Synthetic Applications of Heteroaromatic Betaines with Six-Membered Rings[1]

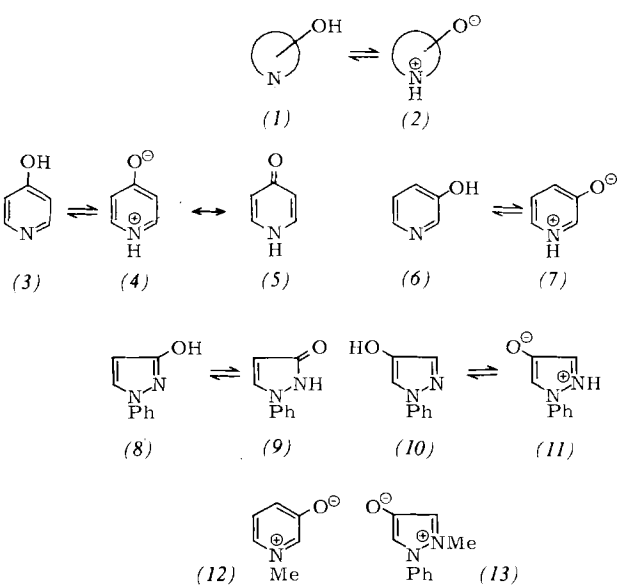
New synthetic methods (14)

By Nicholas Dennis, Alan R. Katritzky, and Yoshito Takeuchi[*]

The cycloadditions of 3-hydroxy-1-methylpyridinium betaines with electron-deficient olefins have been extended to a variety of 1-substituents in place of methyl. Application of resonance theory and later of quantum chemical methods led to rationalization of preceding results and prediction of new reactions. Thermal additions of 2π- and 6π-electron addends at the 2,6-positions and of 4π-electron addends at the 2,4-positions are described. The cycloadducts are highly interesting potential synthetic building blocks.

1. Introduction[***]

Our interest in heteroaromatic betaines was initially aroused by our work on the tautomerism of heterocycles[2]. Heterocycles containing a ring nitrogen atom and a substituent hydroxyl group *(1)* are in tautomeric equilibrium with species *(2)* in which the proton has been transferred to the nitrogen atom. In *(2)* this is written in a zwitterionic form; in many cases, *e.g.* 4-pyridinol *(3)*, the zwitterionic form *(4)* is a resonance structure of a carbonyl compound, as 4-pyridone *(5)*. However when the hydroxyl group is situated β to the nitrogen, as in 3-pyridinol *(6)*, the alternative tautomeric form *(7)* has to be written in the betaine form. Similar possibilities exist in the five-membered ring series; thus, 3-hydroxypyrazoles *(8)* are tautomeric with 3-pyrazolones *(9)* while 4-hydroxypyrazoles *(10)* have zwitterionic tautomers *(11)*. If now the hydrogen attached to nitrogen in the tautomeric species *(7)* and *(11)* is replaced by a methyl group, we arrive at true heteroaromatic betaines *(12)* and *(13)*.



(1) (2) (3) (4) (5) (6) (7) (8) (9) (10) (11) (12) (13)

Heteroaromatic betaines with five-membered rings are known as mesoionic compounds and have been extensively investigated[3]. One of their most interesting properties is that they behave as 1,3 dipoles and undergo 1,3 dipolar additions with a great variety of dipolarophiles[4]. Very much less work has been carried out on heteroaromatic betaines

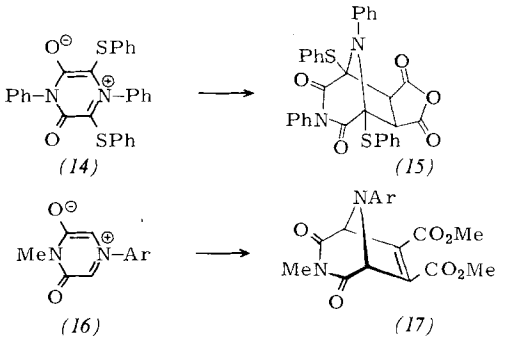
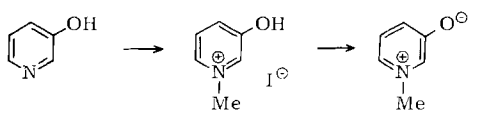
[***] The following abbreviations are used: Me = methyl, Et = ethyl, Ph = phenyl.

with six-membered ring systems of type *(12)*. At about the time we started our work, two short papers appeared giving examples of 1,3 dipolar cycloadditions involving heteroaromatic betaines having six-membered rings. *Honzl* and *Šorm*[5] found that the pyrazinium betaine *(14)* reacted with maleic anhydride to give *(15)*, and *Huisgen* and *Mäder*[6] described a rather similar reaction involving betaine *(16)* and dimethyl acetylenedicarboxylate to afford *(17)* in 70% yield.



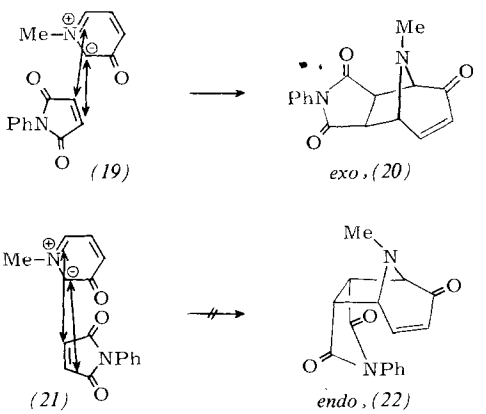
(14) *(15)* *(16)* *(17)*

We had at that time already started to investigate the simpler pyridinium systems and were able to prepare betaine *(12)* from 3-pyridinol *via* the quaternary salt *(18)*, which is most conveniently converted into *(12)* using an ion exchange



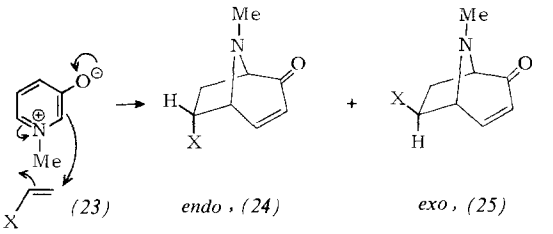
(6) *(18)* *(12)*

resin[7]. 1-Methyl-3-pyridiniumolate *(12)* is not a very pleasant compound with which to work. It is highly hygroscopic and difficult to crystallize. However it does show 1,3 dipolar activity[8] and with *N*-phenylmaleimide it reacts in the sense of *(19)* to yield the *exo*-isomer *(20)* rather than in the sense of *(21)* to give *(22)*.



(19) *exo*, *(20)* *(21)* *endo*, *(22)*

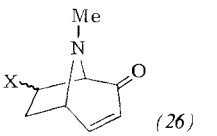
1-Methyl-3-pyridiniumolate *(12)* also reacts with acrylonitrile, methyl acrylate, methyl vinyl ketone, and methyl methacrylate. With each of these unsymmetrical dipolarophiles there are four conceivable reaction products that could be formed. In each case the reaction proceeds in the sense of *(23)* usually to produce a mixture of *endo (24)* and *exo (25)* isomers (Scheme 1). The two alternative regioisomers *(26)* were not detected in any of these reactions. Reactions were successful only with olefinic dipolarophiles containing a strongly electron-withdrawing group. Other olefins do not yield adducts.



(23) *endo*, *(24)* *exo*, *(25)*

Scheme 1. Cycloaddition of 1-methyl-3-pyridiniumolate; X = CN, CO_2CH_3; methyl methacrylate and *N*-phenylmaleimide also react.

The stereo and regio structures of the adducts were deduced from the ^{1}H-NMR spectra; for example, the *exo* adduct *(27)* from 1-methyl-3-pyridiniumolate and acrylonitrile gave the



(26)

NMR spectrum shown in Figure 1. The H-3 doublet is coupled with H-4, the H-4 quartet with H-3 and H-5. However H-5 is seen only as a doublet indicating coupling solely to H-4. The Karplus rule[9] and examination of models show that the coupling constant between H-5 and H-6-*endo* is expected to be very small, while that between H-5 and H-6-*exo* should be large. This at once locates the cyano group in the 6-*exo* position, and the rest of the spectrum confirms this assignment.

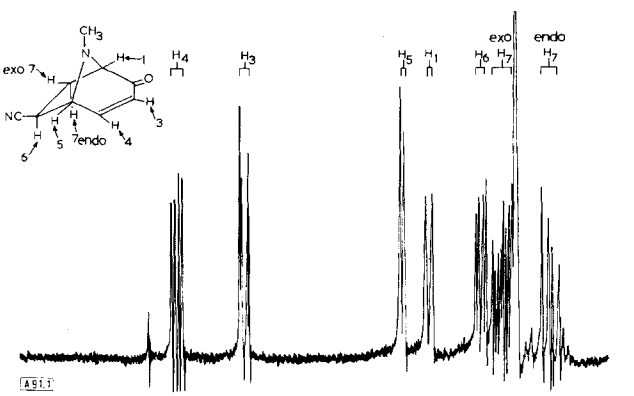


Fig. 1. ^{1}H-NMR spectrum of cycloadduct *exo*-8-methyl-2-oxo-8-azabicyclo[3.2.1]oct-3-ene-6-carbonitrile *(27)* in $CDCl_3$.

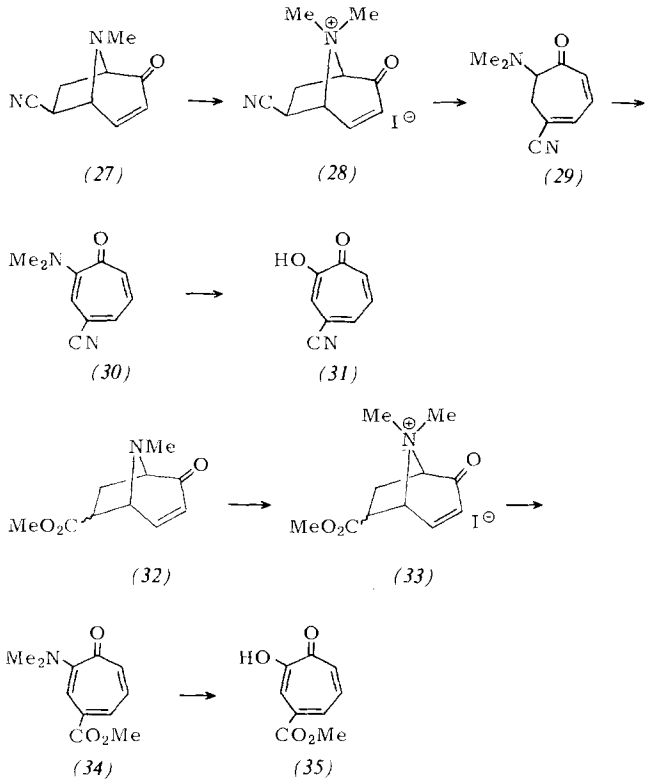
2. Synthesis of Tropones

2.1. General

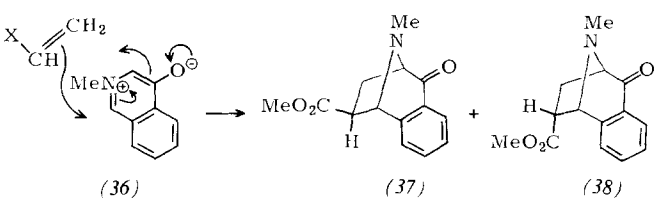
The structure of adduct *(27)* is reminiscent of the tropane alkaloids having the same ring system. One of the classical tropone syntheses is by Hofmann elimination[10] of the tropanes. We converted *(27)* to the methiodide *(28)*, which on reaction with silver oxide or sodium hydrogen carbonate gives the dimethylaminotropone *(30)*. Evidently the intermediate *(29)* undergoes dehydrogenation very easily; this is perhaps caused by oxygen in the air, but even with exclusion of oxygen we were unable to isolate *(29)* and therefore believe that it may disproportionate. The tropone *(30)* is easily hydrolyzed to the corresponding tropolone *(31)*. In this synthesis[11] of tropones and tropolones it is not necessary to separate the two stereoisomeric adducts; thus the mixture of adducts from methyl acrylate *(32)* is converted into the mixed methio-

dides *(33)* from which the tropone *(34)* and the tropolone *(35)* are then obtained (Scheme 2).

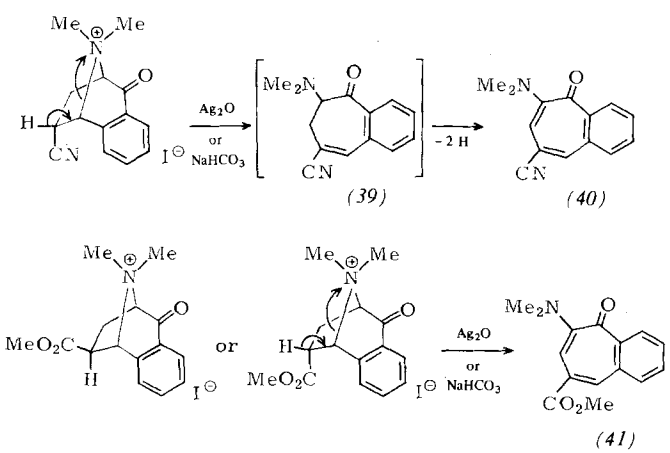


Scheme 2. Formation of tropolones.

This synthesis of tropones can be extended to benzotropones. The isoquinolinium betaine *(36)*[12] reacts as shown with dipolarophiles to again yield mixtures of isomeric adducts; thus, from methyl acrylate *(37)* and *(38)* were isolated (Scheme 3) and again the structures are shown clearly by the NMR spectra. The benzo-annelated tropones *(40)* and *(41)* were prepared from adducts of this type. Once



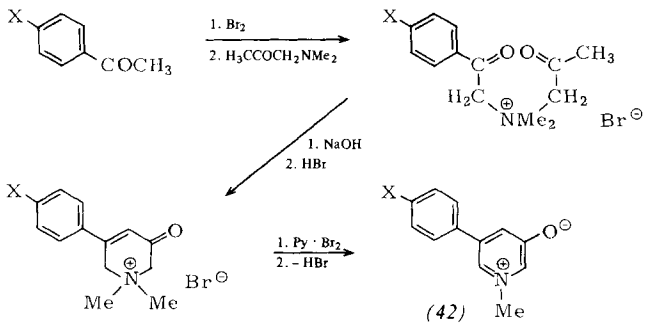
Scheme 3. 1,3-Dipolar additions of isoquinolinium betaine *(36)*. With methyl acrylate ($X=CO_2CH_3$) the isomers *(37)* and *(38)* are obtained.



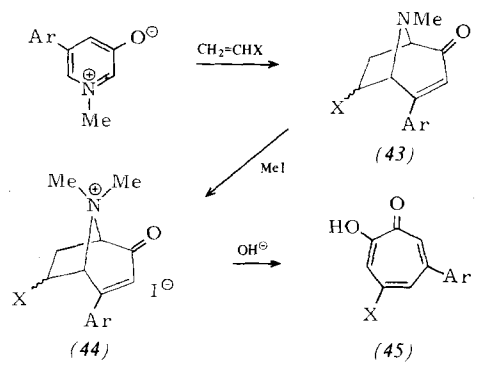
Scheme 4. Preparation of benzo-annelated tropones *(40)* and *(41)*.

again the postulated dihydro derivatives *(39)* could not be isolated (Scheme 4).

The synthesis can be extended to further substituted tropones. For example in Scheme 5 we give the preparation of 5-aryl-1-methyl-3-pyridiniumolates *(42)*[13]; these compounds readily form adducts *(43)*, which can be converted into quaternary salts *(44)* and thus into tropolones *(45)* (Scheme 6).

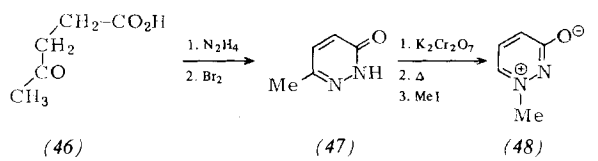


Scheme 5. Preparation of 5-aryl-1-methyl-3-pyridiniumolate *(42)*; X=H, OCH_3, NO_2.

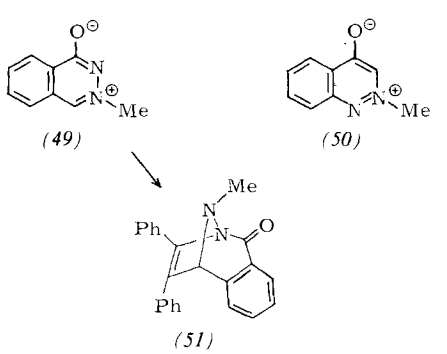


Scheme 6. Preparation of 6-aryl substituted tropolones *(45)*; X=CN, CO_2CH_3; Ar=C_6H_5, *p*-O_2N—C_6H_4, *p*-H_3CO—C_6H_4.

However the placement of further nitrogen atoms in the ring appears to seriously decrease the reactivity. Thus the methylpyridazinium betaine *(48)*[14] prepared as shown (Scheme 7) from *(46)* *via* *(47)* is unreactive toward a wide



Scheme 7. Preparation of 1-methyl-3-pyridaziniumolate *(48)*.



range of dipolarophiles, although the benzo analogs, *i.e.* the phthalazinium betaine[15] *(49)* and the cinnolinium betaine[14, 16, 17] *(50)* do show limited reactivity as 1,3 dipoles.

For example, reaction of *(49)* with diphenylacetylene gives the adduct *(51)*; the earliest example of such a cycloaddition, with the cinnolinium betaine *(50)*, was reported by *Lunt* and *Threlfall*[16].

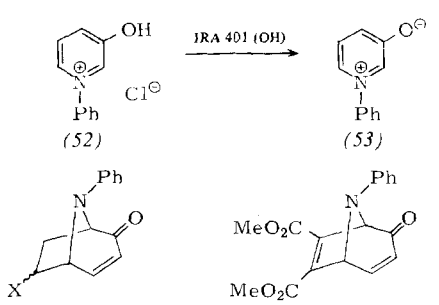
2.2. Synthetic Possibilities

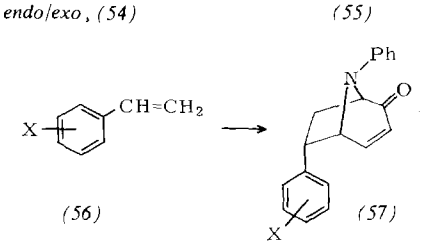
At this stage we might take stock of the synthetic potential of the above described route to tropones. It has indeed several advantages; utilization of readily available starting materials, formation of biologically interesting intermediates, and potential feasibility for large scale preparation. However, it must also be recognized that there are several pronounced disadvantages to the route as presented. The 1-methyl betaines are hygroscopic and difficult to crystallize, the yields of cycloadducts are often only moderate (in the range 30—50%), and the procedure is a somewhat tricky one. Indeed several times we have received enquiries from industrial companies who have encountered difficulties when trying to repeat some of the steps involved. The procedure is reproducible but we do find that some experience is needed to get the best results. Further, the reaction as described succeeds only with dipolarophiles containing strongly electron-withdrawing substituents, and it fails with the simple azine betaines.

In order to try and overcome these limitations, while retaining the advantages, there appeared to be two major alterations possible in the betaine structure: either we could vary the substituent carrying a negative charge and instead of oxygen incorporate nitrogen, carbon or sulfur; alternatively we could replace the methyl group on the nitrogen by other substituents. We have carried out considerable work on both these lines but it is the second that has produced the most interesting results; these will be dealt with in the following.

2.3. 1-Phenyl Betaines

A report[18] dating from 1905 states that the 3-hydroxy-1-phenylpyridinium chloride *(52)* can be produced in good yield from aniline and furfural. We found that this is indeed so and that *(52)* can be converted into the 1-phenyl betaine *(53)* using an ion exchange resin[7]. This 1-phenyl betaine is considerably easier to handle than the 1-methyl betaine,

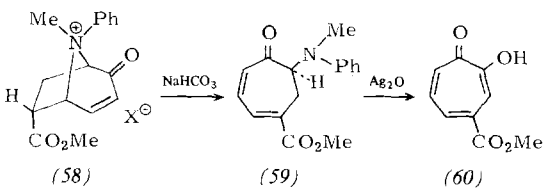




X = *p*-Cl, *p*-Br, 4-Pyridyl

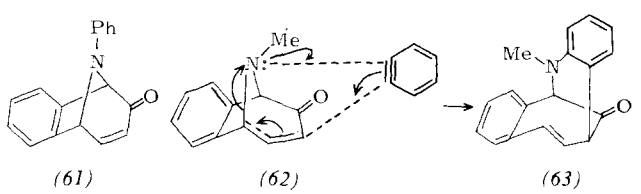
although it is still somewhat hygroscopic. Also it can be liberated *in situ*[19] from the hydrochloride and does react readily with a variety of dipolarophiles; thus mixtures of *endo* and *exo* products *(54)* can be produced[20] from *N*-phenylmaleimide, acrylonitrile, and methyl acrylate. Again only one set of regioisomers was found. Dimethyl acetylenedicarboxylate yielded *(55)* and the styrenes *(56)*[19] gave exclusively the *endo* adducts *(57)*, evidently because of steric reasons. The structures of all these adducts were again demonstrated from the ^{1}H-NMR spectra.

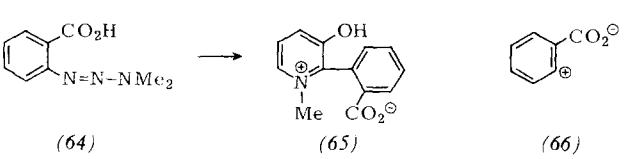
Conversion of the adducts of the 1-phenyl betaine into tropones is more difficult because of the low tendency of the adducts to form quaternary salts. However, using methyltrifluoromethanesulfonate[21], quaternary salts of type *(58)* could be prepared. With sodium hydrogen carbonate we were now able to isolate the dihydrotropone *(59)* which with silver oxide was converted smoothly to the tropolone *(60)* (Scheme 8). The stability of the intermediate dihydrotropone *(59)*—compared to the methyl analog—probably derives from steric effects.



Scheme 8. Preparation of the isolable dihydrotropone methyl-6-(methylphenylamino)-5-oxo-1,3-cycloheptadienecarboxylate *(59)* converted to the tropolone *(60)*.

Another difference between the 1-phenyl and 1-methyl betaines lies in their reactions with dehydrobenzene[22]. The 1-phenyl betaine yields[23] the expected adduct *(61)*; in the case of the 1-methyl betaine the corresponding adduct *(62)* is probably an intermediate—the isolated product[24] was *(63)*, the formation of which can be rationalized as shown by the cycloaddition of a further molecule of dehydrobenzene to *(62)*. Analogous[25–27] cases are known. In the reactions just mentioned, the dehydrobenzene was prepared[22] from

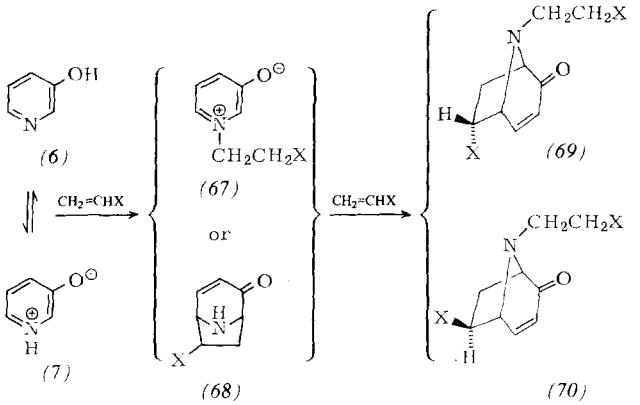




anthranilic acid and amyl nitrite. However, in an attempt to react the 1-methyl betaine with dehydrobenzene from the triazenobenzoic acid *(64)*[28] we obtained the product *(65)*, which could be formed by reaction of the 1-methyl betaine with the dehydrobenzene precursor *(66)*. There is ample previous evidence[29] for the intermediate formation of *(66)*.

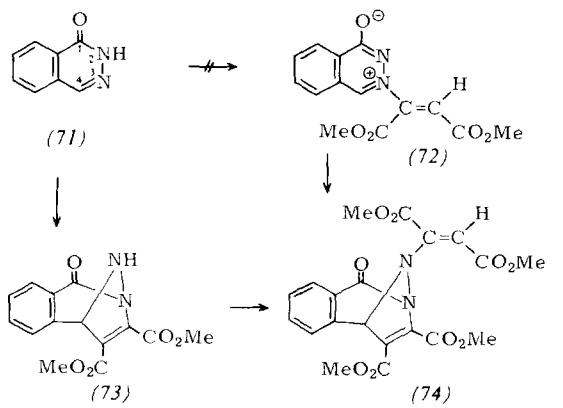
2.4. Betaines with Hydrogen as N-Substituent

As indicated in Section 1, 3-pyridinol *(6)* is a tautomeric compound in equilibrium with the zwitterionic form *(7)*. We now find that with acrylonitrile and methyl acrylate high yields of the *endo* and *exo* adducts *(69)* and *(70)* are formed (Scheme 9). Both adducts contain two molecules of the dipolarophile. Two reaction routes are possible: either initial reaction at the cyclic nitrogen atom with compounds of type *(67)* as intermediates, or alternatively dipolar addition with the betaine to give *(68)* followed by a Michael type addition at the nitrogen atom of *(68)*. Although no direct evidence is yet available to distinguish these possibilities in the reactions



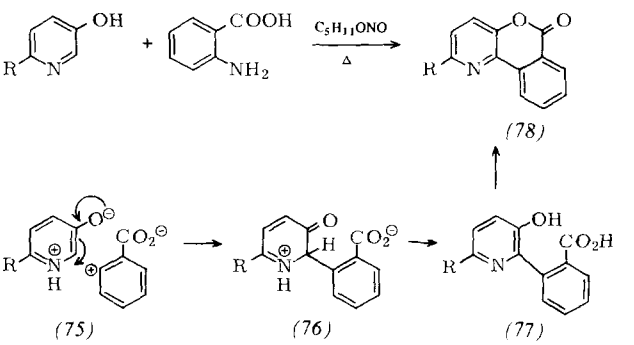
Scheme 9. Dipolar addition of 3-pyridinol *(6)* to acrylonitrile (X = CN), and methyl acrylate ($X = CO_2CH_3$).

of 3-pyridinols, there is, however, for the reaction of 1(2*H*)-phthalazinone *(71)*[30] with dimethyl acetylenedicarboxylate. The two possible routes are set out in Scheme 10; by following the NMR spectrum of the reaction we were able to show that adduct *(74)* was formed by way of intermediate *(73)* and not *(72)*. The signal at $\delta = 6.0$ is seen only at intermediate stages in the reaction; it is assigned to the bridgehead proton of the intermediate 1:1 cycloadduct *(73)*.



Scheme 10. Reaction of 1(2*H*)-phthalazinone *(71)* with dimethyl acetylenedicarboxylate.

The reactions of 3-pyridinols with dehydrobenzene are of interest. Under conditions where 3-pyridinols are allowed to react with excess diazotized anthranilic acid, the product is the expected adduct *(61)*, but when the 3-pyridinols are present in excess then the major product is the tricyclic compound *(78)*[31] formed *via* intermediates *(76)* and *(77)* by reaction of the dehydrobenzene precursor with the zwitterionic form [see *(75)*] (Scheme 11). This reaction is analogous to the formation of compound *(65)*.

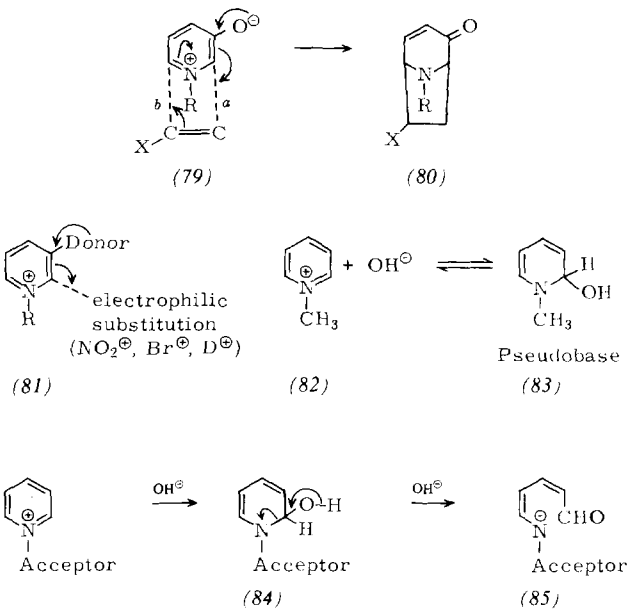


Scheme 11. Synthesis of [2]benzopyrano[4,3-*b*]pyridin-6-ones *(78)*; R = H or CH_3.

3. Mechanism of Cycloaddition

3.1. Valence Bond Treatment of the Cycloaddition Reactions

The regiospecificity of the cycloaddition *(79)* → *(80)* (R = methyl, phenyl, or hydrogen) together with the fact that group X of the dipolarophile needs to be an electron withdrawing substituent, can be explained. In the pyridinium compounds *(81)* the carbon atom at position 2 behaves as the most nucleophilic of the ring carbon atoms. Thus, electrophilic substitution of compounds of this type always occurs at C-2[32]; calculations show that this position has the highest π-electron density[33]. Evidently the bond *a* in *(79)*, between C-2 of the betaine and the C-β of the dipolarophile, is formed before bond *b*. A driving force in the reaction is the donation of electrons from the betaine to the dipolarophile (we believe, however, that these cycloaddition reactions are concerted and give evidence on this point in Section 3.3).



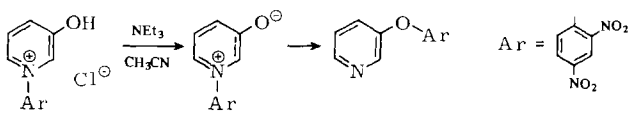
Scheme 12. Mechanism of 1,3-dipolar addition to betaine. Acceptor substituents are CN, SO_3, or 2,4-dinitrophenyl.

Obviously to extend the reaction to dipolarophiles with less electrophilic character, we need to increase the tendency to form bond *b*, and thus to reduce the electron density at the 6-position of the betaine. 1-Methyl- and 1-phenylpyridinium ions form pseudo bases [*e.g.* *(82)* → *(83)*] but this reaction is reversible and the proportion of pseudo base formed under normal conditions is very small[34]. The situation

changes dramatically when the substituent attached to nitrogen in the pyridinium ion is a strong electron accepting group, *e.g.* CN, SO_3, or 2,4-dinitrophenyl. In such cases the intermediate pseudo base *(84)* reacts further with hydroxide ion to give the open-ring product *(85)*[34] (Scheme 12). This reasoning led us to investigate betaines containing strongly electron accepting groups attached to the nitrogen atom.

3.2. 2,4-Dinitrophenyl Betaines

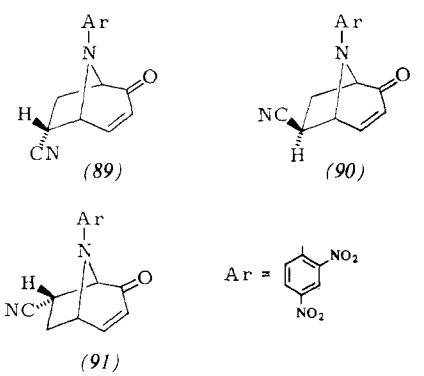
Vompe and *Turitsyna*[35] have reported that 3-pyridinol and 1-chloro-2,4-dinitrobenzene give the quaternary salt *(86)*, which, according to these authors, can be converted by sodium hydrogen carbonate into the betaine *(87)*. Actually, the product they obtained was the ether *(88)* (Scheme 13), which is quite unreactive towards dipolarophiles. We found that the betaine *(87)* can be isolated by treating the salt *(86)* with triethylamine in acetonitrile[36]. As expected it not only isomerizes readily to *(88)*, but also shows very pronounced



(86) *(87)* *(88)*

Scheme 13. Preparation of authentic 2,4-dinitrophenyl betaine 1-(2,4-dinitrophenyl)-3-pyridiniumolate *(87)*.

1,3-dipolar reactivity. Thus with acrylonitrile, in addition to the two expected adducts *(89)* and *(90)*, for the first time a third adduct was obtained in small yield: the regioisomer *(91)*.



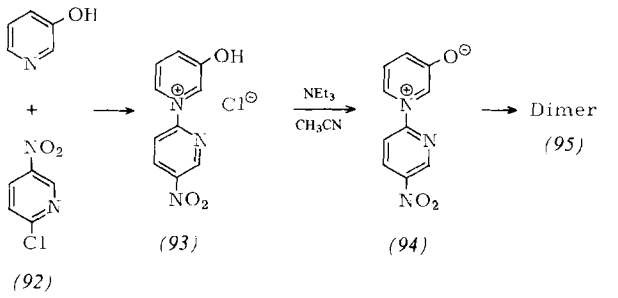
(89) *(90)*

(91)

Considerable further work with the dinitrophenyl betaines of the 3-pyridinols[36] and the 4-isoquinolinols[37] only revealed more clearly their tendency to rearrange to the ether. Because of this limitation we therefore turned to other *N*-substituents.

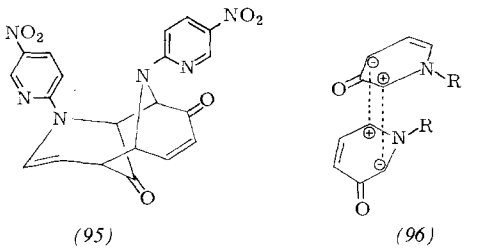
3.3. 5-Nitro-2-pyridyl Betaines

2-Chloro-5-nitropyridine *(92)* reacts readily with 3-pyridinol to give the quaternary salt *(93)* (Scheme 14). When the betaine *(94)* is liberated it soon spontaneously dimerizes to the compound *(95)*. This dimerization[38] involves the addition of the 2,6-positions of one betaine to the 2,4-positions of a second molecule in the sense of *(96)*. The complete stereo- and regiochemistry of the dimer is elucidated from the ^{1}H-NMR spectrum. Extensive decoupling experiments confirmed the assignments.



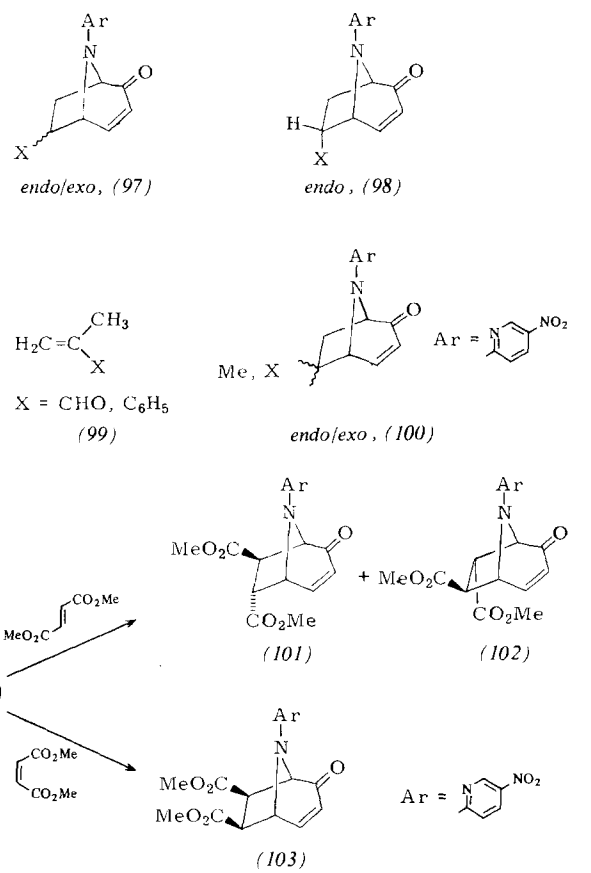
(92) *(93)* *(94)* *(95)*

Scheme 14. Dimerization of the betaine 1-(5-nitro-2-pyridyl)-3-pyridiniumolate *(94)* to *(95)*, m.p. = 169°C (dec.).



(95) *(96)*

Dimer *(95)* evidently dissociates reversibly at 100°C to the monomer, for under these conditions it reacts readily with a wide variety of dipolarophiles to give adducts[39] in good yields. Simple acrylic acid derivatives give mixtures of the *endo* and *exo* products *(97)*. Styrenes and similar compounds give only the *endo* compounds *(98)*, whereas 1,1-disubstituted dipolarophiles *(99)* give *endo* and *exo* compounds *(100)*. The reactions with dimethyl fumarate to give *(101)* and *(102)* and with dimethyl maleate to give *(103)* (Scheme 15) demonstrate the concerted character of the cycloadditions.



Scheme 15. Reactions of the betaine *(94)* with dimethyl fumarate and dimethyl maleate.

Thin layer chromatography showed the absence of the two adducts *(101)* and *(102)* in the reaction mixture from the dimethyl maleate addition, and conversely the absence of adduct *(103)* in the product from the dimethyl fumarate addition.

The nitropyridyl betaine dimer *(95)* also reacts with norbornene, diethyl azodicarboxylate, and various acetylenes. If the dimer fails to react, the monomer, which can be isolated under carefully controlled conditions from the quaternary salt *(93)*, sometimes gives a product. For example with ethyl vinyl ether the *endo* isomer *(98)*, X=OEt, is obtained.

3.4. Molecular Orbital Treatment of Cycloaddition Reactions

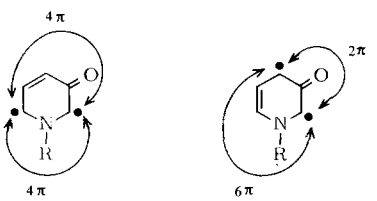
The valence bond rationalization given in Section 3.1 is unsatisfactory in several respects regarding the cycloadditions of the nitropyridyl betaine *(94)*. In particular it does not answer any of the following questions:

1. Why does the dimerization of the nitropyridyl betaine *(94)* involve the 2,6 positions of one molecule and the 2,4-positions of the other?

2. Why is the nitropyridyl betaine *(94)* so much more reactive than the dinitrophenyl betaine *(87)*?

3. Why does ethyl vinyl ether add in the same orientation as an electron deficient dipolarophile to the betaines?

The answer to the first of these questions is provided by application of the concept of orbital symmetry control to these additions. For additions at the 2,6-positions these betaines are 4π fragments; they can be considered as 5 atom fragments bridged by nitrogen or, alternatively, as 3 atom fragments bridged by a 3-carbon unit [cf. *(104)*]. They are thus expected to undergo suprafacial pericyclic reactions with 2π fragments—apart from dimerization all the reactions so far discussed come into this category.

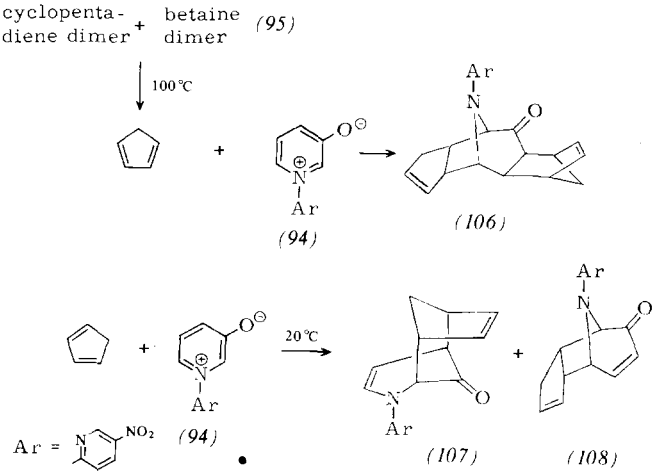


(104) *(105)*

For additions across the 2,4-positions [cf. *(105)*] the betaine can be considered either to be a 6π electron 5 atom fragment with a one carbon atom bridge, or as a 2π electron 3 atom fragment with a two-carbon and one-nitrogen atom bridge. In either case, suprafacial concerted thermal addition would be expected with a 4π fragment. This explains the dimerization and suggests, furthermore, that (a) other 4π fragments should add at the 2,4 positions, and (b) 6π fragments should add thermally at the 2,6-positions.

3.5. Reactions of Betaines with 4π Addends

The pyridyl betaine dimer *(95)* does indeed react with a variety of 1,3-dienes across the 2,4 positions[39]. In these reaction mixtures, the alternative possibility of the diene reacting as a mono-ene across the 2,6 positions also occurs. In suitable cases the reaction can be steered. Thus, if the reaction of *(95)* with cyclopentadiene is carried out at a high temperature—heating the two dimers together at 100 °C—the product

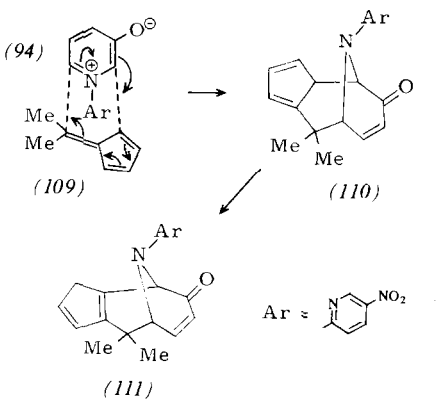


Scheme 16. Reactions of the dimeric pyridyl betaine *(95)* with dimeric cyclopentadiene at 100 °C giving adduct *(106)* (m.p. = 217 °C, 34%) and reaction of the corresponding monomer at 20 °C yielding the adducts *(107)* and *(108)* (m.p. = 194 °C (yield 45%) and 137 °C (yield 36%), resp.).

(106) is formed (Scheme 16). The initial step of the reaction is an addition of the diene as mono-ene across the 2,6 positions; this is followed by a Diels-Alder addition to give the final product. On the other hand, if the reaction between the two monomers is carried out at 20 °C, a mixture of the two expected initial products of addition across the 2,4 and 2,6 positions [*(107)* and *(108)*] is formed (Scheme 16).

3.6. Reaction of Betaines with 6π Addends

The nitropyridyl betaine *(94)* reacts with dimethylfulvene in the sense of *(109)*; the initial adduct *(110)* isomerizes spontaneously to the end product *(111)*. This is a general



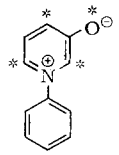
Scheme 17. Reaction of the pyridyl betaine *(94)* with dimethylfulvene.

reaction and similar products to *(111)* have been obtained from phenyl and *p*-methoxyphenylfulvene[39]. The structures of these adducts were again proved by the ^{1}H-NMR spectra.

3.7. Pyrimidinyl Betaines

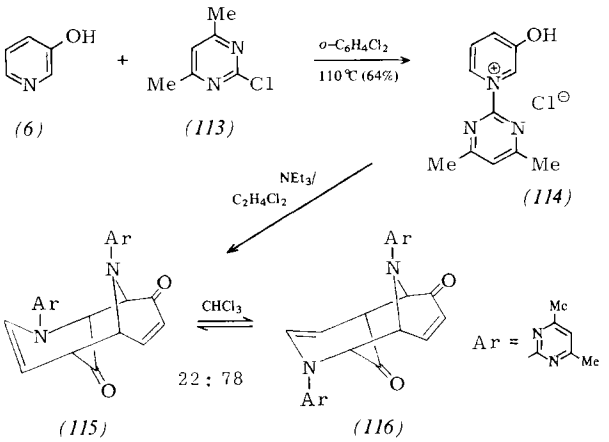
We now turn to the second question in Section 3.4. Why is the nitropyridyl betaine *(94)* more reactive than the dinitrophenyl betaine *(87)*? The reactivity can be measured in the tendency of the former to dimerize, whereas the latter does not. The tendency to dimerization should vary with the LUMO-HOMO energy difference. It is known that extended conjugation decreases this difference and hence we expect the dinitrophenyl betaine *(87)* to be more reactive than the

phenyl betaine *(53)* and this in turn to be more reactive than the methyl betaine *(12)*. This has in fact been confirmed experimentally. Aza substitution at the starred positions of the pyridine ring [see *(112)*] lower the HOMO and hence increase this difference. This explains why pyridazinium betaines such as *(14)* and *(16)* are much less reactive than pyridinium betaines.



(112)

Conversely, aza substitution at the non-starred positions of the pyridine ring and at all positions in the phenyl ring will lower the LUMO; this and the small degree of twisting about the N—C bond explains the high reactivity of the pyridyl betaine *(94)*. This line of argument would further predict that a 1-pyrimidinylpyridinium betaine should be even more reactive. We have recently tested this prediction and found it to be correct[39].



Scheme 18. Synthesis of the dimers *(115)* and *(116)*.

The chloropyrimidine *(113)* reacts with 3-pyridinol *(6)* to give the quaternary salt *(114)*. On treatment with triethylamine in dichloroethane this yields a mixture of two dimers, *(115)* and *(116)* (Scheme 18). Initially the mixture contains only *(115)*, but on standing for several hours the other dimer *(116)* predominates; the mixture at equilibrium contains 78% of *(116)*. The complete structures of the two dimers and their stereochemistry were deduced from the ^{1}H-NMR spectra using extensive decoupling.

In dimerizations of this type there are four possible regio- and stereoisomers (see Scheme 19). In $_\pi4_s+_\pi6_s$ processes[40], *exo* adducts are generally favored. The kinetically controlled products are the *exo* 2,2′-4,6′ derivatives: this isomer is formed exclusively in the dimerization of pyridyl betaine *(94)* to *(95)*, and as initial product in the case of pyrimidinyl betaine *(115)*.

Equation (1)[41] describes the energy for addition at positions rr′ of R to ss′ of S.

$$\Delta E = K\frac{[(C_r^{HO}C_s^{LU}+C_{r'}^{HO}C_{s'}^{LU})\gamma]^2}{E_R^{HO}-E_S^{LU}}+\frac{[(C_r^{LU}C_s^{HO}+C_{r'}^{LU}C_{s'}^{HO})\gamma]^2}{E_S^{HO}-E_R^{LU}} \quad (1)$$

Using the CNDO/2 method[33] we have calculated the HOMO and LUMO coefficients for 1-methylpyridinium betaine *(12)* (Fig. 2); these calculations do indeed predict initial formation of the *exo* 2,2′-4,6′ isomer. In the case of the pyridyl betaine dimer *(95)* the dimerization reaction is only weakly reversible at room temperature so this remains the major product. However, the pyrimidinyl betaine-dimer system, which is much more reactive and probably contains an appreciable amount of monomer in equilibrium, changes fairly rapidly until the dimer *(116)* predominates, which is probably favored on steric grounds over *(115)*.

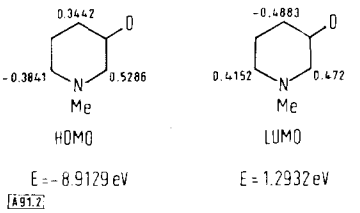


Fig. 2. HOMO and LUMO coefficients of 1-methyl-3-pyridiniumolate *(12)*. ΔE (in eV) is

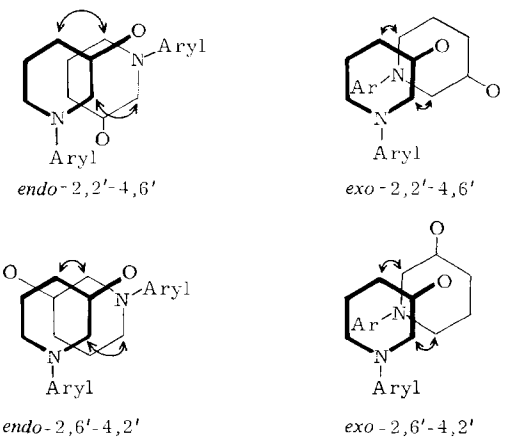
$-3.51\times10^{-2}\gamma^{-2}$ for 2,2′–4,6′
and $-3.41\times10^{-2}\gamma^{-2}$ for 2,6′–4,2′



Scheme 19. Regio- and stereoselectivity of the dimerization of 1-aryl-3-pyridiniumolates.

Preliminary work with the pyrimidinyl betaine showed that it is exceedingly reactive with a wide variety of addends. We believe that the application of these reactions will be of considerable significance in the synthesis of hetero- and carbocyclic compounds with 7—10 membered rings.

3.8. FMO Control of Orientation of Addition of the 2π Electron System

The VB rationalization given in Section 3.1 (Scheme 12) for the exclusive formation of regioisomers of type *(24)* and *(25)* to the exclusion of *(26)*, clearly does not explain why the same orientation of addition is observed in the case of vinyl ethers as in the case of electron-deficient olefins. The third question posed in Section 3.4 has still to be answered. Comparison of the HOMO and LUMO values for 1-methyl-3-pyridiniumolate (Fig. 2) with the corresponding coefficients for (a) electron-deficient and (b) electron-rich olefins shows that the orientations *(24)* and *(25)* are preferred over *(26)* *in both cases*[38, 39], although in (a) the betaine HOMO/olefin LUMO interaction is dominant, while in (b) the betaine LUMO/olefin HOMO interaction is stronger.

Biomimetic Polyene Cyclizations

By William S. Johnson[*]

Certain polyenic substances having *trans* olefinic bonds in a 1,5 relationship can be induced to undergo stereospecific, non-enzymic, cationic cyclization to give polycyclic products with all-*trans* ("natural") configuration. These transformations appear to mimic in principle the biogenetic conversion of squalene into polycyclic triterpenoids. Acetal and allylic alcohol functions are effective initiators for these cyclizations, and methylacetylenic end groups are particularly useful terminators since they lead to five-membered rings. Thus a tetraenic acetal having no chiral centers has been converted in a single step into a tetracyclic product having seven such centers. The process is highly stereoselective, giving only two of 64 possible racemates. Systems have also been developed for effecting the total synthesis of the steroid nucleus in a single step starting from a substrate containing only one ring. The mechanism of these biomimetic cyclizations and also that of their enzymic counterparts is still unknown, but the balance of the evidence favors a synchronous process.

1. Introduction

The strategy for the total synthesis of polycyclic natural products, particularly the steroid and polycyclic triterpenoids, has involved, for the most part, step-by-step annelations, *i.e.*, each new ring is formed one at a time[1]. The biomimetic approach differs in that the plan envisages the production of a number of rings stereospecifically in a single step by the ring closure of an acyclic chain having appositely placed *trans* olefinic bonds, a process analogous to the known biogenetic conversion of squalene into polycyclic triterpenoids, *e.g.*, lanosterol[2], the precursor of cholesterol.

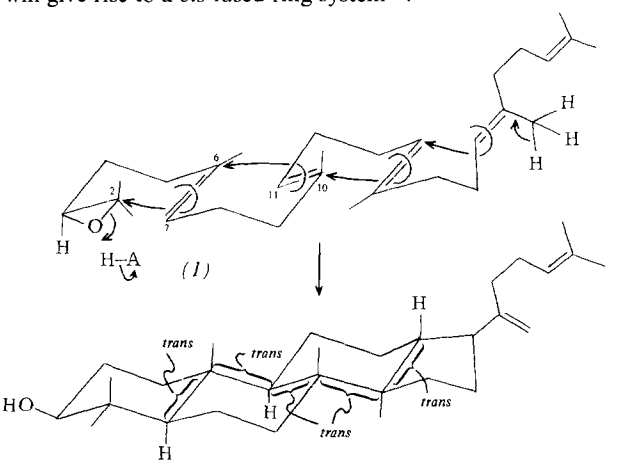
Squalene Lanosterol

In 1955 *Stork et al.*[3] and *Eschenmoser et al.*[4] pointed out that the stereochemical course of the biological cyclization of squalene could be rationalized on stereoelectronic grounds. Their important hypothesis, which immediately stimulated serious biomimetic studies, can be illustrated by considering the conversion of squalene oxide *(1)*, which is a known biogenetic intermediate[5], into the plant triterpenoid dammaradienol *(2)*. The process may be regarded as a sequence of *trans-anti-parallel* electrophilic additions to the olefinic bonds, in the same stereochemical sense that bromine adds stereospecifically to alkenes. Thus protonation of the oxygen atom of squalene oxide *(1)* generates an incipient cationic center at C-2, which attacks the 6,7-olefinic bond, thereby initiating formation of the σ bond between C-2 and C-7. Concomitantly, the cationic center developing at C-6 starts an electrophilic attack on the 10,11-olefinic bond generating the σ bond between C-6 and C-11, *etc.* The addition of C-2 and C-11 to the 6,7-olefinic bond occurs in the *trans* manner, yielding the *trans*-fused ring system found in the product *(2)*. Thus the all-*trans* geometry of the olefinic bonds in squalene results in *trans,trans,trans,trans,trans*-fusion of the four rings in product *(2)*. A corollary to the hypothesis is that a *cis* olefinic bond will give rise to a *cis*-fused ring system[6].



(2)

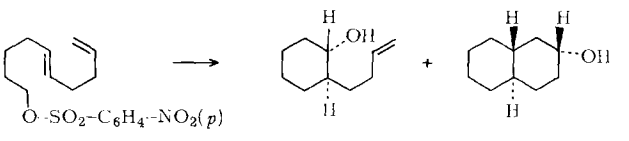
The first studies directed toward non-enzymic biogenetic-like polyene cyclization involved attempts to initiate cyclization by protonation of the terminal olefinic bond of a polyene chain[3, 7, 8]. The results were not promising[6]. Seemingly, much of the difficulty that has been encountered in the acid-catalyzed cyclization of such systems, including squalene, can be attributed to the rather indiscriminate protonation of the substrate, initiating a variety of other cyclizations in addition to the desired reaction. Moreover, the relatively strong acidic conditions generally employed are known to be conducive to deprotonation (hence the production of partially cyclized products) as well as to promoting reactions such as addition to and isomerization of the olefinic bonds.

It was with the hope of obviating these difficulties that we initiated, in 1960, a search for polyolefinic substrates containing an appropriately positioned functional group that could be used to generate a cyclizable cationic carbon center under conditions which would not otherwise affect the olefinic bonds. This requirement appears to be fulfilled, at least in part, by certain polyolefinic epoxides which have been examined extensively by *van Tamelen*[9]. Limitations in space preclude a review of these most interesting studies in the present paper. Other important studies that must be mentioned are the free radical- and mercuric ion-initiated cyclizations of *M. Julia*[10], and the proton- and mercuric ion-initiated cyclizations described by *Semenovsky*[11].

Our very first investigations on the solvolysis of polyenic sulfonate esters (see Section 2) gave useful mechanistic results; however, the yields of cyclized products were extremely poor. From an extensive search for groups more effective than sulfonate esters for initiating cationic polyene cyclizations, only two good initiators emerged: the acetal function and the allylic alcohol function. Our studies with these initiators are reviewed below.

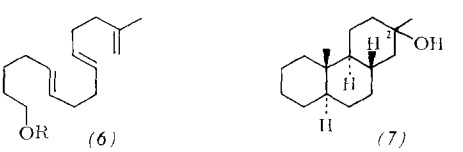
2. Cyclization-Solvolysis of Polyenyl Sulfonate Esters

Careful product analyses have been made of the mixtures obtained upon solvolysis of acyclic olefinic sulfonate esters designed to produce mono-[12], bi-[13], and tricyclic[14] systems[6]. Thus eleven products were identified from the formolysis of the 5,9-decadienyl *p*-nitrobenzenesulfonate *(3)*. The main component (after cleavage of the formate esters) was the monocyclic *trans* alcohol *(4)*, produced in 35% yield. The major bicyclic component was *trans,syn*-2-decalol *(5)* ("natural configuration"). Moreover, all of the bicyclic material (hydrocarbons as well as alcohols), which amounted to 12% yield, consisted exclusively of *trans*-decalin derivatives; no *cis* products were found[13a]. Formolysis of the geometric isomer of *(3)*, having a *cis* instead of a *trans* internal olefinic bond, gave a similar array of products except that they all belonged to the opposite stereochemical series. In particular, the bicyclic components, formed in 16% yield, all belonged to the *cis*-decalin series[13b]. Although the yields of bicyclic products were low, the stereospecificity of their formation represented the first example of a system that followed the theoretical predictions of *Stork*[3] and *Eschenmoser*[4] (see Section 1).



(3) (4) (5)

The product from the acetolysis of the trienyl sulfonate ester *(6)*, R=$SO_2C_6H_4$—NO_2(*p*), was estimated to consist of approximately 20% acyclic material [*(6)*, R=CH_3CO], 40% monocyclic, 8—12% bicyclic, and 2.8% tricyclic substances[14]. The tricyclic product, after cleavage of the acetates, was shown to be exclusively the *trans,trans,trans*-alcohol *(7)*

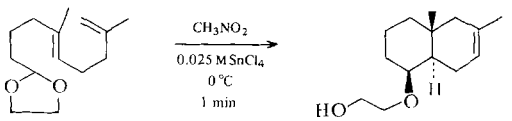


(6) (7)

as a mixture of C-2 epimers. Although the stereospecificity of the reaction was encouraging, the low yield was completely unacceptable.

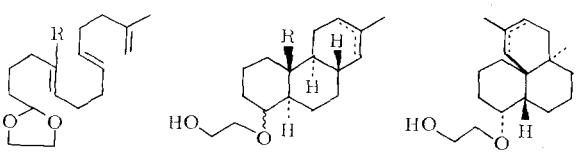
3. Cyclization of Polyenecarbaldehyde Acetals

After an exhaustive study of the cyclization of the *trans*-dienic acetal *(8)*[15, 6], conditions were found for its essentially quantitative conversion into *trans*-bicyclic materials, the major product being the substance *(9)*. It was also demonstrated that the isomeric form of *(8)* with the *cis* internal olefinic bond yielded only *cis*-decalin derivatives, in accordance with the theoretical predictions (see Section 1).



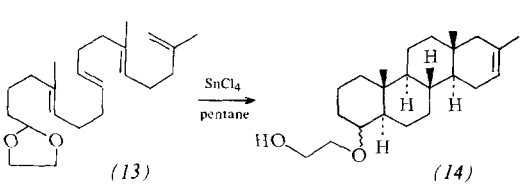
(8) *(9)*

The next objective was to examine the possibility of forming three rings from trienic acetals. Thus the *trans,trans*-acetal *(10)*, R = H, on treatment with stannic chloride in benzene, was converted into a mixture of tricyclic products *(11)*, R = H, all of which belonged to the *trans,trans,trans* ("natural") stereochemical series[14]. Similarly the acetal *(10)*, $R = CH_3$, was converted, in 63 % yield, into the mixture of all-*trans* tricyclic products *(11)*, $R = CH_3$[16]. Surprisingly, when the acetal *(10)*, $R = CH_3$, was cyclized with stannic chloride in nitromethane—conditions which had been so successful with the dienic acetal *(8)*—the reaction took a completely abnormal course involving rearrangement and yielded as the main product (44 % yield) the tricyclic substance *(12)*, whose constitution was established by single crystal X-ray diffraction analysis of a derivative[16].



(10) *(11)* *(12)*

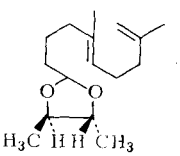
To determine if four rings could be produced in a single step, the cyclization of the tetraenic acetal *(13)* was examined[17]. This substance, on treatment with stannic chloride in pentane, was converted into a mixture of two crystalline D-homosteroidal tetracyclic epimers *(14)*, which belonged exclusively to the all-*trans* stereochemical series. This cyclization, which involves the production of no less than seven asymmetric centers and in this sense is comparable to the conversion of squalene into lanosterol, is remarkably stereoselective, yielding only two of 64 possible racemates. The constitution of *(14)* was established by degradation of the hydroxyethyl side-chain to give the 4-keto compound (the same product was formed from each epimer), and then interrelating



(13) *(14)*

the Wolff-Kishner reduction product with a substance synthesized from a naturally-derived D-homosteroid.

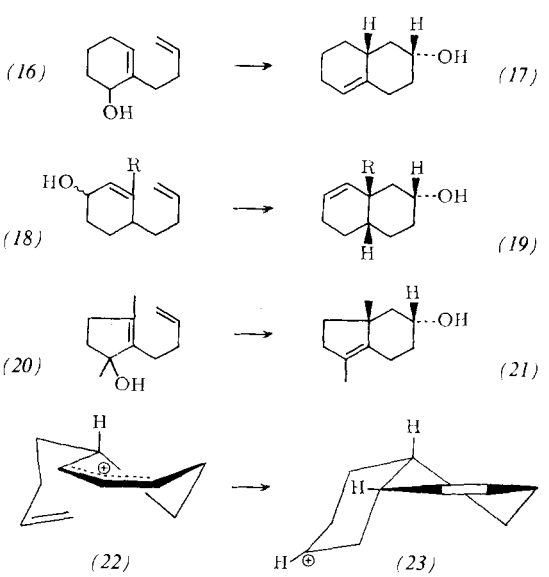
It is important to note that the products of all the biomimetic cyclizations described above were racemic. Thus the tetracyclic products represented by formula *(14)* contained an equal amount of the mirror image of *(14)*. The enzymic cyclization of squalene, on the other hand, proceeds with total asymmetric induction to produce only one enantiomeric form of the polycyclic products. In an effort to simulate this result in a non-enzymic process, we examined the case of the optically active dienic acetal *(15)* derived from (−)-butanediol (*R,R* configuration)[18]. Treatment of *(15)* with stannic chloride in benzene gave bicyclic products which were shown to have enantiomeric ratios of 92 : 8. Thus a very high degree of asymmetric induction has been realized. It will be interesting to see if this strong induction is found in the tetracyclic series.



(15)

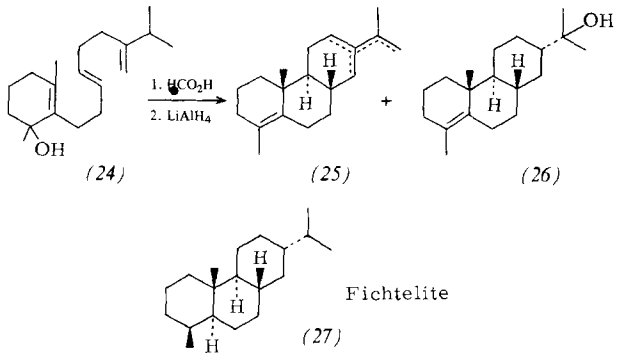
4. Cyclizations Promoted by the Allylic Cation

This type of cyclization is exemplified by the following conversions[6] which are catalyzed by formic acid: *(16)*→*(17)*[19], *(18)*→*(19)*[19, 20], and *(20)*→*(21)*[24a]. The stereospecific formation of the *cis*-fused ring system *(19)* from *(18)* is the expected consequence of the known preference for a cyclohexenyl cation to react with a nucleophile so as to form a *pseudo*-axial bond [see *(22)*→*(23)*].

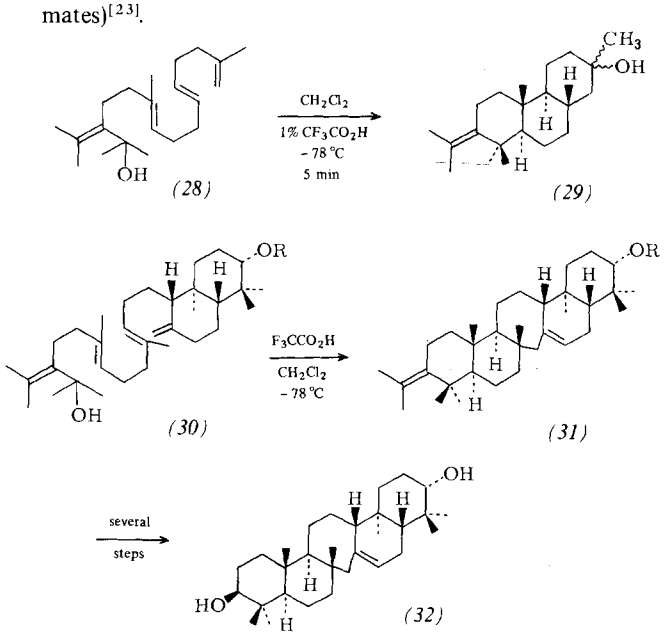


(16) *(17)* *(18)* *(19)* *(20)* *(21)* *(22)* *(23)*

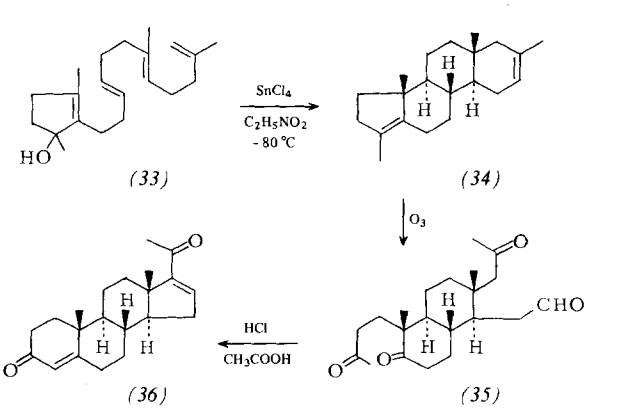
The formation of two new rings by allylic cation promoted cyclization is an efficient process. Thus the trienol *(24)* was quantitatively converted, by the action of cold formic acid, into a mixture of tricyclic products *(25)* and *(26)*. The reaction was stereospecific with respect to the ring fusion *(trans,trans)* as shown by separation and acid-catalyzed interconversion of each of the products, and by their reductive transformation into the natural product (±)-fichtelite *(27)*[21, 6].



Examples of the formation of three new rings follow. The tetramethyl allylic alcohol function, as incorporated in the substrate *(28)*, is an effective cyclization initiator[22], and tricyclic material *(29)* is formed rapidly under exceedingly mild conditions (52% yield). An example of the use of this initiator to effect the total synthesis of a natural product is the cyclization of the tetraenol *(30)*, $R=Si(CH_3)_2t\text{-}C_4H_9$, which involves the formation of three new rings including a seven-membered C-ring. The main product *(31)*, $R=Si(CH_3)_2t\text{-}C_4H_9$, could be converted, *via* selective oxidation of the isopropylidene group followed by reduction and deblocking, into (±)-serratenediol *(32)*, a pentacyclic triterpenoid with nine asymmetric centers (256 possible racemates)[23].

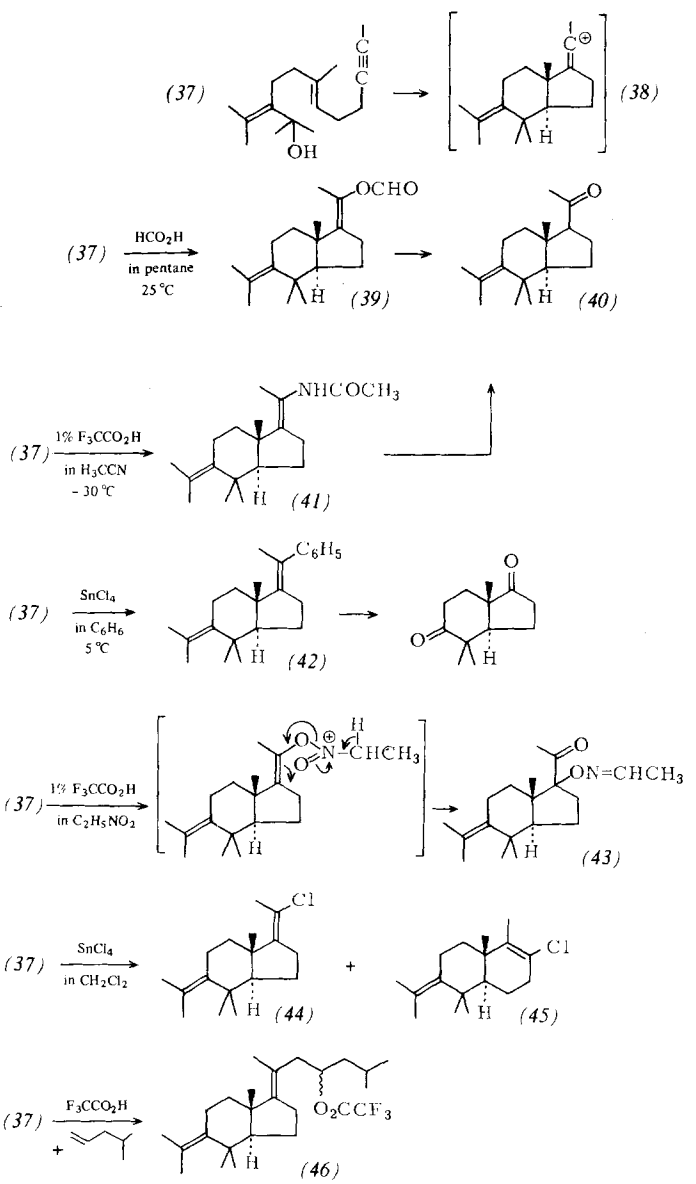


The total synthesis of a steroid was effected *via* cyclization of the tetraenol *(33)* which afforded (70% yield) the crystalline tetracyclic hydrocarbon *(34)*[24]. Ozonolysis of *(34)* gave (65% yield) the triketo aldehyde *(35)* which still retained the five new asymmetric centers that were generated in the cyclization step. Substance *(35)* was finally converted, through a double intramolecular aldol cyclodehydration, into (±)-16,17-dehydroprogesterone *(36)*.



5. Cyclizations Involving Participation of Acetylenic Bonds; Formation of Five-Membered Rings

Because the five-membered ring widely occurs in natural products, particularly in the D ring of steroids, it was of special interest to search for systems which would give five-membered ring closure in biomimetic processes. Since CC triple bonds located in the 5,6-position relative to a developing cationic center have a tendency to cyclize so as to give five-membered rings[25], it seemed reasonable to examine the behavior of such bonds as participants in polyene cyclizations. The dienynol *(37)* was examined as a model system and it did indeed undergo facile acid-catalyzed cyclization to give exclusively the 6/5 *trans*-fused ring system in high yield[26]. Thus upon treatment of *(37)* with formic acid, the enol formate

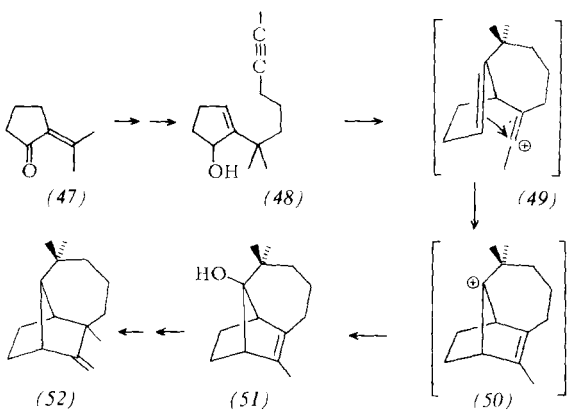


(39)[*] was produced in >90% yield. Hydrolysis yielded the ketone *(40)* which has all of the structural features of the C/D ring system of progesterone.

The cyclization of substance *(37)* involves either an intermediate or a transition state having the properties of a vinyl cation *(38)*. It is especially interesting that such cations can be generated efficiently under extremely mild conditions (*e.g.*, with 1% trifluoroacetic acid in a solvent at −78 °C) from a relatively stable ditertiary allylic cation. The energy for this transformation probably is provided by the conversion of π to σ bonds.

The vinyl cation *(38)* proved to be exceedingly reactive. Thus when it was generated in acetonitrile as the solvent, the nitrile reacted as a nucleophile giving, after work-up, the enamide *(41)*[*][26]. When stannic chloride in benzene—a system that had been employed successfully for the cyclization of olefinic acetals (see Section 3)—was used for the cyclization, the benzene was trapped by the vinyl cation giving the substance *(42)*[*][27]. Trifluoroacetic acid in nitroethane—which was the system of choice for the cyclization of the substrate *(33)* (see Section 4)—effected cyclization with capture of the nitroethane giving what proved to be the oxyimino compound *(43)*[28]. Another example of this type of cyclization is given below, *(53)*→*(68)*. Cyclization with stannic chloride in dichloromethane gave a mixture of five- and six-membered ring vinyl chlorides *(44)*[*] and *(45)*[29]. With trifluoroacetic acid in dichloromethane at −78 °C, the cyclization proceeded to give exclusively the six-membered ring chloride *(45)*, the "rearranged" vinyl cation evidently abstracting chloride ion from the solvent[30]. Finally it has been shown that the vinyl cation *(38)* can react with an alkene, *i.e.*, isohexene, to give the alkylation product *(46)*[*], thus developing the cholesterol-like side-chain. Vinyl cations can also react intramolecularly with olefinic bonds[26]. A case of special interest is described below.

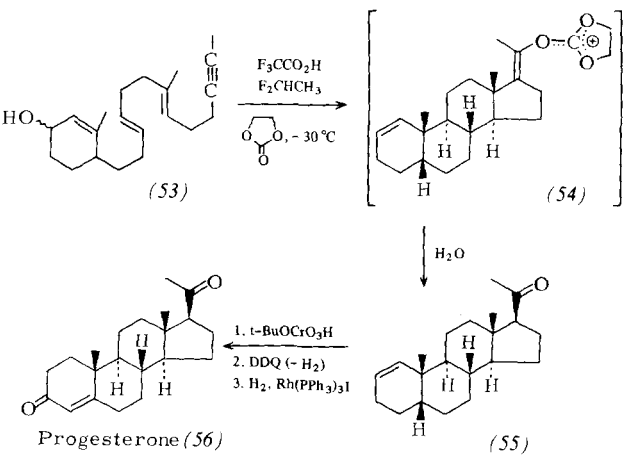
The cyclization of the cyclopentenol *(48)*, which is readily prepared in several steps *via* conjugate addition of the side-chain fragment to the unsaturated ketone *(47)*, proceeds, presumably *via* the cation *(49)* which reacts with the olefinic bond in the five-membered ring to form the 7-*anti*-norbornenyl type cation *(50)*. This tricyclic cation, on reaction with water added during work-up, is converted into the crystalline alcohol *(51)*. Under optimal conditions (CF_3CO_2H, 0 °C, 3 min) the yield for the conversion *(48)*→*(51)* is 75%. The structure of the alcohol *(51)* was established by its transformation



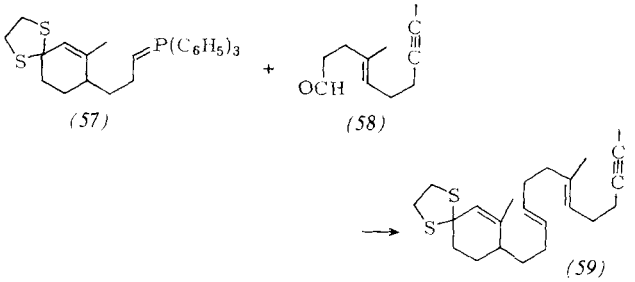
[*] The orientation of the substituents on the olefinic bond attached to the five-membered ring is unknown.

(several steps) into the natural product longifolene *(52)*, which was thus produced in 21% overall yield from 2-isopropylidenecyclopentanone *(47)*[31].

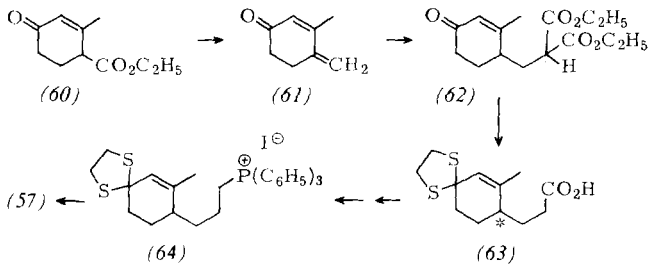
Attention is now turned to the total synthesis of steroids *via* the application of acetylenic participation in biomimetic polyene cyclizations. The trienynol *(53)* appeared to be a promising substrate for cyclization directly to the steroid nucleus. Indeed, under the indicated conditions, it was converted (65% yield) into the pregnenone *(55)* which, in turn, was readily transformed into progesterone *(56)*[32]. Ethylene carbonate was added to the cyclization mixture to serve as a nucleophile for capturing the vinyl cation, possibly in the form of the stabilized cation *(54)*.



Up to this point the synthesis of the cyclization substrates has been ignored. Attention is now turned to the preparation of the trienynol *(53)*[33]. A convergent approach was employed, the key step being the Wittig condensation of the phosphorane *(57)* with the aldehyde *(58)*. The Schlosser modification of the Wittig reaction was used in order to produce a *trans* olefinic bond in the product *(59)*. The conversion of substance *(59)* into the substrate *(53)* involved hydrolysis of the thio ketal to the unsaturated ketone which was reduced with lithium tetrahydridoaluminate.

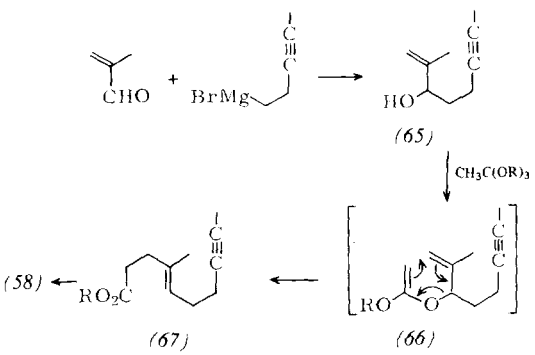


The phosphonium salt *(64)*, required for making the phosphorane *(57)*, was prepared from commercially available Hagemann's ester *(60)*. Conversion to the ethylene ketal followed by reduction with lithium tetrahydridoaluminate, then acid hydrolysis (which also effected dehydration) yielded the dienone *(61)*. This substance underwent a 1,6-Michael addition with malonic ester, giving the keto diester *(62)* which, on hydrolytic decarboxylation followed by reaction with ethanedithiol, was converted into the thio ketal acid *(63)*. This acid has an asymmetric center (indicated by the asterisk) and could be resolved into the (+) and (−) forms as the salts of optically active α-methylbenzylamine. Use of the (+)

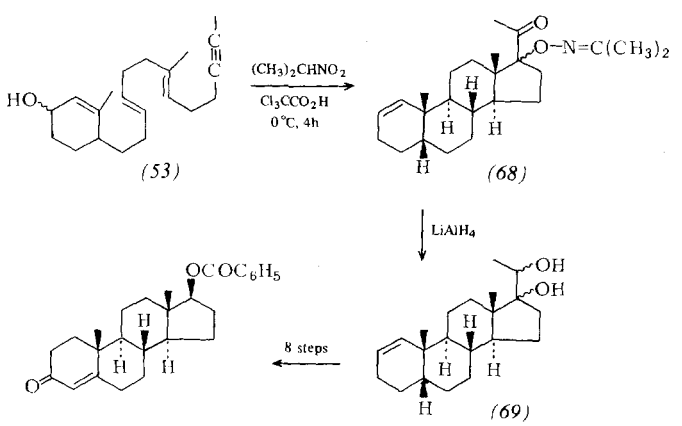


form of *(63)* in the remainder of the synthesis led to (+)-*(56)*, identical with natural progesterone.

The aldehyde *(58)* has been prepared in a variety of ways, one of which involves the addition of 3-pentynylmagnesium bromide to methacrolein. The resulting substituted allylic alcohol *(65)* was warmed with ethyl (or methyl) orthoacetate containing 5% propionic acid which effected the stereospecific orthoacetate Claisen reaction[34], involving the intermediacy of the ketene acetal *(66)*. The resulting enyne ester *(67)* was obtained in >90% yield, and the olefinic bond was >98% in the *trans* (*E*) form.

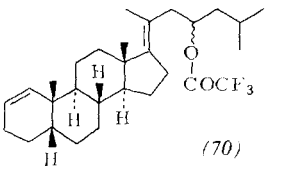


In other cyclization studies the trienynol *(53)* was treated with trichloroacetic acid in 2-nitropropane giving the oxyimino compound *(68)*[28], analogous to the formation of substance *(43)* (see above). This product was converted by hydrogenolysis with lithium tetrahydridoaluminate into the diol *(69)* which was transformed with periodate into the 17-keto compound and thence into testosterone benzoate[35].

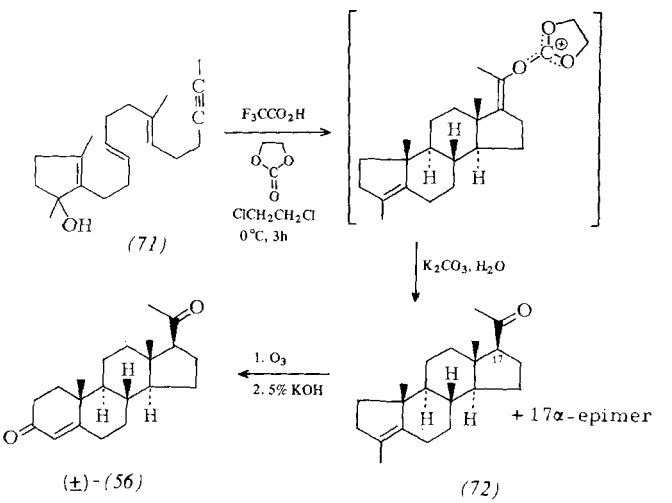


Testosterone benzoate

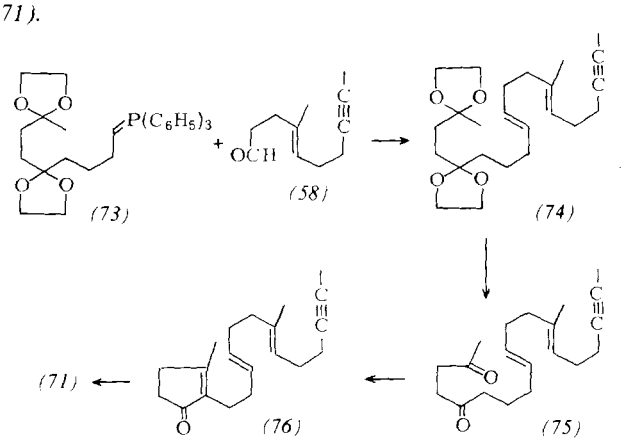
When the trienynol *(53)* was treated with trifluoroacetic acid in 1,1-difluoroethane containing isohexene at −60°C, the resulting vinyl cation reacted with the olefin (see above) to produce the adduct *(70)* in 30% yield[36]. The constitution of this product was proved by interrelationship with material produced from a natural steroid.



Another substrate that proved useful for synthesizing steroids is the cyclopentenol *(71)* which, on cyclization, produced the crystalline ketone *(72)* in 71% yield[26b]. Conversion of this product, *via* ozonolysis followed by intramolecular aldol condensation (see above), into (±)-progesterone was effected in >80% yield.



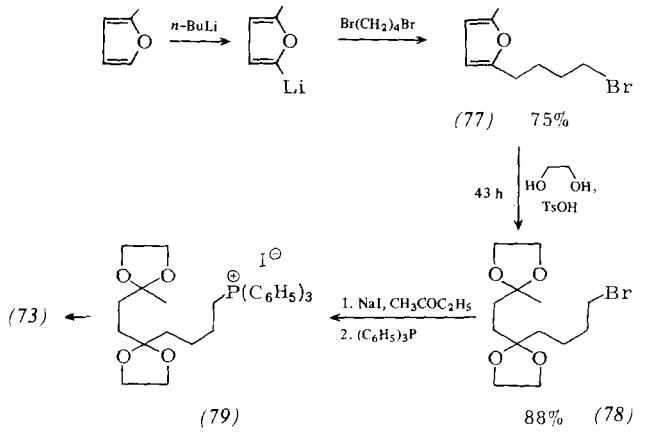
The synthesis of the cyclopentenol *(71)* was effected by the Wittig-Schlosser condensation of the aldehyde *(58)* (prepared as described above) with the phosphorane *(73)* as shown in the flow sheet. The product *(74)* was hydrolyzed to the diketone *(75)* which, in turn, was induced to undergo a base-catalyzed cyclodehydration, giving the unsaturated ketone *(76)*. Reaction of *(76)* with methyllithium gave the substrate *(71)*.



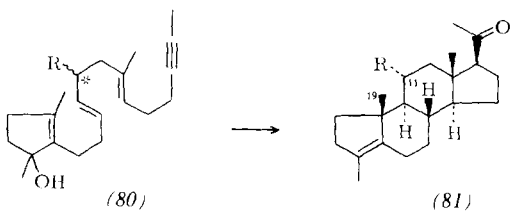
The synthesis of the phosphonium salt *(79)*, required for production of the aforementioned phosphorane *(73)*, was accomplished as summarized in the accompanying flow sheet. The step of particular interest is the cleavage of the furan ring of the alkylation product *(77)* under ketalization conditions, to give the diketal bromide *(78)*.

The cyclization of a number of substrates of the type shown by formula *(80)* has given only the 11α-substituted[*] products

[*] Steroid numbering.

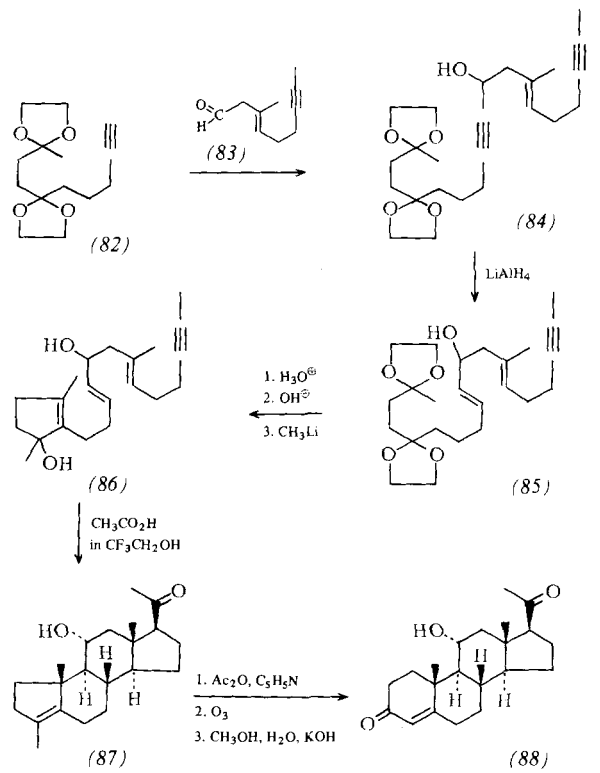


(81), probably because the transition state that would lead to the 11β-epimer involves serious non-bonded (1,3-diaxial type) interactions, *e.g.*, between the developing 11β-substituent and the C-19 methyl. Thus in the case where $R=CH_3$[37], $CH_2CCl=CH_2$[37], and $CH_2CH=CH_2$[37], the reaction *(80)*→*(81)*, which proceeded more slowly requiring more vigorous conditions than when R=H (see above), only one stereoisomeric form of the cyclized products *(87)* was produced in 50—60% yields. The exclusive formation of the 11α-epimer in the cyclization indicated that the reaction involves total asymmetric induction. Thus if the substrate *(80)* were obtained in one enantiomeric form with respect to the asymmetric carbon holding the R group, the product *(81)* should be optically pure. Preliminary studies of the cyclization of partially resolved substrate *(80)*, $R=CH_2CH=CH_2$, did indeed give an optically active tetracyclic product of undetermined enantiomeric purity[38].



In the cyclization *(86)*→*(87)*[39] the reaction appeared to be even slower than those mentioned above, requiring more severe conditions, perhaps because the nucleophilicity of the disubstituted olefinic bond was attenuated by the negative inductive effect of the allylic hydroxyl group. The best yield of the α-hydroxy tetracyclic product that has been produced to date is 40%[40]. Even so, a relatively efficient totally synthetic pathway to cortisone from simple chemicals has been defined[39] as follows:

The aldehyde *(83)* was prepared by reaction of the aforementioned allylic alcohol *(65)* with thionyl chloride to afford the allylically transposed chloride which, in turn, was condensed with the anion of dithiane. Hydrolysis of the product gave the aldehyde *(83)*. The diketal acetylene *(82)* was produced by reaction of lithium acetylide with the lower homolog of the diketal bromide *(78)*. Conversion of the tetracyclic product *(87)* into 11α-hydroxyprogesterone *(88)* was carried out *via* the oxidation-cyclodehydration sequence described above [*(72)*→*(56)*]. The substance *(88)* is a known intermediate in the commercial synthesis (*ca.* 50% overall yield) of hydrocortisone acetate. Although the yields have not been



optimized for a number of steps, the overall yield of *(88)* at the present stage of refinement is 15.4% in 16 steps from methacrolein and 2-methylfuran. The preparation and cyclization of the resolved form of the substrate *(86)* is under study.

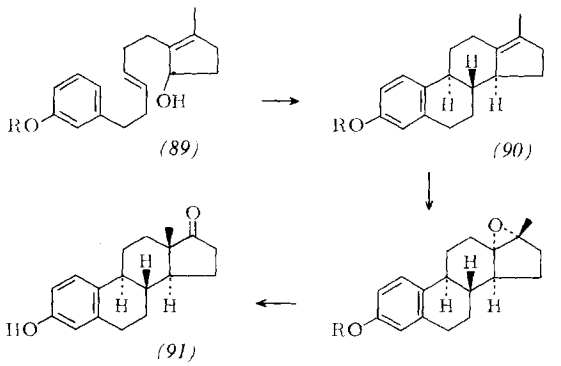
6. Concerning the Mechanism of Polyene Cyclizations

The question of the mechanism of stereospecific cationic polyene cyclizations, whether enzymic or biomimetic, has been open to debate. On the one hand, the intermediacy of partially cyclized cations (classical or bridged) has been shown to be consistent with the observed stereochemical course of such cyclizations[41]. On the other hand, a concerted process in which all of the new CC bonds are formed synchronously represents an equally satisfactory rationalization of the facts. There has been very little direct evidence obtained for deciding between the "stepwise" and the "synchronous" mechanisms; however, at the present time the balance (see below) is somewhat in favor of the latter.

It has been demonstrated by deuterium incorporation experiments that certain enzymic[42] as well as biomimetic[43] polyene cyclizations do not involve partially cyclized olefinic intermediates which would require reprotonation (and consequent deuterium incorporation) in order for the cyclization to continue. This finding, however, does not preclude a stepwise process involving cations which do not deprotonate.

Kinetic studies of solvolysis of a series of substituted dienic *p*-nitrobenzenesulfonates (see formula *(3)* above) in both acetic acid[44] and in trifluoroethanol[45] have shown small, but incremental, rate enhancements by substituting the vinyl hydrogens of the terminal olefinic bond by methyl groups. These effects represent a necessary, but not sufficient, condition for the synchronous mechanism. Other results consistent with the synchronous process are presented below.

In connection with a total synthesis of estrone *(91)* from *(89)*[46], a thorough study was made of the key step, namely



(89) (90) (91)

the Lewis acid-catalyzed biomimetic cyclization *(89)*→*(90)* which proceeds in high yield. In addition to the product *(90)*, there was always obtained some of the isomer resulting from cyclization *ortho*, instead of *para*, to the OR group. The *para*/*ortho* ratio varied depending on the nature of the allylic leaving group in the substrate[47]. For example, in the case of *(89)* having a free hydroxyl group, the ratio was 8.4; on the other hand, when the leaving group was trimethylsilyloxy the ratio was 2.6. Thus the effect of the leaving group is "felt" in the bonding of the aromatic nucleus to the internal olefinic bond, suggestive of a synchronous process. Moreover, kinetic studies of the cyclization of the substrate *(89)* having other groups (*i.e.*, CH_3, H, CF_3) in place of OH in the aromatic nucleus gave decreasing rates as the groups became more electronegative[47]. These findings are also consistent with a synchronous process. Although the evidence points strongly toward a synchronous process in the case of the cyclization *(89)*→*(90)*, it should be emphasized that this result does not constitute proof that all cationic polyene cyclizations are synchronous.

7. Conclusion

Acid-catalyzed biomimetic polyene cyclization of acyclic chains is a viable synthetic tool for the stereospecific formation of polycyclic systems. Acetal as well as allylic alcohol functions are useful initiators for these cyclizations, and methylacetylenic end groups are particularly useful terminators which can give exclusive five-membered ring formation, and thus make possible the total synthesis of the steroid nucleus in a single step starting from a one-ring substrate.

The stereochemical course of natural, enzymic polyene cyclizations may to some extent be guided by the same effects that seem to control the non-enzymic processes, *i.e.*, the course of the reaction results from *trans-anti-parallel* electrophilic addition to the olefinic functions according to the prediction of *Stork et al.*[3a] and *Eschenmoser et al.*[3b].

Special thanks are due to my numerous collaborators who have made many significant contributions to the planning of this research endeavor, and who were completely responsible for its reduction to practice. I wish also to thank the National Institutes of Health and the National Science Foundation who have afforded the major financial support to our program.

Bacteriorhodopsin as an Example of a Light-Driven Proton Pump[**]

By Dieter Oesterhelt[*]

Apart from the long known visual pigments, another retinal protein complex exists in nature, *viz.* bacteriorhodopsin from halobacteria. In contrast to the visual pigments such as the rhodopsins, which act as light sensors in the eye, bacteriorhodopsin actually transforms light energy. This energy conversion is connected with the asymmetric incorporation of bacteriorhodopsin in the lattice structure of the purple membrane which forms patches on the cell surface of halobacteria. Alongside the chlorophyll system, the purple membrane system represents the second light energy conversion principle to be discovered in living nature. Bacteriorhodopsin acts as a light-driven proton pump or as the main component of such a pump system. Absorption of light triggers off a cycle of reactions coupled with the spatially oriented uptake and release of a proton. In the intact cell an electrochemical gradient is thus built up across the cell membrane of the bacterium in which part of the absorbed light energy is stored and which is not dependent upon redox processes as in the case of respiration or photosynthesis. This electrochemical gradient can supply the energy required for ATP synthesis in the cell; a reversible proton-translocating ATPase serves as catalyst system.

1. Introduction

The questions of biological conservation and conversion of energy have long played an important role in bioenergetics. The universal storage form of energy is adenosine triphosphate (ATP)[1]: it stores chemical energy in the form of a high phosphate transfer potential and the free energy of hydrolysis of its phosphoric anhydride bonds serves to drive endergonic processes in the cell, for instance the biosynthesis of endogenous substances and the energy-dependent uptake of nutrients and salts against prevailing concentration gradients. Two pathways have hitherto been known for energy storage by ATP synthesis:

1) Substrate level phosphorylation of adenosine diphosphate (ADP) and

2) electron transport chain phosphorylations (oxidative and photophosphorylation) of ADP.

During energy storage by substrate level phosphorylation, enzyme-catalyzed reactions raise the phosphorylation potential of organic phosphates until ADP can be phosphorylated. The energy required for this kind of ATP formation is supplied by the free energy of *intra*molecular redox reactions, *e.g.* in lactic acid fermentation where one mole of glucose is transformed into two moles of lactate.

In contrast, energy storage by oxidative phosphorylation involves transfer of the electrons of an oxidizable substrate, *e.g.* lactate, *via* a chain of intermediate carriers—termed a respiratory chain—to atmospheric oxygen. Thus here too, redox energy is transformed into the free energy of formation of a phosphoric anhydride bond in the ATP molecule, but *via inter*molecular processes. The way in which ATP synthesis is coupled to oxidation of a substrate molecule has not yet been completely elucidated. In photophosphorylation (*e.g.* in bacteria), light absorption in a chlorophyll molecule effects release of an electron which then finds its way back to the chlorophyll *via* an electron transport chain resembling the respiratory chain. Again, phosphorylation of ADP is coupled to this electron flow. It is called cyclic photophosphorylation.

The bacteriorhodopsin system, the subject of this paper, differs from the previously known types of biological energy storage. Neither the raising of a phosphorylation potential nor a transport of electrons is coupled to its light energy converting function. All available evidence indicates that the absorbed light energy is not initially transformed into redox energy but directly into the energy of an electrochemical gradient which then drives the ATP synthesis. Before going into details about bacteriorhodopsin as a light-driven proton pump, we shall first consider the fundamental difference between substrate level phosphorylation and electron transport chain phosphorylation.

2. Pathways of ATP Formation

The formation of phosphoenolpyruvate *(2)* from 2-phosphoglycerate *(1)* by dehydration and subsequent ATP formation with liberation of pyruvate *(4)* (Fig. 1) may be cited as an example of substrate level phosphorylation. The high phosphorylation potential of phosphoenolpyruvate arises from the proclivity of the nascent enol form *(3)* of the pyruvate to transform into the keto form *(4)*. The free energy of hydrolysis of ATP is 7 kcal/mol, but that of phosphoenolpyruvate 12 kcal/mol.

[**] Based on a lecture delivered at the "Chemiedozenten-Tagung", Düsseldorf, April 1975.

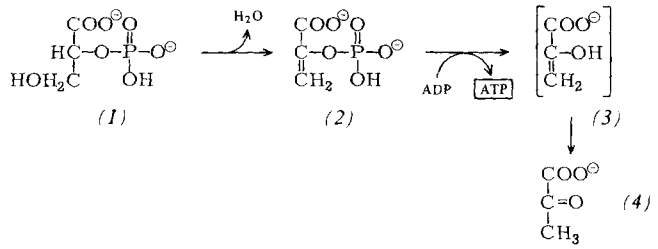

Fig. 1. Formation of ATP from phosphoenolpyruvate (2) and ADP as an example of substrate level phosphorylation.

While the substrate level phosphorylation can be described in terms of familiar transparent reactions, this does not hold for oxidative or photophosphorylation. In the latter cases, ATP synthesis is coupled to electron transport processes which are driven by light or by the negative redox potential of organic compounds. Just how this redox energy is converted into the free energy of hydrolysis of the ATP molecule is the topic of three hypotheses (Fig. 2).

According to the conformational hypothesis, conformational changes are coupled with the redox state in the case of some proteins participating in electron transport chains, *e.g.* cytochromes. As in the chemical hypothesis, a protein-phosphate compound should again have a higher phosphorylation potential in the oxidized than in the reduced state and can therefore phosphorylate ADP.

The third hypothesis, which is nowadays steadily increasing in favor, is the chemiosmotic hypothesis due to *Mitchell*[2]. He assumes that the energy liberated on oxidation of the organic substrate is transformed into an electrochemical gradient between the interior and exterior of the cell, *i.e.* in contrast to the other two hypotheses there is no chemically detectable intermediate between oxidation of the substrate and formation of ATP from ADP and inorganic phosphate. This reaction takes place on an enzyme complex which catalyzes formation of the phosphoric anhydride bond while destroying the electrochemical gradient.

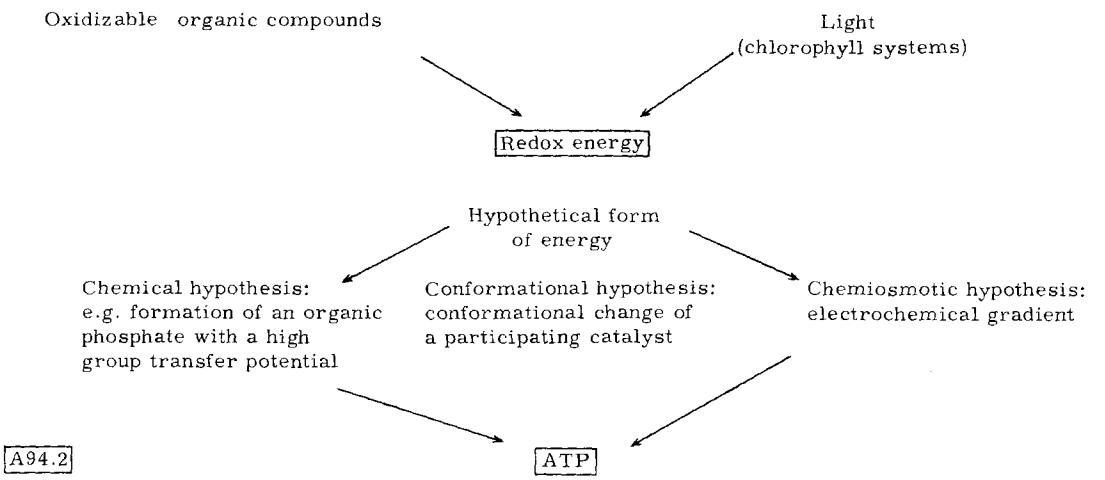

Fig. 2. Hypotheses concerning electron transport chain phosphorylation.

The "chemical hypothesis" states that organic phosphates change their phosphorylation potential simultaneously with their redox state and thus become able to phosphorylate ADP.

Figure 3 shows the requirements for conversion and storage of energy according to the chemiosmotic hypothesis. All electron transport chain phosphorylations occur exclusively on membranes: on the cell membrane in bacteria and on the

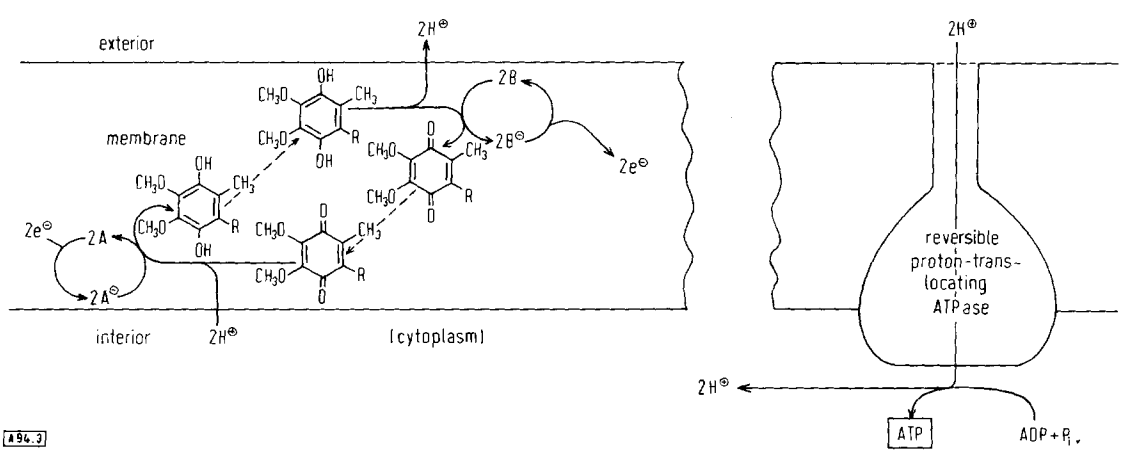

Fig. 3. Example of an electron transport chain phosphorylation (according to *Mitchell*'s chemiosmotic hypothesis, see text for details). Essential conditions are: 1) Presence of a separating membrane; 2) asymmetric distribution of catalysts (A, B) in the membrane; 3) presence of diffusible proton transporters (in this case ubiquinone = coenzyme Q). The dashed arrows between the two (identical) quinone and hydroquinone molecules are intended to indicate the diffusion of these molecules.

inner mitochondrial membrane in higher cells. A membrane is most simply defined as a lipid-protein mixed phase, which separates two aqueous reaction spaces and is semipermeable. The catalysts (A, B) of the electron transport chain are distributed asymmetrically in this phase, *i.e.* they lie more toward the interior or more toward the exterior reaction space. Also of importance is the presence of diffusible "proton transporters" such as quinones and hydroquinones in the membrane. Figure 3 shows a section of an electron transport chain in which—going from left to right—electrons reduce a catalyst A on the "inside" of the membrane to A^-. This ion is reoxidized by a quinone, which, to this end, takes up two protons from the cytoplasm and is converted into the corresponding hydroquinone. The hydroquinone diffuses freely through the membrane and can thus be reoxidized to the quinone by B, a second catalyst in the respiratory chain, on the "outside" of the membrane. Two protons are released to the external medium, and the quinone returns to the cycle. The electrons are transported *via* further intermediate catalysts to the final electron acceptor, frequently oxygen. However, some organisms also utilize nitrate, sulfate, or even organic substances for this purpose. Hence, Figure 3 illustrates that section of a two-electron transfer with which transport of two protons out of the cell through the membrane to the exterior is strictly coupled.

Now what is the result of this proton transport? If the membrane were impermeable to ions, the change in redox potential during oxidation of a substrate would be completely transformed into a membrane potential. This membrane potential is the electrostatic field built up by the transported protons. Such potential differences between the interior and exterior of a cell can reach about 300 mV. Bearing in mind that the charges are separated only by the *ca.* 30 Å—thick lipid phase of the membrane, we see that the field strengths must be of the order of 100000 V/cm, *i.e.* extremely high.

Let us now consider a second non-ideal case in which the cell membrane is hardly permeable to protons but more permeable to other cations, *e.g.* potassium ions. This permeability is due to passive diffusion and can be enhanced by ion transporters like cyclic antibiotics or natural carriers (facilitated diffusion). The driving force for the influx of potassium ions (or other cations) is always the electrostatic field generated by the electron-transport driven proton pump. Depending upon the permeability conditions in the separating membrane, the chemical potential of the protons pumped out

$$\Delta\mu_{H^+} = F\Delta\psi - 2.3RT\Delta\,(\mathrm{pH})$$

will be distributed to differing extents between two quantities, *viz.* the membrane potential (electrostatic field) and the concentration gradient. According to the chemiosmotic hypothesis, the electromotive force is thus converted into a "protonmotive" force

$$\Delta p = \Delta\psi - Z\Delta\,(\mathrm{pH})\,[\mathrm{mV}]; \quad Z = 59$$

which supplies the free energy required for ATP synthesis in the cell interior. To this end, the protons previously pumped out are channeled back into the cell by an enzyme system, called reversible proton-translocating ATPase, with concomitant ATP synthesis (Fig. 3). The overall process of energy storage thus comprises two partial steps:

1) Protons are channeled out of the bacterial cell in a pumping action driven by redox processes and build up a potential gradient.

2) The energy of the returning protons is utilized for the enzymatic synthesis of adenosine triphosphate.

Table 1. Some ATPases whose common catalytic property is the coupling of the electrochemical potential of an ion with the ATP hydrolysis/synthesis equilibrium.

Name	Occurrence	Function
Ca^{2+} ATPase	sarcoplasmic reticulum (muscle)	regulation of Ca level in muscle
Na^+/K^+ ATPase	cell membrane, *e.g.* nerve cells	maintenance of high intracellular K level
H^+ ATPase	mitochondria, bacteria	ATP synthesis

Reversible translocating ATPase is not the only enzyme able to couple an electrochemical gradient with the synthesis and hydrolysis of ATP[2a]. ATP synthesis at the expense of an ionic gradient has been established for both the "calcium pump" of the sarcoplasmic reticulum in muscle and the "sodium-potassium pump" in plasma membranes. However, viewed physiologically, it is the task of the calcium and the sodium-potassium pump to generate an ionic gradient by ATP hydrolysis, but that of the proton pump to exploit such an ionic gradient for ATP synthesis (Table 1). The enzymatic mechanism of the energy coupling is one of the central unsolved problems of biochemistry. Nor has the mode of operation of the proton pump driven by electron transport yet been elucidated.

Let us now return to the bacteriorhodopsin system! Like the electron transport chain of photosynthesis, bacteriorhodopsin can be described as a light-driven proton pump which, embedded in the cell membrane, also builds up an electrochemical gradient that is exploited for ATP synthesis in the cell[3]. Nor is the source of primary energy new in this system—it is simply light as in the case of green plants or photosynthetic bacteria. What is new is the mode of action of this pump, for it is not dependent on a flow of electrons. A cycle of conformational changes of bacteriorhodopsin following light absorption is responsible for the pumping action on protons.

3. Occurrence, Isolation, and Structure of the Purple Membrane

Halobacteria, in which bacteriorhodopsin is found, are truly remarkable organisms. These bacteria live only in common salt solutions of maximum concentration and even survive in crystalline salt. They were discovered in Scandinavia around the beginning of the century on dried salted fish which was considered to be spoilt on account of its reddish color[4].

In seawater basins for salt production or evaporating lagoons, *etc.*, halobacteria reach high cell population densities which give rise to extensive red coloring as a result of their carotenoid pigments. Exceptional properties are the rule for these bacteria. Thus they possess a cell wall made up exclusively of protein aggregates. The cells have a diameter of about 0.5 μm and a length of 5—10 μm. On viewing the cell surface after removal of the wall by freeze fracturing, the cell membrane does not appear to be homogeneous but instead bears patches

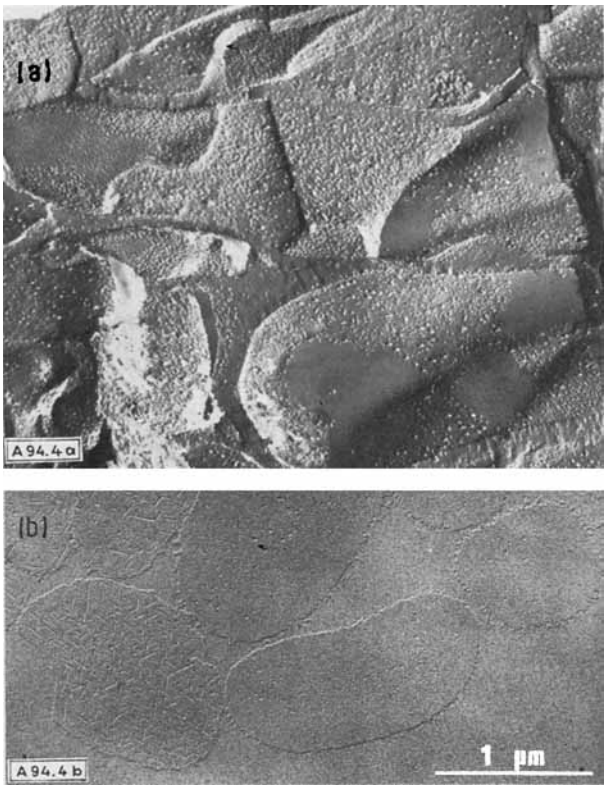

Fig. 4. Electron micrograph of purple membrane patches (*Halobacterium halobium*). a) Purple membrane patches in intact cells. The surface of the patches appears smooth or rough depending upon whether the inside or the outside of a cell is being shown. At the same time, a pronounced structural asymmetry of the membrane patches is to be seen (according to ref. [7]). b) Isolated purple membranes after spraying onto freshly cleaved mica and shadowing with platinum/carbon (photograph by *M. Clavier*).

of about 0.5 µm in diameter (Fig. 4a). Fortunately, these patches can be isolated preparatively and studied *in vitro*: if halobacteria are exposed to pure water, the cells lyze and the cell membrane fragments can be separated by simple centrifugation techniques[5, 6].

The heaviest fraction has a deep purple color and is therefore called the purple membrane fraction. It consists of membrane sheets having a diameter of about 0.5 µm. Physical studies by *Blaurock* and *Stoeckenius* have revealed that this fraction actually comprises the above-mentioned patches which are scattered over the cell membrane as differentiated regions[7]. This purple membrane is composed of 75% protein and 25% lipid. The protein component consists of a sole species, bacteriorhodopsin, whose molecular weight is about 26000 daltons (Fig. 4b). The difference between the inner and outer membrane surfaces is underlined by the appearance of cracks in only half of the membrane patches.

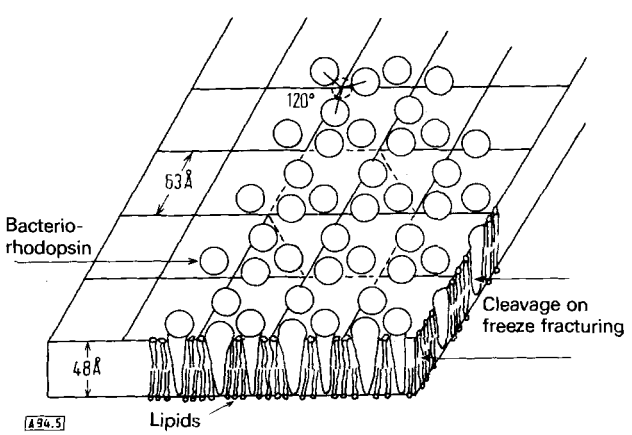

Fig. 5. Schematic representation of the purple membrane structure according to *Blaurock*, *Stoeckenius*, and *Henderson*[7–9].

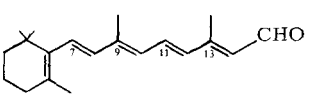
Figure 5 summarizes our present knowledge about the structure of the purple membrane. Bacteriorhodopsin is arranged in groups of three molecules each at the points of a two-dimensional hexagonal lattice. The purple membrane is only about half as thick as other membranes; like the periodic arrangement of the protein, this also emphasizes that the purple membrane is by no means a normal biological membrane. As hinted in Figure 5, the protein molecules span the entire cross-section of the membrane or at least a considerable part thereof; each bacteriorhodopsin molecule is markedly asymmetric and all these molecules are oriented in the same direction. Very recent investigations by *Blaurock* and *Henderson* have shown that a considerable part of the protein is present in helical form and that these helices are arranged perpendicular to the plane of the membrane[8, 9]. The non-uniform distribution of the protein over the two surfaces of the membrane—about two-thirds on one side and one third on the other—can be demonstrated by freeze fracturing and observation of the replicas in an electron microscope. The hexagonal structure of the purple membrane can also be rendered visible by adsorbing membrane patches on *e.g.* mica, drying, and shadowing with platinum/carbon. On shrinking, the membrane cracks along the hexagonal edges; this follows from the observation that the cracks run parallel to each other or at angles of 60 or 120° (cf. Fig. 4b).

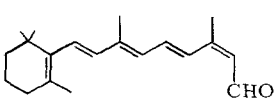
Summarizing, it may be said that bacteriorhodopsin is organized asymmetrically in the cell surface of the bacterium in the form of periodically arranged aggregates, and that this uniform orientation in the membrane structure is an essential prerequisite for the proton pumping action of the molecule.

4. The Chromophore of Bacteriorhodopsin and Its Photochemical Cycle

Halobacterium halobium is the only bacterium in which vitamin A aldehyde (retinal) has so far been detected. This substance otherwise occurs only in organisms having the power of vision.



all-*trans*-retinal



13-*cis*-retinal

Retinal, which exhibits an absorption maximum in the near UV at 380 nm, is covalently bound to the protein bacterioopsin in bacteriorhodopsin. Through interaction with its amino acid side chains, retinal forms a chromophore with the protein; the absorption maximum shows a considerable red shift, occurring at 560 nm, and is responsible for the purple-violet color of the membrane (Fig. 6). The chemical structure of this chromophore is unknown. It is called purple complex and also appears in a test tube on mixing of retinal and bacterioopsin. The specificity is very pronounced; only 13-*cis* and all-*trans* retinal afford the chromophore[10].

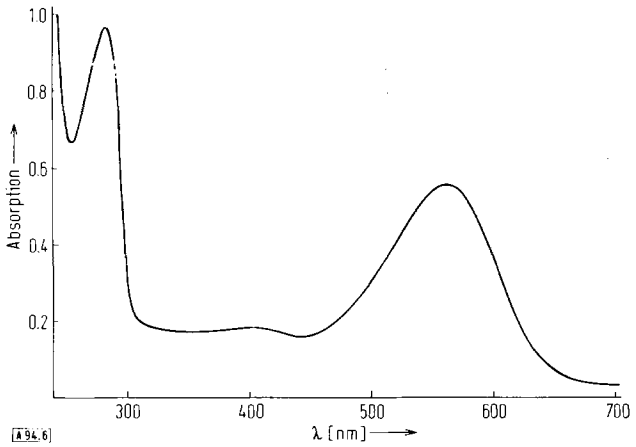


Fig. 6. Absorption spectrum of the purple membrane.

This clearly differs from the visual pigments, whose chromophore can only be formed with 9-*cis*- or 11-*cis*-retinal, *i.e.* the physiological retinal isomer. As light sensors, the visual pigments have a completely different function from the light transducer bacteriorhodopsin; this could be due to the presence of different retinal isomers.

The primary photochemical reactions in the visual pigments and in bacteriorhodopsin are similar. The light quantum absorbed by the chromophore induces changes not only in the chromophore itself but also in the surrounding protein structure. This conformational change triggers the visual process in the case of the visual pigments; in bacteriorhodopsin it leads to a product which regenerates the original chromophore within milliseconds, *i.e.* bacteriorhodopsin is subject to a thermoreversible photochemical reaction. Visual pigments do not display this thermoreversibility. This difference is most probably due to the presence of 11-*cis*-retinal as a component of these retinal-protein complexes. Light induces the isomerization of the thermodynamically unstable (because sterically hindered) 11-*cis* compound to the all-*trans* form which is unable to regenerate the original chromophore. Only an external supply of 11-*cis*-retinal leads to regeneration of the visual pigment rhodopsin[11].

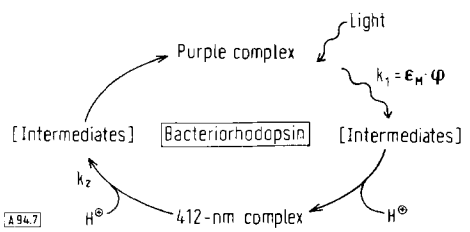

Fig. 7. Photochemical cycle of bacteriorhodopsin.

Figure 7 shows the thermoreversible photochemical reaction of bacteriorhodopsin as a cycle and emphasizes two particular states of the chromophore or the chromoprotein: the purple complex (or 560-nm complex) and the 412-nm complex. Absorption of light by the purple complex ($\varepsilon_M = 63000$) leads with a quantum yield (φ) of about 0.8 *via* one or more intermediates to the 412-nm complex, the longest-lived intermediate of the cyclic reaction sequence. From there, a reaction leads back to the starting state.

Under appropriate irradiation conditions the purple complex and the 412-nm complex form a quasi-steady state mixture whose spectral characteristics can be recorded in a rapid scan spectrophotometer. Figure 8 compares the absorption bands of the two chromophore states. Even if more than two states of the protein are involved in the photochemical cycle of bacteriorhodopsin (B), the rate constants of the formation and decomposition of the longest-lived intermediate (412-nm complex) suffice for derivation of the rate law of this reaction cycle:

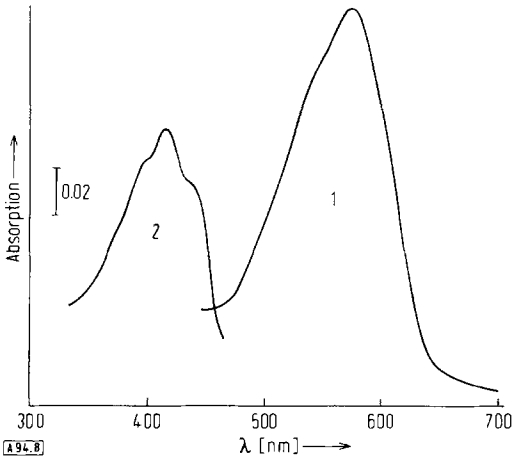

Fig. 8. Absorption bands of the bacteriorhodopsin chromophore in two different states (frozen at −196 °C): 1) purple complex in the dark. 2) the longest-lived intermediate (412-nm complex) of the photochemical cycle in the light.

$$V = \frac{k_2\,[B]}{1 + k_2/\varepsilon\varphi J} \qquad V_{max} = k_2\,[B]$$

$$k_1 = \varepsilon_M \varphi$$

The rate of decay of the 412-nm complex is determined only by its own concentration, whereas the rate of its formation depends upon the light intensity (J) and the concentration of the purple complex. The situation resembles a classical Michaelis-Menten relation between the rate of an enzymatic reaction and the substrate concentration: in the case of bacteriorhodopsin (B) the substrate concentration is replaced by the light intensity. If the intensity is increased the rate of reaction increases until it reaches a constant value k_2 [B] which is independent of light intensity (but dependent upon temperature). This is analogous to the turnover number of an enzyme and can be determined experimentally as k_2. Accordingly, the cycle is found to be repeated about 200 times per second in bacteriorhodopsin at room temperature and light saturation.

Two further properties of the photochemical cycle also deserve mention in this context. Under natural illumination conditions the cycle is light-limited, *i.e.* it does not attain its maximum rate. Moreover, there is a photochemical retroreaction leading from the 412-nm complex to the purple complex[12].

Under suitable experimental conditions the different properties of the purple complex form and the 412-nm complex form of bacteriorhodopsin can be determined[13]. These are:

1) Differing tryptophan fluorescence, indicating conformational differences between the two forms.

2) Differing reactivity of the chromophore toward hydroxylamine and hydridoborate. Only the 412-nm complex (or one of the other intermediates) reacts *via* liberation of retinal oxime or irreversible fixation of a retinyl group to the protein.

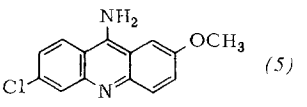
This behavior can be attributed to a differing spatial arrangement of the protein in the environment of the chromophore and/or a change in the electronic structure of the chromophore. In this connection. the difference between the spectra of the two forms is remarkable (cf. Fig. 8). While the purple complex displays the typical spectrum of a retinal compound, the 412-nm form has a three-peak spectrum typical of *retro*-retinals[12], *i.e.* retinals in which the double bonds are shifted by one position.

3) Differing energy content. Part of the light energy absorbed is stored in the 412-nm complex, as is evident from its complete transformation into the purple complex in the dark.

4) Differing p*K* values. Of crucial importance for the function of bacteriorhodopsin as an ion pump is the shift in p*K* values of the protein on going from one form to the other. Protons are liberated on transition to the 412-nm complex, and taken up again on regeneration of the purple complex.

The photochemical cycle of bacteriorhodopsin is thus accompanied by successive release and uptake of a proton. The light energy absorbed, amounting to some 50 kcal/mol, is distributed between the bacteriorhodopsin and the proton. Part of it is transferred to the 412-nm complex and drives the photochemical cycle, while the remainder permits the proton to build up the electrochemical gradient. We may further expect the proton to leave the protein molecule at a site other than that reserved for uptake of the next proton, in other words that each individual bacteriorhodopsin molecule (or possibly, even a defined association of protein and lipid) is a molecular pump. However, a net proton transfer will only be observed if the bacteriorhodopsin molecules are not arranged randomly but all possess the same orientation as in the cell membrane.

The situation in the cell can be simulated by a very simple artificial system which permits the study of bacteriorhodopsin as a proton pump. *Racker* and *Stoeckenius* were the first to show that the purple membrane can be incorporated into lipid films in such a manner that the orientation of bacteriorhodopsin is retained in a system that can form a vesicle (proteoliposome) enclosing a volume separated from the solution and thus serving as a model for a cell[14]. On irradiation of such proteoliposomes the external medium becomes alkaline, *i.e.* the bacteriorhodopsin pumps protons into these vesicles. When the light is switched off, the protons flow back out of the vesicles so that the pH of the external solution returns to its original value (Fig. 9a). Since these protein lipid vesicles are too small to permit pH measurement in their interior we have to resort to an indirect method of establishing the pH gradient. This can be accomplished with fluorescing amines[15] whose unprotonated form can easily penetrate the lipid wall of the vesicles while the protonated cannot do so. Amines such as 9-amino-6-chloro-2-methoxyacridine *(5)* are therefore distributed between the inner and outer phase in accord with the pH gradient. It was shown for chloroplasts and liposomes that the fluorescence of the dye accumulating in the interior is completely suppressed and that the extent of fluorescence suppression is a measure of the resulting pH gradient. The finding shown in Figure 9b confirms our prediction that bacteriorhodopsin transports protons into the interior by a pumping action and that the acridine derivative accumulates. On irradiation the fluorescence of the added dye *(5)* is extinguished; it reappears when the light is switched off.



(5)

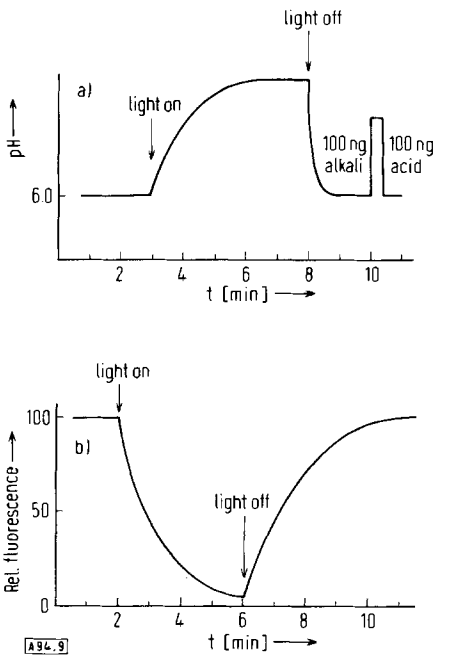


Fig. 9. Demonstration of a light-generated pH gradient with lipid vesicles (proteoliposomes) containing bacteriorhodopsin. a) Reversible pH increase of the exterior medium on illumination (ΔpH $\approx$ 0.1). b) Reversible change in fluorescence of the acridine dye 9-amino-6-chloro-2-methoxyacridine *(5)* in the interior of a lipid vesicle on illumination. Bacteriorhodopsin: 5×10^{-7} mol/l; *(5)*: 2×10^{-6} mol/l.

A pH gradient of the size shown in Figure 9a (ΔpH $\approx$ 0.1) can only arise if the inward pumping of protons is accompanied by an efflux of other cations or an influx of anions. As mentioned in Section 2, this counter-transport can be due to the permeability of the separating layer. However, it could also be an inherent property of the pump molecule, *i.e.* bacteriorhodopsin could take up a potassium ion, for instance, for each proton released in its photochemical cycle. Bacteriorhodopsin would then be a light-driven ion exchanger having a neutral pump effect, *i.e.* the potential component of the proton-motive force generated by the pump would always be equal to zero. We can, however, be sure that bacteriorhodopsin is not an electrically neutral pump of this kind but rather an electrogenic pump, *i.e.* that the photochemical cycle is accompanied only by the cyclic release and uptake of protons. On the one hand, the build-up of the pH gradient and suppression of fluorescence by the pump are limited by a slower process, *e.g.* counterdiffusion of a cation. On the other hand, *Skulachev et al.* have incorporated bacteriorhodopsin into planar lipid films separating two compartments of aqueous electrolyte solutions and succeeded in generating (and measuring) potentials of up to 300 mV in this system by irradiation[16]. Summarizing, we may say that bacteriorhodopsin acts as an electrogenic pump for protons with a turnover number of about 200 s^{-1}.

5. Energy Conversion in the Intact Cell

In the intact cell bacteriorhodopsin is oriented in the opposite direction compared to the situation in proteoliposomes, *i.e.* protons are pumped out of the cell (Fig. 10). It can be

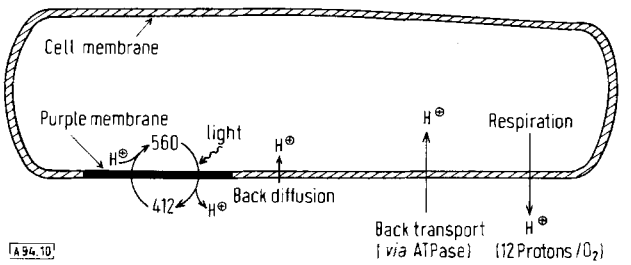

Fig. 10. Schematic representation of the proton translocating events in the halobacterium cell. 412 = 412-nm complex; 560 = purple complex.

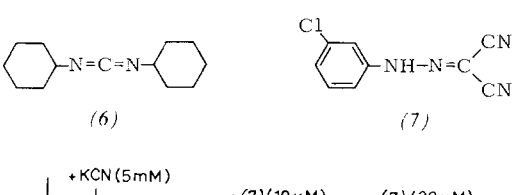
calculated from the turnover number, the bacteriorhodopsin concentration of the cell (about half the cell surface is covered by purple membrane), and the volume of a cell that, given light-saturation, a proton-motive force of about 300 mV can be generated within a millisecond, a value sufficing for ATP synthesis. All other ion flows observed so far are slower, including the passive back-diffusion of protons without performing any work. Thus bacteriorhodopsin-driven ATP synthesis can start-up immediately, but must satisfy a number of requirements: inhibitors of ATPase such as dicyclohexylcarbodiimide *(6)* or uncouplers (substances which drastically raise the permeability of the cell membrane to protons) must suppress the photophosphorylation of the cells. Furthermore, competition is also expected between the light-driven proton pump bacteriorhodopsin and the electron transport-driven proton pump. The two proton pumps do indeed compete; quantitative comparison of absorbed quanta and unconsumed oxygen shows that not only the photochemical cycle of bacteriorhodopsin, but also the energy conversion within the cell under physiological conditions, proceed with a high quantum yield[17].



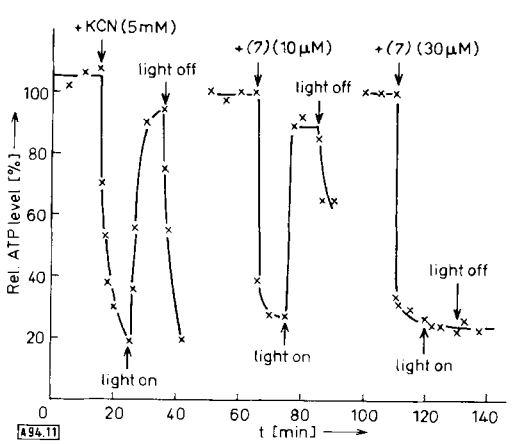


Fig. 11. Effect of cyanide and the uncoupler *m*-chlorophenylhydrazonomalononitrile *(7)* on photophosphorylation in halobacteria (according to ref. [19]).

Photophosphorylation[18, 19] can be detected in halobacteria under anaerobic conditions or after respiratory poisoning by cyanide. Figure 11 shows how added potassium cyanide (5 mmol/l) lowers the intracellular ATP level from 100 to about 20 %, since oxidative phosphorylation is inhibited and substrate level phosphorylation is not operative under the conditions given. If the light is now switched on the ATP level rises to almost the same value as that attained on maximum respiration. Since the halobacteria do not contain chlorophyll this is a new type of phosphorylation. If an uncoupler, *e.g. m*-chlorophenylhydrazonomalononitrile *(7)*, is added to the respiring cells in a further experiment, then at a concentration of 10 µmol/l the respiration is rendered inefficient as an electron-transport driven pump, *i.e.* the ATP level falls because protons no longer synthesize ATP on translocating ATPase but undergo passive diffusion through the now permeable cell membrane, *i.e.* without performing any work. Evidently being a more efficient pump, bacteriorhodopsin can pump the protons out of the cell faster than they can flow back in passively and hence the ATP level returns almost to the original value on irradiation. If the concentration of uncoupler is raised to 30 µmol/l and the permeability of the membrane thus increased still further, the cell ATP level can no longer be enhanced by irradiation.

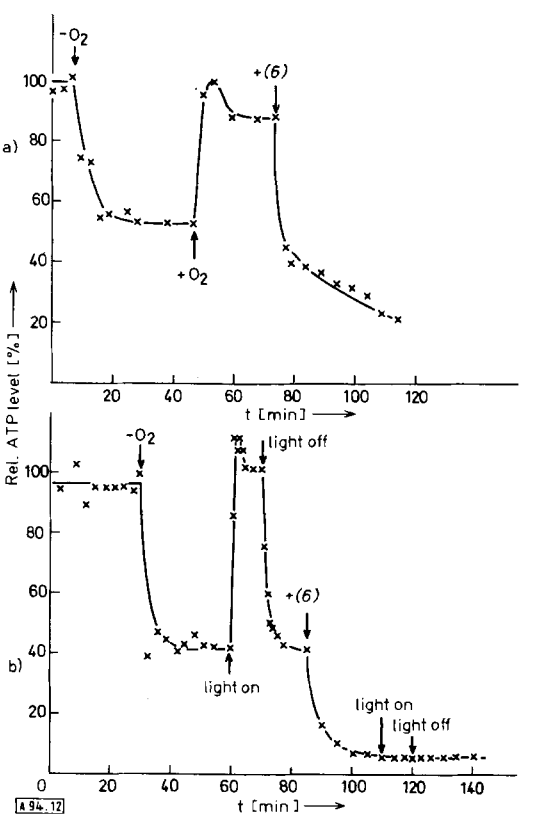

Fig. 12. Comparison between oxidative phosphorylation (a) and photophosphorylation (b) in halobacteria. As inhibitor of reversible proton translocating ATPase, dicyclohexylcarbodiimide *(6)* renders the cells incapable of ATP synthesis in both cases (according to ref. [19]).

Figure 12a illustrates the inhibition of the ATP-synthesizing system by dicyclohexylcarbodiimide *(6)*. Oxygen is first withdrawn reversibly from the cells and the oxidative phosphorylation then inhibited irreversibly by addition of *(6)*. Figure 12b shows the drop in ATP level after switching off the oxygen and the rise in the ATP level on irradiation. Addition

of *(6)* after switching off the light and subsequent irradiation no longer change the ATP level—the pump has been chemically uncoupled from ATP synthesis.

Another prediction arising from the scheme shown in Figure 10 is the interaction of the proton pump with the return transport of protons by the ATPase system. Expectedly, the initial rate of ATP synthesis increases with increasing light intensity since the pumping rate of bacteriorhodopsin also increases with the light intensity. This can continue until the process is limited by the ATP-synthesizing system; the rate of ATP synthesis then remains constant.

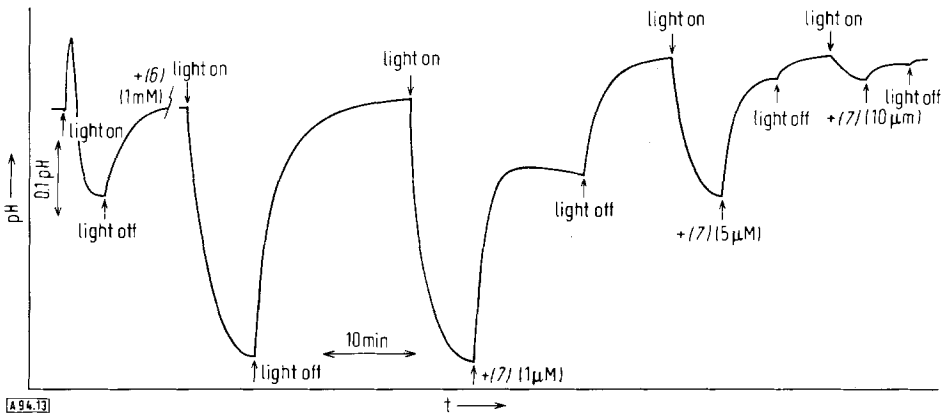

Fig. 13. Uncoupling of the light-driven proton pump from ATP synthesis by dicyclohexylcarbodiimide *(6)* and the increasing drop in efficiency of the proton pump with progressive addition of the uncoupler *m*-chlorophenylhydrazonomalononitrile *(7)* (according to ref. [19]).

That bacteriorhodopsin functions as a light-driven proton pump can also be demonstrated in the cell after inhibition of ATP synthesis. The complicated interplay of the proton pump and ATP level with regard to the pH values in the external medium will not be considered here. If ATP synthesis is uncoupled by dicyclohexylcarbodiimide *(6)* then the action of the proton pump can be studied by itself (Fig. 13). An equilibrium pH is established in the light; its value depends upon the pumping rate and the passive back diffusion of protons. This pH difference of the medium in the light and in the dark becomes increasingly smaller on addition of *m*-chlorophenylhydrazonomalononitrile *(7)* until the cell membrane has become completely permeable to protons.

6. Outlook

In conclusion it should be emphasized that the action of bacteriorhodopsin as a light-driven proton pump can be established and understood both for artificial systems and for the intact cell. However, to this day the chemistry of the chromophore change effecting vectorial expulsion of a proton has defied all attempts at elucidation. It is certainly a challenging task to develop model concepts, say on the basis of retinal-*retro*-retinal transitions, which are able to explain such a process. This would be the first explanation of an active transport process on a molecular level. However, even greater difficulties impede our understanding of how an electrochemical gradient extending across a cell membrane can shift a chemical equilibrium and what enzymatic reactions are involved. This central problem of bioenergetics will undoubtedly require a much longer time for its solution.

The author's own results mentioned in this article were obtained at Munich in the Institut für Biochemie in collaboration with M. Meentzen, L. Schuhmann, and G. Krippahl, at Tübingen in the Friedrich-Miescher-Laboratorium of the Max-Planck-Gesellschaft in collaboration with U. Fischer, R. Hartmann, and H. Michel, and continued at Würzburg in the Institut für Biochemie. I wish to express my thanks to all co-workers for their individual contributions. The 9-amino-6-chloro-2-methoxyacridine was kindly provided by P. Overath. This work has been supported from its inception by the Deutsche Forschungsgemeinschaft.

Far-Infrared Fourier Spectroscopy as a Method for Structure Determination in Chemistry

New analytical methods (4)

By Erich Knözinger[*]

Couched in the often confusing term "Fourier Spectroscopy" is the combined exploitation of a fundamental physical concept, a simple mathematical principle, and use of modern data technology. Introduction of this relatively young method into instrument technology has given great impetus to nuclear magnetic resonance and infrared spectroscopy. The infrared spectroscopic investigation of low frequency molecular vibrations has especially profited; in this connection one speaks of far infrared (FIR) Fourier Spectroscopy, which has opened up numerous interesting applications in organic, inorganic, and physical chemistry.

1. Introduction

Nowadays, the methods of vibrational spectroscopy—IR and Raman spectroscopy—are used along with NMR and mass spectroscopy for the elucidation of chemical structures[1, 4]. In principle they afford an almost complete overview of the vibrational behavior of molecules, from which structural parameters can be determined qualitatively and quantitatively. The two methods are distinguished by the complementary nature of the information which they provide. Vibrations accompanied by a strong change of dipole moment can be observed particularly well in the IR spectrum (intense IR absorption bands); vibrations accompanied by a strong change in polarizability are readily observed in the Raman spectrum (intense Raman lines). If a molecule has a center of symmetry the vibrations are observable either in the IR spectrum only (exclusively IR-active vibrations) or in the Raman spectrum only (exclusively Raman-active vibrations). However, the ideal case for vibration-spectroscopic analysis, in which the frequencies of all normal vibrations of a molecule can be determined, seldom occurs. The reasons for this are far less theoretical than practical ones—equipment parameters and methods of sample preparation effect reduction in information quality, particularly in the region of low frequency vibrations. In the first place more or less pronounced difficulties are met with—depending on the measuring principle in the IR spectroscopic investigation of low frequency vibrations—due to the smallness of the signals to be measured. In this connection the Fourier method or Fourier spectroscopy as a measuring principle has enabled considerable advances to be made over the conventional dispersive methods. One refers to the spectral region of electromagnetic radiation, which on the one hand embraces the low frequency vibrations and on the other is a region in which the advantages of the Fourier method become particularly apparent, as the far IR or FIR region. Its upper and lower limits lie at *ca.* 500 cm^{-1} (20 μm; 1.5×10^{13} Hz) and 10 cm^{-1} (1000 μm; 3.3×10^{11} Hz), respectively. In the present review the types of vibrations to be expected in the FIR region are first briefly characterized. The wealth of structural information which they disclose seems to justify the considerable outlay on apparatus necessary for making the FIR region accessible. Currently one already has the choice of half a dozen commercially available FIR apparatus. They all function, with one exception, on the same measuring principle: the Fourier method. In order to provide a fully illustrative account of this measuring principle and its more important consequences the following review will deal with the most striking advantages of the Fourier method in the FIR region as well as the fundamental principles that it has in common with conventional dispersive methods.

2. Applications of FIR Spectroscopy in Chemistry

What is the information that can be derived from the FIR spectrum of a specific substance? It comprises information about the rotational and vibrational behavior of molecules. In this field the main accent is laid on vibrations since only a very few small molecules such as H_2O, D_2O, H_2S, CO, NH_3, HCl, *etc.*[6, 7] show pure rotational transitions in the FIR region. Apart from these exceptions the typical spectral region for pure rotational transitions is the microwave region. (For gaseous samples rotational transitions can of course be superimposed[5] on vibrational transitions.)

