In addition to the favorable increase in production of animal plankton and fishes, however, the overall consequence of such an algal growth is a negative one. The algae sink, especially on dying, from the upper layers of the water to the growth zone in deeper layers, where they undergo bacterial decomposition; a process involving consumption of large amounts of oxygen. The resulting decrease in oxygen content in the deeper layers is typical of eutrophic lakes[2]. The withdrawal of drinking water can become problematical, and fish spawn can suffer asphyxiation. Finally, anaerobic chemical transformations, with liberation of *e.g.* hydrogen sulfide, can take place on the bed of such a water. The deficiency of oxygen in the water can be replenished only after the summer stagnation when the water is driven into circulation by the wind during the fall and spring time.

A further characteristic of eutrophication is a change in the type and variety of algae. During the transformation of a lake from the oligotrophic, *i.e.* less nourished state, into the eutrophic state, diatomaceae are displaced by green algae,

and these in turn by blue-green algae, whereupon the number of incident types frequently decreases[3].

1.2. Geographical Location

The transformation of oligotrophic, *i.e.* nutrient-deficient water into the eutrophic state has in recent years been mainly observed in those regions where civilization has had a noticeable influence on environmental conditions in the neighborhood of stationary waters, *i.e.* in North America, Scandinavia, and the Netherlands, as well as in the Federal Republic of Germany in Schleswig-Holstein, South Germany, and in some artificial reservoirs. In the Federal Republic of Germany some 5% of the population live in the catchment area of such a water[4].

Eutrophication phenomena are far less discernable in flowing waters than in stagnant waters. The reasons for this are, *inter alia*, that nutrients can be more highly enriched in stagnant waters, since those already taken up by aquatic plants are partly available again after the plants have decayed. Moreover the upper layers of stagnant waters become warmer owing to far less turbulence, and the fact that passage of light is not so impaired by suspended material as in flowing waters[5]. The limiting velocity of flow below which the most intense algal growth is favored has been quoted as 0.3 m/s[6].

Eutrophication is not fundamentally limited to fresh water; it even extends to coastal water[7], creeks, bay[8], and the open sea[9]. In each case, however, the phenomena observed can be rationalized in terms of local conditions.

1.3. Causes of Eutrophication

1.3.1. Algal Growth

The primary production and growth of flora in waters depends on several parameters, including, light, temperature, and water motion[1]. The enhanced growth of such flora resulting from the impact of civilization is due, however, to the increased supply of nutrients that are as necessary for aquatic plants as they are for terrestial plants. Analysis of the dry matter obtained from a few types of algae occurring in eutrophic lakes gives an indication of the most important nutritional elements (Table 1)[10].

Table 1. Composition of dry solids from blue-green algae and green algae [10].

Element [%]	Blue-green alge *Microcystis*	Blue-green algae *Anabaena*	Green algae *Cladophora*
C	46.5	49.7	35.3
N	8.1	9.4	2.3
P	0.7	0.77	0.56
K	0.8	1.2	6.1
Ca	0.53	0.36	1.7
S	0.27	0.53	1.6
Fe	0.27	0.08	0.23
Mg	0.17	0.42	0.23
Na	0.04	0.18	0.18
Mn	0.03	0.008	0.10
Zn	0.005	0.000	0.001
Cu	0.004	0.007	0.019
B	0.0004	—	0.0085

In addition to the elements quoted in Table 1, several others, including molybdenum, vanadium, chlorine, cobalt, silicon were also found to be present—in some cases as many as 20 elements were detected[11]. All of these essential nutrients are contained in the "New Algal Assay Medium" (NAAM), the nutrient solution proposed for laboratory testing of the degree of eutrophication of waters (Table 2)[12].

Table 2. Composition of the nutrient solution NAAM (New Algal Assay Medium) [12].

	[mg/l]		[μg/l]
$NaNO_3$	25.5	H_3BO_3	185.64
K_2HPO_4	1.044	$MnCl_2$	265.27
$MgCl_2 \cdot 6H_2O$	12.39	$ZnCl_2$	32.7
$MgSO_4 \cdot 7H_2O$	14.7	$CoCl_2$	0.78
$CaCl_2 \cdot 2H_2O$	4.41	$CuCl_2$	0.009
$NaHCO_3$	15.0	$Na_2MoO_4 \cdot 2H_2O$	7.26
$Na_2SiO_3 \cdot 5H_2O$	92.7	$FeCl_3$	96.00
		$Na_2EDTA \cdot 2H_2O$	300.000

Of the most essential nutrients, carbon is generally available in abundance, since the carbon dioxide dissolved in the water and the CO_3^{2-} ions and HCO_3^- ions that are in equilibrium with it are supplemented by that from the atmosphere and that arising from the bacterial degradation of organic substances[13]. In most waters nitrogen is available in excess, like potassium and calcium as well as sulfur and iron, since bacteria and blue-green algae are capable of fixing atmospheric nitrogen in organic compounds.

1.3.2. Limitation of Algal Growth

In investigations on the growth limitation factor, the minimum factor as defined by the Liebig law[14], a variety of results had to be obtained for each of the large number of influences relevant to algal growth. Thus, in numerous cases phosphorus was determined as growth limiting[15–18], in other cases the elements nitrogen, iron, carbon, cobalt, magnesium, molybdenum, zinc and magnanese[19–27].

Nevertheless, in order to develop a universally applicable strategy for combatting eutrophication, the view taken presently is that less importance attaches to the question of which substance be under consideration as the minimum factor in an actual case than to whether an element (or possibly two elements) can be effectively restrained from entering the receiving waters. If it is possible to bring the content of this element in the water down to a very low level then it can generally take over the key role of the minimum factor. In this sense efforts have concentrated on phosphorus, and with certain reservations on nitrogen, as the elements which are the main contributors to the eutrophication of receiving waters as a result of the impact of civilization.

Sawyer[28] has quoted a value of 0.01 mg P/l as the most likely concentration below which phosphorus can be expected to have little influence. Other authors quote higher values. An exact determination is complicated by the fact that many algae are capable of storing up to 30 times more phosphorus than they actually require and then releasing it again[3]. More informative as a limiting value, which can only apply for the period after full circulation in the spring, might be the permissible surface loading of a lake. According to *Vollenweider* this amounts to 0.2—0.5 g total-P and 5—10 g total-N per m^2 and year for oligotrophic lakes. Lakes with a yearly loading of *e.g.* 1 g total-P/m^2 and simultaneously 10 g total-N/m^2

are eutrophic. The depth of the lake is an additional parameter which must be taken into account[29].

1.3.3. Nutrient Sources

A systematic overview of all possible sources of phosphorus has been compiled by *Coughlin*[30] (Table 3).

Table 3. Sources of phosphorus [30].

1. Localizable origin
   - 1.1. Effluents from built up areas and municipalities
     - 1.1.1. Human excrements
     - 1.1.2. Domestic wastes
     - 1.1.3. Food wastes
     - 1.1.4. Industrial wastes } in municipal
     - 1.1.5. Collected rainwater } water supply
   - 1.2. Industrial effluents fed directly into watercourses
   - 1.3. Chemical products used in water treatment
2. Diffuse sources
   - 2.1. Rural effluents
     - 2.1.1. Agricultural origin
       - 2.1.1.1. Soil erosion
       - 2.1.1.2. Irrigation water
       - 2.1.1.3. Fertilizer losses
       - 2.1.1.4. Domestic animal excrements
     - 2.1.2. Non-agricultural origin
       - 2.1.2.1. Organic forest wastes
       - 2.1.2.2. Wild animal excrements
   - 2.2. Springs and natural waters
   - 2.3. Inherent reserves in lakes
     - 2.3.1. Sediments
     - 2.3.2. Fauna and flora (biota)
     - 2.3.3. Water systems
   - 2.4. Atmosphere
     - 2.4.1. Rainwater
     - 2.4.2. Dust fallout

For simplification one can consider domestic effluents, *i.e.* municipal sewage, and diffuse rural wastewaters as being the two major sources of nutrients. In the case of the Federal Republic of Germany it can be assumed as a rough estimation that human excrements, detergents—these two together in domestic sewage—and influents of rural origin each supply about one third of the total contribution[31]. In individual cases the proportion of *e.g.* detergent phosphates can be higher —as in Lake Constance where this can be 30—40% higher[32]; in other cases *e.g.* in impounding reservoirs in country districts the proportion from rural wastewaters can predominate[33,34]. For Switzerland an overall contribution of around 30% from human excrements, 40% from detergents and 30% from the erosion of fertilized agricultural soils, including a small proportion from the natural weathering of rocks, has been quoted[35]. It is clear from such data that the problem of phosphorus in wastes must be regarded as a regional one, and that separate solutions have to be found for individual waters and regions.

1.4. Eutrophication Caused by Municipal Sewage

In those cases where the supply of phosphorus stems mainly from communal wastes, it is possible to combat eutrophication by extensive removal of this element. In the case of Lake Erie in North America, which was subjected to a detailed study, it was found that communal wastes accounted for some 59%[36] of the phosphorus entering the lake. A reduction of the phosphorus content in domestic wastes by 95%, in industrial effluents by 90%, and in wastewaters from rural areas by 60% was called for[37].

These values may deviate somewhat from those for other lake districts but they give a good indication of the sort of measures which must be taken. The removal of phosphorus from waters in rural areas is without doubt especially difficult, and its effectiveness is to some extent controversial. However, there is general agreement of opinion on the removal of phosphorus from sewage, as will be shown in the following sections.

2. State of Sewage Purification

2.1. Conventional Sewage Purification

Conventional methods for the purification of sewage consist essentially of physical, biological and, in special cases, chemical processes. Under the physical processes the principal step, usually a mechanical purification step, involves removal of debris and deposition of coarse impurities; under the biological processes we have the aerobic stage where, in this second step, the organic components of the sewage are degraded by bacteria[6]. The sludge precipitating in the mechanical and in the biological steps is usually further degraded and hygienically improved in an anaerobic step in a digester[6]. Such a conventional two-stage sewage purification results in an optically clear effluent which is practically free of suspended solids and has, for example, a maximum content of organic components corresponding to 20 mg BOD_5/l[*].

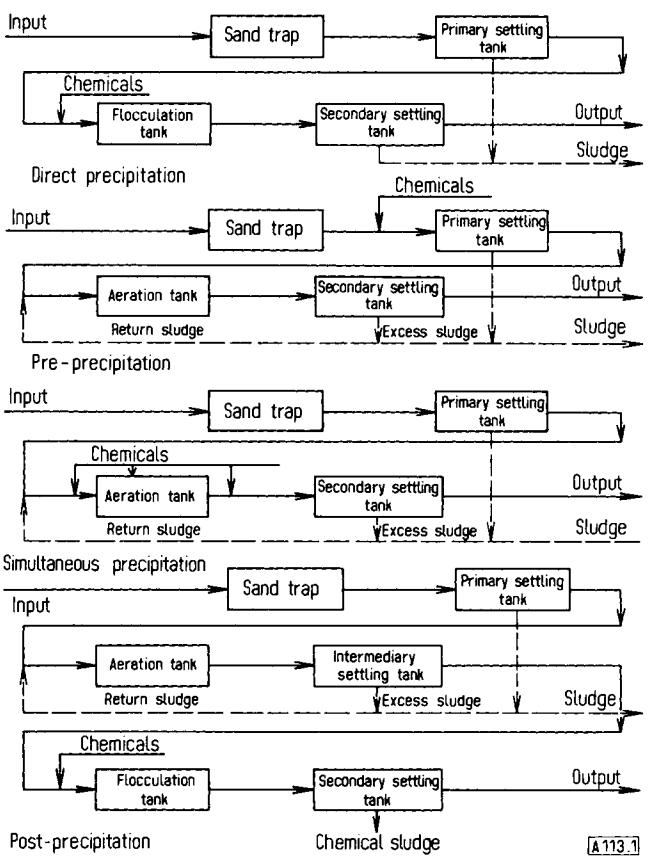

Fig. 1. Methods of precipitation purification for removal of phosphate. In direct precipitation, plant without biological purification steps are employed. For details see Section 3.1.7.

[*] BOD_5 (Biological Oxygen Demand in 5 days) denotes the amount of oxygen required for the oxidative degradation of the organic substances in the water in five days at 20°C in the dark. The amounts of organic constituents are expressed in mg BOD_5/l.

The increased consumption of water and the completion of canalization have led to increasing delivery of sewage to receiving waters. As outlined in the previous sections, recent examinations have shown that additional purification steps are necessary for removal of the nutrients phosphorus and nitrogen.

2.2. Additional Sewage Treatment

A suitable method for the removal of phosphorus is by precipitation as phosphates with iron, aluminum, or calcium salts (see Fig. 1). Methods, albeit expensive ones, have also been developed for the removal of nitrogen.

The greatest progress that has been made in recent years in the removal of phosphorus by precipitation has been in Sweden, where as long ago as 1974 the sewage from 50% of the population in densely populated areas passed through chemical or biological-chemical purification plant[38]. In the Great Lakes area of North America more than 200 sewage treatment plant include precipitation purification, in Switzerland *ca.* 70. Table 4 gives an overview of the sewage treatment plant already known to be in operation in the Federal Republic of Germany and which also incorporate a precipitation step.

Table 4. State of precipitation purification in the Federal Republic of Germany (see Fig. 1). 23 of the 25 precipitation purification plants are located near lakes and impounding reservoirs (for details see Section 3).

Precipitation method	Geographical region	Precipitant	Number of Plant
Direct precipitation	North	Al salts	1
Pre-precipitation	North	Al salts	3
	Central	Al salts, Al/Fe salts	6
	South	Al salts, lime + Fe salts	6
Simultaneous precipitation	North	Fe salts	2
	Central	Fe salts	2
	South	Al salts	4
Post-precipitation	North	Al salts	4
	South	Fe or Al salts	3
Unknown	Central	Fe salts	2
	South	Al salts	2

3. Phosphate Removal

3.1. Purification by Precipitation

3.1.1. Precipitants

The following compounds are commonly employed for the precipitation of phosphates from wastewaters: aluminum sulfate, aluminum chloride, calcium hydroxide, iron(II) sulfate, iron(III) chloride sulfate, and iron(III) chloride.

Because of their hygroscopic nature iron(III) salts are usually employed in dissolved form, whereas aluminum salts are also added in solid form, the products sometimes being granulated so as to facilitate dosage. Commercially available aluminum salts generally contain large amounts of iron. These precipitants are thus mixed precipitants. In precipitation purification the simultaneous employment of two precipitants is also occasionally resorted to[39]. It is often a matter of re-treated waste products or of compounds based on waste substances.

3.1.2. Chemical Aspects of Precipitation

A common feature of the precipitants mentioned is that they form sparingly soluble hydroxides and phosphates. During the precipitation hydroxide phosphates separate out, which according to estimated average M^{III}/P ratios of *ca.* 3:2 have the composition $[M^{III}(OH)]_3(PO_4)_2$[40,41]. Aluminum phosphate having the same Al/P ratio is found in Nature in the form of the mineral wavellite $Al_3(PO_4)_2(OH)_3 \cdot 5H_2O$. Precipitation with lime yields structures, which in their composition correspond to hydroxyapatite $Ca_5(PO_4)_3OH$[42]. Studies on aluminum hydroxide precipitation have proven, *inter alia*, the formation of an octanuclear complex[43], so polynuclear complexes are probably also formed in phosphate precipitation.

Among other things, it is assumed that the metal hydroxide initially formed in the precipitant solution exchanges hydroxide for phosphate ions on entering the phosphate-containing wastewater[44]. If the precipitant is first dissolved in water and then the phosphate-containing wastewater added to it, less phosphate is removed; this shows that the OH^-/PO_4^{3-} exchange proceeds relatively slowly. Under these conditions the hydroxide complexes and flocs have not only been completely formed but are also partially shielded by adsorbed substances. It may be assumed, therefore, that the phosphate is predominantly bound directly to the precipitant cations on rapid mixing with the wastewater. In addition phosphate ions are also removed by adsorption.

The degree of removal e is dependent on the relative amount of precipitant β (M:P), the phosphate content of the wastewater P_z, and the pH of the wastewater after precipitation.

$$e = k_1 + k_2 \log\beta + k_3 \log P_z - k_4\,\mathrm{pH}$$

On testing this equation experimentally, it was found that the results obtained agree satisfactorily (accuracy 5%) with those predicted. k_1, k_2, k_3, and k_4 are empirical constants[44].

The efficiency of the precipitant is dependent on the pH. For precipitation of orthophosphate, iron salts are most efficient at pH = 5, aluminum salts at pH = 6, and lime at pH > 10. Satisfactory removal of orthophosphate has, however, also been observed at pH values varying considerably from those just mentioned[40]. The solubility of the corresponding pure

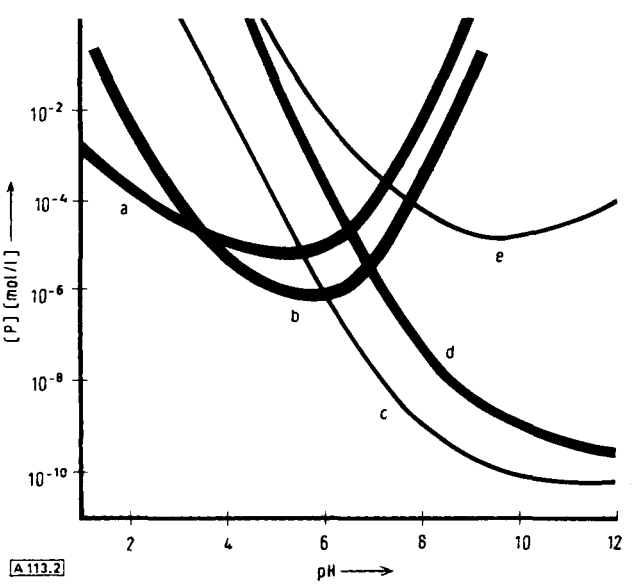

Fig. 2. Solubility of phosphates as a function of pH. a) $FePO_4$, b) $AlPO_4$, c) $Ca_{10}(PO_4)_6F_2$, d) $Ca_{10}(PO_4)_6(OH)_2$, e) $Ca_4H(PO_4)_3$.

phosphates is also at its lowest at the above pH values[45] (Fig. 2).

3.1.3. Orthophosphate and Condensed Phosphates

Domestic wastes contain both inorganic and organic phosphorus compounds. 85—90 % of the phosphorus compounds are of an inorganic nature[40]. These consist predominantly of orthophosphates, since any condensed phosphates also entering the wastewater are partially hydrolyzed before reaching the purification plant[46]. Hydrolysis continues in the purification plant. *Lewin* found that the proportion of condensed phosphates in raw sewage amounted to about 20 %, while no condensed phosphates were present in the water after treatment[47]. Investigations carried out on raw sewage to a communal purification plant yielded the distribution of phosphates listed in Table 5, according to which a considerable portion of the phosphates are already hydrolyzed to phosphate in the preliminary clarification tanks.

Table 5. Distribution of phosphates in the effluent of a sewage treatment plant (P content in mg/l). The plant is designed for a PE of *ca.* 10000 (PE = "population equivalent").

	Total	Orthophosphate	Condensed phosphates			
			Diphosphate	Triphosphate	Others	Σ
Raw sewage						
unfiltered	36.2					
filtered	15.9	10.2	0.7	4.1	0.9	5.7
undissolved	20.3					
Effluent of primary settler						
unfiltered	30.1					
filtered	23.3	21.6	0.35	0.65	0.7	1.7
undissolved	6.8					

The condensed phosphates present are mainly the pentasodium triphosphate $Na_5P_3O_{10}$ arising from detergents, along with tetrasodium diphosphate and higher condensed phosphates.

Condensed phosphates—so far as they are still not hydrolyzed—are precipitated directly, like orthophosphate[40]. The removal of individual condensed phosphates varies according to the pH (Fig. 3).

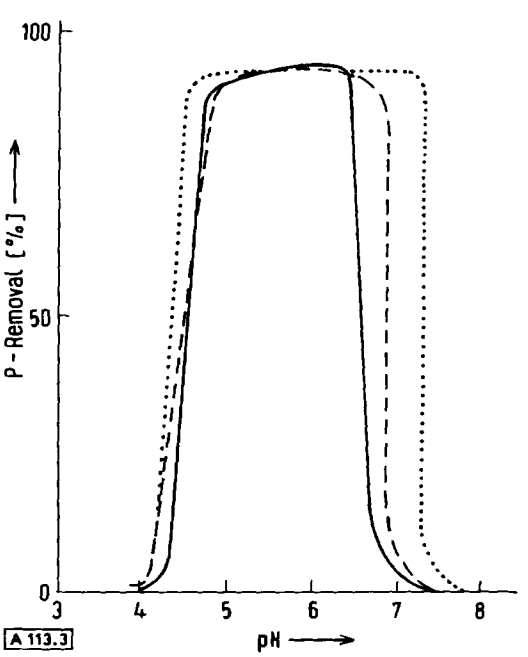

Fig. 3. Removal of condensed phosphates with aluminum sulfate as a function of pH. —— diphosphate, – – – triphosphate, ····· higher condensed phosphates. The pH after precipitation is given.

These diagrams give no indication that the precipitation of condensed phosphates is connected with simultaneous hydrolysis. In the precipitation the degree of removal of triphosphate and orthophosphate is about the same, while under the same conditions it is lower by 5—10 % in the case of diphosphate and by 10—15 % in the case of metaphosphate[48].

It can be assumed that a part of the organically bound phosphorus is also precipitated by adsorption on the flocs. These compounds are converted into inorganic phosphates in the biological purification step, whereupon hydrolysis of the condensed phosphates is also completed at the same time[46].

3.1.4. Amount of Precipitant Required

The molar ratio of aluminum and iron(III) to phosphorus necessary for more than 90 % precipitation of orthophosphate has been reported to be M:P = 1.4:1[41]. In practice ratios up to 2.0:1 are found[40], thus indicating the prevalent undesired precipitation of pure hydroxides. When the optimum amount of precipitant is used, the content of its cations in the effluent is not higher than in the untreated raw sewage input. In the case of simultaneous precipitation (see Fig. 1) with iron salts, *Leumann*[49] found an average of 0.714 mg Fe/l in the effluent compared with 0.206 mg Fe/l in the raw sewage. Similar ratios were found on precipitation with aluminum salts[50].

Higher contents of precipitant cations in the effluent than in the feed are indicative of the presence of complexing agents such as nitrilotriacetic acid, whereby the demand on precipitant is increased[51]. As has already been shown in an OECD survey (Table 6)[52], precipitation with calcium hydroxide requires considerably larger amounts of precipitant than are required in the precipitation with aluminum or iron(III) compounds.

3.1.5. Degree of Phosphate Removal

At a constant M^{III} : P molecular ratio the degree of P removal with a commercial aluminum sulfate/iron(III) sulfate precipitant increases with increasing initial content of phosphorus (Fig. 4). The poorer removal of phosphorus at lower concentration than at higher concentration can be compensated only in part by increasing the amount of precipitant (Fig. 5). In direct comparison with iron(III) chloride, aluminum sulfate gave by far the better degree of phosphate removal[53].

Table 6. Dosage of precipitant and optimum pH ranges for precipitation [52].

Method of precipitation	Al	Fe^{III}	Ca
Pre-precipitation			
Dosage [g/m³]	6—12	10—25	100—150
pH	6—7	≈ 5	>9.5
Simultaneous precipitation			
Dosage [g/m³]	6—10	6—20	—
pH	5.5—7.0	5—7	—
Post-precipitation			
Dosage [g/m³]	6—12	10—25	180—425
pH	5.5—7.5	5	11.5

3.1.6. Flocculation

Separation of the precipitated phosphate is dependent on floc formation. Hydroxide phosphates are initially formed as very small particles which separate only when the zeta potential tends towards zero.

Floc formation and the amount of precipitant required are thus influenced by the ions present in the wastewater. A high zeta potential can be more advantageously reduced by addition of polyelectrolytes than by overdosage of precipitant because the system then leaves the range of pH favorable for flocculation[40].

Destabilization and transport of the colloids requires energy; this can be supplied by stirring. Particular attention must be paid, however, to the velocity gradients in the reaction vessel[54].

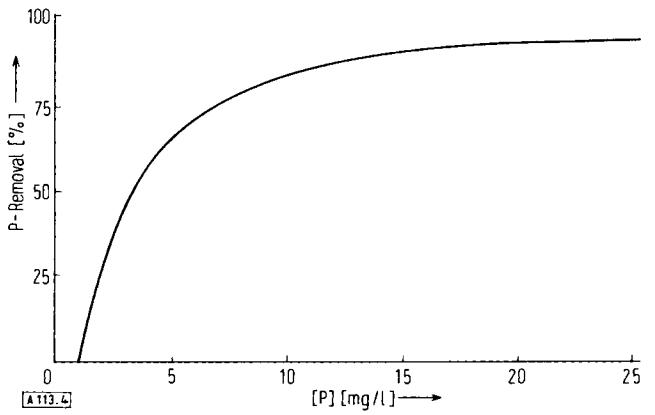

Fig. 4. Phosphate removal at constant pH (after precipitation 6.5±0.3) and constant M^{III}:P ratio (1.6:1).

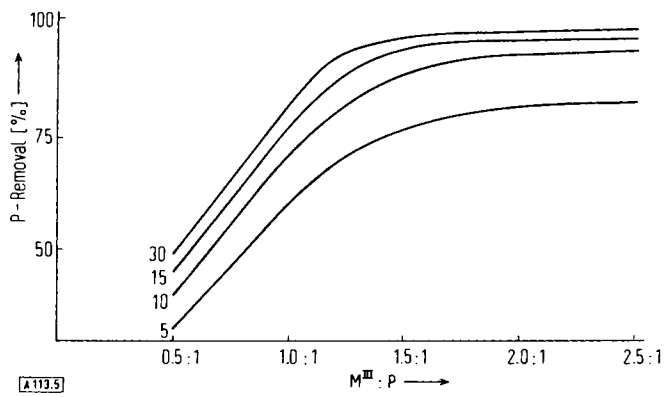

Fig. 5. Phosphate removal as a function of the M^{III}:P ratio and of the initial concentration (given in mg P/l). pH after precipitation 6.5±0.2; mains water with 14° hardness (German scale).

The hardness of the water has only a slight influence on the precipitation. Floc formation is somewhat improved with increasing hardness, and the drop in pH on addition of precipitant is smaller. Ca ions also participate in the precipitation of phosphate, but without notable influence however on the degree of removal observed in laboratory experiments with 15 mg P/l and water hardnesses between 0 and 20° (German scale). The precipitant flocs adsorb colloids; hence other sewage components are removed at the same time as phosphates [organic compounds (expressed as BOD_5), chemically oxidizable compounds (expressed as chemical oxygen demand, COD), heavy metals]. This effect is an essential factor in the assessment of precipitation as a general method for the purification of wastewaters (see Section 4.2).

3.1.7. Possible Incorporation of Precipitation in Sewage Treatment Plants

Purification by precipitation for the removal of phosphate can be carried out in existing one- or two-stage sewage treatment plants under favorable conditions without need for further installations. In some cases, however, construction of a separate "third purification step" is recommended.

In precipitation purification one distinguishes between three processes: pre-precipitation, simultaneous-precipitation, and post-precipitation (the names signify the point at which the precipitation is carried out referred to the biological stage). Pre- and simultaneous-precipitation (Fig. 1) can be employed directly in existing sewage treatment plants; post-precipitation requires incorporation of an additional step in the plant. Sewage purification by precipitation without biological processes is referred to as direct precipitation. Removal of phosphate with aluminum and iron(III) compounds can amount to ≥90% in all the methods quoted. In simultaneous-precipitation the average removal is only 5% less, probably because the phosphates liberated in the mineralization of organic phosphorus compounds are no longer completely collected by the precipitant flocs formed in the feed to the aeration tanks; this disadvantage can be avoided by addition of precipitant to the aeration tank or trickle filter discharge with the usual return sludge ("hybrid precipitation"). With iron(II) sulfate, on the other hand, only *ca.* 80% of the phosphorus is removed in practice in the case of simultaneous precipitation[55].

Pre-precipitation has the advantage that it is less demanding on the biological step since about 60% of the organic compounds (BOD_5load) have already been removed. Moreover, heavy metals, which can have a toxic action on biological degradation, and other toxic substances are removed prior to the biological step. The advantages of post-precipitation lie in the fact that good formation of flocs is guaranteed by optimal mixing in a separate flocculation tank. The results of post-precipitation surpass those of the other methods. Very low phosphate and BOD_5 can be achieved. Irregularities in the previous purification steps can be largely compensated for in post-precipitation. The flocs are separated by sedimentation, flotation or filtration.

3.1.8. Feed and Amount of Precipitants

The precipitants are added either in solid form or in solution. A rapid and intimate mixing of the components must result, and sufficient residence time allowed for floc enlargement.

Flocculation tanks furnished with slow moving stirrers enable adequate agitation for enhanced floc formation. The sewage passes through several flocculation tanks whose stirrers are adjusted to run stepwise at rates ranging from about 0.3 to 0.1 m/s. The overall residence time of the sewage in the flocculation tanks should be about 20—30 minutes.

Flocculation tanks are not available in some existing sewage treatment plants for the incorporation of precipitation purification as *e.g.* pre- or simultaneous precipitation. In these cases a suitable feedpoint in the plant must be sought at which requisite motion of sewage for thorough mixing and for formation of readily settleable flocs is fulfilled. If necessary this motion is effected by installation of extra equipment or by altering the feed of water. Solutions of commercially available precipitants are generally corrosive. The materials used in the construction of plant must therefore be corrosion-resistant. Consequently, the storage and transport of dissolved precipitants are more costly than in the case of solid precipitants, some of which can be transported and stored in normal sheet-steel tanks.

The dosage can be controlled electronically according to various parameters. A simple method of control geared to the amount of feedwater is frequently adopted. Regulation of the dosage according to phosphate loading entails incorporation of an automatic analyzer by means of which the feedwater value is superimposed with a phosphorus value[56]. About 30% of precipitant can be saved in this way and the amount of sludge is also reduced[57].

3.1.9. Separation of Precipitated Sludge

The efficacy of precipitation purification is essentially determined by the separation of the flocs. In pre-precipitation they are separated by sedimentation in preliminary settling tanks. Precipitation purification in the activated sludge step (simultaneous precipitation) usually has a favorable influence on the simultaneous settling of activated sludge in the second or final settling tank. Separation is then possible by flotation, aerated water being added to the sewage so that the flocs float. The sludge separated in this way has a solids content

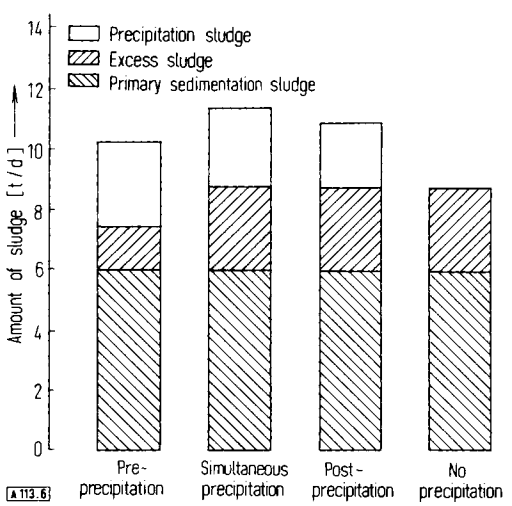

Fig. 6. Precipitated sludge in various precipitation methods. The "excess sludge" is the sludge produced in each case in the activated sludge step (in the aeration tank). The data are for a PE ("population equivalent") of 100000.

three-to fourfold that of sedimented sludge. A flotation tank requires about a third of the area required for a sedimentation tank[58].

When used in solid form, aluminum and iron salts are present as hydrates. The dry solid from the precipitated phosphates has a weight still amounting to only *ca.* 50% that of the precipitant employed, since the dry phosphates are essentially not hydrated. The situation is much different in the case of precipitation with CaO, which alone increases in weight *via* uptake of anions, and the weight of dried solid matter finally amounts to *ca.* 150% that of the starting weight.

The total volume of sludge occurring in a mechanical-biological sewage treatment plant is increased by about 30—50% by precipitation with an essentially unchanged preliminary sludge solids content of 3%[50]. (For details of simultaneous- and post-precipitation see Refs. [59, 60].) The amounts of sludge produced in each of the precipitation methods are compared in Figure 6.

The following increases in dry solids in sludge compared to that in mechanical-biological wastewater purification has been quoted: pre-precipitation 16%, simultaneous precipitation 34%, post-precipitation 28%[40]. Mixed sludges occur in pre- and simultaneous precipitation, a fact that must be taken into consideration in any further treatment. Lime, for example, may not be employed if the sludge is to be subsequently digested.

3.1.10. Handling of Sludges

Sludges obtained by precipitation with aluminum and iron salts do not disturb the processes of dehydration or of stabilization from a biological viewpoint on admixture with primary settler or biological excess sludge. A stabilization (aerobic or anaerobic) of the separable post-precipitation sludge is not necessary, since the proportion of organic matter is small[40]. The post-precipitation sludge can be admixed with the digested, *i.e.* the anaerobically stabilized, sludge to improve the dehydration properties.

Theoretically, the anaerobic stabilization of sewage sludges involves the danger of re-dissolution of the precipitated phosphate, particularly from the iron hydroxide phosphate flocs. However, *Thomas*[61] did not observe any deviations in the content of phosphate in discharge water from a sewage treatment plant after periodic addition of digester effluent. According to other studies the proportion of dissolved phosphates in the digester effluent also remains small on employing precipitation purification[49]. Liberation of phosphate by sulfide ions formed under anaerobic conditions is also considerably suppressed by calcium ions[62]. Besides anaerobic stabilization, an aerobic or a chemical stabilization (with lime) also finds use in sewage sludges. Stabilization is unnecessary in sludge incineration, which can be carried out independently, if necessary with refuse, after dehydration to $\geqq 30\%$ dry solids. Before disposal of sludges, stabilization and dehydration (40% dry solids) as well as a check on the dumping ground is necessary.

Stabilized and thickened sewage sludges can be used agriculturally. The phosphate in precipitation (mixed) sludges is especially useful as a nutrient for plants; in a mixed sludge obtained on precipitation with aluminum sulfate 75% of phosphate soluble in citric acid at a total-P_2O_5 content of 13% was found, in a secondary sewage sludge 70% citric acid solubility

at 28 % total-P_2O_5. Since heavy metals are entrained on precipitation their content in the mixed sludge increases (Table 7). *Anderson* and *Nilson*[63] investigated the extent to which the heavy metals of the sewage sludge are taken up by soil and by vegetation (Table 8).

Table 7. Heavy metals in primary sedimentation sludge (2 % dry solids) of a sewage treatment plant.

	Without precipitation [ppm]	Pre precipitation [ppm]
Fe	380	396
Zn	36	61
Mn	7.0	16.0
Pb	4.0	8.0

Cd	<0.1	0.2
Hg	0.1	0.2

duction was determined *via* the protein content. A reduction of more than 50 % in algal growth in the effluent compared to that in the feed could be detected at dilutions of 1:25 onwards with phosphorus-free nutrient solution NAAM[64].

The decrease from 3.8 to 0.9 mg P/l at the dilutions 1:25 and 1:50 produces at least the same decrease in growth again as that from 24.2 to 3.8 mg P/l. These dilution factors, which resemble natural ratios, gave concentrations nearly the same as that claimed by *Sawyer*[28] (Table 9).

3.1.12. Costs

The human being excretes about 1.7 g of phosphorus per day[65]. Together with a similarly high contribution from washing and cleansing agents, and taking into consideration other household wastes, the daily release of phosphorus into domestic sewage can be assumed to be 4 g per inhabitant. The precipitants frequently employed in sewage treatment in the Federal Republic of Germany cost DM 0.06 to 0.08/mol Al

3.1.11. Algological Tests

With regard to eutrophication it is of interest to assess the nutrient potential of a treated sewage, especially for algae; a simple correlation with the concentrations of constituents cannot be established in each and every case. A suitable method for evaluating the nutrient potential is the Algal Assay Procedure (AAP)[12] in the form of the "Bottle Test". The AAP was first developed in the USA for estimating the degree of eutrophication of receiving waters, and specifies, *inter alia*, the test algae to be employed: *Selenastrum capricornutum* (green alga), *Anabaena flos-aquae* and *Microcystis aeruginosa* (blue-green algae), and a diatomaceae still to be named. A further component of the AAP is the nutrient solution, the New Algal Assay Medium (NAAM, Table 2)[12].

A modified method was used for testing effluents from sewage treatment plant after adequate dilution. The alga pro-

or Fe^{III}. At a molar ratio M:P of 1.4:1 the cost for precipitants would be DM 0.013 per day or DM 4.75 per year per inhabitant. Since *ca.* 30 % of the phosphates are already separated off in the mechanical and biological stages of the sewage treatment plant without precipitation the theoretical cost reduces to DM 3.10 per year per inhabitant. The actual average values quoted in the literature lie somewhat lower. Total operational costs are on average about double those for precipitants (Table 10).

3.2. Ion-Exchange

Exchange resins in the OH or Cl form are used for the removal of phosphate by ion-exchange, the OH form being preferred for the removal of anions. According to *Wagner*[66] residual phosphate contents of 0.5 mg/l are found in the

Table 9. Growth of *Anabaena flos-aquae* in wastewaters at dilutions of 1:25 and 1:50.

	P content [mg/l]	P content [%]	Algal growth [%] 1:25	Algal growth [%] 1:50	P content [mg/l] 1:25	P content [mg/l] 1:50

effluent. The advantage of this method of purification lies in the fact that no initial concentrations have to be measured for optimum control of the process. Measurements of conductivity in the effluent and the possibility of switching over to a second system, which is constantly loaded or regenerated, suffice.

Disadvantageous for converting to this method in practice is the cost of the excess regenerants that are required. The volumes of washer water necessary can amount to 20% of the volume of wastewater to be purified[67]. The regenerates are concentrated solutions of pollutants and must be further treated, whereby the phosphates are expediently removed by precipitation[68]. The exchange materials in use up to the present are not specific. Besides phosphates other anions (SO_4^{2-}, NO_3^-) and organic substances (BOD_5, COD) are also adsorbed or exchanged, and hence the exchange capacity is reduced. It is for these reasons that this purification step has so far not been incorporated in the treatment of municipal sewage.

3.3. Biological-Chemical and Biological Processes

Aerobic biological steps as carried out in activated sludge systems or trickle filter plant aid the microbial respiration of organic sewage components, which in wastewater engineering are measured according to the biological oxygen demand (BOD_5). The biological step not only requires oxygen but also nitrogen and phosphorus as well as trace elements for the maintenance of vital bacterial functions. In a complete sewage treatment plant up to 70% of the dissolved phosphorus in sludge can be converted or adsorbed[69-71].

A number of processes for the removal of phosphorus exploit this effect in that a part of the activated sludge is separated off and further processed under anaerobic conditions. The sludge releases bound phosphate into the overlying liquid, which is separated from the sludge and, *e.g.*, once again subjected to chemical precipitation. In the "Pho-Strip" process[72] lime is used for the precipitation[73]. In the "Bardenpho" process[74] up to 90% of the phosphates are separated biologically. In another process that has been proposed the phosphate from the digester water is separated by warming[75], whereupon a highly nourishing fertilizer, magnesium ammonium phosphate, is precipitated in the presence of magnesium ions.

According to *Bringmann*[76], the water is separated from the sludge after passing the biological step and fed over two biological filters with PVC beads as substrate, whereby it is dosed with Fe^{2+} ions and CO_2. Up to 99.99% P is removed; the residual value of P in the effluent is 0.007 mg/l[77].

According to these results removal of P and its embodiment in a biomass is indeed possible, but since the phosphorus thus bound is remobilizable under anaerobic conditions an absolutely quantitative fixation might here also be possible only by chemical precipitation.

Consequently, these biological processes enable only a concentration of the phosphorus and must be finally supplemented by precipitation purification. Finally, for the biological removal of phosphates other methods are also recommended which can be utilized according to the actual sewage treatment process itself. These include the cultivation of algae ("high rate algal pond system")[78] or of the sedge *Scirpus lacustris*[79] in ponds, as well as the irrigation of, if necessary only mechanically pretreated, sewage on used agricultural and forestry areas[80]. Prerequisite for the latter mentioned methods are suitable local and climatic conditions, so it is doubtful that they will find universal application.

4. Removal of Other Pollutants

4.1. Nitrogen

4.1.1. Oxidation and Reduction Processes

Nitrogen can be present in several forms of combination in waste-waters. Formally negatively charged nitrogen is predominantly present in the form of ammonia or ammonium salts and amines *e.g.* amino acids and urea. Urea, of which the human being excretes about 30 g daily in urine, represents the most important source of nitrogen in municipal sewage[81]. Microbial hydrolysis and subsequent oxidation leads initially

to formation of ammonium ions and then to nitrite and nitrate. Nitrogen in the form of the nitrate is toxic to human beings, which can make itself noticeable in small children as "cyanosis"[82,83]. In the conventional sewage treatment process only up to 20% of the nitrogen is removed, since it does not readily form insoluble compounds (no sedimentation during the preliminary clarification) and in the aerobic biological step only a small part is required for degradation of the biomass. In wastewater treatment the bacterial oxidation of ammonia nitrogen to nitrate in the presence of excess oxygen is referred to as nitrification[6]. In the presence of excess resorbable carbon (BOD_5 carrier) and a deficiency of oxygen, on the other hand, the energy metabolism of aerobic bacteria is, according to *Wuhrmann*[84], so maintained that NO_3^- or NO_2^- function as electron donors in the respiratory chain. N_2 and/or N_2O are formed as final products and are released into the atmosphere in gaseous form. This reduction (denitrification) takes place very rapidly.

4.1.2. Processes for Removal of Nitrogen

Suitable processes for the removal of nitrogen from wastewater on a technical scale are listed in Table 11[85].

Table 11. Processes for removal of nitrogen.

1. Physical processes	Distillation
	Reversed osmosis
	Filtration
2. Chemical and chemical-physical processes	Ammonia stripping
	Ion-exchange
	oxidation, reduction
	Electrodialysis
	Sorption
	Electrochemical processes
3. Biological processes	Embodiment in biomass
	Anaerobic denitrification

Use of the purely physical processes has so far been very limited because of the high investment and energy costs that are generally involved.

Ammonia nitrogen can be removed almost quantitatively in an alkaline environment at pH = 9 to 12 by aeration of the wastewater; for example, up to 98% is removed at pH = 10.8 by passage of *ca.* 3 m^3 air/m^3 wastewater[86]. The ammonia is subsequently adsorbed and neutralized. However, considerable energy, reagent, and investment costs have discouraged application of this method on a large scale. The use of ion-exchangers is also costly owing to the frequent succession of regenerations called for (see Section 3.2).

An attractive method would appear to be that in which NH_4^+ and PO_4^{3-} ions are each exchanged to about 90% simultaneously on zeolites[87]. Regeneration of the zeolite is carried out with $Ca(OH)_2$ solution. Electrodialysis and sorption on activated charcoal for the removal of nitrogen from municipal sewage are at present likewise to be regarded as special methods which are not employed in practice. Moreover, these process steps are primarily intended for the removal of other sewage constituents.

In a process developed in Norway ammonia nitrogen and phosphate ions are each removed to the extent of 82% in one step. The raw sewage is mixed with seawater in an electrolytic cell and electrolyzed at carbon electrodes. This leads to evolution of hydrogen and precipitation of $Ca_3(PO_4)_2$, $MgNH_4PO_4$ and $Mg(OH)_2$, which are subsequently separated by flotation. A byproduct is chlorine, which can be utilized for disinfecting the effluent[88].

In biological processes, bacterially controlled redox reactions are also used in practice for the removal of nitrogen (see Section 4.1.1). According to *Wuhrmann*[89,90,84] the process operates according to the following scheme:

$$\text{NH-compounds} \xrightarrow[\text{microbial oxidation}]{\text{"nitrification"}} NO_2^-, NO_3^- \xrightarrow[\text{microbial reduction}]{\text{"denitrification"}} N_2 \longrightarrow \text{atmosphere}$$

Microbial reduction, an anaerobic metabolism, proceeds satisfactorily only in the presence of sufficient resorbable carbon, which *e.g.* according to *Jeris*[91] is derived from methanol, in order to bring the C:N molar ratio of 2:1 in the sewage to the known optimum value of 7.7:1[92,93]. Thereby nitrate nitrogen can be removed by up to 99%[93].

Despite the additional investment involved, anaerobic denitrification is the most economical possibility for the removal of nitrogen. The process does not exhibit any marked dependence upon temperature and avoids the disadvantage of embodiment of nutrients in biomasses from which they are able to be remobilized[84].

4.2. Heavy Metals and Organic Substances

During the precipitation of phosphates heavy metals are entrapped by the hydroxide phosphate flocs ("collector precipitation"[94]). Hence, in the sludge from the sewage treatment plant the contents of the frequently occurring elements Zn, Mn, Pb and Cu can double and those of Cr, Ni, Cd and Hg increase[95], such that effluents from precipitation plant finally contain only residual quantities of the order of 0.1 mg/l[96] or smaller[48]. Complexing agents interfere with heavy metal precipitation. On addition of 0.025 mmol nitrilotriacetate/l the total content of copper in solution (0.025 mmol/l) during the purification by precipitation remains unchanged, otherwise it would be reduced to less than 0.001 mmol/l[51].

Organic constituents of sewage, expressed as biological (BOD_5) or chemical oxygen demand (COD), also separate out during purification by precipitation. The removal of BOD_5 in the primary settling tank increases from 30% without precipitation to 60% with precipitation, that of COD from 25% to 43%; the corresponding values in the secondary settling tank are 94 to 96% and 72 to 80%, respectively[97]. The effect can be exploited for increasing the efficiency of overloaded biological treatment steps (Table 12).

Table 12. Removal of waste water constituents with and without precipitation purification; precipitation with Al- or Fe salts. Data in % [50]. Data for mechanical-biological purification without precipitation are given for comparison.

	Pre-precipitation		Simultaneous precipitation		Direct precipitation		For comparison
	Precipitant						
	Al	Fe	Al	Fe	Al	Fe	—
P	99	97	94	93	98	97	10
BOD_5	99	93	88	83	77	60	94
COD	91	84	74	60	59	55	67

5. Limitations of the Processes and Alternative Suggestions for Additional Wastewater Treatment

5.1. Recycling in the Water Systems

Even extensive employment of phosphate precipitation in all cases where a stagnant or slowly running water contains phosphorus primarily originating from sewage does not guarantee prevention of eutrophication. Apart from the entry of phosphate from diffuse sources consideration must above all be also given to the receiving water's own reserves of phosphorus in the sediment[98]. Thus, in the case of a lake in Wisconsin no reduction in algal growth was observed after complete restraint of entry sewage[99]. In 1972 a high phosphorus content was measured in Lake Vierwaldstätter which was ascribed to redissolution of phosphate from the sediment due to oxygen difficiency in the depths of the lake. Such redissolution processes have already occurred earlier, before loading of the lake with municipal sewage constituents was put into operation[100]. Recycling also sets in, when dead algae sink to the bed and once again release nutrient elements as a result of bacterial decomposition processes.

5.2. Replacement of Wastewater Components

The onerous concentrations of phosphorus, nitrogen, heavy metals, organic substances *etc.* in sewage allowed to enter receiving waters leads to the question whether this can be remedied by altering the composition of the sewage. In this connection it is considered essential to limit the content of phosphate in detergents. According to the "Law on the Environmental Compatability of Washing and Cleansing Agents" ("Detergent Law"), which came into force on September 1, 1975, legal rulings for the restricted use of phosphates in washing and cleansing agents can be enacted[101]. However, complete removal of the phosphate from detergents is also no decisive remedy, since the contribution of detergent phosphates in municipal sewage varies locally and amounts to no more than 60% even in densely populated areas where there is positive control on phosphate from human excrements. The remaining contribution from human excrements still leads to an accelerated algal growth[36], so phosphate precipitation must be implemented in any case. The problems associated with incorporating other substances in detergents instead of phosphates have already been dealt with elsewhere[102, 31].

6. Conclusion

The causes of accelerated eutrophication, *i.e.* the increasingly observed over-fertilization, especially of stagnant and slowly flowing waters, in the past few years mainly stem from the impact of civilization. Insofar as the influence of canalized municipal sewage predominates over those of diffuse sources the most recommendable measures that can be taken at present to combat eutrophication is the implementation of phosphate precipitation in sewage treatment plant. The effluent from treatment plant must be so effectively freed from phosphorus that it will always be the growth determining factor after adequate dilution in surface waters. In this way longer term contributions can be made toward the sanitation of waters; at the same time retarding factors such as the contribution of diffuse sources and internal recycling in the water systems must be taken into consideration.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Benzo[14]annulene[1]

By *Ute E. Meissner*, *Annelies Gensler*, and *Heinz A. Staab*[*]

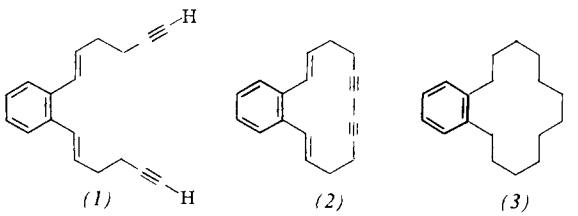
Since 1965 we have been investigating a series of [4*n*]- and [4*n*+2]annulenes annelated with benzenoid systems[1, 2], the aim of our studies being "to ascertain the extent to which nonbenzenoid macrocyclic conjugation is capable of prevailing over π-electron interaction within benzenoid subunits"[2b]. This concept has meanwhile attracted the attention of other research groups, too, interested in assessing the relation of benzenoid to nonbenzenoid aromaticity[3, 4]. Although benzo[14]annulene systems have been included in these studies[4], the parent system itself has so far not been obtained. We now report the synthesis of benzo[14]annulene.

Double Wittig-reaction (*n*-butyllithium, tetrahydrofuran, −35 °C) of 1,2-bis(triphenylphosphoniomethyl)benzene dibromide with 4-pentynal gave a mixture of *cis/trans* isomers of 1,2-bis(1-hexen-5-ynyl)benzene, from which the *trans-trans* isomer *(1)*[5] was isolated (m.p. 31—32 °C, from methanol; 15% yield) by column chromatography (silica gel, CCl_4). Cyclization of *(1)* with copper(II) acetate in dimethylformamide[1] afforded the 14-membered ring system *(2)* (m.p. 115—117 °C, from ethanol; yield 48%)[5] from which benzo[14]annulene [m.p. 106—108 °C, from ligroin (60—70 °C); yield 9%][5] was obtained by isomerization with potassium *tert*-butoxide in *tert*-butanol/benzene.

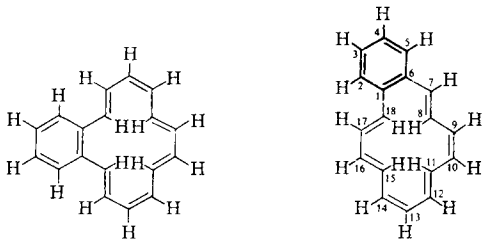
According to ^{1}H-NMR *(vide infra)* the compound obtained is not *(4)*, but *(5)*, which differs from *(4)* in the sequence of double bonds in the 14-membered ring [*(4)*: *ctcttct*; *(5)*: *ctctctt*]. Compound *(4)*, in which coplanarity ought to be more strongly hindered than in *(5)* due to short H···H distances corresponding to *o,o'*-interactions in biphenyl, could

[*] Dr. U. E. Meissner, A. Gensler, and Prof. Dr. H. A. Staab
Institut für Organische Chemie der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (Germany)

not be detected. Hydrogenation of *(5)* with Pd/activated charcoal in benzene gave *(3)*[5], identical with the hydrogenation product of *(2)* obtained under the same conditions (m.p. 58.5—59 °C; 58—59 °C[6]).



(1) *(2)* *(3)*



(4) *(5)*

In the UV spectrum, the transition from the non-conjugated precursors *(1)* and *(2)* to the cyclo-conjugated *(5)* is characterized by a strong bathochromic shift together with an increase in the extinction [*(1)*: λ_{max} = 233.5 nm ($\log\varepsilon$ = 4.391, 260 (4.257); *(2)*: 234 (4.348), 255 (sh, 4.076), in ethanol; *(5)*: 305 (4.703), 360 (sh, 3.666), in cyclohexane].

The ^{1}H-NMR spectrum (220 MHz, CS_2)[7] of *(5)* shows a 1H absorption around δ = 7.7, a further 1H absorption around δ = 7.4, and a 2H multiplet around δ = 7.3. These signals are assigned to the "aromatic" protons H-2, H-5, and H-3/H-4. In addition the spectrum contains a group of signals for eight H-atoms between δ = 7.1 and 6.25 and a further group for four H-atoms between δ = 5.2 and 4.3. The former is assigned to the outer, the latter to the inner protons. This assignment is supported by the fact that a 1H "doublet" with $J \approx 16$ Hz is observed within each of these groups at lowest field strength; they are to be ascribed to the two protons (H-18, H-7) in the α-positions to the benzene ring, one of which (δ = 5.12) is inside, the other (δ = 7.05) on the periphery of the [14]annulene system. This finding as well as the mentioned resonance pattern of the "aromatic" protons, rules out the symmetric structure *(4)*. The difference of 1.93 ppm between the inner and outer α-H absorptions and the upfield, respectively downfield shift as compared to the two equivalent α-H atoms in the nonconjugated precursor *(2)* [+1.51 ppm for the inner H-18, −0.42 ppm for the outer H-7], together with the splitting of the "non-aromatic" protons into a group of eight outer and a group of four inner protons, reveals the diatropic character of the 14-membered ring system in *(5)*. However, as in the [18]annulene series[1,2c], in [14]annulene, too, the induction of a diamagnetic ring current is considerably weakened by the condensation with a benzene ring.

Measurements of the ^{1}H-NMR absorption (220 MHz, hexachlorobutadiene) up to 110 °C do not show the formation of other conformations of *(5)*. With increasing temperature the signals of the inner protons are, however, shifted to lower field (up to −0.25 ppm), those of the outer protons to higher field (up to +0.08 ppm).

Pentacarbonylmonosulfanetungsten, $W(CO)_5SH_2$[**]

By *Max Herberhold* and *Georg Süss*[*]

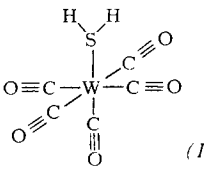
Although hydrogen sulfide reacts with many transition metal compounds, no stable transition metal complexes containing H_2S ligands have so far been reported. Evidently the initial products transform rapidly into complexes with SH ligands or polynuclear complexes with S bridges[1]. Apart from the very unstable "thiohydrates" of a few Lewis acids (*e.g.* $TiCl_4 \cdot xH_2S$, $TiBr_4 \cdot xH_2S$; x = 1, 2)[2] there is ^{1}H-NMR spectroscopic evidence of a platinum complex $(Ph_3P)_2Pt(SH_2)$, which, however, is already converted into the hydride $(Ph_3P)_2Pt(H)(SH)$ in solution[3]. A green manganese complex previously described as "$C_5H_5Mn(CO)_2SH_2$"[4a] has been shown to have the composition $[C_5H_5Mn(CO)_2]_2S$[4b] (cf. Ref. [10]).

We have found that photolysis of hexacarbonyltungsten in solution with simultaneous passage of H_2S gas leads to a relatively stable complex $W(CO)_5SH_2$ *(1)*:

$$W(CO)_6 + H_2S \xrightarrow[\text{n-Pentane}]{h\nu} W(CO)_5SH_2 + CO$$

(1)

The diamagnetic product *(1)* can be isolated from *n*-pentane as green lustrous crystals, which decompose at *ca.* 90 °C in a sealed tube under N_2; in solution (benzene, ether, acetone) the complex slowly decomposes at room temperature. In a high vacuum, *(1)* is volatile at 20 °C although it undergoes partial decomposition.



(1)

All spectroscopic findings indicate that *(1)* contains an unchanged H_2S ligand:

[*] Doz. Dr. M. Herberhold and Dipl.-Chem. G. Süss
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, 8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. *G. S.* is indebted to the Studienstiftung des Deutschen Volkes for a postgraduate grant.

The mass spectrum[5] shows the molecular ion $W(CO)_5SH_2^+$ (*m/e* 358, referred to ^{184}W) with the expected W/S isotopic distribution, as well as all fragments of the series $W(CO)_nSH_2^+$ ($n=4$—0); a further series of the type $W(CO)_nS^+$ ($n=4$—0) can be attributed to loss of hydrogen from $W(CO)_4SH_2^+$ (or the fragments poorer in CO) and to subsequent CO eliminations.

The IR spectrum of *(1)* shows the characteristic pentacarbonyl band pattern (ν(C≡O) 2076(w), 1971(m), 1935(s), and 1916(sh) cm^{-1} in benzene). An S—H valence absorption is observed at 2560 cm^{-1} (KBr)[6].

In the ^1H-NMR spectrum[7] of the complex the singlet of the H_2S protons is shifted downfield compared to free H_2S ($\delta=0.60$ ppm for *(1)* against 0.20 ppm for free H_2S, in each case in [D_8]-toluene at −11 °C). The satellites expected to arise from ^{183}W-^1H spin-spin coupling could not be observed[8a]. A marked downfield shift of the H_2S proton signal of *(1)* occurs in [D_6]-acetone; in addition the chemical shift shows a linear temperature dependence, as is characteristic for intermolecular hydrogen bonds [$\delta=3.93$ (−8 °C), 4.39 (−33 °C), and 4.65 ppm (−60 °C); the corresponding signals of free H_2S appear at $\delta=1.39$, 1.47, and 1.65 ppm[8b]]. It can be concluded from the ^1H-NMR spectrum that the acidity of hydrogen sulfide increases through coordination to the complex fragment [$W(CO)_5$].

Experimental[9a]

Dry H_2S gas is passed through a solution of $W(CO)_6$ (0.35 g, 1 mmol) in *n*-pentane (150 ml), which at the same time is irradiated with a high-pressure mercury arc (Hanovia S-200W). After 3 h the cloudy reaction mixture is filtered through filter flocks and the green filtrate concentrated at −30 °C to a volume of 50 ml. $W(CO)_5SH_2$ *(1)* crystallizes out almost completely. The green crystals are washed several times with *n*-pentane and then dried at −10 °C in a high vacuum; yield 0.11 g (31 %)[9b].

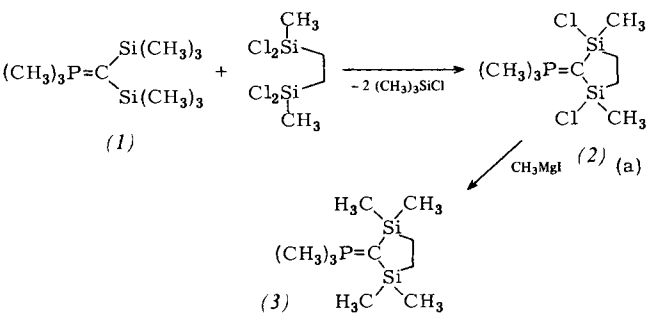
Base-Induced Intramolecular Cyclization of Silicon-Substituted Phosphorus Ylides

By *Hubert Schmidbaur* and *Michael Heimann*[*]

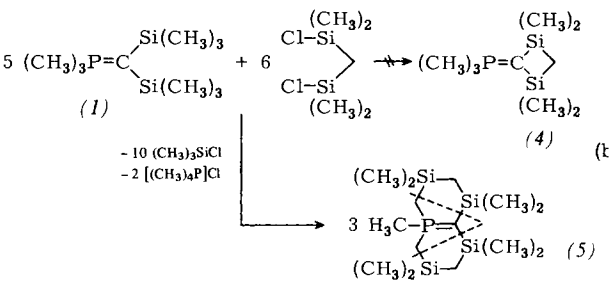
Incorporation of organosilicon substituents at the carbanion of phosphorus ylides can be carried out extraordinarily easily and leads to markedly stabilized products[1]. Transylidation or metalation steps frequently play a role, in which the acidification of protons α to the onium center of the ylide is exploited for synthetic purposes[2].

We have now found in investigations with difunctional organosilicon reagents that also cyclization at the carbanion of the ylide can be achieved, *viz.* by two transsilylation steps in accordance with Eq. (a). Should however the number of potential ring members be too small, then a completely different type of cyclization results if the acidic hydrogen atoms of the methyl groups on phosphorus are mobilized by ylide base or by metalation [Eqs. (b) and (c)].

Reaction of trimethylbis(trimethylsilyl)methylenephosphorane *(1)*[3] with 1,2-bis(methyldichlorosilyl)ethane leads, even at room temperature, in the sense of a transsilylation with loss of trimethylchlorosilane to the ylide heterocycle *(2)* in almost quantitative yield. Methylation of *(2)* with Grignard reagent affords the chlorine-free derivative *(3)*.



Reaction of *(1)* with bis(dimethylchlorosilyl)*methane*, on the other hand, leads to the bicyclic ylide *(5)*. The trans*silylation* proceeds in the molar ratio 1:2 with avoidance of the strained four-membered ring *(4)* (displacement of each of the two $(CH_3)_3Si$ groups of *(1)* by a disilylmethane)[4]. The excess of ylide finally deprotonates successively two of the three methyl groups on phosphorus, thus opening the way for cyclization at these functions and hence for the formation of *(5)*. The withdrawal of protons from alkyl groups of phosphonium centers by ylides is a trans*ylidation* step, which explains the formation of corresponding amounts of phosphonium salt (the broken line in formula *(5)* delineates the reaction components).



Closure of a single six-membered ring is possible by reaction of the same disilylmethane component with doubly lithiated trimethylmethylenephosphorane:

[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. M. Heimann
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, 8000 München 2 (Germany)

$$(CH_3)_3P{=}CH_2 \xrightarrow[-2\ RH]{+2\ LiR} CH_3P(CH_2)_3Li_2 \xrightarrow[-2\ LiCl]{+CH_2[Si(CH_3)_2Cl]_2} \quad (c)$$

(4) + 
(6)

Here, the metalation of the starting ylide corresponds to the deprotonation by excess ylide base. The remaining hydrogen atoms are redistributed in the end products by proton shifts so that the ylide function bears at least one carbanion-stabilizing silyl substituent[1].

In this way *(6)* is formed as the major component of a difficultly separable mixture, which also contains *(4)*. Although *(6)* can be isolated by fractional distillation, separation of completely pure *(4)* has so far not been achieved. If *(6)* is converted into its hydrochloride, however, pure *(4)* remains after filtration. The cyclic silyl ylides *(2)*—*(6)* are highly reactive and remarkably thermostable colorless compounds. Investigation of their chemical properties is in progress[5].

Experimental:

Monocycles (2) and *(3)*: A mixture of *(1)* (14.3 g, 61 mmol) and $[Cl_2(CH_3)SiCH_2]_2$ (31.6 g, 123 mmol) in diethyl ether (100 ml) is stirred for 15 h and then distilled at 25 °C: yield of *(3)* 14.8 g (89 %), b.p. 106—107 °C/0.1 torr.—To a solution of *(2)* (11.2 g) in ether is added dropwise a solution of 2 equivalents of CH_3MgI and the mixture stirred for 15 h at 20 °C; the precipitate is filtered off and the filtrate fractionated: yield of *(3)* 5.7 g (61 %), b.p. 42—45 °C/0.1 torr. ^{1}H-NMR (C_6H_6, TMS external): CH_3Si 0.13 (s, 12H), CH_2 0.87 (s, 4H), CH_3P 0.97 ppm (d, 9H; J(HCP) = 12 Hz).

Bicycle (5): A mixture of *(1)* (4.25 g, 18.1 mmol) and $[Cl(CH_3)_2Si]_2CH_2$ (4.38 g, 21.8 mmol) in the absence of solvent is heated for 48 h at 80 °C. Subsequent filtration and distillation affords 2.2 g (58 %) of *(2)*, b.p. 80 °C/0.1 torr, subl. 25—30 °C/0.001 torr; m.p. 58—59 °C, ^{1}H-NMR (C_6H_6, TMS ext.): CH_3Si −0.07 (s, 12H), 0.25 (s, 6H), 0.29 (s, 6H), CH_2Si −0.60 (s, 4H), CH_2P 0.27 (d, 4H; J(HCP) = 15 Hz), CH_3P 0.67 ppm (d, 3H; J(HCP) = 11.5 Hz). ^{13}C-NMR (in $C_6D_5CD_3$ against C^1, ΔTMS 137 ppm): CH_3Si 17.1 (s), 16.4 (s), 16.1 (s), CH_2Si 12.6 (s), CH_2P 30.9 (d; J(PC) = 44.1 Hz), CH_3P 37.9 ppm (d; J(CP) = 69.1 Hz). ^{29}Si-NMR (C_6D_6, TMS internal): −2.57 (d; J(SiCP) = 5.3 Hz), 3.91 ppm (d, J(SiCP) = 6.1 Hz). ^{31}P-NMR (C_6H_6, H_3PO_4 ext.): $\{^1H\}$ 6.17 ppm.

Monocycle (6): A solution of $(CH_3)_3P{=}CH_2$ (6.5 g, 72 mmol) in THF (40 ml) is treated with two equivalents of *n*-butyllithium in *n*-hexane at −10 °C. After 15 hours' stirring at 20 °C the reaction mixture is diluted with 600 ml THF, cooled to −20 °C, and then treated dropwise within a period of 5 h with a solution of $[Cl(CH_3)_2Si]_2CH_2$ (14.8 g, 73.5 mmol) in THF (100 ml). The solution is allowed to stand for a week at −18 °C; the solvent is removed in a vacuum and the residue filtered free of LiCl and then fractionated. Yield of *(6)* with *(4)*: 8.5 g (54 %), b.p. 100—120 °C or 30 °C/0.001 torr. *(6)* can be gradually enriched in the residue and finally isolated: b.p. 128 °C/50 torr. ^{1}H-NMR (C_6H_6, TMS ext.): CH_3Si −0.28 (d, 6H), −0.12 (d, 6H), CH_2Si −0.62 (s, 2H), CH_2P 0.01 (d, 2H; J(HCP) = 15 Hz), CH −0.89 (d, 1H; J(HCP) = 7.5 Hz), CH_3P 0.62 ppm (d, 6H; J(HCP) = 12.4 Hz). $\{^{31}P\}$-experiments confirmed the assignment of the signals to one and the same compound. After addition of an equivalent of ethereal HCl to bind all *(6)* contained in the mixture, filtration, and evaporation of solvent, pure *(4)* remains [b.p. 65 °C/2 torr, m.p. 23 °C; ^{13}C-$\{^1H\}$-NMR (C_6H_6): CH_3Si 7.3 (s), CH_2 2.9 (d, J(CSiCP) = 37 Hz), CH_3P 20.4 (d, J(PC) = 59 Hz). >C = 13.2 (d, J(PC) = 95 Hz).

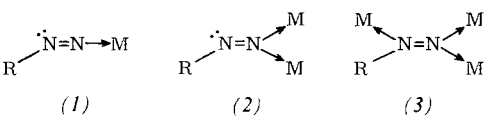
μ-Methanediazo-(*N*,*N*,*N*′)-tris(tetracarbonylmanganese)[1]

By *W. A. Herrmann*, *M. L. Ziegler*, and *Klaus Weidenhammer*[*]

Structural interest and relevance to problems in nitrogen fixation by transition metal complexes have induced the present phase of intense investigation into arenediazometal derivatives[2]. To date, more than one hundred R—N=N complexes have been prepared which contain end-on coordinated ligands, as in *(1)* or *(2)*. The bridged structure *(2)* is represented by only one example[3]. In both coordination modes the *C*-bonded nitrogen atom possesses a free electron pair which should also be accessible to coordination. With the synthesis of methanediazo-(*N*,*N*,*N*′)-tris(tetracarbonylmanganese), $CH_3N_2[Mn(CO)_4]_3$, we have realized this structural possibility *(3)* for the first time.



(1) *(2)* *(3)*

The novel complex is formed in *ca.* 10 % yield among other products[4, 5] in the low temperature reaction of pentacarbonylmanganese hydride with diazomethane. Its composition was established as $C_{13}H_3Mn_3N_2O_{12}$ by total analysis, osmometric molecular weight determination, and high resolution mass spectrum. The latter exhibits the parent ion at m/e = 543.7796 as well as successive loss of all twelve carbonyl groups; the remaining carbonyl-free fragment $(Mn_3N_2CH_3)^+$ (m/e = 207.8439) undergoes an unusual fragmentation introduced by synchronous loss of Mn, HCN, and 2H. Because the analytical and spectroscopic data (Table 1) did not allow an unambiguous structure assignment we carried out a complete three dimensional X-ray analysis[6].

For the methanediazo complex the following structural characteristics were resolved (cf. Fig. 1):

[**] Present address: Department of Chemistry, The Pennsylvania State University, State College, Pennsylvania 16802 (USA)

Table 1. Properties and crystal data of $CH_3N_2[Mn(CO)_4]_3$.

Deep red crystals; air-stable as a solid and in solution (diethyl ether, methylene chloride, acetone); dec. *ca.* 137°C	
IR: ν_{CO}:	2096 vw, 2056 vs (2051 m, sh), 2012 vs, 2002 m, 1988 w, 1970 m, 1964 m, and 1945 cm^{-1} vw (*n*-hexane)
$\nu_{N=N}$:	1586 cm^{-1} vw (KBr)
^{1}H-NMR:	$\tau CH_3 = 5.30$ ppm ([D$_6$]-acetone; TMS int. ref.)
Crystal data:	monoclinic (from Et_2O/CH_2Cl_2 1:1; −35°C) with $a = 989.1(2)$, $b = 1460.7(3)$, $c = 1319.6(5)$ pm, $\beta = 96.23(5)°$, $Z = 4$, $R = 4.5\,\%$, space group C_s^4

1) The metal carbonyl system consists of a bent Mn—Mn—Mn skeleton with typical metal-metal single bond distances.

2) The terminal diazo nitrogen N(1) forms a coordination bridge between Mn(2) and Mn(3), which forces the central manganese atom Mn(2) to have the unusual coordination number 7. According to the noble gas configuration of the metal centers, N(1) formally has to act as a *one*-electron donor towards Mn(2) and as a *two*-electron donor towards Mn(3). The N(1)—Mn(2) and N(1)—Mn(3) distances therefore differ.

3) Acting as a two-electron donor, the central nitrogen atom is bonded to only *one* tetracarbonylmanganese fragment. The N(2)—Mn(1) bond is significantly longer than both the remaining manganese-nitrogen bonds and is hardly likely to contain extensive back bonding contributions.

4) The entire Mn_3N_2C-unit lies within ±1.96 pm of the molecular plane. Mn(1) and Mn(3) have distorted octahedral environment, whereas Mn(2) is at the center of a distorted pentagonal bipyramid.

5) The nitrogen-nitrogen bonding distance (122.4 pm) corresponds to a typical double bond. The metal coordination of N(2) seems to have no effect upon this bond length, but causes a considerable reduction of the NNC angle from 119.7° in the comparable compound $[(CO)_4Mn—N=N—C_6H_5]_2$[3] to 112.3° in the molecule discussed here.

Distances [pm]:		Angles [°]:	
Mn(1)—Mn(2)	282.6(3)	Mn(1)—Mn(2)—Mn(3)	107.4(7)
Mn(2)—Mn(3)	280.7(4)	N(2)— N(1) —Mn(2)	119.9(7)
N(1)—Mn(2)	196.4(8)	Mn(2)— N(1) —Mn(3)	93.8(4)
N(1)—Mn(3)	187.9(8)	N(2)— N(1) —Mn(3)	146.2(7)
N(2)—Mn(1)	206.1(8)	Mn(1)— N(2) —N(1)	107.2(6)
N(1)—N(2)	122.4(11)	N(1)— N(2) —C(1)	112.3(12)
N(2)—C(1)	156.9(15)	Mn(1)— N(2) —C(1)	140.5(11)

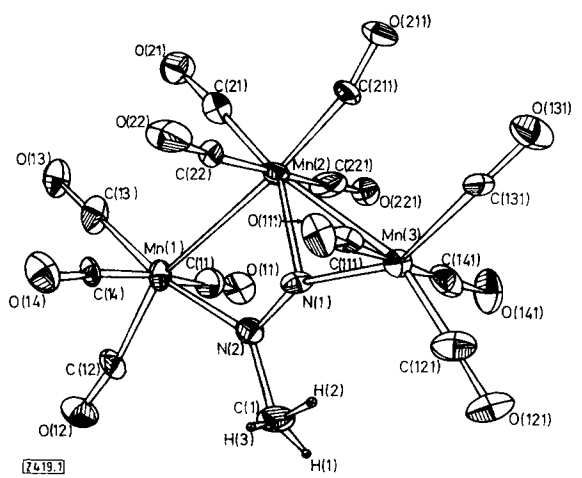

Fig. 1. ORTEP plot of $CH_3N_2[Mn(CO)_4]_3$. The thermal ellipsoids have 50% probability; all atoms are drawn in proper dimensions except hydrogen.

The overall geometry of an end-on complexed R—M=N moiety is not affected in its essential parameters by additional N(2) coordination. According to our results, the introduction of neutral metal carbonyl protecting groups into complexes of the types *(1)* and *(2)* for performing chemical reactions in other parts of the molecule seems promising. Moreover, the preparation of $CH_3N_2[Mn(CO)_4]_3$ shows the utility of diazomethane for the synthesis of the hitherto poorly studied *alkane*diazo compounds[2, 7].

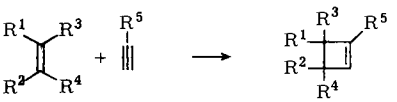
[2+2]-Cycloaddition of Alkynes to Alkenes[**]

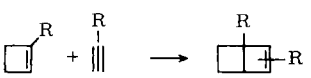
By *Joachim H. Lukas, Frank Baardman*, and *Arjan P. Kouwenhoven*[*]

[2+2] Cycloadditions of allenes to alkenes are feasible in the presence of Lewis acid catalysts[1]. We suspect the reaction to involve a complex of the allene with the Lewis acid which is polarized in the direction of a vinyl cation.



(1) *(2)* *(3)*

We have now found that under similar reaction conditions the allene can be replaced by a 1-alkyne *(2)*; reaction with alkenes *(1)* then affords cyclobutenes *(3)* (Table 1). Dialkyl-substituted alkynes give polymeric products or trimerize to hexaalkyl-benzenes or -Dewar benzenes. Trimerization to 1,3,5-trialkylbenzene occurs as a side reaction with 1-alkynes. In general the ratio of trialkylbenzene to cyclobutene decreases as the size of the alkyl group in the alkyne increases[2].



R = Alkyl *(4)*

Table 1. Examples of [2+2] cycloaddition of 1-alkynes *(2)* to alkenes *(1)* affording cyclobutenes *(3)*.

A New Electrochemical Method of Forming SiSi Bonds

By *Edwin Hengge* and *Georg Litscher*[*]

Only few methods are presently available for generating SiSi linkages. The most commonly used approach in preparative applications consists in a Wurtz-type reaction of halosilanes with an alkali metal. Variants of this reaction, *e.g.* coupling of a halosilane with an organometallic silicon derivative, can be utilized if the corresponding reagents are accessible. Nonspecific methods include pyrolysis and degradations of polymeric structures (*e.g.* of silicides). In isolated cases the photolysis of mercury compounds and dehydrogenation of Si—H bonds with di-*tert*-butyl peroxide may be successful[1].

We have now developed a method whereby products having new SiSi bonds can be obtained under extremely mild conditions from halosilanes. Electrolysis of, *e.g.*, trimethylchlorosilane (Me_3SiCl) in 1,2-dimethoxyethane in the presence of a supporting electrolyte, *e.g.* $[(n\text{-}Bu)_4N]ClO_4$, with mercury electrodes yields hexamethyldisilane ($Me_3SiSiMe_3$). Any aprotic solvent can be used provided that it is stable under the reaction conditions, *e.g.* tetrahydrofuran. Apart from quaternary ammonium salts, lithium chloride can also be used as supporting electrolyte. Desirable, but not essential, is the use of a diaphragm (glass frit).

Of great importance is the choice of electrodes. Lead and mercury have proved suitable as cathode material, lead having the advantage of being a solid and thus favoring a more convenient cell geometry. Apart from lead and mercury, graphite is also suitable as anode material. $PbCl_2$ and Hg_2Cl_2 are formed on use of lead and mercury, respectively. In the case of mercury it suffices to vigorously stir the surface of the electrode to counteract passivation of the electrodes by the chloride. Passivation is also observed with graphite anodes. Platinum is rather susceptible to corrosion when used as anode material. The most suitable cell employed so far has a lead cathode and a mercury anode.

[*] Prof. Dr. E. Hengge and Dipl.-Ing. G. Litscher
Institut für Anorganische Chemie der Technischen Universität
Stremayrgasse 16, A-8010 Graz (Austria)

The electrochemical synthesis of hexamethyldisilane from trimethylchlorosilane will now be considered as a typical procedure illustrating the new method for generating SiSi linkages. The sensitivity of the halosilanes to hydrolysis requires rigorous exclusion of moisture; dry oxygen-free nitrogen is used as inert gas. Electrolysis is performed in a glass vessel with a mercury pool as anode and a lead cathode (current supply by platinum wire sealed into glass); the electrode cross section is 40 cm^2 and the distance between the electrodes is 1.5 cm. Stirring is accomplished with a magnet floating on the mercury. A 150-ml quantity of electrolyte solution—composition 60% 1,2-dimethoxyethane, 40% trimethylchlorosilane, 1 g (0.02 mol/l) of $[(n\text{-}Bu)_4N]ClO_4$—electrolyzed at room temperature, 75 V potential difference, and 1 mA/cm^2 current density afforded hexamethyldisilane in *ca.* 95 % current efficiency. The product isolated by distillation and identified by its boiling point and Raman spectrum is free from hexamethyldisiloxane. The product yield clearly depends upon the duration of electrolysis, *e.g.* 10 g of $Me_3SiSiMe_3$ was obtained after 4 days.

The method appears to have a wide scope. Triphenylchlorosilane can be transformed into hexaphenyldisilane; but also difunctional compounds such as diphenyldichlorosilane react to give hitherto uncharacterized oligomers and polymers (nondistillable oils). Since the use of separate electrode compartments permits contact between substrate and electrode material only and, in contrast to the "Wurtz reaction", the method can be used at low temperatures, it also appears suitable for complicated and sensitive halosilanes.

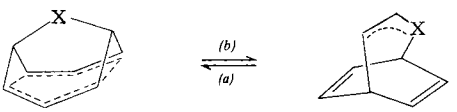
Unsubstituted 9-Azabarbaralane; A π-Destabilized Heterocycle[**]

By *A. G. Anastassiou, E. Reichmanis*, and *A. E. Winston*[*]

Recent experimental work with 9-barbaralyl ions *(1a)*[1] and *(1b)*[2] has demonstrated that p-orbital occupancy at C-9 exerts decisive control on their overall stability. Specifically, ion *(1)* was found to readily interconvert with tautomer *(2)* by a process which is strictly charge controlled and whose direction reveals *(1)* to be π-stabilized as the cation *(1a)* and π-destabilized as the anion *(1b)*.



(1) *(2)*

(a), X = $\overset{\oplus}{C}H$; *(b)*, X = $\overset{\ominus}{C}H$

In light of the above findings we resolved to prepare and examine parent 9-azabarbaralane *(7)* for possible signs of lone-pair induced destabilization.

The steps employed in the synthesis of unsubstituted 9-azabarbaralane *(7)*[3] and its *N*-methyl derivative *(8)*[3] from known[4] azabicyclotrienes *(3)* and *(4)* are given below. Based

[*] Prof. Dr. A. G. Anastassiou, Dr. E. Reichmanis, and A. E. Winston
Department of Chemistry, Syracuse University

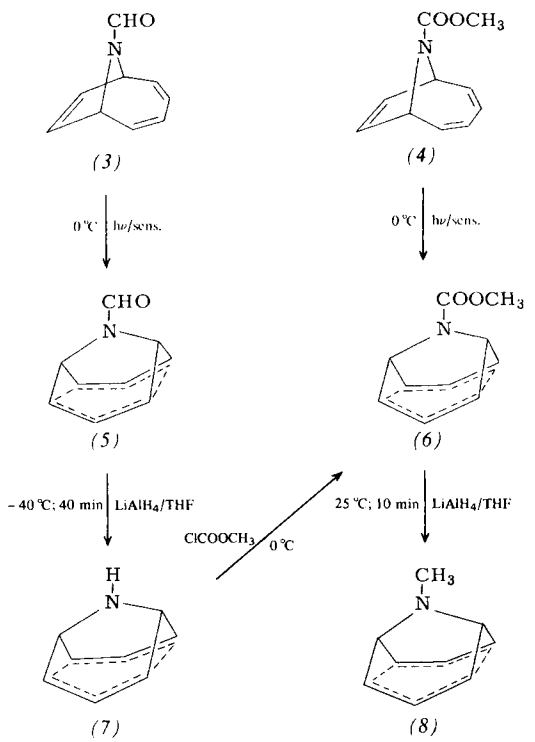
[**] We thank the National Science Foundation (GP 38553X), the Petroleum Research Fund, administered by the American Chemical Society, and Syracuse University for support of this work. We also express our appreciation to Mr. *L. McCandless* for the determination of the 100 MHz NMR spectra.

on their response to thermal excitation the azabarbaralanes described here are divisible into two distinct categories: the pair *(7)* and *(8)* readily rearranges at ambient temperature[5] whereas *(5)*[3,6,7] and *(6)*[3,7] effectively resist change even at elevated temperatures. The difference between the two classes is perhaps best exemplified by direct comparison between *(7)* whose half-life was found (NMR; [D_6]-acetone) to be a mere 18 min ($\Delta G^{\neq} \approx 22$ kcal/mol) at 32 °C and *(5)* which may be recovered unchanged (NMR) after being heated at 140 °C for 30 min! Since of the four 9-azabarbaralanes described here the two that are thermally unstable, *viz. (7)* and *(8)*, are also the only members that incorporate lone pairs which are well accessible electronically for interaction with the homotropilidine moiety of the molecule, one must conclude that the nitrogen lone pair exerts a destabilizing effect on the 9-azabarbaralane system.



Significantly, the notion that lone-pair participation leads to skeletal destabilization of the 9-heterobarbaralane frame receives added support from the observation that the thermal stability of parent amine *(7)* in [D_6]-acetone increases substantially in strongly acidic media, the amount of rearrangement (NMR) decreasing from 50% in 18 min at 32 °C (see above) to <10% in 18 h at 35 °C upon addition of a drop of trifluoroacetic acid.

The situation described here for the 9-azabarbaralanes sharply contrasts with that found in the isomeric azonines where the lone pair exerts a stabilizing influence on the π system[8] but is reminiscent of that encountered with the azepine family where the π system is known to effectively reject the nitrogen lone pair[9]. In short, the unsubstituted fluctional 9-azabarbaralane system shows clear signs of antiheteroaromatic character.

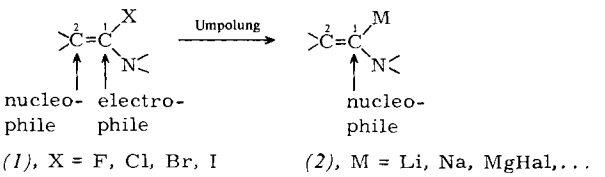
α-Metalated Enamines[**]

By *Chantal Wiaux-Zamar, Jean-Paul Dejonghe, Léon Ghosez, J. F. Normant,* and *J. Villieras*[*]

α-Haloenamines *(1)*[1] react as electrophiles at C-1 and as nucleophiles at C-2. In principle, umpolung of C-1 could be achieved by replacing the carbon-halogen bond by a carbon-



(1), X = F, Cl, Br, I *(2)*, M = Li, Na, MgHal, ...

metal bond. The resulting organometallic compounds *(2)* should behave as synthetic equivalents of acyl anions[2].

In order to establish the reactions of *(2)*, the thermally stable α-chloroenamines *(1a)*–*(1c)* were treated with metallic reagents and then with D_2O (Table 1). The resulting mixtures were analyzed by GLPC and NMR. In independent experiments, products *(3)* and *(4)* were separated and purified and their structures were established by spectroscopic methods or by comparison with authentic samples. The dienes *(4a)*

and *(4b)* were readily hydrolyzed to give the α-diketone *(6)*.

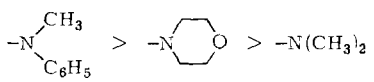
The following observations can be made on the basis of Table 1:

1) Metal-chlorine exchange only occurs in a basic solvent such as tetrahydrofuran (except for Na).

2) The formation of α-metalated enamines *(2)* has been unequivocally demonstrated either by titration or by deuterolysis.

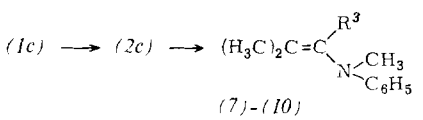
3) Products *(3)* and *(4)* were already present in the mixture before deuterolysis.

4) The amine substituent in *(1)* determines the yield of *(2)* as shown:



This is the reverse order of that observed for the ionization of *(1)* to keteniminium chlorides[1].

The potential of α-metalated enamines *(2)* for nucleophilic aminoalkenylation[4] is illustrated in Table 2 for the case of *(2c)*. It is not yet known to what extent the alkenyl group can be varied.



(7)-(10)

Table 2. Nucleophilic aminoalkenylation with *(2c)*. The yields are based on *(1c)*.

1,3,2-Dioxazolidines by Thermal 1,3-Cycloaddition of Nitro Groups to Strained Olefins

By *Johannes Leitich*[*]

Whereas nitro groups (in the $n\pi^*$ triplet state) are known to undergo photochemical 1,3-addition to olefins, forming 1,3,2-dioxazolidines[1], the corresponding thermal reaction—a "1,3-dipolar cycloaddition"[2] of the nitro group in the electronic ground state—has not been observed so far[2, 3].

We have found this thermal 1,3-cycloaddition to take place when the olefin component is highly strained[4], such as (*Z,E*)-1,5-cyclooctadiene *(2)*, and the nitro component is a nitrobenzene bearing additional electron-withdrawing groups, such as *(1)*. At room temperature (RT) *(1)* and *(2)* smoothly form the adducts *(3a)* to *(3d)* within one to several days.

The reactions proceed at the same rates in the dark or in daylight and at similar rates in various solvents. The steric course is uniform: catalytic hydrogenation of the crude reac-

(1) *(2)* *(3)*

(a), R = 4-NC-C_6H_4
(b), R = 4-O_2N-C_6H_4
(c), R = 3-O_2N-C_6H_4
(d), R = 3-O_2N-5-H_3COOC-C_6H_3
(e), R = C_6H_5

tion mixture from *(1b)* and *(2)* affords *trans*-1,2-cyclooctanediol together with less than 0.3% of the *cis* isomer (GC).

The structure of the adducts *(3)* follows from their CHNO analysis, molar mass, IR and ^{1}H-NMR spectra[1], and especially from the partial hydrogenation of *(3b)* in ethyl acetate with Pd/C, which yields (*Z*)-5-cyclooctene-*trans*-1,2-diol and 4-nitroaniline.

Formation of the adduct *(3e)* from unsubstituted nitrobenzene *(1e)* and *(2)* can just compete with the dimerization of *(2)*[5] (NMR), while no adduct is formed at all with 1-methoxy-4-nitrobenzene or CD_3NO_2 (as solvent) and *(2)*.

The bimolecular rates of formation (l mol^{-1} s^{-1} × 10^6; acetonitrile, 25 °C) of *(3b)* (82) and *(3a)* (7.3) [compared with that of *(3e)* (0.65)] lead on Hammett correlation with the σ_p values[6] to a similar ρ value (2.2) as is obtained for *(3c)* (43) and *(3d)* (150) with the σ_m values (2.4); in contrast, the σ_p^- values afford 1.4. This shows that the electron deficiency at the reacting nitro group is mainly responsible for the addition rather than resonance between the nitrogen lone pair set free during the addition and a (−M) substituent on the benzene ring. Compound *(1b)* reacts about 400 times more slowly with (*E*)-cyclooctene than with *(2)*, corresponding to a difference of 3.5 kcal/mol in $\Delta G^{\neq}$. This accounts for only a small portion of the difference in heats of reaction of *ca.* 12 kcal/mol[4], from which it is deduced that the addition transition state must resemble the starting compounds more closely than the adduct.

The adducts *(3)* are stable for several days in aprotic solvents at room temperature, but rapidly decompose in protic media (methanol). Crystalline *(3a)* and *(3b)* can be stored indefinitely at room temperature. Hence the electron-withdrawing substituents both accelerate the addition and stabilize the adduct.

2-(p-Nitrophenyl)-3a,9a-trans-6,7-cis-3a,4,5,8,9,9a-hexahydrocycloocta[c][1,3,2]dioxazole (3b)[7]

Compounds *(2)* (1 g) and *(1b)* (1.55 g) are left to stand for 2 days at room temperature in tetrahydrofuran (18 ml). The pale yellow solution turns orange. Removal of the solvent at room temperature, addition of chloroform (10 ml) to the residue (dissolution is incomplete), addition of pentane (10 ml), cooling to −70 °C, reheating to room temperature, and rapid filtration under suction afford 0.12 g of unchanged *(1b)*. Treatment of the mother liquor by addition of pentane (40 ml), crystallization at −70 °C, and filtration under suction in the cold yields 1.64 g of crude *(3b)* [containing 7 wt % of *(1b)*]. It is dissolved in warm pentane, freed from small amounts of amorphous orange solids by filtration, and recrystallized at −70 °C. Remaining *(1b)* is sublimed off from the crystals at 50 °C/0.1 torr. Renewed dissolution in pentane, filtration, and crystallization affords pure *(3b)* as yellowish-white crystals, m.p. 101 °C (dec.); UV spectrum (*n*-hexane), λ_{max} = 306 nm (ε = 8900); ^{1}H-NMR ($CDCl_3$, TMS): δ = 1.1–1.9 (m, 2H), 2.0–2.5 (m, 6H), 4.2 (br. AA′ in AA′XX′ system, 2H), 5.65 (m, 2H), 7.45 and 8.2 ppm (AA′BB′ system, 4H). Decomposition occurs on the usual chromatographic adsorbents.

In similar manner *(2)* (1 g) and *(1a)* (2.37 g) in tetrahydrofuran (20 ml) afford, on standing for 5 days, 1.25 g of crude *(3a)* [containing 18 wt % of *(1a)*]. Analogous workup yields pure *(3a)*, colorless crystals, m.p. 98 °C (dec.); UV spectrum (*n*-hexane), λ_{max} = 266 nm (ε = 13200).

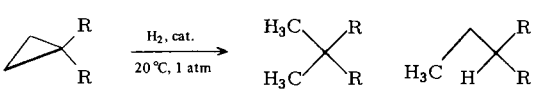
Selective Hydrogenations of 1,1-Disubstituted Cyclopropanes[**]

By *Claus Gröger* and *Hans Musso*[*]

The influence of substituents on cyclopropane bonds has been established experimentally and treated theoretically[2], particularly in the case of the norcaradiene-cycloheptatriene equilibrium. If there is p overlap between the substituent and the Walsh orbitals of the cyclopropane, electron-donating groups weaken the opposite C^2—C^3 bond, whereas electron-withdrawing groups strengthen it. The weakest bond in cyclopropane derivatives should be broken fastest on hydrogenolysis[1]. Neglecting steric effects of the substituents, these electronic factors should determine which bond this will be.



(1) *(2)* *(3)*

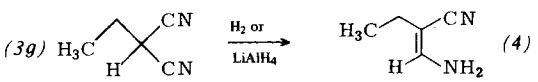
[**] Hydrogenolysis of Small Ring Compounds, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. All new compounds gave correct elemental analyses and spectra.—Part 3: ref. [1].

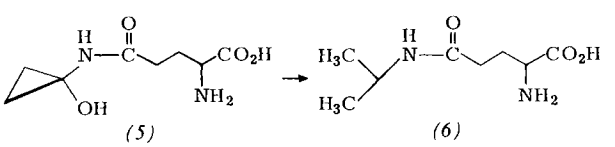
This control is clearly demonstrated by hydrogenation of several 1,1-disubstituted cyclopropane derivatives *(1)* with Pd/C (methanol) or PtO_2 (acetic acid)[3] catalyst to either 2,2-disubstituted *(2)* or 1,1-disubstituted propanes *(3)* respectively (Table 1).

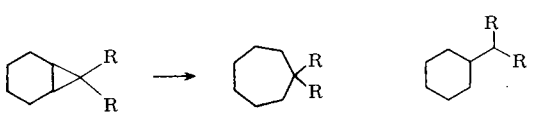
1,1-Dimethylcyclopropane *(1a)* and 1,1-cyclopropanedimethanol *(1b)* provide neopentane *(2a)* and 2,2-dimethyl-1,3-propanediol *(2b)*. The corresponding dimethyl and diethyl dicarboxylates *(1c)* and *(1d)*, the acid *(1e)*, and the amide *(1f)* are hydrogenated to the 2-ethylmalonates *(3c)*—*(3f)* exclusively. The absence of the isomeric compounds in the various products was proven by VPC and NMR with authentic samples of *(3a)* and *(3b)* as well as *(2c)*—*(2f)*[4]. The dinitrile *(1g)* takes up two moles of hydrogen, and forms 3-amino-2-ethylacrylonitrile *(4)*, identified by comparison with the known reduction product of *(3g)* with $LiAlH_4$[5]. Samples taken during hydrogenation of *(1g)* after consumption of one mole of hydrogen contained up to 30% of *(3g)* but no *(2g)*.



There are many examples[6] which can be interpreted in the same way, even though p overlap of alkyl groups is hard to understand. Other cases do not fit into this scheme. Thus, according to ref. [6], *(1a)* affords *(3a)* instead of *(2a)*. Since increasing temperature causes loss of selectivity[8], such hydrogenations should be carried out at room temperature or the lowest temperature possible, if necessary under pressure.

Some of these reactions are useful preparative methods, *e.g.* for the synthesis of geminal dimethylcycloalkanes[7, 8]. The specific ring opening in the hydrogenation of coprine *(5)*[9] to *(6)* also finds a lucid explanation.





(7a), R = CH_3 *(8a)* *(9b)*

(7b), R = CO_2R

Additionally, ring enlargement of a 7,7-dimethylbicyclo[4.1.0]heptane derivative *(7a)* to *(8a)* has been observed[10]. In contrast, the diester *(7b)* afforded cyclohexylmalonic ester *(9b)* exclusively[11]. In bicyclo[*n*.1.0]alkanes, however, the ratio of both alternatives, *viz.* *(8)* and *(9)*, crucially depends on the ring size *n*[12].

Structure of the "True" Metavanadate Ion

By *Joachim Fuchs, Soroush Mahjour*, and *Joachim Pickardt*[*]

Dedicated to Professor Georg Manecke on the occasion of his 60th birthday

Numerous studies[1a] on the size and structure of the isopolyvanadate ion occurring in aqueous vanadate(V) solutions at $Z \approx 1$[1b] (pH ≈ 7) have lead to contradictory conclusions. The various proposals include linear or cyclic trivanadate or tetravanadate ions having tetra- or penta-coordinate vanadium. Structural investigations on salts crystallizing from such solutions have so far failed to provide information relevant to the dissolved state because crystallization from aqueous solution is always accompanied by polymerization of the anion. Thus the anions of anhydrous alkali metal "metavanadates" are composed of VO_4 tetrahedra linked together as endless chains (diopside or spodumene type)[2]. $KVO_3 \cdot H_2O$, $Ca(VO_3)_2 \cdot 2H_2O$[2], and $Sr(VO_3)_2 \cdot 4H_2O$[3] contain chains of edge-linked VO_5 units.

Reaction of V_2O_5 with alcoholic tetrabutylammonium hydroxide solution[4] has now afforded the first isopolyvanadate of "metavanadate" type containing a discrete polyanion, *viz.* $[N(C_4H_9)_4]_3HV_4O_{12}$. This hydrogen tetravanadate is readily soluble in many organic solvents. Osmometric determinations in chloroform revealed a molecular mass of 1210 ($M_{calc.} = 1124$). Single crystals can be grown from solutions in acetone by addition of benzene; they can be stored for some time under the mother liquor or under anhydrous benzene. The intensities of 1630 nonequivalent reflections were measured on a single crystal in a sealed tube under benzene with a Syntex four-circle diffractometer. The compound crystallizes in the space group $P2_1/c$ with the lattice parameters $a = 12.347 \pm 0.005$, $b = 24.463 \pm 0.005$, $c = 23.236 \pm 0.005$ Å; $\beta = 92.476 \pm 0.05°$; $V = 7011.6$ Å^3; $Z = 4$. The vanadium positions were determined by direct methods, and those of the light atoms by successive difference Fourier syntheses. Owing to the unfavorable experimental conditions and a certain degree of disorder of the carbon atoms (terminal groups of the butyl chains) refinement was only possible up to $R = 12.8$%.

The anion proves to be a ring made up of four corner-linked VO_4 tetrahedra (Fig. 1) resembling the tetrametaphosphate[5] and the cyclotetrasilicate ion[6]. The four bridging O atoms form a square, the V atoms lying alternately above and below this plane (symmetry of ring nearly D_{2d}).

Dr. J. Pickardt
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, 1000 Berlin 12 (Germany)

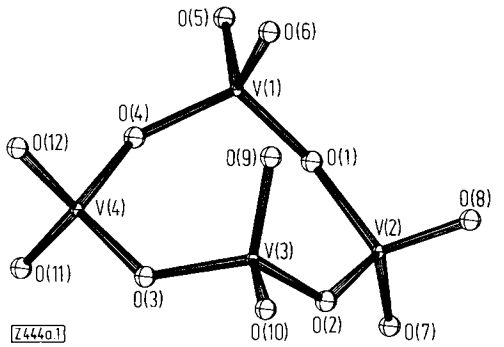

Fig. 1. Anion structure of tetrabutylammonium hydrogen tetravanadate $[N(C_4H_9)_4]_3HV_4O_{12}$.

The distances between the bridging O atoms and vanadium have an average value of 1.80 Å and those between vanadium and the terminal O atoms, except O(9), 1.62 Å. The oxygen atom O(9) is conspicuous for its high temperature factor and its significantly longer V—O distance (1.86 Å); it apparently exists (preferentially) in protonated form. The nitrogen atoms of the cations assume an approximately octahedral arrangement around the polyanion. ^{1}H-NMR measurements in deuteriochloroform show the OH proton to undergo extremely ready exchange (signal at -3.99 ppm).

The Raman spectrum of the tetrabutylammonium salt resembles the spectrum of an alkali metal vanadate solution that has acidified up to the "metavanadate" level ($Z=1$), thus indicating that such solutions also contain the cyclic tetravanadate ion. The polarized bands correspond to totally symmetric vibrations of terminal (947 cm^{-1}) and bridging (477 cm^{-1}) oxygen atoms and of the vanadium atoms (325 cm^{-1}). The bands at 920 and 628 cm^{-1} are assigned to asymmetric vibrations of terminal and bridging oxygen atoms. The symmetrical VOV stretching vibration is expectedly split in the solid state spectrum (512 and 471 cm^{-1}); the angles V(1)—O(1)—V(2) and V(1)—O(4)—V(4) are 132°, the angles V(2)—O(2)—V(3) and V(3)—O(3)—V(4) 146°. The Raman spectrum of a sodium "metavanadate" solution remains unchanged even at high dilutions (up to 4×10^{-3} M in V); there is no evidence for a concentration-dependent equilibrium between tetravanadate and trivanadate ions[7].

Anion Structure of Tetrabutylammonium Octamolybdate $[N(C_4H_9)_4]_4Mo_8O_{26}$

By *Joachim Fuchs* and *Hans Hartl*[*]

Addition of an alcoholic solution of tetrabutylammonium hydroxide to a solution of tetrabutylammonium hexamolybdate $[N(C_4H_9)_4]_2Mo_6O_{19}$ in acetone leads to crystallization of the octamolybdate $[N(C_4H_9)_4]_4Mo_8C_{26}$. The same compound is obtainable in finely crystalline form on treatment of a slightly acidified aqueous solution of sodium molybdate with tetrabutylammonium bromide.

We have solved the structure by X-ray methods on the basis of 3295 nonequivalent reflections measured with a Syntex four-circle diffractometer and refined it to an R value of 5.5 %. In the monoclinic arrangement $P2_1/n$ the compound has the lattice parameters $a=15.086\pm0.003$, $b=15.997\pm0.003$, $c=18.528\pm0.003$ Å; $\beta=91.31\pm0.01°$; $Z=2$.

The centrosymmetric anion consists of a ring made up of six MoO_6 octahedra (as in $TeMo_6O_{24}^{6-}$[1]) linked to one MoO_4 tetrahedron above, and another below, its octahedral cavity (Fig. 1a). However, in view of the widely varying molybdenum-oxygen distances it can also be viewed as a loose addition compound between two MoO_4^{2-} units and a (neutral) Mo_6O_{18} ring made up of distorted MoO_4 tetrahedra. The distances between the Mo atoms and the terminal oxygen atoms O(7) to O(13) range from 1.667 to 1.692 Å, and the distances to the bridging atoms O(4) to O(6) from 1.881 to 1.917 Å. The distances of the tricoordinated atoms O(1) to O(3) (Fig. 2) of the MoO_4^{2-} units to the Mo atoms of the ring are unusual (2.35 to 2.53 Å) and correspond to bond orders of 0.35 to 0.2[2]. Mo(1) is in an almost ideal tetrahedral coordination with the O—Mo(1)—O angles between 108.1 and 110.6°. The distances between adjacent Mo atoms within the ring are 3.378 to 3.409 Å the distances between these atoms and Mo(1) 3.770 to 3.8 6 Å, and the distance Mo(1)—Mo(1′) 3.697 Å. The standard deviations are <0.001 Å for the Mo—Mo distances and <0.01 Å for the Mo—O distances.

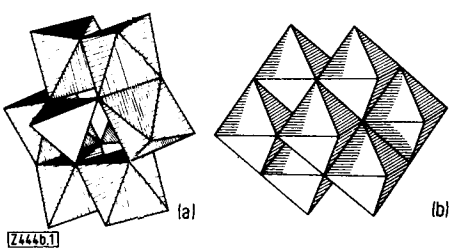

Fig. 1. Polyhedral structural model of $Mo_8O_{26}^{4-}$ in the tetrabutylammonium salt (a) and in the ammonium salt (b)

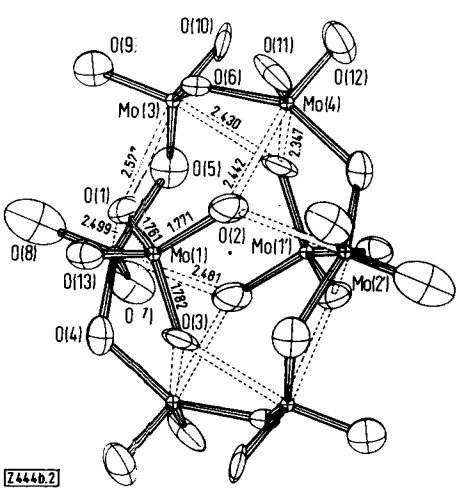

Fig. 2. Anion structure of tetrabuty ammonium octamolybdate; distances in Å.

This anion is an isomer of the anion occurring in ammonium octamolybdate $(NH_4)_4Mo_8O_{26}\cdot4H_2O$[3] which is made up solely of MoO_6 octahedra (cf. Fig. 1). Thus the present struc-

[*] Prof. Dr. J. Fuchs and Prof. Dr. H. Hartl
Institut für Anorganische Chemie FB21-WE1 der Freien Universität Fabeckstrasse 34—36, 1000 Berlin 33 (Germany)

tural elucidation provides the first proof of structural isomerism in discrete isopolyanions. In solution (*e.g.* in acetonitrile) tetrabutylammonium octamolybdate readily transforms into the hexamolybdate $[N(C_4H_9)_4]_2Mo_6O_{19}$. The bonding situation suggests that the mere approach of a negative charge to the oxygen atom O(13) can lead to the release of a MoO_4^{2-} unit. The structure provides an indication of the addition and elimination mechanisms involved in the formation and mutual interconversion of polyions.

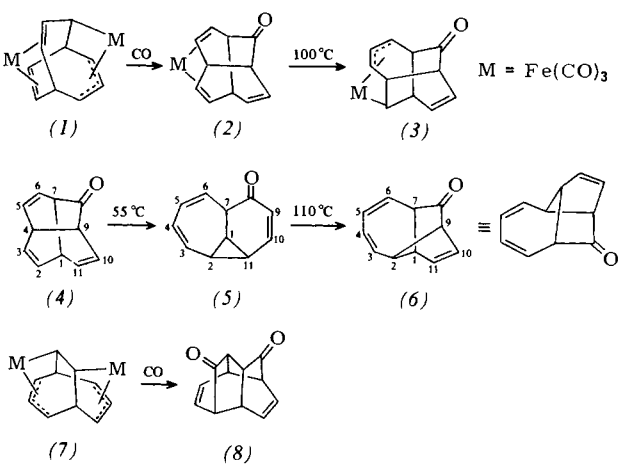
$C_{12}H_{10}O_2$ and Thermolabile $C_{11}H_{10}O$ Ketones from Bullvalene *via* Carbonyliron Complexes[1]

By *Rudolf Aumann*[*]

In the past few years synthetic methods have been reported in which highly reactive organic molecules (carbenes, cyclobutadiene, trimethylenemethane, norbornadienone[2]) have been initially stabilized by coordination to metal atom centers and subsequently liberated from the complex by a change in the oxidation state of the metal or displacement reactions and induced to undergo reaction.

Such a process permitted preparation of the tetracyclic diketone *(8)* and the thermolabile tricyclic monoketone *(4)* from bullvalene *via* the readily accessible carbonyliron complexes *(1)* and *(7)*[3]. Compound *(4)* and the products of its thermal isomerization *(5)* and *(6)* are new representatives of the $C_{11}H_{10}O$ ketones[4], which possess theoretical interest.



(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)* *(8)*

Carbonylation of *(1)* (100 atm of CO, 75°C, 24 h) leads to displacement[5] of the π-allyl/σ-bonded $Fe(CO)_3$ group affording the mononuclear carbonyliron complex *(2)* [80%; yellow crystals, m.p. 100—102°C; $m/e = 298$; IR (hexane): ν(C≡O) 2039, 1977, 1966 cm^{-1}; IR (KBr): ν(>C=O) 1710 cm^{-1}]. Oxidative decomposition of *(2)* with $FeCl_3$ in ether (0°C, 10 min) gives tricyclo[5.4.0.0^{4,9}]undeca-2,5,10-trien-8-one *(4)* [80%; colorless crystals from benzene/hexane, m.p. 80°C; $m/e = 158$; ^{1}H-NMR ($CDCl_3$): $\tau = 3.39$ (dd, H-5, H-11; $J = 6$, 8.5 Hz), 4.06 (AA'XX' system, H-2, H-3), 4.39 (dd, H-6, H-10; $J = 8$, 8.5 Hz), 7.0 ("t", H-7, H-9; $J = 8$, 8 Hz), 7.3 (m, X part of an AA'XX' system, H-1, H-4); ^{13}C-NMR ($CDCl_3$): δ_{TMS}(>C=O) = 206.3 ppm; IR (KBr): ν(>C=O) 1700 cm^{-1}].

In contrast to the carbonyliron complex *(2)* of the ketone *(4)*, which slowly rearranges at 100°C to *(3)* [95% in 3 d; colorless crystals, m.p. 115—117°C; $m/e = 298$; IR (hexane): ν(C≡O) 2054, 1986 cm^{-1}; IR (KBr) ν(>C=O) 1720 cm^{-1}], free *(4)* already isomerizes slowly in solution at 25°C, and quantitatively within 1 h at 55°C by Cope rearrangement to give tricyclo[5.4.0.0^{2,11}]undeca-3,5,9-trien-8-one *(5)* [colorless crystals from hexane, m.p. 47°C; $m/e = 158$; ^{1}H-NMR ($CDCl_3$): $\tau = 3.02$ (dd, H-10; $J = 6$, 10 Hz), 3.56 (dd, H-6, $J = 8$, 11 Hz), 3.9—4.1 (m, H-4, H-5), 4.02 (d, H-9; $J = 10$ Hz), 4.35 (dd, H-3; $J = 11$, *ca.* 3 Hz), 6.80 (dd, H-7; $J = 7.5$, 8 Hz), 7.66 ("q", H-1; $J = 7.5$, 7.5, 7.5 Hz), 7.93 (ddd, H-2; $J = 7.5$, 8, *ca.* 3 Hz), 8.46 (ddd, H-11; $J = 6$, 7.5, 8 Hz); ^{13}C-NMR ($CDCl_3$): δ_{TMS}(>C=O) = 196.5 ppm; IR (KBr): ν(>C=O) 1660 cm^{-1}].

At 110°C compound *(5)* isomerizes cleanly *via* a vinylcyclopropane/cyclopentene rearrangement (*ca.* 95% in 1 h) to tricyclo[5.4.0.0^{2,9}]undeca-3,5,10-trien-8-one *(6)* [colorless crystals from pentane, m.p. 40°C; $m/e = 158$; ^{1}H-NMR ($CDCl_3$): $\tau = 3.12$ (dd, H-11; $J = 5.5$, 3.0 Hz), 3.72 (dd, H-10) $J = 5.5$, 3.5 Hz), 3.7 to 4.3 (m, H-3, H-4, H-5, H-6), 6.55 ("s", H-7), 6.9—7.2 (m, H-2, H-9), 7.43 ("s", H-1); ^{13}C-NMR ($CDCl_3$): δ_{TMS}(>C=O) = 210.0 ppm; IR (KBr): ν(>C=O) 1735 cm^{-1}].

The tetracyclic diketone *(8)* [colorless crystalline needles, m.p. 208°C; $m/e = 186$; ^{1}H-NMR ($CDCl_3$): $\tau = 3.84$ (dd, 2H; $J = 8.0$, 8.0 Hz), 4.15 (dd, 2H; $J = 6.0$, 8.0 Hz), 6.55 (m, M part of an AA'MM' system, 2H), 7.36 ("dd", 2H; $J = 7.5$, 8.0 Hz), 7.52 (A part of an AA'MM' system, 2H); ^{13}C-NMR ($CDCl_3$): δ_{TMS}(>C=O) = 208.7 ppm; IR (KBr): ν(>C=O) 1735 cm^{-1}] is obtainable in quantitative yield by carbonylation of *(7)*[3] (100 atm of CO, 80°C, 2 d).

Na_3NO_3—Not an Orthonitrite

By *Martin Jansen*[*]

So far it has remained unclear whether Na_3NO_3[1,2] exists as a salt of "orthonitrous acid" or as an adduct $Na_2O \cdot NaNO_2$; cryoscopic investigations in molten $LiNO_3$ and in an $LiNO_3/KNO_3$ eutectic indicate existence of the anion NO_3^{3-}[2].

[*] Dr. M. Jansen
Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58,
6300 Giessen (Germany)

We obtained Na_3NO_3 in the form of a golden-yellow, microcrystalline, moisture-sensitive powder by heating equimolar quantities of Na_2O[3] and $NaNO_2$ (Merck, dried by melting *in vacuo*) in a sealed silver crucible (310°C, 3d).

The X-ray power diagrams contain few lines and can be completely indexed for a primitive cubic structure, $a=4.605(3)$ Å (Guinier data). A structural model was found by "trial and error" which led to very good agreement between calculated and observed line intensities (21 Debye-Scherrer lines): space group $Pm3m\text{-}O_h^1$; $Z=1$; O_I at 1 (a), Na at 3 (d), the NO_2^- group centered about 1 (b). If the known geometry of the nitrite ion[4] is retained, examination of the bond distances shows that the most favorable orientation for the NO_2^- fragment arises when the interatomic contacts O...O coincide with one of the [100]~ directions (cf. Fig. 1). Accordingly N and O_{II} occupy the equivalent position 6(f) with $x=0.37$, occupation factor = 1/6 for N and $x=0.27$, occupation factor = 1/3 for O_{II}.

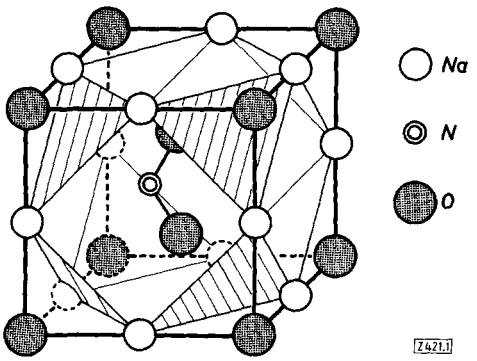

Fig. 1. Crystal structure of Na_3NO_3 (the NO_2^- group is shown in one of the possible orientations).

On the strength of this postulated structure the crystal structure of Na_3NO_3 is derived of the anti-perowskite type corresponding to the formulation $[NO_2^-]ONa_3$ and contains *no* NO_3^{3-} groups. In the meantime a single crystal of Na_3NO_3 has also been obtained; data collection for [100], [110], and [111] confirm the dimensions and symmetry (Laue group m3m).

Single crystal data ought to provide more detailed information about the structure (*e.g.* whether orientation disorder or hindered rotation of the NO_2^- anion occur).

Arsenic Pentachloride, $AsCl_5$[**]

By *Konrad Seppelt*[*]

Fourth-row nonmetals exhibit striking anomalies (instability) in their highest valency states. The best known example is provided by the late discovery of the perbromates[1]; and another may be seen in the phenomenon that both phosphorus pentachloride and antimony pentachloride have long been known but not arsenic pentachloride, although the first attempted preparation was described as early as 1834[2]. Meanwhile there has been no lack of attempts to close that gap[3]. It has now proved possible to detect $AsCl_5$.

Irradiation of a solution of $AsCl_3$ in chlorine with UV light at −105°C affords arsenic pentachloride.

$$AsCl_3 + Cl_2 \underset{-50\,^\circ C}{\overset{-105\,^\circ C,\ h\nu}{\rightleftharpoons}} AsCl_5$$

Gravimetric analysis of the reaction product indicated the composition $AsCl_{4.9}$. Unequivocal identification was accomplished by Raman spectroscopy: the bands of $AsCl_3$ [405, 370, 194, 158 cm^{-1}] disappear and new absorptions [437, 369 (p), 295 (p), 220, 213, 83 cm^{-1}] appear, which on account of their position, intensity, and polarization can only be assigned to $AsCl_5$. This is particulary clear on comparison with the spectra of PCl_5 and $SbCl_5$[4] (see Fig. 1).

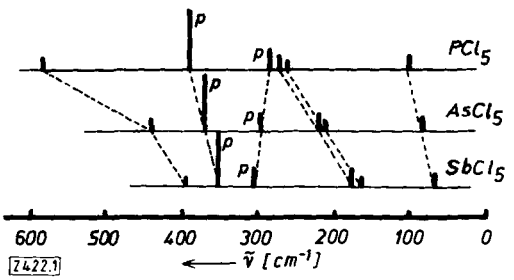

Fig. 1. Raman spectra of the pentahalides ECl_5.

Presumably due to entrained chlorine $AsCl_5$ is a pale yellow solid; it melts with partial decomposition at about −50°C.

The Raman spectrum not only confirms the existence of $AsCl_5$ but also provides structural information. In solution the molecule has a trigonal-bipyramidal structure, as do PCl_5 and $SbCl_5$ in the liquid or dissolved state. However, the same structure is retained in the solid state, *i.e.* the compound does not adopt an ionic structure like that of solid PCl_5 ($=PCl_4^+PCl_6^-$)[5] or dimerize like solid $SbCl_5$ ($=Cl_4SbCl_2SbCl_4$)[6]. It cannot be ruled out though that such transformations may occur very slowly owing to the low temperature.

A cursory consideration of the Raman spectrum also reveals that the As—Cl bonds are no weaker than the P—Cl and Sb—Cl bonds. The instability of $AsCl_5$ must therefore have other reasons. Although the formation reaction is clearly a radical chlorination it can be formally resolved into the following steps:

$$AsCl_3 \xrightarrow{-e} AsCl_3^+ \xrightarrow{+Cl^-} AsCl_4^+ \xrightarrow{+Cl^-} AsCl_5$$

The overall enthalpy of reaction amounts to −22.1 kcal/mol for PCl_5(g) and −17.0 kcal/mol for $SbCl_5$(g). Since formation of the two new arsenic-chlorine bonds should involve approximately the same amount of energy as in the case of phosphorus and antimony the difference must be attributed to the differing ionization energies in the first step of the reaction. Indeed, the ionization of $AsCl_3$ (11.7 eV) is 27.5 kcal/mol higher than that of PCl_3 (10.5 eV)[7]; this energy difference suffices to make the reaction endothermic.

From the vantage point of bond theory the higher ionization energy of $AsCl_3$ will of course mean that the promotion energy into an excited state will also be raised accordingly, *i.e.* $E_{4s\rightarrow 4p,d} > E_{3s\rightarrow 3p,d}$. This unexpected sequence is a consequence of

the *transition metal contraction*: the slight screening of the relatively large nuclear charge of As(Se,Br) by the 3d electrons lowers the 4s orbital, the nonbonding electron pair in $AsCl_3$ having pronounced s character (bond angle 98°). While the situation has become normal again for Sb (Te, I, Xe), the same phenomenon occurs once more in the case of Bi *(lanthanoid contraction)*. This explains why $BiCl_5$ is also still unknown and probably even less stable than $SbCl_5$.

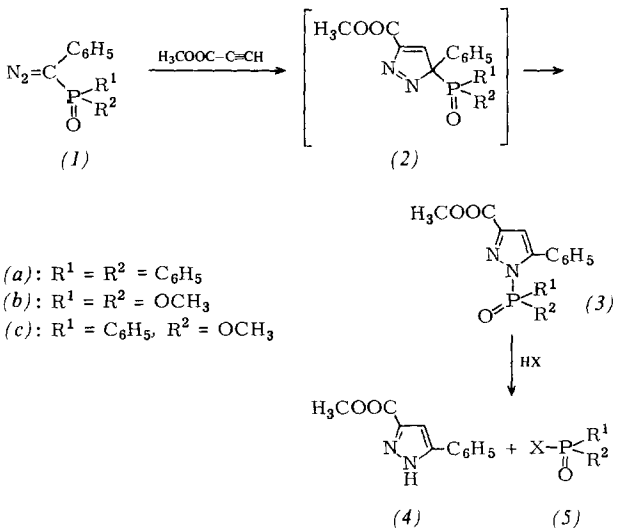
Phosphorylation with 1-Phosphorylpyrazoles[**]

By *Utz Felcht* and *Manfred Regitz*[*]

The phosphoryldiazoalkanes *(1a)*—*(1c)*[1] add regiospecifically to methyl propiolate to give the 3*H*-pyrazoles *(2a)*—*(2c)*, in which the phosphoryl group undergoes a spontaneous [1,5] shift to give the 1-phosphorylpyrazoles *(3a)*—*(3c)* (77—100 %)[2]. These compounds, which can be stored almost indefinitely at 0 °C in the absence of moisture, are suitable reagents for the phosphorylation of, *inter alia*, alcohols, enols, phenols, oximes, amines, α-amino acid esters, hydrazines and azides (see Table 1). This reaction, which can be formulated as *(3)* + HX → *(4)* + *(5)*, is reminiscent of acylation reactions with azolides[3].



(a): $R^1 = R^2 = C_6H_5$
(b): $R^1 = R^2 = OCH_3$
(c): $R^1 = C_6H_5$, $R^2 = OCH_3$

Characteristic of this method are the mild reaction conditions, satisfactory yields of products (see Table 1), and the potential variability of phosphoryl substituents and reaction partners. The problems met with in phosphorylation with difficultly handleable phosphoryl chlorides, which at least in the case of alcohols necessitates employment of auxiliary bases, are not encountered. In particular, the reaction with *(3c)* has proven to be far superior to that with the methyl ester of

Table 1. Phosphorylation of alcohols, enols, phenols, oximes, amines, α-aminocarboxylates, hydrazines and azides with 1-phosphorylpyrazoles *(3)* (typical examples).

[**] Phosphorylation with 1-Phosphorylpyrazoles, Part 1. This work was supported by the Fonds der Chemischen Industrie.

phenylphosphonic chloride[4]. Amines can be phosphorylated even in an aqueous medium without *(3)* being hydrolyzed. The usual workup under anhydrous conditions precludes reaction products sensitive to hydrolysis.

Typical procedure

A solution of *(3c)* (7.1 g, 20 mmol) in methylallyl alcohol/anhydrous acetonitrile (5 ml/50 ml) is heated for 12 h under reflux in the absence of moisture. On cooling to 0 °C, *(4)* crystallizes out (m. p. 138 °C; Ref. [5]: 181—182 °C). The filtrate is concentrated by evaporation at 30 °C/12 torr, the residue taken up in ether (20 ml), and the resulting solution chromatographed on activated charcoal (Merck, 0.5—0.75 mm; column length 50 cm, diameter 3 cm) with 3000 ml ether. The phosphonic ester obtained after removal of solvent by evaporation at 25 °C/12 torr is already thin-layer chromatographically homogeneous; it is finally isolated by bulb-tube distillation at 120 °C (oven temperature)/0.03 torr; yield 3.4 g (75 %). IR (film): 1600 (C=C), 1450 (P-phenyl), 1625 (PO), 1020 cm^{-1} (P—O—C). ^{1}H-NMR ($CDCl_3$): τ = 4.85—5.17 (m, olefinic CH_2), 5.53 (d, $^3J_{P,H}$ = 8.0 Hz, OCH_2), 6.25 (d, $^3J_{PH}$ = 11.0 Hz, OCH_3), 8.25 ppm (m, CH_3-allyl). The elemental analysis is correct.

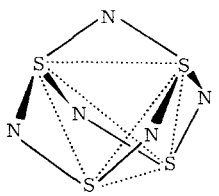
Crystal and Molecular Structure of the Tetrasulfur Pentanitride Anion

By *Wolfgang Flues, Otto J. Scherer, Johannes Weiss*, and *Gotthelf Wolmershäuser*[*]

The structure of a S_4N_4 molecule with an additional N bridge was proposed for the recently discovered species $[S_4N_5]^-$[1]:



[*] Prof. Dr. J. Weiss and Dr. W. Flues
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, 6900 Heidelberg 1 (Germany)
Prof. Dr. O. J. Scherer and Dipl.-Chem. G. Wolmershäuser
Fachbereich Chemie der Universität
Postfach 3049, 6750 Kaiserslautern (Germany)

The correctness of this assumption has now been confirmed by an X-ray structure analysis of $[R_4N]^+[S_4N_5]^-$ *(2)*, R = *n*-C_4H_9.

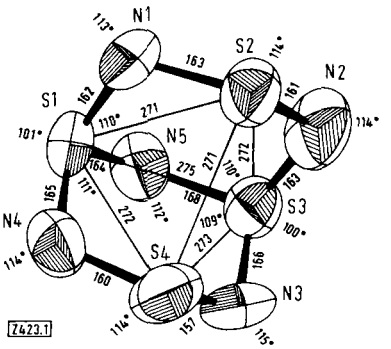


Fig. 1. Structure of $[S_4N_5]^-$ (distances in pm; the thermal ellipsoids correspond to a probability of 50 %).

Compound *(2)* forms monoclinic crystals having a = 1112.5(5), b = 1558.8(6), c = 1348.5(5) pm; β = 90.26(6)°; space group $P2_1/n$; Z = 4. Using Mo-K_α radiation with 2θ = 44° a total of 1307 independent reflections of intensity $I > 2.58\delta(I)$ were recorded on a diffractometer; since the crystal decomposes during the measurement the reflections had to be adjusted to the same level with the aid of a reference reflection. The data were corrected by standard methods. The structure was solved by direct methods and refined with anisotropic temperature factors to an R value of 11.1 %. The positions of the protons were not determined.

Figure 1 shows the S_4N_5 anion with bond lengths, bond angles, and also the S···S distances (standard deviations: S—N 2 pm, S···S 1 pm, angles 1°). Its structure closely resembles that of $[S_4N_5O]^-$[2]. The average value of the S—N bond lengths (163 pm) corresponds to that in S_4N_4 (162 pm)[3] and $[S_4N_5O]^-$ (162 pm)[2]. However, a significant deviation is seen in the maximum difference between the S···S distances: bridging of the fifth tetrahedral edge by a negatively charged N atom in the anion of *(2)* largely equalizes the S···S distances (almost undistorted S tetrahedron) so that approximately equal interactions are to be postulated between all the S atoms.

$[S_4N_5]^-$—the first binary sulfur-nitrogen anion whose structure has been elucidated—may possibly occupy a key position among the SN anions like $[S_4N_3]^+$ among the SN cations or S_4N_4 among the neutral species. In the same way as S_4N_4 corresponds formally to an inverted As_4S_4 structure, this also applies to $[S_4N_5]^-$ and As_4S_5[4] or β-P_4S_5[5].

In analogy with $[(CH_3)_3CNH_3]^+[S_4N_5]^-$[1], methanolysis[6] of *N,N'*-bis(trimethylsilyl)sulfur diimide leads to $[NH_4]^+[S_4N_5]^-$ *(1)*, which can be converted into $[R_4N]^+[S_4N_5]^-$ *(2)* with R_4NOH:

$$Me_3Si{-}N{=}S{=}N{-}SiMe_3 \xrightarrow{CH_3OH} \underset{(1)}{[NH_4]^+[S_4N_5]^-} \xrightarrow[-\,NH_4OH]{+\,R_4NOH}$$

R = n-C_4H_9 $\qquad$ $[R_4N]^+[S_4N_5]^-$ *(2)*

Compound *(2)*, which like *(1)* has been characterized by complete elemental analysis, and IR and mass spectrometry, can easily be examined by UV spectroscopy owing to its greater stability in methanol as compared with $[(CH_3)_3CNH_3]^+[S_4N_5]^-$: λ_{max} = 480 ($\log\varepsilon$ = 1.25), 343 (sh, 3.37), 285 nm (3.75).

Procedure:

(1): $[(CH_3)_3SiN]_2S$[7] (5.16 g, 0.025 mol) and methanol (12 ml, 0.3 mol) are stirred together at room temperature for *ca.* 0.5 h (evolution of gas!). The reaction product precipitated with benzene is filtered off (G3 frit), washed with benzene, and dried under oil-pump vacuum. A further crop of *(1)* precipitates from the filtrate within a few days. Yield 1.1 g (80 %, based on the stoichiometry given in ref. [6]).

(2): Compound *(2)* is formed as a yellow precipitate from an aqueous solution of *(1)* (0.8 g, 3.7 mmol) and $(n\text{-}C_4H_9)_4NOH$ (2.0 g, 7.7 mmol). Yield 1.3 g (80 %). Recrystallization from acetone/ethyl acetate (1 : 1) yields yellow needles.

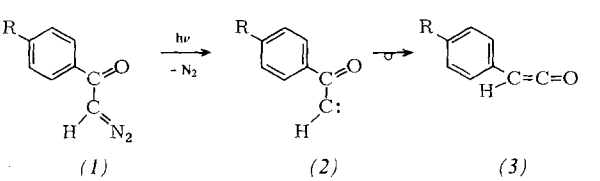
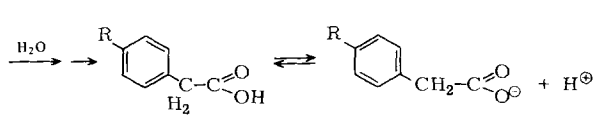
Rate of Acid Formation from Phenylketenes in Aqueous Solution

By *Eberhard Bothe, Herbert Meier, Dietrich Schulte-Frohlinde*, and *Clemens von Sonntag*[*]

We report here on the first measurement of the rate of acid formation from ketenes in aqueous solution. The difficulty met with in this measurement lies in the high rate of reaction of the ketene with water, thus necessitating both rapid preparation of the ketenes *in situ* as well as rapid measurement of acid formation.



(1) *(2)* *(3)*



(4) *(5)*

R = H, F, Cl, CH_3, OCH_3, CN, NO_2

Prof. Dr. H. Meier
Chemisches Institut der Universität Tübingen
[+] Author to whom correspondence should be addressed.

We prepared the ketenes *(3)* from *p*-substituted diazoacetophenones *(1)* *via* carbenes *(2)* by flash-photolytic Wolff rearrangement[1, 2]. On addition of water the ketenes *(3)* are converted into acids *(4)*, whose dissociation gives rise to conductive species *(5)*. The rate of increase of conductivity in solution was measured. The rise time of the electronic setup was 80 ns (the halfwidth of the photoflash being 5 µs). The increase of conductivity was found to be of first order over a duration of more than three halflives. The halflive was independent of the light intensity (factor of 50), of the initial concentration of diazoacetophenone, and of the pH in the range 4—10.8. The concentration of protons formed was between 8×10^{-8} and 4×10^{-6} mol/l. For R = H it was shown that the acid formed had the same pK as phenylacetic acid.

Table 1. Rate constants k of the formation of acids from 4-substituted phenylketenes *(3)* generated *in situ* from diazoacetophenones *(1)* at 26 °C in aqueous solution. $t_{1/2}$ = halflife, σ_p^n = Hammett substituent constant.

R in *(3)*	$t_{1/2}$ [µs]	k [10^3 s^{-1}]	σ_p^n [3]
NO_2	14	49.5	0.778
CN	27	25.6	0.674
Cl	72	9.6	0.238
F	117	5.9	0.056
H	141	4.9	0.000
OCH_3	152	4.5	−0.111
CH_3	184	3.8	−0.129

The rate-determining step for formation of the ions cannot be the dissociation of the acids *(4)*, because this would give a halflife of ≈1 µs. The elimination of nitrogen from *(1)* is limited by the lifetime of the electronically excited singlet state of the diazoketone and is therefore also too rapid. Nor can the rate of rearrangement of the carbenes be rate determining: the order of the relative rates of migration of the fragments is in the reverse order[2, 4] to that for the rates of acid formation (Table 1).

It was concluded previously that the photolytic Wolff rearrangement proceeded predominantly *via* an excited singlet carbene and must therefore take place within the lifetime of excited singlet states[2, 4]. This conclusion is supported by the fact that the presence of atmospheric oxygen does not influence the acid formation. Hence the increase in conductivity must be attributed to the formation of acids *(4)* from the ketenes *(3)*. Whether the ketene hydrate is involved in the formation of the acid is still unknown. It thus remains an open question whether addition of water to the ketene on rearrangement of the ketene hydrate into the acid is the rate determining step.

The formation of acid is surprisingly rapid. In the pH range investigated *viz.* 4—10.8, it is not catalyzed by $H^{\oplus}$ or $OH^{\ominus}$. The activation energy for *(1)*, R = Cl, is 9.3 kcal/mol (frequency factor $10^{10.72}$ s^{-1}). Acid formation from *(1)*. R = H or Cl, proceeds slower in D_2O than in H_2O by a factor of 2 or 1.8, respectively. The dependence on substituents conforms to a linear free energy relationship. Use of the Hammett equation with the constants σ_p^n[3] yields a value $\rho = 1.19$ (correlation coefficient 0.97). Thus, electron withdrawing substituents accelerate acid formation, electron repelling substituents retard it.

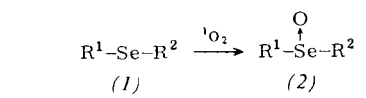
Photo-Oxygenation of Selenides—A New Pathway to Selenoxides

By *L. Hevesi* and *Alain Krief*[*]

We have found that dialkyl and aryl alkyl selenides *(1)* are transformed by photochemically generated singlet oxygen[1] into selenoxides *(2)*[2] (see Table 1), which possess interesting synthetic applications[3].



(1) *(2)*

Table 1. Reactions of selenides with singlet oxygen to form selenoxides. See procedure for reaction conditions.

	R^1	R^2	Reaction time [h]	Yield [%]
a	C_6H_5	CH_3	7	95
b	C_6H_5	$CH_2C_6H_5$	2.5	70 (10) [a]
c	C_6H_5	C_3H_7—CHOH—CH(C_3H_7)	3.5	28 (45) [a, b]
d	CH_3	C_9H_{19}—CH(CH_3)	5	85 (10) [a]
e	CH_3	C_3H_7—CHOH—CH(C_3H_7)	4.5	70 (15) [a, c]

[a] Figures in parentheses refer to the amount of starting material recovered at the conclusion of the reaction.
[b] 27% of 5-octen-4-ol also formed.
[c] 15% of 5-octen-4-ol also formed.

The yields of selenoxides are very high; no selenone formation was observed in any of the reactions. In some cases the known thermal elimination of selenenic acids RSeOH occurred, leading to formation of olefins[3]. This was especially pronounced with β-hydroxy selenides which underwent partial conversion into allyl alcohols (Table 1). The yields of allyl alcohols increase with rising temperature and duration of irradiation. Thus the yield of 5-octen-4-ol from *(1e)* increases from 15% (20°C, 4.5 h) to 42% (50°C, 4.5 h), and that from *(1c)* increases from 27% (20°C, 3.5 h) to 46% (20°C, 17.5 h)[4]. This allyl alcohol is not oxidized on irradiation.

Procedure:

In a typical experiment, compound *(1)* (1 mmol) and Bengal rose (10 mg) are dissolved in anhydrous methanol (120 ml). Oxygen is passed through the stirred solution which is irradiated with a Sylvania iodine lamp (220 V, 650 W) operated at 135 V (≙325 W). The course of the reaction is monitored by thin-layer chromatography. After distillation of solvent the crude mixture is worked up by chromatography.—The products were identified by comparison (IR, ^{1}H-NMR) with authentic material.

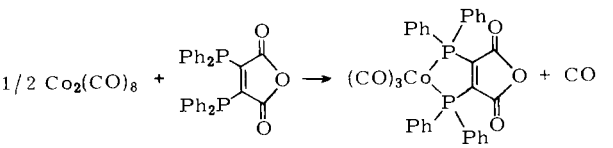
A Mononuclear Paramagnetic Biphosphinotricarbonylcobalt(0) Complex

By *Dieter Fenske*[*]

With few exceptions, such as $V(CO)_6$, carbonylmetal(0) complexes are diamagnetic. The same applies to their phosphane-substituted derivatives. We have now obtained a paramagnetic cobalt(0) complex *(2)* in which five electron pair donors are coordinated to Co. This compound is formed on reaction of $Co_2(CO)_8$ with *(1)*[1,2] in toluene.



(1) *(2)*

Compound *(2)* crystallizes from ether/dichloroethane as dark green column shaped crystals displaying pronounced dichroism in transmitted light. They are air-stable; in solution they decompose slowly to form a red compound which has yet to be characterized.

If the five electron pair donors *(2)* were bound according to the usual rules of complex chemistry then the valence shell of the Co would contain one electron more than the krypton shell. Such a state should not be stable. No distinction is possible on the basis of spectroscopic and ESCA measurements. We have therefore subjected the compound to X-ray structure analysis.

Compound *(2)* crystallizes in the centrosymmetric space group Pnam with $a = 16.76(1)$, $b = 7.871(6)$, $c = 21.24(1)$ Å and

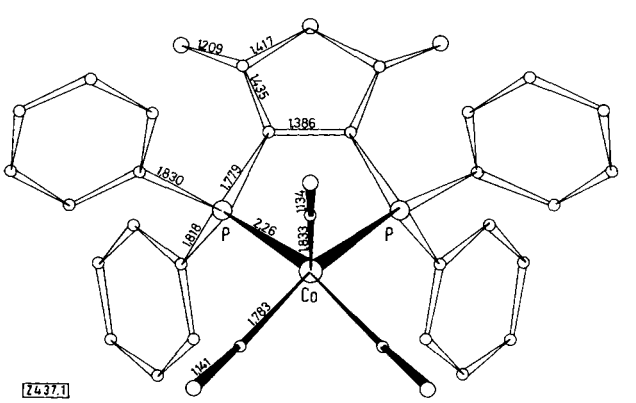


Fig. 1. Molecular structure of [bis(diphenylphosphino)maleic anhydride]tricarbonylcobalt(0) *(2)*. Viewed along the *b* axis.

Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, 4400 Münster (Germany)

$Z=4$. The structure was solved for 1881 diffractometer data (320 of which were unobserved) by the heavy atom method and refined to an R value of 0.046 (Fig. 1).

The P atom of the chelated ligands *(1)* and the C atoms of the carbonyl groups form a distorted square pyramid with a plane of symmetry around the Co atom. The interatomic distances in the CO groups are very short, in accord with the position of the three ν(C≡O) vibrations observed between 2015 and 2075 cm^{-1} in the IR spectrum (KBr). The long C=C bond length in the phosphorus ligand indicates considerable delocalization of the π electrons. In a chelate complex formed by *(1)* and NiI_2 we have found the same C=C bond lengths as in *(2)* but C≡O lengths in the anhydride group which are 0.04 Å shorter than in *(2)*[2]. This difference in bonding is also manifested in the position of the two ν(C≡O) vibrations of the anhydride group which lie at 1840 and 1770 cm^{-1} in the NiI_2 complex of *(1)* but at 1740 and 1670 cm^{-1} in *(2)*.

The higher carbonyl vibration of the CO ligand which corresponds to that of the cationic complex $[Co(CO)_3[P(C_6H_5)_3]_2]^+$[3], and the lower carbonyl vibration of the anhydride group in *(2)* are regarded as indicating that the unpaired electron in *(2)* is delocalized over the phosphorus ligand. In the limiting state this becomes a radical anion, and the fivefold coordinated Co becomes a cation. The ESR signal[4] of this electron recorded in CH_2Cl_2 solution forms three groups of octets in the intensity ratio 1 : 2 : 1 corresponding to coupling of the electron with the phosphorus and the cobalt. The g factor and the coupling constants were found to be $g=2.00418$, $a_P=11.11$ G and $a_{Co}=1.21$ G. Magnetic measurements on the solid afforded $\mu_{eff}=2.10$ BM (at 25 °C). This value indicates a high orbital component of the magnetic moment.

[Bis(diphenylphosphino)maleic anhydride]tricarbonylcobalt(0) (2)

To a solution of $Co_2(CO)_8$ (2.56 g, 7.5 mmol) in toluene (20 ml) is added at 0 °C a solution of *(1)* (7.46 g, 16.0 mmol) in toluene (50 ml). Appearance of a green precipitate within a few minutes is accompanied by evolution of CO. After 30 min, filtration with exclusion of moisture affords *(2)* (8.60 g, 94 %).

Synthesis of Thiepino[4,5-*c*]pyrrole Derivatives Having Sulfur in Different Oxidation States[1]

By *Richard Kreher*, *Helgard Möller*, and *Paul Heinz Wagner*[*]

Cyclizing condensation of pyrrole-3,4-dicarbaldehydes *(1)* with 1,2- or 1,3-bifunctional CH-acidic carbonyl compounds[2] is a versatile synthetic procedure for producing bicyclic hetarenes[3]. Its application to 1,3-bifunctional CH-acidic sulfur compounds *(2)* provides a facile entry to thiepino[4,5-*c*]pyrroles *(3)* having the sulfur atom in different oxidation states.

(3ce), X = CN: yield 50 %, m.p. 308 °C.—*(3cf)*, X = C_6H_5—CO: yield 68 %, m.p. 210—212 °C.—*(3cg)*, X = *p*-Cl—C_6H_4—CO: yield 31 %, m.p. 238 °C.—*(3ch)*, X = *p*-Br—C_6H_4—CO: yield 58 %, m.p. 294 °C.—*(3ci)*, X = *p*-CH_3O—C_6H_4—CO: yield 82 %, m.p. 199 °C.—*(3cj)*, X = *p*-NO_2—C_6H_4—CO: yield 92 %, m.p. 310 °C (dec.)

In the presence of morpholine the dialdehydes *(1)* react smoothly with activated sulfonyl compounds *(2a)*, X = alkoxycarbonyl or aroyl, with elimination of water. The *S,S*-dioxide *(3a)*, R′ = R″ = CH_3, X = H, not directly accessible by this pathway can be obtained from the condensation product *(3ae)*, X = ethoxycarbonyl, by basic solvolysis and thermal decarboxylation (Table 1).

The sulfides *(2c)* can undergo condensation to give *(3c)* provided that the α-methylene groups are activated by cyano or aroyl groups; the effect of ester groups is inadequate in this case (Table 2).

Activation of the sulfide component *(2c)* can also be accomplished by *S*-alkylation. Cyclizing condensation of the sulfonium salts *(2d)* provides access to the heterocyclically conjugated sulfonium salts *(3d)*, which however are obtained in better yields from compounds *(3c)* by *S*-alkylation with trialkyloxonium tetrafluoroborates.

Synthesis of the *S*-oxides *(3b)* can be achieved by application of the same technique only if the sulfoxide component *(2b)* possesses sufficient thermal stability and chemical reactivity.

The structure of the thiepino[4,5-*c*]pyrroles *(3)* follows from their method of preparation and is confirmed by analytical and spectral data. The UV absorption maxima display a considerable structural dependence. A bathochromic shift of the long wave absorption maximum is seen to accompany the change in donor-acceptor properties of the hetero atom

[*] Prof. Dr. R. Kreher, Dipl.-Ing. H. Möller, and Dipl.-Ing. P. H. Wagner
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 14, 6100 Darmstadt (Germany)

in the seven-membered ring: *(3a)*, $\lambda_{max}=375$ nm; *(3d)*, $\lambda_{max}=405$ nm; *(3c)*, $\lambda_{max}=575$ nm.

Compounds *(3)* are of interest mainly as sulfonyl or sulfur-homologous derivatives of isoindole. Representative reactivity studies have so far been performed with the readily accessible *S,S*-dioxides *(3a)*, X = alkoxycarbonyl, which fail to undergo cycloaddition reactions with activated dienophiles (dialkyl acetylenedicarboxylates, dialkyl azodicarboxylates) under the usual conditions.

Photoelectron Spectrum of $H_2C{=}S{=}O$[1]

By *Eric Block, Hans Bock, Shamsher Mohmand, Pavel Rosmus*, and *Bahman Solouki*[*]

Dedicated to Professor Werner Schultheis

In contrast to other known thiocarbonyl *S*-oxides $R_2C{=}S{=}O$[2a], "sulfine" (thioformaldehyde *S*-oxide) $H_2C{=}S{=}O$, an isoelectronic derivative of sulfur dioxide, has so far defied all attempts at synthesis[2b]. The compound can however be generated as a short-lived species ($t_{1/2}\approx 30$—60 min) by pyrolysis of suitable starting materials; 1,3-dithietane 1-oxide[3] and, in particular, methanesulfinyl chloride[3,4] have proved to be suitable starting compounds for recording the photoelectron spectrum (Fig. 1).

The PE spectra of the pyrolysis products (Fig. 1: b and c) contain the bands of thioformaldehyde $H_2C{=}S$[6] (b) and of hydrogen chloride (c).

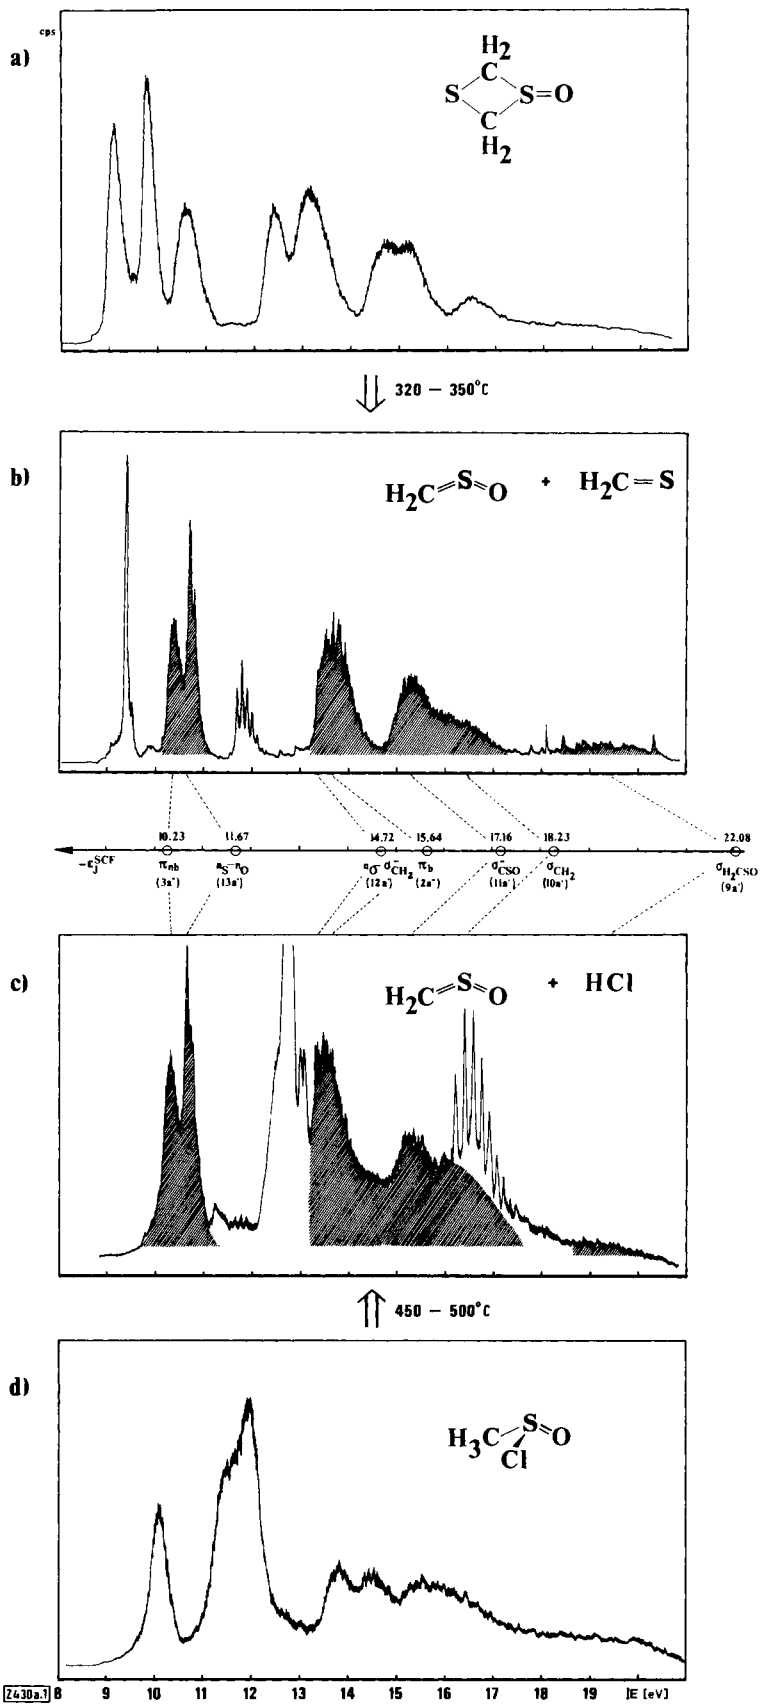

Fig. 1. [He(I)] PE spectra of 1,3-dithietane 1-oxide (a), methanesulfinyl chloride (d), and their pyrolysis products (a→b, d→c).

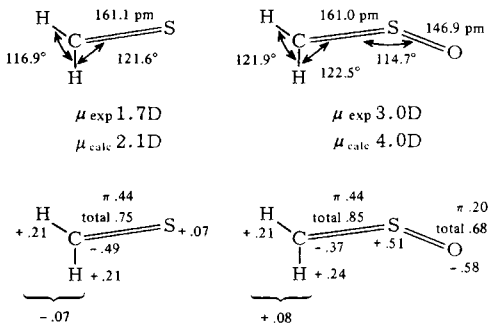
The hatched bands of "sulfine" can be deduced by comparison of the spectra (b) and (c). Their assignment follows from an *ab initio* SCF calculation[7] and by comparison with SSO and OSO[5]; it is supported by the resolved vibrational fine structures in the first three bands and by the change in the relative intensities in the [Ne] photoelectron spectrum[6b].

$H_2C{=}S{=}O$ can be regarded as the *S*-oxide of thioformaldehyde[6]; characteristic molecular data[3] and parameters[7] are:



As can be seen, the angle $\sphericalangle$ HCH is enlarged by incorporation of O; on the other hand the bond length $d_{C=S}$ remains unchanged. Population analysis indicates a redistribution of charge C→S→O; the $\pi_{C=S}$ bond remains constant. In comparison with other X=S=O derivatives the S=O bond is relatively weak—in accord with the experimentally observed[2] reductive elimination of O from thiocarbonyl *S*-oxides.

Photoelectron Spectrum of HN=S=O[1]

By *Bahman Solouki, Pavel Rosmus*, and *Hans Bock*[*]

The only photoelectron spectrum still required for a comparative discussion of bonding in the iso(valence)electronic molecules X=S=O (X = H_2C[1], HN, O[2], S[2]) was that of sulfinyl imide. Of the known methods of preparing[3,4] the compound, which polymerizes on condensation[5], we chose the reaction of Cl_2SO with NH_3 and were able to optimize the conditions with the aid of a PE spectrometer until the bands of the starting materials had largely disappeared (Fig. 1).

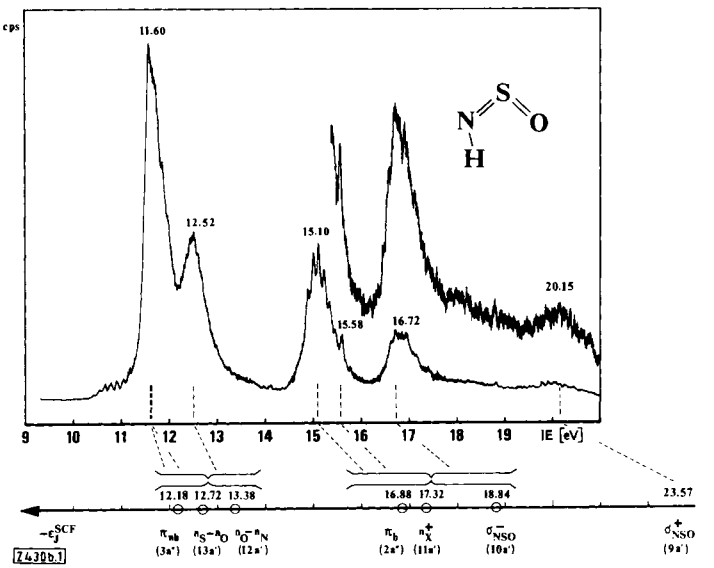

Fig. 1. [He(I)] PE spectrum of sulfinyl imide with assignment by an *ab initio* SCF calculation.

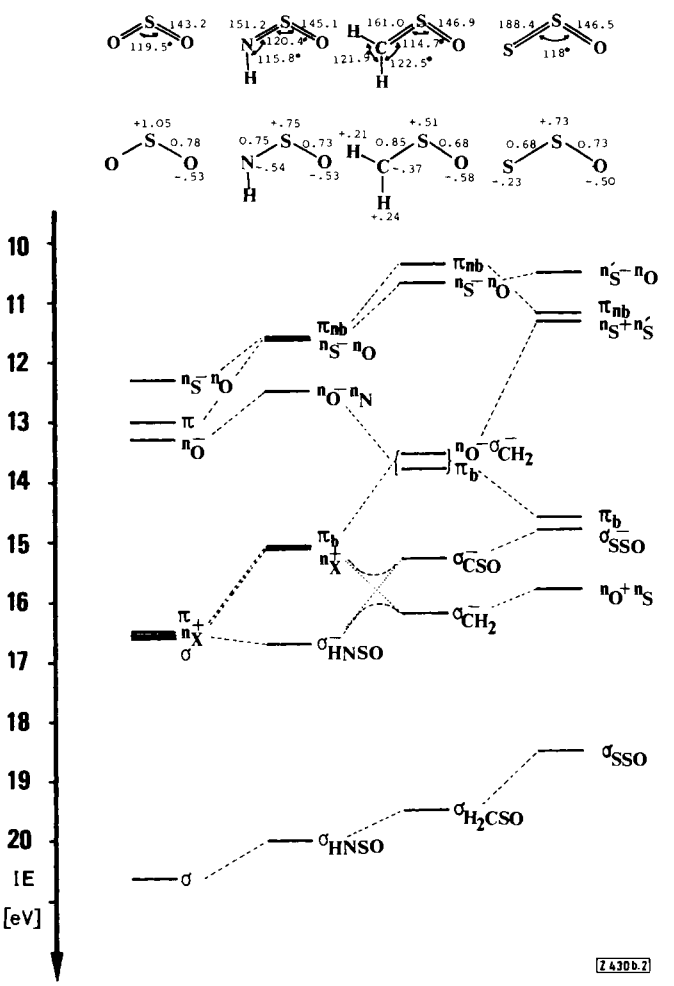

Fig. 2. Comparison of the X=S=O derivatives: ionization energies, characteristic molecular data (bond lengths in pm) and parameters.

[*] Prof. Dr. H. Bock and Dr. B. Solouki
Institut für Anorganische Chemie der Universität
Theodor-Stern-Kai 7, 6000 Frankfurt am Main 70 (Germany)
Dr. P. Rosmus
Institut für Physikalische Chemie III der Universität
Jakob-Welder-Weg 13—15, 6500 Mainz (Germany)

Assignment of the PE bands on the basis of an *ab initio* SCF calculation[6] is supported above all by comparison with OSO and SSO (Fig. 2): all X=S=O skeletons contain 18 valence electrons and—with the exception of $H_2C{=}S{=}O$—3 electron pairs in the plane of the molecule. Two separate regions with three ionizations each are expected according to *Walsh*[7] for such BAB or BAC systems and are indeed observed in all cases except H_2CSO (Figs. 1 and 2): on going from $HN{=}S{=}O$ to $H_2C{=}S{=}O$ the third ionization expectedly shows a sharp increase because the n_N electron pair is replaced by a σ_{CH} bond.

The comparison (Fig. 2) further reveals that the π ionizations π_{nb} and π_b run parallel to the calculated charges on the substituents X: $O > NH \approx S > CH_2$. The terminal oxygen in all derivatives XSO has a similar negative charge, thus leading to varying degrees of polarization in the remaining systems. The calculated bond populations decrease in the order $C{=}S > O{=}S \approx N{=}S > S{=}S$; the weakest S=O bond is found in $H_2C{=}S{=}O$[1].

The ionization energies and calculated quantities permit a better understanding of the properties of the molecules X=S=O: thus OSO proves to be the sole derivative stable under normal conditions; *cis*-HNSO is more stable than the *trans* isomer and is transformed, *inter alia*, into *cis*-NSOH upon irradiation in a matrix[5]; H_2CSO readily loses oxygen[8]; and SSO polymerizes *via* the polar S=S double bond[2].

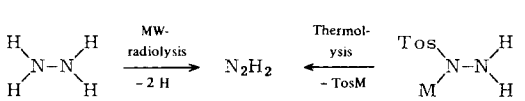
The Existence of Isomeric Diazenes (Diimines)[1]

By *Nils Wiberg, Gerd Fischer,* and *Heinz Bachhuber*[*]

Dedicated to Professor Egon Wiberg on the occasion of his 75th birthday

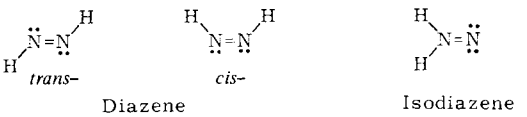
Two methods have hitherto become available for the preparation of *gaseous* diazene (diimine)[4], namely microwave radiolysis of hydrazine[2] and thermolysis of alkali metal tosylhydrazides[3] (for preparation of *dissolved* diazene, cf. ref.[5]).



[*] Prof. Dr. N. Wiberg, Dipl.-Chem. G. Fischer, and Dr. H. Bachhuber
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, 8000 München 2 (Germany)

The N_2H_2 produced from the lithium salt by the second method and purified from the co-products nitrogen and and hydrazine can be deposited as lustrous yellow *solid* diazene on surfaces cooled by liquid nitrogen[3]. In contrast, the N_2H_2 produced by the first method cannot be separated from the co-product ammonia (and other nitrogen hydrides) and can only be condensed together with large quantities of NH_3[2, 6a].

Three possible constitutional or configurational isomers can be envisioned for "diazene":



IR data show the N_2H_2 arising from lithium tosylhydrazide and examined in the solid state at −196 °C to be *trans*-diazene[3]. We have now found, however, that the N_2H_2 produced in the same way from cesium tosylhydrazide, which contains hardly any by-products, differs in its physical and chemical properties from *trans*-diazene, thus indicating formation of an isomer (*cis*-diazene or isodiazene). Thus the intensity ratio of the mass peaks due to the molecular and fragment ions $N_2H_2^+$, N_2H^+, and N_2^+ (18 eV) is 100:32:1 (*trans*-diazene) and 100:46:5 (new isomer). Striking differences are also noted in the ionization and appearance energies of the ions $N_2H_2^+$ and N_2H^+ as determined under strictly comparable conditions for the two diazenes by the RPD method[7a] (cf. Fig. 1)[7b]. Ionization leading to the same fragment N_2H^+ requires 0.56 ± 0.1 eV/molecule more energy in the case of *trans*-diazene than in the case of the isomeric species; thus the latter form has an energy content some 13 kcal/mol (= 54 kJ/mol) greater than that of the former.

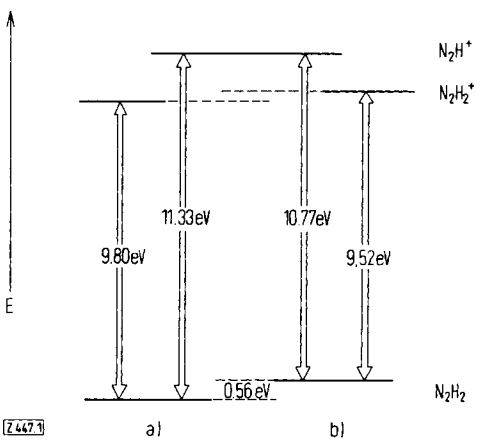


Fig. 1. Energies determined by electron impact (error: ±0.05 eV) for the transitions $N_2H_2 \rightarrow N_2H_2^+ + e$ and $N_2H_2 \rightarrow N_2H^+ + H + e$. The diimine was produced by thermolysis from a) lithium tosylhydrazide (*trans*-diazene) and b) cesium tosylhydrazide (isomeric diazene).

Unlike the yellow *trans*-diazene ($\lambda_{max} = 386$ nm) this isomer ($\lambda_{max} \approx 260$ nm) cannot be deposited without partial decomposition on surfaces cooled by liq. N_2. It also displays a greater reactivity towards ammonia, with which it is shown by IR studies to form a yellow addition compound ($\lambda_{max} = 398$ nm) of unknown structure. The same adduct is also formed from *trans*-diazene and ammonia; however, the reaction requires several hours at 110 K with *trans*-diazene but only a few minutes at 72 K in the case of the isomeric diazene. Hence at 77 K (liquid nitrogen) *trans*-diazene/ammonia are deposited as a co-condensate, but isomeric diazene/ammonia as an adduct.

The N_2H_2 produced together with much ammonia by microwave radiolysis of hydrazine corresponds in its properties to the thermolysis product of cesium tosylhydrazide. The absorption bands of the N_2H_2/NH_3 condensate observed alongside those of ammonia in the IR spectrum recorded at 77 K are not due to *trans*-diazene, as formerly proposed[6], but instead to the adduct immediately formed from the isomeric diazene and ammonia under such conditions[8].

Since its instability has so far precluded recording of a low-temperature IR spectrum of pure "isomeric diazene", its structure still remains open. On account of the relatively large energy difference of the two forms of N_2H_2 (quantum mechanical[9] and chemical considerations indicate similar energy contents for *cis*- and *trans*-diazene) we tentatively prefer the isodiazene over the *cis*-diazene structure for the new isomer. Moreover, the fact that this species can be passed unchanged through several meters of glass tubing without isomerization at low pressures and in the absence of catalysts would also suggest that it is isodiazene. According to the Woodward-Hoffmann rules for the conservation of orbital symmetry, isodiazene, in contrast to *cis*-diazene, cannot readily rearrange to *trans*-diazene; in the presence of catalysts (*e.g.* gaseous hydrogen chloride), however, the expected transformation of the more energetic form into the thermodynamically more stable *trans*-diazene is observed.

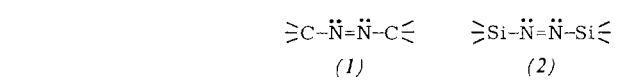
Bis(trimethylsilyl)diazene as a Complex Ligand[1]

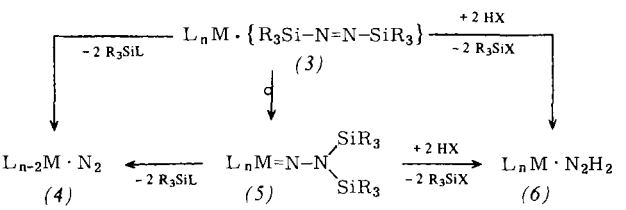
By *Nils Wiberg, H. W. Häring*, and *Oswald Schieda*[*]

Bis(organyl)diazenes (organic azo compounds) having the characteristic atomic grouping *(1)* can coordinate to subgroup metals either *via* their free n-electron pairs to form σ-complexes or *via* their π-electron pair to give π-complexes[2]. Owing to the extremely high and low energy, respectively, of their highest occupied n- and lowest unoccupied π*-molecular orbital[3] relative to those of *(1)*, bis(silyl)diazenes *(2)* should be even more suitable as σ- and π-complex ligands (scope for forming strong bonds with the "basic" n-electron pairs and strong back-bonds with the "acidic" π*-electron vacancy).



(1) *(2)*

Coordination compounds of azosilanes of general type *(3)* attract particular interest on account of the "chemical mobility" of the substituents on the azo group (R_3Si) which is absent in complexes of organic azo compounds. Thus the complexes *(3)* should undergo R_3SiL elimination, R_3Si rearrangement, and protolysis of Si—N bonds according to



to form dinitrogen complexes *(4)*, silylated isodiazene complexes *(5)*[4a], and desilylated diazene complexes *(6)*[4b], respectively. Some impression of the problems involved is given by the reactions of bis(trimethylsilyl)diazene *(2a)* with copper(I) chloride and with bis(cyclopentadienyl)vanadium.

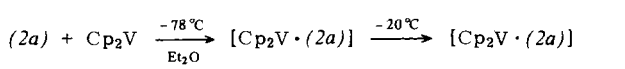
Like organic azo compounds, *(2a)* reacts with copper(I) chloride according to

(2a)

at low temperatures to form a crystalline reddish brown 1:2 adduct[5] which is insoluble in ether; the two CuCl units are probably bonded by way of the two n-electron pairs of *(2a)* as in the case of the corresponding azomethane complex[6] (formation of a *σ-diazene complex*). Above −30°C the dinuclear azosilane complex decomposes with elimination of Me_3SiCl and liberation of nitrogen:

Intermediate formation of a dinitrogen complex *(4)* was not observed. The azosilane complex is not attacked by methanol below −30°C; the silyl groups cannot be removed by protolysis.

At −78°C *(2a)* reacts smoothly with bis(cyclopentadienyl)-vanadium, which yields a π-complex with azobenzene[7], to form a blackish green complex which transforms into a dark reddish brown paramagnetic complex at −20°C, which is stable up to at least 100°C and can therefore be vacuum sublimed at 60°C[8].



black-green dark red-brown

As shown by X-ray structure analysis[9] the ligand *(2a)* is present in the iso-form in the reddish brown complex (formation of an *isodiazene complex*). Apparently Cp_2V initially forms a "normal" complex $Cp_2V \cdot Me_3SiNNSiMe_3$ with *(2a)* (formation of a *π-diazene complex*?) which rearranges to the thermodynamically more favorable isomer $Cp_2V{=}NN(SiMe_3)_2$.

[*] Prof. Dr. N. Wiberg, Dipl.-Chem. H. W. Häring, and O. Schieda
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, 8000 München 2 (Germany)

The action of methanol on the reddish brown compound does not lead to liberation of trimethylsilyl groups but instead, according to

$$2\ Cp_2VNN(SiMe_3)_2 \xrightarrow[-2\ CpH]{+2\ MeOH} [Cp(MeO)VNN(SiMe_3)_2]_2$$

to loss of cyclopentadienyl groups with formation of a brown diamagnetic complex of unknown structure which can be vacuum sublimed at 110°C. Its ^{1}H-NMR spectrum contains only one signal for the trimethylsilyl protons and one for the methoxy protons at $\delta = -22$ and -128 Hz (TMS internal standard, C_6H_6) respectively. The course of reaction can be interpreted by assuming that the vanadium central atom, which formally possesses an "excess" electron (*i.e.* 19 valence electrons)[10] in the complex $Cp_2VNN(SiMe_3)_2$, confers negative partial charges upon the two Cp ligands, thus facilitating attack of the cyclopentadienyl ring by a proton.

Procedure:

A mixture of CuCl (10.1 mmol) and $(Me_3Si)_2N_2$[3] in diethyl ether (50 ml) is stirred with exclusion of oxygen and moisture at −50°C until all the CuCl has dissolved (*ca.* 3 h). During this process, the initially yellow, then reddish brown, and finally colorless solution precipitates reddish brown fine crystals of [*(2a)*·2 CuCl], which is purified by repeated washing with ether.

Combination of Cp_2V (5.0 mmol) in diethyl ether (25 ml) at −78°C with $(Me_3Si)_2N_2$[3] in ether (10 ml) under similar conditions immediately yields a dark green solution which deposits blackish green crystals on concentration. Above −20°C they transform into the dark brown ismeric product $Cp_2V{=}NN(SiMe_3)_2$, m.p. 76—78°C, which can be recrystallized from ether.

Structure of an "Isodiimine" Complex: Bis-(trimethylsilyl)isodiazenebis(cyclopentadienyl)vanadium

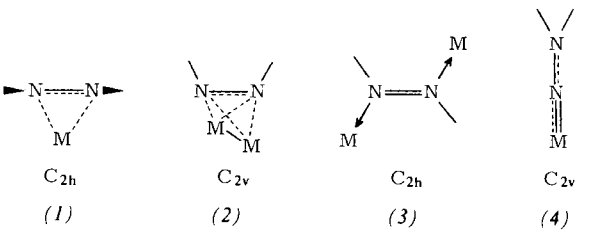
By *Michael Veith*[*]

Complexes of diazene (diimine) derivatives with transition metals can be distinguished according to structural criteria:

1) The azo group froms a π bond to the metal, the substituents on the NN unit being *trans* configurated (type *(1)*). In the case of dinuclear complexes the diazene group spans the coordination centers in such a way that the two metal atoms and the two nitrogen atoms approximately form a tetrahedron (type *(2)*). In both structural types the N—N bond length is considerably greater than in the free molecule and almost reaches the value for a single bond (137—139 pm)[1].

2) The azo group is coordinated to the metal *via* a σ bond (type *(3)*). The N—N bond length is hardly affected (125—126 pm). In this way diazenes usually act as bridging ligands between two metal atoms[2].

3) The substituents on the azo group migrate during complex formation and the resulting 1,2-disubstituted diazene ligand coordinates *via* a multiple bond between the terminal nitrogen and the metal atom (type *(4)*).



The last-named structural type is assumed for the N_2H_2 ligand in the cation of $[W(N_2H_2)Cl(diphos)_2]BPh_4$. Although the positions of the hydrogen atoms could unfortunately not be established on X-ray structure analysis, the N—N bond length of 137 pm, the WNN angle of 171°, and the short W—N distance of 173 pm do evidence a structure of type *(4)*.

In this communication we wish to report the results of a structure determination[4] performed on a complex formed

Selected bond lengths [pm] and angles [°]:

V—N(2)	166.6(6)	Si—C	184(1)	(average value)
N(1)—N(2)	136.9(9)	V—C	240(13)	(average value)
Si—N(1)	175.6(3)			
∢VN(1)N(2)	180	∢SiN(1)Si'	136.7(4)	

by reaction of bis(trimethylsilyl)diazene with bis(cyclopentadienyl)vanadium[5]. The structure of this complex (Fig. 1) provides the first insight into the geometry of a monohaptocoordinated isodiazene.

In the crystal the molecule strictly possesses C_2 symmetry, although deviations from C_{2v} symmetry are only minimal. The V, N(1), and N(2) atoms are located on the twofold axis, *i.e.* in a linear arrangement. The entire isodiazene ligand is strictly planar, a feature which should facilitate delocalization of π electrons from vanadium across to silicon. Other features of the molecular structure are:

1) The V—N bond length is exceptionally short. A metal-nitrogen multiple bond is present, as is also encountered in Cl_3VNCl (V—N, 164.2 pm[6]).

2) The N—N bond length is considerably greater than in free bis(trimethylsilyl)diazene (117.1(7) pm) and thus almost lies in the range of the N—N single bond[7].

3) The mutual eclipsed arrangement of the trimethylsilyl groups is associated with a significant opening of the SiN(1)Si' angle. The SiNSi angle in bis(dioxane)potassium bis(trimethylsilyl)amide[8]—a compound which also has an eclipsed conformation of the Me_3Si groups—amounts to 136.2°.

4) The cyclopentadienyl ligands display a distinct tendency to engage in trihapto rather than the usual pentahapto coordination. Thus the vanadium-carbon distances for C(4), C(5), and C(8) are 20 pm shorter than those for C(6) and C(7). For the same reason the cyclopentadienyl ring is not strictly planar, but is made up of a triangle [C(4), C(5), C(8)] and a planar rectangle [C(5), C(6), C(7), C(8)] whose normals enclose an angle of 6.2°. The deviation from planarity of the five-membered ring is thus directed away from the metal atom.

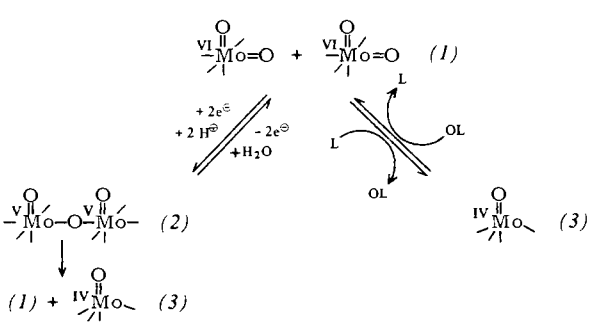
Reviews

Abstracts of selected progress reports and review articles

The reaction mechanism of enzymes containing molybdenum is reviewed by *R. A. D. Wentworth*. The most important enzymes containing Mo catalyze reductions of dinitrogen to ammonia, nitrate to nitrite, and oxidations of sulfite to sulfate, xanthine to uric acid, and aldehydes to carboxylic acids. A discussion of the chemistry of inorganic oxo complexes of Mo^{VI}, Mo^{V}, and Mo^{IV} leads to a new suggestion for the mechanism of oxidase and reductase action:



In its resting state, the enzyme contains two hexacoordinate Mo^{VI} atoms carrying at least two oxo ligands *(1)*. Under physiological conditions these can be reduced to a dinuclear Mo^{V} species *(2)*; *(2)* can disproportionate to a pentacoordinate Mo^{IV} species *(3)* and *(1)*. Species *(3)* is the active entity effecting reduction by taking over an oxo ligand from OL, the oxidized form of the substrate (reductase action). Acting as oxidase, *(1)* loses an oxo ligand to L, the reduced substrate, and forms *(3)*. This mechanism is also able to explain the inhibition of xanthine oxidase by allopurinol. The evolution of bacterial energy metabolism is discussed by *R. E. Dickerson, R. Timkovich,* and *R. J. Almassy* on the basis of the folding of the evolutionarily homologous cytochromes of type c. Oxygen respiration of bacteria and eukaryotes is considered to have developed from a double purpose (photosynthesis and respiration) electron transport chain, as found in the purple non-sulfur bacteria, with loss of photosynthetic capability. An elaborate scheme is drawn up for the development of photosynthesis and respiration in bacteria, beginning with a symbiotic sulfur cycle, followed by development of the Krebs cycle, and culminating in the present symbiotic oxygen cycle between plants and animals. NMR and the periodic system is the theme of a review by *R. K. Harris*. The author does not deal with ^{1}H-, ^{11}B-, ^{13}C-, ^{19}F-, and ^{31}P-NMR spectroscopy, but with the possibility of using more unusual nuclei in NMR studies. Suitable nuclei are those (like ^{1}H, ^{19}F, and ^{31}P) which have spin quantum number $I = 1/2$, which occur in *ca.* 100% natural purity, and which have a relatively high magnetic moment. Apart from the above mentioned nuclei only ^{89}Y, ^{103}Rh, and ^{169}Tm can fulfill these three conditions. But if nuclei with $I > 1/2$ or natural purity $< 100\%$ are also considered, there is at least one nucleus that comes into question in each group of the periodic system. [NMR and the Periodic Table. Chem. Soc. Rev. 5, 1—22 (1976); 81 references]

[Rd 854 IE—F]

Selective reductions with complex hydrides are discussed by *E. R. H. Walker*. $NaBH_4$ and $LiAlH_4$ are universal reducing agents, but their selectivity leaves much to be desired. The author illustrates how the properties of the two reagents alter on changing the solvent, the cation, or replacing some of the hydrogen atoms. For example, $LiBH_4$ can reduce esters and is thus a stronger reducing agent than $NaBH_4$. The derivative $LiBEt_3H$ ("superhydride") *(1)* is an extremely nucleophilic compound which rapidly reduces alkyl halides, but not aryl halides. Compound *(2)*, M = Li or K, permits selective reductions. Alkoxy-substituted $LiAlH_4$, *e.g.* lithium tris(*tert*-butoxy)-hydridoaluminate is a mild reducing agent which selectively reduces acid chlorides to aldehydes. "RED-AL" *(3)* has practically the same reducing action as $LiAlH_4$, but cannot be handled safely and conveniently. [The Functional Group Selectivity of Complex Hydride Reducing Agents. Chem. Soc. Rev. 5, 23—50 (1976); 64 references]

Advances in thin-layer chromatography, particularly in direct combination with thermal procedures, are reviewed in an article by *E. Stahl*. Since the preparation of the sample is often more time-consuming than the actual analysis attempts have been made to develop "on-line" methods. In the simplest case a metal block with a hole bored in it to hold sample and container is used. The metal block is either preheated or heated according to a temperature program; if necessary, volatile components are fed onto a moving DC plate. BOOK REVIEWS

Statistische Versuchsplanung (Statistical Planning of Experiments). By *G. Retzlaff, G. Rust*, and *J. Waibel*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., ix, 211 pp., 52 figs., 52 tables, bound DM 58.—.

The aim of every experimenter is to make his object capable of visualization by physical concepts and if possible quantifiable by physical models. If, however, at the beginning of the investigation there is no physical representation, if the problem becomes very complex because of the many interfering factors and in addition the measurements are subject to considerable errors, or if a certain goal must be reached rapidly and without taking such considerations into account, then statistical planning of the experiment may be useful. The literature on this subject has so far suffered the disadvantage that it is written either in English or in a mathematical abstract form that is difficult for the chemist. The strength of the present book is that, right at the beginning, in about 40 pages, the technique of factorial experiment planning is explained in easily understandable form. Anyone who then has no wish to probe further will still know enough to be able, if necessary, to call in an expert. It is not quite clear why the authors failed to include the process of the steepest gradient (Box-Wilson method) and a suitable example. In the following two chapters the basic statistics (Chapter 3) are treated so far as is necessary for consideration of the error in factorial experiment planning (Chapter 4). Anyone with experience of the halfnormal plot will probably regret that this method is mentioned only in a footnote.

Not all the subsequent chapters will interest the experimental chemist to the same extent. Reference should, however, be made to the chapter on regression calculation (Chapter 7) and the simplex method (in Chapter 9). Summarizing, it can be said that this book can be thoroughly recommended to anyone who has to do with the planning and evaluation of experiments.

Otto Wörz [NB 309 IE]

Transport Phenomena. By *W. J. Beek* and *K. M. K. Muttzall*. John Wiley & Sons. Ltd., London—New York 1975. 1st edit., x, 298 pp., numerous figs. and tables, bound, £ 9.85.

This book is based on a series of lectures. In four chapters it covers the fundamental laws of the transport of momentum, heat, and mass and demonstrates their importance by numerous important examples from process technology.

Following the formulation of the conservation laws in Chapter 1, the principles of flow theory and dimensional analysis are discussed in Chapter 2, and these are then used to work through a large number of important problems (*e.g.* the pressure loss in pipelines of various geometrical shapes, flow measurement, flow through solid beds, fluidized beds, and residence-time distribution). Chapter 3 begins with a discussion of stationary and nonstationary heat conduction, the treatment including questions of heat transfer and heat transmission as well as various types of heat exchangers and problems of heat transfer during boiling and condensation.

In the last chapter the laws of material transport are discussed, covering not merely stationary and nonstationary diffusion but also continuous material exchange in two-phase flows and the influence of diffusion on conversion in homogeneous and heterogeneous reactions.

The book is impressive in the wealth of material offered, this being skilfully assembled so that, in conjunction with exercises tied to the text, it demands the reader's active participation. Since working through the text does not require sophisticated mathematical knowledge, the book can be highly recommended as a course book alongside lectures on the

fundamentals of industrial processes. The many examples that keep close to practice, treated by means of numerous tables and diagrams, also provide stimulation and help to the practising professional.

Diethard Hesse [NB 314 IE]

Einführung in die Theoretische Chemie. Band 1: Quantenmechanische Grundlagen. (Introduction to Theoretical Chemistry. Vol. 1: Quantum-Mechanical Principles.) By *W. Kutzelnigg*. Verlag Chemie, GmbH, Weinheim 1975. 1st edit., xxiii, 297 pp., 23 figs., 9 tables, cloth, DM 68.—.

It is general experience that familiarization with the principles of quantum mechanics proves particularly difficult for the chemist. Very closely connected with this is the usually uncritical, positive or negative, attitude adopted towards the numerical results of quantum-mechanical investigations, which are published today in such large numbers. In this book the author tries to play a mediating role; building on the smallest possible number of mathematical assumptions, he acquaints the reader progressively with the basic formalism and the most important methods and results of quantum mechanics. The approach has indeed been highly successful. Mathematical formulations going beyond the basic facts of differential and integral calculus, with which almost every student of chemistry is nowadays familiar, are given in the Appendix. A very commendable feature is that the author has made it a definite policy not to try to dodge difficulties. Knowledge that the reader does not already possess must be acquired during the study of each successive chapter. Accordingly, for those with little previous knowledge the book will undoubtedly be rather difficult reading.

Some may regard the author's concept of the extent of theoretical chemistry as rather too narrow. According to the list of contents, the second volume will provide a review of the theory of the chemical bond, the various methods of quantum chemistry, and the results of numerical calculations. The present volume is already directed to this end. The author quite consciously left aside anything that was not immediately relevant to his purpose. Time-dependent phenomena such as scattering processes and molecular collisions theory, tunneling phenomena, and theoretical attempts to describe chemical processes, as well as conditions in the energy continuum and relativistic effects are not considered. The numerically evaluable approximation methods for the solution of the Schrödinger equation are naturally treated in great detail.

After a brief section on the basic principles of classical mechanics essential for a description of atoms and molecules, the postulates of quantum mechanics are presented and some simple examples of exactly soluble Schrödinger equations are discussed. Here it should be emphasized that the author is always at pains to find the didactically most favorable formulation. For example, the eigenstates of a harmonic oscillator are derived with the aid of creation and annihilation operators, whereas in other cases conventional methods are preferred for the solution of differential equations. Several sections are devoted to angular momentum operators and their properties and to the hydrogen atom. Two further chapters treat the most important approximation methods of quantum mechanics, variational calculus and perturbation theory. The remaining six sections present a comprehensive theory of atoms that, starting from elementary models, leads up to problems of spin-orbit coupling and electron correlation effects.

Summarizing, this book can be described as an introduction, designed for chemists and eminently successful, to the fundamentals of quantum mechanics. Put together with great skill, the presentation moves in general along the conventional lines of textbooks in this field. It must be specially emphasized that the author really has succeeded in building on a very modest mathematical foundation, gradually leading the reader up to more difficult formalism. Account is taken of the latest developments in quantum chemistry by devoting great attention to the concepts needed for a deeper understanding of numerical methods of calculation. The book can be warmly recommended both to advanced students of chemistry and to trained chemists who wish to learn the fundamental facts of quantum mechanics and their applications in chemistry.

Elementary Processes at Gas/Metal Interfaces[**]

By Gerhard Ertl[*]

Recent years have seen the development of several physical methods for the study of solid surfaces under ultrahigh vacuum conditions, of which the most important are discussed in this progress report. Contemporary views of the chemisorption bond and the factors affecting it are discussed against the background of the adsorption of hydrogen and of carbon monoxide on single crystal surfaces of face-centered cubic transition metals. Catalytic oxidation of CO over palladium and the interaction of oxygen with nickel serve as examples of chemical surface reactions.

1. Introduction

An atom located in the surface layer of a solid occupies an intermediate position between a free atom and an atom in the bulk of a crystal in that a proportion of the chemical valency (otherwise utilized in cohesion) is unsaturated. Suitable particles impinging on the surface from the vapor phase can engage not only in the usual van der Waals interaction (= physical adsorption) but also in chemical bonding. This phenomenon, known as chemisorption, appears to be the primary step of all chemical surface processes.

Reactions on the surface of metals have eminent practical significance; it will suffice to recall the processes of heterogeneous catalysis or corrosion. In spite of tremendous scientific effort in these areas the fundamental elementary steps remain largely unknown and in the absence of reliable predictions work remains mainly empirical. The principal difficulty encountered when dealing with "real" surfaces lies in the multitude of generally uncontrollable parameters (crystallographic orientation, structural defects, impurities, substrate effects, *etc.*) affecting their chemical behavior, which are accessible only poorly, if at all, to the experimental techniques presently available.

The situation is greatly simplified if single-crystal surfaces are used having a uniform orientation which contains a minimum of foreign atoms. The latter requirement can be satisfied only under ultrahigh vacuum (UHV) conditions[1], *i.e.* at residual gas pressures of about 10^{-10} torr. In the past few years several experimental procedures have been developed for the study of such model systems, which provide highly detailed information in some cases. A parallel development has been the very recent intensification of efforts to arrive at a theoretical understanding of surface phenomena.

2. Experimental Methods

A complete description of surface processes includes the following information: The qualitative and quantitative chemical composition of the interface (including the molecular nature of adsorbed species), the geometrical structure, the energy of binding between the surface and the adsorbed particles, dipole moments of adsorption complexes, the energy distribution of electronic states, vibrations, surface diffusion, and the kinetics of ad- and de-sorption and of surface reactions. The relevant questions can be answered to various degrees of satisfaction with the aid of various modern experimental methods. Complete theoretical analysis of the experimental data still runs into considerable difficulties, however, and in some cases we are still far removed from full exploitation of the information available in principle from an experiment. Comprehensive descriptions of surface processes are clearly

[*] Prof. Dr. G. Ertl
Institut für Physikalische Chemie der Universität
Sophienstrasse 11, 8000 München 2 (Germany)

[**] Based on a Plenary Lecture delivered at the General Meeting of the Gesellschaft Deutscher Chemiker at Cologne, September 8—12, 1975.

not to be expected from the use of a single method; this will require combination of various approaches. A selection of the most powerful experimental tools currently available will be presented below.

Thermal Desorption Spectroscopy[2]

A basically simple experiment is to expose a clean surface for a given time to a given partial pressure of the gas of interest[*] at a temperature at which no significant desorption takes place, and then to continuously raise the temperature of the sample under UHV conditions while recording the partial pressure with a suitable measuring device (preferably with a quadrupole mass spectrometer). Figure 1 illustrates a series of such thermal desorption spectra from a Ni(111) surface previously exposed to different doses of hydrogen[3]. Measurements of this kind afford information about adsorption kinetics, the existence of different adsorption states, adsorption energy, the order of reaction of desorption, and (on use of isotope mixtures) the question whether adsorption is accompanied by dissociation of the molecule.

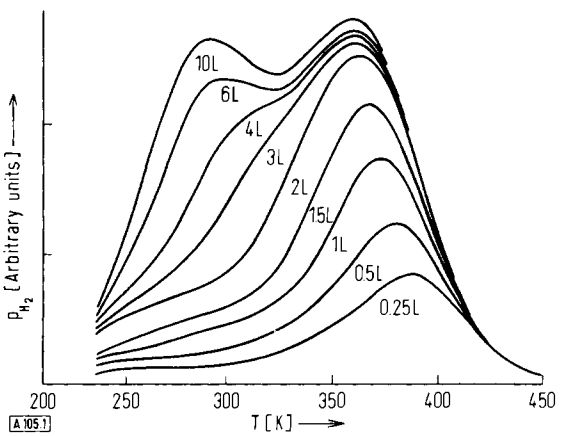

Fig. 1. Thermal desorption spectra for the H_2/Ni(111) system after covering to various extents [3] (1 L = 10^{-6} torr × s).

Change in Work Function[4]

The work function of a metal, *i.e.* the minimum energy required to remove an electron from the Fermi level to the vacuum, is modified by the presence of dipole layers on the surface—such as almost invariably arise on formation of adsorbed phases. Various techniques can be used for highly sensitive measurement of this quantity (with an accuracy of about 1 mV). This reveals the dipole moment of the adsorption complex and its possible variation with the degree of coverage. Moreover, such measurements can, after suitable calibration, provide a convenient measure for the surface concentration of adsorbed particles. If there is a reversible equilibrium between the adsorbed layer and the vapor phase, this procedure can be used for plotting adsorption isotherms from which in turn the so-called isosteric adsorption energies can be derived with the aid of simple thermodynamic relationships[5]. All the adsorption energies reported in the following sections were determined in this way.

[*] The commonest unit employed is 1 L (Langmuir) = 10^{-6} torr · s. This dose will just suffice to completely cover a clean surface with an adsorption layer if each impinging particle is adsorbed.

Secondary Ion Mass Spectrometry (SIMS)[6]

This relatively common technique involves bombardment of the solid with primary ions (usually noble gases) and mass analysis of the secondary ions or neutral particles generated. By reducing the current density of the primary beam this method can be rendered largely non-destructive while still displaying an extremely high sensitivity. The fundamental individual processes are rather complex, however, thus impeding quantitative conclusions.

Ion Backscattering Spectroscopy[7]

In this method a monoenergetic ion beam ($E < 10$ keV) is scattered at a surface and the energy of the scattered ions is analyzed. Application of the laws of conservation of energy and momentum shows that the energy spectrum of the backscattered ions is equivalent to a mass analysis of the surface atoms. This mass analysis is restricted to the outermost atoms provided that the ion energy is not too high. In favorable cases the technique also yields structural information about the position of adsorbed particles. Ion backscattering spectroscopy can, in principle, be easily combined with other methods (*e.g.* LEED and AES) but has not yet found wide application.

By far the most important group of methods is based on the analysis of the energy and/or direction of low energy electrons ($E \leq 1000$ eV) emitted from a solid surface on excitation with suitable primary radiation[8]. The average escape depth of electrons from metals is shown as a function of their energy in Figure 2. It may be seen that this quantity (d) amounts to no more than about two to three atomic layers between 40 and 400 eV, *i.e.* such electrons arise largely from the surface. Among the methods of investigating surfaces which exploit this effect the greatest significance attaches to Auger electron spectroscopy (for elemental analysis), diffraction of low energy electrons (for structural elucidation), and photoelectron spectroscopy (for determination of electronic binding energies and of surface orbitals). The instrumental armamentarium required can be combined in a single apparatus. It should be mentioned that the interaction of electrons with adsorption layers can also lead to chemical changes or desorption. This side effect, while undesirable *per se*, can also be subjected to systematic study as in the method of electron-impact induced desorption (ESD)[9].

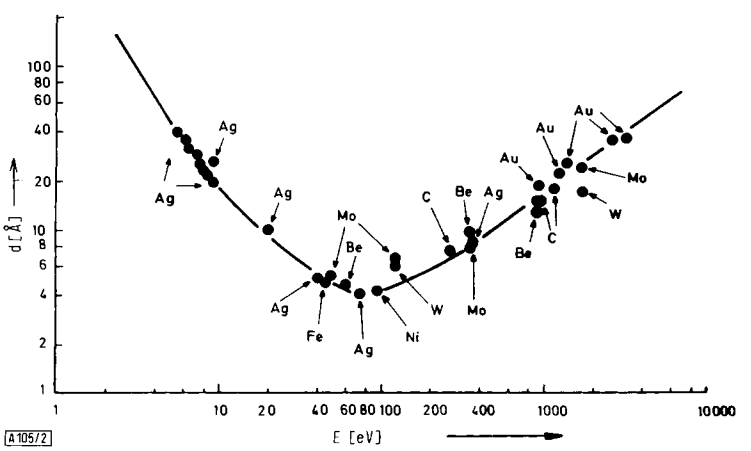

Fig. 2. Average escape depths (d) of electrons from metals as a function of their energy [8].

Auger Electron Spectroscopy[8, 10]

If an electronic core level of an atom is ionized by suitable primary radiation (preferably an electron beam) then the resulting hole is reoccupied by transition of an electron from a higher level. The liberated energy can be transferred non-radiatively in competition with X-ray fluorescence to another (bound) electron which can then be ejected from the solid with corresponding kinetic energy as a so-called Auger electron. In light elements and at energies less than 1000 eV this effect greatly predominates, thus imparting a high degree of sensitivity to the method. The experimental procedure consists in determination of the energy distribution of the emitted secondary electrons—the second derivative is usually recorded for reasons of expedience. The maxima recorded can be assigned to the elements present in the surface region. The Auger electron spectrum of a contaminated nickel surface is shown as an example in Figure 3a. The area examined is determined by the diameter of the primary electron beam and amounts to about 1 mm^2. If desired the electron beam can be focused on a much smaller spot. Line scanning of a given surface region at constant analyzer energy and simultaneous control of the brightness of an oscilloscope image by the intensities of the relevant Auger line permits measurement of the lateral distribution of individual elements on the surface ("scanning Auger"), as illustrated in Figures 3b and 3c.

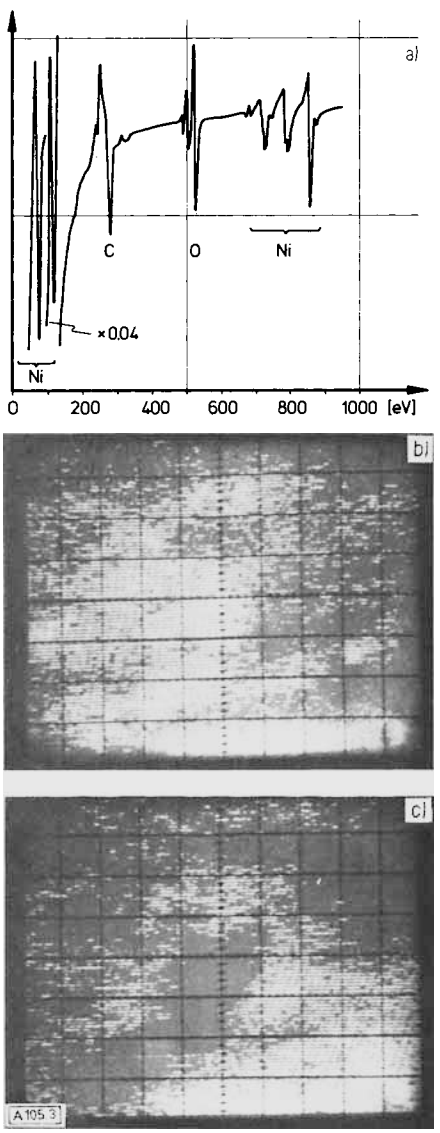

Fig. 3. a) Auger electron spectrum of a nickel surface contaminated with C and O. b) and c) Scanning Auger spectra of the lateral distribution of the elements C and O, respectively, in a surface region measuring 1 × 0.8 mm^2 (*J. Küppers*, unpublished).

Provided an element is distributed only in two dimensions on a surface, the intensity of the corresponding Auger signal is proportional to its surface concentration to a good approximation. So far, *absolute* quantitative analysis has been possible only after calibration and is therefore one of the principle unsolved problems of this method.

Low Energy Electron Diffraction (LEED)[8, 11]

A monoenergetic beam of particles having momentum mv is known to be equivalent to a material wave of wavelength $\lambda = h/mv$. For electrons of energy 150 eV, $\lambda = 1$ Å, *i.e.* interference takes place at surfaces of crystals as first demonstrated by *Davisson* and *Germer*[12]. In several respects the experimental set-up for the LEED technique resembles that for the Laue method for X-ray diffraction: a monoenergetic electron beam impinges normally on a single crystal surface and undergoes partial backscattering in those directions which satisfy the two Laue conditions for lattice periodicity parallel to the surface. Owing to the small depth of penetration of the electrons the third Laue condition (for periodicity in the direction normal to the surface) merely leads to characteristic changes in the intensity of reflections with the wave number of the electrons. After filtering out the inelastically scattered electrons, the elastically diffracted ones are post-accelerated and produce a "diffraction pattern" on a fluorescent screen. Adsorption of gases usually causes the appearance of new diffraction spots. This means that the adsorbed layer forms an ordered structure whose periodicity deviates from that of the substrate. The position of the diffraction spots reveals the unit cell of the surface structure, and in favorable cases also the mutual configuration of the adsorbed particles. Complete structural analysis—and especially determination of distances between the adsorbate and the surface atoms—from the LEED intensities is rendered very difficult by the extensive occurence of multiple scattering effects. Although an adequate theoretical approach has meanwhile been developed, this formidable task has so far only been accomplished in few cases in which adsorbed atoms form simple superstructures (O, S, Se, Te on Ni[13], I/Ag(111)[14]). So far in all instances, the positions with the maximum coordination number (4 on the (100) surface, 3 on the (111) surface) are the adsorption sites occupied.

Photoelectron Spectroscopy[15]

Irradiation of a sample with monochromatic light of sufficient energy can lead to ionization of the occupied electronic levels (with different probabilities). The emitted photoelectrons have a kinetic energy E_{kin} (disregarding multiple-particle effects), which is given by $E_{kin} = h\nu - E'_B$ (conservation of energy). E'_B is termed the "binding energy" of the liberated electron relative to the vacuum level. In general, the energy scale is referred to the Fermi level of the solid, which differs

from the vacuum level by the work function Φ. Applying *Koopmans'* theorem the experimentally determined binding energies are frequently equated to the orbital energies. However, considerable errors may then occur due to neglect of relaxation and correlation effects. Additional effects of this kind will arise compared with the free molecule owing to the presence of a solid surface: their theoretical and experimental treatment remains a largely unsolved problem, and yet a necessary requirement for any quantitative interpretation of changes in orbital energies due to chemisorption bonding.

Photoemission spectra are excited either by soft X-rays (XPS) or by UV light (UPS). The former approach affords mainly information concerning the core levels. Chemisorption levels occurring within the valence band region are better examined by UPS. Excitation is then usually accomplished with He(I) ($h\nu = 21.2$ eV) or He(II) ($h\nu = 40.8$ eV) resonance radiation. Continuous radiation of even higher photon energy is available from an electron synchrotron; however, this light source is accessible to only few researchers[16].

While UPS studies have hitherto been mainly concerned with measurements of the energy distribution of photoelectrons over a relatively large emission angle, interesting variations in intensity with the direction of emission have recently been discovered[17]. The theoretical analysis of these effects is presently undergoing rapid development[18], and holds promise of some insight into the spatial orientation of the relevant orbitals on the solid surface.

3. Mechanism of Chemisorption

Analysis of the thermal desorption spectra for the H_2/Ni(111) system illustrated in Figure 1 reveals, *inter alia*, that desorption corresponds to a second order reaction. Experiments with a mixture of H_2 and D_2 indicated complete equilibration of the isotopes on the surface. Both observations justify the conclusion that hydrogen is adsorbed in atomic form. The energy of the Ni—H bond is only 63 kcal/mol while the dissociation energy of H_2 is 104 kcal/mol. This is certainly a principal reason for the activity of nickel as a hydrogenation catalyst. The dissociative adsorption of the H_2 molecule requires no measurable activation energy, although cleavage of the free molecule needs 104.2 kcal/mol. The way in which this energy threshold is overcome by the surface can be depicted schematically as in the potential energy diagram[19] of Figure 4: on approaching the metal surface a H_2 molecule passes through a shallow energy minimum, corresponding to physisorption. In contrast, a H atom is capable of chemisorption bonding characterized by a deeper minimum closer to the surface. Intersection of the two potential energy curves below the zero point leads to dissociative adsorption without activation energy. Adsorption of hydrogen on copper involved measurable activation energy[20]; the energy curves therefore intersect above the zero energy level.

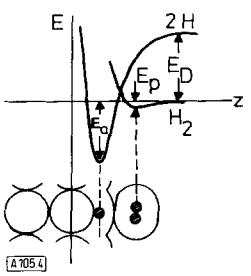

Fig. 4. Potential energy diagram according to *Lennard-Jones* [19] for adsorption of hydrogen on metals. E_D, dissociation energy of H_2 (104 kcal/mol); E_p, adsorption energy for physical (molecular) adsorption; E_a, adsorption energy for atomic chemisorption.

The occurrence of chemisorption between a H atom and a metal surface is illustrated by the energy-level scheme of Figure 5. The metal is represented as a continuum of electronic states occupied up to the Fermi level E_F. As long as the H atom is located at a long distance from the surface its 1s electron is in a state of sharply defined energy (ionization energy $I = 13.6$ eV) lying below the Fermi level of the metal (work function $\Phi \approx 5$—6 eV). A second electron in the 1s level gains only 0.75 eV in energy relative to the vacuum level owing to electron-electron repulsion so that the affinity level A lies above the Fermi level. Therefore only slight transfer of charge will be expected to occur from the metal to the adsorbed H atom, as is manifested in the small dipole moment of about 0.05 D[3] established experimentally, and the bond should be essentially covalent. On coupling of the H atom to the metal a new chemisorption level will arise which is broadened and shifted relative to the H1s orbital. The broadening of this level can be regarded as a consequence of *Heisenberg's* uncertainty principle, *i.e.* an electron has only a limited lifetime in the chemisorption level owing to tunneling to and from the metal. A somewhat different (but equivalent) approach ascribes the broadening to the continuous energy distribution of the set of molecular orbitals formed from the orbital of the adsorbed H atom and a suitable set of metal wave functions.

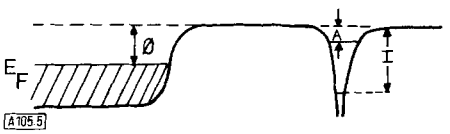

Fig. 5. Energy diagram for interaction of a H atom (right) with a metal surface (left).

The shift results from several contributory factors, *i.e.* the drop in energy due to the chemical bond, an increase due to intraatomic Coulomb interaction, and a further increase arising from the attractive interaction of the ionized atom with its image charge in the metal. A useful concept that can be introduced at this stage is that of the so-called local density of states $\rho(E)$ defined by overlap of the adatom wave function with the metal wave function at a given energy E, *i.e.* describing the energy distribution of the states generated by the chemisorption bond. To a first approximation this local density of states is directly apparent from the energy distribution measured by UV electron spectroscopy (UPS)—or more precisely in the additional emission relative to the pure metal as a result of chemisorption[21]. It should be pointed out, however, that the quantitative analysis of such spectra is still beset by serious theoretical difficulties[8, 15b].

Figure 6 shows the UPS spectra of a pure Ni(111) surface (curve a) and one covered with hydrogen (curve b)[22]. In curve a) a pronounced maximum about 2 eV wide is seen immediately below the Fermi level which arises from the emission from the Ni d band with its high density of states. (The increase on going to lower energy is attributable to the emission of secondary electrons and not to the existence

of further (lower-lying) valence states of high density of states.) After adsorption of hydrogen an additional, relatively broad maximum appears *ca.* 6 eV below E_F (*ca.* 12 eV below the vacuum level) which is identified as the above mentioned chemisorption level. The broadening may possibly also be affected by other (many-particle) effects[23].

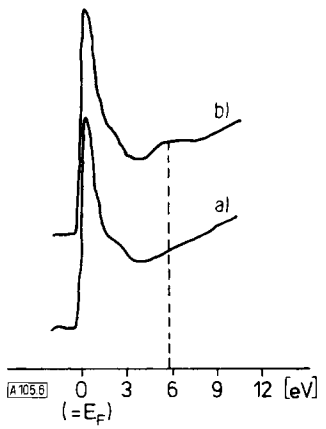

Fig. 6. UV photoelectron spectra ($h\nu = 21.2$ eV) of a) a clean Ni(111) surface and b) one covered with hydrogen.

The first quantitative theory of chemisorption of hydrogen on transition metals was developed by *Newns*[24] within the framework of the so-called Anderson formalism (see below), and considered only coupling of the H1s level with the metal d band. Fitting the adsorption energy to the experimental value affords a chemisorption level at *ca.* 6 eV below E_F, thus corresponding exactly to the additional maximum in the photoemission spectrum. A subsequent EH calculation (extended Hückel theory) for a small cluster of metal atoms showed, however, that the sp band should also play an important role in the chemisorption of hydrogen[25]. Recent confirmation has come from an extension of the formalism used by *Newns* with inclusion of the Ni sp band and of non-orthogonality effects[26]. The chemisorption level should accordingly be centered about 7 eV below E_F.

The theory of chemisorption is presently in a state of flux. It unites essential elements of the quantum chemistry of molecules with those of solid state theory[27]. An important aspect is that the metal represents an open system, *i.e.* provides an inexhaustable supply of electrons. The simplest approach is based on an LCAO-MO model utilizing a Hartree-Fock approximation. A relevant formalism was originally set up by *Anderson*[28] for the treatment of dilute alloys and later applied to the chemisorption problem[24, 26, 29]. Such calculations reveal the tendency for formation of a "surface molecule" in the case of strong chemisorption; this species is composed of the adsorbed particle and a small number of neighboring metal atoms. The latter participate directly in bonding with electronic states split off from the band of the metal utilized (as is seen to be the case in the H/Ni(111) system). The chemisorption bond thus assumes a markedly local character, suggesting a comparison with similar molecular compounds (*e.g.* in the case of CO adsorption described in Section 4 with corresponding polynuclear carbonyl complexes). Furthermore this also provides some justification for confining the theory of chemisorption to the treatment of small clusters. A particularly suitable approach is the SCF-X_α procedure developed by *Slater* and *Johnson*[30] which has already been applied with considerable success to the calculation of ionization energies in a number of systems[31].

A serious problem common to all LCAO-MO procedures is the neglect of correlation effects. These can be included in an extended Anderson model[32]. Another attempted approximation starts from the Heitler-London (VB) method (in which correlation effects are of course overemphasized)[33]. The computational effort involved in such theoretical models is much greater, however, and abandonment of the concept of one-electron states makes direct comparison with orbital-spectroscopic data difficult. The reader is referred to available surveys[27] concerning the points in favor of and against the various procedures.

4. Chemisorption of CO

Carbon monoxide is the molecule whose adsorption properties have been studied most thoroughly so far. The following discussion will be confined to a few cubic face-centered metals. The more complex CO/tungsten system was recently described by *Gomer*[34]. *Ford* has reviewed the results available up to 1970[35].

The adsorption energies of CO on nickel are 26.5 kcal/mol for the (111)-face[36] and 30 kcal/mol for the (100)-[37] and the (110)-face[38]. These values are close to the dissociation energy for $Ni(CO)_4$, *i.e.* 35 kcal/mol[39]. The analogy between carbonyl compound and adsorption complex is also apparent in other properties: adsorption of CO on nickel raises the work function of the metal by about 1.3 eV[36], which is synonymous with partial transfer of electronic charge from the metal to the adsorbate. In $Ni(CO)_4$ *ab initio* SCF-MO calculations likewise revealed an electron transfer to the ligands, producing a positive charge of about $0.5\,e_0$ at the nickel atom[40]. This electron transfer is ascribed to partial population of the $2\pi^*$ MO of the CO molecule, manifested in the IR spectrum as a shift of the CO stretching frequency to lower wave numbers[41]. Finally, comparison of the photoelectron spectra of $Ni(CO)_4$[42] and CO adsorbed on nickel[43], as shown in Figure 7 together with the spectrum of gaseous CO[44], appears remarkable. The three maxima are assigned (in order of increasing ionization energy) to the 5σ, 1π, and 4σ orbitals of CO_g. For $Ni(CO)_4$ the first maximum is due to the Ni d electrons, the following broad band corresponds to overlap of orbitals derived from the 5σ and 1π MOs of the ligand, and the third maximum arises from the CO 4σ orbital[42].

In 1964 *Blyholder* proposed[45] a donor-acceptor mechanism analogous to that responsible for bonding in carbonyl compounds to account for the adsorption of CO on metals (see Fig. 8). According to this model, an electron transfer takes place from the occupied 5σ orbital to the metal and a back-donation of metal d electrons into a chemisorption level derived from the antibonding (initially unoccupied) $2\pi^*$ MO. As a consequence, the energy of the 5σ orbital should be lowered relative to that of the 1π orbital, so that the two levels cannot be resolved in the UPS spectrum and give rise to the broad maximum observed about 8 eV below E_F. Although another interpretation was originally given for the spectroscopic data[43a], this assignment of the UPS maxima

has meanwhile been confirmed by recent theoretical[26,46] and experimental studies[43c,47].

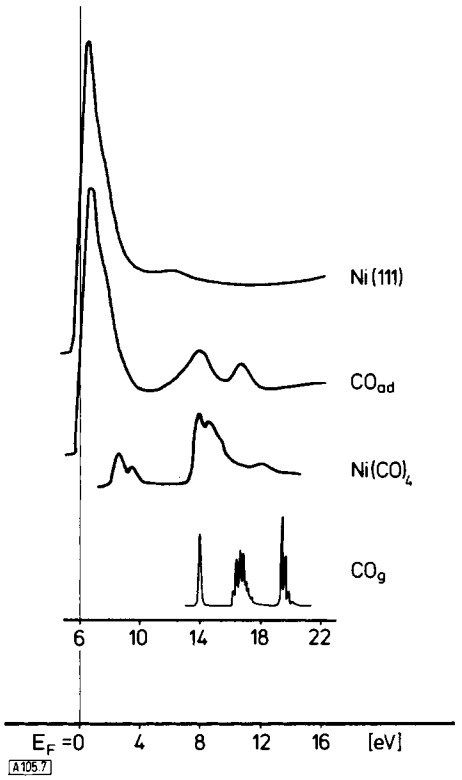

Fig. 7. UV photoelectron spectrum of CO adsorbed on Ni(111) compared with the spectra of $Ni(CO)_4$ and gaseous CO.

A theoretical study[26] has indicated that some 50% of the adsorption energy of CO on a Ni(111) surface (*i.e.* 13 kcal/mol) should arise from coupling of the 5σ orbital to the metal sp bands. In the case of the corresponding surface of the neighboring element copper, coupling of the d electrons to the $2\pi^*$ orbital should play only a very minor role, as

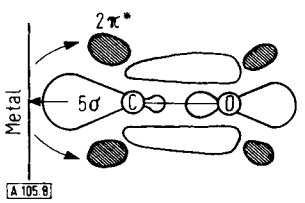

Fig. 8. Donor-acceptor mechanism for the adsorption of CO on metal surfaces.

is confirmed by the far lower adsorption energy of about 12 kcal/mol[43d] and by the reverse sign of the dipole moment (*i.e.* negative excess charge on the metal side)[48]. Table 1 lists the CO adsorption energies for the (111)-faces of various cubic face-centered transition metals. It should be noted that

Table 1. Adsorption energies [kcal/mol] for CO on the (111) faces of cubic face-centered metals [49].

	Ni	Cu
	26.5	12
	Pd	Ag
	34	6.5
Ir	Pt	
33	35	

in all cases except silver the adsorption structures are characterized by identical LEED superstructures, *i.e.* identical surface configurations. The differing adsorption energies are therefore due primarily to the "electronic" factor, *i.e.* the influence of the electronic properties of the solid.

The difference between Pd and Ag is particularly striking. In this context, interesting points arise in connection with the use of alloys. Figure 9 shows the variation of CO adsorption energy as a function of the change in work function (which is a measure for the degree of coverage) for Ag/Pd alloys having various surface compositions[50]. It is seen that for all samples E_{ad} attains the value for pure Pd at very low coverages but at higher surface concentrations even low amounts of Ag bring about a drastic reduction of the adsorption energy, *i.e.* the surfaces become energetically heterogeneous. A qualitative explanation of these findings results from the electronic properties of such alloys, according to which the components essentially retain their electronic structure[51] (thus in Cu/Ni alloys there are still unoccupied d states at the Ni sites, even at high Cu contents[52]) and do not form a "collective" d band, in contrast to former views. Of course it should always be borne in mind in all experiments on alloys that the composition of the surface can deviate considerably from that of the bulk and therefore requires specific careful examination[53].

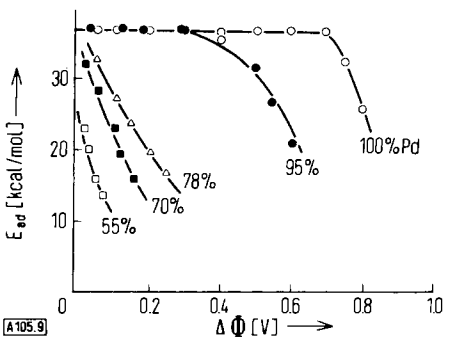

Fig. 9. Adsorption energy for CO on (111) surfaces of Ag/Pd alloys of various surface composition as a function of the change in work function $\Delta\Phi$ [50].

The "geometric" factor embraces the change in adsorption properties, on the one hand with the position of the adsorbate relative to the position of the metal atoms for a given single crystal face, and on the other with the crystallographic orientation, inclusion of structural defects representing a natural extension. These aspects will now be considered with the aid of adsorption of CO on palladium[54].

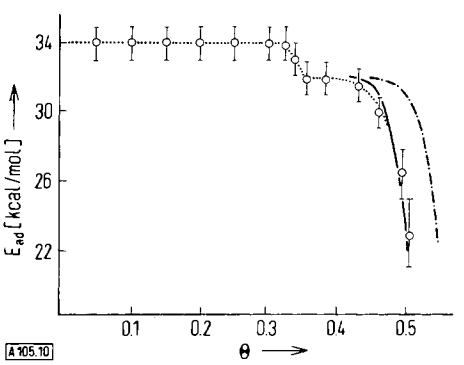

Fig. 10. CO/Pd(111). Adsorption energy as a function of a degree of coverage Φ [55].

Figure 10 shows the variation in the isosteric adsorption energy for CO on Pd(111) as a function of the degree of coverage Θ[55]. E_{ad} is seen to remain constant up to $\Theta = 1/3$, and then suddenly falls by 2 kcal/mol as the degree of coverage further increases. At $\Theta = 1/3$ the LEED diffraction pattern contains additional spots of a superstructure whose pertinent structural model is reproduced in Fig. 11 a. Up to that coverage, all CO molecules can apparently occupy identical energetically

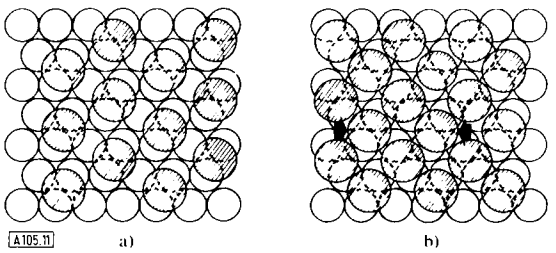

Fig. 11. Structural model for the configuration of adsorbed CO molecules on a Pd(111) surface. a) $\Theta = 1/3$; b) $\Theta = 1/2$: this structure arises by continuous compression of the unit cell shown in a) [55].

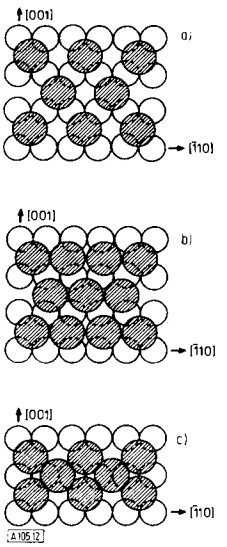

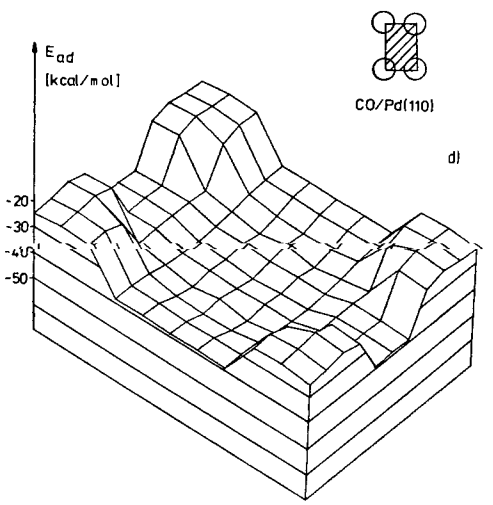

Fig. 12. a)—c) Structural models for the configuration of adsorbed CO molecules on a Pd(110) surface [54]: a) $\Theta = 1/2$; b) $\Theta \approx 3/4$; c) $\Theta = 1$.—d) Theoretical energy profile for the variation of the CO adsorption energy within the unit cell of the Pd(110) surface [26].

favorable sites without engaging in mutual interactions. (Whether these adsorption sites correspond to the "bridging positions" drawn or should be assigned to points between three Pd atoms cannot yet be decided but is immaterial for the present discussions.) As soon as the degree of coverage exceeds the value 1/3 the unit cell of the adsorbate structure is continuously compressed (cf. Fig. 11 b). Surface saturation is characterized by a kind of densest packing of the adsorbed molecules, their "size" corresponding to a diameter of about 3 Å in the present case; this value agrees fairly well with the van der Waals diameter of the CO molecule in the gaseous state[56]. The dot-dash curve in Figure 10 representing the decrease in E_{ad} with increasing Θ was calculated from these data and shows fairly good agreement with experimental data.

Similar behavior was noted for adsorption of CO on a series of other surfaces[36, 38, 49b, 49c, 54, 57]. As a further example, Figure 12 depicts the structural models for the three ordered structures of CO on Pd(110) which are successively formed with increasing degree of coverage[54]. In addition, this figure also shows a theoretically derived energy profile for the variation of the adsorption energy with the position of the CO molecule with respect to the Pd atoms[26]. (This energy profile deviates slightly from a previously published version[29b] owing to the subsequent introduction of coupling between the 5σ orbital and the metallic s electrons.) The position of most favorable energy is accordingly seen to lie between four Pd atoms. However, the area required by the CO molecules precludes occupation of each one of these positions, and an initial closing up of the adsorbed particles along the grooves in the [1̄10]-direction will take place up to about $\Theta = 0.75$. On further increase of the degree of coverage, the less favorable bridging positions will also be occupied until saturation is reached (Fig. 12c).

The general conclusion drawn from these observations is that the CO molecules do not seem to be fixed at specific adsorption sites. Instead, relatively slight differences exist in the adsorption energy over a surface, which permit a relatively high mobility of adsorbed molecules on the one hand, but also lead to a tendency to seek out a compromise between a densest packing and the periodicity of the substrate lattice, which determines the energy minima, for the arrangement of molecules on approaching the saturation limit. An analogy is observed with the polynuclear carbonyl compounds where the maximum number of ligands is likewise determined by their spatial requirements. Moreover, dynamic ^{13}C-NMR studies showed that geometric fixation of the CO molecules already gives way to fast site exchange phenomena at relatively low temperatures[58]. There is no longer any tendency to close packing for small adsorbed particles such as H, O, or N, where the great demand on surface valences for chemisorption bonding limits maximum coverage.

The variation in the initial adsorption energy (*i.e.* the value obtained by extrapolation to $\Theta = 0$) for CO on a series of variously oriented Pd single crystal surfaces is shown in Table 2. Remarkably, this quantity varies by only about 15% although the number of nearest neighbors of the metal atoms varies between 9 [(111)-face] and 6 [(311)-face]. Similar observations have also been recorded *e.g.* for the CO/Ni[36], H_2/Ni[3], and H_2/Pd systems[59], but the experimental data still appear too sparse to justify any general conclusions. Nevertheless, an interesting parallel can be drawn with the finding that numerous reactions occurring on "real" catalysts are not

affected by particle size, *i.e.* are largely insensitive to the structure of the catalyst surface[60].

Table 2. Adsorption energies [kcal/mol] for CO on variously oriented single crystal faces of Pd.

Face	(111)	(100)	(110)	(210)	(311)
E_{ad}	34	36.5	40	35	35.5

One possible way of conferring a closer resemblance to "real" surfaces upon the single crystal surfaces employed as models consists in introducing periodic arrangements of atomic steps which can be conveniently analyzed by the LEED method[61]. No measurable changes in bond energy were recorded for the adsorption of CO on a stepped Pd(111)-surface[54], while a (relatively slight) effect was established on adsorption of hydrogen[59]. Drastic differences between "flat" and stepped Pt(111)-surfaces were found by *Somorjai et al.*[62] for the kinetics of reactions with hydrocarbons.

Hitherto, only the adsorption of the undissociated CO molecule has been discussed. In spite of its high dissociation energy this molecule decomposes fairly easily above 200 °C on nickel surfaces, and even at room temperature on iron surfaces. Studies on the CO/Ni(110) system[63] showed that the carbon atoms eventually unite to form thin layers of graphite which can be reoxidized to CO by oxygen; on the other hand the adsorbed oxygen atoms can react with CO to give CO_2. This rationalizes the mode of action of these metals as catalysts for establishing the Boudouard equilibrium.

5. Interactions between Adsorbed Particles and Surface Reactions

The surface configurations of adsorbed CO molecules mentioned in the previous section can be largely understood in terms of direct through-space interactions owing to the incipient mutual interpenetration of electron shells and dipole-dipole repulsion. However, other long-range interactions frequently also occur (especially with strongly bound small atoms like H, O, or N) which are of an indirect nature (through bond) and are attributable to a coupling *via* the metal electrons involved in the chemisorption bond. Theoretical treatments of this problem[64] have shown that such interactions have an oscillatory character, *i.e.* they may be attractive or repulsive. The adsorbed particles then preferably occupy highly symmetric adsorption sites determined by the periodicity of the substrate lattice. Use of a lattice-gas model of this kind and assuming certain interaction energies permits simulation of thermal desorption spectra[65], the formation of defined LEED superstructures[66], and the appearance of order-disorder transitions[67]. The last-named phenomena represent the two-dimensional analog af phase transitions, such as are known for ordered alloys or ferromagnetic substances, and can be monitored by means of the change in the LEED intensities with temperature[68]. Available data would indicate such interaction energies between adjacent adsorbed particles are several kcal/mol at maximum.

If two different kinds of species A and B are present on the surface then, by analogy with the "normal" thermodynamics of mixed phases, two limiting cases can be discerned, which are likewise basically due to intermolecular interactions[69]:

1) A and B form an ordered mixed phase *(cooperative adsorption)*, the surface configuration and binding energies possibly being different from those of the pure single component adsorption phases. Such an example is provided by the system of H+CO on Ni(111)[70].

2) A and B are completely immiscible *(competitive adsorption)*, *i.e.* the surface exhibits separate domains of the two adsorbed species.

The second case has been observed, *e.g.* in the interaction of oxygen and carbon monoxide with a Pd(111) surface[55] and rationalizes the kinetics of steady-state CO_2 formation. The individual steps of this reaction[71] are listed in Table 3.

Table 3. Steps involved in catalytic oxidation of CO on palladium.

CO	+ *	$\rightleftharpoons$	CO_{ad}	
O_2	+ *	$\rightleftharpoons$	$2\,O_{ad}$	
O_{ad}	+ CO_{ad}	$\rightarrow$	CO_2	*Langmuir-Hinshelwood*
O_{ad}	+ CO	$\rightarrow$	CO_2	*Eley-Rideal*
CO_{ad}	+ $1/2\,O_2$	$\nrightarrow$	CO_2	

The O_2 is adsorbed dissociatively with an adsorption energy of about 60 kcal/mol (CO, 34 kcal/mol) on regions not yet occupied by CO_{ad}. CO molecules impinging from the gas phase onto a surface occupied by O_{ad} react very rapidly, even below room temperature, to give CO_2 which immediately desorbs (Eley-Rideal reaction). Conversely, a surface covered with CO_{ad} ($\Theta_{CO} > 2/3$ max. CO coverage) completely inhibits adsorption or reaction with O_2 although a gain in energy would be associated with displacement of CO_{ad}. If both kinds of particle are located on the surface, then they occupy separate domains having diameters of at least 50–100 Å. The reaction between O_{ad} and CO_{ad} (Langmuir-Hinshelwood reaction) proceeds somewhat slower than that between O_{ad} and CO, and requires an activation energy of 7 kcal/mol[72]. As a consequence of these steps, a steady state formation of CO_2 is only expected if sufficient surface sites are made available for adsorption of O_2 as a result of thermal desorption of CO. The reactant CO thus inhibits the reaction and its desorption becomes rate determining. Figure 13 illustrates this situation with the aid of measurements of the steady state rate of formation of CO_2 and the surface concentration of CO_{ad} as a function of temperature[72].

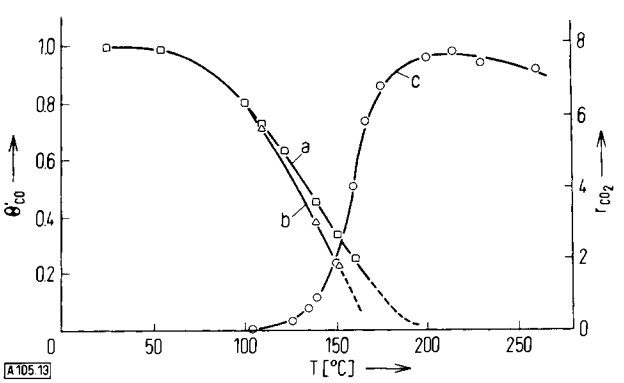

Fig. 13. Catalytic oxidation of CO on a Pd(111) surface: Steady state formation rate r_{CO_2} of CO_2 and relative degree of CO coverage $\Theta'_{CO} = \Theta_{CO}/\Theta_{CO,max}$ as a function of temperature. Curve a, Θ'_{CO} for $p_{CO} = 8 \times 10^{-9}$ torr in absence of O_2; curve b, Θ'_{CO} in a reaction mixture with $p_{O_2} = p_{CO} = 8 \times 10^{-9}$ torr; curve c, r_{CO_2} (in relative units) at $p_{O_2} = p_{CO} = 8 \times 10^{-9}$ torr [72].

A similar situation applies to the catalytic oxidation of CO on single crystal surfaces of Pt[73], Ru[74], and Ir[49b]; modifications are attributable to differing strength of the M—O bond, which renders the reaction O_{ad} + CO rate determining in the case of nickel[75].

Interaction between oxygen and nickel represents another kind of surface reaction leading to formation of three-dimensional compounds (oxide). During the action of O_2 on pure Ni(111) or Ni(100) surfaces formation of chemisorption structures is first observed whose unit cells are related in a simple manner to the periodicity of the metal lattice[76, 77]. In the case of the $c2 \times 2$ structure on Ni(100) the LEED intensities were subjected to detailed theoretical analyses[13]. Each O atom was accordingly found to be located between four Ni atoms at a perpendicular distance of 0.9 Å. The increase in the work function reveals a slight excess negative charge at the oxygen atom. The UPS spectrum[78] (curve b in Fig. 14) exhibits an additional maximum about 5.5 eV below the Fermi level, shown by cluster calculations[79] to arise from chemisorption levels derived from O 2p states. The energy distribution of the Ni d electrons remains largely unaffected at this stage.

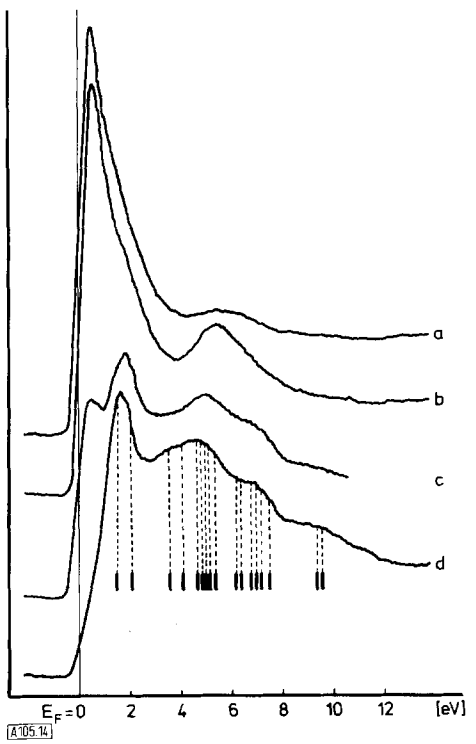

Fig. 14. UV photoelectron spectra ($h\nu = 40.8$ eV) pertaining to the interaction between O_2 and a Ni(111) surface [78]. a, clean surface; b, with a chemisorbed oxygen layer; c, transition to oxide; d, after formation of an epitaxial NiO layer.

After saturation of the chemisorption layer further uptake of oxygen is much slower and leads to formation of an epitaxial NiO layer just a few atomic layers thick[77, 78]. The UPS spectrum (curve c) now also displays drastic changes in the region of the Ni d band. Continuous growth of a thick NiO layer then represents the third stage of this reaction. In the UPS spectrum (curve d) the emission from the metallic d band has completely disappeared, being replaced by a maximum at about 1.7 eV which is assigned to the d states of the Ni^{2+} ions in NiO. Furthermore, a fundamental change observed in the remaining spectrum is in good agreement with the excitation energies calculated for a NiO_6^{10-} cluster[80]. Transition to the oxide is also observed in a discontinuous change in the binding energy of the Ni 2p electrons[81]. As an overall conclusion, it follows that the oxygen chemisorption complex and the oxide are two clearly distinguishable phases whose transformation is not associated with a continuous variation of the valence state or structure.

6. Conclusion

The examples presented in this survey are merely a fraction of the information available and are intended mainly to illustrate the insights into chemical processes occurring on metal surfaces provided by present-day techniques. Apart from further development of experimental and theoretical methods, the main task of the future will be to throw a bridge from the model systems to the situations encountered in practice.

Mechanistic Aspects of Olefin Metathesis

By N. Calderon, E. A. Ofstead, and W. A. Judy[*]

In this paper views regarding the nature of the transition state in olefin metathesis are discussed. Earlier concepts that assumed a pairwise scrambling mechanism have been recently challenged. Metathesis studies involving acyclic as well as cyclic olefins have been reported which strongly suggest a chain process that may involve a carbene-to-metallocycle interconversion as the pathway responsible for transalkylidenation. Catalytic systems that display a low apparent metathesis activity on terminal olefins display a unique specificity in cross reactions with internal olefins. Critical experiments indicate that terminal olefins rapidly undergo regenerative metathesis preferentially. Results suggest that in the transient metallocycle, the most stringent steric requirements occur at the β-carbon, although the origin of this steric demand is not obvious.

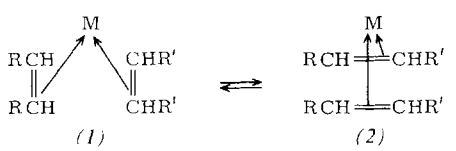
1. Introduction

The results of key experiments which extablished the site of bond cleavage in olefin metathesis[1-3] generated an extensive quest for a mechanism that could rationalize the various aspects of a remarkable new catalytic reaction. Ideally, if one is to obtain a coherent description of a catalytic process on an atomic scale, it is necessary to establish: a) the structure of the catalytic site, b) logistic aspects, *i. e.*, pathways by which incoming reactants replace outgoing products, and c) the nature of the transition state and the intimate electronic transformations that occur along the reaction coordinate.

Characterization of catalyst sites in processes that are promoted by transition metals is not easily accomplished. Many diverse catalysts promote olefin metathesis. These encompass uni- and multicomponent systems derived from various metals having different oxidation states, and may be homogeneous or heterogeneous in nature. Hence, the assignment of a particular structure as being the "true" description of the catalytic site is virtually impossible.

The relevance of ligand exchange processes to the logistics aspect of olefin metathesis is clear. An outstanding feature of certain metathesis catalysts is their capacity to promote rapid reactions at very low concentrations. Extremely fast rates are common, and these could not be realized if an efficient route did not exist for the exchange of incoming and outgoing olefin molecules on the active site of the metal. Using rhodium complexes, *Cramer*[4] demonstrated that ligand exchange processes may proceed by either S_N2 or S_N1 mechanisms, depending primarily on the ligand field surrounding the metal and the availability of coordination sites.

Views regarding the nature of the transition state in olefin metathesis are in a state of flux. Until recently, most proposed schemes for the transalkylidenation process assumed a pairwise scrambling that required an initial bisolefin-metal entity *(1)* bearing two olefinic ligands in a *cis* configuration about the metal. Subsequently, a controversy developed over the detailed nature of the transformation of this complex *(1)* into the corresponding product complex *(2)* [Eq. (a)][*].



(1) *(2)* (a)

Thus, concepts such as quasicyclobutane[5], tetramethylene-metal complex[6], and metallocyclopentane[7] were proposed in attempts to describe the intervening transition state. The fact that a bisolefin-metal complex of type *(1)* has never been isolated for any active metathesis catalyst, lent all of the aforementioned schemes a certain degree of vulnerability. Lately, several publications disclosed results that appear to be incompatible with the reaction pathway depicted in Eq. (a). Rather, they point to a non-pairwise chain mechanism that favors a single olefin molecule complexed to a carbene-bearing metal undergoing interchange *via* a metallocyclobutane intermediate [Eq. (b)][**].

$$\begin{matrix} R'CH{=}M \\ R'CH{=}CHR \end{matrix} \rightleftharpoons \begin{matrix} R'CH \\ \| \\ R'CH \end{matrix} \quad \begin{matrix} M \\ \| \\ CHR \end{matrix} \qquad \text{(b)}$$

The intent of this article is to present an up-to-date account of recent developments toward understanding the mechanism of olefin metathesis, and to compare the relative merits of the two basic schemes. In addition, a discussion is included on a recently discovered characteristic of catalysts which display a low apparent activity with terminal olefins. These have been found to react with mixtures of terminal and internal olefins resulting in the selective formation of cross metathesis products.

2. Vulnerabilities in Pairwise Scrambling Schemes

2.1. Polymerization of Cycloolefins

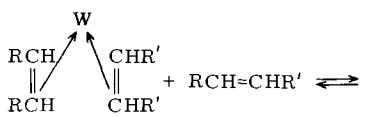
Dolgoplosk[8] suggested that the formation of a high molecular weight product during the initial stage of a cycloolefin metathesis polymerization was inconsistent with a pairwise scrambling mechanism. Indeed, high molecular weight polymers are commonly observed during early stages of cy-

[*] Dr. N. Calderon, E. A. Ofstead, and W. A. Judy
The Goodyear Tire & Rubber Co., Research Division
Akron, Ohio 44316 (USA)

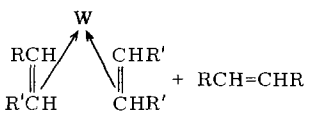
[*] Here and in the following equations the ligands to metal atom M external to the olefin have in most cases been omitted.

[**] For sake of clarity, here and in the following equations the carbene-metal bond has usually been drawn as a double bond; for the character of this bond see Section 4.

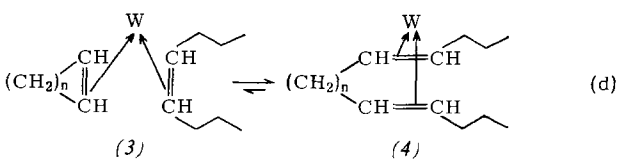
cloolefin polymerizations. For example, the polymer obtained at 6% conversion from cyclooctene using a $WCl_6/C_2H_5OH/C_2H_5AlCl$ catalyst had a molecular weight of about 200000–300000[9]. (This product was accompanied by low molecular weight macrocyclic oligomers not included in the molecular weight value.) This phenomenon requires that cycloolefin polymerizations propagate by some type of chain process rather than by a stepwise growth process. Such a process is nevertheless reconcilable with a pairwise scheme when certain restrictions are invoked[10]. The pairwise mechanism [Eq. (a)] could exhibit a chain reaction character if the rate of the transalkylidenation step were much faster than that of the exchange



(c)



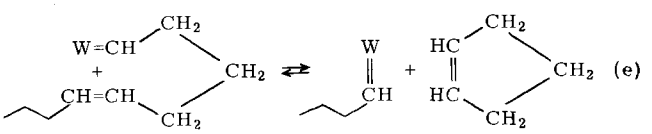
step [Eq. (c)], and if in the propagation step the equilibrium between *(3)* and *(4)* were to lie far on the side of the bidentate complex [Eq. (d)].



(3) *(4)* (d)

On the other hand, if reaction (c) were faster than reaction (a), a transfer-to-monomer process would predominate in the early stages of cycloolefin metathesis, resulting initially in a preponderance of low molecular weight cyclic oligomers and essentially no high molecular weight product.

Chauvin et al., who were first to suggest non-pairwise transalkylidenation *via* a carbene-metal intermediate [see Eq. (b)][11], recently examined the effect of conversion on molecular weight distributions of polymers and copolymers obtained from cyclopentene and cyclooctene[12]. The monomer-polymer and polymer-oligomer equilibria were presented as "back-biting" processes. Hence, for cyclopentene the propagation-depropagation equilibrium involved an intramolecular carbene-metal interchange as depicted in [Eq. (e)].



(e)

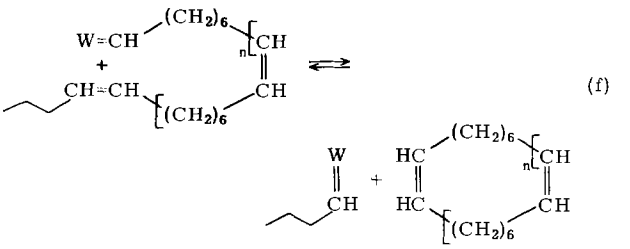
In a similar fashion, the formation of macrocyclic oligomers in cyclooctene polymerization is illustration in Eq. (f).

Two significant points evolve from the non-pairwise scheme illustrated here:

a) The high molecular weight polyalkenamers are linear, even when acyclic olefins are absent in the reaction.

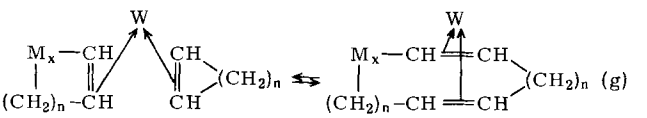
b) Cyclic oligomers are not formed *via* intermolecular condensation of two smaller rings.

In contrast to the above scheme, cycloolefin metathesis *via* a pairwise interchange process predicts that, in the complete



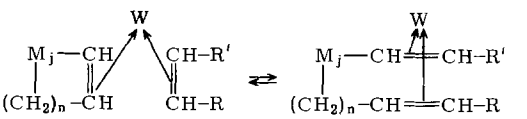
(f)

absence of acyclic olefins, propagation proceeds by macrocyclization as in Eq. (g)[13].



(g)

Linear, open chain macromolecules would be obtained by cross metathesis with acyclic olefins as depicted in Eq. (h) where the acyclic alkylidene moieties become chain ends:



(h)

Furthermore, this mechanism affords cyclic oligomers by both inter- and intramolecular metathesis.

Studies to determine whether polyalkenamers are linear or macrocyclic have been reported by *Scott*[14,15]. By adding varied amounts of chain scission agents to a cycloolefin metathesis and examining their effect on product molecular weight, it was possible to establish the acyclic nature of the high molecular weight polyoctenamer. Figure 1 is a plot of $1/D'$, the reciprocal of the number-average degree of polymerization (determined by vapor phase osmometry), versus τ, the ratio of reacted 3-hexene to cyclooctene. The three lines are theoretical behavior curves for three different cases. Curve A is for the random scission of a mixture of polymer chains which is entirely acyclic, curve B is the theoretical expression for the scission of a mixture of rings and chains, and curve C the case of random scission of cyclic macromolecules. The mathematical derivation of the respective expressions that

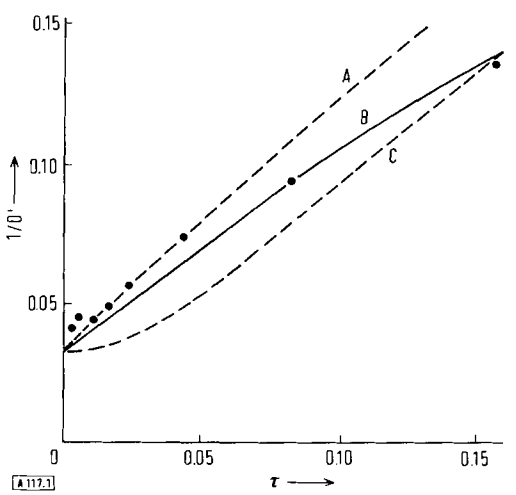


Fig. 1. Dependence of the reciprocal of the number-average degree of polymerization, D', on the mole ratio of reacted 3-hexene to cyclooctene, τ. Theoretical curves are A: all linear chains; B: ring-chain equilibrium; and C: all cyclic polymers.

produce these curves is fully described in ref. [14]. The agreement between the experimental points and curve B is striking. It lends considerable support to the assertion that, in the *absence of any deliberately added acyclic olefin*, polyoctenamer as prepared under the conditions used in that study consisted of high molecular weight linear chains (80—85 % by wt.), while the remaining low molecular weight species were cyclic oligomers having an average molecular weight of about 500.

Extending this work to polypentenamer, *Scott*[15] examined the effect of conversion on the weight-average and number-average molecular weights, as well as the molecular weight distribution. This study revealed that polypentenamer was linear in structure as was polyoctenamer.

The experimental verification that high molecular weight polyalkenamers are linear and not macrocyclic has a limited significance for the mechanism of olefin metathesis. It is compatible with the non-pairwise interchange concept, such as the carbene-metal scheme proposed by *Herisson* and *Chauvin*[11], but it does not exclude entirely the pairwise transalkylidenation scheme. It is recognized that the final, necessary and sufficient condition for ring-chain equilibria, as observed[14-16] and described above[12], is the presence of a trace amount of chain scission reactant, typically an acyclic olefin. Thus, the pairwise scrambling mechanism can be reconciled with the formation of linear chains even when end-groups are not introduced deliberately into the system, if one takes into account (a) the possible *in situ* formation of chain ends during the reaction of the organoaluminum catalyst component with the tungsten salt; or (b) the presence of very small amounts of olefinic impurities.

2.2. Formation of Cyclic Oligomers

Three basic features were established in a study[13] related to the formation of oligomers during cycloolefin metathesis:

1. The oligomers are macrocyclic.
2. The population of macrocyclics is controlled primarily by the double bond frequency along the polymeric chain.
3. The oligomeric macrocyclics and their corresponding high molecular weight polyalkenamer are interconvertible.

As stated earlier, whereas pairwise interchange schemes allow formation of macrocyclic oligomers by two routes, intramolecular "pinching-off" of a cyclic entity from a higher macromolecule and intermolecular condensation of two smaller rings, the carbene-metal scheme provides only one route for cyclic oligomer formation, namely, intramolecular "back-biting" [Eq. (e) and (f)]. By determining quantitatively the relative abundance of the various macrocyclics produced during the metathesis of 1,5-cyclooctadiene, it was demonstrated that these are produced exclusively by an intramolecular process[17, 18].

1,5-Cyclooctadiene is known to yield two series of macrocyclics. One contains "whole" multiples of the monomer $[(C_8H_{12})_n]$, the others may be described as "sesqui-oligomers" $[(C_8H_{12})_n—C_4H_6$, where $n \geq 2]$. Table 1 presents the relative concentrations of the respective macrocycles—the "whole" oligomers (C_{16}, C_{24}, C_{32}...) and the "sesqui-oligomers" (C_{12}, C_{20}, C_{28}...). The results indicate that the molar ratios of the various "sesqui-oligomers" relative to C_{16}, as well as the molar ratios of the "whole" oligomers to C_{16}, remain essentially constant throughout a conversion range of 1.3-to-98.5 %. (The only variant is the C_{12}/C_{16} ratio at 98.5 % conversion, which has been rationalized[18].)

To appreciate the significance of these results one must recognize that, irrespective of the mechanism invoked, the C_{12} oligomer(1,5,9-cyclododecatriene) cannot be produced by any intermolecular process, since the smallest precursor available is a C_8 ring. On the other hand the C_{16} oligomer (1,5,9,13-cyclohexadecatetraene) might be produced, at least in principle, by inter- as well as intramolecular processes. The fact that a significant amount of the C_{12} product was present even at the lowest conversions measured, and that its relative abundance remained constant throughout the course of polymerization is indicative that only one pathway for the formation of cyclic oligomers is operative, namely, an intramolecular process. This argument applies also for the higher oligomers, as clearly indicated in Table 1.

Table 1. Molar ratio of cyclic oligomers $(C_8H_{12})_n$ and sesquioligomers $(C_8H_{12})_n—C_4H_6$ to cyclohexadecatetraene ($C_{16}/C_{16} = 1.0$) (after Ref. [18]).

Conversion [%]	C_{12}/C_{16}	C_{20}/C_{16}	C_{24}/C_{16}	C_{28}/C_{16}	C_{32}/C_{16}
1.3	0.47	0.65	—	—	—
3.2	0.51	0.63	0.32	0.18	—
7.9	0.55	0.63	0.27	0.24	—
9.5	0.48	0.62	0.28	0.25	0.10
19.5	0.52	0.59	0.31	0.27	0.10
36.3	0.52	0.56	0.32	0.18	0.13
51.1	0.51	0.58	0.33	0.26	0.13
61.2	0.53	0.54	0.30	0.19	0.10
98.5	0.93	0.65	0.27	0.23	0.14

Although the data presented above are quite compatible with a non-pairwise metathesis mechanism, they still do not entirely discount the pairwise reaction pathway. The data can be accommodated with a pairwise mechanism by invoking the following kinetic assumptions:

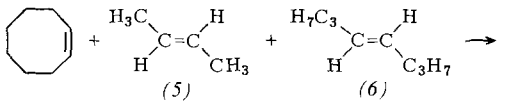
$$\begin{array}{ccccc} (C_4)_{2m} & \rightleftharpoons & (C_8)_m & \xrightarrow[k_p]{+C_8} & (C_8)_{m+1} \\ \Big\downarrow\uparrow k_e & & & & \\ (C_4)_{2m-n} & + & (C_4)_n & & n \geq 3 \end{array} \qquad \text{(i)}$$

In Eq. (i), C_8 denotes 1.5-cyclooctadiene monomer which adds to a $(C_8)_m$ polymer yielding $(C_8)_{m+1}$ with a rate constant for this step of k_p. Since $(C_8)_m$ is structurally indentical to polybutenamer, it may also be represented as $(C_4)_{2m}$. This macromolecule at all times is reversibly interconverted to the respective cyclic oligomer series $(C_4)_n$. If $k_p \gg k_e$, conditions result wherein oligomers are formed *via* the intramolecular route exclusively.

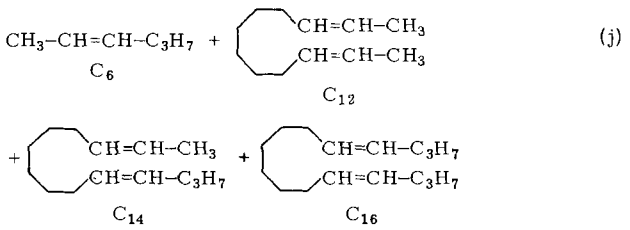
2.3. Cross Metathesis of Acyclic Olefins with Cycloolefins

Cross metathesis studies between acyclic and cyclic olefins, conducted for the purpose of examining telomer compositions, have been reported on different occasions[11, 17-22]. Perhaps the most relevant work with respect to pairwise *vs.* non-pairwise mechanisms is the one disclosed recently by *Katz*[22]. The telomer distribution produced during the early stages of the cross metathesis of cyclooctene with a mixture of *trans*-2-butene and *trans*-2-octene, in the presence of a molybdenum-based catalyst, was monitored. In addition to a

C_6, the cross product of 2-butene and 4-octene, two symmetrical (C_{12} and C_{16}) and one unsymmetrical (C_{14}) dienes were formed [Eq. (j)].



(5) *(6)*



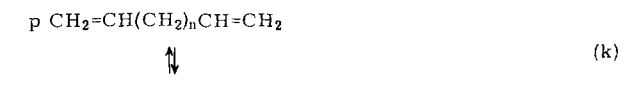
(j)

(In addition, one would expect formation of higher telomer homologs. These were not discussed.) *Katz's* contention was that, if any of the pairwise scrambling schemes were to prevail, the ratios of the unsymmetric to symmetric dienes, C_{14}/C_{12} and C_{14}/C_{16}, would be zero initially. The experiments revealed that the C_{14}/C_{12} and C_{14}/C_{16} ratios were significantly different from zero at the initial stage of the reaction; in fact, the extrapolated values at zero time suggested that the unsymmetric diene was favored initially. This kinetic study strongly supported a non-pairwise reaction scheme, such as the carbene-metal concept, but it did not entirely exclude pairwise schemes. *Katz* conceded that the discriminating merit of his experiment holds true only if one assumes that the transalkylidenation step in pairwise scrambling mechanisms [Eq. (a)] is the rate determining step. However, if the exchange step were rate determining [Eq. (c)] his data could be accounted for by either scheme.

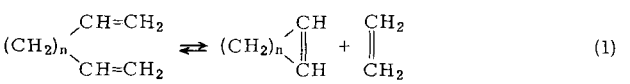
2.4. Metathesis of α,ω-Dienes

Nonconjugated α,ω-dienes, when treated with a metathesis catalyst, may undergo either metathetical polycondensation[23] forming open chain oligomers with terminal double bonds [Eq. (k)], or they may undergo intramolecular metathesis[19] to form a cycloolefin [Eq. (l)]. Both processes will yield ethylene.

The factor which determines which process will prevail at equilibrium depends primarily on the value of *n*, which correlates with the relative thermodynamic stability of a given $+(CH_2)_nCH{=}CH+$ sequence in a ring *versus* a chain. For example, *Dall'Asta*[23] metathesized 1,4-pentadiene and 1,5-hexadiene exclusively to higher molecular weight linear oligomers because the corresponding monomeric cycloolefins



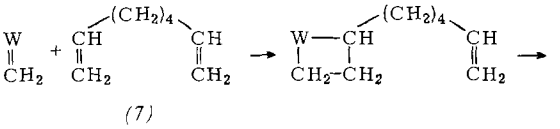
(k)



(l)

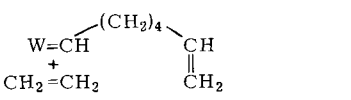
are highly strained. On the other hand, *Kroll*[24] was able to convert 1,7-octadiene to the stable product cyclohexene with 99 % selectivity.

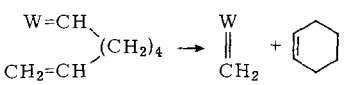
1,7-Octadiene is a substrate which is uniquely suitable for mechanistic studies. There is good evidence to indicate that: a) 1,7-octadiene does not undergo intermolecular metathesis according to Eq. (k), and b) the cyclohexene produced during intramolecular cyclization does not participate in further metathetic processes. These features were exploited by *Grubbs*[25], who studied the metathesis of a mixture of 1,7-octadiene with [1,1,8,8-D_4]-1,7-octadiene, in an attempt to distinguish between a non-pairwise chain mechanism and the pairwise scheme. The non-pairwise path is visualized as shown in Eq. (m) and (n).



(7)

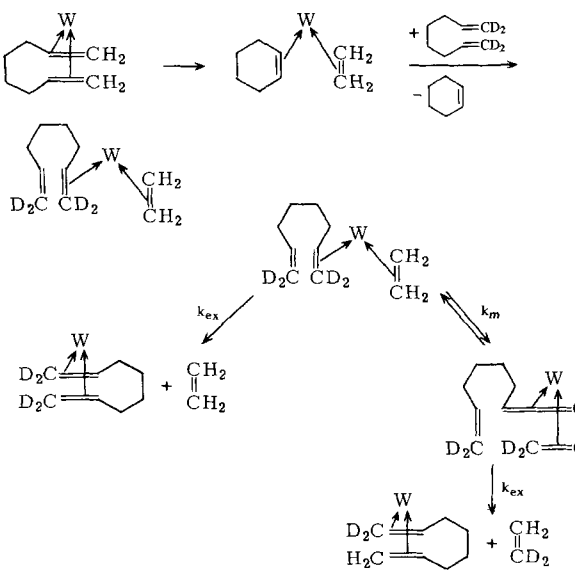
(m)





(n)

It can be demonstrated that for an equimolar mixture of *(7)* and [1,1,8,8-D_4]-*(7)* one expects to obtain a statistical distribution (1:2:1) of [D_4]-, [D_2]- and [D_0]-ethylene at low conversion even in the absence of ethylene redistribution reactions. On the other hand, the pairwise path predicts different distributions of the deuterated ethylenes, depending on the relative rates of metathesis *versus* exchange. The pairwise scheme is presented in Eq. (o) and (p).



(o)

(p)

The di-deuterated and tetra-deuterated bidentate bisolefin complexes produced according to Eq. (p) will then metathesize yielding cyclohexene and the respective ethylenes in accordance with Eq. (o).

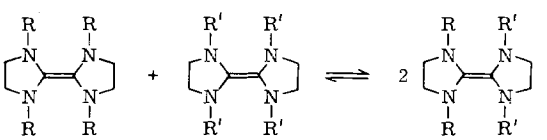
If intramolecular exchange were rapid and $k_{ex} \gg k_m$ (*i.e.*, the transalkylidenation step were rate determining), then one would expect a 1:0:1 distribution of [D_4]-, [D_2]- and [D_0]-ethylene in the initial stage of reaction. Thus, as a cyclohexene is displaced by a 1,7-octadiene [Eq. (o)] the new complex rapidly eliminates ethylene and forms a bidentate species [left

side of Eq. (p)]. If on the other hand $k_m \gg k_{ex}$, the resulting bisolefin complex would undergo transalkylidenation [right side of Eq. (p)], giving rise to the formation of some $CH_2{=}CD_2$ in addition to C_2H_4. *Grubbs* calculated 1:1.6:1 as being the limiting $[D_4]$-, $[D_2]$-, $[D_0]$-ethylene ratio for the process depicted in Eq. (o) and Eq. (p) when $k_m \gg k_{ex}$. Experimentally, the distribution was substantially different from either limiting value. The abundance of the respective ethylenes was closer to a statistical distribution, consistent with a non-pairwise mechanism. A significant finding was that the $[D_4]:[D_2]:[D_0]$ distribution of the residual 1,7-octadiene did not vary from start to finish in this particular metathesis experiment. This strongly indicates that essentially no regenerative intermolecular scrambling of methylenes among terminal double bonds of diene molecules took place. Furthermore, examining the $[D_4]$-, $[D_2]$-, and $[D_0]$-ethylene distribution before and after spiking the reaction mixture with $[D_0]$-ethylene led *Grubbs* to conclude that no significant degree of scrambling among the ethylenes took place under the prevailing reaction conditions.

Heretofore, a discussion of four experimental observations, mentioned quite often as evidence for a non-pairwise scheme for the transalkylidenation step, has been presented. Of these, *Grubb*'s work[25] stands alone as the one that cannot be readily accounted for by pairwise schemes.

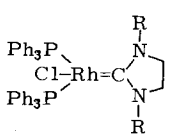
3. Evidence for Carbene-Metal Involvement

Although *Pettit*[6] did not apply "carbene" nomenclature to his pairwise transition state proposal, his description obviously alluded to an involvement of carbenes in olefin metathesis. Since then there have been several experimental disclosures that could be interpreted as providing evidence for carbene involvement in the reaction. *Cardin*[26] observed some disproportionation when he reacted a mixture of unsaturated amines with a rhodium phosphane catalyst [Eq. (q); $R = C_6H_5$, $R' = p\text{-}CH_3\text{—}C_6H_4$].



(q)

As a side product, a rhodium(I) complex with one half of the electron-rich olefin was isolated, for which the structure *(8)* was proposed. (The analogous compound with R′ instead of R has also been found.)



(8)

O'Neill[27] observed that a CoO/MoO_3 supported catalyst, which is active in propylene metathesis, readily decomposed diazomethane into ethylene and N_2:

$$2CH_2N_2 \rightarrow CH_2{=}CH_2 + 2N_2 \qquad (r)$$

It was suggested that the same sites that are active in metathesis "also selectively convert adsorbed methylenes into ethylene". Subsequently, *O'Neill*[28] demonstrated in an elegant fashion that a $Mo(CO)_6/Al_2O_3$ catalyst was capable of converting ethylene into propylene directly:

$$3CH_2{=}CH_2 \rightarrow 2CH_3CH{=}CH_2 \qquad (s)$$

O'Neill attempted to outline a mechanism for this unique $3C_2 \rightarrow 2C_3$ process. The suggested most "straightforward pathway" involved a splitting of one ethylene into methylenes, and addition of each of the latter to another ethylene, followed by rearrangement of the resulting trimethylene into propylene. It must be stressed that, although the catalyst for this process is formally a metathesis catalyst, the two reactions are qualitatively distinct. Any conceivable mechanism for the $3C_2 \rightarrow 2C_3$ reaction must reconcile migration of hydrogens. Selective olefin metathesis reactions do not involve hydrogen migrations. Hence, a carbene mechanism for a $3C_2 \rightarrow 2C_3$ cannot be reasonably "transplanted" to olefin metathesis.

Dolgoplosk[8] was able to demonstrate that an active catalyst for cycloolefin metathesis can be generated by co-reacting WCl_6 or WCl_4 with phenyldiazomethane. In the absence of cycloolefin monomer, a reaction analogous to *O'Neill*'s [Eq. (r)] was observed, and phenyldiazomethane was decomposed to nitrogen and stilbene. *Dolgoplosk* proposed a sequence as depicted in Eq. (t):

$$C_6H_5CH{=}WX_n + C_6H_5CHN_2 \rightarrow N_2 + C_6H_5CH{=}CHC_6H_5 + WX_n \qquad (t)$$

In the presence of cycloolefin monomer a very high molecular weight polyalkenamer is formed. The mechanism adopted for this polymerization is identical to *Chauvin*'s, wherein propagation-depropagation equilibrium [Eq. (e)] occurs at an active carbene-metal chain-end.

Recently, *Casey*[29] isolated $(C_6H_5)_2C{=}W(CO)_5$, a carbene-metal complex free of a heteroatom bonded to $C_{carbene}$. Until this report, it was generally believed that stable metal-carbene complexes required an electron donor heteroatom directly attached to the $C_{carbene}$. Following *Casey*'s work, *Schrock*[30,31] demonstrated that "unstabilized" carbene complexes of tantalum, such as $(CH_3)_3CHC{=}Ta[CH_2C(CH_3)_3]_3$ and $H_2C{=}Ta(C_5H_5)_2(CH_3)$, can be prepared, isolated and characterized.

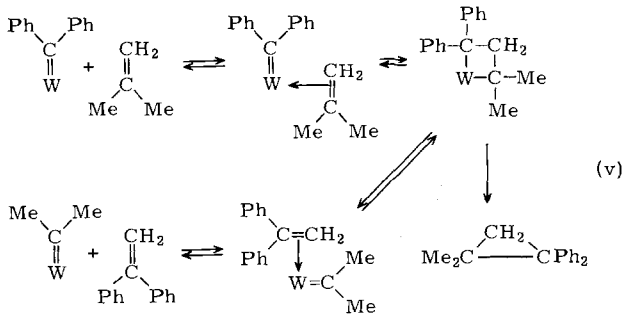
Upon heating $(C_6H_5)_2C{=}W(CO)_5$ with isobutene (100 °C, 2 h) a mixture of products was obtained[32], indicating a net transfer of a $[CH_2]$ group from isobutene to the diphenylcarbene [Eq. (u)].

$$(C_6H_5)_2C{=}W(CO)_5 + (CH_3)_2C{=}CH_2 \longrightarrow$$

$$(CH_3)_2C\overset{CH_2}{\text{———}}C(C_6H_5)_2 + (C_6H_5)_2C{=}CH_2 + W(CO)_5 \qquad (u)$$

The mechanism proposed for this reaction [Eq. (v)] accommodates both the observed cyclopropanation and the methylene transfer from isobutene to the diphenylcarbene (the carbonyl ligands have been omitted).

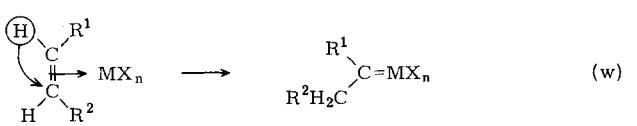
Casey's remarkable experiment, when first carried out, was stoichiometric rather than truly catalytic, and the element of reversibility was lacking. Very recently *Katz*[43] has shown that $(C_6H_5)_2C{=}W(CO)_5$ can in fact act as a metathesis catalyst.



(v)

4. Possible Origins of Carbene-Metal Species

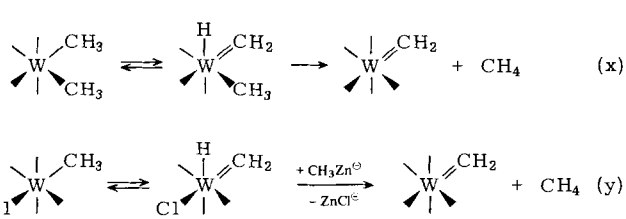
The variety of metals and their derivatives and combinations which demonstrate metathesis activity is very broad. If the non-pairwise carbene-to-metallocycle mechanism is to be accepted, it becomes of interest to examine potential routes to the formation of the initial carbene-metal entity. For this purpose it is convenient to classify metathesis catalysts into two major categories: a) catalyst combinations that do not involve an organometallic component, and b) combinations that involve organometallic cocatalysts. To the first category belong the classical heterogeneous supported catalysts such as MoO_3, $W(CO)_6$, and Re_2O_7 on alumina. Combinations such as WCl_6/AlX_3, or the photochemically induced $W(CO)_6/CCl_4$ which was recently disclosed independently by two research groups[34, 35], are also included in this category. Typical systems belonging to the second category are unmodified and alcohol-modified WCl_6/R_mAlCl_n $(m+n=3)$, $MoCl_5/R_3Al$, WCl_6/R_4Sn, $Mo[(Ph_3P)_2Cl_2(NO)_2]/R_3Al_2Cl_3$ and WCl_6/R_2Zn. As pointed out by *Dolgoplosk*[8], one may speculate that active catalysts of the first category undergo initiation, or in other words produce the original carbene-metal complex, by a process analogous to the one proposed by *Clark*[33], where a methoxycarbene-platinum entity was detected when certain acetylene-platinum complexes were reacted with methanol. The analogous transformation of an olefin-metal is illustrated schematically in Eq. (w).



(w)

It must be emphasized that this proposal is highly speculative, and no experimental evidence exists at present in support of such a process in actual metathesis reactions.

Catalyst systems that are activated by organometallic cocatalysts, presumably forming transition metal intermediates containing at least one alkyl group which is σ-bonded to the metal, are prone to transform into carbene-metal entities. *Muetterties*[36, 37] observed that, during the reaction of WCl_6 with metal alkyls, a significant evolution of alkanes takes



(x)

(y)

place. For example, in the reaction of $(CH_3)_2Zn$ with WCl_6 carried out in a deuterated solvent, methane free of deuterium was produced. It has been proposed that α-hydrogen elimination from the tungsten-methyl group occurs [Eq. (x) or (y)], leading to the formation of the initial carbene-tungsten complex.

The existence of a $W—CH_3 \rightleftarrows W(=CH_2)H$ equilibrium, proceeding by migration of an α-hydrogen from a σ-bonded alkyl to the metal, has also been proposed by *Green*[38] in connection with the reversible rearrangement [Eq. (z)]:

$$[W(C_5H_5)_2(PR_3)CD_3]^{\oplus} \rightleftharpoons [W(C_5H_5)_2(CD_2PR_3)D]^{\oplus} \qquad (z)$$

Recent work by *Schrock* with organotantalum compounds suggests the feasibility of both intramolecular and intermolecular α-hydrogen abstractions as straight-forward routes to isolable carbene-tantalum complexes which are not stabilized by a heteroatom. X-ray and NMR analyses were employed[39] to determine the structure of $CH_2=Ta(C_5H_5)_2CH_3$ and to estimate the energy barrier to rotation about the $Ta=CH_2$ double bond. The complex, as illustrated in Fig. 2, has two eclipsed cyclopentadiene rings. The $H_2C—Ta$ bond length is shorter than the $H_3C—Ta$ bond, indicating some double bond character for the methylene ligand. The methylene ligand is oriented perpendicular to the C—Ta—C plane. These observations are in accord with the concept of a $C_{carbene}$ having an sp^2 hybridization, wherein its vacant p_z orbital can overlap preferably with a hybridized Ta orbital in the C—Ta—C plane.

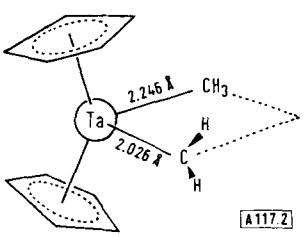


Fig. 2. Structure of the complex $CH_2=Ta(C_5H_5)_2CH_3$.

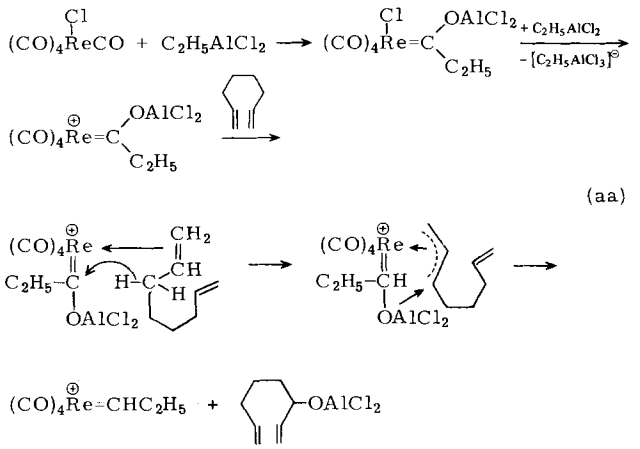
The barriers of rotation for $=CH_2$, $=CHC(CH_3)_3$, and $=CHC_6H_5$ around the respective $C_{carbene}—Ta$ bonds were estimated from temperature-dependent NMR analyses[39]; the free energies of rotations, $\Delta G^{\neq}$, are ≥ 21.4, 16.8, and 19.3 kcal/mol for the respective carbene ligands. These high values directly reflect the significant double bond character of carbene-metal complexes that bear no heteroatom substituents on the carbene carbon atom.

Evidence for an alternate route for the formation of the original carbene-metal entity was submitted recently by *Farona*[40, 41]. Using $Re(CO)_5Cl$ in combination with either $C_2H_5AlCl_2$ or CH_3AlCl_2, the homo-metatheses of 1,7-octadiene and 4-octene was investigated. Using highly sensitive GC-Mass Spectroscopy techniques, he was able to monitor trace amounts of anomalous olefinic products which were proposed as resulting from the first-formed carbene. The first-formed olefins in the metathesis of 1,7-octadiene when $C_2H_5AlCl_2$ cocatalyst was employed were identified as 1-butene and 1,7-decadiene, whereas when 4-octene substrate was used, minute amounts of 3-heptene were found. Accordingly, *Farona* concluded that the original carbene-metal must have been a propylidene-Re entity. In an analogous experiment

using CH_3AlCl_2 cocatalyst, the first-formed olefins suggested the formation of an ethylidene-Re carbene initially.

The proposed mode of formation of the original propylidene-Re complex as postulated by *Farona*[41] is illustrated in Eq. (a, a):



(aa)

The presence of an unusual by-product, octa-1,7-dien-3-one, was claimed as supporting evidence for this scheme.

In conclusion, whereas formation of the original carbene-metal can be explained in catalyst systems that involve metal alkyl components, no experimental work exists to suggest a pathway for carbene formation in catalyst systems that do not employ organometallics. Evidence supports the contention that sp^2-bonding of carbene ligands which are not stabilized by heteroatom substituents is substantial, and the carbene-metal bond should be viewed as a double bond in the proposed carbene-to-metallocycle mechanism.

5. Structural Selectivity in Cross-Metathesis Reactions

Earlier, we disclosed[17, 18, 20] that certain catalysts which display a low apparent metathesis activity with terminal olefins, when employed on mixtures of terminal and internal olefins, lead to the selective formation of cross metathesis products. Table 2 presents the relative distribution of the various cross metathesis products of 1-pentene with *cis*-2-pentene after 25% of the original 2-pentene had been consumed (50% of theoretical equilibrium). Self-metathesis of either olefin will lead to symmetric products; ethylene and 4-octene from 1-pentene, and 2-butene and 3-hexene from 2-pentene. The major products from the cross metathesis were the unsymmetric ones. Depending on the orientation of the incoming olefin with relation to a specific carbene-metal site, one can obtain propylene, 3-heptene, 1-butene and 2-hexene. The data point to the fact that, although 1-pentene is sluggish towards self-metathesis, it readily reacts with 2-pentene to produce the unsymmetric cross products. The results also suggest that 1-pentene, in fact, inhibits the self-metathesis of 2-pentene to the extent that the tendency of 2-pentene to yield cross products with 1-pentene is eight times greater than its tendency to self-metathesize. This observation was recently reconfirmed by *Muetterties*[42] using a $RAlCl_2/WCl_6/ROH$ catalyst on 2-pentene and 1-nonene substrates. A possible hypothesis for this observation is that terminal olefins are, in fact, *more* reactive than internal olefins, but that they prefer to undergo regenerative metathesis *via* either metallocycle *(9)* or *(10)*.

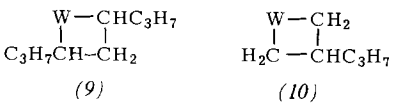
Table 2. Cross metathesis of 1-pentene and *cis*-2-pentene (after Ref. [18]).

$C_3H_7{=}CH_2 + C_2H_5CH{=}CHCH_3$

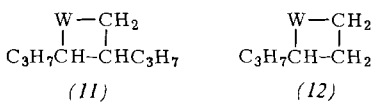
Relative concentrations [a]			
Symmetric		Unsymmetric	
$CH_2{=}CH_2$	1	$CH_3CH{=}CH_2$	4
$C_3H_7CH{=}CHC_3H_7$	1	$C_2H_5CH{=}CHC_3H_7$	4
$CH_3CH{=}CHCH_3$	2	$C_2H_5CH{=}CH_2$	12
$C_2H_5CH{=}CHC_2H_5$	2	$CH_3CH{=}CHC_3H_7$	12

[a] Values at 50% of theoretical equilibrium.

This phenomenon has been recently reconfirmed by *Katz*[43] and *Muetterties*[42]. Evidently, transition states *(11)* and *(12)* are not favored, since they are incompatible with regenerative metathesis.



(9) *(10)*



(11) *(12)*

When terminal and internal olefins are co-reacted, regenerative metathesis prevails, thus inhibiting self-metathesis of the internal olefin. Terminal olefins occupy the catalyst, but occassionally an internal olefin enters the complex, whereupon metathesis yields an unsymmetric product.

The regenerative methathesis of terminal olefins was confirmed experimentally by examining the product distribution in the cross metathesis of 1-pentene with $[D_{10}]$-1-pentene (Table 3).

Table 3. Cross metathesis of 1-pentene and $[D_{10}]$-1-pentene; GC/MS data. C_8H_{16}, $C_8H_8D_8$ and C_8D_{16} formed only in trace amounts (after Ref. [18]).

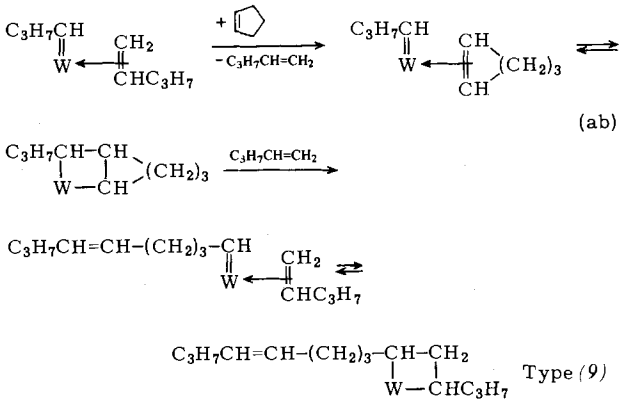
Compounds	*m/e*	Relative concentrations initially	after 10 min	equilibrium (calc.)
$C_3D_7CD{=}CD_2$	80	0.1074	0.0395	0.0115
$C_3D_7CD{=}CH_2$	78	—	0.0685	0.0959
$C_3H_7CH{=}CD_2$	72	—	0.0771	0.0959
$C_3H_7CH{=}CH_2$	70	0.8926	0.8148	0.7967

The data in Table 3 indicate that after a 10 minutes' reaction the original mixture of $C_3H_7CH{=}CH_2$ ($m/e=70$) and $C_3D_7CD{=}CD_2$ ($m/e=80$) underwent about 70% of the theoretical scrambling. Only trace amounts of 4-octenes were formed.

In an attempt to resolve whether regenerative metathesis of terminal olefins proceeds *via* transition state *(9)* or *(10)*, the route of telomer formation was examined in the cross metathesis of 1-pentene and cyclopentene. This has been reported[18, 20] to produce preferentially the homologous series of unsymmetric polyenes of the general formula $C_3H_7CH[{=}CH{-}(CH_2)_3{-}CH{=}]_xCH_2$ (C_{10}, C_{15}, C_{20}...*etc.*), along with minor amounts of the two symmetric homologous series, $CH_2[{=}CH{-}(CH_2)_3{-}CH{=}]_xCH_2$

(C_7, C_{12}, C_{17}, C_{22} *etc.*) and $C_3H_7CH[=CH-(CH_2)_3-CH=]_xCHC_3H_7$ (C_{13}, C_{18}, C_{23}, C_{28} *etc.*)[*]. Figure 3 shows a chromatogram of a [1-pentene + cyclopentene] reaction product mixture. The main peaks are attributed to the unsymmetric homologous compounds.

If regenerative metathesis were to proceed *via* intermediate *(9)*, it is evident that the eventual incorporation of cyclopentene units to form the unsymmetric polyenes will follow sequence (ab):



(ab)

On the other hand, if one assumes that the regenerative metathesis of 1-pentene proceeds *via* transition state *(10)*, then an accounting of the production of the selective unsymmetric polyenes will require the participation of an "unfavored" transition state of type *(11)* [see Eq. (ac)].

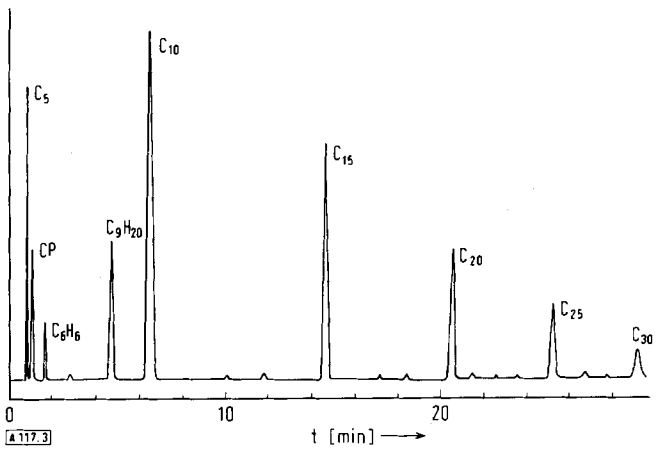


Fig. 3. Gas chromatogram of polyenes obtained in the 1-pentene + cyclopentene cross metathesis (after Ref. [18]).

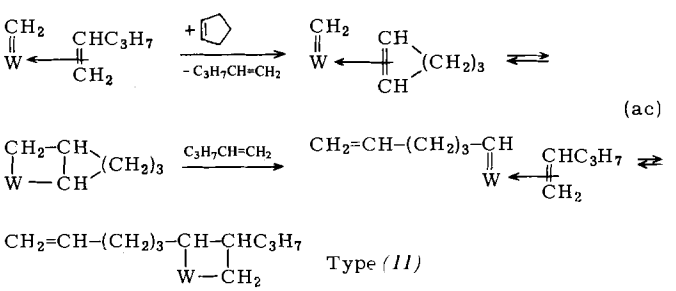


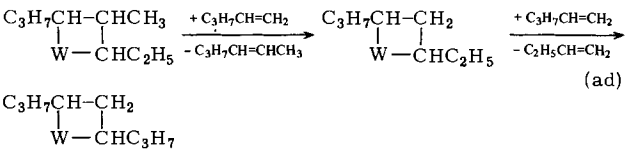
(ac)

[*] In reactions of cyclooctene with α-olefins. *Herisson* and *Chauvin* also found high selectivity at low conversions [11], although a lesser selectivity was observed by *Lal* and *Smith* at higher conversions of the cyclooctene [48].

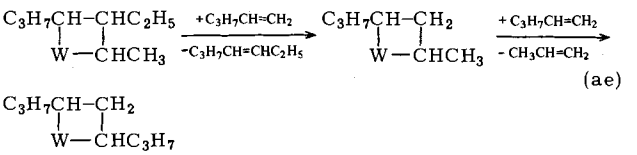
Since two types of carbenes are invoked here, the course of reaction in Eq. (ac) may be energetically less favorable than that of Eq. (ab), which invokes entirely monosubstituted carbenes throughout. However, the results do not unequivocally exclude either scheme.

Studies involving cross-reactions of ethylene with internal olefins might be of value, since types *(11)* and *(12)* would now be unavoidable during the formation of cross-products, and kinetic effects might become discernible.

Some insight into the influence of steric effects on the course of metathesis reactions was revealed in the reaction of 1-pentene with 2-pentene discussed previously. For a reaction sequence analogous to that in Eq. (ab), cross-metathesis would be preceded by formation of $C_3H_7CH{=}W(CH_3CH{=}CHC_2H_5)$, which is capable of yielding two isomeric metallocycle intermediates. These will subsequently afford either 2-hexene and 1-butene [Eq. (ad)] or 3-heptene and propylene [Eq. (ae)].



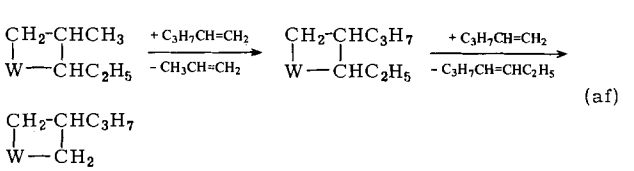
(ad)



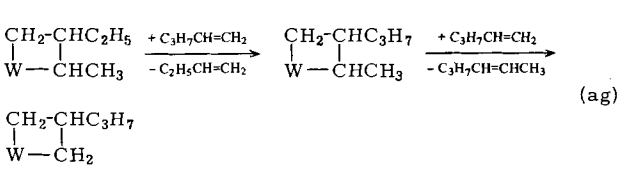
(ae)

The data in Table 2 suggests that, for the catalyst system $(C_2H_5)_2AlCl/WCl_6/ClC_2H_4OH$, reaction sequence (ad) is significantly favored over that of (ae). One must attribute this difference in ease of formation of the respective products to steric hindrance. On the basis of reaction scheme (ae), the implication appears to be that steric interactions involving substituents located on the β-carbon in the transient metallocycle ring are more severe than those for the α-carbon substituents, although the origin of this steric demand is not obvious.

Further evidence for preferential formation of a metallocycle where the least substituted carbon is preferentially the β-carbon was given recently by *Casey*[32, 44]. In model compound studies involving a tungsten compound which contained a bulky diarylcarbene ligand, transfer of an alkylidene unit from a reacting olefin resulted in highly selective transfer of the least substituted alkylidene unit, as described previously in Eq. (v). The authors pointed out that the new metal-carbene species which resulted after metathesis was preferentially that



(af)



(ag)

which possessed the most stable (*i.e.*, highly substituted) carbene.

In considering the steric effects observed in the reaction of 1-pentene with 2-pentene, one can also invoke a scheme which evolves from structure *(9)* [analogous to Eq. (ac)].

The product distribution in Table 2 now indicates pathway (ag) to predominate, and is consistent with the notion that the greatest steric interactions occur nearest the transition metal. Here, crowding due to adjacent ligands about the metal would appear to be a plausible source of these steric effects.

6. Conclusions

Despite numerous new and sophisticated experiments continually being brought to bear on questions regarding the chemistry of olefin metathesis, a number of challenging problems remain unsolved.

The concensus of recent publications is that a chain process, presumably involving a metal-carbene species, is operating, yet arguments in support of the pairwise scheme continue to rise Phoenix-like. Most recently, *Gassman*[45] presented new data to show that, with an appropriately chosen diolefin, quantitative interconversion of the diolefin to a cyclobutane structure could be accomplished using a typical olefin metathesis catalyst. Previously, the failure to observe cyclobutanes during metathesis reactions had been given as one argument against the plausibility of the "quasicyclobutane" transition state. It had been expected that, since two isolated double bonds are energetically comparable to a cyclobutane, both forms should be present under metathesis conditions according to the pairwise scheme. *Gassman* points out that the determining factor may be the relative energies of a pair of coordinated double bonds (substantial stabilization) *vs* a coordinated cyclobutane (very little stabilization), rather than the relative stabilities of the free species.

Mechanisms invoking other intermediates such as the tetrahedral trimethylene model (where all three methylenes are equally related to the metal), as described by *Haines* and *Leigh* in their recent excellent and comprehensive review[46], may also adequately explain metathesis reactions, and cannot be discounted. In fact, several authors have suggested that perhaps more than one pathway for metathesis may be possible, and in a given situation would be determined by the type of catalyst used.

Because of the tremendous variety in reagents which serve to generate metathesis-active species, reconciliation of a common mechanism for metathesis in these diverse systems represent a real challenge. Certainly, the catalysts appear quite tolerant of diversity in ligands about the transition metal, with the possibility of bimetallic species being suggested occassionally.

The origin of stereospecificity in metathesis reactions remains a mystery. Homogeneous catalysts rather universally show a weak *cis*-directing tendency in the reaction of *cis*-olefins. *Basset*[47] demonstrated that regardless of the catalyst used, *cis*-2-pentene afforded about 55 % *cis*-3-hexene and 60 % *cis*-2-butene initially. When cycloolefins are employed, however, wide variations in polymer structure are known to occur, depending upon the catalyst used. Apparently the growing polymer chain exerts a pronounced influence on the stereospecificity of the metathesis process. This phenomenon may be due to multiple coordination of the polymer chain, which cannot occur in the reaction of acyclic olefins.

Chemotherapy of Virus Diseases

By Guy D. Diana and Francis Pancic[*]

The purpose of this review is to provide an overview of current screening methodology and major advances in the area of viral chemotherapy. This presentation will be limited to those drugs which are currently in use and those which having shown activity against major human pathogenic viruses are now being evaluated in man.

1. Introduction

Over the past several years, antiviral chemotherapy has presented a major challenge to medical science. Although numerous antiviral compounds have been reported from experimental screening programs, only a few have been studied clinically and even fewer have become commercially available drugs.

The need for a broad spectrum antiviral agent is pressing, but it would appear that the possibility of finding such a drug is rather remote. Most currently available drugs or those in clinical trials are effective against only specific viruses and, in some cases, against only one particular strain in a group of viruses. Despite these problems, the search for effective antivirals is continuing.

The mechanism of viral replication suggests several points of attack for selective inhibition. The structure of the virus consists of an inner core of nucleic acid surrounded by a protein coat. Viral replication can only take place inside the host cell where the virus uncoats and enters an eclipse phase. This is followed by the replication stage where new nucleic acid is synthesized, and coated with protein, at which point the new virus is released from the cell. An antiviral agent may work directly on the virus particle itself, prevent entry of the virus into the host cell, interfere with the uncoating process, inhibit viral replication, or interfere with the synthesis of the protein coat.

Viral chemotherapy is a quest for selective toxicity. A drug which interferes with viral DNA, RNA, or protein synthesis quite often affects analogous elements of the host cell as well. The requirement of achieving selective toxicity complicates the search for new antiviral agents by the currently available screening methods.

Although many viral diseases such as the common cold (rhinovirus) are self-limiting with a low mortality and high morbidity, they cause much discomfort to the individual and represent millions of lost hours with serious economic repercussions. A drug which would prevent, cure, or shorten the duration of these illnesses would be welcomed.

50 to 75 % of the adult population throughout the world suffers from some form of mucocutaneous lesions produced by herpes virus[1]. In addition, the same group of viruses are responsible for more serious illnesses such as herpetic encephalitis and keratoconjunctivitis.

