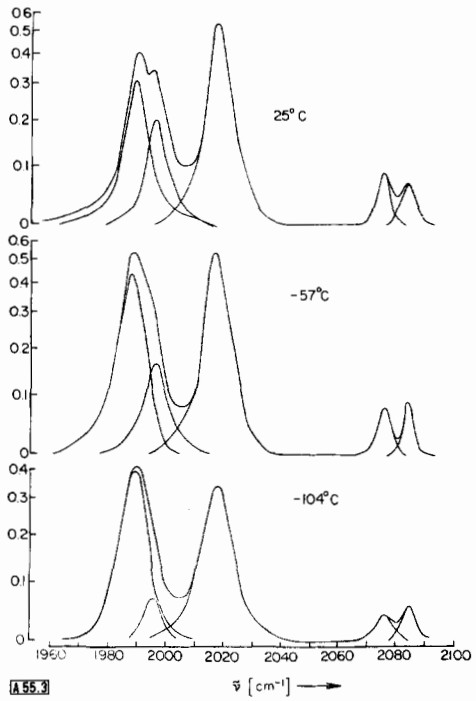

Fig. 3. IR spectra of $Fe(CO)_3(PF_3)_2$ at three different temperatures.

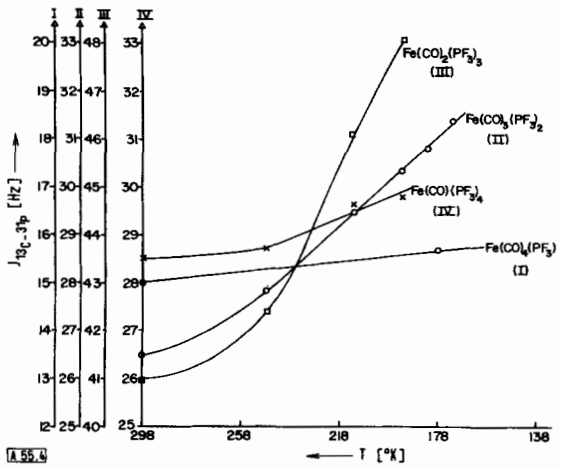

Fig. 4. Observed carbon-phosphorus spin-spin coupling constant $\langle J_{CP} \rangle$ as a function of temperature for the compounds $Fe(CO)_x(PF_3)_{5-x}$.

An analogous temperature effect is inferred from the IR data (cf. Fig. 3) and the $^{13}C-{}^{31}P$ spin-spin coupling constants (Fig. 4). The tendency appears to be the same for the $^{31}P-{}^{31}P$ spin-spin coupling constant $\langle J_{PP'} \rangle$. However, the magnitude of its increase with decreasing temperature is reversed, the biggest change being observed for $Fe(CO)_3(PF_3)_2$ followed by $Fe(CO)_2(PF_3)_3$. This was explained as resulting from different signs for the *trans*, *vic* and *cis* coupling constants of $^2J_{PP'}$[12, 13]. Indeed, a careful analysis using Eq. (9) of the coupling constant $\langle {}^2J_{PP'} \rangle$ in the nonrigid complexes belonging to the series $Fe(CO)_x(PF_3)_{5-x}$ reveals that an angular correlation function exists for $^2J_{PP'}$; in contrast to the normal NMR analysis for the $AA'X_3X'_3$ or $AA'A''X_3X'_3X''_3$ systems, one thus obtains relative signs of the coupling constants $^2J_{PP'}$[1, 14]. The discrepancy which appears to exist between the magnitudes of the coupling constants $^2J_{CP}$ and $^2J_{PP}$ in the case of $Fe(CO)_2(PF_3)_3$ and $Fe(CO)_3(PF_3)_2$ can be explained by inspection of Figures 5 and 6. It is immediately clear for both compounds that the D_{3h} structure is most stable followed by the C_{2v} and C_s structures, respectively. For the observed carbon phosphorus coupling constant this means that the weighting factors of J_{CP}^{trans} and J_{CP}^{vic} decrease in favor of J_{CP}^{cis}. Both changes have an additive effect on $\langle J_{CP} \rangle$. On the other hand, it means for $^2J_{PP'}$ that the weighting factor for $^2J_{PP'}^{vic}$ increases while those of $^2J_{PP'}^{trans}$ and $^2J_{PP'}^{cis}$ decrease. The disappearance of $^2J_{PP'}^{trans}$ in favor of $^2J_{PP'}^{vic}$ would cause the observed coupling constant $\langle J_{PP'} \rangle$ of $Fe(CO)_2(PF_3)_3$ to decrease in magnitude whereas the disappearance of $^2J_{PP'}^{cis}$ from equilibrium causes $\langle J_{PP'} \rangle$ to increase. Thus both changes almost cancel, resulting in only a small net change on the observed $\langle J_{PP'} \rangle$.

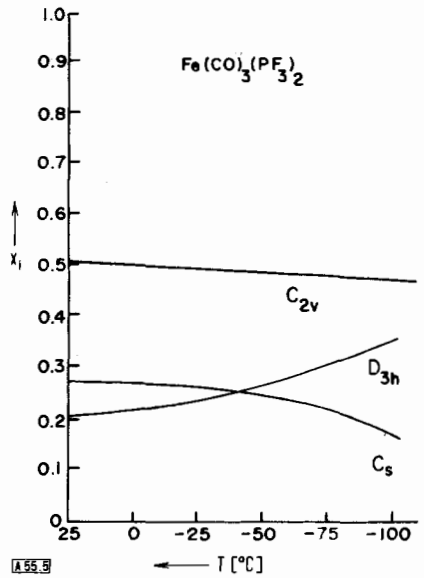

Fig. 5. Mole fractions of the stereoisomers of $Fe(CO)_3(PF_3)_2$ as a function of temperature.

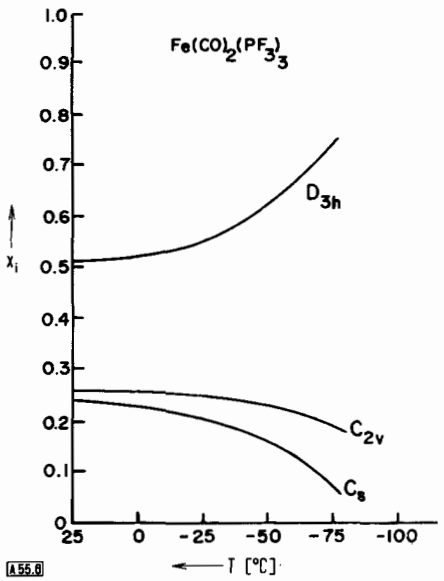

Fig. 6. Mole fractions of the stereoisomers of $Fe(CO)_2(PF_3)_3$ as a function of temperature.

The fact that spin-spin coupling constants can have different signs makes their use more difficult for studying nonrigid structures. If no effect is observed on changing the temperature,

it need not necessarily imply that the system is rigid; rather this could be due to a compensation of temperature effects. Therefore, it is of great importance, if a quantitative understanding of the variable temperature effect on NMR spectra of nonrigid systems is attempted, to study simultaneously the temperature effect on such parameters as the chemical shift and mole fractions obtainable from IR or Raman spectra.

Since the IR bands of the different stereoisomers (Fig. 1) in the CO stretching region are partially superimposed, a band stripping analysis was used to compute the band areas for the various overlapping bands (band analysis with Lorentzian curves (cf. Fig. 3).

The band assignment of the various stereoisomers can be tested from the temperature dependence of the IR spectra. Beer's law demands that the absorption area of a band due to one particular stereoisomer is proportional to its concentration in the mixture. Therefore, if the areas of two bands belonging to the same stereoisomer are plotted against each other, the resulting curve should be a straight line running through the origin of the coordinate system with a slope equal to the ratio of the extinction coefficients of the two bands. This method allows the assignment of pairs of bands belonging to the same stereoisomer. Consider for example the IR stretching region for the compound $Fe(CO)_3(PF_3)_2$ (Fig. 3). This figure clearly indicates that the bands at 2073 and 1993 cm^{-1} belong to the same isomer, as also the bands at 2081 and 2012 cm^{-1}. The remaining band at 1987 cm^{-1} can then be assigned immediately to the D_{3h} species, since this is the only symmetry species considered with a single allowed absorption band in the CO stretching region. This method cannot, however, differentiate between C_{2v} and C_s assignments for the two pairs of bands. This differentiation can be accomplished using the NMR data.

The temperature dependent IR spectra allow us to compute the mole fractions of the different stereoisomers in the mixture at each temperature[11]. The results for $Fe(CO)_3(PF_3)_2$ and $Fe(CO)_2(PF_3)_3$ are summarized in Figures 5 and 6. These mole fractions were inserted into Eq. (7) and yielded the statistical weighting factors a_{ax} and a_{eq} for each compound and temperature.

From the NMR studies, we obtain time-averaged chemical shifts for the various compounds at different temperatures. These, together with the corresponding statistical weighting factors a_{ax} and a_{eq} are used to determine $\delta\sigma^0=|\sigma^0_{ax}-\sigma^0_{eq}|$ employing Eq. (3). In the case of $Fe(CO)_2(PF_3)_3$, a temperature shift of 2.8 ppm was observed between +25 °C and −80 °C. This temperature shift yields $\delta\sigma^0=17.7$ ppm. Since we are dealing with an overdetermined system, we can calculate a mean value for $\delta\sigma^0$ as well as error limits: $\delta\sigma^0 = 17.7 \pm 1.5$ ppm. If this result is inserted in Eq. (5) we obtain for the mean lifetime $\tau_e=9.02\times10^{-11}$ s, which corresponds to an exchange frequency $\nu_e=1.1\times10^{10}\,s^{-1}$ at −20 °C. The accuracy in the measurement of T_2 almost entirely determines the error limit on ν_e. τ_e and ν_e are determined only as limits due to the theory on T_2-measurements. Thus we determined for τ_e an upper limit and for ν_e a lower limit.

By using Eq. (3) we not only obtain $\delta\sigma^0$ but also the magnitudes of the chemical shifts σ^0_{ax} and σ^0_{eq} individually. For $Fe(CO)_5$ we get $\sigma^0_{ax}=-95.6$, and $\sigma^0_{eq}=-77.9$ ppm, relative to benzene. This result has been interpreted as resulting from a greater amount of π back-bonding in the axial position as compared to the equatorial position[15].

3. Interpretation of Findings and Outlook

The flipping frequency, ν_e, of $1.1\times10^{10}\,s^{-1}$ is unexpectedly fast. In addition to determining the flipping frequency, other goals of such measurements are to find a mechanism for the exchange and to determine the energy barrier hindering the intramolecular ligand exchange. Determining the energy barrier E_a is usually achieved by variable temperature measurements of ν_e since according to the Arrhenius equation [Eq. (2)] a plot $\ln k$ *vs* $1/T$ yields E_a. In this case the rate of exchange ν_e corresponds to the rate of reaction k. The temperature range over which values of ν_e may be determined for $Fe(CO)_5$ is severely limited, since pentacarbonyliron freezes at −21 °C[10]. If one of the two unknowns in Eq. (2), ν_e^0 and E_a, can be estimated by an independent method the other can be calculated from a single measurement of ν_e. Therefore we want to try to estimate the magnitude of the frequency factor ν_e^0 by considering possible reaction paths.

The rapid intramolecular ligand exchange determined for $Fe(CO)_5$ has been observed in a great number of trigonal bipyramidal molecules, although the nature of the chemical bond in them varies considerably. One of the well studied examples is PF_5; indeed, all five coordinated phosphorus compounds show this phenomenon. Consequently, the most important feature appears to be geometry. According to *Gillespie*[16], the electron pair repulsion potential in five coordinated compounds is equally well minimized in either a trigonal bipyramid or a tetragonal pyramid; neither is energetically favored. By far the most stable configurations for tetra- or hexacoordinated compounds are the tetrahedron and octahedron, respectively. Both of these geometrical forms belong to a higher symmetry group, namely T_d and O_h, than either the trigonal bipyramid or the tetragonal pyramid which belong to the D_{3h} and C_{4v} groups, respectively. Therefore, one can consider the C_{4v} and D_{3h} structures as geometrical transition states with respect to the T_d or O_h structures. For example, the tendency to achieve either the octahedral or tetrahedral configuration is observed in PCl_5, which dissociates in the solid state:

$$2\,PCl_5 \rightarrow PCl_4^+ + PCl_6^-. \qquad (10)$$

However, in determining the stability, geometrical considerations are not as important as electronic considerations. In the case of metal carbonyls the most decisive factor is the "noble gas" rule. According to this rule, iron as a 3d transition metal tends to achieve the krypton shell. Since in the coordinate bond between CO and iron two electrons are contributed by each CO ligand group, iron(0) needs five CO groups in a mononuclear carbonyl in order to achieve the required 36 electrons of the krypton shell together with its own 26 electrons.

We will now attempt to describe the inversion process in $Fe(CO)_5$ by using a diffusion model involving a Schottky defect in conjunction with the symmetry considerations just presented and the Berry mechanism. Let us consider a layer of a crystal lattice with a Schottky defect. Diffusion of a vacancy occurs through the motion of an adjacent atom along a normal coordinate (diffusion coordinate). The probability that an adjacent atom will pass over a potential barrier ΔE is proportional to $\exp(-E_a/kT)$. If ν_0 is the characteristic

vibrational frequency corresponding to the diffusion coordinate, then the probability of a migration jump is, according to the Arrhenius equation

$$P = \nu_0 \exp[-E_a/kT] \qquad (11)$$

The probability P is called the jump frequency. The frequency factor ν_0 is a vibrational frequency in the IR region (10^{12} to 10^{14} Hz). In analogy with this diffusion model, we consider the C_{4v} structure as an octahedron with a Schottky defect, a vacancy. Similarly, the D_{3h} structure can be considered as a tetrahedron with a defect, in this case a superfluous ligand.

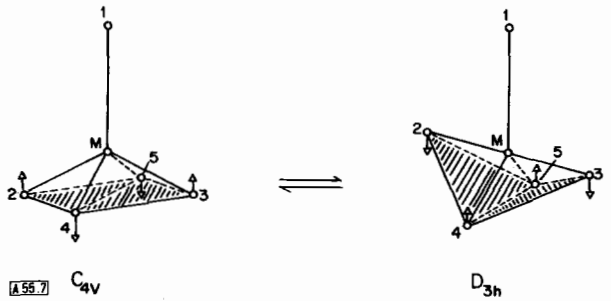

Fig. 7. "Berry-mechanism" for the ligand exchange in trigonal bipyramidal molecules using the C_{4v} and D_{3h} structures as transition states.

The Berry mechanism is presented in Fig. 7. A diffusion coordinate along which the octahedral vacancy in the C_{4v} structure can be filled, must be sought among the normal coordinates of the D_{3h} structure (Fig. 8). Previous investigations have failed to find a normal coordinate corresponding to the path of the Berry mechanism[17]. Since, however, a linear combination of normal modes again yields normal modes, we note that the normal coordinate corresponding to the combination $|\nu_6(E')-\nu_7(E')|$ yields the required diffusion path. Such a combination is usually called a beat frequency and we therefore call the resulting mechanism a beat mechanism. The combination $\nu_6(E')+\nu_7(E')$ results in distorted transition states (cf. Fig. 9) and is therefore excluded from our discussion.

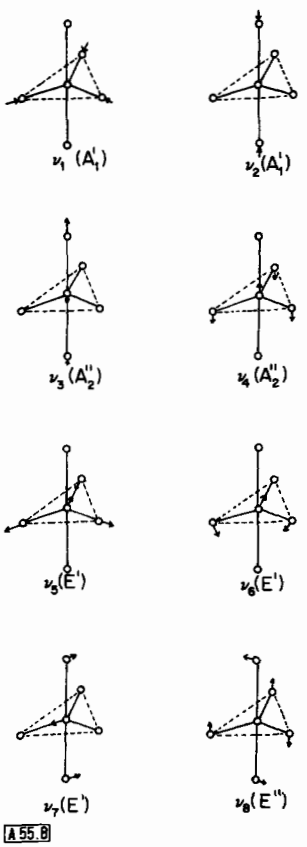

Fig. 8. Normal modes of vibration for the D_{3h} structure.

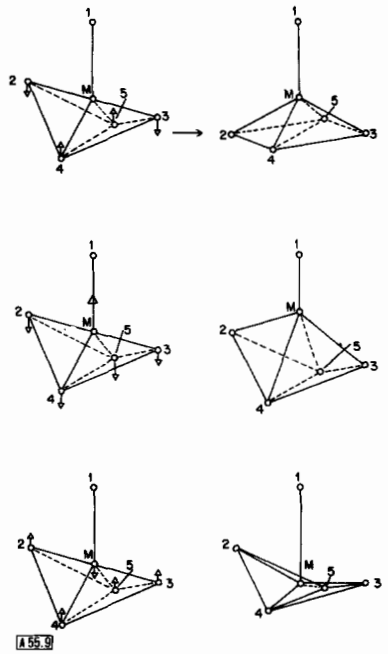

Fig. 9. Linear combination $\nu_6 \pm \nu_7$ of the D_{3h} structure leading to the transition states indicated on the right hand side of the figure. The (+)-combination leads to distorted high energy transition states, whereas the (−)-combination leads to the highly symmetrical and stable C_{4v} structure.

A diffusion coordinate for the transition $C_{4v} \rightarrow D_{3h}$ can be found if we examine the normal coordinates of the C_{4v} structure (Fig. 10): According to the correlation diagram in Fig. 11,

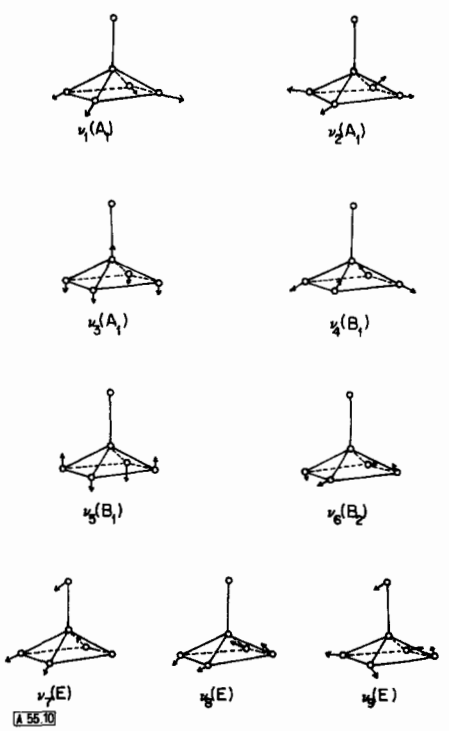

Fig. 10. Normal modes of vibration for the C_{4v} structure.

$\nu_5(B_1)$ of the C_{4v} structure connects with both $\nu_6(E')$ and $\nu_7(E')$ of the D_{3h} structure under angular distortion.

The relative values for $\nu_6(E')$ and $\nu_7(E')$ will differ in the general case. We assign the one with the lower frequency as ν_7, since the axial bending should occur easier than the equatorial bending. There is 120° between next neighbors in the equatorial plane compared to 180° in the axial plane. Symmetry demands that both frequencies become equal only under the C_{4v} "distortion". An identity of both frequencies anywhere else would be an accidental degeneracy and is indicated in Fig. 11 with the dashed horizontal line.

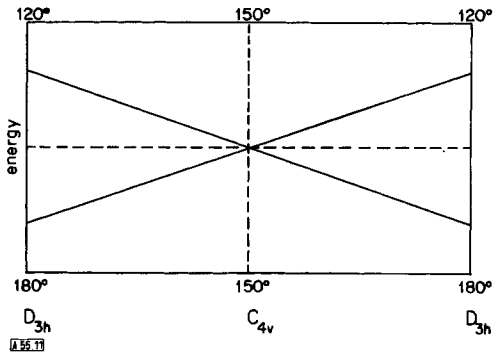

Fig. 11. Energy correlation diagram of angular distortion between $\nu_5(B_1)$ which corresponds to the C_{4v} structure and $\nu_6(E')$ and $\nu_7(E')$ which correspond to the D_{3h} structure.

As mentioned above the inversion frequency for the process $C_{4v}-D_{3h}$ can be described by an Arrhenius-type equation

$$1/\tau_{C_{4v}} = \nu_{C_{4v}\rightarrow D_{3h}} = \nu_5(B_1)\exp(-\Delta E_1/kT). \quad (12)$$

Similarly

$$1/\tau_{D_{3h}} = \nu_{D_{3h}\rightarrow C_{4v}} = \nu_{beat}(E')\exp(-\Delta E_2/kT) \quad (13)$$

where $\tau_{C_{4v}}$, $\tau_{D_{3h}}$ are the mean lifetimes of the C_{4v} and D_{3h} structures, respectively. A complete normal coordinate analysis of $Fe(CO)_5$ under the assumption of a D_{3h} structure has been carried out[18]. In that study $Fe(CO)_5$ was treated like a rigid molecule and the fact that it should also exhibit the C_{4v} structure was totally disregarded. Consequently, there exists the possibility that weak bands which were explained as combination bands or overtones are really due to the C_{4v} structure resulting in a possible misassignment. Nevertheless, we take ν_{beat} from these published results. The two bands considered here are calculated to be at 97 and 104 cm^{-1}, respectively. Consequently, we take ν_{beat} as 7 cm^{-1}. According to the correlation diagram (Fig. 11), $\nu_5(B_1)$ for the C_{4v} structure could be approximated as the average of these two frequencies. Therefore, $\nu_5(B_1)=100\,cm^{-1}$. Since the IR spectrum shows only the D_{3h} structure, we can write for the ratio of the concentrations of the two structural stereoisomers

$$C_{D_{3h}} \gg C_{C_{4v}} \quad (14)$$

Therefore, we conclude that the following relation holds for the corresponding lifetimes

$$\tau_{D_{3h}} \gg \tau_{C_{4v}} \quad (15)$$

The exchange frequency for the overall ligand inversion process for the D_{3h} structure is given by

$$1/\tau_e = \nu_e = \nu_{beat}/2\exp[-\Delta E_2/kT]. \quad (16)$$

The factor $^1/_2$ arises from the fact that the NMR cannot register an exchange between indistinguishable sites. From symmetry considerations we conclude that only half of all exchanges occur between distinguishable sites (Fig. 7). If we insert the experimentally determined ligand exchange frequency of $1.1\times10^{10}\,s^{-1}$ and the estimated value for ν_{beat}, we obtain for the energy barrier $\Delta E_2 = 7.8\cdot10^{-14}$ erg/mol = 1.13 kcal/mol.

Since the NMR experiment can only determine an upper limit for τ_e and a lower limit for ν_e, the calculated height of the energy barrier should be considered as the maximal possible value, *i.e.* $0\leqslant\Delta E_2\leqslant1.13$ kcal/mol. For the ligand exchange frequency in $Fe(CO)_5$ this means: $0.67\leqslant\nu_e\leqslant7.0$ cm^{-1}. For the exchange frequency between the C_{4v} and D_{3h} structures we find for $\Delta E = 0$ and $\Delta E = 1.13$ kcal/mol: $10.7\leqslant\nu_e\leqslant100\,cm^{-1}$.

This frequency is thus at least 14 times faster than the corresponding frequency for the $D_{3h}\rightarrow C_{4v}$ inversion. This is the reason why the IR spectrum shows only normal modes which are due to the D_{3h} structure. The "combination" or "overtones"[18], however, might possibly be explained as normal modes of the C_{4v} structure. These results are clearly consistent with the observation of a sharp IR spectrum for the D_{3h} structure and a time-averaged NMR spectrum, since the maximal exchange frequency is still small compared to the line splitting of 25 cm^{-1} in the CO stretching region (cf. Section 1) and on the other hand the activation energy is too small to slow it down considerably within the experimentally covered temperature range. The lifetimes of the C_{4v} structure are expected to be much shorter. Consequently, its IR spectrum is expected to be partly time-averaged but much weaker.

With time-averaging the number of lines actually observed is smaller than the number of lines deduced from group theory. Another effect of fast exchange for the IR spectra is "inversion splitting", first studied for the NH_3 molecule[19]. By far the most pronounced splitting has been found for the symmetrical bending mode of the ammonia molecule. The obvious reason is that the exchange coordinate is closely related to the normal coordinate of this vibrational mode. For $Fe(CO)_5$, the exchange occurs along an angular coordinate about the iron atom. Therefore, we expect inversion splittings to be important only for bending modes. For CO stretching modes we expect only time-averaging effects. Whereas time-averaging reduces the number of bands, "inversion splitting" increases the number of bands relative to the "no exchange" case.

This has a considerable impact on the matrix isolation technique where metal atoms are cocondensed at 4 °K together with CO gas diluted with Ar, resulting in the production of metal carbonyls and their fragments $M(CO)_x$, where $x = 1, 2, \ldots, n$. These species are usually identified by their IR spectra in the CO stretching region[20]. For the band assignment, the various species are treated as rigid, and group theory is applied in order to predict the number of lines due to a particular molecular fragment. As has been proven for NH_2, a molecular fragment of the ammonia molecule, this technique of band assignment becomes questionable. In its electronic ground state, NH_2 is a bent molecule (C_{2v}) and it behaves in this manner in electronic spectroscopy[21]. Relative to the much slower EPR and IR spectroscopy, how-

ever, it behaves like a linear molecule ($D_{\infty h}$), which is the average of two bent configurations[22]. Indeed, the ESR spectrum of NH_2 even at 4°K results from a "linear" molecule of symmetry $D_{\infty h}$. Similar ideas apply to $M(CO)_2$, where M is a transition metal, lanthanoid or actinoid. The molecular fragment $M(CO)_2$ would usually be expected to be bent (C_{2v})[20]. A fast pseudorotation of the fragment would display a linear configuration ($D_{\infty h}$). The C_{2v} structure would have two bands in the CO stretching region whereas the $D_{\infty h}$ species has only one band. Thus a method of band assignment, which depends importantly on the number of bands, could be misleading when the flipping frequency is fast enough. This study suggests then that a considerable amount of work is needed, possibly including measurement of flipping frequencies, to assure the correct band assignments for lanthanoid and actinoid carbonyls[20].