If we assume a harmonic oscillator the frequency $\tilde{\nu}$ (measured in cm^{-1}) of the vibration of a diatomic molecule can be calculated from the relationship:

$$\tilde{\nu} = \frac{1}{2\pi c}\sqrt{\frac{k}{m_r}} \qquad (1)$$

where m_r is the reduced mass, k the force constant, and c the velocity of light. For polyatomic molecules the one vibration of the diatomic molecule is replaced by a series of so-called normal vibrations. In general the more complicated is the structure of a molecule—and here we include giant molecules such as exist in the form of crystals—the more complicated becomes the calculation of the frequencies and types of its vibrations. Equation (1) can be generalized for polyatomic molecules as follows: The frequency or the wave number of an individual normal vibration is the smaller, the greater the masses (for rotatory vibrations moments of inertia) concerned in the vibration and the smaller the forces (for rotatory vibrations torques) that oppose the displacement of individual molecular components from the equilibrium positions. On the basis of several decades of experience[*] with the assignment of MIR spectra (MIR region: 4000 to *ca.* 400 cm^{-1}) of organic and inorganic substances one can extrapolate from this generalization of relation (1) to the FIR region. One can thus predict

[*] Dr. E. Knözinger
Lehrstuhl für Physikalische Chemie der Gesamthochschule
59 Siegen 21, Postfach 210209 (Germany)

[*] The first absorption spectra in the IR region were measured by *W. W. Coblentz* in 1905.

which molecules will undergo normal vibrations with frequencies in the FIR region.

The relevant types of vibration will be characterized in the following sections and explained by means of examples. The numerical values quoted for the force constants should be regarded as only approximate.

In the present progress report it will not be possible to deal with the numerous applications of FIR spectroscopy in the field of physics particularly solid-state physics. For this purpose the reader is referred to the book by *Möller* and *Rothschild*[2] which contains, *inter alia*, a review of all present-day physical applications of FIR spectroscopy.

2.1. Stretching Vibrations

Normal vibrations are described as stretching vibrations if they lead predominantly to changes in the bond lengths. This type of vibration is observed in the FIR region[9] if heavy constituents are present in the molecule and their movement actually contributes to the change in the relevant bond length. In this connection the heavy constituents are considered—naturally only as a rule—to be the elements of the fourth and higher periods of the Periodic Table. Typical examples of application are the FIR investigations of carbonyl-[10] and halo-metal complexes[11, 12].

The probability of finding a definite stretching vibration in the FIR region is further increased by two effects:

- not only the masses of the atoms but also their ionic radii increase from period to period. The larger the ionic radii of the bonded atoms, the longer is the bond length and, according to Badger's rule[8], the smaller is the force constant.
- it is often not only the masses of the atoms directly involved in a particular chemical bond but also larger masses that are effective, as is shown when under certain conditions the bonded atoms vibrate approximately in phase with the ligands attached to them. In such cases, the term skeletal vibrations is used (Section 2.3).

2.2. Bending Vibrations

Bending vibrations is the term applied to normal vibrations in which mainly the bond angles change. They occur at lower wave numbers than the comparable stretching vibrations, since the forces that oppose displacement of molecular components from their equilibrium positions are always stronger along the direction of the bond than perpendicular to this direction. Thus, bending vibrations are found in the FIR region for all compounds whose stretching vibrations are to be found in that region[9], *e.g.* carbonyl-[10] and halo-metal complexes[11, 12]. Furthermore, bending vibrations also appear in the FIR region when light atoms (elements of the second and third periods) are involved; as an example may be mentioned the bending vibration by which the COC angle in methyl formate or methyl acetate is altered (325 or 303 cm^{-1}). Still lower wave numbers are recorded if whole groups of atoms vibrate completely or approximately in phase with the atoms under consideration; this can be shown *e.g.* for alkyl formates when the alkyl group is larger than a methyl group[13]. In this case the term skeletal vibrations is also used (see Section 2.3).

2.3. Skeletal Vibrations of Macromolecules

The skeleton of macromolecules consists in general of relatively light atoms, *e. g.* carbon atoms, but it undergoes forms of vibration in which large groups of neighboring skeletal atoms vibrating in phase vibrate in opposition to other such groups. The force constant is then approximately of the same magnitude as in the stretching or bending vibrations of skeletal atoms of a comparable smaller, *e.g.* triatomic, molecule; however, in general very much larger masses are concerned, as they are—to a first approximation—the sums of the masses of atoms vibrating in phase. Correspondingly, the wave numbers for such skeletal vibrations are low.

A special case of these skeletal vibrations of macromolecules is provided by the so-called one-dimensional lattice vibrations of long-chain unbranched molecules. These include, for example, the "accordion vibration" of unbranched aliphatic hydrocarbons[14, 15], where the wave number is smaller than 220 cm^{-1} when ten or more carbon atoms are concerned; admittedly, this vibration is Raman-active only when the chain skeleton consists wholly of the same type of atoms (*e.g.* carbons) and when the substituents on the skeletal atoms are all of the same type.

2.4. Skeletal Vibrations of Ring-Shaped Molecules

The skeletal vibrations of ring-shaped molecules generally occur in the FIR region if there are only negligible changes in the bond lengths and bond angles. Such vibrations are observed in the case of planar or almost planar rings, if the ring atoms swing out of the "ring plane". In the case of four- and five-membered rings this form of vibration is known as ring-puckering vibration (cf. Fig. 1).

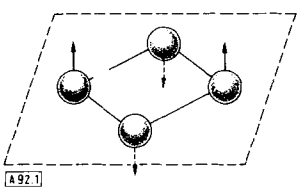

Fig. 1. Schematic representation of the ring puckering vibration of a four-membered ring (for the sake of simplicity the substituents on the ring atoms have been omitted).

In the absence of double bonds the force constant for this type of vibration is determined mainly by the interaction forces between the substituents on the various ring atoms. The magnitude of these forces is of the same order as that of intermolecular interactions; this explains the low wave numbers of ring-puckering vibrations which, for example, are observed for oxetanes between 50 and 160 cm^{-1}[16]. Immediately double bonds are present in the ring, the respective vibrations occur at higher wave numbers.

2.5. Torsional Vibrations

In torsional vibrations (as in ring-puckering vibrations) the bond lengths and bond angles also remain, to a first approximation, unchanged. What is changed is a dihedral angle (Fig. 2), *i.e.* the orientation of two parts of the molecule relative

to one another; here the only degree of freedom is the rotation of the two parts of the molecule (AX_2, BY_2) around the chemical bond (A—B) connecting them. The wave number $\tilde{\tau}$ for the torsional vibration depends on the reduced moment of inertia I_r and on the torque constant D:

$$\tilde{\tau} = \frac{1}{2\pi c}\sqrt{\frac{D}{I_r}} \tag{2}$$

Here the reduced moment of inertia is obtained from the moments of inertia of the two parts of the molecule analogously to the way in which the reduced mass of a diatomic molecule is obtained from the two individual atomic masses. Thus, not only the mass of the atoms taking part in the vibration but also their distance perpendicularly from the rotation axis is responsible for the wave number $\tilde{\tau}$.

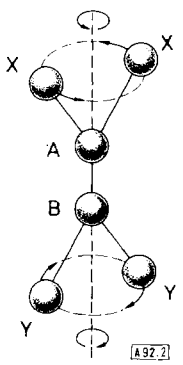

Fig. 2. Schematic representation of the torsional vibration of a molecule X_2ABY_2 around the axis of the A—B bond.

In the case of a torsional vibration around a single bond the torque constant with respect to this bond is determined by the interaction between the substituents on one of the bonded atoms (A) and those on the second atom (B); this means that its value is determined by steric factors. Typical examples are the torsion of methyl groups around C—C, C—O, or C—N single bonds[17–21, 27], the torsion of OH groups in aliphatic alcohols[22], and of NH_2 groups in primary amines[23] or hydrazines[24]. The situation is different for torsional vibrations around a bond axis that has double-bond character. The rotatability around such bonds is more restricted, and the torque constant can be determined largely by the double-bond character. As has been shown by investigations of butadiene and glyoxal and compounds derived therefrom (C—C bond axes with partial double-bond character)[25, 26] and of alkyl esters of carboxylic acids (C—O bond axes with partial double-bond character)[27], the wave numbers for the corresponding torsional vibrations depend largely on the properties of the substituents, which can exert an effect through the reduced moment of inertia and the torque constant (inductive and mesomeric effects).

2.6. Intermolecular Vibrations

The number N of normal vibrations of a nonlinear molecule composed of n atoms can be calculated from the formula:

$$N = 3n - 6 \tag{3}$$

If x molecules containing a total of $n_x = n \cdot x$ atoms come together to form an association, then N_x normal vibrations are observable where

$$N_x = 3n_x - 6$$

Together with expression (3), this gives:

$$N_x - x \cdot N = 6(x-1) \tag{4}$$

In the association there are thus $6(x-1)$ normal vibrations more than in the total of x isolated molecules. Where do these $6(x-1)$ vibrations come from?

The total number of degrees of freedom concerned with rotation, translation, and vibration is constant for a system of $n \cdot x$ atoms independently of how these atoms are combined into molecules and associations. On combination of x molecules to form an association $3(x-1)$ rotational degrees of freedom and $3(x-1)$ translational degrees of freedom disappear. An individual molecule can no longer undergo translation or rotation independently of the others; only the association as a whole has the possibility of this type of movement. These $6(x-1)$ lost rotational and translational degrees of freedom have become the above mentioned $6(x-1)$ additional vibrational (librational and translational vibrations) degrees of freedom in the association. They correspond to the so-called intermolecular vibrations in which the individual molecules vibrate as more or less rigid structures. In this process relatively large masses, namely those of the molecules, move in opposition to relatively weak forces, namely the intermolecular interactions; and this results in low-frequency vibrations generally found in the region below $300\,cm^{-1}$. The force constants have values between 1.0 and 0.001 mdyne/Å and are thus normally smaller by orders of magnitude than the force constants of principal valence bonds (*ca.* 20 to 1 mdyne/Å).

As is well known, the influence of intermolecular interactions on single molecules can be studied by various spectroscopic methods such as MIR, UV/VIS, and NMR spectroscopy. All these methods, however, have in common the feature that they supply only part of the information—they indicate how the skeleton and the electron distribution of a molecule change under the influence of specific intermolecular interactions, but information about the nature of these interactions themselves is obtained only by investigation of the lower-frequency vibrations, *i. e.* by FIR spectroscopy and Raman spectroscopy. Applications of FIR spectroscopy for such purposes are described in Sections 2.6.1 to 2.6.4.

2.6.1. Hydrogen Bonding

Association by means of hydrogen bonding is observed for water, alcohols, carboxylic acids, amines, *etc.*[28] and for their mixtures[31] with other polar compounds in the liquid and solid phase, and frequently also in the gaseous phase. The force constants for vibrations of the individual molecules in the direction of the H bonding are between 1 and 0.1 mdyne/Å; the force constants of the other so-called H-bonding "vibrations" are correspondingly smaller. Study of H bonding by FIR spectroscopy has been particularly detailed for carboxylic acids[29–30]. Intramolecular H bonding is regarded as a special case of this type of intermolecular interaction; as a kind of intermolecular interaction it is observable

in the FIR spectrum only in the form of intramolecular vibrations. Investigations of compounds of the salicylic acid type are still in progress[32].

2.6.2. "Weak" Intermolecular Interactions

Dispersive forces and dipole-dipole interactions *etc.* belong to this group. The force constants are generally smaller by 1 or 2 orders of magnitude than those for H bonding, and the wave numbers of the corresponding vibrations are therefore very low (less than $100\,cm^{-1}$)[32, 34]. Under the usual conditions the absorption bands observed are strongly broadened because of the multivarious intermolecular force constants in solid and liquid samples (cf. Fig. 3). Of particular interest in this connection are π-electron-rich (dispersive forces!) and strongly polar substances (dipole-dipole interaction!). To exhaust the information content of the FIR spectrum additional experimental work (matrix isolation technique[83]) is necessary.

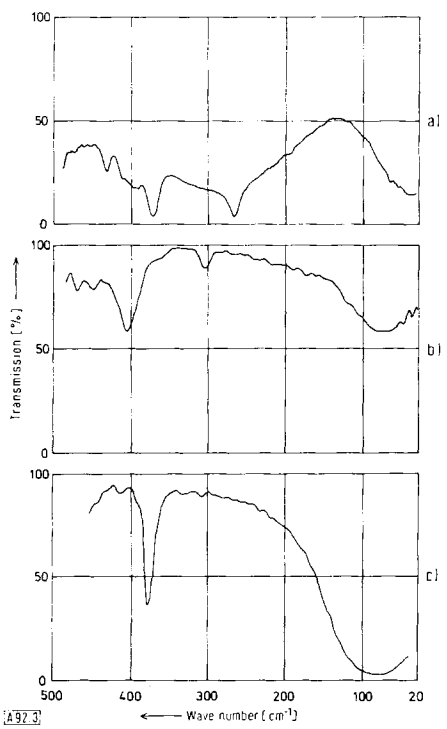

Fig. 3. FIR spectra of a) chloroform and b) benzene (liquid; layer thickness 1 mm) and c) of acetonitrile (dissolved in CCl_4, $c \approx 10$ mol-%; layer thickness 1 mm).

2.6.3. Interactions between Adsorbed Molecules and the Adsorbent

Investigation of the vibrations of adsorbed molecules with respect to the adsorbent enables some conclusions to be made about the nature of the interactions between them[35-37]. *Inter alia*, H bonding, dispersive forces, and dipole-dipole interactions may play a part here.—Such studies are important for surface chemistry and heterogenous catalysis. As examples may be cited studies on the adsorption of water[36, 37] and of organic molecules[35] on silica gel. Admittedly, the information content of the FIR spectra is usually greatly reduced because of the heterogeneity of the surface concerned and the resulting band broadening.

2.6.4. Lattice Forces in Molecular Crystals

Molecular crystals can be regarded as associations in which a very large number of molecules are joined together, whereby various types of interaction force can be observed. The intermolecular vibrations of such a crystal are known as lattice vibrations. Only those lattice vibrations in which neighboring primitive unit cells vibrate in phase can be observed by means of IR and Raman spectroscopy. This means that when the number of intermolecular vibrations of a molecular crystal observable in IR or Raman spectra is being determined, only the number of molecules combined in one primitive unit cell is taken into account; this number replaces the x in Eq. (4). In this case equation (4) must be modified further. Thus, not only the librational and translational vibrations within a primitive unit cell but also the three in-phase librational vibrations of the whole primitive unit cell around the three spatial axes can be observed in the IR and/or the Raman spectra. This is, of course, not the case for the three in-phase translational vibrations of the whole primitive unit cell in the direction of the three spatial axes; these correspond to translatory movement of the whole crystal. The number of lattice vibrations of a molecular crystal that can be observed by the methods of vibration spectroscopy thus amounts not to $6(x-1)$ [Eq. (4)], but to $6x-3$. The spectral region corresponding to these lattice vibrations lies below $200\,cm^{-1}$[33, 38].

The crystalline portions of polymers provide a special problem in crystal structure; in polyethylene, for example, the crystalline portions give rise to a lattice vibration at $72\,cm^{-1}$[39, 40].

If the masses of crystalline components are sufficiently large then, of course, also the lattice vibrations of valence and ionic crystals lie in the FIR region (*e.g.* alkali metal halides such as KBr *etc.*).

3. The Importance of FIR Spectroscopy in Chemistry and its Problems

All compounds that absorb in the FIR region exhibit absorption bands with considerably higher absorbance coefficients ε in the mid IR (MIR) and/or in the UV/VIS region; *e.g.* in the MIR region ε assumes maximum values of about $2000\,l/mol \cdot cm$, whereas the corresponding values in the FIR region are smaller by a factor of at least 1/5; naturally, this makes itself apparent, on the one hand by the amount of sample required and on the other—so as to ensure an acceptable signal-to-noise ratio in the spectrum—by increased demands on the apparatus. Even more pronounced are the differences in absorbance coefficients on comparing the FIR with the UV/VIS region. It thus follows that quantitative analyses can be carried out with very much higher sensitivity and—as regards equipment—more favorable detection limits in these shorter wavelength regions. Consequently, FIR spectroscopy is resorted to only in exceptional cases for the purpose of qualitative analysis and identification of unknown substances. Its main area of application is in structural elucidations.

Although the content of information in the FIR region is undoubtedly smaller than that in the MIR region for many compounds, in particular organic ones, the importance of the FIR region in chemistry, including organic chemistry, is not to be underestimated. The reason is that the assignment

of an FIR spectrum provides access to important physical and physicochemical information:

- The structure of many compounds that contain one or more heavy atoms can be determined with the aid of vibration-spectroscopic methods only if the FIR spectrum is taken into consideration.
- For normal coordinate analysis the information about the vibrational behavior of molecules must be as complete as possible; the low-frequency region cannot be arbitrarily excluded, for the solution is then no more than approximate.
- For determination of thermodynamic functions it is precisely the low-frequency normal vibrations that play a decisive role[41].
- Facts about the potential barriers in interconversion of conformers are closely related to the wave number of torsional and ring-puckering vibrations, which are found exclusively in the FIR region.
- Intermolecular interactions, which are often responsible for the conformation of a compound and decisively determine its physical behavior, can be investigated directly in the FIR region.

The problems of assignment in the FIR region reside in the facts that a large number of different types of vibration (see Sections 2.1 to 2.6) can be observed next to one another and that the concept of group frequencies, which so greatly assist the assignment in the MIR region, is applicable only in exceptional cases in the FIR region. The reason for this is that the low-frequency normal vibrations generally involve a relatively large number of atoms with non-negligible amplitude. This is immediately apparent for skeletal, torsional, and intermolecular vibrations; for example, in a torsional vibration around a specific bond axis there is movement of all the atoms in the molecule except those that occur along this axis. In the case of torsional vibrations one can therefore speak of a group frequency only when the reduced moment of inertia is almost identical with the moment of inertia of the group under study referred to the torsion axis; *i.e.* when this moment of inertia is small in comparison with the corresponding moment of inertia of the other part of the molecule.— An additional complication in the interpretation of the FIR spectrum arises through the increasing intensity of "hot bands" with decreasing wavelength (at 500 cm^{-1} and room temperature already *ca.* 1/10 of the molecules investigated are in the first excited state![41]) and through band-splitting which occurs, *inter alia*, in torsional vibrations and has its origin in special potential curves having two or three minima[17]. Moreover — as in the MIR region— difference bands, combination bands, and overtones can interfere: they usually lead, of course, to weak intensity bands.

How varied the information in the FIR region can be, even for purely organic molecules (only light bonded atoms), is shown in Fig. 4, in which the FIR spectra of some alkyl acetic esters have been collected[27]. The assignment naturally requires the additional introduction of Raman spectroscopy.

Further difficulties arise when attempting to extract the maximum of information from the FIR spectrum in the region around and below 100 cm^{-1}. The reasons for this are as follows:

- "Hot bands" of considerable intensity occur at room temperature in this region of low-frequency vibrations.

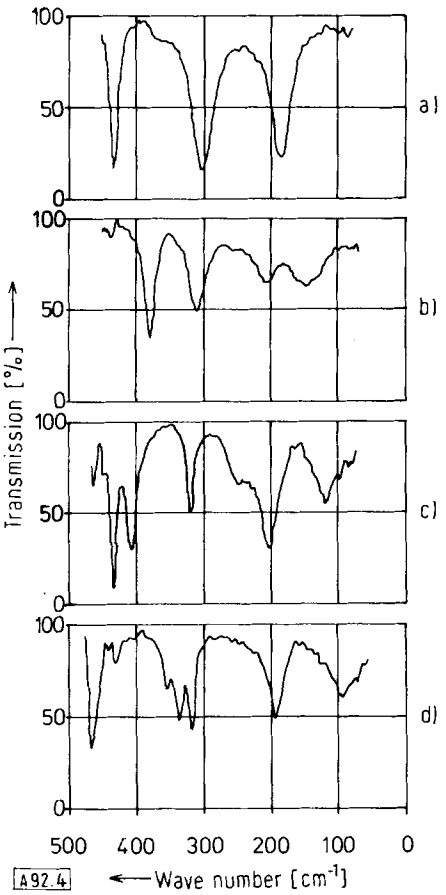

Fig. 4. FIR spectra of alkyl esters of acetic acid, CH_3COOR (dissolved in C_6H_{12}, $c \approx 5$ to 10 mol-%; layer thickness 2 mm): a) $R = CH_3$, b) $R = C_2H_5$, c) $R = i\text{-}C_3H_7$, d) $R = t\text{-}C_4H_9$.

- Low-frequency intramolecular vibrations are strongly influenced by intermolecular interactions.
- The low-frequency vibrations corresponding to the intermolecular interactions in solid and—particularly—liquid phases are usually characterized by a large variety of different force constants.

As a result, a single broad absorption band is found below 100 cm^{-1} for many substances, particularly in the liquid phase (cf. Fig. 3). The information content of this band can possibly be made accessible to the chemist by the matrix isolation technique[83]. This opens up a broad and very interesting field of application for FIR Fourier spectroscopy where, however, because of fundamental difficulties (high radiated power on cooled sample!), the Raman spectrum is no longer expected to have its usual importance as a supplementary source of information.

The assignment of an FIR spectrum is only possible when the sample to be examined has been suitably prepared. For the problems arising in this connection and their solution the reader is referred to the literature[63, 73–82].

4. Principles of the Fourier Method

4.1. The General Problem in Optical Spectroscopy

The general problem in optical spectroscopy, irrespective of the spectral region, is to determine the intensity I of electromagnetic radiation as a function of the frequency ν, the wave number $\tilde{\nu}$ or the wavelength λ. The fact that especially in

IR spectroscopy the transmittance $T_{(\tilde{\nu})} = I_{(\tilde{\nu})}/I_{0(\tilde{\nu})}$, or its negative common logarithm, the absorbance, is used, is of secondary importance and arises because a substance-specific datum is called for that must be independent of the apparatus-specific intensity distribution $I_{0(\tilde{\nu})}$. For the determination of an intensity distribution the series of waves with different wave numbers contained in a polychromatic light wave must be separated from one another in some way[42]. For this purpose a code is needed in which, in accord with information theory[43], a set of values of some measurable quantity A_i is assigned to the set of values of the wave number $\tilde{\nu}_i$:

$$(\tilde{\nu}_i) \Leftrightarrow (A_i) \tag{5}$$

Thus the intensity is measured as a function of this measurable quantity A_i, and the dependence $I_{(\tilde{\nu}_i)}$ is finally determined on decoding.

When choosing the code [Eq. (5)], the properties of electromagnetic radiation must be taken into account. For an unambiguous description of a nonpolarized, monochromatic, electromagnetic wave in a vacuum four quantities are available:

Intensity I
Wave number $\tilde{\nu}$
Direction of propagation $\vec{c}$
Phase state φ

I is one measurable quantity of interest here, and $\tilde{\nu}$ is the other. There are thus two determinable quantities still free that can be used for coding, namely $\vec{c}$ and φ.

$$(\tilde{\nu}_i) \Leftrightarrow (\vec{c}_i) \tag{5a}$$

$$(\tilde{\nu}_i) \Leftrightarrow (\varphi_i) \tag{5b}$$

The problem of coding solves itself if an apparatus is available for use as a light source by means of which monochromatic radiation of variable wave number can be produced. The wave number $\tilde{\nu}_i$ can then always be related to a specific setting X_i of one parameter of the apparatus:

$$(\tilde{\nu}_i) \Leftrightarrow (X_i) \tag{5c}$$

The decision for or against one or the other form of coding depends on the following criteria:

- Unambiguity;
- Accuracy;
- The apparatus required;
- The radiation flux through the measuring equipment.

The far infrared lies between the microwave region ($< 10\,cm^{-1}$) and the mid IR region ($> 500\,cm^{-1}$). The question is whether the methods of coding customary in these last two spectral regions and of long-proved value are applicable and useful in the FIR region.

The microwave region is a domain of nondispersive spectroscopy. Electronically controllable high-frequency tubes are used, *e.g.* reflex klystrons, which act as sources of monochromatic light.

For the medium IR region the so-called conventional dispersive spectroscopy is used. By means of a monochromator each wave train is assigned a specific propagation direction $\vec{c}_i$ corresponding to its wave number $\tilde{\nu}_i$. In practice, we use for this purpose:

- the wave-number dependence of the angle of refraction of light in a suitable prism or
- the wave-number dependence of the angle of diffraction of light by a suitable grating

At a specific distance from the dispersive element (prism or grating) one can thus, given suitable imaging optics, measure the intensity $I_{(\vec{c}_i)}$ corresponding to each direction of propagation by means of an aperture diaphragm and, behind it, a detector. The intensity distribution $I_{(\tilde{\nu}_i)}$ is then obtained by means of the well-known code (5a). Assessed by the previously mentioned criteria, this method of coding is satisfactory except in one respect: the radiation flux from the light source to the detector is considerably reduced. There are two reasons for this reduction:

- To a first approximation, the aperture diaphragm in front of the radiation detector allows the passage only of light with a specific propagation direction and thus with a specific wave number $\tilde{\nu}_i$. All light waves with $\tilde{\nu} \neq \tilde{\nu}_i$ are kept away from the detector.

  Deflection of the light at the dispersive element occurs in one dimension; accordingly, the diaphragm aperture delimiting the radiation flux muxt be a slit. The finer the details of the intensity distribution $I_{(\tilde{\nu})}$ that are to be recorded, the smaller must be the slit width. The radiation flux is thus reduced in comparison with that from a comparable circular aperture (see Section 4.2). A circular aperture can always be used if the code (5a) is not required, *i.e.* if the wave trains of differing wave numbers all have the same direction of propagation.

So long as both intense light sources and sensitive detectors are available for the spectral region under study, the reduction of the light flux is really disadvantageous (that is the signal-to-noise ratio is unfavorable and/or the time of the measurement is prolonged) only in exceptional circumstances. These exceptions occur:

- when there is a strong background absorption (*e.g.* by the solvent),
- in investigations involving high-resolution conditions, and
- in the investigation of microsamples.

Spectral regions, in which the conventional dispersive method, *i.e.* code (5a), leads in most cases to useful results, are the near-IR and the UV/VIS as well as the mid IR.

4.2. Principle of the Fourier Method Regarding Its Use in FIR Spectroscopy

The nondispersive spectroscopy practised in the microwave region is not applicable to the FIR region; electronically controllable high-frequency tubes are available only up to a maximum of a few 100 GHz (100 GHz $\hat{=}$ 3.3 cm^{-1}). It can be expected, however, that in a few years controllable lasers in the FIR region will take over the function of electronically controllable high-frequency tubes in the microwave region.—If conventional dispersive spectroscopy is introduced in the FIR region [coding according to relation (5a)], the reduced radiation flux is disadvantageous even under normal conditions, since only light sources of relatively weak intensity and relatively insensitive radiation detectors are available for the spectral region below $500\,cm^{-1}$.

For the FIR region we thus need a different kind of coding[45, 46]. This is provided by relation (5b), in which a specific phase or phase difference is unambiguously assigned to each wave number while, however, all the wave trains of different

wave number retain the same direction of propagation. The concept of phase difference makes it immediately clear that there must be two waves between which the phase difference exists. Hence the light wave to be investigated must be divided into two partial waves. Let us first assume—for the sake of simplicity—that a monochromatic plane light wave is present and that it has been divided into two partial waves of the same intensity $I_{(\tilde{\nu})}$, same direction of propagation, and same state of polarization. After we have produced a variable phase difference φ between them, we now make these partial waves overlap. The φ-dependent intensity is then measured in the overlap region:

$$I_{(\varphi)}=2I_{(\tilde{\nu})}(1+\cos\varphi) \tag{6}$$

If $\varphi=0$ or an integral multiple of 2π, then $I_{(\varphi)}$ assumes its maximum value of $4I_{(\tilde{\nu})}$. If φ is an odd multiple of π, then $I_{(\varphi)}$ has the lowest possible value, namely zero. $I_{(\varphi)}$ is called the interferogram, and the φ-dependent component in formula (6) is called the interferogram function:

$$F_{(\varphi)}=I_{(\varphi)}-2I_{(\tilde{\nu})}=2I_{(\tilde{\nu})}\cos\varphi \tag{7}$$

For the production of the variable phase difference between the two planar light waves the latter are allowed to traverse different but well-defined paths. The phase difference φ depends on the optical path difference x and on the wavelength λ or wave number $\tilde{\nu}$:

$$\varphi_{(x)}=2\pi\frac{x}{\lambda}=2\pi\tilde{\nu}x \tag{8}$$

Thus, the desired coding is achieved: according to Eq. (8), the wave number $\tilde{\nu}$ is unambiguously assigned a phase difference φ as a function of the optical path difference x. In the present experiment there is thus, according to Eqs. (7) and (8), for the monochromatic light wave under study, a corresponding experimentally measurable harmonic function—the interferogram function $F_{(x)}$—whose amplitude is proportional to the desired quantity $I_{(\tilde{\nu})}$ and whose argument is equal to the phase difference $\varphi_{(x)}=2\pi\tilde{\nu}x$:

$$F_{(x)}=2I_{(\tilde{\nu})}\cos 2\pi\tilde{\nu}x \tag{7a}$$

If, in place of monochromatic light, we are dealing with polychromatic light having any desired continuous intensity distribution, the interferogram functions corresponding to the individual wave numbers overlap without distortion with a fixed phase relationship, given by Eq. (8), between them. For an optical path difference $x=0$ all the wave trains, irrespective of the wave number $\tilde{\nu}$, give an interference maximum. Mathematically speaking, the overlap of the interferogram functions corresponding to the different wave numbers implies integration of the "monochromatic interferogram function" (7a) over all possible values of $\tilde{\nu}$:

$$F_{(x)}=2\int_0^\infty I_{(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} \tag{9}$$

Here $I_{(\tilde{\nu})}$ has the meaning of an intensity density, *i.e.* exactly the quantity that one wishes to determine in spectroscopic investigations. In Fig. 5 the interferogram functions for polychromatic light having a continuous intensity distribution and for monochromatic light are placed side by side. It will be seen that in the former case the amplitudes become smaller and smaller with increasing absolute value of the path difference x and finally reach zero; the cause of this is explained in Section 4.3.

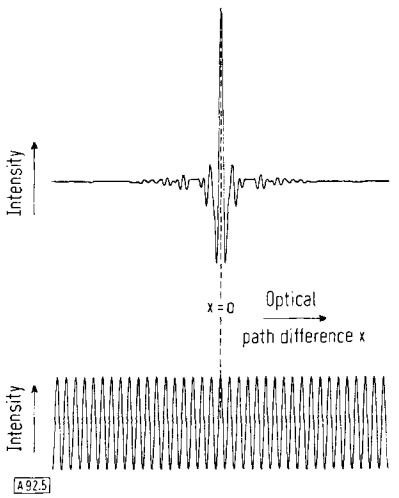

Fig. 5. Interferogram functions (sections) for polychromatic light having a continuous intensity distribution (above) and for strictly monochromatic light (below); the ordinate scales are not all the same.

After its experimental determination, the "polychromatic interferogram function" [Eq. (9)] must be investigated for its harmonic components (characterized by the wave number $\tilde{\nu}$) whose amplitudes all afford the desired value $I_{(\tilde{\nu})}$. The procedure that makes this possible is none other than a mathematical filtering of the function F based on the property of orthogonality of harmonic functions (cf. standard works on higher mathematics):

$$I_{(\tilde{\nu})}=2\int_0^\infty F_{(x)}\cos 2\pi\tilde{\nu}x\,dx \tag{10}$$

The method outlined here for investigating an intensity distribution $I_{(\tilde{\nu})}$ thus differs in fundamentals from conventional dispersive spectroscopy only in that the optical filtering of the polychromatic light wave (in the monochromator) has been replaced by mathematical filtering of the "polychromatic interferogram function" provided by the interference experiment.

Independently of whether the filtering is carried out by the optical or the mathematical method, we are always dealing with a Fourier analysis. The method in which the filtering is mathematical is called Fourier spectroscopy or Fourier transformation spectroscopy (FTS), because here, in the determination of an intensity distribution, the procedure of Fourier analysis or Fourier transformation clearly emerges in its own right.—In both methods interference experiments are carried out (in dispersive spectroscopy with multibeam interference, in Fourier spectroscopy with two-beam interference). In both methods the desired intensity distribution is provided by evaluating the interference pattern. Both methods require Fourier analysis; in conventional dispersive spectroscopy this procedure is effected by the analog monochromator/detector system, in Fourier spectroscopy by a digital or analog computer after or during the recording of the experimental quantities by

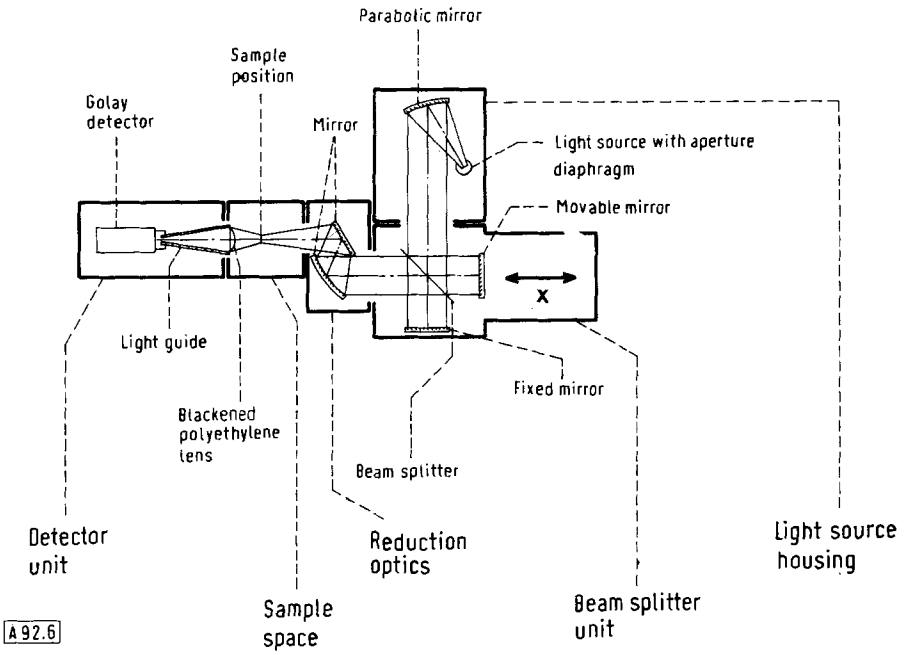

Fig. 6. Construction and optical path of a Michelson interferometer for spectroscopy in the FIR region.

the detector. The physical and mathematical bases of the Fourier method have been clearly described by, *inter alia*, *Genzel*, *Geick*, *Hurley*, *Grosse*, and *Horlick*[44, 47-51]. Specific aspects of Fourier spectroscopy are dealt with in the proceedings of the "Aspen International Conference on Fourier Spectroscopy 1970"[52].

What, then, are the advantages of the Fourier method over the conventional dispersive method?

- In the first place, all wave trains with their different wave numbers reach the detector simultaneously and not in succession. This difference in comparison with conventional dispersive spectroscopy is called "the multiplex advantage" ("Fellgett advantage").
- Secondly, there is no need for the diaphragm aperture to be in the form of a slit, since all the wave trains with their different wave numbers have the same propagation direction. With a circular aperture a radiation flux at least two orders of magnitude higher than with a slit aperture can be achieved for optical systems having the same resolving power (cf. Section 4.3) and the same collimator parameters (focal length, aperture)[4, 44]. In this connection one speaks of "throughput advantage" ("Jacquinot advantage", "étendue advantage", "aperture advantage"). The throughput advantage is naturally partly or wholly lost as soon as—*e.g.* in the investigation of microsamples—the preset aperture of the apparatus is reduced.

Only through the Fourier method has FIR spectroscopy attained its present importance in chemistry for structural determinations. Besides the above-mentioned advantages over the conventional dispersive method, it should be noted that the problems of optical filtering are more easily solved and especially that the optical systems are comparatively simpler (Fig. 6). In this respect the Fourier method is also superior to Hadamard transformation spectroscopy[42, 45, 46, 53] which otherwise is, or at least could be, of equal value. It remains, however, to explain why the Fourier method is not also generally used for the IR and UV/VIS regions.

An important reason for this—among others[44]—is the existence of problems with precision, which are not very important between 20 and 1000 μm (the FIR region) but become greater with decreasing wavelength; the shorter the wavelength of the light under study, the greater is the precision needed so as not to exceed a definite relative limit of error in the determination of the abscissa values for $F_{(x)}$ [see Eq. (9)]. It follows that even in the mid IR region (between 2.5 and 20 μm) very much greater technical effort must be expended[54] to obtain the full advantage of the Fourier method over the conventional dispersive method.

The important components of a Fourier spectrophotometer are the interferometer, which produces the experimental function $I_{(\varphi)}$ or $I_{(x)}$, and the system for evaluating the interferogram data. It is not the purpose of this review to go into details of apparatus[6, 56-62, 64] (see also Refs. [2—4]) or questions of evaluating the interferogram (Fourier transformation)[57, 65-69, 72]; here we shall only relate the theory discussed in this section to practice.

Figure 6 shows schematically the construction of an interferometer used for FIR spectroscopy (Beckman IR-720) and the optical path of the radiation. It functions on the Michelson principle. The two partial waves with the properties described above are produced by splitting the wave amplitude of a plane light wave in the beam splitter unit—this is the only component of the interferometer that is important for the explanation of the principle outlined above. (It can naturally also be the wave front that is split, as occurs in the lamellar grating interferometer[60-62].) The beam splitter itself is a film that absorbs as weakly as possible in the spectral region of interest and which permits part of the incident light to pass through while reflecting the remaining part. The light transmitted through the beam splitter falls on a fixed plane mirror parallel to the wave front. The light reflected from the beam splitter falls on another plane mirror, also parallel to the relevant wave front. Unlike the first mirror, however, the second mirror is movable in the direction normal to the wave front of the beam incident upon it, and its position determines the phase difference between the beams transmitted and reflected at the beam splitter. After respectively reflection and transmission through the splitter the two partial beams

finally reach a region (to the left of the splitter in Fig. 6) where they can overlap (see Section 4.3). Their intensities are exactly the same, since, given ideal mirrors and optimal adjustment, they have the same history. In the region where the two partial beams overlap the resulting intensity can be measured and related to the position of the movable mirror, *i. e.* the interferogram $I_{(x)}$ can be measured. Thence the interferogram function $F_{(x)}$ is obtained by simply subtracting a constant value (which is equal to the integral intensity of the two partial beams), and finally the spectrum $I_{(\tilde{\nu})}$ by subsequent mathematical filtration (Fourier transformation) of $F_{(x)}$.

All other commercially available FIR Fourier apparatus (Polytec Model FIR-30, Digilab/Cambridge Instruments Models FTS-16 and FTS-18, Bruker-Physik Model IFS-114, Coderg Model FS-4000, and Grubb Parsons Models IS-3 and Mark II)—in one or other variant—also function on the Michelson principle.

4.3. The Resolving Power of the Fourier Method

The resolving power A obtainable by means of a grating can be calculated from the expression:

$$A = \frac{\tilde{\nu}}{\Delta\tilde{\nu}} = nN \tag{11}$$

where $\Delta\tilde{\nu}$ is the distance (measured in cm^{-1}) between two infinitely sharp neighboring spectral lines that are just resolved, $\tilde{\nu}$ is the mean wave number for these two lines, N is the number of lines of the grating, and n is the grating order.

$$A = \frac{\tilde{\nu}}{\Delta\tilde{\nu}} = 2n \tag{11a}$$

Such a grating produces very broad interference maxima. This means that generally speaking a very large number of diffraction maxima must be passed through before the first occasion is encountered where the maximum for one spectral line coincides with the minimum of the other, which is the prerequisite for the fact that the existence of two adjacent spectral lines is at all observed in this experiment. As implied in Eq. (11a), the grating order n must be the higher, *i.e.* the optical path difference $n\cdot\lambda$ between the two interfering beams must be larger, the closer together are the two spectral lines, *i. e.* the smaller is $\Delta\tilde{\nu}$.

This result can be applied to the Fourier method: in place of $n\cdot\lambda$ we set the maximal optical path difference x_{max} between the two light waves that are made to overlap:

$$A = \frac{\tilde{\nu}}{\Delta\tilde{\nu}} = 2n = \frac{2n\lambda}{\lambda} = 2\tilde{\nu}x_{max} \tag{11b}$$

In order that two infinitely sharp spectral lines separated by $\Delta\tilde{\nu}$ can just be resolved, x_{max} must have the value prescribed by Eq. (11c):

$$x_{max} = \frac{1}{2\Delta\tilde{\nu}} \tag{11c}$$

$\Delta\tilde{\nu}$ can of course also be regarded as the experimental broadening, depending on the value of x_{max}, of an infinitely sharp spectral line. This is the quantity that in conventional dispersive spectroscopy is usually given as the "spectral slit width".

In practice the spectral lines are never infinitely sharp, a fact that is connected with the finite breadth of the energy levels between which the light emission processes take place.

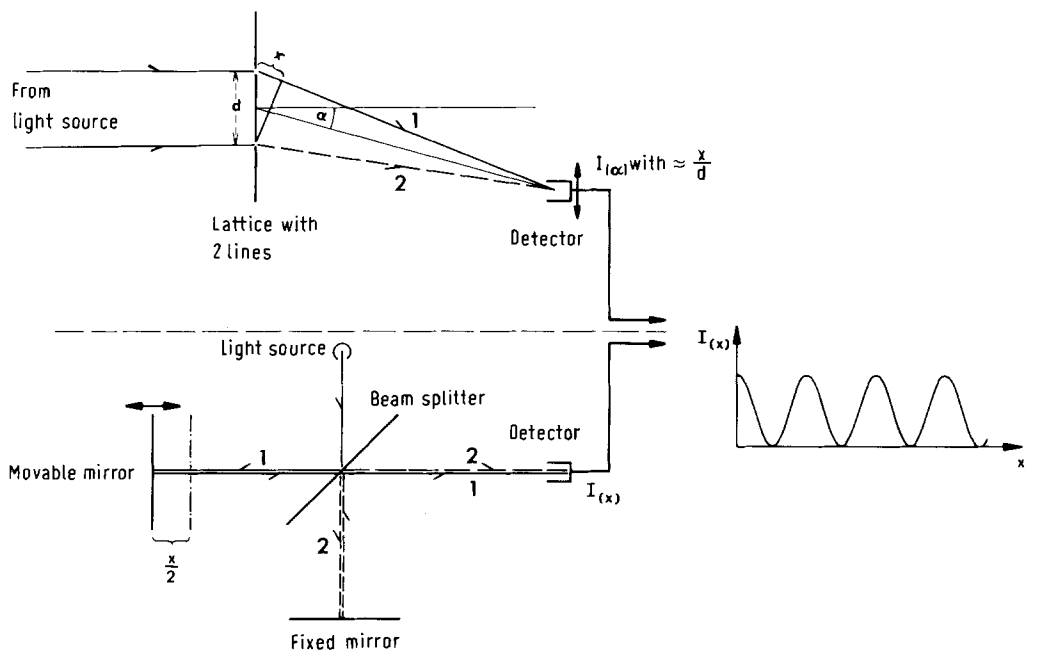

Fig. 7. Schematic representation of the phenomenon of two-beam interference on a grating with two lines (above) and in the Michelson interferometer (below). On the right is sketched the interferogram produced in both cases for strictly monochromatic light.

In the Fourier method a two-beam experiment (cf. Fig. 7: beams 1 and 2) is carried out. So far as the resolving power is concerned this amounts to a diffraction experiment with a grating (Fig. 7) containing only two lines ($N=2$); in this case we have:

The question arises how the finite breadth of the spectral lines is expressed in the interferogram function. For this purpose the Heisenberg uncertainty principle provides an answer:

$$\Delta p \cdot \Delta q \approx \frac{h}{2\pi} \tag{12}$$

where Δp is the uncertainty in momentum and Δq the uncertainty in the position of a particle (*e.g.* a photon) and h is Planck's constant. Taking into account that

$$\Delta p = \Delta\left(\frac{h}{2\pi\lambda}\right) \approx \frac{h}{2\pi}\Delta\tilde{\nu}_{1/2}$$

where $\Delta\tilde{\nu}_{1/2}$ represents the half-width of the emission lines studied, it follows from relation (12) that:

$$\Delta\tilde{\nu}_{1/2} \cdot \Delta q \approx 1$$

For photons we can replace Δq by the length of the wave train under consideration, namely the coherence length l. It follows that

$$l \approx \frac{1}{\Delta\tilde{\nu}_{1/2}} \tag{13}$$

The coherence length of a light wave is the greater, the smaller the half-width of the sharpest of the spectral lines corresponding to the light wave.

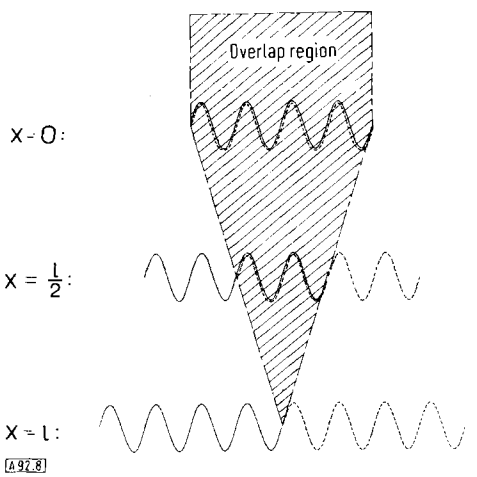

Fig. 8. Schematic representation of the overlap region between two wave trains of coherence length l in dependence on the optical path difference x.

The two partial waves produced from the light wave to be studied (cf. Section 4.2) can only interfere if they overlap completely or partially. Complete overlap occurs (see Fig. 8) when the optical path difference x is zero. The larger is x, the smaller the overlap region becomes and the less marked are the interference phenomena. Accordingly, the modulation amplitude of the interferogram function decreases continually with increasing optical path difference (Fig. 5, upper part), until it becomes zero as soon as the optical path difference equals or exceeds the coherence length ($x \geq l$). In the region where $x \geq l$, the interferogram assumes a constant value which is independent of the optical path difference and corresponds to exactly half of the maximal possible interferogram value (at $x = 0$). The continuous decrease in the interferogram function, which originates in the limited coherence length of the light wave, is called the "self-apodization"[71].

So far only more or less sharp emission lines have been discussed. In vibrational spectroscopy, however, one has to do mostly with continuous emissions weakened by absorption in specific areas. What, then, is the value of the coherence length l for such an intensity distribution, absorption occurring only within a specific spectral interval of width $2\Delta\tilde{\nu}_{1/2}$ (Fig. 9, top) and there has the form prescribed by the transmittance $T_{(\tilde{\nu})}$? The coherence length can be determined by carrying out the interference experiment described in Section 4.2 and thus measuring the region in which the interferogram function depends on the optical path difference.

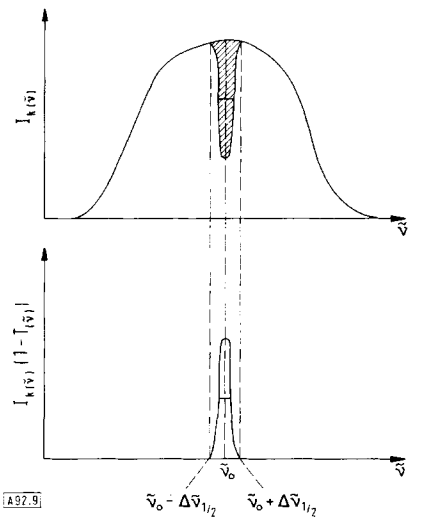

Fig. 9. Determination of the coherence length of light corresponding to a continuous intensity distribution weakened in a narrow spectral interval $2\Delta\tilde{\nu}_{1/2}$ (for explanation see text).

The interferogram function for the intensity distribution discussed here has the following mathematical form [see also Fig. 9 and Eq. (9)]:

$$F_{(x)} = 2\int_0^{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} + 2\int_{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}}^{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}T_{(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} + 2\int_{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}}^{\infty} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu}$$

The subscript k refers to the unweakened continuous intensity distribution.

This equation can be rearranged to:

$$F_{(x)} = 2\int_0^{\infty} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} - 2\int_{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}}^{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} + 2\int_{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}}^{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}T_{(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu}$$

$$F_{(x)} = 2\int_0^{\infty} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} - 2\int_{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}}^{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}(1-T_{(\tilde{\nu})})\cos 2\pi\tilde{\nu}x\,d\tilde{\nu}$$

with

$$2\int_0^{\infty} I_{k(\tilde{\nu})}\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} = F_{k(x)}$$

and

$$2\int_{\tilde{\nu}_0-\Delta\tilde{\nu}_{1/2}}^{\tilde{\nu}_0+\Delta\tilde{\nu}_{1/2}} I_{k(\tilde{\nu})}(1-T_{(\tilde{\nu})})\cos 2\pi\tilde{\nu}x\,d\tilde{\nu} = F_{\Delta\tilde{\nu}_{1/2}(x)}$$

we obtain

$$F_{(x)} = F_{k(x)} - F_{\Delta\tilde{\nu}_{1/2}(x)} \tag{14}$$

The interferogram function $F_{(x)}$ thus has two additive components:

- the contribution $F_{k(x)}$, which corresponds to the broad-band continuous intensity distribution (Fig. 9, upper part) and which decreases "rapidly" to zero (Fig. 5, upper part), and
- the contribution $-F_{\Delta\tilde{\nu}_{1/2}(x)}$, which, except for the minus sign, corresponds to an emission band with the intensity distribution $I_{k(\tilde{\nu})}(1-T_{(\tilde{\nu})})$ and half-width $\Delta\tilde{\nu}_{1/2}$ (Fig. 9, lower part) and which decreases to zero the more "slowly", the smaller is $\Delta\tilde{\nu}_{1/2}$ (half-width of the absorption band).

The coherence length l of a light wave that corresponds to a continuous intensity distribution weakened in the interval $2\Delta\tilde{\nu}_{1/2}$ by absorption (Fig. 9, upper part) can thus be estimated [Eq. (13)] if an indication of the half-width of the sharpest absorption bands to be expected is available. For solid, liquid, or dissolved samples under normal conditions, experience shows that the half-width achieved is less than $10\,cm^{-1}$ only in exceptional cases. With this standard factor Eq. (13) leads to a value of *ca.* 1 mm for the coherence length. If the maximal optical path difference is chosen as $x_{max}=2$ mm, then the total region $0\leqslant x\leqslant l$ in which the interferogram function depends on the optical path difference is usually covered. If $x_{max}<l$, then, as when the spectral slit width in conventional dispersive apparatus is made too large, experimental broadening of the absorption lines is observed, as well as disturbing artefacts—though the latter can be reduced mathematically (by apodization)[47, 70]. If $x_{max}>l$, then the measurement time is increased without any gain in spectral information, and in the region $l<x<x_{max}$ additional noise is recorded which contributes through the Fourier transformation to a worsening of the signal-to-noise ratio throughout the entire spectrum.

4.4. Spectral Region for Measurement by the Fourier Method

The spectral region usable for measurements is determined, as in every spectroscopic method, by the characteristics of the radiation from the light source, the sensitivity characteristics of the detector, and the type and efficiency of the optical apparatus. A further aspect, however, also plays an important part in the Fourier method.

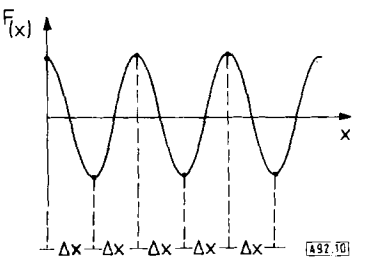

Fig. 10. Determination of the sampling intervals (for explanation see text).

In order to be able to calculate $I_{(\nu)}$ from $F_{(\tilde{x})}$ by Eq. (10) one must care for numerical acquisition of $F_{(x)}$ between $x=0$ and $x=x_{max}$, which is not possible continuously but only at specific intervals Δx (Fig. 10). This procedure in which Eq. (15) is used with $m=0,1,2\ldots$

$$x=m\cdot\Delta x \tag{15}$$

is called digitization of the function $F_{(x)}$, Δx the sampling interval[55]. Due to the digitization of the interferogram function it is, of course, necessary to convert the integral in Eq. (10) into a sum. After the choice of Δx the upper limit of the spectral region to be measured is already fixed because, according to the sampling theorem of information theory, harmonic functions can be characterized unambiguously in digital form only when at least one ordinate value per half-period is sampled. The Fourier transformation of $F_{(x)}$ can thus be effected unambiguously only if this condition is fulfilled for all harmonic functions making up $F_{(x)}$. Since, however, the periods of these harmonic functions are exactly equal to the wavelengths of the polychromatic light studied, only light of wavelength $\lambda>\lambda_{min}$ may contribute to the measured signal $I_{(x)}$; we have:

$$\lambda_{min}=2\Delta x=\frac{1}{\tilde{\nu}_{max}}$$

or

$$\tilde{\nu}_{max}=\frac{1}{2\Delta x} \tag{16}$$

Wave trains with $\tilde{\nu}>\tilde{\nu}_{max}$ contribute intensity to the wave trains with $\tilde{\nu}<\tilde{\nu}_{max}$; this means that the form of coding [relation (5b)] is not unambiguous. Unambiguity can, however, be brought about if all the intensity contributions with wave numbers $\tilde{\nu}>\tilde{\nu}_{max}$ are eliminated by optical or electrical filtering.

The contributions with wave numbers $\tilde{\nu}_2>\tilde{\nu}_{max}$ to the intensity expected at wave numbers $\tilde{\nu}_1<\tilde{\nu}_{max}$ can be determined as follows: The "monochromatic interferogram function"

$$F_{1(x)}=I\cos 2\pi\tilde{\nu}_1 x$$

is assigned to the wave number $\tilde{\nu}_1$. From this, with allowance for Eqs. (15) and (16), we obtain

$$F_{1(m)}=I\cos\frac{m\pi\tilde{\nu}_1}{\tilde{\nu}_{max}}$$

Then we determine all those "monochromatic interferogram functions"

$$F_{2(m)}=I\cos\frac{m\pi\tilde{\nu}_2}{\tilde{\nu}_{max}}$$

that with $\tilde{\nu}_2 > \tilde{\nu}_{max}$ have the same value as $F_{1(m)}$ at the same m; after digitization they can no longer be distinguished from $F_{1(m)}$. Finally, the calculation gives:

$$\tilde{\nu}_2 = \begin{cases} (2n+2)\tilde{\nu}_{max} - \tilde{\nu}_1 \\ 2n \quad \tilde{\nu}_{max} + \tilde{\nu}_1 \end{cases} \tag{17}$$

If it is not certain that all the wave trains with $\tilde{\nu} > \tilde{\nu}_{max}$ are excluded by optical or electrical filtering, then the intensity measured for $\tilde{\nu}_1 < \tilde{\nu}_{max}$ may arise wholly or partially from intensity contributions with $2\tilde{\nu}_{max} \pm \tilde{\nu}_1$, $4\tilde{\nu}_{max} \pm \tilde{\nu}_1$, ... *etc.*, the so-called false light contributions.

The problem of false light contributions arises not only for the Fourier method but also in conventional dispersive spectroscopy. Here the unambiguity of the assignment (5a) can be safeguarded only by optical filtering, which is most efficiently achieved with double or triple monochromators. The false light (also misleadingly called stray light) that has to be filtered out arises mainly from interfering grating orders.

In a search for errors not only the spectrum but also the interferogram should be thoroughly and precisely inspected. Differentiation of the various types of error (*e.g.* electronic disturbances, wrongly chosen instrumental parameters, unsuitable preparation of the sample) is often only possible by checking the interferogram alone ("Qualitative Interferogram Evaluation")[82].

Example 1

Figure 11 shows that a slightly structured, continuous intensity distribution $I_{(\tilde{\nu})}$ provides an interferogram function $F_{(x)}$ that is dependent on the optical path difference x over only a relatively narrow region (Fig. 11a). On the other hand, the optical path difference at which the interferogram function becomes constant (*e.g.* identical to zero) is the larger, the sharper are the spectral lines present in the intensity distribution $I_{(\tilde{\nu})}$ (Fig. 11b, rotational transitions of water vapor).

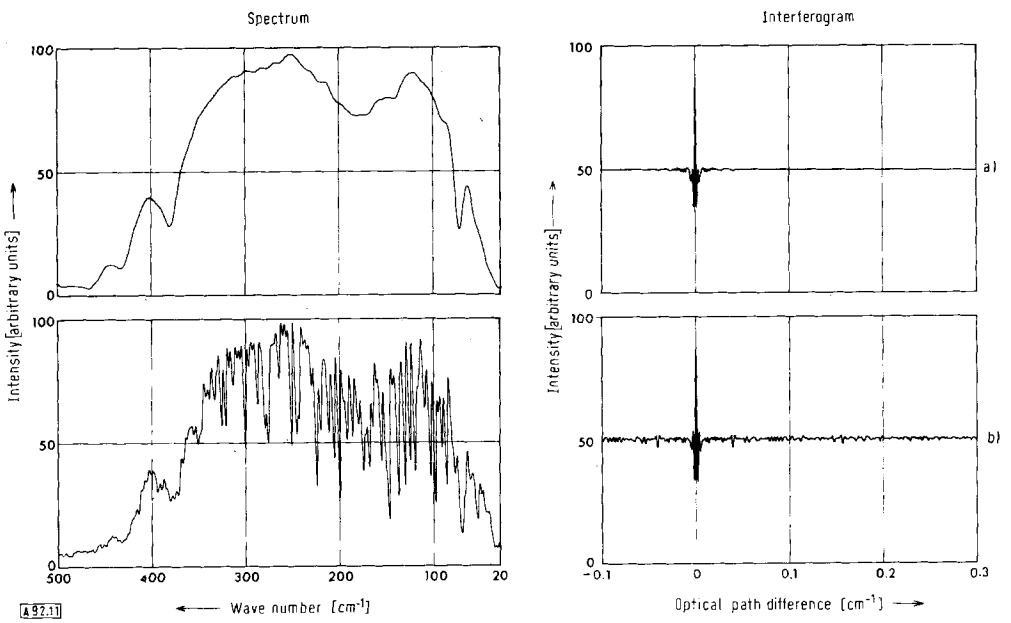

Fig. 11. Comparison of the interferogram and the spectrum in the cases of (a) continuous, and (b) discrete spectral intensity distributions.

A further contribution is provided by light that passes through the monochromator by routes deviating from the prescribed beam path.

5. Simple Examples of the Interpretation of Interferograms

To obtain a spectrum on a Fourier spectrophotometer the Fourier transformation must in principle be carried out quantitatively. This is possible only with the aid of data-processing machines, except for strictly monochromatic radiation (Fig. 5, lower part) or for polychromatic radiation that contains only a few, strictly monochromatic, components, neither of which are of practical interest. After some practice, however valuable qualitative information can be extracted from the interferogram without a quantitative Fourier transformation. The labor of qualitatively interpreting interferograms will materially assist the beginner in appreciating the principle of the Fourier method.

The explanation of this follows from the Heisenberg uncertainty principle (Section 4.3), which provides a connection between the coherence length of a light wave and the half-width of the corresponding spectral lines or bands. Thus, one can infer from the interferogram function alone whether there are more or less sharp emission or absorption areas in the intensity distribution studied.

Example 2

The periods of the harmonic functions that form the interferogram function are the larger, the longer are the wavelengths of the light studied. This can be seen in Figure 12.

The figure shows two intensity distributions—one mainly short-wave with a mean wavelength of about 26 μm (386 cm^{-1}) and a second, mainly long-wave, with a mean wavelength of about 155 μm (65 cm^{-1})—together with the corresponding interferogram functions. The ratio of the mean wavelengths is about 1:6 and the same ratio is found again in the separations of the two central minima in the corresponding interfero-

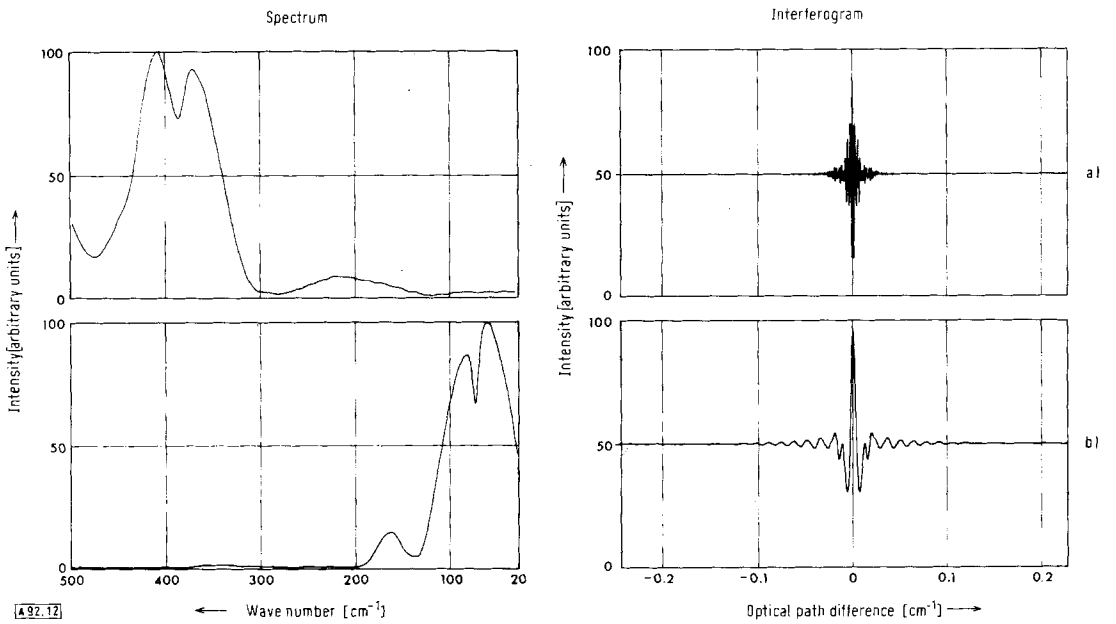

Fig. 12. Comparison of the interferogram and the spectrum for mainly shortwave (a) and mainly long-wave light (b).

gram functions. The other minima in the interferogram function corresponding to the shorter-wave radiation likewise follow one another more closely than in those corresponding to the longer-wave radiation. Thus, from the interferogram function alone one can decide whether mainly short-wave or mainly long-wave light is concerned. In this way one can *e.g.* determine whether the attempts to exclude light-scattering effects during the preparation of the sample were successful.

Example 3

Periodic interference of the FIR spectrum prejudicial to the substance-specific character of the information obtained is often observed; this can have various causes, which can be unambiguously identified from the interferogram function:

- Disturbing impulses in the interferogram function (Fig. 13a); they are caused by electrical or mechanical interferences and are not symmetrical about the position $x=0$.
- Internal reflection in a plane-parallel layer (*e.g.* in the cell, in the sample carrier, or in the sample itself[81,82]); figure 13b illustrates this case: the spectral intensity distribution corresponds to the apparatus characteristic of a Michelson interferometer where a plane-parallel almost absorption-free paraffin wax film about 100 µm thick has been introduced into the path of the beam. The internal reflection in a single plane-parallel layer produces in the interferogram two side-burst peaks arranged symmetrically around $x=0$ (arrows in Fig. 13b). They are converted by the Fourier transformation into the periodic interference observed in the spectrum ("channel spectra"). If we use for the Fourier transformation only that part of the interferogram function that lies between these two maxima, the interference in the spectrum disappears; admittedly, in certain circumstances the resolving power is then too small for the determination of the true band form (see Section 4.3; cf. Fig. 13b and 13c, absorption band at 72 cm^{-1}). The plane-parallelism between the relevant surfaces must then be destroyed in some other way; in the present example this was done with the

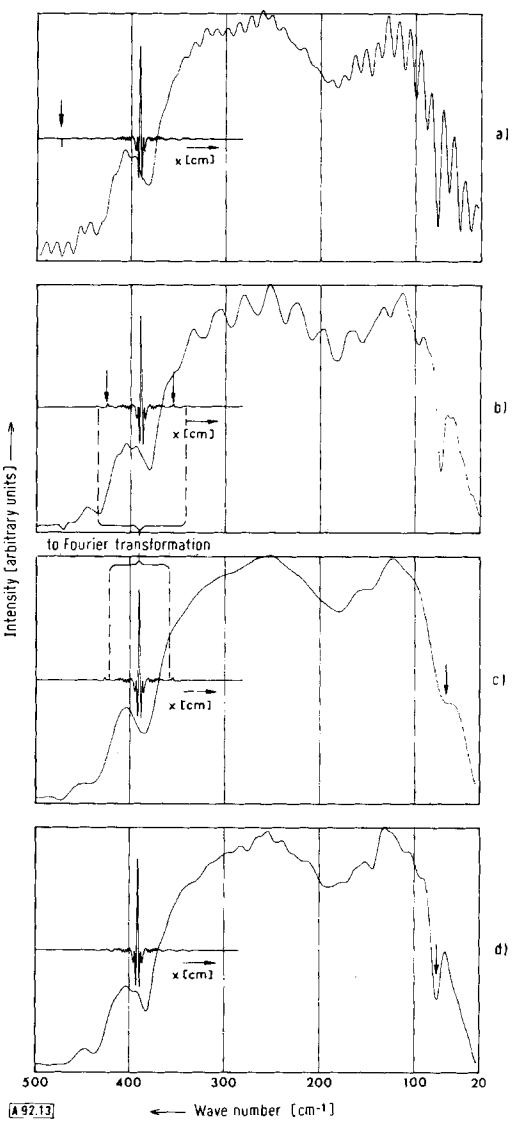

Fig. 13. Causes of periodic interference of the FIR Fourier spectrum (for explanation see text).

paraffin wax film (wedge shaped), which finally gave the interferogram and the spectrum shown in Figure 13d.

- Overlapping of a boxcar function (error in the determination of the interferogram function from the interferogram) or a triangular function (so-called drift in the interferogram) on the interferogram function used for the Fourier transformation[82].

6. Concluding Remarks

Introduction of the Fourier method into FIR spectroscopy has not only led to a considerable facilitation of work and an improvement in the quality of the spectra, but has also fostered interest in the FIR region. This is the case especially for the introduction of FIR spectroscopy into organic chemistry. Owing to the absence of heavy bonded atoms in organic molecules, the information content of the FIR spectrum was long underestimated. It followed that the demands on finance and time made by the measurement of FIR spectra by the conventional dispersive method were rightly assessed as too great. The introduction of the Fourier apparatus has certainly not eased the financial burden, or at the most slightly so in isolated cases; but its efficiency—greater than that of the conventional dispersive apparatus—has encouraged attack on, and indeed in some cases the solution of, the problems set out in Sections 2 and 3. The region below $100\,cm^{-1}$, which is especially important for the study of weak intermolecular interactions, would certainly have remained inaccessible had it not been for the Fourier apparatus, and the expansion of collections of spectra far into the FIR region[84] would presumably never have happened without the Fourier apparatus.

In recent years the Fourier method has received recognition and more extended use in NMR spectroscopy[65, 85-88], as it has in FIR spectroscopy. In particular, ^{13}C-NMR spectroscopy owes its present importance as an analytical tool exclusively to the Fourier method.

This progress report is based on five years experience in the field of FIR Fourier spectroscopy which the author collected in the Anwendungstechnik and Training Department at Beckman Instruments GmbH in München (Germany). Opportunity is taken here to express thankful recognition of the possibilities offered by the firm Beckman to carry out relevant scientific work—particularly in the field of molecular spectroscopy. Thanks are due to Prof. Dr. B. Schrader (Universität Dortmund) and Priv. Doz. Dr. P. Bleckmann (Universität Dortmund) for valuable suggestions and expert opinion on parts of the manuscript, and to Grad. Ing. K. Dabelstein (Beckmann Instruments) for help with the measurements necessary for this work.

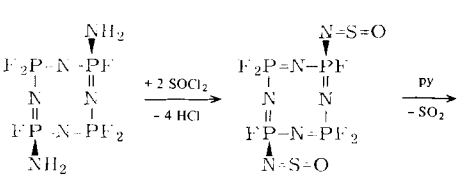
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

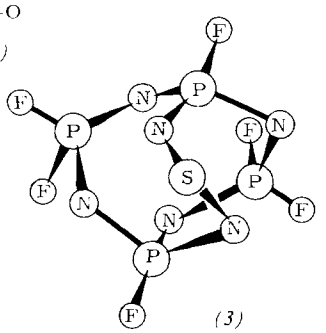
A Cyclophosphazene Spanned by a Sulfur Diimido Group[**]

By *Herbert W. Roesky* and *Enno Janssen*[*]

Although the chemistry of fluorinated cyclophosphazenes has been actively studied in recent years[1], derivatives having inorganic ring bridges have nevertheless remained unknown. Consideration of a model of $P_4N_4F_8$ revealed that a central bridge of this kind would have to have at least three members.



(1) (2)



(3)

Treatment of $P_4N_4F_6(NH_2)_2$ *(1)* with $SOCl_2$ afforded $P_4N_4F_6(NSO)_2$ *(2)*. In the presence of pyridine, *(2)* eliminates sulfur dioxide to give a low yield of 1,5,7,7,10,10-hexafluoro-3λ^4-thia-2,4,6,8,9,11-hexaaza-1λ^5,5λ^5,7λ^5,10λ^5-tetraphospha-bicyclo[3.3.3]undeca-2,3,5,7,9(1),10-hexaene *(3)*.

Compound *(3)* is a yellowish crystalline solid which sublimes at 25 °C/0.5 torr and melts at 57 °C. Its composition is proved by complete elemental analysis, and its monomeric structure in the liquid and gaseous state follows from the molecular weight (exp. 350, cryoscopic in C_6H_6) and the mass spectrum [M^+: *m/e* 354 (48 %)]. In the ^{19}F-NMR spectrum two multiplets appear in the intensity ratio of 1 : 2, their centers of gravity lying at $\delta_F = 59.8$ ppm and 66.2 ppm. The spectrum is independent of temperature, an argument strongly supporting the proposed structure *(3)*.

Procedure:

$P_4N_4F_6(NSO)_2$[2] (4.2 g, 0.01 mol) is heated in the presence of a catalytic amount of pyridine (2 drops) on a water bath for 2 d. Sublimation of the reaction product affords *(3)* (0.28 g, 8 %). This compound is also formed in low yield during the preparation of $P_4N_4F_6(NSCl_2)_2$ by heating of $P_4N_4F_6(NH_2)_2$ and sulfinyl chloride with elimination of SO_2 and HCl.

Tellurium(IV) Iodide: Tetrameric Te_4I_{16} Molecules in the Solid[**]

By *Volker Paulat* and *Bernt Krebs*[*]

The structures of chalcogen(IV) halides investigated up to now are determined largely by the stereochemical activity of the S^{IV}, Se^{IV}, and Te^{IV} nonbonding electron pairs. Gaseous SF_4 and SeF_4 (also $TeCl_4$ in the gas phase)[1] have the monomeric C_{2v} structure predicted by the VSEPR theory[2]; in solid TeF_4, on the other hand, square-pyramidal TeF_5 groups are linked *via* corners to form chains, the localized lone pair (E) completing octahedral TeF_5E coordination[3]. The structures of solid $TeCl_4$[4], $TeBr_4$[5], and $SeCl_4$[6] contain tetrameric

cubane-like molecules with distorted octahedral coordination around Te and Se, the lone pair being largely delocalized.

Our investigations on Te^{IV} iodide showed this compound to have a molecular structure in the solid which has not yet been observed in binary inorganic substances.

Single crystals for X-ray structure analysis were obtained by repeated sublimation at 100 °C in evacuated glass tubes of 5 cm length; the starting material was purified TeI_4, prepared by reaction of concentrated aqueous solutions of telluric acid and hydrogen iodide[7].

TeI_4 crystallizes in the orthorhombic space group Pnma with the cell constants $a = 13.635$, $b = 16.798$, $c = 14.624$ Å, $Z = 16$ TeI_4, $d_x = 5.04$, $d_{exp} = 5.02$ g/cm³ (literature values $a = 13.54$, $b = 16.73$, $c = 14.48$ Å[8]). The structure was solved from 3800 diffractometer data using Patterson methods and was refined to a conventional R factor of 5.3%.

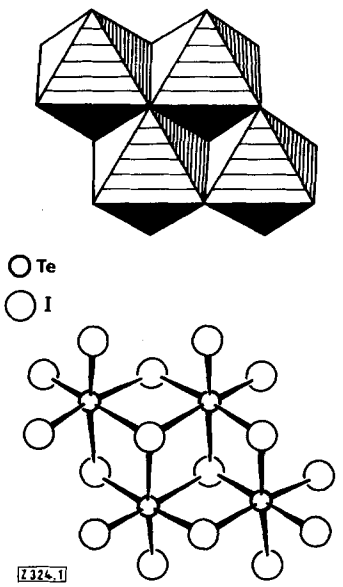

Fig. 1. Molecular structure of tellurium tetraiodide $(TeI_4)_4$ in the crystal.

The structure contains tetrameric Te_4I_{16} molecules as shown in Figure 1 which are built up of edge-sharing TeI_6 octahedra. This structural type has hitherto only been observed in titanium(IV) alkoxides[9]. The Te_4I_{16} molecule has exact C_s symmetry in the crystal, and is very close to an idealized C_{2h} symmetry. The Te—I bond lengths are: 2.752(2) to 2.788(2) Å (terminal, average 2.768 Å), 2.932(2) to 3.278(2) Å (I bonded to 2 Te, average 3.108 Å) and 3.198(3) to 3.241(2) Å (I bonded to 3 Te, average 3.227 Å). The I···I distances in the almost undistorted close packing of iodine atoms (sequence ABAC) are between 3.891(3) and 4.540(2) Å and rule out significant intermolecular bonding.

Comparison of the bond data in the homologous series TeF_4—$TeCl_4(TeBr_4)$—TeI_4 reveals an increasing delocalization of the Te^{IV} lone pair. This effect is likewise observed in compounds of other s^2 elements (Sn^{II}, Pb^{II}, As^{III}, Sb^{III}, Bi^{III}, I^V) and correlates with the gradation of electronegativities and polarizing power of the halogens.

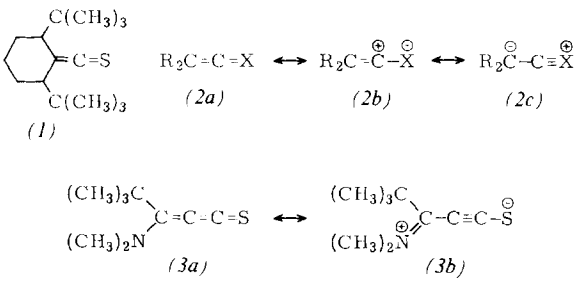
X-Ray Structure Analysis of a Dialkylthioketene

By *Ernst Schaumann*, *Surya Harto*, and *Gunadi Adiwidjaja*[*]

In contrast to the extensively studied ketenes, the thioketenes are generally very unstable. However, some representatives bearing bulky substituents can actually be isolated[1, 2]. An X-ray structure analysis performed on the crystalline thioketene *(1)* (m. p. 37 °C)[2a] should contribute to a better understanding of this class of compounds.



Compound *(1)* forms monoclinic crystals (space group $P2_1/c$; $a = 10.834$, $b = 12.251$, $c = 12.122$ Å; $\beta = 108.35°$). On the basis of 1324 significant reflections the structure was solved by direct methods and, as previously described[3], refined to an R value of 0.045.

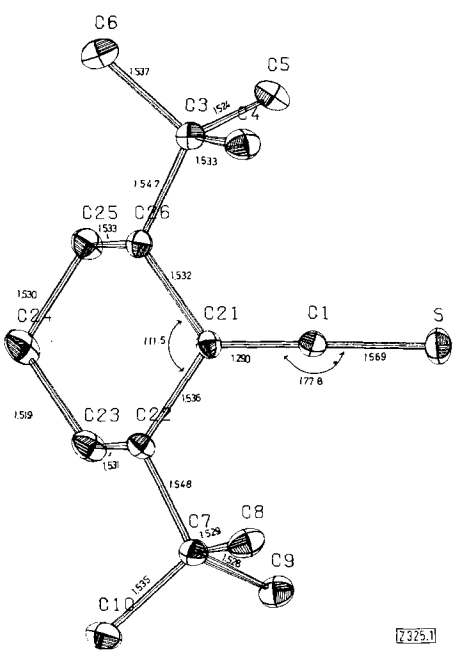


Fig. 1. Molecular structure of thioketene *(1)* with bond lengths [Å] (maximum standard deviation 0.006 Å) and important bond angles [°] (±0.3°).

[*] Dr. E. Schaumann and Dipl.-Chem. S. Harto
Institut für Organische Chemie und Biochemie der Universität
2 Hamburg 13, Martin-Luther-King-Platz 6 (Germany)
Dr. G. Adiwidjaja
Mineralogisch-petrographisches Institut der Universität
2 Hamburg 13, Grindelallee 48 (Germany)

The calculated molecular structure (Fig. 1) confirms the formulation as a monomeric thioketene *(1)*. The practically linear heterocumulene system is joined to a cyclohexane ring in the chair conformation. The *tert*-butyl groups are arranged equatorially in the *gauche* conformation and screen the thioketene system, thus explaining the particular stability of *(1)* and its reluctance to undergo cycloaddition reactions[2b].

The exocyclic double bond C^1—C^{21} is markedly shorter than in ketenes (dimethylketene: $r_{C=C}=1.314$ Å)[4]; a resonance formula *(2c)* weakening the double bond, whose significance in ketenes (X=O) is confirmed by MO calculations[5a] and ^{13}C-NMR data[5b], should therefore play at least no greater role in the thioketenes (X=S) than in the ketenes themselves. In accord with the formal sp hybridization of C^1, the CS bond length in *(1)* is shorter than in thioformaldehyde ($r_{C=S}=1.611$ Å)[6], and also significantly shorter than in the alkylidenethioketene *(3)* ($r_{C=S}=1.621$ Å)[7], which indicates a considerable contribution by the acetylenethiolate resonance structure *(3b)*. On the other hand, the CS bond length in *(1)* is greater than in carbon disulfide ($r_{C=S}=1.554$ Å)[8] where a resonance structure diminishing the electron density in the CS bond, which is analogous to *(2b)*, affects two sulfur atoms and thus becomes less effective for the individual bond. Here it should be noted that the direction indicated by *(2b)* for the polarization of the CS double bond in *(1)* does not follow unequivocally from its reactions[2]. Nor does the S(2p) ESCA spectrum of *(1)*[9], which indicates relatively nonpolar sulfur at 162.7 eV, permit any such decision.

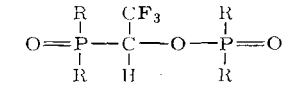
1,1-Bis(diphenylphosphoryl)-2,2,2-trifluoroethanol—A New Intermediate of Trifluoroacetyldiphenylphosphane Oxidation by Molecular Oxygen[**]

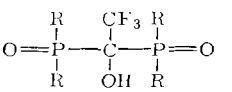
By *Ekkehard Lindner, Hans-Dieter Ebert*, and *Hans Lesiecki*[*]

Combination of (perfluoro)acyl groups with organophosphorus groups generally leads to labile, and hence highly reactive compounds of the type $(RCO)_nPR_{3-n}$[1]. If molecular oxygen is allowed to act on perfluoroacyldiarylphosphanes ($n=1$) then a complicated sequence of reactions ensues at room temperature, with participation of small amounts of H_2O, to form (1-diarylphosphoryl-1*H*-perfluoroalkyl)diarylphosphinates $(OPR_2)_2OCHR_f$, for example *(1)*, carbon dioxide, and the corresponding 1-H-perfluoroalkanes R_fH[2].



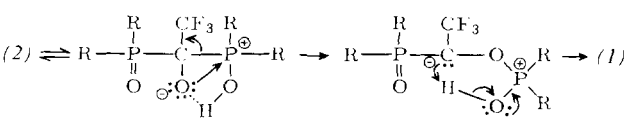
(1), R = C_6H_5

Since this kind of reaction has a considerable scope, we have attempted to gain an insight into the complicated sequence of events and have now succeeded in isolating a new intermediate: If the oxidation of trifluoroacetyldiphenylphosphane in diethyl ether is carried out in a polyethylene vessel then a colorless compound, m. p. 159—161 °C, precipitates within a few minutes, which is identified as 1,1-bis(diphenylphosphoryl)-2,2,2-trifluoroethanol *(2)* on the basis of elemental analysis, and IR and mass spectra.



(2), R = C_6H_5

The IR spectrum of *(2)* contains a broad intense band at 3080 cm^{-1} corresponding to an O—H stretching mode. This absorption is masked by a sharp minimum for the arene C—H vibrations at 3062 cm^{-1}. A band at 1350 cm^{-1} can be interpreted as an O—H deformation frequency. The alcohol *(2)* recently proposed as intermediate in the oxidation of $CF_3COP(C_6H_5)_2$[3] proves to be thermally labile and undergoes irreversible isomerization on heating in various solvents (alcohols, halogenated hydrocarbons, *etc.*) to give the more stable (1-diphenylphosphoryl-2,2,2-trifluoroethyl)diphenylphosphinate *(1)*:



In the usual glass vessels the isomerization *(2)*→*(1)* is catalyzed to such an extent that the isolation of *(2)* becomes impossible. The isomerization can be followed by IR spectroscopy: The broad O—H band disappears in favor of a sharp alkane C—H stretching absorption at 2924 cm^{-1}. The hydrogen atom in *(2)* and *(1)* comes from traces of moisture in the oxygen used and can be replaced by deuterium if the oxygen stream is moistened with D_2O after purification in a molecular sieve.

Procedure:

Through a solution of $CF_3COP(C_6H_5)_2$ (4.5 g, 16 mmol) in diethyl ether prepared in a polyethylene vessel is passed a vigorous current of oxygen. After *ca.* 10 min the alcohol *(2)* precipitates as colorless crystals. The crystals are filtered off, washed with diethyl ether, and vacuum dried. Yield 1—2 %.

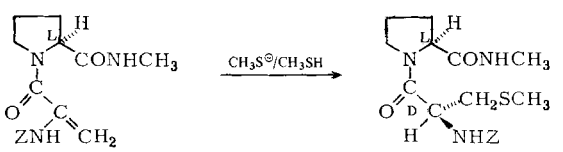
Optical Induction During Biomimetic Formation of Cysteine[**][1]

By *Ulrich Schmidt* and *Elisabeth Öhler*[*]

The peptide hormones kallidin, eledoisin, and β-melanotropin contain L-serine-L-proline segments, and L-cysteinyl-L-proline units are found in the hormones β-corticotropin releasing factor, oxytocin, isotocin, vasopressin, and vasotocin. β-Methyl-D-cysteinyl-L-proline is a component of a heterodetic cyclotetrapeptide in the antibiotics nisin and subtilin[3]. The thioether of this ring is probably formed by intramolecular addition of a mercapto group to the double bond of aminocrotonic acid in α-aminocrotyl-L-prolylglycyl-L-cysteine.

This suggests that the spatial course of addition of hydrogen sulfide or thiols to dehydroalanine—an essential reaction for cysteine biosynthesis—can be directed by an amino acid joined by a peptide-type linkage to dehydroalanine. This concept is confirmed by a simple model: *N*-benzyloxycarbonyldehydroalanyl-L-prolinemethylamide *(1)* adds methanethiol in a sodium methanethiolate-catalyzed reaction to give almost exclusively (optical yield at least 85%) *N*-benzyloxycarbonyl-*S*-methyl-D-cysteinyl-L-prolinemethylamide *(2a)*. The starting compound *(1)* was prepared according to the method of *Patchornik*[4] by reaction of *(2b)* with CH_3Br/HCOOH and degradation of the sulfonium salt in aqueous $NaHCO_3$ solution (yield 75%)[2].



(1) *(2a)*

Z = C_6H_5–CH_2–O–CO [+ 15% *(2b)*]

Compound *(2a)* and the diastereomeric L-cysteinyl derivative *(2b)* can be distinguished on the basis of the chemical shifts of the *S*-methyl and *N*-methyl protons in the NMR spectrum [*(2a)*, δ = 2.10 (s), 2.67 (d); *(2b)*, δ = 2.14 (s), 2.62 (d) (both 100 MHz, in $CDCl_3$, TMS internal standard)]. *(2b)* was obtained in 68% yield from Z-L-Cys(SMe)-OH and L-H-Pro-$NHCH_3$ by the DCC method[2], m.p. 127—130 °C (from ethyl acetate), $[\alpha]_D^{20} = -84°$ ($c = 1.096$ in $CHCl_3$).

In order to establish the configuration of *(2)* beyond doubt we prepared the enantiomer *N*-benzyloxycarbonyl-*S*-methyl-L-cysteinyl-D-prolinemethylamide *(2c)* in 64% yield from Z-L-Cys(SMe)-OH and D-H-Pro-$NHCH_3$ by the DCC method; m.p. 112—113 °C (from ethyl acetate/ether), $[\alpha]_D^{20} = +54°$ ($c = 1.094$ in $CHCl_3$). The enantiomer proved to be identical with *(2a)*, except for the opposite sign of rotation.

N-Benzyloxycarbonyl-S-methyl-D-cysteinyl-L-prolinemethylamide (2a)

A solution of $NaOC_2H_5$ (1 mmol) and methanethiol (500 mg) in anhydrous ethanol (4 ml) is added to a solution of *(1)* (330 mg, 1 mmol) in anhydrous ethanol (4 ml) and the mixture stirred for 2 h. The ethanol is then removed under vacuum, and the residue taken up in dichloromethane (20 ml) and washed twice with H_2O (2 × 3 ml). The CH_2Cl_2 solution is dried over Na_2SO_4, evaporated under vacuum, and the oily residue purified by chromatography on silica gel (eluant: chloroform/methanol 9:1). The NMR spectrum of the oil obtained in this way (in $CDCl_3$) contains signals for both *(2a)* and *(2b)* [*(2a)*:*(2b)* = 8.5:1.5]. On rubbing with ethyl acetate/ether, 290 mg of *(2a)* crystallized; m.p. 105—110 °C (from ethyl acetate/ether); $[\alpha]_D^{20} = -55°$ ($c = 0.985$ in $CHCl_3$), yield 77%.

Synthesis of Phosphorus Ylides at a Cobalt-Complex Center[**]

By *Hans-Friedrich Klein* and *Reinhard Hammer*[*]

During oxidative additions to tetrakis(trimethylphosphane)-cobalt(0)[1] the electronic configuration of the metal changes from d^9 to d^8; this results in a 2:1 stoichiometry for such reactions in accordance with Eq. (1).

$$2\ L_4Co + X\text{–}Y \longrightarrow L_4CoX + L_3CoY + L \qquad (1)$$

L = $(CH_3)_3P$; X = H, Y = Cl; X = CH_3[2], Y = Br

We have found that the addition of 1,1-dihaloalkanes in the sense of Eq. (1) [*e.g.* X = RCHCl, Y = Cl] does not stop at the stage of the haloalkylcobalt(I) complex, but proceeds with 3:2 stoichiometry in accordance with Eq. (2) to give a complex cobalt dihalide having two ylidic alkylenetrimethylphosphorane ligands

$$3\ L_4Co + 2\ R^1R^2CCl_2 \xrightarrow[-10\,°C]{\text{pentane}} [(CH_3)_3PCR^1R^2]_2CoCl_2 + 2\ L_3CoCl + 4\ L \qquad (2)$$

L = $(CH_3)_3P$

(1). $R^1 = R^2 = H$: blue solid[4], 73%
(2). $R^1 = R^2 = D$: blue solid, 75%
(3). $R^1 = H$, $R^2 = CH_3$: blue crystals, 55%, sparingly soluble in THF, dec. > 108 °C
(4). $R^1 = H$, $R^2 = Si(CH_3)_3$: blue crystals, 43%, soluble in benzene and THF, dec. > 76 °C

In this reaction a *chlorine-free* carbene is formally transferred and not a chlorocarbene as in the Wittig reaction[5]. *(1)* has a magnetic moment ($\chi_g = 26.3 \times 10^{-6}$ g cm^{-3}; $\mu_{eff} = 4.3_9\ \mu_B$), which is in good agreement with that of the isoelectronic $[(CH_3)_3PO]_2CoCl_2$[6]. As shown by the IR spectrum on reaction with CD_2Cl_2 deuterium is distributed over all C atoms of *(2)*.

It seems plausible that the overall reaction proceeds in three steps:

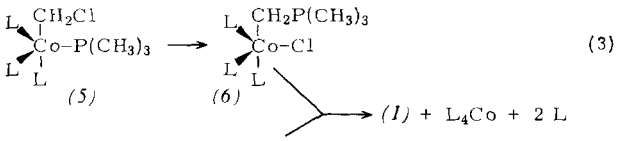
[*] Univ.-Doz. Dr. H.-F. Klein and Dipl.-Chem. R. Hammer
Anorganisch-chemisches Institut der Technischen Universität
8 München 2, Arcisstr. 21 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

1) Oxidative addition according to Eq. (1), for example with $X=CH_2Cl$, $Y=Cl$. The hypothetical intermediate *(5)* in Eq. (3) is formulated analogously to the stable complex L_4CoCH_3[1].

2) Reaction of the carbenoid moiety $Co—CH_2—Cl$ in *(5)* according to Eq. (3) to give *(6)*. In the synthesis of *(1)* according to Eq. (2) the carbene trapping agent cyclohexene can be used as reaction medium without lowering the yield of *(1)* or norcarane being detectable by mass spectroscopy.

3) Disproportionation of the second intermediate *(6)* as already observed earlier in the reaction according to Eq. (4)[4].



(5) *(6)* *(1)* + L_4Co + 2 L (3)

$$2\ L_3CoCl + 2\ (CH_3)_3P{=}CH_2 \qquad (4)$$

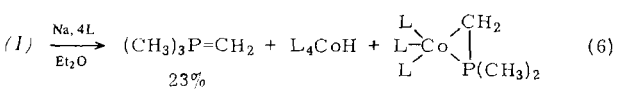
L = $(CH_3)_3P$

Since the by-product L_3CoCl [Eq. (2)] is formed as intermediate of the reduction during production of L_4Co[1], from cobalt chloride, trimethylphosphane (L) and magnesium in tetrahydrofuran (THF), it could be utilized in a simple batch synthesis of *(1)* according to Eq. (5); this affords indeed satisfactory yields:

$$CoCl_2 + 4\ L + 2\ CH_2Cl_2 + 2\ Mg \xrightarrow{THF} (1) + 2\ MgCl_2 + 2\ L \qquad (5)$$

L = $(CH_3)_3P$ 70%

The ylide ligand in *(1)* is strongly bound and is not displaced by chelating agents. It is partially liberated only by reduction with metals in presence of sufficient amounts of trimethylphosphane, but not without a further part being decomposed in some unknown way. The reduced cobalt stabilizes in the form of known trimethylphosphane complexes[4, 7].



(1) $\xrightarrow[Et_2O]{Na,\ 4L}$ $(CH_3)_3P{=}CH_2$ + L_4CoH + $L_3Co(CH_2)P(CH_3)_2$ (6)

23%

L = $(CH_3)_3P$

Procedure:

A mixture of anhydrous $CoCl_2$ (1.33 g, 10.2 mmol), $(CH_3)_3P$ (3.8 ml, 40.0 mmol) and magnesium turnings (500 mg, 20.5 mmol) in THF (30 ml) is stirred at 20 °C under protective gas (nitrogen) until the solution turns reddish brown. A solution of CH_2Cl_2 (1.31 ml), 20.4 mmol) in THF (15 ml) is then cautiously added dropwise such that the brown coloration of the solution is just sustained over the blue precipitate (towards completion the dropwise addition must be carried out very slowly). The final mixture is stirred for 2 h, filtered, and the product washed with 50 ml THF in small portions until the washings are colorless. After 3 hours' drying at 20 °C/0.1 torr, analytically pure *(1)* (2.20 g, 70 %) is obtained.

A suspension of *(1)* (2.00 g, 6.45 mmol) in ether (20 ml) is reduced with Na-sand (500 mg, 22 mmol, from a paraffin suspension, washed with hexane) over a period of 4 days at 20 °C. Trimethylmethylenephosphorane[8] (270 mg, 23 % based on Eq. (6)) can be isolated from the volatile compounds of the reaction solution by fractional condensation. L_4CoH and $L_3Co[CH_2P(CH_3)_2]$ sublime from the residue at 80 °C/0.1 torr in an overall yield of *ca.* 60 %.

Tri-*tert*-butylsilanes: Reactions and Hindered Si—C Rotation

By *Manfred Weidenbruch, Walter Peter*, and *Claude Pierrard*[*]

The reactions of tri-*tert*-butylsilane *(1)*[1–3] and the halosilanes *(2)* to *(4)*[1] readily preparable therefrom are largely determined by steric and electronic effects with the result that their Si—H and Si—Hal bonds differ markedly from those of other organosilanes.

$(t\text{-}C_4H_9)_3SiH$ *(1)* $(t\text{-}C_4H_9)_3SiCl$ *(2)* $(t\text{-}C_4H_9)_3SiBr$ *(3)* $(t\text{-}C_4H_9)_3SiI$ *(4)*

Only in exceptional cases are tri-*tert*-butylsilanes observed to react with nucleophiles, although this reaction, which usually proceeds with inversion of stereochemistry[4], is typical for this class of compounds. For instance, *(2)* fails to react with any of the following reagents: liquid or gaseous ammonia, sodium amide in boiling benzene, or lithium tetrahydridoaluminate in ether. Only under drastic conditions does reaction occur with solid potassium hydroxide in ethanol to give the silanol *(5)* in 82 % yield, which expectedly fails to condense to form disiloxane.

$$(t\text{-}C_4H_9)_3SiCl + KOH \xrightarrow[78\,°C,\ 2d]{C_2H_5OH} (t\text{-}C_4H_9)_3SiOH + KCl$$

(2) *(5)*

The usual methods for synthesis of organofluorosilanes by nucleophilic chlorine-fluorine exchange with SbF_3, ZnF_2, or Na_2SiF_6 are just as ineffective for *(2)* as the action of HF, SbF_3, or $(C_6H_5)_3CBF_4$ in the case of *(1)*. In contrast, the fluorosilane *(6)* is formed smoothly with the Lewis acid phosphorus pentafluoride.

$$(t\text{-}C_4H_9)_3SiH + PF_5 \xrightarrow{120\,°C} (t\text{-}C_4H_9)_3SiF + PF_3 + HF$$

(1) *(6)*

Generally, tri-*tert*-butylsilanes appear to react just as readily, or even faster, with electrophiles as comparable but sterically less hindered triorganosilanes. This is demonstrated especially clearly not only by halogenation reactions[1] but also by reactions with halocarbenes. Whereas *(1)* fails to undergo copper-catalyzed methylene insertion, dihalocarbenes, for which direct electrophilic attack on the Si—H bond has been established[5], give the insertion products *(7)* and *(8)* in 55 % yield each (Table 1).

[*] Prof. Dr. M. Weidenbruch, Dr. W. Peter, and Dr. C. Pierrard
Institut für Anorganische Chemie der Technischen Hochschule
51 Aachen, Templergraben 55 (Germany)

$$(1) + C_6H_5HgCX_3 \xrightarrow[\text{pet. ether}]{120\,^\circ C} (t\text{-}C_4H_9)_3SiCHX_2 + C_6H_5HgX$$

(7), X = Cl
(8), X = Br

Joint action of iodoform and potassium *tert*-butoxide on *(1)* at room temperature also appears to give initially the diiodomethyl derivative, which however decomposes to iodosilane *(4)* on attempted isolation by fractional sublimation. In the absence of base, *(1)* and iodoform undergo hydrogen-iodine exchange to give *(4)* only after prolonged heating in benzene.

Table 1. Tri-*tert*-butylsilanes $(t\text{-}C_4H_9)_3SiX$ *(5)*—*(8)* prepared.

Cpd.	X	M. p. [°C]	^{1}H-NMR ($CDCl_3$)	δ [ppm]
(5)	OH	34—38	1.12 (CH_3)	4.8 (SiOH)
(6)	F	36—38	1.10 (CH_3)	[a]
(7)	$CHCl_2$	205—210	1.30 (CH_3)	5.54 ($CHCl_2$)
(8)	$CHBr_2$	190—195	1.27 (CH_3)	5.24 ($CHBr_2$)

[a] ^{19}F-NMR (CCl_4): δ = 186.7 ppm.

Provided that the fourth substituent is sufficiently bulky the tri-*tert*-butylsilanes obtained permit the first direct proof of hindered rotation in simple alkylsilanes by ^{1}H-NMR spectroscopy. This restriction of free rotation, which has been thoroughly investigated for CC single bonds[6], has not previously been observed in the corresponding silicon compounds on account of the greater Si—C bond length.

In the case of hindered rotation about the Si—C bond the signal of the *tert*-butyl protons should be split into two singlets of relative intensity 2 : 1. That this assumption is correct follows from the low-temperature spectra of tri-*tert*-butyliodosilane *(4)* (Fig. 1).

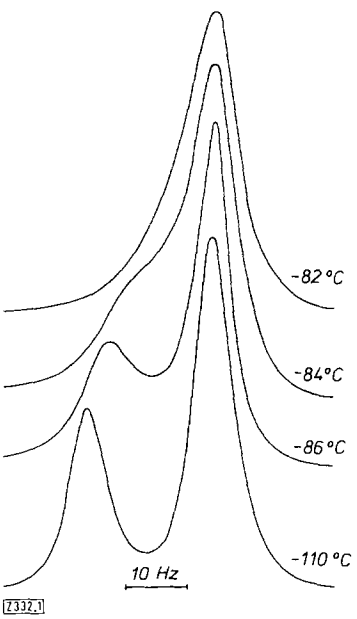

Fig. 1. Low-temperature ^{1}H-NMR spectra of tri-*tert*-butyliodosilane *(4)* (100 MHz).

On cooling of a solution of *(4)* in $CBrF_3$ the singlet of the *tert*-butyl protons at δ = 1.24 ppm becomes broader. In keeping with the slower rotation, splitting begins at −86 °C and continues until at −110 °C two isolated singlets appear at δ = 1.10 and 1.30 ppm in the intensity ratio of 2 : 1. The steric effectiveness of bromine or chlorine is less than that of iodine, with the result that signal splitting is only observed from −93 and −104 °C for compounds *(3)* and *(2)*, respectively. The activation parameters $\Delta G_C^{\ddagger}$ determined for *(2)*, *(3)*, and *(4)* by known methods[7] amount to 37.7, 39.6, and 40.8 kJ mol^{-1}, respectively.

The bulky dihalomethyl groups in *(7)* and *(8)* expectedly exert a highly pronounced influence on the rotation of the *tert*-butyl groups. The reduced symmetry and the additional restriction of free rotation about the Si—CHX_2 bond lead to complicated splitting patterns (first splitting below −74 and −68 °C, respectively) from which the activation parameters cannot be directly determined.

Pentafluoroorthosulfuric Acid, $HOSF_5$

By *Konrad Seppelt*[*]

Sulfur rarely has the coordination number six, whereas it occurs more frequently in the case of selenium, and six is the dominating coordination number for tellurium. The SF_6 derivatives F—OSF_5[1] and $Cs^+OSF_5^-$[2] demonstrate the limits regarding the possible existence of six-coordinated sulfur compounds: the electronegativity of fluorine in $FOSF_5$ prevents an elimination reaction giving F_2 and SOF_4, while $ClOSF_5$ readily decomposes to ClF and SOF_4[3]. On the other hand, the salt $Cs^+OSF_5^-$ is stabilized by high lattice energy, whereas the lattice energy of $K^+OSF_5^-$ does not suffice for stabilization. Hence it was to be expected that $HOSF_5$ should decompose spontaneously into HF and SOF_4. However, this compound can actually be isolated pure, although it does indeed undergo the expected decomposition.

Pentafluoroorthosulfuric acid is prepared from $ClOSF_5$ by hydrolysis or—better—by reaction with hydrochloric acid:

$$ClOSF_5 + H_2O \xrightarrow[-60\,^\circ C]{HF} HOCl + HOSF_5 \qquad (1)$$

$$ClOSF_5 + HCl \xrightarrow{-95\,^\circ C} Cl_2 + HOSF_5 \qquad (2)$$

In reaction (1) $HOSF_5$ can be detected only by NMR spectroscopy, in reaction (2) this product is obtained as a white solid; chlorine and excess HCl can be completely removed by pumping at −95 °C. Pure $HOSF_5$ melts with decomposition to SOF_4 and HF at *ca.* −65 °C.

[*] Priv.-Doz. Dr. K. Seppelt [**]
Anorganisch-chemisches Institut der Universität
69 Heidelberg 1, Im Neuenheimer Feld 270 (Germany)

[**] I am indebted to Dr. *R. Geist* for the recording of the mass spectrum and to the Fonds der Chemischen Industrie for financial support of this work.

The existence and structure of the thermally very sensitive pentafluoroorthosulfuric acid is confirmed by the following methods:

1. The ^{19}F-NMR spectrum (in $CHClF_2$, external standard $CFCl_3$) shows a typical AB_4 system ($\delta_A = -71.8$, $\delta_B = -67.0$ ppm), that differs from the spectrum of the starting compound $ClOSF_5$[3]. It is very similar to the spectrum of the homologous pentafluoroorthoselenic acid—this is not surprising, as structurally similar sulfur and selenium fluorides generally show almost identical NMR spectra[4, 5]. Thus the presence of four equatorial and one axial fluorine atom can be concluded; the proton is observed at $\tau = 2.9$ in the ^{1}H-NMR spectrum.

2. The mass spectrum does not show the molecular ion; the highest peak is, however, the fragment SF_5^+ ($m/e = 127$, 1%), which is accompanied by peaks for SOF_4^+ (124, 1%), SOF_3^+ (105, 100%), SF_3^+ (89, 8%), *etc.*, thus indicating that at least some $HOSF_5$ volatilizes without decomposition.

3. The Raman spectrum (in CH_3F, -120 °C) show bands at 3590 (νOH), 1080 (δOH), 761 ($\nu_s SF_4$), 635, 610 (νSF) and 530, 500 cm^{-1} (δSF). Considering the position and intensity of the peaks it very much resembles the spectrum of SF_6. Substitution of an F atom by an OH group leads to only slight deviations from the selection rule for octahedral symmetry—as is also found in the case of pentafluoroorthoselenic acid[6].

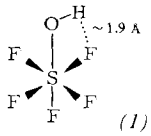
4. Identification of the decomposition products [cf. reaction (3)] is almost equivalent to an elemental analysis.

$$HOSF_5 \longrightarrow SOF_4 + HF \qquad (3)$$

$$HOSeF_5 \longleftarrow SeOF_4 + HF \qquad (4)$$

Reaction (3) proceeds slowly even at -78 °C; at -60 °C $HOSF_5$ has a halflife of *ca.* 15 min (determined by NMR spectroscopy).

The equilibrium of the HF elimination reactions (3) and (4) is shifted completely to the right in the case of sulfur and completely to the left in the case of selenium, once again confirming that selenium behaves more like tellurium (there is no monomeric $TeOF_4$; only the dimer $Te_2O_2F_8$ exists alongside the longer known $HOTeF_5$[5, 7]). The reason for the instability of $HOSF_5$ lies initially in the preferred formation of a sulfur-oxygen double bond (and formation of very stable HF). The decomposition at such a low temperature also suggests an exceptional kinetic instability.



(1)

As can be seen in a molecular model of $HOSF_5$ *(1)* the intramolecular distance H···F is so small (*ca.* 1.9 Å) that elimination of HF is particularly well favored. In $HOSeF_5$ rotation of the proton around the SeO axis is still hindered—as is seen from the vibrational spectrum[8]. Almost free rotation is finally observed in $HOTeF_5$.

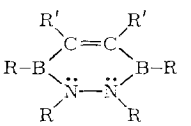
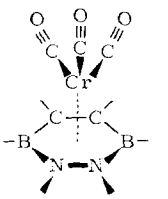
(1,2-Diaza-3,6-dibora-4-cyclohexene)tricarbonylchromium—A Complex with an η^6-$C_2B_2N_2$ Ligand[1]

By *Walter Siebert* and *Roland Full*[*]

The boron-carbon-nitrogen heterocycles isoelectronic to benzene and borazine are potential ligands for metal complexes. We report here on the ligand properties of one of the $C_2B_2N_2$ isomers, 4,5-diethyl-1,2,3,6-tetramethyl-1,2-diaza-3,6-dibora-4-cyclohexene *(1)*, whose synthesis[2] was achieved by reaction of 3,4-diethyl-2,5-dimethyl-1,2,5-thiadiborolene[3] with *N,N'*-dimethylhydrazine. The liquid, air-sensitive 6-electron donor *(1)* reacts with tris(acetonitrile)tricarbonylchromium with displacement of all three CH_3CN-ligands to give the red *hexahapto* complex *(2)*.



(1), R = CH_3, R' = C_2H_5



(2)

The mass spectrum[4] (70 eV) of *(2)* contains signals for the molecular ion $LCr(CO)_3^+$ [L = *(1)*] ($I_{rel} = 30$) and the following fragment ions: $LCrCO^+$(23), LCr^+(77), L^+(8), $\{L - CH_3\}^+$(51), $(CH_3)_4B_2N_2Cr^+$(100), $(C_2H_5)_2C_2Cr^+$(17), $(CH_3)_3BNCr^+$(74), Cr^+(99), CO^+(28).

While *(2)* can be described as "ethylenehydrazine"-tricarbonylchromium according to the 18-electron rule, *Wade*'s concept[5] (systemization of *closo*-, *nido*-, and *arachno*-structures) demands participation of the boron atom in the complex formation, since $n+2$ electron pairs are required for bonds between n skeletal atoms in a *nido* compound. In complex *(2)* the 2(7 + 2) electrons are provided by boron (2 × 2), carbon (2 × 3), and nitrogen (2 × 4). The expected interaction between the boron atoms and chromium atoms is evidenced by the

Table 1. Spectroscopic data for *(1)* and *(2)* [a].

Signal	I_{rel}	*(1)*	*(2)*

high-field shift of the ^{11}B-NMR signal (Table 1), which is consistent with the $\Delta\delta$ values (≈ 8 ppm) reported for the borazinetricarbonylchromium derivatives[6].

As in the corresponding hexamethylborazine compound[6], complex formation effects only a slight high-field shift for the BCH_3 protons in the ^{1}H-NMR spectrum of *(2)*, while the position of the NCH_3 signal is much more strongly influenced. Since the IR spectrum of *(2)*, like that of hexamethylbenzene-[7] and hexamethylborazinetricarbonylchromium[6], shows two CO bands (A_1, E), the local C_{3v} symmetry of the $Cr(CO)_3$ fragment is not disturbed by the $C_2B_2N_2$ ligand. Thus the new $C_2B_2N_2$—$Cr(CO)_3$ bonding system can be included in the series of *hexahapto*(6-electron donor-ligand)tricarbonylchromium complexes.

Experimental procedure:

A stirred mixture of tris(acetonitrile)tricarbonylchromium (1.74 mmol) and *(1)* (2.24 mmol) is heated at 90 °C under a stream of nitrogen for 1 h; stirring is then continued for a further 0.7 h at 90 °C/11 torr. After removal of excess *(1)* by distillation in a vacuum *(2)* can be recovered by sublimation at 120 °C/0.03 torr: red crystals, m.p. 111—112 °C (from hexane), yield 53 %.

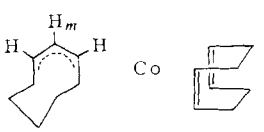
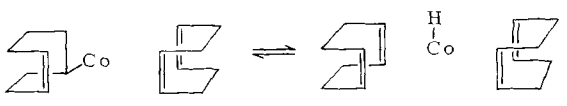
A Lithium-Cobalt Bimetal Complex

By *Helmut Bönnemann, Carl Krüger*, and *Yi-Hung Tsay*[*]

In their chemical behavior 1,5-cyclooctadiene(cyclooctenyl)-cobalt systems of type *(1)* or *(2)* are characterized by the extreme ease with which hydrogen can transfer from enyl ligand to cobalt atom and thus give rise to very reactive Co—H species, *e.g. (2a)*. This "mobile hydrogen" determines the catalytic mode of action of *(1)* and *(2)* toward olefins[1].



(1)



(2) *(2a)*

While *(2)* reacts quantitatively even at 0 °C with trimethylaluminum to form methane—whereby the hydride form *(2a)* was detected—the less reactive π form *(1)* is stable towards this reagent[1].

It has now been found, however, that *(1)* reacts under mild conditions with excess phenyllithium, the mobile hydrogen atom transferring from the cyclooctenyl- to the phenyl-group; the liberated benzene can be detected quantitatively. Between −10 and +20 °C a bimetallic complex of composition *(3)* is formed which is isolated from ethereal solution as golden-red crystals.

$$(1) + 2\ LiC_6H_5 \xrightarrow{(C_2H_5)_2O}$$

$$(C_8H_{12})_2CoLi(LiC_6H_5) \cdot 2\ (C_2H_5)_2O + C_6H_6$$

(3)

(3) is extremely sensitive towards oxygen; it immediately decomposes and turns black in air, but can be stored for long periods at room temperature. According to its NMR spectrum the compound is diamagnetic. From the extremely low conductivity (0.2 μS/cm in ether) it can be concluded that *(3)* is largely homopolar and not present as a dissociated ion pair. The IR spectrum (KBr mull in absence of air) contains numerous absorption bands, but some, typical for aromatic vibrations of free phenyllithium (*e.g.* at 1045, 1210 and 1040 cm^{-1}) are either lacking or strongly shifted; particularly noteworthy is a band, characteristic for the complex, at 1630 cm^{-1} in the region of C=C stretching vibrations. From the ^{1}H-NMR spectrum of *(3)* (100 MHz at 20 °C in [D_8]-THF with TMS as locking signal) it follows that the phenyl group is influenced to an extraordinary extent by the metal atoms, and that the ring current is strongly perturbed [signal shift of the *ortho* ($\tau = 2.47$) as well as *meta* and *para* protons ($\tau = 3.30$) to higher field strengths]. The signals of the coordinated eight-membered ring are likewise shifted upfield relative to *(1)*. The *meso* proton H_m of the starting compound *(1)* does not appear in the spectrum of *(3)*.

The X-ray structural analysis of *(3)* confirms that, surprisingly, the *meso* hydrogen is abstracted from the π-cyclooctenyl group during the action of phenyllithium on the coordinatively unsaturated complex *(1)*.

The crystal structure was deduced from 2371 reflections (329 classed as unobserved; $Mo_{K\alpha} = 0.71069$ Å) measured and refined by a special method ($a = 11.020(5)$, $b = 11.417(3)$, $c = 14.532(4)$ Å; $\alpha = 71.50(2)$, $\beta = 79.85(3)$, $\gamma = 58.44(3)°$; $P\bar{1}$; $Z = 2$; $R = 0.068$). Four coordination sites of the cobalt are occupied by three olefinic double bonds and one phenyl group. The lithium atoms occupy two further positions diametrically

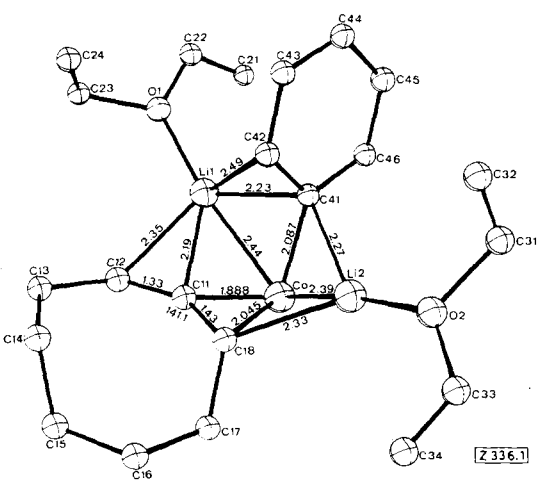


Fig. 1. Molecular structure of the bimetal complex *(3)* [the 1,5-cyclooctadiene ligands bound exclusively to the cobalt, with $d(C{=}C) = 1.39(1)$ and 1.40(1) Å, have been omitted].

[**] X-ray structure analysis.

opposite each other relative to the cobalt atom. Free coordination sites on the lithium are occupied by ether molecules. Characteristic for interactions between main group metals and transition metals in complexes is the incorporation of carbon atoms with formation of multicenter electron-deficient bonds[2] (cf. Fig. 1).

The most important structural characteristics in *(3)* are multicenter bonds of the metals to the phenyl ring (C41) and to the second C_8 unit of the molecule. Noteworthy are the interactions between lithium and the β-C atoms of the phenyl group (C42)[3] as well as the C_8 unit (C12), and particularly the formation of a three-center bond with two different metal atoms at the olefin carbon atom C11 of the former cyclooctenyl group. The Co—C bond to the C11 atom (1.888 Å) is remarkably short.

Experimental procedure:

A stirred suspension of *(1)*[4] (10.0 g, 36.2 mmol) in diethyl ether (150 ml) is treated at −30 °C with a solution of LiC_6H_5 (6.1 g, 72.4 mmol) in ether (100 ml) and the whole warmed to 20 °C within 1 h. The color of the reaction solution gradually changes from dark-brown to red. After further stirring for 1.5 h the solution is evaporated down to *ca.* 150 ml and cooled to −80 °C, whereupon gold-red crystals of *(3)* separate out. Recrystallization from ether affords 8.5 g of the pure product, which is best stored in an ethereal atmosphere at −30 °C.

Ethylenebis(phenylsodium)nickel

By *Klaus Jonas*[*]

In continuation of our studies on alkali-metal compounds of nickel[1, 2] we have checked the reactivity of the (phenylsodium)nickel(0) system toward N_2[3] as well as other multibonded partners, *e.g.* olefins. In this communication we report on the complex ethylenebis(phenylsodium)nickel *(1)*, for which X-ray structural data are already available[5a].

Reaction of all-*trans*-1,5,9-cyclododecatrienenickel(0)[4] (CDT-Ni^0) with a salt free NaC_6H_5/LiC_6H_5 mixture (Na/Li = 2–4 : 1)[3] in the molar ratio $(NaC_6H_5 + LiC_6H_5)/Ni^0 = 2:1$ and ethylene in diethyl ether leads to the two compounds $(NaC_6H_5)_2NiC_2H_4[(C_2H_5)_2O]_2$ *(1a)* and $(LiC_6H_5)_2NiC_2H_4(C_2H_5)_2O$ *(2)*. The previously known complex *(2)* remains in solution, while the new sodium complex *(1a)* precipitates as an orange-red powder (yield 80—90 %).

$$2\,(m\,NaC_6H_5 + n\,LiC_6H_5) + CDT\text{–}Ni^0 \xrightarrow[(C_2H_5)_2O,\ 0\,^\circ C]{C_2H_4}$$

$$m\,(NaC_6H_5)_2NiC_2H_4[(C_2H_5)_2O]_2 + n\,(LiC_6H_5)_2NiC_2H_4(C_2H_5)_2O + CDT$$

(1a) *(2)*

$m/n = 2\text{–}4 : 1$

$m+n = 1$

[*] Dr. K. Jonas
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

In *(1a)* the diethyl ether bonded to sodium can be replaced by stronger n-donors such as tetrahydrofuran (THF) or dimethoxyethane (DME) to give the crystalline complexes *(1b)* and *(1c)* etc.:

$$(1a) \xrightarrow{THF/(C_2H_5)_2O} [(NaC_6H_5)_2NiC_2H_4(THF)_{2.5}]_2 \quad (1b)$$

$$(1a) \xrightarrow{DME/(C_2H_5)_2O} (NaC_6H_5)_2NiC_2H_4(DME)_2 \quad (1c)$$

The composition of compounds *(1a)*, *(1b)* and *(1c)* follows from the nickel and sodium content (determined titrimetrically and by flame spectroscopy) and also by reaction of *(1)* with carbon monoxide, whereby the ethylene is quantitatively liberated. The various n-donors $(C_2H_5)_2O$, THF and DME in *(1a)*, *(1b)* and *(1c)* can be determined quantitatively by gas chromatography after decomposition of the complex with ethanol and distillation. The ^{1}H-NMR spectrum of *(1a)* in [D_8]-THF shows two groups of signals for the phenyl protons at $\tau = 1.9$ and 3.3 in the intensity ratio 4:6. The protons of the ethylene bound to nickel are, like those in the lithium complex *(2)* ($\tau = 9.87$)[1], strongly shielded, and in *(1a)* give rise to a singlet at $\tau = 9.58$.

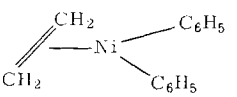
It follows from X-ray structural analysis of the ethylene complex *(1b)* and the (alkali-metal)nickel dinitrogen complexes

$$[\{(LiC_6H_5)_3Ni\}_2N_2\{(C_2H_5)_2O\}_{2\text{–}3}]_2 \quad (3)$$

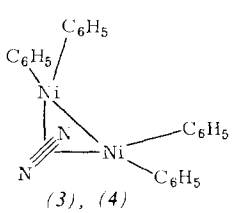
and

$$[C_6H_5\{NaO(C_2H_5)_2\}_2\{(C_6H_5)_2Ni\}_2N_2NaLi_6(OC_2H_5)_4O(C_2H_5)_2]_2 \quad (4)$$

that all three compounds contain characteristic diphenylnickel groups, which interact with the π system of the ethylene and the nitrogen to give a trigonal array of these ligands. The various interactions of the alkali metal atoms have tentatively been ignored in this connection. Whereas only one $(C_6H_5)_2Ni$ group is coupled with the C_2H_4 ligand in complex *(1b)*[5a],



(1b)



(3), *(4)*

in complexes *(3)*[5b] and *(4)*[3] two $(C_6H_5)_2Ni$ groups are bonded side-on to the N_2 ligand *via* the two nickel atoms.

Structure of a Bimetal-Ethylene Complex: $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$

By *David J. Brauer, Carl Krüger, Paul J. Roberts,* and *Yi-Hung Tsay*[*]

Recently, *Jonas*[1] reported the preparation of side-on π-complexes of molecular nitrogen with alkali metal compounds of nickel. In our structural investigations of such bimetallic systems[2, 3] we carried out an X-ray structural analysis of a complex having the composition $C_{48}H_{68}Na_4Ni_2O_5$, which could be obtained from a nitrogen-containing intermediate by crystallization from a diethyl ether/tetrahydrofuran (THF)

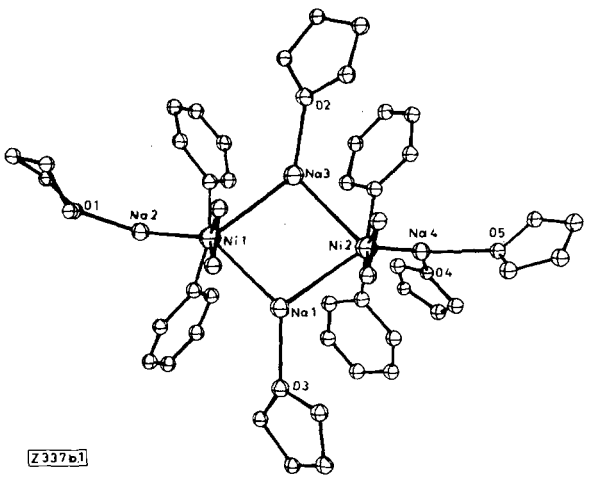

Fig. 1. Molecular structure of the complex $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$.

mixture, as well as by direct synthesis[1]. The red substance crystallizes in the triclinic system (unit cell: $a=9.779(2)$, $b=12.884(3)$, $c=20.811(6)$ Å; $\alpha=94.29(2)$, $\beta=93.05(2)$, $\gamma=104.25(2)°$; space group $P\bar{1}$; $Z=2$). The structure (Fig. 1) was solved by the heavy atom method, from 4024 (1488 unobserved) reflections, with the aid of a phase refinement process and refined to an R value of 0.0742 ($R_w=0.0909$).

The molecule is formally composed of two $(Ph_2NiC_2H_4)$ units and four $Na(THF)_x$ groups ($x=1$ or 2). Characteristic for Ni^0 is the trigonal arrangement of the organic ligands (two σ-bonded[4] phenyl groups and one π-bonded ethylene molecule). The dihedral angles between the plane of the σ-bond ($NiPh_2$) and the plane of the π-bond (NiC_2H_4) in both parts of the molecule are 6.4 and 7.7° in the same direction. Two bridging sodium atoms are bonded to nickel almost perpendicularly to the trigonal plane and give rise to a Ni—Na—Ni—Na four-membered ring. The two nickel atoms are each bonded with a further sodium atom outside of the ring. Additional ion-pair bonding can be detected between these sodium ions and the α-C atoms of the phenyl groups[5] (Na—C 2.56—2.68 Å). Free coordination sites on all Na atoms are occupied by THF; the Na atoms in the ring can bond only one THF molecule whereas those outside of the ring are capable of bonding two THF molecules. However, this possibility is utilized in only one case. Na2 takes up only one THF ligand (Fig. 1) and in addition forms a new type of intermolecular bridge to an ethylene unit of a neighboring complex molecule. This gives rise to a polymeric chain structure in the lattice (cf. Fig. 2), with Na2 at the rear of the Ni-olefin π bond (Na—C 2.75, 2.66 Å). Furthermore, a weak ion-pair interaction is detectable between the Na atoms in the four-membered ring (Na1, Na3) and the CH groups of the olefin. As also in the Ni—C bond lengths of the complexed olefin, this result is only slightly, if at all, reflected in the C—C bond length (C—C 1.45(2) and 1.43(2) Å).

We interpret the formation of the planar metal-metal four-membered ring as resulting from the development of two

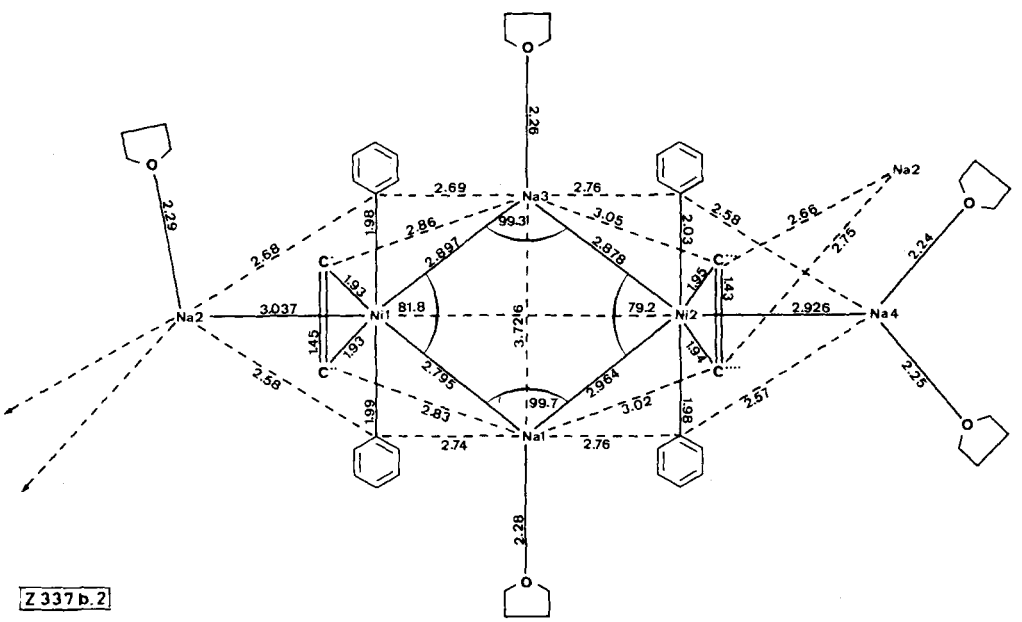

Fig. 2. Bond lengths [Å] and angles [°] in crystalline $[(C_6H_5)_2NiC_2H_4]_2Na_4(THF)_5$.

three-center electron-deficient bonds between Ni and Na^+, with the observed apical angles of 79.2 and 81.8° at the nickel atoms. A weak transannular Na—Na interaction (3.726 Å) cannot be ruled out[6]. No bonding exists, however, between the two Ni atoms (Ni—Ni 4.303 Å).

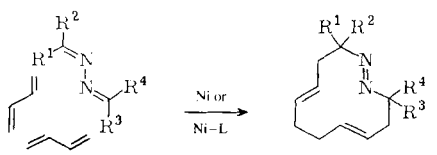
Catalytic Synthesis of 1,2-Diaza-1,5,9-cyclododecatrienes from Butadiene and Azines

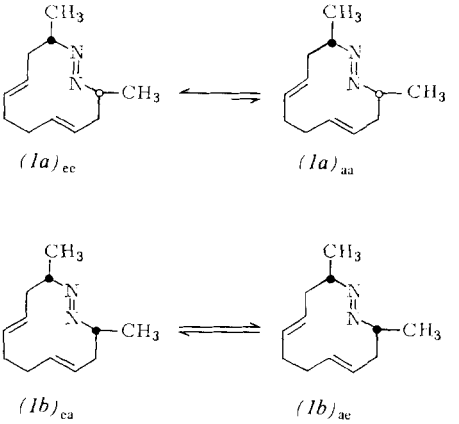
By *Paul Heimbach, Bernard Hugelin, Heinz Peter, Achim Roloff*, and *Eduard Troxler*[*]

Starting points in our investigations were, *inter alia*, publications by *Wilke*[1] and *Heimbach*[2] as well as an observation by *Meyer*[3]. We have now found, in independent studies[4, 5], that 3,3,12,12-substituted 1,2-diaza-1,5,9-cyclododecatrienes *(1)*—*(12)* are formed by catalytic co-oligomerization of ketazines or aldazines with butadiene. We employed nickel catalysts with and without added phosphane or phosphite; the molar ratio of butadiene to azine was 3:1 to 10:1 (see Table 1)[6].



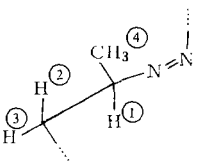
(1)-*(12)*

equatorially, while in the case of the *cis* compound *(1b)* the forms $(1b)_{ea}$ and $(1b)_{ae}$ are in equilibrium.



$(1a)_{ee}$ $(1a)_{aa}$ $(1b)_{ea}$ $(1b)_{ae}$

(1a) and *(1b)* differ greatly from each other, *inter alia*, in the coupling constants of the ^{1}H-NMR spectra. This is clearly seen from a section of the spectrum of the rigid form $(1a)_{ee}$:



Rigid form $(1a)_{ee}$:
$J_{1,2}=11$ Hz; $J_{1,3}=2$ Hz; $J_{1,4}=6.5$ Hz

Flexible forms $(1b)_{ea}$ and $(1b)_{ae}$:
$J_{1,2}=6.5$ Hz (mean value: $11+2$); $J_{1,3}=4$ Hz (mean value); $J_{1,4}=6.5$ Hz.

The IR spectrum of *(1a)* and *(1b)* shows only typical bands for *trans* double bonds (at 1670 and 956 cm^{-1}). A band at 1675 cm^{-1} in the Raman spectrum is indicative of a *trans* arrangement of the —N=N— grouping. If cyclic ketones are used for the synthesis of symmetric ketazines ($R^1=R^2=R^3=R^4=$ alkyl) di-spiro compounds such as *(12)* are formed on co-oligomerization with butadiene.

All compounds were identified and characterized by elemental analysis and ^{1}H-NMR, IR, Raman, and mass spectra.

Table 1. Prepared 1,2-diaza-1,5,9-cyclododecatrienes *(1)*—*(12)*. The yields are based on azine used. Molar ratio butadiene: azine = 3–10:1. Catalyst: see experimental procedure.

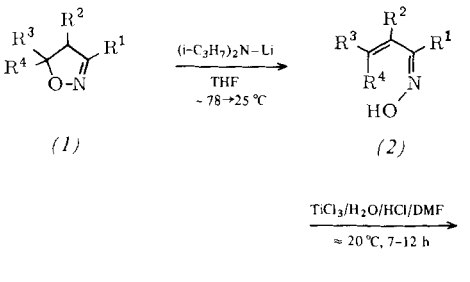
[6] If the carbon atoms of 1,3-dienes are substituted by nitrogen, the perturbation of the reactive centers 1 and 4 will be lowest when the nitrogen is present in positions 2 and 3.

been exploited[2]. Such use requires the availability of methods for retransforming 2-isoxazolines into open-chain products.

We now describe the conversion of substituted isoxazolines *(1)* into unsaturated oximes *(2)* and thence into enones *(3)*. Treatment of 3,5-diphenyl-2-isoxazoline *(1c)* with ethylmagnesium bromide (molar ratio 1:2) at 80–85 °C in diglyme affords a 30% yield of the ring cleavage product (*E,E*)-chalcone oxime *(2c)*. The yield of crystalline *(2c)* increases on use of butyllithium, or even better lithium diisopropylamide, to 60%. The unsaturated oximes *(2)* listed in Table 1 are obtained similarly, each in one stereoisomeric form only (according to the NMR spectra the crude products are also isomerically pure).



(1) *(2)* *(3)*

The crude products *(2)* of ring cleavage can be converted directly and smoothly at room temperature into enones *(3)*

Table 1. α,β-Unsaturated oximes *(2)* and enones *(3)* from 2-isoxazolines *(1)*. The structures of compounds *(2)* and *(3)* [new: *(2b)* and *(2e)*] were established by IR and NMR spectra and by correct elemental analyses.

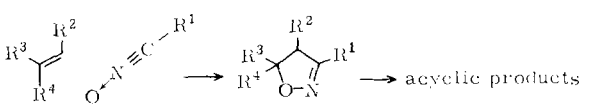
Eliminative Ring Opening of 2-Isoxazolines: A New Route to α,β-Unsaturated Ketones[**]

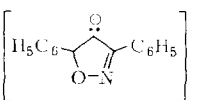
By *Volker Jäger* and *Hartmut Grund*[*]

Substituted 2-isoxazolines (4,5-dihydroisoxazoles) *(1)* are readily accessible under mild conditions by 1,3 dipolar cycloaddition of nitrile oxides to alkenes[1]. This represents a CC bond forming process in which a substituted C_1 unit (nitrile oxide) is combined with a (substituted) C_2 unit (alkene). By suitable choice of reactants, which can be varied within wide limits, a large number of carbon skeletons can be constructed. However, synthetically the inherent possibilities have hardly



(1)

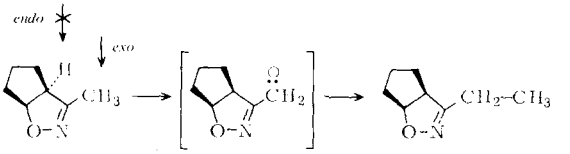
by treatment with an excess of titanium(III) chloride (15% aqueous solution in 4% hydrochloric acid to which has been added an equal volume of dimethylformamide)[3] (see Table 1).



(4c)

endo-anion

The oxime formation occurs *via endo* anion *(4)*[5–8] as shown, for example, by deuterolysis of *(4c)*. If *exo* hydrogen atoms are present in the α position of the CN double bond in *(1)*, then *exo* metalation competes with *endo* metalation/ring cleavage (cf. yields in Table 1). Depending upon the degree of substitution of the *exo* and *endo* positions this should also permit selective CC bond formation *at the isoxazoline stage* and therefore considerably



(1f) *exo*-anion *(1g)*

[*] Dr. V. Jäger and Dipl.-Chem. H. Grund
Institut für Organische Chemie der Universität
63 Giessen, Heinrich-Buff-Ring 58 (Germany)

[**] Syntheses *via* Isoxazolines, Part 1; part of a lecture delivered at the GDCh General Meeting, Cologne, September 1975.—This work was supported by the Deutsche Forschungsgemeinschaft.

enhance the synthetic utility of the 2-isoxazolines. This is illustrated by the reaction of *(1f)* with lithium diisopropylamide, which does not give a ring cleavage product (see Table 1), but affords the 3-ethyl derivative *(1g)* (*exo* alkylation) in >70% yield after addition of methyl iodide.

2-Isoxazolines thus represent latent[6] enones, similar to isoxazoles[6, 9] and isoxazolidines[6]. The scope of the reported acylation sequence remains to be determined; it circumvents carbocationic intermediates and its direction is governed mainly by steric factors, as is usual with nitrile oxide cycloadditions[1].

Conversion of isoxazolines (1) into enones (3):

Compound *(1)* (10 mmol) dissolved in anhydrous THF (10 ml) is slowly added dropwise at −78 °C to a solution of lithium diisopropylamide [from 1.11 g ≙ 10.9 mmol of amine in anhydrous THF (20 ml) and 7.6 ml ≙ 12.1 mmol of *n*-butyllithium in hexane]. After two hours the reaction mixture is allowed to warm slowly to room temperature and hydrolyzed with glacial acetic acid (1.4 ml, ≈23 mmol) and subsequently with saturated sodium chloride solution (20 ml). It is then extracted with three portions of dichloromethane. The combined extracts are washed with water and filtered through a short column packed with sodium sulfate. The solvent is removed and the residue is dissolved in dimethylformamide (50 ml), treated with a solution of titanium(III) chloride (50 ml, 15% in 4% hydrochloric acid), and stirred for 7 to 12 h at room temperature. After addition of water (100 ml) the reaction mixture is extracted three times with ether, the extracts are washed (water, saturated sodium hydrogen carbonate solution, water) and dried over sodium sulfate. Removal of the solvent is followed by bulb tube distillation (10^{-3} to 10^{-1} torr) and crystallization from light petroleum (where necessary with addition of ether) at −30 °C.

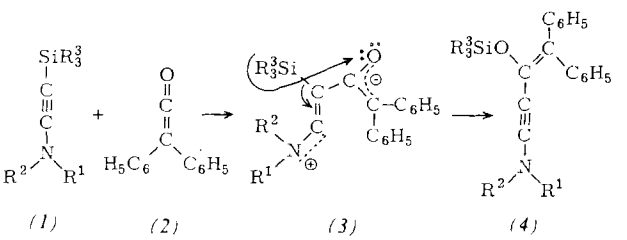
(3-Siloxy-3-buten-1-ynyl)amines

By *Gerhard Himbert*[*]

Ynamines add to the CC and the CO double bond of ketenes with formation of 3-aminocyclobutenones and allenecarboxamides, respectively[1]. The latter are interpreted as isomerization products of initially formed oxete derivatives.

[*] Dr. G. Himbert
Fachbereich Chemie der Universität
675 Kaiserslautern, Postfach 3049 (Germany)

β-Silylated ynamines *(1)*[2], however, are able to follow a different reaction path, as is shown for example by their reaction with diphenylketene *(2)*. At the intermediary stage of the zwitterion *(3)* formation of the four-membered carbocycle and heterocycle is circumvented and a [1,3] silyl shift to the oxygen atom takes place affording the novel (3-siloxy-3-buten-1-ynyl)amines *(4)* (see Table 1)[3], in which the ynamine function is retained. The driving force behind this rearrangement might be the high Si—O bond energy[4].



(1) *(2)* *(3)* *(4)*

Table 1. Prepared (3-siloxy-3-buten-1-ynyl)amines *(4)*.

(4)	R^1	R^2	R^3	Yield [%]	M.p. [°C]	IR [a]

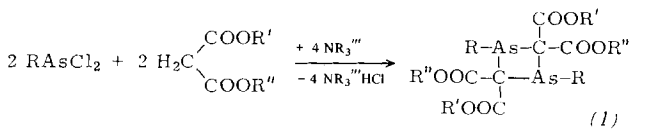
e	CH_3	C_6H_5	C_6H_5	66	138—140	2216
f	C_6H_5	C_6H_5	C_6H_5	64	159—160	2235

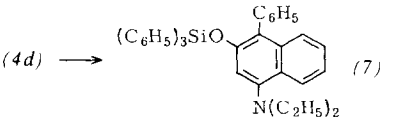
[a] IR (film or Kbr), C≡C absorption.
[b] B.p. 158—165 °C/0.4 torr (bulb-tube distillation).

Appearance of the C≡C and C=C absorptions in the IR spectrum (Table 1) and of the molecular ion M^+ in the mass spectrum lends support to the constitution of the new enynamines. Further support is provided by the fact that hydrolysis and desilylation affords the 3-siloxy-3-buteneamides *(5)* and the acetoacetamides *(6)*.



(1)

N,N-Diethyl[4,4-diphenyl-3-(triphenylsiloxy)-3-buten-1-ynyl]amine *(4d)* rearranges in $CDCl_3$ within 3—4 days with quantitative loss of the CC triple bond into an isomeric compound, whose spectroscopic and analytical data are consistent with the naphthalene structure *(7)*. [^{1}H-NMR ($CDCl_3$): δ = 0.82 (t, $NCCH_3$, J = 7 Hz), 2.89 (q, N—CH_2, J = 7 Hz), 6.74 (s, 2-H)—MS (70 eV): m/e = 549 (100%, M^+), 534 (47%), 259 (73%)].



(7)

N-Methyl-N-phenyl-[4,4-diphenyl-3-(trimethylsiloxy)-3-buten-1-ynyl]amine (4b)

A solution of *(1b)*[2a] (4.06 g, 20 mmol) in ether (50 ml) is treated with diphenylketene (3.88 g, 20 mmol) in ether[5] over a period of 10 min at −30 °C and the whole stirred for a further 2 h at room temperature. The solvent is then removed under reduced pressure and the residue taken up in

50 ml petroleum ether (40–70 °C). After cooling to −70 °C and rubbing, *(4b)* precipitates out as almost colorless crystals.

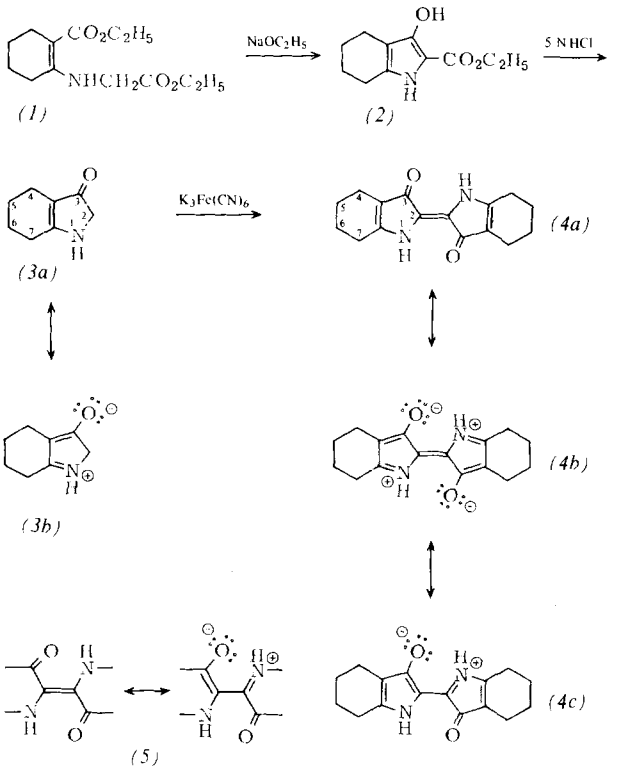
[5] When the addition is performed the other way round contamination with the 2:1 adduct is observed; a second ketene molecule adds to the initially formed *(4)* with predominant formation of cyclobutenone derivatives.



Octahydroindigo[**][1]

By *Georg Pfeiffer, Walter Otting*, and *Helmut Bauer*[*]

4,4',5,5',6,6',7,7'-Octahydroindigo *(4)*, which cannot be synthesized by reduction of indigo[2], is prepared in the following manner:

The condensation product *(1)* obtained from ethyl 2-oxo-1-cyclohexanecarboxylate and glycine ethyl ester is subjected to Dieckmann cyclization to give *(2)*. Acid hydrolysis of *(2)* in refluxing 5 N HCl proceeds with concomitant decarboxylation to 4,5,6,7-tetrahydroindoxyl *(3)*. This method represents an improved and generally applicable route to 4-oxo-2-pyrrolines[3, 4]. Compound *(3)* exhibits a UV spectrum [λ_{max} ($CHCl_3$) = 314 nm ($\log\varepsilon = 4.28$)] and an IR spectrum [in $CHCl_3$: 3445 s, 1655 s, 1575 s cm^{-1}] typical of amino enones[5] and, according to its NMR spectrum, exists in the oxopyrroline form *(3a)*. Both resonance forms *(3a)* and *(3b)* participate in the ground state.