The incidence of herpes progenitalis in man has increased significantly in recent years and may be considered as one of the most common types of venereal disease.

2. Screening Methodology

Several methods are available for screening compounds *in vitro* for antiviral activity, one of which is described in this review.

Since viruses replicate only in living cells, it is necessary to propagate human or animal tissue cells *in vitro* which will be a suitable host for specific viruses. Such a system of growing and propagating cells *in vitro* is known as cell or tissue culture. Primary tissue cultures are monolayers of dispersed cells which are derived from a freshly removed organ and grown in a sterile synthetic nutrient medium containing a complex mixture of amino acids, inorganic salts and often animal blood serum. Cells grow attached to the surface of a sterile glass or plastic vessel.

When the cells from a primary culture are adapted by numerous successive passages to grow indefinitely *in vitro*, they are referred to as cell strains or continuous cell lines. Many such cell strains and lines have been propagated for years in various laboratories, and an initial screening of potential antiviral drugs is commonly carried out in such systems.

When the virus is introduced into a monolayer of susceptible tissue culture cells, it becomes intracellular, replicates as described previously, and proceeds to destroy the cells. This cellular destruction is observed microscopically and is termed the "cytopathic effect" (CPE).

The addition of potentially active antiviral substances shortly after the virus is allowed to adsorb onto the cells may prevent virus replication and inhibit viral CPE. Any compound indicating activity against a given virus is then further examined *in vitro* to determine whether the activity is limited or has broad antiviral potential.

Active compounds are then evaluated in an *in vivo* model to confirm activity. For the *in vivo* evaluation, numerous animal models are available. For example, influenza viruses readily grow in the respiratory tract of mice or ferrets. Herpesvirus grows in various organs of rabbits, guinea pigs, mice, *etc.*

Local or systemic infections can often be produced and various parameters are used to evaluate efficacy and potency; survival of the animal, reduction of the severity of the symptoms, and titer of the virus in treated *versus* placebo animals are the most common criteria.

Sterling-Winthrop Research Institute
Rensselaer, New York 12144 (USA)

The animal experiment as well as the mode of therapy must be designed in such a way to mimic the human condition as closely as possible.

3. The Current Status of Antiviral Chemotherapy in Man

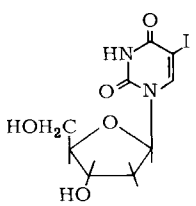
3.1. Herpesvirus

One of the most ubiquitous viral agents in man is Herpes simplex (type 1 and 2), which causes a variety of clinical conditions ranging from the familiar fever blister (herpes labialis) to life-threatening situations arising from herpes encephalitis. The virus usually establishes itself in many sites of the body such as the mouth, genitals, skin, eyes, and nerve tissue and may be reactivated from its latent state after the host is stressed by such things as exposure to sunlight, physical stress, menstrual cycle, or therapy which suppresses the immune system.

3.1.1. 5-Iodo-2'-deoxyuridine (IUDR)

Although herpetic keratoconjunctivitis is not as prevalent as herpes labialis, it is the most crippling disease of the eye and one of the major causes of blindness in the USA. Once present in an individual the disease is hard to eradicate. Relapses of the infection are common with progressively increased ocular damage resulting.

One of the first successful antiviral agents that became a useful drug for the treatment of herpetic keratitis is 5-iodo-2'-deoxyuridine *(1)*, the synthesis of which was first reported by *Prusoff*[2], who studied its effect on microbial growth.



(1), IUDR

It was also found that IUDR reversibly inhibited the cellular utilization of thymine-containing precursors of DNA-thymine. *Herrmann*[3] examined the effect of IUDR on the plaque formation by vaccinia and Herpes simplex viruses. In this test IUDR proved to be a potent viral inhibitor. The corresponding bromo and fluoro homologs were found to be inactive. IUDR was subsequently tested topically against Herpes simplex and vaccinia viruses by *Kaufman*[4], who found the drug to be very effective against herpetic corneal infections. Further clinical studies substantiated the efficacy of IUDR against herpes keratitis. Currently, it is the only commercially available drug for the treatment of this disease.

In the years since the introduction of IUDR, a number of limitations of the drug have been pointed out. It is active chiefly in superficial epithelial keratitis and is not very effective in deeper stromal infections[5]. IUDR inhibits viral DNA synthesis, but it also inhibits host cell DNA replication, with potential for cellular damage on prolonged administration. It does not eradicate the infection completely from the eye and recurrence is not uncommon. Resistant strains of virus have been isolated from patients who did not respond to IUDR treatment[6].

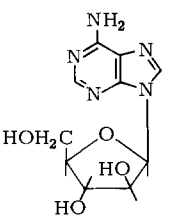
IUDR was ineffective against cutaneous herpes when applied as an ointment or in polyvinyl alcohol on lesions of the face[7]. Other studies, however, indicated that when IUDR was applied as a DMSO solution, the duration of the disease was shortened by 63 % when compared to untreated placebo controls[8].

Herpetic encephalitis is a viral encephalitis found in man, affecting children most often. Although IUDR was tried systemically in numerous cases, there is no clear evidence available that drug treatment significantly influenced the course of the disease[9]. Intravenous administration produced side effects such as thrombocytopenia, leucopenia, and bone marrow depression[10].

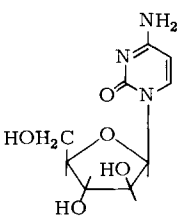
IUDR was reported effective against varicella-zoster (shingles) when it was applied topically as a 40 % DMSO solution[11].

3.1.2. Adenine Arabinoside (Ara-A) and Cytosine Arabinoside (Ara-C)

Two other nucleosides have shown promise as antiviral agents particularly against herpes keratitis—Ara-A *(2)* and Ara-C *(3)*. Ara-A was first synthesized by *Lee*[12] as a potential



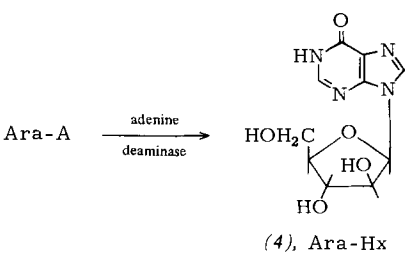
(2), Ara-A



(3), Ara-C

anticancer agent *via* its inhibition of DNA synthesis. Some antitumor activity was observed but it was not considered for this type of therapy. Ara-A was later found active *in vitro* against Herpes simplex virus and vaccinia virus[13], and against cytomegalovirus *in vitro*[14] and *in vivo*[15]. In addition to the broad spectrum of activity *in vitro* against DNA viruses, activity *in vivo* in hamsters was observed against herpes keratitis, intracerebrally innoculated Herpes simplex, and vaccinia virus in mice[16].

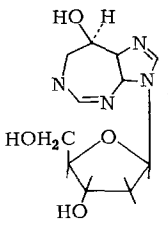
Ara-A is enzymatically converted to 1-β-D-arabinofuranosyl hypoxanthine (Ara-Hx) *(4)* by adenine deaminase. This metabolite has antiviral properties. Recently, it was reported that small quantities of an adenine deaminase inhibitor, Co-vidarabine *(5)*, when administered subcutaneously enhances the



(4), Ara-Hx

in vivo activity of Ara-A against Herpes simplex in mice by a factor of 10 as measured by the number of survivors[17]. No activity was demonstrated when this combination was given orally. Ara-A has exhibited activity against herpes keratitis in man[18].

In the treatment of epithelial keratitis, Ara-A is similar to IUDR with respect to the rapidity of activity. However, in deeper stromal infections, its effectiveness is less certain. Ara-A is recommended for use in patients sensitive or refractory to IUDR treatment or as an alternate to the latter in recurrent keratitis. The drug is reported to be less toxic than IUDR to the corneal epithelium, which is of major significance when the treatment must be extended for a prolonged period of time[19].



(5)

The topical efficacy of Ara-A in herpes progenitalis has not been as well documented as its activity in the eye. In a double blind study, topical administration of Ara-A did not modify the course of the disease in man[20].

In the cutaneous or genital treatment, it is apparent that the drug must be delivered in a suitable vehicle to reach the site of virus replication. Thus, the tissue penetration by the drug plays an essential part in its efficacy.

Ara-A is being evaluated in man in cases of herpetic encephalitis, varicella-zoster, cytomegalovirus disease as well as mucocutaneous herpetic infections. Although none of the studies have reported definitive efficacy of Ara-A treatment, there is some evidence of a favorable response. In systemic treatment, Ara-A must be administered intravenously as an infusion, requiring a large daily fluid intake[21]. Since Ara-A has been found to be teratogenic in rats and rabbits[22, 23], systemic treatment is limited to either life-threatening diseases or those that produce severe disability. At the moment there are 22 centers participating in double blind evaluations of the efficacy of Ara-A in systemic therapy[24].

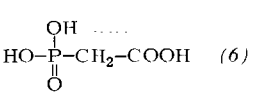
Ara-A[25–30] appears to inhibit DNA polymerase and/or ribonucleotide reductase. However, further studies are required to fully define the mode of action.

Ara-C *(3)* has a spectrum of antiviral activity similar to Ara-A. It is active *in vitro* against DNA viruses (herpesvirus, varicella-zoster, cytomegaloviruses and vaccinia virus)[31] and is clinically useful in the treatment of granulomatic leukemias.

The prospect that Ara-C might be useful in the treatment of disorders caused by varicella-zoster led to the first clinical trial with disseminated zoster[32], a serious disease that develops in immunologically suppressed patients. The condition is often manifest in organ transplant cases or in cancer patients undergoing drug chemotherapy. Unfortunately, Ara-C was not effective in the systemic treatment of this condition and toxicity was evident.

3.1.3. Disodium Phosphonoacetate

Phosphonoacetic acid *(6)*, which has been known for over 50 years, was discovered to have antiviral activity against herpes 1 and 2 when screened *in vitro*[33]. *In vivo* studies on corneal HSV infections in the rabbit, showed that 5% phosphonoacetic acid prepared as the disodium salt, suppressed the herpes keratitis in laboratory animals[34]. It has also been found effective in mice against herpes virus infections of the CNS when administered by intraperitoneal injections[35]. The drug appears to act by blocking DNA-dependent DNA polymerase[36, 37].



(6)

3.2. Human Respiratory Viruses

One of the most prevalent group of viruses are those that affect the upper and lower respiratory tract. Viruses in this class usually produce a low mortality but high morbidity, as for example, the common cold. Influenza, parainfluenza, rhinovirus, respiratory syncytial virus, and adenovirus are not, at the present time, under chemotherapeutic control. Influenza viruses invade both upper and lower respiratory tracts and are responsible for diseases of epidemic proportions. Potentially, influenza may lead to death particularly in individuals with impaired respiratory or circulatory functions. Respiratory syncytial virus which affects the lower respiratory system occurs mainly in the very young where 80% of the reported cases in one study were in the group aged 0—4 years[38]. It has been associated with bronchitis and pneumonia in this age group. Adenovirus also affects the very young but not to the extent of respiratory syncytial virus and manifests itself in a wide range of clinical symptoms varying from skin lesions to gastrointestinal infections and even CNS disease. It is often seen among military recruits, assuming epidemic proportions in army camps.

3.2.1. 1-Aminoadamantane Hydrochloride (Amantadine Hydrochloride)

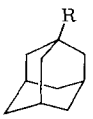
The discovery of the antiviral activity of 1-aminoadamantane *(7a)* against certain strains of influenza[39, 40] created considerable interest. Unfortunately, the spectrum of activity is rather narrow. Amantadine is active, particularly against the A2 strain of influenza, less effective against C strain, and inactive against the B strain.

In a mouse influenza model, where animals were infected intranasally with strain A2, oral or systemic administration of amantadine (25 to 50 mg/kg daily) prevented death in 90 to 100% of animals.

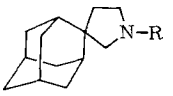
In man, the efficacy of amantadine was demonstrated in controlled clinical trials[41–43]. The drug is most effective when given prophylactically at the time of infection or in the early phase of the disease, where it was shown to be of value in preventing the A2 influenza infection. Therapeutically, it was reported to shorten the course of the disease, reduce the severity of clinical symptoms and shorten the time and duration of fever.

Rimantadine *(7b)*, a homologue of amantadine, in addition to being more active *in vitro* was reported to inhibit other RNA viruses such as rubella, rubeola, respiratory syncytial, and parainfluenza viruses *in vitro*[44].

Numerous modifications have been made in the adamantane structure. *Swallow*[45] found good activity against influenza A2 when an ionizable group was present [as in *(7c)* to *(7e)*] but that activity was considerably reduced with the introduction of a nonionizable group [as in *(7f)* and *(7g)*]. *Schlat-*



(7)



(8)

(7a), R = $NH_2 \cdot HCl$

(7b), R = $CH(CH_3)-NH_2 \cdot HCl$

(7c), R = NH_2

(7d), R = CH_2-NH_2

(7e), R = COOH

(7f), R = $NH-CO-CH_3$

(7g), R = $CO-NH_2$

(7h), R = $NH-CO-NH_2$

(7i), R = $NH-C(=NH)-NH_2$

(7j), R = $NH-C(=NH)-NH-C(=NH)-NH_2$

mann[46] reported that the urea, guanidine, and biguanide derivatives [*(7h)*, *(7i)*, and *(7j)*, respectively] all exhibited activity comparable to amantadine *in vitro*. However, *in vivo* the activity was diminished and undesirable side effects were observed.

In a series of adamantane spiro compounds *(8)*[47], the *N*-methyl derivative was three times more active *in vivo* against influenza A2 Japan and A2 Hong Kong than amantadine *(7a)*. A broader spectrum of activity was observed *in vitro* which included activity against Coxsackie A21 and Rhino 2 (HGP).

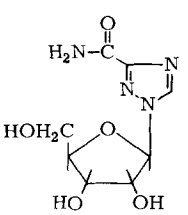
Amantadine is reported to exert its effect in the early phase of viral replication, affecting the penetration of virus into the host cell[48–50]. The virus appears to bind to the surface of the cells in the presence of the drug. The drug does not have virucidal activity outside the host cell.

Some side effects were noted with the administration of amantadine such as mild gastrointestinal irritation and some sporadic central nervous system reactions[51, 52].

Rimantadine *(7b)* as well as spiroadamantane *(8)*, R = CH_3, are currently being evaluated further.

3.2.2 Virazole (Ribavirin)

Virazole *(9)*, a broad spectrum antiviral agent, was synthesized by *Simon et al.*[53] and found effective against both DNA and RNA viruses[54, 55]. Most recently, virazole when administered to mice was 90% effective against influenza[56]. Mode of action studies suggested that the antiviral effect may be the result of an inhibition of GMP synthesis at the step involving the conversion of IMP to XMP.



(9), Virazole

Virazole is currently available in South America where it has undergone clinical trials against influenza A2[57], viral hepatitis[58], and varicella-zoster[59]. In the USA a study at John Wesley County Hospital in Los Angeles indicated that virazole was ineffective against hepatitis B[60].

3.3. Interferon

Interferon is a low molecular weight protein produced in the body as a defense against viral infection. Cellular synthesis of interferon is stimulated by either viral antigen or by a chemical inducer. It is detectable in the blood stream and peak levels appear within 24 hours after infection. In terms of combating viral infection, natural body defense mechanisms would appear to be the ideal system. As a result, a considerable amount of work has been done clinically to study the effect of endogenous interferon in peventing or curing viral infections.

Merigan et al.[61] reported a statistically significant effect when interferon was administered intranasally one day prior to and three days postinfection to volunteers infected with rhinovirus. Treatment prevented the development of clinical symptoms and eliminated virus shedding. Other strains of rhinovirus were not tested but *in vitro* studies would suggest that they might respond favorably to exogenous interferon. *Came et al.*[62] reported the sensitivity *in vitro* of 20 human rhinoviruses to human interferon from two sources, human leucocytes, and human foreskin fibroblasts. They found that the sensitivity of various strains varied depending on the type of tissue culture used to grow the virus as well as on the source of the interferon. In one type of tissue culture a strain of rhinovirus was inhibited with 20 to 40 units, while a different type of the rhinovirus was not inhibited with 5000 units. However, when both viruses were grown in a different type of tissue culture, both were inhibited with relatively low concentrations (0.5 to 5.0 units of interferon).

Interferon was reported to exhibit some effect on the onset of rubella infections[63] when administered systemically beginning 7 h before vaccination. Another study demonstrated the effect of interferon on herpes zoster[64] when administered intramuscularly for 5 days at doses of 100000 units. Finally, 50000—100000 units of interferon was administered topically four times daily to the eye of a patient with IUDR resistant herpetic keratitis and, within 3 days, healing was observed[65].

3.4. Interferon Inducers

3.4.1. Polynucleotides

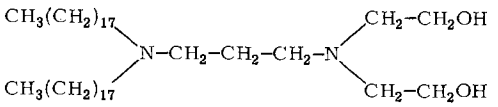
Poly(I,C) has been incorporated into a complex with poly-l-lysine and carboxymethyl cellulose, which is nuclease resistant, and presumably would improve the interferon induction capacity of this polynucleotide[66]. Promising results were obtained in monkeys against, among other viruses, yellow fever and rabies[67].

The stimulation of endogenous interferon by poly(I,C) has also been demonstrated *in vitro* and *in vivo*. The inducer was tested by intranasal administration in human volunteers starting one day prior to the infection by either rhinovirus type 13 or influenza A2[68]. A small but definite reduction of the clinical symptoms in the upper respiratory tract was recorded for drug treated patients. Some reduction of virus shedding was reported for rhinovirus but not for influenza virus.

Toxic effects of poly(I,C) appear to preclude its use in man other than for topical application[69–71].

3.4.2. *N,N*-Dioctadecyl-*N',N'*-bis(2-hydroxyethyl)-1,3-propanediamine

N,N-Dioctadecyl-*N',N'*-bis(2-hydroxyethyl)-1,3-propanediamine *(10)* was found active when administered to mice



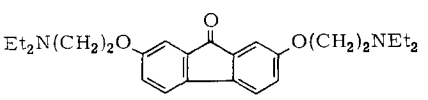
(10)

parenterally 6 to 12 h before infection. It provided protection against lethal infections of encephalomyocarditis and Semliki Forest virus and suppressed pock formation by vaccinia virus[72]. Clinical studies[73,74] substantiated the interferon induction previously seen in animal studies and further indicated that the drug provided protection against rhinovirus-induced disease. A double blind study using this propanediamine was conducted to determine the topical production of interferon by the local cells in the upper respiratory tract against rhinovirus infection. The inducer was administered intranasally starting one day prior to the virus infection. A high titer of interferon was reported in the nasal wash as compared to the placebo control, with decreased infectivity of the virus, reduced severity of the symptoms, and decreased virus shedding.

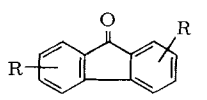
3.4.3. Tilorone

Probably one of the most interesting developments in the area of antiviral chemotherapy was the discovery that a non-polymeric compound 2,7-bis(2-diethylaminoethoxy)-9-fluorenone dihydrochloride *(11)* (tilorone hydrochloride) was able to induce high levels of interferon[75-80]. [Compound *(10)* was unknown at that time[72-74].]

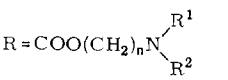
A large number of homologs of *(11)* were prepared in order to establish a structure-activity relationship[81-86], the most effective compounds being the bis(aminoalkyl) esters *(12)* derived from fluorenone. Strongly basic amine functions appeared necessary as well as a C_3 chain separating O from N in the ester side chains. A study by *Kaufman et al.* demonstrated that tilorone failed to elicit detectable interferon in humans. Furthermore, toxicity was seen when the compound was administered either orally or topically. *Kaufman* concluded that even at high topical doses, tilorone hydrochloride is neither safe nor effective[87].



(11)
Tilorone



(12)



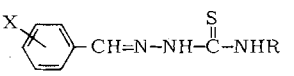
Preliminary clinical results confirm the efficacy of interferon as an antiviral agent. At the present time, however, several barriers stand in the way of its practical application. Interferon is species-specific which limits the source for clinical use. This leads to a second problem which is production of large quantities of human interferon. Technologically, at the present state of the art, it is not feasible to produce interferon on a commercial scale. Finally, the instability of interferon in body fluids requires doses which are probably well in excess of the effective level.

The use of interferon inducers, while attractive in overview, presents problems of toxicity and/or pyrogenicity in man. For example, poly(I,C) is able to reduce the severity of experimentally produced rhinovirus infections when given intranasally but because of its inherent toxic properties, clinicians are proceeding cautiously in advocating its use as part of the antiviral armamentarium.

3.5. Miscellaneous Antiviral Agents

3.5.1. Thiosemicarbazones

The initial discovery that thiosemicarbazones possessed antiviral activity was made by *Hamre*[88-90] who observed a dramatic effect on mortality when benzaldehyde thiosemicarbazone *(13a)*, the *p*-acetamide homolog *(13b)*, and their *N*-isobutyl homologs *(13c)* and *(13d)* were administered to mice innoculated intranasally with vaccinia virus.



(13)

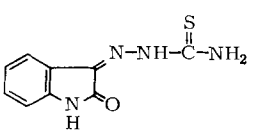
(13a), X = H, R = H

(13b), X = *p*-CH_3–C(=O)–NH, R = H

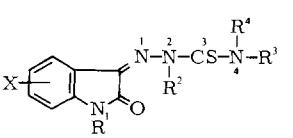
(13c), X = H, R = $CH(CH_3)C_2H_5$

(13d), X = *p*-CH_3–C(=O)–NH, R = $CH(CH_3)C_2H_5$

This development ultimately led to a study of other thiosemicarbazones by *Thompson et al.*[91] who observed a positive effect against this virus with isatin β-thiosemicarbazone *(14)*, when administered in a diet containing 0.6% of the drug.



(14)



(15)

A further study of the efficacy of this compound by *Bauer*[92] indicated that mice medicated subcutaneously with two daily doses of 125 mg/kg each exhibited an excellent survival rate. A structure-activity study was next undertaken by *Bauer*[93] to determine the effects on antiviral activity of the modification of various portions of the isatin β-thiosemicarbazone structure *(15)*. *Bauer* concluded that introduction of substituents into the aromatic ring resulted in reduction or loss of activity. Substitution on the ring nitrogen (R') produced a sharp rise in activity reaching a peak with R'=ethyl. Substitution on the 2 or 4 position of the semicarbazone moiety resulted in complete loss of activity.

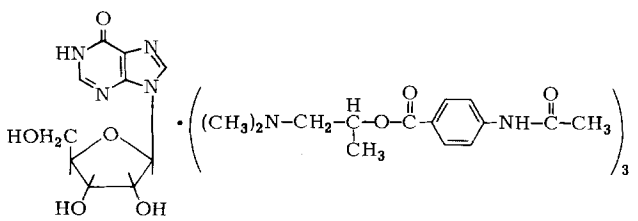
N-Methylisatin β-thiosemicarbazone (methisazone) *(15)*, R'=CH_3, R=H, was selected for further *in vivo* studies and was found effective against both DNA and some RNA viruses[94]. Clinically, the use of the drug has been confined to DNA viruses where it has shown a prophylactic effect

against smallpox[95]. If the disease is clinically apparent the drug is not effective; however, when administered during the incubation period, it diminishes the chance of developing the disease. Thus, in unprotected contacts, vaccination is indicated prior to the treatment with methisazone. Therapeutically, methisazone is effective in complications of vaccination such as viremia vaccination and vaccinia gangrenosa.

3.5.2. Immunostimulators

Although vaccines may be properly classed as immunostimulators, their activity is limited to antibody response to a specific organism as illustrated by smallpox, rubella, and other vaccines. Of late, studies have uncovered the ability of certain compounds to mobilize the body's total resistance mechanism and produce a higher level of resistance in response to an antigen than one would normally expect.

Inosiplex (isoprinosine) *(16)*, was found to be an immunostimulator and in the past several years has been evaluted as an antiviral agent.

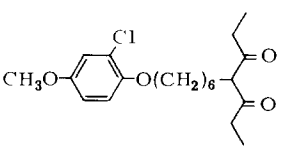


(16)

Thus far, the compound has not been significantly effective against influenza-A in mice[96]. A study in volunteers challenged with A2/Hong Kong influenza virus indicated no effect on the clinical symptoms but did produce a decrease in the amount of virus shed[97]. The administration of Inosiplex orally (1.5 mg qid for 9 days) caused a decrease in the incidence and severity of the illness with a concomitant increase in antibody titers[98]. Inosiplex has been found effective orally against herpes progenitalis, but it was unable to prevent the occurrence of relapse[99].

3.5.3. β-Diketones

Recently, *Diana* and *Pancic* have reported on the antiviral activity of a series of β-diketones[100]. One compound, 4-[6-(2-chloro-4-methoxyphenoxy)hexyl]-3,5-heptanedione *(17)* was



(17), Win 38,020

selected for extensive evaluation *in vitro* and was found effective against rhino- and herpesvirus types 1 and 2. The efficacy against herpesvirus was confirmed in animal models and clinical studies are planned.

4. Conclusions

The most notable advance in the past decade in the area of antiviral chemotherapy has been the development of drugs which are currently in limited clinical use. More is known concerning the structure of viruses and viral replication, making it possible to design compounds which might interfere with viral processes. The stigma attached to antiviral compounds as necessarily being toxic to mammalian cells may become as antiquated as is the assumption that any potential major antiviral agent must be a nucleoside.

It has been stated many times that the advances in antiviral chemotherapy can not be considered analogous to those of antimicrobial chemotherapy. Among the factors which differ between the two are the nature of the resulting diseases, the structure of the organism, and the breadth of the spectrum of activity of the currently available antiviral agents *versus* that of the antibiotics.

Although some experimental drugs are active orally, more success is being achieved with local application, even to the extent of experimentally administering drugs intranasally for upper respiratory infections. This type of therapy could, in fact, have the advantage of reducing drug-related toxicity.

A major factor contributing to the rapid progress in the area is the development of more sophisticated and realistic *in vivo* models. Hopefully, these new models will lead to new, and more effective drugs.

We wish to express our appreciation to Dr. Frederick Nachod, Dr. Joseph Collins, Dr. Paul Came, and Dr. Bernard Steinberg for their suggestions and comments in reviewing this manuscript.

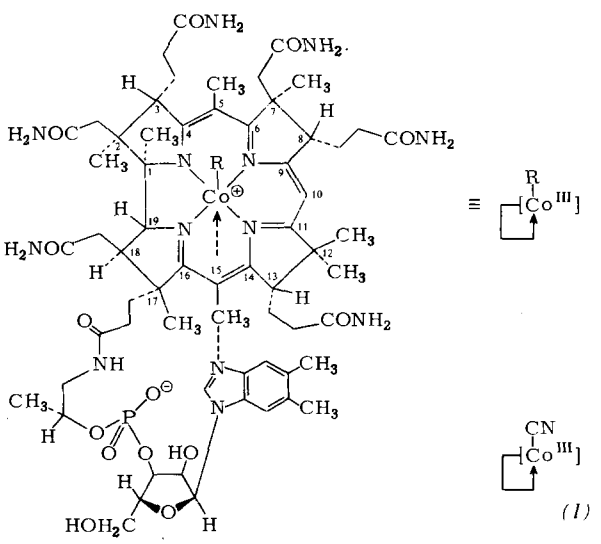
New Developments in the Field of Vitamin B_{12}: Reactions of the Cobalt Atom in Corrins and in Vitamin B_{12} Model Compounds

By G. N. Schrauzer[*]

Studies with vitamin B_{12} model compounds such as the cobaloximes provide a basis for the understanding of the mode of action of corrinoid coenzymes in enzymatic reactions. They also widen our knowledge of the properties and reactions of organocobalt compounds. The present article outlines the most important nonenzymatic reactions of cobalt in vitamin B_{12} and in model compounds of the cobaloxime type.

1. Introduction

The last extensive report on chemical and biochemical developments in the field of vitamin B_{12} (cyanocobalamin) was published in this Journal in 1964[1], shortly after *Crowfoot-Hodgkin* and *Lenhert* demonstrated that coenzyme B_{12} (5'-deoxy-5'-adenosylcobalamin) contains a direct cobalt-carbon bond[2]. This important result indicated for the first time that organometallic reactions occur in biological systems. In view of the complicated structure of vitamin B_{12} *(1)* (see Scheme 1) it furthermore appeared reasonable to assume that the macrocyclic ligand system modifies the properties of cobalt significantly, enabling it to form stable Co—C bonds, for at that time only few rather unstable compounds were known to have Co—C-σ bonds.



(1)

Scheme 1. Structure of an organocobalamin. In vitamin B_{12} (cyanocobalamin) *(1)* R=CN; in coenzyme B_{12} R=5'-deoxy-5'-adenosyl. The ligand system having carbon atoms 1 to 19 and the four central nitrogen atoms is called corrin; see *(9)* in Section 4.

In 1964 *Schrauzer* and *Kohnle*[3] reported that the reactions of the cobalt atom in vitamin B_{12} can be simulated with much simpler complexes. The cobalt(III) complexes of diacetyldioxime *(2)*[4], which were first prepared by *Tschugaev* in 1907, resemble vitamin B_{12} so closely in their chemical properties that they were introduced as coordination-chemical models of vitamin B_{12}, and were named the "cobaloximes" to stress their similarity to the cobalamins. In the ensuing years numerous papers appeared in the literature[4] which confirmed the validity of cobaloximes as vitamin B_{12} model compounds. Other cobalt chelates were studied (see, *e.g.* [4, 5]) and proposed as alternative models (Scheme 2), but it eventually became clear that the simple cobaloximes of type *(2)* simulate the reactions of vitamin B_{12} most closely, both qualitatively and quantitatively. Since they are easily prepared and the required reagents can be found in every inorganic laboratory, none of the other cobalt chelates studied to date have challenged

La Jolla, Calif. 92093 (USA)

the leading position of the cobaloximes in the field of vitamin B_{12} model chemistry. Even ten years ago it was reasonable to expect that studies with cobaloximes would play a role in the eventual elucidation of the mechanism of action of vitamin B_{12}- or coenzyme B_{12}-catalyzed enzymatic reactions[6]. There can be no doubt that this expectation has been fulfilled, even though more work remains to be done. This report outlines the most important properties and reactions of the cobalt atom in the cobalamins as well as in the cobaloximes. Current theories and hypotheses concerning biochemical mechanisms of reactions involving vitamin B_{12}-coenzymes will be discussed in a future paper.

2. Nomenclature

Extensive guidelines for the nomenclature of vitamin B_{12} derivatives exist which will not be described here (for details see, *e.g.*,[7]). The cobalamins (more precisely: cob(III)alamins) contain 5,6-dimethylbenzimidazole as an additional axial ligand, which is linked to the corrin system through a ribofuranosyl-phosphate chain (see Scheme 1). In the cobamides the axial ligand is missing, but the ribofuranosyl-phosphate moiety is still present. The latter may be removed by acid hydrolysis, yielding cobinamides. For our present purposes it is usually not necessary to distinguish cobalamins from cobamides or cobinamides, all will be simply represented by [Co]. The reduced forms of vitamin B_{12} are known as vitamin B_{12r} (cob(II)alamin) and vitamin B_{12s} (cob(I)alamin). The former is a derivative of divalent cobalt, the latter of monovalent cobalt. In cyanocobalamin (vitamin B_{12}) and hydroxocobalamin (vitamin B_{12a}), cobalt is trivalent [see eq. (a)]. We shall represent cobaloximes, which also contain trivalent cobalt, simply by (Co), reduced derivatives will be designated cobaloxime(II) or cobaloxime(I) [see eq. (b)]. All other modifications of the abbreviated nomenclature are obvious. The axial bases in cobaloxime complexes will often not be identified as such and simply represented by "B" (see Table 1).

Table 1. Survey of nomenclature of cobalamins and cobaloximes.

Name	Cobalamines	Cobamides	Cobinamides	Cobaloximes
Constituents	Cobalt(III) + Subst. corrin + Ribofuranosyl phosphate + 5,6-Dimethylbenzimidazole + R	Cobalt(III) + Subst. corrin + Ribofuranosyl phosphate	Cobalt(III) + Subst. corrin	Cobalt(III) + Subst. bis-(glyoxaldioxime) + Base + R
Abbreviations used				
	or	[Co^{III}] or [Co]	[Co^{III}] or [Co]	or
Modifications				
		[Co^{II}]	[Co^{II}]	(Co^{II})
		[Co^{I}]$^{\ominus}$	[Co^{I}]$^{\ominus}$	(Co^{I})$^{\ominus}$

3. Structure

The structure of the first organocobaloxime was determined by *Lenhert*[8] in 1967 and is shown in Figure 1. The observed in-plane Co—N bond distances are essentially identical to those observed in coenzyme B_{12}. The Co—C bond length is also

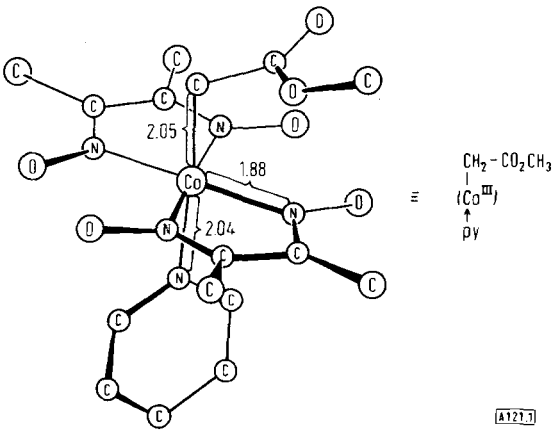

Fig. 1. Structure of methoxycarbonylmethyl(pyridine)cobaloxime (according to [8], distances in Å). Hydrogen atoms are not shown.

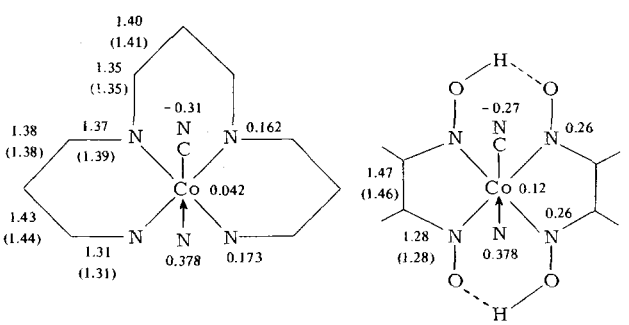
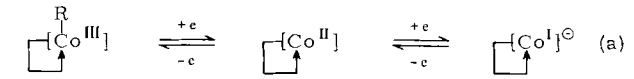
virtually the same, but the axial Co—N distance is somewhat shorter in the cobaloxime than in the cobalamin. We concluded from this that the cobalt in the cobaloximes might carry a slightly greater partial positive charge than in the cobalamins; this suggestion was substantiated by LCAO-MO calculations (see Scheme 3).



Scheme 3. Calculated (experimental) bond distances and π-electron charge distribution in the ground state of models of cyanocobalamin (left) and of the corresponding cobaloxime derivative (right) [16].

4. General Considerations

The biological activity of vitamin B_{12} coenzymes must undoubtedly be associated with the presence of cobalt, whose oxidation-reduction potentials are modified by incorporation into the corrin system. It can now exist not only as a di- and trivalent, but also as a monovalent entity [eq. (a)][11].

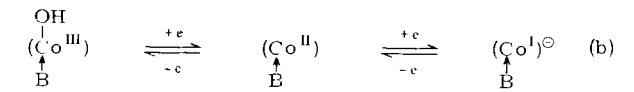


Hydroxo-cobalamin
Vitamin B_{12a}
purple

Vitamin B_{12r}
brown

Vitamin B_{12s}
blue-green

The cobaloximes behave analogously [eq. (b)][9, 10]

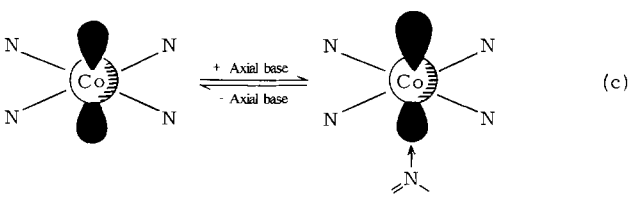


Hydroxo-cobaloxime
red-brown

Cobaloxime (II)
brown

Cobaloxime (I)
blue or blue-green

In the cobalt(I) derivatives, the metal is in a spin-paired d^8 configuration. Two electrons occupy the weakly antibonding $3d_{z^2}$ orbital, and the resulting electron distribution is responsible for the high nucleophilic reactivity of cobalt(I)[11, 12]. Cobalt(I) in the cobaloximes interacts with bases, giving rise to changes in the optical absorption spectrum and chemical reactivity. There is evidence that one molecule of the base interacts with cobalt(I) in the axial position. This changes the electron-distribution of the d_{z^2} orbital as shown in eq. (c). "Hard" bases such as OH^- increase the electron density on cobalt, unsaturated nitrogen bases lower the elec-



(c)

tron density through d_π-p_π interactions. The latter effect leads to a slight diminution of the nucleophilic reactivity. The position of vitamin B_{12s} and of cobalt(I) derivatives of model compounds in *Pearson*'s Nucleophilicity Scale[13] is shown in Table 2. It may be seen that the cobalt(I) derivatives are some of the most powerful nucleophiles known and for this reason have been called "supernucleophiles". Although certain cobalt(I) complexes are apparently even more nucleophilic than vitamin B_{12s} (cob(I)alamin), the latter is presumably the most powerful nucleophile of Nature, especially since it can be readily generated in the physiological pH range. The cobalt(I)-porphyrins, on the other hand, are capable of existence only in nonaqueous media, *e.g.* pyridine, and decompose in water spontaneously with evolution of hydrogen. Vitamin B_{12s} and cobaloximes(I) decompose in neutral or weakly alkaline solutions (pH 10) as well [(eq. (d)], but the rates are comparatively slow.

Table 2. Pearson nucleophilicities [13] (based on CH_3I) of a number of cobalt(I) derivatives and other nucleophiles.

Nucleophile [a]	$n_{Pearson}$
CH_3OH	0.00

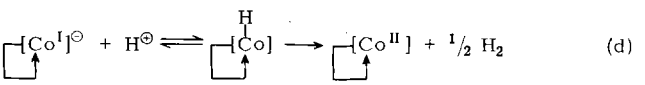
Cobaloxime(I) [H_2O or OH^-]	14.3
Cobinamide(I) [H_2O or OH^-]	14.4
Vitamin B_{12s}	14.4
Cobalt(I)-Salen [b]	*ca.* 14.6
Cobalt(I)-Porphyrins	*ca.* 14.6

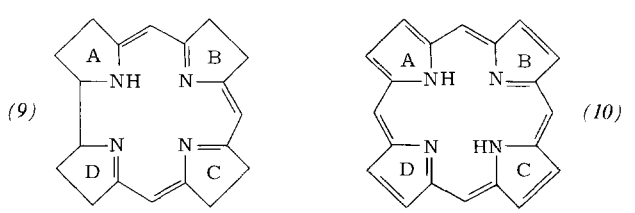
[a] Axial base components in square brackets.
[b] Salen is the tetradentate ligand in *(7)*.



Hydridocobalamin

The decomposition according to eq. (d) is accelerated by noble metal catalysts, *e.g.* Pt; vitamin B_{12s} is a metastable compound in the physiological pH range. The corresponding Brønsted acid hydridocobalamin is unstable in aqueous media. It is presumably a weak acid, since the corresponding hydridocobaloximes are also only weakly dissociated. Solutions of hydridocobalamin are obtained if vitamin B_{12a} (hydroxocob(III)alamin) is reduced with zinc in glacial acetic acid. Generated under these conditions, hydridocobalamin has sufficient life-time to be characterized by its reactions with a variety of substrates and its absorption spectrum. Its reactivity differs from that of vitamin B_{12s}, as will be outlined below (see Section 7).

Cobalt-porphyrins do not occur in Nature, or at least have never been isolated. We would not expect them to have any physiological activity if only because they cannot be reduced to, or maintained in, the Co^I state in aqueous solution. This fact may be used to explain some of the most striking differences between the structure of the corrin system *(9)* and that of the porphyrins *(10)*. Both are related biogenetically, but in *(9)* rings A and D are connected through a direct C—C bond. This causes a marked distortion of the coordination symmetry of the ligand and produces and odd-numbered π-electron system which exists only as a monoanion. The porphyrin ligand possesses an even number of constituent atoms, is highly symmetrical and in metal complexes is present as the dianion. These structural differences cause a weakening of the effective coordinating power of *(9)* relative to *(10)*, which in turn lowers the Co^{II}/Co^I reduction potential.



(9) *(10)*

The azomethine system in *(9)* is reasonably resistant to reducing agents and can be hydrogenated to colorless deriva-

tives only under relatively drastic conditions. The peripheral substituents protect the vitamin B_{12} chromophore against dehydrogenating attack. The propionamide side-chains endow the molecule with hydrophilic character, but the various substituents also serve as points of attachment of the vitamin to apoenzymes or transport proteins.

If it is assumed that vitamin B_{12} functions biologically at least in some cases as a nucleophile, it can be rationalized why the central metal must be cobalt. Of all other elements, only the rare element rhodium could replace cobalt in some of its functions. Rhodium analogs of vitamin B_{12}, *e.g.* a (5,6-dimethylbenzimidazolyl)rhodibamide, have recently become known[14], but initial tests indicate biological inactivity. Investigating the reactions of "rhodoximes", *i.e.* the Rh analogs of the cobaloximes, we predicted[15] that Rh-B_{12} derivatives should be either biologically inactive or less active than vitamin B_{12}, since rhodium(I) nucleophiles are not as reactive as the corresponding cobalt(I) derivatives. Organometallic derivatives of rhodoximes furthermore are as a rule more stable or chemically resistant than organocobaloximes, the same should be true for the respective rhodibamides relative to cobamides.

Why is the 6th coordination position of cobalt blocked with a base, such as 5,6-dimethylbenzimidazole? An at least partial answer to this question can be given if one considers that the Co—C bond in organocorrins is susceptible to reductive cleavage through axial attack. The axial base thus functions as a protecting group and assures that cobalt-bound organic substituents such as the 5′-deoxyadenosyl residue of the coenzyme is not lost due to nonspecific interactions with biogenic reductants.

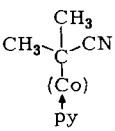
5. Electronic Structure and Bonding

The striking analogies between the chemical properties of the cobalt atom in vitamin B_{12} and in the cobaloximes are primarily a consequence of a fortuitous identity of the effective coordinating power of the four sp^2-hybridized nitrogen atoms in the otherwise unrelated ligand systems. LCAO-MO-calculations (Scheme 3)[16] confirmed this conclusion, since they revealed a nearly identical charge distribution in the atoms surrounding the cobalt atom. The eigenvalues and -vectors of the axial cobalt-ligand bonds were also found to be essentially the same. However, the calculations revealed that the partial positive charge on cobalt is somewhat higher in the cobaloximes than in vitamin B_{12}. This causes a firmer attachment of axial bases in the model compounds as compared to corrins and introduces some differences in reactivity. However, the overall orbital-stabilizing effects of the corrin ligand are by no means specifically dependent on details of the electronic structure of the azomethine system in the molecule, thus permitting their simulation with unrelated simpler ligands. Nevertheless, the original selection of biacetyldioxime complexes *(2)* of cobalt(III) as vitamin B_{12} models was in part fortunate, since the properties of the cobalt complexes depend on the nature of the peripheral dioxime substituents as well. For example, bis(benzildioximato)cobalt complexes are already less suitable for model work, if only because their Co(I) derivatives are less nucleophilic than vitamin B_{12s} or bis(biacetyldioximato)cobalt(I).

The systematic study of other cobalt chelates did not provide any better models of vitamin B_{12}, but furnished examples of nucleophiles with $n_{Pearson}$ values ranging between 10 and 15, *i.e.* supernucleophiles. Substitution of the oxime protons by BF_2 groups yielded complexes of type *(3)* which also proved to be much less nucleophilic than the parent cobaloxime(I) species. A number of Schiff base complexes of cobalt proved somewhat more nucleophilic, but offered no advantage over the cobaloximes. The chelates *(5)* and *(8)* were found to form dialkylcobalt derivatives[17, 18], in contrast to the behavior of cobaloximes, and thus can no longer be regarded as *bona fide* models of vitamin B_{12}. Pentacyanocobalt complexes are known to form organometallic derivatives and have therefore been temporarily regarded as vitamin B_{12} models[19].

6. Reactions of Cobalt(I) Supernucleophiles

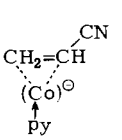
The cobalt(I) supernucleophiles react with conventional alkylating agents to yield organocobalt complexes, the reactions are nucleophilic substitutions and occur with inversion at the α-carbon atom[20]. Epoxides and certain cyclopropane derivatives also react with the cobalt(I) chelates. Stable organocobalt compounds are as a rule formed only if the cobalt-bound carbon is primary or secondary[21]. Tertiary derivatives are isolable only in rare instances. The cobaloxime *(11)* is sufficiently stable to be isolated, but the corresponding derivative of vitamin B_{12} cannot be obtained. This suggests steric hindrance by the corrin ligand. However, electronic effects influence the stabilities of the organocobalt complexes as well.

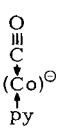


(11)

The cobalt(I) derivatives of cobaloximes form π complexes with activated olefins, for example, with acrylonitrile *(12)*; they also form adducts with carbon monoxide *(13)*. There is some evidence that vitamin B_{12s} also forms π complexes with activated olefins, but these appear to be less stable than the corresponding complexes with cobaloximes (I)[22].

(12)



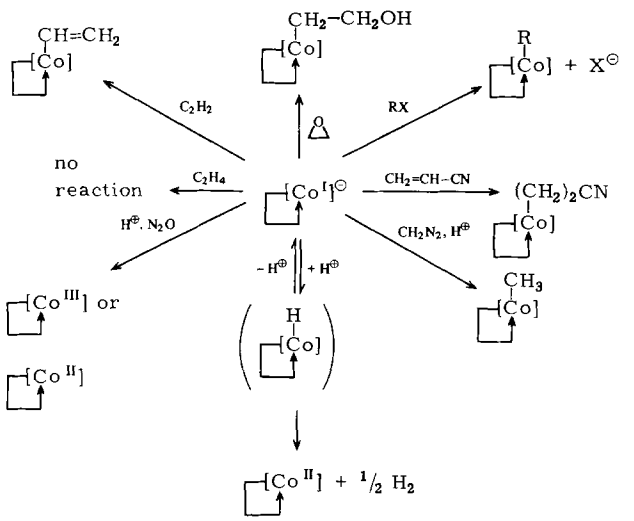


(13)

The π-complex bound axial ligands effectively block the cobalt(I) ion against nucleophilic attack by alkylating agents, although the complexes are labile, and the π-bound ligands can be readily removed, *i.e.* by passing argon through the solutions. The free cobalt(I) nucleophiles are all extremely oxygen-sensitive. They are also oxidized by N_2O[23]. The reaction with N_2O is of interest as it occurs only with cobalt(I), and not with cobalt(II) derivatives. The specific oxidizing action of N_2O was used as a means to detect the corrin nucleophile in certain enzymes, as will be outlined in a future paper. Typical reactions of vitamin B_{12s} (cob(I)alamin) are shown in Scheme 4.

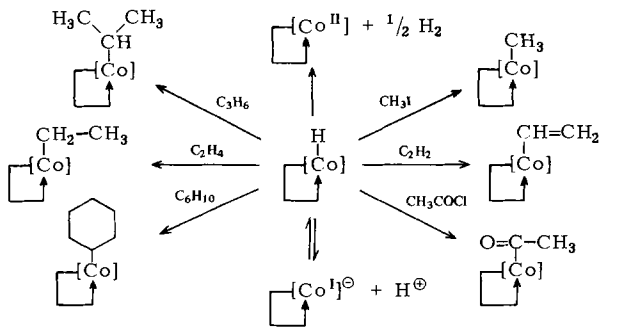
7. Hydridocobalamin and Hydridocobaloximes

It has already been mentioned in Section 4 that the Brønsted acid of vitamin B_{12s} (hydridocobalamin) is unstable in aqueous solution (Scheme 4). Most "hydridocobaloximes" are also unstable in water, especially if nitrogen bases occupy the 6th coordination position. With phosphanes as axial ligands, isolable hydridocobaloximes are formed[24]. Hydridocobaloximes are weak acids with pK_a-values in the order of 10^{-10}. Hydrido(tributylphosphane)cobaloxime is dark blue and is surprisingly soluble in nonpolar media, including *n*-hexane. The hydride is relatively unreactive in nonpolar aprotic solution. For example, no reaction occurs with methyl iodide, ethylene oxide, or ethyl acrylate in dry *n*-hexane.



Scheme 4. Some reactions of the vitamin B_{12} cobalt(I) supernucleophile (vitamin B_{12s}, cob(I)alamin). Cobaloximes(I) also undergo these reactions.

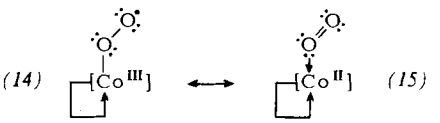
The reduction of hydroxocobalamin (vitamin B_{12a}) with zinc in glacial acetic acid affords solutions of hydridocobalamin[25]. Hydridocobalamin differs from vitamin B_{12s} in that it reacts with simple nonactivated olefins to yield alkycobalamins. With ethylene, ethylcobalamin is formed; with propylene, isopropylcobalamin. Cycloolefins such as norbornene, cyclooctene, and even cyclododecatriene react with hydridocorrins as well to yield secondary cycloalkyl cobalt derivatives which were previously not readily accessible. Some of the reactions of hydridocobalamin are summarized in Scheme 5. Further studies with this interesting compound are presently still in progress.



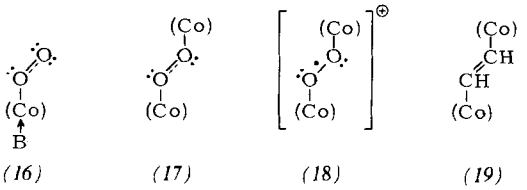
Scheme 5. Some reactions of hydridocobalamin (generated from vitamin B_{12a} by reduction with zinc in glacial acetic acid).

8. Electronic Structure and Reactivity of Cobalt(II) Derivatives

In vitamin B_{12r} and the cobalt(II) derivatives of the cobaloximes the cobalt ion is in a d^7 configuration, the unpaired electron occupies the $3d_{z^2}$ orbital. EPR measurements show that the axial ligand 5,6-dimethylbenzimidazole in vitamin B_{12r} is attached to cobalt[26,27]. Cobaloximes(II) form 1:1 and 1:2 adducts with a variety of bases[28]. The 1:1 adducts are diamagnetic in the solid state, therefore suggesting a dimeric structure with a Co—Co bond. A dimeric rhodoxime with a Rh—Rh bond is known[29]. Vitamin B_{12r} shows no tendency to dimerize, presumably for steric reasons, it also does not generally form adducts with two molecules of base. Vitamin B_{12r} and cobaloximes(II) react with oxygen to yield peroxo complexes. Peroxocobalamin[30] may be regarded as a charge-transfer type complex. Two limiting structures can be written, of which *(14)* has the greatest weight, as evidenced by EPR analysis. Vitamin B_{12r} is a nearly reversible oxygen carrier.



Cobaloximes(II) react with oxygen to yield three different compounds *(16)*—*(18)*. Peroxocobaloximes *(16)* in solution show EPR spectra which are virtually identical to those of peroxocorrins. However, cobaloximes(II) also form diamagnetic μ-peroxodimers of type *(17)*. The latter tend to convert into μ-peroxoradicals *(18)*, presumably by way of a disproportionation reaction. Cobaloximes(II) react with acetylene as well to yield the compound *(19)*[21]. They also react with alkylating agents under certain conditions[21]. On reaction with benzyl halides, benzylcobaloximes are formed[31], the reaction is assumed to be of a free-radical type. It is possible that the reaction of cobaloximes(II) with CCl_4 [eq. (e)][32] also involves homolytic C—Cl bond cleavage.



$$CCl_4 + 2\ (Co^{II}) \longrightarrow \underset{(Co)}{\overset{CCl_3}{|}} + \underset{(Co)}{\overset{Cl}{|}} \qquad (e)$$

Methyl radicals, generated in solution, have been shown to react with vitamin B_{12r} to yield methylcobalamin. Cobaloximes(II) act as catalysts in the reduction of cobaloximes(III) by carbon monoxide [eq. (f)[33]]. The reduction of hydroxocobalamin by carbon monoxide in aqueous solution is also catalyzed by vitamin B_{12r}[34].

Cobaloximes(II) disproportionate in alkaline solution to yield cobalt(III) and cobalt(I) derivatives; the corresponding reaction of vitamin B_{12r} occurs more slowly. Cobaloximes(II),

$$\overset{X}{\underset{|}{(Co^{III})}} + CO + 2\ OH^{\ominus} \xrightarrow[(Co^{II})]{} (Co^{I})^{\ominus} + CO_2 + H_2O + X^{\ominus} \quad (f)$$

but not vitamin B_{12r}, react with molecular hydrogen. The reduction of cobaloximes(III) by H_2 is catalyzed by cobaloximes(II) and yields the cobalt(I) nucleophiles [eq. (g)][21].

$$\overset{X}{\underset{|}{(Co^{III})}} + H_2 + 2\ OH^{\ominus} \xrightarrow[(Co^{II})]{} (Co^{I})^{\ominus} + 2\ H_2O + X^{\ominus} \quad (g)$$

Reaction according to eq. (g) proceeds readily even below room temperature at 1 atm of H_2 and in neutral or alkaline buffered aqueous media. This method of generating the cobalt(I) nucleophiles or hydridocobaloximes is useful for the synthesis of organocobalt complexes. Reacting cobaloximes(II) with H_2 in alkaline solutions yields the cobalt(I) nucleophiles, which react with *e.g.* acrylates to yield β-alkoxycarbonylethylcobaloximes. In neutral buffered solutions hydridocobaloximes are formed as such or *in-situ*; their reaction with acrylic esters affords the corresponding α-isomers[24].

$$(Co^{II}) + {}^1/_2\ H_2 \xrightarrow[\text{pH 10-11}]{} (Co^{I})^{\ominus} \quad (h)$$

$$\xrightarrow{+\ CH_2{=}CH{-}COOR + H^{\oplus}} \underset{(Co)}{CH_2{-}CH_2{-}COOR}$$

$$(Co^{II}) + {}^1/_2\ H_2 \xrightarrow[\text{pH 7-8}]{} \underset{(Co)}{H} \quad (i)$$

$$\xrightarrow{+\ CH_2{=}CH{-}COOR} \underset{(Co)}{H_3C{-}CH(COOR)}$$

With monosubstituted alkynes α- or β-substituted vinylcobaloximes are formed in analogy to eq. (h).

The reaction of cobaloximes(II) with H_2 in the presence of primary amines and formaldehyde gives rise to the formation of *N*-methylated amines *via* isolable aminomethylenecobaloximes *(20)* [eq. (j)][35].

$$CH_2{=}O + RNH_2 + (Co^{II}) + {}^1/_2\ H_2 \xrightarrow[-H_2O]{} \underset{(Co)}{CH_2{-}NHR} \quad (20) \quad (j)$$

$$\xrightarrow{+H_2} CH_3NHR + (Co^{I})^{\ominus} + H^{\oplus}$$

This reactions shows some analogy to *Wallach*'s aminomethylation method and can also be performed catalytically. With thiols in place of amines, the corresponding methylthio compounds are obtained, but in this case intermediate organocobaloximes analogous to *(20)* could not be isolated. A complex of type *(20)*, with $R = C_6H_5$, reacts with NO_2^- to yield a compound in which the $-CH_2-N(NO)-C_6H_5$ residue is attached to cobalt. The reductive cleavage of the Co—C bond in such complexes affords the carcinogenic *N*-methyl-*N*-nitrosoaniline[36].

9. Reactions of the Cobalt(III) Derivatives

The first organocobalt derivatives of corrins[1] and of cobaloximes[3] were synthesized by the reaction of the corresponding Co^{III} derivatives with organomagnesium halides. In aqueous solution, organocobalt complexes can be obtained from Co^{III} derivatives on reaction with carbanions, eq. (k) may be cited as an as yet unpublished example:

$$\overset{OH}{\underset{|}{(Co^{III})}} + [NC{-}\ddot{C}H{-}COOC_2H_5]^{\ominus} \longrightarrow \quad (k)$$

$$\underset{(Co)}{NC{-}CH(COOC_2H_5)} + OH^{\ominus}$$

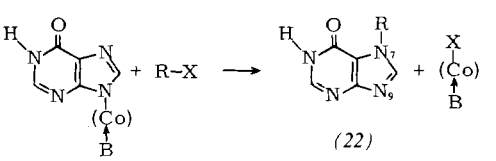
Vinyl ethers react with cobaloximes(III) as well as with hydroxocobalamin in the presence of bases to yield derivatives of formylmethylcobaloxime and -cobalamin, respectively [eq. (l)][37].

$$CH_2{=}CH{-}OR \xrightarrow{+\ OR^{\ominus}} \ddot{C}H_2{-}CH(OR)_2 \xrightarrow{+\ (Co^{III})} \underset{(Co)}{CH_2{-}CH(OR)_2} \quad (l)$$

(21)

The acetals *(21)* can be saponified to the corresponding formylmethylcobalt complexes under appropriate conditions. It is of interest that the acid-cleavage of diacetals and of hemiacetals of formylmethylcobalamin occurs with extensive Co—C bond cleavage. Formylmethylcobalamin was also prepared by the reaction of vitamin B_{12s} (cob(I)alamin) with bromoacetaldehyde. This compound is stable in neutral aqueous solution just as the corresponding cobaloxime derivative, both decompose in acidic media to yield acetaldehyde[38, 39].

Ligand-exchange reactions of cobaloximes(III) have been extensively investigated by many workers and will not be discussed in any detail[40]. A cobaloxime(III) was recently employed for the stereospecific synthesis of N^7-alkylated xanthine and hypoxanthine derivatives. The purine bases are first attached to the Co of the cobaloxime, affording N^9-coordinated adducts whose subsequent alkylation produces the N^7 substituted alkyl purines *(22)* as exemplified in eq. (m)[41].



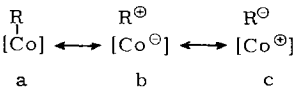
(22) (m)

It may be expected that cobaloximes will become useful reagents in synthetic organic chemistry. Recently, cobaloximes were employed as protecting groups in the synthesis of certain amino acid derivatives[42].

10. Properties and Reactions of the Organocobalt Compounds

Although organocobalt complexes of vitamin B_{12} and of model compounds are routinely described as cobalt(III) com-

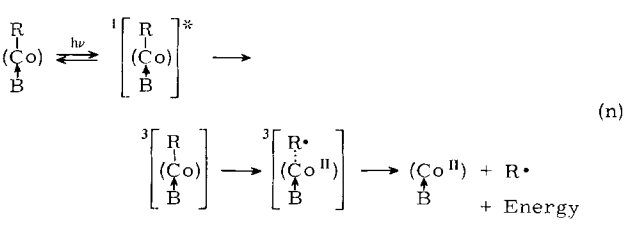
plexes, this formalism can lead to misunderstandings as it ignores the high covalency of the Co—C bonds. It is more realistic to describe the nature of the axial Co—C bonds in terms of the limiting structures a to c; structure a is the most important:



LCAO-MO calculations indicate that the interactions of the carbon sp^3 orbital with the $3d_{z^2}$, $4p_z$, and 4s orbitals of cobalt are mainly responsible for bond stabilization. The axial bonds in cobaloximes and cobalamins possess very similar energy and can be described as multicenter bonds[16]. The organic residue R is accordingly influenced through cobalt by the axial base B, and *vice versa*. These *trans* effects, or vertical conjugation effects, have indeed been detected experimentally. If the organic residue R is an sp^2- or sp-hybridized carbon atom, additional interactions of the π-carbon orbitals with the $3d_{xz}$ and $3d_{yz}$ orbitals of cobalt occur and lead to a stabilization of the axial bond. The axial bond MOs also interact to some extent with the orbitals of the horizontal ligand systems. The axial bonds thus are slightly delocalized over the whole molecule of the complex. The effects of the axial groups on the horizontal ligands are not very important chemically. They are, however, responsible for characteristic changes of the absorption spectra, particularly of vitamin B_{12} derivatives. The effects of variation of the axial substituents on the transition energies of cobalamins have been calculated and are in reasonable agreement with experimental data[7,43].

10.1. Photolysis and Thermolysis of Methylcobalt Complexes

In the absorption spectra of alkylcobaloximes, bands of weak to medium intensity are observed in the range between 350 and 470 nm ($\varepsilon = 1000$—3000). These have been assigned to transitions between axial bond MOs[16]. Irradiation of alkylcobaloximes with light of wavelengths between 500 and 350 nm causes an occupation of antibonding axial bond MOs, which induces the cleavage of the Co—C bond. During the excitation process, intermediate states of the complexes are generated which ultimately decompose into free radicals R• and cobaloxime(II) fragments [eq. (n)].



(n)

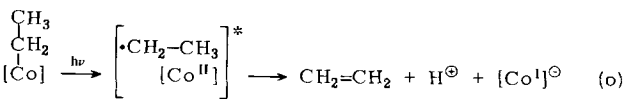
The subsequent reactions of the free radicals depend on their structure and reactivity. Methyl radicals recombine with the cobalt(II) fragments with high efficiency if the photolysis is performed under strictly anaerobic conditions in water. Accordingly, one finds that methylcobaloxime and methylcobalamin are rather resistant to photolysis under these conditions. Some of the methyl radicals diffuse out of the coordination sphere of cobalt and subsequently terminate either by dimerization to ethane, or by hydrogen abstraction, to methane. Photolysis of the same compounds in alcoholic solvents, particularly isopropanol, favors H-abstraction reactions and methane is formed virtually exclusively[44]. Some of the methyl radicals are reduced under the photolysis conditions. This explains, why CH_3D is formed in varying amounts if the methylcobalt complexes are photolyzed in D_2O as the solvent.

The photolysis of trideuteriomethyl-cobalamin and -cobaloxime, respectively, in H_2O produces ethane which consists to 89% of C_2D_6 and to 11% of CH_3CD_3. It appears that ligand-methyl groups are also cleaved off during the photolysis. If methylcobalt complexes are photolyzed in the presence of CN^- ions, methane becomes the main product. The axial coordination of cobalt by CN^- increases the electron density of cobalt; this apparently favors the reduction of methyl radicals. The aerobic photolysis of methyl cobalt complexes is complicated by radical-oxidation reactions. *Via* peroxide-type intermediates, formaldehyde is formed as one of the major products derived from the methyl radicals.

The methylcobalt complexes are stable thermally up to about 170 °C. They decompose at higher temperatures, during the decomposition methyl radicals are formed which terminate to yield methane and ethane as expected. This indicates that the Co—C bond undergoes homolytic cleavage during thermolysis. Photolysis of methylcobaloxime in the presence of vitamin B_{12r} gives rise to the formation of small amounts of methylcobalamin, the vitamin B_{12r} thus acts as a radical scavenger. Benzene similarly traps the methyl radicals produced on photolysis to yield toluene.

10.2. Photolysis and Thermolysis of Higher Alkylcobalt Complexes

During the photolysis of higher alkyl-cobaloximes or -cobalamins, radicals are also the primary products of Co—C bond cleavage. However, the subsequent reactions of the organic radicals are more complicated. Ethylcobalt complexes of vitamin B_{12} and of cobaloximes undergo photolysis to yield ethylene, the cobalt(II) fragments produced are reduced to cobalt(I) derivatives, which in turn decompose with release of hydrogen. The intermediate formation of the cobalt(I) species was clearly demonstrated[44–46]. The overall process can thus be expressed in terms of eq. (o).

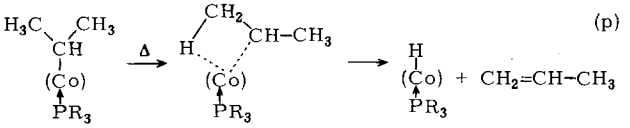


(o)

Higher alkylcobalt derivatives undergo photolysis in analogy to eq. (o), but if the reactions are carried out in alcoholic solvents instead of water alkanes are formed as well as olefins[44]. In the photolysis of alkylcobalt derivatives of salen *(7)*, alkanes are formed which arise from the dimerization of two alkyl radicals. This indicates that the behavior of alkyl radicals depends on the Co^{II}/Co^{I} reduction potential of the cobalt chelates.

Ethylene is the main product of the thermolysis of ethylcobalamin and -cobaloxime, respectively, but traces of ethane and of *n*-butane were also detected.

On aerobic photolysis of the higher alkylcobalt compounds aldehydes and other radical oxidation products are observed. Higher alkenylcobaloximes carrying a terminal C=C bond in the cobalt-bound organic residue produce alkenyl radicals on aerobic photolysis which undergo cyclization reactions prior to the termination step[47]. Alkylperoxo radicals which are formed during aerobic photolysis may also react with the cobaloxime(II) fragments to yield isolable alkylperoxocobalt complexes[47,48]. The quantum yields in typical photolysis reactions of alkylcobaloximes and -cobalamins have been determined[16,49]. Hydridocobaloximes are formed during the thermolysis of certain alkylcobaloximes. Isopropyl(tri-*n*-butylphosphane)cobaloxime decomposes on heating according to eq. (p), possibly *via* a cyclic transition state[24].

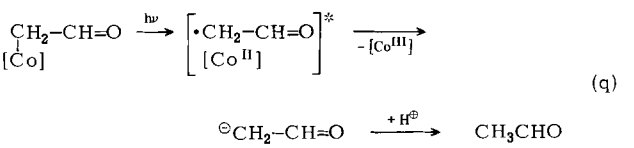


(p)

Another example of a hydridocobaloxime elimination reaction is described in ref. [50].

10.3. Photolysis and Thermolysis of Substituted Alkylcobalt Complexes

The behavior of substituted alkylcobalt complexes on photolysis and thermolysis is determined by the oxidation-reduction potential and constitution of the radicals which are formed during the initial process of Co—C bond cleavage. Inductively electron-attracting substituents in α-position give rise to radicals whose electron affinity may be sufficient to cause oxidation of the cobalt(II) fragments to the cobalt(III) species. The photolysis of formylmethylcobalamin is cited as a typical example [eq. (q)][38]. Acetaldehyde and hydroxocobalamin are the only detectable products, vitamin B_{12r} cannot be observed as it is apparently immediately oxidized to vitamin B_{12a}. Similarly, ethyl acetate is formed in the thermolysis of ethoxycarbonylmethylcobaloxime[21].



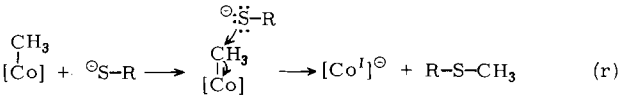
(q)

Substituents in the β-position relative to cobalt influence the photochemical behavior in several ways. Ethylene and acetaldehyde are produced during the photolysis of β-hydroxyethylcobaloxime, for example, indicating that both elimination and rearrangement reactions take place[51].

10.4. Chemical Cleavage of Cobalt-Carbon Bonds

The covalent Co—C bonds in the organocobalt complexes may be cleaved by nucleophilic as well as electrophilic attack, reductive cleavage reactions are also known. The reaction of *n*-alkylcobaloximes and -cobalamins with thiolate ions[52] have been studied in greater detail[53]. Kinetic measurements indicate that they proceed by an SN_2 mechanism [eq. (r)].

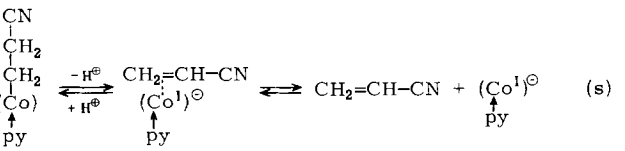
The methylcobaloxime derivatives also react with other nucleophiles, *e.g.* with Cl^-, Br^-, I^-, CN^-, $P(n\text{-}C_4H_9)_3$, $P(C_6H_5)_3$, $C_6H_5—NR^-$, Se^{2-}[54], and also with the cobalt(I) supernucleophiles themselves[54,55]. Higher alkylcobalt derivatives react with some of the nucleophiles as well, but frequently by way of β-elimination rather than nucleophilic substitution. Isopropyl(pyridine)cobaloxime reacts with tri-*n*-butylphosphane rapidly at 50 °C to yield propylene and hydri-



(r)

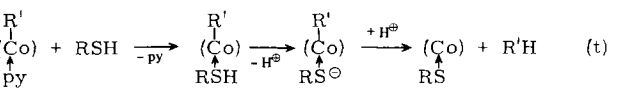
do(tri-*n*-butylphosphane)cobaloxime. Neopentyl(pyridine)cobaloxime, a compound which does not carry hydrogen in the β-position, does not undergo Co—C-bond cleavage, not even on heating with tributylphosphane to 100 °C; the only reaction which is observed is the displacement of the axially bound pyridine by the phosphane[54].

Electron-attracting substituents in the β-position increase the tendency of organocobalt complexes to undergo elimination reactions. β-Cyanoethylcobalamin[56] and the corresponding cobaloxime[21] are base-sensitive and decompose reversibly according to eq. (s)[22].



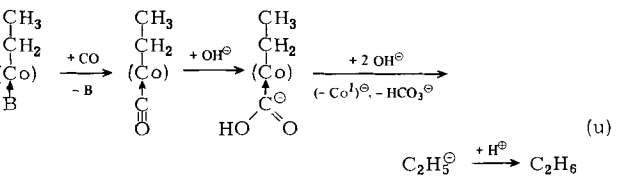
(s)

The reaction of organocobalt complexes with thiolate ions is strongly pH dependent. Nucleophilic transalkylation occurs in alkaline media at high RS^- concentrations. In neutral or weakly acidic solutions Co—C bonds are cleaved reductively according to eq. (t)[57].

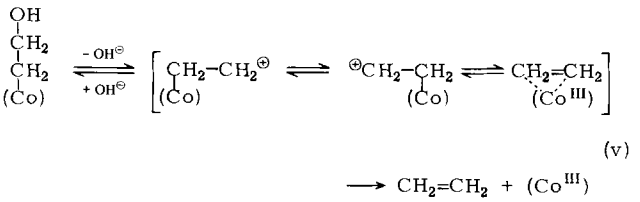


(t)

Reductive cleavage of Co—C bonds occurs preferentially with organocobalt complexes carrying electronegatively substituted alkyl residues. Reductive Co—C bond cleavage reactions were also observed with alkaline CO, stannite, and with dithionite[58]. The reaction with CO in alkali is exemplified for an ethylcobaloxime in eq. (u). The mechanism of Co—C bond cleavage by CO, particularly the *trans* attack in eq. (u), is supported by the observed formation of a CO adduct of methylcobaloxime in nonaqueous solvents[59].

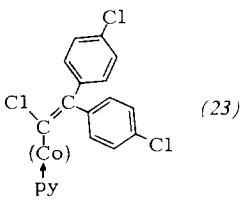


(u)



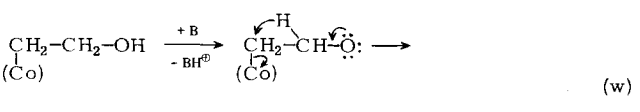
(v)

Cobaloximes and cobalamins with halogen in α-position of the cobalt-bound alkyl group have not yet been isolated. The reaction of cobaloximes(I) with 1,2-dichloroethane causes the spontaneous evolution of ethylene[61]; the presumed intermediate, 2-chloroethylcobaloxime, is evidently quite short lived. α-Haloalkylcobalt complexes are likewise sensitive to alkali. In the reaction of DDT with cobaloxime(I), a complex *(23)* is formed, indicating that not only substitution of Cl^- but also elimination of HCl took place[62,63].



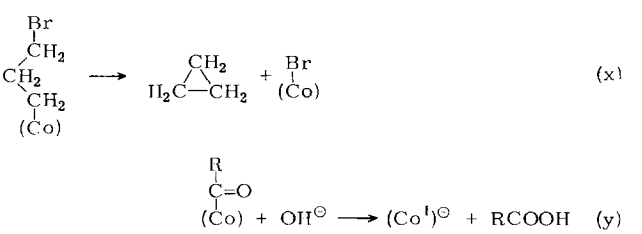
(23)

The base-induced cleavage of 2-hydroxyalkylcobalt complexes is of interest as it produces the cobalt(I) nucleophiles and aldehydes or ketones, respectively[51]. We assumed that reaction eq. (w) is a model of the enzymatic dehydration of ethylene glycol to acetaldehyde:



(w)

The substitution of hydrogen by halogen in γ-position affords stable organocobalt complexes. We found some time ago, however, that γ-bromopropylcobaloxime undergoes thermolysis with formation of cyclopropane [eq. (x)]. Acylcobalamins and -cobaloximes decompose in alkali according to eq. (y)[61,64].

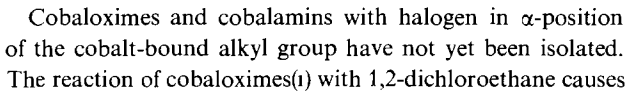


(x)

(y)

10.5. Reactions of Alkylcobalt Complexes with Metal Ions

Methylcobalamin, methylcobaloxime, and higher *n*-alkylcobalt derivatives of both, react with mercuric ion to yield alkylmercuric salts. The Co—C bond in methylcobalt complexes is cleaved by ions such as Au^{3+}, Tl^{3+}, Pt^{2+}, and Pd^{2+}, giving rise to methyl derivatives of metals which have been isolated in some cases[65,66]. The alkylcobalt derivatives of vitamin B_{12} and of cobaloximes thus behave in some respects just as typical organometallic compounds, although they should not be regarded as Nature's Grignard reagents. The cobalt-organic compounds are a rule much more resistant to solvolytic attack than simple organometallic compounds. To saponify *(24)* to the free acid *(25)* it is convenient to dissolve *(24)* in conc. H_2SO_4 followed by dilution with water. The Co—C bond remains intact even under these rather drastic conditions [Eq. (z)][21].

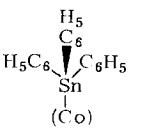


(z)

(24) *(25)*

10.6. Organometallic Derivatives

Cobaloximes with Co—Sn, Co—Ge, Co—Pb, Co—Si, Co—Sb, and Co—Bi bonds were synthesized in 1965 and described in greater detail in 1969[65]. The compound *(26)* is formed by the reaction of cobaloxime(I) with $(C_6H_5)_3SnCl$. It is stable to air and decomposes on reaction with NaOH to yield triphenyltin hydroxide and $(Co^I)^-$; this reaction is reversible. A homolytic cleavage of the Co—Sn bond in *(26)* occurs on irradiation with visible light, the triphenylstannylradical dimerizes to hexaphenyldistannane[67]. Attempts to synthesize analogous compounds of vitamin B_{12} have not yet been successful.



(26)

11. Concluding Remarks

In the present report some of the most important reactions of the cobalt atom in vitamin B_{12} and in cobaloximes have been summarized. Most of the reactions cited may not be surprising to the organic chemist as they are typical for the behavior of organometallic or nucleophilic agents. It is significant, however, that the organometallic derivatives of vitamin B_{12} and those of the model compounds possess both unusual stability *and* reactivity. Vitamin B_{12} appears as an ideally designed biocatalyst; almost all of its complex structural features are necessary to assure high catalytic efficiency and lifetime under enzymatic conditions. The fact that the reactions of cobalt in vitamin B_{12} can be simulated with much simpler compounds is quite surprising, but can be rationalized. Although new reactions of vitamin B_{12} may be discovered in the future, it appears highly probable that the supernucleophilic cobalt(I) derivatives are active forms of vitamin B_{12s} coenzymes.

The results described in the present report were accumulated during the past twelve years. I wish to express my gratitude to my past and present collaborators for their help and contributions.

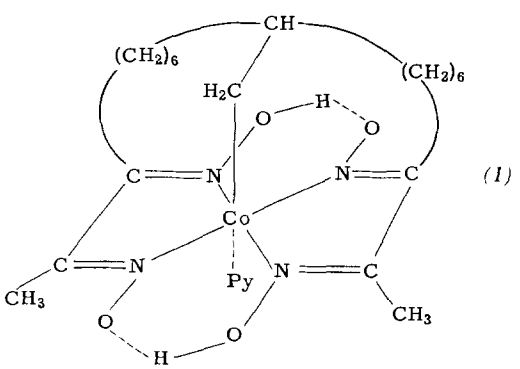
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis and Structure Determination of an Intramolecularly Alkylated Bridged Cobaloxime[**]

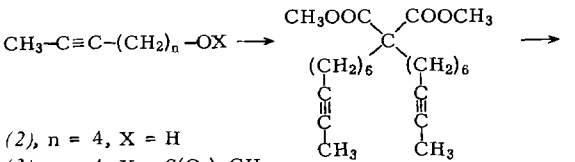
By *Helmut Flohr, Uwe M. Kempe, Wolfgang Pannhorst*, and *János Rétey*[*]

In continuation of our attempts[1,2] to imitate coenzyme B_{12}-dependent enzymatic rearrangements with model catalysts we have synthesized the bridged alkylcobaloxime *(1)*. The starting material employed was 5-heptyn-1-ol *(2)* which is obtainable either by condensation of lithium 1-propyn-1-ide with tetrahydropyranyl 4-bromobutyl ether or by fragmentation of 2,3-epoxy-2-methylcyclohexane tosylhydrazone[3] and subsequent reduction of the resulting aldehyde with $LiAlH_4$.



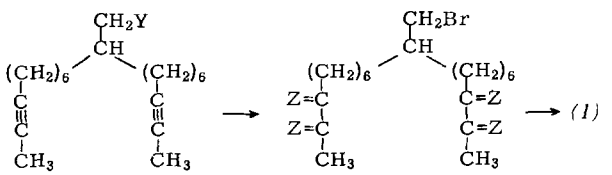
(1)

Compound *(2)* was extended by two C atoms *via* the mesylate *(3)* in a malonic ester synthesis to form 7-nonyn-1-ol *(4)*, the mesylate of which *(5)* could be used for double alkylation of dimethyl malonate. Upon hydrolysis, decarboxylation, and reduction, the bisalkylated malonic ester *(6)* afforded 2-(7-nonynyl)-9-undecyn-1-ol *(7)*, which was converted *via* the mesylate *(8)* into the bromomethyl derivative *(9)*. Ozonization of *(9)* at −18 °C in methanol[4] and subsequent treatment of the peroxide with dimethylsulfide gave the tetraketone *(10)* in 70 % yield. The crystalline tetraoxime *(11)* obtained therefrom was then treated with a stoichiometric amount of cobalt(II) chloride, twice the amount of pyridine, three equivalents of potassium hydroxide, and an excess of $NaBH_4$.



(2), n = 4, X = H
(3), n = 4, X = $S(O_2)$-CH_3
(4), n = 6, X = H
(5), n = 6, X = $S(O_2)$-CH_3

(6)



(7), Y = OH
(8), Y = O-$S(O_2)$-CH_3
(9), Y = Br

(10), Z = O
(11), Z = NOH

The product mixture contained six alkylated cobalt complexes (overall yield *ca.* 20 %) which were separated by thin-layer chromatography. The major product *(1)* [R_f = 0.39, hexane : ethyl acetate : pyridine = 20 : 80 : 1, Merck TLC plate, Kieselgel 60; NMR (270 MHz[5], $CDCl_3$): δ = 0.77—0.92 m; 0.92—1.46 m; 1.46—1.87 m; 1.87—2.05 m; 2.09 d; 2.14 d; 2.17 s (6H); 2.98 d, 3.03 d ($\sum$2H); 7.29 t (2H); 7.69 t (1H); 8.60 d (2H); 18 br. (1H); 18.82 s (1H); UV: λ_{max} = 461 nm (ε = 1190)] was subjected to X-ray diffractometry.

The platelet crystals having a monoclinic habit crystallize from oxydipropionitrile/dichloromethane in the space group $P2_1/c$ with $a = 9.275$, $b = 23.308$, $c = 12.908$ Å, $\beta = 114.48°$; $Z = 4$. Using a Picker diffractometer ($Mo_{K\alpha}$ radiation, graphite monochromator) 4625 symmetrically independent reflections were measured of which 2307 were classified as observed

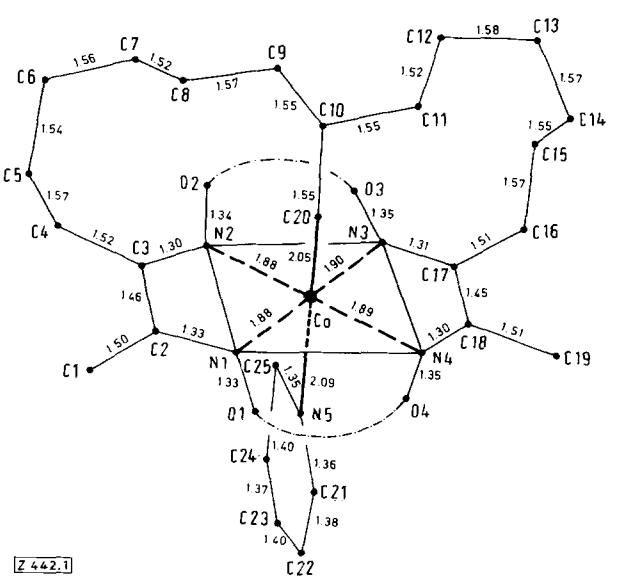


Fig. 1. Structure of the cobaloxime *(1)*. Lengths given in Å.

[**] Up to 1972 this work was supported at the ETH Zürich by the Schweizerischer Nationalfonds and from 1974 by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$[I_{obs.} \geq 3\sigma(I_{obs.})]$. The positions of the Co atoms were determined by a Patterson synthesis, and those of all the other atoms by difference Fourier synthesis. Refinement of the atomic coordinates and anisotropic temperature factor coefficients for the Co, O, N, and C atoms converged at $R = 0.073$.

The structure found for *(1)* (Fig. 1) does not possess a plane of symmetry; the molecules adopt a chiral conformation. The centrosymmetric unit cell contains four (two sets of two enantiomorphic) molecules. The tertiary H atom in the center of the bridge (on C10) is directed towards the planar ligand system. In this system, which includes the four nitrogen atoms (N1 to N4), the four oxygen atoms, and the eight C atoms (C1 to C4; C16 to C19) the individual atomic nuclei deviate by no more than 0.12 Å from the regression plane. The temperature factor coefficients determined indicate that the bridging C atoms (C3 to C17) are ordered in the crystal lattice and that the bridge is comparatively rigid. This contrasts with the structure of the bridged but not intramolecularly alkylated cobaloxime[6].

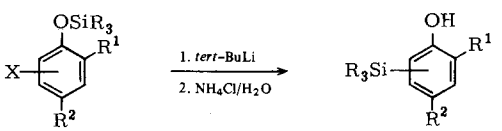
Anionic O→C Rearrangements in Trialkylsiloxybenzenes and Trialkylsiloxypyridines[**]

By *Gerhard Simchen* and *Jörg Pfletschinger*[*]

During studies of *C*-trialkylsilylation reactions[1] we have found that, after prior metalation with *tert*-butyllithium in tetrahydrofuran, bromine-substituted trialkylphenoxysilanes *(1)* rearrange under very mild conditions to trialkylsilylphenols *(2)* (Table 1). After the rearrangement the trialkylsilyl group occupies the position of the halogen.



(1) *(2)*

The reaction proceeds *via* trialkylsiloxy carbanions *(3)* which are in equilibrium with trialkylsilylphenoxide ions *(4)*. The equilibrium shifts in favor of the *C*-silylation products *(4)* with falling temperature.

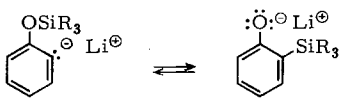
f	4-Br	Me	Me		25	12 h	80	45/0.01
g	4-Br	Et	Me		25	14 h	76	115/0.03

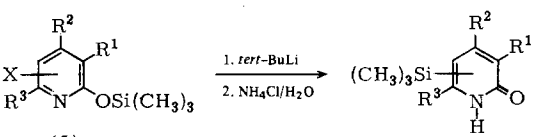
Crossover experiments revealed an intermolecular reaction course for 4-bromotrialkylphenoxysilanes such as *(1e)* and *(1g)*, but an intramolecular mechanism in the case of 2-bromotrialkylphenoxysilanes such as *(1b)* and *(1c)*. Thus a mixture of *(1e)* and *(1g)* gave 19.2% of *(2e)* and 18.3% of *(2g)* together with 25.6% of the crossover products 4-triethylsilylphenol and 18% of *(2f)*. A mixture of *(1b)* and *(1c)* led to 49.5% of *(2b)* and 45.8% of *(2c)*. (Yields determined by gas chromatography.)



(3) *(4)*

In the aliphatic series 1,2-anionic rearrangements with trialkylsilyl shifts are known for benzyl trialkylsilyl ethers[2], and 1,3-anionic rearrangements for hexamethyldisiloxane[3]. Mercuric iodide catalyzes the rearrangement of *O*-alkyl-*O*-trimethylsilylketene acetals to α-trimethylsilyl carboxylic esters[4].

While rearrangement experiments with naphthalene derivatives were not very transparent, the reaction can be extended without difficulty to 3-, 5-, and 6-bromo-2-trimethylsiloxypyridines *(5)* (Table 2).



(5) *(6)*

Table 2. Trimethylsilyl-2-pyridones *(6)* from *(5)*. $(CH_3)_3Si$ occupies the position of X. Me = CH_3, Ph = C_6H_5.

	X	R^1	R^2	R^3	Conditions T[°C]	Conditions t [h]	Yield [%]	M.p. [°C]

d	5-Br	H	H	Me	25	42	47	191—194
e	6-Br	H	Ph		25	22	69	210—212

General procedure:

tert-Butyllithium (20 mmol, as 15% solution in *n*-pentane) is added to *(1)* (10 mmol) in anhydrous tetrahydrofuran (50—100 ml) at −78°C with stirring under very pure nitrogen. After reaction under the conditions listed in Tables 1 and 2 the reaction mixture is hydrolyzed with 20% ammonium chloride solution (100 ml), the phases separated, the non-aqueous phase dried over sodium sulfate, the solvent removed under reduced pressure in a rotary evaporator, and the residue fractionated. In the reaction with pyridines the crude product

is not fractionated but instead dissolved in ether, filtered, and, after removal of the ether, recrystallized from acetonitrile or vacuum sublimed.

Inversion at Phosphorus in Sila-, Germa-, and Stannaphospholanes[**]

By *C. Couret, J. Escudié, J. Satgé*, and *G. Redoulès*[*]

We recently reported the synthesis of the first sila-, germa-, and stannaphospholanes *(1)*[1]. The 2,2-dimethyl-1-phenyl derivatives *(2)* of these compounds are particularly well suited for dynamic NMR investigations, since the diastereotopic methyl groups give rise to two very pronounced doublets in the NMR spectrum (Table 1).

[a] In [D_6]-acetone *vs.* tetramethylsilane as internal standard.
[b] Neat, *vs.* tetramethylsilane as internal standard.

We have determined the coalescence temperatures of compounds *(2)* and calculated the free energy of activation $\Delta G^{\neq}$ for inversion using the Eyring equation:

$$\Delta G^{\neq} = 4.57\, T_c \left(9.97 + \log \frac{T_c}{\Delta \nu}\right)$$

(T_c = coalescence temperature, $\Delta\nu$ = maximum difference between the chemical shifts of the methyl groups). The results are listed in Table 1. *Mislow et al.*[2] have determined a free activation energy of 36 kcal/mol for inversion in the metal-free phospholane *(3)*.

As can be seen from Table 1, there is an almost linear relationship between the free energy of activation of inversion at the phosphorus atom and the electronegativity[3] of the neighboring metal or carbon atoms. These results are in agreement with the observations by *Mislow et al.*[4] on the corresponding open-chain phosphanes.

Optically Active Bridgehead Derivatives of Trishomobarrelene and Trishomobullvalene[**]

By *Werner Spielmann* and *Armin de Meijere*[*]

Bridgehead derivatives of trishomobarrelene *(1a)*[1] and of trishomobullvalene *(2a)*[1a] as well as the unsubstituted hydrocarbon *(2a)* itself possess C_3 symmetry and are consequently chiral. Such optically active compounds are of interest in connection with the question whether, and if so to what extent, the propeller structure of the carbon skeleton makes a significant contribution to the chiroptical properties.

Optically active compounds *(1)* and *(2)* are accessible by resolution of the racemic carboxylic acids *(1b)* and *(2b)*, respectively. Resolution of the diastereomeric salts with

[**] Presented in part at the "Chemiedozententagung" (April 1975) at Düsseldorf and the Eleventh Euchem Bürgenstock Stereochemistry Conference (April/May 1975).—This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG, and Deutsche Shell-Chemie GmbH.

quinine afforded levorotatory material in both cases. Use of D-(+)-α-phenylethylamine led in the case of *(1b)* to enrichment of the (+)-enantiomer, but to enrichment of the (−)-enantiomer in the case of *(2b)*. Dextrorotatory carboxylic acid *(2b)* was obtained using L-(−)-α-phenylethylamine as the optically active auxiliary base.

The maximum rotation of *(1b)* and *(2b)* could be established for the [carbonyl-^{14}C]-carboxylic acids by means of the isotopic dilution method[2]. It could be estimated from the maximum rotations (Table 1) that in the most favorable case *(1b)* was obtained in 72 to 73% optical purity with D-(+)-α-phenylethylamine and *(2b)* in 98 to 99% optical purity with quinine.

[a] Relative direction of rotation based on the (+)-carboxylic acid; average values of several measurements at concentrations $c = 0.3-0.7$ g/100 ml.
[b] Measured at −50°C.

Starting from the optically active carboxylic acids it proved possible to prepare the optically active compounds *(1c)*—*(1f)* as well as *(2a)*, *(2c)*, and *(2d)* (Table 1). Thus the reaction of (+)-*(1b)* and (+)-*(2b)* with lead tetraacetate in the presence of *N*-chlorosuccinimide[3] gave the dextrorotatory bridgehead chlorides (+)-*(1c)* and (+)-*(2c)*, respectively. The bridgehead acetates (+)-*(1e)* and (+)-*(2e)*, of which only (+)-*(1e)* was isolated, were formed as by-products.

Reduction of the (+)-chlorides *(1c)* and *(2c)* with $LiAlD_4$ and $LiAlH_4$ furnished the optically active hydrocarbons [1-D]-trishomobarrelene (−)-*(1f)* and trishomobullvalene (+)-*(2a)*, respectively. Hydrolysis of the (+)-chlorides in aqueous dioxane gave the optically active alcohols (+)-*(1d)* and (+)-*(2d)*.

The exceptional stability of the bridgehead carbenium ions of trishomobarrelene and trishomobullvalene[4] prompted us to attempt generation of the free optically active cations *(1g)* and *(2g)*. On reaction of the chlorides (+)-*(1c)* and (+)-*(2c)* in dichloromethane with antimony pentafluoride at −78°C (cf. ref.[4b]) clear pale yellow solutions were obtained. The two (+)-chlorides afforded carbenium ion solutions displaying negative rotations with surprisingly high rotatory powers (cf. Table 1). The specific rotations of the solutions did not change within 1 to 2 h at −50°C; addition of water gave (+)-*(1d)* and (+)-*(2d)* from which (+)-*(1c)* and (+)-*(2c)* could be regenerated in unchanged optical purity by reaction with thionyl chloride and concentrated hydrochloric acid, respectively. Thus neither *(1g)* nor *(2g)* racemizes under these conditions, although this would be feasible by an intermolecular hydride exchange with the second bridgehead of the molecule in the case of *(1g)*. It appears that this process is not suppressed for steric reasons[5] but rather because intermediate formation of a 1,5-trishomobarrelenylene dication would be required.

The chiral skeletons of *(1)* and *(2)* each contain six chiral centers. Calculations with the aid of *Brewster*'s conformation dissymmetry model[6] permit prediction of the (all-*S*) configuration for the dextrorotatory derivatives *(1b)*—*(1d)*, *(2b)*—*(2d)*, and for (−)-*(1f)*[7]. Assuming that this model[6] correctly reproduces the direction of rotation of compounds *(1)* and *(2)* for a given configuration, a comparison of the calculated and experimental molar rotations becomes informative (Table 2).

Table 2. Calculated [6] and experimental molar rotations [°] of (2*S*,4*S*,6*S*,8*S*,9*S*,11*S*)-1-trishomobarrelene *(1)* and (2*S*,4*S*,8*S*,10*S*,11*S*,13*S*)-1-trishomobullvalene derivatives *(2)*. The direction of rotation is given relative to the (+)-carboxylic acids assuming them to possess the (all-*S*)-configuration.

	X	$[M]_{calc}$	$[M]_{exp}$	$[M]_{exp}-[M]_{calc}$
(1a)	H [a]	0	0	0
(1b)	CO_2H	+260	+238	− 22

(1d)	OH	+ 69	+113	+ 44
(1f)	D	− 4	− 1.8	+ 2.2
(2a)	H [b]	0	+201	+201
(2b)	CO_2H	+260	+503	+243
(2c)	Cl	+443	+562	+119
(2d)	OH	+ 69	+470	+401

[a] (2*S*,4*R*,6*R*,8*S*,9*S*,11*R*)-configuration.
[b] (2*S*,4*R*,8*R*,10*S*,11*S*,13*R*)-configuration.

It is striking that the values $[M]_{exp}-[M]_{calc}$ for *(2)* are all positive, while they are negative or only just positive for *(1)*. Thus it is suspected that, at least in the case of the trishomobullvalene system *(2)*, the chiral propeller structure of the carbon skeleton makes a significant contribution to the overall rotation. In particular, the pronounced rotation of the hydrocarbon *(2a)*—it contains three (*S*)- and three (*R*)-configurated chiral centers and is predicted by the model to display no rotation—could only be explained in this manner. Accordingly, *(2a)* and especially also the free cations *(1g)* and *(2g)* with their high rotatory powers are suitable test cases for advanced models of optical activity[8] and chirality functions[9].

Four Linearly Annelated Cyclobutane Rings: The Tetracyclo[4.4.0.0^{2,5}.0^{7,10}]decane System[**]

By *Hans-Dieter Martin* and *Mirko Hekman*[*]

We recently reported the synthesis[1] of pterodactyladiene *(1)*, a highly strained representative of the $(CH)_{10}$ isomers. In the present communication we now report:

a) The preparation and an unexpected thermal isomerization of pterodactylane *(3)*, the course of which has been established by isotopic labeling.

b) The elucidation of the mechanism of thermolysis of *(1)*.

c) The synthesis and thermolysis of the azo compounds *(2)* and *(4)*. Compound *(2)* provides an entry to the $(CH)_{10}$ energy surface which is distinct from *(1)* and permits a decision between the various reaction pathways proposed for *(1)*.

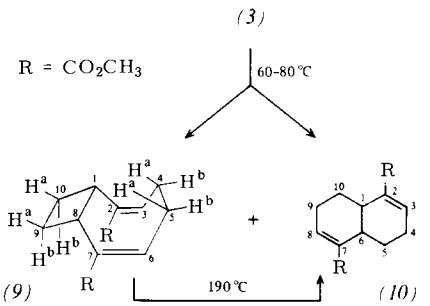
[*] Prof. Dr. H.-D. Martin and Dipl.-Ing. M. Hekman
Institut für Organische Chemie der Universität
Am Hubland, 8700 Würzburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Prof. Dr. *H. Schmid*, Zürich, and Dr. *D. Bellus*, Basel, for discussions, and to Prof. Dr. *J. Sauer*, Regensburg, for communication of unpublished results. A generous gift of COT from the Badische Anilin- und Sodafabrik AG is gratefully acknowledged. Small Rings, Part 18.—Part 17: *H.-D. Martin, S. Kagabu*, and *H.-J. Schiwek*, Tetrahedron Lett. *1975*, 3311.

The fact that *(1)* and *(2)* both give the same product *(7)* shows the first step of thermolysis of *(1)* to be rupture of the central strained bond (path A in ref. [1]). A bicyclo[6.2.0]-decatetraene *(6)* which is unstable under the reaction conditions has been proposed as the first intermediate *en route* from *(1)* to *(7)*. Its tetrahydro derivative *(9)*, which is no longer accessible to electrocyclic ring opening to form a cyclodecapentaene, should be isolable. The behavior of compound *(3)*, from which *(9)* could be formed thermally, therefore attracted our interest.

Thermolysis of pterodactylane *(3)*, m.p. 57—60 °C, prepared from *(1)* by hydrogenation (Pd/C in CH_3OH), in boiling CCl_4 gives not only *(9)* but also surprisingly compound *(10)* (ratio 1 : 1).

The structures *(9)* and *(10)* are based on spectral data, on the oxidative degradation of *(9)* with ozone or $KMnO_4/KIO_4$, which leads to succinic acid, and on the dehydrogenation of *(10)* with dichlorodicyanoquinone (DDQ) to dimethyl 1,5-naphthalenedicarboxylate.



(3)

R = CO_2CH_3

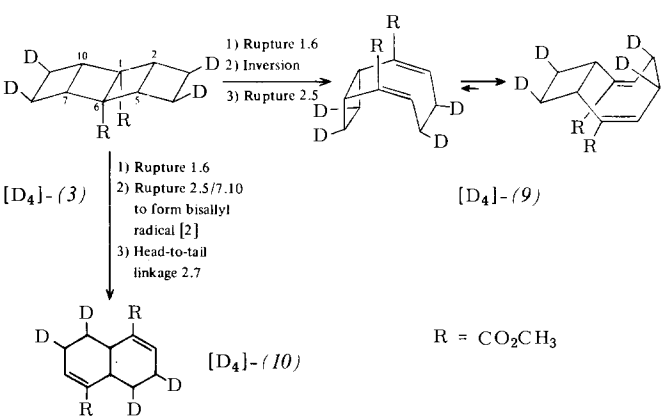
60-80 °C

(9) *(10)*

190 °C

The transformation of *(9)* to *(10)* only at temperatures of about 190 °C shows that *(10)* cannot be regarded as a product of *(9)* under the given reaction conditions (60—80 °C). Rather both *(9)* and *(10)* are formed directly from *(3)*.

The thermolysis of tetradeuteriated *(3)* furnishes evidence for the reorganization of the molecule and for the formation pathway of *(9)* and *(10)*. In $[D_4]$-*(9)* the deuterium occupies the positions 4a,5a,9a, and 10a, and in $[D_4]$-*(10)* positions 4, 5, 9, and 10. The site of deuteriation in *(3)* follows from the NMR spectra of *(3)* and $[D_4]$-*(3)* in the presence of a shift reagent.



1) Rupture 1.6
2) Inversion
3) Rupture 2.5

$[D_4]$-*(3)*

1) Rupture 1.6
2) Rupture 2.5/7.10 to form bisallyl radical [2]
3) Head-to-tail linkage 2.7

$[D_4]$-*(9)*

$[D_4]$-*(10)*

R = CO_2CH_3

The azo compound *(4)*, m.p. 160—162 °C, prepared by diimide reduction of *(2)* (potassium azodicarboxylate and acetic acid at 0 °C) affords *(9)* as major product accompanied by only about 5% of *(10)* on thermolysis. This product distribution is in accord with results obtained for other azo compounds[3].

The kinetic parameters of *(1)*, *(3)*, *(11)*, *(12)*, and *(13)* (Table 1) confirm the uniform mechanism, which is initiated

by cleavage of the central σ-bond; comparison with *(12)* and *(13)* rules out a primary cyclobutene ring opening as (proposed[1]) alternative mechanism in the case of *(1)*. Annelated cyclobutane or cyclobutene rings such as those in *(3)* and *(1)* therefore have practically no influence on the Arrhenius parameters of *(11)*.

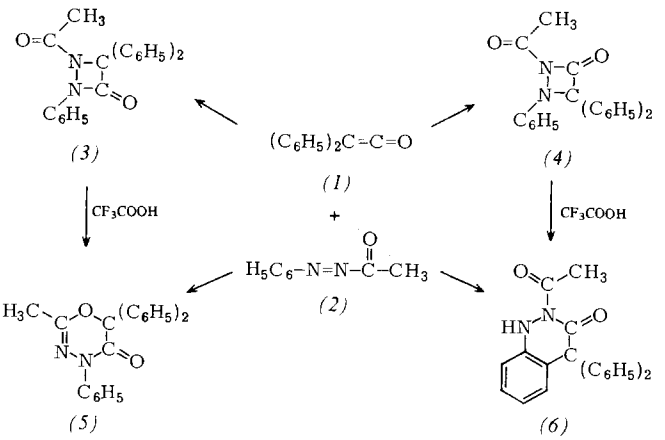
Competing Cycloadditions in the Reaction of Acetylazobenzene with Diphenylketene

By *Sven Sommer*[*]

Among the few cycloadditions undergone by aryl azo compounds of the type Ar—N=N—X [X = Ar, $CH(CH_3)_2$, $N(CH_3)_2$, $CO_2C_2H_5$, C≡N] are to be found the reactions with diphenylketene *(1)*[1-3]. Only [2+2] cycloadducts (1,2-diazetidinones) have so far been isolated as reaction products. In contrast, the reaction of acetylazobenzene *(2)* with *(1)* (1:1 in benzene at room temperature) leads to the two [2+2] cycloadducts *(3)* and *(4)*, to a [4+2] cycloadduct *(5)*, and to a product *(6)* formally arising by [4+2] cycloaddition and subsequent 1,3-H shift.

No mutual interconversion of the products under the reaction conditions could be detected. It is remarkable that in



spite of the considerable difference in electronic character of the substituents attached to the azo group both regioisomers *(3)* and *(4)* should be formed. In contrast, the comparable reactions of arylazonitriles[3] and ethyl benzeneazocarboxylate[2, 4] with *(1)* were found to give only one 1,2-diazetidinone of type *(3)* in each case.

The exothermic reaction of *(1)* with *(2)* is complete within *ca.* 1 h; the ^{1}H-NMR spectrum of the crude solution shows it to proceed quantitatively. Compounds *(3)* and *(4)* are isolated by fractional crystallization from methanol. Pure *(5)* and *(6)* can be obtained by rearrangement of *(3)*[5] and *(4)*, respectively, under the influence of trifluoroacetic acid. Crystalline *(5)* and *(6)* are also obtained on seeding the reaction solution after extensive removal of *(3)* and *(4)*. The structures of *(3)* and *(5)* have been proved by independent syntheses[2, 6], and the structures of *(4)* and *(6)* by IR, ^{1}H-NMR, and ^{13}C-NMR spectra (Table 1).

Table 1. Cycloadducts from diphenylketene *(1)* and acetylazobenzene *(2)*. All compounds gave correct CHN analyses. The product composition was determined from the integrals of the methyl signals in the ^{1}H-NMR spectrum of the crude solution.

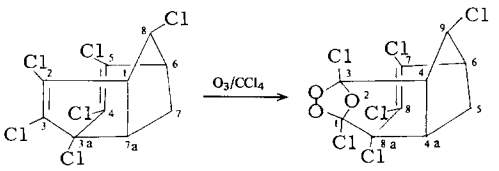
Ozonolysis of 2,3,3a,4,5,8-Hexachloro-3a,6,7,7a-tetrahydro-1,6-methano-1*H*-indene: Isolation of a Stable Ozonide Having a 3,5-Dichloro-1,2,4-trioxolane Structure

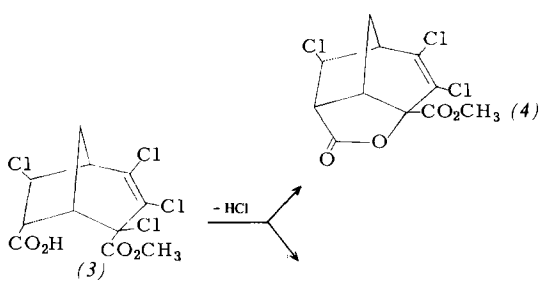
By *Siegmar Gäb*, *Siegfried Nitz*, *Harun Parlar*, and *Friedhelm Korte*[*]

Whereas numerous stable monomeric ozonides (1,2,4-trioxolanes) are known[1] no defined addition compounds have yet been reported between ozone and chlorinated olefins[2]. On reaction of 2,3,3a,4,5,8-hexachloro-3a,6,7,7a-tetrahydro-1,6-methano-1*H*-indene *(1)*[3] with ozone in carbon tetrachloride we have now succeeded in isolating a compound having a 3,5-dichloro-1,2,4-trioxolane structure.

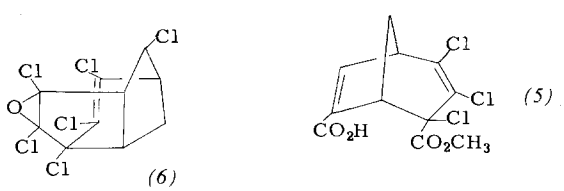


(1) *(2)*

The colorless product 1,3,7,8,8a,9-hexachloro-4a,5,6,8a-tetrahydro-1,3-epidioxy-4,6-methanoisochromane *(2)*, m.p. 100—101 °C, is stable at room temperature. Slow decomposition only occurs on exposure to moisture. Reductive opening with KI in methanol affords the monomethyl ester *(3)*. The structural assignment of *(2)* is based on spectroscopic data and on structural analysis of *(3)* and its dehydrohalogenation products *(4)* and *(5)*[4].



(3) *(4)*



(6) *(5)*

The ^{13}C-NMR data of the epoxide *(6)*[5] show that compound *(2)* is not a primary ozonide.

Procedure:

A solution of *(1)* (1 g) in CCl_4 (100 ml) is ozonized at room temperature until a blue coloration is observed. After 2 h excess ozone is driven off with N_2 and the solvent removed under reduced pressure. The oily residue is purified by column chromatography on silica gel (light petroleum) and recrystallized from *n*-hexane. Yield: 0.85 g (75 %) of *(2)*.

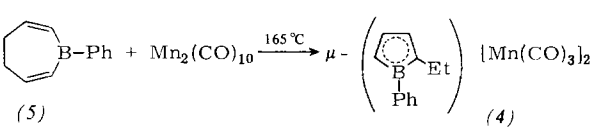
[4] Reaction of *(2)* with KI in CH_3OH gives *(3)* and *(4)* in the ratio 1 : 1.5. Compound *(3)* is quantitatively converted into *(4)* by chromatography on silica gel. Heating of an acetone solution of *(3)* to *ca.* 50 °C gives exclusively compound *(5)*.
[5] Compound *(6)* is produced by reaction of *(1)* with CrO_3 in glacial acetic acid.

A Novel Type of Triple-Decker Complex—Borole as Bridging Ligand[1]

By *Gerhard E. Herberich*, *Joachim Hengesbach*, *Ulrich Kölle*, *Gottfried Huttner*, and *Albin Frank*[*]

Three triple-decker sandwich complexes have so far been reported, namely the $[Ni_2(C_5H_5)_3]^+$ ion[2] *(1)* and two isomers $(\mu\text{-L})Co_2(C_5H_5)_2$[3] *(2)* and *(3)* with planar L = 1,2,3-$C_2B_3H_5$ and 1,2,4-$C_2B_3H_5$, respectively.

We have now found a novel type of triple-decker complex[4] in the form of μ-(1-phenyl-2 ethylborole)bis(tricarbonylmanganese) *(4)*. Surprisingly, *(4)* is formed as main product in the reaction of 1-phenyl-4,5-dihydroborepin[5] *(5)* with $Mn_2(CO)_{10}$ in boiling mesitylene. The *central* ligand is a simple borole derivative[6] which acts as a bridge between two Mn atoms each with three CO groups as *outer* ligands.



(5) *(4)*

The composition of complex *(4)* follows from elemental analysis and the mass spectrum [*m/e* 446 (26 %; $M^+ \equiv LMn_2(CO)_6^+$), successive loss of six CO groups, 278 (87 %; LMn_2^+), 223 (37 %; LMn^+), 55 (100 %; Mn^+)]. The ^{1}H-NMR spectrum reveals the borole ring [τ values in C_6D_6 at 100 MHz and room temperature; Ph: 2.43 m (2H), 2.66 m (3H); H-5: 5.76 t (1H); H-4: 6.43 dd (1H); H-3: 7.84 dd (1H); $J_{34} = 3.7$, $J_{45} = 1.8$ and $J_{35} = 1.3$ Hz; Et: 8.19 q (2H), 9.23 t (3H), $J = 7.3$ Hz], the ^{11}B-NMR spectrum the B atom bound to Mn [δ value in C_6D_6 at room temperature: −17.6 ppm rel. to $BF_3 \cdot OEt_2$ (ext.)]. The IR spectrum shows the typical pattern of a $Mn(CO)_3$ group in an environment deviating strongly from C_{3v} symmetry [ν_{CO} (cm^{-1}) in hexane: 2022 vs, 1963 vs, 1952 vs]; no indications of an interaction between the two $Mn(CO)_3$ groups in the molecule are observed. The constitution of *(4)* cannot be trivial, since apparently a four-electron ligand has substituted four (!) CO groups of $Mn_2(CO)_{10}$. Though the data quoted are in accord with

[*] Prof. Dr. G. E. Herberich, Dr. U. Kölle, and Dipl.-Chem. J. Hengesbach

the triple-decker structure of *(4)*, they do not however provide unequivocal proof thereof. The structure was therefore determined X-ray crystallographically.

$C_{18}H_{13}BMn_2O_6$ *(4)* crystallizes orthorhombically with $a=1429(1)$, $b=1670(1)$, $c=1541(1)$ pm, space group Pbca, $Z=8$. 1113 diffraction data (Syntex-P21) with $I \geq 3.2\sigma$; solution: conventional; refinement: (Syntex-XTL) full matrix, $R_1=0.057$. Figure 1 shows a schematic representation of the molecular structure, the skeletal unit of which is a pentagonal bipyramidal metallocarborane cluster of the *closo* type. The apical positions are occupied by $Mn(CO)_3$ groups; the four carbon atoms and the boron atom of the borole ring occupy the equatorial positions. The disorder which complicates the structural analysis of all previously investigated triple-decker complexes[2b, 3a, 3c] does not occur in the case of *(4)*.

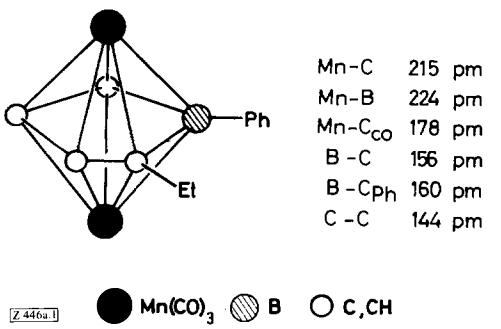

Fig. 1. Molecular structure of the dinuclear borole complex *(4)*.

The bonding in *(4)* is the same as that in metallocarboranes[7]. In a broad sense *(4)* is isoelectronic with *(2)* and *(3)*.

Procedure:

A mixture of *(5)*[5] (1.0 g, 5.95 mmol) and $Mn_2(CO)_{10}$ (2.32 g, 5.95 mmol) in mesitylene (20 ml) is heated under reflux for 70 h. Chromatographic workup (SiO_2-gel with pentane as eluant) affords two main zones: *ca.* 0.45 g (20 %) $Mn_2(CO)_{10}$ and 1.25 g (57 % yield referred to reacted $Mn_2(CO)_{10}$) of *(4)*, m.p. 119—120 °C, no decomposition up to 200 °C. The new complex, which crystallizes from pentane as brown-red needles, is very soluble in CH_2Cl_2, benzene, and acetone, readily soluble in Et_2O, and moderately soluble in pentane. It is somewhat air-sensitive in solution.

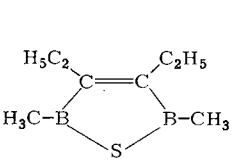
Thiadiborolenebis(tricarbonylmanganese)—A Cluster with Triple-Decker Structure[1]

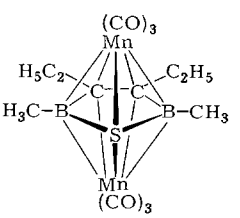
By *Walter Siebert* and *Klemens Kinberger*[*]

The 1,2,5-thiadiborolene *(1)* reacts with metal carbonyls to give the *nido* compounds $[(1)\cdot Cr(CO)_4]$[2a], $[(1)\cdot Fe(CO)_3]$[2b], and $[(1)\cdot Ni(CO)_2]$[1] in which boron metal interactions are present. We now report the first *closo* thiadiborolenebis(metal) compound having a pentagonal bipyramidal structure.

Reaction of *(1)* with $Mn_2(CO)_{10}$ leads to formation of the orange-red complex *(2)* which is thermostable and not air-sensitive but decomposes slowly in chloroform. The mass spectrum (70 eV) of *(2)* contains in addition to the molecular ion $LMn_2(CO)_6^+$ $L=(1)$ ($I_{rel}=6$) the fragments $LMn_2(CO)_4^+$ (21), $LMn_2(CO)_3^+$ (74), $LMn_2(CO)^+$ (36), LMn_2^+ (100), LMn^+ (12), Mn_2S^+ (10), Mn_2^+ (14), Mn^+ (62), and CO^+ (17). The three IR absorptions in the region of the CO stretching vibration and the magnetic equivalence of the methylene protons (Table 1) are in accord with the postulated structure *(2)*



(1)



(2)

(C_{2v} symmetry)[2c]. The upfield shift of $\Delta\delta=43.5$ ppm observed in the ^{11}B-NMR spectrum is indicative of favorable shielding of the boron by increased coordination number compared to the *nido* compounds.

Table 1. Spectroscopic data of *(1)* and *(2)*.

Signal	*(1)*	*(2)*	
^1H-NMR, δ [ppm] against TMS (in $CDCl_3$)			
B—CH_3	0.99 (s, 6)	1.42 (s, 6)	1.36 [a]
C—CH_3	0.87 (t, 6) [b]	1.34 (t, 6) [b]	1.33 [a]
C—CH_2	2.30 (q, 4)	2.52 (q, 4)	2.46 [a]
^{11}B-NMR, δ [ppm] against $BF_3\cdot OEt_2$ (in $CDCl_3$)	66.0 (s)	22.5 (s)	
IR, ν(CO) [cm^{-1}] (in C_2Cl_4)	2021 (s), 1966 (s), 1956 (s)		

[a] In CS_2. [b] $J=7.6$ (±0.1) Hz.

The diamagnetism of *(2)* can be explained under the assumption that the unpaired electrons of the d^7-$Mn(CO)_3$ fragments transfer to the C_2B_2S ring with formation of the $C_2B_2S^{2-}$ dianion isoelectronic with thiophene. As in borolenebis(tricarbonylmanganese) prepared by *Herberich et al.*[3], both $(OC)_3Mn^+$ groups are bound to the ring by six electrons. Hence the structure and bonding of *(2)* also conform to those of a triple-decker complex[3, 4]. According to the $(n+1)$

[*] Prof. Dr. W. Siebert and Dipl.-Chem. K. Kinberger
Fachbereich Chemie der Universität
Lahnberge, 3550 Marburg (Germany)

electron pair rule[5] for *closo* compounds (n = number of skeletal atoms) 16 skeletal electrons are required for occupation of the bonding molecular orbitals in the 7-atom $Mn_2C_2B_2S$ cluster; these are provided by the components C (2 × 3), B (2 × 2), S (4) and $MnCO_3$ (2 × 1).

3,4-Diethyl-2,5-dimethyl-1,2,5-thiadiborolenebis(tricarbonylmanganese) (2)

A mixture of $Mn_2(CO)_{10}$ (2.67 mmol) and *(1)* (2.67 mmol) in 40 ml mesitylene is heated under reflux for 5 h. The small amount of red $[(1)\cdot Mn(CO)_4]_2$ which crystallizes out on cooling is separated off. After removal of mesitylene by distillation the residue is recrystallized twice from pentane (−20 °C): orange-red crystals, m. p. 183–184 °C, dec. > 230 °C, yield 21 %.

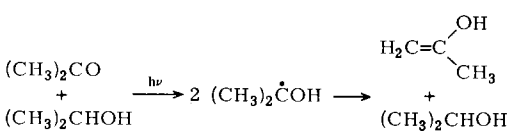
Enols from Norrish Type II Cleavage of Carbonyl Compounds in Solution

By *Andreas Henne* and *Hanns Fischer*[*]

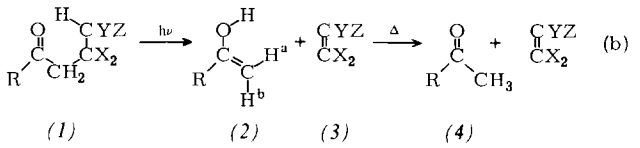
We recently reported that 0.01—0.1 M stationary concentrations of acetone enol are observed during UV irradiation of acetone/2-propanol mixtures at −70 °C, the enol being formed by disproportionation [eq. (a)] of 1-hydroxy-1-methylethyl radicals. It did not decay appreciably within 5000 s[1].



(a)

In this paper, we show that the enols *(2a)*—*(2d)* can be obtained in even higher concentrations from Norrish Type II photoreactions[2] [eq. (b)] of the carbonyl compounds *(1a)*—*(1d)* in appropriate solvents at $T \leq -40$ °C. Only the keto tautomers have previously been reported as products from *(1)* in solution[3].

After 50 minutes' irradiation (filtered light from a Philips SP 1000 W lamp[5], $280 \leq \lambda \leq 350$ nm) of 1 M 5-methyl-2-hexanone *(1a)* in TMS at −70 °C in the sample tube of a VARIAN HA-100 ^{1}H-NMR spectrometer, an NMR spectrum is observed which apart from unconverted reactant *(1a)* (0.13 M), reveals the presence of isobutene *(3a)* (0.80 M), acetone *(4a)* (0.07 M), and acetone enol *(2a)* (0.70 M; NMR[6]: CH_3, $\delta = 1.75$; H^a, $\delta = 3.97$; H^b, $\delta = 3.71$; OH, $\delta = 8.40$ ppm). The concentration of *(2a)* remains approximately constant on



(b)

(1) *(2)* *(3)* *(4)*

	R	X	Y	Z
a	CH_3	H	CH_3	CH_3
b	H	H	H	CH_3
c [4]	$CH_2C(CH_3)_3$	CH_3	H	H
d	C_6H_5	H	H	CH_3

further irradiation, and does not decrease by more than 10 % within 2 h after cessation of irradiation. After briefly warming up the solution to +20 °C a second NMR spectrum is recorded at −70 °C. Evidently an equivalent concentration of *(4a)* has been formed from *(2a)* at +20 °C. Photolysis of *(1a)* in CD_3OD (−70 °C) and CD_3CN/TMS (9:1, −40 °C) produces similar enol concentrations. In the irradiation of *(1b)*—*(1d)* at $T \leq -40$ °C, polar solvents favor[2] the formation of the enols *(2b)*—*(2d)* in high concentrations (Table 1). Warming these enol solutions to room temperature gives the corresponding tautomers *(4b)*—*(4d)*.

The enol-keto tautomerization *(2a)*→*(4a)* was followed between −14 and −35 °C by integration of the NMR signal of the enol at $\delta = 3.97$ ppm (H^1). In TMS, CD_3OH, and CD_3OD this reaction obeys a first order rate law. In TMS the exponential lifetimes of *(2a)* amount to 5300 (−35 °C), 1600 (−26 °C), 560 (−17 °C), and 380 s (−14 °C). For $T \geq -17$ °C these values are smaller than those of di- and trialkyl-substituted enols in solution at 10—37 °C[7]. We believe that the observed lifetimes are determined by acid- or base catalysis arising from solvent impurities or by-products of UV irradiation.

Table 1. Enol concentrations $[(2)]_t$ of *(2a)*—*(2d)* and reactant conversion $[(1)]_0 - [(1)]_t$ (both in mol/l, ±15 %) after irradiation time t at temperature T, starting from *(1a)*—*(1d)* in 1 M solutions.

	T [°C]	t [min]	$[(1)]_0 - [(1)]_t$	$[(2)]_t$
(2a)	−70	50	0.83	0.70 [a]
(2b)	−40	30	0.75	0.20 [b]
(2c)	−40	55	0.72	0.29 [b]
(2d)	−44	30	0.30	0.20 [b]

[a] TMS solvent.
[b] CD_3CN/TMS (9:1) solvent.

In addition to providing a direct proof for the mechanism of the Norrish Type II reactions of *(1a)*—*(1d)* in solution, this observation of enols *(2a)*—*(2d)* in high concentrations may form the basis for the study of enol-keto tautomerizations.

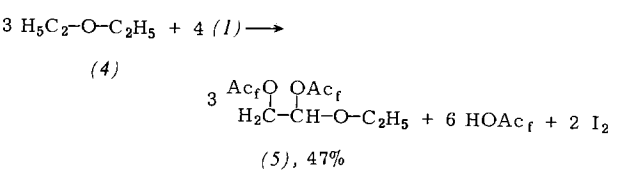
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

If *(1)* is suspended at room temperature in an alkane (or dissolved together with the alkane in a solvent such as dichloromethane), then the alkane is oxidized mainly to mono- and bis(trifluoroacetoxy) derivatives of types *(2)* and *(3)*, while *(1)* is converted into iodine.

Alkanes having tertiary CH groups are oxidized within minutes, those with secondary CH_2 groups within days, and alkanes of neopentane type not at all (Table 1). Reaction of *(1)* with ethers is even faster, involving selective α,β-oxidation with formation of α,β-bis(trifluoroacetoxy) derivatives of type *(5)*. With lead tetraacetate α,β-oxidation occurs only with secondary ethers[2].



(5), 47%

The rate of oxidation of alkanes (and other compounds) increases with increasing electronegativity of the substituent attached to iodine, as shown for instance by experiments with cyclohexane: iodine triacetate[3] does not react at all with it, iodine tris(trifluoroacetate) *(1)* in about three days, and iodine tris(trifluoromethansulfonate)[4] immediately.

The reactions are presumably initiated by an electrophilic attack on the C—H bond, whose σ basicity has been repeatedly demonstrated[5]. Whether the attacking species is *(1)*, $I(OAc_f)_2^{\oplus}$, or even $IOAc_f$ has not been established. Derivatives of (dihydroxyiodo)alkanes, *e.g. (6)*, are unstable (unless the alkyl group is perfluorinated[6]) and undergo 1,1-elimination to give alkyl trifluoroacetates, *e.g. (2)*, or 1,2-elimination affording an alkene which is oxidized stereoselectively to alkylene bis(trifluoroacetates), *e.g. (3)*[1]. The observation that 2-iodobutane gives the same products as butane on treatment with *(1)* suggests that the reaction proceeds *via* bis(trifluoroacetoxy)iodoalkanes *(6)*.

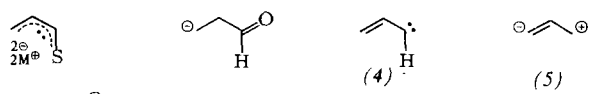
The Magnesium Derivative of Thioacrolein Dianion. A Facile Entry to Vinyl- and Divinyloxiranes[**][1]

By *Dieter Seebach*, *Karl-Heinz Geiss*, and *Manat Pohmakotr*[*]

We recently succeeded in preparing[2, 3] the dianions of the thiocarbonyl compounds thiobenzaldehyde and thioacrolein, which as neutral molecules can exist only at extremely low temperatures[4], in the form of their dilithium derivatives by direct abstraction of two protons from benzyl and allyl thioalcohol, respectively. The organolithium compound *(1)* reacts with electrophiles preferentially in the γ-position to the hetero atom and is thus synthetically equivalent to the anion *(3)*[3, 5]. We now wish to describe the reactions of

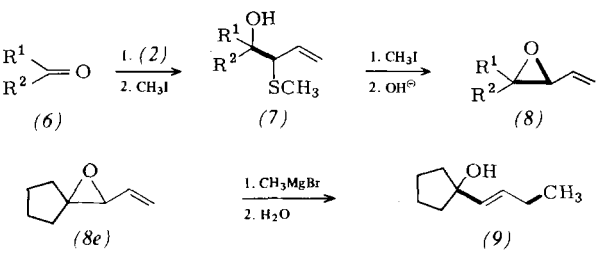


(1), 2 $M^{\oplus}$ = 2 $Li^{\oplus}$ *(3)* *(4)* *(5)*

(2), 2 $M^{\oplus}$ = $Mg^{2\oplus}$

the magnesium derivative *(2)*, readily accessible from *(1)* by transmetalation (addition of 1 equiv. of $MgBr_2$), with aldehydes and ketones which occur almost exclusively (>90 %) in the α-position to the sulfur atom and confer upon this reagent the properties of a synthetic building block with reactivities as shown in *(4)* and *(5)*.

Successive addition of a saturated or α,β-unsaturated aldehyde or ketone *(6)* and methyl iodide to a solution of *(2)* at −80 °C affords very high yields of the adducts *(7)*. Methylation to give the sulfonium salt—again with CH_3I (1.0—1.5 equiv., pure)—and base-induced elimination (0.5 N NaOH/CH_2Cl_2)[6a] converts *(7)* into the vinyloxiranes *(8)* (examples given in Table 1).



(6) *(7)* *(8)* *(8e)* *(9)*

Vinyloxiranes *(8)* are thus accessible more easily and in higher yields than *via* sulfur ylides[6b]. Divinyloxiranes of type *(8c)* and *(8g)* (3,4-epoxides of 1,3,5-hexatrienes) cannot be prepared by C—C linkage *via* the ylides since the latter cyclopropanate α,β-unsaturated carbonyl compounds[6b]. The epoxides *(8)* are useful highly reactive intermediates for the preparation of other compounds. For instance, the three-membered ring in *(8e)* is opened by methylmagnesium bromide to form *(9)*[7] [see *(5)*]; vinyloxiranes undergo thermal rearrangement to dihydrofurans[8a], and divinyloxiranes to 4,5-dihydrooxepins[8b].

Finally, we have also been able to demonstrate in the case of the adduct of *(2)* to methyl vinyl ketone *(6g)* that the 1,2-α-reaction can be transformed into a 1,4-γ-reaction: the potassium alkoxide *(10)* of the product *(7g)* undergoes a Cope rearrangement[9] forming the thioenol ether *(11)* of

Table 1. Synthesis of vinyloxiranes *(8)* *via* the β-(methylthio)alcohols *(7)*. Aldehydes and unsymmetrical ketones *(6)* give mixtures of diastereomers.—Elemental analyses within 0.4 % of the theoretical values are available for products *(7)* and *(8)* listed; IR and NMR spectral data are compatible with the structures.

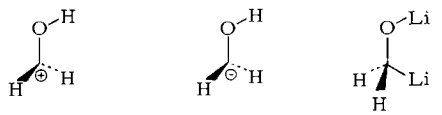
Doubly Metalated Methanol—A Nucleophilic Hydroxymethylation Reagent[**]

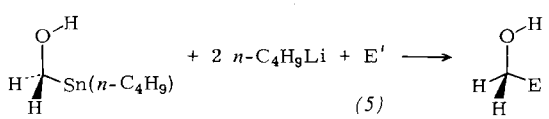
By *Dieter Seebach* and *Norbert Meyer*[*]

Protonated formaldehyde *(1)* is available as an electrophilic hydroxymethylation reagent for synthetic operations[1]. An umpolung of the normal reactivity of *(1)* would be present in *(2)*, which being a tautomer of the methoxide ion is of course not accessible as such.



(1) *(2)* *(3)*

We have found that the alcohol *(4)* available from $(n\text{-}C_4H_9)_3SnMgCl$ and monomeric formaldehyde[2] affords products of type *(6)* on successive addition of *two* equivalents of *n*-butyllithium and one equivalent of an electrophile *(5)* (see experimental procedure and Table 1). Compound *(4)* is probably converted by deprotonation *and* tin/lithium exchange[3] into the dilithium derivative[4] *(3)* which is attacked by electrophiles at the C atom. *(3)* can be regarded as the Li_2 derivative of doubly deprotonated methanol[5]. The reactions leading to *(6c)* to *(6e)* described in this communication are the first direct hydroxymethylations[6] of carbonyl compounds.



(4) *(5)* *(6)*

Table 1. Hydroxymethylation products *(6)* of alkyl halides and carbonyl compounds. Compounds *(6)* are already known. All the physical and spectroscopic data of the samples we isolated accord with those reported in the literature.

	Electrophile E' *(5)*		E	Products *(6)* Yield [%]	Physical data
a	*n*-Octyl chloride	*a*	$n\text{-}C_8H_{17}$	53	$n_D^{20}=1.4335$

f	Di-*tert*-butyl ketone	*e*	$[(CH_3)_3C]_2C(OH)$	41	$n_D^{20}=1.4705$

α-Phenylglycol (6c)

A 1.6 N solution of *n*-butyllithium in hexane (12.5 ml, 20 mmol) is added under argon to a stirred solution of *(4)* (3.2 g, 10 mmol) in light petroleum (b.p. 30—40 °C) at −20 °C. After removal of the bath and 6 hours' stirring at room temperature, the homogeneous solution is cooled to −78 °C and treated with benzaldehyde *(5d)* (1.06 g, 10 mmol). A colorless precipitate is formed. The mixture is allowed to warm up overnight, poured into saturated brine, the phases separated, the aqueous phase extracted with ether, and the combined organic phases dried over K_2CO_3. The residue obtained on evaporation is partly crystalline. Digestion with pentane, cooling to 0 °C, and filtration affords 0.85 g (6.2 mmol) of *(6c)*.

The other products *(6)* listed in Table 1 were prepared in similar manner. Tetrabutyltin can be isolated in 90 % yield in all cases. It can be separated from liquid products *(6)* by filtration of a pentane solution over silica gel.

[3] It is already known that alkoxymethyllithium (*U. Schöllkopf* in Houben-Weyl-Müller: Methoden der Organischen Chemie. Thieme, Stuttgart 1970, Vol. 13/1, p. 133) and dialkylaminomethyllithium compounds [*D. J. Peterson* and *J. F. Ward*, J. Organomet. Chem. *66*, 209 (1974), references cited therein] can be prepared by Sn/Li exchange.
[4] Cf. also doubly metalated thiols: *D. Seebach* and *K. H. Geiss*, Angew. Chem. *86*, 202 (1974); Angew. Chem. Int. Ed. Engl. *13*, 202 (1974); *K. H. Geiss, B. Seuring, R. Pieter*, and *D. Seebach, ibid. 86*, 484 (1974) and *13*, 479 (1974), respectively; *D. Seebach, K. H. Geiss*, and *M. Pohmakotr, ibid. 88*, 449 (1976) and *15*, 437 (1976), respectively.
[5] According to *D. O. DePree* and *J. D. Johnston*, US-Pat. 3239568; Chem. Abstr. *64*, 15921e (1966), double metalations are feasible under extreme conditions. We were unable to obtain a reagent of type *(3)* by reaction of formaldehyde with alkali metals. The high solubility of our reagent in pentane, even at −78 °C, indicates that *(3)* is somehow "complexed" with the R_4Sn present in the solution!
[6] Hydroxymethylation of an alkyl halide has been performed with $LiCH_2BR_2$ [*M. W. Rathke* and *R. Kow*, J. Am. Chem. Soc. *94*, 6854 (1972)].

Synthesis of the γ-Octose of the Quinocycline Complex[**]

By *Hans Paulsen* and *Volker Sinnwell*[*]

The anthracycline antibiotics of the quinocycline complexes isolated from *Streptomyces aureofaciens* contain a hydroxyethyl-branched octose as carbohydrate component[2, 3]. We have synthesized the γ-octose occurring in quinocycline A and isoquinocycline A. In order to elucidate the remarkable stereochemistry of the reaction sequences and their products, the experiments were first performed with the economically accessible compounds of the D series.

Reaction of the epoxy ketose *(6)* with 2-lithio-1,3-dithiane unexpectedly affords *(1)* and *(2)*. The desired adduct having the 4-OH group *trans* to the epoxy group was not observed since it undergoes quantitative epoxide rearrangement[1] into *(1)*. Epoxide rearrangement can be largely suppressed by use of a less polar carbanion. Thus treatment of *(6)* with vinyllithium affords not only *(11)* but also the desired product *(7)* which undergoes only slight rearrangement (10 %).

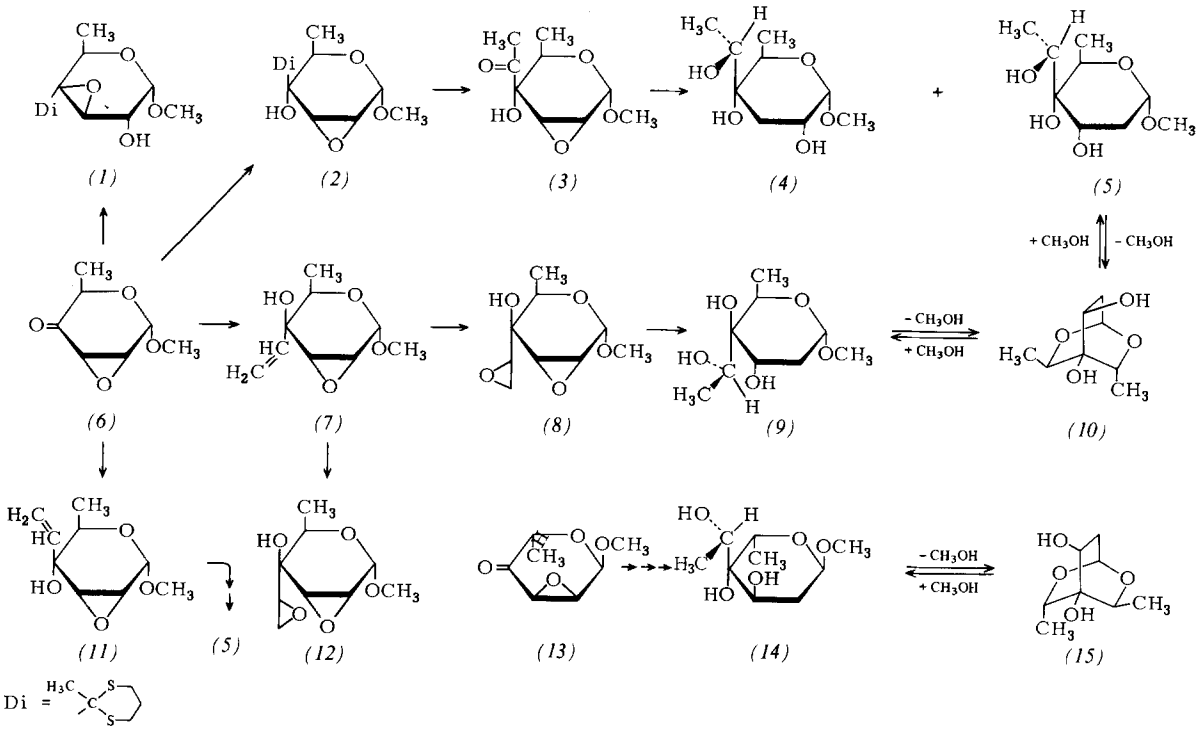
[**] Branched-Chain Sugars, Part 13.—Part 12: ref. [1].

Epoxidation of *(7)* with *m*-chloroperbenzoic acid yields the separable diepoxides *(8)* and *(12)* which can both be selectively reduced with $LiAlH_4$. On reaction of *(8)* with $LiAlH_4$ the epoxide rings are selectively opened at C-2 and C-8. The resulting octose *(9)* (syrup; $[\alpha]=+109.4°$) is the

CAS Registry numbers:
(3), 59463-78-4; *(4)*, 59463-79-5; *(5)*, 59463-80-8; *(6)*, 55533-59-0; *(7)*, 59463-81-9; *(8)*, 59463-82-0; *(9)*, 59463-83-1; *(10)*, 59463-84-2; *(11)*, 59463-85-3; *(12)*, 59463-86-4; *(13)*, 59463-87-5; *(15)*, 59492-29-4; 2-lithio-1,3-dithiane, 36049-90-8; *m*-chloroperbenzoic acid, 937-14-4



D-form of the natural product. Acidic glycosidic cleavage converts *(9)* into the well-crystalline anhydro compound *(10)* (m.p. 146°C; $[\alpha]=+146°$)[4]. The isomeric octoses do not form anhydro compounds so readily. The dioxabicyclo[2.2.2]octane system *(10)* is stabilized by the screw-shaped arrangement of the substituents (right-handed screw in this case).

Surprisingly, *(10)* is also accessible from *(5)*, the product with the "wrong" stereochemistry at the branching point. Compound *(5)* is preparable from *(11)*, or better from *(2)*. The desulfuration product *(3)* obtained from *(2)* undergoes selective reaction in the side chain with $LiAlH_4$ but not in the epoxide ring, thus yielding *(4)* and *(5)*. Hydrolysis of *(5)* likewise furnishes *(10)*.

After clarification of all points in the D series, a direct synthesis was performed in the L series. Starting from the L-epoxy ketose *(13)* *via* compounds corresponding to *(7)* and *(8)* we obtained the octose *(14)* (syrup; $[\alpha]=-101.4°$), which is identical with the natural product. Hydrolysis of *(14)* leads to the L-anhydro compound *(15)* (m.p. 146—147.5°C; $[\alpha]=-147.6°$) with a left-hand screw arrangement of substituents.

It is important that acidic methanolysis of *(5)* leads *via* the equilibrium *(5)*⇋*(10)*⇋*(9)* to an isomerization of *(5)* to *(9)* (α,β form); *(9)* is considerably more stable than *(5)*. Accordingly, no information about the stereochemistry at the branching point of the octose is available from hydrolysis of the quinocycline complex. Fortunately, this question is answered by an X-ray structure analysis of isoquinocycline A[5]. Uncertainty surrounded the stereochemistry in the side chain[6], which has now been established by the above series of reactions.

C—C Linkage of Polyfunctional Molecules by Nucleophilic Addition of Dianions. Synthesis of Pillarose[**]

By *Hans Paulsen, Klaus Roden, Volker Sinnwell*, and *Wolfgang Koebernick*[*]

The scope of nucleophilic addition for forming C—C linkages[2, 3] is drastically restricted if the potential carbanion bears an oxygen atom bound to the α position as an ether, ester, or acetal. On metalation of such compounds, *e.g.* 1,3-dithiane derivatives, direct elimination of RO ensues to form olefins and decomposition products.

The problem can be solved by reacting the free alcohols with the metalating reagent in the molar ratio 1:2, thus converting them into dianions. 2-(1,3-Dithiane)methanol reacts with *n*-butyllithium in THF at −70°C to give the dianion *(2)* which is sufficiently stable under the reaction conditions and reacts almost as well as the 1,3-dithiane monoanion with carbonyl groups. We selected the *galacto*-6-aldehyde *(1)* as

[*] Prof. Dr. H. Paulsen, Dipl.-Chem. K. Roden, Dipl.-Chem. V. Sinnwell, and Dr. W. Koebernick

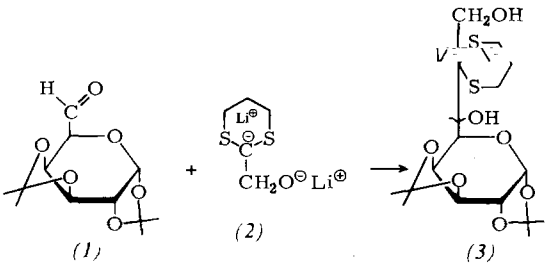
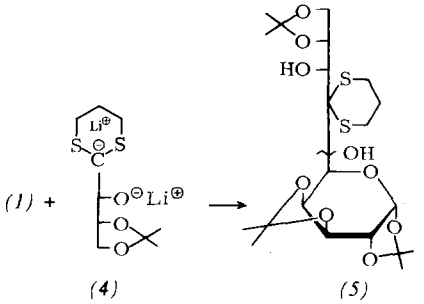
[**] Branched-Chain Sugars, Part 14.—Part 13: ref. [1].

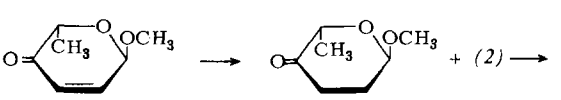
test substance, which smoothly reacts with *(2)* to form the functionalized two-membered chain, thus giving a 54 % yield of *(3)*.



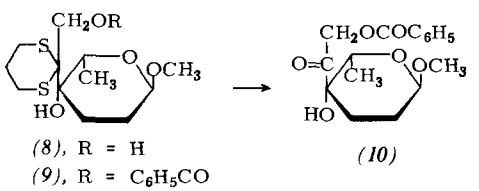
(1) *(2)* *(3)*



(4) *(5)*



(6) *(7)*



(8), R = H
(9), R = C_6H_5CO *(10)*

In order to establish whether the functionalized chain on the 1,3-dithiane group can be elongated, the trimethylene dithioacetal of 3,4-*O*-isopropylidene-D-erythrose was prepared and reacted with *n*-butyllithium in the molar ratio 1:2 at −70 °C in THF. The labile dianion *(4)* that was formed was also reacted with the aldehyde *(1)*. The long-chain sugar *(5)* having ten C atoms is obtained. The process appears to have scope for extension and to be suitable for linkage of prefabricated polyfunctional structural units.

Application of the new process will now be illustrated by the synthesis of the branched-chain sugar pillarose which thus becomes accessible in just a few steps. Pillarose is the carbohydrate component of the antibiotic pillaromycin A isolated from *Streptomyces flavovirens*, which possesses a tetracyclic aglycon and belongs to the group of the anthracyclines which exhibit antitumor activity[4].

The ketose *(7)* obtained from the enone *(6)*[5] by selective hydrogenation shows a strong preference to form *(8)* on reaction with the dianion *(2)*. The two isomeric branched-chain sugars expected as products are formed in the ratio of 9:1. The isomer *(8)* can be crystallized directly (45 %; m.p. 125—127 °C; $[\alpha]_D^{20} = -108°$); its selective benzoylation affords *(9)* (87 %; m.p. 123—124 °C, $[\alpha]_D^{20} = -81.1°$). Desulfuration with $HgO/BF_3 \cdot Et_2O$ furnishes the pillaroside *(10)* (60 %; m.p. 104—106 °C, $[\alpha]_D^{20} = -96°$). The monobenzoate *(10)* is the best-described derivative of pillarose. The physical data and the NMR spectrum are in accord with those of the natural product.

The structure of pillarose[4] has only recently been established by *Fraser-Reid*[6]. The compound *(10)* synthesized corresponds to the relevant formula.

Synthesis of α-Glycosidically Linked Disaccharides of D-Galactosamine[**]

By *Hans Paulsen*, *Čeněk Kolář*, and *Wolfgang Stenzel*[*]

The determinant group of the blood-group specific glycoproteins of type A contains α-glycosidically linked D-galactosamine as the most important component[2, 3]. The same structural unit also occurs in several glycoproteins[3]. A selective synthesis of α-glycosides of D-galactosamine has hitherto been precluded by the inaccessibility of suitable starting compounds and the difficulties involved in application of the "nitrosoglycal method"[4]. We have now been able to solve this problem by use of the "azide method"[5].

The *talo*-epoxide *(1a)* readily available from 1,6-anhydro-β-D-galactose reacts with NaN_3 in ethanol/water to give the 2-azidogalacto compound *(2a)* (74 %; m.p. 89 °C; $[\alpha]_D^{20} = +20.0°$). After benzylation to give *(2b)*, acetolysis to form *(3)* (89 %; syrup; $[\alpha]_D^{20} = +53.0°$) becomes possible. Compound *(3)* can be converted into the α-bromide *(4)* (87 %; syrup; $[\alpha]_D^{20} = +141.0°$) at −20 °C in dichloromethane/HBr. β-Glycosides can be prepared selectively from *(4)*. Thus *(4)* affords the β-glycoside *(8)* (82 %; syrup; $[\alpha]_D^{20} = -39.0°$) on treatment with benzyl alcohol in the presence of Ag_2CO_3/Drierite.

For selective synthesis of α-glycosides compound *(4)* is inverted to the β-chloride *(5)* in a kinetically controlled reaction with tetraethylammonium chloride in acetonitrile. The reaction is monitored by polarimetry and stopped at minimum rotation ($[\alpha]_D^{20} = +30.4°$). The reaction product, which has to be subjected to further reaction immediately upon work-up, affords α-glycosides with alcohols in the presence of Ag_2CO_3.

In order to test the disaccharide synthesis, compound *(5)* was reacted with the 2-azido-*gluco* compound *(6)* in the presence of catalytic amounts of $AgClO_4$. A 66% yield of disaccharide is obtained showing an α,β ratio of 10:1. The α-(1→3)-linked disaccharide *(7)* could be isolated in crystalline form (53 % yield; m.p. 41 °C; $[\alpha]_D^{20} = 98.2°$); the α linkage is confirmed by 270 MHz NMR spectra. The azido glycosides are readily convertible into amino glycosides by hydrogenation

according to known methods. Thus a pathway is now available for selective synthesis of α-glycosides of D-galactosamine.

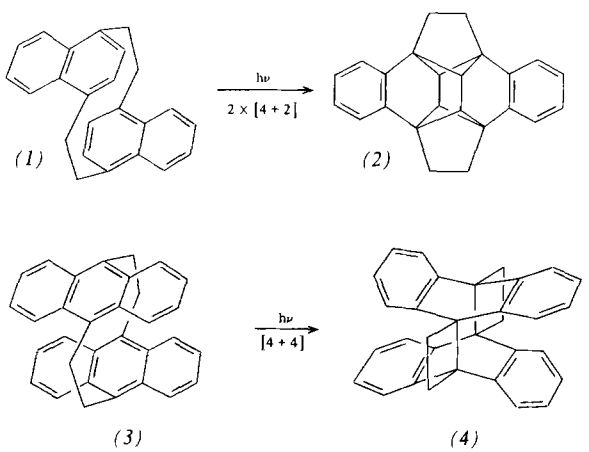
Intramolecular [4+4]Photocycloaddition of [2.2](1,4)-Naphthalenophane

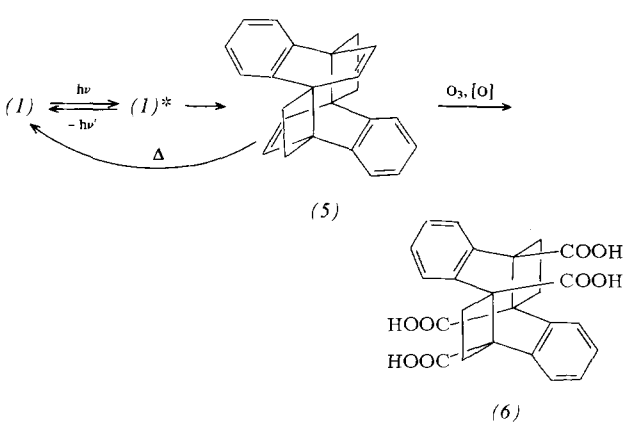
By *Gerd Kaupp* and *Inge Zimmermann*[*]

The twofold intramolecular Diels-Alder reaction occurring on ten days' irradiation of *anti*-[2.2](1,4)naphthalenophane *(1)* to form dibenzoequinene *(2)*[1] is exceptional. The related [2.2](9,10)anthracenophane *(3)* is known to undergo particularly smooth [4+4]photocycloaddition to give *(4)*[2], and numerous naphthalene derivatives suffer intermolecular [4+4]photodimerizations[3]. Since the well-proved approach of empirical conformational analysis with the aid of molecular models[2,4] also suggest the [4+4]reaction to be more favorable geometrically than [4+2]addition in the case of *(1)*, we have examined the photodeactivation of *(1)* by spectroscopic and chemical methods and now report new findings which confirm the predictions of conformational analysis.

Ethano bridges maintain the internal six-membered rings of *(1)* [as in *(3)*][2] in close proximity. Expectedly, a UV spectrum is found [cyclohexane: $\lambda_{max}(\varepsilon)=238$ (39000), 246 (37000), 273 (sh, 6200), 283 (sh, 5600), 302 (sh, 5500), 310 (6000), 320 (sh, 4850), 327 (sh, 3700), 333 nm (sh, 2400)] which extends to higher wavelengths (up to *ca.* 355 nm) than that of 1,4-dimethylnaphthalene[1]. Electronically excited *(1)* must accordingly be regarded, like *(3)*, as an example of an intramolecular excimer. Unlike *(3)*[2], which undergoes exclusive photochemical deactivation, it emits a very broad structureless excimer fluorescence (cyclohexane: $\lambda_{max}^{corr.}=416$ nm; $\Phi_{Fl}=0.021$; acetonitrile: $\lambda_{max}^{corr.}=411$ nm). Even at −196 °C (ether/ethanol = 1:2; $\lambda_{max}^{corr.}=420$ nm) it remains unstructured and is far more intense than the phosphorescence of *(1)* ($\lambda_{max}^{corr.}=527$, 542, 549, 572, 592, 615 nm; $\tau_{Ph}=0.24$ s)[5].



Apart from luminescence, a diminution of the UV absorption with concomitant formation of the [4+4]product *(5)* is observed on long-wave excitation (above 290 nm).



Compound *(5)* is thermolabile. At room temperature it undergoes extremely rapid rearomatization to regenerate *(1)* ($t_{1/2}=76$ s at 20 °C). According to UV analysis this back-reaction is first-order when performed between −15 and +25 °C in toluene and has an activation energy of $E_a=18.65$ kcal/mol

Albertstrasse 21, 7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

and a frequency factor $A=10^{11.85}\,s^{-1}$. Thus derivatization must be performed at as low a temperature as possible. In order to prepare *(6)* [m.p. 315°C (dec.)] compound *(1)* (200 mg) is irradiated in toluene for 1 h (Philips HPK 125 W, Pyrex filter), then ozonized at −80°C with addition of methanol and subjected to oxidative work-up[6].

The cyclic process *(1)* ⇌ *(5)* ⇌ *(1)* proceeds highly uniformly so that at temperatures above 20°C and on prolonged irradiation the thermally more stable escape product *(2)* can be formed (25%; 10 d; 16 fluorescent lamps)[1], although there is no conceivable conformer of *(1)* in which [4+2] reactions giving *(2)* would be geometrically favored over the kinetically preferred [4+4] reaction to form *(5)*.

Since the presumably [as for *(3)* $\overset{h\nu}{\rightleftharpoons}$ *(4)*][2] two-step formation of *(5)* must compete with relatively intense excimer luminescence it would appear to be geometrically hindered. Thus it must be assumed that the internal aromatic rings of the conformers of *(1)* which absorb at longer wavelengths are laterally displaced and not completely parallel to each other. In this way excessive steric interactions are avoided between aliphatic and *peri* H atoms, and photoreaction after long-wave excitation can only occur subsequent to a slight conformational change. A thermal activation threshold must be overcome in the process, for the photochemical [4+4] reaction of *(1)* to form *(5)* (313; 334 nm) is no longer observed at −190°C.—Excitation at shorter wavelengths leads to [6+6] cleavage[7].

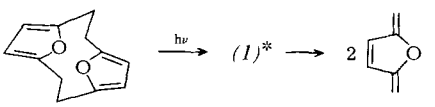
[6+6] Photocleavage of [2.2]Cyclophanes[**]

By *Gerd Kaupp*[*]

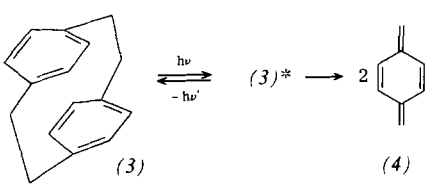
Photochemical [6+6] reactions are of significance as higher members of the cyclovinylogous series of two-step multicenter reactions[1a]. Their success is tied to important conformational conditions. Thus both unproductive radiationless deactivation by conformational changes (such as internal rotation or inversion) and excessive competition from simpler reaction types in smaller sections of the 12-electron system must be avoided. With suitable [2.2]cyclophanes these conditions can be satisfied by restriction of the conformational flexibility and incorporation of the conjugated double bonds in largely planar rings[1b]. We now report new photocleavages of the phanes *(1)*, *(3)*, and *(6)* which confirm these arguments.

[2.2](2,5)Furanophane *(1)*[2] exists in the relatively rigid step-type conformation, as shown by molecular models. Its UV spectrum [cyclohexane: $\lambda_{max}(\varepsilon)$ = 223 (15000), 231 (sh, 10200), 238 (sh, 2740), 246 nm (sh, 1220)] permits excitation with a low pressure mercury lamp. Irradiation (20 or −190°C) is seen to lead to a very rapid build-up of UV spectra corresponding to those of 2,5-dimethylene-2,5-dihydrofuran *(2)*[2a] which can be isolated at −78°C [ether/ethanol = 1:2; 25°C, λ_{max} = 231 sh, 288 sh, 296, 305 sh; −190°C: λ_{max} (E_{rel}) = 232 (0.68), 278 (sh, 0.51), 290 (sh, 0.79), 299.5 (1.00), 312 nm (0.77)]. These spectra are stable for several hours at 25°C and also survive brief irradiation with 313 nm light. No processes competing with [6+6] photocycloreversion of *(1)*, such as fluorescence, can be observed ($\Phi_{Fl} < 10^{-5}$); an isosbestic point is registered at 229 nm.

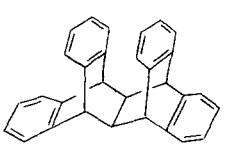


(1) *(2)*

Also in the case of [2.2]paracyclophane *(3)* conformational conditions appear favorable for [6+6] photocleavage to give *p*-quinodimethane *(4)*. On the other hand, transannular interactions are apparent from the UV spectrum[3]. The excimer character of long-wave excited *(3)* is revealed also by an unstructured fluorescence (cyclohexane: $\lambda_{max}^{corr.}$ = 355 nm, Φ_{Fl} = 0.0081)[4]. Substantiation of these concepts comes from the fluorescence of sterically fixed janusene *(5)*[5] having two parallel benzene rings separated by 2.5 Å. As for *(3)* it is unstructured (cyclohexane: $\lambda_{max}^{corr.}$ = 343 nm, Φ_{Fl} = 0.0025; ether/ethanol, −196°C: 340 nm) and thus supplements observations made for *(6)*[6].



(3) *(4)*



(5)

On long-wave excitation of *(3)* (300, 313 nm) no [6+6]cleavage to give *(4)* is observed. Only short-wave excitation leads to [6+6] cycloreversion, albeit significantly more slowly than in the case of *(1)*. At −190°C in ether/ethanol = 1:2 this reaction is manifested directly by the appearance of reproducible UV spectra of *(4)*. The suspected two-step nature of the reaction is confirmed above all by the structure of open-chain alcohol adducts obtained from *(3)* at room temperature[7].

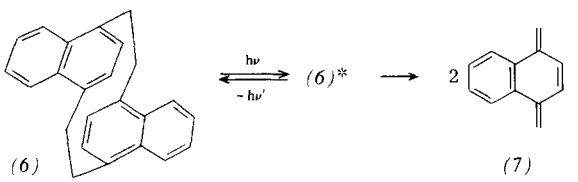
The UV spectra of *(4)* which can now be conveniently recorded lie at much longer wavelengths than those recorded in the gas phase[8a]. Nor do they possess the unstructured bell shape, which has meanwhile been theoretically interpreted, found from film spectra recorded after vacuum pyrolysis of

[*] Doz. Dr. G. Kaupp
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(3)[8b]. It is especially fortunate that ether/ethanol solutions of *(4)* are sufficiently stable after thawing to *ca.* 20°C to permit recording of several UV spectra. Within about 3 h the concentration of *(4)* falls by one half; after 20 h regeneration of *(3)* is complete [20°C; spectral resolution 0.5 nm: λ_{max} (E_{rel}) = 269 (sh, 0.48), 282 (0.78), 292 nm (1.00); −190°C: λ_{max} = 243 sh, 268 sh, 274 sh, 277 sh, 281 sh, 285.5, 289 sh, 293 sh, 298.5 nm]. The assignment of these spectra with the most intense first partial vibrational band to *(4)* is supported by the UV spectrum of 3,6-dimethylene-1-cyclohexene [cyclohexane: 256 (sh, 25200), 264 (30000), 274.5 nm (21200)[9]] and corresponding differences in several linear and branched conjugated azapolyenes, merocyanines, and diketones of the same type[10].

In the same way as *(4)*, compound *(7)* can be prepared by short-wave irradiation (253.7 nm) of *(6)* at −190°C in ether/ethanol = 1:2 (isosbestic points at 256.5 and 313 nm; concerning long-wave irradiation, see ref. [6]). Compound *(7)* is more stable than *(4)* (*ca.* 30% disappearance in 20 h at



(6) *(7)*

25°C). Again it does not display a bell-shaped absorption spectrum[8b, 11] but a clearly structured one with a most intense first partial vibrational band (−190°C: λ_{max} = 258 sh, 269.5, 278 sh, 282, 293.5, 304 sh, 307; 20°C: 267, 280 sh, 291, 303 nm), and is photolabile like *(4)* at elevated temperatures.

In order to prepare *(4)* and *(7)* the reaction medium must still be "fluid". Thus the [6+6] cleavage cannot be performed in EPA at −196°C apparently because the cleavage products cannot diffuse apart in the hard glass. The convenient mode of preparation and the unexpectedly high thermal stability of *(2)*, *(4)*, and *(7)* suggest use of these compounds for cycloadditions.

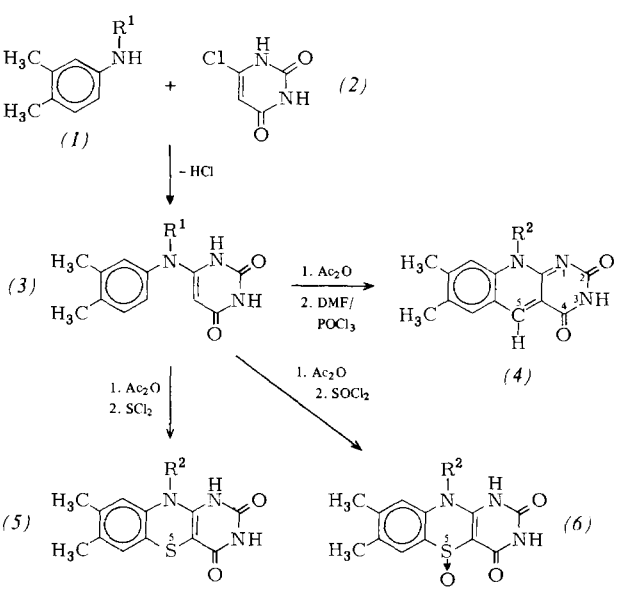
5-Deaza- and 5-Thiariboflavins: A Simple Pathway to Antimetabolites of Vitamin B_2

By *Michael Janda* and *Peter Hemmerich*[*]

The flavocoenzymes derived from vitamin B_2 are vital components of all biological redox chains, animal respiration, plant photosynthesis, and microbial oxygenation (detoxification)[1]. Flavoproteins are unique as switch-over units between hydride and electron transfer; moreover, they compete with hemoproteins in oxygen activation. A relationship between these seemingly unrelated types of activity is revealed by the fact that the $2e^{\ominus}/H^{\ominus}$-conversion, like the reduction of the triplet $^3O_2$, involves spin coupling and decoupling, *i.e.* a forbidden non-conservation of multiplicity. That the chemistry of the flavin-dependent biological oxidoreduction has only recently become fully understood probably lies in the fact that *in vivo* and/or *in vitro* active vitamin B_2 antimetabolites were hardly known.

5-Deazaflavocoenzymes *(4)*, R^2 = ribityl phosphate, have recently been employed for the modification of flavoproteins[2]. 5-Deazaflavoproteins retain the ability to transfer $H^{\ominus}$, *i.e.* the (de)hydrogenation activity, even if to a small extent, but $e^{\ominus}$-transfer and O_2-reduction are completely blocked[3]. It is obvious that the essential biocatalytical difference between the natural flavocoenzyme and its 5-deaza modifications is not to be found in the oxidized state but in the half- and fully-reduced states[4]. To facilitate access to 5-deazariboflavins, we have sought a simple direct synthesis which at the same time can be used for introduction of sulfur in position 5 of the flavin. The 5-thiaflavins *(5)* and *(6)* thus formed act equally strongly on *Phycomyces*[5] as the deaza compounds. We presume—conversely to the situation in 5-deazaflavins—that the $e^{\ominus}$ transferability remains, while $H^{\ominus}$-transfer and O_2-reduction are blocked.



R^1 = Ribityl; R^2 = Tetraacetylribityl

Since the well known synthesis of deazaflavin[6] is tedious and, for ribityl derivatives, very unproductive, we resorted to a new method of flavin synthesis first reported by *Yoneda et al.*[7]. Ribitylxylidine *(1)* (Hoffmann-La Roche, Basel) was condensed with 6-chlorouracil *(2)* and the resulting product *(3)* reacted with DMF/$POCl_3$, SCl_2, or $SOCl_2$ directly after

[*] M. Janda and Prof. Dr. P. Hemmerich
Fachbereich Biologie der Universität
Postfach 7733, 7750 Konstanz (Germany)

acetylation to yield the flavin analogs *(4)*, *(5)*, or *(6)*, respectively, in good yields; they can be converted into the ribityl derivatives by deacetylation.

5-Deazariboflavin (4), $R^2=R^1$

A solution of 6-[*N*-(tetraacetyl-D-ribityl)-3,4-xylidino]uracil *(3)*, $R^1=R^2$, (2.50 g, 4.7 mmol) in DMF (8 ml) is treated with $POCl_3$ (0.80 ml, 8.7 mmol). The mixture is allowed to stand for 30 min at room temperature and for 15 min at 100 °C. It is then poured onto ice, adjusted to pH = 6 with ammonia at 0 °C, and stirred for 30 min. The product is filtered off, and washed with a large volume of water. After drying over P_2O_5, 2.30 g (91 %) of *(4)* is obtained. Deacetylation in 50 % saturated methanolic ammonia solution yields 1.10 g (62 %) *(4)*, $R^2=R^1$, which is thin-layer chromatographically and spectrally identical with authentic material[6].

5-Deaza-5-thia-1H-riboflavin (5), $R^2=R^1$

A solution of *(3)*, $R^1=R^2$, (3.7 mmol) in $CHCl_3$ (5 ml) is treated with SCl_2 (0.50 ml, 7.8 mmol) and stirred for 12 h at room temperature. The solvent is then removed *in vacuo* and the residue taken up in 10 ml DMF. This solution is added dropwise and slowly to 100 ml of a 0.1 M solution of $Na_2S_2O_4$ in 0.1 M phosphate buffer (pH = 7). After complete decoloration the solution is extracted three times with 100 ml $CHCl_3$ and the $CHCl_3$ removed *in vacuo*. The residual oil crystallizes upon addition of diethyl ether; yield 1.30 g (62 %) *(5)*. Deacetylation in 20 ml saturated methanolic ammonia solution affords 0.64 g (44 %) *(5)*, $R^2=R^1$. ^{1}H-NMR (1 N K_2CO_3 in D_2O): $\delta=2.05$ (s, 7,8-CH_3, 6H), 3.52—4.28 (m, 10-ribityl, 7H) and 6.50–6.75 ppm (6,9-CH, 2H); UV: pH = 13, anion, λ_{max} (ε) = 262 (27720), 298 sh (8320), 316 nm sh (3170); pH = 2, neutral entity, λ_{max} (ε) = 252 (18610), 280 sh (9590), and 345 nm sh (1980); $pK = 5.3 \pm 0.1$.

4,6-Diphenylthieno[3,4-*d*][1,3]dioxol-2-one 5,5-Dioxide, A Novel Activating Agent for Peptide Syntheses[**]

By *Oswald Hollitzer, Alfred Seewald*, and *Wolfgang Steglich*[*]

4,6-Diphenylthieno[3,4-*d*][1,3]dioxol-2-one 5,5-dioxide *(2)*, which is readily accessible by reaction of the sulfone *(1)*[1] with phosgene/pyridine, is of preparative interest as a doubly activated cyclic carbonic ester [IR(KBr): $\nu_{CO} = 1895\ cm^{-1}$].

We have found that *(2)* reacts smoothly with carboxylic acids and pyridine in anhydrous aprotic solvents to give the esters *(3)* (Table 1), which as mixed anhydrides of a vinylogous sulfonic acid [IR (KBr): $\nu_{CO} = 1780$—1775 and $1720\ cm^{-1}$] are excellent acyl transferring agents. Simple esters *(3)* can also be prepared directly from *(1)* by the usual acylation methods, but *(2)* is to be preferred in the case of *N*-acylamino acids because of the higher yields and mild reaction conditions.

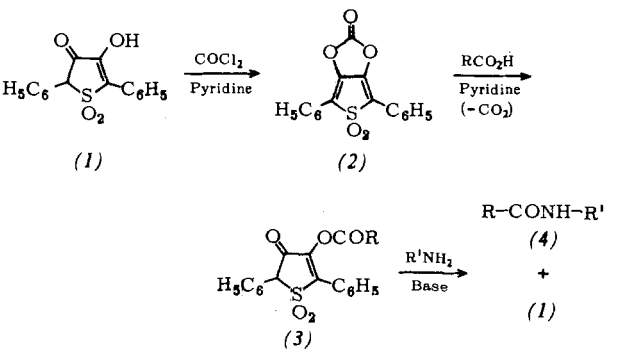

Table 1. 4-Acyloxy-3-oxo-2,5-diphenyl-2,3-dihydrothiophene 1,1-dioxide *(3)* [a].

Cpd.	RCO	Yield [%] [b]	Method [c]	M.p. [°C] [d]	$[\alpha]_{546}^{25}$ [°] [d]
(3a)	H_5C_2CO	70	C	101—102	—
(3b)	$(CH_3)_3CCO$	91	C	177—178	—
(3c)	Z-Val	95	A	161—163	43.5
		82	B

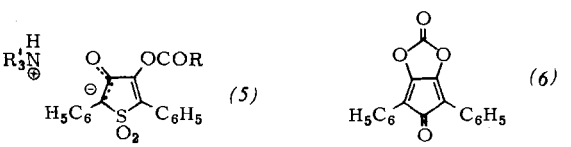
(3g)	Boc-Met	91	A	193—194	37.4

[a] All compounds gave correct elemental analysis.
[b] Crude yields of spectroscopically pure compounds.
[c] A: from carboxylic acid, pyridine and *(2)*; B: from carboxylic acid, *(1)* and dicyclohexylcarbodiimide; C: from carboxylic acid chloride, *(1)* and pyridine.
[d] Values for recrystallized analytically pure compounds. *(3c)*—*(3g)* are present as diastereoisomeric mixtures. [α]: $c = 1$ in dichloromethane.

The activated esters *(3)* are easily crystallizable, stable compounds which on reaction with amines in the presence of 1 mol pyridine or triethylamine readily afford the amides *(4)*. Addition of base prevents retardation of the reaction by the liberated acidic sulfone *(1)*[2]. Particularly advantageous is that on addition of the amine components, the esters *(3)* form orange-red anions *(5)*[3] whose disappearance, accompanied by a color change to pale yellow, indicates completion of reaction. The sulfone *(1)* formed along with the amide *(4)* is easily removed by extraction with aqueous hydrogen carbonate[4]. The activation with *(2)* and the amide coupling to *(4)* can also be carried out as a single vessel reaction without isolation of the activated ester *(3)*.



As shown in Table 2, sterically demanding dipeptide derivatives *(4)* are also formed in almost quantitative yields within

a few minutes. The products were characterized without resort to recrystallization and in most cases were analytically pure. A gas-chromatographic investigation of the *N*-trifluoroacetyl-Pro-Val methyl ester[5] revealed that activation and peptide coupling proceeds without racemization in the case of Z-Pro-Val-OMe[6].

Table 2. *N*-Acyldipeptide esters *(4)* [a].

(4)	Reaction time [min] Base employed	Yield [%]	M.p. [°C] [Lit.-m.p.]	Ref.

[a] Yield and m.p. of crude products after drying in an oil-pump vacuum.
[b] Without isolation of *(3d)* after 60 min preactivation of benzyloxycarbonylproline (Z-Pro) with *(2)* and pyridine.
[c] $[\alpha]_D^{20} = -34.0°$ (Ref. [8]: $-34.3°$); $c = 1$ in DMF.
[d] $[\alpha]_D^{25} = -11.1°$ (Ref. [9]: $-11°$); $c = 0.5$ in DMF.

Competing experiments demonstrate that the esters *(3)* are more effective acyl transferring agents than the *p*- and *o*-nitrophenyl esters commonly employed in peptide syntheses[11]. Thus, after 2 h at room temperature an equimolar mixture of *(3b)*, *p*-nitrophenyl acetate, and benzylamine in THF yields 97% *N*-benzylpivalamide and 3% *N*-benzylacetamide (NMR and GC analysis) even though *(3b)* is sterically grossly disfavored. On reaction of *(3a)* and *o*-nitrophenyl acetate with valine methyl ester in THF a mixture of 99% *N*-propionyl derivative and only 1% *N*-acetyl derivative is formed. We attribute the high activity of the ester *(3)* towards amines to the fact that the enolate group in the anion accelerates the aminolysis by intramolecular base catalysis[12].

In principle the peptide synthesis can also be carried out with 4,6-diphenylcyclopenta[*d*][1,3]dioxol-2,6-dione, which can be prepared analogously to *(2)* from 4-hydroxy-2,5-diphenyl-4-cyclopenten-1,3-dione[13], phosgene, and pyridine [*(6)*: black-violet crystals which decompose above 100°C without any definite melting point; IR (KBr): $\nu_{CO} = 1890$ cm^{-1}].

4,6-Diphenylthieno[3,4-d][1,3]dioxol-2-one 5,5-dioxide (2)

A 20% solution of phosgene in toluene (≈ 0.2 mol) is added dropwise at 20°C to a vigorously stirred solution of 4-hydroxy-3-oxo-2,5-diphenyl-2,3-dihydrothiophene 1,1-dioxide *(1)*[1] (30 g, 0.10 mol) and pyridine (17 ml, 0.21 mol) in dry tetrahydrofuran (600 ml). After 1 h the precipitated pyridinium chloride is filtered off and the filtrate freed of excess phosgene by passage of a stream of dry nitrogen. The filtrate is then concentrated to 2/3 of its original volume, refiltered, and finally concentrated further until crystallization of *(2)* takes place. After allowing to stand for several hours at 0°C, 24 g (73%) of yellow-green fluorescing needles crystallize out which decompose at >250°C. *(1)* can be recovered from the concentrated mother liquor by addition of sodium hydroxide, filtration, and subsequent acidification.

Activated ester (3f) of N-tert-butoxycarbonyl-L-phenylalanine

A mixture of *(2)* (1.96 g, 6.0 mmol), Boc-Phe-OH (1.33 g, 5 mmol), and pyridine (0.49 ml, 6.0 mmol) in anhydrous dichloromethane (50 ml) is stirred for 2 h (evolution of CO_2!). The mixture is washed three times each with 20% citric acid solution and saturated $NaHCO_3$ solution, then once more with citric acid and water. After drying over $MgSO_4$ and evaporation in a vacuum 2.63 g (96%) of the desired compound is obtained (m.p. 169°C; after recrystallization from ethyl acetate/petroleum ether, m.p. 170°C).

N-tert-Butoxycarbonyl-L-phenylalanyl-L-valine methyl ester of type (4)

To the red-orange solution of *(3f)* (1.10 g, 2.0 mmol) and triethylamine (0.61 g, 4.4 mmol) in anhydrous dichloromethane (50 ml) is added valine methyl ester hydrochloride (0.40 g, 2.4 mmol), whereupon the color changes immediately to pale yellow. The mixture is stirred for 15 min at 20°C and worked-up as in the case of *(3f)*. Yield 0.70 g (93%).

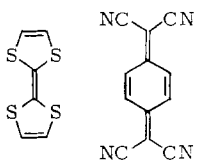
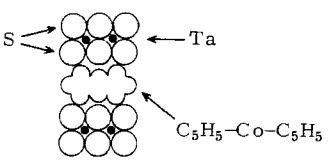
Reviews

Abstracts of selected progress reports and review articles

The electronic properties of some chain and layer compounds are reviewed by *A. D. Yoffe*. Solids having a chain or layer structure can be regarded as "one"- or "two-dimensional" solids if the distance between the molecular units lies in the order of magnitude of van der Waals radii. This leads to very strong anisotropy in electronic and mechanical behavior as well as in vibrational properties. Examples of conductive solids having metal-like chains are the charge transfer complex *(1)*, the polymer $(SN)_x$ and the complex



(1)



(2)

$K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$, which contains linear chains of platinum atoms. In the case of layer compounds the transition metal dichalcogenides MX_2 with molecules or atoms incorporated in them are of special interest. Metallocenes behave as pseudoalkali metals, *e.g.* in *(2)*. [Electronic Properties of Some Chain and Layer Compounds. Chem. Soc. Rev. *5*, 51—78 (1976); 52 references]

[Rd 856 IE—F]

The oxidation of organic compounds with active MnO_2 is the subject of a two-part review by *A. J. Fatiadi*. MnO_2 is a mild reagent for the heterogeneous oxidation of alcohols and hydroxy compounds (unsaturated and saturated aliphatic alcohols, benzyl alcohols, heterocyclic alcohols, polyhydroxy compounds, carbohydrates, phenols), terpenes, steroids and alkaloids. The reaction conditions for the synthetic use of active MnO_2, the selectivity and specifity of MnO_2 as oxidizing agent, and the mechanisms of oxidation (free radical and ionic) are discussed. In the second part the author deals with the use of MnO_2 in benzilic acid type rearrangements, selective dehydrogenation reactions (*e.g.* in steroids and N-heterocycles), and the aromatization of carbocyclic and heterocyclic compounds. MnO_2 is an interesting reagent for the oxidation of primary, secondary, and tertiary amines and amine derivatives (hydroxylamine, oximes, hydrazine, hydrazides, azines, and hydrazones). Also dealt with are, *inter alia* the oxidation of nitriles, indoles, carbazoles, as well as the oxidative dimerization of heterocyclic compounds. [Active Manganese Dioxide Oxidation in Organic Chemistry. Synthesis *1976*, 65—104, 133—167; 697 references]

[Rd 858 IE—M]

The role of membrane proteins in anion transport in erythrocytes is dealt with in an article by *A. Rothstein, Z. I. Cabantchik*, and *P. Knauf*. As is known from affinity labelling experiments, anionic inhibitors of anion transport bind themselves to a membrane protein of molecular weight 100000, which is known as band 3. In part, this protein is exposed on the membrane, and with the aid of hydrophobic amino acid side chains partly interacts with membrane lipids. A model is proposed in which this protein serves as a channel for migration of the anions through the lipid double layer. A binding site for anions at the external exit of this channel is thought to make an anion exchange through a diffusion barrier possible by a local conformational transformation. [Mechanism of Anion Transport in Red Blood Cells: Role of Membrane Proteins. Fed. Proc. *35*, 3—10 (1976); 61 references]

[Rd 859 IE—R]

Biochemical aspects of the toxicology of cadmium are reviewed in an article by *R. L. Singhal, Z. Merali*, and *P. D. Hrdina*. It is known that cadmium accumulates in certain target organs *e.g.* liver and kidney, in which histological alterations are also detectable. In particular the influence of cadmium on the carbohydrate metabolism of the liver, as well as on the adrenal cortex, prostate, testes, pancreas and brain of the rat has been investigated. In most cases the alteration of metabolism lasts up to 28 days after termination of cadmium treatment. [Aspects of the Biochemical Toxicology of Cadmium Fed. Proc. *35*, 75—80 (1976); 51 references]

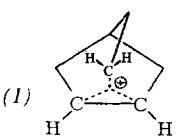
[Rd 860 IE—R]

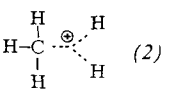
The metabolism of xenobiotica in the lung is the subject of an article by *E. Bingham, R. Niemeier*, and *W. Dalbey*. In this system—isolated lung perfused with autologous blood—benzo[a]pyrene affords the corresponding 3-hydroxy compound, three dihydrodiols and, in a yield amounting to 50% of all metabolites formed, an unidentified polar compound. Pretreatment with 3-methylcholanthrene accelerates the metabolization and slightly alters the product pattern. [Metabolism of Environmental Pollutants by the Isolated Perfused Lung. Fed. Proc. *31*, 81—84 (1976); 19 references]

[Rd 861 IE—R]

The σ-bridged 2-norbornyl cation *(1)* and its significance to chemistry is the title of a survey by *G. A. Olah*. The carbocation *(1)* is an example of carbon compounds having two-electron three-center bonds; in order to distinguish it from the "classical" carbenium ions of type CR_3^+ having normal two-electron two-center bonds it is called a "nonclassical" ion. The parent compound is the methonium ion *(2)*, a pentacoor-

(1)





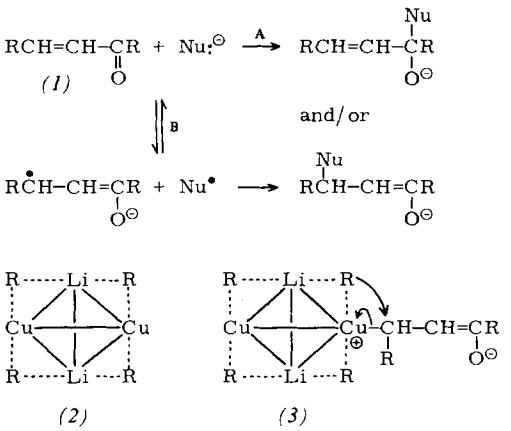
(2)

dinated carbonium ion. After an introduction to the norbornyl problem and a survey of the state of solvolytic investigations, as well as a discussion of NMR, Raman, ESCA, and equilibrium studies, the author states that there is no such thing as a perfectly "classical" carbocation; there is always some degree of delocalization. [The σ-Bridged 2-Norbornyl Cation and Its Significance to Chemistry. Acc. Chem. Res. *9*, 41—52 (1976); 49 references]

[Rd 862 IE—L]

Additions of lithium organocuprates as models for electron-transfer processes are the topic of a review by *H. O. House*. The addition of nucleophiles $Nu:^-$ to unsaturated carbonyl compounds *(1)* (or other electrophiles) can proceed *via* path

A (one step) or path B; in path B only one electron is transferred in the first step. The lithium organocuprates $R_4Cu_2Li_2$ (R = *e.g.* CH_3) *(2)*, which are probably dimeric, apparently react with unsaturated carbonyl compounds *(1)* exclusively *via* path



B. *(3)* might be formed as intermediate. [Use of Lithium Organocuprate Additions as Models for an Electron-Transfer Process. Acc. Chem. Res. 9, 59—67 (1976); 34 references]

[Rd 864 IE—L]

Crystals and long-chain molecules are considered by *L. Mandelkern*. Long-chain molecules having sufficiently regular structure, *e.g.* polyethylene, can form three-dimensional arrangements worthy of the name crystals. Crystallization from diluted solution leads to lamellae 100—200 Å thick and several µm long and wide. Their interfaces are amorphous. Crystallized melts are also made up of lamellae whose thickness can vary between several hundred and several thousand Å. A model of a crystallite is proposed in which a lamellar-type ordered structure is covered by an intermediate layer of moderate order followed by an amorphous layer. [Crystals and Long-Chain Molecules. Acc. Chem. Res. 9, 81—86 (1976); 36 references]

BOOK REVIEWS

Atom-Absorption-Spektroskopie (Atomic Absorption Spectroscopy). By *B. Welz*. Verlag Chemie, GmbH, Weinheim 1975, 2nd completely revised edit., xii, 296 pp., 73 figs., 46 tables, bound, DM 68.—.

After a brief introduction to the physical basis of atomic absorption spectroscopy (AAS) the first part of this book consists of an extensive description of experimental methods and instrumentation; the construction of atomic absorption spectrometers, the use of various primary light sources, possible methods of atomization, as well as the optics and signal registration of the apparatus are described. The second part, which deals with the analytical applications, contains at first general instructions concerning operating techniques and possible sources of interference, and then, separately for each element, special indications for favorable working conditions, these being in some cases supplemented by information about interference and preparation of the samples. Indirect methods for the determination of some compounds and nonmetals are included. A relatively large space is devoted to methods of investigation for specialized areas of application, *e.g.* medicine, geochemistry, metallurgy, petrochemistry, and food and water analysis; in these cases detailed experimental instructions are largely omitted, the reader being referred to the very rich original literature (in all, 1388 references are cited). Finally, in an Appendix, there is a brief comparison of the design of most commercial atomic absorption spectrometers.

The book considers the state of knowledge about AAS up to about the end of 1974. In comparison with the first edition, the work has been extended mainly in the field of flameless procedures, which have gained greatly in importance in recent years. It is particularly welcome that the author describes not only the determination of individual elements on this instrument but also the preparation of the samples, for this is often the major part of the analytical problem. Summarizing, the book can be recommended to all concerned with AAS as a method of analysis. Indeed, it is the only book so far on this subject that has appeared in German.

Reinhard Höhn [NB 318 IE]

Elektrochemie I (Electrochemistry I) (taschentext 41). By *C. H. Hamann* and *W. Vielstich*. Verlag Chemie, GmbH, Weinheim 1975. 1st edit., x, 192 pp., 58 figs., 18 tables, paperback, DM 26.80.

This book from the "taschentext" series deals with the classical fields of electrochemistry, namely electrolytic conduction, electrode potentials from a thermodynamic point of view, and the properties of the electrode/electrolyte phase boundary (models of the electrochemical double layer). It is intended primarily for students who will value the terse way in which the subject is treated.

It is very useful to have an indication of numerical orders of magnitude, *e.g.* in the conductivity table on p. 25.

The relatively detailed discussion of liquid potentials, to which a separate chapter is devoted, is highly welcome, being justified by the importance of these quantities for exact potential measurements. Simple applications of conductivity and potential measurements are treated separately. Electrochemistry in nonaqueous solvents is also considered.

The authors place emphasis on a clear statement of concepts, and in this they have been very successful. In this connection, however, the definition of an ionic conductor on p. 6, which corresponds rather to the exceptional case, should be reconsidered. The simple relationship $\lambda = F \cdot b$ between the ionic equivalent conductivity λ and the mobility b should if possible be placed at the beginning of Chapter 2. The quality and production of the book are such that one awaits with impatience the second volume, in which modern areas such as electrode kinetics, batteries, and organic electrosyntheses will be treated.

Fritz Beck [NB 319 IE]

Dynamic Nuclear Magnetic Resonance Spectroscopy. Edited by *L. M. Jackman* and *F. A. Cotton*. Academic Press, Inc., New York 1975. 1st edit., xiv, 660 pp., numerous figs., and tables, bound, $ 48.00.

The importance of NMR spectroscopy as a method of studying chemical kinetics has long justified a special mono-

graph reviewing the achievements. As editors, *L. M. Jackman* and *F. A. Cotton* have made such an attempt, in which contributions on the technique and application of NMR spectroscopy to time-dependent phenomena are collected under the concept of "dynamic NMR spectroscopy". After an introduction by *H. S. Gutowsky* (22 pp.), *W. G. Klemperer* treats the relationships between reaction mechanisms and NMR exchange processes (22 pp.), and *G. Binsch* describes line shape analysis (38 pp.). There follow two chapters on pulse spectroscopy with applications to exchange processes by *L. W. Reeves* (48 pp.) and measurement of relaxation times by *R. Freeman* and *H. D. W. Hill* (32 pp.). The remainder of the volume is devoted to phenomena that have been brought to light by means of dynamic NMR spectroscopy; rotations around single bonds (*S. Sternhell*, 40 pp.), rotation around partial double bonds (*L. M. Jackman*, 50 pp.), dynamic processes in inorganic and organometallic compounds (*J. P. Jesson* and *E. L. Muetterties*, 64 pp.), in metal chelates (*R. H. Holm*, 60 pp.), in organometallic compounds (*F. A. Cotton*, 64 pp.), in allyl compounds (*K. Vrieze*, 48 pp.), in carbonyl-metal compounds (*R. D. Adams* and *F. A. Cotton*, 34 pp.), in carbenium ions (*A. L. Telkowski* and *M. Saunders*, 20 pp.), in cyclic compounds (*F. A. L. Anet* and *R. Anet*, 78 pp.), and in proton-transfer processes (*E. Grunwald* and *E. K. Ralph*, 28 pp.). This list shows that similar material is not offered in any other place, even if individual subjects have been treated in more detail in specialist monographs. It is only regrettable that there is no chapter on valence tautomerism. It is less painful that there is no contribution on pyramidal inversion, because excellent reviews of this are available. The references are fairly comprehensive up to 1972, and in individual cases also for 1973/74. The experimental results thus remain wholly within the scope of proton-NMR spectroscopy. All in all, this is a book that because of its broad survey of possible applications may interest a wide circle of readers.

Harald Günther [NB 322 IE]

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopedia of Industrial Chemistry). Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), and *W. M. Weigert*. Vol. 9: Butadien bis Cytostatica (Butadiene to Cytostatics). Verlag Chemie, GmbH, Weinheim 1975. 4th edit., xvi, 714 pp., 248 figs., 294 tables, subscription price DM 345.—; individual price *ca.* DM 385.—.

This volume of the 4th edition of "Ullmann" is the third in the alphabetical series[*]. Of its 714 pages, 269 are taken up by chlorine and keywords beginning with "Chlor" (chloroacetaldehyde, chloroformic esters, chloramines, chloroacetic acids, chlorohydrocarbons, *etc.*). Other keywords are taken from inorganic chemistry, including the metals cadmium, cesium, calcium, cerium, and chromium with their compounds of industrial interest, also carbides and cyanogen compounds. Mention may also be made of the organic raw materials and chemicals: butene, butadiene, butanols, butyraldehyde, citric acid, caprolactam, aliphatic and aromatic carboxylic acids. When, as in the last-mentioned case, the keyword covers a group of compounds, then the more important representatives of such a group are treated as sub-entries in alphabetic order—for aliphatic carboxylic acids, for example, acetic, formic, and propionic acid are treated in this way. Similarly, pulp and paper are not treated under cellulose (70 pages including the keywords cellulose ethers, esters, and fibers) but are listed individually at other places. Of the pharmaceuticals, chemotherapeutics (43 pages, not including the antibiotics which appeared in vol. 7) and cytostatics (10 pages) can be found. Special keywords include carcinogens (8 pages) and dry cleaning (6 pages).

As in the earlier volumes, subdivision under the individual keywords is effected, whenever possible, in a similar way, which helps the user to find his way in the book. After the introduction the physical and chemical properties are first treated, then production methods and applications. Demands on quality and analysis as well as other practical problems (handling, storage, shipment, environmental questions) are often added. The conclusion is provided by economic aspects and toxicology as well as a list of references.

In the case of keywords that because of their importance are treated in greater detail, *e. g.* chlorine (56 pages), the presentation has the character of a monograph. Thus, among the physical properties of chlorine one finds tables and diagrams, in which (as elsewhere in the new Ullmann) SI units are generally used. For the production of chlorine by electrolysis of sodium chloride—still the most important method—variants of the mercury and the diaphragm process are explained; here the tabular comparisons of the various cell constructions and of the production costs are particularly valuable.

The up-to-date nature of the presentation emerges impressively when in the section on toxicology under the keyword Aliphatic Chlorohydrocarbons one reads what is reported about vinyl chloride; here 10 references are given from 1974 and two from 1975. In this connection it may be noted that for all the keywords the section on toxicology has been provided by *H. Oettel* (Ludwigshafen, Germany).

The new Ullmann no longer needs a special recommendation, and it is to be hoped that the publishers will bring out further volumes in rapid succession.

Das Spiel — Naturgesetze steuern den Zufall (The Game—Natural Laws Govern Chance). By *M. Eigen* and *R. Winkler*. R. Piper & Co. Verlag, Munich—Zurich 1975. 1st edit., 404 pp., 67 colored figs., bound, DM 38.—.

A game book? The game book, namely the book of "Ludus universalis" to "Ludus vitalis" of 1973. What is the nature (physis) of the world? This age-old question, to which the early Greek thinkers of the 6th century B. C. first sought an answer in rational principles (archai), has not lost its topicality during the two and a half millenia that have passed since then. "The Game", within the definition of the Göttingen Nobel prize winner and his associate, gives the (provisionally) final answer: "We see the game as a natural phenomenon that by its dichotomy of chance and necessity lies at the root of all events" (p. 11). "Once begun by elementary particles, atoms and molecules, it is now continued by our brain cells" (p. 18). Thus the "game" principle, with its interrelation between chance and law, is valid equally for nature *and* mind. It is therefore far more than a game of marbles. On the other hand, the expressed emphasis on the complementarity of chance and law in the factual evolutionary game of matter must be firmly borne in mind before accepting one-sided over-evaluation of any individual aspect. Not only waves and corpuscles, natural chance and natural law, and "creation" and "revelation" are complementary, but also the game of nature and the game of the mind, the starting point and the extension. The discussion in this book deals with the validity of the symbolism of the game concept itself and evaluation of its validity beyond the biophysical-chemical framework. All dogmatism is avoided as is all that is blatantly noncommittal: the former is taken care of by the variety of vantage points, the latter by the specific nature of the details. The Eigen-Winkler game principle, even the outline of which can hardly be indicated here, is a fascinating design of ancient

[*] Cf. Angew. Chem. Int. Ed. Engl. *14*, 578 (1975).

simplicity and complex extensibility whose usefulness for universal interpreations has not yet beeneven explored. Let us hope that the spoil-sports do not get busy!

Friedemann Rex [NB 323 IE]

Mathematik für Naturwissenschaftler (Mathematics for Scientists). By *H.-D. Försterling*. Friedrich Vieweg & Sohn, Verlagsgesellschaft, Braunschweig 1975. 1st edit., 289 pp., numerous figs. and tables, paperback, DM 38.—.

While this book is intended for beginner science students, it will also provide anyone who works seriously through it with the theoretical background suited to many scientific problems.

About a third of its length is taken up by problem sets and their solution. The approach to the problems is developed from the text and, whenever possible, supported by graphical presentation. The examples are chosen simply and from all areas of chemistry and physics. Emphasis is always placed on calculation with real quantities *i.e.* with data containing errors or dimensions, which is helpful for the application of the methods explained to practical problems. (However, the way dimensions are applied in the graphical presentations is somewhat unfortunate.) The readily understandable introduction of concepts and definitions is in line with the book's purpose. The author's up-to-date attitude to the aids becoming increasingly available to the scientist is particularly pleasing: computer programs, *xy*-recorder printouts, *etc.* are freely used. The value of analytical solutions of mathematical problems is emphasized, permitting the user to test his ideas rapidly with pocket or desk calculators. Simple numerical methods are also given.

It is difficult to criticize this book which is of a very high standard factually, didactically, and as far as the printing is concerned. Rather, one would like to see an equally intelligible presentation of vector calculus, calculation of errors, and mathematical statistics, since this text is restricted to the properties of functions of one or more variables. It is hoped that wide circulation of this book will not be hindered by its price.

Penetration and Crosslinking of Macromolecules[**]

By Dietrich Braun[*]

One of the topical problems of macromolecular chemistry is the question of the extent to which macromolecules in solution or in the amorphous solid state can engage in mutual interpenetration. The present article is concerned primarily with recent investigations on crosslinking copolymerization and with inter- and intramolecular reactions of polymers as a contribution to the study of molecular shape.

1. Introduction

The question of the shape of macromolecules in highly dilute solution has long been a focal point of physicochemical investigation in the field of polymers[1]. The overall conformation of the molecules can accordingly be described in general in terms of the model of the ideal random coil, provided that interactional forces of constitutional origin between the repeat units do not lead to a higher, *e.g.* helical, order. This special case has been excluded from the following discussion, although it must be pointed out that even completely helical molecules can form random coils at very high degrees of polymerization.

The picture of an ideal random coil with infinitely thin chain has to be modified in practice because real molecules possess a finite thickness and thus occupy a certain volume; this leads to an "excluded volume", which causes some enlargement of the coil relative to the "ideal state", even at infinitely high dilution. Moreover, the location of one molecule is clearly not available to a second one. Therefore the question arises whether a mutual interpenetration of different coils can be achieved in polymer solutions with increasing concentration or whether the individual macromolecules coexist as completely or partially isolated entities (cell model of *Vollmert*[15]; cf. Fig. 1). The related problems are also of importance for the conformation of polymers in the molten and the amorphous solid state; appropriate studies thus possess not only scientific but also considerable practical interest, *e.g.* for film formation from polymer solutions and for the properties of polymeric melts or glasses. Finally, important conclusions about the structure of networks can be drawn from observa-

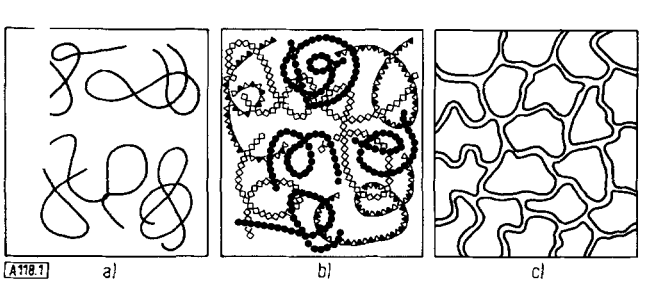

Fig. 1. Schematic representation of the behavior of dissolved macromolecules: a) in highly dilute solutions (particle solution according to *Schurz*[14]); b) on coil interpenetration; c) on hindered interpenetration (cell model of *Vollmert* [15]) or hooking together in the boundary regions of the coils (network solutions according to *Schurz* [14]).

[*] Prof. Dr. D. Braun

Schlossgartenstrasse 6 R, 6100 Darmstadt (Germany)

[**] Based on lectures to the Bezirksgruppe Niedersachsen of the Deutsche Kautschukgesellschaft at Hannover (Jan. 15, 1974), Regional Meetings at Stuttgart (Jan. 9, 1975) and Krefeld-Uerdingen (May 19, 1975), and the General Meeting of the Gesellschaft Deutscher Chemiker, Köln (Sept. 10, 1975), and the Chemische Gesellschaft der DDR, Dresden-Freiberg Regional Group (Oct. 30, 1975).

tions on the curing of duroplastics, *i.e.* crosslinking reactions between linear macromolecules, from their shape in concentrated solutions or melts; a similar situation exists with crosslinking polyreactions. Thus there is also a close relationship between the problem of interpenetration of linear macromolecules and the density of polymeric networks.

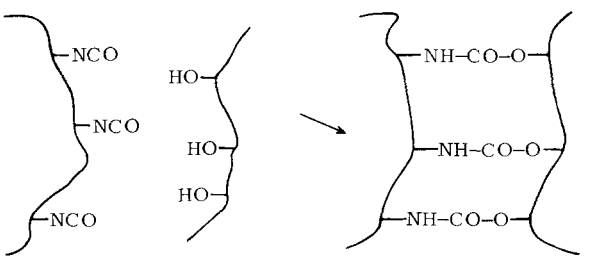
2. Experimental Studies on Coil Interpenetration

While information about the shape and arrangement of chain molecules is available from X-ray studies in the case of partially crystalline solid polymers, this becomes much more difficult for dissolved or amorphous solid polymers. A thermodynamic treatment of polymer solutions according to the Flory-Huggins theory permits deduction of the presence of ideally coiled macromolecules with complete mutual interpenetration[1]. Investigations of aggregation thickness in microheterogeneous block copolymers, light scattering and diffusion of dissolved macromolecules in polymer mixtures, and rheological measurements lead, according to *Hoffmann*[2, 3], to the conclusion that the molecules in amorphous soft polymers and also in normal solution form random, interpenetrating coils. *Pechhold*, on the other hand, has predicted chain molecules to exist as parallel extended bundles of molecules also in the amorphous solid state[4]. In this connection, particular interest attaches to recent work by *Kirste*, who has employed neutron diffraction on mixtures of normal and deuterated amorphous polymers in the solid state and in concentrated solutions to derive information about the size of the coils[5, 6]. Accordingly, the coil dimensions, *e.g.* in solid poly(methyl methacrylate), are practically the same as those measured in low-molecular Θ solvents[*], thus suggesting extensive interpenetration. Other authors[7–9] have also concluded on the basis of various methods of investigation that amorphous polymers form loose, interpenetrating coils.

Opposing evidence comes from some rheological studies[10, 11], whose results can be interpreted by assuming the polymer coils in concentrated solution to preserve the same individuality as in highly dilute systems but with a concentration-dependent compressed coil volume. The "hooking" of the coils occurring above a certain concentration are assumed by *Schurz* to lead to an infinitely extended network[12]. The dependence of the viscosity of the polymers upon their molecular weight ("Bueche-plot") can be used to determine the mesh width of this network[13]. *Schurz* therefore proposed replacement of the distinction between "dilute" and "concentrated" solutions of polymers by the more comprehensive one between "particle solutions" and "network solutions"[14].

A very important contribution to the question of the properties of polymer coils in highly concentrated solutions is due to *Vollmert* and *Stutz*[15]. They attempted to solve the problem by chemical means, with the aid of crosslinking reactions which proceed exclusively by intermolecular mechanisms. To this end a polymer containing the functional group x was mixed with a second polymer containing the functional group y. In this experiment x and y can react with each other quantitatively, but no reaction is possible between x and x or y and y. The concentration-dependent conversion, *i.e.* the consumption of functional groups during the reaction, and the proportion of crosslinked polymer formed will, under certain conditions, afford the degree of interpenetration of the coils.

These experiments were carried out with, *e.g.* a random copolymer of butyl acrylate with 2-isocyanatoethyl acrylate monomer units and a second random copolymer of butyl acrylate with 4-hydroxybutyl acrylate monomer units (Scheme 1). On mixing of the two previously separately dissolved polymers, the conversion displays a pronounced dependence upon the polymer concentration as expected; below 5 wt % conversion was very low and the resulting gel consisted merely of coils linked together only at the surface *via* urethane groups. Although the intermolecular reaction between the coils in the external regions steadily increases as the concentration of polymer rises, the reaction does not go to completion, thus indicating the coils to be largely impenetrable. On use of the polymer containing the same hydroxyl group with hexamethylene diisocyanate as reactant the reaction goes to completion because the low molecular crosslinking agent can penetrate unhindered into the interior of the coils.



Scheme 1

There are two principal objections to the postulated inability of coils to engage in mutual interpenetration: it is conceivable that a rapid reaction between individual functional groups occurring on mixing of the two dissolved polymers may lead to fixation of chain segments; this could stop the system reaching the end point of interpenetration corresponding to maximum entropy. Another argument is the general incompatibility of chemically different polymers; under the experimental conditions employed this could have led to a separation of the NCO- and OH-containing macromolecules and thus simulate an impression of impenetrability of the coils.

Vollmert attempted to counteract these misgivings by permitting reaction of polymers with different contents of functional groups and then extrapolating to any desired low values of functional groups; the chemical difference should then no longer be significant. Even under these conditions the maximum attainable conversion for 30 % polymer solutions is only about 16 to 18 % so that on exclusion of possible hindrance to reaction by crosslinking or incompatibility incomplete interpenetration still has to be assumed. According to this interpretation the reacted functional groups are located only in the outer or contact zones of the coils while the monomer units in the interior of the coils cannot react.

In order to further examine this concept, the reaction of a poly(methyl methacrylate) containing hydroxyl groups with an equivalent amount of a polymer having acyl chloride groups

[*] In a "theta solvent" a polymer solution displays pseudoideal behavior, which of course also depends upon temperature (so-called Θ temperature); $\Delta H_{mix} = \Theta \Delta S_{mix}$.

was investigated near the Θ state[*] in benzene/*n*-hexane mixtures. Approximately the same degree of coil interpenetration was found as in good solvents, *i.e.* 5 to 20% of the coil volume[16]. Hence it follows that the theory of excluded volume is not applicable to the problem of coil interpenetration and in spite of the absence of a thermodynamic hindrance, steric reasons must be responsible for the observed "cell structure" also at the Θ point[17].

Finally, a completely different concept of the morphology of macromolecular materials also deserves mention: *Schoon et al.*[18] regard the structure of such polymers in the dissolved and solid state as a kind of packing of approximately equal sized tertiary spheroids linked together by a common molecular thread. For each polymer the size of the tertiary units is assumed to be a kind of material constant. This picture has been derived mainly from electron microscope studies and from the results of ultrasonic degradation of polymers[19]; no support has yet been obtained from other physical or chemical experiments.

3. Recent Results

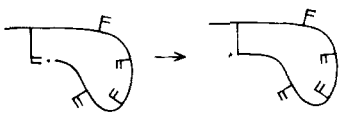
The findings discussed in Sections 1 and 2 show a distinct disagreement to exist between the classical ideas of the coil structure of dissolved and amorphous solid polymers with extensive interpenetration and the cell model supported in particular by the work of *Vollmert* in recent years. Further investigations will therefore have to shed fresh experimental and theoretical light, in order to permit a decision in favor of one of the opposing views or a modification of previous concepts. The present article is concerned mainly with "chemical probes" for examining molecular shape and will not give detailed consideration to any of the purely physical methods employed in recent years. Apart from crosslinking copolymerization, recent experiments on inter- and intramolecular chain linkage are discussed[20]. Among the physico-chemical methods, mention should be made of the use of spin-labeled macromolecules for the study of interactions between various polymers whose monomer units contain unpaired electrons; this technique is still in its infancy (cf., *e.g.*[21]) but holds promise of interesting information about chain mobility of macromolecules and their relaxation phenomena and also about chain conformations. Preliminary results obtained with concentrated poly(vinyl butyrate) solution in ethanol suggest shrinkage of the coils with increasing polymer concentration to below Θ dimensions[21].

3.1. Crosslinking Copolymerization

On copolymerization of a monovinyl compound with a nonconjugated divinyl monomer, the resulting macromolecules branch already after very small conversions since the divinyl compound is tetrafunctional owing to the presence of two reactive double bonds. An active growing chain terminus can therefore react not only with monomer molecules but also with "pendant" double bonds on previously formed "dead" macromolecules so that each unit of the divinyl monomer incorporated into a polymer chain is a potential crosslinking site.

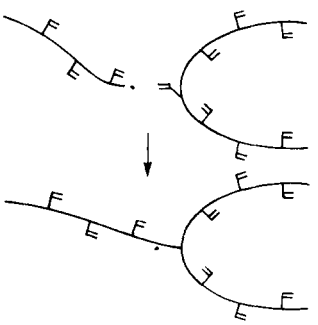
[*] See footnote on p. 452.

On extensive dilution, *i.e.* when the growing chains are largely present as isolated coils, there is a high probability that for a sufficient chain length the active chain end will react with a double bond on the same macromolecule, leading to intramolecular linkage, *i.e.* a cyclization point (Scheme 2).



Scheme 2

In contrast, intermolecular reactions are only possible if the growing chain is sufficiently close to another one, *i.e.* to another coil; this depends mainly on polymer concentration and thus also on the conversion attained in the polymerizing system. This reaction leads to braching sites (Scheme 3).



Scheme 3

Provided that it is possible to determine the ratio of intra- and intermolecular reactions as a function of the conversion, direct conclusions can then be drawn regarding the extent of coil interpenetration. However, a knowledge is required of the reactivity of the active chain ends and the related incorporation ratios of mono- and divinyl compounds into the growing chain, as is an experimental means of distinguishing between cyclization (Scheme 2) and branching reactions (Scheme 3).

3.1.1. Copolymerization Kinetics

Joint polymerization of two or more monoolefins, *e.g.* monovinyl compounds, can be quantitatively described under certain conditions by the known copolymerization equation. On this basis it is also possible to determine the composition of a copolymer from two or more different monomer units as a function of the monomer ratio and the conversion. The calculation becomes somewhat more complicated if a monoolefin (M_1) is copolymerized with a diolefin (M_2). Not only must the two monomers M_1 and M_2 be considered but also the pendant reactive double bond (M_3 from M_2) and the repeat units incorporated *via* the two double bonds (crosslinking sites N from M_2).

Several publications have been concerned with this problem from a kinetic standpoint[22-26]. In contrast to a normal binary copolymerization of two monoolefins with four possible growth steps, crosslinking copolymerization requires consideration of nine growth reactions. Under certain conditions, however, the calculations can be greatly simplified[26]: the double

bonds of the monomeric diolefin M_2 must possess the same polymerization activity as the double bonds M_3 attached to existing polymer chains which have arisen from the same diolefin already polymerized *via* one double bond. Of course, this only applies if the two double bonds are independent of each other and are not conjugated or in resonance, as *e.g.* in *m*-divinylbenzene, and if the diolefin cannot undergo cyclopolymerization. Under these conditions the change in concentration of the monomers, the attached double bonds, and the crosslinking sites can be described in terms of the degree of polymerization by a series of differential equations which can be solved by stepwise integration provided that the copolymerization reactivity ratios are known[26].

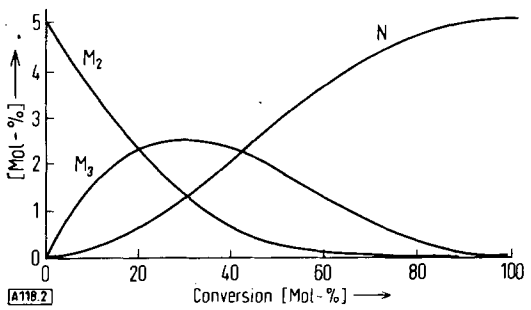


Fig. 2. Copolymerization of ethylene dimethacrylate (EDMA) and styrene. Concentration profile of EDMA (M_2), attached double bonds (M_3), and crosslinking sites (N) as function of conversion for an initial 5 mol % concentration of EDMA.

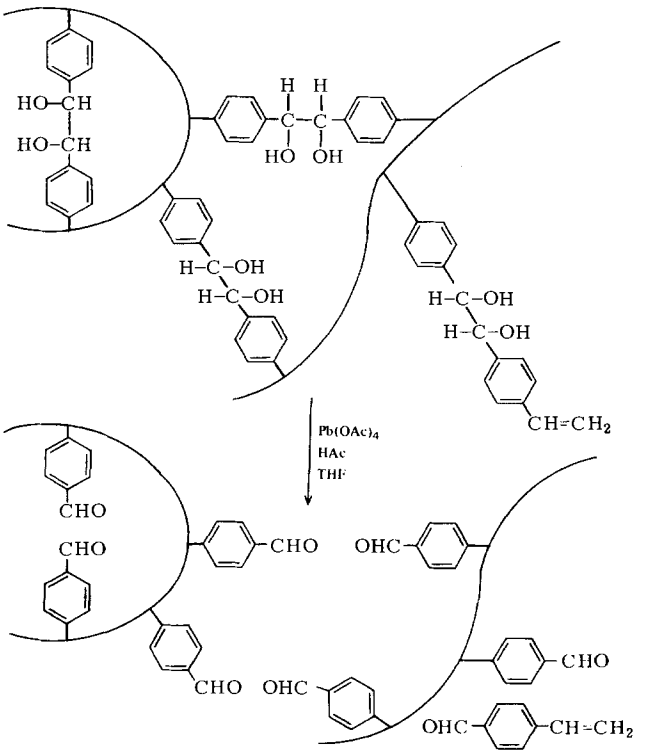
As an example, Figure 2 shows the results obtained for the copolymerization of ethylene dimethacrylate (EDMA) and styrene for 5 mol % of EDMA in the starting mixture. The concentration of the diolefin (M_2, EDMA) initially decreases rapidly, then more slowly until M_2 is completely incorporated into the polymer chain at *ca.* 90 % conversion. Accordingly, the concentration of attached double bonds (M_3) initially increases, reaching a maximum at 30 mol % and then decreases because reaction of these double bonds forms additional crosslinking points (N) which attain the initial concentration of the diolefin at quantitative conversion. Similar situations, dictated by the copolymerization reactivity ratios and the chosen monomer ratios, are observed in other systems[26]. They provide a basis for the following views on the competition between inter- and intramolecular growth steps of crosslinking polyreactions.

3.1.2. Polymers Having Cleavable Network Bridges

A distinction between inter- and intramolecular crosslinking can be accomplished with polymers made up of diolefins which can be cleaved by simple and chemically unequivocal methods after their introduction into a macromolecule. Any opening of intramolecular bonds, *i.e.* rings, in the process will not affect the molecular weight of the polymer, whereas a decrease in molecular weight will occur in the case of splitting intermolecular crosslinks. There are several divinyl compounds which are suitable for such studies. Thus monomers having benzyloxycarbonyl groups[22], which can be cleaved with hydrogen bromide and glacial acetic acid, azomethine groups which are ruptured by acid treatment[23,27], and ethylene glycol groups which can be scissioned by lead tetraacetate[28] have all been used. Scheme 4 illustrates the cleavage of products arising from *e.g.* styrene and 1,2-bis(4-vinylphenyl)-1,2-ethanediol (DSG).



Scheme 4

The crosslinks are opened to form *p*-vinylbenzaldehyde monomer units which can be determined, *e.g.*, by IR spectroscopy[28]. Since determination of the molecular weight of crosslinked, and hence insoluble polymers, is impossible, polymerization must be broken off shortly before the gel point; the

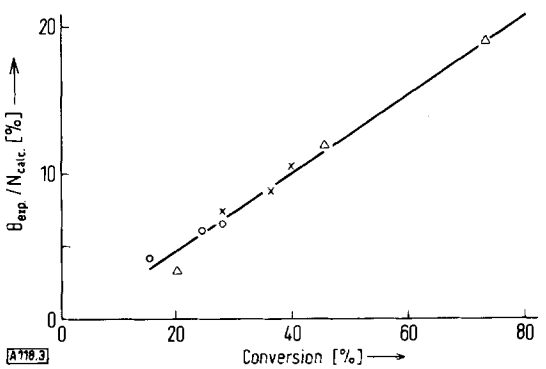


Fig. 3. Ratio of experimentally determined branching sites (B) to the calculated total number of all linkage sites (*i.e.* the sum of branching and cyclization sites) as a function of conversion in the radical copolymerization of 1,2-bis(4-vinylphenyl)-1,2-ethanediol (DSG) and styrene. Initial total monomer concentration 2 mol/l. o, 5 mol %; Δ, 3 mol %, ×, 1 mol % DSG at commencement.

(branched) polymers are then cleaved and the molecular weights recorded before and after cleavage are compared. The experimentally determined number of branching sites

can then be correlated with the total number of crosslinking sites, *i. e.* the sum of the branching and cyclization sites, which can only be computed as an overall sum.

Figure 3 shows the results obtained for copolymers of DSG and styrene. Within a relatively broad range of composition of the starting mixture (between 1 and 5 mol % DSG) the ratio of the experimentally determined branching sites to the sum of the calculated branching and cyclization sites for a given concentration of starting monomer depends practically only upon the conversion. The considerable difference between experiment and calculation demonstrates that in the system investigated up to 20-fold fewer branching sites are formed than were expected. This would indicate that, even for relatively high conversions, *i. e.* in this case high polymer concentrations, there is an unexpectedly large number of cyclization steps during the polymerization, which can only be explained by pronounced hindrance of the access of growing macromolecules to the double bonds attached to other coils. Thus crosslinking copolymerization proves to be an example of strongly hindered coil interpenetration; this finding has considerable consequences for the network structure of the polymers, which is certainly highly inhomogeneous in the case discussed.

However, it must be clearly emphasized that the modest interpenetration found for crosslinking polymerization should not be generalized and applied to linear polymers, for network formation will undoubtedly lead to some shielding of the attached double bonds in the coil interior against approaching polymer chains so that they will react primarily in the boundary regions of the coils.

A deficit of this magnitude between predicted and calculated crosslinking yields as a result of preferential intramolecular cyclization or sterically conditioned incomplete reaction of attached double bonds has repeatedly been observed[22,23,29-32]. The extent of cyclization or of unconsumed attached double bonds is distinctly dependent upon the nature of the tetrafunctional comonomer M_2 and upon the reaction conditions. While it must be assumed at the onset of reaction that chain initiation can occur practically anywhere in the system owing to the high concentration of monomer, the proportion of monomer will fall with increasing conversion, *i.e.* with increasing polymer content; nevertheless, a growing chain is much more likely to encounter a monomer molecule than an unconsumed attached double bond at not too high concentrations of crosslinking agent, *i.e.* $[M_2] \ll [M_1]$, and of course also at very high conversions. Moreover, the proven high degree of cyclization also demonstrates that an intramolecular reaction of the growing chain end with an attached double bond of the same macromolecule occurs much more frequently than intermolecular linkage of different macromolecules. The consequence is the above-mentioned inhomogeneity of the network in which the average inter-crosslink distance and the length of the network chains cannot be calculated solely from the content of crosslinking agent. Thus the "stoichiometric crosslink density" is not only determined by the true intermolecular network bridges and the chain entangling physically effective mainly in the boundary regions of the coils occurring on hindered interpenetration, but must be corrected for the proportion of crosslinking agent "lost" by cyclization, as already pointed out by *Wesslau*[32]. The importance of these findings for the pore structure in polymeric networks, *e.g.* for gel permeation chromatography, and for crosslinking polycondensation can only be mentioned in passing.

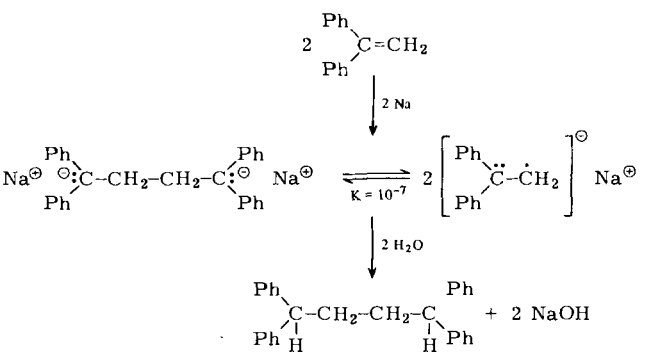
3.2. Reactions of Macromolecules

3.2.1. Polyradical Ions

Low-molecular substances can usually react in high yields with macromolecules bearing functional groups in homogeneous solution; for instance, the polyacrylates containing hydroxyl groups which were used by *Vollmert* undergo over 90 % complete reaction with hexamethylene diisocyanate in the entire accessible range of polymer concentration between about 0 and almost 100 wt %[15]. Again, intermolecular linkage leads to crosslinking and gel formation, while rings are formed by intramolecular reaction. Since the two possibilities cannot be distinguished experimentally, such experiments provide no information about interpenetration of the coils.

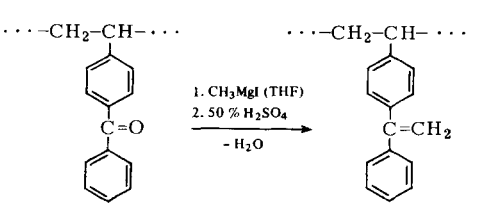
A different situation arises, however, if the polymer contains only one sort of functional groups which can react with each other and thus obviate the need for a low-molecular co-reactant. The question of incompatibility of the reacting polymer chains then also becomes irrelevant because only chemically similar macromolecules are present in the system. However, the functional groups may only be generated on the polymer immediately prior to the intended linking reaction since it will hardly be possible to control the reactions of a polymer whose functional groups can react with each other.

A number of polymeric radical ions are found to be suitable for such purposes. It has long been known that reaction of 1,1-diphenylethylene with sodium rapidly and unequivocally affords radical anions which undergo immediate and practically quantitative dimerization (Scheme 5)[33-35].



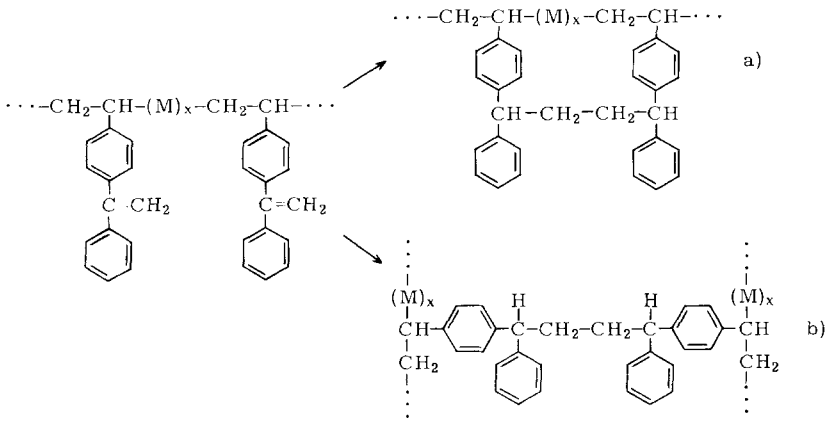
Scheme 5

Polymers containing 1-phenyl-1-(4-vinylphenyl)ethylene monomer units were subjected to analogous reaction with naphthalenesodium. The starting polymers cannot be obtained by polymerization of 1-phenyl-1-(4-vinylphenyl)ethylene, which reacts in a rather obscure manner owing to its two double bonds, but is available by a polymer analogous reaction from 4-vinylbenzophenone/styrene copolymers (Scheme 6)[36,37].



Scheme 6

In these macromolecules the content of functional groups and their mutual separation along the polymer chain can be varied within wide limits. If the reaction with naphthalene-sodium is performed at high polymer dilution and low functional group content, intramolecular linkage will predominate and coil contraction will therefore occur, as is manifested in a decrease in intrinsic viscosity (Scheme 7, cf. Table 1)[38].



Scheme 7. a) Intramolecular reaction; dilute solution, x is small. b) Intermolecular reaction; concentrated solution, x is large.

At very low polymer concentrations the coils are apparently far enough apart to preclude contact or interpenetration. If, under the same concentration conditions, more functional groups are introduced into the polymer and subjected to intramolecular reaction, then relatively small rings will be formed on the macromolecules; as in ladder polymers these rings lead to stiffening of the chain, *i.e.* to an increase in the intrinsic viscosity. However, if the polymer concentration is raised in the reaction, recognizable gel formation occurs above about 2.5 wt %; this is therefore the "critical" concentration above which contact occurs between different coils and intermolecular reaction becomes possible. In a 5 % solution of a polymer with 1 mol % of functional groups about 40 wt % of the polymer will undergo crosslinking; at the same concentration and 5 mol % of functional groups considerably more than 90 % of the coils are linked intermolecularly. Bearing in mind that in the reaction of polymers containing hydroxyl and isocyanate groups described by *Vollmert* only about 2.5 % of all groups had reacted at a polymer concentration of 10 wt % and 5 mol % of functional groups, it follows that in the present case of a chemically homogeneous polymer considerable coil interpenetration must have occurred since the extent of crosslinking would otherwise have been much lower. Since no macromolecular incompatibility is to be expected in the solutions used for generating polyradical ions, the system studied can be viewed as demonstrating that individual coils are not necessarily present above the critical polymer concentration. The reacting polymer chains are subject to at least very extensive interpenetration and thus behave in a fundamentally different manner from the previously described mixtures of chemically different macromolecules in which coil separation occurs for thermodynamic and possibly also for steric reasons.

Table 1. Intrinsic viscosities of styrene/1-phenyl-1-(4-vinylphenyl)ethylene (PVDE) copolymers before and after reaction with naphthalenesodium.

Polymer concentration	pVDE in copolymer [mol-%]	[η] [ml/g] [a] before reaction	after
Particle solution			
0.5 wt %	0.5	83	67
1 wt %	1.0	78	77
	2.0	81	91
	5.0	83	100
Network solution			
2.5 wt %	0.5	83	92
	1.0	78	104
	2.0	81	127

[a] In benzene at 20 °C.

3.2.2. Purely Intramolecular Reactions

In connection with the occurrence of cyclization on reaction of dissolved macromolecules with low-molecular reactants, the limiting case of purely intramolecular reaction warrants special attention. Theoretical calculations have long been available which describe the change in solvent viscosity of a polymer as a function of the number of linkages and of ring size[39].

A linear macromolecule consists of N_m statistical chain segments which in turn contain s_m monomer units. For the overall molecule having a degree of polymerization P, then:

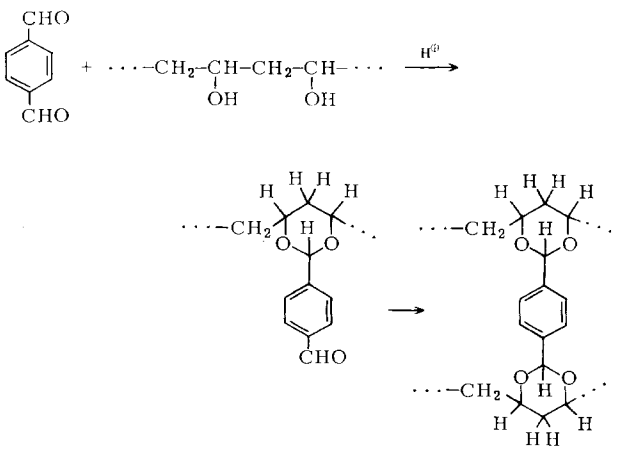
$$P = N_m \cdot s_m$$

If each monomer unit contains one functional group, which can all suitably be linked together (examples, *vide infra*) by a functional reagent, then at very small polymer concentrations a purely intramolecular reaction will occur leading to a greater or lesser number of rings in the chain depending upon the number of linkage sites. *Kuhn* and *Majer*[39] were able to show that the probability of formation of a k-membered ring rapidly decreases with increasing k, and when $k = 50$ is only *ca.* 1‰; the effect of chain length above $N_m = 10^2$ plays a very minor role. Thus mainly small rings are formed within a macromolecule; in this way the coil dimensions are reduced relative to those in the original linear molecule prior to ring formation. In the case of practical interest with only few

cyclizations per macromolecule, *i.e.* small values of ν, it can be shown that the intrinsic viscosity $[\eta]$ of the purely intramolecularly linked polymer is related to that of the starting material $[\eta]_0$ by the following equation:

$$[\eta]=[\eta]_0\left(1-\nu\sqrt{\frac{2}{N_m}}\right)$$

Since, for a given degree of polymerization and known length (s_m) of the statistical chain segment N_m, this equation contains only the number of linkage sites ν and the readily determinable solvent viscosity, its validity can easily be tested, provided that a system is chosen whose linkage reaction proceeds unambiguously even at high dilution. In the preliminary experiments of *Kuhn* and *Balmer*[40], poly(vinyl alcohol) of molecular weight 100000 was allowed to react with terephthalic aldehyde at various polymer concentrations in water, to form acetals (Scheme 8).



Scheme 8

Subsequent detailed investigations[41] on poly(vinyl alcohols) of various chain lengths showed excellent agreement between the calculated and experimental decrease in intrinsic viscosity. Figure 4 shows the change in $[\eta]$ for a poly(vinyl alcohol) of average molecular weight 14200 under various experimental conditions. The condition of low linkage site number stipulated in the derivation of the above equation is satisfied (the range of one molecule of terephthalic aldehyde to 0.4 to 2 macromolecules, *i.e.* to 200 to 2500 monomer units of vinyl alcohol or OH groups). As shown, the viscosity decreases after the reaction for polymer concentrations up to 0.5 wt %, which is not due to chain degradation but to the above-mentioned coil contraction. In reactions above this concentration the intrinsic viscosity rises above that of the starting poly(vinyl alcohol) since the close spatial proximity of the coils leads to intermolecular linkages; up to about 1.5 wt % polymer concentration the molecular weight of the polymer increases two- to three-fold, without gel formation because only few coils are initially linked and a true network has not yet formed. In this system it can therefore be precisely demonstrated that purely intramolecular ring formation only occurs at very low polymer concentrations; in this case the critical concentration of incipient coil contact can be accurately determined without having to resort to the difficultly quantifiable phenomenon of "gel formation". In the purely intramolecular range at 0.1 wt % polymer concentration, the intrinsic viscosity displays a very good agreement between theory and experiment (Fig. 5); the calculations of *Kuhn* and *Majer*[39] are thus confirmed in excellent manner.

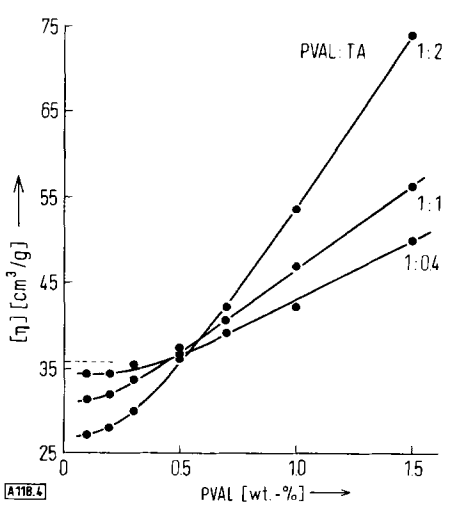


Fig. 4. Intrinsic viscosity (measured at 25 °C in water) after reaction of poly(vinyl alcohol) (PVAL, molecular weight 14200) with terephthalic aldehyde (TA) in 0.1 N HCl at various polymer concentrations and molar ratios (PVAL:TA) of the reactants. ------, intrinsic viscosity of poly(vinyl alcohol).

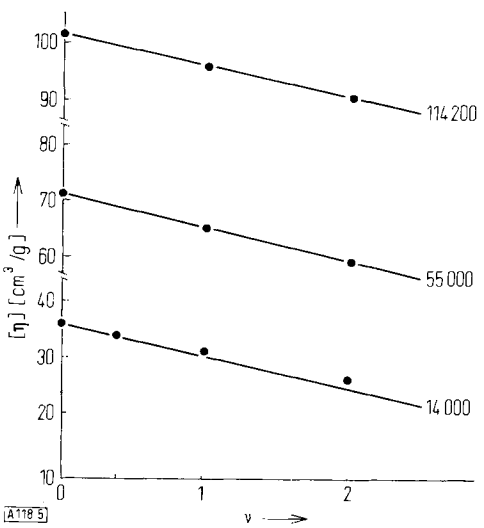

Fig. 5. Intrinsic viscosity (in water at 25 °C) of poly(vinyl alcohols) (PVAL) after reaction with terephthaldehyde (TA) as function of the number of crosslinks ν per macromolecule (reactions with 0.1 wt % polymer concentration in 0.1 N HCl). The number average molecular weight $\bar{M}_n$ is noted alongside the curves. Solid curves calculated, dots experimental.

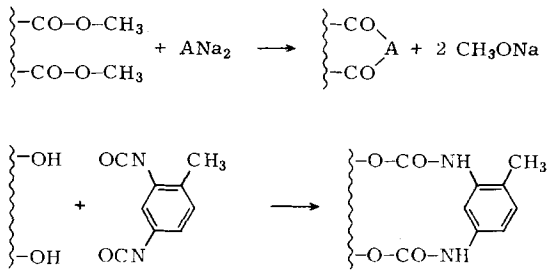
This limiting case of a purely intramolecular reaction will certainly prove applicable to other systems, although hardly any experimental information has yet been published. A significant decrease in intrinsic viscosity was also observed in the purely intramolecular reaction of copolymers of styrene and methyl acrylate with 9,10-dihydroanthracenedisodium (ANa_2) and of styrene/vinyl alcohol copolymers with 2,4-toluylene diisocyanate (Scheme 9)[42].

Similar studies are also available on the reaction of partially esterified poly(vinyl alcohols) with aliphatic and aromatic diacyl chlorides in dilute solution, in which an—albeit relatively slight—decrease in limiting viscosity was likewise observed[43].



Scheme 9

Suitable objects for study would be, *e.g.* complex formation between polymers containing salicylic acid and iron ions[44], as well as reactions of polyacrylic acid solutions and 2,2'-dichloro-*N*-methyldiethylamine as crosslinking agent[39] or of rubber in benzene with suitable vulcanizing agents. Comparison of theory and experiment should also permit conclusions regarding the extent of random or nonrandom ring closures.

4. Conclusion

As is apparent from the investigations described, the present state of the art does not permit a general answer to the question of interpenetration of macromolecular coils. In crosslinking polyreactions and reactions between chemically nonidentical macromolecules in solution, penetration is hindered and generally only slight. In principle, in such cases the true situation is well represented by *Vollmert*'s cell model. The conclusions regarding the structure of crosslinked polymers are of considerable importance. Not only the long-predicted inhomogeneity of networks formed from copolymerizing vinyl- and divinyl compounds at various copolymerization reactivity ratios[45], but also the reactions involved in industrial curing and vulcanization processes have been inadequately investigated with respect to the incompleteness of molecular interpenetration. Particular interest is commanded by studies on the use of defined structural segments for construction of crosslinked polymers; most suited are polyaddition reactions leading to polyurethanes or crosslinked epoxy resins. With the aid of such purpose-built networks, relationships between the structure of chain-linking segments and physical properties of polymers become amenable to study, as described by *Batzer, Lohse,* and *Schmid*[46] in the field of epoxy resins. Formation of only poorly interpenetrating macromolecules is also to be expected in noncrosslinking polycondensation since high molecular weights are then attained only on very high conversions; in the later stages of the reaction, however, hardly any monomer molecules are available and the polymer chains already formed are constrained to react with each other *via* their end groups. Relevant model studies in highly concentrated solutions or melts have yet to be performed.

In contrast to the above cases of hindered coil interpenetration in crosslinking polyreactions and in systems of chemically nonidentical macromolecules, available evidence pertaining to reactions of chemically uniform macromolecules in thermodynamically good solvents clearly suggests pronounced coil interpenetration. In the limiting case of very high dilution, viscosimetric measurements unequivocally demonstrate the intramolecular cyclization reactions exclusively possible far below the critical polymer concentration and provide a theoretical basis for their understanding. The region of incipient coil contact in dilute polymer solution can also be recognized. Little attention has so far been devoted to the effect of solvent quality on coil interpenetration. The practical significance of this problem also deserves mention: on film formation from thermodynamically good solvents, evaporation of the solvent will lead to very dense films; however, if largely nonpenetrating polymer coils are present in thermodynamically poor solvents, a film having a loose porous structure must be expected on solvent evaporation[47]. Phase separation may even occur in mixtures of thermodynamically good and poor solvents of differing volatilities—the resulting systems display macromorphological structures and have found industrial application, *e.g.* as bubble coatings[48]. These are films having a cavity structure resulting from phase separation on drying of the solutions. Owing to the differing refractive indices between film former and air in the bubbles, white coatings of good hiding power are obtained without use of white pigments.

Present-day concepts regarding the problem of coil interpenetration in dissolved and amorphous solid polymers can therefore be summarized thus: Largely noninterpenetrating systems are known which can be adequately described by *Vollmert*'s cell model, as are polymers in which there is very distinct interpenetration of individual coils in keeping with the theory of *Flory*. Even in the latter case, no generalization is yet permissible since neither the influence of solvent quality nor the effect of the "stiffness" of the polymer chain have been studied in detail, and previous work has been mainly concerned with flexible vinyl polymers.

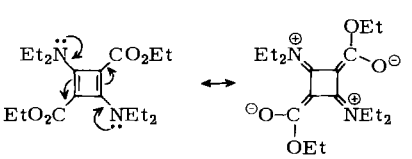
Vinamidines and Vinamidinium Salts—Examples of Stabilized Push-Pull Alkenes

By Douglas Lloyd and Hamish McNab[*]

The name vinamidines has been proposed for 1,5-diazapentadienes; these compounds can be regarded as vinylogous amidines and at the same time as push-pull substituted (and thereby stabilized) alkenes. Vinamidine and vinamidinium structural elements may also form part of a ring system. Characteristic of this class of compounds are their reactivity toward electrophiles (at C_β) and nucleophiles (C_α) and their regenerative character, *i.e.* their tendency to undergo substitution instead of addition reactions. Reactions of vinamidinium salts with nucleophiles are of special preparative value: they lead *e.g.* to pyrazoles, oxazoles, pyrimidines, diazepines, quinolines, and quinolizines.

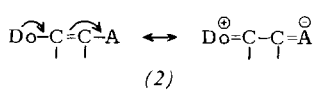
1. Introduction—'Push-Pull' Alkenes and Their General Properties

The 'push-pull' concept has in recent years received some attention because of the way it has been used to provide extra stability to otherwise unstable systems. Perhaps the most obvious example has been its use in providing stable compounds which formally possess a cyclobutadiene ring, *e.g.* *(1a)*[1]. This is stabilized by a push-pull effect between the electron-donating amino groups and the electron-withdrawing ester groups. Thus, in resonance terminology it is possible to write a further contributing form which is dipolar *(1b)*.



(1a) *(1b)*

Any push-pull alkene has an electron-donating group (Do) attached to one end of a double-bond and an electron-withdrawing group (A) to the other end, and these groups interact with each other as illustrated in *(2)*.



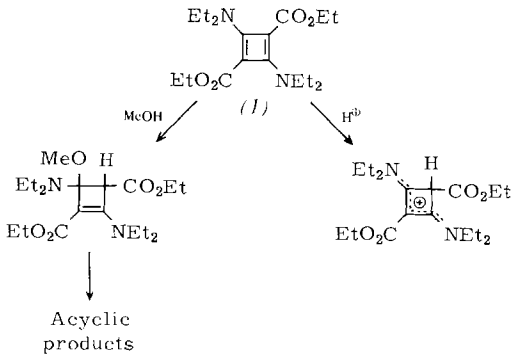
(2)

When electron-donor or electron-acceptor groups are separately attached to alkenes they give rise to, respectively, electron-rich and electron-poor double-bonds, and this results in such alkenes having characteristic properties, *e.g.* the nucleophilic character of enamines, and the electrophilic character of α,β-enones, as shown, for example, by their participation in Michael reactions.

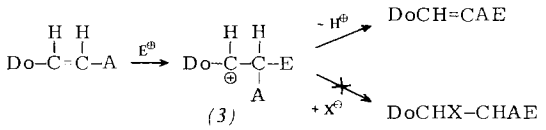
What happens when both electron-donor and electron-acceptor bonds are attached to an alkene group? Depending upon the reaction partner the molecules behave as nucleophiles or as electrophiles. This is nicely exemplified by the reactions of the push-pull cyclobutadiene *(1)*[2].

Another property of push-pull alkenes is their enhanced stability, due to delocalization of electrons from the donor group through the double bond to the acceptor group. This stability leads to such molecules having a tendency to undergo substitution reactions rather than the addition reactions characteristic of most alkenes. For example, in the case of electrophilic attack on push-pull alkenes, loss of a proton from

[*] Dr. D. Lloyd and Dr. H. McNab
Department of Chemistry, Purdie Building
University of St. Andrews
St. Andrews, Fife (Scotland)

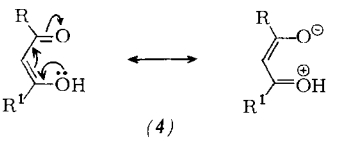


the positively charged intermediate *(3)* tends to take place rather than addition of an anion, because the fundamental stability of the push-pull alkene system is thereby regenerated.



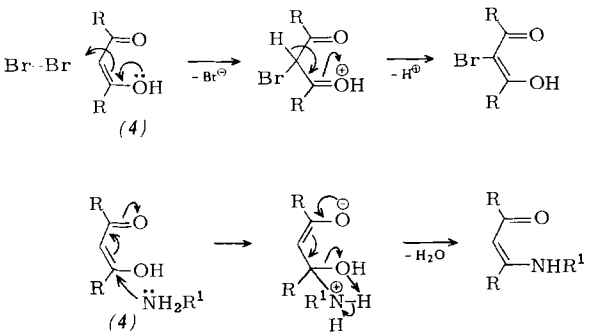
Thus, to summarize, push-pull alkenes are characterized by their reactivity towards both electrophiles and nucleophiles, and by their enhanced stability, which makes them prone to substitution rather than to addition reactions. The compounds thus show meneidic or regenerative character[3], and are also relatively easy compounds to handle. For these reasons they are also suitable reagents for a variety of syntheses.

Probably the first push-pull alkenes to be investigated were the β-diketones *(4)* and their metal derivatives.



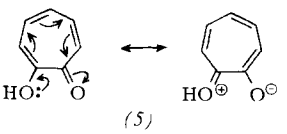
It was at one time thought that in the metal derivatives there was complete cyclic delocalization of electrons involving both the diketone moiety and the metal atom[4], but the present interpretation regards the delocalization as being confined to the diketone part of the molecule[5].

β-Diketones *(4)* provide excellent examples of the reactivity of such systems towards electrophiles and nucleophiles and also of their meneidic character.

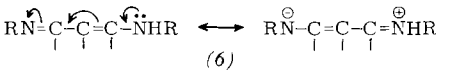


Tropolones *(5)* are vinylogs of β-diketones and their stability and characteristic reactivity are ascribable to their being push-pull alkenes[6].

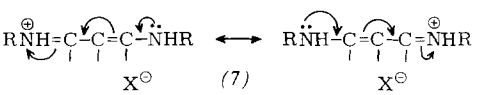
Hence they readily undergo both electrophilic and nucleophilic substitution. This picture of the structure and reactivity of tropolones is in accord with the results of X-ray structure determinations, which show the C(1)—C(2) bond to be effectively single and little involved in the conjugation.



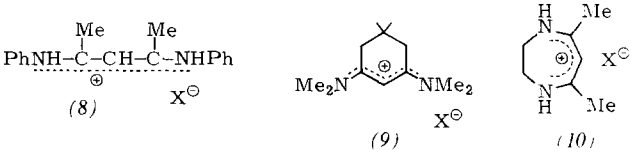
In the examples considered hitherto a carbonyl group always acts as the electron-acceptor group. An imino group can likewise take over this function. If the electron-donor group is an amino group we then have the push-pull alkene system *(6)*.



This has been called a vinamidine system because it represents a vinylog of an amidine[7]. Even more interesting are the vinamidinium salts *(7)*, because they can be symmetrical systems and are therefore particularly stable: The illustrated



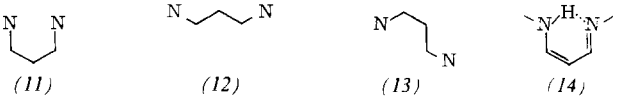
canonical forms are indeed identical and can be likened to Kekulé forms for benzene. Vinamidine and vinamidinium salts may be open-chain or included in ring systems.



Examples of vinamidinium salts are the compounds *(8)* and *(9)*, and the dihydrodiazepinium salts *(10)*. Some of the properties of such systems will now be considered.

2. Shape and Structure of Vinamidines and Vinamidinium Salts

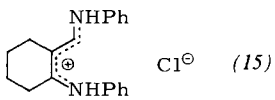
The vinamidine system may take up one of three distinctive shapes: all-*cis* ('U') *(11)*, all-*trans* ('W') *(12)*, and *cis-trans* ('sickle') *(13)*.



Open-chain vinamidines having an NH-group exist predominantly in the U-form[8–10], wherein they are stabilized by intramolecular hydrogen bonding *(14)*. The possibility that these bases possess a non-classical cyclic delocalized system of π-electrons involving the N—H bonds[11] has been ruled out[12]; they are indeed hydrogen-bonded vinamidines.

In contrast, their salts take up the W-configuration. This is shown quite unambiguously by the large vicinal coupling constants in their ^{1}H-NMR spectra[10,13].

In the case of cyclic vinamidines their configuration is forced upon them by the shapes of the rings in which they are incorporated. Thus dihydrodiazepines [cf. *(10)*] must have a U-form and derivatives of 3-imino-1-cyclohexenylamine [cf. *(9)*] must have a W-form, while the cyclohexene derivative *(15)*[14] probably has a sickle-form.

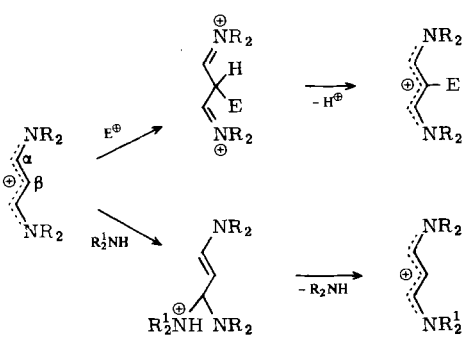


(15)

Within the chains of each of these forms the electrons are completely delocalized. This is clearly shown by the vicinal coupling constants in the ^{1}H-NMR spectra[15,16], and has been confirmed in the case of dihydrodiazepinium salts by X-ray structure determination[17]. There is an alternation of electron density along the systems, the terminal nitrogen atoms bearing the greatest density, while the α- and β-carbon atoms are relatively electron-poor and electron-rich, respectively. This is clearly shown by their ^{13}C-NMR spectra[17a]. Calculations which have been made on the vinamidine system are in accord with this data[18].

3. Reactions of Vinamidines and Vinamidinium Salts

Because of the alternating electron density in vinamidines and vinamidinium salts their α- and β-carbon atoms are, respectively, electrophilic and nucleophilic. Furthermore, attacks by nucleophiles and electrophiles, respectively, at these positions provide intermediate σ-complexes which can then lose a suitable fragment to give substitution products. These reactions proceed as shown in Scheme 1.



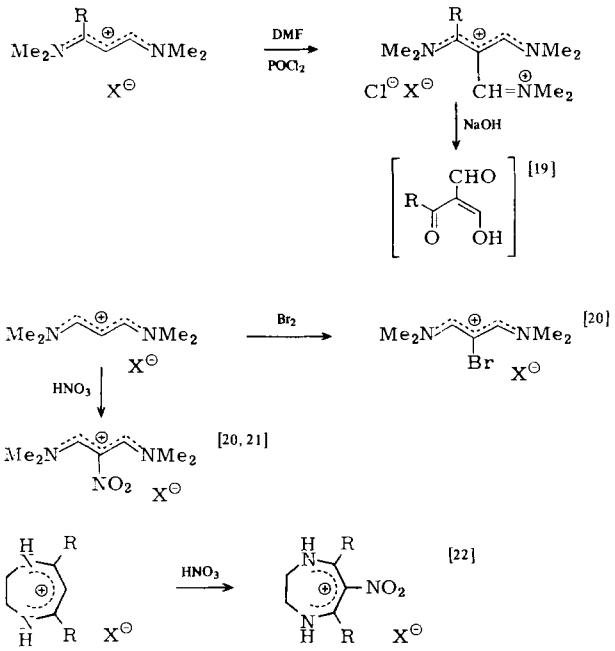
Scheme 1

The latter type of reaction has been of particular utility. Some examples of both types will now be given.

3.1. Reactions with Electrophiles

Both cyclic and acyclic vinamidinium salts react with electrophiles to give β-substituted products. The apparent anomaly that this involves electrophilic attack by one cation on another cation is easily understood when it is realized that vinamidinium ions are examples of electron-rich cations, having six electrons shared over five sites. Examples of such reactions are shown in Scheme 2[19–22].

While the commonest use of this reactivity has been to provide suitable substituted vinamidinium salts, it can also be used for more general purposes, as shown in the first

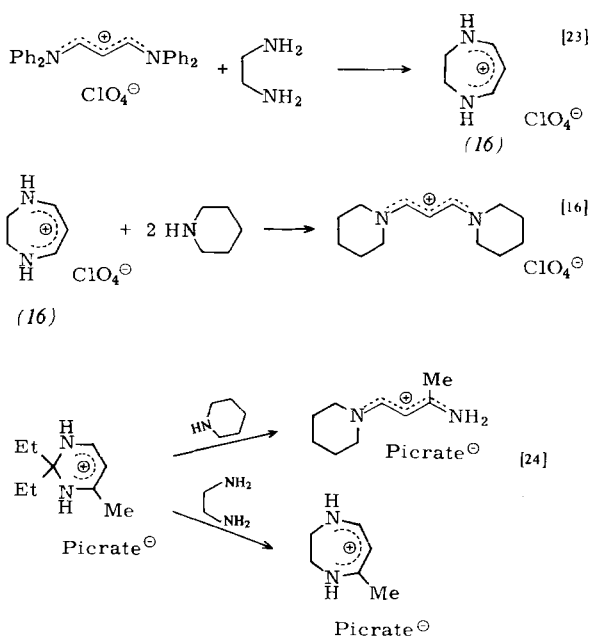


Scheme 2

example, where the reaction ultimately provided a method for the preparation of tricarbonyl compounds.

3.2. Reactions with Nucleophiles

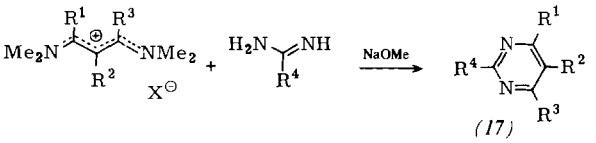
The reactions of vinamidinium salts with nucleophiles have almost all been carried out in order to prepare other types of compounds; sometimes when nitrogen nucleophiles are used the products are themselves examples of different types of vinamidines. Examples are depicted in Scheme 3[16,23,24].



Scheme 3

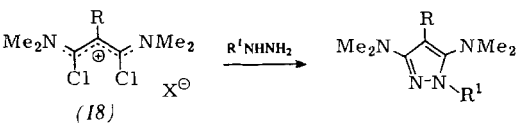
The first of these reactions provides a very convenient and valuable method for the preparation of dihydrodiazepinium salts; indeed the parent salt *(16)* is presently only obtainable in satisfactory yield by such a method[23].

Reaction of vinamidinium salts with amidines[25,26], guanidine[25-27] or thioureas[25-27] leads to a similar displacement of the terminal amino groups to give cyclic products, which in this case are not vinamidinium salts, but pyrimidines such as *(17)*.



(17)

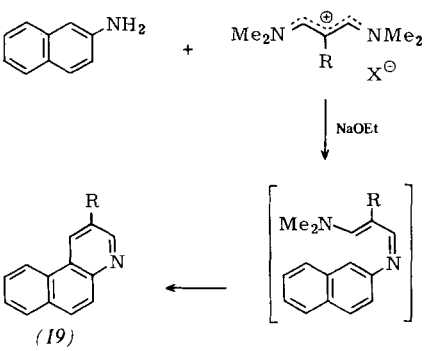
With suitably α-substituted vinamidinium salts, these substituent groups, instead of the terminal amino groups, may be displaced by the attacking nucleophile. Thus α,α'-dichlorovinamidinium salts *(18)* react with hydrazines to give bis(dimethylamino)pyrazoles[28,29].



(18)

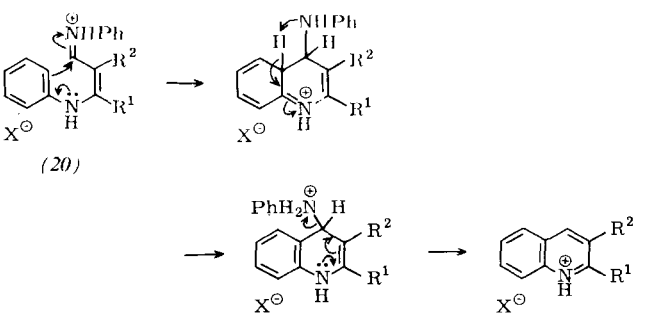
The salts *(18)* react in similar fashion with hydroxylammonium chloride, benzamidine, and *o*-phenylenediamine to give, respectively, bis(dimethylamino)-oxazoles, -pyrimidines, and -benzodiazepines[28].

β-Naphthylamine reacts with vinamidinium salts to give an intermediate which subsequently undergoes intramolecular cyclization to 4-azaphenanthrene derivatives *(19)*[30].



(19)

Some vinamidinium salts are capable of undergoing intramolecular cyclization. For example *N,N'*-diphenylvinamidinium salts *(20)* undergo cyclization with formation of quinoline derivatives when they are heated in acetic acid or in

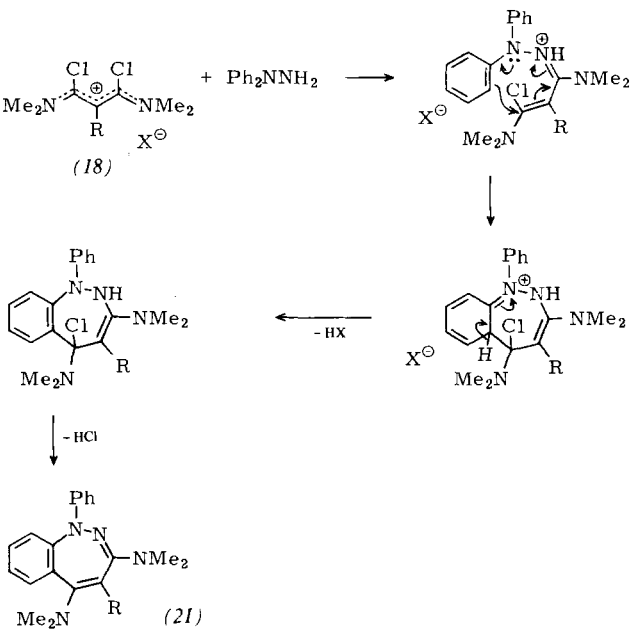


(20)

alcohols of similar boiling point[14]. This provides a very useful method for the synthesis of 2,3- and 1,2,3-substituted quinoline derivatives. Reaction presumably proceeds by the following mechanism[14].

Quinolines have also been prepared from vinamidinium salts by treatment of the latter with concentrated sulfuric acid[30a] or with aluminum chloride[30b].

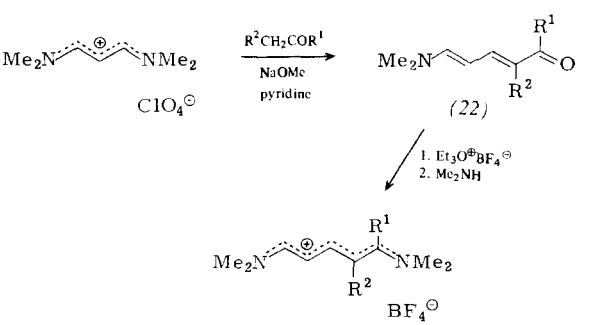
A further example of nitrogen nucleophilic attack on a vinamidinium salt which is followed by intramolecular cyclization is provided by the reaction of *(18)* with *N,N*-diphenylhydrazine to give a 1,2-benzodiazepine *(21)*[28]. Cyclization could involve a process related to that involved in quinoline formation.



(18) *(21)*

Carbon nucleophiles react with vinamidinium salts in an analogous fashion to nitrogen nucleophiles. The carbon nucleophiles are provided by suitable C—H acids in the presence of base; hence a variety of useful syntheses have been performed.

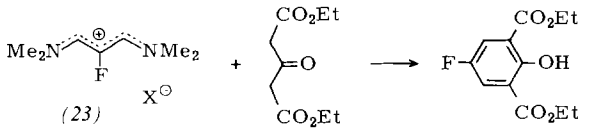
The carbanions derived from α-methyleneketones displace one of the amino groups of vinamidinium salts to give δ-aminopentadienones *(22)*[31], which can be further converted into



(22)

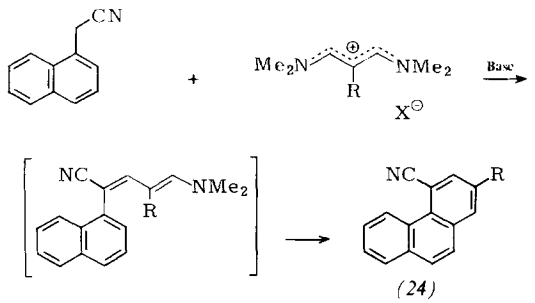
vinylogs of the vinamidinium salts. On reaction of the vinamidinium salt *(23)* with acetonedicarboxylic ester both amino groups are displaced and a phenol is produced[32].

A variety of ring-systems has been prepared by the interaction between vinamidinium salts and the carbanions derived from a number of substituted acetonitriles, RCH_2CN. The

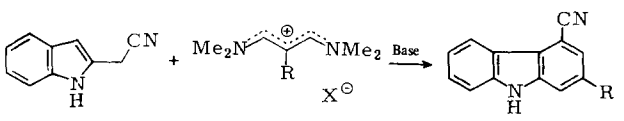


(23)

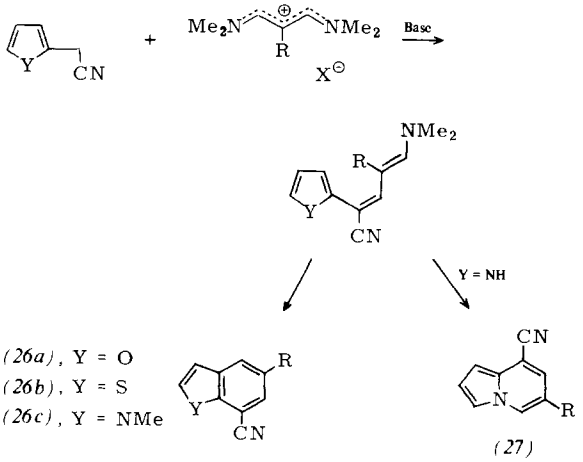
following examples show how this method has been utilized to obtain phenanthrenes (24)[30], carbazoles (25)[30], benzofurans (26a)[33], benzothiophenes (26b)[33], indoles (26c)[33], quinolizines (27)[33], and benzobiphenylenes (28)[34].



(24)

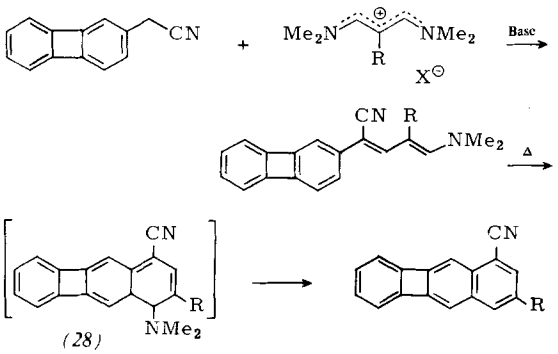


(25)



(26a), Y = O
(26b), Y = S
(26c), Y = NMe

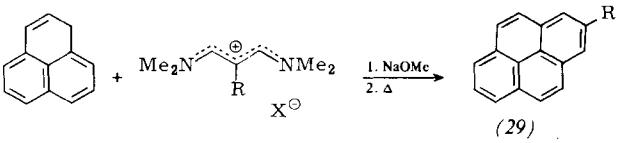
(27)



(28)

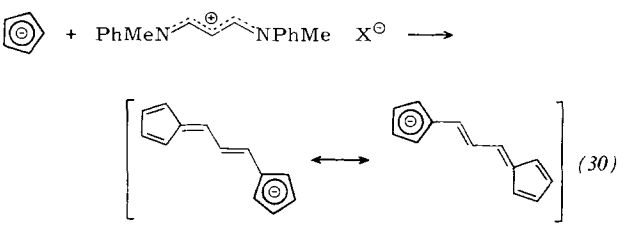
All of these reactions thus consist of initial displacement of one amino group of the vinamidinium salt by the carbanion, with subsequent loss of the second amino group in an intramolecular cyclization reaction.

A number of similar synthetic procedures involving other types of C—H acids have also been reported. Thus pyrenes (29) have been prepared by reactions of vinamidinium salts with phenalene[21, 30, 35, 36].

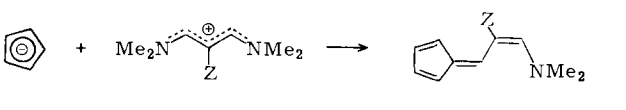


(29)

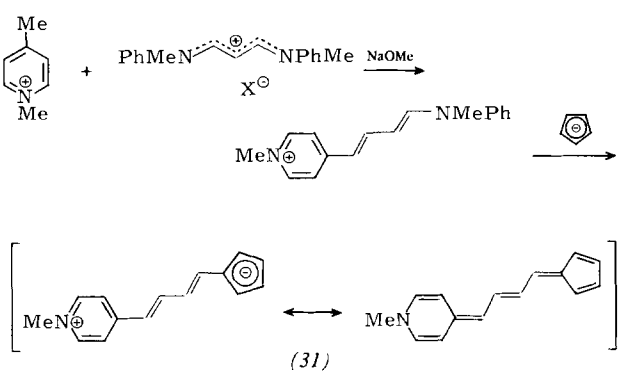
By reaction of a vinamidinium salt with the cyclopentadienide ion the interesting anion (30) was obtained[37]. Indene and fluorene analogs were also prepared[37, 38]. The cyclopentadienide ion has also been used for the preparation of 6-(dimethylaminovinyl)fulvenes[32].



(30)

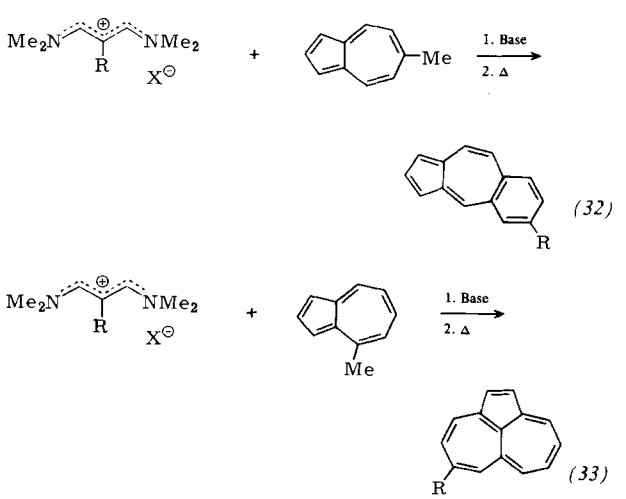


Z = F, Cl



(31)

Yet another interesting cyclopentadienide derivative, (31), was obtained by reaction of a vinamidinium salt with the reactive methyl group of the 1,4-dimethylpyridinium ion and subsequent displacement of the second amino group by cyclopentadienide ion[39].

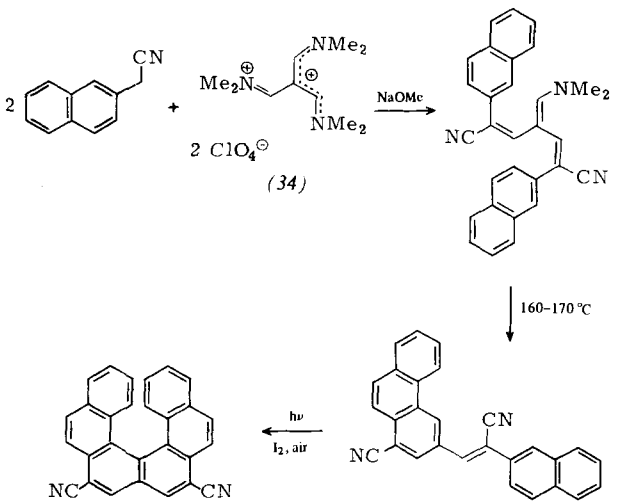


(32)

(33)

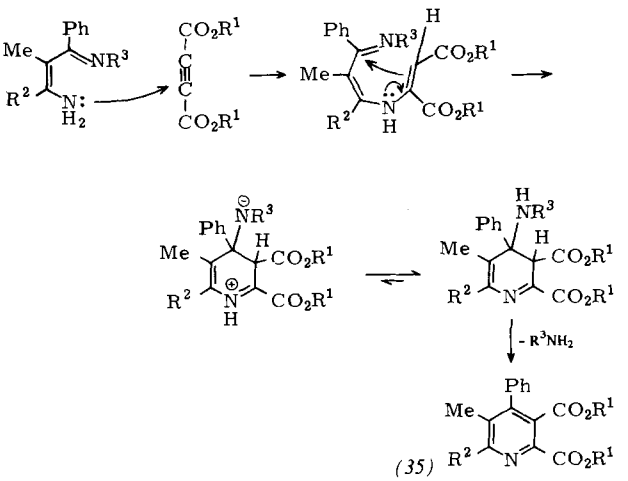
Methyl groups attached to the seven-membered ring of azulene can react as C—H acids; their reactions with vinamidinium salts have been utilized to prepare benzazulenes *(32)* and cyclopentaheptalenes *(33)*[36].

As a final example the interesting synthesis of hexahelicene using the iminiomethylvinamidinium salt *(34)* may be quoted[40].



(34)

A different type of reaction, which presumably involves the vinamidine behaving as a nitrogen nucleophile in addition



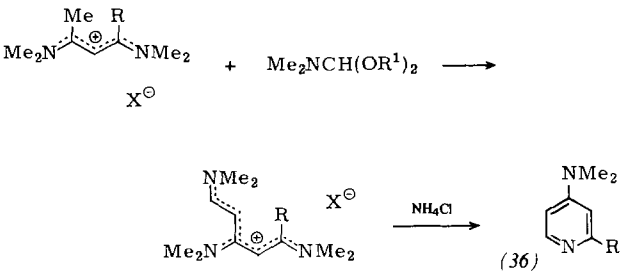
(35)

to undergoing nucleophilic attack, occurs with acetylenedicarboxylic esters, and results in the formation of pyridinedicarboxylic esters *(35)*[40a]. A possible mechanism is outlined below.

3.3. Reactions Involving α-Methyl Groups of Vinamidinium Salts

α-Methyl groups of vinamidinium salts have potential carbanionic reactivity, like that of α- and γ-methyl groups in pyridinium ions; but the synthetic possibilities that this provides have not yet been explored. One example which has been reported is the preparation of 4-(dimethylamino)pyridines *(36)*[41].

If R also represents a methyl group, reaction only takes place at one of the two methyl groups. As might be expected similar reactivity is not shown by β-methyl groups.

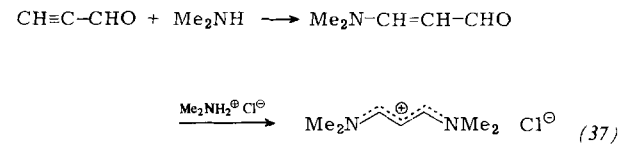


(36)

4. Preparation of Vinamidines and Vinamidinium Salts

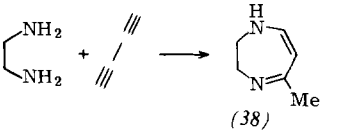
The two commonest methods for the preparation of vinamidines and their salts are the reactions of amines with α,β-alkynones or β-dicarbonyl compounds.

Thus one of the simplest and most commonly used vinamidinium salts is the 1,5-diazapentadienium derivative *(37)*, which has been prepared from propargaldehyde[42].



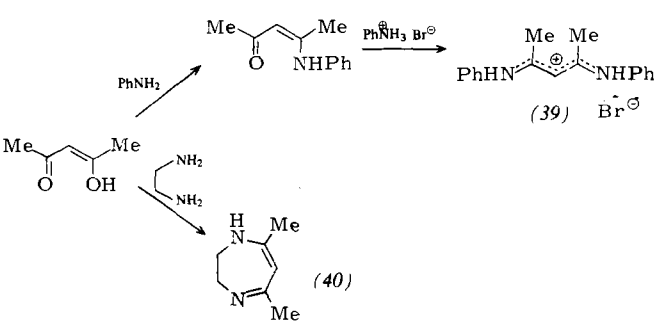
(37)

No cyclic analogs appear to have been made to date by reaction of alkynones with diamines, but the dihydrodiazepine *(38)* has been obtained by addition of ethylenediamine to a 1,3-diyne[43].



(38)

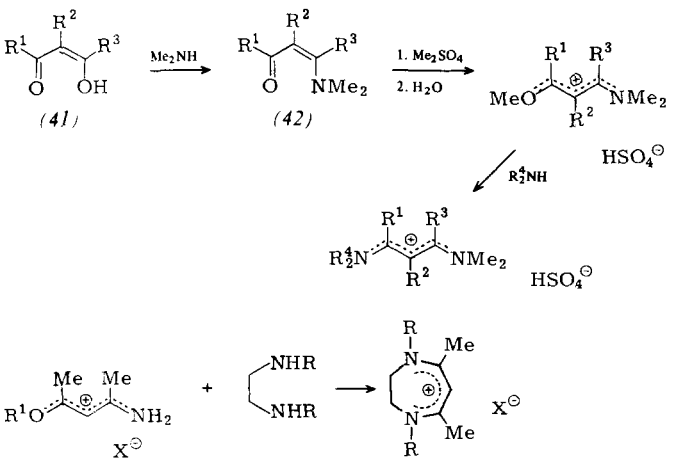
By contrast the reactions between β-diketones and amines have been used to prepare both acyclic[44] and cyclic[45] vinamidines, and their salts, *e.g. (39)* and *(40)*.



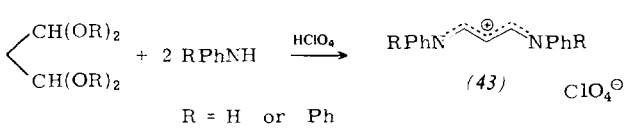
(39) *(40)*

A review of the preparation of dihydrodiazepines has already appeared in the literature[46].

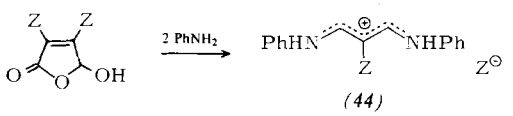
In the preparation of open-chain vinamidinium salts, *e.g. (39)*, the reaction is frequently carried out in two steps as shown in the above example[44]. An alternative stepwise process which is often advantageous involves alkylation of the intermediate oxoenamine *(42)*, followed by replacement of the alkoxy group by an amine[41,46a]. Diamines provide cyclic vinamidinium salts[47].



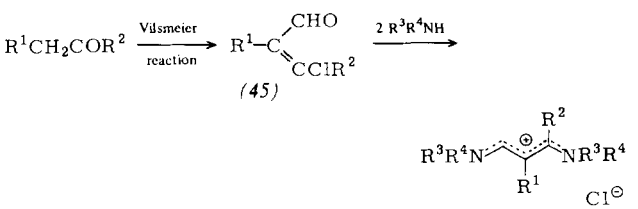
In place of dicarbonyl compounds *(41)* their monoacetals[11,48] or diacetals[8,49] may also be used. Thus the unsubstituted *N,N'*-arylvinamidinium salts *(43)* have been prepared from the tetracetal of malondialdehyde[8,23].



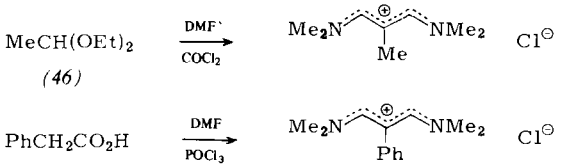
β-Halovinamidinium salts *(44)* have been prepared from mucochloric and mucobromic acids, which are masked β-dicarbonyl compounds[50].



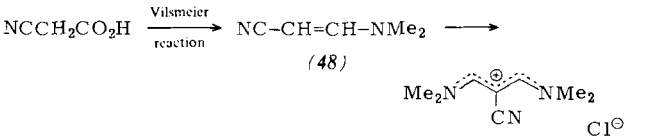
β-Chlorovinylaldehydes *(45)*, which may be regarded as the acid chlorides of the enol forms of β-dicarbonyl compounds, can also serve as starting materials for the preparation of vinamidinium salts[14,51,52]. Since the chloroacrylaldehydes are themselves readily prepared from α-methyleneketones[51,53] this serves as another convenient route to the salts. Vinamidines have also been obtained from β-chlorovinylketones[30a,53a].



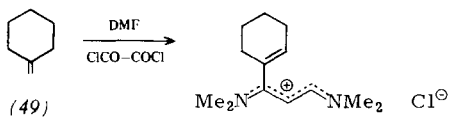
A third general method for the preparation of vinamidinium salts utilizes the Vilsmeier formylation of aldehyde acetals *(46)*[54], haloacetic acids[21,32,55,56], cyanoacetic acid[20], phenylacetic acids *(47)*[21,56] or malonic acids[57].



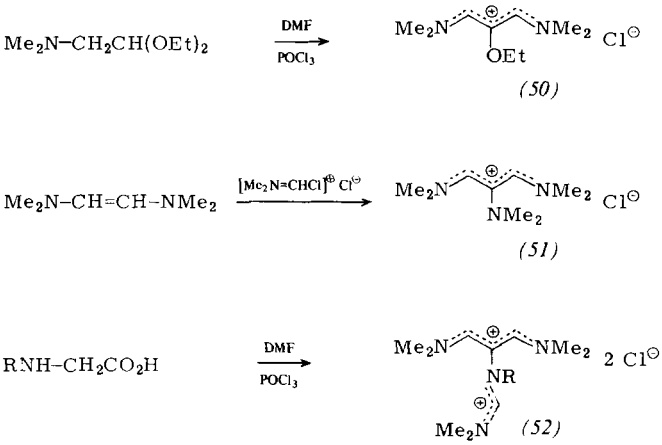
The mechanism of formation from the acids is not fully understood; however, it is known to involve diformylation coupled with decarboxylation. In the case of the reaction from cyanoacetic acid an intermediate *(48)* is obtained[20].



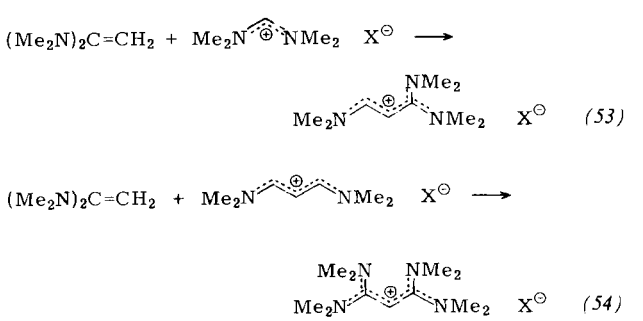
An example of the formation of a vinamidinium salt by Vilsmeier reaction of an alkene *(49)* has also been reported[58].



β-Alkoxy-[59] and β-aminovinamidinium salts[59], *(50)* and *(51)*, respectively, and *(52)*[60] have also been prepared by Vilsmeier-type reactions.



α-Amino- and α,α'-diaminovinamidinium salts *(53)* and *(54)* have been obtained by addition of an α,α-diaminoethylene to a formamidinium salt, and to an unsubstituted vinamidinium salt, respectively[61].

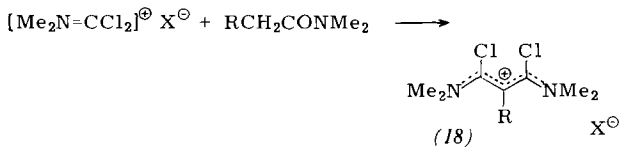


α-Aminovinamidinium salts of type *(53)* have also been prepared in high yield from the reaction between β,β-dichlorovinylketones and aniline[61a].

The synthetically valuable dichlorovinamidinium salts *(18)*, mentioned previously in Section 3.2 in connection with their use in the preparation of heterocycles, are obtained by reaction

of phosgene immonium salts with tertiary amines containing two α hydrogen atoms[28, 29, 62].

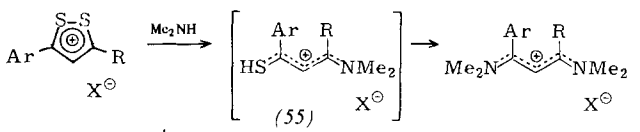
The dichloro compounds *(18)* have also been prepared by addition of phosgene immonium salts to alkynylamines[63].



(18)

Monochlorovinamidinium salts have been prepared by addition of phosgene immonium salts to enamines[28], and by means of a Vilsmeier reaction from *N,N*-dimethylamides containing two α hydrogen atoms[56]. Dibromovinamidinium salts are obtained by the action of hydrogen bromide on malononitrile[63a].

Two non-general methods which have provided vinamidine derivatives merit mention. α-Aryl and α,α'-diaryl derivatives are obtained when dithiolylium salts react with dimethylamine; the thiaaza salt *(55)* is postulated as intermediate[64].



R = H or Ar'

(55)

Dihydropyrimidines *(56)* are obtained by a "witches' brew reaction" from a ketone, a ketoacetal and ammonia in the presence of ammonium nitrate[65, 24].

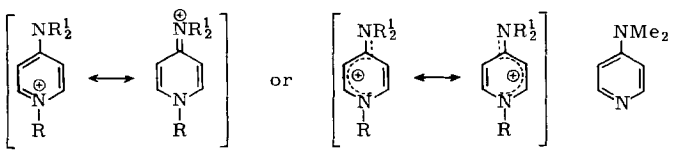
(56)

Finally the reader is referred back to Section 3.2 of this article which deals with reactions of vinamidines with nucleophiles. Examples are given of the interconversion of different vinamidines. Such interconversions are often most valuable for the preparation of specific vinamidines.

5. Special Vinamidines and Vinamidinium Salts

In natural product chemistry the corrins and porphyrins, which are of wide occurrence, contain vinamidine systems. Like their simpler analogs they undergo electrophilic substitution at the β-position[66].

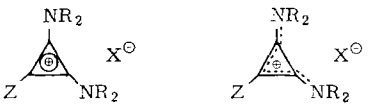
The 4-aminopyridinium system *(57)* is an example of a vinamidinium system which is electronically perturbed by a bridging alkene group.



(57) *(58)*

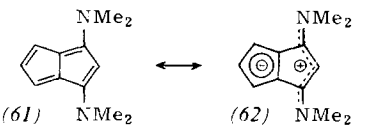
A detailed analysis of vibrational spectra of *(57)* (R = R' = H) shows that the vinamidinium structure is indeed the favored canonical form[67]. Nitration of the cation *(57)* (R = R' = Me) and of the free base *(58)* at the 3-position show similar rates over a wide pH range[68], which suggests that reaction proceeds *via* the cation and then by a typical vinamidinium mechanism (see Scheme 1).

Vinamidinium systems may play a part in stabilizing non-benzenoid systems. Two examples are the di- or triaminocyclopropenium salts *(59)*[69] and the diaminopentalene *(61)*[70].



Z = NR_2 or H

(59) *(60)*

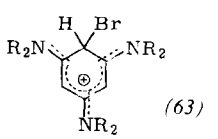


(61) *(62)*

Compound *(61)* unlike simple pentalenes, is stable in air for some hours. A helping factor here may be a contribution from the vinamidinium-cyclopentadienide canonical form *(62)*[70]. The aminocyclopropenium salts are stable in air and in particular are non-hygroscopic and very resistant to attack by water[69]. The bridged vinamidinium form *(60)* could contribute to stabilization in these compounds also. It would be extremely interesting to know if the diamino salts *(59)*↔*(60)*, Z = H, could undergo electrophilic substitution at the 2-position of the ring—unlike normal cyclopropenium salts but in keeping with vinamidinium character.

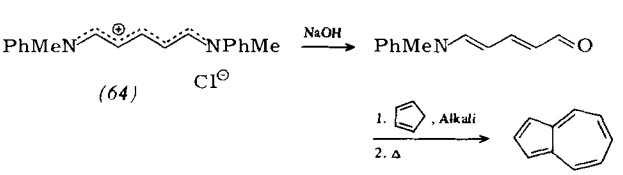
The ready protonation of the push-pull cyclobutadienes such as *(1)*, mentioned in Section 1, may also be assisted by the stabilization conferred upon the resultant ions by their bridged vinamidinium ion structure.

The vinamidinium system was also present in the first Wheland intermediates *(63)*, to be isolated and stable at ambient temperatures[70a].



(63)

Finally, mention should be made of the many vinylogs of vinamidines and vinamidinium salts. For example the readily accessible dianils of glutacondialdehyde *(64)*, prepared by the action of amines on pyridinium salts[42] are important synthetic intermediates, *inter alia*, in the synthesis of azulenes[71].



(64)

Like the vinamidinium salts their vinylogs also undergo electrophilic substitution, at the β-position[20]. Naturally occurring examples of such vinylogs are known[72].

Vinylogous vinamidinium salts are also of considerable commercial importance, for the cyanines, which are used as photographic sensitizers, all contain this structural feature. There is an enormous amount of literature available in this field; a review on cyanines comments that they "have made color photography and high-speed photography possible"[73].

6. Conclusion

There are many interesting aspects of the chemistry of vinamidines and vinamidinium salts. Some of the cyclic compounds of this type have been the subject of detailed study[46], but for the remainder, although there has been much information published about them, especially concerning their use in synthesis, there has been little in the way of systematic comparative studies. Thus comparisons of the effects of changing the amino groups have received little attention. Similarly the reactions of substituent groups, and the effects of such groups on the stability, structure and chemistry of the system, remain relatively little explored. It would also be

(65)

of interest to compare the properties of other hetero-analogs, *e.g.* compounds such as the dithiapentadienium ion *(65)*, whose spectrum has been reported[74].

The Chemistry of Simple Phosphorus-Carbon Compounds

By Heinz Harnisch[*]

With the aid of selected examples an overview is given of the development trends in phosphorus-carbon chemistry over the past few years. An attempt is made to demonstrate the relationships between various parameters and properties such as constitution, basicity, substitution by functional groups, reaction behavior *etc.* of the compounds. In the case of basis compounds containing methylphosphorus groups the state of development of industrially interesting processes is also outlined. In addition, the synthesis of a few bifunctional phosphorus-carbon compounds which can be employed as comonomers in the production of polymers is described.

1. Introduction

The unique properties of the phosphorus atom offer the preparative chemist numerous reaction possibilities, the theoretical chemist the study of numerous phenomena, and the practically oriented researcher access to novel or extended applications in areas such as corrosion resistance, flame resistance, flotation, extraction, and complexation.

Phosphorus-carbon chemistry has gone through a phase of rapid development in the past few years. Research in this sector was stimulated in particular by the introduction of nuclear magnetic resonance spectroscopy, used for elucidating constitution, and the improved accessibility of starting compounds containing simple alkyl or arylphosphorus groups. In this review article an attempt will be made to outline some of the more important developments and findings of current interest in phosphorus-carbon chemistry.

2. Properties and Reaction Behavior of Simple Phosphorus-Carbon Compounds

2.1. Influence of Basicity

The basicity of phosphorus-carbon compounds can be varied according to type and number of organic groups bound to the phosphorus. For example, in the series phosphane,

PH_3	CH_3PH_2	$(CH_3)_2PH$	$(CH_3)_3P$	$(CH_3)_3P{=}CH_2$ (*I*)
$[PH_4]^{\oplus}$	$[CH_3PH_3]^{\oplus}$	$[(CH_3)_2PH_2]^{\oplus}$	$[(CH_3)_3PH]^{\oplus}$	$[(CH_3)_4P]^{\oplus}$
4.31	4.04	3.95	3.88	3.82

Scheme 1. Basicity of the methylphosphanes. The figures below the cations are their relative electron densities (calculated after *Sanderson*).

methylphosphane, dimethylphosphane, trimethylphosphane the basicity of the respective compounds progressively increases, which phenomenon is also evidenced by the decrease in relative electron density of the corresponding phosphonium ions (Scheme 1).

Owing to the particularly large difference between the relative electron densities of PH_4^+ and $CH_3PH_3^+$ the three methylphosphanes can be easily separated from phosphane by treatment with moderately concentrated hydrochloric acid and formation of methylphosphonium ions. By increasing

the pH value the three methylphosphanes are again liberated, one after the other, sharply separated according to their basicity.

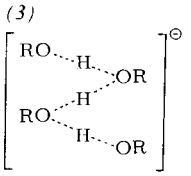
An even stronger base—trimethyl(methylene)phosphorane *(1)*—derives from the tetramethylphosphonium salts. Compound *(1)* can be prepared in good yield from tetramethylphosphonium chloride by splitting off HCl with sodamide according to a new method described by *Köster, Simić,* and *Grassberger*[1].

The ylide *(1)* is more strongly basic than ammonia and, as *Schmidbaur* and *Stühler*[2] have already shown, is therefore capable of converting many ammonium salts into the phosphonium salts, *e.g. (2)*.

$$(CH_3)_3P{=}CH_2 + NH_4SCN \longrightarrow [(CH_3)_4P]^{\oplus}SCN^{\ominus} + NH_3$$
(1) *(2)*

$$(CH_3)_3P{=}CH_2 + 4\ C_2H_5OH \longrightarrow (CH_3)_4POC_2H_5 \cdot 3\ C_2H_5OH$$
(1) *(3)*

$$(CH_3)_4POC_2H_5 \cdot 3\ C_2H_5OH \rightleftharpoons [(CH_3)_4P]^{\oplus}$$
(3)



(4)

Schmidbaur[3] has also proposed an ionic structure *(4)* for the alkoxyphosphoranes *(3)* obtainable by reaction of the ylide *(1)* with alcohols; the anions being bound *via* hydrogen bridges to molecules of the alcohol, which is present in excess. If the basicity of the alkoxyphosphorane is reduced by replacing the methyl groups by phenyl groups[4], progressively less stable products are obtained, the final representative, methylene(triphenyl)phosphorane *(7)*, forming only a labile adduct with methanol.