The surprisingly fast ligand exchange frequency determined for $Fe(CO)_5$ could also help to understand better the IR spectra of $M(CO)_5$ binary carbonyls (where M = Cr, Mo and W)[23]. The species initially prepared by the matrix-photolysis of the appropriate hexacarbonyls was believed to display the C_{4v} structure. The C_{4v} structure displays three bands in the CO stretching region and this was in fact observed. After warming the solid matrix to −170°C, the IR spectra showed only two bands, which were interpreted as being due to the D_{3h} structure. The surprisingly fast exchange which has been established for solid $Fe(CO)_5$ down to helium temperature throws doubt on the interpretation of the observed IR spectra. If ν_e is of the same order of magnitude in the group VIb pentacarbonyls as was found for $Fe(CO)_5$, then the observation of a C_{4v}-species between −196 and −170°C should be impossible. The $M(CO)_5$ photolysis fragments offer an opportunity for the formation of a relatively unstable complex, possibly with the solvent or N_2, at these low temperatures. Such a complex $M(CO)_5X$ would of course make impossible a ligand exchange process following the same type of beat mechanism formulated for $Fe(CO)_5$ in this study. If this complex decomposes, however, at slightly higher temperatures, the flip occurs instantly and what the CO stretching region shows, as in the case of $Fe(CO)_5$, is the D_{3h} structure.

The mean lifetime considered here can be compared to an angular correlation time which was measured for both $Ni(CO)_4$ and $Fe(CO)_5$[10]. The angular correlation time describes the angular reorientation of the entire molecule and is intimately related to the viscosity of a liquid. This reorientation is a random motion, whereas the mean lifetime τ_e is an angular correlation time for the intramolecular angular reorientation of ligand groups around the metal center and occurs only along well defined exchange paths. It is interesting to note that the frequencies and activation energies for both processes are of the same order of magnitude[10]. There appears to be little or no restriction for the angular motion of the ligands around the metal center although a strong interaction exists in the radical direction. Free movement of ligands presupposes an angular mobility of the binding electrons. The electrons occupy "delocalized" orbitals. They are certainly not as mobile as metal electrons in the bulk metal, but the small magnitude of the energy barrier hindering angular motion makes electron "tunneling" a very plausible process. One of the two binding electrons of a CO group may tunnel through a barrier to the adjacent equilibrium position forming a short-lived "bridging carbonyl". The noble gas rule will certainly not be violated. The tunneling of the second electron completes the formation of the C_{4v} structure. The mobility of the binding electrons was previously postulated for metal carbonyls and is consistent with many experimental observations[24].

Very recently, exchange frequencies have also been determined for solid $Fe(CO)_5$ down to helium temperature[25]. The exchange frequencies in the solid are also surprisingly fast (*ca.* 10^4 Hz) and show little temperature dependence. A plot of $\ln \nu_e$ *vs* $1/T$ yields an activation energy ΔE_2 of ≈ 0.9 kcal/mol, which is very similar to the value $0 \leqslant \Delta E_2 \leqslant 1.13$ kcal/mol determined in the measurements described here. This comparison lends strength to both measurements and suggests the existence of a similar very low energy barrier to intramolecular exchange for $Fe(CO)_5$ in both solid and liquid states.

Thanks are due to Dr. R. J. Clark and Dr. H. W. Spiess for many discussions concerning this problem and for carefully reviewing part of the arguments used in this manuscript.

Sulfur Atoms as Ligands in Metal Complexes

By Heinrich Vahrenkamp[*]

Dedicated to Professor Helmut Behrens on the occasion of his 60th birthday

The types of sulfur bonding—as sulfane or sulfide—encountered in the molecules of main-group elements are almost unknown in the chemistry of metal complexes, where the sulfur atoms function instead as two-electron donors by bridging two metal atoms, as four-electron donors by bridging three or four metal atoms, or as six-electron donors by incorporation between four metal atoms. In such complexes, the metal-metal bond can be modified over a wide range by chemical or electrochemical variation of the number of electrons present. The readiness with which polynuclear complexes containing metals and sulfur undergo redox reactions is also utilized by Nature in the active sites of some redox proteins.

1. Introduction

Transition metals and sulfur have an "affinity" for one another, as is discovered by every young chemist when willingly or unwillingly he meets the precipitation of metal sulfides. This also explains why combinations of d-elements with unsubstituted sulfur were known until recently almost exclusively in the form of the metal sulfides. The strong tendency for the formation of sulfidic solids follows from a qualitative picture of bonding. It can be seen most readily in the Pearson acid-base scale[1] where d^n-transition metal ions and sulfide ions are both classed as "soft" groups. Finer details include covalence contributions to, and back-bonding effects in, the metal-sulfur bond and the possibility of metal-metal interactions in sulfide structures[2].

Soluble metal complexes with unsubstituted sulfur as ligand are comparatively rare, however, since they also tend to revert to binary sulfides. Modern transition-metal chemistry with its possibilities for the stabilization of unusual bonding systems first provided a sufficient number of such complexes to justify a review article. Interest in these compounds is topical and their investigation has been stimulated by three factors: 1) The observation that the formation and catalytic activity of metal carbonyls are influenced, sometimes for the better, by sulfur impurities[3]; 2) the broad development of structural chemistry for the polynuclear metal-sulfur complexes[4]; and 3) the discovery that some redox-proteins contain transition-metal ions and "labile" sulfur in their active sites and that this sulfur can be liberated as H_2S by acids[5].

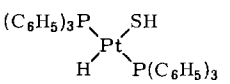
This review is an attempt to classify the known metal-sulfur complexes according to their structural chemistry, to discuss their synthesis and reactivity, and to present the most recent findings pertaining to their biochemical significance. Thiometalates of d^0-transition metals[6] and the incorporation of metals in sulfur rings[7] will not be considered since both topics have recently been surveyed elsewhere.

2. Structural Chemistry of the Complexes

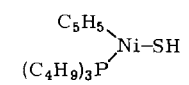
The analogy between oxygen and sulfur no longer holds in transition-metal chemistry. This is shown by the differing structures of oxides and sulfides and by the contrast between the large number of transition-metal aqua ions and the very few complexes with H_2S as the ligand[8, 9]; compound *(1)* is the sole recorded complex that has some degree of stability at room temperature[10]. Similarly, few complexes containing the SH group have been reported; *(2)*[11], *(3)*[12], and *(4)*[13] are the only known complexes containing terminal hydrogensulfide groups.

$C_5H_5(CO)_2Mn{-}SH_2$ *(1)*

$C_5H_5(CO)_3W{-}SH$ *(2)*

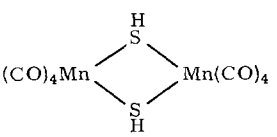


(3)

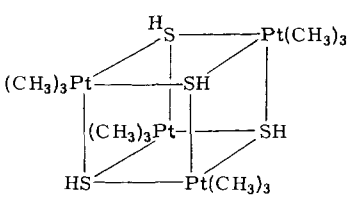


(4)

Even compounds with bridging SH groups, in which the reactivity of the sulfur has been reduced by coordination of its lone pairs, are hardly known; in $[(CO)_4Mn{-}SH]_2$ *(5)*[14] one lone pair on each sulfur atom is blocked, and in $[(CH_3)_3Pt{-}SH]_4$ *(6)*[15] both are blocked.



(5)



(6)

And yet even these complexes can decompose to form metal sulfides. Such decomposition is prevented only when the sulfur-containing ligand is present as an organic sulfur compound. Accordingly, numerous organosulfur complexes of the transition metals are known to exist[16, 17].

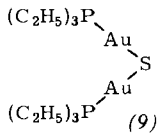
2.1. Metallosulfanes and Molecular Metal Sulfides

The situation for the simplest of sulfur complexes resembles that for the SH complexes: single metal-sulfur bonds do not suffice for stabilization against decomposition. Thus, compounds such as sulfanes of type *(7)* and sulfides of type *(8)* are hardly known in transition-metal chemistry, although they are normal in the main-group chemistry of sulfur.

[*] Prof. Dr. H. Vahrenkamp
Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)

$L_nM{-}S{-}ML_n$ (7) $L_nM{=}S$ (8) L = ligand, M = transition metal

They are found almost exclusively with d^{10}- and d^0-metals[6]; two proven examples are *(9)*[18] and *(10)*[19].



(9)

$Cl_4W{=}S$ *(10)*

The only reported example of such simple complexes in which the d-shell is neither filled nor empty is *(11)*[20].

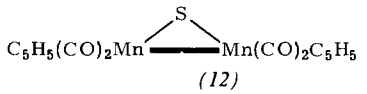
$[(CN)_5\overset{III}{C}o{-}S{-}S{-}\overset{III}{C}o(CN)_5]^{6-}$ *(11)*

Complex *(10)* and the numerous thiometalates of the d^0-species occupy a special position, insofar as the absence of d-electrons in these species (*e.g.* V^V, Mo^{VI}, Re^{VII}) precludes their behaving as typical transition elements but renders them more like main-group elements[6]. Furthermore, the metals cannot be regarded as soft acids in their high oxidation states.

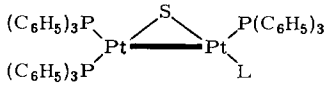
In the metallosulfanes *(7)* and sulfides *(8)* the sulfur behaves as a one- or two-electron donor toward the metal atoms. Its lone pairs are unused and reactive. This is probably the reason for the instability of other complexes of this type. Isolable complexes are obtained by surrounding the metal atom with π-acceptor ligands and by raising the coordination number of the sulfur and of the metal; the former measure implies resorting to the stabilizing principles of organometallic chemistry and the latter implies formation of polynuclear complexes, *i.e.* the occurrence of clusters, and thus an approximation to the stable state of solid metal sulfides.

2.2. Bridging Sulfur Atoms as Two-Electron Donors

The above concepts are implemented most readily in binuclear complexes in which a bridging sulfur atom spans a metal-metal bond to form an M_2S triangle. This triangle is also the simplest section from the lattice of a metal sulfide, *e.g.* the NiAs lattice; it occurs in the manganese complex *(12)*[21] and in the two platinum complexes *(13)*[22] and *(14)*[23, 24].

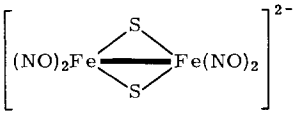


(12)

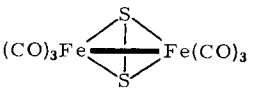


(13), L = $P(C_6H_5)_3$
(14), L = CO

The bonding system M_2S_2, in which two sulfur atoms span two metal atoms, is more common. This class includes the longest-known metal-sulfur complex, the red Roussain salt $K_2[Fe_2S_2(NO)_4]$[25]. The structure *(15)* of its anion was assumed by *Seel*[26] already in 1942 and was later confirmed by structure analysis of the red Roussain ethyl ester[27]; it is related to the structure *(16)*[28] of the complex $Fe_2S_2(CO)_6$[29, 30], which additionally displays an S—S bond.

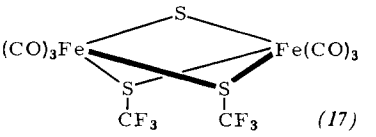


(15)



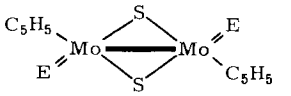
(16)

The stability of the M_2S_2 structural unit permits the additional appearance of metallosulfane and metal sulfide type bonds, *(7)* and *(8)*, which are otherwise uncommon for d"-metals; thus, the complex *(17)*[31] bears a certain resemblance to *(15)* and *(16)*.



(17)

Furthermore, among the Mo_2S_2 compounds both Mo=O[32] and Mo=S bonds[11] occur in terminal units, as shown by the almost identical structures *(18)*[33] and *(19)*[34].



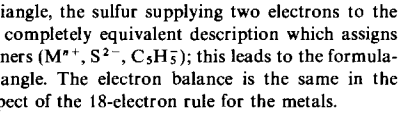
(18), E = O
(19), E = S

The above examples of M_2S_2 complexes are not isolated cases, for the discovery that several redox proteins contain iron, molybdenum, and "labile" sulfur (cf. Section 4) has meanwhile led to the preparation and crystallographic characterization of whole series of complexes containing the structural units Fe_2S_2[35–37] and Mo_2S_2[38–44] accompanied by naturally occurring ligands.

The assumption that the bridging sulfur in the M_2S triangle acts as a two-electron donor and thus that two M—S single bonds are present can be confirmed experimentally. The most convincing evidence comes from the M—S bond lengths: for example, in the molybdenum complexes *(18)* and *(19)* the Mo—S bridge bonds average 2.32 Å in length, whereas the length of the terminal Mo=S double bond in *(19)* is 2.14 Å[34]. If the bridging sulfur atom were a four-electron donor the bridging Mo—S bonds would have to be formulated as double bonds, which would contradict the experimental result[*]

Accordingly, in their complexes such as *(12)*, *(15)*, *(16)*, and *(17)* the metal atoms of the first transition series always attain 18 outer electrons—and the noble gas rule is thus fulfilled—if the bridging sulfur is counted as a two-electron donor. For molybdenum and platinum, however, even in complexes with π-acceptor ligands, an outer electron number of 16 is also common, and this is also so in the complexes *(13)*, *(14)*, *(18)*, and *(19)*.

[*] In the method of counting electrons used here all the bonding partners concerned in the covalent bonding system of these complexes are regarded as neutral particles. For example, the electrically neutral charge distribution *(a)* results for an Mo_2S triangle, the sulfur supplying two electrons to the bonding system. There is a completely equivalent description which assigns charges to the bonding partners (M^{n+}, S^{2-}, $C_5H_5^-$); this leads to the formulation *(b)* for the Mo_2S triangle. The electron balance is the same in the two cases, especially in respect of the 18-electron rule for the metals.



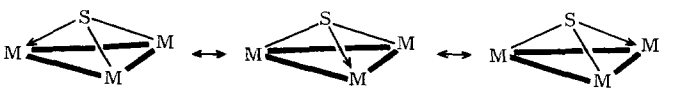
(a) *(b)*

The bridging-sulfur complexes described here cannot be classed among the sulfane derivatives *(7)* since the sulfur bridge occurs almost invariably together with a metal-metal bond and the angle at the bridging sulfur atom (about 75°) cannot be reconciled with the angle at sulfane-sulfur (about 105°). Thus, the metal-sulfur bond cannot be described independently of the metal-metal bonding (cf. Section 2.5). This three-center situation is similar to that for bridging CO groups[45], which also occur only in conjunction with metal-metal bonds and show no ketone character in either their structure or their bonding.

2.3. Sulfur Atoms as Threefold Bridges and Four-Electron Donors

This is the bonding situation specific to stable transition metal-sulfur complexes. As a four-electron donor, sulfur uses one of its lone pairs and forms three covalent bonds. The reactivity of the sulfur is thereby reduced and at the same time the M_3S structural unit represents a still closer approach to the structure of sulfidic solids. Furthermore, an M_3S atomic arrangement has a favorable geometry, for the three metals can interact with one another and, together with the remaining lone pair, provide approximate tetrahedral coordination for the sulfur. This type of bonding is so favorable that it permits enormous variations in the nature and electron configuration of the metals.

If the three metal atoms are the same the M_3S bonding system is normally symmetrical. Thus, there is no difference between the various bonds from the sulfur, as indicated by the individual resonance formulas of the valence-bond description *(20)*. It is justifiable, both qualitatively and quantitatively, to state that the sulfur contributes four electrons to three covalent bonds, without specifying the exact distribution of these electrons.

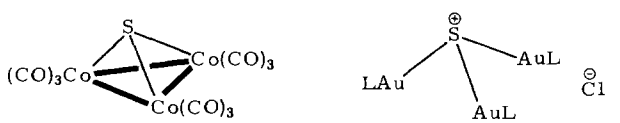


(20a) *(20b)* *(20c)*

When the sulfur is counted as a four-electron donor then for most of these complexes the 18-electron rule, the noble-gas rule of transition-metal chemistry, is fulfilled for all metals. The preference for the M_3S and also for the M_3S_2 structural unit—the latter bridged on both sides—is, however, so strong that some cases are also found in which the electronic configuration departs considerably from the 18-electron rule.

2.3.1. Complexes with the M_3S Structural Unit

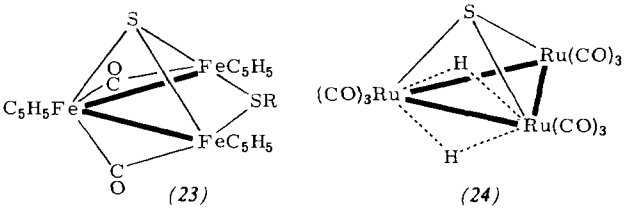
The M_3S structural unit can occur either with or entirely without metal-metal bonding; this is illustrated by the two symmetrical examples *(21)*[46] and *(22)*[18].



(21) *(22)*, L = $P(C_6H_5)_3$

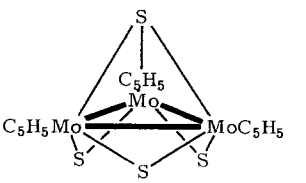
The Co_3S cluster is formed so readily that it is accessible *via* several routes[47–50] and can occur in widely differing structures[46, 51–53].

Somewhat more complicated bonding occurs in the thiol-bridged iron complex *(23)*[54], whose crystal structure has been elucidated[55], and in the ruthenium hydride *(24)*[56, 57].



(23) *(24)*

Finally, the Mo_3S_4 complex *(25)*, which occurs both as a cation and as a neutral complex[11, 58], contains a combination of twofold and threefold bridging sulfur atoms.

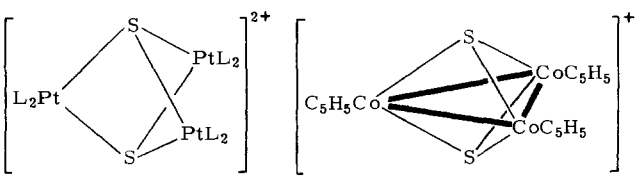


(25)

In this compound there are four sulfur atoms situated at the corners of a tetrahedron; they leave room for a fourth metal atom which, together with the three molybdenum atoms, would span a tetrahedron inverse to this. Together they would provide a M_4S_4-cubane (cf. Fig. 2) seven-eighths of which is complete in the Mo_3S_4 cluster *(25)*.

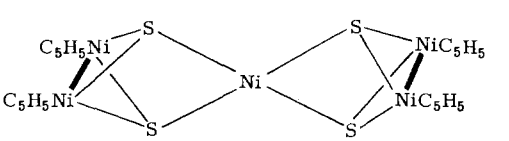
2.3.2. Complexes with the M_3S_2 Structural Unit

There are also examples of various degrees of metal-metal bonding among the M_3S_2 complexes. The extremes are the cations *(26)* without metal-metal bonds[22] and *(27)* with strong metal-metal interaction[59].



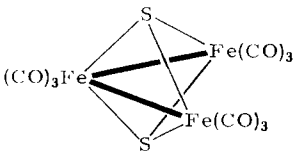
(26), L = $P(CH_3)_2C_6H_5$, $As(CH_3)_2C_6H_5$ *(27)*

The tendency for the formation of these complexes is high and the $(C_5H_5)_3M_3S_2$ system represented by *(27)* occurs in several variants[59–62]; one of these is the pentanuclear nickel complex *(28)*, which exhibits two M_3S_2 skeletons sharing a single corner.

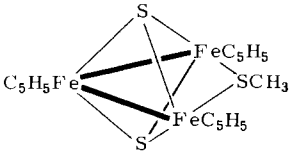


(28)

The longest-known member of this group is enneacarbonyl-triiron disulfide *(29)*, which is a representative of classical Hieber carbonyl chemistry and can be formed in a variety of ways[29, 63–65] and whose structure[66] with its two metal-metal bonds has an isoelectronic analog in the complex *(30)*[67].



(29)

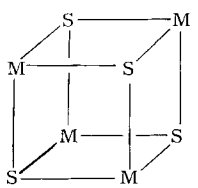


(30)

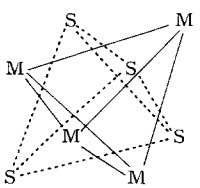
In all these complexes a unit of three metal atoms, which alone would not be stable, is doubly clamped together by the sulfur atoms.

2.3.3. Complexes with the M_4S_4-Cubane Skeleton

The arrangement of four metal atoms and four sulfur atoms in a cubane cluster has a particularly favorable geometry, for it permits the optimal M_3S bonding for the sulfur while satisfying the metal's demand for bonding to several sulfur atoms. In the M_4S_4-cubane each sulfur atom is bonded to three metal atoms, and each metal atom to three sulfur atoms; moreover, metal-metal interaction is also possible. Alternatively the cubane skeleton can be described as a double tetrahedron: one tetrahedron of metal atoms and another of sulfur atoms interpenetrate in inverse arrangement. The formulas *(31)* (cubane) and *(32)* (double tetrahedron) in which the atoms have the same arrangement illustrate the two methods of description.



(31)



(32)

If one interprets the full lines in *(31)* and *(32)* as denoting chemical bonds, then *(31)* represents the case with minimal and *(32)* the case with maximal metal-metal bonding. These cases occur in $[(C_5H_5)CoS]_4$[68] and $[(NO)FeS]_4$[69]; very many intermediate types are possible (cf. Section 2.5).

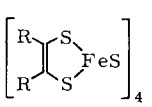
In the cubane clusters the greatest variety is shown by the cyclopentadienyl complexes $[(C_5H_5)MS]_4$ with M = Cr[70], Mo[71], Fe[72, 73], and Co[68, 74]. The metal introduced most frequently into M_4S_4-cubane geometry is iron. Fe_4S_4 structures with four different ligand systems are now known; the compound types are *(33)*[72, 73], *(34)*[69], *(35)*[75, 76], and *(36)*[77, 78].

$[(C_5H_5)FeS]_4$

(33)

$[(NO)FeS]_4$

(34)



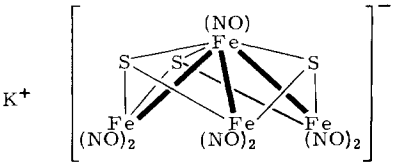
(35)

$[(RS)FeS]_4^{2-}$

(36)

This variety is confirmed by the finding that iron also occurs with Fe_4S_4-cubane geometry in Nature (cf. Section 4.1).

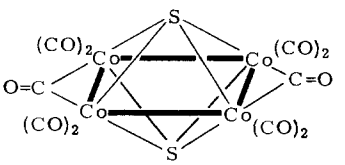
Finally, the black Roussain salt $K[Fe_4S_3(NO)_7]$ *(37)*[25, 26, 79] is an incomplete cubane whose Fe_4S_3 structure is reminiscent of the Mo_3S_4 situation in *(25)*.



(37)

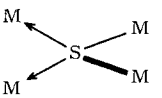
2.4. Sulfur Atoms as Bridges between Four Metal Atoms

So far only one case is known of a sulfur atom located as a four-electron donor above a plane containing four metal atoms, namely the complex $Co_4S_2(CO)_{10}$[3, 48, 49] having structure *(38)*[80].



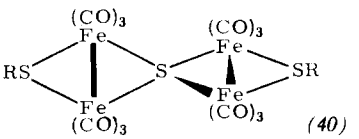
(38)

In all the other examples containing sulfur as a fourfold bridge the sulfur lies in a "tetrahedral hole" between four metal atoms. The sulfur no longer has any lone pairs because all six of its valence electrons are required for the four metal-sulfur bonds. The bonding relationships can be represented schematically as *(39)*, which, however, like *(20)*, is a crude simplification of the mostly symmetrical bonding system.



(39)

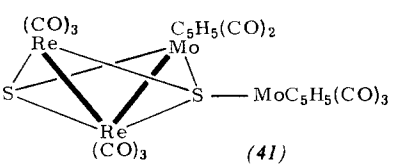
This type of complex exists in the iron compound *(40)* with R = CH_3[81] or R = *tert*-C_4H_9[82], whose structures are related to those of *(16)*[28] and $[(CO)_3Fe—SR]_2$[83], respectively.



(40)

Other complexes contain the SM_4 structural group as part of a complicated bonding skeleton, the arrangement of the metal atoms around the sulfur corresponding only roughly to a tetrahedron. Examples are the complex *(41)*[4] with two different metals and the two rhenium complexes shown in Figure 1. The two last-mentioned complexes are structurally related in that the Re_4S_3 nucleus of $S_3Re_6(CO)_{22}$ *(42)*[84] represents an incomplete cubane which is complete in $S_4Re_8(CO)_{32}$ *(43)*[85], for which an Mn analog exists[86].

Two interesting complexes that tend more toward conventional inorganic chemistry are $SM_4[S_2As(CH_3)_2]_6$ *(44)* with



(41)

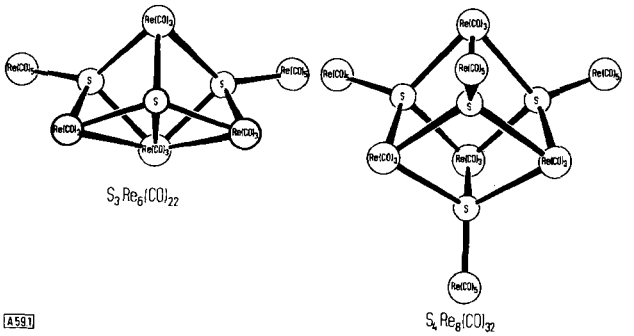


Fig. 1. Schematic structures of the complexes *(42)* and *(43)*.

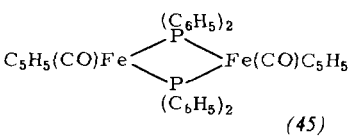
M = Co or Zn[87], whose SM_4 nucleus corresponds to the OM_4 nucleus in the structures derived from basic beryllium acetate[88]. In all the SM_4 complexes with the exception of *(38)* the coordination of the sulfur with four metal atoms corresponds to that in zinc sulfide, *i.e.* to a typical solid. Since the metal atoms in the cubane *(36)* are also surrounded tetrahedrally by four sulfur atoms, molecular sulfur complexes do in fact exist in which the bonding approaches or corresponds to that found in solid-state chemistry. However, no molecules are yet known in which the sulfur atoms are surrounded by six metal atoms, as in most of the transition-metal sulfides.

2.5. Modification of Metal-Metal Bonds

MO calculations for multinuclear transition-metal complexes with basic bridging atoms (P, As, S, Se)[69, 89, 90] by means of the parameter-free model of *Fenske* and *Hall*[91] have shown that the HOMOs and LUMOs[*] in these complexes have predominating metal-atom character and reflect bonding, nonbonding, or antibonding metal-metal interactions. These calculations provide the supplementary explanation of why such enormous variation in the bonding between the metal atoms can arise in the base-bridged multinuclear complexes of which the sulfur-bridged systems are a special case; for on the basis of the MO scheme a change in the number of electrons in the complex primarily affects the metal-metal bond while scarcely affecting the bond from the metal to the bridging atom, which is the actual stabilizing element of the polynuclear complex.

A convincing experimental example is provided by the phosphido-bridged complex *(45)*[89, 92].