Oxidation of *(3)* with $K_3Fe(CN)_6$ at pH 7 affords the dark violet octahydroindigo *(4)*, which is a pyrroleindigo soluble in organic solvents. In aqueous methanolic solution *(4)* can be vatted with $Na_2S_2O_4$ and reoxidized by air. Since a considerable proportion is destroyed by oxidation in this process as well as in the methods generally employed for dyeing cotton, compound *(4)* is hardly suitable for use as a vat dye. Unlike indigo, octahydroindigo *(4)* is very readily deprotonated and protonated, respectively, in alkaline and acid methanolic solution, the color changing to yellow. Deprotonation is rapidly followed by autoxidation.

The electronic spectrum of *(4)* [λ_{max} ($CHCl_3$) = 315 nm ($\log\varepsilon = 4.38$; 520 (4.11)] is analogous to that of tetramethylpyrroleindigo[3, 6], which is however, far less soluble than *(4)*. Thus the "partial hydrogenation" of the two annelated benzene rings of indigo [λ_{max} ($CHCl_3$) = 607 nm] leads to hypsochromic shift of the longest wave absorption maximum by 87 nm. The longest wave absorption maximum of *N,N'*-dimethyloctahydroindigo [λ_{max} ($CHCl_3$) = 582 nm] obtained by methylation of *(4)* shows a hypsochromic shift of 68 nm relative to that of *N,N'*-dimethylindigo [λ_{max} ($CHCl_3$) = 650 nm].

In contrast to the IR spectrum of indigo, that of *(4)* [in $CHCl_3$: 3410 m, 1630 m, 1560 vs cm^{-1}] is distinguished by the very intense band at 1560 cm^{-1}. In this respect, *(4)* resembles the amino enones which all exhibit a similarly strong band in this region. Thus not only the resonance form *(4c)* but also the form *(4b)* analogous to *(3b)* probably contribute to the ground state of *(4)*. The resonance form *(4c)* results from the presence of the fundamental indigo chromophore system *(5)*[7], which no longer exhibits any features of amino enones. Accordingly, octahydroindigo *(4)* possesses both indigo and amino enone character on account of the structural elements *(5)* and *(3)*. This overlapping of characteristics also follows from data calculated by the PPP[7] and MINDO/2 methods[8], which require, *e.g.*, a more pronounced positive character of the nitrogen atoms and a lower C=O bond order in *(4)* than in *(3)* and *(5)*.

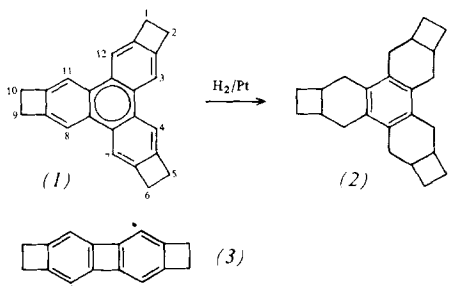
10,11-Dihydrocyclobuta[*b*]triphenylene and 1,2,5,6,-9,10-Hexahydrotriscyclobuta[*b,h,n*]triphenylene[**]

By *R. L. Funk* and *K. P. C. Vollhardt*[*]

The synthesis and properties of various aromatic carbocycles fused to one strained ring have been the subject of considerable recent research activity. There are considerably fewer structures known consisting of two strained rings fused to an aromatic system. We now wish to report the synthesis of 1,2,5,6,9,10-hexahydrotriscyclobuta[*b,h,n*]triphenylene *(1)*, a benzenoid tetracycle to which *three* strained rings are symmetrically fused[1].



(1) *(2)* *(3)*

Treatment of a concentrated (1.2 M) solution of 4-bromo-5-iodo-1,2-dihydrocyclobutabenzene with magnesium (room temperature; 12 h) leads to a complex mixture of halogenated coupled products, in addition to the biphenylene derivative *(3)* and the desired triphenylene derivative *(1)*[2]. The new cyclobutaarene *(1)* was obtained after repeated preparative thin layer chromatography on silica (3% ether in pentane) and fractional crystallization from ether as colorless plates (yield 0.5%) which decomposed above 260 °C without melting. The structural assignment is based on the spectral and chemical properties [MS: $m/e = 306.1406$ (calcd. 306.1408), M^+; ^{1}H-NMR ($CDCl_3$): $\tau = 1.70$ (s), 6.57 (s); electronic spectrum: Fig. 1]. Hydrogenation with Pt (in ethanol) proceeds unusually rapidly to the partially hydrogenated benzene derivative *(2)*[2,6], a colorless oil [^{1}H-NMR (CCl_4): $\tau = 6.6$—8.3 (m); UV (ether): $\lambda_{max} = 227$ sh, 238 sh, 270].

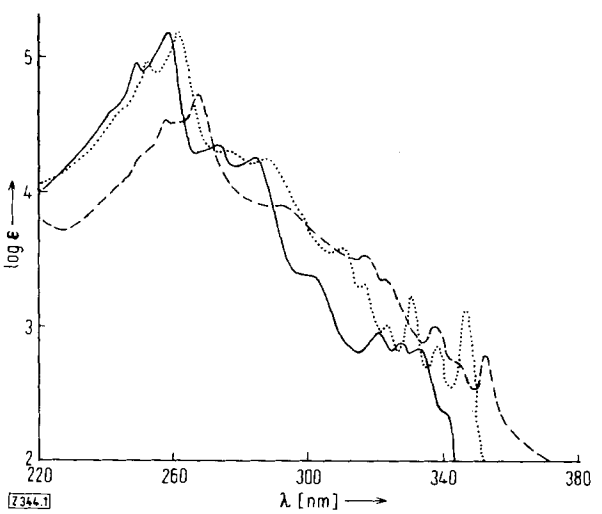


Fig. 1. Electronic spectra of triphenylene (——), *(4)* (·····), and *(1)* (– – –) in 95% ethanol.

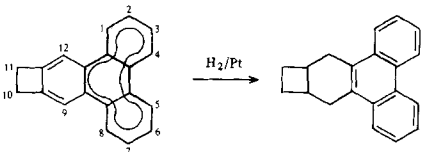
Berkeley, California 94720 (USA)

[**] This work was supported by the Petroleum Research Fund, administered by the American Chemical Society, the Research Corporation and the Energy Research and Development Administration.

For comparison model *(4)* with one annelated cyclobutane ring (10,11-dihydrocyclobuta[*b*]triphenylene) was prepared by the iodine catalyzed oxidative photocyclization[3] of 4,5-diphenyl-1,2-dihydrocyclobutabenzene[4] followed by preparative thin layer chromatography (yield 82%, 38% conversion; m.p. 168—169 °C). The structure assignment is based on the physical and chemical properties. Hydrogenation (Pt) leads to the phenanthrene derivative *(5)*[2] [m.p. 151—152 °C].



(4) *(5)*

The increasing strain in the series triphenylene, *(4)* and *(1)* is reflected in the physical and chemical properties of these compounds. Thus, fusing one cyclobutane ring to triphenylene seems to lead to increased bond localization in one benzene ring as indicated in structure *(4)*. This is evidenced by the chemical shift for 4-H, 5-H ($\tau = 1.32$), intermediate between the corresponding absorptions in the phenanthrene derivative *(5)* ($\tau = 1.25$) and triphenylene ($\tau = 1.44$)[5,7], the relatively high chemical shift for 9-H, 12-H ($\tau = 1.60$) and the ease of hydrogenation of *(4)*[6]. Fusion of three cyclobutane rings seems to result in increased bond fixation as suggested in formula *(1)*. The aromatic signals are shifted an additional 0.1 ppm to higher field due to the cumulative influence of three four-membered rings[7], and hydrogenation is rapid[6] but leaves the central benzene ring intact. This is, of course, in striking contrast to the stringent conditions required to hydrogenate triphenylene[9]. Finally, the electronic spectra (Fig. 1) exhibit strong bathochromic shifts along this series.

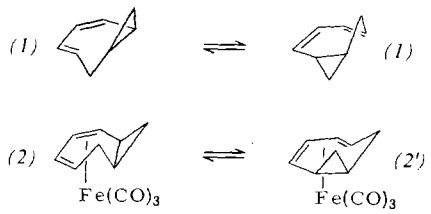
Degenerate Butadienylcyclopropane Rearrangement in Tricyclo[5.3.0.0^{2,10}]deca-3,5-diene

By *Klaus Heger* and *Wolfram Grimme*[*]

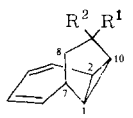
We were recently able to show that above 110 °C bicyclo[5.1.0]octa-2,4-diene *(1)* undergoes degenerate butadienyl-

[*] Dipl.-Chem. K. Heger and Dr. W. Grimme
Institut für Organische Chemie der Universität
5 Köln 41, Greinstrasse 4 (Germany)

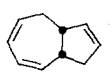
cyclopropane rearrangement; of the two quantum mechanically "allowed" transition states having cisoid or transoid conformation only the latter is involved[1]. However, the tricarbonyliron complex *(2)* having a fixed cisoid conformation formally undergoes the same rearrangement already at 90 °C[2]. The metal apparently lowers the activation barrier for the geometrically less favorable process.



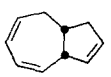
We here report the butadienylcyclopropane rearrangement in tricyclo[5.3.0.0^{2,10}]deca-3,5-diene *(3a)* whose cisoid geometry is fixed by the ethano bridge; no metal is involved in this rearrangement. On treatment with thionyl chloride and tri-*n*-butylamine in ether, tricyclo[5.3.0.0^{2,10}]deca-3,5-dien-9-ol *(3b)*[3] affords the chloride *(3c)*, which is reduced directly by lithium tetrahydridoaluminate in boiling tetrahydrofuran without further purification. Gas chromatography of the resulting hydrocarbon mixture (3 m, 20% Reoplex on kieselguhr, 45 ml He/min, 120 °C) affords *(3a)* [17% based on *(3b)*, retention time 7 min; NMR ($CDCl_3$, TMS internal): $\tau = 3.8$ (m) (2 olefinic H), 4.2 (m) (2 olefinic H), 6.9 (m) (7-H), 7.7—9.0 (m) (7 aliphatic H); UV (dioxane): $\lambda_{max} = 267$ nm ($\varepsilon = 4100$)] alongside the tetrahydroazulenes *(4)*, *(5)*, and *(6)*, probably formed by rearrangement of the chloride *(3c)*.



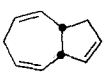
(3a), R^1 = H, R^2 = H
(3b), R^1 = H, R^2 = OH
(3c), R^1 = H, R^2 = Cl
(3d), R^1–R^2 = O
(3e), R^1 = H, R^2 = O_2C–C_6H_4–CO_2H
(3f), R^1 = H, R^2 = O_2C–C_6H_4–$CO_2^{\ominus}$ (+)–$H_3\overset{\oplus}{N}$–CH(CH_3)–C_6H_5



(4)



(5)



(6)

(3a) is stable up to 250 °C in the gas phase—the degenerate rearrangement is not manifested by this compound—and undergoes uniform rearrangement to *(6)* at higher temperature. A homopentadienyl hydrogen shift of the *endo* 9-H rationalizes this process.

Detection of the butadienylcyclopropane rearrangement was accomplished with the labeled compound [D_5]-*(3a)* (the heavily drawn positions are deuterated) prepared in conventional manner: on H/D exchange of 2,4,6-cycloheptatrien-1-ylmethyl diazomethyl ketone[3] in [OD]-ethanol (20 °C, pH 9) the diazomethyl position is labeled; this site becomes position 10 in [D_5]-*(3a)*. Using the same technique (20 °C, pH 14) the two α-methylene protons (8-H) are replaced in *(3d)*. Use of $LiAlD_4$ in the subsequent stepwise reduction of the ketone [D_3]-*(3d)* leads to [D_5]-*(3a)* [NMR ($CDCl_3$, TMS internal): olefinic H as in *(3a)*, $\tau = 6.92$ (t) (7-H), 8.4 (m) (1-H), 8.8 ppm (m) (2-H)[4]. Above 200 °C [D_5]-*(3a)* undergoes butadienylcyclopropane rearrangement in the gas phase to give its labeling isomer [D_5]-*(3'a)* with which it equilibrates [NMR ($CDCl_3$, TMS internal): olefinic H as in *(3a)*, $\tau = 6.92$ (broadened t) (0.5 7-H), 8.4 (m) (1-H), 8.8 ppm (m) (2-H and 0.5 10-H)[4]].

The rearrangement established for [D_5]-*(3a)* by isotopic labeling converts *(3a)* into its mirror image *(3'a)*. Because of the rather unproductive route to *(3a)* we have determined the kinetics of the rearrangement by polarimetry: *(3b)* is converted into the half-ester *(3e)* (40%, m.p. 117—119 °C) by treatment with phthalic anhydride in pyridine; reaction of *(3e)* with (+)-α-phenylethylamine in ethanol/hexane (1:1) gives the salt *(3f)* (79%, m.p. 132—135 °C). After four recrystallizations from ethanol/hexane (1:1) a fraction of constant melting point (46%, m.p. 141—142 °C) is obtained, whose cleavage with 5% hydrochloric acid furnishes the half-ester (−)-*(3e)*[5] (75%, m.p. 119—121 °C). Reduction with $LiAlH_4$ in ether gives the alcohol (−)-*(3b)* [97%, $[\alpha]_D^{20} = -34.5°$ (in $CHCl_3$)] which is transformed into the chloride and reduced as described above. Gas chromatography of the product mixture yields (−)-*(3a)* [14%, $[\alpha]_D^{25} = -10.0°$, $[\alpha]_{407.7}^{20} = -19.5°$ (both in *n*-dodecane)].

Racemization of (−)-*(3a)* was followed up to a loss of at least 60% of rotatory power in 0.1 M dodecane solution at four temperatures between 179 and 193 °C. Tetralin was added as an internal standard to the degassed samples which were then sealed into glass ampoules; each polarimetric measurement ($\lambda = 407.7$ nm) was accompanied by a gas chromatographic loss analysis[6]. The racemization follows first order kinetics, and the temperature dependence of its rate constant is reproduced by the Arrhenius equation

$$\log k = (13.53 \pm 0.2) - (37\,800 \pm 300)/2.303\,RT$$

The free energy of activation of the butadienylcyclopropane rearrangement in *(3a)* is thus about 5.0 kcal/mol higher than that in *(1)*[1]. Bearing in mind that *(1)* must first be transformed into its higher energy transoid conformer, the energy difference for the pericyclic reaction itself in the cisoid as against the transoid transition state should be taken as $\Delta\Delta F^{\neq} \geq 6$ kcal/mol. It remains to be established whether this difference is overcome also in the case of *(3a)* by coordination to the $Fe(CO)_3$ group.

Chlorine Isotope Effects in Ion Exchange Chromatography[**]

By *Klaus G. Heumann* and *Rainer Hoffmann*[*]

Isotope effects on ion exchange equilibria with metal cations have already been repeatedly investigated[1-3]. However, only few studies have been performed on anions; for instance, there is only one relevant publication for chloride which gives no precise details about variations in the isotope effect[4]. In order to gain a better insight into isotope effects in anion exchange equilibria, on the one hand, and to test the possibilities of chromatographic chlorine isotope enrichment, on the other, we have undertaken relevant studies on ion exchange columns.

All experiments were performed in a column (height of packing, 80 cm; column diameter, 1.5 cm) packed with the strongly basic anion exchanger AG1-X10 (NO_3^- form, 200 to 400 mesh, Bio-Rad) at 20 °C. In each run, 200 mg samples of chloride of natural isotope abundance were applied to the column as NaCl and eluted with 0.01, 0.1, or 1 M $NaNO_3$ solution. The elution rate was 0.35—0.40 ml/min. The eluate was collected in fractions and the isotope ratio $^{35}Cl/^{37}Cl$ was determined by thermionic mass spectrometry in several of these fractions.

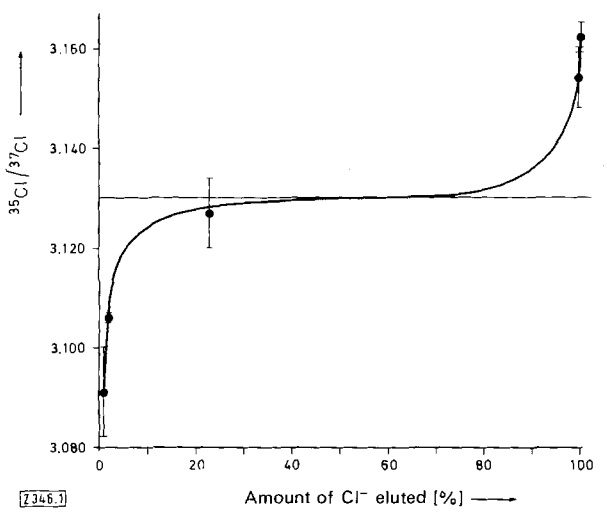

Fig. 1. Isotope ratio $^{35}Cl/^{37}Cl$ as a function of the amount of Cl^- eluted. Eluant: 0.1 M $NaNO_3$. The horizontal line indicates the starting isotope ratio $^{35}Cl/^{37}Cl = 3.130$.

At all concentrations of eluant we found an enrichment of the heavy isotope ^{37}Cl in the first fractions and a depletion of this isotope in the last fractions (see Fig. 1). The differential selectivity of $^{35}Cl^-$ and $^{37}Cl^-$ accords with the results obtained in studies of isotope effects of metals on cation exchangers[1, 3]. This enrichment can be attributed to the slightly greater ionic radius of the lighter metal isotope[1, 5]. Application of this explanation to the Cl^- isotopes would require $^{35}Cl^-$ to have a somewhat larger ionic radius than $^{37}Cl^-$. This assumption is in accord with the ionic radius differences calculated for pairs of halogen isotopes[6]. In a steady state experiment it could be shown that the chlorine isotope effect in the column experiments was not kinetic in origin: after equilibration the same enrichment tendency was observed.

[*] Prof. Dr. K. G. Heumann and Dipl.-Ing. R. Hoffmann
Chemisches Institut der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—We are indebted to Prof. *K. H. Lieser*, Technische Hochschule Darmstadt for the opportunity of performing the mass spectrometric measurements at his institute.

With the aid of a computational method due to *Glueckauf*[7] we have been able to perform the first calculation of the elementary separation factor $\alpha = 1 + \varepsilon$ of one equilibrium stage corresponding to the isotope exchange equilibrium eq. (1) from the results of column chromatography (soln = solution, ex = exchanger):

$$^{35}Cl^-_{soln} + {}^{37}Cl^-_{ex} \rightleftharpoons {}^{35}Cl^-_{ex} + {}^{37}Cl^-_{soln} \quad (1)$$

The elementary isotope effect decreases with increasing concentration of the $NaNO_3$ solution used as eluant (concentration: 0.01, 0.1, and 1.0 mol/l; $\varepsilon = 5.4 \times 10^{-4}$, 3.0×10^{-4}, and 1.9×10^{-4} respectively). This accords with observations made during analogous experiments with lithium isotopes[8]. The results can be explained in terms of the theory of concentrated electrolytes in relation to ion exchange resins[9]. The variation of the isotope effect with the eluant concentration is attributed to differential modification of the activity coefficients of the isotopes in the ion exchanger phase and in the aqueous phase.

Electrophilic Alkylation-Cycloaddition between an Olefinic and an Acetylenic Substrate

By *Karl Griesbaum* and *Wolfgang Seiter*[*]

In order to assess the synthetic possibilities which may arise from cationically induced crossover reactions between olefinic and acetylenic substrates, we are investigating reactions of hydrogen halides with mixtures of olefinic and acetylenic substrates.

In the reaction of anhydrous hydrogen chloride with propene and propyne (molar ratio of 2:1:1, respectively) in the liquid phase, the crossover products *(3)*—*(6)* were obtained, in addition to the products which are formed in the individual reactions of HCl with propene and with propyne, respectively[1]. The crossover products *(3)*—*(6)* have been isolated as colorless liquids by means of preparative gas chromatography (5% Nitrilesilicon oil on Chromosorb G). The previously known compounds *(3)*, *(4)* and *(5)* were identified by NMR and IR spectroscopy. The proposed structure of *(6)* is supported by its elemental analysis, its mass spectrum (M^+ at *m/e* 198, 196, 194) and its 100-MHz ^1H-NMR spectrum (CCl_4): $\delta = 0.93$ (d, isopropyl-CH_3), 1.02 (d, isopropyl-CH_3, $J = 6$ Hz), 1.75 (s, CH_3), 1.85 (s, CH_3), 2.38 (d, 2-H, $J = 10.5$ Hz), AB quartet at $\delta_A = 2.62$, $\delta_B = 2.70$ (2 4-H, $J = 13.5$ Hz), $\delta = 2.07$ (m, isopropyl-H).

Apparently, the crossover products *(3)*—*(6)* are the result of an alkylation of propyne with the isopropyl cation *(1)*. Their formation can be readily rationalized by the intermediacy of the vinyl cation *(2)*. The formation of the trialkyl

substituted dichlorocyclobutane *(6)* can thus be considered as an alkylation-cycloaddition between one molecule of propene, two molecules of propyne and HCl. It is a modification of cycloadditions *via* vinyl cations as intermediates[1, 2] and, as an alternative to the simple [2+2]-cycloadditions, it opens up new possibilities for the one-step synthesis of substituted cyclobutanes.

[1] The major products from the reaction of non-aqueous hydrogen chloride with propyne have been reported by us previously: *K. Griesbaum* and *M. El Abed*, Chem. Ber. *106*, 2001 (1973).

[2] *J. H. Lukas, A. P. Kouwenhoven*, and *F. Baardman*, Angew. Chem. *87*, 740 (1975); Angew. Chem. Int. Ed. Engl. *14*, 709 (1975).

1,3-Diarsacyclobutanes

By *Hans-Jürgen Padberg* and *Günter Bergerhoff*[*]

Whereas arylphosphorus dichlorides eliminate HCl to give 1,2-diphosphacyclopentenes on treatment with malonic esters[1], alkyl- and arylarsenic dichlorides afford 1,3-dialkyl- and 1,3-diaryl-1,3-diarsacyclobutanes *(1)* under the same conditions (Table 1). Hitherto only 1,2-diarsacyclobutene has received brief mention[2].

(1b) crystallizes from benzene as colorless polyhedra and only decomposes above 200 °C. Moreover, it is readily soluble in dichloromethane, chloroform, and tetrahydrofuran, less so in ethanol and ether, and not at all in water, even when hot. On exposure to air the crystals are subject to only insignificant decomposition within several weeks. *(1b)* reacts with equimolar amounts of anhydrous HI or halogen to give $PhAsI_2$, an excess of HI affords AsI_3[3].

The structure of *(1b)* is confirmed by quantitative elimination of HCl during its synthesis and by the results of elemental analysis and cryoscopic molecular weight determination. The mass spectrum contains, *inter alia*, peaks for M^+ (620, 65%) and $(M/2)^+$ (310, 100%). The IR spectrum displays As—Ph absorptions (*e.g.* at 698 and 470 cm^{-1} [4]) and a single C=O absorption at 1710 cm^{-1}, indicating the equivalence of the four ester groups. In analogy to P compounds the absorptions in the range 790—880 cm^{-1} can be interpreted as As—C—As vibrations[5]; however, absorptions typical of As—As compounds are absent[6]. (For the ^{1}H-NMR spectrum, see Table 1.)

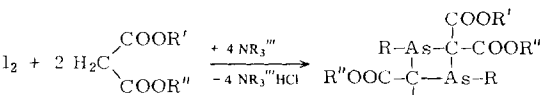

Table 1. Diarsacyclobutanes *(1)* prepared.

(1)	R	R′=R″	^{1}H-NMR [a] H in R	H in R′	M.p. [°C]	Yield [%]

[a] δ values, recorded in $CDCl_3$ at 37 °C, TMS internal standard.
[b] The methylene protons give a duodecet; $\delta_A = 3.59$, $\delta_B = 3.88$, $J_{AB} = 11$ Hz.
[c] In this case the greater bulk of the *tert*-butyl groups apparently leads only to linear products which are still being investigated.
[d] In *(1g)* R′≠R″; R′=C_2H_5, R″=$C(CH_3)_3$; ^{1}H-NMR (H in R″): δ = 1.44 (s).

Fig. 1. Stereo pair of tetraethyl 1,3-diphenyl-1,3-diarsa-2,2,4,4-cyclobutanetetracarboxylate *(1b)*.

As shown in Figure 1, the benzene rings are oriented such that the free rotation of the ester groups is restricted owing to the bonding angle of about 90° at the As atom. The molecule possesses only a two-fold axis and is chiral. The steric hindrance is alleviated on replacement of the phenyl by a methyl group as in *(1e)* and the expected quartet splitting of the CH_2 is then observed.

Tetraethyl 1,3-diphenyl-1,3-diarsa-2,2,4,4-cyclobutanetetracarboxylate (1b)

To a stirred solution of diethyl malonate (5 g, 31 mmol) and triethylamine (6.3 g, 62 mmol) in benzene (125 ml) at room temperature is added dropwise within 2–3 h a solution of phenylarsenic dichloride (6.95 g, 31 mmol) in benzene (50 ml). After 12 h about 90% of the ammonium salt has precipitated and is filtered off. Evaporation of the solvent leaves a faintly yellow substance which is washed with ether/light petroleum and can be recrystallized from benzene/ether.—Compounds *(1a)* and *(1d)*—*(1g)* are prepared in analogous fashion, but preferably washed with methanol/ether.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The chemistry of electronically excited states of coordination compounds is reviewed by *V. Balzani, L. Moggi, M. F. Manfrin, F. Bolletta*, and *G. S. Laurence*. Recent data on sensitization and quenching of photochemical reactions and luminescence of coordination compounds are collected. The kinetics and mechanisms of formation and deactivation of excited states are discussed, and examples for applications in coordination chemistry are given, *e.g.* identification of photoreactive states, increasing of quantum yields, and extension of the photochemically useful spectral range by sensitization. [Quenching and Sensitization Processes of Coordination Compounds. Coord. Chem. Rev. *15*, 321—433; 216 references]

[Rd 806 IE—H]

Biosynthesis and secretion of insulin forms the theme of a review by *M. A. Permutt* and *D. M. Kipnis*. A glucose receptor system of the cell membrane is obviously responsible for the stimulation of insulin secretion by glucose. This stimulation takes place both at the transcription level and thereafter. Phoridzin, a glucoside with high affinity for the glucose carrier system of plasma membranes, strongly stimulates the secretion of insulin; of the many plant lectins that have been studied only one mushroom lectin displayed a stimulating action. The part of the stimulation occurring after transcription is due to an augmented initiation of mRNA. Proinsulin is synthesized in polysomes carrying six to eight ribosomes. The proinsulin mRNA is thus surprisingly long. [Insulin Biosynthesis and Secretion. Fed. Proc. *34*, 1549—1555 (1975); 23 references]

[Rd 812 IE—R]

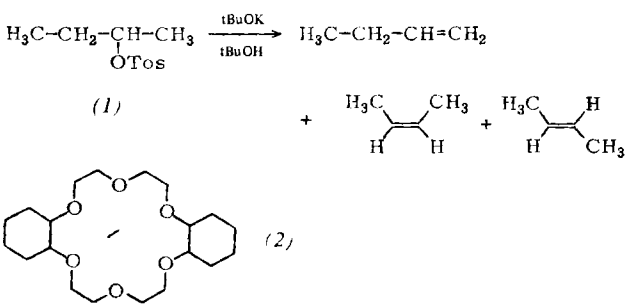
Interaction of insulin with membrane receptors and its relationship to cyclic purine nucleotides and cell growth are reviewed in an article by *M. D. Hollenberg* and *P. Cuatrecasas*. The insulin receptor of fat and liver cells is a large glycoprotein with high insulin-affinity and -specificity; other membrane components also take part in the binding. In order to explain the relationship between insulin and the cyclic nucleotides it is hypothesized that a single cyclase produces both cAMP as well as cGMP, depending on the type of hormonal stimulation. The article also deals with the relationship between insulin action and membrane phosphorylation, influences on cAMP and cGMP levels, on growth, on DNA synthesis, and on the uptake of α-aminoisobutyric acid in fibroblasts—processes which, in part, only take place at unphysiologically high concentrations of insulin. [Insulin: Interaction with Membrane Receptors and Relationship to Cyclic Purine Nucleotides and Cell Growth. Fed. Proc. *34*, 1556—1563 (1975); 99 references]

[Rd 813 IE—R]

The catalytic function of hydrogen which is bound to oxide surfaces is surveyed by *W. K. Hall*. Depending upon the oxide (*e.g.* aluminosilicates, zeolites, alumina, zinc oxide) and the reaction conditions, the hydroxyl groups located on the surface can act as Brønsted acids, or the catalytic activity originates from strongly polar centers arising by loss of water on heating. The reactions and phenomena discussed include the formation of carbenium ions, chemisorption, olefin isomerization, D/H exchange in hydrocarbons, and H_2/D_2 exchange and allotropic conversions. [Catalytic Function of Hydrogen Bound to the Surfaces of Oxides. Acc. Chem. Res. *8*, 257—263 (1975); 48 references]

[Rd 815 IE—L]

Association of ions in base-promoted β-eliminations is reviewed by *R. A. Bartsch*. The β-elimination reaction of the tosylate *(1)* may be cited as example. While *cis*- and *trans*-2-butene are formed in the ratio 1:0.4 with potassium *tert*-butoxide



in *tert*-butyl alcohol at 50 °C, the *trans* isomer predominates (*cis*:*trans* = 1:1.9) on addition of the crown ether *(2)*. This result can be interpreted in terms of complexation of the potassium ion by the crown ether, which considerably reduces the association of the potassium *tert*-butoxide

$$n\,tBuO^{\ominus}\,n\,K^{\oplus} \rightleftharpoons n(tBuO^{\ominus}K^{\oplus}) \rightleftharpoons (tBuO^{\ominus}K^{\oplus})_n$$

There are numerous examples illustrating the influence of ionic association on orientation and stereochemistry in β-eliminations of this kind; alkene synthesis should be facilitated by the use of crown ethers. [Ionic Association in Base-Promoted β-Elimination Reactions. Acc. Chem. Res. *8*, 239—245 (1975); 65 references]

[Rd 817 IE—L]

The structure and properties of collagen and its characterization in the solid state are considered in a review by *J. C. W. Chien*. Some 20—30% of the protein present in vertebrates is in the form of collagen; its concentration is particularly high in skin, sinews, and bones. Apart from the primary to quaternary structure, macroscopic ultrastructures made up of ordered aggregates also have to be considered in collagen. Collagen is semicrystalline. A section each is devoted to application of the two-phase model, mechanical and dielectric properties, denaturation, and biomedical applications. [Solid-State Characterization of the Structure and Properties of Collagen. Rev. Macromol. Chem. *13*, 1—80 (1975); 252 references]

[Rd 818—IE L]

The coupling of "high-energy" phosphate bonds to energy transductions is reviewed in an article by *P. D. Boyer, B. O. Stokes, R. G. Wolcott*, and *C. Degani*. According to recent opinion it would appear that the primary function of the energy in oxidative phosphorylation lies in the liberation of ATP, which is formed on reversal of hydrolysis. The authors suggest that the conformational changes observed on ATP binding and cleavage play an essential role in the function of the mitochondria and also in other ATP-dependent processes, such as muscle contraction. [Coupling of "High-Energy" Phosphate Bonds to Energy Transductions. Fed. Proc. *34*, 1711—1717 (1975); 46 references]

BOOK REVIEWS

Die Analyse der Luft und ihre Verunreinigungen in der freien Atmosphäre und am Arbeitsplatz (Analysis of Air and its Impurities in the Free Atmosphere and at Places of Work). By *W. Leithe*. Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart 1974. 2nd revised and expanded edition, xv, 303 pp., 49 figs., bound, DM 74.—.

A second edition of *Leithe*'s book has now appeared, only a few years after publication of the first. Again we have an essentially practical book providing valuable assistance to the ever-increasing number of users of methods of air analysis. This should be particularly emphasized, because there is in the German language no other presentation of the theme in a monograph that, like the present conveniently handleable volume, is comprehensive, accurate, and topical.

In his subdivision of the subject the author proceeds rigorously from the general to the specialized. First, in a general section, he provides the reader with conceptual and historical basic information, then reports briefly on the legal requirements, measures, and procedures for technological management in various countries as regards purification of the air and labor protection. He follows this up with bibliographic references, and then goes into the sources of atmospheric impurities and the form in which they appear, into the technology of reducing their emission, into the distribution of foreign materials, and into their importance in hygiene, while paying particular attention to limiting values and their definition.

The second main section provides in concentrated form the tools needed for air analysis in industrial practice. Here are discussed the quantitative aspects of the analyses, the purposes of the investigations, and the choice of measuring procedures and the analysis level in special cases, *e.g.* the determination of background impurities. The methods and problems of sampling and of sample enrichment are discussed in detail. The preparation and the use of reference gas mixtures are treated with remarkable topicality in accord with the importance of calibration and of investigation of their effects.

There follows a special methodological section in which, along with test-tube processes, are treated above all and with examples, the instrumental methods relying on the application of spectrochemical, electrochemical, and chromatographic principles, as well as the analytical use of the sense of smell. In view of the rapidity of technical developments, it is not surprising that some of the processes described have meanwhile been abandoned, *e.g.* reversion chromatography. It will not be considered a shortcoming that the author has rejected discussion of remote-measurement methods whose validity is still disputed, *e.g.* Lidar and correlation spectrometry.

More than half of the book is taken up by the specialized part. This part provides analytical methods for air contaminated with a wide variety of inorganic or organic constituents, these methods all being of the nature of complete analytical prescriptions by means of which the work can be carried out without the need to allow for considerable unsuspected difficulties. These prescriptions are enhanced by a wealth of literature references reaching to around 1972; newer developments are thus included, such as the application of chemiluminescence analysis to the determination of ozone and nitrogen oxides. The book ends with tables giving conversion factors, material constants, and limiting values. Taken as a whole, the volume is presented in a pleasant, technically sound, and solid manner, and its few irregularities will surely be corrected at a later date.

Heinrich Hartkamp [NB 286 IE]

Progress in Mass Spectrometry. Fortschritte der Massenspektrometrie. Edited by *H. Budzikiewicz*. **Vol. 1. Indolalkaloide** (Indole Alkaloids). Part 1: Text, Part 2: Spektren (Spectra). By *M. Hesse*. Verlag Chemie, GmbH, Weinheim 1974. 1st Edit., Part 1: xvii, 261 pp., 95 schemes, 42 tables; Part 2: vii, 98 pp., 173 spectra; linen-bound, together DM 98.—. **Vol. 2: Chroman and Related Compounds.** By *S. E. Drewes*. Verlag Chemie, GmbH, Weinheim 1974. 1st Edit., vii, 138 pp., 33 figs., 102 schemes, linen-bound, DM 58.—.

Today it is difficult even for the expert to survey the relationships between structure and mass spectra of a certain class of compounds, because the literature is widely scattered and some of the important data are hidden in the experimental parts of papers. The present series of monographs therefore meets a true need and will provide much saving in literature searches.

In the first volume *Hesse*, who is probably the leading expert on indole alkaloids, gives an exhaustive review of this special field. In the first part the characteristic decomposition reactions of the individual types of compounds are arranged in subgroups and critically discussed, while the second part contains all the relevant spectral data. The most important data and references can be derived from tables at the beginning of each section. The two volumes can serve as models of their kind and will prove invaluable to all who are active in this field.

The second volume, which is compiled by *Drewes* and concerns the mass spectra of chromans and related compounds, is in the reviewer's opinion less successful. For example, the formulas do not contain the numbering of the often complex compounds, which is necessary for rapid under-

standing (in the first volume each compound is numbered throughout), and the formulas are often found only one or two pages before or after they have been mentioned in the text. What is more troublesome is that the author has not always made happy choices and, for example, formulates diradical ions that, for energetic reasons, are certainly not formed (*e.g.* on pp. 74 and 75 the ion with mass 135), although admittedly the ions postulated are useless as criteria since they often have only a low intensity (on p. 76, 3 %). Nevertheless, the author has collected the literature concerning chromans, xanthones, and flavanoids with great diligence, so that the critical reader has a book that will greatly assist him in working his way into the mass spectrometry of this class of compounds.

Gerhard Spiteller [NB 284 IE]

Serumproteine. Bd. 1: Methodische Fortschritte im medizinischen Laboratorium [Serum Proteins. Vol. 1. Progress in Medical Laboratory Techniques]. Edited by *A. Englhardt* and *H. Lommel*. Verlag Chemie GmbH, Weinheim 1974. 1st Edit., 230 pp., 67 figs., 40 tables, bound, DM 52.—.

This books, published in 1974, provides a collection of articles on the qualitative and quantitative analysis of serum proteins. There is no review giving a critical evaluation of the now available methods of clinical diagnosis. The reader must make do with the individual chapters, which are of very varied quality. In some chapters (*e.g.* in the introductory chapter by *A. Englhardt*) the emphasis is on the experimental methods, the main weight being laid on their interpretation. In Chapter II (Special Proteins) there appears to be some lack of coordination, since the explanation and the interpretation of the same methods are repeated in several different contributions. While the schemes are mostly very well drawn, the reproduction of the original diagrams is so bad that it is often barely possible to recognize the essential features. Unfortunately, also, the collection of methods is incomplete, in that newer techniques such as *Laurell*'s "rocket" electrophoresis and the "automatic" techniques for quantitative analysis of plasma proteins are not included. Instead, we have a modification of immunoelectrophoresis by *R. Sanders* and *H. G. Meiers* that is no longer used in general practice. The chapters dealing with immunoelectrophoresis and its interpretation suffer particularly badly from the poor quality of the diagrams in this chapter; however, the experimental instructions are given in detail sufficient to enable the newcomer to use the methods described. Overlapping occurs also in Chapter IV (Lipoproteins), and in Chapter V (Enzymes and Isoenzymes). Chapter VI (Antibodies) contains contributions on experimental methods that are in the main clearly written, critical, and complete, although here too there is some overlap. The tables in the article on "Detection of Australia SH Antigens and Antibodies" contain mainly the older, insensitive methods such as transport electrophoresis, the Mancini technique, and the complement-fixation reaction which are today replaced by more sensitive methods (mentioned only as literature references). In the chapter on the detection of the various autoantibodies the critical evaluation of the methods is incomplete. Where immunofluorescence methods are applied there is no precise description of the microscopic techniques. The book closes with an excellent chapter on the detection and evaluation of antibodies in the thyroid gland.

It is hoped that in future volumes of the series the publishers will see to it that the quality of the printing is improved and that there is thorough in-house editing.

H. Deicher [NB 289 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Verordnung über gefährliche Arbeitsstoffe. (Directive on hazardous working materials.) Textausgabe mit Einführung, ausführlichen Erläuterungen für die Praxis und Formularabbildungen. Chemistry and Biochemistry of Unsaturated Fatty Acids

By Wolf-H. Kunau[*]

Although unsaturated fatty acids have long been known to accompany saturated fatty acids in most lipids, qualitative and quantitative determination of fatty acid patterns only became possible with the advent of modern analytical methods. Present day knowledge of the chemical structure, physical properties, and metabolism of unsaturated fatty acids provides the basis for the development of new concepts of their function. Thus unsaturated fatty acids crucially determine the properties of biological membranes. Moreover, essential fatty acids are precursors of prostaglandins.

1. Introduction

Fatty acids are an essential structural component of nearly all compounds embraced by the term lipid. More than half of the fatty acids encountered in Nature are unsaturated. Neither term—"fatty acid" or "unsaturated"—is unequivocally defined and each is used with various meanings in the literature.

While "fatty acid" formerly meant only a long-chain unbranched monocarboxylic acid, the name is nowadays frequently applied to all acids occurring in lipids. Modern analytical methods have shown that the latter definition covers an extremely heterogeneous group of compounds[1–3].

Used in the broadest sense, the term "unsaturated fatty acids" refers to all acids found in lipids whose carbon skeleton contains at least one multiple bond. These may be *cis* or *trans* double bonds or also triple bonds. Most natural unsaturated fatty acids only contain *cis* double bonds (Fig. 1). Nevertheless, it is common practice to apply the generic name "unsaturated fatty acids" to these compounds. The designations "polyenoic acids" and "polyunsaturated fatty acids (PUFA)" are used synonymously for all acids possessing two or more double bonds.

This review is concerned with unsaturated fatty acids in the narrower sense, *i.e.* only those acids having *cis* double bonds, encountered mainly in the animal kingdom, are considered.

While it was originally the science of nutrition which was primarily concerned with unsaturated fatty acids as "essential nutrients" and even assigned them a temporary place among the vitamins (vitamin F)[4], contemporary interest comes mainly from membrane research and prostaglandin research. It became apparent that, *e.g.*, the functions of membranes are closely related to the properties of the unsaturated fatty acids they contain, and that sensitive methods for assay of unsaturated fatty acids and the possibility of synthesizing radioactively labeled compounds of this kind are essential conditions for the study of many biological questions.

2. Structure and Nomenclature

Unsaturated fatty acids occur in large numbers in practically all living creatures. The unsaturated fatty acids of animal lipids display a particular diversity in their molecular structure. The carbon chains have up to 28 carbon atoms[1]; and some acids have up to seven double bonds[5]. The structures of the acids (Fig. 1) display three common features:

1) The double bonds possess a *cis* configuration;

2) the double bonds are always separated by only *one* methylene group (divinylmethane or polyallyl rhythm); and

3) the first double bond is separated from the carboxyl group by at least *two* methylene groups.

These common structural features reveal common biosynthetic principles[6, 7] (Section 6.1).

$$CH_3-(CH_2)_x-\left[\underset{H}{C}=\underset{H}{C}-CH_2\right]_y-(CH_2)_z-COOH$$

Fig. 1. General structural formula of the most common unsaturated fatty acids occurring in Nature. $x = 1, 4, 5$, and 7; $y = 1$ to 6; $z = 2$ to 7.

Fatty acids containing *trans* double bonds[2, 8] or triple bonds[2, 9] are extremely rare in the animal kingdom. Unsaturated acids whose double bonds are separated by more than one methylene group[1, 3] or by none at all[10] are also hardly encountered in animal lipids. Like the above *cis* unsaturated acids, however, they do frequently occur in fungi and microorganisms.

Saturated and unsaturated fatty acids were initially assigned trivial names, but only few acids are still known by these names, such as oleic acid, linoleic acid, and arachidonic acid. The IUPAC nomenclature has been generally accepted (cf. Table 1). However, the systematic names are often rather long and so various abbreviated notations have been proposed, of which the three most common are illustrated in Table 1.

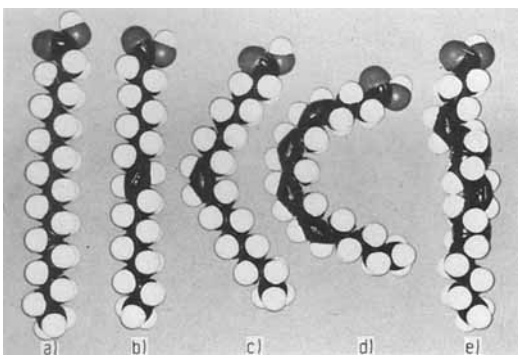
Table 1. Nomenclature of unsaturated fatty acids.

Trivial name	Systematic designation	Abbreviated notation		
		Klenk [7]	*Stoffel* [11]	*Holman* [12]
Oleic acid	*cis*-9-Octadecenoic acid	Δ^9-$C_{18:1}$	$18:1^9$	9-18:1
Elaidic acid	*trans*-9-Octadecenoic acid	*trans*-Δ^9-$C_{18:1}$	*trans*-$18:1^9$	*trans*-9-18:1
Linoleic acid	all-*cis*-9,12-Octadecadienoic acid	$\Delta^{9,12}$-$C_{18:2}$	$18:2^{9,12}$	9,12-18:2
α-Linolenic acid	all-*cis*-9,12,15-Octadecatrienoic acid	$\Delta^{9,12,15}$-$C_{18:3}$	$18:3^{9,12,15}$	9,12,15-18:3
γ-Linolenic acid	all-*cis*-6,9,12-Octadecatrienoic acid	$\Delta^{6,9,12}$-$C_{18:3}$	$18:3^{6,9,12}$	6,9,12-18:3
Arachidonic acid	all-*cis*-5,8,11,14-Eicosatetraenoic acid	$\Delta^{5,8,11,14}$-$C_{20:4}$	$20:4^{5,8,11,14}$	5,8,11,14-20:4

In addition, another nomenclature is frequently used in which the positions of the double bonds are given relative to the methyl end of the molecule[13]. α-Linolenic acid is then 18:3 (ω−3) and γ-linolenic acid 18:3 (ω−6), *i.e.* in the former case the third-from-last carbon atom belongs to the first double bond in the methyl end CH_3—CH_2—CH=CH, and in the second case the sixth-from-last CH_3—$(CH_2)_4$—CH=CH. This method of designation was chosen in order to express biogenetic relations of the acids in their names (Section 6.1.3).

3. Conformation and Physical Properties

Unsaturated fatty acids have physical properties differing from those of the corresponding saturated acids. This is because the double bonds modify the shape of the molecules. In the solid phase the hydrocarbon chain of saturated fatty acids preferentially adopts an extended conformation (Fig. 2a)[14]. In contrast, acids having a *cis* double bond exhibit a kink at the site of the *cis* double bond (Fig. 2c)[15]. With highly unsaturated acids having several *cis* double bonds this leads to a U-shaped or even ring-shaped form (Fig. 2d)[16]. A helical structure is also conceivable as a further strain-free conformation for all-*cis* unsaturated fatty acids (Fig. 2e)[17].



A 86.2

Fig. 2. Stuart-Briegleb models of a) stearic acid; b) elaidic acid; c) oleic acid; d) arachidonic acid—U form; e) arachidonic acid—helical form.

A *trans* double bond has a less drastic influence on the conformation. It effects a parallel shift of the aliphatic groups attached to the double bond in question. The molecule retains its extended shape (Fig. 2b). Hence the physical properties of acids containing *trans* double bonds resemble those of the saturated acids more closely than those of the *cis* compounds. This will now be illustrated with the aid of melting points.

This example was chosen because the temperatures of phase transitions play an increasingly important role in explanations of the properties of biological membranes (Section 7).

For example, oleic acid (*cis*-9-octadecenoic acid) melts at 10—11 °C[18], while the melting point of the *trans* isomer, elaidic acid (44.5—45.5 °C), is much closer to that of the corresponding saturated acid (stearic acid, 69.5 °C)[14]. That this is not an isolated case can be seen from Fig. 3a. The same rule applies to acids having two double bonds (Fig. 3b). Moreover, the two curves in Figure 3 clearly show that

the melting point of an unsaturated acid depends not only on the geometry of the double bonds but also on their position in the hydrocarbon chain. The melting point of an acid having *cis* double bonds deviates most from that of the corresponding saturated acid if the double bonds are located at or near the middle of the molecule. This position of the *cis* double bonds is also found most frequently in naturally occurring acids: *e.g.* oleic (9—18 : 1), vaccenic (11—18 : 1), linoleic (9,12—18 : 2), and plamitoleic acid (9—16 : 1) (concerning the abbreviations, see Table 1).

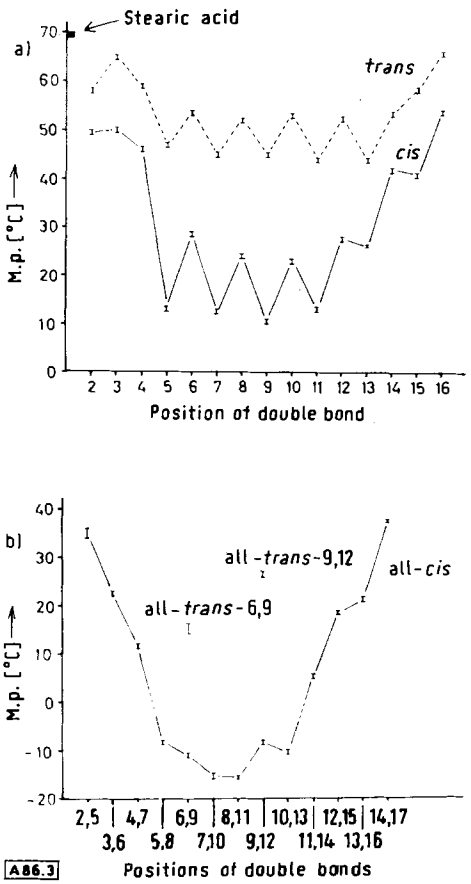


Fig. 3. Melting points of a) complete series of *cis*- and *trans*-octadecenoic acids [14, 18], and b) complete series of all-*cis*-octadecadienoic acids and of 6,9- and 9,12-all-*trans*-octadecadienoic acid [19, 20].

Table 2. Melting points of some all-*cis*-polyenoic acids.

Name	M.p. [°C]	Ref.
all-*cis*-9,12-Octadecadienoic acid	−8 to −9	[19]
all-*cis*-11,14-Octadecadienoic acid	4.5 to 5.5	[19]
all-*cis*-9,11-Octadecadienoic acid	19 to 20	[21]
all-*cis*-11,15-Octadecadienoic acid	11	[22]
all-*cis*-9,12,15-Octadecatrienoic acid	−10	[23]
all-*cis*-5,8,11,14-Eicosatetraenoic acid	−49.5	[23]
all-*cis*-5,8,11,14,17-Eicosapentaenoic acid	−54	[23]

The melting points of some isomeric all-*cis*-octadecadienoic acids listed in Table 2 demonstrate that the second characteristic structural feature of natural unsaturated fatty acids—the polyallylic rhythm—also leads to a lower melting point than is found for acids whose double bonds are either conjugated or isolated by more than one methylene group. Apart from geometry and position of the double bonds as well as the polyallylic rhythm, the number of double bonds also affects the melting point of an unsaturated acid.

The structural features of the natural unsaturated fatty acids—*cis* and not *trans* configuration, double bonds isolated by a methylene group and not conjugated—which appear remarkable from an energetic viewpoint, all combine in endowing the acids with a low melting point.

Numerous factors determine whether the fatty acid molecules adopt the above conformations or others. Importance attaches to the temperature and thus to the state of aggregation. In the crystalline phase a closely packed regular arrangement of molecules is favored[14, 24]. The molecular organization in the liquid phase is largely determined by the environment. If the fatty acids are incorporated into lipids then the intramolecular environment already influences the conformation of the hydrocarbon groups. In polar solvents at concentrations exceeding a characteristic value for each species, *i.e.* the critical micellar concentration, polar lipids (salts of fatty acids, phospholipids, sphingolipids, and free fatty acids) form micelles. In apolar solvents the solvent molecules intervene between the hydrocarbon chains and suppress their interaction[25], partly or completely. This becomes increasingly difficult the greater the London-van der Waals forces are between the chains, *i.e.* the denser the packing of the fatty acid groups. It therefore follows that the solubility of fatty acids in apolar solvents increases with decreasing chain length and increasing number of double bonds[26].

Apart from the crystalline phase and liquid phases, some lipids and lipid mixtures can also form liquid crystalline phases in which the hydrocarbon groups are "molten" (mesophases)[27]. In this state, the individual fatty acids have a greater degree of thermal freedom than in the crystalline phases; however, the overall orientation of the lipid molecules is retained within a wide range of extension in one, two, or three dimensions[28]. The degree of fluidity of the hydrocarbon chains has not yet been elucidated[29]. The crystalline/liquid crystalline phase transition temperatures for lipids depend, *inter alia*, upon the nature of the fatty acids, as do the capillary melting points[30, 31]. For lipids which differ only in their fatty acid composition, those containing acids with *cis* double bonds have lower transition temperatures than the lipids containing saturated acids[32]. These temperatures lie far below the capillary melting points. For instance, transition of dipalmitoyl phosphatidylcholine occurs at 40 °C, whereas the capillary melting point is 230 °C. In the case of dioleoyl phosphatidylcholine the phase transition takes place at −22 °C[30].

All interpretations of differing physical properties of saturated fatty acids, *cis* and *trans* unsaturated fatty acids, as well as lipids containing these acids, are based on the concept that the various conformations of the acids have different spatial requirements (see Fig. 2). Studies on monomolecular lipid films at the water-air interface confirmed these ideas[33]. Such investigations showed that the area required per molecule is higher for lipids with *cis*-unsaturated acids than for corresponding lipids with *trans*-unsaturated or saturated acids.

Reversible transitions of molecular organization in lipids are at the center of intense study because there are indications that these transitions also take place in biological membranes and are of fundamental significance for their functioning (Section 7).

4. Chemical Synthesis[34, 35]

The simplest unsaturated fatty acid, oleic acid, was first prepared in 1934[36]. It was not until 1950 that the first acid with two double bonds, linoleic acid, was simultaneously synthesized by three independent research teams[37, 38]. The principal difficulty of this synthesis is met in avoiding formation of *trans* configurated double bonds or positional isomers alongside the desired *cis* double bonds—a problem that becomes increasingly difficult to solve as the number of double bonds increases. The crucial breakthrough only came with development of the "acetylenic approach"[34, 35, 39]. This consists of an initial synthesis of acids containing triple bonds instead of *cis* double bonds at the correct positions of the molecule; in the final synthetic step these are reduced selectively and stereospecifically to *cis* double bonds. Since all double bonds are introduced simultaneously the likelihood of undesired isomerizations of the *cis* double bonds is limited to the final reaction step of the synthetic sequence.

Attempts have also been made to prepare unsaturated fatty acids by Wittig reaction[40, 41]. Although the stereochemical course of this reaction is largely controllable[40], the approach is unsuitable for construction of highly unsaturated fatty acids containing up to seven double bonds owing to the reaction conditions[35]. The *cis* double bonds can only be introduced successively by this method and the probability of isomerization is therefore high. So far only oleic and linoleic acids have been synthesized with the aid of the Wittig reaction[40, 41]. However, the method has provided valuable results in the preparation of some unsaturated fatty acids having *trans* double bonds or triple bonds that are not readily accessible by the acetylenic approach[41, 42].

Synthesis of unsaturated fatty acids by the acetylenic approach raises two problems:

1) preparation of polyacetylenic acids whose triple bonds are each separated by *one* methylene group, and

2) transformation of the triple bonds into *cis* double bonds.

4.1. Preparation of Polyacetylenic Acids

Polyacetylenic compounds whose triple bonds are all separated by one methylene group are obtained exclusively by condensation of Grignard complexes of ω-alkynes with substituted propargyl halides or propargyl methanesulfonates (Fig. 4)[35, 39, 43, 44]. This reaction requires copper(I) chloride or cyanide as catalyst. Tetrahydrofuran is usually employed as solvent. Synthesis starts from a fitting "methyl end" and the desired carbon skeleton is built up stepwise, the "carboxyl end" being added in the last step (Fig. 5).

$$R^1\text{–}C{\equiv}C\text{–}CH_2\text{–}X + BrMg\text{–}C{\equiv}C\text{–}R^2 \longrightarrow R^1\text{–}C{\equiv}C\text{–}CH_2\text{–}C{\equiv}C\text{–}R^2 + MgBrX$$

Fig. 4. Condensation of the Grignard complex of an ω-alkyne with a substituted propargyl halide or methanesulfonate (X = Br, I, OSO_2CH_3) with Cu^I catalysis.

Initially, building blocks were used which contained one triple bond only, *i.e.* each triple bond was added individually (Fig. 5a). However, in recent years methods have been developed for synthesizing suitable units possessing two triple bonds[46, 47], thus considerably reducing the number of reaction steps (Figs. 5b, 5c)[47, 48].

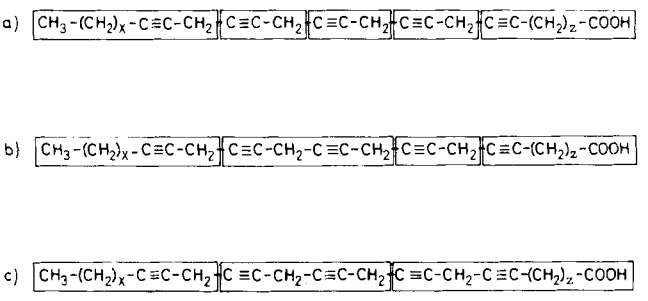

Fig. 5. Schematic survey of building blocks employed in synthesis of polyynoic acids illustrated for a pentaynoic acid. a) Strategy of *Osbond et al.* [39]. b) strategy of *van der Steen et al.* [45], c) strategy of *Kunau* [46].

The above Grignard reaction cannot be employed for preparation of suitable "methyl ends" since the Grignard derivatives of ω-alkynes react only with activated alkyl halides but not with saturated alkyl halides[43]. These starting compounds are therefore prepared by coupling of metal acetylides with alkyl halides in liquid ammonia[43, 44].

So far the most frequently used substituted propargyl halides have been the bromides[34, 39, 45, 47, 49] since the corresponding chlorides are not reactive enough and the iodides were inaccessible until recently[50]. Meanwhile the iodides have proved to be superior to substituted propargyl bromides, especially during the final condensation[48]. The use of substituted propargyl methanesulfonates has hitherto been precluded by their poor accessibility[37] and no systematic study of their application in this reaction has yet been undertaken. However, recent experiments have shown that substituted propargyl methanesulfonates can be prepared in high yield by the method of *Crossland et al.*[51] and that they also react with the Grignard complexes of ω-alkynes[52].

The polyacetylenes and polyacetylenic acids thus obtained are labile substances[53]. Their sensitivity to light and heat becomes all the greater the more triple bonds are present in the molecule and is further enhanced by the presence of terminal 1,4-pentadiyne or even 1,4,7-octatriyne structures[54]. This greatly hinders purification by distillation. Polyynoic acids often polymerize at temperatures between 50 and 100 °C[39, 47]. Above 150 °C spontaneous polymerization may occur.

These acids can be stored only in pure crystalline form at −30 °C for weeks or months. pH values exceeding 7 should be avoided since 1,4-pentadiyne structures readily rearrange to 1,3-diyne and allene structures[55].

4.2. Transformation of Triple Bonds into *cis* Double Bonds

The acetylenic approach requires not only preparation of suitable polyacetylenic acids but also conversion of triple bonds into *cis* double bonds. Use of this method became feasible only on discovery of a catalyst possessing the necessary selectivity—reduction of triple bonds but not of double bonds—and stereospecificity—formation of *cis* but not of *trans* double bonds[56]. The catalyst concerned is composed of palladium on calcium carbonate and contains lead(II) ace-

tate—it is known as the Lindlar catalyst. The required selectivity is achieved by admixture of quinoline.

By-products of partial hydrogenation include acids containing fewer double bonds than there were triple bonds in the polyacetylenic acid to be hydrogenated. Furthermore, acids having one or several *trans* double bonds are also found. The amount of by-products formed depends upon the number of triple bonds in the polyacetylenic acid undergoing partial hydrogenation. Their formation is explained by isomerization and/or hydrogenation of intermediates possessing double bonds in β-position relative to the triple bonds[57]. The desired all-*cis*-polyenoic acid is purified by chromatography on silica gel impregnated with silver nitrate (Section 5.2)[58].

In some cases hydroboration has been used for partial reduction of triple bonds. It was found that boranes with two large bulky groups, *e.g.* diisoamylborane (disiamylborane) can partially reduce triple bonds. This was accomplished not only with a few selected small molecules containing *one* triple bond[59] but also with a series of *poly*ynoic acids[60]. Detailed studies on the selectivity and stereospecificity that can be achieved have yet to be performed.

4.3. Synthesis of Radioactively Labeled Unsaturated Fatty Acids

Replacement of hydrogen by tritium atoms in existing polyenoic acids by the Wilzbach method is unsuitable for preparing radioactively labeled unsaturated fatty acids since hydrogenation of the double bonds takes place[61]. The radioactive label must therefore be introduced during synthesis of the molecule. Two different methods have been adopted for this purpose. The first technique started from unsaturated acids isolated from biological sources and ^{14}C was introduced by chain extension by one (nitrile synthesis) or two carbon atoms (malonic ester synthesis), either directly or after prior partial degradation[62]. Once the total synthesis of unsaturated fatty acids had become possible a second pathway opened up. The reactions of the acetylenic approach were varied in such a manner that the resulting unsaturated acids were labeled either with ^{3}H or with ^{14}C in certain positions[35].

Labeling of the double bonds with tritium is accomplished by partial hydrogenation of polyynoic acids in the presence of tritium. It has not yet been possible to label just one specific position with tritium by the acetylenic approach, although that aim has been achieved by chemical synthesis employing exclusively the Wittig reaction for the preparation of oleic acid and linoleic acid[63]. Higher unsaturated fatty acids stereospecifically tritium-labeled at only one C atom (D or L form) have been obtained by biochemical reactions[64, 65]. The double bonds were introduced into the stereospecifically labeled saturated acid with the aid of microorganisms.

Double labeling with ^{14}C and ^{3}H has so far only been carried out on rare occasions[11, 66, 67]. For most biological applications mixtures of acid molecules labeled with either ^{3}H or ^{14}C prove to be adequate[65].

5. Analysis

Owing to close structural similarities between unsaturated fatty acids, analysis of these substances cannot be based on pronounced differences in their chemical reactivity but is compelled to exploit slight differences in physical properties. This follows directly from the molecular structure of the unsaturated acids which deviate from one another in three parameters only, *i.e.* chain length, and number and positions of the double bonds. Only the double bonds are open to chemical attack. The analytical methods used nowadays for separation and identification of unsaturated acids are admittedly of an advanced technical standard but no method is yet available which permits simultaneous determination of all three parameters even though gas chromatography has been very close to doing so in some cases.

As with other natural products, the problem rarely arises of having to determine the structure of a single pure acid, as for example on completion of a synthesis; usually the unknown acid is present in a mixture and must first be isolated from other acids. Matters are often further complicated by the availability of only milligram or microgram quantities of sample.

5.1. Chemical Methods

Most chemical methods for the analysis of unsaturated fatty acids[58] have meanwhile been displaced by physical techniques and nowadays possess only historical interest. The sole method that is still in common use and has remained unsurpassed in its information yield is the degradation of unsaturated fatty acids by ozone (Fig. 6)[68]. The ozonides formed on ozonolysis can be reduced by triphenylphosphane, dimethyl sulfide, or hydrogen, oxidized by hydrogen peroxide, glacial acetic acid, or performic acid, or pyrolyzed, each mode of treatment giving characteristic fragments depending upon the position of the original double bonds. The fragments can be identified by gas chromatography. Since the fragments arising from methylene groups between the double bonds—*i.e.* malondialdehyde or malonic acid—cannot be quantitatively determined, ozonolysis performed in this way only yields information about the positions of the first and last double bonds but not about the chain length or the number of double bonds. The number and positions of the double bonds can be established by partial ozonolysis[69] or by partial hydrogenation with hydrazine prior to the ozonolysis[70]. The chain length has to be determined by other methods such as gas chromatography of a completely hydrogenated sample (Fig. 6).

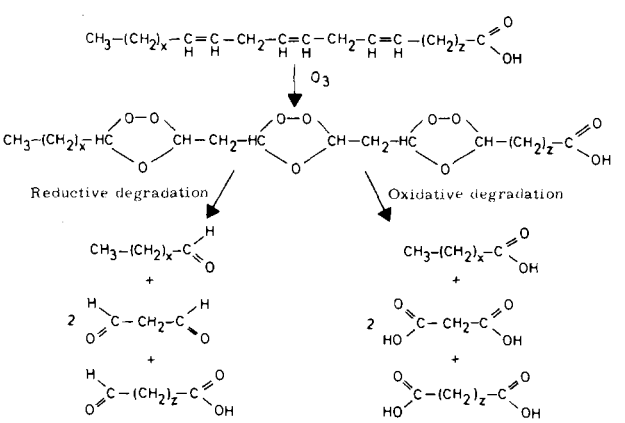

Fig. 6. Ozonolysis of a trienoic acid with subsequent reductive or oxidative ozonide cleavage.

Proof of a structure by ozonolysis must be preceded by isolation of the compound concerned, since the fragments obtained by ozonolysis cannot be assigned to the individual acids. The amount of sample required for this method depends both upon the sensitivity of the detector used for the gas chromatography and also upon the extent to which side reactions can be suppressed during ozonolysis and losses reduced during workup of the cleavage products. A 0.5-mg sample of a pure unsaturated acid usually suffices for structural elucidation by ozone degradation.

5.2. Chromatographic Methods

Analysis of small amounts of unsaturated fatty acids got under way only after development of chromatographic techniques and once authentic samples had become available for comparison. Whereas column chromatography is employed for separation of large amounts of fatty acid mixtures[71], the isolation and identification of small amounts of unsaturated fatty acids is accomplished with gas chromatography[58, 72].

The stationary phases available today permit extensive resolution of the fatty acid mixtures found in nature into their individual components after prior conversion into the methyl esters (Fig. 7). However, structural assignment can only be accomplished by comparison of retention times with those of authentic samples. The similar retention times observed for the methyl esters of many fatty acids (Fig. 7a) sometimes necessitates confirmation of the structure by an independent method.

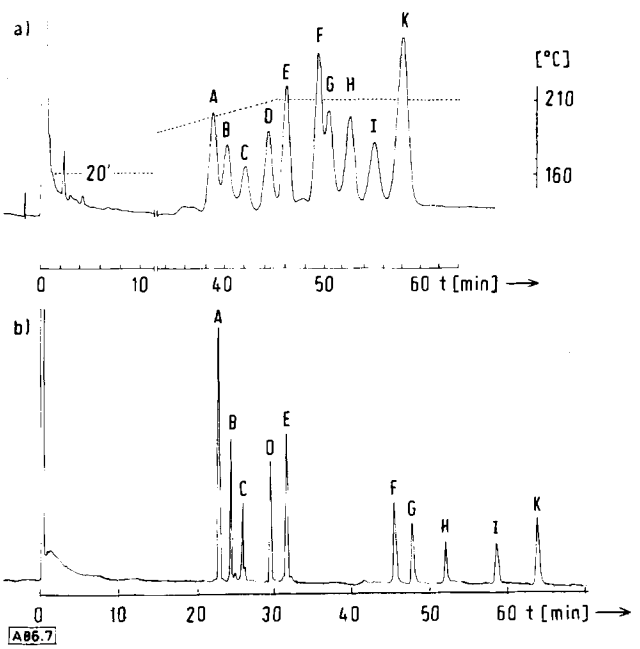

Fig. 7. Gas chromatograms of a synthetic mixture of methyl polyenoates [74] (for abbreviations see Table 1). a) Packed column, 6% DEGS (diethylene glycol succinate), 1.80 m long, glass, 4 mm i.d., temperature program. b) Capillary column, FFAP (free fatty acid phase), 87 m, glass, 0.25 mm i.d., 180 °C. A: 5,8,11—20:3; B: 8,11,14—20:3; C: 5,8,11,14—20:4; D: 8,11,14,17—20:4; E: 5,8,11,14,17—20:5; F: 4,7,10,13—22:4; G: 7,10,13,16—22:4; H: 4,7,10,13,16—22:5; I: 7,10,13,16,19—22:5; K: 4,7,10,13,16,19—22:6.

Capillary column gas chromatography is a considerable improvement: differences in retention times and hence the separating power are greater (Fig. 7b)[73, 74]. However, the columns can only be loaded with a tenth to a hundredth of the amount of material that can be applied to a packed column and the method is therefore unsuitable for preparative purposes.

Thin layer chromatography on silica gel impregnated with silver nitrate is used to separate fatty acid mixtures into fractions which each contain acids having the same number of double bonds[75]. As the number of double bonds increases, the mobility of these coordination complexes in the liquid phase decreases. *Cis* and *trans* isomers can also be separated in this way[76].

5.3. Spectroscopic Methods

While chromatographic methods are indispensable in the separation of polyenoic acids, they are surpassed by spectroscopic techniques in structural analysis. Although UV and IR spectroscopy admittedly revealed only the number[58] or configuration[77] of double bonds, the position of the double bonds has also been established alongside their configuration[78] for a number of polyenoic acids by proton resonance spectroscopy[79, 80]. Systematic studies with complete series of octadecenoic and octadecadienoic acids have shown that unequivocal differentiation of positional isomers by proton resonance spectra is feasible only when the double bonds are not located in the center of the molecule[81]. However, this difficulty can be overcome by the use of shift reagents[80].

Another promising method for the analysis of fatty acids is mass spectrometry. Although polyenoic acids themselves do not give fragmentation patterns betraying the number and positions of the double bonds owing to the ready electron-impact induced migration of the double bonds, such patterns are obtained with their derivatives. Reactions are carried out at the double bonds to give compounds which undergo preferential cleavage between the carbon atoms of the original double bonds and thus lead to characteristic fragments of sufficient intensity.

Studies of this kind have been performed mainly with compounds having one double bond. However, the derivatives used for monoenoic acids are unsuitable for polyenoic acids since the fragmentation schemes are then too complicated[82]. So far only methyl[82, 83] and trimethylsilyl ethers[82] have been used in structural elucidation of polyenoic acids possessing up to five double bonds. The primary fragments of both derivatives tend to lose their ether groups; this occurs in a predictable manner in the trimethylsilyl derivatives[82]. Of the originally vicinal trimethylsilyl groups, only one is left in the resulting fragments. In contrast, the primary fragments of the methyl ether derivatives lose all methoxy groups with equal probability, giving a variety of product fragments in roughly equal abundancies[82, 83]. Therefore the characteristic fragments for localization of the double bonds have much higher intensities in the mass spectra of the trimethylsilyl derivatives than in those of the methyl ether derivatives.

A method of obtaining informative fragmentation patterns without chemical modification of the double bonds has recently been the subject of discussion[84]. Use of substituted amides in place of the saturated acids or their esters should lessen the extent of electron-impact induced migration of the double bonds owing to localization of the positive charge

on the nitrogen. This has meanwhile been successfully implemented for monoenoic acids[85].

Although structural elucidation of unsaturated fatty acids by mass spectrometry requires a pure sample, only microgram quantities are required; combination of gas chromatography and mass spectrometry is therefore an obvious choice for analysis of mixtures. However, initial expectations have not yet been fulfilled: it has so far proved impossible to derivatize a mixture of polyenoic acids in such a way that all the components are present in the same proportions as before derivatization; moreover, the derivatives cannot yet be separated as well as the polyenoic acids themselves in the chromatographic step[82].

6. Metabolism

6.1. Biosynthesis

Starting from acetyl-CoA, saturated fatty acids are built up by the same metabolic pathways in microorganisms, plants, and animals. The enzymes required for this *de novo* synthesis are present as a multienzyme complex—fatty acid synthetase—in yeasts[86], in the alga *Euglena gracilis*[87] under heterotrophic growth conditions, and in the animal kingdom[88, 89]; in contrast, the individual enzymes were isolated from bacteria[90] and plants[91]. The major final product of the *de novo* synthesis in animal cells is palmitic acid ($C_{15}H_{31}COOH$), together with small amounts of myristic ($C_{13}H_{27}COOH$) and stearic acid ($C_{17}H_{35}COOH$)[89].

These *saturated* acids serve as precursors for biosynthesis of the *unsaturated* acids. Since the double bonds are introduced independently of chain elongation this metabolic pathway requires two further enzyme systems:

1) *desaturases*, which introduce *cis* double bonds in an oxygen-dependent reaction, and

2) *enzymes of chain elongation*, which lengthen the final products of the *de novo* synthesis and the desaturase reaction by further C_2 units.

6.1.1. Aerobic Formation of Double Bonds

Except for obligate and facultative anaerobes, introduction of double bonds into the hydrocarbon chain of fatty acids in Nature always occurs independently of the reactions involved in the *de novo* synthesis. In anaerobes the double bonds are already introduced *anaerobically* by fatty acid synthetase during formation of the carbon skeleton by elimination of water from hydroxylated intermediates[92]. Further chain elongation or the presence of desaturases has not been observed in these organisms.

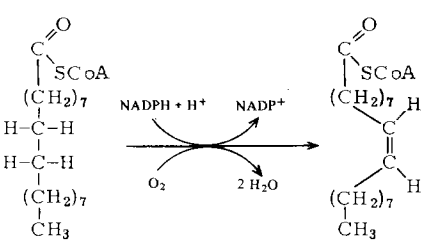

Fig. 8. Aerobic formation of a double bond.

The precise mechanism of formation of isolated *cis* double bonds within a completed carbon chain by desaturases has not yet been entirely elucidated. As far as is known, it is basically the same for microorganisms[92], plants, and animals[93–96] (Fig. 8). The reaction is strictly *aerobic*, the oxygen cannot be replaced by other electron acceptors; reduction equivalents are supplied by NADH or NADPH. These facts favor a mechanism resembling that operative in reactions catalyzed by mixed function oxygenases[97]. However, no hydroxylated products could be detected as intermediates[98, 99].

Removal of hydrogen atoms during formation of the *cis* double bond is strictly stereospecific. This was first established for the conversion of tritiated stearic acid into oleic acid in *Corynebacterium diphtheriae*[100]. D hydrogen atoms are detached stereospecifically from the two prochiral centers, at C-9 and C-10, on formation of the double bond (Fig. 9). The same was found in work with the alga *Chlorella vulgaris* and with chicken liver[99, 101, 102]. These experiments were performed to study the synthesis of oleic acid from stearic acid and of linoleic acid from oleic acid. The stereochemical course was the same as in the bacterial system for introduction of both the first and the second double bond. The hydrogen atoms removed were *erythro* configurated relative to each other, and furthermore, of the four possible hydrogen atoms, only the two having the D configuration were eliminated. The observed kinetic isotope effects[102, 103] suggest that the two hydrogen atoms are removed simultaneously. This would explain the failure of all previous searches for an oxygenated intermediate.

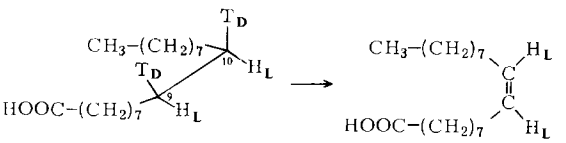

Fig. 9. Stereochemistry of hydrogen elimination in the desaturase reaction.

Although the carboxyl group of the acids does not participate directly in formation of the double bonds, acids are accepted as substrates for desaturases only if the carboxyl group is not present in free form. In animal cells[95] and bacteria[100, 104] only the coenzyme A esters are suitable substrates while in plants desaturases have been found which require the acyl carrier protein (=ACP) derivatives of the acids[93, 105]. Again in contrast to animal cells, it has been proved in some cases for microorganisms that double bonds can also be formed in fatty acid molecules incorporated as acyl groups into complex lipids[106].

Participation of an electron transport chain, *i.e.* a series of proteins transferring electrons from the electron donor NADH or NADPH to the electron acceptor O_2, has been verified for some desaturases. The most detailed knowledge available pertains to a desaturase complex of the alga *Euglena gracilis*[105] since the proteins involved are not bound to membranes, as they are in all other cases investigated so far.

As in *Euglena gracilis*, three proteins are involved in the reaction in rat liver (Fig. 10): a flavoprotein which oxidizes the reduced pyridine nucleotides, transferring the electrons to the second protein (ferredoxin in *Euglena gracilis* or cytochrome b_5 in rat liver). The third protein is most probably the actual O_2-activating enzyme possessing desaturase activity. In rat liver it is inhibited by cyanide and for this reason it is designated cyanide-sensitive factor (=CSF)[107].

These two desaturase complexes, which have been most thoroughly studied up to now, catalyze the transformation of activated stearic acid into activated oleic acid. However, the formation of oleic acid is merely the first step in the biosynthesis of polyunsaturated acids from stearic acid; apart from chain elongation, additional double bonds are introduced in polyallylic rhythm. There is evidence that various desaturases possessing pronounced specificity towards the substrate and the product are involved[96].

A strong indication of the existence of desaturases having different substrate specificity is provided by the fatty acid spectrum of various organisms. Bacteria contain only monounsaturated acids[108]. They synthesize mainly palmitoleic and/or oleic acid from palmitic and stearic acid but cannot introduce any more double bonds into these monoenoic acids. Plant cells are able to do so; they transform stearic acid into oleic, linoleic, and α-linolenic acid[109]. Animal cells are incapable of introducing a second or third double bond into the methyl end of oleic acid[110], but do synthesize more highly unsaturated acids from linoleic and α-linolenic acid if they are administered together with nutrients[111, 112].

The marked action specificity of desaturases is illustrated by the formation of α- or γ-linolenic acid from linoleic acid (Fig. 11). In plants linoleic acid is transformed into α-linolenic acid by introduction of the third double bond in position 15, 16, a reaction beyond the capability of the animal cell. However, in contrast to plants, the latter can introduce the third double bond in position 6, 7 of linoleic acid and thus synthesize γ-linolenic acids.

Evidence so far available on the substrate and action specificity of desaturases suggests that the biosynthesis of 4,7,10,13,16,19-docosahexaenoic acid will require as many as six different desaturases.

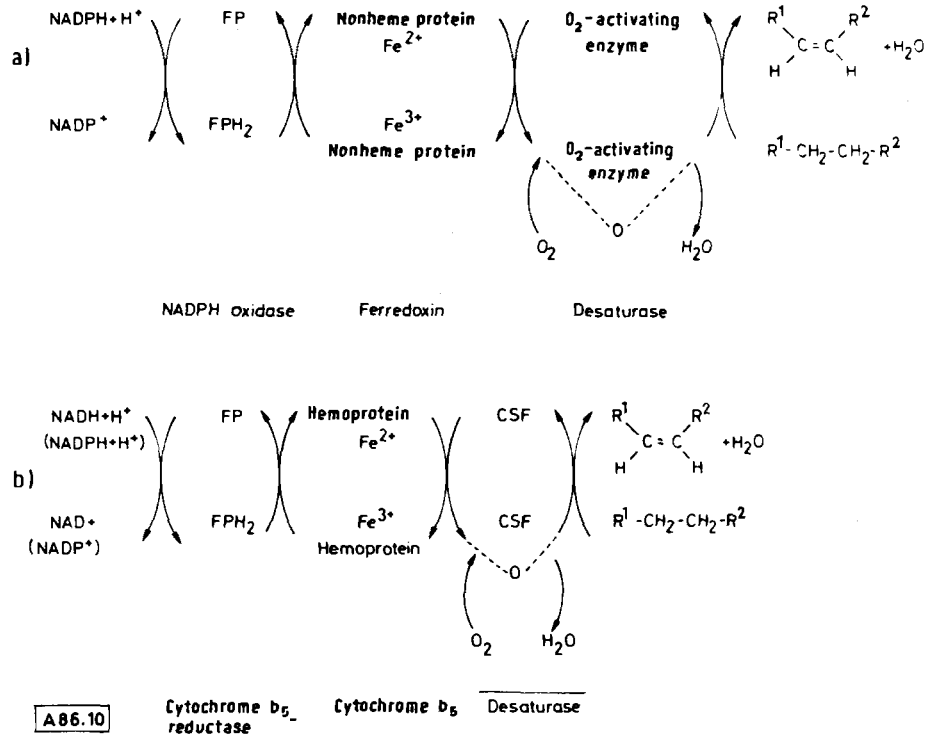

Fig. 10. Electron transport chain for oxygen activation in the desaturase reaction a) in *Euglena gracilis* (according to ref. [92]), b) in the animal organism. FP = flavoprotein, CSF = cyanide sensitive factor.

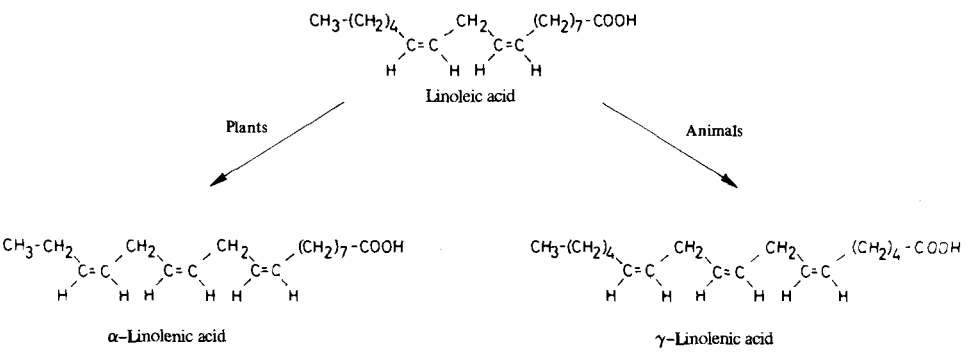

Fig. 11. Specificity of desaturases towards the product. Formation of α- and γ-linolenic acid from linoleic acid.

6.1.2. Chain Elongation

Chain elongation of fatty acids formed in the *de novo* synthesis by fatty acid synthetase is a metabolic process encoun-

tered in numerous eukaryotic microorganisms[113, 114] and in the animal kingdom[111, 112, 115–117]. It is still open whether bacteria and plants also possess enzymes for a chain elongation distinct from the *de novo* synthesis. A malonyl CoA dependent chain elongation has occasionally been observed in plant waxes and bacterial species having exceptionally long fatty acids[118]. Moreover, there is evidence that chain elongation participates alongside *de novo* synthesis in the biosynthesis of C_{18} acids in plants[119].

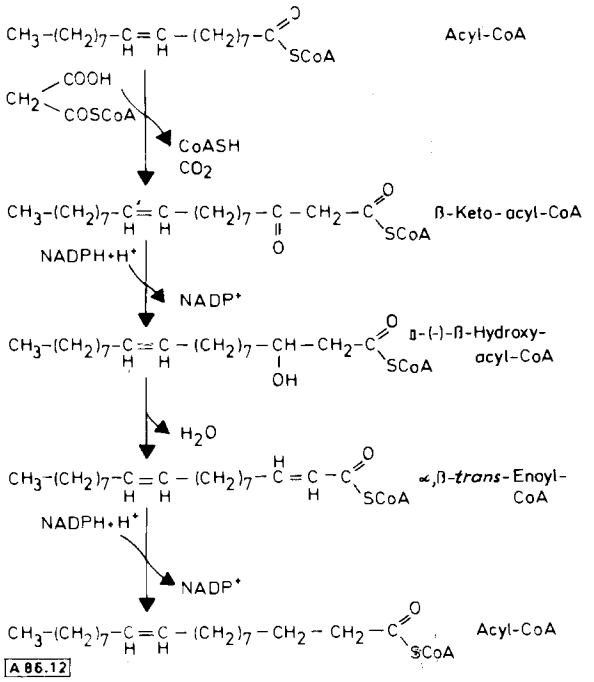

Fig. 12. Course of chain elongation by two carbons, illustrated for oleic acid.

In animal cells the enzymes responsible for chain elongation are located, like the desaturases, on the membranes of the endoplasmic reticulum[115–117]. They have so far resisted all attempts at isolation. All the properties known today have been deduced from experiments on membrane fragments of the endoplasmic reticulum (microsome fraction). The mechanism of chain elongation was established in this way[115, 116] (Fig. 12): the substrates are the coenzyme-A esters of saturated and unsaturated fatty acids which condense with malonyl CoA in the first step, the carboxyl group of the malonyl CoA being liberated as CO_2. As product, this reaction yields a β-keto thioester that is converted, *via* a D-(−)-β-hydroxy- and an α,β-*trans*-enoyl thioester in the three subsequent steps, into the acyl CoA compound, which differs from the starting material by having two additional methylene groups. Hence the same reactions occur as in the *de novo* synthesis on fatty acid synthetase. In both cases the carbon skeleton is extended by two carbon atoms in a cycle of four reactions. This is the reason why both the saturated and the unsaturated fatty acids occurring in Nature exhibit an even number of carbon atoms. However, a fundamental difference between this chain elongation and the *de novo* synthesis is that all the intermediates are present as CoA esters and are not enzyme bound as in the latter case[115, 116].

Most of the studies on chain elongation were performed with microsomal fractions from rat liver. It was found that the optimum substrate specificity of the participating enzymes lies at 10—16 carbon atoms for saturated acids[115]. However, if fatty acids containing more than 16 carbon atoms have two or more *cis* double bonds then they are consumed just as fast as the shorter saturated acids, if not faster[115, 116]. The positions of the double bonds exert an additional effect. The shorter the carboxyl end, *i.e.* the smaller the value of *z* (Fig. 1), the better the unsaturated acids are elongated[116].

It is still largely uncertain whether each one of the four reactions of chain elongation involves just one enzyme of low chain length specificity or several of high specificity. Only in the case of mouse brain endoplasmic reticulum has the existence of three independent elongation systems, strictly specific for chain lengths of 16, 18, and 20 carbon atoms respectively, been established[120].

Apart from the microsomal chain elongation described so far, an ubiquitous mitochondrial enzyme system is also known[121, 122]. It utilizes acetyl CoA instead of malonyl CoA as C_2 donor[123], but the reaction sequence is otherwise identical. The first three steps of acetyl CoA dependent chain elongation appear to be the reversal of the β-oxidation reactions. The fourth reaction, reduction of the α,β-*trans* unsaturated CoA ester, is again catalyzed by a 2-enoyl-CoA reductase, as in chain elongation on the endoplasmic reticulum[122, 124]. This makes the reversal of β-oxidation thermodynamically feasible[122].

The function of mitochondrial chain elongation and its quantitative contribution to the synthesis of fatty acids is a matter of dispute. Reasons of cellular economics would appear to counterindicate an all too important role in the biosynthesis of unsaturated fatty acids. Since the desaturase reaction is restricted solely to the microsomal fraction, the substrates and products of this reaction would have to be transported into the mitochondria prior to chain elongation and removed again afterwards. However, the inner mitochondrial membrane is impermeable to CoA esters[125], which would therefore have to be converted into carnitine esters prior to each transport step[126]. These transport processes are not necessary for chain elongation by the microsomal enzymes. Recent investigations suggest that the function of mitochondrial chain elongation is to be sought in energy metabolism[122]. A quantitative comparison of pork liver cell fractions has revealed that the activity of the microsomal chain elongation is five times greater than that in mitochondria[122a].

6.1.3. Fatty Acid Families and Patterns

The joint action of enzyme systems for chain elongation and introduction of *cis* double bonds on a single acid can lead to a variety of unsaturated fatty acids. They differ in chain length and in the number and positions of the double bonds. Since the desaturases present in animal tissues can only catalyze formation of double bonds in the "carboxyl end", and since chain elongation occurs at the carboxyl group, the unsaturated acids of animal organisms, which are formed by chain elongation and desaturation from the same starting acid, will all possess the same "methyl end". Biosynthetic relationships are reflected by the structures. All acids having the same methyl end are collected together as a "fatty acid family" (fatty acid type) named after the starting acid[111]. The principal starting substrates for the biosynthesis of highly unsaturated fatty acids in animal organisms are palmitoleic, oleic, linoleic; and α-linolenic acids.

The number of possible biosynthetic pathways leading to a particular polyenoic acid becomes greater and greater with the length of the acid and the number of double bonds it contains. The actual route adopted for formation of an unsaturated fatty acid depends upon the sequence of desaturase and elongation steps which can differ in different organisms (see Fig. 13).

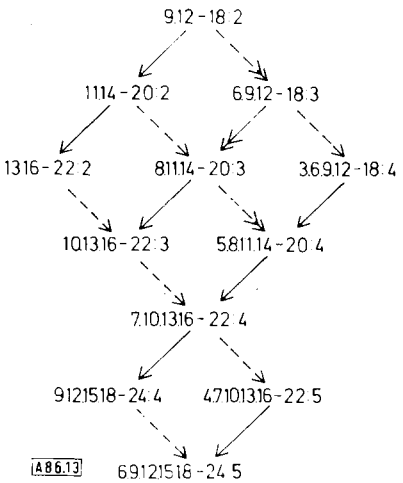

Fig. 13. Conceivable biosynthetic pathways of fatty acids belonging to the linoleic acid family. Participating reactions: chain elongation (→) and desaturase reaction (⇢). The double arrows indicate the preferred formation pathway of arachidonic acid (5,8,11,14-eicosatetraenoic acid) from linoleic acid in the rat (for abbreviations see Table 1).

Studies performed with the microsomal fraction of rat liver have suggested that the qualitative and quantitative composition of the fatty acids of a cell—*i.e.* the fatty acid pattern—may be affected not only by the different reaction rates of various acids in competing reactions[116] but also by the differing competitive inhibition exerted by the members of one fatty acid family on the reactions of acids belonging to another family[127].

Differences in the ability of microorganisms to synthesize unsaturated fatty acids have sometimes been employed to establish phylogenetic relationships[114]. If we restrict our attention to introduction of a third double bond into linoleic acid, there result three groups (Fig. 14). Group A comprises those organisms which form α-linolenic acid from linoleic acid and are thus capable of the reaction typical of the fatty acid metabolism of plants. Organisms of group C, like animal cells, can only convert linoleic acid into γ-linolenic acid. Group B contains all those microorganisms which can synthesize both α- and γ-linolenic acid. If this comparison is extended to include the differing ability to synthesize more highly unsaturated fatty acids, *i.e.* to form further double bonds and elongate the carbon chain, a scheme can be drawn up which shows good agreement with that of phylogenetic development according to *Klein* and *Cronquist*[128].

6.2. Oxidation

Both unsaturated and saturated fatty acids are degraded by β-oxidation in mitochondria[116]. This is a sequence of four steps during which the first two carbon atoms are cleaved from the carboxyl end of an activated fatty acid as acetyl CoA[129]. This process is repeated until the last two carbon atoms of the methyl end of the fatty acid remain behind as acetyl CoA. According to their mechanism the steps involved in β-oxidation in mitochondria appear to be the reversal of the four reactions of *de novo* synthesis in cytoplasm and chain elongation in microsomes. However, malonyl CoA is used for construction while the two carbon atoms cleaved off are liberated as acetyl CoA.

Owing to the *cis* double bonds of unsaturated fatty acids, intermediates occur during their β-oxidation which do not appear on degradation of saturated acids[116, 130]. Hitherto it was assumed that they are 2-*cis*- and 3-*cis*-enoyl-CoA compounds. These thioesters can be transformed into "normal" β-oxidation intermediates by further reactions[131].

Thus 3-*cis*-enoyl compounds are isomerized to 2-*trans*-enoyl-CoA compounds (Fig. 15a). 2-*cis*-Enoyl CoA esters initially add water and form D-(−)-hydroxyacyl-CoA compounds which are subsequently converted into the L-(+) form and thus re-enter the β-oxidation cycle (Fig. 15b).

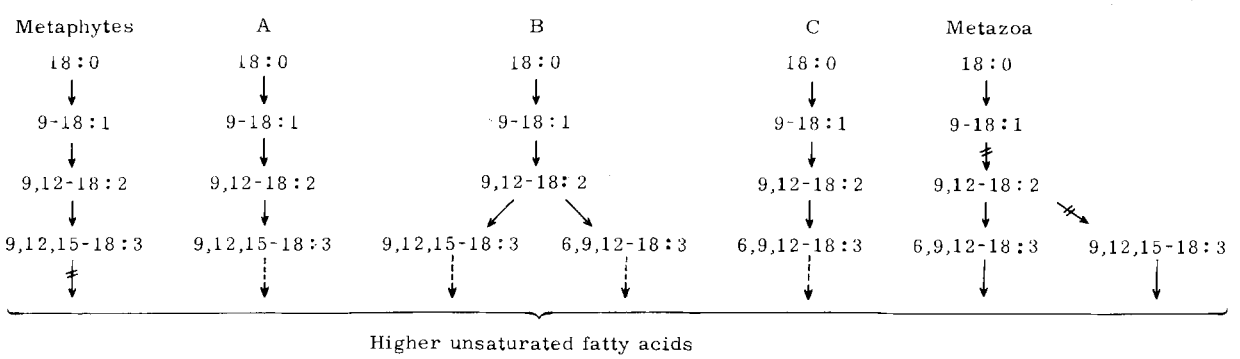

Fig. 14. Comparison of biosynthetic pathways for unsaturated fatty acids in various microorganisms with the synthetic pathways in plants and higher animals. Group A: microorganisms which, like plants, form α-linolenic acid (*e. g. Pyrrophyta, Ascomycetes, Basidomycetes*, yeasts, and *Chlorococcales*). Group B: microorganisms which synthesize both α- and γ-linolenic acids (*e. g. Rhodophyta, Euglenaphyta, Phaephyta, Vovocales, Chytridomycetes, Oomycetes*, and numerous species of *Cyanophytae*). Group C: microorganisms which, like animal cells, convert linoleic acid into γ-linoleic acid (*e. g. Zygomycetes, Sarcodina, Zoomastigophora*, and *Ciliophora*). ⇢: reactions which fail to occur owing to absence of enzymes. →: reactions occurring in some but not all microorganisms of this group.

Recent studies on the substrate specificity of acyl CoA dehydrogenases from bovine liver suggest that unsaturated fatty acids are not oxidized as far as the 2-*cis*-enoyl CoA esters but only up to the stage of 4-*cis*-enoyl CoA esters by β-oxidation[132]. Further degradation can only occur once

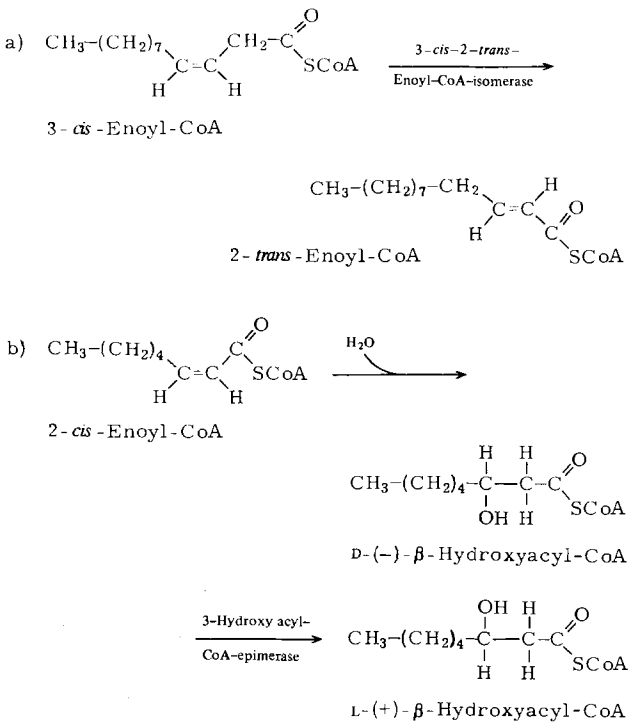

Fig. 15. Reactions which reintroduce the specific degradation intermediates of 2-*cis*-enoyl CoA ester (a) and 3-*cis*-enoyl CoA ester (b) into the β-oxidation cycle of saturated fatty acids.

the double bond in position 4 has been reduced. An enzyme, 4-enoyl CoA reductase, which catalyzes this reaction has been found in animal liver[67, 133].

In contrast to β-oxidation of saturated fatty acids[134], a partial degradation is found to occur with many polyunsaturated fatty acids; *i. e.* detectable amounts of intermediates accumulate[11, 135, 136]. These differ from the starting acids by loss of the first double bond and/or by chain shortening. Loss of the first double bond occurs only when it is located in position 4[67, 136].

Nothing is yet known about regulation mechanisms in degradation of unsaturated fatty acids.

7. Biological Functions

Since the feeding experiments of *Burr* and *Burr*[137] in 1929 it is known that some unsaturated fatty acids are essential dietary constituents for the rat. This significant observation was repeatedly confirmed during the following three decades and extended to other animal species. Detailed reviews describe the deficiency symptoms for essential fatty acids[138]. In 1958, unsaturated fatty acids were shown to be "essential" for childen[139]. A few years ago fatty acid deficiency symptoms were established in patients who had been fed parenterally for prolonged periods[140].

It proved to be particularly difficult to detect which unsaturated fatty acids are the essential ones. Studies on the biosynthesis of unsaturated fatty acids (Section 6.1.1) have shown that animal organisms can synthesize oleic acid but not linoleic acid and α-linolenic acid. Hence the desaturases required for introduction of the second and third double bond into the methyl end of oleic acid are missing. If linoleic and/or α-linolenic acid is administered in the diet of an animal organism then it can synthesize the higher members of both fatty acid families by introduction of further double bonds and chain elongation (Section 6.1.3).

If an attempt were made to derive a definition of the term "essential fatty acids" on this basis, then only linoleic and α-linolenic acids would be strictly essential since all other polyunsaturated fatty acids can be synthesized by animal organisms on supply of suitable precursors. However, another approach has been adopted for defining the expression "essential fatty acids" in that the efficacies of the individual acids in counteracting the symptoms of fatty acid deficiency are compared with one another[141]. It was found that administration of acids belonging to the linoleic acid family best dispelled the symptoms of fatty acid deficiency, and the most effective acid was arachidonic acid[142].

To this day it has not been adequately established in which metabolic reactions or in which structural components of the cell the absence of essential fatty acids can initiate pathological changes. However, two topics have recently come to the fore, which could make important contributions to this subject. Unsaturated fatty acids having 20 carbon atoms and three or four double bonds are precursors of prostaglandins[143] (Fig. 16). The physiological properties of the latter are so varied that there are grounds for believing that the relation to the polyunsaturated fatty acids suffices to explain the essential nature of these acids.

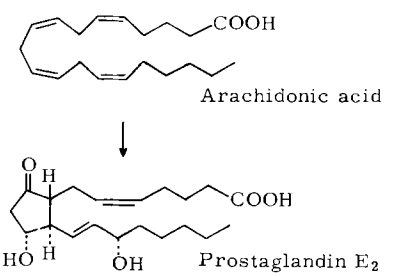

Fig. 16. Formation of prostaglandin E_2 from arachidonic acid.

The second field supplying important knowledge about the biological function of unsaturated fatty acids is membrane biology. As the view is more widely adopted that membranes are not static but dynamic structures whose biological properties depend upon their two fundamental components—proteins and lipids—the membrane lipids and hence also the unsaturated fatty acids continue to attract growing attention.

Judging by their chemical structure, the membrane lipids are extremely heterogeneous[144]. This applies not only to the hydrophilic partial structure but, to an even greater extent, to the hydrophobic part of the molecule, *i. e.* the fatty acid group. The most common membrane lipids are the phospholipids (Fig. 17), which are distinguished from other lipids by their higher content of unsaturated fatty acids[144].

The former view that membrane lipids merely form an apolar phase between aqueous regions and serve as a rigid matrix for biologically active proteins[145] has been modified. Discussions of such varied biological properties of membranes and membrane processes, such as permeability[146], transport properties[147], inhibition of wetting[148], nervous conduction of stimuli[30, 149], enzymatic reactions[150], and the cellular immune reaction[151] assume that they arise from the presence and the physical state of the membrane lipids. The state and transition temperature of reversible phase changes of lipids

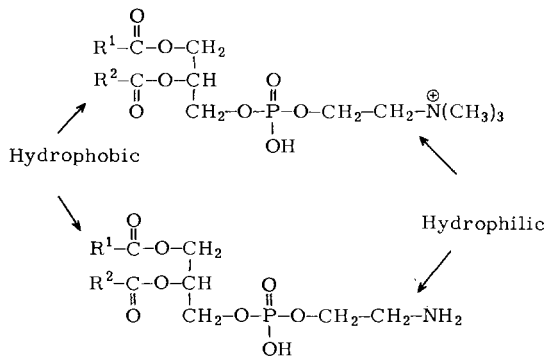

Fig. 17. Structure of the two most frequent phospholipids. Above, phosphatidylcholine (lecithin); below, phosphatidylaminoethanol (cephalin). R^1 and R^2 are long-chain saturated or unsaturated alkyl groups.

are in turn largely determined by the chain length and the number and positions of double bonds in the fatty acids present in the lipids (Section 3).

Reversible phase transitions, as investigated for model membranes[28, 30, 31, 149, 152, 153]—monolayers, bilayers, liposomes—also take place in biological membranes[29-31, 153]. Moreover, preliminary experimental evidence has been obtained that the lipid structure influences the conformation of proteins[154]. It is currently being discussed whether the changes in membrane properties resulting from phase changes of the lipids enable the cell or cell organelles to adapt to changing conditions. Thus it is envisaged that changes in an external parameter promote structural changes in the membrane which in turn lead to a change in function of the membrane[145, 153]. One important task of unsaturated fatty acids in lipids of biological membranes would accordingly lie in the facilitation of reversible phase changes in membrane lipids in the physiological temperature range.

The bewildering heterogeneity of membrane lipids in various types of membranes[144] or even within one membrane was formerly almost uninterpretable, and it was only the relationships sketched out above involving the lipid composition, reversible phase changes, and the "functioning" of a membrane that permitted some understanding of the complexity of membrane lipids.

Viewed from this vantage point, the exceptionally high proportion of highly unsaturated fatty acids—4,7,10,13,16,19-docosahexaenoic acid or 5,8,11,14,17-eicosapentaenoic acid—in the phospholipids of the photoreceptor membrane in the eyes of vertebrates[155] and invertebrates[156] are of particular interest. This fatty acid pattern justifies the assumption that the visual pigment rhodopsin possesses an environment of great mobility[157]. Support for this hypothesis comes from experiments using polarization optical techniques which showed that rhodopsin undergoes rotational movement with a relaxation time of 20 μs in the photoreceptor membrane[158].

Polyunsaturated fatty acids also play a central role in discussions of the pathogenesis and prophylaxis of atherosclerosis[159-161]. This is a significant subgroup of the general degenerative wall diseases of arteries (arteriosclerosis) characterized by development of irregular lipoid deposits (plaques) in the interior layer (intima) of the arterial wall.

The plaques are rich in cholesterol esters[162]. The molecular mechanism of plaque formation has not yet been elucidated. Clinical research has established that atherosclerosis is a multifactorial process[159, 160]. Apart from high blood pressure and smoking, an abnormal increase in blood lipids, especially cholesterol, has been recognized as one of the most significant risk factors.

Today it is universally accepted that polyunsaturated fatty acids reduce the blood level of cholesterol[159-161], and all dietary measures adopted in the prophylaxis of atherosclerosis resort to fats having high contents of these fatty acids. Vegetable oils are particularly suitable for such purposes[160]. However, any conclusions about the origin of excessive cholesterol levels in the blood that may be drawn from such "feeding experiments" should be viewed with great caution[163]. These diets are far too complex for any such interpretations. Apart from the content of saturated and unsaturated fatty acids, other dietary components also have to be considered, *e.g.* cholesterol and vegetable sterols.

8. Conclusion

The past two decades have seen a rapid development in the chemistry and biochemistry of unsaturated fatty acids. Syntheses have been discovered for production of radioactively labeled, highly unsaturated fatty acids in good yields. This was an important requirement for the study of biochemical and biological aspects.

Use of modern analytical techniques has shown that these methods make an important contribution to the structural elucidation of unsaturated fatty acids. Further advances can be expected in the next few years.

The metabolism of unsaturated fatty acids has been examined in general terms. Isolation and characterization of the enzymes involved will provide an insight into the regulation of this area of metabolism.

Especially interesting results may also be expected from membrane biology.

Sequence Analysis of Polypeptides and Proteins by Combined Gas Chromatography-Mass Spectrometry[**]

By Heinz Nau[*]

A new method for determining the amino acid sequence of polypeptides consists in initial partial hydrolysis to yield a complex mixture of oligopeptides. After derivatization to enhance its volatility, the mixture is analyzed by combined gas chromatography and mass spectrometry. The sequence of the polypeptide is established by a computer from the identified oligopeptides. So far polypeptides having up to 40 amino acids have been analyzed by this method. The advantages and disadvantages of the new method compared with the stepwise procedure of the Edman degradation are considered. Since the two methods are based on fundamentally different principles they may prove to be complementary.

1. Introduction

Depending upon their origin and function, proteins may have widely differing physical and chemical properties. Largely inert forms of highly insoluble proteins such as keratin or elastin can be contrasted with the extremely sensitive structures of many hormones (*e.g.* glucagon, insulin) and enzymes (*e.g.* ribonuclease A, chymotrypsin) which catalyze a multitude of reactions and regulate the metabolism of living organisms. Furthermore, the molecular weight is subject to wide variation within this class of natural products (*e.g.* insulin, 51 amino acids[1][***]; a polypeptide chain of an immunoglobulin, 576 amino acids[2]) so that hardly any two proteins have the same physicochemical properties although the same structural principles apply to all proteins. Finally, the chemical variety of their twenty constituent amino acids provides further obstacles to a routine analysis of proteins. A knowledge of their structure is an essential condition for elucidation of the mode of action of these molecules.

Even today, 25 years after the introduction of the Edman degradation[3], successful deciphering of the primary structure of relatively large proteins (sequence analysis) is still a difficult task, although automatic "protein sequencers"[4] have reduced the time and sample weight required. Complete sequence analysis of a protein of unknown structure containing, *e.g.* 200 amino acids takes several years. The result, *i.e.* the "sequence", can only be tested by repeating the analysis. A systematic error will necessarily again falsify the sequence. Classical "structural proof" by total synthesis is illusory in this context: syntheses of polypeptides are even more difficult than their analysis.

A more practicable approach than total synthesis is the development of a second independent analytical procedure providing results that can be compared with those of the automated Edman degradation method. This article describes a method of sequence analysis utilizing a combination of three techniques, *viz.* gas chromatography (GC), mass spectrometry (MS), and computer science. We believe that this method complements the Edman degradation in an ideal manner. The Edman approach requires a free amino group at the N-terminus of a peptide; however, precisely those peptides which are blocked at the N-terminal end can be readily analyzed by mass spectrometry. Nor do amino acids prone to decomposition under the conditions of Edman degradation (*e.g.* Ser, Tyr, or Trp) cause any difficulties in the new method. Furthermore, mass spectrometric techniques furnish the complete sequence of a polypeptide whereas the Edman procedure frequently permits only determination of a partial sequence.

We consider the important contribution of the new procedure to lie in the provision of analyses which are independent of Edman degradation, both chemically and as far as apparatus and method are concerned.

This article first considers the general problems of sequence analysis; the principles of the two above mentioned procedures are then compared and their respective advantages and disadvantages weighed up. An account of the requirements and the modern state of sequence analysis by mass spectrometry is followed by a discussion of its application to the solution of various problems encountered in protein chemistry.

2. Problems and Possibilities of Sequence Analysis

2.1. Edman Degradation Procedure

Polypeptides and proteins are chain-like molecules in which α-amino acids are linked together *via* α-amino and α-carboxyl groups. Given such linkage, an amino group remains free at one end of the chain (N-terminus) and a carboxyl group at the other (C-terminus). Since analysis of the overall structure of such macromolecules has so far run into insuperable difficulties—X-ray diffraction on protein crystals is the nearest approach to this ideal yet to be accomplished—indirect methods of sequence analysis have been developed.

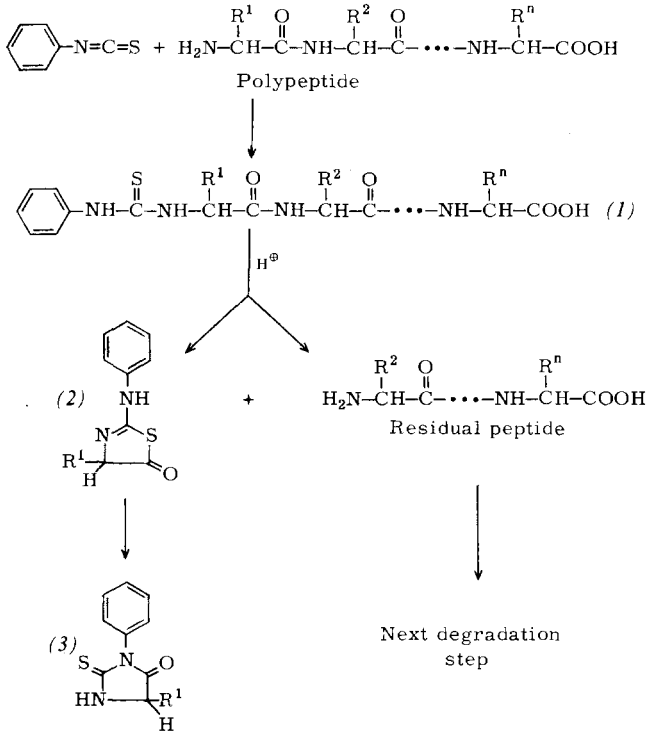
[**] The following abbreviations have been used for amino acids: Gly, glycine; Ala, alanine; Val, valine; Leu, leucine; Ile, isoleucine; Pro, proline; Phe, phenylalanine; Tyr, tyrosine; His, histidine; Trp, troptophan; Ser, serine; Thr, threonine; Asp, aspartic acid; Asn, asparagine; Asx, either Asp or Asn; Glu, glutamic acid; Gln, glutamine; <Glu, 5-oxo-2-pyrrolidinecarboxylic acid; Glx, either Glu, Gln, or <Glu; Lys, lysine; Arg, arginine; Cys, cysteine; Met, methionine.

Other abbreviations: GC-MS, gas chromatography-mass spectrometry; *N*-TFA, *N*-trifluoroacetyl; *N*-PFP, *N*-pentafluoropropionyl; *N*-HFB, *N*-heptafluorobutyryl; OTMS, trimethylsilyl ether; $S_1, S_2, \ldots$, sequence ions in the *N*-TFA, *N*-PFP, and *N*-HFB peptide methyl esters; $A_1, A_2 \ldots$ and $Z_1, Z_2 \ldots$, sequence ions in the polyamino alcohols; M, molecular ion; *I*, retention index; CPI, a potato carboxypeptidase inhibitor; DAP I, dipeptidylamino peptidase I; ng, nanogram (10^{-9} g); pg, picogram (10^{-12} g); OV-17, polymeric methyl (50%) phenyl (50%) silicone oil; Dexsil, polycarborane methyl silicone.

[***] In order to save space citations are often restricted to review articles only.

One such procedure consists in the stepwise liberation of one amino acid after the other—starting from one end of the chain—followed by its isolation and identification. No change may take place in the remainder of the chain since information about its sequence would otherwise be jeopardized. The stepwise consecutive removal of one amino acid at a time from long peptide chains was first accomplished by *Pehr Edman* after numerous trying experiments[3-5].



Scheme 1. Edman degradation.

The "classical" procedure of Edman degradation is shown in Scheme 1. In the first step, the N-terminal amino group of the polypeptide chain is coupled with phenyl isothiocyanate to give the thiourea derivative *(1)*, which is cleaved in a second step. The resulting 2-anilino-5-thiazolinone *(2)* is separated from the shortened polypeptide (residual peptide) and transformed into the 3-phenyl-2-thiohydantoin *(3)* which is identified. The residual peptide can in turn be subjected to the same sequence of reactions, liberating the next amino acid, *etc.* The logical simplicity of the method cannot be improved upon and its successes have been considerable. Thus the overwhelming majority of the polypeptide sequences known today, numbering over 500[6], have been elucidated with the aid of the Edman degradation technique.

However, the most important condition for successful application of this method is the presence of a free amino group at the N-terminus. If it is blocked, as in *N*-acetylated or cyclic peptides, then the peptide cannot be degraded. Furthermore, some amino acids, such as Ser or Trp, are destroyed under the conditions of Edman degradation; Gln can also cyclize under these conditions and thus preclude further degradation. Identification of the liberated amino acid derivatives *(3)* is often also difficult; thus there is no single method suited for all amino acids[7, 8].

Nowadays it is possible to identify between 20 and 40 amino acids, and in exceptional cases over 50, using the protein sequencer developed by *Edman* and *Begg*[4]. However, the degradation reactions cannot be carried on indefinitely since the individual steps do not proceed quantitatively (but in about 96—98% yield) and internal peptide bonds may also be cleaved. In addition, the residual peptide becomes increasingly prone to extraction with the thiazolinone derivative *(2)*, especially when hydrophobic amino acids predominate. Thus in most cases only N-terminal partial sequences but not the entire structures of polypeptides can be elucidated (see Fig. 1). One usually resorts to prior chemical or enzymatic breakdown of the polypeptide into smaller fragments which have to be separated, isolated, and analyzed and whose structure then also provides information about the remaining sequence (at the C terminus) of the polypeptide.

Sequence analysis of a protein thus requires structural elucidation of numerous polypeptides (A, B, C... in Fig. 1), the separation and isolation of the individual polypeptides often being the most difficult and most involved step. Thus, the sequence analysis of thermolysin (316 amino acids) required investigation of 173 fragments[9] and the sequence analysis of a polypeptide chain of IgM immunoglobulin[2] (576 amino acids, the longest chain to have been analyzed so far) required investigation of nearly 600 peptides. A method of sequence analysis which leads not to partial sequences but to complete sequences of polypeptides is therefore highly desirable.

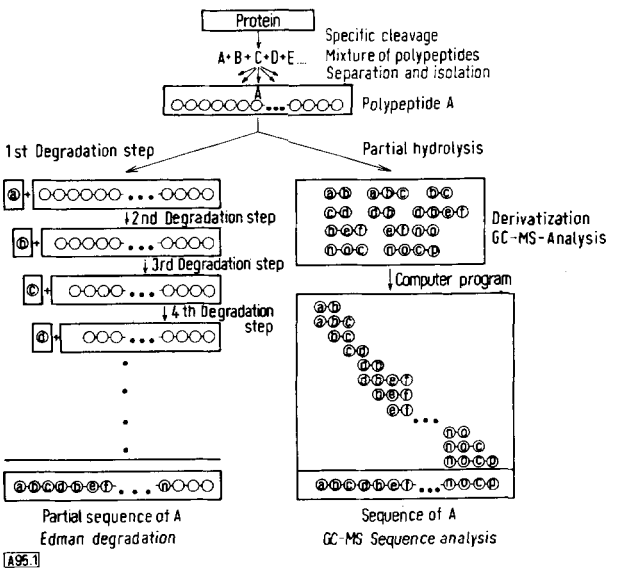


Fig. 1. Schematic comparison of sequence analysis of a polypeptide (A) by Edman degradation and the GC-MS method. Left: The amino acids successively removed by the Edman procedure are identified as derivatives of type *(3)* and lead to a partial sequence of the polypeptide A. Right: Partial hydrolysis of A affords a complex mixture of oligopeptides which is derivatized and identified by GC-MS; the sequence A is assembled from the identified fragments by means of a computer program. Circles marked with small letters symbolize the amino acids identified and the empty circles the unidentified amino acids.

2.2. Gas Chromatography-Mass Spectrometry

The right-hand side of Figure 1 illustrates the principle of the new technique. In contrast to the Edman procedure, the polypeptide A is not shortened in steps, but decomposed into as many oligopeptides with suitable chain lengths as possible by partial acid hydrolysis. All these oligopeptides are identified and the resulting partial sequences combined as in a game of dominos to give the entire sequence A. The

central problem of this method lies in the complete analysis of the very complex hydrolysis mixture which often contains more than 50 oligopeptides. During structural analysis of insulin *Sanger*[11] had to work up such mixtures by chromatography and to isolate and identify the individual oligopeptides, which was an extremely difficult and time consuming task. We have applied combined gas chromatography and mass spectrometry (GC-MS) to the analysis of these mixtures, a technique which permits separation of the components (in the gas chromatograph) and their identification (by the mass spectrometer) in a single experiment[10-13]. A computer is used for collecting and evaluating the extremely high data yield of such a system (GC-MS-computer system).

Sequence analysis with such a system involves four steps:

1) The polypeptide (A in Fig. 1) is split up into oligopeptides. Since all peptide bonds should be represented in these fragments and since the fragments themselves should be of the correct size—di- to hexapeptides which can be analyzed by the GC-MS combination—much depends upon the optimum execution of this reaction step.

2) The mixture of oligopeptides is converted, quantitatively if possible, into the corresponding mixture of volatile derivatives ("derivatization"); the necessary reactions are already performed on a routine basis.

3) The mixture of oligopeptide derivatives is fractionated on a gas chromatography column, the temperature of the column being linearly programmed from 80 to 330 °C. This permits analysis of oligopeptide derivatives having widely differing molecular weights and polarities. The carrier gas is removed before the sample molecules enter the mass spectrometer where they are ionized. We have also standardized this process and can identify derivatives of di- to tetrapeptides, and frequently also of penta- and hexapeptides in a single analytical run. The GC-MS system is controlled by a computer which continually measures the mass spectra (every 5 s). Suitable programs ensure calculation of gas chromatographic and mass spectrometric data (see Section 3.3) and their storage on magnetic tape or microfilm or output *via* a plotter or printout. These data suffice for identification of all oligopeptide derivatives present in the mixture.

4) By means of a computer program the oligopeptides are now joined together according to the "domino principle", yielding the structure of the polypeptide[14] (cf. Fig. 1).

A great advantage of GC-MS sequence analysis compared to sequential degradation methods is that it provides not only an N-terminal partial sequence but the entire sequence of a polypeptide (Fig. 1); the C-terminal part of the macromolecule being identified just as accurately as the N-terminal part. Hence the number of polypeptides (A, B, C ... in Fig. 1) whose structures must be established to deduce the primary structure of a protein should also be reduced.

In addition, the position of each amino acid in the sequence is established not only by a chromatographic parameter (*e.g.* by the R_f value of a colored or fluorescent spot on a thin-layer plate) but above all by the mass spectra of one or several derivatives. Thus the position of the amino acid d Figure 1 is verified by the retention parameters and mass spectra of the derivatives of c-d, d-b, and d-b-e-f. These data are stored permanently on magnetic tape and also on microfilm and can be recalled at any time.

The above GC-MS method is also suited for sequence analysis of peptides with blocked N-termini (see Section 4.2). These peptides can be analyzed without modification, the blocking group being identified at the same time. Nor do amino acids such as Ser, Thr, Trp, which are often decomposed during Edman degradation, cause any difficulties.

3. Conditions for Sequence Analyses of Polypeptides by the GC-MS Method

3.1. Partial Hydrolysis of Polypeptides

The most important method for partial reproducible cleavage of a maximum number of peptide bonds in a polypeptide is *partial acid hydrolysis* (cf. also ref. [1]). A great advantage of this method is that practically all peptide bonds can be cleaved by acid. Under defined conditions (*e.g.* 6 N HCl at 110 °C) there is an optimum hydrolysis time for each polypeptide, after which there is a maximum number of di- to tetrapeptides in the hydrolyzate. Longer hydrolysis times lead to considerable amounts of amino acids, and shorter times to excessively large fragments whose derivatives lack sufficient volatility for identification by the GC-MS method.

A method permitting prediction of this optimum hydrolysis time was therefore developed[15]. For this purpose small samples of the polypeptide are hydrolyzed under widely varying conditions. The resulting mixtures are transformed into *N*-perfluoroacyl peptide methyl esters (see Section 3.2.1) and separated on a gas chromatography column. The amount of oligopeptide derivatives lies in the nanogram range (10^{-9} g) or below. Detection of such small amounts of the fluorinated derivatives was accomplished with the highly selective electron capture detector; even < 1 pg (10^{-12} g) per component can be detected. The optimum hydrolysis time can be deduced from the positions and relative sizes of the peaks.

While all peptide bonds are cleaved by acid, the rates of hydrolysis are subject to wide variation. For instance, a Leu-Leu bond is broken only very slowly owing to steric hindrance by the two isobutyl groups, whereas a Gly-Gly bond is extremely labile. Accordingly, one peptide bond may have undergone quantitative cleavage (*e.g.* Gly-Gly) while another is virtually intact (*e.g.* Leu-Leu). Thus in many cases not all the peptide bonds will be present in the resulting oligopeptide mixture (for example, a Gly-Gly may be absent). This necessitates a second experiment in which the polypeptide is degraded with *enzymes* (with one or several endoproteases such as thermolysin, chymotrypsin, elastase, pepsin, trypsin), usually affording precisely those oligopeptides in good yields which are absent from the acid hydrolyzate. Hitherto, the sum of the oligopeptides identified in the two experiments has always sufficed for determining the structure of the polypeptide under study.

In another novel hydrolytic procedure, a sample of the polypeptide is first degraded by the enzyme dipeptidylaminopeptidase I (DAP I)[16]. This enzyme effects stepwise liberation of dipeptides, starting from the unblocked N-terminus of a peptide. A second sample of the peptide is then shorted by one amino acid by Edman degradation, and the residual peptide subjected to DAP I cleavage. On the basis of the dipeptides identified in the two mixtures, an attempt is then made to establish the structure of the polypeptide. GC-MS is particularly suitable for characterizing such mixtures since dipeptide derivatives are more volatile than derivatives of higher oligopeptides.

However, since only dipeptides are available as fragments, the structures deduced are often rather uncertain in the case of longer polypeptides[17]. A decision between several isomeric sequences must then be reached by supplementary experimentation. Further difficulties arise if the basic amino acids Arg and Lys occupy the N-terminal position or if the polypeptide contains Pro, since these two structural features suppress the activity of the enzyme. We have therefore merely applied these techniques to the structural analysis of relatively small tryptic peptides[18] and to the confirmation of structures determined by other methods[14]. A recent publication has shown[18a] that the inhibitory action of the basic amino acids, but not that of Pro, can be overcome by use of the enzyme dipeptidylaminopeptidase IV; the scope of this hydrolysis method should thereby be enhanced considerably.

3.2. Preparation and Properties of Volatile Peptide Derivatives

The actual analytical process in gas chromatography and also in mass spectrometry takes place in the gaseous phase. The vapor pressure of peptides is, however, too low for these analytical techniques owing to their high polarity and their zwitterionic character. During the past 15 years several research groups have been engaged in the development of peptide derivatives having maximum volatility and displaying mass spectra which permit deduction of the sequence. The "sequence ions"—*i.e.* ions revealing the positions of amino acids in the sequence—should be of high intensity and easily recognizable.

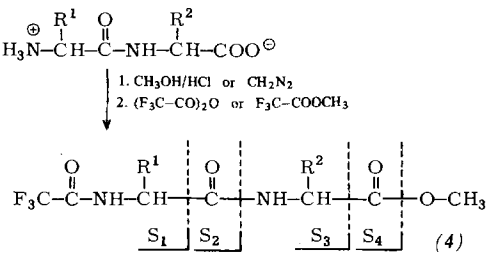
The permethylated peptide derivatives introduced by *Lederer et al.*[19–21] have found wide application; they are prepared by the basic catalyzed action of methyl iodide on *N*-acetyl peptide methyl esters. Although these permethylated derivatives have excellent mass spectrometric properties they usually exhibit inadequate volatility for gas chromatography. The same applies to numerous other peptide derivatives (cf. ref. [22]); they are useful only when pure peptides or very simple mixtures are present and gas chromatography is not required for their separation. However, the sensitivity and time requirement are hardly more favorable than in the classical Edman procedure. Mass spectrometric methods only have a definite advantage in the analysis of peptides having blocked N-termini[23]. Complex peptide mixtures have to be resolved into numerous fractions prior to identification[24].

Three classes of peptide derivative prove to be sufficiently volatile for gas chromatography; their preparation, properties, and applications will be considered in the following sections:

3.2.1. *N*-Perfluoroacyl Peptide Methyl Esters

In 1960, *Weygand et al.*[25] accomplished the first separation of peptide derivatives by gas chromatography, namely *N*-trifluoroacetyl (*N*-TFA) peptide methyl esters *(4)*, which are very easily prepared according to Scheme 2.

The mass spectra of these derivatives[26–29] contain sequence ions formed by cleavage of the peptide chains on both sides of the CO groups with preferential retention of the positive charge in the N-terminal fragment (four ions of this kind, S_1 to S_4, are shown in Scheme 2). These sequence ions are also clearly seen in peptide derivatives having simple (*e.g.* aliphatic) amino acids. The mass spectra of peptide derivatives with trifunctional amino acids are often more difficult



Scheme 2. Synthesis of *N*-trifluoroacetyl peptide methyl esters *(4)*.

to interpret. For instance, the sequence ions S_1 and S_3 are clearly discernable in Figure 2a, whereas the sequence ions S_2 and S_4 appear with very low intensity and are overshadowed by other ions which are of less importance for derivation of the sequence (*e.g. m/e* 162). Verification of the sequence therefore requires recording of high-resolution mass spectra and metastable transitions.

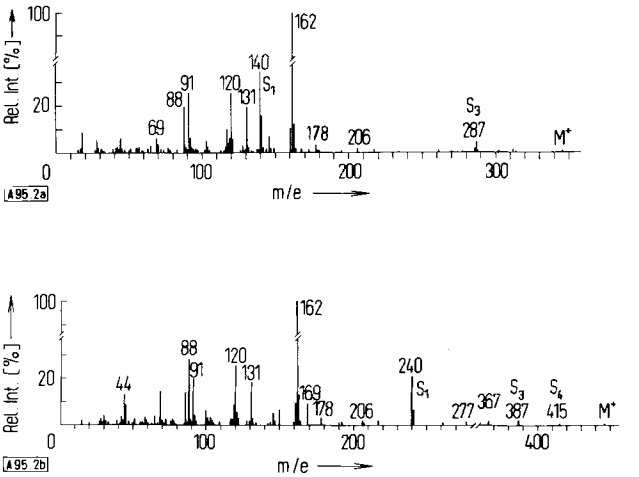


Fig. 2. Comparison of the mass spectra of some Ala-Phe derivatives: a) *N*-TFA-Ala-Phe-OMe *(4a)* [27]; b) *N*-HFB-Ala-Phe-OMe *(5a)* [31]. Fragment ions which cannot be recognized in the formulae *(4a)* and *(5a)* are:

m/e	ion⊕
44	$H_2N{=}CH{-}CH_3$
88	$H_2N{=}CH{-}COOCH_3$
91	C_7H_7 (tropylium)
120	$H_2N{=}CH{-}CH_2{-}C_6H_5$
131	$C_6H_5{-}CH{=}CH{-}C{=}O$
162	$C_6H_5{-}CH{=}CH{-}COOCH_3$

The most important condition for reliable identification of these derivatives is the occurrence and recognition of molecular ions. Molecular ions are easily recognized in mass spectra of pure peptide derivatives; difficulties are sometimes encountered with impure fractions. A number of trifunctional amino acids also had to be transformed in further reactions. Thus amino acids bearing an OH-group in the side chain were *O*-trimethylsilylated; those containing sulfur (Cys, Met) were desulfurated with Raney nickel[28]. *N*-Trifluoroacetyl derivatives *(4)* have so far been mainly employed in the analysis of cyclic peptides[29]; fortunately they contained mainly hydrophobic amino acids which are ideally suited to gas chromatography and mass spectrometry.

N-Pentafluoropropionyl- (*N*-PFP)[30] and *N*-heptafluorobutyryl (*N*-HFB) peptide methyl esters *(5)*[31], formed by the action of the corresponding anhydrides on peptide methyl esters, show mass spectra closely resembling those of *N*-TFA peptide methyl esters (see Figure 2b). Only the ions of the N-terminal moiety are shifted into a higher mass range because of the greater mass of the perfluoroacyl groups. The enhanced

Table 1. Gas chromatographic retention indices (stationary phase: 1% OV 17 [a]) of peptide derivatives [b]. The retention index [42] is a gas chromatographic parameter characterizing the elution of a substance relative to *n*-alkanes; the retention index of $C_{14}H_{30}$ is set at 1400, and that of $C_{22}H_{46}$ at 2200... (see Figs. 7 and 8) (see also Section 3.3).

Peptide	*(4)* TFA... OMe	*(5)* HFB... OMe	*(9)* F_3C-CD_2... OTMS	*(10)* $F_7C_3-CD_2$... OTMS
Ala-Ile	1810	1802	1462	1437

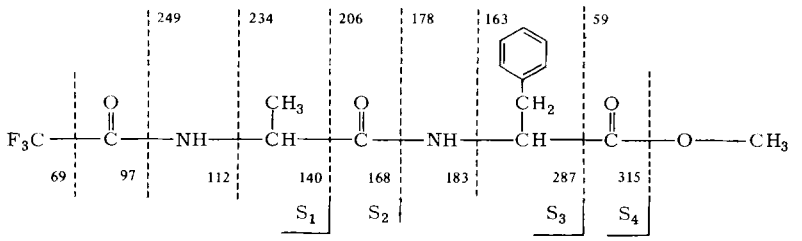
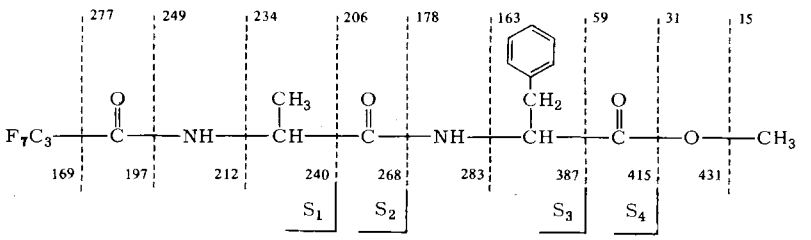
Trp-Glu	—	—	3005	2887

[a] On less polar stationary phases, *e.g.* Dexsil 300, the retention indices decrease by 100–300 units.
[b] The retention indices of the *N*-PFP peptide methyl esters lie between those of the the *N*-TFA and the *N*-HFB analogs.

volatility of these compounds represents an advantage over the *N*-TFA derivatives (Table 1). We have therefore tried out the derivatives *(5)* in the structural elucidation of a naturally occurring polypeptide[32] (Section 4.2).





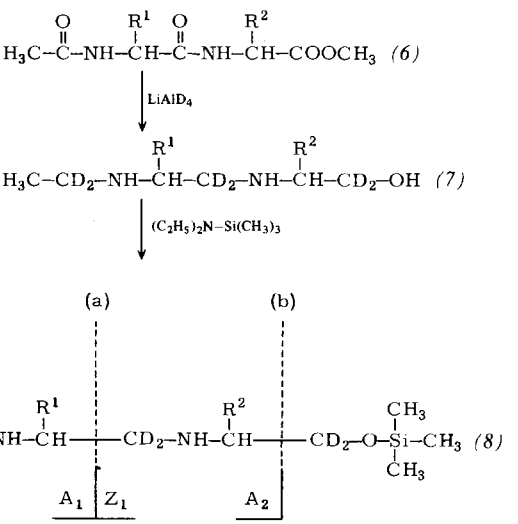
(5a)

3.2.2. Polyamino Alcohol *O*-Trimethylsilyl Derivatives of Peptides

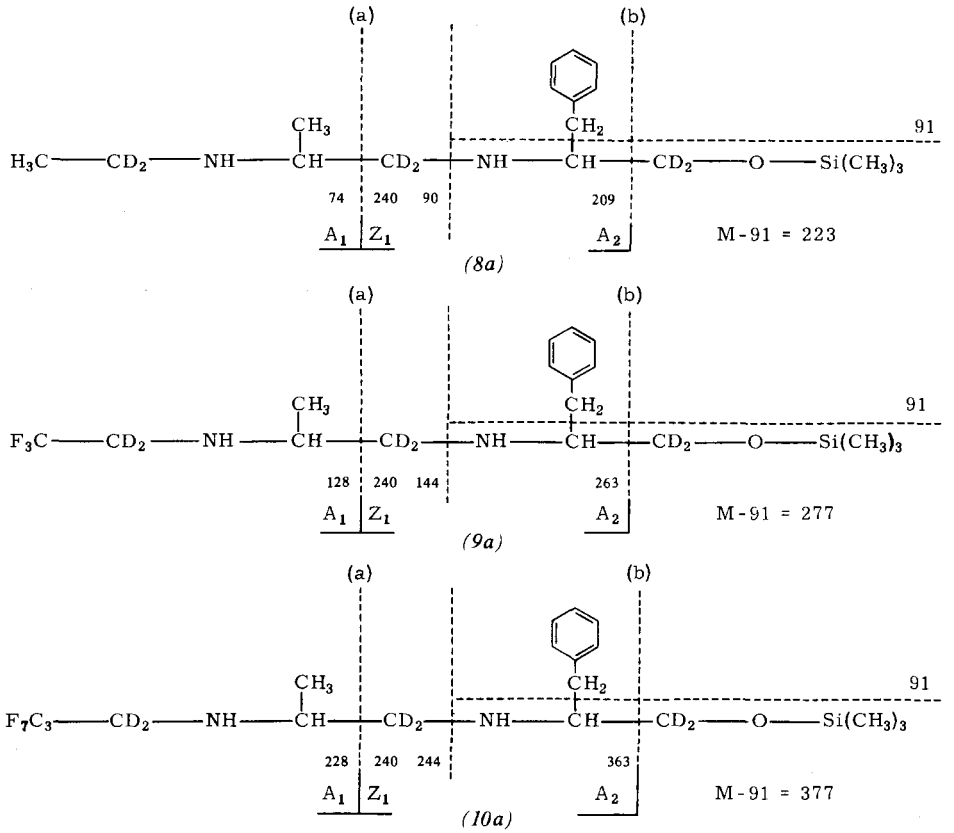
Biemann et al.[33, 34] have proposed a much more radical modification of structure in order to raise the volatility of peptides: all carbonyl groups of *N*-acetyl peptide methyl esters *(6)*—*i.e.* of both the peptide and the ester function—are converted into CH_2 or CD_2 groups by treatment with $LiAlH_4$ or $LiAlD_4$. Since the resulting polyamino alcohols *(7)* still contain free OH groups the method was initially applicable to very simple peptides only. However, transformation of these polar centers into trimethylsilyl ethers affords derivatives *(8)* having properties very suitable for gas chromatography[18].

In addition, the mass spectra of these derivatives are very simple and excellently suited to the elucidation of the amino acid sequence. The derivatives *(8)* no longer contain carbonyl groups and a whole series of fragmentation mechanisms responsible for the complicated nature of the spectra of the derivatives *(4)* and *(5)* no longer appear. The backbone of these compounds consists of ethylenediamine units whose C—C bonds undergo preferential electron impact cleavage; the resulting ions are easily recognized and permit derivation of the sequence ("sequence ions").

Thus cleavage of bond (a) in *(8a)* affords two ions (Fig. 3a). The intense ion A_1 corresponds to the N-terminal amino acid while the less intense Z_1 ion indicates the C-terminal amino acid. Since the masses of the ions A_1 and of the ions Z_1 of all amino acids occurring in proteins are different,



(6) *(7)* *(8)*



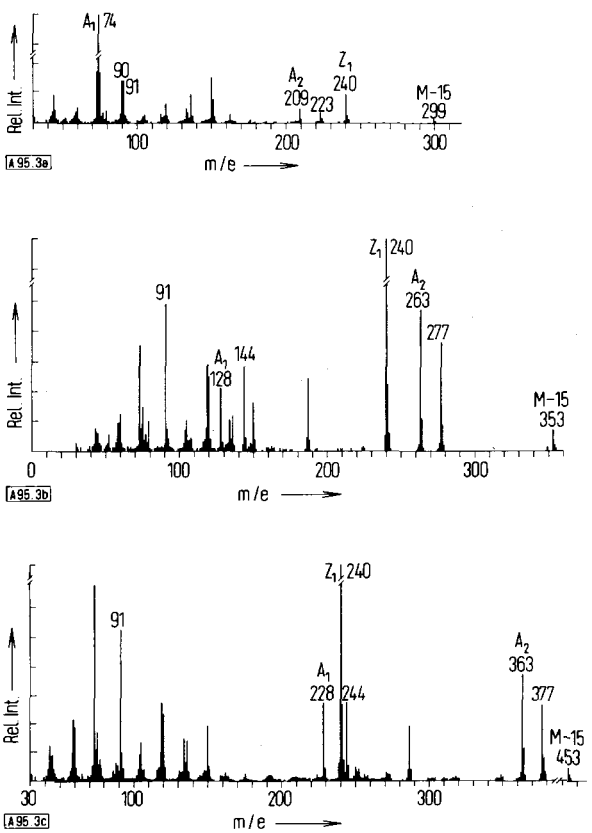


Fig. 3. Comparison of the mass spectra of some polyamino alcohol *O*-trimethylsilyl derivatives from Ala-Phe: a) *N*-dideuterioethyl derivative *(8a)*; b) *N*-trifluorodideuterioethyl derivative *(9a)*; c) *N*-heptafluorodideuteriobutyl derivative *(10a)*.

except for Leu and Ile, the structure of this dipeptide derivative is therefore available. The result can be confirmed by consideration of ion A_2 arising on rupture of bond (b) in *(8a)* and the ion (M − 15) which indicates the mass of the molecular ion, as in all silylated compounds.

The transformation products of longer peptides, *e.g. (8b)*, contain several concatenated ethylenediamine units and thus several C—C bonds subject to cleavage by electron impact (Fig. 4)[18, 35]. The sequences of such peptides can be established in a very simple manner starting from the ion A_1 of the N-terminal amino acid (*m/e* 176 of Thr) *via* the ion A_2 and the higher A ions. This sequence of the peptide is checked by starting from the ion Z_1 of the C-terminal amino acid (*m/e* 251 of Lys) and proceeding *via* the ions Z_2 and Z_3 to Z_4. The (M − 15) ion can also serve as a check. The mass differences between neighboring ions of the A and Z series therefore reveal the individual amino acids and their positions in the sequence.

The principal advantage of this method is that the sequence of a peptide can be built up of readily identified high intensity sequence ions. In contrast, deduction of the sequence of the non-reduced derivatives *(4)* usually requires reliable identification of the very weak molecular ions (see Section 3.2.1).

Peptides containing trifunctional amino acids (including Arg) can also be identified as the derivatives *(8)*. It is, however, a distinct disadvantage that complex His peptides are eluted only as very broad peaks, if at all, from the gas chromatography column; we were therefore compelled to identify these peptide derivatives in an additional experiment by direct evaporation of the sample in the ion source of the mass spectrometer. Only very poor yields were also obtained on derivatization of Gln and Asn peptides. The time consumed by derivatization represents a further drawback. This applies especially to the isolation of the polyamino alcohols *(7)* from the mixture of reduction products, which requires removal of the aluminum salts on an anion exchange column[36].