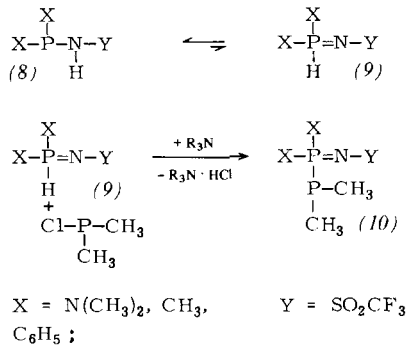
$$(CH_3)_3P{=}CH_2 + CH_3OH \longrightarrow (CH_3)_4POCH_3$$
(1)

$$(CH_3)_2C_6H_5P{=}CH_2 + CH_3OH \rightleftharpoons (CH_3)_3C_6H_5POCH_3$$
(5)

$$CH_3(C_6H_5)_2P{=}CH_2 + CH_3OH \rightleftharpoons (CH_3)_2(C_6H_5)_2POCH_3$$
(6)

$$(C_6H_5)_3P{=}CH_2 + CH_3OH \rightleftharpoons (C_6H_5)_3P{=}CH_2 \cdot CH_3OH$$
(7)

Schmidpeter and *Rossknecht*[5] made the interesting observation that a proton can be shifted from a neighboring amino group to the phosphorus by the presence of basicity-increasing methyl groups on the phosphorus. Imino(diorganyl)phosphoranes *(9)* usually transform spontaneously into the more stable aminophosphanes *(8)*. Tautomers with the P—H grouping could previously only be fixed in ring systems. However, the P—H structure can be forced in acyclic systems by dimethylamino or methyl groups on the phosphorus capable of increasing the basicity and by groups on the nitrogen that greatly increase the acidity. While P—H compounds containing dimethylamino ligands are stable, the corresponding methyl compounds can only be detected as labile intermediates. In the case of the phenyl derivatives the iminophosphorane—aminophosphorane equilibrium lies well over on the side of the amine *(8)*. A complete shift of the equilibrium can be achieved also in the case of the phenyl derivatives[6, 7] if the P—H tautomer is trapped in the form of compound *(10)* with chloro(dimethyl)phosphane.



(8) *(9)* *(9)* *(10)*

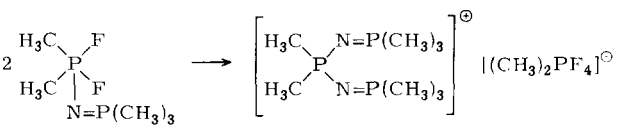
$X = N(CH_3)_2,\ CH_3,\ C_6H_5$; $Y = SO_2CF_3$ etc.

As shown in Scheme 1 the basicity of phosphorus compounds increases on progressive substitution with organic groups. This property was, *inter alia*, exploited for the synthesis of stable phosphonium ions. Conversely, the acidity, and thus stability of the corresponding anions can be reduced by substitution with organic groups. *Schmutzler, Hewson,* and *Peake*[8] have demonstrated this with the hexafluorophosphate ion. Tetrafluoro(organyl)phosphoranes *(11)* can be converted with

$$RPF_4 + CsF \longrightarrow Cs[RPF_5]$$
(11) *(12)*

$$RR'PF_3 + CsF \longrightarrow Cs[RR'PF_4]$$
(13) *(14)*

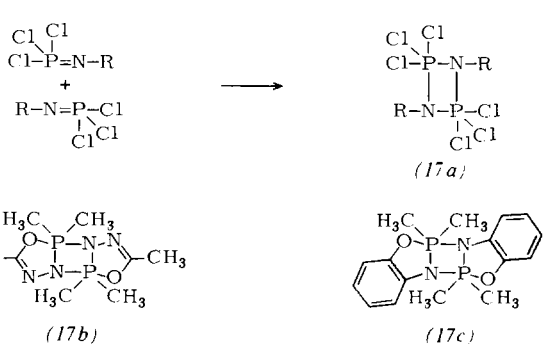
$R = CH_3,\ C_6H_5$; $R' = C_6H_5$



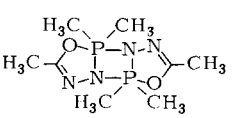
(15) *(16)*

CsF into cesium pentafluoro(organyl)phosphates *(12)*. Trifluoro(diphenyl)- and trifluoro(methyl)phenylphosphoranes are the only diorganylphosphoranes *(13)* with which this reaction has so far been accomplished; trifluoro(dimethyl)phosphorane cannot be transformed into the anion owing to too great a reduction of the acidity by the two methyl groups.

The preparation of compounds *(16)* containing the tetrafluorodimethylphosphate ion was finally achieved by *Schmutzler, Stelzer, and Stadelmann*[9, 10] by disproportionation of the iminophosphorane *(15)*. The dimethylbis(trimethylphosphoranediylamino)phosphonium ion exerts a strong donor action and thus stabilizes the labile anion.



(17a)



(17b)

(17c)

A similar situation arises in the case of the cyclic dimers of phosphazenes, the so-called diazadiphosphetidines *(17)*. Here also the only derivatives that are stable are those such as *(17a)* bearing strongly electronegative substituents on the pentacoordinated phosphorus, but not those with acidity-weakening methyl groups. Synthesis of the methyl compounds *(17b)* and *(17c)* is possible by energetically stabilizing the dimer by incorporation of five-membered rings[11-13]. [Cf. also compound *(63)* in Section 2.5.]

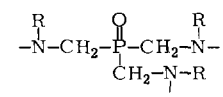
2.2. Influence of Functional Groups on the Phosphorus

Modification of the bonding on the phosphorus as a result of changing the basicity by organic substituents is also of considerable preparative importance. Another property of the P—C bond often plays a key role however: its high stability. This permits stepwise limitation of the reactivity at the phosphorus. The reactive inorganic "standard phosphorus compounds" such as PCl_3, PH_3, PCl_5, $POCl_3$, and even P_4 can undergo several reactions *via* the P—Cl, P—H, and P—P bonds and, where present, *via* the phosphorus lone pair; hence the course of the reaction is frequently of a complex nature. The selective use of only one or two reaction possibilities can therefore seldom be achieved. Consequently the isolation of mono- or bifunctional secondary products required for the synthesis of phosphorus-containing ring or chain molecules or for the fixation of stable side-groups, can be achieved only with difficulty and in poor yields from these compounds.

As a rule phosphane reacts with formaldehyde[14,15] up to the trifunctional tris(hydroxymethyl)phosphane *(18)* or in acidic medium up to the tetrakis(hydroxymethyl)phosphonium chloride *(19)*, which on further reaction, *e.g.* with amines or ammonia, form either highly cross-linked polymers *(20)* or even complex polycycles.

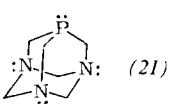
$$PH_3 + 3\ CH_2O \xrightarrow[Cd^{2+}]{} :P(CH_2OH)_3 \quad (18)$$

$$PH_3 + 4\ CH_2O + HCl \longrightarrow [P(CH_2OH)_4]^{\oplus}Cl^{\ominus} \quad (19)$$



(20)

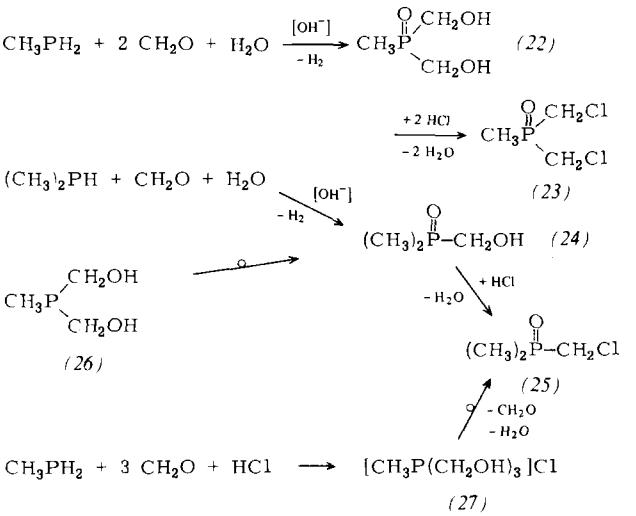
Thus *Daigle et al.*[16] as well as *Fluck* and *Förster*[17] have recently obtained 1,3,5-triaza-7-phosphaadamantane *(21)* from tris(hydroxymethyl)phosphane *(18)*, formaldehyde, and ammonium acetate.



(21)

If, on the other hand, one or two of the phosphorus valencies are "sealed off" with methyl groups the series of mono- and bifunctional P—C compounds becomes readily accessible.

In the presence of catalytic amounts of OH^- ions, the basis compounds CH_3PH_2 and $(CH_3)_2PH$ react with formaldehyde[18] and water as oxidizing agent with liberation of hydrogen and formation of bis(hydroxymethyl)methylphosphane



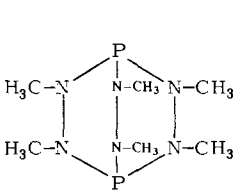
(22) *(23)* *(24)* *(25)* *(26)*

$$CH_3PH_2 + 3\ CH_2O + HCl \longrightarrow [CH_3P(CH_2OH)_3]Cl \quad (27)$$

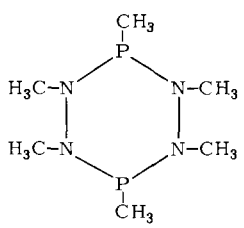
oxide *(22)* and hydroxymethyl(dimethyl)phosphane oxide *(24)*, which can be converted by reaction with hydrogen chloride into the chloromethyl compounds *(23)* and *(25)*, respectively[19]. The phosphane oxides *(24)* and *(25)* are also accessible *via* methylphosphane. Thus *(24)* can be obtained by rearrangement of *(26)*[20,21], and *(25)* by chlorination of *(24)* with HCl[19], as well as in one step *via* pyrolysis of the salt *(27)*[22,23] in which a rearrangement takes place.

The halogen compounds exhibit differences similar to those exhibited by the hydrogen compounds. Here also the reactions with PCl_3 are frequently more complex and yield end products having more complicated structures than in reactions with dichloro(methyl)phosphane or chloro(dimethyl)phosphane.

Thus, as *Nöth, Goetze*, and *Payne* have found[24,25], reaction of hydrazine or hydrazine derivatives with PCl_3 leads to bicyclic compounds of type *(28)* in moderate yields, whereas with dichloro(methyl)phosphane considerably better yields of the monocyclic compounds of type *(29)* are formed[26].

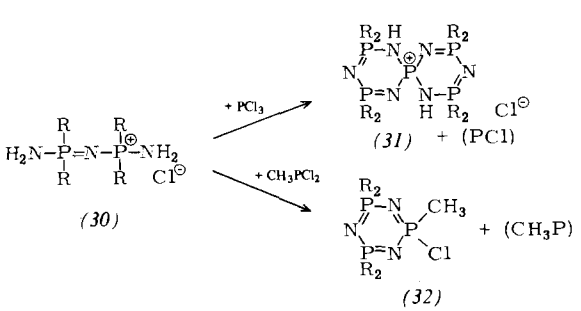


(28)



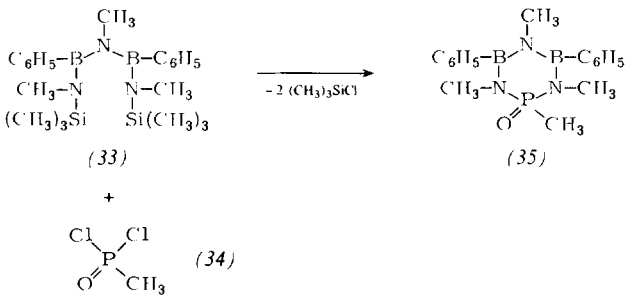
(29)

In the reaction of an aminodiphosphazene derivative *(30)* with PCl_5 investigated by *Schmidpeter* and *Eiletz*[27] a complex spirophosphonium salt *(31)* and an unidentified amorphous substance, designated here as (PCl), are formed. With dichloro(methyl)phosphane on the other hand, a monocyclic phosphazene *(32)* is obtained as end product.



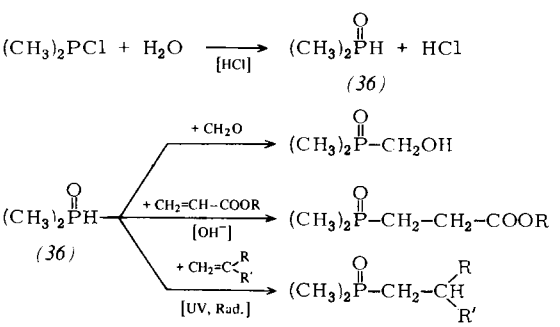
(30) *(31)* + (PCl) *(32)* + (CH_3P)

Like dichloro(methyl)phosphane, the easily accessible methanephosphonic dichloride *(34)* can also be employed for the synthesis of cyclic phosphorus compounds. Thus, *Nöth*[28] synthesized the triazaphosphadiboracyclohexane *(35)* by reaction of *(34)* and the terminally silylated aminoborane *(33)* with cleavage of the Si—N bonds.

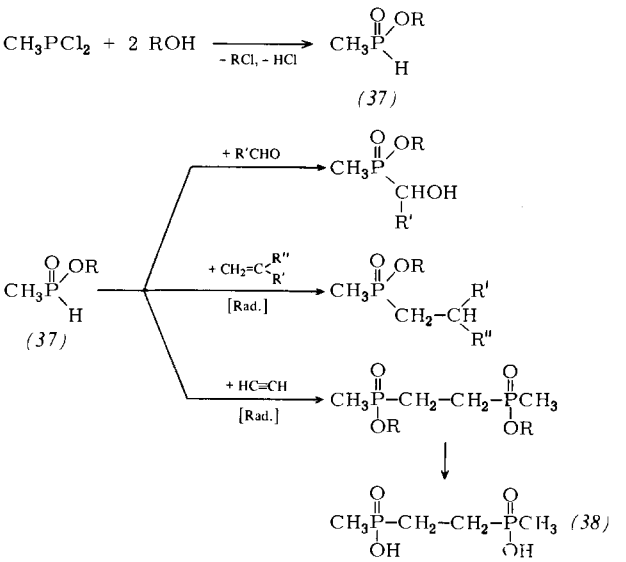


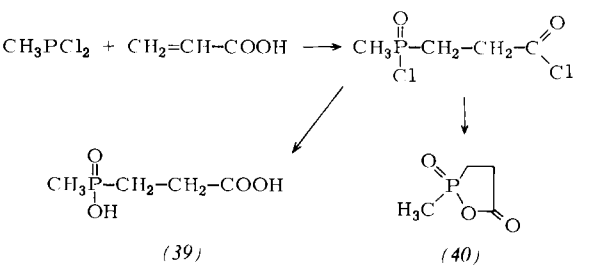
(33) + *(34)* → *(35)*

The chloro(methyl)phosphanes, just like the methylphosphanes, are also suitable for the preparation of numerous simple mono- and bifunctional secondary products. *Kleiner*[29] prepared the dimethylphosphane oxide *(36)* as a stable product in high yields for the first time by solvolysis of chloro(dimethyl)phosphane, a reaction affording entry to numerous possible reactions *via* the P—H bond, *e.g.* with olefins or carbonyl compounds.

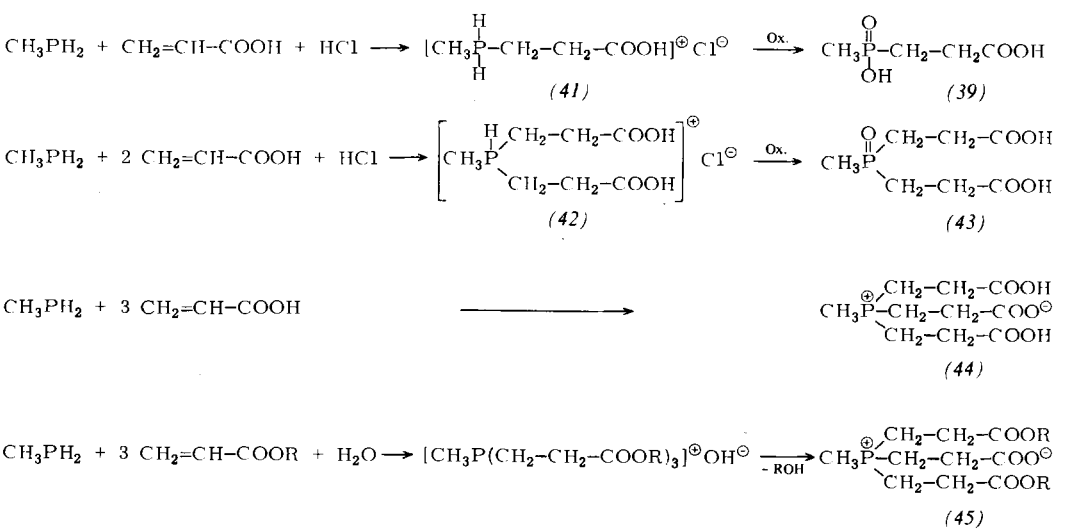


Reaction of dichloro(methyl)phosphane with alcohols furnishes methanephosphonates *(37)*, whose reactive P—H bond undergoes a large variety of reactions, *e.g.* with unactivated α-olefins or carbonyl compounds[30]. Reaction with acetylene gives ethylene-1,2-bis(methylphosphinic acid) *(38)*[31]. Dichloro(methyl)phosphane can also react directly with activated double bonds, *e.g.* with acrylic acid; this affords entry to the 3-[hydroxo(methyl)oxophosphorio]propionic acid ("2-carboxyethyl(methyl)phosphinic acid") *(39)* or its inner anhydride *(40)*[32].

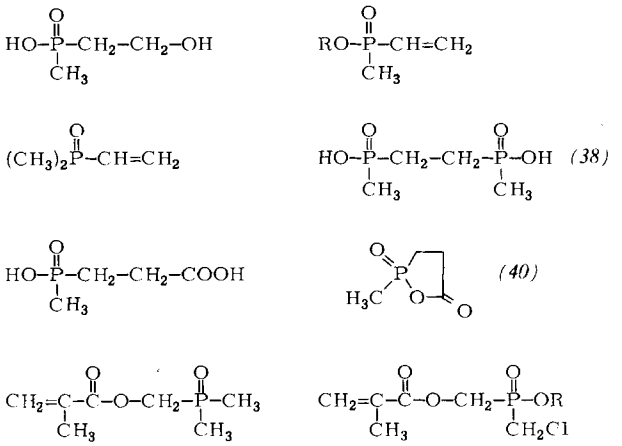




The acid *(39)* is also accessible from methylphosphane, acrylic acid, and hydrochloric acid[33]. Depending on the quantitative proportion of the reactants the initial product is either bis(2-carboxyethyl)methylphosphonium chloride *(42)* or 2-carboxyethyl(methyl)phosphonium chloride *(41)*, which on subsequent oxidation undergo smooth conversion into the



P-methyl3,3′-phosphonoyldipropionic acid ("bis-2-carboxyethyl(methyl)phosphane oxide") *(43)* and the acid *(39)*, respectively. Experiments to synthesise 3,3′-(methyl)phosphanediyldipropionic acid ("tris(2-carboxyethyl)phosphane") from methylphosphane and acrylic acid met without success. The biased inclination of phosphorus to coordination number 4 is so strong that the betaines are formed, which are stable both in the acid form *(44)* as well as in the ester form *(45)*[33].



Scheme 2. Phosphorus-containing comonomers.

At Hoechst AG a large number of compounds which can be employed as comonomers in the production of polyesters, polyacrylics, and polyamides have been synthesized using the parent substances CH_3PH_2, $(CH_3)_2PH$, CH_3PCl_2, and $(CH_3)_2PCl$ and the secondary products $(CH_3)_2P(O)H$ *(36)* and $CH_3P(O)H(OR)$ *(37)* as starting materials. Scheme 2 shows a few of these phosphorus compounds, which even in relatively small amounts have shown excellent flame resistant properties in the polymers produced, often without noticeable impairment of the mechanical or other properties of the polymers; this, *e.g.*, obviates the need for halogen compounds previously necessary in the case of polyesters.

2.3. Influence of the Organic Group on the Reactivity

In the examples mentioned so far the methylphosphorus compounds were favored as starting materials. Naturally many reactions can also be carried out with compounds having other alkyl or aryl groups on phosphorus. The methyl compounds, however, have been favored for the following reasons:

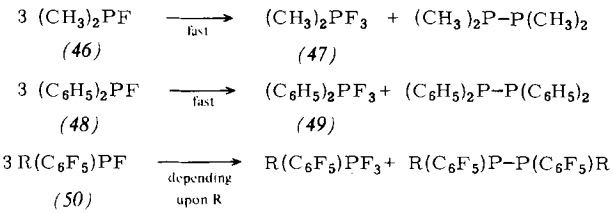
1) In contrast to *aryl*phosphorus chemistry, *alkyl*phosphorus chemistry has been the subject of research and investigation on a wide scale only since about 1960 and is in rapid development;

2) bulky alkyl or aryl groups readily mask the properties or desired effects of the phosphorus atom;

3) of the alkylphosphorus compounds the methyl compounds are the most readily available;

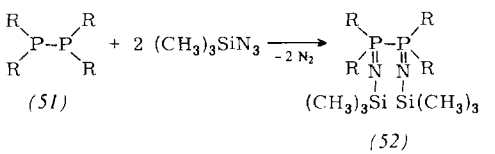
4) the methyl compounds are the most reactive phosphorus compounds without functional groups in the organic substituents. In this connection, both steric and electronic effects might play an important role.

Let us consider a few examples: *Fild* and *Stankiewicz*[34] have studied the disproportionation of the fluorophosphanes. Fluoro(dimethyl)- *(46)* and fluoro(diphenyl)phosphane *(48)* rapidly disproportionate to the phosphoranes *(47)* or *(49)* and the diphosphanes, respectively. If, however, one of the two organic groups is replaced by the pentafluorophenyl group, as in *(50)*, the rate of disproportionation is reduced to such an extent that marked differences in the sense of the quoted sequence of reactivities become noticeable.



$R = CH_3 > C_2H_5 > C_6H_5 > C_6F_5 > t\text{-}C_4H_9$

Appel and *Milker*[35] have investigated the reaction of tetraorganyldiphosphanes *(51)* with trimethylsilyl azide to give the silylated diphosphanediimides *(52)* and established a similar sterically determined dependence of the reactivity of the ligands on the phosphorus. Tetraphenyldiphosphane does not undergo reaction.

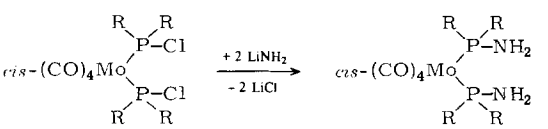


$R = CH_3 > C_2H_5 \approx C_3H_7 \approx C_4H_9 \gg C_6H_5$

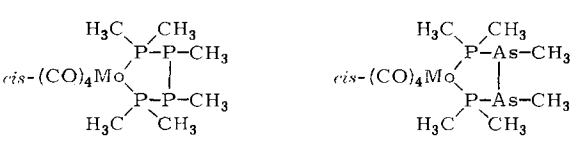
Stelzer, *Johannsen*, and *Unger*[36] were able to show in their investigations on reactions at the coordinated R_2PCl ligands of *cis*-disubstituted molybdenum complexes such as *(53)* that for steric reasons methylphosphorus compounds react with lithium amide to give the amines *(54)* more rapidly and in better yields than the phenyl derivatives (see also Section 2.4).

2.4. Metal Complexes with Organylphosphorus Ligands

Complexation to give *(54)*, $R = CH_3$, leads to stabilization of the amino(dimethyl)phosphane, which is unstable in the free state. *Stelzer* and *Unger* have synthesized the permethylated linear tetraphosphane *(55)* and the diphosphinodiarsane *(56)* from *(54)*, Li instead of NH_2, and CH_3PCl_2

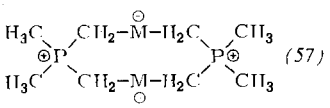


$R = CH_3 > C_6H_5$



and CH_3AsCl_2, respectively[37]. It is possible to stabilize labile compounds by use of the protective function of organic groups and their integration into transition metal complexes.

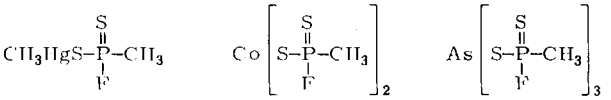
The synthesis of such metal complexes with organylphosphorus ligands has led to a considerable increase in the number of this class of substances being isolated in recent years. For example, *Schmidbaur*[38] has prepared complexes having rather unique structures by reaction of trimethyl(methylene)phosphorane *(1)* with metal salts; examples are the copper and silver complexes of type *(57)*.



(57)

M = Cu, Ag

Novel metal complexes of alkanedithiophosphonic fluorides *(58)*—*(60)* have been prepared by *Roesky et al.*[39].

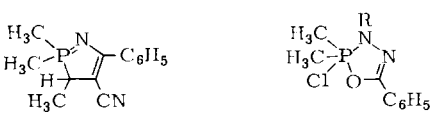


(58) *(59)* *(60)*

2.5. Cyclic Phosphorus-Carbon Compounds

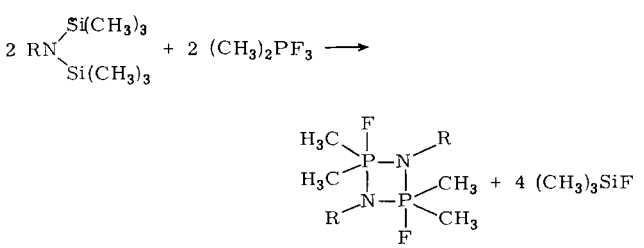
Also worth noting is the synthesis of numerous novel cyclic compounds containing organylphosphorus groups in the ring system. Some of these [*e.g. (29)*, *(31)*, *(32)*, *(35)*, and *(40)*] have already been mentioned in Section 2.2 in connection with the discussion of reaction principles.

Further examples are the 2,2-dimethyl-3*H*-1,2λ^5-azaphospholes *(61)* and oxadiazaphospholines *(62)* synthesized by *Schmidpeter*[13,49].



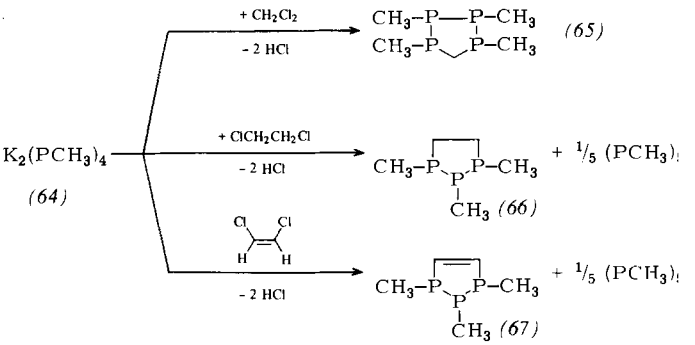
(61) *(62)*

Schmutzler[50] has employed fluoro(methyl)phosphoranes for preparation of the diazadiphosphetidines *(63)*, which at low temperatures exhibit *trans-gauche* isomerization at the phosphorus atoms.



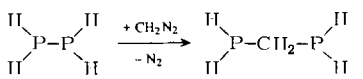
(63)

Heterocycles with cumulated phosphorus atoms can be prepared *via* the dipotassium compounds of organylcyclophosphanes. *Baudler et al.*[40-42] have synthesized tetraphosphacyclopentanes *(65)*, triphosphacyclopentanes *(66)* and triphosphacyclopentenes *(67)*, respectively, by reaction of the methyl- *(64)* and ethylphosphorus compounds with dichloromethane, 1,2-dichloroethane and *cis*-dichloroethylene in accordance with the reaction principle already practiced in the case of the phenyl compounds. Reactions with the C_2 dihalogen compounds do not lead, as one might expect, to six-membered rings, but rather to the obviously more stable five-membered rings.



(64) *(65)* *(66)* *(67)*

Recently the same team[43] investigated the reaction of diphosphane with diazomethane. It proved possible, for instance, to carry out simultaneous coupling of two P—C bonds and insertion of a methyl group between the two phosphorus atoms.



(68)

3. Industrial Synthetic Routes to Simple Phosphorus-Carbon Compounds

A challenging and diversified phosphorus-carbon chemistry can only acquire industrial utility if an economical synthesis of the P—C bond can be realized. Industrial phosphorus-carbon chemistry has so far been based almost exclusively on the di- and trialkylphosphites, compounds providing access to only a limited sector of this branch of chemistry. The paramount question then is: whether and how the versatile basis products CH_3PCl_2, $(CH_3)_2PCl$, CH_3PH_2, and $(CH_3)_2PH$ can be prepared on an industrial scale.

3.1. Chloro(methyl)phosphanes

CH_3PCl_2 was already produced for a limited period in the USA in the second half of the 1960's. The process developed by *Pianfetti*[44] uses PCl_3 and CH_4 as starting materials, which in the presence of homogeneous catalysts, such as O_2, $COCl_2$ or CCl_4, react at 550—600°C *via* a free radical mechanism with formation of hydrogen chloride:

With a brief residence time in the reaction zone and subsequent rapid chilling, yields of up to 85% can be achieved with a 15—20% conversion. Chloro(dimethyl)phosphane is not accessible in this way, since it is no longer stable at the temperature required for the desired reaction to take place.

Hoechst AG is presently operating a pilot scale plant based on this principle and having a capacity of a few tons of CH_3PCl_2 per month. The basic process has been developed by *Gehrmann* and co-workers (Hoechst AG). The product is to be used for the synthesis of halogen-free comonomers required for the production of flame-resistant polyester fibers. In this process, however, separation of the CH_3PCl_2 from excess PCl_3 is relatively difficult since their boiling points lie only about 7°C apart from each other, thus necessitating an involved rectification step.

The pilot-scale production of CH_3PCl_2 *via* a Kinnear-Perren complex *(69)* has been investigated by *Schliebs*[45]. PCl_3, CH_3Cl and $AlCl_3$ are used as starting materials. For the production of small amounts of material this process can have advantages over the Pianfetti process.

$$PCl_3 + CH_3Cl + 2\ AlCl_3 \longrightarrow [CH_3PCl_3]^{\oplus}[Al_2Cl_7]^{\ominus}$$

(69)

$$[CH_3PCl_3]^{\oplus}[Al_2Cl_7]^{\ominus} \xrightarrow[-\ NaAlCl_4]{+\ Al\ +\ NaCl} CH_3PCl_2$$

(69)

Ständeke[51] has investigated the simultaneous pilot-scale production of CH_3PCl_2 and $(CH_3)_2PCl$ by reaction of phosphorus vapor with methyl chloride on activated carbon catalysts at about 400°C.

$$P_4 + 6\ CH_3Cl \xrightarrow[[C_{akt}]]{\approx 400\,^{\circ}C} 2\ CH_3PCl_2 + 2\ (CH_3)_2PCl$$

The process is based on the work of *Maier*[46] and *Bretschneider*[47]. Reaction of phosphorus vapor with methyl chloride proceeds, like that of PCl_3 with methane, *via* a free-radical mechanism. By suitable modification of the process, particularly the addition of hydrogen chloride to inhibit decomposition of the chloro(dimethyl)phosphane that is formed, it was possible to increase the yield of the two major products to more than 80% referred to phosphorus. The overall conversion amounted to *ca.* 20%. The molar ratio of the major products can be altered relatively substantially. The main by-products that are formed are dimethylphosphane, trimethylphosphane and PCl_3.

A large-scale experimental plant based on this process has been operated for a period of time. Despite all efforts, however, the effective life of the catalyst could not be extended to an economically acceptable order of magnitude. At the temperatures required in the process decomposition of the methyl chloride leads to irreversible separation of carbon on the surface of the catalyst and to a large drop in activity.

3.2. Methylphosphanes

Hestermann[48] (Hoechst AG) has investigated the reaction of methyl chloride with PH_3 on activated carbon catalysts. The reaction proceeds at a satisfactory rate at 300°C. Methylphosphane and dimethylphosphane are the major products. A relatively large variation in the molar ratio of the two products is also possible in this process. The main by-products are phosphorus, arising from the decomposition of small amounts of pH_3, and tetramethylphosphonium chloride *(70)* which is formed *via* the trimethylphosphane on further reaction of $(CH_3)_2PH$.

$$PH_3 \xrightarrow[-\ HCl]{+\ CH_3Cl} CH_3PH_2$$

$$PH_3 \xrightarrow[-\ 2\ HCl]{+\ 2\ CH_3Cl} (CH_3)_2PH$$

$$(CH_3)_2PH \xrightarrow[-\ HCl]{+\ CH_3Cl} (CH_3)_3P \xrightarrow{+\ CH_3Cl} [(CH_3)_4P]^{\oplus}Cl^{\ominus}$$

(70)

$$4\ PH_3 \longrightarrow P_4 + 6\ H_2$$

The yield of the two major products has been reported to amount to 75%, based on phosphorus used. Methyl chloride does not decompose at the temperature of the reaction and the catalyst can be regenerated by removal of sublimed *(70)*. The space-time yield in this process is about three times higher than in the phosphorus process.

4. Conclusions

Intensive studies in the field of phosphorus-carbon chemistry by numerous research groups has led to many interesting and far-reaching developments in this sector. Such a multiplicity of theoretical and practical aims and approaches underly the investigations carried out in recent years that phosphorus-carbon chemistry, together with related branches of chemistry in which the properties of the phosphorus atom plays an important role, has become one of the most important as well as most interesting fields of molecular chemistry. It is to be hoped that this rapid development will also lead to a variety of new practical applications of phosphorus-carbon compounds.

Solid State Chemistry of Ionic Fluorides

By Josik Portier[*]

The results of intensive pure research into the chemistry and physics of fluorides can be pieced together to give an overall picture whose discernible outlines hold promise of numerous new compounds having unusual and in some cases unique properties. Modern technology is called upon to exploit them.

1. Introduction

The properties of some fluorinated inorganic materials have been known since antiquity. However, systematic research in this area began less than one hundred years ago, after *Moissan* had succeeded in isolating elemental fluorine. Until 1940, research in the field of fluorine chemistry was limited due to technical difficulties. During the course of World War II, fluorine chemistry began to develop rapidly: the isotopic separation of uranium utilizing uranium hexafluoride required large quantites of fluorine. The handling of the gas was rapidly simplified because of the appearance of corrosion resistant materials, and by the industrial production of liquified hydrogen fluoride and compressed fluorine.

This spectacular development rapidly led to numerous applications, especially of fluorochlorohydrocarbons (freons), tetrafluoroethylene polymers (teflon), sulfur hexafluoride (for its dielectric properties), *etc.* The applications of solid inorganic fluorides are much more limited. One can mention AlF_3 in aluminum metallurgy and the use of various inorganic fluorides in organic fluorination.

A survey shows, however, that in the specialized journals of solid state physical chemistry, ten per cent of the publications are dedicated to fluorides. This interest of researchers for fluorine compounds far exceeds its present industrial application, suggesting that the potential applications of inorganic fluorides are numerous and varied. It is this aspect that we shall develop in this contribution.

2. The Fundamental Properties of the F^- Ion—Consequences for the Physicochemical Properties of Fluorides

Inorganic fluorides have specific properties which distinguish them from other compounds. Since these properties are due to the characteristics of the fluoride ion, it would therefore be logical to start by considering this ion and comparing its properties with those of its neighbors in the Periodic Classification, O^{2-}, S^{2-}, Cl^-[1].

Fluorine possesses the electron configuration $1s^2 2s^2 2p^5$. In the F_2 molecule each fluorine atom contributes an electron to a single covalent bond. The intramolecular distance is 1.435 Å. The dissociation energy of the molecule (37.8 kcal/mol at 298.15 K) is extremely low (O_2, 118.32; Cl_2, 58.02; S_2, 102 kcal/mol). Fluorine is the most electronegative element (F, 4.0; O 3.5; Cl, 3.0; S 2.5 on *Pauling*'s scale) and it will easily adopt the electronic structure of its noble gas neighbor neon ($1s^2 2s^2 2p^6$), leading to the F^- ion which is practically the only stable ionic form of fluorine.

These two properties, low dissociation energy of the molecule and very high electronegativity, explain the history of fluorine chemistry. Its late discovery by *Moissan* and the failure of earlier attempted preparations by *Davy, Ampère*,

and *Faraday* are due to the fact that fluorine reacts with its environment immediately upon formation. It is now known that fluorine reacts with almost all the elements including noble gases—except helium, neon, and argon. Its handling is only possible because of the passivation of certain metals by a protective layer of a nonvolatile fluoride (nickel for example) or the chemical inertness of fluorinated polymers.

This extraordinary reactivity and the exothermic character of the reactions in which it is involved have interested researchers in the fields of rocket propulsion[2]. Indeed, on reaction with hydrogen it gives far higher combustion temperatures (4700 °C) than those obtained with oxygen (3250 °C). As a result, the specific impulse obtained is 380 s whereas it is less than 365 s with oxygen. The technical development of propellants which function with the F_2-H_2 couple has been hampered because of the high chemical reactivity of the halogen as well as the toxic nature of the combustion products. It seems, however, that some tests have been undertaken in the USSR and USA (NASA) with oxygen enriched with fluorine.

The extreme electronegativity of fluorine largely explains the properties of fluorides, which are due mainly to the localized character of the electron: covalence is weak and there are no known fluorides having metallic character.

The ionic radius of the fluoride is of the order 1.33 Å according to *Ahrens*. It is practically the smallest anion. Only the hydride ion in certain combinations has a smaller ionic radius ($\approx$1.20 Å). As a result, the F^- ion is highly mobile in crystal lattices. This property will be discussed later on.

Strong electronegativity and short cation-anion distances confer a high lattice energy upon the fluorides. Their melting and boiling points are therefore higher than those of the other halides. However, these temperatures are still nearly always lower for the fluorides than for the oxides, because the single negative charge of the F^- ion limits their coulombic energy.

3. Chemical and Crystallographic Properties of Fluorides

As a general rule, inorganic fluorides are very inert towards other elements; no halogen or chalcogen is able to displace F from its compounds. Instead, fluorination of oxides is always strongly exothermic:

$$Li_2O + F_2 \rightarrow 2LiF + 1/2\,O_2; \quad \Delta G^\circ_{500} = -144 \text{ kcal}$$
$$MgO + F_2 \rightarrow MgF_2 + 1/2\,O_2; \quad \Delta G^\circ_{500} = -177 \text{ kcal}$$
$$Fe_2O_3 + 3F_2 \rightarrow 2FeF_3 + 3/2\,O_2; \quad \Delta G^\circ_{500} = -278 \text{ kcal}$$
$$ZrO_2 + 2F_2 \rightarrow ZrF_4 + O_2; \quad \Delta G^\circ_{500} = -177 \text{ kcal}$$

A different situation arises when one comes to the hydrogenated compounds. Water and ammonia generally react with the fluorides giving rise in a first step to hydrogen fluoride having a very high bond energy (135 kcal/mol). For example, in the case of rare earth fluorides, the following reactions are observed[3, 4]:

$$LaF_3 + H_2O \rightarrow LaOF + 2HF$$
$$2LaF_3 + 4NH_3 \rightarrow La_2NF_3 + 3NH_4F$$

The final products are the oxides or nitrides.

The hydrolysis reaction constitutes a restraint to the practical application of fluoride. In fact, living in an environment in which the active principles are water and oxygen, the engineer tends to utilize the oxides whose preparation and handling are simpler than those of the fluorides.

F^- has an ionic radius close to that of O^{2-}. As a result, it is possible to replace oxygen by fluorine in a large number of oxides (Table 1). Owing to the differences in the ionic charges, this substitution leads to a change in the oxidation state of the cations. However, this substitution does not succeed in all cases. For instance, it does not seem possible to prepare solid solutions of sodium chloride type. Lithium fluoride does not react with magnesium oxide, although the respective radii of the anions and cations are very similar. In certain structures an ordered distribution of oxygen and fluorine occurs. This is the case, for example, in certain rare earth oxide fluorides. They have a cubic symmetry corresponding to anionic disorder at high temperatures, but display a trigonal symmetry at low temperatures corresponding to an order between oxygen and fluorine[3].

Table 1. Substitution of O^{2-} by F^- in oxide lattices.

Structure	Formula	Example	Mechanism
rutile	$AO_{2-x}F_x$	$VO_{2-x}F_x$	$O^{2-} + V^{4+} = F^- + V^{3+}$ [5]
spinel	$AB_2O_{4-x}F_x$	$Fe_3O_{4-x}F_x$	$O^{2-} + Fe^{3+} = F^- + Fe^{2+}$ [6]
garnet	$A_3B_3C_2O_{12-x}F_x$	$Gd_3Fe_5O_{12-x}F_x$	$O^{2-} + Fe^{3+} = F^- + Fe^{2+}$ [7]
fluorite	$AO_{1-x}F_{1+2x}$	$EuO_{1-x}F_{1+2x}$	$O^{2-} = 2F^-$ [3]

Like O^{2-}, OH^- has a similar ionic radius to F^-. There exist, for example, very extensive solid solutions between the fluorides and hydroxides of trivalent rare earths, corresponding to the formula $La(OH_{1-x}F_x)_3$[8].

The solubility of the oxide and hydroxide ions in the fluorides doubtless constitutes an important obstacle to research into fluorides. Such contamination, even in trace quantities, can drastically change the properties of fluorides and it should be carefully controlled.

In a given structure, the fluoride ion can co-exist with many other anions, *e.g.* those of other halogens (EuFCl)[9], chalcogens (LaSF)[10], and pnictides (ThNF)[11]. Although not a general rule, the tendency towards order between the two anions is here more pronounced than with oxygen. This is a consequence of the significant difference in ionic radii and also the difference in charge for the chalcogens and pnictides.

The similarity of the ionic radii of oxygen and fluorine (1.40 and 1.33 Å on *Ahrens'* scale) suggests a certain analogy

Table 2. Crystallochemical analogies between fluorides and oxides.

Formula	Coordination number of cation	Structure	Example
AX	6	NaCl	LiF and MgO
AX_2	6	rutile	MgF_2 and TiO_2
	8	fluorite	CaF_2 and ZrO_2
AX_3	6	ReO_3	VF_3 and ReO_3
ABX_3	12, 6	perovskite	$KMgF_3$ and $BaTiO_3$
AB_2X_4	4, 6	spinel	Li_2NiF_4 and $NiFe_2O_4$
AB_2X_6	6	trirutile	$LiFe_2F_6$ and Fe_2TeO_6
$A_3B_3C_2X_{12}$	4, 6, 8	garnet	$Na_3Li_3Fe_2F_{12}$ and $Y_3Fe_3Fe_2O_{12}$

between oxide and fluorine crystal chemistry. In fact, the same type of coordination and structure is found when the cations have close ionic radii (Table 2).

However, it seems that only a limited structural variety is open to fluorides. This is probably due to the more pronounced ionic character of the bond. Since the structure adopted depends almost solely on stereochemical factors, the influence of the crystal field or covalence being negligible, it can generally be predicted with relative ease. As an example one can cite the compounds of the 3d transition elements and of the monovalent elements with the general formula $A_xM_yF_z$ where all structures obey the following basic rules (Fig. 1):

- the transition element is always octahedrally coordinated by fluorine;
- the octahedra (MF_6) are either isolated or bonded *via* corners (this rule is true when the radius A of the cation lies between 1 and 1.5 Å);
- all the fluorine atoms participate in the formation of the octahedra[12, 13].

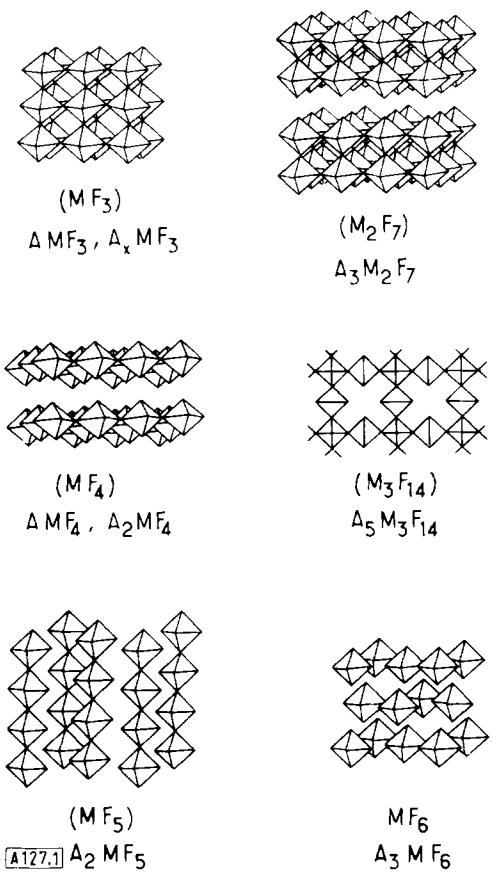

Fig. 1. Ideal arrangement of octahedra in transition metal fluorides $A_xM_yF_z$.

From the point of view of the crystal field theory, the ionic character of the fluorine-transition metal bond makes a weak field ligand of halogen. For the d elements this corresponds to a very weak splitting of the crystal field Δ_{CF}. This splitting is generally too weak to overcome the mutual repulsion of the d electrons, particularly for the first members of the 3d elements as well as for the end members with an oxidation state lower than three. These transition ions then adopt a high spin configuration (Fig. 2). With increasing covalence the crystal field splitting Δ_{CF} becomes greater, so that ligand field stabilization eventually permits electron pairing and low spin configurations may then be observed for the end members of the 3d series, and for 4d and 5d elements. The transition from one configuration to another is observed for nickel in oxidation state +3 (Table 3): the compounds of the A_3NiF_6 type (A = alkali metal) have a low spin configuration at low temperatures and high spin configuration above 100 K[14, 15]. However, in the oxides this transition already occurs for cobalt in the oxidation state +3. Since oxygen gives more covalent bonds than fluorine the crystal field splitting will be greater[16].

Table 3. Number and configuration (high spin ↑↑ or low spin ↑↓) of the d electrons of stable fluorides of the first transition series.

Element \ Oxidation state	+1	+2	+3	+4	+5	+6	+7	+8
Ti			1	0				
V		3	2	1	0			
Cr		↑↑ 4	↑↑ 3	2	1			
Mn		↑↑ 5	↑↑ 4	3				
Fe		↑↑ 6	↑↑ 5					
Co		↑↑ 7	↑↑ 6	5				
Ni		↑↑ 8	↑↓↑↑ 7	↑↓ 6				
Cu	10	↑↑ 9	↑↑ 8	7				

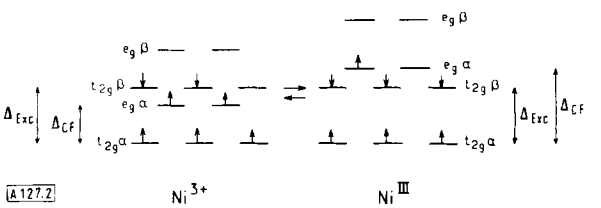

Fig. 2. High spin ⇆ low spin transition for Ni^{3+} compounds.

Fluorine is characteristically able to stabilize high oxidation states (Table 4). This particularly interesting aspect of fluorine chemistry has been studied by the German school under the guidance of *Klemm* and *Hoppe*[17]. This property arises from the pronounced electronegativity of fluorine. It is known that anions of lowest electronegativity stabilize the lowest oxidation states of cations, and the most electronegative anions, the highest oxidation states: iron reacts with iodine to give FeI_2, but with fluorine to give FeF_3. Since fluorine is the most electronegative element, one should expect to find the highest oxidation states in the fluorides. This hypothesis is sometimes true. For example, copper, silver, and gold do not appear to have an oxidation state higher than +3 in their oxides whereas copper and silver fluorides in the +4 oxidation state are known, and the +5 state has been reported for gold fluorides[18]. However, the opposite is often found to apply, as for iron, manganese, ruthenium, rhenium, and osmium. It is difficult to explain this paradox: two contradictory factors may be thought of as governing this phenomenon:

- the exceptional reactivity and electronegativity of fluorine favor the formation of high oxidation states;
- the ionic character of the metal-fluorine bond imposes a localization of the electrons around the fluorine and therefore a high formal cation charge. For a given oxidation state, this charge is weaker in the oxides where greater electronic delocalization appears owing to the formation either of covalent bonds or bonds having a metallic character. This delocalization diminishes the intercationic repulsions which become large for high oxidation states and therefore tends to increase the lattice energy.

Table 4. Maximum oxidation state of transition metals in oxides and fluorides.

Element	Maximum oxidation state		Examples
3d	O	F	
Ti	+4	+4	TiO_2; TiF_4
V	+5	+5	V_2O_5; VF_5
Cr	+6	+6	CrO_3; CrF_6
Mn	+7	+4	$[MnO_4]^-$; $[MnF_6]^{2-}$
Fe	+6	+3	$[FeO_4]^{2-}$; $[FeF_6]^{3-}$
Co	+4	+4	$[CoO_4]^{4-}$; $[CoO_6]^{8-}$; $[CoF_6]^{2-}$
Ni	+4	+4	$[NiO_6]^{8-}$; $[NiF_6]^{2-}$
Cu	+3	+4	$[CuO_6]^{9-}$; $[CuF_6]^{2-}$
4d			
Nb	+5	+5	Nb_2O_5; NbF_5
Mo	+6	+6	MoO_3; MoF_6
Tc	+7		Tc_2O_7
Ru	+8	+6	RuO_4; RuF_6
Rh	+4	+6	RhO_2; RhF_6
Pd	+4	+4	$[PdO_6]^{8-}$; PdF_4
Ag	+3	+4	$[AgO_6]^{9-}$; $[AgF_6]^{2-}$
5d			
Ta	+5	+5	Ta_2O_5; TaF_5
W	+6	+6	WO_3; WF_6
Re	+7	+6	Re_2O_7; ReF_6
Os	+8	+6	OsO_4; OsF_6
Ir	+4	+6	IrO_2; IrF_6
Pt	+4	+6	PtO_2; PtF_6
Au	+3	+5	$[AuO_4]^{5-}$; $[AuF_6]^{2-}$

It is interesting to compare the behavior of the fluorides and oxides as to nonstoichiometry. From the point of view of crystal chemistry, this behavior is not fundamentally different. There exist nonstoichiometric fluorides analogous to the oxides; to the oxides of uranium with the fluorite structure UO_{2+x} there correspond the fluorides of europium with the same structure, EuF_{2+x}[19]; the tungsten bronzes, M_xWO_3 have their homologous fluorinated isotypes M_xFeF_3[20]. However, it is conceivable that this tendency is less marked in the case of fluorides. Almost all the transition element oxides can contain insufficient or excess oxygen; variations in composition of the 3d transition oxides are often particularly large ($TiO_{0.69}$ to $TiO_{1.33}$). However, the corresponding binary fluorides generally have a constant composition. For example, in the iron-oxygen system under equilibrium conditions, two solid solutions are observed whose range extends from $Fe_{0.96}O$ to $Fe_{0.84}O$ and from Fe_3O_4 to Fe_2O_3 while in the iron-fluorine system only definite compositions are observed, FeF_2 and FeF_3 (Fig. 3). This fact should not be surprising; it is well known that the tendency to give definite compounds is all the greater when the electronegativity difference between the ions in the crystal is very high[21].

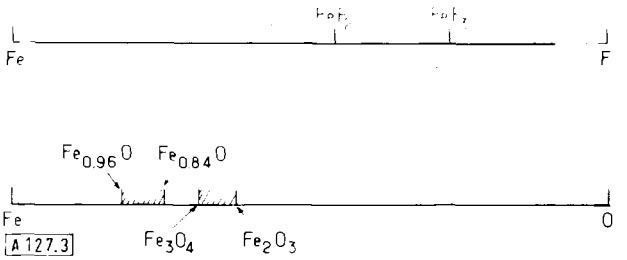

Fig. 3. Comparison between the iron-oxygen and iron-fluorine systems.

Another analogy between the oxides and fluorides is the tendency to form glasses: beryllium fluoride, like silica, combines with alkali fluorides giving glasses whose softening point is very low. The fluorinated glasses do not generally fuse with silicate glasses. This incompatibility, moreover, has been utilized in glassware production: the addition of sodium fluorosilicate to silicate glass brings about opaqueness which is due to the dispersion of the fluorides.

As previously pointed out, the ionic fluorides have moderate melting points associated with a pronounced chemical stability. In the molten state they are almost completely dissociated and have very good solvent properties. These properties suggest a number of applications. In fact, iron age metallurgists added fluorite to iron oxides to lower the melting point of the slag. Moreover, the word "fluor" signifies flow in Latin. It is this property which is used in aluminum metallurgy where bauxite is dissolved in a mixture of fluorite (CaF_2), cryolite (Na_3AlF_6), and aluminum fluoride.

This solvent property is also exploited in crystal synthesis. The crystal growth of many oxides can be accomplished from molten fluorides. One can cite the growth of YIG ($Y_3Fe_5O_{12}$) from melts of PbO and PbF_2.

Another application which appears very promising is the utilization of fluorides in molten salt nuclear reactors[22]. This last application offers a number of advantages over the classical solid fuel reactors, particularly in the area of safety. In addition, use of molten fluorides allows continuous elimination of neutron-absorbing fission products. The salts used in these reactors should possess the following properties:

chemical: stability at high temperature and under irradiation, strong dissolving ability for compounds of the fissile elements (U, Pu, Th);
physical: a moderate melting point, low vapor pressure, high thermal conductivity and thermal capacity;
nucleonic: weak neutron absorption and weak moderating action.

Fluorides satisfy all these requirements. Beryllium fluoride is used for its fusibility and lithium fluoride for its fluidity. The fluorides ThF_4 and UF_4 dissolve in this mixture.

Another related application of molten fluorides is their utilization for thermal energy storage[23]. Energy consumption is discontinuous while production is continuous. Various methods can be used to meet peak demands: electrochemical (batteries, hydrogen production by electrolysis of water); hydraulic (pumping of water into high reservoirs); mechanical (rapid rotation of flywheels). One elegant solution using fluorides has been proposed. Some eutectic mixtures of alkali or alkaline earth fluorides which have high heat capacities and heats of fusion are heated during the off-hours and subse-

quently liberate the absorbed heat on demand. This storage capacity per unit volume and weight is theoretically greater than for the conventional systems. In addition, the materials employed are cheap and abundant.

4. Physical Properties of Fluorides

In this report, we shall limit our attention to the more characteristic physical properties of saltlike fluorides, and to those having presently implementable or potential practical applications.

4.1. Electrical Properties

On the basis of the electronegativity of fluorine, the fluoride can be predicted to be insulators. They have, in fact, no appreciable electric conductivity. The gap between energy bands is usually large ($MgF_2 \Delta E \approx 12$ eV). Thus fluorides could be used for making capacitors, were it not for the fact that they are poor dielectrics: their permittivity is not very high in general, but when it is, they show high dielectric losses (Table 5)[24]. This last property can be explained by an anionic conductivity. As the smallest anion except for the hydride ion, the fluoride ion is highly mobile and one observes that fluorides have a higher anionic conductivity than oxides. Thus PbF_2 which has a similar structure to ZrO_2 is a much better conductor than its oxygenated homolog (Fig. 4). This result can, moreover, be generalized. An ionic solid has an ionic conductivity approaching that of the liquid near its melting point. As a consequence, the lower the melting point, the higher the conductivity. PbF_2 melts at 855 °C, ZrO_2 at 2700 °C.

These properties of fluorides have already been utilized in ion specific electrodes allowing the determination of fluoride ions in solution. They contain a LaF_3 crystal whose conductivity has been raised by doping with EuF_2. On one side of the crystal is placed a normal solution of F^- ions, and on the other side the solution to be measured. The apparatus works as a concentration cell: a potential difference is established between the two solutions which is proportional to the logarithm of the ratio of their concentrations. A calomel or a silver chloride electrode (Fig. 5) serves as standard.

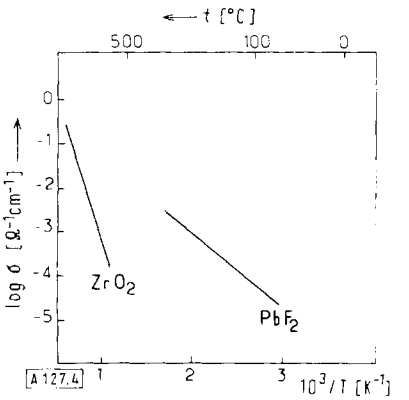

Fig. 4. Change of ionic conductivity with temperature in ZrO_2 and PbF_2.

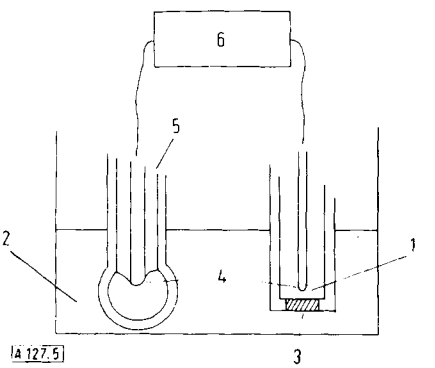

Fig. 5. Ion-specific electrode for fluoride determination (Orion Laboratories). 1, standard solution; 2, sample solution; 3, $LaF_3(EuF_2)$ crystal; 4, Ag/AgCl; 5, reference electrode (Orion recommends an Ag/AgCl electrode with electrolyte bridge and ground glass diaphragm); 6, potentiometer.

Table 5. Relative dielectric constant (ε_r') and loss factor ($\tan\delta$) of some fluorides.

Structure	Coordination number	Fluoride	ε_r'			$\tan\delta \times 10^4$

[a] Or related structure.

The development of electrochemical generators with a solid electrolyte similar to those used in the galvanic chain S/β-Al_2O_3/Na can be envisioned. The negative electrode would be composed of a light and reducing metal such as lithium and the positive electrode composed of an easily reducible fluorinated material, such as the fluorides of some transition elements noted in Section 3 (Fig. 6). The change in free energy of such a system is very high and the voltage produced in such a cell should therefore be very high. By applying *Nernst*'s law to the apparatus depicted and by neglecting the reaction of the positive electrode, one obtains a theoretical voltage of more than six volts. However, the practical application of such an apparatus is limited by the relatively weak ionic conducticity of the known materials, which limit the current flow.

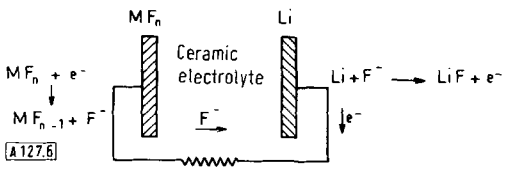

Fig. 6. Electrode reactions in a fluorinated solid electrolyte primary battery.

Other similar devices have been tested; the solid electrolyte was replaced for example, by an aprotic electrolyte ($LiClO_4$ in solution of propylene carbonate), the positive electrode is a carbon fluoride C_xF, and the negative electrode is lithium. The voltage in the open circuit is 3.5 V; the energy densities 3000 Wh/kg[25].

As an alternative to the solid electrolyte generators and those using a liquid electrolyte, a cell has been proposed which contains a low-melting eutectic mixture of fluorides as electrolyte. The positive electrode is the fluoride of a metal having a high oxidation state and the negative electrode is magnesium. The set-up is heated almost to the melting point of the eutectic. The generator discharges in a few minutes due to the great mobility of F^- ions in the molten salts. It was intended to use this apparatus, capable of furnishing a high energy during very short periods, for firing upper stages of space rockets.

Another electrochemical apparatus exploiting the anion conductivity of fluorides deserves mention. A thin layer of LaF_3 is placed between a grid-shaped gold cathode and a reactive anode of bismuth (Fig. 7). The characteristics of the cell depend on the atmosphere in which it is placed. When this atmosphere contains reducible gases (O_2, NO, SO_2) the current strength rapidly increases for a given applied potential V_c. The potential V_c is characteristic of the gaseous species in contact with the cathode while the current is proportional to the concentration of the gas. This device therefore behaves like a selective electrode. This phenomenon is interpreted as a reduction of gas at the cathode, followed by transport of the reduced species in the electrolyte and an oxidation step at the anode. The same cell can function as a fuel cell. Exposed to oxygen it gives in open circuit a voltage of 1.5 V with a lanthanum anode[26].

As previously mentioned (Section 3), fluorine can replace oxygen in a large number of oxides. This substitution naturally involves some modifications of their electric properties. Generally, one observes an increase in resistivity. The observed phenomenon can, however, be more complex: when fluorine is substituted for oxygen in a transition metal oxide, $M^{2n+}O_n^{2-}$,

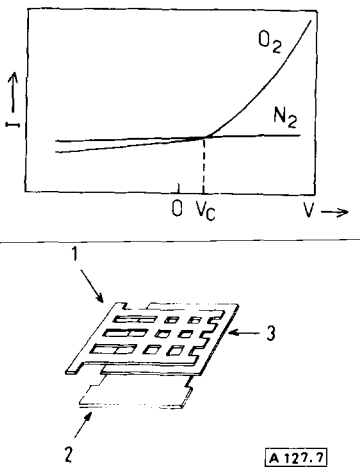

Fig. 7. Gas electrode using solid electrolyte (Philip Morris Research Center, after *Laroy et al.*). 1, grid cathode; 2, anode; 3, LaF_3 electrolyte.

a decrease in the cation charge is necessary to conserve electroneutrality $[M^{2n+}_{(1-x)}M^{(2x-1)+}_x O_{n-x}F_x]$. This corresponds to introduction of an extra d electron into the system. The properties will result from a competition between the localization of electrons by fluorine and increase in the number of these electrons. In VO_2, for example, which shows a semiconductor to metal transition there is first of all an observable decrease in the transition temperature which corresponds to a stabilization of the metallic phase and also a gradual progressive disappearance of the metallic character; VOF is again a semiconductor[5].

Studying the Mössbauer effect of compounds containing the same element in two different oxidation states clearly illustrates the localized character of the electrons in the fluoride in comparison with the chalcogenides or pnictides. The oxides or sulfides of this type are generally semiconducting with a low resistivity while the fluorides remain insulators. Figure 8 shows the Mössbauer spectra for $LiFe^{II}Fe^{III}F_6$[27] and for $Eu^{II}Eu^{III}_2S_4$[28]. For the first compound, the peaks corresponding to Fe^{2+} and Fe^{3+} appear, while for the second, above a certain temperature, only one peak shows up corresponding to a chemical shift intermediate between Eu^{2+} and Eu^{3+}. If in the fluoride the d electrons remain localized, in the sulfide a hopping phenomenon appears such that the Eu^{2+} and Eu^{3+} ions are no longer distinguishable.

The influence of the substitution of oxygen by fluorine on the properties of the ferroelectric oxides has also been studied. It involves a decrease in the Curie ferroelectric temperature which is easily explained by the ionic character of the metal-fluorine bond. The paraelectric-ferroelectric transition is tied to the alignment of the dipole moments, which involves the distortion of the crystal lattice, and is responsible for the spontaneous polarization (P_s) when $T < T_C$. This orientation of the dipoles is a function of the interatomic bonds in the material. It is the directional property of the covalent bond which is responsible for the alignment. The introduction of the strongly electronegative fluoride ions weakens the covalence of the bonds and therefore disturbs the alignment of

the dipoles; the value of P_S is then lowered and consequently so is T_C. The Curie temperature of $Sr_2KNb_5O_{15}$ is 420 K for example, whereas it is only 100 K for $SrK_2Nb_5O_{14}F$[29].

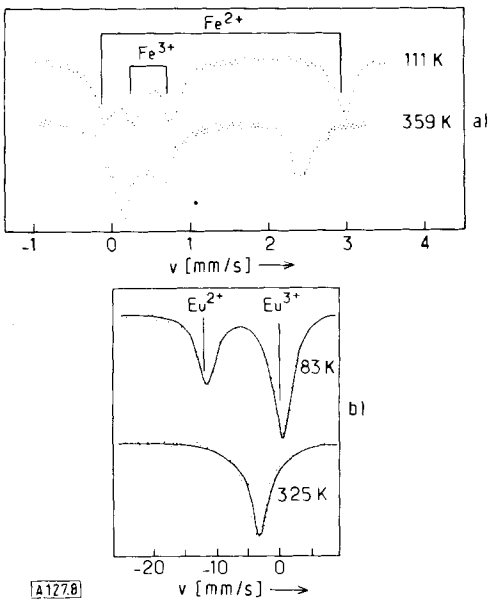

Fig. 8. Electron delocalization illustrated by the Mössbauer effect: a) spectra of $LiFe_2F_6$ [27]; b) spectra of Eu_3S_4 [28].

In the case of the ceramics this substitution also leads to an increase in dielectric constant and a decrease in dielectric losses. The use of these materials for the production of capacitators has been proposed[30].

4.2. Magnetic Properties

Numerous publications are concerned with the magnetic properties of fluorides. This interest of physicists for these materials has several reasons:

- Since fluorides are insulators, their magnetic properties are not influenced by electron delocalization such as often occurs in the oxides or sulfides. The interpretation of the phenomena is therefore simplified.
- Fluorides are transparent in a large spectral range, thus permitting magnetooptical studies.
- A large variety of structures is found in the crystal chemistry of fluorides, in which the transition element is octahedrally coordinated by fluorine. The arrangement of these octahedra makes possible the formation of three-dimensional (AMF_3), two-dimensional (A_2MF_4), and one-dimensional structures (A_2MF_5) each corresponding to a particular magnetic behavior (Fig. 1).
- Fluorine (^{19}F) has a nuclear spin $I=1/2$ and lends itself, therefore, to NMR experiments which permit determination of the percentage of covalence of the metal-fluorine bonds. In this respect it offers an advantage over oxygen whose commonest isotope ^{16}O has zero nuclear spin.

The magnetic behavior of transition element fluorides is not basically different from that of other insulating solids. Hence diamagnetic, paramagnetic, antiferromagnetic, and ferrimagnetic compounds are all represented.

4.2.1. Diamagnetic Compounds

Certain ions of the transition elements whose d layers are partially filled are diamagnetic. This requires an even number of more than 5d electrons and a low spin configuration (Table 3). In the 3d series, this only applies to tetravalent nickel. By contrast, in the 4d and 5d series, where the increase of the covalence involves a reinforcement of the crystal field, almost all such ions are diamagnetic (exception Pd^{2+}).

4.2.2. Paramagnetic Compounds

In the case of transition elements, paramagnetism will be found for those structures whose metal ions are isolated from one another; in other words, when the octahedra do not share any common atom. This is the case for compounds of composition AMF_6, A_2MF_6, A_3MF_6 (Fig. 1), for which the susceptibility generally follows Curie's law.

Trivalent nickel deviates in its behavior: the low-spin/high-spin transition leads to a change in moment of 1.73 μ_B to 3.7 μ_B[14].

In the case of rare earth metals paramagnetic behavior is generally observed.

4.2.3. Antiferromagnetic, Ferrimagnetic, and Ferromagnetic Compounds

When fluorides have structures such that the MF_6 octahedra are no longer isolated but share common geometric elements (corners, edges, faces), a magnetic order appears. Antiferromagnetic or ferrimagnetic properties are then observed. In fact, it is known that the energy which couples two spins S_i and S_j contains an exchange term:

$$H_{ij} = \sum_{ij} J_{ij} S_i S_j$$

The exchange integral J_{ij} is a function of the overlap of the d orbitals of the i-th and j-th atoms. For the transition metal fluorides this overlap is direct when the octahedra are linked either by faces or by edges (Fig. 9a). When the octahedra are linked by corners, a fluorine atom intervenes between the two paramagnetic atoms. The orbitals of i and j therefore overlap by superexchange involving the p orbitals of fluorine (Fig. 9b).

The type of interaction depends on the sign of the exchange integral J ($J<0$ antiferromagnetic, $J>0$ ferromagnetic interaction) and the intensity of the interaction, which is directly linked to the ordering temperature, is also dependent on J.

For an antiferromagnetic compound the Néel temperature is given by:

$$T_N = -\tfrac{2}{3}\frac{J}{k} ZS(S+1)$$

where k is *Boltzmann*'s constant and Z the number of nearest magnetic neighbors.

The exchange integral J is directly linked to the covalence of the bond. It can be shown that for a coupling using a σ bond of the type shown in Figure 9b, $J=-2b^2/U$. In this relationship U is the electrostatic repulsion energy brought about by the electron transfer from one ion to another. For the perovskite $KNiF_3$ for example, U is the energy which separates

the ground state $Ni^{2+}F^-Ni^{2+}$ from the excited state $Ni^{3+}F^-Ni^+$. The transfer integral b_σ depends on the overlap of the d and p orbitals. If E_d and E_p represent respectively the energies of the d and p orbitals concerned, b is equal to $f_\sigma(E_d - E_p)$; f_σ being the fraction of the d electron transferred from the d orbital to the p orbital. The transfer coefficient therefore depends on the covalence of the bond. For $KNiF_3$, f_σ is equal to 3.8 %.

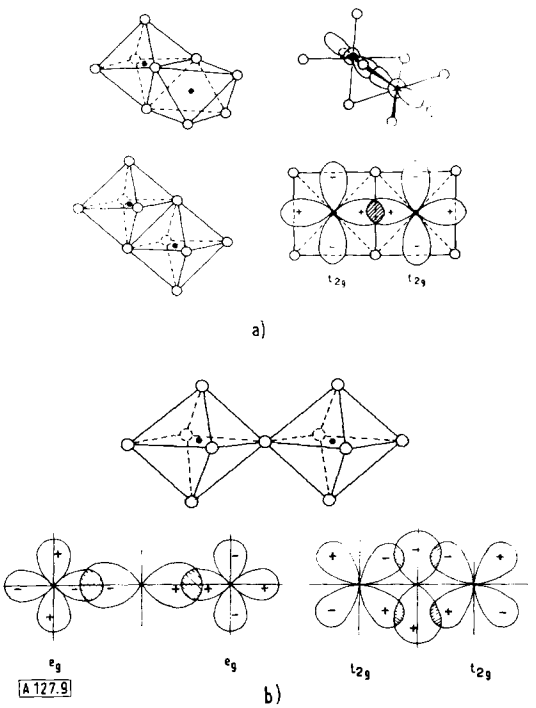

Fig. 9. Bonds involved in magnetic interactions (see text).

The sign of J can be predicted from the rules of *Goodenough-Kanamori*. If electron transfer occurs between one half-occupied orbital and another, the interaction is antiferromagnetic. This is the case for $KNiF_3$ which involves overlapping of the orbitals $d_{(x^2-y^2)}$-p-$d_{(x^2-y^2)}$ (Fig. 9b), the $d_{x^2-y^2}$ orbitals containing only one electron. By contrast, if this same transfer occurs from an occupied or half-occupied orbital to an unoccupied orbital, the interaction will be ferromagnetic as in the example of $Ni^{2+}Mn^{4+}(F^-)_6$ (Fig. 9b) in which a transfer is brought about from the half-occupied e_g orbital of Ni^{2+} to an empty e_g orbital of Mn^{4+}[31].

The preceding considerations allow a comparison between fluorides and oxides. If the same mechanisms are operative, the sign of the interactions will be identical: $LaFeO_3$ and $KMnF_3$ with a perovskite structure are both antiferromagnetic with the same magnetic structure, the Fe^{3+} and Mn^{2+} ions being isoelectronic (d^5). By contrast, the strength of the bonds in a given crystallographic structure will differ: the oxides have a much higher ordering temperature than the fluorides. Although $LaFeO_3$ and FeF_3 both have similar antiferromagnetic structures, the oxide has a Néel temperature of 738 K while that of the fluoride is only 394 K. The exchange integral for a fluoride is therefore only half the size of that in the corresponding oxide.

As a general rule, the ordering temperatures of fluorides are lower than room temperature and practical applications in the field of magnetism are hardly to be expected. Two fluorides, however, are the exceptions to this rule: FeF_3 and CoF_3. They are antiferromagnetic but have a weak ferromagnetism below their Néel temperatures, which are respectively 394 and 460 K. Owing to its transparency in the visible range, a practical application of the magnetooptical properties of FeF_3 was envisioned. In fact, this fluoride could be used as memory material in the treatment of information in the same manner as the lanthanoid orthoferrites. The information is inscribed in these materials by orienting the moments in a small domain of the crystal called a "bubble", which can be displaced by applying a magnetic field. The "bubble" can be usually observed by illuminating the crystal in polarized light because the plane of polarization of the light is rotated in an opposite sense when the light crosses opposing magnetization zones. The ray which crossed the bubble therefore does not have the same polarization as that which crossed the surrounding matter. Unfortunately, the use of FeF_3 is hampered by the difficulty in obtaining large crystals. At room temperature FeF_3 shows a trigonally distorted ReO_3 structure, and becomes cubic at 410 °C. The methods of growing large single crystals generally work above this temperature and therefore the crystallographic transition occurring at 410 °C during the cooling process produces strong internal tension which destroy the single crystal.

The ferrimagnetic fluorides constitute a particularly interesting class of materials (Table 6)[32]. It should be noted that their structures differ from those of ferrimagnetic oxides. In the oxides (spinels, garnets, hexagonal ferrites) the ferrimagnetism arises from the occupation of tetrahedral, octahedral, or dodecahedral sites by the transition elements. The magnetizations of the sublattices thus formed are in opposition (Fig. 10). In the fluorides only the octahedral sites are occupied by the transition element cations and both magnetic sublattices

Table 6. Characteristic data of ferrimagnetic transition metal fluorides [32].

Structure	Compound	T_C [K]	Θ_p [K]	σ_0 [μ_B]

	Cs_2MnNiF_6	61	78	2.40

are therefore composed of octahedra. Ferrimagnetism results then from the way in which the octahedra are joined. In the fluorides of the $BaTiO_3$ type (hexagonal), for example, one of the sublattices consists of octahedra linked by corners and in the other sublattice the octahedra are linked by faces. For the chiolites the octahedra of one of the sublattices are linked by the two corners while in the second they are linked by four corners. In the ferrimagnetic fluorides of the type $MnAlF_5$ the octahedra are linked *via* edges for one of the sublattices and *via* corners for the other.

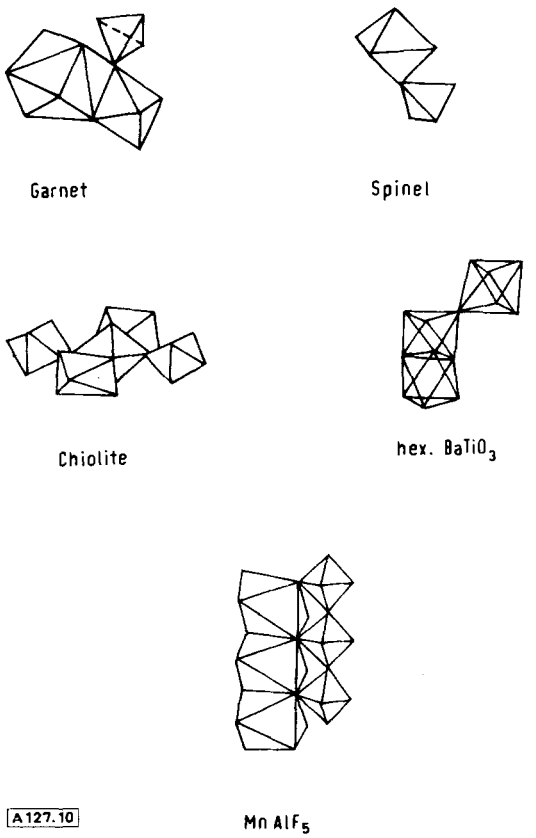

Fig. 10. Arrangement of polyhedra in ferrimagnetic oxides and fluorides.

Very few ferromagnetic fluorides are presently known (K_2CuF_4, TbF_3, $LiTbF_4$), but further examples will probably be discovered in due course.

4.3. Optical Properties

The optical properties of saltlike fluorides are typically those of insulators and therefore are not, in principle, different from those of other halide or oxide insulators. The interesting characteristics of the F^- ion give rise, however, to some unique properties which will be discussed below.

When an insulating crystal, free of defects, is exposed to a beam of photons of increasing energy, one first observes absorption bands corresponding to vibrational transitions. With increasing incident energy of the photons, the absorption bands corresponding to the electronic transition between cation orbitals appear (d-d, f-f, d-f, s-p, ...). The next absorptions to appear are charge transfer bands arising from electron transfer from the anion to the cation (Fig. 11). We will now examine these different regions of the optical spectrum.

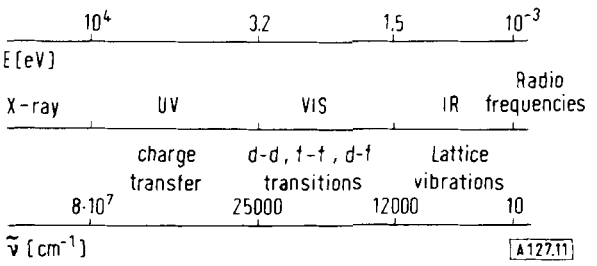

Fig. 11. Interaction between light and crystal as a function of photon energy.

As previously shown in Section 4.1, fluorides are insulators with a large band gap. As a result, the compounds of the elements not absorbing in the visible range (*i.e.* the lighter elements and those for which the d and f layers are full or empty) will be transparent up to the UV region. Magnesium fluoride, for example, as a perfect crystal, will be transparent from $10^6\,cm^{-1}$ (corresponding to the energy threshold where transitions from the valence to the conduction bands occur) to $10^3\,cm^{-1}$ (maximum frequency of lattice vibrations).

The transparency of fluorides has led to their use as windows or prisms in optical instruments. Another well known application is the use of thin layers of magnesium fluoride for coating lenses to decrease reflections and increase the luminosity. These thin layers of magnesium fluoride are also condensed onto solar panels for space satellites.

This property renders fluorides particularly attractive as host lattices for the luminescent ions. In fact, the luminous energy produced by these ions will sustain a very weak decrease by parasitic absorption in fluorinated materials.

At the other end of the spectral range of interest, *i.e.* the infrared, the fluorides do not behave differently from other compounds, in particular, the oxides. The excitation frequencies depend primarily on the mass of the vibrating atoms. They are generally located below $1000\,cm^{-1}$ for fluorides as well as oxides.

Let us now examine the electronic spectrum of the d and f transition elements which are located in the visible and ultraviolet range[33, 34].

For the d elements, for which the electronic levels responsible for those transitions correspond to the external orbitals which are subjected to the ligand field, two types of absorption are observed. The most intense absorptions come from charge transfers, transfer of the p electron of the ligand to the d orbitals of the central ion; they are allowed by *Laporte*'s rule. The weakest correspond to internal transitions in the d configuration and are therefore forbidden by this same rule.

In the fluorides, the transfer of an electron from the F^- ligand to the central atom requires a large amount of energy due to the electronegativity of the halogen. As a result, the corresponding absorptions appear in the ultraviolet range and are not visible. This explains the relative transparency of fluorides as compared with oxides or chlorides: the crystals of FeF_3 are slightly green in hue while those of $FeCl_3$ are deep violet and those of Fe_2O_3 are brown and almost completely opaque. This property renders the fluorides particularly attractive for magnetooptic research and applications.

The spectroscopic properties of compounds containing lanthanoids are of great practical value. The important applica-

tions to which these materials lead are well known, such as the laser operating with a YAG crystal ($Y_3Al_5O_{12}$) doped with neodymium or television screens using the fluorescence of the yttrium oxide sulfide doped with rare earths.

The spectroscopic properties of 4f elements are notably different from those of the d elements. The principal difference derives from the fact that the 4f electrons are protected from the crystalline field by external shells. The energy levels are therefore discreet and result in narrow spectral lines. Another difference is the ability of the lanthanoids to afford fluorescent spectra while this phenomenon is only rarely observed for the d elements. This behavior can be understood when one looks at the configuration curves in Figure 12. The curves of lower energy correspond to the ground level, and those of higher energy to the excited states. The distance r represents the distance from the cation to the anion which is not exactly the same for the two states. In the case of lanthanoids the minimum of the excited state is found inside the ground state curve. Since these minima in the configuration curves are almost superimposed, an excitation can be followed by an emission (Fig. 12a). In contrast, for the d elements which are less well protected from the crystal fields Δr varies considerably and the minimum of the configuration curve of the excited state is found outside of that of the ground state. The system then returns to the ground state without emission, with energy being dissipated by nonradiative emission (Fig. 12b)[35].

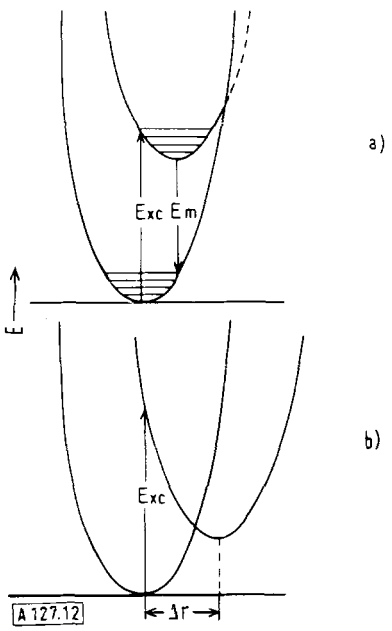

Fig. 12. Diagram of configuration curves for a) a luminescent center and b) a non-luminescent center.

Although the 4f orbitals mix only slightly with the anion orbitals, a certain covalence effect nevertheless exists. This leads to a broadening and to a red shift of the f levels. In the fluorides the covalence will clearly be the weakest, and their absorption and fluorescent spectra are therefore characterized by narrow bands identical with those of isolated ions.

A word should be said about the lifetime of the excited levels. Like the d-d transitions, the f-f transitions are theoretically forbidden by *Laporte*'s rule. They are observed, however, because the wave functions of the electrons taking place in these transitions do not have a pure f character but also a certain amount of p character due to covalency. It is in the fluorides that the f character will be most marked owing to the ionic nature of the bond. Several results derive from this. The more a transition is forbidden, the weaker will be the corresponding emission. In addition, the life of the excited state will be greater as the forbidden state becomes narrower, for a system will return all the more quickly to its ground state if the transition which accompanies this change is possible. It can be then concluded that fluorides have some weak spectral lines and that the duration of the excited states will be long.

The luminescence phenomenon in the rare earth compounds often results from energy transfer. The ion responsible for luminescence, which is named the activator, cannot receive energy directly but only through another ion called the sensitizer (Fig. 13). The sensitizer can be another cation [$(Ce, Tb)F_3$, $S=Ce^{3+}$, $A=Tb^{3+}$] or an anion [$(Y, Eu)VO_4$, $S=VO_4^{3-}$, $A=Eu^{3+}$][35]. The energy transfer requires a mixing of the

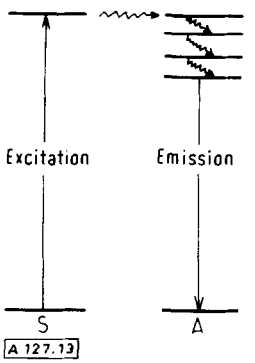

Fig. 13. Energy transfer from a sensitizer (S) to an activator (A).

wave functions of S and of A. In the fluorides, the activator cation is separated from the sensitizer ion by the F^-. The single charge of the fluoride ions leads to high coordination numbers (9 in YF_3, 11 in LaF_3) and the transfer phenomena are possible only by superexchange. Now as we have seen, the overlap of the f orbitals of lanthanoids and the p orbitals of fluorine are weak and the energy transfer difficult. As a result, the fluorides are generally less efficient luminophores than oxides.

This conclusion should, however, be qualified. In the case of the divalent lanthanoids, the energy difference which separates the $4f^n$ and $4f^{n-1}5d^1$ configurations are much smaller than in the case of trivalent rare earths. To the transitions which involve the 5d levels, there correspond large and intense absorption bands as in the case of the 3d elements. In addition, some nonradiative transitions can occur from this band to a 4f excited level which in turn allows an intense fluorescence (Fig. 14).

It is understood that in order to obtain high emission yields it is desirable to have as high a concentration of the activator as possible. However, if this concentration goes beyond a certain value the yield diminishes rapidly. If the probability of transfer from one activator cation to another becomes large as a result of the concentration, the energy of excitation is dissipated in the lattice in the form of heat and no longer contributes to luminescence. In the fluorides

these transfers are difficult due to the blocking effect of fluorine and the critical concentration will be much higher than for the oxides.

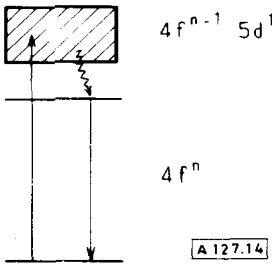

Fig. 14. Energy transfer within a divalent lanthanoid ion.

The transparency of the fluorides in the ultraviolet range, as was previously noted, will likewise play a double role. Excitation generally occurs in this wave length range. If the luminescence directly involves the activator, this property will be advantageous because no excitation energy will be dissipated in the lattice. In contrast, the F^- ions will be poor sensitizers compared with such ions as VO_4^{3-}, BO_3^{3-}, and PO_4^{3-} which readily effect transfers.

This set of specific properties helps in defining the areas of applications of rare earth fluorides. Generally, fluorides are not such good luminophores as oxides for the reasons mentioned above. On the other hand, however, their use has been proposed in the area of lasers for example, as binary or ternary fluorides of yttrium doped with neodymium. The reasons behind this choice are good transparency in the ultraviolet range, which leads to favorable behavior on excitation, slight attenuation, and a sharpness of the emission ray. Nevertheless, these devices do not appear to offer any great advantage over the oxides.

In the field of infrared to visible conversion, fluorides have proved to be exceptionally well suited, and are supplanting the other materials[36]. Efficient up-conversion is observed in the compounds containing two rare earth ions such as Yb^{3+} and Er^{3+} (Fig. 15). The levels of these ions are such that $A_2-A_1 \approx B_2-B_1 \approx B_3-B_2$. The following process takes place: the Yb^{3+} ion absorbs an energy photon $h\nu_1$ in the infrared range and is excited from the A_1 level to the A_2 level. Excitation transfer then occurs between neighboring Yb^{3+} and Er^{3+} ions; the Yb^{3+} ion falls back to the A_1 level and the Er^{3+} ion is promoted from the B_1 level to the B_2 level. If the excited state B_2 has a sufficient lifetime, which is the case with the fluorides, a second photon $h\nu_1$, can be absorbed by Yb^{3+} (transition $A_1 \rightarrow A_2$) before the Er^{3+} ion returns to the ground state. A second excitation transfer is then possible, the Er^{3+} ion moving into the B_3 state while

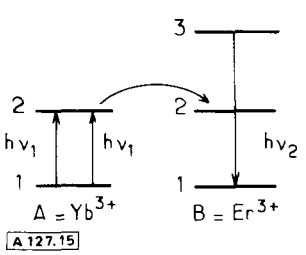

Fig. 15. Conversion of infrared into visible light.

the Yb^{3+} ion falls back to the A_1 level. The final return of the Er^{3+} ion from B_3 to B_1 leads to the emission of a photon $h\nu_2$ such that $\nu_2 \approx 2\nu_1$. The frequency $2\nu_1$ is located in the visible range.

This process can be generalized as the successive energy addition of three, or even four identical photons, or also as the energy addition of two photons of different energies. In this latter case, the fluorescence photon $h\nu_3$ obeys approximately the relationship $\nu_3 \approx \nu_2 + \nu_1$, where ν_1 and ν_2 are the frequencies of the two incident photons.

This phenomenon aroused considerable interest when it was shown that the yield is considerably improved by using Yb^{3+} as the sensitizer ion. It is often called the "Auzel effect" after its discoverer[36].

This mechanism effects the transformation of an infrared radiation into green light by addition of two photons, or into blue light by addition of three photons. Several applications have been envisioned. The Auzel effect can be utilized in quantum meters for detection and visualization of infrared radiation. Electroluminescent diodes are also feasible: a fluoride doped with ytterbium and erbium or with thulium is deposited in powder or single crystal form on the surface of a gallium arsenide diode emitting in the infrared. The radiation is transformed by the fluoride into visible blue or green light. Fluorinated matrices which lead to better yields are alkali-yttrium fluorides.

Yet another phenomenon capable of application has recently been discovered[37]. It involves not only the f-f transitions which were previously noted, but also f-d transitions. While the transfer of an electron into the 5d orbital needs 90000 cm^{-1} in the case of the free Gd^{3+} ion, such a transfer in the case

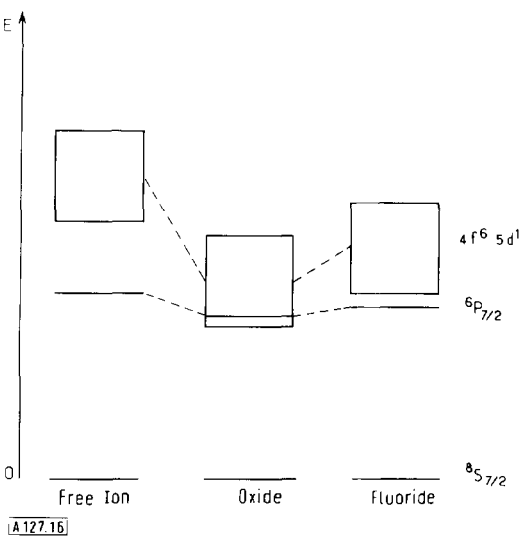

Fig. 16. Energy of the $^6P_{7/2}$ level in relation to the $4f^6 5d^1$ band in Eu^{2+}.

of divalent europium only requires 40000 cm^{-1}. Divalent europium contains seven f electrons, which corresponds to a high correlation energy as is the case for all half-occupied orbitals. As a result, a large energy difference separates the ground state $^8S_{7/2}$ of europium from the first excited level $^6P_{7/2}$ of the $4f^7$ configuration. This system can, therefore, lead to emission of ultraviolet radiation for which practical applications exist. However, this type of transition is not generally observ-

able, since the $5d^1$ levels are located above the $^6P_{7/2}$ level only in the free ion. In most compounds of europium, and especially in the oxides, these levels form a band and overlap with the excited states of the $4f^7$ configuration (Fig. 16). This band, corresponding to the 5d external orbitals, is very sensitive to the crystal field. Only in certain fluorides does it have a sufficiently high energy for the transition $^6P_{7/2}$-$^8S_{7/2}$ to appear. The emitted light is highly monochromatic and can be used either for developing lasers in the near UV or for xerography.

5. Conclusion

After his successful research on fluorine, *Moissan* queried: "Will fluorine never have any applications? It is very difficult to answer this question". History has answered in the affirmative: fluorine has become an industrially important element. In the field of materials, the applications of mineral fluorides are still relatively few and account for only small amounts. In pure research, however, these compounds attract considerable interest owing to their unusual and specific properties. No doubt this speculative work will lead to important applications in the future, some of which can already be discerned. But is that all that really matters? *Moissan* finished his commentary on the use of fluorine with this phrase: "In addition, I can say in all sincerity I was hardly thinking about it at the moment when I undertook this work, and I believe that all the chemists who have attempted such research before me were not thinking further of it: Scientific work is the search for truth".

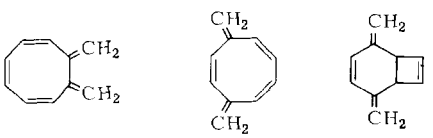
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

5,8-Bis(diphenylmethylene)-1,3,6-cyclooctatriene

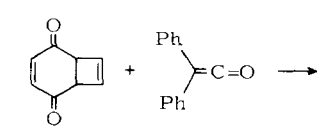
By *Yoshio Kitahara* (deceased), *Masaji Oda*, and *Yasutaka Kayama*[*]

Although 7,8-dimethylene-1,3,5-cyclooctatriene *(1)* has been prepared[1], 5,8-dimethylene-1,3,6-cyclooctatriene *(2)* is still unknown. An attractive synthetic approach to *(2)* consists in the thermal ring opening of its valence isomer 2,5-dimethylenebicyclo[4.2.0]oct-3,7-diene *(3)*.

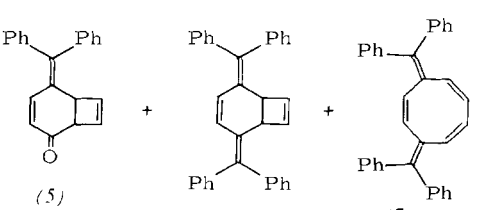


(1) *(2)* *(3)*

The reaction of diphenylketene with *p*-benzoquinone is known to afford diphenylquinomethane and tetraphenylquinodimethane[2]. In order to examine the feasibility of the above-mentioned route, we have prepared 2,5-bis(diphenylmethylene)bicyclo[4.2.0]oct-3,7-diene *(6)*, a valence isomer of 5,8-bis(diphenylmethylene)-1,3,6-cyclooctatriene *(7)*, by an analogous reaction from bicyclo[4.2.0]octa-3,7-diene-2,5-dione *(4)*[3]. The thermal isomerization of *(6)* to *(7)* proved highly successful.



(4)



(5) *(6)* *(7)*

Table 1. Physical data of *(5)*, *(6)*, and *(7)*.

(5): IR (liquid): $\nu_{max} = 1655\ cm^{-1}$ (C=O); ^{1}H-NMR ($CDCl_3$): $\delta = 3.61$ (1H, d, $J = 4.0$ Hz), 3.92 (1H, d, 4.0), 5.77 (1H, d, 10.2), 6.12 (2H, m), 6.9–7.4 ppm (11H, m)

(6): pale yellow prisms; m.p. 202–203 °C; ^{1}H-NMR ($CDCl_3$): $\delta = 3.76$ (2H, s), 6.15 (2H, s), 6.23 (2H, s), 7.17 ppm (20H, m); UV ($CHCl_3$): $\lambda_{max} = 276$ (sh, $\varepsilon = 11200$), 349 nm (34900)

(7): colorless needles: m.p. 181–182 °C; ^{1}H-NMR ($CDCl_3$): $\delta = 5.82$ and 6.02 (4H, A_2B_2), 6.11 (2H, s), 7.14 ppm (20H, m); UV ($CHCl_3$): $\lambda_{max} = 339$ nm ($\varepsilon = 26500$).

Reaction of *(4)* with diphenylketene (2.1 equiv.) in refluxing toluene for three days afforded, after silica gel column chromatography, *(5)*, *(6)*, and *(7)* in 35%, 24%, and 12% yield, respectively. Further reaction of *(5)* with diphenylketene afforded *(6)* and *(7)* in good yields (physical data summarized in Table 1).

The simultaneous formation of *(6)* and *(7)* indicates the thermal ring opening of the cyclobutene of *(6)* to be fairly easy. The rate constant at 144 °C in diphenyl ether is $1.23 \times 10^{-5}\ s^{-1}$, and the activation energy is 36.5 kcal/mol[4].

The absorption maximum of *(7)* is observed at 10 nm shorter wave length than that of *(6)* and the extinction coefficient of *(7)* is appreciably smaller. These observations suggest that while the six-membered ring of *(6)* is probably nearly planar owing to the rigidity of the molecule, the eight-membered ring of *(7)* is not planar, thus reducing the conjugation between the two diphenylmethylene groups through the ring.

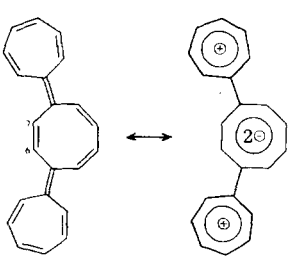
5,8-Bis(7-cycloheptatrienylidene)-1,3,6-cyclooctatriene

By *Yoshio Kitahara* (deceased), *Masaji Oda*, and *Hideo Miyazaki*[*]

It is of interest whether or not 5,8-bis(7-cycloheptatrienylidene)-1,3,6-cyclooctatriene *(1)* shows aromaticity arising from a contribution of the tripolar resonance form *(1')*.

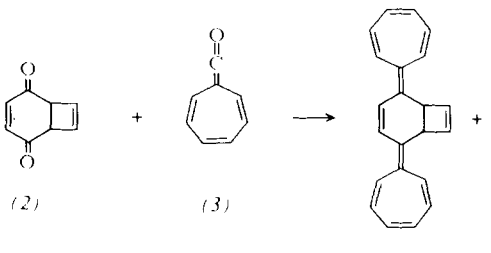


(1) *(1')*

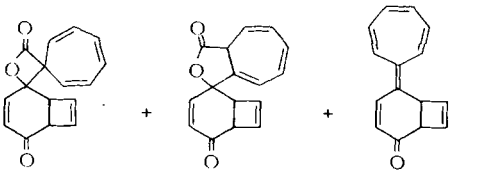
[*] Prof. Dr. Y. Kitahara, Dr. M. Oda, and Dipl.-Chem. H. Miyazaki
Department of Chemistry, Faculty of Science, Tohoku University
Sendai 980 (Japan)

The successful thermal isomerization of 2,5-bis(diphenylmethylene)bicyclo[4.2.0]oct-3,7-diene to 5,8-bis(diphenylmethylene)-1,3,6-cyclooctatriene[1] led us to attempt and to accomplish the synthesis of *(1)* along similar lines.

Reaction[2] of 2,5-dioxobicyclo[4.2.0]oct-3,7-diene *(2)*[3] with 7-carbonylcycloheptatriene *(3)*[4] (2.5 equiv.) generated *in situ* by the action of triethylamine on 1-cycloheptatrienecarbonyl chloride (benzene, room temperature, 16 h) afforded, after silica gel column chromatography and in the order of elution, 2,5-bis(7-cycloheptatrienylidene)bicyclo[4.2.0]oct-3,7-diene *(4)*, a β-lactone *(5)*, a mixture of γ-lactones differing in the positions of the double bond in the seven-membered ring [example: compound *(6)*], and a heptafulvene derivative *(7)* in 2.5 %, 32.1 %, 4.8 %, and 3.2 % yield, respectively[5]. While *(7)* is fairly stable at room temperature, *(4)* is extremely air-sensitive.



(2) *(3)* *(4)*



(5) *(6)* *(7)*

(4) *(1)*

When heated in refluxing benzene, *(5)* largely rearranged to *(6)* (64 %) and the desired decarboxylated product *(7)* was obtained in only 32 % yield. It was found, however, that silica gel in benzene effectively catalyzes quantitative decarboxylation of *(5)* to *(7)* at room temperature[5]. Reaction of *(7)* with *(3)* in refluxing benzene afforded *(4)* in 28 % yield. A simple preparation of *(4)* was achieved (18 % yield) by performing the reaction of *(2)* and *(3)* in refluxing benzene for ten minutes.

On heating a benzene solution of *(4)* at 140 °C in a sealed tube in which air had been rigorously replaced by nitrogen, the ^{1}H-NMR signal of the bridgehead protons of *(4)* at 3.74 ppm completely disappeared after 2 h. The desired compound *(1)* was obtained as a red-brown air-sensitive oil in 73 % yield by careful chromatography under nitrogen on a short silica gel column eluted with *n*-hexane.

Table 1. Physical data of *(1)* and *(4)*.

(1): red-brown oil: IR (liquid): ν_{max} = 3010, 1552, 1260, 727 cm^{-1}; UV (cyclohexane): λ_{max} = 226 (ε = 18600), 414 nm (15100); ^{1}H-NMR (C_6D_6, 100 MHz): δ = 5.5–6.3 ppm [m, including a singlet at 6.16 ppm (*ca.* 2H; H-6, H-7)]. *(4)*: dark red-brown needles; m.p. 148–149 °C (sealed tube); IR (KBr): ν_{max} = 3020, 1559, 730 cm^{-1}; UV (CH_2Cl_2): λ_{max} = 237 (ε = 22400), 434 nm (43600); ^{1}H-NMR ($CDCl_3$): δ = 3.74 (2H, s; H-1, H-6), 5.43–6.45 (12H, m), 6.16 (2H, s), 6.38 ppm (2H, s).

The physical data of *(1)* and *(4)* are listed in Table 1. The ^{1}H-NMR data indicate that *(1)* is a nonaromatic compound. The UV spectra of *(1)* and *(4)* resemble those of the diphenylmethylene analogs[1]. Accordingly, the eight-membered ring of *(1)* may not be planar.

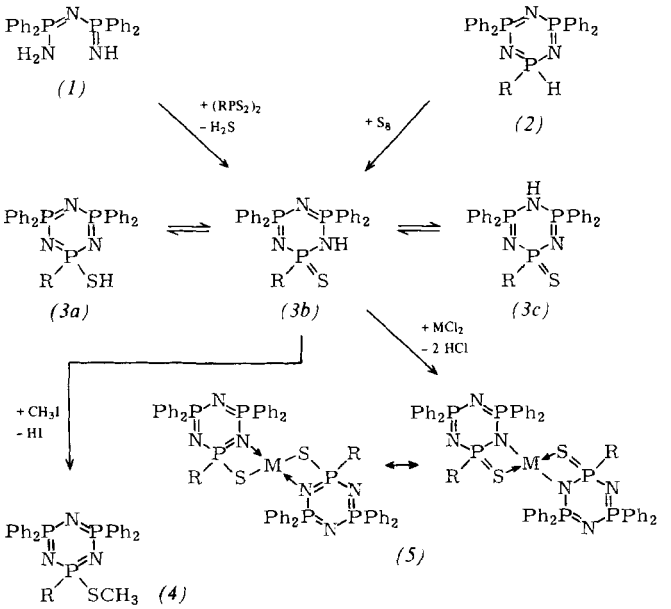
Bis[cyclotri(λ^5-phosphazane)dienethionato]-Ni^{II}, -Pd^{II} and -Pt^{II} Complexes and Their Structure[1]

By *Alfred Schmidpeter, Klaus Blanck,* and *Farid R. Ahmed*[*]

Dedicated to Professor Egon Wiberg on the occasion of his 75th birthday

Cyclotri(λ^5-phosphazane)diene-2-thiones *(3)* are accessible by cyclization[2] of aminodi(λ^5-phosphazene)s *(1)* with perthiophosphonic anhydrides and—as reported here—also by sulfurization of hydridocyclotri(λ^5-phosphazene)s *(2)*. They are present in solution as tautomer *(3b)*, their methyl derivatives *(4)* on the other hand derive from the other tautomer *(3a)*[2]. This follows from the inequivalence and equivalence, respectively, of P^4 and P^6, and from the doublet-splitting of the ^{1}H-NMR signal of the introduced methyl group (Table 1).



(1) *(2)* *(3a)* *(3b)* *(3c)* *(5)* *(4)*

In the form of their anions, compounds *(3)* react with Ni, Pd, and Pt dichlorides to give the bis(thionato)metal(II) complexes *(5)*. The ^{31}P-NMR spectra of *(5)* (Table 1) relate

[b] Solubility too low.

well with those of *(3b)* and, in particular, show P^4 and P^6 once again as nonequivalent. Thus they show that the phosphazene ring is coordinated to the metal atom *via* N^1, and suggest a four-ring chelate derivable from *(3a, b)*, which however, can be constructed only if the generally observed geometry of the participating structural elements is partially altered.

The structure of *(5)*, R = CH_3, M = Ni, was determined X-ray crystallographically by the heavy atom method[3] and refined to $R = 0.041$ and $R_w = 0.040$: space group $P\bar{1}$; $a = 11.142$, $b = 12.598$, $c = 9.620$ Å; $\alpha = 110.82$, $\beta = 77.84$, $\gamma = 102.58°$; $Z = 1$; $d_{calc} = 1.416$, $d_{exp} = 1.415\ g\ cm^{-3}$. The nickel atom forms a crystallographic center of inversion and is surrounded by a rigidly planar array of two sulfur atoms and two nitrogen atoms *i.e.* a sulfur and a geminal nitrogen from each of the two ligands. Both chelate rings are folded along the N^1S diagonals through 25.4°, as required on grounds of symmetry, in opposite directions.

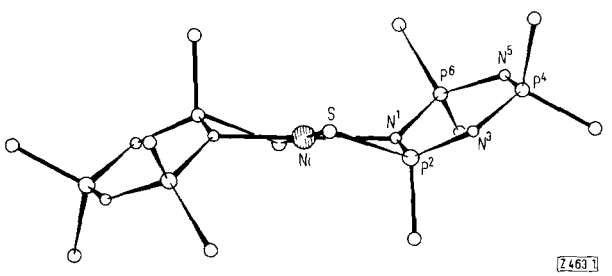

Fig. 1. Molecular structure of the bischelate *(5)*, R = CH_3, M = Ni. Of the eight phenyl groups only the *P*-bonded carbon atoms are shown.

Chelate formation becomes possible because a) the phosphazene nitrogen coordinated to Ni is not planar[4] and is in a very unsymmetrical environment (angle $P^2N^1P^6$ 123.0, P^6N^1Ni 130.2, P^2N^1Ni 95.4°; sum of angles 348.6°), b) its bonds in the ring (N^1—P^2 1.649, N^1—P^6 1.635 Å) are longer than the other PN bonds (1.581—1.591 Å), and c) at P^2 the ligand plane is not perpendicular to the phosphazene plane (dihedral angle 82.5°, while in other cases it deviates by at most 5° from a right angle).

Cyclotri(λ⁵-phosphazane)diene-2-thione (3)

A solution of hydridocyclotri(λ⁵-phosphazene) *(2)* in methylene chloride is treated with a stoichiometric amount of sulfur and heated to boiling. After *ca.* 10 min the sulfur has dissolved, and *(3)* separates out as fine crystals (yield 90—95 %).

Methylthiocyclotri(λ⁵-phosphazene) (4)

1 mmol of *(3)* dissolves after several hours stirring in a solution of 10 ml methylene chloride and 3 ml CH_3I. Evaporation of the solution affords *(4)*-hydroiodide as a solid residue, from which *(4)* is obtainable by recrystallization from acetonitrile/water (1 : 1) (yield 82—88 %).

Cyclotri(λ⁵-phosphazane)dienethionato complexes (5)

To a solution of *(3)* (2 mmol) and sodium methoxide (2 mmol) in methanol (10 ml) is added 1 mmol $NiCl_2(H_2O)_6$ (dissolved in 5 ml of methanol) or $PdCl_2$ (dissolved in 25 ml of acetonitrile) or $(C_6H_5CN)_2PtCl_2$ (dissolved in 10 ml of acetonitrile). A finely crystalline precipitate of *(5)* is formed; in the first and second case immediately, in the third case after 10 minutes' boiling and subsequent cooling. *(5)* is recrystallized from nitrobenzene (yield 80—95 %).

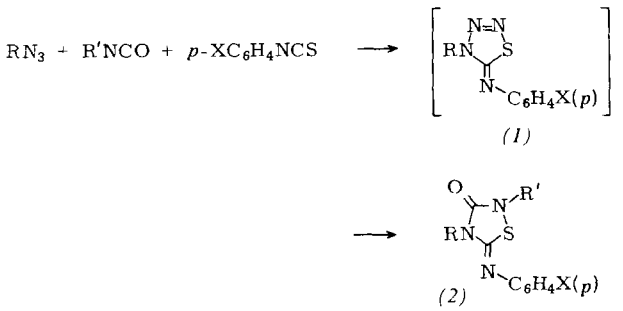
Three-Component Reactions with Aryl Isothiocyanates. Synthesis of 5-Arylimino-1,2,4-thiadiazolidin-3-ones

By *Gerrit L'abbé* and *Gabriël Verhelst*[*]

The use of isothiocyanates in a three-component synthesis of heterocycles is scarcely documented in the literature[1]. In this report we describe a novel synthesis of substituted 5-imino-1,2,4-thiadiazolidin-3-ones which have been prepared previously from isothiocyanates in a three-step procedure[2].

[*] Prof. Dr. G. L. L'abbé and G. Verhelst
Department of Chemistry, University of Leuven
Celestijnenlaan 200 F, B-3030 Heverlee (Belgium)



According to our method the heterocycles *(2)* are obtained in high yields (see Table 1) when alkyl azides, aryl isothiocyanates, and alkyl or aryl isocyanates are mixed together under well-defined conditions (see procedure). Structure assignment of the heterocycles *(2)* was based mainly on IR spectra [KBr, $\nu(C{=}O) \approx 1710$, $\nu(C{=}N) \approx 1630\,cm^{-1}$] and on the ^{13}C-NMR spectra[3].

Table 1. Products *(2a)* to *(2d)* of the three-component reaction and compound *(2e)* obtained from *(1e)*. The yields of *(2a)* to *(2d)* are based on the isocyanate.

Cpd.	R	R'	X	Yield [%]	M.p. [°C]

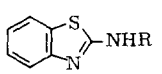
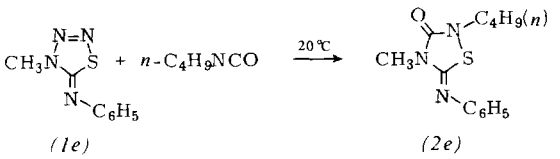
(3a), Z = O
(3b), Z = S



(4a), R = $C_6H_5CH_2$
(4b), R = $n\text{-}C_4H_9$

Mechanistically, the reactions seem to proceed *via* the intermediacy of an iminothiatriazoline *(1)* for several reasons: (i) alkyl azides are known to be thermally stable under the reaction conditions[4], thus excluding a nitrene mechanism; (ii) alkyl azides are also unreactive towards most isocyanates[5], and the tetrazolin-5-one *(3a)* was isolated in only one case as a side product (see Table 1); and (iii) addition of alkyl azides to the C=N bond of isothiocyanates would give 1,4-disubstituted tetrazoline-5-thiones which are, however, thermally stable[6]; the tetrazoline-5-thione *(3b)* was isolated as minor product in only one case (see Table 1). To test our mechanistic interpretation, 4-methyl-5-phenylimino-1,2,3,4-thiatriazoline *(1e)* was synthesized by the method of *Neidlein* and *Tauber*[7]. This compound proved to be thermally stable up to 110°C, at which temperature it decomposed into 2-methylaminobenzothiazole [the 2-aminobenzothiazoles *(4a)* and *(4b)* are formed as by-products on synthesis of *(2c)* and *(2d)*]. In the presence of butyl isocyanate, however, an exothermic reaction already occurs at room temperature and furnishes *(2e)* in 95 % yield. This experiment substantiates the proposed



(1e) *(2e)*

mechanism and clearly points to a bimolecular mechanism in the second stage of the reaction.

General procedure:

To a solution of alkyl azide (0.08 mol) and isocyanate (0.04 mol) at 80°C isothiocyanate (0.02 mol) was added in portions over a period of seven days. Then the excess of azide and heterocumulenes was distilled off *in vacuo* and the residual oil was purified by column chromatography on silica gel using ether/hexane (20:80) as the eluent.

Solvolysis of the Hexafluorophosphate Ion and the Structure of [Tris(μ-difluorophosphato)bis(pentamethylcyclopentadienylrhodium)] Hexafluorophosphate[**]

By *Stephen J. Thompson*, *Pamela M. Bailey*, *Colin White*, and *Peter M. Maitlis*[*]

We report here on the preparation and some properties of the novel dicationic solvate complexes *(2)* and on the observation of the solvolysis of the hexafluorophosphate counterion to give difluorophosphate, which has been characterized as a ligand in the complex *(3)*. In view of the ease with which this reaction occurs care in the use of PF_6^-, and similar counterions previously thought to be inert, is necessary.

The solvate complexes *(2)* were obtained from the dichloro(pentamethylcyclopentadienyl)rhodium or -iridium compounds[1] *(1)* by reaction with $AgPF_6$ in the solvent (solv.). Those with solv. = acetonitrile, pyridine or dimethyl sulfoxide (DMSO) could be isolated but those with solv. = acetone, methanol or dichloromethane could only be obtained

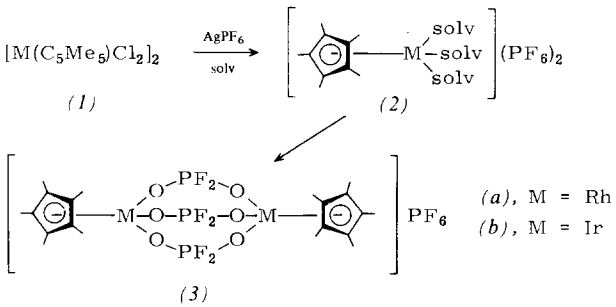
in solution. These complexes react readily with a variety of organic ligands (*e.g.* arenes) to give complexes such as $[M(C_5Me_5)(arene)]^{2+}$.

The rhodium-DMSO complex was shown by its IR spectra to be *O*-bonded to the metal both in the solid (Nujol mull) and in acetone solution [ν(SO) 953 cm^{-1}], but the iridium-DMSO complex was both *O*- and *S*-bonded in the solid [ν(SO) 901, 1135 cm^{-1} in Nujol mull] and only *S*-bonded in acetone solution [ν(SO) 1128 cm^{-1}][2]. These observations suggest that ($Rh^{III}C_5Me_5$) is a "harder" coordination center than ($Ir^{III}C_5Me_5$).



When attempts were made to isolate complex *(2a)*, solv.= Me_2CO, or when the acetone solution was heated (50 °C/12 h), a complex decomposition reaction occurred to give complex *(3a)* which contained bridging PO_2F_2 ligands. This was shown by NMR and IR spectroscopy, by an X-ray structure determination of a crystal of *(3a)* (figure) and by direct synthesis from *(2a)* and HPO_2F_2.

The ^{31}P-NMR spectrum (w.r.t. 85 % H_3PO_4 ext.) of *(3a)* showed a septet due to the PF_6^--anion [$\delta = -166.2$ ppm, $J_{PF} = 708$ Hz] and a triplet due to the PO_2F_2 ligands [$\delta = -33.1$ ppm, $J_{PF} = 952$ Hz] in the ratio of 1:3. The ^{19}F-NMR spectrum (w.r.t. CF_3CO_2H ext.) showed two doublets [$\delta = -5.7$ and $+3.4$ ppm] in a 1:1 ratio, while the ^{1}H-NMR spectrum showed a singlet ($\delta = 1.65$) arising from the ten equivalent methyl groups.

The salt $[C_{20}H_{30}F_6O_6P_3Rh_2]F_6P$, $M = 924.14$, crystallizes monoclinically with $a = 10.186(5)$, $b = 37.68(2)$, $c = 12.82(2)$ Å, $\beta = 98.06(1)°$; $V = 4872$ Å^3; $d_{calc} = 1.889$, $d_{obs} = 1.83$ g/cm^3; $Z = 6$; space group $P2_1$. Three-dimensional X-ray data with $6.5° \leq 2\theta \leq 50°$ were collected with the crystal mounted along the *c* axis on a Stoe STADI 2 diffractometer, using graphite monochromated $Mo_{K\alpha}$ radiation. 4210 independent reflections had $I_{obs} \geq 3\sigma(I_{obs})$. The positions of the six independent rhodium atoms were determined by Patterson superposition methods, and the remaining non-hydrogen atoms found from difference Fourier syntheses. Block diagonal least-squares refinement with constrained geometries for the pentamethylcyclopentadienyl groups reduced *R* to 0.112, at which point a difference Fourier synthesis indicated some of the fluorine atoms to be disordered; this is currently under further investigation. It is not possible to distinguish the O and F atoms of the PO_2F_2 ligands and their formulation as *O*-bonded to Rh rests largely on the ^{19}F-NMR spectrum which shows only one doublet, arising from coupling to ^{31}P, down to -90 °C. A PO_2F_2 ligand which was *O*- and *F*-, or only *F*-bonded to Rh would show different spectroscopic behavior, in particular a coupling to ^{103}Rh (100 %, $I = \frac{1}{2}$).

The hexafluorophosphate ion is normally regarded as extremely stable; it only undergoes very slow hydrolysis in 6 M HCl at 45 °C to phosphate[3] and hydrolysis under alkaline conditions is even slower and again phosphate is the product[4, 5]. Metal ion catalysis has been observed both under acid [by Th^{IV} or Zr^{IV}][6] and under alkaline [by the larger

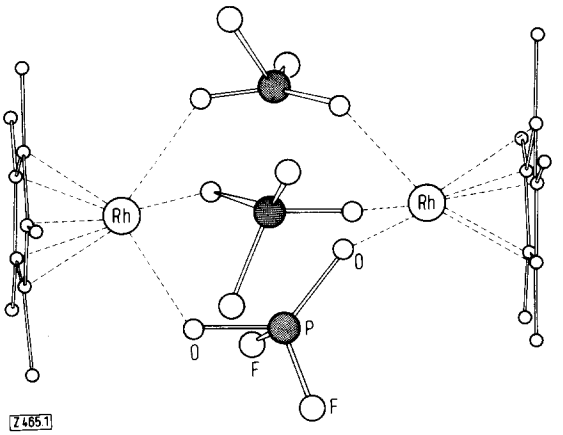


Fig. 1. Structure of the complex cation $[C_5Me_5Rh(PO_2F_2)_3RhC_5Me_5]^+$ in *(3a)*.

alkali-metal ions][5] conditions. In the Al^{III}-catalyzed reactions at low acidity kinetic evidence for the build-up of an intermediate has been given[6] but the present work describes the first defined example of the partial solvolysis of the PF_6^- ion to the $PO_2F_2^-$ ion as well as the first structure determination of a transition metal difluorophosphate complex. It is also noteworthy that the PO_2F_2 ligands bridge two rhodium atoms[7]. The iridium complex *(3b)* was formed analogously from $[Ir(C_5Me_5)(Me_2CO)_3](PF_6)_2$ but it reacted further[8]. Addition of water did not significantly increase the rate of formation of *(3a)* but addition of mesityl oxide caused a substantial acceleration.

The $H_5O_2^+$ Ion in Hydrogen Bromide Dihydrate[***]

By *Rainer Attig* and *Jack M. Williams*[*]

Accurate measurement of the hydrated proton $[H(H_2O)_n]^+$ in the solid state by neutron diffraction has so far been limited to hydrates of strong organic acids[1] or acid metal com-

plexes[2]. According to X-ray crystallographic and spectroscopic findings the crystalline hydrates of the mineral acids may also be formulated as oxonium salts; but their low melting points make it difficult to prepare single crystals large enough for neutron diffraction experiments.

We have now succeeded in preparing a single crystal of hydrogen bromide dihydrate $HBr \cdot 2H_2O$ weighing *ca.* 130 mg in a lead-glass capillary by controlled passage of a hot-wire loop along the capillary in a stream of cold gas[3]. The positions of the O and Br atoms were already known from an earlier X-ray structure analysis[4], from which the probable presence of $H_5O_2^+$ and Br^- ions was concluded. Our neutron diffraction analysis has not only made it possible to confirm the location of the O and Br atoms but also of the H atoms, and to measure the $H_5O_2^+$ ion exactly.

H_5O_2Br crystallizes monoclinically in the space group $P2_1/c$ with the lattice constants (−40°C) $a=4.23$, $b=12.57$, $c=6.94$ Å; $\beta=101.4°$; $Z=4$; d_{exp} (−15°C) = 2.11[5], $d_{calc}=2.15\ g\,cm^{-3}$. Three-dimensional neutron diffraction data were collected with the help of the CP5 reactor at the Argonne National Laboratory. Structure determination based on the positions of the Br and O atoms found by X-ray studies, as well as isotropic and anisotropic refinement for all atoms with 522 independent data corrected for absorption ($\mu=1.62\ cm^{-1}$) with maximum diffraction angle $2\theta=80°$ ($\lambda_n=1.142$ Å) gave an agreement factor of $R=0.149$ (0.094 for 373 reflections $>1\sigma$). The resulting positions of the atoms are listed in Table 1.

Table 1. Atomic coordinates of H_5O_2Br (in brackets: estimated standard deviation to the last decimal place).

	x	y	z

H(21)	0.2223(25)	−0.0115(8)	0.3016(13)
H(22)	0.2321(25)	0.1023(7)	0.3972(15)

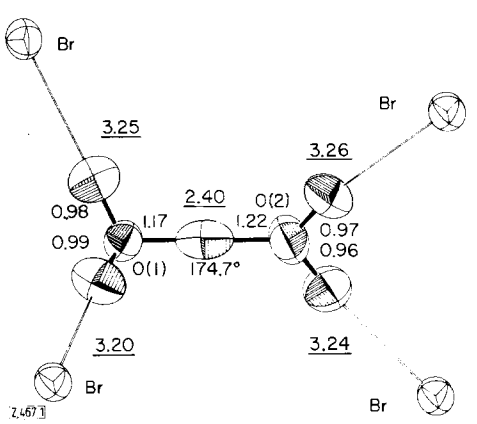

Fig. 1. The cation H_5O_2 in hydrogen bromide dihydrate. Atomic distances in Å, underlined values for distances between O and Br atoms; standard deviation 0.01 Å (for the quoted angle 0.8°).

Figure 1 shows the diaquahydrogen cation with four symmetry equivalent bromide ions as hydrogen bridging partners. The central O—H—O bridge is remarkably short (mean value of previously determined O—O distances in cations of this type amounts to 2.44 Å). The hydrogen atom is not exactly central, even in this short bridge, a finding that can be correlated with the slight asymmetrical environment of the two oxygen atoms in view of the bond lengths and O—Br contacts. A deviation of about 5° from the straight O—H—O arrangement was previously observed in all $H_5O_2^+$ ions, which are not fixed at 180° by a center of symmetry.

In contrast to the terminal hydrogen atoms, the central atom shows its largest vibration amplitude almost in the bond direction—a finding which in similar cases was explained in terms of a broad, flat potential well[6]. There is no evidence of disorder of the hydrogen atom between two half-occupied sites.

Recovery of Chiral α-Ferrocenylalkylamines on Stereoselective Peptide Synthesis by Four-Component Condensation[**]

By *Gerhard Eberle* and *Ivar Ugi*[*]

α-Ferrocenylalkylamines *(4)* have proved well suited as chiral amine components for stereoselective peptide syntheses by four-component condensation[1]. In combination with the recently discovered multiplication of stereoselectivity[2] and the enhancement of stereoselectivity by addition of quaternary ammonium salts of the acid component *(3)*[3] products *(5)* [and *(7)*] of almost uniform stereochemistry can be obtained by use of the amines *(4)*, and especially α-ferrocenylisobutylamine *(4b)*[1,2] (Scheme 1).

Conventional methods of removing the chiral ferrocenylalkyl group from the condensation product *(5)*[1,2] have not hitherto permitted recovery of the chiral amine *(4)*. This is a considerable drawback since the amines *(4)* are usually only preparable with great difficulty[1].

Ratajczak and *Misterkiewicz* recently reported[4] that α-ferrocenylethanol *(9a)* reacts with thioglycolic acid *(6)* in the presence of trifluoroacetic acid to form *(8a)*, and that *(9a)* is accessible from *(8a)* by hydrolysis in the presence of $HgCl_2$, the reaction *(8a)* → *(9a)* belonging to the retentive S_N1 type[5].

We have now found that *N*-(α-ferrocenylalkyl)-peptide derivatives *(5)* are smoothly cleaved by *(6)* in the presence of trifluoroacetic acid into *(7)* and *(8)*, with complete retention of configuration at the chiral center bearing the ferrocenyl ligand.

For instance, treatment of the tripeptide derivative *(5c)*[6] at room temperature in 0.05 M acetone solution with an excess

[*] Dipl.-Chem. G. Eberle and Prof. Dr. I. Ugi

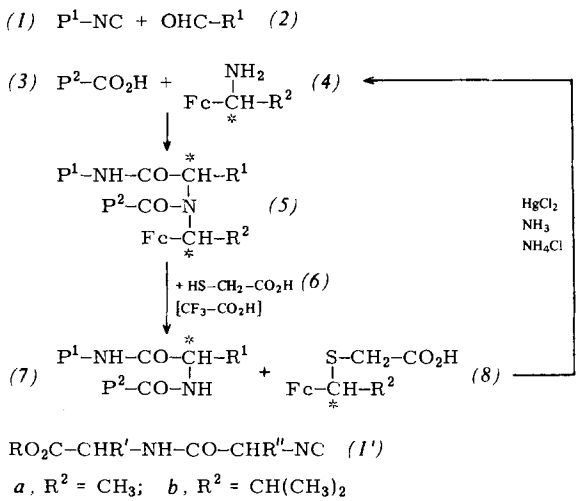
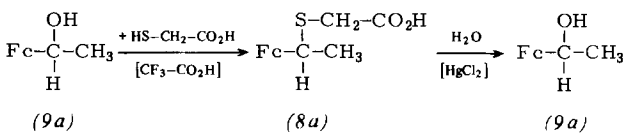
Arcisstrasse 21, 8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

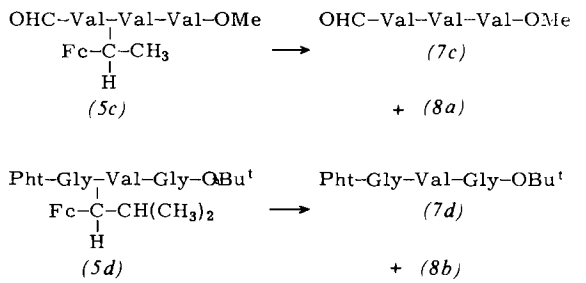


Scheme 1. Stereoselective synthesis of the peptide derivatives *(5)* by four-component condensation of compounds *(1)* to *(4)*, cleavage of *(5)* with thioglycolic acid in the presence of trifluoroacetic acid to give the peptides *(7)* and (α-ferrocenylalkylthio)acetic acids *(8)* and recovery of the chiral starting component *(4)*. *(1)* is an isocyanide derived from an α-amino acid or peptide ester, preferably an *N*-(α-isocyanoacyl)-α-amino acid ester *(1')*. *(2)* is an α-amino aldehyde OHC—CHR—NH_2 and *(3)* is an α-amino acid or a peptide with an N-terminal protective group. Fc = ferrocenyl.

of thioglycolic acid *(6)* and a catalytic amount of trifluoroacetic acid over 24 h affords a 94 % yield of the cleavage products *(8a)* and *(7c)*.—Reaction of *(5d)*[6] in trifluoroacetic acid with thioglycolic acid *(6)* for 48 h furnishes *(8b)* and *(7d)* in 87 % yield.



The *S*-(α-ferrocenylalkyl)thioglycolic acids *(8a)*,*(8b)* thus obtained are optically pure, as demonstrated by comparison with literature data and by further reaction to the amines *(4)*. Dissolution of *(R)*-*(8a)* or *(R)*-*(8b)* in concentrated ammonia and addition of NH_4Cl and $HgCl_2$ (molar ratio 1:2:2) affords, after reaction for 7 to 9 h at 25 °C, *(4a)* in 78 % yield and *(4b)* in 73 % yield, respectively. Both amines *(4)* are 98 to 99 % optically pure.



The readily accessible racemic *S*-(α-ferrocenylalkyl)thioglycolic acids *(8a)*,*(8b)* can be enantiomerized with the aid of (−)-ephedrine[4] and (−)-pseudoephedrine, thus transforming the reaction *(8)* → *(4)* into a new productive approach to chiral α-ferrocenylalkylamines *(4)*.

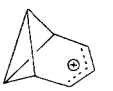
Tricyclo[4.1.0.$0^{2,7}$]heptenyl Cation—A New Isomer of the Tropylium Ion[**]

By *Manfred Christl* and *Gertrud Freitag*[*]

Carbocations having the molecular formula $C_7H_7^{\oplus}$ have been studied in great detail[1], not least because of the theoretical interest attracted by the bonding in the tropylium ion and the 7-norbornadienyl cation. Although a member of this family, the tricyclo[4.1.0.$0^{2,7}$]heptenyl cation *(1)* has so far remained unknown[1b]. We now wish to report a facile entry to this system and its rearrangement.



(1)

On standing for 15 h at 80 °C in an inert solvent such as tetrachloromethane, 7,7-dibromotetracyclo[4.1.0.$0^{2,4}$.$0^{3,5}$]-heptane *(2)* is smoothly transformed into 4,5-dibromotricyclo[4.1.0.$0^{2,7}$]hept-3-ene *(3)*[2], thus providing some indication of the considerable stability of the 4-bromotricycloheptenyl cation *(4)*. Departure of the *endo* bromine as an anion and disrotatory ring opening of the 1,6-bond in *(2)* lead directly to *(4)*, which is trapped by the bromide ion to form *(3)*. In 50 % aqueous acetone containing triethylamine compound *(2)* is no longer stable at room temperature. The polar solvent facilitates ionization to give *(4)* which, on reaction with water as nucleophile, furnishes the alcohol *(5)*[3], b.p. 40—60 °C (bath)/0.01 torr, m.p. 62—65 °C. Compound *(5)* is also accessible from *(3)* in 60—70 % yield by solvolysis in tetrahydrofuran/water or acetone/water mixtures containing triethylamine at room temperature. On treatment with sodium in liquid ammonia at −70 °C *(5)* is converted in *ca.* 60 % yield into the bromine-free species tricyclo[4.1.0.$0^{2,7}$]hept-4-en-3-ol *(6)*[3], b.p. 75—78 °C/15 torr, m.p. 16—19 °C, which has recently been synthesized *via* another route[4].

The 3,5-dinitrobenzoates are accessible from *(5)* and *(6)* in the usual way by treatment with 3,5-dinitrobenzoyl chloride. Entirely as would be expected from the solvolysis behavior of *(3)*, 6 hours' refluxing of *(5)*-dinitrobenzoate[3], m.p. 122—124 °C, in 65 % aqueous acetone in the presence of diisopropylethylamine merely afforded a 65 % yield of *(5)*. In contrast,

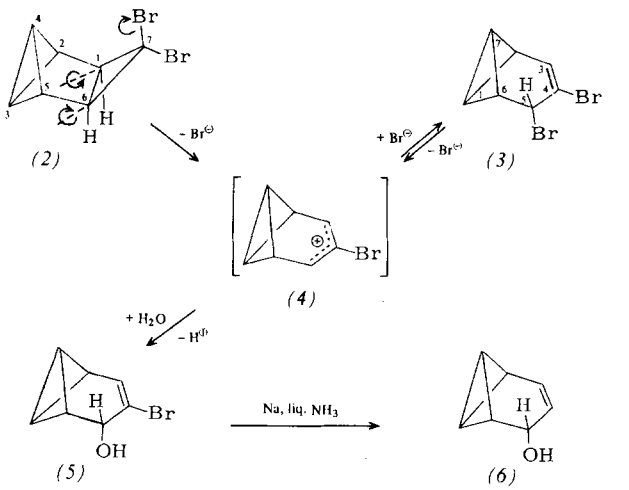
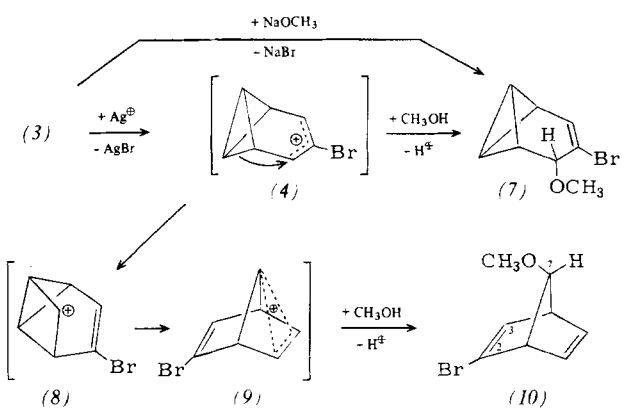
solvolysis of *(6)*-dinitrobenzoate[3], m.p. 94°C, in the same medium for 3 h at 70°C gave a 7:3 mixture of *(6)* and di-2,4,6-cycloheptatrienyl ether. We suspect intermediate formation of *(1)* which rearranges to 7-norbornadienyl cation and thus with water furnishes 7-norbornadienol (see below). The facile conversion of the latter into di-2,4,6-cycloheptatrienyl ether in aqueous alkaline solution has recently been reported[5].



A better insight into the rearrangement is provided by cation *(4)* in a less nucleophilic medium. Dropwise addition of a benzene solution of silver perchlorate at room temperature to a solution of *(3)* in a 15:4:2 mixture of ether, methanol, and triethylamine[6] immediately precipitates silver bromide and a 60% yield of 4-bromo-5-methoxytricyclo[4.1.0.0^{2,7}]-hept-3-ene *(7)* and 2-bromo-*syn*-7-methoxynorbornadiene *(10)* in the ratio 88:12 is isolated. Mixing of toluene solutions of *(3)* and silver perchlorate at 20 or −70°C and subsequent addition of methanol furnishes a 60% yield of *(10)*[3], b.p. 95—105°C (bath)/14 torr, as sole product. The stereochemistry at C-7 follows from the 1.1-Hz coupling constant between H-7 and H-3[7]. *(7)*[3], b.p. 44—45°C/0.04 torr, is formed in 95% yield from *(3)* with sodium methoxide in methanol.



It is improbable that the rearrangement of the cation *(4)* is affected by silver(I) ions since they even fail to attack the neutral species *(7)* under the conditions of the reaction. The transition to the 7-norbornadiene system is most simply explained by a 1,2 shift of one of the four peripheral bicyclobutane bonds to the adjacent cationic center. Thus *(4)* affords *(8)*, 2-bromo-7-norbornadienyl cation in one of the classical formulations[1c]. *(9)* corresponds to the generally accepted bishomocyclopropenyl structure[1]. Approach of the nucleophile methanol from the side of the free double bond, which in this case bears a bromine substituent, at C-7, is characteristic of 7-norbornadienyl cations[1c].

The driving force of the rearrangement, which overcomes the allylic resonance in *(4)*, is most probably the lessening of strain energy on ring expansion *(4)*→*(8)* and the pronounced stability of *(9)*.

New Ring Transformation of Zwitterionic Bicyclic Thiazole Systems

By *Sang-Woo Park, Walter Ried*, and *Walter Schuckmann*[*]

Dedicated to Professor Dr. R. Wegler on the occasion of his 70th birthday

The reaction of phenacyl bromide *(2)* with the bicyclic zwitterionic thiazoles *(1a)* and *(1b)*, which result from a three-component reaction of cyclic thioureas, mercury bis-(phenylacetylide), and phenyl isothiocyanate[1,2], does not yield the bromides *(4)* corresponding to the iodides *(3)*[2]; instead ring opening and renewed cyclization affords the new bicyclic thiazoles 2-[2-(7-benzoyl-5-phenylimino-2,3-dihydro-1*H*-imidazo[1,2-*c*]thiazol-1-yl)-2-phenylvinylthio]acetophenone *(10a)* and 2-[2-(8-benzoyl-6-phenylimino-1,2,3,4-tetrahydrothiazolo[3,4-*a*]pyrimidin-1-yl)-2-phenylvinylthio]acetophenone *(10b)*, respectively.

Since no unequivocal structural information about products *(10)* could be derived from their spectroscopic data, the molecular structure of *(10a)* was solved by X-ray methods. The formula scheme shows the suspected mode of formation of these compounds. Simultaneous formation of the salt *(7)*[3,4] apparently results from a secondary reaction of the unstable primary product *(4)* under the action of *(1)*. Direct reaction of *(1)* with HBr likewise proceeds *via (5)* to give the salt *(7)*, from which the free base *(9)*[2] is obtained with aqueous K_2CO_3 solution. The phenyl isothiocyanate isolated by column chromatography can be trapped as *N,N'*-diphenylthiourea with aniline in methanol.

Table 1. Data for compounds *(10a)* and *(10b)* (correct elemental analyses and mass spectra are available).

	Yield [%]	M.p. [°C]	IR [a] [cm^{-1}]	^{1}H-NMR [b] [δ, ppm]
(10a)	40	197	3060 1680	3.86—4.2 (m; 6H) 6.06 (s; 1H) 6.68—7.96 (m; 20H)
(10b)	32	154	3060 1690	1.5—2.1 (m; 2H) 3.1—4.2 (m; 6H) 5.94 (s; 1H) 6.7—8.1 (m; 20H)

[a] ν(=CH) and ν(C=O) in KBr.
[b] Conditions: 100 MHz, $CDCl_3$, hexamethyldisiloxane as internal standard.

General procedure:

A solution of *(2)* (2 mmol) in acetone (10 ml) is added to a solution of *(1a)* in hot acetone (200 ml; 100 ml in the case of *(1b)*). After refluxing for 5 min and standing at room temperature for several hours the colorless crystals of *(7)* are filtered off and the solvent distilled from the filtrate in a rotary evaporator. After addition of a little chloroform and keeping at room temperature the residue is freed from insoluble components and once again evaporated to dryness. Column chromatography of the residue on silica gel (elution with benzene/ethyl acetate 3:1) furnishes *(10)*. Recrystallization from a little acetone in the cold gives yellow crystals.

Complete Asymmetric Synthesis and Absolute Configuration of an Aminoacylmolybdenum Complex

By *Wolfgang Beck, Wolfgang Danzer, Anh Thu Liu,* and *Gottfried Huttner*[*]

Previously described reactions of η^5-cyclopentadienyltricarbonyl hydrides of molybdenum *(1)* and tungsten with substituted aziridines *(2)*[1] suggested that the β-aminoacyl chelate complexes *(3)* are formed with asymmetric induction.

	R^1	R^2	R^3	*(2)*	*(3)* $[\alpha]_{578}^{23}$ [d]
a	Me	Ph	Me	$(-)_{578}$ [a]	−687°
b	Me	Ph	Me	$(+)_{578}$ [b]	+100°
c	H	H	Me		
d	H	Ph	H		
e	H	H	Et	$(+)_{578}$ [c]	+ 51.3°
f	*t*-Bu	H	H		

[a] *cis*-(2*R*,3*S*); [b] *trans*-(2*S*,3*S*); [c] (3*R*); [d] in acetone.

By reaction of *(1)* with the optically active aziridines *(2a)* and *(2b)* and X-ray structure analysis of the complex *(3a)* we found that complete asymmetric induction occurs at *two* prochiral centers in a specificity-determining step. IR spectra show that the aziridine *(2)* is initially protonated and then undergoes nucleophilic attack at C-2 by the carbonylmetalate ion. Ring opening is regiospecific; in *(2c)* the Mo atom is bonded to the unsubstituted C atom, and in *(2d)* to the phenyl-substituted one.

Reaction of *(2f)* affords the aminoalkyl complex *(4f)*. The intermediacy of the complexes *(4a)* to *(4e)* also follows from the fact that the compound *(5c)*[3], obtained according to *Knoth*[2], can be converted into the chelate complex *(3c)*.

Crucial steps for the stereospecific formation of *(3a)* from *(4a)* are the "CO insertion" and the coordination of the

[*] Prof. Dr. W. Beck, Dipl.-Chem. W. Danzer, and Dipl.-Chem. A. Liu
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, 8000 München 2 (Germany)

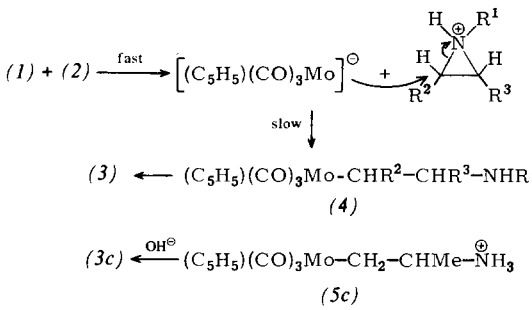
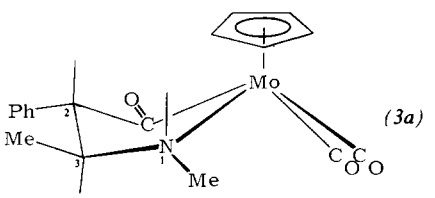
Arcisstrasse 21, 8000 München 2 (Germany)

N atom to the metal. This fixes the asymmetric center at C-2; two new chiral centers are created at N and Mo. Of the 16 possible (considering the conformation of the chelate



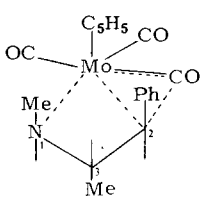
ring) diastereomeric complexes only the isomer *(3a)* is formed (Fig. 1), which does not epimerize in solution according to its ^{1}H- and ^{13}C-NMR spectra.



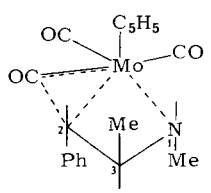
(3a)

Fig. 1. Structure of the tetragonal complex *(3a)* (schematic). S_{Mo}, 1*R*,2*S*,3*S*; space group $P4_12_12$; $a=b=1663\pm1$, $c=1449\pm1$ pm, $d_{X\text{-ray}}=1.26$, $d_{exp}=1.28\,g\,cm^{-3}$, $Z=8$, $R_1=5.6\,\%$ (measurements: Syntex P21; solution: Syntex XTL). Distances and angles expectedly resemble those in the analogous compound *(3)*, $R^1=R^2=R^3=H$ [4]. The absolute configuration depicted follows from the finding that the configuration at the methyl-substituted C atom of the aziridine *(2a)* is retained [5].

The established reaction mechanism requires that the aziridine *(2a)* is opened with inversion at C-2 (*R*→*S*). In contrast, the migration of the alkyl group to the carbonyl carbon atom proceeds with retention[6]. The orientation of the aminoalkyl group in the diastereomeric transition states R_{Mo}-*(6a)* and S_{Mo}-*(6a)* determines the asymmetry at the molybdenum atom. (R_{Mo} and S_{Mo} are defined by viewing the tetragonal pyramid in Fig. 1 from above). CO insertion and N coordination do not necessarily proceed synchronously.



R_{Mo}-*(6a)*



S_{Mo}-*(6a)*

We assume that the transition state R_{Mo}-*(6a)* is energetically less favorable than S_{Mo}-*(6a)* owing to nonbonding intramolecular interactions between the "upward" pointing methyl and phenyl groups and the π-bonded cyclopentadienyl ring. For the chiral chelate ring the δ-conformation is found; only in this conformation are the three ring substituents in the energetically favorable equatorial position.

Applying the same considerations to the reaction of *(1)* with *(2e)* would indicate the resulting complex *(3e)* also to have the S_{Mo} configuration. In fact the CD spectra of *(3a)* and *(3e)* are practically identical, while the CD spectra of *(3a)* and *(3b)* are related as object and mirror image in the range 200—380 nm. Hence the expected R_{Mo} configuration can be deduced for *(3b)*.

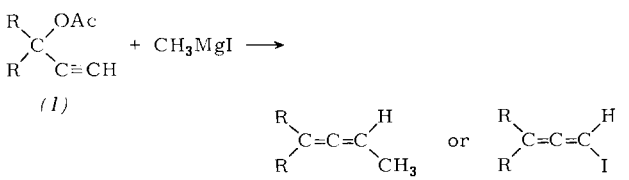
Trialkylallenes from 1,1-Disubstituted Propargylic Acetates

By *Françoise Delbecq* and *Jacques Gore*[*]

We recently reported that the reaction of 1.2 molar equivalents of methylmagnesium iodide with 1,1-disubstituted propargylic acetates *(1)* in ether leads selectively to methylallenes or iodoallenes depending on the experimental conditions[1].



We now report that this reaction can be extended to other Grignard reagents, providing a convenient entry to trialkylallenes *(2)*. The best conditions for obtaining the trialkylallenes consist in adding the solution of the Grignard reagent in ether to a solution of 1 mol of acetate *(1)* and 4 mols of magnesium bromide in the same solvent. All the reactions listed in Table 1 were performed in this way. The number of molar equivalents of the Grignard reagent depends on the type of halide and the ease of formation and further reaction of the radical R·.

The reaction is less satisfactory with Grignard reagents of secondary halides; iodides give better results than bromides but in spite of numerous attempts it was impossible to find conditions under which very good yields of allenes and extensive conversion of acetate could be both maintained. With larger quantities of reagent or increased reaction times, the yields are lower and the reaction product is mainly composed of high molecular unidentified compounds.

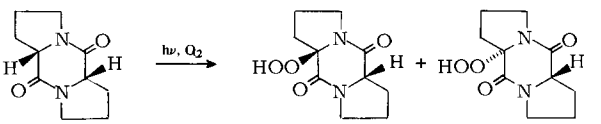
Radical Oxidation of Amino Acid Derivatives

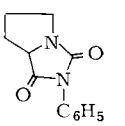
By *Ulrich Schmidt* and *Johannes Häusler*[*]

Dedicated to Professor Helmut Zahn

In recent years, derivatives—and especially dioxopiperazines—of α-hydroxy, α-mercapto, and α,β-dehydro amino acids have frequently been discovered as fungal metabolites[1]. Consideration of their biosynthesis prompted us to investigate the autoxidation of dioxopiperazines such as *(1)*: we found that they undergo ready oxidation to hydroperoxides such as *(2)* and *(3)*. The latter can easily be reduced to alcohols which are transformed into mercaptodioxopiperazines by hydrogen sulfide[2].



(1) *(2)* *(3)*



(4)

Dioxopiperazines are cyclic dipeptides. Their autoxidation can be performed photochemically with benzophenone as sensitizer, or in the dark by the action of radical initiators (peroxides, azo compounds) under oxygen pressure. In some cases the reaction with illumination occurs particularly readily and it is difficult to understand how this sensitivity of cyclic dipeptides has hitherto escaped notice: a 3,6-diethyl-1,4-dimethyl-2,5-piperazinedione preparation stored for four years in a poorly sealed bottle was found to have undergone almost complete oxidation to a mixture of mono- and bis-hydroperoxide. Practically all dioxopiperazine derivatives stored without exclusion of oxygen are found to contain peroxide after a certain time.

cyclo(-L-Pro-L-Pro) *(1)*, *cyclo*(-L-Pro-Gly-), *cyclo*(-L-Pro-Sar-), and 3,6-diethyl-1,4-dimethyl-2,5-piperazinedione were oxidized to mono- and bis-hydroperoxides. The *N*-phenylhydantoin derivative *(4)* could only be oxidized to the monohydroperoxide with the aid of peroxidic catalysis.

The reaction conditions will be presented for compound *(1)* as an example. 15 hours' irradiation (Rayonet reactor, 350-nm light) of *(1)* in ethyl acetate with 1 mol% of benzophenone under an oxygen pressure of 5 atm leads to almost complete conversion into a mixture, of which approximately one half was composed of *cis*-monohydroperoxide *(2)* and *cis*-bishydroperoxide. The major product is *(2)* if oxidation is performed for a shorter period. The best yields of *(2)* are obtained on reaction in daylight (see *Procedure*).

cis- and trans-cyclo(-α-Hydroperoxy-L-Pro-L-Pro-), (2) and (3) respectively

A solution of *(1)* (1.98g) and benzophenone (20mg) in distilled ethyl acetate (50ml) was exposed to sunlight (Vienna, July, largely unclouded) in a 100-ml Erlenmeyer flask. Deposition of hydroperoxides in the form of bundle-like crystals began within two days. The crystalline reaction product was

[*] Prof. Dr. U. Schmidt and Dr. J. Häusler
Organisch-Chemisches Institut der Universität Wien
Währinger Strasse 38, A-1090 Wien (Austria)

filtered off every two days (crude yield 90 %). Recrystallization from chloroform/ethyl acetate removes precipitated *(1)*. Separation of *(2)* and *(3)* (ratio 94:6) and traces of *trans*-bis-hydroperoxide was accomplished by column chromatography (Kieselgel 60, Merck; ethyl acetate/ethanol 4:1). *(2)* and *(3)* form colorless crystals of dec. pt. >140°C (racemic *(2)*, cf. ref. [2a]).

Self-Condensation of β-Dialkylaminocrotonates: A One-Step Synthesis of *N,N*-Dialkylanthranilates[**]

By *Roger L. N. Harris*, *John L. Huppatz*, and *John N. Phillips*[*]

The self-condensation of ethyl β-aminocrotonate in the presence of phosphorus oxide chloride to give the pyridine *(3)* was first reported in 1901[1]. A key step in this reaction is the utilization of the nitrogen atom from one amino group in the formation of the heterocyclic ring. We now report that in the analogous reaction of *N,N*-dialkylaminocrotonates *(1)*, where heterocyclic ring formation is not possible without dealkylation, self-condensation follows a different path, leading in high yield to *N,N*-dialkylanthranilic acid derivatives.

When ethyl β-dimethylaminocrotonate *(1a)* was allowed to react with an excess of $POCl_3$, a mildly exothermic reaction ensued. On work-up, a pale yellow oil was obtained, for which analytical and high resolution mass spectral data indicated the formula $C_{12}H_{16}ClNO_2$. The compound had arisen, therefore, by self-condensation of the crotonate *(1a)*, elimination of dimethylamine, water and ethanol, and addition of HCl. The NMR spectrum ($CDCl_3$) was consistent with a benzene structure bearing ethoxycarbonyl, methyl, chloro and dimethylamino substituents. The remaining two aromatic protons appeared as two broad singlets at $\delta = 6.70$ and 6.75.

The chloro substituent was removed by catalytic hydrogenolysis and the resulting ester hydrolyzed to give 4,*N*,*N*-trimethylanthranilic acid, identical with an authentic sample prepared by reaction of 2-chloro-4-methylbenzoic acid[2] with dimethylamine in DMF in the presence of copper acetate. Chlorination of the original self-condensation product with sulfuryl chloride in chloroform at room temperature gave a fully substituted trichlorobenzene derivative, indicating that the two unsubstituted positions originally present must have been *ortho* and *para* to the dimethylamino group. The self-condensation product is therefore ethyl 6-chloro-4,*N*,*N*-trimethylanthranilate *(2a)*.

The reaction appears to be generally applicable to *N,N*-dialkyl-β-aminocrotonates (see Table 1).

Ethyl 6-chloro-4,N,N-trimethylanthranilate (2a)

(1a) (100 g) was added slowly with stirring to $POCl_3$ (500 ml) cooled externally by a bath of tap-water. The addition was controlled so that the temperature did not exceed 35°C. The mixture was kept overnight then heated on a steambath for

acidic or basic reagents have been developed[1]. We report here on the reactivities of previously unknown acetylides *(2)* generated from trimethylsilylacetylenes such as *(1)* and carbonyl compounds *(3)*. Synthetic reactions in strongly acidic solution, in which an acetylene is activated by a silyl group have been described[3]. The method reported here is the first example of such a use of silyl groups under essentially neutral conditions.

A catalytic amount of tetrabutylammonium fluoride[2] effects the addition of 1-phenyl-2-trimethylsilylacetylene *(1)* to carbonyl compounds *(3)*, *e.g.* aldehydes, and aliphatic and aromatic ketones. The reaction, usually conducted in THF with about 3 mol % of the catalyst, proceeds smoothly at temperatures ranging from −78° to +25°C, and the product yield is generally good (Table 1). Adducts can be isolated either in the silylated form *(4)* or, after hydrolysis with dilute acetic acid, as alcohols *(5)*. α,β-Unsaturated ketones, however, behave in a rather complicated way. While chalcone *(3f)* affords exclusively the adduct *(4f)* in good yield, common conjugated ketones, *e.g.* 2-cyclohexenone, methyl vinyl ketone, benzylidine acetone gave only little or no adducts of type *(4)*. Thus the acetylide *(2)* is less reactive than the corresponding lithium phenylacetylide which afforded satisfactory results also with conjugated ketones. The catalyzed reaction most likely proceeds as shown in the following Scheme[1].

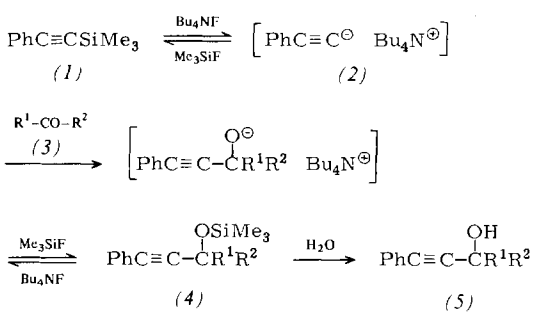

Table 1. Tetrabutylammonium fluoride catalyzed reaction of 1-phenyl-2-trimethylsilylacetylene *(1)* with carbonyl compounds *(3)*. The reaction was carried out in THF at −20°—0°C with 3 mol % of catalyst.

	R^1	R^2	*(4)* Yield [%]	*(5)* Yield [%]

g	Ph	Et		72
h		$-(CH_2)_5-$	87	

[a] Citral.

The method can also be applied to silylacetylenes other than *(1)*. For instance, 1-trimethylsilyl-1-octyne reacts at room temperature with benzophenone to furnish the adduct in good yield.

Recently, a general route to 1-aryl-2-trialkylsilylacetylenes[4] as well as a procedure for the silylation of acetylenes under neutral conditions[2] have been reported. The extremely mild conditions combined with the accessibility of the silylacetylenes will render this catalyzed reaction a valuable synthetic aid.

1-(Phenylethynyl)-1-trimethylsiloxycyclohexane (4h)

A solution of *(1)* (287 mg, 1.65 mmol) and *(3h)* (147 mg, 1.50 mmol) in THF (2 ml) was treated with tetrabutylammonium fluoride (14 mg, 0.05 mmol) at −20°C for 5 min, and then at 0°C for 1 h. The yellow reaction mixture was diluted with hexane, and filtered. After concentration, the residual yellow oil was purified by preparative thin-layer chromatography; yield 354 mg (87 %), b.p. 115°—117°C/1.0 torr.

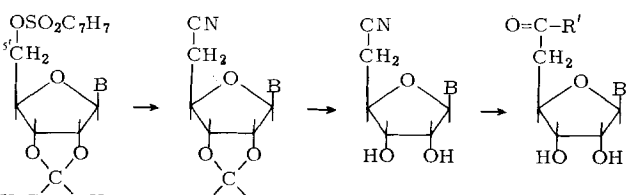
Facile Preparation of 5′-Cyano- and 5′-Carboxynucleosides[**]

By *Wilfried Meyer, Ekkehard Böhnke*, and *Hartmut Follmann*[*]

Nucleoside derivatives substituted at the exocyclic C5′-atom of the ribose moiety are important for the elucidation of structure-function relations in naturally occurring nucleosides and nucleotides and as potential drugs[1–4]. While substitution at C5′ by O, N, S, and halogen functions is generally easy[4, 5], a C—C chain elongation at this site to give "homonucleosides" is possible in only few cases and generally in unsatisfactory yield[1, 2, 6].

We have now found a facile synthesis of 5′-deoxy-5′-cyanonucleosides *(2)* and *(3)* and the 5′-deoxynucleoside-5′-carboxylic acids *(5)* derived from these nitriles. Reaction of the readily accessible 2′,3′-*O*-isopropylidene-5′-*O*-tosyl derivatives of nucleosides such as *(1a)* in dioxane or acetonitrile with alkali cyanides with addition of equimolar amounts of the complexing agent [18]crown-6[7] smoothly affords, *e.g.*, *(2a)*; basic elimination of the aglycon[8], which readily occurs under similar conditions, is not observed; nor is intramolecular cyclization of *(1a)* to give N^3,5′-cycloadenosine. Compound *(1b)* yields not only *(2b)* but also the readily separable O^2,5′-cyclouridine. Compounds *(1a)* and *(1b)* failed to react with cyanides under all tested variations of temperature and solvent when the reaction was attempted without crown ether catalysis. The more reactive 5′-deoxy-5′-iodonucleosides



(1a), (1b) *(2a), (2b)* *(3a), (3b)* *(4a)*, R′ = NH_2 *(5a)*, R′ = OH

a, B = Adenine; *b*, B = Uracil

give only small amounts of the 5'-cyanides beside cyclization and degradation products, regardless of whether a crown ether is present or not[9].

The new compounds, whose structures are confirmed by mass spectra, UV spectra [*(2a)*: $\lambda_{max}=259$ nm; *(2b)*: 258 nm in H_2O, pH 7], and a characteristic IR absorption band at 2250 cm^{-1}, can be divested of the ketalic 2',3' protective function by acid treatment. The water-soluble 5'-deoxy-5'-cyanonucleosides *(3a)* and *(3b)* provide an entry to the nucleosides of 5'-deoxy-β-D-*ribo*hexafuranuronic acid which were formerly inaccessible by a simple pathway. Thus hydrolysis of *(3a)* in alkaline hydrogen peroxide gave both the amide *(4a)* and the 5'-deoxyadenosine-5'-carboxylic acid *(5a)*. Hitherto only analogous carboxylic acid derivatives stemming from adenosine itself were known which are formed as C5'-OH epimer mixtures (cf. ref. [2]). *(5a)* closes the gap between adenosine-5'-uronic acid and 5'-deoxyadenosine-5'-acetic acid[1] and like the latter carboxylic acid is also a model compound for adenosine-5'-phosphate (AMP); for instance, *(5a)* is deaminated to the inosine derivative by the enzyme AMP aminohydrolase (EC 3.5.4.6).

Like the natural nucleosides, *(3a)*, *(3b)*, and *(5a)* in aqueous solution prefer the *anti* conformation of the base relative to the C—N glycosidic bond. This is deduced from the typical downfield shift of the ring proton signals in the ^{1}H-NMR spectrum by the adjacent polar 5'-substituent[10]. *(5a)* exhibits the same long-wave CD spectrum as AMP ($[\Theta]_{260}=-4800$ deg cm^2 $dmol^{-1}$). However, the CD spectrum of *(3a)* displays an exceptionally low ellipticity and in the short-wave region a high ellipticity ($[\Theta]_{260}=-1300$, $[\Theta]_{210}=+7000$ deg cm^2 $dmol^{-1}$); this behavior confirms the relation deduced between structure, conformation, and circular dichroism for other adenosine derivatives with strongly polar 5'-substituents[10].

5'-Deoxy-5'-cyanoadenosine (3a)

Compound *(1a)* (0.92 g, 2 mmol) and [18]crown-6 (0.20 g) are stirred vigorously in anhydrous dioxane (15 ml) with dried KCN (0.65 g, 10 mmol) at room temperature for 20 h. Removal of the solid salts and preparative layer chromatography of the concentrated solution on silica gel with chloroform/methanol (6:1) ($R_f=0.74$) afford *(2a)* (0.35 g, 55 %) which crystallizes as needles (m. p. 202—204 °C) from methanol.—In order to remove the protecting group, *(2a)* (0.32 g) is suspended in 50 % formic acid (5 ml) and left to stand for 5 d at room temperature. Concentration *in vacuo* and freeze drying of the residue from water give a quantitative yield (0.27 g) of pure *(3a)*.

5'-Deoxyadenosine-5'-carboxamide (4a) and -5'-carboxylic acid (5a)

Compound *(3a)* (0.27 g, 1 mmol) is warmed to 30 °C for 1 h in 5% H_2O_2 (5 ml) (pH 10). The solution is then applied to an anion exchange column (formate form) and eluted with a water/formic acid gradient (pH 5 to pH 2) to give the amide *(4a)* (0.16 g, 55 %), a little adenine, and the carboxylic acid *(5a)* (0.07 g, 26 %). Direct hydrolysis of *(4a)* in more strongly alkaline solution led mainly to elimination of adenine.

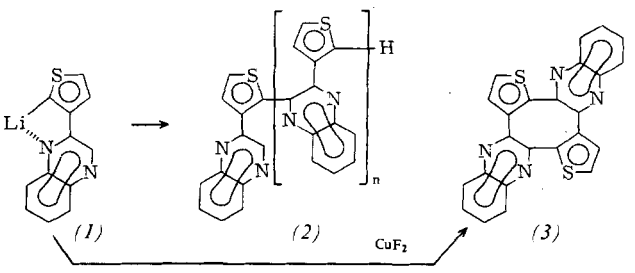
CuF_2-Assisted Synthesis of Heterocyclotetraaromatics by Nucleophilic Aromatic Substitution[**]

By *Thomas Kauffmann* and *Rolf Otter*[*]

Ten heterocyclopolyaromatics[1] were recently prepared in low yield (<26 %)[2] as the first representatives of a new class of substances.

The apparently obvious idea of cyclizing a monolithiated diheteroaromatic like *(1)* containing a strongly nucleophilic and a strongly electrophilic center by double nucleophilic aromatic substitution has not yet been realized. Thus the lithium compound *(1)*, obtained almost quantitatively from the metal-free compound by the action of lithium diisopropylamide, does not yield *(3)* on warming to 34 °C in ether[3] but instead gives the open-chain oligomers *(2)* ($n=1$—5, m. p. 170, 183, 196—198, 227, 242—244 °C, yields 10, 12, 13, 9, 5 %)[4]. This could be a consequence of the chelate bridge in *(1)* which fixes the two reactive centers in the *trans* position unfavorable for cyclization.—The desired cyclization to give *(3)* (m.p. 372—374 °C; yield 9 %) only occurred on treatment of the solution of *(1)* in THF at −20 °C with anhydrous CuF_2 in the molar ratio 1:2.



Unlike *(1)*, the benzo-homologs *(4)* also cyclize without addition of CuF_2. Addition of anhydrous CuF_2 or NiF_2 in the molar ratio 1:2 did however enhance the yield of *(6)* (m. p. 419—420 °C) from 11 to 63 (experiment 3 in Table 1). Thus a heterocyclopolyaromatic has now become available for the first time in preparatively useful yield.—Comparison of the experiments 1, 2, and 4 in Table 1 reveals that CuF_2 also promotes formation of the open-chain dimer *(5)*, $n=1$ (m. p. 231 °C) and the open-chain trimer *(5)*, $n=2$ (m. p. 348—349 °C).

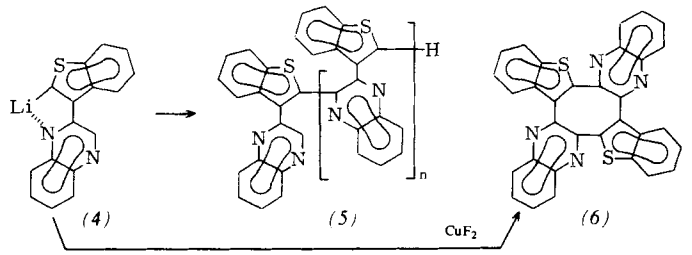
Organisch-Chemisches Institut der Universität
Orléans-Ring 23, 4400 Münster (Germany)

[**] Heterocyclopolyaromatics, Pat. 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Refs. [2a—2c] are to be regarded as Parts 1 to 3.



Preliminary model studies[5] showed that CuF_2 and NiF_2 also favor formation of 2-(2-thienyl)pyridine from 2-lithiothiophene and 2-fluoropyridine: under the reaction conditions employed [30 min −40 °C, 4 h 0 °C, 30 min 20 °C in ether/THF (*ca.* 1 : 1)] the thienylpyridine was formed in 8 % yield without addition of metal fluoride, and in 24 and 12 % yield respectively on addition of NiF_2 and CuF_2 in the molar ratio 1 : 2.—The mode of action of the two transition metal fluorides is still a matter of conjecture.

Table 1. Effect of CuF_2 on the cyclization of *(4)* in THF [3, 4].

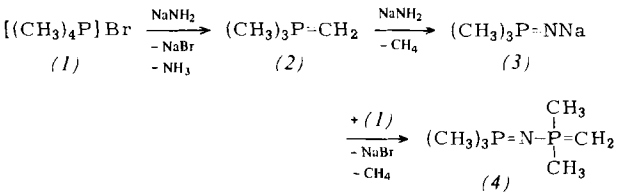
A Methylene-di-λ^5-phosphazene by Amide Cleavage of Tetramethylphosphonium Salts

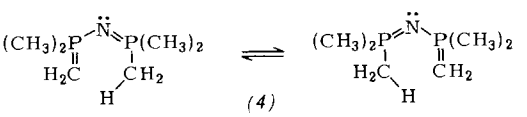
By *Hubert Schmidbaur* and *Hans-Joachim Füller*[*]

It has been reported that the salt-free trimethyl(methylene)-phosphorane *(2)* can be conveniently prepared by dehydrohalogenation of a tetramethylphosphonium salt *(1)* with sodamide in boiling tetrahydrofuran[1]. On carrying out this reaction in our laboratory, however, it has been established that this procedure is not free of side reactions and that, with suitable adjustment of the reaction conditions, the methylene-di-λ^5-phosphazene *(4)* is obtained in high yields. In addition to ammonia there is also methane evolved, which could be identified by gas chromatography.

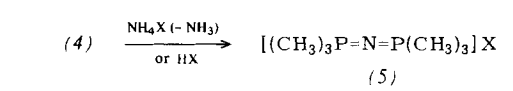
We suspect that the imide[2] *(3)* is formed as a precursor, since cleavage of hydrocarbons from phosphonium salts with alkali metal amide has been observed previously in at least two cases[3]. As a strong nucleophile, the anion of this precursor can then attack a second phosphonium center with cleavage of methane and formation of *(4)*. If the reaction is allowed to proceed at room temperature, instead of reflux temperature, the secondary reactions are (presumably for solubility reasons) more rapid than the primary formation of *(2)*, so the latter is continually being used up.



(4) is a pale yellow, highly reactive liquid which readily crystallizes on cooling. It follows from the ^1H-, ^{13}C-, and ^{31}P-spectra that this ylide is a fluctional compound; at elevated temperature the 17H, the 6C and the 2P atoms each are spectroscopically equivalent! The different positions of the atoms in the molecule can be differentiated only on strong cooling. This phenomenon can be interpreted only as the result of a rapid proton transfer[4], which in *(4)* proceeds both by an intramolecular and by an intermolecular mechanism[5]. The proton transfer in *(2)* is somewhat slower.



Reaction of acids or their ammonium salts[6] with *(4)* leads to the bis(trimethylphosphoranylidene)ammonium salts *(5)*, which were previously only accessible with difficulty *via* another route[2].



Like other ylides[7], *(4)* is an excellent complexing agent for numerous metal centers with which σ-bonded organometallic compounds can be synthesized. Thus, *e.g.*, reaction with trimethylgallium, like the corresponding reaction with *(2)*[9], leads initially to a 1 : 1 adduct *(6)*, m.p. 25—27 °C[8]. In contrast to $(CH_3)_3P—CH_2—Ga(CH_3)_3$, which can be distilled without decomposition[9], *(6)* loses methane on heating and yields the chelate *(7)*, m.p. 68—69 °C[8].

No corresponding precursor is detectable in the reaction of *(4)* with diethylzinc or dimethylcadmium—immediate formation of the chelates *(8)* and *(9)*, respectively, takes place (m.p. 75—77 and 86—88 °C, resp.[8]).

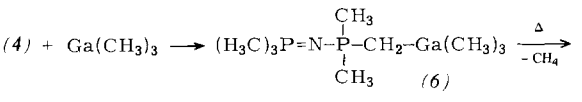
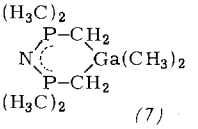
Arcisstrasse 21, 8000 München 2 (Germany)

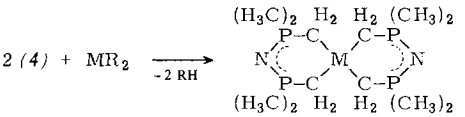


(6)



(7)

Accordingly, analogies can be drawn between *(4)* and acetylacetone and the isoelectronic bis(trimethylphosphoranylidene)methane[10].



(8), M = Zn, R = C_2H_5
(9), M = Cd, R = CH_3

Pentamethyl(methylene)di-λ^5-phosphazene (4)

Compound *(1)* (or the chloride) (68 g, 0.40 mol) is transferred to a suspension of $NaNH_2$ (22 g, 0.56 mol) in THF (750 ml). After 35 hours' stirring at 25 °C in the absence of air and moisture the reaction mixture is filtered and the filtrate fractionated *in vacuo*; after removal of *(2)* as a first fraction, there remains 22.4 g (68%) of *(4)*, b.p. 148–150 °C/30 torr, m.p. 14 °C. ^{1}H-NMR (in [D_8]-toluene at −60 °C, TMS ext.): δ = 1.19 (d, 9H, *J*(HCP) = 13.4 Hz), 1.37 (d, 6H, *J*(HCP) = 13.0 Hz), 0.10 (d, 2H, *J*(HCP) = 6.5 Hz). In {^{31}P} experiments three singlets (9:6:2) are obtained. At 80 °C all signals merge to a single broad singlet. ^{13}C-NMR (as above but at −20 °C, {^{1}H})[11]: δ = 18.0 (dd, 3C, *J*(CP) = 69.1, *J*(CPNP) ≈ 2.9 Hz), 24.2 (dd, 2C, *J*(CP) = 72.8, *J*(CPNP) ≈ 5.1 Hz), 10.0 (dd, 1C, *J*(CP) = 89.7, *J*(CPNC) ≈ 2.9 Hz). At higher temperature signal broadening and collapsing occurs. ^{31}P-NMR (as above but at −80 °C against H_3PO_4 ext., {^{1}H}): $\delta P^1 = 15.5$ (d, *J*(PNP) = 8.0 Hz), $\delta P^2 = 21.1$ (d). On warming signal broadening occurs.

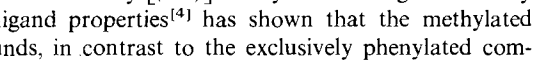
The Ambident Ligand Properties of Bis(trimethylphosphoranylidene)methane

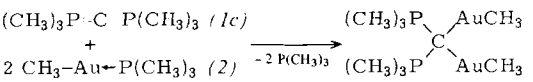
By *Hubert Schmidbaur* and *Oswald Gasser*[*]

Recently, more than ten years after the first synthesis of a "carbodiphosphorane" $R_3P{=}C{=}PR_3$ (with R = C_6H_5) by *Ramirez et al.*[1], we were able to prepare the partially [*(1a)*, *(1b)*][2] and the fully [*(1c)*] methylated analogs[3]. A study of the ligand properties[4] has shown that the methylated compounds, in contrast to the exclusively phenylated compound, show an ambident behavior and are thus novel chelating agents.

(1c) reacts with two equivalents of methyl(trimethylphosphane)gold[5] *(2)* with liberation of two equivalents of the phosphane to give a 1:2 complex, which on the basis of analytical and spectroscopic data can be assigned structure *(3)*.



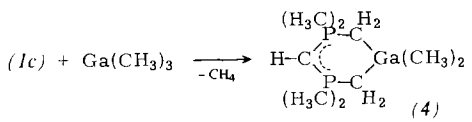
(1a), n = 1; *(1b)*, n = 2; *(1c)*, n = 3



(3)

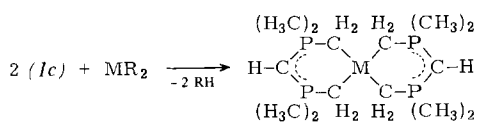
The colorless product *(3)*, which is air-sensitive, thermally stable up to 80 °C and soluble in organic solvents, is a new example of a molecule having two gold atoms bonded to a tetrahedrally coordinated C-atom[6].

In the reaction of equimolar amounts of *(1c)* and trimethylgallium, on the other hand, rapid evolution of methane already takes place slightly above room temperature, and the chelate *(4)* is formed.



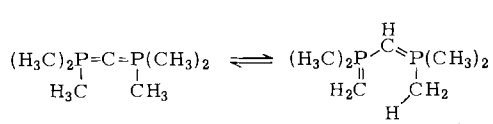
(4)

Finally, reaction of diethylzinc or dimethylcadmium with *(1c)* also proceeds with evolution of alkane, yielding the chelates *(5)* and *(6)*.



(5), M = Zn, R = C_2H_5;
(6), M = Cd, R = CH_3

(4), *(5)*, and *(6)* (m.p. 41, 85, and 84 °C, resp.) are colorless substances which are readily soluble in organic solvents and can be distilled unchanged *in vacuo*; their mass spectra show the molecular ion M^+ as an intense group of signals. Obviously the chelates *(4)*, *(5)*, and *(6)* are formed from the prototropic form *(1c')* of *(1c)*.



(1c) *(1c')*

[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. O. Gasser
Anorganisch-Chemisches Institut der Technischen Universität
Arcisstrasse 21, 8000 München 2 (Germany)

This ambident behavior is reminescent of the corresponding forms of acetylacetone, for each of which metal derivatives have been described[7]. The scope of the chemistry of the simply arylated carbodiphosphoranes[8] is thus significantly broadened. The present strong interest in ylide complexes[4] should therefore be further stimulated, as there are indications for practical uses in the literature[9].

Bis(methylgold)bis(trimethylphosphonio)methanediide (3)

A solution of *(1c)* (290 mg, 1.77 mmol) in ether (5 ml) is added dropwise at −60 °C in an inert atmosphere to a stirred solution of *(2)* (1.02 g, 3.54 mmol) in ether (10 ml). The mixture is then stirred for 1 h at 20 °C, filtered, and the precipitate washed with *n*-pentane and dried in a vacuum. The yield of *(3)* is almost quantitative. ^{1}H-NMR (in CH_2Cl_2, TMS ext.): δ(CH_3Au) = 0.55 (t, 6H, J(HCAuCP) = 1.2 Hz), δ(CH_3P) = 2.34 ($A_9XX'A'_9$, 18H, N = 12.2). ^{1}H-{^{31}P}: s, 6H; s, 18H.

Chelates (4), (5), and (6)

A suspension of *(1c)* (950 mg, 5.8 mmol) in benzene (10 ml) is treated with a solution of $Ga(CH_3)\cdot O(C_2H_5)_2$ (1.1 g, 5.8 mmol), $Zn(C_2H_5)_2$ (360 mg, 2.9 mmol), or $Cd(CH_3)_2$ (400 mg, 2.9 mmol) in benzene (10 ml). The reaction mixture is heated under reflux until evolution of gas (GLC: CH_4 or C_2H_6) is complete; the residue after removal of solvent is then distilled in a vacuum; yield *ca.* 80 % in each case. Complete ^{1}H-, ^{13}C-, and ^{31}P-NMR data are available for all three complexes. Example *(6)*: ^{1}H-NMR (in C_6D_6, TMS ext.): δ = 1.1 (d, 24H, $A_6XX'A'_6$, N = 10.9), −0.1 (d, 8H, $A_2XX'A'_2$, N = 12.0, ^2J(CdCH) = 34.5 Hz), −0.25 (m, 2H). {^{1}H}-^{13}C-NMR (in C_6D_6, C_6D_6 int. conv. to TMS): δ = 23.8 (m, 8C, AXX', N = 61.0), 2.6 (m, 4C, AXX', N = 48.8), 6.8 (t, 2C, ^1J(CH—P) = 119.6 Hz). {^{1}H}-^{31}P-NMR (in C_6H_6, H_3PO_4 ext.): δ = 13.2 (s, ^2J(CdCP) = 48.0 Hz).

Lahnberge, 3550 Marburg (Germany)

atoms C-2, C-6, and C-4 resemble electron-rich 6π-delocalized arenes more closely than 6π-delocalized ylides in their chemical[1] and physical[2] properties. We have now synthesized the first π-complexes *(2)* of such phosphorins with tricarbonylchromium, tricarbonylmolybdenum, and tricarbonyltungsten (Table 1).

All the new complexes, which were obtained as air-stable orange-red to yellow crystals by heating *(1)* with $M(CO)_6$ or $M(CO)_3(CH_3CN)_3$ in dioxane or benzene, afford correct elemental analyses. In their mass spectra the M^+ peak rarely lies above 15%; loss of CO and $M(CO)_3$ is observed.

In each case the upfield shift of the protons at C-3 and C-5 in the ^{1}H-NMR spectra demonstrate that the central λ^5-phosphorin and not one of the peripheral phenyl groups is the actual π-donor. On complex formation to give *(2)* the equivalent groups X in *(1)* (OCH_3 or F) acquire different chemical environments. The signal of the ^{31}P nucleus undergoes only a relatively slight upfield shift on complexation, whereas in the λ^3-phosphorin-carbonylchromium complexes the upfield shift is large[3,4]. The carbonyl groups attached to the metal atom can be recognized from their IR absorption, both in cyclohexane solution and in KBr (see Table 1).

X-Ray structure analysis[5] of *(2a)* and *(2i)* shows that the λ^5-phosphorin ring remains planar on complexation. The P—Cr distance is relatively long in *(2a)*. It becomes significantly shorter on replacement of the OCH_3 groups on the phosphorus by F atoms and the phenyl group at C-4 by the *tert*-butyl group [compound *(2i)*]. This is due to both steric and electronic reasons because the distances P-(C-2)= P-(C-6) are also smaller in *(2i)* than in *(2a)*. No X-ray structure analysis of a typical tricarbonylchromium-ylide complex[6] is yet available. Thus it is not possible to decide to what extent the ylide form or the arene form participate more significantly in the ground state bonding of the λ^5-phosphorin-carbonylmetal complexes *(2)*.

X-Ray Structure Analysis of Two π-Complexes of λ^5-Phosphorins with Tricarbonylchromium

By *Tony Debaerdemaeker*[*]

Dedicated to Professor Erich Hückel on the occasion of his 80th birthday

We have performed X-ray structure analyses of the tricarbonylchromium complexes of 1,1-dimethoxy-2,4,6-triphenyl-λ^5-phosphorin *(1)*[1] and of 4-*tert*-butyl-1,1-difluoro-2,6-diphenyl-λ^5-phosphorin *(2)*[1].

Present address: Sektion für Röntgen- und Elektronenbeugung der Universität
Oberer Eselsberg, 7900 Ulm (Germany)

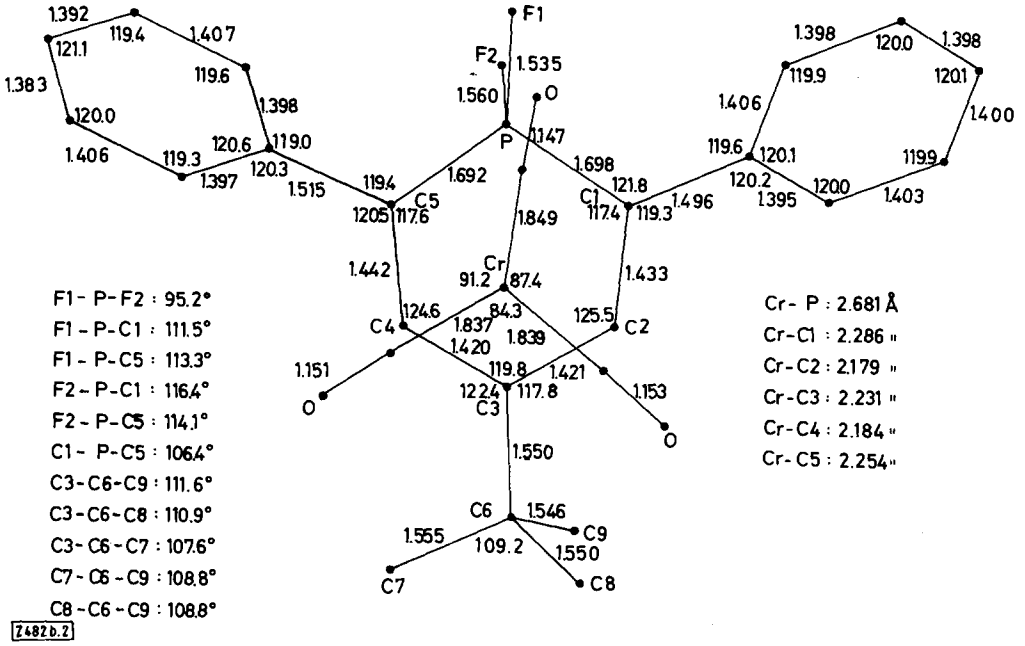

Fig. 2. X-Ray structure analysis of *(2)*.

Compound *(1)* crystallizes in the orthorhombic space group $P2_12_12_1$ with $a=18.655$, $b=15.550$, $c=8.529$ Å, $Z=4$; complex *(2)* crystallizes in the monoclinic space group $P2_1/a$ with $a=15.092$, $b=12.442$, $c=13.119$ Å, $\beta=115.08°$, $Z=4$. The reflections of the two crystals were recorded on an automatic Philips four-circle diffractometer (Mo-Kα radiation). The two structures were solved by direct methods (MULTAN[2]). Refinement with anisotropic temperature factors led to a final value of $R=11.4\,\%$ and $5.9\,\%$ respectively. All the results of importance are to be seen in the two Figures (distances given in Å).

lar reaction) and acylations (except with methoxymethylmagnesium carbonate or acyl cyanides) afford the *O*-derivatives *(3)*, and the nitroaldol reaction [*(1)*→*(2)*, E=R'R''C(OH)] becomes less and less satisfactory the more substituents there are attached to the C atoms to be linked together.

We have found that this situation is open to improvement: addition of two equivalents of *n*-butyllithium (1.6 molar in *n*-hexane) to a solution of a nitroalkane (10 mmol) in THF/HMPT (50 ml/10 ml) stirred at −90 °C[2] leads to dilithium derivatives *(4)* (with $R=C_2H_5$ stable up to −30 °C) whose C-nucleophilicity is drastically enhanced relative to that of *(1)*. Thus the adduct *(2)*, $R=(CH_3)_2CH$, $E=C_6H_5CO$, is obtained by successive addition of one equivalent of methyl benzoate and 2.5 equivalents of HCl (in THF) to *(4)*, $R=(CH_3)_2CH$, at −90 °C. A control experiment with the nitronate *(1)*, $M^{\oplus}=Li^{\oplus}$, generated with one equivalent of butyllithium failed to give any product *(2)* under otherwise identical conditions.

The examples listed in Table 1 show: a) double deprotonation to give *(4)* is successful with a wide range of nitroalkanes (nos. 1—4, 9)[3]; b) the doubly metalated nitroalkanes *(4)* can be *C*-acylated with carboxylic acid derivatives to give α-nitro carbonyl compounds (nos. 1—8); c) *C*-alkylation can be accomplished with *(4)*, $R=SC_6H_5$ (nos. 9, 10); d) the nitroaldol reaction, also possible *via* simple nitronates *(1)* with base catalysis, *e.g.* with aminoethanol[1], proceeds in better yields with *(4)*, especially in cases of steric hindrance (nos. 11—15).

The photochemistry of thiones and the chemistry of the S_2 state are considered by *P. de Mayo*. Thiones can react both in higher and in lower states. Cycloadditions of thiones in the T_1 state are not stereospecific, but do appear to be more regiospecific than for the corresponding ketones. Reactions of the S_2 state in solution have so far only been reported for thiones among the simple chromophores. They formally involve nonregiospecific insertions into CH bonds. A relevant example is the reaction of adamantanethione *(1)* with cyclohexane. The addition of *(1)* to olefinic double bonds does not appear to be regiospecific, but instead stereospecific.

The structure and significance of β_2-microglobulin is reported by *B. A. Cunningham*. Particularly important is the finding that this protein is homologous in its amino sequence with the constant regions of both classes of light chains of the immunoglobulins as well as the constant homology regions of at least three of the heavy chains. β_2-Microglobulins are also found in other vertebrates apart from man. The gene for β_2-microglobulin was probably formed from a precursor which gave cause for formation of the light and heavy chains of the immunoglobulins by duplication. From the wide distribution of β_2-microglobulin on the surface of various cell types it can be expected that the results of analysis of the immunosystem can also be applied to other areas of cell biology. In particular, the connection between β_2-microglobulin and the histocompatibility antigens permits conclusions on the origin, structure, and function of these and other cell surface proteins. [Structure and Significance of β_2-Microglobulins. Fed. Proc. *35*, 1171—1176 (1976); 39 references]

ESCA investigations on industrial catalysts form the theme of a report by *J. S. Brinen*. By ESCA (Electron Spectroscopy for Chemical Analysis) it can be established which elements a surface consists of, which atoms or compounds are chemically bound to it, and which physical and chemical changes accompany the catalytic reaction. The fundamental principles of electron spectroscopy and an outline of sample preparation are followed by a discussion of possible applications *e.g.* investigations on the distribution of promoters (Mo, Co, P), on the carrier material (Al_2O_3), and on the dispersion of metal atoms (Rh/C catalyst). The charging of semi- and nonconductors by the photoelectronic process is also discussed. [Applying Electron Spectroscopy for Chemical Analysis to Industrial Catalysis. Acc. Chem. Res. *9*, 86—92 (1976); 13 References]

The use of cyclic peptides for conformational studies is reviewed by *C. M. Deber, V. Madison*, and *E. R. Blout*. Cyclic peptides containing proline and glycine fulfill the requirements of model compounds which unite biological importance and simple structure. An example is *cyclo*(-Pro-Gly-)$_3$. From the measured ^{13}C-NMR, ^{1}H-NMR, and CD spectra of such peptides and the calculated CD spectra and conformation energies it can be ascertained *e.g.* whether the X-Pro bonds are *cis*- or *trans*-configurated and how the conformation changes in the presence of cations. [Why Cyclic Peptides? Complementary Approaches to Conformations. Acc. Chem. Res. *9*, 106—113 (1976); 45 References]

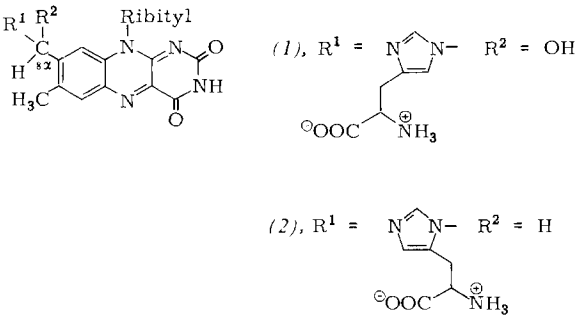
8α-Substituted flavins of biological importance are dealt with in an article by *D. E. Edmonson* and *T. P. Singer*. The compound previously believed to be the 8α-histidine-substituted 8α-hydroxyriboflavin *(1)* has now turned out to be the riboflavin with an isomeric 8α-histidine grouping *(2)*. This finding calls for further discussion of some reaction mechanisms. Moreover,



new findings on covalently bound flavins have opened the way to some interesting possible applications. [8α-Substituted Flavins of Biological Importance: an Updating. FEBS Lett. *64*, 255—265 (1976); 52 references]

[Rd 870 IE—R]

Isolation, properties and distribution of β_2-microglobulins form the theme of an article by *I. Berggård*. These proteins are identical with the light chains of the histocompatability (HL-A) antigens. They may be readily isolated from the urine of individuals whose kidney exhibits a resorption defect. Physicochemical and chemical investigations show that they are very similar in amino acid composition as well as secondary and tertiary structure to isolated immunoglobulin domains. They occur in free form in various body fluids as subunits of the HL-A antigens on cell surfaces. However, a part also appears to be bound to the cell surface in some other way, since the number of the β_2-microglobulin molecules exceeds that of the HL-A antigens. [β_2-Microglobulins. Isolation, Properties, and Distribution. Fed. Proc. *35*, 1167—1170 (1976); 49 references]

[Rd 873 IE—R]

Environmental factors in drug metabolism are discussed in a review by *J. R. Gilette*. Although the activity of the cytochrome-P-450 enzyme is subject to external factors *in vitro*, the pharmacokinetics in the living animal is not necessarily influenced in the expected sense. Still other factors play a role here, such as the influence on elimination mechanisms; even the type of application or the breed of the experimental animal are of significance. Hence one cannot draw conclusions about the influence of environmental factors on drug metabolism in intact animals from *in vitro* experiments. [Environmental Factors in Drug Metabolism. Fed. Proc. *35*, 1142—1147 (1976); references]

BOOK REVIEWS

Quantum Mechanics for Organic Chemists. By *H.-E. Zimmerman*. Academic Press, New York—San Francisco—London 1975. 1st edit., x, 215 pp., numerous figs., bound, $ 16.50.

This book provides an introduction to the methods of MO theory.

The main emphasis in the book is placed on Hückel theory, despite the title's broader connotations. In Chapter 1 this theory is developed by means of procedures for the determination of orbital energies and LCAO-MO coefficients, this approach rapidly leading up to a level of knowledge at which

questions of chemical importance can be treated. Quantum-mechanical principles are added in Chapter 2. Use of symmetry as a calculation aid in Chapter 3 steers the reader towards the formal methods of group theory. Here again we note the basic concept of the book, *i.e.* its intention to ease the organic chemist's entry into theory: the terminology and the instructions for use are introduced before the presentation of formal theory. Chapter 4 considers in brief variants of the Hückel theory and its application to alternant and nonalternant hydrocarbons and to correlation diagrams. Greater detail is devoted to hybrid orbitals. Advanced MO procedures and methods of configurational interaction are outlined in Chapter 5.

An important feature of the book is the detailed working of examples, so that the reader becomes familiar with the methods by the paper-and-pencil method; this is supported by setting up problems and their solution. The detailed presentation of solutions, however, means a diminished amount of material, whose selection reflects the author's field of work, *e.g.* Möbius systems. Unfortunately, some concepts such as wave function and charge density, or eigenvalue and expectation value, are not always sufficiently differentiated. A few incorrect formulas and expressions should be corrected.

Radio-Immunoassay of Steroid Hormones. Edited by *D. Gupta*. Verlag Chemie, GmbH, Weinheim 1975. 1st edit., xiv, 224 pp., 56 figures, 53 tables, linen, DM 58.—.

Part of this book presents the proceedings of a workshop held by the German Endocrine Society in February, 1974. In addition, other authors have contributed further chapters, so that assay methods for all the clinically important steroid hormones have been included. The intention of the book, as stated in the Foreword, was to "review the present state of the art of steroid radioimmunoassay", and in this respect the delay in the appearance of the book can only be regretted.

The topics covered include discussions of the basic principles of radioimmunoassay. These tend to be rather cursory, and are intended for workers already familiar with radioimmunoassay procedures. This volume would have been of increased value if more of the chapters concerning specific assay methods had also contained some discussion of the general problems concerning the assay of that steroid, and some comparative evaluation of the previously published radioimmunoassay methods. However, some chapters provide the reader with a broader insight into the subject matter; those devoted to the discussion of the assay of steroid glucuronides, and of the use of ^{125}I tracers for steroid determination.

It is difficult to decide which readership this volume is intended for—the expert, the clinician, the laboratory worker, or the total beginner. It follows the trend of recent book publications on radioimmunoassay; collecting together a series of methods from workers in this field and attempting to knit them into a comprehensive review. The lack of overall editorial unity in the presentation is regrettable.

E. Jean Wickings [NB 325 IE]

Raman/IR Atlas organischer Verbindungen (Raman/IR atlas of organic compounds). Edited by *B. Schrader* and *W. Meier* on behalf of the Institut für Spektrochemie und Angewandte Spectroskopie, Dortmund. Verlag Chemie, GmbH, Weinheim. 3 instalments in 2 loose-leaf files. 1st instalment 1974, xxxi, 314 pp. with 314 spectra; 2nd instalment 1975, xlii, 344 pp. with 301 spectra. Price per instalment DM 265.— (purchase of complete work is a condition of sale).

The Raman/IR Atlas covers about 1000 organic compounds, divided into 15 principal groups and 93 classes. The authors have taken pains to provide a representative selection of substances.

On each A4 page of the work the IR/FIR and the Raman spectrum of the relevant substance are reproduced together with details of instrumentation (instrument, cell material, preparation technique, spectral slit width, *etc.*) and substance parameters (molecular formula, molecular mass, degree of purity, melting and boiling point).

The spectra of the 1st instalment are redrawn by hand from the original spectra; those of the 2nd instalment are recorded in digital form, computer corrected with respect to the spectral sensitivity of the Raman spectrometer, and subsequently plotted out. Each volume closes with a list of spectra and a formula index.

The quality of the spectra and of their reproduction is excellent. The volumes are very useful compendia of spectra for all those concerned with Raman and IR spectra in research and teaching.

Collisional Activation Mass Spectrometry—A New Probe for Determining the Structure of Ions in the Gas Phase[**]

New analytical methods (7)

By Karsten Levsen and Helmut Schwarz[*]

Organic ions with high translational energy colliding inelastically with neutral atoms or molecules become excited electronically at the expense of their translational energy. The excitation energy enables a wide range of dissociation reactions to occur and the intensity relationships yield information about the structure of the ions concerned and also permit conclusions to be drawn about the mechanism of their formation.

1. Introduction

Mass-spectrometric investigations are affected in many cases by the occurrence of collision-induced processes involving the residual gas so that often, *e.g.* in the study of metastable ions, considerable effort is necessary to eliminate the influence of these collision processes. Only during the last eight years has it been shown by the systematic investigations by *McLafferty*[1], *Jennings*[2] and *Beynon*[3, 4] that these processes, originally considered a nuisance, can in fact provide a wealth of information. The above authors concentrated on the one hand on charge-transfer reactions[4] and on the other hand on collision-induced dissociation processes[1–3, 5, 6]. In the course of this work it became clear that these collision-induced dissociation processes—to which the present article is confined—provide valuable information about organic ions, for example about their physical properties, their structures[*], and the mechanisms of their formation and decomposition. Further, analytical applications become apparent for the determination of the structure of organic compounds and for analysis of mixtures. In what follows the theoretical principles of collision-induced dissociation and the methods of measurement are first described, followed by presentation of the applications.

2. Theoretical Principles

2.1. Energy Transfer

When ions having a high translational energy (a few hundred eV or more) collide inelastically with neutral atoms or molecules, part of their translational energy is converted into excitation energy of the ions which can subsequently lead to the latter's decomposition. A collision-induced dissociation of this kind can also be called a dissociative ion-molecule reaction [in accordance with eq. (a)].

$$[m_1]^+ + N \rightarrow [m_2]^+ + [m_3] + N \qquad (a)$$

[**] Abbreviations: CA: collisional activation; CI: chemical ionization; CID: collision-induced dissociation; DADI: direct analysis of daughter ions; EA: electron attachment; EI: electron impact ionization; FD: field desorption; FI: field ionization; ICR: ion cyclotron resonance; *MI*: metastable ions; *SID*: surface-induced dissociation; MIKE: mass analyzed ion kinetic energy.

[*] The term "structure" refers here solely to the bonding of atoms. Bond lengths, bond angles, configurational or conformational differences, and electron-density distributions, are left out of account. Thus, "structure" is here equivalent to "constitution".

The whole group of fragments of a given primary ion produced by collision is known as the collisional activation (CA) spectrum of this ion[1][*]. If fragment-ions rather than molecular ions are investigated, then the CA spectrum is in some respects the mass spectrum of a fragment.

When the translational energy exceeds 1 keV and the colliding gas atoms are small, the first process that takes place is mainly electronic excitation of the impacting ion[7]. This electronic excitation is converted into vibrational excitation which rapidly (within a few picoseconds) distributes itself statistically over the whole ion and can lead to the rupture of specific bonds. Since the energy-transfer mechanism corresponds to that in the collision of an electron with a neutral molecule in the ion source of a mass spectrometer, it can be described by the quasi-equilibrium theory (QET)[8]. The analogous energy-transfer mechanism is also the reason why the electron impact and the collisional-activation spectra of a molecular ion show the same fragments[1,2,6,9]. This does not necessarily imply that the internal energy distribution in a molecular ion must be the same after collision with electrons and atoms, since this energy distribution is a function of the kinetic energy of the electrons or ions. However, the relative fragment intensities in 70 eV electron impact spectra are very similar to those obtained in collisional-activation spectra of the same molecular ions with 8—10 keV ions[1,2,9], and this makes it probable that the energy distributions are often comparable. In both cases a broad spectrum of excitation energies (0—10 eV) is produced; in collisional activation the energy distribution *after* the collision is only slightly influenced by the energy distribution *prior to* the collision[1c]. The similarity between the collisional-activation spectra and the 70-eV electron impact spectra is due not only to a similar energy distribution but also to a comparable decomposition time, which for instrumental reasons is around 10^{-6} sec in both cases.

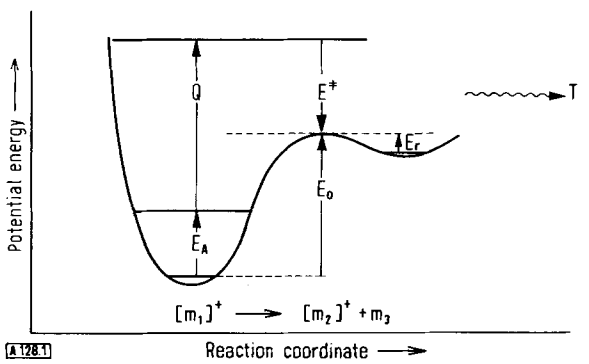

Fig. 1. Energy transfer in collision-induced dissociation. Let the primary ion $[m_1]^+$ have a mean excitation energy E_A before the collision. On inelastic collision an amount Q of the translational energy is converted into internal energy. After overcoming an activation threshold E_0 the excited ion decomposes into a fragment ion $[m_2]^+$ and a neutral particle m_3. The excess ("non-fixed") energy E^+ and the activation energy of the reverse reaction E_r are released partly as translational energy T (signal broadening). (The kinetic shift is left out of account for the sake of clarity.)

The excitation energy that the ion gains in the collision is of the same magnitude as the loss of its translational energy. (The fraction of kinetic energy transferred to the target atom is negligible[*].) The decrease of translational energy, Q, can be measured directly and thus permits a direct determination of the excitation energy transferred. During the subsequent unimolecular dissociation of the excited ion part of the excess energy E^+ ("nonfixed energy"), *i.e.* the energy not required for overcoming the dissociation threshold, is released as translational energy T[**] (the fragment ions and neutral particles fly apart relative to the original center of gravity of the masses), and this leads to unsharpness in the energy and thus to a broadening of the collision-induced signals[6]. An analogous signal broadening is found in the unimolecular dissociation of metastable ions (MI spectra). Since, however, the excitation energy and thus also the excess energy of the ions dissociating by collision are on average much higher, the signals in the CA spectra are generally broader than those in the MI spectra[6]. The relationship between the quantities Q and T is shown in Figure 1.

2.2. Collision-Induced Dissociation

Three types of information can thus be obtained from a collisional activation spectrum: 1. the relative intensities of the secondary ions; 2. the translational energy T released on dissociation; and 3. the excitation energy transferred, Q. While the intensity ratios and the energy T released in a dissociation (*i.e.* the peak half-width) are suitable for the characterization of an ion structure, determination of the excitation energy by means of the value Q (together with T) provides an insight into the thermochemical properties of an ion. Work in which these three values were systematically investigated will now be briefly reported.

The intensity ratios of collision-induced fragments were studied by *McLafferty et al.*[1c] as a function of various parameters. It was found that when the translational energy (velocity) of the impacting ions increases there is not only an increase in the yield of the collision-induced secondary fragments but also a change in the intensity ratios between these fragments. As an immediate consequence of an increase in the mean transferred energies, the intensity of fragments having higher activation energies increases more than does that of fragments with lower activation energies. A similar increase in fragmentation processes with higher activation energy is found at high pressures of the collision gas; this is explained by the occurrence of multiple collisions. The nature of the collision gas, however, has no influence at all on the intensity ratios[1c] (and also generally none on Q and T[6]), although it does influence the yield of collision-induced fragments: as the size of the atoms or molecules decreases, the cross section and thus the yield increases, so that helium and H_2 are particularly suitable collision gases.

Especially important is the finding that the intensity ratio of the collision-induced secondary fragments from a given primary ion depends to only a very small extent on the excitation energy, *i.e.* on the energy distribution *before* the collision, as is shown by varying the electron energy or by comparing the collisional activation spectra of field-ionized or electron-impact-ionized molecules[1c,9]. Dependence on the excitation

[*] The abbreviation CID (collision-induced dissociation) is used in addition to CA (collisional activation) [3].

[*] This assumption is valid for ions that undergo little or no scattering, *i.e.* those selected by the slit arrangement out of all the colliding ions.

[**] Not only the excess energy but also the activation energy of the reverse reaction, E_R (if present), contributes to the translational energy T released.

energy is found only, if at all, with processes involving the lowest activation energies[1c].

The decrease in translational energy Q caused by energy transfer on collision, as also the energy T released on subsequent dissociation, have been studied in detail by *Cooks et al.* for the case of the aliphatic alcohols[6]. It was established, taking into account the internal energy present before the collision, that the decrease in translational energy Q in a specific collision-induced fragment is equal to the excitation energy predicted from the breakdown diagram, at which the fragment in question is most probably formed. Furthermore, the values of Q and T can be used to obtain information on how the excess energy of a highly excited primary ion will be distributed on decomposition between the translational energy T and/or the excitation energy of secondary fragments and/or the neutral particles ejected (energy partitioning). Finally, for diatomic and triatomic molecules it is possible to derive, from the quantity Q, the *electronic* state in which the collision-induced fragments are formed[5].

2.3. Methods of Measurement

Since the place where collision-induced fragments are formed in the mass spectrometer is the same as for metastable ions (one of the field-free regions of the spectrometer), they can be detected by the same methods. Collision induced fragments can be observed in any mass spectrometer working with a magnetic field[1a, 1b, 2, 3, 5, 6]. However, double-focussing spectrometers with "reversed" Nier-Johnson geometry are particularly suitable for this purpose; in these the ion source is followed first by the magnetic and then by the electric sector[11, 12]. Such an arrangement, as used in principle also in the MIKE[11c] or the DADI technique[12] for the detection of metastable ions, is shown schematically in Figure 2.

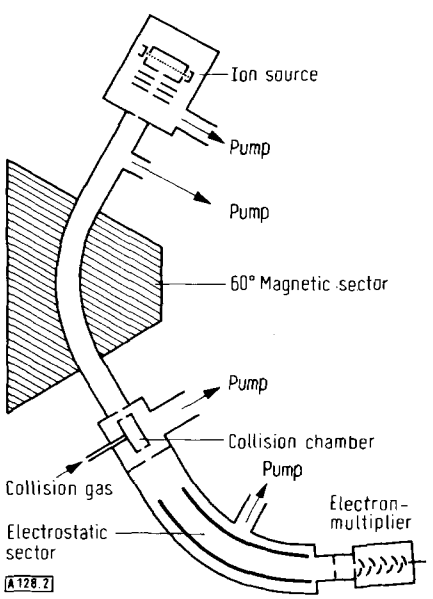

Fig. 2. Schematic layout of a mass spectrometer suitable for the measurement of collisional activation (CA) spectra.

Out of the large number of primary and secondary fragments formed in the ion source the ion to be examined is selected by means of the magnetic field and passes with high translational energy (3—10 keV) into the collision chamber[10]. The collision gas (*e.g.* helium) is admitted through a high-vacuum valve into the collision chamber where the pressure is 10^{-4} to 10^{-5} torr. A differential pumping system prevents all but small amounts of the collision gas from entering the ion source or the electric sector. (To increase the reproducibility in structural studies of organic ions it has proved advantageous not to carry out the investigation at constant pressure but instead at a constant scattering cross section, which is different for ions of different masses.) In a manner analogous to the DADI technique, the collision induced fragments can be subjected to energy and thus mass analysis by scanning of the electrical sector potential.

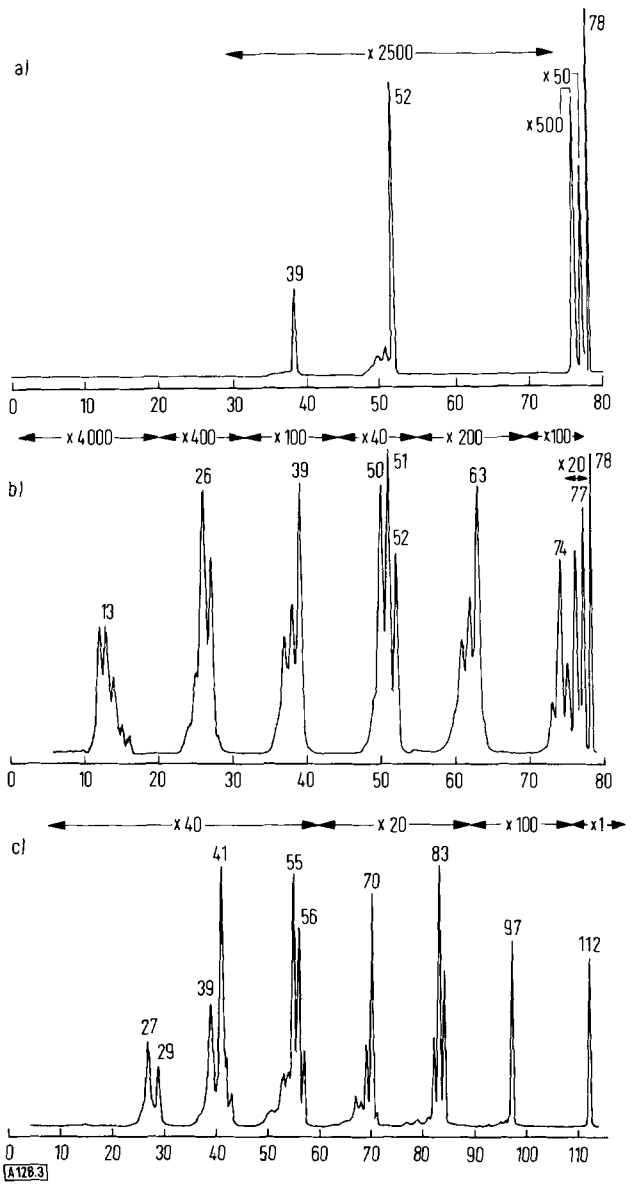

Fig. 3. a) DADI spectrum of the benzene molecular ion ($m/e = 78$); b) CA spectrum of the benzene molecular ion ($m/e = 78$); c) CA spectrum of the 1-octene molecular ion ($m/e = 112$).

Figure 3b shows a collisional activation (CA) spectrum obtained in this way for the benzene molecular ion[*]. In

[*] Strictly speaking, the spectrum in Fig. 3b shows a superposition of collision-induced and unimolecular dissociations, so that a pure CA spectrum is obtained by subtracting the metastable ions corrected for the different scattering cross-sections in Fig. 3a from Fig. 3b. However, this subtraction is not necessary for most analytical purposes.

Figure 3a is shown the same spectrum, but one obtained without a collision gas, *i.e.* a DADI spectrum[12], which contains only the *unimolecular* dissociations of metastable molecular ions. Comparison of Figures 3a and 3b shows that the CA spectrum contains many more signals, more intense but also markedly broader, than there are in the DADI spectrum. The slight shift of the peak maximum in the direction of smaller masses is to be ascribed to the decrease, discussed above, in the translational energy by the amount Q as a result of the collisional excitation. The varying half-widths of the signals, which reflect the translational energy released in the dissociation, are clearly recognizable.

The linear mass scale is an advantage. Nevertheless, the figure also shows at once a considerable drawback of the method. In spite of the relatively small precursor mass of benzene ($m/e=78$) the signals overlap, in some cases to an appreciable extent. Although the resolution is much better with many other compounds because of the smaller amount of energy released in the fragmentation, *e.g.* with 1-octene ($m/e=112$, Fig. 3c), it is rarely possible to resolve individual signals even partially with an accelerating potential of 10 kV and above a precursor mass of $m/e=150$[*]. This does not reduce the method's value for the elucidation of the structure of organic ions, because for this purpose it is only necessary to determine whether two spectra are the same or different. The limited mass resolution does, however, make it considerably more difficult to carry out an isotope-labeling analysis in the case of the larger organic ions. What is favorable, nevertheless, is that only partial incorporation of labeled atoms does not disturb isotope-labeling analyses, since with the above-described magnetic field and electrostatic analyzer arrangement the mass analysis occurs *before* the collision-induced dissociation.

Finally, mention must be made of an interesting variant for the production of collision-induced fragments, described by *Beynon et al.*[13]. In this "surface-induced dissociation" (SID) method the primary ions do not collide with a collision gas but glance a metal surface where collision-induced fragmentation occurs, analogous to that described above[**].

2.4. Characterization of Ion Structures

According to the quasi-equilibrium theory (QET) describing mass-spectrometric dissociation, the intensity ratio of mass-spectrometric fragments depends both on the energy distribution in the primary ion and on the rate constants for dissociation[8]. The rate constants of a given ion are, further, an unequivocal function of the vibrational and rotational frequencies as well as of the activation energies for subsequent dissociations. Ions having the same elementary composition but different structure should thus differ at least partially in their vibrational and rotational frequencies and in the activation energies of the subsequent reactions, and consequently, with the same energy distribution, in the intensity ratio of the subsequent dissociation processes. Since the CA spectra are largely independent of the distribution of excitation energy (see Section 2.1), they reflect the structure of the ion directly. *Thus, if the CA spectra of two ions having the same elementary composition agree both in the intensity ratio and in the peak half-width (translational energy released), then the conclusion is drawn that the structures are identical, and vice versa.* This *comparative* method requires knowledge of the structure of one of the ions. If there is no suitable reference ion, then the structures can in some circumstances be derived from the fragmentation behavior, which in turn can be clarified by isotopic labeling.

If, after the exclusion of the processes with the lowest activation energy[*], the intensity ratio is found to depend on the electron energy, then it can be concluded that a mixture of *non-interconverting* structures is present, the latter being formed simultaneously from the precursor ion by competing mechanisms with different activation energies. Because of the different activation energies the composition of the mixture changes as a function of the excitation energy. On the other hand, if the intensity ratio changes little or not at all with the electron energy it cannot be definitely concluded that only a single structure is involved; *interconverting* structures (isomerization) may be present before the collision, even if the subsequent collision-induced dissociation occurs predominantly through one of them[**].

2.5. Comparison with Other Methods for the Determination of the Structure of Ions in the Gas Phase

The collisional activation technique for the determination of the structure of organic ions competes with several older methods which also differ themselves in the information they provide. If we exclude the very indirect method in which conclusions about the structure of an ion are drawn from the reaction mechanism, the following methods have been used most often[14]:

1. Determination of the heats of formation[15],
2. Investigation of ion-molecule reactions[16],
3. Analysis of dissociation products
   a) intensity ratios in the dissociation of metastable ions (MI)[17].
   b) translational energy T released in the dissociation[18], and
   c) collisional activation spectra[1,2].

All these methods are as a rule comparative, *i.e.* if the heats of formation, the ion-molecule reactions, or the dissociation products are the same for two ions of the same elementary composition, it is concluded that the structures are identical, and *vice versa*. The methods differ in that ions with different excitation energies and different lifetimes are investigated.

In the first two methods those ions are studied whose excitation energy does *not* suffice for dissociation within the mass spectrometric time scale. These ions are therefore described as "stable"[***]. In the determination of the heats of formation

[*] The resolving power for a given precursor ion can be improved by increasing the accelerating potential, since the signal half-width is inversely proportional to the velocity of the primary ion.

[**] Improvements in this technique are currently being studied in many laboratories [20].

[*] Since these processes—recognizable by the presence of intense unimolecular dissociation in the MI spectra—often depend on the energy distribution, any structural assignments based on these peaks, if at all possible, must be made with caution.

[**] In rare cases the absence of an energy-dependence of the CA spectrum may be due to presence of a mixture of non-interconverting structures that happen to have the same kinetic parameters.

[***] "Stability" means that no further decomposition occurs. Of course, isomerization of the ion may perhaps take place.

ions with a minimum of excitation energy are present. (This still depends on the kinetic shift and in particular on the activation energy for the reverse reaction.) In the study of ion molecule reactions at low pressures, *e.g.* by the ion cyclotron resonance technique (ICR)[16] on the average higher excitation energies are involved, reaching up to the lowest dissociation thresholds. In the determination of the structure of ions by analysis of unimolecular decomposition of metastable ions (methods 3a and 3b), however, ions are studied whose energy does suffice for further fragmentation (often also referred to as "unstable" or "reactive" ions). From the quasi-equilibrium theory it can be deduced that these ions are characterized by a well defined excitation energy that is only slightly higher than the lowest dissociation threshold.

The situation with the collisional activation method described here is more complex owing to double excitation. While it is true that most of the ions entering the collision chamber are stable, *i.e.* they have a spectrum of excitation energies that reaches up to the lowest dissociation threshold, the ions that finally undergo collision-induced dissociation are highly excited *reactive* ions. Since with such highly excited ions direct dissociation of the original stable structure is often just as fast (or faster) as an isomerization that is theoretically possible at higher excitation energies, the relative intensities of the collision-induced secondary dissociations reflect to some extent the structure of the stable ions.

Whether the structural information obtained by the above methods differs or not will depend mainly on the isomerization behavior of the ion in question, as may be seen from Figure 4. If the isomerization threshold (E_i) is appreciably higher than the lowest dissociation threshold (E_{oA^+}), then all the methods will yield the same information (Fig. 4a). If, however, $E_i < E_{oA^+}$ (Fig. 4b), it can be shown by means of the metastable characteristic[17] that A^+ and B^+ dissociate *via* the same structure (isomerization), whereas ion cyclotron resonance measurements and heats of formation give different structures for A^+ and B^+. The CA spectra of A^+ and B^+ should also differ, since, although after the collision a considerable amount of isomerization and thus decomposition by way of B^+ can occur, some of the ions A^+ decompose directly. With very low isomerization thresholds (Fig. 4c) it is still possible for different heats of formation to be found for A^+ and B^+. However, in all the other methods most of the ions isomerize already before the fragmentation to a mixture of A^+ and B^+. Moreover, since in CA investigations the energy-richest ions are preferentially excited by collision[19], and since isomerization can also occur after the collision, the CA spectra of A^+ and B^+ differ little if at all[*]. (The collision-induced fragmentation itself occurs both of A^+ and (preferentially) of B^+.) Finally, the intensity ratio of metastable ions will be the same for A^+ and B^+. (Here the dissociation occurs *via* structure B^+.)

Apart from the excitation energies of the ions under study, their lifetimes play a role in the provision of structural information. In most of the methods this lifetime is similar (10^{-7} to 10^{-5} sec); only in ion-molecule reactions in the ICR cell are ions with very much longer lifetimes analyzed (10^{-3} sec).

A discussion of the sources of error in the methods presented here will be of interest. Reliable determination of the heats

[*] Thus, it is not permissible to conclude from identical CA spectra for A^+ and B^+ that there is no isomerization threshold between the two ions. The threshold may only be relatively small ($E_i \ll E_{oA^+}$).

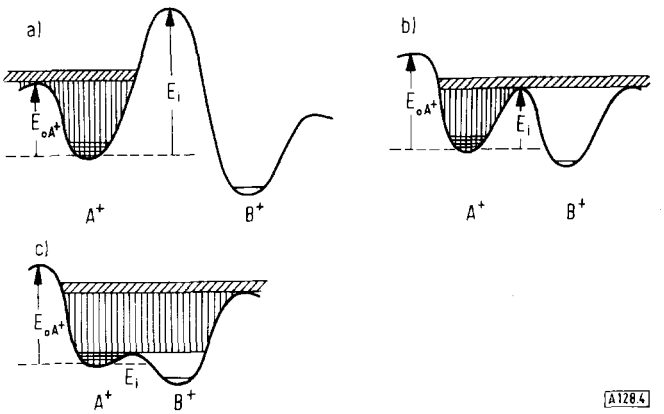

Fig. 4. Influence of internal energy on structural information obtained by different methods about an ion A^+ that may rearrange to an ion B^+ after overcoming an isomerization threshold E_i (the excitation energy region for decomposing metastable ions is hatched diagonally, in CA and ICR investigations vertically, and in measurements of the heats of formation horizontally). a) $E_i \gg E_{oA^+}$; b) $E_i < E_{oA^+}$; c) $E_i \ll E_{oA^+}$.

of formation is often impossible, because the kinetic shift contributing thereto as well as the activation energy for the reverse reaction can generally be obtained experimentally only with difficulty if at all. If the structure of an ion is characterized by means of the intensity ratio of metastable ions (method 3a), the deductions may be false because this intensity ratio depends on the energy distribution. In ion-molecule reactions (ion-cyclotron resonance technique) it is at present not clear to what extent the structure-dependent reactivity of an ion is additionally determined by its excitation energy, the latter being, as discussed above, variable within wide limits.

According to results available so far, the ICR method, CA spectroscopy, and determination of the energy released in the dissociation of metastable ions seem to be the most reliable tools for the determination of ion structures in the gas phase.

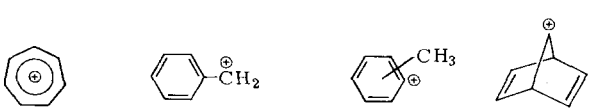
Of these three methods CA is particularly attractive, because a) it is much more sensitive than the other procedures and b) it involves considerably more information (released kinetic energy *and* the intensity ratios of numerous fragments). Its only disadvantage is the poorly defined excitation energy, due to the double excitation.

3. Ion Structures

It was shown in principle in Section 2 when an ion entering the collision chamber will isomerize and what kinetic situation must be present to prevent this process. Examples will now be given for both limiting cases and for transitions between them.

3.1. Carbenium Ions

The classical investigations by *Meyerson et al.*[21] on the structure of gaseous $C_7H_7^{\oplus}$ ions have provoked countless theoretical and experimental studies[*], without it having been

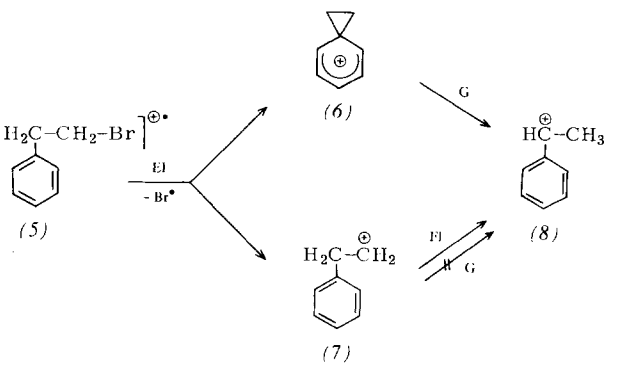


(1) (2) (3) (4)

[*] In this connection particular reference should be made to ICR studies carried out very recently [22].

made conclusively clear in most cases whether the species exists as tropylium ions *(1)* or as benzyl cations *(2)*[23]. The extensive CA investigations by *McLafferty* and *Winkler*[24] on sixty compounds of different structures that yield $C_7H_7^{\oplus}$ on electron impact appear to have closed this chapter of organic mass spectrometry. Contrary to the deductions from the earlier work, it must now be assumed that in most of the compounds investigated, including the $[M-H]^{\oplus}$ ion from cycloheptatriene itself, which was seen as the prototype for *(1)*, an appreciable fraction of stable $C_7H_7^{\oplus}$ ions is present as *(2)*. Furthermore, the above authors showed that, besides these structures, stable *o*-, *m*- and *p*-tolyl cations *(3)*, and even the norbornadienyl cation *(4)*, can be detected when suitable precursors are used. The isomerization threshold between the ions *(1)* to *(4)* appears to be too large for complete equilibration. From the experimental findings it follows further that no $C_7H_7^{\oplus}$ ion possessing only the tropylium structure could be found. Out of all the compounds studied so far the $[M-Cl]^{\oplus}$ ion of (acyclic!) 2,4-heptadien-6-ynyl chloride has the highest proportion of *(1)*, namely >95 %[26][*].

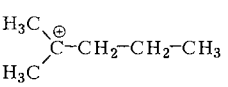
The mutually contradictory results on the structure of gaseous $C_8H_9^{\oplus}$ ions from phenethyl bromide *(5)*[28] could also be largely clarified by CA measurements on deuterated model compounds. Here too a mixture of several species must be present, whose composition was determined by varying the *electron* energy[29]. At the lowest excitation energy (≈11 eV) it contains ethylenebenzenium ions *(6)* as the sole component, whereas in the 70-eV spectra the main proportion consists of 1-phenylethyl cations *(8)*. In the medium-energy region 2-phenethyl cations *(7)* also occur, but, in contrast to the rearrangements of $C_8H_9^{\oplus}$ ions in the condensed phase[30], these do not act in the gas phase as precursors for the ion *(8)* (Scheme 1).



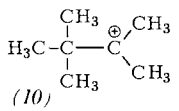
Scheme 1. $C_8H_9^{\oplus}$ ions from phenethyl bromide *(5)*. G = gas phase, Fl = liquid phase, EI = electron-impact ionization.

The problem of the structure of reactive $C_6H_6^{\oplus\cdot}$ radical cations (especially ionized benzene), which has been studied by many groups and by almost every available method, has also recently been clarified by CA measurements[19,31,32]. Investigations of ^{13}C-labeled 1,3-hexadien-5-yne[32] provide, *inter alia*, the first experimental proof that the mechanism previously postulated for the H-scrambling process[23,33] in ionized benzene may proceed reversibly via *acyclic* intermediates (namely 1,3-hexadien-5-yne). It can be further concluded from the CA spectra that hexadiyne radical cations participate only to a minor extent in this equilibrium[31,32], a result that is also in accord with the results of elegant electron impact investigations reported by *Momigny*[34].

In addition to CA investigation of highly unsaturated carbenium ions such as $C_6H_5^{\oplus}$[19,31,35], $C_6H_6^{\oplus\cdot}$[19,31,32], $C_6H_7^{\oplus}$[35], $C_7H_7^{\oplus}$[24,26], $C_7H_8^{\oplus\cdot}$[25,1d], $C_7H_9^{\oplus}$[36], $C_8H_8^{\oplus\cdot}$[31], $C_8H_8^{2\oplus}$[31], $C_8H_9^{\oplus}$[29], and $C_9H_7^{\oplus}$[39] which will not be discussed here, the behavior of more saturated molecular ions and fragment ions on isomerization has also been studied[35,37,38]. To a first approximation, the results obtained so far permit the following generalization: Fragment ions of composition $C_nH_{2n+1}^{\oplus}$ (n=3–7), $C_nH_{2n-1}^{\oplus}$ (n=3–7), and $C_nH_{2n-3}^{\oplus}$ (n=6 or 7) give almost identical CA spectra, independently of the structure of the molecular ions and also independently of the excitation energy, a result that indicates almost complete equilibration of the differently branched ions (Fig. 4c). Although ten molecules having different carbon skeletons were used as precursors, the isomeric $C_6H_{13}^{\oplus}$ ions, for example, decompose largely from one structure, *(9)*, while for $C_7H_{15}^{\oplus}$ decomposition from the structure *(10)* was postulated[37a].



(9)



(10)

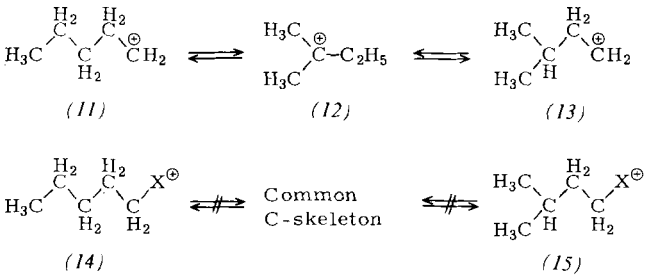
In contrast to this complete isomerization of fragments (even-electron carbenium ions), hardly any isomerization of the carbon skeleton *before* the fragmentation was observed for the molecular ions of isomeric octanes, octenes, cycloalkanes, (except for *n*-propylcyclopentane, which isomerizes to 1-octene before fragmentation), or $C_8H_{14}^{\oplus\cdot}$ radical cations. Hydrogen shifts, however, occur so rapidly that, judged from CA spectra, localization of the double bond, *e.g.* in isomeric octenes, appears so far to be possible only to a very limited extent.

The very different behavior of molecular ions and fragment ions on isomerization appears to be due to the different activation energies E_0 for further decomposition. From measurements of the appearance potentials it can be concluded that the E_0 for further decomposition of fragment ions is generally appreciably greater than the activation energy required for the primary fragmentation of molecular ions. When the relationship between E_0 and kinetic processes, discussed in Section 2.4, is taken into account, this means that for molecular ions $E_i > E_0$ and isomerization is suppressed in favor of fragmentation.

It must be mentioned that this behavior of molecular and fragment ions is not generally valid but that other, still unknown, factors play a part with C_nH_{2n-2} compounds of lower molecular weight[35], with arenes[24,25,31], and with alkynes isomeric with the latter[32,39].

However, the importance of the threshold energy ratio E_i/E_0 for the structural *stability* of the carbon skeleton is shown by a study of isomeric ions containing a heteroatom[40]. Whereas isomeric $C_5H_{11}^{\oplus}$ ions having originally the unbranched skeleton *(11)* or the *iso*-skeleton *(13)* isomerize in 10^{-5} sec to a common structure [probably *(12)*[37,41]], the carbon skeleton hardly isomerizes at all *before* the decomposition if the cation contains a charge-stabilizing group X (Scheme 2).

[*] This result confirms earlier energy measurements and investigations of ^{13}C-labeled acyclic model compounds [27], from which it also follows that a considerable proportion of the $[M-Cl]^{\oplus}$ ions from 2,4-heptadien-6-ynyl chloride must be present as tropylium ions *(1)*.



(11) (12) (13)

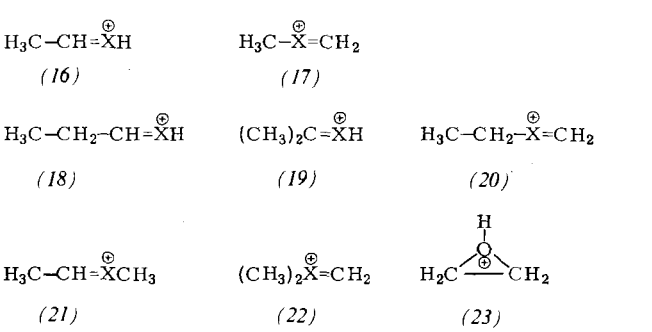
(14) (15)

Scheme 2. Isomerization of carbon skeletons. $X = C{=}O^{\oplus}$, $\overset{\oplus}{O} = CH_2$, $\overset{\oplus}{N}H = CH_2$.

Here too analysis of the energy data shows that the heteroatom group X appreciably increases the potential barrier to isomerization, and this is certainly related to preferential localization of the charge on the heteroatom. The alternative, that the presence of X makes possible other fast reactions that outrun isomerization, probably does not apply here. Similar effects have been found in the CA spectra of immonium ions from oligopeptides containing leucine or isoleucine components. The analytical importance of these differences is discussed in Section 5.

3.2. Oxonium and Immonium Ion

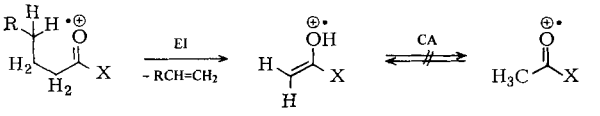
The stabilizing effect of heteroatoms on carbenium centers is well known[*] and is also expressed in the CA spectra of a number of oxonium and immonium ions. In extensive investigations *McLafferty et al.*[1d,43a] detected the structures *(16)*—*(22)* as stable species ($X = O$[1d,43], $X = NH$[43b]). The isomerization thresholds between the ions are so high that rearrangements before or during the collisional activation are almost wholly excluded.



(16) (17) (18) (19) (20) (21) (22) (23)

Since, furthermore, by investigations on numerous precursors it could be shown which structural element of a neutral molecule was to be correlated with which ionic structure, in *unknown* compounds conclusions about the intact molecule could be drawn from the CA spectrum in combination with other mass-spectroscopic data. It is also remarkable that a) a series of structures, *e.g.* protonated epoxides [such as *(23)*], previously considered to be stable, are relatively unstable under CA conditions and rearrange almost quantitatively to *(16)*, $X = O$[1d][**], and b) the CA results are here partly in direct contradiction to interpretations based only on analysis of unimolecular dissociations (including consideration of the kinetic energy released during the dissociation).

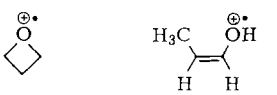
CA investigations of oxygen-containing radical cations of composition $C_2H_4O^{\oplus\bullet}$[46][*], $C_2H_4O_2^{\oplus\bullet}$[48], and $C_3H_6O^{\oplus\bullet}$[49] have also shown that, depending on the primary structure, a series of stable ionic structures exists that are interconvertible with one another only to a limited extent if at all. The structure of ions produced by γ-hydrogen-transfer to carbonyl groups, *e.g.* in *(24)*[50], will be briefly mentioned as an example of non-interconvertible ions. The CA spectra show, in agreement with other methods of investigation, *e.g.* ion cyclotron resonance mass spectrometry, that the energy barrier for interconversion cannot be surmounted (Scheme 3).



(24) (25) (26)

Scheme 3. γ-Hydrogen transfer in radical cations of carbonyl compounds *(24)*, X = H, alkyl, OH.

In principle, several non-interconverting ions can arise whenever the formation of the primary fragment, *e.g.* $C_3H_6O^{\oplus\bullet}$ from $HO(CH_2)_3Y$, Y = Cl, Br, or OH, involves several cyclic transition states sensitively influenced by molecular parameters, *e.g.* bond energies or steric effects, and when isomerization after the fragmentation (*e.g.* elimination of HY) is little favored on energetic grounds. For example, compounds $HO(CH_2)_3Y$ in which Y = Cl, Br, OH afford $C_3H_6O^{\oplus\bullet}$ ions of structures *(27)* and *(28)*, whereas when $Y = OCH_3$ only *(28)* is produced[49].



(27) (28)

Y	(27)	(28)
Cl	60	40
Br	33	67
OH	50	50
OCH_3	0	100

4. Reaction Mechanisms

As has already been mentioned in Section 3, there is a direct correlation between the fragmentation mechanisms and the structures of the ions produced. While labeling studies can provide information on the origin of transferred or eliminated atoms or groups, in the strict sense they contribute little to our knowledge of the structure of the nonreactive species formed. On the contrary, there are many reactions whose mechanism remains obscure in spite of intensive labeling. Here CA spectroscopy with the use of appropriate reference spectra seems to be the method of choice for clarifying the reaction route *via* a determination of the ion structures. In what follows a few examples will be used to show both

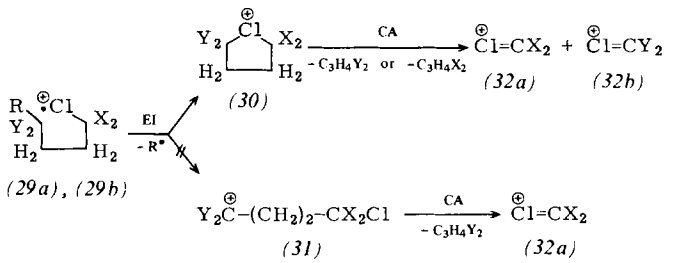
[*] MO calculations show that *e.g.* $CH_2OH^{\oplus}$ and $CH_2NH_2^{\oplus}$ ions are stabilized with respect to $CH_2H^{\oplus}$ ions, by 48 and 66 kcal/mole, respectively [42].

[**] It was recently shown by CA investigations [44] with equipment of considerably improved energy resolution, that ions of structure *(23)* can arise if 2-bromo- or 2-nitroethanol is used as precursor. Also, in the same study [44], the formation of the protonated thiirane *(23)*, S in place of O, was demonstrated, whereas the unbridged $HS{-}CH_2{-}CH_2^{\oplus}$ ion is unstable under CA conditions. SCF-MO calculations [45] lead to the same result.

[*] For $C_2H_4O^{\oplus\bullet}$ ions it could be shown also by analysis of the signal shapes and of the translational energy released in the unimolecular dissociation [47] that, in agreement with CA studies, only a few structures are stable.

the importance and the limitations of collisional activation mass spectrometry in the clarification of such questions.

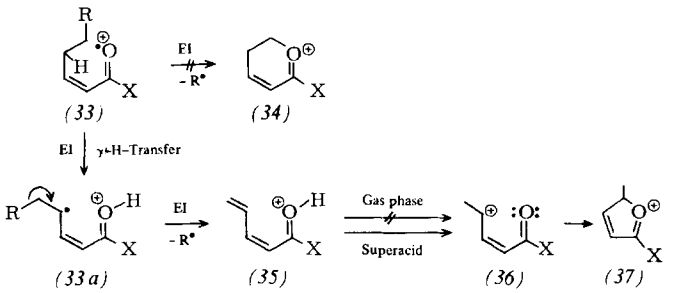
Intense ions of elementary composition $C_4H_8Cl^{\oplus}$ are characteristic for the mass spectra of higher *n*-alkyl chlorides ($n \geq 6$) *(29)*[51]. Although numerous indirect arguments indicated a tetramethylenechloronium ion *(30)* as the structure, direct experimental proof was first achieved by a CA investigation of labeled *n*-alkyl chlorides (Scheme 4)[52]. The finding that *(32a)* and *(32b)* are formed in the same ratio from both precursors *(29a)* and *(29b)* permits only the cyclic structure *(30)* on the grounds of the symmetry properties of *(30)* and *(31)*[*].



(29a), X = H, Y = D; *(29b)*, X = D, Y = H

Scheme 4. Structure of $[M-R]^{\oplus}$ ions obtained from *(29a)* and *(29b)*.

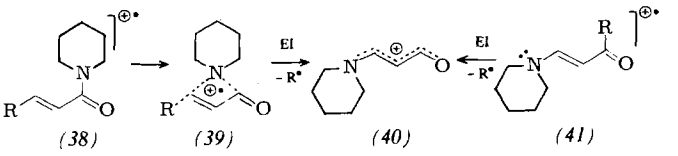
The question of the structure of $[M-Alkyl]^{\oplus}$ fragments from α,β-unsaturated carbonyl compounds (Scheme 5), which received contradictory answers in the literature, could also be decided in favor of the *acyclic* structure *(35)* by CA investigations[53]. Substituted dihydropyrylium ions *(34)*, postulated by *McLafferty*[54], could be excluded with certainty for aldehydes and ketones and with high probability for esters. The course of the reaction is compatible only with a reaction that starts with a γ-hydrogen-transfer and gives the conjugated oxonium ion *(35)* by allylic fission[55]. It is further remarkable that in the gas phase *(35)* does not undergo rearrangement to *(37)*, which *Olah et al.*[56] were able to observe on reaction in a superacid medium.



Scheme 5. Alkyl elimination from radical cations of α,β-unsaturated carbonyl compounds *(33)*, X = H, CH_3, OCH_3; R = alkyl.

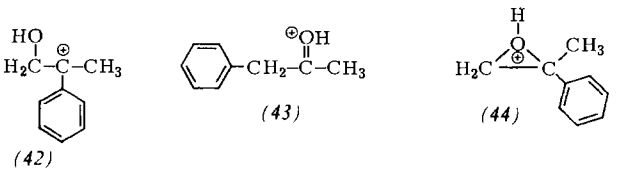
The unusual fragmentation behavior of amides, especially piperidides, of α,β-unsaturated carboxylic acids[57] was also clarified by CA investigations[58]. According to the CA spectra, the $[M-R]^{\oplus}$ ions of *(38)* exist partly as *(40)*; formally speaking the reaction route *(38)* → *(40)* is the first example of an electron-impact-induced intramolecular Michael addition (Scheme 6). The $[M-R]^{\oplus}$ ions from enamino ketones *(41)* serve as reference ions.

[*] It proved possible to exclude complete H/D scrambling [52].

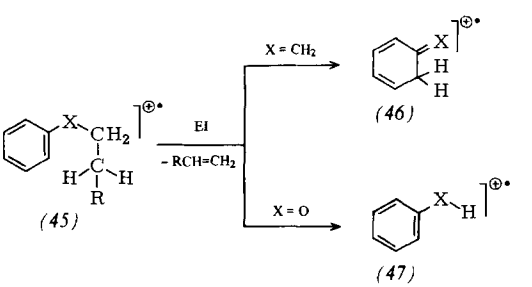


Scheme 6. Radical elimination from radical cations of α,β-unsaturated carboxylic acid piperidides *(38)*, R = alkyl, benzyl, aryl.

Reciprocal[1,2] shifts, which in the limiting case of a concerted course can also be considered as electron-impact-induced dyotropic rearrangements[59], could also be confirmed by CA investigations[60]. For example, the ion *(42)* rearranges completely to *(43)*. The protonated epoxide *(44)* *cannot* be detected under CA conditions.



Much space is devoted in mass-spectrometric literature to hydrogen transfers occurring in alkylarenes with elimination of alkenes, but in many cases it has not been possible to generalize about the transfer mechanism (*e.g.* ring size of the transition state if heteroatoms are incorporated into the side chain) or to clarify the structure of the resulting $[M-Alkene]^{\oplus\bullet}$ ions (Scheme 7). Here again CA spectroscopy provided the answer. Whereas with compounds of the type *(45)*, X = CH_2, the hydrogen transfer takes place exclusively to the benzene ring [formation of *(46)*[25]], ionized phenols *(47)* are formed almost exclusively from alkyl aryl ethers *(45)*, X = O[61][*]. In addition, it could be proved, by a combination of field ionization kinetics (FIK) and CA[61b], that the H-transfer in phenyl *n*-propyl ether (Scheme 7, R = CH_3, X = O) is not preceded by H-scrambling in the side chain, but that the hydrogen is transferred to the oxygen through transition states of various ring sizes; on energetic grounds (lowest activation energy) a transition state with a five-membered ring is favored (transfer of a hydrogen from the methyl group to the oxygen).

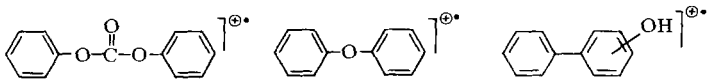


Scheme 7. Alkene elimination with hydrogen transfer from compounds *(45)*, X = CH_2, O; R = H, alkyl.

The question of the structure of the $[M-CO_2]^{\oplus\bullet}$ ions from diphenyl carbonate *(48)*, and thus also of the course of this extrusion reaction, could equally be answered by CA mass spectrometry[63]. In agreement with the results of *Beynon et al.*[64a], the CA results prove that $[M-CO_2]^{\oplus\bullet}$ exists as diphenyl ether *(49)* and not as phenylphenol *(50)*. The differ-

[*] ICR investigations also show that the $[M-Alkene]^{\oplus\bullet}$ ions from alkyl phenyl ethers exist as ionized phenols [62].

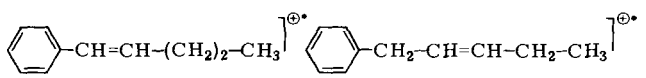
ences observed by *Williams et al.*[64b] in the unimolecular dissociation of the metastable ions from *(49)* and $[M-CO_2]^{\oplus\bullet}$ ions from *(48)* are thus not structure-determined but result from different energy distribution functions that are in principle to be observed when using MI characteristics. It should also be noted here that so far it has not been possible to differentiate and identify position-isomeric arenes by collisional activation mass spectrometry, except for those compounds that show pronounced *ortho* effects in conventional EI spectra: *(49)* and *(50)* give different and interpretable CA spectra, whereas the spectra of *o*-, *m*- and *p*-phenylphenol are identical[63].



(48) *(49)* *(50)*

Finally it should be mentioned that CA spectroscopy in combination with other methods (D-labeling, measurement of appearance potentials, determination of T_{kin}) has contributed substantially to the clarification of the unusual elimination of ammonia from ω-phenylalkylamines *(51)*[65], a reaction that is of interest in connection with Meyerson's concept of "internal solvation of ions in the gas phase"[66a, 66b]. Only *(52)* is formed by elimination of NH_3 from *(51a)*, whereas *(51b)* gives rise to several olefins, including *(53)* and *(54)*, in a complex reaction.

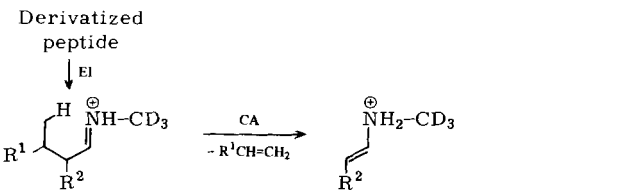
(51a), n = 3 *(52)*
(51b), n = 5



(53) *(54)*

5. Analytical Applications

It is well known that, for example, effective and unequivocal sequence analysis of oligopeptides by mass spectrometry[67] is limited by the following factors: a) the vapor pressure of the sample is too low, b) unspecific pyrolysis reactions occur before the actual electron-impact-induced dissociation and c) the fragmentation behavior of molecular ions and fragment ions is ambiguous, which is a great disadvantage particularly with leucine and isoleucine containing peptides. Whereas the first two effects can be considerably mitigated by use of field desorption mass spectrometry (FD-MS)[68], the limitation due to c) can be reduced by CA spectroscopy: the *structural stability* of the *immonium ions* and the characteristically different CA spectra (see also Section 3.2) serve as a basis for the sequence determination in a peptide. Thus, the CA spectrum of the ion *(55)* shows an intense fragment *(56)* at $m/e=61$ when the peptide derivative contains leucine, whereas if isoleucine is present the fragment *(57)* with $m/e=75$ is formed (Scheme 8)[69]. In the authors' opinion[69], on the basis of the characteristic differences in the CA spectra of other fragment ions, and of the fact that an unequivocal correlation is possible between the CA spectra of non-interconvertible ions and the intact structure of the neutral molecules, even mixtures of oligopeptides can be analyzed.



(55) *(56)*, *m/e* = 61 (R^2 = H)
(57), *m/e* = 75 (R^2 = CH_3)

Scheme 8. Decomposition of immonium ions *(55)* from leucine ($R^1=CH_3$, $R^2=H$) and isoleucine ($R^1=H$, $R^2=CH_3$) fragments.

A completely new procedure for qualitative analysis of mixtures without their previous separation (*e.g.* by gas chromatography) has been proposed by *Levsen* and *Schulten*[70]. These authors pyrolyzed a deoxyribonucleic acid, ionized the pyrolyzate with low electron energy (suppression of fragmentation), and then measured the CA spectra of some selected ions. By comparison with reference spectra they were able to identify, as pyrolysis products *e.g.* methanol, acetonitrile, propargyl alcohol, furan, 2-methylfuran, furfuryl alcohol and α-angelica lactone.

Electron impact in conjunction with collisional activation has also been used by *Kruger et al.*[72] for quantitative mixture analysis. The authors claim that mixture analysis is possible with an accuracy of ±5% if an internal standard is used and report a detection limit of 10^{-10} g.

Because of the multiplicity of fragmentations induced by collisional activation and the fact that the dissociation reactions can be connected with the structure of the reactive species, the CA method should supplement the information from all mass-spectroscopic methods that produce exclusively molecular or quasimolecular ions. The first encouraging works in this direction shows that in combination with, *e.g.* field ionization[9], electron-attachment mass spectrometry[71] (investigation of *negative* ions), or chemical ionization[1d, 44] it is possible to draw conclusions from fragmentation processes about the structure of molecular ions that are stable under the conditions of the ionization method, a feature that was hardly ever possible from FD, FI, EA, or CI spectra alone.

6. Critical Assessment and Prospects

In spite of the undisputed success of mass spectrometry in the elucidation of the structure of organic *compounds*, it is seldom possible by mass spectrometry alone to determine unequivocally the structure of the *ions* formed, and then only—if at all—with the aid of additional techniques. The collisional activation method reviewed here constitutes a very promising supplement to present-day techniques for structure determinations of ions in the gas phase. According to investigations already at hand, the method is reliable, the experimental technique is simple, and the data are easy to interpret. The method shares with most other techniques the disadvantage of being *comparative*. In the absence of suitable reference structures recourse must therefore be taken to additional information, *e.g.* fragmentation behavior, isotopic labeling, and measurement of the appearance potentials; in this connection, com-

bination of CA measurements with isotopic labeling is of special importance.

Although at first the center of interest in CA investigations lay in the structure of organic ions, it may be expected that in future the method will be used more frequently to study reaction mechanisms by clarification of the ion structures. Although the great value of the method for solution of the two problems (ion structures and reaction mechanisms) can hardly be disputed, only the future will show whether the analytical possibilities indicated above are of practical importance; for example, in view of the combination of gas chromatography with mass spectrometry, so widespread today, the direct analysis of mixtures using the CA method will be limited to special problems.

Finally, consider the instrumental side of the method. What is particularly important to note is that all the conventional magnetic instruments can be used for the measurement of CA spectra, which is not the case with the ICR technique. Instruments with the reverse Nier-Johnson configuration are undoubtedly particularly advantageous. Collisional activation mass spectrometry has a higher sensitivity than the competing techniques (ICR and MI), but its limited resolution is a disadvantage. A decisive improvement in resolution was achieved by most groups in 1975 by increasing the acceleration potential to 10 kV. A further doubling of the acceleration potential is conceivable and desirable. A possible alternative to instruments with the reverse configuration is offered by the "linked scan"[20a, 20b], by means of which collisional activation studies can also in principle be carried out with double-focussing instruments of conventional geometry. Only the kinetic energy released in a dissociation cannot be measured by this method.

The spread of a new analytical method depends further, and decisively, on the commercial availability of the necessary instrument. Mass spectrometers with additional equipment for the determination of CA spectra have recently been offered by two companies, so that it may be expected that collisional activation studies will in future be carried out routinely in organic mass spectrometry for the determination of ion structures and reaction mechanisms.

The authors should like to extend their sincere gratitude to Professor F. W. McLafferty, Cornell University (USA), who recognized and systematically studied the potential of collisional activation mass spectrometry for the determination of the structure of organic ions, for his cooperation and for the stimulating influence of his work.

Predictive Molecular Orbital Calculations in Organic Chemistry

By Joseph J. Dannenberg[*]

The utility and importance of predictive, rather than correlative, molecular orbital calculations in organic chemistry are discussed. Examples of the predictive approach to organic synthesis and the study of organic reaction mechanisms are presented.

1. Introduction

A cursory survey of the chemical literature will very quickly demonstrate the increasing proportion dealing with theoretical treatments of Organic Chemistry. The majority of articles dealing with this subject can be properly described as theoretical explanations or rationalizations of known experimental results. This type of work generally takes one of two forms: either an article devoted to the explanation (often with great insight) of certain reactions or categories of reactions, or what often amounts to a theoretical section, added to an experimental paper, which purports to rationalize the results in an acceptable manner. The latter type of discussion is necessarily less detailed, in general, than the former, as it is rarely the unifying force of the article. The increasing acceptance of these theoretical organic studies testifies to the fact that increasing numbers of organic chemists are coming to accept molecular orbital theory as a part of their scientific world and as a useful contribution to organic chemistry, in particular. Thus, molecular orbital calculations are now generally accepted by most organic chemists as being correlative with experimental results. Nevertheless, many organic chemists continue to ask a very reasonable question which can be stated as follows: "How much do we really benefit from calculations that simply tell us that what we have already experimentally demonstrated is correct?"

Implied in this question is the underlying suspicion that the theoretician might not have arrived at the correct result had he not known it at the outset. An example is shown in Figure 1 which is the representation of a lecture slide[1]

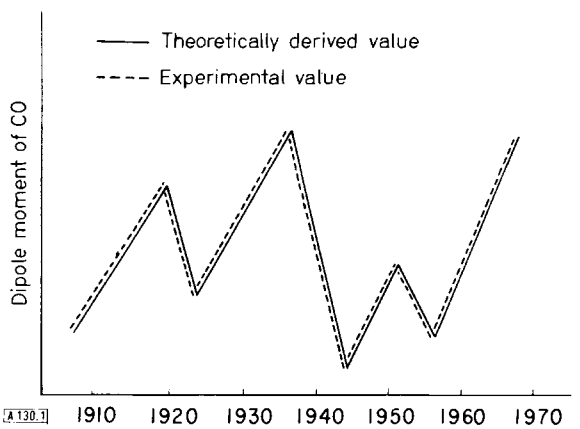

Fig. 1. The experimental and theoretically acceptable values for the dipole moment of carbon monoxide *vs.* time.

belonging to Professor *Turro* which shows the theoretical and experimentally acceptable values of the dipole moment plotted as a function of time.

In the context of the above discussion, we might reasonably pose the following question: "How can molecular orbital theory be more useful to organic chemistry?" The purpose of this review is to demonstrate that at least one viable answer to this question lies in using molecular orbital calculations to help solve the kinds of problems to which organic chemistry is addressed: Synthesis, mechanistic studies, and structure elucidation. Implicit in the suggestion that molecular orbital calculations be used to help solve problems is the idea that these calculations are to be used not only to explain and interpret results, but also to obtain results by suggesting paths of experimentation. In other words, now that we have confidence in the correlative values of molecular orbital theory, it is time that we used it more as a predictive method. This review will illustrate how molecular orbital calculations on individual systems can be used predictively by experimental organic chemists. Its scope shall be limited to the application of predictive MO theory to organic synthesis and reaction mechanisms. We shall not consider structural elucidation of intermediates since the predictive aspects of such calculations are evident and they have already been discussed in the literature to great extent[2]. Photochemical reactivity is also not discussed *per se*, nor are predictions made by rules such as the Woodward-Hoffmann rules, or those recently proposed by *Salem* for photochemical reactions, both due to space limitation and the fact that they are adequately discussed elsewere[3–5]. All the cases discussed will be concerned with calculations that were explicitly predictive in nature.

2. Methods

Many different methods of doing molecular orbital calculations are currently available. These range from simple Hückel theory to large basis set *ab initio* calculations with configuration interaction (CI). The chemist is confronted with the necessity of making a choice among these. The literature contains many articles extolling the virtues or exposing the detriments of one method or other[6]. We take the view, here, that the choice of the method is generally less important for predictive than for correlative calculations. The various MO methods generally agree with each other much more than they disagree. Since predictions must ultimately be supported by experiment, the burden of proof for the ultimate solution of the problem in question will be largely experimental, not theoretical. Thus, it is advisable to choose a method that is easily accessible and not too costly. Methods such as extended Hückel[7], CNDO[8], INDO[9], MINDO[10] and STO3G[11] generally come to mind as logical choices. Each of these has its own advantages and shortcomings (which shall not be discussed here), yet each is probably within the range of quality/cost that would be acceptable to an organic chemist. Obviously, large scale *ab initio* calculations on most systems of current interest to organic chemists would be prohibitively expensive, both in terms of computer time and experienced manpower.

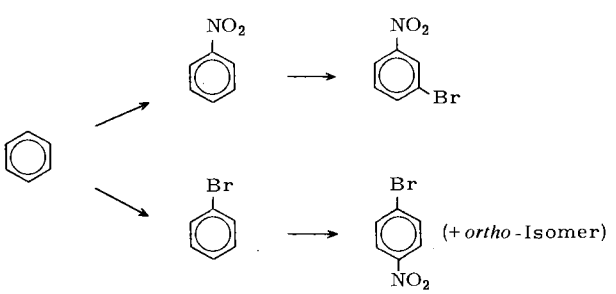
The organic chemist must realize that the results of a molecular orbital calculation at any of the readily accessible levels will not contain the absolute, final word about the system in question. All of the common molecular orbital methods (including the so-called *ab initio* methods[12]) are intrinsically approximative. They are all, therefore, likely to be in error in at least some details. An important criterion for the chemist should be: Do we have sufficient confidence in the prediction of a certain calculation to base an experiment upon its results? If the answer is negative, then one can do more sophisticated calculations until the criterion is met. Exactly what confidence level is acceptable will depend upon the problem at hand. Thus, a prediction that requires a very simple experiment for verification would require a relatively low level of confidence to be acceptable. It may be more costly to increase the confidence level by doing a more detailed calculation than it would be to simply verify the prediction experimentally. This argument becomes more convincing when you remember the result of the more detailed calculation must also be confirmed experimentally. On the other hand, if the experimental verification is costly and time consuming, it might be wise to invest in a more sophisticated calculation before one embarks on what may turn out to be a useless experiment.

It is generally useful to work with readily available programs of established methods, not only because of convenience, but also because there will generally exist a reasonable literature of results using such methods. The results of a particular calculation can often be better interpreted in the context of these results, especially when the limitations of a particular method are of concern.

Finally we must remember that the geometry of the system in question is always part of the input of any MO calculation. The results obtained will be no better than the geometry or geometries used. It is completely absurd to do a very sophisticated and costly calculation on a geometry in which we have little confidence. Part of choosing an appropriate method often includes a means of geometrical optimization of various species and/or reaction paths.

3. Synthesis

All synthetic reactions can be considered in terms of their energy surfaces. Thus, in the simple case of the synthesis of *para*-bromonitrobenzene from benzene, we must first brominate, then nitrate. This can be demonstrated with the aid of a reaction surface such as that of Figure 2. Initial nitration of benzene leads to a point on the surface (nitrobenzene) from which *para*-bromonitrobenzene is inaccessible because



the *col* leading to *meta*-bromonitrobenzene is significantly lower than that leading to the *para* (or *ortho*) product. On the other hand, initial bromination leads to a point on the

surface (bromobenzene) from which *para*-bromonitrobenzene is more accessible. Inspection of this surface would lead the synthetic chemist to choose to brominate then nitrate rather than *vice versa*. Of course, organic chemists know enough about electrophilic aromatic substitution so they do not need to calculate, or even to imagine such a surface in order to choose the correct reaction sequence. There are, nevertheless, cases where consideration of the details of the surface can be extremely useful.

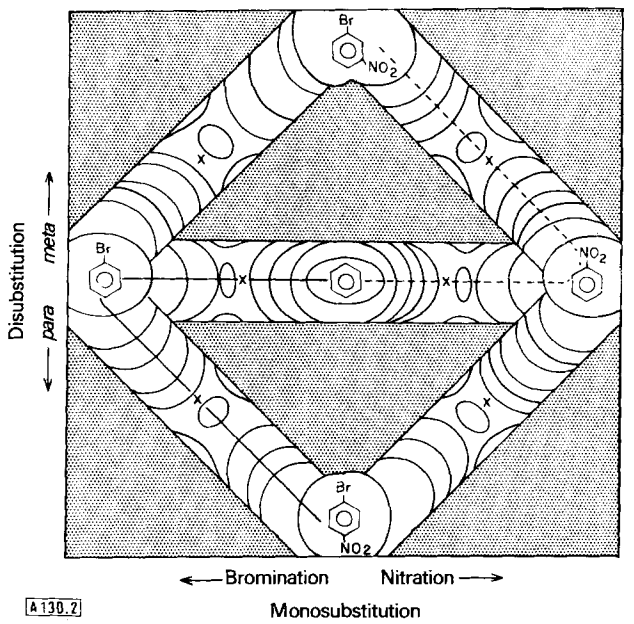


Fig. 2. A composite surface representation of the synthesis of *para*-bromonitrobenzene. The transition state for each step is marked with an "X". The solid line (——) represents the best path toward the desired product, while the dashed line (– – –) represents the best path toward the unwanted *meta* isomer. The surfaces involving *ortho* substitution have been omitted for the sake of clarity.

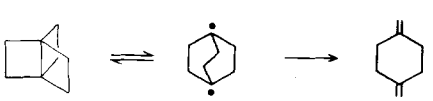
One such case is the synthesis of [2.2.2]propellane. This elusive molecule confounded the synthetic attempts of several research groups for some time[13]. Frequently, attempts to synthesize [2.2.2]propellane or its derivatives led to the production of 1,4-dimethylenecyclohexane or its derivatives. The reason for this became clear when *Hoffmann* and *Stohrer* showed that [2.2.2]propellane was a case of a species in which two different ground states are possible: one with a bond between the bridgehead carbons and one with a radical site at each of these carbons[14]. These were interconverted *via* a transition state in which the HOMO and LUMO crossed in energy. In other words, the HOMO of *(1)* becomes the LUMO of *(2)*.



(1) *(2)* *(3)*

Both *Hoffmann* and *Stohrer*[14], and later *Newton* and *Schulman*[15] in a more refined calculation, predicted the two species to be of similar energy and the interconversion barrier to be small. As *(2)* is readily expected to immediately rearrange to *(3)* since it is an appropriate model for a transition state of the degenerate Cope rearrangement of *(3)*[16], we are no longer surprised to find *(3)* as the ultimate product of an attempted synthesis of *(1)*. The diene *(3)* can arise either from a successful synthesis of *(1)* which decomposes under the conditions of reaction, or from an unsuccessful synthesis of *(1)* where the region of the surface corresponding to *(2)* is attained and this produces *(3)*, rather than *(1)*. The surface tells us that we must avoid attaining the 1,4-diradical structure if our synthesis is to succeed.

One way of attaining the minimum corresponding to *(1)* without passing through the region corresponding to *(2)* was suggested by simple INDO calculations on both the ground and the first triplet states of the system[17]. This calculation predicted the distance between the bridgehead carbons in the triplet state to be intermediate between those of *(1)* and *(2)*. It also suggested that the ground state geometry that corresponds to the optimized triplet lies on the [2.2.2]propellane side of the barrier between *(1)* and *(2)*. Vertical relaxation of the triplet might then provide an accessible pathway to *(1)* that completely avoids *(2)*. The obvious experiment to do based on these calculations was to excite *(3)* to its triplet state which would undoubtably rearrange to the relaxed triplet *(4)*, since the triplet state of an isolated double bond should be much higher in energy. The reaction must be performed at low temperature because the Newton-Schulman surface predicts that *(1)* should have a half-life of only about ½ hour at room temperature[15]. This prediction is in good agreement with the observed[18] half-life for the decomposition of the *N*,*N*-dimethylcarboxamide derivative.

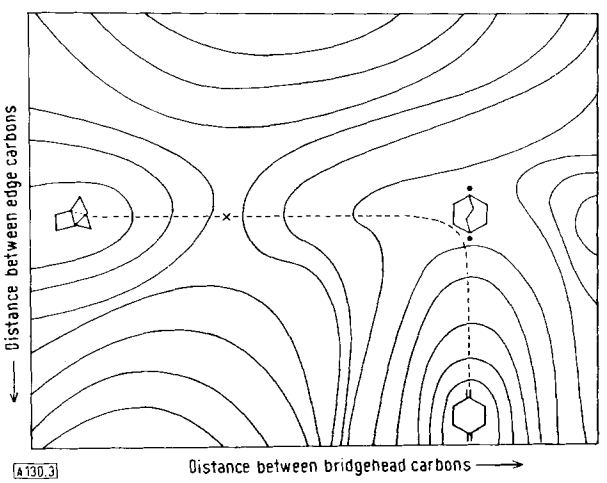


Fig. 3. A possible potential surface for the conversion of [2.2.2]propellane into 1,4-dimethylenecyclohexane. (Fig. 4 represents a horizontal slice through the surface.) The dashed line represents the reaction coordinate. The degenerate Cope rearrangement of 1,4-dimethylenecyclohexane can be understood using this surface by following the reaction path as far as the diradical, then proceeding in another dimension (not plotted) to a degenerate representation of the diene.

The confidence level of this surface (Fig. 4) is not extraordinarily high, due to the propensity of such methods as CNDO and INDO to overestimate the relative stability of small rings[19]. Thus, the ground state surface in Figure 3 is artificially skewed in favor of *(1)*, which may have introduced an error in the calculated position of the *col* between *(1)* and *(2)*. Nevertheless, the extreme simplicity of the suggested experiment (irradiation of 1,4-dimethylenecyclohexane with a suitable triplet sensitizer, at low temperature) made experimentation, rather than a more sophisticated calculation of the triplet

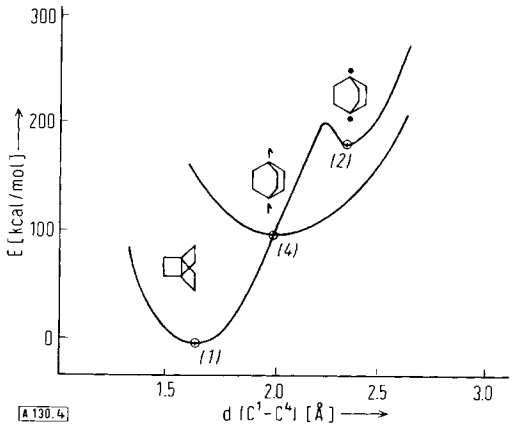

Fig. 4. Plot of energy *vs.* central bond length for the lowest singlet and triplet state of [2.2.2]propellane. Circled points represent optimized geometries. Other bond lengths vary slightly [17].

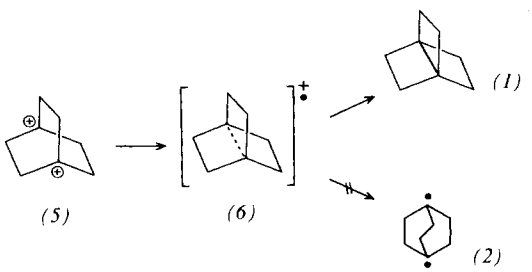
surface, the logical sequel. The fact that [2.2.2]propellane was indeed synthesized by the suggested method[20] indicates that the INDO surfaces were quite useful despite their approximate character. It is doubtful that a more exact surface would have led to a more fruitful experiment.

Another approach to the synthesis of [2.2.2]propellane[21] can be derived starting from consideration of the 1,4-dication of bicyclo[2.2.2]octane *(5)*. NMR spectra[22], as well various kinds of calculations[22,23], are in accord with a structure for *(5)* having a relatively short distance between the bridgehead carbons.

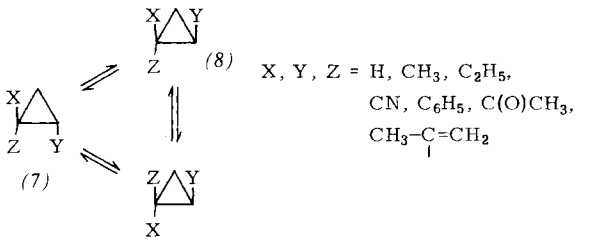


The dication *(5)* is formally equivalent to the dication of [2.2.2]propellane [obtained by removing two electrons from *(1)*]. INDO calculations predict that the stepwise addition of two electrons (reduction) to *(5)* will conserve the short distance between the bridgehead carbons, leading to formation of *(1)* rather than *(2)*. The fact that *(5)* has been prepared only in magic acid[22] whereas *(1)* is expected to be very labile to acid poses a difficult impediment to the realization of a synthesis of *(1)* based on this reaction. If this impediment can be surmounted, the reaction may prove to be the basis of a synthesis of *(1)* in good yield.

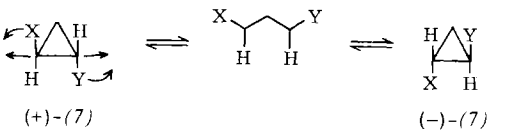
4. Mechanistic Studies

4.1. Cyclopropane Rearrangement

The thermal isomerization of cyclopropane, and particularly the behavior of the presumed trimethylene intermediate, has received considerable theoretical attention during the past several years. Theoretical studies of quite varied levels of sophistication (from extended Hückel calculations with a geometry search in three dimensions[24] to a small basis set SCF *ab initio* calculation in which all 21 internal coordinates were considered[25]) have been reported. These calculations have provoked a number of extremely interesting experimental studies on various model compounds *(7)*[26–29].



On the basis of his extended Hückel calculations with three geometric variables (CCC angle and the torsional angles about each of the two C—C bonds), *Hoffmann* was the first to suggest that there be a relative minimum (or intermediate) on the trimethylene surface that corresponds to a species with all its atoms in the same plane except for the two hydrogens on the central carbon, and a CCC angle of 125°[24]. He further suggested that cyclopropane be preferentially formed from this intermediate by a conrotatory process[24]. The implication of this result is that there ought to exist a low energy path that would convert a molecule of an optically active disubstituted cyclopropane into its enantiomer without the intermediacy of the *cis* isomer.



A few years after *Hoffmann*'s calculation, *Salem et al.* published a detailed surface for trimethylene that specifically considered all 21 internal coordinates[25]. The energies were calculated using a small basis set *ab initio* method that included 2×2 and 3×3 configuration interaction, where important. *Salem*'s surface confirmed *Hoffmann*'s more qualitative observations, while providing much more detail and invaluable insight into the molecular motions involved in the various stages of the reaction[30]. For the first time one could imagine a complete organic chemical reactive process, rather than merely the transition states and/or intermediates. Despite the fact that these and other calculations[31,32] all predicted that the concerted two bond rotation (inversion of *(7)*) should compete favorably with the one bond rotation (*trans*→*cis* isomerization), thermolysis of several appropriately substituted cyclopropanes provided no experimental support for this hypothesis. Confidence in the theoretical predictions eventually led *Berson et al.* to study the thermolyses of *trans*-1,2-dideuteriocyclopropane[33] and *trans*-2-deuteriophenylcyclopropane[34]. Both compounds of type *(7)* exhibit the anticipated double rotation (inversion) process. Apparently, the more drastic substitutions used by previous workers[26–29] were sufficient to cause a significant change in the potential surface. A recent report by *Simonetta et al.* shows that even calculations so simple as extended Hückel account for the difference in reactivities between cyclopropane and various derivatives[35]. An important point to emphasize here is that simple calculations on actual experimental systems are often indicated, even in the presence of extremely sophisticated analyses of model systems.

4.2. Nucleophilic Substitution

The mechanism of nucleophilic substitutions, particularly solvolyses, continues to be an area of considerable interest and importance to organic chemists. Various experimental advances have allowed us to progress from the classical S_N1 and S_N2 ideas of *Ingold*[36], through the kinetically determined intermediates referred to as "intimate" and "solvent-separated ion pairs" by *Winstein*[37], to several additional refinements including "solvent-assistance"[38] and the suggestion that the "S_N2" reaction occur *via* the intermediacy of an "intimate ion pair"[39]. Several mechanistic schemes based upon various distillations of experimental results have recently appeared[39–41]. Theoretical work had been limited to S_N2 reactions, usually the reaction: $F^- + CH_3F \rightarrow CH_3F + F^-$[42, 43]. While reactions of this type are of real interest, particularly in the context of the increasing power of molecular beam techniques, they are only distantly related to the equivalent reactions in solution. Therefore, they are not directly applicable to the design of a solvolysis reaction. We have recently completed an INDO study of the substitution of water upon protonated alcohols[44].

$$H_2O + ROH_2^+ \longrightarrow H_2OR^+ + OH_2$$
$$R = CH_3,\ C_2H_5,\ CH(CH_3)_2$$

The predicted lowest energy reaction paths were calculated by performing extensive geometrical optimization at many points along the reaction coordinate. Analysis of the reaction paths led to the suggestion that the intermediates observed by *Winstein et al.* might better be described as anion-stabilized intermediates (ASI) and anion-cation stabilized intermediates (ACSI) rather than "intimate" and "solvent-separated ion pairs". These intermediates, particularly the ACSI, can be conceived with *defined structures* that allow for experimental verification (see Fig. 5). In addition, once the natures of the intermediates have been theoretically approximated, it

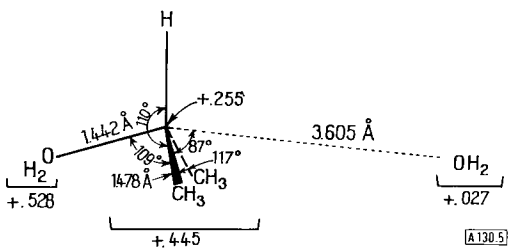


Fig. 5. The calculated geometry for the anion-cation stabilized intermediate (ACSI) for reaction of water with protonated isopropanol.

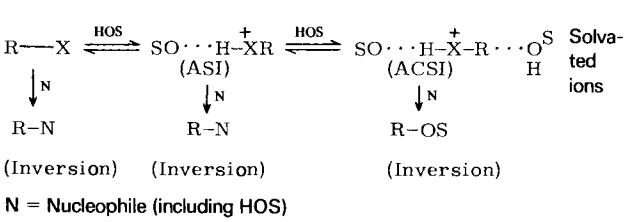
becomes possible to imagine various categories of nucleophilic substitution that can be defined in terms of the anion-stabilizing, cation-stabilizing and general ionic solvating properties of the medium. Thus, it is possible to accommodate many seemingly divergent experimental results using these ideas.



Perhaps the greatest didactic advantage of generating a purely theoretical reaction mechanism is that a continuous, self-consistent picture is generated. Such a formulation can provide a very useful comparison to reaction mechanisms generated from experimental results. The latter are generally analogous to curves generated by extrapolation between points. Since various experiments which are related or extrapolated to the same mechanism are often performed under different conditions, the extrapolation is often necessarily made between points on slightly different reaction surfaces. For example, the measurement of a rate constant provides information about the energy, but not the geometry, of a transition state. A spectrum of a cationic intermediate stabilized in magic acid provides structural information and often some energetic information, about an intermediate, but generally on a reaction surface that may be significantly different from that relating to the rate constant.

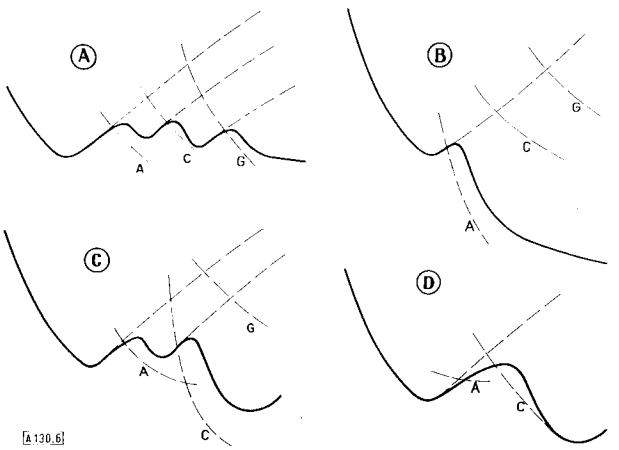


Fig. 6. Energy (vertical) *vs.* reaction path (horizontal) diagrams for various possible types of nucleophilic substitution obtained by adding anion stabilization (A), cation stabilization (C), and general solvation (G) to an arbitrary reaction coordinate for heterolytic R—X bond cleavage. Broken lines indicate individual contributions while the solid line indicates the sum in each case. Ⓐ, anion- and cation-stabilization are sufficiently balanced to allow two intermediates (ASI and ACSI) between reactants and solvated ions. Ⓑ, the solvent is such a strong anion stabilizer (*e.g.* magic acid) that the R—X bond breaks directly into solvated ions. Ⓒ, a moderate anion-stabilizing solvent plus a strong cation-stabilizer (which may be an added nucleophile, *e.g.*, azide) leads to formation of product directly from the first intermediate (ASI). Ⓓ, a poor anion-stabilizing solvent (*i.e.* aprotic) and a strong cation-stabilizer (*i.e.* nucleophile) lead to product by direct attack on the reactant (classical S_N2).

Once an approximate energy surface or reaction path has been calculated, it may become possible to define critical experiments to test the surface at various points. If the results of these experiments are in accord with the predicted reaction path, one can, in general, gain confidence in the entire reaction path (of course, you would have to test the reaction path at an infinity of points to have complete confidence). There is a great conceptual value in such a procedure. An analogy is depicted in Figure 7 in which one tries to determine the best path through a forest. Experiments might show the absence or presence of trees at the points indicated. There are several reasonable ways to connect the unobstructed points in a path. In addition, it is not necessary that all the points must lie on the path. In Figure 7, the location of the path is predicted by theory. Experiments can be performed to determine the presence or absence of obstructions at various points along the predicted path. The presence of such an obstruction would indicate an erroneous prediction. The absence of

obstructions along several properly spaced points along the path would increase confidence in the prediction even if there were shown to be points off the path where obstructions were also absent.

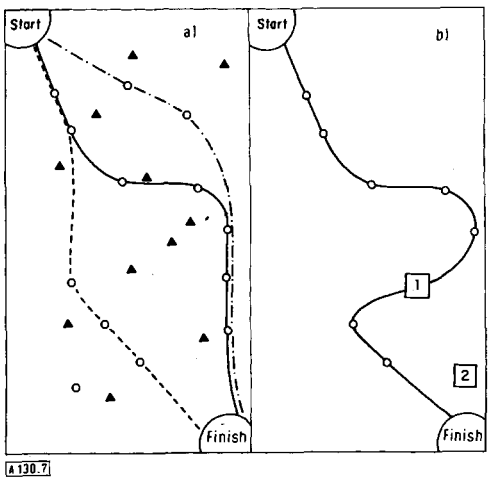

Fig. 7. a) An experimental attempt to find the path (we assume only one exists) through a forest from "start" to "finish". Points marked ▲ represent experimentally determined obstacles (*e.g.* trees); points marked o represent experimentally determined clear areas. There are several reasonable formulations of the path based on these data (——, – – –, ·—·) yet no *a priori* means of choosing among them.
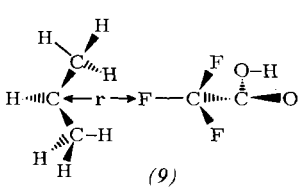
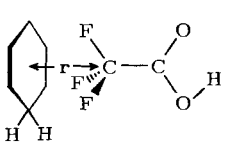
b) A theoretically predicted path through the forest (——) fits many experimental clear areas and encounters no obstacles; yet it is different from the three most obvious paths (cf. a)). Experiments at points 1 and 2 are indicated. A clear area at 1 and (to a lesser extent) an obstacle at 2 would greatly increase our confidence in the prediction.

The calculation of the true energy surface (or reaction path) for a solvolysis reaction would necessarily take into account more geometric variables than is generally practicable: the internal coordinates of the reagents plus a sufficiently large number of solvent molecules[45]. Nevertheless, the organic chemist often knows enough to make a wise choice of a simplified model. Thus $H_2O+ROH_2^+$ is probably a better model for a solvolysis than is F^-+RF since the differential effects of solvation during the course of the reaction should certainly be smaller in the former case.



(9)



(10)

The specific effects of solvents can also sometimes be treated in a predictive manner using molecular orbital theory. Thus, the seemingly anomalous behavior of trifluoroacetic acid (TFA) as a cation solvent has been explained by the suggestion that the trifluoromethyl group might interact with cations in a stabilizing, yet non-nucleophilic (*i.e.* non bond-forming) manner[46]. The prediction of *(9)* as a model for a 2-propyl cation-TFA interaction, and *(10)* as a model for a protonated benzene-TFA interaction should be testable by suitable experiments, some of which are currently being undertaken in our laboratories[47].

5. Conclusion

The predictive powers of even relatively simple molecular orbital calculations can be used to provide the organic chemist with a powerful new tool to help devise experiments and mechanistic theories. This tool can be easily used by organic chemists as the molecular orbital procedures are neither costly nor difficult. The organic chemist can best tailor the calculations to the problem at hand when he performs them himself. He is also best equipped to determine what experiments are likely to be both practical and critical tests of the theoretical predictions. The types of predictive theoretical studies discussed in this review should be treated as approaches, rather than solutions to problems in organic chemistry. An acceptable solution almost always will require experimental verification.

Radioimmunoassay

By Hans Georg Eckert[*]

Biologically active substances are often effective in nanogram or even smaller quantities. Investigations of their mode of action therefore require highly sensitive microanalytical methods of detection. Chemical, chromatographic or spectrometric methods frequently lack the required sensitivity; it was only after the discovery of the radioimmunoassay (RIA) that quantitative determination of minute amounts of substances in the presence of a millionfold excess of other compounds became possible. The radioimmunoassay combines the extreme sensitivity of detection of radioactively labeled substances with the high specificity of immunological reactions. The superiority of radioimmunological methods over other analytical techniques rests upon their sensitivity, specificity, facile application, and especially their broad general scope.

1. Introduction

The first results suggesting the feasibility of the radioimmunological method were obtained in studies performed by *Yalow* and *Berson*[1] in the 1950's. During *in vivo* studies on the metabolism of [^{131}I]-insulin they surprisingly discovered that all diabetics having undergone insulin treatment had formed insulin-binding antibodies. Further studies showed that (i) an excess of insulin saturates the antibody-binding sites and (ii) addition of non-labeled insulin displaces radioactively-labeled [^{131}I]-insulin from the gamma-globulin complex. Thus the foundation was laid for the development of radioimmunoassay.

Further development of this microanalytical *in vitro* technique then led to the first radioimmunoassay for insulin[2, 3], in which an insulin-specific antibody was the key reagent. Almost simultaneously, *Ekins*[4] reported a very similar principle for determining the thyroid hormone thyroxine (T4). However, instead of an antibody, a naturally occurring transport protein, *i.e.* thyroxine-binding globulin (TBG), served as specific binding reagent. On the basis of these studies, numerous radioimmunoassays have since been developed for a wide variety of substances, and variations in the technique have led to a series of similar methods described in numerous books and reviews[5–11], and variously known as saturation analysis, radioligand assay, and competitive protein binding analysis.

The far-reaching significance of and the great interest in these sensitive methods of determination are apparent from the handsome number of over 200 radioimmunoassays available to date. Using these methods, various substances can be determined in nanogram to picogram, and sometimes even smaller amounts without previous separation or enrichment in biological fluids such as plasma, serum, or urine. Table 1 lists a selection of important biologically active substances of various molecular weights which can be determined by radioimmunological methods. Many of the radioimmunoassays so far developed are already commercially available as analytical kits.

2. Principle of the Method

Radioimmunological methods combine the extreme sensitivity of detection of isotopically labeled compounds (isotopic dilution analysis) with the high specificity of immunological reactions. Thus on use of radioisotopes the detection limit is improved up to 10^7-fold over other physicochemical analytical methods. The *in vivo* and *in vitro* immunological reaction is based on the unique fit of antigen (Ag) and antibody (Ab), which correspond as "lock and key" *(Emil Fischer)*. Given a sufficient binding affinity of the antibody a characteristic equilibrium will be established between the reactants and the resulting water-soluble antigen-antibody complex:

$$Ag + Ab \rightleftharpoons Ag \cdot Ab$$

If the unlabeled antigen (Ag) is replaced by radioactively labeled antigen (Ag*) which differs only slightly, if at all, chemically but not in the slightest immunologically then, by analogy

$$Ag^* + Ab \rightleftharpoons Ag^* \cdot Ab$$

Radioimmunological analyses based on these two equations permit determination of minute amounts of the antigen (Ag) provided that three conditions are fulfilled:

Table 1. A selection of some radioimmunoassays for various classes of substances.

Name of Substance	Approx. Molecular Weight
1. Peptide hormones	
Vasopressin	1084
Gastrin	2096
Glucagon	3483
Calcitonin (CT)	3700
Adrenocorticotropin (ACTH)	4576
Insulin	5734
Prolactin (PH)	20000
Growth hormone (GH)	21500
Placenta lactogen (PL)	22000
Thyreotropin (TSH)	25000
Luteinizing hormone (LH)	26000
Follicle stimulating hormone (FSH)	30000
2. Non-peptide hormones	
Serotonin	176
Estrogens, androgens, gestagens	300
Prostaglandins	300
Triiodothyronine (T 3)	651
Thyroxine (T 4)	776
3. Enzymes	
Trypsin	23800
Carboxypeptidase A	34000
Pepsinogen	42000
4. Serum proteins	
Thyroxin-binding globulin (TBG)	65000
Albumin	69000
Immunoglohulins (Ig)	150000
5. Vitamins	
Vitamin D_3	385
Vitamin B_{12}	1355
6. Tumor-associated antigens	
Chorion-gonadotropin (CG)	46000
Alphafetoprotein (AFP)	65000
Carcinoembryonal antigen (CEA)	200000
7. Drugs	
Barbiturates	100–200
Morphine	285
Lysergic diethylamide (LSD)	323
Penicillin G	334
Digoxin/Digitoxin	780
8. Other biologically active substances	
Cyclic adenosine monophosphate (c-AMP)	347
Folic acid	441
Deoxyribonucleic acid (DNA)	10^6
Hepatitis-associated antigen (HBAg)	—

1) The antibody (Ab) cannot distinguish between radioactively labeled substance (Ag*) and the unlabeled compound (Ag) to be determined, *i.e.* the binding constant K is the same for the complexes Ag·Ab and Ag*·Ab.

2) More radioactively labeled antigen molecules (Ag*) must be present than antibody binding sites, *i.e.* the number of antibodies (Ab) must be kept at such a level that free labeled antigen (Ag*) is always present besides the complexes Ag*·Ab (even in the absence of unlabeled substance).

3) In a given experimental system the concentration of radioactive compound and the amount of antibody is kept constant for all test runs. The concentration of unlabeled antigen to be determined is thus the sole variable in this system.

Under the above conditions, radioimmunoassay can readily be understood as competitive protein binding analysis. A variable amount of a substance (Ag) and a constant amount of the same radioactively labeled compound (Ag*) compete for a limited and constant amount of binding sites of the antibody (Ab).

Thus all the fewer radioactively labeled molecules (Ag*) will be bound (B) the more unlabeled Ag are present. The

$$\mathrm{Ag} + \mathrm{Ag}^* + \mathrm{Ab} \rightleftharpoons \underset{(B)}{\mathrm{Ag}\cdot\mathrm{Ab} + \mathrm{Ag}^*} \quad \underset{(F)}{\mathrm{Ag}^*\cdot\mathrm{Ab} + \mathrm{Ag}}$$

extent of binding between radioactive molecules and antibodies is thus a measure for the concentration of the compound to be determined.

The situation is shown in drastically simplified schematic form in Figure 1. In all three examples the above requirements are met. The increasing substance concentration in the first vertical series (0, 2, and 6 molecules) at constant amounts of labeled compound and antibody reduces the number of radioactive antigen-antibody complexes (balance). Specificity precludes reaction between other molecules and antibodies. In order to quantitatively establish what proportion of the labeled compound is complexed after equilibration (B), all the antigen-antibody complexes (Ag*·Ab, Ag·Ab) have to be separated from free, unbound antigen (Ag*, Ag). The most important separation procedures are discussed in the light of their advantages and disadvantages in Section 5. After separation and monitoring of the radioactivity of bound (B) or free phase (F) the content of a sample can be read off directly from a calibration curve plotted for standardized amounts of substance.

After mixing of the chemicals and sufficient incubation time a reversible equilibrium is established in the simplest case which can be described by the law of mass action. A plot of the relation derived

$$\frac{[\mathrm{Ag}\cdot\mathrm{Ab}]}{[\mathrm{Ag}]} = K([\mathrm{Ab}]_0 - [\mathrm{Ag}\cdot\mathrm{Ab}])$$

$[\mathrm{Ab}]_0$ = initial concentration of antibody

or expressed in terms of bound (B) and free phase (F)

$$\frac{[\mathrm{B}]}{[\mathrm{F}]} = K([\mathrm{Ab}]_0 - [\mathrm{B}])$$

is a straight line of slope K. This is called a "Scatchard plot"[12] and permits estimation of the binding constant.

However, this approach is grossly simplified and only gives anything like reliable results when the antigen and antibody are chemically uniform and univalent and react as far as equilibration[13]. This equilibrium should not be perturbed by removal of antibody-bound substance from the free species. Moreover, the reaction should be of first order. In practice these conditions are not satisfied. Antisera nearly always contain several populations of antibodies exhibiting different binding strengths, and this heterogeneity alone will prevent us from obtaining linear Scatchard plots[14] and therefore give only "average" binding constants. The real situation becomes even more complicated when it is remembered that cross reactions can occur with chemically similar or structurally related molecules, and several models have been proposed for its exact description and for estimation of its influence on standard curves. These account for, *e.g.*, varying binding behavior of labeled substance, standard substance, and substance to be determined in a biological fluid[15].