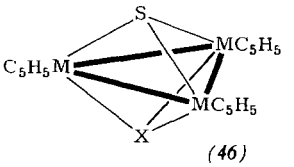


(45)

This must be formulated as a neutral complex without an Fe—Fe bond, because its HOMO is a σ*-orbital with respect to the interaction between the two iron atoms. Oxidation to $(45)^{1+}$ removes an electron from the σ*-orbital, and oxidation to $(45)^{2+}$ transforms the σ*-orbital into the LUMO, with the result that in $(45)^{1+}$ a half and in $(45)^{2+}$ a whole Fe—Fe bond is present. This is confirmed by the Fe—Fe interatomic distances: they amount to 3.49 Å in *(45)*, 3.12 Å in $(45)^{1+}$, and 2.78 Å in $(45)^{2+}$.

[*] HOMO = highest occupied molecular orbital, LUMO = lowest unoccupied molecular orbital.

The chemistry described here for complexes of the transition metals with sulfur contains many examples of this variability of metal-metal bonding. For example, the metal-metal separations in the complexes $(27)^{1+}$[59], $(33)^{1+}$[93], $(33)^{2+}$[94], and $[(C_5H_5)CoS]_4^{+}$[68] are smaller than in the corresponding neutral complexes, since metal-metal antibonding electrons are removed on oxidation. Still more impressive is a comparison of the complexes in which the number of electrons is changed by chemical modification. This modification may consist in the replacement of ligands or of metal atoms, as can be seen, *e.g.*, in the series of complexes *(46)*[59, 61].



(46)

In such a process replacement of the cobalt atoms by nickel atoms changes the total number of electrons by 3, and the four-electron donor sulfur supplies two more electrons than the CO group, a two-electron donor. The metal-metal bond lengths respond dramatically to variations in the number of electrons, while a qualitative MO consideration shows the electrons involved to be antibonding electrons[59, 61]. The numerical values are listed in Table 1.

Table 1. Structural data of complexes $(C_5H_5M)_3SX$ *(46)*.

Complex	Antibonding electrons	Average M—M distance [Å]
$(C_5H_5Co)_3S(CO)$	0	2.45
$(C_5H_5Co)_3S_2^{+}$	1	2.53
$(C_5H_5Co)_3S_2$	2	2.69
$(C_5H_5Ni)_3S_2$	5	2.80

According to the electron count the CO-bridged cobalt complex permits three metal-metal bonds, which are in fact observed. For the Ni_3S_2 complex, however, the count shows five excess electrons; their antibonding character is shown by the very weak Ni—Ni interaction.

Further experimental proof of the metal-metal bonding character of the highest occupied orbitals in such complexes has been provided for compound *(21)*. This complex contains an unpaired electron. A single-crystal ESR study[95] has shown that this electron is to be found in an antibonding A_2 orbital formed from metal d-orbitals. This is confirmed by the structurally similar complex $FeCo_2S(CO)_9$ *(47)*[96], in which a cobalt atom of *(21)* is replaced by iron and from which the antibonding electron is thus absent. Accordingly the metal-metal separation in *(47)* is 0.08 Å shorter than in *(21)*[97].

Aesthetically the deepest impression is imparted by variation in metal-metal bonding in the cubane complexes $[(C_5H_5)MS]_4$. In this series $[(C_5H_5)CoS]_4$[68] should be formulated without any metal-metal bond, since the cyclopentadienyl ligands and the sulfur atoms provide sufficient electrons to complete the 18-electron configuration of each cobalt atom. In the iron compound $[(C_5H_5)FeS]_4$[72, 73], however, there is one electron too few for each iron atom. This is compensated by formation of one metal-metal bond per iron atom, a total of two iron-iron bonds in the cubane, and the electron balance thus restored. Similarly, for $[(C_5H_5)MnS]_4$ two metal-metal

bonds per manganese atom are to be expected, making a total of four in the cubane; this complex is not yet known, but its electron count is approximated by the two complexes $[(C_5H_5)FeS]_4^{2+}$[94] and *(35)*$^{2-}$[76], which have the expected structure. Finally, in $[(C_5H_5)MoS]_4$[71] three metal-metal bonds per molybdenum atom are necessary for all the atoms to attain the noble-gas configuration; accordingly, here the metal atoms form a tetrahedral cluster of type *(32)*. Figure 2 surveys the structural changes in these cubanes.

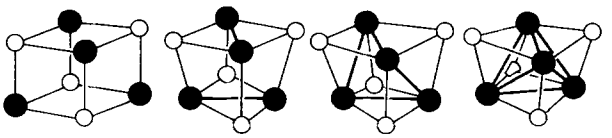


Fig. 2. Structures of M_4S_4 nuclei in the cubane complexes $[(C_5H_5)MS]_4$ with M = Co, Fe, Mn (hypothetical), and Mo. The cyclopentadienyl groups are situated symmetrically on each metal atom.

3. Synthesis and Reactivity

The chemical properties of the transition metal-sulfur complexes have hitherto been largely unexplored, perhaps because many of the complexes result from unusual reactions of unusual reactants and the yields are often low. Nevertheless, the tendency for their formation is illustrated by the fact that transition metals can abstract sulfur atoms from the most varied sulfur compounds.

In only few cases[18, 22, 36, 49, 63, 78, 98, 99] can H_2S or sulfide ions serve as starting materials for the complexes. More often the complexes are formed by the reaction of carbonylmetal derivatives with sulfur[3, 47, 48, 61, 69, 70, 72, 74, 96] or sulfur-transfer agents such as episulfides[11, 32, 64] or disulfanes[31, 49, 50, 54, 72]. From among the unusual sources of sulfur atoms we may mention thiocyanate[21, 81], carbonyl sulfide[23], and *tert*-butylsulfur diimide[60, 69]; in this context the manifold methods of forming the carbonyl-sulfide complexes of iron[29, 30, 63–65, 81, 82] and cobalt[3, 47–50, 53, 96] are especially striking. Most of these preparations are accompanied by the formation of metal sulfide. Stoichiometry can be given only very rarely, and reaction mechanisms never.

One possibility of directed synthesis is to introduce the sulfur as a functional derivative containing removable substituents. The simplest example would be H_2S, but this is too reactive and does not react unambiguously. In a few cases by using bis(trimethyltin) sulfide it was possible to transfer sulfur atoms by successive fission of tin-sulfur bonds with carbonylmetal halides[4, 85, 86], but even then obscure reaction courses could not always be avoided[58, 84, 86].

The thermal stability of the complexes of the transition metals and sulfur, which in some cases is quite high, is an advantage that has hitherto hardly been exploited for investigations of reactivity. Only redox reactions have been studied in detail[36, 37, 59, 68, 69, 75–78, 89, 93, 94]. The effects of altering the number of electrons have been described in Section 2.5, and replacement of CO groups by phosphanes[100, 101] has also been mentioned.

In some cases the sulfur complexes themselves served as the starting materials for the synthesis of related compounds. For instance, the pentanuclear nickel complex *(28)* was formed on decomposition of the trinuclear $(C_5H_5)_3Ni_3S_2$[62], and the cubane $[(C_5H_5)MoS]_4$ (cf. Fig. 2) was obtained by introducing a C_5H_5Mo group into the incomplete cubane *(25)*[71]. Other reactions of this kind are certainly possible, but isolation of the polynuclear structure from the complex reaction mixture would probably be difficult.

4. Biochemical Aspects

The popularization of inorganic biochemistry that resulted from the demand for social relevance in science has also brought certain aspects of metal-sulfur complex chemistry into the forefront of interest. This applies to verification of the complementary nature of the metal and the "labile" sulfur long known as individual constituents of many proteins, and also to the resulting attempts to determine the structure and function of the inorganic part of these proteins[5, 102]. For the most thoroughly investigated systems, namely those of iron and molybdenum, it can be said that we are approaching an understanding of their action. Here the initial difficulties have now been overcome, *e. g.* the oversimplified models proposed by inorganic chemists and the lack of chemical information about the complicated proteins available to biologists.

4.1. Ferredoxin Models

The ferredoxin problem stands out in the extensive literature about iron-sulfur proteins[37, 103–105]. The ferredoxins, proteins containing an even number of iron and "labile" sulfur atoms, are used by many organisms as electron-transfer agents. In view of the considerations in Section 2.5 it seems reasonable to assume that the redox center of these proteins lies in an iron-sulfur cluster, and there has been no lack of attempts to find this redox center and to imitate it in simple compounds. For a long time a handicap of these model investigations was that the isolable Fe_2S_2 and Fe_4S_4 complexes contained the stabilizing π-acceptor ligands which do not occur in Nature. Only very recently could models be developed for which a claim of similarity to Nature is justified.

In Fe_2S_2-ferredoxins each iron atom is known to be bound not only to the "labile" sulfide-sulfur atoms but also to two sulfur atoms of cysteine members of the polypeptide chain. This bonding eliminates almost all the known Fe_2S_2 complexes as model substances[35, 37, 104]. Compound *(48)* is the sole such complex in which the iron atoms are bonded only to sulfur and tetracoordinated[36].

$[(C_2H_5)_4N]_2^{\oplus}$  *(48)*

(48) corresponds to the natural material in its electronic spectra, Mössbauer spectra, and magnetic properties; only the redox potentials are different, because they do not depend only on the immediate coordination sphere of the iron[37, 104].

In contrast to the Fe_2S_2 system, the crystal structures of natural Fe_4S_4 redox proteins are already known. In all three cases they contain cubane-like $(-Cys-S-)_4Fe_4S_4$ structural units[106, 107]. Figure 3 illustrates the very symmetrical structure of the ferredoxin from *Peptococcus aerogenes*, with its two Fe_4S_4-cubane units[107]. Thus, the known simple Fe_4S_4

complexes[69, 72, 73, 75] are again excluded as model substances, even though they are excellent redox systems[90, 108–110]; nevertheless, discussion of the electronic structure of these complexes[69, 90] shows that the bonding differs from that in the natural system.

Only the synthesis and precise physicochemical investigation of the model compounds *(36)*, especially $[(C_6H_5—CH_2S)FeS]_4^{2-}$, provide an adequate approximation to the natural state[77, 78, 111–113]. The complexes *(36)* are comparable in all their spectra with the Fe_4S_4-ferredoxins. In particular, they also exhibit electron delocalization in the various oxidation stages; this means, for example, that the two Fe^{II} and two Fe^{III} ions formally required in the molecules $[(RS)FeS]_4^{2-}$ cannot be distinguished. However, it should be mentioned that the structural elucidation and the imitation of these ferredoxins by models still does not explain their mode of action, and especially their mode of electron transfer[107].

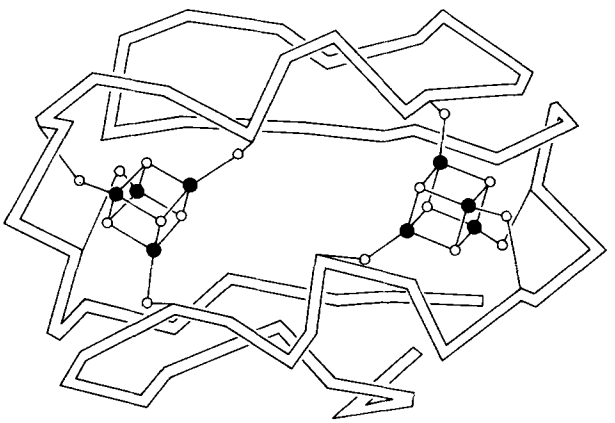

Fig. 3. The polypeptide chain and $[(RS)FeS]_4$ units in the ferredoxin from *Peptococcus aerogenes*.

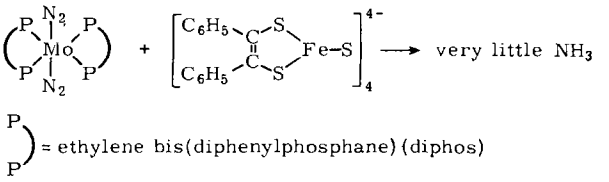
4.2. Models of Molybdenum Enzymes

The biochemistry of molybdenum has not yet afforded such detailed information as in the case of iron[114, 115]. Molybdenum is known essentially to occur in redox enzymes such as xanthine oxidase, aldehyde oxidase, nitrate reductase, and nitrogenase together with sulfur-containing ligands and perhaps also "labile" sulfur. However, caution must be exercised in discussing sulfur-bridged molybdenum complexes such as *(18)* and similar systems[33, 38–44, 98, 99] proposed as model substances.

Owing to the eminent industrial importance of nitrogen fixation[116], particular interest attaches to the enzyme nitrogenase, which converts nitrogen into ammonia under normal conditions. Purification and investigation showed it to consist of two proteins[117, 118]. One of these contains two iron and two "labile" sulfur atoms, and the other one molybdenum and about 16 iron and "labile" sulfur atoms. Thus, sulfur-bridged Mo_2 complexes are excluded, although the iron and sulfur contents are reminiscent of the ferredoxins. Since the nitrogen uptake of the enzyme no longer occurs in the absence of molybdenum, it seems likely that the molybdenum is required for binding of the nitrogen molecule, and the iron-sulfur units for delivery of the reduction equivalents. While this hypothesis has not yet been verified by enzyme studies, it has already been tested in a model experiment with a molybdenum-N_2 complex and a ferredoxin analog[119]:



A similar reaction was attempted with $[(C_2H_5S)FeS]_4^{3-}$[120], but the ammonia yields were always very low and could not even be confirmed in one case[121].

Summarizing, investigation of nitrogenase has not yet advanced to the stage of close cooperation between biology and inorganic chemistry characterizing the ferredoxin problem.

5. Outlook

This progress report, which covers the literature up to the middle of 1974, finds the chemistry of the metal-sulfur complexes in a transitional state. Whereas the main emphasis has hitherto been placed on finding new structural characteristics, interest is now passing to the preparation of such structures and to the study of their practical importance. The ease with which transition-metal compounds undergo redox reactions without changing their chemical composition, as shown by polynuclear complexes in general and by metal-sulfur clusters in particular, could be important in this connection, and should provide a stimulus not only to biochemistry but also to catalysis research. Finally, the question of how far the stabilizing bonding principles in sulfidic solids are retained in the molecular compounds containing transition-metals and sulfur provides a challenge to both the theoretical and the practical chemist.

Our own research reported in this article was supported by the Deutsche Forschungsgemeinschaft and the National Science Foundation. My colleagues and co-workers Dr. V. A. Uchtman, Dr. P. J. Vergamini, and Dipl.-Chem. V. Küllmer participated in this work. The author is grateful to Professor L. F. Dahl of the University of Wisconsin for stimulating these studies and for many vigorous discussions. Prof. L. F. Dahl, Prof. E. O. Fischer, and Dr. W. P. Fehlhammer kindly placed some unpublished results at our disposal.

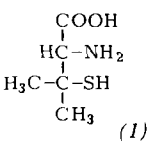
D-Penicillamine—Production and Properties

By Wolfgang M. Weigert, Heribert Offermanns, and Paul Scherberich[*]

The non-naturally occurring amino acid D-penicillamine, originally only of interest as a key substance in the structural elucidation and total synthesis of penicillins is gaining increasing importance as a therapeutic, particularly in the long-term treatment of rheumatoid arthritis. D-Penicillamine which previously was obtained semi-synthetically by degradation of penicillins can now be totally synthesized using a new process which starts from isobutyraldehyde, sulfur, ammonia, and hydrogen cyanide and yields the racemate which is then selectively resolved. The biochemical behavior of D-penicillamine—chelate formation with heavy metal ions, cleavage of disulfide bridges, and condensation with aldehyde groups—affords information related to its therapeutic activity.

1. Introduction

In 1943, during their investigations on the structural elucidation of penicillins, *Abraham et al.*[1, 2] ("The Oxford Group") found all penicillins to give a common degradation product which, in ignorance of its exact structure, was called "penicillamine" because of the presence of an amino group in the molecule. The β,β-dimethylcysteine structure *(1)* postulated by *Cornforth*[1] was later confirmed by the "Oxford Group" on investigation of its reactions and synthesis[1].



(1)

"Penicillamine" is levorotatory in alkine solution and, with respect to its absolute configuration, belongs to the D-series of amino acids. The correct chemical name for "penicillamine" is D-(−)-2-amino-3-mercapto-3-methylbutyric acid. Common synonyms are: D-(−)-β,β-dimethylcysteine; D-(−)-β-mercaptovaline; and D-(−)-2-amino-3-mercaptoisovaleric acid. In this report the substance will be called D-penicillamine.

D-Penicillamine *(1)* was at first solely of interest as a key substance in the structural elucidation of penicillins and as a central building block in their total synthesis[3, 4]. In 1956, D-penicillamine, which itself possesses no antibiotic activity, was first introduced into medicine as a chelating agent to accelerate the elimination of physiological heavy metals present in high, non-physiological concentrations (therapy of Wilson's disease) and non-physiological heavy metals (antidote in heavy metal poisoning)[5, 6].

D-Penicillamine is becoming increasingly important as a basis therapeutic in rheumatoid arthritis (chronic polyarthritis)[7–9]. Further new indications for D-penicillamine, *e. g.* chronic aggressive hepatitis[10–13] and multiple sclerosis[14], are becoming apparent.

Only pure D-penicillamine is of therapeutic importance as the racemate and the L-isomer are toxic. Further differences between D- and L-penicillamine lie in their antagonistic activity towards vitamin B_6 and their molecular biological behavior (see Section 4.3).

2. Manufacture of D-Penicillamine

D-Penicillamine can be manufactured either semi-synthetically by degradation of penicillins or completely synthetically *via* the racemate. Production from penicillins has been considerably improved in the last few years[15]. A new process for the manufacture of fully-synthetic D-penicillamine *via* the racemate and its resolution ("Asinger process") is now also being carried out industrially. Both processes produce highly pure D-penicillamine which is then used as the active ingredient in drug manufacture[*].

2.1. Manufacture of D-Penicillamine by Degradation of Penicillins

On degradation of penicillins [*e. g.* penicillin G *(2)*, Scheme 1]both the β-lactam ring and the thiazolidine ring are opened. The β-lactam ring is best cleaved in the presence of alkali; the resulting penicilloic acid *(3)* is decarboxylated to penilloic acid *(4)*. As a 2-monosubstituted thiazolidine-4-carboxylic acid, *(4)* is relatively stable to hydrolysis. Thus cleavage to D-penicillamine *(1)* and the aldehyde *(5)* requires removal of one or both of the decomposition products from the hydrolysis equilibrium.

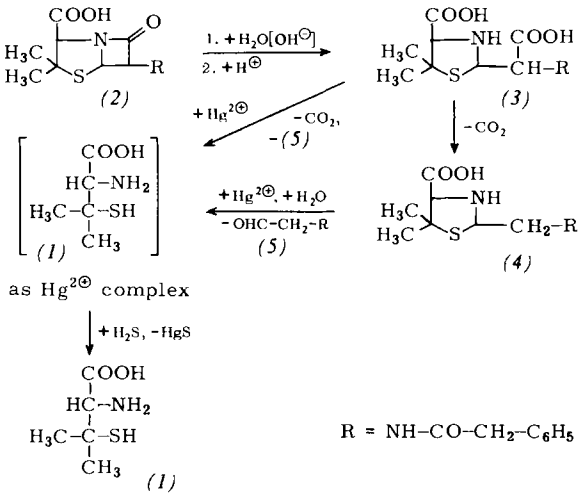
Preferably *(1)* is converted into the sparingly soluble 1:1 or 2:1-D-penicillamine-mercury(II) complexes and separated from the readily soluble product *(5)*[15, 16] (see Section 4.1 for the structure of the complexes).

Treatment with hydrogen sulfide liberates *(1)* from the mercury complex, mercuric sulfide being formed as by-product. Compound *(3)* can also be cleaved directly by mercuric salts. In this variant, decarboxylation and thiazolidine ring opening proceed simultaneously.

In another process the D-penicillamine-mercury 1:1 complex is kept in solution by addition of acid and the aldehyde *(5)*, after reaction with a carbonyl reagent, *e. g.* hydrazine or hydroxylamine, is separated by extraction with an inert organic solvent which is immiscible with water[17].

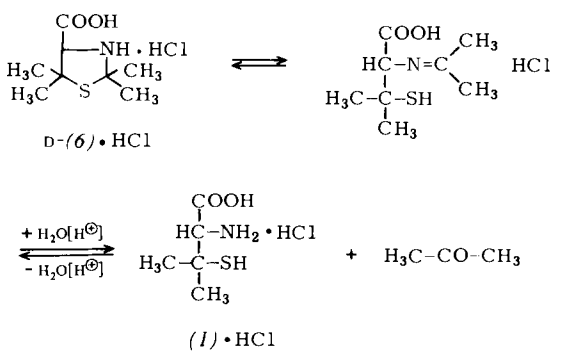
The use of other heavy metal salts in place of the expensive and toxic mercury salts has been recommended[18]. Without the use of heavy metal salts, *(3)* and *(4)* can be converted into D-penicillamine using 5,5-dimethyl-1,3-cyclohexanedione (dimedon)[19] or 4-hydroxycoumarin[20].

[*] D-Penicillamine (semisynthetic): Metalcaptase® (Knoll AG, Ludwigshafen/Heyl & Co, Berlin); D-penicillamine (fully synthetic): Trovolol® (Chemiewerk Homburg, Frankfurt (Main)/Bayer AG, Leverkusen).



Scheme 1

Purification of *(1)* is most suitably carried out by conversion into the hydrogen chloride of D-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid *(6)*. This latter product *(6)* is also known as "D-penicillamine-acetone adduct" or "isopropylidene-D-penicillamine" due to the ease with which it can be reconverted into acetone and *(1)*[30, 31].

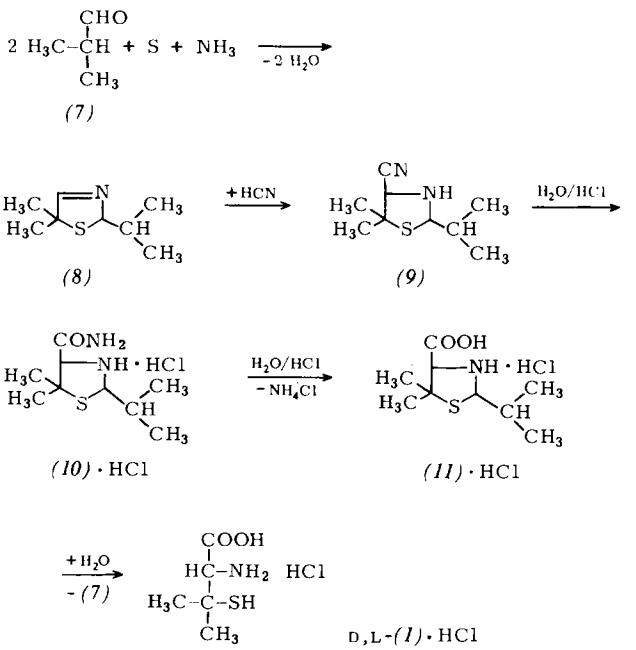


2.2. Manufacture of D-Penicillamine *via* the Racemate

The new fully synthetic process for the manufacture of D,L-penicillamine *via* 3-thiazoline starting from isobutyraldehyde, sulfur, ammonia, and hydrogen cyanide, and the new procedure for obtaining pure D-penicillamine from the racemate without the inevitable production of the L-isomer are based on the fundamental work of *Asinger et al.*[21–24] and have been developed by Degussa/Chemiewerk Homburg[*] to technical maturity[25]. Apart from this technique, which is an alternative to the hydrolysis of penicillins, there are several other procedures for the production of D,L-penicillamine and resolution of the racemate which were primarily developed in connection with the structural elucidation and total synthesis of penicillins during World War II. A description of these methods will be dispensed with here as a detailed review is already available[1]. However, we shall discuss two new synthetic routes, one of which starts from isocyanoethyl acetate and the other utilizes a modified Strecker synthesis.

2.2.1. Synthesis of D,L-Penicillamine *via* 3-Thiazoline

The simultaneous reaction of sulfur and ammonia with isobutyraldehyde *(7)* affords 2-isopropyl-5,5-dimethyl-3-thiazoline *(8)* in *ca.* 80% yield if the resulting water is azeotropically removed (see Scheme 2). Benzene, toluene, cyclohexane, chloroform, or preferably an excess of isobutyraldehyde itself can be used as the azeotropic partner[26]. The 3-thiazoline *(8)* itself is purified by rectification (b.p. 68—70°C/12 torr).



Scheme 2

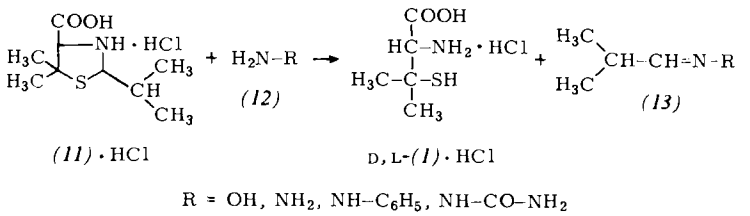
Anhydrous hydrogen cyanide adds across the azomethine group of *(8)* to form 2-isopropyl-5,5-dimethylthiazolidine-4-carbonitrile *(9)* almost quantitatively. The hydrogen cyanide itself can be introduced either as a liquid or as a gas, or actually generated within the reaction mixture itself, for example from sodium cyanide and acids. If addition of HCN is carried out in an inert solvent, *e.g.* diethyl ether or petroleum ether, *(9)* can be isolated in crystalline form (m.p. ≈30°C) by cooling the reaction mixture. It is also possible to work in the absence of solvent and continue directly with the crude nitrile *(9)*.

In order to convert *(9)* into D,L-penicillamine the nitrile group must be saponified to a carboxyl group and the thiazolidine ring opened[27]. This is preferably carried out in several steps: *(9)* dissolved *e.g.* in methanol containing sufficient water to form the amide is treated with hydrogen chloride at 50—65°C. 2-Isopropyl-5,5-dimethylthiazolidine-4-carboxamide hydrogen chloride *(10)*·HCl is then obtained in crystalline form. *(10)*·HCl is subsequently hydrolyzed by refluxing with 10—20% hydrochloric acid to form 2-isopropyl-5,5-dimethylthiazolidine-4-carboxylic acid hydrogen chloride *(11)*·HCl[28]. Use of gaseous hydrogen chloride can be avoided by converting *(9)* into *(10)*·HCl by treatment with at least 30% aqueous hydrochloric acid at 40—70°C[29].