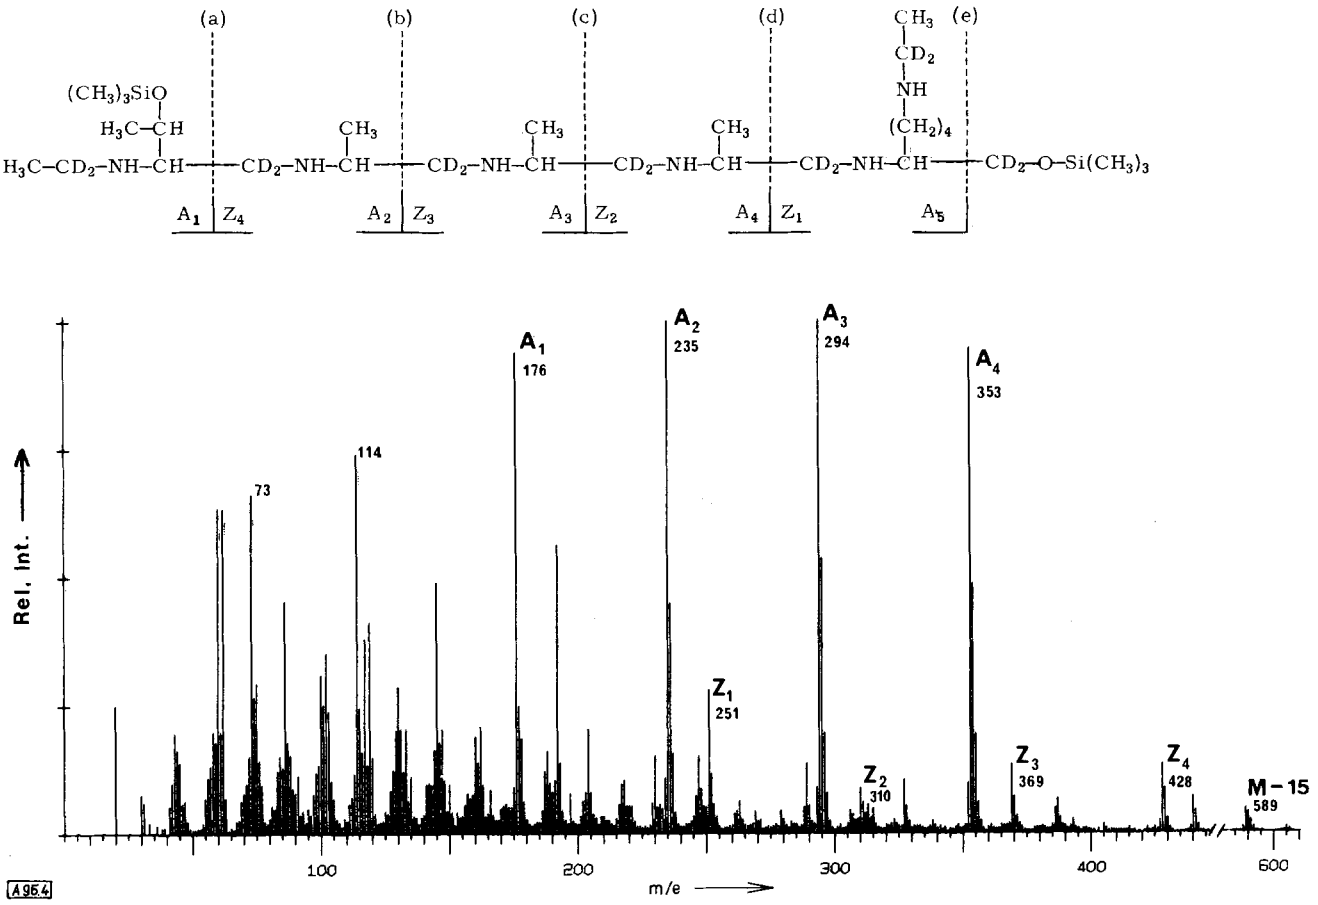

Fig. 4. Mass spectrum of the dideuterioethyl polyamino alcohol *O*-trimethylsilyl derivative *(8b)* obtained from Thr-Ala-Ala-Ala-Lys [35].

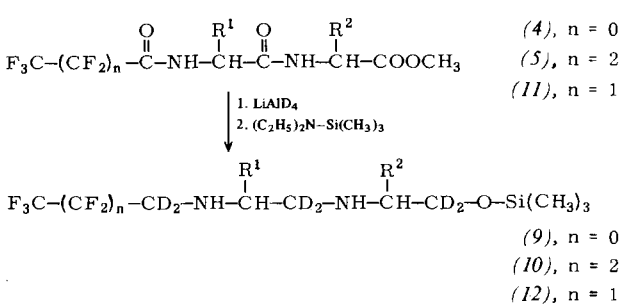
3.2.3. Perfluoroalkyl Polyamino Alcohol *O*-Trimethylsilyl Derivatives of Peptides

We have directed much effort to the search for pathways leading to new peptide derivatives displaying improved properties. Such derivatives should be more volatile than derivatives *(8)*, in order to permit identification of larger peptides, and detection of all amino acids including Arg, Gln, Asn, and His by the GC-MS technique. The derivatization reactions should also be simple to perform and the products should be isolable by extraction wherever necessary.

Since the volatility of *N*-acyl peptide methyl esters increases with increasing fluorine content of the acyl group (see Table 1), it appeared an obvious step to further enhance the volatility of the reduced derivatives *(8)*, which are already eluted earlier than the corresponding perfluoroacyl peptide methyl esters, by incorporation of fluorine atoms. Thus, instead of the *N*-acetyl peptide methyl esters *(6)*, their *N*-TFA, *N*-PFP, and *N*-HFB analogs *(4)*, *(11)*, and *(5)*, respectively, were reduced by $LiAlD_4$. The products could be extracted from the reaction



mixture and *O*-trimethylsilylated to give *(9)*, *(12)*, and *(10)* very simply and in high yield (see ref. [37] for experimental methods).

The retention indices of some dipeptide derivatives of types *(9)* and *(10)* are listed in Table 1. These reduced derivatives are considerably more volatile than the non-reduced derivatives *(4)* and *(5)* (the difference in retention indices amounts to 300 to 400 units). The volatility of the polyamino alcohol derivatives and of the *N*-acyl peptide methyl esters increases with increasing fluorine content[37]; thus the derivatives *(10)* are the most volatile peptide derivatives known today.

As the volatility increases, so does the range of peptides whose derivatives can be identified by GC-MS. The upper limit is determined both by the number of amino acids (length of the peptide) and by their polarity; *e.g.* the derivative of hexaalanine is eluted much earlier (retention index 2640) than that of the highly polar tetrapeptide Ala-CMCys-Trp-Asp (retention index 4210) (CM = carboxymethyl). The retention indices can be predicted for the derivatives of all peptides (see Section 3.3).

The mass spectra of the new derivatives *(9)* and *(10)* contain very intense and easily recognizable sequence ions (Fig. 3b and 3c), which are analogous to the sequence ions of the derivatives *(8)*. Fortunately, the intensity of the sequence ions is well balanced, as is shown by comparison of the mass spectra of the non-fluorinated derivative *(8a)* (Fig. 3a) and the fluorinated derivatives *(9a)* and *(10a)* of Ala-Phe (Fig. 3b and 3c, respectively). The mass spectrum in Fig. 3a is dominated by the A_1 ion of the N-terminal amino acid whereas all the other sequence ions have much lower intensities. In

the mass spectrum shown in Figure 3b the A_1 ion is still clearly seen, although much less intense since the electron-withdrawing fluorine atoms lower the basicity of the nitrogen and hence the stability of the immonium ion:

$F_3C{\leftarrow}CD_2{\leftarrow}\overset{\oplus}{N}H{=}CH{-}CH_3$ A_1-ion of Ala

Accordingly, the intensity of all other sequence ions occurring with low intensity in Figure 3a is greatly enhanced. The same applies to the mass spectrum in Figure 3c with the sole difference that the ions containing the N-terminal amino acid (and therefore the perfluoro group) have mass numbers that are 100 units greater. The A ions are thus shifted into a range of higher mass numbers less affected by background or silyl ions and are therefore easily recognized.

Comparison of the mass spectra of the reduced peptide derivatives *(8a)*, *(9a)*, and *(10a)* (Fig. 3) with those of the non-reduced compounds *(4a)* and *(5a)* (Fig. 2) clearly shows how very much the intensity of the sequence ions is increased by the absence of the carbonyl groups; the mass spectra become simpler and easier to interpret. The contribution of the sequence ions to the overall yield of ions in the mass spectra of derivatives *(9)*, *(10)*, and *(12)* usually lies between 30 and 60 %[38]. In contrast, the mass spectrum of the tripeptide *N*-TFA-Val-Ile-Ala-OMe contains only 9 % of sequence ions[39].

The most important advantage of the new derivatives may be seen in the fact that *all* amino acids can now be determined by the GC-MS method. Although Arg-containing peptides give only low yields on derivatization, we have been able to identify these peptides too in the hydrolysis mixtures of naturally occurring polypeptides (Sections 4.1 and 4.2). The Arg-containing peptides can also be modified by hydrazinolysis in good yield prior to derivatization, the strongly polar guanidino groups being converted into amino groups. Peptides containing Cys are *S*-carboxymethylated or *S*-aminoethylated prior to derivatization. These derivatives are superior to the *S*-benzylated derivatives[40] on account of their higher volatility. Finally, peptides containing His can also be derivatized in high yields and determined by GC-MS (see Section 4.2).

Since there is no difference in mass between the side chains of Leu and Ile, the sequence ions of these two amino acids have the same mass numbers. A distinction between Leu and Ile is possible by examining the relative intensities of the sequence ions of the reduced derivatives *(9)*, *etc.*, and of the non-reduced derivatives *(4)*[29], a procedure sufficing for identification of smaller peptides. In the case of complex peptides, the derivatives have to be compared with authentic peptide derivatives.

3.3. Methods of Identification by GC-MS

The mass spectra of suitable peptide derivatives are adequate for identification of pure fractions of a GC-MS experiment (see Section 3.2). However, since partial hydrolysis of polypeptides leads to extremely complex mixtures—often containing 50 and more fragments—all the components of such mixtures cannot be separated on a single gas chromatography column. The fractions leaving the end of the column often comprise several unseparated peptide derivatives. The *mass spectra* of such fractions are therefore made up of fragment ions of several derivatives, which is a serious obstacle to interpretation. In particular, the identification of trace components is frequently impossible.

These trace components can be identified with the aid of *mass chromatograms*[11] (selection ion records) of sequence ions. The mass chromatograms are obtained by plotting the intensities of individual ions *versus* time (or the serial numbers of continuously recorded mass spectra). The maxima in the mass chromatograms of sequence ions thus reveal peptides having a particular amino acid in a particular position of the sequence; *e.g.* the maxima in the mass chromatogram of the A_1 ion of Thr indicate those peptides which contain Thr at the N-terminus.

In Figure 5a we have plotted the total ion chromatogram of a derivatized polypeptide hydrolyzate, and in Figure 5b the mass chromatogram of the ion *m/e* 114. This fragment ion appears with high intensity in the mass spectra of peptide derivatives containing Lys. The maxima in this mass chromatogram indicate the Lys peptides, which can thus be picked out relatively simply from the maze of the mutually overlapping fractions in spite of the complexity of the mixture.

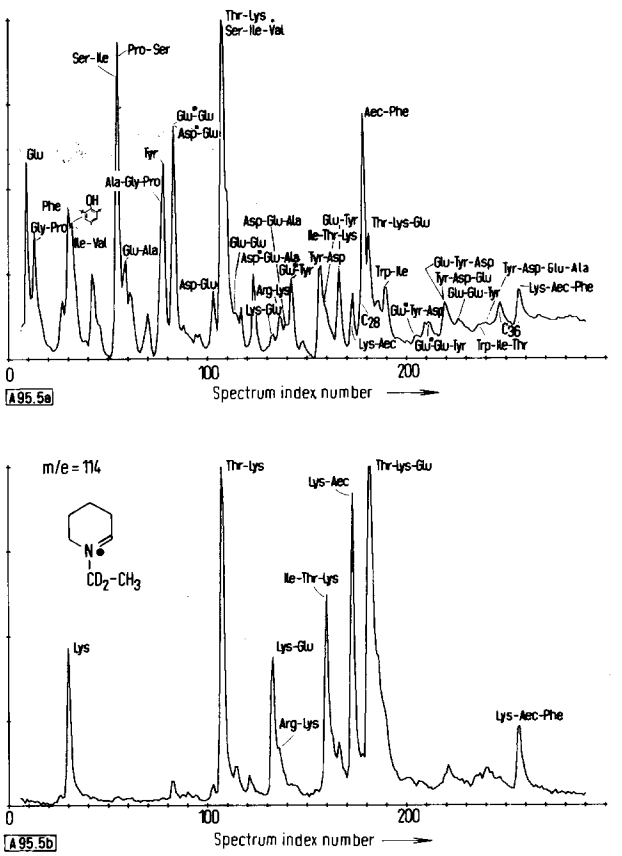


Fig. 5. a) Total ion chromatogram of a mixture of dideuterioethyl polyamino alcohol *O*-trimethylsilyl derivatives of type *(8)*, prepared by partial acid hydrolysis of the eicosapeptide from the C-terminal part of actin [44]; *, identified after elimination of trimethylsilanol; b) mass chromatogram of the ion *m/e* 114. Aec = aminoethylcysteine.

Owing to the chain structure of peptides and peptide derivatives, experience permits prediction of not only their mass spectra but also their gas chromatographic properties[35, 41]. We have chosen the *retention indices*[42] as gas chromatographic parameters; these indices give the positions of the peaks in a gas chromatogram relative to *n*-alkanes introduced with the sample. The parameters are therefore largely independent

of the experimental conditions and hence particularly characteristic.

The retention indices (I) of all polyamino alcohol derivatives can be calculated by simple addition of contributions (Δ) of the individual amino acids. The contribution of the N- and C-terminal groups Δ_t, which decreases with increasing fluorine content (and hence with increasing volatility of the polyamino alcohol derivative) must also be considered:

$$I = \sum_{1}^{n} \Delta_i + \Delta_t$$

The retention indices of two derivatives of type *(8)* are calculated to illustrate the validity of this expression (Δ_t is 735):

I (Tyr-Asp) = 1240 (ΔTyr) + 640 (ΔAsp) + 735 = 2615
I (Ile-Thr-Lys) = 460 (ΔIle) + 535 (ΔThr) + 910 (ΔLys) + 735 = 2640

These calculated values agree well with the measured values (2620 and 2635, respectively), thus confirming the identification of the two peptide derivatives by their mass spectra and mass chromatograms. Calculation of retention indices of fluorinated polyamino alcohol derivatives of very small and very large peptide derivatives required a further correction factor depending upon the size of the derivatives[38]. The resulting values are in good agreement with the experimental data in the broad range between 1400 and 4200.

3.4. Reconstruction of a Polypeptide Sequence from the Oligopeptides

The last step in the GC-MS method of sequence analysis is reconstruction of the sequence of the polypeptide from the oligopeptides resulting on hydrolysis and identified by GC-MS. Reconstruction starts from the N-terminal amino acids (a-b and a-b-c in Fig. 1). Further oligopeptides are then added, thus lengthening the sequence shown in Figure 1 by c-d to give a-b-c-d. To this oligopeptide may be added d-b-e-f, giving the sequence a-b-c-d-b-e-f. The procedure is repeated until the entire structure of the polypeptide has been established. The result can be checked by comparison of the nature and number of the amino acids in this sequence with the result of amino acid analysis of the peptide.

However, it frequently happens that not only one oligopeptide but several can be linked onto a partial sequence. For instance, both b-c and b-e-f can be joined onto the N-terminal oligopeptide a-b (Fig. 1):

a-b + b-c → a-b-c
a-b + b-e-f → a-b-e-f

Two partial sequences result which must be pursued further; each of these sequences can in turn branch further, a feature which greatly complicates the procedure in the case of large polypeptides. We have therefore developed a computer program which performs this stepwise reconstruction automatically[114]. However, an unequivocal result can only be expected if the dipeptides are accompanied by a significant proportion of possible tripeptides and even tetrapeptides. In most cases, a given hydrolysis mixture (*e.g.* an acid hydrolyzate) does not contain all the fragments necessary to unambiguously construct just the one correct sequence, and several isomeric sequences result. A second experiment is then necessary in which hydrolysis is effected by enzymes. The results of the two experiments generally permit deduction of an unequivocal sequence.

4. Examples of Sequence Analysis of Polypeptides by the GC-MS Method

Use of the non-reduced derivatives *(4)*, *(5)*, and *(11)* has already been described in detail[29, 30, 40, 41, 43]. We shall now consider the present state of the art of the GC-MS sequencing method, as illustrated by two examples of sequence analysis of highly complex polypeptides utilizing reduced derivatives of types *(8)*, *(9)*, *(10)*, and *(12)*.

4.1. The C-Terminal Eicosapeptide of Actin

This peptide—the first protein fragment to be identified by GC-MS sequence analysis—was obtained by cyanogen bromide cleavage of actin and contains 20 amino acids. It consists predominantly of trifunctional amino acids, including Arg, His, and Trp which make GC-MS analysis rather difficult. Sequence analysis of this peptide was therefore a realistic test case for the new GC-MS method; above all we wanted to exploit the advantages offered by the direct combination of GC and MS, with the assistance of a computer, and by the peptide derivatives *(8)* which had been developed at that time.

We identified 27 peptides in a partial acid hydrolyzate of this eicosapeptide (Fig. 5a); these species permitted computerized construction of two partial sequences together containing all 20 amino acids (Fig. 6). We then had to link these partial sequences together in the correct manner. The simplest solution to this problem was to determine the N-terminal amino acid (Trp) by conventional methods. All that remained to do was to establish the position of the sole Gln residue which had apparently undergone quantitative conversion into Glu under the conditions of acid hydrolysis. This was also

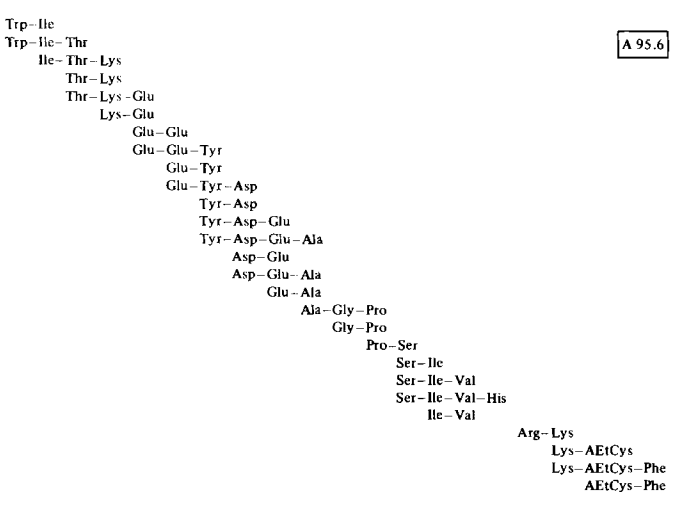

Fig. 6. Stepwise reconstruction of the sequence of the eicosapeptide of actin by overlapping of the oligopeptides identified by GC-MS analysis of a derivatized partial acid hydrolyzate (Fig. 5a) [44]. AEt = aminoethyl.

accomplished in conventional manner—Gln occupies position 5—and the sequence analysis of the eicosapeptide thus concluded[44].

Hence GC-MS analysis of a single hydrolysis mixture of the eicosapeptide and two simple tests for establishing the N-terminal amino acid and the position of the Gln residue were sufficient to determine the complete structure of the polypeptide.

4.2. Potato Carboxypeptidase Inhibitor

This polypeptide contains 39 amino acids—in which all the "difficult" ones are represented—and is by far the largest polypeptide yet to have been analyzed by the GC-MS method. Its analysis enabled us to assess the recently developed derivatives *(9)*, *(10)*, and *(12)*. Since this peptide was also investigated by the automated Edman procedure, we have an opportunity of comparing the two methods.

On starting our investigations we knew that this inhibitor (CPI) apparently consists of a mixture of two polypeptide chains which both possess a blocked N-terminus and differ in the N-terminal regions. We first analyzed the mixture of two peptides obtained by specific cleavage of an Asp-Pro bond from the N-terminal part of the molecule[32]. GC-MS analysis of the derivatized acid hydrolyzate of these two peptides (Fig. 7) revealed a number of oligopeptides including

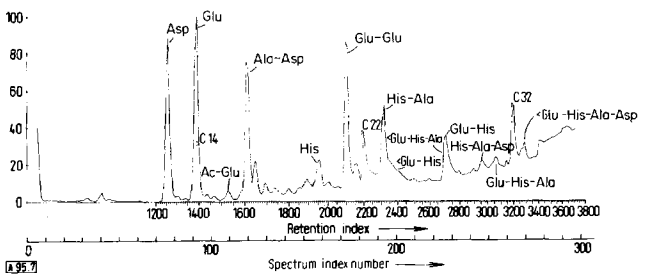

Fig. 7. Total ion chromatogram of trifluorodideuterioethyl polyamino alcohol *O*-trimethylsilyl derivatives of type *(9)* from the partial acid hydrolyzate of the N-terminal part of potato carboxypeptidase inhibitor (CPI) [32].

some containing <Glu (5-oxo-2-pyrrolidinecarboxylic acid) which was thus identified as the blocking group. Overlapping of the peptides listed in Figure 7 yielded the sequence <Glu-Glx-His-Ala-Asx for one of the two peptides. Conventional analyses showed that position 2 is occupied by Gln which is apparently converted into Glu under the conditions of acid hydrolysis. The other peptide was identified as <Glu-His-Ala-Asx in a further experiment. For this purpose the peptide

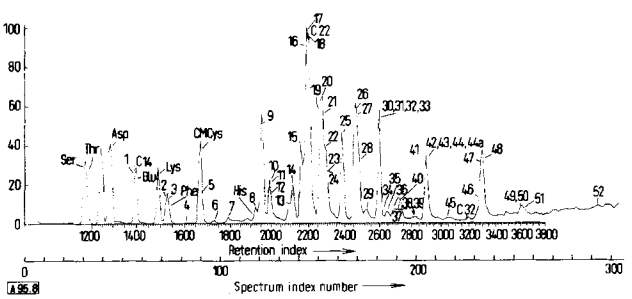

Fig. 8. Total ion chromatogram of trifluorodideuterioethyl polyamino alcohol *O*-trimethylsilyl derivatives *(9)* from the partial acid hydrolyzate of the *S*-carboxymethylated carboxypeptidase inhibitor [38]. The identified peptides are shown with the respective numbers in Fig. 9. 18,34, side products of the derivatization of Ser-Ala-Arg and Pro-Ile-Cys, respectively [38].

mixture was subjected to very brief acid hydrolysis; the resulting peptides were subsequently identified as *N*-HFB peptide methyl esters *(5)* by GC-MS.

It was then explored whether the entire structure of the inhibitor, which consists of a chain of 39 amino acids, could be determined by the GC-MS method. We hydrolyzed a sample of this polypeptide with 6 N HCl and converted the resulting peptide mixture into the derivatives *(9)*. This yielded numerous components which we identified by GC-MS (these peptides are designated by numbers in Fig. 8 and listed in Fig. 9). However, not all peptide bonds were represented

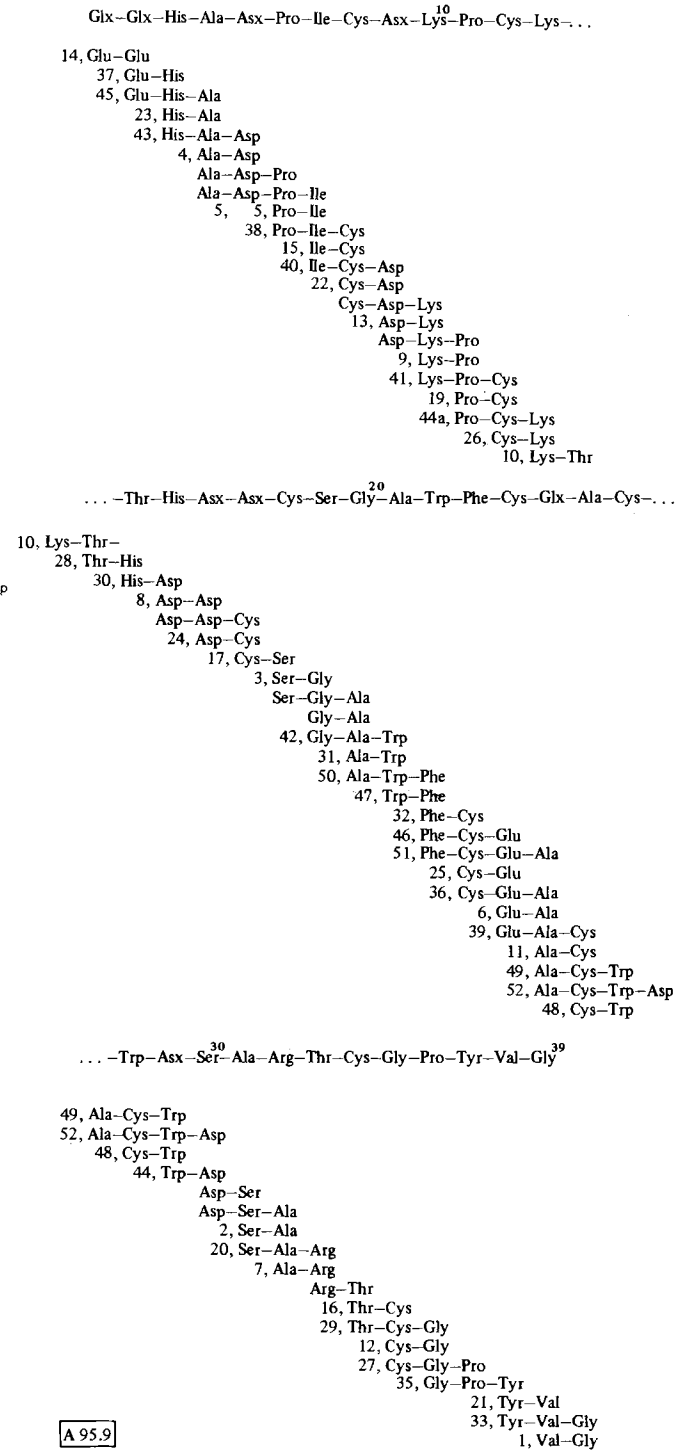

Fig. 9. Stepwise reconstruction of the sequence of the carboxypeptidase inhibitor by overlapping of the oligopeptides identified in the partial acid hydrolyzate (Fig. 8, numbered oligopeptides) and in an enzymatic hydrolyzate (unnumbered oligopeptides) [38].

A 95.10

Fig. 10. Result of a computer program [14] for the reconstruction of polypeptide sequences by overlapping of oligopeptides. The oligopeptides of Fig. 9 served as input (without Asp-Asp-Cys).

in the peptides identified; in fact, one each of the highly acid-labile peptide bonds to the amino groups of Ser and Thr had undergone quantitative cleavage. We therefore hydrolyzed a second portion of the polypeptide sample with enzymes which we expected to extensively degrade the polypeptide and yet not completely cleave the important peptide bonds of Ser and Thr. And we did indeed find peptides having these bonds in the derivatized mixture.

All the identified peptide fragments were then overlapped by a computer program to form the structure of the polypeptide. As seen in Figure 10, two possible sequences were obtained which differ in the position of the underlined Asp residue. We therefore sought evidence for the presence of a peptide in the GC-MS data of the two experiments, whose identification would rule out one of the two species. In fact, we found a derivative of Asp-Asp-Cys which had apparently been formed by elimination of trimethylsilanol from the expected derivative and therefore escaped identification. Hence sequence A was verified (Fig. 10).

The new peptide derivatives *(9)* have proved to be of crucial importance in the sequence analysis of this polypeptide since not only Trp and Arg peptides but also His peptides thus become accessible to GC-MS analysis (Figs. 7 and 8). These His peptides had to be identified in an additional experiment in the sequence analysis of the eicosapeptide of actin.

Which of the Glu and Asp residues are present as Gln and Asn, respectively, in CPI could again not be established by the GC-MS method. We do not yet known the reason for these difficulties. Although the Gln- and Asn-containing test peptides could be detected by the GC-MS method, some of these derivatives could only be prepared in low yield. The unequivocal assignment of the Gln and Asn residues is currently under study[*].

The computer program for overlapping of the individual oligopeptides has proved to be of great value; the result of this program (two possible sequences; Fig. 10) required a further interpretation of the GC-MS findings which finally led to the sole possible sequence. The oligopeptides were identified by GC-MS analyses of only two hydrolysis mixtures of the inhibitor.

[*] *Note added in proof* (December 19, 1975): Two techniques for the unequivocal assignment of the Gln and Asn residues are currently under study. First, the polypeptide is modified by diborane (*M. Z. Atassi* and *A. F. Rosenthal*, Biochem. J. *111*, 593 (1969)) *prior* to partial hydrolysis to reduce the free carboxyl groups (of Asp, Glu, and C-terminal residue) to $-CH_2-OH$ groups. The primary amide groups in the side chains of Asn and Gln are not affected by diborane, but are reduced *after* the partial hydrolysis (at that stage, the primary amides are present as carboxyl groups) by $LiAlD_4$ to $-CD_2-OH$ groups. In the final derivatization mixture Asp and Glu can be distinguished from Asn and Gln *via* measurement of the deuterium contents of the derivatives present.

Secondly, we have developed new peptide derivatives which are obtained by permethylation of *N*-acyl oligopeptide methyl esters [*(4)*, *(5)*, *(6)*, *(11)*] and subsequent $LiAlD_4$-reduction and *O*-trimethylsilylation. The primary amide groups of Asn and Gln are transformed into $-CD_2-N(CH_3)_2$ groups leading to derivatives of Gln and Asn with favorable properties.

Let us now consider the conventional sequence analysis of the polypeptide[32]. Although an automatic sequencer was employed, considerable difficulties were encountered. The N-terminal part of the polypeptide could not be identified since the N-terminus is blocked (see Section 2.1). Furthermore, the sequence of the other part of the molecule could only be established with difficulty. Specific cleavage of the polypeptide afforded fragments which were then separated, isolated, and subjected individually to Edman degradation. Some of these smaller peptides were extracted together with the amino acids liberated and were thus lost. Moreover, several gaps appeared in the sequence, due, for example, to the destruction of Ser residues. Complete sequence determination therefore required the painstaking separation, isolation, and structure analysis of several peptides.

5. Outlook

We have repeatedly posed the cardinal question of the optimum peptide derivatives, which play a fundamental role in sequence analysis by the GC-MS method. At present derivatives *(9)*, *(10)*, and *(12)* are superior to all others, being most volatile and exhibiting readily interpretable spectra. In our opinion these derivatives will therefore be generally adopted, although their preparation is more involved than that of the non-reduced derivatives *(4)*, *(5)*, and *(11)*.

A recent comparison of several non-reduced peptide derivatives showed that not even all the dipeptides could be identified in the form of the derivatives *(4)* and *(11)* or the permethylated derivative[45]. We have therefore studied precisely those peptides from which no volatile non-reduced derivatives could be prepared (*e.g.* Trp-Trp) and found that these peptides can easily be converted into the reduced derivatives *(9)*.

And the work involved? Preparation of the reduced derivatives is more time-consuming than that of the non-reduced derivatives but can be performed in routine manner. The data of a GC-MS experiment are recorded automatically by computer but still have to be interpreted manually. However, since the mass spectra and the gas chromatographic parameters of derivatives *(9)*, *(10)*, and *(12)* can be predicted and since all these data are already stored on magnetic tape, automated identification of the peptide derivatives should therefore also be feasible. The only manual step required would then be the injection of the sample of derivatized polypeptide hydrolyzate onto the separating column of the gas chromatograph; recording and interpretation of the data, and reconstruction of the polypeptide sequence by overlapping of the identified oligopeptides (using the existing program) would take place automatically.

Summarizing, it may be said: The peptide derivatives now available and the GC-MS method permit structural elucidation of polypeptides up to 40 amino acids (Section 4); in

the forseeable future it will be possible to analyze even larger peptides. It is, however, an open question whether the structure of proteins—especially those having more than 300 amino acids—can be determined by the above GC-MS method. The resulting mixtures—possibly containing several hundred peptides—might well be completely characterizable. It is, however, hardly likely that a unique possible sequence would result on overlapping of the identified oligopeptides.

Als already demonstrated by *Eck*[46] in his theoretical treatise, more than 336 peptides, including a significant proportion of possible tetra-, penta-, and hexapeptides, are necessary for structural elucidation of a fairly small protein containing 157 peptide bonds. The development of derivatives having higher and higher vapor pressures is therefore of great importance.

However, an alternative approach should lead more directly to the desired goal. The protein should be cleaved specifically, *e. g.* with trypsin or cyanogen bromide, into a few polypeptides (Fig. 1), which are separated and analyzed individually by the described GC-MS techniques. Since these sequences do not overlap, a further sample of the protein should be subjected to a second selective cleavage into a series of other polypeptides which are in turn analyzed by the GC-MS method. The second set of polypeptides permit correct linkage of the first set in a reconstruction of the protein. These linking proteins could also be identified more elegantly by direct GC-MS analysis of suitable hydrolyzates of the complete protein. Such an analysis could be restricted to a search for peptides whose sequences were already represented in the N-terminal and C-terminal part of the polypeptides from the first set. We have already used this direct GC-MS analysis of protein hydrolyzates with success for identification of modified amino acids in enzymes[47].

Recent years have seen various attempts at direct mass spectrometry of peptides—*i.e.* without prior derivatization. Success has been achieved with chemical[48, 49] and photoionization[50]; field desorption[51] has also been used to analyze peptides—even those containing Arg. So far, though, these methods have only been tried with pure peptides; their true value will only become apparent on successful analysis of mixtures. Perhaps high-pressure liquid chromatography could be combined directly with one of the methods mentioned.

I wish to express my sincere gratitude to my teacher and mentor, Professor Klaus Biemann, M.I.T., Cambridge, Mass. Thanks are also due to my former colleagues at M.I.T.—T. R. Smith, J. E. Biller, H.-J. Förster, J. A. Kelly, R. J. Anderegg, and G. Hudson—for their cooperation and numerous stimulating discussions, and to Doz. Dr. J.-H. Fuhrhop and Dr. E. Lustig for valuable comments and suggestions concerning this paper. Financial support from the Federal Ministry of Research and Technology is gratefully acknowledged.

Unusually High Barriers to Rotation Involving the Tetrahedral Carbon Atom

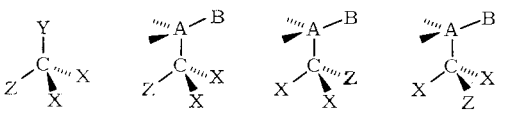
By Michinori Ōki[*]

Rotation about CC single bonds in suitably substituted compounds gives rise to rotational isomers (also called rotamers) which can be isolated if the barrier to rotation is high enough. The present article considers derivatives of triptycene and fluorene whose barriers to rotation are of the order of 30 kcal/mol.

1. Introduction

Restricted rotation about a single bond is an old, yet new field of interest. The classical work by *van't Hoff* and *Le Bel* was criticized from the standpoint that the rotamers predicted by the tetrahedron theory were not isolable. In reply to this criticism, free rotation about a single bond was postulated[1]. It was only in 1936 that the concept of restricted rotation in ethane type molecules was established[2].

According to the theory of rotameric potentials, there are three minima in energy and three rotamers (staggered forms) should be obtainable if the barrier to rotation is high enough to permit their isolation. The simplest example illustrating this concept is a molecule of CX_2YZ type. Although this molecule has no center of asymmetry, it should be resolvable, provided that the barrier is high and either Y or Z which is connected to the central carbon atom *via* a tetrahedral atom does not have threefold symmetry. This applies to the tetrahedrons *(1)*—*(3)* in which −Y has been replaced by ⩾A—B.

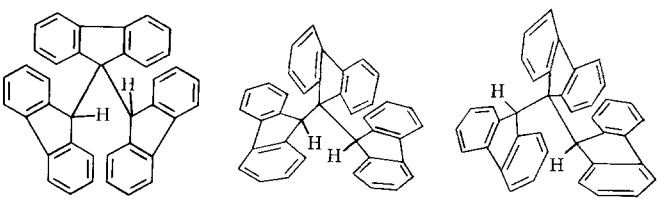


CX_2YZ *(1)* *(2)* *(3)*

(1) has C_{2v} symmetry and is not chiral, whereas *(2)* and *(3)* have no such symmetry and are chiral. If a molecule of CX_2YZ meets these symmetry conditions, it should exist in *meso*, (+), and (−) forms.

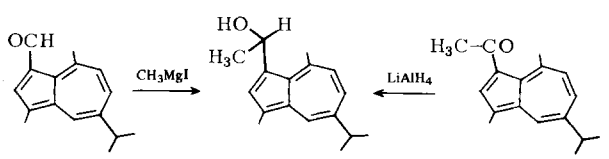
If Y or Z is connected to the central carbon atom *via* a trigonal atom and has no plane of symmetry other than the plane of the triangle itself, there are two stereochemical possibilities. In one case the eclipsed conformation is the stable form and two *meso* forms and two pairs of enantiomers are conceivable. In the other case, the trigonal plane avoids the eclipsed form and at least three pairs of enantiomers are possible.

There are some scattered earlier reports claiming the existence of stable rotamers. As early as 1955, *Suzuki* attributed the existence of two forms of 9,9-bis(9-fluorenyl)fluorene *(4)* to hindered rotation[3] and later assigned the *s-cis,s-cis* and *s-cis,s-trans* structures *(4a)* and *(4b)*, respectively, to these forms on the basis of spectral evidence[4]. However, there are 6 possible rotamers in this compound: one *trans,trans* (*ap,ap*), two *cis,trans* (+*sc,ap* and −*sc,ap*), and three *cis,cis* forms (+*sc*,+*sc* and two +*sc*,−*sc*)[*].



(4) *(4a)* *(4b)*

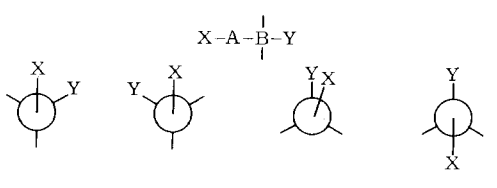
Ukita et al. were able to isolate two forms of compound *(6)*[5]. One was prepared by the reaction of *s*-guaiazulene-1-carbaldehyde *(5)* with methylmagnesium iodide and the other by the reduction of 1-acetyl-*s*-guaiazulene *(7)* with lithium tetrahydridoaluminate. The form prepared by reduction easily deteriorated on heating whereas the other was stable. The authors claimed that the results were best interpreted by assuming the isolation of rotamers: attack by Grignard compound or hydride ion from the least hindered side should produce different isomers.



(5) *(6)* *(7)*

However, a later study on compounds with similar steric properties revealed that the rotational isomer is present in

[*] The symbols *sc* (synclinal), *sp* (synperiplanar), and *ap* (antiperiplanar) used in this article designate the conformation by the torsion angle about an sp^3—sp^2 or an sp^3—sp^3 bond (cf. IUPAC 1968 Tentative Rules, Section E, Fundamental Stereochemistry; J. Org. Chem. *35*, 2849 (1970)). *sc* corresponds to a torsion angle of *ca.* 60°, and + and − indicate the direction of rotation, clockwise and counterclockwise, respectively, of the front atom X required to eclipse the rear atom Y. *sp* and *ap* correspond to the torsion angles of *ca.* 0° and *ca.* 180°, respectively.



Atoms or groups (X and Y) to define the torsion angle are selected according to *R. S. Cahn, C. Ingold,* and *V. Prelog*, Angew. Chem. *78*, 413 (1966); Angew. Chem. Int. Ed. Engl. *5*, 385 (1966).

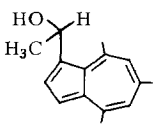
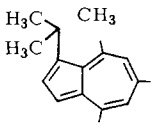
the solid state, at best. ^{1}H-NMR study of *(8)* only showed incipient signal splitting at -70 °C. The room temperature spectra were identical, although several polymorphic forms have been isolated[6]. Even *(9)* only showed line broadening at -25 °C.

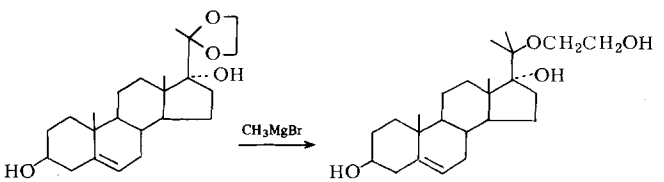


(8)



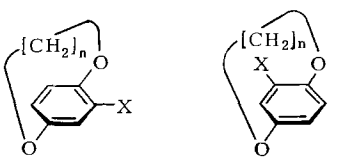
(9)

Kohen et al. treated a steroidal ketal *(10)* with methylmagnesium bromide to obtain two forms *(11)* which exhibited different melting points, ^{1}H-NMR spectra, and optical rotations. They attributed these differences to rotational isomerism[7], but did not equilibrate the isomers. Isolation of the third isomer or equilibration of those isomers would have made the evidence much more convincing.



(10) *(11)*

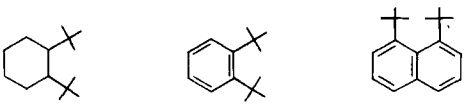
The classical work on optical resolution[8] of [*n*]paracyclophanes and related compounds is a fitting example of rotamer isolation. However, these compounds belong to a different group from those considered in this review in that rotation about multiple sp^3—sp^2 bonds is hindered simultaneously, and they are mentioned only for the sake of completeness. The formula shows some atropisomeric [*n*]paracyclophanes.



In classical work, compounds showing polymorphic behavior were found by accident or were selected by consideration of molecular models. Recent progress in dynamic nuclear magnetic resonance (DNMR), however, has rendered systematic study of the barrier to rotation feasible and permitted prediction of the barrier from available data[9]. The present article surveys this field of chemistry and describes the recent advance of combining DNMR and classical methods in characterizing rotational isomers. Several important aspects of stereochemistry found during the search for stable rotamers will also be described.

2. General Considerations

High barriers to rotation appear to require not only high energy transition states of rotation but also low potential energies in the ground state. A high potential in the transition



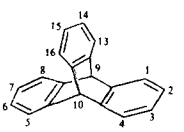
(12) *(13)* *(14)*

state is frequently associated with a high potential in the ground state, but this necessarily lessens the barrier to rotation. Hence, the rather low barriers to rotation in *cis*-1,2-di-*tert*-butylcyclohexane *(12)*[10] 1,2-di-*tert*-butylbenzene *(13)*[11], and 1,8-di-*tert*-butylnaphthalene *(14)* derivatives[12] in spite of the crowdedness in the transition state are believed to be caused by the elevation in the ground state. The low barrier in the azulene derivatives *(6)*, *(8)*, and *(9)* may also be attributed to the same cause.

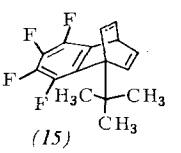
3. Hindered Rotation about sp^3—sp^3 Bonds

3.1. Isolation of Rotamers

An approach to the realization of high barriers to rotation is provided by the triptycenes which can be readily synthesized. Compound *(15)* was found to give two distinct signals in the intensity ratio 2:1 for the *tert*-butyl protons in the ^{1}H-NMR spectrum[13]. The signals began to coalesce at about 120 °C.

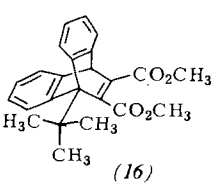


Triptycene

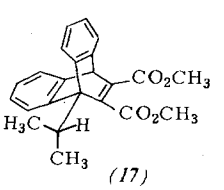


(15)

Although the authors did not mention the barrier to rotation, rough calculation using the chemical shift difference ($\Delta\nu$) and the coalescence temperature (T_c) yielded the free energy of activation $\Delta G_c^{\ddagger}$ at T_c as 20 kcal/mol. Other triptycene-type compounds were also prepared. Compounds *(16)* showed two lines for the *tert*-butyl protons as expected but the ^{1}H-NMR spectrum at 132 °C gave no sign of coalescence or line-broadening, suggesting that the barrier to rotation must be higher than 25 kcal/mol[14]. If we assume the frequency factor A of the Arrhenius equation to be $10^{13}\,s^{-1}$ which is a normal value for internal rotation, then we obtain an activation energy of 23 kcal/mol as the minimum value necessary for isolation of stable rotamers at room temperature (mean lifetime 1 h). Therefore the results with the triptycene analog *(16)* reveal that the steric conditions of this compound meet the requirement for the resolution or isolation of rotamers as stable entities at room temperature.



(16)

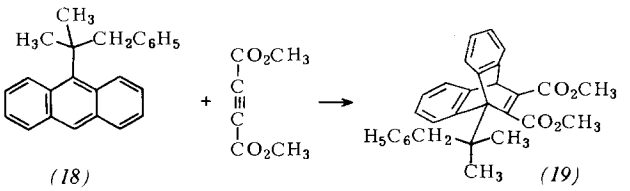


(17)

Since the *tert*-butyl group has threefold symmetry, leading to indistinguishable rotamers, it was replaced by the isopropyl

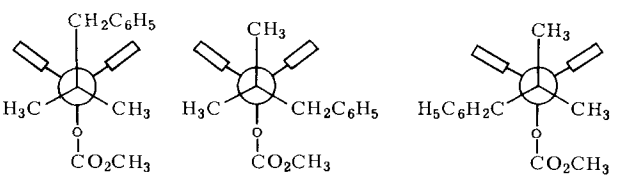
group. However, compound *(17)* could not be resolved into stable rotamers: the activation energy for rotation is only 15 kcal/mol[14].

The results indicate that in order to isolate stable isomers with ethenoanthracene skeleton, the substituent at the bridgehead must be as bulky as the *tert*-butyl group but not have threefold symmetry. Thus compound *(19)* having a benzyl instead of methyl group was prepared[15] by smooth Diels-Alder type addition from *(18)*.



(18) *(19)*

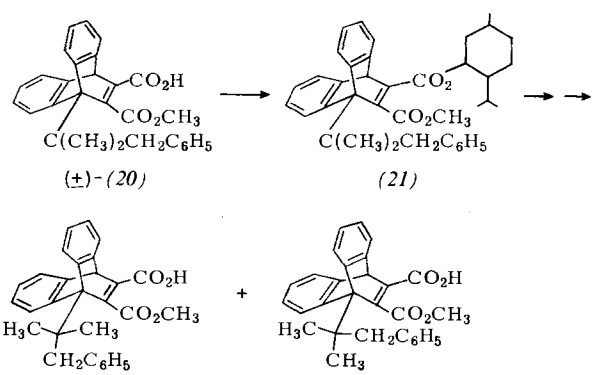
The product gave a ^{1}H-NMR spectrum which exhibited only one signal for the protons of the geminal methyl groups. On heating *(19)* in chlorobenzene, however, increasing amounts of another isomer appear which exhibits two methyl signals and non-equivalent benzyl-methylene protons. These results prove that *(19)* was originally formed by the Diels-Alder reaction in a *meso* form [cf. *(19a)*] which has two methyl groups in equivalent environment. The isomer formed on heating of *(19a)* must be the (±) form [*(19b)* and *(19c)*], because the environments for the two methyls are not equivalent. The nonequivalence of the (diastereotopic) geminal protons of the benzyl group is best interpreted in terms of its proximity to the center of asymmetry.



(19a) *(19b)* *(19c)*

meso or *ap* (±) or ± *sc*

The various rotamers of *(19)* were hydrolyzed to a monocarboxylic acid whose structure is tentatively given as *(20)* because hydrolysis of this compound hardly proceeded further. Resolution of (±)-*(20)* was carried out through crystallization of its (−)-menthyl ester *(21)*. Thus, all three possible rotamers of *(20)* are isolated as stable entities at room temperature

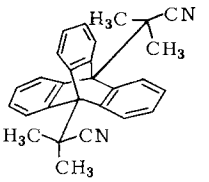


(±)-*(20)* *(21)*

(+)-*(20)* and (−)-*(20)*

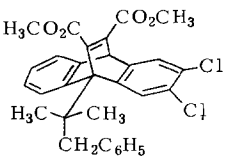
and possess the following characteristics: *meso-(20)*, m. p. 223—225 °C; (+)-*(20)*, m. p. 188—190 °C, $[\alpha]_D^{32}$ +24.8 ($CHCl_3$); (−)-*(20)*, m. p. 188—190 °C, $[\alpha]_D^{32}$ −24.6 ($CHCl_3$)[16].

After the successful separation of isomers of *(19)*, a few subsequent papers reported similar results. *Iwamura* was able to isolate C_2 and C_{2v} forms of *(22)*[17], and *Yamamoto* and *Ōki* reported the isolation of three rotameric forms of *(23)*[18] by chromatographic separation. The latter compounds correspond to diastereomers, although they have only *one* asymmetric carbon atom.



(22)

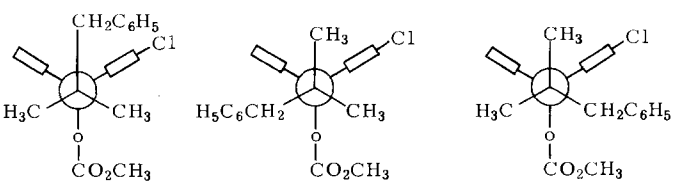
only C_{2v} form shown



(23)

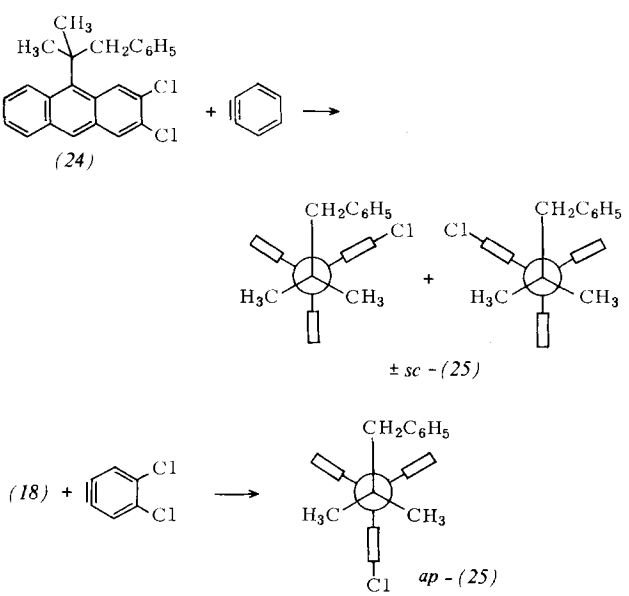
only *ap* form shown

Noteworthy in this context is the stereoselective formation of *(23)*, as already observed in the preparation of *(19)*. Diels-Alder reaction of compound *(24)* with dimethyl acetylenedicarboxylate gave only the *ap* form *(23a)*. The other isomers *(23b)* and *(23c)* were separated after equilibration.



(23a) *(23b)* *(23c)*

Using this technique, it was possible to synthesize ±*sc* and *ap* forms of 2,3-dichloro-9-(α,α-dimethylphenethyl)-triptycene *(25)* separately[19]. Reaction of *(18)* with 4,5-dichlorodi-



(24)

±*sc*-*(25)*

(18) +

ap-*(25)*

dehydrobenzene gave the *ap* form [*ap-(25)*], whereas that of *(24)* with didehydrobenzene produced ±*sc-(25)* only.

3.2. Influence of the Bridging System on the Barrier

Some of the highest barriers to rotation about CC single bonds found in the literature are summarized in Table 1.

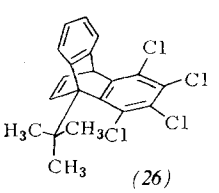
Table 1. Some of the highest barriers for internal rotation.

Compound	E_a [kcal/mol]	log A	Ref.
(19)	33.2	13.3	[16]
(22)	37.7	13	[17]
(25)	33.6	11.7	[19]

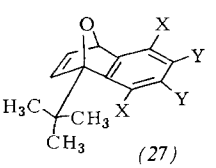
The half-lives of these compounds exceed a thousand years at room temperature; hence the rotamers are extremely stable at ambient temperature.

The triptycene skeleton seems to be ideal for exhibiting the high barrier to rotation: in the ground state, the methyls in the *tert*-butyl group reside comfortably between the three benzene rings and yet the transition state is of very high energy because of severe steric interaction.

The barrier should be lessened on replacing the benzeno bridge by an etheno bridge, as was the case for compound *(19)*. However, a Diels-Alder adduct *(26)* prepared from 1-*tert*-butylnaphthalene and tetrachlorodidehydrobenzene did not show any line broadening at 200 °C[20], indicative of a barrier to rotation exceeding 25 kcal/mol. Thus apart from any additional enhancement by the tetrachlorobenzeno group (see Section 3.4), the ethenoanthracene skelton itself is seen to give a high barrier.



(26)



(27)

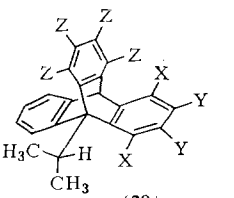
However, replacing the benzeno bridge in *(26)* by an epoxy bridge decreases the barrier to rotation. The methyl signals of compounds *(27)* are sharp singlets at room temperature, whereas they gradually broaden and finally separate into three signals of equal intensity at low temperatures. Total line shape analysis with use of a modified Bloch equation gave satisfactory results and the kinetic parameters were obtained as shown in Table 2[21]. Apparently the barriers are affected by the substituents X and Y on the benzene ring, although only to a limited extent. The type of the bridge seems to be of the prime importance in determining the height of the barrier to rotation.

Table 2. Kinetic parameters for rotation of the *tert*-butyl group in *(27)* (at 25 °C).

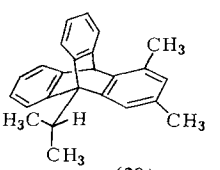
Substituent X	Y	$\Delta G^{\neq}$ [kcal/mol]	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [e.u.]	E_a [kcal/mol]
H	H	9.9 ± 1.0	7.1 ± 0.6	− 9.4 ± 2.3	7.7 ± 0.6
CH_3O	H	11.4 ± 1.0	10.2 ± 0.5	− 4.1 ± 1.0	10.8 ± 0.5
F	F	11.1 ± 1.0	7.6 ± 1.0	−11.8 ± 1.0	8.2 ± 1.0
Cl	Cl	12.0 ± 0.9	10.1 ± 0.6	− 6.5 ± 1.0	10.7 ± 0.6
Br	Br	11.1 ± 0.8	12.4 ± 0.4	4.5 ± 1.6	13.0 ± 0.4

3.3. Effect of Bridgehead Substituents

The sharp decrease in barriers to rotation on going from *tert*-butyl to the isopropyl group is worthy of note. Particular interest therefore attached to the combined effect of the bridgehead substituent and the bridge substituent, since the latter can raise the barrier by several kcal/mol.



(28)



(29)

Table 3. Kinetic parameters for rotation of the isopropyl group in *(28)* (at 25 °C).

Substituent X	Y	Z	$\Delta G^{\neq}$ [kcal/mol]	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [e.u.]	E_a [kcal/mol]
CH_3	H	H	21.8 ± 1.1	17.2 ± 1.4	1.5 ± 1.7	22.0 ± 0.7
CH_3O	H	H	23.6 ± 1.9	21.4 ± 0.7	3.9 ± 2.7	25.4 ± 1.1
Cl	Cl	H	25.5 ± 2.3	30.1 ± 1.4	15.5 ± 2.3	30.7 ± 1.4
Br	Br	H	> 26			
Cl	Cl	Cl	> 26			

Being the second largest alkyl group in the series $(CH_3)_nC_{3-n}$, the isopropyl group is able to induce a high barrier to rotation if the effect of substituents at the bridging system predominates. The barriers to rotation of compounds *(28)* were therefore examined. Total line shape analysis gave satisfactory agreement with the modified Bloch equation. The results are summarized in Table 3[22].

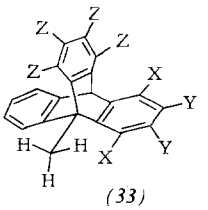
Apparently the barrier is lowest (E_a = 19.9 kcal/mol) for a compound *(29)* which has no substituent in a *peri*-position[*]. However, the barrier is still higher than that in compound

[*] In triptycene, the term *peri*-position should be taken to mean the positions: 1,8; 1,13; 4,5; 4,16; 5,16 and/or 8,13.

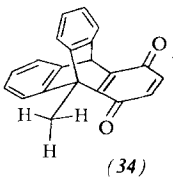
(17) (E_a = 15 kcal/mol), again showing that the barrier is higher for the triptycene skeleton than for the etheno-bridged anthracene skeleton. The barrier is surprisingly high when one or two benzeno bridges carry substituents (*e.g.* halogen). It must therefore be possible to isolate stable rotamers of tetrabromo and octachloro compounds at room temperature but no such attempt has yet been reported.

The ethyl group comes next to the isopropyl group in the alkyl series but there seems to be no report on hindered rotation of this group, probably because of the complexity of analysis of the PMR spectra. Instead, some investigations on substituted methyl groups have been performed. The first such publication was authored by *Sergeyev et al.*[23], who observed the coalescence-splitting phenomenon of the *peri*-proton signals of 9-chloromethyltriptycene *(30)*. The barrier was later recalculated to be 13 kcal/mol[24] using ^{13}C-NMR data.

Soon after this finding, it became clear that substituted 9-methyltriptycenes *(33)* give clearer freezing of the rotation[30]. Those which have a halogen substituent in a *peri*-position give separate signals in the intensity ratio of 2:1 for the methyl protons at low temperatures, whereas those with halogens in two *peri*-positions to the methyl group give distinct AB_2 type signals at low temperatures. The barriers obtained are listed in Table 4. *Anderson* reported separation of a methyl signal of compound *(34)* at low temperatures[31].



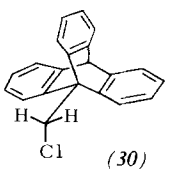
(33)



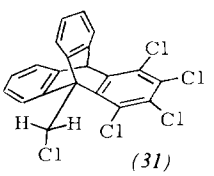
(34)

Table 4. Kinetic parameters for rotation of the methyl group in *(33)* (at 25 °C).

Substituent X	Y	Z	$\Delta G^{\neq}$ [kcal/mol]	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [e.u.]	E_a [kcal/mol]
CH_3	H	H	<8			
CH_3O	H	H	<8			
Cl	Cl	H	10.3±1.0	8.6±0.4	−5.9±2.1	9.2±0.4
Br	Br	H	10.2±1.0	9.6±0.4	−2.1±2.0	10.2±0.4
Cl	Cl	Cl	10.6±1.0	13.5±0.6	9.8±3.0	14.1±0.6
Br	Br	Cl	11.4±0.6	12.4±0.3	3.4±1.3	13.0±0.3
CH_3	H	Cl	11.2±0.7	12.1±0.3	3.0±1.4	12.7±0.3

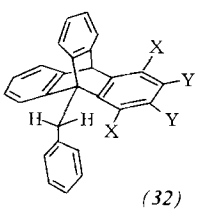


(30)



(31)

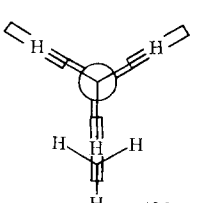
Suzuki and *Ōki* treated a similar compound bearing a chloro substituent at a *peri* position but unfortunately the population was so one-sided that it was not possible to determine the barrier[25]. The barrier to rotation of 9-benzyltriptycenes *(32)* has been roughly estimated to lie in the range of 10—18 kcal/mol[26].



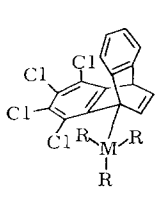
(32)

Methyl, being the smallest alkyl group, is expected to give the lowest barrier to rotation. Indeed, there have been scattered attempts to freeze the rotation of methyl groups; however, the sole evidence obtained consists in line-broadening[27, 28] and one can argue that the broadening may be caused by reasons other than slow rotation. Unambiguous evidence of freezing of the rotation of methyl groups has been presented for the epoxynaphthalenes *(27)*. Their ^{1}H-NMR spectra showed not only broadening of the signals but an unsymmetric line shape at low temperatures[21, 29].

Although the barriers to rotation of the methyl groups of 1,4-dimethyl- and 1,4-dimethoxy-9-methyltriptycenes were too low to be obtained accurately, it was still clear that the barrier for the 1,4-dimethoxy compound is higher than that in the corresponding dimethyl compound. This is an unusual phenomenon, because the van der Waals radius of the methyl group is larger than that of the methoxy group and it is usually thought that the transition state is governed by the steric repulsion between groups concerned. However, this phenomenon is not only found in the methyltriptycenes but also in the isopropyltriptycenes (cf. Table 3). One of the possible explanations for these unusual phenomena is the cogwheeling arrangement of the methyl groups [cf. *(35)*]. It may be argued that it is not the cogwheeling but the raising of the ground state that is responsible for lessening the barrier. However, the high barriers of the bromo compounds contradict this hypothesis: the bromo group should induce a similar barrier to the methyl group, being of almost the same size.



(35)



(36), M = Si, Ge, Sn
R = CH_3

If the central carbon atom of the *tert*-butyl group in *(26)* is replaced by other Group IV elements, the barrier shows a considerable decrease[20]. Elongation of the bond is shown by molecular models to cause more severe overlap with the

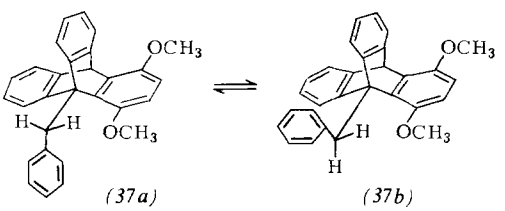
peri-substituent. The decrease in the barrier actually observed is attributed to the easier deformation of the bond angle on descending the Periodic Table.

3.4. Population of Rotamers in Highly Crowded Systems

Population of rotamers in the substituted triptycenes poses another interesting problem. Among 9-isopropyltriptycenes *(28)*, those which have a substituent in a *peri*-position to the isopropyl group exist solely as (±)-forms: no *meso* form was detected even at elevated temperatures. In sharp contrast, 10-isopropyl-1,3-dimethyltriptycene *(29)*, which has no substituent in a *peri*-position, exists as a 2:1 mixture of the (±)- and the *meso* forms, the ratio being the statistical one. Thus the population of the rotamers is regulated by the substituent in a *peri*-position and the type of interaction is repulsive[22]. That only the *meso* form of 1,2,3,4,5,6,7,8-octachloro-9-isopropyltriptycene is known accords with this finding, because the steric repulsion can be minimized in that conformation.

The situation with 9-benzyltriptycene derivatives is in sharp contrast[25]. Especially noteworthy is the case of 9-benzyl-1,4-dimethoxytriptycene which exists as a 2.8:1 mixture of (±) [*(37a)* and its mirror image] and *meso* [*(37b)*] isomers at −40 °C, the ratio being greater than the statistical one in spite of the fact that the (±) form is disfavored by steric effects. Introduction of an electron-withdrawing substituent into the *para* position of the benzyl group enhances the stabilization of the (±) form, whereas an electron-donating substituent has the opposite effect.

9-Chloromethyl-1,4-dimethoxytriptycene exists almost exclusively as the *meso* form.

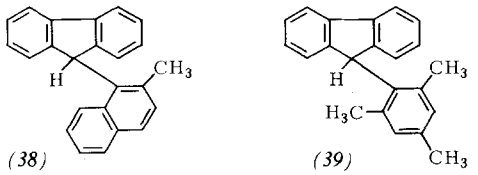


(37a) *(37b)*

This unexpected equilibration was attributed to a charge-transfer type attractive interaction between the substituted benzene rings and the benzene ring of the benzyl group. It seems that the attractive interaction operates between groups of closest proximity if an electron-accepting orbital is available at relatively low level, while the interaction is repulsive if this condition is not fulfilled.

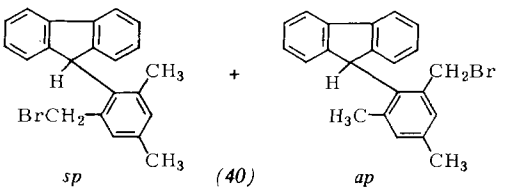
4. Hindered Rotation about sp^3—sp^2 Bonds

Three groups of investigators reported almost simultaneously that 9-substituted fluorene could have high barriers to rotation about the single bond leading to the substituent [32–34]. *Siddall* and *Stewart*[34] were able to concentrate one rotamer of 9-(2-methyl-1-naphthyl)fluorene *(38)* up to >90% purity and another to 58% purity by fractional crystallization. The free energy of activation was found to be 29.2 kcal/mol at 116 °C. They and *Rieker* and *Kessler*[33] pointed out that 9-mesitylfluorene *(39)* could have a barrier to rotation of over 26 kcal/mol from the observation that the signals of the protons of the methyl groups in positions 2 and 6 did not coalesce even at 200 °C.



(38) *(39)*

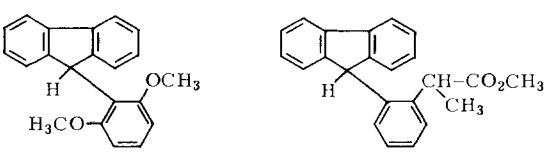
Nakamura and *Ōki*, making use of the DNMR results cited above, succeeded in isolating the pure rotamers of this type, after bromination of compound *(39)* with *N*-bromosuccinimide[35]. The barriers to rotation in compound *(40)* for *sp*→*ap*



sp *(40)* *ap*

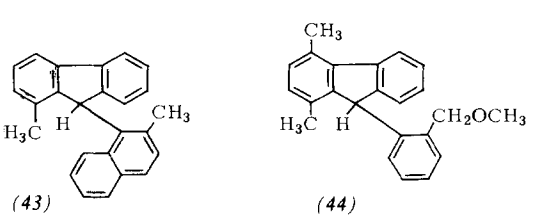
and *ap*→*sp* are almost the same at 27 kcal/mol, the frequency factor being *ca.* $10^{11}\,s^{-1}$. They also succeeded in isolating *sp* and *ap* isomers of 9-(2-methoxy-1-naphthyl)fluorene, the melting points being 125.0—126.0 °C and 121.0—122.0 °C, respectively[36]. The activation energies for the rotations of this compound were found to be rather low, *i.e.* 25 kcal/mol and 24 kcal/mol for *sp*→*ap* and *ap*→*sp*, respectively.

In order to have rotation barriers high enough for isolation of rotamers, it seems necessary to have bulky substituents in positions 2 and 6 of the 9-aryl group. Even 9-(2,6-dimethoxyphenyl)fluorene *(41)* is known to have only 20.6 kcal/mol free energy of activation and compound *(42)* to possess only a low barrier, the coalescence temperature being 60—100 °C for all the signals at 60 MHz[37].



(41) *(42)*

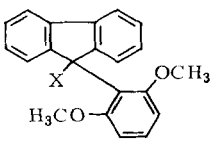
Introduction of a methyl group in position 1 of the fluorene nucleus appears to raise the barrier considerably. Thus compound *(43)* was isolated in two forms (m.p. 152—153.5 °C and 189—191 °C) and the free energy of activation at 166 °C was estimated to be 33.3 kcal/mol[38]. However, this methyl group is not sufficient to permit isolation of fluorene rotamers whose 9-aryl groups are *ortho* substituted. *(44)* is reported to have a free energy of activation of 19.4 kcal/mol at 104 °C[39].



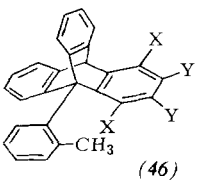
(43) *(44)*

Elevation of the ground state energy has a profound effect on the barriers to rotation of fluorene derivatives. Replacement of the atom in position 9 by hydroxy or chloro group considerably lowers the barrier[32, 33]. The value of E_a is lowered from 19.4 kcal/mol (X=H) to 14.4 (X=OH) and 9.2 kcal/mol (X=Cl). A similar situation is found for triptycene derivatives. 9-Aryltriptycene derivatives *(46)* show a barrier of only 13—14 kcal/mol in spite of the fact that the 9-alkyltriptycenes showed remarkably high barriers[40].

This pronounced effect must be attributed to the rise in ground state energy because of the proximity of the 9-aryl groups to one of the benzeno bridges.

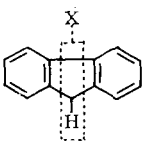


(45)

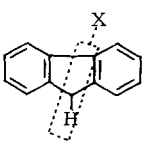


(46)

The mechanism of exchange, observed by ^{1}H-NMR spectroscopy either as a change in line shape or as a decrease or increase in line intensities after isolation of rotamers, might not be a simple internal rotation, especially when the barrier is high. *Ford et al.* carried out a series of experiments to establish the pathway of isomerization of *(43)* and found that the mechanism of exchange between isomers is indeed internal rotation[38].



(47)



(48)

only *ap* forms shown

Finally, there is the problem of the conformation of fluorenes of type *(38)—(45)*. If they exist in the eclipsed form *(47)*[*], the above cases are examples in which all the possible *meso* rotamers were isolated. However, if the non-eclipsed form *(48)* applies, there are still possible rotamers to be isolated. The latter is believed to be the case because, on lowering the temperature, the signal of the bromomethyl protons of compound *(40)* show a tendency to split into an AB quartet[41]. The phenomenon can only be interpreted by assuming the presence of a chiral center. Thus the enantiomers of 9-arylfluorene undergo rapid interchange at room temperature, whereas the isomerization between *ap* and *sp* forms is slow.

[*] The formulation of the other eclipsed arrangement is unreasonable because the steric effect is unfavorable and the methylene protons of *(40)* do not show diastereotopy in the ^{1}H-NMR spectra recorded in various solvents at room temperature.

Oxidation-Reduction Condensation

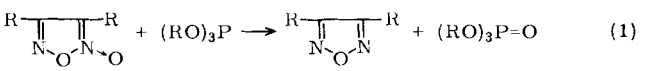
By Teruaki Mukaiyama[*]

This review is concerned with syntheses which can be carried out in the absence of acids and bases. In the case of condensations, *i.e.* the union of two or more reaction partners with elimination of simple molecules such as H_2O or NH_3, the combination of a weak oxidizing agent with a weak reducing agent has proven useful. A particularly suitable reagent for condensations with elimination of water is triphenylphosphane/di(2-pyridyl)disulfane. The phosphane takes up the oxygen atom and is converted into the phosphane oxide, while the disulfane reacts with the two hydrogen atoms to form pyridinethione. Oxidation-reduction condensations have been utilized for the preparation of, *inter alia*, esters, peptides, nucleotides, and macrolides.

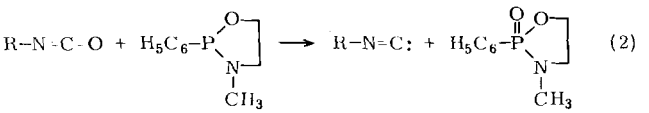
1. Introduction

Ever since strong bases such as alkyllithium compounds became relatively easily accessible, numerous useful syntheses have been developed in which the chemistry of organosulfur derivatives, dianions, alkylcopper compounds or related species plays an integral role. In the case of acids, the discovery of super acids has made it possible to generate synthetically useful carbocations, and Lewis acids[1] have provided the organic chemist with a means of performing numerous versatile syntheses. In the following, we are not concerned with reactions involving strong bases and strong acids but rather with syntheses which are performed in the presence of weak oxidizing agents and weak reducing agents ("oxidation-reduction condensation").

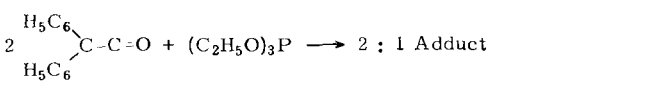
Organic compounds containing trivalent phosphorus, such as trialkylphosphites and trialkyl- or triarylphosphanes can readily take up an oxygen atom and are therefore frequently used as reducing agents, as is illustrated in equations (1)–(4)[2–4].

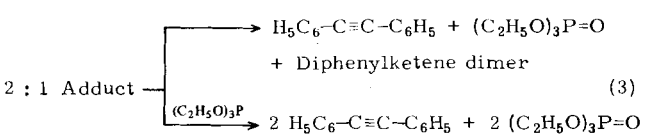


(1)



(2)





(3)

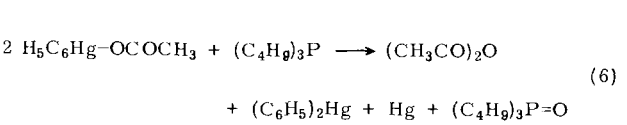
(4)

During the course of our studies on the deoxygenation of ethylene carbonate with phosphanes, it was discovered that mercury(II) acetate, which is employed as catalyst, reacts with phosphorus(III) compounds to yield acetic anhydride. We therefore turned our attention to the possible generation of active acyl groups by the coupled utilization of oxidation and reduction processes. New and practically useful reactions were found which are suitable for the preparation of acid anhydrides, esters, peptides, and nucleotides.

It was found that mercury(II) or mercury(I) salts of carboxylic acids behave as oxidizing reagents toward triethylphosphite or tri-*n*-butylphosphane, yielding the corresponding acid anhydrides along with triethylphosphate or tri-*n*-butylphosphane oxide [Eq. (5)][5], and mercury.

(5)

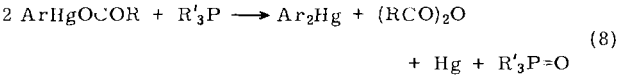
Phenylmercury(II) acetate behaves similarly toward tri-*n*-butylphosphane and affords acetic anhydride in 40—45% yield along with diphenylmercury and mercury [Eq. (6)].



(6)

On the other hand, it is reasonable to assume that arylmercury(II) carboxylates are readily formed on reaction of diarylmercury with carboxylic acids. Hence, by combination of these two reactions it should be possible to prepare acid anhydrides from acids in accordance with equations (7) and (8).

(7)



(8)

Indeed, treatment of diphenyl- or bis(*p*-methoxyphenyl)mercury with tri-*n*-butylphosphane in the presence of 2 equivalents of carboxylic acid leads to formation of the corresponding acid anhydride in high yield along with mercury and tri-*n*-butylphosphane oxide [Eq. (9)][6].

Ar = C_6H_5, *p*-CH_3O-C_6H_4

[*] Prof. Dr. T. Mukaiyama
Department of Chemistry, Faculty of Science
The University of Tokyo
Bunkyo-ku, Tokyo 113 (Japan)

In this reaction, two molecules of carboxylic acid undergo condensation with the help of a hydrogen acceptor (diarylmercury) and an oxygen acceptor (tri-*n*-butylphosphane) to give the anhydride.

Since these dehydration reactions essentially proceed *via* an oxidation and a reduction process it is important that suitable oxidation reagents and reducing reagents (phosphorus(III) compounds) be chosen. It was found that similar dehydration condensation reactions take place successfully *e.g.* with trialkylphosphane and conjugated dicarbonyl compounds such as dibenzoylethylene [Eq. (10)][7].

$$H_5C_6CO{-}CH{=}CH{-}COC_6H_5 + (C_4H_9)_3P + 2\ RCO_2H \longrightarrow (RCO)_2O + H_5C_6CO{-}CH_2{-}CH_2{-}COC_6H_5 + (C_4H_9)_3P{=}O \quad (10)$$

The reaction could be further extended to phosphoric monoesters. Thus, for example, symmetrical diphenyl diphosphate[7] was produced in good yield on treating triethylammonium phenyl hydrogen phosphate with the coupling reagents [Eq. (11)].

$$H_5C_6CO{-}CH{=}CH{-}COC_6H_5 + (C_4H_9)_3P + 2\ H_5C_6O{-}P(=O)(O^{\ominus})\,M^{\oplus} \longrightarrow H_5C_6CO{-}CH_2{-}CH_2{-}COC_6H_5 + (C_4H_9)_3P{=}O + \underset{M = (C_2H_5)_3NH}{} \quad (11)$$

$$+\ H_5C_6O{-}P(=O)(O^{\ominus}){-}O{-}P(=O)(O^{\ominus}){-}OC_6H_5\ \ 2\ M^{\oplus}$$

N,*N*′-Dibenzoyl-*p*-benzoquinone diimine is found to be a more effective hydrogen acceptor. Reaction of carboxylic acids with the quinone imine and triphenylphosphane leads, in accordance with Eq. (12), to the formation of the carboxylic acid anhydride in high yield along with triphenylphosphane oxide and *p*-phenylenedibenzamide[8].

$$H_5C_6CO{-}N{=}\langle\rangle{=}N{-}COC_6H_5 + 2\ RCO_2H + (C_6H_5)_3P \longrightarrow (RCO)_2O + H_5C_6CO{-}NH{-}\langle\rangle{-}NH{-}COC_6H_5 + (C_6H_5)_3P{=}O \quad (12)$$

The phosphonium salts *(1)*, can be prepared from sulfenyl chlorides and triphenylphosphane. On treatment with sodium or triethylammonium salts of carboxylic acids they give the corresponding *S*-arylthiocarboxylates in high yield. The formation of the esters can be explained in terms of initial formation of acyloxyphosphonium thiolates *(2)* which subsequently decompose into the esters in accordance with Eq. (13)[9]. In this reaction, the sulfenyl chloride serves as oxidizing agent.

$$p\text{-}Cl{-}C_6H_4{-}S{-}Cl + (C_6H_5)_3P \longrightarrow \underset{(1)}{[(C_6H_5)_3\overset{\oplus}{P}{-}S{-}C_6H_4{-}Cl]\ Cl^{\ominus}} \xrightarrow{RCO_2^{\ominus}} [(C_6H_5)_3\overset{\oplus}{P}{-}S{-}C_6H_4{-}Cl]\ {}^{\ominus}O_2CR \longrightarrow \underset{(2)}{[(C_6H_5)_3\overset{\oplus}{P}{-}O{-}C(=O){-}R]\ {}^{\ominus}S{-}C_6H_4{-}Cl} \longrightarrow R{-}C(=O){-}S{-}C_6H_4{-}Cl + (C_6H_5)_3P{=}O \quad (13)$$

Similar results are also observed in the reaction of disulfanes with tertiary phosphane in the presence of carboxylic acids

$$R^1COOH + R^2S{-}SR^2 + R^3_3P \longrightarrow R^1CO{-}SR^2 + R^2SH + R^3_3P{=}O \quad (14)$$

which leads to the *S*-alkyl- or *S*-arylthiocarboxylates in high yields along with thiols and phosphane oxides [Eq. (14)][10].

2. Peptide Synthesis

The oxidation-reduction condensation in accordance with Eq. (13) can be extended to the preparation of carboxamides by treating sulfenamides with carboxylic acids in the presence of triphenylphosphane[11]. The key step in Eq. (15) is the formation of an acyloxyphosphonium thiolate *(3)* resulting from an exchange reaction of the sulfenyl group with a carboxylate ion.

Unfortunately, this reaction is not ideally suitable for the preparation of carboxamides because the thiol liberated in the first step reacts further with the sulfenamide to give undesirable side-products, disulfanes and amines. However, this side

$$(C_6H_5)_3P + R^3S{-}NHR^2 \longrightarrow [(C_6H_5)_3\overset{\oplus}{P}{-}SR^3]\ {}^{\ominus}NHR^2 \xrightarrow{R^1CO_2H} [(C_6H_5)_3\overset{\oplus}{P}{-}SR^3]\ {}^{\ominus}O_2CR^1 + H_2NR^2 \longrightarrow \underset{(3)}{[(C_6H_5)_3\overset{\oplus}{P}{-}O{-}C(=O){-}R^1]\ {}^{\ominus}SR^3} + H_2NR^2 \longrightarrow R^1{-}C(=O){-}NHR^2 + (C_6H_5)_3P{=}O + R^3SH \quad (15)$$

reaction can be almost completely avoided if the carboxylic acids are used in the form of their copper(II) salts; the thiolate ions are then trapped as copper(II) thiolates [Eq. (16)][12].

In this way, for example, *N*-butylhexanamide can be prepared in 95% yield from copper(II) hexanoate, triphenylphosphane, and *N*-butylbenzenesulfenamide (molar ratio 1:2:2) at room temperature. Sometimes, an excess of triphenylphosphane must be used in order to complete reaction because it is partly consumed by coordination to the copper(II) thiolate. Thus, 4 equivalents of triphenylphosphane are necessary for the reaction of *N*-benzyl-*o*-nitrobenzenesulfenamide and copper(II) benzoate[12].

$$(R^1CO_2)_2Cu + 2\ R^4S{-}NR^2R^3 + 2\ (C_6H_5)_3P \longrightarrow 2\ R^1{-}C(=O){-}NR^2R^3 + 2\ (C_6H_5)_3P{=}O + (R^4S)_2Cu \quad (16)$$

Sulfenamide derivatives of amino acids are readily available from the reaction of amino acids with sulfenyl chlorides; the sulfenyl groups are generally employed as useful amino-protecting groups in peptide synthesis. For example, reaction of the copper salt (Z-L-Phe—O)$_2$Cu with the ester Nps-Gly-OEt in the presence of triphenylphosphane affords the dipeptide derivative Z-L-Phe-Gly-OEt in high yield [Eq. (17)][12].

$$(Z\text{-L-Phe-O})_2Cu + 2\ Nps\text{-Gly-OEt} + 4\ (C_6H_5)_3P \quad (17)$$
$$\longrightarrow 2\ Z\text{-L-Phe-Gly-OEt} + Cu(S\text{-}C_6H_4\text{-}NO_2)_2 \cdot 2\ P(C_6H_5)_3 + 2\ (C_6H_5)_3P{=}O$$

Z =  Nps =

As shown by the Young test, a racemization takes place in this reaction, probably because of the generation of amino acid ester anions as intermediates. This, however, can be largely avoided by keeping the reaction solution neutral or weakly acidic[12]. Accordingly, free carboxylic acids can be used, as shown in Eq. (18).

$$2\ R^1CO_2H + 2\ R^3S\text{-}NHR^2 + 2\ (C_6H_5)_3P + MCl_2 + 2\ Et_3N \quad (18)$$
$$\rightarrow 2\ R^1CO\text{-}NHR^2 + 2\ (C_6H_5)_3P{=}O + (R^3S)_2M + 2\ Et_3NHCl$$

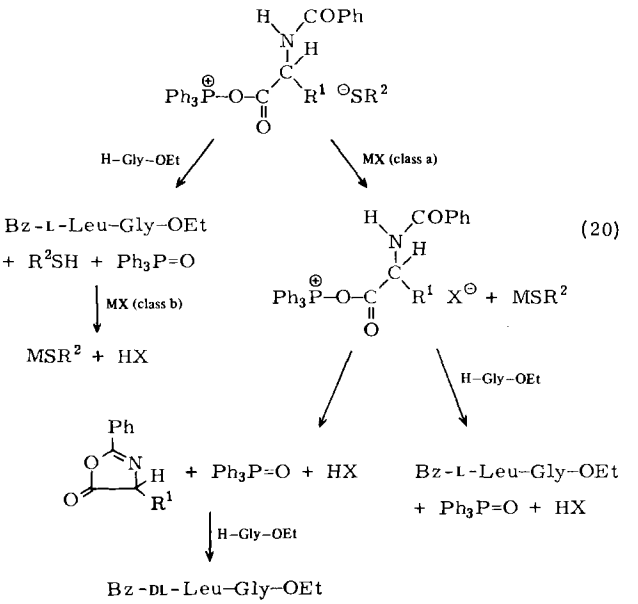
The concept of preparing acyloxyphosphonium salts from arylthiophosphonium salts can be further extended to the synthesis of peptides from triphenylphosphane, diarylsulfanes, amino acids with protected amino groups, and amino acid esters. Thus, Z-L-Phe-Gly-OEt is obtained in accordance with Eq. (19) in high yield by treating Z-L-Phe-OH with H-Gly-OEt in the presence of bis(*o*-nitrophenyl)disulfane, mercury(II) chloride, triphenylphosphane, and triethylamine.

$$Z\text{-L-Phe-OH} + H\text{-Gly-OEt} + HgCl_2 + \text{  } + Ph_3P + 2\ Et_3N \quad (19)$$
$$\longrightarrow Z\text{-L-Phe-Gly-OEt} + Hg(S\text{-}C_6H_4\text{-}NO_2)_2 + Ph_3P{=}O + 2\ Et_3NHCl$$

Other metal salts can also be employed in this reaction, but soft acids such as mercury(II), silver(I), and copper(II) salts are usually found to yield better results. This method makes it possible to synthesize peptides from *N*-protected amino acids and amino acid esters, but racemization takes place if amines are used to trap the hydrogen chloride that is formed. Attempts were therefore made to replace the bases by metal compounds which can form thiolates. These metal compounds (MX) can be classified into two categories:

a) Mercuric salts of urea, succinimide, *p*-nitrophenol *etc.* which afford thiolates on treatment with triphenylphosphane and disulfanes—probably through direct attack by the thiolate ion on the phosphonium salts. In this case, the stabilities of the X^- anions in the salts are expected to have a great effect on racemization. In accord with this assumption, the optical purity of the dipeptides is found, except in the case of *N*-hydroxysuccinimide, to increase as the X^- anion stability increases.

b) Bis(*p*-methoxyphenyl)mercury and *p*-methoxyphenylmercury(II) bromide can react only with thiols to yield mercury(II) thiolates and anisole, but cannot react with the phosphonium thiolates. With these compounds, satisfactory results can be obtained as regards yield and content of L-isomer. The high optical purity in these cases may be attributed to the fact that no oxazolone is formed. The intermediary acyloxyphosphonium salts are attacked only by H-Gly-OEt, whereupon the peptides and thiols are formed, which on reaction with mercury(II) compounds yield mercury(II) thiolates and anisole. Since anisole is produced directly through protonation of the mercury(II) compounds by thiols, no anisyl anion is present during thiolate formation and the formation of oxazolone is prevented [Eq. (20)].



(20)

Bz = C_6H_5CO– R^1 = $-CH_2-CH(CH_3)_2$

A wide variety of solvents, excepting *N*,*N*-dimethylformamide and acetonitrile, can be used in this reaction. The yields and optical purities of the products so obtained are satisfactory[13].

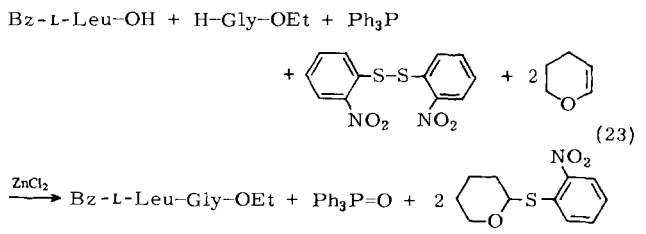
In addition to *p*-methoxyphenylmercury(II) compounds, other kinds of reagents which are reactive enough to capture thiols have also been shown to participate in this type of reaction. For example, sulfenic acid esters, which are known to react with thiols to yield disulfanes, can be effectively used as scavengers [Eq. (21)].

$$R^1S\text{-}OR^2 + R^3SH \longrightarrow R^1S\text{-}S\text{-}R^3 + R^2OH \quad (21)$$

Reaction of Bz-L-Leu-OH with Nps-Gly-OEt in the presence of triphenylphosphane and methyl 2,4-dinitrobenzenesulfenate gives [according to Eq. (22)] Bz-L-Leu-Gly-OEt in high yield and with high optical purity[14].

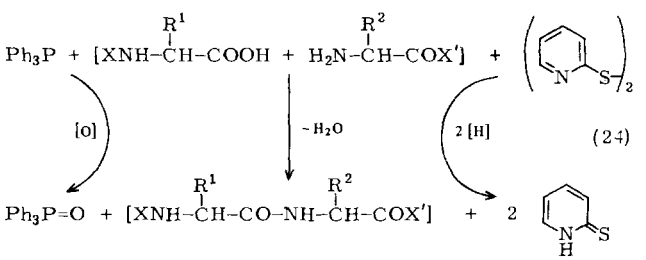
$$Bz\text{-L-Leu-OH} + Nps\text{-Gly-OEt} + Ph_3P + \text{  } \rightarrow \quad (22)$$
$$Bz\text{-L-Leu-Gly-OEt} + Ph_3P{=}O + \text{  } + CH_3OH$$

Further, in a similar reaction, vinyl ethers can also act as thiol scavengers [Eq. (23)][14].



The dipeptides obtained in both of these reactions undergo little racemization and highly optically active products are usually obtained.

Thiols such as 1-pyridinethiol, which bear the mercapto group at the α- or γ-position are well known to exist predominantly in the thione form in solution[15]. Accordingly, peptide synthesis by means of the phosphane-disulfane system appears to take place successfully in the absence of thiol scavengers when disulfanes derived from such thiols are used. In this reaction, 2-pyridinethiol—a hydrogenated product produced along with the peptides—would isomerize to the stable thione form which is unreactive towards the other reaction partners. Thus, treatment of Bz-L-Leu-OH with H-Gly-OEt in the presence of triphenylphosphane and di(2-pyridyl)disulfane is shown to lead to the formation of Bz-L-Leu-Gly-OEt in high yield [cf. Eq. (24)][14].



According to the Young test, racemization is highly suppressed in this reaction system and dipeptides with high optical purity are obtained. For example, synthetic Bz-L-Leu-Gly-OEt was shown to be 96% pure L isomer by the Young test. Other disulfanes such as bis(5-nitro-2-pyridyl)-, di(2-benzothiazolyl)- and di(2-benzimidazolyl)disulfane, which take up hydrogen and similarly isomerize to thiones are suitable for peptide synthesis, but not di(4-pyridyl)disulfane[16].

This reaction is found to offer significant advantages in peptide synthesis. It can be carried out in a wide variety of solvent systems; some modifications are necessary though when acetonitrile or *N*,*N*-dimethylformamide is used. Racemization is largely suppressed if 1 equivalent of 2(1*H*)-pyridinethione is added at room temperature to the acetonitrile (yield: 89%; L isomer: 94%) or 2 equivalents of 2(1*H*)-pyridinethione are added at −30°C to the *N*,*N*-dimethylformamide (yield: 88%; L isomer: 94%) at the beginning of the reaction. In the presence of chloride ions (use of glycine ester hydrochloride and 1 equivalent of triethylamine in chloroform), addition of 2 equivalents of 2(1*H*)-pyridinethione or *N*-hydroxysuccinimide at room temperature gives favorable results [2(1*H*)-pyridinethione (yield: 88%; L isomer: 87%); *N*-hydroxysuccinimide (yield: 91%; L isomer: 86%)].

The presence of water has little effect on the reaction. On initially adding 1 equivalent of 2(1*H*)-pyridinethione in the precence of a tenfold excess of water in dioxane the yield was 90% (L isomer, by the Young test: 94%). Further, the reaction can be carried out over a wide range of temperatures (from −70°C to the boiling point of methylene chloride). The fact that the solvent can be freely chosen makes it possible to employ the solid phase method. A specially practical merit of this method is in its compatibility with most of the other functional groups: no difficulties are encountered when methionine, cysteine, or tryptophan carbonyl groups are coupled with amino groups, and the hydroxyl groups in tyrosine, threonine and serine can be used without protection. Favorable results are also obtained in the case of nitroarginine, which is transformed into the lactam in the usual methods[17] and in the cases of glutamine and asparagine no nitrile formation is observed. For example, whereas water is frequently cleaved at the wrong position in the peptide synthesis with dicyclohexylcarbodiimide (DCC)—as in the formation of anhydro derivatives of asparagine or glutamine—the present method proceeds without complications in this connection because the triphenylphosphane/dipyridyldisulfane reagent is inert toward substrates of low acidity such as amide linkage[18]. Thus, in the reaction according to Eq. (25) with DCC as condensing agent, 35% peptide and 28% anhydro compound are formed

Table 1. Peptides synthesized by oxidation-reduction condensation.

Bzl = C_6H_5-CH_2- (25)

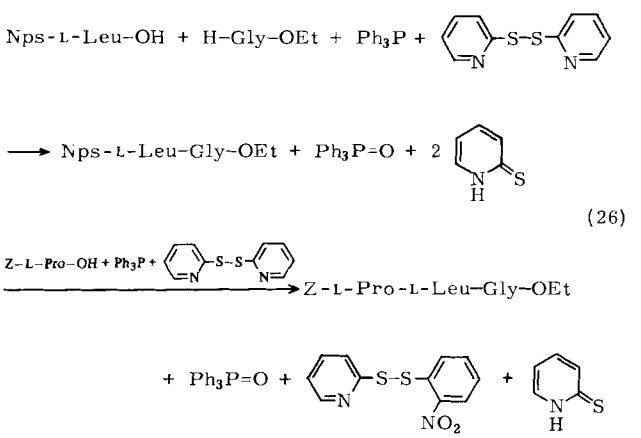
+ Anhydro compound

whereas by oxidation-reduction condensation 73% peptide and only a trace of anhydro compound are obtained.

Hence, analytically pure peptides can be prepared by this extremely simple procedure. Peptides with functional groups in the side chains that have so far been obtained by this procedure are listed in Table 1.

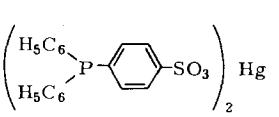
The triphenylphosphane/dipyridyldisulfane reagent (abbrev. $Ph_3P/(PyS)_2$) is very useful for the elongation of a peptide chain by two amino residues. For example, coupling of Nps-L-Leu-OH and H-Gly-OEt by $Ph_3P/(PyS)_2$, followed by the usual washing and drying, and subsequent treatment of the reaction mixture containing Nps-L-Leu-Gly-OEt with Z-L-Pro-OH and $Ph_3P/(PyS)_2$ afforded Z-L-Pro-L-Leu-Gly-OEt in 78% yield [Eq. (26)]. Z-L-Ile-L-Gln-L-Asn-OBu^t was likewise obtained in 72% yield by coupling Z-L-Ile-OH with Nps-L-Gln-L-Asn-OBu^t. Formation of pyroglutamine was not observed; hence, this method is suitable for the synthesis of glutamyl peptides.

Acylamino acids with free COOH groups can also be prepared by oxidation-reduction condensation[18]. The active pentachlorophenyl esters of Gln, Asn and Arg(NO_2) precipitate from the reaction mixture as crystalline products and



(26)

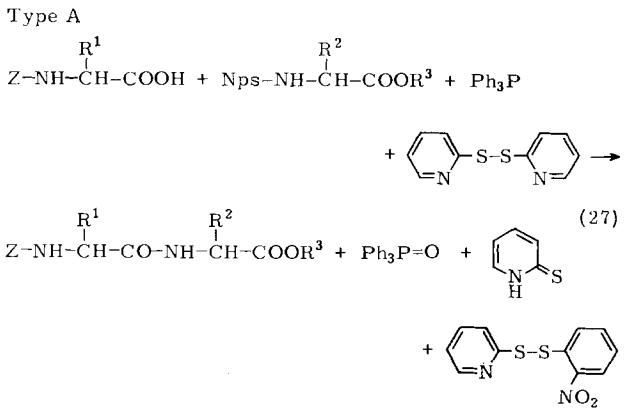
are already analytically pure after simple filtration and washing. More soluble active esters were prepared using the modified phosphane, mercury bis(diphenylphosphinobenzenesulfonate). The phosphane oxides that are formed are removed by washing with water, and the active esters are purified by one recrystallization.



The peptide syntheses by oxidation-reduction condensation with $Ph_3P/(PyS)_2$ are summarized in Equations (27)—(29).

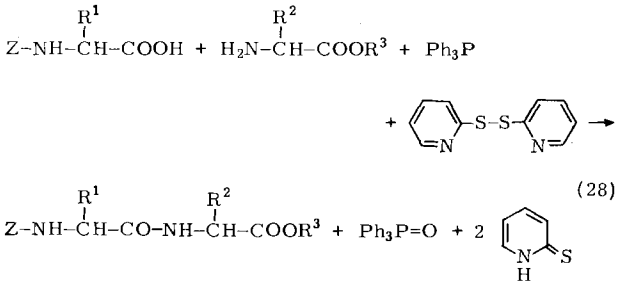
Biologically active oxytocin can be conveniently prepared with these reactions. The protected nonapeptide was obtained in 91% yield by a type C reaction using 50% excess of reagents. After HF treatment and air oxidation, the synthetic oxytocin (in solution) showed a depressor activity of 104 unit/mg[19].

Type A



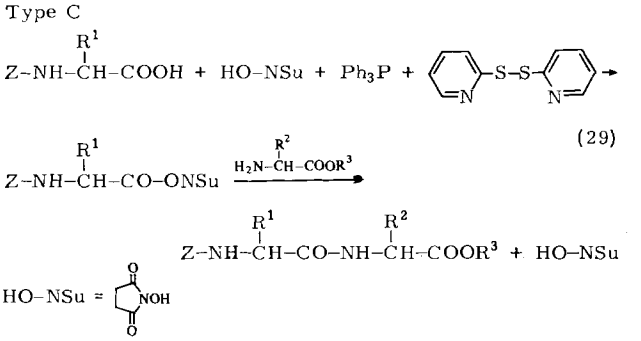
(27)

Type B



(28)

Type C



(29)

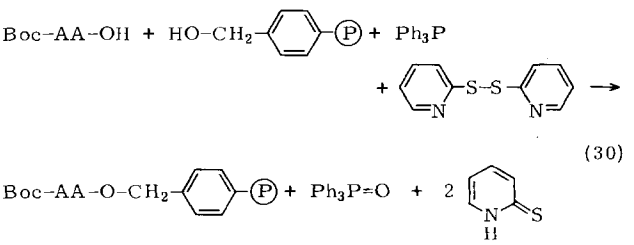
Application of the oxidation-reduction condensation method to solid phase peptide synthesis was also investigated. This study was focused on developing a general procedure for anchoring the first C-terminal amino acid to the polymer support.

In the solid phase peptide synthesis with DCC, the peptide linkages are formed under mild conditions. However, introduction of the first amino acid into the resin necessitates refluxing the amino acids and the resin at 80°C for 48 h. It seems desirable that both the attachment of the first amino acid to the resin and the subsequent couplings can be carried out under mild conditions using the same procedure. Hence the utilization of oxidation-reduction condensation for this purpose was investigated. First, the usual 2% crosslinked chloromethyl resin (Schwarz-Mann, New York, Cl content 2.0 mmol/g) was converted by a well known procedure into a hydroxymethyl resin. Esterification of this resin with various amino acids and peptide fragments [Eq. (30)] was studied; some favorable results were obtained.

Amino acids and peptide fragments are easily attached to the resin by this procedure. No nitrile formation or transesterification was observed in the case of Asp and Glu. Favorable results were also obtained with Arg, Cys and Trp whose

attachment to the resin has previously never been reported. Boc-Met-OH and Boc-His(Bzl)-OH can also be attached.

This method has the following special merits in solid phase peptide synthesis: All Boc amino acids and peptides tested so far can be attached in any desired amount and in relatively homogeneous environment on the resin. This esterification



(30)

AA = Amino acid residue Ⓟ = Polymer;
Boc = $(CH_3)_3C$–O–CO–

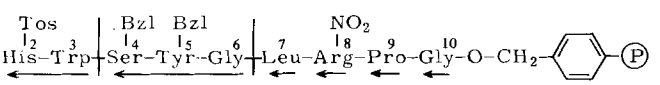
proceeds more rapidly and under milder conditions than in the ordinary method. Moreover, the reaction conditions and preparative operations are the same as for subsequent chain-lengthening acylations and, consequently, incorporation of the esterification step in the automated process is possible. Utilization of this method has led to the successful synthesis of bioactive LH-RH and ACTH.

2.1. Synthesis of LH-RH

LH-RH is the hormone which liberates the luteinizing hormone. Pure LH-RH with the full activity of natural LH-RH was synthesized by oxidation-reduction condensation of peptide fragments on a solid support by employing two types of chain elongation, that from C-terminal amino acid (type A elongation) and that from N-terminal amino acid (type B elongation)[20].

2.1.1. Type A Chain Elongation

The synthesis of the LH-RH-nonapeptide (2—10 sequence) was successfully achieved by the solid phase method as shown in (31). Each arrow corresponds to a coupling step.

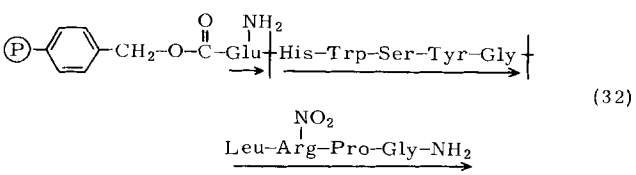


(31)

The nonapeptide was liberated by ammonolysis and was converted into LH-RH by coupling with Glu-OPcp (Pcp = pentachlorophenyl).

2.1.2. Type B Chain Elongation

The building of decapeptide was achieved by employing the three fragments with the 1, 2—6 and 7—10 amino acid sequences as shown in (32).



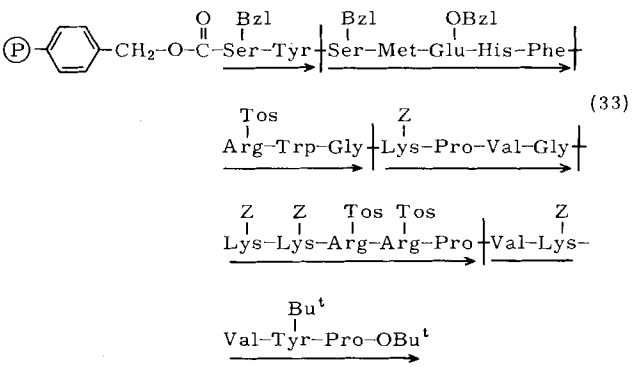
(32)

The decapeptide amide is liberated from the resin with HF and converted into LH-RH by cyclization of the glutaminyl residue. Fully active LH-RH is obtained in 51% yield based on glutamine-resin employed.

In this way, chain elongation can be carried out with minimum protection of side chains and excess amino components can be recovered unchanged.

2.2. Synthesis of $ACTH^{1-24}$

$ACTH^{1-24}$ is synthesized on a solid support by oxidation-reduction condensation as shown in (33)[21].



(33)

The synthesis begins with the N-terminal amino acid (type B elongation). The coupling rates were monitored during the reaction by quantitative determination of the fragments in solution by high pressure liquid chromatography on aminated Hitachi Gel 3010[22].

Pure $ACTH^{1-24} \cdot 7\,AcOH \cdot 9\,H_2O$ was obtained in 25% yield from the initial resin-Ser-Tyr after HF treatment and purification on Sephadex G-25 and carboxymethylcellulose. Amino acid ratios determined after complete enzymatic digestion and acid hydrolysis were in good agreement.

The ACTH activity of this purified peptide was assayed by the ascorbic acid depletion test according to U.S.P. XVIII. Referred to the 2nd international standard it exhibited an activity of 96 (83—128) IU/mg. This value agrees with that given in the literature.

Some of the particular merits of this method for the peptide synthesis are as follows: i) unreacted amino acid derivatives can be recovered and accordingly can be recycled in the chain elongation procedure; ii) the number of protecting groups on the side chains can be reduced; iii) smaller peptide fragments can be synthesized by classical methods from readily available Z-amino acids; iv) diacylations are avoided since excess amino acid derivatives are used in solution; v) the end product is homogeneous since contaminations by similar peptides are eliminated; vi) the number of acidolyses can be reduced—which is of importance for the acid-sensitive tryptophan residue; vii) the progress and completeness of each coupling reaction is easily monitored by high pressure liquid chromatography.

The versatility of this approach, along with a combination of classical syntheses in solution, opens up new possibilities for facile preparation of pure long-chain peptides and significantly extends the scope of solid phase peptide synthesis.

3. Nucleotide Synthesis

The oxidation-reduction condensation reaction can also be used for the synthesis of nucleotide derivatives.

3.1. Synthesis of Nucleoside 2',3'- and 3',5'-Cyclophosphates

Nucleoside-2',3'- and -3',5'-cyclophosphates can be synthesized by oxidation-reduction condensation from nucleoside-2'- and -5'-phosphates, respectively[23]. Table 2 lists some compounds which have so far been obtained in this way.

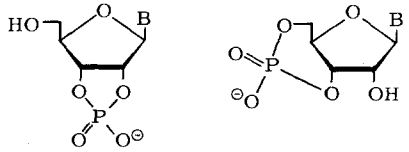


Table 2. Nucleoside cyclophosphates synthesized by oxidation-reduction condensation.

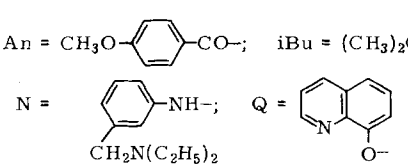
Nucleotide	Yield [%]	Nucleotide	Yield [%]
2',3'-cyclic AMP	quant.	3',5'-cyclic AMP	85
2',3'-cyclic CMP	quant.	3',5'-cyclic CMP	56
2',3'-cyclic GMP	quant.	3',5'-cyclic GMP	85
2',3'-cyclic UMP	quant.	3',5'-cyclic UMP	80
4',5'-cyclic FMN [a]	quant.	3',5'-cyclic TMP	70

[a] FMN refers to flavin mononucleotide.

3.2. Synthesis of Oligonucleotides

3'—5'-linked deoxyribooligonucleotides such as dinucleoside phosphates[23], dinucleotides[24], trinucleoside diphosphates[23, 25], and trinucleotides[26] can also be synthesized in high yields by the new method. A selection of these is shown in Table 3.

Table 3. Oligonucleotides synthesized by oxidation-reduction condensation.

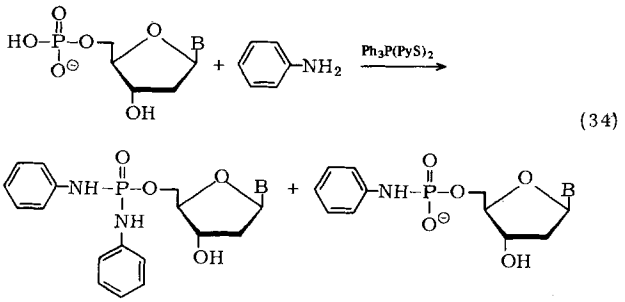


Nucleotide	Yield [%]	Nucleotide	Yield [%]
d(TpT)	90	d(TpC)	84
d(TpA)	86	d(TpG)	80
d(NpA^{Bz}pA^{Bz}OAc)	51	d(NpTpTOAc)	50
d(QpTpC^{An}OAc)	58	d(QpTpG^{iBu}OAc)	55
d(TpApT)	60	d(ApApA)	60
d(NpA^{Bz}pTpTOAc)	74	d(NpA^{Bz}pTpG^{iBu}OAc)	21

Further, TpTpTpT was obtained in 50% yield from TpTpT and 3 equivalents of 3'-*O*-acetylthymidine 5'-phosphate.

3.3. Synthesis of Oligonucleotides with Phosphorodianilidates

Nucleotide 5'-phosphorodianilidates were prepared as shown in the following scheme [Eq. (34)]. The results are summarized in Table 4[27].



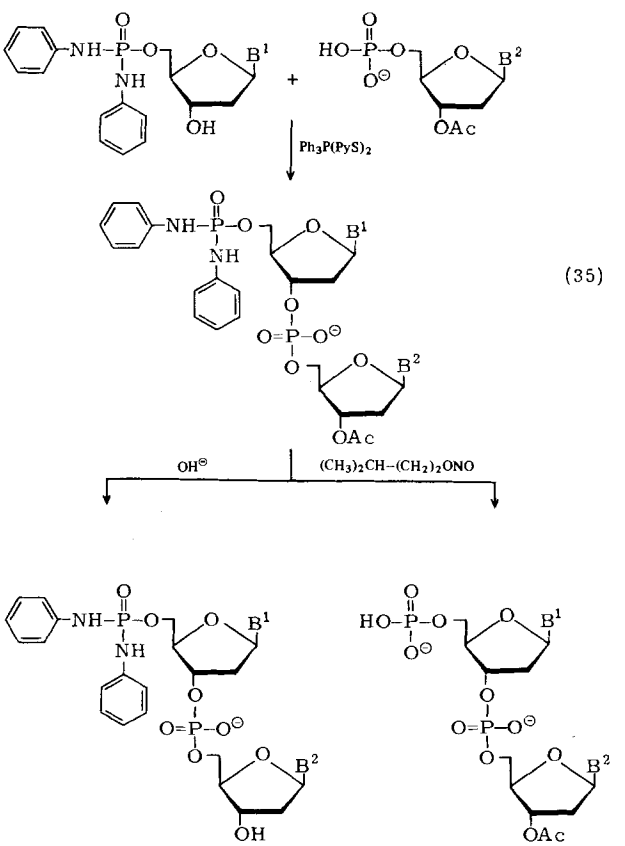
(34)

Table 4. Nucleotide 5'-phosphorodiamidate synthesized by oxidation-reduction condensation.

B	Amine	Reaction time (days)	Yields [%] Phosphoro-monoamidate	Phosphoro-diamidate
T	aniline	2	35	65
T	morpholine	5 [a]	82.5	17.5
		1	57	43
		3	17	64
A^{Bz}	aniline	2	35	65
C^{An}	aniline	2	41	59
G^{iBu}	aniline	2	40	60

[a] Five hours.

Protected dinucleotides (cf. Table 5)[27] can be obtained by condensation of the phosphorodianilidates with protected mononucleotides according to Eq. (35).

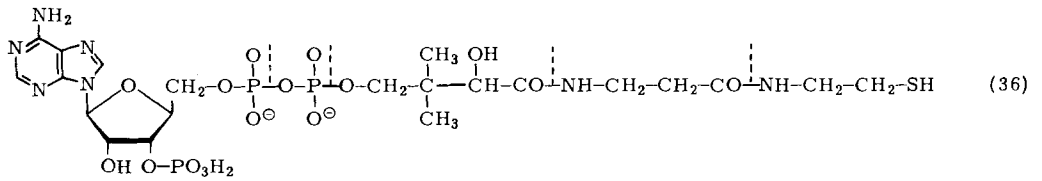


(35)

Table 5. Protected dinucleotides with 5'-phosphate groups synthesized by oxidation-reduction condensation.

Dinucleotide	B^1	B^2	Amount [mmol]	$Ph_3P/(PyS)_2$ [mmol]	Yield [%]
d(pTpTOAc)	dpT	dpTOAc	0.1	0.5	70
d(pTpC^{An}OAc)	dpT	dpC^{An}OAc	0.07	0.5	50
d(pTpA^{Bz}OAc)	dpT	dpA^{Bz}OAc	0.07	0.5	51
d(pA^{Bz}pTOAc)	dpA^{Bz}	dpTOAc	0.1	1	75
d(pA^{Bz}pA^{Bz}OAc)	dpA^{Bz}	dpA^{Bz}OAc	0.1	1	70
d(pA^{Bz}pC^{An}OAc)	dpA^{Bz}	dpC^{An}OAc	0.1	1	70

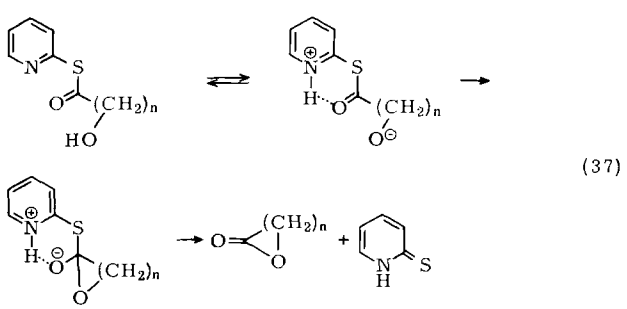
The total synthesis of coenzyme A by utilization of oxidation-reduction condensation in each important step was accomplished in accordance with (36)[28].



(36)

4. Macrolide Synthesis

The oxidation-reduction condensation was used by *Corey et al.*[29] for the internal esterification of hydroxy acids whereby medium- and large-ring lactones are formed. The method proved highly effective and yet mild enough to be used with complex and polyfunctional substrates. *Corey et al.* developed this reaction on the basis of the following consideration: One way of simultaneously activating both the carboxyl and hydroxyl groups for mutual reaction would be to utilize a carboxylic derivative which would favor proton transfer from hydroxyl to carboxylic oxygen. By way of example, an *S*-2-pyridyl ester of an ω-hydroxymonothiocarboxylic acid reacts as shown in Eq. (37). As indicated in Table 6, good to excellent yields are obtained except in the case of the nine-membered ring.



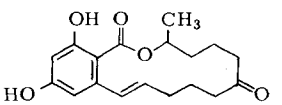
(37)

Table 6. Synthesis of lactones and dimeric lactones (diolides) by cyclization of the *S*-2-pyridyl esters of ω-hydroxycarboxylic acids ($n = 5, 7, 10, 11, 12, 14$) in xylene. After slow addition of thioate to refluxing xylene the whole was further refluxed for a further 10 h.

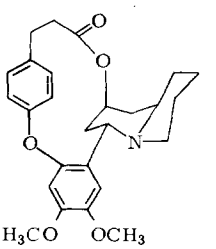
	Lactone			Diolide	
n	Ring size	GLC yield [%]	Isolated yield [%]	Ring size	Isolated yield [%]
5 [a]	7	87	71	14	7
7 [b]	9	25	8	18	41
10 [c]	12	64	47	24	30
11	13	76	66	26	7
12	14	79	68	28	6
14	16	88	80	32	5

[a] Solvent benzene; [b] reaction time 30 h; [c] reaction time 20 h.

The method can also be used for the lactonization of more complex hydroxy acids. Thus a series of novel macrocyclic lactones, such as (±)-zearalenone, prostaglandin F_2 1,9-lactone, prostaglandin F_2 1,15-lactone, the lactone of the polyether antibiotic monensin, brefeldin A, carpaine, vertaline, and erythronolide B were obtained from the hydroxy acid derivatives[29–31].



(±)-Zearalenone

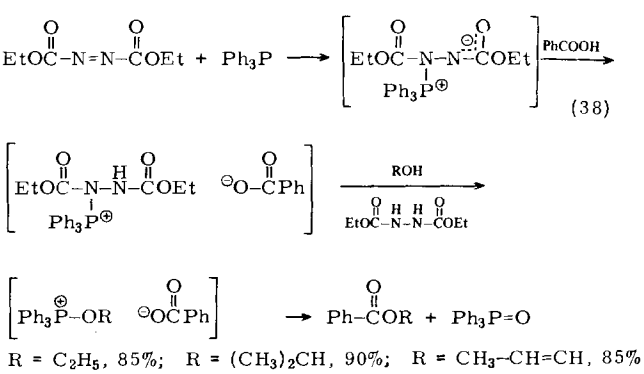


Vertaline

5. Related Reactions

5.1. Oxidation-Reduction Condensations with Triphenylphosphane and Diethylazodicarboxylate

Intermolecular and intramolecular dehydrations with triphenylphosphane and diethylazodicarboxylate have been reported by *Mitsunobu et al.*[32]. The reaction of benzoic acid with alcohols in the presence of this reagent at room temperature resulted in the formation of the corresponding carboxylic esters in good yields. The reaction is assumed to proceed *via* an alkoxyphosphonium salt as shown in Eq. (38).

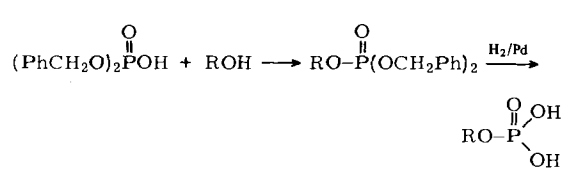


(38)

R = C_2H_5, 85%; R = $(CH_3)_2CH$, 90%; R = CH_3–CH=CH, 85%

Similarly, thymidine and uridine react with carboxylic acids to give the corresponding 5'-*O*-acylnucleosides in good yields[33].

Dibenzyl hydrogen phosphate reacts smoothly with alcohols and with nucleosides in the presence of triphenylphosphane and diethylazodicarboxylate, and after hydrogenolysis, alkyl- and nucleoside-5'-dihydrogen phosphate are formed in good yields[34, 35]. Selective phosphorylation of nucleosides can be effected by this procedure [Eq. (39)][35].



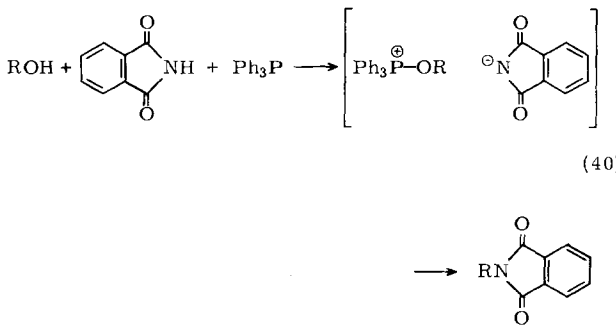
(39)

ROH = C_2H_5OH, 92%; ROH = n-C_3H_7OH, 96%;
ROH = Thymidine, 77%; ROH = Uridine, 63%

That the reaction involves initial activation of alcohol was proved by the reaction of an optically active (*S*)-(+)-2-octanol with benzoic acid to give (*R*)-(−)-2-octyl benzoate in high optical yield[34]. *Bose et al.*[36] have reported that the present system could be utilized for inversion of configuration of unhindered steroids. Treatment of steroid alcohols with carboxylic acids in this way, furnishes stereochemically pure esters with inverted configuration in good yield (75—100%).

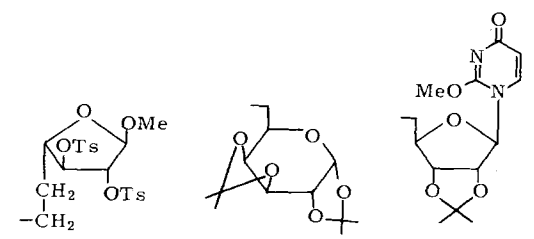
The reaction should therefore be rationalized in terms of alkylation of the carboxylic acid or phosphoric acid rather than acylation or phosphorylation of the alcohol. Namely, the alkoxyphosphonium salt is a strong alkylating reagent.

This system has been used in the alkylation of weak acids such as imides and compounds containing active methylene groups. Thus, reaction of phthalimide with alcohols gives *N*-alkylphthalimides in yields of 60—90% [Eq. (40)][37-39]. Since these products are converted into amines on treatment with hydrazine hydrate, the reaction provides a means of converting alcohols into amines.

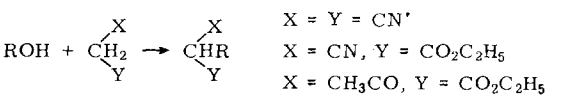


(40)

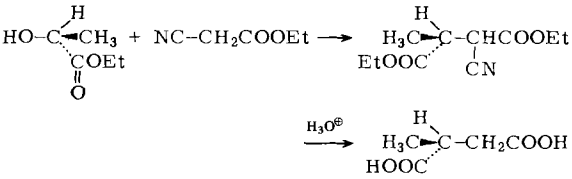
R = CH_3–CH=CH–CH_2–, C_2H_5–, CH_2=CH–CH_2–, n-C_3H_7–, $ClCH_2$–CH_2–, n-C_4H_9–, $C_2H_5O_2C$–CH_2–, CH_3–CH(C_2H_5)–, CH_3–, CH_3–CH(C_6H_{13})–, –C(H)(CH_3)(C_6H_{13})



Moreover, compounds with active methylene groups can also be alkylated with diethylazodicarboxylate and triphenylphosphane [Eq. (41)]. The yield of alkylated product increases



(41)



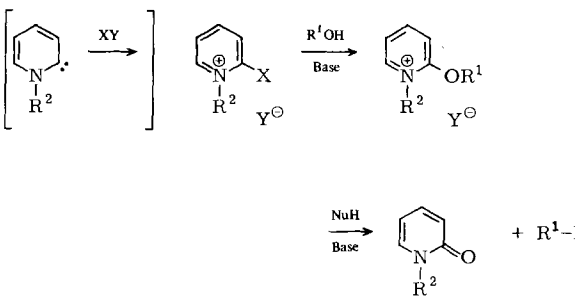
(42)

to 80% when the reaction mixture is allowed to stand for several days. Since the reaction takes place under mild neutral conditions, the procedure ought to be suitable for the synthesis of optically active compounds [Eq. (42)][40].

Recently, *Bittner* and *Assaf* reported that the present system can be utilized for the preparation of aryl ethers. The yield of ether is 75—80% within two hours, while the maximum yield (80—98%) is obtained after the reaction mixture has been left to stand for an additional 12 hours at room temperature[41].

5.2. Condensations with Pyridinium Salts

Recently, a new type of dehydration condensation reaction with pyridinium salts has been developed[42]. This reaction has a wide scope of application; it is suitable, for example, for the synthesis of esters, amides, and phosphoric esters and for alkylations.



(43)

If it is assumed that the pyridinium salt is formed from the given carbene-like species, then the overall reaction could be classed as an oxidation-reduction condensation.

Since all reaction steps take place with involvement of the pyridinium salt, the condensation reaction should be favored from the point of view of entropy. Indeed, the preparation of esters and amides proceeds in high yields even with equivalent amounts of the reactants. Consequently, it would appear that the reaction can be resorted to in numerous synthetic schemes.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Novel 1,2,4-Thiadiazolidine 1-Oxides and 1,1-Dioxides from 2-Imino-1,3-thiazetidines

By *Walter Ried*, *Oskar Mösinger*, and *Walter Schuckmann*[*]

The action of hydrogen peroxide/glacial acetic acid on 2-imino-1,3-thiazetidines *(1)*, which are accessible from *N,N'*-disubstituted thioureas, diiodomethane, and triethylamine[1,2], leads not to the 2-imino-1,3-thiazetidine 1,1-dioxides *(3)*, but, surprisingly, with ring expansion to the 3-oxo-1,2,4-thiadiazolidine 1-oxides *(5)*. The oxidation products were identified by X-ray structure analysis of *(5b)* and *(5c)*[3] since no distinction could be made between the isomers *(3)*—*(5)* on the basis of spectroscopic data (Table 1). The 1,2,4-thiadiazolidine 1-oxide system was recently mentioned for the first time in another connection[4].

We assume that *(5)* is formed *via* the two non-isolable intermediates *(2)* and *(4)*. The initially formed *S*-oxide *(2)* experiences an oxygen insertion resulting in ring expansion analogous to the Baeyer-Villiger oxidation to give *(4)*. Subsequent Dimroth rearrangement leads to *(5)*.

Oxidation of *(5)* with H_2O_2/glacial acetic acid furnishes the 3-oxo-1,2,4-thiadiazolidine 1,1-dioxides *(6)* (Table 1). The reaction affords a novel entry to this class of compound, whose preparation was first reported only recently[5].

1,2,4-Thiadiazolidine 1-oxides (5) and 1,1-dioxides (6)

To a solution of *(1)* (5 mmol) in glacial acetic acid (50 ml) [in the case of *(1f)* 150 ml] is added 2.1 equivalents of hydrogen peroxide (35% aqueous solution). The mixture is allowed to stand for 6 days at room temperature and the solvent removed by distillation in a rotary evaporator. The residue, in the case of *(5e)* and *(5f)*, is recrystallized (white needles) from ethanol. In the case of *(5a)*—*(5d)* the residue is taken up in chloroform, filtered, and the filtrate evaporated to dryness. *(5a)* crystallizes on addition of ethanol/*n*-hexane; *(5b)*—*(5d)* are obtainable (as white crystals) after recrystallization from ethanol.

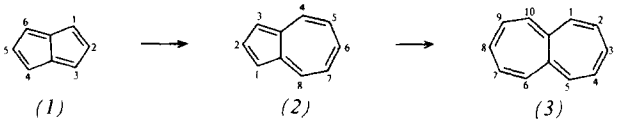
Cycloadditions of Pentalene and Azulene—A Facile Heptalene Synthesis[**]

By *Klaus Hafner, Herbert Diehl,* and *Hans Ulrich Süss*[*]

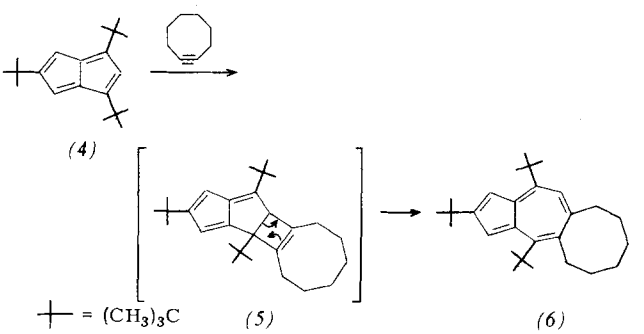
The two lowest homologs of the annulene series, *i.e.* cyclobutadiene and benzene, are known to undergo either thermally or photochemically induced [2+4] and [2+2] cycloadditions with reactive alkynes to give cyclobutene derivatives. Valence isomerization of the latter affords the next higher vinylogous annulene, *i.e.* benzene and cyclooctatetraene respectively[1,2]. A similar transformation should also be feasible



(1) *(2)* *(3)*

in the homologous series of nonalternant bicyclic hydrocarbons pentalene *(1)*, azulene *(2)*, and heptalene *(3)*, which differ from each other by possessing one additional vinylene group each, and thus provide new entries to these ring systems. Studies on transformations of cyclopent[*cd*]azulene[3], 1,3-bis(dimethylamino)pentalene[4], and hexaphenylpentalene[5] with dimethyl acetylenedicarboxylate into derivatives of aceheptylene and azulene prompted us to investigate the ring expansion of *(1)* to *(2)* and above all that of *(2)* to *(3)*. In the course of this work we discovered a surprisingly simple and universal synthesis of stable heptalene derivatives.

Conversion of *pentalene* into *azulene:* As expected, *(4)*[6] which is the simplest pentalene derivative hitherto isolated, rapidly reacts with activated alkynes and especially with the highly strained cyclooctyne at 270 °C (presumably *via* intermediate formation of the cyclobutene derivative *(5)*) to give a 70% yield of 2,4,12-tri-*tert*-butyl-5,6,7,8,9,10-hexahydrocycloocta[*f*]azulene *(6)* (blue radial needles, m.p. 70—72 °C)[7].



(4) *(5)* *(6)*

Exclusive formation of *(6)* even at high temperatures indicates on the one hand the lack of tendency of dimerization of *(4)*, in contrast to pentalene and its methyl derivatives[8] and on the other the marked effect of substituents upon product formation. As in the dimerization of 2-methylpentalene[8] and 1,5-dimethylpentalene[9], cycloaddition in the five-membered ring of *(4)* bearing an alkyl group in position 2 (≡ 5) is hindered—mostly for obvious steric reasons.

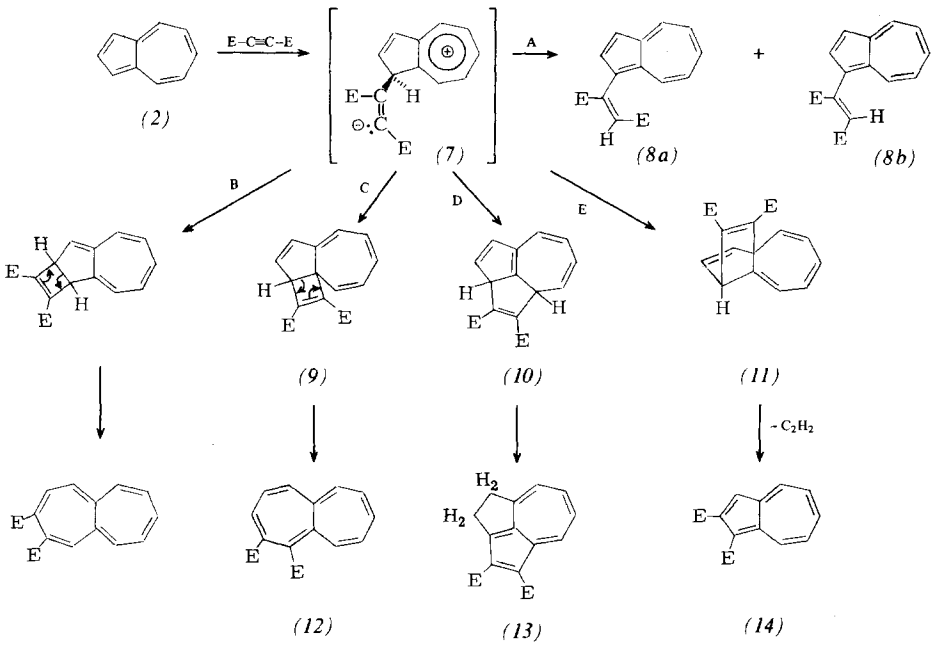
Conversion of *azulene* into *heptalene*: According to an observation by *W. Treibs*[10], azulene *(2)* reacts with acetylenedicarboxylic acid and its esters at elevated temperature and especially in the presence of Lewis acids *via* additive substitution to give 1-azulenylmaleic acid and its esters of type *(8b)*, the resonance stabilized dipolar intermediate *(7)* probably being formed first. It was expected that this intermediate can stabilize basically not only by re-aromatization of the azulene system to give *(8)* but also initially by formation



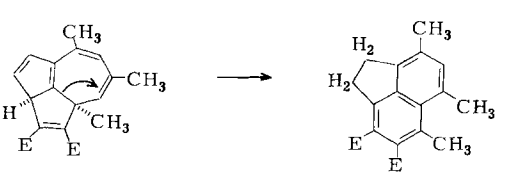
E = $COOCH_3$

of one or several cycloadducts *(9)*—*(11)*. We suspected that *(8)* is formed preferentially in the presence of proton donors or reagents promoting a proton shift, while in their absence the paths B-E may also play a role. Our experiments did confirm these expectations.

Reaction of *(2)* with dimethyl acetylenedicarboxylate in boiling tetralin in the presence of 5% trifluoroacetic acid (1 h) affords 35% of a 1:1 mixture of dimethyl 1-azulenylfumarate *(8a)* and 1-azulenylmaleate *(8b)* (olive green oil)[11] (path A). In contrast, the same reaction of *(2)* without trifluoroacetic acid added does not afford *(8)* but rather 15% of the thermally and air-stable dimethyl 1,2-heptalenedicarboxylate *(12)* [red leaflets, m. p. 114—115 °C; UV (*n*-hexane): $\lambda_{max}=204$ ($\log\varepsilon=4.36$), 266 (4.29), 337 (3.63); 60 MHz ^{1}H-NMR ([D_6]acetone): $\tau=2.73$ (d, $J=7$ Hz, H-3); 3.30—4.30 (m, 7H), 6.29 and 6.36 (s, 2$COOCH_3$)] together with 1% of dimethyl 3,4-dihydro-1,2-cyclopent[*cd*]azulenedicarboxylate *(13)* (violet crystals, m. p. 138—139 °C) and 1% of dimethyl 1,2-azulenedicarboxylate *(14)* (reddish violet crystals, m. p. 49—50 °C)[12]. *(12)*—*(14)* can easily be separated by column chromatography [Al_2O_3; *n*-hexane/ether (5:1)] on account of their different R_f values and colors.

In accord with our assumption, the heptalene derivative *(12)* should result from valence isomerization of *(9)* (path C), the tricyclic species *(13)* from rearomatization of the primary adduct *(10)* to the azulenoid system (path D), and *(14)* from a cycloreversion of the adduct *(11)* with elimination of acetylene (path E). Formation of *(14)* formally resembles the [2+8] cycloaddition of heptafulvene with dimethyl acetylenedicarboxylate, which has already been observed by *Doering et al.*[12] and leads to the same azulene derivative. The surprisingly simple formation of *(12)* from *(2)*, which is also available in larger quantities, provides a convenient preparative entry to numerous derivatives of the heptalene system. That system has hardly been studied and was hitherto only accessible in very low overall yields[13]; its stabilization by two ester groups in positions 1 and 2 corresponds to that of the 3,8-heptalenedicarboxylic ester recently described by *Vogel et al.*[13b]. The spectroscopic properties of *(12)* are in agreement with the nonplanar structure of the bicyclic system, established by X-ray structure analysis[14].

Similarly to *(2)*, alkylated azulenes react with dimethyl acetylenedicarboxylate to form corresponding alkyl derivatives of *(8)*, *(12)*, *(13)*, and *(14)*. Thus the analogous reaction of 4,6,8-trimethylazulene in the presence of 5% trifluoroacetic acid yields 25% each of dimethyl 4,6,8-trimethyl-1-azulenylfumarate (violet crystals, m. p. 106—107 °C) and -maleate (violet crystals, m. p. 109—110 °C) (path A), and 5% of dimethyl 4,6,8-trimethyl-1,2-azulenedicarboxylate (reddish violet crystals, m. p. 138—139 °C) (path E). In contrast, the same reaction in the absence of protic acids leads to 45% of a mixture of thermally stable dimethyl 6,8,10-trimethyl-2,3- and 1,2-heptalenedicarboxylate[11] in the ratio 1:2.5 (paths B and C)



besides 5% of dimethyl 4,6,8-trimethyl-1,2-azulenedicarboxylate (path E) and 4% of dimethyl 5,6,8-trimethyl-3,4-acenaphthylenedicarboxylate *(16)* (yellowish needles, m. p. 179—181 °C) arising from skeletal rearrangement and by hydrogen shift from the adduct *(15)* analogous to *(10)* (path D).

(1a) *(1b)* *(2)*

the bicyclic system from the ^{1}H-NMR spectrum of heptalene[2]. *Vogel, Oth, et al.* synthesized heptalene and stabilized heptalenes, and found heptalene to undergo a fast π-bond shift with an activation energy of 14.7 kJ mol^{-1}[3].

We have performed an X-ray structure analysis on dimethyl 1,2-heptalenedicarboxylate *(2)*[4] which is stabilized by ester groups and has been synthesized by *Hafner* and *Diehl*. Compound *(2)* forms monoclinic red leaflets of m. p. 114—115 °C; $a = 1242 \pm 1$, $b = 818 \pm 1$, $c = 1396 \pm 1$ pm, $\beta = 105.14 \pm 0.05°$, $V_{UC} = 1370 \times 10^6$ pm^3, $Z = 4$, $d_{X\text{-ray}} = 1.310$ g cm^{-3}, $d_{exp} = 1.315$ g cm^{-3}, space group $P2_1/a$.

2160 reflections *hkl* ($0 \le k \le 6$) have been measured with $Cu_{K\alpha}$ radiation ($\lambda = 1.5418$ Å) on a two-circle diffractometer. The structure was solved and refined ($R = 0.098$) with the program system of *Sheldrick*[5].

The heptalene system in *(2)* (Fig. 1a) consists of two boat-shaped seven-membered rings with structural angles of $\alpha = 36.8°$, $\beta = 22.0°$ (substituted ring) and $\alpha = 37.3°$, $\beta = 22.7°$. Although smaller than in other seven-membered rings with three localized double bonds[6], these structural angles nevertheless lead to pronounced deformation of the bicyclic system. The ester groups are twisted by 30° (position 1) and 25° (position 2) relative to the ring. They are arranged in such a way that the slightest mutual approach will lead to maximal

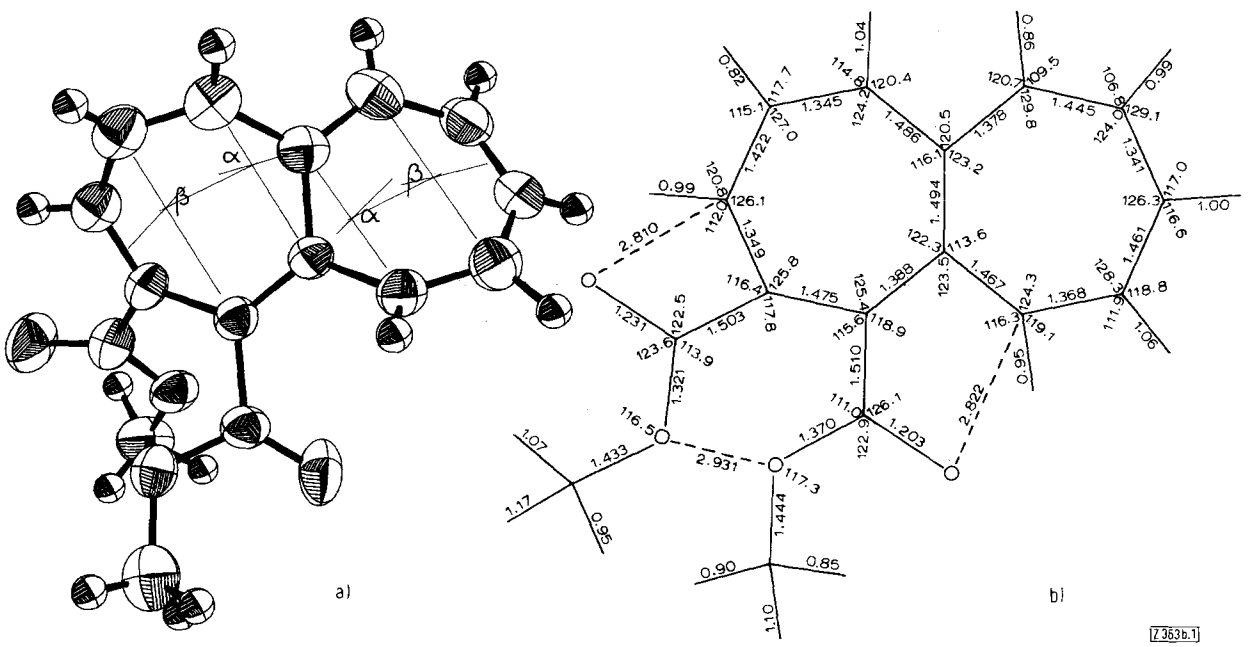

Fig. 1. a) Molecular structure of *(2)*; b) bond lengths and angles (bond lengths in 10^2 pm). Standard deviations: $\sigma_{XX} = 0.8$ pm; $\sigma_{XH} = 7$ pm; $\sigma_{XXX} = 0.5°$; $\sigma_{XXH} = 3.0°$ (X = C, O).

Crystal and Molecular Structure of Dimethyl 1,2-Heptalenedicarboxylate[**]

By *Hans Jörg Lindner* and *Brigitte Kitschke*[*]

Theoretical studies have shown that the localized heptalene structure *(1a)* is energetically preferred over the delocalized structure *(1b)*[1]. *Bertelli* deduced a nonplanar structure of conjugative interaction with the ring system. The bond lengths and angles (Fig. 1b) show an alternance already apparent from the form of the heptalene system.

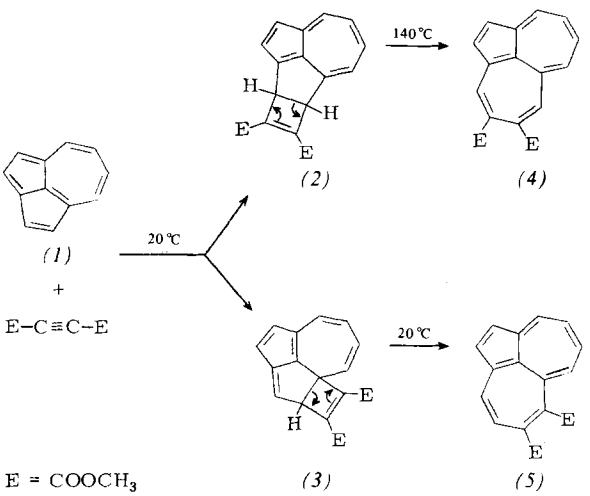
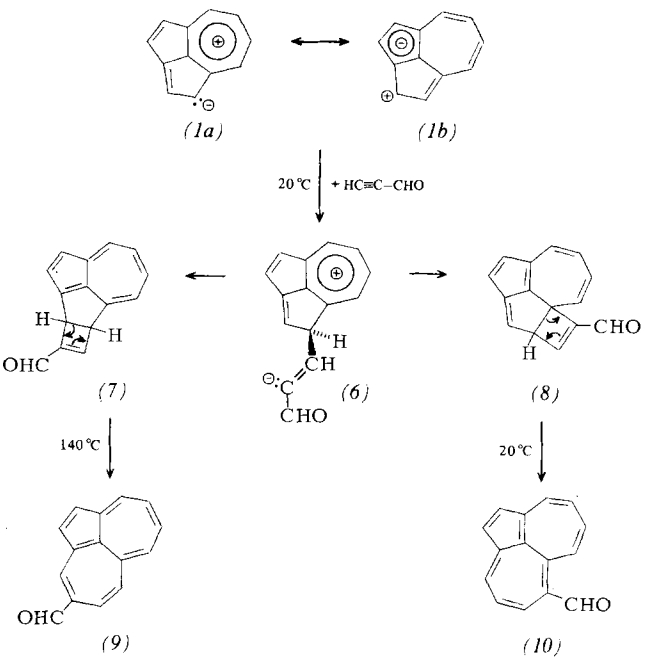
1,4-Dipolar Cycloadditions of Cyclopent[*cd*]azulene[**]

By *Herbert Diehl* and *Klaus Hafner*[*]

Cycloadditions of nonbenzenoid carbo- and heterocyclic conjugated π-electron systems with suitable reactants provide a facile entry to ring systems that were hitherto difficult to prepare, if at all[1]. For instance, cyclopent[*cd*]azulene *(1)*[2] which is now readily accessible reacts with dimethyl acetylenedicarboxylate even at room temperature to give 75% of the 1:1 adduct *(2)* (blue-green leaflets, m.p. 104—105 °C[3]; thermal valence isomerization thereof in boiling xylene yields 95% of dimethyl 4,5-aceheptylenedicarboxylate *(4)* (brown crystals, m.p. 97—98 °C). Formation of small amounts of the isomeric 5,6-diester *(5)* together with *(2)* is in agreement with results of our earlier studies[4]. Compound *(5)* presumably arises from the primary adduct *(3)* which appears to be unstable at as low a temperature as 20 °C. The formation of *(2)* and *(5)* suggests that cycloaddition of *(1)* with alkynes proceeds *via* a two-step mechanism involving a resonance-stabilized 1,4-dipole. The solvent dependence[5] of this cycloaddition and orientation phenomena observed in the reactions of *(1)* with electron-poor and electron-rich alkynes do corroborate this suggestion.