Development of a radioimmunoassay and setting up an experimental system first requires that adequate amounts of

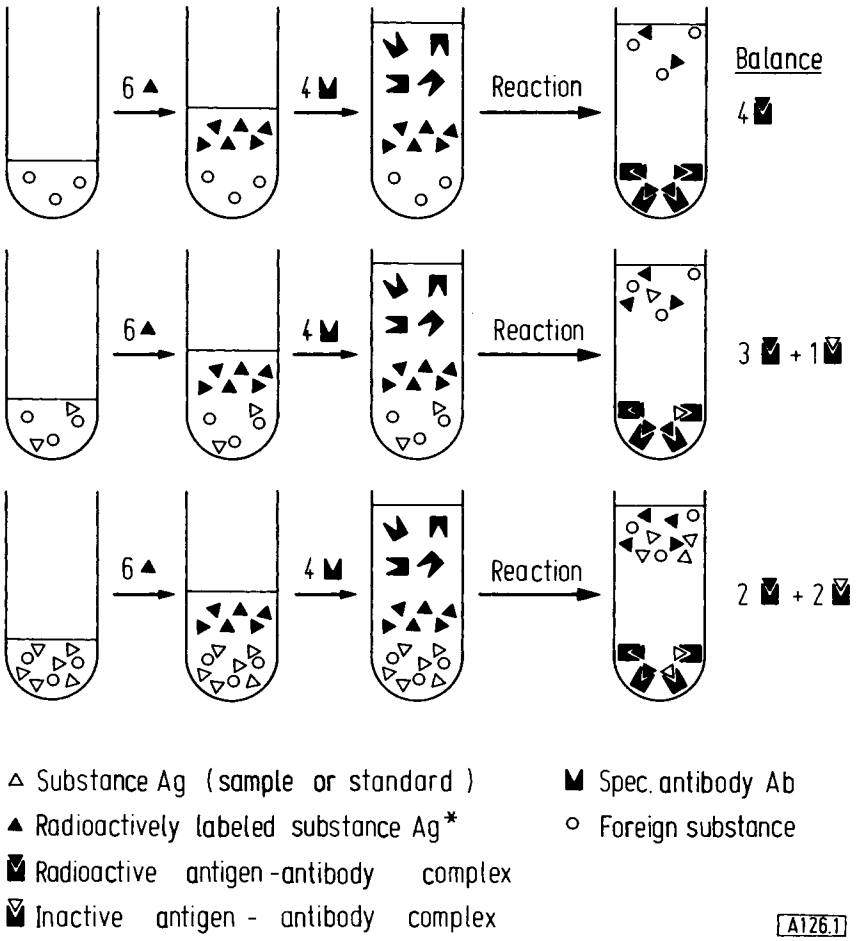

Fig. 1. Schematic representation of the radioimmunoassay principle. A variable amount of the labeled antigen (Ag) and a constant amount of the unlabeled antigen (Ag*) compete for a limited number of binding sites of the antibody (Ab).

the substance to be determined, *e.g.* a hormone, be isolated from biological material and purified or synthesized. After optimum purification a portion of the hormone is radioactively labeled and another portion used for immunization in order to gain antisera, while the unmodified hormone serves as reference for production of a calibration curve. In addition, a suitable reagent is required for separation of antibody-bound hormone from the free hormone.

3. Isotopes and Procedures Used for Radioactive Labeling

The choice of radioisotope and hence the chemical procedure adopted for labeling depends upon various factors. Thus apart from molecular size, structure, stability, and availability of the compound, its purity, retention of immunoreactivity, availability which may be limited in some cases such as hormones, and above all the attainable specific radioactivity all play a significant role. Since the substance to be determined is generally present in nanogram to picogram amounts in the samples, a precise radioimmunological determination is only possible if the amount of labeled substance (tracer) itself is kept very small. Thus to assure a satisfactory detection sensitivity for reasonable measuring times a tracer having an adequate specific radioactivity will be required. A tracer activity of between 100 and 200 mCi/mg will suffice for most radioimmunoassays. About 10 nCi (*ca.* 22000 decays per minute) corresponding to about 60 pg of labeled substance, and sometimes even less, is added to each test tube.

Of all available radioisotopes, preference would be given to ^{14}C for labeling organic substances because the ^{14}C-tagged compounds behave in exactly the same way as the starting compounds. As shown by Table 2, however, the specific radioactivity attainable with ^{14}C is so low that at best 0.1 μg of a substance can be determined. Another disadvantage is that ^{14}C labeling usually requires several synthetic steps and frequently gives only low yields. In addition, ^{14}C labeling is simply impossible for numerous complicated or polymeric natural products such as polypeptides, proteins, and glycoproteins which have hitherto resisted synthesis and are often only available in minute quantities.

Owing to the shortcomings of ^{14}C, relatively small molecules such as steroids, prostaglandins, or drugs are tagged with tritium. The radioactivity is usually introduced by catalytic tritiation of double bonds, by Wilzbach tritiation or by an exchange reaction, *e.g.* halogen for tritium. Tritium compounds also display various disadvantages which preclude their general application. Thus the specific radioactivity is often too low, while tritium compounds of higher activity are relatively unstable. Moreover, recording β-radiation in a liquid scintillation counter involves preparation of a "scintillation cocktail", a complicated and expensive procedure.

Most commonly, an extraneous label is used for radioactive tagging, or in the case of compounds like thyroid hormones

Table 2. Theoretical maximum possible specific radioactivity of a compound when 1 atom of the isotope is incorporated in the molecule.

Isotope	Radioactivity [Ci/mmol]	Half-life	Radiation
^{14}C	0.062	5568 a	β^-
^{3}H	29	12.3 a	β^-
^{75}Se	1080	120.4 d	γ
^{35}S	1488	87 d	β^-
^{125}I	2200	59.7 d	γ
^{131}I	16100	8.1 d	β^-, γ

which contain iodine an exchange labeling with ^{125}I is carried out. This γ-emitter permits labeling of an intact molecule in one step and affords a product of high specific radioactivity (Table 2). Thanks to its long-half-life of 60 d, ^{125}I has almost completely ousted ^{131}I, which is nowadays used practically exclusively for *in vivo* studies.

Iodination is limited to compounds which, like nearly all peptides and proteins, contain the amino acids tyrosine or histidine. It should also be borne in mind that incorporation of iodine into the molecule may cause *inter alia* a change in conformation whose magnitude will depend upon the size of the molecule; hence it may be bound less firmly if at all by the antibody owing to changes in its immunological properties. Such changes in binding properties can be seen directly from a comparison of the immunoreactivity of tracer and unlabeled compound.

Iodine labeling is based upon electrophilic substitution in the activated aromatic ring, *e.g.* in *ortho* position to the hydroxyl group in tyrosine. Practically all procedures developed for this purpose differ merely in the oxidizing agent used for producing radioactive iodine from the ^{125}I anion. In this reaction the substance to be labeled is already present and therefore exposed to the oxidizing agent. This leads to interference by oxidation-sensitive SH groups and amino acids, and hence to undesired changes in the molecule. Use of exceptionally mild oxidizing agents and very short reaction times of 5 to 60 seconds, however, keeps the proportion of degradation products very small or permits their removal by purification of the reaction mixture. Reaction is usually stopped by a reducing agent such as sodium disulfite ($Na_2S_2O_5$) or by dilution with buffer solution.

Of all procedures, the chloramine T method[16, 17] of iodination with a few microgram of substance has found the widest acceptance. In comparison the number of examples in which labeling is performed with iodine monochloride[18, 19], with gaseous chlorine[20], with sodium hypochlorite[21], or by electrolytic means[22] are of minor importance. Increasing use is being made of enzymatic iodination with lactoperoxidase[23] or horse radish peroxidase[24, 25]. Procedures involving activated esters are particularly mild[26, 27]. Thus in a reaction preceding the acylation, for example, 4-[2-(succinimidooxycarbonyl)ethyl]phenol ["*N*-succinimidyl-3-(4-hydroxyphenyl)-propionate"] is radioactively labeled by the chloramine T method, the iodinated compound purified and subsequently allowed to react with free amino groups of the peptide or protein. The procedure has the advantage that sensitive substances do not come into contact with ^{125}I or the reagents required for iodination. Moreover, it provides a means of tagging compounds containing *neither* tyrosine *nor* histidine.

In order to utilize the advantages, *i.e.* high specific radioactivity and simple measurement, of iodine-labeled compounds with low-molecular substances, these haptens (see Section 4) are coupled *via* a bridging group with iodinatable auxiliary compounds such as tyrosine esters, tyramine, or histamine[28, 29]. It should be noted, however, that the new compounds often display completely different immunological properties from the starting compound, which, in extreme cases, can lead to a complete loss of binding to the antibody. The site of linkage between the substance and the auxiliary compound therefore warrants particular attention.

Instead of using these conjugate systems, which can considerably alter both the size and the structure of the molecule, it has meanwhile become possible to directly label steroids with ^{75}Se (Table 2)[30].

After the labeling operation with ^{125}I, the radioactive compound should be immediately removed from the reaction mixture of unreacted ^{125}I, radiation-damaged products, and inactive components. Since the amounts involved are usually of the order of 10 to 50 µg, purification is possible only with effective separating systems such as gel filtration, gel electrophoresis, chromatography, or selective adsorption. After purification the substance is tested for radiochemical homogeneity by chromatography or electrophoresis (Fig. 2).

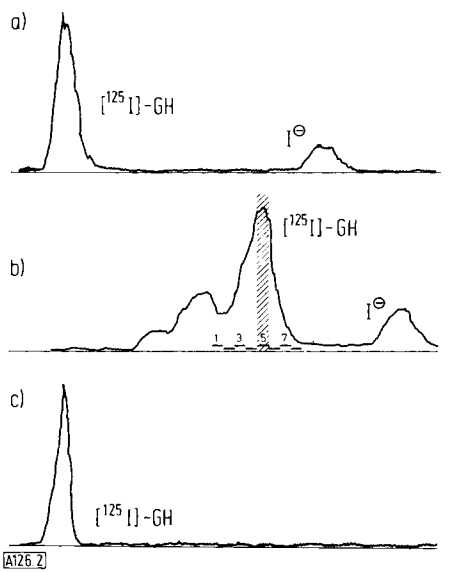

Fig. 2. Purification and testing of ^{125}I-labeled growth hormone [^{125}I-GH]. a) electrophoresis of the reaction mixture; b) purification by gel filtration; c) electrophoresis of fraction 5.

The radiochemical purity of the labeled compound steadily decreases on prolonged storage due to autoradiolysis, *i.e.* modification by radiation and loss of iodine atoms. Decomposition can be kept low and the shelf-life improved by reducing the activity concentration and also by addition of albumin and buffer. A further improvement in stability can be achieved by storage at low temperature (−20 °C) and by freeze-drying of the product.

4. Formation and Properties of Antibodies

Antibodies are endogenous glycoproteins and are regarded as carriers of protection against infection. They are formed in the pertinent lymphoid cells (plasma cells) of the organism on intrusion of an extraneous substance and secreted into the blood circulation. Complex formation with the antibody renders the antigen harmless.

On electrophoresis of serum, antibodies migrate with the γ-globulin fraction. Because of their extensive functional and structural resemblance to γ-globulins they are called immunoglobulins (Ig). They have molecular weights between 150000 (IgG) and 900000 (IgM) and generally consist of two long and two short chains which are linked together by disulfide bridges[31-33].

An essential characteristic of antibodies is the specific binding with the antigen which induced their formation. The reason for the specificity can be seen in the spatially fitting complementary configurations of the antigen determinant groups and the binding groups on the immunoglobin molecule. If the serum containing the antibodies, and therefore known as antiserum, is isolated the antigen-antibody reaction usually occurring *in vivo* can also be employed for quantitative determinations *in vitro*.

Antibody formation depends upon several factors, the most important ones being the form of the antigen offered and the animal species selected for immunization. Species-foreign proteins having a molecular weight in excess of 5000 generally act as antigens. Thus even a slight difference in amino acid sequence or a single amino acid substitution, *e.g.* in insulin, can suffice to produce antigenic properties. Smaller molecules such as the polypeptides gastrin or vasopressin, steroids, thyroid hormones, and drugs, have only little, if any antigenic action. However, antibodies can also be produced against these haptens by linking them in covalent manner to high molecular carriers. The compounds are coupled *via* short bridges (four to six CH_2 groups) to natural or synthetic proteins or polymers such as albumins[34], polylysine[35], or polyethylene glycol. The attached minor molecule (determinant group) then determines the specificity of the antibody, *i.e.* the latter does not react with the complete antigen molecule but with only a small part thereof, the hapten. However, the position at which the hapten molecule is linked to the carrier protein is of crucial importance for the specificity of an antiserum[36]. Positions having functional groups in their immediate vicinity, *e.g.* rings A and D in steroids, should not be changed on conjugate formation.

Animals suitable for immunization are rabbits, as well as guinea pigs, sheep, and goats. In general several animals are immunized simultaneously, the amount of immunogen (antigen) or hapten conjugate depending on the substance and the animal. The substance and the animal also determine the kind of injection (*e.g.* intravenous, subcutaneous, intramuscular), the additives (complete or incomplete Freund's adjuvant), and the time intervals between boosters[37, 38].

Between two injections, serum must be taken and examined to establish whether antibodies have already been formed and if so what quality they have. Since antibodies are even degraded at different rates during immunization the ideal time for bleeding the animals can only be established by constant surveillance. The sera taken from the animals can be used directly without special treatment after corresponding dilution.

The most important criteria for assessment and choice of an antiserum for radioimmunoassay are titer and specificity. By convention, the titer is that antiserum dilution at which 50 % of the offered tracer are bound under standard conditions. Figure 3 shows a dilution curve for an anti-T3 serum obtained by immunization of a rabbit with T3-BSA conjugate (3,3',5-triiodothyronine bovine serum albumin).

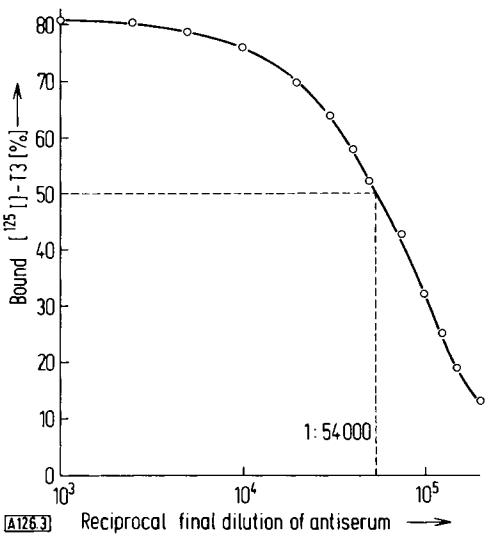

Fig. 3. Antiserum dilution curve for assessing the working concentration (titer) for 50 % binding of tracer.

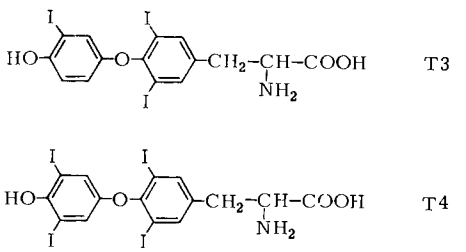

Although the antigen-antibody reaction is exceptionally specific, interference by extraneous molecules must always be reckoned with. These cross reactions are due to molecules of similar structure or those that are closely related. Thus an antibody generated by growth hormone (GH, peptide chain with 190 amino acids) also reacts with placenta lactogen (PL, peptide chain with 191 amino acids), or anti-T3 serum also with the thyroid hormone thyroxine (T4) (Fig. 4).

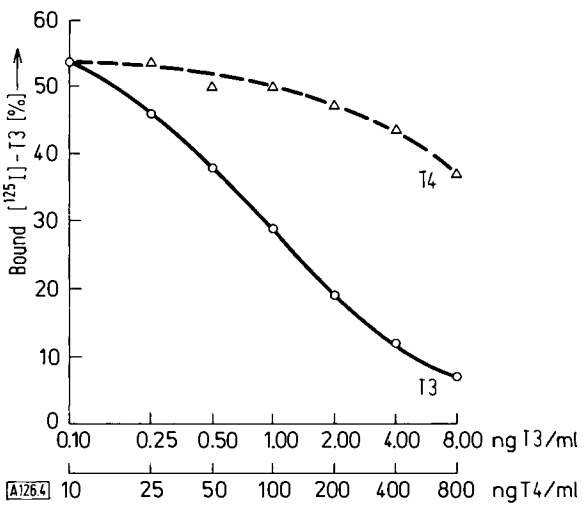

Fig. 4. Determination of specificity of an antibody. Cross reaction of an anti-T3 serum *versus* the structurally related thyroid hormone thyroxine (T4).

To what extent cross reactions can be neglected must be decided from case to case, and is also determined by the

physiological concentration. In the healthy body the thyroid hormones T3 and T4 are present in the ratio 1:50 to 1:100; hence a cross reaction of anti-T3 serum with T4 of only 1% would suffice to seriously falsify a T3 determination. Only an antibody exhibiting an extremely slight cross reaction with T4 (<0.1 %) will give accurate values for T3, as shown by Figure 4.

Antisera can be stored either undiluted or diluted with buffer and frozen to −20°C. To avoid repeated thawing and freezing, the valuable antiserum should be divided up into small portions just sufficient for a series of samples. They become particularly suitable for storage if lyophilized in a dilution suitable for performing the assay. Storage of such preparations is feasible at 2 to 8°C and they remain active for a considerable time.

5. Methods of Separating Antibody-Bound and Free Antigen

After equilibration of the incubation mixture of the reactants Ag, Ag* and Ab, *i.e.* after extensive saturation of the antibody, it remains to establish what percentage of the added radioactive compound has been complexed. This is accomplished by isolating the antibody-bound portion (B) from the free, unbound antigen (F) (see Section 2). It is in the method and execution of this separatory step that the greatest differences are found between the radioimmunoassays so far reported. This is manifested in a whole variety of separation methods, of which the most important are listed in the order of their efficacy in Table 3.

Table 3. Methods and materials for the separation of antibody-bound and free antigen.

Separating action	Method/Material
Partition of the components due to their different mobility and molecular size	Chromatography Electrophoresis Gel filtration Ultracentrifugation
Precipitation of the Ag·Ab complex	Ammonium sulfate Sodium hydrogen sulfite Zirconyl phosphate Ethanol 2-Propanol Dioxane Polyethylene glycol (PEG)
Adsorption of the antigen	Charcoal (also bound to dextran or albumin) Cellulose Silicates Ion-exchange resins
Binding of the antibody to a solid phase	Antibody chemically bound to polymer carrier (ASP) Coated tubes or beads
Immunological complex formation with a second antibody	Double antibody method (DA) Second antibody chemically bound, *e.g.* to activated cellulose (Immunosorbent, DASP)

Separation mainly exploits the properties of the complex, which however show extensive agreement with those of the antibody. Thus the antigen-antibody complexes can very readily be separated from unbound antigen on the basis of molecular size or limited solubility at certain pH values, by way of differing migration rates, by denaturation and precipitation with salt solutions or with organic liquids. Separation could also utilize a further subsequent immunological reaction, in which a second antibody directed against the first antibody, and hence also against the antigen-antibody complex, forms a much larger high-molecular complex. Methods are steadily gaining ground in which the second antibody and in some cases even the first antibody is physically or chemically bound to a solid phase.

A comparative study of the separatory methods is difficult, and it must usually be left to the judgment of the user as to which one of several methods he prefers.

It is essential that two conditions be fulfilled when choosing a method or testing a new separating agent:

1) The separating agent should not interfere with the equilibrium state of the completed reaction, *i.e.* the antigen-antibody complexes must be preserved during the separation.

2) The antibody-bound molecules and the free unbound molecules must be quantitatively separated from one another.

In order to meet both requirements, the separating agent and the separating reaction must both be highly specific. The resting state of the immunological equilibrium or saturation reaction should not be affected, even after prolonged action or reaction times or at various temperatures. The most suitable reagents are therefore those which do not undergo non-specific binding with the radioactively labeled compound and thus cannot cause an undesired co-precipitation. Moreover, the two phases should be separable from each other reliably, fast, simply, and without any great experimental effort. Apart from the above effects, other factors such as composition and concentration of the buffer, the pH values, addition of albumin, and the make-up of the serum also play a role. All these factors require careful testing, particularly with regard to the amount of separating reagent and reaction time.

A frequently employed separation method is shown schematically in Figure 5 (see also Table 3). Apart from the known protein precipitants such as ethanol, 2-propanol, ammonium sulfate solution, and more recently polyethylene glycol, importance also attaches to adsorption agents in which the separatory action arises from adsorption of the free antigen. Among the latter, charcoal and charcoal bound to supports have been widely used because of their great adsorption potency; however, they often exhibit the undesired effect of releasing the antigen from the complex and adsorbing it. On use of charcoal suspensions these effects must be minimized by working at low temperature (4°C) and short reaction times of equal duration.

In the double antibody technique the antigen-antibody complex is completely precipitated by an addition of a second antibody directed against the first antibody. However, this method is often critical, requires centrifuges having high *g* number, and some degree of practice. More reliable and easier to perform in practice is the method in which the second antibody is covalently bound to a solid phase, *e.g.* to cellulose[39]. These immunosorbents are highly stable and can be used against all antibodies of a particular animal species. They are added to the reaction mixture as a suspension, give readily visible precipitates, and are characterized by extremely low nonspecific binding.

Another method that is simple in operation is carried out in polystyrene test tubes whose walls are coated with antibody; alternatively the coating may be applied to small plastic spheres or discs. Separation is then accomplished simply by

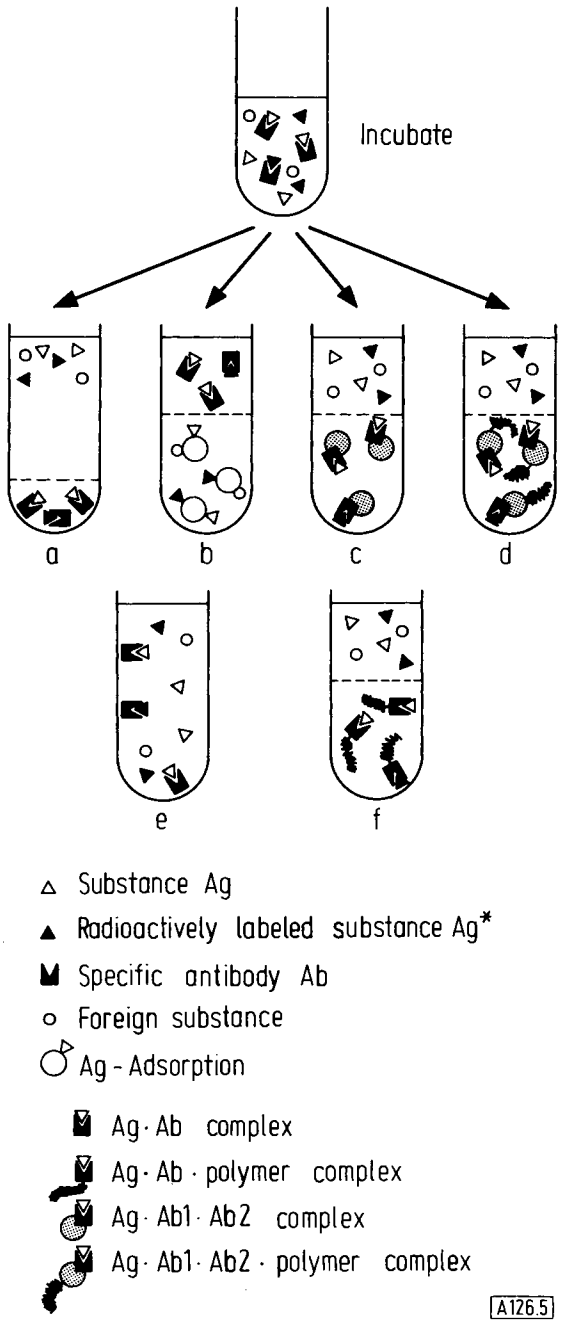

Fig. 5. Schematic representation of the separatory action in radioimmunoassay for the determination of antibody-bound and free substance. a) protein precipitation; b) adsorption agent; c) double antibody (DA); d) immunosorbent (DASP); e) antibody adsorptively bound to the surface; f) antibody chemically bound to polymer.

pouring out the reaction mixture. However, the coatings require large amounts and high concentrations of valuable antiserum, and difficulties are sometimes encountered in ensuring uniform quality. Finally, some radioimmunoassays are known in which the first antibody is already chemically bound to activated polymers, thus permitting direct separation of free and bound substance on completion of the reaction.

In all separating operations, intimate mixing of separating reagent with the incubated reaction mixture and completion of the reaction, which can take minutes or hours, is followed by centrifugation and separation of supernatant from residue. The final operation consists in monitoring the radioactivity of one of the two phases—sediment or supernatant.

6. Execution of Measurement and Evaluation of Results

So far all radioimmunological determinations require plotting of a calibration curve. Furthermore, it is also necessary to include a sample of known content as a check, *e.g.* when determining a hormone in serum.

On execution of a radioimmunoassay exactly equal volumes—generally 100 µl—of the standard solutions of various concentration and of the samples are pipetted into test tubes of *ca.* 2 to 4 ml capacity. The test tubes are usually made of polystyrene or polypropylene and are only used once. To each run are then added exactly equal amounts, *e.g.* 100 or 200 µl, of a solution containing radioactively labeled substance and the dilute antibody solution. Adsorption of reaction components on the walls of the test tubes, and consequent spurious results, are avoided by buffering all solutions and frequently also by addition of albumin as carrier protein.

In general, all determinations are performed in duplicate and sometimes, especially when plotting the calibration curve, even in triplicate. Use of metering pumps, dilution equipment (dilutors, dispensers), and automated pipetting apparatus permits rationalization of most experimental steps. Recent years have seen the development of partly and fully automated analytical systems for routine determinations, which are especially suitable for radioimmunoassays utilizing the same separation technique, *e.g.* the double antibody method or gel filtration[40, 41].

The test tubes have to be incubated for several hours to several days under the most favorable reaction conditions, which have to be determined on working out an assay. Subsequently the free species must be separated from the antibody-bound substance and the reactivity of one of the phases recorded in a "γ-counter" or in the case of ^{3}H-labeled compounds in a liquid scintillation counter. These experimental values permit plotting of the calibration curve and thence the determination of the sample.

Depending upon the kind of plot, the calibration curves have different forms (straight line, hyperbola, sigmoid). For example, the number of counts recorded, the percentage of absolute or of relative binding can be plotted against the concentration or the logarithm of the concentration. Apart from manual methods, mechanical techniques are also suitable for evaluation, of which the logit-log transformation, where the curve is more or less linearized and particularly smoothing by a spline function[42, 43] have proved of value. Which of the numerous methods is employed for evaluation will depend upon the individual radioimmunoassay, and also on the number of samples to be evaluated. However, it is always necessary to plot a calibration curve, even on mechanical evaluation, and to subject its shape to critical scrutiny.

In order to ensure reliability of the results obtained, and thus to guarantee the quality of a radioimmunoassay it is necessary to know a number of characteristic data. These include the specificity and sensitivity, and above all the accuracy, reproducibility, and precision of an assay.

As already mentioned, the specificity of a radioimmunoassay is essentially determined by the antibody. It can be impaired by cross reactions with similar substances and fragments thereof, and also by the separating step. Serum factors, pH value, additives such as albumin, buffer, heparin, or preservatives can also lower the specificity.

Another criterion for assessing a radioimmunoassay is its sensitivity. This signifies the lowest concentration that can be significantly detected. The sensitivity depends upon the specificity of the antibody and is the higher the greater the specific radioactivity of the tracer or the less there is of it in the experimental run. The sensitivity can be regarded as the special case of the accuracy at zero concentration. In practice, the lower detection limit can be established, *e.g.* by subtracting the 3s deviation of the scattering from the initial binding value and reading off the relevant concentration from the calibration curve. The sensitivity of assays in which the immunological reaction is irreversible or measurement is performed at non-equilibrium can occasionally be raised by delayed addition of the radioactively labeled substance ("cold" pre-incubation)[44].

The accuracy attainable in a determination depends upon three errors of various magnitudes. Apart from experimental errors arising in several pipetting steps and interference of the reaction (*e.g.* varying degree of wall adsorption), errors also occur in measuring the radioactivity (*inter alia* statistical error of radioactive decay) and on evaluation of the various samples. Owing to the different nature of these errors, it is clear that the accuracy cannot be the same in each portion of the curve. However, multiple determinations and long counting times can do much to reduce random errors and thus lead to a more accurate result.

A further criterion of quality is reproducibility. Duplicate or multiple determinations on samples of an assay and the resulting deviations from the average value yield the intra-assay reproducibility. It normally lies below 5%. The inter-assay reproducibility is the coefficient of variation obtained on determination of the same sample in several different assay runs using different reagents. Its value lies below 10% for accurate and reproducible radioimmunoassays[45].

It is particularly difficult to assess whether the value found by radioimmunology is the precise value, *i.e.* identical with the unknown true value. In this context it should be pointed out that only the amount of immunologically active substance can be determined. This is not necessarily identical with the amount of biologically active substance. Comparison of normal and abnormal values from various laboratories is feasible only after adjusting one's own standard to an international reference standard[46].

Checks on precision are also possible with test sera determined at various dilutions and recovery measurements in which a known amount of substance is added to a sample. Determination of the sample with and without added substance will reveal whether sample effects falsify the result.

7. Radioassay and Immunoradiometric Assay

Radioassays and variants of immunoradiometric assay (IRMA)[47] are techniques closely related to radioimmunoassay. In radioassay a carrier or transport protein already present in the organism serves as binding partner instead of an antibody. Two radioassays used in thyroid diagnosis, in which thyroxine-binding globulin (TBG) serves as binding reagent, possess immense practical importance.

After secretion by the thyroid the two hormones thyroxine (T4) and triiodothyronine (T3) (see Section 4) are bound almost completely by serum proteins, especially TBG. Thus the TBG binding capacity which can be determined with the radioactive indicator [^{125}I]-T3, provides an indirect measure of thyroid activity. Just as in radioimmunoassay, the bound [^{125}I]-T3 must be isolated and monitored after saturation of the free binding sites. Determination of T4 is based on the fact that it can displace [^{125}I]-T4 from a labeled [^{125}I]-T4-TBG complex to an extent depending upon its concentration. After equilibration, the liberated [^{125}I]-T4 is separated from the complex, *e.g.* with an ion exchanger, and its radioactivity monitored.

$$Ag + Ab^* \rightleftharpoons Ab^* \cdot Ag$$
$$Ab^* + Ag\text{-polymer} \rightleftharpoons Ab^* \cdot Ag\text{-polymer}$$

In contrast to radioimmunoassay, in the immunoradiometric assay it is the antibody and not the antigen which is radioactively tagged and added in excess to the test run. Because of this excess, all antigen molecules are bound by antibodies at the conclusion of reaction, and it is necessary to separate antigen-antibody complex and excess antibody. Apart from a series of advantages, such as greater stability of the iodinated antibody as compared to the labeled antigen, high attainable specific radioactivity (without loss of immunoreactivity) and the high sensitivity in assays for high-molecular compounds, the method also has some drawbacks. Thus the slight difference in size between antibody and antigen-antibody complex often makes separation difficult. It is therefore carried out with an immunosorbent in which the antigen is bound to a polymeric carrier. The antibodies must also be bound to this immunosorbent during iodination, and then released again. These steps are usually accompanied by losses, so that relatively large amounts of the valuable antiserum are required.

If the antigen can bind to two antibody molecules then the sandwich technique (two-site assay) can be implemented. The antigen to be determined is initially allowed to react with an immobilized antibody, the resulting complex washed, and then incubated with the radioactively labeled antibody in a second reaction. This procedure affords a labeled antibody*-antigen-antibody-polymer complex.

The hepatitis B virus antigen (HB·Ag) assay on human serum, one of the commonest immunoradiometric determinations performed, is based on this sandwich technique.

8. Summary

In recent years radioimmunological techniques have greatly improved our understanding of endocrine physiology. These methods are superior to most other analytical procedures, both in diagnosis and in surveillance of therapy, with regard to sensitivity, specificity, general applicability, and experimental simplicity. Routine applications of radioimmunoassay extend beyond biochemistry and clinical chemistry into microbiology, toxicology, and virology, as well as studies on drug metabolism. Applications in early diagnosis of cancer and in monitoring of tumor diseases after therapeutic measures can also be envisaged.

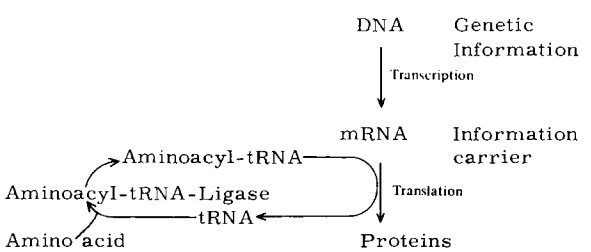
Chemical Methods of Studying Ribosome Structure

By Ernst Küchler[*]

The use of chemical methods, and in particular affinity labeling, has greatly advanced our knowledge about the structure of the active sites of ribosomes. Experiments have shown that ribosomal proteins and ribosomal ribonucleic acids participate in the structure of the binding sites for messenger ribonucleic acid and transfer ribonucleic acid.

1. Introduction

The genetic information of a living cell is recorded in a long filamentous molecule, deoxyribonucleic acid (DNA). DNA does not directly participate in cellular processes, but merely stores information. In order to find expression the genetic information must first be transcribed into a ribonucleic acid (RNA). Because of its information-carrying function this RNA is called messenger RNA (mRNA).



Apart from mRNA, the cell also contains transfer ribonucleic acids (tRNA) and ribosomal ribonucleic acids (rRNA), which have other functions. The nucleotide sequence of mRNA is translated into the amino acid sequence of proteins on the ribosomes. Each group of three consecutive nucleotides is read as the signal for incorporation of a particular amino acid; this sequence of three nucleotides is termed a codon. The key molecules for translation are tRNAs, there being one or more tRNA species for each amino acid occurring in proteins. Binding of the amino acid to the tRNAs is effected by specific enzymes, the amino acyl tRNA ligases; on addition of the amino acid to the protein chain the amino acyl tRNA is "discharged" and can then be amino acylated afresh.

The nucleotide sequence of a codon in the mRNA is recognized by the tRNA by interaction with a nucleotide sequence known as the anticodon. The interactions between codon and anticodon arise by base pairing between the complementary nucleotides (nucleoside monophosphates) adenylic (AMP) and uridylic acid (UMP), and guanylic (GMP) and cytidylic acid (CMP).

tRNAs have chain lengths of 75 to 80 nucleotides. Apart from AMP, CMP, GMP, and UMP (only the nucleosides

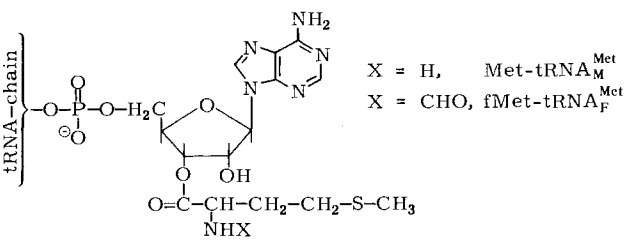
The nucleotide sequence of the tRNA determines its specificity. However, some nucleotide sequences are common to all tRNAs; thus, all tRNAs contain the sequence TΨC at the same position in the polynucleotide chain. Furthermore, the sequence –CCA is always found at the 3′ end of tRNAs. In the amino acyl tRNA the amino acid is linked *via* an ester bond with the ribose of this terminal adenosine. The amino group of the amino acid is therefore free and can be linked *via* a peptide bond to the growing protein chain on the ribosome.



X = H, Met-tRNA$_M^{Met}$
X = CHO, fMet-tRNA$_F^{Met}$

The tRNAs specific for methionine represent a special case. In addition to methionyl tRNA (Met-tRNA$_M^{Met}$) there is also a formylmethionyl tRNA (fMet-tRNA$_F^{Met}$), in which the amino group is "blocked" by a formyl group. This tRNA serves as initiator tRNA. The biosynthesis of all bacterial proteins thus begins when a formylmethionyl group becomes available as the N-terminus of the protein. This formylmethionyl group is removed at a later stage. Specific initiation and termination codons serve as "start" and "stop" signals. The individual steps of the translation of mRNA have received detailed consideration in an earlier review[1] and will therefore be considered only insofar as is necessary for an understanding of ribosome topography.

Ribosomes are cell organelles composed of two subunits, each consisting of rRNA (ribosomal RNA) and proteins. The subunits and the rRNA species are named according to their sedimentation constants. The 30S subunit of the bacterial ribosome having a particle weight of 900000 daltons (D) contains a 16S RNA (550000 D) together with a total of 21 different proteins. The proteins are designated S1 to S21 (S = small subunit)[2]. A more complex composition is found in the 50S subunit. It contains two RNA species, 23S RNA (1100000 D) and 5S RNA (40000 D), and no fewer than 34 different proteins, designated L1 to L34 (L = large subunit)[2]. The complete bacterial ribosome (70S) possesses a particle weight of 2650000 D. Ribosomes from the cells of higher organisms are considerably larger; their particle weights are 4000000 D. However, present-day knowledge appears to indicate that their structures are very similar. In this article we shall restrict our attention to bacterial ribosomes, taking the bacterium *Escherichia coli* as example.

The reason for the size and complexity of ribosomes is probably to be seen in the numerous catalytic functions and events which occur on these organelles with participation of ribosomal components and reversibly bound factors.

Initiation of translation of the mRNA nucleotide sequence into the amino acid sequence of the protein involves not only the fMet-tRNA functioning as initiator but also three initiation factors (IF1, IF2, IF3)[3]. The trinucleotide sequences AUG and GUG serve as initiation codons. To the 30S subunit, containing fMet-tRNA$_F^{Met}$, guanosine triphosphate (GTP), mRNA, and the initiation functions IF1 and IF2, is added the 50S subunit, whereupon the initiation factors are released with concomitant hydrolysis of GTP to guanosine diphosphate (GDP) and phosphate (P_i) (Fig. 1)[4–6].

Following initiation, the amino acyl tRNA (generally: AA-tRNA) corresponding to the next codon will be bound. This involves interaction between the anticodon of the tRNA and the codon of the mRNA, on the one hand, and between the TΨC sequence of the tRNA with a complementary GAA sequence of the ribosomal 50S RNA[7], on the other. The process is catalyzed by the elongation factor EF-Tu, and is accompanied by hydrolysis of a further GTP molecule. The ribosome accordingly possesses binding sites for two molecules of tRNA (see Fig. 1), which are called donor and acceptor site (the term "peptidyl site" is also used synonymously with "donor site"; we prefer the former designation, however, as a more fitting description of its function in peptide elongation).

On formation of the first peptide bond, the formylmethionyl group is transferred from the fMet-tRNA$_F^{Met}$ located at the donor site to the amino acyl tRNA (AA-tRNA) in the acceptor site. A dipeptidyl-tRNA is formed, the reaction being catalyzed by the ribosome itself. The corresponding enzymatic activity—known as peptidyl transferase—is located in the 50S subunit[8]. Before undergoing further elongation the resulting dipeptidyl-tRNA must first be transferred from the acceptor site to the donor site, in order to vacate the acceptor site ready for the next amino acyl tRNA. This process, in which the mRNA also shifts by the length of a codon relative to

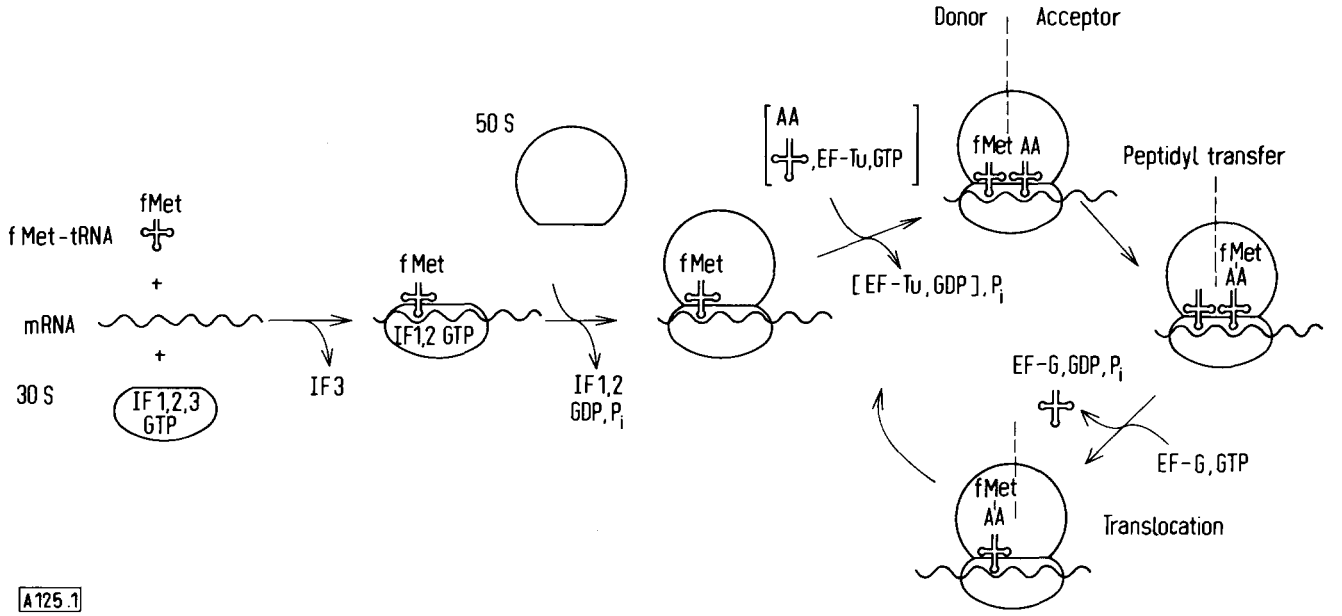


Fig. 1. Scheme of initiation and translation in protein biosynthesis. See text for explanations of abbreviations.

the ribosome, is called translocation. The participating elongation factor EF-G is released after translocation and GTP hydrolysis (see Fig. 1). The ribosome can now bind the amino acyl tRNA corresponding to the next codon with the aid of EF-Tu and GTP to the acceptor site and then repeat the entire cycle again and again until a termination codon appears in the mRNA. The binding sites for EF-Tu and EF-G on the ribosome partially overlap, thus precluding simultaneous attachment of the two factors[9].

The antibiotic puromycin acts as an analog of amino acyl tRNAs[1]. It is bound to the acceptor site and can react with fMet-tRNA$_F^{Met}$ or a peptidyl tRNA located at the donor site to form a peptide bond. The resulting puromycin derivative is released from the ribosome; hence, puromycin effects an artificial termination.

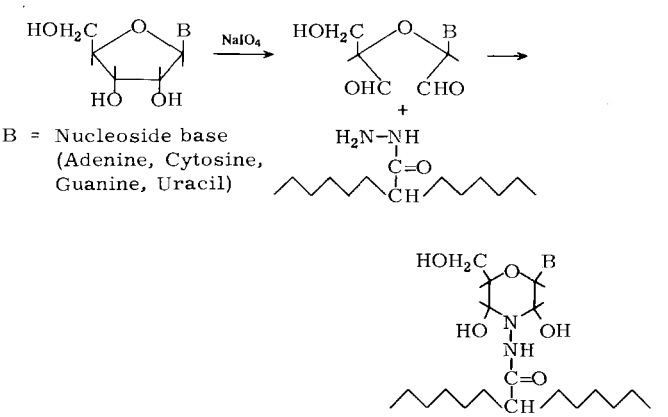
The termination codons UAG, UAA, or UGA could be recognized by the ribosome itself[10] or by the termination factors R 1 and R 2[11]. Chain termination presumably occurs by transfer of the peptide chain to H_2O with the aid of peptidyl transferase[12].

Accordingly, the ribosome must possess binding sites not only specific for tRNA and mRNA, but also for initiation, elongation, and termination factors. Moreover, it must also provide a hydrophobic environment which prevents abortive transfer of the peptide chain to H_2O as a side reaction during transpeptidation on the one hand and enhances interactions between the nucleotides by exclusion of water on the other.

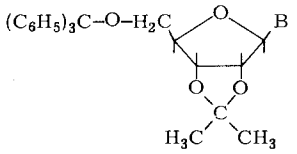
2. Base Pairing between Complementary Nucleosides in Aqueous and Nonaqueous Media

Attempts to directly demonstrate interactions between complementary nucleotide bases in aqueous solutions date back to the initial studies on DNA structure by *Watson* and *Crick*[13]. They long remained unsuccessful because in the absence of the base stacking occurring in the polymers, and as a result of competition of the H_2O molecules in hydrogen bonding, the interactions are so weak that they cannot be detected by conventional physicochemical methods.

In biological systems—such as on biosynthesis of DNA, RNA, and protein—the interactions between nucleotides or short nucleotide sequences probably always take place with partial exclusion of water in the "hydrophobic pockets" of the proteins. Such conditions can be simulated for physicochemical studies by covalent binding of a base to an insoluble carrier material or by use of solvents having low dielectric constants. Base pairing could be detected in both cases.



In order to perform affinity chromatography in an aqueous buffer system, nucleosides were oxidized by periodate to dialdehydes which were covalently bound to the hydrazide groups of an insoluble support material. Mixtures of nucleosides in aqueous buffer were chromatographed over these "nucleoside columns". It was found that uridine is retarded relative to cytidine on "adenosine columns", whereas cytidine is retained more than uridine on "guanosine columns"[14,15]. The same result is obtained on chromatography of the deoxynucleosides thymidine and deoxycytidine, thus showing that the observed effects are attributable to specific interactions between the complementary bases adenine and uracil (or thymine) and between guanine and cytosine. This finding is substantiated by the disappearance of these interactions on replacement of the H atoms participating in hydrogen bonding by methyl groups[16].



B = Nucleoside base (Adenine or Uracil)

Base pairing *via* hydrogen bonds can be observed particularly readily by IR spectroscopy[17]. 2',3',*O*-Isopropylidene-5'-*O*-trityl derivatives of nucleosides in which all OH groups of ribose are substituted dissolve in organic solvents. Since the IR bands of free H atoms and those involved in hydrogen bonding differ, it is possible to determine the binding constants for base pairing. We have established that in CCl_4 the adenosine and the uridine derivative are associated in the ratio 1:1. The tendency of the nucleoside derivative to engage in self-association is much weaker. Various association constants are listed in Table 1. It may be seen that the adenine-uracil base pair is about six times more stable than are the uracil-uracil and adenine-adenine pairs. These findings accord with the results of other authors[18].

Table 1. Association of the 2',3'-*O*-isopropylidene-5'-*O*-trityl derivatives of adenosine and uridine in CCl_4 at 20°C.

Mode of association of derivatives	K_{Ass} [liter/mol]
Uridine-Uridine	1.1×10^2
Adenosine-Adenosine	0.83×10^2
Adenosine-Uridine	5.9×10^2

Of course, such data cannot be applied directly to the bonding between nucleotides in the "hydrophobic pocket" of a protein. Above all there are no steric constraints in solution so that base pairings become possible which just do not occur in double stranded nucleic acids. Such studies nevertheless demonstrate that nucleoside interactions are intensified by a hydrophobic environment. Applied to protein biosynthesis this means that the precision of translation of the mRNA nucleotide sequence into the amino acid sequence can be enhanced by an apolar environment at the site of codon-anticodon interaction. It may therefore be expected that nucleotide interactions due to base pairing will not take place on the hydrated surface of the ribosome but in its interior in a hydrophobic environment.

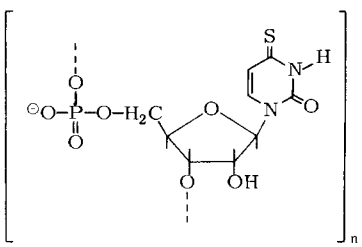
3. Binding of mRNA to the Ribosome. Affinity Labeling

mRNA is bound primarily to the 30S subunit. Several studies have established some connection between the ribosomal protein S1 from this subunit and binding of mRNA. This protein is required for binding of polyuridylic acid [Poly(U)] to ribosomes[19], and conversely Poly(U) protects the protein against degradation by proteases[20]. Poly(U) acts as mRNA and is translated into the protein polyphenylalanine. The protein S1, which can also bind poly(U) in the isolated state[21], is present in only 10 to 30% of ribosomes purified by conventional methods[22]. However, if polysomes are isolated in which all ribosomes are "translationally active", then one molecule of protein S1 is found per ribosome[23]. Protein S1 is necessary for the translation of artificial and natural mRNA[24].

All these findings reveal nothing about which components of the ribosome are actually in the immediate vicinity of the mRNA. We have employed the technique of photoaffinity labeling to identify these components. Affinity labeling provides a means of specifically substituting the active site of an enzyme or a comparable molecule and thus permits its recognition. The biological molecule to be labeled is reacted with a compound Sub-X; Sub is a substrate-like group (or part of a substrate) and X is a reactive group. Owing to the substrate-similarity of Sub, Sub-X is bound to the active center and X (or Sub) can only react with the amino acid chains present there. The aim is to label this side chain with covalently bound X (or Sub) (see Section 6).

In photoaffinity labeling, a substance resembling the natural substrate is bound which reacts with its surroundings on irradiation. Its advantage over conventional affinity labeling is that the duration of reaction between the substrate analog and its environment is precisely defined by the irradiation time.

In our studies we irradiated an analog of Poly(U), poly-4-thiouridylic acid [Poly(s^4U)], in the presence of ribosomes. The naturally occurring 4-thiouracil is one of the "rare bases" in tRNA. On irradiation with 330-nm light the bond between C and S is activated, the S atom oxidized, and the C—S



Poly-4-thiouridylic acid

Poly (s^4U)

bond ruptured by nucleophilic substitution[25]. In the product, side chains of the ribosomal proteins are covalently bonded with the pyrimidine ring. Aliphatic amino groups, *e.g.* the ε-amino group of lysine, can react as nucleophilic groups. Lysine is one of the commonest amino acids in ribosomal proteins[26]. This reaction had already been employed by *Frischauf* and *Scheit* in their studies on DNA-dependent RNA polymerase[27].

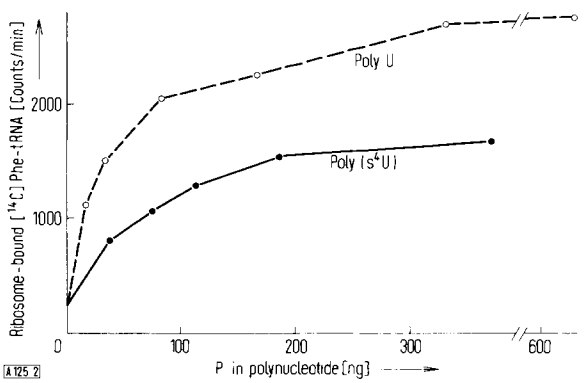


Fig. 2. Binding of [^{14}C]Phe-tRNA to ribosomes in the presence of various amounts of Poly(U) and Poly(s^4U). The [^{14}C]Phe-tRNA was determined by *Leder*'s method [81].

Poly(s^4U), prepared by enzymatic polymerization of 4-thiouridine diphosphate with polynucleotide phosphorylase[28], codes—as shown in Figure 2—like Poly(U) for the binding of phenylalanyl tRNA (Phe-tRNA) to ribosomes and

stimulates the synthesis of polyphenylalanine in the protein-synthesizing system *in vitro*[29]. If complexes of Poly(s^4U), ribosomes, and Phe-tRNA are irradiated with 330-nm light, then polyphenylalanine synthesis is inhibited[30]. Control experiments show that complexes containing Poly(U) instead of Poly(s^4U) as mRNA still synthesize polyphenylalanine in the *in vitro* system after irradiation, indicating that the ribosomes themselves are not inactivated by UV light.

To identify the ribosomal components participating in binding of mRNA, ribosomes incubated with [^{3}H]Poly(s^4U) and Phe-tRNA are irradiated. After digestion of the ribonucleic acids with ribonucleases A and T1 the protein fraction was obtained from the isolated 30S subunits. Electrophoresis on polyacrylamide gels in sodium dodecyl sulfate[31] furnishes a radioactively labeled ribonucleoprotein having a molecular weight of 110000 to 130000 D. Since the molecular weight of the largest ribosomal protein (S1) is only 65000 D it was assumed that the ribonucleoprotein contains several proteins. They were identified by alkaline hydrolysis followed by gel electrophoresis. Most of the radioactivity was found in the protein S1[30]. In addition, radioactivity also appeared in proteins of lower molecular weight. This shows that Poly(s^4U) had reacted with protein S1 and some other proteins. The electrophoretic assignment is confirmed by immunological studies. In this way we could identify the proteins S18 and S21, as well as S1, as components of the ribonucleoprotein complex[32]. Other chemical methods showed that the proteins S1, S18, and S21 are adjacent in the ribosome[33,34]. Identification of the proteins S18 and S21 as components of the mRNA binding site was confirmed by affinity labeling with a derivative of the initiation codon AUG[35].

4. Recognition of the Initiation Site

Apart from the codon AUG or GUG, initiation of protein synthesis requires an additional initiation signal, for AUG codes not only for formylmethionine (fMet) on initiation but also for methionine within the polypeptide chain. Moreover,

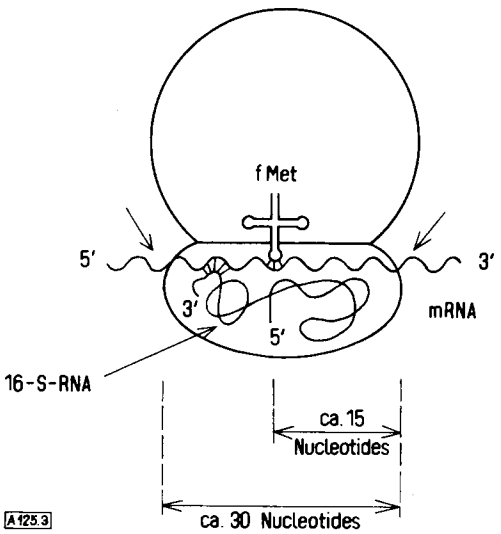

Fig. 3. Scheme for the recognition of the initiation site by the ribosome according to *Shine* and *Dalgarno* [10]. Formation of the initiation complex involves base pairing between a nucleotide sequence at the 3' end of the 16S RNA and a complementary sequence in the mRNA. Furthermore, the initiation codon and the complementary anticodon in fMet-tRNA$_F^{Met}$ also undergo mutual interaction. Since the ribosome protects the bound portion of the mRNA against degradation by ribonuclease, the initiation site of the mRNA can be isolated by treatment with ribonuclease (see Table 2). The arrows indicate the positions of the mRNA up to which ribonuclease cleavage occurs.

Table 2. Complementarity between nucleotide sequences at the 3' end of the 16S RNA from *E. coli* (above) and ribosomal binding sites for natural mRNAs (below). Complementary sequences are underlined. Since the G—C pair is more stable than the A—U pair, the sequences were arranged in such a manner that G—C pairs are preferred. The beginning of the sequence coding for the protein structure is printed in *italics*. The arrows denote those sites in the mRNA ribosome complex at which the mRNA is cleaved by ribonuclease T1 (RNase T1) or ribonuclease A (RNase A). Ribonuclease T1 always attacks after guanine, and ribonuclease A always after pyrimidines (uracil or cytosine).

[a] Two sequences are known for the ribosomal binding site of the mRNA for the R17 coat protein, which differ in one nucleotide (G or A [37, 39]). Replacement of G by A occurs by way of a spontaneous mutation.

whenever a codon ends with A or G and the next codon begins with UG no initiation should occur outside the "reading frame" since it would lead to a protein of no use to the cell.

This initiation signal can only be contained in the nucleotide sequence of the mRNA. In principle, recognition of a sequence in mRNA could arise by interaction with a ribosomal protein or by base pairing with a ribosomal RNA as in codon-anticodon interaction. According to a hypothesis of *Shine* and *Dalgarno*[10] (Fig. 3) the ribosome recognizes the initiation site by base pairing between the nucleotide sequence at the 3′ end of the 16S RNA of the ribosomal 30S subunit and a complementary sequence lying in the vicinity of the initiation triplet. This is illustrated for several examples in Table 2. In the first row the nucleotide sequence of the 3′ end of the 16S RNA is given: the nucleotides responsible for recognition are underlined. They include some nucleotide sequences of the initiation sites of various natural mRNAs. The nucleotides forming the initiation signal are likewise underlined. The sequences are so arranged in the Table that complementary nucleotides appear vertically one below the other. The beginning of the nucleotide sequence coding for the protein is printed in italics. Thus it may be seen that the mRNA for the A protein of phage R17 (a virus attacking *Escherichia coli* and utilizing its translation system for growth) contains the sequence AGGAGGU shortly before the beginning of the information relevant to the structure of the A protein. This sequence is complementary to the UCCUCCA sequence in the 16S RNA and can be bound to it by base pairing.