As a 2-monosubstituted thiazolidine derivative, *(11)*·HCl is extremely stable to hydrolytic ring opening[30, 31]. However it is possible to quantitatively convert *(11)*·HCl into D,L-penicillamine hydrogen chloride if the isobutyraldehyde *(7)* formed is azeotropically steam distilled out of the hydrolysis equilibrium[27]. In a variant of this procedure[32] the isobutyraldehyde is converted with a carbonyl reagent *(12)*, *e.g.* hydroxylamine, hydrazine, phenyl hydrazine, or semicarb-

[*] Degussa/Chemiewerk Homburg (Pharmaceutical Division of Degussa).

azide in aqueous solution into a derivative *(13)* which can be isolated by extraction with an inert organic solvent, *e.g.* toluene or chloroform, which is immiscible with water.



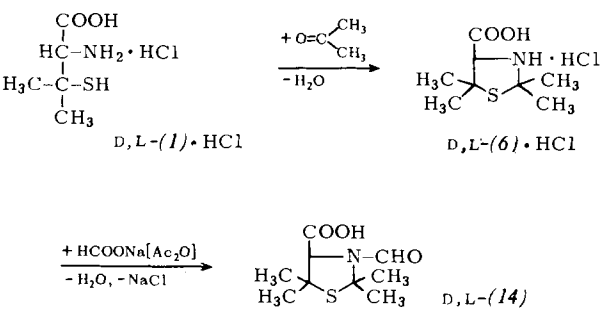
(11) · HCl D,L-*(1)* · HCl

R = OH, NH_2, NH–C_6H_5, NH–CO–NH_2

These methods for ring cleavage of *(11)* · HCl afford an aqueous solution of D,L-penicillamine hydrogen chloride containing ammonium chloride originating from saponification of the nitrile.

The D,L-penicillamine or its hydrogen chloride need not be isolated; after evaporation of the water it is preferable to react the D,L-penicillamine hydrogen chloride, with acetone in an organic solvent, *e. g.* toluene, which is immiscible with water. In this way crystalline D,L-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid hydrogen chloride, D,L-*(6)* · HCl is obtained in admixture with ammonium chloride. From this mixture D,L-penicillamine can be isolated in the pure form or converted into a suitable derivative for resolution.

A new procedure[33] using sodium formate in the presence of acetic anhydride in an organic solvent not miscible with water can be used to advantage for converting D,L-*(6)* · HCl into the corresponding *N*-formyl derivative D,L-*(14)* and permits removal of inorganic salts. The D,L-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid D,L-*(14)*, obtained in high yield and in excellent purity, is well suited for enantiomerization (see Section 2.2.3).



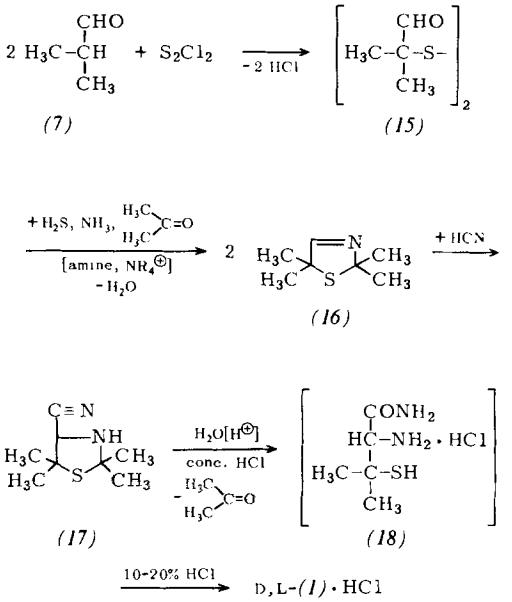
D,L-*(1)* · HCl D,L-*(6)* · HCl

D,L-*(14)*

Using a variant of this technique, D,L-penicillamine can also be prepared from 2,2-dialkyl-5,5-dimethyl-3-thiazolines, and preferably from 2,2,5,5-tetramethyl-3-thiazoline *(16)* (Scheme 3). *(16)* cannot be obtained from isobutyraldehyde *(7)* in one step. For the preparation of *(16)*, isobutyraldehyde is initially reacted with disulfur dichloride to give 2,2'-dithiodiisobutyraldehyde *(15)*[34]. Simultaneous treatment of a mixture of *(15)* and acetone with hydrogen sulfide gas and ammonia gas furnishes *(16)*[35] in satisfactory yields provided that the reaction is carried out in the presence of amines and ammonium salts[36].

The nitrile *(17)* obtained by addition of hydrogen cyanide can be easily hydrolyzed to D,L-penicillamine hydrogen chloride without isolating the intermediate *(18)*[37].

This process does not require a steam distillation or use of a carbonyl reagent for ring cleavage since *(17)* is a 2,2-disubstituted thiazolidine derivative and thus undergoes facile hydrolytic cleavage[31]. Saponification of *(17)* to D,L-*(1)* · HCl has considerable advantages over the previously described pathway *via* the ester of tetramethylthiazolidine-4-carboxylic acid[21]. However, the ease of ring opening in *(17)* does not compensate for the disadvantage of the more complicated synthesis of the thiazoline *(16)* itself.

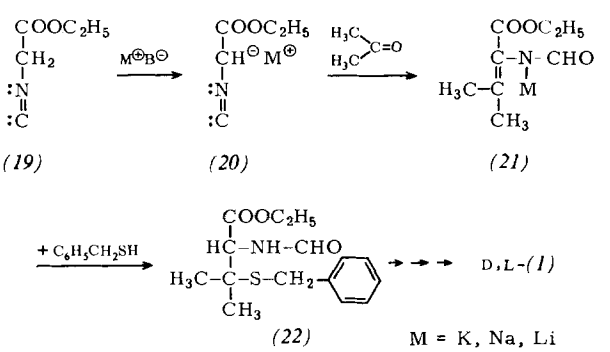


(7) *(15)* *(16)* *(17)* *(18)* D,L-*(1)* · HCl

Scheme 3

2.2.2. Synthesis of D,L-Penicillamine by Other Recent Methods

A general synthesis of *S*-benzyl-*N*-formylcysteines which is also suitable for the manufacture of D,L-*S*-benzyl-*N*-formylpenicillamine developed by *Schöllkopf* and *Hoppe*[38] starts from ethyl isocyanoacetate (see Scheme 4).



(19) *(20)* *(21)* *(22)* M = K, Na, Li D,L-*(1)*

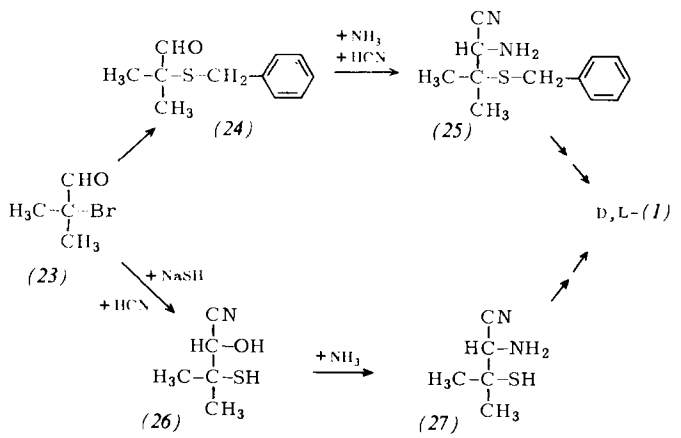
Scheme 4

Metalation of ethyl isocyanoacetate *(19)* by potassium *tert*-butoxide, sodium hydride, or *n*-butyllithium in tetrahydrofuran, and subsequent reaction of the metalated ester *(20)*

with acetone gives the metalated α-formylaminoacrylate *(21)* Treatment of *(21)* with thiobenzyl alcohol and hydrolysis with potassium hydroxide solution yields the ester *(22)* which can be selectively hydrolyzed to D,L-*S*-benzyl-*N*-formylpenicillamine or hydrolytically deformylated and then debenzylated to D,L-penicillamine.

D,L-Penicillamine can also be prepared by a kind of Strecker synthesis[39] (see Scheme 5) in which α-bromoisobutyraldehyde *(23)* is reacted with the sodium salt of thiobenzyl alcohol to give α-benzylthioisobutyraldehyde *(24)*. This product reacts with hydrogen cyanide and ammonia to form the nitrile *(25)*, which can be converted by hydrolysis and debenzylation into D,L-penicillamine in moderate yield.

According to *Ugi* and *Böttner*[40] α-hydroxy-β-mercaptoisovaleronitrile *(26)* can be obtained from α-bromoisobutyraldehyde by reaction with sodium hydrogen sulfide and hydrogen cyanide (see Scheme 5). *(26)* is converted by ammonia into *(27)*, which according to *Böttner*[41] can be saponified to D,L-penicillamine.



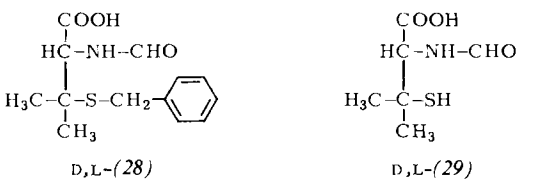
Scheme 5

The methods described in this section do not generally afford pure D,L-penicillamine but rather a derivative suitable for resolution.

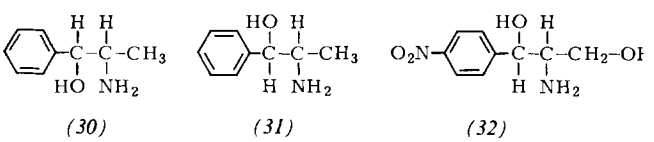
2.2.3. Isolation of D-Penicillamine from the Racemate

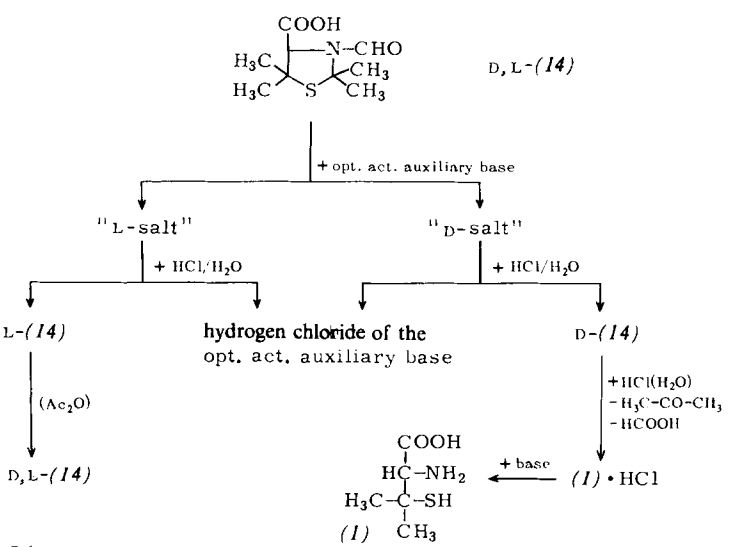
Owing to the widely differing biological properties of the optical antipodes of penicillamine (see Sections 1 and 4.3) it is necessary to quantitatively remove the undesirable L-isomer.

Optical resolution of D,L-penicillamine is performed by the classical method of transforming optical antipodes into diastereoisomers. Thus suitable derivatives of D,L-penicillamine are converted into the diastereomeric salts with alkaloids or other optically active auxiliary bases. Resolution is performed with *N*-acyl derivatives of D,L-penicillamine and of D,L-*S*-benzylpenicillamine as well as with the *N*-acyl derivatives of the condensation products of D,L-penicillamine with carbonyl compounds, especially D,L-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, D,L-*(14)*. The first racemic resolution was achieved by the previously mentioned "Oxford Group"[42] who resolved D,L-*S*-benzyl-*N*-formylpenicillamine, D,L-*(28)* using the alkaloid brucine. D,L-*N*-Formylpenicillamine, D,L-*(29)* and D,L-*(14)* can also be enantiomerized with brucine[43, 44].



Other bases used in the racemic resolution of D,L-penicillamine are thebaine[45], quinidine[46], cinchonidine[46], (−)-ephedrine[44, 46], and (+)-pseudoephedrine[46]. Regarding the need to quantitatively remove the therapeutically undesirable L-penicillamine, the above optical bases are not wholly suitable for obtaining pure D-penicillamine because in some cases the salts of L-penicillamine derivatives crystallize from the solution first. This is a disadvantage since the diastereoisomer which crystallizes out first always possesses the higher purity[47, 48]. Moreover, the yields are unsatisfactory. For an economically viable separation of the antipodes the very expensive or highly toxic alkaloids can hardly be considered. L-





Scheme 6

Lysine[49], (−)-norephedrine *(30)*[50], (−)-pseudonorephedrine *(31)*[51], and D-(−)-*threo*-2-amino-1-(*p*-nitrophenyl)-1,3-propanediol *(32)*[52] are most suitable as auxiliary bases. These bases are preferentially reacted with D,L-*(14)* according to Scheme 6.

In all cases the amine salts of the D-penicillamine derivatives ("D-salts") are obtained as the more insoluble diastereoisomers. In suitable solvents the solubility differences between the diastereoisomeric salts are so large that quantitative removal of the L-penicillamine derivative becomes feasible. The "D-salts" are preferentially treated with dilute hydrochloric acid in the cold to form the water-soluble hydrogen chloride of the optical base and the sparingly water-soluble D-penicillamine derivative D-*(14)*. On deformylation and ring opening D-*(14)* furnishes pure D-penicillamine · HCl, which can be converted into free D-penicillamine *(1)* with, for example, triethylamine in an alcohol.

The amine salt of the L-penicillamine derivative ("L-salt") retained in the mother liquor on resolution is likewise cleaved with dilute hydrochloric acid to give L-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid L-*(14)*. This product is quantitatively racemized, for example, on refluxing in toluene containing catalytic quantities of acetic anhydride[53], and subjected to renewed resolution. It is thus possible—apart from the losses inevitably incurred by processing—to quantitatively obtain D-penicillamine from the racemic penicillamine derivatives. The optically active adjuvant bases can be almost completely recovered.

3. Physical Properties and Analysis of D-Penicillamine

D-Penicillamine *(1)* is a colorless crystalline powder with a weak odor typical of sulfur-containing amino acids, and a characteristic taste. It is relatively soluble in water but less so in alcohols and almost insoluble in ether, chloroform, carbon tetrachloride, and aliphatic or aromatic hydrocarbons.

(1) melts with decomposition at 202—206 °C (Mettler FP melting point apparatus, starting temperature 195 °C, heating rate 2°/min).

Qualitative identification of *(1)* is based on the reaction with iodine solution (decolorized due to oxidation of the SH group), ninhydrin (blue-violet color), phosphortungstic acid (deep blue color), and acetone (colorless precipitate)[54].

Quantitative determination is best carried out by titration against mercuric acetate solution in the presence of diphenylcarbazone as indicator[54]. Traces of impurities, *e. g.* D-penicillamine disulfide *(39)* may be detected either by TLC or, after silylation, by GLC.

In 1 N sodium hydroxide solution [5 g *(1)* in 100 ml] *(1)* is levorotatory. The pure compound *(1)* to be used as a drug constituent should have an optical rotation of −62.5 to −63.5° (at 20 °C in sodium D light = 589 nm). D-Penicillamine prepared according to the "Asinger process" is identical in its physical, spectroscopic, and chemical properties with the material obtained from penicillin. The stereochemical equivalence of the fully and semi-synthetic D-penicillamine can be confirmed by precision polarimetry and ORD spectroscopy. No traces of the L-isomer can be detected in either semi-synthetic or fully-synthetic D-penicillamine used in drugs formulation by present-day physical methods.

The optical purity can also be confirmed[56] by tests with *E. coli* bacteria, whose growth is selectively inhibited by L-penicillamine[55]. Again no difference was found between semi-synthetic and fully-synthetic D-penicillamine.

4. Biochemical Properties of D-Penicillamine

The biochemical properties of D-penicillamine are primarily based on three types of reaction in which the amino and mercapto groups are principally involved:

1) Chelate formation with heavy metal ions; 2) exchange reactions with low molecular and high molecular weight disulfides; 3) condensation with aldehydes.

4.1. Chelate Formation

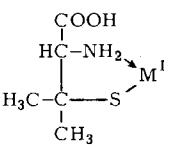
D-Penicillamine is a strong complexing agent and reacts with the majority of heavy metal ions, particularly with those with an affinity for S, to form chelates[57]. While D-penicillamine forms only a 1:1 complex of type *(33)*, *e. g.*, with $Cu^{\oplus}$ ions[58-61], it forms not only 1:1 complexes of types *(33)* and *(34)* but also 2:1 *(35)* or sometimes 3:1 complexes[59-63] with other heavy metal ions.

Depending on the number of functional groups involved in complex formation D-penicillamine functions as a bidentate *(33)* or tridentate ligand *(34)*.

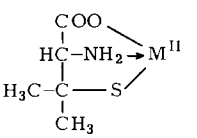
Of the physiological metal ions which participate in complex formation with D-penicillamine, copper, zinc, iron, cobalt, manganese, and nickel deserve mention.

The therapeutic activity of D-penicillamine in the treatment of Wilson's disease is based upon chelate formation with protein-bound copper and its rapid excretion[59, 64, 65]. A similar mode of activity is assumed in for example the treatment of sclerodermia[66] and schizophrenia[67, 68] with D-penicillamine.

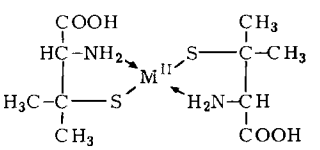
Chelate formation is also the basis for the antidote action of D-penicillamine in heavy metal poisoning, *e. g.* by mercury or lead compounds[69-71].



(33)



(34)



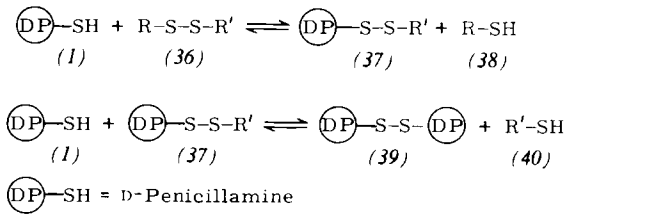
(35)

Undesirable side effects caused by elimination of zinc or other biometals can be avoided by substitution[72].

4.2. Exchange Reactions with Disulfides

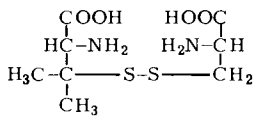
D-Penicillamine *(1)* can react with disulfides *(36)* in organisms according to Scheme 7[73-75]; the mixed disulfide of D-penicillamine *(37)* and the free thiol *(38)* are formed.

(37) can react further with D-penicillamine to give D-penicillamine disulfide *(38)* and the thiol *(40)*.



Scheme 7

The formation of the mixed disulfide *(41)* from D-penicillamine and L-cysteine and of the symmetrical disulfide *(39)* is decisive for the treatment of cystinuria and the associated formation of urinary calculus (cystine stones)[73, 76]. D-Penicillamine disulfide *(39)* and D-penicillamine L-cysteine disulfide *(41)* are much more soluble than cystine and are thus eliminated.

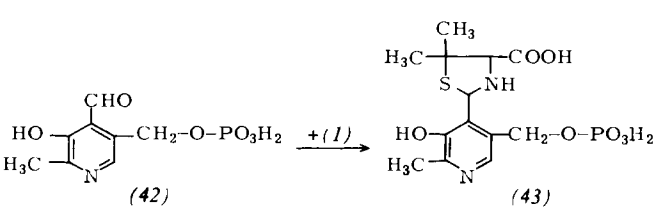


(41)

Similar exchange reactions can also take place with proteins linked intermolecularly through S—S bridges, *e. g.* immunoglobulins, pathological macroglobulins (rheumatic factors) which play an important role in the pathogenesis of rheumatoid arthritis[77–80]. It is suspected that the macroglobulins lose their pathogenic properties through depolymerization according to Scheme 7. This is partly the reason for the use of D-penicillamine in cases of rheumatoid arthritis. The depolymerizing activity of D-penicillamine on macroglobulins was confirmed by *in vitro* experiments[81, 82].

4.3. Reactions with Aldehydes

D-Penicillamine reacts with the aldehyde group of pyridoxal 5'-phosphate *(42)* to form the thiazolidine derivative *(43)*[83–85].

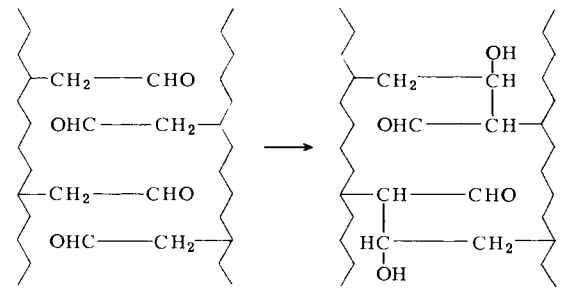


(42) *(43)*

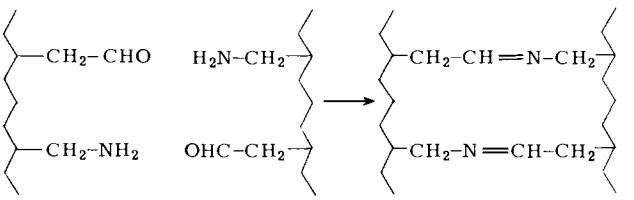
The co-enzyme *(42)* which is formed in the organism from vitamin B_6 plays an important role in amino acid metabolism, in the synthesis of coenzymes, as well as in the biosynthesis of hormones such as adrenalin.

Both isomers of penicillamine possess an anti-vitamin B_6 effect, that of the L-isomer being considerably stronger than that of *(1)*[86, 87]. For this reason, the therapy with D-penicillamine of high stereochemical purity is of particular importance. Vitamin B_6 deficiency symptoms caused by treatment with D-penicillamine are relatively rare and can be corrected by the simultaneous administration of vitamin B_6[88–90]. However, it appears that there is no direct correlation between the reaction of D-penicillamine with *(42)* and its therapeutic activity.

The crosslinking of collagen fibers (tropocollagens) soluble in physiological saline solution to insoluble precollagens plays an important roll in sclerodermia[91–93], chronic aggressive hepatitis[10], and rheumatoid arthritis[94]. The formation of insoluble precollagens is probably initiated by enzymatic oxidation of the ε-amino groups of lysine residues to aldehyde groups. It is assumed that the aldehyde groups are crosslinked *via* aldol condensations (Scheme 8) or by the formation of azomethine bridges (Scheme 9)[95–97].



Scheme 8



Scheme 9

D-Penicillamine reacts with the aldehyde groups of the soluble collagens forming thiazolidines and thus inhibits crosslinking[58, 97].

In contrast to other sulfur-containing amino acids, *e.g.* cysteine D-penicillamine is relatively stable in the organism, and thus its therapeutic activity is fully displayed. It is primarily converted by oxidation or exchange reactions according to Scheme 7 into the disulfides *(39)* and *(41)* and eliminated in this form[98]. Unlike L-penicillamine, D-penicillamine cannot be incorporated into proteins or inhibit protein synthesis[99–101].

Prostaglandins

By Wilhelm Bartmann[*]

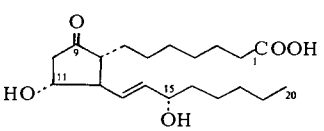
The prostaglandins are lipid-soluble C_{20}-carboxylic acids containing a five-membered ring, several oxygen functions, and at least one double bond. They are found in animal organisms where they stimulate, *inter alia*, the smooth muscle. In the last decade more has been learned about the occurrence, biosynthesis, metabolism and pharmacological properties of the prostaglandins. Analytical methods for their determination, and syntheses for the naturally occurring prostaglandins and their synthetic analogs have been developed. In this report, an attempt is made to show why new knowledge has dramatically stimulated pharmaceutical research in this field.

1. Introduction

In 1965 there appeared in this journal an article dealing primarily with the structural elucidation and biosynthesis of prostaglandins[1]. In the same year some 60 other publications on prostaglandins appeared in the literature. It is estimated that about four papers are now being published each day on these natural products; in the following report, therefore, no attempt has been made to compile a bibliography of prostaglandin research, since numerous excellent reviews, some already in book-form, are available on special aspects of the prostaglandins[2–8].

Generalizing, from the standpoint of the pharmaceutically orientated chemist there have so far been three major phases of development in prostaglandin research:

1. The period of structural elucidation which culminated in 1966 with a joint publication by the research teams of *Bergström et al.* and *van Dorp et al.* on the determination of the absolute configuration of prostaglandin E_1 *(1)*[9].



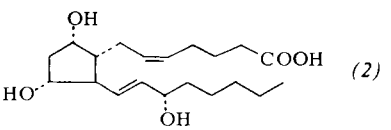
(1)

(1) Prostaglandin E_1 (PGE_1)=(−)-11α,15(*S*)-dihydroxy-9-oxo-13-*trans*-prostenoic acid [**]

2. The synthetic phase in which, from 1965 to 1973, the basic scientific problems of the total synthesis were solved.

3. The molecular-biological phase in which, initially in 1964[10] and intensified since about 1970, the multitudinous, and apparently contradictory, physiological properties of the prostaglandins began to be understood, through the recognition of their molecular biological role in nature (see for example Ref. [7]).

A fourth phase—that of a broad employment of naturally occurring prostaglandins or their synthetic analogs in medicine—has, despite the intensive worldwide efforts of the pharmaceutical industry, not yet got underway if one disregards the single example of the marketing of $PGF_{2\alpha}$ *(2)* as an abortifacient[11].



(2)

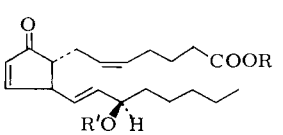
(2) Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)=(−)-9α,11α,15(S)-trihydroxy-5-*cis*-13-*trans*-prostadienoic acid.

In spite of a certain disillusionment, interest in the prostaglandins continues undiminished—on the one hand because of the ubiquity of these natural products, which are structurally and biogenetically related to the long chain fatty acids, and on the other hand because of their manifold biological properties.

2. Occurrence

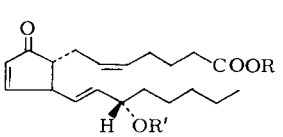
Prostaglandins have been detected in almost all animal organs, albeit in small and tissue-dependent quantities[12]. All investigations carried out so far would suggest that they are synthesized by an enzyme complex, prostaglandin synthetase[13], at the active site and are then rapidly deactivated[14] by another specific enzyme.

Prostaglandins of the A-series or their esters occur in relatively large quantities in a Carribean coral—both in the physiologically inactive (15*R*)-form *(3)* as well as in the active (15*S*)-form *(4)*[15].