Compound *(1)* rapidly reacts with propiolaldehyde in dichloromethane at 20 °C *via* the primarily formed dipolar intermediate *(6)* to give the adducts *(7)* (yield 76%, blue oil) and *(8)*, which as a result of pronounced ring strain immediately undergoes valence isomerization to 3% of 6-aceheptylenecarbaldehyde *(10)*[6] (reddish brown needles, m.p. 65—66 °C). In contrast, *(7)* is only converted into the isomeric 4-carbaldehyde *(9)*[6] (90% yield, yellowish brown crystals, m.p. 75—76 °C) on heating to 140 °C (boiling xylene, 1 h).



However, *(1)* and its 5,7-dimethyl derivative (R = CH_3) combine with *N,N*-diethyl-1-propynylamine, according to the resonance structure *(1b)*, *via* the dipolar intermediate *(11)* (R = H or CH_3) to give exclusively the adduct *(12)* which immediately affords the aceheptylene derivative *(13)* (R = CH_3; yellowish brown oil, m.p. of the 1,3,5-trinitrobenzene derivative 173—174 °C) by cleavage of the cyclobutene ring[7].

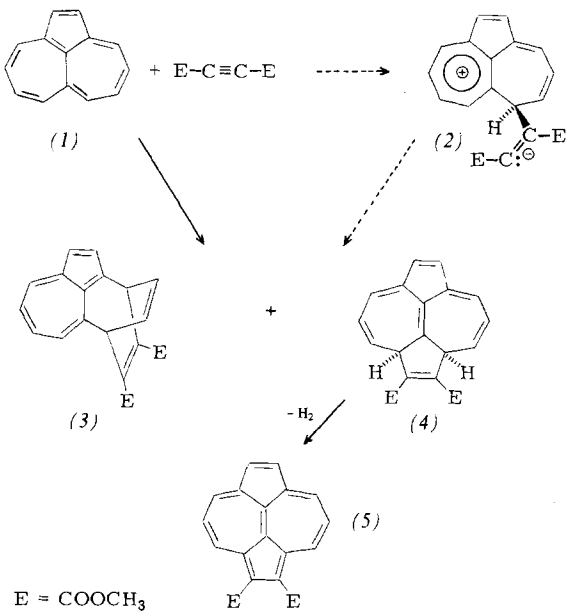
Cycloadditions of Aceheptylene—A Facile Synthesis of Dicyclopenta[*ef,kl*]heptalenes[**]

By *Klaus Hafner, Herbert Diehl*, and *Winfried Richarz*[*]

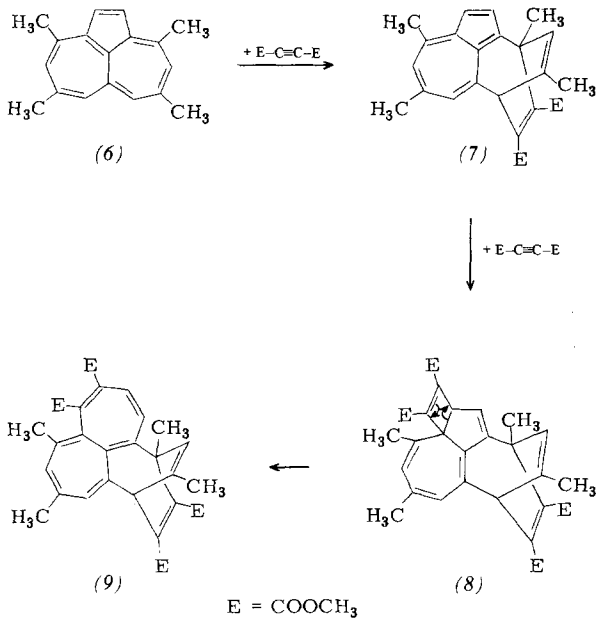
Similarly to pentalene, azulene[1], and cyclopent[*cd*]azulene[2], the readily accessible aceheptylene *(1)*[3] undergoes



cycloaddition with activated alkynes to form novel polycyclic systems in a surprisingly simple manner.

Heating of *(1)* with dimethyl acetylenedicarboxylate in the molar ratio 1:1 in boiling tetralin for 1 h affords 25% of dimethyl 1,2-dicyclopenta[*ef,kl*]heptalenedicarboxylate *(5)* (yellowish brown needles, m.p. 172—173 °C) along with 1% of the Diels-Alder adduct *(3)* (blue-green crystals, m.p. 100—101 °C)[4, 5]. Compound *(5)* presumably results from the primary adduct *(4)*, which like *(3)* can be formed from the dipolar intermediate *(2)* produced on attack by the electron-poor alkyne at the position of highest electron density in *(1)*, or by synchronous cycloaddition. 3,5-Dimethyl-[4] and 3,5,8,10-tetramethylaceheptylene *(6)*[6] also react with the acetylenic ester in a manner analogous to *(1)*, although formation of the Diels-Alder adducts of type *(3)* predominates. The parent tetracyclic system of *(5)* was hitherto accessible in only very low overall yield by multistep syntheses[7]. The spectroscopic properties of *(5)* resemble those of the unsubstituted tetracyclic hydrocarbon as far as comparison is at all justified.

Like azulene, the azulenoid Diels-Alder adducts of type *(3)* undergo a dipolar cycloaddition across positions 1,8a of the azulenoid partial structure on treatment with dimethyl acetylenedicarboxylate. Thus 3,5,8,10-tetramethylaceheptylene *(6)*[6], an electron-rich derivative of *(1)*, reacts with



the acetylenic ester in the molar ratio 1:2 to give 3% of the 3,5,8,10-tetramethyl derivative of *(5)* (light brown needles, m.p. 222 °C), 26% of the Diels-Alder adduct *(7)* (blue green crystals, m.p. 142—143 °C), and 12% of the thermally stable diene adduct of the unknown cyclohepta[*ef*]heptalene *(9)* (orange needles, m.p. 205—206 °C; UV spectrum (dioxane): $\lambda_{max} = 280$ ($\log\varepsilon = 4.16$), 292 (4.17), 347 (3.53), 426 (3.15)). The primary formation of the 1:1 adduct *(7)* is followed by a second cycloaddition to give the adduct *(8)*, valence isomerization of which, *via* cyclobutene ring opening, yields *(9)*.

Compound *(1)* and its derivatives also react with ynamines in unexpectedly high yields *via* cycloaddition; however, the electron-rich alkyne initially attacks the position of lowest electron density. Reaction of *(1)* with *N,N*-diethyl-1-propynylamine leads presumably *via* the dipolar intermediate *(10)*

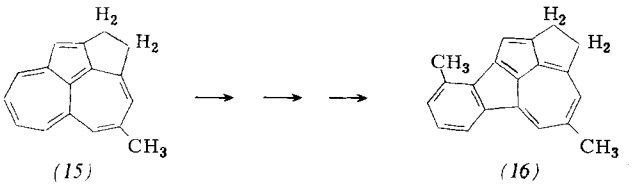
and the cycloadduct *(11)* to the thermally unstable cyclonona[*cd*]azulene derivative *(12)* resulting in cyclobutene ring opening; renewed valence isomerization of *(12)* to *(13)* and subsequent elimination of diethylamine affords a 75% yield of the hitherto inaccessible 10-methylbenzo[*a*]cyclopent[*cd*]azulene *(14)* (yellow-brown platelets, m.p. 136—



(15) *(16)*

137 °C)[8]. In analogous manner, the tetracyclic hydrocarbon *(15)* can be transformed in 21% yield into 4,9-dimethyl-1,2-dihydrobenzo[1,2]dicyclopent[*cd,ij*]azulene *(16)* (bronze colored needles, m.p. 144 °C).

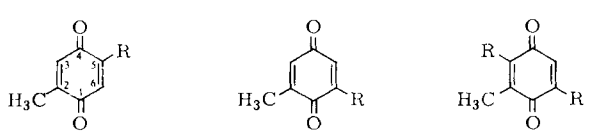
[8] 3,5-Dimethyl- [4] and 3,5,8,10-tetramethylaceheptylene *(6)* [6] react with *N,N*-diethyl-1-propynylamine to give 68% of 3,5-dimethyl- and 92% of the 3,5,7,9-tetramethyl derivative, respectively, of *(14)*.

Oxidative Amination of Toluhydroquinone[**]

By *Suresh C. Srivastava* and *Ulfert Hornemann*[*]

Schäfer and *Aguado*[1] have reported that the interaction of a variety of hydroquinones with arylamines and sodium iodate constitutes a facile route for the preparation of bis(arylamino)-1,4-benzoquinones including *(3)*, for which they gave



(1), R = NHC_6H_5 *(2)*, R = NHC_6H_5 *(3)*, R = NHC_6H_5
(4), R = OH *(5)*, R = OH *(6)*, R = OH

a decomposition point of 147 °C but no data to prove its structure. During our attempts to prepare 3,6-dianilinotoluquinone *(3)* by this route using 10 mmol of toluhydroquinone, 20 mmol of aniline (each dissolved in 75 ml of methanol) and 30 mmol of sodium iodate (dissolved in 75 ml of water) and stirring the mixture for 24 h at room temperature, we observed that the predominant reaction product is 5-anilinotoluquinone *(1)* (50% yield), that *(3)* is obtained in only 26% yield, and that the novel 6-anilinotoluquinone *(2)* is formed in 10% yield.

(1) is also the predominant or a major reaction product when the relative amounts of the reactants are varied. With 10 instead of 20 mmol of aniline the yields of *(1)*, *(2)* and *(3)* are 70%, 15% and 10%, respectively, while when 30 mmol instead of 10 mmol of toluhydroquinone is used the yields of *(1)* and *(2)* are 40% and 50%, respectively, and no *(3)* can be detected. In contrast to these observations, but presumably in accord with results obtained by *Zincke*[2], it was found that a reaction mixture containing 30 mmol toluquinone and 20 mmol aniline in ethanol yielded *(1)* and *(3)* in 60% and 30% yield, respectively, and no detectable quantity of *(2)*.

The composition of the reaction mixtures in most cases is 50—70% of *(1)* *versus* 30—50% of *(2)* plus *(3)*. This may be explained as follows: Assuming that it is the sole function of the iodate to generate toluquinone, the product ratio reflects the difference in the reactivity of position 5 *versus* 6 of toluquinone towards attack by the nucleophilic aniline. Moreover, once any *(2)* has formed it can give rise to *(3)* and the extent of this conversion is dependent on the amount of aniline and the amount of oxidizing agent present in the reaction mixture. This explanation holds for most of the reaction mixtures except for that in which toluhydroquinone and sodium iodate were used in excess of aniline. The observed increase in the amount of *(2)* formed in this case is reproducible but is not readily explained. We suggest that partial formation of a quinhydrone, which would be expected to have the methyl groups oriented in a "*para*" arrangement, may lead to increased accessibility of the 6 position.

Table 1. Physical data for compounds *(1)* to *(6)*. All compounds gave the molecular ion in the mass spectrum.

Cpd.	M.p. [°C] (dec.)	^{1}H-NMR (δ values, in $CDCl_3$)
(1)	150—151	2.05 (d, 3H, J_{23} = 1.5 Hz), 6.13 (s, 1H), 6.52 (br., 1H), 7.24 (br., 5H)
(2)	155—156	2.12 (d, 3H, J_{23} = 2.0 Hz), 6.18 (d, 1H, J_{35} = 2.5 Hz), 6.58 (m, 1H), 7.32 (br., 5H)

(6)	166—171 [b]	1.97 (s, 3H), 7.24 (s, 1H)

[a] M.p. 117—127 °C (dec.) [5]; [b] M.p. 173—175 °C [6].

3,6-Dianilinotoluquinone *(3)* (Table 1) precipitated from the reaction mixture as a yellow brown powder and was recrystallized from chloroform; the compound is presumably identical with the dianilinotoluquinone (m.p. 232—233 °C) prepared by *Zincke*[2]. The filtrate obtained after removal of *(3)* was evaporated to dryness, the residue extracted with methanol and the extract concentrated to yield *(1)* (Table 1) as red crystals; this material is presumably identical with the reaction product obtained by *Schäfer* and *Aguado*[1] and with *Zincke's* monoanilinotoluquinone, (m.p. 144—145 °C). *(2)* (Table 1) was obtained as red crystals after chromatography of the mother liquor on a silica gel column which was

developed with chloroform. The ^{1}H-NMR spectra of *(1)*—*(3)* are in accord with the proposed structures (cf. [3]).

Further proof for the identity of the anilinoquinones *(1)*—*(3)* was obtained by converting them into the known hydroxyquinones *(4)*[4], *(5)*[5] and *(6)*[6], respectively, with refluxing 10% H_2SO_4/methanol (1:1) for 10 min (Table 1). Each reaction mixture was poured into water, the product extracted with chloroform, the chloroform layer dried with Na_2SO_4 before evaporation, and the resulting hydroxyquinones purified by sublimation.

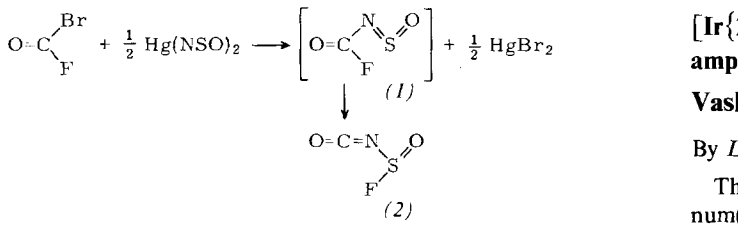
Fluorosulfinyl Isocyanate[**]

By *Hans-Joachim Krannich* and *Wolfgang Sundermeyer*[*]

All previous attempts to prepare halosulfonyl pseudohalides, OSXY, and sulfinyl bispseudohalides, OSY_2 (X = halogen; Y = pseudohalogen) have failed[1]. We have now succeeded in synthesizing the first compound of type OSXY by reaction of fluorocarbonyl bromide[2] with bis(sulfonylamido)mercury(II)[3]. The fluorosulfinyl isocyanate *(2)* is formed in a rearrangement reaction—to our knowledge formerly unobserved—from the expected intermediary fluorocarbonylsulfinylamine *(1)*; the CF bond becomes an SF bond.



OCFBr (*ca.* 27 g) is condensed *via* a high-vacuum apparatus onto $Hg(NSO)_2$ (5.1 g) in a 200 ml Duran glass ampoule; the ampoule is then sealed and shaken for 48 h at 10—15 °C. After removal of the volatile reaction products in a high vacuum the excess OCFBr serving as reaction medium is separated from the product at normal pressure for further use. The combined product after five such treatments afforded 4.5 g of *(2)* (yield 26.7%) as an almost colorless liquid (b. p. 60.5 °C) which slowly turns yellow at room temperature.

While elemental analysis merely affords evidence of the presence of *(1)* or *(2)*, the mass spectrum clearly indicates presence of the isomer *(2)*: $m/e = 109$ molecular ion (rel. int. 57.8%), 90 OS—NCO (12.5), 67 OSF (100), 64 SO_2 (6.3), 48 SO (25), 46 NS (18.8), 42 NCO (14.0), and 32 S (7.8); the transition 109→67 is evidenced by a metastable peak at 41 (calc. 41.18). The ^{19}F-NMR spectrum shows a singlet at −55.5 ppm ($CFCl_3$ ext. standard), which can be attributed to an OSF bond in contrast to an OCF bond[4] (for comparison: CH_3O—S(O)F (−55.6 ppm)[5a], $(CF_3)_2N$—O—S(O)F (−59.5 ppm[5b]). In the IR spectrum there are no carbonyl bands. Bands do occur, however, at 2245 (vs, ν_{as}NCO), 2192 (m, sh), 1348 (s, ν_sNCO), 1281 (vs, νSO), 753 (vs, νSF), 716 (vs, νSN), 610 (vs, δNCO), and 488 cm^{-1} (m) (gas spectrum). Also present is the combination band of the two NCO vibrations at *ca.* 3580 cm^{-1}. In the Raman spectrum the intensity ratio of the two NCO bands is typically reversed.

Our redistribution experiments on carbonyl halides and pseudohalides[6] indicate a relatively high mobility of the fluorine atom in the neighborhood of a carbonyl group. An intermolecular exchange of the fluorine atom between the two C atoms, observable in the case of fluorocarbonyl isocyanate OC(F)NCO by a broad ^{19}F-NMR signal at room temperature[7], leads in the case of *(1)* to an irreversible rearrangement to *(2)*.

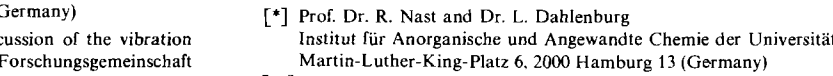
[Ir{2,4,6-$C_6H_2(CH_3)_3$}(CO)(PPh_3)$_2$]—The First Example of *cis-trans* Isomerism in Complexes of the Vaska Type[**]

By *Lutz Dahlenburg* and *Reinhard Nast*[*]

The *cis-trans* isomerism frequently found in planar platinum(II) complexes of the type $[Pt(L)_2(X)(Y)]$ has so far not been observed in the numerous comparable iridium(I) complexes of the Vaska type $IrA(CO)L_2$ (A = univalent anion ligand, L = tertiary phosphane or arsane). On the basis of their ^{1}H- and ^{31}P-NMR spectra and their dipole moments all these compounds prove to have a *trans* configuration, which, in two cases [A, L = Cl, P(*o*-$C_6H_4CH_3)_3$; C_6F_5, P($C_6H_5)_3$] has also been confirmed by X-ray structure analysis[1, 2]. The postulated existence of *cis*-[$IrA(CO)(PPh_3)_2$] [A = H, $C(CN)_3$] is doubtful[3], if not already ruled out[4].

We are now able to show that the σ-mesityl complex *(2)*, which is accessible according to



Mes = 2,4,6-$C_6H_2(CH_3)_3$

consists of an easily separable 10:1 mixture of red *cis-(2a)* and yellow *trans*-form *(2b)*. The identification and purity of the two isomers was confirmed by elemental analysis and molecular weight determination[5] as well as by IR and ^{1}H-NMR spectra (cf. Table 1).

While solutions of pure *(2a)* in chloroform or benzene show no tendency whatsoever to undergo the rearrangement *(2a)* → *(2b)*, complete *cis-trans* isomerization is observed to take place within 24 h in the presence of catalytic amounts of PPh_3. Hence, we consider *(2a)* as the kinetically hindered unstable form and *(2b)* as the thermodynamically stable form.

The configuration of the two isomers follows from the findings listed below:

1. Only the singlet signal expected for the *trans*-grouping P—Ir—P appears in the ^{31}P-NMR spectrum of *(2b)*; *(2a)*, on the other hand, shows the AB spectrum required by *cis* phosphane ligands (Table 1).

2. The measured (benzene, 25 °C) and calculated electric dipole moments (assuming the atomic polarization as 20% of the electron polarization) with values of 6.5 D for *(2a)* and 1.7 D for *(2b)* lie in the range expected for *cis* and *trans* configurations of these complexes respectively[6].

3. The ν(CO) wave numbers (Table 1) measured in $CHCl_3$ are also in agreement with this assignment of configuration, since the doubtless larger σ-donor/π-acceptor ratio of the anionic mesityl group compared to the neutral ligand PPh_3 must influence the ν(CO) values of *trans*-OC-Ir-PPh_3 in *(2a)* and of *trans*-OC-Ir-Mes in *(2b)* in the observed sense.

The isolation of the red mesityl complex *(2a)* affords the first unequivocal proof of the—doubtless sterically determined—existence also of *cis*-configurated compounds of the Vaska type.

Experimental:

A mixture of *(1)* (7.80 g, 0.010 mol) and mesityllithium (0.015 mol) in diethyl ether (1500 ml) is stirred at room temperature for 2 h under protective gas (N_2). After filtration and addition of ethanol (200 ml) the ether is removed by evaporation at normal pressure. Crystallization of red *(2a)* ensues and is practically complete after 6–8 h at room temperature. Yield (after washing with 3 × 20 ml ethanol) 4.7–5.4 g (55–65%).—Approximately 500 mg yellow *(2b)* crystallizes from the mother liquor within a week at 0 °C. Traces of the *cis* complex disappear if *ca.* 1 g portions of the impure crystals are stirred together with 50 mg PPh_3 in 50 ml benzene; concentration of the solution to 10 ml and addition of 10 ml hexane leads to crystallization of the pure *trans* complex *(2b)*.—Pure *(2a)* can be transformed into *(2b)* in 85% yield by the same method.

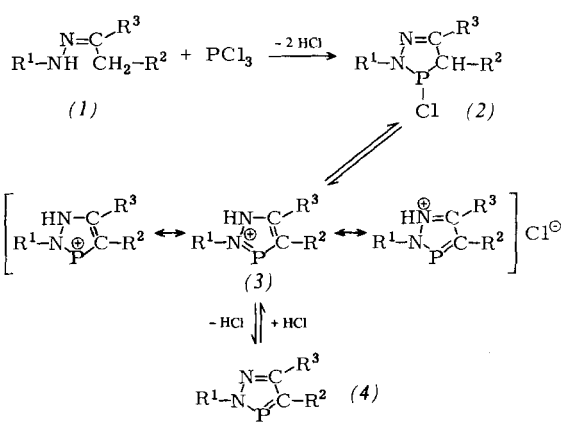
First Example of a Chlorophosphane→Phosphanylium Chloride Transformation: 2-Methyl-1,2,3σ^2-diazaphosphole Hydrochlorides[1]

By *Jörg Luber* and *Alfred Schmidpeter*[*]

The reaction of the hydrazones *(1)* with phosphorus trichloride, which leads by elimination of 3 mol. equiv. of hydrogen chloride to 2*H*-1,2,3σ^2-diazaphospholes *(4)* ($R^1 \neq CH_3$[2]), should proceed *via* 3-chloro-Δ^5-1,2,3σ^3-diazaphospholines *(2)* as intermediates. In two cases these intermediates have actually been isolated ($R^1 = CH_3CO$ or *p*-$CH_3C_6H_4$, $R^2 = H$, $R^3 = CH_3$)[3].

We have now investigated the hitherto unelucidated[4] reaction of methylhydrazones *(1)*, $R^1 = CH_3$, under modified conditions and thus obtained crystalline products *(3)* corresponding to *(2)* in their composition, yet ionic in nature. They are apparently formed from *(2)* by extrusion of the chlorine as an anion leaving a twofold coordinated phosphorus atom in the cyclic cation. The compounds are therefore to be regarded as "phosphenium chlorides" (phosphanylium chlo-



[*] Prof. Dr. A. Schmidpeter and Dr. J. Luber
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, 8000 München 2 (Germany)

rides) and provide the first example of this kind of isomerization[5].

As a result of the proton shift the phosphenium charge in *(3)* can also be distributed over the two nitrogen ring members. However, as is shown by a comparison with the strongly Lewis acidic diaminophosphenium ions[5], this charge distribution alone is inadequate to explain the spontaneous formation of *(3)*. It can be rationalized by the formation of the cyclic 6π-electron system in the cation.

The ionic structure *(3)* and the proton shift are confirmed by the very broad IR band at about 2300 cm^{-1} due to an $NH^+\cdots Cl^-$ hydrogen bond, by the large downfield shift in the ^{31}P-NMR spectrum (Table 1) characteristic of twofold coordinated phosphorus, and by the absence of a proton in position 4 of *(3b)*. Reaction with $HgCl_2$ affords the chloromercurates *((3)*, $HgCl_3$ instead of Cl) whose IR spectrum indicates an unchanged structure.

In the NMR spectrum of *(3a)* the proton on C^4 gives rise to a signal exhibiting a pronounced downfield shift and an exceptionally large coupling constant J_{PCH}, as is also observed in the case of *(4a)* and for the 2,6-protons of σ^2-phosphorine (phosphabenzene, 8.6 ppm and 38 Hz)[6]. This characterizes compounds *(3)* as σ^2-phospha-aromatics (phosphapyrazole hydrochlorides) and clearly distinguishes them from the isomers *(2)* (cf. Table 1).

The hydrochlorides *(3a, b)* readily afford *(4a, b)* so that 1,2,3σ^2-diazaphospholes with $R^1=CH_3$ are now also accessible. Treatment with HCl regenerates the hydrochlorides *(3)*.

In order to prepare the diazaphospholes *(4)* a slurry of hydrochloride *(3)* (25 mmol) in dry benzene (20 ml) is cooled on ice and treated with triethylamine (2.5 g, 25 mmol) in benzene (10 ml) with stirring. Triethylammonium chloride is separated off after 2 h, the benzene evaporated off *in vacuo*, and the residue distilled (yield 60—80 %).

[a] Neat, otherwise in $CDCl_3$ solution.

Owing to the low basicity of *(4)*, the hydrochlorides *(3)* undergo thermal dissociation and are sublimable *via* a dissociation equilibrium. The mass spectra of *(3)* always contain the molecular ion of *(4)* as the peak of highest mass and greatest intensity.

Procedures:

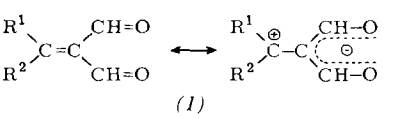
All reactions are carried out under an inert gas (argon). An *N*-methylhydrazone (50 mmol) is added dropwise over 15 min to stirred PCl_3 (34.3 g, 250 mmol) cooled to −30 to −60 °C. After slowly warming to room temperature the mixture is refluxed for 2 h. The hydrochloride *(3)* which crystallizes on cooling is collected on a frit and washed with ether. It is best purified by sublimation at 40—60 °C and reduced pressure or slowly even at atmospheric pressure; yield 55 % *(3a)* and 40 % *(3b)*.

For conversion into the chloromercurates ($HgCl_3$ in place of Cl), compound *(3)* (10 mmol) is dissolved in dry acetonitrile (20 ml) and a solution of $HgCl_2$ (2.7 g, 10 mmol) in acetonitrile (10 ml) is added. The crystals precipitating within 24 h are analytically pure after drying (yield 80 %).

Synthesis of Alkylidenemalondialdehyde Tetramethyl Bisacetals[1]

By *Christian Reichardt, Wilfried Pressler*, and *Ernst-Ulrich Würthwein*[*]

Alkylidenemalondialdehydes of the general formula *(1)* are not only of theoretical interest because of their cross-conju-



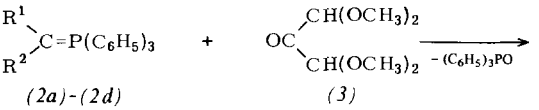
(1)

gated π-electron system, but are also (with $R^1=H$ and $R^2=CO_2R$) valuable intermediates in the synthesis of cephalosporin C[2]. The method described by *Woodward et al.*—aldol addition of the sodium salt of malondialdehyde to mesoxalates

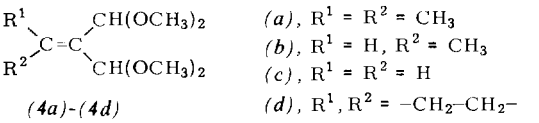
[*] Prof. Dr. C. Reichardt, Dr. W. Pressler, and Dr. E.-U. Würthwein
Fachbereich Chemie der Universität
3550 Marburg, Lahnberge (Germany)

or glyoxylates and subsequent dehydration[2, 3]—is, however, unsuitable for the preparation of simpler alkylidenemalondialdehydes (with R^1, R^2=H or alkyl).—Introduction of two geminal formyl groups by Vilsmeier formylation meets with success only in special cases[4].

We have now found that the alkylidenemalondialdehyde tetramethyl bisacetals *(4a)*—*(4d)* can be prepared by Wittig olefination of the mesoxaldialdehyde tetramethyl bisacetal *(3)*[5] with the intermediary alkylidenetriphenylphosphoranes *(2a)*—*(2d)*.



(2a)-(2d) *(3)*



(4a)-(4d)

(a), $R^1 = R^2 = CH_3$
(b), $R^1 = H$, $R^2 = CH_3$
(c), $R^1 = R^2 = H$
(d), $R^1, R^2 = -CH_2-CH_2-$

For the synthesis of the cyclopropylidene compound *(4d)* the cyclopropylidenetriphenylphosphorane *(2d)*, obtained by reaction of an excess of the corresponding phosphonium salt[6] with potassium *tert*-butoxide in benzene, was heated under reflux for three days with *(3)*. Subsequent distillation afforded *(4d)* as a colorless liquid [b.p. 105—106 °C/12 torr, yield 89 % based on *(3)*; ^{1}H-NMR ($CDCl_3$): $\delta = 1.20$ (s, 4 cyclopropyl H), 3.32 (s, 12 OCH_3), and 4.90 ppm (s, 2 CH)].

The acetals *(4a)*—*(4c)* were obtained in 50, 38, and 26 % yield, respectively, on stirring a mixture of *(3)* 20 h at room temperature with the ylides *(2a)*—*(2c)*, prepared with phenyllithium in ether (see Experimental procedure). Subsequent distillation followed by preparative gas-chromatography of the crude products so obtained afforded analytically pure, colorless, readily volatile liquids whose elemental analyses, mass, IR, and ^{1}H-NMR spectra were consistent with the given constitutions. The compounds *(4a)*—*(4d)* are valuable starting substances for the synthesis of substituted malondialdehydes and heterocycles[7].

Isopropylidenemalondialdehyde tetramethyl bisacetal (4a)

An ethereal solution of phenyllithium, prepared by reaction of bromobenzene (13.0 g, 83 mmol) with lithium shavings (1.9 g, 274 mmol) in dry diethyl ether (150 ml), is added rapidly under N_2 to a suspension of isopropyltriphenylphosphonium bromide[8] (23.1 g, 60 mmol) in diethyl ether (200 ml). After one hours' stirring *(3)* (10.0 g, *ca.* 90 % pure, *ca.* 50 mmol) is added dropwise within 20 min. The viscous suspension is stirred for 20 h at room temperature; the solvent is then removed by distillation (maximum bath temperature 60 °C). The remaining yellow-brown hygroscopic solid is heated to 225 °C at *ca.* 0.2 torr, whereupon *(4a)* distils over at 55—57 °C/0.2 torr as crude product (8.0 g, *ca.* 65 % pure); overall yield [based on pure *(3)* and *(4a)*] *ca.* 50 %. Further purification of the product is accomplished by preparative gas chromatography (Perkin-Elmer F 21, 2 m × 23 mm column with 5 % SE-30 on Chromosorb G-NAW at 135 °C and a column feed-pressure of 1.6 kp/cm^2 N_2). ^{1}H-NMR ($CDCl_3$): $\delta = 1.88$ (s, 6 CH_3), 3.36 (s, 12 OCH_3), 4.85 ppm (s, 2 CH).

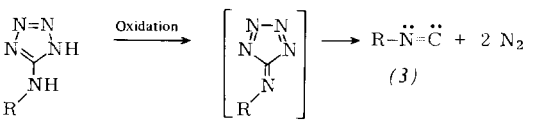
Oxidation of 5-Aminotetraazoles, a New Route to Isocyanides[**]

By *Gerhard Höfle* and *Bernd Lange*[*]

Attempts to prepare the unknown compounds R—CO—N̈=C̈[1] gave us cause to search for reagent-free isocyanide syntheses. The thermal or photochemical fragmentation of imino-substituted cyclic compounds according to the following scheme[2] appeared promising:

As concerted processes these reactions are not symmetry forbidden since the isocyanide fragment can be extruded in a linear or nonlinear manner[3]; they ought to proceed particularly easily provided particles X of low energy are formed.

We report here on a model reaction in which one molecule of isocyanide *(3)* and two molecules of nitrogen are formed from 5-iminotetrazoles *(2)* in a [2+2+2] cycloreversion. Starting materials for the synthesis of *(2)* were the 5-alkyl(aryl)-aminotetrazoles *(1)*, which are readily accessible from commercially available 5-aminotetrazole[4] or monosubstituted thioureas[5].



(1) *(2)* *(3)*

Oxidation of *(1a)*—*(1c)* [R: see Table 1] leads to liberation of two moles of nitrogen and formation of the isocyanides *(3a)*—*(3c)* or the corresponding *N*-substituted formamides. The pentaazafulvenes *(2)* presumed to be formed as intermediates could neither be detected, even at −20 °C, nor trapped with *N*-phenylmaleimide or acetylenedicarboxylates. Oxidation with sodium hypobromite in aqueous medium and with lead tetraacetate/triethylamine in dichloromethane proved to be preparatively useful, while bromine/triethylamine and anodic oxidation[6] are less promising.

As an alternative to the oxidative degradation of *(1)* we attempted the elimination of sodium toluenesulfinate from the salt *(4a)*, which is formed by tosylation of *(1a)* in sodium hydroxide. *(4a)* was found to be unexpectedly stable; it starts

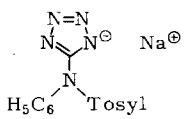
to decompose at 280 °C, whereby, in addition to other unidentified products only small amounts of isocyanide are formed. Irradiation in aqueous solution led to the same result.



(4a)

Phenyl isocyanide (3a)

A solution of lead tetraacetate (2.7 g, 6.1 mmol) in dichloromethane (50 ml) is added dropwise within 15 min at 20 °C to a stirred solution of 5-phenylaminotetrazole *(1a)*[5] (0.89 g, 5.5 mmol) and triethylamine (1.3 g, 12.9 mmol) in dichloromethane (20 ml). The theoretical quantity of nitrogen is liberated. The dark-colored reaction mixture is concentrated in a vacuum at room temperature and the isocyanide *(3a)* extracted with petroleum ether; yield after concentration and distillation in a bulb-tube: 0.40 g (70%), b.p. 70 °C/20 torr.

n-Butyl isocyanide (3b)

To a solution of *n*-butylaminotetrazole *(1b)*[4] (6.25 g, 44.3 mmol) in 2 N sodium hydroxide (50 ml) is added 50 ml dichloromethane and the mixture stirred during dropwise addition of sodium hypobromite solution (4.9 mmol) at 0 °C (*ca.* 15 min). The aqueous phase is then extracted several times with dichloromethane, the combined organic phases dried over $MgSO_4$, and the solvent removed by distillation through a 40-cm packed column. Distillation of the residue affords *(3b)* b.p. 119—120 °C, in 75% yield (2.77 g).

Benzyl isocyanide (3c)

To a solution of 5-benzylaminotetrazole *(1c)*[4] (1.22 g, 7 mmol) in 2 N sodium hydroxide (50 ml) is added 20 ml ether at 0 °C. The stirred mixture is electrolyzed for 4 h at 3.8 V and 0.55 A[6]. The aqueous phase is extracted serveral times with ether, the combined organic phases dried with $MgSO_4$ and concentrated *in vacuo*. Distillation of the residue in a bulb-tube affords *(3c)*, b.p. 100 °C/16 torr in 48° yield (0.39 g).

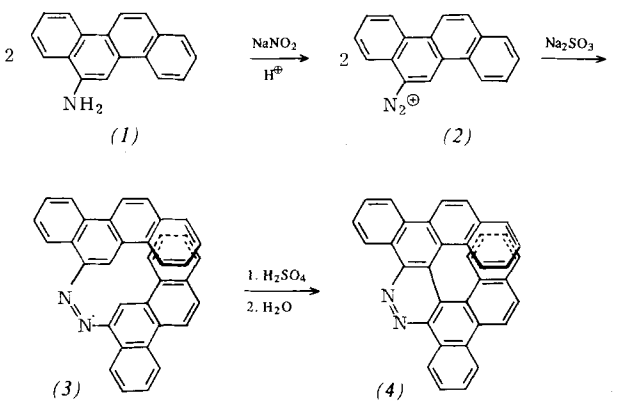
Simple Synthesis and Resolution of a Diaza[7]helicene[**]

By *Hermann Rau* and *Otto Schuster*[*]

Diazahelicenes[1] containing a —N=N-grouping possess the structural elements of aromatic azo compounds. Since azo compounds behave spectroscopically and photochemically differently from the analogous carbon compounds on account of the longwave $n \rightarrow \pi^*$ transition[2], such diazahelicenes can be expected to display interesting properties.



We report here on a simple and very productive two-step synthesis of the diazadibenzo[7]helicene *(4)*[3] and on its resolution.

A suspension of 6-aminochrysene *(1)* (0.01 mol) in glacial acetic acid (20 ml) and conc. hydrochloric acid (7 ml) was diazotized to *(2)* with a solution of sodium nitrite (0.7 g) in water (3 ml). The cold solution was buffered with sodium acetate (3 g, anhydrous) in water (15 ml) and then treated dropwise with a saturated solution of sodium sulfite (1.55 g)[5] in water, whereupon 6,6'-azochrysene *(3)* precipitated out. After 10 minutes at 70 °C, *(3)* was filtered off, washed, and dried; yield 98%. A sample of the product, after recrystallization from toluene, was found to transform without melting at 268 °C into a yellow fluorescent solid which was not identical with the helicene *(4)*.—Crude *(3)* was dissolved in conc. sulfuric acid and precipitated almost quantitatively as helicene *(4)* on careful addition to water. After purification on a silica-gel-60 column with benzene, *(4)* was obtained as a yellow, strongly fluorescing substance of m.p. 345 °C.

The structure of *(4)* was confirmed by mass and CD spectra. The rapid quantitative transformation of *(3)* into *(4)* is surprising, for this would require that *(3)* be present only in the *cis* form.

The resolution of *(4)* was carried out with the π complexing agent TAPA, synthesized according to *Newman*'s method[6]. *(4)* and a threefold excess of (−)-TAPA were treated at 40 °C with just sufficient chloroform to dissolve them. After one day at 4 °C dark-red crystals of the complex of (−)-TAPA and an enantiomer of *(4)* had precipitated out. The crystals

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

were dissolved in benzene and the solution subjected to chromatographic separation on a silica-gel-60 column with benzene.

Weight for weight, the ellipticities of the two enantiomer fractions were of the same magnitude but of different sign (±2%). This is indicative of complete separation, for otherwise equal values with opposite signs can occur only when the precipitated enantiomers and those remaining in solution each contain the same proportion of the other enantiomer[7]. The optical activity was not increased by a second resolution step.

In contrast to the analogous carbon compounds *(3)* is not cyclized to *(4)* in toluene/iodine with polarized light[8]. This is consistent with the photochemical behavior of azobenzene. A protonated form, which in the case of azobenzene can be photocyclized[9], is not formed—even in 70% perchloric acid.

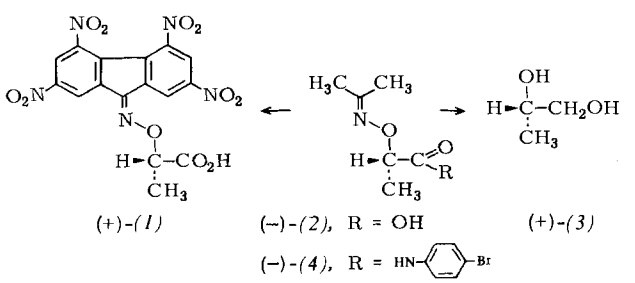
Absolute Configuration of 2-(2,4,5,7-Tetranitro-9-fluorenylideneaminooxy)propionic Acid (TAPA)[**]

By *Thorsten Kemmer*, *William S. Sheldrick*, and *Hans Brockmann jr.*[*]

Since its use for the separation of enantiomers of hexahelicene[1, 2] 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid (TAPA) *(1)* has proved to be a valuable reagent for the resolution of racemic Lewis bases, especially of those



(+)-*(1)* (−)-*(2)*, R = OH (+)-*(3)*
(−)-*(4)*, R = HN-C6H4-Br

[*] Dipl.-Chem. T. Kemmer, Dr. W. S. Sheldrick, and Prof. Dr. H. Brockmann jr.
Gesellschaft für Molekularbiologische Forschung mbH
Mascheroder Weg 1, 3300 Braunschweig-Stöckheim (Germany)

[**] This work was supported by the Technologie-Programm des Bundesministeriums für Forschung und Technologie and by the Fonds der Chemischen Industrie.

which contain no functional groups and therefore cannot be resolved by conventional methods.

Knowledge of the absolute configuration of *(1)* appeared essential if we were to improve our understanding of the interactions in the diastereomeric charge transfer complex.

To this end we have employed two independent methods: chemical correlation of *(1)* *via* 2-(isopropylideneaminooxy)-propionic acid *(2)* with 1,2-propanediol *(3)* and X-ray structure analysis of a derivative of *(2)*. The results obtained by the two approaches were in mutual agreement.

(−)-*(2)* can be converted into (+)-*(1)* by transoximation with 2,4,5,7-tetranitrofluorenone[1]. Reduction of *(2)* with $LiAlH_4$ in ether affords 1,2-propanediol *(3)*, which was transformed into the dibenzoate to facilitate characterization and purification. Subsequent hydrolysis of (−)-*(2)* ($[\alpha]_{578}^{22} = -34°$; $c = 1$, H_2O) gives *S*-(+)-*(3)*[3] ($[\alpha]_{578}^{22} = 8.2°$; $c = 0.17$; CH_3OH); (+)-*(2)* likewise leads to (−)-*(3)*[4]. Since no attack at the center of asymmetry is involved in this correlation the *S* configuration is therefore established for (+)-TAPA.

X-Ray structure analysis was performed on a crystal of (−)-2-(isopropylideneaminooxy)propion-*p*-bromoanilide *(4)* ($[\alpha]_D^{23} = -29°$; $c = 1$; benzene) which is readily accessible from (−)-*(2)* ($[\alpha]_D^{23} = -32°$; $c = 1$; H_2O) by aminolysis of the corresponding carboximidazolide[5] with *p*-bromoaniline. Compound *(4)* forms monoclinic crystals, $P2_1$, with $a = 12.979(5)$, $b = 10.411(6)$, $c = 10.138(4)$ Å; $\beta = 96.95(4)°$; $Z = 4$; $d_{calc.} = 1.46\,g\,cm^{-3}$. The structure was solved by Patterson and subsequent difference Fourier synthesis and refined to $R = 0.066$, $R_G = 0.082$ for 3242 independent reflections [Syntex $P2_1$, four-circle diffractometer, $(\Theta - 2\Theta)$ operation, $I \geq 2\sigma(I)$].

The methyl hydrogen atoms could not be unequivocally localized. The calculated positions of the other hydrogen atoms were included in the final cycles together with their associated isotropic temperature factors. The crystal lattice of *(4)* contains two mutually independent molecules which do not differ significantly with regard to their geometrical parameters; both exhibit the *S* configuration.

With the inverse coordinates $(-x, -y, -z)$ of the molecule (*i.e.* with those of the *R* form) the values of *R* and R_G deteriorate to 0.081 and 0.107 respectively. Thus the *S* configuration of (−)-*(4)*, and hence of (+)-*(1)*, is unequivocally proven.

Cumulated Ylides as Building Blocks for the Synthesis of Heterocycles

By *Hans Jürgen Bestmann*, *Günter Schmid*, and *Dieter Sandmeier*[*]

Cumulated ylides *(1)*[1] react with compounds of type *(2)*, containing an acidic Y—H bond (Y = hetero atom) and a carbonyl function (Z = C—R) or a nitroso group (Z = N) in the same molecule, to give the heterocyclic compounds *(4)*.

[*] Prof. Dr. H. J. Bestmann, Dr. G. Schmid, and Dipl.-Chem. D. Sandmeier
Institut für Organische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Henkestr. 42 (Germany)

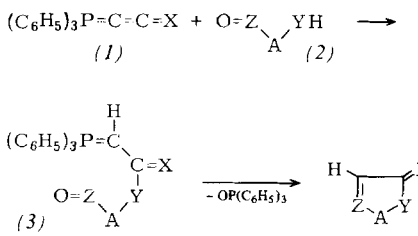
Table 1. Heterocyclic compounds *(4)* and *(7)* from cumulated ylides *(1)* and molecules of general structure *(2)* and *(5)*.

(2)	*(4)*	X	M.p. [°C] *(4)*	Yield [%]
		O	117	73
		$N-C_6H_5$	137	68
		$C_{13}H_8$ [a]	197	41
		$C_{13}H_8$ [a]	162	78
		O	149	58
		$N-C_6H_5$	209	29
		$N-C_6H_5$	183	71
		O	81	86
		$N-C_6H_5$	99	81

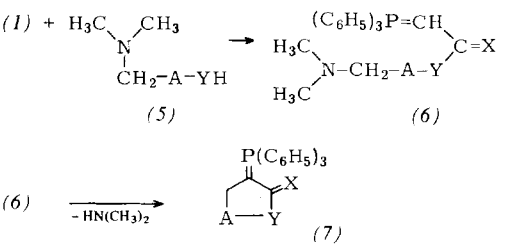
(5)	*(7)*	X	M.p. [°C] *(7)*	Yield [%]
		O	217	69
		S	172 [b]	93

[a] $C_{13}H_8$ = 9-fluorenylidene. [b] Softening begins without definite melting point.

The initial step of the reaction is addition of *(2)* to *(1)* to give *(3)*, from which *(4)* is formed by intramolecular Wittig reaction (Table 1).



The Z=O moiety in *(2)* can also be replaced by a Mannich base grouping $-CH_2-N-(CH_3)_2$. The intermediary product *(6)* formed from the resulting molecule *(5)* cyclizes with elimination of dimethylamine to give the ylide *(7)*, which can be employed in a number of further reactions[2] (Table 1).



Correct elemental analyses and spectroscopic data exist for all compounds *(4)* and *(7)* listed in Table 1.

Heterocycles (4)

(2) (10 mmol) is added slowly to a stirred solution of *(1)* (10 mmol) in anhydrous benzene (30 ml). The mixture is allowed to stand for 2—3 days or heated under reflux for *ca.* 24 h. After removal of solvent the residue is treated with hot methanol or isopropanol, filtered, and the filtrate transferred to a refrigerator. Compound *(4)* crystallizes out and can be purified by recrystallization from isopropanol or benzene/methanol.

Phosphoranes (7)

A stirred solution of *(1)* (10 mmol) and *(5)* (10 mmol) in anhydrous benzene (50 ml) is heated under reflux in an apparatus through which a slow stream of N_2 is allowed to pass. When evolution of dimethylamine is complete the reaction mixture is stirred for a further hour before removal of the solvent in a vacuum and recrystallization of the residue from ethyl acetate or benzene/ethyl acetate.

Synthesis of the 2*H*-1-Thiacyclobutabenzene System[**]

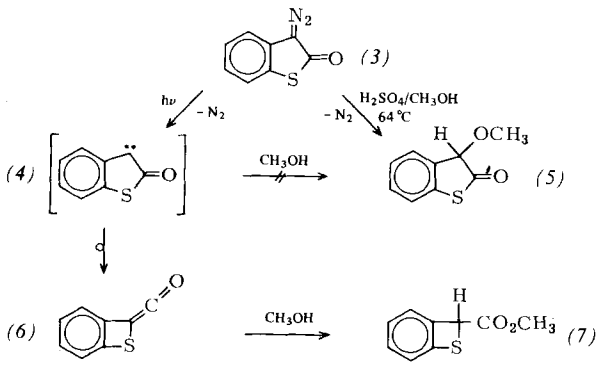
By *Erika Voigt* and *Herbert Meier*[*]

Thiete *(1)* and its simple derivatives are labile compounds at room temperature and tend to polymerize[1]. Their 1,1-dioxides *(2)*[2] are considerably more stable and better to handle. Stabilization is also possible by incorporation of the double bond of the system in an annelated benzene ring.

(1) *(2)*

We succeeded in synthesizing the first heterocycle of the type 2*H*-1-thiacyclobutabenzene (2*H*-1-benzothiete) by photolysis ($\lambda > 290$ nm) of the 3-diazo-2-oxo-2,3-dihydrobenzo[*b*]-thiophene *(3)*.

The photochemical primary step affords the carbene *(4)*, which subsequently rearranges to the ketene *(6)*. Addition of methanol to *(6)* leads to the methyl 2*H*-1-benzothiete-2-carboxylate *(7)* (b.p. 73 °C/0.06 torr, yield 30%). An alternative reaction which *(4)* might undergo is insertion into the O—H bond of the methanol with formation of the 3-methoxy-2-oxo-2,3-dihydrobenzo[*b*]thiophene *(5)*[3]. For confirmation of the structure of *(7)* we have prepared *(5)*, m.p. 50 °C, in 40% yield *via* an independent route by acid-catalyzed decomposition of *(3)*.

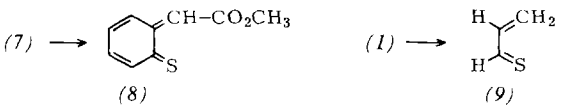


In contrast to the corresponding aza compounds *(5)* cannot be obtained by photolysis of *(3)*[4].

For the spectroscopic characterization of *(7)* a comparison with *(5)* and *(3)* is useful. The CO stretching vibration in the IR spectrum of *(3)* appears—as is usual for α-diazo carbonyl compounds—at low wave numbers (in KBr: 1640 cm^{-1}). In the thiolactone *(5)* the absorption is shifted to 1705 cm^{-1}, and in *(7)* it reaches the normal value of 1740 cm^{-1} for saturated aliphatic esters.

The ^{1}H-NMR spectrum of *(5)* recorded in $CDCl_3$ shows one singlet for the tertiary hydrogen at $\delta = 5.0$ ppm and one for the methyl protons at $\delta = 3.5$ ppm. In the case of the ester *(7)* both signals are shifted to lower field strengths (5.2 and 3.8 ppm, respectively). Especially informative are the ^{13}C-NMR spectra. The carbonyl carbon and the carbon atom adjacent to it give a marked high field shift of *ca.* 35 ppm on going from *(5)* through *(3)* to *(7)* ($\delta = 203.1$, 186.4 and 169.4 ppm, $\delta = 85.1$, 70.6, and 49.2, respectively; in $CDCl_3$, TMS internal)[5]. The resonance of the methyl C-atom in *(5)* lies at lower field strength than that of *(7)* ($\delta = 56.7$ and 52.8 ppm, respectively).

In contrast to *(3)* and *(5)* the bicyclic fundamental structural unit of *(7)* is considerably more stable towards fragmentation in the mass spectrometer.



(8) *(9)*

We attribute the greater thermal stability of *(7)* over *(1)* to the fact that the ring opening *(7)*→*(8)* is very much less energetically favorable than that of *(1)*→*(9)*.

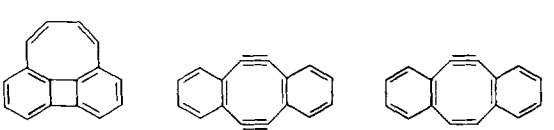
5,6,9,10-Tetradehydrobenzocyclooctene, the Simplest Known Planar Neutral Conjugated Eight-Membered Carbocycle[1]

By *Henry N. C. Wong* and *Franz Sondheimer*[*]

The only known systems containing presumably planar neutral conjugated eight-membered rings are the dibenzoannelated compounds *(1)*[2], *(2)*[1, 3], and *(3)*[1]. As expected, the eight-membered rings in these substances prove to be paratropic ("antiaromatic"). It was desirable to make available simpler derivatives of these interesting systems. We now describe the synthesis of the very unstable 5,6,9,10-tetradehydrobenzocyclooctene ("benzo-1,5-cyclooctadiene-3,7-diyne") *(5)*, the simplest member yet isolated[4].



(1) *(2)* *(3)*

5,10-Dibromobenzocyclooctene ("3,8-dibromobenzocyclooctatetraene") *(4)* was prepared in *ca.* 10% overall yield by the photoinduced bromination of biphenylene in carbon tetrachloride (500 Watt clear lamp) for 30 minutes, followed by treatment of the resulting mixture of tetra- and hexabromocompounds[6] with an excess of sodium iodide in dimethylformamide at 50 °C for 4 hours[7]. The dibromide *(4)* in tetrahydrofuran was dehydrobrominated by addition to a stirred solution of potassium *tert*-butoxide (6 molar equivalents) in tetra-

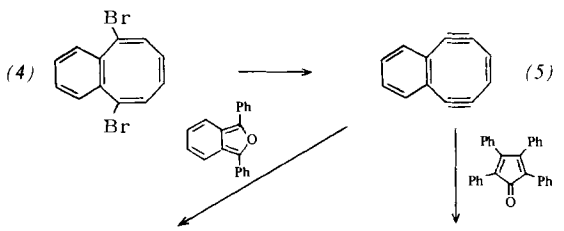
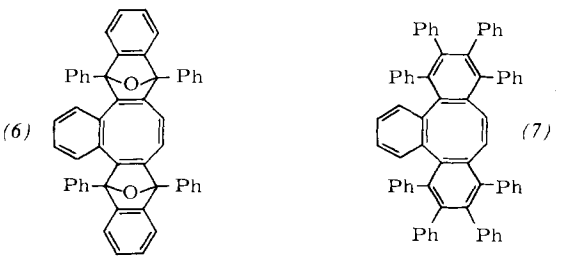
hydrofuran during 30 seconds at room temperature. Successive addition of 2 N hydrochloric acid, extraction with ether, drying, evaporation under reduced pressure at 0 °C, chromatography on alumina (Woelm, neutral, act. III) and elution with pentane yielded the diacetylene *(5)*. The isolation and chromatography procedure must be carried out as rapidly as possible (usually *ca.* 15 minutes) in view of the instability of *(5)*.

(5) is a yellow oil, which decomposes within a few minutes at 0 °C. It is also quite unstable in solution; this caused difficulties in estimating the yield and fully characterizing the substance (*e.g.*, no mass spectrum or satisfactory elemental analysis could be obtained). The charakteristic electronic spectrum of *(5)* in pentane showed maxima at 228 (ε = 23700), 233 (23300), 238sh (27000), 244 (46600), 249 (40700), 257 (71900), 327 (580), 332 (590), 341 (750), 345 (820), 361 (890), and 366 sh nm (750)[8]. The IR spectrum (CCl_4) exhibited a weak C≡C stretching band at *ca.* 2100 cm^{-1}. The ^{1}H-NMR spectrum ($CDCl_3$, 100 MHz, −20 °C) showed a sharp olefinic singlet at τ = 5.07 (which gradually disappeared on standing), but the exact location of the benzenoid multiplet was obscured by the appearance of bands due to decomposition products.





The structure of *(5)* was confirmed by the similarity of its electronic spectrum to that of *(2)*[1], the hypsochromic shifts of the three main maxima being 12—14 nm. The presence of two strained acetylenes in *(5)* was confirmed by its ready reaction with dienes. Thus, treatment of freshly prepared *(5)* with an excess of 1,3-diphenylisobenzofuran in pentane/ether at room temperature gave the bis-adduct *(6)*[9] (apparently as a single isomer), as colorless crystals, m. p. 208—209 °C; *m/e* 690.252 (calcd. 690.255); λ_{max} (dioxane) 228 (ε = 18100), 240 (24500), 258 (9100), 265sh (8100), 272sh (5900), and 282sh nm (3200); ^{1}H-NMR (CCl_4, 60 MHz), τ = 2.00—2.30 (m, 8H), 2.40—2.70 (m, 12H). 2.75—3.05 (including a sharp band at τ = 2.98) (m, 14H).

Treatment of *(5)* with an excess of 2,3,4,5-tetraphenylcyclopentadienone in pentane/ether at 40 °C led to the previously described[5] substance *(7)*[9], presumably derived from the initial adduct by elimination of carbon monoxide. Compound *(7)* formed colorless crystals, m. p. 305—307 °C (m. p. 308—312 °C[5]).

The similarity of the electronic spectrum of *(5)* to that of the benzoanalog *(2)* provides evidence that the eight-membered ring in *(5)* is essentially planar, as found for *(2)*[3]. The high-field resonance of the olefinic protons in the ^{1}H-NMR spectrum of *(5)* indicates the paratropicity ("antiaromaticity") of the eight-membered ring, as expected of a planar 4*n* π-system.

$[W_3O_4F_9]^{5-}$: A Complex Ion of Tungsten(IV) Containing a W_3 Group

By *Karl Mennemann* and *Rainer Mattes*[*]

We have now been able to obtain the first oxofluoro anion of tungsten(IV): The ammonium salt $(NH_4)_5[W_3O_4F_9]\cdot 3H_2O$ is formed when a solution of the tungsten(V) compound $(NH_4)_2[W_2O_4(C_2O_4)_2(H_2O)_2]\cdot 0.5(NH_4)_2(C_2O_4)H_2O$[1] in 40% HF is heated to 70 °C and subsequently neutralized with $(NH_4)_2CO_3$. Under these conditions W^V disproportionates to W^{IV} and W^{VI}.

The anion $[W_3O_4F_9]^{5-}$ is diamagnetic and displays a hitherto unknown central atom to ligand ratio of 3:13. Surprisingly, it does not contain terminal oxygen atoms. In the IR spectrum (800—1000 cm^{-1}) the corresponding bands are absent. The intense bands at 780, 740, and 700 cm^{-1} are assigned to the stretching vibrations of the bridging oxygen atoms. The W—F stretching vibrations appear between 530 and 460 cm^{-1}. As shown by X-ray structure analysis[3] (cf. Fig. 1), the complex ion $[W_3O_4F_9]^{5-}$ is trinuclear; it has approximate C_{3v} symmetry and contains a cyclic W_3 group.

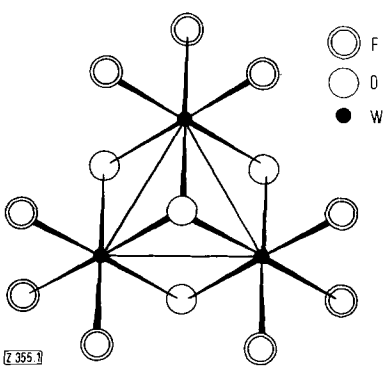

Fig. 1. Structure of the complex anion in $(NH_4)_5[W_3O_4F_9]\cdot 3H_2O$.

[*] Prof. Dr. R. Mattes and Dipl.-Chem. K. Mennemann
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9—11, 4400 Münster (Germany)

The tungsten-tungsten bond length of 251.5(1) pm and magnetic behavior are consistent with the presence of W—W single bonds [cf. WO_2: d(WW) = 249 pm (double bond)[4]; $W_2Cl_9^{3-}$: d(WW) = 241 pm (triple bond)[5]].

Disregarding the metal atoms, each tungsten atom is surrounded by a distorted octahedron of three terminally bound fluorine atoms and three bridging oxygen atoms [d(WF): six bonds with lengths between 196(2) and 204(2) pm, mean value 201 pm, and three bonds each *trans* to the μ_3 oxygen and each with a length of 207(2) pm. Three of the four oxygen atoms lie 121 pm below [d(WO): 191(2) to 199(2) pm, mean value 195 pm] and the fourth (μ_3-O) 148 pm above the W_3 plane [d(WO): 207(2) pm, $\sphericalangle$WOW 74.9(1)°]. Similar structural units are to be seen in the three-dimensional crosslinked structures of Nb_3Cl_8[6] and $Zn_2Mo_3O_8$[7].

$[W_3O_4F_9]^{5-}$ represents the first example of an oxofluoro anion of a transition element not bearing terminally bound oxygen atoms. In the case of oxofluoro compounds with a central atom having d^0 configuration oxygen favors the terminal positions, since the effective charge of the central atom can be reduced by the formation of M—O π bonds. The polynuclear oxofluoro anions of Mo^{V}[8] and W^{V}[9] contain bridging oxygen atoms along with terminal ones. In $[W_3O_4F_9]^{5-}$ the formation of M—O π bonds does not take place because of the still lower oxidation state of the central atom.

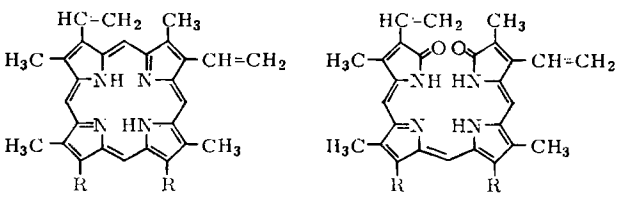
Synthetic amorphous calcium phosphate and its relation to the mineral matter of bones is the subject of a review by *A. S. Posner* and *F. Betts*. Inorganic constituents of bones are primarily calcium phosphate having the same Ca : P ratio as in hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ and CO_3^{2-}, alongside traces of citrate and metal ions. The extremely small size of the crystals in bone material (200—300 Å) precludes X-ray studies on single crystals. Model studies showed that precipitation of hydroxyapatite from strongly supersaturated solutions always yields amorphous calcium phosphate initially which transforms autocatalytically to hydroxyapatite but can also be stabilized. Amorphous calcium phosphate obtained in this way, extremely finely divided synthetic hydroxyapatite, and mineral bone material were compared by X-ray diffraction techniques. Accordingly, the mineral bone material of adults probably consists predominantly of carbonate-containing hydroxyapatite whose structure is characterized by dislocations. [Synthetic Amorphous Calcium Phosphate and Its Relation to Bone Mineral Structure. Acc. Chem. Res. *8*, 273—281 (1975); 42 references]

[Rd 816—L IE]

The electron as a chemical entity is dealt with by *F. S. Dainton* in the "Faraday Lecture". Introductory theoretical considerations of the electron in condensed systems is followed by a discussion of how this species can be generated and how its most important physical and chemical properties have been elucidated. Knowledge about the solvated electron contributes, *inter alia*, to a better understanding of industrially important processes such as the hydrodimerization of acrylic compounds (*e.g.* acrylonitrile → hexanedinitrile) or the coupling of pyridine to give bipyridyl. [The Electron as a Chemical Entity. Chem. Soc. Rev. *4*, 323—362 (1975); 58 references]

[Rd 819 IE—F]

Bile pigments are summarized in an article by *M. F. Hudson* and *K. M. Smith*. Bile pigments are formed in nature by oxidative degradation of the prosthetic groups of hemopro-



(1) R = CH_2CH_2COOH *(2)*

teins. One example is the ring opening of the iron complex of protoporphyrin IX *(1)* to give biliverdin IXα *(2)* which in mammals undergoes further rearrangement. In mammals bile pigments are only waste products, whereas in lower animals they are often of vital importance, *e.g.* as pigments for protective coloring and as components of defense secretions; protein-bound bile pigments are photosynthetically active. [Bile Pigments. Chem. Soc. Rev. *4*, 363—399 (1975); 110 references]

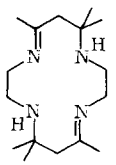
[Rd 820 IE—F]

Spin-lattice relaxation is designated by *L. D. Hall* in the "Tate and Lyle Lecture" as a fourth dimension for ^{1}H-NMR spectroscopy. In the ^{1}H-NMR spectra three types of parameters are usually evaluated: chemical shift, coupling constants, and areas under the signals. With newly developed instruments and techniques it has become possible to carry out routine measurements of spin-lattice relaxation times (T_1 values). The T_1 values reflect, *inter alia*, the spatial arrangement of the

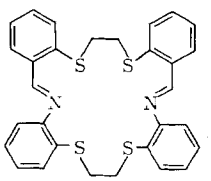
observed protons; the utility of this method is demonstrated using the investigation of carbohydrates as example. [Spin-Lattice Relaxation: A Fourth Dimension for Proton NMR Spectroscopy. Chem. Soc. Rev. *4*, 401—420 (1975); 33 references]

[Rd 821 IE—F]

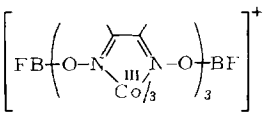
Transition metal complexes of synthetic macrocyclic ligands are discussed in an article by *L. F. Lindoy*. In addition to cyclic polyethers of the "crown" type, ring systems containing



(1)



(2)



(3)

nitrogen as donor, *e.g. (1)*, have also been investigated as ligands. Sulfur and phosphorus can also function as donor atoms. Crown compounds do not as a rule form stable complexes with transition metal ions, although ligands of type *(1)* do. Complete incorporation of a transition metal of the first series requires a 13 to 16-membered ring, in which the nitrogen atoms must be so arranged that five-, six-, or seven-membered rings are formed in the coordination of the metal ion. Ligands such as *(2)* having larger rings have to undergo twisting. *(3)* is an example of a three-dimensional "cage-like" complex. In addition to an outline of the synthesis and reactions of these compounds, models of biological macrocyclic systems such as vitamin B_{12} are also discussed. [Transition Metal Complexes of Synthetic Macrocyclic Ligands. Chem. Soc. Rev. *4*, 421—441 (1975); 95 references]

[Rd 822 IE—F]

Cyanides of metals from the 4th—7th subgroups are reviewed by *W. P. Griffith*. Though cyano complexes of all coordination numbers from eight to two are known, in the 4th—7th subgroups only octa-, hepta-, and hexacoordination have been established. The versatility of cyanide in the stabilization of oxidation states is exemplified by Mo and W (V to 0) and Re (VI to I). Methods of preparation are outlined, and metal-to-cyanide bonding is discussed. Transition metals with few d electrons will tend to use all five *n*d orbitals as well as $(n+1)$s and $(n+1)$p orbitals. The main part of the paper describes the chemistry of these complexes. [Cyanide Complexes of the Early Transition Metals (Group IVa—VIIa). Coord. Chem. Rev. *17*, 177—247 (1975); 359 references]

[Rd 823 IE—H]

BOOK REVIEWS

Methodicum Chimicum. General editor *F. Korte*. Vol. 6: C—N Compounds. Edited by *F. Zymalkowski*. Georg Thieme Verlag, Stuttgart and Academic Press, New York—London 1974. 1st Edit., viii, 864 pp., 104 tables, bound, DM 390.—.

The present volume[*] describes the methods used for the preparation of organic compounds containing nitrogenous groups. The chapters are arranged by compound classes, those treated being amines, carboxylic and thiocarboxylic acid derivatives containing nitrogenous groups, aliphatic diazo compounds*, organic *N*-oxides, hydrazines and hydrazones, aromatic diazonium salts*, oximes*, nitroso compounds, azido compounds*, amino carboxylic acids, azo and azoxy compounds, nitro compounds, hydroxylamines, nitriles, quaternary ammonium compounds, isocyanides/cyanates/thiocyanates, aziridines and azetidines, as well as aromatic hydrazo compounds. The chapters do not appear in the book in the same order as the above list but in the order of length, which varies from a maximum of 127 pages (for amines) to a minimum of 5 pages. There is no chapter on imines; moreover, rather unfortunately, the enamines are not treated separately but together with aliphatic and aromatic amines and are thus scattered.

The chapters are subdivided very rigidly according to the type of the preparative method (substitution, addition, redox reaction, condensation *etc.*); the range of application, the choice of reagents and reaction conditions, and the side reactions are discussed in detail. Particularly valuable are the tabulations, in some of which various processes are compared while in others examples are given of special methods and their yields. For experimental details the reader is directed to the original literature or to previous comprehensive publications, *e.g.* Houben-Weyl. The reactions of the various classes are described very briefly, if at all; only the chapters provided with an asterisk in the above list contain detailed descriptions of the possible reactions.

In spite of the large number (37) of authors who have contributed to this volume, the text is very uniform; there is hardly any overlapping, although Strecker synthesis appears in the chapters on amino carboxylic acids and on nitriles. This is due to the systematic approach, which occasionally degenerates into excessive formalism (Preface: "It was unavoidable that some methods of preparing organic nitrogen compounds could be treated either as N—N bonding or as rearrangements of other organo-nitrogen compounds"). Unfortunately this formal systematization is also the basis of the 56-page subject index, whose preparation must have been extremely laborious but which, in the reviewer's opinion, prevents rapid location of data not given in the clear contents list at the beginning of the book. Alongside a few general (and necessarily incomplete) headings such as "analysis" and named reactions, the index contains mainly individual compounds namely systematically according to Chemical Abstracts style and also groups of compounds ("amine/acetyl-alkyl"). In the last category, which is certainly very valuable for searches, the systematic approach is taken so far that, *e.g.* "enamines" contains only the statement "see under corresp. alkene"; in other cases the situation is not very clear: under "alkene/α-amino" we find two page numbers, one of which (p. 495) refers to the preparation of enamines from acetylenes and the other (p. 533) to that of allylamines from amides of α,β-unsaturated carboxylic acids; under "1-alkene/1-amino" we find only a

[*] Cf. Angew. Chem. *86*, 170 (1974); Angew. Chem. Int. Ed. Engl. *13*, 213 (1974).

single entry (p. 507), concerning the catalytic hydrogenation of aromatic nitro compounds containing "alk-1-en-1-yl substituents". It would be wise if the indexes of future volumes were constructed in a manner more adapted to their primary purpose.

In view of its comprehensive content and clear presentation this volume can be considered as an important reference work for problems of synthesis; for organic-chemical libraries it may be regarded as essential.

Günter Kresze [NB 294 IE]

Allgemeine und spezielle Pharmakologie und Toxicologie. (General and Specialized Pharmacology and Toxicology). Edited by *W. Forth, D. Henschler*, and *W. Rummel*. Wissenschaftsverlag, Bibliographisches Institut, Mannheim–Vienna–Zurich, 1975, 606 pp., numerous figures and tables, bound, DM 78.—.

In this book 25 authors set themselves the task of describing the material content of pharmacology and toxicology in relation to one another. Based on the subject list of the approbation law, the first part is devoted to general pharmacology and describes the interaction between drugs and living organisms. These principles make it easier to understand the appreciably larger second part concerned with the specialized pharmacology of organs and the possibilities available for treating them with drugs. Further chapters deal with the use of X-ray contrast media, the chemotherapy of infectious diseases, and the formation and treatment of tumors. An extensive section on poisons provides the conclusion.

The intention of this arrangement was to present in connected form material that is divided during studies between different departments. All the textual material concerned with pharmacotherapy is picked out in red. In this way the beginner who does not yet understand the principles merely has to turn the pages, while the more knowledgeable reader has in front of him all that belongs together. The large number of illustrations, usually in two colors, makes the text very easy to interpret, while numerous formulas in modern formulation and excellently drawn provide an easy overall view of the subject.

The reviewer, who is not a medical man, finds the underlying idea very good indeed. The pharmacological aspects are described with didactic skill and are easy for the general scientist to understand. Unfortunately, the information content of the individual chapters is very varied, as can be shown by comparing the section on endocrine pharmacology with the neighboring section on vitamins: in the former there are clear schematic illustrations of the mechanisms of action and regulation, and clear and detailed formulas for the biogenesis and metabolism of hormones; in contrast, for vitamins only brief indications are given in the text.

Apart from the section on vitamins, the sections on antimycotics, antiprotozoal drugs, and anthelmintics are underdeveloped from the point of view of the pharmaceutical chemist, as they are treated in a total of barely three pages and, after all, hundreds of millions of people suffer continuously from malaria, bilharzia, or hookworm.

Thus, although the scheme of the book is so illuminating, it could be greatly improved by thorough revision, which should not only root out the numerous printing errors and many wrong formulas but also remove factual errors; for example, phenazone is very readily soluble in water, chloral hydrate is not a chlorinated alcohol, tubocurarine is monoquaternary, colchicine is not the same as demecolcine, and if carboxylesterases really hydrolyze amides such as phenacetin or salicylamide this should be explained in more detail for the benefit of the uninitiated.

Thus, the Forth-Henschler-Rummel book in its present form is an attractively produced and impressive source of information; after thorough revision it would become a first-class textbook that would probably be in great demand.

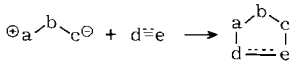
Intramolecular 1,3-Dipolar Cycloaddition Reactions

By Albert Padwa[*]

The intramolecular 1,3-dipolar cycloaddition reaction of suitably functionalized 1,3-dipoles represents a general scheme for the synthesis of novel fused ring heterocycles. Such reactions of a number of 1,3-dipoles are summarized and the general outline and potential analogies for these reactions noted. While the immediate aim of this review is to survey and correlate published work, it is hoped that general and specific points in need of study will be revealed and will stimulate further work in this fertile field.

1. Introduction

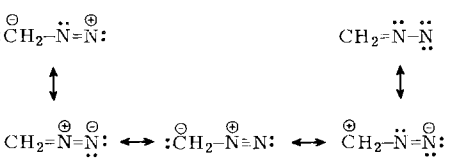
Huisgen et al. were the first to recognize fully the general concept and scope of 1,3-dipolar cycloadditions[1–5], a reaction of considerable scope for the synthesis of five-membered heterocyclic rings. 1,3-Dipolar cycloadditions are bimolecular in nature and involve the addition of a 1,3-dipole to a multiple bond system leading to five-membered heterocycles, according to Scheme 1.



Scheme 1

A 1,3-dipole is basically a system of three atoms over which are distributed four π electrons as in the allyl anion system. The three atoms can be a wide variety of combinations of C, O, and N. The dipolarophile can be virtually any double or triple bond. The term "1,3-dipole" arose because in valence bond theory such compounds can only be described in terms of dipolar resonance contributors, as shown for diazomethane.

The extreme 1,3-dipolar forms with their complementary nucleophilic and electrophilic centers readily explain the tendency to undergo addition to π bonds. Indeed, it must be possible to write 1,3-dipolar forms for all such species which undergo this type of addition.



Huisgen et al. have systematically studied the mechanism of 1,3-dipolar cycloadditions[1–3]. In the great majority of 1,3-cycloadditions, the reaction rate is not markedly influenced by the dielectric constant of the solvent medium in which the reaction is conducted. The independence of solvent polarity[6], the very negative entropies of activation[7], and the stereospecificity and regiospecificity[2] point to a highly ordered transition state. In most instances of 1,3-dipolar cycloaddition reactions, when two isomers are possible as a result of the use of unsymmetrical reagents, one isomer usually predominates, often to the exclusion of the other[8, 9].

The principal question that arises when considering the regiospecificity of 1,3-dipolar additions is whether the two new σ bonds formed on addition of the 1,3-dipole to the dipolarophile are formed simultaneously or one after the other. The mechanism that has emerged from *Huisgen*'s group is

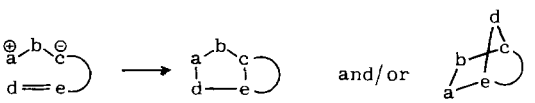
[*] Prof. Dr. A. Padwa
Department of Chemistry,
State University of New York at Buffalo
Buffalo, New York 14214 (USA)

that of a single-step, four-center, "no-mechanism" cycloaddition, in which the two new bonds are both partially formed in the transition state, although not necessarily to the same extent[1-3]. A symmetry-energy correlation diagram reveals that such a thermal cycloaddition reaction is an allowed process[2, 10, 11]. An alternative mechanism that has been proposed is a two-step process involving a spin-paired diradical intermediate[12].

The regioselectivity of 1,3-dipolar cycloaddition reactions has, until recently, been a most difficult phenomenon to explain. Rationalizations of regioselectivity based on a concerted transition state model have invoked both electronic and steric effects[1-3, 13]. A solution to the vexing problem of regioselectivity in 1,3-dipolar cycloadditions has recently been proposed by *Houk et al.*[14-17], who used the frontier orbital method for rationalizing the effect of substituents on rates and regioselectivity of 1,3-dipolar cycloadditions. According to the frontier orbital treatment of 1,3-dipolar cycloadditions[14-18], the relative reactivity of a given 1,3-dipole toward a series of dipolarophiles will be determined primarily by the extent of stabilization afforded the transition state by interaction of the frontier orbitals of the two reactants. Reactions have been classified[18] into three types depending on whether the dominant interaction is between the highest occupied molecular orbital (HOMO) of the dipole and the lowest unoccupied molecular orbital (LUMO) of the dipolarophile, or the dipole LUMO and the dipolarophile HOMO, or whether both these interactions are of equal significance. The energies of both HOMOs are increased by the presence of electron-donating (including alkyl) and conjugating substituents and the energies of both LUMOs are decreased by electron-withdrawing and conjugating substituents[14-17].

This frontier orbital model also deals with the problem of regioselectivity of addition. In order to predict regioselectivity, it becomes necessary to determine the relative magnitudes of the coefficients in the HOMO and LUMO of the 1,3-dipole and dipolarophile. The favored cycloadduct will be that formed by union of the atoms with the largest coefficients. Further mechanistic discussion is to be found in the original literature.

In spite of the copious literature dealing with bimolecular 1,3-dipolar cycloaddition reactions, intramolecular examples have received only a minimum of attention. 1,3-Dipoles bearing a functional group able to behave as a dipolarophile are extremely interesting substrates. In fact, the intramolecular cycloaddition of a properly functionalized 1,3-dipole represents a general scheme for the synthesis of novel fused ring heterocycles (see Scheme 2).

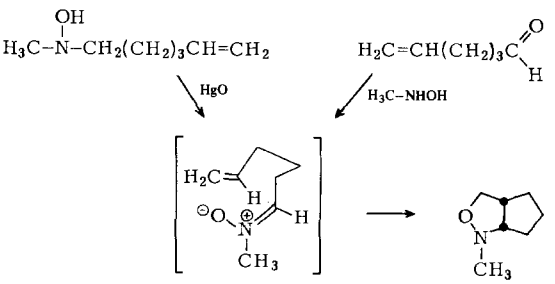


Scheme 2

In the present paper, the findings dealing with intramolecular 1,3-dipolar cycloadditions will be reviewed.

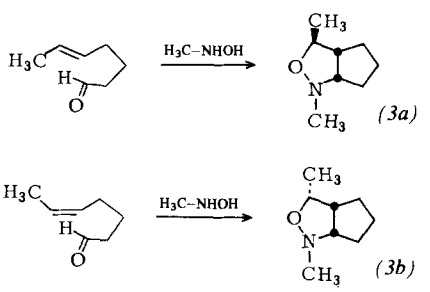
2. Nitrones

1,3-Dipolar cycloadditions of nitrones have been reported with a variety of alkynes, alkenes, isocyanates, isothiocyanates, thiocarbonyl compounds, phosphoranes, sulfenes, and sulfinyl groups[19]. All these reactions are usually carried out by heating the two reagents together in an inert solvent, and the products are often easily isolated in high yield. It should be pointed out that the cycloadducts are not stable in all cases and sometimes undergo interesting transformations. Whereas the cycloaddition of a simple alkene to a simple nitrone produces a simple isoxazolidine, a fused bicyclic isoxazolidine *(2)* can be formed when the alkene and nitrone moieties are suitably arranged in the same molecule. This useful synthetic idea was first investigated by *LeBel et al.*[20], using molecules in which the nitrone was separated by a propylene or butylene chain from the alkene. The unsaturated nitrone *(1)* was not isolated but was generated either by oxidation of an *N*-alkenylhydroxylamine or by condensation of an unsaturated aldehyde with *N*-methylhydroxylamine.



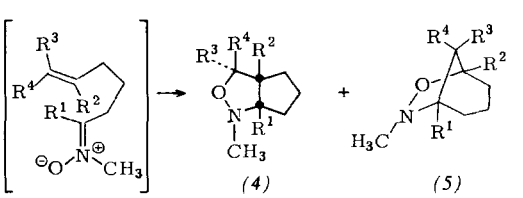
(1) *(2)*

When the cycloaddition was carried out with *trans*- and *cis*-5-heptenal, two different isoxazolidines, *(3a)* and *(3b)*, respectively, were obtained. It is apparent from these results that the intramolecular addition is kinetically controlled and that the configuration of the olefin is retained in the product isoxazolidine. Internal cycloaddition to give the *cis* fused bicyclo[3.3.0]octane skeleton is preferred since closure to the highly strained *trans* fused isomer would involve a transition state of much higher energy.



(3a) *(3b)*

A preference was found for the formation of the (fused) bicyclo[3.3.0]octane system *(4)*, but the (bridged) bicyclo[3.2.1]octane system *(5)* appeared when bond formation between the 2-position of the alkene and the α-position of the nitrone was hindered by substitution in those positions[21].

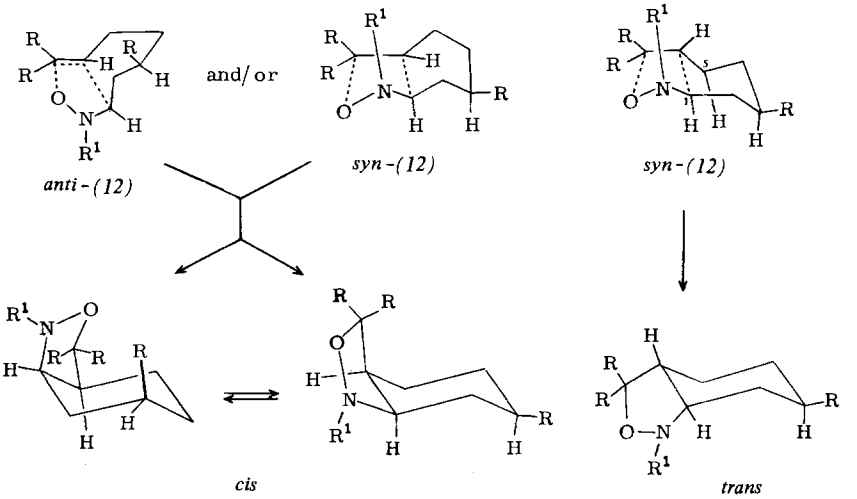


(4) *(5)*

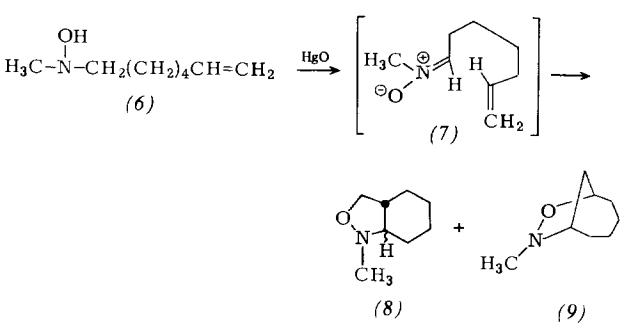
For example, when only one of the substituents R^1, R^2, R^3, and R^4 is a methyl group and the others hydrogen atoms, only the fused product *(4)* is formed, but when $R^1=R^2=CH_3$

and $R^3=R^4=H$ approximately equal amounts of fused *(4)* and bridged *(5)* products are formed. The presence of methyl groups in these positions (*i.e.* $R^1=R^2=CH_3$) forces them to be strongly eclipsed in the transition state leading to the normal fused product *(4)*. In this case, the severe steric interactions allow for the competing formation of the bridged product *(5)*.

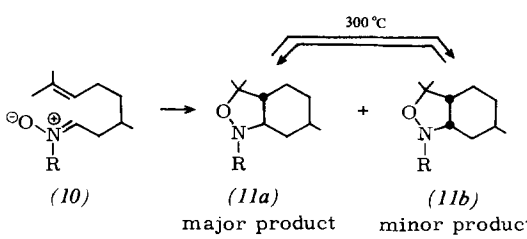
isoxazolidine into nitrone *(10)* followed by ring closure to give a product with the opposite stereochemistry. This isomerization represents an example of the reversibility of the intramolecular cycloaddition of an unsaturated nitrone. Retro 1,3-dipolar additions have been previously noted with intermolecular examples of nitrone-olefin adducts[24] and provides reasonable analogy for the above interconversion.



The cycloaddition reaction was extended to include the homologous nitrone *(7)*[22]. Mercuric oxide oxidation of *N*-6-heptenyl-*N*-methylhydroxylamine *(6)* afforded a mixture of *cis*- and *trans*-*N*-methyl-8-oxa-7-azabicyclo[4.3.0]nonane *(8)* (ratio 2:1) as well as lesser quantities of a product having the bicyclo[4.2.1]nonane structure *(9)*.



Under conditions of kinetic control, the *cis* ring fusion [cf. *(8)*] predominated in the condensation of 6-heptenal with methylhydroxylamine. However, the major product *(11a)* derived from (+)-citronellal and *N*-substituted hydroxylamines was shown to have the *trans* ring fusion. In this

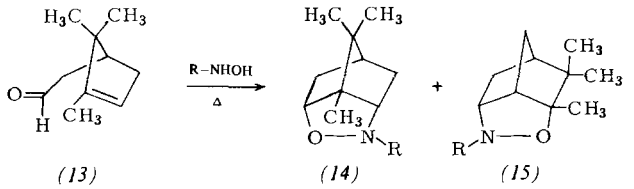


case the stereochemistry was found to be temperature dependent; increasing proportions of *(11b)* were obtained at high reaction temperatures[23]. At 300 °C the *trans* fused isoxazolidine *(11a)* undergoes partial isomerization to the *cis* isomer. This process was rationalized by thermal conversion of the

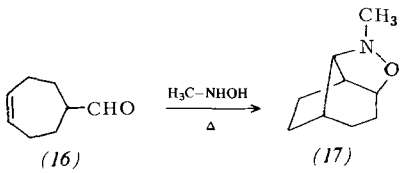
In order to rationalize the stereochemical results, *LeBel* suggested that the transition state leading to *cis* ring fusion requires the potential six-membered carbocyclic ring to adopt a twist conformation. A slightly deformed chair arrangement will produce the *trans*-isomer. Examination of models indicates that orbital overlap for 1,3-addition is favorable for a *cis* ring juncture for both *syn*- and *anti*-configurations of the intermediate nitrone *(12)*. Effective overlap in the transition state for formation of a *trans*-fused product is essentially precluded with an *anti* nitrone, and only the more favorable *syn* arrangement can lead to product. It is quite reasonable to assume that the ground state equilibrium composition of the nitrone favors the *anti* configuration. If the barrier to *syn*→*anti* isomerism is of the order of magnitude of the activation energies for intramolecular addition, then *cis* product will be favored. On the other hand, if the barrier to rotation in the nitrone is low, then the ratio of products will depend only on the difference in free energy levels of the respective transition states (Curtin-Hammett principle). In the transition state leading to *trans* isomer, a significant interaction develops between the 1-H and the 5-methylene group which allows the seemingly less favorable twist arrangement of the tetramethylene chain leading to *cis*-isomer to compete successfully. This would account for the observed isomer ratio of 2:1 (*cis*/*trans*) in the condensation of 6-heptenal with methylhydroxylamine. With citronellal, the *trans* product is more stable than the *cis* compound, and product development control predominates.

LeBel et al. further demonstrated the utility and synthetic scope of the intramolecular 1,3-dipolar cycloaddition of nitrones by preparing a variety of polycyclic isoxazolidines[21, 25–27]. Examples include the syntheses of compounds *(14)*, *(15)*, *(17)*, *(19)*, *(21)*, *(23)*, and *(25)*.

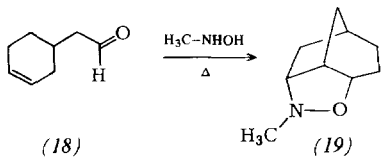
These ring closure reactions were suggested to be initiated by electrophilic attack of the nitrone on the olefin, the nitrone carbon atom thus resembling a carbenium ion center[25]. No



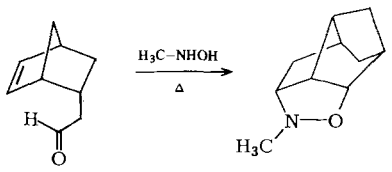
(13) (14) (15)



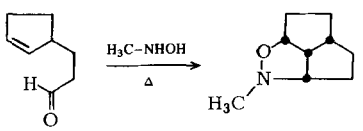
(16) (17)



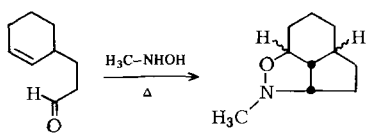
(18) (19)



(20) (21)



(22) (23)

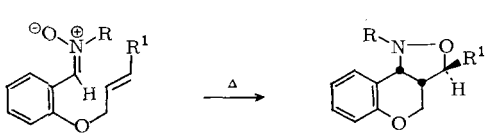


(24) (25)

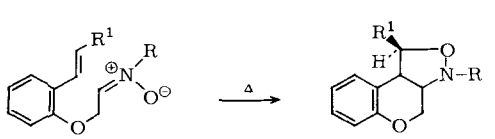
distinction was made between a one-step process or a two-stage mechanism involving a rapid second step.

Oppolzer et al.[28-30] have extended the intramolecular 1,3-dipolar cycloaddition reaction to include nitrone-alkenes separated by chains that generally incorporate a benzene ring and a heteroatom to produce isoxazolidines *(27)* and *(29)*.

In most of the cases examined the isoxazolidine was found to contain a *cis*-ring junction between the heterorings. Adducts

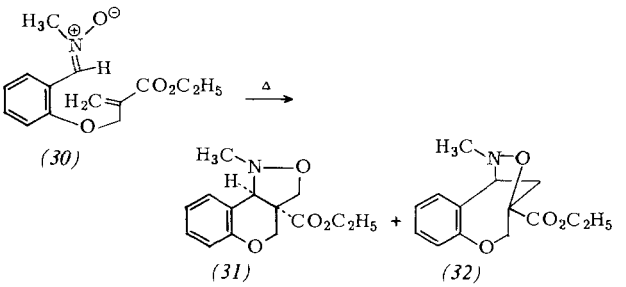


(26) (27)

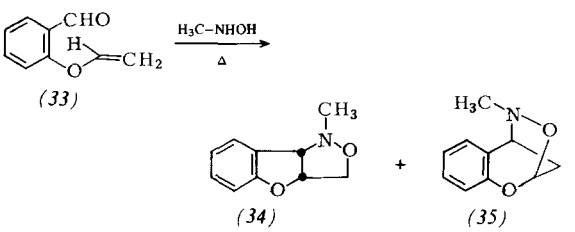


(28) (29)

with bridged structures such as *(32)* and *(35)* were also formed in some cases[28-30].

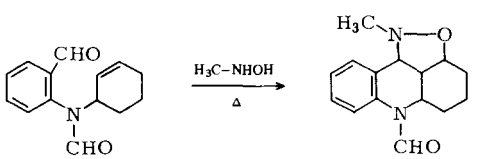


(30) (31) (32)



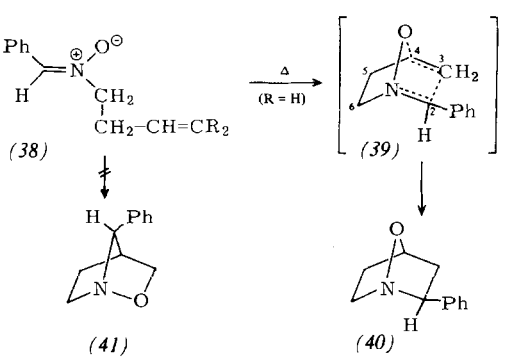
(33) (34) (35)

Also, the ether oxygen can be replaced by a formamido group which results in the formation of the related tetrahydroquinoline product *(37)*[28].



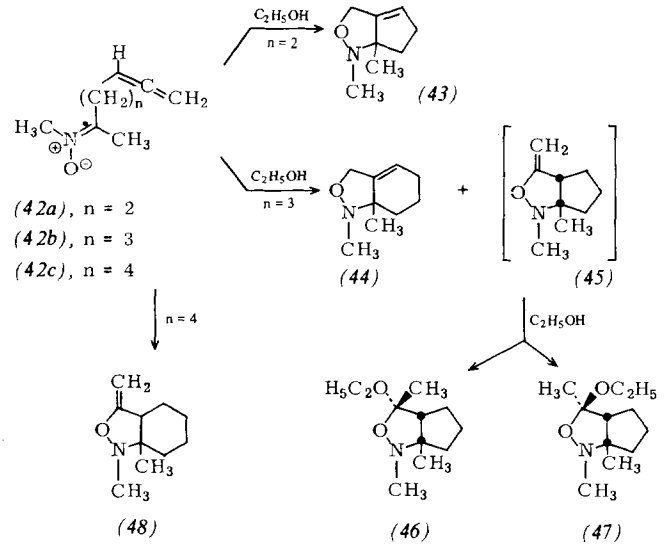
(36) (37)

When the alkene functionality is attached to the nitrone's nitrogen atom, only bridged structures are formed[31]. In the case of *N*-3-butenyl nitrone *(38)*, the terminal alkene carbon atom takes part in CC bond formation.



(38) (39) (41) (40)

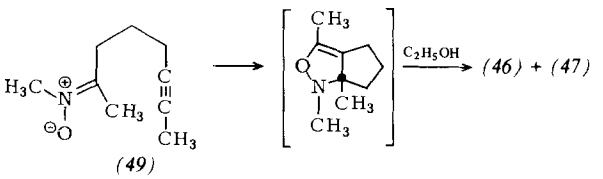
Cycloaddition fails for the *N*-butenyl system where R = CH_3, presumably owing to considerable steric hindrance in the transition state. The preferential formation of *(40)* rather than *(41)* has been attributed to steric destabilization of the transition state for the formation of the latter compound[31]. Inspection of Dreiding models of nitrone *(38)* reveals that significant σ overlap between O and C-4 and between C-2 and C-3 in transition state *(39)* cannot develop simultaneously unless the latter assumes product-like geometry[31]. The preference for *(40)* could also be explained by electronic factors. The formation of this isomer corresponds to the electronically favored addition direction of a nitrone to a monosubstituted ethylene[32].



(42a), n = 2
(42b), n = 3
(42c), n = 4

(43) (44) (45) (48) (46) (47)

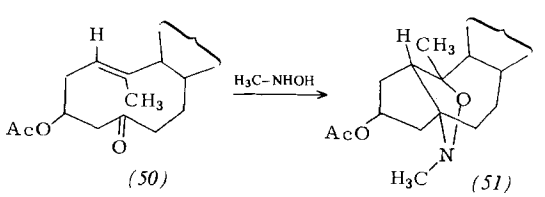
The intramolecular cyclization of allenic nitrones was found to afford several novel bicyclic products[33]. Treatment of 5,6-heptadien-2-one with *N*-methylhydroxylamine gave a transient nitrone *(42a)* which produced the unsaturated bicyclic isoxazolidine *(43)* by intramolecular cycloaddition at the terminal double bond of the allenic function. Cyclization of the homologous nitrone *(42b)* gave bicyclic adduct *(44)* as well as the stereoisomeric isoxazolidines *(46)* and *(47)*. The data indicate that the *exo*-methyleneisoxazolidine *(45)* is initially formed by addition of the nitrone to the internal bond of the allenic group. Subsequent acid catalyzed addition of ethanol produced the ethers *(46)* and *(47)*. A related set of reactions occurred with acetylenic nitrone *(49)*[33].



(49) (46) + (47)

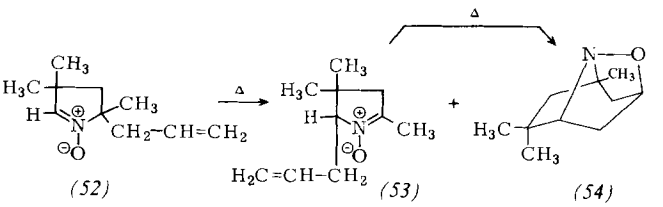
Treatment of 7,8-nonadien-2-one with *N*-methylhydroxylamine gave nitrone *(42c)* which cyclized to bicyclic adduct *(48)* by addition of the nitrone moiety to the internal carbon-carbon double bond of the allenic function. Thus the product formed in these intramolecular cyclizations depends on the separation of the allene and nitrone groups.

Reaction of the 1(10)-unsaturated *trans*-5-oxo-5,10-secosteroid *(50)* with *N*-methylhydroxylamine has been reported to give a non-isolable nitrone which undergoes spontaneous transannular cyclization with formation of the *N*-methylisoxazolidine derivative *(51)* in over 60% yield[34]. The geometry of the *trans*-cyclodecenone ring in the modified steroid compound is favorable for transannular 1,3-dipolar cycloaddition. In contrast, the diastereomeric 1(10)-unsaturated *cis* nitrone system does not undergo intramolecular 1,3-dipolar addition since the double bond between C-1 and C-10 and the trigonal C-5 atom of the *cis*-cyclodecenone ring are too far apart to permit the internal cyclization reaction to occur.



(50) (51)

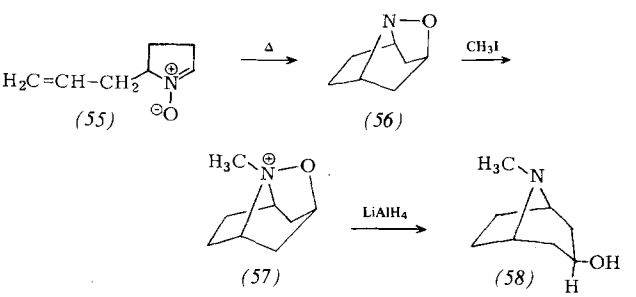
Bapat et al.[35] have recently described the thermal behavior of a cyclic nitrone, 5-allyl-3,3,5-trimethyl-1-pyrroline *N*-oxide *(52)*, which gives both a Cope rearrangement product *(53)* and an internal cycloaddition product *(54)* when heated in an inert solvent[35]. The proportions of the two rearranged products varied as a function of the thermal conditions used.



(52) (53) (54)

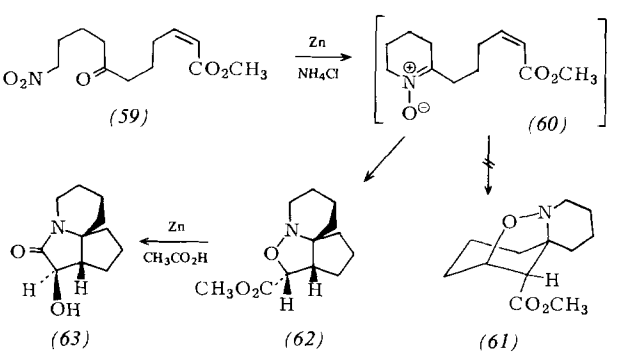
Heating nitrone *(52)* in boiling toluene for 1 h gave the Cope rearrangement product *(53)* as the only isolable product. The rearranged nitrone *(53)* was slowly converted into cycloadduct *(54)* in boiling xylene, and this cycloadduct could most conveniently be prepared by heating *(52)* in boiling xylene for 5 h. Thus the formation of cycloadduct *(54)* can be attributed to cyclization of the rearranged nitrone *(53)*.

The intramolecular dipolar addition of 5-allyl-1-pyrroline *N*-oxide *(55)* has been found to give a cycloadduct *(56)* which is a useful precursor of the tropane skeleton[36]. This conversion was achieved by methylation of *(56)* with methyl iodide to give the quarternary salt *(57)* which gives pseudotropine *(58)* upon reduction with lithium tetrahydridoaluminate.



(55) (56) (57) (58)

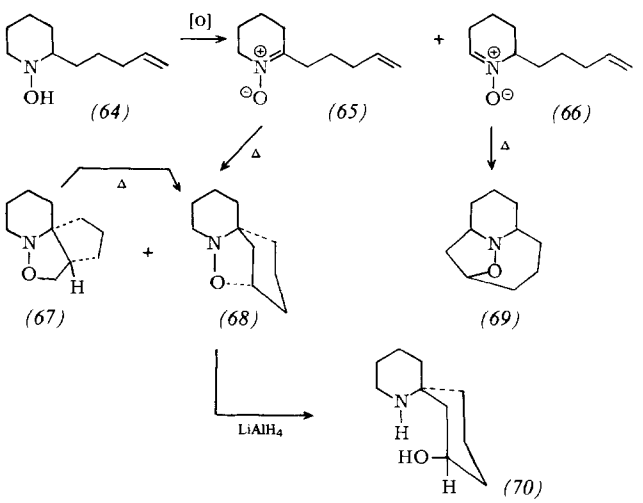
An elegant approach to the ring skeleton of histrionicotoxin involving an intramolecular cyclization of a nitrone moiety with an activated olefin has recently been attempted by two groups of workers[37, 38]. Cyclization of nitrone ester *(60)* was considered to offer high promise for producing the desired ring system *(61)* of histrionicotoxin. However, treatment of nitro-ketone *(59)* in aqueous methanol with zinc and ammonium chloride gave only cycloadduct *(62)* *via* spontaneous cyclization of a transient nitrone intermediate *(60)*. Chemical evidence for the structure of *(62)* was obtained



(59) (60) (63) (62) (61)

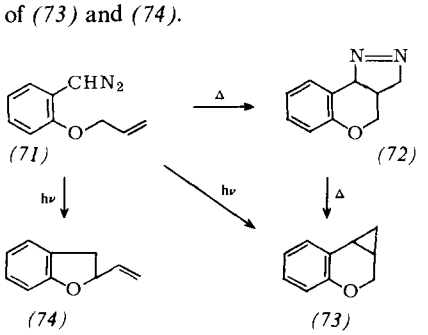
by cleavage of the nitrogen-oxygen bond with zinc and acetic acid to the hydroxy lactam *(63)*. The formation of *(62)* rather than *(61)* from the nitrone cyclization was attributed to the greater steric interactions in the transition state leading to *(61)*[37].

It is interesting to note that cyclization of the closely related unsaturated nitrone *(65)* resulted in the formation of both regioisomers *(67)* and *(68)*[38]. Nitrone *(65)* as well as smaller quantities of the isomeric nitrone *(66)* were generated by oxidation of the hydroxylamine derivative *(64)*. The major cycloadduct *(67)* was thermally isomerized to the thermodynamically more stable compound *(68)* having a bicyclo[3.2.1]octane partial structure, presumably by way of a 1,3-dipolar cycloreversion. Reduction of the nitrogen-oxygen bond of *(68)* afforded *cis*-1-azaspiro[5.5]undecan-8-ol *(70)* which contains the skeleton of histrionicotoxin (without side chains)[37, 38].

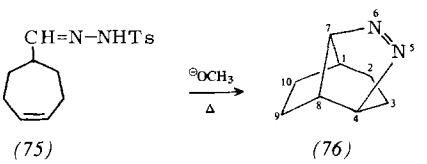


3. Diazoalkanes

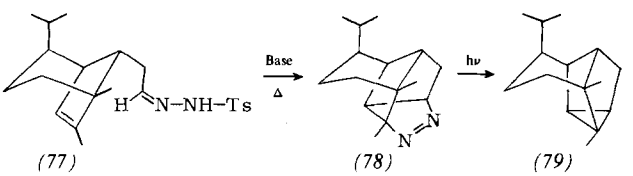
1,3-Dipolar cycloadditions of diazoalkanes to multiple bonds was first observed in 1888 by *Buchner*[39]. Since the initial report, many examples have appeared in the literature[1-5]. There are, however, only a few reports dealing with the intramolecular addition of diazoalkanes to carbon-carbon double bonds. *Kirmse* and *Dietrich* reported that the thermolysis of *(71)* gave 1-pyrazoline *(72)* in 80% yield[40]. On further heating, the initially formed 1-pyrazoline lost nitrogen to give the corresponding cyclopropane *(73)*. In contrast to the thermal results, photolysis of *(71)* produced a mixture of *(73)* and *(74)*.



The major product of the reaction of 4-cycloheptenecarbaldehyde tosylhydrazone *(75)* was found to be 5,6-diazatricyclo[5.3.0.0^{4,8}]dec-5-ene *(76)*[41]. This product was formed by intramolecular 1,3-cycloaddition of the diazomethane part of the molecule to the double bond. The authors noted that the double bond has a considerable activating influence on the decomposition of the tosylhydrazone anion and that the cycloaddition of the diazomethane moiety occurred much faster than the competing reaction of carbene formation. Normally pyrazoline formation with unactivated double bonds is a very sluggish reaction[1]. The significant lowering of the temperature at which the tosylhydrazone anion decomposed was attributed to double-bond participation[41].

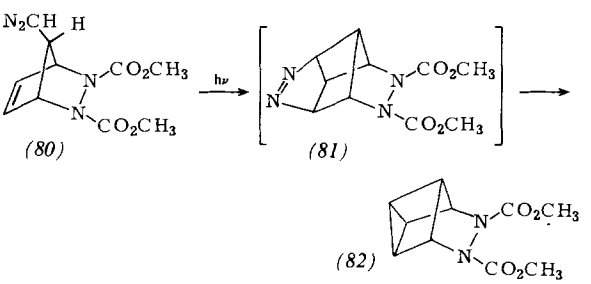


A similar internal cycloaddition occurred[42] when the lithium salt of tosylhydrazone *(77)* was heated at 120 °C. The cycloadduct obtained *(78)* (81 %) was converted into cyclocopacamphene *(79)* on further photolysis. The facile intramolecular 1,3-dipolar cycloaddition of the intermediate olefinic diazoalkane to give *(78)* is presumably related to the proximity



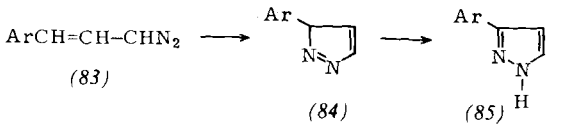
of the two reacting functional groups and to the fairly strained nature of the olefinic double bond.

Trost et al.[43, 44] have recently developed a simple approach to the 7,8-diazatetracyclo[3.3.0^{2,4}.0^{3,6}]oct-7-ene system *(82)*. Irradiation of diazo compound *(80)* generated the tetracyclic framework *(82)* in reasonable yield. The success of the photol-



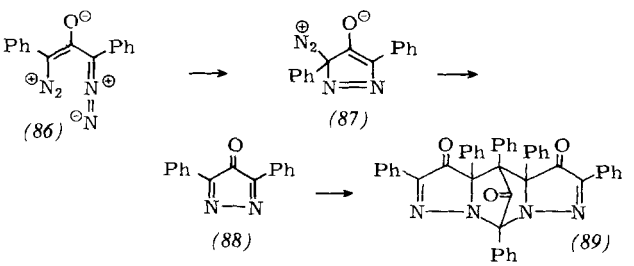
ysis of *(80)* in producing *(82)* is quite interesting in light of *Hoffmann*'s calculations regarding the geometry for singlet carbene additions[45]. These calculations indicate that for a concerted cycloaddition the p orbital of the carbene overlaps in a σ manner with one end of the ethylene π bond. This lopsided configuration is unattainable in the carbene derived from *(80)* without severely distorting the rigid bicyclic framework. The authors suggested that the formation of *(82)* might, in fact, proceed by initial 1,3-dipolar addition of the diazo group to the double bond to produce pyrazoline *(81)*. Extrusion of nitrogen from this transient intermediate could then account for the formation of *(82)*. The photoconversion *(80)* → *(81)* would have to occur from some high vibrational level of the ground state since photochemical 1,3-dipolar cycloadditions are symmetry forbidden.

In 1935 it was briefly reported that 3-diazopropene slowly decomposes at room temperature to give pyrazole[46, 47]. Subsequent investigations showed that this is a general reaction of this class of diazo compounds[48–50]. The small ρ value for the cyclization of 1-aryl-3-diazopropenes, the rate enhancement by aryl conjugation with the carbon-carbon double bond, and the relative insensitivity of the reaction rate to structural changes led *Hart* and *Brewbaker*[50] to conclude that cyclization of 3-diazoalkenes to pyrazoles is an intramolecular, concerted 1,3-dipolar cycloaddition.



(83) *(84)* *(85)*

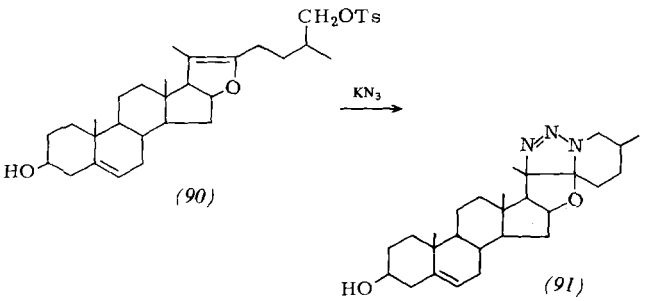
A similar reaction has been reported[51] to occur upon thermal decomposition of the bis-diazo ketone *(86)*. The formation of a trimer *(89)* in this reaction suggested the intermediacy of 3,5-diphenyl-1,2-diaza-4-cyclopentadienone *(88)*. The formation of *(88)* was proposed to involve an electrocyclic ring closure of the bis-diazo ketone *(86)* to give *(87)*, followed by rapid disengagement of nitrogen. The conversion of *(86)* into *(87)* represents another example of the intramolecular cycloaddition of vinyldiazomethanes to pyrazoles[46–50].



(86) *(87)* *(88)* *(89)*

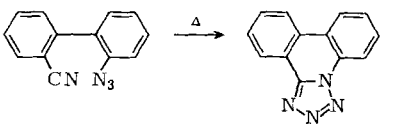
4. Azides

Organic azides are well known to behave as 1,3-dipoles in thermal cycloaddition reactions[1–3]. The first example of this reaction was observed by *Michael* in 1893[52]. With azides, intramolecular cycloadditions have been occasionally reported[53, 54], but systematic data are available only for a series of azidoalkenes[55]. *Uhle* reported that the displacement of the *p*-toluenesulfonate function of the pseudodiosgenin derivative *(90)* with potassium azide in dimethylformamide is followed by 1,3-dipolar cycloaddition to the enol ether olefinic bond to furnish a triazoline derivative *(91)*[53].



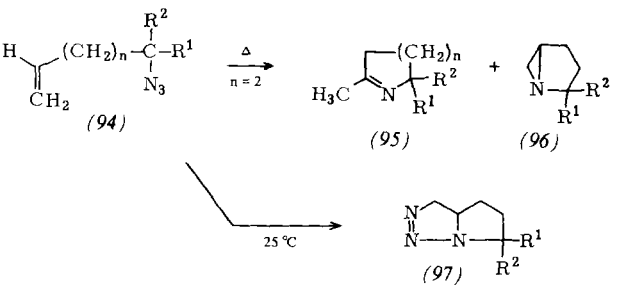
(90) *(91)*

Although less reactive than CC triple bonds, CN triple bonds are known to undergo 1,3-dipolar cycloadditions with some organic azides[5]. The first authenticated case of an azide other than hydrogen azide adding to a nitrile was observed with 2'-azido-2-biphenylcarbonitrile *(92)*[54]. Thermolysis of *(92)* resulted in the formation of tetrazolophenanthridine *(93)*. This transformation can best be described as an intramolecular 1,3-dipolar cycloaddition reaction.



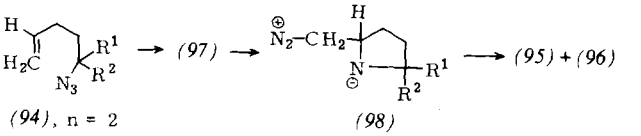
(92) *(93)*

The synthesis and thermal decomposition of various olefinic azides *(94)* to give 1-azabicyclo[3.1.0]hexanes *(96)* and cyclic imines *(95)* has been described by *Logothetis*[55]. The azides were decomposed under a variety of conditions. When the thermolysis was carried out in a hydrocarbon solvent at 80 °C,



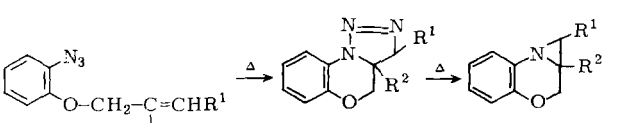
(94) *(95)* *(96)* *(97)*

the decomposition products comprised a mixture of cyclic imines and 1-azabicyclo[3.1.0]hexanes. On the other hand, when the olefinic azides were allowed to stand at 25 °C for 2 months, the isomeric triazolines *(97)* were formed in quantitative yield. Decomposition of the triazolines under conditions identical with the decomposition of the corresponding azides gave *(95)* and *(96)*. On the basis of these results, it was suggested that the triazolines are intermediates in the decomposition of all the olefinic azides studied. Allyl azide and 4-azido-1-pentene cannot undergo internal 1,3-dipolar cycloaddition to give a triazoline similar to *(97)* because of the high degree of strain in such a structure. As a result, their decomposition is very sluggish and no products analogous to *(95)* and *(96)* are formed. The mechanism proposed to explain the formation of *(95)* and *(96)* is outlined below. A nitrene intermediate was completely excluded in these reactions.



(94), n = 2 *(98)*

The intramolecular 1,3-dipolar cycloaddition of aryl azides bearing alkenyl, alkynyl, and nitrile groups has recently been reported by *Fusco et al.*[56]. The decomposition of *(99)* carried out in refluxing benzene gave aziridines *(101)*. The formation of these products involves initial intramolecular cycloaddition

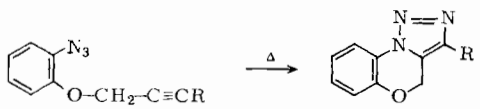


(99) *(100)* *(101)*

$R^1 = R^2 = H$; $R^1 = H$, $R^2 = CH_3$; $R^1 = Ph$, $R^2 = H$

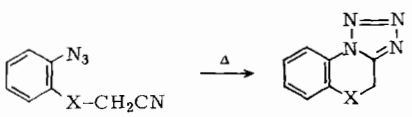
leading to the unstable triazoline system *(100)*. The intervention of such an intermediate was deduced by carrying out the decomposition of *(99)* at room temperature in hexadeuteriobenzene and monitoring the reaction progress by NMR analyses. In addition to the signals of the starting azide and the final product, the spectrum clearly showed a set of signals corresponding to triazoline *(100)*.

Thermolysis of the corresponding alkyne *(102)* gave triazole *(103)* as the only decomposition product. This is the first reported example of the intramolecular cycloaddition of the azido group to an acetylenic function. While the transformation of azide *(102b)* was complete after 3 h, under the same conditions compound *(102a)* entirely disappeared after 15 min. The greater reactivity of *(102a)* in comparison to *(102b)* was somewhat unexpected considering that the conjugated alkynes are usually better dipolarophiles than the unconjugated[57]. The bulky phenyl substituent present in *(102b)* apparently hinders the approach of the reactant groups and consequently decreases the rate of cycloaddition.



(102a), R = H *(103a)*, R = H
(102b), R = Ph *(103b)*, R = Ph

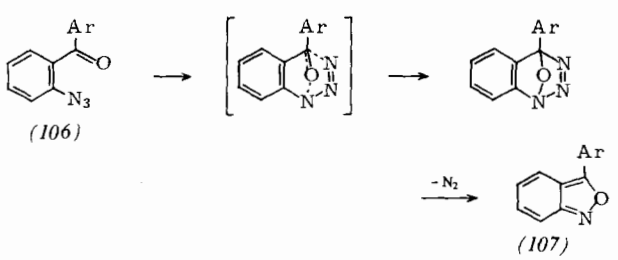
The ring closure of the related azidonitrile system *(104)* has also been studied. The formation of tetrazole derivatives *(105)* was interpreted in terms of an intramolecular 1,3-dipolar cycloaddition. In intermolecular terms, only nitrile groups activated by electron-withdrawing substituents have been shown to behave as dipolarophiles toward azides[5]. The



(104) X = O, CH_2 *(105)*

mutual *ortho* disposition of the two interacting groups in *(104)* provides a favorable stereochemical relationship for intramolecular cycloaddition. Some activating effect by the oxygen atom could be responsible for the greater reactivity in the case X = O.

Ortho-substituted phenyl azides are known to decompose much more rapidly than the corresponding *meta* or *para* isomers. This rate enhancement has been noted primarily in those systems where the *ortho* substituent has some type of α,β-unsaturation and in which the decomposition leads to cyclization. Several workers[58] have suggested that the reaction does not involve a nitrene intermediate but instead proceeds *via* a concerted mechanism in which cyclization and loss of nitrogen are concurrent. On the basis of a kinetic

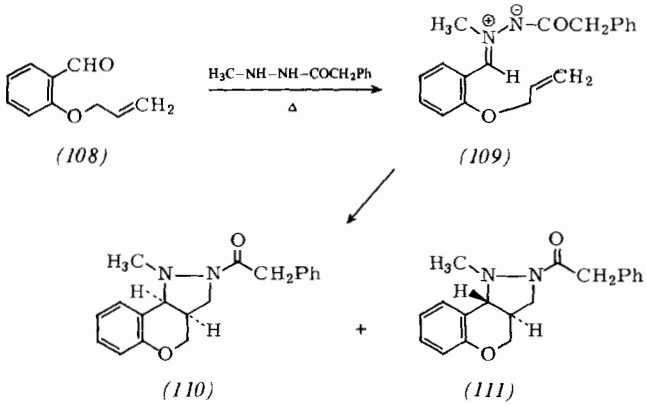


(106) *(107)*

investigation, *Hall et al.*[59] suggested that the cyclization of *o*-azidobenzophenones *(106)* to 3-aryl-2,1-benzoisoxazoles *(107)* can best be explained as proceeding *via* an intramolecular 1,3-dipolar cycloaddition across the carbonyl function. The following mechanism was proposed to account for the kinetic observations.

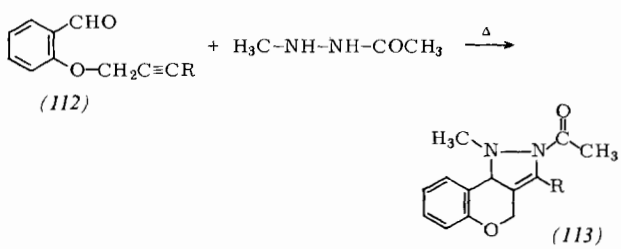
5. Azomethine Imines

These 1,3-dipoles are normally not isolable, but their facile preparation *in situ* from storable precursors makes them easy to use. One convenient procedure for the synthesis of a variety of azomethine imines involves the reaction of 1,2-disubstituted hydrazines with carbonyl compounds[3]. *Huisgen*'s group has shown that the 1,3-dipoles prepared in this fashion are readily intercepted with olefinic dipolarophiles to give pyrazolidines[3]. *Oppolzer*[60] extended this reaction to include systems which contained the olefin and azomethine imine portions in the same molecule[61,62]. For example, treatment of *o*-allyloxybenzaldehyde *(108)* with *N*-methyl-*N'*-phenylacetylhydrazine gave cycloadducts *(110)* and *(111)*. This reaction presumably proceeds through the intermediacy of azomethine imine *(109)* which undergoes a subsequent intramolecular cycloaddition.



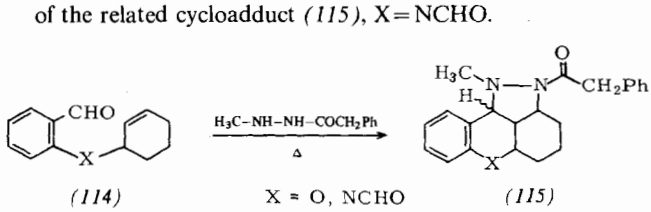
(108) *(109)* *(110)* *(111)*

Similarly, reaction of the related acetylenic derivative *(112)* with *N*-acetyl-*N'*-methylhydrazine gave cycloadduct *(113)* in high yield[62].



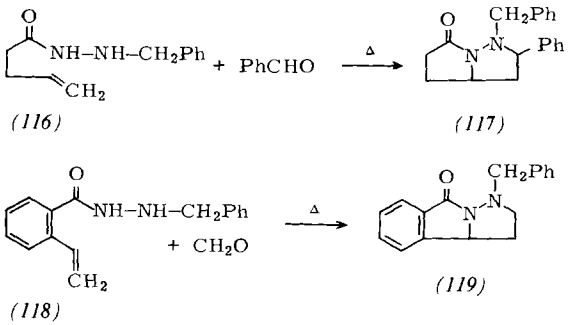
(112) *(113)*

Oppolzer[62] also found that the ether oxygen could be replaced by a formamido group, which results in the formation of the related cycloadduct *(115)*, X = NCHO.



(114) X = O, NCHO *(115)*

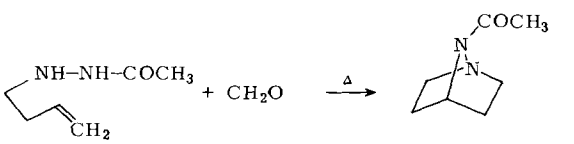
The cyclization was extended to include the reaction of *N*-benzyl-*N'*-(4-pentenoyl)hydrazine *(116)* with benzaldehyde to give cycloadduct *(117)*[61]. Similarly, treatment of *(118)* with formaldehyde produced *(119)*. Both sets of reactions proceed through the intermediacy of an azomethine imine.



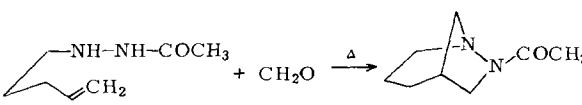
(116) *(117)*

(118) *(119)*

N-Acyl-*N'*-alkylhydrazines react with an aldehyde only on the alkyl substituted nitrogen, thus permitting a regioselective preparation of pyrazolidines with different *N*-substituents. *Oppolzer* showed that the intramolecular 1,3-dipolar cycloaddition reactions of these azomethine imines represent a convenient and simple method for the synthesis of some novel diazabicyclic ring systems. For instance, reaction of *(120)* as well as the homologous olefin *(122)* with formaldehyde gave the 1,7-diazabicyclo[2.2.1]heptane *(121)* and 1,7-diazabicyclo[3.2.1]octane *(123)* in high yield[61].

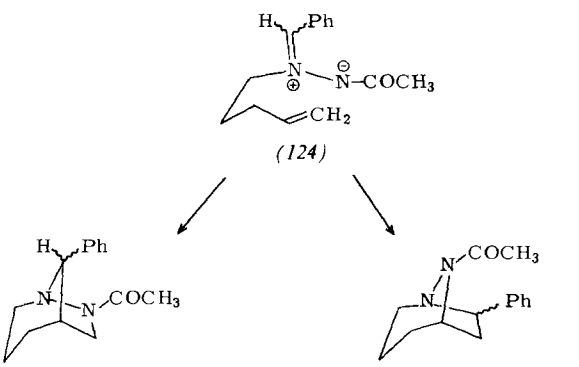


(120) *(121)*



(122) *(123)*

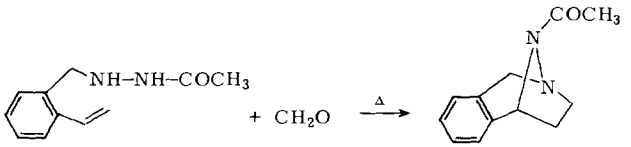
When the condensation was carried out between *(122)* and benzaldehyde, a mixture of two structural cycloadducts was obtained. In this case, cyclization of the transient azomethine imine *(124)* occurs spontaneously and produces a mixture of *(125)* and *(126)*.



(124)

(125), major product *(126)*, minor product

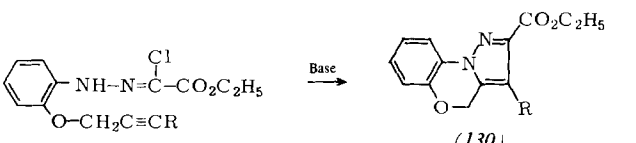
The related *N*-acetyl-*N'*-(*o*-vinylbenzyl)hydrazine *(127)* undergoes a similar intramolecular cycloaddition to produce the partially hydrated 2,5-imino-2-benzazepine *(128)* in 40% yield.



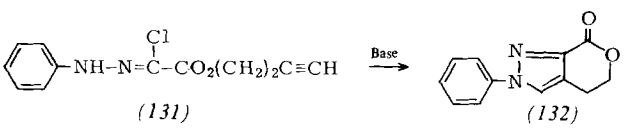
(127) *(128)*

6. Nitrile Imines

Nitrile imines are compounds containing the grouping $R-\overset{\ominus}{N}-\overset{\oplus}{N}\equiv C-R'$. The most convenient method for generation of this class of 1,3-dipoles involves the action of tertiary bases on hydrazidoyl halides such as *(129)* and *(131)*[63]. Here again the 1,3-dipole cannot be isolated and the external dipolarophile must be present in the reaction mixture from the outset. Treatment of *(129)* with base leads to a nitrile imine which can be readily intercepted by the adjacent acetylenic functionality present in the molecule to give the pyrazole *(130)*[64]. Similarly, treatment of *(131)* with base affords cycloadduct *(132)*. These ring closures are particularly interesting in that they involve cycloadditions with unconjugated alkynes, substrates which are generally unreactive toward nitrile imines[65]. Furthermore, while the usual orientation of monosubstituted acetylenes in the intermolecular cycloadducts with nitrile imines is such as to afford 5-substituted pyrazoles[63, 65, 66] obtainment of the 4-substituted pyrazole *(132)* reveals that in a properly chosen substrate the regiospecificity of monosubstituted acetylenes can be inverted.



(129) *(130)*



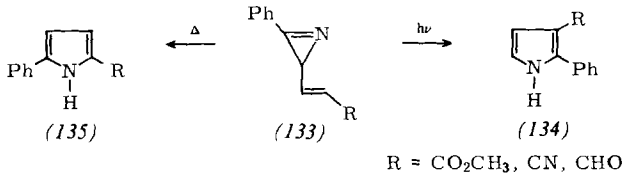
(131) *(132)*

7. Nitrile Ylides

Nitrile ylides are a young but thoroughly investigated class of 1,3-dipoles[1-3]. Access to this class of dipoles can be realized by (a) treatment of imidoyl halides with base[67], (b) thermal or photochemical elimination of phosphoric acid ester from 2,3-dihydro-1,4,2λ^5-oxazaphospholes[68], and (c) photolysis of 2*H*-azirines[69, 70]. The greatest opportunity for structural variation is offered by the latter route. *Padwa*[69] and *Schmid*[70] have independently shown that irradiation of 2*H*-azirines leads to irreversible ring opening and the formation of nitrile ylides as intermediates. These species may be intercepted with a wide variety of dipolarophiles to form five-membered ring heterocycles.

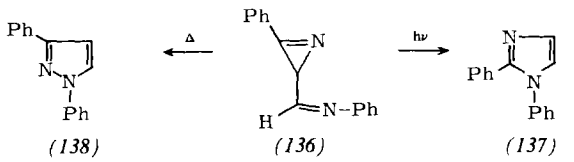
Whereas the cycloaddition of 2*H*-azirines with simple olefins produces 1-pyrrolines, a rearranged isomer can be formed when the alkene and azirine moieties are suitably arranged in the same molecule. This intramolecular cycloaddition was first observed by *Padwa et al.*[71, 72] using 2-vinyl substituted azirines. Irradiation of *(133)* in benzene afforded a 2,3-disub-

stituted pyrrole *(134)* while thermolysis gave a 2,5-disubstituted pyrrole *(135)*. Photolysis of *(136)* proceeded similarly and gave 1,2-diphenylimidazole *(137)* as the exclusive photoproduct. This stands in marked contrast to the thermal reaction of *(136)* which afforded 1,3-diphenylpyrazole *(138)* as the only product.



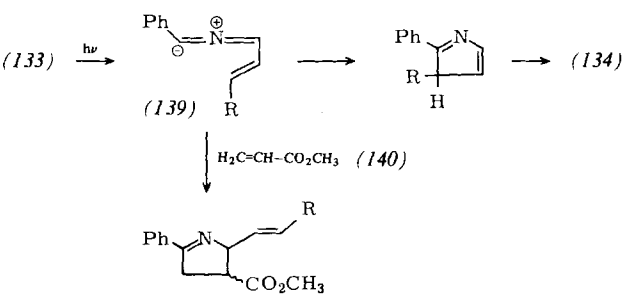
(135) *(133)* *(134)*

R = CO_2CH_3, CN, CHO

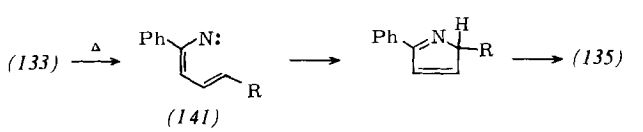


(138) *(136)* *(137)*

The evidence obtained clearly indicates that the photorearrangements of *(133)* and *(136)* proceed by a mechanism which involves a nitrile ylide intermediate. This conclusion was reached by carrying out the irradiation of *(133)* in the presence of a trapping agent *(140)*. Under these conditions, the formation of the 2,3-disubstituted pyrrole *(134)*, which is formed in high yield in the absence of a trapping reagent, is entirely suppressed. Intramolecular cycloaddition of the nitrile ylide intermediate *(139)* followed by a 1,3-sigmatropic hydrogen shift of the initially formed five-membered ring readily accounts for the formation of *(134)* as the final product.

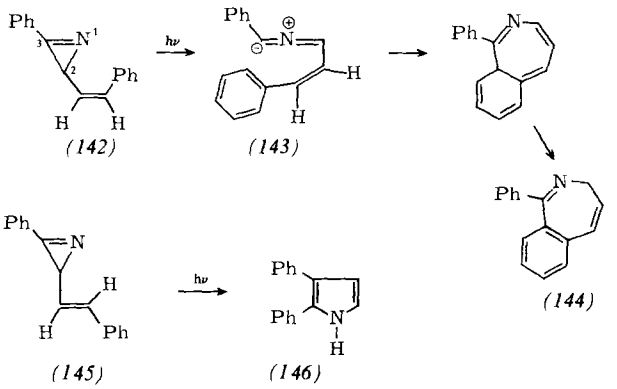


The thermal transformations observed with these systems, on the other hand, have been rationalized in terms of an equilibration of the 2*H*-azirine with a transient vinyl nitrene *(141)* which subsequently rearranges to the 2,5-disubstituted pyrrole.



(141)

In contrast to the photochemical results encountered with *(133)*, the presence of a *cis*-styryl side chain in the 2-position of the azirine ring *(142)* leads to ring expansion and gives benzazepine *(144)*. The 2-[2-(α- and β-naphthyl)vinyl]-3-phenyl-2*H*-azirines behaved similarly and proceeded with complete regiospecificity. The photolysis of the isomeric *trans*-styrylazirine *(145)* took an entirely different course and produced 2,3-diphenylpyrrole *(146)* as the major product. The results indicate that opening of the azirine ring followed by intramolecular cyclization proceeds at a faster rate than *cis*-

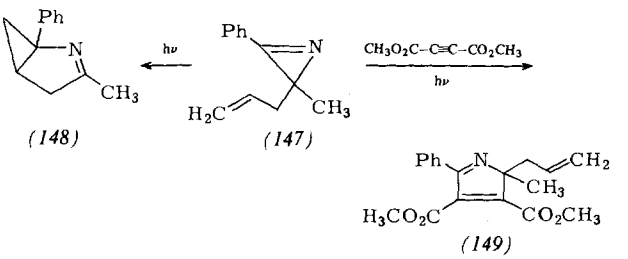


(142) *(143)* *(144)*

(145) *(146)*

trans-isomerization about the CC double bond. The preference for cyclization of *(143)* to a seven-membered ring was attributed to stereoelectronic factors. Closure of the linear dipolar intermediate *(143)* obtained from *(142)* occurs more easily *via* a seven-membered transition state and leads to the preferential formation of benzazepine *(144)*. Cyclization of the nitrile ylide derived from the *trans* isomer to a seven-membered ring is precluded on structural grounds and formation of 2,3-diphenylpyrrole *(146)* occurred instead.

Nitrile ylides have been classified by *Huisgen*[1-3] as nitrilium betaines, a class of 1,3-dipoles containing a central nitrogen atom and a CN π-bond orthogonal to the 4π-allyl system. Among the possible resonance forms of a nitrile ylide, a carbene structure can be envisioned which makes conceivable a 1,1-cycloaddition of this 1,3-dipole. Recently, *Padwa* and *Carlsen* reported the first example of such a cycloaddition[73].

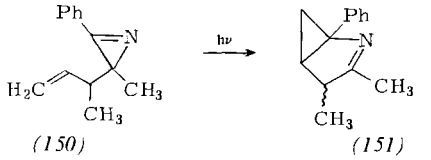


(148) *(147)* *(149)*

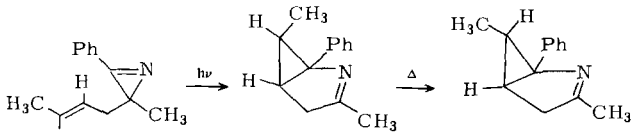
These authors found that irradiation of 2-allyl-2-methyl-3-phenyl-2*H*-azirine *(147)* gave 3-methyl-1-phenyl-2-azabicyclo[3.1.0]hex-2-ene *(148)* as the exclusive photoproduct. Photolysis of *(147)* in the presence of excess dimethyl acetylenedicarboxylate resulted in the trapping of the normal nitrile ylide and afforded cycloadduct *(149)* in high yield. Under these conditions, the formation of *(148)*, which is produced in quantitative yield in the absence of a trapping reagent, was entirely suppressed.

The photoreactions of the closely related methyl-substituted azirines *(150)* and *(152)* were also examined. Irradiation of *(150)* produced azabicyclohexene *(151)* while photolysis of *(152)* gave the analogous compound *(153)* as the primary photoproduct. Upon standing at room temperature, *(153)* epimerized to the thermodynamically more stable *exo*-isomer *(154)*.

The formation of the photoproducts *(148)*, *(151)*, and *(153)* was found to be completely suppressed when the irradiations were carried out in the presence of methyl acrylate *(140)*. The only products formed under these conditions were the usual 1-pyrrolines.

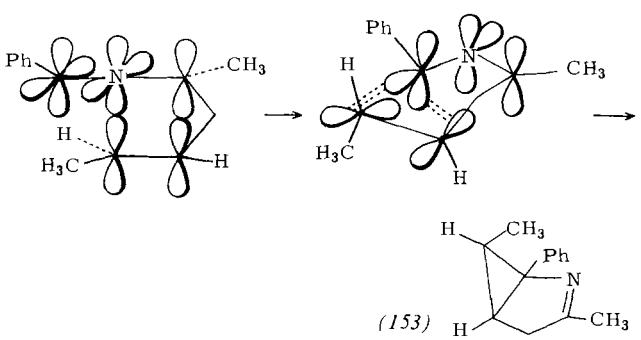


(150) (151)



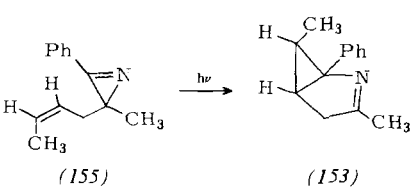
(152) (153) (154)

Padwa and *Carlsen*[73] have pointed out that bimolecular 1,3-dipolar additions proceed *via* a "two-plane" orientation complex in which the dipole and dipolarophile approach each other in parallel planes[1-3]. In order to achieve this type of transition state, the linear nitrile ylides derived from the irradiation of these allylazirines must first bend. This involves disruption of the orthogonal π bond at some modest energy cost but leaves the allyl anion π system undisturbed. The cycloaddition of allylazirines *(147)*, *(150)*, and *(152)* with added dipolarophiles proceeds in this fashion and affords 1-pyrroline derivatives [*e.g. (149)*] as the primary cycloadducts. Inspection of molecular models of the allyl substituted nitrile ylides indicates that the normal "two-plane" orientation approach of the linear nitrile ylide and the allyl π system is impossible as a result of the geometric restrictions imposed on the system. Product formation is possible, however, if the linear nitrile ylide undergoes rehybridization to give a species of bent geometry which subsequently undergoes 1,1-cycloaddition with the neighboring double bond. The most favorable transition state for the 1,1-cycloaddition reaction is one in which the π-orbitals of the nitrile ylide and olefinic double bond are orthogonal. This orthogonality could, in principle, permit the occurrence of a concerted orbital symmetry-allowed [$_{\omega}2_s+_{\pi}2_a$] process and thus accommodate the formation of the thermodynamically less favored *endo* isomer *(153)*.

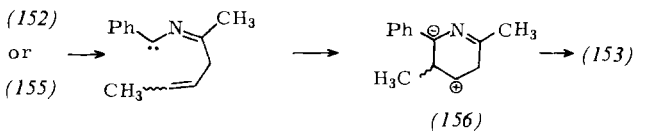


(153)

More recent work[74], however, has shown that irradiation of the *cis*-substituted azirine *(155)* also produced azabicyclohexene *(153)*. This observation indicates that the 1,1-cycloaddition process is stereoselective but not stereospecific. A reasonable explanation to account for the observed stereoselectivity is that the 1,1-cycloaddition process occurs by initial attack of the carbene carbon on the terminal position of the double bond. Such an attack will generate a six-membered ring dipole *(156)* which contains a secondary carbenium ion



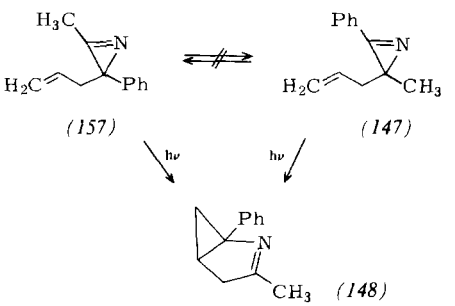
(155) (153)



(152) or (155) (156) (153)

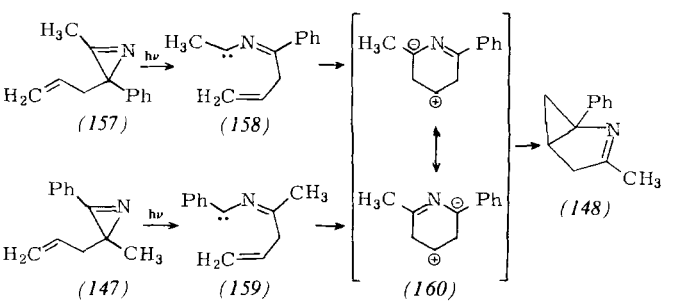
as well as an azaallyl anion portion. Collapse of this new 1,3-dipole to the thermodynamically favored *exo* product *(154)* will result in a severe torsional barrier on closure. On the other hand, collapse to the thermodynamically less favored *endo* isomer *(153)* moves the phenyl and methyl groups increasingly further apart and would account for the formation of the less stable product.

Supporting evidence for this suggestion was obtained by irradiating the isomeric 3-methyl-2*H*-azirine system *(157)*. Photolysis of this azirine results in the quantitative formation of azabicyclohexene *(148)*. This is the same azabicyclohexene that was formed from the irradiation of azirine *(147)*. A control experiment showed that *(147)* and *(157)* were not interconverted under the photolytic conditions.



(157) (147) (148)

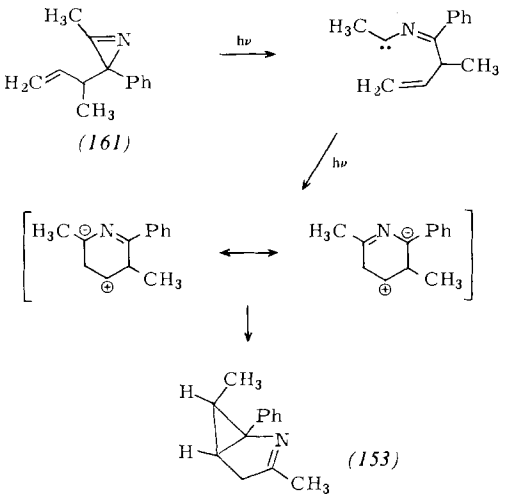
The formation of *(148)* from *(157)* is perfectly consistent with the generation of a six-membered ring dipole *(160)*. Thus, cyclization of the initially formed carbene *(158)* generates *(160)* which closes to azabicyclohexene *(148)*. The same six-membered ring dipole is also formed from azirine *(147)*.



(157) (158) (148) (147) (159) (160)

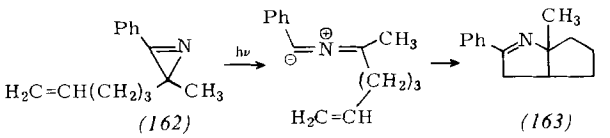
Thus the stereoselectivity observed with azirines *(152)* and *(155)* as well as the regiospecificity encountered with azirines *(147)* and *(157)* can be attributed to a two-step cyclization path which involves a six-membered ring dipole. The formation of *endo*-azabicyclohexene *(153)* from methylazirine *(161)* provides additional support for this interpretation.