....U C C U C C A....   16-S-RNA
     ‖ ‖‖ ‖ ‖‖ ‖‖ ‖
....A G G A G G U....   R17-A-Protein
```

The other examples in Table 2 demonstrate that this scheme also applies to the initiation sites of other mRNAs, complementarity always obtaining between the initiation signal and nucleotides at the 3′ end of the 16S RNA. The length of the complementary sequence is seven base pairs in the case of the mRNA corresponding to the A protein of R17 phage, and four to five base pairs for the other examples cited. Experimental verification of this hypothesis has recently been reported by *Steitz* and *Jakes*[42]. The differing lengths of the complementary sequences and the associated variation in the affinity of the ribosome for the initiation sites could, together with the secondary structure of the mRNA, determine the frequency of initiation and thus that of translation.

As shown in Section 3, protein S1 is located in the mRNA binding site in the ribosome and, according to the results of other authors, is also bound to the 3′ end of the 16S RNA[43]. Short double-stranded regions of nucleic acids consisting of only four to five base pairs are very unstable in aqueous media, but could be stabilized by a hydrophobic environment (see Section 2). Thus it appears very likely that protein S1 stabilizes interactions between the 3′ end of the 16S RNA and the initiation sequence of the mRNA by acting as a "hydrophobic pocket", and thereby contributes to recognition of the initiation sites in the mRNA.

5. Codon-Anticodon Interaction on Initiation

The ribosomal site at which codon-anticodon interaction takes place (donor site, see Fig. 1) can most readily be located with the aid of the mRNA. Experiments with radioactive Poly(U) have shown that the ribosome protects a section of mRNA some 30 nucleotides long against degradation by ribonuclease A[44]. Using mRNAs of known sequence permitted determination of the distance between the donor site and the entering and leaving sites of mRNA on the ribosome. Since the direction of movement of the ribosome during translation is from the 5′ end to the 3′ end of the mRNA, the leaving and entering sites of the mRNA on the ribosome correspond respectively to the 5′ and 3′ end of the ribonuclease-resistant mRNA fragment (Figs. 1 and 3).

Comparison of the ribosomal binding sites for natural mRNAs in Table 2 reveals that cleavage by ribonucleases always occurs at or directly after the fifth codon of the sequence coding for the protein structure. (The exact position of cleavage will of course also depend upon the specificity of the ribonuclease since ribonuclease A only attacks after U and C, and ribonuclease T1 only after G.) This result was obtained both by nucleotide sequence determination[34-41], and by *in vitro* translation of the fragment of R17 coat protein gene obtained[45,46]. On the basis of these data it is possible to estimate the distances in the ribosome. The distance between two nucleotides in a polynucleotide is 3.4 Å in the stacked form, and 7 Å in the extended form[45]. Given 15 nucleotides between the donor site and the point of entry of mRNA in the ribosome, the distance corresponds to 50 to 100 Å. The diameter of the ribosome is about 200 Å. Assuming the overall length of polynucleotide enclosed in the ribosome to be about 30 nucleotides[44], then the donor site will lie approximately in the middle.

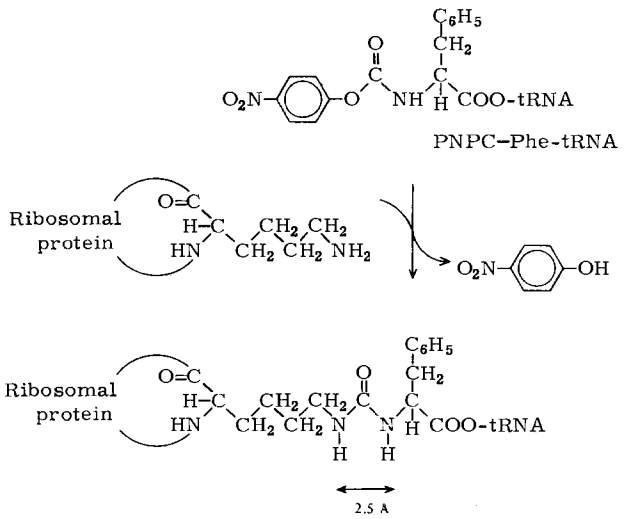
6. The Peptidyl Transferase Site

There are apparently two sites in amino acyl tRNA for interaction with the ribosome: the TΨC region which interacts with a complementary nucleotide sequence in the 5S RNA of the 50S subunit[7], and the amino acylated CCA terminus, which can even be bound by the 50S subunit in isolated form as an amino acylated oligonucleotide fragment[47]. The bound fragment can participate in the peptidyl transferase reaction, showing that it is bound to the correct site in the ribosome. We employ the expression peptidyl transferase center for this catalytic center of the ribosome, initially without distinguishing between the donor and acceptor site.

In order to identify the components of the peptidyl transferase center we resorted once more to the technique of affinity labeling (see Section 3). *Bruton* and *Hartley*[48] proposed the use of the *N*-(*p*-nitrophenoxycarbonyl) derivative of the amino acyl tRNA for affinity labeling of amino acyl tRNA ligases. The *p*-nitrophenoxycarbonyl group (PNPC group) contains an activated ester bond which can be cleaved by nucleophilic substitution, with *p*-nitrophenol acting as leaving group.

Once again the ε-amino group is the principal contender as nucleophilic reactant[49]. Reaction with amino groups of nucleoside bases is improbable owing to the low basicity of such groups.

For conversion into the reagent, Phe-tRNA bearing a [^{3}H]label in the phenylalanine group was treated with *p*-nitrophenyl chloroformate under conditions which only permit reaction at the amino group of the phenylalanyl residue. The resulting *N*-(*p*-nitrophenoxycarbonyl)-phenylalanyl-tRNA



was subsequently incubated with 20 mmol Mg^{2+} per liter and with ribosomes in the presence of Poly(U). After dissociation of the 70S ribosome and centrifugation the radioactivity was found exclusively in the 50S subunit. The radioactively labeled 50S subunits were denatured and the RNA degraded by treatment with ribonucleases A and T1.

The labeled proteins were identified by two-dimensional gel electrophoresis according to *Kaltschmidt* and *Wittmann*[2] and by immunological methods[50]. Most of the reactivity was found in protein L27, less in protein L15, and small amounts in proteins L2 and L16[51].

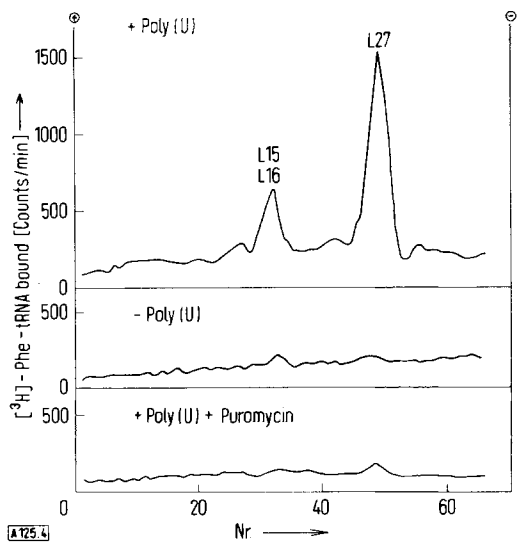


Fig. 4. Affinity labeling of the ribosomal peptidyl transferase site with PNPC-[^{3}H]Phe-tRNA. The reaction only occurs in the presence of Poly(U) and is inhibited by puromycin. The method of *Czernilofsky et al.* [51, 82] was adopted for incubation, for separation of the labeled proteins by one-dimensional polyacrylamide gel electrophoresis, and for identification of the proteins.

Figure 4 shows the results of one-dimensional electrophoresis of isolated L proteins. The radioactivity appears in two bands, corresponding essentially to proteins L15+L16, and L27. It is seen from this Figure that [^{3}H]Phe-tRNA is bound to ribosomal protein only in the presence of Poly(U). Binding of the tRNA derivative is inhibited by puromycin, which reacts with the amino acyl tRNA bound to the donor site to form amino acyl puromycin with release of the amino acid from the ribosome[1]. Thus it is demonstrated that the major proportion of the PNPC-Phe-tRNA reacts with the donor site of the ribosome, from which we deduce that the modified CCA terminus of the PNPC-Phe-tRNA enters into reaction with the peptidyl transferase center of the ribosome. However, since the *N*-acylated Phe-tRNA can be bound both to the donor and to the acceptor site, it cannot be ruled out that a slight amount of PNPC-Phe-tRNA has actually reacted with the acceptor site.

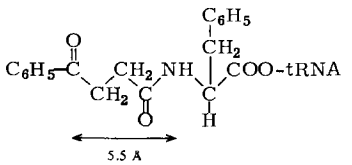
In order to distinguish between the proteins of the donor and the acceptor site we employed a system containing R17 RNA as mRNA together with purified initiation factors, GTP, and the PNPC derivative of the initiator tRNA Met-$tRNA_F^{Met}$ in the presence of 5 mmol of Mg^{2+} per liter. Under these conditions the initiator tRNA is bound exclusively to the donor site[52]. Since the specificity of binding is determined by the $tRNA_F^{Met}$ structure and the initiation factor IF2, we may expect that it is retained for the PNPC-Met-$tRNA_F^{Met}$ derivative. In the ribosomal complex, PNPC-[^{35}S]Met-$tRNA_F^{Met}$ reacts primarily with protein L27 and to a slight extent with protein L15[52]. The reaction was dependent upon the presence of initiation factors and R17 RNA. Hence proteins L27 and L15 are situated at the donor site.

Presumably the CCA ends of the two participating tRNAs come into close spatial proximity during the peptidyl transferase reaction. Since peptidyl transfer proceeds in only one direction, *i.e.* from the donor to the acceptor site, we have to assume that this directional dependence is a manifestation of structural differences between the binding sites for the CCA ends of the two tRNAs. Thus it appears most likely that different proteins are labeled on reaction at the donor and acceptor sites.

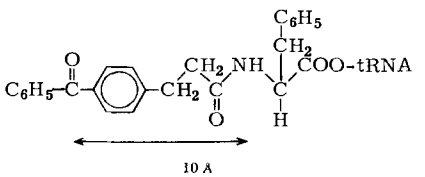
Other authors have used *N*-(bromoacetyl)amino acyl tRNA for affinity labeling, and labeled proteins L27 and L2 from the donor site[53, 54]. The labeling of L27 accords with our own results, but qualitative differences are apparent in the case of L2. Such deviations are to be expected, however, because the PNPC group reacts preferentially with amino groups[49], while bromoacetyl displays a proclivity for reaction with mercapto groups[53]. Protein L16 is the binding protein for the antibiotic chloramphenicol, as demonstrated by reconstitution experiments[55] and labeling studies with the analogous compound iodamphenicol[56]. Chloramphenicol is bound to the acceptor site, and protein L16 should therefore have been labeled from the acceptor site. This agrees with our findings: L16 is labeled only by PNPC-Phe-tRNA but not with PNPC-Met-$tRNA_F^{Met}$, which is specific for the donor site[51, 52]. The labeling of L16 is further enhanced if the conditions are chosen such that the bromoacetyl-Phe-tRNA binds preferentially to the acceptor site[57]. In these studies aromatic azides such as 4-(4-azido-2-nitrophenoxy)phenylacetyl and *N*-(4-azido-2-nitrophenyl)glycyl derivatives of amino acyl tRNAs substituted at the amino acyl NH_2 group were also used. After photoactivation a covalent bond was found at proteins L11 and L18[58]. Protein L11 has been considered as a candidate for peptidyl transferase[59–61]. Proteins L18 and L25 form a complex with 5S RNA which is bound to the 23S RNA *via* protein L5[62].

23S RNA appears to participate directly in the structure of the peptidyl transferase center. Pertinent evidence comes from photoaffinity labeling experiments with *N*-(diazomalonyl)-Phe-tRNA[63], with azido aryl derivatives such as *N*-(4-azido-2-nitrobenzoyl)-Phe-tRNA[64] and *p*-azido-*N*-(*tert*-

butoxycarbonyl)phenylalanyl-Phe-tRNA[65], and with arylcarbonyl derivatives such as 3-benzoylpropionyl-Phe-tRNA (BP-Phe-tRNA) and 3-(4-benzoylphenyl)propionyl-Phe-tRNA (BPP-Phe-tRNA)[66]. We have concerned ourselves with the last-named compound. The carbonyl groups are incorporated in the form of hydroxyl groups into the ribosomal protein to be labeled.

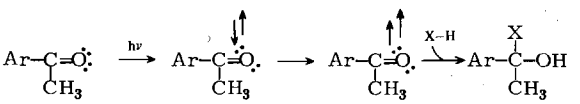


BP-Phe-tRNA



BPP-Phe-tRNA

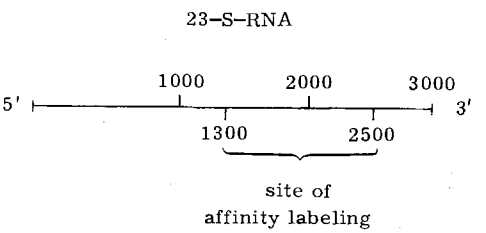
The carbonyl group of aromatic ketones can be excited into a triplet state by UV light of wavelength 320 nm. The excitation energy is *ca.* 70 kcal/mol, roughly corresponding to the dissociation energy of an easily broken C—H bond (dissociation energy for expulsion of a hydrogen atom from the methyl group of toluene: 77 kcal/mol), and is thus considerably lower than the energy required for dissociation of the O—H bond in water, *i.e.* 117.5 kcal/mol[67-69]. Aromatic ketones are therefore particularly suitable for photoaffinity labeling in aqueous systems because no losses can occur by reaction with H_2O. Arylcarbonyl derivatives of amino acyl tRNAs should accordingly give higher yields on photoaffinity labeling of ribosomes than are usually obtained by that technique. Model reactions have shown that acetophenone and benzophenone react with both peptides[69] and nucleosides[70] on photoactivation. Hence aromatic ketones possess the additional advantage of low specificity.



After complex formation between ribosomes, BP- or BPP-[^{3}H]Phe-tRNA, and Poly(U) as mRNA, followed by irradiation, the radioactivity of the 50S subunit was found exclusively in 23S RNA. The significance of this result is underscored by the fact that the distances between the reactive carbonyl group and the amino acyl group of the tRNA differ widely in the two derivatives (5.5 and 10 Å, respectively): labeling of the 23S RNA therefore cannot merely be the result of an accidentally favorable steric arrangement.

After photoaffinity labeling the ribosome still showed peptidyl transferase activity. If a ribosomal complex with Poly(U) and non-radioactively labeled BPP-Phe-tRNA is first irradiated to form the covalent bond between 23S RNA and BPP-Phe-tRNA, and then incubated with [^{3}H]Phe-tRNA, the [^{3}H]radioactivity is likewise bound covalently to 23S RNA. Since the sample contained no radioactivity at the time of irradiation, the [^{3}H]Phe can only have been bound to the 23S RNA by formation of a peptide bond with the covalently linked BPP-Phe-tRNA. However, this is possible only if the photoaffinity reaction between BPP-Phe-tRNA and 23S RNA has taken place at the donor site because no peptidyl transferase reaction could otherwise occur with [^{3}H]Phe-tRNA[70].

Use of suitable degradation methods permits determination of the approximate labeling position in the 23S RNA molecule. 23S RNA consists of about 3000 nucleotides. After partial digestion with ribonucleases, fragments can be isolated which embrace the 1300 nucleotides of the 5′ end and the 500 nucleotides of the 3′ end. These fragments were not labeled. On the other hand, an 18S fragment representing the 23S RNA from nucleotide 1300 to the 3′ end contained the entire radioactivity. Hence it may be concluded that the covalent bond is formed at a position between the bases 1300 and 2500[66].



As can be seen, the peptidyl transferase center is of complex structure. Even on exclusive formation of the derivatized amino acyl tRNA at the donor site, a variety of proteins and 23S RNA are labeled. In this context, particular importance attends the affinity labeling experiments with photoactivatable groups of low specificity such as diazomalonic acid, aromatic azides, and aromatic ketones, which all indicate 23S RNA to be a component of the donor site[63-66]. However, it was also shown by protein labeling that covalently bound amino acyl tRNA is still capable of the peptidyl transferase reaction, thus proving that proteins also belong to the donor site. Hence it may be concluded that the amino acyl group of the tRNA does not have to occupy a particular position in the donor site for the peptidyl transferase reaction to occur. This suggests a certain degree of flexibility in the peptidyl transferase center. On the other hand, it can hardly be imagined that there should not be a preferred binding site guaranteeing maximum rate and efficiency of the amino acyl transfer. 23S RNA might contain such a binding site to which the CCA end of the tRNA is linked by interaction with complementary bases. Confirmation of this hypothesis will have to await sequence analysis of 23S RNA at the position of reaction with BPP-Phe-tRNA.

7. Conclusion and Outlook

An understanding of the processes involved in protein biosynthesis is dependent upon a knowledge of ribosome structure. Precisely this field has undergone important advances[79] during the past few years through the introduction of crosslinking reagents[71,72], the perfection of reconstitution methods[73,74], and electron microscope studies on ribosome dimers linked by antibodies[75-78]. Attempts have already been made to calculate three-dimensional models of the 30S subunit from these results[80].

Affinity labeling permits investigation of the binding sites for natural substrates and thus constitutes an important addition to the other techniques. Moreover, a kind of cinematographic record of a reaction can be obtained with the aid of photoaffinity labeling. This technique opens up new possibilities, especially for systems where the ribosomes carry out processes involving motion.

Although our knowledge of the processes taking place in ribosomes has been greatly extended by the intensive studies of recent years, we still cannot completely describe the mechanism of protein synthesis on a molecular level. However, the methodological armamentarium is now available for obtaining a picture of the ribosome which not only reproduces the steric arrangement of the proteins and nucleic acids but also permits a detailed understanding of protein synthesis.

I am indebted to many friends and colleagues at this institute and other research establishments for discussions, criticism, and valuable stimulation. Particular mention should be made of the fruitful cooperation with Dr. G. Stöffler, Max-Planck-Institut für Molekulare Genetik, Berlin, and Dr. K. H. Scheit, Max-Planck-Institut für Biophysikalische Chemie, Göttingen. Thanks are also due to Prof. Dr. H. Tuppy and my colleagues at the Institut für Biochemie, Vienna, for critical perusal of the manuscript. Financial support by the Fonds zur Förderung der wissenschaftlichen Forschung is gratefully acknowledged.

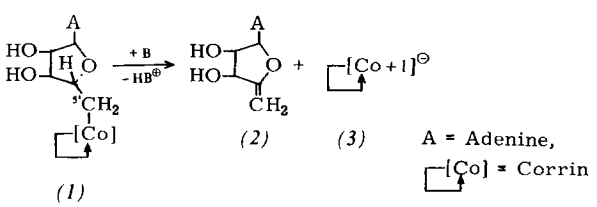
COMMUNICATIONS

Detection of 4',5'-Anhydroadenosine as the Cleavage Product of Coenzyme B_{12} in Functional Holoenzymes[**]

By *R. N. Katz*, *T. M. Vickrey*, and *G. N. Schrauzer*[*]

Coenzyme B_{12} (5'-deoxyadenosylcobalamin) *(1)* undergoes Co—C bond cleavage on reaction with bases to yield 4',5'-anhydroadenosine *(2)* and the nucleophilic Co(I)-corrin derivative *(3)* (vitamin B_{12s}). A reaction of this type was proposed as a possible mechanism of enzymatic coenzyme B_{12} activation, as it generates the highly reactive Co(I)-corrin nucleophile *(3)* from *(1)* in the absence of an external reducing agent[1].



(1) *(2)* *(3)*

Initial experiments with ^{14}C-labeled *(1)* and ethanolamine deaminase revealed the presence of *(2)* in the reacting functional holoenzyme[2]. The presence of enzyme-bound *(3)* is indicated by the inactivating effect of N_2O, a mild oxidizing agent which acts as a selective oxidant of Co(I)-nucleophiles.

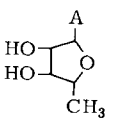
La Jolla, Calif. 92093 (USA)

[**] This work was supported by Grant 28485X of the National Science Foundation (USA). We thank Drs. *H. P. C. Hogenkamp*, *J. G. Moffat*, *J. Verheyden*, and *B. M. Babior* for gifts of ^3H-labeled coenzyme B_{12}, authentic *(2)*, and purified ethanolamine deaminase. We also thank Dr. *E. A. Stadtbauer* for experimental assistance in early phases of this work.

To obtain further support for our concept of the mechanism of enzymatic coenzyme B_{12} activation, we have since performed similar experiments with D,L-propanediol hydrolase (dioldehydrase), this time with 5'-^3H-labeled coenzyme B_{12}. Commercially available enzyme from Pierell, S.p.A. (Milan, Italy), was incubated with ^3H-labeled coenzyme under argon at 25°C in the dark. After 15—30 min, the incubates were lyophilized in the dark. The solid residues were treated with 0.5 ml of CH_3OH and authentic unlabeled *(2)*, as well as 5'-deoxyadenosine *(4)*, were added. Drops of the methanolic solutions were spotted on Whatman No. 1 paper strips and



(4)

chromatographed in the dark, using water-saturated 2-butanol as the ascending phase, or on silica gel plates with ethyl acetate/methanol (6:1) as the eluent. The presence of ^3H-labeled *(2)* and of *(4)* was ascertained by measurement of the ^3H-radioactivity profiles and comparison of the R_f-values[3]. A typical activity profile, which demonstrates the presence of *(2)* and possibly of traces of *(4)*, is shown in Figure 1.

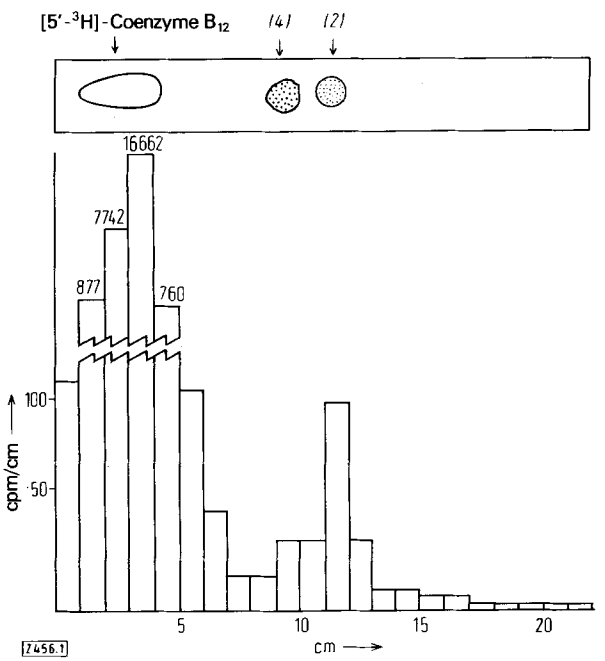


Fig. 1. Radioactivity profile of a paper chromatogram (Whatman No. 1) of the freeze-dried residue of a reacting solution of D,L-propanediol hydrolase incubated with 5'-^3H-labeled coenzyme B_{12} and D,L-propanediol as the substrate. The contours of the spots of *(2)* and *(4)*, which both were added prior to chromatography (ascending phase: water-saturated 2-butanol), were visualized under UV light and by exposure to I_2 vapor. ^3H-radioactivity was mainly present in the spot consisting of authentic *(2)*.

The identity of *(2)* was ascertained by spraying the chromatograms with a 1% solution of $KMnO_4$ in 2% aqueous sodium carbonate. This reagent is relatively unreactive towards *(4)*, but rapidly oxidizes *(2)* at the olefinic double bond[4]. This reaction was accompanied by a loss of ^3H-radioactivity in the respective spot to 38% of the original value. Compound *(4)* was occasionally observed in larger amounts than in Figure 1, but was often also not detected at all. Since *(1)* undergoes reductive Co—C bond cleavage to yield *(4)*[5], we consider it as a by-product of a side-reaction unrelated to the process of enzymatic catalysis.

Compound *(2)* was detectable only if the incubations were performed with exclusion of oxygen and mild methods of work-up, such as lyophilization at −78 °C (dry ice/acetone), and with active enzyme preparations[6].

Analogous experiments with purified ethanolamine ammonia lyase produced similar results; a radioactivity profile of a chromatography strip is shown in Figure 2.

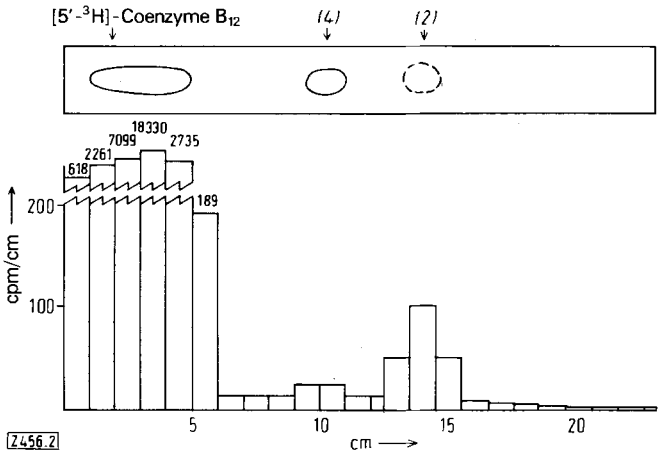

Fig. 2. Radioactivity profile of a paper chromatogram (Whatman No. 1) of the freeze-dried residue of a reacting solution of ethanolamine deaminase incubated with 5'-^{3}H-labeled coenzyme B_{12} (reaction conditions as outlined in Refs. [2] and [6]).

The detection of *(2)* in two coenzyme B_{12}-dependent enzymes supports our concept according to which *(1)* is enzymatically activated by Co—C-bond *heterolysis* rather than homolysis and that the highly nucleophilic Co(I)-derivative of the corrinoid cofactor is the catalytically active species.

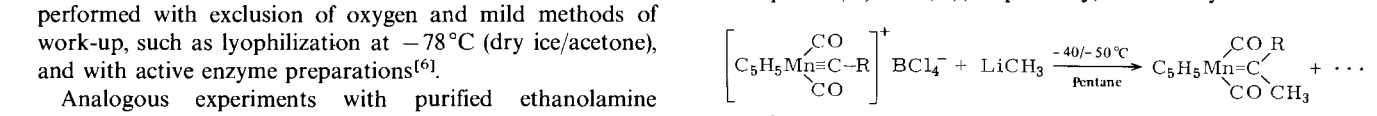
[6] The experiments were performed in Pyrex centrifuge tubes of 15 ml capacity which were rubber-serum-capped, flushed with pure argon for 20 min, and covered with aluminum foil for protection against light. One vial of the commercial enzyme (29 mg, 7.0 units) was dissolved in 7.0 ml of 0.01 M potassium phosphate buffer (pH 7.4) containing 2% v/v of D,L-propanediol. As a rule, 0.9 ml of enzyme stock solution was injected into the centrifuge tubes and the reaction was initiated by the addition of 0.1 ml of a solution containing 12.6 nmoles of coenzyme B_{12}. The ^{3}H-activity of the coenzyme solution added was 11.3 nC (25000 cpm).

Dimethylcarbene- and Methylphenylcarbenedicarbonyl(η-cyclopentadienyl)manganese[1]

By *Ernst Otto Fischer, Roger Lee Clough, Gerhard Besl*, and *Fritz Roland Kreissl*[*]

The novel manganese compounds *(1)* and *(2)* are the first transition metal-carbene complexes in which a dialkyl or an alkylarylcarbene is stabilized as ligand to a metal atom, in this case manganese. Diarylcarbene complexes of the same system have already been reported[2].

(1) and *(2)* are formed on reaction of the cationic carbyne complexes *(3)* and *(4)*, respectively, with methyllithium:

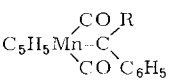


(3), R = CH_3
(4), R = C_6H_5

(1), R = CH_3
(2), R = C_6H_5

The red, crystalline products are readily soluble in organic solvents. Their composition and structure follows from elemental analysis and spectroscopic investigations.

In each case the IR spectra (in *n*-hexane) show two intense bands in the ν_{CO} region. Their shift to higher wave numbers compared to the analogous phenylmethoxycarbene complex *(6)*[3] supports the assumption of stronger back-bonding from metal to carbene carbon.



(5), R = C_6H_5
(6), R = OCH_3

Arcisstrasse 21, 8000 München 2 (Germany)

due to fragments after successive loss of two CO groups, the carbene residue, and the C_5H_5 ligand.

Experimental:

All work is carried out in anhydrous and oxygen-free solvents under N_2.

Dicarbonyl(η-cyclopentadienyl)methylcarbynemanganese tetrachloroborate (3): BCl_3 is added to a stirred solution of $C_5H_5Mn(CO)_2C[CH_3(OCH_3)]$[3] (1.76 g, 7.5 mmol) in pentane (100 ml) at −40 °C. The precipitate which is formed is filtered off, washed several times with pentane, and dried in a high vacuum. For further purification the substance is dissolved in CH_2Cl_2 and covered with pentane. After drying, analytically pure *(3)* is obtained in the form of a finely crystalline, yellow-orange thermolabile powder. Yield 2.16 g (80.7 %).

Dicarbonyl(η-cyclopentadienyl)dimethylcarbenemanganese (1): To a suspension of *(3)* (1.94 g, 5.45 mmol) in pentane (50 ml) at −40 °C is added a suspension of $LiCH_3$ (120 mg, 5.45 mmol) in the same amount of the same solvent. After 3 hours' stirring at −40 °C the red solution is separated from the solid components of the reaction mixture, concentrated to 50 ml, and chromatographed on a silica gel column at −25 °C with pentane. Of the three zones which are formed the middle (red) one contains the desired product. After removal of solvent and recrystallization, *(1)* is obtained as dark red crystals which melt below room temperature. Yield: 220 mg (18.5 %).

Dicarbonyl(η-cyclopentadienyl)methylphenylcarbenemanganese (2): To a suspension of *(4)*[4] (3.1 g, 7 mmol) [preparation analogous to that of *(3)*] in pentane (20 ml) is added a solution of $LiCH_3$ (10.5 mmol) in ether. The mixture is stirred for 7 h at −50 °C. After removal of solvent the residue is chromatographed on silica gel at −40 °C, first with pentane and later with pentane/ether. After two recrystallizations from pentane, *(2)* is obtained as red crystals, m. p. 35—36 °C. Yield: 260 mg (14 %).

Intercalation Compounds of Zirconium Phosphate

By *Dietmar Behrendt*, *Klaus Beneke*, and *Gerhard Lagaly*[*]

The ability of layer compounds to form intercalation compounds requires a particular kind of structure and bonding between the layers. Apart from graphite only few inorganic layer compounds capable of intercalating neutral molecules between the layers were hitherto known: kaolinite[1]; binary sulfides like TiS_2 and TaS_2[2]; and crystalline silicic acids[3].

We have now found that crystalline M^{IV} phosphates $M(HXO_4)_2 \cdot nH_2O$, with M = Zr, Si, Sn, Ce and X = P, As take up certain neutral molecules to form a large number of intercalation compounds. Zirconium phosphate $Zr(HPO_4)_2 \cdot nH_2O$ ($n = 0, 1, 2$) may be cited as an example. The layer structure of the monohydrate was established by *Clearfield*[4] and confirmed with the aid of cation exchange experiments with *n*-alkylammonium ions by *Michel* and *Weiss*[5].

All three hydrates can be used for formation of intercalation compounds. For this purpose the zirconium phosphates are allowed to react for several days at 60—80 °C with the corresponding liquids, and in the case of solid guest compounds with an excess of a concentrated aqueous solution. $Zr(HPO_4)_2 \cdot 2H_2O$ (γ-ZrP according to ref. [4]) reacts with a larger number of guest molecules than the monohydrate (α-ZrP) because the zirconium phosphate layers are widely separated from each other by bimolecular water layers. γ-ZrP also reacts with long-chain compounds (*e.g.* hexanol : basal spacing : 24.9 Å; butyronitrile : 21.3 Å). The intercalation compounds of $Zr(HPO_4)_2$ (β-ZrP) are identical with those of γ-ZrP provided they are not prepared with exclusion of water because β-ZrP immediately transforms into γ-ZrP in the presence of H_2O.

The basal spacings of the intercalation compounds of α-ZrP and γ-ZrP are different (Table 1). In α-ZrP they repeatedly suggest that the H_2O molecules are replaced by approximately

Table 1. Basal spacings d_L of the intercalation compounds of $Zr(HPO_4)_2 \cdot H_2O$ (α-ZrP) and $Zr(HPO_4)_2 \cdot 2H_2O$ (γ-ZrP).

	Intercalated molecule	Basal spacing d_L [Å] α-ZrP	γ-ZrP
		7.6	12.3
(1)	Dimethyl sulfoxide	10.8	16.2
(2)	*N*-Methylformamide	10.5	15.9
(3)	*N,N*-Dimethylformamide	11.2	15.8
(4)	Urea [a]	9.4	13.6

(8)	Piperidine	13.4	17.8

[a] Concentrated aqueous solution.

spherical guest molecules (Table 2). The increase in basal spacing Δd_L is then equal to the diameter of the intercalated molecule *D* minus 2.8 Å (diameter of a water molecule). Of course, this cannot hold if the intercalated molecule is unable to adopt a spherical shape, as in the case of piperidine. Urea compounds warrant interest; only the unsymmetrical methyl derivative *(5)* appears to assume a spherical shape.

The intercalation compounds of α-ZrP are characterized by their remarkable stability. The guest molecules are retained so firmly between the layers that their removal is difficult even *in vacuo* above 100 °C. The monohydrate itself displays similar stability.

Many guest molecules in γ-ZrP replace only one H_2O molecule; the increase in basal spacing is then equal to or slightly greater than *D* minus 2.8 Å. In some cases (urea, *N,N*-dimethylurea, glycol, glycerol) both H_2O molecules are replaced by an intercalated molecule (Δd_L significantly smaller than *D* minus 2.8 Å).

The reaction of α-ZrP and γ-ZrP with alkylamines[6] to form compounds with large basal spacings (*e.g.* α-ZrP + hexylamine : 23.3 Å; + dodecylamine : 36.4 Å) is also an intercalation reaction. However, the alkylamines are bound with formation of alkylammonium ions and unlike the other intercalated compounds cannot be washed out.

Zirconium phosphate has a number of superior properties compared with other intercalating compounds: apart from their ability to intercalate neutral molecules between the layers, their protons have been known for some time to be susceptible to cation exchange reactions in the normal pH range, in

particular by alkali metal ions[7] and long chain organic cations[5]. Thus zirconium phosphate is capable of undergoing two types of interface reactions which are mutually excluded in the compounds studied hitherto: the clay mineral kaolinite only forms intercalation compounds, whereas the clay mineral montmorillonite has a pronounced cation exchange capacity.

Conformations and N-Inversion Barriers in Tropane Compounds[1]

By *Hans-Jörg Schneider* and *Lothar Sturm*[*]

The focal point of the controversy surrounding the conformation of piperidine is the question whether the lone pair or a substituent such as hydrogen assumes the equatorial position at the nitrogen, which is regarded as being the less hindered[2]. We have attempted to apply ^{13}C-NMR low-temperature spectroscopy to inversion at nitrogen but exchange between equatorial and axial N—H bonds proved to be too fast in the case of piperidine. However, by introducing the C6—C7 bridge it was possible to slow down the inversion to such an extent that two conformers having distinct pairs of signals for all C atoms except C3 appear in the ^{13}C-NMR spectra of the resulting tropane compounds *(1)* at low temperatures. e-*(1)* is the conformer with equatorial *N*-substituent, and a-*(1)* that having axial *N*-substituent (relative to the piperidine system).

The ground state energy difference (Table 1) calculated for *(1a)* from the intensity ratios agrees with the value obtained by ^{1}H-NMR spectroscopy (0.90 kcal/mol) from the split CH_3 signal at −100 °C. While the methyl group accordingly displays a pronounced conformative preference, the ^{13}C-NMR study on nortropane *(1e)* under the same conditions reveals an almost *equal* population of e-*(1e)* and a-*(1e)*. Thus the approximately equal effective interaction magnitude of a lone pair and hydrogen have become experimentally demonstrable for a given molecular geometry.

Assignment of the observed conformations to e-*(1)* and a-*(1)* is based on the shielding due to the *syn*-γ effect of the methyl group[3] which should be up to 6 ppm greater for C2,4 in a-*(1)*, X = CH_3, and C6,7 in e-*(1)*, X = CH_3. The shift effects actually found for the γ-C atoms in e-*(1)* and a-*(1)*, X = CH_3, are about 4 ppm greater, which is attributable to additional shielding by the lone pair in the case of an antiperiplanar arrangement of the C_β—C_γ bond [as in a-*(1)* with regard to C2,4, but not in e-*(1)* with regard to C6,7]. This shielding which has important implications for the shift

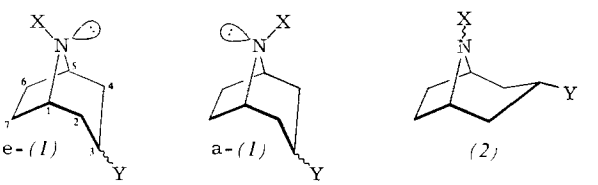

Table 1. ^{13}C-NMR shifts, ground state energy differences (ΔG^0), and inversion barriers (ΔG^*, ΔH^*, ΔS^*) in tropane conformers *(1)*. Shifts are relative to TMS [ppm]. An asterisk signifies interchangeable assignments; the energy parameters (in kcal/mol and cal K^{-1} mol^{-1} respectively) are the best values from measurement of four pairs of signals in each case [three for *(1e)*], the errors given are the mean deviations obtained from regression analysis (without systematic errors). ΔG^* was determined by complete line shape analysis over a range of about 50°.

mechanism[4] is reduced on participation of the lone pair in hydrogen bonding (*e.g.* with methanol, Table 1).

Bulky substituents in the *endo*-3-position of tropanes *(1)* can lead to adoption of the boat form *(2)* or to flattening[5] of the chair. The *endo*-3-methyl compound *(1d)* can be prepared by reaction of tropinone with methyllithium, dehydration of the resulting tertiary alcohol, and subsequent hydrogenation. Its existence in the boat form *(2)* can be ruled out in the same way as for tropine *(1b)* on the basis of the ^{13}C-NMR shifts, which in particular for C3 should appear some −7 ppm upfield for *(2)*. In fact the signals of C3 and (C3)-CH_3 recorded above 230 K display a broadening of 1—2 Hz which must be attributed to some slight participation of the boat form *(2)*. The flattening of the piperidine chair reduces hindrance by the axial hydrogen atoms on C2 and C4 and thus shifts the N-invertomer equilibrium in favor of a-*(1)* (see Table 1).

Preliminary measurements confirm the shift of the invertomer equilibrium by protic solvents which is frequently discussed for piperidine. It appears that the conformer having the axial electron pair e-*(1d)* will profit more from hydrogen bonding with methanol than will a-*(1d)*. In the case of the piperidine analog nortropane *(1e)* inversion is so fast in the presence of methanol that not even line broadening can be observed at −100 °C. Line shape analyses with 10, 6, and 2 mol % of nortropane in $CFCl_3$ and with admixture of dimethylformamide indicate an almost constant inversion barrier to within ±0.15 kcal/mol, so that the unexpectedly small activation energy (see Table 1) relative to the *N*-methyl compound cannot be explained by participation of an intermolecular proton exchange but rather in terms of an additional tunneling mechanism[6, 7].

The significantly negative ΔS^* value for nortropane *(1e)* can likewise be regarded as the result of a tunneling contribution decreasing with rising temperature. The increase in activation energy on going from $CFCl_3$ to CH_3OH in the case of *(1b)* is attributable to the desolvation necessary in the inversion transition state in a protic solvent[6].

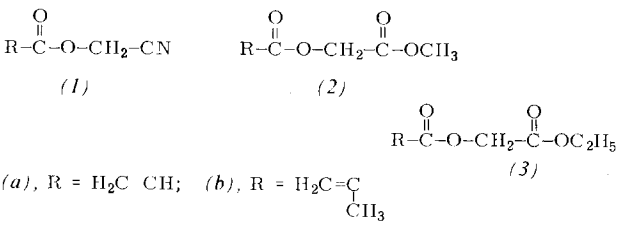
Crosslinked Polymers Having Activated Ester Groups—A Versatile Support Material[**]

By *Hubert Köster* and *Walter Heidmann*[*]

Since the use of a polystyrene crosslinked with 1 to 2 % of divinylbenzene for solid phase synthesis of polypeptides by *Merrifield*[1], variously functionalized polymers have found application in the synthesis of oligomeric natural products, as polymeric reagents, for immobilization of enzymes, and in affinity chromatography. The first two applications mainly utilize inert hydrophobic polymers having a defined functional group, while the last two require hydrophilic polymers.

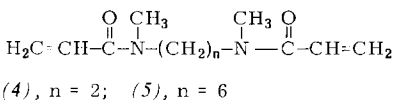
It appeared of interest to develop a single insoluble swellable polymer from which products having different properties can be generated and therefore can be utilized for all four kinds of application. With this aim in mind we have synthesized the acrylic esters *(1a)*, *(2a)*, and *(3a)*, as well as the methacrylic esters *(1b)*, *(2b)*, and *(3b)*[2] and polymerized them in



(1) *(2)* *(3)*

(a), R = H_2C=CH; *(b)*, R = H_2C=C(CH$_3$)

the presence of *N*,*N*′-dimethyl-*N*,*N*′-ethylenebis(acrylamide) *(4)* or *N*,*N*′-dimethyl-*N*,*N*′-hexamethylenebis(acrylamide) *(5)* as crosslinking reagents and of *N*,*N*-dimethylacrylamide to improve the solubility of the crosslinking agent. A non-macroporous bead polymer is obtained. If inert components (*e.g.* 1-heptanol, *n*-butyl acetate, di-*n*-butyl ether) are present during the polymerization step macroporous bead polymers can also be obtained.



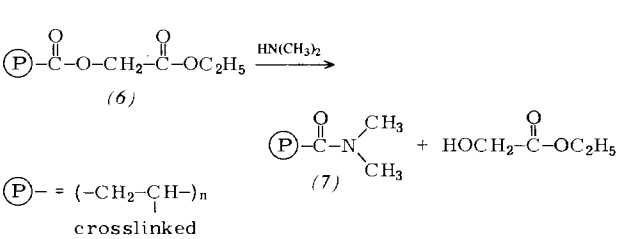
(4), n = 2; *(5)*, n = 6

Polymeric ester (6)

A mixture of ester *(3a)* (17.8 g), *N*,*N*-dimethylacrylamide (1.8 g, 10 wt %), compound *(4)* (0.4 g, 2 wt %), and azoisobutyronitrile (100 mg) was added under N_2 to a stirred (720 rpm) solution of polyvinyl alcohol (3 g) in water (250 ml). After polymerization for 1 h at 60 °C, 2 h at 70 °C, and 2 h at 80 °C the product was washed with hot water, ethanol, acetone, benzene, acetone, ethanol, and ether and dried *in vacuo* at 50 °C. The sieve fraction of 0.1 to 0.315 mm particle diameter was used. Yield of (6): 12.1 g (61 %).

The bead polymers of acrylic esters are soft, and those of methacrylic esters hard and flowable. They have a degree of swelling (volume after solvation relative to volume of dry beads) of 6 in acetone and DMSO, 4 in dimethylformamide and acetonitrile, and 2 in benzene and ethyl acetate.

The activated ester groups in polymer *(6)* provide a means of incorporating other functional groups into the product. Thus reaction of *(6)* with dimethylamine affords the polymeric carboxamide *(7)*. As a result of the excellent miscibility of



(6) *(7)*

Ⓟ = (−CH$_2$−CH(−)−)$_n$ crosslinked

Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, 2000 Hamburg 13 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

N,N-dimethylacrylamide with most solvents (*e.g.* water, alcohols, benzene, light petroleum) a bead polymer *(7)* is only accessible in this way.

Polymeric carboxamide (7)

To a suspension of polymer *(6)* (12.1 g) in acetone (350 ml) and glacial acetic acid (600 mg) in a glass autoclave cooled to 0 °C is added anhydrous dimethylamine (100 ml). The mixture was shaken for 30 min at room temperature and 24 h at 50 °C; after washing with acetone, ether, acetone, pyridine, ethanol, acetone, and ether the polymer was dried *in vacuo* at 50 °C. Elemental analysis (N 4.9 %) shows the polymer to contain 34.7 mol % of amide groups. *(7)* possesses excellent solvation properties. The degree of swelling is 12 in pyridine, 15 in dimethyl sulfoxide, 10 in dimethylformamide, 5 in water, 5 in ethanol, and 12 in water/methanol (1 : 1, v/v).

It is also possible to react the activated ester groups in *(6)* first with a limiting amount of a nucleophile (primary reactant) and subsequently with another nucleophile (secondary reactant). In this way the amount of primary reactant to be introduced and the solvation (swelling) properties of its environment can be varied within wide limits. In *(7)* part of the *N,N*-dimethylamide groups obtained on reaction with an excess of dimethylamine can be hydrolyzed to carboxyl groups. A polymer of this kind is used in the solid phase synthesis of oligonucleotides[3].

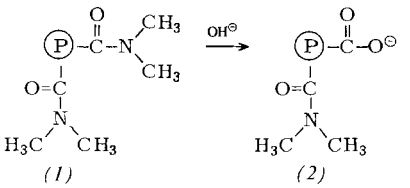
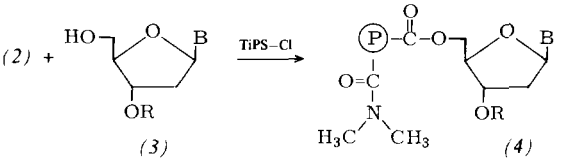
Oligonucleotide Synthesis on a Polymeric Support with Avoidance of Failure Sequences[1][**]

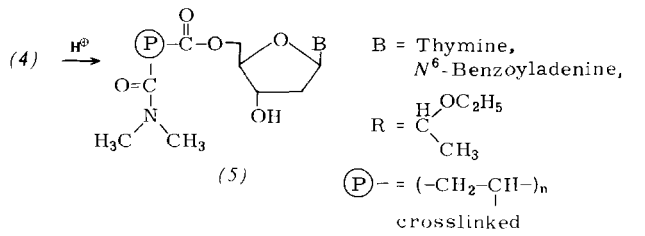
By *Walter Heidmann* and *Hubert Köster*[*]

Using a non-macroporous polystyrene crosslinked with 1 % of divinylbenzene, *Merrifield* and *Gutte*[2] were able to synthesize polypeptide chains having a molecular weight of more than 15000. Since the decanucleotides required for a DNA synthesis have a molecular weight of only *ca.* 5000[3], a weakly crosslinked, non-macroporous polymer should possess cavities of adequate size to permit its functioning as a support for an oligonucleotide synthesis. A disadvantage of this support for synthesis of oligonucleotides using the diester concept has so far consisted in the failure to find satisfactory swelling conditions for the nonpolar polymer bearing polar oligonucleotide chains.

Our previous communication[4] described the synthesis of a support *(1)* devoid of these difficulties. The carboxylate groups in *(2)*, which arise by partial hydrolysis of the amide groups in *(1)*, serve to anchor the first nucleoside *(3)*. It is protected by the acid-labile α-ethoxyethyl group at the 3'-OH group[5]. Esterification is accomplished after activation of the carboxylate groups of *(2)* with 2,4,6-triisopropylbenzenesulfonyl chloride (TiPS—Cl).





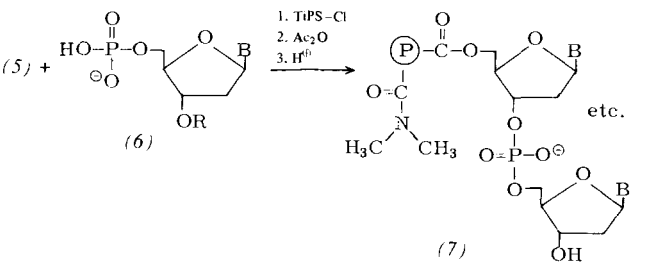


Carrier-bound nucleoside (5)

The support *(2)* (4 g, 1.6 mmol of carboxylate groups) was shaken for 24 h at room temperature in pyridine (50 ml) containing TiPS—Cl (8 mmol). The activated polymer was washed with pyridine and ether in the absence of moisture and shaken with the nucleoside *(3)* (7.2 mmol) in pyridine (20 ml) at room temperature. The unreacted activated carboxylate groups were blocked by 6 hours' shaking with an excess of methanol. The product *(4)* was washed with pyridine and ether and dried *in vacuo*. It contained 85 μmol *(3)*/g, which could be released by treatment with conc. aqueous ammonia for 16 h at room temperature or with 1 N aqueous sodium hydroxide at 0 °C for 30 min. Removal of the α-ethoxyethyl group from the carrier-bound nucleoside *(4)* could be accomplished quantitatively by 15 hours' shaking in glacial acetic acid/water/methanol (3 : 4 : 3, v/v). After thorough washing with pyridine, ethanol/water (1 : 1, v/v), and ether the product *(5)* is dried *in vacuo* at 40 °C.

Carrier-bound dinucleotide (7)

The support *(5)* (1 g, 85 μmol of bound nucleoside) is shaken in pyridine (10 ml) with the nucleotide *(6)* (4 mmol) and TiPS—Cl (8 mmol) for 8 h. Washing with pyridine is followed by drying *in vacuo*. The product is shaken for 16 h with acetic anhydride/pyridine (1 : 1, v/v, 10 ml) at room temperature, washed with pyridine and ether, and the α-ethoxyethyl group then removed. After washing and drying of *(7)* the nucleotide chain can once again be elongated.



Use of an alkali-labile anchoring and an acid-labile 3'-*O* protecting group permits blocking of those 3'-OH groups which have failed to react in a condensation reaction by acylation, thus avoiding failure sequences. Furthermore using

this strategy, the heterocyclic bases remain fully acylated prior to each condensation. Since removal from the carrier is feasible under conditions not affecting the *N*-acyl groups the trunk sequences can be re-used after chromatographic separation.

Hydrophobic Interactions between Metal Complexes of Aromatic Ligands and 3-(Trimethylsilyl)-1-propanesulfonate and Their ^{1}H-NMR Spectroscopic Detection[**]

By *Paul R. Mitchell* and *Helmut Sigel*[*]

Although tetramethylsilane has been almost universally accepted as the reference standard for proton NMR in non-aqueous solutions, various reference compounds have been used in aqueous solutions including acetonitrile, dioxane, *tert*-butanol, and the tetramethylammonium, 3-(trimethylsilyl)propionate *(2)*, and 3-(trimethylsilyl)-1-propanesulfonate ("DSS") ions *(1)*. With high concentrations of aromatic solutes[1] hydrophobic interactions involving trimethylsilyl groups[2] may influence the NMR spectrum; however, such concentrations are not normally used for routine NMR work. Micelle formation, which also has an effect, only occurs at very high concentrations of the trimethylsilyl compound[3], which may also act as a surfactant[4].

However, when $(CH_3)_3Si[CH_2]_3SO_3^{\ominus}$ *(1)* was used as a reference in an investigation of the NMR spectrum of metal complexes, anomalous chemical shifts were observed in the presence of $[Zn(phen)]^{2+}$ or of $[Zn(bipy)]^{2+}$, which were not observed in the presence of zinc ions, or 1,10-phenanthroline (phen), or 2,2'-bipyridyl (bipy) alone. The methyl resonance of *(1)*, measured relative to the tetramethylammonium ion as reference[5], shifts by up to 0.4 or 0.25 ppm, respectively, in the presence of high concentrations of $[Zn(phen)]^{2+}$ ($\approx$0.3 M) or of $[Zn(bipy)]^{2+}$ ($\approx$0.6 M) (see Fig. 1), but much larger concentrations of Zn^{2+} (2 M) have no measurable effect. Saturated solutions of phenanthroline ($\approx$0.02 M) and of bipyridyl ($\approx$0.05 M) have a much smaller effect (*ca.* 0.02 ppm) which is however less than a third of that observed for the same concentration of $[Zn(phen)]^{2+}$ or $[Zn(bipy)]^{2+}$. Conversely, a small shift (*ca.* 0.05 ppm) in the proton resonances of $[Zn(phen)]^{2+}$ occurs; the proton NMR of phenanthroline itself is also considerably affected by the solvent environment. 3-(Trimethylsilyl)propionate *(2)* behaves in exactly the same way although the maximum shift observed is somewhat smaller, $\approx$0.3 ppm and $\approx$0.2 ppm for $[Zn(phen)]^{2+}$ and $[Zn(bipy)]^{2+}$, respectively. In the presence of $[Cu(phen)]^{2+}$ or $[Cu(bipy)]^{2+}$ the methyl resonance of *(1)* is broadened considerably and shifted, whereas the same concentration of Cu^{2+} itself has a much smaller effect.

[**] The support of this work by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung is gratefully acknowledged.

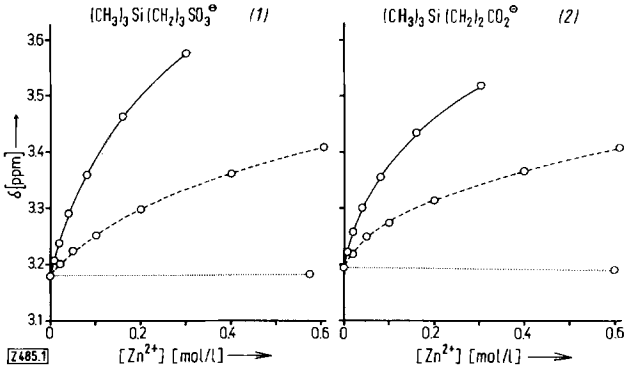

Fig. 1. Displacement of the methyl resonance in the ^{1}H-NMR spectrum of trimethylsilyl derivatives *(1)* and *(2)* (each 10^{-2} M) in the presence of Zn^{2+} (····), $[Zn(bipy)]^{2+}$ (----), or $[Zn(phen)]^{2+}$ (——) at 35 °C ($I \geq 0.1$; $NaNO_3$).

The effect on the NMR spectrum can be completely explained by the formation of ternary complexes[6] between *(1)* or *(2)* and $[Zn(phen)]^{2+}$ or $[Zn(bipy)]^{2+}$. Indeed, plotting the reciprocal of the displacement of the methyl resonance of *(2)* (data of Fig. 1) against $1/[Zn(phen)^{2+}]$ or $1/[Zn(bipy)^{2+}]$ gives $K \approx 10$ l/mol: this stability constant is about the same as is generally observed for Zn^{2+} complexes of carboxylates[7]. The results for *(1)* are consistent with a slightly lower stability appropriate for sulfonate complexes. The mutual effect of the aromatic ligand on the methyl resonance in *(1)* or *(2)* and *vice versa* indicates a hydrophobic interaction between these two moieties in the ternary complex. Comparison of the effects of Cu^{2+}, $[Cu(bipy)]^{2+}$, and $[Cu(phen)]^{2+}$ leads to the same conclusion.

Although hydrophobic interactions may have a stability as high as aromatic stacking interactions[8], they have not previously been observed in ternary complexes of metal ions: aromatic stacking interactions[6, 9] are known to affect the stability of ternary complexes[9]. In addition, ionic interactions have recently been observed in ternary complexes[10].

As even with low concentrations of trimethylsilyl reference compounds (5—10 mM), and the concentrations of metal complexes which are usually used in NMR studies (50—100 mM), shifts of up to 0.2 ppm were observed, these trimethylsilyl references should only be used circumspectly in the presence of complexes of labile metal ions.

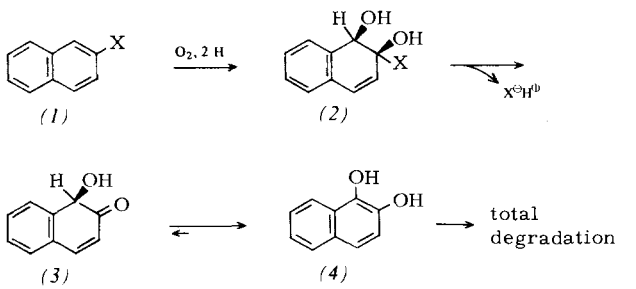
Microbiological Synthesis of (+)-*cis*-1,2-Dihydroxy-1,2-dihydronaphthalene-2-carboxylic Acid

By *Hans-Joachim Knackmuss*, *Wilhelm Beckmann*, and *Walter Otting*[*]

We recently reported the partial degradation of methylarenes by a haloarene-utilizing *Pseudomonas* strain[1]. Methyl-substituted metabolites accumulated in preparative amounts at the catabolic step corresponding to elimination of halide since the analogous elimination of the methyl anion is impossible. We can now demonstrate by another example the general applicability of this approach to the preparation of compounds which are not easily accessible by chemical synthesis.

Pseudomonas testosteroni strain A 3 (DSM 676) was isolated from sewage samples by continuous enrichment on naphthalene *(1a)* and subsequently on naphthalene-2-sulfonic acid *(1c)*. The bacterium utilizes *(1a)*, *(1c)*, or 2-naphthol *(1b)* as sole source of carbon. Induction experiments and inhibition kinetics show the organism to possess an exceptionally nonspecific naphthalene dioxygenase which hydroxylates the above substrates and channels them into the catabolic pathway of naphthalene.



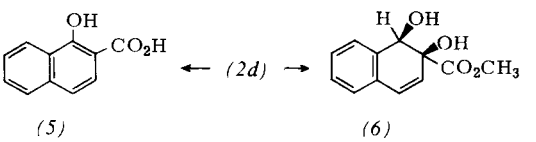
(a), X = H; *(b)*, X = OH; *(c)*, X = SO_3H; *(d)*, X = CO_2H

During the degradation of naphthalene the intermediate *(2a)* undergoes enzymatic dehydrogenation to 1,2-naphthalenediol[2]. Analogous oxygenation of *(1b)* and *(1c)* leads to labile intermediates *(2b)* and *(2c)*, respectively, which spontaneously eliminate hydroxide and hydrogen sulfite yielding *(4)* without dehydrogenation.

As a structural analog of the sulfonic acid *(1c)*, naphthalene-2-carboxylic acid *(1d)* is likewise readily hydroxylated. However, formate cannot be spontaneously eliminated from the reaction product *(2d)*, which consequently accumulates. Since the double hydroxylation requires two reduction equivalents (NAD(P)H)[2], the amount of carboxylic acid *(1d)* which can be cooxidized by resting cells is limited. Constitutively utilizable substrates providing NAD(P)H, such as succinate or malate, raise the yield of the cooxidation product.

Salicylic acid is highly suitable as a metabolizable substrate for the conversion of naphthalene-2-carboxylic acid *(1d)* on a preparative scale. Without inhibiting the turnover of *(1d)* this permits rapid bacterial growth as well as formation of reduction equivalents, and also acts as inducer of all enzymes of the naphthalene pathway, including naphthalene dioxygenase[3].

Cells of *P. testosteroni* A 3 which grow on salicylate cooxidize 2 g *(1d)*/liter without loss of activity (6.5 μmol/g protein·min). *(2d)* is formed in quantitative yield (high-pressure liquid chromatography). Acid extraction of the culture fluid with ethyl acetate gives almost pure (+)-*cis*-1,2-dihydroxy-1,2-dihydronaphthalene-2-carboxylic acid *(2d)*. Crystallization from ethyl methyl ketone furnishes colorless crystals of m.p. 147 °C [yield 74 %, $[\alpha]_D^{25} = 29.1 \pm 2°$ ($c = 1$, methanol), MS (high resolution): $M^+ = 206.0589$, calc. 206.0579][4].



Under acidic conditions, compound *(2d)* rearomatizes with elimination of water to give 1-hydroxynaphthalene-2-carboxylic acid *(5)* (>95 %). Treatment with diazomethane in ethanol/ether leads to the methyl ester *(6)* [m.p. 124 °C (from cyclohexane); MS (high resolution): $M^+ = 220.0740$, calc. 220.0736][4], which is more stable than the acid *(2d)*.

On treatment with 2,2-dimethoxypropane/HCl the methyl ester *(6)* readily affords the 1,2-isopropylidene derivative [yield 89 %, m.p. 94 °C (from hexane), $[\alpha]_D^{25} = 244° \pm 2°$ ($c = 1$, methanol), MS (high resolution): $M^+ = 260.1051$, calc. 260.1049][4].

cis-1,2-Dihydro diols have always been identified as the initial products in the metabolism of naphthalene[2] and other arenes[5] by bacteria. Only the *cis* isomer of *(2a)* reacts with 2,2-dimethoxypropane[2]. Since *(2d)* can be derivatized in corresponding manner and cell-free extracts of *P. testosteroni* only react with (+)-*cis*-*(2a)* the *cis* configuration can be deduced for *(2d)*.

Asymmetric Synthesis of α-Substituted Ketones by Metalation and Alkylation of Chiral Hydrazones[**]

By *Dieter Enders* and *Herbert Eichenauer*[*]

Effective asymmetric synthesis with C—C coupling and simultaneous generation of a new chirality center are rare. A versatile method for the regio- and enantioselective α-alkylation of ketones is still lacking. Asymmetric alkylations *via* metal derivatives of chiral imines[1] afford only unsatisfactory chemical and optical yields of desired products.

We have now developed a method permitting the asymmetric synthesis of α-substituted ketones *(5)* in good chemical yields and in part high enantiomeric purity. The method involves conversion of the ketones *(1)* into the chiral hydra-

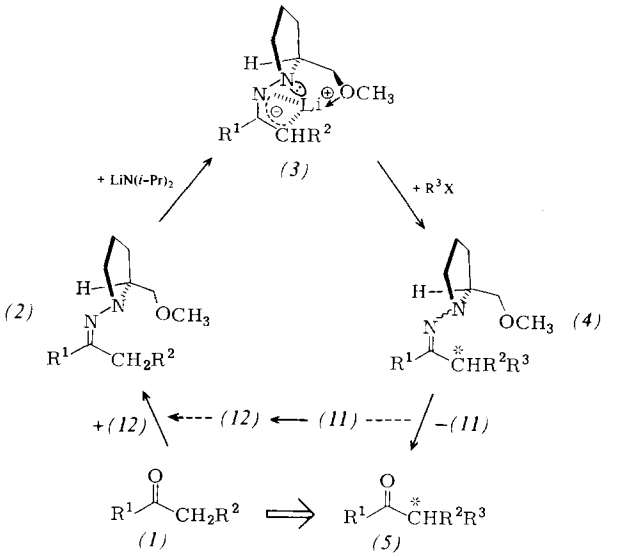
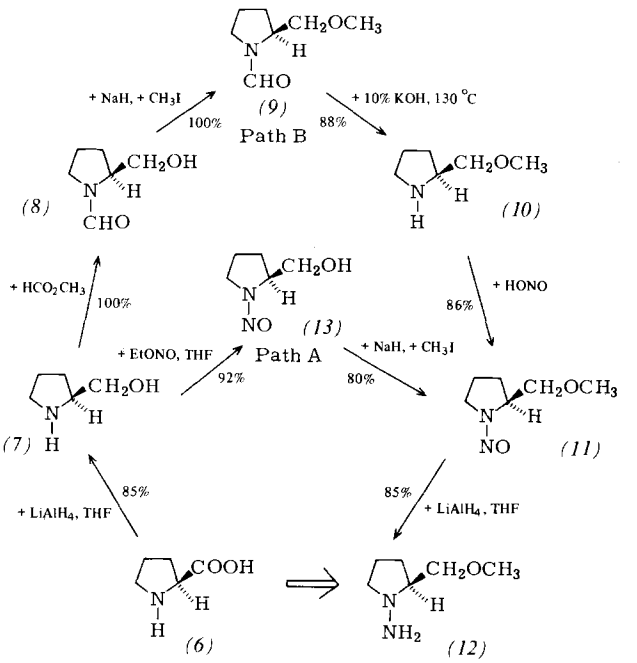
Institut für Organische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Giessen (Germany)

[**] This work was supported by a Liebig-Stipendium from the Verband der Chemischen Industrie to D. E. The authors thank Herr *E. Röcker* and Herr *K. Schneider* for the preparation of compound *(12)*.

zones *(2)*, metalation with lithium diisopropylamide to the metal derivatives *(3)*[2], alkylation to *(4)*, and regeneration of the now substituted ketones *(5)* by ozonolysis or hydrolysis.

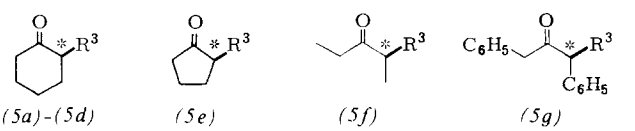




(*S*)-1-Amino-2-methoxymethylpyrrolidine *(12)*, which can be prepared in large amounts from the commercially available amino acid (*S*)-proline *(6)*, is used as chiral reagent. The total yield of *(12)* is 53% for route A, 55% for route B. In both cases purification of the (*S*)-prolinol *(7)* and the end product *(12)* by distillation suffices[3]. The chiral hydrazine *(12)* [colorless oil, b.p. 56—57°C/3 torr, ^{1}H-NMR (CCl_4): $\delta = 3.32$ (s, OCH_3), IR (film): 3340 cm^{-1} (NH_2), $[\alpha]_D^{20} = -50°$ ($c = 1$, benzene)] can be stored over a period of months in the refrigerator.

The hydrazones *(2)* and *(4)* are distillable oils[4], while the lithium compounds form colorless precipitates. Two methods are available for the step *(4)* → *(5)*. Ozonolysis at −78°C gives rise to a mixture of *(5)* and *(11)*, which after separation of the ketones *(5)* can be isolated in 80—90% yield and permits recovery of the chiral reagent *(12)*. In the alternative method reaction with excess methyl iodide generates salts of *(4)* which are hydrolyzed to *(5)* in a two-phase system (*n*-pentane/1 N HCl). The results are listed in Table 1.

The enantiomeric purity varies greatly, depending on the structure of the ketones *(1)* and R^3X. The ketones *(5a)*—*(5f)*, which are remarkably stable towards racemization, are configurationally related, since the chelates *(3)* are preferably alkylated from the "underside" of the molecule.



(5a)-(5d) *(5e)* *(5f)* *(5g)*

Table 1. Optically active ketones *(5)* prepared by asymmetric synthesis. The newly coupled C—C bonds are shown in bold print. Compounds *(4)* were generally converted into *(5)* by ozonolysis; *(5d)* and *(5f)*, however, were obtained by hydrolysis of the salts of *(4)*.

[a] First value: rotation of the distilled, spectroscopically and gas-chromatographically pure ketones. Second value: rotation quoted in the literature (values in degrees).

[b] Chemical yields based on chiral hydrazone *(2)*. In brackets: total yields.

[c] Values by *R. Kuhn, H. E. Driesen,* and *H. J. Haas,* Justus Liebigs Ann. Chem. *718*, 98 (1968): ORD ($c = 0.5$, MeOH), $[\alpha]^{20}$ (nm) = +992° (268), −878° (307). Under the same conditions we found the values: +492° (268), −430 (307) = 50% enantiomeric purity; since this value deviates greatly from those of the other 2-alkylcyclohexanones we believe that our product has a greater optical purity than 50%.

[d] Determined NMR spectroscopically with the shift reagent tris[3-(heptafluoro-1-hydroxybutylidene)-(d)-camphorato]europium(III) (Aldrich).

(R)-2-n-Propylcyclohexanone (5c) from cyclohexanone

Compound *(12)* (2.6 g, 20 mmol) is treated with cyclohexanone (2.19 ml, 21 mmol) with stirring at room temperature and then heated to 60 °C for 8 h. The crude product is dissolved in CH_2Cl_2 and the resulting solution dried over sodium sulfate, concentrated in a rotary evaporator, and finally distilled. *(2)*, $R^1/R^2 = -(CH_2)_4-$, is obtained in 90 % yield (3.78 g) as a colorless oil, b. p. 72—73 °C/0.025 torr, $[\alpha]_D^{20} = +290°$ ($c = 0.5$, benzene). *(2)* (2.1 g, 10 mmol) is added dropwise with stirring at 0 °C to a solution of lithium diisopropylamide (prepared from 6.5 ml 1.6 N *n*-butyllithium solution and 1.7 ml diisopropylamine in 50 ml tetrahydrofuran at 0 °C). After 2 h the reaction mixture is cooled to −100 °C and 1.0 ml (10.5 mmol) of *n*-propyl iodide is added dropwise. The mixture is stirred for a further 3 h, allowed to warm to room temperature, treated with ether, dried over magnesium sulfate and the solvent removed. A solution of the crude product in CH_2Cl_2 (50 ml) is cooled to −78 °C and treated with ozone until the solution is colored blue. After removal of excess ozone by introduction of argon, warming, and concentration, *(5c)* is separated from the nitrosamine *(11)* by molecular distillation over glass wool (oil bath temperature 125 °C/18 torr).

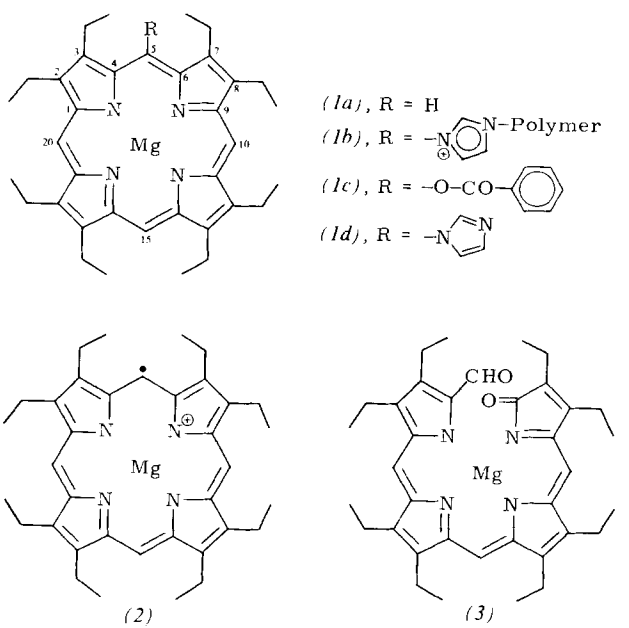
Reaction of Magnesium Porphyrinates in Polymers Containing Imidazole

By *S. Besecke, B. Evans, G. H. Barnett, K. M. Smith*, and *J.-H. Fuhrhop*[*]

The π radicals of magnesium porphyrinates, *e. g.* of protochlorophyll and chlorophyll a, play a central role in the biosynthesis of chlorophylls[1] and in photosynthesis[2]. In biological systems the chromophores are bound to proteins or lipoproteins which embed the highly reactive radicals in a hydrophobic matrix and thus protect them from irreversible destruction by external nucleophiles such as water. We have studied the reactions of magnesium octaethylporphyrin *(1a)* (as the simplest chlorophyll model) in synthetic copolymers of styrene and 1-vinylimidazole (as a model for hydrophobic, possibly electron-conducting[3] protein components), the proportion of imidazole being varied between 0.1 and 20 mol %.

Irradiation of *(1a)* in a solid matrix of polystyrene containing 0.1 % or less of 1-vinylimidazole in the presence of oxygen rapidly gives rise to the previously characterized compound formylbiliverdin *(3)*[4] in more than 80 % yield, *i. e.* the magnesium porphyrin added molecular oxygen at its periphery. Use of a copolymer containing 20 % of imidazole under otherwise identical conditions led to quantitative conversion of *(1a)* into its π radical cation *(2)*[2] within one hour. No addition of oxygen took place. Dissolution of the polymer-porphyrin mixture in benzene and reduction with triethylamine regenerated the magnesium porphyrin *(1a)* in over 80 % yield. Both the radical *(2)* and formylbiliverdin *(3)* were stable for months in the solid polymer, while they quantitatively decomposed within a few hours in solution.



(2)

(3)

Chemical oxidation of *(1a)* with benzoyl peroxide in a benzene solution containing the polymer with 20 % imidazole took a different course. Although the radical cation *(2)* was again generated initially, it immediately reacted with the polymer to form new covalent bonds. Shaking of the resulting solution with 10 % hydrochloric acid containing 50 % of ethanol did demetalate the polymer-bound magnesium porphyrin, but the porphyrin dication could not be transferred to the water/ethanol phase. Our explanation of this behavior assumes that benzoyl peroxide oxidizes not only the magnesium porphyrin *(1a)* to the radical *(2)* but also the imidazole to the imidazole radical. The two radicals then react together to form *(1b)*.

In order to confirm the formation of *(1b)* we oxidized a mixture of *(1a)* and imidazole in chloroform with benzoyl peroxide. Apart from 20% of 5-benzoyloxyporphyrin *(1c)* we obtained 60 % of the expected 5-imidazolyl derivative *(1d)*.

On the basis of these findings we suspect that in biological systems chlorophyll is protected from irreversible autoxidation not only by carotenes but also by surrounding proteins, and that addition of imidazole and protein constituents of similar

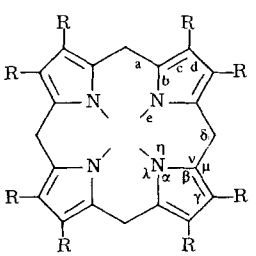
Structure of *N,N,N',N'''*-Tetramethyl-2,3,7,8,12,13,17,18-octakis(carboxymethyl)porphyrinogen Dihydrate[**]

By *Gisela Sawitzki* and *Hans Georg von Schnering*[*]

Franck and *Wegner* recently succeeded in preparing cyclic tetrapyrroles with four *N*-methyl groups for the first time[1]. We have carried out an X-ray structure analysis on a representative of this long-sought class of compounds[2], *viz.* *N,N',N'',N'''*-tetramethyl-2,3,7,8,12,13,17,18-octakis(carboxymethyl)porphyrinogen *(1)*, which crystallizes as the dihydrate.



(1),
R = CH_2–COOH

(1) crystallizes in the monoclinic space group I2/c-C_{2h}^6 with $a=15.914(3)$, $b=18.288(4)$, $c=14.387(3)$ Å, $\beta=109.61(2)°$, and $Z=4$ molecules per unit cell. The structure was solved by direct methods (MULTAN)[3] and refined[5] to $R=0.065$ for 1755 reflections with $I>2\sigma(I)$ (four-circle diffractometer SYNTEX-$P\bar{1}$, CuKα, ω-scan, $2\theta_{max}=100°$[4]). After anisotropic refinement of the heavy atoms N, C, and O, the greater part of the H atoms could be located in a ΔF map. The H atoms were included in the last cycles of refinement with average isotropic thermal parameters.

The molecule displays crystallographic C_2-symmetry. The mean distances and angles in the skeleton are [cf. formula *(1)*] $a=1.506(7)$, $b=1.385(8)$, $c=1.373(6)$, $d=1.416(2)$, $e=1.462(9)$ Å; $\alpha=109.1(1)$, $\beta=107.6(5)$, $\gamma=107.9(3)$, $\delta=116.2(8)$, $\lambda=126.6(1)$, $\eta=124.1(3)$, $\nu=123.0(17)$, and $\mu=129.0(11)°$. The normals of the pyrrole rings are inclined by 61 and by 65°, respectively, to the C_2 axis of the molecule. Two of the *N*-methyl groups are rigidly fixed by neighboring groups, the other two show free rotation within a range of ±30° (the H atoms of these groups appeared as diffuse maxima). The shortest H—H distances between different groups are about 2.2 Å.

The porphyrinogen skeleton is "bridged" by two symmetrically equivalent side chains and two molecules of water (cf. Fig. 1), the carboxyl groups of the side chains being linked

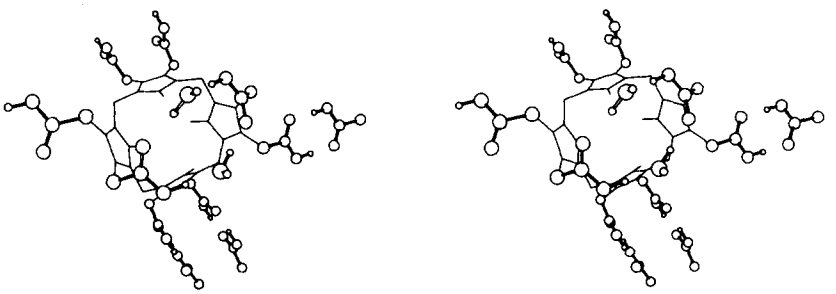


Fig. 1. Stereoscopic representation (ORTEP [6]) of a molecule, viewed almost along the C_2 axis. The porphyrinogen skeleton is outlined. The atoms of the side chains and the H_2O molecules are represented by circles. In the upper part the mutual orientation of COOH groups and H_2O molecules (H bonds omitted) can be recognized. The intermolecular H bonds are indicated for selected COOH groups of neighboring molecules.

to the H_2O molecules by hydrogen bonds (O—O distances = 2.6 and 2.8 Å). The H_2O molecules and the COOH groups are both proton donors and proton acceptors. The other carboxyl groups of the side chains are likewise connected by hydrogen bonds with carboxyl groups of four neighboring molecules (O—O distances = 2.6 to 2.7 Å). In this way an infinite two dimensional molecular lattice is built up. This result accords with the ready cleavage of the crystals along their needle axis.

In our opinion the intramolecular hydrogen bonds between COOH groups and H_2O molecules contribute substantially to the stabilization of the unusual conformation.

Indirect Determination of the Half-Wave Reduction Potentials of Benzene and [2.2]Paracyclophane[**]

By *Fabian Gerson, Hiroaki Ohya-Nishiguchi,* and *Christoph Wydler*[*]

The half-wave reduction potential $E_{1/2}$ of benzene lies in a range (< −3 V) which is inaccessible for polarographic stu-

[*] Prof. Dr. F. Gerson, Dr. H. Ohya-Nishiguchi, and Dr. Ch. Wydler

CH-4056 Basel (Switzerland)

[**] This work has been supported by the Schweizerischer Nationalfonds (Project Nr. 2.313.75).

dies. A "theoretical" estimate of this value can be obtained by extrapolation from the linear relationship (1) between the observed half-wave reduction potentials $E_{1/2}$ of conjugated π-systems and the calculated energies of the lowest unoccupied orbitals (LUMOs).

$$E_{1/2} = -0.92 + 2.37x \text{ [volt]} \quad (1)$$

The values $E_{1/2}$ are polarographic data measured against the saturated calomel electrode, and the numbers x characterize the HMO energies ($\alpha + x\beta$) of the LUMOs[1]. The half-wave reduction potential of benzene ($x = -1.00$) resulting by extrapolation from eq. (1) is -3.29 V.

The finding[2] that benzene can also be electrolytically reduced in an ethereal solvent to its radical anion suggests an analogous, "experimental" procedure for the evaluation of the half-wave potential. A prerequisite for such a procedure is a linear relationship between the minimum voltages V_a, at which the ESR spectra of the radical anions appear during the electrolysis, and the polarographic data $E_{1/2}$. That this prerequisite has been met is shown by the appearance voltages V_a measured in the present work for the radical anions of 20 hydrocarbons and plotted in Figure 1 *vs.* the corresponding values $E_{1/2}$. The pertinent regression line has the equation

$$V_a = (1.92 \pm 0.06) E_{1/2} \quad (2)$$

with a correlation coefficient of 0.991 and a deviation from the origin (0.007) which is far below the significance threshold.

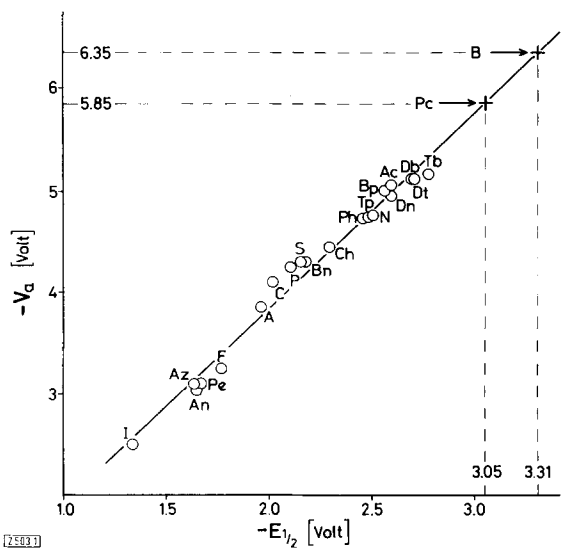

Fig. 1. Plot of appearance voltages V_a *vs.* half-wave reduction potentials $E_{1/2}$. A = anthracene; Ac = acenaphthene; An = acenaphthylene; Az = azulene; B = benzene; Bn = biphenylene; Bp = biphenyl; C = coronene; Ch = chrysene; Db = 4,4'-dimethylbiphenyl; Dn = 2,3-dimethylnaphthalene; Dt = 4,4'-di-*tert*-butylbiphenyl; F = fluoranthene; I = indeno[1,2,3-*cd*]fluoranthene; N = naphthalene; P = pyrene; Pc = [2.2]paracyclophane; Pe = perylene; Ph = phenanthrene; S = stilbene; Tb = 3,3',5,5'-tetra-*tert*-butylbiphenyl; Tp = triphenylene.

The half-wave reduction potentials $E_{1/2}$ in equation (2) and Figure 1 were either taken from the compilation by *Streitwieser*[1] or determined in a laboratory of our Department[3, 4]. They refer to the saturated calomel electrode as standard. On the other hand, the appearance voltages V_a are not bound to any conventional reference level and may thus be compared only with data obtained under the same conditions. The electrolytic cell used throughout the entire series had a cylindrical form and contained a helical cathode of amalgamated gold, along with an anode of platinum wire placed along the cell axis[5]. 1,2-Dimethoxyethane and 0.1 M tetrabutylammonium perchlorate served as the solvent and supporting salt, respectively. The temperature was -90 °C. According to the original quantity weighed in, the concentration of each hydrocarbon ought to be 5×10^{-3} mol/liter. However, in the case of some aromatics of poor solubility, the actual concentration was lower, which may be one of the reasons for the deviation of the corresponding data V_a from the regression line in Figure 1. For each hydrocarbon several measurements were performed in order to determine the minimum value for the appearance voltage V_a. Such a value was considered as reliable when it could be reproduced within an experimental error of ± 0.05 V.

Extrapolation of the equation (2) to the appearance voltage V_a (Fig. 1) for the radical anion of benzene yields $E_{1/2} = -3.31 \pm 0.12$ V (90% confidence limits) as an "expermental" estimate of the half-wave reduction potential of benzene in excellent agreement with the "theoretical" result of -3.29 V. Obviously, values of $E_{1/2}$ can be estimated in a similar way for other compounds of low electron affinity, provided that such compounds are electrolytically convertible into their radical anions. An example is [2.2]paracyclophane for which equation (2) affords a half-wave reduction potential $E_{1/2} = -3.05 \pm 0.12$ V (Fig. 1). It is worth mentioning that in this case an extrapolation of equation (1) is not as straightforward as for benzene, since the HMO model is not directly applicable to [2.2]paracyclophane. The values $E_{1/2}$ found for the two hydrocarbons are in accord with a previous report which points to a distinctly higher electron affinity of [2.2]paracyclophane relative to that of benzene[6].

Isolation and Infrared Spectrum of Iodine Azide

By *Kurt Dehnicke*[*]

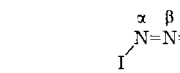
Far less is known about the chemistry of iodine azide than about that of chlorine azide and bromine azide[1]. The preparation of IN_3 from iodine and silver azide in ether, which leads to very readily decomposable solutions, has been reported[2], as has the ability of IN_3 to undergo stereospecific addition to olefinic double bonds, for which IN_3 generated from sodium azide and iodine chloride in acetonitrile is employed *in situ*[3].

We have found that solutions of iodine azide in dichloromethane, carbon tetrachloride, and benzene are much more stable than those in ether. 1 to 3% solutions are obtained by dropwise addition with stirring at 0 °C of I_2 solutions of corresponding concentration to freshly precipitated silver azide freed from water. Solutions of this concentration can be manipulated without danger, and can even be dried without decomposition over phosphorus pentoxide.

[*] Prof. Dr. K. Dehnicke
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg (Germany)

Careful evaporation of solvent CH_2Cl_2 leaves a residue of golden yellow, hygroscopic, and somewhat light-sensitive needle-shaped and extensively intermeshed crystals of IN_3, of which only very small amounts were prepared owing to their explosive nature. Under normal pressure they can be sublimed at room temperature on to a cold finger maintained at −78 °C. No melting point can be recorded because the sublimation point lies at 24 °C/760 torr.

The IR spectrum of IN_3 recorded both in solution and in Nujol emulsion (Table 1) is compatible with the structure *(1)* which is bent at the α-N atom and has the molecular symmetry C_s.



(1)

Table 1. IR spectrum of iodine azide (C_s symmetry).

In benzene [cm^{-1}]	Intensity	Crystalline [cm^{-1}]	Intensity	Assignment	
3242	w	3242	vw	$\nu_{as}+\nu_s(N_3)$	
		2460	vw	$2\times\nu_s(N_3)$	
2058	vs	2045	vs	$\nu_{as}(N_3)$	A′
1176	m	1240	m	$\nu_s(N_3)$	A′
		648	vw	$\delta(N_3)$	A′
578	w	580	w	$\gamma(N_3)$	A″
338	m	338	m	ν(N—I)	A′

Apart from the INN deformation vibration (A′) to be expected below the range of measurement (down to 250 cm^{-1}) all the fundamental vibrations can be assigned. Two special features of the spectrum warrant attention:

1) The two N_3 stretching vibrations having symmetric and asymmetric character move apart significantly during the transition solid/dissolved. This might be connected with a favoring of the diazonium structure of IN_3 in the dissolved state. However, an intermolecular interaction is more likely and would lead to deviation from linearity of the NNN group in the crystalline state, as observed for some heavy metal azides[4].

2) The I—N stretching frequency lies at 338 cm^{-1} and thus at considerably longer wavelengths than to be expected from the series FN_3 [ν(FN) = 869 cm^{-1}][5], ClN_3 [ν(ClN) = 719 cm^{-1}][5, 6], BrN_3 [ν(BrN) = 687 cm^{-1}][5]. This result can be explained by a pronounced polarity of the iodine-nitrogen bond as shown in *(2)*.

(2)

Iodine azide should therefore react with metal iodides *via* substitution. Indeed boron triiodide and iodine azide immediately deposit I_2 and form the unknown compound diiodine borazide[7].

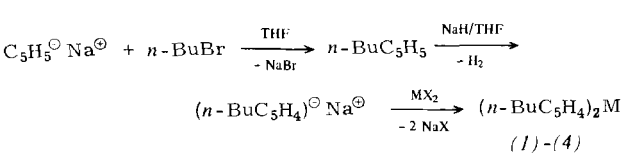
A New Probe for C-C Hyperconjugation: ^{13}C-NMR on Paramagnetic Metallocenes[1]

By *Karl Eberl*, *Frank Herwig Köhler*, and *Lothar Mayring*[*]

On the basis of *Mulliken*'s concept of hyperconjugation[2], C-C hyperconjugation can be regarded as a particularly important variant of this phenomenon. It warrants attention in the large number of organic and organometallic compounds in which C-C σ bonds can interact with π orbitals of aromatic systems or heteroatoms. The Baker-Nathan effect was considered to be an especially significant indication of hyperconjugation, C-C hyperconjugation being thought much smaller than C-H hyperconjugation[3]. However, this effect was found to arise rather from changes in solvation[4]. Very recent *ab initio* calculations even show C-C hyperconjugation to make an important contribution to the stability of acetyl cations[5]. This situation has long awaited experimental elucidation.

The development of paramagnetic ^{13}C-NMR spectroscopy[6] now permits study of C-C hyperconjugation with the aid of a generally applicable method. Suitable molecules are paramagnetic metallocenes. In these compounds part of the spin density of the unpaired electrons is delocalized into the π system of the ligand. From that position there exists the possiblity of hyperconjugational transfer to the β-C atoms of substituents located on the cyclopentadienyl groups. In this way the unpaired spin density becomes an indicator of C-C hyperconjugation. It causes exceptionally large ^{13}C shifts $\delta(^{13}C)$ which serve as a sensitive probe.

A versatile test is possible with *n*-butyl-substituted metallocenes. These compounds contain not only β-C but also γ-C and δ-C atoms, which are hardly affected by C-C hyperconjugation. The hitherto unknown 1,1′-di-*n*-butyl metallocenes of vanadium *(1)*, chromium *(2)*, cobalt *(3)*, and nickel *(4)* can be obtained in 50 to 80 % yield by the following method (yield of intermediates: 42 and 75 %)[6].



(1)–*(4)*

Compounds *(1)* to *(4)* are highly air-sensitive, deeply colored liquids. Elemental analyses confirm their purity, and ^{13}C-NMR spectra their molecular structure (typical example in Fig. 1). The precise $\delta(^{13}C)$ are listed in Table 1. Their assignment follows from the chemical shifts, intensities, and multiplicities, as well as from earlier findings[6].

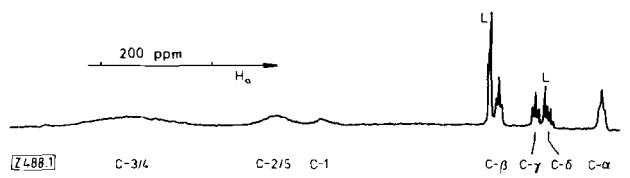


Fig. 1. ^{13}C-NMR spectrum of $(n\text{-}BuC_5H_4)_2Co$ *(3)* at 309 K. L = [D_8]-toluene. Concerning assignment, see Fig. 2.

In order to facilitate comparison of *(1)*—*(4)* we converted the $\delta(^{13}C)$ values in the known way[7, 8] into hyperfine interaction constants *A*. In connection with C-C hyperconjugation we are interested in the magnitudes of *A* at the *n*-butyl C atoms. The curves plotted in Fig. 2 reveal that |*A*| is excep-

(4)	Ni	[c]	[c]	[c]	+612	−380	−40	+ 2

[a] Measured in ppm relative to solvent ([D_8]-toluene), converted to shifts relative to 1,1'-di-*n*-butylferrocene; downfield shifts negative; temperature 309 K; instrument: Bruker HX 90; digital accuracy 1 ppm/data point.
[b] Cf. Fig. 2.
[c] Not yet observed owing to excessive line width.

tionally large at β-C. The selective transfer of unpaired spin density to C-β is due to C-C hyperconjugation.

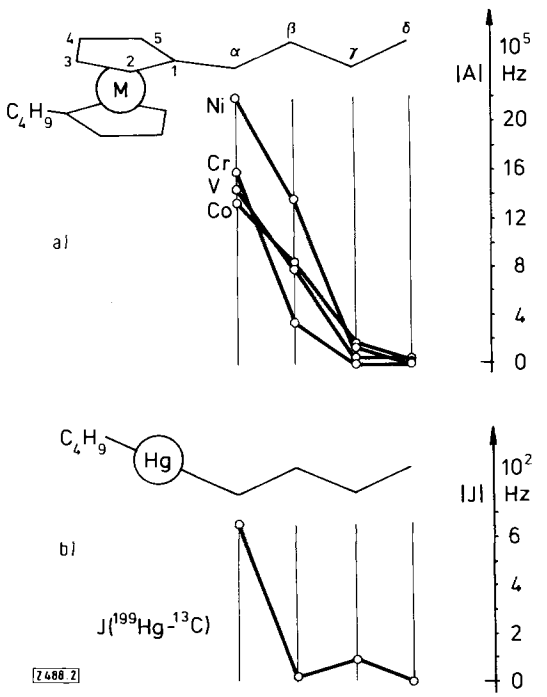

Fig. 2. a) Electron spin transfer into the *n*-butyl group of the paramagnetic metallocenes *(1)* to *(4)* with C-C hyperconjugation. b) Nuclear spin transfer into the *n*-butyl group of $(n\text{-Bu})_2Hg$ without C-C hyperconjugation.

For the sake of substantiation we also consider the comparison with the nuclear coupling constants $J(^{199}Hg\text{-}^{13}C)$ of di-*n*-butylmercury[9] (cf. Fig. 2). Both the nuclear spin coupling and the delocalization of unpaired electrons are mediated by Fermi contact interaction[10]. In contrast to the metallocenes *(1)* to *(4)* no C-C hyperconjugation to the β-C atom is to be expected in di-*n*-butylmercury[11]; $^2J(^{199}Hg\text{-}^{13}C)$ is accordingly very small in Figure 2.

^{13}C-NMR measurements on paramagnetic molecules is a versatile and rapid probe for C-C hyperconjugation; the natural abundance of ^{13}C suffices for the measurements. We are therefore attempting to derive quantitative results.

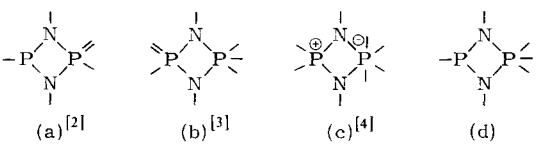
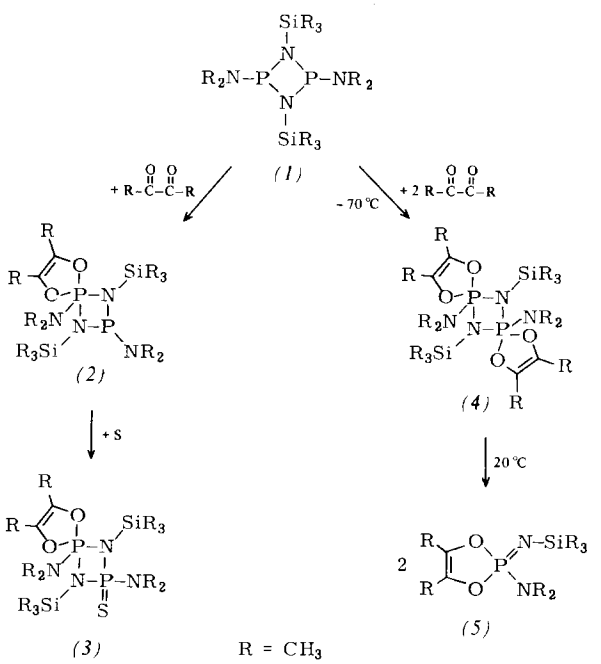
Isolation of a Diaza-λ^3,λ^5- and a Thermodynamically Unstable Diaza-λ^5,λ^5-diphosphetidine

By *Werner Zeiss*[*]

The chemistry of the diazadiphosphetidines[1] has recently been extended to include compounds of the type *(a)*—*(c)*, the two phosphorus atoms possesing different oxidation and/or coordination numbers.



Partial oxidation of the diaza-λ^3,λ^3-diphosphetidine *(1)* recently prepared by us[5] with biacetyl yields a compound of type *(d)*, namely the diaza-λ^3,λ^5-diphosphetidine *(2)*. As expected, P^{III} in *(2)* is still readily oxidizable: reaction with sulfur leads quantitatively to *(3)*, a further diazadiphosphetidine of type *(b)* (Table 1).



(1) reacts smoothly with an excess of biacetyl at low temperature to give the isolable diaza-λ^5,λ^5-diphosphetidine *(4)*, which, in solution at room temperature, decomposes quantitatively within 24 h to the monomeric phosphazene *(5)*. In contrast to crystalline *(4)*, *(5)* is a colorless liquid which crystallizes at −27 °C and does not re-dimerize to *(4)*, even in the crystalline state (Table 1).

[a] Shifts w.r.t. H_3PO_4 (external) or TMS (internal) as standard; $\delta^{31}P$ to higher field, $\delta^{1}H$ to lower field quoted as positive.
[b] Coordination number 5.
[c] Coordination number 4.
[d] Not observed.
[e] $[X_6A]_2$ spin system.
[f] Arbitrary assignment.
[g] $J = J_{PNCH} + J_{PNPCH}$.

The thermodynamic instability of *(4)* compared to that of its monomer *(5)* is consistent with expectation, since the presence of bulky groups on nitrogen[6] together with electron-donor groups on phosphorus is known to inhibit dimerization of a phosphazene in all cases investigated so far. However, under the mild conditions mentioned the reaction sequence *(1)*→*(4)*→*(5)* evidently runs kinetically controlled, thus permitting isolation of *(4)*.

2,4-Bis(dimethylamino)-6,7-dimethyl-1,3-bis(trimethylsilyl)-5,8-dioxa-1,3-diaza-2λ³,4λ⁵-diphosphaspiro[3.4]oct-6-ene (2)

A solution of *(1)* (1.9 g, 5.85 mmol) in anhydrous CH_2Cl_2 (5 ml) is cooled with stirring to −70 °C. The solution is then treated with biacetyl (0.5 g, 5.82 mmol) and allowed to warm to room temperature. After removal of solvent *in vacuo* *(2)* can be crystallized from a minimal amount of acetonitrile as colorless crystals: yield 1.3 g (54 %), m.p. 52 °C (sealed tube).

5,7-Bis(dimethylamino)-2,3,9,10-tetramethyl-6,12-bis(trimethylsilyl)-1,4,8,11-tetraoxa-6,12-diaza-5λ⁵,7λ⁵-diphosphadispiro-[4.1.4.1]dodeca-2,9-diene (4)

To a stirred solution of *(1)* (4.75 g, 14.7 mmol) in anhydrous CH_2Cl_2 at −75 °C is added 2.7 g (31.4 mmol) biacetyl. Crystals begin to form almost immediately. On completion of crystallization the reaction product is allowed to warm to −30 °C, whereupon total dissolution takes place. The solution is covered with dry acetonitrile (30 ml) and allowed to stand for 24 h at −20 °C. The colorless crystals which are formed, and which can be stored almost indefinitely at −20 °C, are filtered off on a Gooch frit in the absence of moisture and dried *in vacuo* at room temperature. Yield of *(4)*: 3.2 g (44 %), m.p. 76—78 °C (dec.) (sealed tube).

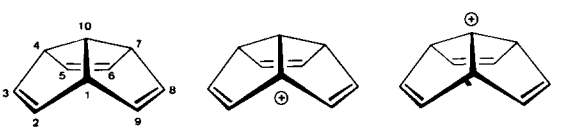
Stability of Triquinacenyl Cations and Triquinacenyl Radicals

By *Peter Bischof*[*]

In nonplanar π-systems the σ-π interactions can not be neglected. It will be shown here, for example, that this interaction is important in the bridgehead cations *(2)* (1-triquinacenyl cation) and *(3)* (10-triquinacenyl cation) and in the corresponding radicals *(2')* and *(3')*.



(1) *(2)* *(3)*

The structures of *(2)* and *(3)* were optimized by MINDO/3 calculations[1]. The structural data of the geometries obtained are listed in Table 1. The calculation reveals that the cation *(2)* is about 23 kcal/mol more stable than *(3)*. An upper limit of the activation energy for transformation of *(3)* into *(2)* was calculated as 9 kcal/mol[2]. For comparison, the exper-

imentally determined activation energy for the 1,2 hydride shift on the 2-norbornyl cation is 10 kcal/mol[3].

These relative energy predictions have now been confirmed experimentally[4]. The calculated flattening of the carbenium ion into an almost planar divinylcarbenium ion is supported by the ^{1}H- and ^{13}C-NMR spectra[4].

Calculation with a UHF open-shell version of MINDO/3[5] shows the same stability sequence for the radicals *(2')* and *(3')*: Radical *(2')* is about 10.5 kcal/mol more stable than *(3')*. The calculated structural data are also listed in Table 1.

The stabilization of *(2)* by interaction with the conjugated double bonds is consistent with expectation. The optimized structure shows a marked shortening of the C^1C^2 and C^1C^9 bond lengths; the positive charge is distributed over the pentadienyl system.

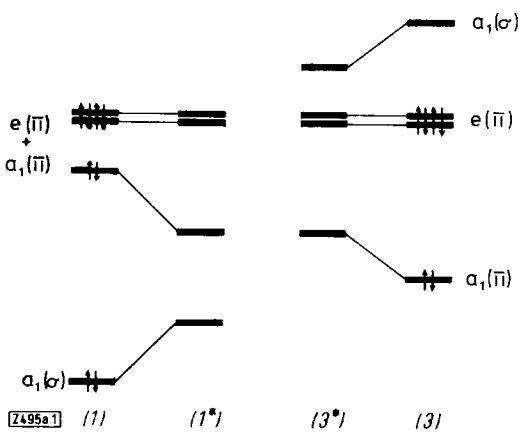

Fig. 1. Qualitative σ-π interaction diagram for triquinacene *(1)* and the 10-triquinacenyl cation *(3)*.

Generation of the cation *(3)* from *(1)* is likewise favored. This is due to σ-π interaction. The explanation is shown in Figure 1, where the relevant σ and π orbitals in *(1)* and *(3)* are compared with those of the corresponding models *(1*)* and *(3*)* without σ-π interaction. It is known that interaction between the two occupied orbitals $a_1(\sigma)$ and $a_1(\pi)$ in *(1)* leads to destabilization of the molecule[6]. On the other hand, interaction between the low-lying unoccupied orbital $a_1(\sigma)$ and the occupied orbital $a_1(\pi)$ in *(3)* must lead to stabilization of the cation. Analogous arguments apply in the case of radicals *(2')* and *(3')*. Accordingly, both the heterolytic and the homolytic cleavage of the $C^{10}H$ bond are accelerated by σ-π interaction.

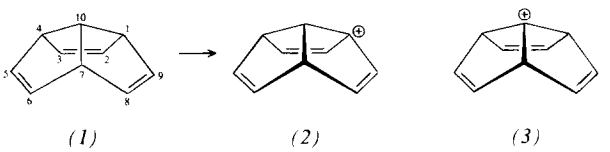
Bridgehead Cations of Tricyclo[5.2.1.0^{4,10}]deca-2,5,8-triene (Triquinacene)[**]

By *Dieter Bosse* and *Armin de Meijere*[*]

Carbenium ion centers on both types of bridgehead positions of triquinacene *(1)*[1] ought, in contrast to a comparable system without double bonds, to be stabilized by interaction of the vacant bridgehead orbitals with the π orbitals of the double bonds. As the structural data of *(1)*[2] show, the 1-triquinacenyl cation *(2)* should be a twofold allyl-stabilized bridgehead cation. Semiempirical calculations[3] confirm this; moreover, they show that the 10-triquinacenyl cation *(3)* ought to be stabilized too, albeit to a lesser extent.

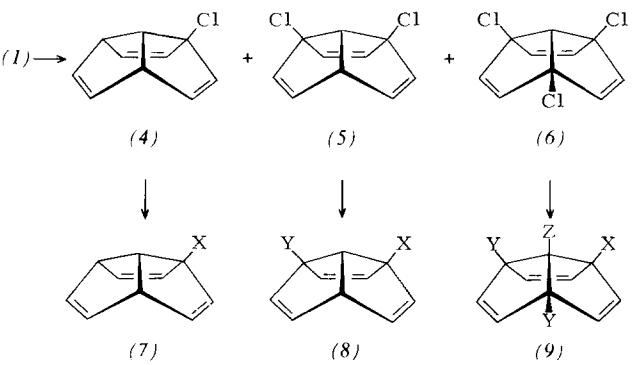


(1) *(2)* *(3)*

We have therefore investigated the possibilities of generating the bridgehead carbenium ions of *(1)*.

Photochlorination of *(1)* with *tert*-butyl hypochlorite at −50°C in trichlorofluoromethane (Frigen 11) affords a mixture of 1-chloro- *(4)*, 1,4-dichloro- *(5)*, and 1,4,7-trichlorotriquinacene *(6)*. The relative yields of *(4)*, *(5)*, and *(6)* can be varied by altering the ratio *(1)* : *tert*-butyl hypochlorite. On using a 3.6 molar excess the trichloride *(6)* was formed in *ca.* 75% yield and could be obtained pure by recrystallization[4]. *(4)* and *(5)* were isolated by preparative gas chromatography[4]. 10-chlorotriquinacene could not be detected in the product mixture.

(4) is sensitive to heat and light: in 80% dioxane/water it is completely hydrolyzed within 30 min at room temperature to 1-triquinacenol *(7a)*[4]; methanolysis leads to *(7b)*, reacence of sodium methoxide, *(5)* and *(6)* can also be converted tion with dimethylamine to *(7c)*[4]. In methanol in the presinto the methyl ethers *(8b)*[4] and *(9b)*[4], respectively. While *(5)* is completely hydrolyzed to the dialcohol *(8)*[4] within



(4) *(5)* *(6)*

(7) *(8)* *(9)*

(a), X, Y = OH; *(b)*, X, Y = OCH_3, Z = H; *(c)*, X = $N(CH_3)_2$; *(d)*, X = ⊕, Y = Cl, Z = H; *(e)*, X, Y = OCD_3, Z = D

5 h in boiling dioxane/water, *(6)* remains unchanged even after 72 h under the same conditions. This difference in behavior of *(6)* on hydrolysis and methanolysis can only be interpreted in terms of an elimination-addition mechanism[5], for reaction with [D_4]-methanol/sodium methoxide affords exclusively 10-deuterio-1,4,7-tris(trideuteriomethoxy)triquinacene

Allylic positions	5.46 (m, H^4, H^7)	5.22 (m, H^7)		56.48 (C^4, C^7)	56.46 (C^7)	72.29 (C^4, C^7)
					73.61 (C^4)	

[a] Relative to tetramethylsilane.

(9e). A "dehydrotriquinacene"[6] (tricyclo[5.2.1.$0^{4,10}$]deca-1(10),2,5,8-tetraene and/or tricyclo[5.2.1.$0^{4,10}$]deca-1(2),3,5,8-tetraene) must occur as an intermediate; the chlorides *(4)*, *(5)*, *(6)*, and especially the dimethylaminotriquinacene *(7c)*, may be considered as potential precursors of this class of compounds.

For the generation and investigation of free carbocations of the triquinacene system all three chlorides *(4)*, *(5)*, and *(6)* were allowed to react with antimony pentafluoride in sulfuryl chloride fluoride at −78 °C and the ^{1}H- and ^{13}C-NMR spectra of the reaction mixture were recorded (see Table 1). According to these, only the monocations *(7d)* [≡ *(2)*], *(8d)*, and *(9d)*, respectively, were present in each case. Their kinetic stability increases with increasing chlorine substitution; thus *(7d)* already decomposes at −40 °C, whereas *(9d)* is still detectable spectroscopically even after 15 min at 25 °C. Trapping experiments with sodium methoxide in methanol led to the methyl ethers *(7b)*, *(8b)*, and *(9b)*, respectively, in good yields.

The ^{1}H- and ^{13}C-NMR spectroscopic data of the free carbenium ions show that almost planar divinylcarbenium ion units are present in these species. Increasing chlorine substitution in *(8d)* and *(9d)* leads to a lowering of the electron deficit in the divinylcarbenium ion units and thus to high-field shifts of the ^{1}H- and ^{13}C-NMR signals.

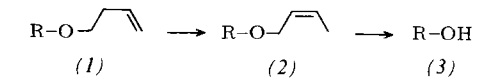
Cleavage of Allyl Ethers with Pd/C[**]

By *Roland Boss* and *Rolf Scheffold*[*]

Allyl ethers *(1)* are to a large extent stable under basic and acid conditions. Because of this property the allyl group is often used as protecting group for alcohols. Removal of the protecting group is usually effected by isomerization of the allyl ether to the corresponding enol ether *(2)* with subsequent H^+ or Hg^{2+}[1] catalyzed hydrolysis or oxidative cleavage[2].



(1) *(2)* *(3)*

Since the known methods[3] for allyl ether cleavage did not lead to the alcohol *(9a)* in the case of the glycidonitrile allyl ether *(9)* we investigated the heterogeneously catalyzed isomerization of allyl ethers to *cis*-enol ethers. We found palladium/activated charcoal to be a particularly suitable catalyst for this purpose[4].

If isomerization is carried out under conditions favoring hydrolysis of the *cis*-enol ethers the cleavage products alcohol and propionaldehyde are obtained directly. Since both the catalyst as well as the propionaldehyde (b.p. 49 °C) can be separated very easily this allyl ether cleavage is very useful (cf. examples in Table 1). That the allyl protecting group can be selectively removed besides other protecting groups is illustrated by the examples glycerol 1-allyl 2,3-dibenzyl ether *(7)*.

The allyl ether to be cleaved is heated for a few hours at 60° to 80 °C in a mixed solvent (see Table 1) in the presence of a trace of *p*-toluenesulfonic acid or mineral acid (*e.g.* perchloric acid) and a catalytic amount of palladium on activated charcoal[5]. In the case of sensitive substrates, *e.g.* the glycidonitrile *(9)*, the cleavage can be carried out over a prolonged period of time (up to *ca.* 6 days) at room temperature.

Using this method 2,5-dihydrofuran can be cleaved smoothly in methanol/water to 4-hydroxybutanol, while 3-methoxycyclohexene remains unchanged under comparable conditions. This finding would suggest that a cisoid conformation of the allyl ether partial structure is a prerequisite for the palladium-catalyzed isomerization[3].

Experimental

Glycerol 1,2-dibenzyl ether *(7a)*: A solution of *(7)* (1.00 g, 3.2 mmol) in methanol (10 ml) and water (2 ml) is treated with palladium/activated charcoal (0.1 g) and toluenesulfonic acid (0.1 g). The resulting suspension is boiled under reflux with stirring for 24 hours. After removal of catalyst by centrifugation the solution is extracted with ether, the solvent removed in a rotary evaporator, and the residue distilled. The yield of *(7a)* (b.p. 150 °C/0.05 torr[2]) is 0.85 g (97 %).

Methyl 2-(4-hydroxymethyl-2-methoxy-6-oxo-4-vinyl-1-cyclohexenyl)acrylate *(8a)*: To a solution of *(8)* (3.9 g, 13.3 mmol) in anhydrous methanol (170 ml) is added palladium/

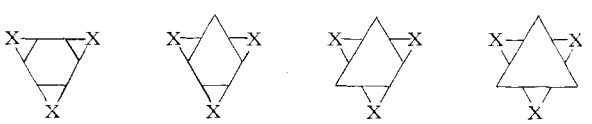
[4] We used the hydrogenation catalyst 10 % palladium on activated charcoal obtainable from Fluka. Experiments with rhodium on activated charcoal also gave positive results; ruthenium and platinum on activated charcoal proved less useful. This is in agreement with the finding that palladium proves to have the greatest tendency for shifting double bonds in hydrogenations. Cf. also *P. N. Rylander*, Adv. Chem. Ser. *98*, 150 (1971).
[5] As is to be expected the allyl cleavage is blocked by traces of "catalyst poisons" such as thiophenol and potassium cyanide. It is therefore recommended that the reaction vessel be cleaned with chromic sulfuric acid, washed with potassium hydroxide solution, and finally rinsed with demineralized water.

Synthesis of *cis*-Trioxa-tris-σ-homotropilidene[**]

By *Horst Prinzbach* and *Christoph Rücker*[*]

Preparative and mechanistic objectives stimulated extension of our work on the tris-σ-homobenzenes *(1)* (X = CR_2, O, NR, S)[1] to investigation of the homologs *(2)*—*(4)*. After having recently described the first valence isomeric σ/π-hexahomobenzenes *(4)*[2], we now report the dioxa-bis- and trioxa-tris-σ-homotropilidenes *(2)* (X = O)[3].



(1) *(2)* *(3)* *(4)*

Mainly because of our particular interest in the stereoelectronic features of valence isomerization in the *cis*-trioxide *(10)*, we have commenced our study program in this area with an investigation of the chances and stereoselectivity of a stepwise epoxidation of tropilidene. On reaction of excess peroxy acid (peroxyacetic acid, *m*-chloroperoxybenzoic acid) with the readily accessible oxide *(5)*[4] in dichloromethane/Na_2CO_3 the four dioxides *(6)*—*(9)* are formed, whereby the dioxide *(6)* is, according to a capillary-GC/MS analysis, the least favored product (total yield of products up to 40 %, ratio in a typical experiment *ca.* 6:26:27:41). Preparative gas chromatography affords pure *(7)* and a mixture of *(8)*/*(9)*

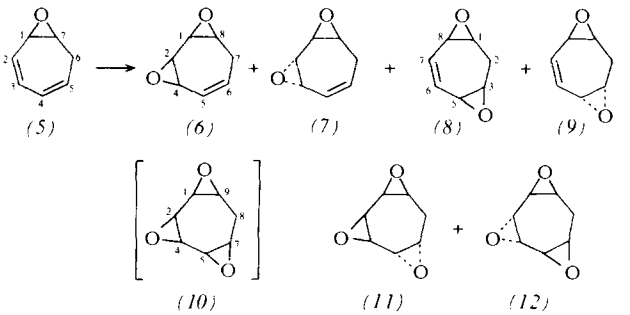
Richter*, respectively, for the NMR and GC/MS analyses. *Ch. Rücker* thanks the Studienstiftung des Deutschen Volkes for a graduate study grant.

($\tau_{2(2')\text{-H}}=7.7$ and $\tau_{2\text{-H}}=8.7$, $\tau_{2'\text{-H}}=7.2$, respectively). Epoxidation of *(6)* through *(9)*, however, is achievable only under very drastic conditions [*m*-chloroperoxybenzoic acid, boiling 1,2-dichloroethane (b.p. 83°C), 2,6-di-*tert*-butylphenol[5]]; accordingly, the proportion of by-products and loss of oxidizing agent are high.



(5) *(6)* *(7)* *(8)* *(9)*

(10) *(11)* *(12)*

The two trioxides identified by GC/MS analysis of the complex reaction mixture and isolated in very small amounts as a mixture (*ca.* 1:1) are confirmed as being *(11)* and *(12)*, respectively, by their ^{13}C-data [$CDCl_3$, $\delta=53.2$ ppm, 52.9, 52.5, 52.4, 51.4, 50.7, 27.4 (C-8) and $\delta=52.1$ ppm, 50.9, 50.4, 32.5 (C-8), respectively]. Accordingly, this serves as a preparatively useful route to *(7)* and, with limitations—considerable problems exist regarding separation—also to *(8)* and *(9)*, but not to compounds *(10)*—*(12)*.

We have found a route—based on the synthesis of the trioxide *(1)* (X=O)[6]—to the compound *(10)* undetectable direct oxidation of *(5)*, namely the reaction sequence *(5)* → *(13)* → *(14)* → *(15)*/*(16)* → *(10)*. The critical *anti-cis*-1,4 addition of bromine to *(5)* can be accomplished—albeit with not yet optimized regio- and stereospecificity (65%)—in Na_2CO_3-buffered dichloromethane solution at −78°C; chromatographically [silica gel, benzene/cyclohexane (1:1), 0°C] purified *(13)* (m.p. 51°C) is stable in solution below −60°C, but is slowly converted into an isomeric mixture at higher temperatures. The *anti*-2,5 position of the Br residues follows, above all, from the ^{1}H-NMR data (Table 1). The *cis*-hydroxylation *(13)* → *(14a)* with potassium permanganate at 0°C (acetone/water, $MgSO_4$) is still impaired by the partial isomerization of *(13)*; the crystalline diol (m.p. 130°C) isolated in yields of 35% to 45% was analyzed ^{1}H-NMR spectroscopically as diacetate *(14b)* (m.p. 148—149°C). On the basis of the coupling parameters (Table 1) twist-like conformations with quasi-equatorial arrangement of the residues on C-2, C-3 and quasi-axial arrangement of those on C-4,'C-5 are most likely for *(14a)*/*(14b)*. The twofold epoxide formation *(14a)* → *(10)* with three equivalents of potassium methoxide (MeOH, THF) proceeds without noticeable competition at 20°C. Chromatography (DC) and ^{1}H-NMR spectrometry reveal only one intermediate which has limited kinetic stability under the given conditions. The product isolated in very small amounts along with *(14)* and *(10)* on using only one equivalent of base is the non-crystalline *(15a)*, which was converted into the crystalline acetate *(15b)* (m.p. 137°C) in the conventional way. The preferred formation of *(15)* was to be expected on account of the steric conditions in *(14)*, without us so far being able to definitely rule out *(16)* as a further intermediate.

The structure of the *cis*-trioxide *(10)* (colorless crystals, m.p. 165°C, yield >90%, not optimized) is confirmed by the stereochemistry of its precursors and by its spectral data. On the basis of the comparable magnitude of $J_{7,8}$ ($J_{8,9}$) and $J_{7,8'}$ ($J_{8',9}$) *(10)* ought to be present as cisoid *(10a)*, and not as the transoid boat *(10b)*, less plausible because of transannular interactions. For both conformations, with a

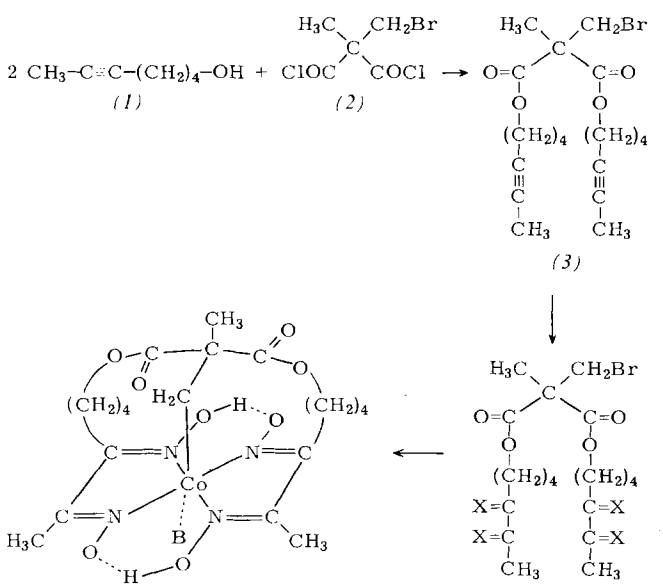
Synthesis, Structure Determination, and Rearrangement of a Model for the Active Site of Methylmalonyl-CoA Mutase with Incorporated Substrate[**]

By *Helmut Flohr*, *Wolfgang Pannhorst*, and *János Rétey*[*]

Dedicated to Professor Vladimir Prelog on the occasion of his 70th birthday

It has recently been shown by us[1] and by others[2] that a malonic ester substituted in the β-position with cobalt can rearrange into the corresponding succinic ester. Although a chemically analogous case for the enzyme-catalyzed isomerization of methylmalonyl-CoA to succinyl-CoA has thus been found, this model is in many respects not in keeping with the conditions at the active site of the enzyme. Soon after homolytic cleavage of the cobalt-carbon bond the malonic ester "substrate" loses contact with the central cobalt atom and, thus deprived of that atom's catalytic effect, is no longer able to rearrange[3]. This could explain the low[2] and variable[1] yields of rearrangement product. In order to better simulate the situation on the enzyme, we synthesized a cobalt complex in which the "substrate" is anchored covalently by two methylene bridges to a planar part of the complex.

5-Heptyn-1-ol *(1)*[4, 7] was reacted with 2-bromomethyl-2-methylmalonic acid dichloride *(2)* to give the diester *(3)*, which on treatment with ozone at −18 °C[5, 7] yielded the crude tetraketone *(4)*. The tetraoxime *(5)* obtained from *(4)* in 80% yield [referred to *(3)*] was finally allowed to react in dilute ethanolic solution with a stoichiometric amount of cobalt(II) chloride, twice the amount of pyridine, three equivalents of potassium hydroxide, and excess $NaBH_4$. Alkylated cobalt complexes were isolated from the mixture in 17% yield [referred to *(5)*]. Subsequent thin-layer chromatographic separation and recrystallization from acetone/water (with 1% pyridine) afforded the major product *(6)* in pure form in 7% yield [referred to *(5)*]. $R_f = 0.44$, chloroform : isopropanol : pyridine = 94 : 5 : 1, Macherey-Nagel plates, SILG-25-UV$_{254}$.



(6), B = Pyridine
(7), B = Methanol

(4), X = O
(5), X = NOH

Comparison of the ^{1}H-NMR[6] and UV spectra with those of known cobaloximes[1, 7] revealed without doubt that the product was the intramolecularly alkylated cobalt complex *(6)*.

Irradiation of a methanolic solution of *(6)* with a mercury high-pressure lamp for 60 min in the absence of oxygen led to replacement of the pyridine ligand by methanol. Thin-layer chromatography of the photoproduct (chloroform: isopropanol = 95:5, $R_f = 0.11$; hexane : isopropanol : methanol = 5 : 2 : 1, $R_f = 0.11$) afforded the cobaloxime *(7)*.

(7) crystallizes from CD_3OD in the space group $P\bar{1}$ with $a = 11.090$, $b = 13.772$, $c = 8.971$ Å; $\alpha = 99.75$, $\beta = 119.49$, $\gamma = 84.83°$; $Z = 2$. A total of 3076 symmetrically independent reflections were measured on a Picker diffractometer (MoK_z radiation), of which 2269 were classified as observed. The positions of the Co atoms were determined by a Patterson synthesis, the positions of all the other atoms other than hydrogen by difference Fourier syntheses. Refinement of the atomic coordinates and the anisotropic temperature factor coefficients for atoms other than hydrogen converged at $R = 0.056$.

Cobaloxime *(7)* adopts in the crystal lattice a chiral conformation; the ester carbonyl groups of the bridges point in opposite directions. The methyl group in the bridge center (on C-10) projects away from the plane of the equatorial ligands. The angle Co—C20—C'10 is 127.5°, compared with 125° and 117.3° for the corresponding angles in coenzyme B_{12}[8] and in methylene-bridged cobaloxime[7], respectively.

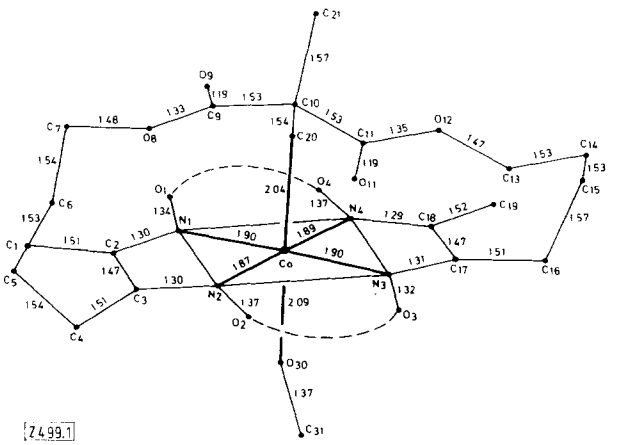


Fig. 1. Structure of the cobaloxime *(7)*. Lengths given in Å.

A solution of *(6)* (16 mg) in anhydrous methanol (15 ml) was purged repeatedly with nitrogen. The cooled solution (*ca.* 15 °C) was then irradiated with a mercury high-pressure lamp (125 W, Phillips) from a distance of 5 cm. Thin-layer chromatographic monitoring of the reaction showed that all Co-alkyl bonds were cleaved after 12 hours. After hydrolysis with excess ethanolic potassium hydroxide the solvent was removed *in vacuo*, the residue treated with 2 ml 1 N HCl and continuously extracted with ether. Thin-layer chromatographic investigation showed that the ether extract contained methylsuccinic acid as the sole organic acid. In particular, no dimethylmalonic acid could be detected. Thin-layer chromatography of the crude product (chloroform : glacial acetic acid = 5:1, $R_f = 0.47$, and diisopropyl ether: formic acid: water = 90:7:3, $R_f = 0.61$) afforded crystalline methylsuccinic

acid (m.p. 105—108 °C, ^{1}H-NMR and IR spectra identical with those of an authentic sample) in 82% yield (3 mg).

We explain the above results as follows: The light-induced homolysis of the cobalt-carbon bond leads to the radical *(8)*, which with participation of the cobalt rearranges reversibly into the radical *(9)*. Recombination in *(9)* would lead to the unstable *tert*-alkylcobaloxime *(10)*[9]. Of the species *(8)*, *(9)* and *(10)*, which are in equilibrium with each other, *(9)* has the highest population and can be stabilized to *(11)* by irreversible H-abstraction from the solvent. For radical *(8)* this reaction cannot compete with that of the intramolecular recombination leading to the stable *(6)*. The rearrangement might start from the radical species *(8)* or *(9)*; however a cobalt-stabilized intermediate *(12)* which could break down either to *(8)* or *(9)* would also be plausible.

Structure and Density Distribution of Bonding Electrons of Cumulenes[**]

By *Hermann Irngartinger* and *Hans-Ulrich Jäger*[*]

We have determined the structures of the cumulenes *(1)* and *(2)*[1] at room temperature and carried out low-temperature measurements for ascertaining the density distribution of bonding electrons in hexapentaene *(1)*[2]. For *(1)* and *(2)* the measurements at room temperature (MoK_α radiation; graphite monochromator; $\sin\theta/\lambda \leq 0.66$) gave R values of 0.067 and 0.064, respectively, after refinement with all reflections. The crystallographic data are listed in Table 1. In the case of the triene *(2)* full 2/m molecular symmetry is preserved in the crystal, which to our knowledge has never been found previously in an organic compound in the solid state. The averaged bond lengths and angles (Fig. 1) are corrected to "rigid body motion".

Table 1. Crystallographic constants of *(1)* and *(2)*.

	(1)		*(2)*
22 °C		−165 °C	22 °C
a = 8.444(1) Å		8.253(1) Å	a = 14.485(2) Å
b = 11.536(2)		11.498(2)	b = 10.021(2)
c = 12.040(2)		11.756(1)	c = 13.576(2)
β = 114.91°(1)		113.94°(1)	
$P2_1/c$; Z = 2			Cmca; Z = 4
$D_{calc.}$ = 1.013		1.056	1.013 g·cm^{-3}

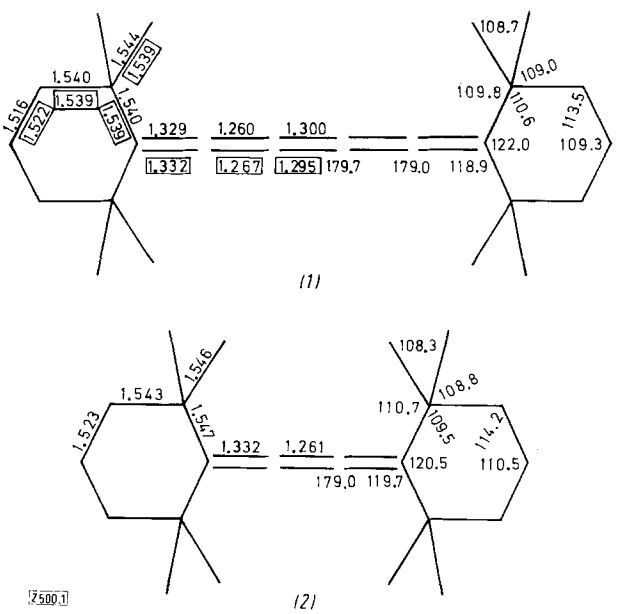

Fig. 1. Averaged bond lengths [Å] and angles [°] of 1,4-bis(2,2,6,6-tetramethylcyclohexylidene)butatriene *(1)* and 1,2-bis(2,2,6,6-tetramethylcyclohexylidene)ethylene *(2)*. The low-temperature values are framed.

From the bond angles it can be seen that the cumulene systems *(1)* and *(2)* are linear. The terminal C(sp^2)—C(sp) double bond of the triene system *(2)* with a value of 1.332 Å is slightly shorter than the standard value for a C(sp^2)—C(sp^2) double bond (1.34 Å). In *(2)* the central double bond situated between two sp-hybridized atoms is significantly shortened (1.261 Å). Similar differences in the double bonds have been found in unsubstituted butatriene[3] and in tetraphenylbutatriene[4]. The terminal double bonds in hexapentaene *(1)* are identical with the corresponding bonds in the butatriene *(2)*. The central C(sp)—C(sp) double bond with 1.300 Å, however, is longer than the neighboring bond of similar type. In contrast to the theoretically calculated bond lengths of 1.310 (terminal), 1.292, 1.292 Å (central)[5] for unsubstituted hexapentaene, our measurements indicate a clear alternation of bond lengths in the cumulene system of the hexapentaene *(1)*.

For determination of the electron density distribution in *(1)* four independent sets of reflections with a total of 28000 intensities were recorded at −165 °C up to $\sin\theta/\lambda \leq 1.2$ on

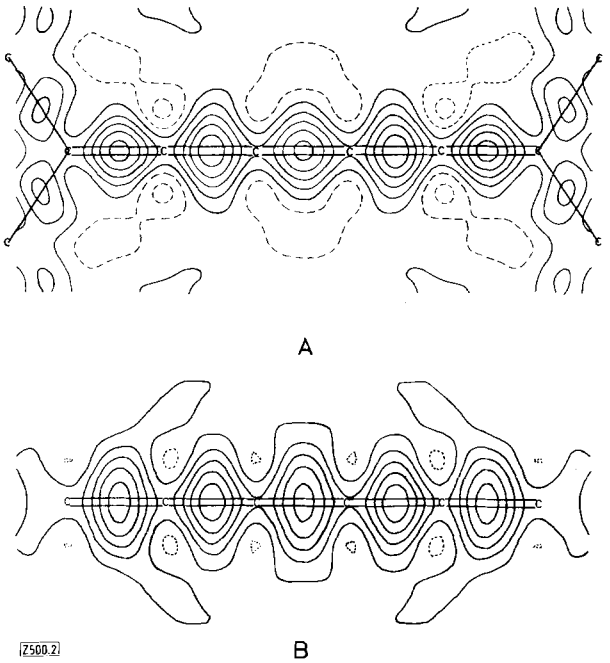

Fig. 2. Density distribution of bonding electrons in the cumulene system of *(1)* in a plane A, which contains the C atoms 2 and 6 of the cyclohexane ring, and a plane B perpendicular to A. The contour interval is 0.1 e/Å^3. Negative portions are drawn with dotted lines.

a computer-controlled Siemens diffractometer furnished with a Leybold-Heraeus low-temperature device[6]. After subsequent averaging of data, the refinement (C anisotropically, H isotropically) was carried out only with reflections of higher order in the range $0.7 \leq \sin\theta/\lambda \leq 1.2$ and yielded an R value of 0.04. The difference in density was computed from the atomic coordinates and temperature factors obtained using the set of data up to $\sin\theta/\lambda = 0.8$. The electron density distribution in the bonds of the cumulene system of *(1)* is depicted in Figure 2 for two sections perpendicular to each other along the cumulene axis. In section A, which contains the carbon atoms of the substituents, the bonding electron density of the second and fourth double bond is more strongly elongated vertical to the bond axis than in the neighboring double bonds, while in section B the elongation in the first, third and fifth double bond is strongest. The theoretical conceptions of the arrangement of π electrons in the double bonds of cumulated systems are thus in accord with our results.

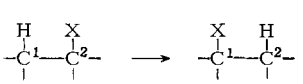
ABSTRACTS

The vitamin B_{12} coenzyme forms the subject of a review by *R. H. Abeles* and *D. Dolphin*. Coenzyme B_{12} carries a covalently bound 5'-deoxy-5'-adenosyl group instead of the cyano group of the vitamin (cyanocobalamin); both compounds are cobalt(III) derivatives. Coenzyme B_{12} and a few alkylcobalamins are the only known organometal compounds in Nature. Ten enzymatic reactions are presently known in which the coenzyme B_{12} is needed as cofactor. Nine of these proceed according to the following scheme:



The review also deals with the hydrogen transfer step and with the mode of action of the coenzyme. [The Vitamin B_{12} Coenzyme. Acc. Chem. Res. *9*, 114—120 (1976); 57 References]

[Rd 869 IE—L]

New synthetic methods for monocyclic 1*H*-, 2*H*-, and 3*H*-pyrroles are described by *J. M. Patterson*. The synthesis of 1*H*-pyrroles from cyclic precursors involves ring substitution, substituent migration, elimination, rearrangement, ring expansion and ring contraction reactions. Available for the synthesis of 1*H*-pyrroles from acyclic precursors by ring closure are, *inter alia:* dicarbonyl compounds, unsaturated compounds such as dienes, nitriles, alkynes, and enamines as well as amino- and halocarbonyl compounds. 2*H*- and 3*H*-pyrroles are obtained by alkylation of 1*H*-pyrroles, thermal isomerization, photoisomerization, ring closure of suitably substituted precursors, and in an oxidative way (photo- or electrochemically). [Recent Synthetic Methods for Pyrroles and Pyrrolenines (2*H* or 3*H*-Pyrroles). Synthesis *1976*, 281—304; 242 references]

[Rd 871 IE—M]

The spectral, potentiometric, and energy-linked properties of cytochrome c oxidase in mitochondria are discussed by *M. K. H. Wikström*, *H. J. Harmon*, *W. J. Ingledew*, and *B. Chance* from new points of view. Contrary to the generally accepted hypothesis, cytochromes a and a_3 are not both responsible for the α-band at 605 nm; the band is in fact due only to cytochrome a. The two hemes of cytochrome oxidase take part in strong interaction with one another, which is expressed in the redox properties, the spin state, and the light absorption of the enzyme. The effect of ligands on cytochrome c oxidase is discussed on the basis of new knowledge; the consequences of the heme-heme interaction for the mode of action of the enzyme and its control by the energy state of the mitochon-

drion are particularly emphasized [A Re-Evaluation of the Spectral, Potentiometric and Energy-Linked Properties of Cytochrome c Oxidase in Mitochondria. FEBS Lett. *65*, 259—277 (1976); 59 references]

[Rd 875 IE—R]

The pathway of nitrogen assimilation in plants forms the subject of a paper by *B. J. Miflin* and *P. J. Lea*. In contrast to the long-held hypothesis that the main pathway is the reductive amination of α-ketoglutarate, recent investigations indicate that in the case of a deficiency of ammonia most bacteria take an alternative path *via* glutamine synthetase and glutamine-α-ketoglutarate aminotransferase (glutamate synthase). This aminotransferase is also found in higher plants and green and blue algae. The only exception is formed by the fungi. There are, therefore, grounds for the assumption that the assimilation of ammonia into amino-acid metabolism in plants and bacteria normally takes place through the glutamine synthetase—glutamate synthase pathway, while the route *via* glutamate dehydrogenase is chosen only when there is an excess of ammonia. [The Pathway of Nitrogen Assimilation in Plants. Phytochemistry *15*, 873—885 (1976); 148 references]

[Rd 877 IE—R]

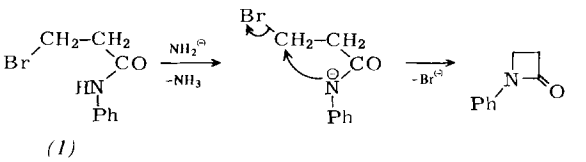
Plant constituents with potential anticancer and cytotoxic activity are discussed by *G. A. Cordell* and *N. R. Farnsworth*. The *Catharanthus* alkaloids vincaleukoblastin and leurocristin are of particular interest because of their antitumoral activity. Cytotoxic compounds from *Catharanthus* species belong to the β-anilinoacrylate group of indole alkaloids. In addition, representatives of these species show other pharmacological effects such as hypoglycemic or antiviral activity. The antitumoral principles of *Chelodonium majus* are sanguinarine and chelerythrine; chelidonine and protopine have cytotoxic effects. A promising group of benzophenanthridine alkaloids includes fagaronine (antitumoral activity) and the strongly cytotoxic nitidine. Cytotoxic compounds are present in Boehmeria species *(Urticaceae)*. Cryptopleurine displays antiviral and antitumoral activity. Both activities are also found in macrolide alkaloids, of which maytansine from *Maytenus senegalensis* is to be tested clinically in the near future. Of lignanes with antitumoral and cytotoxic activities, podophyllotoxin is singled out. A compound of relatively simple structure from *Jacaranda caucana*, jacaranone shows activity both *in vitro* and *in vivo*. The antitumoral activity of many plants is due to their tannin content. [A Review of Selected Potential Anticancer Plant Principles. Heterocycles *4*, 393—427; 100 references].

[Rd 878 IE—M]

The sesquiterpenes formed by Solanaceae under stress conditions are the subject of an article by *A. Stoessl*, *J. B. Stothers*, and *E. W. B. Ward*. The chemistry and some physical properties of these compounds are reviewed. Particular importance is attached to the ^{1}H- and ^{13}C-NMR spectra. The compounds are closely related to one another biogenetically. Their biological function may consist in protection of the plants against fungal infections. [Sesquiterpene Stress Compounds of the Solanaceae. Phytochemistry *15*, 855—872 (1976); 156 references].

[Rd 876 IE—R]

The synthesis of β-lactams (2-azetidinones) is considered by *N. S. Isaacs*. β-Lactams occur in Nature, *e.g.* in penicillins and cephalosporins. The four-membered ring system is accessible, *inter alia*, by cyclization of C_3N systems like *(1)*, by non-concerted cycloaddition, by [2+2] cycloaddition, by ring



(1)

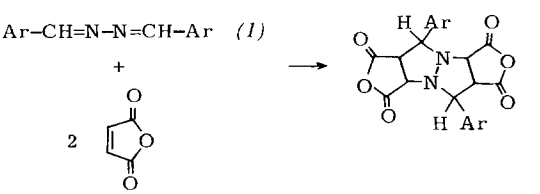
expansion, and by ring contraction. Modifications of the resulting β-lactam considerably extend the scope of these syntheses; derivatized penicillins and cephalosporins are of considerable importance. [Synthetic Routes to β-Lactams. Chem. Soc. Rev. *5*, 181–202 (1976); 170 references]

[Rd 880 IE—F]

Structural chemistry within zeolite A is the theme of a survey by *K. Seff*. Zeolites are aluminosilicates having a relatively rigid anionic skeleton and crystallographically well defined channels and cavities in which are located exchangeable cations, and in some cases guest molecules such as water which can also be replaced. Zeolites act as catalysts, ion exchangers, and selective sorption agents. Accurate structural determinations on zeolite single crystals prepared in various ways and having different cations and guest molecules should help us to understand the mode of action of zeolites. [Structural Chemistry inside Zeolite A. Acc. Chem. Res. *9*, 121–128 (1976); 32 references]

[Rd 882 IE—L]

Reactions of azines and imines with dienophiles are discussed by *T. Wagner-Jauregg*. Aromatic aldehyde azines *(1)* undergo criss-cross addition with two equivalents of dienophile to give 1,5-diazabicyclo[3.3.0]octane derivatives. This singular mode of reaction of *(1)* is observed not only with typical dienophiles like maleic anhydride but also with cyanic acid, thiocyanic acid, or phenyl isocyanate. Hexafluoroacetone azine also adds two equivalents of electron-rich olefins, azomethinimines being detected as intermediates. Schiff bases of aromatic



aldehydes undergo 1,4-cycloaddition with acetylenic dienophiles to give partially hydrogenated pyridines, and with olefinic dienophiles to form spiro compounds.—The article also considers the numerous types of dienophile addition to heterocycles having C=N double bonds and to azines and Schiff bases of cyclic ketones. [Reaktionen von Azinen und Iminen (Azomethinen, Schiffschen Basen) mit Dienophilen. Synthesis *1976*, 349–373; 153 references]

[Rd 883 IE—M]

Reaktionstypen in der anorganischen Chemie (Reaction types in inorganic chemistry). By *I. Fitz*. Akademie-Verlag, Berlin 1975. 1st Edit., 465 pp., 98 figures, 105 tables, bound, DM 58.—

This book, which is concerned with the laws governing inorganic reactions in aqueous solution, is divided into nine sections. A general chapter about bonding and chemical reactivity is directly followed by an account of the principles of chemical reaction—then follow the most important types of reaction: complex reactions, redox reactions, and acid-base reactions. The work concludes with polymerization and depolymerization reactions, coupled reactions, and a survey of the common and distinguishing features of inorganic reaction types.

The first chapter mainly compares and contrasts the various kinds of chemical bonds, not always as clearly as desired. Terms such as bond lengths, ionic and atomic radii, force constants, bond energies, polarizability, electronegativity, and electron affinity have not been forgotten. It ends with a brief introduction to ligand field theory.

Before describing the three reaction types, the author attempts to clarify the principles of a chemical reaction by demonstrating the significant role of thermodynamics and kinetics in inorganic reactions in aqueous solution. Free energy and free enthalpy are just as important as, say, entropy in complex chemistry. Terms connected with kinetics such as activation energy, transition state, kinetic isotope effects, steric influence, and electronic effects are considered in detail. Predictions of the course and mechanism of a chemical reaction on the basis of thermodynamics and kinetics conclude this section.

In connection with complex reactions particular emphasis is placed upon thermodynamic aspects and ligand field theory. A separate section is devoted to stereochemistry and the stereochemical consequences of substitution reactions whose mechanisms are discussed with the aid of numerous examples.

Among the most important reaction types in organic chemistry are redox and acid-base systems. In both cases we are concerned with "particle-transfer reactions". An historical development of the concepts is given, and all relevant modern theories are mentioned. In such cases the present book replaces an analytical textbook for the treatment of redox equilibria and all kinds of pH calculations are discussed in the same great detail as the double logarithmic Hägg diagrams of corresponding acid-base pairs.

The work supplements available inorganic and analytical textbooks for undergraduates, even though the subject matter is sometimes of a more advanced nature. Clear tabulations of data are abundant. It is only regrettable that a number of factual and printing errors have crept into the book. Thus not all alkali halides have the NaCl structure, as claimed in Table 9. Table 16 contains misleading printing errors in the hybridizations and bond angles; the examples of Table 17 would have been better in Table 16. A better choice of examples would also have been desirable. For this reason the book can only be recommended with reservation.

Ekkehard Lindner [NB 328 IE]

Lehrbuch der Elektrochemie (Textbook of Electrochemistry). By *J. Koryta, J. Dvořák,* and *V. Boháčková*. Translated by *Helga Bažantová*. Springer-Verlag, Vienna—New York 1975. 1st Edit., xv, 348 pp., 108 figures, bound, 145.—.

The decision to market a translation of the Czech work "Textbook of electrochemistry" probably represents something of a gamble, particularly since the opportunities for developing a completely new concept deviating from the usual presentation and didactic approach are rather limited. Although the treatment of individual topics in this book resembles that in other textbooks, a certain degree of originality is to be seen in the subdivision of the material.

Our attention is first directed to equilibria in electrolytes, a brief introduction containing definitions of equilibrium constants and activities and activity coefficients being followed immediately by the Debye-Hückel law and its extension, as well as methods for determining the activity coefficients of electrolytes. There follow the theory of weak electrolytes and a consideration of the pH value, paying attention to varying definitions and acidity functions. The chapter closes with an account of ampholytes and polyelectrolytes.

The second chapter is concerned with the transport processes so important for practical electrolysis and electrochemical methods of analysis. Not only diffusion and migration, but also convective diffusion, which is frequently neglected in other books, are all considered.

The third chapter discusses equilibria in heterogeneous electrochemical systems, *i.e.* equilibrium electrode potentials or equilibrium cell potentials. The electrochemical double layer is also described.

A brief treatment of membrane electrochemistry follows in the fourth chapter, which closes with a very short account of the electrochemistry of biological membranes. The final chapter is devoted to electrode kinetics.

The book is supplemented by a mathematical appendix, in which the applications of Laplace transformation to the solution of the diffusion problems of Chapter 2 is presented.

On 320 pages the book deals with all the important fundamental aspects of electrochemistry in a correct, competent, and lively manner. Concerning the didactic concept, however, it should be mentioned that in the chapter on electrode kinetics the reader often misses the right figure at the right place, and that some of the figures do more to disguise the situation than elucidate it (Fig. 3.11a, 3.19, 5.2, 5.3).

Unfortunately the translator's German leaves much to be desired, containing numerous Anglicisms, Gallicisms, and old-fashioned expressions. These weaknesses, however, could easily be remedied in a second edition.

Hartmut Wendt [NB 329 IE]

Röntgenbeugung an Kristallen (X-Ray Diffraction by Crystals). By *K. H. Jost*. Akademie-Verlag, Berlin 1975. 1st edit., xii, 404 pp., 332 figs., 18 tables, bound, *ca.* DM 98.—.

Contrary to what might be assumed from the title, this book does not deal with the method of crystal structure determination. Instead, the origin of X-ray diffraction diagrams and their recording and evaluation are described.

After two introductory chapters on the excitation of X-rays and the fundamental concepts of crystallography, the production of diffraction diagrams is discussed with particularly detailed treatment of the influence of disorders, thermal motion of atoms, and superstructures. The procedures now customary for recording the diffraction patterns and for measuring intensities are then presented, and the newer types of apparatus such as the Gandolfi camera and the Kappa four-circle diffractometer are also mentioned. A relatively large amount of space is taken up by a description of the methods of evaluation in comparison with that devoted to the determination of unit cell dimensions, symmetry and intensity.

The last chapter deals with powder methods and their application. Noteworthy is that topics such as the investigation

of texture, indexing according to ITO for any desired symmetry, and the investigations of pressure and temperature variations are also discussed.

With its detailed and clear presentation of themes, which are seldom treated elsewhere, this book fills a gap and provides a valuable supplement to books previously available on crystal-structure determination. In spite of the rather high price it can thus be strongly recommended to all concerned with X-ray diffraction.

Joachim Strähle [NB 330 IE]

Zum Ablauf ionischer Polymerisationsreaktionen (The course of Ionic Polymerizations). By *G. Heublein*. Akademie-Verlag, Berlin 1975. 1st edit., viii, 316 pp., numerous figs. and tables, bound, *ca.* DM 58.—.

In comparison with the industrially much more important field of radical polyreactions there are considerably fewer proven results on ionic polymerizations. Thus, it is only in recent years that many of the "classical" concepts of cationic polyreactions have had to be revised. A critical presentation of the present state of our knowledge of ionic polyreactions is thus a difficult but undoubtedly highly valuable exercise.

Following a brief comparison of ionic and radical polymerizations and a general outline of the course of ionic polymerizations, the book treats first cationically and then anionically initiated polyreactions; a subsequent chapter is devoted to ionic copolymerizations. In a section contributed by *P. Hallpap* the current possibilities for quantifying description of ionic polymerizations are collected together with their quantum-chemical treatment.

A field as wide as this cannot be described in all its parts in equal detail; one misses, *e.g.* the recent investigations by *P. H. Plesch*'s school on cocatalyst-free cationic initiation of polymerization with aluminum trichloride and the pseudocationic polymerizations by ester formation. Objections in principle must be noted concerning some of the concepts used; the phrase "Mischpolymerisation" (mixed polymerization) should be finally banned from scientific literature according to IUPAC rules. To describe the growth step of polymerizations as the "Polyadditionsschritt" (polyaddition step) (*e.g.* p. 16), is at least an error of judgement, since in German it can easily lead to confusion with other polyadditions occurring according to totally different mechanisms.

These minor details do not, however, detract from the book's value as an easily readable summary for a currently important area of macromolecular chemistry, particularly as the more than 600 literature references make it possible to delve deeper into the subject. A more serious deficiency—and one that must certainly be corrected in a new edition—is the absence of a subject index, particularly as the contents list is only crudely sectionalized.

Dietrich Braun [NB 331 IE]

IR-Spektroskopie—Eine Einführung. (Taschentext 43/44) (IR Spectroscopy—An Introduction. Pocket book 43/44). By *H. Günzler* and *H. Böck*. Verlag Chemie/Physik Verlag, Weinheim 1975. 1st edit., xv, 363 pp., 152 figs., 50 tables, paperback, DM 38.—.

The main emphasis of this book is laid on the description of group frequencies of organic compounds, which are discussed very expertly with the aid of many original spectra and tables. Inorganic compounds are mentioned in only one sentence. Details of the apparatus, its maintenance, and of the preparation of samples are discussed at length; this part is of real practical value even for the experienced user, and treatment of special techniques takes up much space.

Theoretical principles up to the rotational vibration spectra of an anharmonic oscillator are treated in only 30 pages. Without giving any derivation the authors cite the Schrödinger equation as a kind of magic formula from which everything else can follow; here there are formulations that run from the unfortunate through the inexact to the false, and other chapters too are not free from them.

Because of the weaknesses in its treatment of the theoretical principles and its concentration on applications in organic chemistry, this book is certainly no general introduction to IR spectroscopy. The limitation to organic compounds should have been stated in the title.

Gerhard Lehmann [NB 332 IE]

Fortschritte der Massenspektrometrie. Progress in Mass Spectrometry. Edited by *H. Budzikiewicz*. Vol. 3. Alkaloide, ausser Indol-Triterpen-, und Steroidalkaloide. By *M. Hesse* and *H. P. Bernhard*. Verlag Chemie, GmbH, Weinheim 1975. 1st edit., xvii, 372 pp., 112 figs., 83 tables, bound, DM 148.—.

In order to take into account the complexity and structural variety of this group of natural products the authors confine themselves in this book in the Progress series[*] to the nitrogen compounds that are not classifiable as indole, triterpene, steroid, or ergot alkaloids. The classification principle for the remaining compounds—structurally considered still imposing in number—is based on the practicable but not always relevant assumption that in alkaloids the decompositions induced by electron impact generally start from ionized nitrogen. In consequence, therefore, the "nitrogen" structural element is set up as the centerpoint, while the traditional classification based on skeletal or chromophore type and on biogenetic relationships serve as secondary classification characteristics.

The presentation of the immense volume of material succeeds by skilful choice and combination of line spectra, principal routes of decomposition, conclusions by analogy (allowed and forbidden), critical commentaries on spectral interpretation, and a comprehensive literature search (1082 references distributed over seven main chapters that in turn are subdivided into 125 fields). The authors have succeeded very well indeed in directing the reader rapidly and clearly (often with use of structural formulas) to the data relevant to analytical use by means of precise formulation and designation of key fragments. Mechanistic aspects are, in general, considered and used for spectral interpretation only insofar as they have been proved by experiment.

In spite of the extensive data material involved (an index, arranged by molecular weight and names of 1260 compounds, as well as a comprehensive subject index allow rapid orientation), this book will not only be valuable to the typical alkaloid chemist but will also prove to be a (provocative) source for mechanistic studies, as repeatedly indicated by the authors' views and limits. How helpful and important is well-based knowledge of the decomposition principles for a correct interpretation of the mass spectra of alkaloids is shown impressively by Chapter 6 (putrescine, spermidine, and spermine alkaloids). On the basis of studies of model compounds, carried out by the Zurich group, it is demonstrated, *inter alia*, that the apparent complexity of the mass spectra of these alkaloids is due to the simple interaction of nonbonded centers (*e.g.* specific, reciprocal H-transfers or electron-impact-induced S_Ni reactions).

The book constitutes an important addition to the standard works already available for chemists concerned with the analytical side of alkaloid chemistry.

Chemische Reaktionstechnik (Chemical Reaction Engineering). By *K. Dialer* and *A. Löwe*. Carl Hanser Verlag, Munich–Vienna 1975, 1st edit., 108 pp., 44 figs., 8 tables, board, DM 22.—.

This monograph is intended as an introduction to the field, aimed in particular at chemists and process engineers. It should serve chemists as a supplement to the usual sectors of chemistry and as an insight into the application of chemical and physicochemical principles to the planning and design of industrial installations, especially reactors. The relationships between unit operations and processes for conversion of materials are indicated for the benefit of chemical engineers.

The authors' aim has been to offer "a brief systematic introduction to the principles of reaction engineering, and especially as a concise revision of examination material".

The basic principles of reaction engineering are first explained, starting from a good introduction into the importance and systematics of the field, and are followed by the essentials of homogeneous and heterogeneous reactions. Simple methods of designing chemical reactors are first discussed, followed by the complex relationships between ideal model presentations and real conditions. The following chapters treat the possibility of performing the process with different aims in view, *e.g.* conversion, yield, selectivity, *etc.* Finally, there are questions of application, such as acquisition of data, scaling up, and optimization. The book presents a successful selection of the most important themes from the broad field of chemical reaction engineering, and does so meaningfully. Particularly praiseworthy is the excellent collection of references that extend to very recent times and make it possible to handle problems of industrial reactions in a manner corresponding to the current state of the art. Because of the brief and concentrated presentation, however, only those who already have some previous knowledge of reaction kinetics and transport processes will get full value out of the monograph.

Polar Effects in Organic Reactions

By Cyril A. Grob[*]

Attempts to gauge the effect of polar substituents on organic reaction rates by means of "inductive substituent constants" are based on the assumption that these effects are independent of the type of reaction observed. The measured rate constants of nucleophilic substitution reactions show, however, that this assumption is only partly justified even for saturated molecules. It is invalid if the substituent and the reaction center are an electron donor and an electron acceptor, respectively, which are hyperconjugated by way of σ-bonds. In extreme cases the resulting polarization can lead to heterolytic fragmentation.

1. Introduction

The common description of organic compounds by symbols such as ROH, RCHO, or RCOOH implies that chemical changes occur at the functional groups, in the above cases at the hydroxyl, formyl, or carboxyl group, respectively, while the rest of the molecule is left unaffected. In view of the large number of organic compounds and their variety it would not be possible to describe their reactions without this simplification. However, the study of structure-reactivity relationships and physical properties of organic molecules soon shows that the functional group is affected by the group R in at least three different ways, *i.e.* by polar, conjugative, or steric effects[1].

Steric effects are most easily visualized because they can be described simply in terms of space-filling and the impenetrability of atoms. Conjugative effects such as occur in unsaturated, conjugated molecules, are harder to interpret. Intermediate are the polar effects of monopolar and dipolar substituents that are not conjugated with the reaction center but influence it electrostatically. These three effects are rarely observed in isolation, but their conceptual differentiation is of great value, especially for didactic purposes.

This article is concerned with the polar effects of substituents in saturated compounds, first with new attempts to assess them quantitatively by assigning them so-called inductive substituent constants. For this purpose the model with which the transmission of the substituent effect is described, *i.e.* the field model or the inductive model[1], is irrelevant[*]. Ideally such constants should gauge the influence of the substituent on the reaction center correctly and independently of the nature of the reaction. The third and fourth sections of this review are therefore devoted to the question whether the new constants are able to correctly correlate polar substituent effects in simple reactions.

2. Determination of Inductive Substituent Constants

The dissociation constants K_a (or the pK_a values) of carboxylic acids [reaction (a)] have long been used to detect and to measure polar effects quantitatively[3].

$$RCH_2COOH + H_2O \overset{K_a}{\rightleftharpoons} RCH_2COO^{\ominus} + H_3O^{\oplus} \qquad (a)$$

On this basis chloroacetic acid (R = Cl) is *ca.* 80 times stronger than acetic acid, and trimethylammonioacetic acid [$R = (CH_3)_3N^+$] [more precisely, the carboxymethyl(trimethyl)ammonium cation] is *ca.* 100 times stronger. The examples illustrate the powerful effect of the C—Cl dipole and particularly of the positive monopole on the equilibrium. Nor have attempts been lacking to apply the pK_a values of substituted acetic acids to the definition of inductive substituent constants, *e.g.* by *Charton*'s σ_I constants[4], which are proportional to the pK_a values.

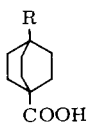
St. Johanns-Ring 19, CH-4056 Basel (Switzerland)

[*] New findings, however, clearly indicate the superiority of the former (electrostatic) model [2].

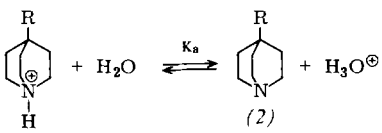
However, the substituent constants derived in this way have only limited validity, because the dissociation constants and even the relative strengths of carboxylic acids are strongly temperature-dependent[5], the reason being that the entropy term $T\Delta S^0$ contributes more strongly to the free dissociation enthalpy ΔG^0 than does the enthalpy term ΔH^0[*] as a result of the large increase in solvation when a neutral acid is ionized according to reaction (a). Furthermore, bulky α-substituents hinder solvation of the anion, so that steric effects may be superimposed on the polar effects[6].

Another frequently used method for the quantitative evaluation of polar effects is one due to *Taft*[7]. This method is based on measurements of the differences between the rates of acid and alkaline hydrolysis of acetic esters. The basic assumption underlying this method, *i.e.* that steric effects are thereby eliminated, has recently been questioned[6, 8]. Nevertheless, substituent constants σ_I or σ^* ($\sigma_I = 0.45\,\sigma^*$[7]) derived in this way have often been used with success in studies of structure-reactivity relationships.



(1)

The pK_a values of rigid bicyclic acids, such as the 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids *(1)* studied by *Roberts*, are largely free from steric influences[9]. In these acids the substituent R is at a considerable distance from the reaction center and the measurable polar effect is consequently rather weak, a disadvantage in addition to the temperature dependence of the pK_a values of carboxylic acids mentioned above.



(b)

(2)

These disadvantages do not apply to the 4-substituted quinuclidines *(2)* investigated by us[10] and by others[11]. In these highly symmetrical compounds the bond to the 4-substituent lies on the molecular axis and is relatively close to the reaction center (*ca.* 2.5 Å) without sterically hindering solvation. In addition, the polar effect is transmitted through a region of low effective dielectric constant, and should thus act strongly on the pK_a values and be largely independent of the solvent. What is of particular importance is that in reaction (b) two cations are in equilibrium with one another. Therefore solvation and thus the contribution of the temperature-dependent entropy term to the free energy of the reaction is less important than it is for the carboxylic acid models. These advantages are somewhat offset by the difficulties encountered in synthesizing the compounds *(2)*[10] and which have presented an obstacle to systematic studies. In spite of this, the pK_a values of some forty representatives in water have been measured[12].

The results obtained so far appear to fulfil these expectations, in that polar effects are particularly strongly transmitted. Thus, the difference between the strongest base, 4-*tert*-butylquinuclidine, and the weakest, 4-nitroquinuclidine, is 3.63 pK_a units. This difference is greater than that for the corresponding substituted acetic acids, where it is only 3.08 units although in the latter case the substituents are separated from the dissociating proton by one less σ-bond.

The pK_a values of the quinuclidines studied so far at several temperatures show that the enthalpy term ΔH^0 is the main contributor to the free enthalpy of dissociation ΔG^0 and that the entropy term $T\Delta S^0$ is much less important than in reaction (a)[12]. Moreover, in the cases so far studied by us the influence of the substituents has proved to be almost independent of the dielectric constant (DC) of the solvent. For example, the decrease in the pK_a value of quinuclidine due to the 4-acetyl group was *ca.* 13 % in water ($DC = 78$), 80 % methylcellosolve ($DC = 33$), 50 % ethanol ($DC = 49$), and in 80 % ethanol ($DC = 35$). The decrease in pK_a due to the 4-cyano group was *ca.* 26 % in all four solvents. The polar effect is therefore transmitted almost entirely within the molecule.

On the basis of the pK_a values of quinuclidine (pK_a^H) and its 4-derivatives (pK_a^R) in water at 25 °C the new inductive substitution constants σ_I^q can be defined as:

$$pK_a^H - pK_a^R = \rho\,\sigma_I^q$$

where ρ is the reaction constant, which is arbitrarily chosen as unity. The letter q in the symbol σ_I^q indicates that quinuclidines act as models. Table 1 lists some of the substituent constants determined in this way (an exhaustive list is given in [12]).

Table 1. Inductive substituent constants σ_I^q derived from pK_a values of 4-R-substituted quinuclidines *(2)*.

$COOC_2H_5$	1.70	I	2.34

It would lie beyond the scope of this article to discuss each individual constant here, but some important findings deserve special mention. The basicities of the 4-alkylquinuclidines, namely the methyl, ethyl, isopropyl and *tert*-butyl derivatives, whose polar effects have now been reliably determined by pK_a measurements for the first time, increase in the expected order[1]. The differences are small, as also in the case of the 3-alkylquinuclidines *(3)*[10c], but they are nonetheless significant. Thus the usual order for the inductive effects of the alkyl groups is found[1], except for the position of hydrogen within the series. In fact, the methyl group proves to be somewhat base-weakening, the ethyl group almost equivalent to hydrogen, thus confirming more recent observations[13]. However, this order applies only when these groups are bonded to a saturated, *i.e.* sp^3-hybridized, carbon atom, for on unsaturated sp^2-hybridized carbon the methyl group is distinctly base-strengthening. This follows from the pK_a values for

[*] For example, in the case of acetic acid $T\Delta S^0$ and ΔH^0 are respectively −6.57 and −0.137 kcal/mol [5].

dehydroquinuclidine *(4a)* (9.88) and for its 3-methyl derivative *(4b)* (10.11)[14].

(3)

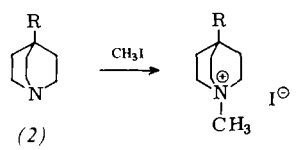
(4a), R = H
(4b), R = CH_3

As expected, the alkenyl, alkynyl, and aryl groups are electron-attracting as compared with alkyl groups. This applies particularly to groups containing heteroatoms, the most effective ones being the halogens, the cyano, and the nitro group.

If the σ_I^q values and the σ_I constants of *Taft* and *Charton* mentioned above were equivalent measures of polar substituent effects, then there should be a linear relationship between them. They do indeed correlate to a certain extent, but not particularly well[12] (*i.e.* with correlation coefficients of 0.906 and 0.949, respectively). The deviations are probably due to the different models (quinuclidines, acetic esters, acetic acids) and reactions (pK_a values and rate constants), used in the determination of the substituent constants—an indication of the problems in defining generally valid polar substituent constants.

3. Substituent Effects in a Bimolecular Nucleophilic Substitution

How then do the new σ_I^q values stand the test of correlating substituent effects in simple nucleophilic substitution reactions? As a first example let us consider the quaternization of 4-substituted quinuclidines *(2)* with methyl iodide in methanol, a bimolecular (S_N2) nucleophilic substitution [reaction (c)]. This Menshutkin reaction is very similar to the standard reaction (b) insofar as here too the nitrogen adopts a positive charge; however, in contrast to protonation, reaction (c) is irreversible.



(2) (c)

Measurement of the second-order rate constant for thirty 4-substituted quinuclidines[15] shows that quaternization responds less strongly to polar substituent effects than does the protonation reaction (b). For example, 4-nitroquinuclidine, which is less basic than quinuclidine by 3.48 pK_a units, reacts 6.7 times slower than the latter, indicating that less positive charge has developed in the transition state of the reaction. Furthermore, if the logarithms of the second-order rate constants ($\log k$) are plotted against the corresponding σ_I^q values, there is considerable scattering around the regression line (Fig. 1, correlation coefficient 0.975).

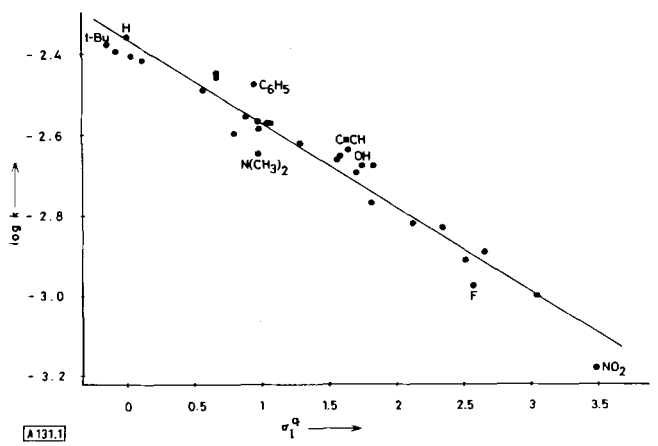


Fig. 1. Relationship between $\log k$ for the quaternization of 4-substituted quinuclidines *(2)* by methyl iodide [reaction (c)] and the inductive substituent constants σ_I^q. Only some of the substituents are considered in the Figure.

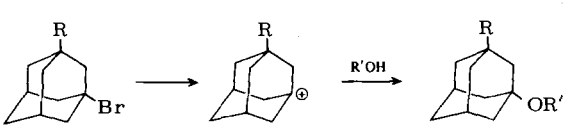
Only a small part of this scattering can be caused by solvent effects, *e.g.* hydrogen bonding between methanol and the quinuclidine nitrogen[16], as shown by analysis of the deviations and by experiments in acetonitrile. The scattering should rather be ascribed to the fact that in this case substituent effects on a reversible reaction (pK_a) are compared with those on an irreversible reaction ($\log k$). Thus, it is assumed that the substituents influence equilibrium constants and rate constants in the same way and that the free reaction enthalpies and the free activation enthalpies are strictly proportional to one another. This assumption upon which free-energy relationships, such as the Hammett equation[17], are based has certainly only limited validity, a fact that is usually overlooked.

The slope of the regression line in Figure 1 gives a reaction constant ρ of -0.21. For the reversible protonation of 4-substituted quinuclidines *(2)* [reaction (b)] the value of ρ was arbitrarily set at 1. The above negative value of ρ thus confirms that quaternization [reaction (c)] responds less strongly to polar substituent effects, and moreover, it does so in the opposite direction.

4. Substituent Effects in a Solvolytic Reaction

Polar substituents should have a more marked effect on the formation of carbenium ions than on the production of ammonium ions. The former event occurs in the solvolysis of 1-substituted 3-bromoadamantanes *(5)* in 80% ethanol, in that ionization to the adamantanyl cations *(6)* is involved in the rate-determining step [reaction (d)]. In a rapid subsequent step these cations are converted into adamantanols *(7a)* and their ethyl ethers *(7b)*.



(5) *(6)* *(7a)*, R' = H
(7b), R' = C_2H_5 (d)

The question is whether the ionization of *(5)* is influenced by the substituent R in the same way as the reversible protonation of the corresponding quinuclidines *(2)*. If the polar substituent effects were generally valid, there should be a linear relationship between the σ_I^q values and the logarithms of the rate constants ($\log k$), since the latter are proportional to the free activation enthalpies of ionization.

Recently we have prepared and investigated some of those 1-substituted 3-bromoadamantanes *(5)* for which the σ_I^q values of the substituents are known[18]. The first-order rate constants (k) and the relative k values (relative to R = H) are listed in Table 2 together with the corresponding σ_I^q values[12]. (Some of these rate constants had been determined

previously[13c, 13d, 13f].) In Figure 2 the logarithms of the rate constants (log$k$) are plotted against the σ_I^q values.

Table 2. Absolute and relative first-order rate constants of 1-R-substituted 3-bromoadamantanes *(5)* in 80 vol-% ethanol at 70.0°C, inductive substituent constants σ_I^q (see Table 1), and acceleration of the solvolysis of *(5)* derived from the regression line in Figure 2.

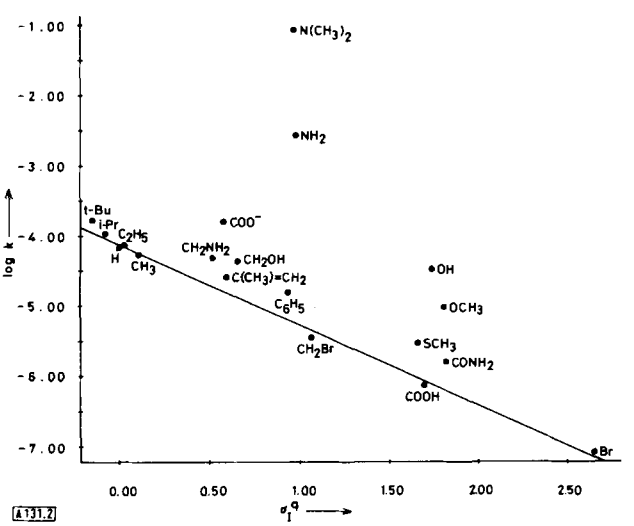

Fig. 2. Relationship between log$k$ for solvolysis of 1-substituted 3-bromoadamantanes *(5)* in 80 vol-% ethanol [reaction (d)] and their inductive substituent constants σ_I^q.

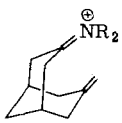
The substituents R in compounds *(5a)* to *(5t)* (Table 2) can be divided into three groups on the basis of the products formed in the reaction and the distribution of the points in Figure 2. The first group comprises the derivatives *(5a)* to *(5h)*; these react exclusively by substitution to yield *(7a)* and *(7b)*, and their log$k$ values correlate very well with the σ_I^q (correlation coefficient 0.998) with the exception of the *tert*-butyl derivative *(5e)*. The compound *(5e)* reacts 1.5 times as fast as would be expected on the basis of the regression line in Figure 2, and borders on the second group which comprises compounds *(5i)* to *(5p)*. This second group also reacts by substitution, but the correlation between log$k$ and σ_I^q can no longer be recognized, since the compounds react 1.7 to 15 times faster than predicted by the respective inductive substituent constants. The last column of Table 2 shows the accelerations based on the regression line in Figure 2[19].

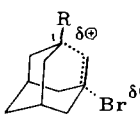
Finally, a third group can be recognized, comprising the derivatives *(5q)* to *(5t)*. Ionization of these compounds is accelerated still more strongly and, in contrast to the previous two groups, heterolytic fragmentation also occurs (for definition of this reaction type cf.[20]). Thus, 3-bromoadamantanol *(5q)* and the corresponding alkoxide *(5t)* formed in the presence of sodium hydroxide yield on solvolysis the unsaturated ketone *(8)* in yields of 70 and 100% respectively. The amines *(5r)* and *(5s)* fragment quantitatively to the immonium ions *(9a)* and *(9b)*, respectively, as previously observed[21].

(8)



(9a), R = H
(9b), R = CH_3

The calculated acceleration of the alcohol *(5q)* is 44, and that of its conjugate base *(5t)* can be estimated to be greater than 10^5[*]. For the amines *(5r)* and *(5s)* the acceleration of ionization due to the amino groups amounts to 4.7×10^2 and 1.5×10^4, respectively. There can therefore be no doubt that these four compounds fragment by the synchronous or concerted mechanism[**][23]. Their ionization is thus accompanied by fission of the C(1)—C(2) σ-bond and assisted by the frangomeric effect of the 1-substituent, as expressed in the representation *(10)* of the transition state[***].



(10)

Whereas the reactivity of the derivatives *(5q)* to *(5t)* is determined by the frangomeric effect of the substituents, it depends only on the polar effect of the substituents in compounds *(5b)* to *(5h)*, as shown by the good correlation between log$k$ and the corresponding σ_I^q values. The reaction constant ρ of -1.14 calculated from the slope of the regression line in Figure 2 shows that ionization of *(5b)* to *(5h)* responds only slightly more to the respective substituents than do the pK_a values of the 4-substituted quinuclidines *(2)* (by definition, $\rho = 1$); furthermore, the sign of ρ is reversed, *i.e.* ionization is retarded by electron-attracting substituents.

It is difficult to interpret the reactivity of compounds *(5i)* to *(5p)*, which also react by substitution but in some cases considerably faster than expected from the σ_I^q values of the 1-substituents.

Acceleration by the carboxylate *(5l)* and methoxy *(5p)* groups is particularly marked, amounting to factors of 10 and 15 respectively (Table 2). The smallest accelerations are caused by the methylvinyl and the *tert*-butyl group.

Since this additional effect only appears during the activation process, *i.e.* in the transition state of the reaction, it

[*] The pK_a and thus the σ_I^q value of the conjugate base of 4-hydroxyquinuclidine cannot be determined [12].

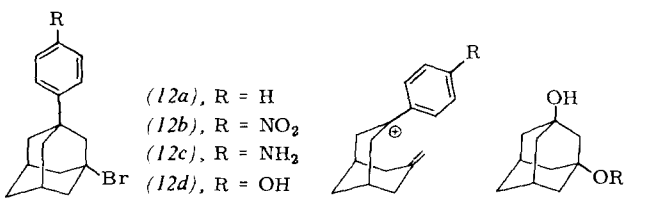
[**] We now a prefer the term "concerted" [22].

[***] The frangomeric effect is the acceleration of the ionization rate due to the concerted mechanism of fragmentation [23].

must depend on the polarizability of the substituents. An additional polarization occurring by the inductive[*] mechanism was called the inductomeric effect by *Ingold*[1,24]. This differentiation between the inductive effect operating in the ground state and the variable inductomeric effect appearing during the activation process is generally neglected due to a lack of experimental evidence. The findings discussed above appear, however, to justify this differentiation. Nevertheless, another less probable explanation for the higher reactivities of compounds *(5i)* to *(5p)* should also be mentioned.

(11) *(6)*

The solvolysis of compounds *(5q)* to *(5t)* shows that concerted fragmentation to give the ring-opened products *(8)* and *(9)* occurs when R is a strongly electron-donating group such as O^- or NR_2. (For further examples see [22].) The reactions occur with frangomeric acceleration, *i.e.* their rate is greatly increased in comparison with simple ionization to adamantanyl cations *(6)*. It is conceivable that compounds *(5i)* to *(5p)* also undergo concerted fragmentation, but that the cations of type *(11)* formed initially then rapidly recyclize to yield adamantanyl cations, which subsequently afford the substitution products *(7)* by the addition of water or ethanol. The products *(7)* would thus arise by a fragmentation and recombination process.



(12a), R = H
(12b), R = NO_2
(12c), R = NH_2
(12d), R = OH

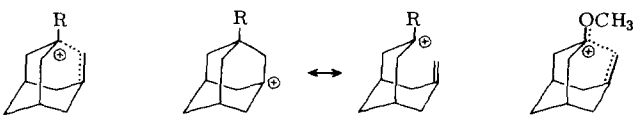
(12a) ≡ *(5n)* *(13)* *(14a)*, R = H
(14b), R = C_2H_5

The first objection to this hypothesis is that careful analysis of the reaction solutions has disclosed no trace of the products that would result from cations *(11)*; secondly, investigations of the reaction of 1-aryl-3-bromoadamantanes *(12a)* to *(12d)* in 80% ethanol which, like the reactions of *(5a)* to *(5h)*, leads exclusively to substitution products, shows that no intermediate conjugated, ring-opened cation *(13)* is formed. If the ionization led directly to such a cation then the logarithms of the rate constants should correlate with *Brown*'s substituent constants σ^+[25] and give rise to a strongly negative reaction constant ρ. However, the log*k* values correlate better with the normal *Hammett* σ_p constants with $\rho = -0.84$, as is to be expected for the formation of an unconjugated adamantanyl cation *(6)*.

Finally, mention should be made of the reaction of 3-bromo-1-adamantanol *(5q)*; this is a borderline case, since it leads to the fragmentation product *(8)* and the substitution products *(14a)* and *(14b)* in the ratio of 7:3. The substitution products could possibly be formed by fragmentation-recombination, *i.e.* by way of the unsaturated ketone *(8)* and its cyclization product, the cation *(6)*, R = OH, especially as in acid solutions *(8)* cyclizes to 1,3-adamantanediol *(14a)*. However, control experiments show that the unsaturated ketone *(8)* does not cyclize under the basic solvolysis conditions used for the alcohol *(5q)*, namely in the presence of 1 to 4 equivalents of triethylamine, so that this ketone cannot be a precursor of the substitution products. In this case, therefore, concerted fragmentation to the ketone *(8)* and ionization to 3-hydroxy-1-adamantanyl cation *(6)*, R = OH, are evidently competing.

The results of solvolyses of the 3-bromoadamantanes *(5)* show that the polar effects of substituents are not constant: on the contrary they adjust to the requirements of the particular reaction. We shall now consider how the substituents act upon the reaction center.

In the derivatives *(5b)* to *(5h)*, whose log*k* values correlate well with the σ_I^q values, the substituent effect can be transmitted by simple polarization of the σ-bonds, *i.e.* as in the 4-substituted quinuclidines *(2)*, the reversible protonation of which [reaction (b)] serves as a reference for the substituent effect. In the remaining derivatives *(5i)* to *(5t)* this polarization increases continuously until fission of the C(1)—C(2) bond, *i.e.* fragmentation, occurs. This point is reached at compound *(5q)*, *i.e.* when R = OH, because this group can stabilize the positive charge arising on C(1) in the transition state *(10)* by its +M effect.



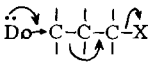
(15) *(6)* *(11)* *(16)*

Presumably delocalization of the electrons of the C(1)—C(2) bond also occurs in the transition state of ionization of the compounds *(5m)* to *(5p)*, thus leading to the mesomeric carbenium ion *(15)*. Description of this cation by the canonical forms *(6)* ↔ *(11)* makes it clear that the positive charge is distributed to C(3) as well as to C(1), where it can be stabilized by the substituents. The canonical forms also imply conjugation of a C—C bond with a cationic center, *i.e.* C—C *hyperconjugation*. An effect of this kind has been postulated in the past for S_N1 solvolyses but experimental evidence has so far been lacking[13c,13d].

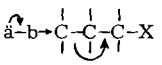
The distribution of positive charge over C(1) and C(3) is indicated also by the fact that the methoxy group in *(5p)* accelerates ionization five times as strongly as the methylthio group does in *(5o)* (Table 2) although oxygen exerts a greater electron-attracting effect than sulfur (as shown by the σ_I^q values). This surprising result indicates considerable delocalization of the free electron pair of the oxygen as shown in *(16)*, while delocalization is less pronounced in the thioether *(5o)* because of the weaker +M effect of sulfur[26]. The rate-enhancing effect of the methylvinyl *(5m)* and the phenyl group *(5n)* can be similarly explained, namely by delocalization of π-electrons. According to this view the rate-enhancing effect of the substituents in the derivatives *(5m)* to *(5p)* is due to the fact that an electron-donor Do is *hyperconjugated* to the reaction center, as formulated in *(17)*.

If this assumption is correct, heterolytic fragmentation occurs when hyperconjugation of a σ-bond merges with cleav-

[*] As opposed to a conjugative mechanism.



(17)



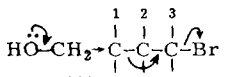
(18)

age, a process in which other than C—C bonds may be involved. These ideas correspond to the concept of "through bond coupling" recently derived by quantum-chemical (MO) calculations[27]. The calculations confirm also the stereoelectronic conditions for fragmentation as previously demonstrated experimentally[23] and which are satisfied in the adamantane derivatives *(5)*.

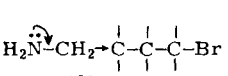
It is more difficult to interpret the rate-enhancing effect of the $HOCH_2$, H_2NCH_2, H_2NCO and ^-OOC groups in compounds *(5i)* to *(5l)*, which are unexpected on the basis of their σ_I^q values. A common feature is that they are potentially electrofugal groups a—b, *i.e.* they form a fragmentable system in combination with a central group c—d and a nucleofugal group X in accordance with reaction (e)[20].

$$a\text{–}b\text{–}c\text{–}d\text{–}X \longrightarrow a\text{–}b^{\oplus} + c{=}d + X^{\ominus} \qquad (e)$$

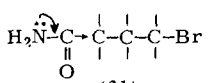
The four groups cited above thus act as electron-donors if coupled to a fragmentable system containing an acceptor, *i.e.* the nucleofuge. It then seems plausible that these same groups act as electron-donors if, in accordance with *(18)*, they are *hyperconjugated* to a cationic reaction center, as is the case with compounds *(5i)* to *(5l)*. Their role is not easy to describe with conventional symbols, especially since the $-I$ effect predominates, as shown by the k_{rel} values in Table 2. Nevertheless, the arrows in the partial formulas *(19)* to *(22)* do express the fact that these groups augment hyperconjugation of the C(1)—C(2) bond by increasing the electron density at C(1).



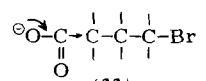
(19)



(20)



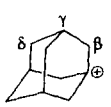
(21)



(22)

The resulting accelerations, by factors of 2.5 to 10, are relatively small and only partially compensate the inductive effect; but it is precisely small effects that are so difficult to detect and that often escape rational interpretation.

It remains to be mentioned that C—C hyperconjugation seems to appear even in the unsubstituted 1-adamantanyl cation *(23)*. This follows from its ^{1}H-NMR spectrum in the



(23)

non-nucleophilic medium SbF_5/SO_2[28] [chemical shifts (δ-values in ppm): 4.50 (H-β), 5.42 (H-γ), 2.67 (H-δ)]. In contrast to other tertiary carbenium ions, where the β-protons are most strongly deshielded, the signals of the γ-bridgehead protons appear at lowest field. This behavior is explicable if one assumes that in the unsubstituted cation also part of the positive charge is transferred to the γ-carbons as expressed in the canonical forms *(6)* ↔ *(11)*, R = H. This kind of stabilization was discussed previously by *Schleyer*[28,29] and by us[13c], but was regarded as unlikely because 1-bromo-3-methyladamantane *(5b)* reacts somewhat more slowly than 1-bromoadamantane *(5a)* itself (cf. Table 2). At that time it was believed that a 1-methyl group should favor C—C hyperconjugation in the cation *(15)*. However, now that it has been shown that a methyl group attached to an sp^3-hybridized carbon is electron-attracting relative to hydrogen (cf. Table 1), this objection is no longer valid. Moreover, the correlation between $\log k$ and σ_I^q in Figure 2 shows that more strongly electron-donating groups than alkyl groups are required to produce kinetically significant C—C hyperconjugation.

5. Conclusions

As shown in this review, the inductive substituent constants σ_I^q derived from pK_a values of 4-substituted quinuclidines *(2)* are of only limited use in predicting the polar effects of these substituents in other reactions of saturated molecules. Thus, in the quaternization of 4-substituted quinuclidines the rate constants show distinct deviations from the expected values. In the solvolysis of 1-substituted 3-bromoadamantanes *(5)* the correlation of the rate constants with σ_I^q is very good in some cases but non-existent in others. The deviations can be explained by the polarization of the substituents by the reaction center; this reaction-promoting effect is especially pronounced when strong electron-donors or potentially electrofugal groups are hyperconjugated with the reaction center.

Polar substituent effects thus depend on the nature of the reaction and are therefore variable, a view that has already become accepted for substituent effects in conjugated aromatic systems[30]. For this reason relatively narrow limits are imposed on all attempts to derive quantitative relationships between structure and reactivity.

Kink-Block and Gauche-Block Structures of Bimolecular Films

By Gerhard Lagaly[*]

Layer silicates and some other layer compounds can take up organic compounds such as long-chain alkanols and alkylammonium ions with formation of ordered bimolecular films. This system enables new ideas to be developed concerning the structure of monomolecular and bimolecular films: the films form reversible kink-block and gauche-block structures. Conclusions can be derived about the structure of the lipid layers in membranes.

1. Introduction

The function of biological membranes[1, 2] is connected with bimolecular lipid layers which interact with proteins. *Robertson*'s model, and especially *Kreutz*'s model ("Basic structure of the biomembrane") give ideas of the association between lipid and protein layers[2–4] (Fig. 1).

The lipid layer can be regarded as a bimolecular lamellar array of long alkyl chains which act as supports for the proteins. However, this by no means exhausts their function. The similar, but not identical, chemical compositions of the lipid regions in many membranes[5, 6] and the significance of constituents of the lipid layers such as cholesterol, gangliosides, glycolipids and, especially, unsaturated compounds[7, 8] for the function of the membrane show that the lipid regions are active structural units of the membrane.

In order to understand the function of the lipid layers, systems with simplified chemical compositions containing monomolecular or bimolecular films have now been investigated for 50 years (Fig. 1). The films form several discrete phases; depending on the system, the phase transitions can be induced thermally[9–13], by variation of electrolyte concentrations[2, 14, 16–20], or by interaction with macromolecules[2, 21–23].

In spite of intensive investigations, little detailed information has so far been obtained about orientation and arrangement of the alkyl chains in the different phases. In most cases an order-disorder transformation from a crystalline to a liquid-like state through a kind of "chain melting" has been discussed[18, 24–29]. This interpretation attaches insufficient importance to the multiplicity of phase transitions in the region of the alkyl chain lamellas. What other possibilities, however, do alkyl chains have for forming different phases

Olshausenstrasse 40/60, 2300 Kiel (Germany)

in monomolecular or bimolecular films. Can simple structural types be found which are based as far as possible on a common principle?

We obtain additional information from a system that has been developed in solid-state chemistry and to which the most recent results from the physics of high polymers were applied: bimolecular films are formed between solid surfaces in layer crystals and are investigated by X-rays.

2. Preparation of Bimolecular Films in Layer Crystals

In the model system bimolecular films are built up between relatively rigid inorganic layers of layer compounds (Fig. 2). A wide range of layer compounds can be used: mica-type layer silicates[30,31], sodium silicates[32], niobates[33], uranates[34,35], vanadates[36,44], titanates[37,44], zirconium phosphates[38], graphitic acids[39], crystalline silicic **acids**[40], hydrated vanadium **oxides**[44], calcium salts of phosphoric acid **esters**[41], titanium disulfide[42].

The bimolecular films between the layers of mica-type layer silicates have been investigated in particular detail.

The starting materials are layer silicates such as vermiculite, beidellite, saponite, nontronite, hectorite, and the montmorillonites. The montmorillonites ("bentonites") are used on a large scale industrially as clay minerals. These minerals are built like mica and consist of silicate layers stacked on one another (Fig. 3)[45,46]. The layers are negatively charged, since in the tetrahedral layers Si^{4+} ions are replaced isomorphously by trivalent ions (Al^{3+} ions) and, in the octahedral layer Al^{3+} ions are replaced by divalent ions (especially Mg^{2+} but also Fe^{2+}) and Mg^{2+} ions by Li^{+} ions (hectorite). Cationic defects in the octahedral layers and possibly H^{+} defects ($V_{H^{\cdot}}$) on OH^{-} groups (OH^{-} replaced by O^{2-} and $V_{H^{\cdot}}$) contribute to the negative charge. In the micas the charge density is $\xi = 1.0$ eq/(Si, Al)$_4O_{10}$ unit; vermiculites have $\xi = 0.6$—0.8, beidellite $\xi = 0.4$—0.5, and montmorillonites $\xi = 0.2$—0.4[31,47]. To compensate the negative charges of the layer, cations (Ca^{2+}, Mg^{2+} or alkali-metal ions) are bound between the layers, and these can be exchanged by other cations.

To build up the films between the layers of the mica-type layer silicates, long-chain compounds must be introduced. It has been found that particularly uniform films with highly reproducible properties are formed when primary long-chain *n*-alkanols are used (Fig. 2). To avoid the influence of the small inorganic interlayer cations as point defects[43], the cations are replaced by primary long-chain *n*-alkylammonium ions, which then form the bimolecular film in combination with the alkanol molecules. (Experimentally, the inorganic interlayer cations are first replaced by the alkylammonium ions in aqueous solutions[30,31,47]. The alkylammonium deri-

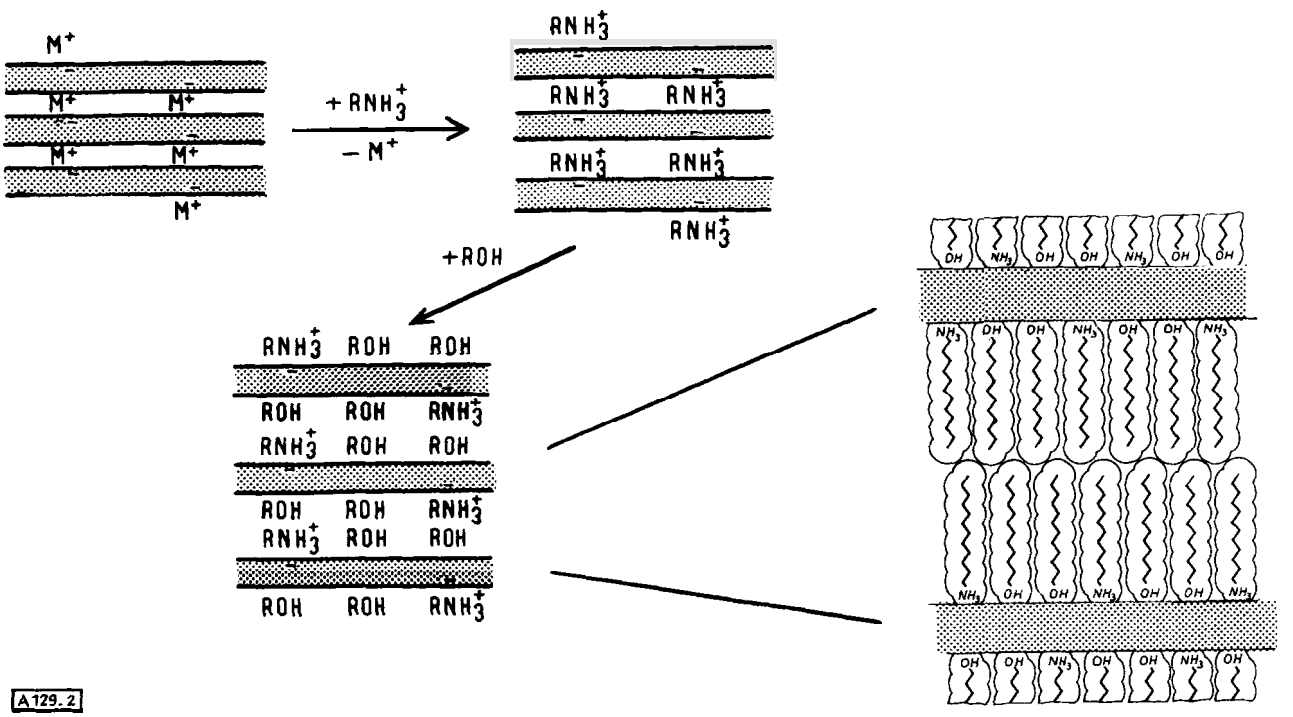

Fig. 2. Bimolecular films in an inorganic layer crystal formed by replacement of the interlayer metal cations by alkylammonium ions and incorporation of alkanol molecules ($R = C_nH_{2n+1}$, M^{+} = metal ion).

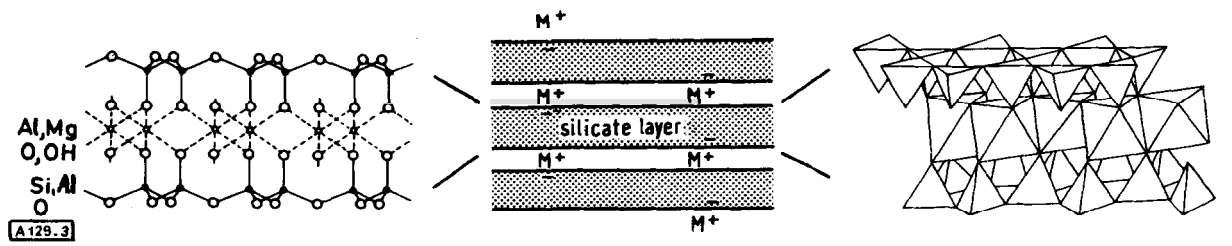

Fig. 3. Example of an inorganic layer compound suitable for the formation of bimolecular films in a layer crystal: mica-type layer silicates $M^{\xi}_{\xi}\{(Mg^{2+},Al^{3+},Fe^{2+},Fe^{3+})_{2\text{ to }3}(OH^{-},O^{2-},F^{-})_2(Si^{4+},Al^{3+},Fe^{3+})_4O_{10}\}^{\xi-}$.

vatives are then treated with the liquid alkanol, which is taken up between the layers within a few minutes[30, 31, 48].)

In films of alkyl chains of the same length or approximately the same length (maximum difference 6 C-atoms), two polar long-chain compounds, *i.e.* two alkyl chains, are bound per formula unit $(Si,Al)_4O_{10}$[31] because the polar end-groups of the long chain compounds are fixed in the pseudohexagonal holes in the tetrahedral sheets (Fig. 3, right). Small deviations from 2.0 chains per unit can occur[48].

Table 1. Examples of the average composition of bimolecular films in mica-type layer silicates. (Alkyl chains in the alkanol ROH and in the alkylammonium ion RNH_3^+ same or different, but the difference not too large [31]).

Layer crystal	Present per $(Si,Al)_4O_{10}$ unit: ROH	RNH_3^+	Ratio	Area/chain [Å]²
Muscovite	1.0	1.0	1.0	23.4
Vermiculite (South Africa)	1.3_3	0.67	2.0	24.5
Beidellite (No. III, Rhön)	1.5_7	0.43	3.65	23.3
Montmorillonite (Cyprus)	1.6_4	0.36	4.6	23.3
Montomorillonite (M 26, Wyoming)	1.7_2	0.28	6.1	23.3
Hectorite (H 1, California)	1.7_6	0.24	7.3	24.1

Table 1 gives the film compositions in the case of the layer silicates used most frequently. Since there are two alkyl chains in the bimolecular film per formula unit (=half the elementary cell), with an area of $a_0b_0/2 = 49$ Å² (vermiculites) and $a_0b_0/2 = 46.5$ Å² (montmorillonites and beidellite), the packing density of the chains is 24.5 and 23.2_5 Å²/chain (Table 1).

3. Phase Transitions in Bimolecular Films

3.1. X-Ray Results

The incorporation of alkylammonium ions and alkanol molecules between the silicate layers leads to the regular sequence: ... film—silicate layer—film—silicate layer—.... Since all films have the same thickness, in the X-ray diagram an integral series of (00l) interferences is observed up to high orders. From the d_{00l}-values the basal spacing $d_L = l d_{00l}$ is taken. The film thickness D can be estimated from the basal spacing d_L if the thickness of the silicate layer (9.5 Å) is deducted. Since the dimensions of the silicate sheets remain constant, any change in the film thickness is shown up in the basal spacing.

Characteristic changes take place with rising temperature (Fig. 4): both in films of alkyl chains of the same length and in films of alkyl chains of different lengths (*i.e.* alkanol molecules longer or shorter than the alkylammonium ions), the thickness of the film decreases in steps of 1—1.2 Å. A decrease of 1.1 Å is found particularly frequently[49]. The number of the steps increases with increasing chain length. In the case of chains of different lengths, the number depends on which of the two types of compounds has the longer chain.

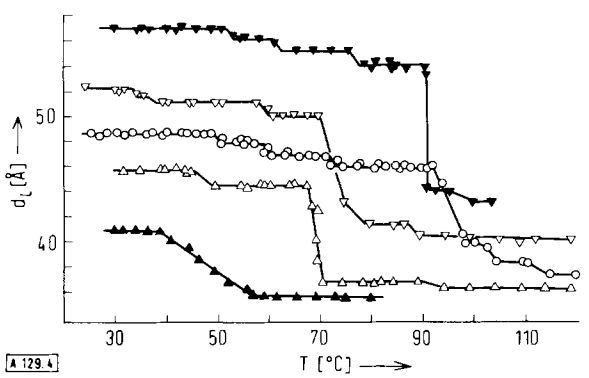

Fig. 4. Changes in the thickness of bimolecular films of alkylammonium ions and alkanol molecules between silicate layers (beidellite) with temperature. The following parameters are given: the basal spacing d_L; n_C = number of C atoms in the alkylammonium ion; n_A = number of C atoms in the alkanol; the ratio of alkylammonium ions to alkanol ≈ 0.43/1.57. △ $n_C = 10$, $n_A = 14$; ▲ $n_C = 14$, $n_A = 10$; ○ $n_C = 14$, $n_A = 14$; ▼ $n_C = 14$, $n_A = 18$; ▽ $n_C = 18$, $n_A = 14$.

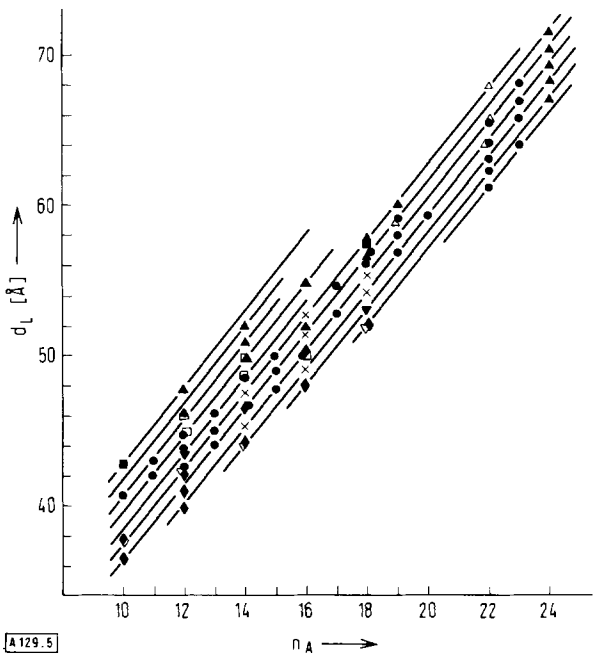

Fig. 5. Basal spacing d_L in the case of bimolecular films in *all-trans* block and kink-block structures (β-phases) between silicate layers: dependence on the number of C atoms in the alkanol (n_A). System as in Fig. 4 with ● $n_C = 10$, ▼, ▽ $n_C = 12$, ● $n_C = 14$, ■, □ $n_C = 16$, ▲, △ $n_C = 18$, × : Several coinciding values. *All-trans* denotes the extended saturated alkyl chain. For the term "kink-block structure", see Section 4.2.

Fig. 5 shows the basal spacings at the steps (see Fig. 4) for several combinations of chain lengths. They all form parallel straight lines separated by a distance of 1—1.2 Å, *i.e.* the observed basal spacings differ by 1—1.2 Å or a multiple thereof.

The temperature at which the film thickness decreases depends on the chain length and on the chain-length difference (Table 2). In general, the transition temperature rises somewhat with increasing length of the alkanol molecule (n_A). In the vertical series (increase in the length of the alkylammonium ions (n_C) at constant chain length of the alkanol) some irregularities occur; in most cases the transition temperatures also increase.

After the small steps of 1—1.2 Å, the basal spacing decreases drastically at higher temperatures by several Å. If the temperature rises further again small steps of 0.5—1 Å are observed. The maximum basal spacings of these high-temperature forms change somewhat less regularly with the chain length. Nevertheless, Fig. 6 shows that up to $n_A = 16$ they increase

Table 2. Transition temperatures within the series of kink-block phases [a] and for kink-block phases into gauche-block phases [a] (underlined figures); layer silicate: V: vermiculite (South Africa), B: beidellite; M: montmorillonite (Wyoming). n_C and n_A represent the numbers of C atoms in the alkylammonium ion and in the alkanol, respectively. The figures given are the temperatures at which the transition starts (decrease in film thickness).

n_C		$n_A=10$	$n_A=12$	$n_A=14$	$n_A=16$	$n_A=18$

[a] These terms are explained in Sections 4.2 and 5.1.

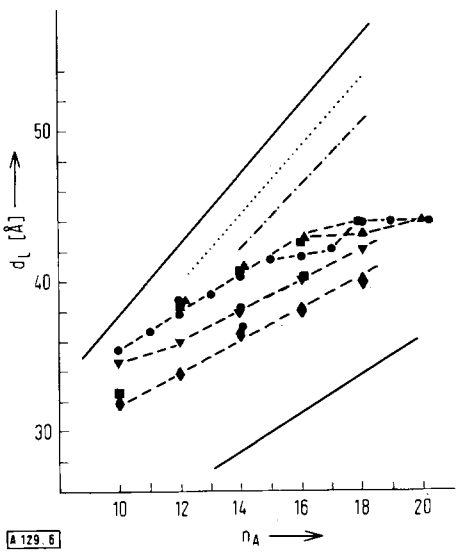

Fig. 6. Basal spacings d_L in the case of bimolecular films in gauche-block structures between silicate layers: dependence on the chain length of the alkanol (n_A). System as in Fig. 4 with ◆ $n_C=10$, ▼ $n_C=12$, ● $n_C=14$, ■ $n_C=16$, ▲ $n_C=18$; calculated values: —— monomolecular (bottom) and bimolecular (top) films, vertical alkyl chains; ·—· bimolecular chains inclined at 34° to the layer normal; .... bimolecular helical structures. For the term "gauche-block structure" see Section 5.1.

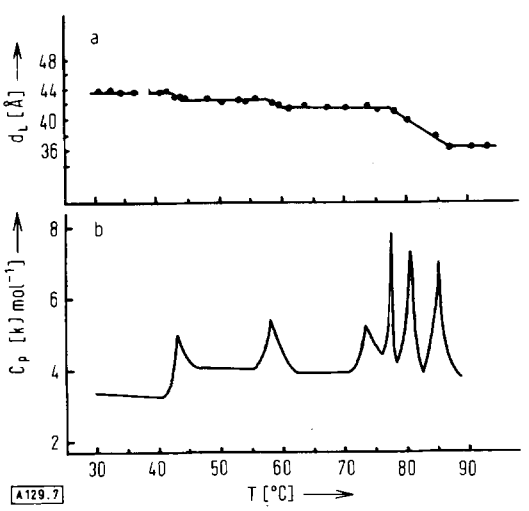

Fig. 7. Temperature dependence a) of the basal spacing d_L and b) of the specific heat C_p (referred to mol beidellite) for a bimolecular film between silicate layers (beidellite). System as Fig. 4 with $n_C=n_A=12$.

almost linearly with n_A. The transition temperature depends on the chain length (Fig. 14). It rises steeply with increasing chain length of the alkanol (n_A), but decreases again slightly for $n_A>n_C$.

3.2. Calorimetric Measurements

Measurements of the specific heat give an insight into the nature of the transition. This is demonstrated in Figure 7 for dodecylammonium-beidellite/dodecanol as an example. Within the series of the β-forms[*], the specific heat shows pronounced maxima just at the transition temperatures. The transition into the α_1-form takes place within the relatively large temperature range of almost 10°C and obviously passes through several steps, since four maxima are clearly apparent. (The stepwise transformation is probably the reason for the "quasi-melting" observed by *Stohrer* and *Noack*[51] in the nuclear resonance spectrum.) The striking point here is that, before the three sharp maxima, there is a maximum similar to the maxima observed at 42 and 60°C. Obviously a transition analogous to that at 42 and 60°C first takes place (β_3 into β_4!), but this is followed immediately by the transition into the α_1-form. Since the α_1-form contains less alkanol than the β_3-form, and at the transition point alkanol is expressed from the interlayer space, one of the maxima, probably the first of the three sharp ones, should be assigned directly to desorption of alkanol. The changes in the specific heat at the transition temperature show clearly that the individual forms are discrete phases which undergo transformation into one another. The form of the maxima indicates that the transitions are neither first-order phase transitions nor λ-transitions[49].

4. Conformations of Alkyl Chains in Lamellar Arrays

4.1. Possible Interpretations of the Observed Phase Changes

It could be assumed that the film thickness is reduced by an increasing tilting of the alkyl chains. In the β_1-phase the basal spacings are so large that they can be produced only by fully extended alkyl chains (all-*trans* conformation)

[*] To simplify the description the individual forms are here called the β- and α-forms (see Fig. 10); no uniform nomenclature for these and other forms of mono- and bimolecular films has yet been introduced [50].

perpendicular to the silicate layers. An argument against an oblique arrangement of the alkyl chains is the fact that the basal spacings of the β-phases always decrease by 1—1.2 Å regardless of the chain length. For the transition from the β- to the α-phases tilting of the alkyl chains cannot be excluded *a priori*.

Another possible explanation is based on the assumption that the chains are shortened by special types of conformational changes.

4.2. Kink-Isomeric Chain Conformations

Because of free rotation, an isolated alkyl chain can adopt a large number of rotational isomers. Fig. 8 gives information on the relationship between the *trans* position (rotation angle 0° at the energy minimum) of a C—C bond and two *gauche* positions with energies about 0.6 kcal/mol higher (2.51 kJ·mol^{-1}) [rotation angle *ca.* 112° (=g) and *ca.* −112° (=$\bar{g}$)[52, 53]]. In a lamellar structure of alkyl chains, such as is present in paraffins, polyethylene, and in mono- and oligomolecular films, however, only those conformations can occur

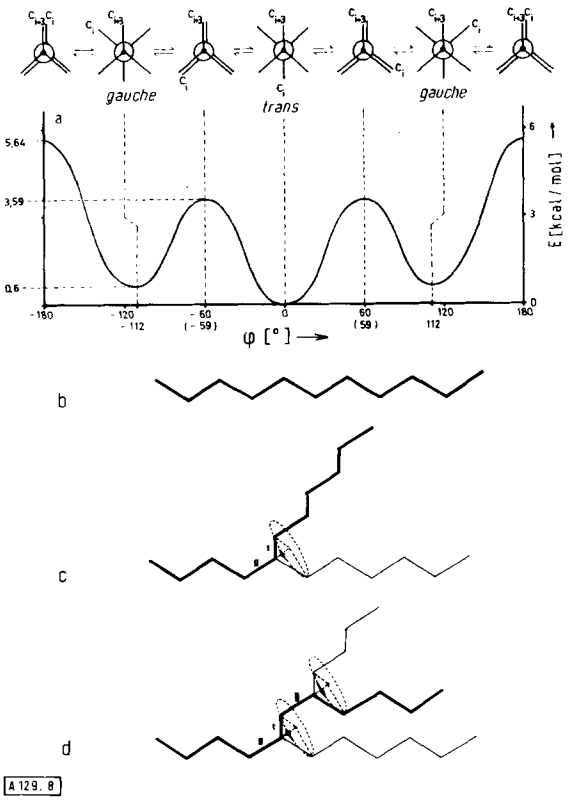

Fig. 8. a) Rotational potential (according to Refs. [54, 61]) and formation of kinks in alkyl chains; b) *all-trans* chain; c) chain with isolated *gauche* bond; d) chain with one kink.

in which the stretched nature of the chains is essentially retained. The most important group of conformations originate from regular sequences of *trans* and *gauche* bonds (Fig. 9). These conformations are called kinks: 2g1-kinks (conformation ... ttt*gtḡ*ttt ...), 2g2-kinks (... ttt*gttt*ḡttt ...), and 3g2-kinks (... ttt*gtḡtg*ttt ...). The formation of a kink in an alkyl chain shortens it by 1.27 Å[*] or a multiple thereof. (The symbol 3g2 means that the kink comprises three *gauche* bonds and

[*] This value applies to isolated alkyl chains. It may be smaller in alkyl chain lamellas, depending on the packing density [54].

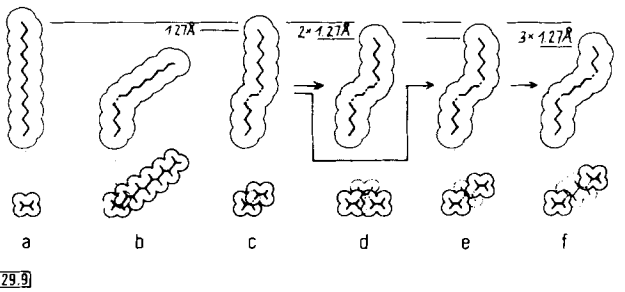

Fig. 9. Various types of kinks (after *Pechhold*) and alkyl chains with isolated *gauche* bonds. a) ttttttttttt (*all-trans*); b) tttgttttttt (isolated *gauche* bond); c) tttgtḡttttt (2g1 kink); d) tttgtḡtgtttt (3g2 kink); e) tttgtttḡtttt (2g2 kink); f) tttgtttttḡtt (2g3 kink).

shortens the chain by 2 × 1.27 Å.) In addition to the kinks, certain g-t sequences may occur throughout the whole chain; this gives rise to helical structures: 3_1-helix: gtgtgt... or gtḡtgtḡt...; 2_1-helix: nearly ...gggg...[55]. In the helical conformations kink-like defects may occur, *e.g.* in gtgtgt defects such as gtḡtgt or gtttgt, which can actually have negative defect energies[55], (Table 3).

Table 3. Defect energies of kinks in isolated alkyl chains and in alkyl chains in lamellar structures (after [52, 54, 55, 61]; 2g1 kinks see Fig. 9c).

	Defect energy [kJ·mol^{-1}]
2g1 kink in trans alkyl chains	
Kinks in isolated alkyl chains	5.0
Kinks as individual defects in a close packed alkyl chain lamella (as in polyethylene)	31.4 [a]
Kinks in a kink block [a] consisting of seven alkyl chains [b]	18.9 [a]
Kinks in a linear kink block [b]	21.0 [a]
Defects in helical chains	
ḡ-Defect in the gtgtgt helix	4.9
t-Defect in the gtgtgt helix	− 3.7

[a] Energetically most favorable figures [52].
[b] Cf. Fig. 10.

The concept of kinks is due to *Pechhold*[56], who showed in a number of papers that kinks occur as defects and as structural elements in paraffins, polymers, and polymer melts. Similar defects have been mentioned by *McMahon et al.*[57]. *Hosemann* has shown that the radiation-induced cross-linking of alkyl chains in polyethylene may be due to the presence of kinks, and that the paracrystallinity of polyethylene is connected with kink formation[58–60].

5. Kink-Block and Gauche-Block Structures

The decrease in the basal spacing in the β-phases by 1.0—1.2 Å (Fig. 10a) corresponds exactly to the shortening of alkyl chains by kinks. Approximately the value for an isolated alkyl chain is reached, since the packing density of about 24 Å^2/chain is considerably smaller than in paraffins and polyethylene (*ca.* 19 Å^2/chain) and the influence of neighboring alkyl chains is not so strong.

In the stability range of the β-phases the (00*l*)-reflections are rational up to high orders. This means that within a crystal all the layers have the same separation and the films are equally thick from layer to layer. The kinks cannot occur as isolated defects (Fig. 10b) but must be aggregated regularly into kink-blocks (Fig. 10c and 10d). In such kink-blocks the displacement caused by the kinks runs obliquely through

the film. These kinks are structural elements. In addition, isolated kinks can also occur as isolated defects.

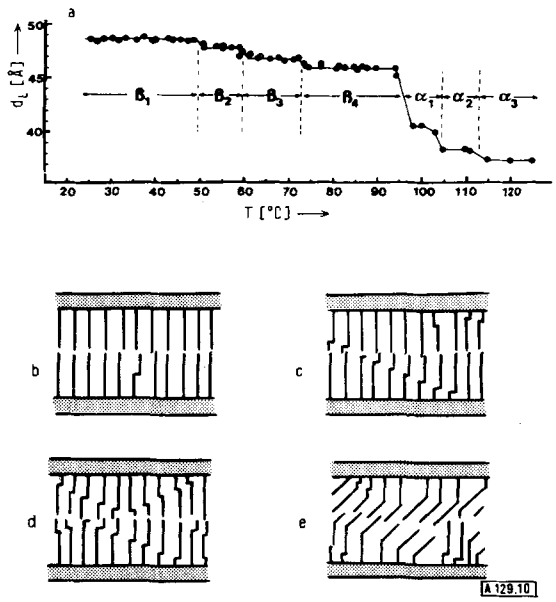

Fig. 10. Conformation of alkyl chains in a bimolecular film. a) Sequence of phases in bimolecular films between silicate layers (example $n_C = n_A = 14$, as in Fig. 4); b) *all-trans* block with a kink as an isolated defect; c) kink-block β_2; d) kink-block β_3; e) gauche-block.

The following phases may be distinguished (Fig. 10a):

β_1: All the chains are in the *all-trans*-conformation; kinks occur at the most as isolated defects and do not affect the layer separation (Fig. 10b).

β_2: A displacement due to ordered kinks runs through the whole bimolecular film. One kink occurs per pair of chains (that is two chains one above the other in the bimolecular film). *All-trans* chains (Fig. 10c) and pairs of chains with two kinks occur as isolated defects.

β_3: Two kinks occur per pair of chains, and either each chain of the pair contains one kink or one of the chains contains both kinks. Chain pairs with one kink and three kinks and, in very low concentration, *all-trans* chains occur as isolated defects (Fig. 10d).

β_ω: Contains pairs of chains with $\omega-1$ kinks and as isolated defects pairs with $\omega-2$, $\omega-3$... and ω kinks.

According to *Pechhold*'s calculations[61], the concentration of defects due to too few or too many kinks is of the order of 0.07 defects/chain. In addition, defects due to kinks in wrong positions may occur. Since the kinks are highly mobile in the chain direction[29, 62], these defects should easily disappear by displacement of the kinks along the chain.

5.1. Gauche-Block Structures

The film thickness of the high-temperature phases $\alpha_1, \alpha_2, \ldots$ cannot be interpreted as consistently as that of the low-temperature phases $\beta_1, \beta_2, \ldots$ In the first place it could be supposed that at the transition temperature so much alcohol is lost that the bimolecular film transforms into a monomolecular one. This is not the case. The film thicknesses lie clearly between the values calculated for bimolecular and monomolecular arrangements (Fig. 6).

It could be assumed that at the transition temperature $T_{\beta/\alpha}$ the state with a relatively low kink concentration passes into a state with a high kink concentration, similarly to what has been postulated for the rotational transformation of paraffins and for melts of polyethylene[56, 63]. This idea approaches closely the model for the liquid-crystalline phase of lipids due to *McCammon* and *Deutsch*[13]. However, the decrease in the film thickness could only be explained by kink densities that exceed the maximum possible number of kinks per chain. For simple helical forms (3_1-, 2_1-helices) the observed basal spacings are clearly too low. On the other hand, kinks of higher order ...$gt_x\bar{g}$... could occur. The necessary shortening of the chain requires relatively high values of x, *e.g.* for $n_A = 14$ each chain pair must contain two kinks with $x=3$ or one kink with $x=2$ and one with $x=4$, and so on. This leads to large parts of the chains being tilted to the layer normals. The above model can be considered only as a special case of the "gauche-block" model. In the gauche-block model it is assumed that relatively large parts of the chain are tilted to the layer normal because of a shifting of *gauche* bonds away from one another (Fig. 10e, and 11f). It is likely that gtg-conformations play an important role in the oblique arrangement of parts of the chains. According to *Pechhold*, these conformations are fundamentally involved in the meander-like structures in polymer melts[61, 63, 64]. Since the *gauche* bonds are not parts of kink-like conformations we use the expression "gauche-block structures".

In consequence of the loose packing the influence of the end-group interaction increases. It may be possible that some chains are inclined at 34° to the layer normal at their polar ends. This steric arrangement corresponds to an energetically particularly favorable arrangement of the NH_3 group and has been observed repeatedly[30, 98].

The packing density can be estimated by gravimetric measurements as about 1.3 alkyl chains per formula unit; it is therefore only slightly higher than the packing in monomolecular films (1.0 alkyl chains per formula unit). The area requirement per chain is about $2 \times 23.2/1.3 = 36\,Å^2$. Film thicknesses corresponding to gauche-block structures have also been measured in compounds such as niobates $K_4Nb_6O_{17}$[33] and alkylammonium polyphosphates[46, 65] with similar packing densities of the alkyl chains.

The proposed model is similar to the models used by *Whittington* and *Chapman*[66] and a model due to *McFarland* and *McConnell*[67]. In *Scott*'s statistical lipid model[12], gauche-block-like conformations are very important[12].

5.2. Influence of Chain Length on Kink-Block Formation

In the preceding sections systems with alkyl chains of the same length ($n_C = n_A$) and those with chains of different lengths in the alkylammonium ion and the alkanol molecule ($n_C \neq n_A$) were scarcely distinguished. The stepwise decrease in the film thickness by 1—1.2 Å and the transition into high-temperature phases occur in systems with alkyl chains of different lengths exactly as in the systems with chains of equal lengths. In systems with $n_A \neq n_C$ the changes of the basal spacings frequently appear to be even sharper, *i.e.* they appear to take place within a narrower temperature range.

The basal spacings shown in Figure 5 permit important deductions concerning the structure of the films. Bimolecular arrangements with vertical alkyl chains occur with alkyl chains of different lengths as well. In contrast to monomolecular films, however, there are several types of structures, depending

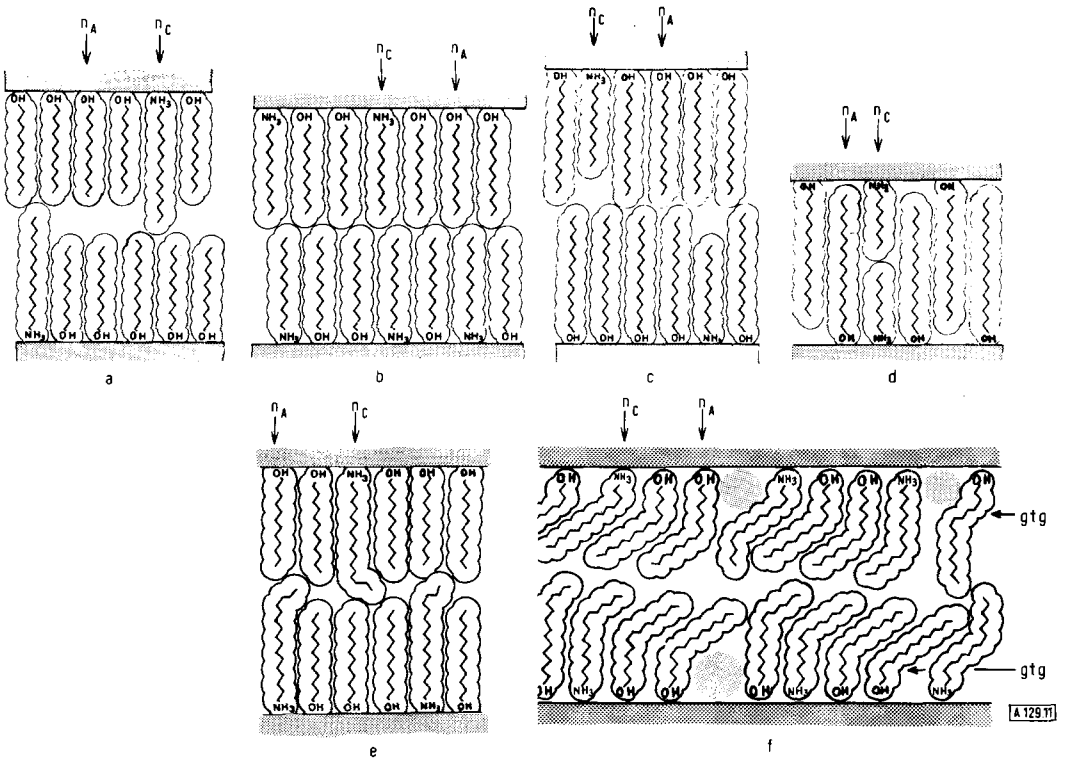

Fig. 11. Possible chain arrangements in bimolecular films. a) $n_A < n_C$, structure-determining pairs $\{n_C + n_A\}$; b) $n_A = n_C$; c) $n_A > n_C$, structure-determining pairs $\{n_A + n_A\}$; d) $n_A \approx 2n_C$, structure-determining pairs $\{n_C + n_C\}$; e) reduction of the vacancy volumes by kinks and isolated gauche bonds at the ends of the chains; f) gauche-block structure with partially filled cavities.

on whether short and short or long and long or short and long alkyl chains are opposite one another (Fig. 11). Two alkanol molecules (symbol $\{n_A + n_A\}$), two alkylammonium ions ($\{n_C + n_C\}$), or one alkylammonium ion and one alkanol molecule ($\{n_A + n_C\}$) may be one above the other. As Table 4 shows, the thickness of the bimolecular film is determined by the longest pairs that appear with greater frequency: for $n_A < n_C$ by the pairs $\{n_A + n_C\}$, for $n_A > n_C$ by the pairs $\{n_A + n_A\}$ (see Refs. [48, 49]). Holes (CH_2 vacancies) remain in the central region between the shorter chains (Fig. 11). In the case of very large differences in the chain length, the longer chains are shortened, probably by kinks or by *gauche* bonds at chain ends allowing the terminal methyl groups to move into the holes. In both cases the film thickness decreases by 1—1.2 Å (Fig. 11 e). In fact, differences of 1.1 Å or multiples of 1.1 Å are observed very frequently. Deviations can be caused by a different type of packing of the terminal methyl groups in the loosely-packed central region.

The films are sufficiently stable only when the region of the dense, undisturbed packing of the alkyl chains is sufficiently large. It must correspond to at least one alkyl chain with 12 carbon atoms on either side of the loosely-packed central region.

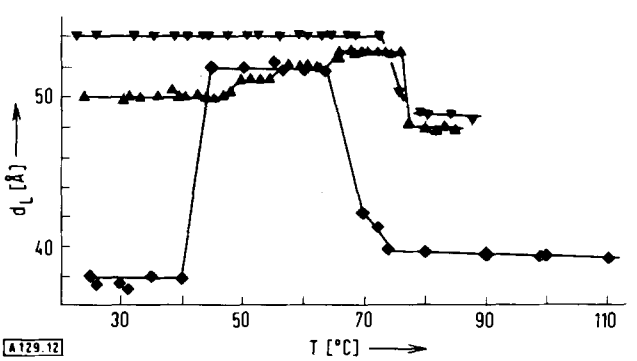

Fig. 12. Example of the sequence of phases in bimolecular films between silicate layers with large chain-length differences. System as in Fig. 4 with ◆ $n_C = 10$, $n_A = 18$; △ $n_C = 10$, $n_A = 24$, ▼ $n_C = 10$, $n_A = 26$ [69].

If the differences between the chain lengths are very large (*e.g.* $n_C = 10$, $n_A > 17$, $n_C = 14$, $n_A > 23$) other types of structure are observed (provisionally denoted as γ-phases). In many cases where $n_A \approx 2n_C$, alkanol molecules of approximately the same length are inserted between the $\{n_C + n_C\}$ pairs of alkylammonium ions: the structure becomes bimolecular with respect to the alkylammonium ions and monomolecular with respect to the alkanol molecules (Fig. 11d). With rising temperature additional alkanol molecules are taken up and β-structures are formed (Fig. 12). When the alkanol molecules are considerably longer than two alkylammonium ions opposite one another, structures with folded alkanol chains may occur. The stepwise increase of the basal spacing with rising temperature could indicate a shifting of the folds toward the chain ends in agreement with theoretical considerations[68].

6. Theory of Kink-Block and Gauche-Block Formation

6.1. Energy Data on Kink-Block Formation

It has been deduced from C_p measurements[49, 69], that the energy of formation of a kink in the kink-blocks is 0.7—0.8 kcal/mol (2.9—3.4 kJ·mol^{-1}) (Table 5). These values are not very accurate, since they were determined graphically from the C_p values, and the number of kinks per formula unit is not known precisely. Nevertheless, they show the order of magnitude, which is surprisingly low. In close-packed polyethylene the defect energy of a kinked alkyl chain is 7—11 kcal/mol (29—46 kJ·mol^{-1}); by aggregation of the defects it falls to half this value (Table 3)[54]. For an isolated alkyl chain the defect energy (1.3 kcal/mol) (5.4$_5$ kJ·mol^{-1}) is about twice the difference in energy between the *trans* and *gauche* states[52, 53].

The observed defect energy is still lower than this value. Since the basal spacing decreases on the formation of kink-blocks, for infinitely large layers the volume decreases and the packing density increases. The resulting gain in van der Waals energy leads to a slight decrease in the energy of kink formation. The effect should disappear with decreasing particle size. Nothing is yet known concerning its dependence on the particle size. The reduced defect energy is also revealed by the activation energy of kink relaxation, which is less than half of that in paraffins (4.7 kcal/mol as compared with 11–12 kcal/mol)[51].

The high defect energy in close-packed systems opposes the formation of a true kink-block in the alkylammonium-uvanite/alkanol complexes with dense packing of the alkyl chains. The defect energy for the formation of a kink in the nucleation step (more than 7 kcal/mol) in this system is obviously so high that nuclei which do grow into kink-blocks would appear only at temperatures above the transition point into the α-phase[99].

The change in entropy in the tetradecylammonium-beidellite/tetradecanol system is 2.3 cal·deg^{-1}·mol^{-1} (9.6 J·K^{-1}·mol^{-1}) for all three phase transitions (Table 5). *Pechhold*[61] calculated a value of 2.5 cal·deg^{-1}·mol^{-1} (10.5 J·K^{-1}·mol^{-1}), which is in very good agreement. The calculated values fall slightly for the three phase transitions; the experimental values are not sufficiently accurate to show such a change. In systems with alkyl chains of different lengths the transformation entropies are considerably higher.

Table 5. Enthalpies ΔH and entropies ΔS for kink-block and gauche-block formation (from C_p measurements on beidellite [49, 69]; the values are referred to 1 mol of beidellite).

T[°C]	Transition	ΔH [kJ·mol^{-1}]	ΔS [J·K^{-1}·mol^{-1}]

6.2. The Cooperativity of Kink-Block Formation

Phase transitions in monomolecular films take place cooperatively in most cases[62, 70–72]. Kink-block formation is also a cooperative process[56, 61, 63, 64, 73, 74]. In a lamella of alkyl chains the probability of kink formation in one alkyl chain depends on the state of the neighboring chains. The probability is higher if a neighboring chain already contains a kink. The growth step, however, becomes appreciably faster than the nucleation step only if the kink is formed in a position favorable with respect to the neighboring chains. Steric effects play a fundamental role in this process. In the formation of a kink in a chain (nucleation step), the displaced part of the chain thrusts against the neighboring chains (Fig. 13), which give way by the formation of kinks. The reaction continues to the next chain (growth step), a kink in one chain being always displaced by two C atoms in relation to the neighboring chain. An ordered kink-block is formed.

The sharpness of the transition should increase with increasing chain length, since the cooperative length[71] and the dimensions of the kink-blocks become larger. In the case of the transitions within the kink-block phases this cannot be recognized particularly clearly from the steps in the basal spacings, while it is very pronounced on transformation in gauche-blocks.

The geometric prerequisites appear to be optimal in the case of the layer silicates: the packing density is about 24 Å^2, and the alkyl chains are arranged in a pseudohexagonal pattern. In the uranium micas the packing density is just as large, but because of the square arrangement of the alkyl chains no regular kink-blocks are formed. In the square arrangement the cooperative coupling remains one-dimensional, the growth step takes place only within individual rows of alkyl chains, and each row requires its own nucleation step[100].

So far there have been only a few attempts at a theoretical treatment of kink-block formation in bimolecular films. According to *Pechhold*[61], the gap compliance between the two monolayers contributes to cooperativity. This arises in view of the fact that even below the temperature of kink-block formation (in the $\beta_1 \rightleftharpoons \beta_2$ transition) a few chains contain

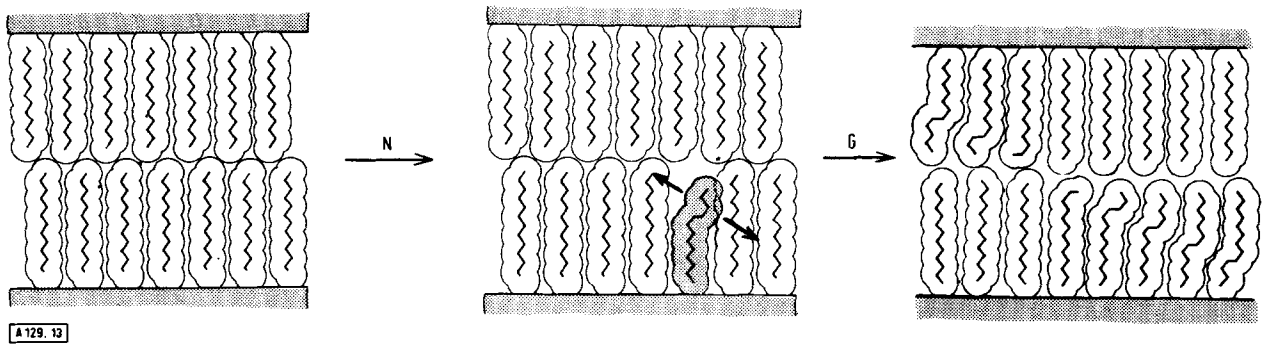

Fig. 13. Nucleation (N) and growth step (G) in the formation of kink-blocks.

kinks, and because of the rigid silicate layer the energy is raised by deformation of non-fitting chains. With $\Delta H = 0.83$ kcal/mol (3.48 kJ·mol^{-1}) and $\Delta S = 1.29$ cal·deg^{-1}·mol^{-1} (5.40 J·K^{-1}·mol^{-1}) for kink formation calculated and observed transition temperatures are in good agreement.

Baur[73-75] has made other attempts to treat the cooperative phase transitions in lamellas of alkyl chains. The calculations show that the formation of a sequence of kink-blocks in cooperative steps requires a sufficiently high aggregation tendency, *i. e.* definite values of the interaction energies between defect-free alkyl chains and alkyl chains with kinks as defects.

Because of cooperativity, the transitions in the series of kink-block structures do not correspond to first order transitions or to λ-transitions, as follows clearly from the C_p measurements (Fig. 7). As long ago as 1939—1942, *Harkins*[76, 77] and *Derivichian*[78] stated that phase transitions in monomolecular films may be of higher order[79]. *Baur* has calculated the multiplicity of changes in C_p on phase transitions in alkyl chain lamellas[73-75].

In our considerations so far the bimolecular film has been regarded as an individual alkyl chain lamella, although it is composed of two chemical individuals—the alkanol molecules and the alkylammonium ions. Since their ratio in the group of layer silicates investigated can vary from 1.8/0.2 = 9 to about 1.0/1.0 (for beidellite 1.57/0.43 = 3.7), this assumption can be checked. The same temperature dependence is observed in alkanol complexes of other layer silicates (vermiculites, montmorillonites): a sequence of β-phases occurs, which are transformed at higher temperatures into α-phases. Within the stability range of the β-phases the transition temperatures of the individual layer silicates are close to one another (Table 2). The ratio of alkylammonium ions to alkanol molecules has a clear effect on the transition temperature ($T_{\beta/\alpha}$) in the α-phase (Fig. 14), at which alkanol is expelled from the interlayer space. At a higher ratio of alkanol to ammonium ions than in beidellite, $T_{\beta/\alpha}$ is lower and is usually near one of the transition temperatures in the series of kink-block phases, *i. e.* instead of a kink-block a gauche-block is now formed. (This idea is supported by C_p measurements (Fig. 7), according to which at $T_{\beta/\alpha}$ a kink-block $\beta_{\omega+1}$ is formed which immediately changes into a gauche-block.) it is therefore possible, at least to a first approximation, to regard the bimolecular film of alkylammonium ions and alkanol molecules as a uniform alkyl chain lamella.

6.3. Transition into Gauche-Block Structures

The number of possible kink-block phases that are formed with rising temperature is limited. It is determined by an upper limit in the number of kinks in the structure-determining pairs of alkyl chains. (The β_ω-phase has $\omega - 1$ kinks per pair of alkyl chains.) This limiting value is smaller than the maximum possible number of kinks in the alkyl chain. It can be obtained in terms of the ratio C_K of the number of kinks to the number n of C atoms in the structure-determining pair of alkyl chains, and lies between 0.10 and 0.18[49]:

$$C_{K,\max} = 0.07 + 0.002\,n.$$

$C_{K,\max}$ gives the highest concentration of kinks in the β-phase.

The transition temperature $T_{\beta/\alpha}$ of the kink-block phase β_ω into the gauche-block phase α_1 has a maximum at $n_A = n_C$ (Fig. 14a). When $n_A \neq n_C$, the film contains holes (vacancies of CH_2 groups) and has lower transition points. The transition temperatures can therefore be represented as a function of the vacancy concentration (Fig. 14b). Again they lie on two straight lines for $n_A < n_C$ and $n_A > n_C$; for $n_A < n_C$ the $T_{\beta/\alpha}$ decreases strongly with increasing concentration of vacancies,

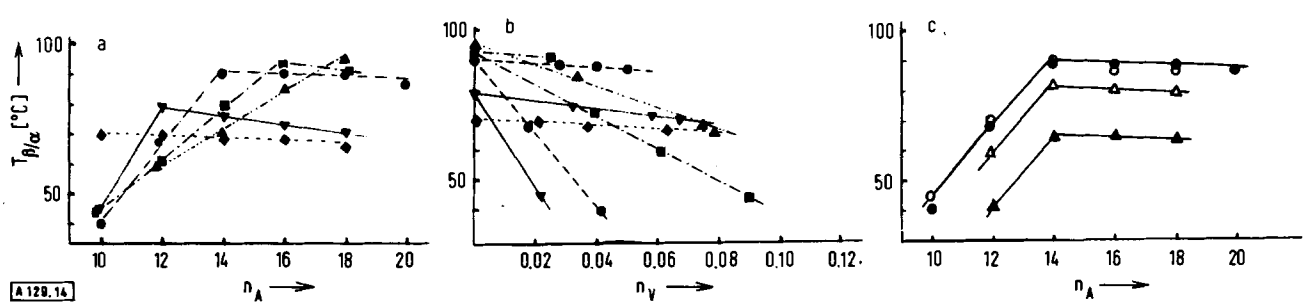

Fig. 14. Transition temperatures $T_{\beta/\alpha}$ of kink-blocks into gauche-block structures. a) As a function of the chain length of the alkanol n_A. System as in Fig. 4 with ◆ $n_C = 10$, ▼ $n_C = 12$, ● $n_C = 14$, ■ $n_C = 16$, ▲ $n_C = 18$; b) as a function of the concentration of vacancies n_V (vacancies/—CH_2); system as in a); c) with various ratios x of alkanol molecules and alkylammonium ions as a function of n_A for $n_C = 14$; ○ $x \approx 2.0$ (vermiculite); ● $x \approx 3.7$ (beidellite); △ $x \approx 4.6$ (Cyprus montmorillonite); ▲ $x \approx 6.1$ (Wyoming montmorillonite).

and this to an extent that is the greater, the shorter is the alkylammonium ion. For $n_A > n_C$ the transition temperatures fall slightly with the concentration of vacancies and are almost the same for $n_C = 14$ to 18. $T_{\beta/\alpha}$ is not a continuous function over the whole range, since the vacancies are not distributed uniformly over the film but are concentrated in the central region.

6.4. Structure of Bimolecular Films with Different Chemical Compositions

The structure and thermal behavior of bimolecular films depend on the type of polar molecules incorporated. So far it has not been possible to understand the complete variability of the film structure. If, for example, an alkan-1-ol is replaced by an alkan-2-ol, no typical kink-blocks appear. In the low-temperature forms the alkyl chains probably form simple helical conformations[55, 83]. At low temperatures, alkanediols give monomolecular films which, with rising temperature, pass into β-forms and finally into α-phases.

In connection with models of biomembranes the influence of double bonds in the alkyl chain[7] has been investigated in detail[80]. With the *cis* chains too kink-block phases are encountered at low temperatures. The *cis* chains are incorporated in the kink-blocks in the form of kink-like conformations *cis*-t-g (Fig. 15). They reduce the size of the kink-blocks and lower the temperatures of transition into gauche-block structures. If, in addition, alkyl chains of different lengths are present, and the concentration of double bonds is sufficiently high the transition temperature falls below 40 °C, so that gauche-block structures become stable in the physiological range of temperatures.

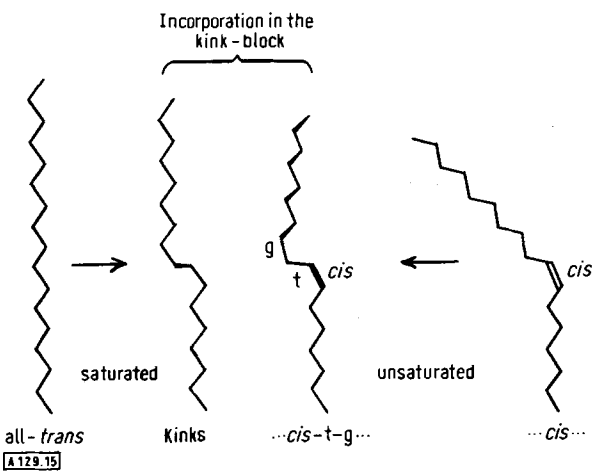

Fig. 15. Incorporation of *cis* unsaturated alkyl chains as *cis*-t-g conformers in kink-blocks. For comparison: transition of an *all-trans* chain into a chain with one kink.

Mono-, di-, and triglycerides[81] and glycerol ethers are also incorporated. At low temperatures, the high basal spacings correspond to structures similar to kink-blocks. At high temperatures, the structure changes into the α-form.

In relation to biomembranes, it is interesting to examine whether and how macromolecules can be incorporated in alkyl chain lamellas. These investigations are still in their initial stage, but in the case of simple linear macromolecules some characteristic results have already been obtained. Alkyl polyglycol ethers, for example, form bimolecular β- or α-phases with alkylammonium ions, depending on the degree of condensation[82]; on the other hand, polyvinyl alcohol is taken up with formation of monomolecular films having characteristic alkyl chain conformations[83]. The bimolecular structure is suppressed in favor of the formation of hydrogen bonds between the OH groups of the polyvinyl alcohol and the silicate layers. The results on the incorporation of proteins are still not very clear[84].

7. Conclusions

Only in the last few years has the phase change detected in lipid films by numerous methods of investigation[*] and even the generalized term of "chain melting" been clarified by model ideas. *Nagle*[79], *Seelig* and *Niederberger*[29], *Scott*[12], and *McCammon* and *Deutsch*[13] have related "chain melting" to the formation of *gauche* bonds and kinks in the alkyl chains. The concept of kink-block and gauche-block structures[48, 80] surpasses these ideas, since it permits a greater variability of phases and phase transitions. Important consequences for the structure of bimolecular films can be obtained. The investigations show that the alkyl chains in bimolecular films may still adopt *all-trans* conformations and be perpendicular to the layer even if the packing density is lower than in the crystalline compounds (*n*-alkanols, fatty acids, polyethylene with 19 Å²/chain). The lower limit lies at about 26 Å²/chain. The stability of the loose structure is probably due to less regular orientations of the planes of the carbon skeleton of the *all-trans* chains.

The films form kink-block structures in cooperative reaction steps by rotational isomerizations of the alkyl chains. The structural transitions can be initiated by raising the temperature. The formation of kink-block structures is associated with a packing density of about 22—25 Å²/chain. If an upper limit of the kink concentration is exceeded, the kink-blocks rearrange into gauche-blocks and the packing density of the chains falls to 33—40 Å²/chain.

The discovery that bimolecular films may contain high concentrations of holes (vacancies of CH_2 groups) must be regarded as another important conclusion. The maximum vacancy concentration is of the order of 0.05 vacancies/—CH_2, *i.e.* one vacancy to about 20 CH_2 units. In the model system, the vacancies are not distributed statistically but are concentrated in the central region of the bimolecular film. It is also not likely that a statistical distribution is formed. Even in polymer melts (with considerably higher vacancy concentrations) obviously no statistical distribution of the vacancies arises[85]. Films with vacancies change just as easily into kink-block and gauche-block structures as films without structural vacancies (alkyl chains with equal lengths); the transition temperatures depend on the vacancy concentration.

"Chain melting" of the lipids corresponds to the transition into gauche-block structures. The film thicknesses fall in a similar manner to the model system (*e.g.* by 10 Å in the case of dioctadecyllecithin[11] and 10.6 Å in the case of octadecylammonium-beidellite/octadecanol). The heats of transition are of the same order of magnitude: dihexadecyllecithin 8.7 kcal/mol, dioctadecyllecithin 10.7 kcal/mol[9], model system (referred to two alkyl chains per mol): 8—10 kcal/mol.

[*] For example ESR [24—26, 28], DNMR [18, 25], fluorescence measurements and dilatometry [27, 97], DTA [9—11, 97], and X-ray investigations [9, 11, 97].

Similar types of structure occur in biomembranes. Certainly, the order and structure in the kink-block phases of the lipid layers are not as high as in the model system, since a large number of different molecules is present. On the other hand the disturbance due to unsaturated alkyl chains with *cis* double bonds, for example, is not so high as might be assumed *a priori*. The *cis* chains do not interfere with the kink-block structure but adapt themselves by suitable conformations to the kink-block[80] (Fig. 15). However, they make the kink-blocks smaller and therefore reduce the temperature of transition into gauche-blocks.

The gauche-block structures should be of equal importance. Meanderlike gauche-block structures could actually determine the stress-strain behavior of muscle[87]. In gauche-block structures the less regular chain conformation and looser packing with larger cavities facilitates the incorporation of other molecules. The model in Fig. 11f resembles *Shah*'s concept: intermolecular cavities in mixed monomolecular films are filled with inserted molecules (Figs. 8 and 9 in Ref. [14]). According to the structural investigations reported by *Hitchcock et al.*[88], the long alkyl chains attached to glycerol are deformed by *gauche* bonds to such an extent that they form dense monomolecular films. Other molecules can be incorporated in these films only if cavities are produced by conformational changes in the alkyl chains. Possible structural changes are transitions into gauche-block structures.

In biomembranes, kink-block/gauche-block transitions may possibly be initiated by changes in the electrolyte system. The structure of the lipid region may also be changed by interaction with the membrane proteins[21-23].

The transitions between kink-block and gauche-block structures as a function of the chemical composition will affect the properties and reactions of membranes, such as permeability, transport processes[62], energy transformations[89], information processes, the conduction of stimuli in nerves, enzyme reactions, contact inhibition, and immune reactions. In these cases the hysteresis phenomena occurring in the kink-block/gauche-block transitions[48] should be of particular significance. A dynamic equilibrium may exist, between the kink-blocks and gauche-blocks similar to that proposed in the "fluid mosaic model"[22, 25, 90] between "crystalline" and "liquid-crystalline" regions.

Particular thanks are due to Prof. Armin Weiss of the University of Munich, for his encouraging interest and generous support and participation in the investigations. I am indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support with personnel and materials.

Detoxification of Automotive Exhaust Gases with Multifunctional Catalysts

By Wolfgang M. Weigert (deceased) and Edgar Koberstein[*]

Carbon monoxide, hydrocarbons, and nitrogen oxides can be simultaneously transformed into inoffensive substances on multifunctional catalysts. Consisting of noble metals or base metal oxides deposited on an inert support, these catalysts can be used in monolithic form or as granular packings. Compared with other methods of automotive exhaust detoxification, multifunctional catalysts are distinguished by incurring fuel savings.

1. Introduction

The ecological problems caused by the emission of automotive exhaust gases have already been surveyed in numerous publications[1-6]. Just how serious atmospheric pollution by the exhaust from internal combustion engines has become is apparent from Figure 1. Pollutants present in these exhaust gases are hydrocarbons—polycyclic arenes being the most serious offenders—carbon monoxide, nitrogen oxides, sulfur dioxide, sulfur trioxide, and solids. In the Federal Republic of Germany alone some 3650×10^3 t of carbon monoxide, 475×10^3 t of hydrocarbons, 815×10^3 t of nitrogen oxides, and 60×10^3 t of sulfur dioxide were emitted by motor vehicles in 1969.

Countries having high motor vehicle densities have introduced legislation stipulating limits for the emission of hydrocarbons, carbon monoxide, and nitrogen oxides and defining conditions for their measurement. Hence the motor industry

[*] Dr. W. M. Weigert and Dr. E. Koberstein
Degussa
Postfach 2644, D-6000 Frankfurt 1 (Germany)

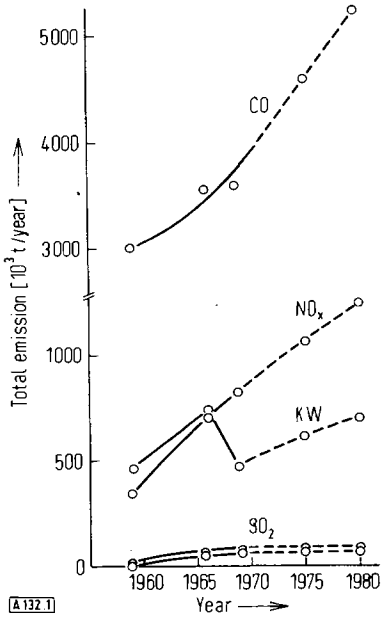

Fig. 1. Pollutants emitted by motor vehicles in the Federal Republic of Germany according to investigations by the Federal Ministry of the Interior [3]. HC = hydrocarbons.

is compelled to adopt suitable measures to comply with these stipulations. Differences in legislation from country to country and frequent changes in the requirements make this task difficult.

As an example, Table 1 lists the automotive exhaust standards presently valid in the USA and those expected in the future. By 1980 legislation is expected in the Federal Republic of Germany which will limit the pollutants in exhaust gases to one-tenth of the average values of 1969.

Table 1. US standards for automotive exhaust gases. Procedure: CVS-75 [14b].

Model year	Emissions standards [gram/mile]		
	Hydro-carbons	CO	NO_x
1975 California	0.9	9	2.0
1975 remaining USA	1.5	15	3.1
1976 California	0.9	9	2.0
1976 remaining USA	1.5	15	3.1
1977 California	0.41	9	1.5
1977 remaining USA	1.5	15	2.0
1978 [a]	0.41	3.4	0.40
1978—1982 [b]	1.5; 0.9; 0.41	15; 9; 3.4	3.1; 2.0; 1.0; 0.40

[a] According to the Clean Air Act (presently valid legislation; Muskie standards).
[b] Various proposed amendments to the Clean Air Act.

Several approaches to the reduction of pollutant emission have been examined with a view to satisfying these requirements.

Engine modifications are considered as a means of largely avoiding pollutant formation: these include the conception of radically different propulsion units for motor vehicles and changes in the design of the gasoline engine. More progress has been made in developing techniques for purifying the exhaust of conventional Otto cycle engines. In this connection, catalytic reactors converting the pollutants into the inoffensive gases carbon dioxide, nitrogen, and water have proved to be of great value. In particular, such reactors effect almost complete removal of polycyclic arenes (Fig. 2).

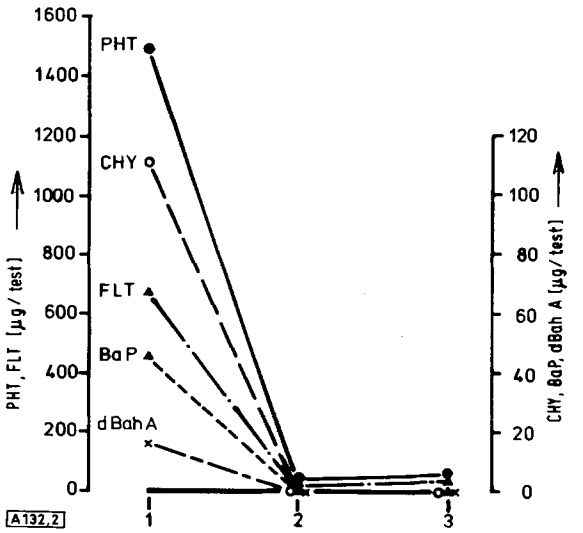

Fig. 2. Removal of polycyclic arenes from automotive exhaust gases by catalytic reactors. 1, without catalyst; 2, catalyst of type N; 3, catalyst of type E. PHT = phenanthrene; CHY = chrysene; FLT = fluoranthene; BaP = benzo[*a*]pyrene; dBahA = dibenz[*a,h*]anthracene.

In the USA several million vehicles have already been equipped with catalytic devices. Reports of American vehicle manufacturers about the performance of this new automotive component are positive. Hence catalytic exhaust detoxification can be regarded as having stood up to its first full-scale testing[7–9].

Development has not reached an end, however. Table 1 shows that increasingly stringent demands will be placed on exhaust purification in the future. Accordingly, new types of catalysts will have to be developed and it is with these that the present report is concerned.

2. Chemical Reactions in the Catalytic Detoxification of Automotive Exhaust Gases

The following overall reactions (1) to (9) occur during the transformation of pollutants emitted by engines into inoffensive compounds.

(1) $C_mH_n + (m + n/4)O_2 \longrightarrow m\,CO_2 + n/2\,H_2O$

(2) $CO + 1/2\,O_2 \longrightarrow CO_2$

(3) $H_2 + 1/2\,O_2 \longrightarrow H_2O$

(4) $NO + CO \longrightarrow 1/2\,N_2 + CO_2$

(5) $2\,(m + n/4)NO + C_mH_n \longrightarrow (m + n/4)N_2 + n/2\,H_2O + m\,CO_2$

(6) $NO + H_2 \longrightarrow 1/2\,N_2 + H_2O$

(7) $NO + 5/2\,H_2 \longrightarrow NH_3 + H_2O$

(8) $NH_3 + 5/4\,O_2 \longrightarrow NO + 3/2\,H_2O$

(9) $CO + H_2O \rightleftharpoons CO_2 + H_2$

From a thermodynamic standpoint all these reactions except (9) can go to completion; however, they require catalysts (for ΔG values see [10]).

An adequate supply of oxygen in the exhaust gas is essential for reactions (1) to (3). Several satisfactory oxidation catalysts have already been developed for these reactions. On use of these catalysts the nitrogen oxides were emitted largely

unchanged. So far, units containing oxidation catalysts have sufficed to meet the standards.

In view of the stricter legislation to be expected, however, methods must also be found for removing nitrogen oxides from the exhaust gases, *i.e.* for carrying out reactions (4) to (6). Since the reducing agents carbon monoxide, hydrocarbons, or hydrogen must be present for these processes, there should be no preceding oxidation reactions. It therefore seemed obvious to work with two separate catalysts (two-bed process). The first reactor contains a reduction catalyst which removes nitrogen oxides from the gas mixture. This is possible only if the exhaust gases comprise a reducing gas mixture, *i.e.* the engine must be driven in such a way that there is no oxygen in the exhaust. Prior to entering the second reactor containing the oxidation catalyst a secondary air supply to the exhaust gas is necessary (Fig. 3).

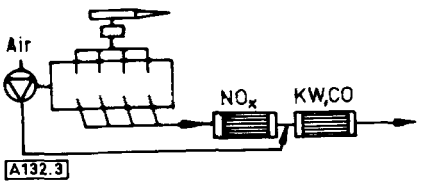

Fig. 3. Catalytic two-bed process. KW = hydrocarbons.

Although this technique considerably reduces the amount of pollutants in the exhaust gas, it nevertheless has its drawbacks. The two-bed solution places considerable demands on the equipment. Moreover, the usual catalysts are not sufficiently selective, so that part of the nitric oxide (up to 50 %) is reduced to ammonia according to eq. (7) and then partly reoxidized to nitrogen oxide according to eq. (8) in the second reactor.

In addition, the sulfur dioxide present in the exhaust gas is converted into sulfur trioxide. Emissions standards will probably be laid down for this compound in the near future. And finally, the two catalyst beds lead to considerable flow resistance, thus greatly increasing fuel consumption.

3. Multifunctional Catalysts

3.1. Action of Multifunctional Catalysts

The recently discovered catalysts which simultaneously mediate the oxidation and reduction reactions (1) to (6) represent a better solution (for their structure see Section 3.3). These multifunctional catalysts eliminate the three pollutants hydrocarbons, nitric oxide, and carbon monoxide, and are therefore also termed "three-way catalysts". However, the "three-way system" works satisfactorily only if it is operated within a certain limited oxygen partial pressure range in the exhaust gas.

The behavior of such catalysts is characterized with the aid of lambda curves. The conversion of the individual pollutants is plotted as a function of the air/fuel ratio characterized by the value λ (Fig. 4). λ is defined as the ratio of the amount of air introduced to the calculated air requirement for complete reaction. It is unity for stoichiometric conditions. The oxygen partial pressure in the exhaust also rises with increasing λ.

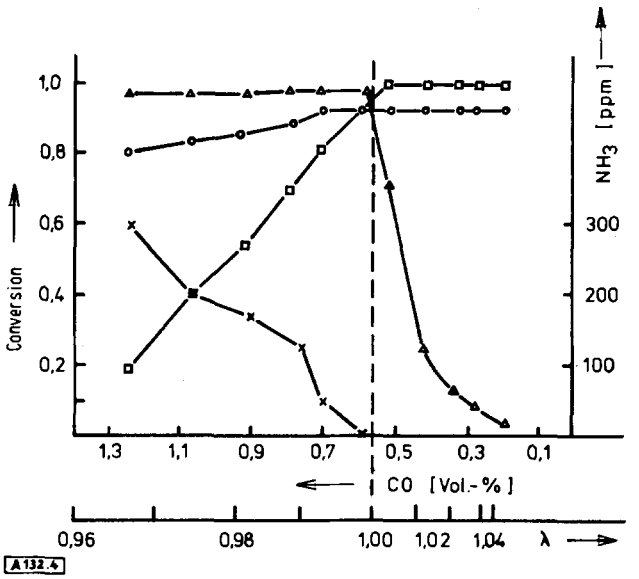

Fig. 4. Characteristic conversion curves lambda curves) for a multifunctional catalyst. □ CO, ○ hydrocarbons, △ NO_x, × NH_3.

Consideration of the conversion curves (Fig. 4) reveals an increase in conversion of hydrocarbons and of carbon monoxide with increasing λ. At $\lambda > 1$, a good catalyst permits practically complete conversion of the oxidizable pollutants.

Figure 4 refers to a catalyst that preferentially accelerates oxidation of hydrocarbons, which is generally desirable owing to the greater difficulty experienced in attaining the emissions standards for these pollutants. In the reducing range ($\lambda < 1$) nitric oxide is transformed almost quantitatively into nitrogen; at $\lambda > 1$ the conversion falls off rapidly.

The shape of the curve is a measure of the quality of a multifunctional catalyst. While the limited conversion in the range $\lambda < 1$ is attributable mainly to a stoichiometric deficit of oxygen and partly also to mass transfer phenomena under normal operating temperatures[10], the extent of the nitric oxide reactions in the range $\lambda > 1$ is restricted by the reaction kinetics and can therefore be influenced by the choice of catalyst. Reactions (4) to (6) are significant for removal of nitric oxide. As λ increases, reactions (1) to (3) begin to compete with reactions (4) to (6). For all catalysts so far known, the rate constants of reactions (1) to (3) predominate, and these reactions are therefore always preferred. This is also shown by Figure 5 which represents measurements performed with model gases in a laboratory reactor. Even on drastically increasing the carbon monoxide concentration, the conversion of nitric oxide is determined practically only by the oxygen partial pressure.

Thus only slight shifts of the nitric oxide conversion curves can be expected from the catalysts: however, these shifts are of considerable practical importance as they create a "lambda window", *i.e.* a λ range in which all pollutants simultaneously undergo almost quantitative reaction. Good three-way catalysts are also expected to suppress ammonia formation, which is shown to be feasible by Figure 4.

According to Figure 6, SO_2 is converted into SO_3 over multifunctional catalysts only at $\lambda \gg 1$. Thus the necessity of maintaining the window, *i.e.* of working at $\lambda \approx 1$, confers the added advantage of negligible SO_3 emission upon multifunctional catalysts as against conventional oxidation catalysts.

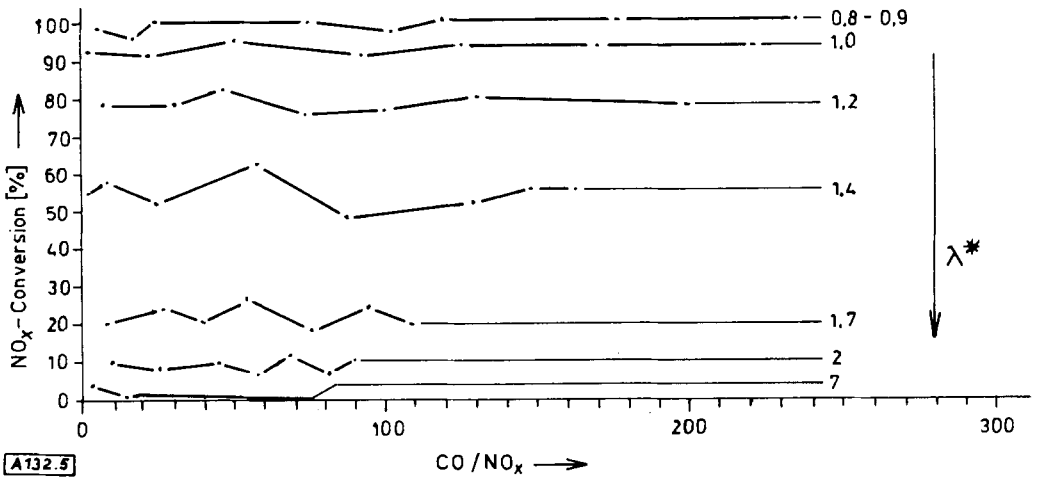

Fig. 5. Nitrogen oxide conversions at various oxygen concentrations in model gas mixtures at 700 °C. λ^* is a relative measure of the oxygen partial pressure. The CO/NO_x ratio is on a vol %/vol % basis. Space velocity 25000 h^{-1}.

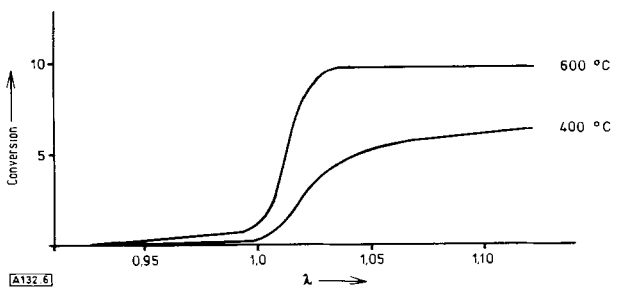

Fig. 6. Lambda curves for a multifunctional catalyst. The conversion of SO_2 into SO_3 was tested.

The conversion of pollutants also depends upon the temperature, a pertinent example being shown for $\lambda = 1.035$ in Figure 7. The temperature dependence of conversion is different for each pollutant. This is understandable because the activation energy E and frequency factor A will presumably differ in the Arrhenius equation

$$k_i = A_i \exp -E/RT$$

for reactions (1) to (6). Temperature effects of this kind can also play a role in practical application of the catalysts since widely fluctuating reaction conditions will attend the various operating states in a driving cycle.

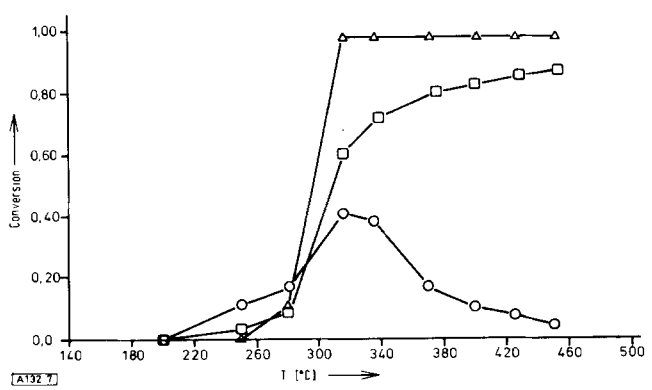

Fig. 7. Influence of gas temperature on the conversion of pollutants at a constant value of $\lambda = 1.035$. △ CO, □ hydrocarbons, ○ NO_x. Space velocity 70000 h .

A three-dimensional plot of pollutant conversions as function of λ and temperature furnishes typical surfaces for the various catalyst types. Figure 8 shows an example.

A knowledge of the pertinent motor characteristics permits choice and optimal adaptation of suitable catalysts on the basis of these results.

3.2. Methods of Maintaining the "Lambda Window"

The carburetors in present-day use lead to such extreme variation in the air/fuel ratio that the "lambda window" required for currently known multifunctional catalysts cannot be maintained. For this reason, modified carburetors on the one hand and controlled injection systems on the other have been developed which permit a considerably more accurate control of the value of λ for all kinds of operating conditions.

3.2.1. Fuel Injection

Fuel injection systems for Otto cycle engines have been in use for a considerable time. We distinguish between mechanically and electronically controlled systems.

Among the mechanically controlled devices special mention should be made of the "K-Jetronic" system[11]. In this approach the gasoline is continuously measured out *via* a fuel proportioning system which is mechanically controlled by an air meter located in front of the choke plate.

However, the fuel can also be measured out by electromagnetic injection valves whose opening times are determined by an electronic control device. In principle, several parameters are fed electrically to the control device and modify the opening times of the magnetic valves according to a given program. In the "L-Jetronic"[12], for instance, the engine speed and amount of air serve as input data.

3.2.2. Oxygen Sensor

On extension to include other control quantities these fuel injection systems can be used for catalytic three-way systems. As shown above the oxygen partial pressure plays a crucial role in the efficiency of multifunctional catalytic systems. Incorporation of an oxygen sensor in the exhaust pipe in front of the catalytic reactor permits measurement of the oxygen partial pressure which is used as an electrical control

signal in the control device. The oxygen sensor is an electrochemical oxygen concentration cell with a solid electrolyte (oxides with oxygen ion conduction). In this way a closed loop control be generated which guarantees an adequate "lambda window" also for varying operating conditions.

3.2.3. Modified Carburetors

Carburetors are modified with the intention of more exact control of the oxygen partial pressure. Approaches in which suitable amounts of additional air, again controlled by an oxygen sensor, are introduced may be cited for purposes of illustration[13]. The functioning and lifetime of the individual components, and especially the oxygen sensor, play a part in determining whether multifunctional catalysts are adopted, since it is only the overall system which is of interest in practice.

3.3. Composition of Multifunctional Catalysts

The demands placed on an automotive exhaust catalyst are exceptionally taxing. It must possess high mechanical strength, especially high compression strength and resistance to attrition. Above all, however, it must be thermally stable. In contrast to catalysts for chemical processes which operate at fairly constant temperatures, the exhaust gas catalyst must also display full activity under conditions of rapid and pronounced temperature fluctuations. It must detoxify the exhaust gases emitted under cold-start conditions, and it should not be damaged at excess temperatures such as may occur when the ignition fails.

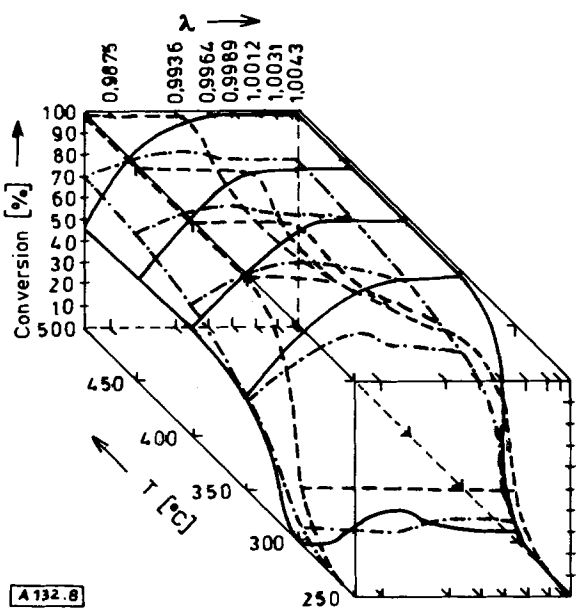

Fig. 8. Conversion curves of a multifunctional catalyst as a function of the temperature and the value of λ (catalyst characteristic). —— CO, -·-·- hydrocarbons, --- NO_x.

Figure 9 depicts a catalytic converter and multifunctional catalysts.

3.3.1. Support Material

Multifunctional catalysts are available as pellets or in monolithic form. A monolithic support consists of a single shaped unit penetrated by numerous channels. Parts of the cross sections of two catalysts having different kinds of monolithic supports are shown in Figure 10.

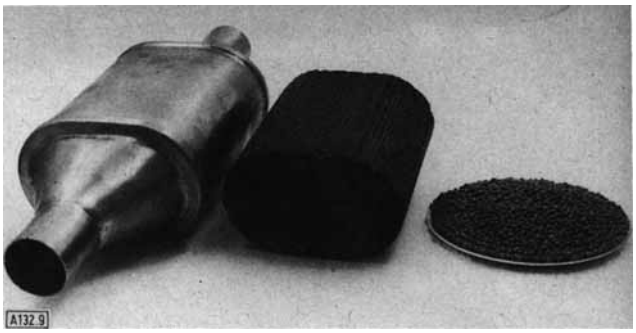

Fig. 9. Ready-for-use catalytic converter; monolithic catalyst; pelletized catalyst. Dimensions of converter: *ca.* 17 cm × 14 cm × 10 cm.

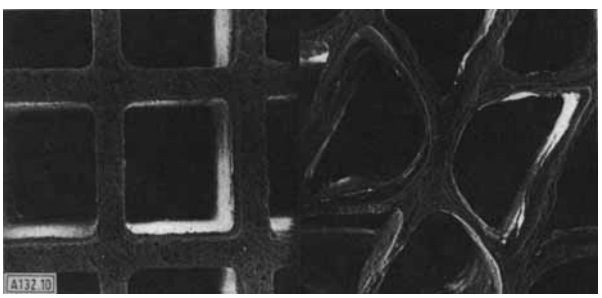

Fig. 10. Cross sections of monolithic catalysts (scanning electron micrographs).

The best material for ceramic supports has proved to be cordierite. This material has a favorable coefficient of thermal expansion, endowing the support with the good thermoshock properties required by the rapid temperature changes in automotive exhaust detoxification units. Depending upon the kind of engine and vehicle, the monolithic supports are used in various shapes and sizes, and with various channel cross sections and cell densities (number of channels per unit surface area).

The course of reactions (1) to (9) is also determined by mass transfer processes[10]. Hence the conversion of pollutants into inoffensive gases will also be affected by the cell density and the channel cross section of the monolithic catalyst material.

Supports for pellet type catalysts usually consist of spherical or extruded γ-alumina. The thermal stability and the resistance to attrition are generally not so good as with monolithic supports. Hence the use of pellet catalysts is nowadays limited to purification of exhaust gases from large motors since the thermal and vibrational stresses are comparatively smaller for such engines.

3.3.2. Active Coating

The catalyst support is coated with a layer of the active catalyst consisting either of base metal oxides or of noble metals. Active base metal phases are deposited directly on the ceramic supports. If a support is to be coated with noble metals then an intermediate oxide layer—in most cases also alumina—must first be applied.

Among the noble metal catalysts those containing platinum/rhodium/base metal phases have proved to be of utility.

Changes in the ratios of these components, the overall noble metal content, and the support material permit directed variation of the function of the catalyst.

Base metal oxide systems can also possess good multifunctional properties. The lambda curves are shown for such a catalyst in Figure 11. Base metal catalysts frequently contain nickel compounds. Relatively high gas temperatures are essential for the application of base metal catalysts.

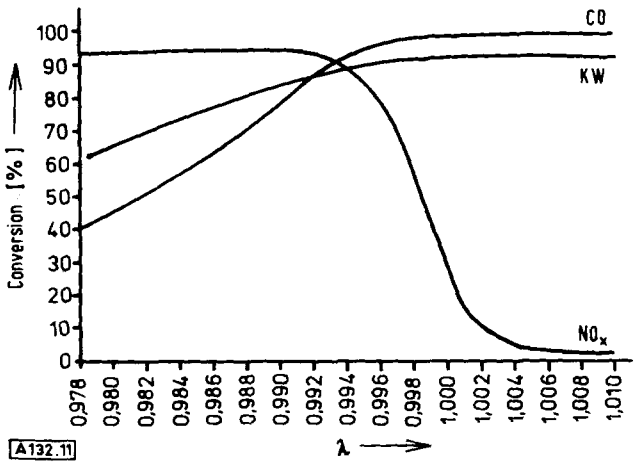

Fig. 11. Lambda curves for a multifunctional base metal oxide catalyst. KW = hydrocarbons.

In contrast, the noble metal catalysts also function at low temperatures, *i.e.* under cold-start conditions, but are easily poisoned by fuel additives and therefore require use of unleaded gasoline.

4. Use of Multifunctional Catalysts for Modified Processes

The above multifunctional catalysts permit extensive removal of all pollutants, even satisfying the most stringent emissions standards yet proposed (Muskie standards—Table 1). Operation within the "lambda window", *i.e.* around $\lambda = 1$, is a condition which in turn requires additional apparatus.

Now if higher emissions standards are to be tolerated for nitric oxide, as is also under discussion, then the motor can be operated with a larger λ window which would mean an inherent simplification of carburetion; an oxygen sensor would no longer be essential and the simpler K-Jetronic could be employed instead of the L-Jetronic system.

If the current US emissions standards were to stay, contrary to expectation, at the present levels, they could easily be met by the conventional oxidation catalysts. But even then, use of three-way catalysts would still have the advantage of requiring no secondary air supply.

Finally, mention should also be made of concepts directed at using multifunctional catalysts for the two-bed approach (reduction catalyst followed by oxidation catalyst, see Fig. 3). A multifunctional catalyst is employed for the reduction step and operated at $\lambda < 1$, but in the proximity of the stoichiometric point. This mode of operation avoids the formation of ammonia otherwise occurring in the double-reactor procedure.

5. Methods of Testing and Characterization of Catalysts

Just as important as emissions standards for pollutants are the standardized methods of testing the catalysts. The US government agencies prescribe the simulation of a particular driving cycle on a dynamometer corresponding to a typical cycle encountered in practice (Fig. 12). The exhaust gases emitted are collected in a constant volume sampler. Very exact measurements of emitted pollutants are possible in this way.

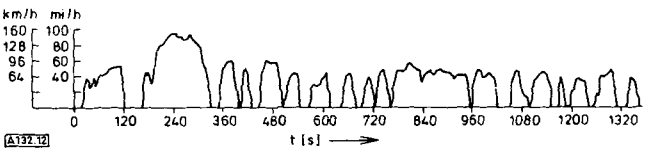

Fig. 12. CVS test 75, operating cycle.

This test is too involved and yet insufficiently specific for the development of catalysts since not only the catalyst but the entire system, including the engine, is estimated. Various shortened procedures have therefore been developed specifically for the characterization of catalysts. In a preliminary screening test model gas mixtures are used; automotive exhaust gases are used at a later stage.

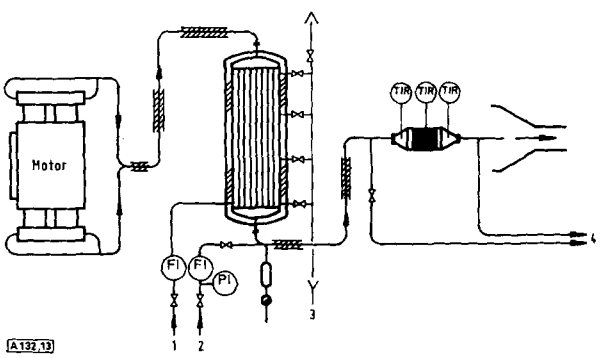

Fig. 13. Engine test for characterization of multifunctional catalysts. 1, cooling water; 2, air; 3, cooling water exit; 4, concerning analysis, FI, flow indicator; PI, pressure indicator; TIR, temperature indicator and recorder.

The approach described below has proved suitable for the development of multifunctional catalysts (Fig. 13). A stationarily operated engine is used which is loaded by an eddy-current brake; the fuel/air mixture can be precisely regulated by means of an electronic control device. The exhaust gases emitted by this engine are passed through a heat exchanger in which their temperature can be adjusted to any desired value and subsequently passed over the catalyst. The concentrations of hydrocarbons, carbon monoxide, nitrogen oxides, carbon dioxide, and oxygen are measured in front of and behind the catalyst with the aid of the instrumentation prescribed by the US tests[14]:

Hydrocarbons	– flame ionization detector
CO and CO_2	– ND infrared instruments
NO_x	– chemoluminesence instrument
O_2 (not stipulated)	– Magnos instrument (Hartmann & Braun)

Furthermore, the temperatures are registered immediately prior to entering and after leaving the catalyst and in its middle. All the parameters required for characterizing a catalyst, such as reaction temperature, concentrations of reactants, and space velocity, can be definitely and reproducibly adjusted with this equipment.

Characterization of three-way catalysts generally requires performance of the measurements described in Sections 5.1 to 5.3.

5.1. Conversion at Operating Temperature

Lambda curves are plotted, *i.e.* conversion curves for the pollutant components hydrocarbons, CO, and NO_x in the range $\lambda = 0.95$ to 1.05, whence the "lambda windows" (distance on the lambda scale between, for instance, 80% conversion of CO and of NO_x) and the intersection of the conversion curves for CO and NO_x can be deduced.

5.2. Low-Temperature Activity

In order to characterize its warm-up behavior, which is so important in practice, the catalyst is exposed to gases of increasing temperature, starting from 180°C, and the conversion measured.

5.3. Aging

In order to assess thermal damage the catalysts are subjected to heat treatment in a furnace and then tested in the same way to reveal any loss in activity or shift in the warm-up curve. A more realistic aging is accomplished in operation with an engine fed on a fuel/air mixture adjusted to give such a high CO concentration in the exhaust gas that the catalyst temperature increases to a predetermined maximum temperature of, *e.g.* 950 or 1000°C. At given time intervals the change in catalyst activity is checked by plotting a lambda curve and a warm-up curve.

6. Outlook

The methods adopted for detoxification of automotive exhaust gases in the future will depend upon the relevant legislation. If a reduction of nitrogen oxides is also prescribed then use of multifunctional catalysts appears attractive for several reasons. Requiring lambda values approximately equal to unity, this approach leads automatically to a very favorable fuel consumption and only slight SO_3 formation. Only one catalytic reactor is required and a secondary supply of air becomes unnecessary. However, these advantages are bought at the price of more stringent demands on the composition of the fuel/air mixture.

At the present state of the art, the catalytic three-way process is undoubtedly the most attractive possibility for extensive purification of automotive exhaust gases while maintaining favorable fuel consumption.

We are indebted to Dr. Hensel and Mr. Völker for their assistance.

Orbital Correspondence Analysis in Maximum Symmetry[**]

By E. Amitai Halevi[*]

The use of Orbital Correspondence Analysis in Maximum Symmetry (OCAMS) for determining the allowed course of a reaction is described in terms of the familiar "A, S" notation. Several well known thermal and photochemical reactions are used as examples: Polyene cyclization; the fragmentation and dimerization of cyclobutadiene; $[_\pi 4 + _\pi 2]$ cycloaddition; the isomerization of Dewar-benzene. The relation of OCAMS to the classical correlation procedures of *Woodward* and *Hoffmann* and of *Longuet-Higgins* and *Abrahamson* is brought out, as are the sources of the occasionally contradictory predictions of OCAMS and of the classical procedures.

1. Introduction

Although the recognition that symmetry is an important factor in chemical reactivity goes back nearly half a century[1], it was only after the appearance on these pages of *Woodward* and *Hoffmann*'s classic paper[2] that considerations of symmetry became an essential component of the way nearly all chemists, organic chemists in particular, think about reaction mechanism.

Since then, developments in the field have been so rapid and so diverse that the proposal of yet another, formally different, approach to the subject[3] cannot but be greeted with reserve. Even after the theoretical soundness of the new method has been established[4], its proponent is apt to be asked:

1) Does it contain any genuinely novel features which take it so far beyond conventional procedures as to make it worth mastering?

2) If so, is it simple enough to learn and sufficiently easy to apply that it can hope to gain acceptance as a practical substitute for the conventional procedures, whenever the latter fail to yield unambiguous conclusions?

This report is an attempt to answer these two questions in the affirmative as regards Orbital Correspondence Analysis in Maximum Symmetry (OCAMS)[3,4]. Like the *Woodward-Hoffmann* approach and unlike methods that adopt a valence bond formalism[5,6] or take configuration interaction into account[7], and even though it can be used as a basis for state-correlation studies which include electron interaction[8], OCAMS is essentially a one-electron, Hückel molecular orbital procedure. Moreover, although orbital symmetry and molecular topology are evidently related, explicit consideration of topology[9,10] or aromaticity[11,12,6a] is avoided. Finally, no special weight is placed on the frontier orbitals[13,14], all of the occupied orbitals of reactant and product being afforded equal *a priori* status.

OCAMS is related to several aspects of *Bader*'s pioneering work[15], which has more recently been revived and extended[16,17], and also has certain features in common with the method newly proposed by *McIver*[18]. However, its closest relative is *Woodward* and *Hoffmann*'s orbital correlation procedure[19], which was formally justified by *Longuet-Higgins* and *Abrahamson* in terms of configuration correlation[20]. Accordingly, the procedure and findings of OCAMS will be repeatedly compared in the ensuing discussion with those of the WHLHA analysis which, in addition to being similar to it in outlook, is by far the best known of the earlier methods. For the latter reason too, the commonly used "S,A" notation will be adopted in this report instead of group-theoretical notation, which—although it is both more compact and less ambiguous—is unfamiliar to many organic chemists.

2. Orbital Correspondence Analysis: Polyene Cyclization

In their first communication[13], *Woodward* and *Hoffmann* discussed the cyclization of polyenes solely in terms of the symmetry properties of their highest occupied and lowest unoccupied molecular orbitals (HOMOs and LUMOs). In their second communication[19], they returned to the same reaction, which *Longuet-Higgins* and *Abrahamson* also used as a central example[20], but now considered correlations between all the molecular orbitals of the reactant and product that might be involved in the reaction. The present discussion will therefore begin with a brief review of the familiar WHLHA analysis of the cyclization of *s-cis*-butadiene to cyclobutene, which will facilitate the exposition of OCAMS that is to follow.

2.1. WHLHA Correlation Procedure

It is seen at the top of Figure 1 that the reactant *(1)* and product *(2)* have two symmetry elements in common: A twofold rotational axis C_2 and a mirror plane m which bisects the molecule. *(1)* and *(2)*, which belong to the symmetry point group C_{2v}, each also has reflection symmetry in the molecular plane, but this third symmetry element, which we might denote by m', is discarded as "useless", since it does not bisect bonds made or broken in the reaction[2].

In the order to convert *(1)* into *(2)*, the two methylene groups must each be rotated by 90°, but if they are twisted separately, all molecular symmetry is destroyed along the reaction path. By carrying out the two rotations in a concerted manner, either C_2 or m—but not both—can be retained as a symmetry element; which one is retained depends on whether the two methylene groups are rotated in the same (conrotation) or the opposite sense (disrotation). Two correlation diagrams are then set up, one for each mode. In each, the symmetry properties of the molecular orbitals are specified with respect to that symmetry element which is retained along the reaction path, *i.e.* C_2 in the conrotation (Fig. 1a) and

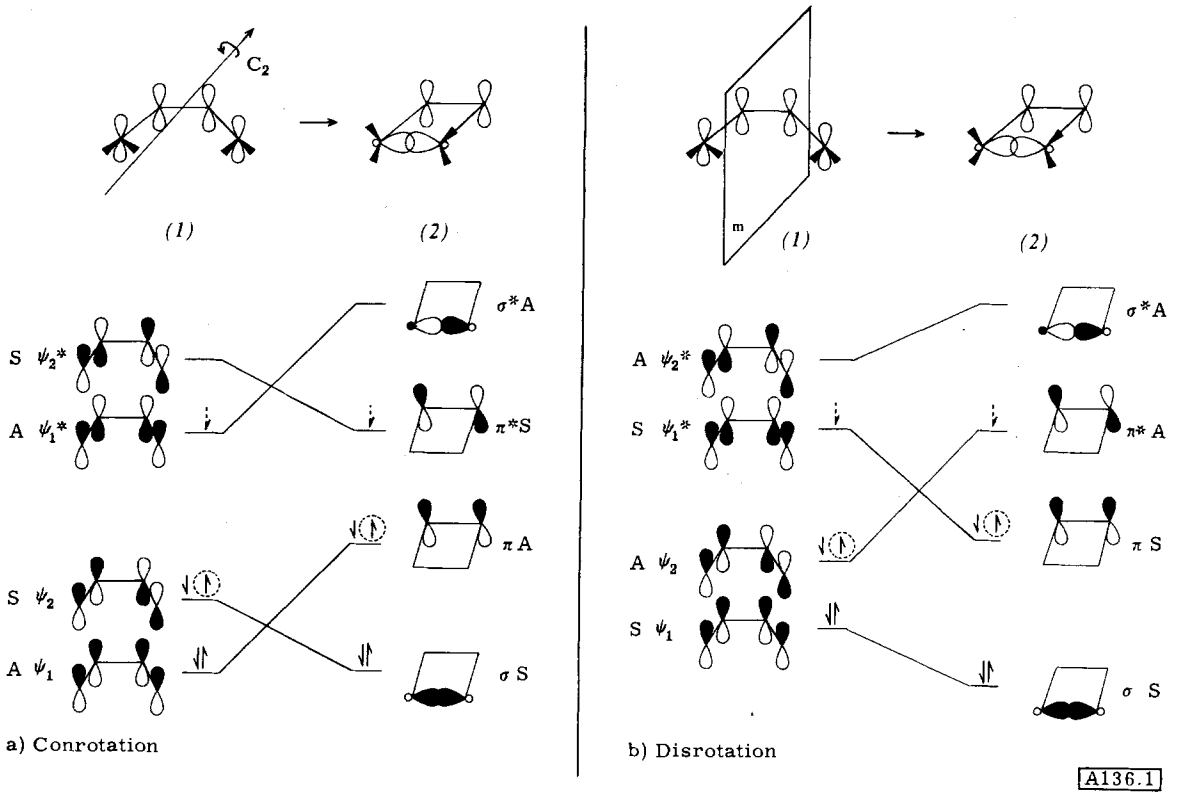

Fig. 1. WHLHA correlation diagrams for cyclization of *s-cis*-butadiene.

m in the disrotation (Fig. 1 b). The stacking of the molecular orbitals in order of increasing energy, which is of course the same in both diagrams, is self-evident, as is their characterization as S (symmetric) or A (antisymmetric) in each of the two modes. Correlation lines are drawn between orbitals of similar symmetry, care being taken not to violate the quantum mechanical rule that prevents two lines correlating pairs of orbitals with the same symmetry from crossing. (Non-crossing rule.)

Figure 1 a shows that the two orbitals which are doubly occupied in the ground state of the diene correlate with the two occupied orbitals of the product along a conrotatory pathway. In terms of configuration correlation, the ground-state configurations of reactant and product correlate with each other: $\psi_1(A)^2\psi_2(S)^2 \Leftrightarrow \sigma(S)^2\pi(A)^2$. From the viewpoint of either orbital or configuration correlation, the thermal, ground-state, reaction can be characterized as conrotatorily "allowed". In contrast, Figure 1 b shows thermal cyclization along the disrotatory pathway to be "forbidden", whether one invokes the orbital cross-correlation between occupied and unoccupied orbitals, familiarly referred to as a "HOMO-LUMO crossing", or the failure of the ground-state configurations to intercorrelate: $\psi_1(S)^2\psi_2(A)^2 \not\Leftrightarrow \sigma(S)^2\pi(S)^2$.

Before going on to the excited state reaction, we must recognize that no one-electron analysis can distinguish between singlet and triplet states having the same orbital occupancy. In anticipation of our discussion of open shell reactions (Section 5) the arrows in Figure 1 representing spin have been drawn so as to suggest a triplet state reaction. At this stage, however, the excited state reaction is discussed as if it were the same for both multiplicities.

Returning to Figure 1 a, we focus our attention on the excitation from ψ_2 (HOMO) to ψ_1^* (LUMO), which causes each to be singly-occupied. Since singly-occupied ψ_2 correlates with doubly-occupied σ rather than with singly-occupied π or π^*, the conrotatory excited state reaction is "forbidden", a conclusion borne out by the lack of configuration correlation between the lowest excited states: $\psi_1(A)^2\psi_2(S)^1\psi_1^*(A)^1 \not\Leftrightarrow \sigma(S)^2\pi(A)^1\pi^*(S)^1$.

From Figure 1 b we see that, thanks to the cross-correlation between the singly-occupied HOMOs and LUMOs and the fact that the doubly-occupied ψ_1 and σ are both S, or —equivalently and more compactly—because: $\psi_1(S)^2\psi_2(A)^1\psi_1^*(S)^1 \Leftrightarrow \sigma(S)^2\pi(S)^1\pi^*(A)^1$, the photochemical reaction is "allowed" along a disrotatory pathway.

For the purpose of comparison with OCAMS, we note two important features of WHLHA:

1) Not all the symmetry elements common to reactant and product are used in the analysis. Specifically, reflection in the molecular plane m' has been dismissed as "unimportant".

2) Reaction paths corresponding to different ways of reducing symmetry are analyzed separately. The symmetry-breaking motion (here a conrotation or a disrotation) is not considered explicitly; rather, its consequences are explored by characterizing each orbital with respect to the symmetry elements that are retained after the distortion has been applied, in our example either C_2 or m but not both.

It will now be shown how OCAMS elicits the same information about polyene cyclization in a rather different way, *i.e.* by investigating the symmetry properties not only of the molecular orbitals but also of the symmetry-breaking motions, and by ensuring that their symmetry is specified with respect to all, not just an arbitrarily selected few, of the symmetry elements common to the reactant and product.

2.2. Direct Correspondence

We first examine the symmetry of the MOs with respect to both of the "important" symmetry elements. Figure 2 which

is essentially a superposition of Figures 1a and 1b, shows that, in the original geometry, the MOs fall into four types: (1) SS—symmetric with respect to both C_2 and m; (2) AA—antisymmetric with respect to both; (3) SA—symmetric with respect to C_2 but antisymmetric with respect to m; and (4) AS—*vice versa*. Orbitals of the first two types evidently lie in the molecular plane and are symmetric to reflection in it m′, whereas those of the third and fourth type have a node in the molecular plane and are thus antisymmetric to m′. Clearly, types (1) and (2) are σ-orbitals whereas types (3) and (4) are π-orbitals. If we wished to make the π or σ nature of each orbital explicit, we might add a third A or S, referring to the symmetry with respect to m′, to those for C_2 and m. Then, AS would become ASA, SA would be SAA and the two of σ type would be SSS and AAS. In C_{2v} symmetry, this overspecification is unnecessary, the π or σ character of each orbital being evident without it. The symmetry properties with respect to C_2, m and m′ are fully determined in terms of any two of them[21].

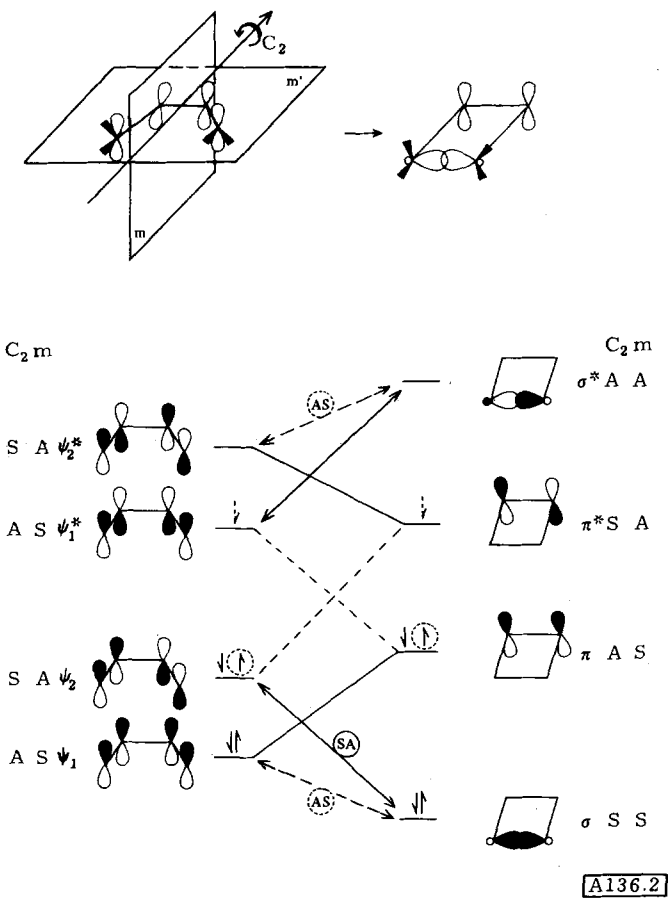

Fig. 2. Correspondence diagram for cyclization of *s-cis*-butadiene.

Direct correspondence
Conrotatory
Disrotatory
Induced correspondence
SA
AS

Two of the four π-orbitals of butadiene can be brought into *direct correspondence* (SA↔SA; AS↔AS) with those of cyclobutene, ensuring that two reactant orbitals could correlate with two of the product without any reduction of symmetry at all. Moreover, if the symmetry does happen to be reduced by a conrotation or a disrotation, these pairs of orbitals could still correlate with each other, since their symmetry properties are identical with respect to both C_2 and m and would remain so with respect to which ever one of them is retained along the pathway.

Note, however, that π corresponds with both ψ_1 and ψ_1^* while π^* corresponds with both ψ_2 and ψ_2^*, whereas, along any reaction path, each orbital of the product can correlate with only one reactant orbital. Therefore, a correspondence line between orbitals of the same overall symmetry, *i.e.*, one that denotes a direct correspondence, merely indicates that the two orbitals *can* correlate whether or not the symmetry of the reacting system is reduced, but not whether they *will* correlate. The eventual orbital correlations, which differ for different reaction paths, can hardly be ascertained before the nature of the pathway has been determined[22]. Since the two σ-orbitals, notably σ(SS) which is doubly-occupied in both the ground and first excited state, are left out of all the direct correspondences, it is obvious that cyclization cannot take place unless symmetry is reduced, and the onus is placed firmly on the requirement that two electrons be taken from a π-orbital of butadiene and delivered to a σ-orbital of cyclobutene.

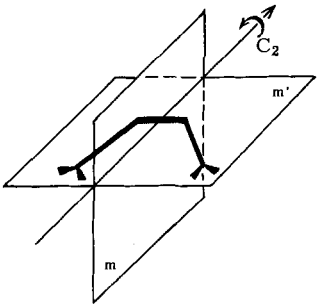
2.3. Induced Correspondence

We must therefore find a way of inducing a correspondence between one of the doubly occupied π-orbitals of butadiene and the bonding σ-orbital of cyclobutene. For this purpose a procedure is borrowed from the way spectroscopic selection rules are deduced, and reformulated as follows: *Correspondence between two orbitals, both of which are either symmetric or antisymmetric with respect to a given symmetry element, can only be induced by a displacement which is symmetric with respect to that element. If one orbital is symmetric and the other is antisymmetric with respect to a given element, they can be brought into correspondence only by a displacement that is antisymmetric with respect to that element.*

For example, in order to induce a correspondence of the type AS↔SS, the system must be distorted along a coordinate that is antisymmetric with respect to C_2 but symmetric with respect to m, *i.e.* one that can be represented as AS. Alternatively to induce the correspondence SA↔SS (and/or AS↔AA) a motion of type SA is called for.

The specification of the symmetry properties of displacements, which is common practice in vibrational spectroscopy, is less familiar to organic chemists than the similar characterization of molecular orbitals, but it is no more difficult. Figure 3 shows a number of symmetry coordinates, *i.e.* coordinates that are either symmetric or antisymmetric with respect to all the symmetry elements of the system, by means of arrows depicting the motion of the individual atoms. If, on application of a given symmetry coordinate—say *m*—to the molecule, all the arrows go into themselves or into arrows identical with them in length and direction, the coordinate is S with respect to m. If m takes all the arrows into arrows of the same length pointing in the opposite directions, it is A. If it does neither, the displacement depicted is not a symmetry coordinate[23].

The correspondence diagram in Figure 2 can now be completed by adding the required induced correspondences (denoted by two-headed arrows labeled according to the symmetry of the inducing coordinate) to the direct correspondences between occupied orbitals. For the ground-state reaction, ψ_2(SA)↔σ(SS) clearly calls for an SA distortion, which Figure



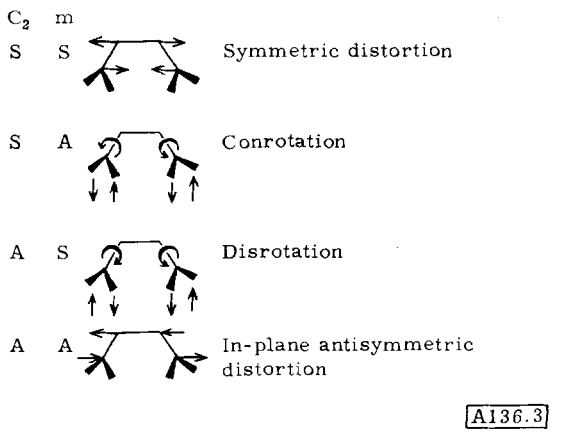


Fig. 3. Some symmetry coordinates of *s-cis*-butadiene.

3 identifies to be a conrotation. Similarly, in the excited state reaction, a disrotation, which Figure 3 characterized as AS, is suitable for inducing the required correspondence: $\psi_1(AS) \leftrightarrow \sigma(SS)$. The agreement with the WHLHA predictions becomes all the more evident when it is noted that the set of correspondences, direct and induced, selected by a conrotation (full lines in Fig. 2) reproduce the correlation lines of Figure 1 a, whereas the disrotatory correspondences (dashed lines in Fig. 2) similarly reproduce Figure 1 b.

2.4. Has Anything Been Gained?

Since the predictions of OCAMS are identical with those of WHLHA for polyene cyclization, we shall have to go on to less simple reactions in order to illustrate the greater predictive power of the former. Several marginal advantages are, however, already perceptible.

a) The driving force for the reaction, and the factor governing its stereochemistry in both the thermal and photochemical reactions, is clearly identified to be formation of a σ bond from a pair of electrons originating in a π-orbital. This point is obscured in the conventional analysis, in which π and σ orbitals, each of which can be either S or A with respect to C_2 or m, are not formally distinguished from each other.

b) The justification for regarding certain symmetry elements as more important than others becomes clear. C_2 is the essential symmetry element for a conrotation, as m is for a disrotation, because it is the one diagnostic symmetry element that is not destroyed along the reaction coordinate. The lesser importance of m' in this reaction, does not depend on its failure to bisect bonds made or broken in the reaction, but rather on the fact that it is not retained along either pathway leading to polyene cyclization. In other reactions, to be discussed in subsequent sections, it can be put to good diagnostic use, whether or not it bisects bonds made or broken[24].

c) By characterizing the orbitals fully before symmetry is reduced, OCAMS eliminates the necessity for choosing the pathway by intuition or by trial and error. This feature can be particularly important in reactions for which the possible pathways are less intuitively obvious than they are in our example, and where a possible reaction path might therefore conceivably be overlooked.

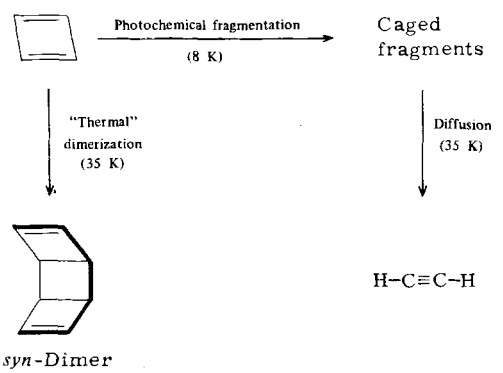
3. Maximum Symmetry: Reactions of Cyclobutadiene

Chapman et al., having produced cyclobutadiene photochemically at very low temperatures in an argon matrix, found it to react as summarized in Scheme 1[25]. These reactions will be used to demonstrate the advantages of two aspects of maximum symmetry:

a) Allowing a preferred reaction path to emerge from a correspondence diagram, rather than choosing several possible pathways by intuition and analyzing them individually for "allowedness".

b) Retaining all the symmetry elements that are necessary to characterize the system fully, rather than arbitrarily selecting several of them as more important than others.

Scheme 1.



3.1. Fragmentation of Cyclobutadiene

The ground state of cyclobutadiene is almost certainly a planar singlet, but whether it is rectangular as required by Hückel theory or whether electron correlation is strong enough to preferentially stabilize it in the square geometry, is less clear[26,27]. In either case, fragmentation to two acetylene molecules necessarily distinguishes between the bonds that are to be ruptured and those that will remain intact in the product. The "reactant" can thus be regarded either as one of the two equivalent isomers of cyclobutadiene, or—if the lowest singlet is indeed square-planar—as having been distorted slightly in the direction of eventual fragmentation.

We begin once more with the WHLHA approach, and characterize the molecular orbitals in Figure 4 on the basis of the two "important" mirror planes, m_1 and m_2, that bisect the π-bonds being formed and the σ-bonds being broken respectively. The four occupied orbitals and the lowest unoccupied orbital (which is the only one shown in the figure) on either side are ordered on the basis of the usual considerations: σ-interactions are stronger than π-interactions, the energy

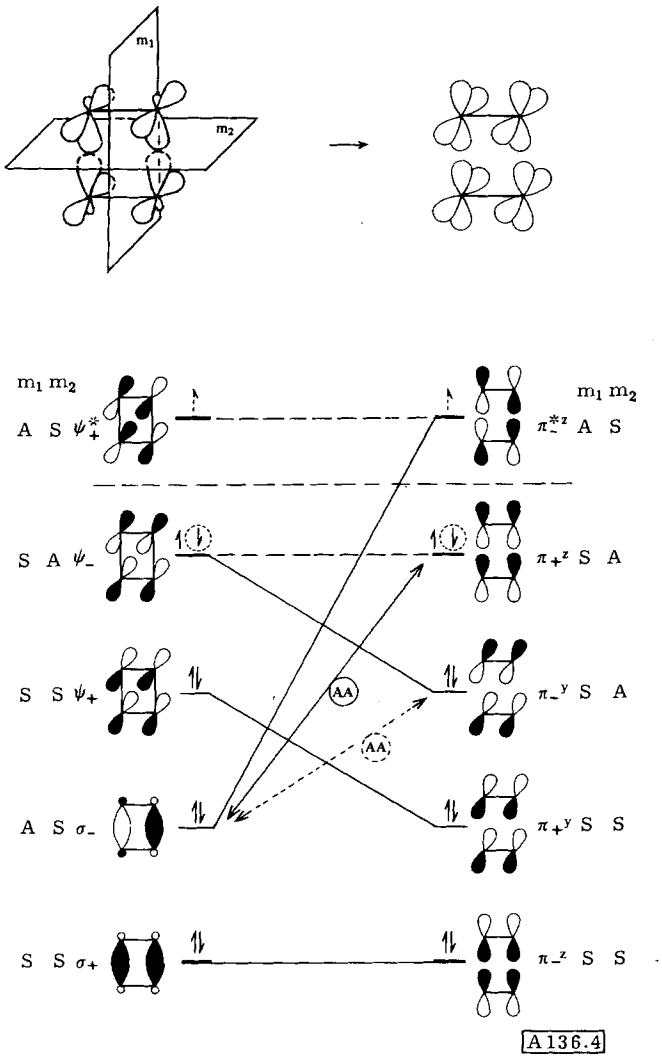


Fig. 4. Preliminary analysis of fragmentation of cyclobutadiene (higher unoccupied orbitals not shown).
Full lines: WHLHA correlations. Two-headed arrows: Induced correspondences (full—thermal; dashed—photochemical).

increases with the number of nodal surfaces, *etc.*... Two specific points should be noted:

1) ψ_- and ψ_+^*, which would have the same energy in a square-planar molecule, are split as shown to become the HOMO and LUMO, respectively.

2) As must often be done when the "product" is made up from two separate molecules, it is thought of as representing a point along the reaction coordinate at which they are still close enough to interact. Otherwise, all four combinations of the bonding π-orbitals would be degenerate, and there would be no justification for characterizing π^{*z}_-, the most bonding combination of the π* orbitals, as the LUMO and ignoring the other three.

When the usual WHLHA correlation lines are drawn into Figure 4, the reaction is found to be both thermally and photochemically forbidden, because the strongly bonding doubly-occupied orbital σ-(AS) correlates with the LUMO, which is unoccupied in the ground-state and only singly-occupied in the lowest excited state.

Adopting those features of OCAMS which have already been introduced, we can regard the WHLHA correlation lines as direct correspondences and investigate whether the missing correspondence can be induced by a distortion that might serve as a reasonable reaction coordinate. In the ground state reaction this is: $\sigma_-(AS) \leftrightarrow \pi^z_+(SA)$, which can be induced by distortion along an AA symmetry coordinate. In the excited state reaction, the singly-occupied HOMOs and LUMOs correspond directly with one another, so the required correspondence is: $\sigma_-(AS) \leftrightarrow \pi^y_-(SA)$, which also requires a distortion of type AA. The observed photochemical fragmentation can thus be rationalized on the basis of a reaction coordinate that is antisymmetric to both m_1 and m_2; but then, why is thermal fragmentation, which seems to require the same type of reaction coordinate, not observed too?[28]

The reason for the apparent discrepancy is that two coordinates—or two orbitals for that matter—can both be characterized as AA and still not be symmetrically equivalent, because their characterization on the basis of m_1 and m_2, alone is inadequate in the higher symmetry adopted for the system[29].

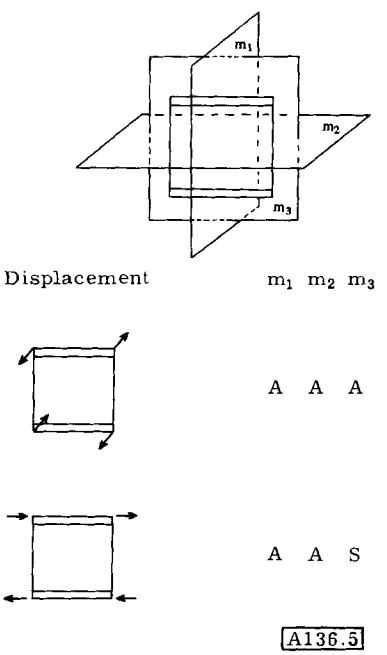

Fig. 5. AA coordinates of cyclobutadiene.

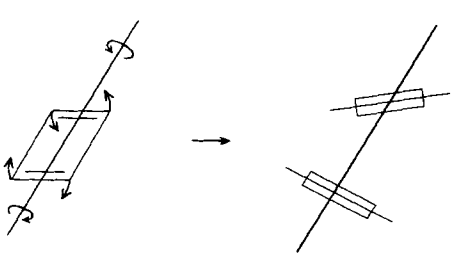
Of the two AA coordinates in Figure 5, one is an "out-of-plane twist" that is antisymmetric with respect to the discarded symmetry element m_3 and the other is an "in-plane glide", symmetric to m_3. The former, which is fully characterized as AAA, might serve as a reasonable reaction coordinate for concerted rupture of both σ bonds to yield two acetylene molecules, as in Scheme 2; the latter, AAS, coordinate would not, since weakening of the bonds initially on the sides of the rectangle would presumably be accompanied by bonding across the diagonal to form a transoid four-carbon chain.

Scheme 2.



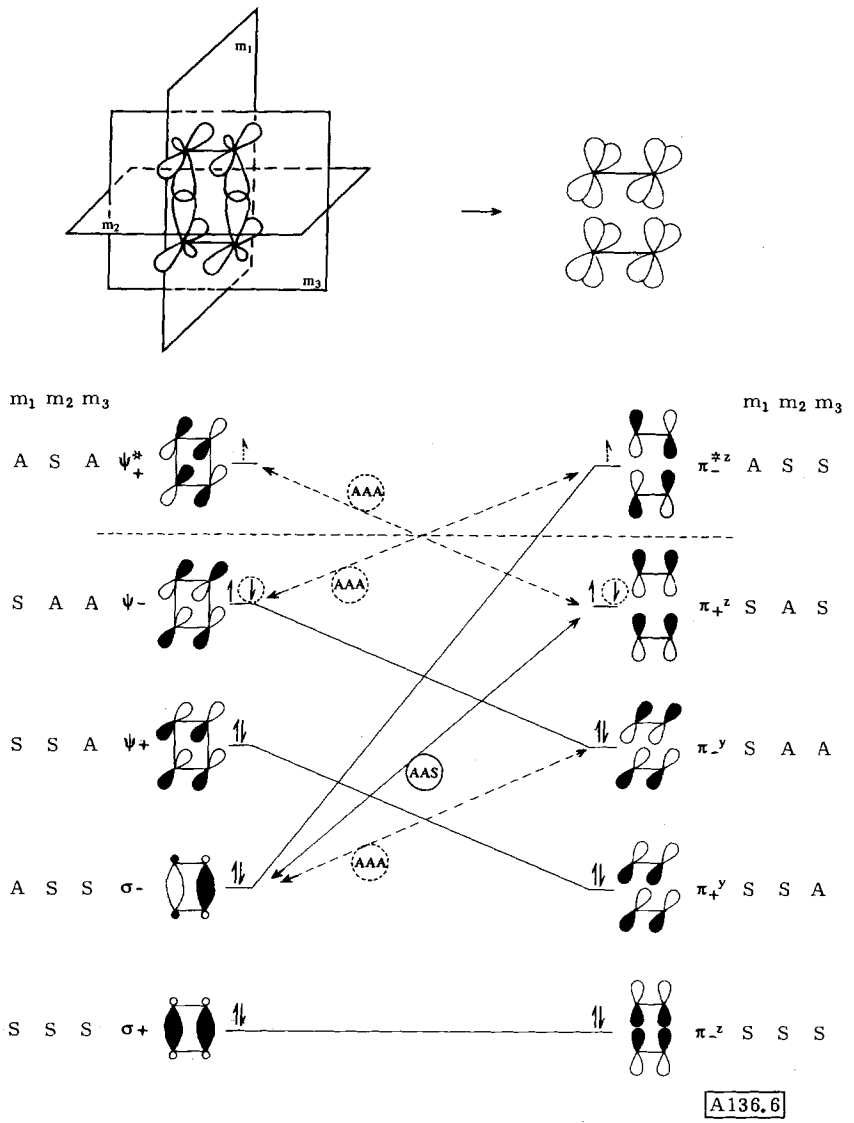


Fig. 6. Correspondence diagram for fragmentation of cyclobutadiene (higher unoccupied orbitals not shown).

In order to determine which of these two coordinates to associate with the thermal and which with the photochemical fragmentation, Figure 4 is redrawn as Figure 6, in which the orbitals are characterized with respect to m_1, m_2, and m_3.

The direct correspondences between the three pairs of bonding orbitals remain as before. The correspondence that has to be induced in order to allow thermal fragmentation is now seen to be of the unsuitable AAS type, and—since a reaction that is formally "allowed" by a coordinate that is geometrically unsuited to serve as a reaction coordinate is as surely prevented from taking place as one that is formally "forbidden"—failure to observe it is understandable. The $\sigma_-(ASS) \leftrightarrow \pi^y_-(SAA)$ correspondence needed to allow photochemical fragmentation is just the type shown in Scheme 2 to be appropriate. The same AAA coordinate is also capable of inducing a cross-correspondence between HOMO and LUMO, which are no longer in direct correspondence, as Figure 4 erroneously had them. The observed fragmentation behavior has thus been rationalized, but only after carrying out the analysis in *maximum symmetry*.

3.2. Dimerization of Cyclobutadiene: Alternative Product Stereochemistry

The choice of the geometry in which the analysis is carried out is not crucial; a poor choice is corrected by OCAMS by suggesting a reorientation to another geometry. The axial, noncoplanar, orientation at the top of Figure 7 was chosen for the analysis of cyclobutadiene dimerization in order to illustrate three points:

a) Maximum symmetry does not imply the imposition on the system of as many symmetry elements as possible. In the geometry adopted, the system is evidently less symmetrical than in the plane-rectangular orientation (cf. Fig. 8a) which—in addition to the three rotational axes—also has three mirror planes and a center of inversion. Figure 8a implies a product with a planar cyclobutane ring whereas Figure 7 suggests that the central ring is puckered. The two are interconvertible by means of a slight, energetically inexpensive, twist about the longitudinal axis[30], so it is fully to be expected that analyses in both geometries would yield the same result—as indeed they do. The T-orientation shown in Figure 8b has

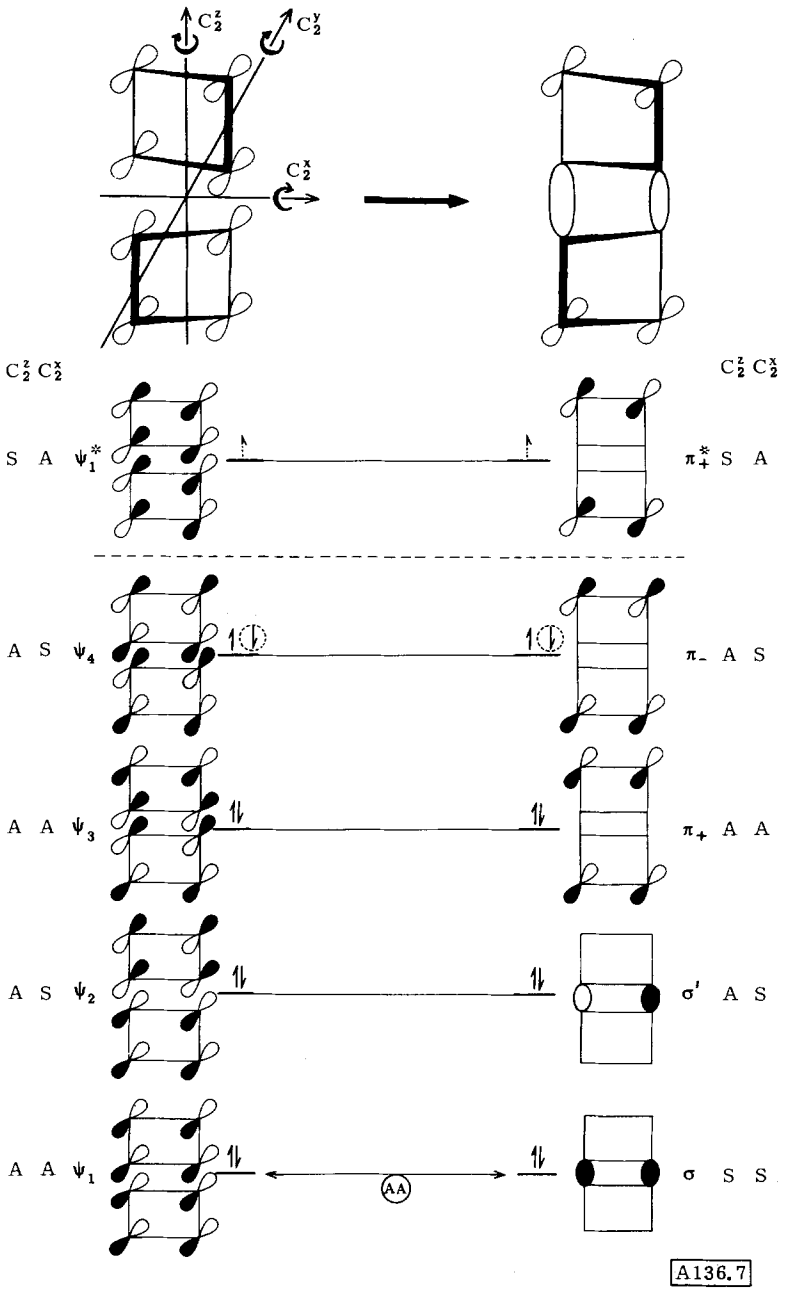

Fig. 7. Correspondence diagram for dimerization of cyclobutadiene (higher unoccupied orbitals not shown).

as many symmetry elements as the axial orientation, but it is inherently less symmetrical in that the upper molecule can use either of its two π-bonds for σ-bonding to the lower molecule, whereas the latter is constrained to bond *via* the two carbon atoms nearest to its partner. Such orientations can lead to erroneous conclusions and are avoided.

b) Rotational axes alone suffice to characterize orbitals and coordinates, mirror planes offering no particular advantages over them.

c) The analysis can be carried out in an assumed geometry which cannot possibly be that of a stable product. The axially symmetric dimer shown at the upper right of Figure 7 is too strained to be a real molecule, nor does it stand for one. What it does represent is a point along the reaction pathway at which the reactants have come close enough for σ bonding between them to begin, but beyond which increasing steric strain forces the system into either the *syn* or *anti*

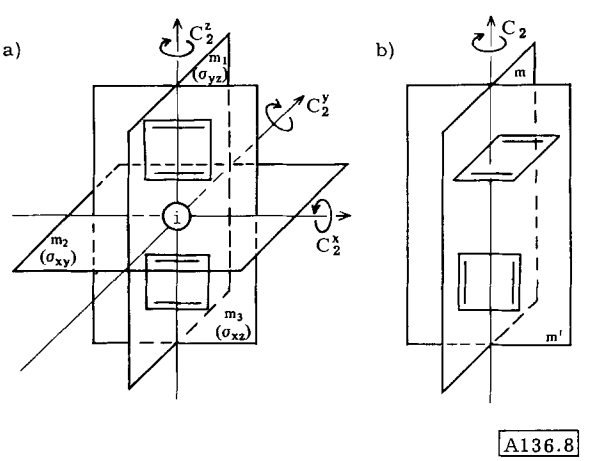

Fig. 8. Alternative initial orientations: a) Plane rectangular (acceptable); b) T-orientation (unacceptable—see text).

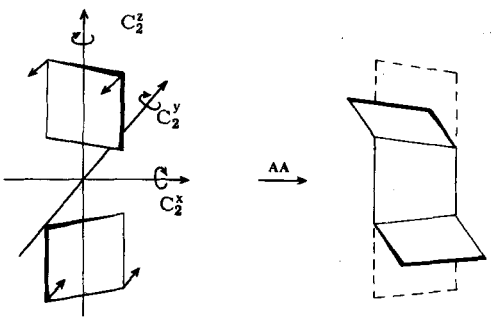
conformation. Which of the two stereoisomeric products will be preferred is ascertained with the aid of the correspondence diagram.

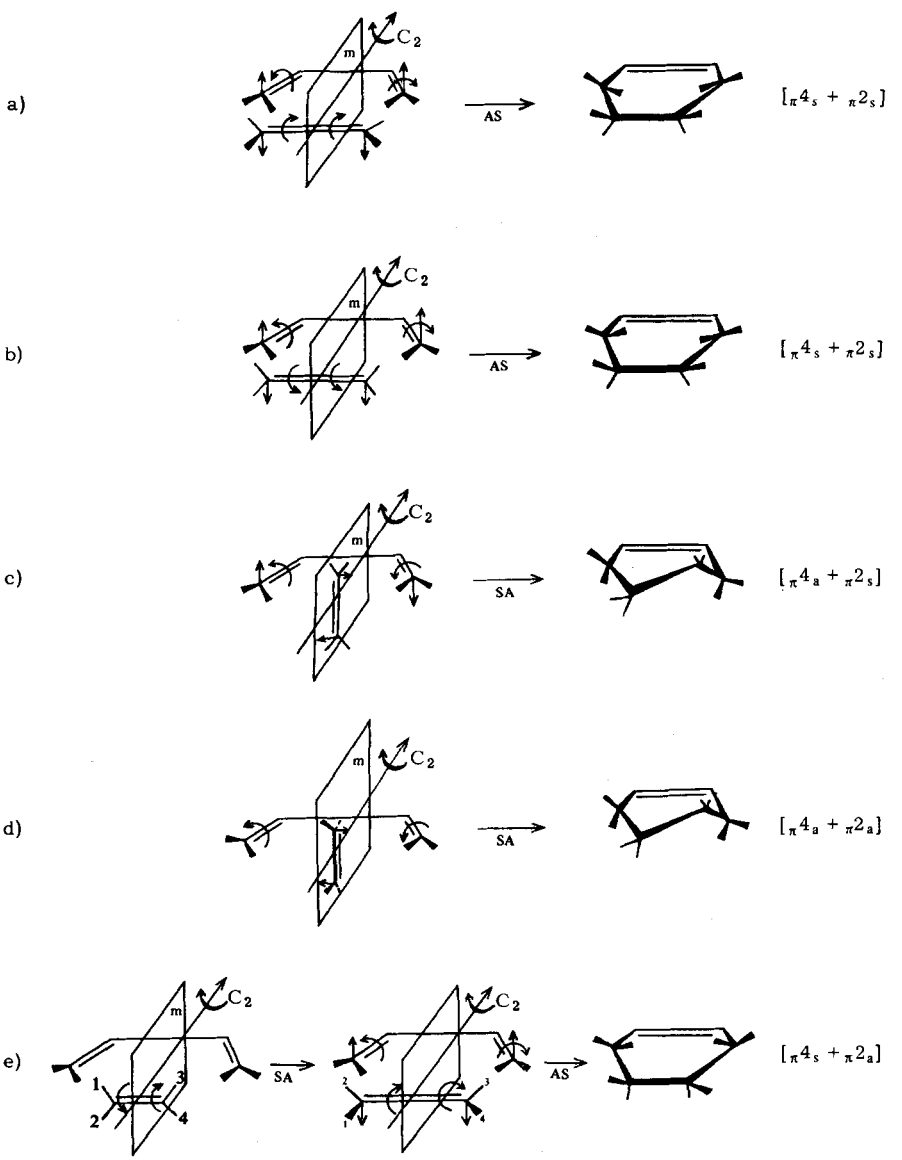
Like the products of fragmentation in Figure 6, the reactant molecules are brought close enough to interact. Provided that the twist of the two reactants about the z-axis is not too great, the ordering of the orbitals—which allows us to ignore all of the antibonding orbitals above the LUMO—is self-evident[31]. As in C_{2v}, two of the three diagnostic symmetry elements suffice to characterize the molecular orbitals fully. The choice of C_2^x and C_2^z, rather than of either one of them and C_2^y, is arbitrary.

The three uppermost pairs of doubly-occupied orbitals are in direct correspondence, so the ground-state reaction is allowed by motion along an AA coordinate (*i.e.* antisymmetric to C_2^x and C_2^z and thus necessarily symmetric to C_2^y), which induces the remaining correspondence $\psi_1(AA) \leftrightarrow \sigma(SS)$. The folding motion leading to the *syn*-dimer, shown in Scheme 3, evidently has the proper symmetry; the alternative folding motion towards the *anti* conformation is easily seen to have unsuitable AS symmetry. We might also note that the stereochemical requirements of the thermal and photochemical reactions are the same, and that photochemical fragmentation of the *syn*-dimer to cyclobutadiene would be expected to occur whereas that of the *anti*-dimer would not.

Scheme 3.



Woodward and *Hoffmann*[2] characterize the formation of either dimer as thermally allowed by virtue of the reaction



A136.9

Fig. 9. Possible pathways for $[\pi 4 + \pi 2]$ cycloaddition.

being a $[\pi 4_s + \pi 2_a]$ cycloaddition, but favor the *syn*-isomer on the basis of secondary orbital interactions. To OCAMS, the reaction cannot uniquely be characterized as $[\pi 4_s + \pi 2_s]$ any more than $[\pi 4_s + \pi 4_s]$ or $[\pi 2_s + \pi 2_s]$, and the preference for the observed *syn*-isomer emerges from it as unambiguously primary.

4. Symmetry, Geometry, and Energy: $[\pi 4 + \pi 2]$ Cycloaddition

Although the predictions of OCAMS with regard to the prototype Diels-Alder reaction, cycloaddition of ethylene to butadiene, do not differ essentially from those of WHLHA, this familiar reaction serves as a good vehicle for conveying several additional features of the method:

a) How the choice of an orientation of reactants and products in which to carry out the analysis affects the results of that analysis.

b) How the method can be applied to systems in which the product is inherently less symmetrical than the reactant, because it may be formed as one of several chemically identical isomers, differing only in the bonding sequence of indistinguishable atoms.

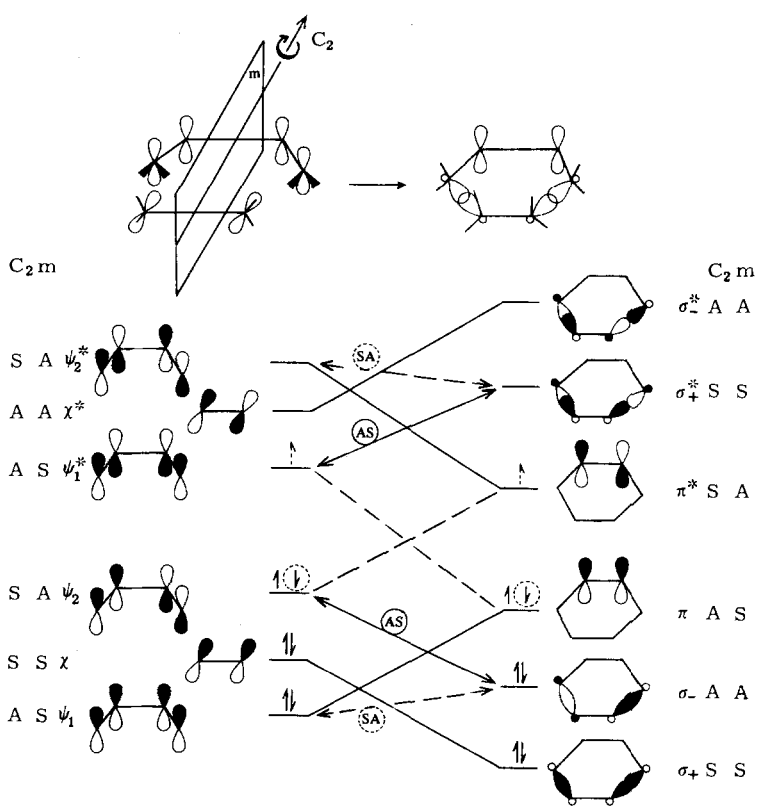
c) How a possible reaction path that is not a symmetry coordinate can be investigated.

d) How far symmetry alone can take us, and when considerations of energy—always implicit in orbital symmetry arguments—must be made explicit.

Woodward and *Hoffmann*[2] characterize ground-state cycloaddition as "allowed" when both reactants react suprafacially $[\pi 4_s + \pi 2_s]$ or antarafacially $[\pi 4_a + \pi 2_a]$ and the excited state reaction as allowed when either—but not both—of the reaction partners reacts antarafacially, *i.e.* $[\pi 4_s + \pi 2_a]$ or $[\pi 4_a + \pi 2_s]$.

The coplanar orientation of the reactants, shown in Figure 9a, emphasizes the analogy with a six-membered aromatic ring, and seems to be a good starting point for the allowed $[\pi 4_s + \pi 2_s]$ reaction, but it is certainly not the only one. For example, in Figure 9b, the ethylene molecule has been rotated about its axis so that each of its methylene groups is bisected by the plane containing the butadiene skeleton; this is an equally good initial orientation for $[\pi 4_s + \pi 2_s]$ cycloaddition proceeding along an AS coordinate. Beginning with the orientation in 9c, a geometry suitable for $[\pi 4_a + \pi 2_s]$ cycloaddition is obtained by motion along the SA coordinate pictured. The initial mutual disposition of reactants shown in 9d would seem to be an eminently suitable one from which to begin along the SA pathway leading to $[\pi 4_a + \pi 2_a]$ cycloaddition. The fourth mode of cycloaddition, $[\pi 4_s + \pi 2_a]$, does not suggest an initial geometry from which the reaction can proceed along a single symmetry coordinate. A suitable reaction coordinate can, however, be put together out of a sequence of two: Beginning from the same initial orientation as in 9b, 9e proceeds *via* a conrotatory twist of the ethylenic CH_2 groups by 90° and generates a coplanar orientation which differs from that of 9a only in that the H-atoms—say 1 and 3—that were initially *cis* to one other have become *trans*. When this is followed by the same AS coordinate as in 9a, *cis*-geometry is obtained once more, but the ethylene has reacted antarafacially.

Clearly, whereas some initial orientations appear to be particularly well suited to a single pathway, others can serve as good starting points for more than one, and some pathways—



A136.10

Fig. 10. Correspondence diagram for $[\pi 4 + \pi 2]$ cycloaddition (initial geometry of Fig. 9b).

notably that for $[\pi 4_s + \pi 2_a]$ cycloaddition—do not seem to have a good starting point at all. A good method of analyzing reaction pathways by symmetry should not be dependent on the way the problem has been set up. We will find that OCAMS is substantially independent of the geometrical model employed, but not entirely: A poor choice of an assumed initial orientation of reactants may obscure a possible pathway; it will not, however, let a "forbidden" pathway appear to be "allowed".

4.1. The Choice of an Initial Geometry

Rather than begin with the too-familiar orientation a of Figure 9 with its intimations of aromaticity, we base the correspondence diagram, Figure 10, on that of b. The "product" is also drawn as if it had C_{2v} geometry, although it will certainly be forced out of planarity and go into either a *cis*- or a *trans*-conformation. As in cyclobutadiene dimerization (Section 3.2), it represents a point along the reaction coordinate just before the way in which symmetry is to be broken has been chosen by the reacting system.

In the thermal reaction there are two direct correspondences: $\psi_1(AS) \leftrightarrow \pi(AS)$ and $\chi(SS) \leftrightarrow \sigma_+(SS)$, whereas the third $\psi_2(SA) \leftrightarrow \sigma_-(AA)$ is induced by an AS motion. A coordinate that is appropriately symmetric to m and antisymmetric to C_2 is that shown in Figure 9b, which is—except for the disrotation at the terminal carbons of the diene—merely a reorientation that costs no energy. The $[\pi 4_s + \pi 2_s]$ reaction is thus judged to be eminently allowed. The $[\pi 4_a + \pi 2_a]$ reaction, in contrast, does not emerge from the analysis at all.

Going on to the photochemical reaction, we see that the HOMO-LUMO cross-correspondence is direct and thus imposes no stereochemical requirements. Of the two-electron correspondences, $\chi(SS) \leftrightarrow \sigma_+(SS)$ remains, but now $\psi_1(AS)$ must be brought into correspondence with $\sigma_-(AA)$ by means of an SA displacement very similar to that in Figure 9c and also leading to $[\pi 4_a + \pi 2_s]$ cycloaddition. Now it is $[\pi 4_s + \pi 2_a]$ cycloaddition, which has the advantage of leading to a more stable *cis*-joined product that does not appear.

We try again, starting with the coplanar arrangement of Figure 9a and construct the new correspondence diagram shown in Figure 11. The two π-systems interact and, as a result, the "reactant's" π-orbitals now display marked similarity to those of a distorted benzene ring, but the orbital order is unchanged. The correspondences look different from those of Figure 10, but the conclusions are not; they are merely more complete. In the thermal reaction, there is only one direct correspondence: $\chi(AS) \leftrightarrow \pi(AS)$. The two remaining correspondences can be induced in one of two ways: 1) An AS coordinate, such as that of Figure 9a leading to $[\pi 4_s + \pi 2_s]$

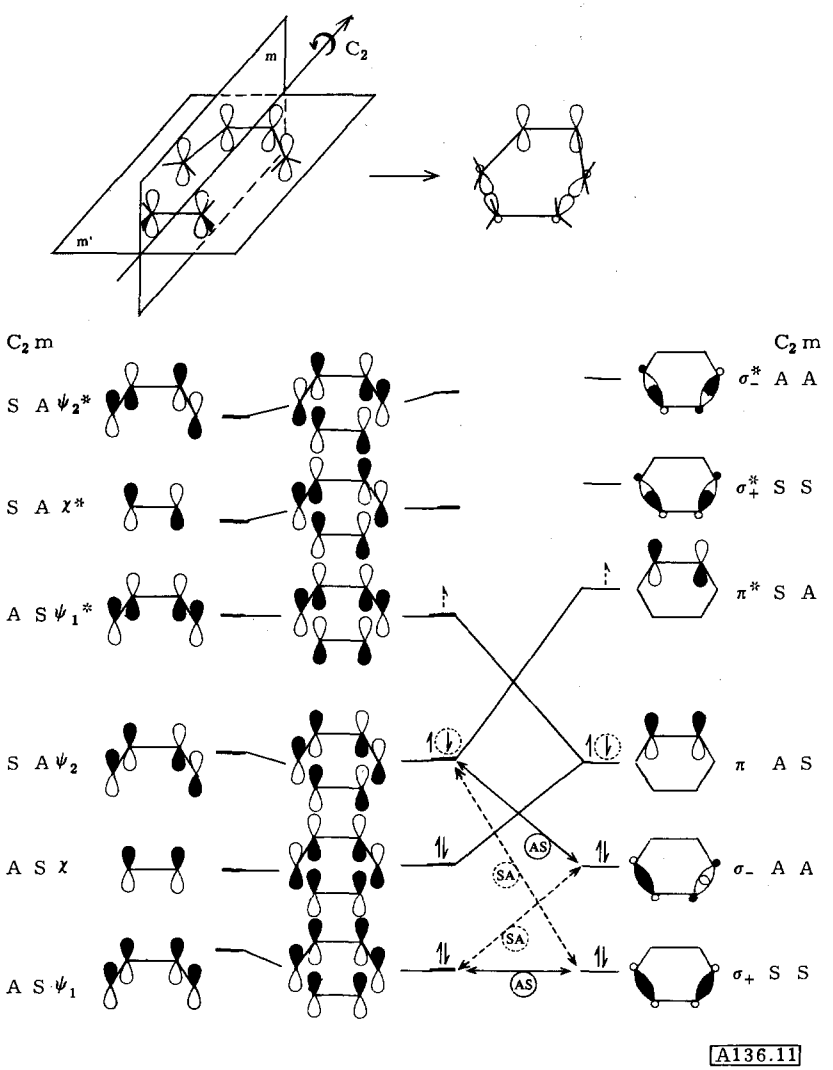


Fig. 11. Correspondence diagram for $[\pi 4 + \pi 2]$ cycloaddition (initial geometry of Fig. 9a).

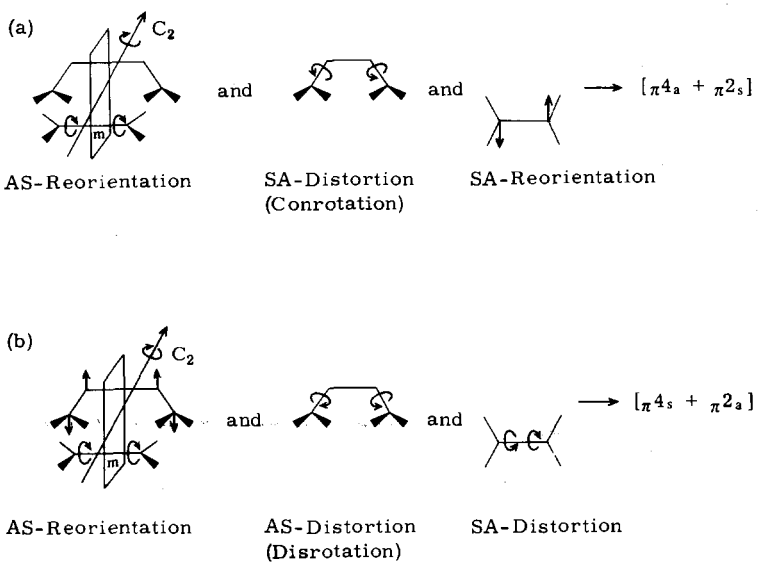
cycloaddition, induces $\psi_1(AS) \leftrightarrow \sigma_+(SS)$ and $\psi_2(SA) \leftrightarrow \sigma_-(AA)$; 2) Motion along an SA coordinate induces: $\psi_1(AS) \leftrightarrow \sigma_-(AA)$ and $\psi_2(SA) \leftrightarrow \sigma_+(SS)$. We now note that a rotation of the ethylene molecule about the C_2 axis, which is SA in character, generates the initial orientation of Figure 9d and thus leads to $[\pi 4_a + \pi 2_a]$ cycloaddition. The reorientation costs no energy; the conrotatory distortion in 9d is no more severe than that in 9c. Thus, apart from the inherent instability of the *trans*-joined product, $[\pi 4_a + \pi 2_a]$ cycloaddition is allowed.

Why then does this mode of reaction not emerge from Figure 10? It is not the "aromaticity" of the coplanar orientation assumed in Figure 11 that makes it a better choice; the π-interaction does not change the orbital sequence and so—for qualitative purposes—it is irrelevant. The advantage of the coplanar orientation is simply that it can be brought into a suitable geometry for either $[\pi 4_s + \pi 2_s]$ or $[\pi 4_a + \pi 2_a]$ cycloaddition by motion along a single symmetry coordinate, AS or SA respectively. The initial disposition of reactants in Figure 9b is ideal for $[\pi 4_s + \pi 2_s]$ but it is too remote from that required for $[\pi 4_a + \pi 2_a]$. In order to convert the initial geometry of Figure 9b to that of Figure 9d, motion must occur along two symmetry coordinates in which only the ethylene molecule is rotated: (1) About its longitudinal axis (AS) to the initial orientation of a; (2) about the C_2 axis (SA). Another possible sequence is: (1') about the C_2 axis to the orientation in c; (2') about its "new" longitudinal axis (AA). Neither of these reorientation sequences costs any energy, but both formally destroy the symmetry of the system completely before restoring it, so the prediction of Figure 11, that thermal $[\pi 4_a + \pi 2_a]$ cycloaddition is allowed, is not made by Figure 10.

Another paradox concerns the photochemical $[\pi 4_a + \pi 2_s]$ reaction, that does not appear in Figure 11, even though it is allowed by Figure 10. In both, the HOMO-LUMO correspondences are direct, but in Figure 11 the two lowest reactant orbitals are AS orbitals whereas in the product one is AA and the other is SS. As a result, a proper reaction coordinate for photochemical cycloaddition would involve motion along both an AS and a SA coordinate. When it is realized that the initial orientation of Figure 9a is converted by rotation of ethylene about its axis (AS) to that of Figure 9b, from which—as confirmed by Figure 10—a rotation about the C_2 axis (SA) leads to $[\pi 4_a + \pi 2_s]$ cycloaddition, the paradox is resolved.

We have seen some of the limitations of symmetry arguments when these are divorced from consideration of energy, particularly when either the reactant or product is a pair of molecules that can be arbitrarily oriented relative to one another. Characterizing motions in terms of their symmetry properties alone cannot distinguish reorientations, which cost no energy, from molecular distortions, which do. Thus the sequence just described, in which an AS reorientation followed by an SA reaction coordinate that includes a rather mild distortion, is equivalent—purely in terms of symmetry—to the composite motion of Figure 9e. It is obvious from the dissection of these two composite motions in Scheme 4 that they are energetically very different: It is the fact that two of the symmetry coordinates in (a) are reorientations whereas two of (b) are distortions—one quite severe—that makes photochemical $[\pi 4_a + \pi 2_s]$ cycloaddition different from the $[\pi 4_s + \pi 2_a]$ mode. Therefore, though the former leads to a less stable product, it can be regarded as genuinely "allowed", whereas the latter cannot[32].

Scheme 4.



4.2. Alternate Bonding Patterns

An important property of $[\pi 4_a + \pi 2_s]$ and $[\pi 4_a + \pi 2_a]$ cycloadditions, which they share with many other reactions, is illustrated in Figure 12. At the top left and right of the figure are the respective initial orientations of Figure 9c and 9d, which are interconvertible by means of a rotation of ethylene about its longitudinal axis (AA). The reactant pair has C_{2v} symmetry in both orientations and the molecular orbitals are characterized accordingly.

The product, as represented at the top center of Figure 12, is less symmetric, since it can be formed in either of two bonding sequences: [1ul4] or [1lu4], depending on whether the upper carbon atom of ethylene bonds to C_1 and the lower to C_4, or *vice versa*. As in previous examples, we can define the "product" to represent a point along the

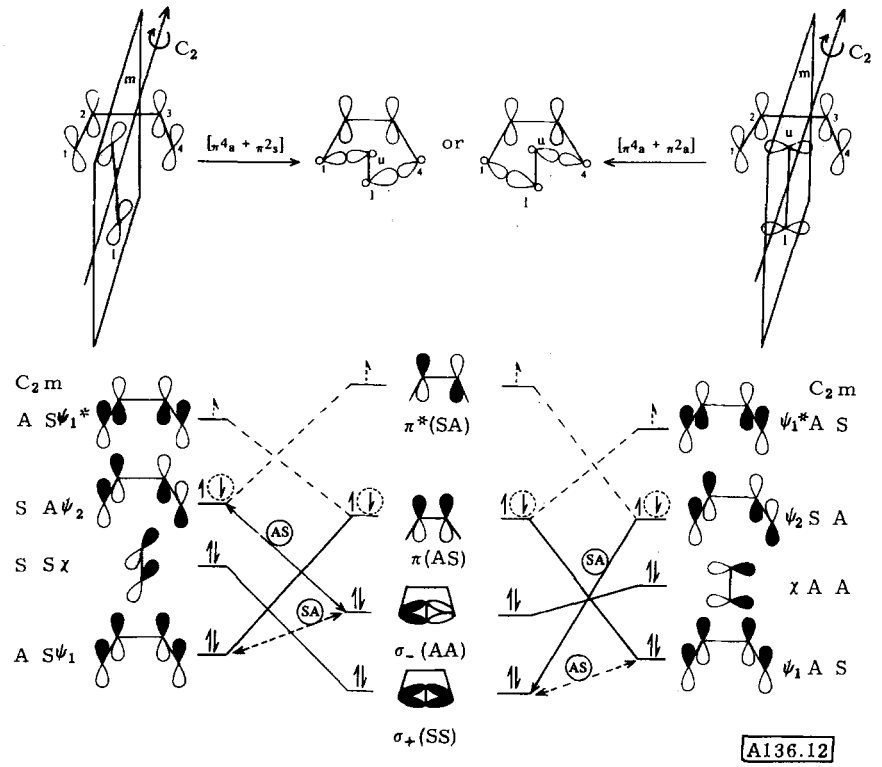


Fig. 12. Correspondence diagrams for $[\pi 4_a + \pi 2_s]$ and $[\pi 4_a + \pi 2_a]$ cycloaddition (higher unoccupied orbitals not shown).

reaction coordinate just before symmetry is reduced below that of the reactants. Now, however, the fact that two bonding schemes—not just two possible geometries—can be generated, must be reflected in the symmetry properties of the product's molecular orbitals.

The HOMO, π, and the LUMO, π^*, pose no problem; they are the same in both enantiomers. Neither do the two lowest orbitals of either product. In [1ul4], they are the symmetric and antisymmetric combinations of the 1—u and 4—l σ bonds; in [1lu4] they are the analogous linear combinations of 1—l and 4—u. In order to restore C_{2v} symmetry to the product, it is generalized to include both alternatives, so that the lowest orbital is represented by a suitable superposition of the two symmetric combinations and the second by a superposition of the antisymmetric ones. The question that arises is how to specify correctly the phase of each superposition. Specifically, should the lowest orbital be SS as in the figure, or should it be the *a priori* equally valid SA orbital, in which 4—l and 1—u are of opposite phase to 1—l and 4—u? The decision is dictated by the requirement that the generalized orbital be consistent with an equal probability of forming either enantiomer. Since C_1, for example, must be equally bonding with C_u and C_l a moment before the course of the reaction has been chosen, 1—u and 1—l must have the same phase. This condition suffices to fix $\sigma_+(SS)$ and $\sigma_-(AA)$ as the two σ-orbitals of the generalized product.

The correspondence lines are drawn in the usual way. Thermal $[\pi 4_a + \pi 2_s]$ cycloaddition formally requires that the $\psi_2(SA) \leftrightarrow \sigma_-(AA)$ correspondence be induced by an AS displacement, but geometry requires an SA motion, as is evident from Figure 9c. The latter does have the proper symmetry to induce the $\psi_1(AS) \leftrightarrow \sigma_-(AA)$ correspondence required for photochemical $[\pi 4_a + \pi 2_s]$ cycloaddition, which is therefore allowed. Conversely it is the thermal $[\pi 4_a + \pi 2_a]$ cycloaddition which is allowed under the geometrically appropriate SA displacement shown in Figure 9d, whereas the photochemical reaction calls for an unsuitable AS motion. Our previous conclusions have thus been reinforced. The correspondence diagrams in Figure 12 are different from those of Figures 10 and 11, but the conclusions from them are all mutually consistent and the additional bits of insight supplied by each of them complement one another.

5. Open Shell Reactions

The three topics taken up in this section are related by the fact that unpaired electrons enter into all of them:

1) Odd-electron systems lend themselves as easily to OCAMS as do those with an even number of electrons, though their photochemical reactions introduce a new ambiguity.

2) The distinction between the photochemical reactions of singlet and triplet excited states goes beyond any qualitative molecular orbital theory, which necessarily neglects electron correlation, but does call for some comment in the present context.

3) Several reactions in which the product has a different spin-multiplicity from that of the reactant have been reported, and will presumably become more common. An orbital method like OCAMS cannot deal with such reactions without modification, but a suggestion can be made as to the direction which a possibly fruitful extension of the present approach might take.

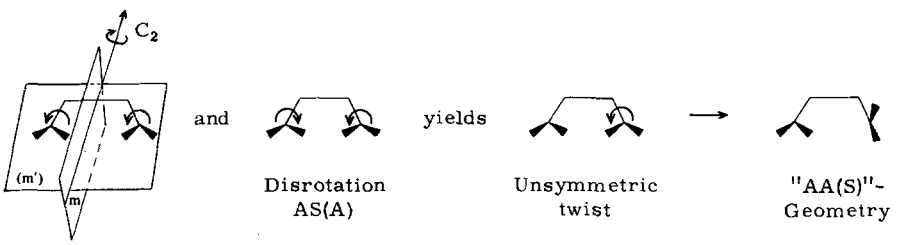
5.1. Odd Electron Reactions: Cyclization of Butadiene Anion

When an electron is added to *s-cis*-butadiene, it occupies the LUMO, ψ_2^*, of Figure 2, which becomes a correspondence diagram for the thermal cyclization of the radical anion, pro-

vided the five arrows are taken to represent five electrons, rather than four in two alternative configurations.

As in the thermal cyclization of the neutral diene, correspondence between ψ_1(AS) and π(AS) is direct, and the remaining two-electron correspondence, ψ_2(SA)$\leftrightarrow\sigma$(SS) calls for a conrotation. The one-electron correspondence $\psi\dagger$(AS)$\leftrightarrow\pi^*$(SA) requires an AA displacement, which can be seen in Figure 3 to describe neither a conrotation nor a disrotation, but an in-plane distortion. It is, however, shown in Scheme 5 that a 45° disrotation following a 45° conrotation generates a 90° twist of a single methylene group to a geometry that—if only momentarily—is symmetric to m' but not to C_2 or m. Scheme 5 expresses schematically the fact that—in a limited way—a superposition of an AS and an SA motion is the equivalent of an AA motion[33].

Scheme 5.