(3)

(3a), R = R' = H
(3b), R = CH_3, R' = CH_3CO



(4)

(4a), R = R' = H
(4b), R = CH_3, R' = CH_3CO

Up to 1.5 % by weight of a mixture of several prostaglandins has been isolated from the cortex of wet frozen horny corals *Plexaura homomalla*. This naturally occurring source is already being commercially exploited[16]. The prostaglandins A so obtained serve as starting material for other natural and synthetic prostaglandins.

From results published in the literature so far it would appear doubtful that this biological source will acquire the same degree of importance for the industrial production of prostaglandins as the isolation of the diosgenins from dioscorea species has for the partial synthesis of steroid hormones.

[*] Dr. W. Bartmann
Hoechst AG, Pharma Synthese
623 Frankfurt (M) 80, Postfach 800320 (Germany)

[**] For the structure of other prostaglandins and their nomenclature see also formulas *(2)*, *(4)*, *(7)*, and *(47)* and Ref. [6].

The physiological role played by prostaglandins occurring in marine organisms is as yet unclear[15]; equally unclear is their mode of formation in these lower forms of life[17]. While prostaglandins are known to occur in a very early stage of evolution in the animal kingdom they have not been demonstrated with certainty in the plant kingdom[18].

Prostaglandin-synthetase has been found in a broad spectrum of species including primates, pigs, sheep, and rats down to fishes, mussels and lobsters, thus indicating that the prostaglandins have a basic regulatory function[13].

3. Analysis

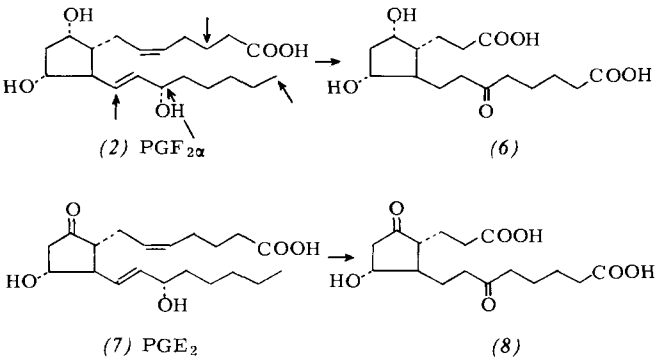
The determination of prostaglandin-synthetase activities and prostaglandin concentrations in tissue is prerequisite for an understanding of the physiological role of prostaglandins. There are, for example, hypotheses which postulate a basic causal interrelation between prostaglandin tissue levels that vary from the norm, and certain types of illnesses (see Section 6).

The determination of prostaglandins normally produced in various tissues abounds in difficulties. The prostaglandins are rapidly deactivated; for example 43% of PGE_1 *(1)* is converted into less polar metabolites[20] after a single passage through the kidney of a dog, while up to 95% of the prostaglandins E_1 *(1)*, E_2 *(7)* and $F_{2\alpha}$ *(2)* are metabolized after a single passage through the lungs of cats, dogs or rabbits[19]. There are also indications that prostaglandin synthetase is stimulated during work-up of the prostaglandins from animal tissues[13, 27], and that prostaglandin levels are simulated which are never met with under "normal conditions".

The relatively expensive, complicated and time-consuming chemical-analytical techniques for the work-up of tissues, and the isolation and concentration of prostaglandins in the presence of comparatively large quantities of lipids and fatty acids having similar physical parameters form the subjects of numerous publications in which the detection of prostaglandins by means of gas chromatography of special derivatives[21], gas chromatography combined with mass spectrometry[22–24], radioimmunoassay[25] and the enzymatic test[26] are reported. It would appear that the most reliable method to date for the determination of "normal" prostaglandin levels in blood plasma is that of the mass spectrometric determination of prostaglandin metabolites[27]. After having laid down the foundations for the determination of prostaglandin concentrations under normal and pathological conditions the standardization and reduction in cost of the analytical methods will in all probability stimulate research into ways of using the determination of prostaglandin concentrations as a diagnostic method.

4. Metabolism

The only essential difference in the metabolism of the prostaglandins and that of the long chain fatty acids lies in the two initial and—for the deactivation—rate-determining steps. The stereospecific 15(*S*)-hydroxyprostaglandin dehydrogenase oxidizes the alcohol function to a ketone, the 13-14-prostaglandin reductase hydrogenates the double bond, and then β- and ω-oxidation follow. Scheme 1 outlines the metabolism of $PGF_{2\alpha}$ *(2)*[28] and PGE_2 *(7)*[29] to the dicarboxylic acids *(6)* and *(8)*, respectively, in humans (for additional metabolites see Refs. [30, 31]).



Scheme 1. Metabolism of prostaglandins $PGF_{2\alpha}$ *(2)* and PGE_2 *(7)* to 19-carboxy-9α,11α-dihydroxy-15-oxo- *(6)* and 19-carboxy-11α-hydroxy-9,15-dioxo-2,3,4,5-tetranorprostenoic acid *(8)*. The arrows in *(2)* indicate the sites of the enzymatic attack.

A therapeutic target is to find ways of slowing down the deactivation of prostaglandins. Considering the ubiquitous occurrence of prostaglandins, the metabolizing enzyme should if possible be locally inhibited. The synthesis of antagonists which displace the prostaglandins from the receptor will be dealt with more closely in Section 5.

In this connection one has also to think of the synthetic prostaglandin analogs, in which the known biochemical degradation reactions can be inhibited or slowed down by suitable structural variations.

5. Biosynthesis

If there is a deficiency or over-production of local hormones[32]—prostaglandins have been defined as such—ways are sought to stimulate or inhibit their biosynthesis, respectively.

In 1964 two laboratories reported that unsaturated fatty acids are precursors of prostaglandins[33, 34] and in 1965 that both oxygen atoms on the ring of the primary prostaglandins E and F originate from the same oxygen molecule[35, 36]. The reaction is catalized by a multienzyme complex, prostaglandin synthetase, which requires several cofactors for the oxidative rearrangement of the essential fatty acids into prostaglandins. Concepts about the mechanistic course of the reaction were developed in 1966[37] and 1967[38][*].

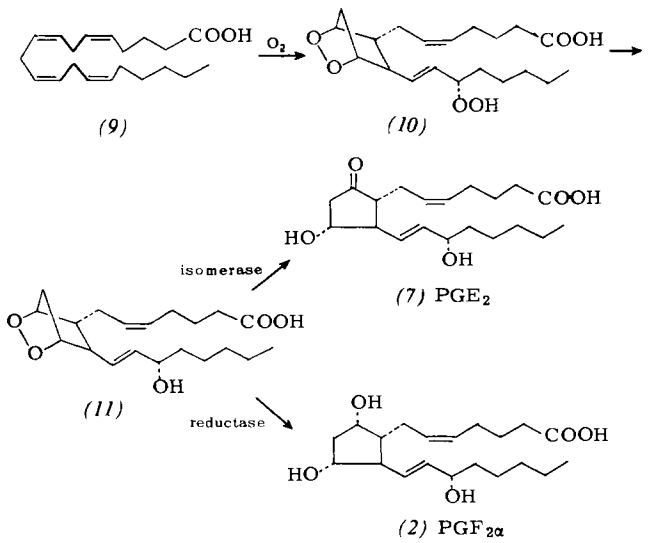
In 1973 previously postulated intermediates of the enzymatic synthesis of prostaglandins E from polyunsaturated fatty acids, were isolated[42–44].

The biosynthesis proceeds in accordance with previously developed concepts in at least three sequential reaction steps. The twofold attack of oxygen is followed by a reduction and isomerization, or a further reduction.

Scheme 2 illustrates these steps.

Of considerable importance from a pharmaceutical standpoint is, on the one hand, *Vane*'s discovery that this biosynthesis can be inhibited by non-steroid anti-inflammatory drugs such as aspirin or indomethacin and, on the other hand, the observations made by numerous research teams that prostaglandins

[*] Details on the elucidation of the biosynthesis can be found in the reviews cited under Refs. [39—41].



Scheme 2. The biosynthesis of prostaglandin E_2 *(7)* and $F_{2\alpha}$ *(2)* from arachidonic acid *(9)*.

or their precursors cause fever and pain and bring about inflammation[32]. The inhibition of prostaglandin synthetase by non-steroid anti-inflammatory agents, as for example in the experimental procedures of *Takeguchi* and *Sih*[45], already forms the basis of a test used in the search for new anti-inflammatory agents. Prostaglandins exercise different activities in different tissues of a given animal species. For example, in the stomach they apparently have a protective function against the overproduction of gastric acids[46]. It is thus understandable why ulcers are observed on administration of high dosages of non-steriod anti-inflammatory drugs, as are occasionally necessary for example for the treatment of rheumatic illnesses.

The problem of finding a non-steroid anti-rheumatic therapeutic which does not adversely affect the stomach is thus basically difficult to solve.

Prostaglandin synthetases from different tissues exhibit varying sensitivity toward medicaments having aspirin-like activity. Herein lies the explanation for the existence of antipyretics similar to aspirin but without an anti-inflammatory component[32]. The complex problem—prostaglandins and production of pain, inflammation, fever—especially rheumatism and peptic ulcers—will be the subject of investigations for years to come, both in basic research institutes and in more practically orientated scientific laboratories of drug houses.

6. Pharmacological Activity

6.1. Abortive and Luteolytic Activity

Despite their close "association" with cyclic AMP *(vide infra)*, prostaglandins exhibit a number of biological qualities that—in contrast to cyclic AMP, which so far has not found a use in medicine—may prove to be of practical value. In the first place one has to consider local applications based on the influence of prostaglandins upon the smooth muscle.

$PGF_{2\alpha}$ and its synthetic analogs are currently being tested throughout the world as abortificiants in the second trimester of pregnancy; they are described by several schools of medicine as the agents of choice[5].

Prostaglandins cannot yet compete, however, with methods currently in use for the induction of abortion in the first and third trimester of pregnancy.

Fundamental investigations which should answer the question of whether $PGF_{2\alpha}$ is a luteolytic hormone in mammals led to positive results on working with ewes[47]. Ovulation can also be induced by $PGF_{2\alpha}$ or its synthetic analogs in cows, mares and sows. Thus a practical application of prostaglandins in the synchronization of oestrus in herds of animals is a distinct possibility[48].

The often discussed question whether prostaglandins can supplement steroids in birth control—a question which is at the same time coupled with the question whether $PGF_{2\alpha}$ is a luteolytic hormone in primates—requires further fundamental research before it can be answered.

6.2. Bronchospasmolytic Activity

Another activity, particularly of prostaglandins of the E and A series, illustrates once again the apparent contradictory biological properties of the prostaglandins. In biological experiments these prostaglandins are recognized by their spasmogenic activity on the isolated smooth muscle, *e.g.*, on the isolated stomach of the rat (Fig. 1).

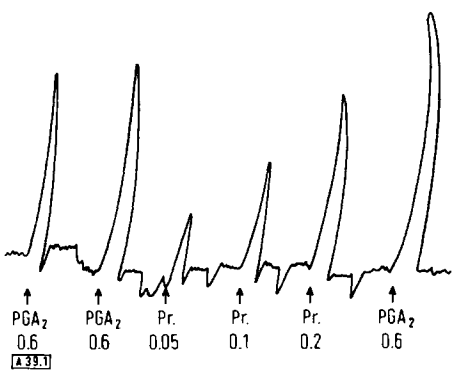


Fig. 1. Dosage-dependent contracting activity of the synthetic prostaglandin (±)-10,11-dihydro-PGA_1 (Pr) *(13a)* on isolated strips of rat stromach compared with natural PGA_2 *(47)*. The figures indicate concentrations in µg/ml.

However these prostaglandins have a relaxing effect on the smooth muscle of the bronchial tract thus suggesting that they or their synthetic analogs might be suitable for the treatment of the acute asthmatic crisis.

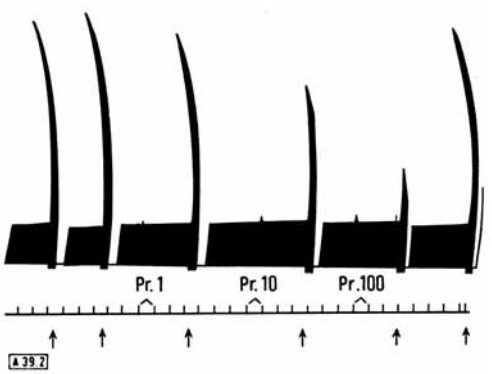

Fig. 2. Dosage-dependent depression of bronchial spasms in guinea pigs induced by 4 µg histamine/kg as a function of the quantity of (±)-10,11-dihydro-PGA_1 (Pr) *(13a)*. The figures represent doses in ng/animal. 1 Subdivision = 1 minute.

Fig. 2 illustrates how bronchial spasms produced by histamine in guinea pigs can be dosage-dependently depressed by pretreatment with (±)-10,11-dihydro-PGA_1 *(13a)*. The transient activity of prostaglandins due to their rapid metabolization is advantageous in this case; for example, repeated administration of this bronchospasmolytic does not lead to an accumulation of the active substance.

6.3. Inhibition of Gastric Secretion

Regulation of gastric secretion by prostaglandins could possibly be used in the treatment of hyperacidity, and perhaps prostaglandin derivatives can be used in ulcer therapy[49].

It has not definitely been proven that the influence of prostaglandins on gastric secretion is due primarily to a change in the blood circulation through the gastric mucosa[50].

6.4. Cardiovascular Activity and Blood Pressure

The hypotensive and simultaneous diuretic and sodium diuretic activity of renally produced prostaglandins is of fundamental interest in basic investigations concerning the treatment of essential hypertension[51, 52]. The hypothesis that prostaglandins of the A or E series are natural antagonists of the pressor peptides angiotension I or II seems to be confirmed.

In this context the question whether PGA_2 *(47)* or PGE_2 *(7)* is the—hypothetical—renal, sodium diuretic and antihypertensive hormone[53, 54] is of secondary importance, from the standpoint of the synthetic chemist. The properties of prostaglandin analogs—and only such compounds could be of practical value in the treatment of essential hypertension if they can be given orally and demonstrate a prolonged activity—do not always correspond quantitatively to the naturally occurring parent substances, particularly in the A and E series.

The possible role which the essential fatty acids may play in the prophylaxis of circulatory diseases could be derived from the fact that they are biogenetic precursors of the prostaglandins[55, 56].

In principle it is possible to extend the transient—lasting at the most ten minutes—hypotensive activity of the natural prostaglandins E and A by the synthesis of suitable derivatives, and it is also possible to replace, at least in animal experiments, the intravenous administration by oral administration[57]. Continued investigations with prostaglandins will undoubtedly lead to practical results in the treatment of hypertension, although when and in what form cannot be predicted.

A large number of other physiological properties are still the subject of fundamental research and therefore are currently of more interest to the biologist than to the chemist, who is looking for criteria which will allow him to modify basic principles provided by nature in such a way that selected properties can be optimized and others suppressed. In this connection one should remember the numerous modifications of the steriod skeleton which have led to the development of new drugs.

7. Structure—Activity Relationships

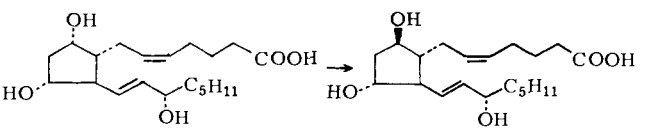
In order to produce drugs having the desired activity, structure-activity relationships must first be clarified. Qualitative differences (for one organ in one animal species) can easily be recognized in the case of naturally occurring prostaglandins of the E and F series; for example prostaglandin $F_{2\alpha}$ *(2)* exercises a spasmogenic activity on the bronchial muscle whereas PGE_2 *(7)* exhibits spasmolytic activity[58].

It has not yet been possible to decide whether the difference in physiological activity between the prostaglandins E and A—probably pharmaceutically useful—is of a qualitative or quantitative nature. The qualitative differences between the prostaglandins of the E and F series can also be confirmed by molecular biological investigations[59]. It remains to be seen whether intermediates in the biosynthesis possess particular activities which the relatively stable end-products, the prostaglandins, lack. Although we are still a long way from compiling a catalog of structure-activity relationships it is possible on the basis of the available biological results to assume that prostaglandins are not unspecific surface-active agents but rather that they require for their activity definite structures, definite configurations and possibly even definite conformations.

This can be illustrated by a few examples.

1. All investigations on structural variations published so far in the literature suggest that the characteristic activity of natural prostaglandins, *i.e.*, the influence upon the tone of the smooth muscle, is associated with a cyclopentane ring bearing at least one oxygen function.

2. The spatial arrangement of the oxygen substituents is important for the type of activity; thus, for example, the bronchospasmogenic properties of $PGF_{2\alpha}$ *(2)* are transformed into bronchospasmolytic properties on configurational inversion of the substitutents on C^9[60].



(2) $PGF_{2\alpha}$ *(12)*

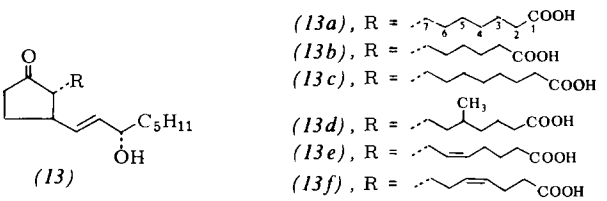
3. The length of the side chain carrying the carboxylic group in compounds of the 10,11-dihydro-PGA_1 type *(13)* is important for optimal activity. For example, lengthening or shortening of this chain by only one methylene group drastically reduces the spasmogenic activity[61].

4. The conformation of this side chain also influences the activity.

If, for example, a proton on the 2-, 3-, 4-, 5-, or 6-position of 10,11-dihydroprostaglandin A, *(13a)*, a compound which is closely related in structure and biological properties to naturally occurring PGA_1, is substituted by a methyl group—a procedure in which the lipophilic nature of the 2-, 3-, 4-, 5-, or 6 substituted molecules being compared remains essentially unaltered while steric relationships change, then the maximum spasmogenic activity as measured on the isolated stomach of the rat is obtained with the 5-methyl compound *(13d)*[61]. A possible explanation for this is that in the 5-methyl compound the zig-zag arrangement of the side chain, which has been proven for a natural crystalline prostaglandin by X-ray analysis[62] and has been required for solutions of prostaglandins[63], is the least disturbed. In its spasmogenic activity, however, the 5-methyl compound is considerably less active than 10,11-dihydroprostaglandin A_1 *(13a)*. However,

a final statement will only be possible after a separation of racemates and diastereomers.

On going from 10,11-dihydroprostaglandin A_2 *(13e)* to its double-bond isomer 7-[2-(3-hydroxy-1-*trans*-octenyl)-5-oxocyclopentyl]-4-*cis*-heptenoic acid *(13f)* a clear separation of the hypotensive and spasmogenic activities of *(13e)* is achieved. *(13f)* does not reduce the blood pressure whereas its spasmogenic activity is comparable to that of *(13e)*[61].



These results lead to the indirect conclusion that for prostaglandins there are specific receptors at the site of activity which are sensitive to stereochemical changes and that receptors from tissues of different organs are influenced to different extents by structural and configurational changes in the prostaglandins interacting with them.

8. Receptors

Proof of the existence of special prostaglandin binding proteins, which are receptors for prostaglandin E, has been obtained in isolated mouse ovaries[64], in rat stomach[65], in the liver[66], in thyroid glands[68] and in the luteal cells of several animal species[67]. Furthermore, these experiments lead to the hypothesis that such receptors are localized in cell membrane. The extensive investigations by *Sutherland*[69] have shown that the adenyl cyclase which is localized in the cell membrane controls the tissue levels of cyclic AMP, the "second messenger".

The interaction between cyclic AMP and prostaglandins was first observed as long ago as 1964[10]. Today, we have evidence that the activity of prostaglandin E on the above mentioned receptors is based upon its influence on the level of cyclic AMP, and is in general coupled with an increased synthesis of this material.

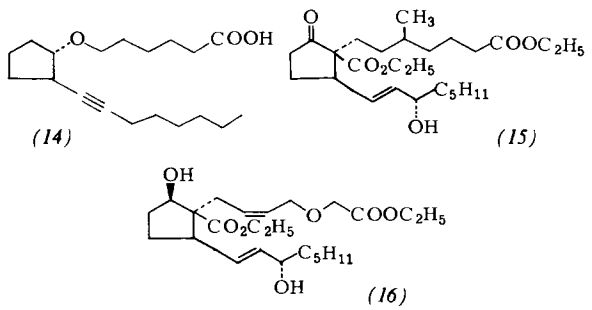
A receptor for $PGF_{2\alpha}$ in luteal cells of sheep has recently been detected[70]. In physiological concentrations, however, $PGF_{2\alpha}$ does not influence the level of cyclic AMP, but probably that of cyclic GMP[59].

A general hypothesis which unequivocally regards the prostaglandins as a link in an information chain, does not as yet exist. However, the stimulation of progesterone synthesis in the ovaries of mice can probably be regarded as an activity of the "messenger PGE_2"[64].

9. Prostaglandin Antagonists

Other compounds apart from naturally occurring prostaglandins can attack the prostaglandin receptors and either competitively or non-competitively inhibit their activity.

Compounds structurally related to natural prostaglandins, are the 7-oxaprostaglandins *(14)*[71]. These compounds competitively inhibit the spasmogenic activity of prostaglandins and can also displace PGE_2 *(7)* from the receptor[64]. 8-Ethoxycarbonyl-10,11-dihydroprostaglandins A *(15)* and *(16)* have recently been synthesized and these inhibit the spasmogenic activity of natural prostaglandins to a greater extent than do the 7-oxaprostaglandins[61].

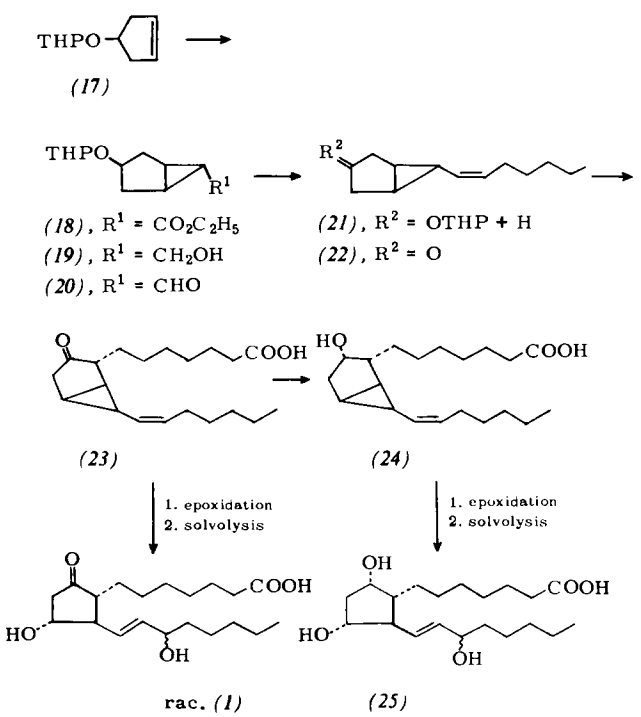


Further examples of prostaglandin antagonists are dibenzoxazine derivatives and polyphloretin phosphate[*].

The prostaglandins E stimulate the production of cyclic AMP in rat brain homogenates. This stimulation is inhibited by morphine[73]. Morphine does not, however, inhibit prostaglandin biosynthesis. Further experiments are necessary to clarify the question of whether this is a true antagonism and whether the analgesic activity of certain centrally attacking analgesics can be solely derived from their properties as prostaglandin antagonists.

10. Chemistry of the Prostaglandins

While the physiological role of prostaglandins and their potential therapeutical usefulness are still the subject of basic



Scheme 3. The most important steps in the synthesis of rac. prostaglandin E_1 *(1)* and $F_{1\alpha}$ *(25)* after *Just* and *Simonovitch* [74]. THP = Tetrahydropyranyl.

[*] Detailed information on substances which inhibit the activity of prostaglandins and on their therapeutic potentialities, may be found in Ref. [72].

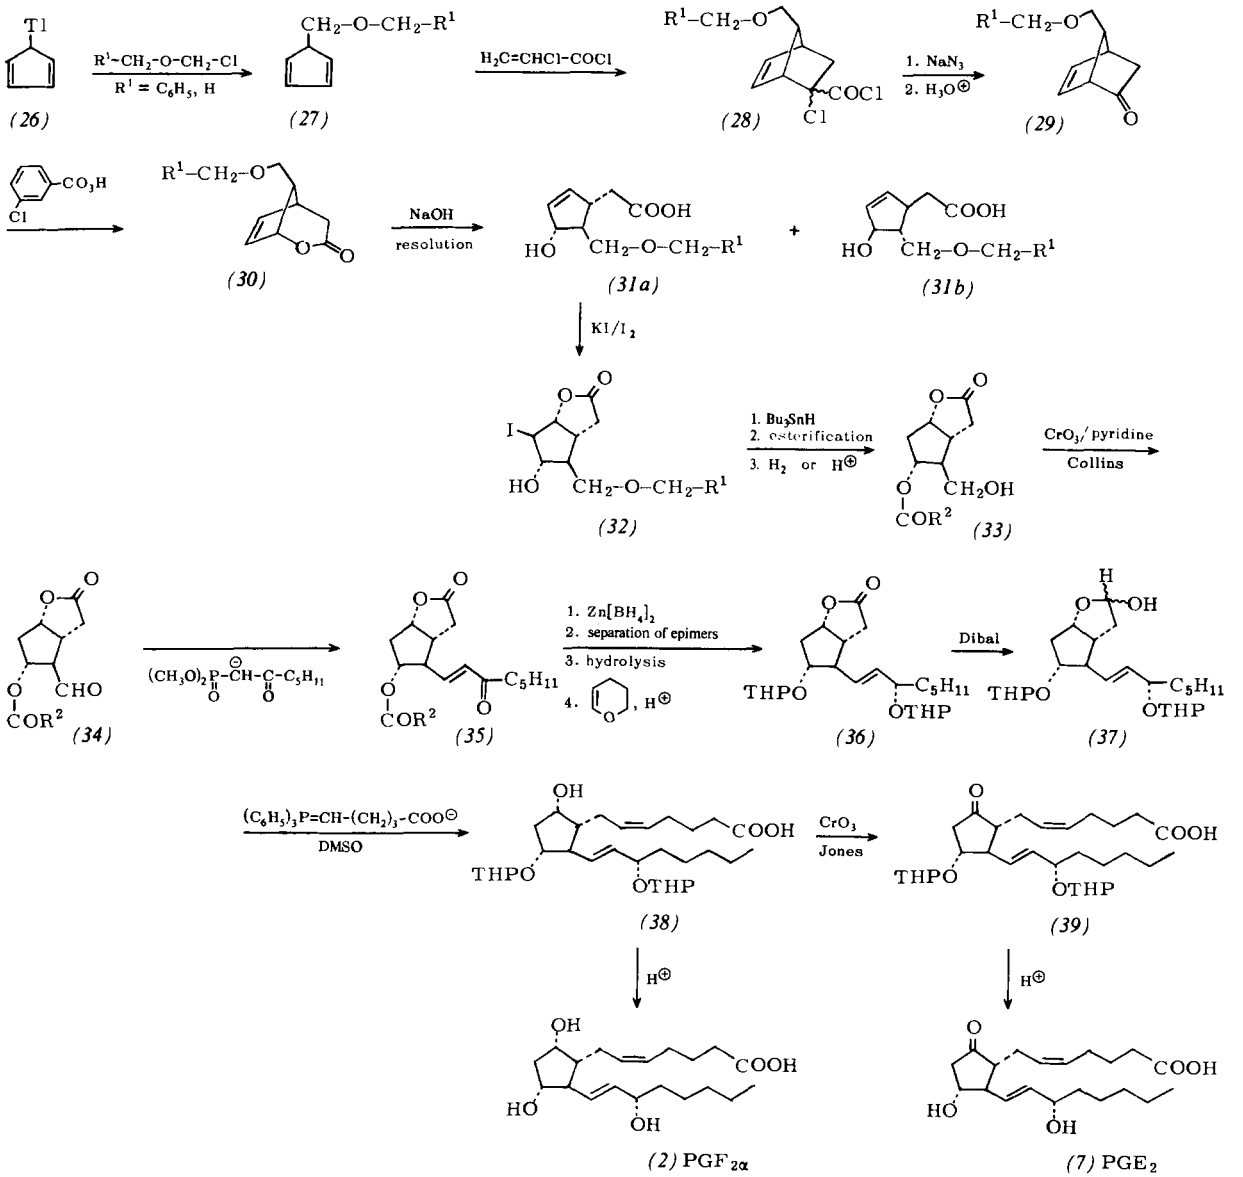
research, despite countless publications, the scientific problems of the synthesis have been fundamentally solved.