When the chain between the azirine ring and the alkene end is extended to three carbon atoms, the normal mode of 1,3-intramolecular dipolar cycloaddition occurs. For example, irradiation of azirine *(162)* gave 1-pyrroline *(163)*



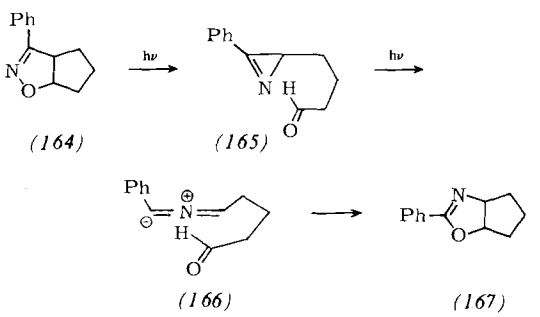
(161) (153)

in quantitative yield[75]. In this case, the methylene chain is sufficiently long to allow the dipole and olefinic portions to approach each other in parallel planes.



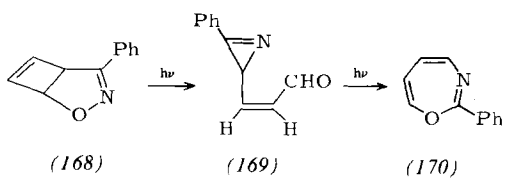
(162) (163)

In a related case, *Schmid et al.* reported on the photoisomerization of 2-isoxazoline *(164)* to oxazoline *(167)*[76]. The reaction was proposed to proceed *via* a transient azirine *(165)*. This intermediate was not isolated but was suggested to undergo rapid ring opening to nitrile ylide *(166)* which cyclized to the observed photoproduct *via* an internal 1,3-dipolar cycloaddition reaction.



(164) (165) (166) (167)

The related 4-phenyl-2-oxa-3-azabicyclo[3.2.0]hepta-3,6-diene *(168)* system undergoes a similar photochemical rearrangement to produce 2-phenyl-1,3-oxazepine *(170)*[77]. This reaction has been proposed to involve an azirine intermediate *(169)* which subsequently cyclizes to the observed product.

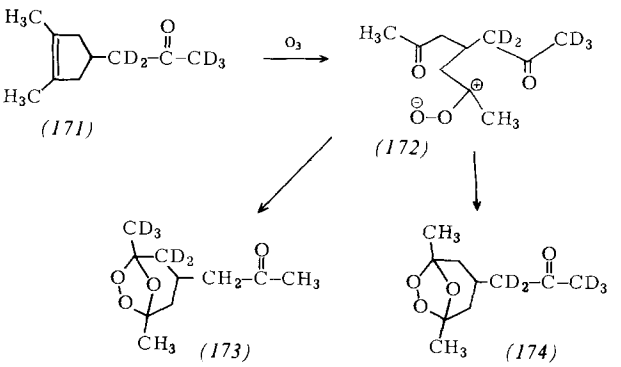


(168) (169) (170)

When the chain between the azirine ring and olefinic portion is reduced to two carbon atoms, no cycloadduct was obtained. In this case, the "two-plane" orientation approach of the linear nitrile ylide and the π system is too difficult to attain and other competing processes occur[75].

8. Carbonyl Oxides

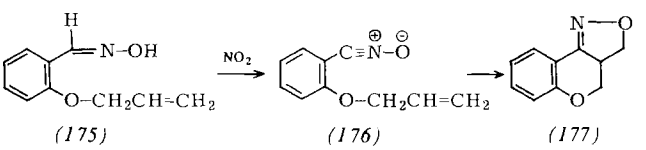
Carbonyl oxides (Criegee zwitterions) have never been isolated, but indirect evidence for their existence is abundant[78, 79]. These unusual species are usually generated by ozonolysis of a suitable olefin, although more recent evidence has been presented for their formation by reaction of a carbene with oxygen[80]. *Criegee* presented evidence which indicates that ozonides may be formed by the 1,3-dipolar addition of carbonyl oxides to carbonyl compounds[78]. Some recent work by *Criegee*'s group has shown that the ozonolysis of 1,2-disubstituted 1-cyclopentenes, *e. g. (171)*, containing different substituents in the 4-position of the ring produces carbonyl oxides such as *(172)* as reaction intermediates[81]. These dipoles undergo intramolecular 1,3-dipolar cycloaddition with each of the two functional groups present. Thus two different ozonides are formed, in the present case *(173)* and *(174)*.



(171) (172) (173) (174)

9. Nitrile Oxides

1,3-Dipoles of this class can be conveniently generated by the base treatment of hydroxamic acid chlorides or by oxidation of aldoximes[82]. Numerous cycloadditions involving nitrile oxides had already been described when the general concept of 1,3-dipolar cycloadditions was formulated by *Huisgen et al.*[1]. Oxidation of 2-allyloxybenzaldehyde oxime *(175)* by nitrogen dioxide has recently been reported to give the fused ring compound *(177)*, the product of an intramolecular cycloaddition of the intermediate nitrile oxide *(176)*[83].

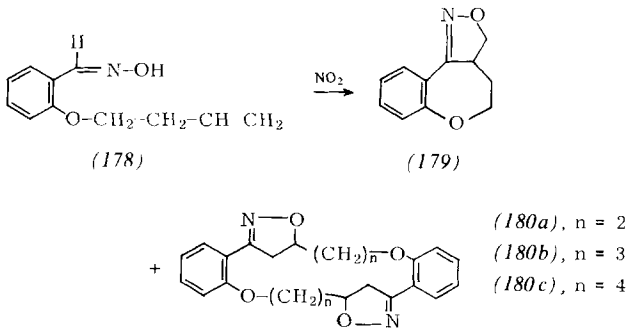


(175) (176) (177)

Nitrile oxides generally undergo bimolecular 1,3-dipolar cycloaddition with terminal double bonds to give 5-substituted 2-isoxazolines[82, 84, 85]. Obtainment of the 4-substituted 2-isoxazoline *(177)* in the intramolecular cycloaddition of *(175)*, indicates that geometrical factors can force the reaction to occur in the opposite manner from that normally encountered.

This observation led *Garanti et al.* to examine the intramolecular 1,3-dipolar cycloaddition reaction as a function of chain length between the dipole and dipolarophile[86]. Treatment of aldoxime *(178)* with nitrogen dioxide gave a mixture of *(179)* (17%) and *(180a)* (2%).

With the next higher homologs, the reaction afforded compounds *(180b)* and *(180c)* together with a sizable quantity of uncharacterized resinous material. These results clearly



(178) (179)

(180a), n = 2
(180b), n = 3
(180c), n = 4

indicate that the chain length between the dipole and dipolarophile groups has a substantial effect on the intramolecular cycloaddition. Thus, while aldoxime *(175)* gave *(177)* in 42% yield, formation of *(179)* from *(178)* occurred to a minor extent (17%) and no internal adduct could be obtained from the next higher homologs. The formation of the large ring compounds *(180a)*—*(180c)* involves an initial intermolecular cycloaddition to give long chain intermediates which are capable of undergoing a subsequent intramolecular ring closure to the final product.

10. Conclusion

Intramolecular 1,3-dipolar cycloaddition is an extremely versatile and important reaction. The range of synthetic possibilities which it opens for the construction of fused heterocycles is extremely large. A number of dipoles which undergo this reaction have been summarized and the general outlines and potential analogies for these reactions noted. Further work will be needed to clarify some of the mechanistic features. The development of general synthetic routes leading to new heterocyclic systems using this reaction offers considerable challenge and promise.

The Fischer-Tropsch Synthesis: Molecular Weight Distribution of Primary Products and Reaction Mechanism

By G. Henrici-Olivé and S. Olivé[*]

An evaluation of literature data concerning the production of hydrocarbons and alcohols by the Fischer-Tropsch procedure indicates that the molecular weight distribution of the primary products can be described by the Schulz-Flory equation ("normal" or "most probable" distribution). It follows that the highest attainable selectivity for a given molecular weight range can be calculated. A reaction mechanism is suggested.

1. Introduction

The oil embargo, and the escalation in price of crude oil, have brought about a considerable increase in the price of oil-based raw materials such as paraffins, olefins, alcohols, *etc.* Although the eventual exhaustion of petroleum resources has been predicted for a considerable time, the present shortage actually occurred several years earlier than expected, and the chemical industry, with its current reliance on oil-based raw materials, is particularly affected.

As oil becomes more and more expensive, chemists revert to coal as a source of carbon which had almost been forgotten in the course of the years. Some fifty years ago, however, German chemists were already confronted with the same problem. Germany, possessing huge stocks of coal, but completely inadequate oil resources, was forced to undertake the transformation of coal into liquid hydrocarbons. As early as 1924, *Franz Fischer* published a book on this subject[1]. In the succeeding decades two processes were simultaneously developed to great industrial importance: the catalytic hydrogenation of coal at high pressure (Bergius process), and the catalytic synthesis of hydrocarbons from carbon monoxide and hydrogen, obtained from coal and water, at normal and medium pressure (Fischer-Tropsch process). During World War II this development reached its zenith.

After 1945 the situation changed. European pre-embargo prices of oil and coal were comparable (about \$ 30—40 per ton), but coal has an unfavorable TOE (ton of oil equivalent): 1 ½ tons of coal supply the same energy as 1 ton of oil. Moreover, the ease of automating transport systems and feedlines for refineries, production plants, industrial and domestic heating, *etc.* has helped oil to oust the dirty and inconvenient material coal. Even at present-day prices of about \$ 100 per ton of petroleum *versus* \$ 70—80 per ton of coal, the production of gasoline from coal does not appear immediately attractive. However, one of the sound effects of the embargo shock has been to create a feeling of responsibility for the future. Apart from the search for other sources of energy such as nuclear, geothermal, water, and wind power, scientific and industrial investigations turn back to coal.

The present study describes some possibilities and limitations of the synthesis of hydrocarbons and alcohols from CO and H_2 (Fischer-Tropsch synthesis). Moreover, an estimate is made of how much product of a given degree of polymerization may be expected in the most favorable case. The basis of this estimate is the observation that products obtained by this process exhibit a characteristic distribution of chain length, as we found during the evaluation of literature data. We have applied concepts originating in the field of molecular catalysis with defined transition metal complexes and from polymer chemistry to mechanistic details reported by various authors, and suggest a reaction mechanism for the Fischer-Tropsch synthesis.

2. Development and Present Status of the Fischer-Tropsch Synthesis

At the beginning of the synthesis of hydrocarbons from CO and H_2 stands the classical methane synthesis of *Sabatier* and *Senderens* in 1902[2], but it was not until 1922 that *Fischer* and *Tropsch* obtained their first patent on "Synthol", a mixture of oxygen-containing derivatives of hydrocarbons, produced from CO and H_2 at over 100 atm and at 400 °C, with alkali-treated iron shavings as catalyst[3]. There are several competent review articles describing the further development of the Fischer-Tropsch synthesis[4], which we do not intend to duplicate. We shall restrict ourselves to some highlights, with emphasis on the present status.

In 1925 *Fischer* and *Tropsch* succeeded in directing the synthesis to give predominantly hydrocarbons; they patented a normal pressure process, operating in the temperature range 250—300 °C, and using Fe/ZnO or Co/Cr_2O_3 as catalyst[5]. In 1936/37 *Fischer* and *Pichler* found that working at medium pressure (5—30 atm), with cobalt[6] or iron[7] catalysts, substantially improved yield and catalyst lifetime. Using a ruthenium catalyst, and working at high pressure (1000—2000 atm) and temperature (140—200 °C), *Pichler et al.* could orient the synthesis to high melting linear paraffins having molecular weights up to 10^6[4d, 8]; the "polymethylenes" obtained are practically identical with Ziegler polyethylene.

[*] Dr. G. Henrici-Olivé and Prof. Dr. S. Olivé
Monsanto Research S. A.
Eggbühlstrasse 36, CH-8050 Zürich (Switzerland)

More recently, interest appears to have shifted back towards the original oxygen-containing products of the first "Synthol" process. High pressure and high temperature processes have been reported to give aliphatic alcohols in the C_1—C_{18} range, important raw materials for detergents, plasticizers, *etc.*[9]. In recent Russian Patents[9d], iron catalysts have been used, at temperatures in the range 160—220°C, pressures of 50—300 atm, and $H_2/CO = 5:1$ to 20:1, to produce liquid oxygen-containing compounds in the range C_1—C_{20}, mostly alcohols. Subsequent hydrogenation over Cu/Cr catalysts increases the yield of alcohols. At high space velocity, selectivities up to 86% (expressed as percentage of alcohols in total liquid product boiling below 160°C) are claimed[9e].

This brief summary may, at the same time, give an impression of the versatility of the Fischer-Tropsch synthesis: depending upon catalyst, pressure and temperature, the process can be oriented predominantly to liquid hydrocarbons, waxes, or alcohols. Nevertheless the oil-based processes for the production of these chemicals have replaced the Fischer-Tropsch synthesis almost completely for the reasons mentioned in Section 1. The only important industrial plant for the production of gasoline, gas oil, and paraffins from coal by the Fischer-Tropsch procedure is located in South Africa, where the price of coal is still very attractive (about 1/6 of that in Western Germany, in 1970[4d]). The South African Coal, Oil and Gas Corporation Ltd. (Sasol) uses an intermediate pressure process (20—25 atm), with iron catalysts. Fixed bed and circulating catalyst procedures have been developed there to high technical maturity. Table 1 and 2 compare the products obtained by the two processes[4d].

Table 1. Comparison of the products obtained with fixed bed catalyst and with circulating catalyst (in weight-%) [4d].

Fraction	Fixed bed catalyst (220—240°C)	Circulating catalyst (310—340°C)
C_3—C_4	5.6	7.7
C_5—C_{11} (gasoline)	33.4	72.3
Gas oil	16.6	3.4
Paraffin, m.p. <60°C	22.1	3.0
Paraffin, m.p. 95—97°C	18.0	—
Alcohols, ketones	4.3	12.6
Acids	traces	1.0

The iron catalyst for the fixed bed process is prepared by precipitation of iron hydroxide with silica gel. The process operates at 220—240°C, 25 atm, and at a H_2/CO ratio of 1.8:1. A conversion of about 70% per pass (referred to carbon) is obtained. The catalyst for the circulating catalyst procedure is produced by melting iron oxide and additives in an electric furnace at 1500°C and milling the melt to a fine powder; the latter is circulated in the reaction volume, impelled by the incoming gas stream. (Reaction conditions: 310—340°C; 24 atm; $H_2/CO = 6:1$). The conversion per pass (referred to CO) is >90%. This process gives a considerably lower average molecular weight of the products, with a maximum in the gasoline range, and a higher content of oxygen containing derivatives (Table 1). Furthermore, there is a remarkably high fraction of olefins in the product (Table 2). The fixed bed process, on the other hand, gives a higher content of gas oil and waxy paraffins, alkenes and alkanes being present in comparable amounts. In fact, Sasol operates a combination of both processes, which permits a flexible adaptation to market requirements.

Table 2. Comparison of the composition of the liquid fraction for fixed bed catalyst and circulating catalyst (in vol.-%) [4d].

Components	Fixed bed catalyst		Circulating catalyst	
	C_5—C_{10}	C_{11}—C_{18}	C_5—C_{10}	C_{11}—C_{18}
Olefins	50	40	70	60
Paraffins	45	55	13	15
Oxygen-containing compounds	5	5	12	10
Aromatics	-	—	5	15

3. The Primary Products

The synthesis of hydrocarbons involves stepwise incorporation of one carbon atom at a time with simultaneous formation of water, according to the overall equation:

$$n\mathrm{CO} + 2n\mathrm{H_2} \rightarrow (\mathrm{CH_2})_n + n\mathrm{H_2O} \quad (1)$$

The mixture generally contains paraffins, olefins, alcohols, aldehydes, acids, esters and aromatic compounds in varying amounts. Even in the early days of the process[10, 11] it was found that the main products obtained with cobalt catalysts were linear olefins and paraffins, and that the small amount of nonlinear products consisted predominantly of monomethyl branched compounds. Since olefins and paraffins were found to have the same carbon skeleton, it was assumed that the olefins are the primary products of the synthesis, and that the paraffins are formed therefrom by subsequent hydrogenation.

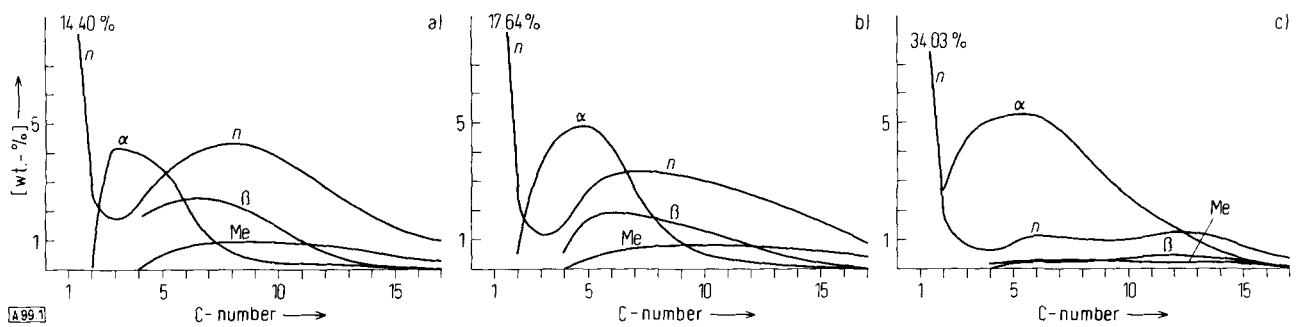

Fig. 1. Composition of the Fischer-Tropsch mixture of hydrocarbons as a function of the space velocity: a) 78 h^{-1}, b) 337 h^{-1}, c) 2380 h^{-1}. n = n-paraffins, α = α-olefins, β = β-olefins, Me = methyl-paraffins. Catalyst = Co/ThO_2 (after [14]). The space velocity is defined as the volume of synthesis gas pervolume of catalyst and hour.

The olefinic component of the hydrocarbons consists mainly of α- and β-olefins (1- and 2-alkenes). The fact that the concentration of α-olefins is generally much higher than that corresponding to the thermodynamic equilibrium led *Friedel* and *Anderson*[12] to the conclusion that α-olefins should be the primary products of the synthesis.

This conclusion was confirmed by *Pichler et al.*[13], who were able to show that the α-olefins content of the product increases with increasing space velocity of the synthesis gas feed. This observation is represented in Figure 1. At longer residence time (low space velocity) the primarily formed α-olefins are transformed in secondary reactions into β-olefins, linear paraffins, and methyl-branched products. In all cases there is a remarkably high content of methane.

In contrast to the secondary products mentioned, the alcohol fraction among the products was found to be independent of space velocity. *Pichler et al.*[14] concluded convincingly that the alcohols are also primary products of the process. The authors indicated that there might be a common precursor for linear α-olefins and linear alcohols.

4. Secondary Reactions of the α-Olefins

The development of more efficient gas chromatographic methods (capillary columns, radio gas chromatography) has recently permitted a detailed determination of the many isomers contained in the synthesis products, and hence provided an insight into the course of the secondary reactions. *Pichler et al.*[15,4d] reported a complete analysis of the C_7 hydrocarbon fraction of Sasol's fixed bed catalysis product. The authors showed that this fraction is >91 % linear, and that the nonlinear part is >90 % monomethyl-, 6 % dimethyl- and 2.5 % ethyl-branched. The approximative composition of the linear part is 51 % heptane, 31 % 1-heptene, 17 % *cis*- and *trans*-2-heptene, and only 1 % *cis*- and *trans*-3-heptene.

Another important contribution towards the mechanism of the secondary reaction of the α-olefin was made by *Schulz et al.*[16]: ^{14}C-tagged ethylene, propylene, 1-butene, or 1-hexadecene were added to the synthesis gas, and the fate of these α-olefins was monitored by radio gas chromatography. With cobalt catalysts over 90 % of the added olefin reacts. With iron systems the reaction is somewhat slower. Most of the olefin is converted to alkane by hydrogenation. But α-olefins are also incorporated into the growing chain, or they can start a new chain. With increasing molecular weight the incorporation of the α-olefins decreases, as expected from their polymerization chemistry; it is significant only for ethylene and propylene. The incorporation of ethylene does not lead to branching, that of propylene gives methyl branches.

Simultaneously, α-olefins are split, with breaking of the double bond. Since this splitting occurs in a hydrogen atmosphere, additional methane is formed by this secondary process. With some 0.5 vol.% of [1-^{14}C]-1-alkene in the feed, 4—9% of the ^{14}C was found as methane in the product. Interestingly also [2-^{14}C]-propene gave a considerable amount of tagged methane. Hence the above decomposition reactions [(a)—(c)] have to be considered.

$$H_2C{=}CH_2 \longrightarrow 2\ CH_4 \qquad (a)$$

$$H_3C{-}CH{=}CH_2 \longrightarrow \begin{cases} H_3C{-}CH_3 + CH_4 \\ 3\ CH_4 \end{cases} \qquad (b)$$

$$R{-}CH{=}CH_2 \longrightarrow R{-}CH_3 + CH_4 \qquad (c)$$

The splitting of the olefins is more important with cobalt catalysts than with iron systems (cf. the high methane content in Fig. 1). The opposite is true for the incorporation reaction.

Neither Co nor Fe produce significant cracking of the paraffins. ^{14}C-tagged butane added to the synthesis gases could be recovered unchanged in over 99 % yield.

5. Distribution of the Molecular Weights

Figure 2 shows a typical distribution curve of the hydrocarbons obtained with a cobalt catalyst[14]. With the exception of the high methane content, the curve is strongly reminiscent of the Schulz-Flory distribution of molecular weights, frequently found in oligomerization and polymerization processes ("most-probable" or "normal" distribution). As an example, the oligomerization of ethylene, where chain propagation and chain transfer are the main reactions determining the distribution of molecular weights, was treated recently[17].

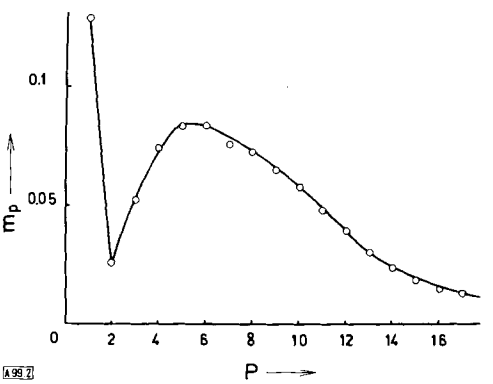

Fig. 2. Distribution of chain lengths of hydrocarbons; run a) of Fig. 1 (cf. Ref. [14]). m_P = weight fraction of oligomers having degree of polymerization P (= number of C atoms).

Fischer-Tropsch synthesis is actually a polymerization (oligomerization) process, where the "monomer" is replaced by $(CO+2H_2)$ [see Eq. (1) in Section 3]. Consequently, we may treat this process in terms of polymerization kinetics, as outlined formerly for ethylene oligomerization.

Although the chain propagation is a multistep reaction (see Section 6), its rate (r_p) may be defined from a kinetic point of view, as

$$r_p = + \frac{d[-CH_2-]}{dt} \qquad (2)$$

In typical Fischer-Tropsch synthesis, the rate of propagation r_p remains constant over weeks, *i.e.* we may assume that the concentration of active centers remains constant. This means that no termination reactions leading to annihilation of the growing centers take place. If one further takes into account that the number of chains produced is by far greater than the number of active centers, it appears evident that the reaction interrupting the chain growth and leading to oligomers has to be a chain transfer reaction, in the course of which the chain leaves the metal, and a new chain can be started at the metal. Since the primary compounds are

α-olefins, the carrier of the kinetic chain has to be a metal hydride. The chain transfer reaction can be described as

$$R{-}CH_2{-}CH_2{-}Metal \rightleftarrows R{-}CH{=}CH_2 + H{-}Metal$$

and is assumed to be of the same nature as the well known β-hydrogen abstraction, observed frequently with soluble transition metal-alkyl complexes (see, *e.g.*[17]). Its rate (r_{tr}) is given by Eq. (3). The metal hydride continues the kinetic chain (cf. Section 6).

$$r_{tr} = + \frac{d[\text{Olefin}]}{dt} \tag{3}$$

The Schulz-Flory distribution of molecular weights is given by[18][*]:

$$m_P = (\ln^2 \alpha) P \alpha^P \tag{4}$$

where m_P represents the weight fraction of the oligomers of a certain degree of polymerization P (here number of carbons in the chain). α is the probability of chain growth defined as

$$\alpha = \frac{r_p}{r_p + r_{tr}} \tag{5}$$

Eq. (4) can be expressed in logarithmic form

$$\log \frac{m_P}{P} = \log(\ln^2 \alpha) + P \log \alpha \tag{6}$$

If for a given polymer the graphical representation of $\log(m_P/P)$ *versus* P gives a straight line, and α, as determined from the slope ($=\log\alpha$) and from the intercept with the ordinate [$=\log(\ln^2\alpha)$], are in good agreement, the molecular weight distribution of this polymer obeys the Schulz-Flory distribution law.

Unfortunately only few distributions suitable for evaluation have been reported in the literature. They are, however, sufficient to give a definite answer.

Figures 3 and 4 refer to Fischer-Tropsch syntheses oriented towards the production of hydrocarbons. Since the primary α-olefins are partly transformed into inner olefins (isomerization) and paraffins (hydrogenation), the weight fraction m_P for each degree of polymerization is the sum of olefins and paraffins of the same number of carbons. Figure 3 is a plot of the data of Figure 2 according to Eq. (6). In the range C_4—C_{12}, the experimental points lie on a straight line. C_1 is too high and C_2 and C_3 are too low, as are the values beyond C_{13}. The value of α is 0.81 from the slope, and 0.80 from the intercept.

Figure 4 shows the same plot for data of *Anderson et al.*[4b]. The range C_3—C_{13} gives a reasonable straight line. Again here the value of C_1 is too high and the values of C_2 and beyond C_{13} are too low. From the slope a value of $\alpha = 0.87$ is obtained; from the intercept $\alpha = 0.86$.

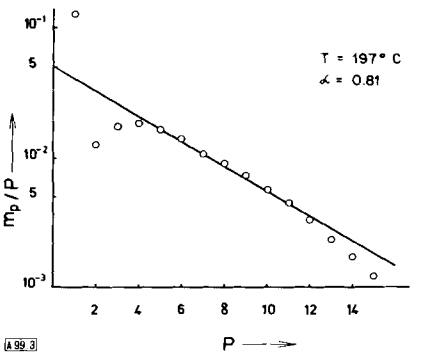

Fig. 3. Plot of hydrocarbon data of Fig. 2 according to Eq. (6).

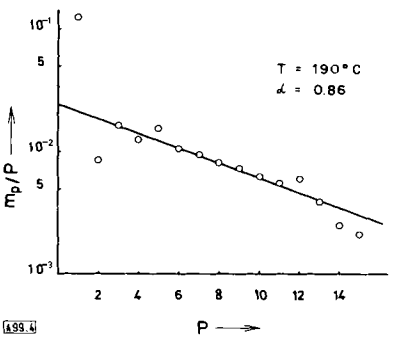

Fig. 4. Hydrocarbon data (after [4b]) represented according to Eq. (6). Cobalt catalyst.

The reasons for the deviations in the range C_1—C_3 have already been mentioned: the α-olefins with the greatest ability to be coordinatively bonded to a transition metal (ethylene > propylene) are partly lost by decomposition to methane and, to a lesser extent, by incorporation into growing chains. At the upper end of the distribution, the hydrocarbons formed tend to have longer residence times on the catalyst due to their lower mobility. Presumably they are partly polymerized, partly cracked, or even carbonized. An additional uncertainty in this range may be caused by the fact that the high boiling fractions give very broad peaks on gas chromatography; their values tend to be underestimated[17].

As mentioned in Section 2, the Fischer-Tropsch synthesis can be oriented to give predominantly alcohols, by proper selection of catalyst and reaction conditions. Using the data of *Kagan et al.*[9e], we applied Eq. (6) also to alcohols. Figure 5 shows two sets of data, obtained with different catalysts. For the Fe_3O_4 catalyst modified with Al_2O_3 and K_2O (Fig. 5a) an average value of $\alpha = 0.37$ has been calculated, from the slope (0.38) and from the intercept (0.36). Data of the pure Fe_3O_4 system (Fig. 5b) give the same value, $\alpha = 0.54$, from slope and intercept.

The examples show that the molecular weight distribution of the products of Fischer-Tropsch syntheses are of the Schulz-Flory type. This fact permits calculation of the maximum selectivity for a certain molecular weight range for a given α, making use of Eq. (4)[17]. In Figure 6, curve a represents the sum of products C_4—C_{10} ($\sum C_4$—C_{10}) as a function of α. The range C_4—C_{10} was chosen as an interesting one for olefins and alcohols. Of course, any other range can easily be computed. The curve indicates that the highest possible amount of C_4—C_{10} to be obtained will represent about 50% of the total amount of olefins (or alcohols) produced, at a

[*] Eq. (4) is the version given by *G. V. Schulz*; the distribution function given by *Flory* reads, with the present nomenclature:

$$m_P = (1-\alpha)^2 P \alpha^{P-1}$$

At $\alpha \geq 0.5$ both equations are equivalent [18]. For the presently intended determination of α from a graphical evaluation of experimental fractionation data, both equations give identical results.

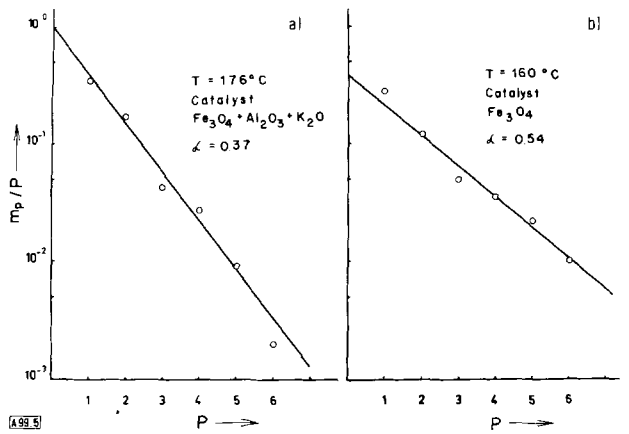

Fig. 5. Molecular weight distributions of alcohols (after [9e]) represented according to Eq. (6).

value of $\alpha \approx 0.7$. It may be noted that under these conditions C_1—C_3 is about 35%, and $>C_{10}$ about 15% of the total product. Curve b shows the sum of the products C_2—C_4 ($\sum C_2$—C_4) also as a function of α. The maximum attainable corresponds to about 56% at a value of $\alpha \approx 0.45$. A large amount of C_1 and small amounts of products higher than C_4 constitute the remainder.

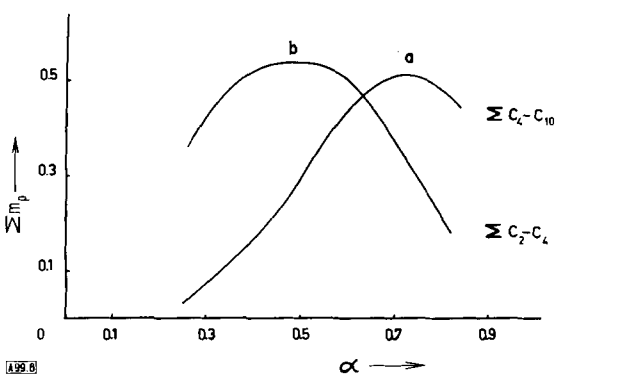

Fig. 6. Weight fractions of different ranges as a function of α, calculated according to Eq. (4).

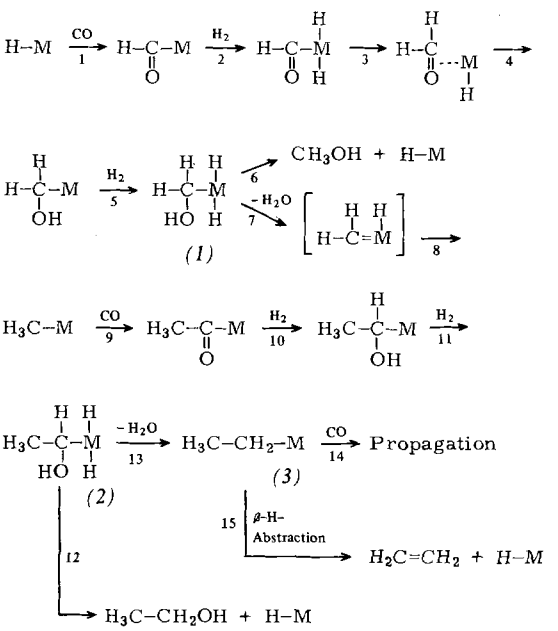
Since these calculated curves are invariant consequences of the Schulz-Flory molecular weight distribution, future work can now be directed to the search for those experimental conditions (catalyst composition, pressure, temperature, feed gas composition, space velocity, *etc.*), which would give the α value recognized as the most favorable for a desired molecular weight range [cf. Fig. 6 and Eq. (5)].

6. Reaction Mechanism

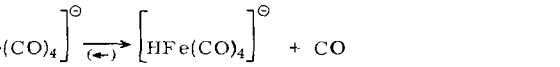
The sum of the information reported in the preceding Sections, and gathered from various sources, prompted us to suggest a unified reaction mechanism for the Fischer-Tropsch synthesis. In formulating such a reaction scheme we follow a contemporary trend, probably first expressed by *Nyholm*[19], of looking at heterogeneous catalysis with transition metals more from the point of view of individual active centers and of their coordination chemistry, than from that of "active surfaces". Therefore we have tried to base the suggested reaction scheme, as far as possible, on individual steps well established in the homogeneous catalysis with soluble transition metal complexes. Such individual steps are, *e.g.*, coordination of CO and of olefins, oxidative addition and reductive elimination, insertion, as well as β-H abstraction (β-H transfer)[20]. The mechanism must also take into account that alcohols as well as α-olefins are primary products; this excludes the former as precursors of the latter.

The suggested mechanism is represented in Scheme 1. The initial metal hydride may be assumed to arise during the activation of the catalyst. Carbon monoxide is coordinated to the metal center and inserted into the M—H bond (step 1)[*]. A hydrogen molecule is oxidatively added to the metal center (step 2). Reductive elimination of the acyl ligand and one of the hydride ligands gives formaldehyde plus a metal hydride (step 3); the former, however, does not leave the metal center, but remains coordinatively bonded through its C=O group (aldehydes are not primary products of the Fischer-Tropsch reaction, cf. Section 3). Addition of the metal hydride to the aldehyde is the next step (step 4), followed by another oxidative addition of H_2 (step 5). Intermediate *(1)* can react in one of two possible ways: reductive elimination (step 6) to give methanol and a metal hydride which can continue the kinetic chain, or elimination of water, with the intermediate formation of a carbenoid ligand (step 7), which rearranges to give σ-bonded methyl ligand (step 8). Now the next CO molecule can be coordinated and inserted (step 9). The next step (step 10) actually summarizes the result of three steps, corresponding to steps 2—4, with the difference that the carbon chain is now increased by one unit. Oxidative addition of H_2 (step 11) leads to the intermediate *(2)* which can again undergo two alternative reactions, giving either the alcohol by reductive elimination (step 12), or the alkyl group by H_2O elimination (step 13, which summarizes the two steps



Scheme 1. Mechanism of the Fischer-Tropsch reaction.

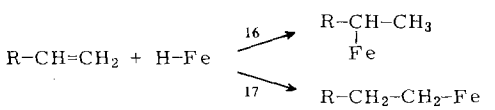
[*] *The insertion of CO into a M—H bond has never been reported.* But the reverse reaction



has been recently investigated [21], indicating that the equilibrium lies far on the right. Nevertheless, kinetically significant amounts of the reaction product of the carbonylation of a metal hydride may well be expected to be present.

corresponding to steps 7 and 8). The alkylmetal compound can either add CO and thus contribute to chain propagation (step 14) or, by β-H transfer, give an α-olefin (ethylene at this stage) and a metal hydride which continues the kinetic chain (step 15).

Presumably, the metal hydride is also responsible for the secondary reactions such as hydrogenation and incorporation of the α-olefins. Coordination and insertion of an α-olefin into a M—H bond can occur in either of two ways:



Step 16 and further growth will lead to monomethyl-branched compounds, whereas step 17 gives a linear prolongation of the previously olefinic chain. This explains why methyl branching is the only significant branching experimentally observed.

At present, this reaction mechanism cannot be more than a working hypothesis which explains, at least qualitatively, most of the experimental findings, without violating known reaction patterns of transition metal centers.

Several questions remain open; *e. g.* why is alcohol formation favored by high pressure and high H_2/CO ratio? Or, why has it not been possible so far to carry out a Fischer-Tropsch synthesis in solution, with a soluble transition metal complex? The answer to the latter question may be related to a general phenomenon in heterogeneous catalysis: solid reduced transition metal catalysts have, on their surfaces, low valent, coordinatively unsaturated metal species which easily offer the sites required for catalysis, whereas in solution coordination of solvent molecules or cluster formation tend to block such sites.

New analytical methods (5)

Integrated Dust Analysis by Physical Methods

By Hanns Malissa[*]

Environmental analyses show that the air which we breathe, and which is so essential to life, is in general a mixture of gaseous, liquid, and solid components. The solid airborne particles, whose concentration, homogeneity, chemical composition, size, and shape can vary over wide ranges, and whose origin may be "natural" or "artificial" are referred to as "dust". Dust particles can act, *inter alia*, as condensation nuclei, catalysts, and directly as hazardous materials. Unfortunately, we still know far too little about dust. Dust analysis is extremely difficult and challenging, even for modern analytical chemistry; it is still far from being fully automated. The simultaneous determination of as many "dust parameters" as possible, and particularly the synoptic consideration of all available data against a background of physicochemical and technological knowledge on the development, transformation, and effects of dust, are summarized as "integrated dust analysis".

1. Introduction

With the concept "integrated dust analysis" an attempt is made to express the fact that the nature and effects of dust can only be understood if the dust sample is examined as completely as possible *in situ*, and that *one* analytical method alone is not adequate for this purpose.

The present review outlines the significance and performance of integrated dust analysis and then goes on to consider a few general problems of dust analysis.

Most difficulties in the assessment of analytical results stem not only from the sample or the methods employed, but rather from the problem formulated.

[*] Prof. Dr. H. Malissa
Institut für Analytische Chemie und Mikrochemie der Technischen Universität
Getreidemarkt 9, A-1060 Wien (Austria)

The primary question in the case of dust analysis is: "What is dust and where do the limits of its analysis lie?"

According to *Bibbero* and *Young*[1] dust is defined as solid particles of "any size", *i.e.* airborne particles ranging from 10^{-4} µm (small molecules, large ions) to 10^{3} µm (particles already visible to the naked eye). It is in this range of particle size, which stretches over some seven orders of magnitude and in which inhomogeneities of chemical composition and shape arise due to adhesion and agglomeration, where the main problems of dust analysis lie.

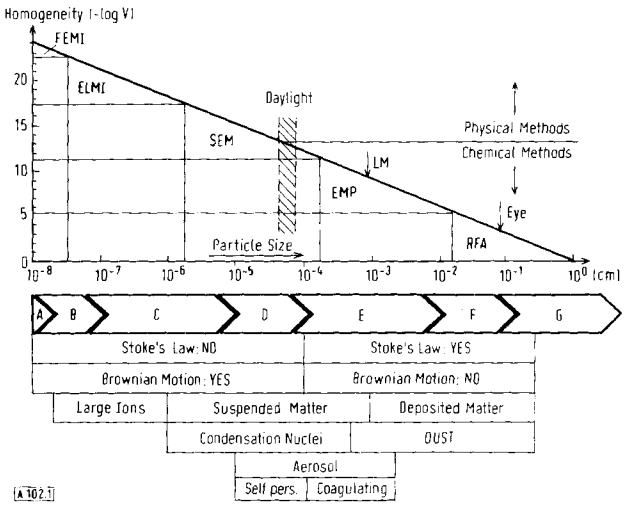

Fig. 1. Particle size in environmental analysis. LM = light microscope, RFA = X-ray fluorescence analysis, EMP = electron microprobe, SEM = scanning electron microscopy, ELMI = electron microscopy, FEMI = field electron microscopy. A: atoms, B: molecules; C: Aitken particles; D: large particles; E: giant particles; F: fine solids; G: coarse solids.

Figure 1 illustrates the interrelations between particle size, physical behavior, and homogeneity. The behavior of the particles (such as motion, adsorption and absorption, or chemical reactions) is determined by the physical and chemical laws that are valid for finely divided material. As a measurement of homogeneity[2] we use the logarithm of the reciprocal of the analytical volume (log $1/V$), which—within a certain standard deviation—yields the same result in measurements on samples taken from various sites as in repeated measurements on one and the same sample. The question of homogeneity is directly related to the degree of resolution of the method of examination employed. For X-ray fluorescence analysis (RFA), particles under 100 µm are in all events homogeneous, whereas if electron probe microanalysis or scanning electron microscopy (SEM) is employed they could be heterogeneous.

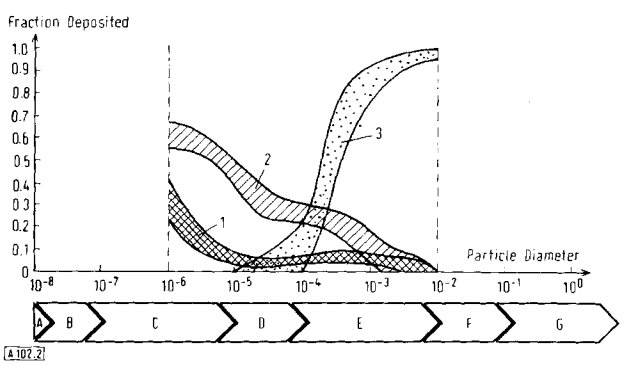

Fig. 2. Deposition of dust according to particle size. 1: tracheobronchial; 2: pulmonary; 3: nasopharyngeal (cf. also Fig. 1).

This means that the RFA method suffices up to homogeneity class 5, the SEM method up to 16. The highest homogeneity would be achieved if every atom in the sample were the same as the rest (homogeneity class 24).

It is already well known that the harmfulness of dust does not depend on the chemical composition alone, but also on the particle size and shape. Recent work by *Natusch* and *Wallace*[3] shows that small particles are generally more dangerous than large ones. The reason for this lies in the processes of breathing and deposition (cf. Fig. 2). Usually the dangerous components such as lead, cadmium, selenium *etc.* are present as small particles. It was found for example that prolonged exposure to coarse grained MnO_2 was not injurous to health, whereas a finer dust of the same substance (80% of the particle diameters <2 µm) caused pneumonitis. The influence of particle shape has so far not been studied in great detail, but one can assume that angular particles are more dangerous than rounded ones. This opens up yet another field for cooperative research (analysts, doctors, *etc.*). Furthermore, it is also known that dust is far from being a homogeneous product—neither from the point of view of particle size or shape, nor from the standpoint of composition. This leads to considerable difficulties in analysis, but can make the investigation of dust a very interesting task. In the analytical sense dust is an agglomerate, the characterization of which demands special consideration of the problems of homogeneity; for its clarification the methods of stereometric analysis are resorted to.

Detailed characterization of dust requires the following analytical steps (where possible, carried out simultaneously):

1. Average analysis of all or individual elements;
2. Identification and quantitative analysis of individual particles of dust;
3. Determination of particle mass (concentration), particle size, and particle-size distribution;
4. Determination of morphology.

Together with stereometric analysis[2] they form the basis of integrated dust analysis. Today the analyst has a wealth of equipment at his disposal for carrying out these determinations, so, in principle, achievement of the aims of such an analysis is not impossible.

2. Sampling

The arsenal of apparatus normally employed for the sampling of airborne dust, which has a particle size of approx. 0.01 to 100 µm, includes filters, dust collectors, electrostatic separators, cyclones, and impactors.

The widely adopted technique of dust sampling with the aid of filters is highly efficient. By using millipore filters with a defined pore-size, dust having a particle size down to 0.1 µm can be trapped with almost 100% efficiency.

Dust collectors are cheap and easy to handle but have the disadvantage that the dust must be separated from rainwater before the analysis. As a side-effect any SO_2 dissolved in the water can react with the dust and thus lead to a change in composition. A further disadvantage is the time required for sampling.

Electrostatic separators are best suited for the collection of smaller dust particles—down to a particle size of 0.01 µm. Cyclones are optimal for the separation of larger particles

(down to 5 μm). Impactors offer the advantage of simultaneous collection and fractionation of particles (working range down to 0.01 μm).

Next to deciding the correct method of sampling, greatest importance attaches to the choice of sampling site. This depends in the first place on the purpose of the investigation: immission or emission measurements. In each case meteorological factors such as wind direction, wind strength, temperature, moisture *etc.* must be taken into consideration.

A further important parameter is the duration of sampling. Each sample collected over a definite period of time yields average data for that interval of time (cf. Fig. 3), *e.g.* the daily average concentration of lead in the atmosphere, if collected over 24 h. If, on the other hand, the sampling time is shortened to 12 h, one obtains not only the daily average value but also the main deviations occurring half-daily. Sampling at three-hourly intervals leads to even more detailed information—for example that the lead concentration is especially high at peak traffic times.

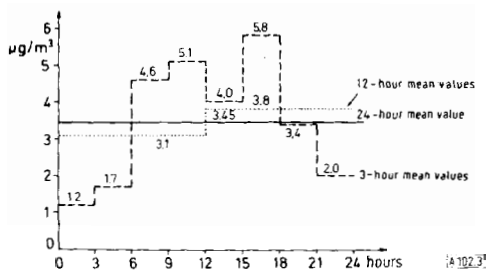

Fig. 3. Dependence of analytical information on duration of sampling. – Example: lead content of air at a street crossing in Vienna (after *Hartl, Müllner, Resch,* and *Wagner*).

Generally speaking, the information content of a sample is the higher, the shorter is the duration of sampling and the more complete is the analysis. The shortest possible duration of sampling is determined by the time required to separate the minimum amount of dust needed for the analysis.

Since the average concentration of dust in towns is about 100 to 50 μg/m³ and since dust can be separated from *ca.* 20–100 m³ of air per hour, the amounts of sample available for analysis lie in the milligram range. This leads to the first unavoidable claim on the technique of analysis to be employed: only micro methods are adequately suitable. If one now considers that a series of physiologically important elements are present in nanogram or microgram quantities in these few milligrams of dust sample we arrive at the second important feature required of the analytical technique: The methods must be highly sensitive, as defined in terms of trace analysis. Summarizing, this means that micro-trace methods are required for dust analysis. Also characteristic of such samples is that dusts are complex multi-element systems and the element to be determined can be present over a wide range of concentration (of % to ppb). Hence the overall analytical problem is "simply" that the analyst must have at his disposal non-destructive multi-element methods for the analysis of microsamples which can cope with a concentration range of about eight orders of magnitude and a particle-size range of about seven orders of magnitude.

If we check the arsenal of modern analytical chemistry with regard to the attributes required, we find that physical micromethods are best suited for dust analysis, since only these comply with the requirements of the sample and the previously formulated problem. The problem cannot however be solved on the basis of a single method.

3. Determination of Average Composition

In integrated dust analysis determination of the average composition is not only important, but essential—and especially for keeping a check on single particle analysis. The most important methods at the moment for the average analysis of a dust are X-ray fluorescence analysis (RFA) and atomic absorption spectroscopy (AAS).

The RFA method can be used for the qualitative and quantitative analysis of all elements having atomic numbers greater than 11 (Na)[4–6]. The practical execution of the analysis using the appropriate standards is simple—usually the filter loaded with dust is analyzed directly (without further treatment) (Fig. 4). Since the depth of signal generation in fluorescence excitation is about 50 μm, filter material is also excited along with the thin layer of dust. The characteristic intensity of the element being measured is directly proportional to the excited amount of element A in dust and filter. The correct intensity of an element in the dust is obtained by subtraction of the intensity of A in a blank filter. Since the surface area analyzed is usually *ca.* 3 cm², then with a signal generation depth of *ca.* 50 μm, a volume of *ca.* 0.02 cm³ will be excited. If the density is 2 g/cm³, then approximately 40 mg of sample of a compact material is analyzed; however, in the case of analysis of dust on filter paper the value is considerably lower.

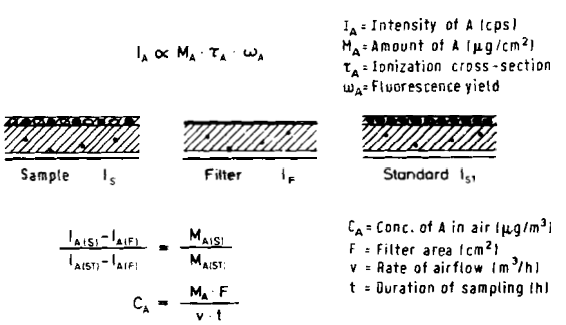

Fig. 4. Quantitative analysis of filter dust with the RFA method.

The quantitative analysis is based on comparison measurements against one or more standards; in most cases these are filters loaded with a definite amount of the element to be determined[7]. The standards are often prepared by spraying a compound on the surface of the filter paper. *Gilfrich et al.*[4] have pointed out the errors that can arise if soluble salts are used as standards instead of insoluble compounds (*e.g.*, for Mg and Al, correction factors of 31 and 20% respectively, are necessary).

It is a matter of conjecture whether this type of standardization really is the best, since the element to be analyzed is often present in different compounds. Thus, *e.g.*, Pb can be bound to oxygen, halide or sulfate. Depending on the chemical shift the band maxima of Pb can lie at different wavelengths. This effect, of course, plays only a subordinate role in RFA, since the resolution in this method is low. However, the effect is relevant in the case of electron probe microanalysis (EMP).

From the ratio of count rates (cf. Fig. 4)

$$\frac{I_{A(S)}-I_{A(F)}}{I_{A(ST)}-I_{A(F)}}$$

one obtains the amount of element deposited. The result is normally given in $\mu g/cm^2$ and converted into the usual concentrations used for hazardous solid materials. The multichannel analyzers presently being used in many industrial establishments have proved very useful for the analysis of dusts; they enable the simultaneous determination of 20 elements in approximately 2 min (in automated operation).

It follows from the direct proportionality between the intensity of a characteristic X-ray line and the fluorescence yield, that elements of the 2nd period cannot be determined with sufficient sensitivity by the RFA method because ω_A drops below 1% at such low atomic numbers.

Excitation with electrons in the macroprobe is useful for the quantitative analysis of these elements, especially C and O, since the decrease in fluorescence is compensated by a corresponding increase in ionization cross-section on account of the different mechanism of signal generation.

As example, we might mention here the determination of the C content of street dust with the macroprobe[8]. In the analysis of samples of street dust collected during a survey in Vienna (Fig. 5), which was concerned with the local and yearly change of concentration of nine elements, carbon contents of 2.7 to 9.2% were routinely determined. The dust sample collected in April, with a value of 7.7% (average value of all 26 collection points), shows the highest proportion of carbon. This can be ascribed to domestic heating systems which give rise to considerable emission of soot. In summer the C-values are around 25% lower.

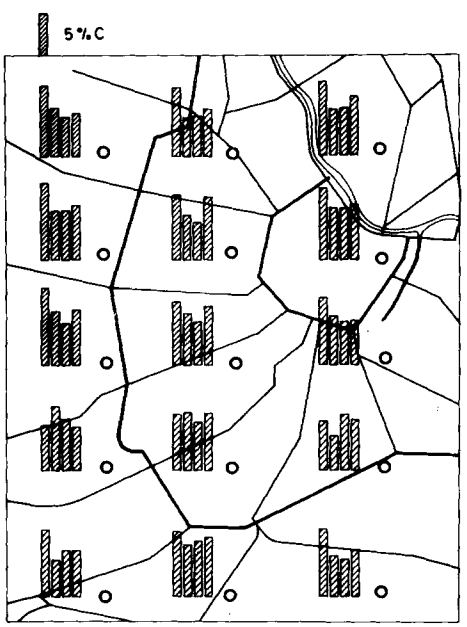

Fig. 5. Dust cadastre of Vienna: Carbon content of street dust [8].

A further disadvantage of RFA (but in this case seemingly slight disadvantage in comparison to the advantages) is the dependence of the signal intensity of an element on the particle size of the dust. At particle diameters of more than 5 μm, intensity losses of 50 to 90% can occur. The reason for this is that the absorption of the characteristic radiation in larger particles is stronger than in smaller ones.

Since the particle size distribution is usually unknown, corrections for this effect can rarely be made. Thus, the accuracy of dust analyses by the RFA method lies in the region of *ca.* ±20%. Though this is perfectly satisfactory in the majority of analyses, in individual cases a higher accuracy—if possible still with the same sensitivity—is desired. Atomic absorption spectrometry (AAS) would be suitable for such analyses[9,10].

At present, AAS provides good results only for liquid samples. This means that the dust sample must be dissolved—either partially (*e.g.* with HNO_3/HCl) or completely (*e.g.* with HF/HNO_3 under pressure in a teflon bomb or with $LiBO_2$)[11]. About 0.5 to 1 mg of sample is required for the determination of an element. The individual elements can so far be analyzed only sequentially, but with great accuracy.

Each chemical workup of the dust has the disadvantage that, on the one hand contamination with impurities can occur, and, on the other, that the bonding of the elements can no longer be determined; moreover, dilution of the system takes place. Because of this dilution—100 mg of dust becomes 100 ml of solution, *i.e.* a dilution of the order of 10^3—AAS, though in itself a sensitive method, does not usually show a higher sensitivity than RFA on evaporation of the sample in a flame.

Table 1 compares the sensitivities of the determination of Cu, Zn, and Pb by various methods. The limits of detection are based on the content of the element in the dust. It can be seen that the detection limit of AAS, the method usually employed, is poorer with flame evaporation than that of RFA, but the precision is better.

Table 1. Sensitivity of the determination of Cu, Zn, and Pb in dust (calculated according to Refs. [4, 6, 12]).

Method	Amount of sample	Limit of detection [a] [ppm]			Precision and reproducibility [% rel.]
		Cu	Zn	Pb	
RFA	1 mg/cm²	10	10	50	≈20
AAS (flame)	1 mg/ml	50	10	200	≈ 1–5
AAS (Graphite tube cuvette)	1 mg/ml	0.05	0.01	0.1	≈10–30
Optical emission spectroscopy	20 mg	10	10	1	≈10–100

[a] Based on concentration in the dust.

The sensitivity of AAS can be increased either by chemical enrichment of the trace metals in the sample solution or by use of the graphite tube cuvette. In the case of the elements quoted an increase in sensitivity by a factor of about 10^3 is possible with the graphite tube cuvette; however, the accuracy of the determination decreases to *ca.* ±30% rel. (after *Coleman*[12]). The most recent development of employing so-called plasma torches and incorporating gratings on a Rowland circle is receiving a great deal of attention, since it will probably enable the simultaneous flame-photometric determination of several elements in very low concentrations.

In some cases (*e.g.* Pb) better limits of detection are achievable with optical emission spectroscopy, since this is also a method in which the sample is excited directly without

dilution. However, the results can often be regarded as only semiquantitative.

Table 2. Quantitative investigation of a fly ash by X-ray fluorescence analysis (RFA) and atomic absorption spectroscopy (AAS) [4].

Element	RFA [μg/cm²]	AAS [μg/cm²]
S	3.2	
K	3.5	
Ca	0.30	
Fe	0.30	0.28
Ni	0.40	0.008
Cu	0.80	0.11
Zn	13	11
Cd		0.097
Pb	4.4	4.8

Table 2 shows the efficiency of RFA and of AAS in dust analysis using the results obtained for a sample of fly ash. The main elements, which are present in the ng or μg range, can be determined with RFA and/or AAS. Generally speaking the results can be said to be in good agreement. Large differences can be attributed to lack of sample homogeneity. In this connection it must be pointed out that precision and reproducibility in the analysis of dusts are also influenced, to a not inconsiderable amount, by the statistical error—*i.e.* by the small number of dust particles to be analyzed. This statistical error can be conveniently calculated with the aid of a formula described by *Wilson*[13], which, to a first approximation, states that the statistical error is $100/\sqrt{N_A}$, *i.e.* inversely proportional to the square root of the number of particles analyzed. Thus, in the analysis of Cu, one has to reckon with a statistical error of ±30% rel. (RFA) for a Cu content of 10 ppm, assuming a particle size of 5 μm. Of particular interest among the numerous new developments in AAS are the variants with microwave-plasma torches and multichannel grating spectrometers, since the amount of sample required is small and an automatic, simultaneous determination of up to 64 elements is possible.

Other methods used for carrying out average analyses of highest sensitivity are spark-emission mass spectrometry and neutron activation analysis. In comparison with the previously described methods they have considerable disadvantages—such as highly expensive apparatus, long analysis times, low accuracy *etc.*—and consequently find little application.

4. Analysis of Single Dust Particles

The most suitable method for the identification of dust components is the elemental analysis of single dust particles. Since airborne dust has a particle size range of *ca.* 100 to 0.01 μm the electron microprobe can be used for the analysis of single particles. The volume of sample excited by the fine-focused electron beam in point measurements is only a few μm^3 and thus makes a selective analysis of single particles possible. Sample preparation is simple: the filter dusts employed in RFA measurements can be analyzed directly after they have been coated with a thin layer of electrically conducting carbon by evaporation; loose dusts, such as are obtained in other dust collecting methods are transferred to a teflon platelet coated with adhesive carbon conductivity paste. Figure 6 shows a typical example of a dust analysis

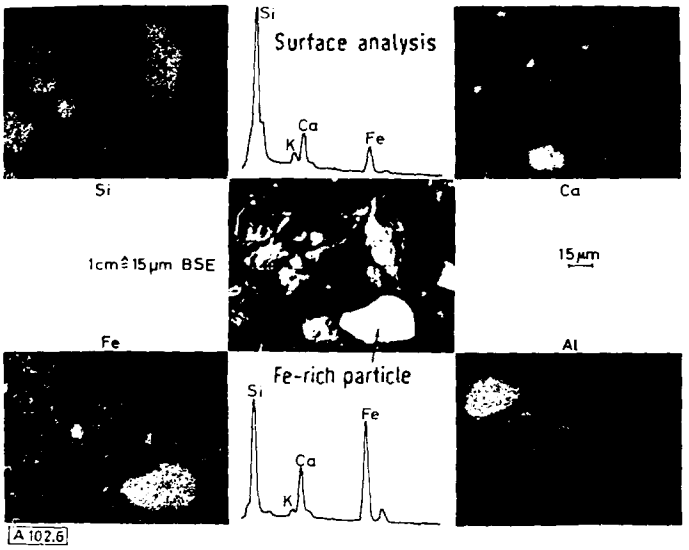

Fig. 6. Electron microprobe analysis of airborne particles.

with the microprobe. The electron back-scatter picture (center) not only gives information about the average atomic number, but also about the shape of the single particle. The energy-dispersion X-ray spectrum (upper right, center) yields semi-quantitative information about the concentration of the elements having atomic numbers greater than 11 (Na) that are present in the area scanned. This result might also serve as guide for any subsequent AAS investigation, in that suitable lamps and preparative steps can be carefully selected. The distribution of the elements can be plotted as the element-specific X-ray signals; the distribution pictures make it possible to give semi-quantitative information about the elemental composition of individual particles—thus, that the particle on the upper left, for example, is an aluminum silicate. The next task consists in quantitatively analyzing a single particle by point counting. The energy-dispersive X-ray spectrometer is well suited for the analysis of rough surfaces, since all elements at the same angle are measured. Crystal spectrometers must be employed for the determination of elements of the 2nd period. In binary systems, quantitative analysis is achieved

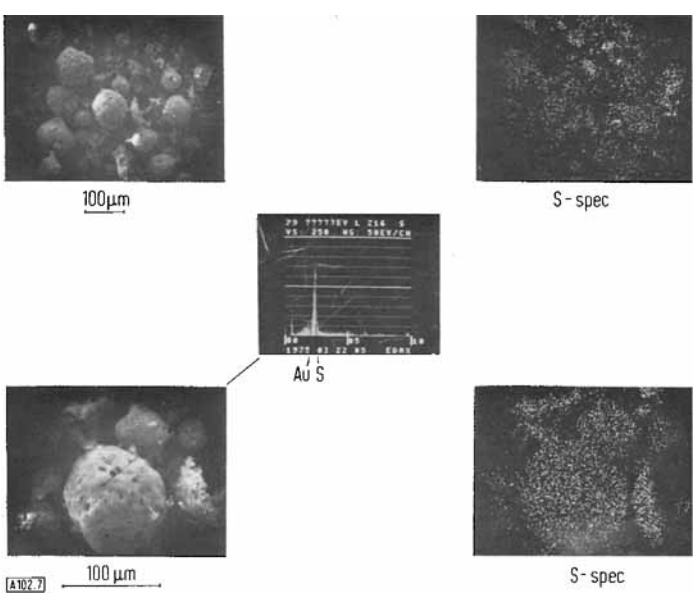

Fig. 7. Scanning electron microscopy of a dust particle collected in the vicinity of a district heating plant with energy dispersive X-ray analysis.

by evaluation of the counting rates and comparison with the corresponding data for standards containing the elements under consideration, since this quantity is largely independent of surface roughness and particle size—*i.e.* it still applies to particles that are smaller than the volume excited. Because of the roughness of the particle surface the achievable accuracy of the analysis is less than in polished samples, and lies in favorable cases at about 5–20% rel. This, however, is satisfactory in most cases.

The application of this technique and wavelength dispersion analysis can afford a wealth of information. Figure 7 shows electron back-scatter pictures (left) of single dust particles. The presence of sulfur was determined by recording an energy dispersive X-ray spectrum (center) and its distribution plotted with the wavelength dispersive spectrometer (right). In order to obtain more information about the sulfur compounds present, a temperature differentiated relative conductometric S and C analysis was carried out (cf. Fig. 8a)[14]. This method yields specific and typical degassing curves for carbon and for sulfur compounds.

Figure 8 shows that the degassing or combustion of such components can be very different, depending on the dust. In the dust of the first example, which contains 60.6% C and 10.9% S, loss of sulfur begins at 270°C. 20% of the total content is lost below 500°C, then a further 40% up to 600°C. In the interval to 1000°C the sample slowly loses another 20% of sulfur, and finally the rest in the interval up to 1200°C. In contrast, the volatilization of carbon proceeds very much differently. It is entirely lost within 200° at relatively low temperature.

Investigation of a dust, which was collected at the same time at another site by the Bergerhoff method, and which also proved to contain similar spherules (Fig. 9) but in smaller proportion gave total carbon and total sulfur contents of 8.4% and 1.8%, respectively. The degassing curves (Fig. 8b) are markedly different. 80% of the sulfur in this second example is volatile only above 1100°C. Loss of carbon is retarded and shows a significant step at 600°C for a residue of *ca.* 20%. From volatility curves the presence of "organic" and "inorganic" carbon as well as sulfur can be concluded. Thermal decomposition of $CaSO_4$ takes place between 1100 and 1300°C. The decomposition of $CaCO_3$ begins at 825°C, that of $MgCO_3$ at 325°C.

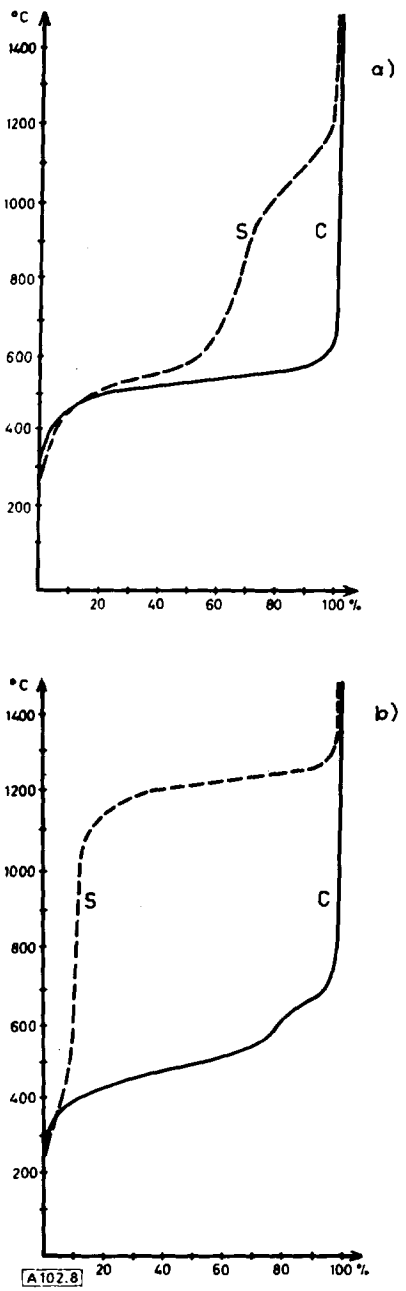

Fig. 8. Relative conductometric carbon and sulfur analysis with a temperature program: a) dust with 60.6% C and 10.9% S (cf. Fig. 7); b) dust with 8.4% C and 1.8% S (cf. Fig. 9).

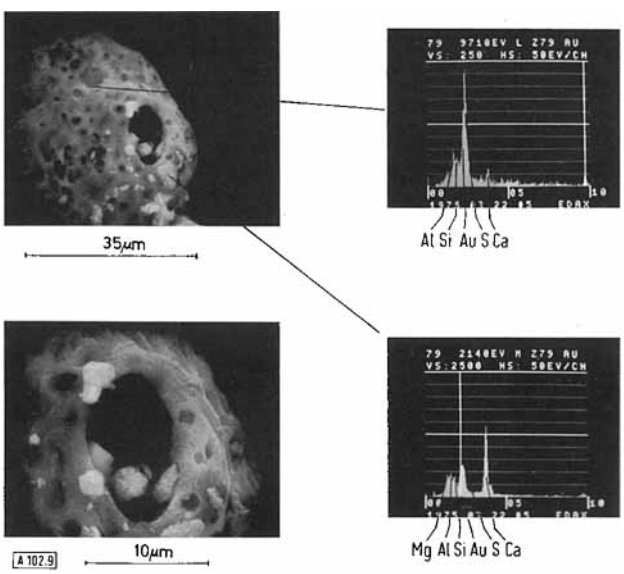

Fig. 9. SEM picture and energy dispersive X-ray analysis of a dust particle collected in a city.

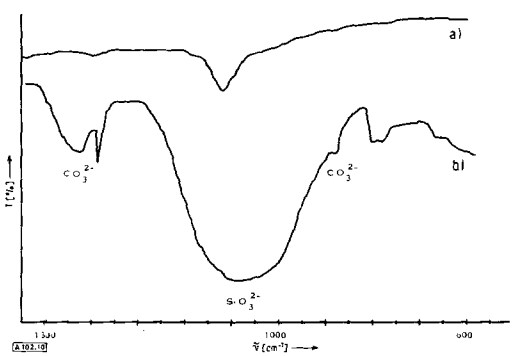

Fig. 10. IR spectra of, a) soot (cf. Fig. 7), and b) street dust (cf. Fig. 9).

In the IR spectrum of another fraction of this sample two bands are observed which can be assigned to the carbonate (Fig. 10b). Further investigations are called for in this obviously productive sector.

From the electron microprobe analysis (EMP) of the dust particles referred to in Figure 9 it follows that relatively large carbon particles are accompanied in this case by many small (1–5 μm) particles of other composition. The spectrum of the small particles shows that they contain more Mg and Ca and less Al and Si. Such particles are even found in the centers of the carbon particles. It is to be assumed that all particles can exhibit various effects and take on all sorts of attitudes.

In a modified analytical method the dust particles are inbedded in a resin; after polishing, the accuracy of the quantitative elemental analysis for particle sizes above 10 μm is improved to 1–2% rel. Using this method *Pietzner* and *Schiffers*[15] were able to identify the particles in waste gas from coal firing. In this connection the particle atlas by *McCrone et al.*[16] is very useful.

The ESCA method, which was introduced by *Siegbahn et al.*[17] and whose use in dust analysis has been particularly well demonstrated by *Novakov*[18], affords additional information. Thus, for example, it could be shown experimentally that soot plays an important role in the catalytic oxidation of SO_2 to SO_3 in the atmosphere. Auger spectroscopy likewise affords further information about chemical bonding. It ought to be utilized more than hitherto for research into the reactions between gaseous and solid substances polluting the atmosphere. Auger transitions as well as autoionizations can be excited by X-rays and by electron bombardment. Basic knowledge has already been gained with studies on CO[17].

In many cases it is not possible to arrive at an unequivocal clarification by elemental analysis, especially if several compounds differ only very slightly in their composition (*e.g.* PbO, PbO_2, and Pb_3O_4 or some silicates). The elemental information obtained with the microprobe must then be supplemented with compound-specific information—*e.g.* from valence band spectroscopy[19]. As can be seen from Figure 11, using the oxygen-K bands of Fe_2O_3 and $Fe_2(SO_4)_3$, the valence band spectra of an element in various compounds show clear differences in band position, width, shape and intensity ratios. These differences can serve for the identification of compounds.

In the case of the lead-oxygen compounds (Fig. 12) the intensity ratios between satellites and main band in the oxygen spectrum, their half-width, and asymmetric number are typical for a definite compound. This permitted characterization of the lead-containing dust particle shown in Figure 13.

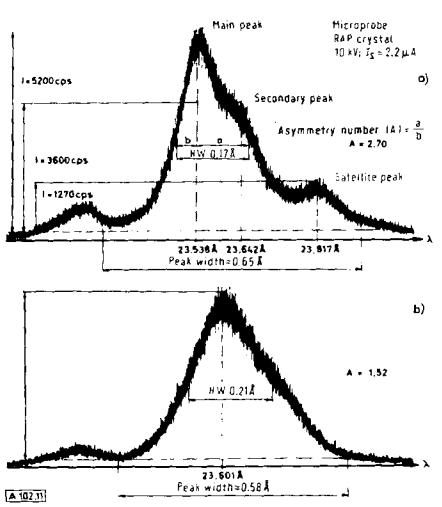

Fig. 11. Oxygen valence band spectrum of, a) $Fe_2(SO_4)_3$ and b) Fe_2O_3 [19].

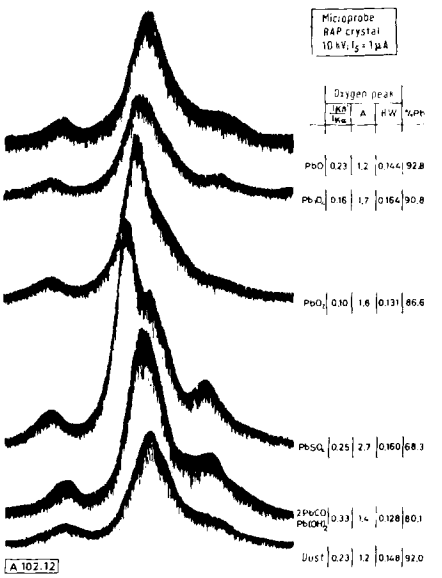

Fig. 12. Oxygen valence band spectra of some lead compounds [19].

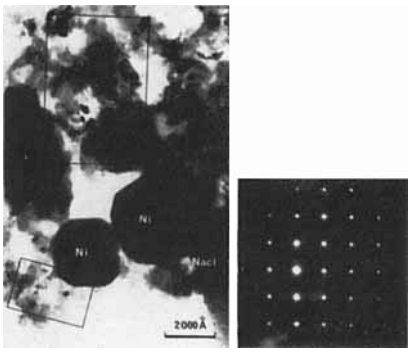
Fig. 13. a) Back-scattered electron picture and b) lead distribution of dust (1 cm = 60 μm).

X-Ray diffraction is also suitable for the identification of compounds occurring in a dust sample, particularly if preliminary data—*e.g.* average elemental analysis and composition of individual dust components—are available. This method was used by *Rickards*[20] for the determination of asbestos in dust and for differentiation of the various types of asbestos. The application of X-ray diffraction for the identification of compounds has the disadvantage, however, that the evaluation of multielement systems is tedious and the method insensitive. The limit of detection lies at 1–10 wt% of the compound in the sample. This constitutes a particular disadvantage if the particle size of the dust component sought is less than 1 μm, since an identification on the basis of elemental analysis with the microprobe is then impossible.

For particle sizes below 1 μm there is still the possibility of identifying the compounds contained in a single particle by recording an electron diffraction diagram[21]. Particles down to 100 Å diameter can be identified in this way—provided preliminary supporting data are available, *e.g.* on the qualitative elemental analysis, obtainable in one operation with a modern scanning transmission electron microscope (Fig. 14).

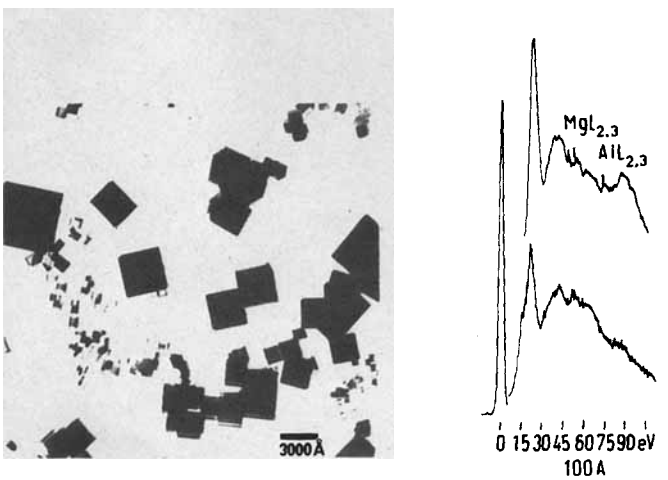


A 102.14 a) b)

Fig. 14. a) SEM micrograph of a nickel ore, roasted with NaCl; b) electron diffraction diagram of a NaCl particle.

Thus, in investigations on fluorine-containing airborne particles, *Radczewski*[22] was able to differentiate between the naturally occurring cubic K_2SiF_6 and the hexagonal K_2SiF_6, formed in industrial processes. This finding provides an important indication to the origin of the fluoride contamination.

Another technique employed in the identification of small particles is the evaluation of energy-loss spectra of the transmitted electrons in a scanning transmission electron microscope. Figure 15 shows a sample of MgO particles and their energy-loss spectra. Discrete bands in the continuum correspond to discrete energy-loss by the electrons in the ionization of an atom. The $MgL_{2,3}$ bands arise from the ionization of the magnesium $2p_{1/2}$ and $2p_{3/2}$ orbitals. A qualitative analysis would appear to be possible by determination of the ionization energies. The lateral resolution of this method is *ca.* 100 Å.



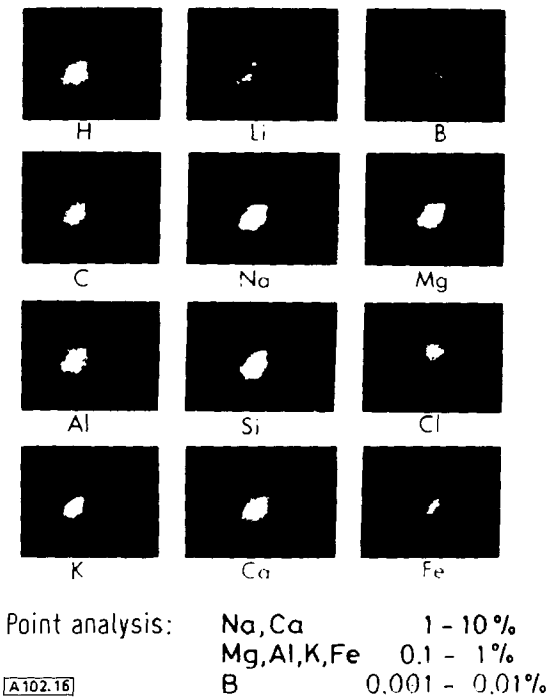
A 102.15

Fig. 15. Energy-loss spectrum of MgO particles on an evaporated Al layer.

A further limitation to the use of the microprobe arises from the relative insensitivity of the EMP method: the detection limit lies at a concentration of *ca.* 0.1%, with an excited volume of a few μm^3; this means that trace components of a single dust particle cannot be detected, even though the microprobe permits very low absolute detection limits (*ca.* 10^{-5} g).

As an extension to electron microprobe analysis, a further possibility is ion microprobe analysis, which, because of the higher effective cross-section of signal generation and lack of background interference, has a sensitivity that is higher by a factor of 10^2 to 10^5.

As with the electron microprobe the distribution of the elements to be found in the dust particles can also be recorded with the ion microprobe using the scanning technique, the distribution in this case being isotope-specific. Figure 16 shows as example the ion microprobe analysis of an approx. 8 μm particle of lampback. The main advantage here is that elements whose local concentration lies in the 0.001% range—as in the case of B in this instance—as well as elements of very low atomic number are still detectable. In the local analysis of the dust particle illustrated in Figure 16, *McHugh* and



A 102.16

Fig. 16. Ion microprobe analysis of an oil soot particle [23].

Stevens[23] were able to determine semi-quantitatively 21 elements in the concentration range from 10 ppm to more than 10%.

The great importance of local trace analysis is that the particle's content of trace elements often depends in a characteristic way on the emitters. Thus, *Anderson*[24] was able to identify the emitters by determing the Be content of asbestos fibers (ppm) in dust.

5. Morphology

In addition to the average analysis and single particle analysis of a dust, the determination of the morphology of the particles is frequently also very informative.

The morphology of the dust particles—*i.e.* size, shape, and surface characteristics—is of great importance from the physiological standpoint. Thus, the possibility of penetration of dust into the lungs depends on the particle size (cf. Section 1). Of the physiological effects of shape, it is known that pointed, rigid fibrous particles (*e.g.* asbestos fibers) are especially dangerous. The surface properties are decisive for the dust's ability to adsorb volatile noxious substances and thus evoke synergistic effects.

The investigation of dust morphology requires the use of the light microscope (lower limit *ca.* 1 μm particle diameters[16]) and the scanning electron microscope (lower limit *ca.* 100 Å particle diameters). SEM pictures (cf. Fig. 17) are by far the most informative[11] because higher resolutions and much sharper definitions are possible.

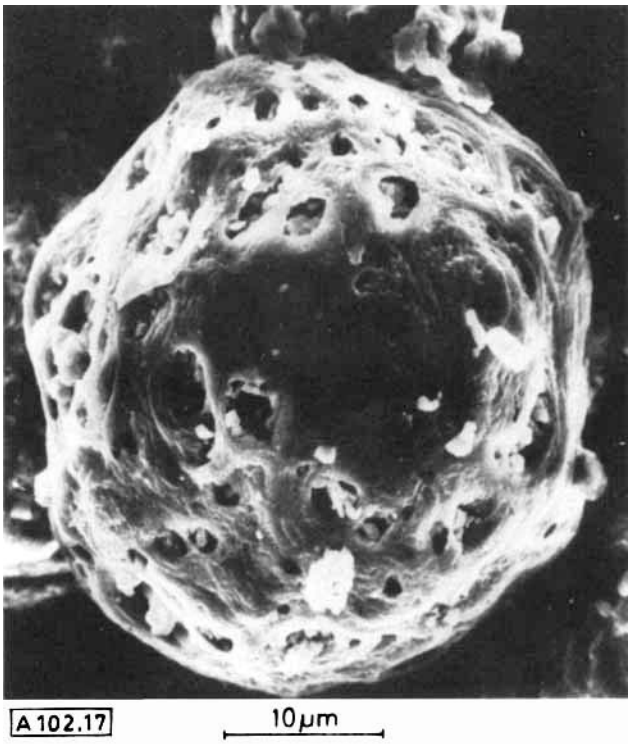


Fig. 17. SEM picture of an oil soot particle (magnification 2000 ×).

Special advantages are offered by an energy dispersion spectrometer fitted with a scanning transmission electron microscope, since such an apparatus enables the analysis of single particles, the determination of crystal structures by recording electron diffraction diagrams, and the morphological investigation to be carried out in one operation.

6. Conclusions

Integrated dust analysis, a novel analytical strategy in which physical, chemical, geometrical, and mathematical operations are combined, provides a wealth of very detailed data. It is still in the early stages of development, but rapid progress is expected in this sector over the next few years. The whole field of dust analysis must be re-examined and the methods of sampling, the possibilities of stereometric investigation of a sample by point, linear, and area analysis with new equipment (*e.g.* phase integrator) brought into line with new concepts and methods of interpretation.

The main analytical points are:

- the chemical composition of the region of sample examined;
- the qualitative and quantitative analysis of single particles;
- the total number of all selected particles;
- the particle size and particle-size distribution;
- the morphology.

The synoptic consideration of the results and the chemical and mathematical evaluation of the data will lead to the desired information.

Application of Catalyzed Reactions in Analytical Chemistry

New analytical methods (6)

By Herbert Weisz[*]

Catalyzed reactions are becoming increasingly important in analytical chemistry, and especially in trace analysis. The acceleration of a particular reaction (indicator reaction) promoted by the catalyst provides information about the catalyst concentration. Substances which lower or raise the activity of a catalyst (inhibitors or activators, respectively) can likewise be determined in this way. The course of a reaction is usually monitored by physical measuring techniques. Various methods of conducting these kinetic-catalytic studies are discussed in this article.—Use of catalyzed reactions for end point detection in volumetric analysis is also feasible.

1. Introduction

Whenever a definite relationship exists between the extent of a physical phenomenon and the amount of substance giving rise to this phenomenon, measurement of this property can be employed for quantitative determination of that substance. All measurable properties can be utilized for this purpose. During the measurement, the system must be in a state of sufficient stability, *i.e.* in thermodynamic equilibrium.

On the other hand, precisely the change of a property of a system with time may be monitored, *i.e.* time may be employed as an additional measured quantity.

Kinetic analytical techniques of this kind have found increasing application in recent years. Detailed accounts are to be found in the monographs by *Frost* and *Pearson*[1] and *Mark* and *Rechnitz*[2], and especially on practical analytical aspects in the book by *Yatsimirskii*[3]; some more recent surveys should also be mentioned[4–6].

An important group of kinetic analytical methods is based on the use of catalyzed reactions.

These techniques attract particular interest in analytical chemistry, doubtless because they provide a highly sensitive means of detection or quantitative determination of the catalyst itself.

Catalysts are substances which increase the rate of a chemical reaction. The requisite lowering of the activation energy proceeds in such a way that the catalyst is regenerated and thus maintains a constant concentration in the system; hence even small amounts of catalyst can effect high conversions, thus accounting for the high sensitivity of catalytic-kinetic methods.

Catalytic reactions have long held a firm place in qualitative analysis. Mention need only be made of the extremely sensitive iodine-azide reaction for the detection of sulfide[7]; iodine and sodium azide practically fail to react with each other, reaction occurring only on addition of sulfide (or various other compounds of divalent sulfur):

$$I_2 + 2N_3^- \xrightarrow{S^{2-}} 2I^- + 3N_2$$

It is readily observed, both by the disappearance of the brown color of the iodine and by the development of gas bubbles (nitrogen).

[*] Prof. Dr. H. Weisz
Lehrstuhl für Analytische Chemie
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

Analytical methods based on the use of catalyzed reactions are of great importance in present-day trace analysis, primarily owing to their frequently marked selectivity (especially in enzymatic analytical methods) and their high sensitivity, comparable with those of activation analysis.

Let us consider the reaction of two substances accelerated by a catalyst K

$$A + B \xrightarrow{K} X + Y$$

The concentration of K can be determined from the extent of this acceleration. The procedure adopted entails monitoring the rate of reaction between the substances A and B for a change in concentration of one of the starting materials (A or B) or of one of the reaction products (X or Y).

The reaction employed for determination (or detection) of the catalyst is called an indicator reaction. That substance whose change in concentration serves as a measure of the progress of the reaction is termed an indicator substance. It may be either a reactant (A or B, iodine in the case of the iodine-azide reaction) or a product (X or Y, elemental nitrogen in the case of the iodine-azide reaction).

The progress of the indicator reaction can therefore be followed by monitoring the depletion of a reactant or the accumulation of a product.

Assuming the indicator reaction to obey the following rate law:

$$\frac{dC_x}{dt} = kC_K C_A C_B \qquad (1)$$

k = rate constant; C_A, C_B = concentration of reactant A and B respectively at a time t

then the reaction is of second order since the catalyst concentration of C_K remains unchanged.

Now if one of the reactants, say B, is present in such excess that its concentration can also be regarded as constant, then we have a reaction of pseudo-first order:

$$\frac{dC_x}{dt} = kC_B^0 C_K C_A = k'C_K C_A = k'C_K(C_A^0 - C_X) \qquad (2)$$

C_A^0, C_B^0 = concentration of A and B, respectively, at time $t = 0$
$k' = kC_B^0$

If it is possible to determine even very small amounts of the indicator substance X by a sufficiently sensitive method of measurement (a small depletion of A is much more difficult

to determine) then determination of the reaction rate can be restricted to the initial state of the reaction. This means that during this brief period the concentration of reactant A can also be viewed as constant and we have a reaction of pseudo-zero order:

$$\frac{dC_X}{dt} \approx k' C_K C_A^0 = k'' C_K = \text{constant} \quad (k'' = k' C_A^0) \tag{3}$$

We see that in the initial state the reaction rate is directly proportional to the catalyst concentration C_K. Integration of this relation affords:

$$C_X \approx k'' C_K t \tag{4}$$

Equations (3) and (4) are the basis of the so-called differential methods. Three basic methods are available for determining the catalyst:

1) Tangent method: the change in concentration of X (C_X) is continuously observed and registered *versus* time. The slope of the resulting straight line, $\tan\alpha$, is a measure of the catalyst concentration (C_K). In the calibration graph the $\tan\alpha$ values are plotted against the corresponding catalyst concentrations.

2) Fixed time method: the amount of reaction product X formed within a fixed, predetermined time interval from the start of the indicator reaction is determined. In the calibration graph the C_X values are plotted against the corresponding catalyst concentrations C_K.

3) Fixed concentration or variable time method: the time which elapses from the start of the reaction until C_X has attained a certain predetermined value is measured. The reciprocal of this time plotted against the pertinent catalyst concentration affords the calibration graph.

If measurements have to be extended beyond the initial state, *i.e.* if the concentration of the reactant A present in lower concentration can no longer be regarded as constant (after consumption of more than 10% of A), then integral methods are used instead of differential ones. They are based on the integrated form of the differential rate law [cf. eq. (2)]:

$$\ln \frac{C_A^0}{C_A^0 - C_X} = k' C_K t$$

There is no longer a linear relation between C_X and t [as in eq. (4)] but a logarithmic one instead. Nevertheless, the three basic methods just described can still be employed.

By suitable choice of reaction conditions (concentration, pH value, temperature, ionic strength) the order of reaction can be modified in such a way that a simple, optimally linear, relation exists between the catalyst concentration and the reaction rate. Most of the indicator reactions used in analytical practice are modified so that they approximately correspond to the above conditions of a pseudo-first order reaction. (Theoretical aspects receive detailed treatment in the monographs[1-3].)

The most frequently used technique for determining the catalytic activity of a sample is the following: The two reactants of the indicator reaction (one generally in great excess) are brought together and the reaction initiated by admixture of the catalyst to the determined. In some cases it is more convenient to first mix one reactant with the catalyst and then start the reaction with the aid of the second reactant; this procedure is recommended above all when the contribution of the uncatalyzed reaction cannot be neglected.

The course of reaction can be followed by chemical or physical methods.

The chemical approach is practicable only in the fixed time method: the reaction is stopped after a suitably chosen time; this can be achieved by rapid cooling or a drastic pH change or, most frequently, by addition of an inhibitor which has a sufficient "braking" effect on the catalytic activity. Then either the unconsumed component of the reactant serving as indicator substance or the product formed since the start of reaction can be determined chemically (generally by volumetric analysis).

Measurement by physical techniques can be applied to all three methods—tangent method, fixed time method, fixed concentration method. This approach entails measurement of the change in some physical property of the system which is proportional to the change in concentration of the indicator substance concerned.

In most of the examples given in the literature, the reaction rate is determined by photometry in the reaction vessel itself which serves as a measuring cell in the spectrophotometer.

Other frequently used methods include highly sensitive fluorescence measurements, potentiometry, biamperometry, conductometry, and, especially recently, enthalpimetric monitoring of the reaction course by thermometric methods; the last method is particularly versatile, thanks to the sensitive thermistors nowadays available.

Since the reaction rate is extremely dependent on temperature (cf. Arrhenius equation) the reaction vessel must always be well thermostated; the enthalpimetric method clearly represents an exception where, by way of contrast, adiabatic reaction conditions must be employed (*e.g.* in Dewar vessels).

The results are usually evaluated by graphical extrapolation from a calibration graph.

Now not only the catalysts themselves can be determined by these kinetic methods but, indirectly, any substance which may influence catalytic activity: inhibitors, activators, reactivators.

Inhibitors, which lower the activity of a catalyst (*e.g.* by precipitation or complexation), are determined by adding the inhibitor to a known amount of catalyst and establishing the fall in the reaction rate by one of the above methods.

A fitting example is the determination of nanogram quantities of mercury by inhibition of the iodide-catalyzed cerium-arsenic reaction[8] (see Section 2.1) (1 ng = 10^{-9} g).

Reactivators (sometimes called pseudoactivators) can reactivate, *i.e.* liberate (*e.g.* by demasking), a catalyst present in an inactive inhibited form (*e.g.* as a complex); measurement of the activity of the reactivated catalyst affords a means of analytically determining such substances: manganese(II) catalyzes the oxidative decoloration of alizarin S by hydrogen peroxide; *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*',*N*'-tetraacetic acid inhibits the manganese catalyst by complexation. Now since lead is able to displace manganese from this complex—and thus regenerate its catalytic activity—microgram quantities of lead can be determined indirectly by this method[8] (1 µg = 10^{-6} g).

Activators enhance the activity of a catalyst and therefore become accessible to determination. For instance, arsenic(III) enhances the catalytic action of osmium on the reaction

between bromate and iodide and has been determined in this way[9].

In principle, a reactant of a catalyzed reaction can also be determined—albeit with a predictably lower sensitivity. This possibility is only employed in enzymatic analyses ("determination of substrate").

2. Indicator Reactions

The reactions used for determining catalytic activity must satisfy a number of conditions:

The extent of uncatalyzed reaction should be as low as possible (ideally zero).

The course of reaction should be easy to monitor, wherever possible by several methods (*e.g.* photometry, potentiometry, thermometry).

The catalyzed reaction should not be too fast, but, for practical reasons, not too slow either; if it is too fast ($t_{1/2} < 10$ s) the time required for thorough mixing of reactants can no longer be neglected.

Hitherto redox reactions and enzyme reactions have been employed most widely as indicator reactions. In addition, limited use has also been made of homogeneous catalyzed exchange reactions of complexes with mono- and multi-dentate ligands.

Concerning the heterogeneous catalyzed electrode reactions already described by *Heyrovsky*[10] (catalytic "waves" in polarography) the reader is referred to the literature.

2.1. Redox Reactions

The principal oxidizing agents used are: hydrogen peroxide, peroxoborate, oxygen, oxoanions such as bromate, iodate, nitrate, peroxosulfate, periodate; the reducing agents include iodide, thiosulfate, arsenate(III), a series of organic dyes such as alizarin, malachite green, azo dyes (*e.g.* methyl orange), other organic substances such as hydroquinone, α-naphthylamine, *p*-phenetidine, *o*-tolidine.

Catalysts that can be directly determined by these reactions include: copper, iron, manganese, titanium, zirconium(IV), thorium(IV), molybdenum(VI), tungsten(VI). Redox reactions catalyzed by osmium and ruthenium have been studied particularly thoroughly.

Other redox systems have also been employed for kinetic determination of catalysts, for example the cerium-arsenic reaction proposed as long ago as 1934 by *Sandell* and *Kolthoff*[11]; it is catalyzed by iodide and by osmium:

$$2Ce^{IV} + As^{III} \xrightarrow[Os]{I^-} 2Ce^{III} + As^{V}$$

yellow colorless

This reaction has since found numerous applications, being an especially favorable indicator reaction: it can be readily monitored by photometry, potentiometry (change in Ce^{IV}: Ce^{III} ratio), biamperometry, and thermometry.

The iodine-azide reaction mentioned in Section 1 which is catalyzed by divalent sulfur has also been frequently utilized.

Some metals such as copper and manganese catalyze the decomposition of hydrogen peroxide; this reaction can be followed particularly well by thermometry.

The reviews cited[4-6] list numerous examples of such reactions, and a selection of recent developments is presented in Table 1.

Table 1. Some examples of redox reactions.

Substance	Reaction	Ref.
Vanadium in blood	*p*-Hydrazinobenzenesulfonic acid + ClO_3^-	[12]
Chromium	*o*-Dianisidine + H_2O_2	[13]
Molybdenum in plants	$I^- + H_2O_2$	[14]
Manganese	Alizarin S + H_2O_2	[8]
Iron in plants	*p*-Phenetidine + H_2O_2	[15]
Ruthenium in minerals	*o*-Dianisidine + IO_4^-	[16]
Osmium, ruthenium	α-Naphthylamine + NO_3^-	[17]
Osmium	$As^{III} + BrO_3^-$	[18]
Cobalt in reactor cooling water	Alizarin red S + H_2O_2	[19]
Copper	$S_2O_3^{2-} + Fe^{III}$	[20]

An interesting group of redox reactions warranting mention are the peroxide oxidation of luminol or lucigenin catalyzed by various metals (copper, manganese, chromium, cobalt) during which chemiluminescence occurs. The light emitted can easily be measured by photometry (possibly with the aid of a photomultiplier). In this way 26 pg/ml of chromium(III) are determinable by a flow technique[21] (1 picogram = 10^{-12} g).

2.2. Ligand Exchange Reactions

A fitting example is the silver ion-catalyzed exchange reaction between hexacyanoferrate(II) und 2,2'-bipyridine (bipy)[22]:

$$[Fe(CN)_6]^{4-} + 3\,bipy \xrightarrow{Ag^+} [Fe(bipy)_3]^{2+} + 6CN^-$$

In similar manner, traces of mercury in the air have been determined by hexacyanoferrate and nitrosonaphthol[23].

An exchange reaction involving complexes with multidentate ligands is the following process which has been called a "coordination chain reaction": copper-edta and and nickel-trien react together *via* ligand exchange to form copper-triene and nickel-edta; the reaction rate is greatly accelerated by small amounts of additional complexing agent ethylenediaminetetraacetic acid (edta) or *N,N'*-bis(2-aminoethyl)ethylenediamine ("triethylenetetramine", trien). The course of reaction can be conveniently followed by photometry[24].

2.3. Enzyme Reactions

The determination of enzyme activity is based on the same principles as that of the catalytic activity of inorganic substances. Enzyme reactions are employed primarily in clinical and biochemical laboratories.

Apart from enzyme activity, substrates, *i.e.* reactants, can also be determined highly selectively *e.g.* glucose by means of glucose oxidase:

$$Glucose + H_2O + O_2 \xrightarrow{\text{glucose oxidase}} Gluconic\ acid + H_2O_2$$

$$H_2O_2 + 2I^- + 2H^+ \xrightarrow{Mo} I_2 + 2H_2O$$

This represents an example of the coupling of two catalyzed reactions. The rate of iodine formation provides a measure of the glucose concentration[25].

As in the analysis of other catalysts, any substance having a positive or negative effect on the catalytic (here enzymatic) activity, can be determined. Various metal ions inhibit enzymes; for instance, pg quantities of silver or mercury can be determined by inhibition of alcohol dehydrogenase[26]. Moreover, non-metals can also be determined by this method: pig liver esterase is significantly inhibited by traces of fluoride[27]. Particular significance may be attributed to the quantitative determination of pesticides (*e.g.* Lindane, Aldrin, DDT) by way of their inhibitor action on enzymes such as lipase, phosphatase, and above all cholinesterase[28].

Reactivation of inhibited enzymes can be utilized for quantitative determination of the reactivator; thus traces of cyanide and sulfide are determined by measuring the reactivation of invertase inhibited by mercury[29].

On removal of the metal ion from a metalloenzyme (*e.g.* zinc from alkaline phosphatase by ethylenediaminetetraacetic acid) there is a loss of enzyme activity; slight traces of the same metal (in this case zinc) reactivate the enzyme. This provides a highly sensitive determination of the activator[30].

The extensive field of enzymatic analysis is considered at great length in the books by *Bergmeyer*[31] and *Guibault*[28]; just a few indications of possible application will suffice in this article.

3. Determinations Employing Closed and Open Systems

A whole series of possible methods are available for the quantitative interpretation of the catalyzed reaction for determining the catalyst. An initial distinction is made between "closed" and "open" systems: closed systems are those in which there is no external intervention during the reaction; neither reactant nor product are added or removed once the catalytic reaction has started.

In open systems, on the other hand, reactants are added and/or products removed during the reaction.

3.1. Closed Systems

The general procedure described in Section 1 illustrates the use of a closed system. Let us now briefly consider three further methods of this kind.

The visual procedure referred to as the "simultaneous comparison method" by *Bognar* (1963)[32] is based on a simple experimental set-up described as early as 1922 by *Hahn* and *Leimbach:* equal volumes of a solution of reactant A and increasing known amounts of catalyst K are pipeted into a series of test tubes; the sample solution having an unknown concentration of K is then placed in one of these test tubes. Immediately, equal volumes of a solution of reactant B are added simultaneously, thus starting the reaction in all cases.

Observation of changes occurring in the individual mixtures—*e.g.* coloration, decoloration—reveals which of the standards corresponds most closely to the sample in its behavior. Under identical conditions, equal changes clearly also mean corresponding catalyst concentrations. This method utilizes a "dynamic colorimetric standard scale".

Since all reactions proceed simultaneously under the same conditions there is no need for thermostating; moreover, neither time nor concentration have to be measured directly.

While this "simultaneous comparison method" probably represents the nearest approach to the "tangent method", systems of the "Landolt type" provide an opportunity of carrying out processes which can be regarded as "fixed concentration methods".

A slow reaction is connected with a fast one by the product X of the former (slow) reaction. Hence it follows that X can only be present in the free state once all the R has been consumed, *i.e.* the system must be deficient in R.

$$\begin{aligned} A + B &\rightarrow X + Y \quad \text{slow} \\ X + R &\rightarrow E \quad\quad \text{fast} \end{aligned}$$

If the first reaction can be accelerated by a catalyst, then the time elapsing between the start of reaction and the appearance of free X, the "induction period", is a measure of the catalyst concentration: the shorter the induction period the greater is the catalyst concentration.

This "chronometric" method has been successfully applied to the determination of a series of catalytically active metal ions (Fe, Mo, Zr, V)[33]. For example:

$$BrO_3^- + 5Br^- + 6H^+ \xrightarrow[pH \approx 5]{V} 3Br_2 + 3H_2O$$

$$3Br_2 + 3\,\text{ascorbic acid} \rightarrow 6Br^- + 6H^+ + 3\,\text{dehydroascorbic acid}$$

This is a self-regenerating system, the reactant B (Br^-) of the first reaction being re-formed in the second reaction. Only after all the ascorbic acid has been consumed does bromine appear momentarily and can be detected, for example, with a fluorescence indicator (trypan red)[34].

The next procedure we shall consider is a catalytic difference method: two vessels contain equal amounts of a reaction mixture A + B and the catalyst serving to accelerate the inhibited reaction, albeit at different concentrations (sample K_p and standard K_v); thus the two systems differ only in the concentration of catalyst

$$\text{sample:} \quad A + B \xrightarrow{K_p} X + Y$$

$$\text{standard:} \quad A + B \xrightarrow{K_v} X + Y$$

Whatever property of the system is employed for monitoring the reaction course—*e.g.* the extinction or the potential—the difference between the two measured values will always initially be zero. Subsequently, however, the differing catalyst concentrations in the two mixtures will lead to a steadily increasing difference which rises to a maximum; finally, after reaction has reached completion in the two systems (this may take a considerable time) the difference is again zero.

This change in the difference with time will provide some information about the ratio of the catalyst concentrations, either from the height of the maximum, from the area under the curve, or from the slope of the curve leading up to the maximum; hence it should be possible to establish the unknown concentration in the sample.

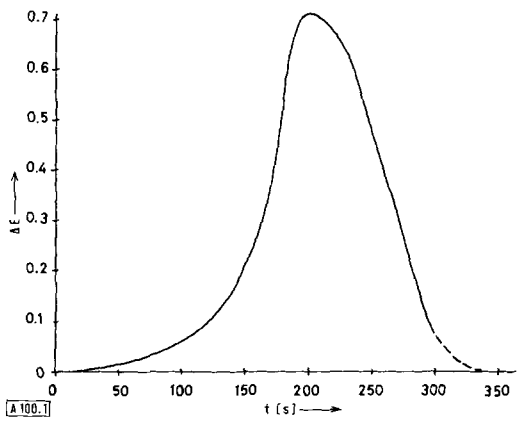

Fig. 1. Variation of extinction difference with time.

Figure 1 shows a curve obtained in such an experiment, namely the photometrically recorded difference in extinction in the copper-catalyzed reaction

$$2Fe^{III} + 2S_2O_3^{2-} \xrightarrow{Cu} 2Fe^{II} + S_4O_6^{2-}$$

The intensely red complex of iron(III) with thiocyanate serves as indicator of the course of reaction.

This reaction was utilized for the determination of copper (1—25 μg in 10 ml; standard always 5 μg). It proved most convenient to employ the maximum difference in extinction, occurring within minutes, in evaluation of the results; once this value has been recorded measurement can stop, there being no need to record the entire curve. The desired copper concentration can be extrapolated from a calibration curve. Measurement can readily be performed in a Lange colorimeter[20, 35].

In such difference determinations the reaction course can also be followed by potentiometric[20], thermometric, and conductometric methods[36].

3.2. Open Systems

Flow, "steady state", and "stat" methods should be mentioned under this heading. They all have in common that the course of reaction is subjected to external influence by addition of reactants and/or removal of products.

In the "stat" methods[37] a given state of the system is arbitrarily imposed and maintained during the reaction by addition of a reagent. The system itself controls this addition; the rate of addition of reagent necessary for maintaining the given state provides a measure of the reaction rate and hence for the catalyst concentration to be determined. The factor maintained, and thus serving the control function, is a physical property of the system dependent upon the concentration of a reactant, a product, or the ratio of reactant to product.

Let us again consider the general reaction

$$A + B \xrightarrow{K} X + Y$$

and assume B to be present in considerable excess so that its concentration can be regarded as constant; then, if the reaction course is followed by measurement of A:

$$-\frac{dC_A}{dt} = kC_K C_A$$

Now if A is supplied at the same rate at which it is consumed in the reaction, it follows, because C_A is no longer a variable, that:

$$-\frac{dC_A}{dt} = k'C_K$$

This is therefore a reaction of "quasi"-zero order: the reaction rate remains constant over a relatively long period, *i.e.* beyond the initial state, and the rate of addition is proportional to the catalyst concentration C_K.

An example utilizing photometric control may serve as an illustration[38]: manganese catalyzes the oxidation of malachite green by periodate (at pH = 3–4), reaction being accompanied by decoloration:

$$IO_4^- + \text{malachite green} \xrightarrow{Mn} \text{colorless product}$$

A schematic diagram of the apparatus, termed "extinctiostat" ("absorptiostat") is shown in Figure 2: the thermostated

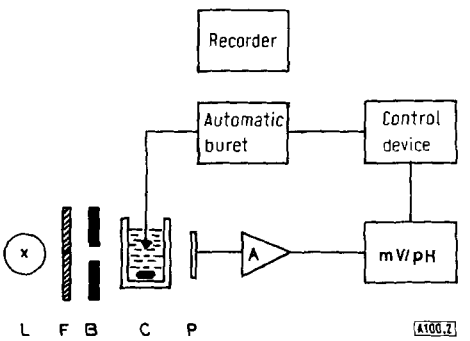

Fig. 2. Extinctiostat (absorptiostat). L, light source; F, monochromatic filter; B, iris diaphragm; C, thermostated cell; P, photocell; A, amplifier.

cell C contains the reaction mixture (malachite green + IO_4^-) with the Mn solution to be determined; L is the light source (here 619 nm). The signal from the photocell (P) is amplified (A), registered as a potential by a mV meter and fed to the control device. Here the measured value is compared with a given set potential. This set potential corresponds to a certain set extinction in the cell and thus logically to a definite selected concentration of malachite green. The difference between the set and the actual potential, and thus between the set and actual concentration of malachite green, arising in the course of the reaction, is corrected by a command to the buret: the deficit at any time is compensated by addition

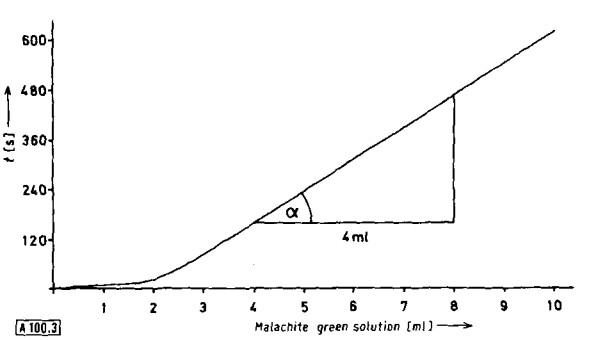

Fig. 3. Curve plotted for 7.5 μgMn/45 ml catalyzing the oxidation of malachite green by periodate.

of a corresponding amount of malachite green standard solution. The recorder registers the rate of addition (ml/min) of standard solution; this provides a measure of the catalyst concentration (Mn) to be determined. A curve of this kind as registered by the recorder is shown in Figure 3. Evaluation is based on the cotangent of α (vol/time) taken from the plot. A calibration graph is plotted with several cotangent α values for known manganese concentrations.

The pH stat procedure[39] and methods employing a potentiostat[40], a biamperostat[41], and a luminostat[42] all function in analogous manner; in the last-named case the chemiluminescence occurring on reaction of luminol with hydrogen peroxide is maintained constant by controlled addition of H_2O_2. Metals catalyzing this reaction, *e.g.* copper, can be determined by this technique.

While all these "stat" methods involve addition of some reagent controlled by a change of a physical phenomenon in the system itself, "steady-state" methods entail admixture of a reactant at a constant rate. This technique was employed in a similar form by *Pearson* and *Piette*[43] for determining kinetic data of noncatalyzed reactions. To a system containing one of the two reactants (A) in great excess as well as the catalyst (K) to be determined is added the other reactant (B) at constant rate by means of a motor-driven piston buret. The reaction A+B starts directly upon addition of the first small portion of B, albeit very slowly owing to the initially very low concentration of reactant B in the system. This means, however, that not even the minute amount of B will be completely consumed.

Since B is added continuously, its concentration and hence also the rate of reaction A+B will increase; and so will the consumption of B.

After some time a stage is reached at which precisely the same amount of B is consumed per unit time as is added from the buret. A steady state of the system—with regard to the concentration of B—is then attained and will persist for some time.

Whatever physical property, whatever phenomenon is chosen for measuring the steady-state concentration of B, *e.g.* the extinction or the potential, it serves as a measure for the reaction rate and thus, under otherwise identical conditions, as a measure for the concentration of catalyst to be determined. As always, a calibration graph is used in evaluation; the reciprocal value of the steady state concentration (or the corresponding measurement, *e.g.* extinction or potential) is plotted *versus* the catalyst concentration.

In this way it was possible, for example, to determine between 60 and 650 ng of iodide using the Sandell-Kolthoff reaction between arsenic(III) and cerium(IV): the iodide sample is added to an excess of arsenic(III) and an approximately 10^{-2} M solution of cerium(IV) added from a motor-driven piston buret at a rate of about 10 µl/min to a reaction volume of about 10 ml. The change in optical density (at 420 nm) is recorded. After a few minutes a steady state is attained, the extinction remaining unaltered[44].

In the methods just described one of the reactants is added to the other, the rate of addition being either constant or regulated by the system itself.

It is, of course, also possible not only to add a reagent but to simultaneously remove an equal volume of reaction solution. This is practiced in flow methods. A flow apparatus is schematically depicted in Figure 4.

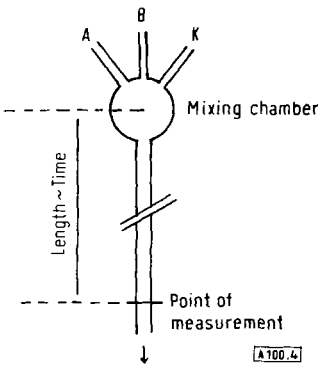

Fig. 4. Schematic representation of flow tube. A, B, reactants; K, catalyst.

The reactants A and B and the solution of the catalyst K to be determined flow separately into a mixing chamber, whence they enter a flow tube. At a given point, some property of the system (potential, optical density, *etc.*) is continuously monitored. The distance between the mixing chamber and the point of measurement corresponds to a certain fixed time, provided of course that the flow rate is constant.

The value measured provides a measure of the catalyst concentration.

The flow technique is well suited to continuous analysis, any change in catalyst concentration will clearly alter the value measured.

Although this kind of kinetic method has been known for over five decades there are only few analytical applications. *Wilson*[45] used such an experimental set-up for continuous determination of molybdenum (1—50 µg) with the aid of the reaction of peroxoborate with iodide.

Whereas steady-state, but different, concentrations of reactants and products will be established at different positions of the flow tube if the reaction conditions remain unchanged, that variant of the flow technique employing thorough back mixing ("capacity flow cell")[46] is characterized by attainment of an effectively uniform steady-state concentration of the reactants and products throughout the entire reaction vessel. This method will now be illustrated by the manganese-catalyzed oxidation—and hence decoloration—of alizarin S by hydrogen peroxide[8]: the manganese to be determined and

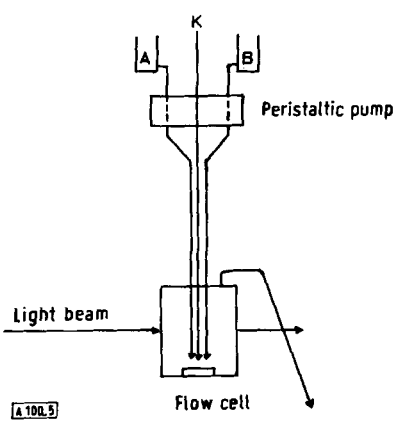

Fig. 5. Schematic representation of a flow cell. A, B, K, see Fig. 4.

the reactants alizarin S and hydrogen peroxide flow separately into a flow cell (cf. Fig. 5) where they are immediately thoroughly mixed. After some time a steady state is established

with regard to the concentration of all reactants and products. The concentration of alizarin S is continuously monitored by photometry and recorded. It affords a measure of the amount of catalyst: the higher the concentration of manganese the lower the concentration of alizarin S.

As with all other catalytic-kinetic methods, these flow methods can also be used for determining inhibitors, activators, reactivators.

Special flow techniques have also been developed for following very fast reactions (*e.g.* stopped flow, accelerated flow methods)[2]; however, they have only rarely been employed for analytical purposes.

The flow technique is also well suited to automation. A detailed report has recently been published on automation and instrumentation of kinetic analytical procedures employing open and closed systems[47].

4. Catalytic End Point Indication in Volumetric Analysis

All the methods discussed so far require quantitative determination of catalytic activity in order to determine the catalyst itself or, indirectly, an inhibitor, activator, or reactivator. On use of catalyzed reactions for end point determination in volumetric analysis, it suffices to establish qualitatively that the catalyst is present at a concentration high enough to detectably enhance the rate of an indicator reaction. During the past few years catalytic reactions have been employed for indication purposes in volumetric determinations[3]. A review of this comparatively young field has recently been written by *Hadjiioannou*[48].

The volumetric solution (K) which catalyzes the reaction between substances A and B is added from a buret. This volumetric solution can be used for titration *versus* a substance (an inhibitor) which drastically impairs the activity of the catalyst K, possibly by precipitation or complexation. The first excess drop of solution from the buret (*i.e.* of catalyst K) accelerates the indicator reaction between A and B; this is exploited for end-point detection.

The method is illustrated by the precipitation titration of silver with potassium iodide standard solution: to the silver solution to be determined is added yellow cerium(IV) sulfate solution and arsenic(III); titration with 0.1 N potassium iodide is then performed with vigorous stirring(!). Iodide ion is precipitated as silver iodide. The first excess potassium iodide catalyzes the cerium-arsenic indicator reaction and the yellow cerium(IV) solution is immediately decolorized[49].

Chloride, bromide, iodide, and thiocyanate can also be determined in this way by back titration.

Such catalytic end-point determinations have the advantage that the excess of titration reagent is not consumed in a stoichiometric reaction with an indicator but merely acts as a catalyst; a very small excess of volumetric reagent is able to catalyze reactions of comparatively large amounts of the reagent mixture serving as indicator.

An example of reducing catalytic activity (inhibition) as a result of complex formation is provided by the titration of ethylenediaminetetraacetic acid with a cobalt volumetric solution; oxidation of Tiron by peroxoborate (gold coloration) serves as indicator reaction[49].

The end point does not have to be determined visually; any physical method permitting determination of changes accompanying the occurrence of the indicator reaction in the system can be utilized. Thus catalytic end-point determinations employing potentiometry[50], biamperometry, photometry[51], and thermometry[52, 53] have all been described.

The last-mentioned procedure appears especially interesting since it is not the slight evolution of heat during the actual titration reaction (catalyst + inhibitor) which serves for end-point recognition, but instead the much greater one accompanying the indicator reaction (A + B) which occurs once the end-point is passed.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

trans-Pentacarbonylrhenio(phenylcarbyne)tetracarbonylmolybdenum: A Transition Metal Carbyne Complex Containing a Metal-Metal Bond[1]

By *Ernst Otto Fischer*, *Gottfried Huttner*, *Tassilo Lothar Lindner*, *Albin Frank*, and *Fritz Roland Kreissl*[*]

trans-Bromo(tetracarbonyl)carbyne complexes of chromium, molybdenum, and tungsten[2] react with sodium pentacarbonylmanganate(−I)[3a] and -rhenate(−I)[3b] *via* halogen/carbonylmetal exchange at low temperature to give new dinuclear carbyne compounds:

$$(CO)_5M'Na + BrM(CO)_4{\equiv}CC_6H_5 \xrightarrow[-25\,^\circ C]{THF} (CO)_5M'\text{–}M(CO)_4{\equiv}CC_6H_5 + NaBr$$

M' = Mn, Re; M = Cr, Mo, W

The yellow to orange colored products are readily soluble in both polar and apolar organic solvents and exhibit greater thermal stability than the corresponding bromo complexes. Their stability increases on going from the Mn—Cr to the Re—W derivatives. All the compounds were verified by total elemental analysis, by IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectrometric investigations, and by X-ray structure analysis. We selected $(CO)_5Re—Mo(CO)_4{\equiv}CC_6H_5$ as representative for characterization of the new type of compound.

In the region of the ν_{CO} frequencies the IR spectrum (in *n*-hexane) of this complex displays the five bands expected (2 E and 3 A_1)[4] for the carbyne ligand in an axial position at 2104 m, 2049 m, 2019 vs, 1975 s, and 1968 s cm^{-1}. The ^{1}H-NMR spectrum contains the multiplet due to the phenyl protons at 7.63 ppm (in CD_2Cl_2, −20 °C, TMS internal standard). The ^{13}C-NMR findings accord with our ideas about the structure of the dinuclear carbyne complex: Owing to Br/$(CO)_5$Re exchange the signals of the carbyne carbon atom, and also of the carbon atom belonging to the CO group attached to molybdenum, are shifted downfield relative to the starting complex[5]; the carbonyl signal of the $(CO)_5$Re group appears as a very broad signal as a result of the nuclear spin of 5/2 in the case of both rhenium isotopes; the four signals of the aromatic carbon atoms are observed in the usual range [in [D_8]-THF, relative to solvent (67.32 ppm), δ = 293.98 ($C_{carb.}$), 215.44 (CO_{Mo}), 199.40 br (CO_{Re}), 146.23, 133.13, 132.16, 129.35 ppm (C_6H_5)].

The structure of the new compound was confirmed by X-ray structure analysis [973 independent reflections ("Syntex P21"); solution with "Syntex XTL" (R_1 = 0.051)]: space group C2/c; a = 1084.4, b = 1712.7, c = 1042.4 pm; β = 91.2°; Z = 4.

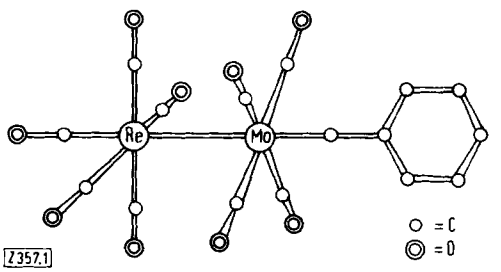

Fig. 1. Structure of $(CO)_5Re—Mo(CO)_4{\equiv}CC_6H_5$.

On account of the space group symmetry (twofold axis of rotation) the *trans*-CO—Re—Mo—$C_{carbyne}$ grouping is strictly linear. The Re—Mo bond having a length of 311.1 ± 0.2 pm is to be regarded as a single bond (for comparison: η-$C_5H_5(CO)_3Mo—Re(CO)_5$ 312 pm[6]). The Mo—$C_{carbyne}$ distance is 183.5 ± 2.5 pm and thus corresponds, within the limits of error, to the sum of the triple bond radii of Mo≡Mo[7] and C≡C[8] (122.4 + 60.5 = 182.9 pm). As in the decacarbonyl compounds of Mn[9a] and Tc[9b], the equatorial carbonyl groups are in a staggered arrangement and bent toward each other (by 9.6°).

Procedure:

All operations should be carried out under nitrogen with dried (Na, P_4O_{10}) and N_2-saturated solvents. A THF solution of $NaRe(CO)_5$ (1.75 g, 5 mmol) is reacted at −25 °C with $BrMo(CO)_4CC_6H_5$ (1.89 g, 5 mmol) in THF (25 ml). The mixture is stirred for 30 min and the solvent then removed in a high vacuum. The crude product obtained by extraction with pentane is purified by chromatography in pentane/methylene chloride on silica gel at −20 °C. Recrystallization from pentane affords analytically pure $(CO)_5Re—Mo(CO)_4{\equiv}CC_6H_5$, orange crystals, m.p. 85—87 °C; yield 32%.

Bromyl Cation, $[BrO_2]^+$ [**]

By *Eberhard Jacob*[*]

Dedicated to Professor Josef Goubeau on the occasion of his 75th birthday

The co-condensation of highly reactive components at low temperatures[1] offers a means of moderating otherwise uncontrollable reactions and of directing them along preparatively interesting pathways. This approach has now permitted the first generation and stabilization of the bromyl cation as the fluoroantimonate *(2a)* by slow warming of a co-condensate of bromyl fluoride *(1)*[2] and an excess of antimony pentafluoride, prepared at −196 °C, to room temperature in a high vacuum.

$$\underset{(1)}{BrO_2F} + SbF_5 \xrightarrow{SbF_5} \underset{(2a)}{[BrO_2]^+[SbF_6(SbF_5)_{1.24}]^-}$$

An inhomogeneous distribution[3] of *(1)* in the co-condensate is manifested in a red coloration owing to formation of the thermally more stable dibromine salt *(3)*:

$$9\underset{(1)}{BrO_2F} + 5\,SbF_5 \rightarrow 4\underset{(3)}{[Br_2]^+[SbF_6]^-} + \underset{(4)}{[BrF_4]^+[SbF_6]^-} + 9O_2$$

$[BrO_2]^+$ is already formed at temperatures below −80 °C in a solid state reaction. Compound *(2a)* is difficult to obtain colorless (usually yellowish because of traces of dark red *(3)*). It is stable at room temperature (dissociation pressure $<10^{-3}$ torr). Atmospheric moisture or warming to 80 °C effects rapid decomposition. Thermal degradation leads by way of evolution of oxygen to *(3)* and *(4)* as primary products. Vacuum pyrolysis of *(2a)* in the presence of an excess of sodium fluoride permits precise determination of the amount of $[BrO_2]^+$ in *(2a)*.

$$3(2a) + 6.72\,NaF \xrightarrow{250\,^\circ C} 6.72\,NaSbF_6 + 3O_2 + BrF_3 + Br_2$$

The salt-like character of *(2a)* is apparent from its IR and Raman spectra. In addition to the characteristic frequencies expected for $[Sb_2F_{11}]^-$ and $[Sb_3F_{16}]^-$[4], the only other bands found showed the frequency shifts calculated for a bent $[BrO_2]^+$ species having C_{2v} symmetry on isotope substitution[5]. The fundamental vibrations of the cation reveal the similarities expected for isoelectronic species with those of monomeric selenium dioxide (cf. Table 1).

Table 1. Fundamental vibrations of the bromyl cation and of selenium dioxide [a].

	$\nu_1(A_1)$		$\nu_2(A_1)$		$\nu_3(B_1)$	
	IR	Raman	IR	Raman	IR	Raman
$[Br^{18}O_2]^+$	832 vw	825 s	354 s	355 m	897 s	889 m
$[BrO_2]^+$	876 vw	865 s	375 s	375 m	930 s	932 m
SeO_2 [6]	922 w	933 s	373 s	382 m	965 s	967 m

[a] Monomeric SeO_2 in an argon matrix.

Bromyl hexafluoroarsenate, $[BrO_2]^+[AsF_6]^-$ *(2b)*, arises on co-condensation of *(1)* and arsenic pentafluoride at −196 °C and warming to −50 °C. In a high vacuum *(2b)* volatilizes above −35 °C with decomposition. The IR spectrum of a thin film of this salt shows the fundamental vibrations of the cation and the anion[7].

[**] Low-temperature co-condensation of fluorine compounds, Part 1.

Procedure:

BrO_2F (3.1 g, 24 mmol) from a storage vessel cooled to −7 °C and SbF_5 (28.3 g, 130 mmol) are simultaneously passed through two concentric tubes into the lower part of a 2-l stainless steel vessel cooled with liquid nitrogen, where they condense. Throughout the co-condensation (1 h), warming (3 h), and pumping off of excess SbF_5 at room temperature to constant weight a maximum vacuum is maintained. The reaction product is collected with exclusion of moisture; yield 8.6 g (13 mmol) $[BrO_2]^+[SbF_6(SbF_5)_{1.24}]^-$.

Xenon Oxide Difluoride, $XeOF_2$ [**]

By *Eberhard Jacob* and *Robert Opferkuch*[*]

Dedicated to Professor Josef Goubeau on the occasion of his 75th birthday

We have been able to synthesize and isolate a xenon oxide difluoride which has formerly only been detected by spectroscopy[2]; the method employed was low-temperature co-condensation. A solid co-condensate of xenon tetrafluoride and water (molar ratio 1 : 1.1) transforms into xenon oxide difluoride between −80 and −50 °C.

$$XeF_4 + H_2O \longrightarrow XeOF_2 + 2\,HF$$

In order to avoid the reaction[3]

$$XeF_4 + 2H_2O \rightarrow Xe + O_2 + 4HF$$

the hydrogen fluoride liberated on hydrolysis is continuously pumped off.

$XeOF_2$ is a pale yellow nonvolatile solid which is stable up to −25 °C. It decomposes on slow warming (≈20 °C/h) to −15 °C with decoloration according to [4]:

$$2XeOF_2 \rightarrow XeO_2F_2 + XeF_2$$

[*] Dr. E. Jacob and Dipl.-Chem. R. Opferkuch
Institut für Kernverfahrenstechnik des Kernforschungszentrums
Postfach 3640, 7500 Karlsruhe 1 (Germany)
Abteilung für Anorganische Chemie der Universität
Oberer Eselsberg O 26, 7900 Ulm (Germany)

[**] Low-temperature co-condensation of fluorine compounds, Part 2.–Part 1: ref. [1].

This thermolysis of $XeOF_2$ in vacuum can be utilized for synthesis of the difficultly accessible XeO_2F_2, since the other product formed, XeF_2, sublimes at $-15\,^{\circ}C$. At $25\,^{\circ}C$, XeO_2F_2 slowly decomposes to XeF_2 and O_2.—Faster warming of $XeOF_2$ ($>20\,^{\circ}C$/h) leads to an explosion. Condensation of SbF_5 or AsF_5 onto $XeOF_2$ initiates explosive decomposition even at $-196\,^{\circ}C$. This also happens in contact with solid mercury. For indirect analysis of $XeOF_2$ the products of controlled thermolysis were therefore reacted with quartz wool:

$$XeO_2F_2 + XeF_2 + SiO_2 \rightarrow 2Xe + 2O_2 + SiF_4$$

The fluorine content (calc. 20.5 %, exp. 20.6 %) was obtained from the consumption of SiO_2 and from the fluoride analysis after hydrolysis of the SiF_4, the results of the two procedures showing mutual agreement.

The IR spectra of $XeOF_2$ and $Xe^{18}OF_2$ (99 %) were recorded for thin films ($-30\,^{\circ}C$)[5]: 751 (705) m, 715 (668) vw, 510 (515) vs, 498, 490 (496, 488) s, 210 s. The Raman spectra (powder spectra at $-196\,^{\circ}C$) show the following lines[5]: 751 (714), 1.2—1.9; 738 (700), 10; 497.5 (497.5), 6.2—6.5; 469.5 (469.5), 6.3—6.4; 299.5 (291), 0.8—0.9; 288 (278.5), 0.6; 171.5 (161.5), 1.5—1.6; 154 (—), 0.9; 135 (137), 1.0; 111.5 (104), 2.2. The frequency 715—750 cm^{-1}, which is very low for a Xe—O stretching vibration, contraindicates the presence of monomeric $XeOF_2$ having C_{2v} symmetry[2], instead suggesting oxygen bridging.

Procedure:

XeF_4 (1.53 g, 7.4 mmol) and H_2O (144 mg, 8 mmol) are simultaneously passed from cooled storage vessels (0 and $-22\,^{\circ}C$, respectively) *via* two concentric tubes into a vessel (100 ml, Teflon PFA$^+$) cooled to $-196\,^{\circ}C$ under dynamic vacuum conditions. Raising of the temperature to $-80\,^{\circ}C$ initiates the reaction (yellow coloration!). The reaction proceeds faster at $-63\,^{\circ}C$ (2 h) and goes to completion at $-47\,^{\circ}C$ (1 h) (liberation of HF ceases). The product $XeOF_2$ (1.3 g, 7 mmol) can be manipulated safely below $-40\,^{\circ}C$ in a dry atmosphere (glovebox).

Hexafluororhenium(VII), $[ReF_6]^+$

By *Eberhard Jacob* and *Manfred Fähnle*[*]

Dedicated to Professor Josef Goubeau on the occasion of his 75th birthday

In contrast to our previous knowledge[1], rhenium hexafluoride and rhenium heptafluoride exhibit distinct differences in their reactions. ReF_7, but not ReF_6, reacts with photochemically generated fluorine atoms in an argon or fluorine matrix at 27 K[2] according to

$$ReF_7 + F \rightarrow ReF_6 + F_2$$

Hence it follows that the first bond dissociation energy of ReF_7 is lower than the dissociation energy of the fluorine molecule, while that of ReF_6 is larger. Whereas fluorine atoms are unable to oxidize ReF_6, the very pronounced electron affinity of platinum hexafluoride should permit formation of the hexafluororhenium(VII) cation. Decoloration of the dark red vapor of PtF_6 by ReF_6 in a nonstoichiometric reaction with formation of a red solid as sole product can only be rationalized by assuming the production of $[ReF_6]^+[PtF_6]^-$. On the other hand, it is not surprising that no reaction takes place between ReF_7 and PtF_6 in the absence of light.

ReF_7 should therefore be capable of functioning as a fluoride donor. Thus, unlike ReF_6, it reacts with antimony pentafluoride to form hexafluororhenium(VII) fluoroantimonates.

$$\underset{(1)}{[ReF_6]^+[SbF_6]^-} \longleftarrow ReF_7 + SbF_5 \xrightarrow{SbF_5} \underset{(2)}{[ReF_6]^+[Sb_2F_{11}]^-}$$

The hexafluoroantimonate *(1)* is formed on one day's heating of an excess of ReF_7 with SbF_5 at $250\,^{\circ}C$ in a fluorine atmosphere. During the reaction and cooling the temperature of the nickel reactor must be uniform. The undecafluorodiantimonate *(2)* is most conveniently prepared by high-pressure fluorination of a stoichiometric rhenium/antimony mixture at $400\,^{\circ}C$ and subsequent homogenization (annealing at $200\,^{\circ}C$). The compositions of the cream-colored compounds *(1)* and *(2)* were established by quantitative synthesis. *(1)* does not have a measurable vapor pressure at $25\,^{\circ}C$. Vacuum thermolysis of *(2)* at $90\,^{\circ}C$ affords a product containing less antimony, but does not lead to *(1)*. Hydrolysis of *(1)* in air is surprisingly slow, that of *(2)* much faster. The hydrolysis products are colorless solutions containing perrhenate. The pronounced stability of *(1)* can be attributed to very favorable lattice energies (only octahedral ions).

Apart from the bands characteristic for $[SbF_6]^-$[3] and $[Sb_2F_{11}]^-$[4], the vibrational spectra of *(1)* and *(2)* display five bands which are assigned to the octahedral species $[ReF_6]^+$[5]; three Raman lines at 797 (10), 734 (4.6—4.9), and 359 (2) cm^{-1} correspond to fundamentals $\nu_1(A_{1g})$, $\nu_2(E_g)$, and $\nu_5(F_{2g})$; two IR bands at 783 (s) and 353 (m) cm^{-1} belong to the representation F_{1u} (ν_3 and ν_4). The fundamental modes of $[ReF_6]^+$ thus appear at considerably higher wave numbers than those of all metal hexafluorides. Having a value of 6 mdyn/Å[6] the valence force constant is significantly larger than those of WF_6 and ReF_6 (*ca.* 5.1 mdyn/Å); it is indicative of a multiple bonding component of the Re—F bond arising from the deficiency of electrons at the central atom[7].

$[ReF_6]^+$ is the first fluorocation of a transition metal. The fluorides of the main group elements have fluoride donor properties when the difference in electronegativity between the central atom and fluorine is low[8]. Thus the donor action of ReF_7 indicates a high electronegativity of Re^{VII}.

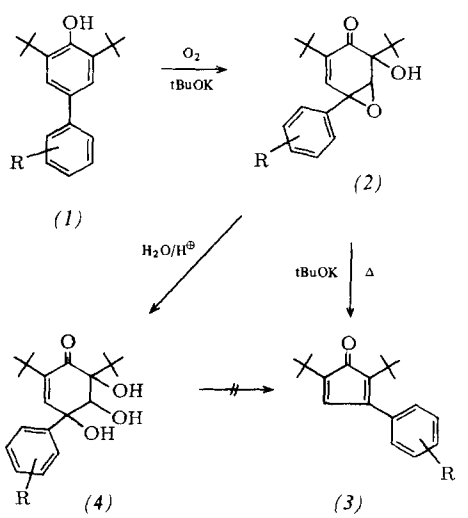
Synthesis of 3-Aryl-2,5-di-*tert*-butyl-2,4-cyclopentadienones by Base-Catalyzed Oxygenation of 4-Aryl-2,6-di-*tert*-butylphenols

By *Akira Nishinaga, Toshio Itahara, Teruo Matsuura, Anton Rieker*, and *Dieter Koch*[*]

Sterically hindered phenols are employed as antioxidants. Hence, the investigation of their autoxidation and oxidative degradation is of interest.

The potassium *tert*-butoxide (tBuOK) catalyzed oxygenation of *tert*-butylated phenols depends strongly on the solvent: in hexamethylphosphoric triamide (HMPA) or dimethylformamide (DMF) molecular oxygen attacks only the *p*-position and in *tert*-butanol (tBuOH) only in the *o*-position, giving in each case exclusively epoxy-*p*-quinols and epoxy-*o*-quinols, respectively[1,2].

We now find that 4-aryl-2,6-di-*tert*-butylphenols *(1)* are not oxygenated in the presence of tBuOK in DMF, HMPA or methanol, but are very readily in tBuOH at 75°C. The latter reaction affords a novel and convenient route to the 3-aryl-2,5-di-*tert*-butyl-2,4-cyclopentadienones *(3)*. The structure of compounds *(3)* is confirmed by analytical and spectroscopic data (Table 1).



Other products isolated in the reaction are the epoxy-*o* quinols *(2)*. Their structures are given by analytical and spectroscopic data and by comparison with analogous compounds[2]. If higher yields of the epoxy-*o*-quinols *(2)* are desired the reaction is better carried out at 0°C.

When *(2a)* is heated in tBuOH containing tBuOK under N_2 *(3a)* is formed in almost quantitative yield, whereas *(4a)* does not react under these conditions. The compound *(2b)* behaves analogously. These results show that *(3)* is formed *via (2)* in the base-catalyzed oxygenation of *(1)*.

Electron-donating substituents accelerate the reaction, electron withdrawing and sterically hindered substituents retard it. The opening of the epoxy ring in *(2)* appears to be affected likewise by the substituents in the aryl ring. This is supported by the fact that the yields of *(3)* increase at the cost of the epoxy-*o*-quinols *(2)* when the duration of oxygenation is prolonged. The reaction path *(2)*→*(3)* promoted by bases is characteristic for aromatically substituted epoxy-*o*-quinols *(2)*; the aliphatically substituted 2,4,6-tri-*tert*-butyl-4,5-epoxy-6-hydroxy-2-cyclohexenone[2] yields 2,4,5-tri-*tert*-butyl-3-hydroxy-2-cyclopentenone[3].

Experimental:

(3a) from *(1a)*: O_2 is bubbled through a solution of 2 mmol *(1a)* in 10 ml tBuOH containing 5 mmol tBuOK at 75°C. The reaction mixture immediately turns orange-red; after 30 min reaction is complete. After removal of solvent and treatment with aqueous NH_4Cl solution *(3a)* is obtained in almost quantitative yield; orange-red prisms (from methanol).

(3b)—(3h): Procedure analogous to that for *(3a)*: Reaction time 1 h. The reaction mixture is poured into an excess of aqueous NH_4Cl solution, extracted with petroleum ether, and separated on silica gel with petroleum ether/CH_2Cl_2 (9:1) from the epoxy-*o*-quinols *(2)* that are also present.

(2a) from *(1a)*: O_2 is bubbled through a solution of 16 mmol *(1a)* and 67 mmol tBuOK in 100 ml tBuOH/pet. ether (1:1) at 0°C for 3h and the solution finally neutralized with aqueous NH_4Cl: 55% *(2a)*, pale yellow prisms (from petroleum ether), m.p. 95—97°C, along with 25% *(3a)*.

(3a) and *(3b)* from *(2a)* and *(2b)*, resp.: N_2 is passed through the solution of 0.2 mmol *(2a)* or *(2b)* and 0.5 mmol tBuOK im 1 ml tBuOH at 75°C. The yields of *(3a)* and *(3b)* determined by NMR spectroscopy after 30 min and 14 h, respectively, were 99% *(3a)* and 70% *(3b)*.

Table 1. Cyclopentadienones *(3)* by oxygenation of 4-aryl-2,6-di-*tert*-butylphenols *(1)* at 75°C. Yields refer to isolated products (orange needles or prisms from methanol).

Synthesis of Olefins from α-Silyl Carbanions and Carbonyl Compounds[1]

By *Willy Dumont* and *Alain Krief*[*]

We report here on a method for the synthesis of olefins from monosubstituted α-silyl carbanions *(2)* and carbonyl compounds. This work illustrates another example of C—Se bond cleavage by *n*-butyllithium as a new methodology for the synthesis of carbanions, especially for those not accessible by classical procedures[2].

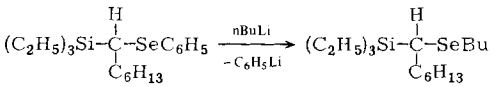
[*] Dr. W. Dumont and Prof. Dr. A. Krief
Département de Chimie, Facultés Universitaires de Namur
61, rue de Bruxelles, B-5000 Namur (Belgium)

We have now found that monosubstituted methyl α-silylmethyl selenides *(1a)*—*(1c)*[5] can be cleaved up to 0 °C by *n*-butyllithium (THF, 1 h, 0 °C). The resulting carbanions *(2)* can react with carbonyl compounds *(3)* to give β-hydroxyalkylsilanes *(4)*[6], which are then transformed into olefins *(5)* in excellent yields by known procedures[7].

An interesting feature is the formation of the olefin *(5a)* (40% yield)[6] from deoxybenzoin and ethyl-1-(triethylsilyl) carbanion; this olefin is obtained in very low yield (≈10%) when ethylidenetriphenylphosphorane is reacted with the same ketone.



(1d) *(6)*

In the case of the phenyl selenide derivative *(1d)* only phenyl-Se bond cleavage is observed; butyl α-silyl selenide *(6)* is formed in 60% yield. (Phenyl lithium is trapped by its reaction with carbonyl compounds when the latter are added.)

The highly substituted methyl α-silylmethyl selenide *(1e)* is more difficult to react with *n*-butyllithium (THF, 3 h, 20 °C); some butyl methyl selenide is indeed formed but, as yet, we do not have any evidence of the formation of a carbanion of type *(2)* (with CH_3 instead of H).

$Ge_4S_6Br_4$—The First Sulfide Halide of Germanium[**]

By *Siegfried Pohl*[*]

Although sulfide halides of silicon have been known for some time[1] in the form of 1,3,2,4-dithiadisiletanes and their polycyclic oligomers no defined sulfide halides of germanium[2] or tin have so far been reported. A compound of the composition $Ge_4S_6Br_4$ has now been isolated by reaction of $GeBr_4$ with H_2S in carbon disulfide.

$$4\ GeBr_4 + 6\ H_2S \xrightarrow[AlBr_3]{CS_2} Ge_4S_6Br_4 + 12\ HBr$$

(1)

The almost colorless product *(1)*, m.p. 305°C (dec.), is stable in air. The difficultly crystallizable compound is only attacked by water on warming and dissolves with decomposition in caustic alkali.

A complete X-ray structure analysis shows that tetragermanium hexasulfide tetrabromide crystallizes triclinically in the space group $P\bar{1}$ with lattice constants: $a=8.806$, $b=9.940$, $c=10.104$ Å; $\alpha=86.04$, $\beta=64.08$, $\gamma=89.82°$; $V=793$ Å^3; $Z=2$. Refinement of 2228 observed reflections (single crystal data measured on a four circle diffractometer) converged to an unweighted R value of 8.7 % (without absorption correction). The molecule of *(1)* proves to have an adamantane-like structure (cf. Fig. 1). The deviations from T_d symmetry in the solid state are significant.

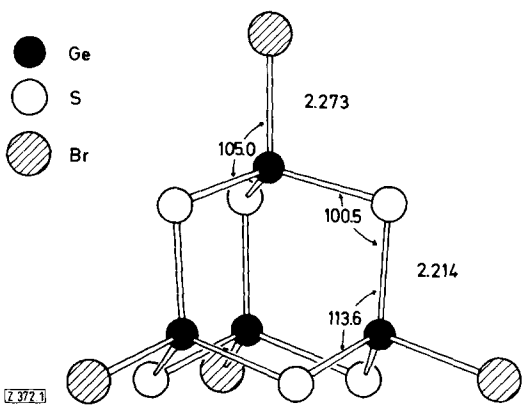

Fig. 1. Molecular structure of $Ge_4S_6Br_4$ in the solid state with mean bond lengths [Å] and angles [°].