Consequently, our prediction from Figure 2 would be that the two-electron correspondences require thermal cyclization of the butadiene radical anion to be fundamentally conrotatory, but that, in order to induce the one-electron correspondence as well, some disrotation must be admixed into the conrotation, *i.e.* the two methylene groups would be expected to rotate at somewhat different rates[34].

Figure 2 can also be used to discuss the photochemical reaction. The identity of the first excited state of the product is irrelevant, since there is no apparent reason for the excited reactant not to correlate smoothly with the ground state of the product. In the excited state of the diene anion $\psi\ddagger$(SA), rather than $\psi\dagger$(AS), is singly occupied, and its correspondence to π^*(SA) is direct, so the conrotatory excited state reaction is allowed. The reverse photochemical reaction is also allowed under a conrotation, if we assume the excitation in the cyclobutene anion to be $\pi^*\rightarrow\sigma^*$, because the σ^*(AA)$\leftrightarrow\psi\dagger$(AS) correspondence, like that between σ(SS) and ψ_2(SA) requires a conrotation. If the lowest excited state were formed by a $\pi\rightarrow\pi^*$ excitation instead, the π^*(SA)$\leftrightarrow\psi_2$(SA) and π(AS)$\leftrightarrow\psi\dagger$(AS) correspondences would be direct, but that between σ(SS) and ψ_1(AS) would call for a disrotatory, AS-type, displacement. Thus, as will always be the case in photochemical reactions, a reliable prediction cannot be made unless the reactive excited state is known, though—as has been noted—a firm characterization of the lowest excited state of the product can be dispensed with when there is only one unpaired electron in the system.

5.2. Comments on Photochemical Reactions

The applicability of orbital symmetry arguments to photochemical reactions, a question which has generated extensive discussion[35], will only be touched upon briefly here.

In the preceding example it was noted that, in contrast to thermal reactions, where it is sufficient to know which orbitals are occupied and which are vacant, a reliable OCAMS treatment of a photochemical reaction requires—at the very least—identification of the HOMO and LUMO of the reactant. When the reactant has only one unpaired electron, this is also a sufficient condition, but in photochemical reactions of even-electron systems it is not. *Van der Lugt* and *Oosterhoff* early raised the question whether a reactant excited by a two-electron excitation to a state in which both were in the LUMO would not "funnel through" to the ground-state, in much the same way as has been postulated above for odd-electron systems, so rapidly that the first excited singlet ($HOMO^1$ $LUMO^1$) is bypassed entirely[36]. Even when the first excited singlet is formed, internal-conversion to a vibrationally excited ground-state molecule must be considered. The product will then be formed in its ground-state whenever, before the reactant is vibrationally deactivated, vibrational energy can find its way into a coordinate of proper symmetry—and geometry—to induce the necessary correspondence to the ground state of the product. Internal conversion is ordinarily such a facile process—except perhaps for very small molecules in the dilute gas phase—that is seems reasonable to doubt whether configuration correlation between the lowest excited singlet states of reactant and product can be a reliable qualitative criterion for the prediction of photochemical pathways.

It is with this reservation in mind that all of the correspondence diagrams in this report have been drawn so as to suggest that the photochemical reaction occurs between the lowest triplets of the reactant and product. These are sufficiently long-lived with respect to intersystem crossing to the reactant ground-state for an "allowed" open-shell reaction to be considered a generally accessible pathway connecting them. To be sure, a reaction in which the lowest triplet of the reactant crosses over smoothly to the ground-state singlet of the product can be envisaged. Such a process would be analogous to the thermal singlet-triplet reactions to be discussed briefly in the following subsection, and would similarly occur only in special circumstances. Ordinarily, the triplet state of the reactant would presumably either decay to its own singlet ground-state, in which case the reaction would not occur, or maintain its multiplicity until the triplet product has been produced, and can decay at leisure to its own ground-state.

5.3. Singlet-Triplet Reactions: Isomerization of Dewar-Benzene

Several reactions have recently been described in which a relatively unstable reactant in its singlet ground-state either

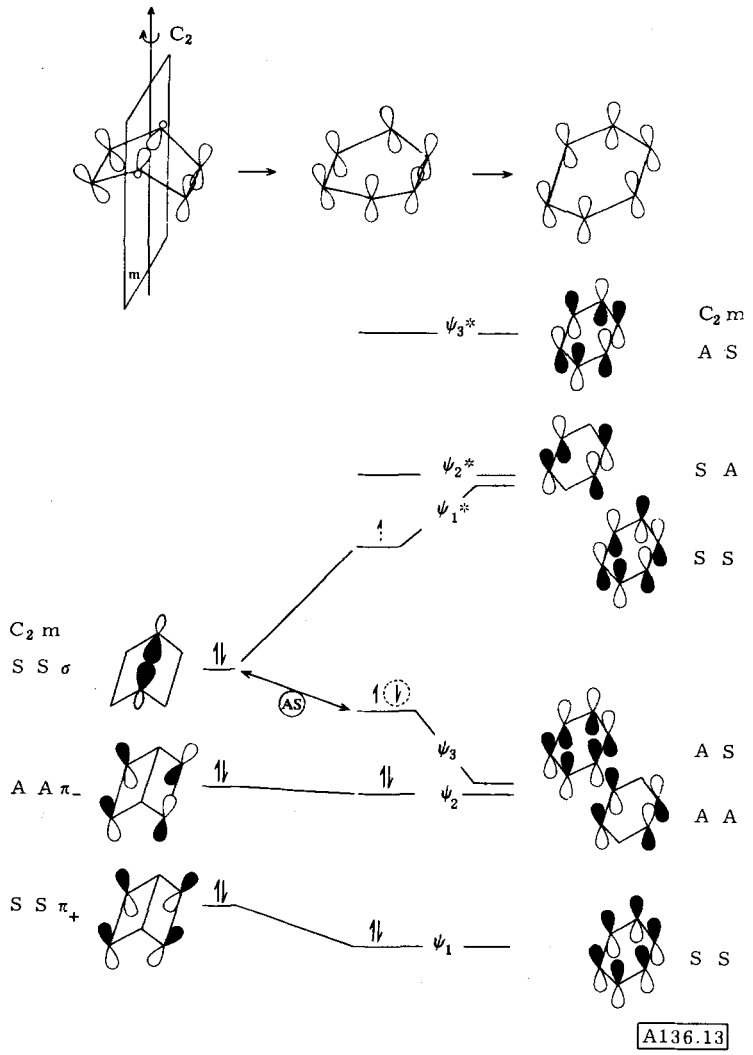


Fig. 13. Correspondence diagram for Dewar-benzene—benzene isomerization (higher unoccupied orbitals of reactant not shown).

decomposes to a singlet and a triplet fragment or isomerizes to the triplet of its more stable isomer[37].

The correspondence diagram for the interconversion of Dewar-benzene and benzene shown in Figure 13 includes only the three occupied orbitals of the reactant. The familiar six molecular orbitals of benzene, which include two degenerate pairs, are shown at the extreme right. The simplest way of bringing reactant and product to a common symmetry, in this example C_{2v}, is to work backwards and distort the product slightly in the direction of the reactant, *i.e.* to bend two *para*-disposed carbon atoms out of the molecular plane towards one another. As a result, the two degeneracies are split as shown, ψ_3(AS) going up in energy and ψ_1^*(SS) going down.

In the thermal reaction, the one correspondence that is not direct is σ(SS)$\leftrightarrow\psi_3$(AS), which requires distortion of the Dewar-benzene molecule along a coordinate that is antisymmetric with respect to C_2 but symmetric with respect to m. If one of the σ-bonded carbon atoms were pulled outward along an AS coordinate, such as that shown at the top of Figure 14, the other atom would move in the same direction and the long bond would not be ruptured. Such a motion is clearly inappropriate for generating ground-state benzene, so thermal isomerization is forbidden.

The total energy of Dewar-benzene is not only higher than that of ground-state benzene, but is above that of its lowest triplet as well. Its conversion to the latter can occur if two conditions are fulfilled simultaneously:

1) A mechanism is provided for uncoupling the antiparallel spins of an electron pair in one doubly-occupied orbital, prefer-

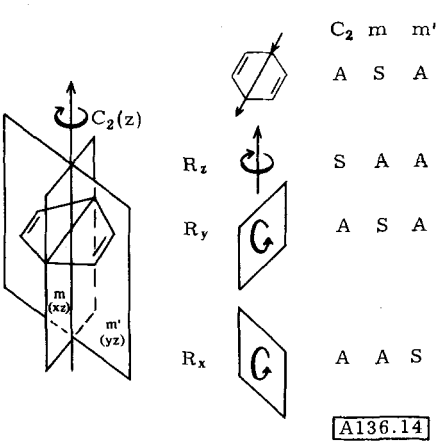

Fig. 14. Geometrically inappropriate AS-coordinate and the three rotational coordinates of Dewar-benzene.

entially that in σ(SS), which is not in direct correspondence with a doubly-occupied orbital of the product;

2) one of these electrons can then pass directly over to $\psi_3^\dagger$(SS), but an AS perturbation must still be found that will allow the other electron to pass from σ(SS) to ψ_3(AS).

A mechanism with the correct properties to fulfil both requirements at once is spin-orbit coupling. The three components of spin of a triplet have the symmetry properties of rotations about three perpendicular axes. In Figure 14 we see that rotation in the *xz*-plane, that including m, is of the proper symmetry to induce a correspondence between an SS and AS orbital. It must be stressed that we are not speaking of a molecular rotation, which—though it has the proper symmetry—does not affect the potential energy of the reacting system and is therefore ineffective. The perturbation is spin-orbit coupling which, as it uncouples the opposing spins of a pair of electrons, produces a net spin about just the right axis—*y* in our example—to generate the lowest triplet of benzene.

Although a spin-orbit coupling mechanism of this type has been shown to be theoretically sound, and to be of reasonable magnitude in at least one case[38], there is as yet neither experimental nor theoretical evidence that it is in fact operative. Moreover, since it represents at best a future modification designed to broaden the scope of OCAMS beyond its present limits, it provides an appropriate point at which to conclude this report.

[21] If the molecule lies in the *xz*-plane, with its C_2 axis along *z*, then: $SS = A_1$; $SA = A_2$; $AA = B_1$; $AS = B_2$. Each of these denotes a different one of the four irreducible representations of C_{2v}, so the symmetry of each orbital has been fully characterized.
[22] We distinguish between correlation and correspondence by denoting the former by ⇔ and the latter by ↔.
[23] OCAMS avoids degenerate coordinates, to which these criteria do not apply, just as it avoids degenerate orbitals. See Sections 3.1, 3.2, and 5.3 for examples.
[24] See also: *W. G. Dauben*, *L. Salem*, and *N. J. Turro*, Acc. Chem. Res. *8*, 41 (1975). These authors point out that the "plane containing the pertinent reaction centers" is, for many photochemical reactions, "the discriminating symmetry element".

[26] *W. J. Hehre* and *J. A. Pople*, J. Am. Chem. Soc. *97*, 6941 (1975), and references therein.
[27] An OCAMS analysis and a Hückel-Hubbard state-correlation study both show that the two equivalent plane-rectangular isomers could rapidly be interconverted *via* a rhomboid transition state. (*E. A. Halevi*, *F. A. Matsen*, and *T. L. Welsher*, to be published).
[28] *R. J. Buenker* and *S. D. Peyerimhoff*, J. Chem. Phys. *48*, 354 (1968), calculated cyclobutadiene to be less stable than two acetylene molecules, but the difference is not large. One might therefore argue that, since this finding is inconclusive, thermal fragmentation, though "allowed" by symmetry, may be prevented by its endothermicity. Whatever the energetics, the symmetry analysis so far has been too superficial to permit characterization of either the thermal or the photochemical reaction as allowed.
[29] A plane-rectangular system has the eight symmetry elements of D_{2h}, but m_1, m_2, and m_3 can easily be shown to exhaust its eight irreducible representations, just as C_2 and m suffice to span the four of C_{2v} (see ref. [21]).
[30] *J. M. Stone* and *I. M. Mills*, Mol. Phys. *18*, 631 (1970).
[31] If the two rings are twisted until their planes are perpendicular, ψ_1 and ψ_2 become indistinguishable, as do ψ_3 and ψ_4. Likewise, the bonding pattern of the product becomes indeterminate. A slight twist back towards coplanarity removes all these ambiguities.
[32] A "photochemical Diels-Alder reaction" which is formally $[\pi 4_s + \pi 2_a]$ does seem to occur in the cyclization of hexatriene. In this case, however, the reaction is allowed by OCAMS because the "diene" and "dienophile" are part of the same conjugated polyene. This reaction, and also contravention of the Woodward-Hoffmann rule concerning thermal $[\pi 2_s + \pi 2_a]$ cycloaddition, are discussed at length in ref. [3].
[33] As explained in ref. [4], the composite coordinate (AS *and* SA) is equivalent *in second order* to an AA symmetry coordinate. Formally, the reducible representation $[A_2 + B_2]$ introduces second order terms of the irreducible representation: $A_2 \times B_2 = B_1$ into the potential energy.
[34] *M. J. S. Dewar* and *S. Kirschner*, J. Am. Chem. Soc. *96*, 6809 (1974) have shown that the "forbiddenness" of the disrotatory thermal cyclobutene-butadiene interconversion, is greatly relieved when the rotation at the two ends of the bond being ruptured is not constrained to be synchronous.

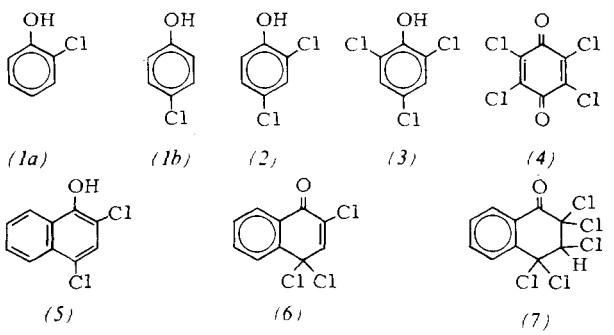
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Nonpollutative Chlorination and Chlorinating Oxidation of Phenols[**]

By *Hans Lübbecke* and *Peter Boldt*[*]

On production of chloranil *(4)* from phenol and chlorine, hydrochloric acid is formed as a polluting by-product[1].—We have now found that *(4)* can be obtained in 94 and 88% yield respectively without by-products (except water) by treatment of phenol or hydroquinone with hydrogen peroxide/hydrochloric acid. Starting from phenol it is convenient, as in the present-day industrial process[1], to isolate *(3)* as an intermediate. Production of *(3)*, the mixture of *(1a)* and *(1b)* (*ca.* 1:1), of *(2)*, and of *(4)* (from hydroquinone) can be performed with a slight excess of hydrogen peroxide. The same applies to the reaction of α-naphthol to give *(5)*, *(6)*, and *(7)*. [*(6)* and *(7)* are intermediates for the preparation of 2-chloro- and 2,3-dichloro-1,4-naphthoquinone[2].] *(3)*, *(4)*, and *(7)* are obtained directly in pure form (conditions given in Table 1).



(1a) *(1b)* *(2)* *(3)* *(4)*

(5) *(6)* *(7)*

As illustrated by the preparation of *(3)* and *(4)* the yields can be raised or the amount of hydrogen peroxide reduced by addition of magnesium chloride.

Use of hydrogen peroxide/hydrochloric acid instead of chlorine gas also offers the advantages of easier handling and measuring when working on a laboratory scale[3].

2,4,6-Trichlorophenol (3)

30% hydrogen peroxide (40 ml, 0.4 mol) is added within 15 min to a stirred, ice-cooled mixture of phenol (9.4 g, 0.1 mol), magnesium chloride (10 g, 0.11 mol), and conc. hydrochloric acid (150 ml). Warming to 50°C for 4 h, followed by filtration and drying yielded 19.4 g (99%) of *(3)*.

Cloranil (4) from (3)

30% hydrogen peroxide (15 ml) is added dropwise within 15 min to a mixture of *(3)* (3.5 g, 18 mmol) and magnesium chloride (26 g, 0.27 mol), the temperature is then raised to 100°C and a further amount of hydrogen peroxide (25 ml, total amount 0.4 mol) added in three portions—at intervals of 6 h—and stirring continued for 32 h at 100°C. After washing with methanol and drying the filter cake yielded 4.2 g (96%) of *(4)*.—The other products were prepared in the same way as *(3)*.

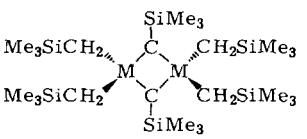
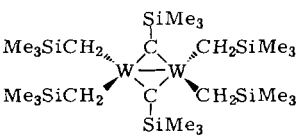
Tetrakis(trimethylsilylmethyl)bis(μ-trimethylsilylmethylidyne)ditungsten[**]

By *Richard A. Andersen, A. Lee Galyer,* and *Geoffrey Wilkinson*[*]

The first examples of bridged carbyne complexes were the compounds $(RCH_2)_2M(\mu\text{-}CR)_2M(CH_2R)_2$, M = Nb, Ta; R = $SiMe_3$, which were obtained by the interaction of MCl_5 with Me_3SiCH_2MgCl in diethyl ether/petroleum mixture[1]. Confirmation of the structure (1) proposed on the basis of NMR spectra was provided by X-ray crystallography of the niobium complex[2]. The four-membered M_2C_2 ring can be regarded as quasi-aromatic and no metal-metal bonding need be involved.



(1)



(2)

We have now synthesized a new example of this type of alkyl derivative by the interaction of tungsten(IV) chloride and $(Me_3SiCH_2)_2Mg$ in tetrahydrofuran[3]. The ^{1}H-NMR spectrum of the red-brown polycrystalline complex $(RCH_2)_2W(\mu\text{-}CR)_2W(CH_2R)_2$, R = $SiMe_3$, has resonances at τ = 9.72, 9.87, and 9.45 in area ratios 18:4:9 due to $(CH_3)_3SiCH_2W$, $(CH_3)_3SiCH_2W$, and $(CH_3)_3SiCW$ respectively. The structure *(2)* is further defined by the ^{13}C-NMR spectrum (Table 1), particularly by the strongly deshielded bridging carbyne carbon atom. The ^{13}C-NMR spectra of the niobium and tantalum analogs and also of the metal-metal bonded species[4] $(RCH_2)_3M{\equiv}M(CH_2R)_3$, M = Mo and W; R = $SiMe_3$, are also given for comparison. The diamagnetism of the tungsten compound where the metal atom is formally pentavalent as in the Nb and Ta complexes requires the presence of a W—W single bond in addition to the bridge groups.

Table 1. ^{13}C-NMR data of alkylmetal compounds [a].

	$(CH_3)_3SiCH_2$	$(CH_3)_3SiCH_2$	$(CH_3)_3SiC$
$(Me_3SiCH_2)_4W_2(CSiMe_3)_2$ [b]	2.20, 3.00	69.0	354
$(Me_3SiCH_2)_4Nb_2(CSiMe_3)_2$	3.41, 3.98	64.2	406
$(Me_3SiCH_2)_4Ta_2(CSiMe_3)_2$	3.63, 4.97	79.3	406
$(Me_3SiCH_2)_6Mo_2$	4.60	65.0	
$(Me_3SiCH_2)_6W_2$ [c]	4.70	79.6	

[a] Varian XL-100 spectrometer, 25.14 MHz, in C_6D_6, δ values (in ppm, $\delta_{C_6D_6}$ = 129 ppm).
[b] $J(^{183}W\text{-}^{13}C)$ = 74 Hz.
[c] $J(^{183}W\text{-}^{13}C)$ = 79 Hz.

The presence of alkyl and alkylidyne groups in the same molecule is supported by deuterolysis. The tungsten complex is not hydrolyzed by D_2O neat or in decalin solution but with 6 M D_2SO_4 it gives Me_4Si (76% D_1, 8.8% D_2, and 14% D_3; determined by mass spectrometry). The tantalum complex with D_2O gives Me_4Si (74% D_1, 8.8% D_2, and 16.2% D_3). The niobium complex is inert to water but it was previously shown[1] to react with chlorine to give Me_3SiCH_2Cl and Me_3SiCl.

The carbyne compound could not be isolated from the interaction of WCl_6, WCl_5, or WCl_4 with $(Me_3SiCH_2)_2Mg$ in petroleum and only $(Me_3SiCH_2)_6W_2$ was obtained. By contrast, in tetrahydrofuran, WCl_6 and $(Me_3SiCH_2)_2Mg$ afford a red oil whose ^{1}H-NMR spectrum contains resonances attributable to both $(Me_3SiCH_2)_6W_2$ and the carbyne complex; however, chromatography in petroleum on neutral alumina yielded only the former.

It appears that ether solvents are of major importance in the deprotonation of the Me_3SiCH_2 group, possibly through increased basicity. Deprotonation of methylene groups has also been noted for tetrabenzyltitanium with tribenzylaluminum[5] and of a neopentyltantalum by neopentyllithium[6].

Experimental:

Bis(trimethylsilylmethyl)magnesium (10.3 ml of a 1.25 M diethyl ether solution, 13 mmol) was added to a suspension of WCl_4[7] (2.20 g, 0.0064 mol) in tetrahydrofuran (50 ml). After stirring 12 h all the WCl_4 appeared to dissolve. The volatile material was evaporated to dryness and heated (70—100 °C) in vacuum for 24 h. Extraction of the solid with petroleum (40—60 °C) yielded a brown-red solution which was filtered, concentrated to *ca.* 1 ml, and cooled (−70 °C). The brown-red polycrystalline, glass-like solid was collected and dried in vacuum: yield 0.5 g of $C_{24}H_{62}Si_6W_2$. The compound sublimes at 140—150 °C/10^{-3} torr.

A CH-Carbene Complex of Iron by Metal-Induced Fragmentation of Two Bonds of a Bicyclopentane Unit[1]

By *Rudolf Aumann, Horst Wörmann,* and *Carl Krüger*[*]

The decomposition of intermediary metallacyclobutanes *(1)* to carbene complexes and olefins has been discussed as the decisive step of olefin metathesis[2].

A variant of this reaction sequence based on the model reaction *(4)* → *(5)* → *(7)* has been verified by isolation of organometallic intermediates. The carbon atoms corresponding to C_a, C_b, and C_c are indicated as dots in the formulas.

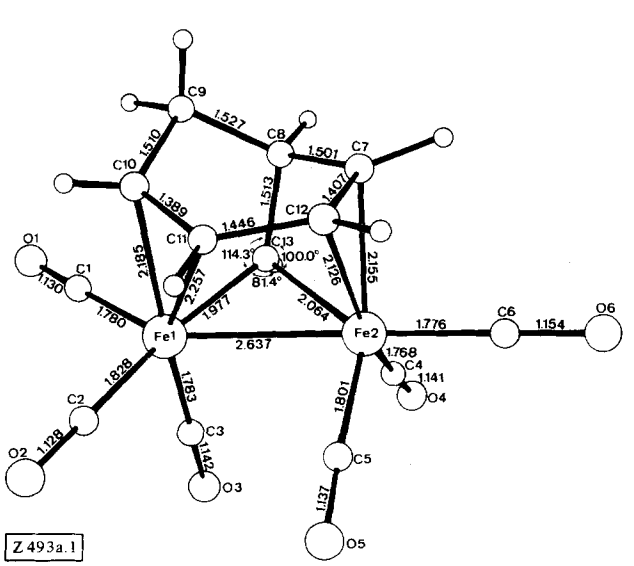
Low-temperature photolysis of $Fe(CO)_5$ in the presence of tricyclo[3.2.0.0^{2,7}]hept-3-ene *(2)*[3] affords the tetracarbonyl complex *(3)* as a yellow, thermolabile oil. On prolonged photolysis, *(3)* decomposes smoothly with loss of carbon monoxide and subsequent opening of bond a of the bicyclopentane unit to the π-allyl σ-complex *(4)*, whose acyl derivative can be isolated in crystalline form (21 %, m.p. 60 °C). (In the acyl derivative a carbonyl group is inserted in the Fe—C bond.) We have been able to show that the ketone complex *(6)* (*ca.* 95 %, m.p. 87.5 °C) is formed from *(4)* in the presence of free carbon monoxide at 20 °C. If, however, *(4)* or its acyl derivative is allowed to react with cyclohexene-$Fe(CO)_4$[4] at −20 °C, the dinuclear carbene complex *(7)* is obtained as main product (22 %, m.p. 98 °C) along with small amounts of *(6)*.

The ketone complex *(6)* is formed from a ketene precursor, which can be trapped as the methyl ester with methanol[5]. From the stereochemistry of the trapped product we believe that intermediary occurrence of the mononuclear carbene complex *(5)* can be concluded. *(5)* is a plausible precursor of the carbene complex *(7)* in which the carbene carbon is stabilized by two $Fe(CO)_3$ groups.

Stepwise transformation of the hydrocarbon *(2)* into the carbene complex *(7)* with cleavage of adjacent bonds[6] a and b of the bicyclopentane unit afforded evidence for the fragmentation of a metallacycle into a carbene and an olefin component, as has been postulated in the case of olefin metathesis. The structures of the complexes *(3)*, *(4)*, *(6)*, and *(7)* were determined on the basis of IR, ^{1}H-NMR, and ^{13}C-NMR measurements. In addition, a crystal structure analysis was carried out on the complex *(7)* (Fig. 1). The synthesis of *(7)* is the first example of the preparation of a hydrocarbon-carbene complex[6, 7] by metal-induced fragmentation of a strained hydrocarbon.

The bond length (2.63 Å) typical for carbene-bridged Fe—Fe bonds[9] is not further increased by the novel bridging of two iron atoms by a π-bonded, almost planar 1,3-diene unit (C10=C11—C12=C7) and also by the carbene carbon (C13). The Fe—$C_{carbene}$ distances are unequal [1.977(3), 2.064(3) Å] but both lie within the expected range[10]. $C_{carbene}$ occupies an apical position to the trigonal pyramidal Fe2 atom, and also a position in the trigonal plane of the similar type Fe1 atom. The same applies for the π-bonded part of the molecule. Hence different bonding (Fe—C10—C11 and Fe2—C7—C12) occurs in the π-bonded 1,3-diene system. The different Fe—$C_{carbene}$ distances are also understandable. Finally, they make a twisted arrangement of the two $Fe(CO)_3$ groups possible.



Z 493a.1

Fig. 1. Crystal structure of the dinuclear carbene complex *(7)*. $a = 19.273(3)$, $b = 13.858(1)$, $c = 10.2347(7)$ Å, space group Pbca, $Z = 8$, MoK_α radiation, 2940 reflections, of which 793 unobserved, $R = 0.0295$ ($R_w = 0.035$) [8].

Oxidative Addition of the Central Bond of a Bicyclopentane System to Iron[1]

By *Rudolf Aumann* and *Heinz Averbeck*[*]

An *exo* attack of the metal on the bridge of the bicyclic system[4] is postulated as the primary step in transition-metal catalyzed isomerizations[2] or cycloadditions of bicyclo[2.1.0]-pentanes to olefins[3]. We have now succeeded in isolating stable iron complexes arising from such an attack.

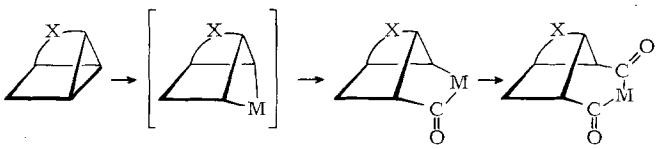
The light-induced reaction of hydrocarbons *(1a)* and *(1b)* with pentacarbonyliron (20°C, ether, Hg high-pressure lamp, 20 and 3h, respectively) yields the colorless tetracarbonylferrapolycyclics *(3a)* (37%, m.p. 115°C, IR ν(M)—C≡O: 2099, 2040, 2026, 2016 cm^{-1}, νC=O 1673 cm^{-1}) and *(3b)* (85% m.p. 96°C, IR ν(M)—C≡O: 2097, 2037, 2020, 2012 cm^{-1}, νC=O 1673 cm^{-1}), which further react with carbon monoxide smoothly to the bis(acyl) compounds *(4a)* (*ca.* 95%, slow decomposition above 100°C, IR ν(M)—C≡O: 2108, 2052, 2050, 2016 cm^{-1}, νC=O 1634 cm^{-1}) and *(4b)* (*ca.* 95%, slow decomposition above 85°C, IR ν(M)—C≡O: 2106, 2050, 2047, 2013 cm^{-1}, νC=O 1633 cm^{-1}).



(1) *(2)* *(3)* *(4)*

M = $Fe(CO)_4$; *a* X = ; *b* X =

The methanotetrahydronaphthalene moiety of *(3a)* could be identified on the basis of experimentally determined proton coupling constants refined by computer simulation (Fig. 1). In accord with the proposed structure, on addition of $Eu(fod)_3$ to a C_6H_6 solution of the compound the resonance signals at $\delta_{TMS}=2.35$, 1.90, 3.23 ppm are the most strongly shifted to low field.

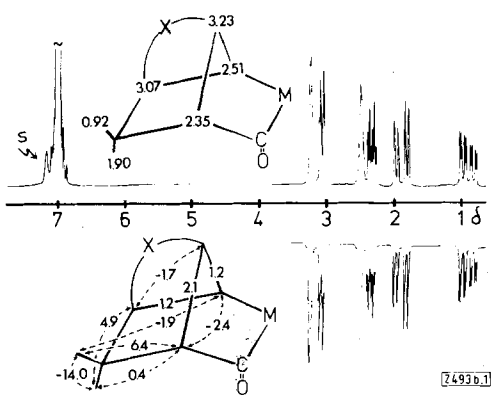


Fig. 1. ^{1}H-NMR spectrum of *(3a)* (C_6D_6, 90 MHz). Above: experimental, below: computer-simulated spectrum using the quoted parameters (δ values, coupling constants in Hz). S = solvent.

According to ^{1}H-NMR measurements compounds *(3b)*, *(4a)*, and *(4b)* contain the same structural elements as *(3a)*.

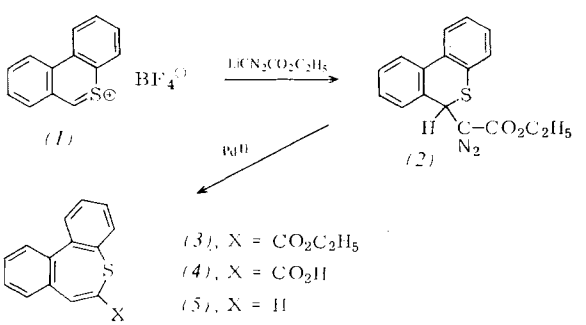
New Synthetic Entry to the Thiepin System.—Benzo[*d*]thiepin and Dibenzo[*bd*]thiepin

By *Kazuhiro Nakasuji, Koichi Kawamura, Toshio Ishihara*, and *Ichiro Murata*[*]

Because of the ease of sulfur extrusion, extremely mild conditions have to be employed for synthesis of the thiepin system. We have previously found it possible to prepare benzo[*b*]thiepin[1] by Rh^I-catalyzed isomerization of 6-thiatetracyclo[5.4.0.$0^{2,4}$.$0^{3,5}$]undeca-1(7),8,10-triene[2], a valence isomer of benzo[*b*]thiepin, under mild condition. We now describe the synthesis of benzo[*d*]- and dibenzo[*bd*]thiepin systems.

The readily accessible dibenzothiopyrylium tetrafluoroborate *(1)*[3] reacts with ethyl lithiodiazoacetate[4] in a 1:1 mixture of diethyl ether and tetrahydrofuran at −120°C to form diazo compound *(2)* [yellow oil, 32% yield]. Treatment of *(2)* with π-allylpalladium chloride dimer (5 mole %) in a 1:2 mixture of chloroform and carbon tetrachloride at 0°C and allowing to warm to room temperature for 2h affords the desired 6-ethoxycarbonyldibenzo[*bd*]thiepin *(3)*[5] quantitatively as a pale yellow oil. The spectra of *(3)* was fully consistent with the thiepin structure. Despite the presence of the thiepin skeleton, *(3)* is a stable compound and fails to transform into 9-ethoxycarbonylphenanthrene even at elevated temperature in the presence of triphenylphosphane. Alkaline hydrolysis of *(3)* gives the free acid *(4)* [pale yellow plates, m.p. 220°C (dec.), 93% yield]. Decarboxylation of *(4)* with copper in quinoline at 150°C for 30 min leads to the parent dibenzo[*bd*]thiepin *(5)* (colorless plates, m.p. 82 to 83°C) which on thermolysis in refluxing xylene in the presence of triphenylphosphane for 1 day furnishes phenanthrene.



The synthetic utility of the ring enlargement reaction was illustrated by its application to the diazo compound *(7)* [yellow oil, 53% yield] which was prepared from benzothiopyrylium tetrafluoroborate *(6)*[6]. When *(7)* was subjected to reaction with π-allylpalladium chloride dimer under the same condition as in the case of *(2)*, the product isolated was

ethyl β-naphthoate. However, treatment of *(7)* with the Pd-catalyst at −10 °C for 2 h followed by low temperature column chromatography on silica gel (deactivated with 6% water) at −40 °C with a 1:10 mixture of diethyl ether and light petroleum provides pure *(8)*. The structure assignment for *(8)* was based on its ^{1}H-NMR data. Thermal transformation of *(8)* into naphthalene and sulfur was monitored by ^{1}H-NMR and the half-life of *(8)* was found to be 54 min at 24 °C.

Table 1. Spectral data of compounds *(2)*, *(3)*, *(5)*, *(7)* and *(8)*.

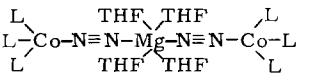
A Novel Hetero-Bimetallic Dinitrogen Complex[**]

By *Reinhard Hammer, Hans-Friedrich Klein, Ulrich Schubert, Albin Frank*, and *Gottfried Huttner*[*]

Phosphane complexes of cobalt in low oxidation states show a tendency to take up molecular nitrogen[1]. It therefore appeared somewhat surprising that the compounds L_4CoH[2] and L_4Co[3,4] [L = $(CH_3)_3P$] failed to show such a tendency.

We have now found that the generally smooth reduction of $CoCl_2/(CH_3)_3P$ in tetrahydrofuran by magnesium turnings[4] under N_2 as protective gas, which yields L_4Co, can be induced to undergo an unusual further step under modified conditions: with a fivefold excess of magnesium and longer reaction times (3 d, 20 °C) the dark brown solution reproducibly lightens to orange yellow. Extraction of the residue with pentane/THF (50:1) furnishes good yields (70%) of an orange diamagnetic compound *(1)* [dec. > 82 °C, ν(N≡N): 2068 cm^{-1} in hexane, 2058 cm^{-1} in THF] whose crystals effloresce in a vacuum and in a current of N_2.



(1), L = $(CH_3)_3P$

In the absence of a clean magnesium surface L_4Co fails to take up molecular nitrogen; tetrahydrofuran cannot be replaced by other O donors (ether, dioxane, glycol dimethyl ether). Moreover, solutions of $NaCoL_4$ or $KCoL_4$ in these ethers do not take up any nitrogen, while lithium metal, which like magnesium reacts with N_2 at room temperature, does permit incorporation of N_2 on reduction of L_4Co. The activation of the molecular nitrogen by reactive metal surfaces must therefore be of crucial importance.

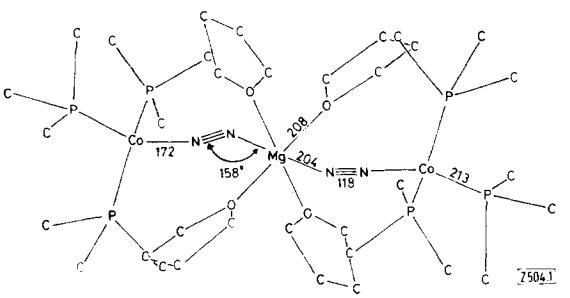


Fig. 1. Crystal structure of *(1)*[5]. Bond lengths in pm.

The structure of compound *(1)* was determined by X-ray methods (Fig. 1). *(1)* contains a center of symmetry. An octahedrally coordinated magnesium atom in the center of the complex bears four equatorial tetrahydrofuran ligands. The axial positions of the coordination octahedron are occupied by N_2 groups which are each simultaneously bound as bridging ligands to a $(Me_3P)_3Co$ unit. The Mg—N—N—Co grouping is bent at the nitrogen bonded to the magnesium (158°). Like the relatively long N—N distance (118 pm), this indicates a significant change in the bonding on going from free to complexed N_2. The other bond lengths and angles correspond to the usual values[6].

The composition of *(1)* shows some resemblance to a class of new alkali metal dinitrogen complexes discovered by *K. Jonas*[7]; however, *(1)* contains end-on N_2 bridges between a transition metal and an electropositive main group element.

In solvents of low polarity (pentane, benzene, toluene) *(1)* decomposes with deposition of metal and evolution of nitrogen to form L_4Co. A freshly prepared solution (0.1% in toluene, frozen to a glass at 77 K) already displays the EPR spectrum of L_4Co[3]. However, dilute THF solutions are also paramagnetic: their EPR signal (77 K) consists of a broad Lorentzian line (g = 2.059, half-width 160 G) with four of eight hyperfine lines (^{57}Co, I = 7/2, A^{Co} = 90 G) being recognizable on the high field side. We assign this signal to dinitrogentris(trimethylphosphane)cobalt(0) *(2)*, whose presence in solution is also indicated by the smooth substitution reactions occurring with π-acceptor ligands according to eq. (a).

$$[L_3CoN_2] + 2\,L' \longrightarrow L_2CoL'_2 + N_2 + L \qquad (a)$$

(2)

L = $(CH_3)_3P$

2 L' = $C_6H_5N{=}NC_6H_5$, $C_6H_5CH{=}CHC_6H_5$, 2,2'-bipyridyl, 2 CO

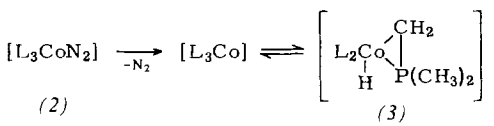
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The IR spectrum of a Nujol mull of *(1)* suggests that N_2 elimination is followed initially by stabilization of the L_3Co fragment such as in *(3)*, because the ν(CoH) band grows at the expense of the ν(NN) band, and then by formation of L_4Co.



(2) *(3)*

ν(NN) = 2064 cm^{-1} ν(CoH) = 1830 cm^{-1} (br)

Reversible filling of a coordination vacancy on the metal by C—H cleavage of a trimethylphosphane ligand is not without precedent[8]; nor is a CoCP three-membered ring[9].

1*H*-Cyclopropa[*a*]naphthalene from 2,3-Benzo-1,6-methano[10]annulene

By *Shigeo Tanimoto, Rainer Schäfer, Joachim Ippen*, and *Emanuel Vogel*[*]

Dedicated to Professor Leonhard Birkofer on the occasion of his 65th birthday

1*H*-Cyclopropa[*a*]naphthalene *(1)* and 1*H*-cyclopropa[*b*]naphthalene *(2)* warrant interest with regard to the possibility of localizing the bonds of aromatic nuclei by annelation of three-membered rings. While *(2)* has recently been prepared by dehydrohalogenation of 7,7-dichloro-3,4-benzonorcarene[1], *(1)* has hitherto remained unknown.

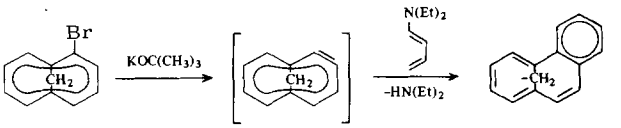
The synthesis of *(1)* has now been accomplished starting from 2,3-benzo-1,6-methano[10]annulene *(4)*, which is also described in this communication for the first time, by Diels-Alder reaction and Alder-Rickert cleavage[2].

[*] Prof. Dr. S. Tanimoto, Dr. R. Schäfer, Dr. J. Ippen, and Prof. Dr. E. Vogel
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

Prof. *S. Tanimoto* (Institute for Chemical Research, Kyoto University, Uji, Kyoto-Fu 611, Japan) thanks the Alexander-von-Humbolt-Stiftung for a grant.

(1) *(2)*

2,3-Benzo-1,6-methano[10]annulene *(4)* is obtained on heating a mixture of 2-bromo-1,6-methano[10]annulene *(3)* and *N*,*N*-diethyl-1,3-butadienylamine (8-fold excess) with potassium *tert*-butoxide (6-fold excess) in toluene with stirring (105°C; 15 h), chromatographing with pentane over silica gel, and recrystallizing from pentane (cooling to −35°C). The yield of *(4)* (pale yellow needles, m.p. 47–48°C) is 20%.



(3) *(4)*

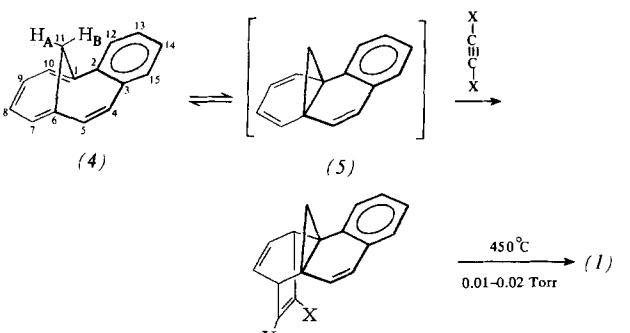
Although the ^{1}H-NMR spectrum (100 MHz; [D_6]acetone) of *(4)* is relatively complex, the observed coupling and a comparison with the spectra of the 5,7,10-trideuterio compound[3] and of phenanthrene permit the following assignment of the resonance signals: τ = 2.96 (H_4), 2.67 (H_5), 3.01 (H_7), 2.74 (H_8, H_9), 2.66 (H_{10}), 1.66 (H_{12}), 2.50 (H_{13}), 2.45 (H_{14}), 2.15 (H_{15}), 8.62 (H_{11B}), and 10.06 (H_{11A}); $J_{4,5}$ = 11.05 Hz, $J_{11A,11B}$ = 9.0 Hz[4].

The ^{1}H-NMR data and the ^{13}C-NMR spectrum provide no indication of an equilibrium between *(4)* and its norcaradiene valence tautomer *(5)*.

The weakening of the diamagnetic ring current in the [10]annulene ring of *(4)* expected as a result of benzo-annelation is most clearly manifested in the resonance signals of the bridge protons for they are shifted 1.9 and 0.5 ppm, respectively, downfield relative to those in 1,6-methano[10]annulene[5]. More subtle NMR findings such as the relatively large vicinal coupling constant $J_{4,5}$, the relation $\tau(H_7) > \tau(H_8)$[5], and the chemical shift difference of the bridge protons [$\tau(H_{11A}) \gg \tau(H_{11B})$] even suggest that the π bonds in the [10]annulene ring are largely localized according to the cycloheptatriene canonical structure *(4)*.

In accord with the π-electron structure deduced from the NMR spectrum, *(4)* reacts in boiling benzene (3 h) with dicyanoacetylene, giving an almost quantitative yield of the adduct *(6a)* [colorless crystals, m.p. 183—184°C (from ethanol)]. Reaction with dimethyl acetylenedicarboxylate in benzene at 120°C (10 h) affords *(6b)*, m.p. 147—148°C (from *n*-hexane).

The adducts *(6a)* and *(6b)* decompose uniformly and completely to give 1*H*-cyclopropa[*a*]naphthalene *(1)* and phthalodinitrile and dimethyl phthalate, respectively, on pyrolysis at 450°C and 0.01 to 0.02 torr in a quartz tube (length 40 cm,



(4) *(5)*

(6a), X = CN
(6b), X = CO_2CH_3

i. d. 5 mm). After chromatography over alumina (Brockmann) with pentane (argon atmosphere; −20 °C) and crystallization from pentane at −78 °C, *(1)* is obtained as nacreous colorless platelets of m. p. 19—20 °C (partial polymerization or decomposition); yields: 68 % from *(6a)*, 83 % from *(6b)*[6].

The ^{1}H-NMR spectrum (60 MHz; CCl_4; −20 °C) of *(1)* shows a complex multiplet at $\tau = 2.00$ to 2.76 (6 aromatic protons), in which an AB system can be made out at $\tau = 2.32$ (H_3) and 2.57 (H_2), $J_{2,3} = 6.9$ Hz, and a singlet at $\tau = 6.58$ (CH_2 protons). The spectrum corresponds to that of the isomer *(2)*, especially in the finding that the protons of the benzene ring adjacent to the three-membered ring absorb in the range for aromatic protons. Since $J_{2,3}$ also agrees in magnitude with the vicinal coupling constant $J_{1,2}$ (8.28 Hz) of naphthalene[7], a significant degree of bond fixation appears just as improbable in *(1)* as in *(2)*.

Apart from the above reasoning, the UV spectrum of *(1)* justifies our regarding the hydrocarbon as a derivative of naphthalene. Furthermore, the other spectra all document the close resemblance between *(1)* and *(2)* rather than revealing any bonding anomalies due to ring strain.

As in *(2)* and cyclopropabenzene, the three-membered ring of *(1)* undergoes solvolytic cleavage at one of the CH_2—C bonds when the molecule is exposed to the catalytic action of H^+ and Ag^+ ions.

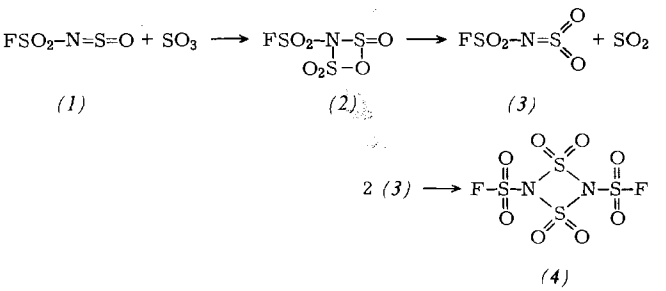
A New Cyclic SN Compound: 1,1,3,3-Tetraoxo-2,4-difluorosulfonylcyclodiaza-λ^6-thiane[**]

By *Klaus-Dieter Schmidt, Rüdiger Mews*, and *Oskar Glemser*[*]

N-(Fluorosulfonyl)sulfur oxide imide *(1)*[1] reacts with sulfur trioxide to give the cyclic end product *(4)*. On the basis of the results obtained in other studies[2] we assume that the reaction proceeds in analogy with the formation of sultones. In contrast to the reaction of $FCONSF_2$ with SO_3[2b], in which the β-sultone could be isolated, sultone *(2)* immediately decomposes with elimination of sulfur dioxide, which was detected by IR spectroscopy. The primary product *(3)*, formally a derivative of sulfimide, appears to be unstable as the monomer; it immediately dimerizes to *(4)*.



The composition and structure of the compound are confirmed by elemental analysis, characteristic fragments in the mass spectrum, and by its IR and Raman spectra. Compound *(4)* is a water-clear liquid (m.p. +16.5 °C) which fumes profusely on exposure to air and reacts vigorously with organic compounds. Decomposition sets in on warming to above 30 °C.

$(FSO_2NSO_2)_2$ represents a new type of the extremely rare four-membered SN ring system. Among the other members, the planar[3] S_2N_2[4] and its addition compounds $S_2N_2 \cdot A$ ($A = SbCl_5$, BCl_3)[5] have been known for some time. Less certainty surrounds the existence of $S_2N_2 \cdot R_2$ (R = *tert*-butyl)[6], while $(F_3C—S{=}N)_2$ can be prepared only with difficulty and in very small amounts[7]. Apart from the present four-membered ring with $n = 2$, other known representatives of the $(RNSO_2)_n$ type include higher-membered rings with $n = 3$ or 4 ($R = CH_3$ *etc.*)[8] and $n = 6$ in $(HNSO_2)_6$[9].

1,1,3,3-Tetraoxo-2,4-difluorosulfonylcyclodiaza-λ^6-thiane (4)

All operations were performed in carefully dried glass apparatus with exclusion of atmospheric moisture.

Stabilized SO_3 (66.7 g, 0.833 mol) is added dropwise to ice-cooled FSO_2NSO (120.8 g, 0.833 mol) and the reaction mixture slowly allowed to warm up to room temperature. In the course of several days SO_2 (49.8 g) condenses in the protective trap. The reaction mixture is subjected to N_2 pressure filtration, and on subsequent low-temperature vacuum condensation of the liquid phase product *(4)* collects in a trap cooled to −20 °C. Repeated distillation affords the pure compound (107.9 g, 0.34 mol; 80 %).

IR spectrum (CaF_2 plates were used because the substance reacts with KBr and NaCl; capillary film) [cm^{-1}]: 1490 vs, 1450 vs, 1330 w, 1230 vs, 1205 vs.—Raman spectrum [cm^{-1}]: 1494 w (br), 1445 w (br), 1372 vw, 1263 vs, 1247 w, 1218 w, 915 vw, 847 w (br), 832 w, 803 w (br), 659 vs, 576 w, 541 w, 517 vw, 472 w, 454 w, 432 w, 383 w, 338 vs, 324 w, 278 s, 261 m, 216 s, 179 w, 135 w.—Mass spectrum (*m/e*): 322 M^+ (16 %), 161 FSO_2NSO_2 (100 %), 142 SO_2NSO_2 (20 %), 83 FSO_2 (58 %), 67 SOF (10 %), 64 SO_2 (49 %), 48 SO (20 %), 46 NS (5 %).—^{19}F-NMR spectrum: $\delta_{SF} = -58.7$ ppm (relative to $CFCl_3$ as external standard).

Molecular Structure of $C_5H_5Mn(CO)_2[(C_6H_5)_2C{=}C{=}O]$. — Out-of-Plane Deformation of the Diphenylketene Ligand[1]

By *A. D. Redhouse* and *W. A. Herrmann*[*]

Structural data for metal complexes containing heterocumulenes as ligands are known in only a few cases. In the diphenylketene complexes $(\eta\text{-}C_5H_4R)Mn(CO)_2[(C_6H_5)_2C{=}C{=}O]$ (R = H: *(1)*; R = CH_3: *(2)*) spectroscopic as well as chemical evidence indicates that the "heterocumulene" is bound to the metal *via* a π-olefin system without the participation of the carbonyl oxygen[2]. X-Ray structure determination of *(1)* revealed for the first time the structural parameters of a coordinated ketene. We solved the structure using heavy atom procedures based on 686 independent non-zero reflections (Mo-K_γ radiation, microdensitometer techniques[3]) and refined it by least-squares methods to a conventional *R* value of 0.083.

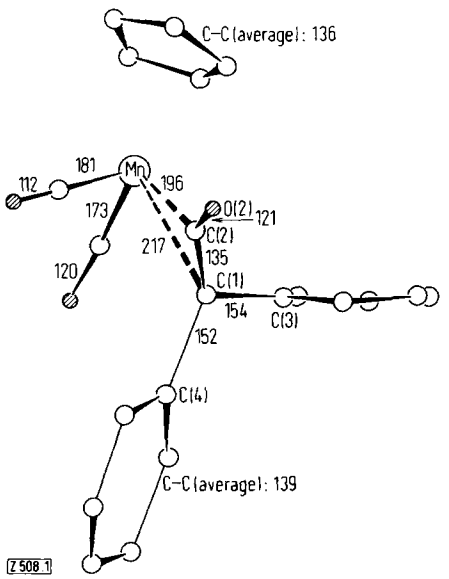

Fig. 1. Molecular structure of dicarbonyl(η-cyclopentadienyl)(diphenylketene)manganese *(1)*; bond lengths in pm. —Crystal data: $C_{21}H_{15}MnO_3$, rel. molecular weight 370.3, dark yellow monoclinic crystals from *n*-hexane/diethylether (5:2, −35 °C), $a = 678(2)$ pm, $b = 1397(2)$ pm, $c = 1863(2)$ pm, $\beta = 99.55°$, $d_m = 1.40$ g cm^{-3}, $d_{calc} = 1.41$ g cm^{-3} for $Z = 4$, space group $P2_1/c$.

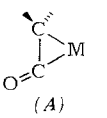
The following structural data are characteristic for the diphenylketene ligand in *(1)* (cf. Fig. 1):

1) The heterocumulene framework is no longer linear in the complex molecule (∢C(1)C(2)O(2) = 145°). It should be noted that this is an out-of-plane deformation, the dihedral angle between the plane defined by C(1), C(2), C(3), and C(4) and the plane defined by C(1), C(2), and O(2) being 89°.

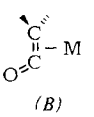
2) The C(1)—C(2) distance of 135(2) pm is not only typical of a C=C double bond but also greater than that found in free ketenes (*e.g.* dimethylketene[4]: 127.1 pm). In contrast, the C=O bond length of the ketene carbonyl group is not affected significantly on coordination of the ligand (dimethylketene[4]: 117.9 pm; complex *(1)*: 121(2) pm).

3) The distances of the carbon atoms C(1) and C(2) from the metal atom are clearly different from each other (217(2) and 196(2) pm, respectively). This could be the result of steric interactions between one of the two phenyl rings and the metal carbonyl groups. On the other hand, the Mn—C(1) distance compares favorably with values found for typical Mn—C(π-olefin) systems such as $C_5H_5Mn(CO)_2$(norbornadiene) (217 pm)[5a] or $C_5H_5Mn(CO)_2$(methylvinylketone) (214.9—217.5 pm)[5b], whereas Mn—C(2) is by comparison very short.

The considerable deviation of the ligand from linearity suggests an alternative formulation of *(1)* and *(2)* as "metallacyclopropanone" systems *(A)* as proposed by *Beck et al.* for the platinum complex $[P(C_6H_5)_3]_2Pt[(C_6H_5)_2C{=}C{=}O]$[6]. Both models *(A)* and *(B)* represent extreme descriptions of the bonding of unsaturated systems in metal complexes.



(A)



(B)

The overall geometry of the coordinated ketene is very similar to that of coordinated carbon dioxide and carbon disulfide ligands[7], which are also nonlinear. The bonding in these complexes has been interpreted in terms of the geometry of an excited state of the ligand. However, there is no excited state in which ketene has an out-of-plane deformation and at the same time a short C=C distance. The first excited state $^3A'$ ($^3A_1$) for ketene with an out-of-plane deformation possesses an extremely long C—C distance (154 pm) as well as a small CCO angle (123°)[8a]. Interpretation of the transition metal—ketene bond in terms of the excited state of the ketene does not therefore seem possible.

Coordination of the heterocumulene gives rise to characteristic changes in the ^{13}C-NMR parameters too (Table 1): The

Table 1. ^{13}C-NMR parameters of free and complexed diphenylketene [a].

	δ(C1)	δ(C2)	δ(M—CO)	δ(C_5H_4R)	δ(CH_3)	δ(C_6H_5)			
						C_1	C_o	C_m	C_p
$(C_6H_5)_2C{=}C{=}O$ (= L)	47.0 [8b]	201.3 [8b]	—	—	—	131.4	129.9	128.3	126.9
$C_5H_5Mn(CO)_2L$ *(1)*	− 4.1	237.5	238.0	89.0	—	141.8	129.4	128.8	126.3

resonance of the terminal carbon atom C(1) is shifted to higher field by *ca.* 50 ppm, whereas the carbonyl carbon atom becomes deshielded, and very much resembles, in terms of chemical shifts, metal carbonyl groups.

If the coordinated diphenylketene is formally considered as a bidentate ligand, the structural analogy of *(1)* and *(2)* with the square-pyramidal asymmetric compounds of the type $C_5H_5M(CO)_2(L—L')$ (M = Mo, W; L—L' = N—N'- and N—C-chelate ligands) first described by *Brunner*[9] becomes apparent. The chiral environment of the central metal in *(1)* and *(2)* should be detectable, for instance, by NMR spectroscopy. The ^{13}C-NMR spectra (Table 1) exhibit between −55 °C and room temperature only *one* signal for the terminal M—CO groups. Both the phenyl groups are seen to possess identical signals for corresponding ring positions. The diastereotopic effect upon the α- and β-C-positions in the cyclopentadienyl ring of *(2)*, expected on the basis of molecular asymmetry, is not observed. This indicates that the enantiomeric forms of the diphenylketene complexes undergo fast [NMR time scale] equilibration *via* symmetrical transition states[10].

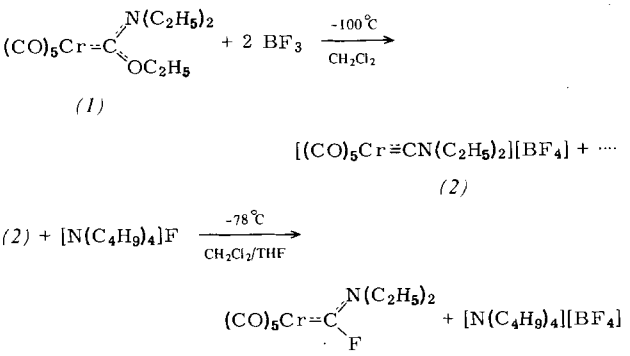
Pentacarbonyl(diethylaminofluorocarbene)chromium[1]

By *Ernst Otto Fischer, Willi Kleine*, and *Fritz Roland Kreissl*[*]

In analogy with the preparation of pentacarbonyl(diethylaminochlorocarbene)chromium[2], we attempted to prepare the first fluorocarbene complex by passing boron trifluoride into a solution of pentacarbonyl(diethylaminoethoxycarbene)chromium *(1)*[3], but only succeeded in initially isolating pentacarbonyl(diethylaminocarbyne)chromium tetrafluoroborate *(2)* as dark red crystals sensitive to air and heat. However, on reaction of this compound with tetrabutylammonium fluoride we obtained yellow crystalline pentacarbonyl(diethylaminofluorocarbene)chromium *(3)*, m.p. 40 °C.



Compositions and structures of the new complexes *(2)* and *(3)* are confirmed by elemental analysis and spectroscopic studies.

In the ν_{CO} range the IR spectra of *(1)*, *(2)*, and *(3)* (solution in CH_2Cl_2) show two absorptions corresponding to a $Cr(CO)_5$ group having pseudo-C_{4v} symmetry; relative to the carbene complexes *(1)* and *(3)* (2053 w, 1920 vs and 2064 w, 1930 vs cm^{-1}, respectively) the two bands of the carbyne complex *(2)* (2132 w, 2024 vs cm^{-1}) are shifted considerably to shorter wavelengths as a result of the positive charge.

In the ^1H-NMR spectrum the diethylamino group of *(2)* gives rise to a quartet and a triplet in the intensity ratio 4:6 (Table 1). On conversion of *(2)* into the fluorocarbene complex *(3)* the two *N*-ethyl groups are fixed in different environments owing to a p_π-p_π double bond component between the carbene carbon and the nitrogen atom[4], thus leading to signal splitting; a further splitting of the *N*-methylene protons in the *Z* position is due to interaction with the fluorine atom.

Table 1. ^1H-NMR spectra of complexes *(2)* and *(3)* in [D$_6$]acetone at −20 °C; δ values in ppm relative to CHD_2COCD_3 = 2.03 ppm.

	NCH_2 (*E*)	NCH_2 (*Z*)	NCH_2CH_3 (*E*,*Z*)
(2)	*3.98 (q)*		*1.53 (t)*
(3)	4.36 (q)	3.66 (q) [a]	1.36 (t), 1.23 (t)

[a] $^4J_{F-H}$ = 5 Hz.

The ^{13}C-NMR data are in accord with the structures of *(2)* and *(3)* (Table 2). Relative to *(1)* and *(3)* the positive charge leads to a paramagnetic shift of the carbyne carbon atom of *(2)* but to an upfield shift of the carbonyl ligands. The absence of splitting of the NEt_2 signals indicates a linear arrangement of the Cr—C(carbyne)—N system. The signal of the carbene carbon in *(3)* is split into a doublet by interaction with the fluorine atom; further F—C coupling occurs with the *cis* orientated CO groups and the *Z*-NCH_2 group.

Table 2. ^{13}C-NMR spectra of complexes *(2)* and *(3)* in CD_2Cl_2 at −30 °C; values in ppm relative to CD_2Cl_2 = 54.16 ppm.

	Cr-C	CO_{cis}	CO_{trans}	NCH_2 (*E*)	NCH_2 (*Z*)	NCH_2CH_3 (*E*,*Z*)
(2)	282.22	207.68	201.85	49.63		13.70
(3)	245.70 [a]	216.52 [b]	221.48	49.30	43.85 [c]	14.35, 13.70

[a] $^1J_{F-C}$ = 393.1 Hz; [b] $^3J_{F-C}$ = 9.8 Hz; [c] $^3J_{F-C}$ = 17.1 Hz.

In its ^{19}F-NMR spectrum (δ values relative to CF_3COOH), compound *(2)* only shows one sharp signal at −73.13 ppm for the tetrahedral anion $[BF_4]^-$ as expected. *(3)* displays a triplet at 152.30 ppm which is due to coupling ($^4J_{F-H}$ = 5 Hz) with the *Z*-NCH_2 group.

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. W. Kleine, and Dr. F. R. Kreissl
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

The linear conductivity-concentration relationship observed in highly dilute solutions of *(2)* underlines the saltlike character of the carbyne complex.

In contrast to the analogous chlorocarbene complex[2], the fluorocarbene complex *(3)* is very stable. The chlorocarbene complex gives *trans*-chloro(tetracarbonyl)diethylaminocarbynechromium in CH_2Cl_2 solution at temperatures up to 30 °C, and pentacarbonyl(ethyl isocyanide)chromium is formed at 35—40 °C. No comparable reactions of *(3)* were observed under similar conditions.

Procedure:

All operations should be performed under N_2 and with dried, N_2-saturated solvents.

On passage of BF_3 into a solution of *(1)* (1.6 g, 5 mmol) in CH_2Cl_2 (50 ml) at −100 °C, the initially yellow solution turns red. After warming up to −30 °C the solution is evaporated to dryness and the red residue repeatedly washed with ether. For further purification the substance is dissolved in CH_2Cl_2 and transferred onto a cooled frit filled with silica gel. After washing out impurities with CH_2Cl_2 and ether, compound *(2)* is eluted with methanol and recrystallized from CH_2Cl_2/Et_2O. Yield: 1.45 g (80 %).

A solution of $[N(C_4H_9)_4]F$ (1.31 g, 5 mmol) in THF (20 ml) is added dropwise to a solution of *(2)* (1.82 g, 5 mmol) in CH_2Cl_2 (20 ml) at −78 °C, the color changes from red to yellow. After 0.5 h the solvent mixture is drawn off and the residue chromatographed on silica gel with CH_2Cl_2 at −20 °C. The yellow zone contains the desired product *(3)*, which is recrystallized from ether/pentane. Yield: 0.9 g (61 %).

Reactions of Arenetricarbonylchromium Complexes with Nitrosyl Chloride[**]

By *Max Herberhold* and *Wolfgang Bernhagen*[*]

According to investigations by *Connelly et al.*[1,2] complexes of the type $(ar)Cr(CO)_3$ *(1)* react with nitrosyl hexafluorophosphate (in methanol/toluene, nitromethane or liquid sulfur dioxide) *via* substitution of one CO ligand to give yellow, air-stable salts:

$$(ar)Cr(CO)_3 + NO^+PF_6^- \rightarrow [(ar)Cr(CO)_2NO]^+PF_6^- + CO$$
(1) *(2)*

ar = $C_6H_nMe_{6-n}$ (n = 3-6)

[*] Doz. Dr. M. Herberhold and Dr. W. Bernhagen
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We found that the corresponding reaction with nitrosyl chloride (in tetrahydrofuran or methylene dichloride) at room temperature leads to complete decarbonylation of *(1)*; attempted characterization of the paramagnetic, NO-containing products (ν(N≡O) 1852 and 1710 cm^{-1} resp.) has so far met without success. However, below −30 °C intense red solutions are formed which contain reactive complex fragments of the type $[CrCl(CO)_2NO]$ *(3)* as main component:

$$(ar)Cr(CO)_3 + ClNO \xrightarrow[-30\,^\circ C]{(THF)} [CrCl(CO)_2NO] + ar + CO$$
(1) *(3)*

ar = benzene, mesitylene, hexamethylbenzene, cycloheptatriene, *p*-substituted toluene X-C_6H_4-Me (X = F, OMe, NMe_2)

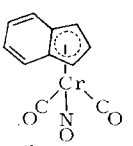
The composition and preparative significance of the—presumably solvent-stabilized—complex fragment *(3)* is shown by the following results:

1. IR spectra of THF solutions of *(3)* at −30 °C always show the same absorptions for a dicarbonylnitrosyl grouping (ν(C≡O) 2024 and 1942, ν(N≡O) 1681 cm^{-1}); the frequencies do not depend on the nature of the starting complex *(1)*. This means that the π-bonded arene ligand (ar) is cleaved from the metal on reaction of *(1)* with ClNO. On warming the solution to +20 °C the $Cr(CO)_2NO$ absorptions disappear; at the same time CO is liberated[3].

2. Addition of solid cyclopentadienylsodium to the red THF solution of *(3)* affords the well-known orange-red complex $CpCr(CO)_2NO$ *(4a)*[4] in about 40 % yield:

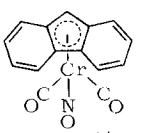
$$[CrCl(CO)_2NO] + CpNa \xrightarrow{(THF)} CpCr(CO)_2NO + NaCl$$
(3) *(4a)*

Analogous reactions with solutions of indenyl- and fluorenyllithium lead to the novel complexes *(4b)* and *(4c)*, respectively, in about 20—40 % yields:



(4b)

ν(C≡O) 2019, 1946
ν(N≡O) 1699 cm^{-1} (benzene)



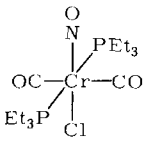
(4c)

ν(C≡O) 2014, 1942
ν(N≡O) 1697 cm^{-1} (benzene)

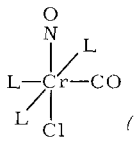
In both cases a *pentahapto*-coordination of the π-bonded ligand is to be assumed, as has also been postulated for the isoelectronic indenyl- and fluorenyltricarbonylmanganese complexes[5].

3. On reaction of the red THF solution of *(3)* with two-electron ligands (L) containing N or P, diamagnetic complexes are obtained which derive from a so far unknown parent compound *trans*-$[CrCl(CO)_4NO]$. Reaction with pyridine (py) affords the adduct $CrCl(CO)_2(py)_2NO$ *(5)* containing the CO-ligands in *cis* position. Similar products with *cis*-dicarbonyl grouping are also formed with bidentate chelate ligands such as 2,2'-bipyridyl (bpy) or ethylenebis(diphenylphosphane) (diphos).

In contrast, reaction of the THF solution of *(3)* with monodentate P-containing ligands leads to either *trans*-dicarbonyl or monocarbonyl complexes. In the case of the yellow complex containing triethylphosphane, $CrCl(CO)_2(PEt_3)_2NO$ *(6)*, both the CO and the PEt_3 ligands must be *trans* to each other (C_{2v} symmetry) on the basis of the IR spectrum (ν(C≡O) 1949 cm^{-1}) (Table 1) and the ^{31}P-NMR spectrum (singlet at δ = 35.02 ppm[6]), cf. ref.[7].



(6)



(7a), L = PMe_3
(7b), L = PMe_2Ph
(7c), L = $P(OMe)_3$

On reaction with an excess of trimethylphosphane, dimethylphenylphosphane or trimethylphosphite, compounds of the type *mer*-$[CrCl(CO)L_3(NO)]$ (7) are obtained. The meridial configuration follows from the ^{31}P-NMR spectrum[6], which shows an AB_2 pattern (*e.g.* (7c): $\delta(A) = 166.5$, $\delta(B) = 173.3$ ppm; $J_{AB} = 89$ Hz); of the three alternative structural possibilities that with Cl and NO ligands *trans* to each other is expected to be preferred.

Table 1. Characteristic IR-absorptions (in THF solution).

Complex	Color	ν(C≡O) [cm^{-1}]	ν(N≡O) [cm^{-1}]

[a] The band is split.

Experimental[8]

A solution of ClNO (6 ml, 3.24 mmol) in THF is added dropwise to a solution of (mesitylene)$CrCO_3$ (0.93 g, 3.63 mmol) in THF (60 ml) at −78 °C; evolution of gas and red coloration of the solution indicate formation of the reactive intermediate (3).

Dicarbonyl(indenyl)nitrosylchromium (4b): To the THF solution of (3) at −78 °C is added a solution of indenyllithium (7 mmol) (prepared from indene and CH_3Li in Et_2O at −30 °C). After thawing, the reaction mixture is stirred for 2 h at room temperature, filtered, the filtrate evaporated to dryness and the resulting residue (4b) extracted with pentane and purified by both chromatography (Al_2O_3/pentane) and double recrystallization from pentane. Red-gold platelets, m.p. 41—42 °C (under N_2); yield 0.28 g (34.1 %).

Carbonylchloronitrosyl[mer-tris(trimethyl phosphite)]chromium (7c): To the THF solution of (3) at −78 °C is added 2 ml (16.9 mmol) $P(OMe)_3$ and the mixture stirred without cooling for *ca.* 10 h. (7c) is extracted from the residue of the filtered reaction solution with CH_2Cl_2 and purified by chromatography (Al_2O_3/CH_2Cl_2). Yellow crystals from CH_2Cl_2/pentane (−78 °C), m.p. 81 °C (under N_2); yield 0.51 g (30.1 %).

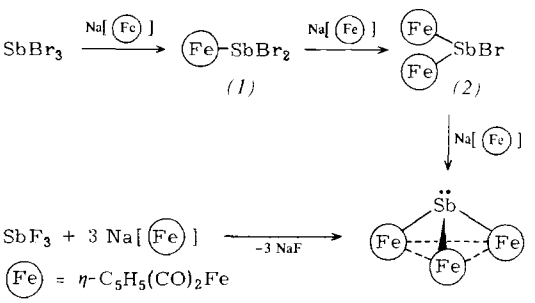
Tris[dicarbonyl(η-cyclopentadienyl)ferrio]stibane—A 5B-Element Base with Total Transition-Metal Substitution[1]

By *Wolfgang Malisch* and *Peter Panster*[*]

Contrary to earlier assumptions[2], simple transition-metal substituted 5B-element derivatives of the type $L_nM—ER_2$ (E = P, As, Sb) are frequently capable of existing in substance[1,3] and exhibit increasing stability towards aggregation and elimination processes along the series phosphorus, arsenic, antimony[1,4]. Permetalation therefore seems possible, especially in the case of the higher homologs. Previously it could be demonstrated in three cases, but only with products in which the M_3E group is integrated in a specific cluster system[5].

We have now been able to synthesize for the first time a permetalated 5B-element base of the usual bonding type by heterogeneous reaction of $SbBr_3$ or SbF_3 with $Na[Fe(CO)_2(C_5H_5)]$.

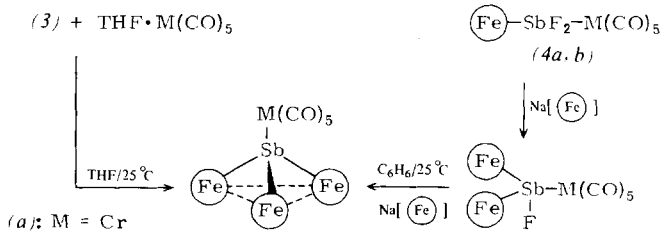


(3), black-brown needles, 165-167 °C (dec.)

Whereas the mono- and dimetalated intermediates are also isolable by use of $SbBr_3$ (in cyclohexane)[6], halogen/transition-metal exchange starting with SbF_3 (in benzene) immediately leads to (3), in spite of the stoichiometry. Both methods afford the surprisingly thermostable permetalated stibane together with the dinuclear complex $[\eta\text{-}C_5H_5(CO)_2Fe]_2$, which can be formed in the synthesis both by attack of the nucleophile $[\eta\text{-}C_5H_5(CO)_2Fe]^-$ at an already coupled Fe—Sb bond as well as by subsequent decomposition of (3). The tendency to undergo elimination is chiefly observed in polar media such as tetrahydrofuran; on dissolution in halogenated solvents spontaneous decomposition takes place.

Supporting evidence for the proposed constitution of (3) is provided by the stepwise metalation of $SbBr_3$ and by the readiness of (3) to add coordinatively to a complex fragment with preservation of its bonding skeleton:

[*] Priv.-Doz. Dr. W. Malisch and Dr. P. Panster
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)



Because of its sensitivity towards solvolysis this reaction of *(3)* gives, despite mild conditions, only moderate yields (35 and 32 %, resp.) of *(6a)* and *(6b)*, so the more favorable route for the synthesis of *(6)* is "transition-metal metalation" of the SbF_2-bridged dinuclear complexes *(4a)* and *(4b)*[7]. The fluoride/metalate exchange also proceeds extremely rapidly at bridging Sb-atoms, but, in contrast to the metalation of SbF_3, a directed synthesis of intermediates, *e.g. (5a)* is also possible. *(6a)* and *(6b)* are examples of a bonding type in which all valence electrons of the 5B-element atom are used for bonding to transition metal atoms. Both complexes decompose on melting with evolution of $M(CO)_6$; the degradation with elimination of $[\eta\text{-}C_5H_5(CO)_2Fe]_2$ is only of secondary importance. The coordinate requirement of the lone pair of electrons accordingly effects stabilization of the ferriostibane moiety, but at the same time promotes lability of the CO ligand in the $Cp(CO)_2Fe$ grouping.

The IR spectra reveal a high σ-donor/π-acceptor ratio for the novel ligand system *(3)* $[A_1^{(2)}(M(CO)_5)$: 2042 cm^{-1} (Cr), 2052 cm^{-1} (W)], mainly as a result of the pronounced electron-donor properties of the metal substituents.

Experimental:

Tris[dicarbonyl(η-cyclopentadienyl)ferrio]stibane (3):

$Na[Fe(CO)_2(C_5H_5)]$ (0.30 g, 1.50 mmol) and *(2)* (0.78 g, 1.40 mmol) are combined in 80 ml cyclohexane; the heterogeneous reaction mixture is stirred at room temperature for 55 h. The solution is warmed briefly to 60—70 °C and filtered; on cooling, *(3)* slowly crystallizes. The crystals are filtered off, washed three times with 15 ml ether (40 °C), and finally dried in a vacuum. Yield 0.61 g (66.8 %).

Pentacarbonyl{tris[dicarbonyl(η-cyclopentadienyl)-ferrio]-stibane}chromium(0) (6a):

(4a) (0.53 g) (1.00 mmol) is allowed to react with $Na[Fe(CO)_2(C_5H_5)]$ (0.40 g, 2.00 mmol) in benzene (40 ml) for 2 days at 25 °C. The solution is concentrated to 20 ml, heated to boiling and filtered. The pure, quadrinuclear complex *(6a)* is isolable from the filtrate after two recrystallizations from benzene. Yield: 0.47 g (68.3 %).

Cyclization Reactions at Electropositive Silicon[**]

By *Uwe Klingebiel* and *Anton Meller*[*]

We were recently able to show that incorporation of bulky substituents into monoalkylaminofluorosilanes[1, 2] led, in the cyclization reaction with butyllithium with loss of lithium fluoride and butane, to suppression of dimerization in favor of a nucleophilic rearrangement at the positively charged silicon[3].

A slight variation (diminution) in the size of the substituent groups on the central silicon atom of such monoalkylaminofluorosilanes, *e.g.* in *(1)*, leads under comparable reaction conditions—as we have now shown—to another type of cyclization process in silicon chemistry[4]: Because of the high reactivity of the silicenium intermediate, in intact monoalkylamino groups a proton is removed from a methylsilylamino group with ring closure to *(3)* and formation of butane.

In contrast the aminofluorosilane *(2)*, which is bulkier than *(1)*, once again reacts in the usual way[3], with migration of a methanide ion and ring closure to *(4)*; this, together with the formation of butane with the hydrogen atom of the monoalkylamino group provides evidence for the occurrence of silicenium ylide[3].

On changing the reaction conditions (solvent, temperature) expected transitions between the three types of cyclization depending on the substituents R are observed[5]. In the rearrangement reactions the corresponding *n*-butyl substituted cyclobutane could also be isolated as by-product.

Bis(tri-*tert*-butylsilyl)cadmium: The First Silylcadmium Compound Isolated in Substance[**]

By *Lutz Rösch* and *Hartwig Müller*[*]

Previous investigations[1] on the synthesis of silylmetal compounds according to

$$n\ R_3SiH + R'_nM \longrightarrow (R_3Si)_nM + n\ R'H$$

R = Et, Ph; R' = Et, Ph, *t*Bu;
M = main group metal

have shown that this "hydride reaction" proceeds in the expected manner only under drastic conditions. The main drawback of this method was that many of the silylmetal compounds thus synthesized could not be isolated from the reaction mixture but only their existence demonstrated on the basis of secondary reactions—*e.g.* also in the case of the only previously known organosilylcadmium compound, bis(triethylsilyl)cadmium[2].

Should in fact a hydride transfer be the determining factor in the course of the reaction then polarization of the silane hydrogen is of decisive importance; consequently, tri-*tert*-butylsilane[3] [low Si—H stretching frequency at 2080 cm^{-1}, small $^1J(^1H\text{-}^{29}Si)$ coupling constant of 179.7 Hz and chemical shift of 3.39 ppm rel. TMS] ought to be a particularly effective silylating reagent.

We have found that tri-*tert*-butylsilane *(1)* reacts with diethylcadmium *(2)* in the molecular ratio 2:1 with loss of ethane already at 90 °C:

$$2\ (t\text{-}C_4H_9)_3SiH + (C_2H_5)_2Cd \longrightarrow [(t\text{-}C_4H_9)_3Si]_2Cd + 2\ C_2H_6$$
(1) *(2)* *(3)*

As reaction proceeds the liquid mixture of *(1)* and *(2)* gradually solidifies; colorless crystals are formed, which after purification by recrystallization from benzene can be identified by spectroscopic investigation and elemental analysis as bis(tri-*tert*-butylsilyl)cadmium *(3)*.

[*] Dr. L. Rösch and Dipl.-Chem. H. Müller
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. *R. Zeisberg* of the Institut für Organische Chemie der TU Berlin for recording the ^{13}C-NMR spectra.

The ^{1}H-NMR spectrum (60 MHz; rel. C_6H_6 int.) of *(3)* shows only one signal at 1.33 ppm (converted to TMS), which expectedly exhibits no coupling with cadmium (^{111}Cd, $I=1/2$, rel. abundance 12.86%; ^{113}Cd, $I=1/2$, rel. abundance 12.34%). In contrast the ^{13}C-NMR spectrum (20 MHz; rel. C_6D_6 int.) shows two signals at 95.06 and 102.58 ppm, both flanked by coupling satellites [$^2J(^{13}C\text{-}^{111/113}Cd)=31$ Hz, $^3J(^{13}C\text{-}^{111/113}Cd)=11.4$ Hz]. No Si—H stretching vibrations are observed in the IR spectrum (solution in Nujol, CsI disks).

Experimental:

All operations were carried out under an atmosphere of dry oxygen-free argon. The starting compounds *(1)* and *(2)* were prepared by known methods[4]. *(1)* (7.5 mmol) and *(2)* (3.75 mmol) were transferred to a 25 ml flask furnished with an argon inlet and a reflux condenser connected to a gas burette *via* a bubbler. On heating to 90°C, 156 ml gas was evolved within 24 h (IR: C_2H_6; *ca.* 86%). Unconsumed *(1)* could be removed at 60°C/2.5×10^{-5} mbar. The crude product was purified by recrystallization from benzene. *(3)* was obtained as pale yellow crystals m.p. *ca.* 140°C (decomp.) which turned green-black on exposure to air and moisture.

Carbanion Complexes of Nickel(0)

By *Klaus Jonas, Klaus Richard Pörschke, Carl Krüger*, and *Yi-Hung Tsay*[*]

Transition-metal(0) compounds in which simple carbanions such as CH_3^- or $C_2H_5^-$ are coordinated as electron donors to the metal atom were, to our knowledge, previously unknown[1,2]. We report here on novel nickel(0) complexes in which such a σ-M^0—C bonding is present.

During investigations on alkali metal compounds of nickel[3] we found that reaction of binary Ni^0-olefin complexes such as (CDT)Ni or $(COD)_2Ni$[4] with organolithium compounds LiR (Ni/LiR = 1:1) and ethylene in the presence of strong n-donor ligands such as tetrahydrofuran or *N,N,N',N'*-tetramethylethylenediamine leads to complexes in which two ethylene molecules besides a carbanion ligand R^- are bonded to a nickel atom with formation of a $R\text{—}Ni^0(C_2H_4)_2$ anion.

$$(COD)_2Ni + LiR + 2\ C_2H_4 + 2\ (CH_3)_2N\text{—}CH_2CH_2\text{—}N(CH_3)_2 \xrightarrow[-2\ COD]{Et_2O}$$

$$\left[Li\left\{(CH_3)_2NCH_2CH_2N(CH_3)_2\right\}_2\right]^{\oplus}\left[R\text{—}Ni(C_2H_4)_2\right]^{\ominus}$$

(1a), R = CH_3
(1b), R = C_2H_5
(1c), R = C_6H_5

COD = 1,5-cyclooctadiene

The complexes *(1)* are characterized by elemental analysis and ^{1}H-NMR data, as well as by reaction with ethanol or carbon monoxide. With ethanol two equivalents of diamine are liberated per equivalent of Li; the ethyl compound *(1b)* yields the calculated amount of ethylene and ethane, while the methyl compound *(1a)* yields also the calculated amount of methane together with ethylene and ethane (from ethylene). On the other hand, the ethylene moiety in *(1a)*, *(1b)* and *(1c)* can also be displaced quantitatively (as C_2H_4) by carbon monoxide.

In the ^{1}H-NMR spectrum of *(1)* (in [D_8]-THF) the signals of the amine protons are not shifted compared to free amine; it thus follows that the amine ligands initially coordinated to the lithium are completely displaced by [D_8]-THF. In all three cases singlets are found for the protons of the ethylene ligands coordinated to nickel, for *(1a)* at $\tau=8.26$, *(1b)* at $\tau=8.42$ and for *(1c)* at $\tau=8.34$. The signals of the phenyl protons in *(1c)* appear at $\tau=2.4$ and 3.4 (intensity ratio 2:3). The methyl protons in *(1a)* are observed as a singlet at $\tau=10.58$, while the ethyl compound *(1b)* shows a triplet for the methyl protons at $\tau=8.76$ and a quartet for the methylene protons at $\tau=9.42$ with $J=7.5$ Hz. All ^{1}H-NMR spectra are essentially temperature-independent in the range −80°C to +20°C. Exchange between complexed and added free ethylene is not observed.

The specific conductivities of complexes *(1)* are $1\text{—}2\times10^{-3}$ Ω^{-1} cm^{-1} (0.25 M in THF at −30°C), and thus correspond closely to the value quoted for $LiClO_4$ in THF; hence the compounds are obviously largely ionic. Also in agreement with this is the result of X-ray structure analysis, according to which *(1a)* is composed of separated $Li[(CH_3)_2NCH_2CH_2N(CH_3)_2]_2$ cations and $CH_3Ni(C_2H_4)_2$ anions in the crystalline state.

Crystal data [*(1a)*][5]: $a=10.022(2)$, $b=16.121(3)$, $c=14.501(1)$ Å; $\beta=96.82(1)°$; space group $P2_1/n$, $Z=4$; 3395 reflections, 1694 of which are considered unobserved; $R=0.069$.

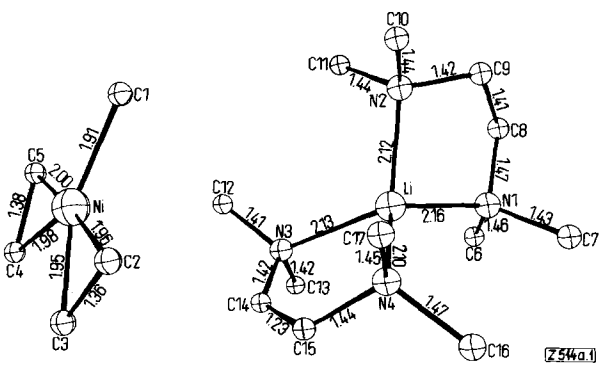

Fig. 1. Crystal structure of the carbanion complex *(1a)*.

In *(1a)* the two ethylene molecules together with the methyl group are oriented exactly trigonal-planar about the nickel atom (Fig. 1). The Ni—C1 σ-bond with a value of 1.91 Å is unusually short[6]. The short C=C bond lengths in the ethylene indicate only weak bonding to the nickel. The two diamine ligands surround the lithium cation tetrahedrally. In the solid state the complex is one-dimensionally polymeric; each lithium cation is situated equidistant between two Ni—CH_3 units (Li—Cl* 5.351 and 5.390 Å; Li—Ni* 5.777 and 5.800 Å).

[**] X-ray structure analysis.

Experimental:

A mixture of $(COD)_2Ni$[4] (6.36 g, 23.1 mmol) and *N,N,N',N'*-tetramethylethylenediamine (20 ml) in ether (80 ml) is saturated with ethylene at −20 °C. A solution of $LiCH_3$ (24 mmol) in ether [from $Hg(CH_3)_2$ and Li in $(C_2H_5)_2O$] is then added and the mixture stirred and allowed to warm to room temperature. A clear, yellow solution is obtained. On re-cooling to −60 °C *(1a)* crystallizes out (yield 7.6 g, 89 %). *(1a)* and *(1c)* are stable under argon at room temperature.

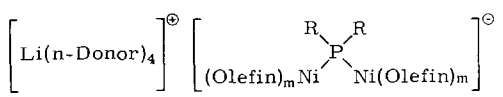
The Anion PR_2^- as Single Bridge between Two Nickel(0) Coordination Centers

By *Klaus Jonas* and *Ludwig Schieferstein*[*]

The previously known transition-metal complexes with phosphido bridges contain almost without exception relatively tightly bound groups such as CO, PR_3 or η^5-C_5H_5 as further ligands[1], thus making ligand exchange reactions relatively difficult. The observation that treatment of organolithium compounds with ethylene leads to formation of stable carbanion-nickel(0) complexes[2] gave us cause to investigate also the reactivity of lithium diorganylphosphides towards nickel(0)-olefin complexes. In contrast to the carbanion, the anion PR_2^- should be able to bind two Ni^0-olefin moieties *via* the two donor orbitals of the phosphorus to give an ionic multimetal system *(1)* containing two neighboring nickel atoms and easily displaceable olefin ligands.



(1)

We have found that reaction of $(COD)_2Ni$[4] with $LiPR_2$[3] ($Ni/LiPR_2 = 2:1$) and ethylene leads to complexes of type *(1)* in high yields.

$$2\ (COD)_2Ni + LiPR_2 + 4\ C_2H_4 \xrightarrow[-30\,°C\ \text{bis}\ 0\,°C]{THF} (1) + 4\ COD$$

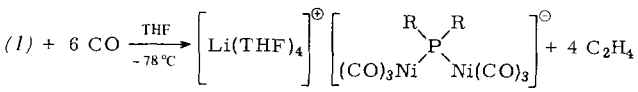
(1a), R = C_6H_{11}, n-Donor = THF, Olefin = C_2H_4, m = 2

(1b), R = C_6H_5, n-Donor = THF, Olefin = C_2H_4, m = 2

COD = 1.5-cyclooctadiene

The novel compounds *(1a)* and *(1b)* are characterized by complete elemental analysis and ^{1}H-NMR spectra. For both complexes the spectra show only a narrow, slightly split (evidently by ^{31}P-coupling) signal at $\tau = 7.7$ for all 16 ethylene protons, even at −80 °C. Unlike *(1a)*, for *(1b)* exchange between complexed and added free ethylene is observed.

As displacement experiments have already shown, the bound ethylene in *(1)* can be readily replaced quantitatively by other olefins such as butadiene, as well as by carbon monoxide, with complete retention of the anionic R_2PNi_2-moiety. Thus, on reaction with CO the previously unknown carbonyl complexes *(2)* are formed, which are characterized by elemental



(2a), R = C_6H_{11}, ν_{CO} in THF: 2030 (w), 2006 (s), 1945 cm^{-1} (br, vs)

(2b), R = C_6H_5, ν_{CO} in THF: 2039 (s), 2019 (s), 1960 cm^{-1} (br, vs)

analysis and IR spectra. Reaction of $(COD)_2Ni$ and $LiPR_2$ in the molar ratio 1:1 with ethylene leads to formation of the lithium phosphide-nickel(0) complex in which the phosphorus atom is bound to only one $Ni^0(C_2H_4)_2$ group.

$$(COD)_2Ni + LiPR_2 + 2\ C_2H_4 \xrightarrow[-30\,°C]{THF} (3) + 2\ COD$$

(3a) $(THF)_3Li{-}P(C_6H_{11})_2Ni(C_2H_4)_2$, $\tau_{CH_2=CH_2} = 7.7$

(3b) $[Li(THF)_4]^{\oplus}\ [(C_6H_5)_2PNi(C_2H_4)_2]^{\ominus}$, $\tau_{CH_2=CH_2} = 7.7$

The specific conductivities of the complexes *(1)* and *(3)* (0.25 M in THF at −30 °C) are *ca.* $10^{-3}\ \Omega^{-1}\ cm^{-1}$ for *(1)* and *ca.* $10^{-4}\ \Omega^{-1}\ cm^{-1}$ for *(3)* in the series:

$$\sigma_{(1a)} \approx \sigma_{(1b)} \gg \sigma_{(3b)} > \sigma_{(3a)}$$

As expected the complexes *(1)* prove to be the stronger electrolytes, since both donor orbitals of the phosphorus interact with $Ni^0(C_2H_4)_2$ groups and as a consequence there is hardly any chance for interaction with the lithium cation. The greater conductivity of *(3b)* compared to that of *(3a)* can be explained in terms of a higher stabilization of the anion by the two phenyl groups bound to the phosphorus.

Whether the Li—P bond in *(3a)* can be utilized for introduction of other metal centers is at present under investigation.

Experimental:

A mixture of $(COD)_2Ni$[4] (2.75 g, 10 mmol) and $LiP(C_6H_{11})_2$[3] (1.02 g, 5 mmol) in tetrahydrofuran (20 ml) is stirred at −30°—0 °C under ethylene until a clear solution is obtained. After addition of diethyl ether *(1a)* crystallizes at −80 °C (16 h) [yield 3.25 g (90 %)]. *(1a)* and *(3a)* have limited stability at room temperature.

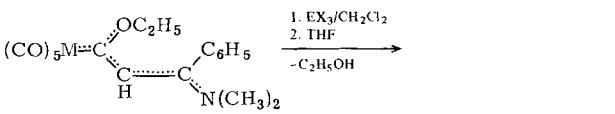
3-Dimethylamino-3-phenylallenylidene, A Novel Ligand at the Pentacarbonyl-chromium and -tungsten Skeleton[1]

By *Ernst Otto Fischer, Hans-Jürgen Kalder, Albin Frank, Frank Herwig Köhler*, and *Gottfried Huttner*[*]

Stepwise reaction of the carbene complexes pentacarbonyl(3-dimethylamino-3-phenyl-1-ethoxy-2-propenylidene)-chromium *(1)* and -tungsten *(2)*[2] with a Lewis acid (BF_3, $Al(C_2H_5)_3$) and a weak base (tetrahydrofuran) leads by 1,2 elimination of ethanol to formation of pentacarbonyl-(3-dimethylamino-3-phenylallenylidene)chromium *(3)* and -tungsten *(4)*, respectively.



(1) M = Cr, EX_3 = BF_3 *(3)*
(2) M = W, EX_3 = $Al(C_2H_5)_3$ *(4)*

The novel compounds *(3)* and *(4)* are to our knowledge the first transition-metal complexes containing "cumulogous carbene ligands"[8]. Composition and structure of these red-violet complexes are confirmed by elemental analysis, IR, NMR and mass spectra and, in the case of *(3)*, by an X-ray structure analysis[3] (Fig. 1).

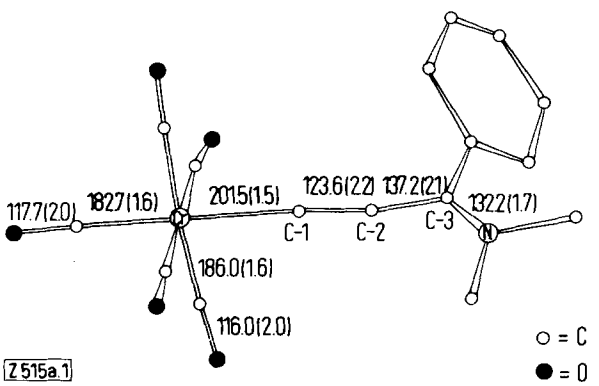


Fig. 1. Molecular structure of the allenylidene-chromium complex *(3)*.

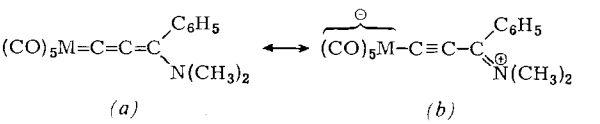
The metal-carbon bond length in the almost linear heterocumulene moiety of *(3)* is nearly the same size as in phenyl(methoxy)carbenepentacarbonylchromium[4] corresponding to a bond order of between 1 and 2. This, and the very short (C-1)—(C-2) and (C-3)—N bond lengths indicate a considerable contribution of the mesomeric structure (b).



(a) *(b)*

The same conclusions can be drawn from the following spectroscopic results in the case of the tungsten complex *(4)*.

As in dialkylaminocarbene complexes[5] the position of the most intense ν_{CO} absorption (E) at 1923 cm^{-1} in the IR spectrum (in THF) is characteristic for a relatively high negative partial charge at the metal, the appearance of two different ^{1}H-NMR signals for the two NCH_3 groups at $\delta = 3.33$ and 3.75 ppm (in $CDCl_3$) for a partial double bond between C-3 and the dialkylamino group.

The ^{13}C resonances of the carbonyl ligands and the three allenic carbon atoms (Table 1) can be unambiguously assigned only on the basis of the ^{183}W-^{13}C coupling constants[6].

Table 1. ^{13}C-NMR spectrum of the allenylidenetungsten complex *(4)* at 305 K in $[D_8]$-THF (section).

	C-1	C-2	C-3	CO_{cis}	CO_{trans}
δ [ppm]	198.9	121.3	157.5	198.4	204.3
J (^{183}W-^{13}C) [Hz]	102.5	26.9	<5	124.5	131.8

The polarization of the cumulene system is easily recognizable from the chemical shifts; moreover, there is notable similarity in the bonding of the allenylidene and of carbonyl ligands (cf. resonance formulas (a) and (b)) as shown by δ(C-1) and $^1J(^{183}W\text{-}^{13}C\text{-}1)$. However, in accordance with the difference in bond orders the ^{183}W-^{13}C coupling constant for CO_{trans} is larger than that for CO_{cis}. Hence in agreement with the IR and ^{1}H-NMR data—there must, in contrast to the two known vinylidene ligands[7], be a higher σ-donor/π-acceptor ratio for the dimethylamino-3-phenylallenylidene ligands than for carbon monoxide. Thus (especially from the point of view of the bonding at C-3) *(3)* and *(4)* can be regarded as cumulogous carbene complexes.

Experimental:

All work must be carried out under nitrogen and with dried (Na, P_4O_{10}) as well as N_2-saturated solvents.

(3): BF_3 is injected for 10 min, into a stirred solution of *(1)* (570 mg, 1.44 mol) in CH_2Cl_2 (15 ml) at −78 °C. The mixture is concentrated to 2 ml in a high vacuum with warming to −30 °C and the adduct precipitated with 30 ml pentane and dried briefly in a high vacuum. The residue is taken up in THF, chromatographed in ether/THF on silica gel at 10 °C, and recrystallized from THF/pentane: red-violet crystals, decomposition above 125 °C; yield 150 mg (30 %).

(4): A mixture of *(2)* (1.4 g, 2.66 mmol) and $Al(C_2H_5)_3$ (0.36 ml, 2.64 mmol) in CH_2Cl_2 (30 ml) is stirred at room temperature for 5 h. The solvent is removed, the residue taken up in THF and purified in the same way as *(3)*: red-violet crystals, decomposition above 132 °C (m.p. 151 °C); yield 410 mg (32 %).

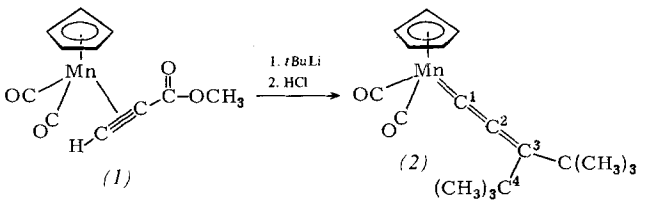
Simple Synthesis of Dicarbonyl(η-cyclopentadienyl)-(3,3-di-*tert*-butylallenylidene)manganese

By *Heinz Berke*[*]

Studies on the reaction behavior of acetylene derivatives bound to a coordinatively saturated metal center have so far not been reported in the literature. Dicarbonyl(η-cyclopentadienyl)(methylpropiolate)manganese *(1)*, which is readily accessible by photochemical synthesis at −30 to −40°C in ether, was allowed to react with *tert*-butyllithium in ether at −20 to −30°C, whereupon an acetylide complex was probably formed as intermediate; after protolysis, dicarbonyl(η-cyclopentadienyl)(3,3-di-*tert*-butylallenylidene)manganese *(2)* could be isolated in high yield as a very stable end product.



(1) *(2)*

The red-brown crystalline dialkylallenylidene complex[1] *(2)*, m. p. 121—122°C, can be purified by vacuum sublimation at 35—50°C. Its composition and structure follows from elemental analysis and spectroscopic (IR, MS, ^{1}H- and ^{13}C-NMR) findings.

In addition to the absorptions of the carbonyl ligands (1995 s(A') and 1940 cm^{-1} s(A''), soln. in *n*-hexane; 1972 s(A') and 1904 cm^{-1} s(A''), solid, KBr), the IR spectrum contains a further band in the 5 μm region which is assigned to the C=C=C group (ν_{as}(C=C=C) 1922 cm^{-1} m, soln. in *n*-hexane; 1875 cm^{-1} m, solid, KBr). The ^{1}H-NMR spectrum shows in addition to the singlet for the C_5H_5 protons (4.75 ppm; C_6D_6, TMS), only one signal for the two *tert*-butyl groups (1.33 ppm; C_6D_6, TMS) which displays no noticeable changes from −90°C to +90°C. Presumably rotation of the allenylidene ligand about the Mn—C bond is unhindered. Assignment of the seven signals in the ^{1}H broad-band decoupled ^{13}C-NMR spectrum is simplified by the fact that two signals of ^{13}C nuclei not coupled with protons are considerably broadened by coupling with ^{55}Mn (CO and C-1). Noteworthy is the extraordinarily large chemical shift for C-1, which is to be interpreted in terms of only partial compensation of the electron deficit of this atom by metal back-bonding and by conjugation to the cumulene system[1, 2].

Chemical shifts in the ^{13}C-NMR spectrum of *(2)* at 20°C in C_6D_6 rel. to TMS.

	CO	C_5H_5	C-1	C-2	C-3	C-4	CH_3
δ [ppm]	229.79	88.37	331.18	213.61	167.51	45.11	31.58

The mass spectrum of *(2)* contains the molecular ion at *m/e* = 326 and fragments due to successive loss of CO, fragmentation in the allenylidene ligand, and complete cleavage of the latter. A mass peak at *m/e* = 300 could be due to dimerized allenylidene. In fact, yellow tetra-*tert*-butylhexapentaene[3] [IR(CCl_4): 2960, 2920, 2870, 2030, 1997, 1943 cm^{-1}; ^{1}H-NMR (CCl_4, TMS): δ = 1.28 ppm] can be isolated either from the residue of the sublimation of *(2)* or directly by thermolysis of *(2)* at 100°C and normal pressure, subsequent vacuum sublimation at 80°C and crystallization from ethanol (yield 52%).

Experimental:

A solution of $C_5H_5Mn(CO)_3$ (1.5 g, 7.35 mmol) in diethyl ether (250 ml) is irradiated under protective gas in a circulation vessel at −50 to −60°C with a mercury high-pressure lamp for 2 h. To the red solution is added 1 ml (11.07 mmol) methyl propiolate and the mixture warmed to room temperature. After removal of solvent the residue is chromatographed on silica gel under protective gas. Residual $C_5H_5Mn(CO)_3$ is eluted as a first zone with petroleum ether/CH_2Cl_2 (3:1), and thereafter the orange zone of *(1)* with petroleum ether/CH_2Cl_2 (1:2); yield of almost pure *(1)*: 1.32 g (71%) [IR (*n*-hexane): 2030 w (C≡C), 1995 s, 1940 s (C≡O), 1707 cm^{-1} m (>C=O); ^{1}H-NMR (C_6D_6, TMS): δ = 3.5 (CH_3), 4.11 (C_5H_5), 5.71 ppm (CH); MS: *m/e* = 260 (M^+)].

A solution of *tert*-butyllithium (8.31 mmol) in hexane is added under protective gas at −20 to −30°C to a stirred solution of *(1)* (720 mg, 2.77 mmol) in ether (100 ml). After 0.5 h the reaction mixture is treated with ethereal hydrochloric acid and filtered from LiCl at room temperature. After removal of solvent the residue is sublimed in a vacuum, firstly at 35°C and then at 50°C, the first oily portion being discarded; yield of *(2)*, 810 mg (89.5%).

Monochlorides of the Lanthanoids: GdCl and TbCl

By *Arndt Simon, Hansjürgen Mattausch*, and *Norbert Holzer*[*]

So far the compound Gd_2Cl_3 has represented the most metal-rich rare-earth halide. On account of metal-metal bonding Gd_2Cl_3 contains unusual structural units[1] which should be capable of variation and thus lead to a broad chemistry of reduced rare-earth metal halides (X/M < 2)[2]. Investigations have led to isolation of the isostructural Tb_2Cl_3 and shown that both compounds can be reduced further with formation of the monohalides. GdCl and TbCl are formed on heating the respective metals with their trichlorides to 800°C in a sealed tantalum vessel. Both compounds form graphite-colored, crystalline platelets and are isotypic with ZrCl[3].

Büsnauer Strasse 171, D-7000 Stuttgart 80 (Germany)

The terbium compound has the analytically determined composition $TbCl_{1.09\pm0.04}$. The crystals decompose in moist air and react in water with evolution of hydrogen. According to the structure, GdCl and TbCl are expected to display two-dimensional metallic conductivity; to check this, however, larger crystals than could previously be obtained are required. There is already evidence for metal-rich halides of other lanthanoids too[*].

Data from single crystal and powder diffraction are listed in Table 1 for the new compounds.

Table 1. Lattice constants according to modified Guinier photographs [4] for GdCl, TbCl and Tb_2Cl_3; preliminary atomic parameters for GdCl and TbCl; standard deviations in the last place are shown in brackets.

MCl:	space group $R\bar{3}m$; *(6c)* $z(M)\approx 0.116$, $z(Cl)\approx 0.385$	
	GdCl:	$a=3.819(1)$, $c=27.482(6)$ Å
	TbCl:	$a=3.787(1)$, $c=27.461(5)$ Å
M_2Cl_3:	space group Cm	
	Gd_2Cl_3 [1b]:	$a=15.237$, $b=3.869$, $c=10.179$ Å, $\beta=117.66°$
	Tb_2Cl_3:	$a=15.184(9)$, $b=3.869(3)$, $c=10.135(6)$ Å, $\beta=118.07(5)°$

In the monohalides close-packed double layers of metal atoms alternate with double layers of non-metal atoms (XMMX...XMMX...). Consequently there is a close relationship with the layer structures of the CdI_2 type (XMX...XMX...) as well as with the structures of Ag_2F[5], Hf_2S[6] *etc.* (XMM...XMM).

A further consideration which might also lead to an understanding of the unusual Ag_2F and Hf_2S structures is provided by a comparison with the structure of the M_2Cl_3 compounds (Fig. 1) and their resemblence to the transition-metal cluster compounds: *e.g.* MoX_2 (X = Cl, Br, I) contains Mo_6X_8 clusters linked *via* halogen bridges[7]. Decreasing the number of non-metal atoms first leads to the isolated cluster as in Mo_6Se_8[8]. Increasing the metal content further calls for M—M coupling of metal octahedra; in Mo_5As_4[9] ($\triangleq Mo_{2/2}Mo_4As_{8/2}$) "condensation" *via* opposite corners of octahedra takes place with formation of chains.

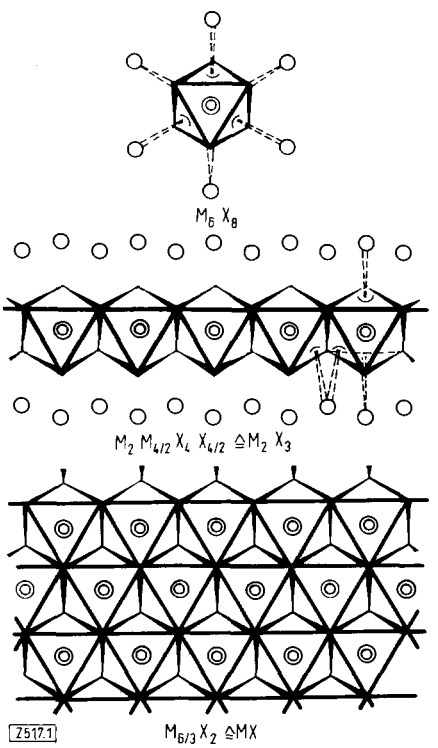

Fig. 1. Structural relationship between the rare-earth metal chlorides MX and M_2X_3 (X = Cl) and the transition-metal cluster compounds: M_6X_8 clusters are coupled *via* opposite edges in compounds M_2X_3 (octahedron chain). Further "condensation" leads to layers of octahedra in compounds MX. An XMMX layer is shown perpendicular to the projection (open circles: Cl).

Examples of cluster coupling *via* common edges are also known: thus condensation *via* neighboring edges of the M_6-octahedron leads to an arrangement like that already found in Nb_2Se[10] ($\triangleq Nb_2NbNb_{3/3}Se_{4/2}$). On the other hand, the structure of the rare-earth metal compounds M_2Cl_3 corresponds to a direct M—M coupling of oppositely situated octahedron edges ($\triangleq M_2M_{4/2}Cl_4Cl_{4/2}$). The structure of the monochloride MCl (Fig. 1) can be derived easily by further condensation. The metal-atom double layers consist of M_6 octahedra coupled edge to edge on all sides. Two oppositely situated faces of each octahedron are (as in the M_6X_8 group) occupied by halogen atoms ($\triangleq M_{6/3}Cl_2$). Interestingly, the arrangement of atoms around every individual M_6 octahedron is the same in the rare-earth metal halides as in the M_6X_8 cluster, with the exception that six of the non-metal atoms are replaced by metal atoms of a neighboring octahedron (cf. Fig. 1).

Structural considerations point to bonding analogies between lanthanoids and some 4d- and 5d-metals. The necessity of a higher metal content as a requisite for cluster formation in lanthanoids (small number of valence electrons) leads automatically to condensed cluster systems in the case of these elements.

Photochemical Liberation of 1-Naphthylamine from *cis*-Dichlorobis(1-naphthylamino)platinum(II)[**]

By *Arnd Vogler* and *Alfred Kern*[*]

While aromatic amines in the ground state are good bases, the electron density at the amine nitrogen is drastically reduced in the first excited singlet state[1]. We have now been able to show for the first time that an aromatic amine consequently loses its ability to coordinate to a metal on absorption of light and is therefore liberated from a complex.

[*] Prof. Dr. A. Vogler and Dipl.-Chem. Alfred Kern
Institut für Chemie der Universität
Postfach, D-8400 Regensburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

The complex *cis*-Pt(II)(1-naphthylamine)$_2$Cl$_2$ was synthesized by reaction of K_2PtCl_4 with 1-naphthylamine in water/dimethylformamide (DMF) and obtained analytically pure by recrystallization. The *cis* assignment (C_{2v}) follows from the presence of two IR bands (339 and 328 cm^{-1}) in the Pt—Cl stretching frequency range[2]. The photochemical behavior of the complex is also compatible only with a *cis* geometry. In the absorption spectrum the intense $\pi\pi^*$-intraligand band of the coordinated amine appears at 293 nm and the first LF band as a weak shoulder at 380 nm.

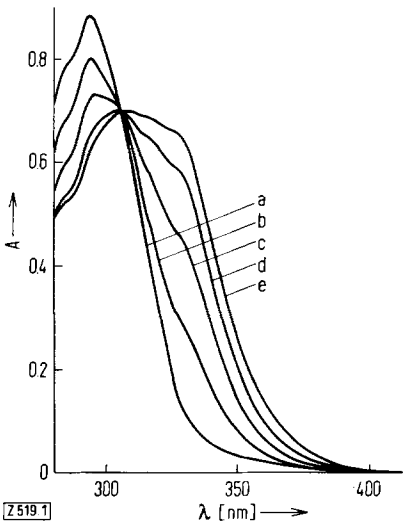

Fig. 1. Change in the absorption spectrum during the photolysis of a solution of the complex *cis*-Pt(1-naphthylamine)$_2$Cl$_2$ (7.2×10^{-5} mol/liter) in H_2O/DMF (50:50) in a 1-cm cell. Excitation source: $\lambda>280$ nm; duration of irradiation: a, 0; b, 1.5; c, 2.25; d, 3.75; e, 6 min.

Irradiation of *cis*-Pt(1-naphthylamine)$_2$Cl$_2$ dissolved in H_2O/DMF with light of wavelengths >280 nm leads to liberation of the amine which was detected by its fluorescence ($\lambda_{max}=440$ nm) and conversion into an azo dye. The change in the absorption spectrum of *cis*-Pt(1-naphthylamine)$_2$Cl$_2$ with increasing duration of irradiation displays an isosbestic point at 307 nm (Fig. 1). If substitution of naphthylamine by a solvent molecule (S) according to

cis-Pt(1-Naphthylamine)$_2$Cl$_2$ + S →
cis-Pt(1-Naphthylamine)(S)Cl$_2$ + 1-Naphthylamine

is the sole photochemical reaction, then the intraligand absorptions of the complexed naphthylamine ligands in the starting and the product complex should be additive because the naphthylamine ligands in both complexes are situated *trans* to the same ligand (chloride) and are therefore engaged in the same kind of bonding due to the *trans* effect in square-planar complexes[2]. This assumption could be substantiated by simulation of the spectral change. Mixtures of *cis*-Pt(1-naphthylamine)$_2$Cl$_2$ and free 1-naphthylamine in various ratios but with a constant total concentration gave rise to the same spectral changes as in Figure 1. This additivity would not be expected for substitution of chloride or a *cis/trans* isomerization since the change of the ligand situated *trans* to the naphthylamine would have modified the position and the intensity of the intraligand band. The substitution of chloride and the isomerization but not the release of amine are initiated by excited LF or CT states of comparable Pt(II) complexes[3].

The quantum yield was determined by initiating the reaction by excitation at two wavelengths (280 and 313 nm) lying within the absorption band of coordinated 1-naphthylamine. A value of $\phi=0.1\pm0.02$ was obtained in each case. Radiation of 435-nm light into the LF band did not lead to substitution of 1-naphthylamine ($\phi<10^{-3}$).

Reaction of *N*-Protected Succinimides with α-Lithiated Acetic Acid Derivatives[**]

By *Albert Gossauer*, *Wolfgang Hirsch*, and *Reinhard Kutschan*[*]

Succinimides are known to react at one—occasionally at both—carbonyl group(s) with alkyl- or alkynyl-Grignard reagents as well as under the conditions of the Reformatsky, Wittig, or Horner reactions[1]. Owing to the acidity of the hydrogen atom bonded to the nitrogen, however, only *N*-substituted derivatives react with both Grignard reagents and non-resonance-stabilized phosphorus ylides. Although *N*-unsubstituted succinimides react with the slightly basic cyanomethylenetriphenylphosphorane high temperatures (about 200 °C) are necessary to obtain reasonable yields of the desired products (cf. [1]).

We have found that succinimides *(2)* which are protected by a methoxycarbonyl group attached to the nitrogen atom readily react at −78 °C with α-lithiated acetic acid derivatives (cf. Table 1). After reaction, the protecting group can be smoothly removed by treatment of the product with $NaHCO_3$ in boiling methanol.

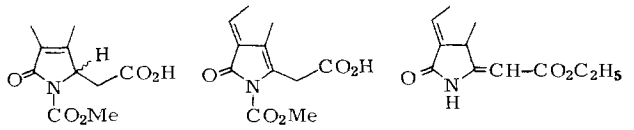
more reliable tool for the study of this kind of ring-chain tautomerism than other conventional methods[2]. Thus, compounds *(3a)*, X = $CO_2C_2H_5$ and *(3a)*, X = CO_2-*tert*-Bu[4] were found to occur in the chain form *(4)*, whereas the reaction products obtained from *(2b)* and *(2c)* are γ-hydroxy lactams *(3)*. Accordingly, cleavage of the *tert*-butyl group from *(4)*,



(5) *(6)* *(7)(Z + E)*

X = CO_2-*tert*-Bu, by means of hydrogen chloride in nitromethane at 0 °C[5] affords a β-oxo carboxylic acid derivative which readily loses carbon dioxide, whereas, under the same conditions, the γ-hydroxy lactams *(3b)* and *(3c)* yield the corresponding 5-oxopyrrolin-2-ylacetic acids *(5)* and *(6)*, respectively. The formation of *(6)* confirms the structure given for *(3c)*, X = CO_2-*tert*-Bu, which is, therefore, formed regiospecifically from *(2c)*. In contrast, thermal dehydration[6] of *(3b)* and *(3c)*, both with X = $CO_2C_2H_5$, yields the corresponding enamides [*e.g. (7)* from *(3c)*].

Experimental

Introduction of the protecting group into *(1)*: A solution of the imide *(1)*[7] in anhydrous *tert*-butanol (0.1 mol in 50 ml) is treated with a 1 M solution of potassium *tert*-butoxide in *tert*-butanol (100 ml). The solid product, obtained after removal of the solvent, is suspended in dry ether (150 ml), methyl chloroformate (30 ml) is *slowly* added dropwise to the suspension, and the mixture is heated for 5 h under reflux. The KCl which separates is filtered off, the filtrate concentrated to dryness by evaporation of the solvent, and the residue purified by crystallization, if necessary after chromatography of the crude product on silica gel with ether/*n*-hexane (7:3) as eluent.

Reaction of *(2)* with α-lithiated acetic acid derivatives ($LiCH_2X$): Lithium hexamethyldisilylamide[8] (0.1 mol) is dissolved in dry tetrahydrofuran (100 ml) and the solution is chilled to −78 °C. After ethyl acetate, *tert*-butyl acetate, or acetonitrile (0.11 mol) has been slowly dropped into the stirred solution, the mixture is stirred for further 30 min at −78 °C. To the resulting solution of the corresponding α-lithiated acetic acid derivative, is added dropwise a solution of the *N*-methoxycarbonylsuccinimide *(2)* in anhydrous tetrahydrofuran (0.05 mol in 50 ml) over 15 min. The mixture is allowed to stand for 1 h at −78 °C and then neutralized with aqueous HCl (10%) with vigorous stirring. When the solution has reached room temperature, the solvent is removed *in vacuo*, the residue disolved in CH_2Cl_2, and the remaining LiCl filtered off. After removal of the solvent, the crude product can be purified by chromatography on silica gel with ether/*n*-hexane (7:3) as eluent.

Synthesis of an Isomer-Free Tetravaline Derivative by Stereoselective Four-Component Condensation and Exponential Multiplication of Selectivity

By *Reinhard Urban, Gerhard Eberle, Dieter Marquarding, Dieter Rehn, Hendrik Rehn*, and *Ivar Ugi*[*]

According to the variant of the four-component condensation described in ref. [1], we have carried out the reaction of *N*-formyl-L-valine *(1)* with (*R*)-1-ferrocenyl-2-methylpropanamine *(2-R)*, 2-methylpropanal *(3)*, and *N*-(2-isocyano-3-methylbutanoyl)-L-valine methyl ester *(4)*. The diastereomeric products *(5n)* and *(5p)* were formed in the ratio 91.2:8.8. The stereoselectivity can be enhanced by addition of two mol. equiv. of tetraethylammonium *N*-formyl-L-valinate (see procedure): the ratio then increases to *(5n)*:*(5p)* = 98.5:1.5.

(5n) and *(5p)* can be resolved by chromatography on silica gel with dichloromethane/ethyl acetate (20:1) or by recrystallization from light petroleum/chloroform (10:1). A particularly effective preparation of pure *(5n)* can be accomplished by selective acidolysis of the mixture of *(5n)* and *(5p)*, which amounts to an exponential multiplication of the selectivity of the four-component condensation: *(5p)* is cleaved some 230 times faster to give *(6p)* than *(5n)* to give *(6n)* on treatment with trifluoroacetic acid and thioglycolic acid[2] (see Table 1).

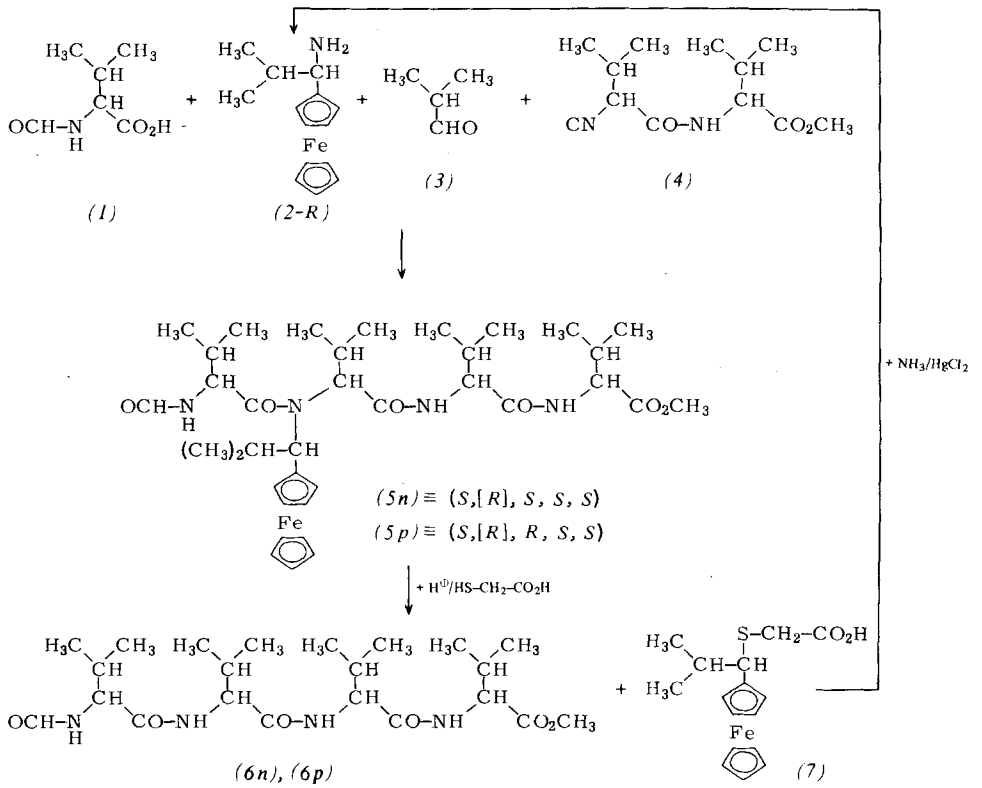
Table 1. Selective acidolysis of *(5n)* + *(5p)* = 98.5:1.5 with trifluoroacetic acid in dichloromethane at 20 °C.

Duration [min]	Loss of *(5n)* [%]	Ratio *(5n)*:*(5p)* after acidolysis
2	0.1	98.8 : 1.2 [a]
10	0.5	99.5 : 0.5 [a]
28	1.2	99.93 : 0.07 [b]
85	4.2	> 99.98 : 0.02 [c]

[a] Determined gravimetrically.
[b] Determined by high pressure liquid chromatography.
[c] *(5p)* could no longer be detected in the product by thin layer chromatography, high pressure liquid chromatography, and comparison of the specific rotatory powers [detection limits of all methods *ca.* 0.02% of *(5p)* in a mixture with *(5n)*].

The time dependence of the concentrations $c_{n,t}$ and $c_{p,t}$ of *(5n)* and *(5p)* respectively is described by the equations

[*] Dr. R. Urban, Dipl.-Chem. G. Eberle, Dr. D. Marquarding, Dr. D. Rehn, H. Rehn, and Prof. Dr. I. Ugi [+]
Institut für Organische Chemie der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)
[+] To whom correspondence should be addressed.



(a) and (b) [$c_{n,0}$ and $c_{p,0}$ = initial concentrations, k_n and k_p = rate constants of acidolysis].

$$c_{n,t} = c_{n,0} \cdot e^{-k_n \cdot t} \quad \text{(a)}$$

$$c_{p,t} = c_{p,0} \cdot e^{-k_p \cdot t} \quad \text{(b)}$$

With $k_p/k_t = x = 230$ and $\tau = t/t_{1/2,n}$ [where $t_{1/2,n}$ = half-life of *(5n)* = 1500 min] we obtain eq. (c).

$$c_{n,\tau}/c_{p,\tau} = (c_{n,0}/c_{p,0}) \cdot 2^{(x-1)\cdot\tau} \quad \text{(c)}$$

The selectivity multiplication factor

$$V = 2^{(x-1)\tau}$$

increases steeply and indefinitely for $x > 1$ and $\tau \geq 0$ with increasing duration of reaction and it becomes possible to isolate the isomer *(5n)* in extremely high purity after removal of *(6p)* and *(7)* by stopping the acidolysis at the right time. The procedure resembles the production of optically active compounds from racemates by reactions which consume one enantiomer faster than the other.

(6n) is obtained from isolated *(5n)* by renewed acidolysis in the presence of thioglycolic acid. The asymmetrically inducing amine component *(2-R)* is resynthesized from *(7)*.

Procedure:

Synthesis of *(5n)* and *(5p)*: *(2-R)* (2.57 g, 10 mmol) is dissolved in anhydrous ether (20 ml) and freshly distilled *(3)* (0.8 g, 11 mmol) then added at 20 °C. Water produced is removed with a molecular sieve (4 Å). After 2 h the reaction mixture is evaporated *in vacuo* and the residue dissolved in anhydrous methanol (500 ml). To the stirred solution at −78 °C are successively added dropwise the isocyanide component *(4)* (2.4 g, 10 mmol) dissolved in anhydrous methanol (200 ml) and *(1)* (1.45 g, 10 mmol) and tetraethylammonium *N*-formyl-L-valinate (5.5 g, 20 mmol) together dissolved in anhydrous methanol (300 ml). After reacting for 35 h at −78 °C the mixture is poured into water (500 ml), extracted with ether, the ether phase washed with a 3 % aqueous solution of tartaric acid, 0.5 N aqueous NaOH, and water, and concentrated *in vacuo*. Yield of *(5n)* + *(5p)* = 43 %. Resolution of *(5n)* and *(5p)* was accomplished by chromatography over kieselgel 60 (Merck: 70 to 230 mesh) with dichloromethane/ethyl acetate (20:1).—*(5n)*: m.p. 163 to 164 °C, $[\alpha]_D^{20} = +152.1°$, $[\alpha]_{546}^{20} = +298.7°$ ($c = 1.3$, C_2H_5OH).—*(5p)*: m.p. 165 °C, $[\alpha]_D^{20} = +412.7°$, $[\alpha]_{546}^{20} = +671.8°$ ($c = 1.7$, C_2H_5OH).

Selective acidolysis of *(5p)*: The mixture of *(5n)* and *(5p)* (0.5 g) is dissolved in dichloromethane (20 ml), treated with trifluoroacetic acid (0.8 ml) at 20 °C, and immediately thereafter with thioglycolic acid (5 g). The reaction mixture is allowed to stand at 20 °C. Acidolysis is terminated by addition of saturated aqueous $NaHCO_3$ solution, extraction with ether, repeated extraction with water, and evaporation *in vacuo*. The residue consists of unreacted *(5n)* or, after short reaction times, a mixture of *(5n)* and *(5p)* enriched in *(5n)*.

Acidolysis of *(5n)*: The same procedure is adopted as for the mixture of *(5n)* and *(5p)* and the reaction is allowed to progress until *(5n)* can no longer be detected by thin layer chromatography. The solution is extracted with water, the extract neutralized and shaken with dichloromethane. Vacuum evaporation of the dichloromethane extract affords *(6n)* in 92 % yield based on *(5n)*. M.p. 176 °C, $[\alpha]_D^{20} = -47.2°$, $[\alpha]_{546}^{20} = -52.0$ °C ($c = 0.2$, C_2H_5OH).

Synthesis of 1,2,3,5-Hexatetraene[1]

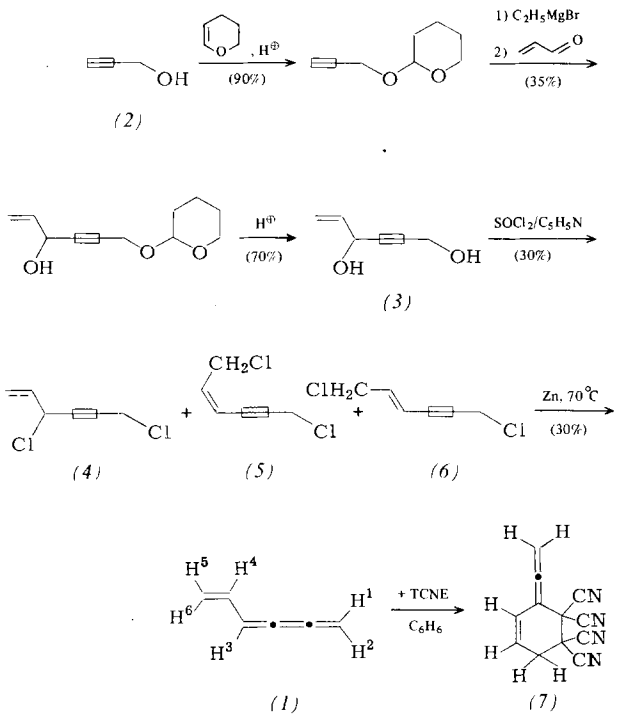
By *Helmut Maurer* and *Henning Hopf*[*]

Linear C_6H_6 hydrocarbons are preparatively useful starting materials in hydrocarbon chemistry and are suitable model

[*] Prof. Dr. H. Hopf and Dipl.-Chem. H. Maurer
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

substances for spectroscopic investigations. A total of twelve such linear "acyclic benzene isomers" may be formulated, ten of which are already known[2]. We report here on the synthesis of 1,2,3,5-hexatetraene *(1)*, the penultimate member of this series of compounds[3]. The tetraene *(1)* is a monosubstituted[3] cumulene and thus belongs to a group of highly reactive polyolefins, about which little is known.

In analogy to a procedure described by *Arens et al.*[4], *(1)* was synthesized as follows: propargyl alcohol *(2)* was converted, *via* the intermediates shown in the scheme, into the diol *(3)*[5]. Reaction of *(3)* with thionyl chloride/pyridine afforded the isomeric dichlorides *(4)* to *(6)*, which were separated gas chromatographically on an Apiezon column (140 °C) and identified by the usual spectroscopic methods[5] (product ratio *(4)*: [*(5)*+*(6)*] = 60:40).



Dechlorination and rearrangement of the unseparated dichloride mixture was accomplished by treatment with zinc dust in diethylene glycol dibutyl ether[6] at 70 °C. The compound *(1)* was quickly removed from the reaction flask (at *ca.* 0.1 torr) as it formed, and allowed to freeze out in a nitrogen-cooled trap (yield of crude product 30 %). Fractional re-condensation in a high-vacuum unit afforded pure *(1)* as a colorless liquid stable at −78 °C in the absence of oxygen. When the temperature is allowed to exceed −40 °C exothermic decomposition rapidly sets in, accompanied by a change in color of the liquid product from colorless through brilliant yellow and brown to black. Dilute solutions of *(1)* in dichloromethane or ether, on the other hand, are stable for several hours at −10 °C. In the NMR spectrum (−40 °C, $CDCl_3$) of *(1)*, which according to the mass spectrum has a molecular weight of 78, there appear two complex multiplets, one between $\delta = 6.56$ and 6.08 (2H) the other between 5.62 and 5.00 (4H); these can be ascribed to the protons H^3 and H^4 and H^1, H^2, H^5, and H^6, respectively. The vibrational spectrum (in $CDCl_3$), which contains very few bands, shows maxima at 2040 and 825 cm^{-1} (—CH=C=C=CH_2) as well as at 3080, 3000, 1605, 1005, and 980 cm^{-1} (—CH=CH_2). Attempts to carry out an elemental analysis and to record a quantitative electron spectrum failed due to the instability of *(1)*. Nevertheless, the band positions and shape of the qualitative spectrum (in ethanol) [$\lambda_{max} = 228$ (weak) and 278 nm (strong)] are in accord with the UV spectra of the other [3]cumulenes[7].

For chemical structure proof, *(1)* was trapped with tetracyanoethylene in dichloromethane at −78 °C. The Diels-Alder adduct *(7)* (white platelets from ethanol, m.p. 130—131 °C) was formed, whose structure was confirmed spectroscopically[5] as well as by elemental analysis.

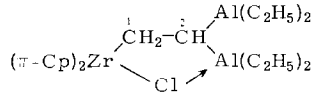
Extreme Bond Angle Distortion in Organozirconium Compounds Active Toward Ethylene[**]

By *Walter Kaminsky, Jürgen Kopf, Hansjörg Sinn*, and *Hans-Jürgen Vollmer*[*]

We have recently reported on the structure of *Al,Zr*-μ-chloro-1-[dicyclopentadienylzirconio(IV)]-2,2-bis(diethylalumino)ethane *(1)*[1].



(1), Cp = Cyclopentadienyl

The angle to C-1 of the alkyl ligand substituted twice by diethylalumino groups at C-2 is only 76°; nevertheless, this can be explained by formation of a five-membered ring as a result of dative bonding between the chlorine atom and an aluminum atom. Dynamic NMR measurements showed, however, that the dative bond is not very strong[2].

We have now carried out X-ray spectrographic investigations on compound *(2)* and the compound *(3)* formed from *(1)* by replacement of chlorine by a cyclopentadienyl moiety.

[**] Based on a lecture delivered at the Makromoleculares Kolloquium in Freiburg, March 1976.

Ring formation as in *(1)* should be impossible in these compounds.

Remarkably, it was found that the σ-bonded atomic grouping Zr—CH_2—C is always characterized by an angle of only 76° at the CH_2 group. Fig. 1 shows the corresponding atomic groupings of compounds *(1)* to *(3)* for comparison.

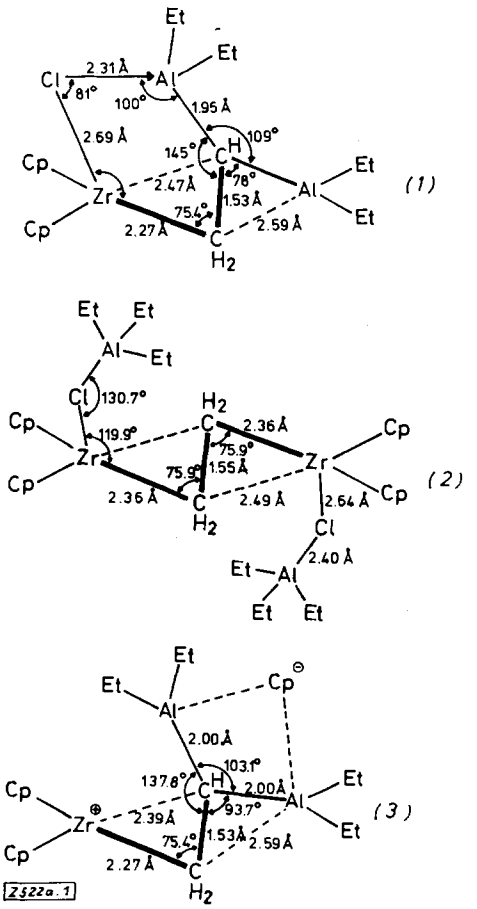

Fig. 1. Comparison of corresponding structural elements of compounds *(1)*, *(2)*, and *(3)*. Note the angle at C(1) in *(1)* and *(3)* and at C(1) and C(2) in *(2)*.

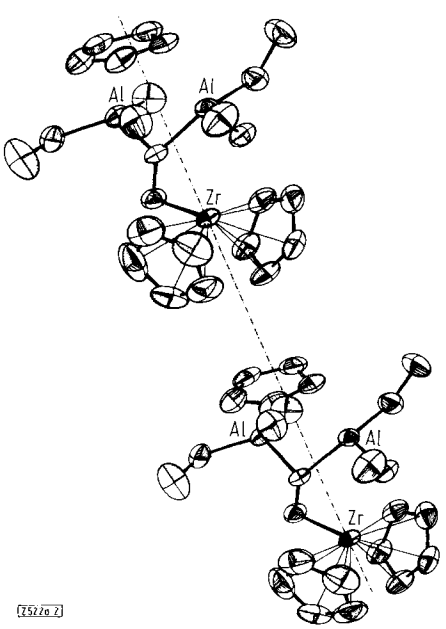

Fig. 2. ORTEP projection of two molecules of *(3)*. The *R* value is 0.03. A detailed account by *J. Kopf* is in preparation. Note the symmetrical position of the third cyclopentadienyl ring with respect to the Zr—Zr axis.

The third cyclopentadienyl ring in *(3)* shows a remarkable arrangement, completely deviating from the σ- or π-bonding cyclopentadienyl rings in bis(η-cyclopentadienyl)bis(σ-cyclopentadienyl)titanium(IV)[3] and (σ-cyclopenta-2,4-dien-1-yl)tris(η-cyclopentadienyl)zirconium(IV)[4]. It is released from $Zr(IV)^{\oplus}$ as the anion and arranged symmetrically in the lattice between two neighboring zirconium centers (Fig. 2). The ^{1}H-NMR spectrum shows singlets for the cyclopentadienyl rings of *(3)* at $\delta = 6.62$, 5.33, and 5.27 ppm in the ratio 1:1:1. The compound has a dipole moment of 5.4 Debye.

The completely halogen-free compound *(3)* is soluble in hydrocarbons and inserts α-olefins and 1,3-dienes to give compounds whose structures have so far not been elucidated.

The halogen-containing compounds *(1)* and *(2)* react with α-olefins and 1,3-dienes on addition of excess trimethylaluminum, and especially on addition of triethylaluminum and water; dehalogenation takes place, presumably with formation of alumoxanes[5], to give very active homogeneous catalysts for the polymerization of α-olefins, particularly of ethylene.

Halogen-Free Soluble Ziegler Catalysts for the Polymerization of Ethylene. Control of Molecular Weight by Choice of Temperature[**]

By *Arne Andresen, Hans-Günther Cordes, Jens Herwig, Walter Kaminsky, Alexander Merck, Renke Mottweiler, Joachim Pein, Hansjörg Sinn*, and *Hans-Jürgen Vollmer*[*]

Catalyst systems based on bis(cyclopentadienyl)titanium(IV) chloride with alkylaluminum chlorides or trialkylaluminum polymerize ethylene. With decreasing chlorine content their activity generally decreases while their rate of reduction increases[1]. Analogous Zr compounds, which are not reduced at room temperature, show no polymerization activity[2].

D. S. Breslow has recently shown that the activity of the known homogeneous chlorine-containing systems based on bis(cyclopentadienyl)titanium(IV) is increased on addition of water[3]. In systems completely free of chlorine, complex formation between titanium or zirconium compound and trialkylaluminum is not observed, either NMR- or UV-spectroscopically[4], or even cryoscopically[5], while in the presence of one chlorine atom per atom of transition metal [starting

[**] Based on a lecture delivered at the Molekulares Kolloquium in Freiburg, March 1976.—The observations related in this communication have led to patent applications being made. Future license fees were covenanted to the Hansische Universitätsstiftung on the occasion of the 70th birthday of *Franz Patat*. We thank the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for financial support of our work.

from bis(cyclopentadienyl)methyltitanium(IV) monochloride] complex formation is almost quantitative[6]. Surprisingly, however, not only halogen-deficient but also halogen-free systems exhibited β-hydrogen transfer (and α-hydrogen transfer, but much more slowly) with formation of dimetalloalkanes[7]. NMR-spectroscopic investigation of such a reaction in the presence of ethylene revealed a weak but lasting insertion of ethylene with formation of polyethylene[4b]. Addition of traces of chloride in the form of bis(cyclopentadienyl)titanium(IV) chloride lowered the yield of polyethylene, initiated the known reduction reaction to the expected extent and accelerated it[8]. On the other hand, the yield increased to 600000 g polyethylene/g titanium and the activity to 400000 g polyethylene/g titanium/h when one equivalent of trimethyl- or triethylaluminum previously treated with water was added to dialkylbis(cyclopentadienyl)titanium(IV) [alkyl, *e.g.* methyl] (cf. Table 1 and example 1).

sence of ethylene leads to slow degradation of the starting compound (curve A_3).

If, on the other hand, addition is carried out in the presence of ethylene a long-wave absorbing species with a band maximum at 390 nm (curves A_4 and A_5) is formed in the course of a few minutes. The rate of formation of the compound characterized by $\lambda_{max} = 390$ nm is strongly dependent on the concentration of the reaction partners.

If trimethylaluminum previously treated with water is added in the presence of propylene (Fig. 1b) degradation of the starting compound is observed. Polypropylene was not found. On removal and replacement of the propylene by ethylene the maximum arises at 390 nm and polymerization of the ethylene ensues. That is, the band at 390 nm is formed only on simultaneous presence of halogen-free bis(cyclopentadienyl)titanium(IV) with water-treated trialkylaluminum and ethylene (Fig. 1c).

Table 1. Ethylene polymerization with the system bis(cyclopentadienyl)dimethyltitanium(IV), trimethylaluminum, and water.

Yield of polyethylene [g/l]	Time [h]	Temp. [°C]	Titanium concentration [mol/l]	Amount of water added [mol/l]	Rel. Mol. Wt. (viscometric)
33.6	112	21	7×10^{-4}	$< 0.25 \times 10^{-3}$	3800000
43.2	1.5	21	7×10^{-4}	4.6×10^{-3}	200000
57.6	1.5	50	3.5×10^{-4}	4.6×10^{-3}	90000
34.2	1.5	12	1.1×10^{-6}	7.5×10^{-3}	—

Interestingly, compounds formed on the basis of bis(cyclopentadienyl)zirconium(IV) and exhibiting no polymerization activity—even in the case of completely dehalogenated secondary products[9]—can also become very active polymerization catalysts by addition of trialkylaluminum previously treated with water. These systems excel in that products with relative masses between a few million and a few hundred can be generated at almost constant activity by suitably choosing the reaction temperature (Table 2).

Table 2. Control of molecular weight by choice of temperature in the polymerization of ethylene with tri(cyclopentadienyl)zirconium—aluminum compounds.

Yield of polyethylene [g/l]	Time [h]	Temp. [°C]	Zirconium concentration [mol/l]	Rel. Mol. Wt. (viscometric)
81	64	50	2.2×10^{-3}	1500000
45	48	60	2.2×10^{-3}	363000
45	64	70	2.2×10^{-3}	225000
90	88	80	2.2×10^{-3}	40000
80	64	90	2.2×10^{-3}	oils and waxes [a]

[a] Predominantly α-olefins of empirical formula $C_{2n}H_{4n}$ ($n = 2, 3, 4 \ldots$).

Preliminary experiments show a maximum activity at an $Al:H_2O$ ratio of 2:1 to 5:1. Evidently water and trialkylaluminum react with each other, for the activity disappears if the $Al:H_2O$ ratio drops below 1:3, *i.e.* all alkyl groups are hydrolyzed. Presumably alumoxanes are formed[10].

Aging processes were not observed, and in particular no reduction which would be comparable to that observed under the conditions in halogen-containing systems.

If the solution of catalyst is mixed with polyethylene and the solvent removed, "gas-phase polymerization" takes place after admission of ethylene (see example 2).

We found that the spectrum of bis(cyclopentadienyl)dimethyltitanium(IV) (Fig. 1a, curve A_1) remains unaltered—aside from dilution effects (curve A_2)—on addition of trimethylaluminum (which shows no absorption) in the absence of ethylene. Addition of trimethylaluminum treated with water in the ab-

Curve A_4: A_3 in the presence of ethylene. Recorded after 5 min. Curve A_5: A_4, recorded after 25 min.

b) Curve B_1: 1.5 mmol $Cp_2Ti(CH_3)_2$/liter toluene (=curve A_1). Curve B_2: B_1 + saturation with propylene. Curve B_3: $B_2 + Al(CH_3)_3$ treated with H_2O (14.4 mmol/liter). Curve B_4: B_3 after 5 mins.

c) Curve C_1: 1.5 mmol $Cp_2Ti(CH_3)_2$/liter toluene (=curve A_1). Curve C_2: $C_1 + Al(CH_3)_3$ treated with H_2O (14.4 mmol/liter) + saturation with propylene. Recorded after 5 min (=curve B_4). Curve C_3: C_2, propylene removed and ethylene admitted under pressure. Recorded after 7 min. Curve C_4: C_3, recorded after 16 min.

Experimental

Example 1: Trimethylaluminum (4×10^{-3} mol) and water (2.3×10^{-3} mol) are added at 12°C to 350 ml toluene in a glandless 1l agitator autoclave after careful evacuation and bake out. Bis(cyclopentadienyl)dimethyltitanium(IV) (3.7×10^{-7} mol) is then introduced and the mixture allowed to react with ethylene at 8 bar. The reaction is terminated after 90 min, and the polyethylene filtered off and dried. Yield: 11.4g. Activity: 1.11×10^6 mol ethylene per mol titanium compound

per 1.5 h. (= 644000 g polyethylene/g titanium/1.5 h = 430000 g polyethylene/g titanium/h).

Example 2: A solution of bis(cyclopentadienyl)dimethyltitanium(IV) (2.5×10^{-5} mol) in toluene (1 ml) and a solution of trimethylaluminum (5.2×10^{-3} mol) in toluene (5 ml) and water (2.6×10^{-3} mol) are added at 21 °C wall temperature to 2 g polyethylene (MW = 200000) in a glandless 1 l agitator autoclave after careful evacuation and bake out. After removal of solvent, ethylene is introduced at 8 bar. The ethylene pressure which drops to 4 bar during polymerization is increased from time to time to 8 bar. The rate of uptake of ethylene drops within the first hour to a value (about one-half the initial value) obviously determined by diffusion, and then remains constant. Since further stirring is not possible the reaction is terminated after 48 h. 49 g of polyethylene is formed. A relative molecular mass of about 4×10^6 was determined viscometrically.

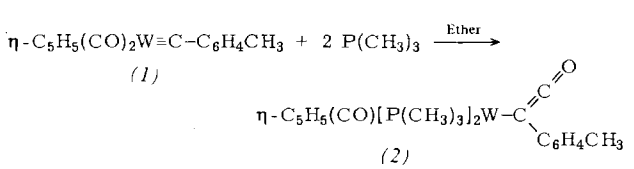
Carbonyl-η-cyclopentadienyl-(4-methylphenylketenyl)-bis(trimethylphosphane)tungsten— A Novel, Stable Transition Metal-Substituted Ketene

By *Fritz R. Kreissl*, *Albin Frank*, *Ulrich Schubert*, *Tassilo L. Lindner*, and *Gottfried Huttner*[*][**]

On allowing dicarbonyl-η-cyclopentadienyl-(4-methylphenylcarbyne)tungsten *(1)*[1] to react with trimethylphosphane at −40 °C we obtained the novel transition metal substituted ketene *(2)*.



[*] Dr. F. R. Kreissl [+], Dipl.-Chem. A. Frank, Dr. U. Schubert, Dipl.-Chem. T. L. Lindner, and Doz. Dr. G. Huttner
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, D-8000 München 2 (Germany)
[+] Author to whom correspondence should be addressed.

[**] The authors wish to thank Prof. *E. O. Fischer* and the Deutsche Forschungsgemeinschaft for support of this work.

The metal-catalyzed formation of ketene moieties was previously observed in the synthesis of ketenide complexes of the type M_2C_2O (M = Cu, Ag, Au)[2]. Reactions of ketenes with carbonyl-transition metal complexes, on the other hand, led either *via* deoxygenation and/or decarbonylation to mainly polynuclear metal compounds[3] or to dicarbonyl-η-cyclopentadienyl-η-diphenylketenemanganese complexes[4].

Compound *(2)*, which precipitates as orange-yellow diamagnetic crystals, is soluble in dichloromethane but not in *n*-pentane. In solution at room temperature one of the phosphane ligands is rapidly cleaved. Composition and structure of the new ketene *(2)*[5] have been confirmed by elemental analysis, IR and NMR spectra, and by an X-ray structure analysis[6] (Fig. 1).

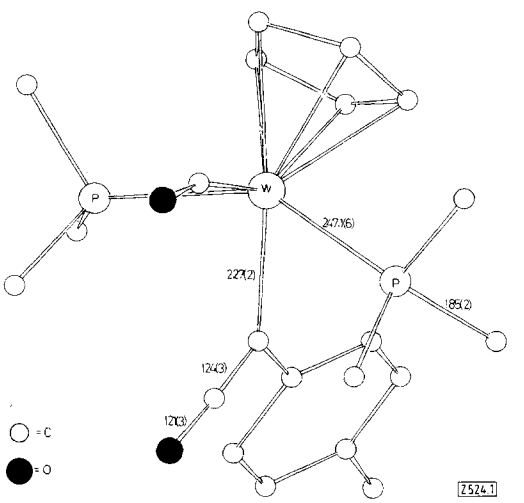


Fig. 1. Structure of ketene *(2)*.

The $W—C_{ketene}$ bond having a length of 227(2) pm is to be regarded as a single bond (for comparison: $W—C_{phenyl}$ in $\eta\text{-}C_5H_5(CO)_3W—C_6H_5$: 232 pm[7]). The lengths of the C=C- and C=O-double bonds in the ketene do not deviate significantly from those given in the literature for the free ketene [131(1) and 116(1) pm[8], respectively]. The tungsten-phosphorus distance with a value of 247.1(6) pm is shorter than the sum of the single-bond radii (W *ca.* 159 pm[9], P 110 pm[10]). The other bond lengths and angles in *(2)* correspond to the usual values.

Experimental:

All operations are carried out under nitrogen and in anhydrous (Na, P_4O_{10}) solvents saturated with N_2. A solution of *(1)* (1.02 g, 2.5 mmol) in ether (30 ml) is treated with 0.5 g (6.6 mmol) trimethylphosphane[11] at −40 °C and the mixture stirred for 36 hours. Orange-yellow crystals precipitate from the originally yellow solution. The solvent is decanted and the precipitate recrystallized from dichloromethane/pentane, washed three times with 25 ml cooled pentane, and finally dried for 10 hours at −30 °C *in vacuo*. Orange-yellow crystals, yield 86 % based on *(1)*.

Dimeric Bistetrathiotungstatostannate—A Novel Coordination Compound with Non-Equivalent and Tridentate WS_4^{2-} Ligands

By *Achim Müller*, *Irene Paulat-Böschen*, *Bernt Krebs*, and *Horst Dornfeld*[*]

Polynuclear complexes having metal-sulfur-metal bonds frequently present interesting aspects of structural chemistry[1]. We have now succeeded in preparing the orange colored compound *(1)* by combining solutions of $SnCl_2 \cdot 2H_2O$ and $[(C_6H_5)_4P]_2WS_4$ in dimethylformamide, and in characterizing it by elemental analysis, X-ray structure analysis, and by measurement of the vibrational spectrum. *(1)* exhibits structural features which were previously unknown.

$$[(C_6H_5)_4P)]_4[Sn_2(WS_4)_4]$$
(1)

(1) crystallizes in the triclinic space group $P\bar{1}$ with lattice parameters: $a = 14.642(3)$ Å; $b = 14.240(3)$ Å; $c = 12.895(9)$ Å; $\alpha = 94.79(4)°$; $\beta = 99.28(4)°$; $\gamma = 106.08(2)°$; $V = 2526.3$ Å^3; $Z = 1$ $[(C_6H_5)_4P]_2[Sn(WS_4)_2]$. For determining the structure the intensities of 6470 non-equivalent reflections were measured (data collection up to $\sin\theta/\lambda = 0.528$ Å^{-1}) with a Syntex-$P2_1$ four-circle diffractometer. The structure was determined by Patterson and Fourier methods and refined to an R value of 6.8% (W, Sn, S and P atoms with anisotropic temperature factors; C atoms with isotropic temperature factors).

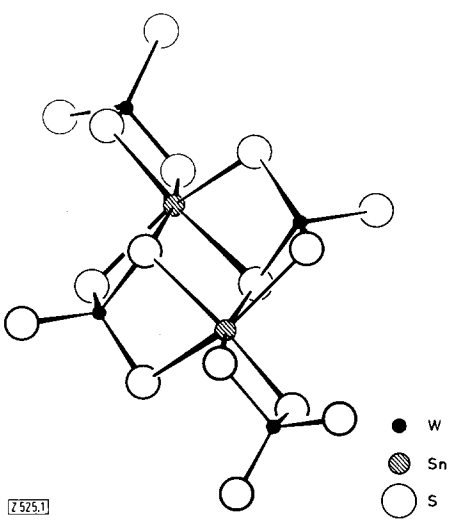

Fig. 1. Structure of the dimeric anion $[Sn_2(WS_4)_4]^{4-}$.

Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld (Germany)
[+] Author to whom correspondence should be addressed.

Figure 1 shows the structure of the $[Sn_2(WS_4)_4]^{4-}$ complex. The anion formally contains two central SnS_6 octahedra coupled *via* a common edge. These octahedra are bonded to the four non-equivalent WS_4 tetrahedra *via* common edges. Particularly worth noting is the type of coordination of the ligands. Two of the WS_4^{2-} ions are coordinated as bidentate ligands to the Sn and possess two free S atoms. The other WS_4^{2-} ions coordinate as tridentate ligands and have only one free S atom. These tridentate WS_4 ligands contain a triply bonded sulfur atom. The SnS_6 octahedra are highly distorted, mainly due to the stereochemical influence of the lone pair on the Sn^{II}.

The bonds from W have the following lengths: to the free S atoms, 2.148(7)—2.168(7) Å; to the doubly bonded bridging S atoms, 2.178(6)—2.239(6) Å; to the triply bonded S atom, 2.212(6) Å. The distances from the Sn to the doubly bonded S atoms, 2.710(8)—3.047(8) Å, are shorter than those to the triply bonded S atoms 2.956(6) and 3.093(6) Å. The W...Sn and Sn...Sn distances are 3.508(6) and 4.647(2) Å, respectively. The four-membered WS_2Sn and SnS_2Sn ring systems are planar.

Owing to the non-equivalent WS_4^{2-} ligands, the vibrational spectrum is complex and therefore could not be used for the structure determination. The IR spectrum shows strong and characteristic bands in the WS stretching vibrations region at 491 and 485 [$\nu(WS_{free})$] as well as at 462, 440, 434, and 422 cm^{-1} [$\nu(WS_{bridge})$].

Polarogram and Reactions of a Short-Lived Oxidation Product of the Carbonate Ion

By *Michael Grätzel*, *Arnim Henglein*, *Rainer Scheerer*, and *Peter Toffel*[*]

Polarographic waves of free radicals can be observed in the 10^{-5} s range if the radicals are generated in the proximity of a dropping mercury electrode by a pulse of high-energy radiation[1,2]. Depending upon the potential of the electrode either anodic or cathodic waves are registered which provide an insight into the redox behavior of the radicals. The carbonate radical ion is generated on irradiation of a 10^{-2} M aqueous Na_2CO_3 solution saturated with N_2O; the OH radicals produced by radiolysis of water immediately oxidize carbonate[3] according to:

$$OH + CO_3^{2-} \rightarrow OH^- + CO_3^-$$

At potentials < 0.25 V (*vs.* hydrogen electrode) cathodic waves are observed which rapidly decay (Fig. 1, bottom right) owing to electrochemical consumption of the radical according to equation (1).

$$CO_3^- + e^- \rightarrow CO_3^{2-} \qquad (1)$$

In solution CO_3^- has a lifetime of more than 1 ms, as revealed by the diminution of its absorption at 600 nm. For greater

[*] Dr. M. Grätzel, Prof. Dr. A. Henglein, Dipl.-Chem. R. Scheerer, and Dipl.-Chem. P. Toffel
Hahn-Meitner-Institut für Kernforschung Berlin GmbH, Bereich Strahlenchemie
Glienicker Strasse 100, D-1000 Berlin 39 (Germany)

positive electrode potentials anodic waves are observed. The polarogram of CO_3^- measured 40 μs after its generation and depicted in Figure 1 shows that the transition from reduction according to equation (1) to oxidation according to equation (2) occurs within a relatively narrow voltage range. The theory

$$CO_3^- \rightarrow CO_3 + e^- \qquad (2)$$

of the polarography of free radicals[2] interprets this observation as indicating that the standard redox potential of the CO_3^-/CO_3^{2-} system is more positive than that of the CO_3/CO_3^- system.

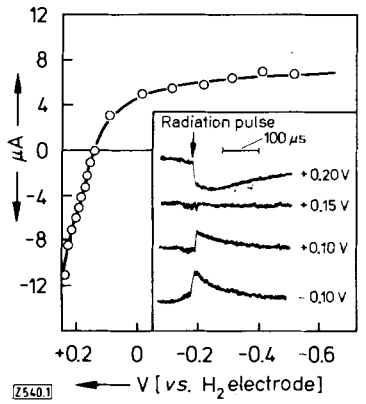

Fig. 1. Polarogram of the CO_3^- radical; cathodic waves positive, anodic waves negative. Bottom right: current-time plots for various electrode potentials.

CO_3^- can abstract an electron from numerous substances having a redox potential less than 1.0 V. On the other hand, transfer of an electron from CO_3^- to duroquinone has also been detected[4]; duroquinone has a standard redox potential for a one-electron transfer of −0.235 V[5]. The carbon trioxide CO_3 formed in this reaction decomposes to carbon dioxide and oxygen.

The ability of CO_3^- to function both as a one-electron donor and as a one-electron acceptor appears particularly interesting in connection with light-induced, carbonate-catalyzed decomposition of water to produce oxygen. As has recently been demonstrated[4, 6], triplet states of some quinones and nitro compounds oxidize CO_3^{2-} to CO_3^-. On the basis of these findings it is now possible to set up a photo-electrochemical half-cell for the production of O_2:

$$\begin{array}{lcl} & X \xrightarrow{h\nu} & X^* \\ X^* + CO_3^{2-} & \rightarrow & X^- + CO_3^- \\ CO_3^- + X & \rightarrow & X^- + CO_3 \\ CO_3 & \rightarrow & CO_2 + \tfrac{1}{2}O_2 \\ CO_2 + H_2O & \rightarrow & CO_3^{2-} + 2H^+ \\ \hline 2X + H_2O & \xrightarrow{h\nu} & 2X^- + 2H^+ + \tfrac{1}{2}O_2 \end{array}$$

The oxygen originates from the carbonate in the early stages of irradiation, as has also been postulated for the photosynthetic system[7].

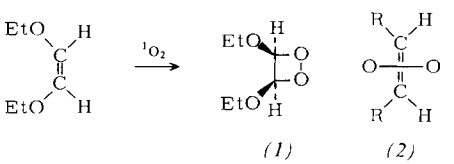
ABSTRACTS

1,2-Dioxetanes, which are formed by addition of singlet oxygen to CC double bonds, are dealt with by *P. D. Bartlett* in his "Ingold Lecture". Singlet oxygen is the only reagent capable of fast and stereospecific Diels-Alder reactions and [2+2]additions to CC double bonds. Such an addition is the formation of dioxetane *(1)* which could begin with an antarafacial approach of olefin and $^1O_2$ as shown in *(2)*. Thermal cleavage



(1) *(2)*

of 1,2-dioxetanes affords two carbonyl fragments, generally with chemiluminescence. [Four-membered Rings and Reaction Mechanisms. Chem. Soc. Rev. 5, 149—163 (1976); 41 references]

The influence of isotopic substitution on diffusion in liquids is the subject of a report by *R. Mills* and *K. R. Harris.* Modification of the mass of a diffusing molecule and measurement of the resulting change in its mobility permits assessment of the influence of mass on the rate of diffusion. The rate of diffusion depends upon factors such as mass, shape, and interaction potentials. If the diffusing molecules are different then the influence of mass is usually masked. Most self-diffusion data can be explained in terms of classical theory. The change in mass has hardly any effect on the diffusion of tracers. [The Effect of Isotopic Substitution on Diffusion in Liquids. Chem. Soc. Rev. 5, 215—231 (1976); 52 references]

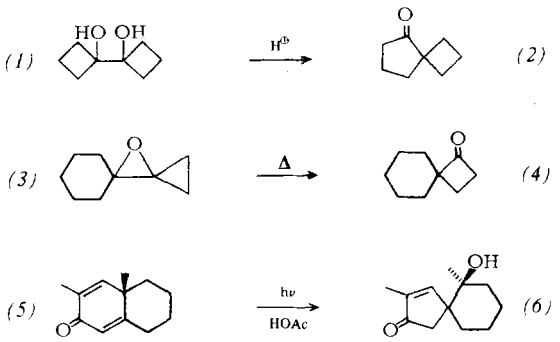
[Rd 881 IE—F]

Synthesis of fluoro-organic compounds by high-temperature conversion of saturated, unsaturated, aromatic, and heterocyclic fluorine compounds is treated in a review by *V. B. Platonov* and *G. G. Yakobson.* While the pyrolysis of perfluorinated paraffins affords complex mixtures partially fluorinated and fluoro halo compounds give fluorinated alkenes and arenes in high yields. The thermal conversion of perfluorocycloalkanes is strongly dependent upon ring size. Pyrolysis of polytetrafluoroethylene leads to perfluoroalkenes, -cycloalkenes, -alkanes, and -arenes, while perfluoroalkenes and -alkynes cyclize and perfluorocycloalkenes are transformed into perfluoroalkenes, -arenes, and condensation products. Thermolysis

of unsaturated compounds in the presence of difluorocarbene generators (difluorochloromethane, tetrafluoroethylene) furnishes high yields of fluorinated arenes which disproportionate and isomerize on heating. Homologs of perfluorinated arenes and heterocycles can be obtained by pyrolysis in the presence of difluorocarbene generators. [The Application of Thermolytic Reactions for the Syntheses of Fluoro-Organic Compounds. Synthesis *1976*, 374—384; 88 references]

[Rd 884 IE—M]

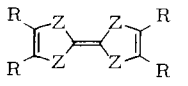
The synthesis of carbocyclic spiro compounds *via* rearrangement routes is reviewed by *A. P. Krapcho*. Acid-catalyzed reactions include, *inter alia*, pinacol rearrangements [*(1)*→*(2)*]; examples of thermal rearrangements are provided, *inter alia*, by the oxiranes [*(3)*→*(4)*] and alkenes. Spiro compounds



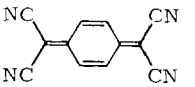
can also be obtained by photochemical excitation of cyclic cross-conjugated dienones and other compounds [*(5)*→*(6)*], as well as by other rearrangement processes such as reductions, solvolyses, and eliminations. [Synthesis of Carbocyclic Spiro Compounds *via* Rearrangement Routes. Synthesis *1976*, 425—444; 184 references]

[Rd 885 IE—M]

The synthesis of tetrathiafulvalenes *(1)* and tetraselenafulvalenes *(2)* is dealt with in an article by *M. Narita* and *C. U. Pittmann, Jr.* Compounds *(1)* are prepared, *inter alia*, by deprotonation of 1,3-dithiolylium ions and desulfurization of 2-thioxo-1,3-dithiols with P^{III} compounds. Compounds *(2)* are obtained analogously from 2-selenoxo-1,3-diselenols. *(1)*



(1), Z = S
(2), Z = Se



(3)

and *(2)* are of interest, primarily because they react with tetracyanoquinodimethane *(3)* and other electron acceptors to give charge transfer complexes which behave electrically and optically like unidimensional metals at room temperature. [Preparation of Tetrathiafulvalenes (TTF) and their Selenium Analogs—Tetraselenafulvalenes (TSeF). Synthesis *1976*, 489—514; 91 references]

[Rd 886 IE—M]

Reactions on single-crystal surfaces forms the subject of a review by *G. A. Somorjai*. Catalytic and other reactions on solid surfaces can be truly understood only if the elementary steps of surface chemical reactions are known. It has proven useful to combine studies of surface structure and composition with kinetic studies of reaction rate and reaction path. In the studies described, freshly cleaved metal single-crystals were used. Their surface was investigated before and after the reaction. The gas or gas mixture was directed onto the crystal surface in the form of a molecular beam, whose scattering and composition could be monitored. [Reactions on Single-Crystal Surfaces. Acc. Chem. Res. *9*, 248—256 (1976); 42 references]

BOOK REVIEWS

The Theory of Molecular Spectroscopy. Vol. 1. The Quantum Mechanics and Group Theory of Vibrating and Rotating Molecules. By *C. J. H. Schutte*. North-Holland Publ. Co., Amsterdam 1976. 1st edit., 512 pp., numerous figs., bound, Hfl. 170.—/$ 67.95.

This work, planned for two volumes, is intended for scientists active in the field of rotational and rotation-vibrational spectroscopy and for interested advanced students.

The present first volume is divided into six chapters and an extensive appendix. In the first chapter (41 pages) a short section is provided that gives the mathematical basis essential for understanding subsequent parts of the book. Particular stress is laid on the treatment of linear vector space, on the theory of matrices, and on matrix representation of linear operators.

The second chapter (80 pages) contains a fundamental introduction to group theory and its applicability to molecular spectroscopy; two separate specialized sections of this chapter deal with the approaches to group-theoretical treatment of nonrigid molecules and with the prerequisites for application of group theory to the spectra of solids. The chapter is rounded off by three sections of the appendix that contain, *inter alia*, the character tables for 51 point groups, subgroups and supergroups, as well as correlation tables.

In the third chapter (66 pages) some quantum-mechanical principles are outlined: the subjects are not only the basic postulates and most important methods of calculation in quantum mechanics, but also details of harmonic and anharmonic oscillators, quantum mechanics of angular momentum, calculation of the hydrogen atom and the Pauli principle.

The fourth chapter (39 pages) is concerned with the exact, classical and quantum-mechanical Hamiltonian operator for vibrating and rotating molecules.

In the fifth chapter (73 pages) the Born-Oppenheimer approximation is presented for H_2^+ and the H_2 molecules. Further sections of this chapter deal with the matching experimental data and potential functions, with the quantum-mechanical virial theorem, and with theoretical approaches to the calculation of dipole moments and molecular polarizabilities.

The final chapter (81 pages) deals with the interaction of electromagnetic radiation and matter; semiclassical treatment of this problem is used to derive the selection rules for rotational and vibrational transitions in absorption spectra. The chapter concludes with a brief presentation of the theory of Raman spectroscopy.

Numerous textbooks are cited at the beginning of each chapter as a guide to further reading. A comprehensive index

facilitates the reader's search for individual problems. The chapters are well arranged as far as subject matter is concerned, but the WKB method that is mentioned several times in Chapter 5 really deserved a short introduction within the framework of the third chapter. A larger number of mathematical examples would enhance the value of the book.

Taken as a whole, this first volume can be regarded as successful because of its clear, easily readable, and concise presentation of the subject.

Rainer Moormann [NB 337 IE]

Kunststoff-Handbuch. Band 1, Grundlagen (Plastics Handbook. Vol. 1, Fundamentals). Edited by *R. Vieweg* and *D. Braun*. Carl Hanser Verlag, Munich-Vienna 1975. 1st Edit., xx, 1342 pp., 942 figs., 113 tables, linen, DM 595.—.

The eleven-volume Plastics Handbook is completed by the volume on "Fundamentals" that has now appeared[*]. Since the Handbook is intended to provide information on the possible uses of plastics not only for chemists and physicists but also for manufacturers, architects, electrical engineers, *etc.*, this "General" volume on the scientific and industrial basics of the plastics sector has long been anxiously awaited. Even though the editors emphasize that it was never their intention to provide a textbook of macromolecular chemistry and physics and of plastics technology, it must be recognized and noted that they have succeeded excellently in setting out, in clear and readily comprehensible form, the knowledge of fundamentals essential for the volumes on individual topics.

The basic principles of the chemistry and then the physics of plastics are treated in well-devised and clear sections, with much space devoted to measurements and test procedures. Particular mention may be made of a chapter in which the properties of plastics are compared with those of other materials. A further section treats the principles of plastics processing, *e.g.* their forming, joining, separation, and improvement, including the principles of mold construction and the various equipment for injection molding, extrusion presses, and blowers.

Finally, separate chapters deal with the principles of plastics standardization from a national and an international standpoint, with the economics of plastics and relevant statistics, and with organizations and research institutes.

Understanding of the specialist volumes will be found easier and deeper if the reader also consults the corresponding chapter in the "General" volume. It is a remarkable achievement to have coordinated the contributions of many authors into a compilation that can be understood even by the non-expert. For all those interested in a deeper insight the rich reference list at the end of each chapter provides a sufficient introduction into the original literature.

With this volume the Plastics Handbook receives its accolade as a complete work, for the good reviews, the instructive illustrations, and the good subject index simplify its use by all those interested in plastics. With this work, which has no equal in the world literature, the editors and the publisher have done a great service to the plastics sector. Both the "General" volume and the complete work can be recommended without any reservations as of great use to all who develop, manufacture, or use plastics.

Subnuclear Components. Preparation and Fractionation. Edited by *G. D. Birnie*. Butterworths, London 1976. 1st edit., 334 pp., numerous figs. and tables, bound, £ 15.00.

Following the successful introduction of "Subcellular Components" the appearance of "Subnuclear Components" provides another highly practical book from the same editor. *G. D. Birnie* has succeeded, together with a renowned group of research-experienced collaborators, in selecting and testing critically a large number of published methods for the isolation and fractionation of eukaryotic cell nuclei.

The individual sections provide, in clear arrangement, a wealth of experimental detail about the isolation of cell nuclei, cell membranes, nucleoli, chromatin, histones, non-histone proteins, and nuclear RNA and DNA. The advantages and disadvantages of the methods for special applications and difficulties arising therein are discussed in detail; criteria are announced that can be brought in to assess the chemical and biological quality of the preparations.

Analytical procedures for the characterization of the isolated structures or molecules naturally take up a large space in each chapter. Besides the electron-optical techniques and conventional methods such as the determination of enzyme activities or the amino-acid composition of proteins, less known methods are described, such as isopyknic centrifuging in metrizamide gradients or the isoelectric focussing of non-histone proteins.

It is made clear, particularly in the chapter on the isolation of chromatin, that experimental results obtained in the fractionation of the cell nucleus depend largely on the conditions used during the preparation and must be interpreted accordingly. It is thus very important that the reader obtains not only an introduction to the choice of methods for his own research but also indications on how to evaluate published data.

Catalyzed Addition of Aldehydes to Activated Double Bonds —A New Synthetic Approach

New synthetic methods (17)

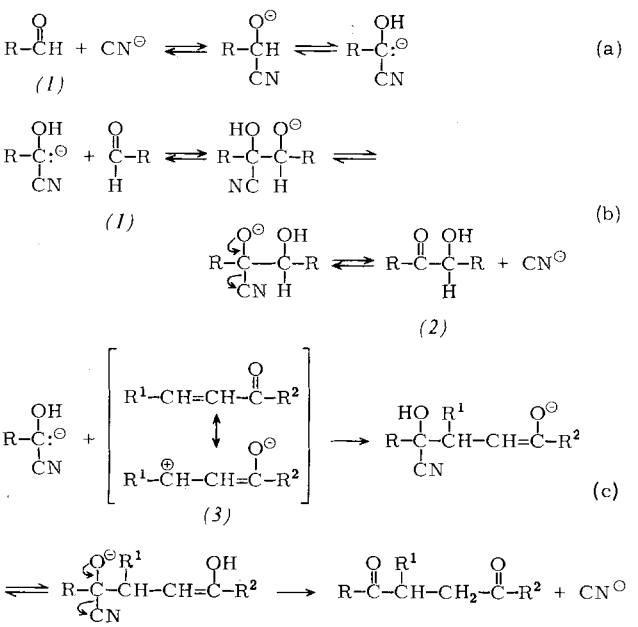
By Hermann Stetter[*]

In the presence of cyanide ions as catalyst, aromatic and heterocyclic aldehydes can be smoothly added to α,β-unsaturated ketones, esters, and nitriles in aprotic solvents to form γ-diketones, 4-oxo carboxylic esters, and 4-oxo nitriles. Thiazolium salts in the presence of bases are also suitable catalysts; they permit not only addition of aromatic and heterocyclic aldehydes but also the addition of aliphatic aldehydes.

1. General

One of the longest known reactions of organic chemistry is the benzoin condensation, in which aromatic and heterocyclic aldehydes *(1)* are transformed into acyloins (α-hydroxy ketones) *(2)*. Cyanide ions serve as catalysts. The reaction is reversible, and dependent upon the formation of a carbanion stabilized by the nitrile group. We found that this carbanion can be added to the double bond of α,β-unsaturated ketones, esters, and nitriles; an irreversible reaction then occurs to give γ-diketones, 4-oxo carboxylic esters, and 4-oxo nitriles[1].

The mechanism is formulated for the addition of aldehydes *(1)* to α,β-unsaturated carbonyl compounds *(3)*. Formation of benzoin *(2)* is reversible and kinetically controlled [eq. (a) to (c)].



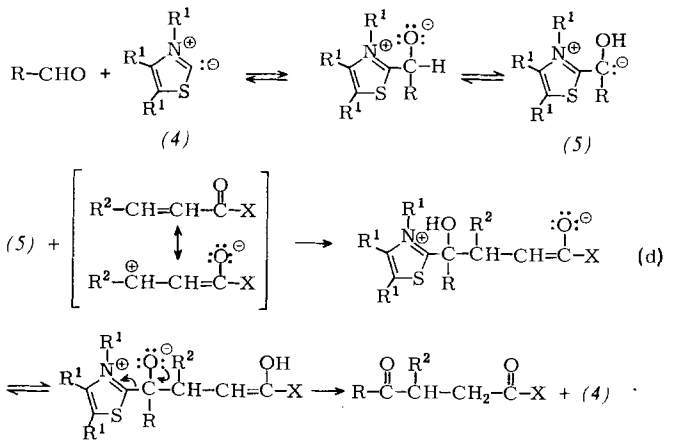
It is essential that the reaction be carried out in aprotic solvents, general preference being given to dimethylformamide. Being a fast reversible reaction, benzoin formation [eq. (b)] precedes addition [eq. (c)]. Thus use of the respective benzoin instead of the aldehyde gives the same products. Between 0.1 and 0.5 equivalent of sodium or potassium cyanide serves as catalyst. The reaction time is generally 1 to 4 h at *ca.* 35 °C. Attempted reaction fails with aliphatic aldehydes because they preferentially undergo aldol condensation under the influence of the strongly alkaline cyanide salts. Addition of aliphatic aldehydes has been accomplished by the following route:

It is known from biochemistry that vitamin B_1 (thiamine) can convert aliphatic aldehydes into acyloins in buffered

[*] Professor Dr. H. Stetter
Institut für Organische Chemie der Technischen Hochschule
Prof.-Pirlet-Strasse 1, D-5100 Aachen (Germany)

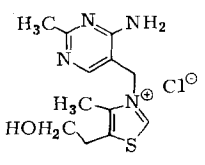
aqueous solutions[2]. The catalytic activity is associated with the thiazolium component of the vitamin. In the presence of bases, quaternary thiazolium salts are transformed into the ylide structure *(4)*, the ylide being able to exert a catalytic effect resembling that of the cyanide ion in benzoin condensation.

It is also known that thiazolium salts can in general assume this catalytic function. And similar observations have also been made with other azolium salts, *e.g.* benzimidazolium salts and benzo- and naphtho[2,1-*d*]thiazolium salts[2, 3]. We have successfully employed thiazolium salts in the presence of bases as catalysts for addition of aliphatic, and also aromatic and heterocyclic, aldehydes to α,β-unsaturated ketones, esters, and nitriles. Reactions yields γ-diketones, 4-oxo carboxylic esters, and 4-oxo nitriles, respectively [eq. (d)][4].

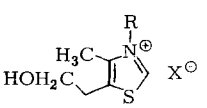


(d)

Extensive studies on quaternary thiazolium salts, *e.g.* 1,3-thiazole, 4,5-dimethyl-1,3-thiazole, and poly-4-methyl-5-vinyl-1,3-thiazole, and corresponding salts of other heterocycles, *e.g.* 1-methylbenzimidazole and 4-*p*-chlorophenyl-1,2,4-triazole demonstrated catalytic activity in nearly all the salts tested. However, since there seems to be no decisive advantage over the use of quaternary salts of 5-(2-hydroxyethyl)-4-methyl-1,3-thiazole only salts of this inexpensive, commercially available thiazole [Merck AG, Darmstadt (Germany)] were used. With aliphatic aldehydes, *N*-benzylated salts such as 3-benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium chloride (Cat. 1) proved most suitable, while aromatic aldehydes responded best to *N*-alkylated salts such as 3-ethyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium bromide (Cat. 2) or 5-(2-hydroxyethyl)-3,4-dimethylthiazolium iodide (Cat. 3)[20]. Both kinds of catalyst were suitable for heterocyclic aldehydes. (Tested procedures for making the catalysts are to be found at the end of this article.)



Thiamine



Cat. 1, R = $C_6H_5CH_2$, X = Cl
Cat. 2, R = C_2H_5, X = Br
Cat. 3, R = CH_3, X = I

The most suitable bases are triethylamine and sodium acetate. The amount of catalyst is usually 0.1 equivalent but can be reduced to 0.05 equivalent. Both protic solvents like alcohol and aprotic ones like dimethylformamide and dioxane may be considered. Working without solvent also has its advantages in many cases. Under nitrogen, reaction times of 6 to 15 h and temperatures of 60 to 80 °C are necessary. As in the case of cyanide catalysis, the benzoins can be used instead of the aromatic and heterocyclic aldehydes, since benzoin formation is once again the initial kinetically controlled reaction. Aliphatic aldehydes could not be replaced by the acyloins.

2. Production of γ-Diketones

2.1. By Addition of Aliphatic Aldehydes to α,β-Unsaturated Ketones

As already mentioned, the addition of aliphatic aldehydes to α,β-unsaturated ketones can only proceed on catalysis by azolium salts. The examples listed in Table 1 were carried out exclusively with Cat. 1. A large number of aliphatic aldehydes could be converted into γ-diketones by reaction with aliphatic, aromatic, and heterocyclic α,β-unsaturated ketones. Working without solvent was frequently advantageous.

Table 1. γ-Diketones from aliphatic aldehydes and α,β-unsaturated ketones. Catalyst: Cat. 1.

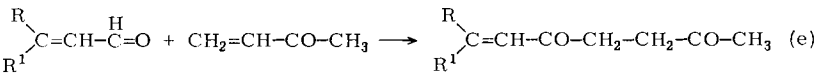
Unsaturated and substituted aliphatic aldehydes can be used with equal success in the reaction. α,β-Unsaturated aldehydes could be transformed in satisfactory yields only on working in solvents. The hardly known δ,ε-unsaturated γ-diketones are obtained as products [eq. (e)].

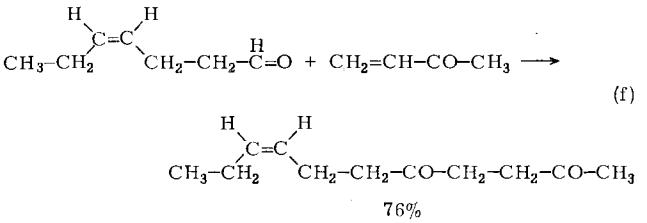
If the double bond is not conjugated with a carbonyl group then the addition can also be performed without solvent, as illustrated by the example of the preparation of *cis*-8-undecene-2,5-dione from *cis*-4-heptenal and butenone [eq. (f)][5].



(e)

$R = C_6H_5$, $R^1 = H$: 58%[7] $R = R^1 = C_6H_5$: 77%[7]

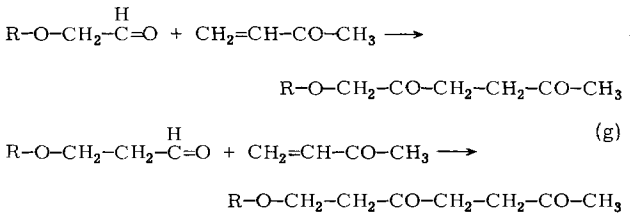
$R = R^1 = CH_3$: 52%[10] $R = (CH_3)_2C{=}CH{-}CH_2{-}CH_2$, $R^1 = CH_3$: 65%[11]



(f)

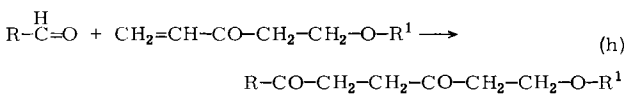
76%

A smooth reaction is also observed with aldehydes containing ether groups. Both ethers of glycolaldehyde and β-alkoxypropionaldehydes have been added to butenone. The δ-[12] and ε-alkoxy γ-diketones[10] could be obtained in 50—70% yield according to eq. (g).



(g)

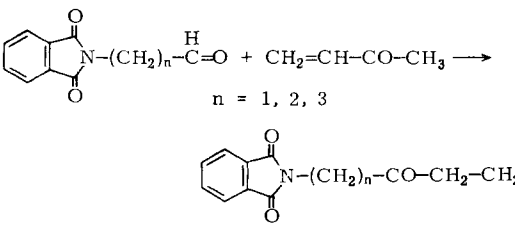
γ-Diketones containing ether groups are also obtained by addition of aldehydes to vinyl ketones bearing ether groups.



(h)

The addition of numerous aliphatic aldehydes according to eq. (h) has been accomplished in yields ranging around 80%[13].

Recent studies have shown that phthalimidoaldehydes can be added to butenone in yields of 66—75% [eq. (i)][14].



(i)

In the last-mentioned examples butenone was most commonly employed as unsaturated ketone. All the reactions can be performed with other unsaturated ketones, *e.g.* ethyl vinyl ketones, benzylideneacetone, and benzylideneacetophenone.

2.2. By Addition of Aromatic Aldehydes to α,β-Unsaturated Ketones

The most suitable technique for addition of aromatic aldehydes to α,β-unsaturated ketones utilizes cyanide catalysis in dimethylformamide as solvent. In practice, however, all the additions can also be accomplished with thiazolium salts as catalysts, preferably Cat. 2. Both unsubstituted aromatic aldehydes and those bearing substituents in the ring can add to aliphatic, aromatic, and heterocyclic α,β-unsaturated

Table 2. γ-Diketones from aromatic aldehydes and α,β-unsaturated ketones.

(j)

ketones. *ortho*-Substituted benzaldehydes, which do not react on cyanide catalysis, represent an exception. In such cases satisfactory results are obtained on catalysis with thiazolium salts if vinyl ketones are co-reactants. For example, thiazolium salt-catalyzed reaction of 2-chlorobenzaldehyde with butenone affords the adduct in 56 % yield, while no reaction is observed on cyanide catalyst [eq. (j)][11].

Catalysis by thiazolium salts also gives better results with alkoxy aldehydes, whereas cyanide catalysis frequently fails (Table 2).

2.3. By Addition of Heterocyclic Aldehydes to α,β-Unsaturated Ketones

As with aromatic aldehydes, addition of heterocyclic aldehydes can be catalyzed by cyanide or thiazolium salt (Table 3). Cyanide catalysis is generally preferable; however, in some cases satisfactory results are obtained only on catalysis with thiazolium salts. Thus 2-pyridinecarbaldehyde still undergoes smooth addition to benzylideneacetophenone on cyanide catalysis, but good results are obtained only on thiazolium salt catalysis with other unsaturated ketones such as butenone. The reason probably lies in the specific structure of 2-pyridoin, which is stabilized by hydrogen bonding and therefore hinders the reverse reaction required on cyanide catalysis [cf. eq. (b)].

With furfural too, thiazolium salt catalysis can often be advantageous since the reaction products are obtained directly in high purity whereas formation of resinous products can interfere with work-up in the case of cyanide catalysis (Table 3).

Table 3. γ-Diketones from heterocyclic aldehydes and α,β-unsaturated ketones.

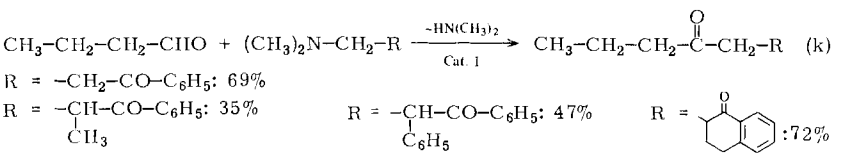
2.4. By Addition of Aldehydes with Application of Mannich Bases

In the Michael addition, Mannich bases can often be used in place of α,β-unsaturated ketones. The reaction then proceeds *via* an elimination-addition mechanism. We found that the α,β-unsaturated ketones can also be replaced by Mannich bases in the catalyzed addition of aldehydes. The aliphatic aldehydes could react with Mannich bases on catalysis with thiazolium salts. The best results were obtained on working in dimethylformamide at 80 to 90 °C. Examples are shown in eq. (k)[19].



(k)

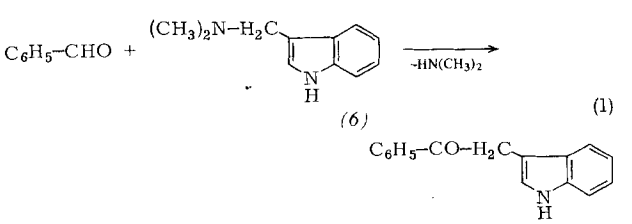
Aromatic and heterocyclic aldehydes can also be cleanly added to Mannich bases in cyanide-catalyzed reaction to give γ-diketones on working at 35 to 100 °C in dimethylformamide. Table 4 surveys the reactions with benzaldehyde.

Table 4. γ-Diketones from benzaldehyde and Mannich bases [19].

$C_6H_5-CHO + (CH_3)_2N-CH_2-CHR^1-CO-R^2 \longrightarrow C_6H_5-CO-CH_2-CHR^1-CO-R^2$

R^1	R^2	T [°C]	Yield [%]
H	CH_3	40	47
H	i-C_3H_7	70	60
$-(CH_2)_4-$		40	10
H	C_6H_5	35	64
CH_3	C_6H_5	100	49
C_6H_5	C_6H_5	40	58
		40	63

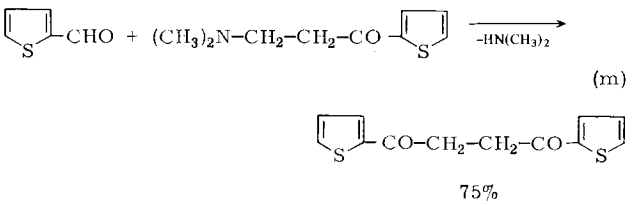
The alkaloid gramin *(6)*, which is readily accessible by Mannich reaction from indole, formaldehyde, and dimethylamine, also reacts with benzaldehyde in the presence of a cyanide catalyst to give a 52 % yield of ω-(3-indolyl)acetophenone [eq. (l)][19].



(l)

Examples for the use of heterocyclic aldehydes are the reactions of 3-pyridinecarbaldehyde with 3-dimethylamino-1-

phenyl-1-propanone[18] (35%), of furfural with 3-dimethylamino-1-(2-furyl)-1-propanone[4], and of 2-thiophenecarbaldehyde with 3-dimethylamino-1-(2-thienyl)-1-propanone [eq. (m)][17].



(m)

75%

Particular interest attaches to the use of Mannich bases of unsaturated ketones, which leads to unsaturated γ-diketones of the same type as are obtained on addition of α,β-unsaturated aldehydes when catalyzed by thiazolium salts [see eq. (e)]. In some cases it proved necessary to use the methylammonium iodide instead of the simple Mannich base (Table 5).

Table 5. γ-Diketones from aldehydes and Mannich bases. Catalyst: thiazolium salts [19].

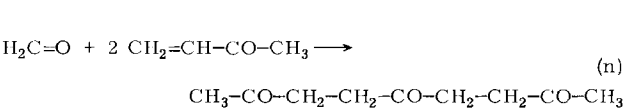
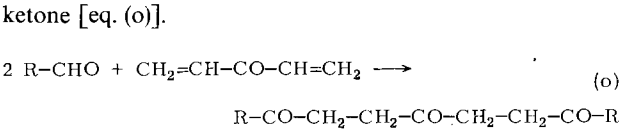
3. Preparation of Tri- and Polyketones

Addition of formaldehyde to butenone catalyzed by thiazolium salts gives 2,5,8-nonanetrione in 27% yield[7, 8].



(n)

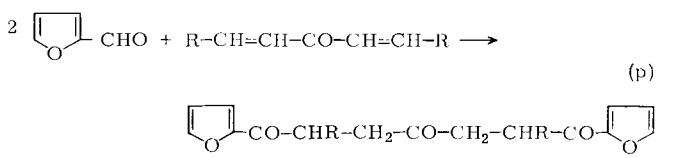
Such 1,4,7-triketones can be obtained much more readily by thiazolium salt-catalyzed addition of aldehydes to divinyl ketone [eq. (o)].



(o)

With aliphatic aldehydes the best results are achieved on working without solvent, whereas working in dimethylformamide is preferred with aromatic and heterocyclic aldehydes. The following aldehydes were transformed by divinyl ketone into the triketones[20]: acetaldehyde (70% yield), propanal (60%), *n*-butanal (65%), *i*-butanal (62%), *n*-pentanal (62%), *n*-hexanal (65%), *n*-heptanal (64%), *n*-octanal (66%), *n*-decanol (63%), benzaldehyde (55%), *p*-chlorobenzaldehyde (60%), *p*-methoxybenzaldehyde (30%), furfural (50%), and 2-thiophenecarbaldehyde (51%).

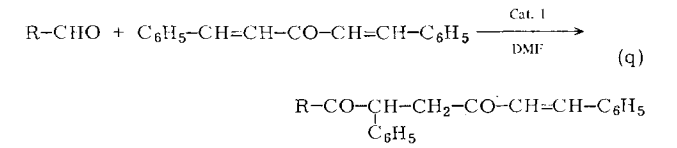
Furfural could be smoothly added to dibenzylideneacetone and difurfurylideneacetone, giving the triketones [eq. (p)][20].



(p)

R = C_6H_5: 54%; R = 2-Furyl: 44%

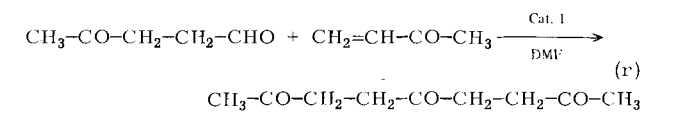
Interestingly, the addition of aliphatic aldehydes could only be accomplished in the ratio 1:1 [eq. (q)], the products being unsaturated γ-diketones[20].



(q)

R = CH_3: 85%; R = C_2H_5: 72%; R = n-C_4H_9: 65%

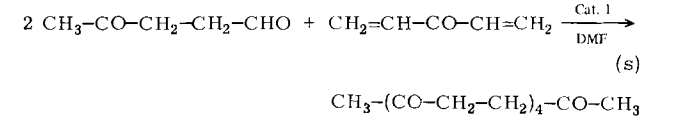
The addition of levulinaldehyde to α,β-unsaturated ketones leads according to eq. (r) to 1,4,7-triketones[20].



(r)

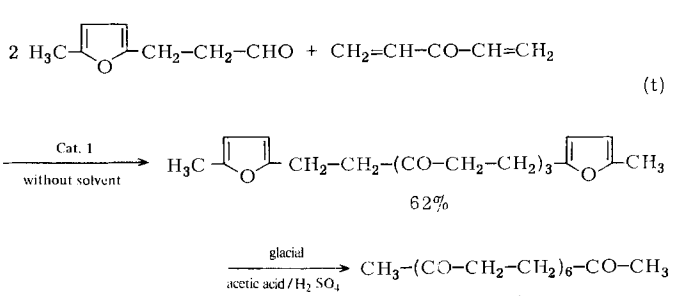
60%

If 2 mol of levulinaldehyde is allowed to act upon 1 mol of divinyl ketone then 2,5,8,11,14-pentadecanepentone is obtained in 40% yield [eq. (s)][20].



(s)

In one case a heptaketone, 2,5,8,11,14,17,20-heneicosaneheptone, could be obtained according to eq. (t). The preparation consisted in addition of 3-(5-methyl-2-furyl)propanal to divinyl ketone in the ratio 2:1 followed by hydrolysis of the adduct[20].

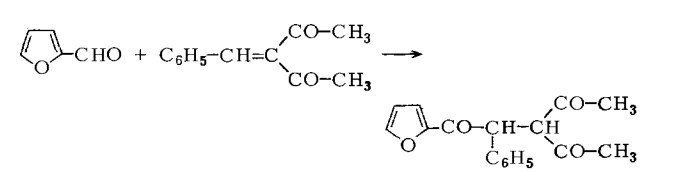


(t)

62%

70%

The thiazolium salt-catalyzed addition of aldehydes to alkylidene- or arylidene-β-diketones leads to branched triketones. Thus, for example, addition of furfural to benzylideneacetylace-



tone in ethanol as solvent affords 3-acetyl-1-(2-furyl)-2-phenylpentane-1,4-dione in 63% yield[20a].

A pathway to tetraketones leads *via* addition of dialdehydes to α,β-unsaturated ketones. Addition occurs only on catalysis with thiazolium salts, both for aliphatic and for aromatic and heterocyclic aldehydes. The yields of tetraketones generally remain below 50% (Table 6).

Table 6. Tetraketones from dialdehydes and butenone [20].

$$OHC\text{-}X\text{-}CHO + 2\ CH_2{=}CH\text{-}CO\text{-}CH_3 \longrightarrow CH_3\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}X\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}CH_3$$

p-C_6H_4	Cat. 3	Ethanol	29

4. Production of Dioxo Carboxylic Esters

Succinaldehydic methyl ester could be added to a series of vinyl ketones according to eq. (u), giving 4,7-dioxo carboxylic ester[21].

$$CH_3OOC\text{-}CH_2\text{-}CH_2\text{-}CHO + CH_2{=}CH\text{-}CO\text{-}R \xrightarrow[\text{Dioxane}]{\text{Cat. 1}} CH_3OOC\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}R \quad (u)$$

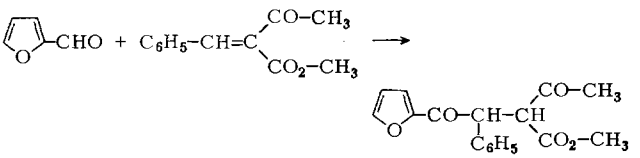
R = *n*-Pentyl: 64%; R = *n*-Hexyl: 69%; R = *n*-Heptyl: 71%; R = *n*-Octyl: 69%

Esters of this type are also obtained by adding aldehydes according to eq. (v) under the same conditions to methyl 4-oxohexenoate[22].

$$R\text{-}CHO + CH_2{=}CH\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}COOCH_3 \longrightarrow R\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}COOCH_3 \quad (v)$$

R = Ethyl: 50%; R = *n*-Propyl: 52%; R = *n*-Butyl: 61%; R = *n*-Pentyl: 57%; R = *n*-Hexyl: 55%; R = *n*-Heptyl: 54%

Branched diketo carboxylic esters are obtained by thiazolium salt-catalyzed addition of aldehyde to alkylidene- or arylidene-β-keto carboxylic esters. Thus addition of furfural to the methyl ester of benzylideneacetoacetic acid in dioxane as solvent yields 1-(2-furyl)-3-methoxycarbonyl-2-phenylpentane-1,4-dione in 75% yield[20a].



5. Production of 4-Oxo Nitriles

Aromatic and heterocyclic aldehydes can be added extremely smoothly to α,β-unsaturated nitriles if the reaction is subjected to cyanide catalysis; high yields of 4-oxo nitriles are obtained [eq. (a) and (w)].

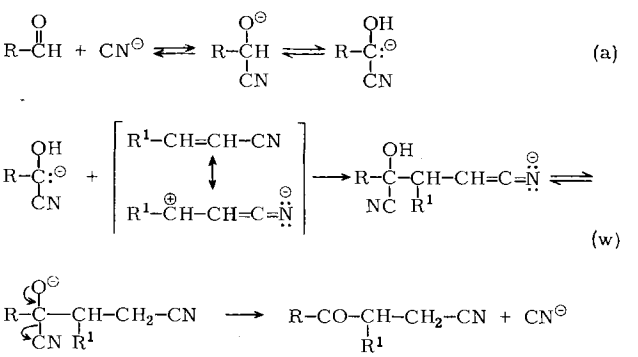


Table 7. 4-Oxo nitriles from aldehydes and α,β-unsaturated nitriles.

$$R\text{-}CHO + R^1\text{-}CH{=}CR^2\text{-}CN \longrightarrow R\text{-}CO\text{-}CHR^1\text{-}CHR^2\text{-}CN$$

Dimethylformamide was found to be the best solvent. Sodium cyanide is required in amounts between 0.1 and 0.5 mol per mol of aldehyde. Aliphatic aldehydes can only be added to α,β-unsaturated nitriles on catalysis by thiazolium salts; aromatic and heterocyclic aldehyde also reacts under those conditions. In contrast to cyanide catalysis, however, satisfactory results are obtained only with acrylonitrile (Table 7).

Dialdehydes such as 2,5-thiophenedicarbaldehyde can also be added to acrylonitrile in the presence of cyanide ions [eq. (x)][17].

41%

6. Production of 4-Oxo Carboxylic Esters

In the presence of cyanide ions as catalyst, aromatic and heterocyclic aldehydes add to α,β-unsaturated carboxylic esters, forming 4-oxo carboxylic esters. The most suitable solvent is dimethylformamide, and the amount of catalyst is generally 0.1—0.5 equivalent. High-boiling oils which were not further characterized appeared as by-products. They are probably esters of acyloins also present in equilibrium. It is known that cyanide ions are excellent transesterification catalysts.

This transesterification can be suppressed by variation of the ester component. The yields admittedly increase on going from the methyl, *via* the ethyl and the isopropyl, to the *tert*-butyl esters; however, even on use of *tert*-butyl esters it was not possible to completely avoid side reactions. Overall, the cyanide-catalyzed addition of aldehydes to α,β-unsaturated esters is less favorable than the corresponding additions to α,β-unsaturated nitriles and ketones.

Both aliphatic and heterocyclic aldehydes undergo thiazolium-catalyzed addition to acrylic esters; however, the yields are not entirely satisfactory (Table 8).

Table 8. γ-Oxo carboxylic esters from aldehydes and α,β-unsaturated esters.

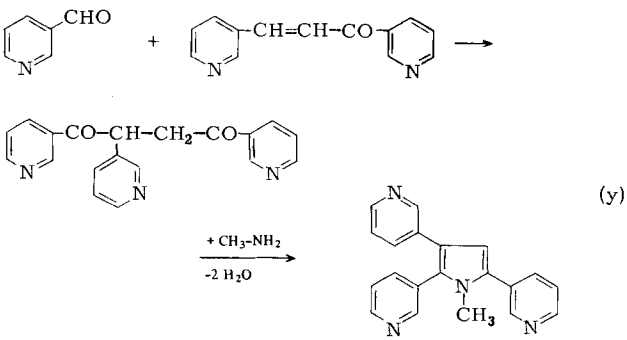
7. Significance of the New Synthetic Approach

The synthetic approach described in this article is characterized by exceptional versatility, simplicity of operation, and high yields. The procedure is superior to most reactions for the synthesis of γ-diketones, 4-oxo nitriles, and 4-oxo carboxylic esters by virtue of its purely catalytic nature. The compounds produced are highly important intermediates of synthetic organic chemistry.

Starting from γ-diketones, it is very easy to prepare furans, pyrroles, thiophenes, and pyridazines. Most of the newly prepared diketones were characterized as the *N*-phenylpyrroles.

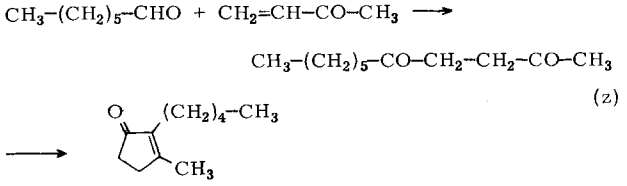
The versatility of this simple procedure can be illustrated for the synthesis of *N*-methyl-2,3,5-tri(3-pyridyl)pyrrole[9] [eq. (y)].



(y)

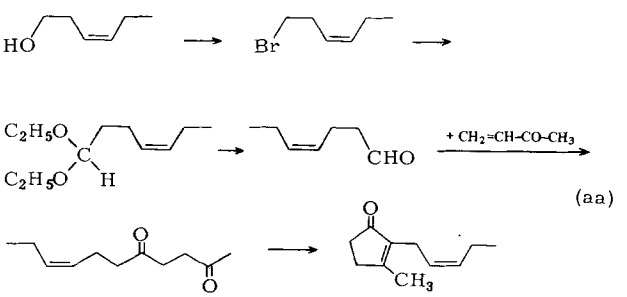
The possibility of obtained derivatives of cyclopentenone starting from γ-diketones by cyclizing aldol condensation is of particular interest. Many of the γ-diketones obtained were converted into cyclopentenones. Since numerous natural products, such as jasmine odors, prostaglandins, and pyrethrolone contain the cyclopentenone ring as structural unit, or can be derived therefrom, the reaction becomes particularly important.

In order to prepare the odiferous substance dihydrojasmone, 2,5-undecanedione [accessible in 80% yield by addition of *n*-heptanal to butenone] was subjected to cyclizing aldol condensation [eq. (z)][5].



(z)

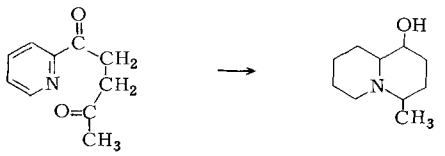
cis-Jasmone, which is also an odiferous substance, was produced according to eq. (aa) from *cis*-3-hexen-1-ol (leaf alcohol), which was converted into 1-bromo-*cis*-3-hexene and its Grignard compound. On treatment with diethyl phenylorthoformate the Grignard compound gave 7,7-diethoxy-*cis*-3-hep-



(aa)

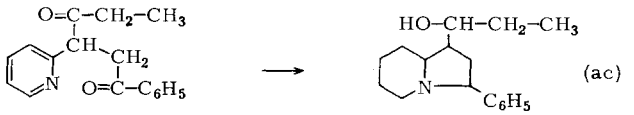
tene which could be converted into *cis*-4-heptenal with formic acid. The *cis*-8-undecene-2,5-dione resulting from addition of butenone furnished natural *cis*-jasmone by cyclizing aldol condensation[5]. The key step is addition of the aldehyde which can also be prepared by another pathway.

The γ-diketones readily accessible by addition of 2-pyridinecarbaldehyde to α,β-unsaturated ketones open up a facile entry to quinolizidines. Thus 4-methyl-1-quinolizidinol could be prepared in 75 % yield from 1-(2-pyridyl)-1,4-pentanedione by hydrogenation with platinum oxide in glacial acetic acid[9].



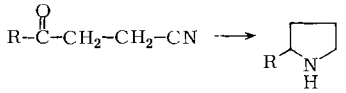
(ab)

Analogous hydrogenation of 1-phenyl-3-(2-pyridyl)-1,4-hexanedione likewise accessible *via* our reaction, which gives 1-(3-phenyl-1-indolizidinyl)-1-propanol according to eq. (ac) in 87 % yield[9], leads into the indolizidine series.



(ac)

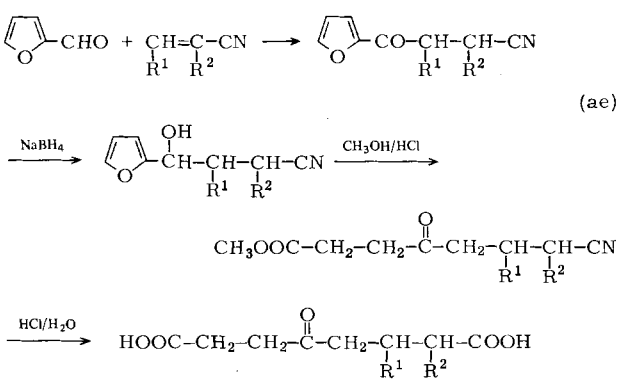
Numerous 4-oxo nitriles and their reaction products are also accessible by the aldehyde addition described. Catalytic hydrogenation to give pyrrolidines [eq. (ad)] is an important reaction.



(ad)

Among the numerous ring closures[29], special mention should be made of the facile nicotine synthesis utilizing the 4-oxo nitrile readily obtained in 80 % yield by addition of 3-pyridinecarbaldehyde to acrylonitrile[30].

The 4-oxo nitriles easily produced by addition of furfural to α,β-unsaturated nitriles according to eq. (ae) can be reduced by sodium tetrahydridoborate to form 4-hydroxy nitriles, which can be converted by Marckwald cleavage and hydrolysis into 4-oxooctanedioic acids. It is not necessary to isolate the intermediates[27].

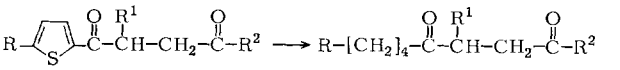


(ae)

$R^1 = R^2 = H$; $R^1 = CH_3$, $R^2 = H$; $R^1 = H$, $R^2 = CH_3$; $R^1 = C_6H_5$, $R^2 = H$

The γ-diketones and 4-oxo nitriles readily accessible by addition of thiophenecarbaldehydes could be converted by desulfurizing ring cleavage into aliphatic γ-diketones and 4-oxo carboxylic acids. The best results were obtained on desulfuration by Raney nickel in ethyl methyl ketone (Table 9)[17].

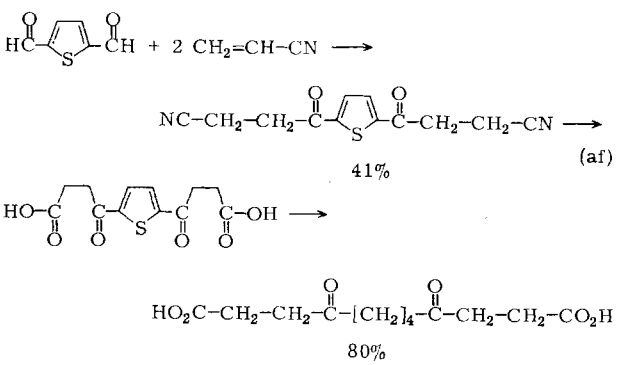
Table 9. γ-Diketones and 4-oxo carboxylic acids from thiophene derivatives [17].



R	R^1	R^2	Yield [%]
H	H	CH_3	60
H	C_6H_5	CH_3	77
H	C_6H_5	C_6H_5	75
H	C_6H_5	2-Thienyl [a]	58
H	H	2-Thienyl [a]	51
H	H	OH	77
H	CH_3	OH	83
H	C_6H_5	OH	78
CH_3	H	OH	79

[a] After reaction $R^2 = n$-butyl.

4,9-Dioxododecanedioic acid was prepared from 2,5-thiophenedicarbaldehyde according to eq. (af) [see eq. (x)][17].



(af)

The brief selection of examples presented above should provide an indication of the suitability of the compounds obtained as starting materials for other reactions. However, in view of the sheer volume of possibilities all such indications can only remain fragmentary.

8. Experimental

3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium chloride (Cat. 1)[5]

5-(2-Hydroxyethyl)-4-methyl-1,3-thiazole (143.2 g, 1 mol; commercial product, *ex.* Merck AG, Darmstadt), freshly distilled benzyl chloride (126.6 g, 1 mol), and dry acetonitrile (500 ml) are mixed together in a 1000-ml three-necked flask fitted with a stirrer, a reflux condenser, and a stopper. The mixture is heated for 24 h under reflux and then allowed to cool to room temperature with constant stirring. (The product precipitates from the boiling solution on seeding after 12 h.) The product is isolated by vacuum filtration, washed colorless, subjected to preliminary drying, and then dried with gentle turning in a water-pump vacuum (bath temperature 90 °C). Yield 220.8 g (82%), m.p. 140–140.5 °C.

3-Ethyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium bromide (Cat. 2)[6]

5-(2-Hydroxyethyl)-4-methyl-1,3-thiazole (143.2 g, 1 mol), bromoethane (109.0 g, 1 mol), and dry acetonitrile (500 ml) are mixed in a 1000-ml round-bottom flask with a reflux condenser (potassium hydroxide drying tube) and heated under reflux for 24 h. After cooling, the acetonitrile is removed and the residue treated with isopropyl alcohol (200 ml). Ether is then added until the solution retains a very slight turbidity and then seeded or rubbed. After crystallization is complete the precipitate is filtered off under suction, washed

with ether, and the ether-moist product dried in a water-pump vacuum. The product is hygroscopic. Yield 192.2 g (76%), m.p. 85.0–86.5 °C.

2,5-Undecanedione[5]

Heptanal (57.1 g, 0.5 mol), butenone (35.1 g, 0.5 mol), and Cat. 1 (13.5 g, 0.05 mol) are united in a 250-ml three-necked flask fitted with stirrer, reflux condenser (with drying tube), dropping funnel, and gas entry tube. Triethylamine (30.3 g, 0.3 mol) is rapidly added from the dropping funnel; the mixture is stirred with heating under nitrogen for 8 h. Work-up is by pouring into 1% sulfuric acid (500 ml), thorough shaking, and extraction with chloroform (4 × 100 ml). The chloroform phase is washed with water, sodium hydrogen carbonate solution, and once again with water. After removal of chloroform the mixture is distilled over a 30-cm Vigreux column. Yield 71.8 g (78%), b.p. 128 °C/8 torr, m.p. 33–34 °C (from pentane, −18 °C).

If the reaction is performed in ethanol (500 ml) with the same quantities of starting materials then 12 hours' refluxing are required. After removal of the ethanol by distillation, the mixture is worked up in the same way; yield *ca.* 72%.

1-Phenyl-1,4-pentanedione[15]

A solution of freshly distilled benzaldehyde (10.6 g, 100 mmol) and anhydrous DMF (50 ml) is added dropwise within 10 min to a stirred mixture of sodium cyanide (0.49 g, 10 mmol) and DMF (50 ml) at 35 °C. After 5 minutes' stirring, a solution of freshly distilled methyl vinyl ketone (5.3 g, 75 mmol) in DMF (100 ml) is added at 35 °C over 20 min. Stirring is continued for 1 h at the same temperature and the reaction mixture then treated with twice the amount of water. After repeated extraction with chloroform the combined extracts are washed with dilute hydrochloric acid (pH 2), then with sodium hydrogen carbonate solution, and finally with water. After removal of solvent, the residue is vacuum distilled. Yield 10.8 g (82%), b.p. 93–94 °C/0.1 torr, m.p. 28–29 °C (from isopropyl alcohol).

2,4-Di(2-furyl)-1-phenyl-1,4-butanedione[9]

Benzaldehyde (6.9 g, 0.06 mol), 1,3-di(2-furyl)-2-propen-1-one (9.3 g, 0.05 mol), Cat. 2 (2.5 g, 0.01 mol), triethylamine (10.1 g, 0.1 mol), and dry ethanol (25 ml) are united in a 100-ml three-necked flask fitted with a stirrer, a gas tube, and a reflux condenser with a potassium hydroxide drying tube. The mixture is stirred for 15 h at 70 °C in a slow stream of nitrogen. After cooling the volatile components are distilled off in a water-pump vacuum. The residue is taken in water (200 ml) and dilute H_2SO_4 (25 ml), thoroughly shaken, and extracted several times with $CHCl_3$. The combined organic phases are washed with sodium hydrogen carbonate solution and a little water and then dried with $MgSO_4$. After filtration the solvent is distilled off and the residue recrystallized from isopropyl alcohol. Yield 12.0 g (82%), m.p. 79–80 °C.

1-Oxo-2-(2-oxopentyl)tetralin[19]

2-(Dimethylaminomethyl)-1-oxotetralin (40.4 g, 0.2 mol), Cat. 1 (10.78 g, 0.04 mol), and anhydrous DMF (200 ml) are transferred into 500-ml three-necked flask fitted with a stirrer, reflux condenser with drying tube (KOH), and a pressure-equalizing dropping funnel with nitrogen entry tube. After warming to 80–90 °C, triethylamine (16.2 g, 0.16 mol) is added; butyraldehyde (28.84 g, 0.4 mol) is subsequently added dropwise over 1.5 h. The reaction mixture is stirred for another 2 h. The solvent is then distilled off and the oily residue added to water (500 ml). The aqueous phase is acidified with dilute hydrochloric acid and extracted with ether (4 × 100 ml). The combined ether extracts are neutralized with dilute $NaHCO_3$ solution, washed with water, and then dried over Na_2SO_4. Removal of ether is followed by vacuum distillation of the residue. Yield 32.8 g (72%), b.p. 134 °C/0.2 torr.

1,4-Di(2-thienyl)-1,4-butanedione[17]

A solution of freshly distilled 2-thiophenecarbaldehyde (14 g, 125 mmol) in anhydrous DMF (40 ml) is added to a mixture of sodium cyanide (10 mmol) and DMF (40 ml). After addition of 3-dimethylamino-1-(2-thienyl)-1-propanone (18.3 g, 100 mmol; from 22.5 g of hydrochloride) in DMF (100 ml), stirring is continued for another 2 h prior to addition of twice the amount of water. After repeated extraction with chloroform the combined extracts are washed neutral. The solvent is distilled off and the residue recrystallized from ethanol. Yield 18.8 g (75%), m.p. 130–131 °C.

5,8,11-Pentadecanetrione[20]

Cat. 1 (7 g, 0.025 mol), triethylamine (30 g, 0.3 mol), divinyl ketone (11 g, 0.135 mol), and pentanal (26.4 g, 0.30) are successively introduced into a 250-ml three-necked flask fitted with a reflux condenser carrying a KOH drying tube, a stirrer, and a gas inlet tube. The mixture is heated under nitrogen up to an oil-bath temperature of 65 °C. After distilling off the triethylamine, the residue is dissolved in chloroform and the chloroform phase washed with sodium hydrogen carbonate and common salt solution. The aqueous phase is again extracted with chloroform and the combined chloroform phases concentrated *in vacuo*. The residue is recrystallized from methanol. Yield 20.5 g (62%), m.p. 84 °C.

4-Oxo-4-phenylbutyronitrile[24]

A solution of freshly distilled benzaldehyde (10.6 g, 0.1 mol) in anhydrous dimethylformamide (50 ml) is added over 10 min to a stirred mixture of sodium cyanide (2.45 g, 0.05 mol) and dimethylformamide (50 ml) at 35 °C. Stirring is continued for another 5 min and then freshly distilled acrylonitrile (4.0 g, 0.075 mol) in dimethylformamide (100 ml) is added dropwise over 20 min at 35 °C. The mixture is stirred for 3 h at the same temperature and then treated with twice the amount of water. After repeated extraction with chloroform the combined extracts are washed with dilute sulfuric acid (pH 2), then with sodium hydrogen carbonate solution, and finally with water. The solvent is removed and the residue vacuum distilled. Yield 9.5 g (80%), b.p. 114 °C/0.3 torr, m.p. 70 °C.

Molecular Complexes and Oxygen Adducts of Tetrapyrrole Pigments

By Jürgen-Hinrich Fuhrhop[*]

Metalloporphyrins not carrying functional groups and the π-radicals of these species form comparably stable coplanar π-π-dimers by means of various types of weak interactions. Chlorophyll a and other derivatives containing carbonyl groups add water and aggregate into molecular complexes by means of hydrogen bonds. Such aggregates are of special interest in connection with a new hypothesis for the photo-oxidation of water to oxygen during photosynthesis. Finally, some new discoveries concerning the structure and reactivity of heme-oxygen complexes are discussed.

"I think that a great field which we can call chemistry or can call molecular biology, if we want, in which there are possibilities of tremendous progress, is the field of the explanation of the highly specific weak interactions between molecules showing up in biological systems.

I think that the various phenomena of biological specificity are determined by the rather weak interactions between molecules ... the sitting together of two molecules over a considerable area so that the forces of attraction are summed up over this area into an effective bond between the molecules. Here we are pretty largely ignorant still. We don't know why it is for the most part ..., why one drug is physiologically active and another substance is not physiologically active. We may have some rather vague general ideas about why this takes place, but these need to be made specific. We need to get a penetrating and reliable theory of the weak interactions between molecules responsible for biological specificity and in general of the dependence of the physiological properties of substances on their molecular structure.

I consider this a branch of chemistry and I think that this is a field in which there should be tremendous progress during the next decade or two".

Extract from an interview with Prof. Linus Pauling (Men and Molecules, the unique ACS radio series No. 366, "The Committed Scientist", around 1970).

1. Introduction

Linus Pauling's answer to the question on further development of chemistry opens up the chapter of modern natural product chemistry of greatest interest to the author of this review. Not only the determination and synthesis of primary structures appear to him to deserve the closest attention, but also the discovery of the specific interactions between biologically active materials. For the organic chemist this means, first of all, the preparation and analysis of simple molecule complexes and an attempt to understand the fundamental noncovalent bonding forces. For such work associations of symmetrical molecules are initially preferable, since their spectra, crystal structure, and reaction patterns are naturally easier to interpret than those of structurally very complex components. Among the associations the simplest to analyze are generally the dimers, since their properties can be correlated directly with one monomeric molecule. Dimers of a natural product, often with solvent molecules as integrating components, are therefore usually the first object of study. Once the noncovalent reactivity of a class of compounds has been more or less clarified, complexes with other types of natural products can be analyzed, and here the choice of mixed associations will be greatly influenced by biochemical findings. The present review describes the properties of some important molecular complexes of porphyrins, chlorophylls, and bile pigments, as well as those of their derivatives. At the same time, when it appears useful, the relationships to observations and models used by the biochemist and biophysicist will be indicated.

2. Dimers and Higher Aggregates of Porphyrins not Possessing Functional Side Chains

Porphyrins and their metal complexes behave in solution similarly to the polycyclic arenes: they form sandwich dimers with an interplanar separation of 3.5—4 Å (Fig. 1a). The bonding relationships in such dimers have been briefly discussed for the ground state by *Chandra* and *Sudhindra* for the cases of naphthalene and anthracene[1]. The following were considered to be the important components of the bonding forces in dimers:

a) *Electrostatic interactions* between the σ-electron charges on the ring carbons (*ca.* −0.1) and the positive partial charges on the hydrogens (*ca.* +0.1) of the neighboring molecule;

b) *Delocalization of the π-electrons* over both molecules:

c) *π-π-Dispersion forces, i.e.* forces of attraction between the π-electrons of one molecule and the atomic nuclei of the other. *Coulson* has shown that, in comparison with these, in molecules containing more than four double bonds the σ-σ-dispersion forces are negligibly small[2] (van der Waals-London forces).

The bonding interactions are opposed by two types of repulsion forces: those between π-electrons and those between positivized hydrogen atoms or substituents in neighboring molecules. The bonding enthalpies of naphthalene and anthracene dimers amount to about 3 kcal/mol; for porphyrin dimers appreciably larger values have been measured (6 to 10 kcal/mol)[3], presumably due simply to the larger molecular surfaces, which lead to larger van der Waals-London forces.

d) *Hydrophobic or, more generally, "solvophobic" effects* play an important part, presumably because of the large surface of the porphyrins. Effects of this kind in aqueous media have often been investigated[4]. If apolar molecules are suspended

in an aqueous medium, the hydrogen bonds of the water are broken without their place being taken by other polar interactions. To reduce to a minimum this energetically unfavorable boring of holes through the water structure, the hydrophobic agents are compressed to molecular aggregates, to oil droplets. It may be assumed that the aggregation of porphyrins is favored by analogous disturbances in the solvent structure of polar organic solvents[5] such as methanol and acetonitrile.

e) *π-Radicals of the chromophore* can bunch together to diamagnetic dimers, whereby there is formed either a new σ-bond in the molecular plane (*e.g.* the dimer of the triphenylmethyl radical, $\Delta H = -11.5$ kcal/mol)[6, 7] or a π-π-bond perpendicular to the molecular plane (*e.g.* the dimer of the *N*-ethyldihydrophenazinyl radical, $\Delta H \approx -2$ kcal/mol)[8].

None of the above five types of bonding forces can be measured directly. Our knowledge is limited to the total bonding enthalpies and structures of the dimers, from the changes in which on variation of chromophore, substituents, and the medium one can draw qualitative conclusions about the nature of the bonding forces.

Porphine *(1a)*, the unsubstituted parent compound of the porphyrins, is sparingly soluble in organic solvents and exists in the form of ill-defined aggregates. This is expressed, for example, in complicated, strongly solvent-dependent, and often time-dependent electronic spectra with broad shoulders on the absorption bands. Octamethylporphyrin *(1b)* is still more strongly aggregated and almost insoluble in all solvents, presumably because of its greater molecular weight, the higher electron density in the chromophore, and the greater number of hydrogen atoms. Octaethylporphyrin *(1c)*, however, and all higher homologs are more soluble by one to two orders of magnitude than porphine in chloroform, pyridine, *etc.* Similarly, all the hydrophobic derivatives of the natural porphyrins and chlorophylls, *e.g.* protoporphyrin dimethyl ester *(2a)*

and methylpheophorbide a *(3a)*, are very readily soluble in many organic solvents[9]. These surprising and by no means trivial solubility differences are probably caused by space filling by the alkyl side chains, which prevent aggregation beyond the dimer stage (Fig. 1). The crystal structures of nearly all porphyrins studied so far—here, however, including porphine[10, 11]—contain porphyrin dimers as repeat units (separation of porphyrin planes 3.4 to 4.2 Å).

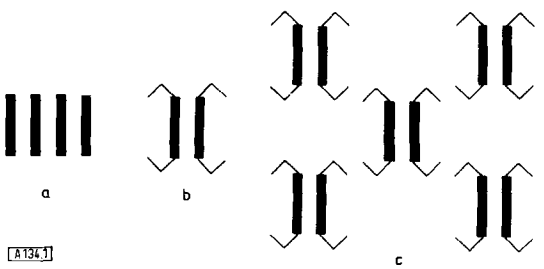

Fig. 1. a) Unsubstituted planar compounds showing large flat areas, which include *e.g.*, unsubstituted porphine *(1a)*, and form dimers or higher aggregates in which the molecular planes lie one over the other with a separation of 3.5 to 4.5 Å. b) Porphyrins with several fairly large substituents, *e.g.* ethyl groups, still form dimers but further aggregation is difficult. Radicals from porphyrins and chlorophyll, for example, afford diamagnetic dimers in completely reversible reactions but do not form insoluble polymers. c) The tendency to form dimers and space-filling by the substituents account for the commonest crystal structure (here shown only two-dimensionally) of porphyrins and their metal complexes.

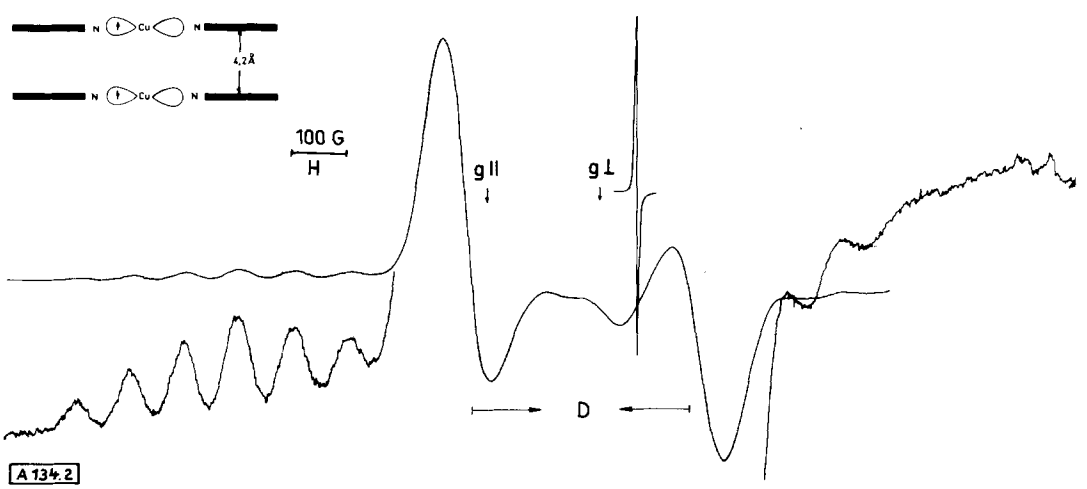

Fig. 2. When the dimer of a porphyrin radical contains copper(II) ions, *e.g. (1h)*, a molecule in the triplet state results, since the two unpaired copper electrons are localized largely in the porphyrin plane and cannot pair.

Electrochemical oxidation of the magnesium *(1d)* or zinc *(1e)* complex of porphine to the π-radical cation leads to formation on the platinum electrode of a black precipitate which is insoluble in all solvents including concentrated sulfuric acid; it is presumably a graphite-like polymer of porphine[12]. π-Radical cations of the metal complexes of octaethylporphyrin *(1f)* to *(1h)*, however, do not polymerize but instead form only stable π-π'-dimers in many solvents, *e.g.* acetonitrile or methanol/chloroform (10:1). The bonding enthalpy has been measured as 14 to 18 kcal/mol, which is extremely high when compared with those of other radical dimers (see above). Moreover, a new absorption band is observed in the near infrared, with an oscillator strength of about 0.7[13]. Although no X-ray structure analysis of these diamagnetic radical dimers has yet been successful, their structure can be derived from the ESR spectra of the copper(II) complexes, *e.g. (1h)*. The unpaired electron of the copper(II) ion, which has the d^9 configuration, is localized to the extent of 98% in the $d_{x^2-y^2}$ orbital in the porphyrin plane. The ESR spectrum of the π-π'-dimer of the π-radical cation shows, as in Fig. 2, hyperfine splitting by both copper ions, and the copper-copper separation can be estimated as 4.2 Å from the coupling constants D of the signal (Fig. 2)[14]. The separation of the two copper ions, which corresponds approximately to the extension of the d-orbitals, is intelligible only if the two porphyrin planes are parallel to each other.

In the meantime we detected π-π'-dimers of porphyrin radicals from porphyrins[13], chlorins[14], and oxophlorins[15], from zinc[14], copper[14], vanadium[14], and nickel complexes, and in such different solvents as methanol[13] and toluene[14]. Bond enthalpies of 14 to 18 kcal/mol were found in all cases. From these results it can be concluded that both delocalization of π-electrons (bonding force b) and the simultaneous formation of a π-π'-bond perpendicular to the porphyrin plane by pairing of the lone electrons (bonding force e) are the determining bonding forces in these dimers. Furthermore, the bond enthalpies in polar solvents (methanol, water, acetonitrile) appear to be about 2 to 3 kcal/mol greater than in apolar solvents[13] (bonding force d).

A splendid exotic will form the last example of porphyrin dimers not containing functional groups. If a porphyrin is treated in tetrahydrofuran/dichloromethane with mercury(II) acetate, one obtains a complex containing three mercury, two acetate, and two porphyrin ions (Fig. 3), whose NMR spectrum shows weak splittings due to the interaction of the two porphyrin nuclei[16].

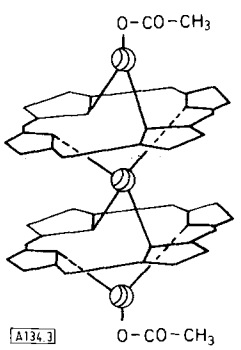

Fig. 3. Mercury(II) ions and porphyrins form together double-decker sandwich complexes that readily rearrange to normal porphyrin complexes. The structure of this dimer was derived from NMR spectra and elemental analyses.

On addition of pyridine the dimer breaks apart and the normal mercury complex is formed. This unusual association presumably owes its existence to two unusual properties of the mercury(II) ion: its relatively large ionic radius of 1.1 Å, which prevents its entry into the interior of the porphyrin, and its tendency to form covalent bonds, which makes loss of acetic acid difficult.

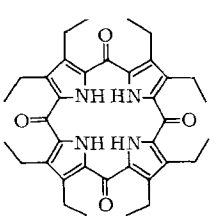
So far only the dimers of the simplest porphyrins and their metal complexes have been described above. All these are well defined and their bonding can be qualitatively well explained. However, we have already learnt about seven types of bonding, and it should be clear that bio-(in)organic chemists who plan syntheses of new molecular complexes will be faced with manifold problems[17]. The next stage of complexity is reached with porphyrin derivatives that contain carbonyl groups.

3. Dimers and Higher Aggregations of Porphyrin Derivatives Containing Carbonyl Groups

Aldehyde or ketone groups conjugated with pyrrole or porphyrin rings act as strong electron donors[18] and form hydrogen bridges with OH and NH proton donors. The strength of the bond is the greater the more easily can the OH or NH bond be broken and the richer is the carbonyl group in electrons. In other molecules NH—O and OH—O bond lengths of *ca.* 2.7 to 3.0 Å and bond angles between 120 and 180° have been found[19]. Electrostatic interactions have most commonly been assumed as the bonding principle, *i.e.* the positive hydrogen atom is attracted by two heteroatoms and simultaneously decreases the repulsion between them. In accord with this, *Allen*[20,21] recently formulated a simple and convincing model of the hydrogen bridge in which the bond energy E_D of a series of hydrogen-bridged dimers is given by eq. (a):

$$E_D = K\mu_{A-H}\Delta I/R \qquad \text{(a)}$$

where K is a constant, μ_{A-H} is the dipole moment of the monomer providing the proton, ΔI is an expression containing the difference between the ionization potentials of the two atoms bound by the proton, and R is the separation between these atoms.



• 2 H_2O *(4)*

Octaethyl-5,10,15,20-tetraoxoporphyrinogen (octaethylxanthoporphyrinogen) *(4)* forms the simplest known hydrogen-bonded aggregate of a porphyrin on which the important structure-controlling factors of this weak interaction can be demonstrated[23,24]. The molecule contains four acidic NH protons, which bind two water molecules, one above and one below the center of the porphyrinogen[25]. The requirements that the hydrogen bonds should be as nearly linear as possible, and that the van der Waals radii of the atoms concerned permit the porphyrinogens and the oxygen atoms

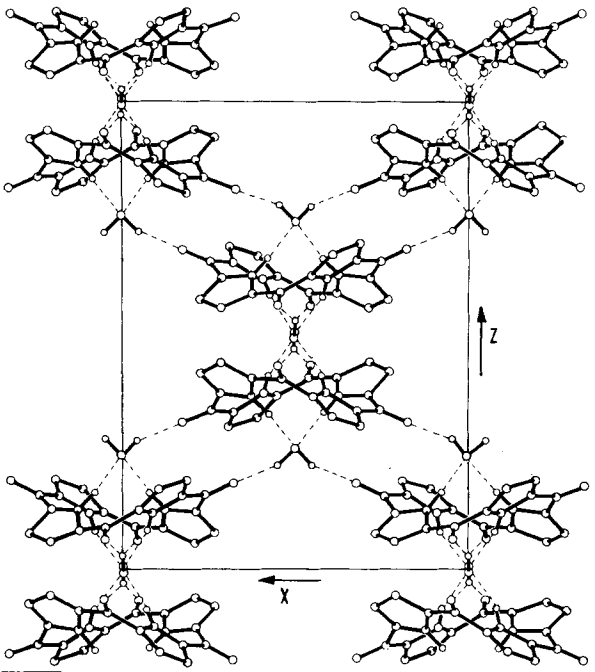


Fig. 4. Water is bonded by linear NH—O bridges above and below the center of the xanthoporphyrinogen *(4)*, leading to a wavy molecular structure. The protons of the water molecule form hydrogen bridges with the carbonyl groups of neighboring porphyrinogen molecules. The crystal lattice resembles long tubes stacked on one another, within which water molecules are fixed. The structure exemplifies an economical principle that is repeatedly observed in the molecular complexes discussed here, namely that all the acidic protons and all the oxygens are, whenever possible, linked by hydrogen bridges.

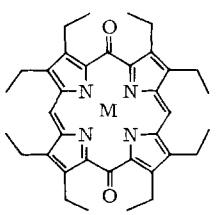
of the water to approach each other to no closer than about 2.7 Å, result in rotation of the pyrrole rings out of the porphyrin plane (Fig. 4). The dihydrate also contains the four acidic protons of the water molecules; these bind four carbonyl oxygen atoms of neighboring porphyrinogen molecules in a symmetrical manner, and this leads to cylindrical linking of the chromophore chains. The whole structure thus resembles a stack of interconnected tubes in which the positions of the water molecules are fixed with well-defined separations of 2.4 and 4.8 Å. The effect that the water has on the crystal formation of *(4)* can also be easily demonstrated macroscopically: the water of crystallization can be removed only above 150°C under high vacuum, and the crystals then disintegrate into a powder.



(5a), M = 2 H
(5b), M = Zn

Reduction of xanthoporphyrinogens by sodium tetrahydridoborate leads to the formation of 5,15-porphinoquinones such as *(5a)*, which have recently become a center of interest[15, 22, 26–28]. On chromatography of the zinc derivative *(5b)* on silica gel a stable dimer can be isolated, whose peculiar chemical reactivity (see Section 6) can be understood only when the crystal structure is recognized: each central zinc ion is bound to a molecule of methanol whose proton is hydrogen-bonded to the neighboring carbonyl oxygen; the zinc-bound methanol of the second porphinoquinone is attached to the first molecule in a similar manner, so that a dimer is formed in which the parallel porphyrin planes are shifted with respect to each other by half the length of the molecule (Fig. 5).

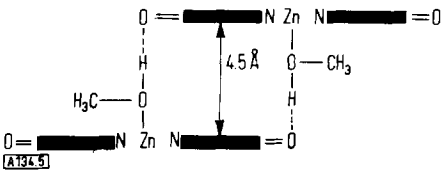


Fig. 5. Two 5,15-dioxoporphodimethene ("porphinoquinone") molecules are linked by methanol molecules bonded on the one hand coordinately to the central zinc ion and on the other by hydrogen bridges to a carbonyl group of a neighboring molecule. Semiquinone radicals formed on reduction are probably stabilized by this dimer formation.

Similar but much more complicated relationships are found in the case of chlorophyll *(3b)*. Here the central magnesium ion binds one water molecule, which can be attached to the carbonyl group of the carbocyclic ring E. Moreover, the magnesium ion itself is probably sufficiently electrophilic to add to the β-oxo ester group of ring E of a second chlorophyll molecule. These basic possibilities of association lead to a large number of dimeric and polymeric aggregates which have been clarified by very thorough NMR and IR investigations, mainly by *J. J. Katz et al.* In the present review only the two most important dimer structures elucidated by *Katz* and an X-ray structure analysis by *Strouse* will be discussed; details of the methods used in these investigations will be found in reviews by *Katz*[29–31] and in some other papers[32–34].

The principles of spectroscopic analysis of chlorophyll aggregates are based mainly on the following facts:

1. The IR absorption of the oxo group in the carboxylic ring E lies at 1695 cm^{-1}. If chlorophyll aggregates in extremely dry apolar solvents (*e.g.* CCl_4), the intensity of this band diminishes and an "association band" appears at 1652 cm^{-1}. The origin of this band can be seen in the formation of a C=O—Mg group, as indicated in Fig. 6.

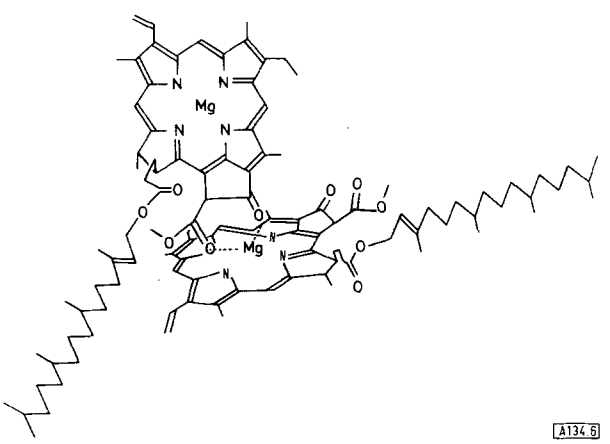

Fig. 6. In the anhydrous dimer of chlorophyll the central magnesium ion of one molecule is bound coordinately to the carbonyl groups of the carbocyclic ring E of the other molecule. The structure is based on IR and NMR data.

2. In a dimer according to Fig. 6 some parts of the two chromophores lie very close to one another, while others are further apart. Since strong ring currents are induced in

macrocycles of the porphyrin type in the NMR experiment, conclusions can be drawn about the structure of the aggregates from changes in the chemical shifts, *e.g.* of proton signals of the substituents, on increasing the concentration: the larger the shift, the closer are the two macrocycles in the region concerned. Addition of a disintegrating solvent at relatively high concentration is often used as a test: the chemical shifts must then return to values corresponding to the monomer. Analogous ^{13}C-NMR measurements lead to similar results[35].

3. In hydrated chlorophyll aggregates the band at 1652 cm^{-1} is replaced by absorption at 1638 cm^{-1}, which is assigned to a C=O...HO(H)—Mg grouping: a water molecule is inserted between the magnesium ion and the carbocyclic ring E of the neighboring molecule, and a dimer having the structure shown in Fig. 7 is obtained. This too is supported by extensive NMR data.

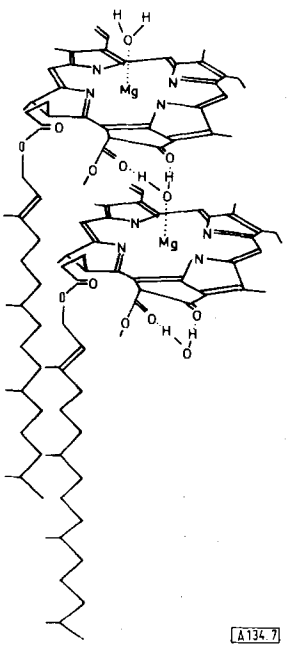

Fig. 7. If a water molecule is added to the anhydrous chlorophyll dimer (Fig. 6) a new dimer is formed, containing defined hydrogen bonds. The structure follows from IR and NMR data.

Under many different conditions the dimers can be converted into higher aggregates, whereupon shifts of the 660 nm chlorophyll absorption to 740 nm are observed in the electronic spectra. The structures of the aggregates are in many cases proved by use of deuterated derivatives, other metal complexes, or metal-free bases, by molecular-weight determinations, elemental analyses, *etc.* However, we think that complete certainty about such complex structures as those in Figs. 6 and 7 cannot be provided by NMR, ESR, or IR experiments, no matter how careful they are. Only X-ray structure analysis provides a trustworthy guide to such formations. If, on the other hand, the structure of the molecular aggregates in the crystal is in accord with all spectroscopic structural parameters obtained for a solution, then it appears permissible at the present time to conclude that the environmental relationships of at least two molecules are identical in solution and in the crystal.

Some years ago, in fact, *Strouse* succeeded in clarifying the structure of a dihydrate of ethylchlorophyllide a *(3d)* by X-ray analysis[36]. The important structural features are given in Fig. 8. One water molecule occupies the fifth coordination position of the magnesium. A second water molecule is joined to the first and to the carbonyl oxygen of the ester group on ring E by means of two hydrogen bridges. In this

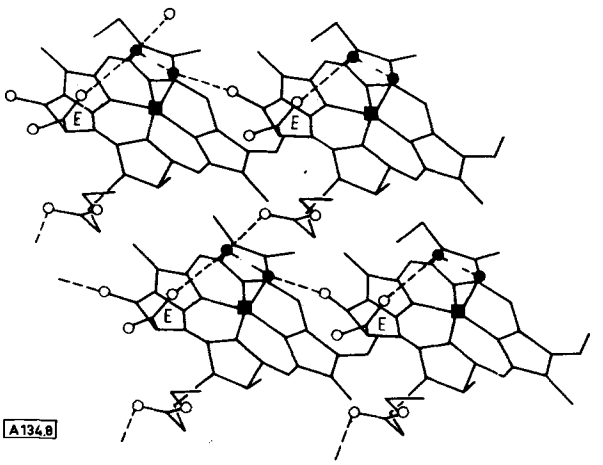

Fig. 8. X-ray molecular structure of ethylchlorophyllide a *(3d)*. Two molecules of water link the magnesium ion intramolecularly to its own carbocyclic ring E and intermolecularly to two further molecules. The resulting network structure probably corresponds in general to the structure of the light-gathering chlorophyll aggregate *in vivo*. ○ = >CO; ● = H_2O; ■ = Mg.

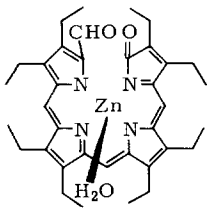
way one proton of each water molecule remains free for intermolecular bridging. The proton of the water bound to magnesium binds the ketone oxygen atom of ring E of a neighboring molecule, in complete agreement with *Katz*'s dimer shown in Fig. 7. A chlorophyll chain is thus formed (shown horizontal in Fig. 8). The intramolecular unbound proton of the second water molecule is linked to the carbonyl oxygen of the ester group on ring E of another molecule, whereby a second chlorophyll chain arises (that show vertical in Fig. 8). This structure provides no contradiction of importance to the structures proposed by *Katz*, but supplements them in important points about which the spectroscopic data convey no information. The reason for this is clear: superposed porphyrin macrocycles can be recognized at once in the NMR spectra, but porphyrin molecules lying side by side can barely be distinguished from monomers.

Before leaving the field of tetrapyrrole chromophores held together by hydrogen bonds, we can compare the simple crystal structure of xanthoporphyrinogen dihydrate [*(4)*] (Fig. 4) with the complicated structure of chlorophyllide a dihydrate [*(3d)*·2H_2O] (Fig. 8). In the former the two water molecules, one above and one below the plane of the chromophore, together with the bridge bonds stabilize a structure corresponding to bundles of tubes within which water molecules are fixed. In the magnesium complex *(3d)* the two water molecules lie on the same side of the chlorophyll derivative and by analogous interactions form a network on whose surface the water is coordinated. In both cases the structures can be derived directly from the properties of the components [essentially the acidity of the NH protons in *(4)*, the favored fivefold coordination of the magnesium in *(3d)*, and the electronegative carbonyl groups in *(4)* and *(3d)*]. The fundamental principles are clearly a) neutralization of positive (on the central metal) and negative (on the carbonyl groups) partial charges by attachment of water and b) coordinative saturation of all the protons capable of hydrogen bonding.

4. An Open-Chain Dimer

Photo-oxidation of metalloporphyrins with molecular oxygen leads to formylbiliverdins[37,38] *e.g.* the zinc complex *(6)*, *i.e.* it leads to fission of the macrocycle at a methine bridge. In this way conformational changes become possible that appear to be excluded for the rigid porphyrin ligands. If *(6)* is crystallized from neutral solvents, brown plates are obtained (λ_{max} = 830 nm) whose X-ray structure analysis displays a cyclic-planar ligand (Fig. 9)[39]. The same conformation in solution was proved by ESR spectroscopy for the copper complex of that ligand[40].



(6)

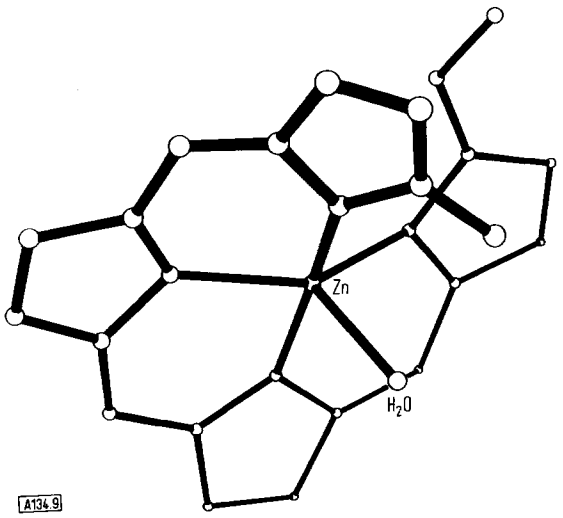


Fig. 9. Molecular structure of the zinc complex of synthetic octaethylformylbiliverdin *(6)*. One water molecule is bonded coordinately and presumably stabilizes the planar arrangement of the four nitrogens of the biliverdin ligands.

One structural peculiarity was striking, namely that the central zinc ion in *(6)* binds a water molecule. If the solution of *(6)* is acidified a reversible color change from brown to green (λ_{max} = 730 nm) is observed. Structure analysis of the green crystals disclosed a bis-helical dimer in which the two zinc ions were each bonded to one-half of both chromophores (Fig. 10). For this rearrangement the driving force is once more easy to identify, and once more a new effect comes into play: it is assumed that as the pH decreases the water molecule of the hydrate shown in Fig. 9 is protonated and immediately thereafter splits from the zinc ion.

Whereas the square-planar arrangement of ligands of the biliverdin chromophore around the zinc ion is stable in the case of the fivefold coordinated metal, after dehydration the now fourfold coordinated zinc seeks to attain a tetrahedral configuration of the four surrounding nitrogens. This is in no way possible with *one* bilatriene chromophore. Instead, two formylbiliverdin molecules intertwine so that each of the two pyrromethene units of one chromophore can engage two corners of a tetrahedron. In fact both zinc ions in the structure shown in Fig. 10 attain a tetrahedral arrangement

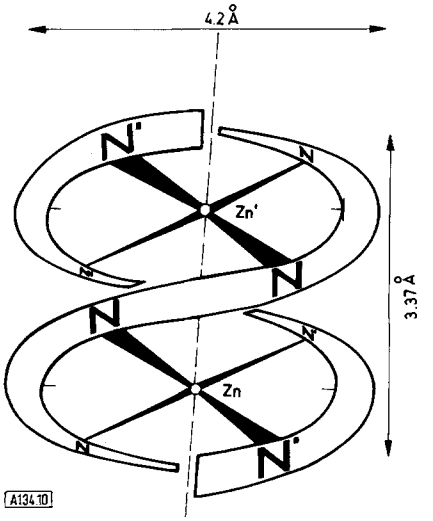

Fig. 10. If a solution of biliverdinate *(6)* is acidified, the water molecule is split off. The now fourfold-coordinated zinc ion strives toward a tetrahedral environment and attains this by reversible formation of the bis-helical dimer drawn schematically (see Ref. [39]).

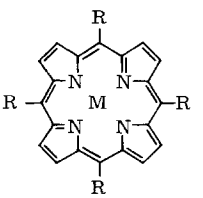
of the surrounding nitrogen electrons in this way. It is now striking to find that the reaction is easily reversible: if an acid solution of the bis-helical dimer is neutralized, the structure shown in Fig. 9 is regenerated.

5. Dissociation of Aggregated Porphyrins

Hemes and chlorophylls aggregate both in aqueous solution and in an apolar medium. If the porphyrin units isolated from natural systems are required, the chromophore is fixed in a polymeric matrix. Stable iron(II)-oxygen complexes, for example, can be formed only if reaction with a further molecule is prevented (see below). For chemical and physical investigations of monomeric metalloporphyrins the synthetic porphyrins *(7a)* to *(7c)* are particularly suitable, built into micelles rather in the manner shown in Fig. 11. Proof of the resolution of *(7a)* and *(7b)* into monomers in the micelles was provided by ESR spectroscopy for the paramagnetic copper complexes *(7d)* and *(7e)*: if these copper complexes were dissolved in water an unresolved ESR spectrum was observed, whereas on addition of the micelle-forming lauryl sulfate the hyperfine structure of the monomeric copper complexes appeared[41].



(7a), M = 2 H, R = $(CH_2)_8$–COOH
(7b), M = 2 H, R = $(CH_2)_8$–CH=CH–SO_3H
(7c), M = 2 H, R = $(CH_2)_9$–$\overset{\oplus}{N}(C_2H_5)_2CH_3$
(7d), M = Cu, R = $(CH_2)_8$–COOH
(7e), M = Cu, R = $(CH_2)_8$–CH=CH–SO_3H

Hemoglobin contains four heme molecules, each of which consists of one iron(II)-porphyrin and is rigidly coordinated to one imidazole base of the globin. The average separation of the porphyrin ligands is about 30 Å (Fig. 12)[42,43]. Nevertheless, there is a very close relationship between all four chromophores; if the sixth coordination site of one heme is loaded with oxygen, then all four subunits of the hemoglobin rearrange so as to make easier similar loading of the other heme units. This phenomenon was the starting point of the *Jacob* and

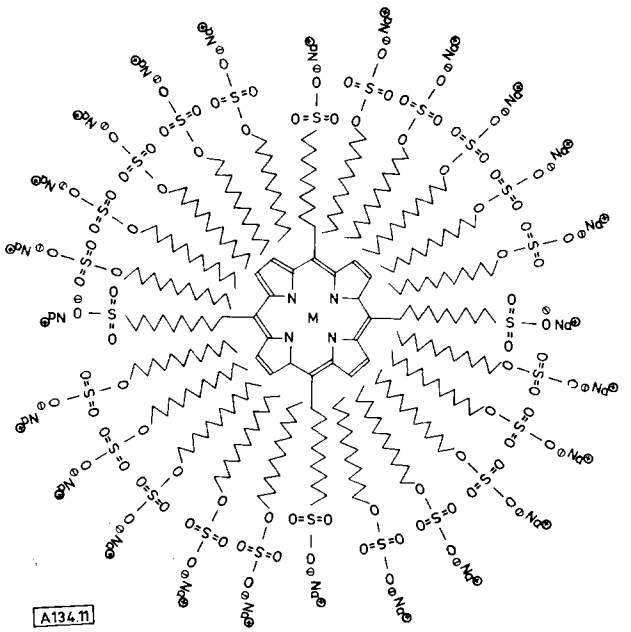


Fig. 11. By a suitable choice of detergents and substituted porphyrins, monomolecular porphyrin solutions are obtained in which the chromophore is localized in the hydrophobic interior of the micelles.

Monod allosteric model of enzyme regulation and is still today a central theme in structural chemistry.

It is now known from X-ray structure analyses of deoxyhemoglobin and of (partially decomposed) oxyhemoglobin that in the total course of oxygenation the essentially hydrophobic contact positions of the subunits change along the full lines in Fig. 12, although the overall structure of the protein remains largely unchanged. It must now be assumed that the first oxygenation leads to extensive disturbances of the interactions between the subunits, and that this accelerates the oxygenation of the other subunits[44].

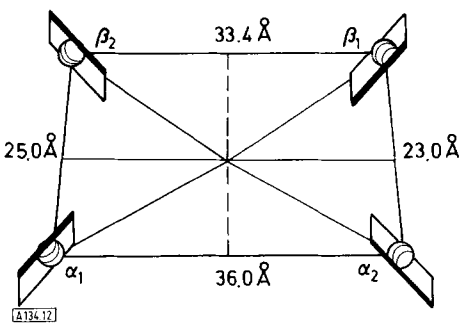

Fig. 12. The fixed relative positions of the heme molecules in oxyhemoglobin prevent their direct interaction, so that autoxidation of the heme is prevented. Nevertheless, adsorption of oxygen occurs through the four heme molecules by a cooperative action which is achieved by drastic changes in conformation on addition of the oxygen (the allosteric effect). The full lines indicate mainly hydrophobic interactions between unlike chains, while the broken line indicates the mainly polar interaction between like chains.

The structure of the unusual, water-soluble protein from *Chlorobium limicola* with a molecular weight of about 130000 and a total of twenty-one bacteriochlorophyll molecules[45] was recently clarified by X-ray spectroscopy. First it was shown that there were three identical subunits of molecular weight 42000, each containing seven bacteriochlorophyll molecules, and their structure was elucidated (Fig. 13). Here too it was assumed that the seven chromophores, each separated from the next by 12 Å, supported each other in their biological functions. The protein complex as a whole conducts excitation energy from the "antenna" chlorophyll molecules, which absorb sunlight, to the photochemical centers where the light energy is converted into chemical energy. Stepwise energy transport by the protein is obviously possible, although no direct overlapping of the chlorophyll orbitals occurs and although the space between the chlorophyll molecules consists of purely hydrophobic regions of little structure. Experimentally, fluorescence and circular dichroism measurements, which will not be discussed here, prove that all seven bacteriochlorophyll molecules of one subunit are connected with one another by exciton interactions[45]. For separations >20 Å, such as must be overcome for energy transport between the subunits, the Förster mechanism can be brought into play[45].

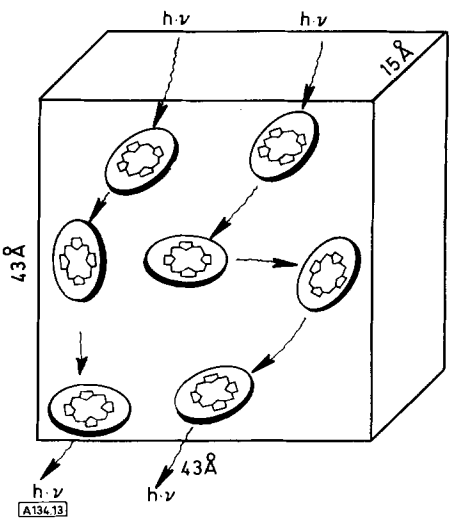

Fig. 13. The here strongly schematized molecular structure of a water-soluble bacteriochlorophyll protein shows that the chromophore molecules are not aggregated and that the space between them is strongly hydrophobic. Exciton and Förster mechanisms are discussed in relation to the transfer of quanta between the bacteriochlorophyll molecules of this light-conducting complex.

In nature all intermediate stages are found between, on the one hand, very extended aggregates resembling a crystal surface, in which the porphyrins are directly coupled to one another and, on the other, complexes in which high-molecular proteins contain isolated porphyrin islands. These complicated structures have often been characterized only by electronic spectra and lengthy biochemical interpretations. The few complexes discussed in this review form a solid nucleus for further work; they show that porphyrins usually act cooperatively and that the structure of biological, high-molecular porphyrin complexes at once also defined the mode of action: the "crystal flatness" of extended chlorophyll is suitable for collection of light, the parallel arrangements of chlorophyll chromophores with a separation of 20 Å are optimally suitable for the conduction of light, and the regulation of oxygen-absorption is best effected by flexible proteins with isolated porphyrin islands.

6. The Chemical Reactivity of Porphyrin Aggregates

Since the aggregates described in the preceding sections have been discovered and elucidated only recently, very little is known of their chemical reactivity in comparison with the monomers. Fundamental differences are to be expected above all in photo- and redox-chemistry, since in sandwich

dimers the unpaired electrons of triplet states and radicals can be smeared over the two π-systems and the axial ligands. Two examples, recently discussed but still somewhat speculative, may illustrate this point.

If the zinc complex *(5b)* is reduced by dithionite in hexamethylphosphorotriamide, then only the dimer with bridging methanol forms a semiquinone radical that is stable for hours under nitrogen, whereas the monomer decomposes irreversibly under these conditions within a few seconds. Furthermore, the ESR signal of the semiquinonoid radical is extremely narrow (<1 gauss), which indicates distribution of the unpaired electrons over two or more molecules. It seems reasonable to assume that the hydrogen bridge protons of the structure shown in Fig. 5 achieve considerable stabilization of the semiquinone radical anions formed in the reduction.

There are at present two contradictory theories about the role of chlorophyll dimers in the oxidation of water, and these enliven the interest in these aggregates.

According to *Katz*[31], a water-bridged chlorophyll dimer (Chl HOH Chl) at the photosynthesis reaction center is linked to the antennae-chlorophyll aggregate $(Chl_2)_n$ (see above) and to an electron-acceptor and an electron-donor:

	$X^{\ominus}$	
$(Chl_2)_n$	[Chl HOH Chl]	Y
antennae chlorophyll	"special pair" $X^{\ominus}$ = electron donor	electron acceptor

The assumption of a special chlorophyll dimer ("special pair") at the reaction center is supported here again by the observation of a particularly narrow ESR signal (line width *ca.* 1 gauss) for the oxidized photoreaction center, and this permits distribution of the unpaired electrons over at least two chromophore molecules to be assumed. Irradiation of this complex is held to lead, by way of the excited state, to a new charge distribution in the dimer in accordance with:

	$X^{\ominus}$	
$(Chl_2)_n$	$[Chl^{\oplus}\ OH^{\ominus}H^{\oplus}\ Chl^{\ominus}\cdot]$	Y

Thereafter the chlorophyll radical cation oxidizes first $X^{\ominus}$ and indirectly water, while the chlorophyll radical anion maintains the reductive part of the photosynthesis by way of Y.

Experimentally, both *Katz*[31] and *Dutton et al.*[46] have demonstrated the occurrence of the triplet state in photosynthesis, and this could indicate the above cation-anion radical pair.

Whereas *Katz* bases his considerations on the unsymmetrical dimer of Fig. 7, *Fong*[33,34] and *Wang*[47] assume a symmetrical sandwich dimer containing two water molecules, and make the interesting speculation that its triplet state might have an unusually long life. If this were so, the energy of a singlet state from the antennae-chlorophyll could be added to the energy of the relatively low-lying dimer-triplet state. Thus, the oxidation of water could be effected in two steps [eq. (b) and (c)], each involving one energy-rich charge-transfer triplet state $Chl^{\oplus}\cdot(H_2O)_2Chl^{\ominus}\cdot$ without the necessity to invoke further redox systems (*e.g.* the often postulated manganese ion of higher oxidation numbers).

$$H_2O \xrightarrow{h\cdot\nu} OH^{\bullet} + H^{\oplus} + e^{\ominus} \qquad (b)$$

$$OH^{\bullet} \xrightarrow{h\cdot\nu} O + H^{\oplus} + e^{\ominus} \qquad (c)$$

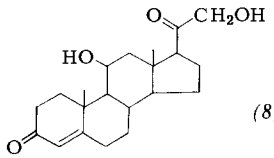
Currently attempts are being made throughout the world to synthesize porphyrin aggregates in solids in order to cleave water by sunlight in analogy to the natural process. A first, hitherto unconfirmed, success has been announced by *Wang*, who covered aluminum foil with *ca.* seventy monomolecular layers of zinc porphyrin, dipped this deeply colored photoanode into an iron(III) salt solution, and on irradiation with red light obtained potentials *ca.* 1 volt greater than that of a platinum electrode; two electrodes arranged one behind the other led to evolution of oxygen from water[47]. If this experiment and its interpretation withstand critical testing, then intensive investigations of this system with a view to industrial utilization would appear attractive. Experiments with lipid membranes are already a center of interest. If an aqueous solution of an oxidizing agent (*e.g.* Fe^{3+}) is separated by a bimolecular lipid membrane from a solution of a reducing agent (*e.g.* Fe^{2+}), the two solutions are stable next to each other for a long time: no electron transport takes place through the membrane. If, however, the membranes contain oxidizable porphyrins, *e.g.* chlorophyll, then a slow charge equalization between the two solutions can be observed, and light accelerates this by many orders of magnitude. At the same time photopotentials of about 100 mV appear between the membrane surfaces[48], these corresponding approximately to the pH-gradients that arise in photosynthesis on the membrane of vesicles of the photosynthetic system (thylacoids). Very little is yet known about the importance of porphyrin aggregation in this system.

Finally, an evolutionary-historical point may be noted. The photosyntheses that we observe today are based on the reversible formation of energy-enriched and thus chemically extremely reactive molecular states (triplet states, radicals). In monomolecular solutions, *e.g.* in chloroform, chlorophyll is decomposed very rapidly on irradiation and oxidation. In aggregates, however, the unpaired electron of the chromophore molecule is distributed over at least two partners, greatly reducing the reactivity of the individual centers in the molecule and thus protecting the system from destruction.

It is perfectly conceivable that in prebiotic time—and particularly then—organic molecules had a chance of surviving and becoming components of biological systems if, first, they could assume a useful role (here conversion of sunlight into chemical energy), and, secondly, if they did not themselves fall victim to their own functional reactivity. Other examples could be seen in the protection of nucleic and amino acids, which are sensitive to hydrolysis and redox systems, by integration into the complex structures of polymers (≈aggregates).

7. Molecular Complexes of Porphyrins with Other Natural Products

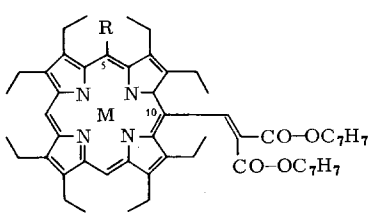
Although interest is nowadays concentrated on chlorophyll dimers in connection with the reaction center for photosynthesis, aggregates with other natural π-systems have also been studied. In particular, flavins[49] and quinones[50] form with chlorophyll charge-transfer complexes that may perhaps be involved in the redox chains of photosynthesis. So far, however, the structure is not known for any of these complexes, and we shall therefore not treat them further here. However, detailed CIDNP investigations have been reported for quinone complexes[50b].



(8)

Complexes between paramagnetic metalloporphyrins and steroids[51] are of a different type. *Hill et al.* have investigated these complexes by NMR methods similar to those used by *Katz* for chlorophyll aggregates. A 5×10^{-2} molar solution of corticosterone *(8)* showed, for example, that on titration with the cobalt(II)-porphyrin *(2b)* strong paramagnetic shifts of the protons on Cl > C2 > C3 > C4 > C11 occurred, while the other signals were hardly shifted at all. As a result of these findings and of systematic measurements of relative line widths, a 1:1 molecular complex was postulated with the following structural details. The steroid lies parallel to the porphyrin and presents its unhindered α-side to the latter; the mean separation between the two molecules is 5 to 8 Å, with C9 of the steroid lying approximately over the center of the porphyrin. The predominant bonding force between the porphyrin as a prototype of an aromatic natural product and the steroid with its rigid cycloalkene system is presumed to be electrostatic—as the bonding forces described in Section 2. In the physiologically important iron(II) complexes coordinated water could drastically alter the structure by the formation of hydrogen bonds and be the "specifying" factor. Such complexes are of extreme interest in connection with the specific oxidation of steroids by heme catalysts and molecular oxygen (see Section 9).

In this connection a remarkable observation on [2,2-bis(benzyloxycarbonyl)vinyl]porphyrins *(9a)* and *(9b)* should be noted. The phenyl group of the benzyl ester grouping lying



(9a), M = Cu, R = CHO
(9b), M = Ni, R = H

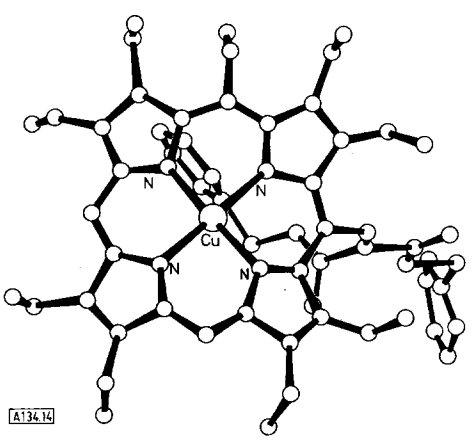


Fig. 14. Molecular structure of the dibenzyl ester of porphyrin *(9a)*. The phenyl group *cis* to the porphyrin sits *perpendicularly* almost directly above the center of the porphyrin.

cis to the porphyrin occurs in solution exactly above the center of the macrocycle; this can easily be demonstrated by NMR spectroscopy of *(9b)* and can be ascribed to interactions of the type discussed in Section 2 (types a to c). X-Ray structure analysis shows that the phenyl group in *(9a)* lies *perpendicular* to the plane of the porphyrin (Fig. 14); this was hardly to be expected in view of the current ideas on interactions between π-systems[52]. Now it has been found, in somewhat remote analogy to our case, by physical investigations of benzene, that this compound also is aggregated, and indeed always in such a way that two benzene rings are perpendicular to one another. This conformation is retained even in the gas phase[53]. The possible binding force has been only tentatively indicated (quadrupole interactions?).

8. Oxygen Complexes of Iron(II)-Porphyrins

This area has been studied unusually intensively during the last five years and shows the miserable "signal-to-noise ratio" typical of popular subjects. In other words, most of the experimental papers on oxygen complexes are repetitive in nature. In what follows we shall try to indicate the most important lines of development.

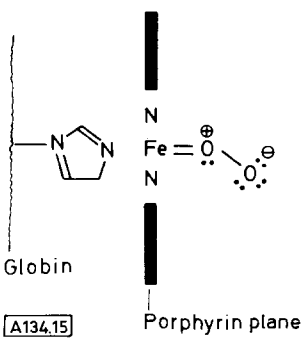

Fig. 15. The electron structure of the oxygen-bonding center in oxyhemoglobin according to *Pauling*.

Many years ago *Linus Pauling* suggested the electron structure reproduced in Fig. 15 for the oxygen adduct of the heme in hemoglobin (oxyhemoglobin, HbO_2)[54]. This structure takes account of the diamagnetism of the HbO_2, explains the increased acidity of the imidazole in HbO_2 ($pK = 6.8$) in comparison with free Hb ($pK = 7.8$), maintains the electron neutrality of the central iron atom in heme, and permits the following verifiable, specific predictions: the angle between the Fe—O and the O—O bond should be about 120°. The Fe—O bond should be as long as, or shorter than, the sum of the covalent radii (≈1.9 Å), and the oxygen atom should show IR bands and O—O bond lengths corresponding approximately to a single bond. Furthermore, the oxygen molecule should be polarized but not negatively charged in the sense of a hyperoxide anion ($Fe^{III}—O_2^{\ominus}$). Recently the first oxygen complex of "picket-fence" iron porphyrin was obtained in crystalline form—such a complex is sterically protected on one side by the fence, and a provisional X-ray structure analysis, to be accepted with caution ($R = 0.15$), has been published[55] (Fig. 16). This structure agrees beautifully with *Pauling*'s predictions[56]: the oxygen is indeed attached end-on at an angle ($\alpha_{exp} = 136°$), and the Fe—O and O—O separations amount to 1.75 and 1.24 Å, respectively. However, the IR stretching vibration of the O—O bond in the above oxygen

complex is reputedly at 1385 cm^{-1}, which has not been found for any other end-on oxygen complex; indeed, all the complexes so far characterized as of this type show a band near 1100 cm^{-1}[62], which is close to that in potassium hyperoxide KO_2 ($\nu O_2 = 1145\ cm^{-1}$). The absence of this band in the picket-fence oxygen complex leaves open some doubt about the molecular structure proposed[76].

The problem of the electronic structure of the active center in HbO_2 is, however, by no means resolved. The relative stability of the iron(II)-oxygen complex shown in Fig. 16 already provides important clues. Other iron(II)-porphyrins,

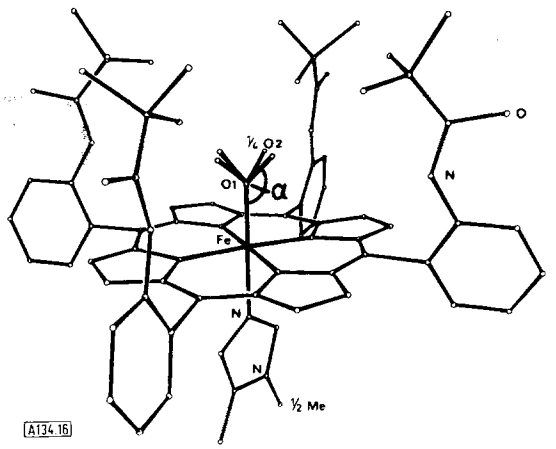

Fig. 16. Provisional and still disputed [76] molecular structure of the iron(II)-oxygen complex of the α,α,α,α-atropic isomer of *meso*-tetrakis(*o*-pivalamido)-porphyrin. This compound is the first crystalline iron-porphyrin oxygen complex. The structure corresponds to *Pauling*'s prediction.

e.g. protoheme *(2c)*[57] and tetraphenylheme[58], form analogous complexes with oxygen in the presence of imidazole derivatives below −40 °C; at higher temperatures irreversible oxidation to iron(III)-porphyrins sets in. This difference probably rests on the fact that the oxygen molecule in the complex of Fig. 16 is sterically so shielded that the addition of a second iron(II)-porphyrin and subsequent autoxidation according to eq. (d) cannot occur[59] (B = base, *e.g.* imidazole):

$$\begin{aligned} &B{-}Fe^{II}O_2 + Fe^{II}{-}B \rightleftarrows B{-}Fe^{II}O_2Fe^{II}{-}B \\ &\rightarrow 2\,B{-}Fe^{III}{-}O^{\bullet} \xrightarrow{2B-Fe^{II}} \\ &\quad 2\,B{-}Fe^{III}{-}O{-}Fe^{III}{-}B \end{aligned} \qquad (d)$$

Nevertheless, the complex shown in Fig. 16 is also oxidized rapidly in protonic solvents and more slowly in aprotic ones, giving iron(III)-porphyrins, for which the proton-catalyzed reaction (e) seems suitable:

$$Fe^{II}O_2 + H^+ + H_2O \rightarrow Fe^{III}OH + H_2O_2 \qquad (e)$$

In the above case the proton could be derived from the amide groups with which the porphyrin is substituted.

Finally, *Caughey* showed that the oxygen in oxyhemoglobin can be split off by anions (*e.g.* Cl^-, N_3^-)[60] or by reducing agents (*e.g.* hydroquinone, salicylic acid)[61], affording hyperoxide anion, while the iron is oxidized to the trivalent state [see, *e.g.* eq. (f) and (g)].

$$HbO_2 + ArO^- \rightarrow HbO_2^- + ArO^{\bullet} \qquad (f)$$

$$HbO_2^- + 2H_2O \rightarrow HbOH + H_2O_2 + OH^- \qquad (g)$$

The resistance of oxyhemoglobin to autoxidation thus apparently rests not on a special type of bonding of the oxygen but rather on shielding of the bonding center against reducing agents (including a second iron(II)-porphyrin) and nucleophiles.

In *Hill*'s hands[63] an important experiment has confirmed, in particular, *Pauling*'s and *Caughey*'s picture of oxyhemoglobin. *Hill* treated an iron(III)-porphyrin at low temperatures (to prevent dimerization) with electrochemically produced hyperoxide anions and obtained an oxygen complex whose spectrum corresponded to a large extent with that of oxymyoglobin. It should also be pointed out that there is a paramagnetic analog of the diamagnetic HbO_2: If the iron-porphyrin is replaced by a cobalt-porphyrin, then that too adds oxygen; in this case the oxygen molecule clearly exists as a hyperoxide anion and can be identified by ESR spectroscopy[64, 65].

Summarizing, it can be stated that kinetic stabilization of an iron-oxygen complex in the porphyrin series should succeed when dimerization of two heme molecules can be prevented in a hydrophobic, proton-free environment; this concept is realized in the biological heme enzymes in which the porphyrin is bound covalently or coordinatively in a hydrophobic matrix (see for example Fig. 15). More recent experiments have shown that free iron(II)-porphyrins or their oxygen complex can be kept unchanged for as long as desired in synthetic hydrophobic polymers[66, 67]; there, however, it is presumably the inflexibility of the synthetic polymers that makes the addition of oxygen slower by many orders of magnitude than it is in HbO_2.

The occurrence and strength of the end-on bond of the oxygen to heme depend largely on the π-donor-acceptor properties of the axial ligands in *trans*-positions. Oxygen complexes are stabilized considerably better by imidazole than by *e.g.* piperidine or pyridine[68]. If axial ligands are completely absent, then 1:1 oxygen complexes with heme are formed only in the crystalline state and their ESR spectra demonstrate the occurrence of a high-spin iron(III)-porphyrin radical anion [($g = 6$) and ($g = 2$) signals]. The IR spectrum shows a stretching vibration band at 1600 cm^{-1} that is very similar to the band of the free oxygen molecule ($\nu_{O_2} = 1555\ cm^{-1}$), and the visible electronic spectrum also indicates the occurrence of a π-radical.

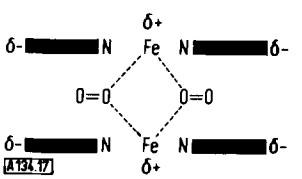

Fig. 17. Iron(II)-porphyrins without axial ligands form, with oxygen, molecular complexes in which the central iron ion probably transfers electrons to the oxygen, and this oxygen then undergoes back-bonding to the porphyrin ligands. Indications of this structure are obtained mainly from IR and ESR spectra.

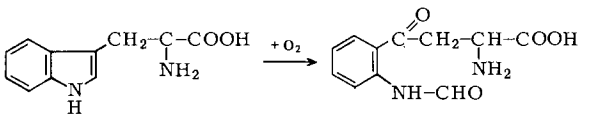
If the oxygen is pumped off, the iron(II)-porphyrin is regenerated. Thus, the structure is revealed as probably a dimeric heme in which two oxygen molecules are bonded by weak donor-acceptor interactions to the positive charge centers of the two iron(III) ions and to the negatively charged porphyrin radicals.

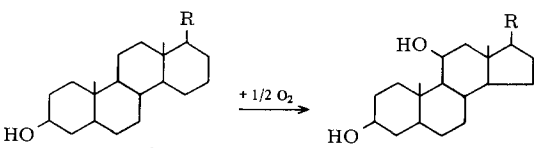
9. Reactivity of the Heme-bound Oxygen *in vivo* and *in vitro*

Ascorbic acid, phenoxide ions, and other easily oxidized substrates are rapidly oxidized even by the oxygen of oxyhemoglobin (HbO_2)[61]. Tryptophan-oxidase is a heme enzyme that, similarly to hemoglobin, is built of four subunits and catalyzes the addition of an oxygen atom to tryptophan *(10)*.



(10)

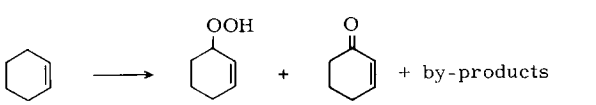
The "hyperoxide anion" of HbO_2 is here presumably bonded also to a copper ion, which could explain the special reactivity of the oxygen[69]. The most reactive and thus the most interesting heme enzyme is cytochrome P 450, which introduces oxygen atoms into unactivated CH_2 groups, formally as in *(11)*.



(11)

Cytochrome P 450 acts as the end of a short electron-transport chain that does not form ATP, and with oxygen it probably forms an extremely electron-rich iron(II)-hyperoxide complex containing a cysteine-sulfur atom as the sixth ligand ($-S-Fe^{II}-O_2^-$ radical)[70]. The oxygen is here so basic that it deprotonates fluorene[71]. Other mechanisms are, however, provisionally not excluded[72].

The attempts to imitate the catalytic activity of the heme enzymes *in vitro* by means of metalloporphyrins have been lamentably unsuccessful. Only radical chain peroxidations occur, as for example in the reaction of cyclohexene *(12)* illustrated, this being catalyzed by some metalloporphyrins[73, 74]. Such reactions are, however, catalyzed by innumerable metal complexes; a peroxide formed primarily is decomposed and probably no "oxygen activation" is involved, so that the expensive heme analog has been wasted.



(12)

Catalysis by bismetal systems in which the oxygen molecule is twice bonded and polarized is at the moment the most hopeful route. For example, a pair often used in biology is heme and copper ions bonded to a protein.

10. Prospects

The central problems for the future in this field are the synthesis of suitable molecular complexes of chlorophyll and porphyrins for conversion of light into redox energy (~membrane potential) and for specific catalytic oxidation of organic substrates by molecular oxygen. Both these problem areas are of extreme interest both scientifically and, in principle, for industry. Among specific starting points the following possibilities appear: syntheses and photochemical investigations of hydrated magnesium-porphyrin dimers (see Sections 3 and 6), construction of photoelectrodes from monomolecular porphyrin layers or aggregates with micellar double layers[48] (see Section 6), and synthesis of porphyrins with intramolecularly defined ligand fields as well as covalently fixed electron-donors (see Section 9). These problems are currently under worldwide study and important progress may be expected in the near future.

In conclusion, let us return to *Pauling*'s remarks cited at the beginning of this review. Investigations to determine structure and syntheses of specific molecular complexes do not, of course, provide any "penetrating and reliable theory of weak interactions", but, in accord with one of the valued traditions of organic chemistry, they enable general rules to be derived and from these rules, prognoses. Specifically, complex systems of varied utility may thereby be obtained.

"What the chemist does in a situation like this is to analyze many molecules of a similar kind and get some empirical rules. It is not very satisfactory from the point of view of a physicist who is trying to understand from first principles. But the problem of the chemist is different. He must try to guess ahead of time what is going to happen with molecules that haven't been made yet, or which aren't understood completely ... (Don't forget that the reason a physicist can really calculate from first principles is that he chooses only simple problems)[75a] ... and lo and behold!, the chemists are almost always correct"[75b].

The Gesellschaft für Biotechnologische Forschung, under the direction of Frau Dr. M.-R. Kula, has provided the best possible support for the review and for our own experiments described therein. The work has been financially supported by the Bundesminister für Forschung und Technologie (BMFT) by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Prof. Dr. H. Pommer of BASF placed 300 g of precious octaethylporphyrin at our disposal. Messrs. Hoechst (Frankfurt) and Riedel-de Haën (Hanover) presented us with a thousand liters of glacial acetic acid for the preparation of hemin, wherein we were assisted by Messrs. Buchler (Braunschweig). Specialist advice and willingness for friendly discussion from Prof. Dr. H. H. Inhoffen, Dr. E. Lustig, Prof. Dr. H. Brockmann, Jr., Dr. J. Subramanian, Prof. Dr. D. Mauzerall, and Priv.-Doz. Dr. W. S. Sheldrick were irreplaceable prerequisites for the success of our own work. The experimental bases of the work discussed in this review were provided by Dr. S. Besecke, Dr. C. Mengersen, Dr. P. Wasser, Dr. L. Witte, and Dipl.-Chem. R. Schlözer. X-Ray structure analyses were carried out by Dr. W. S. Sheldrick, G. Struckmeier, and U. Thewalt. To all these Institutions and chemists I should like to express my sincere thanks.

Hence the structure given in Figure 16 becomes all the more likely.

Processing of Plastic Waste and Scrap Tires into Chemical Raw Materials, Especially by Pyrolysis[**]

By Hansjörg Sinn, Walter Kaminsky, and Jörg Janning[*]

Dedicated to DECHEMA on the occasion of its 50th anniversary

An account of the occurrence of pyrolyzable material and the state of development of pyrolysis processes in the USA and Japan is followed by a description of laboratory and pilot-scale experiments designed to exploit the raw material content of pyrolyzable substances rather than the heating value. Plastic waste and scrap tires can be pyrolyzed to give up to 40% by weight of aromatic compounds in fluidized sand beds which are surprisingly insensitive to the unit size of the feed material.

1. Motive for the Investigations

"If man had found huge heaps of a gray-white powder with the average composition of today's plastic production instead of crude oil and coal deposits, a chemical industry would undoubtedly have developed on the basis of this material". This insight, mentioned in an application to the Max-Buchner-Forschungsstiftung in 1969, has motivated our investigations into pyrolysis of plastic waste.

In 1973 6.4×10^6 tons of plastics were produced in the Federal Republic of Germany (FRG) and 5.1×10^6 tons were consumed, 1.0×10^6 tons of which were used as packaging materials. The total amount of waste plastics in the FRG was 1.4×10^6 tons in 1973, of which 1.0×10^6 tons were domestic or similar industrial waste. 700000 tons of this waste was short-life packaging. The weight-percentage of plastic in domestic waste fluctuates between 3 and 5 %, and the volume-percentage between 10 and 15 %. 135000 tons of waste comes from the production of the plastics producing and manufacturing industries. PVC, which comprises 0.6 wt-% of domestic waste, causes almost half of the HCl emission arising from domestic waste incineration. It was predicted that the volume of scrap tires for 1974 would total 340000 tons, of which 200000 tons require disposal[1].

As long as 90 % of world crude oil production is used for generating energy, the incineration of worn-out and used products of crude oil will continue to compete with all other utilization methods. For instance, the plastic material in domestic waste significantly raises its calorific value. The data from the Frankfurt municipal waste incinerator (Fig. 1) show a distinct reduction in calorific value because of a 6% drop in plastic production[3] in 1974. Existing waste incineration plants are designed for a definite calorific value of the feed. Increased calorific values because of greater proportions of plastic material in the waste causes localized reductions in the incinerator and therefore limits the throughput of the plants. A fundamentally different situation would arise, if a lower percentage of crude oil were used as fuel material. Nevertheless, in the FRG the weight production of plastics is equivalent to the amount of its crude oil production. Remarkable in this context is the fact that the Middle East extracts a yearly 400000 tons per rig; on the other hand the FRG only extracts approximately 2200 tons and the USA an average of 1200 tons per rig per annum. Furthermore the cost of land drilling in the USA or the FRG is approximately 500000 DM per drill[4]. Clearly, even small pyrolysis plants would be economically viable at the present time if

1) the pyrolysis products were comparable with or superior to crude oil,
2) the costs of investment did not exceed 500000 DM per 1000 tons per annum,
3) the process were self-supporting in energy, and
4) the running costs were equivalent to those of oil rigs.

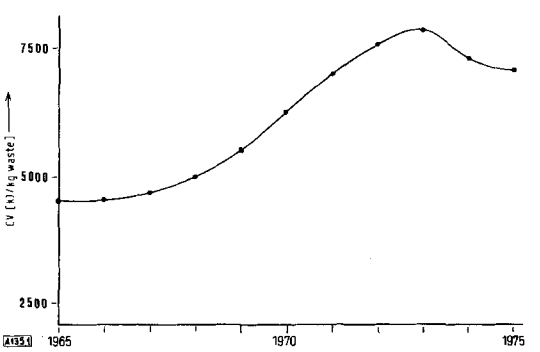

Fig. 1. Change in calorific value (CV) of refuse burnt in the Frankfurt municipal incineration plant (see [3]). There was a constant rise in the calorific value until 1973, and since 1974 it has decreased by around 9 %. In the first half of 1975 it had not yet increased. The reason for the decrease is not easily explained. However, it is certainly related to the decrease in plastics production (about 6% from 1973 to 1974) and the 25% decrease in 1975 in paper sales.

We know today that conditions 1 and 3 can be met. The fulfillment of condition 2 seems to be possible. Information is not yet available for a decision on condition 4; the feed costs are a decisive factor, because of the unknown expense of the separation process required to provide a feed consisting almost exclusively of plastics.

Numerous pyrolysis plants have been developed for processing unseparated waste to save on separation costs and aiming specifically at conversion into energy. An excellent survey of these processes together with a list of the original publica-

[**] Based on lectures held during a conference organized by the Swiss Engineers' and Architects' Association (Schweizerischer Ingenieur- und Architektenverein) on April 10, 1976 in Basel, at ACHEMA 1976, on July 19, 1976 in Frankfurt/Main, and at the meeting of the members engaged in the VKE-Project "Conversion of Plastic Wastes" (Wiederverwertung von Kunststoffabfällen) on April 27, 1974 in Frankfurt/Main.

tions is given in the conference paper "Conversion of Refuse to Energy"[2].

A comparative study of the waste incineration and pyrolysis processes by *Tanner*[5] comes to the following conclusions: One of the major advantages of pyrolysis is the minimization of gas production. All gas-containing components, especially the dust precipitators can be smaller than in incineration plants. An additional advantage seems to be that the energy obtained turns out to be storable, although it is still debatable whether this advantage justifies the installation of the process. The necessity of crushing the feed prior to pyrolysis is seen as a disadvantage.

Inoffensive and hygienic disposal is *Tanner*'s main preoccupation, economic aspects being of secondary importance. The following assumptions are made concerning the present state of development (see Table 1): In the near future the classical incineration processes will be improved; on the other hand the various pyrolysis processes present a new and interesting approach, but it will take another five to eight years before their effectiveness can be definitely assessed.

reactor, hot particles of char provide the energy needed to pyrolyze the organic material. The char, which is actually the solid residue of the pyrolysis reaction, enters the reactor after having been heated to a temperature of 760°C and is mixed turbulently with the organic material. Five parts by weight of char will be mixed with each part of organic material. The pyrolysis reaction takes place as the char-waste mixture proceeds through the reactor. The organic feedstock is broken down into a gas and char mixture. Because this reaction is endothermic, the temperature of the mixture will fall to about 510°C by the time it leaves the reactor.

A mechanical separator or cyclone is used to remove the char from the gas. The char which now consists of the char fed into the reactor as well as that newly formed by the pyrolysis reaction, is stored for re-use in the reactor. Before being recirculated to the reactor, this stored char is reheated. Excess char is removed for disposal in a sanitary landfill.

The process gas that has been separated from the char will be cooled quickly to 80°C in an oil decanter. In this device, oil is sprayed into the gas stream, causing it to cool.

Comparison of a fuel oil with the pyrolysis oil of the San Diego plant and the liquid fraction obtained on fluidized bed pyrolysis of a representative mixture of thermoplastic material is of interest in this context. The pyrolysis oil from unseparated waste is seen to be relatively highly oxidized (see Table 2).

The more demanding pyrolysis processes require a relatively sophisticated feed preparation. The Garrett process for instance utilizes two shredders and two-stage air classification. The actual pyrolysis step is described by *Levy*[7] as follows: The pyrolysis reactor is a vertical stainless steel pipe through which the organic feedstock is blown pneumatically. In the

The cooling must be done very quickly to stop the chemical reactions taking place in the gas and thus prevent a reduction in the yield of fuel. The oil used for cooling is a combination of the liquid fuel produced by the plant and No. 2 fuel oil. After cooling, the liquid fuel settles in the base of the decanter.

The remaining gas stream is subjected to a series of clean-up steps and then compressed. Part of this gas will be used as the oxygen-free medium for pneumatically transporting both the organic feedstock and the char into and through the pyrolysis reactor, and the remainder is used for energy production. It is useful to bear in mind the differences and similarities between the above process and the fluidized bed

process for the pyrolysis of plastics which is discussed later in the paper.

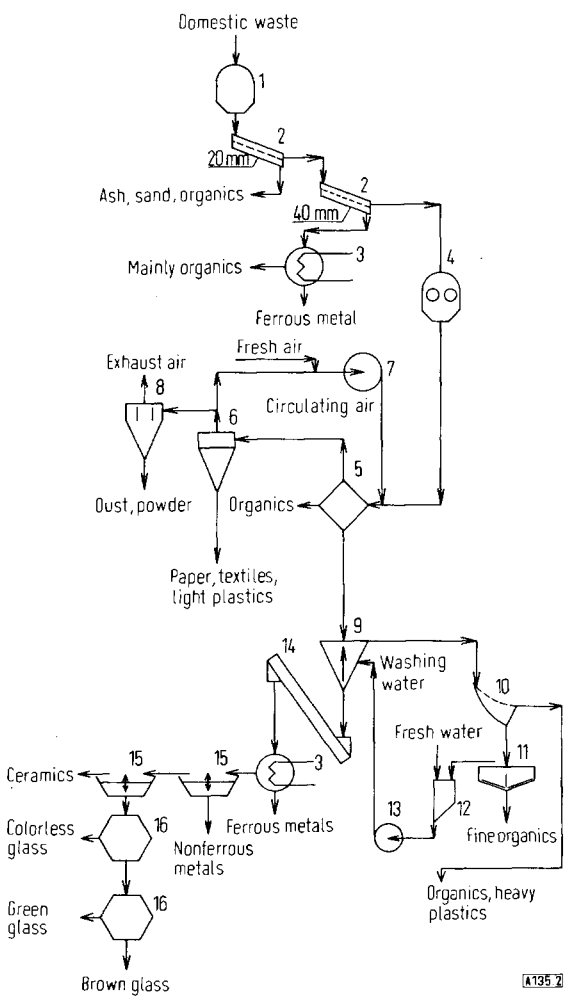

Fig. 2. The flow scheme of the domestic waste separation plant at the Technische Hochschule Aachen (see [12]). 1, feed precrusher; 2, fine sieve; 3, magnetic separator; 4, cutting roller mill; 5, air classifier; 6, cyclone; 7, ventilator; 8, dust separator; 9, fluidizing classifier; 10, water separation sieve; 11, thickener; 12, bottom product; 13, pump; 14, discharge and water separation system; 15, specific gravity separator; 16, optical-mechanical separator.

Opposing processes of this kind are those which need no feed preparation. The Destrugas process[8] for example heats up the unsorted waste in externally heated retorts. 500 m^3 of gas is produced per ton of waste, two thirds of which is used for maintaining the heat of the process. About 150 m^3 of gas can be given off; its constituents are: H_2 55%, CH_4 10%, hydrocarbons 2%, CO 11%, CO_2 18%, and H_2O 4%.

According to experience gained in preparing waste for pyrolysis processes, the problem of separating waste into its component parts can be regarded as solvable. However, these processes are economically sound only if a number of valuable substances or their basic constituents are separated out before pyrolysis. In Franklin, Ohio, the 150 t/d *Black Clawson* process[9] involves a wet pre-separation of materials similar to the technology known from paper mills. A comparable process is the *Krauss-Maffei* R 80 process[10]: From the light weight part of the waste material the paper is "dissolved" in a kind of pulper and the plastics and textiles remain separable in the form of a "plait", which could be the supply for pyrolysis processes.

The *Bureau of Mines*, USA, operates a pilot plant dry process to separate waste into its components. Rotary mills and air classifiers are combined and an electrostatic precipitation of plastic material is being experimented with [9, 11]. *Hoberg*[12] at the Technische Hochschule Aachen has improved the process by incorporating liquid filled flow and gravity classifiers (see Fig. 2).

An additional source of feed for pyrolysis processes is provided by scrapped cars, with their relatively high proportions of plastic material. In 1973, 3643000 sedan cars with an average weight of one ton each were produced in the FRG. They will have to be scrapped at some point. In each ton there is about 250 kg of plastics, glass, rubber, textiles, and cardboard which are easy to separate. This gives a total amount of one million tons of non-metal material a year, which is on the increase. At present this material is granulated and dumped.

Furthermore a considerable amount of plastic material (some 10000 t/a) comes from scrap wiring material. At present the copper core is regarded as the more desirable material,

and the plastic or rubber insulation is just burnt off in retort furnaces (an antediluvian process) with considerable emission of HCl gas. Mechanical stripping processes are also available for separating the metal and the insulation, but the dumping cost for the insulating material reaches 40 DM/ton.

Oda et al.[16] developed a process that dehydrochlorinates plastic waste with a content of 20 wt-% of PVC at 280 to 300°C with retention times of 40 minutes, the HCl gas produced being dissolved to form hydrochloric acid. The char produced by this process and the rest of the remaining non-

Table 3. Composition of pyrolyzable waste and scrap material (data from Northrhine-Westphalia, FRG) (see [14]).

Finally it should be noted that the Funabashi project has proved the feasibility of separate collection of waste[13]. A list of pyrolyzable waste material produced in Northrhine-Westphalia is shown in Table 3[14].

2. Pyrolysis of Separated Plastic Material

Almost identical decomposition graphs were reported for relatively long retention time in the pyrolysis zone (>20 minutes) by *Matsumoto et al.*[15] and *Oda et al.*[16] (Fig. 3 and 4).

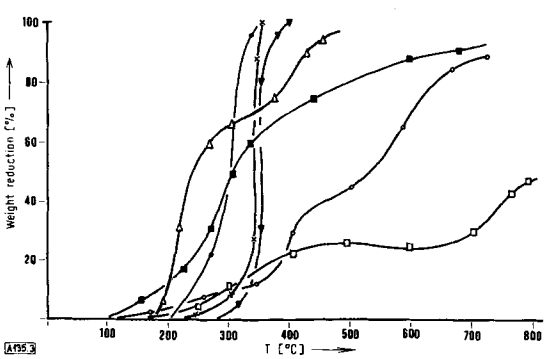

Fig. 3. Thermal decomposition characteristics (see [15, 16]). ●, polypropylene; ×, polyethylene; ▼, polystyrene; △, PVC (hard type); ■, urea resin; ○, phenol resin; □, polyester.

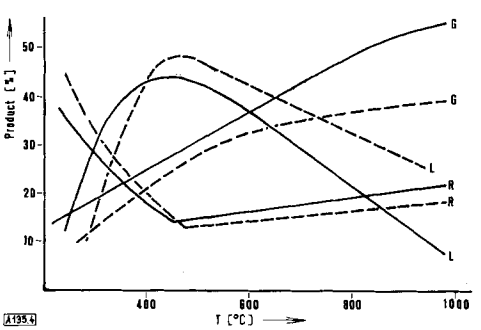

Fig. 4. Product composition *vs.* decomposition temperature (—·— retention time 1.5 h, ---- retention time 0.5 h); G, gaseous products; L, liquid products; R, residue (see [15]).

decomposed plastic material is burned with excess air in an incinerator. The combustion gases leave a Venturi scrubber with *ca.* 10 ppm HCl, up to 50 mg Pb per normal cubic meter, and 0.8 mg Cd per normal cubic meter. The waste water goes through a coal filter with a pH of 7.8, <0.01 ppm cadmium, and 0.1 ppm lead. A 5 t/d pilot plant was constructed in 1973 in Koshigaya city. The plant meets the requirement that water and air pollution be avoided.

Kitaoka et al.[17], *Shimizu et al.*[18], and *Speth*[19] have proposed essentially the same method for manufacturing a fuel oil (used on site) from the waste arising in polyethylene production. The waste is decomposed in externally heated agitator

vessels at 420 to 455°C, whereupon almost 90 wt-% of the feed is converted into oil with a gross calorific value of 11000 kcal/kg plus 5 % of C_1 to C_4 hydrocarbon gases. The amount of char produced is low. The processes are characterized by long residence times and recycling of hydrocarbons having high boiling points to the reaction vessel. The Japanese plant which processes one ton per hour has been running since 1971; operating data are available as well as running costs. The average energy needed for pyrolysis is 200 kcal/kg. The total costs are 22000 yen per ton (*ca.* 74 $/ton), but calculating the profits from the oil produced on the one hand and the savings on dumping costs on the other there is an overall profit of 650 yen per ton (*ca.* 2 $/ton).

Matsumoto et al.[15] have shown that it is preferable to process plastic material containing PVC in two stages, *viz.* prior dehydrochlorination and the gasification of hydrocarbons at a higher temperature. A semi-commercial pilot plant was built in 1971 and has a capacity of 100kg/h. Figure 5 shows a flow diagram of this plant. The feed material is treated in a melting vessel 8 at about 300°C. The chlorine present in the PVC is liberated mainly as HCl gas and is condensed by an absorption process 14. The molten plastic material is then fed into decomposition vessel 9 containing a cracking zone and a reflux zone. The former is kept at a constant temperature of 400 to 500°C depending on the kind of material. Forced circulation of the molten plastics is necessary for an even temperature distribution within the vessel. The temperature of the reflux zone is adjusted to ensure return of the waxy components to the cracker and to keep the gaseous products to a minimum. Typical test results are shown in Table 4. The economic minimum size of a commercial plant should be approximately 20 tons per day for industrial plastic waste, and 50 tons per day for municipal plastic waste.

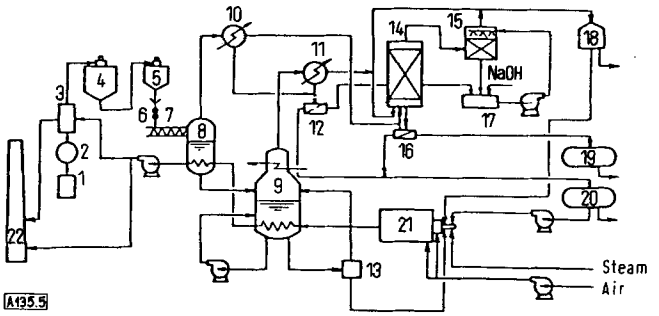

Fig. 5. Process flow diagram of the two stage plant of *Matsumoto et al.* (see [15]). 1, waste plastics; 2, crusher; 3, dryer; 4, storage tank; 5, feed hopper; 6, rotary valve; 7, screw feeder; 8, melting vessel; 9, thermal decomposition vessel; 10 and 11, condensers; 12, oil separator; 13, take-out device for decomposition residue; 14, absorption tower; 15, neutralization tower; 16, oil separator; 17, alkali tank; 18, gas holder; 19, hydrochloric acid tank; 20, recovered oil tank; 21, furnace; 22, chimney.

One hundred tons of domestic refuse produces 160 to 170 tons of steam (at 300 to 350°C) which will crack about 80 tons of industrial waste into fuel oil after being superheated to 500 to 650°C. The amount of fuel necessary for superheating this amount of steam is only about seven tons of oil. A one ton per day pilot plant for the processing of foam polystyrene by using superheated steam has recently been completed. Attempts to regain the basic compounds of polyurethane foam, polyamide and polyester, by hydrolytic decomposition also warrant mention in this context (see Section 6).

A five tons per day plant, which has been operated by Jacult at Yoga since 1974, uses the Fluid Cracking Process developed in Japan[23] (cf. the scheme in [21]). A sand cracker with a diameter of one meter is heated by partial combustion

Table 4. Typical test results with pilot plant run by Mitsubishi Heavy Industries (see [15]). Polypropylenes (1) and (2) are the atactic and isotactic froms.

[a] Composition: Low density polyethylene 35.7%; high density polyethylene 14.2%; polypropylene 10.8%; polystyrene 16.9%; PVC 18.0%; other components 4.4%.

Similar investigations by *Tsutsumi*[20] were published earlier[21]. The use of microwave heating to melt and to preseparate HCl should again be noted. The actual pyrolysis reactor is an externally heated screw chamber. Interestingly, *Tsutsumi* now doubts that the process will be economically feasible[22]. His remarkable new proposal is a pyrolysis process using superheated steam at 500 to 650°C generated in waste incinerators (see Fig. 6).

of the feed material to 350 to 600°C for the decomposition of non-returnable polystyrene bottles.

Some 80 to 85 wt-% of the feed material is transformed into oil in a plant with an energy requirement of 26 kW, a steam requirement of 500 kg/h, and a cooling-water requirement of 5 m^3/h. The oil has an average molecular weight of 176 and contains 1.5 % benzene, toluene, ethyl benzene, 62% styrene, and 30% di- and oligo-styrene, besides smaller

amounts of higher-boiling fractions. The investments costs for 1973 were one million DM[23]. The process is said to be applicable to other plastic materials containing up to 10

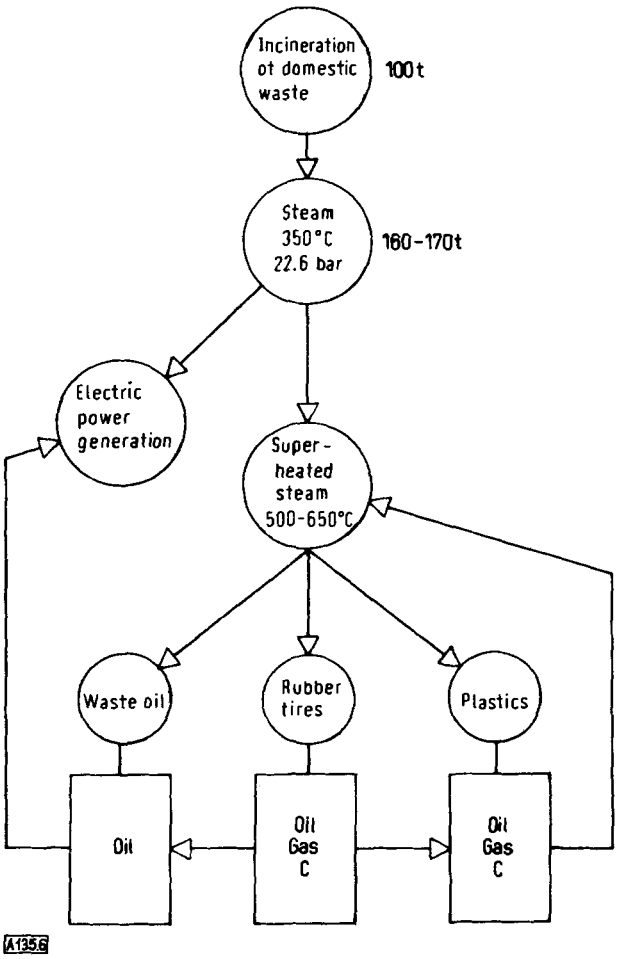

Fig. 6. Proposed future process for the recycling of industrial waste (see [22]). Pyrolysis products: 70 to 95% oil from waste oil; 40% oil, 20 to 25% gas and 30 to 35% carbon residue from scrap tires; 90 to 92% oil, 8 to 9% gas and 2 to 3% carbon residue from plastic material.

wt-% PVC and also to scrap tires. As a result of partial combustion, which of course has a favorable influence on energy requirements, the product oils contain oxidized compounds (calorific value 9510 kcal/kg, that of styrene 10060 kcal/kg).

A similar plant with a throughput of three tons of plastic per day was constructed in 1973 by Sumitomo Machinery and Shipbuilding Co.[24] in the Tshiba factory at a cost of 1.2×10^6 DM. During the test runs at 450 to 500°C about 75 wt-% of the feed material was converted into fuel oil. The sand fluidized bed is maintained by an air stream from uderneath and about 15% of the plastic material fed in must be burnt to produce the energy required for the decomposition. After cyclone separation of the char, the hot gaseous products are passed to a rectification column. Non-condensable gases are burned off and the combustion gases released into the atmosphere after washing out the HCl.

No fluidized bed pyrolysis processes are operated without oxygen in Japan. The alternative use of gases and oils produced by pyrolysis processes, apart from providing energy, does not seem to have been considered. Recycling in the sense of regaining basic materials is nevertheless being planned in future developments.

One special case is the pyrolysis process (10 kg/h) developed by the Osaka Municipal Technical Research Institute (OMTRI) in which dehydrochlorination of PVC at 300 to 350°C produces polyene compounds that can be transformed into ion exchangers[25].

A part of the research project "Conversion of Plastic Waste"[26] funded by the VKE is the hydrolytic decomposition of polyurethane and polyesters carried out by Bayer AG[53-80]. *Grigat*[27] showed that the hydrolysis of polyurethane in screw chambers by passage of steam leads to toluylenediamine (which can be reprocessed with phosgene into toluylene diisocyanate) and polyether, such as is synthesized from 1,2-ethanediol and alkylene oxide. Thus, in this hydrolysis process, the C atom introduced as phosgene on synthesis of the isocyanate is removed from the urethane as CO_2.

Current research in Hamburg is concerned with assessing the suitability of plastic scrap as a source of raw materials. After the conclusion of laboratory scale experiments[28,29] our research has become part of the VKE project "Conversion of Plastic Waste"[26,30]. *Menzel*[28] used a fluidized sand bed and *Perkow*[29] a molten salt reactor, each with a throughput of 0.1 kg/h for their investigations. The laboratory-scale apparatus for fluidized bed pyrolysis[31,21,28] is shown and explained in Figure 7.

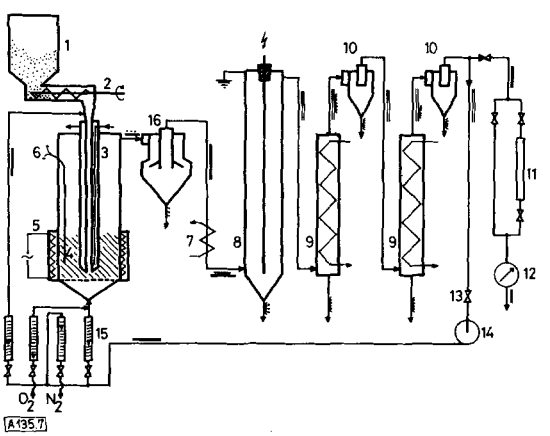

Fig. 7. Flow diagram of the laboratory test plant of fluidized bed pyrolysis by *Menzel* [28]. 1, plastic feed hopper; 2, screw conveyor; 3, downpipe with cooling jacket; 4, fluidized bed reactor; 5, cyclone 1; 6, cooler; 7, electrostatic precipitator; 8, intensive cooler 1; 9, cyclone 2; 10, intensive cooler 2; 11, cyclone 3; 12, gas sampler; 13, gas meter; 14, compressor; 15, rotameter.

Perkow's[29] molten salt reactor allowed sophisticated measurements of the amount of energy needed for the pyrolysis (Table 5).

Although the molten salt reactor has a lower energy requirement than the fluidized bed reactor, we decided, because of the corrosion and the higher build up of char residue, not to proceed any further with this research at present.

After we had been requested to construct a 10 kg/h pilot plant[30] we conducted experiments with a prototype reactor we named TPT. A conventional 110 liter garbage can was used, equipped with bent gas inlet tubes. To observe the principle of indirect heating and to avoid any pollution of the products, we used fire tubes inside the sand bed which had been developed by *Menzel*, *Kaminsky*, and *Tysarczyk* by scaling down the commercial tubes invented by *Schmidt*[32]

Table 5. Comparison of the measured and calculated data for the energy balance of the molten salt reactor. Pyrolysis at 690 °C (see [29]).

(see Figs. 8 and 9). Heat transfer (mainly radiation) to the feed material is therefore indirect with air excluded: the glowing tubes (steel 1.4876) are surrounded by fluidized sand and feed material.

The reactor was fed manually with plastic sticks weighing 20 g each *via* a cooled tube. Once we found that the heated fluidized bed is not adversely affected by pieces weighing even more than 1 kg, we constructed an air lock on top of a feed tube. An idea of the relative size of this part of the reactor can be gained from Figure 10.

The prototype reactor filled with 40 kg of very fine sand processes 20 kg of polyethylene or 15 kg of scrap tires per hour. The latter were introduced in pieces of up to 1.3 kg each (in a long experiment 0.7-kg pieces were fed in at 3-minute intervals). At present the pyrolysis gases are burned without any further treatment in an enclosed, low noise flue gas flare which has been placed at our disposal by BASF. Typical results of pyrolysis are shown in Table 6.

Earlier graphs[21] proving the dependence of the product composition upon temperature, especially in molten salt, warrant mention in this context. Figures 11 a to 11 d show the corresponding results of pyrolysis of polyethylene, polypropylene, polystyrene, and crushed scrap tires in a fluidized bed reactor.

In addition to the investigations mentioned above, *Janning* is carrying out pyrolysis experiments with added steam in

3. A Pilot Plant

The preliminary experiments described above led to the design of a pilot plant whose overall layout is shown in Figure 13. Plastic material is pyrolyzed in a fluidized bed reactor utilizing quartz sand heated to about 800°C. The fluidizing medium is preheated pyrolysis gas and heating is maintained by radiating fire tubes in which either propane or pyrolysis gas can be burned. The feed enters the sand bed either at the top of the reactor through an air lock (ZR 1) or through a water-cooled screw feeder (ZR 2 with S 1) at the side.

of about 15° and carries the bent gas inlet tubes. These tubes are movable vertically so that their distance from the bottom of the fluidized bed can be varied. With this arrangement there is a variable settling zone for small metal pieces such as will be desposited on pyrolytic stripping of copper-cored wiring. A flanged inspection cover is fitted to the bottom of the gas distribution zone.

The pyrolysis gas produced is cleaned together with the fluidizing gas in a cyclone (Z 1); especially if the feed contains of scrap tire material, char and zinc oxide will be precipitated. The cleaned gas is led to the condenser (K 1) which is actually a vertical tubular heat exchanger. In the case of condenser failure, a three way cock allows the gas to be fed directly to the flare. The gas leaves the condenser (K 1) at 20 to 50°C, or at 100°C if the cooling capacity is reduced to avoid clogging by paraffin waxes. Condensed products collect in a receiver (G 1).

In a counter-current packed washer (K 2) the gas is then cooled to −20°C. The condensed products are dissolved in the scrubber oil and can be collected in a container (G 2). This container feeds the scrubber oil pump. For cooling the scrubber oil to −20°C a counter-current tubular heat exchanger (WT 1) is used. The liquid products collected are processed together with the scrubber oil in a glass rectification column.

The non-condensable components of the pyrolysis gas are compressed to 2 to 3 bar and stored in a gasometer. Fluidizing gas as well as fuel gas for the radiating fire tubes are tapped off as required. The fluidizing gas is preheated to 400°C in a counter-current heat exchanger (WT 2) by the exhaust gas of the four fire tubes.

The plant is equipped with numerous data-collecting instruments. Because we have deliberately separated the hot and

cold parts of the plant, the latter, together with the processing of the pyrolysis oil, are situated in an explosion-proof room. Surveillance is carried out by continuous analysis of

the room air as well as by explosion limit controls. The pyrolysis gas is analyzed automatically by a gas chromatograph every hour. Some basic components are continuously monitored by infrared spectroscopy.

Installation of the pilot plant in our institute necessitates all these safety precautions; at the same time it is of great didactic value. The plant is currently being installed by Claudius Peters AG.

4. Investigations on the Pyrolysis Reaction

A comparison of pyrolysis in a fluidized bed (with nitrogen or pyrolysis gas as fluidizing agent) and the molten salt reactor has been made by *Krebs*[33] (see Fig. 14). Experiments with recycled pyrolysis gas show a surprisingly high production of aromatic compounds. Decomposition experiments on particular mixtures gave a more or less additive spectrum of products; pyrolysis of a model mixture (in a ratio of polyethylene : polypropylene : polystyrene : PVC = 7:1:2:2 which is comparable with the composition of the plastics fraction of domestic waste), however, shows that the fraction of aliphatic compounds produced can decrease rapidly even at lower temperatures owing to interaction between the products. At 640 °C 2.0 wt-% of long chain hydrocarbons ($>C_9$) were found; in the absence of interaction 13.6 wt-% would have been produced.

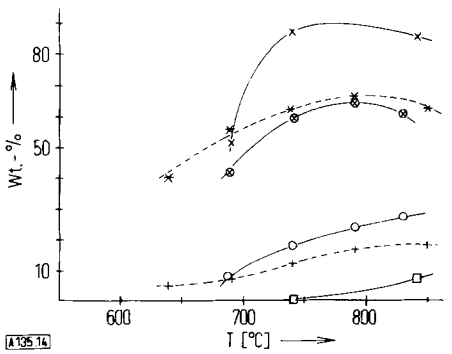

Fig. 14. Pyrolysis of polyethylene (compiled from [28, 29]). —— in fluidized bed reactor, --- in molten salt reactor: ×, Σ gases: H_2 and C_1 to C_4 (fluidizing medium: nitrogen); ⊗, Σ gases: H_2 and C_1 to C_4 (crackgas); ○, Σ aromatic compounds: C_6 to C_{10} (crackgas); □, Σ aromatic compounds: C_6 to C_{10} (nitrogen); *, Σ gases: H_2 and C_1 to C_4; +, Σ aromatic compounds: C_6 to C_{10}.

The surprisingly high and variable yield of aromatic compounds were examined in three further postgraduate investigations. *Krebs*[33] studied the decomposition of single polyethylene particles as a function of the temperature of the molten salt, the depth of immersion in the melt, and particle size by measuring the increase in pressure of the gas above the melt. The events observed after placing the particle on the surface of the melt can be described as follows:

The particle heats up immediately and softens but retains its round shape, at least until the end of the induction period [t_I] which is limited by the onset of the cracking. The explanation for the dependence of the induction time on the mass of the particle (t_I proportional to $m^{1/3}$) and the measurements of the temperature of the particle during decomposition correspond to the above observations (see Fig. 15).

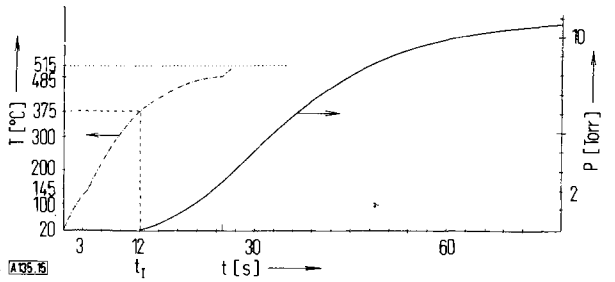

Fig. 15. Pyrolysis of single plastic particles in molten salt reactor (see [33]). Rise of the temperature in the particle and pressure in the reactor *vs.* time. ....., temperature of the melt; t_I, induction period.

Bock[34] studied the decomposition of single polyethylene particles in a sand bed "fluidized" by a vibrator, by monitoring the pressure arising as a function of time together with the temperature movement inside the particle.

The pressure *vs.* time graphs obtained in both studies show a typical S-shape. The induction time during the decomposition of a polyethylene particle of 2.5 mg drops from 8 to 0.8 s with a temperature increase of 515 to 725 °C. During this time, incipient cracking into long chain aliphatic compounds ($\geq C_{30}$) is observed.

One main difference between fluidizing bed and molten salt reactors consists in the actual reaction volume. In molten salt pyrolysis, the reaction volume of the gaseous products is essentially the gas layer between the polyethylene particle and the melt. As the volume of this gas layer and the amount of gas produced is proportional to the surface area of particle, the residence time changes with the temperature. The actual reaction volume in the fluidized bed is in fact greater than that in the molten salt; on the other hand the residence time of the gas produced is determined not only by the dimensions of the fluidized bed itself (diameter, height of expansion) but also by the gas penetration therein. This provides an explanation for the following observations:

1) The average molecular weights of the products in a simulated fluidized bed are considerably lower than those of the molten salt (and the real fluidized bed) because of the higher ratio of the amount of gas produced to the actual reaction volume and the consequent increase in residence time;

2) the drop in standardized final pressures (P_R/m) with increasing mass (m) because of a shortening of the residence time with increasing amounts of gas produced in constant volume.

The latter fact opens up the possibility of varying the residence times of the cracked products by feeding the fluidized bed reactor with different amounts of plastic per unit time. This could be used to achieve a desired composition of cracked products.

Finally *Döring*[35], using a 300-cm long fluid bed, which was divided into eight compartmentalized sections, took pyrolysis gas samples of the homogeneous sand/plastic mixture flowing down the tube in order to establish the relationship between the composition of the pyrolysis products and time. A significant result is shown in Figure 17.

In accord with the above three investigations the following picture emerges:

1) Polyethylene particles with a diameter of 0.5 to 0.8 mm melt in less than 0.2 seconds and the surface of the globule formed is covered with hot sand grains. Larger particles release

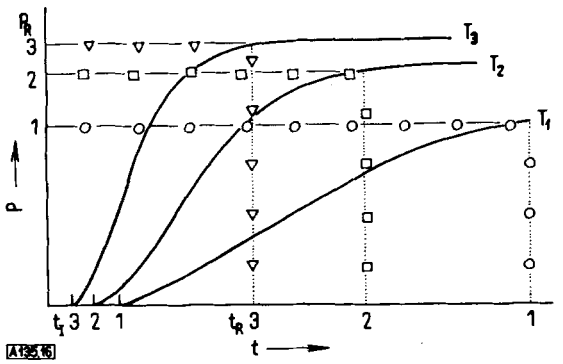

Fig. 16. Standardized pressure curves (see [34]). Pyrolysis of polyethylene at different temperatures ($T_1 < T_2 < T_3$); t_i, induction period; t_R, reaction time; P_R final pressure.

globules from their surface layer according to the amount of heat input.

2) As the temperature of the molten layer increases, pre-pyrolysis to long chain aliphatic compounds (C_{25} to C_{40}) takes place at 300 to 350 °C in the globule.

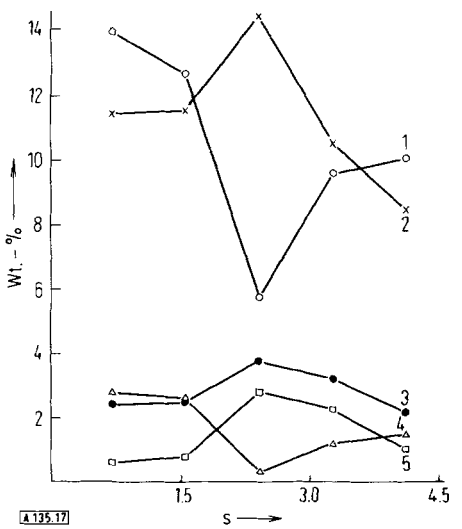

Fig. 17. Pyrolysis of polyethylene in a flow bed reactor at 700 °C (see [35]). Composition of each gas sample depending on the retention time of the granulated polyethylene feed. Retention times shown (1.5, 3.0, and 4.5 seconds) correspond to reactor lengths of 1, 2, and 3 m. 1, benzene; 2, propene; 3, butadiene; 4, toluene; 5, isobutene.

a) A postcracking of these aliphatic compounds occurs as the hot sand grains move onto free sites on the surface of the partially globulized particle. This produces, *inter alia*, C_3 and C_4 olefins which react in the gas/particle interface with its high concentration and temperature to form aromatic compounds with release of hydrogen.

b) Through the shearing force in the fluid bed, an "exchange" of sand grains takes place at the surface of the globulized plastic. Small amounts of the thin molten boundary layer are still attached to the sheared off particles, which are pyrolyzed by collision with hotter sand grains. The compounds thus produced are aliphatic ones or olefins. Of the latter, the C_3 and C_4 compounds form aromatic compounds in the laminar interface which also has a high temperature and high concentration. The gas experiences a relatively long residence time in the interface.

3) After further heating and pre-pyrolysis the globules disintegrate owing to volatilization of the low molecular weight compounds produced and to the shearing forces mentioned. The particles collide with hot sand grains and are cracked. The high gas production leads to shorter residence times of the products in the laminar interface and hence to cooling. Consequently, the amount of aromatic compounds produced drops, as does the post-cracking of the long chain aliphatic compounds. The amount of aliphatic compounds produced therefore increases at the end of the fluid bed.

4) Relatively cool sand grains with a layer of melted plastic on their surfaces collide with hot sand grains and the events described in 2) take place.

From these experiments it can be deduced that the spectrum of products can be varied according to the particle size of the feed, even in full-scale plants. A high yield of aromatic compounds results from high local concentrations of C_2, C_3, and C_4 olefins. This was proved directly by adding these gases during the pyrolysis in the laboratory test reactor as well as by feeding large pieces into the pilot plant reactor.

5. Pyrolysis of Scrap Tires

Pyrolysis of scrap tires has frequently been mentioned above. *Schnecko*[36] has recently published a review on it. At the moment the process of burning the scrap tires developed by Gummi-Maier[37] seems to be a satisfactory method of disposal. Successful pyrolysis experiments in an indirectly heated rotary kiln were made by Cobe Steel[38,39]. Similar results will certainly be produced from the Herbold plant[40]. In the Ruhr area a 100 kg/h pilot plant is being built by a consortium of different firms[14] for processing a mixture of used cabling and wiring, scrap tires, and acid resins from the production of phenoplasts. Pyrolysis conditions should be adjusted to give maximum yields of liquid hydrocarbons as well as unsaturated C_5 to C_{10} hydrocarbons and homogeneous depolymerized products. One of the essential demands is the collection of pollutant material at one end of the process. Concerning the solid pyrolysis products, investigations of the conditions and the possibilities of regaining the metal contained in the scrap tires, provided that it is of satisfactory quality, and the regaining of zinc oxide filler are well to the fore at present[41].

Investigations into the utility of the carbon soot separated and into production of an active charcoal-like product are being carried out.

Takamura et al.[42] have shown that the carbon soot produced by pyrolysis of scrap tires can be reused as filler for new tires and also processed into active charcoal.

Gasification in autoclaves[39] and vacuum pyrolysis[43] are also being actively considered, but process development is still at an early stage. All the processes mentioned above use crushed feed which causes considerable expense. Our observations using large pieces of tires for the fluidized bed pyrolysis, would certainly suggest that a suitably dimensioned fluidized sand bed could pyrolyze scrap tires without prior size reduction, with a space-time yield of 1.3 tons.

6. Interim Summary

It is hardly surprising that polymers are pyrolyzed in fluidized sand beds. The relatively high yields of aromatic compounds obtained in very fine sand beds are understandable

in view of the investigations on single plastic particles. While pyrolysis with indirectly heated sand beds excluding oxygen is certainly disadvantageous with regard to the process heat supply, it does afford decomposition products that can be separated in adequate purity at low cost, and which can be reused as chemical raw materials. This could turn out to be economically viable if the price of raw materials for chemical processes remains higher than that of hydrocarbon fuels, or if hydrocarbons relinquish their role as the principal source of energy. To minimize separation costs, and to avoid corrosion damage and pollutant emissions, it would seem appropriate (i) to eliminate hydrolyzable material from a mixture of plastic waste by hydrolysis at temperatures below 200 °C[53–80], (ii) to dehydrochlorinate the residue at 350 °C, and (iii) to pyrolyze the dehydrochlorinated polyenes together with the hydrocarbon-rich polymers at 600 to 800 °C. Catalytically active fluidized beds following the actual pyrolysis reactor would limit and standardize the product spectrum. Studies on this aspect of current research and process data pertaining to the pilot plant described in Section 3 will be published in future paper.

The authors wish to thank their colleagues in the "Pyrolyse" research team (W. Balcerek, J. Döring, J. Fritz, H. Krebs, H. Rost, H. Schacht, H. Timmann, S. Tysarczyk, and M. Wentzel), the Association of the Plastics Producing Industry (Verband Kunststofferzeugende Industrie, VKE), and the Federal Ministry of Research and Technology (BMFT) for financing the pyrolysis project in Hamburg, as well as the Chemical Industry Fund (Fonds der Chemischen Industrie) for their continuous support. We are also grateful to all those who were so willing to communicate information and whom we met in the USA (Janning) and Japan (Sinn)[21]. We are indebted to Dr. E. Grigat, Bayer AG, Werk Dormagen, for the list of publications[53–80] on hydrolysis of plastic waste. Finally we would like to thank the Max-Buchner-Forschungsstiftung on behalf of several colleagues of the research group for support at the beginning of the project.

Dual-Wavelength Spectrophotometry

By Shozo Shibata[*]

At present, dual-wavelength spectrophotometry is probably the least well known of the techniques of absorption spectrophotometry. However, recent improvements in application techniques have shown that for various organic and inorganic materials dual-wavelength spectrophotometry can provide higher sensitivity and selectivity than conventional spectrophotometry. This article reviews the principles and scope of dual-wavelength spectrophotometry, including derivative absorption spectrophotometry, in the hope that these techniques may be adopted more frequently in the future for resolving many analytical problems.

1. Introduction

In 1951 *Chance*[1,2] proposed a new technique, "dual-wavelength spectrophotometry", for the measurement of turbid samples in biochemical analysis, and many important papers based on this technique have since been reported in this special field. Although the dual-wavelength technique is used primarily for the rapid and precise measurement of small absorbance changes at fixed pairs of wavelengths in turbid suspensions, it is also useful for the measurement of transparent solutions. However, this new technique remained unfamiliar in analytical and other branches of general chemistry up to the time of our systematic experiments[3-12]. Perhaps the main reason for this was that "dual-wavelength" was confused with "dual-beam", and that dual-wavelength was erroneously assumed to involve taking absorption measurements at two wavelengths and solving for concentration with simultaneous equations. In addition to this misunderstanding, many chemists were unable to appreciate the essential significance of differential absorbance ΔA. It is hoped that the present review might contribute to dual-wavelength spectrophotometry, including differential absorption spectrophotometry (derivative spectrometry), being fully exploited in the future as a valuable tool for resolving many analytical problems.

2. Principle of the Method

Since the dual-wavelength technique is not yet very familiar in analytical chemistry, we shall first of all describe the principle involved.

In dual-wavelength measurement, light from a highly stabilized tungsten-iodide or deuterium lamp is divided into two beams in two grating monochromators. The light beams of different wavelength from the two gratings are time-shared through a single cell by means of a rotating sector, and the difference ΔA between the absorbances at wavelength λ_1 and λ_2 is measured. Even a very slight change in the absorbance of a sample can thus be determined accurately on using maximum scale expansion. Since only one cell is used in the dual-wavelength method, various errors which are likely to occur in classical spectrophotometry, such as those due to deviations in cell position or cell constant, and to differences between sample and reference solution, such as turbidity and concentration, can be completely eliminated. Namely, dual-wavelength spectrophotometry minimizes the problems of scattering, unequal pathlengths and unequal reagent concentrations by using the sample itself as the reference solution. The principle of the method is shown schematically in Figure 1.

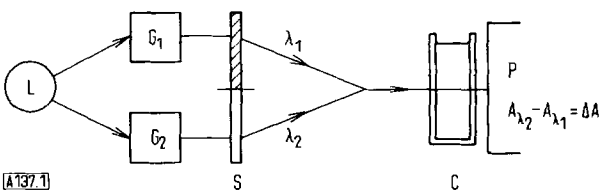

Fig. 1. Principle of dual-wavelength spectrophotometry. L, light source; G_1, G_2, gratings; P, photomultiplier; S, rotating sector; C, cell.

The photosignals are converted into electrical signals by means of a head-on type photomultiplier and are led into the gate circuit through the pre-amplifier. The gate circuit, operated by reference signals synchronized with the chopper, transmits alternate signals in the sequence λ_1 signal, zero signal, λ_2 signal, zero signal, and so on, to the respective hold circuits provided for the λ_1, λ_2, and zero signals. Undesirable influences such as light source fluctuation are automatically eliminated by controlling the voltage applied to the photomultiplier by means of the reference signal (λ_1 signal); the difference between the applied voltage and the reference voltage remains constant at zero signal. The signal-hold circuit feeds back this output to give a correction which makes the pre-amplifier output zero when no photosignal is received. This prevents any spurious signals that may be caused by the dark current of the photomultiplier or stray light. The λ_2 signal is used as the sample signal, and linear recording is made either of transmittance or, through a log converter, of absorbance. By these electrical techniques the peak noise is reduced to 0.0002 of the absorbance. The absorbance scale is therefore expanded one hundred-fold in comparison with conventional spectrophotometers; consequently, the dual-wavelength method is especially useful for measuring very small amounts of samples, and for observing the behavior of substances in very low absorbance ranges.

3. Background of the Principle

Normally, in conventional spectrophotometry the net absorbance A of the sample at fixed wavelength λ is measured by comparison with the reference solution, as shown in Figure 2. If, however, the sample solution contains any other back-

[*] Dr. S. Shibata
Government Industrial Research Institute
1-Chome, Hirate-machi, Kita-ku, 462 Nagoya (Japan)

ground caused by turbidity or interfering components, determination of the component under investigation is no longer possible.

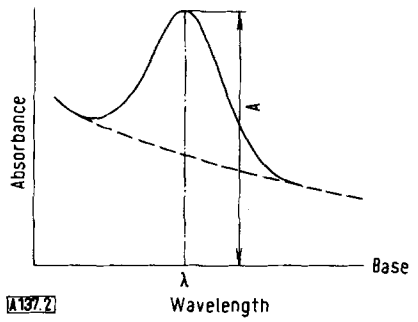

Fig. 2. Measuring absorbance in conventional spectrophotometry.

Actually, the measurement of total absorbance is not absolutely necessary for the quantitative determination of any component or chemical reaction. Hence, in dual-wavelength spectrophotometry, the absorbance difference ΔA between two wavelengths λ_1 and λ_2 is measured as shown in Figure 3, so that no reference solution is required. The most important prerequisite is a linearity or proportionality between measured signals and concentration of the component under investigation. Thus, many types of background can be eliminated by selecting a suitable combination of two wavelengths.

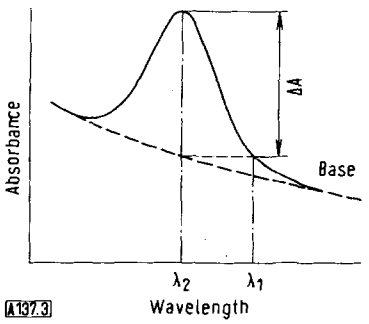

Fig. 3. Measuring absorbance in dual-wavelength spectrophotometry.

In kinetic experiments on the course of a chemical reaction, a wavelength that is not absorbed or an isosbestic point is generally chosen for the "reference beam", and another wavelength that is strongly absorbed by the sample is chosen for the "analytical beam". In this way, the pseudo-absorbance depending on the scattering or any other interfering backgrounds can be cancelled with dual-wavelength measurement; that is, the pseudo-absorbance A_p is detected at λ_1, and the pseudo-absorbance and genuine absorbance A_g are detected at λ_2. The absorbance difference ΔA between λ_1 and λ_2 can then be determined instrumentally.

$$A_{\lambda 2} - A_{\lambda 1} = \Delta A = (A_p + A_g) - A_p = A_g \qquad (1)$$

Quite generally, the special merits of dual-wavelength spectrophotometry are as follows:

1. Extremely small variations in absorbance can be detected[14] in samples having comparatively strong absorbance and pronounced scattering properties. Such small variations can be detected simply by taking the balance between the absorbance values at two different wavelengths λ_1 and λ_2. Hence, the dilutions and filtrations often required for the preparation of samples in conventional spectrophotometry are no longer necessary.

2. Exact measurement of a sample whose absorbance is very weak without having to use a reference solution. Usually the full-scale absorbance is 0.000 to 0.010 or 0.005 for the smallest measurement range.

3. The simultaneous determination of the components of a mixture as well as the masking of components can be carried out very easily.

4. Derivative spectra can be produced by means of wavelength scanning with λ_1 and λ_2 values set close to one another, so that many materials can be determined.

5. If a reference sample is unavailable, a special relative spectrum or genuine absorption spectrum can be obtained by means of wavelength scanning with fixed λ_1.

6. Kinetics of simultaneous reactions in a sample can be monitored with two-pen recorders at λ_1 and λ_2 respectively.

7. All instruments can be used both for the dual-wavelength method as well as for the conventional split-beam method.

4. Chemical Reactions in Turbid Solution

Figure 4 shows the absorption spectra of the oxidized and reduced forms of cytochrome c. In this example, the isosbestic point chosen as the reference wavelength is designated as λ_1. The wavelength chosen for the absorption measurement is designated λ_2, the absorption maximum for the reduced form. Although three other isosbestic points exist, the closest isosbestic point to λ_1 should be chosen so as to guarantee

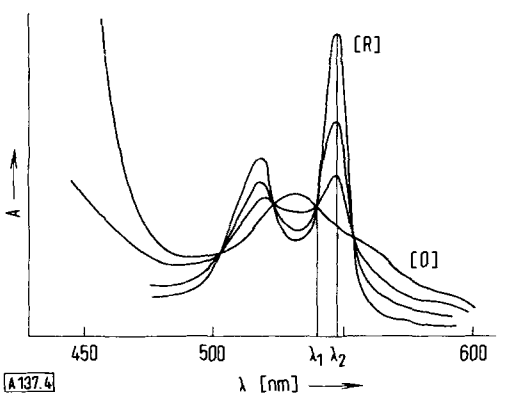

Fig. 4. Absorption spectra of oxidized [O] and reduced [R] cytochrome c.

scattering similarities; this is necessary since scattering, as known for Rayleigh scattering, is wavelength dependent. Thus, we can monitor the degree of reduction of the sample with time. In dual-wavelength spectrophotometry changes in particle size due to swelling or aging are also of little consequence; hence, this method is extremely well suited for the investigation of mitochondria suspensions. Generally, the optical chopper

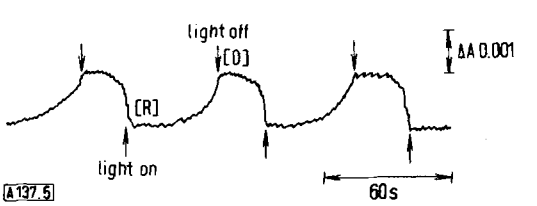

Fig. 5. Photooxidation of cytochrome f.

in commercially available dual-wavelength spectrophotometers operates at 600 to 1000 Hz. Consequently, the measurement of rapid chemical reactions is also possible. Figure 5 shows the photochemical redox reaction of cytochrome f.

5. Analysis of Mixtures

On using the dual-wavelength technique, the simultaneous analysis of multicomponent systems, or masking of the various components, can be carried out very easily and accurately without any calculations.

5.1. Equi-absorption Method

Suppose that a two-component sample contains x and y. The measured absorbances at each wavelength λ_1 and λ_2 are

$$A_{\lambda 1} = \varepsilon_x c_x + \varepsilon_y c_y \quad (2)$$

$$A_{\lambda 2} = \varepsilon_x c_x + \varepsilon'_y c_y \quad (3)$$

where, ε_x and ε_y are the molar absorptivities of the x and y components at λ_1, respectively; ε'_x and ε'_y are the molar absorptivities of the two components at λ_2; c_x and c_y are the concentrations (mol/l) of the components.

Then, the absorbance obtained in the dual-wavelength measurement is

$$A_{\lambda 2} - A_{\lambda 1} = \Delta A = (\varepsilon'_x c_x + \varepsilon'_y c_y) - (\varepsilon_x c_x + \varepsilon_y c_y) \quad (4)$$

If the second component y shows the same absorbance at both wavelengths λ_1 and λ_2, *i.e.* if $A_{y\lambda 2} - A_{y\lambda 1} = 0$, equation (4) simplifies to

$$\Delta A = \varepsilon'_x c_x - \varepsilon_x c_x \quad (5)$$

Since the difference absorbance ΔA is now no longer dependent on the concentration of the component y, it is possible to eliminate the influence due to component y.

5.1.1. Initial Selection of Approximate Values for λ_1 and λ_2

This can be done either by drawing diagrams or by investigating the individual components by wavelength scanning with one wavelength fixed.

Figure 6 shows the absorption spectra of arsenazo I (3-[(2-arsonophenyl)azo]-4,5-dihydroxy-2,7-naphthalenedisulfonic acid) and arsenazoIII (3,6-bis[(2-arsonophenyl)azo]-4,5-dihydroxynaphthalene-2,7-disulfonic acid) in aqueous solution at pH 2.0. As a rule, the synthesis and purification of bisazo compounds is very difficult because the corresponding monoazo compound is also always formed in the reaction. Therefore, the purity must be checked. If the wavelength of maximum absorbance for arsenazo I at 502 nm is chosen as the analytical wavelength, λ_2, a line is drawn vertically from this peak to the *x* axis. A point of intersection is then obtained on the absorption spectrum of arsenazo III, and a line is drawn from this point, parallel to the *x* axis, to another absorption point λ_1. At the combination λ_1, λ_2, the baseline remains unchanged when the concentration of arsenazo III is altered, *i.e.* $A_{\lambda 2} - A_{\lambda 1} = \Delta A = 0$. Accordingly,

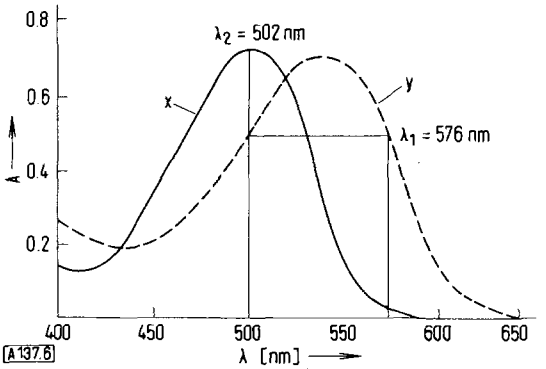