The first total synthesis of the prostaglandins E_1 and $F_{1\alpha}$ was reported by *Just* and *Simonovitch* in 1967[74]; although its reproduction initially produced problems, it formed the basis for extensive synthetic work by the Upjohn company, who, from 1968 to 1973, published modifications of the original principles of the synthesis[75–77]. The fundamental step in the *Just* synthesis consisted in a stereospecific opening of a cyclopropyl oxide of *(23)* in which the α-hydroxy group in position 11 together with the *trans* double bond in position 13—14 were stereospecifically introduced, whereas epimers were obtained on C^{15}. The essential steps of the synthesis are illustrated in Scheme 3.

The first synthesis of an optically active prostaglandin was accomplished by *Corey* at Havard University in 1969[79], about one year after he had reported the total synthesis of the racemates of the prostaglandins E_1 and F_1[78].

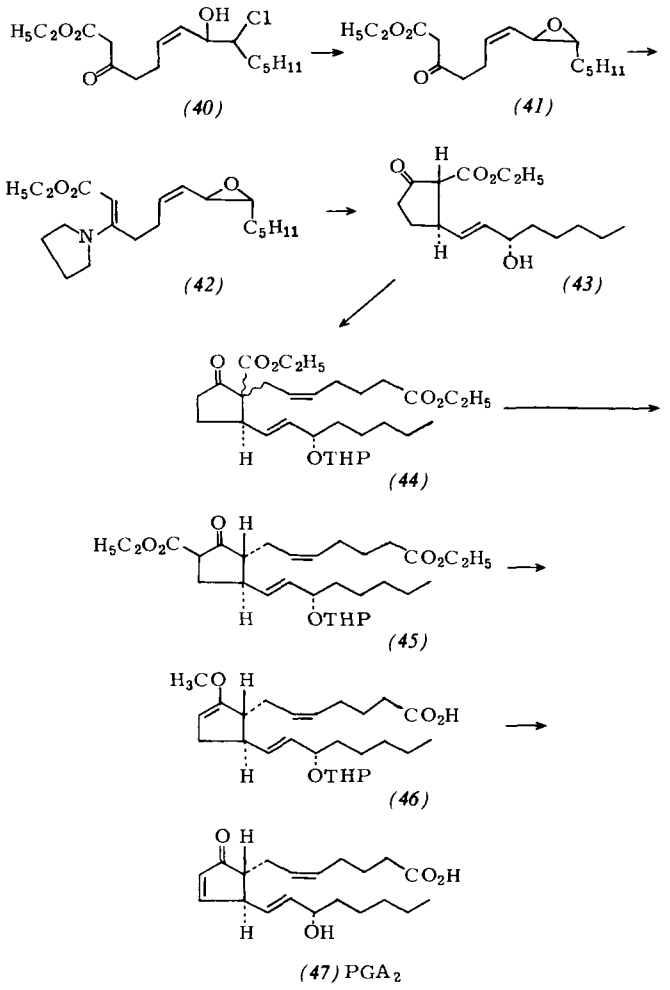
The important synthesis described by the Harvard group[80], by which primarily prostaglandins of the E_2 and $F_{2\alpha}$ series together with a number of non-natural analogs can be synthesized, uses the Diels-Alder reaction as the initial step. This synthesis has been developed in industrial laboratories up to pilot plant production. Starting with the intermediate *(28)*, obtained by the Diels-Alder reaction just mentioned, a synthon *(34)* is built up containing four of five chiral centers of $PGF_{2\alpha}$. Resolution of the optical antipodes is also possible at an early stage (Scheme 4)[80].

As the introduction of the *trans* double bond in the lower side chain using the Horner-Emmons-Wittig reaction *(34)*→*(35)* and the introduction of the *cis* double bond in the upper side chain using a variation of the Wittig reaction *(37)*→*(38)* proceed stereospecifically, the only non-stereospecific reaction of this synthesis was, initially, the reduction of the 15-keto compound *(35)* to the corresponding alcohol. However, using special reducing agents this reaction could also be carried out stereoselectively[81]. This synthesis has been varied and extended, not only in the laboratories of Harvard University but also in several industrial laboratories. For example, new ways have been described for the production of the intermediate *(34)*[82–84].



Scheme 4. Synthesis of prostaglandin $F_{2\alpha}$ *(2)* and E_2 *(7)* according to *Corey et al.* [80]. THP = Tetrahydropyranyl, Dibal = Diisobutylaluminum hydride.

Lack of space prevents commenting on all the previously published total prostaglandin syntheses. Of the syntheses whereby also the *S*-configuration of the OH group on C^{15} could be stereospecifically introduced, mention must be made of the total synthesis of prostaglandin A_2 *(47)* by *Mathieu et al.* (Roussel-Uclaf), the essential stage of which consists of an intramolecular S_N2' reaction in which the asymmetric carbon atoms are introduced into positions 12 and 15 (Scheme 5)[85].



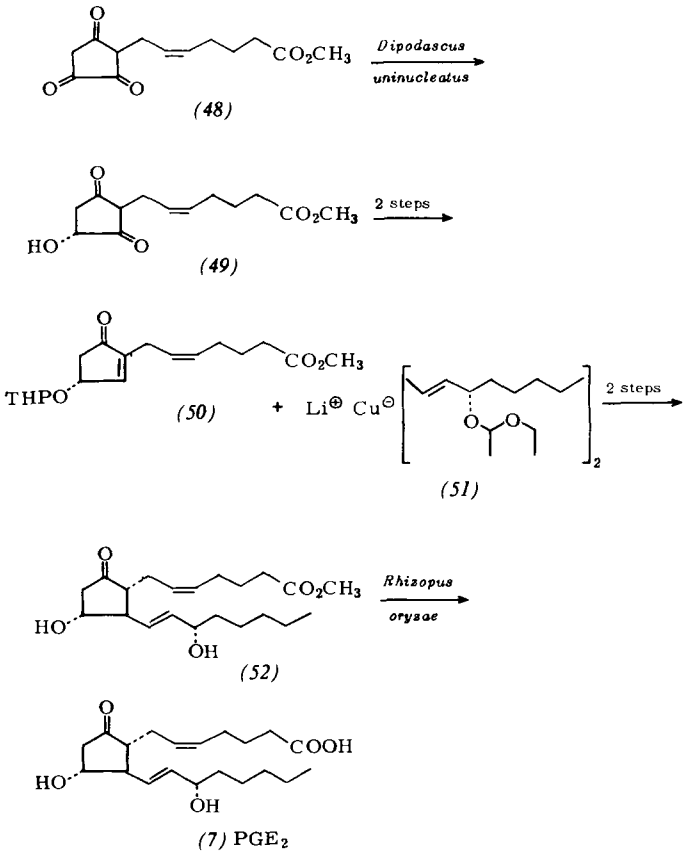
Scheme 5. Synthesis of prostaglandin A_2 *(47)* according to *Mathieu et al.* [85]. THP = Tetrahydropyranyl.

Both the Syntex group[87] and *Sih*[86] of the University of Wisconsin almost simultaneously reported the synthesis of prostaglandins using the conjugated addition of organocopper compounds to substituted cyclopentenones.

As illustrated in reaction Scheme 6, *Sih*[86] used an additional microbiological reduction and a microbiological esterification in his stereospecific total synthesis.

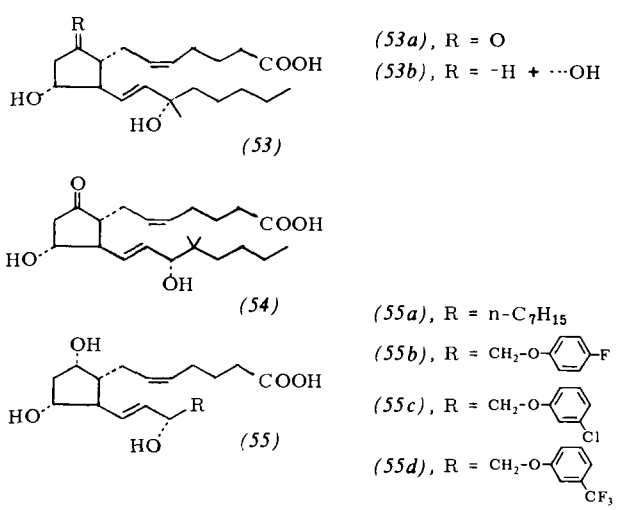
Synthetic work on prostaglandins is at present concentrated in industry, which is less interested in the stereospecific total synthesis of the natural products than in syntheses which can produce a series of structural and configurational analogs.

With such synthetic analogs the aim is to achieve a) a split of the pharmacological activities and b) in general a prolongation of certain activities. 15-Methyl-$PGF_{2\alpha}$ *(53b)*, 15-methyl-PGE_2 *(53a)* and 16,16-dimethyl-PGE_2 *(54)*[49, 88] are substances which, as a result of a hindered or totally suppressed attack of 15(*S*)-prostaglandin dehydrogenase, are metabolized more slowly and, as a result of their increased half-life, are



Scheme 6. Synthesis of prostaglandin E_2 *(7)* according to *Sih* [86]. THP = Tetrahydropyranyl.

better abortificiants and inhibitors of gastic secretion than the unsubstituted compounds. Analogs of $PGF_{2\alpha}$ *(55a)*—*(55d)*[48] exhibit in animal experiments an increased luteolytic activity. It is understandable that economic considerations conflict with the optimal exchange of information in this field.



11. Closing Remarks

Bearing in mind the amount of information to be covered, the selection in this paper of individual aspects of prostaglandin research has, to a certain extent, been somewhat arbitrary. This limitation, however, does not affect the statement that

from the extensive research being carried out on this class of natural products substantial progress in medicine, pharmacy and chemistry can be expected.

I wish to thank Dr. Babej for providing me with experimental biological results and Dr. Kunstmann for a critical review of the manuscript.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Cationic Carbyne-Metal Complexes—Tetracarbonyl-*trans*-(trimethylphosphane)(methylcarbyne)chromium(I) Tetrahaloborates from Tetracarbonyl-*trans*-(trimethylphosphane)[methoxy(methyl)carbene]chromium(0) and Boron Trihalides[1]

By *Ernst Otto Fischer* and *Konrad Richter*[*]

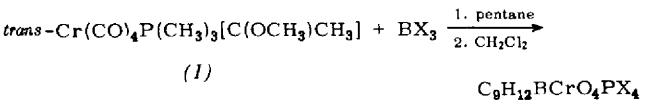
By reaction of pentacarbonyl[(methoxy)methyl(or phenyl)-carbene] complexes of chromium, molybdenum, and tungsten[2] with boron trihalides in alkanes at low temperature we were able in our laboratory to isolate the first stable representatives[3] of a class of compounds that contain as ligand a group $\equiv C-R$ ($R = CH_3$ or C_6H_5) triply bonded to the metal, *i.e.* a carbyne ligand. Since then two new possibilities for syntheses of carbyne complexes have been found: reaction of lithium (benzoyl)pentacarbonyltungstate(I) with dibromotriphenylphosphorane[4] and removal of water from pentacarbonyl(hydroxyorganylcarbene)tungsten(0) complexes with dicyclohexylcarbodiimide[5].

Independently of the route by which these compounds are formed, the course of the reaction involved in their formation involves three steps that are analogous in principle:

1. Removal of the OR′ group ($R' = CH_3$[3], Li[4], or H[5]) with the electron pair that produces the link to the previous carbene-carbon;
2. Elimination of a CO molecule from the complex;
3. Entry of a formally anionic group X^- (X = Cl, Br, I[3, 4], or $(CO)_5WCRO$[5]) in the position *trans* to the newly formed carbyne ligand.

The question arose as to how carbene complexes would react in which a ligand with a different, higher σ-donor/π-acceptor ratio in *trans*-position to the carbene ligand would at least hinder step 3.

On treatment of *trans*-$Cr(CO)_4P(CH_3)_3[C(OCH_3)CH_3]$[6] with BX_3 (X = Cl or Br) in pentane at a low temperature we obtained a reaction that occurred similarly to the formation of carbyne complexes but in which no evolution of CO could be observed; this afforded yellow, diamagnetic products for which, after careful purification by recrystallization from CH_2Cl_2, the molecular formula $C_9H_{12}BCrO_4PX_4$ was found by total analysis.



(1)

$C_9H_{12}BCrO_4PX_4$

(2), X = Cl
(3), X = Br

We were able to elucidate the structure of these compounds by IR, ^{1}H-NMR, and ^{13}C-NMR spectroscopy as well as on the basis of their chemical behavior.

The IR spectra of *(2)* and *(3)* (in CH_2Cl_2, LiF prism) in the ν_{CO} region show a very intense band (E_u) at 2045 and 2044 cm^{-1}, respectively, as well as very weak absorption (A_{1g}) at 2116 and 2115 cm^{-1}, respectively, and a shoulder (B_{1g}) at 2070 cm^{-1}. The number of bands and their intensity ratios indicate octahedral *trans*-disubstituted tetracarbonyl complexes. The shift of the very intense E_u-band with respect to the corresponding band of *(1)* amounts to approximately 150 cm^{-1} towards higher wavelengths.

The ^{1}H-NMR spectra of *(2)* and *(3)*, which are compared with that of *(1)* in Table 1, show that on the one hand the methoxy group is removed by the reaction whereas on the other the phosphane ligand in *trans*-position is retained in the complex. Positivization of the overall complex is proved by the shifts to lower field observed particularly for the protons of the methyl group bound to the former carbene-carbon but also for the phosphane protons.

Table 1. ^{1}H-NMR properties of the complexes *(1)*—*(3)* in CD_2Cl_2 at −40 °C (τ values relative to $CH_2Cl_2 = 4.57$; intensities and multiplicity s = singlet, d = doublet; coupling constants in Hz).

	OCH_3	CH_3	PCH_3
(1)	5.34 (1s)	7.09 (1s)	8.51 (3d) $^2J_{PH} = 7.5$
(2)	—	6.75 (1d) $^4J_{PH} = 4.5$	8.32 (3d) $^2J_{PH} = 9.5$
(3)	—	6.72 (1d) $^4J_{PH} = 4.5$	8.30 (3d) $^2J_{PH} = 9.5$

Table 2. ^{13}C-NMR data from complexes *(1)*—*(3)* in CD_2Cl_2 at −40 °C (ppm relative to TMS int. [*(1)*] or $CD_2Cl_2 = 54.26$ ppm [*(2)*, *(3)*]; coupling constants in Hz).

	CrC	CO	OCH_3	CCH_3	PCH_3
(1)	352.07 $^2J_{PC} = 12.2$	222.94 $^2J_{PC} = 12.2$	65.16	48.87	19.96 $J_{PC} = 24.4$
(2)	365.42 [a]	209.38 $^2J_{PC} = 17.9$	—	47.03	17.30 $J_{PC} = 29.8$
(3)	[b]	209.35 $^2J_{PC} = 17.1$	—	46.61	17.10 $J_{PC} = 26.9$

[a] *J* could not be determined; [b] resonance was not found.

The ^{13}C-NMR spectra of *(2)* and *(3)* contain four resonance signals (assignments in Table 2). The appearance of only one resonance for the CO-carbon atoms shows the equivalence of the CO groups, which agrees well with the IR-spectroscopic finding that the *trans*-disubstitution is retained in the reaction.

It is striking that the compounds *(2)* and *(3)* agree almost completely in their spectroscopic data. This justifies the conclusion that the portion of the compound containing the CO groups, the protons and the carbon atoms is independent of the halogen-containing portion, at least in solution, and possibly identical in the two compounds.

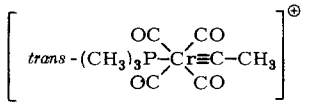
On the basis of these arguments we ascribe the structure



to the new complexes. We assume that in pentane an "adduct" *trans*-$Cr(CO)_4P(CH_3)_3[C(OCH_3)CH_3]\cdot BX_3$ is first formed but that it cannot be studied because of its insolubility in apolar solvents and because of the by-products arising in the reaction. On dissolution in CH_2Cl_2 the "adduct" dissociates, whereupon even at $-20\,^{\circ}C$ the $BX_3OCH_3^-$ first formed presumably disproportionates in a rapid reaction with the excess of BX_3 to give BX_4^- and $B(OCH_3)_3$. That *(2)* and *(3)* have salt-like character can also be deduced from the electrolytic conductivity of their solutions in CH_2Cl_2: for very dilute solutions we observed linear dependence of the conductivity on concentration.

A final proof of structure was provided by reaction of *(2)* with anhydrous C_2H_5OH. As proved by IR, ^{1}H-NMR, and mass spectroscopic investigations as well as by total analysis, this leads to *trans*-$Cr(CO)_4P(CH_3)_3[C(OC_2H_5)CH_3]$ *(4)*, *i.e.* back to a carbene complex in which the OCH_3 group (of the initial complex *(1)*) is replaced by the OC_2H_5 group.

(4): IR (in hexane; ν_{CO}): 2008 vw (A_{1g}), 1936 w (B_{1g}), 1891 vs, br (E_u) cm^{-1}. ^{1}H-NMR (in [D_8]-toluene, 0 °C; τ-values, TMS int.): 5.28 q OCH_2, 7.18 s CCH_3, 8.85 t OCH_2CH_3, 9.00 d ($J = 7.5$ Hz) $P(CH_3)_3$. The mass spectrum shows the molecular ion ($m/e = 312$) and successive loss of 4 CO (284, 256, 228, 200); there follow removal of C_2H_5 (171), of COC_2H_5 (143) and of the whole carbene ligand (128).

Compounds of this new ionic type resemble uncharged carbyne complexes in many of their properties. They show clearly that when the *trans*-position in carbene complexes is blocked the reaction with BX_3 stops after removal of the OCH_3 group. Studies with π-$C_5H_5Mn(CO)_2C(OCH_3)C_6H_5$[7] and with π-$C_6H_3(CH_3)_3Cr(CO)_2C(OCH_3)C_6H_5$[8] show that this reaction principle can be generalized. At the same time they provide valuable indications on the mechanism of carbyne complex formation. Finally the reaction with nucleophiles opens up a new possibility for synthesis of carbene complexes, as is exemplified by the reaction of *(2)* with ethanol.

Experimental:

All operations must be carried out under N_2 and with dry (CaH_2, P_4O_{10}) solvents presaturated with N_2!

1. BCl_3 is passed into a solution of *(1)* (3 g) in pentane (75 ml) in a frit cooled to $-25\,^{\circ}C$ (or BBr_3 is added in slight excess from a pipette). When the originally orange-red solution is completely decolorized the pentane is sucked off and the yellowish-white precipitate is washed with pentane. The substance that slowly crystallizes at $-78\,^{\circ}C$ is recrystallized twice from CH_2Cl_2. Pouring off the mother-liquor, washing with pentane at $-78\,^{\circ}C$, and drying for several hours in a high vacuum affords beautiful pale yellow crystals. Further amounts of the product (as a yellow powder) can be obtained from the mother-liquors by addition of pentane. Yield: 72% of *(2)* or 60% of *(3)*.

2. C_2H_5OH (100 ml) is added to *(2)* (2 g) at $-30\,^{\circ}C$. On slow warming up to 0 °C, with stirring, *(2)* dissolves to an orange-red solution. After addition of some pentane, the solution is poured into a NaH_2PO_4/Na_2HPO_4 buffer solution. The orange-red pentane phase that separates contains mainly *(4)*, with a little $Cr(CO)_5P(CH_3)_3$. The aqueous phase is extracted a further three times with pentane, and the combined extracts are then dried over Na_2SO_4. Separation of $Cr(CO)_5P(CH_3)_3$ and decomposition products is achieved by chromatography at 0 °C on silica gel with pentane as eluant. Yield: 65% of *(4)*.

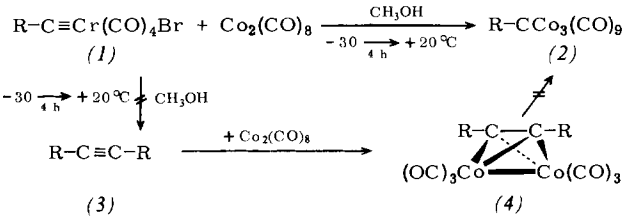
Transfer of Carbyne Ligands from Chromium to Cobalt[1]

By *Ernst Otto Fischer* and *Albrecht Däweritz*[*]

We have succeeded in transferring carbyne ligands from one metal to another for the first time. *trans*-Bromomethyl- and -phenylcarbynetetracarbonylchromium complexes *(1a, b)*[2] react with octacarbonyldicobalt in methanol under very mild conditions (−30 to +20 °C, 4 h) to form the μ_3-methinylenneacarbonyltricobalt complexes *(2a, b)* which have been known for a long time[3–5]. The products were confirmed by ^{1}H-NMR spectroscopy [$(CD_3)_2CO$, TMS internal; *(2a)*, $\delta = 3.73$ ppm ([6]: 3.65)], IR spectroscopy (Table), mass spectrometry [M^+ *(2a)*, *m/e* 456; *(2b)*, *m/e* 518, fragmentation patterns identical to those reported in refs. [7, 8], 50 eV, boat source], and by complete elemental analysis.



(a), R = CH_3
(b), R = C_6H_5

It could be ruled out that μ_3-methinylenneacarbonyltricobalt complexes *(2)* are formed under the above conditions *via* dimerization of the carbyne ligands to alkynes *(3)* and formation of alkynehexacarbonyldicobalt complexes *(4)*. Alkyne would have immediately yielded the stable species *(4)*, which could not be detected. The absence of *(3)* and *(4)* also indicates that, in contrast to the course assumed for photolytic reactions of diethylmercury bisdiazoacetate with bromopentacarbonylmanganese[9] or alkenes[10], no free carbynes occur during the reaction.

IR spectroscopic data (ν_{CO}, cm^{-1}, *n*-hexane):

(2a):	2101 (w)	2050 (vs)	2037 (s)	2016 (w)
	2102.4	2052.0	2038.2	2018.0 [5]
(2b):	2101 (m)	2053 (vs)	2039 (s)	2020 (sh)
	2101.4	2054.2	2039.9	2020.9 [5]

8 München 2, Arcisstrasse 21 (Germany)

Procedure:

All operations were performed in dry, oxygen-free solvents under N_2. *(1a)* (677 mg, 2.5 mmol) [*(1b)* (833 mg, 2.5 mmol)] and $Co_2(CO)_8$ (1.29 g, 3.75 mmol) are dissolved in cooled methanol at −30 °C and the temperature of the stirred reaction mixture allowed to rise to +20 °C within 4 h. The color of the mixture changes from ocher to brownish violet during the process and after evolution of gas has ceased the mixture is extracted several times with pentane at −95 °C. The solvent is removed from the extracts and the residue vacuum-sublimed on to a finger cooled with solid CO_2. *(2a)*, m.p. 183—185 °C (dec.) [183—185 °C (dec.)[11]], yield 130 mg (0.29 mmol) = 10.6% based on *(1a)*. *(2b)*, m.p. 104—105 °C [105—107 °C[12]], yield 92 mg (0.18 mmol) = 7.1% based on *(1b)*.

Chemistry of *cis*-Triazatris-σ-homobenzene. 3σ→3π Isomerization to the 1,4,7-Triaza-2,5,8-cyclononatriene System[**]

By *Horst Prinzbach, Reinhard Schwesinger, Manfred Breuninger, Bernd Gallenkamp*, and *Dieter Hunkler*[*]

Thermal isomerization reactions of type *cis*-tris-σ-homobenzene *(1)* → 1,4,7-cyclononatriene *(2)* are presently attracting interest (i) preparatively as providing an entry to nine-membered rings, and (ii) theoretically as sterically and energetically predestinated 6-electron concerted processes[1, 2].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are grateful to Dr. *H. Fritz* for performing the the ^{13}C measurements, and Prof. Dr. *H. Achenbach* for the MS.