The mean values of the lengths of chemically equivalent bonds and of some of the bond angles are given in Fig. 1. The maximum deviations of these mean values are ±0.027 Å for the Ge—S distance and ±0.010 Å for the Ge—Br distance; hence, all bond lengths lie in the range expected for Ge—S (cf. *e.g.* Ref. [3]) and Ge—Br single bonds[4].

In the Raman spectrum of solid *(1)* [70 (6), 106 (3.5), 110 (3.5), 124 (9), 126 (sh), 150 (10), 188 (2), 192 (3.5), 334 (4), 363 (8), 369 (3), 419 (1) cm^{-1} (estimated intensities from 0—10)] the peak at 363 cm^{-1} can be assigned to the symmetrical vibration of the Ge_4S_6 cage, the peaks at 192 and 188 cm^{-1} to the symmetrical Ge—Br stretching vibration.

In the FIR spectrum [73 (5), 185 (9), 300 (10), 365 (7), 380 (6), 420 (10) cm^{-1} (estimated intensities from 0—10); Nujol suspension] the two strongest bands at 420 and 300 cm^{-1} correspond to the asymmetric Ge—S and Ge—Br stretching vibrations, respectively.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

It should also be possible to prepare a series of other sulfide halides of germanium(IV) and of tin(IV) using the same synthetic principle as that for *(1)*. Indeed, we have already isolated a germanium sulfide iodide[5], which probably has the same structure as that of *(1)*. Moreover, the previously difficultly isolable thioacids[6] and thiooxo compounds[7] of germanium and tin ought to be preparatively easily accessible *via* the corresponding sulfide halides.

Experimental:

H_2S is passed for 72 h into a boiling solution of $GeBr_4$ (20 g, 50 mmol) in CS_2 (250 ml; containing catalytic amounts of $AlBr_3$) in a two-necked flask fitted with gas inlet tube and multiple coil condenser, the solvent being repeatedly replaced during the reaction. The solvent is finally removed, unreacted $GeBr_4$ distilled off, and the glassy residue dissolved in CS_2. After 4—5 d at −10°C the filtered pale yellow solution starts to crystallize; crystallization is very slow, and on completion affords 6.5 g (65 %) of *(1)*. Attempts to accelerate the crystallization by strong concentration of the solution have always resulted in a predominantly amorphous product.

Tetracarbonylcobaltiopentacarbonylmanganiomercury, $(CO)_4Co—Hg—Mn(CO)_5$

By *Manfred Zöller* and *M. L. Ziegler*[*]

Compounds of mercury, cadmium, or zinc of the type Mm_2 (m = carbonylmetal group, *e.g.* $Co(CO)_4$, $Mn(CO)_5$) containing metal-metal bonds have been known for some time[1]. Corresponding unsymmetrical species mMm′ have hitherto only been accessible in cases where the carbonylmetal substituent m′ also contains an η-cyclopentadienyl ligand (*e.g.* η-$C_5H_5Fe(CO)_2$—Cd—$Co(CO)_4$)[2]. On reaction of $Mn(CO)_5Br$ with $NaCo(CO)_4$ in the presence of mercury we found evidence that very small amounts of $(CO)_4CoHgMn(CO)_5$ *(1)* are formed alongside $MnCo(CO)_9$. A better entry to this compound was found in the exchange reaction:

$$Hg[Mn(CO)_5]_2 + Hg[Co(CO)_4]_2 \rightleftharpoons 2\ (CO)_4Co—Hg—Mn(CO)_5 \quad (a)$$

(1)

Attempts to prepare the homologous zinc and cadmium compounds have so far remained unsuccessful.

Evidence for the equilibrium (a) is provided by two-dimensional layer chromatography: application of analytically pure

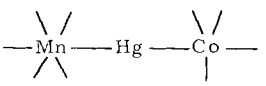
(1) to a DC plate followed by development of a normal chromatogram leads to only one zone; chromatography perpendicular to the original direction of migration after about 15 min affords not only *(1)* but also $Hg[Mn(CO)_5]_2$ and $Hg[Co(CO)_4]_2$ as separate zones.

The composition of *(1)* is confirmed by elemental analysis and the mass spectrum (rel. molecular mass 567.7987 (4.6 ppm)). The IR spectrum (*n*-pentane) contains six bands in the ν_{CO} region. Assuming free rotation about the manganese-mercury and the cobalt-mercury bond in solution, the symmetry of the "fragments" $Mn(CO)_5$ and $Co(CO)_4$, respectively, will apply, *i.e.*, for



C_{4v} ($Mn(CO)_5$) and C_{3v} ($Co(CO)_4$) point symmetry with three IR active CO stretching vibrations each ($2A_1+1E$, and $2A_1+1E$), in accord with the observed spectrum. The trigonal bipyramidal arrangement at the cobalt atom is also reasonable in the light of the results of an X-ray structure analysis of η-$C_5H_5Fe(CO)_2$—Hg—$Co(CO)_4$[2].

Procedure:

$Mn_2Hg(CO)_{10}$ (296 mg, 0.5 mmol) and $Co_2Hg(CO)_8$ (272 mg, 0.5 mmol) are stirred for 12 h in boiling acetone under N_2. After all the $Mn_2Hg(CO)_{10}$ has dissolved a deepening of color from yellow to orange takes place. The filtered solution is evaporated to dryness and the orange residue extracted with cyclohexane (30 ml), leaving unreacted $Mn_2Hg(CO)_{10}$ as residue. Separation of *(1)* and $Co_2Hg(CO)_8$ is accomplished by preparative layer chromatography under N_2 (silica gel PF_{254}, cyclohexane, layer thickness 1 mm): the first zone ($R_F=2.85$) contains unreacted $Co_2Hg(CO)_8$, and the second one ($R_F=1.61$) product *(1)*.—The second zone is cut out and *(1)* dissolved out by acetone (30 ml). The solution is evaporated at 0 °C under water pump vacuum, and the residue taken up in acetone (1 ml) and *n*-pentane (4 ml). At −18 °C this solution precipitates pale yellow crystals [yield 40 mg (14 %); m.p. 115 °C (dec.); IR data (ν_{CO} in cm^{-1}): 2098 w, 2075 sh, 2061 s, 2002 vs, 1998 vs, 1979 m].—All manipulations must be performed rapidly and under nitrogen since *(1)* undergoes significant dismutation to the symmetrical starting compounds within 1 h at room temperature.

Use of Crosslinked Poly(4-vinylpyridine) as HCl Acceptor[**]

By *Manfred L. Hallensleben* and *Hellmuth Wurm*[*]

During the synthesis of organic compounds that are sensitive to hydrolysis the HCl liberated is usually converted into salts with tertiary amines, aniline, or pyridine which, however, cannot generally be removed quantitatively from the reaction mixture. This has an interfering effect, especially in the synthesis and purification of small amounts of substances.

Crosslinked polymers are generally insoluble in all solvents and merely swell to a greater or lesser extent. If HCl is bound to a crosslinked nitrogen base then the resulting salt[1] can readily be removed quantitatively by filtration or centrifugation from the reaction solution.

We have developed reliable methods for the synthesis of a suitable crosslinked poly(4-vinylpyridine) and its regeneration. This gel can be employed in all organic solvents, polar solvents leading to swelling of the gel and thus raising its capacity.

Crosslinked poly(4-vinylpyridine)

4-Vinylpyridine (20 g, 0.19 mol) which has been freshly distilled over KOH, technical grade divinylbenzene (1.4 g, containing *ca.* 50 % *p*-ethylvinylbenzene, remainder *m*- and *p*-divinylbenzene) which has been freshly distilled under N_2, and azoisobutyronitrile (328 mg, crystallized from ether, 0.1 mol-% based on 4-vinylpyridine) are vigorously stirred together with distilled water (750 ml). After passage of N_2 for 1 h and heating to 60 °C for 30 h in a thermostated bath, the mixture is cooled, the water poured off, and the gel extracted with methanol in a large Kutscher-Steudel extraction apparatus to remove soluble components. It is subsequently dried *in vacuo* at 64 °C; yield 17—18 g.

N-Trimethylsilylbenzamide

A solution of trimethylchlorosilane (6.6 g, 65 mmol) in dry chloroform (30 ml) is added dropwise to a vigorously stirred mixture of dry benzamide (6.7 g, 55 mmol) and crosslinked poly(4-vinylpyridine) (6.3 g, 60 mequiv.) in dry chloroform at 40 °C. Stirring is continued for 30 min and the mixture then filtered through a glass frit with exclusion of moisture. After removal of solvent essentially pure *N*-trimethylsilylbenzamide is obtained.—Regeneration of the HCl acceptor is conveniently accomplished by stirring of the gel with dilute methanolic NaOH, filtration through a Buchner funnel, washing with water and then with methanol, and finally drying *in vacuo*.

syn-Tricyclo[5.1.0.0^{2,4}]oct-5-ene-3,8-dicarboxylate[**]

By *Gerd Kaupp* and *Klaus Rösch*[*]

The photolysis of 1,3,6-cyclooctatriene proceeds *via* an intramolecular Diels-Alder reaction to give *anti*-bishomobenzene *(3)*[1]. In contrast, 5,8-*cis*-disubstituted 1,3,6-cyclooctatrienes should permit the synthesis of *syn*-bishomobenzenes *(4)*

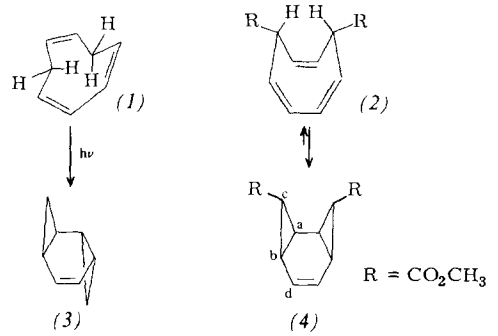
Institut für makromolekulare Chemie der Universität
Stefan-Meier-Strasse 31, 7800 Freiburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

[*] Doz. Dr. G. Kaupp and K. Rösch
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

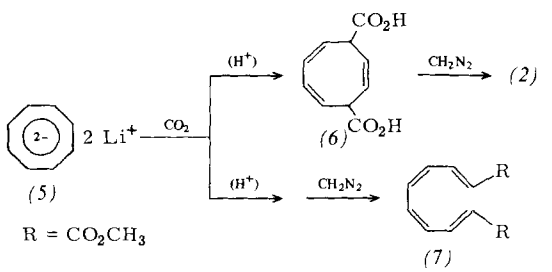
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are grateful to BASF AG, Ludwigshafen, for a gift of cyclooctatetraene and to Dr. *H. Fritz*, Ciba-Geigy AG, Basel, for recording the ^{13}C-NMR spectra.

because they do not exist in a rotationally symmetrical conformation (analogous to *(1)*) for steric reasons but instead, at the expense of a transannular H/H interaction, most probably in a conformation having a symmetry plane (corresponding to *(2)*).

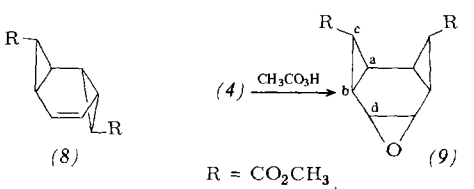


Since only heterocyclic *syn*-bishomobenzene derivatives have hitherto been synthesized[2, 3] we attempted to prepare the dicarboxylic ester *(2)* from cyclooctatetraenedilithium *(5)*, carbon dioxide, and diazomethane. To our surprise we isolated 29 % of *(4)* and 6 % of *(7)* as reaction products.

This result contradicts earlier reports that *(5)* reacts with CO_2 to give either 80 % of *(6)*[4] or (after the action of CH_2N_2) 50 to 65 % of *(7)* together with 0 to 3 % of *(2)*[5]:



The differing findings still require an explanation. The structure of *(4)* ($C_{12}H_{14}O_4$[6], m.p. 87—89 °C) follows unequivocally from a comparison with the *anti* isomer *(8)*[7], its ^{1}H-NMR spectrum [$CDCl_3$: δ = 0.7—1.0 (2 H^c, m), 1.6—2.05 (2 H^b, m), 2.05—2.4 (2 H^a, m), 3.73 (6H, s), 6.05—6.3 ppm (2 H^d, m); coupling between H^b and H^d], and epoxidization to give *(9)*[6] [m.p. 185—187 °C; NMR ($CDCl_3$): δ = 1.35—1.6 (2 H^c, m), 1.7—2.25 (4 $H^{a,b}$, m), 3.3—3.35 (2 H^d, m), 3.75 ppm (6H, s)]. For steric reasons and because of the relatively narrow NMR signal of the epoxide ring protons the *syn/anti* structure is assigned to *(9)*. It is formed from *(4)* and peracetic acid in methylene chloride in the presence of solid disodium hydrogen phosphate (24 h stirring at *ca.* 25 °C; 84 % yield after crystallization from benzene).



The crystals of the readily accessible *syn*-bishomobenzene derivative *(4)* can be stored for several days at room temperature. In solution it equilibrates within a few hours with *ca.* 20 % of *(2)* at room temperature [NMR ($CDCl_3$): δ = 3.76 (6H, s), 4.15—4.4 (2H, br. t, J = 5.1 Hz), 5.7—6.1 ppm (6H, m)]. On heating to 60 °C for half an hour the proportion of *(2)* increases but irreversible reactions then also compete.

The possibility of virtually unhindered attack at the double bond endows *(4)* with considerable potential as a synthetic reagent.

Dimethyl syn-tricyclo[5.1.0.0^{2,4}]oct-5-ene-3,8-dicarboxylate (4):

A solution of *(5)*[4, 5], prepared from cyclooctatetraene (15.5 g) and lithium (2.1 g) in diethyl ether/tetrahydrofuran (9 : 1, 500 ml) under argon, is poured on to dry ice (*ca.* 500 g) in a stream of inert gas (danger of ignition!). After addition of ether (100 ml) and (at room temperature) water (200 ml) and conc. HCl (60 ml) the mixture is filtered under suction from 7.0 g of precipitate (yielding 1.0 g of *(7)* with CH_2N_2). Treatment with a further portion of conc. HCl (40 ml) affords 19.9 g of residue after extraction with ether (2 l) and evaporation, of which 11.4 g dissolve in 250 ml of ether at 25 °C (affording 0.8 g of *(7)* and 1.0 g of *(4)* on esterification and chromatography). On treatment with diazomethane in methanol/ether and chromatography over SiO_2 with CH_2Cl_2 the remainder gives 8.7 g of *(4)*, which is recrystallized from CH_3OH at −20 °C.

[+] Author to whom correspondence should be addressed.

from its diazo precursor to organometallic compounds[3]. We now report the introduction of unfragmented diazomethane, CH_2N_2, into a manganese complex with an unusual structure.

Reaction of pentacarbonyl manganese hydride in tetrahydrofuran at −85 °C with excess diazomethane and subsequent column chromatography at room temperature afforded a light yellow, easily crystallized, air stable and thermally stable (*ca.* 115 °C dec.) compound[4]. From the complete elemental analysis and high resolution mass spectrum it follows that the diamagnetic compound formed according to

$$2\ Mn(CO)_5H + CH_2N_2 \xrightarrow[-H_2]{THF/-85\,^\circ C} Mn_2(CO)_{10}CH_2N_2 \quad (1)$$

has the empirical formula $C_{11}H_2Mn_2N_2O_{10}$; the osmometric molecular weight determination also confirms the presence of a binuclear neutral compound *(1)*. The carbene insertion product $(CO)_5MnCH_3$ discovered by *Hieber et al.*[5] was not found in the final product under our experimental conditions.

On electron impact ionization of *(1)* in the mass spectrometer (Varian MAT CH 5; $P_E = 70$ eV; Em = 300 μA; $T_Q = 80$ °C; direct inlet $T = 50$ °C) the molecular ion ($m/e = 432$) successively loses ten CO groups, with the base peak at $[M-9CO]^+$ ($m/e = 180$); further decomposition of $Mn_2CH_2N_2^+$ proceeds *via* $MnCH_2N_2^+$ to $MnCH_2^+$ ($m/e = 69$, rel. int. 52 %). Besides the $Mn_2(CO)_{10}CH_2N_2$ series a decay series of mononuclear ions starting from $(CO)_5MnCH_2N_2^+$ ($m/e = 237$) is also observed.

Although the mass spectrometric high resolution analysis of the parent and the fragment ions proved incorporation of intact diazomethane in the complex molecule, no proton signals could be detected in the ^{1}H-NMR spectrum. In order to clarify this dichotomy we carried out a complete three dimensional X-ray structure analysis of *(1)*[6]. It showed that diazomethane has, indeed, been introduced as an unfragmented species into a binuclear complex consisting of both $Mn(CO)_5$- and $Mn(CO)_4$-moieties (Fig. 1). *(1)* is part of an unusual four-membered framework arising from conversion of a terminal carbonyl group into an acyl function. The bridging system is coplanar including both hydrogen atoms localized by X-ray analysis.

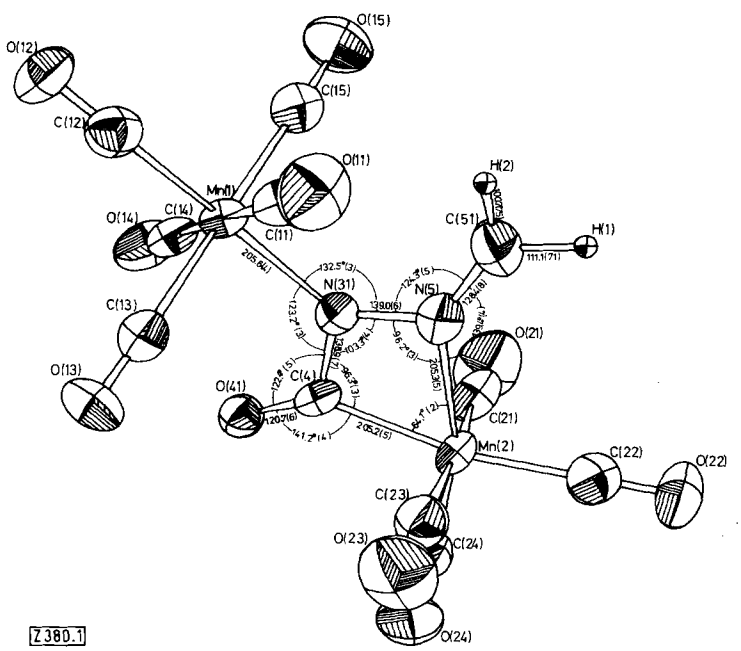

Fig. 1. ORTEP plot of the molecular structure of *(1)*. The thermal ellipsoids have 50 % probability; all atoms are drawn in proper dimensions except for hydrogen (bond lengths in pm).

The IR spectra of *(1)* can also be interpreted on the basis of these structural data: The intense bands at 1644 and 1575 cm^{-1} (KBr) are assigned to the ketonic CO and the N=CH_2-groups, respectively. From the nine possible IR active valence vibrations (7A′+2A″) of the terminal CO groups postulated by a vibration analysis for a molecule of symmetry C_s, eight are observed as separate bands (2122 w, 2086 m, 2062 vw, 2036 vs, 2027 vs, 2005 s-vs, 1988 vs, and 1966 cm^{-1} vs; cyclohexane).

The synthesis of *(1)* is the first example of coordination of diazomethane to metal *via* both nitrogen atoms. Our results demonstrate that the basicity of the diazo carbon atom is not necessarily the key function for the special reactivity of diazomethane toward metal compounds. The initial reactions can also occur exclusively at the diazo group if the metal complex fulfills chemical and structural requirements.

Cyclopropanation of [2.2]Paracyclophanes[1]

By *Klaus Menke* and *Henning Hopf*[*]

As X-ray structure analysis shows[2], in [2.2]paracyclophane-1,9-diene, and presumably also in the parent hydrocarbon [2.2]paracyclophane *(1)*[3], the aromatic hydrogen atoms do not lie in the plane of the benzene rings but are bent toward the hydrogens of the opposite benzene ring. This unusual structural feature is ascribed to a partial rehybridization of the benzene carbon atoms ($sp^2 \rightarrow sp^3$). A consequence is that part of the π-electron density is shifted to the outside faces of the molecule and the energetically unfavorable transannular penetration of the π-systems of the two benzene rings pressed face-to-face is reduced[3]. As a result of this increased external electron density, *(1)* and its derivatives ought to readily undergo addition reactions with divalent species–carbenes, nitrenes, and possibly oxygen in the case of epoxidation. The cyclopropanation of tetramethyl [2.2]paracyclophane-4,5,12,13-tetracarboxylate *(2)* described here confirms this assumption.

(2) reacts already at 10–15 °C with a 40-fold excess of diazomethane[4] in dichloromethane in the presence of cataly-

(6), R = CO_2CH_3

unknown and probably very unstable parent hydrocarbon *cis*-bishomobenzene *(5)* have recently been reported the compounds mentioned here, excluding the diester *(6)*[8] detected

Methylenation of [2.2]Paracyclophane-1,9-diene and [2.2]Paracyclophane[**]

By *Reinhard Näder* and *Armin de Meijere*[*]

In [2.2]paracyclophane *(3)* the C—C σ-bond orbitals of the two bridges are parallel to the π-orbital axes of the benzene

[*] Dipl.-Chem. R. Näder and Prof. Dr. A. de Meijere

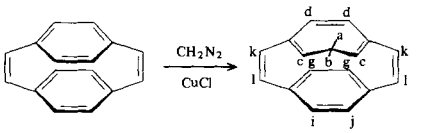
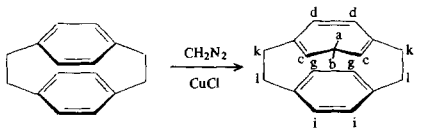
Tammannstraße 2, 3400 Göttingen (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie

rings; they thus promote interaction between the two non-conjugated benzene rings, as is revealed, for example, in the UV spectrum of *(3)*[1]. Model calculations have shown that this interaction ought to increase considerably with bridging by two cyclopropane rings[2] in the place of the ethylene bridges.

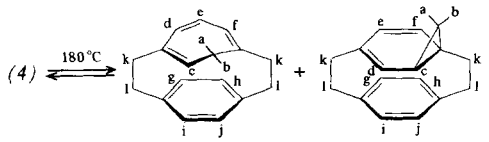
[2.2]Paracyclophane-1,9-diene *(1)*[3] appeared to us to be a suitable starting compound for the synthesis of $[0^{1,3}.0^{10,12}]$[3.3]paracyclophane, since olefinic double bonds are usually cyclopropanated much more readily than aromatic double bonds[4]. *(1)* reacts smoothly with diazomethane in the presence of copper(I) chloride. Even on reaction with



(1) *(2)*



(3) *(4)*



(5) *(6)*

small amounts of diazomethane several products were obtained, which, according to their relative molecular weights (combined GC-MS), could only be the mono-, di-, and trimethylenated derivatives of *(1)*. On further reaction the product pattern steadily changed in favor of the di-, tri-, and higher methylenated products, though *(1)* was always present in excess. Consequently, the monoadduct is more readily methylenated than the starting material. This can be rationalized only in terms of initial attack at a benzene ring and not at an olefinic double bond; because of the concomitant removal of aromaticity, this ring undergoes further reaction more rapidly than the remaining aromatic ring.

Only one monoadduct[5] has so far been isolated pure by preparative gas chromatography. According to its ^{1}H-NMR spectroscopic data (Table 1) the structure *(2)*[6] was assigned to it. Structures with a bridged norcaradiene system can be disregarded, as is immediately apparent on comparison with ^{1}H-NMR data for known norcaradiene derivatives[7]. The structure isomeric with *(2)*, and containing a 1,4-bridged cycloheptatriene ring, can be ruled out on the basis of double resonance experiments.

[2.2]Paracyclophane *(3)* reacts analogously to *(1)* with diazomethane/copper(I) chloride to give a mixture of mono-, di-, tri-, and higher methylenated products, as has been established by combined GC-MS molecular weight determinations. *(3)* reacts more slowly than *(1)*, evidently because of the less pronounced deformation of the benzene rings than in *(1)*[9].

According to its 270-MHz ^{1}H-NMR spectrum (Table 1), the monoadduct[6] which was isolated by gas chromatography and appeared to be homogeneous on several analytical GC columns, consists of the isomers *(4)*, *(5)*, and *(6)*. The assignment of structures *(4)* and *(5)* is confirmed analogously to that of *(2)* and by comparison with the ^{1}H-NMR data of cycloheptatriene[7]. The weak intensity NMR signals of H^a, H^b, and H^c and a few other signals which can neither belong to *(4)* nor to *(5)*, are consistent only with structure *(6)* containing a bridged norcaradiene system [amount of *(6)* < 10%].

The composition of the mixture of isomeric monoadducts of *(3)* depends on the column temperature during gas-chromatographic separation. A sample isolated at 140 °C contained 64% *(4)* and 36% *(5)*, whereas a sample trapped at 180 °C proved to contain 44% *(4)*, 47% *(5)*, and 9% *(6)*. While *(4)*, and possibly also *(6)*, are primary products, *(5)* can only be formed by a [1.5]-hydrogen shift from *(4)*.

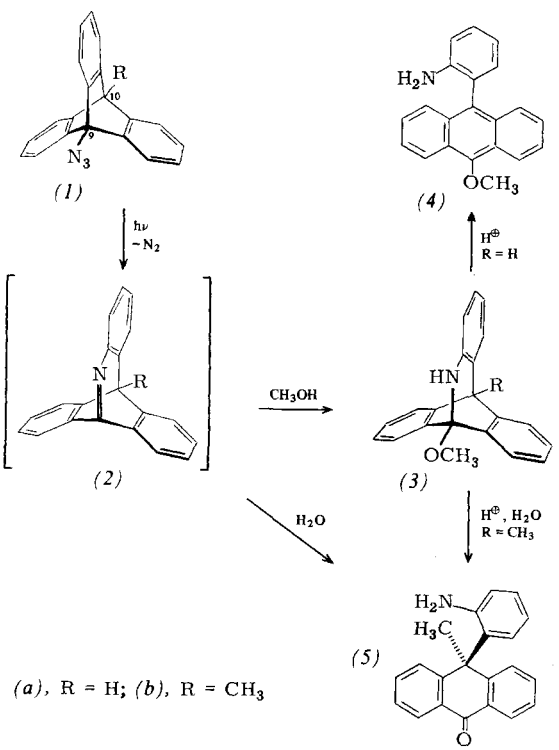
Photolysis of 9-Azidotriptycenes[**]

By *Helmut Quast* and *Philipp Eckert*[*]

The photolysis of 1-azidoadamantane led to formation of a strained "bridgehead imine" (the bridgehead is the C atom of the >C=N— group), whose presence was established by secondary reactions[1]. In order to check whether the solvation of the azido group plays a role in the photolysis—as assumed in the case of 1-azidonorbornane[2]—we have investigated the 9-azidotriptycenes *(1)*, in which this solvation does not occur for steric reasons. Obviously, the possible formation of the very highly strained, hypothetical "bridgehead imine" *(2)* attracted most attention.

The 9-azidotriptycenes *(1a)* and *(1b)*[3] are readily accessible by reaction of the corresponding 9-lithiotriptycenes[4] with *p*-toluenesulfonyl azide in ether and subsequent thermolysis of the resulting triazene salts in boiling benzene[5] (yield 78 and 75%, respectively, based on the 9-bromotriptycenes).

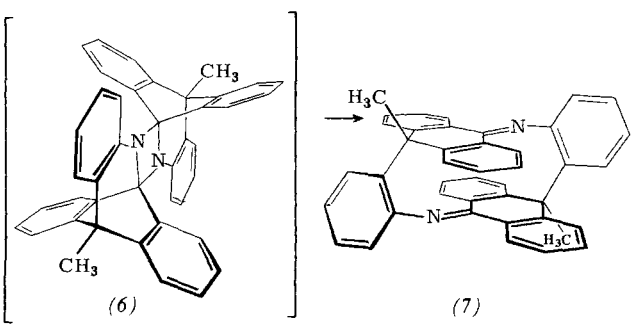


(a), R = H; *(b)*, R = CH_3

Photolysis[6] of *(1a)* and *(1b)* in methanol yielded 64 and 42%, respectively, of the azahomotriptycenes *(3)*[3], which can be regarded as adducts of the solvent to *(2)*. Whereas *(3a)* was already rapidly converted into the anthracene derivative *(4)* by trace amounts of acid in deuteriochloroform, *(3b)* was expectedly far less sensitive to acid. Only on prolonged heating in methanol/2N hydrochloric acid (4:1) was the ring opened quantitatively to the anthrone *(5)*, which by diazotization and reduction with hypophosphorous acid was converted to 10-methyl-10-phenyl-anthrone[7]. *(5)* is formed directly in 90% yield on irradiation of *(1b)* in dioxane/water (2.4:1) or *tert*-butyl alcohol. Photolysis[6] of *(1a)* in cyclohexane followed by preparative layer chromatography affords 53% of an intensely orange, yellow fluorescing product, which sublimes at 310°C/5×10^{-5} torr, decomposes at 325°C, and is formally a dimer of *(2a)*. Under the same conditions *(1b)* produces two dimers of *(2b)*. Whereas the structure of the yellow product (yield 21%, m.p. 339°C) has been elucidate[3], that of the colorless compound (yield 29%, dec. pt. 376–380°C) is still unknown.

The 270-MHz ^{1}H-NMR spectrum[8] in D_8-dioxane showed only *one* singlet (1.87 ppm) for the two methyl groups and a $(ABCD)_2$ system which could be simulated with $\delta_A = 8.040$, $\delta_B = 7.276$, $\delta_C \approx 7.124$, $\delta_D = 6.555$ ppm and $J_{AB} = 7.76$, $J_{AC} = 1.85$, $J_{AD} = 0$, $J_{BC} = 7.04$, $J_{BD} = 1.44$, $J_{CD} = 8.65$ Hz. The remaining protons gave only two remarkably broad, almost unresolved signals at 6.6 (4H) and 7.1 ppm (12H). The fact that the 42 C-atoms present showed only 15 signals in the ^{13}C-NMR spectrum (25.2 MHz, D_8-dioxane[8]) provided further evidence for a symmetric structure. The signal appearing at lowest field (151.1 ppm) and a strong IR absorption at 1648 cm^{-1} are indicative of C=N bonding and hence of a possible degradation.

The smooth hydrolytic cleavage by heating with methanol/2N hydrochloric acid finally furnished *two* mols of *(5)*, and thus confirmed structure *(7)*. However, it is still unknown whether the *trans*-configuration as depicted or a *cis*-configuration having C_2-symmetry is preferred. According to the NMR spectra rapid diastereomerization takes place already at ambient temperature.



The surprising formation of the phane structure *(7)* with a 14-membered ring can be explained by *(2b)*→*(6)*→*(7)*. The analogous *acid-catalyzed* transformation of a seven-membered cyclic imine is already known[9].

The parallel photochemical behavior of such differing bridge-head azides as 1-azidoadamantane and *(1)* indicates that solvation effects do not play a decisive role and that bridgehead azides in general are simple precursors of highly strained "bridgehead imines".

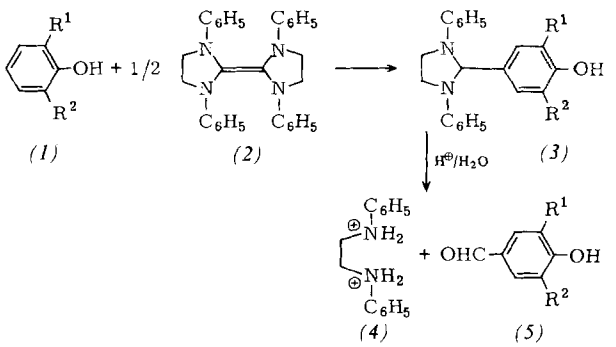
Synthesis of Phenolaldehydes with Electron-Rich Olefins[1]

By *Jürgen Hocker*, *Henning Giesecke*, and *Rudolf Merten*[*]

The methods commonly employed for the synthesis of phenolaldehydes frequently afford mixtures of *o*- and *p*-isomers in only moderate yields[2].

We have now found that cyclic aminals of phenolaldehydes *(3)* can often be obtained in good yields when phenols *(1)* are allowed to react with electron-rich olefins such as 1,1',3,3'-tetraphenyl-2,2'-biimidazolidinylidene *(2)*[3]. *(2)* is readily accessible from *N,N'*-diphenylethylenediamine and triethyl orthoformate and is easy to handle on account of its being only slightly sensitive toward oxidation. The cyclic aminal group enters preferably *para* to the phenolic OH group (Table 1).



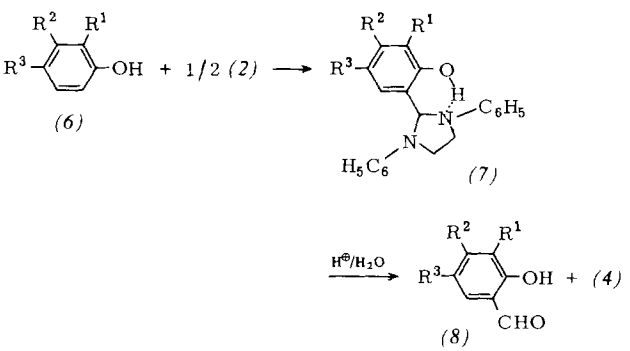
(1) *(2)* *(3)* *(4)* *(5)*

Table 1. 4-Aminals *(3)* from phenols *(1)* and 1,1',3,3'-tetraphenyl-2,2'-biimidazolidinylidene *(2)* in boiling dimethylformamide.

(3)	R^1	R^2	Yield [%]	*t* [min]
a [a]	H	H	55	10
b	CH_3	CH_3	58	15
c	*i*-C_3H_7	*i*-C_3H_7	26	15
d	*t*-C_4H_9	*t*-C_4H_9	84	15
e	CH_3	Cl	74	5
f	Cl	Cl	58	10

[a] The bis-aminal 1-(1,3-diphenyl-2-imidazolidinyl)-4-(1,3-diphenyl-2-imidazolidinyloxy)benzene is obtained, which smoothly hydrolyzes to *p*-hydroxybenzaldehyde.

If the *p*-position of the phenol is blocked or sterically hindered the reaction proceeds very selectively *via* the 2-aminals *(7)* to the salicylaldehydes *(8)* (Table 2).



(6) *(7)* *(8)*

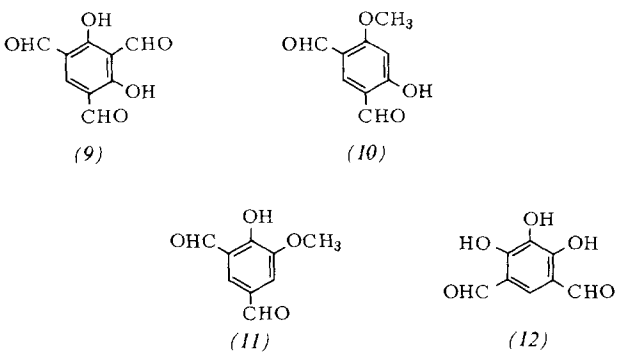
Table 2. 2-Aminals *(7)* from phenols *(6)* and 1,1',3,3'-tetraphenyl-2,2'-biimidazolidinylidene *(2)* in boiling dimethylformamide.

(7)	R^1	R^2	R^3	Yield [%]	*t* [min]
a	CH_3	H	CH_3	30	180
b	H	$N(CH_3)_2$	CH_3	65	40
c	H	$N(CH_3)_2$	H	53	60
d	—N=CH—CH=CH—		H	76	420 [a]
e	H	T^1 [b]	H	67	30
f	H	T^2 [c]	H	46	60
g	H	T^3 [d]	H	56	90
h	H	T^4 [e]	H	68 [f]	110

[a] In boiling toluene.
[b] T^1 = 4-methyl-5-phenyl-2*H*-1,2,3-triazol-2-yl.
[c] T^2 = 4-phenyl-2*H*-1,2,3-triazol-2-yl.
[d] T^3 = 4-ethyl-5-methyl-2*H*-1,2,3-triazol-2-yl.
[e] T^4 = 2*H*-naphtho[1,2-*d*]triazol-2-yl.
[f] With 100% excess of *(2)*.

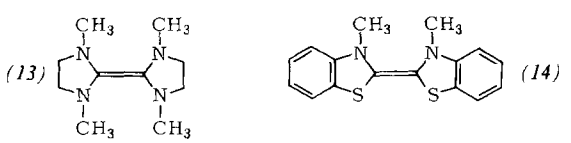
The cyclic aminals *(3)* and *(7)* can be hydrolyzed quantitatively with mineral acids to the corresponding aldehydes *(5)* and *(8)* respectively, and to the salt of *N,N'*-diphenylethylenediamine *(4)*.

Polyhydroxy compounds or their ethers containing at least one free phenolic OH group may likewise be employed in the new aldehyde synthesis, whereupon incorporation of more than one aldehyde group in the benzene nucleus is preferred. Examples are the aldehydes *(9)*–*(12)* [yields of aminal and aldehyde: *(9)*, 65 and 96%; *(10)*, 57 and 87%; *(11)*, 54 and 81%; *(12)*, 82 and 50%].



(9) *(10)* *(11)* *(12)*

Other electron-rich olefins such as *(13)*[4] (highly reactive, but difficultly accessible and highly sensitive to oxidation) and *(14)*[5] (hydrolysis of the NS-aminals difficult) have also proved to be useful reaction partners in such syntheses.



(13) *(14)*

4-(1,3-Diphenyl-2-imidazolidinyl)-2,6-dimethylphenol (3b)

A mixture of *(2)* (4.44 g, 0.01 mol) and 2,6-dimethylphenol (2.44 g, 0.02 mol) in dimethylformamide (15 ml) is heated to boiling under nitrogen for 10 min. The solvent is removed under vacuum and the residue recrystallized from isopropanol. *(3b)* is obtained as pale yellow needles in 58% yield (4.0 g, m.p. 166–167 °C).

4-Hydroxy-3,5-dimethylbenzaldehyde (5b)

A suspension of *(3b)* (2.0 g) in semi-concentrated hydrochloric acid (50 ml) is stirred for 1 h at 80 °C. The suspension is then extracted with ether and the organic phase dried over

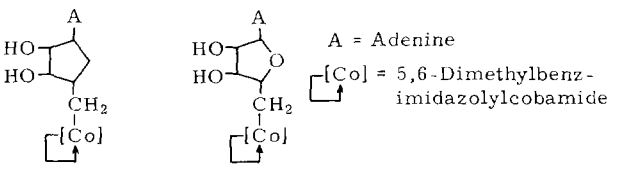
Photochemical Induction of Enzymatic Activity of a Carbocyclic Analog of Coenzyme B_{12}: A Contribution to the Elucidation of the Mechanism of Action of Coenzyme B_{12}[**]

By *G. N. Schrauzer, R. Nathan Katz, J. H. Grate*, and *T. M. Vickrey*[*]

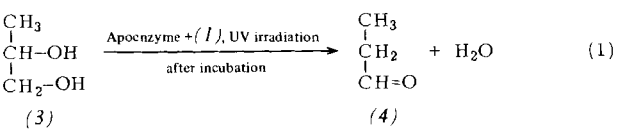
Compound *(1)*, first prepared by *Abeles et al.*[1][***], differs from coenzyme B_{12} (5'-deoxyadenosylcobalamin) *(2)* merely in that the ether-oxygen in the ribofuranosyl moiety is replaced



(1) *(2)*

by a CH_2 group. As experiments with D,L-propanediol hydrolase (dioldehydrase, E.C. 4.2.1.28) have shown, coenzyme B_{12} analog *(1)* exhibits significantly less coenzyme activity than *(2)*[1,2]. Most recent studies indicate[3] that *(1)* cannot replace the natural coenzyme *(2)*, but inhibits the action of ribonucleotide reductase from *Lactobacillus leichmannii*. Whereas the holoenzyme of dioldehydrase with *(2)* is inactivated by oxygen, the corresponding complex of *(1)* with the dioldehydrase apoenzyme has been described as air-insensitive[1]. This led us to conclude that the apoenzyme is incapable of cleaving the Co—C bond in *(1)* with similar efficiency as compared to its reaction with *(2)*.

Our own experiments with dioldehydrase from *Aerobacter aerogenes*[4] and with 1,2-propanediol *(3)* as the substrate, performed under rigorous exclusion of air and in the dark, indicate that *(1)* possesses only about 16% of the activity of the coenzyme B_{12} *(2)* under identical conditions. Brief UV irradiation[5] of the complex of apoenzyme and *(1)* after 15 min incubation produces an active enzyme which catalyzes the dehydration of 1,2-propanediol at room temperature in the dark to propionaldehyde *(4)* [Table I, and Eq. (1)].



(3) *(4)* (1)

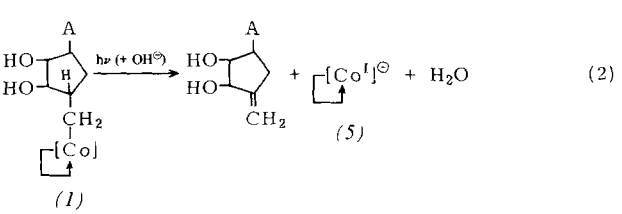
Table 1. Yields of propionaldehyde from the enzymatic dehydration of 1,2-propanediol by dioldehydrase under various conditions in the presence of *(1)* or *(2)*. Incubation time: 40 min at 23 °C.—Three ampoules of commercial apoenzyme containing 29 mg of protein each, were dissolved in 22.5 ml of deaerated 0.01 M potassium phosphate buffer (pH 8.0), the aqueous buffer solution contained 2% 1,2-propanediol and was stored under argon. All assays were performed using 0.9 ml of the enzyme solution (in closed centrifuge tubes, 15 ml capacity). The cofactors *(1)* and *(2)*, 20 nm of each, were added in aqueous form (0.1 ml). The aldehyde was determined colorimetrically as outlined in Ref. [10].

No.	System:	Yields of *(4)* [μmol]	[%]
1	Apoenzyme + *(2)*, anaerobic, normal conditions	4.60	100
2	Apoenzyme + *(1)*, anaerobic, UV-irradiated [a]	3.60	78
3	As in No. 2, but under 1 atm of N_2O	2.90	63
4	As in No. 2, under 1 atm of O_2	1.44	31
5	Apoenzyme + *(1)*, anaerobic in the dark	0.75	16
6	Denatured apoenzyme [b] + *(1)*, irradiated	0	0
7	*(1)* + 1,2-propanediol, anaerobic, irradiated	0	0
8	1,2-Propanediol + apoenzyme, irradiated	0	0

[a] The enzyme solution was irradiated for 3 min after 15 min of incubation at 23 °C.
[b] Heat-denatured enzyme.

The irradiated holoenzyme remains active for about 40—60 min; the kinetic course of the reaction closely resembles that of the enzyme with *(2)* as the cofactor under normal assay conditions. The coenzyme activity of *(1)* after irradiation becomes nearly equal to that of *(2)* at the same concentration in the dark. The irradiated enzyme complex with *(1)* is oxygen sensitive and is also partially inactivated by N_2O (Table 1). In view of the selective oxidizing action of N_2O[6], the latter observation suggests the presence of enzyme-bound vitamin B_{12s} *(5)* (*i.e.* the powerfully nucleophilic Co(I)-corrin derivative) as the actually active form of the corrinoid cofactor[7].

Vitamin B_{12s} is also formed along with vitamin B_{12r} during the anaerobic photolysis of *(1)* in weakly alkaline aqueous solutions [Eq. (2)][8]. A slow degradation to vitamin B_{12s} also occurs on interaction of *(1)* with strong bases (*e.g.* 2 N aqueous NaOH) in the dark.



(1) *(5)* (2)

The formation of vitamin B_{12s} and of olefins in the anaerobic photolysis of higher alkylcobalamins has been demonstrated previously[9]. It also has been shown that *(2)* undergoes degradation [in analogy to Eq. (2)] on interaction with bases in the dark. The base-induced formation of enzyme-bound vitamin B_{12s} is presumably responsible for the observed activity of the complex of *(1)* and the apoenzyme of the dioldehydrase; the diminished activity could be due to the higher base-resistance of *(1)* relative to *(2)*.

[***] We thank Professor *H. P. C. Hogenkamp* for supplying us with a sample of authentic carbocyclic coenzyme B_{12} [compound *(1)*].

Our observations demonstrate that the Co—C bond of enzyme-bound *(1)* is not alternately closed and broken during the catalytic reaction with the substrate. If this were so, irradiation of the enzyme complex should not have had any significant effect on the rate of the subsequent enzymatic reaction in the dark.

The present results do not necessarily support the currently popular idea that coenzyme B_{12} dependent enzymatic reactions occur *via* organic radicals and that the coenzyme is activated enzymatically by the homolysis of the Co—C bond. On the contrary, our findings are fully consistent with the previously postulated[7, 10] heterolytic mechanism of enzymatic coenzyme B_{12}-activation[11].

pounds exhibiting sp^3 configuration at the aldehydic C atom. The CH acidity of sp^2 configurated C atoms is known to be greater than that of sp^3 configurated C atoms. However, this phenomenon can hardly be exploited in the case of the aldehyde itself, since addition to the carbonyl group proceeds considerably faster than dissociation of the aldehyde proton.

Having observed that 1,4-dihydronicotinamide derivatives *(1)* can be deprotonated at C-2[4] we attempted to perform nucleophilic acylations with functionally substituted aldehydes. For this purpose we converted the β-acyl aldehydes *(2)* into the enamines *(3)*; the nonparticipating carbonyl group was not protected. The first experiments with various bases showed, however, that in compounds of type *(3)* Michael addition and addition to the carbonyl group are faster than deprotonation. Nevertheless, it was also observed that the temperature dependence of these competing reactions differs. Below −100 °C deprotonation is faster so that *(3)* affords the β-acylvinyl anion *(4)*[5] almost quantitatively. Presumably, complex formation with the neighboring carbonyl group plays a role here[4]. Once formed, the anion *(4)* is stable at least up to room temperature. It can be deuterated with CH_3OD, alkylated with alkyl iodides, and acylated with esters to give polyfunctional components (Table 1)[6].

Synthesis of Trinuclear Sandwich-Like Cyclopentadienyl Complexes Containing Two Different Metal Atom Centers[**]

By *Wolfgang Kläui* and *Helmut Werner*[*]

Reaction of bis(η-cyclopentadienyl)cobalt (cobaltocene) with dialkyl phosphonates leads to trinuclear complexes of type *(1)* in almost quantitative yield:

$$3\ Co(C_5H_5)_2 + 6\ HPO(OR)_2 \longrightarrow (C_5H_5)_2Co_3[PO(OR)_2]_6 + 4\ C_5H_6 + H_2\ (?)$$

(1a), R = CH_3
(1b), R = C_2H_5

According to a crystal structure determination carried out on *(1a)*[1] the three cobalt atoms are arranged linearly. Two of them are equivalent, each being coordinated with a cyclopentadienyl ring and the phosphorus atoms of three phosphonato groups; the third (central) cobalt atom is located at a center of symmetry and is surrounded octahedrally by six oxygen atoms. *(1a)* and *(1b)* are not attacked by air and are so stable thermally that they can be sublimed undecomposed at 250 °C in a high vacuum.

During investigations on the reactivity of the trinuclear complexes *(1a)* and *(1b)* we recently found that they react with concentrated mineral acids HX and undergo protonation at the oxygen atoms. From conductivity measurements and NMR data it can be concluded that an equilibrium is established[2]:

$$(C_5H_5)_2Co_3[PO(OR)_2]_6 + 4\ HX \rightleftharpoons 2\ [C_5H_5CoPO(OR)_2\{P(OH)(OR)_2\}_2]X + CoX_2$$

(2a), R = CH_3
(2b), R = C_2H_5

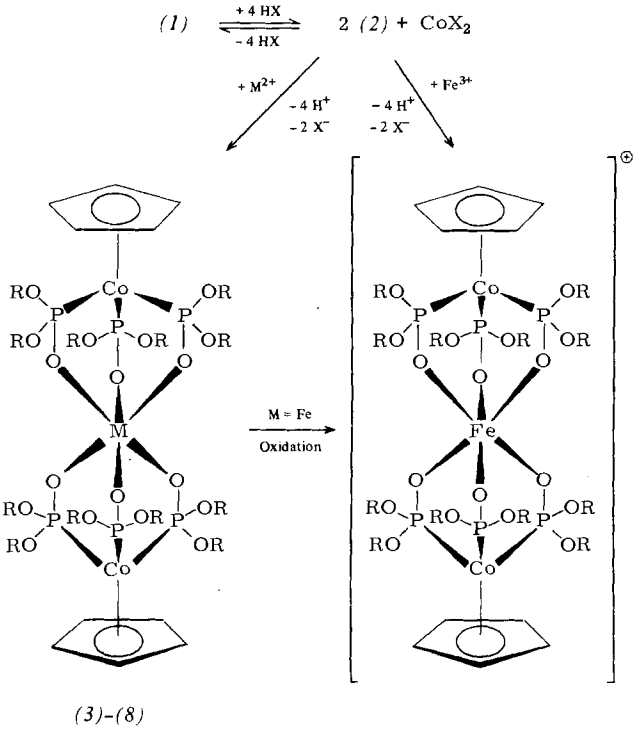
[**] This work was supported by the Schweizerischer Nationalfonds zur Unterstützung der wissenschaftlichen Forschung. We thank Herr *L. Beck* for his valuable participation in the experimental work.

We have now succeeded in performing the reverse reactions of *(2a)* and *(2b)* (X = BF_4), respectively, with Co^{2+} and synthesizing the trinuclear complexes *(1a)* and *(1b)* from the corresponding cationic monocyclopentadienylcobalt compound. Instead of compounds *(2)*, the salts $[C_5H_5Co\{PO(OR)_2\}_3BF]BF_4$[3] obtainable from them can be used as starting material. Also other transition metal ions M^{2+} react analogously to Co^{2+}; hence, trinuclear complexes of the general composition $(C_5H_5)_2Co_2M[PO(OR)_2]_6$ (*(3b)*, M = Mn; *(4b)*, M = Fe; *(5a,b)*, M = Ni; *(6a,b)*, M = Cu; *(7a,b)*, M = Zn; *(8b)*, M = Cd; R = CH_3 *(a)*, C_2H_5 *(b)*) *containing two different metals as coordination centers in the same molecule* are accessible *via* this route (see Scheme 1). A suitable solvent for the reaction is aqueous methanol, in which the salt-like starting compounds are readily soluble, whereas the neutral trinuclear complexes are very sparingly soluble. The syntheses of *(3)*–*(8)* are therefore preferably carried out as precipitation reactions.



Schema 1

As the X-ray powder diagrams of *(1b)* and *(3b)*–*(8b)* illustrate, all these compounds are isotypic and therefore probably have a similar structure to that of *(1a)*[1]. The trinuclear complexes are, with the exception of *(4b)*, light-yellow, easily crystallizable solids which are stable towards air and moderately to readily soluble in CCl_4, $CHCl_3$, and CH_2Cl_2. *(4b)* is brownish-violet; it is oxidized by air only slowly in the solid state, but rapidly in solution. Oxidation leads quantitatively to the yellow cation $[(C_5H_5)_2Co_2Fe\{PO(OC_2H_5)_2\}_6]^+$, which formally contains Fe^{3+} as central atom and can also be obtained directly by reaction of *(2b)* (X = BF_4) or $[C_5H_5Co\{PO(OC_2H_5)_2\}_3BF]BF_4$ with $FeCl_3$ (see Scheme 1). The tetrafluoroborate salt of this cation has solubility properties largely resembling those of $[C_5H_5Co\{PO(OC_2H_5)_2\}_3BF]BF_4$, *i.e.* it is readily soluble in acetone, methanol, methylene chloride, but insoluble in CCl_4 and hydrocarbons.

Like *(1)*, the trinuclear complexes *(3)*–*(6)* are also paramagnetic. The ^{1}H-NMR spectra of the diamagnetic species *(7b)* and *(8b)* are almost identical and show no influence

of the central metal atom (Zn^{2+} and Cd^{2+}, resp.) on the chemical shifts of the η-C_5H_5 and OC_2H_5 signals.

Preliminary experiments have shown that the alkaline earth metal ions Mg^{2+} and Ca^{2+} and, surprisingly, Hg^{2+} are also precipitated with the organometallic chelating agents $[C_5H_5Co\{PO(OC_2H_5)_2\}_3]^-$ (prepared from $[C_5H_5CoPO(OC_2H_5)_2\{P(OH)(OC_2H_5)_2\}_2]^+$ or $[C_5H_5Co\{PO(OC_2H_5)_2\}_3BF]^+$). Current investigations ought to clarify how selective the precipitation properties of the new chelating agents are and whether in each case (*i.e.* also with the larger M^{2+} ions) trinuclear complexes are formed in which—as in *(1a)*—the six oxygen atoms of the phosphonato groups are coordinated octahedrally to the central metal atom.

Experimental:

$[C_5H_5Co\{PO(OC_2H_5)_2\}_3BF]BF_4$ (125 mg, 0.19 mmol) is dissolved in methanol (10 ml) and the resulting solution diluted with water (10 ml). 6 ml of a 0.02 M aqueous solution of MCl_2 or MSO_4 (M = Mn, Fe, Ni, Cu, Zn, Cd) is now added slowly to the stirred solution. After 30 min the precipitate that has formed is filtered off and washed with water until no Cl^- or SO_4^{2-}, respectively, can be detected in the filtrate. The product is dried in a high vacuum, washed with methanol, re-dried, and finally recrystallized from CCl_4. Yield: 40 to 95% *(3b)–(8b)*.

Temperature Dependence of the Selectivity of π and σ Radicals[**]

By *Bernd Giese*[*]

A standard method for detecting[1] and assessing the reactivity[2] of short-lived intermediates consists in measuring their kinetic selectivity in an appropriate competition system. Studies on alkyl and aryl radials *(1)* have shown a mixture of $BrCCl_3$ and CCl_4 to be a suitable system[3].

$$RBr \xleftarrow[k_{Br}]{BrCCl_3} R\cdot \xrightarrow[k_{Cl}]{CCl_4} RCl$$

(2) *(1)* *(3)*

If the more reactive component $BrCCl_3$ is used in at least 10 M excess relative to the total amount of radical *(1)* then equation (a) describes the selectivity $\varkappa$.

$$\varkappa = \frac{k_{Br}}{k_{Cl}} = \frac{[RBr]\,[CCl_4]}{[RCl]\,[BrCCl_3]} \qquad (a)$$

[*] Dr. B. Giese
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Little attention has hitherto been paid to the temperature dependence of the selectivity $\varkappa$ because the radicals are preferably formed from peresters or azo compounds[3] at elevated temperatures. It was only our observation that the bromides *(2)* and the chlorides *(3)* are formed instantaneously down to −20 °C[4] on reaction of organomercury salts with $NaBH_4$ in $BrCCl_3/CCl_4$ mixtures which permitted measurement of kinetic selectivity of the radicals *(1)* over a large temperature range. The reaction obeys a radical chain mechanism[5].

Initiation:
$$RHgX \xrightarrow{NaBH_4} RHgH$$
$$RHgH \longrightarrow RHg\cdot + H\cdot$$

Chain:
$$RHg\cdot \longrightarrow R\cdot + Hg$$
$$R\cdot + XCCl_3 \longrightarrow RX + \cdot CCl_3$$
(1) *(2)*, X = Br; *(3)*, X = Cl
$$\cdot CCl_3 + RHgH \longrightarrow HCCl_3 + RHg\cdot$$

Chloroform could be detected by gas chromatography; mercury was deposited directly from the solution. The selectivities of the radicals obtained from organomercury salts and from peresters[6] lie on a straight line for a given radical R· in the Eyring plot in a temperature range between −20 and +130 °C (Fig. 1).

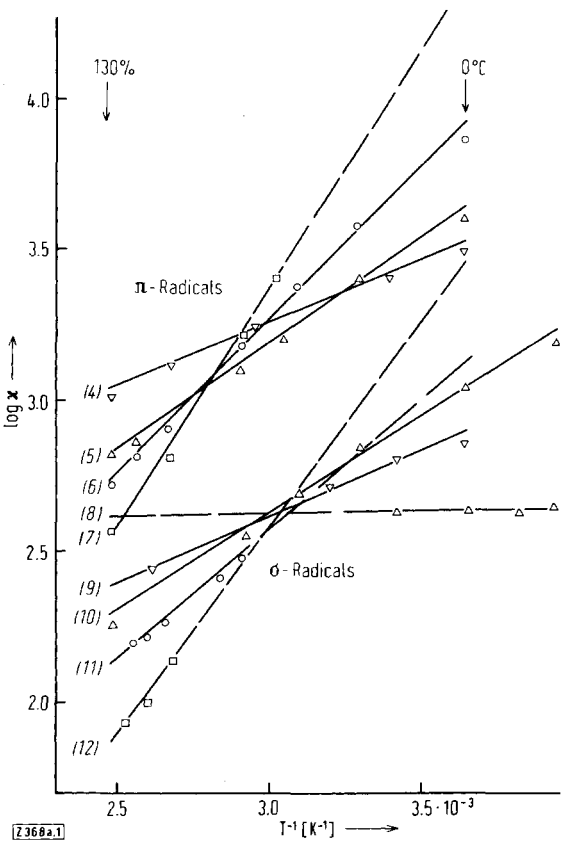

Fig. 1. Temperature dependence of the selectivity of some π and σ radicals [7] (see Table 1) in the competition system $BrCCl_3/CCl_4$. Limitations of space preclude consideration of all the radicals listed in Table 1.

Surprisingly, π and σ radicals[7] each form a pencil of straight lines in the Eyring plot, the selectivities of the π radicals coinciding in the region of 60±20 °C and those of the σ radicals at 50±10 °C (Fig. 1). Above and below these

temperatures the sequences of selectivities are reversed. At 0 °C the gradation of selectivities corresponds to expectation: thus the bulky *tert*-undecyl radical *(7)* is considerably more selective than the methyl radical *(4)*. In the series of σ radicals the shielded 2-*tert*-butylphenyl radical *(12)* is more selective than the unsubstituted vinyl radical *(8)*. At 130 °C, on the other hand, the methyl radical *(4)* is the most selective π radical and the vinyl radical *(8)* the most selective σ radical (Fig. 1).

Furthermore, above 80 °C the differences in selectivity do not decrease as expected for the π and σ radicals with rising temperature; instead they become greater. No structure-selectivity relationship exists in this competition system because the gradation of selectivity depends essentially upon the temperature.

Table 1. Differences in activation enthalpies [kcal/mol] (mean error ±5%) and in entropies of activation [e.u.] (mean error ±10%) of π and σ radicals in the competition system $BrCCl_3/CCl_4$.

π radical	$\cdot CH_3$ *(4)*	1-$\dot{C}_6H_{13}$	1-$\dot{C}_7H_{15}$	1-$\dot{C}_8H_{17}$ *(5)*	$C_4H_9C(CH_3)_2\dot{C}H_2$ [3]	2-$\dot{C}_8H_{17}$ *(6)*
$\Delta H^{\ddagger}_{Cl}-\Delta H^{\ddagger}_{Br}$	2.1	3.3	3.3	3.4	5.5	4.7
$\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}$	−9.3	−5.9	−5.6	−5.3	+1.2	−0.8
π radical	c-$\dot{C}_6H_{11}$	c-$\dot{C}_7H_{13}$			$C_8H_{17}\dot{C}(CH_3)_2$ *(7)*	$CH_3\dot{C}(C_2H_5)_2$
$\Delta H^{\ddagger}_{Cl}-\Delta H^{\ddagger}_{Br}$	4.3	4.6	4.7	4.7	7.8	8.8
$\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}$	−1.4	−1.2	−1.0	0.0	+8.0	+10.5
σ radical	$CH_2{=}\dot{C}H$ *(8)*	c-$\dot{C}_3H_5$ *(9)*	 *(10)*	C_6H_5 *(11)* [3]		2-t-C_4H_9—$\dot{C}_6H_4$ *(12)* [3]
$\Delta H^{\ddagger}_{Cl}-\Delta H^{\ddagger}_{Br}$	0.13	1.9	2.7	3.4		6.9
$\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}$	−11.7	−6.4	−3.5	−1.5		+8.5

In contrast, the differences in activation enthalpies display a regular gradation independent of temperature (Table 1). The activation parameters are obtained from the slope and intersection of the Eyring plot according to eq. (d), which results from eqs. (b) and (c) on subtraction.

$$\log\frac{k_{Br}}{T} = \log\frac{k}{h} + \frac{\Delta S^{\ddagger}_{Br}}{2.303\,R} - \frac{\Delta H^{\ddagger}_{Br}}{2.303\,R\cdot T} \qquad (b)$$

$$\log\frac{k_{Cl}}{T} = \log\frac{k}{h} + \frac{\Delta S^{\ddagger}_{Cl}}{2.303\,R} - \frac{\Delta H^{\ddagger}_{Cl}}{2.303\,R\cdot T} \qquad (c)$$

$$\log\frac{k_{Br}}{k_{Cl}} = \frac{\Delta H^{\ddagger}_{Cl}-\Delta H^{\ddagger}_{Br}}{2.303\,R\cdot T} - \frac{\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}}{2.303\,R} \qquad (d)$$

The data in Table 1 show that the differences in activation enthalpies increase with increasing shielding of the radical center in the π and σ radicals. Thus a linear correlation is obtained between the activation enthalpies and the steric E_s^c parameters[8]. Steric factors therefore dominate in these radical competition reactions. Conclusions about structurally determined properties of the intermediates are permissible only if the differences between the entropies of activation are also taken into consideration; a structure-selectivity discussion can lead to completely erroneous results[9].

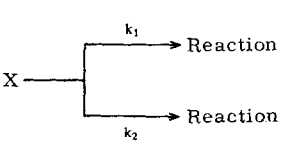
The Isoselective Relationship: Limitations and Prospects of the Structure-Selectivity Discussion[**]

By *Bernd Giese*[*]

The observation that the orders of selectivities of π and σ radicals R in the competition system $BrCCl_3/CCl_4$ are reversed between 40 and 80 °C[1] is of fundamental significance for the applicability of the principle of kinetic selectivity[2]. A condition for any structure-selectivity discussion is the existence of a linear free energy relationship[3] between the activation data of the competing reactions (1) and (2) and steric,



(1)

(2)

[*] Dr. B. Giese
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

inductive, mesomeric, or any other structural parameters[4] (X = intermediate).

This condition can be formulated as the isokinetic relationship[5]:

$$\delta\Delta H_1^{\ddagger} = \beta_1 \cdot \delta\Delta S_1^{\ddagger} \quad (3)$$
$$\delta\Delta H_2^{\ddagger} = \beta_2 \cdot \delta\Delta S_2^{\ddagger} \quad (4)$$

δ indicates that only the changes in the activation data are compared on structural variation of X. The proportionality factors β_1 and β_2 are the isokinetic temperatures at which the rate constants k_1 and k_2 coincide within a given series of reactions. These isokinetic temperatures usually lie far above the range of measurement and frequently represent no more than computational quantities whose physical significance is a matter of dispute[5]. If the reactions (1) and (2) are linearly related with the same structural parameters then changes in their activation data can also be correlated with each other:

$$\delta\Delta H_2^{\ddagger} = \alpha_H \cdot \delta\Delta H_1^{\ddagger} \quad (5)$$
$$\delta\Delta S_2^{\ddagger} = \alpha_S \cdot \delta\Delta S_1^{\ddagger} \quad (6)$$

The proportionality factors α_H and α_S reflect the sensitivity of the reactions (1) and (2) towards variation of the intermediate X. Introduction of two proportionality factors allows the possibility that structural modification of X might have a varying effect on the differences between the enthalpies and the entropies of activation.

Coincidence of the selectivities k_1/k_2 is defined by eq. (7):

$$\delta \log(k_1/k_2) \equiv 0 \quad (7)$$

The temperature at which the selectivity becomes independent of variation of the intermediate X is obtained from the Eyring equation as:

$$0 \equiv \delta \log \frac{k_1}{k_2} = \frac{\delta\Delta H_2^{\ddagger} - \delta\Delta H_1^{\ddagger}}{2.303 \cdot R \cdot T_{is}} - \frac{\delta\Delta S_2^{\ddagger} - \delta\Delta S_1^{\ddagger}}{2.303 \cdot R} \quad (8)$$

$$T_{is} = \frac{(\alpha_H - 1)\delta\Delta H_1^{\ddagger}}{(\alpha_S - 1)\delta\Delta S_1^{\ddagger}} = \frac{\alpha_S(\alpha_H - 1)\delta\Delta H_2^{\ddagger}}{\alpha_H(\alpha_S - 1)\delta\Delta S_2^{\ddagger}} \quad (9)$$

This temperature T_{is}, given explicitly in eq. (9) after rearrangement of eq. (8), should be designated as the isoselective temperature. Combination of eqs. (3), (4), and (9) indicates the relation between the isoselective temperature and the isokinetic temperatures of the individual reactions.

$$T_{is} = \frac{\alpha_H - 1}{\alpha_S - 1}\beta_1 = \frac{\alpha_S(\alpha_H - 1)}{\alpha_H(\alpha_S - 1)}\beta_2 \quad (10)$$

Only when $\alpha_S = \alpha_H$, the influence of structural variation in X on the differences in the entropies and enthalpies of activation on going from reaction (1) to reaction (2) becomes equal, is the isoselective temperature T_{is} identical with the isokinetic temperatures β_1 and β_2 and therefore in most cases lies far outside the range of measurement.

$\alpha_S = \alpha_H$: $T_{is} = \beta_2 = \beta_1$

If, as in the case of reactions of carbon radicals with $BrCCl_3/CCl_4$, the change in the entropy of activation is greater than the change in enthalpy of activation[1] then the isoselective point drops to lower temperatures and can fall in the range of measurement[6].

$\alpha_S > \alpha_H$: $T_{is} < \beta_2 < \beta_1$

The proportionality factors α_S and α_H are related to the isokinetic temperatures β_1 and β_2 according to equations (3) to (6) thus:

$$\alpha_S/\alpha_H = \beta_1/\beta_2 \quad (11)$$

A difference in the isokinetic temperatures of the individual reactions ($\beta_1 > \beta_2$) accordingly reduces the isoselective temperature. Since different isokinetic temperatures are to be expected for the different reactions (1) and (2)[5] widely deviating competing reactions are of little help in the structure-selectivity discussion. Even the difference between the abstraction of bromine and chlorine by carbon radicals in the competition system $BrCCl_3/CCl_4$ leads to a reversal of the order of selectivities between 40 and 80 °C[1]. Many structure-selectivity relationships should therefore be subjected to critical scrutiny. The isoselective temperature is readily determined. By analogy with eqs. (3) and (4), eq. (12) indicates that the slope in a plot of $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ *versus* $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ is the isoselective temperature.

$$\delta(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}) = T_{is} \cdot \delta(\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}) \quad (12)$$

The isoselective relationship (12) can be tested with the aid of competing radical abstraction of halogen from $BrCCl_3$ and CCl_4 for which the isoselective temperatures and the differences in the activation parameters were measured[1]. Plotting these activation enthalpies *versus* the activation entropies affords a straight line each for π and σ radicals respectively (Fig. 1). Their slopes of 320 K ± 10% and 310 K ± 5%, respectively, yield the isoselective temperature for the π radicals as 50 ± 30 °C and that for the σ radicals as 40 ± 20 °C. These values are in agreement with the temperature ranges in which the orders of selectivity of the π and σ radicals are reversed in the Eyring plot[1].

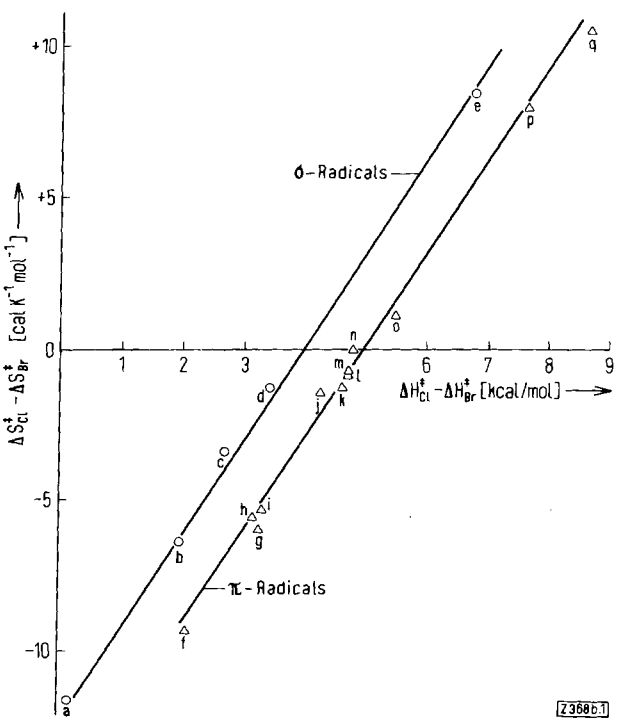


Fig. 1. Graphical check of the isoselective relation (12) for the abstraction of halogen by π and σ radicals in the competition system $BrCCl_3/CCl_4$. The activation parameters are taken from ref. [1]. The indices Br and Cl refer to the reactions of the radicals with $BrCCl_3$ and CCl_4 radicals, respectively: a, $CH_2{=}\dot{C}H$; b, c-$\dot{C}_3H_5$; c, 7-norbornyl radical; d, $\dot{C}_6H_5$; e, 2-t-C_4H_9—$\dot{C}_6H_4$; f, $\dot{C}H_3$; g, 1-$\dot{C}_6H_{13}$; h, 1-$\dot{C}_7H_{15}$; i, 1-$\dot{C}_8H_{17}$; j, c-$\dot{C}_6H_{11}$; k, c-$\dot{C}_7H_{13}$; l, 2-norbornyl radical: m, 2-$\dot{C}_8H_{17}$; n, bicyclo[2.2.2]oct-2-yl radical; o, $C_4H_9C(CH_3)_2\dot{C}H_2$; p, $C_8H_{17}\dot{C}(CH_3)_2$; q, $CH_3\dot{C}(C_2H_5)_2$.

The fact that π and σ radicals obey two different isoselective relationships (Fig. 1), leading to the appearance of two pencils of straight lines in the Eyring plot[1], opens up a further possible application: just as the isokinetic relationship is typical for a uniform reaction mechanism[5], the existence of the isoselective relationship (12) indicates formation of intermediates of the same structural type. Thus the isoselective relationship promises to become a new diagnostic criterion.

[6] The selectivity $\varkappa = k_1/k_2$ is defined such that reaction (2) has a higher enthalpy of activation than reaction (1); α_H is then greater than unity. It is assumed that β_1 and β_2 are positive.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The effects of supersonic transports on the earth's ozone mantle is the subject of a review by *H. S. Johnston*. Ozone in the stratosphere removes most of the sun's middle-ultraviolet radiation. This type of radiation has a damaging effect on DNA and causes, *inter alia*, skin cancer and bacterial mutations. Supersonic transports inject active nitrogen oxides (NO and NO_2) directly into the stratosphere. If they are not reversibly converted into nitric acid and removed as rainout after transport into the troposphere, as are the natural nitrogen oxides, they transform O_3 into O_2.—Ozone destruction by natural nitrogen oxides is counterbalanced by the photochemical regeneration of ozone. [Ground-Level Effects of Supersonic Transports in the Stratosphere. Acc. Chem. Res. *8*, 289–294 (1975); 35 references]

[Rd 824 IE—L]

Heterogeneous polymers are dealt with in an article by *E. Helfand*, with special attention being focused on interfaces between immiscible polymers and block copolymers. An attempt is made to describe qualitatively from a simple molecular point of view the entropy and energy terms which control the systems' physical features. Special consideration is given to the conditions governing phase separation. [Block Polymers, Polymer-Polymer Interfaces, and the Theory of Inhomogeneous Polymers. Acc. Chem. Res. *8*, 295–299 (1975); 28 references]

[Rd 825 IE—L]

^{13}C-NMR and the determination of the conformations of biological molecules forms the theme of an article by *I. C. P. Smith*, *H. J. Jennings*, and *R. Deslauriers*. In this sector ^{13}C-NMR spectra offer certain advantages over ^{1}H-NMR spectra. The greater dispersion of ^{13}C-NMR shifts and the removal of ^{1}H coupling by broad-band irradiation allow, *e.g.*, a detailed study of polynucleotides whose ^{1}H-NMR spectra are difficult or impossible to evaluate. Information on conformational changes of backbones can be derived from ^{13}C-^{31}P couplings.—Investigations on carbohydrates (complex glucans, polysaccharide antigens) and peptide hormones (thyrotropin-releasing hormone, oxytocin, vassopressin) are also discussed. [Carbon-13 Nuclear Magnetic Resonance and the Conformations of Biological Molecules. Acc. Chem. Res. *8*, 306–313 (1975); 45 references]

[Rd 827 IE—L]

Drugs used in the treatment of cancer are reviewed in an article by T. A. Connors. Direct chemotherapy, which is suitable for only a few forms of cancer, is being increasingly supplemented by a therapy to back up surgical measures, *i.e.* a therapy to combat metastasis at the earliest possible moment. The article is largely devoted to a description of electrophilic reactants, antibiotics, antimetabolites, and mitosis inhibitors, which are active against cancer and of attempts being made to improve their selectivity. [Drugs Used in the Treatment of Cancer. FEBS Lett. *57*, 223–233 (1975); 29 references]

[Rd 828 IE—R]

Mitochondrial ATP-phosphate exchange and the site of uncoupling of oxidative phosphorylation are reported on by *Y. Hatefi*, *W. G. Hanstein*, *Y. Galante*, and *D. L. Stiggall*. Five enzyme complexes which participate in electron transport and in oxidative phosphorylation have been isolated from bovine heart mitochondria. Four of these are the already well-known electron transfer complexes. The fifth is an energy conserving complex which catalyzes ATP-phosphate exchange and hydrolysis. The exchange reaction is sensitive toward uncoupling reagents. The photoaffinity uncoupler 2-azido-4-nitrophenol (NPA) binds only to this fifth complex, namely to a peptide of molecular weight 26000–30000. Its bonding is competitively inhibited by other uncouplers. Picrate also exhibits uncoupling action, but cannot pass through the membrane. In contrast to NPA it is a poor protonophore. [Mitochondrial ATP-P_i Exchange Complex and the Site of Uncoupling of Oxidative Phosphorylation. Fed. Proc. *34*, 1699–1706 (1975), 27 references]

[Rd 829 IE—R]

The biosynthesis of serum albumin is discussed in the light of recent knowledge by *P. N. Campbell*. It has been established that albumin, similarly to a series of other proteins, is formed from the precursor "proalbumin", which contains an additional penta- or hexapeptide on the N-terminal. This finding explains a few inconsistencies of earlier experiments on albumin biosynthesis. The additional peptide is said to be important for correct folding of the completed protein or for transport through the membrane of the endoplasmic reticulum after the synthesis. [The Biosynthesis of Serum Albumin. FEBS Lett. *54*, 119–121 (1975); 13 references]

[Rd 830 IE—R]

The antibiotic inhibition of mitochondrial ATP synthesis is the title of an article by *H. Lardy, P. Reed,* and *C.-H. C. Lin.* Fourteen antibiotics have been found which inhibit the oxidative phosphorylation and the ATPase stimulated by uncouplers in mitochondria. These antibiotics can be classified into four types according to the site of their binding to the ATPase. The first binding position binds two molecules aurovertin per molecule ATPase, the second binds efrapeptin and is probably the catalytic site. These two binding positions are found on purified ATPase. The other two binding positions occur only on membrane-bound ATPase. They are probably adjacent to each other, since several antibiotics influence both positions at the same time. [Antibiotic Inhibitors of Mitochondrial ATP Synthesis. Fed. Proc. *34*, 1707–1710 (1975); 21 references]

[Rd 831 IE—R]

Disodium tetracarbonylferrate, which can be regarded as a transition metal analog of Grignard reagents, is the subject of an article by *J. P. Collman.* The reagent *(1)* is prepared in the following manner:

$$Fe(CO)_5 + Na \xrightarrow[C_6H_5\text{-}CO\text{-}C_6H_5]{\text{Dioxane, 100 °C}} Na_2Fe(CO)_4 \cdot 1.5\ \text{Dioxane}$$

(1)

(1) can be used for transforming, *e.g.* alkyl halides and sulfonates into aldehydes, unsymmetrical ketones, carboxylic acids, esters, and amides. Conjugated olefins are reduced extremely selectively. Conversion of the ω-bromonitrile *(2)* into the

$$NC\text{-}(CH_2)_6\text{-}Br \xrightarrow[2.\ n\text{-}C_7F_{15}COCl]{1.\ (1),\ THF,\ CO} NC\text{-}(CH_2)_6\text{-}CO\text{-}C_7F_{15}$$

(2) *(3)*

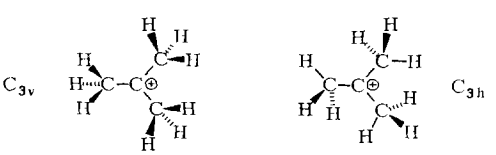
ketone *(3)* may be cited as an example; this also illustrates the failure of *(1)* to attack other functional groups. Further advantages of *(1)* are high yields and stereospecificity; its disadvantages are a pyrophoric nature and high basicity. [Disodium Tetracarbonylferrate—a Transition-Metal Analog of a Grignard Reagent. Acc. Chem. Res. *8*, 342—347 (1975); 34 references]

[Rd 832 IE—L]

The crystal face dependence of the surface chemistry of tungsten is surveyed by *R. R. Rye.* Body-centered cubic tungsten has been most thoroughly studied in this respect; the surface of its single crystals can readily be purified and characterized. Experiments conducted in ultrahigh vacuum ($<10^{-9}$ torr) revealed that the faces (111), (211), (100), and (110) differ considerably in their absorption properties. Experiments with hydrogen and ethylene are reported. [Crystallographic Dependence in the Surface Chemistry of Tungsten. Acc. Chem. Res. *8*, 347—354 (1975); 49 references]

[Rd 833 IE—L]

Theoretical approaches to the structure of carbocations is the title of a review by *W. J. Hehre.* Although hundreds of carbocations have meanwhile been generated in superacid media, the exact spatial structure of not a single species is known. For instance, does the *tert*-butyl cation *(1)* possess C_{3v} or



(1)

C_{3h} symmetry (propeller from)? Modern *ab initio* methods permit routine calculation of the three-dimensional structure of small organic molecules and ions. Bond lengths and angles determined by the STO-3G method deviate from the experimental values by only *ca.* 0.02 Å and *ca.* 2°, respectively, in the case of neutral hydrocarbons having up to four heavy atoms. In contrast to the predictions based on IR and Raman spectra, the STO-3G method indicates preference of the propeller form in the ground state.—Furthermore, the article also considers allyl, benzyl, and cyclopropyl cations, as well as CH_5^+ and $CH_3\text{—}CH_4^+$. [Theoretical Approaches to the Structure of Carbocations. Acc. Chem. Res. *8*, 369—376 (1975); 31 references]

[Rd 834 IE—L]

The photochemistry of organic sulfur compounds is reviewed by *J. D. Coyle.* In thiols the S—H bond is dissociated homolytically by radiation (254 nm); methanethiol decomposes into hydrogen, dimethyl sulfide, and methane. Of preparative value are, *e.g.* the addition of thiols to alkenes and the intramolecular variant of this reaction, which leads to sulfur-containing heterocycles *(1)*. In thiocarbonyl compounds, hydrogen abstraction or cycloaddition with unsaturated compounds, *e.g.* to give *(2)*, predominates.—Photoreactions of five-membered sulfur heterocycles containing 6π-electrons and of sulfonyl compounds are also discussed. [Photochemistry of Organic Sulfur Compounds. Chem. Soc. Rev. *4*, 523–532 (1975); 29 references]

[Rd 836 IE—F]

The photodegradation and stabilization of commercial polyolefins are dealt with in an article by *N. S. Allen* and *J. F. McKellar.* The term "polyolefins" covers low- and high-pressure polyethylene polypropylene, and poly(4-methyl-1-pentene). The photochemistry of the polyolefins can be divided into three main fields: photodegradation (or oxidation), sensitized photodegradation (or oxidation), and photostabilization. The photochemical properties of the polyolefins depend considerably on the state of contamination. Universally valid mechanisms cannot as yet be laid down. [Photodegradation and Stabilization of Commercial Polyolefins. Chem. Soc. Rev. *4*, 533–547 (1975); 44 references]

[Rd 837 IE—F]

Alkali-metal complexes in aqueous solution is the subject of a review by *D. Midgley.* These complexes are only weak, but nevertheless important because alkali-metal ions occur in high concentrations, *e.g.* in seawater and biological systems. Reliable data obtained by direct measurement of the equilibrium with ion-selective electrodes are now available. Inorganic and organic complexes as well as complexes with macrocyclic and biologically important compounds are discussed; in addition to stability constants the article also quotes, *inter alia,* spectroscopic and electrochemical properties. [Alkali-metal Complexes in Aqueous Solution. Chem. Soc. Rev. *4*, 549–568 (1975); 126 references]

[Rd 838 IE—F]

Chemical Applications of Pattern Recognition. By *P. C. Jurs* and *T. L. Isenhour*. John Wiley and Sons, New York—London 1975. 1st Edit., vii, 184 pp., numerous tables, bound, £ 8.25.

The reader of analytical journals will discover that increasing reference is made to publications in which operational techniques derived from information science are applied. One of these methods is *pattern recognition*. The customary application of this procedure in chemistry is for the identification of substances in a compilation of substance properties (usually spectroscopic data).

In their book *Jurs* and *Isenhour* give a survey of the principles of *pattern recognition* and how it can be applied in chemistry. As "chemical criteria" they use, *inter alia*, mass spectra, IR spectra, and also electrochemical data, the latter in some cases in combination with mass spectra, IR spectra, boiling and melting points, and so on. On a very extensive series of substances they demonstrate the results that can thus be achieved. Each chapter concludes with a literature review.

It would undoubtedly be very useful for the chemist to have an intelligible book on *pattern recognition* tailored to the chemical mode of thinking, for the analyst at least will be obliged in the foreseeable future to familiarize himself with this procedure and its possible applications. However, the authors have to a very large extent retained the language of information science, so that the book is very difficult to read, at least for chemists trained in German-language countries. However, there is also another problem that arises once again: namely, what was long a simple matter becomes unintelligible when presented in the formalism of information science!

Egon Fahr [NB 299 IE]

Instrumental Methods of Analysis. By *H. H. Willard, L. L. Merritt, Jr.*, and *J. A. Dean*. D. van Nostrand Company, New York—Wokingham 1974. 5th Edit., xix, 860 pp., numerous figs., bound, £ 8.50.

The question of the extent and method of giving chemists an insight into the "black box" of an apparatus for instrumental analysis have long been a standard discussion theme for colloquia and seminars concerned with this field. In the present book the authors provide the answers in a quite masterly manner. In 27 chapters they demonstrate, usually starting from didactically excellent drawings, the general principles and apparatus for the methods of instrumental analysis (after two chapters on electronic components: absorption spectroscopy in the UV/visible and IR regions, fluorescence spectroscopy, Raman, NMR, and ESR spectroscopy, X-ray and radiochemical methods, flame photometry, atomic absorption and emission spectroscopy, refractometry and interferometry, polarimetric, ORD, and CD methods, mass spectrometry, thermal analysis, gas chromatography, electrochemical methods, pH, ion-selective and potentiometric titrations, automated analytical procedures). The individual chapters are sensibly subdivided; they also contain proposals for instrumental investigations in practice and training exercises (problems), as well as a bibliography and details of the literature cited. The book closes with a very extensive subject index (29 pages).

The text is didactically excellent and a wealth of instructive illustrations is provided. The new and rarer techniques such as Fourier IR and NMR spectroscopy, ENDOR and ELDOR, cycloid, ion-cyclotron resonance, quadrupole and monopole mass spectrometry are also described. Unfortunately, the literature cited also contains references to journals that the German reader will hardly find useful (*e.g.* Ind. Eng. Chem., Anal. Ed.; Off. Dig. Fed. Soc. Paint Technol.).

The book is indeed one of the best in the field of instrumental analysis and is an extremely useful reference work for all who are actively teaching this profession and for those who require information, even on one brief occasion, about a specific method—the principles of its apparatus and the possibilities of its application.

Egon Fahr [NB 301 IE]

Handbook of Chemistry and Physics. Edited by *R. C. Weast*. CRC Press, Cleveland (Ohio), 1975, 56th edit., 2361 pp., bound, DM 89.—.

The fact that after 57 years of existence a book has gone through 56 editions, which differ from one another by improvements and modernizations, is probably rare even among handbooks. It indicates not only the usefulness of the book but also the commitment of the editor and the 131 scientists named as his "Collaborators and Contributors" and the "Physics Editorial Board". The word "Chemistry" ist rightly placed first in the title, for of its 2361 pages, 1497 are devoted to the three sections "The Elements and Inorganic Compounds" (421 pp.), "Organic Compounds" (797 pp.), and "General Chemical" (279 pp.). In addition to this, the book contains mathematical tables (192 pages), a Section called "General Physical Constants" (253 pages), where many points of importance and interest to the chemist are to be found, and a "Miscellaneous" chapter (352 pages) which provides much information useful in practice (densities of various solids and liquids, hardness tables, surface tensions, viscosities, critical temperatures and pressures, and a long table of "Definitions and Formulas", to mention only a few). The book is a mine of information, all of which is easily retrievable thanks to a subject index comprising 57 pages. Each table is provided with all the necessary explanations and is thus completely self-consistent. The reader is always informed what unit to assign to a numerical value, although here adherence to the international conventions would be desirable: an upper case K for kilo in KeV, or Kcal is simply wrong, cu.cm instead of cm^3 is not much better, and g-mol is today just as superfluous as g-cal. These, however, are only minor gripes. For the person who likes to have his private data bank close to his desk and who wants to find the particular value he needs with a minimum of searching, there is no handbook offering better value for money.

Helmut Grünewald [NB 305 IE]

Comprehensive Biochemistry. Vol. 29B: Comparative Biochemistry. Molecular Evolution, Part 2. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier Scientific Publication Company, Amsterdam 1975. 1st Edit., xii, 284 pp., numerous figs. and tables, bound, $ 34.60.

The history of the development of various forms of life has gained a new dimension by the changeover from descriptive to quantitative biology. Moreover, refinement of the methods has made it possible to include molecular structures in the comparisons of their historical development. Microorganisms are undoubtedly the earliest inhabitants of the Earth; they have already survived at least 10^{12} generations and have thus been able to try out innumerable mutations in their efforts to utilize optimally the living space provided by the planet. Unlike algae, protozoa, and fungi, during this process they have not developed morphological variations to the same extent as their capacity for selective metabolism and biochemical mechanisms.

The first section of this volume offers a survey of the conclusions drawn about the molecular evolution of bacteria from their comparative biochemistry. In about 70 pages and with citation of nearly 250 references, *J. deLey* and *K. Kesters* give a clear description of current conclusions about the evolution of free-living into high-grade parasitic forms, the origin of mitochondria and chloroplasts, and the relationship between the deoxyribonucleic acids of various species such as can be derived from comparative analytical data. The development of catabolic and anabolic capacities, of a well-adapted energy economy, and of control mechanisms for the coordination of these processes are now clear examples of metabolic evolution, and are supplemented by comparisons of bacterial cytochromes, iron-sulfur proteins, and Gram-characteristics at the molecular level.

Using the systematic coordinates developed in volume 29A together with their complicated nomenclature, *M. Florkin* describes the biochemical evolution of animals in a comprehensive essay supported by 400 references. The essay begins with a discussion of the interactions between the environment and the biochemical individual, phylogenetic relationships are then developed from amino-acid sequences, and finally the physiological-chemical development of animals is explained with examples (some of which coincide with the author's historical exposition in volume 30). After the amino-acid constituents required for their function had been established, the protein-synthesizing machinery was adapted to the synthesis of structural proteins, enzymes, hormones, carrier proteins, and immunoglobulins; the enzymes were then again optimized for the individual cycles and these in turn were diversified in relation to the given environment. Such sweeping generalizations are never possible without serious exceptions that will cause the critical reader to reconsider specific points and, when possible, to undertake further research, thus eventually leading to new understanding.

The last chapter, also by *M. Florkin*, deals in barely 20 pages (75 references) with a mainly historical review of the ideas and experiments in the field of prebiontic development, in which appropriate space is devoted to the physicochemical models that presently seem attractive.

This volume, which brings the complete work[*] a stage nearer to its end, although more and more due to the efforts of one individual, is not only "comprehensive" but almost throughout "comprehensible". Rather than merely cataloging facts, it offers both interesting reading and a broad survey of the modern picture of molecular evolution without sidetracking into narrow specialities. The book is produced in the usual manner consistent with its price.

L. Jaenicke [NB 292 IE]

[*] Cf. Angew. Chem. *87*, 750 (1975); Angew. Chem. Int. Ed. Engl. *14*, 719 (1975).

Les Grandes Reactions de la Synthèse Organique [The Principal Reactions in Organic Synthesis]. By *J. Mathieu*, *R. Panico*, and *J. Weill-Raynal*. Hermann, Editeurs des Sciences et des Arts, Paris 1975, 1st Edit., xiv, 341 pp., bound, F. 76.—.

This book attempts to describe organic syntheses in 320 pages of text. Ionic reactions form its main part, but thermal, photochemical, and radical reactions are also well covered. There is also one chapter each on degradative and rearrangement reactions of interest to syntheses. The formula schemes are connected by a minimum of cursive text, usually only one to three lines. Each chapter begins with a short general introduction and provides an extremely concise review. Naturally the book is not exhaustive, but the authors have succeeded in providing the student with a "first library" that goes far beyond the "Organikum" and can perhaps be compared with the much larger "Weygand-Hilgetag"; still closer comparison would be with the two volumes "Formation of C—C-Chains or Aromatic Rings", also by *J. Mathieu* and *J. Weill-Raynal*. These leading industrial chemists, noted for their research work, are also University lecturers (as also is *R. Panico*), which is rare in France. Because of their experience they are well able to present current knowledge in readily understandable form. The bibliographic references are unfortunately given without the authors' names; correspondingly, there is no author index. Nevertheless, the book can be recommended as a source of information for all organic chemists interested in synthesis.

Heinz Günter Viehe [NB 293 IE]

Correlation Tables for the Structural Determination of Organic Compounds. By *M. Pestemer*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., vi, 157 pp., bound, DM 98.—.

The book contains two pages of text (English and German), the remainder being taken up by tables. The unsaturation or ring-number R, according to which the compounds are arranged, is introduced in the text. The tables contain the molecular and structural formulas of the individual compounds, as well as the wave numbers, log ε, and the wavelengths of the measured absorption bands. About 2300 organic compounds are treated (hetero atoms N, O, S, P, and halogens).

This tabular form has the advantage of being clear and easily scanned. It would certainly have been easier for the organic chemist to handle if R had been defined more simply (*e.g.* for uncharged systems R = number of double bonds + number of rings).

As in all tabulations the choice of the compounds is arbitrary; for instance, one can find no information about phenyl azide, benzotropone, or chloronaphthalene. Some alkyl azides (pp. 24 and 41) are wrongly formulated as triazirines.

A lower price would have been welcome.

Rolf Gleiter [NB 295 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Organochromium Compounds. By *R. P. A. Sneeden*. From the series "Organometallic Chemistry". Edited by *P. M. Maitlis*, *F. G. A. Stone*, and *R. West*. Academic Press, New York 1975. viii, 327 pp., bound, $ 33.00.

High Temperature Vapors. Science and Technology. By *J. W. Hastie*. From the series "Materials Science and Technology". Edited by *A. M. Alper*, *J. L. Margrave*, and *A. S. Nowick*. Academic Press, New York 1975. xvi, 480 pp., bound, $ 35.00.

Exchange *in vitro* of Subunits between Enzymes from Different Organisms: Chimeras of Enzymes

By Guido R. Hartmann[*]

Dedicated to Professor Feodor Lynen on the occasion of his 65th birthday

Most intracellular enzymes are made up of several identical or different subunits. The more remote any two organisms are phylogenetically, the greater will be the differences in amino acid sequence of a given enzyme. Nevertheless, numerous examples exist of specific association between chemically different subunits, or even of the formation of enzyme chimeras. They span not only the boundaries between related organisms but also the deep rift between prokaryotic and eukaryotic cells. Exchange of subunits between enzymes of similar activity but differing origin can be rationalized by assuming enzymes to possess functionally defined types of three-dimensional structures.

1. Introduction

The amino acid sequence of proteins is extremely varied. Even enzymes of identical catalytic activity have far from identical amino acid compositions in different organisms. An example that has been studied particularly thoroughly is cytochrome c isolated from plants and from lower as well as higher animals; the length and amino acid sequence of the polypeptide chain has ben determined. Notwithstanding identical biological function, significant differences are found in the length of the protein chain and quite considerable variations in the sequence of amino acids. The differences are all the greater the farther the organisms under study are separated phylogenetically[1]. However, this sets no limits as to the polymorphism of enzymes, the occurrence of isoenzymes showing that even in a single organism several forms of a protein may be present having the same catalytic specificity in spite of differences in molecular structure[2].

[*] Prof. Dr. G. R. Hartmann
Chemisches Laboratorium der Ludwig-Maximilians-Universität München
Institut für Biochemie
Karlstrasse 23, 8000 München 2 (Germany)

Under natural conditions, the amino acid sequence of a polypeptide chain also determines the biologically active three-dimensional structure: enzymes which have somehow lost their three-dimensional structure without damage to the polypeptide chain spontaneously refold, albeit at different rates, to their original shape[3]. In keeping with the enormous variety of amino acid sequences in polypeptide chains there should be just as many protein three-dimensional structures in nature.

Most intracellular enzymes contain more than one polypeptide chain[4]. One distinguishes between homopolymeric enzymes, made up of a frequently even number of identical subunits and heteropolymeric enzymes composed of different subunits. The isolated subunits are usually, but not always, inactive.

The binding between the subunits in the complete and active enzyme is mediated by highly specific interactions determined by the amino acid sequences of the subunits, for enzymes consisting of subunits also spontaneously renature to the biologically active quaternary structure after complete unfolding of the polypeptide chains[5]. The high specificity of association between the subunits of an enzyme is demonstrated by the regeneration of the original activities of all the individual enzymes on renaturation of a mixture of various dissociated

polymeric enzymes[6] Analysis of normal and of pathological hemoglobins has revealed that association to the active quaternary structure requires perfectly fitting areas of contact between the subunits. Even the slightest change, such as replacement of a single amino acid, can have an interfering effect[7].

In the light of these considerations one would hardly expect the subunits of oligomeric enzymes to combine in disregard of barriers between species to give catalytically active hybrid structures. The frequently considerable differences between the amino acid sequences of proteins serving the same function in different organisms should not permit association. Surprisingly, however, several experimental investigations have shown that such enzyme associates, named chimeras after a fabulous creature of antiquity (cf. Homer, Iliad, 6th Song, Verse 181), can nevertheless be formed *in vitro* and even *in vivo* from subunits arising from different species.

2. Hybrids of Homopolymeric Enzymes

2.1. Hybrids of Dimeric Enzymes

An example of intergeneric hybrid formation (by exchange of subunits) has long been known to occur in the case of alkaline phosphatase (EC 3.1.3.1) from bacteria. Under certain conditions, this enzyme exists as a dimer of two identical subunits. It has been isolated from both *Escherichia coli* and *Serratia marcescens*. The two proteins are chemically very different. Thus the peptide patterns obtained on tryptic degradation are not the same; and an antiserum produced by the phosphatase from *Escherichia coli* hardly reacts with the enzyme from *Serratia marcescens*.

If the two enzymes are dissociated into their subunits by treatment with 6 M urea in the presence of thioglycolic acid, the two solutions combined, and the action of the denaturing agent stopped by dilution, then a considerable proportion of the enzymatic activity is regenerated during several hours' incubation at 37 °C. Electrophoretic analysis reveals not only the bands of the original enzymes characterized by their various migration rates but protein exhibiting an electrophoretic mobility intermediate between those of the starting enzymes. We know from numerous studies on isoenzymes[2] that the appearance of proteins with modified electrophoretic mobility under these conditions is indicative of hybrid formation, *i.e.* generation of associates of subunits of the two original enzymes. *Levinthal et al.*[8] justifiably conclude that in this experiment too, in which enzymes from different species were used, a hybrid consisting of one subunit ^{e}U of the *Escherichia coli* enzyme and one subunit ^{s}U of the *Serratia marcescens* enzyme is formed according to equation (1).

$$(^{e}U)_2 + (^{s}U)_2 \rightarrow 2(^{e}U\,^{s}U) \quad (1)$$

It would seem that protein-protein interactions occur between the heterologous subunits which resemble those between the autologous subunits[8]. The hybrid protein isolated by electrophoresis displays phosphatase activity. However, this is not necessarily due to the hybrid itself, but could possibly arise from monomeric subunits or parent enzymes that may be present in a dissociative equilibrium (2)

$$2(^{e}U\,^{s}U) \rightleftharpoons 2\,^{e}U + 2\,^{s}U \rightleftharpoons (^{e}U)_2 + (^{s}U)_2 \quad (2)$$

under the conditions of activity assay. In this context, the observation that the equilibrium (2) can be shifted in either direction by foreign molecules warrants mention[9].

2.2. Hybrids of Tetrameric Enzymes

On reaction between the subunits U of tetrameric homopolymeric enzymes from two organisms a and b several hybrids can be formed. Just on the basis of their stoichiometric composition, three hybrids ($^{a}U^{b}U_3$; $^{a}U_2{}^{b}U_2$; $^{a}U_3{}^{b}U$) are possible. But for any given composition various spatial arrangements (planar or tetrahedral) are feasible in the associate. Since the equilibria between the various spatial structures may differ from those of the parent enzymes even more molecular species can occur under certain circumstances[10]. The existence of the many conceivable interspecies hybrids will be decided not only by thermodynamic aspects but also by the kinetic factors of formation and decomposition[11]. Hence the number of hybrids observed will differ from case to case.

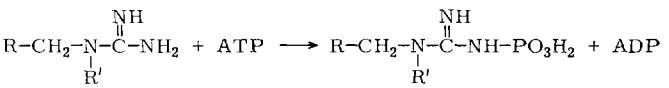
Examples of chimera formation in enzymes composed of four identical subunits have been observed for the Schiff-base-forming aldolase (EC 4.1.2.13)[12-15], L-lactate dehydrogenase (EC 1.1.1.27)[16-18], and D-glycerinaldehyde-3-phosphate dehydrogenase (EC 1.2.1.12)[11, 19-23]. Formation of interspecies hybrids in these enzymes is favored by their ready dissociation under relatively mild conditions. Accordingly, effectors which promote dissociation of the enzymes into their subunits, such as ATP in the case of D-glycerinaldehyde-3-phosphate dehydrogenase[22], greatly accelerate hybrid formation.

It is found that the phylogenetic separation between the hybridizing subunits can be very large and embraces the whole range of eukaryotes (*e.g.* beef × rabbit[13], trout × rabbit[22], Drosophila × rabbit[14], roundworm × rabbit[15, 21], yeast × rabbit[19, 20, 23]). In a number of cases the associated polypeptide chains differ so greatly from each other that they no longer show immunological cross-reactions. Evidence for hybrid formation usually follows from the difference in electrophoretic mobility between the products and the starting enzymes. Strictly speaking this merely indicates association of the subunits of different origin. Whether, and to what extent, the observed enzymatic activity is attributable to the hybrids cannot be said for the reasons stated above for the intergeneric hybrid of alkaline phosphatase (Section 2.1).

2.3. Hybrids between Enzymes of Related Activity

A particularly remarkable case of chimera formation is that between the subunits of creatine kinase (EC 2.7.3.2) from rabbit brain and L-arginine kinase (EC 2.7.3.3) of the sea cucumber. These are two enzymes which differ not only in origin but also, in spite of any similarity in the reactions catalyzed, in their substrate. They both consist of two subunits having relative molecular masses of about 40000. After dissociation of a mixture of the two enzymes into the subunits with urea, analysis of the proteins present after reactivation shows the presence of a new protein whose rate of electrophoretic migration lies between the values of the original enzymes[24]. This species is most probably the hybrid enzyme, for reaction of both creatine and arginine to form the corresponding phosphorylated products according to equation (3) is catalyzed

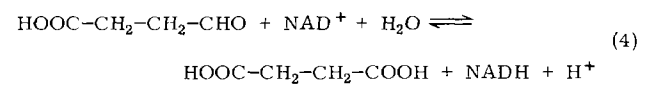
in this protein zone, whereas each of the starting enzymes can only react with one of the two substrates. However, for the same reasons as were cited for the chimeras of phosphatase the conversion of both substrates in this protein zone is not necessarily due to the hybrid itself.



(3)

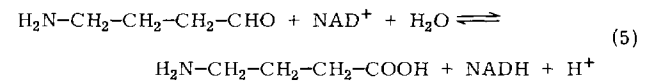
R = $COO^{\ominus}$, R' = CH_3: Creatine
R = $(CH_2)_2$-$CH(NH_2)$-$COO^{\ominus}$, R' = H: Arginine

Hybridizations between subunits of enzymes displaying different specificity even appear to occur *in vivo*. Thus apart from a dehydrogenase (EC 1.2.1.24), converting succinic



(4)

semialdehyde with the aid of NAD^+ into succinic acid according to eq. (4), and a chromatographically distinct dehydrogenase (EC 1.2.1.19), transforming 4-aminobutanal with NAD^+ into γ-aminobutyric acid according to eq. (5), two further dehydrogenases have been isolated from a *Pseudomonas*



(5)

strain which can each react with both substrates. Judging by the relative molecular masses, their composition of different subunits, and their antigenic properties, the two last-mentioned species are hybrids of the two starting enzymes[25]. Remarkably, the subunits of the two parent enzymes associate with the same stoichiometry in the hybrids in spite of the considerable difference of about 20000 in their relative molecular masses.

3. Hybrids of Heteropolymeric Enzymes

3.1. Hybrids of Enzymes with Two Different Subunits

For the reasons discussed in Section 2.1 it is very difficult to establish in the case of hybrids of homopolymeric enzymes whether the enzyme activity observed in electrophoretically isolated proteins is really attributable to the chimeras. However such proof is required to demonstrate that association of the heterologous subunits is as specific as that of the autologous subunits in the active parent enzymes. This question can be answered much more easily with hybrids of enzymes made up of different subunits (say α and β), for in such a case the isolated subunits α and β have no activity of their own, or one differing from that of the intact complex (αβ). Now if a mixture of subunit $^a\alpha$ from species a with subunit $^b\beta$ from species b displays the characteristic activity of the complete parent enzyme (αβ) it is established that the interactions between the heterologous subunits in the enzyme chimera ($^a\alpha^b\beta$) correspond to those in the parent enzymes ($^a\alpha^a\beta$) and ($^b\alpha^b\beta$), in as far as is necessary for establishment of catalytic activity.

Bacterial tryptophan synthetase (EC 4.2.1.20) consists of two subunits of different size which can readily be separated. Unlike the complete enzyme the isolated subunits, although enzymatically active, are incapable of catalyzing the reaction of indole 3-glycerophosphate with serine to give tryptophan and D-glycerinaldehyde 3-phosphate. It has been possible to combine the two subunits from a series of Enterobacteriacae *(e.g. Escherichia coli, Salmonella dysenteriae, Enterobacter aerogenes, Serratia marcescens)* over the species boundaries, in spite of considerable differences in amino acid sequence, to form hybrids exhibiting the activity of the complete parent enzymes[26–28]. In some cases it even proved possible to form hybrids from subunits of enzymes from gram negative and gram positive microorganisms[29, 30], and even of enzymes from bacteria and blue-green algae[31].

Active enzyme hybrids could also be obtained from bacterial anthranilate synthetase complex (EC 4.1.3.27) which is likewise composed of two different subunits (α and β). However, not every combination of a subunit from a bacterium a with a subunit from another bacterium b leads to an active hybrid [equations (6a) and (6b)]. If

$$^a\alpha + {}^b\beta \rightarrow (^a\alpha^b\beta) \text{ active,} \qquad (6a)$$

it does not always follow that

$$^b\alpha + {}^a\beta \rightarrow (^b\alpha^a\beta) \text{ active} \qquad (6b)$$

In these experiments subunits of enzymes from such widely differing classes of Eubacteria as *Bacillus, Pseudomonas, Acinetobacter*, and *Enterobacter* were incubated together[32–36]. That enzymatic activity does not always appear demonstrates that biological diversification can indeed also lead to modifications of the regions of the polypeptide chains of importance for interactions between the subunits.

Chimeras can even be prepared *in vitro* from bacterial protein complexes in which one subunit catalyzes the entire reaction while the other subunit merely carries the binding site of an allosteric effector; like the parent enzymes these chimeras are also subject to allosteric regulation. This is demonstrated by the formation of two active hybrids of aspartate transcarbamylase (EC 2.1.3.2) with allosteric control from the isolated subunits of *Escherichia coli* and *Salmonella typhimurium*[37].

To the above examples from the field of prokaryotes one can add the chimeras of heteropolymeric enzymes from eukaryotes. Thus the α- and β-polypeptide chains of hemoglobin from such different species as elephant, ass, mouse, and frog can associate with each other to form hybrids[38], which in all cases examined so far display the characteristic proton-dependent oxygen uptake of the complete tetramer[39].

3.2. Hybrids of Enzymes Having Several Different Subunits

3.2.1. Hybrids of DNA-Dependent RNA Polymerase

We may expect a precisely interlocking shape extending over particularly large regions, and thus very narrowly limited and specific interactions between the subunits, in those proteins which are made up of several different polypeptide chains and do not dissociate under the conditions of a biological environment.

Such an enzyme is bacterial DNA-dependent RNA polymerase (EC 2.7.7.6). It catalyzes the synthesis of RNA from ribonucleoside triphosphates under the control of DNA acting as template. The enzyme is usually isolated from bacteria as a complex of four different protein subunits α, β, β', and σ having the stoichiometric composition $\alpha_2\beta\beta'\sigma$. Only the σ subunit can sometimes be removed from the complex by ion-exchange chromatography without resorting to more drastic measures. The core enzyme having the stoichiometric composition $\alpha_2\beta\beta'$, however, is so stable that it dissociates only in detergents such as dodecyl sulfate or in 6 M urea. None of the isolated subunits displays any enzymatic activity. For this reason it cannot be established whether the function of the individual subunits in the catalytically active intact complex changes from species to species. Comparison of the RNA polymerase from *Escherichia coli* with that from various bacteriophages or from mitochondria, which contains just a single polypeptide chain[40-43], shows that DNA-dependent RNA polymerase is certainly not identical, or even similar, in all organisms. And even among bacteria, significant differences in size (Table 1) and charge are observed[44,45] between subunits from different species. Bacterial RNA polymerases are also very different in their antigenic properties. For instance, neither the enzyme from *Escherichia coli* reacts with the antibody active against the enzyme from *Micrococcus luteus*, nor does the *Micrococcus* enzyme with the antibody active against the *Coli* enzyme[45a]

Table 1. Relative molecular masses of the subunits of RNA polymerase from *Escherichia coli* and *Micrococcus luteus* [45].

Subunit	*E. coli*	*M. luteus*
Smallest subunit (α)	39000	44000
Medium-sized subunit (σ)	95000	80000
Second-largest subunit (β)	155000	146000
Largest subunit (β')	165000	151000

Nevertheless, comparison of physical data does not permit any comparison of the functions of the subunits. In such cases, functional equivalence can only be proved by mutual exchange of the subunits.

Such an exchange involving two bacteria, which differ considerably on the basis of their DNA composition and all other taxonomic criteria, *viz.* the gram-negative *Escherichia coli* and the gram-positive *Micrococcus luteus*, has been studied in detail. It proved possible to replace the subunits α, β', and σ in the RNA polymerase from *Escherichia coli* by the similar but different-sized subunits of the *Micrococcus* enzyme; DNA-dependent RNA synthesis was observed with these enzyme chimeras. Similarly, replacement of the smallest and the second-largest subunit in the *Micrococcus luteus* polymerase by subunits of the *Escherichia coli* enzyme also leads to active enzyme chimeras (Table 2)[45,46].—Attempts to obtain active hybrids containing the largest subunit from *Escherichia coli* and the second-largest from *Micrococcus luteus* have so far failed.

The resulting chimeras display differing activities, based on the amount of protein employed. It has yet to be established whether the low activity registered in some cases is attributable to an unfavorable association equilibrium between the subunits or whether the hybrid complex formed possesses a low specific activity. As in all other cases of intergeneric enzyme hybrids, precise characterization still has to be performed, especially with regard to physicochemical properties.

During the catalysis of RNA synthesis the various subunits must fulfill corresponding functions in the two bacteria. Otherwise it would be impossible to rationalize the observation

Table 2. Exchange of subunits between the RNA polymerases from *Escherichia coli* and *Micrococcus luteus* [45, 46]. +, formation of a catalytically active chimera; −, no detectable enzymatic activity.

Subunit exchanged	in *E. coli* RNA polymerase	in *M. luteus* RNA polymerase
Smallest subunit (α)	+	+
Medium-sized subunit (σ)	+	−
Second-largest subunit (β)	−	+
Largest subunit (β')	+	−

that each subunit can be replaced by a corresponding subunit from the other bacterium in at least one of the two enzymes. Moreover, any subunit can replace only one subunit in the polymerase of the other bacterium. Thus an unequivocal functional assignment of the subunits of the two bacteria is possible. At no stage of the divergent development of the two bacterial strains has a transfer of functional purposes in RNA synthesis taken place between one polymerase subunit and another.

The feasibility of exchange of subunits between various species of bacteria provides a strong indication that not only the function, but also the shape required for specific mutual association of the subunits, is very similar. Otherwise the formation of functioning enzyme chimeras would hardly be understandable. The similarity between the corresponding subunits from different bacteria is so great that mutations in the subunits can be effective beyond taxonomic boundaries. For example, a mutation in the gene of the β-subunit of RNA polymerase from *Escherichia coli* has the result that this enzyme is no longer inhibited by the antibiotic rifampicin[47]. An incorporation of the mutated subunit into the rifampicin-sensitive RNA polymerase from *Micrococcus luteus* yields an enzyme chimera that is resistant to the antibiotic[45].

Hybridization of the core complex $\alpha_2\beta\beta'$ with the subunit σ has been accomplished with such different bacteria as *Escherichia coli*, *Bacillus subtilis*, *Bacillus megatherium*, *Bacillus cereus*, *Azotobacter vinelandii*, *Pseudomonas aeruginosa*, and *Micrococcus luteus*[45,46,48-52]. Success of the experiment can be easily deduced from the appearance of enzymatic activity characteristic of the complete enzyme $\alpha_2\beta\beta'\sigma$. A protein has even been discovered in the chloroplasts of the single-cell alga *Chlamydomonas reinhardtii* which acts as the σ subunit on the core enzyme $\alpha_2\beta\beta'$ of RNA polymerase from *Escherichia coli*[53].

Reaction of the subunit σ of a bacterium a with the heterologous core enzyme of another bacterium b, does not always imply that the σ subunit of bacterium b will form an active enzyme chimera with the core enzyme of a. This observation can be utilized to test which subunit in the core enzyme $\alpha_2\beta\beta'$ is particularly important for the action of σ. Accordingly, the β' subunit is important for the function of σ in *Escherichia coli*, since σ from *Escherichia coli* can only complement the core enzyme $\alpha_2\beta\beta'$ to form the active polymerase when an RNA polymerase hybrid contains the β' subunit from *Escherichia coli*[45]. All these results support the concept of a fundamentally similar kind of organization of the RNA synthesis system in bacteria.

3.2.2. Hybrids of Bacterial Ribosomes

Similar observations as for RNA polymerase have been made on ribosomes from bacteria. Ribosomes catalyze the synthesis of proteins from activated amino acids on mRNA with participation of several "soluble" proteins. Ribosomes are made up of a larger and a smaller subunit, which are in turn made up of RNA and 34 and 20 polypeptides, respectively. It had already been observed in 1966 that the two ribosomal subunits from gram-positive *Bacillus subtilis* and gram-negative *Escherichia coli* can be cross-hybridized[54]. The functional equivalence of the subunits and the contact surfaces necessary for catalytically active interactions must therefore have been retained during the evolution of ribosome structure. The functional similarity even extends as far as the individual proteins, for it is possible to replace almost every ribosomal *Escherichia coli* protein by an equivalent protein from *Bacillus stearothermophilus*, during reconstitution of the smaller ribosomal subunit from the isolated proteins and RNA, although some of the *Bacillus stearothermophilus* proteins differ considerably from the corresponding *Escherichia coli* proteins with regard to amino acid composition, electrophoretic behavior, and immunochemical criteria[55].

Some ribosomal proteins are responsible for species-specific peculiarities as are observed, *e.g.*, in protein synthesis on the RNA of bacteriophage R 17. Such peculiarities also occur in the chimeras obtained on incorporation of these protein in heterologous ribosomes[56, 57]. Furthermore, not only can ribosomal proteins be exchanged, but also ribosomal RNA between the ribosomes of different bacteria[58].

3.2.3. Hybridizations with "Soluble" Protein Factors

Apart from ribosomes, "soluble" protein factors affecting the processes occurring at the ribosomes participate in protein synthesis. "Soluble" proteins from various bacteria were found to be active on heterologous ribosomes in spite of unmistakable immunochemical differences[59–62]. Moreover, this applies not only to the protein synthesis system from prokaryotes but also to that from eukaryotes[63, 64]. Together with the detection of chimeras of RNA polymerase and of ribosomes, all these experiments strongly suggest that the entire transcription and translation systems of prokaryotes are functionally similar in spite of differences detected between the components from different bacteria.

Joint functioning of proteins of very different origins has also been demonstrated in other complex biosynthetic systems. For instance, the acyl carrier protein in the multienzyme system of fatty acid synthesis of *Escherichia coli* can be replaced by the analogous protein from *Agrobacterium tumefaciens* or from the chloroplasts of the mesoderm of the avocado pear[65]. From among the vertebrates, the multicomponent system required for muscle contraction deserves mention. Here the Ca^{2+}-binding troponine subunit of the rabbit can be replaced by a corresponding protein from a shrimp[66].

4. Hybrids between Proteins from Prokaryotes and Eukaryotes

In Nature, a deep rift appears to exist between the prokaryotes, lacking a cell nucleus, and the eukaryotes, which do have a cell nucleus[67]. The question thus arises as to how far the protein subunits have retained their function and possibly even their ability to engage in functional cooperation across the frontier between prokaryotes and eukaryotes. Associate formation was observed between the subunits of 3-glycerinaldehyde 3-phosphate dehydrogenase from *Escherichia coli* and rabbit or pig[23]. The same has been reported for the subunits of triose phosphate isomerase (EC 5.3.1.1) from *Bacillus stearothermophilus* and chicken[23]. Initial studies on ribosomes are now also available. The ribosome subunits of eukaryotes are significantly larger than the corresponding subunits from bacteria. Nevertheless, the small ribosome subunit of the shrimp *Artemia salina*, a eukaryote, can cooperate with the large ribosome subunit from *Escherichia coli* in an albeit restricted functional interaction (*i.e.* only in the catalysis of polyuridylic-dependent dipeptide synthesis). The physicochemical interactions between subunits displaying such far-reaching phylogenetic differences are very weak. In order to detect their association glutardialdehyde was added as cross-linking agent during dipeptide synthesis; the hybrid ribosomes thus stabilized by covalent bridging could be detected by the sedimentation velocities in the ultracentrifuge[68]. In another case, cooperation of the small eukaryotic ribosome subunit from *Chlorella* with the large subunit from bacteria could be established by ribosome-dependent synthesis of guanosine tetra- and penta-phosphate[69].

Finally, it also proved possible to remove two acidic proteins from eukaryotic ribosomes of yeast and functionally replace them by two ribosomal proteins from *Escherichia coli*[70]. In this case, however, there exists an immunologically demonstrable relationship[71].

5. Conclusions

The numerous examples of chimeras of enzymes which can be formed *in vitro* can be supplemented by those arising *in vivo*, for example on crossing genetically related yeasts[72] or after fusion of somatic cells of such diverse origin as hamster, mouse, man, or rat[73]. Hybrid immunoglobulins made up of polypeptide chains arising from mouse and man have even been observed[74]. Hence, exchange of subunits between proteins from different organisms is not a special case, but rather possesses general importance throughout the whole of living Nature.

How are we to interpret the ability of subunits of widely differing origin, which vary so much in length, amino acid composition and sequence, and in their antigenic properties to mutually replace each other in oligomeric enzymes? Studies performed on hemoglobin[7] in particular have shown that precisely fitting contact surfaces are essential for cooperation of different polypeptide chains in an aggregate. Accordingly, it must be suspected that the regions necessary for mutual interactions and the function necessary for the catalyzed overall reaction are retained by subunits in oligomeric enzymes across the boundaries of species.

Preliminary evidence was provided by comparative immunochemical investigations[75]. And very strong support has come from X-ray studies: whale myoglobin and the hemoglobin of an insect larva, which differ in more than 80% of their amino acid sequence, have almost identical three-dimensional structures[76, 77]. Some confirmation may also be seen in the observation that the three-dimensional structure of

glycerinaldehyde 3-phosphate dehydrogenase consisting of four equal subunits is practically identical, whether from a bacterium or from lobster, although the two enzymes differ considerably in their amino acid sequences[78]. Other functionally related but phylogenetically different proteins likewise possess very similar structural regions[79]. The three-dimensional structure is apparently more important for function than amino acid sequence. Hence enzymes can be classified not only according to function, but also according to their three-dimensional shape.

The reason for proteins with different amino acid compositions to exhibit very similar folding may be seen in the very similar influence exerted on three-dimensional structure by many amino acids. Thus threonine, serine, or valine, leucine, and isoleucine all have a similar effect on the folding of a polypeptide chain[80]. They can thus undergo mutual replacement without causing any great change in folding. Evolutionary changes in the amino acid sequence of proteins arising from different species and yet having the same function are limited only in so far as that part of the three-dimensional structure which is essential for functioning is not allowed to alter. The existence of chimeras of enzymes thus also becomes understandable, for if the folding of polypeptide chains has changed so little in the course of evolution then the subunits of enzymes having the same catalytic activity will still fit each other spatially, regardless of barriers between species. The interlocking shape is conserved so well as to permit association, and, in many cases, catalytically active cooperation.

Our own studies mentioned in this article were supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Biosynthesis of the Purple Membrane of Halobacteria

By Manfred Sumper, Heribert Reitmeier, and Dieter Oesterhelt[*]

Dedicated to Professor Feodor Lynen on the occasion of his 65th birthday

Halobacteria are extremely specialized organisms. They live exclusively in saturated solutions of common salt. The cell membrane of these bacteria exhibit insular regions which can be isolated by membrane fractionation. These regions consist of a lipid matrix containing bateriorhodopsin molecules in a hexagonal crystalline arrangement. Bacteriorhodopsin is a deep purple retinal-protein complex ("purple membrane"). The purple membrane functions as a light energy converter.—How can such a differentiated membrane region arise? *In vivo* studies on the biosynthesis of the purple membrane showed another cell membrane fraction, the so-called brown membrane, to be a biosynthetic precursor. Bacterioopsin (the retinal-free protein) is initially incorporated into the brown membrane and can only form the purple membrane by crystallization in an energy-dependent reaction after prior reaction with retinal. This reaction is reversible. Removal of the retinal by formation of retinal oxime causes the purple membrane regions to disappear. Reconstitution of the bacteriorhodopsin by addition of retinal regenerates the purple membrane.

1. Introduction

During the past decade, studies on biological membrane systems have led to a generally accepted model of membrane structure known as the fluid mosaic model[1]. In essence, this model describes a membrane as a solution of oriented protein molecules in a two-dimensional lipid matrix. Such a concept allows for essentially free diffusion of both lipid molecules and membrane proteins in the plane of the membrane.

This normal case contrasts with special cases in which the membrane protein forms a two-dimensional crystalline network. Such a case is encountered in the cell membrane of halobacteria where the retinal-protein complex bacteriorhodopsin forms a crystal lattice detectable in the intact cell[2,3]. These crystalline regions can be liberated by membrane fragmentation and isolated. Owing to their intense color these membrane fragments are termed the purple membrane[4-6]. In contrast to the visual pigments (*e.g.* rhodopsin) which act as light sensors, bacteriorhodopsin functions as a light energy converter[7]. Absorption of light triggers a photochemical cycle, to which is coupled the transport of a proton through the membrane. The resulting electrochemical gradient of the proton is utilized for ATP synthesis in the cell (reviewed in ref. [8]).

The composition and structure of the purple membrane were found to be unusually simple. Knowledge of both the function and the structure makes the purple membrane a suitable model for studies on the biosynthesis of a membrane and its regulation.

2. Regulation Phenomena in the Synthesis of the Purple Membrane

2.1. Chemical Composition of the Purple Membrane

Isolated purple membrane consists of *ca.* 75% (pigment-containing) protein and 25% lipid, corresponding to about ten

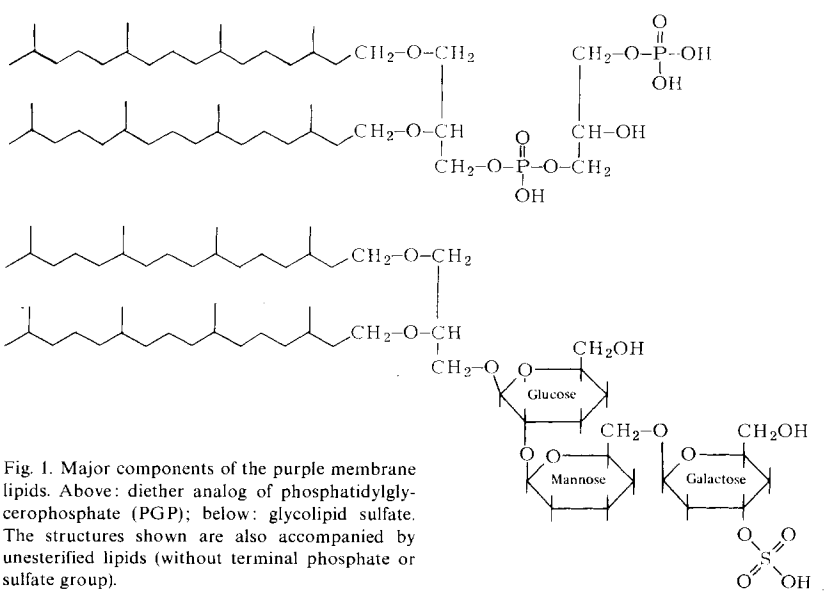

Fig. 1. Major components of the purple membrane lipids. Above: diether analog of phosphatidylglycerophosphate (PGP); below: glycolipid sulfate. The structures shown are also accompanied by unesterified lipids (without terminal phosphate or sulfate group).

[*] M. Sumper, H. Reitmaier, and D. Oesterhelt
Institut für Biochemie der Universität
Röntgenring 11, 8700 Würzburg (Germany)

lipid molecules for every protein molecule. The sole protein species present is bacteriorhodopsin, a protein molecule having a molecular weight of about 26000 daltons and containing one retinal molecule[2]. The retinal-free protein is called bacterioopsin. More than 50% of the lipids comprise a diether analog of phosphatidylglycerophosphate, and a further 30% two glycolipids (Fig. 1). A special feature of halobacterial lipids is the absence of fatty acids; the invariable side chain of the isoprenoid alcohol dihydrophytol bound by an ether-type linkage appears in their place[9].

2.2. Influence of Oxygen and Light on Purple Membrane Synthesis

Halobacteria whose growth is not limited by restricted oxygen supply do not synthesize the purple membrane[20]. Falling oxygen partial pressure in the medium triggers the synthesis of the purple membrane, directly or indirectly. Thus, since this membrane does not belong to the constitutive equipment of the bacteria but can be utilized as a light energy converter, its function clearly appears to be that of an "emergency power generator" for the cell. When the rate of ATP synthesis *via* oxidative phosphorylation becomes inadequate the purple membrane system is brought into operation. Light does not have a similar effect on purple membrane synthesis (cf. Section 3.2).

Studies on this inducible membrane synthesis must have the ultimate aim of elucidating the time-based control of synthesis of all membrane components, *i.e.* of pigment (retinal), protein (bacterioopsin), and lipid, and in particular of answering the question of the correlation of the three synthetic pathways.

3. Synthesis of the Components of the Purple Membrane

3.1. Carotenoid Synthesis in Halobacteria

Formation of bacteriorhodopsin and thus of purple membrane is necessarily dependent on the presence of vitamin

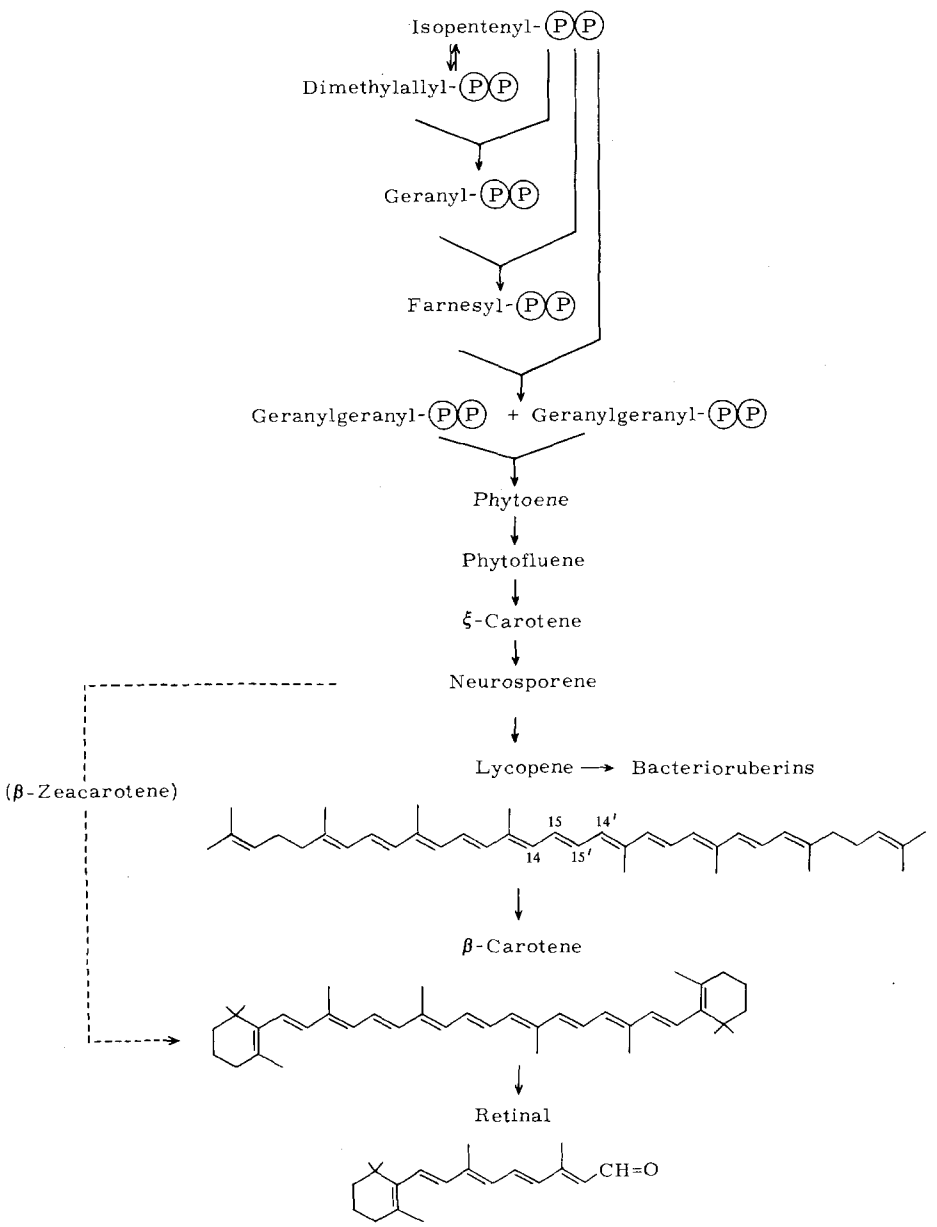

Fig. 2. Schematic representation of carotenoid biosynthesis. Ⓟ Ⓟ = pyrophosphate.

A aldehyde (retinal). In animals, retinal is formed by oxidative cleavage of the central double bond of β-carotene. β-Carotene itself is formed in plant systems from isopentenyl pyrophosphate *via* the pathway sketched out in Figure 2 and consumed by animals as provitamin A[10–15].

The two syntheses mentioned above are most probably also involved in *de novo* retinal synthesis in halobacteria, as shown by numerous recent experiments. On the one hand, the intermediates postulated in Figure 2 could be directly detected in some cases, and on the other the synthesis of β-carotene from isopentenyl pyrophosphate has recently been demonstrated in an *in vitro* system from *H. cutirubrum*[16, 17]. A special feature of carotenoid synthesis in halobacteria is the appearance of C_{50}-carotenoids, particularly bacterioruberins, as major products. They are formed by linkage of two C_5 isoprene building blocks to the ends of a C_{40}-carotenoid[18]. It remains an open question whether lycopene is a joint intermediate of β-carotene (retinal) and bacterioruberin synthesis. A conceivable alternative route is the pathway leading to β-carotene *via* β-zeacarotene as formulated in Figure 2[19].

3.2. Influence of Oxygen and Light on the Pigment Synthesis

In order to minimize interference in the analysis of biosynthetic precursors of retinal, all studies were performed with a mutant of *H. halobium* which does not synthesize bacterioruberins (*H. halobium* R_1M_1). Figure 3 compares the spectra of wild-type bacterial cells and the derived mutant cells R_1M_1. While the absorption bands of the bacterioruberins mask those of all other components in the wild-type cells, the individual absorption bands of bacteriorhodopsin, cytochromes, and lycopene can be recognized in the case of R_1M_1 cells.

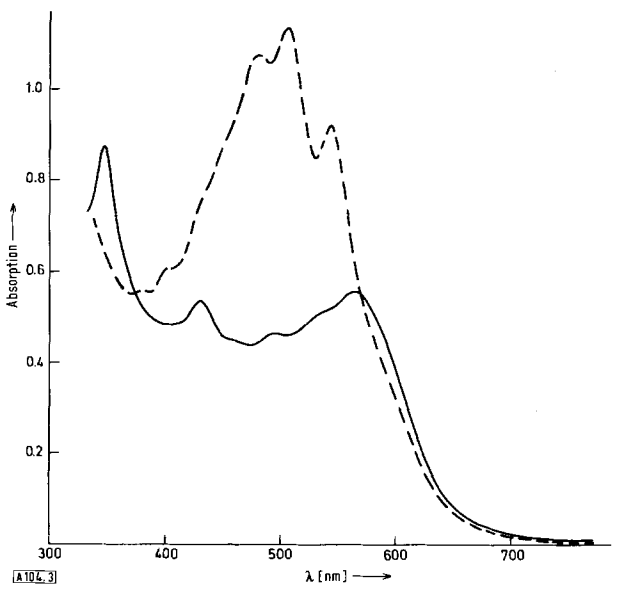

Fig. 3. Absorption spectra of halobacteria cells: wild type cells (– – – –) and R_1M_1 mutants (——).

Determination of the pigments lycopene, β-carotene, and retinal was accomplished by spectroscopy after acetone extraction of cell lyzates. The retinal bound in bacteriorhodopsin is liberated under these conditions and can therefore be determined by the specific color reaction due to *Futterman*[21].

Figure 4 shows the change of concentration of the individual pigments with time in a growing halobacteria culture. The pigment pattern for adequate oxygen supply is shown in Figure 4a, and that for insufficient aeration is seen in Figure 4b. Cells having a sufficient supply of oxygen attain only 10 to 20% of the normal retinal content. The occurrence of retinal coincides with the appearance of the purple membrane in the cells. Optimal synthesis of retinal leads to low concentrations of lycopene, and conversely a low retinal concentration results in a high lycopene level.

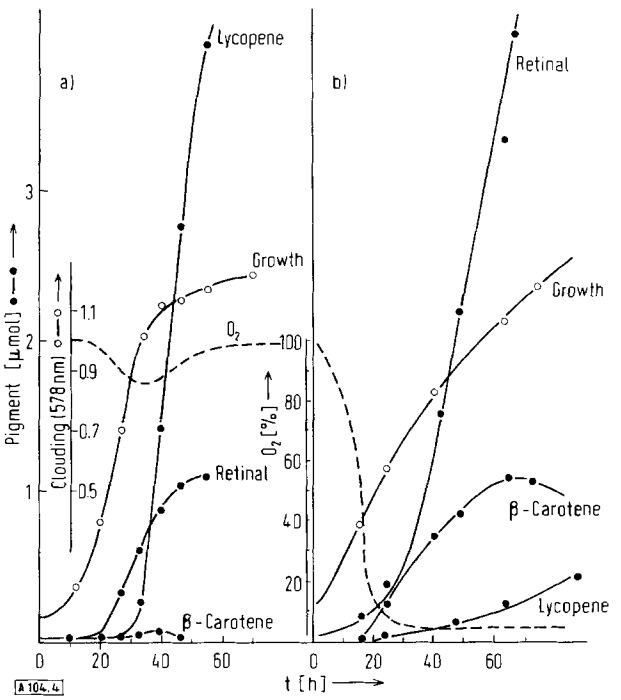

Fig. 4. Carotenoid synthesis in halobacteria under various growth conditions: a, optimal aeration; b, growth-limiting aeration.
The cells were cultured in a 14-liter Magnaferm (New Brunswick) fermenter on a complex medium (250 g NaCl, 20 g $MgSO_4 \cdot 7\,H_2O$, 2 g KCl, 3 g trisodium citrate $\cdot 2\,H_2O$, and 10 g Oxoid Pepton L 37 per liter) with illumination rpm; aeration in case b, 120 liter/h, 300 rpm.
Samples (100 ml) were taken at the times given. The pigments were extracted from the centrifuged cells with acetone/H_2O (9:1) and, after transferring to light petroleum (boiling range 50 to 70 °C), applied to an alumina column (16 g, Activity Grade II–III). Elution of β-carotene: 60 ml 20% ether in light petroleum. Elution of retinal: further 140 ml of the same mixture. Elution of lycopene: 40 ml ether. β-Carotene and lycopene were determined by spectroscopy in hexane solution, and retinal according to ref. [21]. The amounts of the pigments are given for 10 l of cell culture.

In order to examine the influence of light, the experiment depicted in Figure 4 was repeated with dark cultures. The same qualitative result was obtained; however, the β-carotene concentration is about five-fold higher. Part of the β-carotene may be destroyed on illumination; there is no compelling reason to assume intervention of a regulatory phenomenon between the synthesis of β-carotene and that of retinal.

3.3. Synthesis of Bacteriorhodopsin and of Lipids

An interesting question concerns the course of bacterioopsin synthesis with time. Conceivably, bacterioopsin could belong to the constitutive proteins of the cell; that being so it would account for a constant proportion of the protein population

of the cell in each growth phase. Figure 5 shows the protein pattern of whole cells in four consecutive growth phases and correlates it with the occurrence of the purple membrane. While almost all detectable protein species appear qualitatively unchanged the proportion of bacterioopsin increases synchronously with the appearance of the purple membrane even in the stationary growth phase of the cells.

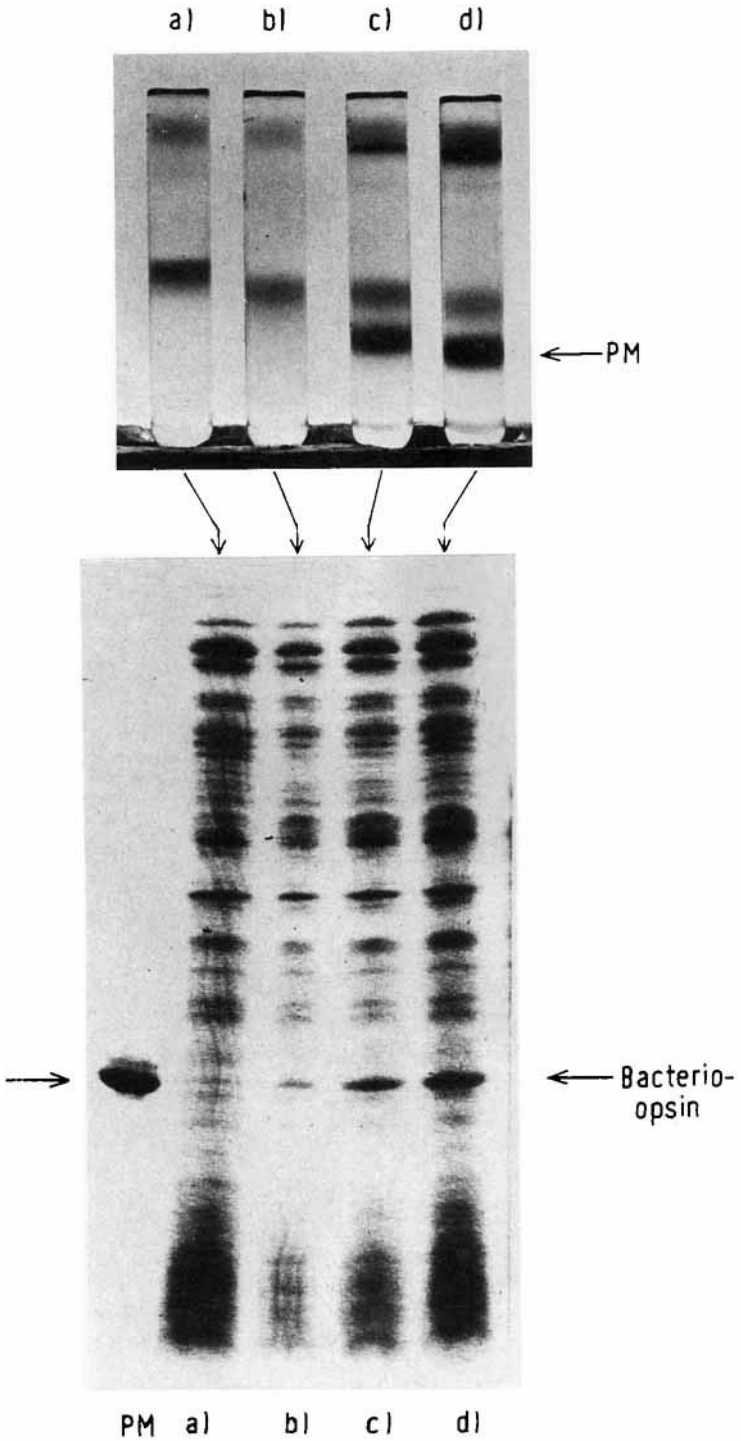

Fig. 5. Analysis of the content of purple membrane (above) and bacterioopsin (below) of halobacteria cells in four consecutive phases of the growth curve (for limiting aeration). a, logarithmic phase (47 h); b, late logarithmic phase (55 h); c and d, early (72 h) and late (101 h) stationary phase.
Equal amounts of cells were lyzed with water, placed on a sucrose density gradient (20–45%), and centrifuged at 200000 g overnight. Aliquots of the lyzate were separated by electrophoresis on polyacrylamide gels (gradient gels: 10–25%) in the presence of 0.1% sodium dodecyl sulfate. Isolated purple membrane (PM) served as bacterioopsin reference.

^{32}P and ^{35}S labeling experiments[22] were undertaken to examine the time-dependent control of synthesis of the purple membrane lipids. It was found that the purple membrane lipids are formed long before the start of retinal and bacterioopsin synthesis, *i.e.* the lipids required for formation of the purple membrane are taken from the lipid reservoir of the cell.