Fig. 6. Selection of λ_1 and λ_2 by drawing figures. pH 2.0, 2.0 mg/100 ml of each component, arsenazo I (x) and arsenazo III (y).

any variation in the concentration of the arsenazo III has no influence on the determination of arsenazo I unless the soluble species is altered as a result of polymerization. Of course, at the selected combination of λ_1 and λ_2, the ΔA value for arsenazo I should be sufficiently large for measurement. For the system shown in Figure 6, the combination 502—567 nm would be selected. Generally, selection of the combination of λ_1 and λ_2 depends on the shape of each spectrum. If the maximum absorbance wavelength cannot be used as the analytical wavelength, any other suitable wavelength in the absorption spectrum can be selected.

Although in the above description, λ_1 and λ_2 are determined for a single concentration of arsenazo III, it is also possible to use several samples having different concentrations. This method then enables any changes in the soluble species, caused by polymerization, dissociation or other chemical or physical effects, to be easily checked from the shape of the spectra. Initially, it is necessary to choose an analytical wavelength from the normal absorption spectrum of arsenazo I; as mentioned above 502 nm was selected. The fixed wavelength λ_2 is then set at 502 nm, and the absorption spectra at various concentrations of arsenazo III are measured with λ_1 as the scanning wavelength. If the soluble species remain unaltered, an isosbestic point can be observed on the baseline, *i.e.* the differential absorbance ΔA between 502 nm and this point is zero. Spectra obtained in this way for arsenazo III are shown in Figure 7.

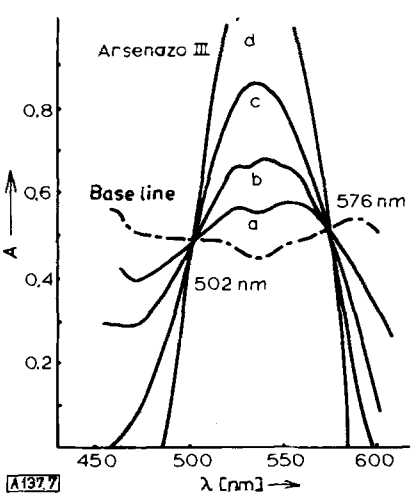

Fig. 7. Selection of λ_1 and λ_2 from absorption spectra with λ_2 fixed (502.0 nm) and λ_1 as the scanning wavelength. Arsenazo III (mg/100 ml): a) 1.0; b) 2.0; c) 4.0; d) 8.0.

5.1.2. Precision Method of Selecting Optimum Wavelength

In this method, the changes in the differential absorbance as a function of variation in concentration, in our example of arsenazo III, are measured 5 or 6 times in the vicinity of the temporary wavelength settings, so that λ_1 and λ_2 can be finally set at wavelengths which minimize changes in the difference of absorbance. The wavelength λ_1 is first altered in one direction or the other by about 1 nm and the direction and size of the change in ΔA observed. Then, both wavelengths are finally adjusted successively until the differential absorbance becomes zero despite variations in the concentration of arsenazo III. The procedure for selecting λ_1 and λ_2 in this way is shown in Figure 8.

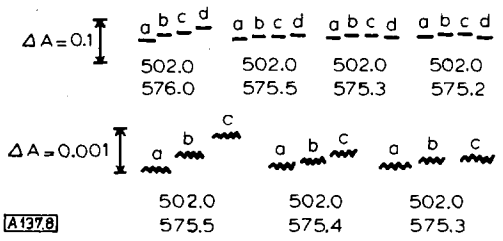

Fig. 8. Precise method for selection of λ_1 and λ_2. Arsenazo III (mg/ml): a) 0.25; b) 0.50; c) 1.00; d) 2.00.

With a scale range of 0.1 absorbance unit, this procedure presents few problems; but great care is needed when the full scale range is 0.01 absorbance unit. In this way a suitable combination for λ_1 and λ_2 of 502.0 and 575.3 nm was established for the determination of arsenazo I in the presence of arsenazo III at pH 2. Optimum selection of λ_1 and λ_2 for the determination of arsenazo III can be accomplished in a similar way. This method enables easy and accurate determination of about 0.5 % of arsenazo I in arsenazo III[7].

5.2. Signal Multiplier Method

When the absorptions of the second component y differ from each other at each of the combinations of two wavelengths, as shown in Figure 9, then the signal multiplier in the instrument is adjusted, so that the second component y does show the same absorbance at wavelengths λ_1 and λ_2, *e.g.*

$$\varepsilon_y c_y = k\varepsilon'_y c_y \tag{6}$$

Then

$$A_{\lambda 2} - A_{\lambda 1} = \Delta A = k(\varepsilon'_x c_x + \varepsilon'_y c_y) - (\varepsilon_x c_x + \varepsilon_y c_y) = k\varepsilon'_x c_x - \varepsilon_x c_x \tag{7}$$

Since the differential absorbance ΔA is independent of the concentration of the component y in Eq. (7), it is possible to determine quantitatively the x component in the mixture. In this technique, two signals for λ_1 and λ_2 are converted into absorbance values by the log-converters, and independently multiplied by means of the function generators. Hence, the differential absorbance ΔA obtainable with this measurement is

$$\Delta A = k_2 A_{\lambda 2} - k_1 A_{\lambda 1} \tag{8}$$

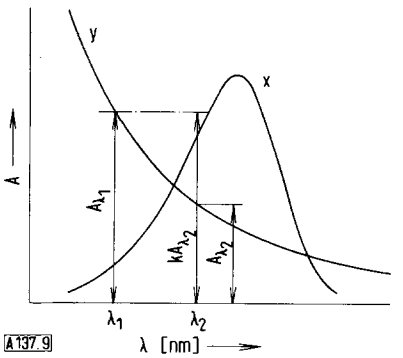

Fig. 9. Principle of signal multiplier method.

5.2.1. Determination of Three-Component Mixtures[24]

If we can choose two wavelengths λ_1 and λ_2 at the intersection of the absorption curves of two components y and z, the x component in the mixture can be determined as follows:

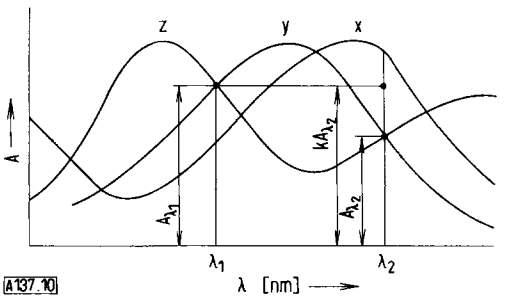

Fig. 10. Analysis of three-component mixtures.

As shown in Figure 10, the absorbance at λ_2 is adjusted to the same value as at λ_1 by the function generator. Then,

$$\varepsilon_y c_y = \varepsilon_z c_z = k\varepsilon'_y c_y = k\varepsilon'_z c_z \tag{9}$$

from which it follows that

$$A_{\lambda 2} - A_{\lambda 1} = \Delta A = k\varepsilon'_x c_x - \varepsilon_x c_x \tag{10}$$

Practical examples demonstrating the successful application of dual-wavelength spectrophotometry to multicomponent systems include the analysis of mixtures of phthalic acid

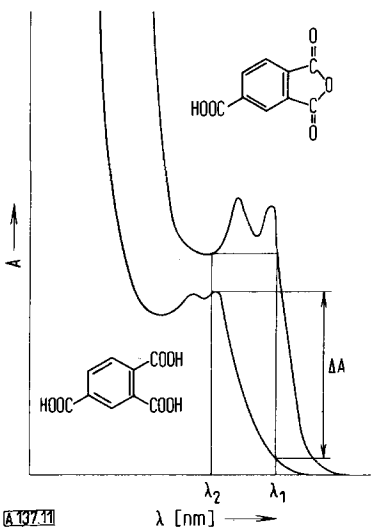

Fig. 11. Determination of trimellitic acid in the presence of its anhydride. $\lambda_1 = 307.6$ nm; $\lambda_2 = 290$ nm.

isomers, of mixtures of food coloring agents, of L-fucose in serum, of the vitamins A and E, polystyrene in durene[22], ephedrine in alkaloids, of amylose[15], and of trimellitic acid and its anhydride (Fig. 11), salicylic acid and 3- and 5-nitrosalicylic acid[21], and of isomeric guaiacol sulfonates in pharmaceutical preparations[13].

6. High-Sensitivity Analysis of Inorganic Substances

Many highly sensitive chromogenic reagents for metals (complexing agents) with molar absorptivities of the order of 10^5 are now known. Therefore, the combination of these reagents with the dual-wavelength technique affords a remarkably sensitive colorimetric method.

6.1. Determination of ppb Amounts of Cobalt with 4-[(3,5-Dichloro-2-pyridyl)azo]-*m*-phenylenediamine[6, 10]

In the conventional method the net absorption of the sample at the wavelength of maximum absorption of the cobalt complex relative to water or reagent blank is measured. In dual-wavelength measurements λ_1 is set to the wavelength for the absorption peak of the complex and λ_2 to the wavelength for the absorption peak of the reagent. Hence, the decrease in the reagent absorption caused by the complex formation is directly additive to the change in absorbance caused by the chelation. Thus the apparent molar absorptivity of the cobalt chelate is increased appreciably (see Fig. 12). By this method, for example, the calibration curve for 1—5 ppb of cobalt is linear through the origin with a slope corresponding to a value for $\Delta A_{570-424\,nm}$ of 0.0028 per ppb of cobalt.

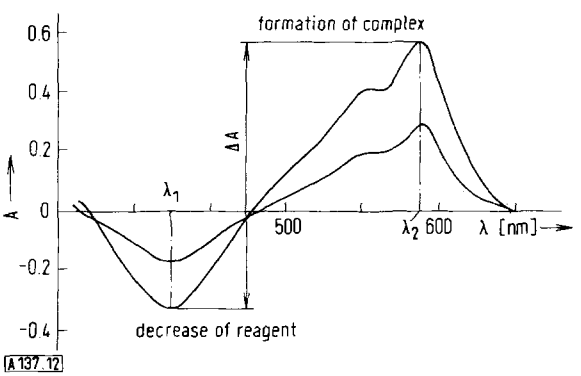

Fig. 12. Differential absorption spectra of 4-[(3,5-dichloro-2-pyridyl)azo]-*m*-phenylenediaminecobalt complexes.

$$\Delta A = A_{\lambda 2} - (-A_{\lambda 1}) = A_{\lambda 2} + A_{\lambda 1}.$$

The dual-wavelength method increases the apparent molar absorptivity of the cobalt-4-[(5-chloro-2-pyridyl)azo]-*m*-phenylenediamine complex ("5-Cl-PADAB"), (Merck) from $1.13 \times 10^5\,l\,mol^{-1}\,cm^{-1}$ to $1.75 \times 10^5\,l\,mol^{-1}\,cm^{-1}$. Generally, the choice of the combination of two wavelengths is unlimited (cf. Fig. 13).

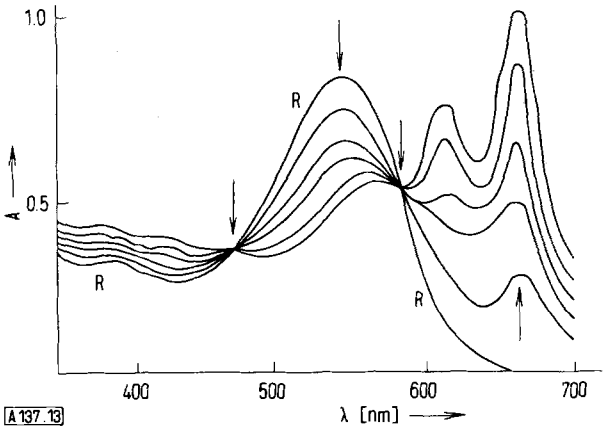

Fig. 13. Absorption spectra of the thorium-arsenazo III complex. 8 N HCl solution, R = Arsenazo III.

6.2. Determination of ppb Amounts of Mercury with Dithizone in Aqueous Solution[27]

Dithizone can be dissolved in aqueous solutions of triton X 100; hence trace amounts of mercury can be determined in an aqueous solution without solvent extraction. The use of large amounts of dithizone can be avoided by using the equi-absorption method (cf. Fig. 14). In this method, the dithizone should be converted into more stable oxidized yellow species by addition of hydrogen peroxide.

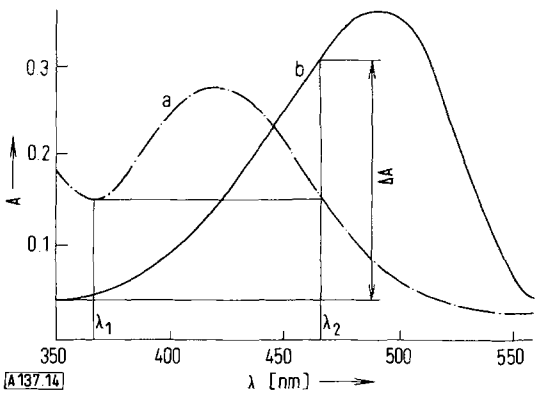

Fig. 14. Determination of mercury with dithizone. $\lambda_1 = 368$ nm, $\lambda_2 = 468$ nm. (a) Dithizone, (b) mercury dithizonate.

The detection limit of the method is 1.8 ppb of mercury and the calibration curve remains linear up to about 40 ppb.

7. Derivative Absorption Spectrometry

The advantages of directly recording a curve of the first or second order differential coefficient of absorbance A or transmission T with respect to wavelength λ, *i.e.* $dA/d\lambda$ or $d^2A/d\lambda^2$, *versus* wavelength, have already been pointed out by *Giese* and *French*[20], and *Saidel*[19]. The first derivative spectrum can be recorded with a conventional double-beam instrument and attachments or with a specially designed derivative spectrophotometer; however, these techniques are rather complicated. Such spectra can be recorded easily by dual-wavelength measurements, if the two wavelengths λ_1 and λ_2 are set very close to each other (usually 1—2 nm), and scanned simultaneously. A further advantage is that these differential spectra can also be recorded electrically.

The merits of directly recording a curve of the first or second order differential coefficient of absorbance or transmission are as follows:

1. Even when two or more absorption bands completely or almost completely overlap, each of the bands can be detected.

2. Very small absorption bands which lie on a steep flank of an absorption curve, and any shoulders in the absorption curves, are clearly resolved.

3. Very broad absorption bands can be located accurately.

4. Generally, the differential coefficient at a specific wavelength is linearly related to the concentration of the corresponding components, thus permitting their determination.

5. Variations in turbidity or background caused by interfering components do not affect measurements, since λ_1 and λ_2 are set close to each other.

It would appear, therefore, that derivative spectrophotometry should facilitate the detection and determination, of, for example, impurities in drugs and chemicals, of food additives, and of industrial wastes. In addition to its use in chemical analyses, this method is also very useful for determination of the fine structure of numerous organic compounds[26].

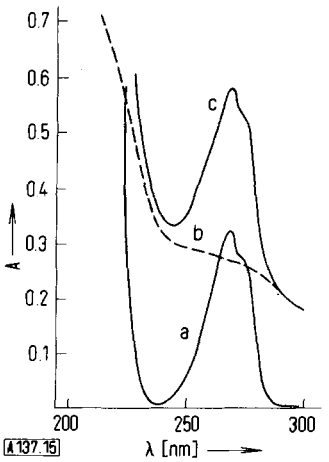

Fig. 15. Absorption spectra of phenol. a) Phenol in aqueous solution; b) turbid industrial waste free from phenol; c) phenol in turbid industrial waste.

Figure 15 shows that the absorption spectrum of phenol in industrial wastes is increased appreciably by the effects of turbid materials, thus making an accurate analysis of phenol in turbid solution very difficult by conventional spectrophotometry. The first derivative spectra of phenol in industrial wastes are shown in Figure 16; here, it can be seen that the distance between the maximum and minimum of the differential coefficient of the absorption band of phenol is constant, *i.e.* the background underlying the absorption band of interest has been eliminated[11].

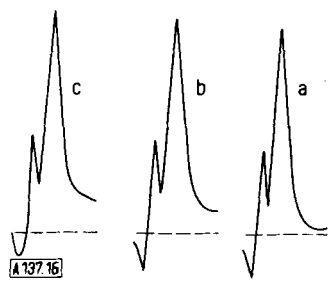

Fig. 16. First-derivative absorption spectra of phenol at various concentrations of turbid materials. Turbidity: a < b < c.

The qualitative and quantitative determination of a mixture of phenols is illustrated in Figure 17[8]. While the components cannot be distinguished in their normal absorption spectra, the derivative spectra clearly show two components, *i.e.* 2,4-dichlorophenol and 2,4,6-trichlorophenol. The second-derivative spectra of two food additives are shown in Figure 18. The influence of New Coccine (C.I. 16255) has been almost eliminated from the spectrum of Phloxine (C.I. 45410).

A second-derivative spectrophotometer for use in the measurement of very small concentrations of certain gases in common air pollutants, such as ammonia, sulfur dioxide, nitrogen mono- and dioxide, ozone, and carbon monoxide, has recently been reported by *Williams* and *Harger*[25].

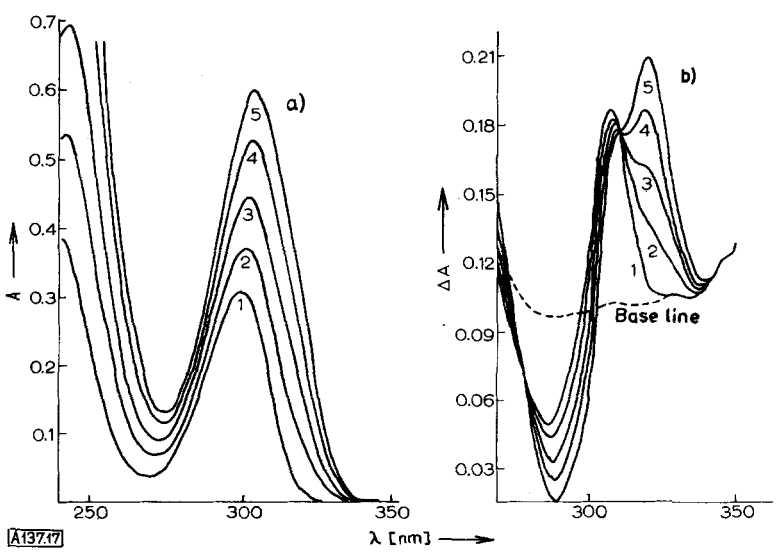

Fig. 17. Analysis of phenol mixtures. a) Absorption spectra; b) derivative spectra ($\Delta\lambda = 2$ nm, $S = 0.25$ mm). 1) 2,4-Dichlorophenol, 10 ppm; 2) (1) plus 5 ppm 2,4,6-trichlorophenol (TCP); 3) (1) plus 10 ppm TCP; 4) (1) plus 15 ppm TCP; 5) (1) plus 20 ppm TCP.

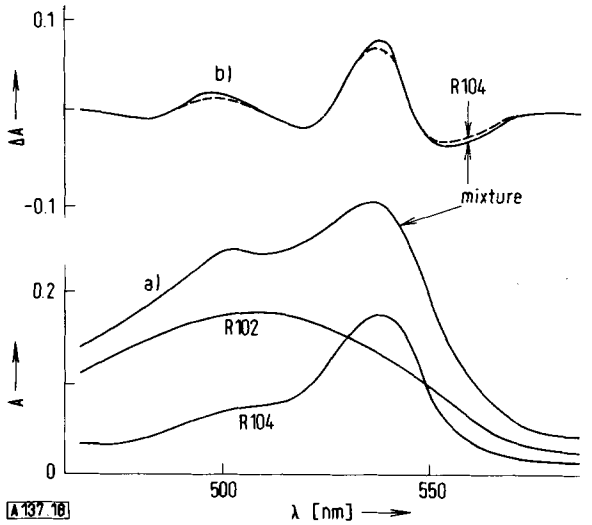

Fig. 18. Second-derivative spectra of food color mixtures. a) Absorption spectra, R 102 (New Coccine, C.I. 16255) and R 104 (Phloxine, C.I. 45410). b) Second-derivative spectra.

8. Densitometry by Means of Dual-Wavelength Measurements[17, 23]

The characteristic features of the dual-wavelength spectrophotometer can be utilized so as to compensate background interference by determining the optical densities at two carefully selected wavelengths. The advantage of this technique is that both the analytical and reference wavelengths pass through exactly the same portion of, *e.g.* a chromatogram[18], thus eliminating any artefacts due to substrate differences.

9. Simultaneous Monitoring of Two Phenomena

If it is desired to monitor the courses of two simultaneous reactions at arbitrary wavelengths λ_1 and λ_2, kinetic measurements can be carried out under identical conditions by utilizing only one cell and a two-pen recorder.

10. Summary

Many other useful applications of dual-wavelength spectrophotometry may be expected, *e.g.* in colloid titrations, photometric titrations in turbid samples, capillary spectrophotometry[12], determination of complex formation constants by ligand exchange reactions, and investigation of various catalytic, fluorescence, or photochemical reactions. At the present time, it is not only useful in analytical chemistry but also in process control in industrial chemistry. For instance, this technique has been applied to quality control of inks, thermopapers, photochromic materials[16], pharmaceutical products, and industrial waste.

Although the dual-wavelength technique is generally simple to use, the measurements on some chemical reactions at small absorbances is appreciably influenced by temperature. Therefore, temperature control of the cell compartment is advisable.

The ability of dual-wavelength spectrophotometry to extend the proven effectiveness of ultraviolet/visible absorption spectrophotometric techniques by overcoming limitations in selectivity and sensitivity has certainly been demonstrated in the field of general analytical spectrophotometry. The following short bibliography is representative and not exhaustive. A comprehensive bibliography may be obtained from our laboratory.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

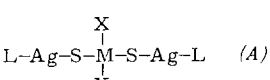
Complexes Having Thiometalate Ions as Bridging Ligands

By *Elisabeth Königer-Ahlborn* and *Achim Müller*[*]

Dedicated to Professor Oskar Glemser on the occasion of his 65th birthday

Unlike oxometalate ions, thiometalate ions can be bonded as bidentate chelate ligands in transition metal complexes such as $[Ni(WS_4)_2]^{2-}$ [1]. No complex has hiterto been reported in which a thiometalate ion acts as a bidentate bridging ligand.

We have now been able to isolate the compounds $[(C_6H_5)_3PAgS]_2MoS_2$ (violet) *(1)*, $[(C_6H_5)_3PAgS]_2MoOS$ (red) *(2)*, $[(C_6H_5)_3PAgS]_2MoO_2$ (orange) *(3)*, $[(C_6H_5)_3PAgS]_2WS_2$ (orange) *(4)*, and $[(C_6H_5)_3PAgS]_2WOS$ (yellow) *(5)* in crystalline form, and to characterize them by elemental analysis, powder diffraction diagrams, and vibrational and electronic absorption spectra.



M = Mo, W; X = O, S; L = $(C_6H_5)_3P$

The vibrational spectra reveal that all compounds of the homologous series possess a trinuclear skeleton corresponding to structure *(A)* (cf. Table 1).

Compared with the weighted average of the frequencies of the MS stretching vibrations of the free ions (*e.g.* MoS_4^{2-}: $\nu_1 = 458$, $\nu_3 = 472\,cm^{-1}$ [2]; $\nu_{av} = 469\,cm^{-1}$) the spectra of the corresponding complexes display bands that are shifted to lower wave numbers and can be assigned to MS bridge vibrations. Coordination of all the chalcogen atoms is ruled out because frequencies of the stretching vibrations of terminal MO or MS groups are observed in the spectra. They are expectedly shifted to higher wave numbers relative to the weighted average of the stretching frequencies of the free ions[2]. We have already drawn analogous conclusions for compounds in which these anions occur as chelate ligands. Confirmatory evidence subsequently came from experimental data for compounds substituted by metal isotopes and from complete crystal structure determinations[3].

Compared with the bands in the electronic absorption spectra of the free ions[1], which correspond to charge transfer transitions, some broadening of these bands is observed in the present compounds.

Powder diffraction patterns show *(1)* and *(4)*, as well as *(2)* and *(5)*, to be isotypic.

Procedure:

A solution of $(NH_4)_2MoS_4$[4] (0.16 g) [or Cs_2MoOS_3 (0.3 g)[5], $(NH_4)_2MoO_2S_2$ (0.14 g)[4], $(NH_4)_2WS_4$ (0.22 g)[6], or Cs_2WOS_3 (0.35 g)[5]] in H_2O (*ca.* 100 ml) is extracted with a solution of $(C_6H_5)_3P$ (0.73 g) and $AgNO_3$ (0.21 g) in CH_2Cl_2 (25 ml). The complex *(1)*, *(2)*, *(3)*, *(4)*, or *(5)* is slowly precipitated from the organic phase by addition of acetone (10 ml) and *n*-pentane (50 ml). (While all the other compounds are obtained pure, soluble impurities must be removed from *(4)* by repeated treatment with CH_2Cl_2.) All the new complexes are only sparingly soluble in organic solvents such as CH_2Cl_2, acetone, and nitromethane.

Table 1. Stretching vibrations (principal bands) [a] in the vibrational spectra of the complexes *(1)* to *(5)* (in cm^{-1}).

Complex		ν(MO)	$\nu(MS)_t$	$\nu(MS)_{br}$	ν(AgS)
$[(C_6H_5)_3PAgS]_2MoS_2$ *(1)*	IR	—	515 [a]	453 (s) 438 (s)	257 (w)
$[(C_6H_5)_3PAgS]_2MoOS$ *(2)*	R	930 (w)	520 (w)	444 (m) 426 (s)	257 (m)
$[(C_6H_5)_3PAgS]_2MoO_2$ *(3)*	IR	921 (s) 884 (s)		445 (m) 429 (s)	257 (w)
$[(C_6H_5)_3PAgS]_2WS_2$ *(4)*	R	—	523 (w) 511 (s)	446 (s) 424 (m)	258 (m)
$[(C_6H_5)_3PAgS]_2WOS$ *(5)*	R	945 (m)	521 (w)	446 (s) 427 (m)	264 (m) 257 (m)

[a] Since $\nu(MS)_t$ is masked in the IR spectrum by a strong band of the $(C_6H_5)_3P$ group, the Raman frequencies are given in those cases where the Raman spectrum could be measured.

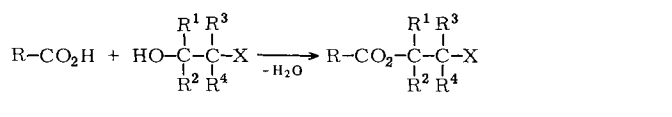
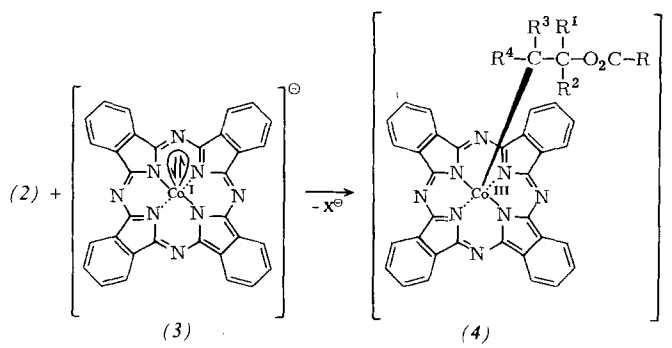
A New Technique of Protecting Groups—Cleavage of β-Halogenated Alkyl Esters with Supernucleophilic Cobalt(I)-phthalocyanine[1]

By *Heiner Eckert* and *Ivar Ugi*[*]

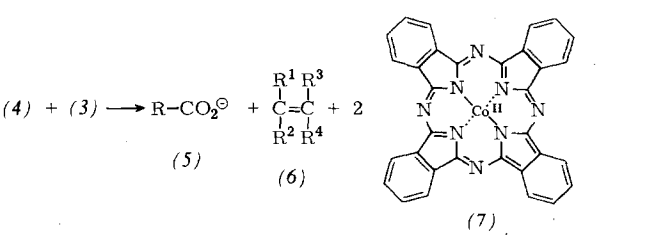
Carboxy groups of α-amino acids and peptides can be protected by esterification with β-halogenated alcohols *(1)* at the C terminus[2]. β-Halogenated alcohols of potential utility are 2-chloroethanol *(1a)* and 2-bromoethanol *(1b)*, 2,2-dibromopropanol *(1c)*, 2,2,2-trichloroethanol *(1d)*, and 2,2,2-trichloro-*tert*-butanol *(1e)* (chloretone).



(1) *(2)*



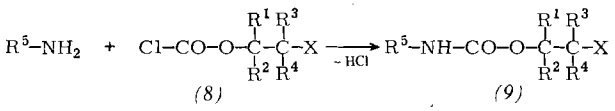
(3) *(4)*



(5) *(6)* *(7)*

$R^1 = R^2 = H, CH_3$; $R^3 = H, CH_3, Cl$; $R^4 = H, X$; $X = Br, Cl$

Amino groups can be provided with urethane protecting groups by reaction with the chloroformates *(8)* of the above alcohols.



(8) *(9)*

Apart from the base-sensitivity of the derivatives of *(1d)*, the lability of urethanes derived from *(1a)* and *(1b)* in alkali hydroxide solution, and the ease of reductive cleavage of the C—X bonds, the protecting groups mentioned are inert towards the deblocking reagents commonly used in peptide chemistry.

We have now found that β-halogenated alkyl esters and urethanes can be cleaved by cobalt(I)-phthalocyanine *(3)*[3] with Li^+ or Na^+ as counterion in methanol, acetonitrile, or acetone at 0 to 20°C. Preliminary experiments had shown that *(3)* is superior to cobaloxime(I)[4] for various reasons.

Cleavage generally proceeds in 60 to 98% yield at a rate that is determined primarily by the constitution of the β-haloalkyl group (see Tables 1 and 2). The reaction is usually three- to ten times slower when performed in acetonitrile and acetone.

Table 1. Reaction times for complete removal of N terminal 2-haloalkoxycarbonyl protecting groups from the urethanes *(9)* with *(3)* in 0.1 M solution at 20°C and the yields of isolated amine component obtained.

N terminal protecting group	Reaction time in methanol	acetone	Yield of amine component [%]
$Cl—CH_2—CH_2—O_2C—$	40 h	—	83 [a]
$Br—CH_2—CH_2—O_2C—$	30—90 min	20 h	70—89 [b]
$H_3C—CBr_2—CH_2—O_2C—$	< 1 min	3 min	77 [c]
$Cl_3C—CH_2—O_2C—$	< 1 min	5 min	91 [c]

[a] Aniline.
[b] Aniline (70—86), amino ester (76—89), dipeptide ester (82), tripeptide ester (80).
[c] Amino ester.

Table 2. Reaction times for complete removal of C terminal 2-haloalkyl protecting groups from the esters *(2)* with *(3)* in 0.1 M solution at 20°C and the yields of isolated acid component obtained.

C terminal protecting group	Reaction time in methanol	aceto-nitrile	acetone	Yield of acid component [%]

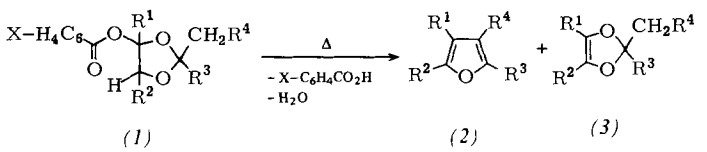
Synthesis of Furan Derivatives from 4-Benzoyloxy-1,3-dioxolane Derivatives

By *Hans-Dieter Scharf* and *Erich Wolters*[*]

Pyrolysis of the readily accessible 4-benzoyloxy-1,3-dioxolane derivatives *(1)*[1] affords, *via* elimination of benzoic acid and water, the furan derivatives *(2)* and small amounts (5 to 10%) of the 1,3-dioxole derivatives *(3)*. The reaction is catalyzed by acids.



(1) *(2)* *(3)*

At 230°C furan yields of 70—90% are obtained when X = *o*-CH_3. At 400°C and 10^{-3} torr the 1,3-dioxole derivatives *(3)* are obtained in 30 to 35 yield. No furans are formed under these conditions.

Under pyrolysis conditions the 1,3-dioxole derivatives *(3)* undergo proton-catalyzed rearrangement to the furan derivatives *(2)*, so that with suitable control of the pyrolysis their formation can be completely suppressed in favor of the furans.

Thus, 2,2-dimethyl-4-methylene-1,3-dioxolane *(4)* as well as 2,2-dimethyl-4-methyl-1,3-dioxole *(6)* rearrange under these conditions to the 2,4-dimethylfuran *(7)*. This suggests the reaction sequence is initiated by 1,3-dioxolan-4-ylium ion *(5)*[2].

Compared to the Paal-Knorr synthesis the reaction described here has the advantage of easy accessibility of starting compounds and compared to the Feist-Benary synthesis the advantage of free choice of substituents in position 3.

General Procedure

Synthesis of the 4-benzoyloxy-1,3-dioxolane derivatives *(1)*:

A mixture of 1,3-dioxolane (1.0 mol) and CuBr (0.5 g) in anhydrous benzene (500 ml) is heated to boiling under nitrogen. *tert*-Butyl peroxybenzoate (0.8 mol) is added dropwise to the stirred mixture over a period of 2—2.5 hours. The CuBr goes into solution with deep blue coloration. The mixture is heated for a further 16 hours then extracted with Na_2CO_3 solution. The aqueous phase is washed several times with ether and the combined organic phases dried over Na_2SO_4. After removal of solvent in a rotary evaporator, the residue is distilled under vacuum in a molecular distillation apparatus.

Pyrolysis of the 4-benzoyloxy-1,3-dioxolane derivatives *(1)*:

Compound *(1)* (0.5 mol) is introduced dropwise over a period of 1.5 h into a flask heated to 230°C and containing a small amount of molten *o*-toluic acid which is stirred with a magnetic stirrer. The furan *(2)* that is formed is slowly distilled off together with water over a 30 cm Vigreux column at normal pressure or under vacuum depending upon the derivative concerned. The distillate is washed with Na_2CO_3 solution, dried, and distilled.

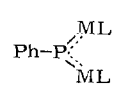
Phosphinidene Complexes as π Ligands[**]

By *Gottfried Huttner, Gerhard Mohr*, and *Albin Frank*[*]

Phenylphosphinidene Ph—P can be stabilized as a bridging ligand in dinuclear transition metal complexes of type *(1)*[1].

In such compounds the octet vacancy at the phosphorus is filled by back bonding from the occupied d orbitals of



(1)

ML = $Mn(CO)_2C_5H_5$

[*] Doz. Dr. G. Huttner, Dipl.-Chem. G. Mohr, and Dipl.-Chem. A. Frank

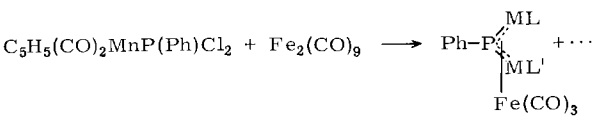
Arcisstrasse 21, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the metal. The trigonal-planar coordination of phosphorus and the properties of the phosphinidene complexes *(1)* suggest description of the bonding in the M═P═M group in terms of the model of a three-center 4π electron system[1,2].

We have now found further evidence substantiating the correctness of this model concept: On attempted dehalogenation of the dichlorophosphane complex $C_5H_5(CO)_2MnP(Ph)Cl_2$ with $Fe_2(CO)_9$ we observed formation of a compound of the novel type *(2)*.



$C_5H_5(CO)_2MnP(Ph)Cl_2 + Fe_2(CO)_9 \longrightarrow$ Ph–P(ML)(ML')–Fe(CO)$_3$ + ···

ML = $Mn(CO)_2C_5H_5$, ML' = $Fe(CO)_4$ *(2)*

The dinuclear phosphinidene complex $C_5H_5(CO)_2Mn{=}P(Ph){=}Fe(CO)_4$ expected as the primary product of dehalogenation could not be detected; instead, the "trinuclear" complex *(2)* is formed in which the three-center 4π system Mn═P═Fe is coordinated as a π ligand to a $Fe(CO)_3$ group (Fig. 1)[3].

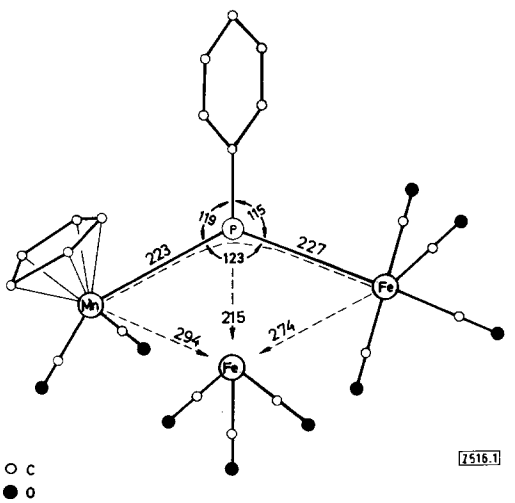


Fig. 1. Molecular structure of the complex *(2)*; distances [pm] and angles [°].

X-Ray structure analysis shows that *(2)* is not a phosphido cluster containing tetracoordinated phosphorus[4,5]: the manganese atom is coplanar with the phosphorus atom, the phenyl carbon atom, and the iron atom of the $Fe(CO)_4$ group (maximum deviation 17 pm). Thus the coordination of the phosphorus in *(2)* corresponds to the trigonal-planar environment observed for the phosphorus atom in dinuclear phosphinidene complexes of type *(1)*. The metal-metal bonds in *(2)* are relatively long[6] and reflect the unusual bonding characterizing this complex, in which the manganese atom and the iron atom of the $Fe(CO)_4$ act as the terminal atoms of a three-center 4π ligand system.

Procedure:

All operations are performed in solvent freed from oxygen and water and under N_2.

$Fe_2(CO)_9$ (1.28 g, 3.52 mmol) is suspended in a solution of $C_5H_5(CO)_2MnP(Ph)Cl_2$ (1.08 g, 3.05 mmol) in toluene (40 ml) and the mixture stirred for 48 h at 40 °C. Filtration from the brown precipitate affords a red solution which is concentrated with silica gel (3 g) at 20 °C until the silica gel appears dry. The silica gel loaded with reaction product is applied at 10 °C to a chromatography column (16 × 2.5 cm; *n*-pentane; silica gel, Merck, 0.063 to 0.200 mm). With pentane/toluene (5:1) a red and a yellowish brown zone are eluted, which both contain very little substance. With pentane/toluene (2:1) there follows a green zone from which deep green crystals of analytically pure *(2)* can be isolated by removal of the solvent and recrystallization from hexane. Further elution with pentane/toluene (1:1) gives a deep red zone of $C_5H_5MnFe_2PPh(CO)_8$[7]. *(2)* is readily soluble in hexane or toluene and is air-stable in the solid state; m.p. 178 °C (dec.); yield: 100 mg (6 %).

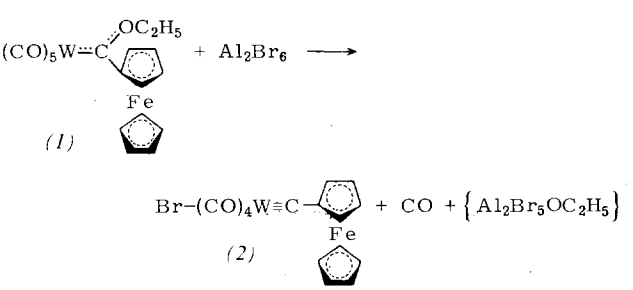
trans-Bromo(tetracarbonyl)ferrocenylcarbynetungsten[1]

By *Ernst Otto Fischer, Monika Schluge*, and *Jürgen Otto Besenhard*[*]

On reaction of pentacarbonylethoxy(ferrocenyl)carbenetungsten(0) *(1)*[2] with aluminum bromide at low temperature we obtained crystalline, raspberry-red *trans*-bromo(tetracarbonyl)ferrocenylcarbynetungsten *(2)*. The diamagnetic complex, which is only sparingly soluble in hexane yet readily soluble in polar solvents such as CH_2Cl_2 and acetone, is stable at room temperature for several hours in the solid state even when exposed to the air; in solution slow decomposition takes place above −10 °C.



$(CO)_5W{=}C(OC_2H_5)$–Fe + Al_2Br_6 ⟶ *(1)*

Br–$(CO)_4W{=}C$–Fe *(2)* + CO + $\{Al_2Br_5OC_2H_5\}$

The IR spectrum of *(2)* (in CH_2Cl_2) shows a strong band (E) at 2020 cm^{-1} and a weak band (A_1) at 2112 cm^{-1} in the ν_{CO} region.—In the ^{1}H-NMR spectrum ([D_6]-acetone solution at −30 °C; rel. TMS int.) three signals appear at

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. M. Schluge, and Dr. J. O. Besenhard
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

$\delta = 4.58$ (S,5) [C_5H_5], 4.60 (M,2), and 5.00 ppm (M,2) [C_5H_4].—The ^{13}C-NMR spectrum (CD_2Cl_2 solution at -30°C; rel. $CD_2Cl_2 = 54.2$ ppm) shows six signals at $\delta = 275.1$ ($C_{carbyne}$), 193.4 (CO), 89.5, 72.7, 71.6, and 71.0 ppm ($C_{10}H_9Fe$)[3].

The mass spectrum of *(2)* contains the molecular ion at $m/e = 572$ (referred to ^{184}W, ^{56}Fe, and ^{79}Br; ion source TO4, 50 eV).

The reversibility of the oxidation of *(2)* was proven by cyclic voltammetry in 0.5 M KPF_6/DME (1,2-dimethoxyethane; -20°C). The difference between the anodic and cathodic peak potential confirms that a reversible one-electron transfer is involved, as in the case of ferrocene (FcH). Since the electrochemical oxidation of $X(CO)_4W{\equiv}C{-}C{\equiv}CPh$ (X = Cl, Br, I) only takes place irreversibly and does not begin below the range $+1.5$ to $+1.8$ V *vs.* SCE[4] we attribute the reversible oxidation of *(2)* to formation of the carbyne-substituted ferrocenium ion $(2)^+$. There is no indication of a secondary reaction of $(2)^+$—the quotient of the cathodic and anodic peak currents iP_c/iP_a is almost unity, irrespective of the rate of polarization v. Owing to the withdrawal of electrons from the Fc system by the complex carbynetungsten group, $E_{1/2}$ *(2)*/$(2)^+$ is shifted about $+280$ mV *vs.* $E_{1/2}$FcH/FcH$^+$; the ratio iP_a(FcH)/iP_a *(2)* yields a diffusion coefficient for *(2)* which is smaller than that for ferrocene by a factor of about 2.

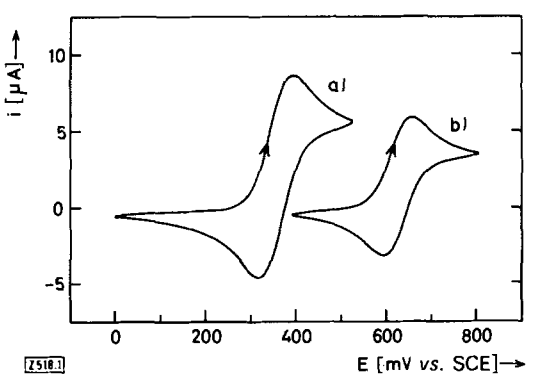


Fig. 1. Cyclovoltammogram of a) ferrocene, and b) *(2)* at Pt. $c = 2 \times 10^{-3}$ mol·l^{-1}; $v = 100$ mV·s^{-1}.

A linear relationship between $E_{1/2}$XFc/XFc$^+$ and the Hammett constants σ_m and σ_p of the substituents X has been demonstrated on many occasions for substituted ferrocenes (XFc)[5]. From the correlation curves determined by *Hoh, McEwen,* and *Kleinberg*[5], values of $\sigma_m = +0.45$ and $\sigma_p = +0.59$ were calculated for $X{=}C{\equiv}W(CO)_4Br$. These values approximate those for $X{=}C{\equiv}N$ ($\sigma_m = +0.56$; $\sigma_p = +0.66$) and thus confirm, in accord with other data, the "electron attracting" influence of the carbyne group.

Experimental:

All operations are carried out in anhydrous, oxygen-free solvents in an inert atmosphere (N_2).

Al_2Br_6 (0.79 g, 1.5 mmol) is added spatula-wise at -78°C to a solution of *(1)* (1.132 g, 2 mmol) in CH_2Cl_2 (70 ml). The solution, which changes color from red-black to deep-blue, is then warmed until gentle evolution of gas occurs. Meanwhile the solution turns raspberry-red in color. It is now stirred for 40 min at -15°C. Adducts of the carbyne complex with Al_2Br_6 are destroyed by addition of about 10 ml methanol. The product is purified by column chromatography on silica gel at -30°C. Dark-red, unreacted *(1)* is first eluted (with CH_2Cl_2/pentane, 1:1). The second, raspberry-red zone is eluted with pure CH_2Cl_2, the eluate evaporated to dryness, and the resulting residue washed three times with pentane at -78°C: cryptocrystalline product; decomposes above 70°C; yield 0.80 g (70 %).

Carbene-Analogous Germylene Complexes[**]

By *Peter Jutzi* and *Wolfgang Steiner*[*]

Using an oxygen-germanium-ylide complex as starting material we have been able to prepare the first true germylene complexes. Thus, reaction of pentacarbonyl[dichloro(tetrahydrofuran)germylene]chromium(0) [compound *(1)*][1] with trimethyl(mesitylthio)silane *(2a)* or trimethyl(methylthio)silane *(2b)* leads, *via* loss of trimethylchlorosilane and tetrahydrofuran, to [bis(mesitylthio)germylene]pentacarbonylchromium(0) [compound *(3a)*] and [bis(methylthio)germylene]-pentacarbonylchromium(0) [compound *(3b)*], respectively.

$$(CO)_5Cr{\leftarrow}\underset{\uparrow}{Ge}Cl_2 + 2\ RSSi(CH_3)_3 \xrightarrow[THF]{} \underset{(1)}{\quad} \qquad \underset{(2)}{\quad}$$

$$(CO)_5Cr{\leftarrow}Ge(SR)_2 + THF + 2\ (CH_3)_3SiCl \qquad (3)$$

(a): R = 2,4,6-trimethylphenyl ; *(b)*: R = CH_3

The complexes *(3a)* and *(3b)* are stable toward atmospheric oxygen but somewhat sensitive toward hydrolysis. They precipitate as orange yellow cubic crystals [*(3a)*, decomp. pt. 141 °C] and yellow-green needles [*(3b)* decomp. pt. 112 °C], respectively, and are very soluble in chlorinated hydrocarbons, carbon disulfide, and benzene, but only moderately soluble in hydrocarbons. The structures have been confirmed by spectroscopic and analytical data and, in the case of *(3a)*, by an X-ray structure analysis[2]. Mass spectra and molecular weight determinations (cryoscopically in benzene) confirm the monomeric structure of the compounds. In the IR spectra (in CH_2Cl_2) three absorptions which correspond to local C_{4v} symmetry are observed in the region of the νCO vibrations [*(3a)*: 2060 (s,A_1), 1990 (m,A_1), 1955 (s,E) cm^{-1}; *(3b)*: 2050 (s,A_1), 1990 (m,A_1), 1945 (s,E) cm^{-1}]. The position of the long-wave A_1 vibration is indicative of the $Ge(SR)_2$ ligands being good π-acceptors. The synthesis of pentacarbonyl(dichlorogermylene)chromium(0) [compound *(4)*] by cleavage of

$$(3a) + 2/3\ BCl_3 \longrightarrow (CO)_5Cr{\leftarrow}GeCl_2 + 2/3\ B(SR)_3 \qquad (4)$$

[*] Doz. Dr. P. Jutzi and Dipl.-Chem. W. Steiner
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

THF from *(1)* is not possible[1]. We have succeeded in preparing this complex, however, by reaction of *(3a)* with boron trichloride.

Compound *(4)* precipitates as bright red, needle-like crystals, (decomp. pt. 105 °C), has solubility properties comparable to those of *(3a)* and *(3b)*, but, unlike the latter two compounds, is extremely sensitive toward air and moisture. Its structure was also confirmed by spectroscopic and analytical data. Molecular weight determinations and the mass spectrum are consistent with the monomeric structure of the complex. IR spectrum: νCO (in CH_2Cl_2): 2075 (s,A_1), 1985 (m,A_1), 1960 (s,E) cm^{-1}; νGe—Cl (in Nujol): 360 (w), 320 (w) cm^{-1}. The germylene complexes *(3a)*, *(3b)*, and *(4)* can be readily converted into the corresponding ylide complexes by addition of bases (ether, tertiary amines, or tertiary phosphanes).

Experimental

Preparation of *(3a)* and *(3b)*: 20 mmol of *(2)* or *(3)* [4.48 g *(2)*; 2.40 g *(3)*] is added dropwise to a solution of *(1)* (10 mmol, 2.04 g) in benzene (30 ml) and the mixture is stirred for 30 min at 50 °C. After removal of volatile components the remaining oil is extracted with petroleum ether (boiling range 50—70 °C). On concentration of the extract *(3a)* and *(3b)*, respectively, crystallize out. Recrystallization from petroleum ether affords the analytically pure complexes. Yields: 4.50 g (79 %) *(3a)*; 0.7 g (19 %) *(3b)*.

Preparation of *(4)*: A solution of *(3a)* (10 mmol, 5.67 g) in 100 ml petroleum ether (boiling range 50 to 70 °C) is added to a solution of BCl_3 (6.8 mmol, 0.80 g) in 50 ml petroleum ether at −30 °C. An orange-yellow precipitate of *(4)* immediately separates out and is filtered after 30 minutes' stirring at 0 °C. Recrystallization from petroleum ether affords analytically pure *(4)*. Yield 1.25 g (37 %).

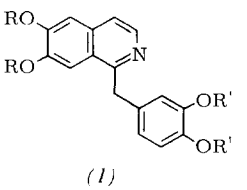
Papaverine Crown Ethers[**]

By *Fritz Vögtle* and *Klaus Frensch*[*]

The endohydrophilic/exolipophilic structure of the crown ethers permits lipophilization of alkali metal ions. As synthetic analogs of the well-known ionophores, neutral ligands of the crown ether type have contributed greatly to our understanding of selective ion transport processes in biological membranes.

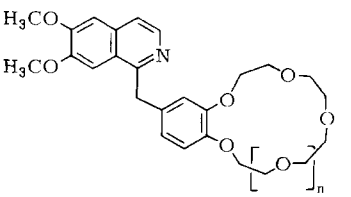
The present communication concerns the novel concept of altering the hydrophilic/lipophilic properties of physiologically active molecules by intramolecular incorporation of crown ether rings and especially of enabling or facilitating selective complex formation with alkali or alkaline-earth metal ions. Thereby it ought to be possible to modify the physiological action, *e.g.* as regards rate and site of attack. The isoquinoline alkaloid papaverine *(1a)*, that constitutes about 0.5 to 1.0 % of opium and is used as an antispasmodic, *e.g.* for relieving spasms of the gastro-intestinal and the bile duct, was considered the best candidate for initial model experiments on account of the two catechol partial structures already present.

We were able to prepare the crown-ether type bridged analog of benzo[15]crown-5[1], papaverine derivative *(2)* (m.p. 104 °C), in 25 % yield by reaction of the doubly demethylated papaverine *(1b)*[2] with 1,11-dichloro-3,6,9-trioxaundecane without employing the dilution principle[3].



(1)

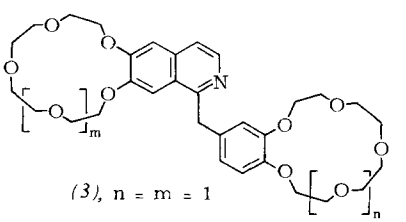
(a): R = R' = CH_3
(b): R = CH_3, R' = H
(c): R = R' = H



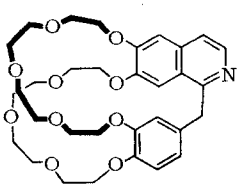
(2), n = 1

Reaction of the hydrobromide of *(1c)*[2,4] with 1,11-dichloro-3,6,9-trioxaundecane afforded a doubly crowned product of the composition *(3)* or *(4)* (m.p. 109—110 °C; sinters at 100 °C) in 20 % yield[3]. From a comparison of the NMR spectra of *(2)* and *(3)* it was assumed that *(3)* was present, yet nanogram thin-layer chromatography of the analytically pure substance (silica gel F_{254}, methanol/water = 1:1) revealed the presence of further components, presumably *(4a)*, *(4b)* or corresponding oligomers.

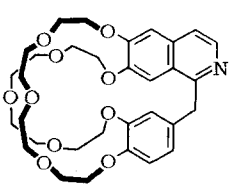
The composition of *(2)* and *(3)* was confirmed by elemental analysis and by high resolution mass spectrometry.



(3), n = m = 1



(4a)



(4b)

The ^{1}H-NMR spectra of *(2)* and *(3)* show besides the characteristic signals for the papaverine moiety[5]—including the benzyl —CH_2— singlet at δ = 4.52 ppm — the characteristic —OCH_2— absorption pattern for the crown ether bridges centered around δ = 3.75 and 3.95 ppm (in $CDCl_3$ and CD_3OD, resp.).

While solid potassium permanganate cannot be dissolved in chloroform with papaverine, this is readily possible with the bridged papaverines *(2)* and *(3)*. As expected the violet color of the solution is much more intense with the doubly crowned ether *(3)* than with *(2)*. *(2)*, of which we obtained gram amounts, reacts with $Ca(SCN)_2 \cdot 4H_2O$ even in the cold in ethyl acetate with formation of mm-long crystalline needles of the 1:1 complex, which contains one molecule of water of crystallization and melts at 173 °C[6]. Its IR spectrum shows a strong and sharp characteristic band at 2055 cm^{-1}, its ^{1}H-NMR spectrum slight shifts of the OCH_2—CH_2O— protons [in $(CD_3)_2SO$].

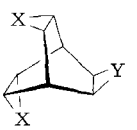
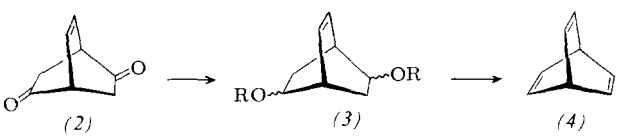
3,7,10-Trioxapentacyclo[3.3.3.$0^{2,4}$.$0^{6,8}$.$0^{9,11}$]-undecane (3,7,10-Trioxatrishomobarrelene)[**]

By *Christian Weitemeyer* and *Armin de Meijere*[*]

Pentacyclo[3.3.3.$0^{2,4}$.$0^{6,8}$.$0^{9,11}$]undecane (trishomobarrelene) *(1)*, X = Y = CH_2[1] is characterized by its extraordinary bridgehead reactivity[2] and its propeller-like molecular shape[3]. For the same reasons heteratrishomobarrelenes, *i.e.* compounds of the type *(1)* with X = CH_2, Y = O, S, NH or Y = CH_2, X = O, S, NH and particularly the C_{3h} symmetrical substances with X = Y = O, S, NH, are also of interest.



(1)



(2) *(3)* *(4)*

(a), R = H
(b), R = C(S)–O–$C_6H_4CH_3$

Preparation of the first representative of this series was accomplished using the barrelene *(4)* as starting material, which according to *Zimmerman et al.*[4] is accessible *via* a nine-step synthesis, but for which we have found a simpler route, namely reduction of the bicyclo[2.2.2]oct-7-ene-2,5-dione *(2)*[5] with $LiAlH_4$ to the bicyclo[2.2.2]oct-7-ene-2,5-diol *(3a)*[6], reaction with 4-methylphenyl chlorothioformate[7] to give the bis(4-methylphenyl)thionocarbonate *(3b)*[6] the thermolysis of which at 170°C affords *(4)* in an overall yield of 20%[8].

In the oxidation of *(4)* with a 50% excess of 3-chloroperoxybenzoic acid in dichloromethane in the presence of potassium hydrogen carbonate, *exo,exo*-3,7-dioxatetracyclo[3.3.2.$0^{2,4}$.$0^{6,8}$]dec-9-ene *(5)* and *endo,exo,syn*-3,7,10-trioxatrishomobarrelene *(6)* were formed. Sublimation of the crude

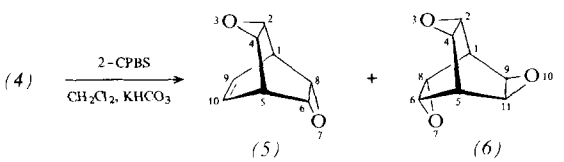
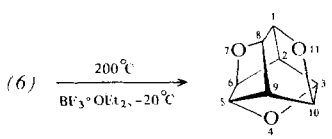
products afforded a mixture of *(5)* and *(6)* in 46% yield [ratio *(5)*:*(6)*=1:1.7]. *(5)* and *(6)* could be obtained in pure form by gas-chromatographic separation, and were then characterized by ^{1}H-NMR spectroscopy[6]. The spectrum (100 MHz, CCl_4) of the dioxatrishomobarrelene *(5)* shows three signals at $\tau = 4.59$ [AA′ part of a AA′XX′ system, 9(10)-H], 6.75 [m, 1(5)-H] and 6.84 [s, 2(4,6,8)-H], that of the trioxide *(6)* (m.p. 202°C, decomp.) only two signals at $\tau = 7.01$ [m, 2(4,6,8,9,11)-H] and 7.14 [m, 1(5)-H].





The thermal rearrangement of *(6)* is interesting: after 3.5 h at 200°C 20% is rearranged to an isomeric compound (m.p. 204°C) the ^{1}H-NMR spectrum of which (100 MHz, $CDCl_3$) shows two signals at $\tau = 5.29$ [AA′ part of a AA′XX′ system, 1(3,5,6,8,10)-H] and 7.60 [m, 2(9)-H], and corroborates the structure of the 4,7,11-trioxapentacyclo[6.3.0.$0^{2,6}$.$0^{3,10}$.$9^{5,9}$]-undecane *(7)*[6]. In the presence of catalytic amounts of boron trifluoride-diethyl ether, rearrangement is already quantitative within 5 min at −20°C. Although *(7)* has a spherical molecular shape very similar to that of *(6)*, its volatility is considerably higher, for the retention time in the gas-chromatogram (SE-30 column) is only about one-half that of *(6)*.

The pentacyclic compound *(7)*, composed exclusively of tetrahydrofuran units, is a 4,7,11-trioxa analog of the well-known (D_3)-trishomocubane[9]. Unlike *(6)*, the hydrocarbon *(1)*, (X=Y=CH_2) does not rearrange into (D_3)-trishomocubane, even in the presence of aluminum bromide[10].

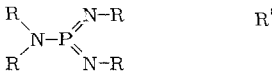
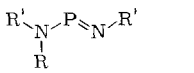
Structure of a Phosphorus-Nitrogen Ylide Having Twofold Coordinated Phosphorus

By *Siegfried Pohl*[*]

While the structure of a phosphorus-nitrogen ylide with pentavalent phosphorus of coordination number three *(1)* has been established by X-ray structure analysis[1], no such study has yet been performed on aminoiminophosphanes[2] of type *(2)* which are liquids under normal conditions.



(1), R = $Si(CH_3)_3$



(2), R = $Si(CH_3)_3$, R′ = $C(CH_3)_3$

The first structure determination on a λ^3-phosphazene was intended primarily to settle any question of an analogy between the bonding of the phosphorus in this compound and that in phosphamethine cyanines and phosphabenzene derivatives and the extent of polarization of the P—N_{imine} bond. The measurements were performed on trimethylsilyl(*tert*-butyl)-amino(*tert*-butyl)iminophosphane *(2)* (m.p. 17 to 19°C)[2] at −10±2°C[3]. The compound forms orthorhombic crystals, Pnma, having $a = 11.228(3)$, $b = 10.063(3)$, $c = 14.282(5)$ Å, $V = 1614$ Å^3, $Z = 4$. The structure was solved with diffractometer data by the direct method of symbolic addition[4].

In the solid the molecule has C_s symmetry. The phosphorus is twofold coordinated to nitrogen atoms; the P—N bond lengths are 1.544(4) and 1.658(4) Å. The P—N_{imine} distance in *(2)* is somewhat greater than in the aminodiiminophosphorane *(1)* (1.503 Å)[1]. Although no comparable data are yet available for phosphorus(III) compounds, the P—N bond lengths reported so far[5] would rule out any significant contribution of a polar resonance structure to *(2)*. Weak d_π-p_π double bond contributions favored by the geometry of the molecule can be assumed for the P—N_{amine} bond. A remarkable feature of *(2)* is the size of the NPN angle (104.9°), due to extensive participation of p orbitals in the phosphorus bonds. Thus the structure determination reveals an extensive analogy with the phosphamethine cyanines and phosphaben-

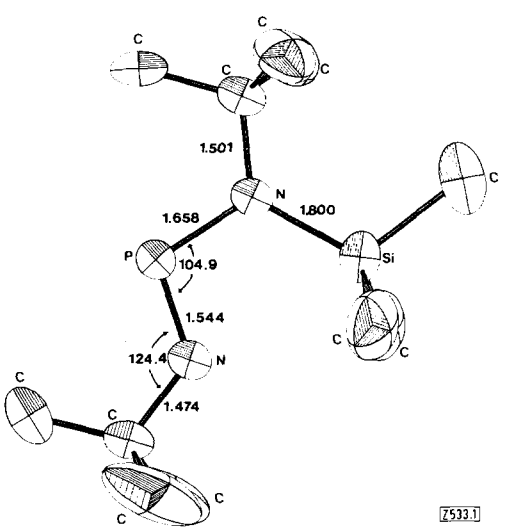


Fig. 1. Molecular structure of trimethylsilyl(*tert*-butyl)amino(*tert*-butyl)iminophosphane in the crystal (vibrational ellipsoids of 50% probability) with bond lengths [Å] and angles [°].

[*] Dr. S. Pohl
Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld 1 (Germany)

zene derivatives which also exhibit angles of similar size at the twofold coordinated phosphorus atom[5]. In contrast, the complex $(CO)_5Cr[P(NCR_3)N(SiR_3)_2]$ ($R=CH_3$) which contains an aminoiminophosphane almost identical to *(2)* as ligand is found to have an NPN angle of 119.7° and thus a completely different hybridization at the phosphorus[6].

The other distances and angles in *(2)* correspond to expectation (Fig. 1). The average values of the Si—C and C—C bond lengths are 1.850 and 1.518 Å, respectively. As seen from the size of the vibrational ellipsoids the *tert*-butyl group attached to the imine nitrogen is not completely fixed sterically. Hence localization of the H atoms was feasible only for the other methyl groups.

Differences in the Temperature Dependence of Reaction Parameters in Linear "Free Energy" Relationships[**]

By *Bernd Giese*[*]

The linear free energy relationships (a) have proved their value in the elucidation of reaction mechanisms and in the planning and optimization of synthetic reaction steps[1].

$$\log \frac{k_X}{k_0} = p_r \cdot p_s \qquad \text{(a)}$$

If equation (a) describes the effect of substituents (variation of X) on the rate constant k_X[2] of a series of reactions, then the substituent constants p_s determined in standard reactions and the experimentally determined reactivity differences ($\log k_X - \log k_0$) afford the reaction parameters p_r, which are thus typical selectivity values[3].

It has recently been shown that the selectivities of the radicals R$^\bullet$ in the competition system $BrCCl_3/CCl_4$ depend to such an extent upon the temperature that they coincide in the range 40–80°C and their order is reversed above 80°C[4]. It may therefore be expected that the reaction parameters p_r of various series of reactions become equal at certain temperatures and that the differences in the reaction parameters ($p_{r1} - p_{r2}$) consequently adopt different signs above and below this temperature. This temperature dependence of the reaction parameters can also be demonstrated with the aid of the radical halogen abstractions in the competition system $BrCCl_3/CCl_4$.

$$RCl \xleftarrow[k_{Cl}]{CCl_4} R^\bullet \xrightarrow[k_{Br}]{BrCCl_3} RBr$$

[*] Priv.-Doz. Dr. B. Giese
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The Taft-Hancock equation (b) has here proved its value as a linear free energy relationship[5]:

$$\log \frac{k_R}{k_{CH_3}} = \delta_X \cdot E_s^c \qquad \text{(b)}$$

where δ_X (X = Br, Cl) are the reaction parameters and E_s^c the ateric substituent constants for the different radicals R$^\bullet$[6].

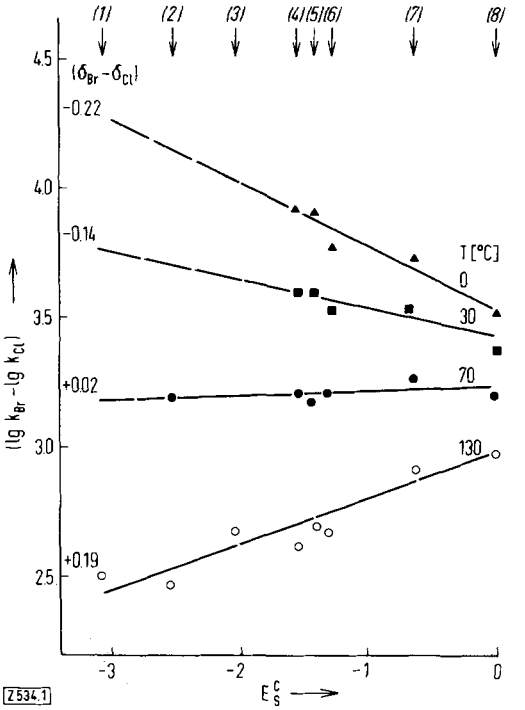

Fig. 1. Dependence of the differences in reactivity ($\log k_{Br} - \log k_{Cl}$) for the alkyl radicals *(1)*–*(8)* on the steric E_s^c constants between 0 and 130°C. *(1)*, $CH_3\dot{C}(C_2H_5)_2$; *(2)*, $C_8H_{17}\dot{C}(CH_3)_2$; *(3)*, $C_4H_9C(CH_3)_2\dot{C}H_2$; *(4)*, c-$\dot{C}_7H_{13}$; *(5)*, c-$\dot{C}_6H_{11}$; *(6)*, 2-$\dot{C}_8H_{17}$; *(7)*, 1-$\dot{C}_7H_{15}$; *(8)*, $\dot{C}H_3$.

The straight lines in Figure 1 show that in the temperature range of 0 to 130°C the radical selectivities ($\log k_{Br} - \log k_{Cl}$) depend upon the group size of the radicals *(1)* to *(8)* in a manner described by the Taft-Hancock relationship (b). Polar effects do not play any role, although the electrophilic CCl_3 radical[8] is displaced by alkyl radicals of various nucleophilicities[9] in these radical substitution reactions[7]. Release of the same CCl_3 radical on abstraction of bromine and chlorine in the competition system $BrCCl_3/CCl_4$ leads to extensive compensation of the polar effects in the transition states *(9)* and *(10)*[10] so that essentially only the differing steric interactions of bromine and chlorine transfer onto the radicals *(1)* to *(8)* become effective.

$$[\overset{\delta+}{R}\cdots\cdots Br\cdots\overset{\delta-}{C}Cl_3]^\bullet \qquad [\overset{\delta+}{R}\cdots Cl\cdots\overset{\delta-}{C}Cl_3]^\bullet$$

(9) *(10)*

The slopes of the straight lines in Figure 1 indicate the differences in the reaction parameters ($\delta_{Br} - \delta_{Cl}$). Their opposing signs at 0°C [$(\delta_{Br} - \delta_{Cl}) = -0.22$] and 130°C [$(\delta_{Br} - \delta_{Cl}) = +0.19$] show that the reaction parameters δ_{Br} and δ_{Cl} vary differently with temperature and are equal at about 60°C. This accords with the experimentally determined isoselective temperature (T_{is}) at which the radical selectivities coincide in the $BrCCl_3/CCl_4$ system[11]. As for the selectivities[4] a comparison of the reaction parameters leads to false conclusions if the isoselective temperature of the competing series of reactions lies below the temperature of measurement. The interpretation of reaction parameters therefore requires at

least a qualitative knowledge of their variation with temperature.

Chemical Waves in the 2,4-Pentanedione/Potassium Bromate System

By *Wolfgang Jessen*, *Heinrich G. Busse*, and *Bent Havsteen*[*]

A homogeneous solution in which a chemical reaction is taking place usually remains monodisperse. We now report an exception[1].

Into the lid of a Petri dish (90 mm diameter) at 10 °C were successively introduced: 2.0 M H_2SO_4 (7.5 ml), 0.3 M $KBrO_3$ (3.75 ml), H_2O (3.75 ml), and tris(2,4-pentanedionato)manganese(III) (81.4 mg). After mixing, the bottom of the Petri dish is placed in the solution. Glass spacers ensure that there is a 2 mm-thick liquid layer between the two glass surfaces.

After about 10 min, a small yellow spot (pacemaker) suddenly appears in the initially homogeneous solution which is kept at room temperature. The spot steadily expands while the remaining solution stays colorless. Once it has reached a diameter of about 10 mm, the solution decolorizes starting from the center of the circle, while the periphery continues to grow. After a brief pause a yellow spot is reformed in the center of the ring, and a second ring migrates through the solution. Instead of a system of concentric rings, spirals may appear or ring formation may simultaneously occur at several places in the solution to give a pattern of the kind shown in Figure 1. This Figure shows the state of a solution 20 min after the admixture of 2,4-pentanedione (as its Mn^{III} complex). About 40 min later, the pattern had disappeared and the solution was again monodisperse. The solution remained clear all the time; toward the end of the reaction only a slight cloudiness appeared but no precipitate was formed.

Compared with other known systems[1], the one described here has the advantage that it neither forms a precipitate nor liberates a gas. Consequently, it can also be contained in a sealed vessel. We believe it to be a suitable model for the experimental and theoretical study of chemical oscillations in time and space. At present, however, too little is known about the reaction course to explain the observed phenomena.

C-Substitution of Nucleosides with the Aid of the Eschenmoser Sulfide Contraction[1]

By *Helmut Vorbrüggen* and *Konrad Krolikiewicz*[*]

Among the numerous chemical modifications of nucleosides and nucleotides suitable for preparing analogs of biological interest, very little attention has so far been paid to C-substitution in the α- or γ-position to the heterocyclic nitrogen atoms[2].

We have therefore applied the Eschenmoser sulfide contraction[3] to the readily accessible *S*-alkyl derivatives[4] of 6-thiopurine and of 2- or 4-thiopyrimidine nucleosides.

The *S*-alkyl derivatives *(1)* of 6-thiopurine nucleosides reacted with strong bases and triphenylphosphane to give the *C*-alkylated nucleosides *(2)*, generally in good yield. The products were hydrolyzed to give the free crystalline compounds *(3)*[5] (see Table 1 for details).

The 6-phenacylthiopurine afforded, analogously to *(1a)*, 6-phenacylpurine (m.p. 248 °C) in 88 % yield.

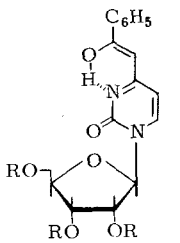
(5b), $R^2 = H$, $R^1 = CH_3$, X = N



(6a), R = COC_6H_5
(6b), R = H

In analogous manner, 2 hours' refluxing of the *S*-phenacyl derivative of 4-thiouridine 2',3',5'-tri-*O*-benzoate[7] in DMF gave the benzoylated 4-phenacyl derivative *(6a)* [m.p. 213 to 215°C][5] in 66% yield, but 6 hours' refluxing in xylene with 0.1 equiv. $(CH_3)_3COK$/4 equiv. triphenylphosphane afforded the same product in 90% yield. Saponification with CH_3OH/NH_3 gave the free phenacyl derivative *(6b)*, m.p. 182 to 184°C, in 90% yield.

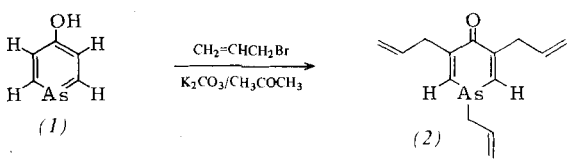
Allylation of 4-Hydroxyarsenin—Arsenic-Carbon Hetero-Cope Rearrangement

By *Gottfried Märkl* and *Jang B. Rampal*[*]

Dedicated to Professor Leopold Horner on the occasion of his 65th birthday

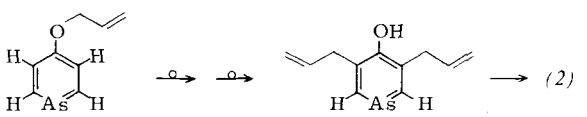
We recently reported 4-hydroxyarsenin *(1)* (arsaphenol)[1], the first simple heterocyclic phenol, which exists only in the hydroxy form. On reaction with allyl bromide in boiling acetone (12 h in the presence of K_2CO_3) according to the general synthesis of allyl phenyl ethers[2], *(1)* gives 1,3,5-triallyl-1-arsacyclohexa-2,5-dien-4-one *(2)* as the sole product.



(1) *(2)*

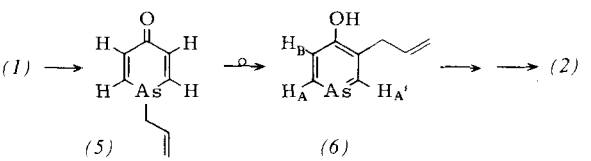
There are three possible pathways for the formation of *(2)*:

a) Formation of the allyl ether *(3)*, subsequent Claisen *ortho*-allyl ether rearrangement, and repetition of this reaction sequence leads to 3,5-diallyl-4-hydroxyarsenin *(4)*. Renewed allyl ether formation followed by *para*-Claisen rearrangement or direct allylation at the arsenic can give *(2)*.



(3) *(4)*

(b) Direct *C*-allylation in the 2,5-position and subsequent allylation at the arsenic.

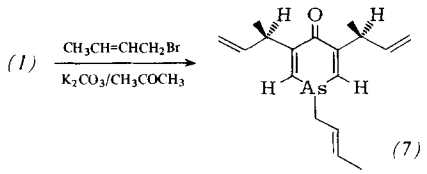


(5) *(6)*

[*] Prof. Dr. G. Märkl and Dr. J. B. Rampal
Fachbereich Chemie und Pharmazie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

(c) Allylation at the arsenic to form *(5)*, [3s,3s]-sigmatropic shift of the allyl group into the 3- or 5-position as a hetero-Cope rearrangement to give *(6)*, and repetition of this reaction sequence.

Pathway (b) can be ruled out: crotyl bromide reacts with *(1)* to give *(7)* in which the crotyl moieties in positions



3 and 5 have undergone inversion. This inversion is possible only by way of *ortho*-Claisen rearrangement corresponding to *(3)* → *(4)* or by hetero-Cope rearrangement corresponding to *(5)* → *(6)*. Pathway (a) is rather unlikely since non-catalytic allyl ether rearrangement of the phenols[3] and the 2- or 4-hydroxypyridines[4] by a Claisen type mechanism requires more drastic conditions (150 to 250°C) than formation of *(2)* and *(4)*.

Reaction of *(1)* with allyl bromide in acetone at 25°C (24 h in the presence of K_2CO_3) also gives only compound *(2)*. Formation of *(3)* is not observed. Changing the solvent (from protic to dipolar/aprotic), the allyl halide, or the base had no effect.

After 4 hours' reaction at 25°C the product is a mixture of *(2)*, *(5)*, and 1,3-diallyl-1-arsacyclohexa-2,5-dien-4-one *(8)*, which was analyzed by ^{1}H-NMR and mass spectrometry (*m/e* = 196; 236; 276).

After 1 hour's reaction at 25°C the major product is *(5)*. It could not be prepared pure, since it rearranges quantitatively to *(6)* within a few hours at as low a temperature as 0 to 5°C.

Since *(5)*, *(6)*, and *(8)* can be converted into *(2)* under the same conditions as *(1)*, these compounds are intermediates of the reaction *(1)* → *(2)*. The formation of *(2)* is thus the result of two exceptionally easy hetero-Cope rearrangements, *i.e.* of [3s,3s]-shifts of the allyl moieties from the arsenic to C-3 and C-5 in compounds *(5)* and *(8)* followed by *As*-allylation of *(4)*. The driving force of these rearrangements is probably the aromatization of the arsacyclohexadienone intermediates. The rearrangement products are then again susceptible to *As*-allylation.

The Thionitrosyl Cation NS^+ as a Synthetic Reagent[**]

By *Rüdiger Mews*[*]

Dedicated to Professor Oskar Glemser on the occasion of his 65th birthday

The thionitrosyl compounds ("thiazyl salts") $NS^+MF_6^-$ *(1)* were obtained by *Glemser* and *Koch*[1] on reaction of thiazyl fluoride NSF with the Lewis acids MF_5 (M = As, Sb). For preparative purposes these salts are best synthesized in liquid sulfur dioxide; purification of *(1a)* can be accomplished by sublimation at oil-pump vacuum (40°C), and that of *(1b)* by heating to 100°C and recrystallization of the residue from SO_2/SO_2ClF[2].

$$NSF + MF_5 \xrightarrow{SO_2\ liq.} NS^+MF_6^-$$

(1a), M = As; *(1b)*, M = Sb

The cation of *(1)* is readily attacked by anions or nucleophiles. In the absence of other reactants the salts *(1)* can be stored indefinitely in dry glass containers.

We have hitherto examined three possible modes of reaction:

1) Reaction of the thionitrosyl cation with anions:

$$\underset{(2)}{(1a) + NO^+CF_3SO_3^-} \xrightarrow[-NO^+AsF_6^-]{SO_2\ liq.} \underset{(3)}{NS^+CF_3SO_3^-}$$

The colorless product *(3)*, m.p. 120°C, is extremely sensitive to hydrolysis. Comparison of the Raman spectra of *(2)* and *(3)* indicates the solid to have an ionic structure (νSN 1443 cm^{-1}). Its ease of sublimation shows the compound to exist as the monomer, at least in the gas phase.

2) Reaction of the thionitrosyl cation with nucleophiles[3]:

$$(1) + S_4N_4 \xrightarrow{SOCl_2} \underset{(4)}{\{S_4N_4 \cdot (NS^+MF_6^-)\}} \longrightarrow S_5N_5^+MF_6^-$$

(5a), M = As; *(5b)*, M = Sb

Insertion of a SN unit into S_4N_4 affords the yellow pentathiazyl salts *(5a)* and *(5b)*, m.p. 267 and 175°C, respectively, in

[*] Dr. R. Mews
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

yields of 80%. Nothing can be said about the nature of the primary product *(4)*; both a simple addition of the nucleophile to the sulfur of *(1)* and a cycloaddition are conceivable.

When carried out in liquid SO_2 the reaction affords a black solid *(6)*, dec. 110°C, together with other unidentified substances.

$$(1a) + S_4N_4 \xrightarrow{SO_2\ liq.} (S_5N_5^+AsF_6^-)_x$$
(6)

Elemental analysis indicates the composition $S_5N_5^+AsF_6^-$; the IR spectrum contains strong bands at 700 ($\nu_3AsF_6^-$) and 850 cm^{-1} (br). The latter finding suggests that *(6)* is polymeric. The ratio (NS): AsF_6 in *(6)* can be varied by changing the stoichiometry; a drop in this ratio (increase in charge on the polymer) is associated with a shift of νNS to higher wave numbers.

3) Reaction of the thionitrosyl cation with polar bonds:

$$(1) + \overset{\delta+}{Cl}S-\overset{\delta-}{Cl} \xrightarrow{SO_2\ liq.} N(SCl)_2^+MF_6^-$$
(7a), M = As; *(7b)*, M = Sb

The first synthesis of the cation in *(7)* was accomplished starting from NSF_3 and BCl_3[4], and it is also obtainable from SCl_2, $(NSCl)_3$, and MCl_3[5]. According to the formulation adopted here, the compounds *(7)* can be regarded as derivatives of $ClSN{=}SCl_2$ or $ClSN{=}SClF$; however, reactions between *(7)* and NOCl only lead to decomposition products. The reaction of *(1)* with SCl_2 can be generalized for sulfenyl chlorides: the salts $[CF_3SNSCl]^+MF_6^-$ and $[(CF_3)_2C{=}N{-}SNSCl]^+MF_6^-$ could be prepared from CF_3SCl and $(CF_3)_2C{=}N{-}SCl$, respectively, and *(1)*[6].

Experimental

For the preparation of thionitrosyl trifluoromethanesulfonate *(3)*, compound *(1a)* is stirred with a slight excess of *(2)* for 24 h at room temperature in liquid SO_2. After removal of the SO_2, compound *(3)* can be isolated from the residue by sublimation.

For the preparation of the pentathiazyl salts *(5)*, compound *(1)* and S_4N_4 (molar ratio 1:1) are stirred in $SOCl_2$ at room temperature until the initially dark solution over the precipitated salt turns yellow. *(5)* is separated by filtration and washed with $SOCl_2$.—The analogous reaction performed in SO_2 affords, in the course of several days, compound *(6)* which is insoluble in SO_2; it is freed from side-products by washing with that solvent (yield *ca.* 60%).

Compounds *(7)* are formed in liquid SO_2 at room temperature (reaction time *ca.* 10 h). The solvent and a slight excess of sulfenyl chloride are removed *in vacuo*. The salts are left behind in analytically pure form (quantitative yield).

1,3,2λ²,4-Diazaphosphoniaaluminatacyclobutane: A Cyclic Zwitterion Having Twofold Coordinated Phosphorus[1]

By *Edgar Niecke* and *Rainer Kröher*[*]

Dedicated to Professor Oskar Glemser on the occasion of his 65th birthday

Phosphorus-nitrogen compounds having twofold coordinated phosphorus are known in the form of aminophosphanylium salts *(1)* and iminophosphanes *(2)*.

$$[-\overset{\oplus}{P}-N<]\ X^{\ominus} \qquad -P{=}N-$$
(1) *(2)*

We have now succeeded in synthesizing the zwitterionic compounds *(4)* and *(5)* by reaction of bis(trimethylsilyl)-amino(trimethylsilylimino)phosphane *(3)* with aluminum trichloride.

$$2\ R_2N{-}P{=}NR + Al_2Cl_6 \longrightarrow 2\ R_2N{-}\overset{\oplus}{P}{-}N(R)(\overset{\ominus}{Al}Cl_3) \longrightarrow$$
(3) *(4)*

$$2\ R{-}N\langle P\rangle N{-}R + 2\ RCl$$
$$Al^{\ominus}(Cl)(Cl)$$
(5)

R = $Si(CH_3)_3$

(4) and *(5)* are colorless solids which are extremely sensitive to hydrolysis. Above 40°C *(4)* undergoes significant transformation into *(5)*, which itself is remarkably thermostable (m.p. 103°C). Four-membered phosphorus heterocycles having zwitterionic structure were formerly only known with fourfold and sixfold coordinated phosphorus[2].

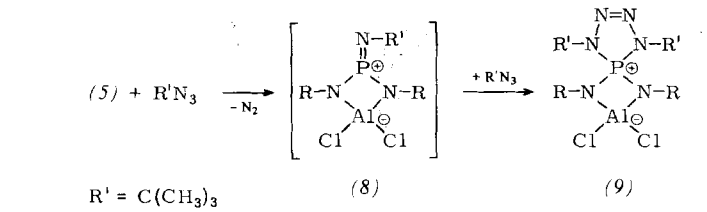
The zwitterionic structure of the compounds is evidenced by the downfield shift of the ^{31}P-NMR resonance signal on going from *(3)* [$\delta = -325.5$ ppm[3]] to *(4)* [$\delta = -450.4$ ppm] and on comparison of *(5)* [$\delta = -379.3$ ppm] with the isoelectronic 1,3,2,4-diazaphosphasilacyclobutan-2-ylium cation *(7)* [$\delta = -343.1$ ppm], a representative of the class of compounds *(1)*. Compound *(7)* could be prepared from the chlorophosphane *(6)*[4] by reaction with aluminum trichloride.

$$2\ R{-}N\langle P(Cl)\rangle N{-}R + Al_2Cl_6 \longrightarrow 2\ R{-}N\langle \overset{\oplus}{P}\rangle N{-}R\ [AlCl_4]^{\ominus}$$
$$Si(Cl)(Cl)$$
(6) *(7)*

Compound *(5)* reacts with *tert*-butyl azide to give the spiroheterocycle *(9)*, which is to be regarded as the P—N cycloaddition product of the iminophosphorane *(8)* and *tert*-

[*] Dr. E. Niecke and Dipl.-Chem. R. Kröher
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

butyl azide. Attempts to liberate the threefold coordinated phosphorus compound *(8)* by heating the adduct *(9)* were unsuccessful.



(5) + $R'N_3$ $\xrightarrow{-N_2}$ *(8)* $\xrightarrow{+R'N_3}$ *(9)*

$R' = C(CH_3)_3$

[a] 30% solution in $C_6H_5CH_3$ for *(4)*, in CH_2Cl_2 for *(5)*, *(7)*, and *(9)*. [b] Nujol mull. [c] $\delta(^{31}P, {}^{1}H) < 0$ signifies lower field than the standard (H_3PO_4 external or TMS international). [d] $[(CH_3)_3Si]_2N$. [e] Raman.

The structure of *(9)* is supported by the appearance of a strong Raman line at 1445 cm^{-1} [ν(N=N)] and the equivalence of the signals of the *tert*-butyl protons in the ^{1}H-NMR spectrum (cf. Table 1). The compositions of all the compounds are confirmed by the results of elemental analysis and, in the case of *(5)* and *(9)*, by the appearance of the molecular ion as the highest peak in the mass spectrum[5].

Procedures:

(4) and *(5)*: A solution of *(3)* (28 g, 0.1 mol) in toluene (30 ml) is added dropwise to a stirred and cooled (0 °C) suspension of $AlCl_3$ (13.5 g, 0.1 mol) in toluene (30 ml) with rigorous exclusion of moisture. The solution is stirred for 3—4 h at room temperature and then briefly heated to 40 °C. The solvent and the trimethylsilyl chloride are drawn off *in vacuo*. The residue is taken up in toluene (50 ml), crystallized at −20 °C, and purified by a single recrystallization. Yield 31 g (75%) of *(4)*.

On thermolysis at 70 °C/0.1 torr in a sublimation apparatus, compound *(4)* (20.5 g, 0.05 mol) furnishes *(5)* (13 g), which is purified by another sublimation step at 60 °C/0.1 torr. Yield 11.5 g (78%) of *(5)*, m.p. 103 to 104 °C.

(7): Compound *(6)* (6.8 g, 0.02 mol) is added dropwise to a stirred and cooled (0 °C) suspension of $AlCl_3$ (2.5 g, 0.02 mol) in toluene (10 ml). Compound *(7)* precipitates as a white solid. The solution is stirred until it is colorless. The solid is filtered off on a frit, washed several times with toluene, recrystallized from dichloromethane at −20 °C, and vacuum dried. Yield 7.4 g (78%) of *(7)*, dec. p. 70 °C.

(9): *tert*-Butyl azide (5 g, 0.05 mol) is added to a stirred solution of *(5)* (6.1 g, 0.02 mol) in toluene (30 ml) at room temperature; slight warming occurs and N_2 is liberated. When evolution of N_2 has ceased the solvent and unreacted azide are removed *in vacuo*. The residue is recrystallized from toluene at −70 °C and vacuum dried. Yield 7.9 g (84%) of *(9)*, m.p. 95 °C (dec.).

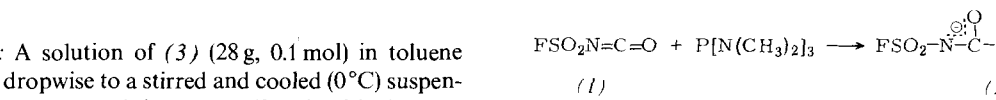
Phosphorus Betaines[**]

By *Herbert W. Roesky* and *Georg Sidiropoulos*[*]

Dedicated to Professor Oskar Glemser on the occasion of his 65th birthday

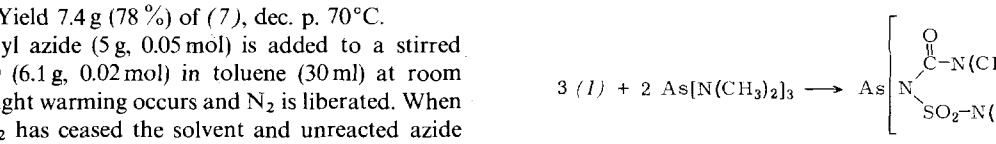
Surprisingly, very stable zwitterions *(2)* can be obtained from tertiary phosphanes and fluorosulfonyl isocyanate *(1)*.



$FSO_2N{=}C{=}O + P[N(CH_3)_2]_3 \longrightarrow FSO_2{-}\overset{\ominus}{N}{-}\overset{O}{\overset{\|}{C}}{-}\overset{\oplus}{P}[N(CH_3)_2]_3$

(1) *(2)*

While *(1)* and water react with explosive violence and its adduct with a tertiary amine proves to be unstable[1], compound *(2)* can be recrystallized from water without decomposition. Strong evidence supporting the betaine structure was obtained from IR and NMR studies[2]: in the IR spectrum the C=O stretching frequency is observed at 1620 wave numbers. The ^{19}F-NMR spectrum contains a doublet due to coupling with the phosphorus atom ($\delta_F = -50.52$ ppm, $CFCl_3$ as external standard, $J_{F-P} = 22$ Hz). Owing to coupling between the fluorine atom and the protons the ^{31}P-NMR spectrum displays a multiplet ($\delta_P = -34.2$ ppm in CH_3CN, 85% H_3PO_4 as external standard). The chemical shift lies in the range expected for tetracoordinated phosphorus. The ^{1}H- and ^{13}C-NMR data confirm the structure *(2)*, and elemental analysis indicates the empirical formula $C_4H_{18}FN_4O_3$.



3 *(1)* + 2 $As[N(CH_3)_2]_3 \longrightarrow As\left[N(SO_2{-}N(CH_3)_2)(C(=O){-}N(CH_3)_2)\right]_3 + AsF_3$

(3)

A corresponding betaine can be prepared with $(C_6H_5)_3P$. Tertiary arsanes behave completely differently: Reaction of

[**] This work was supported by gifts of chemicals from Hoechst AG.

(1) and $As[N(CH_3)_2]_3$ proceeds *via* rearrangement to give *(3)* and AsF_3.

Procedure:

Synthesis of *(2)*: Compound *(1)* (0.1 mol, 12.5 g) dissolved in CH_2Cl_2 (50 ml) and $P[N(CH_3)_2]_3$ in CH_2Cl_2 (50 ml) are added from two dropping funnels to vigorously stirred CH_2Cl_2 (150 ml) at −30 °C in a 500-ml three-necked flask. When addition is complete, the mixture is warmed to room temperature and the solvent removed under vacuum. The residue is a light brown solid which is recrystallized from CH_3CN or H_2O. M.p. 140 to 142 °C.

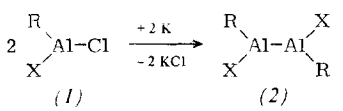
The Al—Al Bond as a Readily Accessible Structural Unit in Organometallic Compounds

By *Heinz Hoberg* and *Siegfried Krause*[*]

Although evidence for the occurrence of Al—Al bonds has been reported[1], there is no lack of critical observations casting doubt on the existence of this type of bond[2].

The stability of an Al—Al bond ought to be influenced by substituents having a +M or +I effect. Indeed, we have found that reaction (a)[3] (the dehalogenation of R(X)Al—Cl *(1)*, X = R^1_2N, R^1O, R = R^1 = *i*-C_4H_9, with alkali metals in apolar solvents *e.g.* hexane) involving deposition of Al does not take place, or if so only to a very limited extent. Instead, Al—Al units *(2)* are formed which, after filtration from accompanying alkali metal halide and unreacted alkali, can be identified by the formation of deuterium on solvolysis with CH_3OD [Equation (b)].

$$3R_2Al—Cl + 3M \rightarrow 2R_3Al + Al + 3MCl \quad (a)$$
(R = *n*-alkyl, aryl; M = alkali metal)



(1) *(2)*

$$\xrightarrow[-2\ Al(OCH_3)_3]{+6\ CH_3OD} D_2 + 2\ RD + 2\ XD \quad (b)$$

	R	X	D_2 formation [% amount calc. from Eq. (b)]
(a)	C_2H_5	CH_3O	0
(b)	*i*-C_4H_9	*i*-C_4H_9O	92
(c)	C_2H_5	$(CH_3)_2N$	0
(d)	*i*-C_4H_9	$(CH_3)_2N$	88
(e)	*i*-C_4H_9	*i*-C_4H_9	96

The +I effect of methyl groups in R and/or R^1 stabilizes the Al—Al group in *(2)*, as is shown by the formation of deuterium on solvolysis of *(2b)* and *(2d)*. "Stable" Al—Al units are also formed when exclusively *i*-C_4H_9 moieties are bonded to the aluminum. Thus, reaction of (*i*-$C_4H_9)_2$Al—Cl *(1e)* with potassium (1:1) leads to a product *(2e)* containing *ca.* 96% Al—Al units. Solvolysis with CH_3OD affords *i*-C_4H_9D and D_2 in the ratio 4:0.96 (calc. 4:1). Formation of a small amount of HD (*ca.* 4%) is probably due to the presence of Al—H or of CH_3OH in the CH_3OD.

A further indication that the *i*-C_4H_9 moieties in *(2e)* stabilize the Al—Al bond is provided by the fact that addition of $(C_2H_5)_3Al$ to a solution of *(2e)* (0.4 M in hexane) leads *via* alkyl exchange[4], to formation of unstable (C_2H_5)Al—Al units which undergo reaction with separation of Al. Deposition of Al does not take place on addition of (*i*-$C_4H_9)_3$Al.

Whether steric effects associated with the *i*-C_4H_9 moiety also contribute to the stability of the Al—Al bond is as yet undecided. The compounds *(2)* are diamagnetic and consequently are not present as R_2Al radicals[5]. They cannot be purified by distillation; on distillation of the dark-brown solution, monomeric triisobutylaluminum *(3e)* distils over at *ca.* 80 °C and 10^{-3} torr, apparently as a result of disproportionation. The remaining "polymeric" *(4)*[6] of unknown structure shows a Al:RD:D_2 ratio of 1.3:1.6:1 instead of 2:4:1 as for *(2e)*. It decomposes above *ca.* 130 °C to (*i*-$C_4H_9)_3$Al and aluminum.

$$n(i\text{-}C_4H_9)_2Al—Al(i\text{-}C_4H_9)_2 \rightarrow$$
(2e)
$$(n-1)(i\text{-}C_4H_9)_3Al +$$
(3e)
$$(i\text{-}C_4H_9)_2Al—(Al\text{-}i\text{-}C_4H_9)_{(n-1)}—Al(i\text{-}C_4H_9)_2$$
(4)

These results could also constitute confirmatory evidence for occurrence of the hitherto questionable Al—Al bond in the reaction of Al atoms with 2-butene[7].

Tetraisobutyldialuminum (2e)

1.6 g (40 mmol) potassium (pellets) is added to a solution of diisobutylaluminum chloride *(1e)* (7.0 g, 40 mmol) in hexane (100 ml) cooled to 0 °C and the mixture stirred vigorously for *ca.* 120 h. The KCl (2.9 g) which separates out is filtered off and solvent removed from the filtrate at 0 °C/12 torr. Residue: 5.6 g (viscous, brown), Al: calc. 19.1%, found 18.7%. Solvolysis: with 5 ml CH_3OD, 0.436 g residue affords 131.6 Nml *i*-C_4H_9D, 31.6 Nml D_2, and 2.3 Nml HD (determined mass spectrometrically).

Nitrogen Transfer from a Diazoalkane to a Metal Center[1]

By *Manfred L. Ziegler, Klaus Weidenhammer, Hartmut Zeiner, Philip S. Skell,* and *Wolfgang A. Herrmann*[*]

Diazoalkanes are thermolytically, photolytically, or catalytically cleaved into carbenes and dinitrogen. While stable transition metal-carbene complexes can be prepared by means of such reactions, syntheses of organometallic derivatives of molecular nitrogen starting from diazoalkanes were hitherto unknown.

In investigations on the complex chemistry of halodiazoalkanes we have now observed halogen-free, nitrogen-containing coordination compounds: reaction of the tetrahydrofuran complexes $(\eta\text{-}RC_5H_4)Mn(CO)_2THF$ [*(1a)*, R=H; *(1b)*, $R=CH_3$] with 1,1,1-trifluorodiazoethane *(2)* at −80 to +25°C yields the diamagnetic dinitrogen complexes *(3a)* and *(3b)*, which can be separated from other products by column chromatography.

$[(\eta\text{-}C_5H_5)Mn(CO)_2]_2N_2$ *(3a)* $[(\eta\text{-}CH_3C_5H_4)Mn(CO)_2]_2N_2$ *(3b)*

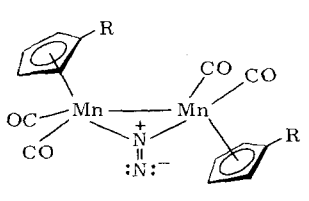
μ-Dinitrogen-bis(dicarbonyl-η-cyclopentadienylmanganese) *(3a)* and its derivative *(3b)* methylated in the C_5-ring are light-brown crystalline compounds which are air-stable for a brief period of time and are also thermally stable up to their decomposition temperatures (85 to 86°C and 73 to 74°C, resp.). Solutions in hydrocarbons or polar solvents (acetone, CH_2Cl_2) on the other hand, are extremely air-sensitive. We have characterized the compounds by elemental analysis, low- and high-resolution mass spectrometry, osmometric molecular weight determinations, and by ^{1}H-NMR and IR spectra (Table 1).

Table 1. Spectroscopic data of the dinitrogen complexes *(3a)* and *(3b)*.

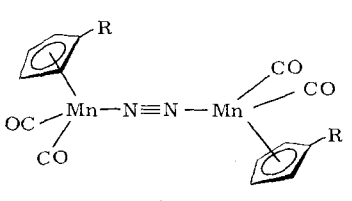
(3a): IR (*n*-pentane): 1975 m-s (ν_{N_2}), 1962 vs and 1918 vs (ν_{CO}).—^{1}H-NMR (100-MHz FT spectrum; C_6D_6; int. TMS): 6.10 ppm (singlet τC_5H_5).—MS (70 eV; T_Q 80°C; AEI MS-902): M^+ (*m/e* 380; rel. int. 100%); $(M-N_2)^+$ (352; <1); $(M-N_2-CO)^+$ (324; 11); $(M-N_2-2CO)^+$ (296; 12); $(M-N_2-3CO)^+$ (268; 40); $(M-N_2-4CO)^+$ (240; 18); $(C_5H_5)Mn(C_5H_6)^+$ (186; 30); $(C_5H_5)_2Mn^+$ (185; 41).

(3b): IR (*n*-pentane): 1971 m-s (ν_{N_2}), 1958 vs and 1913 vs (ν_{CO}).—^{1}H-NMR (100-MHz FT spectrum; C_6D_6; int. TMS: 6.19 and 8.50 ppm (AA'BB' center and singlet, resp., τC_5H_4 and τCH_3, resp.).—MS (70 eV; T_Q 60°C; AEI MS-902): M^+ (*m/e* 408; rel. int. 9%); $(M-N_2)^+$ (380; <1); $(M-N_2-CO)^+$ (352; 3); $(M-N_2-2CO)^+$ (324; 10); $(M-N_2-3CO)^+$ (296; 3); $(M-N_2-4CO)^+$ (268; 9); $(CH_3C_5H_4)_2Mn^+$ (213; 100).

The spectroscopic and analytical data are consistent with two isomeric structures *(A)* and *(B)* for *(3a)* and *(3b)* with *N,N*- and *N,N'*-coordinated dinitrogen, respectively. The linearly bridged isomer *(B)*, with R=H, has already been



(A)



(B)

described as a green compound that is unstable under normal conditions[2], and the IR spectrum was inconsistent with the presence of a centrosymmetric molecule. A complete three-dimensional X-ray structure analysis of *(3b)*[3], however, proved that *(3b)* belonged to the *N,N'*-coordinated type of compound *(B)* (Fig. 1): The N_2 ligand in the almost linear Mn—N≡N—Mn system [∢Mn,N,N = 176.5(4)°] has a N—N bond length of 111.8(7) pm. Crystallographically, *(3b)* has a center of symmetry (Z=2), the two cyclopentadienyl rings being *trans* to each other. The interplanar angle is 0°.

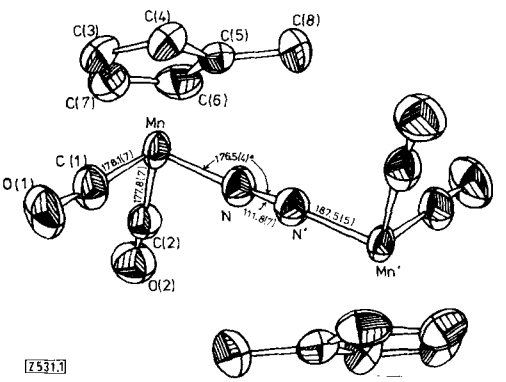


Fig. 1. ORTEP representation of molecule *(3b)*. The thermal ellipsoids correspond to the 50% probability surfaces; all atoms are drawn to scale (bond lengths in pm).

The preferred loss of N_2 from *(3a)* and *(3b)* in the mass spectrometer is unexpected for structure *(B)* and indicates a possible equilibrium between *(A)* and *(B)* in the ground state or in the M^+ state. A comparable initial cleavage of N_2 is known in the case of 1,3-substituted triazenes[4].

Thermal or catalytic cleavage of N_2 from *(2)* cannot be responsible for the formation of the dinitrogen complexes *(3a)* and *(3b)*: *(1a)* and *(1b)* react with N_2 at atmospheric pressure[5] and high pressure[6] to give the mononuclear complexes $(\eta\text{-}RC_5H_4)Mn(CO)_2N_2$[5] exclusively. Compounds *(3a)* and *(3b)* are therefore the result of a diazoalkane → metal complex nitrogen transfer. The experimental findings presented here do not suffice for a full interpretation of the mechanism, but it may be assumed that the terminal attack of the diazo function on the organometallic fragment $(\eta\text{-}RC_5H_4)Mn(CO)_2$ represents the primary step. That a primary end-on coordination of diazoalkanes is possible in the system mentioned here follows from isolation of a 1:1 complex which is thermally stable up to *ca.* 80°C on using diethyl diazomalonate instead of *(2)*[7]. The driving force for the elimination of the carbene substituents from the complexed diazoalkane is probably the intramolecular stabilization (by a 1,2 fluorine shift[8]). Also in accord with this postulate is the formation of *(3b)*, likewise observed on reaction with diazoethane [H instead of F in *(2)*], but absent on reaction with diazomethane[9].

The complete series N_2, $C_5H_5Mn(CO)_2N_2$[5], and μ-$N_2[C_5H_5Mn(CO)_2]_2$ makes it clear that the bond order of of dinitrogen expressed as a precentage lowering of the stretching vibration frequency decreases by comparable amounts in the first ($N_2 \rightarrow M—N_2$) and second ($M—N_2 \rightarrow M—N\equiv N—M$) complexation steps (6.9 and 8.9%, resp.):

	:N≡N:	M—N≡N:	M—N≡N—M
ν_{N_2} (cm^{-1})	2331	2169	1975

Experimental:

A 0.5 M solution of *(2)*[11] in diethyl ether (10 ml) is added dropwise to a solution of $(\eta\text{-}RC_5H_4)Mn(CO)_2THF$ [*(1a)* or *(1b)*, resp.][10], prepared from $(\eta\text{-}C_5H_5)Mn(CO)_3$ (2.04 g, 10 mmol) or $(\eta\text{-}CH_3C_5H_4)Mn(CO)_3$ (2.18 g, 10 mmol), in THF (150 ml). On warming to room temperature the initially wine-red solution turns orange-yellow. After 3 h the solvent is evaporated in a vacuum, the residue extracted with *n*-pentane, and the extract purified by chromatography with *n*-pentane/benzene (2:1) on silica gel (Fischer Scientific Co, 100—200 mesh; $l=40$, $\phi=1.2$ cm; 10 °C). Recrystallization from *n*-pentane at −35 °C furnishes analytically pure *(3a)* or *(3b)*. Yield: 45 to 175 mg (not optimized).—*(3b)* is also isolated after reaction of *(1b)* with diazoethane, but is not formed with diazomethane[9] or diethyl diazomalonate[6].

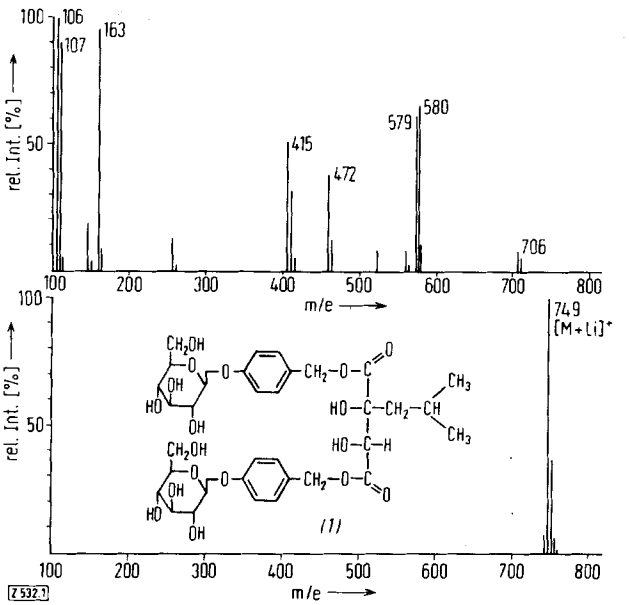
Li^+-Attachment—A Soft Ionization Method in Field Desorption Mass Spectrometry

By *Hans J. Veith*[*]

The molecular weights of non-volatile substances can be determined by means of field desorption mass spectrometry[1]. However, thermal and field-induced fragmentations frequently occur at the anode temperature necessary for the desorption of polar compounds. In the following it is shown that by Li^+-attachment[2] extraordinarily stable cluster ions $[M+Li]^+$[3] are formed which also permit the molecular weights of thermally sensitive substances to be determined.

$Li^+[CH_3B(C_6H_5)_3]^-$ or $Li^+[B(C_6H_5)_4]^-$ serve as Li^+ donors. The emitter filament is dipped into a saturated methanolic solution of the lithium salt and then heated for a short while at *ca.* 150 °C in a high vacuum. The substance under investigation is then applied to the emitter in the usual way[1]. Under these conditions the FD mass spectrum of sucrose ($M=342$) shows exclusively a quasi-molecular ion $[M+Li]^+$ at $m/e=349$. While in the normal FD spectrum of sucrose an $[M+1]^+$ ion occurs as base peak at $m/e=343$ within only a narrow temperature range and an increase in temperature effects immediate fragmentations, an increase in the heating current by more than 5 mA is necessary before the $[M+Li]^+$ ion is accompanied by the protonated molecular ion $[M+1]^+$ (relative intensity 3%) and fragment ions in the Li^+-attachment spectrum. Thus, Li^+-attachment permits differentiation between the M^+ and $[M+1]^+$ ions of unknown compounds. Moreover, the fragmentations are suppressed by the formation of the stable non-radical $[M+Li]^+$ ions, *i.e.* the mass spectrum contains only the signal for the quasi-molecular ion $[M+Li]^+$. Hence, it can be established whether the sample being analyzed is a mixture or a pure compound.



No peaks for the M^+ or $[M+1]^+$ ion are observed in the FD mass spectrum of the glucoside loroglossin *(1)*, $M=742$][4]. Apart from the fragmentations there is merely one additional line at $m/e=706$ for $[M-2H_2O]^+$ (Fig. 1, above). On the other hand the Li^+-attachment spectrum shows an intense signal for the quasi-molecular ion $[M+Li]^+$ at $m/e=749$ (Fig. 1, below). Hence, Li^+-attachment also facilitates generation of quasi-molecular ions of those substances whose normal FD spectrum contains no signals for the molecular ion.

$[(CH_3)_3SiNH]_2PN_3S_2$: An Unusual Dark Blue Sulfur-Nitrogen-Phosphorus Compound[1]

By *Rolf Appel* and *Mechthild Halstenberg*[*]

We have found that tetrasulfur tetranitride *(2)* also numbers among those sulfur-nitrogen compounds having SN multiple

[*] Dr. H. J. Veith
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 15, D-6100 Darmstadt (Germany)

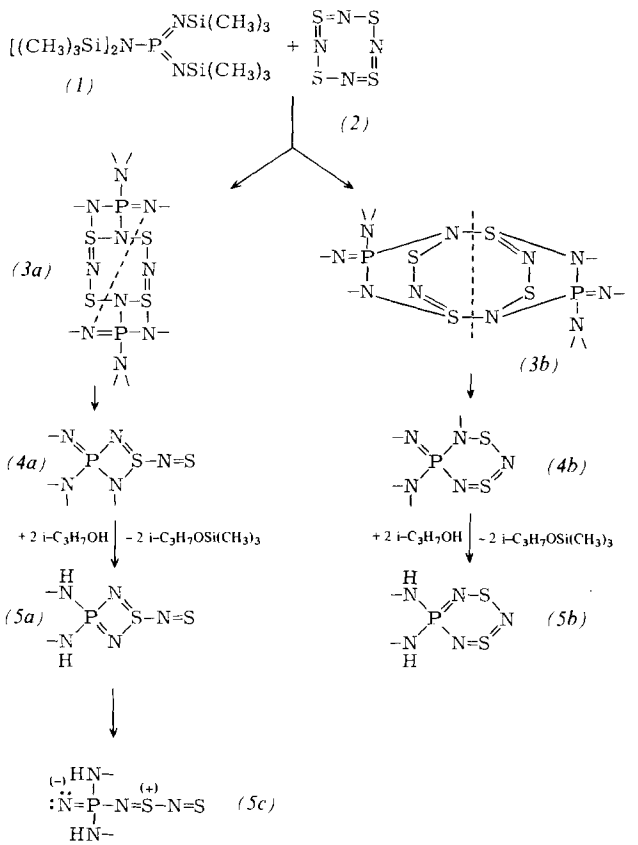
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

bonds which undergo cycloaddition with aminobis(imino)-phosphorane *(1)*[2, 3].

On addition of S_4N_4 to a solution of *(1)* in *n*-pentane (or benzene or ether) the solution turns dark red-brown, and an orange-yellow precipitate *(3)* appears which is shown by elemental analysis and molecular mass determination to be the diadduct of *(1)* to *(2)*, *i.e.* $S_4N_4 \cdot 2[Tms_2NP(NTms)_2]$ (Tms = trimethylsilyl).

The filtrate contains yet another homogeneous substance *(4)* of the same composition but having a molecular mass only half as large as the diadduct, which we therefore formulate as $S_2N_2 \cdot [Tms_2NP(NTms)_2]$. After removal of the solvent this brown-red substance can be purified by distillation. It crystallizes around room temperature and is extremely sensitive to hydrolysis. Even the slightest traces of moisture which creep through the grease sealing the ground glass joints of the apparatus lead to an intense blue color of the film of substance attached to the glass wall. On hydrolysis two silyl groups are eliminated as silyl ether. The same process can be accomplished by dissolution of the substance in isopropanol. Apart from isopropyl silyl ether the reaction yields a blue-violet compound *(5)* of composition $C_6H_{20}N_5PS_2Si_2$. This product, which is readily soluble in numerous solvents, crystallizes from *n*-pentane as dark blue-violet needles with a metallic sheen (m.p. 104 °C) closely resembling $KMnO_4$ crystals.



Concerning the reaction course and the structures of compounds *(3)*, *(4)*, and *(5)* we are still not able to decide between two possible suggestions which differ in the assumption of a 1,2- or a 1,4-cycloaddition to S_4N_4. In the case of 1,2-addition the tricyclic diadduct *(3a)* would contain two four-membered rings alongside the eight-membered ring of S_4N_4, while a 1,4-addition such as has recently been observed in the reaction of S_4N_4 with chlorosulfonyl isocyanate[4], would link up the P—N bonds of two molecules of *(1)* with one of *(2)* to from a tricyclic system *(3b)* consisting of an eight-membered ring and two six-membered rings.

Although the diadduct *(3)* can be isolated in rather poor yield it is unstable and decomposes symmetrically into the brown-red substance *(4)* of half the molecular mass for which the structure *(4a)* or *(4b)* comes into consideration. This compound, which is also accessible in good yield by heating of *(1)* with *N,N'*-bis(trimethylsilyl)trisulfur tetranitride *(6)*[5] according to

is stable in the absence of moisture. With proton-active compounds protonation takes place at two nitrogen atoms and two trimethylsilyl groups are eliminated. This reaction, which is accompanied by the impressive deepening of color, is shown by NMR studies to be accompanied by a proton exchange. It is impossible to decide between the four-membered ring structure *(5a)* or the six-membered ring structure *(5b)* for the dark-blue compound *(5)* only on the basis of the ^1H, ^{13}C, and ^{31}P-NMR data.

Both proposed structures *(5a)* and *(5b)* are supported by elemental analyses and molecular mass determinations. They also accord with the clear-cut formation reaction and NMR data. Predictably, the ^{31}P-NMR spectra of the compounds *(3)*, *(4)*, and *(5)* in C_6H_6 each contain only one singlet at $\delta = +6.0$, $+25.1$, and -1.5 ppm, respectively; owing to the ready decomposition of *(3)* into *(4)* the signal of the latter also appears at $+25.1$ ppm in the spectrum of *(3)*. The signals of the silyl protons (in C_6D_6) display the following chemical shifts: *(3)*, $\delta = -0.43$ and -0.52 ppm in the ratio 3:1; *(4)*, $\delta = -0.32$ and -0.39 ppm in the ratio 3:1; *(5)*, $\delta = -0.15$ ppm; a broad signal at $\delta = -2.5$ ppm is to be assigned to the NH protons.

The ^{13}C-NMR spectra (in C_6D_6) are informative. The spectrum of *(4)* recorded at 22.6 MHz contains three signals at $\delta = -2.8$ (s), -3.7 (d, $^3J_{PNSiC} = 4$ Hz), and -4.7 ppm (s), in the intensity ratios 1:1:2. At 15.08 MHz the signal at $\delta = -3.7$ ppm also appears as a doublet with the same coupling constant. The coupling takes place between the C atom of the silylimino group and the P atom; it is also observed with *(1)*. During the protonation of *(4)* to *(5)* occurring on alcoholysis the exocyclic silylimino group is transformed into a silylamino group, whereupon the coupling disappears. In PN compounds coupling with more distant atoms is observed primarily with double bond systems, being much weaker in the case of single bonds.

In its ^{13}C spectrum at 22.6 MHz compound *(5)* merely displays a singlet at $\delta = -1.2$. The intense dark blue-violet color of *(5)* ($\lambda_{max}^{isooctane} = 570$ nm, $\varepsilon_{max} = 1070 \times 10^3$ cm^2 mol^{-1}) might possibly be best interpreted with the aid of the terminal thionitroso group, which to our knowledge has not hitherto been observed. However, an unusual and rather unlikely feature of structure *(5a)* is the appearance of two double bonds in the four-membered ring since pπ-dπ double bonds lead to an increase in the bond angles at P and S. We therefore consider it more probable that the strained ring resulting from a 1,2-cycloaddition would open to give an open-chain structure such as *(5c)*. Further evidence against *(5a)* is provided by the mass spectrum of *(5)* in which the molecular signal appears as base peak, thus indicating *(5)* to be surprisingly stable.

An X-ray structure analysis already in progress should reveal the nature of the structure and bonding.

Procedure:

Compound *(1)* (7.32 g, 20.0 mmol) is dissolved in *n*-pentane (60 ml) and the stirred solution mixed with S_4N_4 (1.84 g, 10 mmol).

a) After 6 h the resulting *(3)* is filtered off [yield *ca.* 38 %, m.p. 140 °C (dec.)] and compound *(4)* vacuum-distilled [yield 49 %, b.p. 113 °C/10^{-3} torr].

b) After 6 h isopropanol (10 ml) is added and the mixture stirred for 3 h before evaporating to dryness. The residue is taken up twice in *n*-pentane (2 × 50 ml), filtered hot, and the filtrate cooled to −78 °C, whereupon compound *(5)* crystallizes [yield 37 %, m.p. 104 °C].

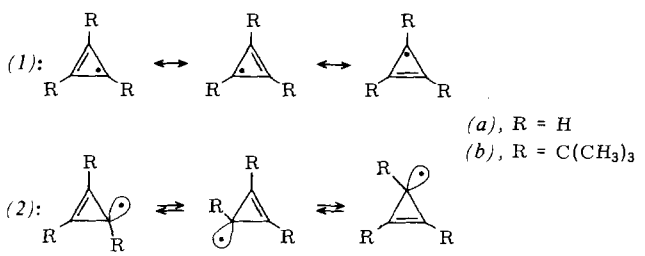
Electronic Structure of Tri-*tert*-butylcyclopropenyl[1]

By *Kurt Schreiner* and *Armin Berndt*[*]

Depending on the method of calculation employed a quantum mechanical examination of the electronic structure of the cyclopropenyl radical shows it to have aromatic, antiaromatic or σ character[2]. On irradiation of di-*tert*-butyl peroxide in cyclopropene a radical was obtained[3], whose *g*-factor with a value of 2.0061 lies outside the characteristic range (2.0025 ± 0.0005) for carbon radicals without heteroatoms. Even if the radical concerned is the desired cyclopropenyl radical, no decision could be made between the structures *(1a)* (aromatic π-radical) and *(2a)* (rapid equilibrium of energetically equivalent σ-radicals) on the basis of the observed proton coupling constants $a^H = 13.5$ G for three equivalent protons, since a^H values of *ca.* 10 G are expected for both radicals[4].



π- and σ-radicals can be distinguished unequivocally on the basis of their ^{13}C-ESR coupling constants, since the finite s character of the orbital of the unpaired electron in σ-radicals leads *via* direct Fermi contact to comparatively large a^C values. If, to a first approximation, it is assumed that the ring C-atoms of a cyclopropenyl radical have ^{13}C coupling constants similar to those of the comparable C-atoms of the vinyl radical ($a^C_\alpha = 107.57$, $a^C_\beta = -8.55$ G)[6] or 2,4,6-tri-*tert*-butylphenyl radical ($a^C_\alpha = 122.5$, $a^C_{ortho} = -6.16$ G)[7], then an a^C value of 30 to 37 G can be predicted for the ring C-atoms of *(2)* by weighted averaging (rapid equilibrium). On the other hand, the Karplus-Fraenkel expression[8] gives a a^C value of only *ca.* 4 G for the ring C-atoms of *(1)*.

With samples containing ^{13}C in natural abundance, ^{13}C-ESR coupling constants are conveniently accessible in the case of radicals kinetically stabilized by steric hindrance. We therefore carried out the reaction of tri-*tert*-butylcyclopropene with photochemically generated *tert*-butoxyl radicals in the ESR cell. Figure 1 shows the ESR spectrum (singlet) obtained at +55 °C in benzene together with the ^{13}C satellites occurring at higher amplification. The *g*-factor of 2.0026 and the number and relative intensities of the satellite signals are consistent with the constitution of a tri-*tert*-butylcyclopropenyl radical of structure *(1b)* or *(2b)*. From the intensities of the signals the coupling constant $a^C = 2.5$ G must be assigned to the nine methyl C-atoms; $a^C = 5.0$ G and $a^C = 30.0$ G then belong to the quarternary C-atoms of the *tert*-butyl groups and to the ring C-atoms, respectively.

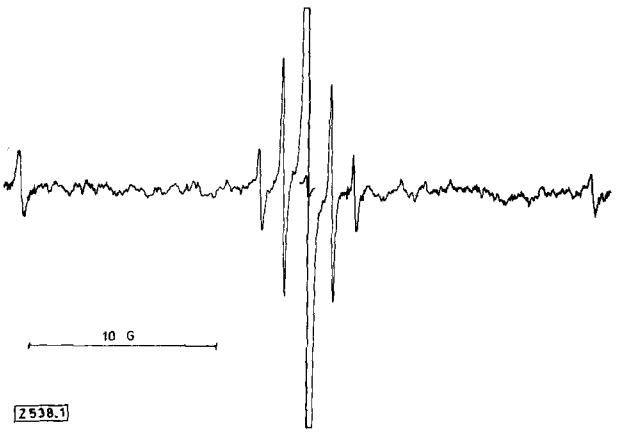


Fig. 1. ESR spectrum of the tri-*tert*-butylcyclopropenyl radical in benzene at +55 °C at low (small singlet in the middle) and high amplification. The difference in intensity of the outer satellite signals is due to decreasing radical concentration during the measurement.

Since from observations on other *tert*-butyl substituted π radicals, ^{13}C coupling constants of *ca.* 4 G each (as for the ring C-atoms) are to be expected for the methyl and quarternary C-atoms of the *tert*-butyl groups in *(1b)*, tri-*tert*-butylcyclopropenyl cannot have the electronic structure *(1b)*. The σ electronic structure *(2b)* is proven by the ^{13}C coupling constants of the ring C-atoms (30 G) lying within the predicted range.

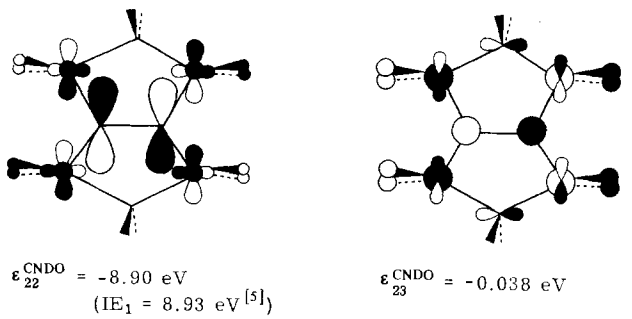
Radical Cation and Radical Anion of a Tetrasilyl-Substituted Ethylene[1, 2]

By *Hans Bock, Georg Brähler, Gerhard Fritz,* and *Eberhard Matern*[*]

Trimethylsilyl substituents have a differential effect on the individual molecular states of neighboring π systems: In general they act as π acceptors in radical anions[3a] or carbanions[3b], are weak donors in the ground state of the neutral compound[3c], and—as will be shown in the present communication—are able to considerably delocalize the positive charge in radical cations.

Experience shows[4] that radical cations $M^{\cdot\oplus}$ can be generated in solution from molecules M having first ionization energies $IE_1 \leq 8$ eV and characterized by ESR spectroscopy. Thus the first band in the photoelectron spectrum of the tetrasilyl-substituted ethylene derivative 2,2,4,4,6,6,8,8-octamethyl-2,4,6,8-tetrasilabicyclo[3.3.0]oct-1-ene[5] occurs at 7.98 eV, and the ESR spectrum of its radical cation is observed after reaction with $AlCl_3$ in CH_2Cl_2 at 180 K (Fig. 1).

A striking difference is observed in the ^{29}Si coupling constants $a^{\oplus}_{^{29}Si} = 22.71\ G \gg a^{\ominus}_{^{29}Si} = 6.72\ G$ (Fig. 1A): this is an interesting finding in view of the fact that double fixation of five-membered rings should lead to comparable geometries at the silicon sites of $M^{\cdot\oplus}$ and $M^{\cdot\ominus}$. CNDO calculations on the planar[7] parent compound 2,4,6,8-tetrasilabicyclo[3.3.0]oct-1-ene[5] show the inner orbitals to be:



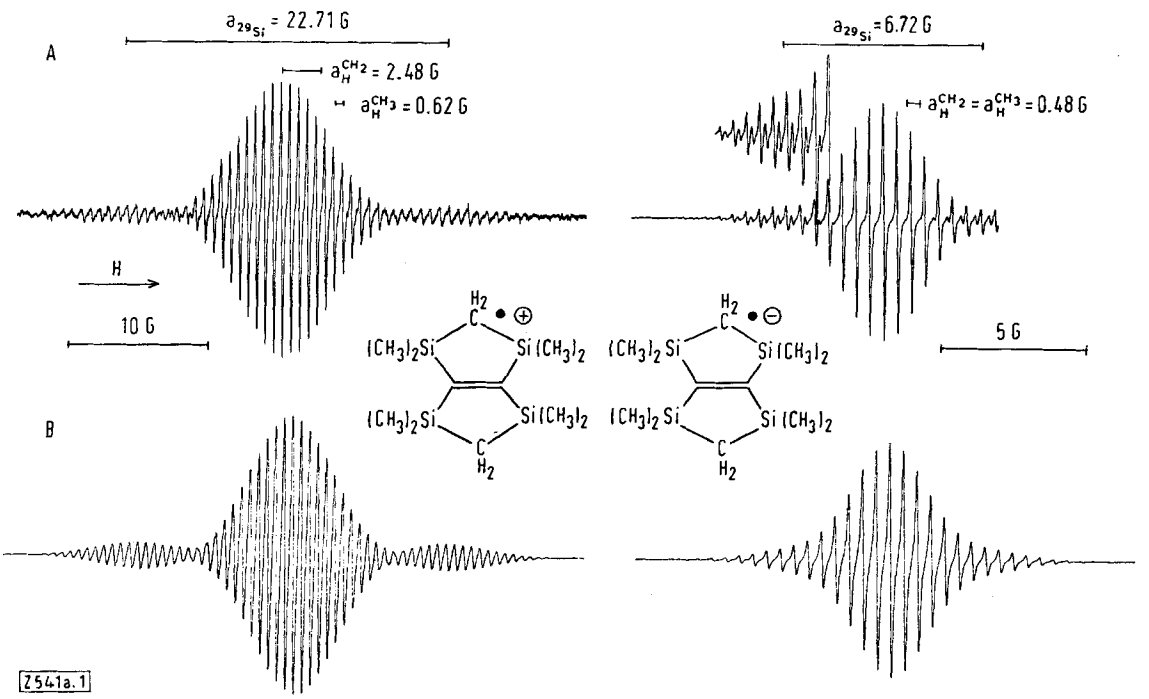


Fig. 1. Experimental (A) and simulated (B) ESR spectra of the radical cation and the radical anion of 2,2,4,4,6,6,8,8-octamethyl-2,4,6,8-tetrasilabicyclo[3.3.0]oct-1-ene.

The corresponding radical anion $M^{\cdot\ominus}$ can be generated with potassium in dimethoxyethane at 300 K; its ESR spectrum (Fig. 1) is only *ca.* 15 G wide and thus considerably narrower than that of the cation (*ca.* 35 G). The spectrum is expected to contain 25 signals for 24 methyl protons in the intensity ratio outermost line:central line = 1:2704156, a quintet for the four methylene protons, and a doublet for one ^{29}Si isotope per molecule (abundance 4.70 %, $I_{^{29}Si} = 1/2$). The ESR spectra were initially simulated without considering possible ^{13}C coupling and assuming degenerate constants $a_H^{CH_2} = n \times a_H^{CH_3}$[6] (Fig. 1B).

Bending by 30° along the C=C edge, *i.e.* ∢SiCSi = 122°, does not alter the type of orbital. Accordingly, the cation and the anion of the tetrasilyl-substituted ethylene should not represent π radicals but instead σ radicals and thus a new type of "persistent"[8] radical ion.

Radical Cations of Tetrasilyl-Substituted Hydrazines[1, 2]

By *Hans Bock, Wolfgang Kaim,* and *John W. Connolly*[*]

The radical anions of ethylene derivatives $R_2C{=}CR_2^{\bullet\ominus}$ are isoelectronic to the radical cations of similarly substituted hydrazines $R_2N{-}NR_2^{\bullet\oplus}$. In contrast to the isotope ^{12}C, however, ^{14}N has a nuclear spin and therefore provides ESR information ($I_{^{14}N}=1$) about the spin populations at the sites of the central bond. For these it follows only *indirectly* from comparison of the ^{29}Si coupling constants of tetrasilyl-substituted ethylene radical ions ($a^{\bullet\ominus}_{^{29}Si} \ll a^{\bullet\oplus}_{^{29}Si}$)[1,2] that they should be greater in the anion than in the corresponding cation.

Photoelectron spectra exhibit first ionization energies $IE_1 \leq 8$ eV for both bicyclic and open-chain tetrakis(trialkylsilyl)hydrazines. These compounds can accordingly be oxidized electrochemically and by $AlCl_3$, $AgBF_4$, or $SbCl_5$ in CH_2Cl_2 to the radical cations (Fig. 1), which are stable at room temperature in spite of their SiN bonds[3].

The ESR spectrum of the bicyclic derivative (Fig. 1) is dominated by the ^{14}N quintet; high resolution permits recognition of the more intense signals of the 25-line system of the 24 methyl protons, the quintet of the 4 methylene protons, and the doublet of one ^{29}Si isotope per molecule (abundance 4.70 %, $I_{^{29}Si}=1/2$). The ESR data are compared with those of tetraalkylhydrazines and of the isoelectronic ethylene radical anion in Table 1.

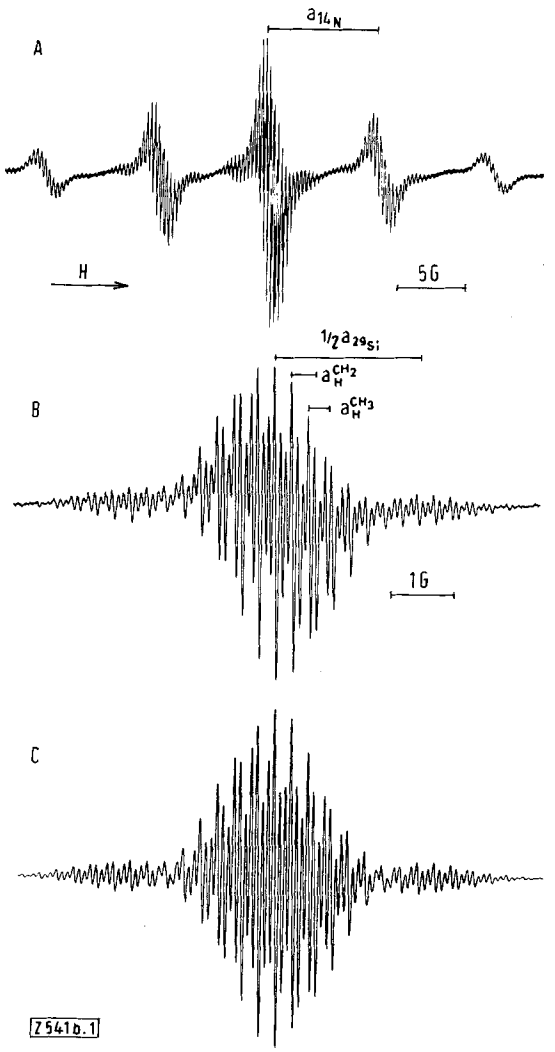

Fig. 1. Complete ESR spectrum (A), highly resolved central line (B) and its computer simulation (C) of the radical cation of 2,2,4,4,6,6,8,8-octamethyl-1,5-diaza-2,4,6,8-tetrasilabicyclo[3.3.0]octane (recording temperature: complete spectrum 300 K, section 240 K [4]).

Table 1. ESR coupling constants a_X [G] of tetrasilylhydrazine radical cations, tetraalkylhydrazine radical cations [4b], and tetrasilylethylene radical anion [1] (R = CH_3).

					$a_{^{14}N}$	8.68	7.52	17.6	11.9	—
$a_H^{CH_2}$ (β)	—	—	15.6	11.9	—
(γ)	0.4 [a]	—	0.8	[b]	0.48
a_H^{β}	0.30	0.13	—	[b]	0.48
$a_{^{29}Si}$	5.00 [c]	[b]	—	—	6.7

[a] Temperature dependent (300 K: 0.38 G; 170 K: 0.43 G).
[b] Not observed.
[c] Temperature dependent (300 K: 5.00 G; 180 K: 5.30 G).

Comparison of the coupling constants reveals:

1) The difference between the ^{14}N coupling constants of bicyclic and open-chain hydrazine radical cations is considerably smaller for the tetrasilylated derivatives (1.2G) than for the tetraalkylated ones (cf. Table 1 and ref. [4b]). This can be interpreted by assuming that the bulky substituents

[*] Prof. Dr. H. Bock and Dipl.-Chem. W. Kaim

Theodor-Stern-Kai 7, D-6000 Frankfurt am Main 70 (Germany)
Prof. Dr. J. W. Connolly
Department of Chemistry, University of Missouri
Kansas City, Missouri 64110 (USA)

extensively flatten the molecular skeleton around the nitrogen atoms and that the SiNSi angle (presumably near 120°) will therefore change less than the CNC angle.

2) The ^{14}N coupling constant of the tetrakis(trimethylsilyl)-hydrazine radical cation is at least 3 G smaller than that of analogous tetraalkyl derivatives[6] and equal to that of the tetraphenylhydrazine radical cation[5]. Thus trimethylsilyl and phenyl groups lower the spin density at the nitrogen atoms to the same extent.

3) The coupling constants of the bicyclic tetrasilylhydrazine radical cation differ considerably from those of the corresponding (nonmethylated)[6] tetraalkyl derivative, but are comparable with those of the isoelectronik tetrasilylethylene radical anion. In the latter system the larger coupling constants of the peripheral hydrogen atoms (Table 1: $a_H^{CH_2(\gamma)}$ and $a_H^{CH_3}$) and the larger $a_{^{29}Si}$ value[7] suggests a somewhat lower spin density in the central $>C=C<^{\ominus}$ bond relative to $>N-N<^{\oplus}$

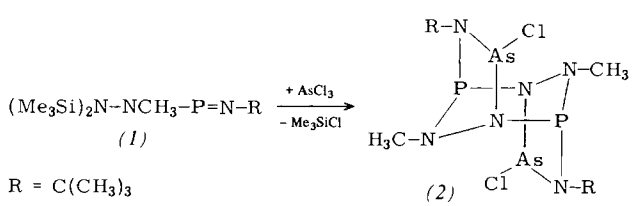
Synthesis and Structure of a Hexaazadiphosphadiarsatricyclodecane

By *Otto J. Scherer, Walter Glässel, Gottfried Huttner, Albin Frank*, and *Peter Friedrich*[*]

Hitherto, exclusively adamantane-type structures have been demonstrated or proposed for the wide class of substances derived from ten-membered heterocycles P_4X_6 with, for example, X = O, NR or CH_2. We report here on the first case of a structure of the tricyclodecane type *(2)*.

Compound *(2)* is formed on reacting 2-phospha-1-tetrazene *(1)*[1] with arsenic trichloride:



[*] Prof. Dr. O. J. Scherer and Dipl.-Chem. W. Glässel
Fachbereich Chemie der Universität
Postfach 3049, D-6750 Kaiserslautern (Germany)
Doz. Dr. G. Huttner, Dipl.-Chem. A. Frank, and Dipl.-Chem. P. Friedrich
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

The product[2], which can be purified by sublimation—or better by recrystallization from C_6H_6 or CCl_4—slowly decomposes above 110 °C. The compound is readily soluble in CH_2Cl_2 and $CHCl_3$ in the cold, and in C_6H_6, *n*-hexane, and CCl_4[3] on warming. In the mass spectrum the largest fragment detectable at 70 and at 17 eV is the half-molecule [17 eV: $m/e = 255$ (4 % $M/2^+$), 220 (100 % $M/2^+ - Cl$)]. The relative molecular mass found ebullioscopically (benzene) is 519.

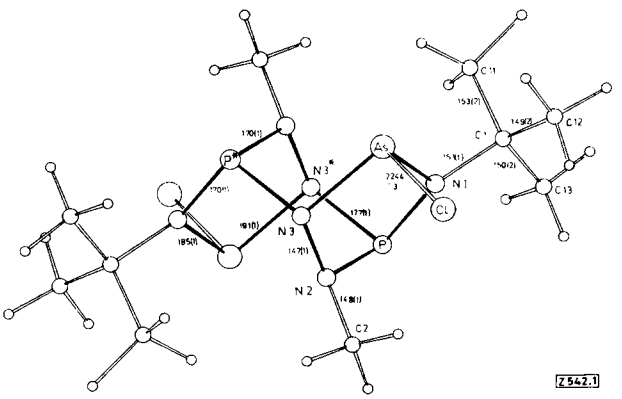


Fig. 1. Structure of *(2)*.

Figure 1 shows the results of an X-ray structure analysis[4]. *(2)* contains an inversion-symmetric (C_i symmetry) ten-membered polycycle [N3* and P* arise from N3 and P by inversion], which can be regarded as being made up of two identical five-membered rings As—N1—P—N2—N3. The As, N1, P, and N3 atoms lie to within 7 pm in a plane, which is at an angle of 41° to the N3, N2, P plane. The P—N bonds within the five-membered ring have a length of 170 pm and are shorter than the P—N3* bond coupling the two rings. The N—N, N—As, and As—Cl bond lengths correspond with those of single bonds[5].

Experimental:

A solution of $AsCl_3$ (5.9 g, 32.5 mmol) in ether (10 ml) is added dropwise to an ice-cold solution of *(1)* (9.0 g, 30.9 mmol) in ether (20 ml). The mixture is stirred for 1/2 h at room temperature and the apparatus evacuated under water-pump vacuum until the mixture becomes solid. The solid is taken up in 15 ml ether and the resulting solution stirred for 10 h, centrifuged, and the solvent removed under water-pump vacuum. The residue is then dissolved in 5 ml boiling benzene. On allowing to stand, crystals start to separate out after *ca.* 1 h. The residue of centrifugation is dried at 12 torr and recrystallized from 10 ml benzene. The combined crystals (3.27 g, 41 %) are recrystallized from hot benzene and washed with ice-cold CCl_4. Yield 1.95 g (25 %).

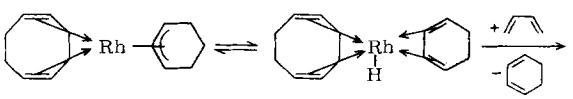
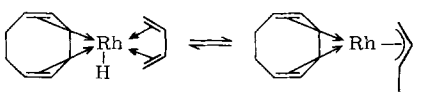
Cyclohexenyl(1,5-cyclooctadiene)iridium—η-Diene Hydride or Enyl Structure[**]

By *Jörn Müller*, *Walter Holzinger*, and *Helmut Menig*[*]

The transfer of a hydrogen atom from an η-enyl- or η-dienyl ligand to the central metal atom should play an important role in numerous reactions of π-complexes with olefins, *e.g.* ligand-exchange processes which are partial steps of catalytic isomerizations and oligomerizations of alkenes and dienes. Thus the ligand exchange[1] in the reaction of cyclohexenyl(1,5-cyclooctadiene)rhodium *(1)*[2] with butadiene may perhaps be most simply explained in terms of the formation of hydride intermediates [*(1a)*, *(1b)*].

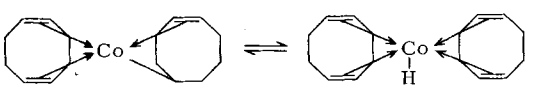


(1) *(1a)*



(1b)

Similarly the reactive behavior of 1,5-cyclooctadiene(4-5-η-cyclooctenyl)cobalt *(2)* suggests that this complex is in equilibrium with a hydride form *(2a)*[3].

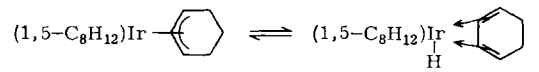


(2) *(2a)*

So far, however, there has been no direct spectroscopic evidence for an equilibrium of the type *(1)*⇌*(1a)* or *(2)*⇌*(2a)*.

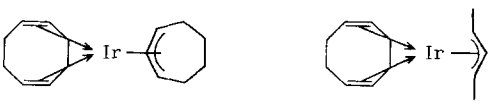
We have now synthesized and investigated the analog of *(1)*, the iridium compound *(3)*. Reaction under UV radiation of di-μ-chlorobis[(1,5-cyclooctadiene)iridium] *(4)*[4] with 1,3-cyclohexadiene in the presence of i-C_3H_7MgBr furnished *(3)* in the form of yellow-brown crystals. Spectroscopic findings prove that *(3)* is in equilibrium with a hydride form at room temperature, and that the six-membered ring ligand has a fluxional structure.

Evidence for the existence of an Ir—H bond is provided by the occurrence of a medium-strength absorption at 2010 cm^{-1} in the IR spectrum (KBr) and a broad singlet at $\tau = 12.6$ in the ^{1}H-NMR spectrum ([D_8]toluene). The protons of the cyclohexadiene ligand likewise give rise to only one singlet at $\tau = 6.76$. Both singlets become sharper on warming the solution; on cooling they broaden and at *ca.* 280 K disappear into the background. Accordingly, there must be rapid interchange between the forms *(3a)* and *(3b)*; collapse of the proton signal of the cyclohexadiene ligands comes about because hydride addition and abstraction, respectively, can take place at both sides of the π-system, so that this "rotates" over all six ring positions.



(3a) *(3b)*

On lowering the temperature the equilibrium shifts in favor of *(3a)*. This is confirmed by the temperature-dependence of the ^{13}C-NMR spectrum[5]. Cycloheptenyl(1,5-cyclooctadiene)iridium *(5)*, obtained by reaction of *(4)* with 1,3-cycloheptadiene in the presence of i-C_3H_7MgBr, behaves in exactly the same way as *(3)*. On the other hand, the 1,5-cyclooctadiene(pentenyl)iridium *(6)*, synthesized in a similar way, has so far yielded no evidence of a hydride form.



(5) *(6)*

Experimental:

All work must be carried out under nitrogen or argon. 1,3-Cyclohexadiene (2 ml) is added to a suspension of *(4)* (1.62 g, 2.41 mmol) in ether (20 ml) at −78 °C; a Grignard solution prepared from Mg (182 mg, 7.49 mmol) and i-C_3H_7Br (0.7 ml) in ether (30 ml) is then added with vigorous stirring. The mixture is allowed to warm slowly to 20 °C and irradiated for 5 h with UV light (Hg high-pressure lamp Q 81, Heraeus, Hanau). Solvent and excess diene are then removed by evaporation, the residue eluted with hexane (150 ml), and the resulting solution concentrated and chromatographed on an Al_2O_3 (5 % H_2O) column (length 50 cm, diameter 1.5 cm) with hexane. Analytically pure *(3)* crystallizes from the yellow-brown eluate at −78 °C. Yield 1.09 g (2.86 mmol; 59 %), m.p. 68—69 °C.

Simplified Synthesis of Bis(triphenylphosphoranylidene)methane

By *Rolf Appel*, *Fritz Knoll*, *Heinfried Schöler*, and *Horst-Dieter Wihler*[*]

Hexaorganylcarbodiphosphoranes of type $R_3P{=}C{=}PR_3$ are extremely reactive compounds[1-3] which on account of their pronounced ylide character avidly abstract protons and halogen[4]. Their wide-spread use, however, has hitherto been

[*] Prof. Dr. R. Appel, Dr. F. Knoll, Dipl.-Chem. H. F. Schöler, and Dipl.-Chem. H.-D. Wihler
Anorganisch-chemisches Institut der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

thwarted by the effort involved in their preparation. The reaction of triphenylphosphane with tetrachloromethane in polar solvents[5] recently described by us affords convenient entry to the bis(triphenylphosphoranylidene)methane *(2)*. [Chloro(triphenylphosphoranylidene)methyl]triphenylphosphonium chloride *(1)* and dichlorotriphenylphosphorane are formed in quantitative yield.

$$3\ Ph_3P + CCl_4 \longrightarrow \left[Ph_3P{=}C(Cl){=}PPh_3\right]^+ Cl^- + Ph_3PCl_2$$

(1)

We have now found that *(1)* can be readily dechlorinated to *(2)* by reaction with tris(dimethylamino)phosphane.

$$(1) + P[N(CH_3)_2]_3 \longrightarrow Ph_3P{=}C{=}PPh_3 + PCl_2[N(CH_3)_2]_3$$

(2)

Attempts to prepare the particularly reactive hexamethylcarbodiphosphorane[3] analog by dechlorination of [chloro(trimethylphosphoranylidene)methyl]trimethylphosphonium chloride *(3)*, now readily accessible from trimethylphosphane and CCl_4, were not as successful as had been hoped[6]. Dechlorination of *(3)* does in fact take place, but bis(trimethylphosphoranylidene)methane proves to be such an extremely strong base[3], which abstracts hydrogen chloride from dichlorotris(dimethylamino)phosphorane, so that only [(trimethylphosphoranylidene)methyl]trimethylphosphonium chloride *(4)* is found.

$$\left[(CH_3)_3P{=}C(Cl){=}P(CH_3)_3\right]^+ Cl^- \xrightarrow{P[N(CH_3)_2]_3} \left[(CH_3)_3P{=}CH{=}P(CH_3)_3\right]^+ Cl^-$$

(3) *(4)*

Experimental:

The reaction is carried out in a 250 ml round-bottomed flask fitted with side-tap and return frit which has previously been baked out and purged with argon. A mixture of *(1)* (40.0 g, 0.066 mol) and tris(dimethylamino)phosphane (10.8 g, 0.066 mol) is stirred in 150 ml benzene. Only a small amount of *(1)* dissolves and the suspension slowly turns yellow. After 24 hours the mixture is brought as quickly as possible to boiling (preheated oil-bath) and immediately filtered through the return frit. On cooling, *(2)* crystallizes from the already turbid filtrate. *(2)* is filtered off, washed twice with diethyl ether, and finally dried in a vacuum at room temperature. Yield 21.8 g (61%); m.p. 213—215 °C, literature[1]: 208—210 °C.

Determination of the Absolute Configuration of Chiral Thiols by ^{1}H-NMR Spectroscopy of Diastereomeric Thiol Esters[**]

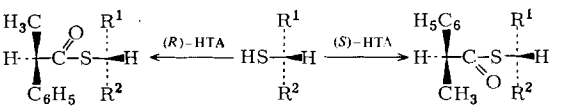
By *Günter Helmchen* and *Roland Schmierer*[*]

Dedicated to Professor Vladimir Prelog on the occasion of his 70th birthday

Several simple methods for determining the absolute configuration and enantiomeric purity of chiral alcohols and amines have already been reported[1]. The lack of corresponding methods for thiols has hitherto considerably hindered stereochemical and mechanistic studies on this class of substances[2]. We have now found that diastereomeric thiol esters of hydratropic acid (HTA) and other α-substituted phenylacetic acids differ significantly in their ^{1}H-NMR spectra. The relative configuration of the thiol esters and—since the absolute configuration of HTA is known[3]—the absolute configuration of the thiols can be determined in a simple way from the signs of the differences in the signal positions of constitutionally equivalent protons. In many cases it is also possible to determine the composition of mixtures of diastereomers, and thus the entiomeric purity of the thiols, on the basis of their NMR spectra or by gas chromatography.

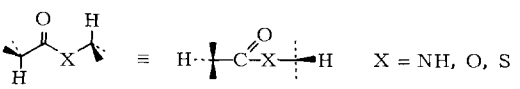
Our method can be summerized as a *rule*: A chiral thiol $HSCHR^1R^2$ possesses the absolute configuration *(1)*, if the signal of group R^1 of thiol ester *(2)* appears further downfield than the signal of group R^1 of thiol ester *(3)*, and/or the signal of group R^2 of thiol ester *(2)* appears further upfield than the signal of group R^2 of thiol ester *(3)*.

The rule is based on two arguments:



(2) *(1)* *(3)*

1. Data from the literature as well as a comparison of the ^{1}H-NMR spectra of analogous amides, esters, and thiol esters of α-alkylphenylacetic acids show that these compounds have an approximately planar basic structure *(4)*. Diastereomeric HTA thiol esters derived from the same thiol accordingly have the conformations *(2)* and *(3)*.



(4)

2. The different positions of the signals of the diastereotopic groups R^1 and R^2 result from a different shielding effect (up-field shift) of the phenyl group. The shielding effect on the group R^2 is stronger in *(2)* ("cisoid" arrangement of R^2 and phenyl) than in *(3)* ("transoid" arrangement of R^2 and phenyl). The converse applies for R^1.

The rule was checked experimentally on the compounds of known absolute configuration[4] listed in Table 1. Further confirmation follows from the fact that extensive agreement exists with analogous amides and esters, for which a corre-

sponding rule has been confirmed without exception on more than 30 diastereomeric pairs.

Experimental:

A solution of 1 mmol thiol and 3 mmol 2-phenylpropionyl chloride in 5 ml carbon tetrachloride through which nitrogen is allowed to bubble is warmed to 50—60°C, until thin-layer chromatograms indicate that the desired conversion has taken place (1—3 days). For decomposition of the excess acyl chloride the mixture is concentrated *in vacuo* and the residue stirred for *ca.* 2 h with 2 ml dioxane/water (1:1). The solution is taken up in ether/benzene (7:3) and this is extracted with 1 N NaOH and water, dried and evaporated down. The thiol esters which are obtained in 80—90% yield are purified, if necessary, by preparative thin layer or column chromatography (UV absorption at 254 nm).

Enantiomerically pure 2-phenylpropionyl chloride is obtained by reaction of optically pure HTA[3] (3 mmol) with oxalyl chloride (2 ml) for 5 min at room temperature. The solution is subsequently concentrated *in vacuo* and the residue is taken up in 0.5 ml of dry benzene and evaporated down. This is repeated twice. Distillation of the product or addition of tertiary amines leads to partial racemization.

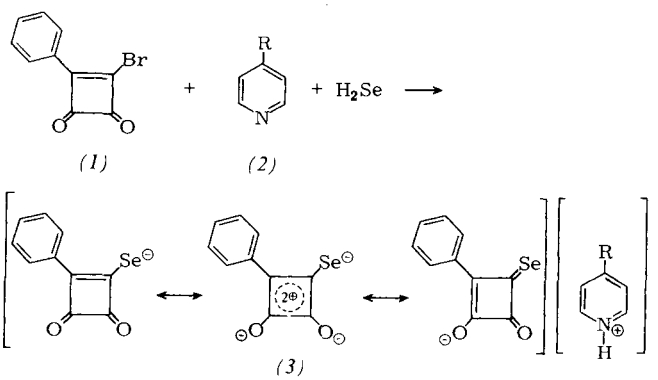
Bond-Delocalized Cyclobuteneselenones

By *Arthur H. Schmidt, Walter Ried*, and *Peter Pustoslemsek*[*]

Organoselenium compounds have recently attracted considerable attention, with representatives having delocalized bonds commanding particular theoretical interest[1]. We now wish to present the first report of cyclobutenes having delocalized bond systems which incorporate selenium as substituent.

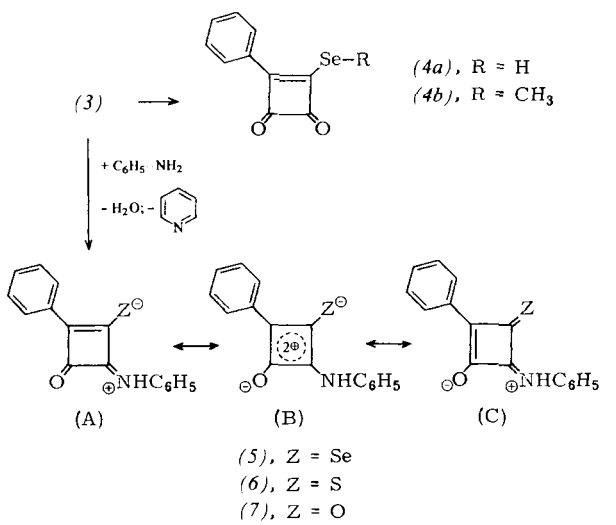
Dropwise addition of benzene solutions of *(1)* to pyridines *(2)* saturated with anhydrous hydrogen selenide[2] affords good yields of the pyridinium salts *(3)*. They are dark in color and are stable in the crystalline and dissolved states. Deposition of metallic selenium occurs only on prolonged heating of a solution in ethanol, especially in the presence of atmospheric oxygen. The IR spectra of the pyridinium 3-phenyl-4-selenatocyclobutenediylium-1,2-diolates *(3)* (Table 1) accord with the proposed salt structure.



(1) *(2)* *(3)*

(a): R = H; *(b)*: R = CH_3

Addition of the pyridinium salt *(3a)* or *(3b)* to 6 N hydrochloric acid yields 3-hydroseleno-4-phenyl-3-cyclobutene-1,2-dione *(4a)* as a yellow powder. Its structure was established by reaction with methyl iodide to give *(4b)*, which also arises on treatment of *(3a)* or *(3b)* with methyl iodide.



(4a), R = H
(4b), R = CH_3

(A) (B) (C)

(5), Z = Se
(6), Z = S
(7), Z = O

In keeping with its electrophilic character the four-membered ring system of the pyridinium salts *(3)* is readily attacked by nucleophilic reagents. Thus heating of equimolar solu-

Electron Impact Induced Ether Cleavage by Anchimeric Participation of Silyl and Germyl Groups[1][**]

By *Helmut Schwarz* and *Manfred T. Reetz*[*]

Electron impact induced cleavages of O—C bonds with elimination of radicals and charge localization on the oxygen function require considerable energy and therefore afford intense fragment ions only in exceptional cases[2]. We recently found that (silyl)methyl alkyl ethers of type *(1a)* rearrange *via* rupture of the O—C bond to form *(3)* in the mass spectrometer[1]. Further investigations have now shown that this *new* kind of electron impact induced ether cleavage always occurs when the transition state *(2)* is stabilized by anchimeric participation[3] of $X(CH_3)_3$ groups (X = Si, Ge).

As shown by Table 1, the fragment ions relevant to our discussion are generated with widely varying intensities, depending upon the structure of the molecular ions. While the elimination of $X(CH_3)_3$ as radicals and also the formation of $[X(CH_3)_3]^+$ and $[R]^+$ can be explained by conventional rules of mass spectrometry (influence of activation energy and/or frequency factor), a complex mechanism must be assumed to account for cleavage of the O—R bond with generation of $[M-R]^+$ ion.

The hypothesis that this process could be a simple α cleavage is ruled out by the following experimental data: In the 13-eV spectra, usually dominated by processes of *lowest* activation energy, the $[M-R]^+$ ions from *all* compounds except *(1g)* are by far the most intense fragments (contribution to total ion current >83%), whereas, for example, formation of $[X(CH_3)_3]^+$ by dissociation of the relatively weak C—Si and C—Ge bond is strongly suppressed. Since genesis of $[M-R]^+$ fails to occur in the case of the *tert*-butyl derivative *(1g)*, in spite of the possibility of eliminating a low-energy benzyl radical, it must be assumed that the energy balance of ether cleavage in the silyl and germyl compounds *(1a)* to *(1f)* is considerably improved by *simultaneous* intramolecular bonding. A model can be seen in the neighboring group participation of silyl and germyl groups, in which coordination in the transition state *(2)* due to d orbitals weakens the O—R bond and thus permits rearrangement to the oxonium ion *(3)*. The absence of $[M-R]^+$ ions in the case of *(1g)* supports the decisive role of the silyl and germyl groups and shows that the generation of oxonium ions by an alternative migration of the C^9—C^{10} σ bond of the fluorenyl system to the oxygen, which is accompanied by ring expansion, cannot compete with silyl and germyl migration[4]. The observation that hydrogen scrambling processes—which are otherwise

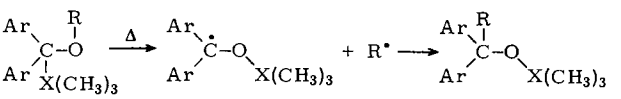
[a] The percentage intensities are based on $\%\Sigma_{40}$, including the contributions of all isotopes of Ge and Si. All data are average values of at least four measurements. The ionization energies correspond to the nominal values. Experimental conditions: CH 7 mass spectrometer (Varian MAT); emitter current 300 and 100 μA, respectively; temperature of ion source 200°C; direct introduction of sample (vaporization temperature 45—65°C).

very pronounced in the low-energy spectra of arenes[5]—do *not* occur in the compounds under study (the molecular ions of the deuterated derivatives *(1c)* and *(1f)* lose exclusively $C_3H_3D_2^{\bullet}$) likewise indicates a kinetically fast process favored by the silyl and germyl groups. That the $[M-R]^+$ ions do indeed have an oxonium structure *(3)* is proved by the DADI spectra[6]. Those recorded for *(1a)*, *(1b)*, *(1c)*, *(4a)*, and *(4b)*—the last-named two yield an ion *(3)* by α cleavage which is used as reference structure—are identical with earlier published spectra of silylated fluorenonium ions *(3)*[1,7].



(5) (6)

A comparison of the electron impact induced transformation of the molecular ions *(1)* with the thermal reaction of the corresponding neutral molecule *(5)* is remarkable. At 160 to 195°C the silyl derivatives *(5)*, X = Si, undergo a formal dyotropic rearrangement[8] to give *(6)*, in which the O—C bonds are homolytically cleaved with anchimeric assistance[9]. In comparison, the *tert*-butyl derivative is completely thermally stable *(5)*, X = C, R = $CH_2C_6H_5$. For reasons not yet explained, this strict correspondence between thermal and electron impact induced behavior[1,4] does not apply to the analogous germyl compounds *(5)*, X = Ge. The latter decompose just like the silyl derivatives in the mass spectrometer but react slower by orders of magnitude on thermolysis[10].

[6] Concerning the topic "Ion structures and properties of metastable ions" (*i.e.* also DADI spectra) see a) *R. G. Cooks, J. H. Beynon, R. M. Caprioli*, and *G. R. Lester*: Metastable Ions. Elsevier, Amsterdam 1973; b) *U. P. Schlunegger*, Angew. Chem. *87*, 731 (1975); Angew. Chem. Int. Ed. Engl. *14*, 679 (1975); c) *K. Levsen* and *H. Schwarz*, *ibid. 88*, 589 (1976) and *15*, 509 (1976).

[7] Since we have not yet been able to synthesize germyl derivatives having structure *(4)*, X = Ge, we cannot yet offer direct proof of the structures of the ions $[M-R]^+$ from *(1d)*, *(1e)*, and *(1f)* but only deduce analogous structures from the similar reactions of germyl and silyl ethers (see Table 1). The fact that the ionic yield curves for the $[M-R]^+$ ions from *(1a)* to *(1f)* display a relatively small slope (which is typical for rearrangements, cf. ref. [6a, c]) rules out a simple α cleavage of the O—C bond in which the liberated oxenium ion would be stabilized by hyperconjugation of the C-metal bond.

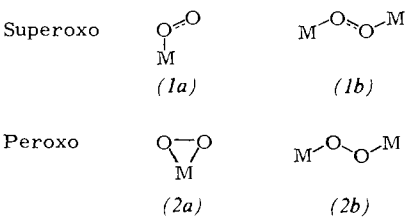
Reviews

Abstracts of selected progress reports and review articles

Dioxygen-metal complexes containing covalent bonds are reviewed in an article by *L. Vaska*. The most important types are superoxo [*(1a)*, *(1b)*] and peroxo compounds [*(2a)*, *(2b)*] (oversimplified diagrams). Nearly all transition metals form dioxygen complexes; the formal oxidation states of the



(1a) *(1b)* *(2a)* *(2b)*

metals in these species range from 2 through 6. Most of the complexes belong to the type *(2a)*. [Dioxygen-Metal Complexes: Toward a Unified View. Acc. Chem. Res. *9*, 175—183 (1976); 64 references]

Genetics and biological evolution was the subject under discussion at the 4th FASEB (Federation of American Societies for Experimental Biology) conference. Main themes of the conference were selection and genetic drift in molecular evolution, function and evolutionary changes in proteins, origin of new proteins, evolution of multigene systems, evolution of membrane transport and selection of somatic cells. Numerous prominent authors contributed articles to each of the individual themes under discussion. [Genetics and Molecular Evolution. Fed. Proc. *35*, 2077—2204 (1976); 28 references]

[Rd 889 IE—R]

The self-association of tubulin has been examined from the physical-chemical point of view by *S. N. Timasheff*, *R. P. Frigon*, and *J. C. Lee*. The theory put forward by *Gilbert*[1] affords the basis for a quantitative treatment of such processes. Tubulin monomers undergo association equivalently; only the last (presumably the 26th) monomer associates with a higher constant since a cyclic structure can then be formed. Higher temperatures and the presence of Mg ions favor polymerization, whereas high pressures suppress formation of polymers. In glycerol-containing buffers, tubulin can even be reconstituted to complete microtubuli without requiring high-molecular nucleation centers. [A Solution Physical-Chemical Examination of the Self-Association of Tubulin. Fed. Proc. *35*, 1886—1891 (1976); 33 references]

[1] *G. A. Gilbert*, Discuss. Faraday Soc. *20*, 67 (1955).

Protein-protein interactions in the regulation of lactose synthase is the theme of an article by *K. Brew* and *J. T. Powell*. Lactose synthase is known to be composed of a galactosyl transferase and α-lactalbumin. The normal substrate of galactosyl transferase is *N*-acetylglucosamine or glycoproteins which contain this sugar. α-Lactalbumin modifies the enzymatic activity of the transferase by reducing the Michaelis constant of the galactose receptor glucose by a power of three. Kinetic studies indicate an ordered sequential mechanism for substrate formation during the catalysis. α-Lactalbumin resembles in many respects lysozyme and thus probably also the glycoprotein substrates of the transferase. Interaction between α-lactalbumin and the transferase is influenced by substrates as well as by Mn^{2+} ions. [Substrate-Dependent Protein-Protein Interactions in the Regulation of Lactose Synthase. Fed. Proc. *35*, 1892—1898 (1976); 26 references]

[Rd 891 IE—R]

The interrelationship between arginine, glutamic acid and proline in metabolism and nutrition is the theme of an article authored by *R. E. Austic*. The chicken can produce only a part of its proline requirements; thus, proline becomes an essential amino acid. Although arginine, glutamic acid and ornithine can in principle be transformed into proline, these sources are insufficient to satisfy demand. It therefore remains to be investigated which enzymatic reactions are responsible for the bottleneck along the pathway from the mentioned amino acids to proline. [Nutritional and Metabolic Interrelationships of Arginine, Glutamic Acid and Proline in the Chicken. Fed. Proc. *35*, 1914—1916 (1976); 46 references]

[Rd 892 IE—R]

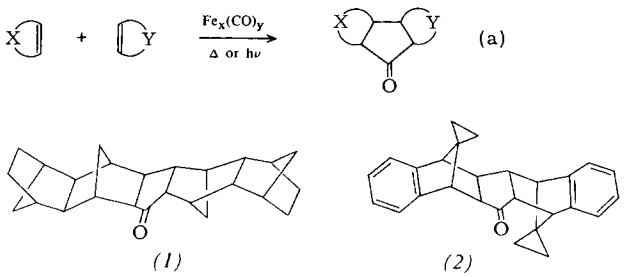
Subunit-subunit interactions of transcarboxylase are outlined in an article by *H. G. Wood*. This biotin-containing enzyme is present in propionic acid bacteria, where it catalyzes the transcarboxylation of methylmalonyl coenzyme A to pyruvate to propionyl coenzyme A and oxalacetate. In contrast to other biotin enzymes, free carbonic acid does not participate. The enzyme consists of several subunits. A central subunit comprises several (according to latest findings six) peripheral subunits linked together *via* a third and very flexible type. The subunits can be further dissociated and, in part, recombined. The individual units can be assigned to definite catalytic steps. [Subunit Interactions of Transcarboxylase. Fed. Proc. *35*, 1899—1907 (1976); 11 references]

[Rd 893 IE—R]

Nutritional and metabolic interrelationships among sulfur compounds in avian nutrition is reviewed by *D. H. Baker*. Bird foods generally contain cysteine as the limiting sulfur-containing amino acid. Economically, D,L-methionine or its hydroxy analog is usually employed in order to counter the deficiency in cysteine. Methionine can be converted into cysteine in the metabolism, but not the converse, most likely because the cystathionine synthetase reaction is irreversible. High doses of methionine are toxic, leading to emptying of the threonine pool. Inorganic sulfate can partly meet the sulfur requirement, but only the demand for cysteine and not for methionine decreases. Younger birds require choline. Methionine cannot fulfil this requirement. In older birds self-synthesis of choline suffices. [Nutritional and Metabolic Interrelationships among Sulfur Compounds in Avian Nutrition. Fed. Proc. *35*, 1917 to 1922 (1976); 65 references]

[Rd 894 IE—R]

The stereospecific formation of cyclic ketones from strained olefins and carbonyliron compounds is the theme of a report by *E. Weissberger* and *P. Laszlo*. Cyclopentanone derivatives such as *(1)* and *(2)* can be prepared in satisfactory yields (62 and 42 %, resp.) according to the general reaction (a). $Fe(CO)_5$, $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ are suitable iron(0) com-



ponents. [Stereospecific Cyclic Ketone Formation with Iron(0): Anatomy of an Interligand Reaction. Acc. Chem. Res. 9, 209—217 (1976); 60 references]

[Rd 895 IE—L]

σ-Bonded organic derivatives of f elements are reviewed in an article by *M. Tsutsui, N. Ely,* and *R. Dubois.* Most organoactinoid complexes with σ- and π-ligands belong to the $Cp_3U—R$ type compounds (cp = η^5-cyclopentadienyl, R = alkyl, aryl, alkynyl); an example is $Cp_3U—C{\equiv}C—C_6H_5$. The Cp_3U moiety can also occur as substituent in a ferrocenyl molecule. Organolanthanoid complexes include not only the $Cp_2Ln—R$ type but also the $CpLnR_2$ type, *e.g.* $CpHo(C{\equiv}C—C_6H_5)_2$. Whether f-orbitals participate in the covalent bonding has not as yet been unequivocally explained. The catalytic action of the complexes $Cp_3U—R$ (R = methyl, phenyl, benzyl) in the oligomerization of olefins has, on the other hand, already been proven. [σ-Bonded Organic Derivatives of f Elements. Acc. Chem. Res. 9, 217—222 (1976); 58 references]

BOOK REVIEWS

Einführung in die Physikalische Chemie (Introduction to Physical Chemistry). By *H. Labhart.* Springer-Verlag, Berlin—Heidelberg—New York 1975. 1st edit. Part 1: Chemische Thermodynamik (Chemical Thermodynamics). xii, 167 pp., 38 figs., bound, DM 16.—; Part 2: Kinetik (Kinetics). x, 105 pp., 23 figs., bound, DM 13.60; Part 3: Molekülstatistik (Molecular Statistics), xi, 126 pp., 19 figs., bound, DM 14.—; Part 4: Molekülbau (Molecular Structure). x, 171 pp., 45 figs., bound, DM 16.—; Part 5: Molekülspektroskopie (Molecular Spectroscopy). x, 138 pp., 52 figs., bound, DM 16.—.

This "Introduction to Physical Chemistry", which had its origin in the author's lectures to chemistry students in their third to sixth semester at Zürich, is conceived in such a way that access to physical chemistry can be gained through the description of either macroscopic (Parts 1 and 2, also Part 3) or microscopic properties (Parts 4 and 5, also Part 3). The contents are selected in accordance with the above scheme. The author prefers the deductive approach of set purpose, and therefore stresses, *inter alia,* the limits of model representations and the nature of approximations. The selection of the material is consequently such as to be free from the need to base the teaching on as many facts as possible.

In its first four chapters, Part 1 provides the concepts and fundamental principles of thermodynamics. In Chapter 5 are described applications of thermodynamics to phase equilibria in one- and multicomponent systems as well as, relatively briefly, to reaction equilibria and electrochemical equilibria. The reviewer felt it was a disadvantage—and in fact this applies to all five Parts of the work—that relatively few arithmetical examples are provided and, furthermore, that there are no problems to check one's progress. In many places it would have been advantageous for the beginner to have more frequent indications of the practicability of an experiment and its evaluation. It should be noted that SI units are not used consistently.

Part 2 gives the foundations of reaction kinetics, and extends these by a chapter on transport phenomena, diffusion, heat conduction, and viscosity. Up to Chapter 5.4 the principles required for understanding kinetics are outlined. In Chapter 5.5 enzymatic reactions, photoreactions, and the pressure dependence of gas reactions are briefly reported. Chapter 6 shows the empirical dependences (temperature, solvent, structure) of rate constants in homogeneous reactions, and Chapter 8 provides an introduction to the theory of kinetic constants (rate constants, diffusion constants), this foreshadowing the concepts of molecular statistics worked out in Part 3.

In its first chapter Part 3 gives, in very concise form, the basics of molecular statistics and explains the connection with thermodynamic variables and calculation of partition functions. Applications of Maxwell-Boltzmann statistics are illustrated in the following Chapters 2 (gases), 3 (liquids), and 4 (solids). Solids and phase transition problems are mentioned only briefly in Part 3. On the other hand—presumably owing to the subdivision of the whole work—the predominantly experimental section concerned with electrolyte solutions is placed in Chapter 3.5.5, pages 88—100.

In Part 4 the principles are laid down for understanding the electronic structure of molecules, beginning with the time-independent Schrödinger equation. The postulates of quantum mechanics (Chapter 2.2) are outlined in a compact section (Chapter 2.1) with the aid of mathematics. After treatment of some one-particle problems (electron in a potential box of finite depth, oscillator, rotator, hydrogen atom) in Chapter 3, there follows in Chapter 4 a brief account of important approximation procedures for many-particle problems. The electronic structure of the atom is described in Chapter 5. Chapter 6 treats diatomic molecules with special reference to the H_2 molecule, and Chapter 7 polyatomic molecules and the HMO model. In Chapter 8, facts about empirical properties of molecules (shape, energy, charge distribution, reactivity) are presented and discussed on the basis of results of experimental methods of investigation (Part 5).

Part 5 describes spectroscopic methods for the investigation of molecules; an introductory chapter is followed in turn by sections on nuclear magnetic resonance, electron spin resonance, transitions between rotational states, transitions between vibrational states, transitions between electronic states, photoelectron spectroscopy, and X-ray fluorescence spectroscopy. Concentration on the generally most important methods currently available to chemists for the determination of molecular properties has here provided a compact and highly informative review.

Each of the five Parts has an appendix containing useful and important details and/or further derivations. The mathematical and physical background needed for the individual Parts varies, being highest in the first chapters of Part 4, but generally speaking all five Parts can be read easily and with interest.

Some problems of physical chemistry are only touched upon or not treated at all, *e.g.* surfaces, solid state, metals, magnetochemistry, and d-electron systems. However, this must not be considered a limitation, since the fundamental concept of the work necessitated concentrating on the main points.

Each of the five Parts can be used separately. Cross-references to concepts, formulas, *etc.* in other Parts are rare. This interesting work can be welcomed and recommended as a whole, and provides a worthwhile addition to currently available textbooks.

Wolfgang Haase [NB 340 IE]

Principles of Food Science. Part 1: Food Chemistry. Edited by *O. R. Fennema.* Marcel Dekker Inc., New York—Basle 1976. 1st edit., xi, 792 pp., bound, sfr. 170.—.

The interdisciplinary character of food science is illustrated by the make-up of this work, whose three parts are devoted to chemistry, microbiology, and technology of foodstuffs. The purpose of the present Part 1 is to review the structure and composition of foodstuffs, their properties, and chemical changes. The book is intended for advanced students and experts in neighboring fields who already have a sound basic knowledge of organic chemistry and biochemistry. The treatment begins with the main constituents of foods, such as water and ice, carbohydrates, lipids, and proteins, then substances occurring in lower concentrations such as enzymes, vitamins, and inorganic compounds, dyes, and flavoring substances, as well as other desirable or undesirable constituents or additives. Subsequent sections are directed at the structure of foodstuffs and describe the make-up and properties of muscle tissue and plant tissue, of dispersions, and of liquid foods such as milk and eggs. Each chapter is supplemented by numerous references to more recent work.

The 19 authors of the individual sections have all earnestly striven to seek out the important structural and chemical properties of foodstuffs and to clarify the relationships between the chemical reactions and the behavior of the food on storage or further processing. Other matters, such as questions of analysis, of biosynthetic connections between constituents, and special features of individual foodstuffs are thus often passed over. Even though the weight is in many places unevenly distributed, and many interesting details are omitted, the book gives a valuable and comprehensive reflection of the whole field and records the scientific principles of food chemistry on the basis of the most recent state of knowledge.

Hans-Peter Thier [NB 341 IE]

The Chemistry of Cyano Complexes of the Transition Metals. Organometallic Chemistry—A Series of Monographs. By *A. G. Sharpe.* Academic Press, London—New York—San Francisco, 1976. 1st edit., xi, 302 pp., bound, £ 10.40.

Written by an expert, this book provides as it were a supplement to the review of the chemistry of cyano complexes of the transition elements that appeared in "Advances in Inorganic Chemistry and Radiochemistry" *8*, 83 (1966). The selected arrangement begins with the cyano compounds of metals of the third subgroup, including the little that is known about complexes of the lanthanides and actinides, and finishes with complexes of metals of the second subgroup. This permits the reader to orient himself rapidly in the book, particularly because there is a vertical order within each chapter, with increasing oxidation number for each individual element. *Sharpe* does not take information uncritically from the literature, but comments from his own experience and directs attention to what is as yet unexplored. The result is thus quite different from a mere barren text. In the introduction—kept rather short—the general aspects are discussed, including methods of preparation and the structural chemistry of the cyano complexes. With normal vibrations it would have been better not to restrict the data to tetrahedral, square-planar and octahedral species, but to treat also the other types with coordination numbers of 2, 3, 5, and 7. A disadvantage of the book is the almost complete absence of illustrations and summarizing tables. Nevertheless, the book can be recommended to every complex chemist as a very reliable source of scientific information and stimulation.

Kurt Dehnicke [NB 343 IE]

Lehrprogramm Atombau und Periodensystem (Programmed Learning—Atomic Structure and the Periodic System) (Pocketbook 47). By *Christa Braig.* Verlag Chemie/Physik Verlag, Weinheim 1976. 1st edit., x, 146 pp., 40 figs., 2 foldout tables, paperback, DM 12.80.

Complaints are always voiced about the very variable chemical knowledge possessed by students beginning their study of natural science. The above pocketbook is designed to enable particularly those students who have been badly taught to make themselves familiar with atomic structure and the periodic system by a brief private course of study with the aid of two learning programs.

The learning program for atomic structure contains three chapters: the elementary particles within the atom, the atomic nucleus, and the electron shell. The program on the periodic system comprises the following sections: definition of concepts, the make-up of the periodic system, and the periodicity of some properties of main-group elements.

The subject matter is presented with beautiful clarity, and great care has been taken to avoid printing errors. The book seems very suitable for its readership.

The fundamental remarks about the model concept (p. 2) are particularly helpful to the beginner. From the reviewer's own experience it is by no means superfluous to give the mass of the proton (p. 5) with all the zeros. Under the keyword "Hund's rule" (p. 61) it might have been mentioned that this is only *one* of Hund's rules.

The further titles planned with a similar purpose will be welcome.

Hartmut Plautz [NB 346 IE]

Industrielle Organische Chemie (Industrial Organic Chemistry). By *K. Weissermel* and *H.-J. Arpe.* Verlag Chemie GmbH, Weinheim/B. 1976. 1st edit., xii, 378 pp., 32 figs., 20 foldout tables, linen bound, DM 68.—.

The authors of this modern book know current organic industry and its interrelationships both as a whole and in detail from their own experience, and their book provides the reader with highly topical information on the essential starting materials and intermediates. The problems and prospects of energy and raw material resources are described (15 pages) with particular reference to the wake of the oil crisis, followed by detailed treatment of the preparation, use, and importance of the basic products of industrial syntheses (35 pages), then successively olefins (20), acetylenes (10), 1,3-dienes (18), syntheses from carbon monoxide (17), oxidation products of ethylene (41), alcohols (17), vinyl-halogen and vinyl-oxygen compounds (18), components for polyamides (24), reaction products from propene (33), production and conversions of aromatic compounds (20), transformation products of benzene (38), and the oxidation products of xylene and naphthalene (17). The volume ends with an Appendix (30 pages) giving schemes of processes and products, definitions of specific reaction parameters, tradenames, and sources, and finally an index (16 pages).

The whole work is not a textbook of organic-chemical technology but rather an exact informative review of a large part of present-day organic chemical industry with brief flashbacks into history and prospects for the future.

The book is addressed to a wide circle of readers. The advanced student is shown industrial interrelations and the young chemist just going into industry or taking his first steps toward it is particularly borne in mind: the over-all picture of industrial organic chemistry, which he had hitherto had to piece together from a multiplicity of detail over a long period, can now be grasped within a few weekends. The book should really be presented to every chemist on being offered his first appointment.

On another level, the work is a valuable source of information for the experimental industrial chemist on processes, syntheses, and important production figures.

For the university lecturer it offers important industrial interrelationships, new directions, and research problems. Last but not least, because of its clear and uncomplicated language, the book can lead the chemist's colleagues in industry, be they engineers or salesmen, toward a better understanding of the often complex relationships.

From the didactic point of view, the division of the text into a main column, an extract containing important facts in a side margin, and at the end of the book schemes of products and processes covering all parts of the book is very helpful. The reading is uninterrupted by literature references; these do not appear in the text at all. In their place there is, at the end of the book, a collection of general and specialized literature (up to 1975) arranged by the text sections.

A work of this kind, containing snapshots of individual pieces of information about industrial organic chemistry, cannot remain up-to-date for very long. Production figures change quickly, manufactures are stopped or expanded, processes are improved or abandoned. The authors will thus endeavor to keep the information in line with current practice.

The production of the book is excellent. The reviewer did not find a single misprint in the text. However, not all the references were correctly given or were immediately traceable.

On page 63, line 5, it could also have been mentioned that *tert*-butyl methyl ether is a fuel additive harmless to the environment. In the treatment of hydroformylation on page 101, Section 6.1, it would have been desirable to mention that *Roelen* found not only propionaldehyde but also diethyl ketone to be formed on treatment of ethylene with CO/H_2. On page 93 there should have been a mention that BASF had previously studied the acetone-acetylene process for the preparation of isoprene and had produced this important monomer also by this process (Merling synthesis).

This successful and useful book should be widely distributed in the specialist circles and in related disciplines. Strongly recommended.

Willi Ziegenbein [NB 347 IE]

Physiologische Chemie. Eine Einführung in die medizinische Biochemie für Studierende der Medizin und Ärzte. (Physiological Chemistry. An introduction to medicinal biochemistry for medical students and doctors.) By *H. A. Harper, G. Löffler, R. E. Petrides*, and *L. Weiss*. Springer-Verlag, Berlin—Heidelberg—New York 1975. xii, 940 pp., 644 figs., 189 tables, bound, DM 88.—.

Among the recent textbooks on biochemistry and physiological chemistry the excellently illustrated, stimulatingly written, and didactically exceptional books by *Lehninger* and *Stryer* have set new standards. The present "Physiological Chemistry" from a team of German translators and collaborators, however, takes as standard the contents list of the "Gegenstandskatalogs für die ärztliche Vorprüfung" (Subject Catalog for Medical Examinations) and as its basis a valued but now conceptually outdated American work.

The textbook is in the main suited to the intended type of reader. Alongside the classical contents (cell components and cell metabolism), more space than usual is devoted to consideration of the chapter that is elsewhere neglected in "Biochemistry" (water and electrolyte balance, metabolism of various organs and compartments, contractile systems, hormones, immune systems, and finally nutrition). This often leads to repetitions which are not always in agreement as to facts (ascorbic acid).

The arrangement of the extensive material makes the book a kind of reference work for the application of biochemical knowledge in medical practice. This is also helped by the good style and of technique printing used. However, more than 20 striking errors in structural formulas should be noted, particularly those of nucleotides and heterocycles. Stereochemical errors are frequent. Weaknesses appear in the treatment of thermodynamic principles and in the structure of biopolymers. Unfortunately there are no excercises as a necessary element of checking one's progress.

This textbook cannot be recommended for students of biochemistry as the principal or subsidiary subject. It does not provide an impression of the broad intellectual and experimental achievements that have raised biochemistry to its present imposing level, nor does it familiarize the reader with modern trends of development; for example, plasmids (episomal DNA) are mentioned only once and are not included in the subject index. The scientist is given only an indirect glance at pathobiochemical deviations and some clinical diagnostic applications.

The "Gegenstandskatalog" has led to other, unfortunately also factually incorrect, recent textbooks. Whether "Harper, Löffler, Petrides, Weiss" will be adopted depends finally on the price, which far is exceeds that what students can afford to pay.

Dieter Palm [NB 334 IE]

Fine Particles. Aerosol Generation, Measurement, Sampling and Analysis. Edited by *B. Y. H. Liu*. Academic Press, London—New York—San Francisco 1976. 1st edit., xii, 837 pp., numerous figs., bound, $ 34.50.

This book is a collection of 34 lectures delivered at the Symposium on Fine Particles held in Minneapolis in 1975. It begins with reviews of the research activity in several geographic areas. Methods of producing aerosols are then described. Jet atomizers, ultrasonic atomizers, processes involving evaporation, powder sprays, periodic dispersion of a liquid stream, and other possibilities are discussed. The chapter on aerosol sampling contains contributions on size selective sampling on impactors and centrifuges, which can be considered not only as sampling apparatus but also as high-resolution size-analyzers. Chapter 4, on measurement and analysis of aerosols, contains discussions of optical particle-size analysis with and without the use of lasers, flame-ionization detectors, electrical methods of measurement, condensation nuclei counters, piezoelectric mass detectors, as well as mass detectors that make use of β-ray attenuation.

Some of the contributions are very detailed: for example, *O. G. Raabe*'s article on aerosol production takes up 54 pages with 212 references. This comprehensiveness almost completely closes the gaps between the individual contributions that naturally occur in a collection of lectures. The volume thus qualifies as one of the most complete books on modern experimental techniques for use in the aerosol field, and it can be assumed that it will soon be seen on the desk of every scientist concerned with aerosols.

Dieter Hochrainer [NB 345 IE]

Farbenlehre und Farbmessung. By *W. Schultze*. Springer-Verlag, Berlin—Heidelberg—New York 1975. 3rd revised edit., vii, 97 pp., 57 figs., bound, DM 32.—.

This book is currently the only Introduction in the German language to color measurement and its applications in daily industrial practice. Mathematical expositions are largely avoided, and with a few exceptions this certainly makes it easier to understand "color metrics".

Two-thirds of the contents are devoted to the principles of color measurement (*inter alia* the CIE system color coordinates X, Y, Z, apparatus for color measurement, evaluation of color differences) together with scattered references to physiology (*e.g.* color blindness), while the remainder deals with questions of immediate practical value (tolerances, principles of color match calculations, color depth and color saturation, color reproduction). In 86 text pages many aspects can be covered only superficially, which also means that some terms introduced in the first part of the book cannot be explained until later. The 135 literature references will certainly help those who want more detailed information.

This small book can be recommended as a useful and easily readable review to practical workers and to all who occasionally come into contact with color measurements.

Fritz Heinrich [NB 335 IE]

Hochdruck-Flüssigkeits-Chromatographie (High-Pressure Liquid Chromatography). By *H. Engelhardt*. Springer-Verlag, Berlin—Heidelberg—New York 1975. 1st edit., x, 213 pp., 52 figs., 17 tables, bound, DM 56.—.

As stated by the author in the Foreword, the object of this 200-page book is to provide the newcomer to high-pressure liquid chromatography with a review of the apparatus, separation processes, and applicability of the method. Little stress is laid on the theory of chromatographic separation, but rather on a detailed discussion of the components of a high-pressure liquid chromatograph. Pumping systems, detectors, carrier materials, and stationary phases are described in detail. In addition, the author gives a clear description of the four types of liquid chromatography, augmented by representative examples of applications, with the greatest emphasis on the parameters that influence a separation.

It must, however, be said that the main purpose of the work, giving the experimentalist decisive help in obtaining a high-pressure liquid chromatograph, is unfulfilled by the present book. Much of the information is only of academic interest, since on the one hand apparatus is described (*e.g.* detectors) that is not supplied commercially, and on the other hand the user will seldom be in the author's position to construct or rebuild apparatus as would follow from a study of the book. Most users will find it impossible for practical reasons to obtain components such as pumps and detectors from the various distributors. A complete working system from one manufacturer, selected for a specific planned application, is usually the better answer, even if the high hopes attached to it often fall short in reality.

Karl Zech [NB 342 IE]

BAG-Farben-Lexikon (BAG Color Lexicon). International Lexicon of Procedures and Methods for the Preparation, Use, and Testing of Varnishes, Paints, and Similar Protective and Decorative Materials for All Industrial and Commercial Uses. By *H. Hadert*. BAG Brunner Verlag AG, Zürich/Verlag Chemie, GmbH, Weinheim 1976. 1st edit., 356 pp., plastic, DM 95.—.

This is the first book of its kind in the German language. It is aimed not only at the specialist but also at the users of varnishes, varnish ingredients, pigments, dyes, solvents, *etc.* In this Lexicon is collected a wealth of keywords from the varnish, paint, leather, and printing ink industries. A large part of the keywords consists of the tradenames of products and apparatus; the remainder are chemical, physical, and industrial terms. At the end of the explanatory text for very many of the industrial products there is a reference to the "Index of Manufacturers and Suppliers" in which the supplier company will be found with its full postal address.

The Index of Manufacturers and Suppliers is at the end of the book; this part of the Lexicon is printed on yellow paper to facilitate its location. If the reader requires additional information about a commercial product he can apply directly to the suppliers without losing time in searching for the address.

Gaseous Chloride Complexes with Halogen Bridges—Homo-Complexes and Hetero-Complexes

By Harald Schäfer[*]

The chemistry of the gaseous halide complexes which have been observed in large numbers in recent years is discussed for the example of chlorides. *Homo-complexes*—dimeric or polymeric chloride molecules containing chlorine-bridge linkages [*e.g.* $(NaCl)_n$, $n=2$—4; $(CuCl)_n$, $n=2$—5; $(BeCl_2)_n$, $n=2$—4; Pd_6Cl_{12}]—occur through broad areas of the Periodic Table. Comparison of the dissociation enthalpy of such molecules with the vaporization enthalpy of the liquid chlorides is particularly informative. *Hetero-complexes* are formed from different chloride molecules by linkage through Cl bridges. Not only 1:1 complexes (*e.g.* $NaAlCl_4$, $TlPbCl_3$, $KThCl_5$, $CdPbCl_4$, $AlUCl_8$) but also larger molecules (*e.g.* $CoAl_2Cl_8$, $CrAl_3Cl_{12}$, Cu_2UCl_6, In_2UCl_{10}) are known. Types of formulas, structures, and above all the formation enthalpies of such complexes are discussed critically. Hetero-complexes are useful in chemical transport reactions, as aids in syntheses, and in gas-chromatographic separations (lanthanoids, actinoids). They also play a part in many industrial processes (chlorination of ores) and in recently developed types of high-pressure discharge tubes.

1. Introduction

In 1857, during the classical period of molecular-weight determinations by *Dumas*' method, *Sainte-Claire-Deville* and *Troost*[1–3] discovered the dimeric nature of the gaseous trichlorides of aluminum and iron. This was long regarded as a special case.

Although *Kossel*'s theory suggested that gaseous dimers of the type

Na^+Cl^-
Cl^-Na^+

would be formed, such molecules were only observed in 1948 by *Ionov*[4] with the aid of mass spectroscopy. This observation, however, had few repercussions, probably because of the language barrier. The existence of dimeric alkali-metal halides attracted attention a few years later on publication of molecular-beam experiments by *Kusch et al.*[5], which were supplemented by *O'Konski* and *Higuchi*'s electrostatic calculations[6]. Mass-spectroscopic observations then followed in many laboratories, and today dimeric chloride molecules are known for almost 50 elements[7].

The existence of still larger aggregates was first demonstrated in 1950 by *Brewer* and *Lofgren*'s discovery of the very stable Cu_3Cl_3 molecule in the gas phase[8].

We designate as *homo-complexes* all aggregates composed of identical monomers.

The combination of dissimilar monomers into hetero-complexes was first observed for gaseous $NaAlCl_4$ and $KAlCl_4$ (*Fischer* 1949[9]; *Grothe* 1950[10]); gaseous hetero-complexes were subsequently found to be common. Reviews of gaseous complexes of type AMX_n, where A = an alkali metal and X = F or Cl, are already available[11–14].

[*] Prof. Dr. H. Schäfer
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

Important new impetus was provided in 1970 by *Dewing*'s investigations[15] into the volatilization of dichlorides ($MgCl_2$, $CaCl_2$, $CoCl_2$, $NiCl_2$, *etc.*) in a current of the gaseous trichloride of aluminum or iron. This field is now in a phase of lively development, the main interest being centered on the discovery of the formulas of new gaseous complexes and their thermodynamic properties. Possible applications are also beginning to appear.

The stability of the complexes can be determined by current methods of measuring equilibria, such as: a) measurement of the total pressure above melts of the components and chemical analysis of the distillate; b) optical measurement of equilibria by means of ligand field spectra; c) mass-spectrometric analysis of the equilibrated gases; d) entrainment measurements. Chemical transport experiments can also yield important information.

2. Dimeric Chloride Molecules

2.1. Occurrence and Stability

In analogy to the known structure of the Al_2Cl_6 molecule it is assumed that the metal atoms in other dimeric halides are also linked by double halogen bridges, a structure that, with its high symmetry, is reasonable in view of the mainly ionic nature of the bonds.

Table 1 shows the dimeric dichlorides so far known and their dissociation enthalpies.

b) Gaseous dimers of lower stability are to be expected for the *pentachlorides* of *Nb, Ta, Mo, W, Tc, and Re*; $NbCl_5$, $TaCl_5$, $MoCl_5$, and $ReCl_5$ form molecular lattices composed of dimers, and $NbCl_5$ is known to dissolve in dimeric form in CCl_4[17]. Of the *lower chlorides* in this group only *one* gaseous dimer is known, namely W_2Cl_6[18]; this, however, is not considered here because it probably contains a W—W bond, just as metal-metal bonds are of decisive importance for many lower (solid) halides in this group. We consider here only those molecules that are held together by halide bridges only. The U_2Cl_{10} molecule not only occurs in the crystal lattice and in CCl_4 solution, but also has a considerable stability in the gas phase[19]; however, there are no data for the monomer and thus none for ΔH^0 (diss).

c) The solid chlorides of *Ru, Os, Rh, and Ir* decompose to the elements on heating. In the gas phase the monomeric chlorides occur only in low concentrations, even in the presence of chlorine. Appreciable concentrations of the dimers held together by Cl bridges are thus not to be expected.

d) Non-ionic forces play an important part for the chlorides of *Pd, Pt, Cu, and Ag*, which has the result that certain arrangements (bond angles, coordination figures) are favored that can be realized only on the formation of larger aggregates (Pd_6Cl_{12}, Pt_6Cl_{12}, Cu_3Cl_3, Ag_3Cl_3). In addition, there is thermal instability: $CuCl_2$ decomposes on heating into CuCl and Cl_2. The *planar* gas molecule Au_2Cl_6 is known, but the monomeric trichloride cannot be obtained owing to its thermal decomposition into $Au_2Cl_{2,g}$, Au_s, and Cl_2, so that the dissociation enthalpy cannot be measured by the usual methods. The properties of $Au_2Cl_{2,g}$ are still not known.

Table 1. Dissociation $(MCl_x)_{2,g} \rightleftharpoons 2\,MCl_{x,g}$
ΔH^0(diss, 298) in kcal/mol of dimer; values after [7] (for VCl_2 after [16]).

LiCl 49.5	$BeCl_2$ 24.0											BCl_3 (6)	C	N	O	F	Ne

KCl 45.0	$CaCl_2$ 50.3	$ScCl_3$ 47.6	$TiCl_4$ (9)	VCl_2 34	$CrCl_2$ 49.3	$MnCl_2$ 38.9	$FeCl_2$ 37.0	$CoCl_2$ 36.5	$NiCl_2$ 34.6	Cu	$ZnCl_2$ 26.5	$GaCl_3$ 21.6	$GeCl_4$ (8) $SnCl_4$ (9)	$AsCl_3$ (9)	Se	Br	Kr
RbCl 42.9	$SrCl_2$ 51.2	YCl_3 49.6	$ZrCl_4$ 15.3	$NbCl_5$ (12)	$MoCl_5$ (12)	Tc	Ru	Rh	Pd	Ag	$CdCl_2$ 27.3	$InCl_3$ 29.7	$SnCl_2$ 22.8	$SbCl_3$ 11.2	$TeCl_4$ (15)	I	Xe
CsCl 42.9	$BaCl_2$ 47.1	$LaCl_3$ 50.8	$HfCl_4$ 15.4	$TaCl_5$ (12)	WCl_5 (13)	Re	Os	Ir	Pt	Au	$HgCl_2$ 13.0	TlCl 29.1	$PbCl_2$ 30.5	$BiCl_3$ 15.4	Po	At	Rn
Fr	Ra	Ac															
		Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	$LuCl_3$ 49.6		
		$ThCl_4$ 31.0	Pa	UCl_4 26.1 UCl_5	Np	Pu	Am										

A distinct pattern can be recognized:

a) The dissociation enthalpies of the dimers decrease monotonically along the series LiCl, $BeCl_2$, BCl_3 and NaCl, $MgCl_2$, $AlCl_3$. In the higher periods, where the series can be followed to the tetra- and pentachlorides, the appearance of a maximum and a strong decrease on the transition MCl_3/MCl_4 are readily identifiable. It follows that filling of the coordination sphere plays an important part: the coordination number 4 with tetrahedral coordination of the central atom is energetically favored, its attainment is favorable, and exceeding it is unfavorable (cf. also $TiCl_3/TiCl_4$ and $FeCl_2/FeCl_3$).

e) The tendency to form dimers is naturally less well expressed among the nonmetal chlorides. The nonmetal atoms are shielded either by the halide ligands or by lone-electron pairs, so that there is no opportunity to increase the coordination number.

f) It is striking that there is no special place among the dissociation enthalpies for the halides of aluminum or of iron(III). The singularity of these (and similar) trihalides lies in the relatively low stability of the condensed phase and

the associated low vaporization temperature, the gas phase consisting mainly of dimers even though ΔH^0(diss) is not unusually large.

g) The molecules Ga_2Cl_2, Ga_2Cl_4[20–23], In_2Cl_2, and In_2Cl_4[21–24] have not been taken into consideration. It is not certain whether M—M bonds appear in these cases. It may be that Ga_2Cl_4 and In_2Cl_4 should be placed among the hetero-complexes as $GaCl \cdot GaCl_3$ and $InCl \cdot InCl_3$.

2.2. Dissociation of the Dimer and Vaporization of the Liquid Phase

Dissociation of the dimer and the liquid → gaseous monomer transition

$$(MCl_x)_{2,g} \rightleftharpoons MCl_{x,g} + MCl_{x,g}; \quad \Delta H^0(\text{diss}) \qquad (1)$$
$$(MCl_x)_{n,l} \rightleftharpoons (MCl_x)_{n-1,l} + MCl_{x,g}; \quad \Delta H^0(\text{vap,mono}) \qquad (2)$$

are related to one another insofar as the aggregate is smallest when $n=2$ and largest when $n=\infty$ (liquid). It is thus meaningful to compare ΔH^0(diss) and ΔH^0(vap,mono) with one another. This is done for a uniform reference state, namely the (absolute) boiling point of the chloride or, more exactly, the temperature Tb at which the vapor pressure of the monomer above the melt amounts to 1 atm. Since we do not have good experimental values available for the vaporization enthalpies of all chlorides, it is useful to replace ΔH^0(vap, mono, Tb) by $Tb \cdot \Delta S^0$(vap,mono, Tb):

$$\frac{\Delta H^0(\text{diss}, Tb)}{\Delta H^0(\text{vap,mono}, Tb)} = \frac{\Delta H^0(\text{diss}, Tb)}{Tb \cdot \Delta S^0(\text{vap,mono}, Tb)} = f$$

If ΔH^0(diss, Tb) and ΔH^0(vap,mono, Tb) are of the same magnitude, as is usually the case, then $f \approx 1$ and we have:

$$Q = \Delta H^0(\text{diss}, Tb)/Tb = f \cdot \Delta S^0(\text{vap,mono}, Tb) \approx 22\ \text{cal/K} \cdot \text{mol}$$

provided that ΔS^0(vap,mono, Tb) has the normal Trouton constant.

As shown in Table 2, the Q values are generally of the expected magnitude. Exceptions are discussed below:

In most cases the available data do not lead us to expect accuracy exceeding ± 3 cal/K·mol. The Q values often also need correction because when the vapor pressure was determined it was not known that the gas phase contained not only the monomer but also larger aggregates; thus, the value given for Tb in the literature is too low and Q is too large. However, the effect is not very serious. In spite of such uncertainties useful estimates of the dissociation enthalpies of the dimers can be obtained in this way.

The few examples with relatively large Q are particularly interesting. Two limiting cases can be distinguished:

a) ΔH^0(vap,mono, Tb) is still approximately equal to ΔH^0(diss, Tb) but *both* values are unusually large. Thus, ΔS^0(vap, mono, Tb) is also particularly large. This clearly occurs for $BeCl_2$ [ΔS^0(vap,mono, Tb) = 31.4 cal/K] and for $CrCl_2$ [ΔS^0(vap,mono, Tb) = 30 cal/K] and could indicate a polymeric structure of the melt (chain polymers analogous to the solid state?)

b) ΔH^0(diss, Tb) is appreciably greater than ΔH^0(vap, mono, Tb); in other words, $f > 1$; however, ΔS^0(vap, mono, Tb) is normal at ≈ 22 cal/K. This is so for LiCl [ΔS^0(vap, mono, Tb)] = 22.8 cal/K] and NaCl [ΔS^0(vap,mono, Tb) = 22.0 cal/K] as well as for $AlCl_3$ [ΔS^0(vap,mono, Tb) = 23.9 cal/K]. Other trichlorides ($TiCl_3$, $FeCl_3$, $GaCl_3$, $InCl_3$) should probably be aligned along these.—For *aluminum chloride* the following *model considerations* can be set up: It is known that the melt consists of Al_2Cl_6 molecules. If we neglect intermolecular forces, then ΔH^0(vap,Al_2Cl_6) = 0 and ΔH^0(vap, $AlCl_3$) = $^1/_2 \Delta H^0$(diss). Then, further, ΔH^0(diss)/ΔH^0(vap, $AlCl_3$) = $f = 2$, and finally $Q = \Delta S^0$(vap,$AlCl_3$, Tb) $\times f \approx 22 \times 2 \approx 44$ cal/K or, with the true vaporization entropy, $23.9 \times 2 = 47.8$ cal/K. This is an upper limit; the experimental value (Table 2) is $Q = 40.4$ cal/K.

Thermodynamic interpretation: If ΔH^0(vap,mono) = ΔH^0(diss), this implies that the vaporization enthalpy of the dimer is the same as that of the monomer, $\Delta H^0(vap,mono) = \Delta H^0(vap,dimer)$. However, since in general ΔS^0(vap,mono) > ΔS^0(vap,dimer), it follows that in these cases P(monomer) > P(dimer).

Finally, it must be remembered that although $Q = \Delta H^0$(diss)/Tb has indeed the dimension of entropy, it is not the standard entropy of dissociation, since P(dimer, Tb) ≠ 1 atm. In all cases a large value of Q indicates a (relatively) large concentration of the dimer.

Table 2. $Q = \Delta H^0$(diss, Tb)/Tb in cal/K·mol of dimer.

LiCl 27.7	$BeCl_2$ 28.6											B	C	N	O	F	Ne
NaCl 25.7	$MgCl_2$ 22.0											$AlCl_3$ 40.4	Si	P	S	Cl	Ar
			$TiCl_3$ 33.9				$FeCl_3$ 35.8										
KCl 24.4	$CaCl_2$ 21.1	$ScCl_3$ 32.9	$TiCl_4$	VCl_2	$CrCl_2$ 29.8	$MnCl_2$ 24.3	$FeCl_2$ 25.9	$CoCl_2$ 25.9	$NiCl_2$ 26.3	Cu	$ZnCl_2$ 25.0	$GaCl_3$ 35.7	$GeCl_4$	$AsCl_3$	Se	Br	Kr

		$ThCl_4$ 22.9	Pa	UCl_4 21.7	Np	Pu	Am										

2.3. Relation to the Formation of Dimers on Sublimation of the Elements

The approximate equality of ΔH^0(diss, *Tb*) and ΔH^0(vap, mono, *Tb*) valid for many chlorides implies that energetically the shorter bond lengths in the dimer compensate approximately for the greater number of neighbors in the liquid state.

Pauling[25] and later *Goldfinger et al.*[26] concerned themselves with the relation between the dissociation enthalpy $D^0(M_2)$ of the dimer of an element M and the sublimation enthalpy ΔH^0(subl) of the monomer, using values applying to 0 K. They found $\alpha = \Delta H^0(\text{subl})/D_0^0(M_2)$ to range from 0.5 to 12. The value of the quotient α depends on the electronic configuration of M. For the chlorides the quotient $f \approx 1$, analogous to $1/\alpha$, is much less variable than the above mentioned range, and this is understandable because in the chlorides the various atoms M are shielded by Cl ligands.

3. Larger Homo-Complexes $(MCl_x)_n$ with $n = 3$—6

3.1. Model Considerations

The situation in which ΔH^0(diss, *Tb*) $\approx$ ΔH^0(vap, mono, *Tb*) in the dissociation of $(MCl_x)_n$ to MCl_x where $n = 2$ or ∞ can be generalized for other values of n. That will be done here for one model case.

In the general equation

$$(MCl_x)_n \rightleftharpoons (n-1)MCl_x + MCl_x; \quad \Delta H_n^0 \tag{3}$$

$(n-1)$ is the number of dissociation steps for complete breakdown of $(MCl_x)_n$ into monomers, and ΔH_n^0 $(n-1)$ is the *dissociation enthalpy per step*; in the model we regard this amount as independent of n. Then for the splitting of MCl_x out of the liquid phase $MCl_{x,l} \hat{=} (MCl_x)_\infty$, we have $\Delta H_\infty^0/(\infty - 1) = \Delta H_\infty^0/\infty = \Delta H^0$(vap, mono).

A value of $\Delta H^0/(n-1)$ that is independent of n also implies independence of the vaporization enthalpy from the number n of vaporizing molecules. If $\Delta H_n^0/(n-1) =$ const it follows further that, *e.g.*

$$(MCl_x)_2 + (MCl_x)_4 \rightleftharpoons 2(MCl_x)_3; \quad \Delta H^0 = 0 \tag{4}$$

and

$$(MCl_x)_6 \rightleftharpoons 2(MCl_x)_3; \quad \Delta H_n^0/(n-1) \tag{5}$$

If the ΔS^0 per dissociation step were constant, then (at a given temperature) the dissociation constants per step would also be constant, $K_{1,2} = K_{2,3} = K_{3,4} \ldots$

$$\begin{array}{lll} (MCl_x)_2 \rightleftharpoons MCl_x + MCl_x; & K_{1,2}; & n=2 \\ (MCl_x)_3 \rightleftharpoons MCl_x + (MCl_x)_2; & K_{2,3}; & n=3 \\ (MCl_x)_4 \rightleftharpoons MCl_x + (MCl_x)_3; & K_{3,4}; & n=4 \end{array}$$

$$(MCl_x)_4 \rightleftharpoons 4MCl_x; \quad K_{1,4} = K_{1,2} \cdot K_{2,3} \cdot K_{3,4} \tag{6}$$

or, generalizing,

$$(MCl_x)_n \rightleftharpoons nMCl_x; \quad K_{1,n} = K_{1,2}^{(n-1)} \tag{7}$$

Within the range of validity of this model higher polymers would then be observed only when the concentration of dimers is also large. If the concentration of dimers is small, then as n increases the concentration of higher aggregates falls rapidly below the limit of experimental detection.

3.2. The Real Situation

The term $\Delta H_n^0/(n-1)$ is temperature-dependent. For homogeneous gaseous equilibria of the type $(MCl_x)_n \rightleftharpoons nMCl_x$, however, $\Delta C_p/(n-1)$ is almost independent of n (for $n = 2 \ldots 10$). This means that the ΔH^0 balance of the dissociation steps within a gaseous system can be compared at any desired temperature. This is not the case when $n = \infty$, that is for vaporization of the monomer from the liquid phase. Here ΔC_p and thus T play appreciable roles; ΔH^0(vap, *Tb*) < ΔH^0(vap, 298 K). Therefore, values of $\Delta H_n^0/(n-1)$ calculated for vaporization are placed below in braces { }.

The larger homo-complexes, in which the metal atoms are linked through halogen atoms, can be divided into three groups according to the nature of the bonding.

3.2.1. Polymers with Mainly Ionic Bonding

Typical examples are the trimeric and tetrameric alkali-metal chlorides. Here it is seen that trimerization and tetramerization can, according to the model, be considered energetically as an intermediate stage between dimerization and condensation to the liquid phase; the dissociation enthalpy per step is almost constant within one system, as shown by the following values (cf. Table 3) (kcal; 298 K):

$\Delta H_n^0/(n-1)$: $Li_2Cl_{2,g}$ (49.5); $Li_3Cl_{3,g}$ (49.9); {$LiCl_l$ (46.6)}
$Na_2Cl_{2,g}$ (48.6); $Na_3Cl_{3,g}$ (48.0); $Na_4Cl_{4,g}$ (47.1); {$NaCl_l$ (48.9)}

Qualitative observations are also available for Li_4Cl_4[27].

Subdivision into the individual dissociation steps leads to Table 3.

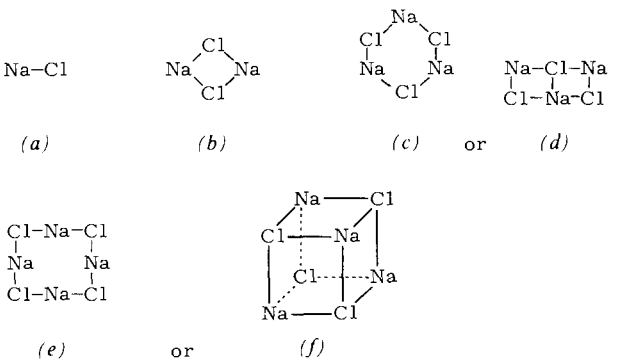
Table 3. Stepwise dissociation of $(LiCl)_n$ and $(NaCl)_n$.

Reaction	$\Delta H^0(298)$ [kcal]	$\Delta S^0(298)$ [cal/K]	$\Delta H^0(1000)$ [kcal]	$\Delta S^0(1000)$ [cal/K]	Ref.
$Li_2Cl_{2,g} \rightleftharpoons LiCl_g + LiCl_g$	49.5	32.7	48.3	30.7	[28]
$Li_3Cl_{3,g} \rightleftharpoons LiCl_g + Li_2Cl_{2,g}$	50.3	39.6	49.3	38.3	[28]
$LiCl_l \rightleftharpoons LiCl_g$	46.6	32.1	42.6	25.7	[28]
$Na_2Cl_{2,g} \rightleftharpoons NaCl_g + NaCl_g$	48.6	32.0	47.4	29.9	[28]
$Na_3Cl_{3,g} \rightleftharpoons NaCl_g + Na_2Cl_{2,g}$	47.3	38.8	46.4	37.8	[29] [a]
$Na_4Cl_{4,g} \rightleftharpoons NaCl_g + Na_3Cl_{3,g}$	(45.3)		(41.9)		[29] [a]
$NaCl_l \rightleftharpoons NaCl_g$	48.9	32.2	45.0	26.2	[28]

[a] Determined by data in [28] and estimated C_P values.

Constancy of the values of $\Delta H_n^0/(n-1)$ within the experimental error was observed previously for *oxides, e.g.* $(PbO)_n$ with $n=1-6$[30]; $(GeO)_n$ with $n=1-3$[31]; $(SnO)_n$ with $n=1-4$[32]; $(BeO)_n$ with $n=1-6$[28,33]; and $(WO_3)_n$ with $n=1-4$[28].

Here clearly there is a regularity that often occurs and that can be interpreted to mean that the energetic effect of increasing coordination with increasing n is largely compensated by the concomitant increase in bond lengths. This result is remarkable in view of the *structures* of the aggregates.



On the basis of IR spectra *Snelson*[34] concluded that Li_2F_2 had a planar ring structure and also considered a planar cyclic structure to be a possibility for Li_3F_3. According to calculations carried out by *Feather* and *Searcy*[29], for ionic bonds the structures *(e)* and *(f)* are energetically nearly equivalent for tetrameric NaCl; this is true, according to our own electrostatic calculations, also for structures *(c)* and *(d)* of the trimer. It should be noted that *(a)*, *(b)*, *(d)*, and *(f)* are sections from the structure of the NaCl crystal lattice.

Influence of reaction entropies: The model outlined in Section 3.1 was used for the case where, for the aggregation step, not only ΔH^0 but also ΔS^0 is constant. However, if we now examine the observed entropy values (Table 3) we see that there are considerable variations. The relatively large ΔS^0 values for the dissociation of the alkali-metal chloride trimers (and tetramers) have the result that their concentrations in saturated NaCl vapor decrease systematically starting from the dimers. This is clearly seen in the mass spectrum of saturated NaCl vapor (Table 4); cf. also the mass spectra of alkali-metal halides reported by *Berkowitz* and *Chupka*[27].

Table 4. Relative intensities of fragments in the mass spectrum of NaCl vapor saturated at 968 K, after *Feather* and *Searcy* [29]. The fragments arise mainly from the parent molecules specified.

Fragment	Relative fragment intensity	Parent molecule
Na^+	1.00	NaCl
$NaCl^+$	0.49	NaCl
Na_2Cl^+	0.88	Na_2Cl_2
$Na_3Cl_2^+$	0.0068	Na_3Cl_3
$Na_4Cl_3^+$	0.00010	Na_4Cl_4

The proportion of polymers in the vapor tends toward zero as the state of aggregation increases, this being in qualitative agreement with the original model.

From all the preceding considerations it follows that, with the means available today, aggregates with $n \geq 3$ will be detectable only if they can compete thermodynamically with condensation ($n=\infty$). *This is to be expected only for the chlorides with large values of Q.* It is thus not surprising that mass spectrometry has already led to the detection of Be_3Cl_6, Be_4Cl_8[35], Cr_3Cl_6, Cr_4Cl_8[37,38], Al_3Cl_9[39,40], Fe_3Cl_9[40], and Sc_3Cl_9[41]. For $(CrCl_2)_n$ we have quantitative data from *Rat'kovsky* and *Pribytkova*[37]; these correspond to the following $\Delta H_n^0/(n-1)$ values (980 K; values in kcal):

$Cr_2Cl_{4,g}$ (53); $Cr_3Cl_{6,g}$ (52); $Cr_4Cl_{8,g}$ (52)

The Mg_3Cl_6 molecule observed in small concentrations[42] does not fit into this scheme; here, however, the Q value is uncertain and the reported value may be too low.

3.2.2. Polymers in which Atomic Bonding Contributions Determine the Structures

$(CuCl)_n$ and $(AgCl)_n$ differ from polymeric alkali-metal halides in that the molecule with $n=3$ is considerably more stable than that with $n=2$. Only those members of the $(PdCl_2)_n$ and $(PtCl_2)_n$ series are formed for which $n=1$ and $n=6$. These facts must be interpreted as a preference for specific structures.

$(CuCl)_n$: Following the discovery of the Cu_3Cl_3 molecule by *Brewer* and *Lofgren*[8], the vapor of $(CuCl)_n$ was examined several times by mass spectroscopy[43-47]. That work substantiated the occurrence of Cu_2Cl_2, Cu_3Cl_3, Cu_4Cl_4, and Cu_5Cl_5; only at a higher temperature does monomeric CuCl become the main constituent of the gas phase. Assumption of Cu_6Cl_6 as an appreciable constituent[48] was contradicted by the mass spectra, which disclosed a clear fall in intensity along the series $Cu_3Cl_3^+$ (100), $Cu_4Cl_4^+$ (80), $Cu_5Cl_5^+$ (0.5). From measurements of the appearance energies[46] it follows that $Cu_3Cl_3^+$ cannot arise by fragmentation of Cu_6Cl_6.

Combination of the known formation enthalpy[28] or CuCl with the mass-spectroscopic data reported by *Guido et al.*[46] (and with estimated C_p values) enabled the following dissociation enthalpy per step to be evaluated; more recent values obtained by the same research group[45] are here given in parentheses; $\Delta H_n^0/(n-1)$ at 298 K in kcal for formation from the monomer are:

Cu_2Cl_2: not reported (43.5); Cu_3Cl_3: 63.5 (57); Cu_4Cl_4: 60 (54); Cu_5Cl_5: 57 (not reported); $CuCl_l$: 53.1[28].

The structure of the Cu_3Cl_3 molecule was determined by *Wong* and *Schomaker*[49] by electron diffraction to be a planar six-membered ring with $\sphericalangle CuClCu = 90°$. This is in agreement with the IR spectroscopic measurements (argon matrix) by *Cesaro et al.*[50]. The same authors assumed a strongly distorted cube as the structure of Cu_4Cl_4, but a planar ring structure seems more probable for Cu_4Cl_4 by analogy with Cu_3Cl_3, and also because the units $Cu_4O_4^{4-}$ and $Ag_4O_4^{4-}$, isoelectronic with Cu_4Cl_4 and Ag_4Cl_4, occur with square-planar ring structures ($\sphericalangle MOM = 90°$) in the crystal structure of KCuO, KAgO, and related compounds[51,52].

$(AgCl)_n$: Observations of the mass spectrum of silver chloride vapor are available from several groups[53-59]. In all cases the molecules AgCl and Ag_3Cl_3 were found as constituents of the vapor, but Ag_2Cl_2, Ag_4Cl_4, and Ag_5Cl_5 could also be observed by particularly sensitive measurements[56]. The disputed and rather improbable existence of the molecule Ag_3Cl_2 will not be considered in this review.

Below we use the ΔH^0 values obtained by *Wagner* and *Grimley*[56] from the temperature-dependence of the vapor pressure; the $\Delta H_n^0/(n-1)$ at 950 K in kcal for dissociation to the monomer are:

Ag_2Cl_2 (45.7); Ag_3Cl_3 (50.8); Ag_4Cl_4 (48.1); $AgCl_l$ (46.2)

The structures of the polymeric silver chloride molecules may well correspond to those of $(CuCl)_n$.

$(PdCl_2)_n$: On volatilization of $PdCl_2$ (350 °C) one observes only the ions $Pd_6Cl_{12}^+$ in the mass spectrometer at an electron energy of 15 eV; the vapor thus contains exclusively Pd_6Cl_{12} molecules[60]. Above 1000 °C monomeric $PdCl_2$ is the predominant molecule in the gas (equilibrium $Pd_s + Cl_2 \rightleftharpoons PdCl_{2,g}$[61]).

$(PtCl_2)_n$: If $PtCl_2$ is volatilized at 240 °C in the heating chamber of the mass spectrometer, the ions $(PtCl_2)_n^+$ can be observed, along with other fragments, with intensities that decrease as n goes from 6 to 1. From the determination of the appearance energies it follows that Pt_6Cl_{12} is the only parent molecule[44,62]. Monomeric $PtCl_{2,g}$ occurs in equilibrium with Pt and Cl_2 above 700 °C in concentrations that increase with rising temperature[63]. In the gas state Pd_6Cl_{12} and Pt_6Cl_{12} very probably have the same structure as that in the molecular lattice separable from the gas phase. This structure has been determined by X-ray structure analysis[60,64]. For $PdCl_2$ and $PtCl_2$ the preference for the hexamer rather than other stages of aggregation is clearly due to the fact that only this molecular structure permits all the Pd(Pt) atoms to assume square-planar coordination. The same coordination is found in the endless chains of solid α-$PdCl_2$. These facts are reflected in the ΔH^0 values as follows:

$$Pd_6Cl_{12,g} \rightleftharpoons 6\,PdCl_{2,g}, \quad \Delta H^0(298) = 306 \text{ kcal} \tag{8}$$

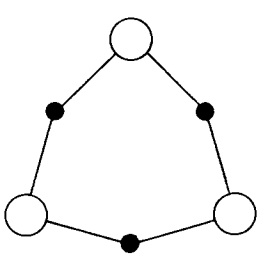
$$\alpha\text{-}PdCl_{2,s} \rightleftharpoons PdCl_{2,g}; \quad \Delta H^0(298) = 60 \text{ kcal} \tag{9}$$

$\Delta H_n^0/(n-1)$ at 298 K in kcal (values from [65]):
Pd_6Cl_{12} (61.2); $PdCl_{2,s}$ (60)

Similarly, for $PtCl_2$ (298 K; kcal[65]) we have:

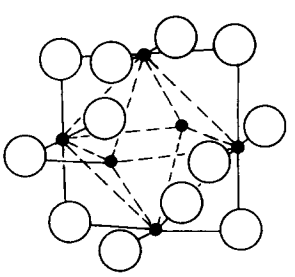
$\Delta H_n^0/(n-1)$: Pt_6Cl_{12} (55); $PtCl_{2,s}$ (54.9)

Because of structural analogies, the *solid* rather than the liquid dichloride is used for comparison in the above cases.



Cu_3Cl_3

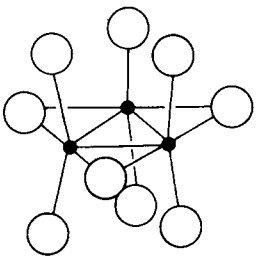
∢ CuClCu = 90°
∢ ClCuCl = 150°



Pt_6Cl_{12} and Pd_6Cl_{12}

3.2.3. Polymers with Cl Bridges and Metal-Metal Bonds

The most important representative of this class of compounds is Re_3Cl_9, whose structure in the molecular lattice has been determined by X-ray analysis[66,67].



Re_3Cl_9

The mass spectrum shows that the compounds vaporizes as Re_3Cl_9[68,69], and that the Re_3 unit is very stable. From the atomic separations it follows that the molecule is held together not only by Cl bridges but also by Re—Re bonds. A similar situation clearly occurs in the molecules W_3Cl_9[18] and Tc_3Cl_{12}[70] that have been observed by mass spectrometry. These clusters are mentioned here only to round off the picture.

4. 1:1 Hetero-Complexes

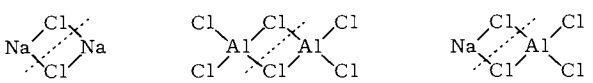
Just as the union of two identical monomers leads to the dimer (or 1:1 homo-complex), so 1:1 hetero-complexes arise from two different monomers, for example:

$$NaCl_g + AlCl_{3,g} \rightleftharpoons NaAlCl_{4,g} \tag{10}$$

A summary of the present state of knowledge is provided by Table 5.

It is advantageous to write the equation for complex formation in a form such that the coordination numbers do not change, *i.e.* starting with dimers, thus:

$$\tfrac{1}{2}\,Na_2Cl_2 + \tfrac{1}{2}\,Al_2Cl_6 \rightleftharpoons NaAlCl_4 \tag{11}$$



A general formulation is:

$$\tfrac{1}{2}\,A_2 + \tfrac{1}{2}\,B_2 \rightleftharpoons AB \tag{12}$$

For such a process the entropy balance $\Delta S^0 \approx$ zero if the slight influence of the symmetry number σ is neglected:

$$\Delta S_\sigma^0 = -R \ln \left[\frac{\sigma(AB)}{(\sigma(A_2)\cdot\sigma(B_2))^{1/2}} \right]$$

Furthermore, ΔC_p = zero is a good approximation. Finally, ΔH^0 will also depart little from zero[107] because the bonds in the reactants and products are similar in kind and number. Differences between A and B have only slight effect beyond the chlorine bridges:

$$\Delta H^0(AB) = \tfrac{1}{2}\,\Delta H^0(A_2) + \tfrac{1}{2}\,\Delta H^0(B_2) + Y \tag{13}$$

This approach is similar to *Pauling*'s classical derivation of electronegativity. The importance of Y is clearly as follows: dimerization enthalpies of about 50 chlorides are known; their combination leads to $n(n-1)/2 = 1225$ hetero-complexes

Table 5. 1:1 Hetero-complexes. Cf. [71]; the references cited there are not repeated here.

Valence of the cations	Complexes observed
1,1	$AA'Cl_2$ (A,A' = Li...Cs, cf. Table 7) $NaCuCl_2$ [72]; $TlCuCl_2$ [47] $AAgCl_2$ (A = Li...Cs) [73]
1,2	$NaBeCl_3$; $KBeCl_3$; $KMgCl_3$; $KCaCl_3$; $KSrCl_3$ $ACrCl_3$ (A = K, Rb, Cs) [74—76] $AMnCl_3$ (A = Li...Cs) [77—79] $AFeCl_3$ (A = Li...Cs) [78, 80, 81] $ACoCl_3$ (A = Li...Cs) [82, 83] $NaZnCl_3$; $KZnCl_3$ [84]; $TlZnCl_3$ [109] $ACdCl_3$ (A = Na...Cs, Tl) $ASnCl_3$ (A = Na...Cs) [85—87] $APbCl_3$ (A = Na...Cs, Tl)

Table 9) $NaBiCl_4$ [94]
1,4	$KThCl_5$ [95]; $AThCl_5$ (A = Tl, Cu, Ag) [47] $AUCl_5$ (A = Tl, Cu) [47]
1,5	$NaCl/NbCl_5$ [96]
2,2	$CdPbCl_4$
2,3	$BeAlCl_5$; $BeFeCl_5$; $BeInCl_5$ $ZnInCl_5$; $SnInCl_5$ $HgAlCl_5$ [97]; $SnBiCl_5$ [98]
2,4	$BeZrCl_6$; $BeUCl_6$; $PbThCl_6$ [99]
3,3	$AlGaCl_6$ [100]; $AlVCl_6$ [101]; $AlFeCl_6$ [40, 102, 166]; $AlCl_3 \cdot AuCl_3$ [89] $AlSbCl_6$; $AlBiCl_6$ [103] $GaInCl_6$ [104]; $AlInCl_6$ [167] $FeAuCl_6$ $EuLuCl_6$ [105]
3,5	$AlUCl_8$; $InUCl_8$ $AlCl_3/PCl_5$ [106]
4,4	$ThUCl_8$

of the 1:1 type; given useful rules for the value of Y, we have available the formation enthalpies of these complexes and can use them in thermodynamic calculations. We give below, therefore, a systematic tabulation of the Y values so far as present experimental findings permit.

1) For *compounds* $MM'Cl_x$ *not containing an alkali metal*, Y is zero within the limits of experimental error (Table 6).

Table 6. Y values (298 K) for alkali-free 1:1 hetero-complexes in kcal/mol complex; data without references are cited from [108].

$TlZnCl_3$ (−3.9) [109]; $TlCdCl_3$ (−1.7); $TlPbCl_3$ (−3.4); $TlInCl_4$ (+0.7); $TlThCl_5$ (−1.5); $TlUCl_5$ (−2.9); $CdPbCl_4$ (−1.9); $BeInCl_5$ (+1.1); $ZnInCl_5$ (+2.8); $SnInCl_5$ (+0.9); $PbThCl_6$ (−1.3); $AlGaCl_6$ (−0.7) [100]; $AlInCl_6$ (−1.8) [167]; $AlFeCl_6$ (0) [166]; $GaInCl_6$ (+0.7) [104]; $EuLuCl_6$ (+2.5) [105]; $AlUCl_8$ (+1.3) [19]; $ThUCl_8$ (−0.9)

2) In *combinations of two alkali-metal chlorides* $AA'Cl_2$, Y is small, but becomes noticeably more electronegative with increasing difference between the binary components (Table 7).

Table 7. Y value (*ca.* 1000 K) for mixed alkali-metal chloride 1:1 complexes in kcal/mol complex.

	LiCl	NaCl	KCl	RbCl	CsCl
LiCl	0				
NaCl		0			
KCl		−1.6 [110]	0		
RbCl		−5.8 [11]	0 [11] −1.1 [110]	0	
CsCl	−7.9 [11] −5.6 [111]	−5.2 [11]	−2.7 [11]	−1.0 [110]	0

The Y values in Table 7 are valid for approximately 1000 K with $\Delta S^0(1000) \equiv 0$. If the symmetry number is lowered by writing $\Delta S^0 = R \ln 2 = 1.38$ cal/K, then the Y values become 1.38 kcal more positive.

3) *Hetero-complexes* $AMCl_x$ *with* A = *an alkali metal* are distinctly more stable than the hetero-complexes discussed under headings 1 and 2. Admittedly, determination of reliable thermodynamic data meets here with special difficulties because of the coexistence of several gaseous complexes (cf. Section 6) and/or because of the occurrence of melts as bottom components. In some cases this leads to abnormal results for the reaction entropy, in other cases to a wide scatter of the derived thermodynamic values. The compilation in Table 8 is a critical selection from the extensive literature. Some cases have been newly evaluated. In all cases ΔH^0 was recalculated for 298 K by introducing estimated ΔC_p values. For $CsLuCl_4$, see below.

Table 8. Y values (298 K) for 1:1 hetero-complexes that contain one alkali-metal atom; in kcal/mol complex.

$KMgCl_3$	−17.3 (±5) [112]	$KScCl_4$	−12 (±2) [41]
$KCaCl_3$	−17.4 (±4) [112]	$KLaCl_4$	−17.5 (±3) [113]
$NaAlCl_4$	−13.0 (±3) [9, 108]	$CsLuCl_4$	−11 (±4)
$NaSnCl_3$	−16.3 (±3) [85]	$NaCuCl_2$	− 6.8 (±3) [72]
$KSnCl_3$	−16.1 (±3) [86]	$NaZnCl_3$	− 4.5 (±2) [114]
$RbSnCl_3$	−16.2 (±3) [87]	$LiFeCl_3$	− 1 (±2) [115]
$CsSnCl_3$	−16.2 (±3) [87]	$NaFeCl_4$	− 8.8 (±2) [116]

Table 8 gives the impression that the Y values for the main-group elements M are more uniform (−13 to −17 kcal) than for the transition elements M (−1 to −17 kcal). New measurements are urgently needed.

For the systems $ACl/SnCl_2$ (Table 8), $ACl/LnCl_3$ (Table 9), and $ACl/ScCl_3$[41] the value of Y is almost independent of the nature of the alkali-metal atom (A = Li...Cs).

Combinations of alkali-metal chlorides with lanthanoid chlorides were studied by *Novikov et al.* (Table 9): these authors determined values of ΔH^0 and ΔS^0 for the formation of $ALnCl_{4,g}$ from ACl_g and $LnCl_{3,g}$ by means of the temperature-dependence of the equilibrium position. To keep the influence of experimental errors small, Table 9 contains ΔG^0 values for the mean measurement temperature (1350 K) and not the ΔH^0 values. There is then no detectable variation of the stabilities of the complexes in the series of rare-earth metals (as for Li...Cs).

Clearly the ΔG^0 (1350) for all the unmeasured combinations $AlnCl_4$ can be estimated with good accuracy by means of Table 9. For conversion to other temperatures the introduction of $\Delta S^0(298) = -36$ cal/K and $\Delta C_p = 3$ cal/K is recommended.

Table 9. ΔG^0(1350 K) for $ACl_g + LnCl_{3,g} \rightleftharpoons ALnCl_{4,g}$; kcal/mol.

	Y	La	Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
Li	−12.6 [93]								−18.0 [117]		−14.7 [118]					−13.3 [119]
Na	−16.3 [120]	−25.5 (?) [121]			−17.3 [122, 123]								−17.1 [122]			
K	−16.8 [113]	−18.8 [113]	−17.0 [124]	−15.3 [124]	−15.3 [124]								−15.8 [125]			
Cs					−17.0 [126]						−15.6 [127]		−16.4 [126]			−11.4 [119]

The Y value for the extreme case $CsLuCl_4$ (Table 8) was obtained in this way.

5. Larger Hetero-Complexes

5.1. Review, Formula Types, Structures

It is apparent from Table 10 that many large hetero-complexes are known.

The following structural types are characteristic and show clearly the importance of filling the coordination sphere:

Molecule			Coordination
$NaCl \cdot AlCl_3$		[A]	Na (2); Al (4, tetr.) C_{2v} symmetry
$BeCl_2 \cdot 2\,AlCl_3$		[B]	Al (4, tetr.); Be (4, tetr.)
$AlCl_3 \cdot FeCl_3$		[C]	Al (4, tetr.); Fe (4, tetr.)
$FeCl_3 \cdot AuCl_3$		[D]	Fe (4, tetr.); Au (4, plan.)
$PdCl_2 \cdot 2\,AlCl_3$		[E]	Al (4, tetr.); Pd (4, plan.) [130]
$CrCl_2 \cdot 2\,AlCl_3$		[F]	Al (4, tetr.); Cr^{II} (6, oct.) [128] analogous to $NiAl_2Cl_8$ [130]
$CrCl_3 \cdot 3\,AlCl_3$		[G]	Al (4, tetr.); Cr^{III} (6, oct.) [141]
$UCl_4 \cdot 2\,AlCl_3$		[H]	Al (4, tetr.); U^{IV} (6, oct.)
$UCl_5 \cdot AlCl_3$		[I]	Al (4, tetr.); U^{V} (6, oct.) [19]

In $NaAlCl_4$ [A] the position of the Na atom is uncertain (whether at a corner, edge, or face of the $AlCl_4$ tetrahedron), but it is probably above one edge (cf. also $NaAlF_4$[142] and $LiAlF_4$[143]).

The structure [B] given for $BeAl_2Cl_8$ is based on the existence of molecules $AlCl_3(BeCl_2)_nAlCl_3$ with $n=1$ to 3 and their probable relation to the tetrahedron chains $(BeCl_{4/2})_\infty$ in the structure of solid $BeCl_2$; cf. $BeCl_2/FeCl_3$ and $BeCl_2/InCl_3$ (Table 10). The structures [E] to [G] and [I] correspond to the observed ligand field spectra. The spectra measured for $CoCl_2 \cdot 2AlCl_3$ have not yet led to an unambiguous

Table 10. Larger hetero-complexes. Cf. [71]; the references given there are not repeated here.

Valence of the cations	Complexes observed

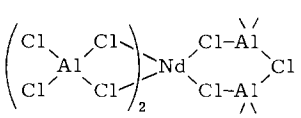
interpretation between tetrahedral and octahedral coordination of the Co[132, 133].

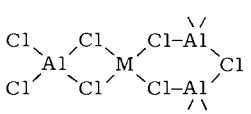
The formulas of the gaseous complexes [K] to [N] require the *structural unit* Al_2Cl_7 (cf. Section 6).

$NdCl_3 \cdot 4\,AlCl_3$ [144]



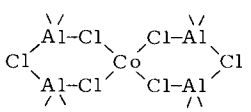
[K]

$MCl_2 \cdot 3\,AlCl_3$ [15]
M = Mg, Ca, Mn, Co



[L]

$CoCl_2 \cdot 4\,AlCl_3$ [133]

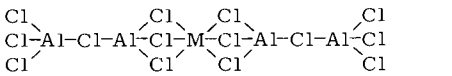


[M]

The structural group Al_2Cl_7, which is obviously very mobile at the Al—Cl—Al angle, is known to be bent in the crystal lattice of the compound $Te_4(Al_2Cl_7)_2$[145] and straight in melts[146] containing the equilibrium:

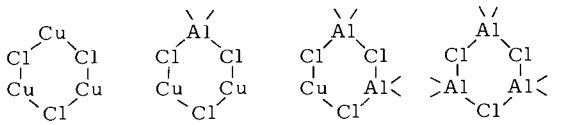
$$2\,AlCl_4^- + Al_2Cl_6 \rightleftharpoons 2\,Al_2Cl_7^- \qquad (14)$$

In the cases of $TiCl_2$, VCl_2, $CrCl_2$, $MnCl_2$, $FeCl_2$, $CoCl_2$, $NiCl_2$, and $CuCl_2$ in $AlCl_3$ melts the octahedral Cl-coordination of all the named M^{2+} follows from the ligand field spectra. The structure [N] is assumed for these complexes[147].

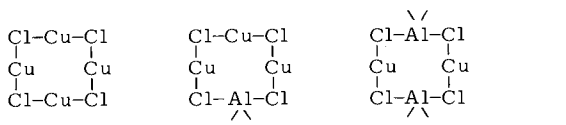


[N]

Ring structures, such as are known for Cu_3Cl_3[49] and assumed for Cu_4Cl_4, Ag_3Cl_3, and Al_3Cl_9, clearly also occur among the heterocomplexes. This is indicated by the series of compounds [O] and [P].



Cu_3Cl_3 Cu_2AlCl_5 $CuAl_2Cl_7$ Al_3Cl_9 [O]



Cu_4Cl_4 Cu_3AlCl_6 $Cu_2Al_2Cl_8$ [P]

The formulas of many complexes require coordinations that are unknown among *solid* chlorides, *e. g.* the coordination numbers 3 and 5 in the molecules $TlPbCl_3$ and $TlThCl_5$. Furthermore, for the $BeAlCl_5$ molecule it appears reasonable to discuss the arrangement of two face-bonded tetrahedra, although face-bonded tetrahedra are avoided in crystal structures. The infinitely extended anion packing in coordination lattices can place at the disposition of the cations positions that are energetically more favorable than is possible with small molecules. Care is therefore needed in drawing conclusions about the structure of molecules from the coordination polyhedra in crystals; this is also true when a compound has "accidentally" the same analytical composition in the solid state and in the gas phase.

5.2. Thermodynamics

Dewing[15] and *Papatheodorou*[131] have previously pointed out that the ion M^{2+} in the gaseous complex MAl_2Cl_8 is bonded similarly to that in the solid dichloride MCl_2. In both cases the M^{2+} is surrounded by Cl^- ions. Closer examination shows that there is a definite connection between the change in coordination number (ΔC.N.) on complex formation and the ΔH^0 balance: a loss of coordination energy shifts the ΔH^0 balance toward more positive values [cf. (15)—(19)].

$$\underset{\text{C.N. } 6}{NaCl_s} + \underset{6}{FeCl_{3,s}} \rightleftharpoons \underset{2\ 4}{NaFeCl_{4,g}};\ \Delta H^0(298) = +39\,\text{kcal};\ \Delta\text{C.N.} = -6 \qquad (15)$$

$$\underset{\text{C.N. } 6}{NaCl_s} + 0.5\,\underset{4}{Fe_2Cl_{6,g}} \rightleftharpoons \underset{2\ 4}{NaFeCl_{4,g}};\ \Delta H^0(298) = +22\,\text{kcal};\ \Delta\text{C.N.} = -4 \qquad (16)$$

$$\underset{\text{C.N. } 2}{0.5\,Na_2Cl_{2,g}} + \underset{6}{FeCl_{3,s}} \rightleftharpoons \underset{2\ 4}{NaFeCl_{4,g}};\ \Delta H^0(298) = +8.5\,\text{kcal};\ \Delta\text{C.N.} = -2 \qquad (17)$$

$$\underset{\text{C.N. } 2}{0.5\,Na_2Cl_{2,g}} + \underset{4(+x)}{FeCl_{3,l}} \rightleftharpoons \underset{2\ 4}{NaFeCl_{4,g}};\ \Delta H^0(298) = 0\,\text{kcal};\ \Delta\text{C.N.} = (-x) \qquad (18)$$

$$\underset{\text{C.N. } 2}{0.5\,Na_2Cl_{2,g}} + \underset{4}{0.5\,Fe_2Cl_{6,g}} \rightleftharpoons \underset{2\ 4}{NaFeCl_{4,g}};\ \Delta H^0(298) = -8.8\,\text{kcal};\ \Delta\text{C.N.} = 0$$

Similar results are found for other systems. (19)

If in reactions of the type solid + gas ⇌ gaseous complex the solid reactant is so chosen that the change in coordination number ΔC.N. on formation of the complex remains as low as possible, then the reaction enthalpy corresponds approximately to the heat of fusion of the solid component (cf. Table 11): the loss of coordination energy occurring on the solid → gaseous complex transition is of similar magnitude to that in the solid → liquid transition. This can be useful in estimations.

The following observations a) to d) are in accord with these considerations:

a) The complex $CoAl_2Cl_8$ is distinctly more stable than the corresponding nickel complex. This is also reflected in the greater rate of transport of $CoCl_2$ in chemical transport experiments. The heats of fusion of $CoCl_2$ and $NiCl_2$ differ in the same direction (Table 11).

b) Chemical transport experiments with $MoCl_2/Al_2Cl_6$ and WCl_2/Al_2Cl_6 at 500/400 °C proved negative[151]. These dichlorides have the structural formula $[M_6Cl_8]Cl_2Cl_{4/2}$. The solid state is stabilized not only by chlorine bridges but also by metal-metal bonds in the octahedral M_6 groups. Gas complexes which do not contain metal-metal bonds cannot compete energetically. The absence of $AlCl_3$ complexes with $MoCl_2$ or WCl_2 and the existence of such complexes with $CrCl_2$ can be ascribed to the structure of the solid dichlorides. The fact that the dichlorides $PdCl_2$ and $PtCl_2$, which contain no metal-metal bonds, can form gaseous complexes with $AlCl_3$ (*i.e.* MAl_2Cl_8) in spite of their cluster structure (M_6Cl_{12}) fits into this picture.

c) According to the views expressed above, the ΔH^0 for complex formation as in Table 11 should be independent of the nature of the readily volatilized reactant formulated as dimer M_2Cl_6[Al_2Cl_6, Fe_2Cl_6, Ga_2Cl_6...]. In fact the reactions affording the Fe^{III} complexes are only 2 kcal/mol more strongly endothermic than those affording the Al complexes.

d) Reactions 14 and 17 in Table 11 are also noteworthy. In both cases $UCl_{4,s}$ is converted into the complex with C.N. = 6, while the Al or Tl retains its coordination number unchanged. The ΔH^0 values are thus almost equal.

Table 11. Thermodynamic data for the formation of gaseous complexes. Literature data partly re-evaluated (cf. [108]) [a]. ΔH^0(melt) refers to solid reactants at their melting points (for values without references see [148]).

Compounds with formulas that differ from the previously assumed "basic types" are collected, together with their thermodynamic data, in Table 12.

Here too complex formations are weakly endothermic, as are those formulated in Table 11. However, considerable uncertainty attaches to most of the values given in Table 12, for which the complexity of the systems concerned is partly respon-

sible; also, some of the formulas are not yet fully proved. For example, the measurements in the system $CoCl_2/Al_2Cl_6$ can be evaluated in a form that allows $CoAl_3Cl_{11}$ or $CoAl_4Cl_{14}$ to be present alongside the strongly dominant complex $CoAl_2Cl_8$[113]; probably, indeed, all three complexes are present together. The uncertainty of the data arises from the large entropy differences between reactions of the same type (Table 12, Nos. 1 to 5). Critical examination of the reaction entropies, elsewhere so informative, does not at once lead to progress since there are no reliable ΔS^0 values for large gaseous complexes. The loss of translational entropy on the formation of complexes containing Al_2Cl_7 ligands is clearly almost compensated by the large vibrational entropy of the mainly ionic and thus easily deformable complexes. Without such an effect the measurable concentration of complexes containing Al_2Cl_7 ligands would be difficult to understand, for the ΔH^0 term should not be decisive for the formation of the larger complex for reasons of coordination. The data from *Dell'Anna* and *Emmenegger*[133] for eq. (20) point in the same direction:

$$Co(AlCl_4)_{2,g} + Al_2Cl_{6,g} \rightleftharpoons Co(Al_2Cl_7)_{2,g}; \quad \Delta H^0 = 3\,\text{kcal}; \quad \Delta S^0 = 2\,\text{cal/K} \qquad (20)$$

6. Several Complexes in Equilibrium with One Another

The coexistence of several complexes in equilibrium systems should in principle be expected. For the systems considered in this review the probability attaching to such coexistence of differing gaseous complexes is increased because of the predominantly ionic and thus unspecific bonding forces. This raises for each such system the questions whether the complex described is accompanied by other observable complexes, and to what extent the presence of these other observable complexes may have falsified the thermodynamic data determined for the "main" complex. Answering these questions runs into experimental difficulties, and the same is true for mass spectrometry which usually provides so much information but where large hetero-complexes composed of chlorides could undergo far-reaching fragmentation.

6.1. Systems Not Containing Alkali Metals

For coexistence of complexes containing $AlCl_4$ and Al_2Cl_7 groups, *e.g.* $CoAl_2Cl_8$, $CoAl_3Cl_{11}$, and $CoAl_4Cl_{14}$ see Section 5.2. The unknown 1:1 complex $CoAlCl_5$ could—as estimates have shown[108]—have only slight importance in comparison with $CoAl_2Cl_8$.

For *combinations containing TlCl, CuCl, or InCl₃* there are quantitative data [eq. (21) to (37)][47].

$$TlCl_g + InCl_{3,g} \rightleftharpoons TlInCl_{4,g}; \quad \Delta H^0 = -27.9\,\text{kcal} \qquad (21)$$
$$2TlCl_g + InCl_{3,g} \rightleftharpoons Tl_2InCl_{5,g}; \quad \Delta H^0 = -50.0\,\text{kcal} \qquad (22)$$

Here there is an uncertainty, since the fragment $Tl_2InCl_4^+$ observed in the mass spectrometer was ascribed to Tl_2InCl_5. In complexes *containing alkali metals*—which however are a special case—the fragments $A_2MCl_4^+$ are derived mainly from $A_2M_2Cl_8$.

$$CuCl_g + ThCl_{4,g} \rightleftharpoons CuThCl_{5,g}; \quad \Delta H^0 = -46.3\,\text{kcal} \qquad (23)$$
$$2CuCl_g + ThCl_{4,g} \rightleftharpoons Cu_2ThCl_{6,g}; \quad \Delta H^0 = -100.2\,\text{kcal} \qquad (24)$$
$$CuCl_g + 2ThCl_{4,g} \rightleftharpoons CuTh_2Cl_{9,g}; \quad \Delta H^0 = -80.9\,\text{kcal} \qquad (25)$$

$$TlCl_g + ThCl_{4,g} \rightleftharpoons TlThCl_{5,g}; \quad \Delta H^0 = -27.3\,\text{kcal} \qquad (26)$$
$$2TlCl_g + ThCl_{4,g} \rightleftharpoons Tl_2ThCl_{6,g}; \quad \Delta H^0 = -64.1\,\text{kcal} \qquad (27)$$

$$CuCl_g + UCl_{4,g} \rightleftharpoons CuUCl_{5,g}; \quad \Delta H^0 = -46.7\,\text{kcal} \qquad (28)$$
$$2CuCl_g + UCl_{4,g} \rightleftharpoons Cu_2UCl_{6,g}; \quad \Delta H^0 = -101.6\,\text{kcal} \qquad (29)$$

$$TlCl_g + UCl_{4,g} \rightleftharpoons TlUCl_{5,g}; \quad \Delta H^0 = -29.2\,\text{kcal} \qquad (30)$$
$$2TlCl_g + UCl_{4,g} \rightleftharpoons Tl_2UCl_{6,g}; \quad \Delta H^0 = -65.6\,\text{kcal} \qquad (31)$$
$$TlCl_g + 2UCl_{4,g} \rightleftharpoons TlU_2Cl_{9,g}; \quad \Delta H^0 = -58.4\,\text{kcal} \qquad (32)$$

$$BeCl_{2,g} + InCl_{3,g} \rightleftharpoons BeInCl_{5,g}; \quad \Delta H^0 = -25.0\,\text{kcal} \qquad (33)$$
$$2BeCl_{2,g} + InCl_{3,g} \rightleftharpoons Be_2InCl_{7,g}; \quad \Delta H^0 = -53.0\,\text{kcal} \qquad (34)$$
$$3BeCl_{2,g} + InCl_{3,g} \rightleftharpoons Be_3InCl_{9,g}; \quad \Delta H^0 = -80.2\,\text{kcal} \qquad (35)$$

$$ZnCl_{2,g} + InCl_{3,g} \rightleftharpoons ZnInCl_{5,g}; \quad \Delta H^0 = -24.6\,\text{kcal} \qquad (36)$$
$$SnCl_{2,g} + InCl_{3,g} \rightleftharpoons SnInCl_{5,g}; \quad \Delta H^0 = -24.5\,\text{kcal} \qquad (37)$$

These reaction enthalpies, derived from mass spectra, have limits of error of approximately ± 2 kcal. Critical examination leads to the following conclusions:

a) On 1:1 addition of M'Cl to MCl_x the ΔH^0 is roughly half as large as for 2:1 addition.

b) Statement a) can be refined by noting that C.N.=4 ($TlInCl_4$) or 6 (Cu_2ThCl_6; Tl_2ThCl_6; Cu_2UCl_6; Tl_2UCl_6) for M is distinctly favored over C.N.=5, as shown by the ΔH^0 values.

c) If in larger complexes identical central atoms M are linked by Cl bridges, their formation in the sense of eq. (38) to (44) is energetically comparable with dimerization of MCl_x, and the effect of coordination number is again evident.

$$ThCl_{4,g} + ThCl_{4,g} \rightleftharpoons Th_2Cl_{8,g}; \quad \Delta H^0 = -31.0\,\text{kcal} \qquad (38)$$
$$CuThCl_{5,g} + ThCl_{4,g} \rightleftharpoons CuTh_2Cl_{9,g}; \quad \Delta H^0 = -34.6\,\text{kcal} \qquad (39)$$

$$UCl_{4,g} + UCl_{4,g} \rightleftharpoons U_2Cl_{8,g}; \quad \Delta H^0 = -26.1\,\text{kcal} \qquad (40)$$
$$TlUCl_{5,g} + UCl_{4,g} \rightleftharpoons TlU_2Cl_{9,g}; \quad \Delta H^0 = -29.2\,\text{kcal} \qquad (41)$$

$$BeCl_{2,g} + BeCl_{2,g} \rightleftharpoons Be_2Cl_{4,g}; \quad \Delta H^0 = -24.0\,\text{kcal} \qquad (42)$$
$$BeInCl_{5,g} + BeCl_{2,g} \rightleftharpoons Be_2InCl_{7,g}; \quad \Delta H^0 = -28.0\,\text{kcal} \qquad (43)$$
$$Be_2InCl_{7,g} + BeCl_{2,g} \rightleftharpoons Be_3InCl_{9,g}; \quad \Delta H^0 = -27.2\,\text{kcal} \qquad (44)$$

d) Complexes containing CuCl are characterized by particularly great stability, and the same may be the case for AgCl complexes. This is explained by the high aggregation enthalpy of the monochloride.

6.2. Systems Containing Alkali Metals

In larger hetero-complexes containing two alkali-metal atoms as well as the metal atom M, the alkali-metal atoms have a positive partial charge owing to their low electronegativity. This effect is increased in the positively charged molecular ion that arises primarily by electron impact. Further fragmentation is prescribed by such a charge profile. It leads mainly or exclusively to fragment ions that contain the A atoms but are impoverished in M, and whose origin is not immediately evident. Tracing the fragments back to the initial complex requires additional studies that have not yet been done for chloride complexes. For *fluoride* complexes, however, *Sidorov et al.* in particular have developed methods for decoding the mass spectra of equilibrium systems of several complexes con-

taining alkali-metals[152]. Examples of gaseous complexes observed in this way are:

NaF/BeF_2 system: $NaBeF_3$, Na_2BeF_4, $(NaBeF_3)_2$ [153]
KF/AlF_3 system: $KAlF_4$, K_2AlF_5, $(KAlF_4)_2$ [154]
NaF/GaF_3 system: $NaGaF_4$, Na_2GaF_5, $(NaGaF_4)_2$ [155]

Chloride systems apparently behave analogously, so that a certain amount of order becomes recognizable in the build-up of such equilibrium systems.

ACl/MCl_2: With this combination the fragment $AMCl_2^+$ is generally observed in the mass spectrometer, and can be unambiguously ascribed to the $AMCl_3$ molecule. When A = K, and M = Mn, Fe, Co, Ni or Pb, the fragment $A_2MCl_3^+$ is also observed[156], this indicating the existence of a further complex A_2MCl_4 or $(AMCl_3)_2$.

ACl/MCl_3: In the systems $KCl/AlCl_3$ and $ACl/GaCl_3$ (A = Na, K, Rb, Cs) the fragment $AMCl_3^+$ derived from $AMCl_4$ was observed mass-spectrometrically together with $A_2MCl_4^+$, which is formed from A_2MCl_5 or $(AMCl_4)_2$[156].

7. Practical Significance of Gaseous Complexes

General considerations: Gaseous complexes formed from halide molecules are labile in the kinetic sense. The components AX_m and BX_n bound in the complex are available for further reaction without kinetic hindrance provided that the thermo-

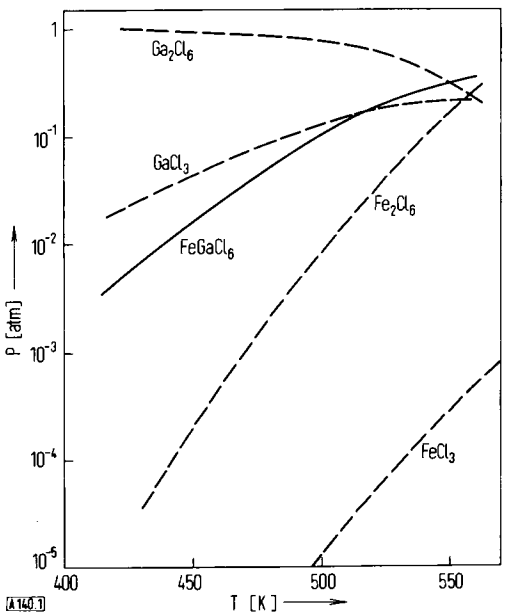

Fig. 1. Equilibrium pressures above solid iron(III) chloride in the presence of gallium (III) chlorides at $\Sigma P = 1$ atm.

dynamics demand it. The situation is particularly clear when one investigates whether a given equilibrium system is altered by addition of one of the components of the complex. Examples of this are shown in Figures 1 to 4.

Figure 1 makes it clear that the addition of a large excess of the readily volatile component $GaCl_3$ (Ga_2Cl_6) of the complex causes an appreciable increase in the total Fe content of the gas phase, although the stability of the complex is low, as shown by the fact that $\log K_P = 0$ for the reaction

$$\tfrac{1}{2}\,Fe_2Cl_{6,g} + \tfrac{1}{2}\,Ga_2Cl_{6,g} \rightleftharpoons FeGaCl_{6,g} \qquad (45)$$

(see Section 4).

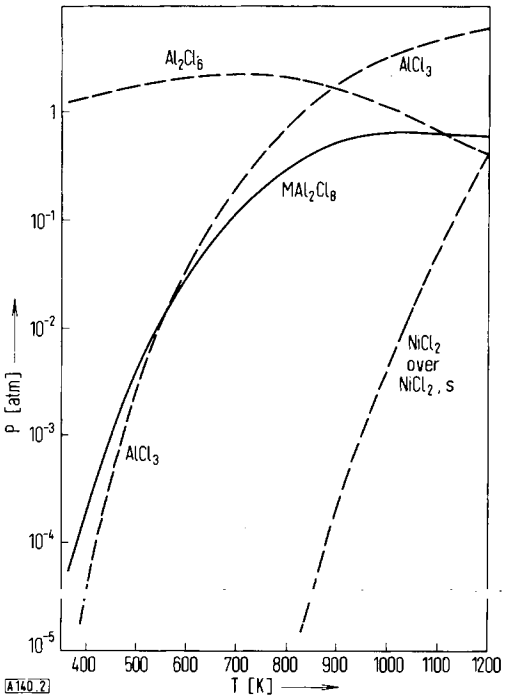

Fig. 2. Equilibrium pressures above solid nickel(II) chloride for the case in which the reaction space is filled at 293 K with Al_2Cl_6 at a (hypothetical) partial pressure of 1 atm.

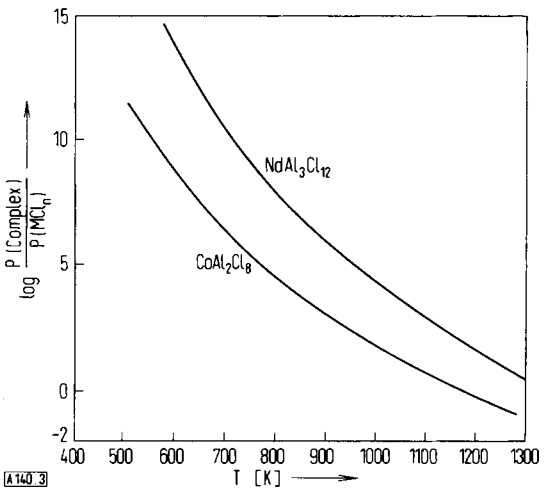

Fig. 3. Comparison of the saturation pressures above solid $CoCl_2$ and $NdCl_3$ with equilibrium pressures of the $AlCl_3$ complexes. Filling of the reaction space as in Figure 2.

It is also important that the relevant concentrations of the complexes decrease with rising temperature and that there is an upper temperature limit above which complex formation can be neglected for practical purposes because the uncomplexed components strongly predominate (cf. Figures 1—4 and [157]).

Table 13 provides a survey of the large number of complex-forming systems with the single important requirement that one of the readily volatile trichlorides $AlCl_3$, $GaCl_3$, $InCl_3$, or $FeCl_3$ shall function as complex-former[108].

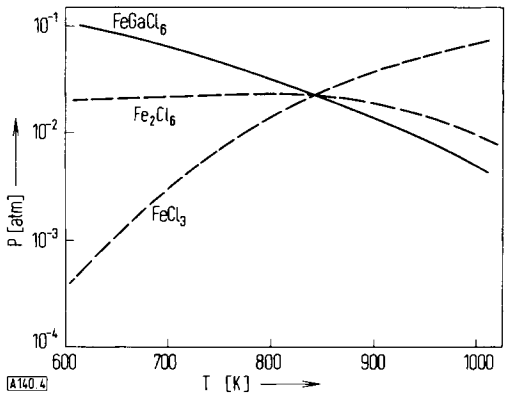

Fig. 4. Equilibrium pressures of the Fe-containing molecules above α-Fe_2O_3 as the bottom material, as set up in the presence of HCl and $GaCl_3$ (Ga_2Cl_6) when $\Sigma P = 4$ atm and $Ga/H = 1$. $Ga/H = [P(GaCl_3) + 2P(Ga_2Cl_6) + P(FeGaCl_6)] : [P(HCl) + 2P(H_2O)]$.

Finally we show by examples that the family of gaseous complexes also deserves interest from the practical point of view.

Gaseous complexes in preparative chemistry: Relatively slightly volatile halides (*e.g.* $TiCl_3$, VCl_3, $CrCl_3$, $MnCl_2$, $FeCl_2$, $CoCl_2$, $NiCl_2$, $CuCl_2$, $ScCl_3$, YCl_3, $LaCl_3$, $ThCl_4$, UCl_4) can be transported chemically through temperature gradients by means of readily volatilized complex-formers ($AlCl_3$, $GaCl_3$, $InCl_3$, or $FeCl_3$) and can thus be obtained crystalline at much lower temperatures than can be used for their sublimation[96]. The combination of this chemical transport, which takes care of the mobility of the components, together with other reactions, leads to new synthetic routes, *e.g.* for $CrCl_2$[129], Pd_2Al[89] and $HgCr_2Se_4$[96]. Other references to this type of problem have been collected by *Emmenegger*[157]. The separation of lanthanoids and actinoids by gas chromatography of the aluminum chloride complexes[138,139] is also worth noting.

Gaseous complexes in industrial problems: When studying the electrolytic separation of aluminum from melts containing $AlCl_3$[158], *Grothe*[10] observed that alkali-metal chlorides—and also magnesium chloride—were volatilized in considerable quantities with aluminum chloride, being carried away in the gas released at the anode. The gaseous fluoride complex $NaAlF_4$ plays a similar part in the usual industrial extraction of aluminum[159]. *Dewing*[15] noted the volatilization of $MgCl_2$ and $CaCl_2$ with the formation of $AlCl_3$ complexes in connection with the studies of the "aluminum(I) chloride process" (isolation of Al by chemical transport by the reversible reaction $2Al_l + AlCl_{3,g} \rightleftharpoons 3AlCl_g$).

In the isolation of copper from copper ores the so-called "segregation process" has proved valuable[72]. In this the oxidic copper ore is heated in the presence of NaCl, SiO_2, C, and H_2O_g. The HCl first produced leads to the formation of $Cu_3Cl_{3,g}$, which is finally reduced by the H_2 and deposited on the carbon-containing granules. According to *Gross* and *Stuart*'s thermodynamic investigation of the process[72], this scheme needs supplementation in that a NaCl/CuCl melt is formed as an intermediate stage and that in the subsequent step not only $Cu_3Cl_{3,g}$ but also the gaseous complexes $NaCuCl_2$ and $NaCu_2Cl_3$ play a considerable role in transporting the copper onto the carbon.

In the treatment of sulfidic copper ores with chlorine with the aim of converting the copper into water-soluble $CuCl_2$ and at the same time volatilizing the chlorides of sulfur and iron, *Spreckelmeyer*[160] found that appreciable volatilization of $CuCl_2$ began when the iron content ($FeCl_3$) was high. The explanation for this is provided by the existence of the gaseous complex $CuFe_2Cl_8$, whose reversible formation has been observed during chemical transport of $CuCl_2$ with $FeCl_3$ (Fe_2Cl_6)[96].

Gaseous complexes in high-pressure discharge tubes: Discharge tubes filled with mercury, which also contain argon as the ignition gas, are important because of their high light output. Their further development, with the object of improving the light yield and achieving a radiation similar to daylight, requires the inclusion also of other elements whose atoms can be excited in the plasma column (*ca.* 6000 K). The content of such elements in the gas space is limited by their saturation pressure at the temperature of the tube wall (*ca.* 1000 K). This threshold can be passed if halides are used in place of the elements. The halides are decomposed in the plasma and re-formed near the wall. The more deciding factor is now the saturation pressure of the halides at the wall. This pressure is still lower than desired when particularly efficient radiators such as scandium or the lanthanoids are used, and thus complex formers have been added to produce more easily volatilized gaseous complexes such as AMI_4; examples are $ScI_3 + NaI$[161] and $CeI_3 + NaI + CsI$[162–164]. Iodides are favored for this purpose because, in contrast to the analogous chloride systems, they do not lead to attack on the tungsten electrodes (by the free halogen).

Table 13. Elements whose chlorides form gaseous complexes with $AlCl_3$ (or $GaCl_3$, $InCl_3$ or $FeCl_3$). Bold type denotes that the formation of a gaseous complex has been proved. Parentheses denote that such complex formation can be safely assumed, but that this has not yet been investigated.

Gaseous complexes in high-pressure discharge tubes: Discharge tubes filled with mercury, which also contain argon as the ignition gas, are important because of their high light output. Their further development, with the object of improving the light yield and achieving a radiation similar to daylight, requires the inclusion also of other elements whose atoms can be excited in the plasma column (*ca.* 6000 K). The content of such elements in the gas space is limited by their saturation pressure at the temperature of the tube wall (*ca.* 1000 K). This threshold can be passed if halides are used in place of the elements. The halides are decomposed in the plasma and re-formed near the wall. The more deciding factor is now the saturation pressure of the halides at the wall. This pressure is still lower than desired when particularly efficient radiators such as scandium or the lanthanoids are used, and thus complex formers have been added to produce more easily volatilized gaseous complexes such as AMI_4; examples are $ScI_3 + NaI$[161] and $CeI_3 + NaI + CsI$[162–164]. Iodides are favored for this purpose because, in contrast to the analogous chloride systems, they do not lead to attack on the tungsten electrodes (by the free halogen).

It may be expected that further information about the practical utilization of gaseous complexes will soon appear. In this connection one might bear in mind, for example, the removal of impurities as well as their fixation (masking) in the form of gas complexes during the preparation of doped or very pure materials.

8. Unanswered Questions

The chemistry of gaseous complexes has now been clarified to an extent that allows the principal problems still awaiting

solution to be named. In the author's opinion these are the following:

1) *Thermodynamics*

a) The basis for estimating the stability of 1:1 hetero-complexes, and particularly of complexes containing alkali metals, should be broadened by reliable measurements. The object of this would be to systematize the *Y* values.

b) The analogy of the *chloride* complexes to those of *fluorides*, *bromides*, and *iodides* is obvious. It would be important and useful to discover quantitative relationships between the various halide complexes.

c) The approximation formulas and rules customarily used today for estimating normal entropies were developed for small molecules. They fail for very large, ionic, gaseous complexes. In these complexes energetically low, easily excited, vibrations clearly lead to unusually large entropy values. Quantitative investigations in this area are needed. Promising routes would be exploration of the IR and Raman spectra of gaseous complexes condensed in a matrix.

d) A special problem is presented by the existence of equilibrium systems containing several complexes (cf. Section 6). Even analysis of such mixtures is difficult. After a sufficiently wide experimental basis has been worked out, the numerical material obtained should be examined for systematic relationships.

2) *Structures*

The structural concepts so far reached are, with few exceptions, based on ligand field spectra. In these admittedly the coordination of only the cation providing the color is determined. The capacity of other methods of investigation to provide information is often diminished by the complicated composition of the equilibrium gas. In this area too vibration spectroscopy with matrix isolation could help matters forward.

3. In *preparative investigations* the existence of gaseous complexes and their application should be taken more seriously into account. Some of the complexes existing in the gas phase can, according to our observations, also be obtained in apolar or weakly polar solvents. Studies in this direction must be continued. They could open up the possibility of new reactions, particularly for compounds of the transition elements.

I am indebted to Dr. M. Binnewies for his welcome collaboration and helpful discussions. I should also like to acknowledge with thanks the experimental contributions from my associates: M. Aits, W. Domke, J. Karbinski, J. Krüger, B. Küssner, K. Lascelles, R. Laumanns, H. B. Merker, J. Nowitzki, H. Rabeneck, M. Trenkel, K. Wagner, and H. Wächter.

Is Gold Chemistry a Topical Field of Study?

By Hubert Schmidbaur[*]

The question raised in the title of this progress report is answered point for point with an emphatic "yes": Ranging from metallic gold, *via* clusters of gold atoms in low valence states, compounds of Au^{I}, Au^{II}, Au^{III}, and Au^{V}, organogold derivatives, ylide and carbene complexes, to the catalytic activity of gold it embraces a long-neglected area of chemistry holding promise of many a discovery.

1. Introduction

1.1. Historical

Metallic gold has from antiquity been regarded as the very epitome of material value. The continuing practice of striking coins in this metal (if not as legal currency, then as an inflation hedge and a speculative form of investment), the still at least partly valid relation between actual currencies and national gold reserves (Fort Knox!), and finally the undisputed preference for gold as the basic material of jewelry are an obvious reason for and a clear manifestation of this idea. The idea therefore grew up not only among laymen, but also among chemists, that gold should be ascribed a special place among the elements. It is not uncommon to encounter the prejudice that occupation with gold *chemistry* reveals an inability to grasp reality since the use of gold for purposes other than those mentioned above is inconceivable. The question of "relevance" is therefore best disregarded in this context.

Continuing in this vein, a general survey of the principal combinations of the element does indeed show that in most chemical systems elemental gold is distinctly favored thermodynamically over its compounds[1]. Nature itself has predestined gold's role as a noble metal in the truest sense of the word. Thus apart from its combinations with strongly oxidizing halogens, gold chemistry is a chemistry of metastable compounds and leads almost invariably—whether desired or not—to elemental gold as the essentially stable species. With few exceptions the metal also occurs as elemental gold in its natural deposits[1].

1.2. The Present Situation

Such a standpoint nevertheless overlooks a number of aspects which present this neglected area of inorganic and organometallic chemistry in a much more favorable light. It should first be mentioned that the price of gold is currently much lower than that of many so-called "rare" metals. For instance, platinum, palladium, iridium, rhodium, osmium, and ruthenium are traded at a price much higher than that of gold. Yet these metals and their compounds are frequently utilized in practice and are still under intensive study. Moreover, gold is on no account one of the rarest elements and its abundance far exceeds that of most of the above noble metals. Its scarcity may therefore merely be a result of hoarding reserves.

[*] Prof. Dr. H. Schmidbaur
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München (Germany)

In addition the *uses* of gold are no longer restricted to coinage and jewelry, but are steadily increasing in number and scope. An example that has received considerable publicity through spectacular photographs is the coating of aerospace equipment with a bright gold plating; and another one is the gold coating of radiation-inhibiting window panes characterizing the appearance of numerous modern buildings. Gold is also used in collectors for solar energy and is predicted to have a great future in that field.

Even more manifold but less evident to the casual observer is the role of gold in the microcosm of the latest generation of electronic equipment; many components and circuits would be unthinkable without gold.

An old rule of *catalyst* research appears to regard gold as a black sheep among the noble metals, for it has so far found practically no catalytic application. The activity of the neighboring elements platinum and palladium underlines this shortcoming. However, recent findings suggest that these ideas may soon be due for revision.

Finally, mention should be made of the use of gold in *medicine* and *dentistry*. Although many attempts have been made to develop new methods for treating polyarthritis, the classical field of application of gold therapy, we still cannot dispense with this "chrysotherapy". It remains a topic for research to discover gold compounds in which therapeutic action and heavy metal toxicity are related as favorably as possible[2].

This brief survey should demonstrate that research into gold chemistry often has a very realistic basis. Most of the new working forms of gold are obtained *via* gold compounds, and a deepening of our understanding of their chemistry is therefore highly desirable.

An attempt is made in the following to trace advances and developmental trends with the aid of important contributions to gold chemistry dating from the past five years, and to stimulate further study of this most enchanting material. No claim can be made to completeness, and the choice is necessarily subjective. *Organogold compounds* are treated separately (Section 7), an approach justified by the unparalleled development of this field of gold chemistry[3]. This promotes clearer understanding by providing an opportunity for a more detailed examination of various aspects.

2. Elemental Gold and Clusters of Gold Atoms in Low Valence States

2.1. Gold Vapor and Gold Metal

The three states of aggregation of elemental gold were studied in considerable detail at a very early stage[1]. A very remarkable

result is that, above the boiling point of the metal, gold vapor consists primarily of dimers Au_2 characterized by one of the largest dissociation energies known for homonuclear diatomic molecules[4]. The experimental value $E_D = 232$ kJ/mol exceeds the dissociation energy of almost all halogens and interhalogen compounds of type A_2 and AB.

There has therefore been no lack of attempts[5-7] to trap the Au_2 species by complex formation; simple donors should give products *(1a)* isoelectronic with the mercury(I) compounds *(1b)*:

$$\text{Au–Metal} \xrightarrow{\Delta} \text{Au–Au} + 2\ \text{:L} \longrightarrow \text{L–Au–Au–L} \quad (1a)$$

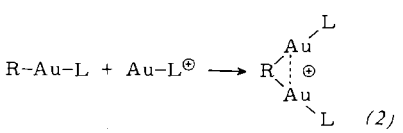
$$\text{Hg–Hg}^{2\oplus} + 2\ \text{:X}^{\ominus} \longrightarrow \text{X–Hg–Hg–X} \quad (1b)$$

The ligands L tried were mainly phosphanes R_3P or sulfanes R_2S. Astonishingly, not a single complex *(1a)* has yet been isolated, or even detected. The same applies to reduction experiments on gold compounds in solution, which have long been known to afford a large variety of gold colloids[1]. However, the occurrence of discrete, well-defined polyatomic aggregates, *i.e.* clusters, has recently been detected. The metallic nuclei of these clusters which are enclosed by a sheath of ligands may be regarded as a link between the particles found in the metal vapor and the practically infinite aggregates of the molten and the crystalline metal. No other metal has yet been found to form as many different homoatomic clusters as gold. A knowledge of the structure of such species can provide valuable information pertaining to metal nuclei, their formation and their growth[5].

2.2. Gold Clusters

Metallic gold crystallizes in a cubic face-centered lattice, with each metal atom being surrounded by 12 equidistant neighbors (Au—Au distance 288.4 pm). The mechanical and electrical properties of this soft, readily workable metal having good electrical and thermal conductivity can be attributed principally to this lattice type (m.p. 1064.43 °C, b.p. 2860 °C).

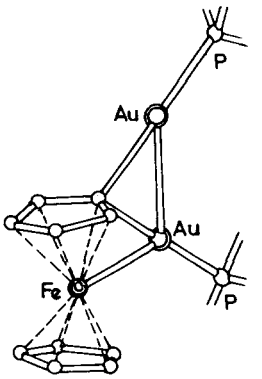
The smallest metal aggregate containing two atoms in a low oxidation state (<1), the Au_2 unit, was first discovered by *Nesmeyanov et al.* in organogold compounds of type *(2)*[8]. However, this is not the simple unbridged form [cf. *(1a)*], but the triatomic CAu_2 structural unit in which a tetrahedrally coordinated C atom serves as a bridge between two gold atoms in direct contact. Such species are formed on reaction of RAuL complexes with $AuL^{\oplus}$ ions:



(2)

R is initially a triply coordinated C atom of an aromatic or olefinic group which achieves the coordination number 4 in the course of the reaction: $R = C_6H_5$, $C_6H_4CH_3$, $CH_2{=}CH$, ferrocenyl (Fc), *etc.* The last-named example [*(3)*] has been confirmed by an X-ray study[9].

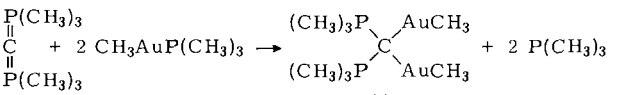
The Au—Au distance is 277 pm and is thus shorter than in metallic gold. (Compounds containing $Au_2^{4\oplus}$ units will be considered in Section 4.)



$[Fc\{AuP(C_6H_5)_3\}_2]^{\oplus}\ BF_4^{\ominus}$

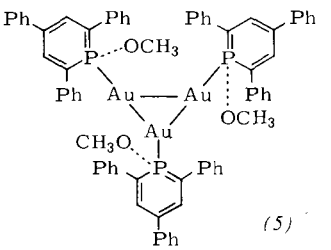
(3)

Compounds have also been found in which two gold atoms *not* linked together are bonded to the same C atom. While a first series of examples[8] closely resemble those of type *(2)*, a second class can be derived from the carbodiphosphoranes $R_3P{=}C{=}PR_3$[10]. The latter readily form 1 : 2 complexes with gold(I) reactants, according to



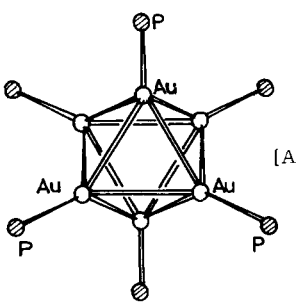
(4)

Dimroth et al.[11] recently postulated a structure containing an Au_3 unit for a compound formed on reaction of the AuCl complex of 2,4,6-triphenyl-λ^3-phosphorin[12] with sodium methoxide. Determination of the relative molecular mass indicated the trimer, and spectroscopic data accord with structure *(5)*.



(5)

The next larger cluster unit, a Au_6 octahedron, was first discovered in the group of gold compounds studied in great detail by *Malatesta et al.* during recent years[13]. They were prepared by careful reduction of phosphane complexes LAuX (X = (pseudo)halogen, L = phosphane) and the products isolated by employing special crystallization techniques. Some of the products have the composition $[Au_6L_6]^{2\oplus} + 2X^{\ominus}$, thus implying a formal oxidation state of +0.33 for the gold atoms.

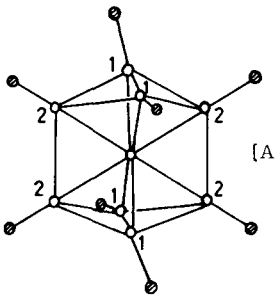


$[Au_6\{P(p\text{-}C_6H_4CH_3)_3\}_6]^{2\oplus} \cdot 2\ [B(C_6H_5)_4]^{\ominus}$

(6a)

The structure was determined by X-ray analysis on *(6a)*. The Au—Au distance of *ca.* 300 pm in the cation is longer than in metallic gold!

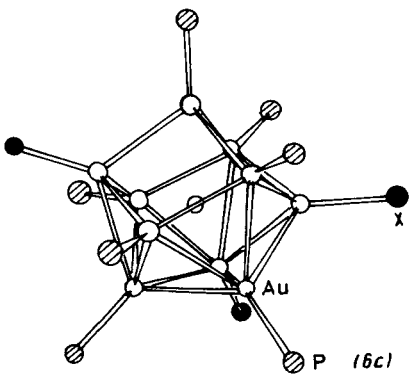
The same reduction, usually carried out (like many processes yielding gold colloids) with alkali tetrahydridoborates, affords products of composition $[Au_9L_8]^{3\oplus}\cdot 3X^{\ominus}$ as a further type of cluster. Once again the gold can be assigned an average oxidation state (+0.33), but structure *(6b)* shows one of the metal atoms to occupy a distinctive central position. The metal nucleation is clearly appreciated, even though the coordination is initially only 8. The Au—Au distance (*ca.* 276 pm) is already approaching that in the metal[14].



$[Au_9\{P(p\text{-}C_6H_4CH_3)_3\}_8]^{3\oplus}\cdot 3\ [PF_6]^{\ominus}$

(6b)

In clusters of formula $[Au_{11}L_7]^{3\oplus}\cdot 3X^{\ominus}$ a coordination number of 10 is achieved[15a], with Au—Au distances of *ca.* 270 (central) and 290 pm (peripheral) and an average oxidation number of only +0.27. The nucleation in *(6c)* has therefore almost reached the arrangement in the metal. Knowledge of the precise geometry of the atomic arrangement permits an approximative theoretical treatment of the electronic configuration[15b].



(6c)

The numerous complexes displaying direct contact between the atoms of *gold and other metals* also include clusters, of which those involving Li, Cu, or Zn warrant particular mention. The structures proposed contain metallic units reminiscent of the structural components of alloys[16a,b]:

$Au_2Zn_2(C_6H_5)_6$

$Au_2Li_2[C_6H_4CH_2N(CH_3)_2]_4$

$Au_2Cu_2[C_6H_4CH_2N(CH_3)_2]_4$

Analogous copper and silver compounds are also known[16c].

Discrete gold-transition metal bonds not leading to clusters occur in many carbonyl complexes. The following examples demonstrate that up to three gold atoms can be bonded to a metal center:

$(C_6H_5)_3P\text{–}Au\text{–}Fe(CO)_3NO$[17]

$[(C_6H_5)_3P\text{–}Au]_2Fe(CO)_4$[18]

$[(C_6H_5)_3P\text{–}Au]_3Re(CO)_4$[19]

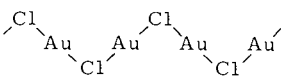
$(C_6H_5)_3P\text{–}Au\text{–}V(CO)_6$[20]

$(C_6H_5)_3P\text{–}Au\text{–}Mn(CO)_4P(OC_6H_5)_3$[21]

3. Compounds of Gold(I)

3.1. Simple Halides and Halo Complexes

Among the gold(I) halides, the chloride, bromide, and iodide have long been known, but only the structure of the last-mentioned halide had been adequately characterized[22]. Only very recently has the crystal structure of AuCl been studied in two laboratories and fully elucidated. X-Ray diffraction analysis of single crystals prepared by chemical transport indicated the angled chain structure, as also occurs in AuI; however, the bond angle at the chlorine is seen to be considerably greater, and the X—Au—X unit is expectedly considerably extended[23]:



Vibrational spectra in the long wave region were reported almost simultaneously which provide more detailed information about force constants and bond orders in gold(I) halides. The hitherto unmeasured bond angle at bromine in AuBr was also predicted[24,25].

Earlier indications for the existence of halo complexes $AuX_2^{\ominus}$ were confirmed by isolation and vibrational spectra of tetraalkylammonium salts such as $[(C_2H_5)_4N]^{\oplus}AuX_2^{\ominus}$, X = Cl, Br, I[26]. The same type of compound was studied in dimethyl sulfoxide solution by electrochemical methods[27]. An example of the X-ray elucidation of the linear triatomic $BrAuBr^{\ominus}$ unit is provided by the structure of bis(di-*n*-butyl-dithiocarbamato)gold(III) dibromoaurate(I)[28]. In contrast, it proved impossible to detect $AuX_2^{\ominus}$ in *molten* gold(I) and alkali halides. Pertinent melt studies of importance for electrochemical gold coating of surfaces resulted in disproportionation[29].

Gold(I) halides are good complexing agents. In recent years attention has been focused mainly on complexes with sulfur and phosphorus donor ligands. However, a facile new synthesis has also been found for the carbonyl complex first prepared over 50 years ago[30]:

$$H_3O^{\oplus}AuCl_4^{\ominus} + 2\ CO \xrightarrow{SOCl_2} 3\ HCl + SO_2 + COCl_2 + Au(CO)Cl$$

Although thermolabile, this carbonyl derivative, which readily dissolves in organic solvents, is a versatile starting material for the synthesis of other Au^I complexes since the CO ligand can be replaced with great ease[31]. The exceptionally short-wave ν(CO) absorption of the compound (2158 cm^{-1}) likewise indicates weak interaction between ligand and metal atom[30,31].

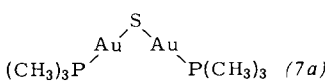
Gold-halogen vibrations were also closely examined specifically on pyridine complexes[32] and constitute an important part of most publications about sulfide and phosphane complexes.

The complex chemistry of gold with pseudohalogens has been surveyed only recently[33,34].

3.2. Sulfur Compounds

Early interest was shown in compounds of sulfur and gold because they were employed for thermal production of gold coatings on ceramics, porcelain, glass, and metal (and later also plastics). This concerns less the pure sulfides than organosulfur derivatives. Incidentally, gold is the only metal not to react directly with sulfur!

Apart from Au_2S, the nature of gold(I) sulfides and thiolates having the formula Au_2S_n and AuSR, respectively, remains largely unelucidated[35,36]. Valuable information has been obtained, though, from some phosphane complexes of these compounds. For instance, a well-defined bis(phosphane) complex of Au_2S *(7a)* is formed from trimethylphosphane-gold chloride and H_2S[37]. Closely related are the complex thiolates *(7b)*—*(7e)*[37–39].



(7a)

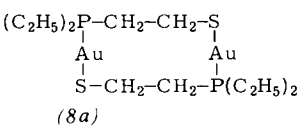
$(CH_3)_3P{-}Au{-}SC_2H_5$ *(7b)*

$(CH_3)_3P{-}Au{-}SC(CH_3)_3$ *(7c)*

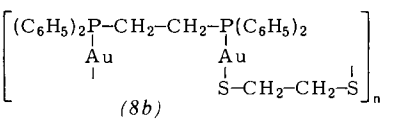
$(C_6H_5)_3P{-}Au{-}SCH_2C_6H_5$ *(7d)*

$(CH_3)_3P{-}Au{-}SCH_2CH_2S{-}Au{-}P(CH_3)_3$ *(7e)*

Compounds having the composition and presumed structure *(8)* have been prepared for therapeutic purposes[40]; *(8a)* has antiarthritic properties.



(8a)



(8b)

Gold(I) salts also form stable complexes with *thioureas*, which, having a ligand ratio of 1:2, are formulated as ionic compounds[41]:

$[(R_2N)_2CS{-}Au{-}SC(NR_2)_2]^{\oplus}X^{\ominus}$ R = H, Alkyl; X = ClO_4, BF_4, CH_3COO

They are of interest for analytical purposes. Analogous bonding has meanwhile been established for the classical *thiosulfate* complex *(9)* by X-ray analysis[42]:

$Na_3[O_3SS{-}Au{-}SSO_3] \cdot 2\,H_2O$ *(9)*

Like the corresponding silver complex, this coordination compound played an important role in the infancy of photography, for which products with gold toning were characteristic[43]. It was also used for treatment of arthritis, tuberculosis, and leprosy[44].

The complex chemistry of the Au^I ion with *thioethers* is extensive, but has so far provided few surprises. Numerous compounds have been characterized by spectroscopy, *e.g.* refs.[45–47]:

$R_2S{-}Au{-}X$ R = CH_3; X = Cl, Br; R = $CH_2C_6H_5$; X = Cl

Such gold complexes are of importance in the extraction of the noble metal[48].

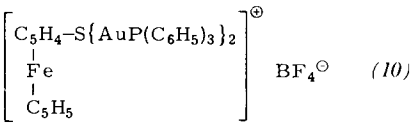
Another series of compounds is derived from *phosphane sulfides* and *selenides:* typical examples are[38,49,50]:

$(C_6H_5)_3PX \cdot AuCl$

$(C_6H_5)_3AsS \cdot AuCl$ X = S, Se

In the *gold/selenium/tellurium* system the new phases AuSe and Au_2SeTe were discovered[36].

Ferrocene thiolate occurs as a bridging ligand in the gold complex *(10)*[51].



(10)

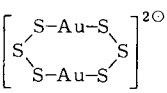
Gold atoms are also found as "ligands" of *chalcogenonium centers* in the complexes $[(LAu)_3S]^{\oplus}X^{\ominus}$, which are accessible with surprising ease *via* silyl sulfide precursors[52]. Triauriose-lenonium salts were obtained in similar manner[37]:

$$3\,R_3PAuCl + (CH_3)_3SiSeSi(CH_3)_3 \longrightarrow 2\,(CH_3)_3SiCl + [(R_3PAu)_3Se]^{\oplus}Cl^{\ominus}$$

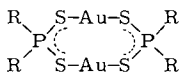
Unlike the silylthio derivatives, siloxy derivatives of Au^I do not suffer heterolysis to give oxonium salts[53]: compounds such as $R_3P{-}Au{-}OSi(CH_3)_3$, $R = CH_3, C_6H_5$, *etc.* are stable. However, *Nesmeyanov et al.* have described examples of triauriooxonium salts $[(R_3PAu)_3O]^{\oplus}X^{\ominus}$[54].

Bridged complexes having bidentate sulfur or selenium ligands

Monovalent gold has a pronounced tendency to form sulfur complexes, in which two metal atoms of coordination number 2 (and with linear configuration of their ligands) are components of an eight-membered ring. The oldest example, whose structure originally defied explanation[55], is probably the gold(I) trisulfide anion $AuS_3^{\ominus}$ shown by recent findings to require formulation as $Au_2S_6^{2\ominus}$:



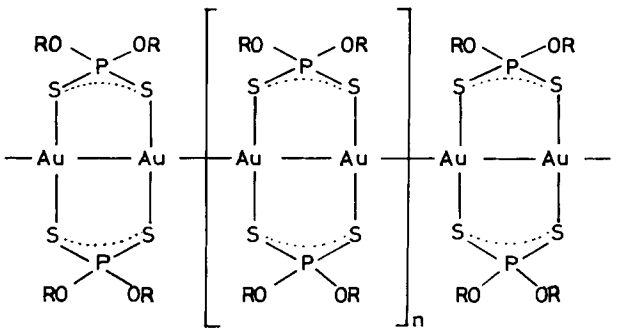
This compound was soon joined by Au^I *dithio-phosphates* and *-phosphinates* whose dimeric nature has been confirmed; X-ray data are also available[56].



(11), R = O-*i*-C_3H_7
(12), R = C_2H_5, C_3H_7, C_4H_9

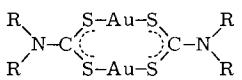
The dithiophosphates are suitable as additives to lubricants, being soluble in mineral oils and displaying novel lubricating phenomena by deposition of very fine noble metal coatings on mechanical and thermal stress. Crystal structure determination shows the diisopropyldithiophosphate *(11)* to be a

polymer containing a chain of gold atoms; like the dithiophosphinates *(12)* it exists as the dimer in solution[57].



Owing to their ready solubility and volatility, the dithiophosphinates *(12)* have been proposed for gas chromatographic isolation and detection of gold[58].

A second class of such sulfur complexes is found in the Au^I *dithio(or diseleno)-carbamates*. An example has also been subjected to X-ray analysis[59], and others to detailed analytical and spectroscopic studies[60–62].



The therapeutic potential of the thiophosphate and carbamate complexes has also been proposed for examination, but no final results have yet been published[2].

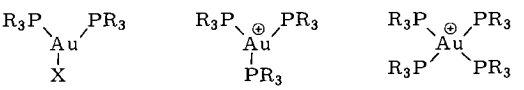
3.3. Phosphorus Compounds

In accord with present-day ideas of bonding in metal complexes, Au^I as a slightly charged, large, and easily polarizable metal ion forms particularly stable coordination compounds with phosphorus (and with sulfur). Very many complexes of this type are known, mainly with triorganophosphane ligands. Apart from the commonest types of compound

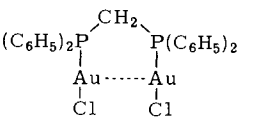
$R_3P–Au–X$

$[R_3P–Au–PR_3]^{\oplus}X^{\ominus}$

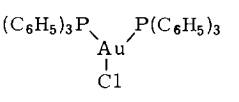
representatives having higher coordination numbers also exist[31]:



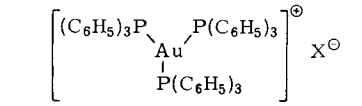
In the case of the simplest type R_3PAuX numerous new examples have been discovered in recent years[31,63–69]. The range of compounds extends from the complexes of phosphane itself (R = H)[70] *via* those of trialkyl-, triaryl-, and alkylarylphosphanes, to those of phosphites (R = OR') or aminophosphanes ($R = NR'_2$). These are supplemented by analogous arsane and stibane compounds. Halide, pseudohalide, carboxylate[71,72], and also carbaborane anions (*e.g.* 2,3-$B_4C_6H_7^{\ominus}$ and $B_{10}C_2H_{10}R^{\ominus}$, R = H, CH_3, C_6H_5)[73] may serve as ligand X[73]. The crystal structure of the 2:1 complex of AuCl with methylenebis(diphenylphosphane) has been elucidated[74a]. It shows a remarkably short Au—Au distance.



In compounds having *two* phosphane ligands, $(R_3P)_2AuX$, the structure is frequently dependent upon the environment. If X is a good leaving group then an ionic structure $[R_3P–Au–PR_3]X$ will be observed in the crystal, and certainly in solvating solvents[31,75]. In contrast, bis(triphenylphosphane)gold chloride *(13)* is not ionic in the crystal and contains Au^I having a coordination number of 3[76].



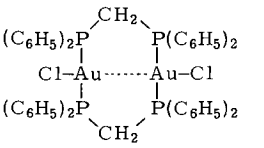
(13)



(14), X = B_9SH_{12}
(15), X = $Ta(CO)_6$

Trigonal-planar Au^I is also found in tris(triphenylphosphane)gold thiadecaborate *(14)*[77] and in the hexacarbonyltantalate *(15)*[78] whose structure has been confirmed by X-ray analysis. With less bulky phosphanes and large poorly coordinating ligands X even the $AuP_4^{\oplus}$ configuration may be achieved[31,78–80].

The 1:1 complex of AuCl and methylenebis(diphenylphosphane) has the structure of an eight-membered ring with weak transannular Au—Au interactions between trigonal planar metal atoms[74b]:



Triethylphosphanegold(I) chloride has recently been proposed for a hitherto unknown variant of gold therapy[81a]. It appears to display a number of important advantages over the sulfur compounds (thiomalate, thiogluconate, *etc.*) formerly used almost exclusively[81b]. The substance has a strong inhibitory action on mycoplasmic infections *in vitro*[82].

4. Gold(II) Compounds

4.1. Au^I/Au^{III} Compounds

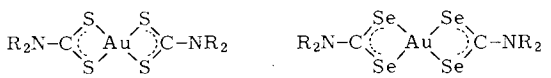
Compounds have long appeared in the literature in which gold formally has the oxidation number +2[83]. Meanwhile, it has been found that most of them are actually Au^I/Au^{III} combinations. Some representatives have been characterized by X-ray methods, and others by magnetochemistry or spectroscopy. In some cases simple analogies were sufficient:

Empirical formula	Structure
$AuSO_4$	$Au^IAu^{III}(SO_4)_2$
AuO, AuS	$Au^IAu^{III}O_2$, $Au^IAu^{III}S_2$
$Cs[AuX_3]$	$Cs_2[AuX_2][AuX_4]$; X = Cl, Br, I
$(C_6H_5CH_2)_2S \cdot AuX_2$	$(C_6H_5CH_2)_2SAuX$, $(C_6H_5CH_2)_2SAuX_3$
Au(Hdmg)Cl	$Au^IAu^{III}(Hdmg)_2Cl_2$
$(n\text{-}C_4H_9)_2NCS_2AuCl$	$[\{(n\text{-}C_4H_9)_2NCS_2\}_2Au]^{\oplus}AuCl_2^{\ominus}$

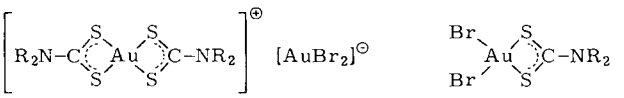
The presence of $Au_2^{4\oplus}$ in place of Au^I/Au^{III} has not been ruled out in the first two examples.

4.2. True Au^{II} Compounds

Recent studies have shown there to be four types of compounds qualifying as true gold(II) derivatives in which all the metal atoms have the same chemical environment. In addition to phthalocyanine-Au^{II}[84] ("AuPc") and an unusual carbaborane complex ("Au^{II} carbollide")[85], this class includes the *dithiocarbamates* of composition $Au(S_2CNR_2)_2$[86] first described in 1959. The uneven number of electrons (d^9 configuration of metal!) in these compounds, which are obtained by conproportionation of Au^I/Au^{III} or by reduction and oxidation, respectively, of Au^{III} and Au^I, has been detected primarily by ESR measurements. A bischelate structure is assumed, which probably also applies to the selenium analog[87].

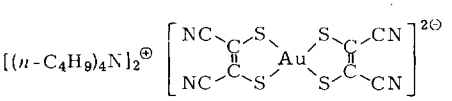


It should be pointed out that halodithiocarbamates such as *(16)* possess an Au^I/Au^{III} structure (cf. Section 4.1). The dihalodithiocarbamates have analogous configurations, *e.g.* *(17)*[28,88,89].



(16) *(17)*

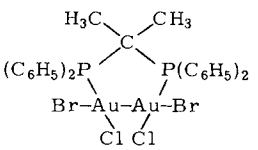
The fourth type of Au^{II} compound was discovered in the *cis*-1,2-dicyanoethylenedithiolates (*"maleonitriledithiolates"*), and is likewise accessible by a variety of synthetic approaches[90].



Identification was again accomplished by magnetochemistry and ESR spectroscopy [$\mu_{eff} = 1.85\ \mu_B$; $g = 2.009$, hyperfine splitting $A = 41.7$ G (^{197}Au: $I = 3/2$)]. Any remaining doubts as to the existence of true Au^{II} complexes were finally dispelled once the nature of these compounds had been established.

4.3. $Au_2^{4\oplus}$ Compounds

The AuCl complexes of methylenebis(phosphanes) undergo oxidative addition of one mole of halogen to yield formally a gold complex of oxidation state +II. Mössbauer and ESCA investigations have confirmed this proposal and the following formula is therefore assigned[91]:

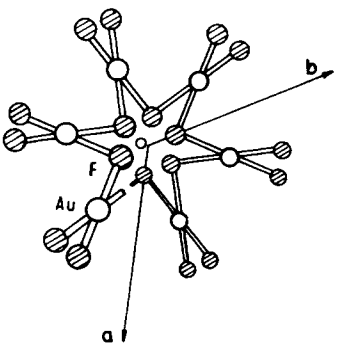


These products are diamagnetic, as expected, but a crystal structure determination has not yet been carried out. A new type of $Au_2^{4\oplus}$ compound is described in connection with organogold compounds (Section 7.5).

5. Gold(III) Compounds

5.1. Gold Trihalides and Their Halo Complexes

Gold forms trihalides only with fluorine, chlorine, and bromine. The structure of the trifluoride was long unknown. It was only the advent of modern improved methods of synthesis and single crystal growth, for which it is no longer a problem even with such a hard to handle substance as AuF_3, which permitted complete elucidation of its structure[92]. In contrast to the structure of the dimers of $AuCl_3$ and $AuBr_3$, this compound exists as helical polymers whose AuF_3 units are linked together *via* fluorine bridges:



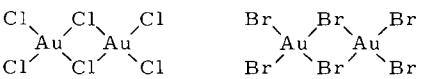
Gold trichloride, on the other hand, is dimeric in the solid state, in many solvents, and in the gaseous phase; it numbers among the most thoroughly studied compounds of gold[1]. A particularly convenient preparation was recently discovered[30]:

$$2\ H_3O^{\oplus}AuCl_4^{\ominus} + 2\ SOCl_2 \longrightarrow 2\ SO_2 + 6\ HCl + Au_2Cl_6$$

Furthermore, the first synthesis of a well-defined oxide halide AuOCl[93] has also been accomplished, and the enthalpy of formation of the oxide Au_2O_3 could be accurately determined[94]. Both compounds are hydrolysis products of the trihalides.

Gold(III) sulfide, selenide, and telluride halides are discrete phases in the gold/chalcogen/halogen system. Typical examples are AuSeCl, AuSeBr[95a,b], $AuTe_2Cl$, and $AuTe_2I$[95c]. In the gaseous phase, $AuCl_3$ and $FeCl_3$ form a complex $AuFeCl_6$[96].

The structure of gold tribromide, likewise a well-known compound, was determined only recently[97]; it closely resembles that of the trichloride.



Crystallographic data were also reported for $Rb[AuBr_4]$ and $Rb_2[Au_2Br_6]$[98].

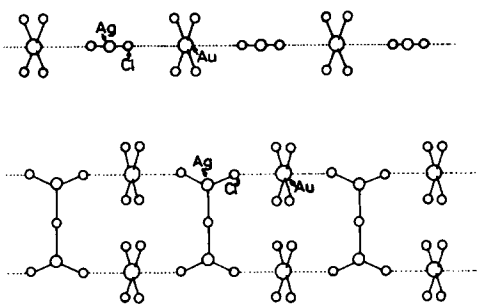
Such *haloaurate complexes*, and especially the tetrachloroaurate unit, are components of numerous salt-like compounds. Their structure and bonding are known[99-104]. $AuCl_4^{\ominus}$ will occur not only in crystalline compounds but also in molten salts[29].

Syntheses and structural elucidations of tetrafluoroaurates are almost all comparatively recent. The square-planar anion structure was confirmed for a series of alkali and alkaline earth salts. The potassium compound crystallizes in the $KBrF_4$ type[105].

$M^I[AuF_4]$ $\quad$ $M^{II}[AuF_4]_2$

M^I = Li, Na, K, Rb $\quad$ M^{II} = Mg, Ba

Among the mixed noble metal haloaurates, the particularly attractive structures of the complexes $Cs_2AuAgCl_6$ and $(NH_4)_6Au_3Ag_2Cl_{17}$ deserve special mention[106]:



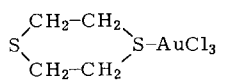
They are characterized by alternation of $AuCl_4^{\ominus}$ with $AgCl_2^{\ominus}$ and $Ag_2Cl_5^{3\ominus}$ groups [cf. also $Cs_2(AuCl_2)(AuCl_4)$ in Section 4.1].

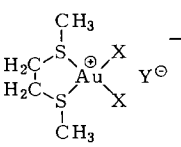
The mechanisms of reactions of the square-planar $AuCl_4^{\ominus}$ ion with various substrates have seen several attempts at elucidation; however, the individual reaction sequences often differ considerably[107-111] and thus defy generalization. Gold(III) pseudohalides have already been surveyed[33, 112, 113].

5.2. Compounds of Au^{III} with Sulfur, Phosphorus, and Other Elements

Gold(III) halides also form complexes with thioethers, but they are less stable than the gold(I) compounds. Fitting examples are[46, 47, 114]:

$(C_6H_5CH_2)_2S{-}AuCl_3$





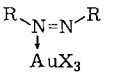
X	Y
Cl	$AuCl_4$
Cl	$AuCl_4 \cdot 2\ C_2H_5OH$
Br	Br
I	I

Corresponding coordination compounds exist with diphenylthiourea[115] and dimethyl sulfoxide[116], which is presumably coordinated *via* the S atom. The thiocarbamates[117], dithiomalonamides[118], and dithiooxamides[119] have already been mentioned in part[89].

Gold(III) *fluorosulfate* $Au(SO_3F)_3$, which does not strictly number among the gold-sulfur compounds, was synthesized just a few years ago; its structure has not yet been completely established[120].

As for other noble metals, an anhydrous *nitrato complex* of composition $[Au(NO_3)_4]^{\ominus}$ has also been obtained for gold[121]. The analytical data indicate the nitrato group to act as a unidentate ligand.

As expected, gold trihalides from stable complexes with nitriles[122], amines[123], phosphane oxides and sulfides[38, 124], and with triorganophosphanes. Trichloro(triphenylphosphane)gold has been studied by X-rays and shows the expected square-planar ligand arrangement[125]. In contrast to Au^I halides, those of Au^{III} also form complexes with azo compounds, which have an asymmetric structure[126]:



Older literature records the formation of "fulminating gold" on ammonolysis of tetrachloroauric acid. This complex reaction is currently being reinvestigated, and the stability constants of the Au^{III}-ammine complexes have been determined[127a] and the crystal structure of $[Au(NH_3)_4](NO_3)_3$ solved[127b]. The Au^{III} complexes of amino acids[128a, b], aldimines[128c], and tetracyclines[128d] cannot be discussed in the present report.

6. Gold(V) Compounds

Until a few years ago gold in the oxidation state +5 was unknown. Only in connection with the chemistry of noble gas halides did it become possible to accomplish the surprising synthesis of hexafluoroaurates(V); careful study left no doubt as to this new d^6 valence state of gold. Meanwhile, their synthesis is possible without the noble gas fluorides since other fluorination methods also lead to the desired result[129]:

$$AuF_3 + 2\ XeF_2 + 5\ F_2 \longrightarrow [F_5XeFXeF_5][AuF_6]$$

$$CsAuF_4 + F_2 \longrightarrow Cs[AuF_6]$$

$$AuF_3 + O_2 + 3/2\ F_2 \longrightarrow O_2^{\oplus}[AuF_6]^{\ominus}$$

The $AuF_6^{\ominus}$ ion is octahedral and corresponds to $PtF_6^{2\ominus}$ and other long-known analogous anions. Very recent work has extended the series of its salts to include $KrF[AuF_6]$[130]. Uncomplexed gold pentafluoride AuF_5 is formed as an orange powder on vacuum pyrolysis of the $KrF^{\oplus}$- or $O_2^{\oplus}$-hexafluoroaurates[130].

7. Organogold Compounds

7.1. Alkylgold(I) Complexes and Dialkylaurates(I)

Pure, not complex-stabilized alkylgold compounds RAu have not yet been isolated. However, the number of complexes derived therefrom is steadily increasing. A tabular summary of such triphenylphosphane complexes should underline the broad scope of the investigations performed so far[31, 131-136].

R—Au—PR'_3	R	R'	Ref.
	CH_3	CH_3, C_6H_5	[131a]
	C_2H_5, *n*-C_3H_7	C_6H_5	[134a]
	i-C_3H_7, *n*-C_4H_9	C_6H_5	[134a]
	s-C_4H_9, *t*-C_4H_9	C_6H_5	[134a]
	$(CH_3)_3CCH_2$	C_6H_5	[133, 134a]
	$(CH_3)_3SiCH_2$	C_6H_5	[132, 133]
	CH_3COCH_2	C_6H_5	[136a]
	CF_3	C_6H_5	[136b]

In addition to these examples the cyclopentadienyl compounds, which have been shown to possess a fluxional structure with an Au—C σ bond[137], also warrant mention. The ferrocene derivatives, in which the cyclopentadienyl group is also a constituent of the π-complex, represent an interesting variant of this compound type[138].

Nearly all the publications cited contain detailed information about the spectroscopic properties of the RAuL complexes[139]. The simplicity of their NMR spectra proved to be particularly useful in the study of their reactions[131,132,134,135].

It was already known that R—Au—L complexes react with alkylmetal compounds presumably forming $R—Au—R^{\ominus}$ anions[140]; however, these species could not be directly detected. Recent studies have now demonstrated that such products are stable both in the presence of stabilizing phosphane donors[141] and in solvate-free complexes[142] up to room temperature and even beyond. An example of the first-named case is:

$$CH_3AuP(C_6H_5)_3 + CH_3Li \longrightarrow (CH_3)_2AuP(C_6H_5)_3Li$$

The structure of the product is not accurately known[141]. If effective coordinative saturation of the lithium ion is ensured then the thermal stability increases sharply and salts are formed which are made up of linear dialkylgold anions and chelate cations, *e.g.*[142]:

$$[\{(CH_3)_2NCH_2CH_2N(CH_3)_2\}Li]^{\oplus}\,[CH_3-Au-CH_3]^{\ominus}$$

The compounds obtained in this way react with alkyl halides to form trialkylgold(III) complexes which decompose with reductive elimination of alkane under suitable conditions[141b,143]. They are therefore suspected to play a role in the formation of C—C linkages catalyzed by gold(I) salts, which start from alkylmetal compounds and alkyl halides[143]. Copper(I) salts are used more frequently for this reaction. The $R—Au—R^{\ominus}$ ions correspond to the neutral mercury compounds R—Hg—R.

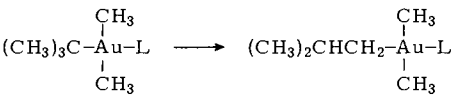
7.2. Oxidative Addition of Alkylgold(I) Complexes and Mechanistic Aspects

Methyl iodide reacts with methyl(trimethylphosphane)-gold(I), giving ethane and iodo(trimethylphosphane)gold(I) *via* unknown intermediates[144]. The initial step was interpreted as an oxidative addition to give an unisolable product. Subsequent investigations with other ligands then showed the reaction to take the following course[134b]:

$$CH_3Au\cdot L + CH_3I \longrightarrow (CH_3)_2AuI\cdot L$$
$$(CH_3)_2AuI\cdot L + CH_3Au\cdot L \longrightarrow (CH_3)_3Au\cdot L + L\cdot AuI$$
$$(CH_3)_3Au\cdot L \longrightarrow C_2H_6 + CH_3Au\cdot L$$
$$\overline{CH_3Au\cdot L + CH_3I \longrightarrow C_2H_6 + L\cdot AuI}$$

Thus CH_3AuL unexpectedly has a *methylating* action on the dimethylgold(III) iodide complex, giving the $(CH_3)_3Au$ complex which then decomposes with elimination of ethane. This final step is still unexplained, since pure $(CH_3)_3AuL$ is stable under the reaction conditions, and the by-products apparently catalyze its reductive decomposition[145].

Analogous reactions involving more complex alkyl groups attached to the gold atom can also lead to isomerization, mainly in the Au^{III} state[143]; one such process is the rearrangement of a *tert*-butyl group into an isobutyl group according to [143]:



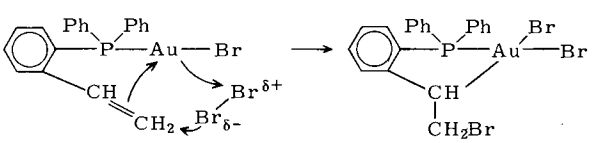
The rate of this rearrangement corresponds to a first-order reaction with respect to the concentration of complex, but is independent of the phosphane concentration [L]. Hence a predissociation to free L and trialkylgold is deduced. NMR measurements also suggested an associative mechanism to be unlikely for ligand substitution of R_3AuL complexes[131]; preparative experiments nevertheless demonstrated the ready substitution of L in the presence of an excess of competing ligands[131].

Alkylgold(I) complexes, but not alkylgold(III) complexes, surprisingly react with thiophenol by a radical mechanism[39,146].

7.3. Alkylgold(III) Complexes and Tetraalkylaurates(III)

Like free alkylgold(I) molecules, those of trialkylgold(III) are unknown. The number of complexes has rapidly increased, however, and many examples have been examined in detail. In addition to the $R_3Au\cdot L$ type itself[131,134,135], the monofunctional derivatives $R_2XAu\cdot L$ are particularly interesting; they generally exist as the *cis* isomers[147]. Most of these new compounds were obtained by conventional synthetic methods or as products of oxidative addition to alkylgold(I) complexes (cf. Section 7.2)[141–145].

A special case is seen in the formation of heterocycles by halogenation of an olefinic precursor and alcoholysis of the intermediate with ring expansion; this reaction is almost without precedent. The structure of these compounds has been established by X-ray methods[148].



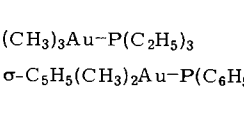
Tetraalkylaurates(III) have been synthesized in similar manner to the defined dialkylaurates(I). Coordinative saturation of the cation (Li^+) by polydentate ligands enhances the stability of the salts to such an extent that they can be isolated in pure form and can also be stored above room temperature[142]. The following formulas give some indication of typical alkylgold(III) compounds[132,149–151]:

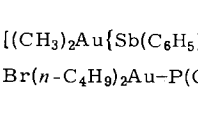
$(CH_3)_3Au—P(C_2H_5)_3$

$[(CH_3)_2Au\{Sb(C_6H_5)_3\}_2]^{\oplus}ClO_4^{\ominus}$

$\sigma\text{-}C_5H_5(CH_3)_2Au—P(C_6H_5)_3$

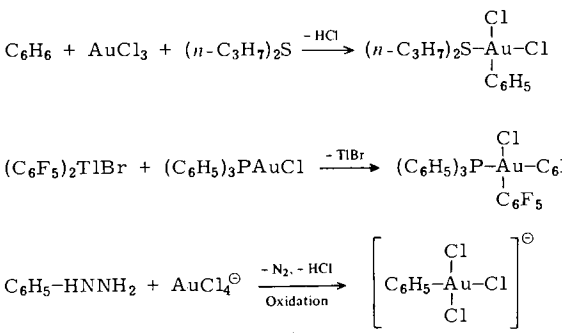
$Br(n\text{-}C_4H_9)_2Au—P(C_6H_5)_3$



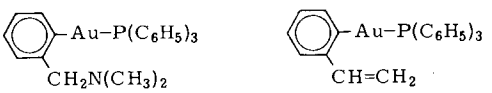


7.4. Arylgold(I) and -gold(III) Compounds

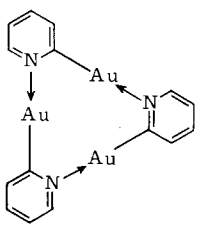
Arylgold compounds were practically unknown until very recently[3]; the first well-characterized examples date from 1972[152]. Meanwhile, considerable advances have been made in their preparation by improvement of the phenylation process[153-155], in particular by the use of phenylthallium reagents[156,157]. This applies above all to perhaloaryl derivatives. A selection of equations shows the synthetic methods used and the structures of the products, which have been confirmed in part by X-ray methods[158,159].



The first case is an example of the classical "auration" of aromatic compounds according to *Kharasch* and *Isbell*[160], which frequently gives poor results in other cases. Phenylgold(I) complexes such as $C_6H_5AuP(C_6H_5)_3$[155] were described by *Perevalova et al.*[155]. Their *ortho/para* substituted homologs display a pronounced thermal stability[161,162], *e.g.*



The structure of aurated pyridine[163], like that of 1-pyrazolylgold(I)[164] which is also trimeric, is a particularly attractive example of the wide range of structural variation.



7.5. Gold(I,II,III) Ylide Complexes

The considerable number of compound types and their manifold structural phenomena justify devotion of a separate section to the gold derivatives of phosphorus, arsenic, and sulfur ylides[165]. The compounds are distinguished by exceptional thermal stability and strongly modified chemical reactivity.

$CH_3-Au-CH_2-P(CH_3)_3$

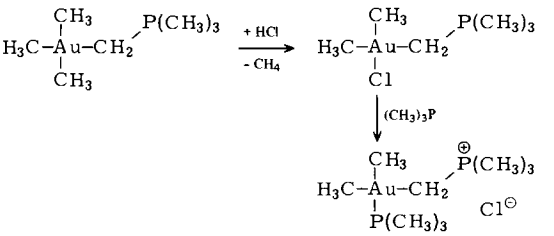
$(CH_3)_3Si-CH_2-Au-CH_2-P(CH_3)_3$

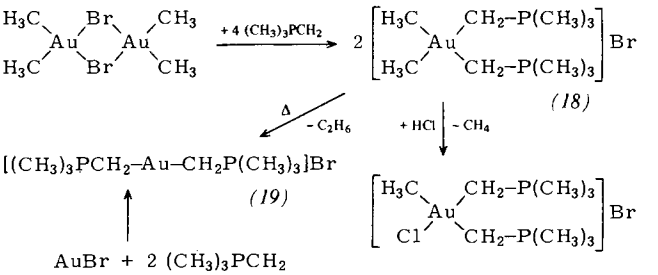
$[(CH_3)_3P-Au-CH_2-P(CH_3)_3]Cl$

$[(CH_3)_3P-CH_2-Au-CH_2-P(CH_3)_3]Cl$

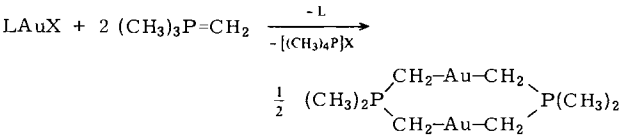
The prototype of this class is methyl(trimethylphosphoniomethylide)gold(I) and its homologs and the corresponding phosphane compounds and bis(ylide)gold salts[166a].

These substances arise from suitable gold(I) precursors by substitution of phosphane or halogen. Gold(III) ylide complexes are obtained analogously from trialkylgold components[166b]:

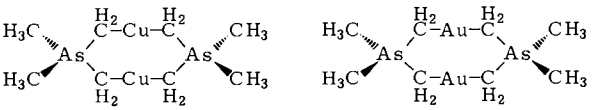




The bis(ylide)gold(III) salt *(18)* can be transformed into the bis(ylide)gold(I) salt *(19)* by thermally induced reductive elimination of ethane[166b]. A further type of gold-ylide complex is accessible by transylidation in the presence of an excess of ylide base. There result cyclic compounds in which two gold atoms have a linear arrangement of ligands[166c]:

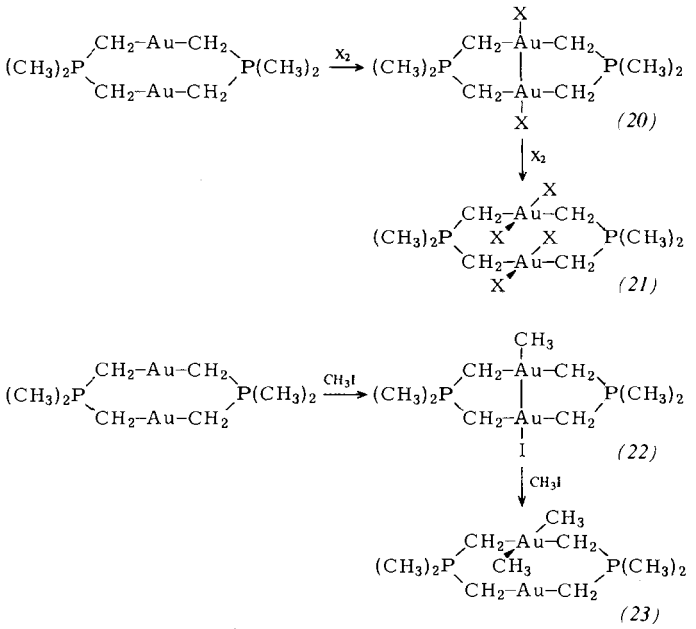


Such heterocycles have been prepared with various substituents on the phosphorus atom, and an arsenic analog has also been synthesized with $(CH_3)_3As{=}CH_2$[167]. The crystal structure of the corresponding copper compound is already known[168]. Recently, the structure of the ethyl-substituted gold analog was also determined[167].



On reaction with halogens, the above heterocycles initially afford bicyclic derivatives *(20)* having a transannular Au—Au bond[166c]. A crystal structure analysis is available for the ethyl compound[169]. Once again $Au_2^{4\oplus}$ units, and thus gold atoms in the formal oxidation state +2 (cf. Section 4.3), are encountered. On treatment with methyl iodide, oxidative addition proceeds as with halogen to give a product *(22)* which yields *(23)* on methylation[166c].

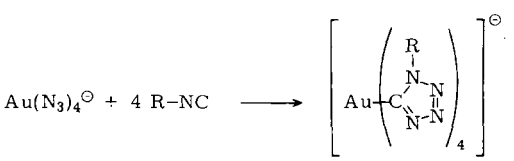
Further halogenation of the dihalides *(20)* finally results in rupture of the Au—Au bond to give the Au^{III} heterocycle

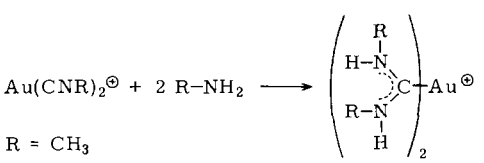


(21). Mössbauer and ESCA spectra confirm the different valence states of the metal atoms in the products *(20)* and *(23)*[170].

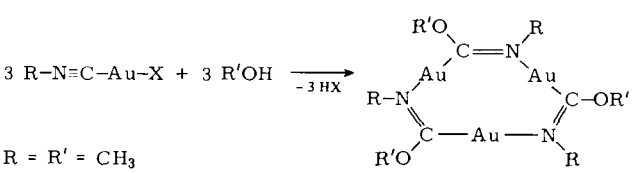
7.6. Carbene Complexes of Gold

In the course of the rapidly developing chemistry of metal-carbene complexes, Au^{I} and Au^{III} have been examined to establish their suitability as coordination centers for carbenoid ligands. Thus was born a new subdiscipline of organogold chemistry. The first examples of such compounds were obtained by addition reactions with isocyanides[171,172] or their complexes[173-175]:

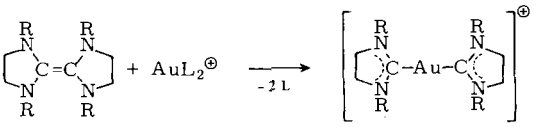




X-Ray structural data are available for all types[171b,176]. Monoisocyanide complexes form cyclic products with alcohols[177]:



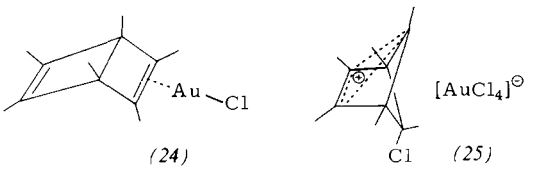
A new synthetic procedure for carbene complexes, as shown in the following equation, is applicable to many metals and gives very good yields in the case of Au^{I}[178]:



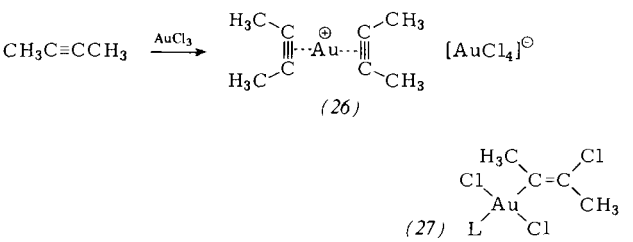
7.7. Reactions of Alkenes and Alkynes with Gold Compounds

Studies by *Hüttel et al.*[179] have shown that above all gold(I) salts can form π-complexes with a whole series of olefins, some of which display pronounced stability. These findings have mainly been surveyed on an earlier occasion[3].

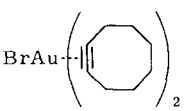
In more recent studies, interest has been focused on more specific problems, *e.g.* on the reaction between hexamethyl-Dewar benzene and gold trichloride, which leads to an AuCl complex *(24)* of the hydrocarbon and to the tetrachloroaurate of its monochlorination product *(25)*[179b].



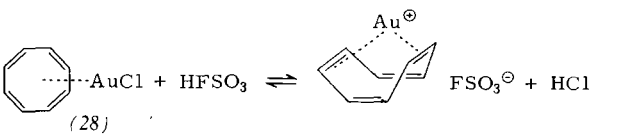
The interaction of acetylenes with gold halides leads in the case of dimethylacetylene[180] to π-complexes, *e.g. (26)*, which, however, rearrange into σ-compounds such as *(27)* under mild reaction conditions.



Cyclooctyne reacts with AuBr to give a 2:1 complex of unknown structure which possesses a remarkably high stability[181].



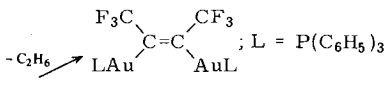
Cyclooctatetraene forms only a very weak complex *(28)* with AuCl; its formation constant was determined as $K = 9.1$ l/mol[182]. Its reaction with fluorosulfuric acid gives a presumably ionic product:



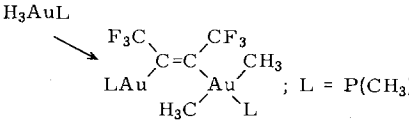
(28) and $AuCl_3$, as well as COT and $AuCl_3$ (with partial reduction to AuCl), give an unstable complex of composition $COT \cdot Au_2Cl_4$, whose Mössbauer spectrum clearly reveals the Au^{I}/Au^{III} combination; an unequivocal structure could not yet be assigned[182].

In the case of fluoroolefins practically no π-coordination occurs, either with Au^{I} or with Au^{III}—instead insertion or elimination is observed in all cases reported so far[183]:

$C_2F_4 + CH_3AuL \longrightarrow CH_3CF_2CF_2AuL$



$CF_3{-}C{\equiv}C{-}CF_3 + 2\ CH_3AuL$



In the last example, the structure of the reaction product was proved by X-ray analysis and by Mössbauer spectroscopy[184a] after other proposals had originally been put forward[184b].

With $CF_3C{\equiv}CH$, CH_3AuL and $(CH_3)_3AuL$ give the products $LAu{-}C{\equiv}C{-}CF_3$ and *cis*-$(CH_3)_2AuL{-}C{\equiv}C{-}CF_3$, respectively[184b].

The examples of olefin/gold interaction listed above suggest that this metal could also assume a role as a catalyst in olefin reactions. Indeed, strong supporting evidence is already available, for example in the electrooxidation of ethylene at gold electrodes[185]. Current-carrying gold surfaces also catalyze the air-oxidation of propene, the reaction displaying considerable selectivity[186]. Tetrachloroauric acid on a silica support catalyzes the hydrogenation of olefins[187]. Hydrogenation of ethylene is catalyzed by $HAuCl_4$ in the presence of SbX_5[188].

The recently synthesized gold(I) ketenide Au_2C_2O[189] also appears to show a catalytic activity[190] resembling that of gold(I) acetylide[191].

A final example of a pronounced catalytic activity of gold has been obtained very recently. A gold film condensed onto a support material catalyzes hydrogen/deuterium exchange of alkylsilanes at as low a temperature as 195 K[192]. Surprisingly, however, this effect disappears at room temperature!

In conclusion, reports should also be mentioned according to which microorganisms are capable of enzymatic dissolution of elemental gold, and could therefore be made responsible for leaching out gold-bearing rock and enriching the metal in concentrated deposits. This "bioorganic aspect" again shows the kind of surprises to be expected in gold chemistry.

Hormone Receptors

By Klaus Lübke, Ekkehard Schillinger, and Michael Töpert[*]

Corpora non agunt nisi fixata — *Paul Ehrlich (1845—1915)*

Hormone receptors are proteins located on the cell membrane or in the cell cytoplasm. Their function is to recognize and bind the respective hormone; the biological action of the hormone originates from the hormone-receptor complex. Specific receptors have been found for all known hormones. Monitoring the equilibration between hormone, receptor, and hormone-receptor complex ("determination of receptor binding") permits quantitative determinations of hormones, allows the characterization of endocrinal disturbances, and contributes to the elucidation of structure-affinity relationships.

1. Introduction

A common feature of all hormones is their participation in the control of biological processes. Hormones function by transmitting information which leads to a triggering of cell-specific activities. They can only fulfil the role of a "first messenger" if recognized by their target organs and distinguished from other compounds. A decisive step in the recognition process is the binding of the hormone to its receptor (a protein). The biological activity of a hormone (or a hormone analog) is determined by the concentration of the hormone-receptor complex at the site of action and by the intrinsic activity[1, 2] of the complex. The concentration of the hormone-receptor complex depends upon the availability of the hormone at the site of action and upon its affinity for the receptor (Fig. 1).

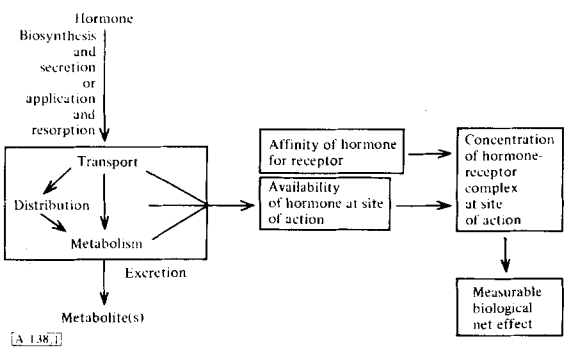

Fig. 1. Factors affecting the concentration of the hormone-receptor complex, and hence the biological activity, *in vivo*.

The hormone-receptor complex may be formed on or inside the cell. In the former case the hormone finds its specific receptor on the surface ot the cell membrane. There is no need for it to penetrate into the cell; instead it triggers an intracellular process by binding to the membrane-bound receptor. In the latter case the hormone does have to penetrate into the cell before a hormone-receptor complex can be formed. The former group includes all peptide and proteohormones, the biogenic amines, and the prostaglandins, while the latter group comprises all steroid hormones, thyroxine, and triiodothyronine.

Müllerstrasse 170–178, D-1000 Berlin 65 (Germany)

2. The Hormone-Receptor Complex

The existence of specific hormone receptors and their importance in hormone action were postulated long ago[3]. However, experimental detection of the receptors, present only in very low concentration, was long thwarted by the lack of suitable experimental methods, and only became possible once hormones could be labeled with sufficiently high specific radioactivity. In the early 1960's *Jensen et al.* used tritium-labeled estradiol to characterize the first cytoplasmic (intracellular) hormone receptor[4]. A few years later *Cuatrecasas*[5], *Lefkowitz et al.*[6], and *Goodfriend et al.*[7] were able to detect the first membrane-bound receptors using ACTH, insulin, and angiotensin, respectively, labeled with radioactive iodine. Specific receptors were subsequently reported for all hormones and concepts formulated for hormone-receptor binding and its significance for hormonal action.

2.1. Definition of the Hormone Receptor

A hormone receptor has to fulfil a number of requirements[8]:

1) The specificity of the receptor must be very high and comply with known structure-activity relations.

2) The number of binding sites must be limited.

3) The occurrence of receptors in various tissues should correlate with the response of the respective tissue to the hormone.

4) Owing to the very low physiological concentrations of hormones the receptor must have a high affinity for the hormone.

5) Hormone-receptor binding must be reversible in order to terminate the physiological effect and permit fresh stimulation.

It is important to distinguish between receptor binding, characterized by high affinity with low capacity, and non-specific binding to other hormone-binding proteins. The latter typically exhibits a low affinity at very high capacity.

2.2. Membrane-Bound Hormone Receptors

The intracellular sequence of reactions triggered by binding of a hormone to its membrane-bound receptor is determined not by the hormone but rather by the properties of the cell. Thus adrenocorticotropic hormone (ACTH) and interstitial cell stimulating hormone (ICSH, LH) stimulate the same reaction, *viz.* conversion of cholesterol into pregnenolone (3-hydroxy-5-pregnen-20-one). The fact that different end products are formed (mainly corticoids in the adrenal cortex and mainly androgens, estrogens, and gestagens in the germ cells) is attributable to the specific enzymatic pattern of these cells (Fig. 2).

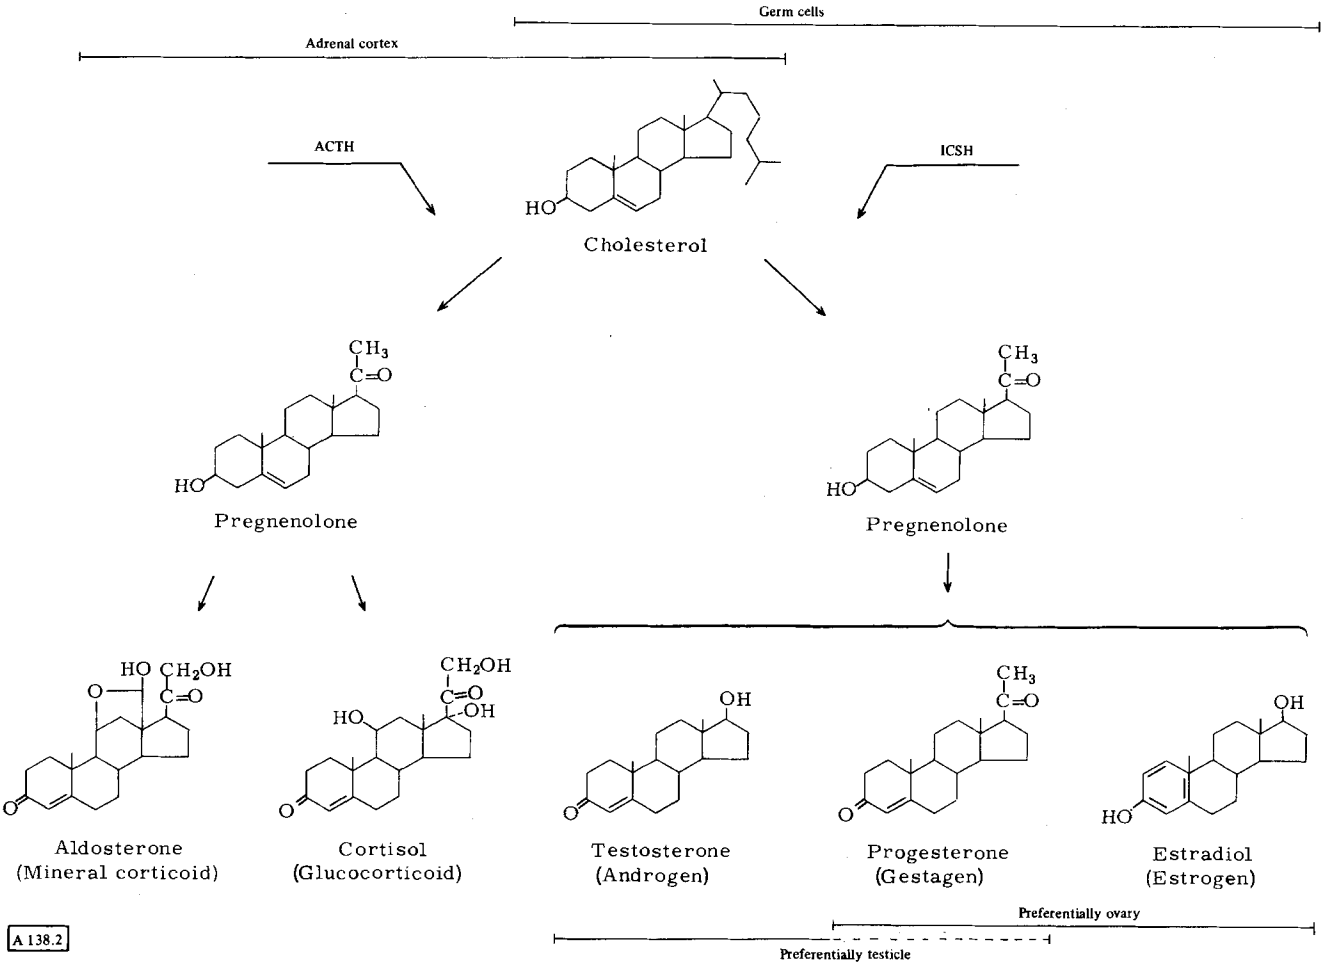

Fig. 2. Hormonal stimulation of steroid production in the adrenal cortex and in the germ cells (according to ref. [7a]). ACTH, adrenocorticotropic hormone; ICSH, interstitial cell stimulating hormone.

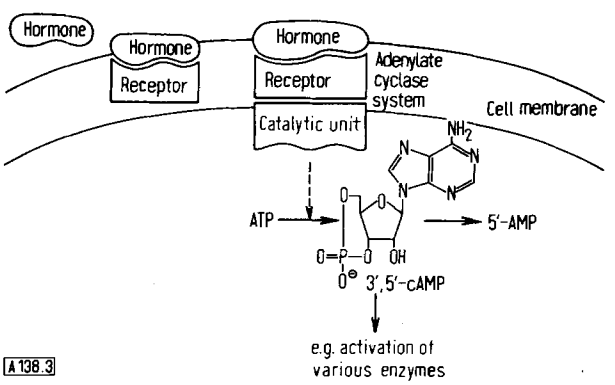

Fig. 3. Scheme of hormone action *via* a membrane bound receptor.

The intracellular processes are controlled by a "second messenger". In many cases this role is fulfilled by cyclic 3',5'-adenosine monophosphate (3',5'-cAMP) (Fig. 3). However, 3',5'-cAMP can only be produced from ATP once the enzyme adenylate cyclase has been activated. *Cuatrecasas*[8] has postulated that the receptor and the enzyme initially occur separately in the membrane. It is then the hormone-receptor complex which combines with the enzyme and effects its activation.

2.3. Cytoplasmic Hormone Receptors

Binding of the hormone to a cytoplasmic (intracellular) receptor requires that the hormone penetrates into the cell. Whereas a simple diffusion was formerly assumed to be responsible, evidence now exists that transport into the cell is a specific process, possibly controlled by membrane-bound proteins[9]. The hormone-receptor complex is first formed within the cell and, after activation, can penetrate into the cell nucleus (Fig. 4). This activation is temperature-dependent and linked with a change in the sedimentation constant[10]. Several models have been proposed to account for formation and activation of the complex, *e. g.* involving allosteric processes, dimerization of the hormone-receptor complex, and its aggregation with other proteins. An acceptor specific for the hormone-receptor complex is assumed to exist in the cell nucleus, which, for example, effects synthesis of the proteins important for hormonal action *via* transcription and translation by switching off a repressor.

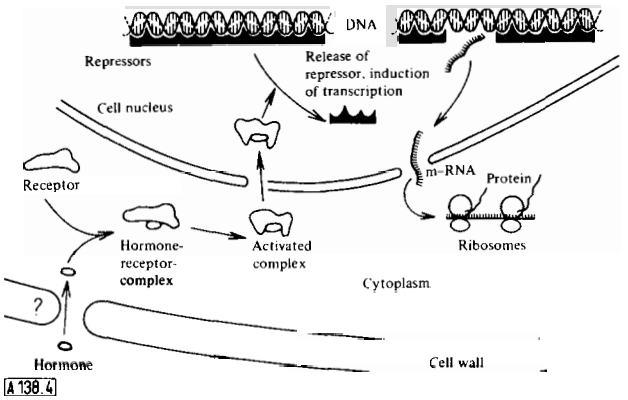

Fig. 4. Scheme of hormone action *via* a cytoplasmic receptor

3. Formation of the Hormone-Receptor Complex

Studies on the formation of the hormone-receptor complex should take into account the following theoretical and practical problems.

3.1. Formation of the Hormone-Receptor Complex as an Equilibrium Reaction

To understand hormone(H)-receptor(R) binding it is sufficient to consider the following two equilibria for membrane-bound receptors (a) and cytoplasmic (intracellular) receptors (b) respectively:

a) Membrane-bound receptor

$$H + R \rightleftharpoons H{-}R \xrightleftharpoons[\text{Cyclase}]{} H{-}R{-}\text{Cyclase}$$

b) Cytoplasmic receptor

$$H + R \rightleftharpoons H{-}R \rightleftharpoons H{-}R_{\text{activated}}$$

These are formation of the hormone-receptor complex H – R (for a and b) and activation of the cyclase system (cf. Fig. 3) for (a) and temperature-dependent activation of the hormone-receptor complex (cf. Fig. 4) in case (b). Depending on the kind of binding assay and on the experimental conditions, either the first equilibrium only or more or less the sum of the two equilibria will be determined.

3.2. "Direct" Determination of the Receptor Binding

If the hormone or hormone analog is present in radioactively labeled form then its binding to the receptor is open to direct measurement. The readily measurable concentrations of the hormone-receptor complex (H – R) and of the free hormone (H) are preferentially used as variables. Graphic representations of complex formation leading to straight lines are of considerable advantage (Fig. 5)[11]. Slope and intercepts permit calculation of binding parameters. Most frequent use is made of the equation reported by *Scatchard*[12] (cf. also Fig. 5e), which is derived as follows:

$$H + R \rightleftarrows H{-}R \text{ and } \frac{[H-R]}{[H][R]} = K$$

Putting

$$[R] = [R_0] - [H-R]$$

then

$$\frac{[H-R]}{[H]\cdot([R_0]-[H-R])} = K$$

or

$$\frac{[H-R]}{[H]} = K\cdot([R_0]-[H-R])$$

$$\frac{[H-R]}{[H][R_0]} = K\cdot\frac{[R_0]-[H-R]}{[R_0]}$$

$$\frac{[H-R]}{[H][R_0]} = K\cdot\left(1-\frac{[H-R]}{[R_0]}\right)$$

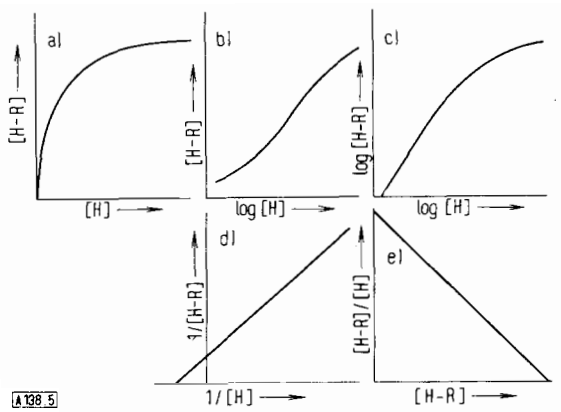

Fig. 5. Plot of formation of the hormone-receptor complex (H – R). a) [H – R] = f[H]; b) [H – R] = f(log[H]); c) log[H – R] = f(log[H]); d) 1/[H – R] = f(1/[H]); e) [H – R]/[H] = f([H – R]) (plot according to *Scatchard*).

In practice, the overall concentration of receptor $[R_0]$ is used instead of the generally unknown concentration of free receptor [R]; $[R_0]$ is assumed to be proportional to the readily measurable concentration of protein. The slope of the straight line gives the affinity constant K, and the intercept with the abscissa provides a measure for the number of binding sites.

Application of the law of mass action requires that the measurements be performed below the saturation range of the receptor (Fig. 6). After equilibration, the free and receptor bound hormone are separated and assayed. The receptor concentration in a preparation is normally of the order of $<10^{-8}$ mol/l. Determination of such low concentrations is only possible with hormones having specific activities of more than 10 Ci/mmol. Tritium and, in the case of proteohormones, iodine isotopes are used in practice. The presence of one or more tritium atoms in a molecule has hardly any effect on its affinity for a receptor. However, incorporation of an iodine atom, having roughly the same size as a benzene ring, may well modify the stereochemistry and physical chemistry of the molecule and thus impair its affinity towards the receptor. The situation is further complicated by the fact that

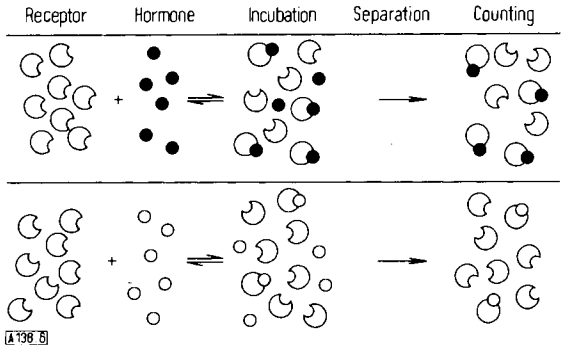

Fig. 6. Schematic representation of "direct" measurement of receptor binding. ●, hormone with high affinity; ○, hormone with slight affinity for the receptor.

more than one amino acid may be iodinated in most proteohormones. Hence the presence of several analogs displaying various degrees of iodination, and possibly different affinities for the receptor must be expected, together with non-iodinated hormone. The synthesis of analogs of insulin mono-iodinated at various sites demonstrated that these derivatives may cover the entire spectrum from inactive to fully active[13-15].

Graphical representations permit scrutenization of theoretical binding models by comparison of calculated and experimental plots. Thus a Scatchard plot in which an increase up to a maximum precedes the linearly decreasing range indicates a cooperative effect in complex formation (Fig. 7a).

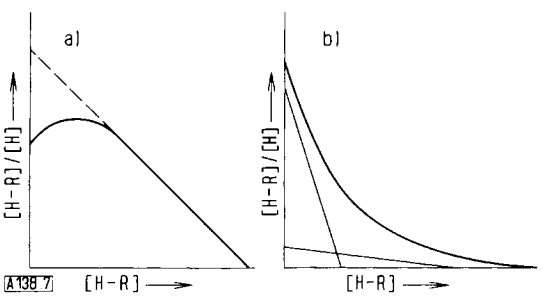

Fig. 7. Scatchard plot, a) for cooperative binding and b) in the presence of two binding sites.

The Scatchard equation occasionally results in a continuous curve. This can be attributed to the presence of more than one binding site. Such curves can be resolved graphically[16] or by computer iteration into two or more straight lines (Fig. 7b). In this way two binding sites have been demonstrated for many hormones such as insulin and prostaglandins[17, 18].

A non-linear Scatchard curve may also arise because a mixture of compounds having different affinities was present instead of a homogeneous hormone. This is to be expected primarily with iodinated proteohormones[19, 20].

In the "direct" measurement of receptor binding it must be assumed that not only formation of the hormone-receptor complex but also the second equilibrium—activation of the cyclase system or of the cytoplasmic receptor complex—are also monitored. The resulting apparent association constants are then too high.

3.3. Determination of Hormone-Receptor Binding by the Method of Competitive Protein Binding

The method of competitive protein binding must be used if the test substance (hormone or hormone analog) is not present in radioactively labeled form. This technique requires a radioactively labeled reference substance. The proportion of reference sample bound by the receptor is reduced by the test substance (Fig. 8). This reduction of receptor binding is termed competition. It depends upon the concentration

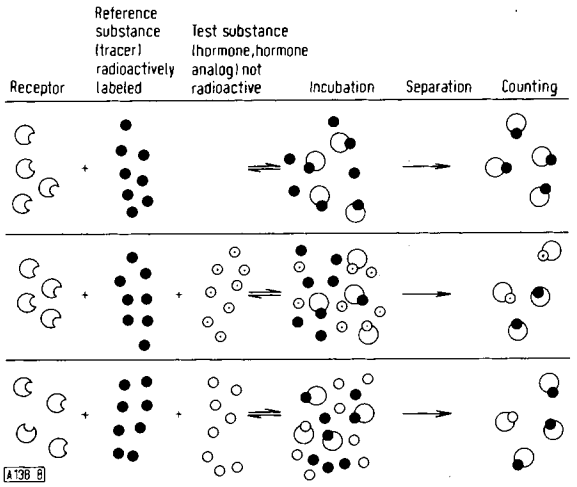

Fig. 8. Schematic representation of competitive determination of receptor binding. ●, radioactively labeled reference (tracer); ⊙, nonradioactive test substance (hormone) having the same affinity for the receptor as the reference substance; ○, nonradioactive test substance (hormone) having less affinity for the receptor than the reference substance.

of sample and upon its affinity towards the receptor. In contrast to the "direct" determination of binding, the measurements must be performed in the saturation range of the receptor. After incubation, the binding sites of the receptor are saturated; the subsequent reaction (activation of the cytoplasmic hormone-receptor complex or of the cyclase system) should therefore have no effect on the ratio in which reference substance and the sample are bound.

The competition curves obtained for varying concentrations of sample at constant concentration of reference substance have a sigmoidal shape typical for protein binding. They can be linearized within a wide range, for example by the logit-log transformation originally developed by *Rodbard* for radioimmunoassays[21] (Fig. 9).

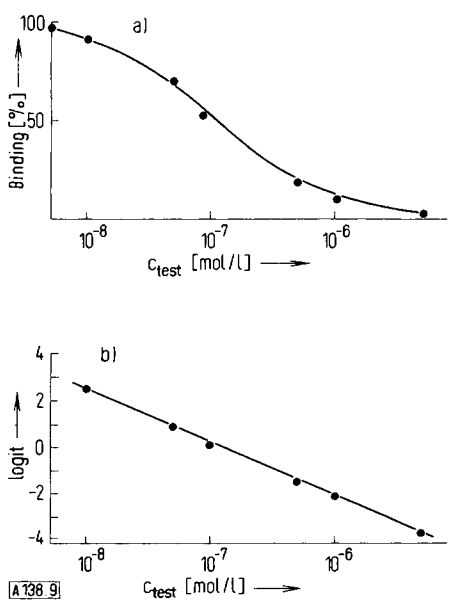

Fig. 9. a) Competition curve and b) its linearization by logit-log transformation according to *Rodbard* [21]. $\ln[\%\text{ binding}/(100-\%\text{ binding})] = f(\log c_{test})$. c_{test} = concentration of test substance.

A drawback of the method of competitive protein binding is that the competition curves obtained for several samples with the same receptor are often not parallel. The relative affinity therefore cannot be calculated simply from these competition curves. Considerable experimental and mathematical effort would be required. In practice, this problem is circumvented by relating arbitrarily selected points on these curves, usually that of 50 % competition, with one another. Experience gained with non-parallel competition curves can be confirmed by simulation on an analog computer and by calculation of such curves[22] (Fig. 10).

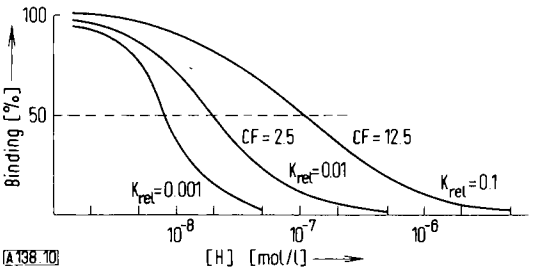

Fig. 10. Competition curves obtained by simulation on an analog computer. K_{rel} = relative association constant (given), CF = competition factor. See text for details.