Thermolysis of *cis*-triazatris-σ-homobenzenes *(3b)—(3e)* has now rendered the first derivatives *(6b)—(6e)* of the 1,4,7-triaza-2,5,8-cyclononatriene system (1*H*-4,7-dihydro-1,4,7-triazonine) accessible. The *N,N',N''*-trisubstituted starting materials can be prepared conventionally from the triimine *(3a)*[3]: *(3b)* (methanesulfonic anhydride, pyridine; colorless crystals, yield 60%, m.p. 235 °C, ^1H-NMR (D_6-DMSO): τ = 6.78, ^{13}C-NMR: δ = 30.5 ppm)[4]; *(3c)* (*p*-toluenesulfonic anhydride, triethylamine; colorless needles, yield 70%, m.p. 186 °C, ^1H-NMR ($CDCl_3$): τ = 6.83, ^{13}C-NMR: δ = 31.1 ppm); *(3d)* (methyl chloroformate, Levatit MP 62 ion exchanger; colorless platelets, yield 65%, m.p. 95 °C (clouding above 80 °C), ^1H-NMR (CH_2Cl_2): τ = 7.17, ^{13}C-NMR (C_6D_6): δ = 30.06 ppm); *(3e)* (methyl methanesulfonate, Na_2CO_3, methanol; colorless crystals, yield 80%, m.p. 95 °C (dec.), ^1H-NMR (CCl_4): τ = 8.6, ^{13}C-NMR: δ = 33.5 ppm); *(3f)* (only produced in solution, $NOBF_4$, pyridine/$CHCl_3$, −20 °C; ^1H-NMR: τ = 6.45). The question of the arrangement of the *N*-substituents which is topical in connection with the crystal structure of *(3a)*[6] has been decided in favor of the all-*exo* configuration by ^1H- and ^{13}C-NMR spectra and pK_a measurements[7a].

	(a)	(b)	(c)	(d)	(e)	(f)
R	H	SO_2CH_3	$SO_2C_6H_4CH_3$	CO_2CH_3	CH_3	NO

Depending upon the kind of *N*-substitution, thermal isomerization of *(3b)—(3e)*[7b] to the π-analogs *(6b)—(6e)* requires a widely varying activation energy characterized by the approximately determined half-lives ($t_{1/2}$ *(3b)*: 160 °C (dimethyl sulfone), *ca.* 25 min; *(3c)*: 160 °C (dimethyl sulfone), *ca.* 12 min; *(3d)*: 60 °C ($CHCl_3$), *ca.* 57 min; *(3e)*: 60 °C (CCl_4), *ca.* 50 min, ($CHCl_3$), *ca.* 75 min, (water), *ca.* 900 min); the reaction proceeds uniformly. The gradation from *(3b)* to *(3d)* is parallel to the effect of these substituents on the benzene imine/azepine equilibrium[8]. While the trimethyl compound cannot be fitted into this series, the observed pronounced solvent effect, due to intermolecular hydrogen bonding, underlines the significance of the n-electron pair on nitrogen for the strength of the aziridine C—C bond, which has also been theoretically justified[9]. We consider intramolecular hydrogen bonds to be responsible for the enhanced thermal stability of the triimine *(3a)* relative to that of *(3e)*. In dimethyl sulfone *(3a)* is stable up to *ca.* 120 °C and decomposes with polymerization at 140 °C (N_2, 10 min) without any triene *(6a)* being observed by ^1H-NMR spectroscopy.

An argument opposing an ylide-type intermediate *(5)* or favoring a concerted process *(4)*, which, however, cannot be very convincing[10], comes from the absence of adduct formation when, *e.g.*, *(3d)* is thermolyzed in the presence of an excess of dimethyl acetylenedicarboxylate. The specificity of 3σ→3π isomerization in the case of the urethane *(3d)* is informative, inasmuch as the potential competing reaction involving C—N cleavage and forming oxazoline does not become operative. So far the only exception in the series

(3) is the trinitroso compound *(3f)*, in which cleavage to *(6f)* has no chance compared to the elimination of N_2O (giving over 50% of benzene) which occurs above $-10°C$.

The triazanonatrienes bearing electron-withdrawing substituents *(6b)* (colorless crystals, m.p. 210°C (dec.), ^{1}H-NMR (CD_3CN): $\tau = 4.05$, ^{13}C-NMR: $\delta = 119.4$ ppm), *(6c)* (colorless crystals, m.p. 150°C (dec.), ^{1}H-NMR ($CDCl_3$): $\tau = 4.40$, ^{13}C-NMR: $\delta = 119.0$ ppm), and *(6d)* (colorless oil, ^{1}H-NMR ($CDCl_3$): $\tau = 4.16$, ^{13}C-NMR: $\delta = 119.5$ ppm) are fairly stable thermally and on air exposure. Trimethyl derivative *(6e)* (colorless oil, m.p. *ca.* 0—10°C, ^{1}H-NMR ($CDCl_3$): $\tau = 5.29$, ^{13}C-NMR: $\delta = 123.3$ ppm), on the other hand, displays the typical pronounced sensitivity of enamines towards oxygen; it forms a deep red solid complex with trinitrobenzene[11]. Evidence for a preferential crown conformation having a mobility comparable with that of trioxanonatriene[12] and considerably enhanced relative to the hydrocarbon *(2)*[13] comes from the ^{1}H- and ^{13}C-data, and especially from the temperature measurements performed on *(6e)* which, unlike *(6d)*, displays no substituent-dependent variation with temperature.

[11] So far the trimethyl compound *(6e)* is the only member to exhibit the mechanistically obscure reaction occurring on warming in solution (benzene, 150°C), but not in the gas phase, and affording a 40% yield of the dimethyl derivative *(8)* of the unknown dihydropyrrolo[3,2-*b*]pyrrole (colorless volatile crystals, m.p. 110°C). Its UV and NMR data indicate a relationship to naphthalene (UV: $\lambda_{max} = 260$ nm ($\varepsilon = 17450$), ^{1}H-NMR (CCl_4): $\tau = 6.4$ ($2CH_3$), 4.3 (2H), 3.65 (2H), $J_{AB} = 2.6$ Hz); *R. Schwesinger*, Dissertation, Universität Freiburg 1975.

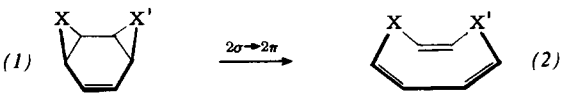
cis-Diazabis-σ-homobenzene. Synthesis and $2\sigma \rightarrow 2\pi$ Isomerization to 1,4-Diaza-2,5,7-cyclooctatriene Derivatives[**]

By *Horst Prinzbach, Manfred Breuninger, Bernd Gallenkamp, Reinhard Schwesinger*, and *Dieter Hunkler*[*]

While the hydrocarbon *(1a)* (*cis*-"bis-σ-homobenzene"), which is expected to be thermally labile, is still unknown, the mono- and bis-hetero analogs *(1b)*[1]—*(1d)*[2] have been isolated in recent years. Their $2\sigma \rightarrow 2\pi$ isomerization opens a simple route to the heterocyclooctatrienes *(2b)—(2d)*.



(1) $\xrightarrow{2\sigma \rightarrow 2\pi}$ *(2)*

(a), X = X' = CH_2
(b), X = CH_2, X' = O
(c), X = CH_2, X' = N-Tos
(d), X = X' = O
(e), X = X' = NR

A synthetic route to the hitherto unknown diaza systems *(1e)* and *(2e)* was seen in the pathway entailing *N*-nitrosation of *cis*-"benzene triimines"[3] and N_2O elimination. Since *N*-nitrosoaziridines generally decompose between -20 and $0°C$[4], the prospects for identification or isolation of the *cis*-diazabis-σ-homobenzenes were favorable. However, it could not be ruled out that N_2O elimination and valence isomerization proceed synchronously—symmetry-allowed as a nonlinear cheletropic process—and lead directly [cf. *(7)*] to the diazacyclooctatrienes.

Basically in analogy to the *N,N',N''*-trisubstituted derivatives[3] we have prepared from *(3)* the bissulfonamide *(4a)*, the bisurethane *(4b)*, and the dimethyl derivative *(4c)* and separated them by crystallization or by chromatography, involving considerable losses in some cases, from the mono- or trisubstituted by-products (Table 1).

At $-40°C$ *(4a)* reacts fast ($CHCl_3$, pyridine) with nitrosyl tetrafluoroborate to form nitrosoaziridine *(5a)*; the progress of the reaction can be followed by observing the paramagnetic shift of the H^A signal ($\tau = 6.7$). On warming of the deep yellow solution to $-10°C$, evolution of N_2O is rapidly initiated;

Table 1. *N,N'*-Disubstituted products of types *(4)*, *(6)*, and *(8)* [5].

(4a): 2 equiv. *p*-toluenesulfonic anhydride, triethylamine, CH_2Cl_2, 0 °C, colorless needles, > 130 °C dec., yield 60 %, ^{1}H-NMR ($CDCl_3$): $\tau = 7.8$ (H^A), 6.5—6.9 (H^BH^C)

(4b): 2 equiv. methyl chloroformate, Levatit MP 62, $CHCl_3$, 0 °C, colorless needles, m.p. 123—124 °C (dec.), yield 60 %, ^{1}H-NMR ($CDCl_3$): $\tau = 7.7$ (H^A), 6.75—7.2 (H^BH^C), ^{13}C-NMR ($CDCl_3$): $\delta = 32.8$ ppm (C^B), 30.1 (C^C), 24.7 (C^A)

(4c): 2 equiv. methyl methanesulfonate, Na_2CO_3, methanol, 20 °C, colorless deliquescent needles, m.p. 51 °C, yield 45%, ^{1}H-NMR ($CDCl_3$): $\tau = 7.9$ (H^A), 8.3 (H^BH^C)

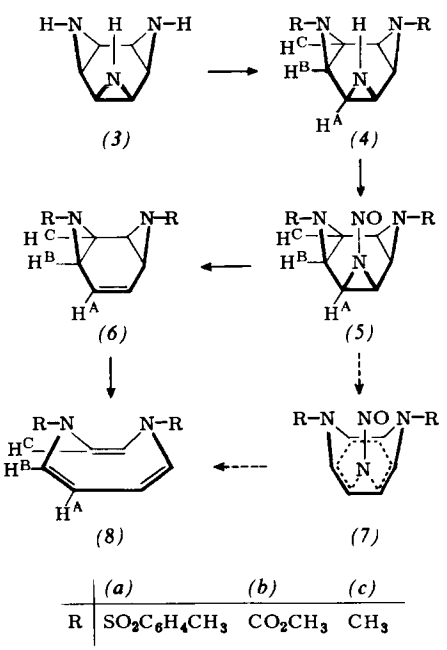
(6a): colorless needles, > 120 °C isomerization to *(8a)*, yield 70%, ^{1}H-NMR ($CDCl_3$): $\tau = 6.4$—6.8 (H^BH^C), 3.7 (H^A), ^{13}C-NMR ($CDCl_3$): $\delta = 127.7$ ppm (C^A), 33.3, 32.5 (C^BC^C); MS: *m/e* 416 (M^+)

(6c): ^{1}H-NMR ($CDCl_3$, −30 °C): $\tau = 8.1$ (H^C), 7.94 (H^B), 3.69 (H^A), 7.51 ($2CH_3$)

(8a): colorless crystals (CCl_4), m.p. 169 °C, ^{1}H-NMR ($CDCl_3$): $\tau = 4.53$ (H^A), 3.69 (H^C), 3.62 (H^B), ^{13}C-NMR ($CDCl_3$): $\delta = 122.0$ ppm (C^B), 116.5 (C^A), 109.0 (C^C)

(8b): colorless crystals (isopropanol), m.p. 81—82 °C, ^{1}H-NMR ($CDCl_3$): $\tau = 4.38$ (H^A), 3.99 (H^C), 3.77 (H^B), ^{13}C-NMR ($CDCl_3$): $\delta = 126.5$ ppm (C^B), 118.6 (C^A), 112.4 (C^C)

(8c): colorless oil, ^{1}H-NMR ($CDCl_3$): $\tau = 4.37$ (H^A), 4.12 (H^C), 3.50 (H^B), 6.02 ($2CH_3$), MS: *m/e* 136 (M^+)



R	(a) $SO_2C_6H_4CH_3$	(b) CO_2CH_3	(c) CH_3

the product (70 %) isolated as colorless crystals (CH_2Cl_2) is confirmed as *cis*-"benzene diimine" *(6a)* by its spectroscopic data, and especially by NMR comparison with *(2c)* and *(2d)*. At 75 °C (in solution) *(6a)* undergoes fast uniform isomerization to 1,4-diaza-2,5,7-cyclooctatriene (1,4-dihydro-1,4-diazocine) *(8a)*. The nitroso derivative *(5b)* ($\tau(H^A) = 6.8$) prepared analogously from *(4b)* in $CHCl_3$ solution likewise decomposes above *ca.* −10 °C with the—not unexpected—difference that *(6b)* is not detectable under these conditions and the triene *(8b)* appears immediately and quantitatively. Compound *(5c)*, which is more labile than *(5a)* and *(5b)* and is prepared at −60 °C ($CHCl_3$, 1,4-diazabicyclo[2.2.2]octane) already eliminates N_2O between −35 and −30 °C; under these conditions *(6c)* is stable and identifiable by NMR spectroscopy. It has a half-life of *ca.* 2 min at 20 °C ($CHCl_3$), under which conditions it is converted uniformly into *(8c)* (Table 1).

Judging from these first three examples *(6a)*—*(6c)* the *cis*-"benzene diimine" system fits well into the pattern set by the "benzene imines" and *cis*-"benzene triimines" and by 1,4-dioxocin[2] and 1,4-dithiocin[6] with respect to its readiness to undergo $2\sigma \rightarrow 2\pi$ valence isomerization and its spectroscopic properties.

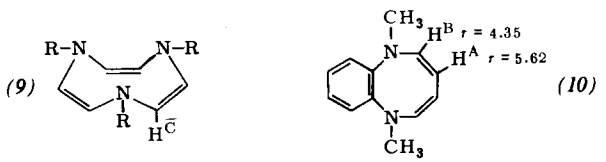
The following comparisons reveal an interesting aspect in connection with the potential "aromaticity" of 1,4-dihydrodiazocine *(8)*[7], and in general of the 1,4-dihetero[8]annulenes:

1) The chemical shifts of the proton pairs H^A, H^B, H^C in the derivatives *(8a)*—*(8c)* differ only slightly (Table 1). In the triazonine skeleton *(9)*[3]—as the nearest olefin model—the same substituents cause a $\Delta\delta$ value of over 1 ppm. $\tau(H^C)$ is slightly smaller for *(8b)* than for *(9b)*, but 1.17 ppm smaller for *(8c)* than for *(9c)*.

2) ^{1}H- and ^{13}C-N—CH_3 signals in *(8c)* are paramagnetically shifted by 0.9 and 8.2 ppm, respectively, as compared with the corresponding signals in *(9c)*.

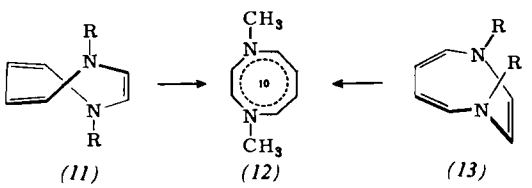
3) The $\tau(H^A)$ and $\tau(H^B)$ values in dimethylbenzodiazocine *(10)*[8] are *ca.* 1.3 and 0.8 ppm larger than in *(8c)*.

4) The ^{13}C-signals of the ring carbon atoms in *(8c)* ($\delta = 117.1$ ppm (C^B), 102.5 (C^A), 91.8 (C^C)) show substantial diamagnetic shifts with respect to those of the ring carbon atoms in *(9c)* and *(8a)*, *(8b)* (Table 1).



R	Tos *(9a)*	CO_2CH_3 *(9b)*	CH_3 *(9c)*
$\tau(H^C)$	4.40	4.16	5.29

The still tentative interpretation—decisive information is expected from the parent compound *(8)*, R = H, and its dianion[7]—states that in contrast to the situation in *(8a)* and *(8b)* or in 1,4-dioxocin[2] and 1,4-dithiocin[6] effective cyclic 10-electron delocalization induces a diamagnetic ring current *(12)* with flattening of the twist conformation *(11)*



preferred over *(13)* for *(8a)* and *(8b)*. Thus striking analogies become apparent between the 1,4-dihetero[8]annulenes and the extensively studied hetero[9]annulenes[9].

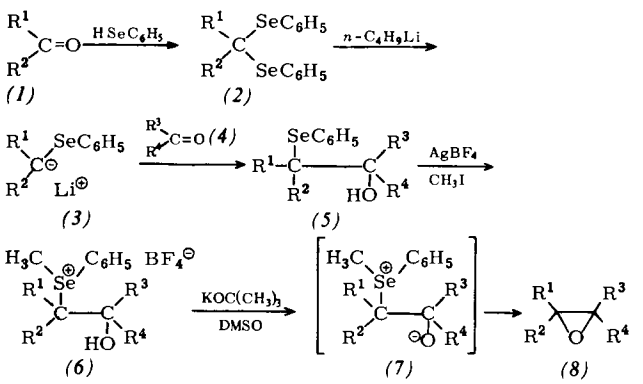
New Synthetic Route to Di- and Trisubstituted Epoxides[1]

By *Willy Dumont* and *Alain Krief*[*]

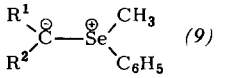
This communication reports the application of the C—Se bond cleavage to the connective synthesis of epoxides *(8)* starting from the carbonyl compounds *(1)* and *(4)*.

We[2] and *Seebach*[5] recently synthesized some β-hydroxyalkyl phenyl selenides *(5)* by reacting the selenoacetals *(2)* with *n*-butyllithium and trapping the resulting carbanions *(3)*[3-4] with carbonyl compounds *(4)*.

We have now found that β-hydroxyalkylselenonium salts *(6)* can be readily formed when β-hydroxyalkylphenyl selenides *(5)*, $R^1 = H$, $R^2 = H$, alkyl, are treated with methyl iodide in the presence of silver tetrafluoroborate[6]: subsequent treatment of the crude salts *(6)* with base (potassium *tert*-butoxide in DMSO) produces the desired epoxide *(8)* and methyl phenyl selenide *via* the betaine *(7)* (Table 1).



This betaine *(7)* is identical with that produced by addition of the ylide *(9)* to the carbonyl compound *(4)*[7].



(9)

The proposed synthon permits the synthesis of, *e.g.*, the epoxides *(8d)* and *(8g)* from the highly enolizable deoxybenzoin [35%, 28% overall yield based on *(4)*]; these epoxides are not accessible by standard procedures[7-9].

Unfortunately, we were unable to synthesize β-hydroxyalkylselenonium salts *(6)*, R^1, R^2 = alkyl. For instance, reaction of *(5j)* instead of *(6j)* yields 3-methyl-3-phenyl-2-butanone (80%). Tetrasubstituted epoxides are also not yet accessible by this route.

β-Hydroxyselenonium salts (6) and epoxides (8):

Methyl iodide (2.4 mmol) is added under N_2 at 20°C to a mixture of $AgBF_4$ (2.2 mmol) and *(5)* (2 mmol) in dry ether (5 ml). [*(5)*[2] was purified by TLC (silica gel; ether/petroleum ether 1:9).] After 2 h, the mixture is shaken with CH_2Cl_2 (50 ml) and silver iodide is filtered off. The CH_2Cl_2 is evaporated *in vacuo* and the salt *(6)* washed with ether (3 × 10 ml) and used without further purification.

(6) is dissolved in DMSO (10 ml) and $KOC(CH_3)_3$ is added (10% excess). After 2 h at 20°C, the mixture is extracted with ether (3 × 50 ml). The ethereal fractions are dried and evaporated and the epoxide *(8)* purified by TLC (silica gel, ether/petroleum ether 5:95).

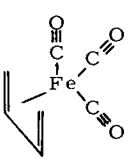
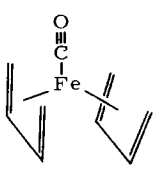
Bis(1,3-butadiene)monocarbonylmanganese—A Paramagnetic Butadiene Complex[**]

By *Max Herberhold* and *Abbas Razavi*[*]

Irradiation of pentacarbonyliron in the presence of 1,3-butadiene in solution affords two substitution products containing bidentate *cis*-butadiene chelate ligands: $Fe(CO)_3C_4H_6$ *(1)*[1] and $Fe(CO)(C_4H_6)_2$ *(2)*[1, 2]. The molecular structures of *(1)*[3] and *(2)*[4] have been determined by X-ray methods[5]. We have now photolyzed tetracarbonylnitrosylmanganese, which is isoelectronic with $Fe(CO)_5$, in the presence of 1,3-butadiene in order to establish the existence of the complexes $Mn(CO)_2(NO)C_4H_6$ *(3)* and $[Mn(NO)(C_4H_6)_2]$ analogous to *(1)* and *(2)*, respectively. Surprisingly, we found *(3)* to be accompanied not by the expected bis(1,3-butadiene)mononitrosylmanganese, which would possess a noble gas configuration, but by a paramagnetic complex of composition $Mn(CO)(C_4H_6)_2$ *(4)*.



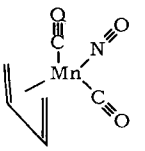
(1)



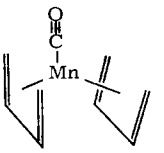
(2)

Irradiation of a THF solution of $Mn(CO)_4NO$ and excess 1,3-butadiene at −30 °C affords a green solution containing (at least) three new complexes. On chromatography of the reaction products, a yellow and a blue-green zone (I and II, respectively) can be eluted with benzene, and then an olive-green zone (III) with THF.

Zone I (yellow) essentially contains $Mn(CO)_2(NO)C_4H_6$ *(3)*. The diamagnetic complex is readily soluble in all organic solvents and volatile in a high vacuum at room temperature; on removal of solvent it is obtained as a yellow oil which solidifies at about 15 °C. The IR spectrum contains two C≡O stretching vibrations of approximately equal intensity at 2045 and 1994 cm^{-1} and an N≡O stretching band at 1751 cm^{-1} (in *n*-pentane). In the ^{1}H-NMR spectrum the characteristic pattern of the *cis*-butadiene ligand is observed with its three symmetrical groups of signals ($\tau = 5.08$ (2H), 8.53 (2H), and 9.95 (2H); in $[D_6]$benzene); the signal at $\tau = 5.08$ is due to the two protons on C^2 and C^3. Very similar ^{1}H-NMR spectra have been reported for the butadiene-iron complexes *(1)*[2, 8], *(2)*[2, 9], and $Fe(PF_3)(C_4H_6)_2$[10], as well as for a series of other butadiene-metal compounds[11]. In the mass spectrum[12] of *(3)* the molecular ion (*m/e* 195, $I_{rel.}$ 8.7%) is accompanied by the fragments $Mn(CO)(NO)C_4H_6^+$ (167, 15.0%), $Mn(NO)C_4H_6^+$ (139, 17.7%), $Mn(C_4H_6)^+$ (109, 14.7%), and Mn^+ (55, 100%); all ligand eliminations can be identified from metastable transitions.



(3)



(4)

Zone II (blue-green) affords $Mn(CO)(C_4H_6)_2$ *(4)*, which crystallizes as long needles from *n*-pentane (dec. pt. ≈150 °C). Their composition is confirmed by elemental analysis and by the mass spectrum[12], which reveals stepwise loss of the CO group and the two diene ligands: $Mn(CO)(C_4H_6)_2^+$ (*m/e* 191, $I_{rel.}$ 2.2%), $Mn(C_4H_6)_2^+$, (163, 27.4%), $Mn(C_4H_6)^+$ (109, 17.7%), Mn^+ (55, 100%). Here too, all the fragmentation steps are indicated by metastable transitions. The IR spectrum exhibits only one strong C≡O stretching absorption (1968 cm^{-1}, *n*-pentane). The complex *(4)* is paramagnetic, corresponding to one unpaired electron[13]. The ESR spectrum[14] in *n*-pentane solution shows an interaction of the single electron with the nuclear spin of the manganese ($I = 5/2$); the *g* factor is 2.018 (half-width 20 G). Splitting of the 6 absorptions by interaction with the nuclear spins of the butadiene protons is not observed. Just one signal (half-width 65 G) appears in the solid state; its asymmetric shape indicates slight differences in the *g* factors along the preferred directions of the molecular axes. To our knowledge paramagnetic complexes with *cis*-butadiene chelate ligands have not previously been reported. Complex *(4)* has a molecular structure[15] of symmetry C_{2v} corresponding to the iron complex *(2)*[4]; the CO ligand coincides with the C_2 axis.

The zone eluted with THF (zone III, green) comprises complexes containing $[Mn(NO)_3]$ groups. The IR spectrum indicates the presence of the adduct $[Mn(NO)_3(THF)]$ (ν(N≡O) 1778 (w), 1666 (vs) cm^{-1})[16] which decomposes on removal of the solvent. Butadiene is incapable of diplacing coordinated THF in THF solution to form $Mn(NO)_3C_4H_6$. In contrast, addition of triphenylphosphane to the green solution yields the known $Mn(NO)_3(PPh_3)$ (ν(N≡O) 1776, 1686/1679 cm^{-1})[16].

Irradiation of $Mn_2(CO)_{10}$ in the presence of 1,3-butadiene in solution affords a small yield of a dinuclear complex $Mn_2(CO)_8C_4H_6$[17] which contains both an Mn—Mn bond and a *trans*-butadiene bridging ligand[18]. Derivatives with two butadiene ligands per metal atom are not formed in detectable amounts.

Procedure[19]:

A solution of $Mn_2(CO)_{10}$ (0.390 g, 1 mmol) in THF (300 ml) is "photonitrosylated"[16] for about 15 min; $Mn(CO)_4NO$ is then condensed from the dark red solution with the solvent THF and thus separated from unchanged $Mn_2(CO)_{10}$ and from $[Mn(NO)_3(THF)]$. Two THF solutions of $Mn(CO)_4NO$ prepared in this way are united and about 20—25 ml of 1,3-butadiene condensed in at −30 °C. After 3 hours' irradiation (high pressure mercury arc, Hanovia L-450 W) at −30 °C the homogeneous green solution is dried and the residue

chromatographed in benzene over silica gel. The first zone contains *(3)* (20 mg, 2.6%), the second *(4)* (15—30 mg, 2—4%). Elution with THF affords a third fraction from which $Mn(NO)_3(PPh_3)$ (82 mg, 15%) is obtained after addition of triphenylphosphane. The low yields of *(3)* and *(4)* based on $Mn_2(CO)_{10}$ are partly due to the low efficiency of the photonitrosylation method[16] employed in the preparation of $Mn(CO)_4NO$ which affords a very pure product in a short time.

Crystal and Molecular Structure of Bis(1,3-butadiene)-monocarbonylmanganese[**]

By *Gottfried Huttner, Dietmar Neugebauer,* and *Abbas Razavi*[*]

The X-ray structure determination of bis(1,3-butadiene)-monocarbonylmanganese *(1)* first prepared by *Herberhold et al.*[1] should establish whether the electronic configuration of *(1)*, which deviates from the noble gas rule, has any detectable effect on the structure of the molecule[2], and whether the interaction between the unpaired electrons of different molecules induces specific changes in the lattice.