The three curves which were calculated for relative dissociation constants (K_{rel}) of 0.1, 0.01, and 0.001 are not parallel. Moreover, the concentrations determined for 50 % competition are not in the ratio 1:10 and 1:100, but 1:2.5 and 1:12.5. These values should therefore not be designated as relative affinities. Instead the term "competition factor" (CF) has been proposed. It is defined as the ratio of the concentration of the test sample (c_{test}) and that of the reference substance ($c_{ref.}$) required for 50% competition:

$$CF = \frac{c_{test} \text{ at } 50\,\% \text{ competition}}{c_{ref.} \text{ at } 50\,\% \text{ competition}}$$

4. Receptor Preparations

Receptor preparations are preferentially obtained from typical target organs of the respective hormone. For some hormones several kinds of tissue are suitable (Table 1).

Table 1. Tissues suitable for receptor preparations.

Hormone	Tissue
ACTH (adrenocorticotropic hormone)	Adrenal cortex
Calcitonin	Kidney, bone, lymphocytes
Glucagon	Liver, pancreas, adipose tissue, heart
Gonadotropins:	
HCG (human choriongonadotropin)	Testes, ovary
LH, ICSH (interstitial cell stimulating hormone)	Testes, ovary
FSH (follicle stimulating hormone)	Ovary
Insulin	Liver, adipose tissue, lymphocytes, muscle
Catecholamines	Myocardium, liver, erythrocytes, uterus, adipose tissue, brain
Oxytocin	Frog skin, mamma, adipose tissue, uterus
Prolactin	Mamma
Prostaglandins	Uterus, ovary, adipose tissue, liver, kidney, adrenal cortex, thyroid, thrombocytes

The choise of tissue often depends upon the problem to be solved. Thus the relationship between insulin and lipid metabolism are best studied with receptors of fat cells or of the liver. The choice of animal species can also be important. For instance, considerable concentration differences could be established for corticoid receptors[23] in various species (Table 2).

Table 2. Concentration of corticoid receptor in rat and rabbit tissue.

Tissue	Juvenile rat	Juvenile rabbit
	[pmol receptor/mg protein]	
Liver	0.64	0.12
Skeletal muscle	0.06	0.03
Heart	0.26	0.13
Brain	0.19	0.12
Kidney	0.23	0.16
Testes	0.15	0.22
Thymus	0.45	0.65
Lung	0.02	0.53
Stomach	0.08	0.19
Spleen	0.07	0.27

Isolation of a receptor is extremely difficult. Therefore crude receptor preparations are frequently used. The procedure for cytoplasmic receptors is relatively simple. The cytosol available after homogenization of the tissue and centrifugation is employed almost exclusively as sample preparation.

The preparation of a membrane-bound receptor offers more variation. Reports have been published using intact discrete cells (*e.g.* erythrocytes, lymphocytes) or cells liberated from tissue by treatment with proteolytic enzymes (liver cells, fat cells, *etc.*). Use of intact cells often permits examination of subsequent biological reactions, *e.g.* activation of the adenylate cyclase system, parallel to hormone binding studies. Rather impure membrane fractions are often employed as receptor preparations instead of intact cells. Membrane-bound receptors have also been successfully solubilized by treatment with preferably nonionic detergents, without significantly affecting the binding. However, it has yet to be proved that such a soluble hormone-receptor complex still has a biologically relevant intrinsic activity after reconstitution.

5. Receptor-Binding Assay

The receptor preparation must be incubated with the hormone under conditions ensuring stability of the receptor and equilibrium (see Sections 3.1). Experiments with the rather unstable soluble (cytoplasmic) receptors are usually performed between 4 and 15 °C, rarely at higher temperatures. Incubation of the more stable membrane-bound receptors are often carried out at room temperature, and sometimes at 37 °C. Equilibrium is generally reached within a few minutes to several hours. Separation of free and receptor-bound hormone requires special attention; it should be performed under conditions where dissociation of the hormone-receptor complex is minimal. A compromise usually has to be met between optimal separation and time-saving performance.

Different separation techniques are described in the available literature. Density differences are exploited in separation by ultracentrifugation[23a]. For larger differences in density, *e.g.* for membrane fractions or intact whole cells, low speed centrifugation will suffice[40]. A particularly elegant

method for fat cells consists in floatation through an oil layer of intermediate specific gravity[23b]. Separation by molecular size can be accomplished with membrane filters[23c] or by gel chromatography[23d]. Charge differences are utilized in gel electrophoresis[23e]. Separation is also possible by binding the free hormone to adsorbents. These adsorption procedures, specifically with dextran-coated activated charcoal, find frequent application. They do have the drawback, however, that the pronounced affinity of the adsorbent for the hormone can interfere with the equilibrium. In all separations it is advisable to work at low temperature to suppress dissociation of the hormone-receptor complex.

6. Applications of the Receptor-Binding Assay

Having discussed the theoretical and methodological principles of the receptor-binding test, its applications will now be discussed (with the aid of selected examples).

6.1. Radioreceptor Assay as a Method of Quantitative Hormone Determination

Like a radioimmunological assay[22a], the radioreceptor assay can be used for determining hormone concentrations in tissue samples and body fluids. A hormone-specific receptor preparation is used instead of antibodies.

Whereas a radioimmunoassay will embrace structurally similar compounds, irrespective of their biological activity, a radioreceptor assay will register all substances having the hormone-specific biological activity, regardless of whether they are structurally related to the original hormone.

The generally low stability of the receptors compared with the immunoglobulins can be a handicap. This is particularly true for cytoplasmic receptors; the only assay so far reported with these receptors is one for estradiol[24]. Assays with the more stable membrane-bound receptors have been described for ACTH[25], glucagon[26], insulin[27], growth hormone[28], and the gonadotropins[29-31] and prostaglandin E_2[32]. Based on the receptor assay for HCG (human choriongonadotropin), an extremely sensitive pregnancy test has been developed which can already detect a pregnancy six to eight days after conception[33].

6.2. The Receptor-Binding Assay for Characterization of Endocrine Disturbances

In some cases it has been possible to correlate endocrine disorders with the receptor content of the relevant tissue. The relationship between disturbances of carbohydrate and lipid metabolism and the content of insulin receptors has been studied particularly thoroughly. In the carbohydrate and lipid metabolism of man and animals several pathological states are characterized by an increased or diminished insulin level in the plasma[34]. The concentration of insulin receptors measured in such cases appears to be inversely correlated with the insulin concentration (Table 3). Thus it was deduced that insulin itself regulates the receptor concentration. At high insulin levels the equilibrium will be shifted strongly in favor of receptor-complex formation. Therefore, a low number of receptor molecules will suffice for the full biological activity of insulin. Conversely, at low insulin concentrations

Table 3. Relationship between insulin concentration in the plasma and insulin receptor concentration (measured in various tissues) in endocrine disorders. ↑, increased; ↓ decreased concentration.

	Insulin concentration	Receptor concentration
Man:		
Obesity	↑	↓
Obesity + Diet	normal	normal
Maturity-onset diabetes	normal or ↑	↓
Maturity-onset diabetes + Sulfonylurea	normal	normal
Animal:		
Diabetes		
(Chinese hamster)	↓	↑
Hypophysectomy	↓	↑
Adrenalectomy	↓	↑
Corticoid excess	↑	↓

complex formation will be promoted by increasing the receptor concentration[35, 36]. It could be shown in animals and man that essentially normal receptor concentrations are re-established on reaching a normal insulin level after normalizing the pathological state, *e.g.* by a suitable diet.

Current interest is presently focused upon assays for estrogen receptors in cases of breast cancer (mammacarcinoma). Approximately one half of the tumor tissue samples could be shown to contain estrogen receptors (hormone-dependent tumors). Tumors which are not affected by treatment with estrogens are termed autonomous[37-39].

In the case of estrogen-dependent tumors a regression can often be achieved by treatment with antiestrogens, and less frequently with androgens. Hormone therapy is often supported by ovarectomy, adrenalectomy, and occasionally by hypophysectomy in order to stop production of endogenous hormones. A regression is observed in about 60% of the cases treated in this way. Hormone treatment and ablative surgical measures are generally unsuccessful in the case of autonomous tumors. Such tumors require administration of cytostatics (Fig. 11).

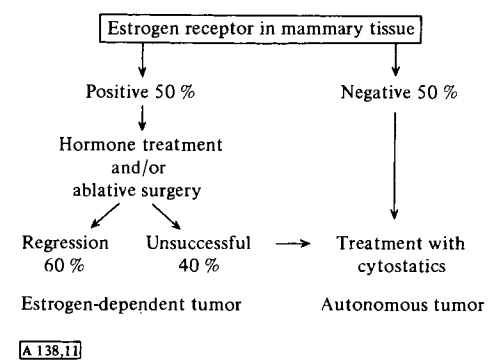

Fig. 11. Treatment of a mammacarcinoma depending upon its content of estrogen receptor.

The receptor-binding assay permits classification of the tumor and thus indicates the necessary form of treatment. In the case of autonomous tumors drastic surgery can then be avoided.

6.3. Receptor-Binding Assay to Determine Structure-Affinity Relations

The receptor-binding assay plays an important role in studies on structure-activity relations of hormones. The principal goal of such work, known generally as drug design, is the

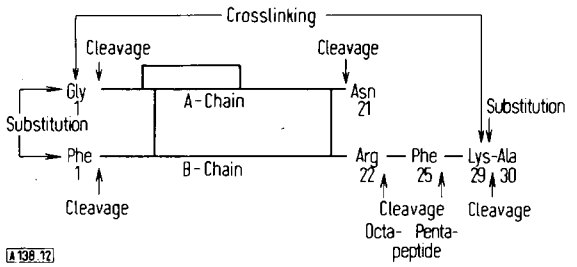

Fig. 12. Structural modification of insulin.

development of active compounds superior to the native hormone. Potentially interesting compounds are those having enhanced activity, which can be achieved by a higher concentration at the site of action, by a higher affinity for the receptor, or by raising the intrinsic activity of the hormone-receptor complex (cf. Fig. 1). Many hormones have a broad spectrum of biological action. The search for compounds displaying a dissociation in their action profile is therefore important.

The effect of structural modification on the binding to the receptor has been impressively demonstrated for insulin[40-42]. Various insulin analogs are bound to fat cells or liver cell membranes to a lesser extent than the native hormone, and the biological activity measured *in vitro* usually also decreases. However, the maximum biological effect can always be achieved by using a sufficiently high concentration dependent upon the particular modification. Accordingly, while the affinity for the receptor may change on modification, the intrinsic activity of the receptor complex does not. Studies on insulin were facilitated by the possibility of clear-cut modification of the molecule. Removal of the N- or C-terminal amino acid from the A chain, or of a C-terminal penta- or octapeptide from the B chain leads to a distinct loss of affinity. In contrast, removal of the N-terminal amino acid from the B chain is well tolerated (Fig. 12).

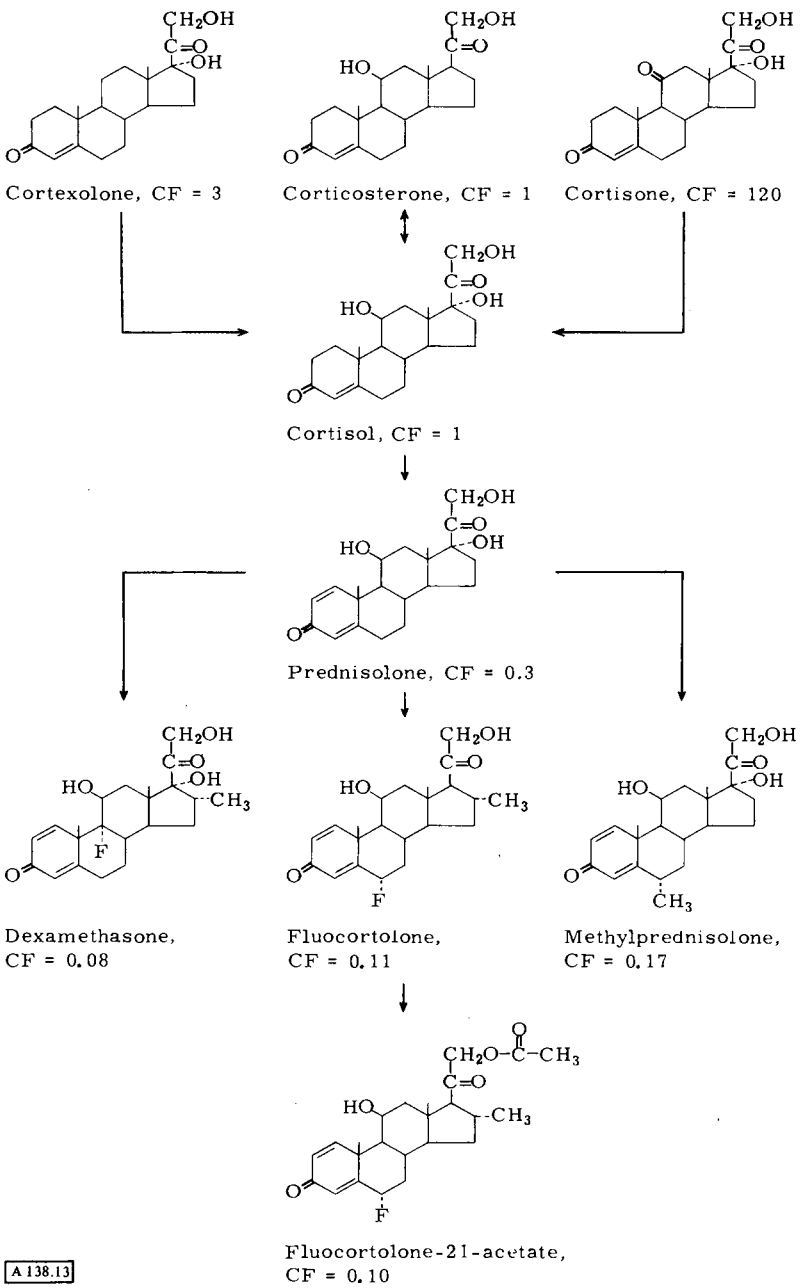

Fig. 13. Binding of glucocorticoids to the receptor (rat thymus). *CF* = competition factor (see Section 3.3).

Substitution of the terminal amino groups or introduction of intramolecular bridges reduces the affinity, but it is not lost entirely. Many of these derivatives nevertheless lead to a pronounced reduction of blood sugar levels *in vivo*. This effect is attributed to the enhanced resistance of the modified molecule towards enzymatic degradation in the liver.

The receptor binding of glucocorticoids will serve as a further example (Fig. 13)[43]. Starting from cortisol, loss of the 11β-hydroxyl group (cortexolone) but not of the 17α-hydroxyl group (corticosterone) reduces hormone binding. Oxidation to the 11-ketone (cortisone) strongly impairs its affinity. The biological activity still observed for 11-oxo corticoids is attributable to their *in vivo* reduction to the 11-hydroxy derivative. Introduction of 1,2-double bond (prednisolone) enhances the affinity towards the receptor. The biological activity also increases. Glucocorticoids exhibiting even stronger binding to the receptor are obtained by introduction of fluorine atoms into the 9α or 6α position. A methyl group in the 16α position also has a favorable effect. Esterification of the 21-hydroxyl function with a short-chain carboxylic acid has practically no effect on binding. Only upon esterification with the longer valeric acid is binding reduced.

Pregnadiene-21-carboxylic esters[44] represent a new class of glucocorticoids. They exhibit moderate to good binding, irrespective of the chain length of the alcohol component. In spite of this affinity, the derivatives are ineffective in all systemic inflammation tests. The reason is to be found in their fast hydrolysis to the free acid which is devoid of receptor affinity (Fig. 14).

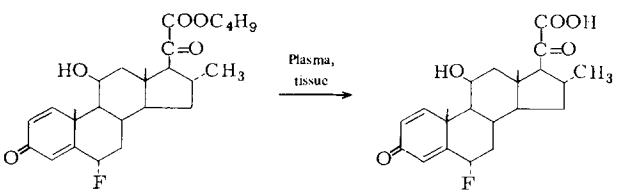

Fig. 14. Locally active corticoid with a labile bond designed to prevent systemic activity.

These compounds deserve considerable interest as local anti-inflammatory agents having practically no systemic side-effects.

7. Outlook

Numerous aspects of hormone-receptor interaction have been investigated since the description of the first receptor protein. However, there still remain many unanswered questions concerning, for example, isolation and characterization of receptor proteins, their amino acid sequence and conformation, and the structure of the receptor molecule as an integral component of the cell membrane. Little is also known about the mechanism of receptor-controlled gene expression and the regulation of receptor biosynthesis.

New findings in all these areas will further our knowledge of hormone action.

Molecular Aspects of Sickle Cell Disease

By Michael R. Waterman and G. Larry Cottam[*]

Sickle cell hemoglobin (hemoglobin S) contains valine instead of glutamic acid in position 6 of the β-chain. Few detectable conformational differences exist between hemoglobin S and normal adult hemoglobin (hemoglobin A). Following loss of oxygen, sickle cell hemoglobin (hemoglobin S) self associates to form a liquid crystal phase which distorts the erythrocyte into the sickle shape thereby resulting in the clinical symptomology associated with sickle cell anemia. This gel contains deoxyhemoglobin S monomers and polymers in equilibrium. The polymerization process is known to have a negative temperature coefficient, to be pH dependent, and to be extremely dependent on hemoglobin S concentration. The polymerization of deoxyhemoglobin S appears to be entropically driven and occurs in two kinetic phases, a delay period and a rapid polymerization process. The polymer consists of tubules containing six or eight strands of deoxyhemoglobin S tetramers which align with one another. Each strand is wound around the tubule with a pitch of about 3000 Å, but the precise nature of the intermolecular hemoglobin S contacts is not known. Subsequent alignment of the tubules occurs and results in the tactoids observed in (S/S) erythrocytes. While many of the details of polymer formation and structure remain to be elucidated, several attempts to chemically alter the sickling phenomenon have been carried out. As yet, however, no satisfactory chemical treatment has been discovered.

1. Introduction

Sickle cell anemia was first reported in 1910 by *Herrick*[1], who described a patient that had elongated and sickle shaped red blood cells. In an extensive study *Neel*[2] demonstrated that sickle cell disease is inherited in a Mendelian fashion, as previously suggested by *Huck*[3]. *Neel* also explained the existence of clinically benign individuals (sickle cell trait) as being heterozygous for hemoglobin S and individuals with sickle cell anemia as being homozygous for hemoglobin S. However, the first chemical description of the disease and the fact that it was the result of an abnormal hemoglobin molecule awaited the application of electrophoretic techniques, with which *Pauling et al.* in 1949 succeeded in separating the sickle hemoglobin from the normal hemoglobin[4].

In 1957, *Ingram* applied the techniques of peptide mapping to determine the precise chemical differences between hemoglobin A and hemoglobin S. Normal adult hemoglobin (hemoglobin A) contains four polypeptide chains which consist of two identical α-chains of 141 amino acid residues and two identical β-chains which contain 146 amino acid residues ($\alpha_2\beta_2$). *Ingram* was able to demonstrate that hemoglobin S contained a single amino acid substitution different from hemoglobin A. In the β-chain, the amino acid valine has been substituted for glutamic acid six residues from the amino terminus[5]. Except for this one amino acid, all other amino acids in the α- and β-chains of hemoglobin S are identical to those found in hemoglobin A. Thus, hemoglobin S contains two normal α-chains in addition to two abnormal β-chains and is written as $\alpha_2\beta_2^{6\,Glu\rightarrow Val}$. Individuals with sickle cell trait have hemoglobin S and hemoglobin A, while individuals with sickle cell anemia have only hemoglobin S.

The clinical manifestations of sickle cell anemia, *i.e.* the anemia and the acute ischemia and infarction of tissues and, therefore, the chronic loss of organ function, are a consequence of the cell sickling phenomenon. This phenomenon, in turn, has been shown to result from the polymerization of deoxy-

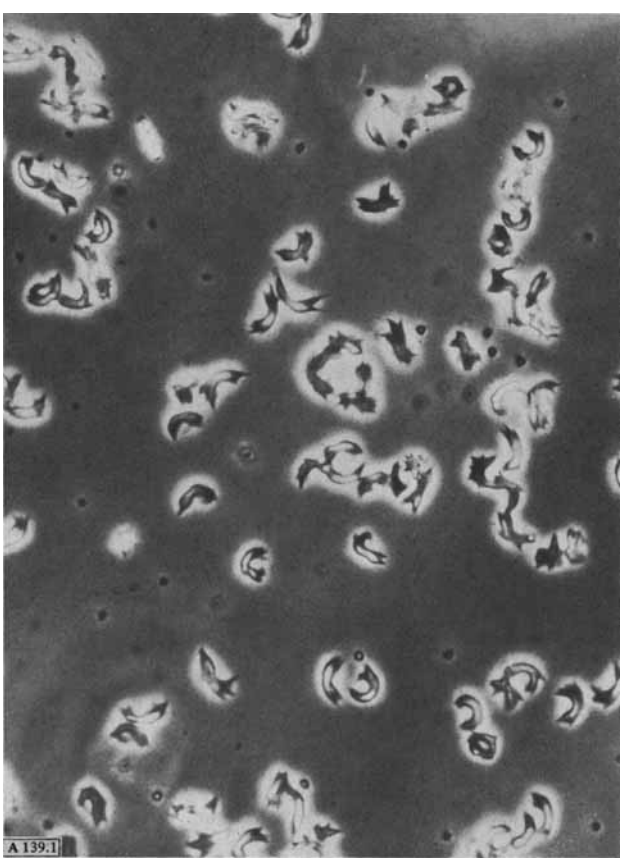

Fig. 1. Microscopic appearance of sickled erythrocytes. Oxygen was removed from these erythrocytes chemically, using a 1 % solution of sodium metabisulfite.

hemoglobin S molecules[*] inside the erythrocyte. As the hemoglobin S molecules give up oxygen to surrounding tissues, they aggregate into large fibers which distort the erythrocyte membrane into the sickle shape (Fig. 1). The polymerization manifests itself as gel formation. This is in contrast to normal adult hemoglobin which, upon deoxygenation, remains in solution. Sickled cells are less pliable than normal red cells and tend to become trapped in capillary beds, resulting in an occlusion of blood flow and ultimately tissue damage. An enormous amount of clinical literature has appeared on sickle cell anemia over the years and is beyond the scope of this article; however, the reader's attention is drawn to a few recent reviews which have been written on the subject[6-10].

The number of studies on the biochemical and biophysical aspects of sickle cell disease has increased explosively in recent years, particularly in the United States. It is the purpose of this article to review the most pertinent aspects of these works. Due to the great complexity of the polymerization process, much of the work has been phenomenological in nature. However, it is clear that a consistent pattern is developing from several different types of experimental approaches and an understanding of the fundamental structural, kinetic and equilibrium properties of this complicated interaction between protein molecules is emerging. It is hoped that from this understanding a useful clinical regimen will arise for the treatment of this molecular disease.

2. Early Studies of Gelation

Following the elucidation of the primary sequence of hemoglobin S, relatively few biochemical studies were undertaken to determine the nature of the aggregation process until the present decade. Since 1970, the aggregation process has been studied extensively, using numerous physical methods to unravel its complex nature. Some crucial observations made between 1950 and 1970, however, provided a basis for the recent experiments.

The first important observation was made by *Harris*; he found that the viscosity of red cell hemolysates from individuals with sickle cell anemia increases markedly upon deoxygenation. Upon lysing the erythrocytes, he was able to show a concentration-dependent viscosity change following oxygen removal. At high concentrations of hemoglobin S (235 mg/ml), he observed a semi-solid gel-like state which had an optical birefringence similar to that observed in erythrocytes[11]. The gelation, which can be made reversible by the reintroduction of oxygen[12], occurs even in the presence of other hemoglobins such as hemoglobin A[13]. However, a minimal amount of hemoglobin S must be present for gelation to occur (cf. also Table 5). The diagnostic significance of the gelation for identification of hemoglobin S has also been considered.

Another important observation was made by *Itano*. He showed that deoxyhemoglobin S dissolves much more sparingly in 2.24 M phosphate buffer at pH 7.0 than does deoxyhemoglobin A[14]. The reduced solubility of deoxyhemoglobin S in concentrated salt solution has been exploited by several investigators in studying the parameters of the polymerization process[15-17]. In addition, use has been made of this observation in the development of a solubility method for the detection of hemoglobin S in mass screening programs.

In 1957, *Allison* reinvestigated the reported viscosity changes and showed that oxyhemoglobins S and A and deoxyhemoglobin A all had the same viscosity characteristics over a concentration range of 5 to 250 mg/ml and a temperature range of 0 to 40 °C. Deoxyhemoglobin S, on the other hand, behaved quite differently. At concentrations in excess of 120 mg/ml, a sharp increase in viscosity was observed as the temperature of the solution was increased above about 15 °C. On cooling, the viscosity decreased again[18]. The reversibility of the polymerization process by lowering the temperature is an extremely important property which has been exploited in virtually every study since its discovery. Conversely, at any set temperature above *ca.* 15 °C, there is a sharp increase in viscosity as the hemoglobin S concentration is increased (see Table 1).

Table 1. Specific viscosities η_{sp} of aqueous solutions of deoxyhemoglobins A and S as a function of concentration c at 37 °C [18].

Deoxyhemoglobin A		Deoxyhemoglobin S	
c [mg/ml]	η_{sp}	c [mg/ml]	η_{sp}
50	1.5	50	1.5
110	5	100	4.5
200	20	115	5.7
275	41	125	8.5
		130	43.5
		150	gel

A valuable contribution made by *Murayama* was the concept that the negative temperature coefficient of gelation is an indication of the importance of hydrophobic interactions in polymer formation[19]. This is consistent with an amino acid substitution of valine for glutamic acid, and several attempts to design anti-sickling compounds have been based on this concept. In summary, these early studies established that gelation is a highly concerted process dependent on temperature, hemoglobin concentration and oxygen tension.

3. Differences between Hemoglobin S and A

Perhaps the most frustrating aspect of the study of the aggregation of deoxyhemoglobin S is the fact that the physical properties of the hemoglobin S molecules in the polymer appear not to differ from those of the molecules in solution. Careful studies, including the use of polarized absorption spectroscopy[20], have shown that the optical properties of the heme group do not change upon polymerization. Other portions of the molecule have been probed by use of nitroxide spin-labels, and no conformational changes could be observed upon polymerization. The β_{93} cysteine residues have been used as a site of attachment for spin-labels in hemoglobin A to monitor by electron spin resonance the conformational changes which take place during reversible ligand binding[21,22]. When spin-labels were attached to this site in hemoglobin S, the same oxy-deoxy transition as with hemoglobin A could be observed, but no change was observed in going from the deoxy-solution to deoxy-gel state[23]. This result is illustrated in Fig. 2. It follows that the region around the β_{93} cysteine residues in deoxyhemoglobin S is not perturbed upon polymerization and, therefore, that some portions of the surface of the protein remain unaltered. Preliminary

[*] The designation deoxyhemoglobin shall be used here whenever it should be emphasized that deoxygenated hemoglobin is involved.

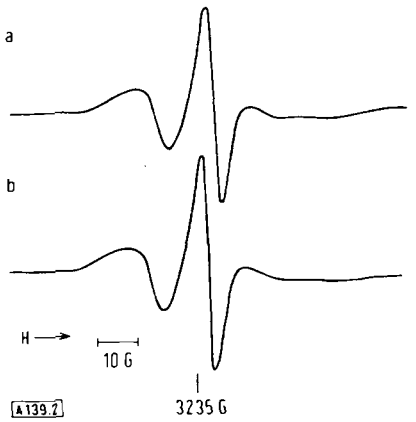

Fig. 2. Electron spin resonance spectra of deoxyhemoglobin S spin-labeled with 3-(2-iodoacetamido)-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl *(1)* at the β_{93} cysteine residues. a) Sample at 53 mg/ml (not a gel), b) sample at 283 mg/ml (a gel). The spectra were recorded at 23°C.

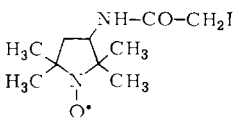
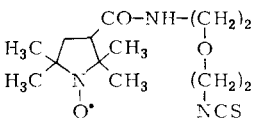
studies in which 3-{[2-(2-isothiocyanatoethoxy)ethyl]carbamoyl}-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl *(2)* was employed for the spin labeling indicate that the N-terminal residues of the β-chains in hemoglobin S are also insensitive to changes which may occur upon aggregation[24]. The



(1)



(2)

enthalpy change in the polymerization process has been estimated to be relatively small, a result which also indicates no large conformational change in the deoxyhemoglobin S molecules during gelation[25, 26]. Needless to say, this inability to find a property of the hemoglobin S molecule which changes upon polymerization has complicated the study of this process.

With respect to differences between hemoglobin S and hemoglobin A, two interesting observations have recently been made. *Asakura et al.* observed that oxyhemoglobin S is very much less stable toward mechanical shaking than is oxyhemoglobin A[27]. This instability is unique for the oxygenated form and, therefore, strongly suggests conformational differences between oxyhemoglobin S and oxyhemoglobin A. Using high-resolution ^{1}H-NMR spectroscopy, *Ho et al.* have detected small pK differences in three surface histidyl residues between deoxyhemoglobin S and deoxyhemoglobin A[28]. The largest of these differences is found to be 0.2 pK unit. The assignment of these residues is not complete, but it is clear that these results reflect localized conformational differences on the surface of the deoxyhemoglobin S molecule with respect to deoxyhemoglobin A. Therefore, it must be concluded that some structural differences exist between hemoglobin S and hemoglobin A in solution, but these differences are subtle and thus far have not been useful as probes for the study of the polymerization process. To date, it has been necessary to take advantage of the changes in the physical characteristics of the solution to study polymerization.

The techniques of immunology may also lead to a better understanding of slight conformational differences between hemoglobin S and hemoglobin A. Recently, the β-chain of hemoglobin S has been used to elicit antibodies[32]. An antibody population with specificity for the N-terminal region of this β-chain was then isolated by affinity chromatography. Cross reactivity with the β-chain of hemoglobin A or hemoglobin α-chains was not observed[33]. This method has potential utility in both the detection and quantification of hemoglobin S, as well as in the study of conformational differences between hemoglobin A and hemoglobin S.

The function of hemoglobin is sensitive to its conformation and thus might provide a tool to distinguish small differences between the two hemoglobins. However, the oxygen binding parameters of dilute solutions of hemoglobin S are indistinguishable from those of hemoglobin A[29]. Differences between oxygen binding parameters of hemoglobin S and hemoglobin A have been observed in whole blood[30, 31]. Blood containing hemoglobin S is found to have a significantly lower oxygen affinity; this is most likely due to the aggregation of deoxyhemoglobin S which tends to stabilize the T (deoxy) configuration, thereby shifting the equilibrium curve to the right. The clinical implications of the relationship between the extent of this shift and various red cell parameters such as volume, hemoglobin concentration and 2,3-diphosphoglycerate concentration are not completely clear. The shifting of the equilibrium curve may well have important consequences with respect to the severity of the disease.

4. Kinetic and Thermodynamic Studies

The kinetics of the sol-gel transition have recently been studied by a variety of methods. Widely different techniques such as viscosity measurements[34, 35], calorimetry[36], and measurement of birefringence[36], turbidity[37], and nuclear magnetic resonance water line widths[38], as well as transverse water proton relaxation times[39] have all shown that there is a delay period prior to the onset of the polymerization process on warming a solution of deoxyhemoglobin S from 4°C to ambient temperature or higher. The gel formation itself follows the delay period and is rapid. The length of the delay period is found to be dependent on the hemoglobin

Table 2. Summary of the kinetic delay times t_d in the polymerization of deoxyhemoglobin S as measured by different techniques.

Method, or property measured	Temperature jump [°C]	Hemoglobin S concentration [mg/ml]	t_d [min]	Ref.
Calorimetry	0→20	233	50	[36]
Optical birefringence	0→20	233	50	[36]
Turbidity	2→30	200	5	[37]
Viscosity	2→25	176	36	[34]
Viscosity	2→21	208	12	[35]
Water proton NMR linewidths	0→21.5	267	10	[38]
Transverse water proton relaxation times	4→37	170	20	[39]

concentration and the temperature to which the system is warmed. The delay time for the polymerization process has been expressed as:

$$1/t_d = \gamma S^n$$

where t_d is the delay time, S is the supersaturation ratio (total hemoglobin S concentration divided by the minimum concentration for gelation) while n and γ are parameters independent of the experimental conditions[36]. The value of the

constant γ is 10^{-6} s. The value of n represents the number of monomers in the nucleation species and is high, at least 30. A summary of the delay times observed by different methods and under different conditions is given in Table 2.

It is possible that different techniques are monitoring different aspects of the overall polymerization process, but a significant delay time is seen in all cases. The length of the delay period is temperature dependent and apparently the reciprocal of the delay time increases logarithmically with increasing temperature[38]. On comparing the temperature dependence of the delay time as determined from optical birefringence, turbidity and reciprocal amplitude of the water proton magnetic resonance line, it was found that all three techniques gave similar results[38]. The length of the delay period is also reciprocally related to a very high power (≈ 30) of the hemoglobin concentration. *Eaton et al.* therefore proposed a model in which the rate determining step is the formation of thermodynamically unstable nuclei of approximately 30 deoxyhemoglobin S molecules[20]. The delay time has important implications clinically and will be discussed later (in Section 7).

From a kinetic standpoint the self association of deoxyhemoglobin S molecules is strongly dependent on hemoglobin concentration and temperature and probably other parameters such as pH. The concentration dependence seems to be manifested in two ways, one being a delay time before the onset of polymerization and the other being the rate at which polymer formation proceeds. Figure 3 shows the water proton

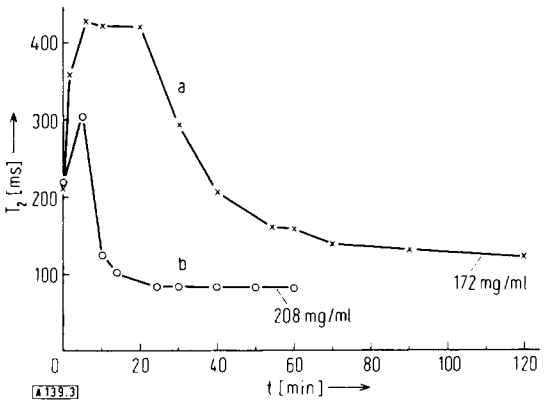


Fig. 3. Transverse water proton relaxation times (T_2) as a function of time at two hemoglobin S concentrations (a: 172 mg/ml; b: 208 mg/ml). The time zero T_2 values were measured at 4 °C and all other T_2 values were measured at 37 °C. The pH in both samples was 7.0; hemoglobin S was maintained in the deoxy form by addition of $Na_2S_2O_4$ [39].

relaxation times (T_2) as a function of time in the polymerization of deoxyhemoglobin S. It can be seen that the delay time t_d decreases greatly with increasing hemoglobin concentration (172 mg/ml: 20 min, 208 mg/ml: 5 min), and the rate of polymer formation increases. It is clear that this concentration dependence is not hemoglobin S specific. In Figure 4 it is seen that by adding 40 mg/ml hemoglobin A to a solution of 170 mg/ml hemoglobin S, the delay time is similarly decreased and the rate of polymerization is increased. The results resemble those obtained with a solution of 208 mg/ml hemoglobin S (Fig. 3b)[39]. The more subtle aspects of the kinetics of hemoglobin S polymerization remain to be elucidated. In particular, investigations on solutions in which hemoglobin S is present in the same concentrations as in erythrocytes have yet to be carried out.

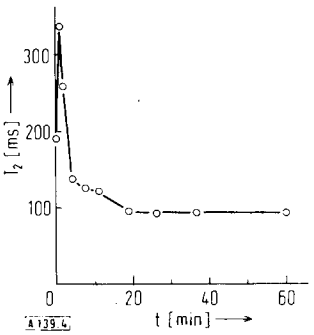

Fig. 4. Transverse water proton relaxation times (T_2) as a function of time in a solution of hemoglobin containing 170 mg ml hemoglobin S and 40 mg ml hemoglobin A. Other conditions were as described for Figure 3 [39].

As pointed out above, the size of the nucleation species has been estimated to contain at least 30 hemoglobin molecules[20]. Studies on the equilibrium properties of the deoxyhemoglobin S system have been largely concerned with the question of whether small aggregates of deoxyhemoglobin S, a few hemoglobin molecules in size, are present in the sol-gel transition. From equilibrium centrifugation studies, contradictory data has been obtained. Observations with a schlieren optical system showed a pre-gelation transition zone which could be ascribed to intermediates[40]. On the other hand, observations with a Rayleigh interferometer provided no evidence for aggregates with less than 20 hemoglobin molecules; hence it is concluded that the polymerization process is a very concerted one[41]. Light scattering studies have indicated that pre-gelation aggregates may exist in solution and that the polymerization process is linear, rather than concerted[42].

From the measurement of spin-lattice relaxation rates of solvent water protons, it has been estimated that about 90% of the deoxyhemoglobin S molecules remain in solution at 10 °C while at 35 °C virtually all are incorporated into the gel[43]. Centrifugation studies indicate that the gel consists of deoxyhemoglobin S monomers in equilibrium with a solid polymer phase[26, 44]. Measurements of longitudinal water proton relaxation times (T_1) have suggested that interactions between oxyhemoglobin S molecules may occur within erythrocytes[45]. Determination of transverse water proton relaxation times (T_2) has been useful in the study of the deoxyhemoglobin S aggregation process and has recently shed some light on the controversy surrounding pre-gelation aggregates[46–49]. In this technique, the T_2 value is monitored as a function of time (see Fig. 3 and 4). The technique is applicable to both intact erythrocytes and isolated hemoglobin solutions[46]. It has been used, for example, to study the influence of pH[48] and potential anti-sickling agents[50] on the polymerization process. In order to explain the observed drop in T_2 the three water environment model was proposed[47]: free water, water of hydration, and irrotationally bound water. Table 3 summarizes the model in terms of the mol fractions of water in each environment and its characteristic correlation

Table 3. Three water environments inside intact erythrocytes [47].

Water Environment	Mol Fraction	Correlation Time τ_c [s]
Free Water (Bulk Water)	0.98	3×10^{-11}
Water of Hydration	0.013 0.015	$2\ 4 \times 10^{-9}$
Irrotationally Bound Water	0.002	$\geq 10^{-7}$

time τ_c. Upon polymerization the correlation time of the "irrotationally" bound water fraction increases and gives rise to the observed decrease in relaxation time T_2. Thus the reduced T_2 value is a function of the degree of polymerization in the deoxyhemoglobin S solution.

One must now ask how high the degree of polymerization must be in order to yield the observed changes in T_2? This has been approached by assuming a linear polymer model and calculating the expected correlation times for comparison with those actually observed in solutions of deoxyhemoglobin S[49]. The correlation time of oxyhemoglobin S is 2.23×10^{-8} s, while that observed for polymerized deoxyhemoglobin S is 2.64×10^{-7} s[49]. It can be seen from Table 4 that a linear association of from one to seven hemoglobin S molecules can yield the range of observed correlation times. Thus, the measurement of transverse water proton relaxation rates is sensitive to the initial events of polymerization. This result is supported by the fact that with S/S erythrocytes, an *n*-value of 2.5 is obtained when the change in T_2 is measured as a function of oxyhemoglobin concentration and expressed as a Hill plot. Therefore, in this special case the deoxygenation of hemoglobin can be measured by this technique[49]. Since the onset and rate of polymerization are very concentration dependent, it may be assumed that intermediate states do exist and an understanding of their formation and disappearance is essential to an overall understanding of the polymerization process.

Table 4. Calculated correlation times for linear polymerization of deoxyhemoglobin S [49]. Calculations were made assuming hemoglobin as a sphere of 64 Å diameter. The degree of association gives the number of molecules in the linear polymer and is also the axial ratio.

Degree of Association	τ_c [s]
1	2.23×10^{-8}
2	5.20×10^{-8}
3	9.14×10^{-8}
4	1.35×10^{-7}
5	1.81×10^{-7}
6	2.26×10^{-7}
7	2.75×10^{-7}

Thermodynamic measurements do not rule out the existence of small polymers. The enthalpy of polymerization is 2—4 kcal/mol[25, 26] and the increase in entropy of about 25 cal/K^{-1} mol^{-1} at 20°C is considered to be the driving force for the reaction[26]. This entropy change is smaller than described for some other biological polymerization processes and is compatible with the existence of stable, small polymers[26].

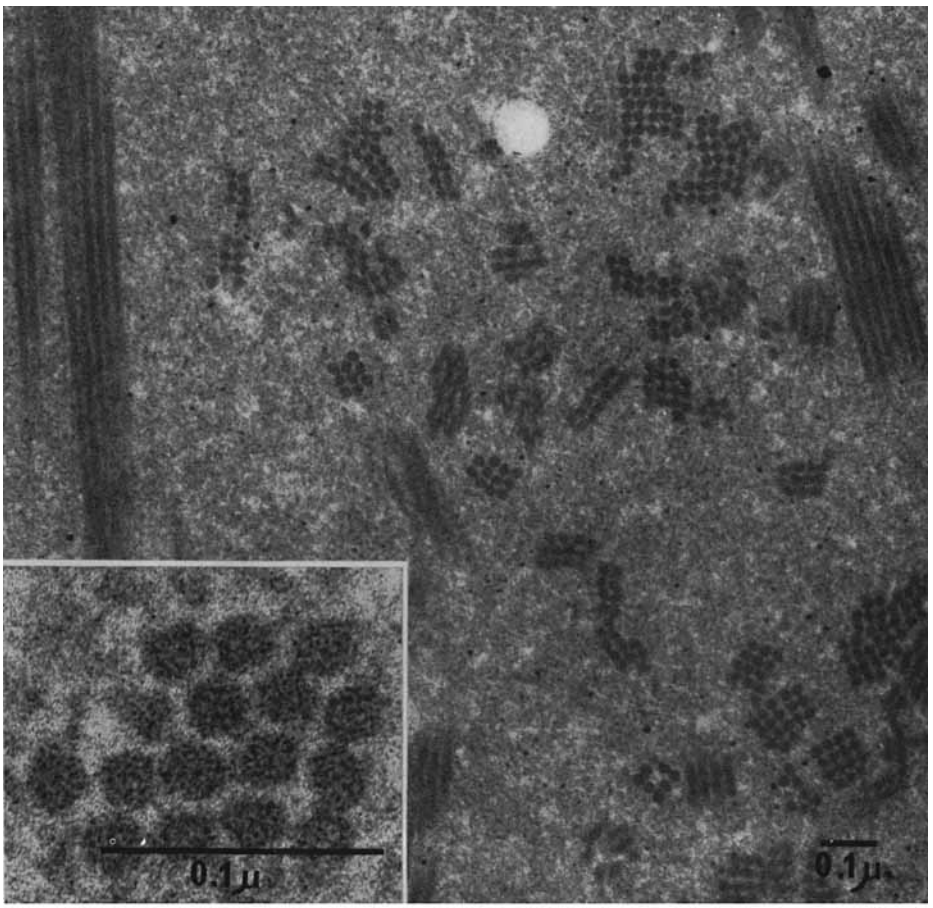
Minton has proposed a two-step thermodynamic model for the gelation of hemoglobin S[51–54]. In this model, deoxyhemoglobin S molecules exist in the monomer form until a critical concentration is attained. Above this concentration rod-like microtubules form by a process which is thermodynamically equivalent to precipitation. The rod-like aggregates then spontaneously align to form the gel when their volume fraction exceeds a critical value. The critical volume fraction is sensitive to the length of the rod-like forms in solution; the longer the rod length, the lower the volume fraction necessary for alignment. This model is reported to be consistent with experimental observations and has been applied to both the chemical inhibition of gelation and the influence of oxyhemoglobin S on the gelation process.

In summary, the aggregation of deoxyhemoglobin S is a concentration- and temperature-dependent process consisting of several discernable steps whose driving force is the increase in entropy. Kinetically, there is a delay period before the polymerization begins. During this delay period there appears to be no formation of stable small polymers. In contrast, however, stable small polymers apparently are formed during the aggregation phase of the overall process, and they serve as precursors to the nucleation species which is larger than 30 hemoglobin molecules. In the light of what is known concerning the structure of the polymer described in the next section, there must be kinetic processes such as the alignment of tubules which remain to be sorted out from the overall process.

5. Structure of Crystals and Fibers

Considerable interest has been focused on the structure of the deoxyhemoglobin S polymer. It is anticipated that by understanding the fiber structure, and in particular the intermolecular amino acid contacts, it might be possible to design a specific anti-sickling agent. Considerable detail concerning the fiber structure has been obtained from electron microscopy (Fig. 5). This technique has shown that deoxyhemoglobin S in erythrocytes and in isolated solution forms tubules having an outside diameter of about 170 Å[19, 55, 56]. These studies show that fibers are formed by alignment of the tubules with each other. Early studies by *Finch et al.*[57] and *Edelstein et al.*[58] produced evidence that the tubule is made up of rings of six hemoglobin tetramers stacked on top of each other with a helical pitch to the arrangement of rings. In the two studies noted above, there were differences in the helical pitch and the alignment of tubules, but the model stemming from these studies showed that there are three kinds of intermolecular hemoglobin contacts which result in fiber formation. These are up-down within the tubule, resulting in the long axis of the tubule; side-side within the tubule, resulting in the ring structure of the tubule; and interactions between the tubules, resulting in alignment and therefore fiber formation. Recent electron microscopy studies suggested that the tubules are eight-stranded (Fig. 6), rather than six-stranded, and that the adjacent strands in the tubule long axis are staggered with respect to each other by half the repeat distance[59].

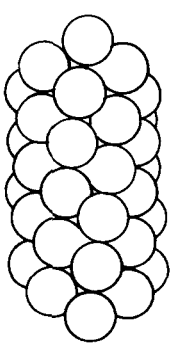
It is not known at present which amino acids are involved in these interactions; however, some information is available concerning contact points between deoxyhemoglobin S molecules. X-ray diffraction patterns have been obtained from deoxyhemoglobin S gels[60] and recently the 5 Å and 3 Å X-ray structures of deoxyhemoglobin S crystals have been determined[61, 62]. It is interesting that much of the data from the 3 Å X-ray study is in good agreement with the electron microscopic data and other information known about fiber structure. For example, in 1973 *Hofrichter et al.* established, by measuring absorption of polarized light, the maximum angle (23°) which could exist between the tubular axis and the molecular *x* axis[20]. In the crystal, this angle is less than 10°. In addition, several of the known sites which affect the gelation process are found to be intermolecular contacts in the crystals. For example, one of the β_6 residues is involved in the side-side contacts, as is one of the β_{73} residues. In



A 139.5

Fig. 5. Transmission electron micrograph of hemolysate from S/S erythrocytes upon deoxygenation showing both the longitudinal and transverse sections of the fibers from Ref. [69].

hemoglobin C_{Harlem}, there is an Asp→Asn substitution at β_{73} in addition to the Glu→Val substitution at position β_6. This results in an increased concentration necessary for gelation to occur[63]. Several other sites which have been suspected of being involved in intermolecular contacts from studies with abnormal hemoglobins are also implicated in the crystallographic data. Furthermore, the structure of deoxyhemoglobin S does not differ significantly from that of deoxyhemoglobin A in the β_6 region. From crystallographic data a model tubule can be constructed which has many similarities with the eight-stranded model described above. It is also suggested that the tubule consists of double strands in which the molecules are staggered by half the repeat distance[62].



A139.6

Fig. 6. Model of eight-stranded deoxyhemoglobin S fiber along the longitudinal axis, as suggested from X-ray and electron microscopy studies [59, 62]. Each circle represents a single molecule of deoxyhemoglobin S.

Further studies on the mapping of the intermolecular contact points have been carried out using hybrid hemoglobins consisting of mutant α-chains and hemoglobin S β-chains[17]. In these studies, the solubilities of the hybrid hemoglobins have been measured in order to assess the influence of the α-chain abnormalities on the polymerization process. The results appear to be consistent with those derived from X-ray crystallography and electron microscopy. In addition, they have been found, in part, to be consistent with the computer modeling approach to the determination of the intermolecular contact points[64].

While many details of the deoxyhemoglobin S fiber remain to be determined, it is clear that the fiber consists of tubules made up of strands of deoxyhemoglobin S molecules. The contacts between molecules and between strands probably do not involve many amino acids so that much of the surface of the hemoglobin molecule is free to the solvent. The forces which result in tubule formation do not change the measurable properties of the hemoglobin molecules. However, the tubular fibers which are formed are sufficiently stable thermodynamically to force the erythrocyte membrane into the sickled shape.

6. Non-Gelling Hemoglobins

It is well recognized that while homozygosity for hemoglobin S (sickle cell anemia) is often associated with severe clinical symptomology, heterozygosity for hemoglobin S (sickle cell

trait) is a clinically benign state. Therefore, non-gelling hemoglobins, such as hemoglobins A and F, have been extensively studied for their effect on the polymerization process[13, 65, 66].

Expanding on the original work of *Singer* and *Singer*[13], *Bookchin* and *Nagel* have developed a widely-used technique for this type of study. In these experiments, the minimum gelation concentration (MGC) is measured under a specific set of conditions (0.15 M phosphate buffer, pH 7.35, 25°C), the MGC being the concentration of hemoglobin below which no gelation will occur. By using a constant set of conditions, it is possible to study not only the effect of non-gelling hemoglobins on the MGC, but also potential anti-sickling agents and mutations in the hemoglobin S molecule at positions other than β_6.

Table 5. Effect of non-gelling hemoglobins (Hb) on the MGC [60, 61] of deoxyhemoglobin S. The normal hemoglobin concentration in the erythrocytes is 320 to 340 mg/ml.

Hemoglobin composition	MGC [mg/ml]
100 % HbS	235–248
50 % HbS + 50 % HbA	301
50 % HbS + 50 % HbF	353–366
100 % HbC_{Harlem} [a]	362
50 % HbS + 50 % Hb Korle-Bu [b]	355–361

[a] HbC_{Harlem} contains two substitutions in the β-chain ($\beta_6^{Glu\rightarrow Val}$ and $\beta_{73}^{Asp\rightarrow Asn}$).
[b] Hb Korle-Bu contains one substitution in the β-chain ($\beta_{73}^{Asp\rightarrow Asn}$).

In Table 5, the effect of non-gelling hemoglobins on the MGC of hemoglobin S is shown. As can be seen, both hemoglobins A and F substantially increase the MGC, hemoglobin F being more effective than hemoglobin A. In addition, the substitution of Asp→Asn at β_{73} also significantly increases the MGC. An equal amount of hemoglobin A raises the MGC to approximately the hemoglobin concentration inside the erythrocyte, while hemoglobin F raises this concentration above that found in erythrocytes. Therefore, while cells which contain hemoglobins A and S in approximately equal concentration are known to sickle upon complete deoxygenation *in vitro*, they probably never experience a low enough oxygen concentration *in vivo* to sickle. Hence, the normal sickle trait hemoglobin profile (45 % hemoglobin S and 55 % hemoglobin A) is a benign condition clinically. Another point to be drawn from Table 5 is that an amino acid substitution far from the β_6 position can have a profound influence on the MGC. This is due to the multiple amino acid contacts which are necessary for fiber formation.

The mechanism by which non-gelling hemoglobins change the MGC is unknown. However, hybrid tetramers ($\alpha_2\beta_A\beta_s$) have been observed in mixtures of hemoglobin A and hemoglobin S[67], and it has been shown experimentally that under conditions where hybrid tetramers can form, the MGC is increased, but not to the level observed under conditions where hybrid tetramers are not present[68]. Therefore, non-gelling hemoglobins may be incorporated into the fiber structure in two ways, as complete tetramers and as hybrid tetramers; the latter combination results in an increase in the MGC but still permits gelation to occur[69]. Certainly, the possible role of hybrid tetramers in gel formation in hemoglobin mixtures deserves further consideration.

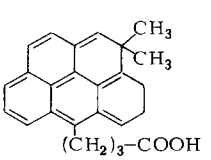
However, the effect of non-gelling hemoglobins increasing the MGC is not sufficient to explain the clinical differences between sickle cell anemia and sickle cell trait. The hemoglobin concentration in normal erythrocytes ranges between 320 and 340 mg/ml. From Table 5 it is clear that 50 % hemoglobin F instead of 50 % hemoglobin A would be very advantageous, since it raises the MGC above the normal red cell hemoglobin concentration. The occurrence of 50 % hemoglobin F, however, is extremely rare. On the other hand, 50 % hemoglobin A also raises the MGC, but not above the normal red cell hemoglobin concentration. It is estimated that between 8 and 10 % of the black population in the United States have about 45 % hemoglobin S and 55 % hemoglobin A (sickle cell trait), and the erythrocytes from these individuals are known to sickle following complete removal of oxygen. Therefore, hemoglobin A must have another role in addition to raising the MGC.

It has recently been shown using the measurement of water proton relaxation times, that polymerization occurs immediately and concomitantly with deoxygenation in S/S erythrocytes[49]. In heterozygous erythrocytes (A/S or C/S) there is a delay in the onset of polymerization until a critical level of deoxyhemoglobin is achieved. The critical level of deoxyhemoglobin is dependent on the amount of hemoglobin S present in the erythrocytes, the more hemoglobin S the lower the level of deoxyhemoglobin necessary for the onset of polymerization.

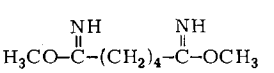
Therefore, non-gelling hemoglobins play at least two important roles in the polymerization process which must, in part, be responsible for the clinically benign state of sickle cell trait. They increase the MGC and they increase the level of deoxygenation which must be achieved before the onset of the polymerization process. It is also anticipated that non-gelling hemoglobins will prove to alter the kinetics of the polymerization process in a favorable manner, *i.e.*, slow down the rate of polymerization.

7. Chemical Alteration of Gelation

An important goal in the study of the molecular aspects of deoxyhemoglobin S polymerization is to find a chemical solution to this serious and widespread disease. In view of what is known about polymerization, several different compounds have been studied as potential anti-sickling agents. The chemicals studied can be classified into two categories; those which covalently modify hemoglobin S and those which non-covalently alter the polymerization process. Examples of the non-covalent modifiers are urea[70], organic solvents[71], alkylureas[72], amino acids such as lysine, arginine, and aspartic acid[73], and 2,2-dimethyl-3,4-dihydro-2*H*-benzo[*c*,*d*]pyrene-6-butyric acid *(3)*[74]. While these compounds, which do



(3)



(4)

not form covalent derivatives of hemoglobin S, represent various degrees of potency as anti-sickling agents *in vitro*, there is no conclusive evidence that any of them reduce the clinical symptoms associated with the disease. In several cases, the toxicity of the compound has yet to be determined.

The covalent modifiers which have been studied most extensively are cyanate[75-77], carbamyl phosphate[78] and the bifunctional cross-linking agent, dimethyladipimidate *(4)*[79]. While the toxicity of the latter two compounds has yet to be clearly established, the studies with cyanate are extensive and illustrate the two major problems of covalent modification: it is difficult to covalently modify only hemoglobin *in vivo*, and moreover to do so without impairing the oxygen delivery function of hemoglobin. Therefore one may want to modify only a few of the total number of amino acids of a specific type. For instance, in cyanate treatment of erythrocytes, cyanate was found to be incorporated to a large degree into the hemoglobin, predominately at the amino terminal valine residues. Yet a small amount of cyanate is bound to other proteins resulting in deleterious clinical side effects, particularly in the nervous system and the eye. As recently discussed by *Manning*[80], many principles have been derived from studies on the carbamylation of hemoglobin S which should also apply to other studies where covalent modification of hemoglobin is attempted. Carbamylation of hemoglobin S occurs primarily at the amino terminal valine residues with the α-chain residues reacting faster than β-chain residues. The anti-sickling effect of cyanate seems to result from two quite different effects. Modification at the α-chain amino terminal residues produces a hemoglobin which has a higher affinity for oxygen and therefore polymerization of this modified hemoglobin S will only occur at lower oxygen tensions[81]. On the other hand, carbamylation of the β-chain amino terminal residues significantly increases the MGC of hemoglobin S[81]. Therefore, a covalent modification can have multiple effects on the polymerization process.

To date, no chemical modifier of the polymerization process has been found which would be useful in the general clinical treatment of sickle cell anemia. This is not to say, however, that such a compound does not exist, and the search for an agent to specifically inhibit or slow down the gelation phenomenon will continue at an accelerated rate as more information becomes available about the biochemical aspects of the process.

The above mentioned compounds have been studied because they have the potential to prevent cell sickling under the conditions of reduced oxygen tension. *Eaton et al.* have recently presented the interesting hypothesis that one approach to reducing the clinical severity of sickle cell anemia is to control the delay time observed in kinetic studies[82]. It is possible that the delay time could be lengthened by some treatment such that it would become longer than the time required for red cell transit through the blood circulation (≈ 15 s). Under these circumstances, reoxygenation of hemoglobin S would serve as the anti-sickling process. This hypothesis opens up fruitful areas of both clinical and basic research as to the role of the delay time in the clinical severity of the disease and the perturbations of the hemoglobin environment which are effective in lengthening the delay time.

The ultimate answer to the problem of sickle cell anemia may lie in the elucidation of the mechanism by which the switch from fetal hemoglobin (hemoglobin F) synthesis to adult hemoglobin synthesis takes place. Since the capacity to synthesize fetal hemoglobin is present in adults, it may be possible some day to turn on synthesis of this hemoglobin, thereby producing heterozygous S/F trait individuals from homozygous S/S individuals. Since sickle cell trait is a clinically benign condition, considerable effort will be invested in this direction in future years.

8. Conclusion

The authors hope that this rather selective review will provide chemists with an insight into the chemical events which are responsible for the clinical symptoms associated with sickle cell anemia. In addition to the problems remaining to be solved, it is hoped that the reader has gained an appreciation for the vigor with which these problems are being tackled in many different laboratories. It is not overly optimistic to anticipate that the structural, kinetic and equilibrium properties of the self association of deoxyhemoglobin S will be much better understood by the end of the present decade and that a chemical solution to the problem will be in sight. In fact it is likely that the treatment of the disease will go through several different phases, each arising because of new advances in the areas of biochemical and biophysical aspects of hemoglobin S.

The authors wish to acknowledge the support of Contract No. NO1-HB-2-2954 by the Sickle Cell Disease Branch of the National Heart and Lung Institute, National Institutes of Health. One of us (MRW) also acknowledges the support of Research Grant RO1-AM16188 from the National Institutes of Health. The kindness of Dr. John F. Bertles in providing the photograph used in Figure 5 is greatly appreciated.

Conformational Studies on Twelve-Membered Heterocycles. Crystal Structure of 5,18-Dimethyl-5,18-diazatribenzo[*a*,*e*,*i*]cyclododecene-6,17(5*H*,18*H*)-dione

By *W. David Ollis, Julia Stephanidou Stephanatou, J. Fraser Stoddart, Andrew Quick, Donald Rogers*, and *David J. Williams*[*]

The synthesis and conformational behavior of the *N*,*N*′,*N*″-trimethyl[1] and *N*,*N*′,*N*″-tribenzyl[2] derivatives of trianthranilide have been described recently. We now discuss the confor-

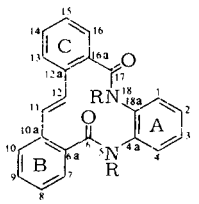
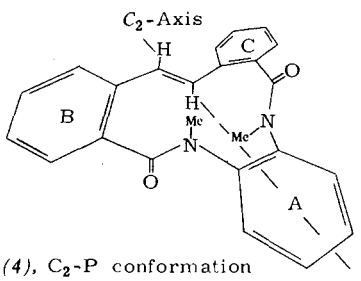
mational properties of the *N,N'*-dimethyl *(2)* and the *N,N'*-dibenzyl *(3)* derivatives of the twelve-membered olefinic bislactam *(1)*[3]:

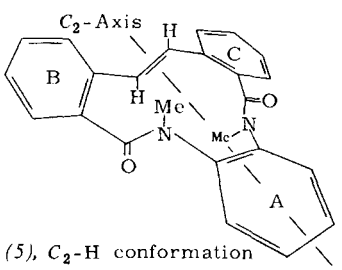


(1), R = H
(2), R = CH_3
(3), R = CH_2-C_6H_5

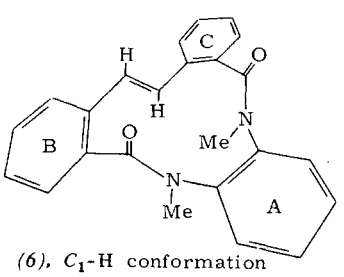
The ^{1}H-NMR spectrum of *(2)* in $CDCl_3/CS_2$ (1:1) at +20°C exhibited singlets at $\tau = 2.90$ and 6.85 for the olefinic and *N*-methyl protons, respectively. No change occurred in the spectrum on cooling the solution to −90°C.



(4), C_2-P conformation



(5), C_2-H conformation



(6), C_1-H conformation

There are three possible non-planar chiral conformations [*(4)*, *(5)*, and *(6)*] to consider for *(2)* which retain two *trans*-amide linkages and the *trans*-olefinic bond [C(11)—C(12)]. The C_2-propeller conformation *(4)* has an approximately parallel alignment of the *trans*-olefinic bond with ring A. In contrast, in the C_2-helix conformation *(5)*, the *trans*-olefinic bond is approximately orthogonal to ring A. The interconversion between the C_2—P *(4)*, C_2—H *(5)*, and C_1—H *(6)* conformations and their enantiomers (C_2—P*, C_2—H*, and C_1—H*) is described by the conformational itinerary given in Figure 1 which includes two pairs of degenerate C_1-helical conformations *(6)* labeled (C_1—H1 and C_1—H2) and (C_1—H1* and C_1—H2*).

These considerations and the ^{1}H-NMR spectroscopic evidence show that *(2)* exists in solution as either (i) inverting C_2—P *(4)*, (ii) inverting C_2—H *(5)*, (iii) rapidly interconverting C_2—P *(4)* and C_2—H *(5)*, or (iv) rapidly inverting C_1—H1 or C_1—H2 *(6)* conformations. Possibilities (iii) and (iv) necessitate rapid re-orientation of the *trans*-olefinic bond at

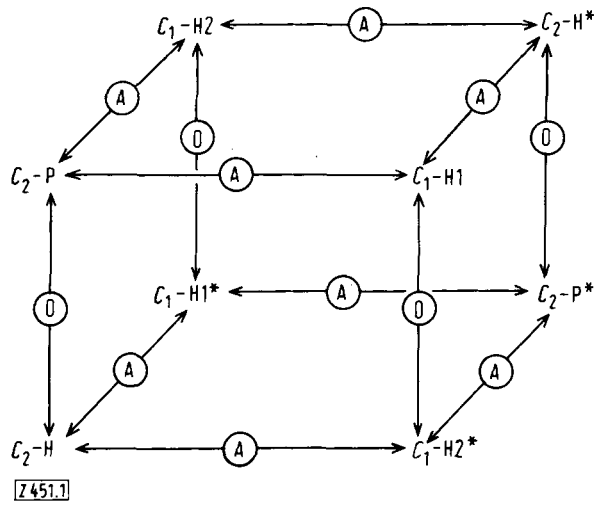


Fig. 1. Conformational changes in derivatives of *(1)*. Ⓐ≡ *trans*-Amide bond re-orientation. Ⓞ ≡ *trans*-Olefinic bond re-orientation.

−80°C: such a process is expected to be slow on the ^{1}H-NMR time scale. However, even if (iii) or (iv) are excluded on the basis of essentially negative evidence, then a decision between (i) and (ii) is still not possible on the basis of ^{1}H-NMR spectroscopy alone. An X-ray crystallographic investigation was therefore undertaken to determine the solid state conformation of the bislactam *(2)*.

(2) crystallizes from methanol as well-formed parallelopipeds. They are orthorhombic $Pna2_1$, $a = 10.708$, $b = 28.233$, $c = 6.197$ Å, $Z = 4$ (2 right-handed, 2 left-handed). Intensities of 1993 reflections were measured on a Siemens diffractometer with $Cu_{K\alpha}$ radiation ($\theta \leq 71°$) and, of these, 18 were reckoned unobserved. The structure was solved by direct methods and refined to a current *R* value of 0.053 showing (Fig. 2) that the molecule adopts a distorted C_2—P conformation *(4)*.

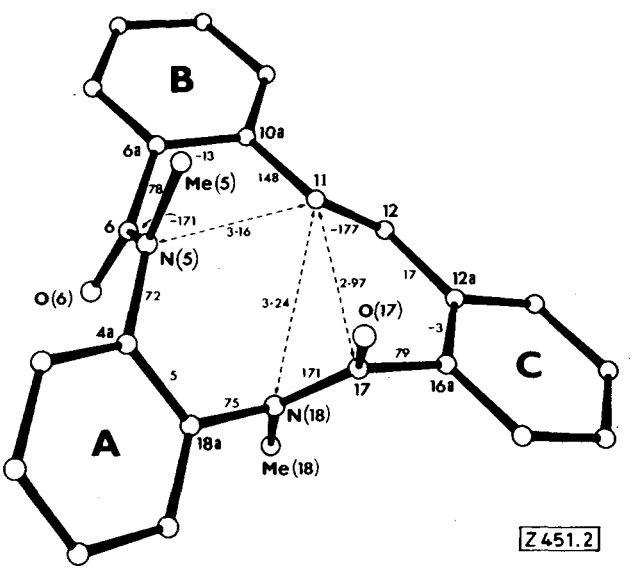

Fig. 2. Torsional angles [°] and some interatomic distances [Å] in the 12-membered ring of the *N,N'*-dimethyl bislactam *(2)*.

The angles between the rings A, B, and C are 35° (A and B), 33° (A and C), and 13° (B and C). The torsional angles (see Fig. 2) show that the planes of the two NMe—CO groups lie roughly perpendicular to the aromatic rings with their *N*-methyl groups on opposite sides of the twelve-membered ring. The olefinic carbon, C(11), protrudes into the twelve-membered ring so as to be nearly equidistant from N(5) and N(18) (3.16 and 3.24 Å, respectively) and only 2.97 Å from C(17).

This distortion of the C_2-propeller conformation *(4)* destroys the molecular C_2-axis and is undoubtedly due to the conjugational demands satisfied by an approach towards a planar stilbenoid grouping in the molecule. The bond angles [129° at C(11) and 126° at C(12)] are very similar to the average of 126.2° found in the recently redetermined structure of *trans*-stilbene[4]. The remainder of the molecule constitutes an asymmetric arrangement around the *trans*-olefinic bond giving torsional angles of 32° and 17° along the C(10a)—C(11) and C(12)—C(12a) bonds, respectively.

The ^{1}H-NMR spectrum of *(3)* in $CDCl_3$ at +20°C exhibits an AB system ($\tau_A = 5.30$, $\tau_B = 5.47$, $J_{AB} = 14.8$ Hz) for the *N*-benzylic methylene protons. When the temperature-dependence was examined in CD_3SOCD_3, the AB system coalesced to give a singlet at +134°C. The rate constant of 94.5 s^{-1}, calculated at the coalescence temperature[5], corresponds to a $\Delta G^{\neq}$ of 20.4 kcal/mol for ring inversion. This is most likely to involve C_2—P$\rightleftharpoons$$C_2$—P* inversion, assuming that the compounds *(2)* and *(3)* are both associated with a preference for the propeller-type conformation *(4)*.

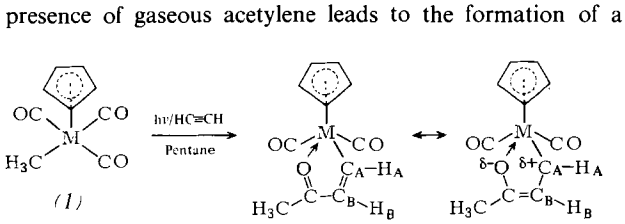
The Photochemical Addition of Acetylene to Tricarbonyl(η^5-cyclopentadienyl)methylmolybdenum and -tungsten

By *Helmut Guido Alt*[*]

The irradiation of transition-metal carbonyls in the presence of potential ligands usually leads *via* cleavage of a CO group to substitution products[1]. In this communication a photoinduced addition of acetylene to $C_5H_5M(CO)_3CH_3$ *(1)* (M = Mo, W) is reported in which the metallocyclic complex of type *(2)* is formed.

The UV irradiation of a pentane solution of *(1)* in the presence of gaseous acetylene leads to the formation of a red, diamagnetic compound *(2)* of formal composition $C_5H_5M(CO)_2(C_2H_2COCH_3)$ (M = Mo, W) as main product. It had been expected from the stoichiometry of the reaction that *(2)* should contain a π-bonded acetylene ligand as well as a σ-bonded acetyl group. Indeed, complexes of the type $C_5H_5M(CO)_2L(COCH_3)$ (M = Cr, Mo, W) are formed, when $C_5H_5M(CO)_3CH_3$ is allowed to react photochemically or thermally with ligands L (*e.g.* triphenylphosphane, trimethyl phosphite)[2]. Spectroscopic characterization of *(2)*, however, revealed that acetylene is not incorporated in the complex simply as a monodentate π-ligand (L).



(1) *(2)*

(a): M = Mo
(b): M = W

Spectroscopic findings are consistent with the formation of a five-membered metallocyclic ring in *(2a)* and *(2b)*. In each case the IR spectrum (in pentane solution) contains two ν(C≡O) absorptions (at 1980, 1905 and 1972, 1897 cm^{-1}, respectively) corresponding to the two CO ligands. The solid-state spectra (KBr) of *(2a)* and *(2b)* exhibit a new band (at 1488 and 1470 cm^{-1}, respectively), which is assigned to the ketonic C=O stretching vibration[3].

The ^{1}H-NMR spectra show singlets for the C_5H_5 and the CH_3 protons. The "acetylene" pattern is shifted very strongly downfield and is split into an AB system; the doublet at low field is assigned to the proton H_A. From the difference in the chemical shifts of H_A and H_B ($\Delta\delta \approx 5$ ppm) it can be concluded that the two protons of the C_2H_2 unit must be in very different environments. Similarly strongly deshielded protons are also observed in the formal acetylene complex $Mo(S_2PR_2)_2(CO)(C_2H_2)$[4], for which the presence of a metallocyclic three-membered ring has been discussed. The coupling constants $J(H_AH_B)$ in *(2a)* and *(2b)* are characteristic for *cis* olefinic protons. Measurements on *(2b)* in [D_8]toluene show no change in the AB system up to 110°C, thus indicating hindered rotation of the acetylene ligand[5].

^{1}H-NMR spectra (in [D_6]acetone; all δ-values in ppm rel. to TMS int.):

	$\delta(C_5H_5)$	$\delta(CH_3)$	$\delta(C_2H_2)$ [H_A/H_B]	$J(H_AH_B$ [Hz]
(1a)	5.59	0.36	—	—
(1b)	5.72	0.42	—	—
(2a)	5.59	2.43	12.01, 7.20	8.6
(2b)	5.70	2.46	12.20, 7.20	9.6

^{13}C-NMR spectra (in [D_6]acetone; all δ-values in ppm rel. to TMS int.):

	δ(M—CO)	$\delta(C_2H_2)[C_AC_B]$	δ(C=O)	$\delta(C_5H_5)$	$\delta(CH_3)$
(2a)	248.35	247.05, 131.73	201.96	93.75	24.38
(2b)	239.18	237.67, 131.72	200.02	92.89	22.98

The unusually strong polarization of the two olefinic carbons in *(2)* is confirmed by the ^{13}C-NMR spectrum, which, in the case of *(2b)* shows an additional ^{13}C-^{183}W coupling of the α-C atom of the five-membered ring with the central atom (73 Hz) besides the ^{13}C-^{183}W coupling of the two terminal CO ligands (154 Hz). Together with the observed chemical shifts this finding affords unequivocal assignment of C_A and C_B.

The photoreactions of *(1)* with methylacetylene, phenylacetylene, and diphenylacetylene likewise lead to metallocyclic complexes[2b].

Experimental:

All operations are carried out under argon and with anhydrous solvents. A solution of *(1)* (3 mmol) in pentane (300 ml) is irradiated for 30 min with a mercury high-pressure lamp (Hanovia L-450W), a slow stream of acetylene being passed

[*] Dr. H. G. Alt
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

through the reaction solution at the same time. The dark red-brown suspension that is formed is concentrated by evaporation and the oily residue chromatographed with benzene on silica gel. The first (red) zone contains *(1)* and small amounts of an unknown by-product, the second (orange zone) the complex *(2)*. Recrystallization from pentane at −79 °C affords analytically pure, cherry-red crystals. Yield: 0.077 g (9 %) *(2a)*, m.p. 65 °C; 0.056 g (5 %) *(2b)*, m.p. 74 °C.

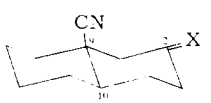
Partial Asymmetric Diels-Alder Reaction with an α-Chloronitroso Compound

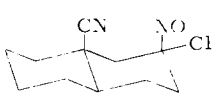
By *Helmut Nitsch* and *Günter Kresze*[*]

In non-catalyzed Diels-Alder reactions of open-chain or cyclic dienes with acrylates, fumarates or glyoxylates of optically active alcohols, the optical yields are generally low (≤ 13 %). We report here on a heterodienophile whose cycloadditions with 1,3-dienes are more selective.

Reaction of the oxime *(2)* (m.p. 140 °C) of 9-cyano-*trans*-2-decalone *(1)*[1] with *tert*-butyl hypochlorite affords a 2-chloro-2-nitroso-9-cyanodecalin *(3)* (m.p. 69 °C; 60 % yield), in which

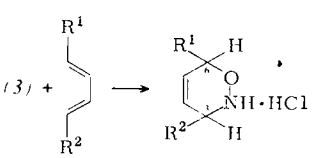


(1), X = O
(2), X = NOH



(3)

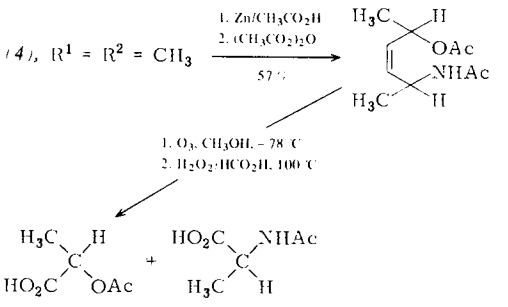
the NO group is axial[2]. This compound reacts slowly with an excess of 1- or 1,4-substituted 1,3-dienes in methanol with cleavage of the decalin moiety to give the adducts *(4)* in *very* good yields.



(4)

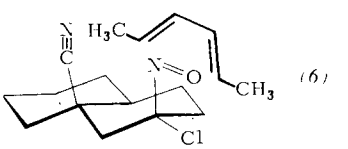
R^1	R^2
CH_3	H
CH_3	CH_3
C_6H_5	CH_3

(1) can be resolved into the antipodes *via* its methoxycarbonylhydrazone[3]; according to the sign of its Cotton effect ($\Delta\varepsilon = +1.45$ at 290.5 nm), (+)-*(1)*, $[\alpha]_{578}^{22} = +82.5°$ (ethanol, $c = 0.831$), has 9*R*,10*S* configuration. (−)-(2*S*,9*R*,10*S*)-*(3)*, $[\alpha]_{578}^{22} = -125°$ (ethanol, $c = 0.480$), obtained from (+)-*(1)* reacts (20 °C, 7d) with *trans*,*trans*-2,4-hexadiene to give optically active *(4)*, $R^1 = R^2 = CH_3$, in 83 % yield; the free base of *(4)*, b.p. 32 °C/1.5 torr, has $[\alpha]_{578}^{22} = -25.9°$ (CH_2Cl_2, $c = 0.71$).



(5)

Degradation of *(4)*, $R^1 = R^2 = CH_3$, according to the above scheme leads to a mixture of acids from which the *O*-acetyllactic acid *(5)* can be separated by chromatography on silica gel; *(5)*, b.p. 51 °C/27 torr, has $[\alpha]_{589}^{27} = -23.1°$ (acetonitrile, $c = 0.735$). This corresponds to an optical purity of 39 % and the *S*-configuration of C-6 in *(4)*.



(6)

Only a few model structures come under discussion for the transition state formed by *(3)* and the diene, because of the bulkiness and rigidity of *(3)*. The proposed structure *(6)* is most consistent with the observed preference of the 3*R*,6*S*-configuration in *(4)*. The assumed preference of the position of the NO group relative to the decalin moiety is—at least for the crystalline state—confirmed by X-ray structure analysis[2].

The optical yield of the reaction described here can, of course, be improved by variation of the structure in the diene. This type of Diels-Alder reaction ought then afford a convenient entry not only to the synthesis of optically active, hydrogenated 1,2-oxazines, but also to numerous secondary products of these compounds.

Am Klopferspitz, D-8033 Martinsried (Germany)

main product, which undergoes stereoselective Diels-Alder addition with 1,3-dienes[1]. Elucidation of the mechanism of this reaction required X-ray determination of the configuration and conformation of *(1)*.

(1)

Since *(1)* is very sensitive to light, it had to be handled with extensive exclusion of light even during measurement of the reflection intensities. Blue monoclinic crystals were obtained from solutions in *n*-hexane and petroleum ether[2]. Space group: $P2_1n$ with $a = 13.27_9$, $b = 15.08_5$, $c = 11.71_6$ Å, $\gamma = 84.85°$; $D_{exp} = 1.28\ g \cdot cm^{-3}$; $Z = 8$ (2 molecules per asymmetric unit), $D_X = 1.29\ g \cdot cm^{-3}$. With aid of an automatic single crystal diffractometer using Cu-Kα radiation (Ni filter) 4436 independent reflections were recorded in the range $0 \leq \theta \leq 70°$ (θ 2θ scan, 5-point measurement); 1404 reflections were unobserved ($I \leq 2\sigma_I$). The structure was solved by direct methods using the PHASDT program[3]. An *E* Fourier synthesis with the 300 greatest *E* values reproduced all the atoms (except H) to be expected from the constitutional formula. In the course of least-squares refinement – first with isotropic and then anisotropic temperature parameters – it could be shown by a difference Fourier synthesis, which also revealed all the H positions, that each molecule shows a second O position of the nitroso group having different population parameters. The ratio of the population parameters of the two O positions was 8:2 for one molecule and 7:3 for the other. Refinement converged at an *R* value of 5.9 %.

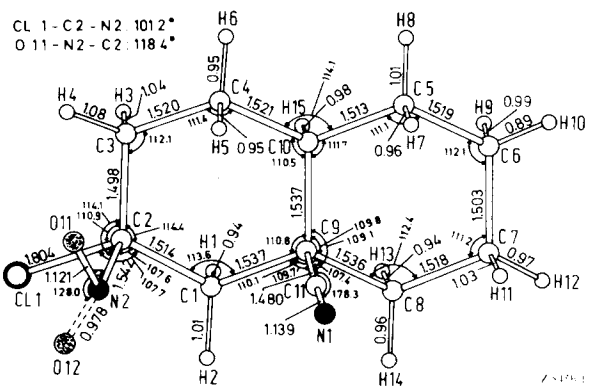

Fig. 1. Molecular structure of *r*-9,*t*-2-chloro-*c*-2-nitroso-*trans*-decalin-9-carbonitrile. The bond lengths and angles given are average values for both molecules of the asymmetric unit. The average standard deviations of the distances are 0.01 Å (except C—H: 0.03 Å; O-12—N-2: 0.02 Å), and those of the angles 0.3° (except O-12—N-2—C-2: 1°).

Figure 1 shows the molecular structure of *(1)*. The cyano group on C-9 and the nitroso group on C-2 are *cis* configurated. Steric interaction between these substituents leads to some deformation of the *trans*-decalin system: the chair shaped six-membered ring C-1 to C-9 is noticeably flattened at C-1 and C-2, as shown by the internal angles of 113.6 and 114.4° at these atoms. The NO and the C≡N groups are directed away from each other, as seen from the nonparallel bonds C-2—N-2 and C-9—C-11 in Figure 1.

The nitroso group can adopt two conformations which interconvert by rotation about C-2—N-2. In the principal oxygen site (O-11) the bonds N=O and C-2—C-3 are almost eclipsed, and in the secondary oxygen position (O-12) this applies to the bonds N=O and C-2—Cl-1. The main conformation found in the crystalline state of the nitroso group permits a steric description of the transition state of the Diels-Alder reaction of *(1)* and explains the stereoselectivity found[1].

The sp^3—sp^2 type bond C-2—N-2 is unusually long at 1.54 Å, whereas the length of the C≡N bond at 1.14 Å corresponds to expectations.

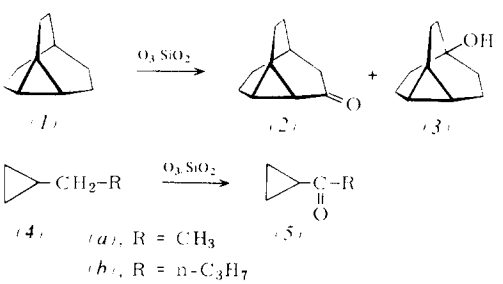
Oxidation of Cyclopropyl Hydrocarbons with Ozone[**]

By *Ehrhardt Proksch* and *Armin de Meijere*[*]

Cyclopropylcarbonyl compounds are important intermediates in preparative organic chemistry. We have found that "dry ozonization"[1] is a method for directed functionalization of cyclopropyl hydrocarbons in the α-position to the cyclopropyl group. It affords convenient entry even to those cyclopropylcarbonyl compounds for which precursors are as yet unknown or are only difficultly accessible.

In the reaction of cycloalkanes with ozone, which is adsorbed on silica gel, the tertiary positions are preferably hydroxylated[1]. Reaction of tricyclo[3.3.2.0^{2,8}]decane (hexahydrobullvalene) *(1)*, however, predominantly affords tricyclo-



[3.3.2.0^{2,8}]decan-3-one *(2)*[2] (87 % of the mixture of products) along with smaller amounts of tricyclo[3.3.2.0^{2,8}]decan-5-ol *(3)* (in 9 % yield). This preference for the secondary C—H bonds in the α-position to the cyclopropyl group is general.

Thus, the *n*-alkylcyclopropanes *(4)* yield the *n*-alkyl cyclopropyl ketones *(5)* as main products (see Table 1). The bicyclo[*n*.1.0]alkan-2-ones *(7)* are accessible in good yields from

the bicyclo[n.1.0]alkanes *(6)*; bicyclo[n.1.0]alkan-3-ones *(9)* are formed as byproducts along with traces of the diketones *(10)*.

Exceptions are the bicyclo[2.1.0]pentane *(6)*, $n=1$, which yields, *inter alia*, cyclopropylacetic acid[9], and compound *(6e)* (see Table 1). The apparent difference in the reactions of *(6d)* and *(6e)* is consistent with the observation that energetically different carbenium ions occur as intermediates in the solvolysis of 3,5-dinitrobenzoates of the *cis*- and *trans*-bicyclo[6.1.0]nonan-2-ols[10]. Obviously, the actual radical attack of ozone at a C—H bond[11] will be determined by a polar effect[12] favoring attack at such positions at which a partial

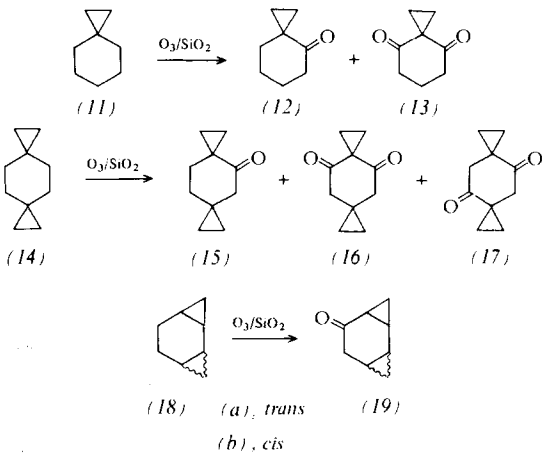

Table 1. Composition of product mixtures obtained on "dry ozonization" of cyclopropyl hydrocarbons.

Educt		Amount of product (%) [a]								Ref.
(4a)	*(4a)*	5	*(5a)*	95						[3]
(4b)	*(4b)*	5	*(5b)*	87						[4]
(6a)	*(6a)*	2	*(7a)*	93	*(8a)*	5		*(10a)*	0	[3, 5]
(6b)	*(6b)*	3	*(7b)*	95	*(8b)*	1		*(10b)*	1	[2, 3]
(6c)	*(6c)*	2	*(7c)*	85	*(8c)*	0	*(9c)* 11	*(10c)*	2	[3, 6]
(6d)	*(6d)*	3	*(7d)*	88	*(8d)*	0	*(9d)* 7	*(10d)*	2	[7]
(6e)	*(6e)*	10	*(7e)*	36	*(8e)*	10	*(9e)* 40	*(10e)*	4	[7]
(11)	*(11)*	9	*(12)*	64	*(13)*	27				[2, 3]

(18a)	*(18a)*	4	*(19a)*	96						[2]
(18b)	*(18b)*	27	*(19b)*	73						[2]

[a] As a rule, 200–500 mg of the hydrocarbon was ozonized. In an experiment with 500 mg *(6b)* the yield of chromatographically isolated *(7b)* was 60 %. In other isolations using larger quantities the yields are 20–30 % higher.

positive charge can be stabilized by the cyclopropyl neighboring group. Accordingly, the selectivity of the ketonization is greater in the case of spiro[2.5]octane *(11)* than in *(6)*: α-oxidation to the spiro[2.5]octan-4-one *(12)* and the dione *(13)* takes place exclusively. The dispiro[2.2.2.2]decane *(14)* affords about equal amounts of the monoketone *(15)* and the isomeric diketones *(16)* and *(17)*.

Starting from the *trans*- and *cis*-tricyclo[5.1.0.0^{2,4}]octanes *(18a)* and *(18b)* this method affords the first entry to the tricyclo[5.1.0.0^{2,4}]octan-6-ones *(19a)* and *(19b)*, which are of importance as precursors for the *trans*-[13] and the previously unknown *cis*-tris-σ-homobenzene.

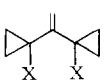
Coupling Reactions of Vinylidenedicyclopropanes Doubly Halogenated in Allylic Positions—A Productive Synthesis of Trispiro[2.0.2.0.2.0]nonane ([3]Rotane)[**]

By *Lutz Fitjer*[*]

Vinylidenedicyclopropanes *(1)* which are doubly halogenated and metalated in the allylic positions were formerly unknown. They contain a tricyclopropyl synthon and as 1,3-difunctional molecules should possess considerable potential for the formation of cyclic systems. It therefore appeared particularly rewarding to examine their utility in the synthesis of the otherwise difficultly accessible [n]rotanes *(2)*, $n=3$, 4, 5...



(1), X = Halogen, Metal

(2), n = 3, 4, 5...

We now report the first synthesis of two vinylidenedicyclopropanes *(6)* and *(8)* which are doubly halogenated in their allylic positions; their intramolecular coupling to give the dispiroheptanes *(7)*[1] and *(9)* provides an entry to the entire [n]rotane series *(2)*[1, 2].

We obtained *(6)*[3] and *(8)*[3] by double ring opening of dicyclopropyl ketone *(3)*[4] with bromine in chloroform, recyclization of the resulting *meso*/(±)-1,3,5,7-tetrabromoheptan-4-one *(4)*[3] with sodium hydroxide in diethylene glycol to give 1,1'-dibromodicyclopropyl ketone *(5)*[3, 5], and subsequent methylenation and cyclopropylidenation, respectively, in the presence of potassium *tert*-butoxide.

Metalation and intramolecular coupling of *(6)* and *(8)* to form 7-methylenedispiro[2.0.2.1]heptane *(7)*[1] and 7-cyclopropylidenedispiro[2.0.2.1]heptane *(9)*[3] was accomplished

[*] Dr. L. Fitjer

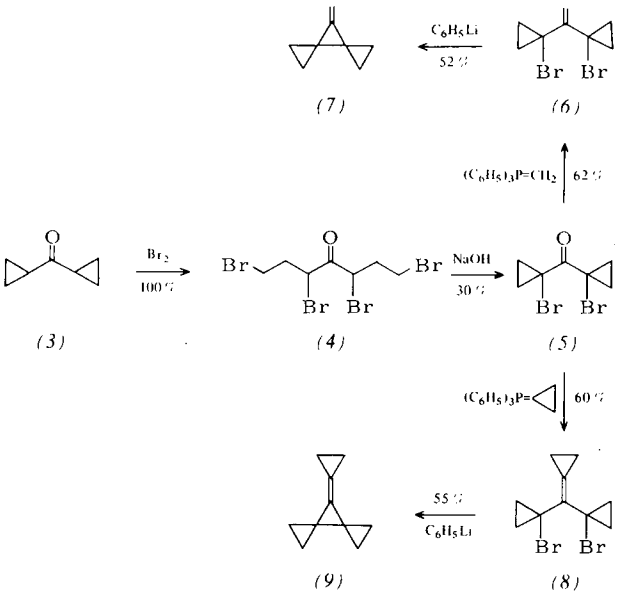
Tammannstrasse 2, D-3400 Göttingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.



with phenyllithium in ether. Methyl-, *n*-butyl-, and *tert*-butyllithium led to dialkylated products.

The above method of preparing *(7)* and *(9)* means that productive syntheses are available for all rotanes. While *(7)* can be transformed quantitatively into [3]rotane *(2)*, $n=3$, by cyclopropanation[6], the higher rotanes *(2)*, $n=4$, 5, 6 can all be prepared by way of *(9)*[2].

Experimental:

To prepare *(5)*, two equivalents of bromine were added dropwise to a solution of *(3)*[4] in chloroform maintained at 50 to 60°C and the compound *(4)*, obtained in crude state on removal of the solvent, was cyclized by dropping it into a suspension of three equivalents of sodium hydroxide in diethylene glycol at 40 to 50°C. Methylenation and cyclopropylidenation were accomplished by treating benzene solutions of *(5)* at 60°C portionwise with 1:1 mixtures of methyl- and cyclopropyl-triphenylphosphonium bromide, respectively, and potassium *tert*-butoxide; reactions were stopped when no ketone could be detected, even after hydrolysis. Compounds *(7)* and *(9)* were prepared by dropwise addition of ethereal solutions of *(6)* and *(8)* at 0°C to 1.1 equivalents of phenyllithium in ether.

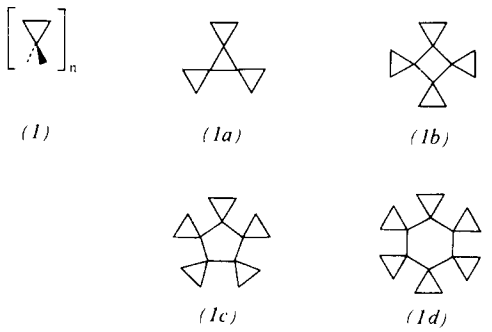
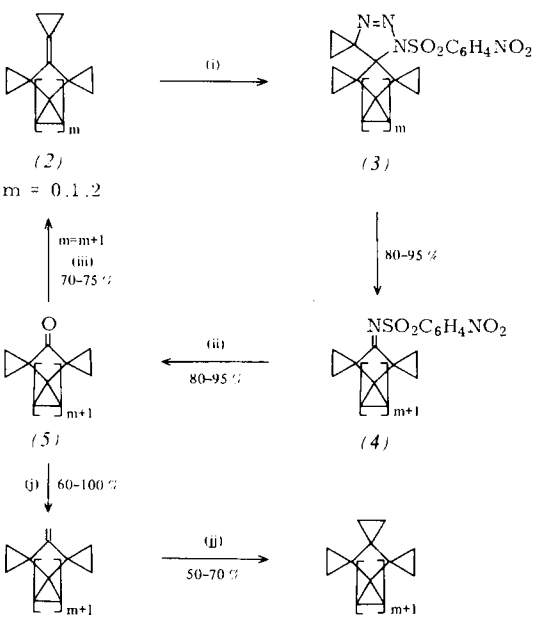
A Universal Rotane Synthesis—Hexaspiro[2.0.2.0.2.0.2.0.2.0.2.0]octadecane ([6]Rotane)[**]

By *Lutz Fitjer*[*]

Although the synthesis of the first [*n*]rotanes *(1b)* and *(1c)* was accomplished several years ago, neither the reactions nor the physicochemical properties of these hydrocarbons have yet been studied in detail. One reason is the restricted availability of the rotanes so far reported [*(1a)* to *(1c)*], which are accessible only by mutually independent total syntheses[1].



We have reported[2] a productive synthesis of [3]rotane *(1)*, $n=3$, and now present a method permitting the synthesis of each of the higher rotanes *(1)*, $n=4$, 5, 6. The main feature of this synthesis is a closed homologation sequence *(2)* → *(3)* → *(4)* → *(5)* → *(2)* which can, in principle, be repeated as often as desired. Its utility stems from the pronounced regioselectivity with which *p*-nitrobenzenesulfonyl azide (i) adds to the cyclopropylidenepolyspiroalkanes *(2)*[3]. Reaction proceeds *via* the unstable 2-triazolines *(3)* to give the ring-expanded imides *(4)*, which can be converted into the ketones *(5)* by alkaline hydrolysis (ii). At this stage a choice is possible



(i): p-$NO_2C_6H_4SO_2N_3$
(ii): KOH/CH_3OH
(iii): $(C_6H_5)_3P=$ [2]
(j): $(C_6H_5)_3P=CH_2$ [1a, 1b, 2]
(jj): CH_2I_2, Zn/Cu [1a, 1b], Zn/Ag [6]

[*] Dr. L. Fitjer
Organisch-Chemisches Institut der Universität
Tammannstrasse 2, D-3400 Göttingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

between methylenation (j) with subsequent cyclopropanation (jj), to give the rotanes *(1)* with $n=m+4$, or cyclopropylidenation (iii), in order to repeat the homologation sequence.

Starting from 7-cyclopropylidenedispiro[2.0.2.1]heptane *(2)*, $m=0$[2], we have not only devised a convenient preparation of the key compounds *(5)*, $m=0$ and $m=1$, for the known syntheses of [4]rotane *(1b)*[1a] and [5]rotane *(1c)*[1b], but also accomplished the first preparation of [6]rotane *(1d)* *via* *(5)*, $m=2$[5].

Since the partial structure of *(2)* responsible for the regioselectivity of the cycloaddition *(2)* → *(3)* does not change for $m>2$, the method described should permit synthesis of [*n*]rotanes with $n>6$.

[6]Rotane *(1d)* crystallizes from ether as coarse platelets (m.p. 211 to 214 °C) and is shown by its IR, ^{1}H-NMR, and ^{13}C-NMR spectra to exist in a fixed chair form at room temperature.

In order to determine the inversion barrier we have studied the temperature dependence of its ^{1}H-NMR spectrum (100 MHz, hexachlorobutadiene, *p*-dichlorobenzene as internal standard): the AA'BB' system centered at $\delta_{TMS}=0.05$ ppm with $\Delta\nu=83.3\pm0.2$ Hz, which is characteristic for *(1d)*, coalesces at 177 ± 2 °C. Insertion of these data into the Eyring relation affords $\Delta G^{\ddagger}_{450}=22.0\pm0.1$ kcal/mol, the highest inversion barrier for a cyclohexane derivative so far known.

Experimental:

The cyclopropylidenepolyspiroalkanes *(2)* are homologized by refluxing solutions of *p*-nitrobenzenesulfonyl azide in acetonitrile (saturated in the cold) with equivalent amounts of *(2)* for 12 to 16 h, hydrolyzing the imides *(4)* (which crystallize on cooling) with 5 % methanolic potassium hydroxide solution at 60 °C, and cyclopropylidenating the resulting ketones *(5)* in the manner described in ref. [2]. Compound *(1d)* is prepared by methylenating *(5)*, $m=2$, as described in ref. [2] and cyclopropanating *(6)*, $m=2$, by the procedure given in ref. [6].

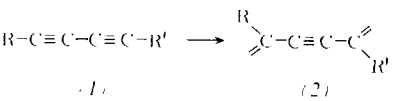
Polymerization of Tricosa-10,12-diynoic Acid in Multilayers

By *B. Tieke*, *G. Wegner*, *D. Naegele*, and *H. Ringsdorf*[*]

Oriented layers constructed from monomolecular films by means of the Langmuir-Blodgett (LB) technique have achieved great significance in physicochemical studies. However, most are unstable, and ultimately break apart in order to reorganize in the form of microcrystals. Hence, attempts have not been lacking to construct such layers from long-chain vinyl derivatives and to polymerize these with retention of the layer structure[1]. More suitable for this purpose ought to be the topochemical polymerization of diacetylenes, which leads with retention of the molecular packing in the crystal lattice to chains containing conjugated double and triple bonds[2]. The fact that the single crystals of polydiacetylenes studied so far have proven themselves as one-dimensional semiconductors[3] aroused additional interest in the construction of extended multilayers of these polymers.



(1) *(2)*

R = $-(CH_2)_9-CH_3$
R' = $-(CH_2)_8-CO_2H$

Using the LB technique[4] we have prepared multilayers on quartz supports of the Cd salt of tricosa-10,12-diynoic acid *(1)* from monomolecular films. They were characterized by their UV spectra and by measurement of the (001) reflections in the X-ray diffractometer. The long spacing (5 orders) was found to be 51.5 Å. Since the length of the molecule as estimated from known bond lengths and angles amounts to *ca.* 30 Å, the molecules must be oriented head-to-head-to-tail-to-tail in the layers, *i.e.* Y layers must be present. The angle of the longest molecular axis to the surface of the support is then *ca.* 60°. The absorption bands of the conjugated triple bonds appear at $\lambda=217$, 230, 242, and 256 nm.

The multilayer was polymerized by irradiation at 254 nm. The UV spectrum obtained after 20 min corresponds to that of the pure polymer *(2)*. Maxima are observed at 537 nm

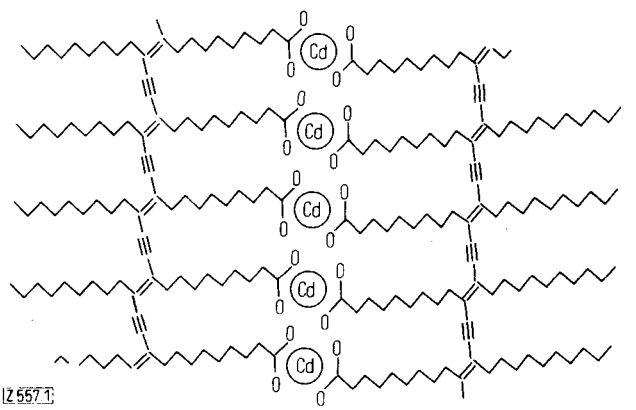


Fig. 1. Structure of a layer after polymerization.

($\varepsilon = 1.5 \times 10^4$ cm^{-1}) and 498 nm ($\varepsilon = 1.63 \times 10^4$ cm^{-1}). The X-ray data show that the arrangement of the layers remains unaltered. The polymer layers (Fig. 1 shows their structure) are stable at room temperature under normal laboratory conditions (O_2, light, *etc.*) and show no signs of reorganization even after several months.

Synthesis of (1)[5]:

Undecynoic acid (0.02 mol) is neutralized with 10% KOH (15 ml). To this solution are added successively hydroxylamine hydrochloride (100 mg) and copper(I) chloride (500 mg) in 70% aqueous ethylamine (4 g). A solution of 1-iodo-1-dodecyne (0.02 mol) in methanol (10 ml) is then added dropwise with vigorous stirring to the cold reaction mixture. After acidification with 2 N H_2SO_4 the mixture is extracted with ether, the etheral phase dried over sodium sulfate, and the ether removed by distillation. The residue is treated with petroleum ether (b.p. 40—60°C), from which *(1)* crystallizes on cooling. Yield: 3.5 g (45.5%); m.p. 56.5°C.

Preparation of multilayers of (1):

(1) was sprayed onto an aqueous 2×10^{-4} M solution of $CdCl_2$ in a Langmuir trough. The monomolecular films that were formed were successively transferred by the LB technique onto ultra-pure quartz platlets until a multilayer of defined thickness was obtained.

S_4N_4 Bridge Ligand: Structure of $CuCl \cdot S_4N_4$[**]

By *Ulf Thewalt*[*]

Addition compounds of S_4N_4 and Lewis acids are well known[1]. In the X-ray spectrographically investigated compounds $SbCl_5 \cdot S_4N_4$[2] and $BF_3 \cdot S_4N_4$[3], S_4N_4 functions as monodentate ligand, which is bound *via* a N atom to the central atom of the Lewis acid. Both compounds contain discrete $MX_n \cdot S_4N_4$ structural units.

Since the empirical formulas of the novel compounds $CuCl \cdot S_4N_4$, $CuBr \cdot S_4N_4$, and $CuCl_2 \cdot S_4N_4$ afford no clue to the actual structure of the complexes an X-ray structure analysis[4] was carried out on $CuCl \cdot S_4N_4$ *(1)*. Compound *(1)* is slowly formed on allowing a solution of S_4N_4 and $CuCl_2 \cdot 2H_2O$ in benzene/ethanol to stand for several hours. The well-formed, lustrous, anthracite-black crystals are stable towards air and water, do not dissolve in any of the common solvents, and decompose without melting on being heated.

Sektion für Röntgen- und Elektronbeugung der Universität
Oberer Eselsberg, D-7900 Ulm (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

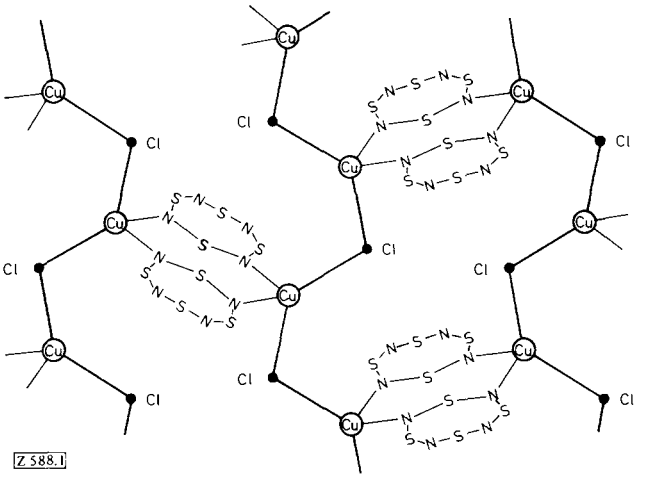

Fig. 1. Structure of a $[CuCl \cdot S_4N_4]_x$ layer (schematic).

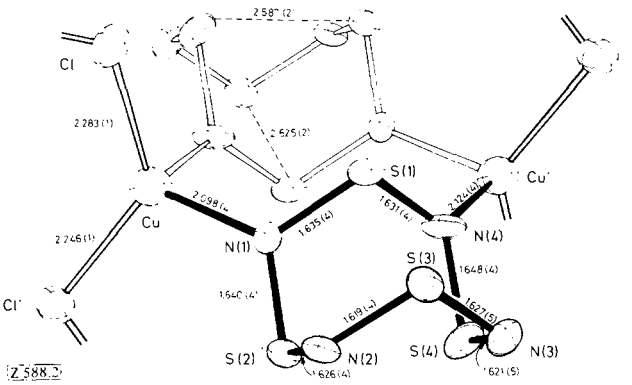

Fig. 2. Section from the crystal structure of $CuCl \cdot S_4N_4$ *(1)* with bond lengths in Å. The internal angles in the S_4N_4 unit are: S(1) 103.6(2)°, S(2) 104.4(2)°, S(3) 104.8(2)°, S(4) 103.9(2)°, N(1) 112.8(2)°, N(2) 113.6(2)°, N(3) 113.7(2)°, N(4) 112.6(2)°; other bond angles: Cl—Cu—Cl' 129.1(1)°, N(1)—Cu—N(4') 103.9(2)°, Cu—Cl—Cu'' 110.0(1)°, S(1)—N(1)—Cu 120.6(2)°, S(2)—N(1)—Cu 125.3(2)°, S(1)—N(4)—Cu' 126.9(2)°, S(4)—N(4)—Cu' 119.9(2)°.

In the crystal, zig-zag chains $[Cu—Cl]_x$ are present and all are oriented parallel to the *z* axis (long axis of the crystal, cf. Fig. 1). Cu atoms of neighboring chains are each bridged by two S_4N_4 rings. The resulting layers and neighboring layers of the same type are held together by Van der Waals forces. As in $SbCl_5 \cdot S_4N_4$ and $BF_3 \cdot S_4N_4$, the S_4N_4 moiety in *(1)* is bound *via* nitrogen to the metal atom; however, in *(1)* a S_4N_4 ring is bound by two coordinate bonds. The Cu atom is tetrahedrally coordinated. Surprisingly, the S_4N_4 group in *(1)* differs only slightly in its dimensions and not at all in its conformation from free S_4N_4[6]; the N atoms lie at the corners of a square (exactly in one plane), the S atoms are situated alternately above and below this square, and there are two short transannular S···S distances. In comparison, the S_4N_4 group in the complexes $SbCl_5 \cdot S_4N_4$ and $BF_3 \cdot S_4N_4$ has an inverse conformation, *i.e.* with the S atoms occupying the corners of a square[2, 3].

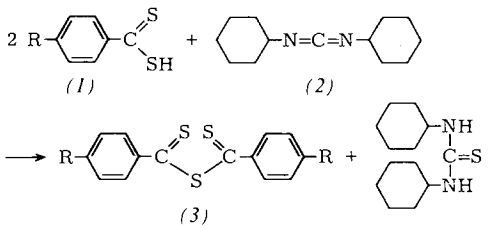
Isolation of Crystalline Bis(thioacyl) Sulfides

By *Shinzi Kato*, *Tomonori Katada*, and *Masateru Mizuta*[*]

While carboxylic anhydrides are well known, their sulfur analogs *(3)* have remained unknown so far because of their instability[1].

We now report the isolation of the first bis(thioaroyl) sulfides *(3)*. The compounds listed in Table 1 are obtained on reaction of aromatic dithiocarboxylic acids *(1)* with dicyclohexylcarbodiimide *(2)* at 0°C. The crystalline thioanhydrides *(3a)* and *(3b)* are fairly stable in the solid state at room temperature in the dark, but the oily compounds *(3c)* and *(3d)* decompose completely within 1 h under similar conditions.



(1) *(2)* *(3)*

Table 1. Bis(thioaroyl) sulfides *(3)* synthesized.

	R	Yield [%]	M.p. [°C]	UV (cyclohexane) λ_{max}	(ε_{max})	IR (KBr) $\nu_{as}C{=}S$ [cm^{-1}]
(3a)	CH_3	80	74—75	334 nm (25000)	568 nm (150)	1232, 1242
(3b)	CH_3O	85	65—66	355 nm (35900)	559 nm (365)	1245, 1270
(3c)	H	75	oil	307 nm (14600)	548 nm (145)	1245 [a]
(3d)	Cl	78	oil	323 nm (16800)	548 nm (155)	1245 [a]

[a] Neat.

The structures proposed for *(3a)* to *(3d)* are in accord with the results of elemental analysis and UV, IR, and ^{1}H-NMR spectroscopic data. The UV absorption at 310 to 350 nm is due to the $\pi \rightarrow \pi^*$ transition, and that at 550 to 570 to the $n \rightarrow \pi^*$ transition of the thiocarbonyl groups.

Experimental:

Freshly prepared 4-methyldithiobenzoic acid *(1a)* (3.36 g, 0.02 mol) and *N,N'*-dicyclohexylcarbodiimide *(2)* (2.06 g, 0.01 mol) are stirred in *n*-hexane (80 ml) under nitrogen for 1 h at 0°C. Removal of the precipitate (*N,N'*-dicyclohexylthiourea, 2.28 g) by filtration, evaporation of the solvent, and recrystallization of the resulting residue from petroleum ether (b. p. < 40°C) gives dark green needle crystals of bis(4-methylthiobenzoyl)sulfide *(3a)* (2.46 g, 80%).—NMR (CCl_4): δ [ppm]: 2.32 (s, 6H, CH_3), 7.05 (*ca.* d, 4H), 7.82 (*ca.* d, 4H).

Arsenic Oxide Trichloride, $AsOCl_3$[**]

By *Konrad Seppelt*[*]

Like arsenic pentachloride, which remained undiscovered for some 140 years, existence of the oxide chloride of arsenic, $AsOCl_3$ has so far not been reported. On the other hand $POCl_3$ has been known since 1847 and is presently produced on an industrial scale.

Two problems were expected to beset the preparation of $AsOCl_3$: a) decomposition with evolution of chlorine and reduction to trivalent arsenic, and b) the tendency of the As=O double bond to polymerization, for $AsOF_3$ is known only in the polymeric form[1]. Attempts to prepare $AsOCl_3$ by careful hydrolysis of $AsCl_5$[2] met without success because the HCl formed catalyzed the decomposition of $AsCl_5$. However, $AsOCl_3$ can be prepared surprisingly simply by ozonization of $AsCl_3$ in inert solvents at low temperatures.

The reaction proceeds quantitatively and results in precipitation of $AsOCl_3$. Its structure is proved by the mass spectrum [m/e = 196 ($AsOCl_3^+$, 42%), 180 ($AsCl_3^+$, 50%), 161 ($AsOCl_2^+$, 100%), and other fragments], the Raman and IR spectrum (987 cm p, 441 dp, 412 p, 256 dp, 201 p, 160 dp) and by stoichiometric take-up of ozone.

$$AsCl_5 \xrightarrow{H_2O/HCl} AsCl_3 + Cl_2$$

$$AsCl_3 + O_3 \xrightarrow[-78\,°C]{CFCl_3/CH_2Cl_2} AsOCl_3 + O_2$$

Arsenic oxide trichloride is a colorless, crystalline solid, which is considerably more thermally stable than arsenic pentachloride. As expected $AsOCl_3$ has a pyramidal structure, the oxygen atom being double bonded. This is confirmed by the Raman spectrum, which closely resembles that of $AsCl_3$ with regard to some of the bands. A calculation of force constants[3] gives a value of $f = 7.47$ mdyne/Å for the arsenic-oxygen bond, *i. e.* $AsOCl_3$ is one of the few compounds containing a real arsenic-oxygen double bond. The calculation also

[*] Priv.-Doz. Dr. K. Seppelt
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg 1

[**] This work was supported by the Fonds der Chemischen Industrie. The mass spectra were recorded by Dr. *R. Geist*.

shows that the strength of the arsenic-chlorine bond increases [2.04→2.59 mdyne/Å] in the transition $AsCl_3 \rightarrow AsOCl_3$, exactly as in the system $PCl_3 \rightarrow POCl_3$ [2.34→2.98 mdyne/Å]. The compounds are therefore also related in the details of their bonding.

$AsOCl_3$ slowly decomposes at −25 °C, and much more rapidly at *ca.* 0 °C, with formation of $As_2O_3Cl_4$.

$$3\ AsOCl_3 \longrightarrow AsCl_3 + Cl_2 + As_2O_3Cl_4$$

This compound is stable up to 150 °C. Its vibrational spectrum reveals disappearance of the As=O double bond, thus ruling out the structure $P_2O_3Cl_4[Cl_2P(O)—O—(O)PCl_2]$. It is also not volatile, but decomposes above 200 °C with loss of $AsCl_3+Cl_2$ to give "As_2O_5"—a process which can be readily monitored in the mass spectrum.

$As_2O_3Cl_4$ is obviously a polymer. It can be isolated in analytically pure form, but is X-ray amorphous. No crystallization takes place even after 50 hours' annealing at 120 °C. In this compounds arsenic is doubtless pentacoordinated, or hexacoordinated by way of chlorine bridges.

Bis(η-1,5-cyclooctadiene)cobaltlithium

By *Klaus Jonas, Richard Mynott, Carl Krüger, Janine C. Sekutowski*, and *Yi-Hung Tsay*[*]

Nickel(0)-olefin complexes which do not contain pronounced acceptors as ligands form defined dilithium-nickel-olefin complexes with lithium[1]. We now wish to report a further example of this class of compounds.

Reaction of metallocene complexes $(C_5H_5)_2M$ with an alkali metal leads to release of the two C_5H_5 rings and formation of alkali metal-C_5H_5 and elemental transition metal[2]. In the case of cobaltocene and nickelocene we have now found that the deposition of transition metal is suppressed on addition of cyclooctadiene (COD). The new cobalt complex *(3)* and the known nickel complexes *(1)*[3] and *(2)*[1] can then be isolated in high yield [*e.g. (3)*: 85 %][7].

$$(C_5H_5)_2Co \xrightarrow[THF,\ 0\,°C]{Li,\ COD} C_5H_5CoCOD + LiC_5H_5$$

$$C_5H_5CoCOD \xrightarrow[THF,\ 0\,°C]{2\ Li,\ COD} (COD)_2CoLi(THF)_x\ (3) + LiC_5H_5$$

$$(C_5H_5)_2Ni \xrightarrow[THF,\ 0\,°C]{2\ Li,\ 2\ COD} (COD)_2Ni + 2\ LiC_5H_5$$

$$(COD)_2Ni \xrightarrow[THF,\ 0\,°C]{2\ Li} (COD)_2NiLi_2(THF)_4\ (2)$$

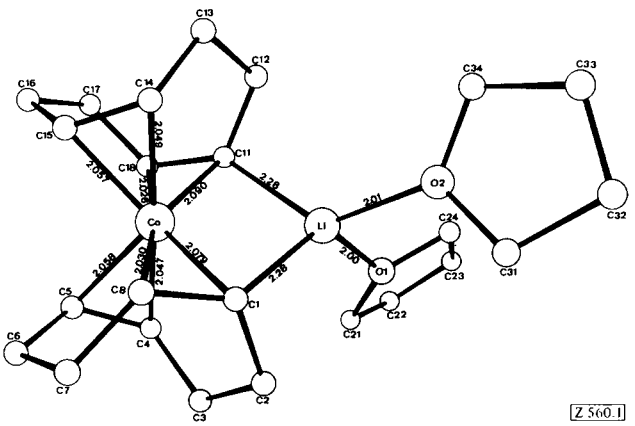
Recrystallization of *(3)* from ether gives

$(COD)_2CoLi(THF)_2$ *(3a)*

and on addition of dimethoxyethane (DME), yellow crystals of

$(COD)_2CoLi(DME)_3$ *(3b)*

are obtained. The new cobalt complexes *(3)* were characterized by metal analyses and by their reaction with CO, in which four CO per LiCo were consumed with displacement of COD. The IR spectrum (THF) shows all four double bonds are complexed both in *(3)* and in the isoelectronic compound *(1)*. The ^1H-NMR spectrum ([D_8]THF, RT) of *(3b)* displays two broad signals at $\tau = 7.57$ (—CH_2) and $\tau = 7.9$ (CH=CH), intensity ratio 2:1, for the cyclooctadiene.



Z 560.1

Fig. 1. Crystal structure of $(COD)_2CoLi(THF)_2$ *(3a)*.

Figure 1 shows the result of an X-ray structure analysis of *(3a)* [$a = 14.094(1)$, $b = 18.799(3)$, $c = 17.500(3)$ Å, $\beta = 97.74(1)°$, space group C2/c, 3219 reflections, 1485 unobserved, $R = 0.064$]. The bond angles at the cobalt atoms diverge pairwise so markedly from an ideal tetrahedron (such as occurs in the isoelectronic complex $Ni(COD)_2$[4]) that the molecule is better described as a trigonal bipyramid. Its equatorial positions are occupied by Li and by one double bond each of the two olefinic ligands [C1—C8: 1.413(7) Å; C11—C18: 1.419(7) Å]. Owing to bridging with the axial positions of the Co [C4—C5: 1.391(8) Å; C14—C15: 1.401(8) Å] the COD ligands assume a highly distorted boat conformation. Short Li—C distances (Li—C1; Li—C11) indicate strong ion-pair interaction[5] between the Li atom in a tetrahedral environment and C atoms of the double bonds in equatorial positions. The Li—Co distance [2.654(8) Å] is significantly longer than the sum of the respective covalent radii.

The ^{13}C-NMR spectrum[6] of *(3a)* at room temperature shows only two signals for the COD at 69.1 and 34.7 ppm ([D_8]THF) or at 69.5 and 33.7 ppm ([D_8]toluene). On cooling a solution in [D_8]THF the COD signals become much broader only below −60 °C. In [D_8]toluene, on the other hand, broadening begins at 0 °C, and at −77 °C eight signals of approximately equal intensity are observed. Four of the signals lie at 79.6, 74.3, 71.5, and 50.7 ppm (all d, average chemical shift 69.0 ppm), and the other four at 38.3, 38.0, 30.2, and 29.0 ppm (all t, average chemical shift 33.9 ppm). These temperature effects are reversible. The ^{13}C-NMR spectrum of *(3a)* in [D_8]toluene at −77 °C is compatible with the structure of the crystalline complex: owing to the equatorial position of the Li atom on the cobalt, four distinct pairs of olefinic and aliphatic C atoms are expected. On raising the temperature in [D_8]toluene, the Li atom is found to undergo a shift in

the $(COD)_2Co$ group. The strongly solvating $[D_8]$THF accelerates this exchange.

Bis(diorganylphosphinodithioformato-*S*,*P*)nickel(II) Complexes—Novel Four-Membered Ring Chelates[**]

By *Jürgen Kopf*, *Rudolf Lenck*, *Sigurjon N. Olafsson*, and *Reinhard Kramolowsky*[*]

Substituted dithioformate ions of type *(1)* react with many elements to give well known[1] four-membered ring chelates in which they coordinate *via* the two S atoms. A chelate formation with the donor atom of the residue Y and an S atom has been discussed but not proven[2].

(1) Y = NR_2, OR, SR

As novel ligands of type *(1)*, we prepared the phosphinodithioformates *(2)* by reaction of secondary phosphanes and carbon disulfide in the presence of aqueous potassium hydroxide[3,4].

$$R_2PH + CS_2 + KOH \rightarrow R_2PCS_2^-K^+ + H_2O$$

(2)

(a): R = C_6H_5[4]
(b): R = cyclo-C_6H_{11}
(c): R = $C_6H_5CH_2$

The salts *(2)* react with nickel(II) salts to give apolar, diamagnetic bis(chelates) *(3)* having the composition $[Ni(S_2CPR_2)_2]$[4,5]. We have now found that the anions of *(2)* occur as P,S-bonded chelates in these complexes, for, in contrast to *(2)*, they do not react in organic solvents at room temperature with sulfur[6]. The high-frequency position of a band attributable to an approximate C=S stretching vibration in the IR spectra (cf. Table 1) also provides evidence for this structure.

Table 1. Physical properties of complexes *(3)*.

	Color	M.p. (dec.) [°C]	IR (KBr) νC=S [cm^{-1}]
(3a)	orange	198—202 [a]	1100 vs. br
(3b)	red	206—209 [b]	1087 vs. br
(3c)	rust red	153—156 [c]	1092 vs. br

[a] Dissolved in dibromomethane and precipitated with ether.
[b] From benzene.
[c] From dibromomethane/acetone.

Proof of the structure was afforded by an X-ray structure analysis of *(3b)*, which on the basis of 2121 significant reflections was solved by usual methods and refined to an *R* value 0.072. *(3b)* crystallizes in the triclinic space group $P\bar{1}$ with $a = 1073.9$, $b = 1124.5$, $c = 1448.3$ pm; $\alpha = 90.58$, $\beta = 91.12$, $\gamma = 116.94°$; $Z = 2$. The nickel atom forms an inversion center and is bonded in a planar array to two *trans* P and S atoms (see Fig. 1).

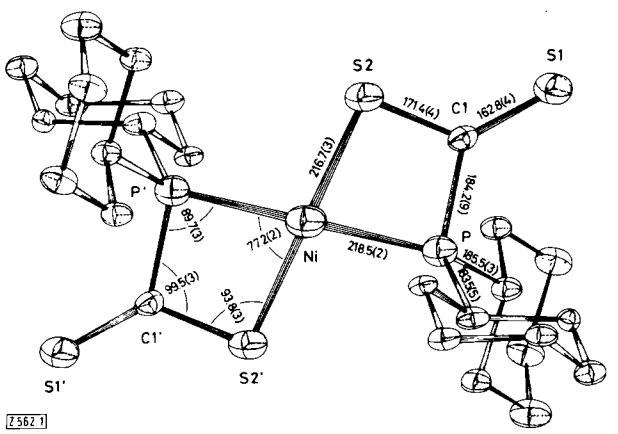

Fig. 1. Molecular structure of the bis(chelate) *(3b)* with important bond lengths (righthand side) and important bond angles (lefthand side); standard deviations in parentheses.

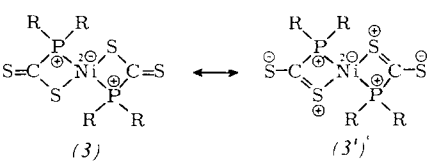
The exocyclic C—S bond is significantly longer than in thioformaldehyde ($r_{C=S} = 161.1$ pm)[7], and the endocyclic C—S distance is shorter than the value ($r_{C-S} = 176$ to 178 pm)[8] calculated for $C(sp^2)$—S single bonds. Together, these findings are consistent with a marked contribution of the resonance structure *(3')*. The Ni—S and Ni—P bond lengths are notably



(3) *(3')*

shorter than in all previously investigated four-membered ring chelates containing a NiS_4 skeleton ($r_{Ni-S} = 218$ to 224 pm)[1b] or planar nickel(II) complexes with *trans*-NiP_2X_2 coordination ($r_{Ni-P} = 225$ to 238 pm; X = Cl, Br)[9].

Experimental

Potassium diorganylphosphinodithioformates *(2)*: All operations must be carried out under nitrogen. A solution of the secondary phosphane (30 mmol) and carbon disulfide (30 mmol) in tetrahydrofuran (25 ml) is treated with a saturated aqueous solution of potassium hydroxide and the mixture stirred vigorously for 15 h at room temperature. After concentration of the THF solution and addition of ether [or of *n*-hexane in the case of *(2c)*] *(2)* separates out as fine, bright-pink to red crystals. Yield 80 to 85 %.

Bis(diorganylphosphinodithioformato-*S,P*)nickel(II) complex *(3)*: A solution of *(2)* (10 mmol) [in the case of *(2a)* in acetone and ether (25 ml of each), in the case of *(2b)* in acetone (25 ml), and in the case of *(2c)* in THF (20 ml) and ether (75 ml)] prepared under nitrogen is added dropwise to a solution of $Ni(NO_3)_2(H_2O)_6$ (5 mmol) in acetone (50 ml) [in the case of *(2a)* in acetone and ether (50 ml of each)]. The finely crystalline precipitate of complex *(3)* is filtered off, washed thoroughly with water and acetone, and recrystallized as quoted in Table 1. Yield 75 to 85 %.

All compounds *(2)* and *(3)* gave correct analyses[10].

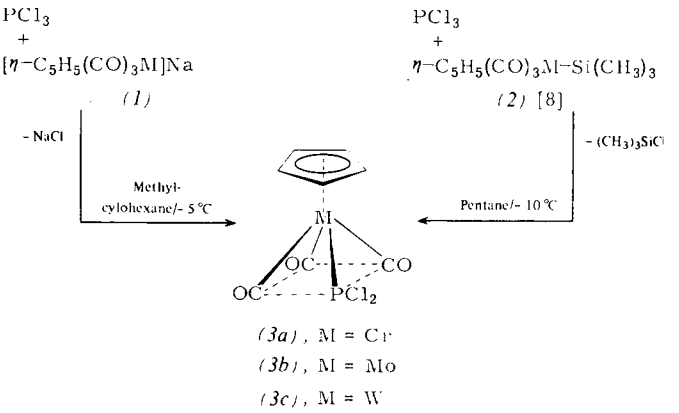
Functional Transition-Metal Phosphanes[1]

By *Wolfgang Malisch* and *Robert Alsmann*[*]

Transition metal-substituted phosphanes have a strong tendency to undergo agglomeration with ligand elimination[2]. Only in a few sterically or electronically favorable cases are they preparatively accessible[3]. We have now been able to prepare the first functional representatives *(3)* of this class of compounds, which are obtained as air-sensitive, deeply colored crystals by metalation of phosphorus trichloride with salts of type *(1)*, or with trimethylsilyl complexes *(2)* derived therefrom.

Compounds *(3a)*—*(3c)* are only moderately soluble in pentane and cyclohexane; they are much more readily soluble in benzene or THF, but rapidly decompose with formation of the complex metal halides *(4)*. Decomposition increases in the series *(3a)* ≪ *(3c)* < *(3b)* and can be thermally accelerated[4]. The complex metal halide is accompanied by



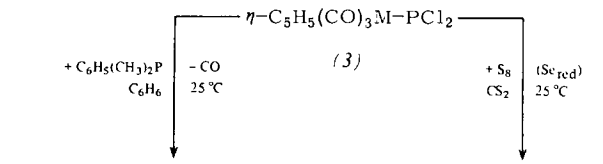
(3a), M = Cr
(3b), M = Mo
(3c), M = W

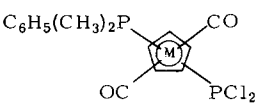
a P- and Cl-containing product which we formulate, for stoichiometric reasons, as $(PCl)_x$.

$$\underset{(3)}{\eta\text{-}C_5H_5(CO)_3M\text{—}PCl_2} \rightarrow \underset{(4)}{\eta\text{-}C_5H_5(CO)_3MCl} + (PCl)_x$$

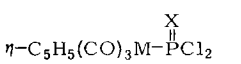
Therefore satisfactory yields (60 to 70 %) of *(3)* are only achieved in apolar solvents, especially if—starting from *(2)*—homogeneous reaction ensures a minimal stress.

The decomposition *(3)* → *(4)* affords evidence for compounds *(3)* being transition-metal analogs of alkali metal-chlorophosphanes, postulated in the reaction of polychlorinated phosphorus(III) compounds with alkali metals[5]. They are more stable, however, and should, as related systems[4] be suitable for the generation of phosphorus(I) units[6]. We presume that weakening of the central bond is the initial step of the decomposition and that a high charge density on the transition metal and phosphorus serves as the driving force for the decomposition. Consistent with this hypothesis, replacement of carbon monoxide by organylphosphane—which exclusively affords the *trans*-isomer *(5)* and strengthens the already electronically unfavorable state—leads to metal phosphanes which lose metal halide even more readily.





(5), M = Cr
νCO: 1944(w), 1871(vs)
(Benzene)



(6a), M = Cr, X = S
(6b), M = W, X = S
(6c), M = W, X = Se

On the other hand, attachment of sulfur or selenium [*(6)*] *via* the lone pair on phosphorus, stabilizes the metal-phosphorus bond. Compounds *(6)* are formed without catalytic assistance or thermal induction and cannot be reconverted into *(3)* by strongly basic organylphosphanes (which merely substitute *trans* CO).

The number, position, and intensity of the carbonyl stretching vibrations confirm the square monopyramidal ligand arrangement at the metal atom in *(3)*, *(5)*, and *(6)* (local symmetry C_s). Direct coupling of phosphorus and metal fol-

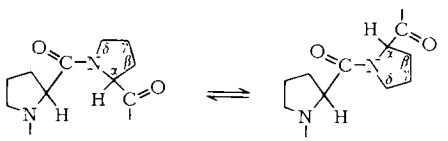
NMR Spectroscopic Detection of *cis* and *trans* Peptide Bonds in Unprotected Oligo-L-prolines[**]

By *Manfred Rothe* and *Hans Rott*[*]

Dedicated to Professor Leopold Horner on the occasion of his 65th birthday

Poly-L-proline forms two helix structures which are characterized by the *trans*- and *cis*-configurations of their peptide bonds (polyproline II and I). In the *cis-trans* isomerization the C_α protons of the pyrrolidine ring change their positions relative to the peptide carbonyl group. The isomers can therefore be distinguished on the basis of the chemical shifts of their C_α—H resonances: $\tau_I = 5.48$ ppm, $\tau_{II} = 5.19$ ppm in CD_3COOD.



I: *cis* II: *trans*

In order to examine whether helix formation already occurs in short proline chains and to find out what influence the chain length has on the stabilization of the helical structures, we synthesized molecularly homogeneous, unsubstituted oligomers of the L-proline[1]

H—(Pro)$_n$—OH with $n = 2$ to 40

We found that the tendency to form all-*trans*- and all-*cis*-peptides depends on the chain length of the oligomer and on the solvent. Strong interactions between the solvent (water, carboxylic acids) and the peptide carbonyl groups, *e.g.* by hydrogen bonding[2], stabilize the *trans*-helix, whereas weak interactions (unsubstituted aliphatic alcohols) promote the

[**] Conformations of Linear Proline Oligomers, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen, Germany. Part 3: *M. Rothe*, *R. Theysohn*, *K.-D. Steffen*, *H.-J. Schneider*, *M. Zamani*, *M. Kostrzewa*, and *W. Schindler*, Angew. Chem. *82*, 557 (1970); Angew. Chem. Int. Ed. Engl. *9*, 535 (1970).

cis-helix. The differing strength of the bonding between solvent and peptide carbonyl groups could be determined from small differences in the τ values of the C_α—H resonances (CF_3COOD: 5.10 ppm; CD_3COOD: 5.19 ppm; D_2O: 5.24 ppm; CF_3CD_2OD: 5.26 ppm; CD_3OD: 5.31 ppm). In CD_3COOD and CF_3COOD all oligopeptides have the *trans*-configuration. We found that there is a distinct dependence of the configuration on chain length in the other solvents, di- and triprolines behaving differently from the higher oligoprolines: in D_2O, di- and triproline are in *cis-trans* equilibrium; from $n=4$ onwards only *trans* peptide bonds are formed. In CD_3OD, diproline is completely and triproline extensively *cis* configurated, respectively. The proportion of *cis* bonds ($\tau=5.50$ ppm) passes through a minimum at $n=4$ and increases rapidly with increasing chain length; the all-*cis* configuration is reached at $n>10$. The reverse behavior was observed in CF_3CD_2OD: here diproline is likewise completely *cis* configurated; in the oligomers with $n=3$ to 10, both *cis* and *trans* peptide bonds occur. From $n=12$ onwards we found exclusively *trans* peptide bonds. In the case of C- and N-protected oligoprolines, however, apart from in the first disordered four members, only all-*trans* peptide bonds are found[4]. The ability of di- and triprolines to form *cis* peptide bonds is consistent with the pronounced tendency to form cyclotriprolyls and, particularly, cyclodiprolyls[3].

While only the signal of the *cis*- or *trans*-isomer appears in the range of C_α protons in the ^{1}H-NMR spectra of the polyproline and the oligomers with $n>15$, the spectra of the lower oligomers contain additional resonances which arise from the N- and C-terminal proline residues. The τ values of the C-terminal proline residue depend on the position of the dissociation equilibrium of the carboxyl group, and hence on the solvent (CF_3COOD: 5.1 ppm; CD_3COOD: 5.4 ppm; D_2O, CF_3CD_2OD, CD_3OD: 5.7 ppm).

Crystal Structure of $Te_5O_4F_{22}$[**]

By *Hans Pritzkow* and *Konrad Seppelt*[*]

Sulfur and selenium form the monomeric compounds SOF_4 and $SeOF_4$[1a], whereas in the case of tellurium only polymeric $(TeOF_4)_n$ and oligomers of the type $F_5Te—(OTeF_4)_n—OTeF_5$ have been described[1b]. Little is known about the structures of these compounds. Previously it had been assumed that they contained O—TeF_4—O octahedra coupled *via* oxygen and it is unclear whether the two oxygen atoms occupy the *cis* or *trans* position. Polymeric $(TeOF_4)_n$ is formed in the pyrolysis of $B(OTeF_5)_3$[1b] and in the fluorination of $As(OTeF_5)_3$[2].

$$As(OTeF_5)_3 \xrightarrow{F_2} [AsF_2(OTeF_5)_3] \rightarrow AsF_5 + (TeOF_4)_n$$

[*] Dr. H. Pritzkow and Priv.-Doz. Dr. K. Seppelt
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

From the polymeric mixture obtained by the latter reaction we were able to isolate a component having the composition $Te_5O_4F_{22}$. It is a crystalline, sublimable solid which melts at 76 °C; it was characterized by its vibrational, mass, and NMR spectra[2]. A crystal structure analysis has now been carried out on this apparently complicated oxide fluoride of tellurium.

$Te_5O_4F_{22}$ crystallizes tetragonally, space group $I4_1/a$ with the cell parameters $a=8.816(2)$, $c=20.341(6)$ Å and $Z=4$ formula units in the unit cell. The structure was solved with Patterson and difference Fourier syntheses and refined by the method of least squares (1178 independent reflections with $I>\sigma$, all atoms anisotropic) to $R=0.049$.

The compound is made up of isolated $TeF_2(OTeF_5)_4$ octahedra (Fig. 1). Four outer octahedra are coupled *via* their

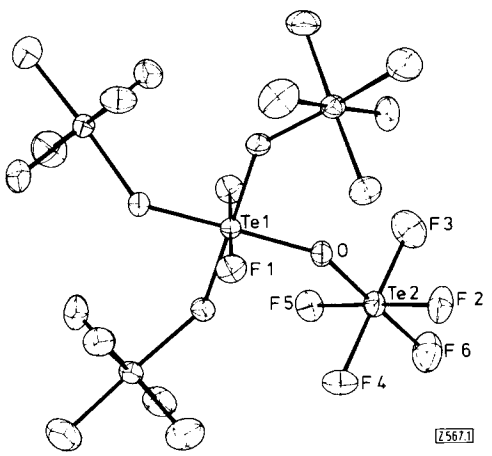

Fig. 1. Molecular structure of $Te_5O_4F_{22}$.

corners to a central octahedron. Limiting tellurium to an octahedral environment and allowing no oxygen double bonds, there are still twelve possible isomers for a molecule of formula $Te_5O_4F_{22}$. Surprisingly, the substance under investigation occurs only in the highly symmetric arrangement. This finding is in accord with the ^{19}F-NMR spectrum of $Te_5O_4F_{22}$.

Since no short intermolecular distances occur, the geometry of the molecule is determined only by intramolecular forces. Remarkably, the tellurium-fluorine bonds in the central octahedron are somewhat longer (1.849 Å) than the others (1.798 to 1.819 Å). The large Te—O—Te angle (139.4°) could be due to repulsion between the tellurium atoms[3]. In the related compounds $Xe(OSeF_5)_2$ and $U(OTeF_5)_6$ the corresponding angles are 125° and 170°, respectively[4]. From these large differences it may be assumed that double bonding leads to stretching of the angle. It would then follow that the d-orbital participation in the case of tellurium is greater than in the case of selenium, while in the case of uranium even f-orbitals participate in the bonding.

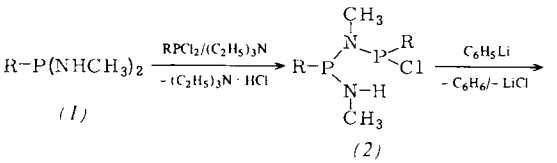
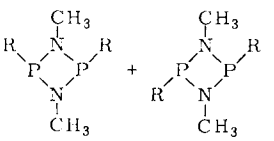
Synthesis and Isolation of *cis*- and *trans*-1,3,2λ^3,4λ^3-Diazadiphosphetidine

By *Otto J. Scherer* and *Günter Schnabl*[*]

In contrast to the *cis*- and *trans*-1,3,2λ^5,4λ^5-diazadiphosphetidine-2,4-dithiones already characterized by crystal structure analysis[1] and the 1,3,2λ^3,4λ^5-diazadiphosphetidin-4-ones or 4-thiones, some of which are detectable in solution as mixtures of *cis*- and *trans*-isomers[2], all the 1,3,2λ^3,4λ^3-diphosphetidines that have been synthesized thus far and investigated NMR spectroscopically exist in only one isomeric form[3]. With the isolation of *(2)*[4] we have now been able to demonstrate for the first time the existence of the postulated intermediates[3b, 5] in some 1,3,2λ^3,4λ^3-diphosphetidine syntheses and have found a method for preparation of *cis*- and *trans*-1,3,2λ^3,4λ^3-diazadiphosphetidines [*(3a)* and *(3b)*].



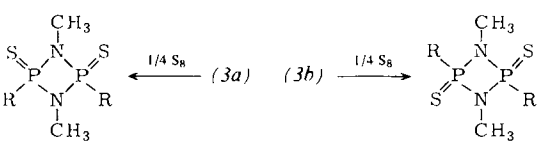
(1) *(2)*



(3a), *cis* *(3b)*, *trans*

R = C(CH$_3$)$_3$

(3b), whose structure was confirmed by a crystal structure analysis[8], shows an unusual downfield shift in the ^{31}P-NMR spectrum (Table 1). Compounds *(3a)* and *(3b)* are oxidized stereospecifically by elemental sulfur (in ice-cold pentane) to the 1,3,2λ^5,4λ^5-diazadiphosphetidin-2,4-dithiones *(4a)* and *(4b)*, respectively, which also differ markedly in their melting points.



(4a), *cis* *(4b)*, *trans*

R = C(CH$_3$)$_3$.

[*] Prof. Dr. O. J. Scherer and Dipl.-Chem. G. Schnabl
Fachbereich Chemie der Universität
Pfaffenbergstrasse 95, D-6750 Kaiserslautern (Germany)

No transformation into the other isomer could be detected by NMR spectroscopy on warming *(3a)* or *(3b)* to *ca.* 140 °C for several hours.

Experimental:

Synthesis of *(3a)* and *(3b)*: A solution of phenyllithium (52.8 mmol) in ether (44 ml) is added dropwise with stirring to an ice-cold solution of *(2)*[6] (13.0 g, 48.0 mmol) in pentane (250 ml). The mixture is then allowed to warm to room temperature, stirred for a further 3 hours, and filtered on a G3 frit. The filtrate is concentrated in a vacuum and fractionally distilled. *(3b)* sublimes on the cold finger, while *(3a)* drips into the receiver. *(3b)* is purified by resublimation (oil-pump vacuum) and *(3a)* by redistillation in a 10-cm Vigreux column. B.p. 32—34 °C/0.1 torr *(3a)*, subl. temp. 55—70 °C (bath temperature)/0.1 torr *(3b)*.

Synthesis of Cycloheptasulfur Oxide, S_7O[1]

By *Ralf Steudel* and *Torsten Sandow*[*]

Compounds containing cumulated sulfur-sulfur bonds, such as S_8, R_2S_3, or R_2S_4, can be oxidized with trifluoroperoxyacetic acid to sulfoxides (S_8O; R_2S_nO, $n = 3$ or 4)[2]. We have now

[*] Prof. Dr. R. Steudel and Dipl.-Chem. T. Sandow
Institut für Anorganische und Analytische Chemie
der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

found that cycloheptasulfur[3] reacts smoothly with CF_3CO_3H at -20 °C in dichloromethane to give S_7O in 45% yield:

$$S_7 + CF_3CO_3H \rightarrow S_7O + CF_3CO_2H$$

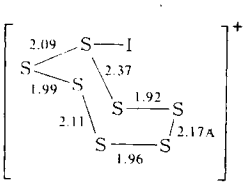
S_7O crystallizes from CH_2Cl_2 as orange, at -80 °C yellow, transparent monoclinic crystals having a density of 2.1$_5$ g·cm^{-3} (25 °C). Elemental analysis and osmometric determination (at 0 °C in CH_2Cl_2) of the relative molecular mass (calc. 240; obs. 244) confirm the formula.

S_7O decomposes completely within 24 h at 25 °C in diffuse daylight, but only within several days in the dark. At -50 °C the compound can be stored for longer periods without decomposition. It melts at 55 °C (SO_2 evolution), and on decomposition at normal pressure gives SO_2 and polymeric sulfur, which according to its Raman spectrum contains only a small amount of S_8. The mass spectrometrically[4] investigated decomposition in a high vacuum proceeds, as in the case of S_8O[5], according to the following equation:

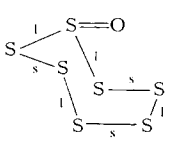
$$S_7O \rightarrow S_2O + \frac{5}{n} S_n$$

The ions SO^+, S_2O^+, and S_n^+ ($n = 1$ to 8; S_2^+ most abundant, followed by S_5^+) were detected, but no molecular ion was observed (sample temperature 60 °C).

The Raman spectrum[4] of S_7O recorded at -90 °C could be assigned by comparison with the spectra of S_7[6] and S_8O[7] and enabled some conclusions to be drawn about the molecular structure. The molecule S_7 belongs to the point group C_1[8], to which S_7O must therefore also belong, *i.e.* all 18 normal vibrations are Raman active. Of these, 17 could be identified (Table 1), *viz.* ν_{SO} (which in the crystal is split into three components)[9], 1 δ_{SSO}, 7 ν_{SS}, and the 8 deformation and torsion vibrations of the ring. Since the spectra of S_7 and S_7O are very similar in the region of the ring deformation vibrations, both compounds must contain rings having the same conformation. On the other hand, there is no similarity in the SS stretching vibrations, a fact which can be attributed to the influence of the oxygen atom (cf. the pair S_8/S_8O[7b, 10]). The SS nuclear separations determined from the wave numbers of the SS stretching vibrations[11] are: 1.93, 1.97, 1.99, 2.11, 2.14, 2.17, and 2.19 Å [three short (s) and four long (l) bonds compared with the single bond length of 2.06 Å[12]]. S_7O



S_7I^+ [13]



S_7O

thus resembles the isoelectronic cation S_7I^+, which was recently isolated as the hexafluoroantimonate and characterized by X-ray structure analysis[13]. The SO nuclear separation obtained from ν_{SO} using valence force constants[15] calculated according to the two-body model[14] is 1.48 Å.

The synthesis of S_7O raises the question whether the hypothetical S_7S, isoelectronic with S_7O and isomeric with cyclooctasulfur, might be considered as a component of liquid or gaseous sulfur.

Table 1. Wave numbers and intensities of the normal vibrations in the Raman spectrum of crystalline S_7O (cm^{-1}; sample temperature -90 °C, spectral split width 1.5 cm^{-1}, intensities: vs very strong, s strong, m moderate, w weak, vw very weak; ν stretching vibration, δ deformation vibration, τ torsion vibration.

1113 vw	ν_{SO}	390 w	δ_{SSO}	209 w	δ_{ring} and τ_{ring}
1102 w		372 w-m	ν_{SS}	193 m	
1098 vw		345 m		165 s	
575 m	ν_{SS}	325 vs		158 m	
534 w		292 s	δ_{ring}	129 w-m	
517 m		281 m			
402 w		232 s			

Experimental

$(CF_3CO)_2O$ (4.4 ml) is added with vigorous stirring at 0 °C to a suspension of H_2O_2 (0.91 g; 80%) in CH_2Cl_2 (95 ml, purified by column chromatography on basic Al_2O_3). The reaction mixture is warmed to 25 °C and stirred until no droplets of H_2O_2 are discernible. S_7 (272 mg) is dissolved in ultrapure CH_2Cl_2 (80 ml) at 0 °C and the solution protected against exposure to light. The CF_3CO_3H solution (5.6 ml) is then added dropwise with stirring within 15 min at -20 °C. The golden-yellow mixture is stirred for one hour and then cooled to -70 °C, whereupon S_7O (130 mg, 45%) crystallizes out. The crystals are collected on a cooled glass frit at -30 °C in the absence of moisture, washed with a little cold CH_2Cl_2, and dried in an oil-pump vacuum. If necessary the product is recrystallized from CH_2Cl_2 (50 ml) by dissolution at 0 °C and cooling to -80 °C.

Formation of Carbenium Ions in the Reaction of Aluminum Chloride with *tert*-Butyl Chloride in Liquid Hydrogen Chloride

By *Franz Kalchschmid* and *Erwin Mayer*[*]

The catalytic action of aluminum chloride in Friedel-Crafts reactions is usually explained in terms of intermediary occurrence of carbenium ions. However, a spectroscopic identifica-

[*] Dr. F. Kalchschmid and Dr. E. Mayer [+]
Institut für Anorganische und Analytische Chemie der Universität Innrain 52, A-6020 Innsbruck (Austria)
[+] Author to whom correspondence should be addressed.

tion of these intermediates has, to our knowledge, so far proved unsuccessful. At low temperatures weak donor-acceptor complexes between alkyl chloride and aluminum chloride have been detected[1]. In the reaction of *tert*-butyl chloride with $AlCl_3$ at $-78\,^{\circ}C$ a crystalline 1:1 complex could be isolated[2], which according to the ^{1}H-NMR signal of the *tert*-butyl group, however, does not contain a carbocation. Only reaction of alkyl chlorides with SbF_5, FSO_3-SbF_5, and HF-SbF_5 gave stable carbenium ions[1].

We have established that *tert*-butyl chloride reacts with excess $AlCl_3$ in anhydrous liquid hydrogen chloride quantitatively with formation of the carbenium ion *(1)*.

$$C(CH_3)_3Cl + Al_2Cl_6 \rightarrow [C(CH_3)_3^+][Al_2Cl_7^-]$$
(1)

The reaction was carried out in sealed glass ampoules and was complete within a few minutes at 25 °C. *(1)* was identified ^{1}H-NMR spectroscopically at 25 °C (singlet at −4.38 ppm, TMS as external standard; cf. −4.45 ppm for $[C(CH_3)_3^+][Sb_2F_{11}^-]$ in pure SbF_5[3]) and by a low-temperature IR spectrum of the product remaining after removal of the hydrogen chloride at −112 °C[4]. The IR absorptions (2958 cm^{-1} w, 2780 m, 2720 sh, 1452 m, 1285 vs, 1265 vs, 1195 m, 1110 sh, 1068 s, 957 s, 900 s) were very similar to the values published by *Olah*[3, 5] except for differences in intensities and band splitting. From the absence of the intense IR bands of *tert*-butyl chloride it could be concluded that the reaction was quantitative. Investigation of the Raman spectrum was rendered difficult by strong fluorescence of the HCl solution above 400 cm^{-1}; nevertheless, characterization of the anion as $Al_2Cl_7^-$ (bands at 317 cm^{-1} vs, 160 m, 97 m)[6] was possible.

The rate of formation of $[C(CH_3)_3]^+$ depends on the purity and particle size of the $AlCl_3$ employed. For Raman investigations specially purified $AlCl_3$ reacts within hours at −60 °C, less carefully purified samples react only slowly even at −30 °C. The course of the reaction can be followed ^{1}H-NMR spectroscopically by the shift of the *tert*-butyl singlet at −1.94 ppm (*tert*-butyl chloride in HCl at −60 °C) to the value for $[C(CH_3)_3]^+$ (−4.38 ppm). As in investigations carried out by *Olah*, exchange between carbenium ion and unreacted *tert*-butyl chloride leads to only one singlet, whose chemical shift lies between these two values, depending on the concentration.

Solutions of $[C(CH_3)_3]^+[Al_2Cl_7]^-$ in liquid HCl are stable for weeks at 25 °C and discolor only slowly. Solutions stored at −30 °C remain colorless. Solid $[C(CH_3)_3^+][Al_2Cl_7^-]$, obtained by removal of HCl at −112 °C, already decomposes at *ca.* −50 °C.

Reaction of aluminum bromide with *tert*-butyl bromide in liquid HBr likewise furnishes the ion $[(C(CH_3)_3]^+$ (^{1}H-NMR signal at −4.7 ppm). Hence, it should be possible to carry out the first complete investigation of the IR and Raman spectra of the *tert*-butyl cation, since the $[Al_2Br_7]^-$ bands are strongly shifted compared to those of $[Al_2Cl_7]^-$.

Experimental:

The reactions were carried out in sealed glass ampoules. Thick-walled ampoules had to be used since liquid hydrochloride develops a vapor pressure of 60 atm at 36 °C. 5-mm NMR tubes having a wall-thickness of 0.7 mm have proved to be sufficiently stable up to 30 °C. For safety, however, the NMR spectra were recorded at or below −30 °C. Typical concentrations for an NMR experiment: 1 mmol Al_2Cl_6, 0.5 mmol *tert*-butyl chloride, and 7 mmol HCl. The substances were sealed in tubes under vacuum at −196 °C in the absence of moisture. The concentration of *tert*-butyl chloride in this mixture, and hence of the $[C(CH_3)_3]^+$ present after the reaction, was about 1.5 mol/l.

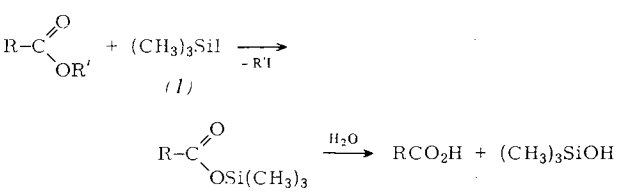
Cleavage of Esters and Ethers with Iodotrimethylsilane[**]

By *Tse-Lok Ho* and *George A. Olah*[*]

Reagents for nonsaponificative ester hydrolysis are generally powerful nucleophiles which promote O-alkyl cleavage. They are exemplified by lithium iodide/alkylpyridines[1], potassium thiocyanate/dimethylformamide[2], and alkali thiolates in aprotic solvents[3].

We wish to report that iodotrimethylsilane *(1)*[4] is a useful reagent for mild ester cleavage. Selected examples are shown in Table 1. It is seen that difficulties are encountered only with the highly hindered methyl pivalate; in this case a longer reaction time is needed and the yield of free acid is somewhat lower.



(1)

Table 1. Yields of free acid on ester cleavage with iodotrimethylsilane.

R′	R	Reaction time [h]	Yield [%]
CH_3	C_6H_5	2	80
	2-Br—C_6H_4	2	81
	C_6H_5—CH_2	2	78
	C_9H_{19}	2	75
	cyclohexyl	2	80
	$(CH_3)_3C$	18	55
C_2H_5	C_6H_5	4	72
	C_6H_5—CH_2	4	70
C_6H_5—CH_2	C_6H_5	2	86
	cyclohexyl	2	90

The advantages of iodotrimethylsilane over lithium iodide as demethylating agent are: neutral and milder reaction conditions (lower temperature, shorter reaction time) and the absence of solubility problems in aprotic solvents.

Cleveland, Ohio 44106 (USA)

[**] Synthetic Methods and Reactions, Part 29.—This work was supported by the National Science Foundation.—Part 28: *T.-L. Ho, M. Henninger*, and *G. Olah*: Synthesis, in press.

Aromatic aliphatic ethers are also cleaved by *(1)*, although in lower yield. Prolonged heating (24h) of *(2a)*, *(2b)*, and *(2c)*, respectively, with the reagent gives 48% phenol, 22% *o*-cresol, and 40% 1-naphthol. Aliphatic ethers are stable under these conditions. The reactions proceed after the manner of a preferred "hardsoft" interaction, which also explains the known cleavage of ethers with HI.

$$\underset{(2)}{Ar{-}O{-}CH_3} + (1) \xrightarrow[-CH_3I]{+H_2O} ArOH + (CH_3)_3SiOH$$

(a): Ar = C_6H_5
(b): Ar = o-CH_3-C_6H_4
(c): Ar = 1-Naphthyl

Procedure for ester cleavage

A mixture of an appropriate ester (5 mmol) and iodotrimethylsilane (2.0 g, 10 mmol) is heated to 100 °C, with exclusion of atmospheric moisture, for the time period specified in Table 1. The cooled reaction mixture is diluted with ether (25 ml), washed with 0.5 N sodium hydroxide (2 × 30 ml), the alkaline solutions are acidified and extracted with chloroform (2 × 30 ml). The dried extracts give TLC-pure carboxylic acid upon solvent removal.

Heterocyclic Systems with 12 π-Electrons[**][1]

By *Richard Neidlein* and *Hartmut Seel*[*]

Dedicated to Professor Erich Hückel on the occasion of his 80th birthday

Heterocyclic systems with 12 π-electrons which are iso-π-electronic with phenalenium ions were previously unknown. We report here on the first representatives of this class of compounds, *viz.* the heterocyclic cations of type *(5)*.

Using the preparative route outlined in the scheme below we obtained the orange 2-bromo-5*H*-naphtho[1,8-*bc*]-thiophen-5-one *(4a)* from 3-(chloromethyl)-1-benzothiophene *(1)*[2] *via* the intermediates *(2)* and *(3)*. Reaction of *(4a)* with triethyloxonium tetrafluoroborate in dichloromethane at room temperature afforded the 2-bromo-5-ethoxynaphtho[1,8-*bc*]thiolylium tetrafluoroborate *(5a)* as exceptionally moisture-sensitive, black-red crystals (Table 1).

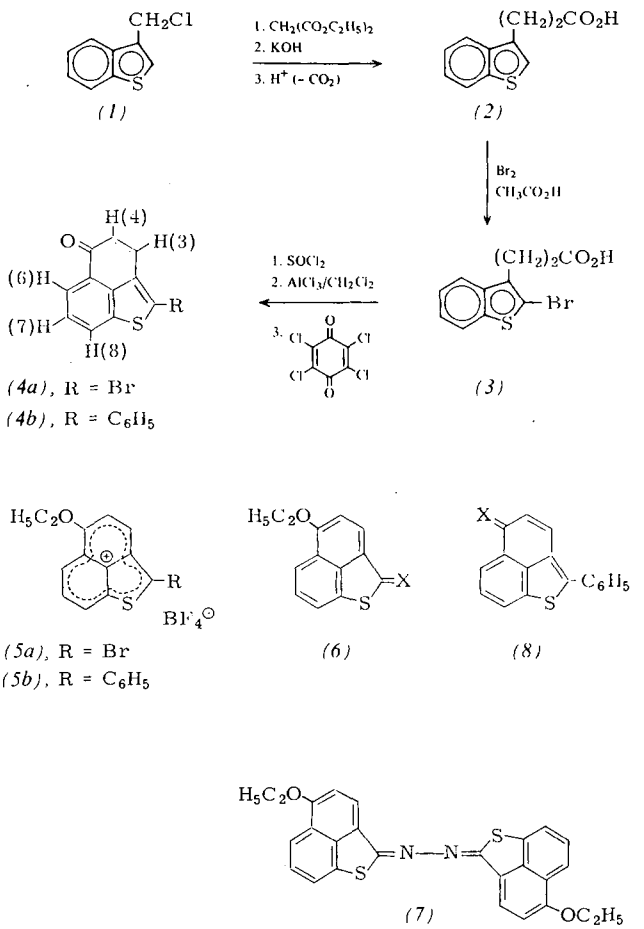

Table 1. Physical properties of compounds *(4)* and *(5)*.

(4a): M.p. 163–164 °C; ^{1}H-NMR ($CDCl_3$): δ = 7.56 ppm (d, H_3, J = 10 Hz), 6.66 (d, H_4, J = 10 Hz), 8.14 (d of d, H_6, J_{ortho} = 8 Hz, J_{meta} = 1 Hz), 7.60 (t, H_7, J = 8 Hz), 7.96 (d of d, H_8, J_{ortho} = 8 Hz, J_{meta} = 1 Hz); IR (KBr): C=O 1625 cm^{-1}, ($CHCl_3$): C=O 1635 cm^{-1}; UV (CH_3OH): λ_{max} = 236 nm (ε = 8640), 265 (12830), 275 (11750), 369 (16620).

(4b): M.p. 137–138 °C; ^{1}H-NMR ($CDCl_3$): δ = 7.65 ppm (d, H_3, J = 10 Hz), 6.55 (d, H_4, J = 10 Hz), 8.13 (d of d, H_6, J_{ortho} = 7 Hz, J_{meta} = 1 Hz), 7.47 (t, H_7), 7.90 (d of d, H_8, J_{ortho} = 8 Hz, J_{meta} = 1 Hz); IR (KBr): C=O 1635 cm^{-1}, ($CHCl_3$): 1630 cm^{-1}; UV (CH_3OH): λ_{max} = 388 nm (ε = 12630).

(5a): ^{1}H-NMR (CD_3CN): δ = 1.68 ppm (t, CH_3—, J = 7 Hz), 4.78 (q, —CH_2—, J = 7 Hz), 7.5–8.8 (H_3, H_4, H_6–H_8); UV (CH_2Cl_2): λ_{max} = 434 nm (ε = 9200).

(5b): M.p. 160–162 °C; ^{1}H-NMR (CF_3COOH): δ = 1.67 ppm (t, CH_3—, J = 7 Hz), 4.84 (q, —CH_2—, J = 7 Hz), 7.6–9.0 (C_6H_5—, H_3, H_4, H_6–H_8); UV (CH_2Cl_2): λ_{max} = 456 nm (ε = 12800).

(5a) reacts with C- or N-nucleophiles in the presence of Hünig base[3] to give compounds of type *(6)*. With hydrazine the violet azine *(7)* is formed.

Reaction of 2-phenyl-5*H*-naphtho[1,8-*bc*]thiophen-5-one *(4b)*[4] with triethyloxonium tetrafluoroborate at 35 to 40 °C leads to the orange-red, very stable salt *(5b)* in 71% yield. This reacts with C- or N-nucleophiles in the presence of Hünig base[3] with elimination of the C_2H_5O group to give products of type *(8)*. The compounds *(8a)* and *(8b)* are iso-π-electronic with phenafulvenes[5] (Table 2).

Experimental:

Synthesis of *(3)*: *(2)* is dissolved in 90% acetic acid (3.5 liters) and the solution warmed to 75°C. A solution of Br_2 (1 mol) in 90% acetic acid is then added dropwise and the mixture stirred for 30 min at 75°C. The cooled solution is poured into 15 liters of water and the resulting precipitate of *(3)* dried and recrystallized from methanol; yield 90%, m.p. 116–117°C.

Synthesis of *(4a)*: A mixture of *(3)* (0.653 mol) and $SOCl_2$ (640 ml) is heated under reflux for 1 h. Excess SO_2Cl_2 is removed, the residue taken up in 4.18 liters anhydrous CH_2Cl_2 and the resulting solution cooled to −10°C and treated portionwise with $AlCl_3$ (0.848 mol). The mixture is stirred for 3 h at −5°C, treated with 60 g $Na_2SO_4 \cdot 10H_2O$ and stirred for a further 4 h at −5°C. It is then washed with H_2O, three times with $NaHCO_3$ solution, and the CH_2Cl_2 solution finally dried over $MgSO_4$. After removal of CH_2Cl_2 the residue (orange-yellow crystals) is recrystallized from acetic acid; yield 84%, m.p. 108–110°C. 0.0754 mol of this substance is heated under reflux for 3 h with 0.468 mol chloranil in 1.5 liters *tert*-butanol. The reaction mixture is then filtered, the *tert*-butanol removed, and the residue taken up in $CHCl_3$; the resulting solution is washed four times with H_2O, four times with 5% NaOH, a further two times with water, and finally dried over $MgSO_4$. After removal of CH_2Cl_2 the remaining orange crystals are recrystallized from acetic acid; yield 75%, m.p. 163–164°C.

Synthesis of *(5a)*: A stirred solution of *(4a)* (1.89 mmol) in anhydrous dichloroethane is treated at 35–40°C with 1.89 mmol triethyloxonium tetrafluoroborate. The resulting deep ruby-red solution is stirred for 20 min, cooled to 0°C, and treated with anhydrous ether, whereupon *(5a)* precipitates as a finely crystalline salt which is used immediately in further reactions. Yield 70 to 80%.

Synthesis of *(5b)*: A stirred solution of *(4b)*[4] (1.91 mmol) in anhydrous dichloroethane (4 ml) is treated at 35 to 40°C with 1.91 mmol triethyloxonium tetrafluoroborate. After 1 h aqueous ethanol is added, whereupon the orange-red salt *(5b)* precipitates. Yield 71%, m.p. 160–162°C.

Synthesis of *(6a)*: $CH_2(CN)_2$ (1.89 mmol) is added to a stirred solution of *(5a)* (1.89 mmol) in anhydrous CH_3CN (10 ml) at room temperature. Hünig base (3.78 mmol) is added to the mixture, which is stirred for 1 h and then allowed to stand overnight at −15°C. Red crystals precipitate; yield 55%.

Synthesis of *(8a)*: A mixture of *(5b)* (1 mmol) and monosodiomalononitrile (1 mmol) in anhydrous tetrahydrofuran (10 ml) is heated under reflux for 24 h. The solvent is removed and the residue chromatographed with benzene an a column packed with silica gel 60 (Merck). After removal of benzene from the eluate *(8a)* is obtained in 16% yield.

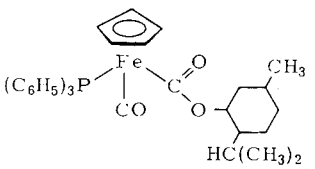
Structure and Absolute Configuration of an Organo-Iron Compound Having Iron as Chiral Center[1]

By *M. George Reisner*, *Ivan Bernal*, *Henri Brunner*, and *Manfred Muschiol*[*]

The absolute configurations are known of optically active organo-Mo compounds with square pyramidal coordination around the metal atom[2] and of ferrocene derivatives[3] in which the metal atom is not the chiral center. We now describe the structure and absolute configuration of compound *(1)*, in which the iron atom is bonded to four different ligands[4].



(1), $[\alpha]_{579} < 0$

Compound *(1)* crystallizes in the orthorhombic space group $P2_12_12_1$ with $a = 11.201(3)$, $b = 14.817(7)$, and $c = 18.976(3)$ Å; $V = 3149.36$ Å^3; $d_{exp} = 1.12(2)$ and $d_{calc} = 1.10$ g/cm^3 for a unit cell with four molecules. A total of 4422 independent reflections was collected with a computer-controlled diffractometer using monochromatized Mo-Kα radiation ($\lambda = 0.71069$ Å) to $2\Theta \leq 60°$. The structure was solved and refined using 2194 reflections for which $I(hkl) > 3\sigma[I(hkl)]$. The final $R(F)$ and $R_w(F)$ values were, respectively, 0.066 and 0.072. The absolute configuration of *(1)* was determined by refinement of the entire data set with the two possible enantiomeric configura-

Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] Recipient of a US Senior Scientist Award administered by the Alexander von Humboldt-Foundation; present address (1976–1977): Institut für Chemie der Universität, Universitätsstrasse 31, D-8400 Regensburg (Germany).

tions as models and by direct measurement of those 26 Friedel pairs (four measurements for each pair) for which the differences between $F_{calc}(hkl)$, $F_0(hkl)$, and $F_0(\bar{h}\bar{k}\bar{l})$ was largest. Both methods give the same result. The absolute configuration of *(1)*, shown in Figure 1, also confirms the known[5] absolute configurations of the three chiral centers in the menthyl moiety.

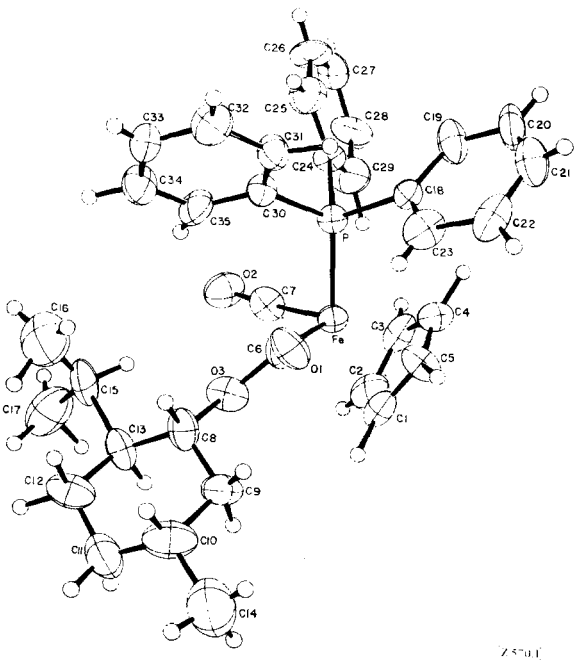

Fig. 1. Structure and absolute configuration of *(1)*. $[\alpha]_{578}<0$.

The Fe—C(C_5H_5) distances average to 2.113(21) Å; other interesting distances are: Fe—P = 2.214(2), Fe—COOR = 1.825(6), Fe—CO = 1.670(7), and C—O (in CO) = 1.206(9) Å. The distances and angles within the triphenylphosphane and menthyl groups compare well with accepted literature values.

With the extension of the *R,S*-system[6] to polyhapto ligands in organometallic complexes[7] the priority sequence of the ligands in *(1)* is $C_5H_5 > P(C_6H_5)_3 > COOC_{10}H_{19} > CO$. The configuration at the Fe atom consequently is (*S*).

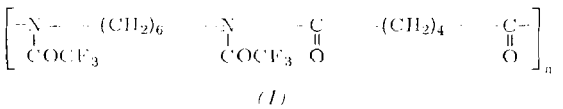
Trifluoroacetylation of Amines with *N*-Trifluoroacetyl-Nylon 66[1]

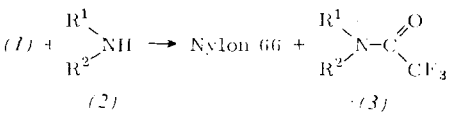
By *Hermann Schuttenberg* and *Rolf C. Schulz*[*]

Reaction of poly(hexamethyleneadipamide) (Nylon 66) with trifluoroacetic anhydride affords high yields of a product which is soluble in tetrahydrofuran (THF), dioxane, chlorinated hydrocarbons, acetone, acetonitrile, or dimethylformamide (DMF). Elemental analysis and IR and NMR spectra are consistent with the substance being a polymer containing the repeating unit *(1)*.



(1)

When treated with water at room temperature the polymer liberates trifluoroacetic acid quantitatively; no detectable degradation of the polyamide chain occurs, either during the synthesis of *(1)* or on treatment with water. The polyamide content of *(1)* can be determined by titration of the liberated trifluoroacetic acid; it agrees up to 98 % with the elemental analysis. Hydrolysis with D_2O[2] furnishes a Nylon 66 extensively deuterated at the nitrogen. Similarly to low molecular *N*-trifluoroacetyl compounds[3], *(1)* can also be employed for the trifluoroacetylation of amines *(2)*.



(2) *(3)*

Table 1. Reactions of *(1)* with amines *(2)* for the preparation of trifluoroacetamides *(3)*. Reaction medium: acetonitrile; room temperature, duration of reaction 12 h; yields and melting points of crude products.

Amine *(2)*	Yield of *(3)* [%]	M.p. [°C] [Lit.-m.p.]	Ref.
Benzylamine	91	73–74 [74–75]	[5]
L-(−)-α-Methylbenzylamine	93	95–96 [96–98]	[6]
Aniline	89	86–87 [89–90]	[5]
n-Hexylamine	95	3–4 [a]	[5]
Hexamethylenediamine	96	119–120 [121–123]	[5]
Piperidine	95	[a]	[5]
p-Nitroaniline	40	[a]	[7]

[a] Identified by comparison of the IR spectra and by gas chromatography with authentic samples.

To carry out the reaction, *(1)* is suspended in acetonitrile. During the course of the reaction Nylon 66 is formed and can be easily separated by filtration. On concentrating the filtrate the corresponding trifluoroacetamide *(3)* is obtained (see Table 1).

Remarkably, *(1)* reacts only slowly, if at all, with some amines, even though these amines react readily with trifluoroacetic anhydride. This selectivity can be exploited for the separation of mixtures of amines. Alcohols can likewise be converted into the trifluoroacetyl derivatives with *(1)*.

Experimental:

Synthesis of *(1)*: Trifluoroacetic acid anhydride (10 ml) is added with vigorous stirring at 0 °C to a suspension of finely

powdered poly(hexamethyleneadipamide)[4] in chloroform (50 ml). The mixture is allowed to warm slowly with continuous stirring to room temperature; after about 6 h a clear solution is obtained which is then added dropwise to 300 ml ether. Stirring is continued for a further 2 h before the precipitated polymer is separated by decantation, washed with ether, filtered, and dried in a vacuum. Yield 6.5 g (95%). IR (film): $\nu_{CO} = 1715\ cm^{-1}$; no NH band, no amide II band. ^{1}H-NMR ($CDCl_3$): $\delta = 3.73$ (4H), 2.87 (4H), 1.76; 1.45 (m, 12H) ppm.

Analysis: *(1)* (60 to 95 mg) is dissolved in THF (10 ml) and treated with water (0.5 ml). The mixture is stirred for 12 h at room temperature and the liberated trifluoroacetic acid titrated potentiometrically with 0.1 N NaOH (without separation of precipitated Nylon 66).

Reaction with amines: *(1)* (230 mg, 0.55×10^{-3} mol) is added to a solution of the amine (1 mmol) in acetonitrile (5 ml; previously dried over CaH_2). The mixture is stirred at room temperature for 12 h, centrifuged, and the residue washed twice with 5 ml acetonitrile. Concentration of the combined solutions furnishes the trifluoroacetamide *(3)*.

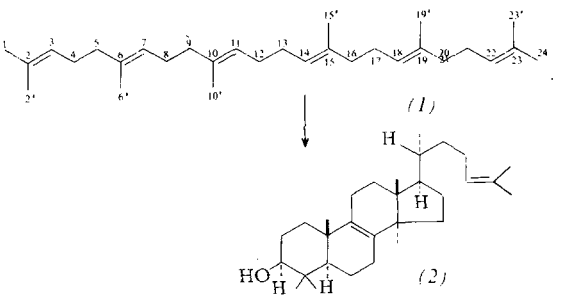
The Crystal Structure of Squalene

By *Josef Ernst, William S. Sheldrick*, and *Jürgen-Hinrich Fuhrhop*[*]

The *in vivo* and *in vitro* cyclization of squalene *(1)* to lanosterol requires epoxidation of a terminal double bond. This reaction proceeds regioselectively only in polar solvents, *e.g.* in glycol dimethyl ether/water mixtures. *Van Tamelen*[1] therefore formulated a coiled structure for *(1)* in that type of media which ought to be stabilized by hydrophobic interactions and in which the inner double bonds would be protected from chemical attack.

In order to check this hypothesis we have subjected squalene crystals which had been obtained from methanol/ether (5:2) to an X-ray structure analysis.

After several recrystallizations at −17 to −30 °C we obtained monoclinic crystals having a melting range −4.8



(1)

(2)

to −5.2 °C which could be easily manipulated in a cold stream of nitrogen and measured in the four-circle diffractometer fitted with low-temperature equipment.

Space group $P2_1/n$ with $a = 7.660(23)$, $b = 6.281(2)$, $c = 28.492(9)$ Å; $\beta = 93.17(9)°$; $Z = 2$; $d_{calc} = 1.00\ g\ cm^{-3}$. The structure was solved by direct methods and refined to $R_w = 0.093$ for 1035 independent reflections (Syntex $P2_1$, $F \geq 4.0\sigma(F)$). The positions of the hydrogen atoms could be located in difference Fourier syntheses and were afterwards included as fixed parameters in the final refinement cycles. The carbon atoms were assigned anisotropic temperature factors.

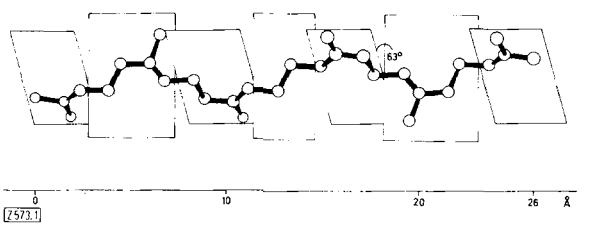


Fig. 1. Projection of the squalene molecule onto the best plane through carbon atoms 3,4,5,6,6',7,8,11,12.

The molecular structure (Fig. 1) shows C_i symmetry and a stretched conformation. The symmetric unit can be represented as sharing two planes which are at an angle of 62.8° to each other. Carbon atoms 3,4,7,8,11, and 12 lie on the lines of intersection. Conformation and orientation of the molecules in the crystal lattice (Fig. 2) are determined by the steric interactions between methyl and methylene groups.

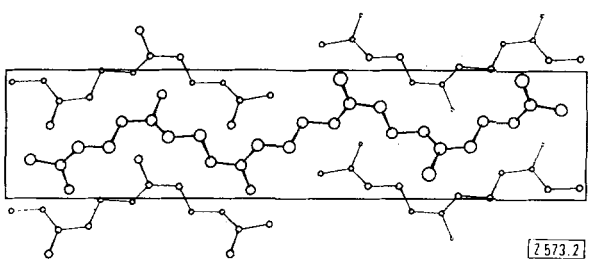

Fig. 2. Projection along the [100] axis.

The structure resembles that of the squalene hexahydrochloride[2] and of the monomeric unit of "crystalline rubber"[3].

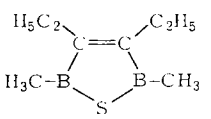
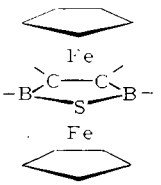
μ-Thiadiborolenebis(η-cyclopentadienyliron)—Preparation and Structure of a New Triple-Decker Sandwich Complex[1]

By *Walter Seibert, Thomas Renk, Klemens Kinberger, Manfred Bochmann*, and *Carl Krüger*[*]

3,4-Diethyl-2,5-dimethyl-1,2,5-thiadiborolene *(1)* serves as a bridging ligand to form the triple-decker complex *(1)*·$[Mn(CO)_3]_2$ with the one-electron donor fragment $Mn(CO)_3$[1]. We now describe the compound *(1)*·$[Fe(C_2H_5)]_2$ *(2)* which is formed on reaction of *(1)* with $[\eta\text{-}C_5H_5Fe(CO)_2]_2$ in mesitylene at 160°C.



(1)



(2)

The triple-decker sandwich structure follows from the analytical and spectroscopic data of *(2)*, which is air-stable, degraded by HI, and first detected in the mass spectrum[2]. The molecular ion ($I_{rel}=88$) is accompanied at 70eV by the fragments $\{M-CH_3\}^+$ (8), $\{M-(C_2H_5C)_2BCH_3\}^+$ (11), $(C_5H_5Fe)_2BCH_3^+$ (11), $C_5H_5FeSB(CH_3)_2^+$ (12), $(C_5H_5)_2Fe^+$ (100), and $C_5H_5Fe^+$ (26).

The crystal structure of *(2)* was deduced from 4072 reflections [1921 unobserved (2σ), cell data: $a=8.729(1)$, $b=16.800(2)$, $c=13.474(2)$ Å, $\beta=72.20(1)°$, $Z=4$, space group $P2_1/c$, $R=0.059$]. The result is shown in Figure 1. The Fe—Fe distance [3.236(1) Å] is considerably shorter than the Mn—Mn distance in the triple-decker complex *(1)*·$[Mn(CO)_3]_2$ [3.506(1) Å][3] and than the Ni—Ni distance in $(C_5H_5)_3Ni_2^+$ [3.576 Å][4]. The central thiadiborolene ring *(1)* is planar. Its geometry corresponds to earlier results[5]. Both cyclopentadienyl rings display rotational disorder.

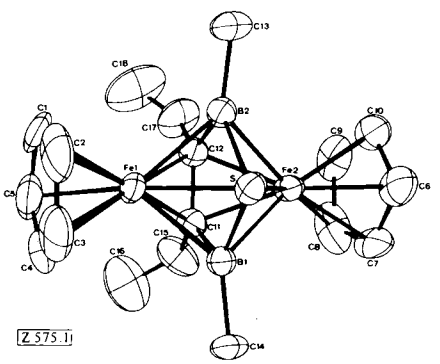


Fig. 1. Crystal structure of the complex *(2)*.

In the ^{1}H-NMR spectrum [$\delta=3.43$ (s, 10), 2.67 (q, 4), 1.62 (s, 6), and 1.48 (t, 6) ppm (in CS_2 *vs.* internal TMS)] the quartet establishes the magnetic equivalence of the methylene protons and hence—as for *(1)*·$[Mn(CO)_3]_2$—the triple-decker structure. The ^{11}B-NMR signal at $\delta=12.0$ ppm [in CS_2 *vs.* external $BF_3\cdot O(C_2H_5)_2$; *(1)*: $\delta=66.0$ ppm] indicates strong electronic shielding of the boron atoms.

Complex *(2)* is formally derived from the red triple-decker sandwich[6] 1,7,2,3-$(\eta\text{-}C_5H_5Co)_2C_2B_3H_5$ by replacement of the 5-B atom by sulfur, requiring a transition from Co-d^6 to Fe-d^6. However, the electronic structure of the green compound *(2)* and that of the green μ-borolebis(η-cyclopentadienyliron)[7] should rather be comparable with that of the green 1,7,2,4-isomer of $(\eta\text{-}C_5H_5Co)_2C_2B_3H_5$. In the Fe and Co triple-decker sandwich compounds three 6 π electron ligands are held together by two d^6 metal ions. These are 30-electron triple-decker complexes, whereas $(C_5H_5)_3Ni_2^+$[8] has 34 valence electrons[9].

Procedure:

Synthesis of *(2)*: $[C_5H_5Fe(CO)_2]_2$ (4.73 mmol) and *(1)* (4.73 mmol) are heated at 160 to 170°C in mesitylene (50 ml) for 8 h. Precipitated iron (0.32 g) is filtered off, the solvent removed, and the residue worked up by chromatography (silica gel/pentane). Sublimation of ferrocene (0.5 g) from the eluate is followed by that of *(2)* at 90°C/0.1 torr: dark green crystals, dec. 230°C (from pentane, at −20°C), yield 11 %.

Photoisomerization and Photocleavage of Bicyclo-[4.2.0]octa-2,4-dienes[**]

By *Gerd Kaupp* and *Ernst Jostkleigrewe*[*]

Neither simple nor more sophisticated theoretical approaches can as yet explain the rather unclear and, in part, contradictory results of the photolysis of numerous [2+2]cycloadducts of benzene. We report here on the photolysis of the model compounds *(1a)*[1], *(1c)*[2], *(6a)*[3], and *(6b)*[3].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *H. Fritz* (Ciba-Geigy AG, Basel) for recording the ^{13}C-NMR spectra.

In the bicyclo[4.2.0]octa-2,4-dienes *(1)* and *(6)* the valence-tautomerism equilibria with *(2)* and *(7)*, respectively, lie wholly on the side of the bicycles. ^{1}H- and ^{13}C-NMR spectra at -40 to 50°C verify this observation[4]. The photolyses of *(1)* and *(6)* lead without competing fluorescence ($\Phi_{fl} < 10^{-4}$) to cleavage and isomerization reactions with high quantum and product yields (see Table 1). First of all, the allylic or bisallylic four-membered ring bonds are cleaved reversibly. The former corresponds to the stereochemically demonstrated two-step mechanism of cleavage of benzo-annelated derivatives[5]; the latter presumably leads directly to the cyclooctatrienes *(2)* and *(7)*[6], which react further with ring opening to give the octatetraenes *(4)*[7]. Compound *(4a)* is protected from reverse reactions to *(1a)* or *(6a)* by secondary photolyses, which generally terminate at the all-*trans* isomer *(5a)* are formed thermally. As expected, the increased yields thus obtained are wavelength dependent (best results at 253.7 nm).

The data quoted in Table 1 can be interpreted as follows: In the case of the anhydride *(6b)* the bisallylic four-membered ring bond is not cleaved, apparently because the five-membered ring restricts the conformational flexibility necessary for ring expansion to *(7b)* too strongly. When additional rings are absent, as in *(1a)*, *(1c)*, and *(6a)*, cleavage competes with valence isomerization to cyclooctatrienes after absorption of light. The data given in Table 1 show that cleavage competes all the more effectively the more the steric hindrance is relaxed by the initial formation of the diradical [*(3)*]. The reverse reactions afford the most convenient route so far to the syntheses of *(1a)* and *(6a)* from *(4a)*.

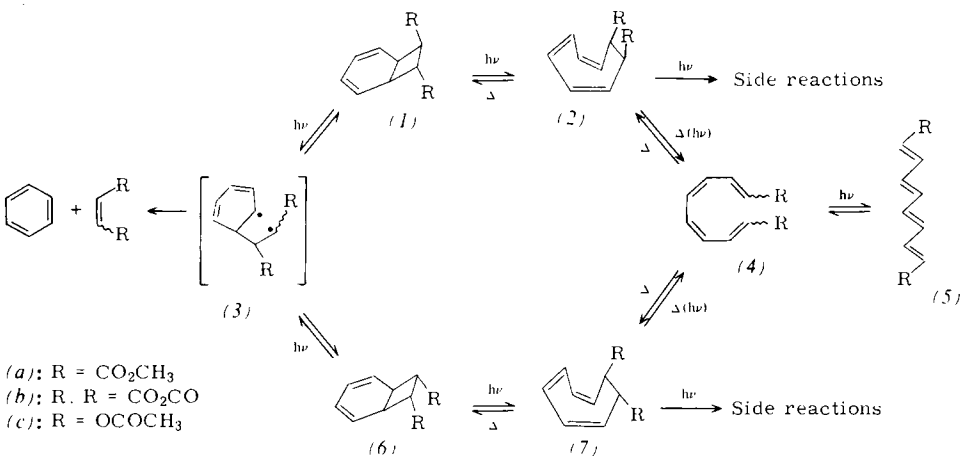

Table 1. Products of the photolysis of bicyclo[4.2.0]octa-2,4-dienes in acetonitrile at 20°C [a].

Compound	λ_{max} (nm) (ε)	Benzene Yield [%]	(4)⇌(5) Yield [%]	Cleavage / Isomerization	Quantum yield [b]
(1a)	273.5 (3500); 295 (sh)	80–85	12–15	5.6	0.50
(6a)	273.5 (3500) 295 (sh)	70–75	22–25	3.0	0.56
(6b)	274.5 (3350)	100	0.0		0.56
(1c)	262 (sh); 267 (3800) 286 (sh); 291 (sh)	10–11	47 [c]	<0.2	0.43 [d]

[a] Saturated with N_2 or air; at 300, 274 or 253.7 nm; complete conversion.
[b] Decrease of *(1)* or *(6)* and increase of benzene and *(5)*; the time-dependent *cis,trans* ratios were taken into consideration with the aid of band positions and ε values.
[c] Maximum enrichment because of the photolability of *(5c)*.
[d] Measurement at -10°C; $\lambda_{max} = 275$ (sh), 286 (sh), 297, 309.5 (ε = 60000), 323 nm.

[CH_3CN: $\lambda_{max}(\varepsilon) = 304$ (sh, 22000), 319 (sh, 44000), 332.5 (67000), 348.5 nm (61500)]. A lowering of temperature is necessary only in the case of *(4c)* (see Table 1).

The formula scheme is confirmed by photolyses at -190°C: the yields of benzene remain unchanged (excitation at 300 and 274 nm), *i.e.* the reactivity of *(3)* is undiminished. The thermal secondary reactions of the intermediates *(2a)*, *(2c)*, and *(7a)*, on the other hand, are frozen in at -190°C. The yields of *(4)* quoted in Table 1 can no longer be achieved by secondary *photolyses* of *(2)* and *(7)* (0.1, 5, and 4% *(4)* from *(1a)*, *(1c)*, and *(6a)*). If the solution is warmed before all of the cyclooctatriene [*(2)*, *(7)*] has been consumed in the secondary photolyses, considerable amounts of *(4)*

Experimental:

cis,cis,cis,trans-(4a) and *trans,cis,cis,trans-(4a)*: The cooled solution of cyclooctatetraenedilithium (prepared from 15 g COT and 2.1 g Li) in 500 ml ether/THF (9:1)[8] is added dropwise over a period of 1 h at -60°C under argon to a solution of methyl chloroformate (47 g) in 300 ml ether. The mixture is stirred for 1 h at -60°C and 12 h at 20°C; it is then filtered, concentrated in a rotary evaporator, and the resulting residue treated with 300 ml cold methanol to initiate crystallization: 1.1 g *cis,cis,cis,trans-(4a)* [m.p. 112°C; ^{1}H-NMR (C_6D_6): two OCH_3 signals, $\delta = 3.39$ and 3.45 ppm]. The filter residue is stirred in 500 ml water. 3.0 g of dry residue is isolated,

extraction of which with 31 boiling petroleum ether (b.p. 30—50°C; duration ca. 1 min) and cooling to −30°C affords 1.3 g *trans,cis,cis,trans-(4a)*[9] in the form of fine needles [m.p. 118°C; ^{1}H-NMR (C_6D_6): one OCH_3 signal, $\delta = 3.44$ ppm, $\Delta\nu_{1/2} \leq 0.6$ Hz; UV(CH_3CN): $\lambda_{max}(\varepsilon) = 300$ (sh, 20500), 314 (36000), 327 (48300), 343 nm (40500)].

Synthesis of *(1a)* and *(6a)*:

Solutions of *trans,cis,cis,trans-(4a)* and *cis,cis,cis,trans-(4a)*, respectively, in benzene are heated to 80°C for 2 h [*(1a)* can also be obtained from the dried crude product by hot-vapor extraction with petroleum ether (b.p. 50—80°C; 10 h)]. Yields after molecular distillation (5×10^{-4} torr, bath 40°C, condensate −20°C): at least 90%.—*(1a)*: m.p. 34°C; ^{1}H-NMR ($CDCl_3$): two OCH_3 signals, $\delta = 3.70$, 3.72 ppm; ^{13}C-NMR: 12 signals.—*(6a)*: m.p. 24°C; ^{1}H-NMR ($CDCl_3$): one OCH_3 signal, $\delta = 3.70$ ppm; ^{13}C-NMR: 6 signals.

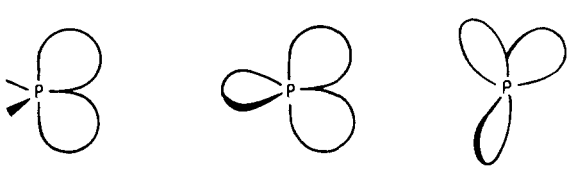
A Tricyclic Phosphorane with Axial Annelation[1]

By *Alfred Schmidpeter*, *Dietmar Schomburg*, *William S. Sheldrick*, and *Josef Helmut Weinmaier*[*]

In phosphoranes having a bicyclo[3.2.0]heptane or bicyclo[3.3.0]octane skeleton the two rings incorporating the trigonal-bipyramidal bridgehead phosphorus always adopt an approximately or precisely meridional spatial arrangement *(A)*[2–4]. The axis of the bipyramid is then bent towards the bond common to the two rings, and the angle between the other two equatorial bonds is consequently[3] reduced to 110—113°. The question arises: Will this narrowing of the angle suffice to accommodate a further small ring in the otherwise avoided diequatorial orientation *(A')* or will an additional small ring once again assume the axial-equatorial position and thus impose the *per se* less favorable facial arrangement *(B')* of the bicyclic system?



(A) *(A')* *(B')*

[*] Prof. Dr. A. Schmidpeter and Dipl.-Chem. J. H. Weinmaier
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

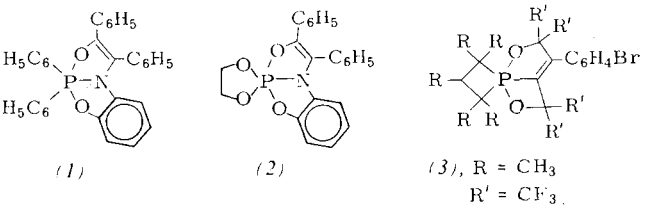
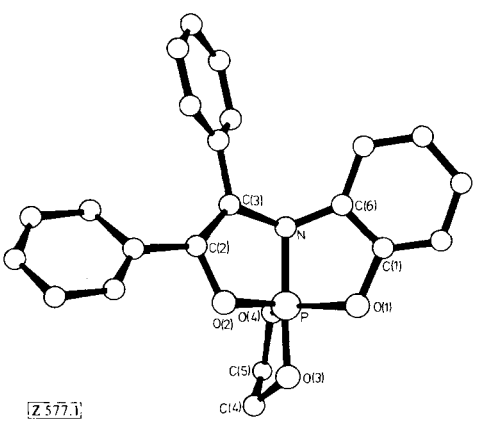
We have found that compounds in which pentacovalent phosphorus serves as bridgehead and spiro center of three five-membered rings can readily be prepared by the method described for the synthesis of *(1)*[5]. One of the resulting products, *viz. (2)*, has been subjected to structural analysis[6].



(1) *(2)* *(3)*, R = CH_3, R' = CF_3

Figure 1 shows that the axial annelation *(B')* occurs in *(2)*, and is particularly obvious from the drastic difference in the N—P—O^3 and N—P—O^4 angles which would actually be equivalent on the basis of the molecular skeleton (Table 1). All the angles at the phosphorus atom can be described to a good approximation in terms of an 85% transition from the meridional arrangement *(A')* of the bicyclic to the facial arrangement *(B')*, as the angles in *(1)* had likewise been described in terms of a 15% transition[2]. Since the two rings in facial orientation are bent towards each other the bridgehead nitrogen is not planar, as is usually the case[2–4], but slightly pyramidal (sum of the angles = 353°).



[Z 577 IE]

Fig. 1. Molecular structure of 8,8-(1,2-ethanediolato)-2,3-diphenyl[1,3,2λ^5]oxazaphospholino[2,3-*b*]benzo[*d*][1,3,2λ^5]oxazaphospholine *(2)*.

Table 1. Bond angles [°] at phosphorus and lengths [Å] of bonds emanating from phosphorus and the adjacent bonds in *(2)*, as compared with the equivalent bonds in *(1)*.

	(2)	*(1)*		*(2)*	*(1)*
O^1—P—O^2	134.0(1)	171.6(3)	P—O^1	1.637(2)	1.763(5)
O^1—P—O^3	86.9(1)		P—O^2	1.635(2)	1.700(5)
O^2—P—O^3	89.6(1)		P—N	1.755(2)	1.703(6)
O^1—P—O^4	115.6(1)		P—O^3	1.654(2)	
O^2—P—O^4	110.4(1)		P—O^4	1.595(2)	
O^1—P—N	89.3(1)	87.6(3)	O^1—C^1	1.395(4)	1.347(8)
O^2—P—N	88.4(1)	86.6(3)	O^2—C^2	1.413(3)	1.376(5)
N—P—O^3	172.4(1)		N—C^6	1.400(3)	1.421(8)
N—P—O^4	93.5(1)		N—C^3	1.406(3)	1.427(5)
O^3—P—O^4	94.1(1)		O^3—C^4	1.421(4)	
			O^4—C^5	1.446(5)	

The difference between the structures *(A')* and *(B')* is also seen in the bond lengths of the bicyclic skeleton of *(1)* and *(2)*. The PO^1 and PO^2 bonds, which are axial in *(1)* and equatorial in *(2)*, are shortened by 8 and 4% respectively, and the PN bond which is equatorial in *(1)* and axial in *(2)* grows longer by 3%. Concomitantly, the adjacent OC bonds become 3% longer, and the NC bonds 2% shorter. The PO bonds of the dioxaphospholane ring differ from each

other by 4%, one being axial and the other equatorial, and the adjacent CO bonds by 2% in the opposite sense.

Structure *(B')* would indicate the four protons of the dioxaphospholane ring *(2)* to differ from each other; in solution, however, they are found to be equivalent by NMR. Hence *(B')* must exist in mobile equilibrium with other structures [including *(A')*] in solution.

In a very recent publication[7], *Trippett et al.* describe the phosphorane *(3)*, which, having the same structural alternatives *(A')/(B')*, adopts the C_s structure *(A')*, presumably owing to the greater difference in electronegativity between the atoms exchanging positions: On going from *(A')* to *(B')* an O,O pair must relinquish its apical position to on O,N pair in the case of *(2)*, but to a C,C pair in the case of *(3)*.

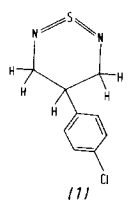
X-Ray Structure Analysis of a 4,5-Dihydro-3H-1λ⁴,2,6-thiadiazine

By *Alfred Gieren* and *Franz Pertlik*[*]

X-ray structure analyses of non-cyclic sulfur diimides[1] led to the conclusion that the S^{IV}=N bond lengths (*ca.* 1.53 Å) are independent of the substituents at the SN_2 group and of the configuration at the S=N bonds.

We have now carried out an X-ray structure analysis of the cyclic sulfur diimide 4-(4-chlorophenyl)-4,5-dihydro-3*H*-1λ⁴,2,6-thiadiazine *(1)*[2].



(1)

The compound crystallizes from ethanol in the monoclinic space group $P2_1/n$; lattice constants: $a = 12.58_1$, $b = 10.95_6$, $c = 7.27_7$ Å, $\beta = 103.0_9°$; $D_{exp} = 1.44_1$ g·cm^{-3}, $D_{X\text{-ray}} = 1.45_7$ g·cm^{-3}; $Z = 4$. 1876 independent reflections were measured on an automatic single crystal diffractometer with Cu-K_α radiation up to a maximum θ value of 70° (5-value measurement, θ/2θ scan); 183 reflections were unobserved ($I \leq 2\sigma_I$). The structure was solved by direct methods. All atoms (except H) could be located by an E-Fourier synthesis with the 300 largest E-values. Refinement by the method of least squares (full matrix), first using isotropic and then anisotropic temperature parameters initially gave an *R* value of 8.2%. At this stage of the refinement all hydrogen atoms could be located in a difference Fourier synthesis. On inclusion of the H-atoms with isotropic thermal parameters the refinement converged at an *R* value of 4.1%.

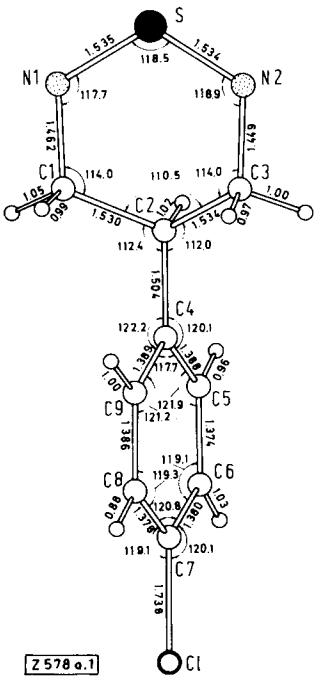


Fig. 1. Molecular structure of 4-(4-chlorophenyl)-4,5-dihydro-3*H*-1λ⁴,2,6-thiadiazine *(1)*. The standard deviations of the given bond lengths vary between 0.003 and 0.005 Å (except C—H: 0.03–0.04 Å), those of the angles between 0.2 and 0.3°.

Figure 1 shows the molecular structure. The ring containing the SN_2 group has a half-boat conformation with the apex at C-2. The *p*-chlorophenyl moiety occupies an equatorial position at C-2 and is orientated almost perpendicularly to the best plane through the heterocyclic ring. The best planes through the coplanar atoms of the two six-membered rings are at an angle of 84° to each other. To a good approximation the molecule contains a plane of symmetry perpendicular to the heterocyclic ring in the plane of the *p*-chlorophenyl ring. The cause of the half-boat conformation is the coplanarity of the sulfur diimide group with the substituents at the nitrogen atoms. In the meantime the same conformation has been found in the $S_3N_3O_4$ anion[3] and in a cyclotetraphosphazene bridged by a sulfur diimido group[4], in which the SN_2 group is likewise part of a six-membered ring.

The length of the S=N double bond is 1.534 Å and agrees within limits of error with the S=N bond lengths in the reference compounds. Since the substituents at the N atoms in *(1)* do not allow π-interaction with the SN_2 system it can be concluded from the above agreement that the length of the S^{IV}=N bond in organic sulfur diimides is independent of the nature of the substituents, even though the reactive behavior of the SN_2 group is subject to a distinct substituent effect. The configuration at the S^{IV}=N double bond also has no influence on the bond length.

The angle at the sulfur atom is 118.5° and obviously varies only within narrow limits. In the open-chain reference compounds it is 117°[1a] and 115°[1b], in the cyclic compounds 119°[3,4].

Dr. F. Pertlik
Institut für Mineralogie und Kristallographie der Universität
Dr. Karl Lueger-Ring 1, A-1010 Wien (Austria)

The nitrogen atoms of the SN_2 group are sp^2 hybridized, which follows not only from the bond angles at the N atoms (118.3°), but also from the N—C bond lengths (1.455 Å). These bond lengths correspond to the value for N—C single bonds of the type sp^2-sp^3. The angles at C-1 and C-2 are about 4.5° wider than an ideal tetrahedral angle.

The structure of *(1)* contradicts a "double ylide" structure[5] in sulfur diimides.

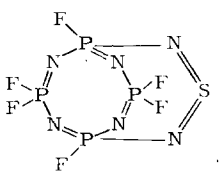
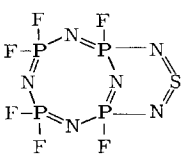
The Structure of a Cyclotetraphosphazene Bridged by a Sulfur Diimido Group

By *Alfred Gieren, Bernhard Dederer, Herbert W. Roesky*, and *Enno Janssen*[*]

The synthesis of a novel cyclotetraphosphazene bridged by a sulfur diimido group has recently been reported[1]. The constitution *(1a)* was proposed for the compound. Such a constitution assumes a non-planar arrangement of the P—N=S=N—P system and would be inconsistent with recent X-ray structure analyses[2, 3], which indicate a coplanar arrangement of the SN_2 system and the substituents at the nitrogen atoms as being characteristic for sulfur diimides. We have therefore carried out an X-ray structure analysis of *(1)*.



(1a)



(1b)

The crystals of *(1)* obtained by sublimation crystallize in the monoclinic space group $P2_1/b$ with $a = 9.43_6$, $b = 20.10_2$, $c = 11.62_2$ Å; $\gamma = 103.5_2°$. The unit cell contains eight formula units (2 formula units/asymmetric unit). The crystal structure has an additional pseudosymmetry of the space group B2/b, since reflections of the type $h+l=2n+1$ are on average much weaker than those of the type $h+l=2n$. This pseudoextinction comes about since the greater parts of the two molecules of the asymmetric unit can to a good approximation be interconverted by the translation $(\vec{a}+\vec{c})/2$. 6176 independent reflections were measured with MoK_α-radiation (Nb filter) on an automatic single crystal diffractometer up to a maximum θ value of 30° (5-value measurement; $\theta/2\theta$ scan). 2109 reflections were unobserved ($I \leq 2\sigma_I$). The structure was solved by direct methods. An E-Fourier synthesis with 213 phased reflections showed the positions of the phosphorus atoms which fulfil the higher symmetry of the space group B2/b. In a subsequent Fourier synthesis with all reflections phased by the phosphorus atoms it was possible to recognize the sulfur atoms which breached the symmetry of the more highly symmetrical space group. The remaining atoms (F and N) could be located by a further Fourier synthesis with inclusion of the sulfur atoms in the phase determination. Refinement by the method of least squares, first using isotropic and then anisotropic temperature factors converged at an R value of 5.2% (observed reflections).

Max-Planck-Institut für Biochemie, Abt. Strukturforschung I
Am Klopferspitz, D-8033 Martinsried (Germany)
Prof. Dr. H. W. Roesky and Dr. E. Janssen
Anorganisch-chemisches Institut I der Universität
Niederurseler Hang, D-6000 Frankfurt 50 (Germany)

The analysis showed that *(1)* does not have the proposed constitution *(1a)*[1], but that of a 9λ⁴-thia-2,4,6,8,10,11-hexaaza-1λ⁵,3λ⁵,5λ⁵,7λ⁵-tetraphosphabicyclo[5.3.1]undeca-1,3,5,7(11),8,9-hexaene *(1b)*. The bridging of the cyclotetraphosphazene system by the SN_2 group permits planar arrangement of the P—N=S=N—P system (Fig. 1). The six-membered ring arising by virtue of the SN_2 bridge proves to have a half-boat conformation with the apex at N-4. This conformation is consistent with that of the 4-(4-chlorophenyl)-4,5-dihydro-3*H*-1λ⁴,2,6-thiadiazine[3], in which the SN_2 group is likewise part of a six-membered ring.

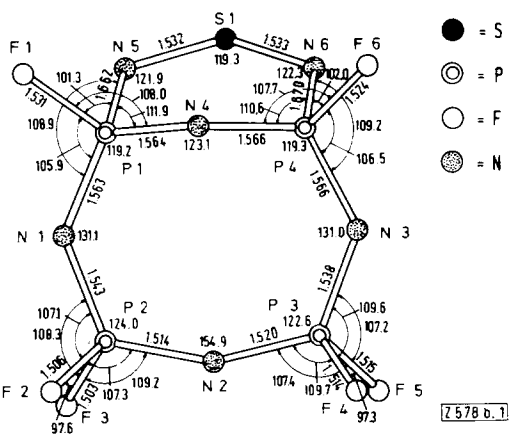

Fig. 1. Structure of the 9λ⁴-thia-2,4,6,8,10,11-hexaaza-1λ⁵,3λ⁵,5λ⁵,7λ⁵-tetraphosphabicyclo[5.3.1]undeca-1,3,5,7(11),8,9-hexaene *(1b)*. The bond lengths and angles have been averaged over the two molecules of the asymmetric unit. The mean standard deviations are 0.003 Å for the bond lengths and 0.2° for the bond angles.

The eight-membered cyclotetraphosphazene ring has a crown-saddle conformation, the larger part of which is flattened out. Except at N-4 the eight-membered ring is almost planar. The greatest deviation from planarity of the best plane through its atoms (excluding N-4) is only 0.11 Å. In the crystalline state the molecule has, to a first approximation, a plane of symmetry through S-1, N-4, and N-2 perpendicular to the best plane through the eight- and six-membered rings.

The S—N bonds are 1.53 Å long and are pure S^{IV}=N double bonds, as has also been found in all other sulfur diimides investigate by X-ray structure analysis. The angle at the sulfur atom (119.3°) is practically the same as that in 4-(4-chlorophenyl)-4,5-dihydro-3*H*-1λ⁴,2,6-thiadiazine[3]: (118.5°). The S—N bond lengths point to the fact that there is no coupling between the d_π-p_π electron system of the SN_2 group and that of the cyclotetraphosphazene ring. This fact is also supported by the P—N bond lengths. In the cyclotetraphosphazene ring the P—N bond lengths vary between 1.56 and 1.51 Å and thus evidence distinct partial double bonding, whereas the P—N bond lengths to the SN_2 system (1.67 Å) are more than 0.1 Å longer. The variation in the length of the P—N bonds in the phosphazene ring can be correlated with the degree of fluorine substitution at the phosphorus atom and the bond angles at the N atoms: the P—N bond length is shorter the higher the degree of F-substitution and the

large the bond angle at N. The bond angle at N-2 is much larger and, with a value of 154.9 , is to our knowledge the largest bond angle so far found at a formally sp^2 hybridized nitrogen atom.

Reaction between Molybdate(VI), Cyanide, and Hydrogen Sulfide

By *Michael G. B. Drew, Philip C. H. Mitchell*, and *Christopher F. Pygall*[*]

Complexes of molybdenum with sulfide as ligand may serve as models of the binding of inorganic sulfide in molybdoenzymes, *e.g.* xanthine oxidase. We have therefore determined the structures of the complex anions *(1)*[1] and *(2)*[2] isolated from reaction of H_2S and CN^- with aqueous solutions of molybdate(VI) as their salts *(1a)* and *(2a)* by single-crystal X-ray crystallography[3]. There was also formed during the reaction a new heptacyanomolybdenate(II) anion *(3)*, which we have isolated as the potassium salt *(3a)* and structurally characterized[4]. The anion is pentagonal bipyramidal.

$Ba_3[Mo_2S_2(CN)_8] \cdot 14\ H_2O$
(1a)

$K_7[Mo_2S(CN)_{12}] \cdot 0.5\ [MoO_4]^{2-} \cdot 5\ H_2O$
(2a)

$K_5[Mo(CN)_7] \cdot 2\ H_2O$
(3a)

The structures of the anions are shown in Figure 1. In anion *(1)* the Mo_2S_2 group is planar. The Mo—S bond lengths [2.36(1) and 2.37(1) Å] are comparable with those in the well-known di-μ-sulfidomolybdenum(V) complexes[5] but the Mo—Mo distance [2.644(5) Å] is shorter and the Mo—S—Mo angles [67.9(3) and 68.3(3)°] smaller. The IR bands at 444 and 320 cm^{-1} are assigned to vibrations of the MoS_2Mo group.

In the anion *(2)* the molybdenum atoms are seven-coordinate pentagonal bipyramidal and are bridged through an axial sulfur atom. The Mo—S—Mo angle is 169.5(3)°. The Mo—S bonds [2.172(5) Å] are exceptionally short and identical within experimental error to those in $[MoS_4]^{2-}$[6]. The anion *(2)* is the first example of a molybdenum complex with a single sulfide bridge. Assignment of the IR band at 623 cm^{-1} was hitherto uncertain[2] but we can now assign it to the ν_{as}(MoSMo) vibration [we calculate ν_{as} for the MoSMo group to be *ca.* 600 cm^{-1}].

Having determined the structures of *(1)* and *(2)* and isolated the salts we can now understand the reaction between $[MoO_4]^{2-}$, H_2S, and CN^-: in the absence of oxygen reaction

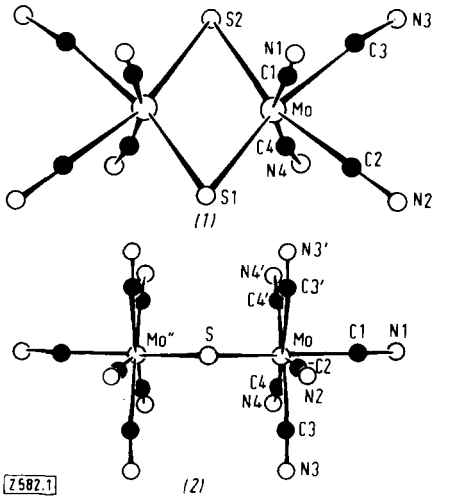

Fig. 1. Structures of anions *(1)* and *(2)*.

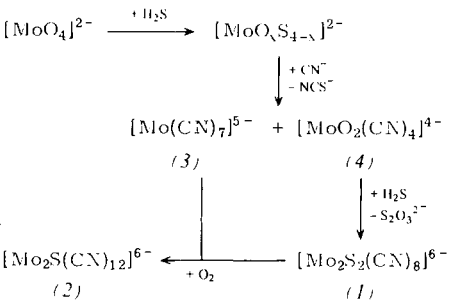
yields *(1)* and *(3)*, and in the presence of oxygen these products react further to give *(2)*. The anion *(4)*, already known, was an intermediate[7]. The reaction is remarkable in that molybdenum(VI) is reduced to molybdenum(II) in aqueous solution under mild conditions. Evidently cyanide stabilizes low-valent molybdenum; with oxygen- and nitrogen-donor ligands reduction below molybdenum(III) is not possible in aqueous solution.



The initial reduction of Mo^{VI} with formation of thiocyanate

$$S^{2-} + CN^- \rightarrow NCS^- + 2e^-$$

warrants interest in that a similar reaction occurs when cyanide deactivates the molybdoenzyme xanthine oxidase[8]. This observation and other evidence suggest that the "labile sulfur" of xanthine oxidase is sulfide terminally bound to molybdenum.

Procedure:

MoO_3 (7.0 g) was dissolved in water (100 ml) containing KOH (5.8 g). KCN (25.3 g) was added to this solution and the resulting solution was freed from dissolved oxygen by repeated evacuation and back-filling with N_2 in a Schlenk tube fitted with a sintered glass gas inlet. H_2S was passed through the solution for 0.5 h. The solution, after standing overnight, deposited blue crystals of $K_6[Mo_2S_2(CN)_8] \cdot 4H_2O$, which were filtered off. The filtrate, after cooling in ice, gave a mixture of yellow crystals of $K_5[Mo(CN)_7] \cdot H_2O$ and more blue crystals.

The barium salt *(1a)* was prepared by fractional crystallization from a solution containing the potassium salt and barium chloride.

Compound *(2a)* was prepared according to ref. [2] but crystals were only obtained when the molybdate impurity was not removed.

ABSTRACTS

The use of transition metals in organic synthesis is reviewed in an article by *A. P. Kozikowski* and *H. F. Wetter*. The article is subdivided according to types of transformation. Cleavage of a functional group, as in the decarbonylation of acyl halides and aldehydes is catalyzed *e.g.* by chlorotris(triphenylphosphane)rhodium, $Fe(CO)_5$, $KHFe(CO)_4$, and $Ni(CO)_4$. Insertion reactions in the presence of $Na_2Fe(CO)_4$, $Fe(CO)_5$, or Pd^{II} enable preparation of aldehydes *etc.* from alkyl bromides, iodides, and tosylates. Transition metals activate alkene, alkyne, and allyl systems, and thus permit access to addition reactions or to introduction of functional groups. Further methods for the formation of CC bonds are iron(III) pivalate catalyzed coupling of alkyl halides with Grignard compounds and the dimerization of isoprene by a Pd^{II} system. Palladium, nickel, rhodium, and iron compounds are frequently used a catalysts in the synthesis of cyclic compounds having three to seven (and more) members. [Transition Metals in Organic Synthesis. Synthesis *1976*, 561—590; 144 references]

[Rd 897 IE—M]

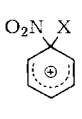
***Ipso* attack in aromatic nitration** is reported on by *R. B. Moodie* and *K. Schofield*. The following reactions take place in the presence of sulfuric or perchloric acid:

$$ArH + NO_2^{\oplus} \rightleftharpoons [ArH \cdot NO_2^{\oplus}]$$

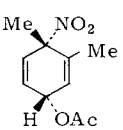
$$[ArH \cdot NO_2^{\oplus}] \rightleftharpoons \underset{NO_2}{\overset{\oplus}{Ar}\overset{H}{\diagup}} \longrightarrow ArNO_2 + H^{\oplus}$$

(1)

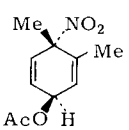
The position of the nitro group in the end product is determined during formation of the intermediate *(1)*. The ion NO_2^+ cannot only enter the ring at a position *ortho*, *meta*, or *para* to a substituent X, but also at the *ipso* position, *i.e.* at the position already bearing a substituent [cf. *(2)*]. Thus, the nitration of *o*-xylene with nitric acid/acetic anhydride



(2)



(3a)



(3b)

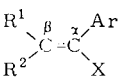
proceeds *via* the moderately stable stereoisomers *(3a)* and *(3b)*. [Ipso Attack in Aromatic Nitration. Acc. Chem. Res. *9*, 287—292 (1976); 58 references]

[Rd 898 IE—L]

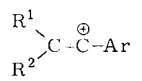
Sulfenic acid groups in proteins form the theme of a paper by *W. S. Allison*. Free SH groups in proteins can be readily oxidized *in vitro* to SOH groups. Since almost all sulfenic acids are unstable and the SOH group has no characteristic spectroscopic properties their occurrence had to be proven indirectly. If Cys-149 is present in glyceraldehyde 3-phosphate dehydrogenase in the SOH form, the enzyme does not act as dehydrogenase but as acyl phosphatase. SOH groups in general could possibly play a role in enzyme-catalyzed reactions. [Formation and Reactions of Sulfenic Acids in Proteins. Acc. Chem. Res. *9*, 293—299 (1976); 46 references]

[Rd 899 IE—L]

The solvolysis of α-arylvinyl derivatives *(1)* is described in an article by *Z. Rappoport*. The sp^2 hybridization of the vinyl carbon of a vinyl compound increases its electronegativity, strengthens the bond to the leaving group X, and infers a lower self-solvolytic reactivity for the system than for saturated systems. For compensation compounds containing highly activating substituents are employed. Bulky β-substituents have



(1)



(2)

a strong influence on the behavior of the α-arylvinyl compounds *(1)*. In many cases the solvolysis proceeds *via* free, linear, selective α-arylvinyl cations *(2)*. [Solvolysis of α-Arylvinyl Derivatives. Acc. Chem. Res. *9*, 265—273 (1976); 46 references]

[Rd 900 IE—L]

Transition-metal dialkylamides and disilylamides are dealt with in paper by *D. C. Bradley* and *M. H. Chisolm*. These compounds, *e.g.* $W(NMe_2)_6$ and $Mn[N(SiMe_3)_2(THF)$, contain transition-metal nitrogen bonds and in many cases are characterized by having unusual coordination numbers. Use of extremely bulky ligands such as $N(i\text{-}Pr)_2$ and $N(SiMe_3)_2$ has enabled isolation of complexes having coordination number two or three, *e.g.* $Cr[N(i\text{-}Pr)_2]_3$. Less bulky ligands such as NMe_2 or NEt_2 allow higher coordination numbers and in lower valency metal complexes oligomerization may occur by bridge formation between metal and ligand or by direct metal-metal bonding. An example is $Mo_2(NMe_2)_6$. [Transition-Metal Dialkylamides and Disilylamides. Acc. Chem. Res. *9*, 273—280 (1976); 108 references]

[Rd 901 IE—L]

Microbial Transformations of Non-Steroid Cyclic Compounds. By *K. Kieslich*. Georg Thieme Verlag, Stuttgart 1976. 1st edit., xxii, 1262 pp., 449 formula schemes, 225 tables, bound, DM 196.—.

The first volume of "Neuere Methoden der präparativen Organischen Chemie" (edited by *W. Foerst*) contains a section on the "Use of Biochemical Oxidation and Reduction for Preparative Purposes," in which *F. G. Fischer* describes the application of microorganisms in chemical reactions. Since this publication in the 'forties' many processes for the microbial treatment of organic compounds have been developed, so that *Klaus Kieslich* has now been able to present a very comprehensive book. Microbial steroid reactions, which have been extensively investigated, are not dealt with, since there have already been summarizing publications on this subject.

After a rather short introduction of eight pages on the methods and techniques of preparation of organic compounds with the aid of microorganisms, the possible reactions are reviewed in chapters on: 1. alicyclic compounds, 2. terpenoids, 3. aromatic compounds, 4. O-heterocycles, 5. N-heterocycles, 6. alkaloids, 7. two- and three-N heterocycles, 8. S-, O,S-, S,N- and other heterocycles, and 9. carbohydrates. The greater part of the book (826 pages) consists of a tabular presentation divided as follows: 1. oxidations, 2. reductions, 3. hydrolyses, 4. elimination of water and condensations, 5. degradations, 6. formation of new carbon-carbon or heteroatom bonds, 7. isomerizations and rearrangements. An alphabetical list of the microorganisms used is appended. The literature is covered by 1932 references up to 1973/74, with an addendum up to 1975. In a work of this scope errors and omissions are practically unavoidable. For example, in the tabulation part oxidative breakdown of aromatic compounds by bacteria is said to proceed by way of an epoxide and a *trans*-dihydrodihydroxy compound, whereas the correct interpretation with the formation of the *cis*-compound is given by the author himself on page 89.

The theme of this book can be classified as "biotechnology", a subject that is pursued in English-speaking countries and especially in Japan in accord with its importance. In West Germany much ground still has to be made up, and thus wide distribution of this book is desirable in spite of its high price.

Franz Lingens [NB 349 IE]

Experimentelle Einführung in Grundlagen und Methoden der Chemie (Experimental Introduction to the Principles and Methods of Chemistry). By *E. J. Slowinski, W. L. Masterton* and *W. C. Wolsey*. Gustav Fischer Verlag, Stuttgart 1976. 1st edit., viii, 327 pp., 18 figs., 7 flow diagrams, 10 SEM Photographs and 15 tables, paperback, DM 29.80.

The experimental chemistry book follows the trend, observed in recent years, of departing from the long-practised concept of overloading the student in his first semesters with a wealth of reading and experiments.

Here again, then, the selected material is treated by means of experiments. Several experimental procedures are presented for each theme, whether from physical, inorganic, or organic chemistry, and the selection is left to the person in charge of the class. The procedures are thoroughly worked out and are backed up by the theory needed for their understanding. The authors have further attempted, and in the reviewer's opinion successfully, to stimulate the student by questions to a critical appraisal of the apparatus and experiments and, when necessary, to extending their knowledge by referring to textbooks. The book takes the student first through the various possibilities of chemical separations and then treats the important laws of stoichiometry, calorimetry, and chemical bonding. Next come experiments on themes involving chemical equilibria, chemical kinetics, acids and bases, complex chemistry, and electrochemistry. In the remaining 80 pages the principles of qualitative analysis are presented, and here too there is no dearth of theoretical and practical explanations.

The formats and diagrams by which the student should evaluate his experimental data are well-chosen.

Thus, the book satisfies the demands that must be made on a practical chemistry text. It can be recommended without reservations for all practical work in which students are to be introduced to the methods and principles of chemistry.

Lothar Knoll [NB 350 IE]

Handbook of Organic Reagents in Inorganic Analysis. By *Z. Holzbecher, L. Diviš, M. Král, L. Šúcha*, and *F. Vláčil*. Translated by *S. Kortlý*. John Wiley & Sons, Inc., New York–London 1976. 1st edit., 734 pp., 90 figs., 90 tables, bound, $ 41.80.

According to the foreword, this book is intended as an introduction into the theory and practice of organic reagents on the grounds that up to the present there have been few monographs other than ones dealing with either of these aspects alone (which, however, is not true at least of the German and the Russian languages). However sensibly the combination is effected, the reader will, according to his standpoint, easily find something to disagree with in one or the other part. The theory is in part elementary—indeed trivial—and much of it seems superfluous. Nevertheless, some sections are very well written, for example those about absorption spectra and luminescence. The experimentalist will search in vain for a specific analytical procedure, though it must be said that it is in the practical part that the greatest value of the book will be found.

The book contains six main chapters. Following an introduction (30 pp.) the theoretical aspects are first laid down: in the second chapter (90 pp.) "Structure and Properties of Organic Reagents and their Compounds with Metals" the discussion deals with the nature of bonding in complexes, stereochemistry, isomerism, absorption spectra, luminescence, solubility, and structure. The third chapter (60 pp), "Equilibria of Organic Reagents in Solution" covers thermodynamics, kinetics, redox reactions, distribution and precipitation equilibria, and masking.

In the practical part, Chapter 4 (100 pp.) entitled "Applications of Organic Reagents in Inorganic Analysis" treats all the important analytical operations; it contains several very well written sections, particularly that on chelometric titration with an extensive table providing the choice of indicators. Chapter 5, on "Analytical Applications of Organic Reagents" (200 pp.), is probably the most important part of the book; in 50 sections and 50 tables arranged according to the periodic table it presents suitable reagents for each element from hydrogen to platinum together with keyword data for methods of determination, reaction conditions, range of determinations, and interferences. This chapter is certainly of great value to every analyst and for all who work with organic reagents. Nevertheless, the tabular presentation does not replace a real set of procedures, and one is thus referred to the original literature. Here, however, we falter, for the selection of references is incomplete. This, of course, cannot ever be completely avoided, for the author must be given the right of subjective choice, but it should never occur, as it does here, that there is no citation for many of the reagents and methods listed in

the tables. The sixth chapter (100 pp.), "Choice of Reagents Used in Analytical Chemistry", contains a collection of the formulas, names, and most important properties of organic reagents, and thus forms the requisite supplement to the preceding chapter.

The book is intended for a wide circle of readers and users, each of whom will find in it something useful and worthwhile. The student can certainly draw some gain from the very elementary theoretical chapters; users of organic reagents will use the practical chapters with success. Certain deficiencies, however, should not be overlooked.

Fritz Umland [NB 351 IE]

Laborpraxis—Quantitative Analyse. (Laboratory Practice—Quantitative Analysis.) By *W. Feler* and *C. Räthe*. Verlag Chemie, GmbH, Weinheim 1976. 1st edit., 128 pp., 21 figs., paperback, DM 12.80.

This book deals with gravimetry and mass analysis. Although the theoretical foundations of these methods are sometimes treated too skimpily, many general, useful, and valuable tips are to be found in the practical part. Procedures for some selected gravimetric determinations are described in detail, namely individual determinations of iron, nickel, aluminum, sulfate, and calcium, and separations of iron from nickel, calcium from magnesium, lead from copper. The mass-analytical part contains neutralization volumetric analysis, precipitation volumetric analysis, complexometry, and the most important procedure of redox volumetric analysis (permanganometry, chromatometry, and iodometry). Detailed experimental procedures supplement the theoretical considerations of these methods. The book is thus of interest above all to the experimentalist, *i.e.* the laboratory assistant or chemical technician, but also to the student in his first semesters.

More recent methods, such as precipitation from homogeneous solution or titration with the aid of ion-selective electrodes, are not described. On the credit side, errors are considered along with the detailed analytical directions; questions and exercises (with answers) stimulate the reader to think for himself. Unfortunately, the book suffers from a number of printing errors.

Siegbert Pantel [NB 352 IE]

Elektrochemische Bauelemente (Electrochemical Components). By *A. F. Bogenschütz* and *W. Krusemark*. Verlag Chemie GmbH, Weinheim 1976. 1st edit., x, 247 pp., 211 figs., 26 tables, bound, DM 145.—.

The coulometer, developed by *Faraday* in marketable form as early as 1840, and the electrolytic capacitor, now about 100 years old, are among the components that still hold an undisputed position in electrochemical engineering. The authors describe such perfected products but in addition do not shirk from offering many addenda and ideas for their development. Here we find the time switch (*e.g.* sea-water-activated silver/gold cells), the electrolytic information-storage devices (*e.g.* metistron and memistor), electrokinetic components (*e.g.* the solion) and electrochromic displays.

The whole book is easy for the non-expert to read, and is made easier to understand by the extremely instructive drawings and circuit diagrams. One would have liked to see more regular comparison with electronic apparatus against which these new cells must compete. Wherever ionic mobility is important for the operation of the apparatus the electronic elements must win on speed. In addition, chemical material transfer is reversible only to a limited degree, which has its effect on the life of the apparatus. A critical assessment of the prospects of specific developments should be incorporated in a new edition.

Sensors such as are used in medicine and environmental surveillance are described, as are controllers and switches, all with the same clarity noted above. Perhaps more space could be secured for this part of the book by deleting sections such as those on electrochemical thermocouples, radiation dosimeters, and coulometric determination of layer thicknesses.

The book, which construes the term "components" in a very broad sense, can be recommended both as a review and as a reference work. The 603 references provided facilitate entry into the original literature.

Ferdinand v. Sturm [NB 353 IE]

Aspects of Organic Photochemistry. By *W. M. Horspool*. Academic Press Inc., Ltd., London 1976. 1st edit., 290 pp., bound, £ 9.50.

According to the Preface, this book was written as an introduction for undergraduates and graduates facing their final examination. It is divided into nine chapters: introduction to the physical principles of photochemistry, experimental methods, the Woodward-Hoffmann rules, photochemistry of unsaturated and aromatic compounds, reactions of ketones, photochemistry of enones, oxidation and reduction reactions and finally "miscellaneous" reactions.

The main part of the book (about 200 out of its 280 pages) is devoted to preparative organic photochemistry. The author has taken great trouble to make the wealth of material easier to follow by extensive subsectioning; that this has been only partly successful is due to the involved and often inexact description of the contents.

The first chapters—"Physical Principles" and "The Woodward-Hoffmann Rules"—are inadequate as an introduction. Besides very vague statements (*e.g.* on p. 17, "Thus the molecules in the excited state are considerably more reactive in the excited state and endeavour to return to the ground state as rapidly as possible"), the text also contains a large number of serious errors which must lead to considerable confusion.

One could perhaps use this book together with others when collecting information on a specific class of reactions; however, it cannot be recommended as a beginner's introduction to the field of organic photochemistry.

Karl-Heinz Grellmann [NB 354 IE]

Solid State Photochemistry. A Collection of Papers by *G. M. J. Schmidt* and his Collaborators Describing a Symbiotic Relationship between X-Ray Crystallography and Synthetic Organic Photochemistry. Edited by *D. Ginsburg*. Monographs in Modern Chemistry, Vol. 8. Edited by *H. F. Ebel*. Verlag Chemie, Weinheim—New York 1976. 1st edit., viii, 280 pp., bound, DM 86.—.

This book, which appeared in memory of *G. M. J. Schmidt* in connection with the fifth anniversary of his death, was conceived as a report on the current state of organic solid-state chemistry which is controlled by the topology of the crystal structure in the sense of minimal change in the atomic positions, and which was called topochemistry by *Schmidt* in his capacity as its founder. The concept was extended by his student *Cohen* in the same sense. The title chosen by the editor is not really accurate, since *Schmidt* himself drew heterogeneous gas/crystal reactions into the range of his considerations and investigations. The greatest part of the book is occupied by reprints of 31 publications by *Schmidt* and his students. From these the preparative possibilities and the limits of the methods become clear; short passages by *D. Ginsburg* as editor link the various texts. The closing articles by *M. D. Cohen*, *J. D. Dunitz*, and *G. S. Hammond* treat the present, past, and future of the field. *Cohen* describes further development of research in this area at the Weizmann Institute; *Dunitz* draws

a very lively, clearcut picture of *Schmidt*, based on personal memories, and of his influence on X-ray structure determination from 1919 to 1971; *Hammond* raises the difficult question about the future of solid-state chemistry, but answers it only from the quantitative point of view.

In spite of its heterogeneity the book succeeds in providing interesting stimulation and insight even for those unfamiliar with the subject, and in this sense can be warmly recommended.

Gerhard Lehmann [NB 355 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Structure and Bonding. Edited by *J. D. Dunitz, P. Hemmerich, J. A. Ibers, C. K. Jørgensen, J. B. Neilands, D. Reinen,* and *R. J. P. Williams.* Vol. 29: Biochemistry. Springer-Verlag, Berlin 1976. iv, 219 pp., bound, DM 68.—.—ISBN 3-540-07886-X.

Physico-Chemical and Biological Applications. By *B. Lindman* and *S. Forsén.* Springer-Verlag, Berlin 1976. xiv, 368 pp., bound, DM 96.—.—ISBN 3-540-07725-1.

Advances in Chromatography, Vol. 14. Edited by *J. C. Giddings, E. Grushka, J. Cazes,* and *P. R. Brown.* Marcel Dekker, New York 1976. xiii, 459 pp., bound, SFrs. 114.—.—ISBN 0-8247-6436-6.

Landolt-Börnstein: Numerical Data and Functional Relationships in Science and Technology. New Series. Edited by *K.-H. Hellwege.* Group 2: Atomic and Molecular Physics. Vol. 8 (Supplement to Vol. 2): Magnetic Properties of Coordination and Organometallic Transition Metal Compounds. By *E. König* and *G. König.* Springer-Verlag, Berlin 1976. xxxvi, 1163 pp., bound, DM 1100.—.—ISBN 3-540-07441-4.

Gmelins Handbuch der Anorganischen Chemie. Main work, System No. 47: Blei. Part A: Geschichtliches. Vorkommen. 2a: Kosmochemie. Geochemie. Springer-Verlag, Berlin 1976. 8th Edit., xiv, 280 pp., bound, DM 581.—.—ISBN 3-540-93324-7.

Crystallographic Computing Techniques. Edited by *F. R. Ahmed, K. Huml,* and *B. Sedlaček.* Munksgaard, Kopenhagen 1976. 503 pp., bound, D.kr. 336.—.—Proceedings of an International Summer School Organized by The Commission on Crystallographic Computing of the International Union of Crystallography, Prague/ČSSR, July 28—August 5, 1975.—ISBN 87-16-02132-0.

Transition Metal Organometallics in Organic Synthesis, Vol. I. Edited by *H. Alper.* Vol. 33-I of the series "Organic Chemistry". Edited by *A. T. Blomquist* and *H. H. Wasserman.* Academic Press, New York 1976. ix, 258 pp., bound, $ 26.50.—ISBN 0-12-053101-1.

Proceedings of the First European Symposium on Thermal Analysis. (University of Salford, U. K., 20—24 September 1976, Organized by the Thermal Methods Group of the Analytical Division of the Chemical Society.) Edited by *D. Dollimore.* Heyden, London 1976. xxxv, 458 pp., bound, £ 11.50.—ISBN 0-85501-172-6.

SUBJECT INDEX

FP = Full paper (review article) LA = Literature abstract
SC = Short communication
G.E. = Reference to Volume *88* (1976) of the German Edition of Angewandte Chemie.
References are given for Review Articles and Short Communications only.

ABSOLUTE configuration, The ~ of 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid (TAPA) (SC) 115 [G.E. 93]
Determination of the ~ of chiral thiols by ^{1}H-NMR spectroscopy of diastereomeric thiol esters (SC) 703 [G.E. 770]
Structure and ~ of an organo-iron compound having iron as chiral center (SC) 776 [G.E. 847]
Aceheptylene, Cycloadditions of ~. Facile synthesis of dicyclopenta[ef,kl]heptalenes (SC) 108 [G.E. 125]
Acetic acid derivatives, Reaction of N-protected succinimides with α-lithiated ~ (SC) 626 [G.E. 642]
Acetylenes, Fluoride catalyzed addition of silyl-~ to carbonyl compounds (SC) 498 [G.E. 539]
The photochemical addition of acetylene to tricarbonyl(η^5-cyclopentadienyl)methylmolybdenum and -tungsten (SC) 759 [G.E. 800]
Polymerization of tricosa-10,12-diynoic acid in multilayers (SC) 764 [G.E. 805]
Palladium(II)-induced oligomerization (LA)
Acylation, Nucleophilic ~ with β-acylenamines (SC) 171 [G.E. 193]
4,6-Diphenylthieno[3,4-d][1,3]dioxol-2-one 5,5-dioxide, a novel activating agent for peptide syntheses (SC) 444 [G.E. 480]
β-Acyl enamines, Nucleophilic acylation with ~ (SC) 171 [G.E. 193]
Adipose tissue, Bioenergetics of mitochondria in brown ~ (LA) 318
Air analysis, Die Analyse der Luft und ihre Verunreinigungen in der freien Atmosphäre und am Arbeitsplatz (Book Review) 58
Aldehydes, Catalyzed addition of ~ to activated double bonds—a new synthetic approach (FP) 639 [G.E. 695]
Alkaloids, Plant constituents with potential anticancer and cytotoxic activity (LA) 564
Alkenes, [2+2]-cycloaddition of alkynes to ~ (SC) 369 [G.E. 412]
Alkylation-cycloaddition, Electrophilic ~ between an olefinic and an acetylenic substrate (SC) 55 [G.E. 59]
Alkylidenemalondialdehyde, Synthesis of ~ tetramethyl bisacetals (SC) 113 [G.E. 88]
Alkynes, Electrophilic alkylation-cycloaddition between an olefinic and an acetylenic substrate (SC) 55 [G.E. 59]
[2+2]-Cycloaddition to alkenes (SC) 369 [G.E. 412]
Allenes, Trialkyl-~ from 1,1-disubstituted propargylic acetates (SC) 496 [G.E. 537]
Allopolarization, Concept of ~. Effects of substituents on reactions of ambifunctional anions (FP) 321 [G.E. 389]
Allylation of 4-hydroxyarsenin—arsenic-carbon hetero-Cope rearrangement (SC) 690 [G.E. 728]
Allyl ethers, Cleavage with Pd/C (SC) 558 [G.E. 578]
Aluminum chloride, Formation of carbenium ions in the reaction of ~ with tert-butylchloride in liquid hydrogen chloride (SC) 773 [G.E. 849]
Aluminum compounds, The Al—Al bond as a readily accessible structural unit in organometallic compounds (SC) 694 [G.E. 760]
1,3,2λ^3,4-Diazaphosphoniaaluminatacyclobutane: A cyclic zwitterion having twofold coordinated phosphorus (SC) 692 [G.E. 758]
Ambifunctional anions, Concept of allopolarization. Effects of substituents on reactions of ~ (FP) 321 [G.E. 389]
Amide cleavage, A methylenedi-λ^5-phosphazene by ~ of tetramethylphosphonium salts (SC) 501 [G.E. 541]
Amides, Transition-metal dialkyl-~ and disilyl-~ (LA) 785
Amination, Oxidative ~ of toluhydroquinone (SC) 109 [G.E. 87]
Amines, Stereospecific synthesis of β-bromo-~ by ionic addition of diethyl dibromophosphoramidate to a double bond (SC) 302 [G.E. 302]
Trifluoroacetylation of ~ with N-trifluoroacetyl-Nylon 66 (SC) 777 [G.E. 848]
Amino acids, Synthesis of α,β-dehydro esters of ~ and N-tert-butoxycarbonyl α,β-dehydro ~ (SC) 294 [G.E. 295]
Macrocyclic peptides in anionic polymers of amino acid N-carboxylic anhydrides (SC) 307 [G.E. 338]
Radical oxidation of amino acid derivatives (SC) 497 [G.E. 538]
Aminoalkylation, New variant of the Mannich reaction (SC) 239 [G.E. 261]
Nucleophilic ~. Lithiated N,N-dimethylthiopivalamide (SC) 313 [G.E. 339]
Amino groups, Phosphorus(III) derivative with sterically fixed bis(trimethylsilyl)-~ (SC) 309 [G.E. 305]
Analysis, Instrumental Methods of ~ (Book Review) 178
Handbook of organic reagents in inorganic ~ (Book Review) 786
Laborpraxis—Quantitative Analyse (Book Review) 787
Analytical methods, Far-infrared Fourier spectroscopy as a method for structure determination in chemistry (FP) 25 [G.E. 1]
Integrated dust analysis (FP) 141 [G.E. 168]
Application of catalyzed reactions in analytical chemistry (FP) 150 [G.E. 177]
Collisional activation mass spectrometry—a new probe for determining the structure of ions in the gas phase (FP) 509 [G.E. 589]
Radioimmunoassay (FP) 525 [G.E. 565]
Dual-wavelength spectrophotometry (FP) 673 [G.E. 750]
Anhydrides, Macrocyclic peptides in anionic polymers of amino acid N-carboxylic ~ (SC) 307 [G.E. 338]
4',5'-Anhydroadenosine, Detection as the cleavage product of coenzyme B_{12} in functional holoenzymes (SC) 542 [G.E. 583]
Anthranilates, Self-condensation of β-dialkylaminocrotonates: a one-step synthesis of N,N-dialkyl-~ (SC) 498 [G.E. 539]
Antibiotics, Antibiotic inhibition of mitochondrial ATP synthesis (LA) 177
Antimony complexes, Tris[dicarbonyl(η-cyclopentadienyl)ferrio]stibane—A 5B-element base with total transition-metal substitution (S) 618 [G.E. 680]
Arginine, The interrelationship between ~, glutamic acid and proline in metabolism and nutrition (LA) 707
Arsenic compounds, Synthesis and structure of a hexaazadiphosphadiarsatricyclodecane (SC) 701 [G.E. 768]
Arsenic oxide trichloride, $AsOCl_3$ (SC) 766 [G.E. 806]
Arsenic pentachloride, $AsCl_5$ (SC) 377 [G.E. 410]
Arsenin, Allylation of 4-hydroxy-~—arsenic-carbon hetero-Cope rearrangement (SC) 690 [G.E. 728]
"Arsenobenzene", C_6H_5—As=As—C_6H_5, as a bridging μ_3 ligand in a transition metal complex (SC) 234 [G.E. 255]
Asymmetric synthesis of α-substituted ketones by metalation and alkylation of chiral hydrazones (SC) 549 [G.E. 579]
Atomic absorption spectroscopy, Atom-Absorption-Spektroskopie (Book Review) 447
Atomic structure, Lehrprogramm Atombau und Periodensystem (Book Review) 709
Automotive exhaust detoxification with multifunctional catalysts (FP) 586 [G.E. 657]
9-Azabarbaralane, Unsubstituted ~: A π-destabilized heterocycle (SC) 370 [G.E. 382]
2-Azetidinones, Synthesis of β-lactams (LA) 564
9-Azidotriptycenes, Photolysis (SC) 168 [G.E. 150]
Azines, Catalytic synthesis of 1,2-diaza-1,5,9-cyclododecatrienes from butadiene and ~ (SC) 49 [G.E. 29]
Reactions of ~ and imines with dienophiles (LA) 564
Azobenzene, Carbonylchromium complexes of ~ (SC) 230 [G.E. 227]
Azo compounds, Competing cycloadditions in the reaction of acetylazobenzene with diphenylketene (SC) 432 [G.E. 449]
Azulene, Cycloadditions of pentalene and ~—A facile heptalene synthesis (SC) 104 [G.E. 121]

BACTERIORHODOPSIN, ~ as an example of a light-driven proton pump (FP) 17 [G.E. 16]
Biosynthesis of the purple membrane of halobacteria (FP) 187 [G.E. 203]
Barriers to rotation, Unusually high ~ involving the tetrahedral carbon atom (FP) 87 [G.E. 67]
Benzene, Mechanism of the thermal conversion of 3,3'-bicyclopropenyls into ~ derivatives (SC) 232 [G.E. 254]
Continuous electrocatalytic synthesis of phenol from ~ and hydrogen peroxide (SC) 294 [G.E. 306]
Indirect determination of the half-wave reduction potentials of ~ and [2.2]paracyclophane (SC) 552 [G.E. 617]
Benzo[14]annulene (SC) 365 [G.E. 374]
Benzothiepin, Low-temperature X-ray structure analysis of 1-~ (SC) 297 [G.E. 295]
New synthetic entry to the thiepin system.—Benzo[d]thiepin and dibenzo[bd]thiepin (SC) 611 [G.E. 650]
Betaines, Synthetic applications of heteroaromatic ~ with six-membered rings (FP) 1 [G.E. 41]
Bicyclo[4.2.0]octa-2,4-dienes, Photoisomerization and photocleavage of ~ (SC) 779 [G.E. 812]
Bicyclopentane, A CH carbene complex of iron by metal-induced fragmentation of two bonds of a ~ unit (SC) 609 [G.E. 640]
Oxidative addition of the central bond of a ~ system to iron (SC) 610 [G.E. 641]
3,3'-Bicyclopropenyl, Mechanism of the thermal conversion of ~-s into benzene derivatives (SC) 232 [G.E. 254]
Bicyclopropyl, Interaction of the Walsh orbitals in ~ (SC) 310 [G.E. 343]
Bile pigments (LR) 119
Bimolecular films, Kink-block and gauche-block structures of ~ (FP) 575 [G.E. 628]
Biochemistry, Comprehensive ~ (Book Review) 178
Biochemie (Book Review) 318
Biomimetic polyene cyclizations (FP) 9 [G.E. 33]
Bond angle distortion, Extreme ~ in organozirconium compounds active toward ethylene (SC) 629 [G.E. 688]
Bond order, Correlation between the β-effect of methyl groups on $\delta(^{13}C)$ and the C_α—C_β

π-~ (SC) 303 [G.E. 335]
Bones, Synthetic amorphous calcium phosphate (LR) 119
Boranes, Simple synthesis of cyclopentadienyl-~ (SC) 295 [G.E. 333]
Borolan-1-ylamine, Tris(3-methylborolan-1-yl)amine, an electron-deficient triborylamine (SC) 235 [G.E. 231]
Borole, Novel type of triple-decker complex—~ as bridging ligand (SC) 433 [G.E. 450]
Boron compounds, (1,2-Diaza-3,6-dibora-4-cyclohexene)tricarbonylchromium—A complex with an η^6-$C_2B_2N_2$ ligand (SC) 45 [G.E. 55]
Bridgehead derivatives, Optically active ~ of trishomobarrelene and trishomobullvalene (SC) 429 [G.E. 446]
Bromate, Chemical waves in the 2,4-pentanedione/potassium ~ system (SC) 689 [G.E. 728]
β-Bromoamines, Stereospecific synthesis by ionic addition of diethyl dibromophosphoramidate to a double bond (SC) 302 [G.E. 302]
Bromyl cation, $[BrO_2]$ (SC) 158 [G.E. 189]
Bullvalene, $C_{12}H_{10}O$ and thermolabile $C_{11}H_{10}O$ ketones from ~ via carbonyliron complexes (SC) 376 [G.E. 375]
Butadiene, Catalytic synthesis of 1,2-diaza-1,5,9-cyclododecatrienes from ~ and azines (SC) 49 [G.E. 29]
tert-Butyl chloride, Formation of carbenium ions in the reaction of aluminum chloride with ~ in liquid hydrogen chloride (SC) 773 [G.E. 849]

CADMIUM, Biochemical aspects of the toxicology of ~ (LA) 446
Cadmium compounds, Bis(tri-tert-butylsilyl)-cadmium: The first silylcadmium compound isolated in substance (SC) 620 [G.E. 681]
Calcium phosphate, Synthetic amorphous ~ (LA) 119
Cancer, Drugs used in treatment (LA) 176
Carbanion complexes of nickel (SC) 621 [G.E. 682]
Carbene complexes, Dimethylcarbene- and methylphenylcarbenedicarbonyl(η-cyclopentadienyl)manganese (SC) 543 [G.E. 584]
CH ~ of iron by metal-induced fragmentation of two bonds of a bicyclopentane unit (SC) 609 [G.E. 640]
Pentacarbonyl(diethylaminofluorocarbene)chromium (SC) 616 [G.E. 646]
3-Dimethylamino-3-phenylallenylidene. A novel ligand at the pentacarbonylchromium and -tungsten skeleton (SC) 623 [G.E. 683]
Simple synthesis of dicarbonyl(η-cyclopentadienyl)-(3,3-di-tert-butylallenylidene)-manganese (SC) 624 [G.E. 684]
Carbenium ions, Formation of ~ in the reaction of aluminum chloride with tert-butyl-chloride in liquid hydrogen chloride (SC) 773 [G.E. 849]
Carbocations, Theoretical approaches to the structure of ~ (LA) 177
Carbonate ion, Polarogram and reactions of a short-lived oxidation product of ~ (SC) 633 [G.E. 690]
Carbonyl compounds, Synthesis of olefins from α-silyl carbanions and ~ (SC) 161 [G.E. 184]
α-Hydroxycarboxamides from N,N-bis-(methoxymethyl)carbamoyllithium and ~ (SC) 293 [G.E. 296]
Fluoride-catalyzed addition of silylacetylenes to ~ (SC) 498 [G.E. 539]
Carboxamides, α-Hydroxy-~ from N,N-bis-(methoxymethyl)carbamoyllithium and carbonyl compounds (SC) 293 [G.E. 296]
Carboxylic acids, Regioselective chlorination of centered methylene groups in di-~ (SC) 306 [G.E. 334]
Carbyne complex, trans-Pentacarbonylrhenio-(phenylcarbyne)tetracarbonylmolybdenum: A transition metal ~ containing a metal-metal bond (SC) 157 [G.E. 163]
μ-Bromo-μ-phenylmethylidynebis(tetracarbonylrhenium) (SC) 231 [G.E. 228]
Tetrakis(trimethylsilylmethyl)bis(μ-trimethylsilylmethylidyne)ditungsten (SC) 609 [G.E. 692]
trans-Bromo(tetracarbonyl)ferrocenylcarbyne-tungsten (SC) 683 [G.E. 719]
Catalysts, ESCA investigations on industrial ~ (LA) 507
Catalyzed reactions, Application in analytical chemistry (FP) 150 [G.E. 177]
C—C Linkage of polyfunctional molecules by nucleophilic addition of dianions. Synthesis of pillarose (SC) 439 [G.E. 477]
Chelate ligand, 2,2''-Bis(diphenylphosphino)-2',3',5',6'-tetraphenyl-p-terphenyl as an arene ~ for rhodium(I) (SC) 241 [G.E. 260]
Chemical waves in the 2,4-pentanedione potassium bromate system (SC) 689 [G.E. 728]
Chemotherapy of virus diseases (FP) 410 [G.E. 458]
Chimeras of enzymes, Exchange in vitro of subunits between enzymes from different organisms: ~ (FP) 181 [G.E. 197]
Chloride complexes, Gaseous ~ with halogen bridges—homo-complexes and hetero-complexes (FP) 713 [G.E. 775]
Chlorination, Regioselective ~ of centered methylene groups in dicarboxylic acids (SC) 306 [G.E. 334]
Nonpollutative ~ and chlorinating oxidation of phenols (SC) 608 [G.E. 641]
Chlorine isotope effects in ion exchange chromatography (SC) 55 [G.E. 54]
Chlorophosphane, First example of a ~-phosphanylium chloride transformation. 2-Methyl-1,2,3λ^2-diazaphosphole hydrochlorides (SC) 111 [G.E. 91]
Chromatography, Advances in thin-layer ~ (LA) 389
Hochdruck-Flüssigkeits-Chromatographie (Book Review) 711
Chromium, π-Complexes of λ^5-phosphorins with tricarbonyl-~, tricarbonylmolybdenum, or tricarbonyltungsten (SC) 503 [G.E. 543]
Chromium complexes, (1,2-Diaza-3,6-dibora-4-cyclohexene)tricarbonylchromium—A complex with an η^6-$C_2B_2N_2$ ligand (SC) 45 [G.E. 55]
Carbonyl-~ of azobenzene (SC) 230 [G.E. 227]
"Arsenobenzene", C_6H_5—As=As—C_6H_5, as a bridging μ_3 ligand in a transition metal complex (SC) 234 [G.E. 255]
X-ray structure analysis of two π-complexes of λ^5-phosphorins with tricarbonylchromium (SC) 504 [G.E. 544]
Pentacarbonyl(diethylaminofluorocarbene)chromium (SC) 616 [G.E. 646]
Reactions of arenetricarbonyl-~ with nitrosyl chloride (SC) 617 [G.E. 651]
3-Dimethylamino-3-phenylallenylidene. A novel ligand at the pentacarbonylchromium and -tungsten skeleton (SC) 623 [G.E. 683]
Functional transition-metal phosphanes (SC) 769 [G.E. 809]
Coal, Production of oil by hydrogenation of ~ (FP) 341 [G.E. 348]
Cobaloximes, New developments in the field of vitamin B_{12}: Reactions of the cobalt atom in corrins and in vitamin B_{12} model compounds (FP) 417 [G.E. 465]
Synthesis and structure determination of an intramolecularly alkylated bridged cobaloxime (SC) 427 [G.E. 443]
Cobalt complexes, Synthesis of phosphorus ylides at a ~ center (SC) 42 [G.E. 61]
A lithium-cobalt bimetal complex (SC) 46 [G.E. 50]
Tetracarbonylcobaltiopentacarbonylmanganiomercury, $(CO)_4Co$—Hg—$Mn(CO)_5$ (SC) 162 [G.E. 188]
A mononuclear paramagnetic biphosphinotricarbonylcobalt(0) complex (SC) 381 [G.E. 415]
A novel hetero-bimetallic dinitrogen complex (SC) 612 [G.E. 648]
Cobalt compounds, New developments in the field of vitamin B_{12}: Reactions of the cobalt atom in corrins and in vitamin B_{12} model compounds (FP) 417 [G.E. 465]
Synthesis, structure determination, and rearrangement of a model for the active site of methylmalonyl-CoA mutase with incorporated substrate (SC) 561 [G.E. 613]
Bis(η-1,5-cyclooctadiene)cobaltlithium (SC) 767 [G.E. 808]
Cobalt(I)-Phthalocyanine, A new technique of protecting groups—cleavage of β-halogenated alkyl esters with supernucleophilic ~ (SC) 681 [G.E. 717]
Coenzyme B_{12}, Photochemical induction of enzymatic activity of a carbocyclic analog of ~: a contribution to the elucidation of the mechanism of action of ~ (SC) 170 [G.E. 186]
Synthesis and structure determination of an intramolecularly alkylated bridged cobaloxime (SC) 427 [G.E. 443]
Detection of 4',5'-anhydroadenosine as the cleavage product of ~ in functional holoenzymes (SC) 542 [G.E. 583]
Vitamin B_{12} coenzyme (LA) 563
Collagen, Structure and properties (LA) 58
Color Lexicon, BAG Farben-Lexikon (Book Review) 711
Complexation chromatography, Separation of deuteriated ethylenes $C_2H_{4-n}D_n$ by ~ on a rhodium(I) complex (SC) 304 [G.E. 336]
Complexes, Gaseous chloride ~ with halogen bridges—homo-~ and hetero-~ (FP) 713 [G.E. 775]
Synthesis of trinuclear sandwich-like cyclopentadienyl ~ containing two different metal atom centers (SC) 172 [G.E. 187]
Use of the isoselectivity principle for distinguishing cationic π- and σ ~ (SC) 237 [G.E. 258]
Complex formation with tetraazacycloalkane-N,N',N'',N'''-tetraacetic acids as a function of ring size (SC) 686 [G.E. 760]
Transition metal ~ of synthetic macrocyclic ligands (LA) 120
Alkali-metal ~ in aqueous solution (LA) 177
Condensation, Oxidation-reduction ~ (FP) 94 [G.E. 111]
Conformation, The conformational behavior of 5,10,11,12-tetrahydrodibenzo[a,d]cyclooctene (SC) 224 [G.E. 224]
~-s and N-inversion barriers in tropane compounds (SC) 545 [G.E. 574]
Conformational studies on twelve-membered cyclic heterocycles. Crystal structure of 5,18-dimethyl-5,18-diazatribenzo[a,e,i]-cyclododecene-6,17(5H,18H)-dione (SC) 757 [G.E. 798]
^{13}C-NMR spectroscopy and the determination of the ~-s of biological molecules (LA) 176
~ of piperidine (LA) 245
Use of cyclic peptides for conformational studies (LA) 507
Conformational diastereoisomers, Isolation of ~ of N,N',N''-tribenzyltrianthranilide (SC) 223
Cope rearrangement, ~ with dipolar intermediates (SC) 299 [G.E. 298]
Hetero ~-s with dipolar intermediates (SC) 301 [G.E. 300]
Copper compounds, S_4N_4 bridge ligand: structure of $CuCl \cdot S_4N_4$ (SC) 765 [G.E. 807]
Additions of lithium organocuprates as models for electron-transfer processes (LA) 446
Crosslinking, Penetration and ~ of macromolecules (FP) 451 [G.E. 487]
Crotonates, Self-condensation of β-dialkylamino-~: a one-step synthesis of N,N-dialkylanthranilates (SC) 498 [G.E. 539]
Crown ethers, Papaverine ~ (SC) 685 [G.E. 722]
Crystal face dependence of the surface chemistry of tungsten (LA) 177
Crystal surfaces, Reactions on surfaces of single crystals (LA) 635
Crystals and long-chain molecules (LA) 447
Cyanides of metals from the 4th—7th subgroups (LA) 120
Cyano complexes, The chemistry of ~ of the transition metals (Book Review) 709
Cyclizations, Biomimetic polyene ~ (FP) 9 [G.E. 33]
Cycloadditions, Synthetic applications of heteroaromatic betaines with six-membered

rings (FP) 1 [G.E. 41]
Intramolecular 1,3-dipolar ~ (FP) 123 [G.E. 131]
Competing ~ in the reaction of acetylazobenzene with diphenylketene (SC) 432 [G.E. 449]
Cyclobutadiene—A square singlet molecule? (SC) 226 [G.E. 252]
Cyclobutane, 1,3,2λ³,4-diazaphosphoniaaluminata-~: A cyclic zwitterion having twofold coordinated phosphorus (SC) 692 [G.E. 758]
Cyclobutane rings, Four linearly annelated ~: the tetracyclo[4.4.0.0^{2,5}.0^{7,10}]decane system (SC) 431 [G.E. 447]
Cyclobuta[b]triphenylene, 10,11-Dihydro-~ and 1,2,5,6,9,10-hexahydrotriscyclobuta[b,h,n]triphenylene (SC) 53 [G.E. 63]
Cyclobuteneselenones, Bond-delocalized ~ (SC) 704 [G.E. 771]
Cyclodiaza-λ⁶-thiane, A new cyclic SN compound: 1,1,3,3-tetraoxo-2,4-difluorosulfonyl-~ (SC) 614 [G.E. 646]
Cycloheptatsulfur oxide, Synthesis of ~, S_7O (SC) 772 [G.E. 854]
Cyclooctadiene, Cyclohexenyl(1,5-~)iridium —η-diene hydride or enyl structure (SC) 702 [G.E. 768]
Bis(η-1,5-~)cobaltlithium (SC) 767 [G.E. 808]
Cyclooctatriene, 5,8-Bis(diphenylmethylene)-1,3,6-~ (SC) 487 [G.E. 536]
5,8-Bis(7-cycloheptatrienylidene)-1,3,6-~ (SC) 487 [G.E. 536]
2,4-Cyclopentadienones, Synthesis of 3-aryl-2,5-di-tert-butyl-~ by base-catalyzed oxygenation of 4-aryl-2,6-di-tert-butylphenols (SC) 160 [G.E. 154]
Cyclopentadienylboranes, Simple synthesis (SC) 295 [G.E. 333]
Cyclopentadienyl complexes, Synthesis of trinuclear sandwich-like ~ containing two different metal atom centers (SC) 172 [G.E. 187]
Cyclopent[cd]azulene, 1,4-Dipolar cycloadditions (SC) 107 [G.E. 124]
[2.2]Cyclophanes, [6+6]Photocleavage (SC) 442 [G.E. 482]
Cyclophosphazene spanned by a sulfur diimido group (SC) 39 [G.E. 24]
1H-Cyclopropa[a]naphthalene from 2,3-benzo-1,6-methano[10]annulene (SC) 613 [G.E. 643]
Cyclopropanation of [2.2]paracyclophanes (SC) 165 [G.E. 152]
Cyclopropane rearrangement, Degenerate butadienyl-~ in tricyclo[5.3.0.0^{2,10}]deca-3,5-diene (SC) 53 [G.E. 63]
Cyclopropanes, Interaction of the Walsh orbitals in bicyclopropyl (SC) 310 [G.E. 343]
Selective hydrogenations of 1,1-disubstituted ~ (SC) 373 [G.E. 415]
Coupling reactions of vinylidenedi-~ doubly halogenated in allylic positions—a productive synthesis of trispiro[2.0.2.0.2.0]nonane ([3]rotane) (SC) 762 [G.E. 803]
1-Cyclopropene-1-carboxylates from 1-chloro-1-cyclopropanecarboxylic acids (SC) 244 [G.E. 259]
Cyclopropenyl, Electronic structure of tri-tert-butyl-~ (SC) 698 [G.E. 764]
Cyclopropyl hydrocarbons, Oxidation of ~ with ozone (SC) 761 [G.E. 802]
Cyclotetraphosphazene, The structure of a ~ spanned by a sulfur diimido group (SC) 783 [G.E. 853]
Cysteine, Optical induction during biomimetic formation of ~ (SC) 42 [G.E. 54]
Cytochrome c oxidase, Spectral, potentiometric, and energy-linked properties of ~ in mitochondria (LA) 563

5-DEAZARIBOFLAVIN and 5-thiariboflavins: a simple pathway to antimetabolites of vitamin B_2 (SC) 443 [G.E. 475]
α,β-Dehydro amino acids, Synthesis of esters of ~ and N-tert-butoxycarbonyl ~ (SC) 294 [G.E. 295]
Detoxification of automotive exhaust gases with multifunctional catalysts (Fp) 586 [G.E. 657]
Deuterioethylenes, Separation of ~ $C_2H_{4-n}D_n$ by complexation chromatography on a rhodium(I) complex (SC) 304 [G.E. 336]
1,3-Diarsacyclobutanes (SC) 56 [G.E. 60]
1,2-Diaza-1,5,9-cyclododecatrienes, Catalytic synthesis from butadiene and azines (SC) 49 [G.E. 29]
Diazadiphosphetidines, Isolation of a diaza-λ³,λ⁵- and a thermodynamically unstable diaza-λ⁵,λ⁵-diphosphetidine (SC) 555 [G.E. 582]
Synthesis and isolation of cis- and trans-1,3,2λ³,4λ³-diazadiphosphetidine (SC) 772 [G.E. 845]
Diaza[7]helicene, Simple synthesis and resolution (SC) 114 [G.E. 90]
1,2,3λ²-Diazaphosphole, First example of a chlorophosphane phosphanylium chloride transformation: 2-methyl-~ hydrochlorides (SC) 111 [G.E. 91]
5,18-Diazatribenzo[a,e,i]cyclododecene-6,17(5H,18H)-dione, Conformational studies on twelve-membered cyclic heterocycles. Crystal structure of ~ (SC) 757 [G.E. 798]
Diazene, Existence of isomeric ~-s (diimines) (SC) 385 [G.E. 386]
Bis(trimethylsilyl)-~ as a complex ligand (SC) 386 [G.E. 383]
Structure of an "isodiimine" complex: bis-(trimethylsilyl)iso-~-bis(cyclopentadienyl)-vanadium (SC) 387 [G.E. 384]
Diazoalkane, Nitrogen transfer from a ~ to a metal center (SC) 695 [G.E. 761]
Diazo compounds, μ-Methanediazo(N,N,N')-tris(tetracarbonylmanganese) (SC) 368 [G.E. 379]
Diazomethane, $Mn_2(CO)_{10}CH_2N_2$, a stable organometallic derivative of ~ (SC) 164 [G.E. 191]
Diazonium ions, Nitrogen as leaving group: aliphatic ~ (FP) 251 [G.E. 273]
Dibenzo[a,d]cyclooctene, Conformational behavior of 5,10,11,12-tetrahydro-~ (SC) 224 [G.E. 224]
Dibenzo[bd]thiepin, New synthetic entry to the thiepin system.—Benzo[d]thiepin and ~ (SC) 611 [G.E. 650]
Dictionary, Russian-English chemical and polytechnical ~ (Book Review) 247
Dicyclopenta[ef, kl]heptalenes, Cycloadditions of aceheptylene. Facile synthesis of ~ (SC) 108 [G.E. 125]
Diels-Alder reaction, Partial asymmetric ~ with an α-chloronitroso compound (SC) 760 [G.E. 801]
Diffusion, Influence of isotopic substitution on ~ in liquids (LA) 634
Diimine, Bis(trimethylgermyl)-~ (SC) 236 [G.E. 257]
Existence of isomeric diazenes (~-s) (SC) 385 [G.E. 386]
Bis(trimethylsilyl)diazene as a complex ligand (SC) 386 [G.E. 383]
Structure of an "isodiimine" complex: bis(trimethylsilyl)isodiazenebis(cyclopentadienyl)vanadium (SC) 387 [G.E. 384]
1,3,2-Dioxazolidines by thermal 1,3-cycloaddition of nitro groups to strained olefins (SC) 372 [G.E. 416]
1,2-Dioxetanes (LA) 634
1,3-Dioxolane derivatives, Synthesis of furan derivatives from 4-benzoyloxy-1,3-~ (SC) 682 [G.E. 718]
Diphenylmethyl groups, Magnetic nonequivalence of the C atoms of prochiral ~ in ^{13}C-NMR spectroscopy (SC) 234 [G.E. 256]
1,3-Dipolar cycloadditions, Intramolecular ~ (FP) 123 [G.E. 131]
Disaccharides, Synthesis of α-glycosidically linked ~ of D-galactosamine (SC) 440 [G.E. 478]
Double bonds, Catalyzed addition of aldehydes to activated ~—a new synthetic approach (FP) 639 [G.E. 695]
Drug metabolism, Environmental factors (LA) 507
Drugs used in treatment of cancer (LA) 176
Dual-wavelength spectrophotometry (FP) 673 [G.E. 750]
Dust analysis, Integrated ~ by physical methods (FP) 141 [G.E. 168]

ELECTROCATALYTIC synthesis, Continuous ~ of phenol from benzene and hydrogen peroxide (SC) 294 [G.E. 306]
Electrochemical components, Elektrochemische Bauelemente (Book Review) 787
Electrochemistry, A new electrochemical method of forming SiSi bonds (SC) 370 [G.E. 414]
Elektrolytgleichgewichte und Elektrochemie (Book Review) 247
Elektrochemie (Book Review) 447
Lehrbuch der Elektrochemie (Book Review) 565
Electro-deprotection—electrochemical removal of protecting groups (SC) 281 [G.E. 283]
Electron, The ~ as a chemical entity (LA) 119
Electron density distribution, Structure and density distribution of bonding electrons of cumulenes (SC) 562 [G.E. 615]
f-Elements, σ-Bonded organic derivatives of ~ (LA) 708
Eliminations, Association of ions in base-promoted β-~ (LA) 57
Distinction between concerted and nonconcerted ~ (LA) 317
Enamines, α-Metalated ~ (SC) 371 [G.E. 417]
Enantioselective reactions, Enantioselective Wagner-Meerwein rearrangement in chiral solvents under high pressure (SC) 243 [G.E. 230]
Energy metabolism, Evolution of bacterial ~ (LA) 388
Energy transductions, Coupling of "high-energy" phosphate bonds to ~ (LA) 58
Enkephalin, Total synthesis of methionine-~ (SC) 297 [G.E. 332]
Enols from Norrish type II cleavage of carbonyl compounds in solution (SC) 435 [G.E. 445]
Environmental chemistry Vol. 1. (Book Review) 246
Enzymes, Exchange in vitro of subunits between ~ from different organisms: chimeras of ~ (FP) 181 [G.E. 197]
Reaction mechanism of ~ containing molybdenum (LA) 388
Eschenmoser sulfide contraction, C-substitution of nucleosides with the aid of the ~ (SC) 689 [G.E. 724]
ESR spectroscopy, Electronic structure of tri-tert-butylcyclopropenyl (SC) 698 [G.E. 764]
Radical cation and radical anion of a tetrasilyl-substituted ethylene (SC) 699 [G.E. 765]
Radical cations of tetrasilyl-substituted hydrazines (SC) 700 [G.E. 766]
Esters, Catalyzed addition of aldehydes to activated double bonds—new synthetic approach (FP) 639 [G.E. 695]
Ether cleavage, Cleavage of allyl ethers with Pd/C (SC) 558 [G.E. 578]
Electron impact induced ~ by anchimeric participation of silyl and germyl groups (SC) 705 [G.E. 726]
Cleavage of esters and ethers with iodotrimethylsilane (SC) 774 [G.E. 847]
Ethylene, Separation of deuteriated ~-s $C_2H_{4-n}D_n$ by complexation chromatography on a rhodium(I) complex (SC) 304 [G.E. 336]
Extreme bond angle distortion in organozirconium compounds active toward ~ (SC) 629 [G.E. 688]
Halogen-free soluble Ziegler catalysts for polymerization of ~. Control of molecular weight by choice of temperature (SC) 630 [G.E. 689]
Ethylene complexes, Ethylenebis(phenylsodium)nickel (SC) 47 [G.E. 51]
Structure of a bimetal-~: $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$ (SC) 48 [G.E. 52]
Eutrophication and wastewater purification (FP) 354 [G.E. 354]

Evolution, Genetics and biological ~ (LA) 707
Excited states, Chemistry of electronically ~ of coordination compounds (LA) 57
Exhaust gases, Detoxification of automotive ~ with multifunctional catalysts (FP) 586 [G.E. 657]
Experimental chemistry, Experimentelle Einführung in Grundlagen und Methoden der Chemie (Book Review) 786

FAR-INFRARED Fourier spectroscopy as a method for structure determination in chemistry (FP) 25 [G.E. 1]
Fatty acids, Chemistry and biochemistry of unsaturated ~ (FP) 61 [G.E. 97]
Some new chemical properties of unsaturated C_{18} acids (LA) 317
α-Ferrocenylalkylamines, Recovery of chiral ~ on stereoselective peptide synthesis by four-component condensation (SC) 492 [G.E. 509]
Field desorption mass spectrometry, Li^+-attachment—a soft ionization method in ~ (SC) 696 [G.E. 762]
Fine Particles (Book Review) 710
Fischer-Tropsch synthesis: molecular weight distribution of primary products and reaction mechanism (FP) 136 [G.E. 144]
Flavins, 8α-Substituted ~ of biological importance (LA) 507
Fluorene, Unusually high barriers to rotation involving the tetrahedral carbon atom (FP) 87 [G.E. 67]
Fluorides, Solid state chemistry of ionic ~ (FP) 475 [G.E. 524]
Fluorine compounds, Pentafluoroorthosulfuric acid, $HOSF_5$ (SC) 44 [G.E. 56]
Fluorosulfinylimidosulfur oxide difluoride (SC) 311 [G.E. 338]
Fluoro-organic compounds, Synthesis of ~ by high-temperature conversion of saturated, unsaturated, aromatic, and heterocyclic fluorine compounds (LA) 634
Fluorosulfinyl isocyanate (SC) 110 [G.E. 88]
D-Forosamine, Synthesis of ~, the 4-dimethylamino sugar from spiramycin (SC) 302 [G.E. 301]
Food Science, Principles of ~, Part 1: Food chemistry (Book Review) 709
Four-component condensation, Synthesis of an isomer-free tetravaline derivative by stereoselective ~ and exponential multiplication of selectivity (SC) 627 [G.E. 644]
Fourier spectroscopy, Far-infrared ~ as a method for structure determination in chemistry (FP) 25 [G.E. 1]
Furan derivatives, Synthesis of ~ from 4-Benzoyloxy-1,3-dioxolane derivatives (SC) 682 [G.E. 718]

GADOLINIUM chloride, Monochlorides of the lanthanoids: ~ and TbCl (SC) 624 [G.E. 685]
D-Galactosamine, Synthesis of α-glycosidically linked disaccharides of ~ (SC) 440 [G.E. 478]
Games, Das Spiel—Naturgesetze steuern den Zufall (Book Review) 448
Gas chromatography, Sequence analysis of polypeptides and proteins by combined ~-mass spectrometry (FP) 75 [G.E. 74]
Gas/metal interfaces, Elementary processes at ~ (FP) 391 [G.E. 423]
Gauche-block structures, Kink-block structures and ~ of bimolecular films (FP) 575 [G.E. 628]
General chemistry, Allgemeine und anorganische Chemie (Book Review) 319
Genetics and biological evolution (LA) 707
Germanium compounds, $Ge_4S_6Br_4$—The first sulfide halide of germanium (SC) 162 [G.E. 162]
Triorganophosphane-dichloro- and -dibromogermanediyl and -stannanediyl: phosphane-stabilized Ge^{II} and Sn^{II} halides (SC) 308 [G.E. 303]
Novel redox reactions of tri-tert-butyl phosphane with tetrahalides of germanium and tin (SC) 308 [G.E. 304]
Germaphospholanes, Inversion at phosphorus in sila-, germa- and stannaphospholanes (SC) 429 [G.E. 445]
Germyl compounds, Electron impact induced ether cleavage by anchimeric participation of silyl and germyl groups (SC) 705 [G.E. 726]
Germyldiimine, Bis(trimethylgermyl)diimine (SC) 236 [G.E. 257]
Germylene complexes, Carbene-analogous ~ (SC) 684 [G.E. 720]
Glass—a continuing challenge to chemistry (FP) 346 [G.E. 365]
Glutamic acid, The interrelationship between arginine, ~, and proline in metabolism and nutrition (LA) 707
Gold chemistry, Is ~ a topical field of study? (FP) 728 [G.E. 830]

HALIDE complexes, Gaseous chloride complexes with halogen bridges—homo-complexes and hetero-complexes (FP) 713 [G.E. 775]
β-Halogenated alkyl esters, A new technique of protecting groups—cleavage of ~ with supernucleophilic cobalt(I)-phthalocyanine (SC) 681 [G.E. 717]
Halobacteria, Biosynthesis of the purple membrane of ~ (FP) 187 [G.E. 203]
Handbook of chemistry and physics (Book Review) 178
Handbook of organic reagents in inorganic analysis (Book Review) 786
Hemoglobin, Molecular aspects of sickle cell disease (FP) 749 [G.E. 821]
Heptalene, Cycloadditions of pentalene and azulene—A facile ~ synthesis (SC) 104 [G.E. 121]
Crystal and molecular structure of dimethyl 1,2-~ dicarboxylate (SC) 106 [G.E. 123]
Hetero Cope rearrangements, with dipolar intermediates (SC) 301 [G.E. 300]
Allylation of 4-hydroxyarsenin—arsenic-carbon ~ (SC) 690 [G.E. 728]
Heterocycles, Cumulated ylides as building blocks for the synthesis of ~ (SC) 115 [G.E. 92]
Conformational studies on twelve-membered ~. Crystal structure of 5,18-dimethyl-5,18-diazatribenzo[a,e,i]cyclododecene-6,17(5H,18H)-dione (SC) 757 [G.E. 798]
Heterocyclotetraaromatics, CuF_2-assisted synthesis of ~ by nucleophilic aromatic substitution (SC) 500 [G.E. 513]
Hexafluorophosphate, Solvolysis of the ~ ion and the structure of [tris(μ-difluorophosphato)bis(pentamethylcyclopentadienylrhodium)] ~ (SC) 490 [G.E. 506]
Hexafluororhenium(VII), $[ReF_6]^+$ (SC) 159 [G.E. 190]
1,2,3,5-Hexatetraene, Synthesis (SC) 628 [G.E. 687]
Hormone receptors (FP) 741 [G.E. 790]
Hormones, Survey of hormone-receptor interactions (LA) 318
Hydrazines, Radical cations of tetrasilyl-substituted ~ (SC) 700 [G.E. 766]
Hydrazones, Asymmetric synthesis of α-substituted ketones by metalation and alkylation of chiral ~ (SC) 549 [G.E. 579]
Hydrides, Selective reductions with complex ~ (LA) 389
Hydrocarbon cation, The cyclohept[a]acenaphthylenylium ion (SC) 240 [G.E. 262]
Hydrogenation, Selective ~ of 1,1-disubstituted cyclopropanes (SC) 373 [G.E. 415]
Hydrogen bond, The $H_5O_2^+$ ion in hydrogen bromide dihydrate (SC) 491 [G.E. 507]
Hydrogen chloride, Use of crosslinked poly(4-vinylpyridine) as ~ acceptor (SC) 163 [G.E. 192]
Hydrogen peroxide, Continuous electrocatalytic synthesis of phenol from benzene and ~ (SC) 294 [G.E. 306]
Hydrogen sulfide, Pentacarbonylmonosulfanetungsten, $W(CO)_5SH_2$ (SC) 366 [G.E. 375]
Reaction between molybdate(VI), cyanide, and ~ (SC) 784 [G.E. 855]
Hydrophobic interactions between metal complexes of aromatic ligands and 3-(trimethylsilyl)-1-propanesulfonate and their ^{1}H-NMR spectroscopic detection (SC) 548 [G.E. 585]
Hydroxymethylation, Doubly metalated methanol—A nucleophilic ~ reagent (SC) 438 [G.E. 484]
Hydrozirconation: A new transition metal reagent for organic synthesis (FP) 333 [G.E. 402]
Hyperconjugation, A new probe for C—C ~: ^{13}C-NMR on paramagnetic metallocenes (SC) 554 [G.E. 575]

IMIDAZOLE, Reaction of magnesium porphyrinates in polymers containing ~ (SC) 551 [G.E. 616]
Imines, Reactions of azines and ~ with dienophiles (LA) 564
Industrial chemistry, Technische Chemie—Eine Einführung in die chemische Reaktionstechnik (Book Review) 246
Industrial organic chemistry, Industrielle Organische Chemie (Book Review) 709
Inorganic analysis, Handbook of organic reagents in ~ (Book Review) 786
Inorganic chemistry, Allgemeine und anorganische Chemie (Book Review) 319
Insulin (LA) 57
Intercalation compounds of zirconium phosphate (SC) 544 [G.E. 608]
Intermediates, Use of the isoselectivity principle for distinguishing cationic- and σ complexes (SC) 237 [G.E. 258]
Inversion at phosphorus in sila-, germa- and stannaphospholanes (SC) 429 [G.E. 445]
Inversion barriers, Conformations and N-~ in tropane compounds (SC) 545 [G.E. 574]
Iodine azide, Isolation and infrared spectrum (SC) 553 [G.E. 612]
Iodine tris(trifluoroacetate), Selective oxidation of alkanes and ethers with ~ (SC) 436 [G.E. 478]
Ion exchange chromatography, Chlorine isotope effects in ~ (SC) 55 [G.E. 54]
Ionization, Li^+-attachment—a soft ~ method in field desorption mass spectrometry (SC) 696 [G.E. 762]
Ion structure, Collisional activation mass spectrometry—a new probe for determining ~ in the gas phase (FP) 509 [G.E. 589]
Iridium complexes, $[Ir\{2,4,6\text{-}C_6H_2(CH_3)_3\}(CO)(PPh_3)_2]$—The first example of cis-trans isomerism in complexes of the Vaska type (SC) 110 [G.E. 127]
Iridium compounds, Cyclohexenyl(1,5-cyclooctadiene)iridium—η-diene hydride or enyl structure (SC) 702 [G.E. 768]
Iron complexes, $C_{12}H_{10}O$ and thermolabile $C_{11}H_{10}O$ ketones from bullvalene via carbonyl-~ (SC) 376 [G.E. 375]
A CH carbene-~ by metal-induced fragmentation of two bonds of a bicyclopentane unit (SC) 609 [G.E. 640]
Oxidative addition of the central bond of a bicyclopentane system to iron (SC) 610 [G.E. 641]
Tris[dicarbonyl(η-cyclopentadienyl)ferrio]-stibane—A 5B-element base with total transition-metal substitution (SC) 618 [G.E. 680]
trans-Bromo(tetracarbonyl)ferrocenylcarbynetungsten (SC) 683 [G.E. 719]
μ-Thiadiborolenebis(η-cyclopentadienyliron)—preparation and structure of a new triple-decker sandwich complex (SC) 779 [G.E. 850]
Iron compounds, Structure and absolute configuration of an organo-iron compound having iron as chiral center (SC) 776 [G.E. 847]
Disodium tetracarbonylferrate (LA) 177
IR Spectroscopy, Raman IR Atlas organischer Verbindungen (Book Review) 508
IR-Spektroskopie—Eine Einführung (Book Review) 566
Isocyanides, Oxidation of 5-aminotetraazoles, a new route to ~ (SC) 113 [G.E. 89]
Isodiazene, Existence of isomeric diazenes (diimines) (SC) 385 [G.E. 386]
Structure of an "isodiimine" complex: bis-

(trimethylsilyl)-~-bis(cyclopentadienyl)-vanadium (SC) 387 [G.E. 384]
Isoselectivity principle. Use for distinguishing cationic π- and σ complexes (SC) 237 [G.E. 258]
Isothiocyanates. Three-component reactions with aryl ~. Synthesis of 5-arylimino-1,2,4-thiadiazolidin-3-ones (SC) 489 [G.E. 510]
Isotope effects. Chlorine ~ in ion exchange chromatography (SC) 55 [G.E. 54]
Isotopic substitution. Influence on diffusion in liquids (LA) 634
2-Isoxazolines. Eliminative ring opening of ~: a new route to α,β-unsaturated ketones (SC) 50 [G.E. 27]

KETENE. Rate of acid formation from phenyl-~-s in aqueous solution (SC) 380 [G.E. 413]
Competing cycloadditions in the reaction of acetylazobenzene with diphenyl-~ (SC) 432 [G.E. 449]
Molecular structure of $C_5H_5Mn(CO)_2[(C_6H_5)_2C=C=O]$. Out-of-plane deformation of the diphenyl-~ ligand (SC) 615 [G.E. 652]
Carbonyl-η-cyclopentadienyl-(4-methylphenylketenyl)bis(trimethylphosphane)-tungsten—A novel, stable transition metal-substituted ~ (SC) 632 [G.E. 649]
Ketones. Catalyzed addition of aldehydes to activated double bonds—a new synthetic approach (FP) 639 [G.E. 695]
Eliminative ring opening of 2-isoxazolines: a new route to α,β-unsaturated ~ (SC) 50 [G.E. 27]
$C_{12}H_{10}O$ and thermolabile $C_{11}H_{10}O$ ~ from bullvalene via carbonyliron complexes (SC) 376 [G.E. 375]
Enols from Norrish type II cleavage of carbonyl compounds in solution (SC) 435 [G.E. 445]
Asymmetric synthesis of α-substituted ~ by metalation and alkylation of chiral hydrazones (SC) 549 [G.E. 579]
The stereospecific formation of cyclic ~ (LA) 707
Kinetics. Rate of acid formation from phenylketenes in aqueous solution (SC) 380 [G.E. 413]
Auswertung und Analyse kinetischer Messungen (Book Review) 247
Kink-block and gauche-block structures of bimolecular films (FP) 575 [G.E. 628]

LABORATORY practice. Laborpraxis—Quantitative Analyse (Book Review) 787
β-Lactams. Synthesis (LA) 564
Lactose synthase. Protein-protein interactions in the regulation of ~ (LA) 707
Layer compounds. Kink-block and gauche-block structures of bimolecular films (FP) 575 [G.E. 628]
Electronic properties of some chain and ~ (LA) 446
Leaving groups. Nitrogen as ~: aliphatic diazonium ions (FP) 251 [G.E. 273]
Legumin. The legume storage proteins ~ and vicilin (LA) 318
Life. Search for ~ in the solar system (LA) 245
Ligand properties. The ambident ~ of bis(trimethylphosphoranylidene)methane (SC) 502 [G.E. 542]
Linear "free energy" relationships. Differences in the temperature dependence of reaction parameters in ~ (SC) 688 [G.E. 723]
N-Lithioaminofluorosilane. Synthesis (SC) 313 [G.E. 304]
Lithium complexes. A lithium-cobalt bimetal complex (SC) 46 [G.E. 50]
Lithium compounds. α-Hydroxycarboxamides from N,N-bis(methoxymethyl)carbamoyllithium and carbonyl compounds (SC) 293 [G.E. 296]
Nucleophilic aminoalkylation. Lithiated N,N-dimethylthiopivalamide (SC) 313 [G.E. 339]
Doubly metalated methanol—A nucleophilic hydroxymethylation reagent (SC) 438 [G.E. 484]
C—C linkage of polyfunctional molecules by nucleophilic addition of dianions. Synthesis of pillarose (SC) 439 [G.E. 477]
Reaction of N-protected succinimides with α-lithiated acetic acid derivatives (SC) 626 [G.E. 642]
Li^+-attachment—a soft ionization method in field desorption mass spectrometry (SC) 696 [G.E. 762]
Bis(η-1,5-cyclooctadiene)cobaltlithium (SC) 767 [G.E. 808]
Additions of lithium organocuprates as models for electron-transfer processes (LA) 446

MACROCYCLIC ligands. Transition metal complexes of synthetic ~ (LA) 120
Macromolecules. Penetration and crosslinking of ~ (FP) 451 [G.E. 487]
Magnesium complexes. A novel hetero-bimetallic dinitrogen complex (SC) 612 [G.E. 648]
Magnesium compounds. The magnesium derivative of thioacrolein dianion. A facile entry to vinyl- and divinyloxiranes (SC) 437 [G.E. 449]
Malondialdehyde. Synthesis of alkylidene-~ tetramethyl bisacetals (SC) 113 [G.E. 88]
Manganese complexes. Tetracarbonylcobaltiopentacarbonylmanganiomercury, $(CO)_4Co—Hg—Mn(CO)_5$ (SC) 162 [G.E. 188]
$Mn_2(CO)_{10}CH_2N_2$, a stable organometallic derivative of diazomethane (SC) 164 [G.E. 191]
μ-Methanediazo-(N,N,N')-tris(tetracarbonylmanganese) (SC) 368 [G.E. 379]
Thiadiborolenebis(tricarbonylmanganese)—A cluster with triple-decker structure (SC) 434 [G.E. 451]
Dimethylcarbene- and methylphenylcarbene-dicarbonyl(η-cyclopentadienyl)manganese (SC) 543 [G.E. 584]
Molecular structure of $C_5H_5Mn(CO)_2[(C_6H_5)_2C=C=O]$. Out-of-plane deformation of diphenylketene ligand (SC) 615 [G.E. 652]
Simple synthesis of dicarbonyl(η-cyclopentadienyl)-(3,3-di-tert-butylallenylidene)-manganese (SC) 624 [G.E. 684]
Manganese dioxide. Oxidation of organic compounds with active ~ (LA) 446
Mannich reaction. New variant (SC) 239 [G.E. 261]
Mass spectrometry. Sequence analysis of polypeptides and proteins by combined gas chromatography-~ (FP) 75 [G.E. 74]
Collisional activation ~—a new probe for determining the structure of ions in the gas phase (FP) 509 [G.E. 589]
Li^+-attachment—a soft ionization method in field desorption ~ (SC) 696 [G.E. 762]
Electron impact induced ether cleavage by anchimeric participation of silyl and germyl groups (SC) 705 [G.E. 726]
Progress in ~ (Book Review) 58, 566
Mathematics. Mathematik für Naturwissenschaftler (Book Review) 449
Membrane proteins. Role in anion transport in erythrocytes (LA) 446
Membranes. Techniques of chemistry. Vol. VII: ~ in separations (Book Review) 247
Mercury compounds. Tetracarbonylcobaltiopentacarbonylmanganiomercury, $(CO)_4Co—Hg—Mn(CO)_5$ (SC) 162 [G.E.
Metallocenes. New probe for C—C hyperconjugation: ^{13}C-NMR on paramagnetic ~ (SC) 554 [G.E. 575]
Metavanadate ion. Structure of the "true" ~ (SC) 374 [G.E. 385]
1,6-Methano[10]annulene. 1H-Cyclopropa[a]-naphthalene from 2,3-benzo-~ (SC) 613 [G.E. 643]
Methanol. Doubly metalated ~—A nucleophilic hydroxymethylation reagent (SC) 438 [G.E. 484]
Methionine-enkephalin. Total synthesis (SC) 297 [G.E. 332]
Methodicum Chimicum (Book Review) 120
Methylenation of [2.2]paracyclophane-1,9-diene and [2.2]paracyclophane (SC) 166 [G.E. 153]
Methylmalonyl-CoA mutase. Synthesis, structure determination, and rearrangement of a model for the active site of ~ with incorporated substrate (SC) 561 [G.E. 613]
Microbial transformations of nonsteroid cyclic compounds (Book Review) 786
Microbiological synthesis of (+)-cis-1,2-dihydroxy-1,2-dihydronaphthalene-2-carboxylic acid (SC) 549 [G.E. 581]
$β_2$-Microglobulin. Structure and significance (LA) 506
Isolation, properties, and distribution (LA) 507
Mink, Mustelan, the malodorous substance from the anal gland of the ~ (Mustela vison) and the polecat (Mustela putorius) (SC) 242 [G.E. 228]
Mitochondria. Bioenergetics of ~ in brown adipose tissue (LA) 318
Molecular geometry. Molekülgeometrie (Book Review) 318
Molecular orbital calculations. Predictive ~ in organic chemistry (FP) 519 [G.E. 602]
Molecular spectroscopy. The theory of ~ (Book Review) 635
Molybdenum. Reaction mechanism of enzymes containing ~ (LA) 388
Molybdenum complexes. trans-Pentacarbonylrhenio(phenylcarbyne)tetracarbonylmolybdenum: a transition metal carbyne complex containing a metal-metal bond (SC) 157 [G.E. 163]
1-Naphthyl rotation and metal-centered rearrangement in square-pyramidal ~ (SC) 316 [G.E. 342]
Complete asymmetric synthesis and absolute configuration of an aminoacylmolybdenum complex (SC) 495 [G.E. 511]
π-Complexes of λ^5-phosphorins with tricarbonylchromium, tricarbonylmolybdenum, or tricarbonyltungsten (SC) 503 [G.E. 543]
The photochemical addition of acetylene to tricarbonyl(η^5-cyclopentadienyl)methylmolybdenum and -tungsten (SC) 759 [G.E. 800]
Reaction between molybdate(VI), cyanide, and hydrogen sulfide (SC) 784 [G.E. 855]
Molybdenum compounds. Anion structure of tetrabutylammonium octamolybdate $[N(C_4H_9)_4]_4Mo_8O_{26}$ (SC) 375 [G.E. 385]
Functional transition-metal phosphanes (SC) 769 [G.E. 809]
Multilayers. Polymerization of tricosa-10,12-diynoic acid in ~ (SC) 764 [G.E. 805]
Mustelan, the malodorous substance from the anal gland of the mink (Mustela vison) and the polecat (Mustela putorius) (SC) 242 [G.E. 228]

NAPHTHALENE-2-carboxylic acid. Microbiological synthesis of (+)-cis-1,2-dihydroxy-1,2-dihydro-~ (SC) 549 [G.E. 581]
Naphthalene 1,2;3,4-dioxide, syn- and anti-~ (SC) 229 [G.E. 268]
Naphthalene 1,4-endoperoxide (SC) 228 [G.E. 262]
[2.2](1,4)Naphthalenophane. Intramolecular [4+4]photocycloaddition (SC) 441 [G.E. 482]
5H-Naphtho[1,8-bc]thiophen-5-one. Heterocyclic systems with 12π-electrons (SC) 775 [G.E. 810]
1-Naphthylamine. Photochemical liberation from cis-dichlorobis(1-naphthylamino)platinum(II) (SC) 625 [G.E. 686]
1-Naphthyl rotation and metal-centered rearrangement in square-pyramidal molybdenum complexes (SC) 316 [G.E. 342]
Nickel complexes. Ethylenebis(phenylsodium)nickel (SC) 47 [G.E. 51]
Structure of a bimetal-ethylene complex: $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$ (SC) 48 [G.E. 52]
Bis[cyclotri(λ^5-phosphazene)dienethionato]-Ni^{II}, -Pd^{II} and -Pt^{II} complexes and their structure (SC) 488 [G.E. 505]
Carbanion complexes of nickel (SC) 621 [G.E. 682]
The anion PR_2 as single bridge between two

nickel(0) coordination centers (SC) 622 [G.E. 682]
Bis(diorganylphosphinodithioformato S,P)-nickel(II) complexes—Novel fourmembered ring chelates (SC) 768 [G.E. 811]
Nitration, Ipso attack in aromatic ~ (LA) 785
Nitriles, The analogy between O and $C(CN)_2$ (FP) 261 [G.E. 311]
Catalyzed addition of aldehydes to activated double bonds—new synthetic approach (FP) 639 [G.E. 695]
Nitrites, Na_3NO_3—Not an ortho-~ (SC) 376 [G.E. 410]
Nitroalkanes, α,α-Doubly deprotonated ~. Enhancement of the C-nucleophilicity of nitronates (SC) 505 [G.E. 540]
Nitro compounds, 1,3,2-Dioxazolidines by thermal 1,3-cycloaddition of nitro groups to strained olefins (SC) 372 [G.E. 416]
Nitrogen assimilation, Pathway of ~ in plants (LA) 564
Nitrogen complex, Novel hetero-bimetallic dinitrogen complex (SC) 612 [G.E. 648]
Nitrogen compounds, Crystal structure of a platinum complex containing NCl_2 ligands: $[Pt(NH_3)_3(NCl_2)_2Cl]Cl$ (SC) 225 [G.E. 225]
Synthesis of the $S_3N_2^+$ radical cation (SC) 226 [G.E. 226]
Fluorosulfinylimidosulfur oxide difluoride (SC) 311 [G.E. 338]
Crystal and molecular structure of the tetrasulfur pentanitride anion (SC) 379 [G.E. 411]
New cyclic SN compound: 1,1,3,3-tetraoxo-2,4-difluorosulfonylcyclodiaza-λ^6-thiane (SC) 614 [G.E. 646]
Cyclizations at electropositive silicon (SC) 619 [G.E. 647]
$[(CH_3)_3SiNH]_2PN_3S_2$: An unusual dark blue sulfur nitrogen phosphorus compound (SC) 696 [G.E. 763]
S_4N_4 bridge ligand: structure of $CuCl \cdot S_4N_4$ (SC) 765 [G.E. 807]
Synthesis and structure of a hexaazadiphosphadiarsatricyclodecane (SC) 701 [G.E. 768]
Nitrogen-phosphorus ylide, Structure of a ~ having twofold coordinated phosphorus (SC) 687 [G.E. 723]
Nitrogen transfer from a diazoalkane to a metal center (SC) 695 [G.E. 761]
Nitroso compounds, X-ray structure analysis of r-9,7,2-chloro-c-2-nitroso-trans-decalin-9-carbonitrile (SC) 760 [G.E. 802]
Partial asymmetric diels-Alder reaction with an α-chloronitroso compound (SC) 760 [G.E. 801]
Nitrosyl chloride, Reactions with arenetricarbonylchromium complexes (SC) 617 [G.E. 651]
NMR spectroscopy, Magnetic nonequivalence of the C atoms of prochiral diphenylmethyl groups in ^{13}C-~ (SC) 234 [G.E. 256]
Correlation between the β-effect of methyl groups on $\delta(^{13}C)$ and the C_α—C_β π-bond order (SC) 303 [G.E. 335]
Hydrophobic interactions between metal complexes of aromatic ligands and 3-(trimethylsilyl)-1-propanesulfonate and their ^1H-NMR spectroscopic detection (SC) 548 [G.E. 585]
New probe for C—C hyperconjugation: ^{13}C-~ on paramagnetic metallocenes (SC) 554 [G.E. 575]
Determination of the absolute configuration of chiral thiols by ^1H-~ of diastereomeric thiol esters (SC) 703 [G.E. 770]
NMR spectroscopic detection of cis and trans peptide bonds in unprotected oligo-L-proline (SC) 770 [G.E. 844]
^{13}C-~ and the determination of the conformations of biological molecules (LA) 176
~ and the periodic system (LA) 389
Dynamic ~ (Book Review) 447
2-Norbornyl cation, The σ-bridged ~ (LA) 446
Nucleophilicity, α,α-Doubly deprotonated nitroalkanes. Enhancement of the C-~ of nitronates (SC) 505 [G.E. 540]
Nucleosides, Facile preparation of 5′-cyano- and 5′-carboxy-~ (SC) 499 [G.E. 512]
C-substitution of ~ with the aid of the Eschenmoser sulfide contraction (SC) 689 [G.E. 724]
Nucleotides, Oligonucleotide synthesis on a polymeric support with avoidance of failure sequences (SC) 547 [G.E. 577]
Nutrition, Nutritional and metabolic interrelationships among sulfur compounds in avian ~ (LA) 707

OCTAHYDROINDIGO (SC) 52 [G.E. 53]
Octamolybdate, Anion structure of tetrabutylammonium ~ $[N(C_4H_9)_4]_4Mo_8O_{26}$ (SC) 375 [G.E. 385]
γ-Octose, Synthesis of the ~ of the quinocycline complex (SC) 438 [G.E. 476]
Oil, Production by hydrogenation of coal (FP) 341 [G.E. 348]
Olefin metathesis, Mechanistic Aspects (FP) 401 [G.E. 433]
CH carbene complex of iron by metal-induced fragmentation of two bonds of a bicyclopentane unit (SC) 609 [G.E. 640]
Olefins, Synthesis from α-silyl carbanions and carbonyl compounds (SC) 161 [G.E. 184]
Synthesis of phenolaldehydes with electron-rich ~ (SC) 169 [G.E. 151]
Stereospecific synthesis of β-bromoamines by ionic addition of diethyl dibromophosphoramidate to a double bond (SC) 302 [G.E. 302]
1,3,2-Dioxazolidines by thermal 1,3-cycloaddition of nitro groups to strained ~ (SC) 372 [G.E. 416]
Oligonucleotide synthesis on a polymeric support with avoidance of failure sequences (SC) 547 [G.E. 577]
Oligo-L-prolines, NMR spectroscopic detection of cis and trans peptide bonds in unprotected ~ (SC) 770 [G.E. 844]
Oligopyridines, Specific synthesis of substituted pyridines and ~ (LA) 245
Optical induction during biomimetic formation of cysteine (SC) 42 [G.E. 54]
Orbital correspondence analysis in maximum symmetry (OCAMS) (FP) 593 [G.E. 664]
Orbitals, Interaction of the Walsh ~ in bicyclopropyl (SC) 310 [G.E. 343]
Organometallic chemistry, Several annual surveys (LA) 246
Orthonitrite, Na_3NO_3—Not an ~ (SC) 376 [G.E. 410]
Oscillations, Chemical waves in the 2,4-pentanedione potassium bromate system (SC) 689 [G.E. 728]
2-Oxazolines, Synthetic utility (FP) 270 [G.E. 321]
Oxidation, Selective ~ of alkanes and ethers with iodine tris(trifluoroacetate) (SC) 436 [G.E. 478]
Radical ~ of amino acid derivatives (SC) 497 [G.E. 538]
~ of organic compounds with active MnO_2 (LA) 446
Oxidation-reduction condensations (FP) 94 [G.E. 111]
Oxidative amination of toluhydroquinone (SC) 109 [G.E. 87]
Oxygen adducts, Molecular complexes and ~ of tetrapyrrole pigments (FP) 648 [G.E. 704]
Oxygen 1,1-Bis(diphenylphosphoryl)-2,2,2-trifluoroethanol—A new intermediate of trifluoroacetyldiphenylphosphane oxidation by molecular ~ (SC) 41 [G.E. 25]
Oxygenation, Photo-~ of selenides—a new pathway to selenoxides (SC) 381 [G.E. 413]
Oxygen carriers, Synthetic ~ of biological interest (LA) 245
Oxygen complexes, Dioxygen-metal complexes (LA) 707
Oxygen compounds, Analogy between O and $C(CN)_2$ (FP) 261 [G.E. 311]
Ozone, Oxidation of alkylidenetriphenylphosphoranes with phosphite-~ adducts (SC) 298 [G.E. 297]
Oxidation of cyclopropyl hydrocarbons with ~ (SC) 761 [G.E. 802]
Effects of supersonic transport on the Earth's ~ mantle (LA) 176
Ozonides, Ozonolysis of 2,3,3a,5,6,8-hexachloro-3a,6,7,7a-tetrahydro-1,6-methano-1H-indene: isolation of a stable ~ having a 3,5-dichloro-1,2,4-trioxolane structure (SC) 433 [G.E. 479]

PALLADIUM, Cleavage of allyl ethers with Pd/C (SC) 558 [G.E. 578]
Palladium complexes, Bis[cyclotri(λ^5-phosphazene)dienethionato]-Ni^{II}, -Pd^{II} and -Pt^{II} complexes and their structure (SC) 488 [G.E. 505]
Palladium compounds, Palladium(II)-induced oligomerization of acetylenes (LA) 507
Papaverine crown ethers (SC) 685 [G.E. 722]
[2.2]Paracyclophane, Cyclopropanation of ~-s (SC) 165 [G.E. 152]
Methylenation of ~-1,9-diene and ~ (SC) 166 [G.E. 153]
Indirect determination of the half-wave reduction potentials of benzene and ~ (SC) 552 [G.E. 617]
[2.2]Paracyclophane-1,9-diene, Methylenation of ~ and [2.2]paracyclophane (SC) 166 [G.E. 153]
Pattern recognition, Chemical applications (Book Review) 178
Penetration and crosslinking of macromolecules (FP) 451 [G.E. 487]
Pentafluoroorthosulfuric acid, $HOSF_5$ (SC) 44 [G.E. 56]
Pentafulvene, [6 + 2]cycloadditions of ~. Facile pentalene synthesis (SC) 314 [G.E. 341]
Pentalene, Cycloadditions of ~ and azulene—Facile heptalene synthesis (SC) 104 [G.E. 121]
[6 + 2]cycloadditions of pentafulvene. Facile ~ synthesis (SC) 314 [G.E. 341]
2,4-Pentanedione, Chemical waves in the 2,4-~/potassium bromate system (SC) 689 [G.E. 728]
Peptides, Macrocyclic ~ in anionic polymers of amino acid N-carboxylic anhydrides (SC) 307 [G.E. 338]
NMR spectroscopic detection of cis and trans peptide bonds in unprotected oligo-L-proline (SC) 770 [G.E. 844]
Use of cyclic ~ for conformational studies (LA) 507
Peptide synthesis, Synthesis of (poly-)peptides with phosphorous diester triazolides (SC) 305 [G.E. 337]
4,6-Diphenylthieno[3,4-d][1,3]dioxol-2-one 5,5-dioxide, a novel activating agent for ~ (SC) 444 [G.E. 480]
Recovery of chiral α-ferrocenylalkylamines on stereoselective ~ by four-component condensation (SC) 492 [G.E. 509]
Synthesis of an isomer-free tetravaline derivative by stereoselective four-component condensation and exponential multiplication of selectivity (SC) 627 [G.E. 644]
Periodic system, Lehrprogramm Atombau und Periodensystem (Book Review) 709
Pharmacology, Allgemeine und spezielle Pharmakologie und Toxikologie (Book Review) 121
Phenol, Continuous electrocatalytic synthesis of ~ from benzene and hydrogen peroxide (SC) 294 [G.E. 306]
Phenolaldehydes, Synthesis of ~ with electron-rich olefins (SC) 169 [G.E. 151]
Phenols, Synthesis of 3-aryl-2,5-di-tert-butyl-2,4-cyclopentadienones by base-catalyzed oxygenation of 4-aryl-2,6-di-tert-butyl-~ (SC) 160 [G.E. 154]
Nonpollutative chlorination and chlorinating oxidation of ~ (SC) 608 [G.E. 641]
Phenylketenes, Rate of acid formation from ~ in aqueous solution (SC) 380 [G.E. 413]
Phosphanes, Triorganophosphanedichloro- and -dibromogermanediyl and -stannanediyl: phosphane-stabilized Ge^{II} and Sn^{II} halides (SC) 308 [G.E. 303]
Novel redox reactions of tri-tert-butylphosphane with tetrahalides of germanium and tin (SC) 308 [G.E. 304]
A phosphorus(III) derivative with sterically fixed bis(trimethylsilyl)amino groups (SC) 309 [G.E. 305]
Mononuclear paramagnetic biphosphinotri-

carbonylcobalt(0) complex (SC) 381 [G.E. 415]
Functional transition-metal ~ (SC) 769 [G.E. 809]
Phosphanylium chloride, First example of a chlorophosphane-~ transformation. 2-Methyl-1,2,3λ^2-diazaphosphole hydrochlorides (SC) 111 [G.E. 91]
Phosphate bonds, Coupling of "high-energy" ~ to energy transductions (LA) 58
6λ^5-Phosphatricyclo[3.3.1.0^{2,7}]non-3-ene, X-ray structure analysis of 6-methyl-6-oxo-3,5,7-triphenyl-~, the product of unusual intramolecular reactions (SC) 238 [G.E. 229]
Phosphazene, Cyclo-~ spanned by a sulfur diimido group (SC) 39 [G.E. 24]
Methylenedi-λ^5-~ by amide cleavage of tetramethylphosphonium salts (SC) 501 [G.E. 541]
The structure of a cyclotetra-~ spanned by a sulfur diimido group (SC) 783 [G.E. 853]
Phosphide complexes, The anion PR_2 as single bridge between two nickel(0) coordination centers (SC) 622 [G.E. 682]
Phosphinidene complexes as ligands (SC) 682 [G.E. 719]
Phosphite-ozone adducts, Oxidation of alkylidenetriphenylphosphoranes with ~ (SC) 298 [G.E. 297]
Phospholanes, Inversion at phosphorus in sila-, germa- and stanna-~ (SC) 429 [G.E. 445]
Phosphonium salts, A methylenedi-λ^5-phosphazene by amide cleavage of tetramethyl-~ (SC) 501 [G.E. 541]
Phosphoramidate, Stereospecific synthesis of β-bromoamines by ionic addition of diethyl dibromo-~ to a double bond (SC) 302 [G.E. 302]
Phosphoranes, Oxidation of alkylidenetriphenyl-~ with phosphite-ozone adducts (SC) 298 [G.E. 297]
(Dichloromethylene)triphenylphosphorane (SC) 315 [G.E. 340]
A tricyclic phosphorane with axial annelation (SC) 781 [G.E. 851]
Phosphorin rearrangement, X-Ray structure analysis of 6-methyl-6-oxo-3,5,7-triphenyl-6λ^5-phosphatricyclo[3.3.1.0^{2,7}]non-3-ene, the product of unusual intramolecular reactions (SC) 238 [G.E. 229]
Phosphorins, π-Complexes of λ^5-~ with tricarbonylchromium, tricarbonylmolybdenum, or tricarbonyltungsten (SC) 503 [G.E. 543]
X-Ray structure analysis of two π-complexes of λ^5-~ with tricarbonylchromium (SC) 504 [G.E. 544]
Phosphorous diester triazolides, Synthesis of (poly-)peptides with ~ (SC) 305 [G.E. 337]
Phosphorus betaines (SC) 693 [G.E. 759]
Phosphorus-carbon compounds, Chemistry of simple ~ (FP) 468 [G.E. 517]
Phosphorus compounds, 1,1-Bis(diphenylphosphoryl)-2,2,2-trifluoroethanol—A new intermediate of trifluoroacetyldiphenylphosphane oxidation by molecular oxygen (SC) 41 [G.E. 25]
First example of a chlorophosphane-phosphanylium chloride transformation: 2-methyl-1,2,3λ^2-diazaphosphole hydrochlorides (SC) 111 [G.E. 91]
Bis[cyclotri(λ^5-phosphazene)dienethionato]-Ni^{II}, -Pd^{II} and -Pt^{II} complexes and their structure (SC) 488 [G.E. 505]
Solvolysis of the hexafluorophosphate ion and the structure of [tris(μ-difluorophosphato)bis(pentamethylcyclopentadienylrhodium)]hexafluorophosphate (SC) 490 [G.E. 506]
The ambident ligand properties of bis(trimethylphosphoranylidene)methane (SC) 502 [G.E. 542]
Isolation of a diaza-λ^3,λ^5- and a thermodynamically unstable diaza-λ^5,λ^5-diphosphetidine (SC) 555 [G.E. 582]
1,3,2λ^2,4-diazaphosphoniaaluminatacyclobutane: A cyclic zwitterion having twofold coordinated phosphorus (SC) 692 [G.E. 758]
[$(CH_3)_3SiNH]_2PN_3S_2$: An unusual dark blue sulfur nitrogen phosphorus compound (SC) 696 [G.E. 763]
Synthesis and structure of a hexaazadiphosphadiarsatricyclodecane (SC) 701 [G.E. 768]
Simplified synthesis of bis(triphenylphosphoranylidene)methane (SC) 702 [G.E. 769]
Bis(diorganylphosphinodithioformato S,P)-nickel(II) complexes—novel four-membered ring chelates (SC) 768 [G.E. 811]
Synthesis and isolation of cis- and trans-1,3,2λ^3,4λ^3-diazadiphosphetidine (SC) 772 [G.E. 845]
Phosphorus ylides, Synthesis of ~ at a cobalt-complex center (SC) 42 [G.E. 61]
Base-induced intramolecular cyclization of silicon substituted ~ (SC) 367 [G.E. 376]
Structure of a phosphorus-nitrogen ylide having twofold coordinated phosphorus (SC) 687 [G.E. 723]
Phosphorylation, ~ with 1-phosphorylpyrazoles (SC) 378 [G.E. 377]
Mitochondrial ATP-phosphate exchange and the site of uncoupling of oxidative ~ (LA) 176
1-Phosphorylpyrazoles, Phosphorylation with ~ (SC) 378 [G.E. 377]
Photochemistry, Enols from Norrish type II cleavage of carbonyl compounds in solution (SC) 435 [G.E. 445]
Photochemical liberation of 1-naphthylamine from cis-dichlorobis(1-naphthylamino)platinum(II) (SC) 625 [G.E. 686]
~ of organic sulfur compounds (LA) 177
~ of thiones and the chemistry of the S_2 state (LA) 506
Solid state ~ (Book Review) 787
Aspects of organic ~ (Book Review) 787
Photocleavage, [6+6]-~ of [2.2]cyclophanes (SC) 442 [G.E. 482]
Photocycloaddition, Intramolecular [4+4]-~ of [2.2](1,4)naphthalenophane (SC) 441 [G.E. 482]
Photoelectron spectroscopy, Photoelectron spectrum of $H_2C{=}S{=}O$ (SC) 383 [G.E. 380]
Photoelectron spectrum of $HN{=}S{=}O$ (SC) 384 [G.E. 381]
Photoisomerization and photocleavage of bicyclo[4.2.0]octa-2,4-dienes (SC) 779 [G.E. 812]
Photo-oxygenation of selenides—a new pathway to selenoxides (SC) 381 [G.E. 413]
Physical chemistry, Einführung in die Physikalische Chemie (Book Review) 708
Physiological chemistry, Physiologische Chemie (Book review) 710
Pillarose, C—C linkage of polyfunctional molecules by nucleophilic addition of dianions. Synthesis of ~ (SC) 439 [G.E. 477]
Piperidine, Conformation (LA) 245
Planning of experiments, Statistische Versuchsplanung (Book Review) 389
Plastics handbook, Kunststoff-Handbuch (Book Review) 636
Plastic Waste, Processing of ~ and scrap tires into chemical raw materials, especially by pyrolysis (FP) 660 [G.E. 737]
Platinum complexes, Crystal structure of a platinum complex containing NCl_2 ligands: [Pt$(NH_3)_3(NCl_2)_2$Cl]Cl (SC) 225 [G.E. 225]
Bis[cyclotri(λ^5-phosphazene)dienethionato]-Ni^{II}, -Pd^{II} and -Pt^{II} complexes and their structure (SC) 488 [G.E. 505]
Photochemical liberation of 1-naphthylamine from cis-dichlorobis(1-naphthylamino)platinum(II) (SC) 625 [G.E. 686]
Polar effects in organic reactions (FP) 569 [G.E. 621]
Polecat, Mustelan, the malodorous substance from the anal gland of the mink (Mustela vison) and the ~ (Mustela putorius) (SC) 242 [G.E. 228]
Polyene cyclizations, Biomimetic ~ (FP) 9 [G.E. 33]
Polyethylene, Extreme bond angle distortion in organozirconium compounds active toward ethylene (SC) 629 [G.E. 688]
Halogen-free soluble Ziegler catalysts for the polymerization of ethylene. Control of molecular weight by choice of temperature (SC) 630 [G.E. 689]
Polymerizations, Zum Ablauf ionischer Polymerisationsreaktionen (Book Review) 566
Polymers, Penetration and crosslinking of macromolecules (FP) 451 [G.E. 487]
Crosslinked ~ having activated ester groups—a versatile support material (SC) 546 [G.E. 576]
Reaction of magnesium porphyrinates in ~ containing imidazole (SC) 551 [G.E. 616]
Heterogeneous ~ (LA) 176
Polyolefins, Photodegradation and stabilization of commercial ~ (LA) 177
Polypeptides, Sequence analysis of ~ and proteins by combined gas chromatography-mass spectrometry (FP) 75 [G.E. 74]
Poly(4-vinylpyridine), Use of crosslinked ~ as HCl acceptor (SC) 163 [G.E. 192]
Porphyrinates, Reaction of magnesium ~ in polymers containing imidazole (SC) 551 [G.E. 616]
Porphyrinogen, Structure of N,N′,N″,N‴-tetramethyl-2,3,7,8,12,13,17,18-octakis(carboxymethyl)-~ dihydrate (SC) 552 [G.E. 616]
Porphyrins, Molecular complexes and oxygen adducts of tetrapyrole pigments (FP) 648 [G.E. 704]
Proline, NMR spectroscopic detection of cis and trans peptide bonds in unprotected oligo-L-~ (SC) 770 [G.E. 844]
The interrelationship between arginine, glutamic acid, and ~ in metabolism and nutrition (LA) 707
Propargylic acetates, Trialkylallenes from 1,1-disubstituted ~ (SC) 496 [G.E. 537]
Propeller molecules, Stereochemical consequences of correlated rotation in ~ (LA) 317
Prostaglandins, A synthesis of ~: strategy and reality (FP) 207 [G.E. 244]
~ (LA) 245
Protecting groups, Electro-deprotection—electrochemical removal of ~ (FP) 281 [G.E. 283]
A new technique of ~—cleavage of β-halogenated alkyl esters with supernucleophilic cobalt(I)-phthalocyanine (SC) 681 [G.E. 717]
Proteins, Sequence analysis of polypeptides and ~ by combined gas chromatography-mass spectrometry (FP) 75 [G.E. 74]
Protein-protein interactions in the regulation of lactose synthase (LA) 707
Sulfenic acid groups in ~ (LA) 785
Proton, The $H_5O_2^+$ ion in hydrogen bromide dihydrate (SC) 491 [G.E. 507]
Proton pump, Bacteriorhodopsin as an example of a light-driven ~ (FP) 17 [G.E. 16]
Pterodactylane, Four linearly annelated cyclobutane rings: the tetracyclo[4.4.0.0^{2,5}.0^{7,10}]-decane system (SC) 431 [G.E. 447]
Purple membrane, Biosynthesis of the ~ of halobacteria (FP) 187 [G.E. 203]
Pyrazoles, Phosphorylation with 1-phosphoryl-~ (SC) 378 [G.E. 377]
Pyridines, Specific synthesis of substituted ~ and oligo-~ (LA) 245
Pyridinium betaines, Synthetic applications of heteroaromatic betaines with six-membered rings (FP) 1 [G.E. 41]
Pyrolysis, Processing of plastic waste and scrap tires into chemical raw materials, especially by ~ (FP) 660 [G.E. 737]
Pyrroles, New synthetic methods for monocyclic 1H-, 2H-, and 3H-~ (LA) 563

QUANTUM mechanical principles, Einführung in die Theoretische Chemie (Book Review) 390
Quantum mechanics for organic chemists (Book Review) 507
Quinocycline, Synthesis of the γ-octose of the ~ complex (SC) 438 [G.E. 476]

RADICAL anion and radical cation of a tetrasilyl-substituted ethylene (SC) 699 [G.E. 765]
Radical cation and radical anion of a tetrasilyl-substituted ethylene (SC) 699 [G.E. 765]

Radical cations, of tetrasilyl-substituted hydrazines (SC) 700 [G.E. 766]
Radicals, Temperature dependence of the selectivity of π- and σ ~ (SC) 173 [G.E. 159]
Persistent carbon-centered ~ (LA) 317
Radioimmunoassay (FP) 525 [G.E. 565]
~ of steroid hormones (Book Review) 508
Raman spectroscopy, Raman IR Atlas organischer Verbindungen (Book Review) 508
Raw materials (LA) 246
Reaction engineering, Chemische Reaktionstechnik (Book Review) 567
Reaction parameters, Differences in the temperature dependence of ~ in linear "free energy" relationships (SC) 688 [G.E. 723]
Reaction types, Reaktionstypen in der anorganischen Chemie (Book Review) 565
Rearrangement, X-Ray structure analysis of 6-methyl-6-oxo-3,5,7-triphenyl-6λ⁵-phosphatricyclo[3.3.1.0^{2,7}]non-3-ene, the product of unusual intramolecular reactions (SC) 238 [G.E. 229]
Anionic O→C ~-s in trialkylsiloxybenzenes and trialkylsiloxypyridines (SC) 428 [G.E. 444]
Receptors, Hormone ~ (FP) 741 [G.E. 790]
Survey of hormone-receptor interactions (LA) 318
Redox reactions, Novel ~ of tri-tert-butylphosphane with tetrahalides of germanium and tin (SC) 308 [G.E. 304]
Reduction potentials, Indirect determination of the half-wave ~ of benzene and [2.2]paracyclophane (SC) 552 [G.E. 617]
Rhenium complexes, μ-Bromo-μ-phenylmethylidynebis(tetracarbonylrhenium) (SC) 231 [G.E. 228]
Rhenium compounds, trans-Pentacarbonylrhenio(phenylcarbyne)tetracarbonylmolybdenum: A transition metal carbyne complex containing a metal-metal bond (SC) 157 [G.E. 163]
Hexafluororhenium(VII), $[ReFe_6]^+$ (SC) 159 [G.E. 190]
Rhodium complexes, 2,2''-Bis(diphenylphosphino)-2',3',5',6'-tetraphenyl-p-terphenyl as an arene chelate ligand for rhodium(I) (SC) 241 [G.E. 260]
Separation of deuteriated ethylenes $C_2H_{4-n}D_n$ by complexation chromatography on a rhodium(I) complex (SC) 304 [G.E. 336]
Solvolysis of the hexafluorophosphate ion and the structure of [tris(μ-difluorophosphato)bis(pentamethylcyclopentadienylrhodium)]hexafluorophosphate (SC) 490 [G.E. 506]
Ribosome structure, Chemical methods of studying ~ (FP) 533 [G.E. 555]
Ring opening, Eliminative ~ of 2-isoxazolines: a new route to α,β-unsaturated ketones (SC) 50 [G.E. 27]
Rotamers, Unusually high barriers to rotation involving the tetrahedral carbon atom (FP) 87 [G.E. 67]
Rotanes, Coupling reactions of vinylidenedicyclopropanes doubly halogenated in allylic positions—a productive synthesis of trispiro[2.0.2.0.2.0]nonane ([3]rotane) (SC) 762 [G.E. 803]
A universal rotane synthesis—hexaspiro[2.0.2.0.2.0.2.0.2.0.2.0]octadecane (SC) 763 [G.E. 804]
Rotation, Unusually high barriers to ~ involving the tetrahedral carbon atom (FP) 87 [G.E. 67]
Stereochemical consequences of correlated ~ in propeller molecules (LA) 317
Rydberg states (LA) 246

SCRAP tires, Processing of plastic waste and ~ into chemical raw materials, especially by pyrolysis (FP) 660 [G.E. 737]
Selectivity, Temperature dependence of the ~ of π- and σ radicals (SC) 173 [G.E. 159]
The isoselective relationship: limitations and prospects of the structure-~ discussion (SC) 174 [G.E. 161]
Selectivity values, Differences in the temperature dependence of reaction parameters in linear "free energy" relationships (SC) 688 [G.E. 723]
Selenides, Photo-oxygenation of ~—a new pathway to selenoxides (SC) 381 [G.E. 413]
Selenium compounds, Bond-delocalized cyclobuteneselenones (SC) 704 [G.E. 771]
Synthesis of tetrathiafulvalenes and tetraselenafulvalenes (LA) 635
Selenoxides, Photo-oxygenation of selenides—a new pathway to ~ (SC) 381 [G.E. 413]
Self-association, The ~ of tubulin (LA) 707
Separation processes, Techniques of chemistry. Vol. VII: Membranes in separations (Book Review) 247
Sequence analysis of polypeptides and proteins by combined gas chromatography-mass spectrometry (FP) 75 [G.E. 74]
Serum albumin, Biosynthesis (LA) 176
Serum proteins, Serumproteine (Book Review) 59
Sesquiterpenes formed by Solanaceae under stress conditions (LA) 564
Sickle cell disease, Molecular aspects of ~ (FP) 749 [G.E. 821]
Silanes, Tri-tert-butyl-~: reactions and hindered Si—C rotation (SC) 43 [G.E. 26]
Synthesis of N-lithioaminofluorosilane (SC) 313 [G.E. 304]
Cleavage of esters and ethers with iodotrimethylsilane (SC) 774 [G.E. 847]
Silaphospholanes, Inversion at phosphorus in ~, and germa- and stannaphospholanes (SC) 429 [G.E. 445]
Silicon compounds, Base-induced intramolecular cyclization of silicon-substituted phosphorus ylides (SC) 367 [G.E. 376]
New electrochemical method of forming SiSi bonds (SC) 370 [G.E. 414]
Hydrophobic interactions between metal complexes of aromatic ligands and 3-(trimethylsilyl)-1-propanesulfonate and their ^{1}H-NMR spectroscopic detection (SC) 548 [G.E. 585]
Cyclization reactions at electropositive silicon (SC) 619 [G.E. 647]
Radical cation and radical anion of a tetrasilyl-substituted ethylene (SC) 699 [G.E. 765]
Radical cations of tetrasilyl-substituted hydrazines (SC) 700 [G.E. 766]
Silicon-nitrogen ylide, Nucleophilic 1,3-rearrangement at silicon—Indirect evidence for a ~ (SC) 312 [G.E. 307]
(3-Siloxy-3-buten-1-ynyl)amines (SC) 51 [G.E. 59]
Silylacetylenes, Fluoride-catalyzed addition to carbonyl compounds (SC) 498 [G.E. 539]
Silylamides, Transition-metal dialkylamides and di-~ (LA) 785
Silylcadmium compound, Bis(tri-tert-butylsilyl)cadmium: The first ~ isolated in substance (SC) 620 [G.E. 681]
α-Silyl carbanions, Synthesis of olefins from ~ and carbonyl compounds (SC) 161 [G.E. 184]
Silyl compounds, A phosphorus(III) derivative with sterically fixed bis(trimethylsilyl)amino groups (SC) 309 [G.E. 305]
Electron Impact induced ether cleavage by anchimeric participation of silyl and germyl groups (SC) 705 [G.E. 726]
Silyloxy compounds, Anionic O→C rearrangements in trialkylsiloxybenzenes and trialkylsiloxypyridines (SC) 428 [G.E. 444]
Single-crystal surfaces, Reactions on ~ (LA) 635
Sodium complexes, Ethylenebis(phenylsodium)nickel (SC) 47 [G.E. 51]
Structure of a bimetal-ethylene complex: $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$ (SC) 48 [G.E. 52]
Solid phase synthesis, Crosslinked polymers having activated ester groups—a versatile support material (SC) 546 [G.E. 576]
Oligonucleotide synthesis on a polymeric support with avoidance of failure sequences (SC) 547 [G.E. 577]
Spectrophotometry, Dual-wavelength ~ (FP) 673 [G.E. 750]
Spectroscopy, Far-infrared Fourier ~ as a method for structure determination in chemistry (FP) 25 [G.E. 1]
ESCA investigations on industrial catalysts (LA) 507
Theory of molecular ~ (Book Review) 635
Spin-lattice relaxation (LA) 119
Spiramycin, Synthesis of D-forosamine, the 4-dimethylamino sugar from ~ (SC) 302 [G.E. 301]
Spiro compounds, Synthesis of carbocyclic ~ (LA) 635
Squalene, The crystal structure of ~ (SC) 778 [G.E. 851]
Stannaphospholanes, Inversion at phosphorus in sila- and germaphospholanes and ~ (SC) 429 [G.E. 445]
Stereoisomerism, Isolation of conformational diastereoisomers of N,N',N''-tribenzyltrianthranilide (SC) 223 [G.E. 223]
Steroid hormones, Radioimmunoassay of ~ (Book Review) 508
Storage proteins, The legume ~ legumin and vicilin (LA) 318
Structural determination, Correlation tables for the ~ of organic compounds (Book Review) 179
Subnuclear components (Book Review) 636
Substituent effects, Concept of allopolarization. ~ on the reactions of ambifunctional anions (FP) 321 [G.E. 389]
Polar effects in organic reactions (FP) 569 [G.E. 621]
Succinimides, Reaction of N-protected ~ with α-lithiated acetic acid derivatives (SC) 626 [G.E. 642]
Sulfenic acid groups in proteins (LA) 785
Sulfide contraction, C-substitution of nucleosides with the aid of the Eschenmoser ~ (SC) 689 [G.E. 725]
Sulfides, Isolation of crystalline bis(thioacyl)~ (SC) 766 [G.E. 844]
Sulfine, Photoelectron spectrum of $H_2C{=}S{=}O$ (SC) 383 [G.E. 380]
Sulfinyl imide, Photoelectron spectrum of $HN{=}S{=}O$ (SC) 384 [G.E. 381]
Sulfur compounds, Fluorosulfinylimidosulfur oxide difluoride (SC) 311 [G.E. 338]
Crystal and molecular structure of the tetrasulfur pentanitride anion (SC) 379 [G.E. 411]
Synthesis of thiepino[4,5-c]pyrrole derivatives having sulfur in different oxidation states (SC) 382 [G.E. 419]
A new cyclic SN compound: 1,1,3,3-tetraoxo-2,4-difluorosulfonylcyclodiaza-λ⁶-thiane (SC) 614 [G.E. 646]
$[(CH_3)_3SiNH]_2PN_3S_2$: An unusual dark blue sulfur nitrogen phosphorus compound (SC) 696 [G.E. 763]
S_4N_4 bridge ligand: structure of $CuCl{\cdot}S_4N_4$ (SC) 765 [G.E. 807]
Synthesis of cycloheptasulfur oxide, S_7O (SC) 772 [G.E. 854]
Photochemistry of organic ~ (LA) 177
Nutritional and metabolic interrelationships among ~ in avian nutrition (LA) 707
Sulfur diimide, The structure of a cyclotetraphosphazene spanned by a sulfur diimido group (SC) 783 [G.E. 853]
Sulfur-nitrogen compounds, Synthesis of the $S_3N_2^+$ radical cation (SC) 226 [G.E. 226]
Surface, Crystal face dependence of the ~ chemistry of tungsten (LA) 177
Surface reactions, Elementary processes at gas/metal interfaces (FP) 391 [G.E. 423]
Synthetic methods, Synthetic applications of heteroaromatic betaines with six-membered rings (FP) 1 [G.E. 41]
The synthetic utility of 2-oxazolines (FP) 270 [G.E. 321]
Hydrozirconation: A new transition metal reagent for organic synthesis (FP) 333 [G.E. 402]
Catalyzed addition of aldehydes to activated double bonds—a new synthetic approach (FP) 639 [G.E. 695]
Synthesis, Les grandes reactions de la synthese organique (Book Review) 179

TELLURIUM compounds, Crystal structure of $Te_5O_4F_{22}$ (SC) 771 [G.E. 846]
Tellurium(IV) iodide: Tetrameric Te_4I_{16} molecules in the solid (SC) 39 [G.E. 28]
Terbium chloride, Monochlorides of the lanthanoids: GdCl and ~ (SC) 624 [G.E. 685]
p-Terphenyl, 2,2''-Bis(diphenylphosphino)-2',3',5',6'-tetraphenyl-~ as an arene chelate ligand for rhodium(I) (SC) 241 [G.E. 260]
Tetraazacycloalkane-N,N',N'',N'''-tetraacetic acids, Complex formation with ~ as a function of ring size (SC) 686 [G.E. 760]
Tetraazoles, Oxidation of 5-amino-~, a new route to isocyanides (SC) 113 [G.E. 89]
Tetracyclo[4.4.0.0^{2,5}.0^{7,10}]decane, Four linearly annelated cyclobutane rings: the ~ system (SC) 431 [G.E. 447]
5,6,9,10-Tetrahydrobenzocyclooctene, the simplest known planar neutral conjugated eight-membered carbocycle (SC) 117 [G.E. 126]
2-(2,4,5,7-Tetranitro-9-fluorenylideneaminooxy)propionic acid, Absolute configuration (SC) 115 [G.E. 93]
Tetrapyrrole pigments, Molecular complexes and oxygen adducts of ~ (FP) 648 [G.E. 704]
Tetraselenafulvalenes, Synthesis of tetrathiafulvalenes and ~ (LA) 635
Tetrathiafulvalenes, Synthesis of ~ and tetraselenafulvalenes (LA) 635
Tetrathiotungstatostannate, Dimeric bis-~—A novel coordination compound with nonequivalent and tridentate WS_4^{2-} ligands (SC) 633 [G.E. 691]
Tetravaline derivative, Synthesis of an isomer-free ~ by stereoselective four-component condensation and exponential multiplication of selectivity (SC) 627 [G.E. 644]
2H-1-Thiacyclobutabenzene, Synthesis of the ~ system (SC) 117 [G.E. 94]
3H-1λ^4,2,6-thiadiazine, X-ray structure analysis of a 4,5-dihydro-~ (SC) 782 [G.E. 852]
1,2,4-Thiadiazolidine oxides, Novel 1,2,4-thiadiazolidine 1-oxides and 1,1-dioxides from 2-imino-1,3-thiazetidines (SC) 103 [G.E. 120]
1,2,4-Thiadiazolidin-3-ones, Three-component reactions with aryl isothiocyanates. Synthesis of 5-arylimino-~ (SC) 489 [G.E. 510]
1,2,5-Thiadiborolene, Thiadiborolenebis(tricarbonylmanganese)—A cluster with triple-decker structure (SC) 434 [G.E. 451]
μ-Thiadiborolenebis(η-cyclopentadienyliron—preparation and structure of a new triple-decker sandwich complex (SC) 779 [G.E. 850]
5-Thiariboflavins, 5-Deazariboflavins and ~: a simple pathway to antimetabolites of vitamin B_2 (SC) 443 [G.E. 475]
1,3-Thiazetidines, Novel 1,2,4-thiadiazolidine 1-oxides and 1,1-dioxides from 2-imino-~ (SC) 103 [G.E. 120]
Thiazole, New ring transformation of zwitterionic bicyclic ~ systems (SC) 494 [G.E. 511]
Thieno[3,4-d][1,3]dioxol-2-one, 4,6-Diphenyl-~ 5,5-dioxide, a novel activating agent for peptide syntheses (SC) 444 [G.E. 480]
Thiepin, Low-temperature X-ray structure analysis of 1-benzo-~ (SC) 297 [G.E. 295]
New synthetic entry to the ~ system.—Benzo[d]-~ and dibenzo[bd]-~ (SC) 611 [G.E. 650]
Thiepino[4,5-c]pyrrole, Synthesis of ~ derivatives having sulfur in different oxidation states (SC) 382 [G.E. 419]
Thietane, Mustelan, the malodorous substance from the anal gland of the mink (Mustela vison) and the polecat (Mustela putorius) (SC) 242 [G.E. 228]
Thioacrolein dianion, The magnesium derivative of ~. A facile entry to vinyl- and divinyloxiranes (SC) 437 [G.E. 449]
(Thioacyl)sulfides, Isolation of crystalline bis-~ (SC) 766 [G.E. 844]
Thioformaldehyde S-oxide, Photoelectron spectrum of $H_2C{=}S{=}O$ (SC) 383 [G.E. 380]
Thioformates, Bis(diorganylphosphinodithioformato-S,P)nickel(II) complexes—Novel four-membered ring chelates (SC) 768 [G.E. 811]
Thioketene, X-Ray structure analysis of a dialkyl-~ (SC) 40 [G.E. 25]
Thiols, Determination of the absolute configuration of chiral ~ by ^{1}H-NMR spectroscopy of diastereomeric thiol esters (SC) 703 [G.E. 770]
Thiometalate ions, Complexes having ~ as bridging ligands (SC) 680 [G.E. 725]
Thiones, Photochemistry of ~ and the chemistry of the S_2 state (LA) 506
Thionitrosyl cation, The ~ NS^+ as a synthetic reagent (SC) 691 [G.E. 757]
Thiopivalamide, Nucleophilic aminoalkylation. Lithiated N,N-Dimethyl-~ (SC) 313 [G.E. 339]
Tin compounds, Triorganophosphanedichloro- and -dibromogermanediyl and -stannanediyl: phosphane-stabilized Ge^{II} and Sn^{II} halides (SC) 308 [G.E. 303]
Novel redox reactions of tri-tert-butylphosphane with tetrahalides of germanium and tin (SC) 308 [G.E. 304]
Dimeric bistetrathiotungstatostannate—A novel coordination compound with nonequivalent and tridentate WS_4^{2-} ligands (SC) 633 [G.E. 691]
Toluhydroquinone, Oxidative amination (SC) 109 [G.E. 87]
Toxicology, Biochemical aspects of the ~ of cadmium (LA) 446
Allgemeine und spezielle Pharmakologie und Toxikologie (Book Review) 121
Trace analysis, Application of catalyzed reactions in analytical chemistry (FP) 150 [G.E. 177]
Transcarboxylase, Subunit-subunit interactions of ~ (LA) 707
trans-Decalin-9-carbonitrile, X-ray structure analysis of r-9,t-2-chloro-c-2-nitroso-~ (SC) 760 [G.E. 802]
Transition metals, The use of ~ in organic synthesis (LA) 785
Transport phenomena (Book Review) 389
Trianthranilide, Isolation of conformational diastereoisomers of N,N',N''-tribenzyl-~ (SC) 223 [G.E. 223]
Triazolides, Synthesis of (poly-)peptides with phosphorous diester ~ (SC) 305 [G.E. 337]
Triborylamine, Tris(3-methylborolan-1-yl)-amine, an electron-deficient ~ (SC) 235 [G.E. 231]
Tricosa-10,12-diynoic acid, Polymerization of ~ in multilayers (SC) 764 [G.E. 805]
Tricyclo[5.3.0.0^{2,10}]deca-3,5-diene, Degenerate butadienylcyclopropane rearrangement in ~ (SC) 53 [G.E. 63]
Tricyclo[4.1.0.0^{2,7}]heptenyl cation—a new isomer of the tropylium ion (SC) 493 [G.E. 508]
syn-Tricyclo[5.1.0.0^{2,4}]oct-5-ene-3,8-dicarboxylate (SC) 163 [G.E. 185]
Trifluoroacetylation of amines with N-trifluoroacetyl-Nylon 66 (SC) 777 [G.E. 848]
3,7,10-Trioxapentacycloundecane, 3,7,10-Trioxapentacyclo[3.3.3.0^{2,4}.0^{6,8}.0^{9,11}]-undecane (3,7,10-Trioxatrishomobarrelene) (SC) 686 [G.E. 721]
3,7,10-Trioxatrishomobarrelene,3,7,10-Trioxapentacyclo[3.3.3.0^{2,4}.0^{6,8}.0^{9,11}]-undecane (~) (SC) 686 [G.E. 721]
cis-Trioxatris-σ-homotropilidene, Synthesis (SC) 559 [G.E. 611]
1,2,4-Trioxolane, Ozonolysis of 2,3,3a,4,5,8-hexachloro-3a,6,7,7a-tetrahydro-1,6-methano-1H-indene: isolation of a stable ozonide having a 3,5-dichloro-~ structure (SC) 433 [G.E. 479]
Triple-decker complexes, Novel type of ~—borole as bridging ligand (SC) 433 [G.E. 450]
μ-Thiadiborolenebis(η-cyclopentadienyliron)—preparation and structure of a new triple-decker sandwich complex (SC) 779 [G.E. 850]
Thiadiborolenebis(tricarbonylmanganese)—A cluster with triple-decker structure (SC) 434 [G.E. 451]
Triptycene, Unusually high barriers to rotation involving the tetrahedral carbon atom (FP) 87 [G.E. 67]
Triquinacene, Stability of triquinacenyl cations and triquinacenyl radicals (SC) 556 [G.E. 609]
Bridgehead cations of tricyclo[5.2.1.0^{4,10}]-deca-2,5,8-triene (triquinacene) (SC) 557 [G.E. 610]
Triquinacenyl cations, Stability of ~ and triquinacenyl radicals (SC) 556 [G.E. 609]
Bridgehead cations of tricyclo[5.2.1.0^{4,10}]-deca-2,5,8-triene (triquinacene) (SC) 557 [G.E. 610]
Triscyclobuta[b,h,n]triphenylene, 10,11-Dihydrocyclobuta[b]triphenylene and 1,2,5,6,9,10-hexahydro-~ (SC) 53 [G.E. 63]
Trishomobarrelene, Optically active bridgehead derivatives of ~ and trishomobullvalene (SC) 429 [G.E. 446]
Trishomobullvalene, Optically active bridgehead derivatives of trishomobarrelene and ~ (SC) 429 [G.E. 446]
Tropane, Conformations and N-inversion barriers in ~ compounds (SC) 545 [G.E. 574]
Tubulin, The self-association of ~ (LA) 707
Tungsten, Crystal face dependence of the surface chemistry of ~ (LA) 177
Tungsten complexes, π-Complexes of λ^5-phosphorins with tricarbonylchromium, tricarbonylmolybdenum, or tricarbonyltungsten (SC) 503 [G.E. 543]
Tetrakis(trimethylsilylmethyl)bis(μ-trimethylsilylmethylidyne)ditungsten (SC) 609 [G.E. 692]
Carbonyl-η-cyclopentadienyl-(4-methylphenylketenyl)bis(trimethylphosphane)-tungsten—A novel, stable transition metal-substituted ketene (SC) 632 [G.E. 649]
3-Dimethylamino-3-phenylallenylidene. A novel ligand at the pentacarbonylchromium and -tungsten skeleton (SC) 623 [G.E. 683]
trans-Bromo(tetracarbonyl)ferrocenylcarbyne-tungsten (SC) 683 [G.E. 719]
The photochemical addition of acetylene to tricarbonyl(η^5-cyclopentadienyl)methylmolybdenum and -tungsten (SC) 759 [G.E. 800]
Tungsten compounds, $[W_3O_4F_9]^{5-}$: A complex ion of tungsten(IV) containing a W_3 group (SC) 118 [G.E. 92]
Pentacarbonylmonosulfanetungsten, $W(CO)_5SH_2$ (SC) 366 [G.E. 375]
Dimeric bistetrathiotungstatostannate—A novel coordination compound with nonequivalent and tridentate WS_4^{2-} ligands (SC) 633 [G.E. 691]
Functional transition-metal phosphanes (SC) 769 [G.E. 809]

ULLMANN's Encyclopedia of Industrial Chemistry, Ullmanns Encyklopädie der technischen Chemie (Book Review) 448

VANADIUM compounds, Structure of the "True" metavanadate ion (SC) 374 [G.E. 385]
Vaska complexes, $[Ir\{2,4,6\text{-}C_6H_2(CH_3)_3\}(CO)(PPh_3)_2]$—The first example of cis-trans-isomerism in complexes of the Vaska type (SC) 110 [G.E. 127]
Vicilin, The legume storage proteins legumin and ~ (LA) 318
Vinamidines and vinamidinium salts—examples of stabilized push-pull alkenes (FP) 459 [G.E. 496]
Vinamidinium salts, Vinamidines and ~—examples of stabilized push-pull alkenes (FP) 459 [G.E. 496]
Vinyl compounds, The solvolysis of α-arylvinyl derivatives (LA) 785
Vinylidenedicyclopropanes, Coupling reactions of ~ doubly halogenated in allylic positions—a productive synthesis of trispiro[2.0.2.0.2.0.]nonane ([3]rotane) (SC) 762 [G.E. 803]
Vinyloxiranes, The magnesium derivative of thioacrolein dianion. A facile entry to ~ and divinyloxiranes (SC) 437 [G.E. 449]
Virus diseases, Chemotherapy of ~ (FP) 410 [G.E. 458]
Vitamin B_2, 5-Deaza- and 5-thiariboflavins:

a simple pathway to antimetabolites of ~ (SC) 443 [G.E. 475]
Vitamin B_{12}, New developments in the field of ~: Reactions of the cobalt atom in corrins and in ~ model compounds (FP) 417 [G.E. 465]
Photochemical induction of enzymatic activity of a carbocyclic analog of coenzyme B_{12}: a contribution to the elucidation of the mechanism of action of coenzyme B_{12} (SC) 170 [G.E. 186]
Vitamin B_{12} coenzyme (LA) 563

WAGNER-Meerwein rearrangement, Enantioselective ~ in chiral solvents under high pressure (SC) 243 [G.E. 230]
Wastewater purification, Eutrophication and ~ (FP) 354 [G.E. 354]
Water, Eutrophication and waste-~ purification (FP) 354 [G.E. 354]
Water analysis, Analysis of water (Book Review) 319

XENOBIOTICS, Metabolism of ~ in the lung (LA) 446
Xenon oxide difluoride, $XeOF_2$ (SC) 158 [G.E. 190]
X-Ray diffraction, Röntgenbeugung an Kristallen (Book Review) 565

YLIDES, Cumulated ~ as building blocks for the synthesis of heterocycles (SC) 115 [G.E. 92]
Structure of a phosphorus-nitrogen ylide having twofold coordinated phosphorus (SC) 687 [G.E. 723]
Ynamines, (3-siloxy-3-buten-1-ynyl)amines (SC) 51 [G.E. 59]

ZEOLITE A, Structural chemistry within ~ (LA) 564
Ziegler catalysts, Halogen-free soluble ~ for the polymerization of ethylene. Control of molecular weight by choice of temperature (SC) 630 [G.E. 689]
Zirconium compounds, Hydrozirconation: A new transition metal reagent for organic synthesis (FP) 333 [G.E. 402]
Extreme bond angle distortion in organo-~ active toward ethylene (SC) 629 [G.E. 688]
Zirconium phosphate, Intercalation compounds of ~ (SC) 544 [G.E. 608]