Crystal data: $(C_4H_6)_2MnCO$ *(1)*, relative molecular mass 191.13, tetragonal; $a = b = 780 \pm 1$, $c = 721 \pm 1$ pm; $\alpha = \beta = \gamma = 90°$; $V = (439 \pm 2) \times 10^6$ pm^3; $Z = 2$; $d_{X\text{-ray}} = 1.446 \pm 0.006$, $d_{exp} = 1.44 \pm 0.01$ g cm^{-3}; space group $P\bar{4}2_1m$[3]. Figure 1 shows the structure of *(1)*, Figure 2 depicts its crystal structure, and Table 1 lists its positional parameters.

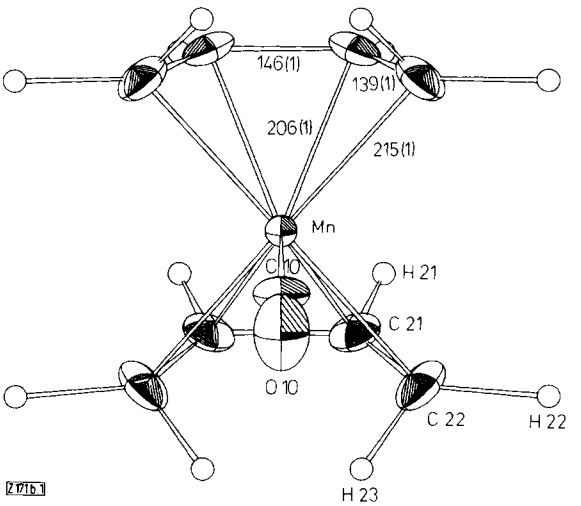

Fig. 1. Molecular structure of $(C_4H_6)_2MnCO$ *(1)*; bond lengths given in pm.

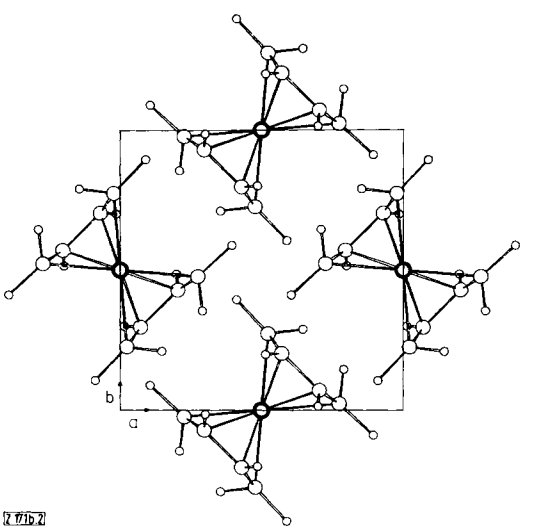

Fig. 2. Crystal lattice of $(C_4H_6)_2MnCO$ *(1)*.

Table 1. Atomic parameters of $(C_4H_6)_2MnCO$ *(1)* (standard deviations in units of the last decimal place given in parentheses).

Atom	x/a	y/b	z/c
Mn	0.0	0.5	0.27648 (19)
C(10)	0.0	0.5	0.5313 (17)
O(10)	0.0	0.5	0.6876 (21)
C(21)	0.2033 (9)	0.4289 (12)	0.1114 (14)
C(22)	0.2741 (9)	0.4769 (16)	0.2800 (17)
H(21)	0.200 (20)	0.485 (18)	−0.001 (17)
H(22)	0.290 (18)	0.354 (20)	0.329 (30)
H(23)	0.394 (18)	0.589 (18)	0.306 (29)

Structural analysis ($R_1 = 0.077$) shows that *(1)* crystallizes in the same space group as four other bis(butadiene)metal complexes: $(C_4H_6)_2Fe(CO)$ *(2)*[4], $(C_4H_6)_2FePF_3$ *(3)*[5], $(C_4H_6)_2RhCl$ *(4)*[6], and $(C_4H_6)_2IrCl$ *(5)*[7]. The isomorphism of the crystal structure of the diamagnetic compounds *(2)*—

(5) with the lattice structure of the paramagnetic complex *(1)* (Fig. 2) clearly demonstrates that the intermolecular interactions between the unpaired electrons in the lattice of *(1)* have no detectable effect upon the structure of the solid. The molecular structure of *(1)* likewise displays no fundamental deviations from those of the diamagnetic compounds *(2)*—*(5)*.

Like the analogs *(2)*—*(5)*, compound *(1)* possesses crystallographic C_{2v} symmetry. For this reason the butadiene ligands are strictly planar. Their "opening" points in the direction of the terminal CO group and the angle between their planes is 11.8°; their terminal carbon atoms form the base of an almost square pyramid whose apex is occupied by the carbonyl group (Mn—C_{CO}: 184±1 pm, C—O: 113±2 pm). Within the limits of error the manganese atom lies in the plane described by the terminal carbon atoms (±1 pm).

While the bond lengths in free butadiene correspond approximately to the values expected for C—C single and C=C double bonds[8], complexed butadiene ligands show compensation of bond lengths, as can be detected in *(1)* (Fig. 1) and likewise in its structural analogs *(2)*—*(5)*. Another characteristic feature of complexed butadiene is the closing of the C=C—C angle from 122.9±0.5°[8] in the free ligand to 118±1° in *(1)*, as has been found in all bis(butadiene)metal complexes so far investigated[9]. The difference in the distance between the metal and the central (Mn—C(21): 206±1 pm) and the terminal carbon atoms (Mn—C(22): 215±1 pm) is in full accord with analogous findings for other butadiene-metal complexes.

Compound *(1)* is the first bis(1,3-butadiene)metal complex whose hydrogen atoms have been located by X-ray analysis. Although the method does not give very accurate positional parameters for the protons (±17 pm) they show beyond any doubt that the *cis* H atoms of the terminal CH_2 groups (H(22) in Fig. 1) lie above the plane of the butadiene ligands on the side opposite to the metal (deviation: +72 pm). The *trans* H atoms (H(23) in Fig. 1), on the other hand, are situated in the ligand plane, while the hydrogen atoms H(21) bonded to the central carbon atoms occupy positions below this plane (deviation: −24 pm). Similar deviations observed for mono(1,3-butadiene)metal complexes were interpreted in terms of a rehybridization of the carbon atoms of the butadiene ligand[10].

Our results show that the presence of an unpaired electron in *(1)* affects neither the molecular structure of the complex nor its lattice structure.

Structure and Absolute Configuration of an Optically Active Square Pyramidal Molybdenum Complex[1]

By *S. J. La Placa*, *Ivan Bernal*, *Henri Brunner*, and *W. A. Herrmann*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 60th birthday

The X-ray structure analysis of $(+)_{579}$-$[C_5H_5Mo(CO)_2NN']^+PF_6^-$ *(1)* (NN' = Schiff base derived from 2-pyridinecarbaldehyde and S-(−)-α-phenylethylamine) represents the first determination of the absolute configuration of an organometallic compound in which the transition metal atom constitutes the asymmetric center.

The orthorhombic single crystals of *(1)*[2, 3], obtained from acetone/methylene chloride/ethanol (20 : 3 : 1), crystallize in the polar space group $P2_12_12_1$ with cell constants $a = 12.245(5)$, $b = 9.237(4)$, $c = 20.693(7)$ Å; $V = 2340.53$ Å^3; $d_{exp} = 1.62$, $d_{calc.} = 1.61(2)$ g·cm^{-3}. The unit cell contains 4 molecules. 9730 *hkl* and *hkl̄* data were obtained with a computer-controlled diffractometer using monochromatized MoKα radiation (λ = 0.71069 Å) to $2\theta \leq 72°$. To solve and refine the structure, the reduced and averaged set with $2\theta \leq 41.6°$ (2359 reflections) was used. At this stage of the refinement, the residuals $R(F)$ and $R_w(F)$ are 7.3 and 9.0%, respectively.

The absolute configuration of *(1)* was determined by comparing 46 pairs of reflections of the type *hkl* and *hkl̄*, taking advantage of the anomalous scattering of Mo and P for MoKα radiation (Fig. 1).

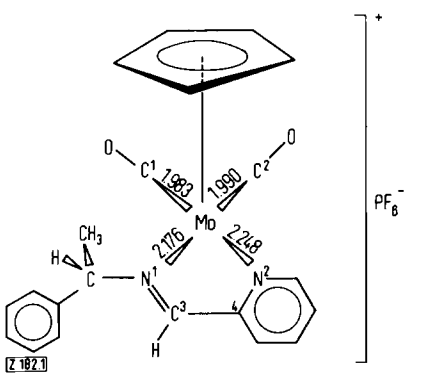

Fig. 1. Structure and absolute configuration of $(+)_{579}$-$[C_5H_5Mo(CO)_2NN']^+PF_6^-$ *(1)*.

Table 1. Bond angles [°] in the complex cation of *(1)*.

C1MoN1	N1MoN2	N2MoC2	C2MoC1
120.9	72.4	130.4	73.9
MoN1C3	N1C3C4	C3C4N2	C4N2Mo
118.7	118.0	115.4	115.2

In the approximately square pyramidal cation, the center of the π-bonded cyclopentadienyl ring occupies the apex of the pyramid. The 5 Mo—C distances are 2.265—2.369 Å. The

atoms C1, C2, N1 and N2 are nearly coplanar, about 0.5 Å below the Mo atom. The most important distances and bond angles are given in Figure 1 and Table 1.

The X-ray structure analysis confirms the *S* configuration of the α-phenylethyl group. Before the configuration at the Mo atom can be specified with the *R,S*-system[4], rules for the treatment of π-bonded ligands must be developed.

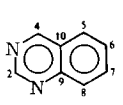
Covalent Hydration—New Results Using ^{13}C-NMR Spectroscopy[1]

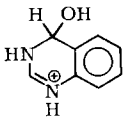
By *Ulrich Ewers*, *Harald Günther*, and *Lothar Jaenicke*[*]

The structure of covalent hydrates that are formed by addition of water to CN double bonds in nitrogen heterocycles[2] has been elucidated so far mainly with the help of UV spectroscopy[2, 3]. We now show that more precise and reliable information is obtained from ^{13}C-NMR spectroscopy because of the sensitivity of chemical shifts to hybridization changes and substituent effects.

According to previous results[4] quinazoline (1,3-diazanaphthalene) exists in $CDCl_3$ as neutral species *(1)* and in 2 N H_2SO_4 as protonated hydrate *(2)*. Hydrate formation is recognized ^{13}C-NMR spectroscopically by the strong shielding

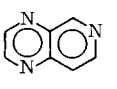


(1)

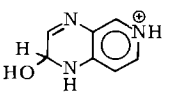


(2)

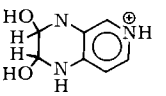
experienced by C-4 (Table 1), whose resonance shifts to 72.4 ppm, *i.e.* into the region typical for "carbinol" carbons. In addition, protonation at N-1 documents itself through upfield shifts for C-2 and C-9. Protonation alone does not change δ(4) significantly, since for the anhydrous cation *(1$^{\oplus}$)* (CF_3COOH) we find a value of 159.2 ppm.



(3)



(4)



(5)

Pyrido[3,4-*b*]pyrazine (1,4,6-triazanaphthalene) *(3)* was formulated in 1 N H_2SO_4 initially as protonated monohydrate *(4)*[5] and later as dihydrate *(5)*[5]. In the ^{13}C-NMR spectrum (Fig. 1) we find *two* resonances at 73.7 and 74.5 ppm. Therefore, *(5)* must be present, whose structure is also compatible with the other δ(^{13}C)-values. With the exception of C-9 all carbon resonances are strongly shielded as a result of protonation at N-6 and NH-substitution at C-9 and C-10. Since only five C(sp^2) resonances are observed, a mixture of two monohydrates can be ruled out.

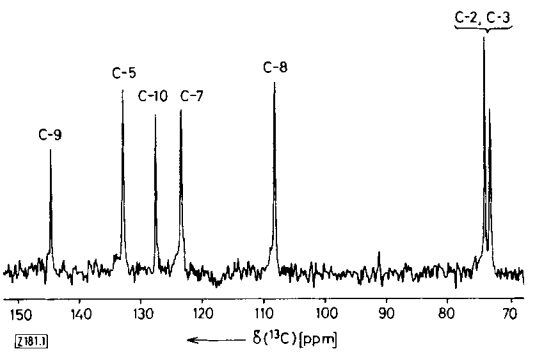


Fig. 1. ^{13}C-NMR spectrum of 1,4,6-triazanaphthalene in 1 N H_2SO_4; δ-values refer to TMS as standard (cf. footnote in Table 1).

New results were obtained through ^{13}C-NMR spectroscopy for pteridine (1,3,5,8-tetra-azanaphthalene) *(6)*. Owing to slow hydration in aqueous solution, freshly prepared solutions of *(6)* at first show δ(^{13}C)-values that are also observed in $CDCl_3$[7] (Table 1). However, after equilibration (12 h) a spectrum is obtained that shows, besides the signals due to *(6)*, *three* CHOH-resonances at 73.7, 73.9, and 75.1 ppm. We assume that, already at pH 6.8 in addition to the monohydrate *(7)*[2] the dihydrate *(8)* is formed in almost equal amount. This interpretation would also best explain the new signals

Table 1. δ(^{13}C)-values (in ppm, relative to TMS) in heteroaromatics and their hydrates [a].

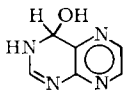
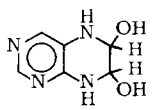
(6)



(7)



(8)

found for sp^2 carbons (Table 1). For a trihydrate only 3 additional resonances are expected, whereas a mixture of three different monohydrates should yield 15 signals. Products of ring opening reactions cannot explain the spectrum, since they contain only sp^2 carbons and, in particular, should display a characteristic carbonyl resonance; *(8)* has so far been obtained in protonated form at pH 2[6].

The results for *(3)* and *(6)* each show that one heteroaromatic ring is preserved during hydrate formation. This finding is consistent with the fact that pyridine and pyrimidine do not form hydrates. The existence of a pteridine dihydrate under physiological conditions as substrate of xanthine oxidase could explain the formation of leukopterine as a degradation product of pteridine cofactors[10].

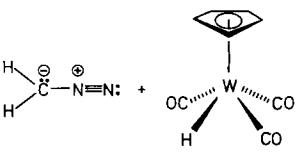
Metal-Stabilized *C*-Protonated Diazomethane: A Methanediazonium Complex[1]

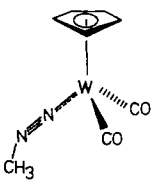
By *Wolfgang A. Herrmann*[*]

On reaction with simple aliphatic diazo compounds transition metal hydrides are generally converted into the corresponding alkyl derivatives, which can be explained as formal carbene insertion into the polar metal-hydrogen bond[2, 3]. In the course of investigations designed to elucidate the diazo method leading to carbene complexes of transition metals[4], diazomethane has now been stabilized as an intact, subsequently protonated molecule by coordination to a metal.

Addition of an excess of diazomethane *(1)* at −85 °C to a THF solution of cyclopentadienyltricarbonyltungsten hydride *(2)* followed by a gradual raising of the temperature to +25 °C affords a dark red neutral compound *(3)* which can be isolated by column chromatography. Compound *(3)* is extremely air-sensitive in solution, and slowly decomposes with evolution of gas when heated to above its melting range of 36—39 °C in a sealed tube.



(1) (2)



(3)

Complete elemental analysis and spectroscopic data show the new complex to possess a diazomethane ligand which has been protonated at the originally sp^2-hybridized carbon atom, and is bound to the metal *via* the terminal nitrogen atom, as a characteristic structural component. While the stretching vibrations of the two metal carbonyl groups are observed in the IR spectrum (benzene) at 1968 vs and 1886 cm^{-1} vs, the bands at 1635 s and 1595 cm^{-1} m are to be assigned to the stretching vibrations of the complexed azo function[5, 6]. The ^1H-NMR spectrum (60 MHz; $CDCl_3$; external TMS) establishes the presence of the cyclopentadienyl ring ($\tau = 4.17$ ppm, singlet) as well as the newly formed methyl group ($\tau = 6.37$ ppm, singlet); absorption no longer occurs in the high-field hydride region. The proposed structure is further supported by the mass spectrum of *(3)* which shows, in addition to the intense molecular peak (*m/e* 350 for ^{186}W), successive elimination of CH_3, N_2, and the two CO groups (70 eV; direct inlet at 10 °C; ion source 30—40 °C).

The above reaction which entails a lowering of the coordination number of the central metal is the first example of CO substitution effected by diazomethane, even though it is associated with a 1,4-hydrogen shift[7]. The ligand CH_3N_2 which corresponds to the highly unstable methanediazonium ion assumes the function of a neutral three-electron donor in the complex.

Procedure:

All operations are carried out with rigorous exclusion of oxygen and moisture (N_2 atmosphere).—A precooled (−35 °C) approximately 0.25 M ethanol-free solution of *(1)* (10 mmol) in diethyl ether[8] is added dropwise to a magnetically stirred solution of *(2)*[2] (1.67 g, 5 mmol) in THF (100 ml) at −85 °C in a thermostated darkened Schlenk flask (programmed cryostat LAUDA K 120 W). After 1 h at −85 °C the mixture is warmed to room temperature over 12 h and stirring continued to complete the reaction (12 h). Chromatography of the concentrated crude product at +10 °C over silica gel 60 (Merck 7734; $l = 80$, $\varnothing = 1.8$ cm) with benzene permits elution of a rapidly migrating yellow zone whose residue affords the methyl derivative $C_5H_5W(CO)_3CH_3$[2] (26 mg, 1.5 %) on high vacuum sublimation at 55 °C. A second red zone is concentrated and rechromatographed under the same conditions. The complex *(3)* initially obtained as a red oil yields fine crystals on reprecipitation (diethyl ether/*n*-pentane; 0 °C) and is analytically pure after recrystallization from diethyl ether/*n*-pentane (1:2) at −100 °C and several hours' drying in high vacuum (0 °C). Yield 1.08 g (62 %).

Selective Oxidation of the Methyl Group of *p*-Cresols by Base-Catalyzed Oxygenation

By *Akira Nishinaga*, *Toshio Itahara*, and *Teruo Matsuura*[*]

Oxidation of simple alkylarenes to arenecarboxylic acids by base-catalyzed oxygenation in diphenyl sulfoxide[1] or hexamethylphosphoramide (HMPA)[2] is well known. In contrast, little work has been done on side-chain oxidation of alkylphenols because the benzene ring is normally attacked under the reaction conditions. Thus oxygenation of alkylphenols in HMPA/potassium *tert*-butoxide affords 4-hydroxy-5,6-epoxy-2-cyclohexenone derivatives quantitatively[3]. We have now found that if a large excess of potassium *tert*-butoxide is used in dimethylformamide (DMF) the methyl group of substituted *p*-cresols *(1)* is exclusively oxygenated, affording the corresponding *p*-hydroxybenzaldehydes *(2)* in excellent yield (Table 1).

No oxidation of the *o*-methyl group was observed for 2,4,6-trimethylphenol *(1b)*, 2,4-xylenol *(1c)*, and *o*-cresol. *m*-Cresols did not react. The reactivity of the *p*-methyl group depends upon the *o*-substituent and decreases in the order $C(CH_3)_3 > OCH_3 > CH_3 > H > Br$ (Table 1). The use of an excess of base is essential for this selective oxidation; oxidation of the benzene ring increases with decreasing amount of butoxide. The failure of 3,5-di-*tert*-butyl-1-methyl-4-oxo-2,5-cyclohexadienyl hydroperoxide *(3)* [formed from the *p*-cresol *(1a)* by oxygenation in aqueous alkaline solution] to give the *p*-hydroxybenzaldehyde *(2a)* on treatment with potassium *tert*-butoxide in DMF[3] indicates that the reaction does not proceed *via* a hydroperoxide.

General procedure:

Oxygen is passed through a solution of a substituted *p*-cresol *(1)* (2 mmol) in DMF (20 ml) containing potassium *tert*-butoxide (20 mmol) at room temperature. After acidification of the reaction mixture and extraction with ether the aldehydes *(2)* are isolated by TLC and identified by comparison with authentic material (IR and NMR).

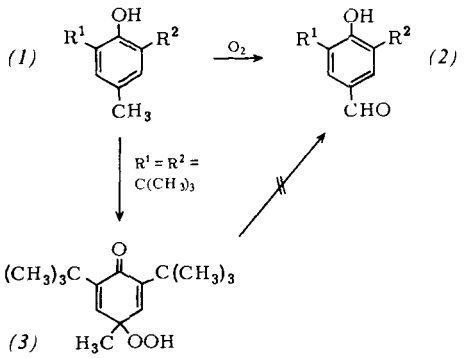

Table 1. Formation of *p*-hydroxybenzaldehydes *(2)* by base-catalyzed oxygenation of *p*-cresols *(1)* at room temperature with potassium *tert*-butoxide as base.

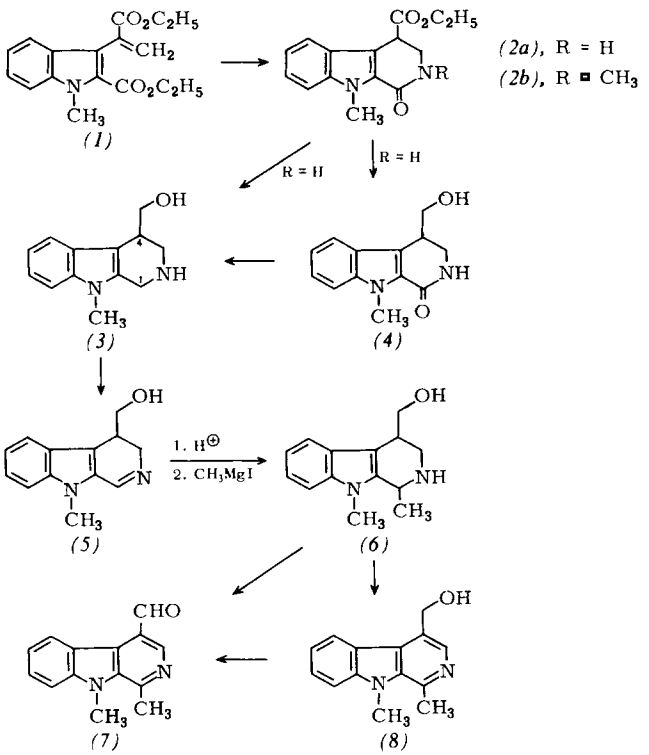
Facile Entry to 1,4-Disubstituted β-Carboline Derivatives. Total Synthesis of N^a-Methylbrevicollin[1][**]

By *Wolfgang Müller*, *Reinhard Preuss*, and *Ekkehard Winterfeldt*[*]

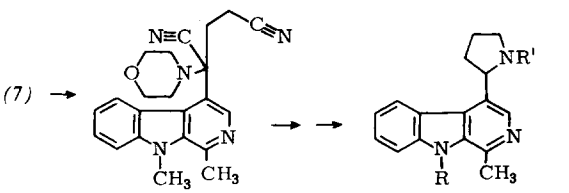
In principle the proton-catalyzed condensation of α-substituted indole compounds with ketones is a known process[2]. We have now found that indole synthesis from methylphenylhydrazine and ethyl pyruvate immediately yields the product *(1)*, and have also established the intermediate occurrence of ethyl *N*-methylindole-2-carboxylate in the reaction. Thus even this acceptor-substituted indole derivative reacts with the carbonyl group of the pyruvate. However, *N*-methylindole-2-carbaldehyde and 2-acetyl-*N*-methylindole do not undergo this condensation. Compound *(1)* proves to be a highly useful and versatile starting material[***] for the synthesis of 1,4-disubstituted β-carboline derivatives such as *(7)*—*(10)*[3].



Compound *(1)* reacts with ammonia or methylamine to form the lactams *(2a)* and *(2b)*, respectively. Reduction of *(2a)* with $LiAlH_4$ proceeds with high selectivity and affords the lactam alcohol *(4)* at room temperature whereas the cyclic amine *(3)* is obtained under reflux. The latter compound is well suited to the introduction of alkyl groups on C^1. The dihydropyridine *(5)*, readily obtainable by lead tetraacetate oxidation, reacts smoothly as the hydrogen chloride with Grignard compounds to give, for example, *(6)*, which directly affords the aldehyde *(7)* on oxidation of small portions with MnO_2. When working on a larger scale it is convenient to first prepare *(8)* with lead tetraacetate and then to obtain the aldehyde *(7)* by treatment of *(8)* with MnO_2.

This aldehyde is an interesting intermediate for the introduction of substituents on C^4. As an example we shall describe the conversion of *(7)* into N^a-methylbrevicollin *(10b)* by a method resembling that used by *Leete*[4] for the synthesis of pyrrolidine derivatives.

Reaction of *(7)* with morpholine and cyanide ion and subsequent Michael addition to acrylonitrile affords the morpholinodinitrile *(9)*. Acid hydrolysis to the keto nitrile followed by reductive cyclization gives *(10a)*, which is converted into N^a-methylbrevicollin *(10b)* by reductive methylation (formaldehyde and cyanotrihydridoborate). This base is found to be identical to the methylation product of brevicollin *(10c)* in all its spectroscopic data and on thin-layer chromatography[5].



Procedure:

(1): Glacial acetic acid (720 ml) and H_2SO_4 (80 ml) are mixed together and 1,1-methylphenylhydrazine (60 g, 0.453 mol) is added dropwise under N_2 to the warm mixture, the temperature being maintained under 50 °C. Ethyl pyruvate (114 g, 0.99 mol) is then added dropwise, the temperature being kept below 70 °C. After completion of reaction the mixture is poured onto five times its volume of ice water and extracted several times with ether. The ethereal phase is washed three times with water, neutralized with Na_2CO_3 solution, and dried over Na_2SO_4. The solvent is drawn off and the residue distilled at 150—170 °C/0.02 torr. The yellowish oily distillate is stirred with ether whereupon crystallization sets in. Yield after recrystallization from ether/5% methanol: 96.2 g (71%), m.p. 72 °C.

(7): Compound *(8)* is refluxed for 3 h in $CHCl_3$ with a tenfold weight of activated MnO_2 (according to *Attenburrow*). Yellow oblong crystals, yield 85%, m.p. 171 °C.

(10b): Compound *(10a)* (33 mg) in CH_3OH (10 ml) containing CH_2O (200 mg) is reduced at room temperature with an excess of $NaBH_3CN$ (40 mg). The reaction is complete within a few minutes. Yield 26.2 mg (82%), m.p. 162 °C (racemate).