4. Membrane Fractions from Halobacteria

4.1. The Purple Membrane as a Differentiated Membrane Region

The isolated purple membrane contains bacteriorhodopsin molecules in a two-dimensional hexagonal crystalline arrangement[3]. Electron micrographs of intact cells obtained by the freeze fracturing technique demonstrated the same arrangement of bacteriorhodopsin in the cell membrane. Thus according to these studies, the purple membrane also exists *in vivo* as a differentiated insular region of the cell membrane[3]. The genesis of such a differentiated region is an interesting problem. Direct crystallization of bacteriorhodopsin immediately after its incorporation into the cell membrane is conceivable. Alternatively, biosynthetic precursors of the purple membrane might also exist in the form of differentiated regions in the cell membrane. Fragmentation experiments on the cell membrane and subsequent analysis of the fragments may serve to answer these questions.

Those membrane fractions which contain bacteriorhodopsin, bacterioopsin, or one of the biosynthetic precursors of retinal will be of interest in investigations on the biosynthesis of the purple membrane.

4.2. Fragmentation of the Cell Membrane

A drop in salt concentration of the medium leads to lysis of halobacteria, *i.e.* the cytoplasm of the cell is liberated[4]. Membranes are usually fractionated by density gradient centrifugation in sucrose. Density gradient centrifugation of the membrane component of halobacterial cell lyzates in the presence of 0.5 M NaCl affords a principal membrane fraction whose absorption spectrum is depicted in Figure 6. The absorption bands at 340, 419 and 560 nm are due to lycopene, cytochrome, and bacteriorhodopsin. Centrifugation of the same lyzate in the absence of NaCl gives rise to three membrane fractions A, B, C having different absorption properties. Fraction A contains all the lycopene, fraction B all the cytochrome and part of the bacteriorhodopsin, and fraction C (purple membrane) only bacteriorhodopsin. This separation suggests that the cell membrane is made up of differentiated regions.

Table 1 lists some properties of the membrane fractions A, B, and C. Owing to their characteristic colors they are known as red membrane (membrane fraction RM 340), as brown membrane, and as purple membrane.

Membrane fraction RM 340 is characterized by several unusual properties: its protein content lies below 5% of its dry weight; this is the reason for its low buoyant density. A strong absorption at 340 nm is unusual for lycopene. Addition of organic solvents (*e.g.* acetone) drastically

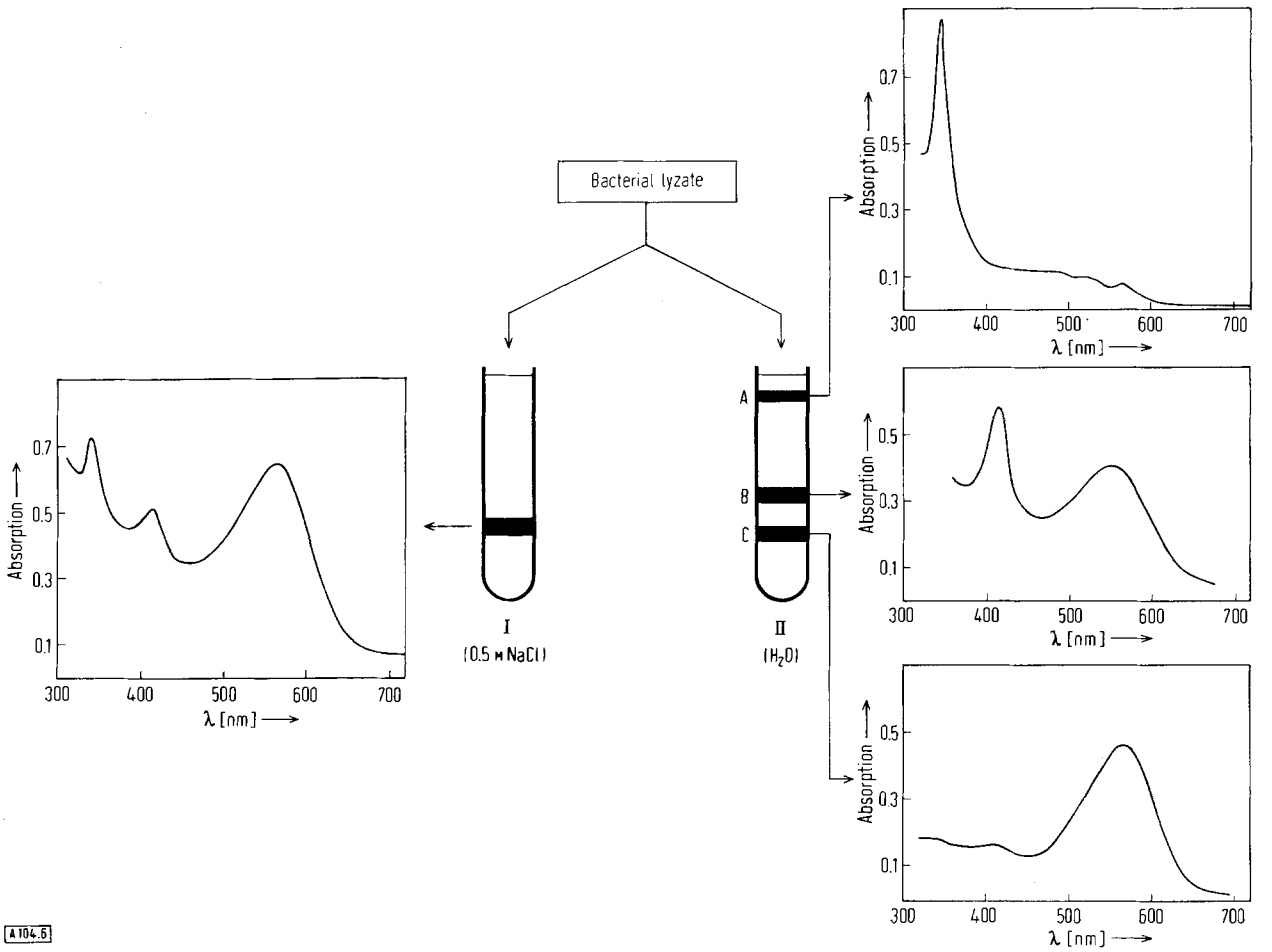

Fig. 6. Fragmentation of the cell membrane at low ionic strength. A cell lyzate was placed on a sucrose density gradient (20 to 45%) with (I) and without (II) NaCl (0.5) and centrifuged at 200000 g overnight. The spectra of the individual fractions were recorded with an Aminico DW2 instrument. A, red membrane; B, brown membrane; C, purple membrane (see text).

Table 1. Some properties of the various membrane fractions A, B, and C (see Fig. 6).

Fraction	Absorption maxima [nm]	Density [g/cm³]	Protein content [%]	Pigment
A: red membrane RM 340	340 (492, 523, 565)	*ca.* 1.06	5	lycopene
B: brown membrane	419, 560	*ca.* 1.14	?	heme, retinal
C: purple membrane	560	1.18	*ca.* 75	retinal

changes the absorption spectrum (Fig. 7); it then corresponds to that of all-*trans*-lycopene. Identity of the pigment of RM 340 and lycopene was further substantiated by its melting point and mass spectrum. The all-*trans* configuration was demonstrated by iodine-catalyzed isomerization to a mixture of the *cis* and *trans* isomers[23].

The unusual absorption behavior of lycopene in the RM 340 membrane fraction is not easy to interpret. The existence of a *cis* isomer in the membrane which transforms into all-*trans* lycopene upon addition of organic solvents appears unlikely: isomers displaying such high absorption in the "*cis* region" and so little in the visible are unknown[23]. It is more reasonable to assume that the lycopene molecule is twisted around its 14–15 and 14′–15′ single bonds (cf. Fig. 2). An *s-cis* conformer of this kind has a rod-like shape in which the π electrons of the central double bond are perpendicular to the π-electron system of the rest of the molecule. This interrupts the conjugated π-electron system containing eleven double bonds: two partial systems result, each containing five conjugated double

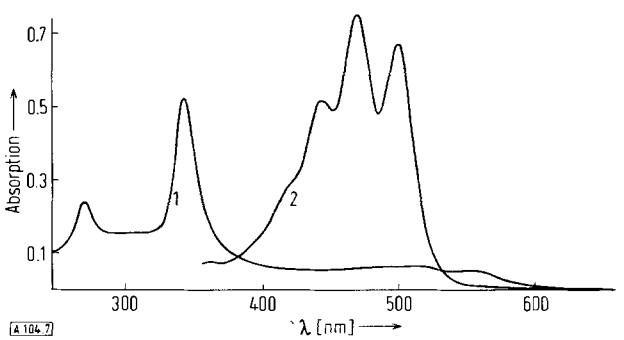

Fig. 7. Detection of lycopene as pigment of the red membrane RM 340. 1, absorption spectrum of RM 340 in water; 2, in acetone.

bonds. Thus the absorption at 340 nm and the high extinction coefficient ($\varepsilon_M = 120000\ M^{-1}\ cm^{-1}$) can be rationalized.

The brown membrane exhibits two characteristic absorptions. That at 419 nm must be assigned to a cytochrome

b type because the heme group can be extracted and as a pyridinium complex shows characteristic absorption bands at 418, 524, and 554 nm in the difference spectrum (reduced/oxidized). All the criteria tested (*e.g.* photochemical properties) indicate that the absorption band at 560 nm should be assigned to bacteriorhodopsin. The bacteriorhodopsin content of the brown membrane is also confirmed by electrophoretic analysis of the proteins present in this membrane. Two major components are obtained, one of which migrates in a manner identical to bacterioopsin and the other probably being the protein component of the heme chromophore.

5. *In vivo* Experiments on Purple Membrane Biosynthesis

All the experiments considered so far show a close correlation to exist between the synthesis of retinal and that of the purple membrane. A strategy designed to detect possible intermediates of membrane formation utilizes specific inhibitors for the synthetic pathways leading to the individual membrane component, *e.g.* inhibitors of protein biosynthesis, carotenoid synthesis, or lipid synthesis.

Table 2. Influence of nicotine on the carotenoid content of halobacteria. Halobacteria were cultured with or without nicotine in the medium. (No change in the growth rate takes place up to 1 mM nicotine.) Concerning the analysis of the pigments in the stationary phase, cf. legend of Fig. 4.

Pigment	Nicotine [mM]			
	0	0.1	0.5	1.0
Lycopene	100%	enhancement 100%–500%		
β-Carotene	100%	<1%	<1%	<1%
Retinal	100%	8%	2%	<1%

Let us now consider the results obtained so far with nicotine, an inhibitor of β-carotene formation. As shown by Table 2, formation of β-carotene in halobacteria is inhibited between 0.1 and 1 mM nicotine in the medium, with a concomitant increase in the lycopene content of the cells (nicotine cells). This result is to be expected from the known fact that nicotine inhibits cyclization of lycopene to β-carotene[24]. If the synthesis of bacterioopsin is regulated by retinal then nicotine must inhibit bacterioopsin synthesis at the same time as that of retinal. However, this is not the case. Bacterioopsin is formed in cells in the presence of nicotine (*i.e.* in the absence of retinal).

The question thus arises as to the localization of the bacterioopsin in the cell membranes of the "nicotine cells". If bacterioopsin behaves like bacteriorhodopsin, then a colorless membrane fraction of equal density and composition has to be expected in place of the purple membrane. The simplest test for bacterioopsin consists in addition of retinal, whereupon bacteriorhodopsin is reconstituted[26]. This method was applied to the membrane fractions of "nicotine cells" after density gradient centrifugation. Surprisingly, the entire bacterioopsin is found in the brown membrane (Fig. 8).

Apparently the brown membrane is a precursor of the purple membrane. Newly formed bacterioopsin occurs initially in the brown membrane and can only "crystallize to form the purple membrane" after reaction with retinal, affording bacteriorhodopsin. This working hypothesis is illustrated in Fig. 9.

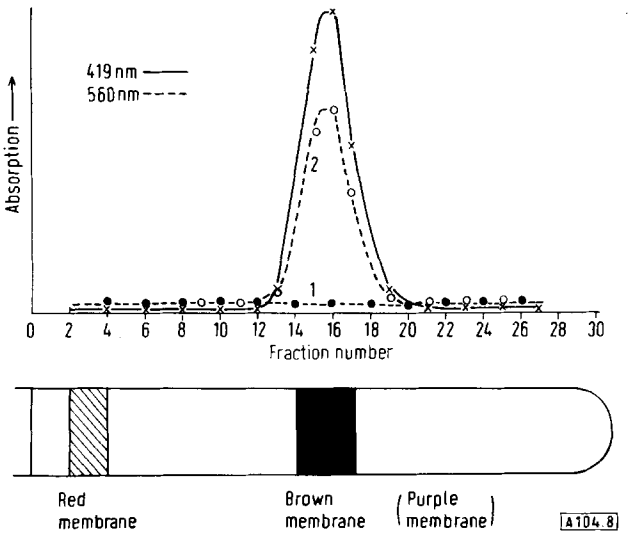

Fig. 8. Detection and localization of bacterioopsin in "retinal-free" cells. The cells were cultured in the presence of 1 mM nicotine with limiting aeration. The membrane fractions were separated by density gradient centrifugation (cf. Fig. 6). The absorption of the fractions were measured at 419 and at 560 nm before (curve 1) and after addition of retinal (curve 2).

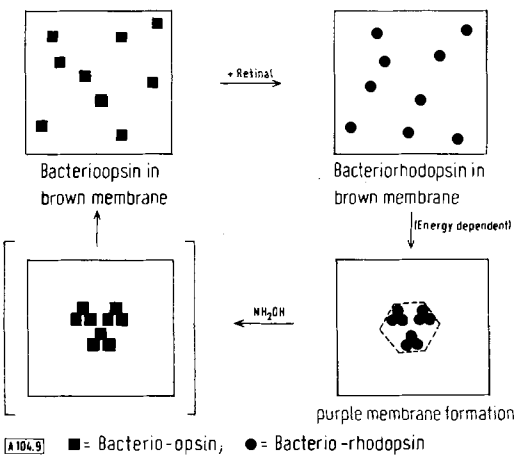

Fig. 9. Schematic representation of a working hypothesis of purple membrane formation.

Addition of retinal to "nicotine cells" should accordingly give rise to purple membrane formation, provided retinal can diffuse into the cell membrane. The feasibility of such diffusion is apparent from Figure 10. In this experiment "nicotine cells" were merely suspended in saturated salt solution (basal salt), *i.e.* without any source of energy, and treated with retinal. Once bacteriorhodopsin has formed the purple membrane should be formed by crystallization. Figure 11a shows that this does not happen, all the bacteriorhodopsin formed remaining localized in the brown membrane. Bacteriorhodopsin clearly does not crystallize spontaneously.

If the experiment of Figure 11a is repeated in the presence of a source of energy, *e.g.* L-alanine, the purple membrane is formed. The energy dependence of purple membrane formation from the brown membrane also followed from the ability of light to serve as energy source for this process in place of alanine. Since light absorbed by bacteriorhodopsin raises

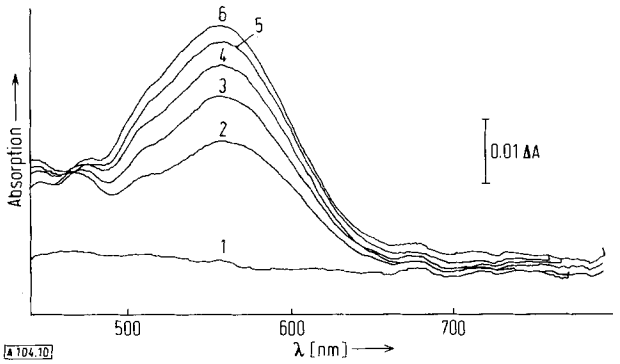

Fig. 10. Reconstitution of bacteriorhodopsin in "retinal-free" cells by addition of retinal.
Cells cultured in the presence of nicotine (1 mM) were resuspended in basal salt containing 1 mM nicotine (250 g NaCl, 2 g KCl, 20 g $MgSO_4 \cdot 7H_2O$ per liter). After treatment of the cell suspension with retinal the difference spectrum was recorded (Aminco DW 2) at various times: 1, before addition of retinal; 2–6, after 11, 18, 31, 77, and 122 min.

the ATP level of the cells it seems an obvious step to assume the occurrence of some ATP-dependent modification of one of the purple membrane components.

on abstraction of retinal from the purple membrane by reaction with hydroxylamine (cf. Fig. 9). X-Ray diffraction experiments indicate that the purple membrane loses its lattice structure on bleaching with NH_2OH and regains it on addition of retinal[25]. Isolated patches of purple membrane necessarily constrain the bacterioopsin to adopt a dense packing so that no change in density is to be expected for the bleached purple membrane (apomembrane); nor has any such change been detected experimentally. In contrast, a lateral diffusion of bacterioopsin in the cell membrane should be feasible in intact cells leading to dissolution of the purple membrane regions (cf. Fig. 9). Confirmation is provided by density gradient centrifugation of the lyzates obtained from cells treated with NH_2OH and analysis of the membrane fractions: the entire bacterioopsin is now located in the brown membrane.

6. Conclusion

The studies described in this article merely represent the first steps toward an understanding of the synthesis and association of membrane building blocks and the regulation of

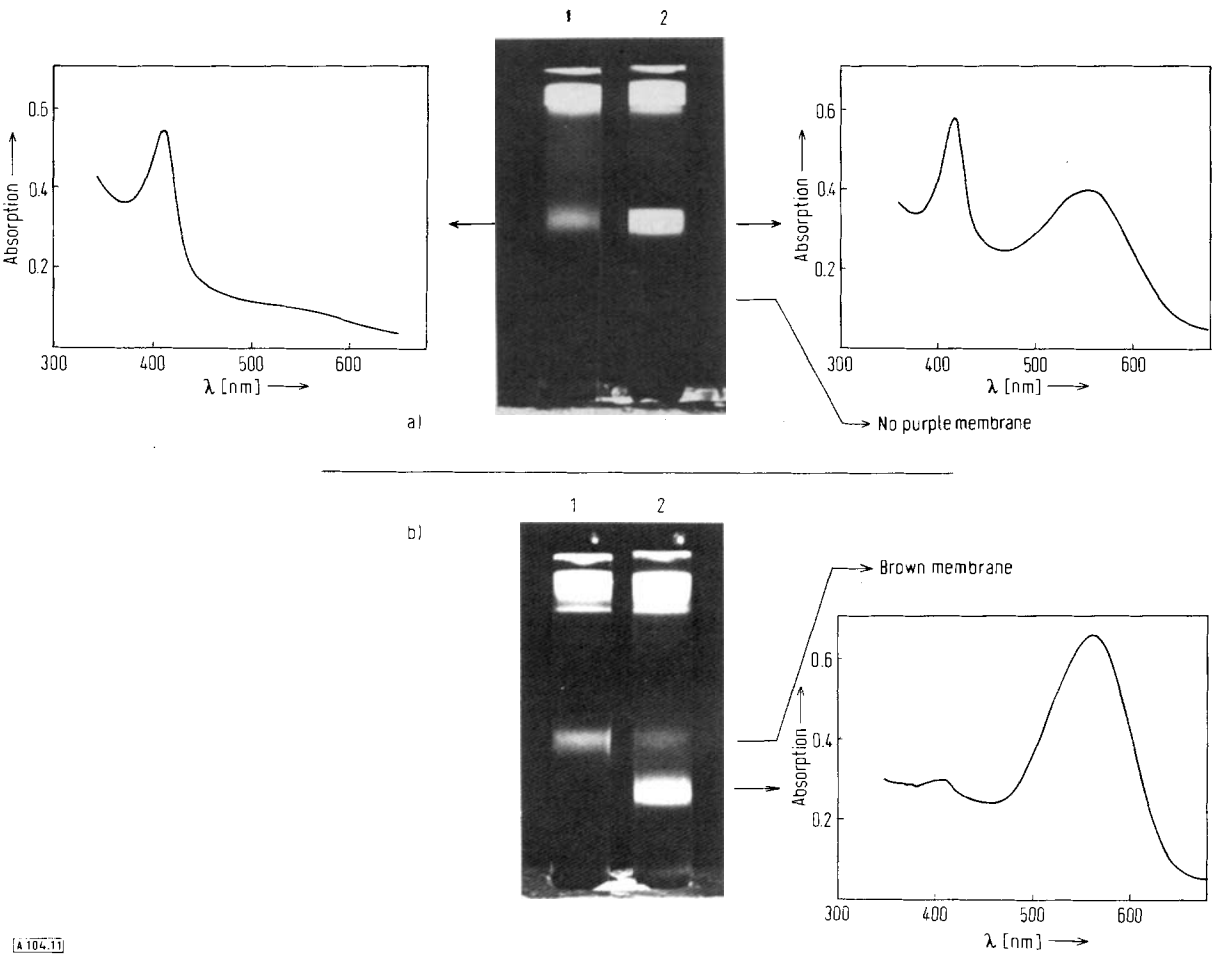

Fig. 11. "Crystallization" of bacteriorhodopsin in the brown membrane to from the purple membrane. a) "retinal-free" cells were suspended in basal salt (containing 1 mM nicotine); one half was treated with retinal and incubated at 40°C for 8 h. (For analysis of the membrane fractions see Fig. 6.) 1, without retinal; 2, with retinal. b) as for a) except for addition of 0.5% L-alanine to the incubation medium. 1, without retinal; 2, with retinal.

As shown by the above experiments, bacterioopsin is not able to form the lattice structure of the purple membrane. Such a property of bacterioopsin should also be detectable such processes. However, they have already clearly demonstrated the suitability of the halobacterial system for experimental work in this area.

We are indebted to Ms G. Herrmann for conscientious assistance and Ms C. Sieber for her patience in preparing the manuscript. Support by the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Neuron Models

By Bernd Hamprecht[*]

Dedicated to Professor Feodor Lynen on the occasion of his 65th birthday

The nervous system is made up of several kinds of cells which should ideally be examined separately in biochemical studies. Since we are not yet able to isolate the different kinds of cells, use is made of cell lines derived from a single cell which are isolated from tumors of the nervous system and which can be reproduced at will in the same way as bacteria. They include cell lines isolated from a mouse neuroblastoma which exhibit some of the properties of nerve cells. Hybrid cells obtained by fusion of mouse neuroblastoma cells with rat glioma cells display even more characteristics of nerve cells. This article considers properties which justify our regarding the hybrid cells as neuron models. Application of the cells to problems of the nervous system is then demonstrated: 1) processing of information arriving in the form of mutually opposing hormonal signals; 2) mode of action of morphine.

1. Introduction

The brain is a complex structure consisting of various cell types. If the cells of the blood vessel system are left out of account, the most important cells are the neurons (nerve cells) and the glial cells; each type comprises about 50% of the cell mass in the brain.

The neurons are joined together by connections called synapses and possess a highly specialized and characteristic structure that can be seen in an electron microscope (Fig. 1). At the synapses information is transferred from one (presynaptic) nerve cell to another (postsynaptic) nerve cell. The membranes of the presynaptic and the postsynaptic cells are separated by a gap. Information is transferred by means of a small molecule (the neurotransmitter) which passes from the presynaptic cell into the synaptic gap when the presynaptic cell is excited. The neurotransmitter diffuses from the presynaptic membrane through the synaptic gap onto the membrane of the postsynaptic target cell. There it becomes bound to highly specific receptors and in that process discharges electric signals into the target cell or suppresses signals that have been evoked by other neurotransmitters in other synapses

on the same cell. Not only the experimentally demonstrated and the potential neurotransmitters [acetylcholine *(1a)*, dopamine *(2a)*, norepinephrine *(2b)*, serotonin *(3)*, histamine *(4)*, glutamate *(5)*, glycine *(6)*, γ-aminobutyrate *(7)*, taurine *(8)*, the undecapeptide "substance P" *(9)*; see Table 1] but also substances that probably act as modulators of neuronal activity [prostaglandins such as prostaglandin E_1 *(10)* and adenosine *(11)*] have been recognized; all these substances are known collectively as neurohormones.

According to the morphology, one differentiates five types in the cerebellar cortex; they are arranged in space in an extremely precise and constant manner and are connected with one another by means of synapses[1]. The neurons can be divided into classes from many different points of view. One possibility is to arrange them according to the type of neurotransmitter that they synthesize and use for the transfer of information, *i. e.* according to their output; thus, one speaks of cholinergic, dopaminergic, adrenergic, and other neurons. They could also be arranged according to the neurotransmitters and neurohormones to which they respond, *i. e.* according to their input. There are probably 20 or more neurotransmitters, neurotransmitter "candidates", and other hormone-like factors[2]. Different combinations of receptors for these substances on the neuron surface could lead to a very large number of different cell types. It is not known whether there

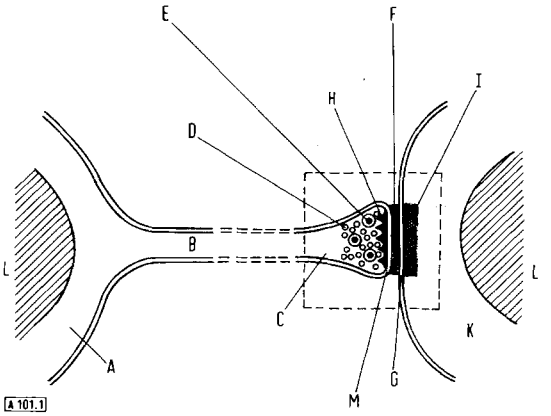

Fig. 1. Diagrammatic sketch of a synapse between two nerve cells. The left-hand, presynaptic nerve cell (A) sends out a cell extension (B) (called a nerve fiber or axon), whose end is thickened to a flask-like shape (C). The nerve ending contains, *inter alia*, a large number of small vesicles which store a neurotransmitter. When the neurotransmitter is acetylcholine the vesicles have a diameter of 500 Å, when it is norepinephrine a diameter of 2000 Å. Because of the electron-transparency of the samples prepared for electron microscopy, the small vesicles storing acetylcholine are called "clear" vesicles (D); correspondingly, the large vesicles storing norepinephrine are called "dense-core" vesicles (E) because of their dark nucleus. The nerve ending is separated from the postsynaptic membrane (G) by the synaptic gap (F) 250 Å wide. The synaptic gap contains proteins which fasten the presynaptic and postsynaptic cells very firmly to one another. In the electron microscope presynaptic and postsynaptic specializations (H and I) are also seen, their functions being, however, unknown. The extent of the synapse is the square marked by a broken line. It should be noted that the relative sizes in the sketch do not correspond to reality: the nerve ending is drawn too large in relation to the two cells, the vesicles too large in relation to the nerve ending, and the gap too large in relation to the vesicles.—K = postsynaptic cell, L = cell nucleus, M = presynaptic membrane.

is a lowest and a highest value for the number of neurohormones to which a single nerve cell reacts, *i. e.* to the number of neurohormones for which the cell can possess receptors on its surface.

Glial cells are divided essentially into two classes, astrocytes and oligodendrocytes. The latter surround the nerve fibers (axons) extending from the neurons in the same way as cable insulation surrounds a cable. Little, however, is known about the function of astrocytes.

The biochemistry of the nervous system can be investigated on tissue sections or tissue homogenates. This, however, only yields mean values averaged for all the cells and it must be taken into consideration that external influences can trigger off chains of interactions between different cells and that constituents previously divided among different cells can occur in one compartment in the homogenate. The observed effects can thus be ascribed to one definite cell type only with difficulty; just as the chemist likes to work with pure substances, so the biochemist wants pure enzymes and "pure cells"; he would like to study each type of cell in isolation and then reconstruct the original complex structures gradually by combination of the various cell types or to create them anew for study. In such investigations methods from the disciplines of biochemistry, cell biology, pharmacology, electrophysiology, and immunology will all prove helpful.

Fractions of cut-off nerve endings, so-called synaptosomes, can be centrifuged off from brain homogenates[3]; after further fractionation, these are particularly well suited for many biochemical investigations.

To learn the properties of individual cell types one can "dissociate" brains into individual cells by enzymes and mechanical forces and separate these cells by centrifuging[4, 5].

The low viability and purity of the enriched neuron or glial-cell fractions limits their use and the information obtainable from the experimental results.

Dissociated brain or spinal cord cells attach themselves from suspensions to the bottom of a Petri dish[6]. Some of the cells then reproduce themselves. By choosing the conditions of the cell culture one can decide whether mainly neurons or mainly glial cells shall survive, but presumably such cultures are also mixtures of various cell types. In mixed cell cultures from nerve and muscle tissues it has proved possible to establish synapses between the neurons and the muscle cells[7-12].

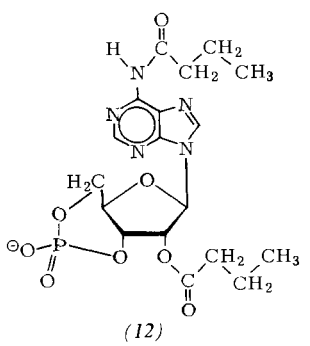
If suspensions of dissociated embryonal brain cells are shaken in small Erlenmeyer flasks for a few days at a specific rate, they reaggregate into structures resembling the original tissue[13-17]. In this process functions of the nervous system are produced that were absent in the embryonal cells[15,17].

2. Neuroblastoma Cells

Another way of obtaining "pure cells" is by isolation and cloning (*i.e.* reproduction of the descendants of a single cell) of cells from tumors of the nervous system. These cells can be cultured like microorganisms in large quantities. They are generally grown as a coating on the bottom of a plastic culture vessel incompletely filled with a culture medium. *Gabriella Augusti-Tocco*, in *Gordon Sato*'s laboratory, was the first to succeed in adapting neuroblastoma cells to culture conditions and to demonstrate that they possessed the differentiated functions of the nervous system[18]. The neuroblastoma was a spontaneous tumor found in a newborn mouse in the neighborhood of the spinal column; it has been further cultured for more than 30 years as a transplantation tumor. Several laboratories have confirmed these experiments and extended them further[19-22]. Currently studies are also in progress with neuroblastoma cells from man[23] and rats[24]. Since the properties of neuroblastoma cells have been summarized in several reviews[6,11,25-27], the present article will be restricted to mentioning only some of their particularly characteristic functions.

2.1. Cell Extensions

Neuroblastoma cells form extensions that resemble nerve fibers[18-20,28-33]. The cells send these out under conditions that are unfavorable for cell multiplication, such as removal



(12)

of the serum from the culture medium[28,34,35], addition of bromo-[36,37] or fluorodeoxyuridine[19], 6-thioguanine[38], cytosine arabinoside[34], or dimethyl sulfoxide[39], production of a hypertonic medium[40], or X-ray irradiation[31]. Formation of such extensions has also been observed in the presence of nerve growth factor[41,42] or a factor produced from glial cells[43], of prostaglandin E_1 *(10)*[33], of dibutyryl cyclic AMP *(12)*[29,30][*], and of inhibitors of cyclic AMP-phosphodiesterase, *e.g.* papaverine[32].

2.2. Excitability of the Membranes

As a further function characteristic of nerve cells, neuroblastoma cells may contain excitable membranes. The excitation may be produced electrically[44,45] or chemically[46-48]. In the former technique a current pulse is sent through the plasma membrane *via* a microelectrode introduced into the cell (Fig. 2). The current is directed so that the interior of the cell,

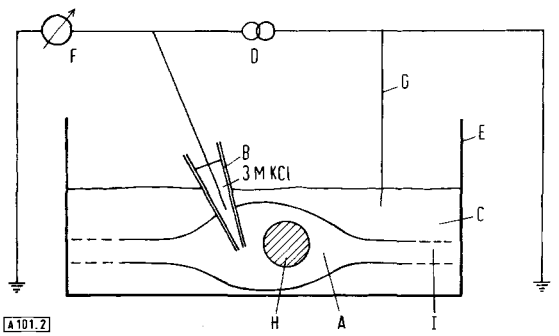


Fig. 2. Principle of the electrophysiological investigation of a single cell in culture. The cell (A) (diameter 0.01 to 0.1 mm) is penetrated by a microelectrode (B). The electrode is a conical glass capillary filled with 3 M KCl, the diameter of its point being less than 1 µm. The potential between the cell interior and the growth medium (C) (which is at ground potential) is called the membrane resting potential, and is generally about −50 mV. This potential can be artificially raised by an external potential source (D) to a value at which, within a few milliseconds, the permeability of the membrane to specific ions is changed dramatically (action potential). The cell and the microelectrode are drawn much too large in relation to the culture dish (E). F = voltmeter (oscilloscope), G = reference electrode, H = cell nucleus, I = cell extension (axon).

which is negatively charged with respect to the medium, is depolarized to a less negative potential; membrane excitation spreading over the cell surface is thereby produced, *i.e.* an action potential. In chemical excitation acetylcholine, which acts as a transmitter at the connections between motor nerves and muscles, is metered out from a micropipette onto the cell surface iontophoretically by short current pulses.

2.3. Neurohormone Receptors

Neurotransmitters can introduce an action potential only if the target cells have appropriate receptors on their surface. On binding to these receptors, neurotransmitters and other neurohormones such as morphine can also produce other effects: they may activate the enzymes adenylate cyclase[49,50] or guanylate cyclase and thus cause an increase in the intracellular concentration of cyclic AMP[51-55] or cyclic GMP[56-60] (Fig. 3). The cyclic nucleotides probably act as intracellular mediators (second messengers) of extracellular hormones[61]

[*] Abbreviations: cyclic AMP = adenosine 3',5'-cyclic monophosphate; cyclic GMP = guanosine 3',5'-cyclic monophosphate; dibutyryl cyclic AMP = N^6,$O^{2'}$-dibutyryladenosine 3',5'-cyclic monophosphate.

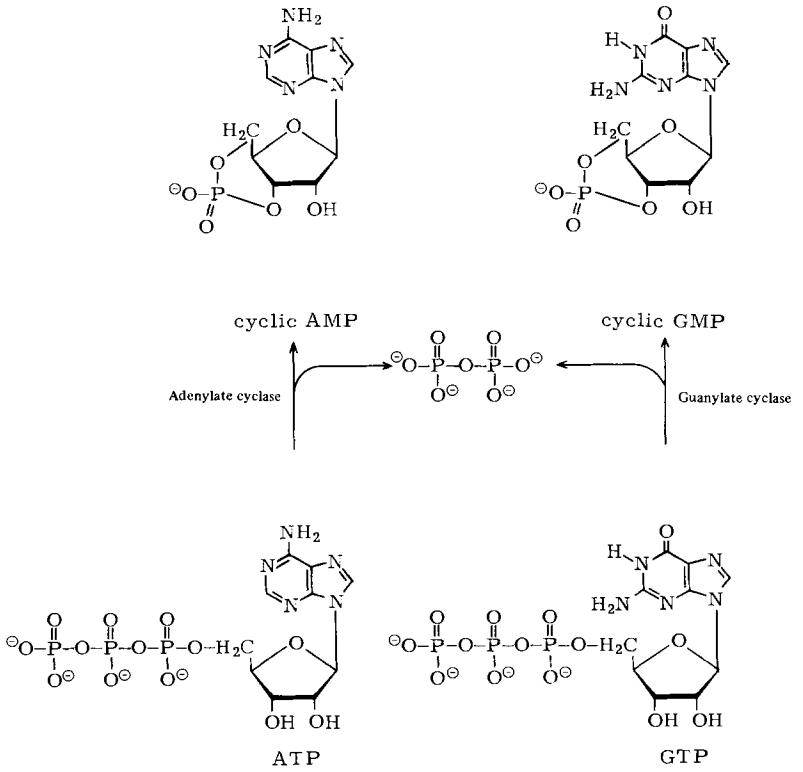

Fig. 3. Formation of cyclic AMP from ATP by the enzyme adenylate cyclase and formation of cyclic GMP from GTP by guanylate cyclase.

This, however, has so far been shown conclusively only for cyclic AMP[62]

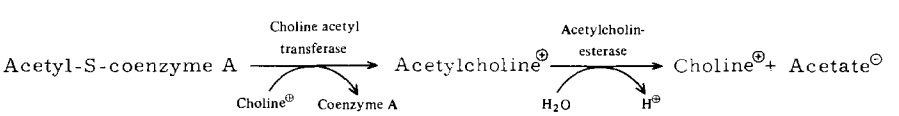
To detect receptors for neurotransmitters (and other hormones) one can also measure the specific binding of radioactively labeled neurotransmitters or their analogs or competitive inhibitors (antagonists) on the plasma membrane. Antagonists are usually favored for such studies because of their high binding constants (which are due to the low dissociation rate constants); the polypeptide α-bungarotoxin isolated from snake venom is such an antagonist for acetylcholine. Nevertheless, binding of α-bungarotoxin to neuroblastoma cells has so far been found possible in only one laboratory[63].

2.4. Transport Systems for Neurotransmitters and Their Precursors

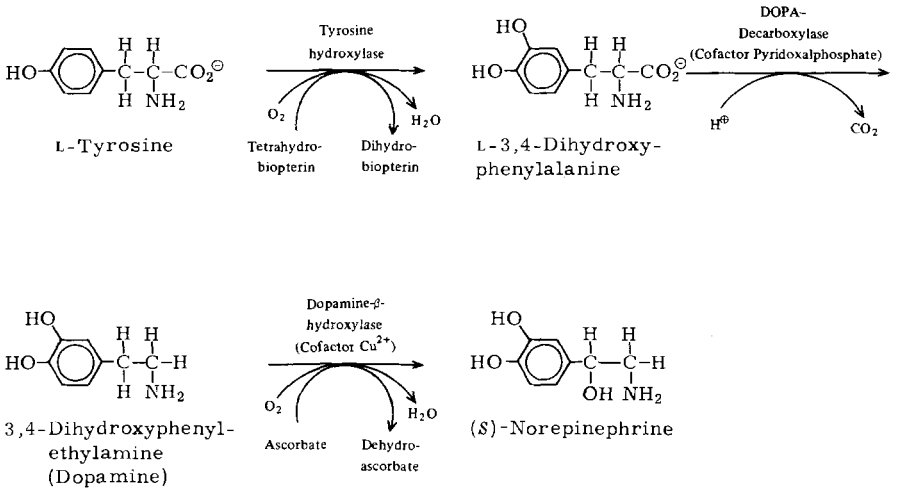
In order to excite the plasma membrane of the postsynaptic cell, the neurotransmitter ejected from the presynaptic nerve cell must be rapidly removed from the synaptic gap; failing this, it accumulates there and transfer of new information by the neurotransmitter becomes impossible. Its removal can be effected in two ways. In the first case the neurotransmitter in the synaptic gap may be changed by enzymes bound to the membrane, *e.g.* cleaved. The best example of this is the inactivation of acetylcholine *(1a)* by hydrolysis in the presence of the enzyme acetylcholinesterase; the choline formed is probably taken up by the surrounding cells (neurons, glia), most of it presumably by the presynaptic cells that had released the acetylcholine. In the second case the removal occurs by reuptake alone; this occurs *e.g.* for norepinephrine *(2b)*, serotonin *(3)*, and histamine *(4)*, and one can thus consider the transport systems for choline and norepinephrine as "differentiated properties" of cells of the nervous system. Neuroblastoma cells also possess such transport systems for choline[64,65], dopamine *(2a)* and norepinephrine[66,67], γ-aminobutyrate *(7)*[68,69], glycine *(6)*[27,70], and taurine *(8)*[70].

2.5. Enzymes Synthesizing Neurotransmitters

Like nerve cells, neuroblastoma cells have the ability not only of reacting to neurotransmitters but also themselves synthesizing such information carriers. They may contain the enzyme choline acetyltransferase [EC 2.3.1.6][18,22,24,71-75] which catalyzes the biosynthesis of acetylcholine (Scheme 1). Other neuroblastoma cells contain the enzyme tyrosine hydroxylase [EC 1.14.3.a][18,22,74,76,77] and dopamine β-hydroxylase [EC 1.14.2.1][78-80], which take part in the synthesis of the dopamine and norepinephrine found in the cells[81-83] (Scheme 2).



Scheme 1. Biosynthesis and hydrolysis of acetylcholine.



Scheme 2. Biosynthesis of dopamine and norepinephrine.

3. (Neuroblastoma × Glioma) Hybrid Cells

3.1. Preparation of the Hybrids

The formation of multinuclear cells by fusion of single cells was known already in the 19th century. In 1960 *Barsky et al.*[84] observed that cells of various mouse strains fuse spontaneously during culture to give hybrid cells whose nuclei contain chromosomes of both parent cells. *Harris* and *Watkins*[85] made use of *Okada*'s observation[86,87] that Sendai virus (a parainfluenza virus) fuses cells to form multinuclear giant cells in high yield, and even united cells of different species, such as man and mouse, by this method. The resulting multinuclear cells are called heterokaryons. Such cells occasionally divide, forming chromatin spindles common to the chromosomes of all nuclei. The resulting daughter cells then contain only one nucleus, this having the chromosomes of both parent cells; they are thus called hybrid cells (Fig. 4). If two cell lines mutated at different enzyme-coding gene positions are used for such hybridization[88], they complement each other in the hybrid to form a wild type[88]. It is then

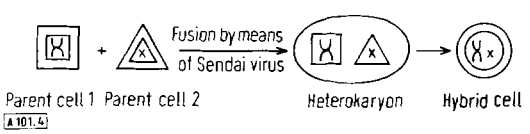


Fig. 4. Scheme of cell hybridization. The difference between the parent cell lines is symbolized by their different shapes. The internal small squares, triangles, and circles represent the cell nuclei. The internal X-shaped structures denote two different types of chromosomes.

only necessary to select in favor of the wild type rather than the mutant in order to obtain a wild-type-like population of hybrid cells. More or less homogeneous cell lines can be obtained by cloning these hybrid cells.

Fusion of a mouse neuroblastoma line (N4TG3 or N18TG2[89-92]) with a glioma line derived from a rat glial tumor (C6-BU-1) gave hybrid cells containing surprisingly high choline acetyltransferase activity; this activity was very low or nonexistent in the parent cells.

The (N18TG2 × C6-BU-1) hybrid clones 108CC5 and 108CC15 in particular have properties of neurons. They will be discussed first below in order to show that they can be regarded as models for nerve cells; it will be demonstrated by two examples how such cells can be studied as models for those cell problems that can be investigated only with difficulty by other methods.

3.2. Neurotransmitter Enzymes

The activity of the choline acetyltransferase can be controlled. It depends strongly on the cell density in the culture and can be increased by culturing the cells in the presence of dibutyryl cyclic AMP *(12)* to values such as are found in brain homogenates[91,92]. The hybrid cells cannot synthesize either dopamine *(2a)* or norepinephrine *(2b)* from tyrosine, because they contain no tyrosine hydroxylase which is the first enzyme in this biochemical pathway (see Scheme 2). The third enzyme of this process, namely dopamine β-hydroxylase, is however present[80].

3.3. Differentiation of Hybrid Cells

If the (neuroblastoma × glioma) hybrid lines 108CC5 or 108CC15 are exposed to a growth medium 1 mM in dibutyryl cyclic AMP *(12)*, their reproduction rate decreases greatly and they begin to differentiate[80,91-93]. In one or two weeks the cells, previously mostly round (Fig. 5A), send out long extensions (Fig. 5B—D). Like the axons of normal nerve cells, these extensions contain fibrous structures, namely 100 Å-long filaments and bundles of microtubules as well as "clear" and "dense-core" vesicles (Fig. 1) with diameters of 500—700 and 2000—3000 Å respectively[93]. The clear vesicles resemble the acetylcholine-storage vesicles of cholinergic nerve endings, but it is not yet known whether in the case of the hybrids they contain the acetylcholine formed in the cells. The dense-core vesicles resemble those of adrenergic nerve cells of the sympathetic nervous system; there they contain, *inter alia*, norepinephrine, the energy-storing substance adenosine triphosphate, and dopamine β-hydroxylase (Scheme 2); we presume that this enzyme is also localized in the dense-core vesicles of the hybrids; the vesicles of the hybrid cells cannot contain norepinephrine, since the first enzyme shown in Scheme 2 for this synthesis chain is missing (see Section 2.5).

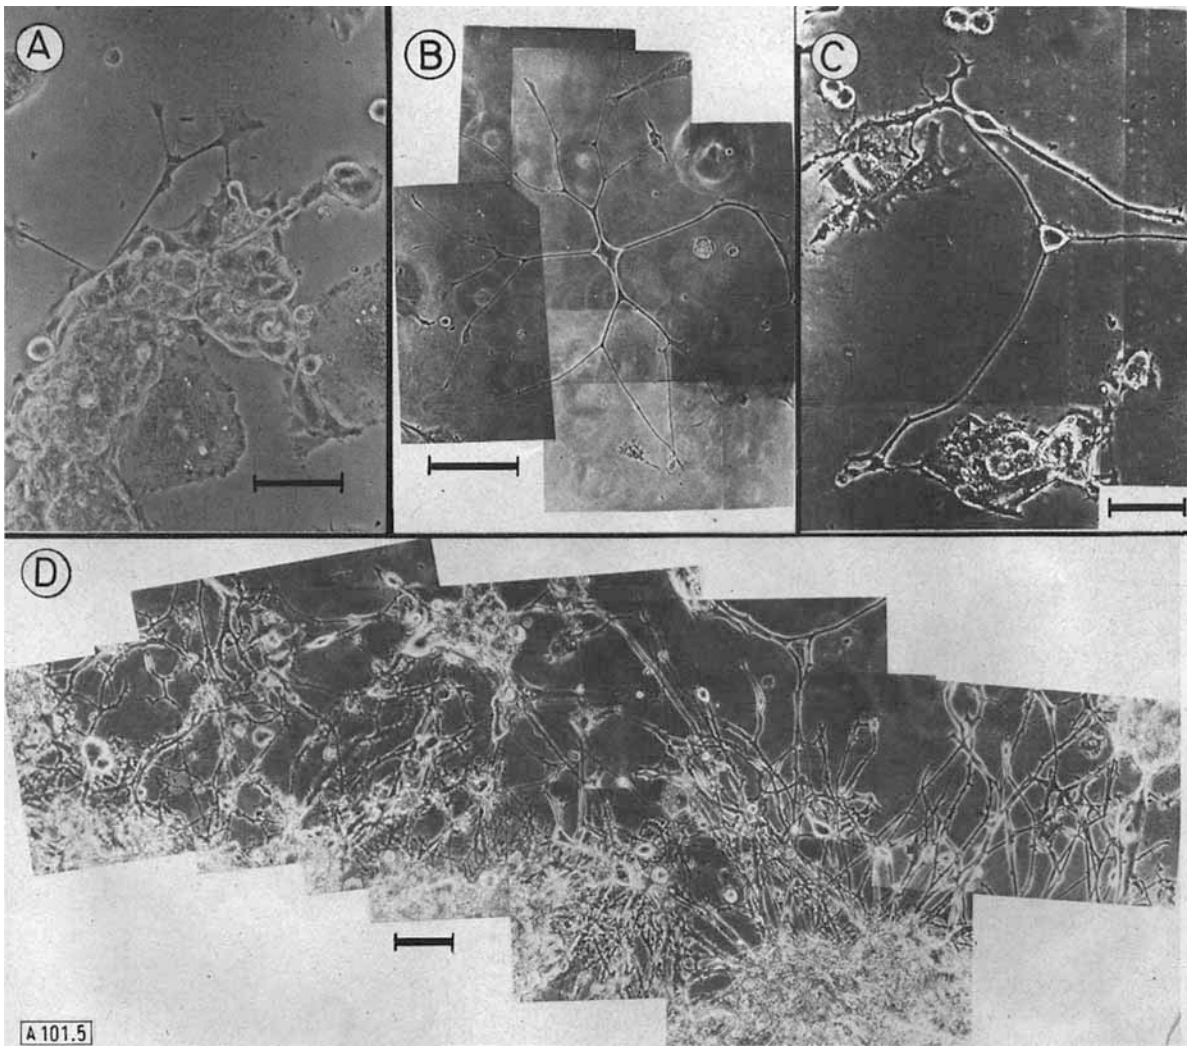

Fig. 5. A: Normal self-replicating (undifferentiated) (neuroblastoma × glioma) hybrid cells 108CC5. B—D: Hybrid cells differentiated by treatment with dibutyryl cyclic AMP. Pictures A [80] and B [80, 91] are reproduced from earlier publications. Scale: 100 µm.

3.4. Electrical Excitability and Cations

If a depolarizing electric pulse is allowed to flow through the plasma membrane of a differentiated hybrid cell by means of a microelectrode placed in the cell interior (Fig. 2), the cell releases an action potential that can be recorded by means of the same electrode (Fig. 6)[91]. The increasing phase of the action potential is generally derived from a passive inflow of Na^+ ions into the cell and the falling phase from a passive outflow of K^+ ions[94].

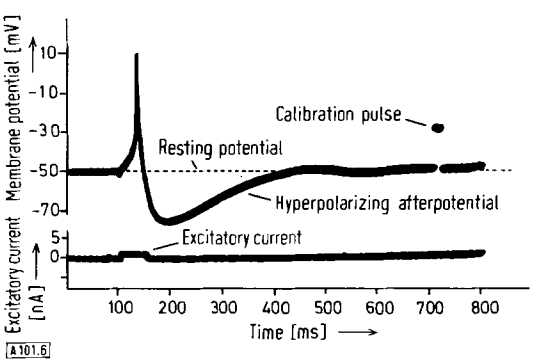

Fig. 6. Oscilloscope traces of an action potential triggered off by a depolarizing excitatory current through the plasma membrane of a hybrid cell 108CC5. Upper trace: membrane potential. A reference pulse of 20 mV and 20 ms duration appears after the action potential. Lower trace: depolarizing current 1 nA and 50 ms [91].

The inflow of Na^+ ions into the hybrid cells can be inhibited by tetrodotoxin, the poison of the Japanese globefish[95]. However, if the Ca^{2+} concentration in the medium is increased, dramatic changes in the electrical properties are observed[91, 95]:

1) Tetrodotoxin no longer inhibits the action potential.
2) Cells that previously had a weakly developed action potential (Figs. 7A, C) now have a well developed one (Fig. 7B) and often respond to a single depolarizing excitation pulse with hundreds of action potentials (Fig. 7D).
3) The excitation threshold for the release of an action potential by an electric pulse or by acetylcholine is greatly lowered.
4) The hyperpolarizing afterpotential of the cells (Figs. 7B, D), which follows on the falling branch of the action potential, is enormously increased.

The insensitivity of the action potential to tetrodotoxin indicates that with an increased Ca^{2+} concentration the inward flow must be of Ca^{2+} and not of Na^+ ions. This assumption was correct because action potentials can also be obtained in the absence of Na^+ provided that sufficient Ca^{2+} is present. Furthermore, these action potentials can be inhibited by the

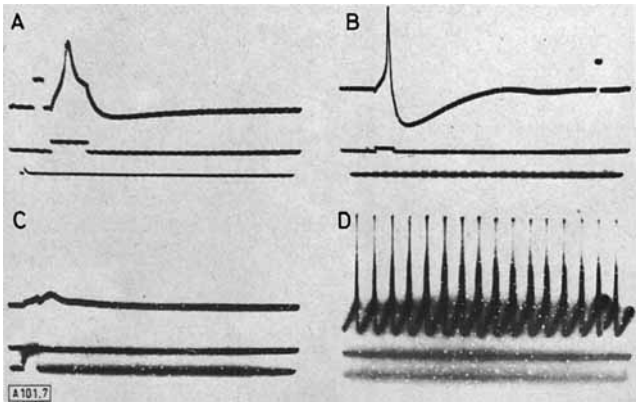

Fig. 7. Effect of increasing the Ca^{2+} concentration in the external medium on the action potential of hybrid cells 108CC15 (A, B) and 108CC5 (C, D). Oscilloscope traces A and C before, and B and D after, the addition of 10 µl (B) or 20 µl (D) of 0.5 M $CaCl_2$ to the medium above the cell under study. D: A single acetylcholine pulse produced a series of more than 200 action potentials, some of which are shown [91].

Ca^{2+} antagonists Co^{2+}, Mn^{2+}, Mg^{2+}, and La^{3+} as well as by organic inhibitors of the Ca^{2+} inflow[95]; the activity and specificity of these substances was proved on other systems having Ca^{2+}/K^+ action potentials.

3.5. Electrical Excitability and Receptors

Action potentials are released if acetylcholine is metered out iontophoretically onto the surface of differentiated hybrid cells[91]. These potentials migrate over the surface of the entire cell. The action of the acetylcholine can be inhibited reversibly by atropine or D-tubocurarine, and irreversibly by α-bungarotoxin[91]. As with skeletal muscle fibers, so with these hybrids high doses of acetylcholine cause transient insensitivity to further acetylcholine[91].

Norepinephrine and morphine[57], as well as dopamine[96,97], also depolarize (Fig. 2) the hybrid cells and trigger off action potentials, whereas prostaglandin E_1 increases the membrane potential (hyperpolarization)[57].

3.6. Neurohormones and Cyclic Nucleotides

Prostaglandins, like cyclic nucleotides, occur in all animal tissues and thus also in the nervous system. They are formed enzymatically from dihomo-γ-linolenic acid or from arachidonic acid. They appear to exert their action locally, *i.e.* in the neighborhood of the cells that produce them. In accord with the functions of the various organs, they influence a considerable number of different processes in the organism[98–101]. A change in the intracellular level of cyclic nucleotides could be one common denominator of the diverse prostaglandin actions. Prostaglandin E_1 *(10)* increases the intracellular concentration of cyclic AMP in the hybrid cells 50- to 100-fold in 10 min[102–105]. Fig. 8 shows that the half-maximal effect occurs at a 20 nM concentration of PGE_1[103].

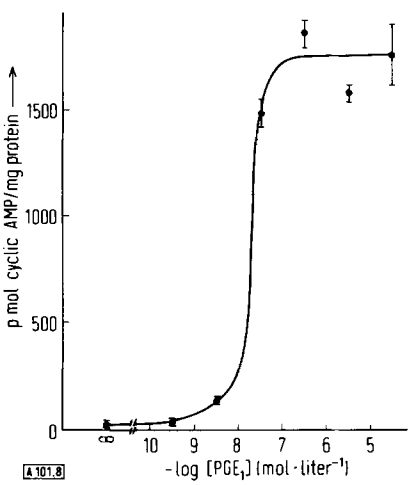

Fig. 8 Dependence of the intracellular concentration of cyclic AMP on the PGE_1 concentration in the medium. Replica plastic dishes containing hybrid cells 108CC15 were incubated for 10 min at 37 °C with increasing concentrations of PGE_1 and then analyzed for their cyclic AMP content [103].

If the cells are incubated with the maximal stimulating concentration of PGE_1 and increasing concentrations of acetyl-

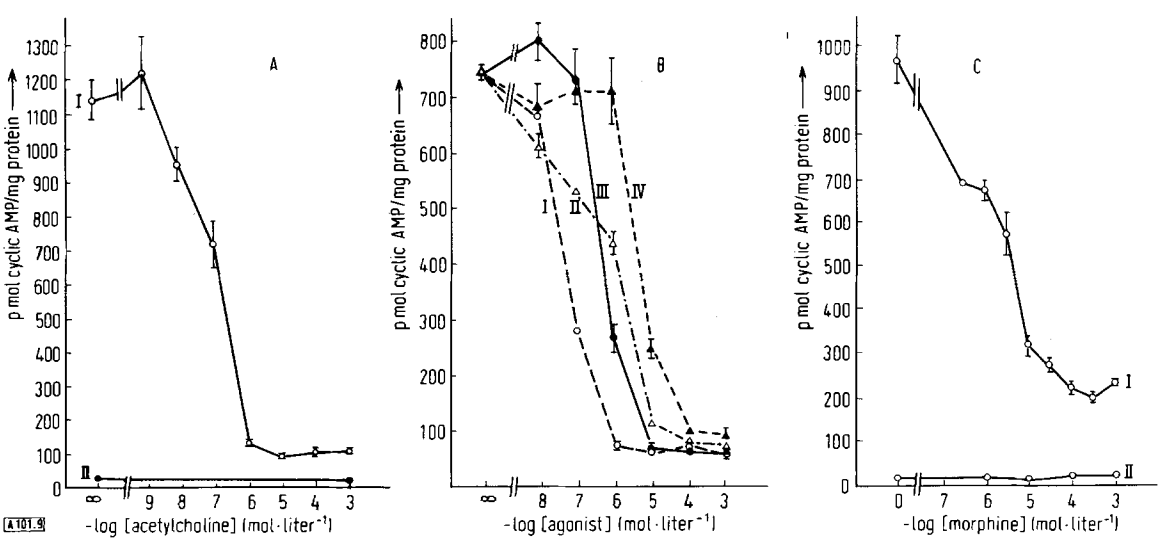

Fig. 9. Inhibition of the increase caused by 3 µm PGE_1 in the level of cyclic AMP in hybrid cells 108CC15 on treatment with acetylcholine (A) [56], adrenergic agonists (B) [57], and morphine (C) [104].—A, curve I: presence of PGE_1; curve II: absence of PGE_1.—B: All experiments in the presence of PGE_1, curve I: norepinephrine *(2b)*; II: phenylephrine *(2d)*; III: dopamine *(2a)*; (IV): isoproterenol *(2c)*.—C, curve I: presence of PGE_1; curve II: absence of PGE_1.

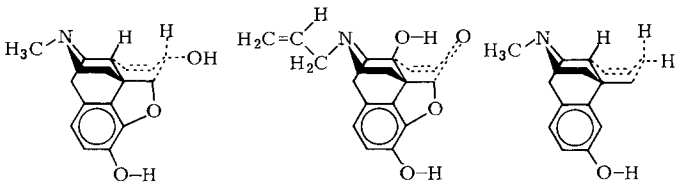
choline[56] (Fig. 9A), or of adrenergic neurotransmitters (agonists) such as norepinephrine[57] (Fig. 9B) or with morphine *(13)*[104] (Fig. 9C), then most of the increase in the level of cyclic AMP does not occur. The action of the acetylcholine (Fig. 9A) can be inhibited by atropine, but not by D-tubocurarine, which indicates the presence of a muscarinic but not of a nicotinic acetylcholine receptor of the hybrid cells[56]. From the fact that norepinephrine *(2b)* is effective at a much lower concentration than isoproterenol *(2c)* it can be concluded that an adrenergic α- but not a β-receptor is present. The results of experiments with specific norepinephrine antagonists support this conclusion[57]. The effect of morphine can also be prevented by a specific inhibitor, naloxone *(14)*[104]. Each inhibitor only prevents the action of the appropriate agonist; thus, naloxone does not inhibit the action of acetylcholine or of norepinephrine[103]. From this and other investigations[106] we conclude that all the receptors of hybrid cells are different molecules. Today there is no doubt that they are proteins[107]. Substances with morphine-like activity, such as levorphanol *(15)*, methadone, heroin, and meperidine, also behave like morphine in hybrid-cell systems[103].



(13) *(14)* *(15)*

The inhibitory action of acetylcholine, norepinephrine, and morphine is not confined to the increase in the level of cyclic AMP produced by PGE_1. Adenosine *(11)* and isobutylmethylxanthine, like PGE_1, increase the cyclic AMP concentration in the hybrid cells[108, 109], the former by increasing the rate of synthesis and the latter by blocking degradation. In both cases the increase in the level of cyclic AMP is hindered by acetylcholine[56], norepinephrine[57], or morphine. From this it is concluded that all three substances decrease the level of cyclic AMP by reducing the rate of synthesis. In agreement with this, measurements of the adenylate cyclase activity of hybrid-cell homogenates have shown that morphine prevents the increase in this activity by PGE_1[110].

These discussions permit two problems to be recognized, to whose solution hybrid cells can contribute:

1) The processing of information reaching a cell in the form of antagonizing hormonal signals.

2) The mechanism of the action of opiates.

Below we shall turn our attention successively to these two questions.

3.7. Biochemical Processing of Hormone-Borne Information

The physiological effects of hormones that increase the cellular level of cyclic AMP are in opposition to those caused by hormones that increase the level of cyclic GMP[111]. Following a proposal by *S. Cha, N. D. Goldberg et al.* considered this dualism to be analogous to the ancient mutually contradictory Chinese principles of Yin and Yang[112, 113]. Our presumption in agreement with these concepts was confirmed by the fact that the decreases in the levels of cyclic AMP caused by acetylcholine, norepinephrine, or morphine and its analogs should be accompanied by increases in the levels of cyclic GMP[58, 59, 114]. Surprisingly, the increase

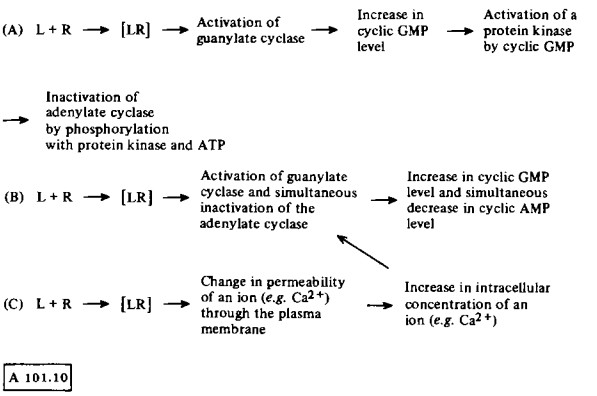


Fig. 10. Three hypotheses for the activation of the guanylate cyclase activity and inhibition of adenylate cyclase activity by binding of the ligands L (acetylcholine, norepinephrine, or morphine) to their receptors R.

in the level of cyclic GMP is of only very short duration. Thus, the maximum of the level of cyclic GMP in the presence of carbamoylcholine *(1b)*, a synthetic analog of acetylcholine, is reached already after 1 min. After about 10 min the values can be back to the original level[58]. Similar observations have been made for norepinephrine and morphine[59]. In all cases the concentrations of cyclic AMP and cyclic GMP take opposing courses. If the level of the former sank below its original value then that of the latter rose above its original level, and *vice versa.*

How can one picture the molecular mechanism of these opposing regulations? On what plane do they occur? Fig. 10 presents three hypotheses. Other groups of investigators came to similar views[115–117]. Further experiments with hybrid cells are required for a decision between these possibilities.

It is striking that acetylcholine, norepinephrine, and morphine, which increase the level of cyclic GMP, have a depolarizing action on the hybrid-cell membrane, whereas PGE_1, which raises the level of cyclic AMP has a hyperpolarizing effect[57]. Similar relationships between PGE_1 and norepinephrine have been found for brown fat cells[118]. These parallels permit the assumption either that depolarization of the cell membrane and activation of the guanylate cyclase on the one hand and hyperpolarization and activation of the adenylate cyclase on the other are linked causally, or that they have a common origin.

Furthermore, it seems important that in hybrid cells the substances acetylcholine, norepinephrine, and morphine which raise the level of cyclic GMP can overcome (*i.e.* dominate) the action of the compounds PGE_1 and adenosine which raise the level of cyclic AMP. The decision between the three hypotheses set out in Fig. 10 is also likely to provide evidence concerning the dominance of the guanylate cyclase system over the adenylate cyclase system.

3.8. Investigations of the Action of Morphine

3.8.1. The Acute Action of Morphine

The contraction of the smooth muscles of the small intestine produced by PGE_1 is inhibited by morphine[119–121]. Since

PGE_1 increases the level of cyclic AMP in neuroblastoma[51, 52] and hybrid cells[102], it became desirable to test whether morphine would also suppress the action of PGE_1 in this system. Experimentally, in intact neuroblastoma[104, 106, 122] and (neuroblastoma × glioma) hybrid cells[106] (Fig. 9C) morphine hinders the increase in the levels of cyclic AMP caused by PGE_1 and inhibits the stimulation of adenylate cyclase by PGE_1 in hybrid-cell homogenates[110] or rat-brain homogenates[123]. The presence of morphine receptors was established not only by these indirect methods but also directly by stereospecific binding of radioactive dihydromorphine to intact neuroblastoma and hybrid cells[105].

The next question is whether *all* cells in which the level of cyclic AMP increases in the presence of PGE_1 react to morphine. Rat glioma cells and (rat glioma × mouse fibroblast) hybrids are elicited by PGE_1 to form cyclic AMP[102]; in no case does morphine inhibit this process[106]. These experiments show that the receptors for PGE_1 and morphine are present independently of one another, and the question just raised must thus be answered in the negative. Since inhibition of the PGE_1 action by morphine is not competitive[102], *i.e.* since PGE_1 and morphine do not compete for the same binding site, the PGE_1 and morphine receptors are not identical. The action of morphine is independent of that of PGE_1. Whatever agent is used to increase the level of cyclic AMP, morphine inhibits that effect[108] insofar as morphine receptors are present.

The inhibiting effect of opiates on the increase in the level of cyclic AMP by PGE_1 in neuroblastoma and hybrid cells is stereospecific. Levorphanol *(15)*, which behaves like morphine in animal experiments, also acts like morphine in the cell system, whereas dextrorphan, which is an enantiomer of levorphanol and inactive in the animal, has no effect on

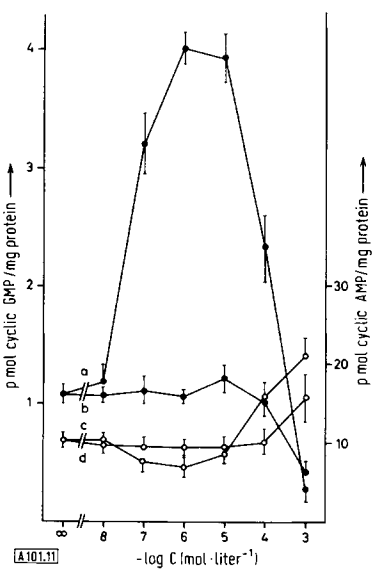

Fig. 11. Influence of the concentration of levorphanol and dextrorphan on the level of cyclic GMP and cyclic AMP in hybrid cells. The cells were incubated for 10 min with levorphanol (curves a and c) or dextrorphan (curves b and d). Curves a and b: cyclic GMP; curves c and d: cyclic AMP [114].

the cell system[57, 110]. Naloxone *(14)* is a morphine antagonist used in cases of morphine poisoning; it has no opiate action itself, although the structure contains the morphinan skeleton. In cell cultures too naloxone inhibits the action of morphine[104, 105]. As mentioned in Section 3.6, an increase in the level of cyclic GMP occurs alongside a decrease in the level of cyclic AMP[114]. Opiates act stereospecifically not only when they decrease the level of cyclic AMP but also when they raise the level of cyclic GMP; levorphanol *(15)*, but not dextrorphan, acts like morphine (Fig. 11, curves a and b). The effect of levorphanol is maximal in the concentration region of 1 to 10 μM (Fig. 11, curve a); at higher concentrations there is a smaller increase, and finally a sharp fall in the level of cyclic GMP is observed; the fall in the level of cyclic GMP is paralleled by a rise in the level of cyclic AMP (Fig. 11, curve c). The importance that cyclic GMP may have for the regulation of the level of cyclic AMP was discussed in Section 3.7.

Neuroblastoma cells and—because of their greater sensitivity to morphine and neurohormones[56, 104, 110]—especially hybrid cells are thus useful models for investigating the biochemistry involved in the action of morphine. It is well known that analgesia is the medicinally important acute action of morphine. On the basis of the studies with model systems it can be assumed that an increase in the level of cyclic AMP is responsible for the feeling of "pain" in the neurons important for registration of pain and that a decrease in the level of cyclic AMP is thus correlated with a decrease in pain or even a strong sensation of well-being.

Like the neurotransmitters acetylcholine and norepinephrine, morphine inhibits the rise in the level of cyclic AMP caused by PGE_1 and increases the level of cyclic GMP. Is morphine then a neurotransmitter? The answer must be "No", because morphine is not formed in the animal body. Morphine could, however, imitate an endogenous neurotransmitter, and in fact this has meanwhile been proved by several groups of investigators. "Endogenous morphine" (endorphine) is a small peptide[*] with a relative molecular weight of 1000 to 2000[124–130]; partially purified endorphine also has morphine-like action in the hybrid-cell system[131]. Furthermore, there is evidence that the hybrid cells produce one or more factors behaving similarly to morphine[132]. An analogy between the action of norepinephrine and that of morphine is also found in the intact animal: when injected into the brain of rats, norepinephrine, like morphine, has an analgesic effect[133]. Naloxone, a morphine antagonist, does not inhibit the effect of norepinephrine. Thus, it can be presumed that norepinephrine does not act indirectly by causing a release of endorphine.

3.8.2. Chronic Action of Morphine; Morphine Tolerance, Dependence, and Withdrawal

Following long-term action of morphine on hybrid-cell cultures some phenomena are observed that can be treated as biochemical correlates of morphine tolerance, dependence, and withdrawal[134, 135]. After at least 15 h of preincubation of hybrid cells with morphine, subsequent main incubation (10 min) with PGE_1 (in the absence of morphine) causes the

[*] *Note added in proof* (April 2, 1976): Meanwhile two such peptides, called enkephalin, have been analyzed and synthesized. Their sequences are H-Tyr-Gly-Gly-Phe-Leu-OH and H-Tyr-Gly-Gly-Phe-Met-OH (*J. Hughes, T. W. Smith, H. W. Kosterlitz, L. A. Fothergill, B. A. Morgan,* and *H. R. Morris*, Nature *258*, 577 (1975)). Synthetic enkephalin shows acute and long-term morphine-like actions on the hybrid cells (*M. Brandt, R. J. Gullis, K. Fischer, C. Buchen, B. Hamprecht, L. Moroder,* and *E. Wünsch*, to be published).

level of cyclic AMP to reach about twice the value it had before the preincubation with morphine (Fig. 12, curve a)[134].

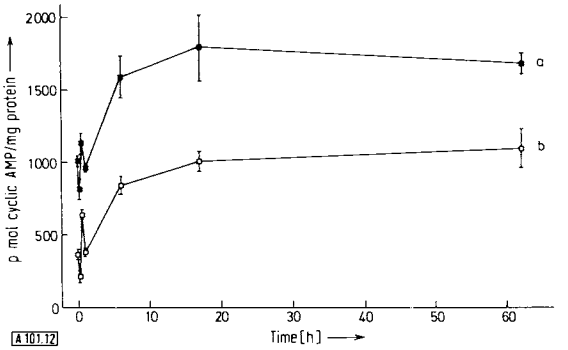

Fig. 12. Time course of the development of the response to PGE_1 during pretreatment of the hybrid cells with 10 μM of morphine. After preincubation times shown by the experimental points the cells were washed and then incubated for 10 min at 37°C with 3 μM of PGE_1 (curve a) or 3 μM of PGE_1 + 100 μM of morphine (curve b) before the content of cyclic AMP in the cells was measured [134].

If, however, the morphine is omitted during the preincubation the reaction of the cells to PGE_1 does not change. After any length of preincubation with morphine (between 0 and 62 h) the effect of the PGE_1 on the level of cyclic AMP is always inhibited by morphine (Fig. 12, curve b).

We regard the hybrid cells as a model of morphine-sensitive cells in the brain. Suppose that the level of cyclic AMP shown by the first experimental point on curve a in Fig. 12 corresponds to the normal finding for man or animal, and that the first experimental point on curve b corresponds to the feeling of special well-being that follows the use of morphine. We can then assume that an increase in the level of cyclic AMP denotes a decrease in the well-being rising to markedly unpleasant sensations. If after chronic administration of morphine and subsequent withdrawal of the drug a constant amount of PGE_1 causes a level of cyclic AMP greater than before the treatment with morphine, this denotes increased ill-feeling (Fig. 12, curve a, *e.g.* $t = 18$ h). Ill-feeling can be converted into a feeling of normality by administration of morphine

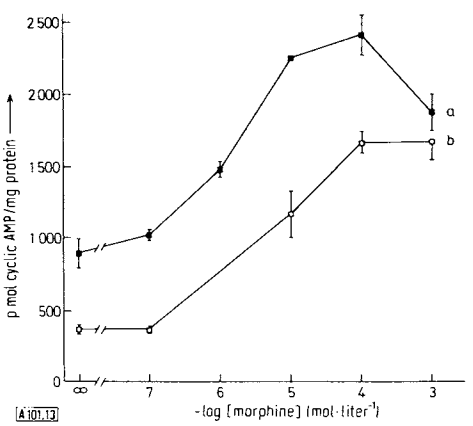

Fig. 13. Relation between the response to PGE_1 and the morphine concentration during a preincubation period of 15 h. After the preincubation the cells were treated as described in Fig. 12.

(transition from curve a to curve b, for example at $t = 18$ h). To produce a pronounced feeling of well-being an amount of morphine must now be taken that exceeds that required at, *e.g.* $t = 0$ (morphine tolerance). Conversely, the transition from curve b to curve a at, *e.g.*, $t = 18$ h corresponds to a withdrawal syndrome. Development of an increased response to PGE_1 depends on the morphine concentration during the preincubation period (15 h) (Fig. 13). The occurrence of morphine tolerance in hybrid cells is hindered by cycloheximide, which is an inhibitor of protein biosynthesis[132, 134]. Such inhibitors also prevent the formation of morphine tolerance in animals[136–138]. We know nothing about the nature of the proteins (*e.g.* adenylate cyclase?) whose synthesis is important for development of the tolerance phenomenon.

Since the short-term effects of acetylcholine and norepinephrine are the same as those of morphine (see Section 3.6), this analogy was also to be expected for the long-term effects. Because of the rapid degradation of acetylcholine *(1a)* and norepinephrine *(2b)* in cell cultures, their stable analogs carbamoylcholine *(1b)* and isoproterenol *(2c)* were used experimentally. Even after preincubation with these agents the hybrid cells showed greatly increased reaction to PGE_1 (Table 2)[134]. It follows that morphine, acetylcholine, and norepinephrine, as well as their analogs, produce the same long-term effects. This equality of action of the three substances does not hold after injection into an animal. Acetylcholine and norepinephrine are degraded in the periphery before they reach the brain. Also, both they and their analogs, unlike morphine, do not cross the blood-brain barrier; thus, they cannot pass on to the neurons. In addition, it should not necessarily be expected that morphine-sensitive cells in the brain possess also receptors for acetylcholine or norepinephrine. The experiments with model cells show that morphine does not occupy any special position and that tolerance can in principle be produced also by other substances.

Table 2. Effect of preincubation (36 h) of hybrid cells with various agents on the level of cyclic AMP that was found after the main incubation with PGE_1 [134].

Preincubation with 10 μM	Main incubation with 3 μM of PGE_1: cyclic AMP (pmol/mg protein)
	1310 ± 50
Morphine *(13)*	2540 ± 230
Carbamoylcholine *(1b)*	2560 ± 60
Isoproterenol *(2c)*	5620 ± 100

How is the short-term action of acetylcholine, norepinephrine, and morphine connected with their long-term action? On their application to the surface ot the hybrid cells the most important result is the binding of the ligands to their receptors. This acceptance, by the specific receptor, of information reaching the cell from outside corresponds to the uptake of information by a radio antenna tuned to a particular frequency. Binding of the ligand L to the receptor R (Fig. 14) presumably causes alterations in its structure that lead to changes in the membrane structure (ΔStr). These in turn result in changes in the ion permeabilities (Δg), which produce the first detectable event, namely an alteration of the membrane potential (ΔU) and of the intracellular ion concentration (ΔC_I). The changes in cyclase activity (ΔA) are noticed next by the change in the concentration of cyclic nucleotides (ΔC_{cNMP}). Finally, after many hours, one finds an increased response of the cells to PGE_1 (tolerance T). What is the course of the causal chain? Perhaps as in Fig. 14A, where a change

in the concentration of the cyclic nucleotide is a prerequisite for the appearance of the long-term effect T? Or as in Fig. 14B, where the change in the ion concentration C_I in the cell causes the long-term effect T, whereas the change in the

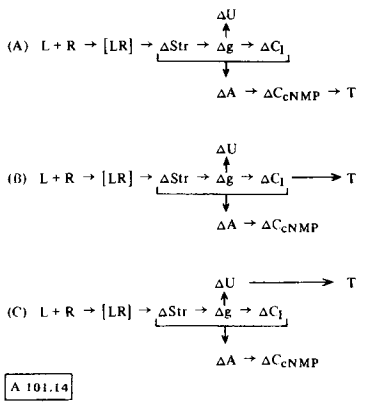

Fig. 14. Three hypotheses for development of the tolerance effect T on long-term action of opiates or cholinergic or adrenergic agonists. L: ligand (agonist). R: receptor. [LR]: ligand-receptor complex. ΔStr: structural alteration of the receptor and/or membrane. Δg: alteration of ion permeability. ΔC_I: alteration of intracellular ion concentrations. ΔU: alteration of the membrane potential. ΔA: alteration of the specific activity of cyclases. ΔC_{cNMP}: alteration of the intracellular concentration of cyclic nucleotides. T: tolerance.

level of cyclic nucleotides (ΔC_{cNMP}) is only a phenomenon running parallel to the development of T? Or as in Fig. 14C, where the change in the membrane potential provides the decisive impulse for development of the tolerance T? All three possibilities could be tested experimentally. In particular, it would seem interesting to exert an influence on ΔStr by changing the lipid composition of the membrane, which could be readily done for cell cultures.

4. Problems that Can Be Studied on the Hybrid Cell System

The first section of this review was devoted to the properties of neuroblastoma cells and of (neuroblastoma × glioma) hybrid cells, including their neuronal "luxury functions" (functions unnecessary for survival of the cells during culture). These characteristics are recapitulated in Table 3. The example

Table 3. Properties of (neuroblastoma × glioma) hybrid cells.

A) Neuronal characteristics:
Cell extensions (neurites)
Choline acetyltransferase
Dopamine β-hydroxylase
Clear vesicles (acetylcholine storage?)
"Dense-core" vesicles (norepinephrine storage?)
Action potential (excitable electrically or chemically)
B) Receptors [a] for:
Acetylcholine *(1a)*
Norepinephrine *(2b)*
Morphine *(13)* (endorphine)
Prostaglandin E_1 *(10)*
Adenosine *(11)*

[a] Insofar as the action of all the listed substances is transmitted through receptors. This list will probably be extended as a result of further findings.

of morphine action will now be used to show that problems almost insoluble by animal or tissue experiments can be brought nearer to solution by the use of model systems. For example, it is not yet possible to isolate specific regions of the brain so rapidly that the levels of cyclic nucleotides are not drastically altered during the isolation procedure, yet that would be essential for animal experiments with morphine of the type described above.

It is repeatedly asked whether the results obtained with cell cultures mirror events in the animal or in man, so that they can be applied to the normal organism. This question is justified, for the culture cells are separated from the surrounding tissue constituents and exist in an environment whose chemical composition may differ in important ways from that in the tissue. In addition, tumor and hybrid-cell lines in particular contain chromosome populations that are not whole-number multiples of a simple chromosome set (aneuploidy); their chromosome number ranges from cell to cell around a mean value. Nevertheless, these cells contain no new information in their genome beyond that present in "normal" cells. It is currently assumed that there is no information in a genome beyond that necessary somewhere in the organism; if that were not so, it would have been eliminated during evolution. If this is correct, then all the molecular functions observed in cell systems must also occur in the animal body at some time and in some place. The environment and aneuploidy can then produce only quantitative, and not qualitative, deviations from the state normal in the animal.

It will always be difficult to correlate a model cell with a specific cell in the body, since the model cell may be unique in its combination of phenotypic characteristics. Such a correlation is, however, not necessary. One chooses a type of model cell simply because it provides the best basis for studying the properties of interest, and the other characteristics presented by it need not necessarily interfere. Hybridization of other permanent neuronal cell lines with one another, or of a permanent cell line with isolated neurons, will probably permit new cell lines containing new combinations of characteristics to be produced; experiments in this direction are in progress[139]. The results of cell-culture experiments must be tested on the intact organism.

Because of the homogeneity and often almost unlimited replicability of cultivated cell material, serial experiments can be carried out, as in bacteriology, with replica cultures. However, cell culture systems are reminiscent not only of the techniques of microbiology. It is pertinent to consider that neuroblastoma cells may be the *Escherichia coli* of neurobiology[26]: animal experiments can be carried out on the basis of experiments with cell cultures in a more controlled manner than is otherwise possible. Behavior of cell cultures that deviates from the norm for the intact tissue need not be a disadvantage. On the contrary, it has already led to the discovery of new regulatory hormone-like factors[140].

Table 4 lists problems for whose solution model systems such as (neuroblastoma × glioma) hybrid cells may, we believe, be helpful. At the head of the list is that most important of the functions of the nervous system, namely memory, and the brief discussion below concerns only that aspect. As described above, cells "remember" in long-term experiments the influence of cholinergic and adrenergic agents or of morphine. Also, the enormous transient increase in cyclic AMP phosphodiesterase activity after long-term incubation with PGE_1[108] can be interpreted as a memory function since, owing to the rapid degradation of cyclic AMP, the subsequent incubation with PGE_1 can effect only a slight increase in the level

of cyclic AMP. Naturally, great care is required here: one could regard every increase of enzyme activity in the liver after injection of hydrocortisone into an animal as the liver cells' "memory" of their "hormonal past". However, there is an important difference between neurons and liver cells: owing to the interconnection of the neurons one can "inquire" about the state of neurons that is altered under the influence of neurotransmitters and this information can be processed

Table 4. Problems that can probably be studied on hybrid cells by biochemical, cell-biological, pharmacological, and physiological methods.

1) Memory: storage, conservation, and recall of information
2) Synapses: formation (neuron-neuron, neuron-muscle, neuron-gland cell), function, cellular interaction
3) Differentiation: triggering and promoting factors (hormones), genesis of neurotransmitter storage vesicles, regeneration of nerve fibers
4) Intercellular communication: neurons with astroglia, neurons with axon-isolating Schwann cells
5) Neurotropic viruses [141]: virus diseases of the nervous system, "slow viruses"
6) Drugs: mode of action, metabolism
7) Neuronal membranes: characteristic constituents, metabolism, influence of the lipid composition of the membrane on membrane functions (action potential, receptors), lipid-protein interaction
8) Neurotransmitters: regulation of the formation and degradation, mechanism of reabsorption
9) Nutrition: influence of the supply of amino acids, sugars, and lipids on the development and function of neurons and glial cells
10) Trophics: controlled growth of nerves, controlled migration of neurons and glial cells
11) Axoplasmic transport
12) Cell movement (pulsation)
13) Constituents of the nervous system with known structure but unknown function

further in the brain. In the most unfavorable case experiments with hybrid cells could show what memory is not, and thus lead indirectly to its clarification.

I am grateful to my critical and industrious collaborators and to reliable and hard-working technical assistants. I am particularly indebted to Professor Lynen for his understanding and great help in building up our working group. My thanks also extend to the Sonderforschungsbereich 51 of the Deutsche Forschungsgemeinschaft for financial support, and to several publishers for permission to use previously published material[56, 57, 91, 92, 103, 104, 114, 134].

A Synthesis of Prostaglandins: Strategy and Reality[**]

By Ivan Ernest[*]

The prostaglandin synthesis developed in the Woodward Research Institute at Basel serves to provide an unusual look behind the scenes. A candid account is presented of the sometimes tortuous chronological sequence of ideas and experiments during work on a challenging synthesis.

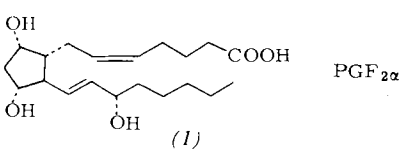
1. Introduction

Fortunately or not, the sober and dispassionate form of today's scientific publications does not leave much room to express or even suggest the creative motivation and atmosphere in which ideas originate and are further developed. To fill that gap with at least one example and in the hope that such an unusual presentation may have a beneficial effect a full insight into the process of design and development of a "classical" synthesis is given in the following paragraphs. For that purpose, our choice fell upon the synthesis of prostaglandins accomplished not long ago in the Woodward Research Institute at Basel. The synthesis, already published as a preliminary communication[1], will not now be presented in the conventional form, *i. e.* as if every step in the final version were foreseen from the very beginning, but rather as a sincere and more or less complete account of the chronological development of ideas and experimentation which finally led to the solution of the problem.

The prostaglandins are a large family of compounds with many promising pharmaceutical aspects: however, the multiplicity of physiological activities, so typical of the individual members, makes their medical application still somewhat problematic and the preference for any single compound very difficult.

Therefore any new synthesis had to be a general synthesis allowing a large-scale production of *any* desired natural prostaglandin. Moreover, it should provide an entry to as large a number of analogs as possible.

Fortunately enough, all known prostaglandins have closely related structures. This facilitates derivation of the common key intermediate for their synthesis. In such a case, the choice of key intermediate is guided by the structure of the most complicated member of the group to be synthesized: This approach maximizes the chance of synthesizing *all* members.



$PGF_{2\alpha}$

(1)

Formula *(1)* shows such a complicated representative of prostaglandins, *i.e.* $PGF_{2\alpha}$. It is not only one of the most interesting and most thoroughly studied members of the whole family from a physiological and medical point of view, but it also represents a great challenge to the synthetic chemist, combining in a single molecule most of the structural elements to be considered in the synthesis of any member of the group. Indeed, it has been shown that once a synthetic route to this compound had been found, the way was open to the other prostaglandins.

The structural challenges of $PGF_{2\alpha}$ are obvious. First there are the five chiral centers, four of them situated in a single cyclopentane ring, the remaining one forming part of a secondary, allylic alcohol grouping. Further, the reader will note two, mutually *trans* oriented, aliphatic side chains each with a double bond, one of which is *cis* disubstituted and isolated in a hydrocarbon chain of a fatty acid, and the other *trans* disubstituted and part of the allylic system in the other side chain of the molecule. The allylic hydroxyl is one of three secondary alcoholic groups, the other two being located, in a mutual *cis* orientation, in the five-membered ring.

The accumulation of a relatively large number of stereochemical elements in a rather simple and poorly functionalized molecule decided the basic character of our synthesis: A highly stereospecific solution of the synthetic problem had to be found.

2. The Dialdehyde *(2a)* as Planned Key Intermediate (The "Cyclooctatetraene Approach")

How was the structure of the common key intermediate of the synthesis to be described here derived from the structure of $PGF_{2\alpha}$? The dividing lines in *(1a)* suggest a dissection of the $PGF_{2\alpha}$ molecule at the sites of its double bonds in a kind of mental retro-Wittig reaction. By this imaginary operation, the prostaglandin structure falls apart into an interesting dialdehyde *(2a)* still containing four of the five chiral centers of $PGF_{2\alpha}$ and two side chain residues which—in the

[**] Based on lecture presented at the "Symposium on Strategy in Organic Synthesis", Louvain-la-Neuve, March 1974.

synthesis—should be affixed to the above fragment by means of appropriate phosphorus ylides. The possibility of constructing the side chains of $PGF_{2\alpha}$ in such a way—an approach having obvious advantages for the synthesis of other prostanoids from the same key intermediate as well—was demonstrated before by *Corey*[2].

However, the famous Corey synthesis does not involve the dialdehyde *(2a)*, but rather a non-aldehydic key intermediate in which the aldehyde groups needed for the Wittig reactions are created separately in the further course of the synthesis immediately before each olefination, one by oxidation of a primary alcohol, which first has to be liberated from a protecting ether linkage, the other by reduction of a γ-lactone.

The idea of designing a synthetic scheme with *direct* formation of the dialdehyde *(2a)*, *i.e.* without the need for any additional oxidative-reductive transformations, was of course tempting. It was obvious that the "upper" aldehyde group, being part of a γ-hydroxy aldehyde system, would very probably exist as a hemiacetal [*(2b)*, R = H], form analogous cyclic acetals with alcohols [*(2b)*, R = alkyl], and might even be forced to enter into an interaction with both hydroxyl groups of the cyclopentane ring to form a tricyclic acetal *(2c)*. Similarly, two bicyclic enol ethers *(2d)* and *(2e)* could result from interaction of the above mentioned aldehyde group with one or the other hydroxyl function, respectively. In all these bi- or tricyclic structures, the two original aldehyde groups would be sufficiently differentiated—a prerequisite for the two Wittig reactions planned.

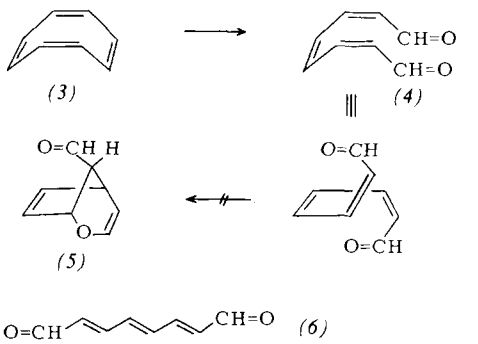
Thus, the dialdehyde *(2a)* or, more properly, its cyclic acetals or enol ethers, seemed to fulfill all the requirements of a good key intermediate:

Each one of these derivatives appeared to be universal for the entire prostaglandin group, as well as for a wide range of analogs;
in each case, most of the stereochemical problems of the synthesis would be solved;
each one of them bore the functions needed for the synthesis, either in their final form or in a form from which they are readily accessible;
they all complied with the useful principle of an internal and mutual protection of functional groups, which not only reduces the total number of synthetic steps and obviates the need for special protecting agents, but also makes the intermediate structures as simple as possible. Moreover, as will be shown later, the principle of mutual internal protection can serve the further purpose of providing excellent stereochemical control in the synthetic operations.

2.1. The Aldehyde *(5)* as Planned Precursor

It was initially proposed to derive a bicyclic, eight carbon atom structure *(5)*, which was very closely related to the desired ones, in two steps from readily available cyclooctatetraene *(3)*. A selective oxidative cleavage, *e.g.* ozonolysis, of one of the double bonds of this hydrocarbon should give all-*cis*-octatrienedial *(4)*, which in turn, in its spiral conformation, should undergo an internal Diels-Alder reaction. This reaction would provide the bicyclic system *(5)* with a cyclopentene ring bridged by an enol-ether grouping. The enol-ether bridge represents the acetaldehyde side chain and one of the hydroxyl groups of the key intermediate C_8-dialdehyde in a mutually protected form securing at the same time their desired *cis* orientation. The stereochemistry of the Diels-Alder reaction would further result in a *trans* orientation of the free aldehyde group to the enol-ether bridge—exactly as desired for our key intermediate. Thus, the five-membered ring of our key intermediate, three of its four chiral centers in correct configurations, three of its four functional groups directly in their proper functionalities, and an additional double bond for an easy introduction of the missing function, a hydroxyl group, would be created in one single step.

The literature supplied some encouraging data for this plan. There was an observation by *Wibaut* and *Sixma*[3] that on ozonization of cyclooctatetraene, the first mole of ozone is consumed faster than the following ones, thus suggesting the possibility of a selective cleavage of only one double bond. And there was a precedent for the Diels-Alder reaction between two unsaturated aldehydes in a cyclodimerization, under special conditions, of methacrolein[4].



In fact, ozonization of cyclooctatetraene at −78 °C with one equivalent of ozone in various solvents proved the correctness of the idea of a selective cleavage of one double bond, but, unfortunately, the experiments also suggested a very low stability of the resulting all-*cis*-dialdehyde *(4)*: its presence in the ozonization product could be proved by NMR spectroscopy, but all attempts to isolate the compound, or even to store the ozonization product, afforded a polymeric material on the one hand, and the much more stable and nicely crystalline, but entirely useless all-*trans*-isomer *(6)* on the other. Under no conditions tried could formation of the desired Diels-Alder product be detected.

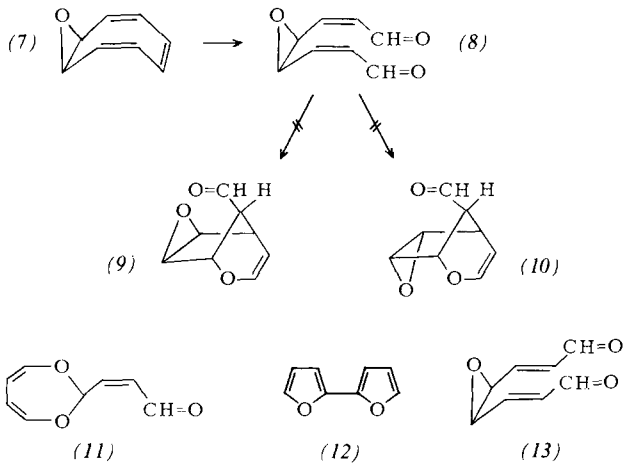
2.2. The Aldehyde *(9)* or *(10)* as Planned Precursor

The original idea, appealing as it was, did not work in the case of compound *(4)*. However, it was too attractive to be abandonded before all its potentialities had been exhausted. Since the instability of the all-*cis*-dialdehyde, obviously inherent in its high degree of unsaturation, seemed to be a major impeding factor, a correction of the initial plan was next suggested which should interrupt the conjugation while still maintaining the dialdehyde molecule in the all-*cis* configuration:

Cyclooctatetraene monoxide *(7)*, a known compound easily prepared from the hydrocarbon by peracid oxidation, should afford, on selective monoozonization, the all-*cis*-epoxydialdehyde *(8)*, hopefully more stable than the intermediate *(4)* first thought of. Besides interrupting the conjugation and keeping the molecule in the right configuration for the Diels-Alder

reaction, epoxidation would introduce the oxygen substituent missing in the original approach.

On the other hand, use of cyclooctatetraene oxide as starting material would incur additional risks: there were now two types of double bonds in the starting material and the ozonization could take place at the wrong site; the Diels-Alder reaction could *a priori* give two different products [*(9)* and *(10)*] of which only one might provide—by cleavage of the epoxide ring—the desired *cis* configuration of the two, 1,3-located, oxygenated functions.



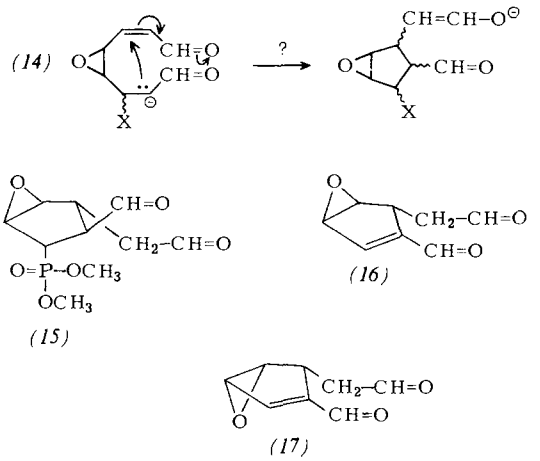
However, we were prepared to take the risks, especially since some of them no longer appeared that dangerous on thorough consideration. For instance, we could deduce that the most probable site of attack by ozone would be, as desired, the double bond most remote from the epoxide ring. This expectation proved to be correct and the new, crystalline all-*cis*-epoxydialdehyde *(8)* was the only defined product and could be isolated in satisfactory yields from the ozonization mixture.

As expected, the epoxy dialdehyde *(8)* was more stable than the conjugated all-*cis*-octatrienedial *(4)*. It could be chromatographed on silica gel and stored at low temperatures; on the other hand, it proved to be a very reactive compound with a special liking for surprising reactions. Thus, on heating at 100 °C in a hydrocarbon solvent, a rather unexpected electrocyclic reaction took place instead of the desired Diels-Alder cycloaddition and the interesting dioxacycloheptadiene derivative *(11)*—a combination of maleic and enolized succinic dialdehydes—was formed.

There were two more escape routes by which the dialdehyde avoided the planned Diels-Alder reaction (for which the orbital overlap in the spiral conformation was probably not very favorable): With acids and with some metal salts (mercuric sulfate), 2,2'-bifuryl *(12)* was formed. And with basic agents such as pyridine or triphenylphosphane, the *cis*-dialdehyde changed to the more stable *trans,trans*-isomer *(13)* (again useless for a direct Diels-Alder reaction).

2.3. The Aldehydes *(15)*, *(16)*, and *(17)* as Precursors

We felt that the *cis-trans* isomerization *(8)* → *(13)* deserved more consideration in spite of the disappointing result. A reversible Michael addition of the base (nucleophile) to the conjugated system of the α,β-unsaturated aldehyde was the most probable mechanism and this raised the question whether a carbanion of the type of *(14)* formed by addition of a suitable nucleophile to one of the unsaturated branches would not attack the other branch in a kind of Michael addition, thus forming a cyclopentane system. In other words: If the one-step Diels-Alder reaction could not be realized, could we not at least achieve a step-wise ring-closure leading to the same or a similar result?



For that purpose, a number of nucleophiles were tried under various conditions on both the *cis-(8)* and the *trans*-epoxy dialdehyde *(13)*. (The *trans* stereochemistry of the double bond should not be restrictive in a stepwise process and a *cis*-to-*trans* isomerization was to be expected anyway under the conditions proposed.)

The first cyclopentane formation was observed with the *cis*-dialdehyde and excess trimethyl phosphite (methylene chloride, room temperature): In a mechanistically not entirely transparent process, dimethyl 2-formyl-3-formylmethyl-4,5-epoxycyclopentanephosphonate of the probable stereochemistry shown in *(15)* was produced in variable yields (40—50 %). The structure of this compound was somewhat reminiscent of that of *(2a)*, but the epoxide ring and the acetaldehyde side chain were *trans* oriented, and the phosphonate group was by no means an ideal substitute for the oxygenated function planned for that position of our key intermediate: The C—P bond was too strong and resisted all attempts at substitution or elimination.

Therefore we were very pleased when on treatment (in tetrahydrofuran or methylene chloride) with alkali *p*-toluenesulfinates in suspension or in homogeneous (dimethylformamide) solutions, both the *cis-(8)* and the *trans*-epoxy dialdehyde *(13)* were transformed to the novel dialdehyde *(16)* (37—42%). Here the nucleophilic reagent was not incorporated into the molecule, and a double bond conjugated to an aldehyde group was ready for the introduction of the missing hydroxyl.

The spectroscopic evidence left some doubts whether *(16)* or *(17)* had been formed, but another finding soon helped to answer this question unequivocally: With piperidine and piperidinium acetate, both epoxy dialdehydes *(8)* and *(13)* gave a stereoisomer of the novel dialdehyde and on comparison of the spectral data of both isomers it became obvious that in the product of sulfinate-catalyzed cyclization the groups were *trans* oriented [*(16)*] and in that of piperidine-catalyzed reaction *cis* oriented [*(17)*].

When compared to the structure of the desired dihydroxy dialdehyde *(2a)*, the isomer *(17)* in particular looked like a promising advanced intermediate. It was only three steps away from cyclooctatetraene and the epoxide ring merely had to be transformed into a—properly placed—hydroxyl group and another oxygen function to be introduced to convert the compound into one of the previously discussed forms of the key intermediate *(2)*.

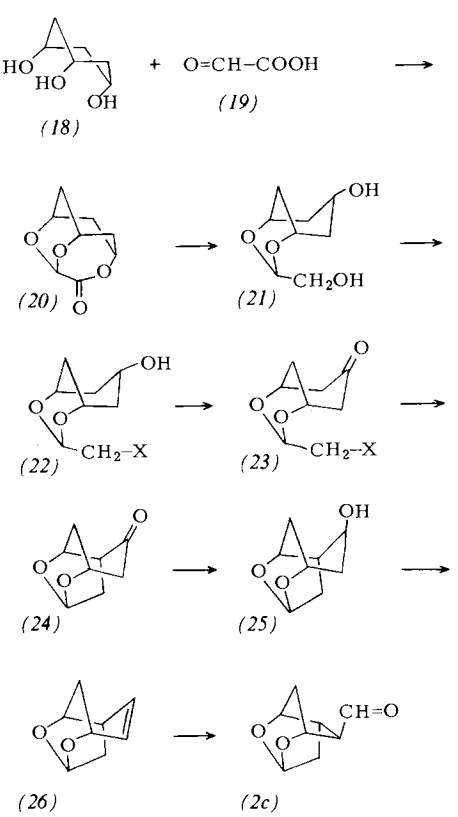
In the introduction to this paper, fairness and openness were pledged and the moment has now come to honor that promise. The good-looking scheme above does not tell much about problems of isolation and varying yields of rather unstable and hard-to-handle intermediates, and, as more and more information accumulated on the chemistry of the cyclic dialdehyde *(17)* the bigger grew the question marks between its formula and those of the desired final products.

At this time an entirely new approach to prostaglandin synthesis was designed as a potential alternative to the "cyclooctatetraene pathway". It soon became clear that this route showed great promise and all efforts were finally concentrated on this chance.

3. The Aldehyde *(2c)* as Planned Intermediate

3.1. Dioxaprotoadamantanone *(24)* as Planned Precursor

In the new approach, the basic concept of prostaglandin synthesis remained unchanged, *i.e.* the same C_8-dialdehyde unit was to be synthesized as key intermediate; however, among its previously discussed forms preference was now given to the tricyclic acetal aldehyde *(2c)*.



The starting materials were again simple and readily available: *cis*-1,3,5-cyclohexanetriol *(18)* (deliberately shown in its rather unusual axial conformation), easily prepared from phloroglucinol by Raney nickel hydrogenation, and the commercially available glyoxylic acid *(19)*. Why these two particular components?

Firstly, any two hydroxyl groups of the symmetrical triol have both the correct mutual 1,3-position *and* the *cis* configuration of the two ring hydroxyls in $PGF_{2\alpha}$ and, consequently, of the two acetal oxygens of the planned key intermediate *(2c)*. Two of the total of four chiral centers of the key intermediate were here "preformed" and the question of stereospecific introduction of the oxygenated substituents—as the reader may recall, a major problem in the cyclooctatetraene approach—was avoided by choosing this starting material.

Further, it was hoped that the six-membered ring of this component could later be contracted to a cyclopentane ring, the one carbon "in excess" becoming the aldehyde group of the key intermediate. For that purpose, the third hydroxyl group of the triol might be a welcome temporary functionality. Moreover, this third hydroxyl was to serve as an *ad interim* handle in the process of joining the triol with the other component.

The other component had to provide the two carbon atoms of the acetaldehyde side chain (protected in the key intermediate *(2c)* as a cyclic acetal). In glyoxylic acid, the aldehyde group was directly available and its notoriously high reactivity augured well for the planned reaction in which its mutual protection with two hydroxyls of the triol would be established. The carboxyl group, which should supply the other carbon of the acetaldehyde side chain, seemed to be, at the outset of the synthesis, an excellent counterpart to the hydroxyl "handle" in the joining process.

In other words, the plan was to combine, with the help of an acidic catalyst, cyclohexanetriol and glyoxylic acid to give the tricyclic acetal lactone *(20)*.

On subsequent reduction of the lactone grouping to the bicyclic, primary-secondary diol *(21)*, the other carbon atom originating from the glyoxylic acid would also reach the right oxidation level needed for the side chain, while the original aldehyde group would stay protected as an acetal.

Next, the side chain needed to be connected with the ring by a carbon-carbon bond. A conceivable way of achieving such a connection seemed to consist in transforming the primary hydroxyl of *(21)*, *e.g.* by a selective tosylation or mesylation, into a better leaving group [cf. *(22)*, $X = OSO_2R$] and oxidizing the secondary alcoholic group to a ketone. In the resulting, symmetrical ketone *(23)*, $X = OSO_2R$, the carbonyl would activate its α-positions for a base-induced intramolecular alkylation by the side chain sulfonate. (Here the reader will finally appreciate the help of the lactone "handle" in the first step of this sequence in securing the right stereochemical orientation of the side chain.)

In this way, dioxaprotoadamantanone *(24)* displaying many structural features in common with the tricyclic key intermediate *(2c)* should be formed. Only a ring contraction of a cyclohexanone to a cyclopentane carboxaldehyde would then be needed to complete the synthesis of the latter.

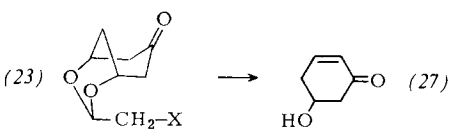
A number of methods were *a priori* available and there was no special preference for any one of them in the original plan, except that some restrictions were expected in connection with the general acid-lability of acetals (the same was true also for the preceding reactions). Of course, some possibilities were considered more often and as more promising than

others and our flow-sheet depicts, in rather general terms, such a "somewhat preferred" scheme: Reduction of the tricyclic ketone to dioxaprotoadamantanol *(25)*, a (probably two-step) elimination to the corresponding tricyclic olefin *(26)*, and, finally, a one- or multi-step ring-contraction of the latter to the cyclopentanecarbaldehyde derivative *(2c)*.

Let us now turn our attention to the first experimental results of this approach: an optimistic start and the first difficulties.

As expected, when cyclohexanetriol *(18)* and glyoxylic acid *(19)* were heated in a suitable solvent (*e.g.* glyme) in the presence of an acid catalyst (Amberlyst 15), a complicated multifunctional reaction process took place from which the nicely crystalline trioxahomoadamantanone *(20)* resulted as the only isolable product in a yield of more than 85 %.

The lactone grouping of this novel compound could be easily reduced by a number of agents, but best of all by sodium tetrahydridoborate in ethanol, in almost quantitative yield to the bicyclic primary-secondary diol *(21)*. In full agreement with the plan, the reactivity of the two hydroxyl groups in *(21)* proved to be sufficiently differentiated for a highly selective tosylation of the primary alcohol. The crystalline monotosylate *(22)*, X = OTs, resulting in good yield on treatment of the diol in pyridine (−20 °C) with slightly more than one equivalent of tosyl chloride, was next oxidized by chromium oxide-pyridine complex in methylene chloride to the, again nicely crystalline, bicyclic ketone *(23)*, X = OTs (92 % yield).

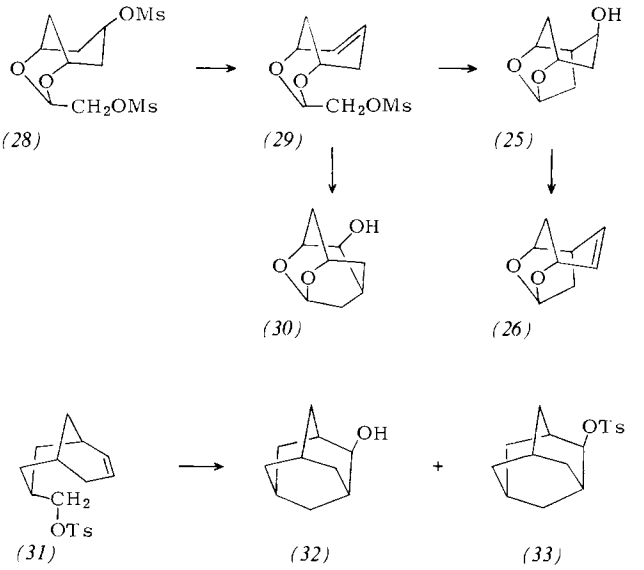


However, when the latter compound was treated with various basic agents (potassium *tert*-butoxide in *tert*-butanol or in glyme, 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in benzene, solid sodium carbonate at 250 °C/0.5 torr, *etc.*) to initiate the desired intramolecular alkylation, a feared alternative reaction, namely elimination of the alkoxy-type substituent from the β-position, took place and, instead of the tricyclic ketone, a rather trivial cyclohexenone derivative *(27)* was obtained. Thus, the new plan badly needed correction.

3.2. The Olefin Mesylate *(29)* as Precursor

It seemed conceivable to transform the diol *(21)*—*via* a ditosylate or dimesylate *(28)*—into a bicyclic olefin monosulfonate *(29)* and to use the latter as substrate in a solvolytic reaction, in the hope that the π-electrons of the double bond would participate in the process and thus provide a carbon-carbon bond between the ring and the side chain. The literature supplied several examples of such a π-route to polycyclic systems, the closest one to our case being that described by *Raber*, *Kane*, and *Schleyer*[5]:

The unsaturated bicyclic tosylate *(31)*—a carbocyclic analog of the olefin-sulfonate *(29)*—when hydrolyzed in 80 % aqueous acetone at 25 °C afforded 95 % of 2-adamantanol *(32)*, along with 5 % of 2-adamantyl tosylate *(33)*, the reaction being 10^4 times faster than the solvolysis of the corresponding saturated compound under otherwise similar conditions.



Another, even more amazing manifestation of the propensity of the unsaturated compound *(31)* for cyclization was its spontaneous transformation into 2-adamantyl tosylate *(33)* in deuteriochloroform at 6 °C.

As already mentioned, the geometry of our olefin mesylate *(29)* would be very similar to that of the substrate *(31)* including even the right orientation of the side chain for a reaction with the double bond. Consequently π-participation in solvolysis was to be expected even here. However, an open question was what effect the two oxygen atoms would have both on the rate of solvolysis and which of the doubly bonded carbon atoms in *(29)* would become involved in the new carbon-carbon bond. The latter question was especially important for our plans.

Schleyer's case exemplifies the preference in carbocyclic chemistry for the unstrained adamantyl system; the exclusive formation of 2-adamantyl derivatives suggested that, whatever the steric and polar effects of the two oxygen atoms in our substrate might be, dioxaadamantol *(30)* would be an unstrained compound and hence warrant consideration as a possible solvolysis product of *(29)*.

Of course, this direction of bond formation would by no means be ideal for our purpose, since the side chain in the key intermediate *(2c)* should be connected to the carbon *next* to the oxygen-substituted ring member, but again, there were carbocyclic examples available of how to convert a 2-adamantyl derivative into protoadamantene, *i.e.* into a carbocyclic analog of the tricyclic olefin *(26)* of our synthetic scheme.

Moreover, we could expect that in our olefin mesylate *(29)* the inductive effect of the oxygen in the allylic position to the double bond might reverse the mode of addition observed in the carbocyclic system in the desired sense by concentrating the π-electrons at the closer carbon of the double bond and thus increasing its nucleophilicity. The same effect should also destabilize the otherwise stereochemically preferred 2-adamantyl carbonium ion and lead to the same result, *i.e.* formation of the dioxaprotoadamantyl alcohol *(25)*.

Let us once more turn our attention from the plan to experimental reality. This time the adjusted scheme worked perfectly: The bicyclic dimesylate *(28)*, the product of a high-yield reaction of the diol *(21)* with excess mesyl chloride in pyridine, when treated with basic agents under various

conditions, afforded the desired olefin mesylate *(29)* in invariably good yields.

Here a small practical note is timely: For the latter elimination reaction we tried a large variety of bases, the fancy ones such as DBU in dimethyl sulfoxide or tetrabutylammonium fluoride in dimethylformamide first, only to find later that potassium hydroxide in isopropanol did the job just as well and that five minutes' refluxing with this inexpensive reagent afforded *(29)* simply and in excellent yields.

The very first solvolysis of the olefin mesylate in boiling aqueous potassium carbonate—a simple experiment attended by much excitement—substantiated our expectations: it was gratifying to isolate the nicely crystalline dioxaprotoadamantanol *(25)* as by far the major product of the reaction. A thorough analysis later revealed about 5—8 % of the less desirable isomeric dioxaadamantanol *(30)* in the crude alcoholic product, thus showing that the difference in the energies of activation of the two competing ring closures was only small. However, the presence of the isomer *(30)* did not cause any practical complications; it could be easily removed in the course of the following steps.

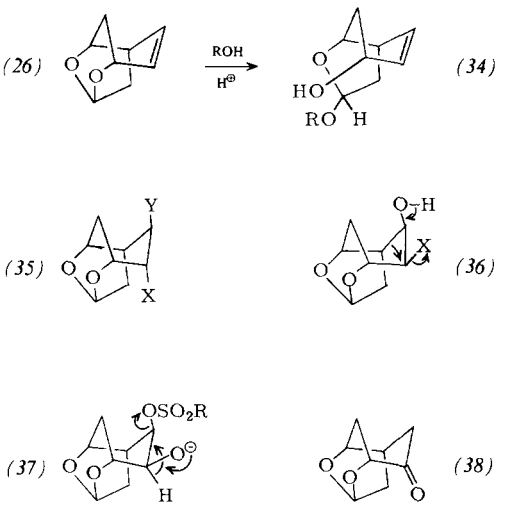
Dioxaprotoadamantanol *(25)* was the second chiral compound in our sequence—the first one was the olefin mesylate *(29)*—but it was the first one suitable for a resolution. For this purpose the racemic alcohol was converted into a diastereomeric mixture of esters of (+)-ketopinic acid, from which the less soluble (−)-diastereomer could be obtained pure on repeated crystallization from ethyl acetate in a yield of 78 %. The positive Cotton effect displayed by the corresponding ketone proved the levorotatory alcohol obtained from the ester diastereomer mentioned by alkaline hydrolysis to have the absolute configuration shown in *(25)*. It was the configuration needed for the synthesis of natural $PGF_{2\alpha}$. (From this point on, the synthesis was followed on two lines, both with racemic and with optically active materials.)

The tricyclic alcohol *(25)* was transformed in two simple operations—mesylation and elimination with KOH in isopropanol—into the corresponding olefin [dioxaprotoadamantene *(26)*] in an overall yield of 88 %. At this point, the reader will appreciate that the correction of the original scheme was not just an inconvenient emergency solution: It abbreviated the route to *(25)* by one step and the yields of all steps up to the olefinic compound *(26)* were excellent.

3.3. The Planned Ring Contraction of Dioxaprotoadamantene *(26)* to *(2c)*

The tricyclic olefin *(26)* was a chemically very interesting compound; however, not all of its reactions were desirable or useful for its final ring contraction to *(2c)*. Thus, the obviously strained cyclic acetal system of *(26)* proved to be extremely sensitive toward acids. Even trace amounts of aqueous or alcoholic acids opened the tricyclic system to form the corresponding bicyclic hydroxy hemiacetal *(34)*, R = H, and hydroxy acetals *(34)*, R = alkyl, respectively. With acids in the absence of any hydroxylic agent, insoluble polymeric material was immediately formed, obviously by a similar mechanism. This pronounced instability toward acids was certainly one of the reasons why a "direct" ring contraction of the tricyclic olefin *(26)* with thallium salts failed under various conditions.

A number of electrophilic agents such as bromine, bromonitrate, iodoazide, dichlorourethane, *etc.* added to the double bond of the dioxaprotoadamantene *(26)*, most of them in a both highly stereo- and regiospecific way, to give diaxial products of the common structure *(35)*.



The preference for diaxial products, although perfectly understandable, was by no means favorable for the planned ring contraction. As documented by many examples, a ring contraction of a 1,2-disubstituted cyclohexane can take place only when the leaving substituent is *equatorial* and thus antiperiplanar to the migrating C—C bond.

Only one addition reaction among those we tried afforded a promising adduct in this respect: Hydroxylation with osmium tetroxide giving the crystalline *cis*-diol *(36)*, X = OH, in an acceptable yield of about 55 %.

It could be expected that, on treatment with one equivalent of a sulfonyl chloride, only the equatorial hydroxyl of this diol would react to give a product *(36)*, $X = OSO_2R$, ideally suited for a ring-contracting elimination.

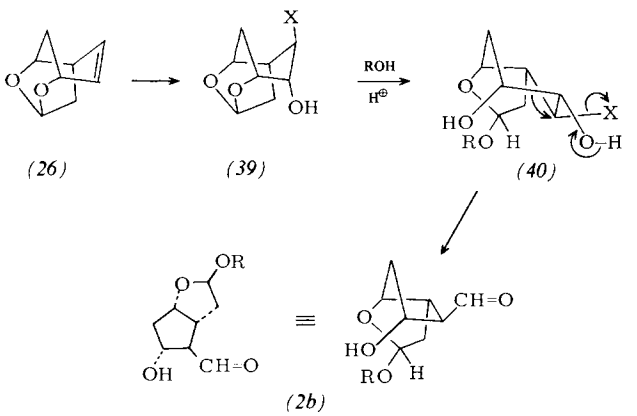
The first part of the plan was easy to implement: Even with an excess of brosyl chloride in pyridine, only the equatorial monobrosylate *(36)*, $X = OSO_2C_6H_4Br$, was formed in an excellent yield. However, when the compound was solvolyzed in boiling aqueous glyme in the presence of potassium carbonate, or on treatment with potassium *tert*-butoxide in *tert*-butanol, a rather unexpected product was obtained instead of the desired *(2c)*: the tricyclic cyclohexanone derivative *(38)*.

What could have happened here? The desired ring contraction, perfectly permissible from a stereochemical vantage point, would develop a temporary positive charge on the "brosylate carbon" and was thus obviously impeded by a destabilizing negative inductive effect of the neighboring acetal oxygen [an effect we have already met in the preferred formation of our dioxaprotoadamantanol *(25)*]. This probably opened the way for a less usual, but not entirely unknown reaction, *i.e.* a sulfonyl transfer from one oxygen to the other. In the isomeric brosylate *(37)* thus formed, the above-mentioned inductive effect was no longer operative and elimination of the sulfonate group with a hydride shift from an antiperiplanar position took place, resulting in the formation of the ketone *(38)*. It was also conceivable that an increase in the steric strain was another factor disfavoring a ring contraction.

If we summarize the accumulating experimental evidence at this point, the tricyclic olefin *(26)* would appear as a uniquely unsuitable intermediate: all its characteristic features—steric strain, destabilizing polar effects, acid-lability, preference for diaxial adducts—seemed to oppose our ring contraction plans.

4. The Aldehyde *(2b)* as Key Intermediate

If we did not want to give *(26)* up as an intermediate, it was necessary to change our approach to it. It occurred to us that the following scheme or one like it could provide a solution to this problem.

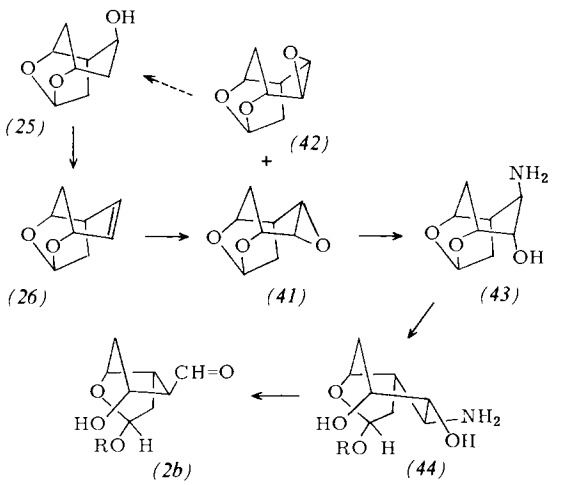


A diaxial adduct of the common formula *(39)* was needed in which X would be either a good leaving group or a function easily convertible into a good leaving group. It was obvious from molecular models and from experimental evidence on model compounds that, if we then opened the tricyclic system of such a derivative the cyclohexane ring, forced in the rigid original system of *(39)* into its boat conformation, would be able to assume the much more preferred chair form *(40)* with both substituents (X and OH) flipping into equatorial positions. Ring opening of this kind by acid-catalyzed alcoholysis has already been mentioned in Section 3.3 in connection with the tricyclic olefin *(26)*.

An elimination of X could then proceed with migration of the antiperiplanar carbon-carbon ring bond thus producing a cyclopentanecarbaldehyde with the aldehyde group in a *trans* position to the other three substituents. In other words: an excellent bicyclic key intermediate already considered previously [*(2b)*] would be formed. In this way, the hitherto hostile properties of the tricyclic olefin *(26)*, *i.e.* formation of diaxial adducts, easy acid-catalyzed cleavage, and the trend to diminish rather than to increase the ring strain, would all be used to our advantage. The following paragraphs will show how this idea was transformed into reality.

When treated at room temperature with a methanolic solution of benzonitrile and hydrogen peroxide in the presence of solid potassium hydrogen carbonate[6] the tricyclic olefin *(26)* was converted into a mixture of two crystalline stereoisomeric epoxides in which the desired *endo* isomer *(41)* was the major component. Since the *exo*-epoxide *(42)* could be easily separated by alumina column chromatography and returned to the synthetic scheme by lithium tetrahydridoaluminate reduction to the tricyclic alcohol *(25)*, its formation did not involve any appreciable loss of material. It is interesting to note that with *m*-chloroperbenzoic acid in methylene chloride or in chloroform, the ratio of both epoxides was reversed and mainly the unwanted *exo* isomer *(42)* was formed.

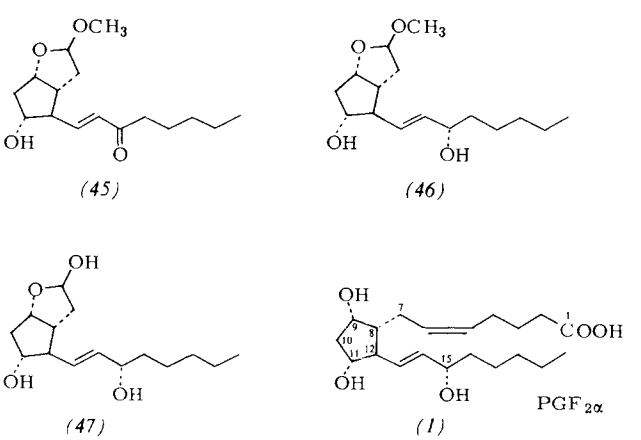
The *endo*-epoxide *(41)* was next heated at 100°C for 2h with concentrated aqueous ammonia. As a consequence of



the rigid conformation of the substrate, the epoxide ring was opened regiospecifically and a single product, the crystalline diaxial amino alcohol *(43)* was isolated in a yield of more than 90%.

When a solution of *(43)* in an excess of methanolic hydrogen chloride was stirred at room temperature, a crystalline hydrochloride soon started to precipitate and was finally obtained in quantitative yield. Its elemental analysis and spectral behavior were in full agreement with the structure of the bicyclic amino diol acetal *(44)*, $R=CH_3$. A large increase in the value of the vicinal coupling constant between the hydrogens on the two carbons bearing the OH and NH_2 groups [from $J\approx 0$ in *(43)* to $J=11$ Hz in *(44)*] was convincing proof for the expected conformational change, the original equatorial position of these two hydrogens having become axial.

As a pleasant consequence of this conformational change, the next step took the expected course: Diazotization of the hydrochloride of *(44)* dissolved in dilute aqueous acetic acid (containing some sodium acetate) with an excess of sodium nitrite afforded the desired key intermediate *(2b)* in yields of 80—85%. Unfortunately, if by no means surprisingly, this crucial intermediate of our prostaglandin synthesis was the only noncrystalline compound of the whole sequence to this



point and, as a rather unstable β-hydroxy aldehyde, unsuitable for further purification. However, both its spectral and its chemical behaviour unequivocally confirmed its structure.

The acetal aldehyde *(2b)* fulfilled our expectations as a useful intermediate for the prostaglandin synthesis. Thus, when it was heated at 60 °C in glyme with 1-(triphenyl- or 1-(tributylphosphoranylidene)-2-heptanone, a crystalline unsaturated ketone was formed in yields of 75—79 %; elemental analysis as well as all spectral evidence pointed to the structure *(45)*. The ketone was reduced with zinc tetrahydridoborate to an approximately equimolar mixture of the diol *(46)* and its 15β-epimer. Both isomers were separated by column chromatography and the unwanted β-epimer recycled by manganese dioxide oxidation to the enone *(45)*.

Both epimeric diols were characterized by spectral data and by nicely crystalline and well analyzing bis-*p*-nitrobenzoates. The racemic diols had been prepared by an entirely different sequence in 1970 by *Corey* and *Noyori*[7] and the 15α-epimer *(46)* converted into DL-$PGF_{2\alpha}$.

Adopting the procedure of these authors for the last two steps we first hydrolyzed the acetal function of *(46)* to the corresponding hemiacetal *(47)* using a dilute hydrogen chloride solution in aqueous acetonitrile (or glyme). And. when the crude hemiacetal was treated at 50 °C with an excess of ω-(triphenylphosphoranylidene)pentanoate in dimethyl sulfoxide. racemic or. in case of the optically active starting material, dextrorotatory prostaglandin $F_{2\alpha}$ *(1)* were obtained in yields of about 80 %. Both the spectral and chromatographic behavior of our synthetic products as well as the optical rotation of the dextrorotatory compound were in agreement with the published data for DL and natural $PGF_{2\alpha}$.

Thus, after somewhat less than a year of concentrated effort, the desired objective of the synthesis of prostaglandins was successfully achieved. As the present report shows, the way was not always straight and smooth. However, the proper choice of the key intermediate, the flexibility inherent in the synthetic conception, and the consequential and creative adaptation of the plans to new, experimental experience made the final solution of the synthesis possible without sacrificing any of its aspired features: high stereospecifity, low number of synthetic steps, avoidance of special protecting operations, simple and easily accessible starting materials, simple reagents, simple, efficient and easy-to-perform reactions.

Chemical Ecology— A Chapter of Modern Natural Products Chemistry[**]

By Hermann Schildknecht[*]

The chemical reaction of arthropods to their environment, *i.e.* their chemical ecology, can be studied particularly well with water beetles. *Stenus comma*, an aquatic beetle weighing only 2.5 mg, saves itself from drowning with the aid of an alkaloid, and the water beetle *Ilybius fenestratus* defends itself against small mammalian predators with a compound belonging to the same class. The water beetle *Platambus maculatus* employs a diterpene for precisely the same purpose and the whirligig beetle a norsesquiterpene, which also offers protection against troublesome microorganisms. As chemical artists, the ants can hardly be surpassed. In particular, the myrmecine ants guarantee their food supplies with plant growth substances. Since these compounds, depending upon concentration, can also act as inhibitors, we are confronted with an excellent example of an ecological equilibrium being established with the aid of organic chemicals. Even the little parasitic bombardier beetle *Paussus favieri* is tolerated, on account of its defensive chemistry, in the nest of the myrmecine ant *Pheidole*. In contrast, inorganic compounds are largely responsible for the stability of spiders' webs.

1. Introduction

The ability of living creatures to adjust to the world in which they live, to shape and maintain their *Lebensraum* and to propagate therein is a consequence of aeons of development, during the course of which all organisms have come to terms with reality[1].

The result is an optimal adaptation of fungi, plants, and animals to their environment—both on the level of cellular development and on the level of morphogenesis—which is characterized by pronounced interaction between the individual species and its environment. The entire field of science concerned with the relations of an organism to its surrounding

external world, to the organic and inorganic conditions of its existence, was designated ecology by *E. Haeckel* over a century ago[2]. As in all areas of life, chemically defined substances will play a role here—if they are known then we are justified in speaking about "chemical ecology". Chemical ecology attempts to interpret biological phenomena in terms of chemical compounds, and to answer the question "wherefore?". However, this only became feasible with the advent of methods for isolating, purifying, and analyzing minute quantities of natural products, *i.e.* methods permitting comprehensive analysis.

One of the most interesting and instructive biotic communities is the biocenosis in and around bodies of water, *i.e.* where life most probably originated and developed. In the course of millions of years, just as elsewhere in the biosphere, an equilibrium state was reached with regulatory processes which protect the way of life of, *e.g.* insects against interfering effects of widely differing kinds. Thus water is directly and indirectly an essential component of the biotope of animals living on the banks of stagnant or flowing water; however, it becomes highly dangerous if they cannot swim.

2. Chemical Ecology of *Stenus comma*

While hunting for springtail on the banks, the strangely blue-green colored staphylinid *Stenus comma*, measuring some 5 mm (Fig. 1), sometimes loses its grip in a light breath of

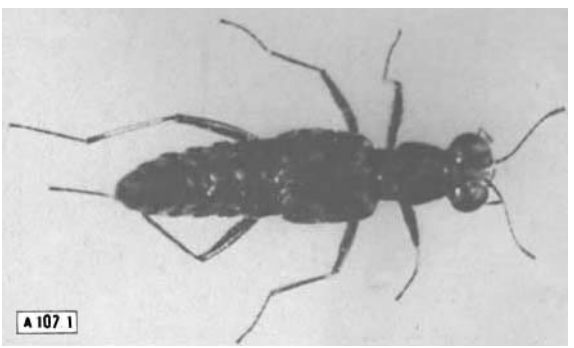

Fig. 1. *Stenus comma*.

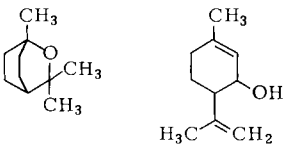
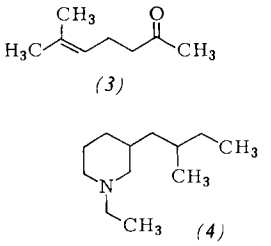
wind—after all it only weighs 2.5 mg—and falls into the water. With a great effort it can keep itself above water by crawling and would reach the bank with great difficulty—or not at all if it were caught in a current and driven further away from land—if it were not able to move over the surface of the water without using its legs[3]. After briefly dipping the tip of its abdomen into the water it can dash over the surface at 40 to 75 cm/s, using its mobile abdomen as a rudder; like a water skier it does not sink at that speed.

More than 70 years ago, *Billard* and *Bruyant*[4] *recognized* that beetles of the genus *Stenus* are propelled forwards by a substance released from their anal end onto the surface of the water and compared its action with that of camphor or thymol. Indeed, the beetle secretion extracted from water with ether has an odor resembling that of eucalyptus oil, while also being amine-like. In order to perform detailed analyses we distilled the abdomens of 1000 beetles, extracted the distillate with benzene, concentrated the solution by ice zone melting, and separated it into five fractions by gas chromatography[5]. The substance present in the second most important fraction (0.8 mg) was found by mass spectrometry to have a molecular formula $C_{10}H_{18}O$ and was identified primarily by ^{1}H-NMR spectroscopy as 1,8-cineole *(1)* (eucalyptol); the substances occurring in two other less important fractions were identified as an isomer of isopiperitenol *(2)* and as 6-methyl-5-hepten-2-one *(3)* by comparison of IR spectra.



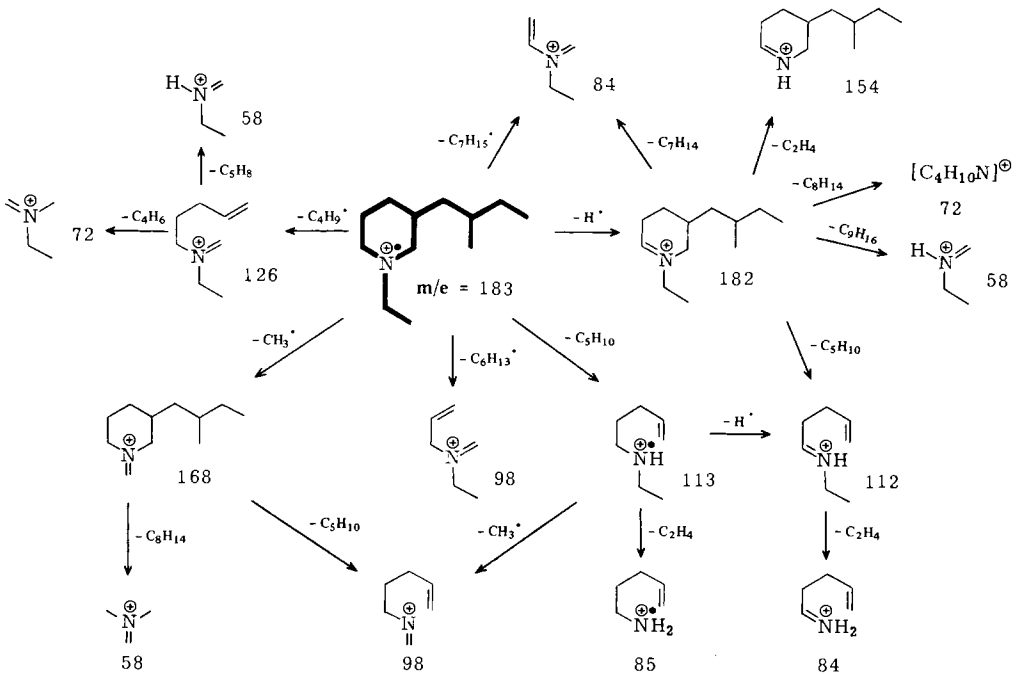


This substance alone would explain the propelling action of the secretion because eucalyptol spreads well on water. However, apart from the little pygidial defensive bladder in which it stores compounds *(1)*—*(3)*, *Stenus comma* also possesses a larger bladder from which two fractions having an unpleasant amine-type odor are obtained on workup as described above. The substance present in the principal fraction, 6 mg from 1000 beetles, was called stenusin; it is an oily compound having the molecular formula $C_{12}H_{25}N$. All structures deduced mainly from ^{1}H-NMR data were shown, by comprehensive spectral comparison of synthetic piperidine and perhydroazepine derivatives with the natural product, to be incorrect[6]. This provided a particularly clear demonstration that even the slightest deviation in absorption spectra of comparison substances must be given serious consideration in the structural elucidation of an unknown natural compound. We finally concluded, contrary to the predictions based on ^{1}H-NMR spectra, from a detailed mass-spectrometric analysis that the doubly substituted piperidine derivative *(4)* must be present. The fragmentation scheme affording structural proof is based, *inter alia*, on measurements of metastable transitions[7].

Stenusin *(4)* constitutes 80 % of the pygidial gland secretion of *Stenus comma* and purely on that basis is the actual propellant. Confirmatory evidence comes from the physical data[*]. As expected for a substance which spreads on water, stenusin is only very sparingly soluble in water (0.03 wt.-%) and therefore lowers the surface tension only slightly, from 72.8 to 49 dyn/cm[*]. This is reason enough for not speaking of "relaxation" swimming, although this term is frequently encountered in the literature[8], because stenusin *(4)* does not lower the surface tension of water to 25—30 dyn/cm like normal surfactants. Instead, the high spreading pressure of $p = 28.46$ dyn/cm is responsible for the motion of the beetle.

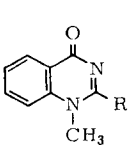
As already hinted, *Stenus comma* possesses two pairs[9] of abdominal bladders filled with chemicals, which most probably originated as defensive organs. This conclusion is supported by chemical aspects, since the contents of such pygidial defensive glands will have formerly prevented attack by microorganisms as in the case of land beetles[10]; a suitable compound is 1,8-cineole *(1)* which is known as an antiseptic. We may

[*] We are grateful to Dr. *Pohlemann*, BASF AG, for determining the physical data of stenusin.

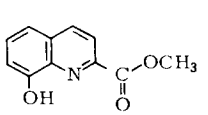


assume that in the course of evolution the chances of survival proved to be greater as the beetle is not only resistant to microorganisms but can also move rapidly on water. A suitable compound favoring development of this mode of swimming was eucalyptol *(1)* having a surface tension of $\sigma = 28.5$ dyn/cm; however, owing to its relatively high solubility of 0.3 % its spreading pressure is only $p = 2.16$ dyn/cm. Perhaps by chance, oxygen was replaced by nitrogen in the biogenesis of the terpenoids of the small pygidial defensive glands: the result was the diterpenoid stenusin *(4)* having a low solubility in water and hence an extremely high spreading rate of 32.5 cm/s, yet maintaining sufficient solubility to avoid permanent "contamination" of the surface. Moreover, stenusin renders the body of the beetle strongly hydrophilic and thus reduces drag by as much as 30 %. The little staphylinid *Stenus comma* therefore skates over the water, rather than swimming, on releasing its propellant.

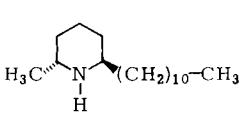
Stenusin is the third alkaloid we have found as defensive substances in arthropods. Glomerine, from the segmental glands of the millipede *Glomeris marginata*, was identified as 1,2-dimethyl-4-quinazolone *(5) inter alia* by electron pyrolysis[11]; in addition, the sticky colorless and odorless toxic secretion is found to contain the homologous 2-ethyl-1-methyl-4-quinazolone *(6)*. Methyl 8-hydroquinolinecarboxylate *(7)* is the predominant toxin in the prothoracic defensive secretion of *Ilybius fenestratus*[12] which leads an amphibious existence and has therefore developed toxins active against cold-blooded predators in and around the water and also against small mammals living on land. The toxin active against mammals is the alkaloid *(7)*, while steroids[10] are used in defense



(5), R = CH_3
(6), R = C_2H_5



(7)



(8)

against predatory fish. The alkaloid colors the secretion yellow; thus the blackish-brown water beetle displays the animal warning colors yellow/black only when in acute danger, *e.g.* when taken between thumb and index finger it presses two large drops of poison from two slits at the front edge of the prothorax.

All three alkaloids *(4)*, *(5)*, and *(7)* exhibit the same effect when administered to mice: they produce clonic spasms. In the absence of comparative experiments, it cannot yet be said whether stenusin *(4)* is also used as a defensive substance against insectivores, as established so far only for glomerine *(5)* and for the alkaloid *(7)* from *I. fenestratus*. In this context, it is interesting to note that the defensive alkaloid of the fire ant *Solenopsis saevissima*, solenopsin A *(8)*, is also a piperidine derivative[13].

3. The Defensive Chemistry of *Platambus maculatus*

Just as *Stenus comma* have developed a terpenoid and an alkaloid as defensive substances in the course of their evolution, the water beetles of the Colymbetinae subfamily also seem to have evolved along similar lines, except that in the latter case the two classes of compounds appear in two different species. As mentioned in Section 2, the substance accompanying the steroids in *Ilybius* is an alkaloid. In another species of the Colymbetinae, namely *Platambus maculatus* we expectly found a steroid, accompanied not by an alkaloid but by a crystallizing sesquiterpene[14].

Pl. maculatus, a water beetle measuring 7–8 mm and bearing a characteristic yellow marking on its black elytra, is found in the sluggishly flowing side-arms of the Isar river between aquatic plants or under pebbles. Its prothorax is partly transparent, permitting recognition of its prothoracic defensive bladders, filled with milky defensive secretion, as if through an inspection window glazed with yellow chitin (Fig. 2). The beetle visibly empties these bladders if stimulated on the head and the secretion can be drawn into fine glass capillaries and collected in methanol.

From 1000 bettles we first obtained 1 mg of the steroid *(9)*, melting at 232—234 °C. By thin-layer chromatography we also isolated 10 µg per beetle of a defensive substance *(15)*, melting at 63 °C, which we called platambin. Its structure was elucidated by modern physical methods and by micropre-

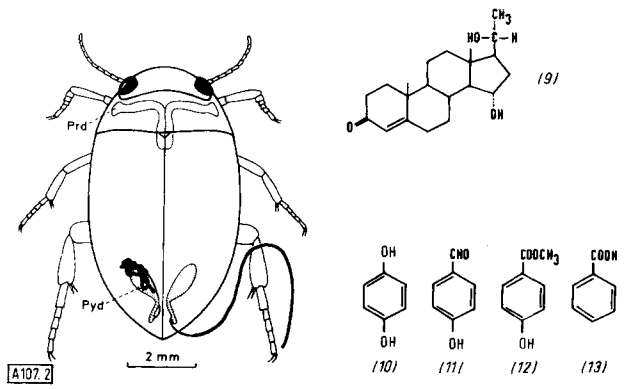


Fig. 2. The fast swimmer *Pl. maculatus* and its defensive substances *(9)* to *(13)*. Prd = prothoracic defensive glands, Pyd = pygidial defensive glands.

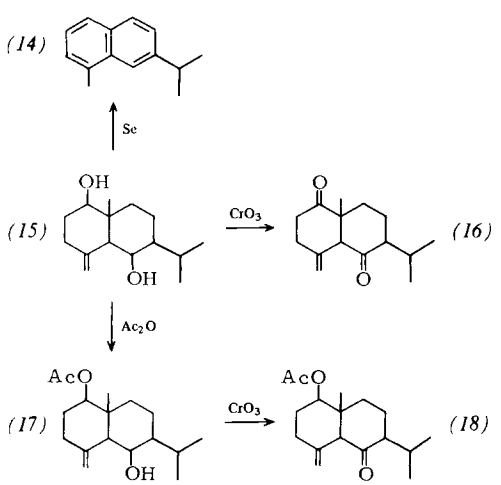
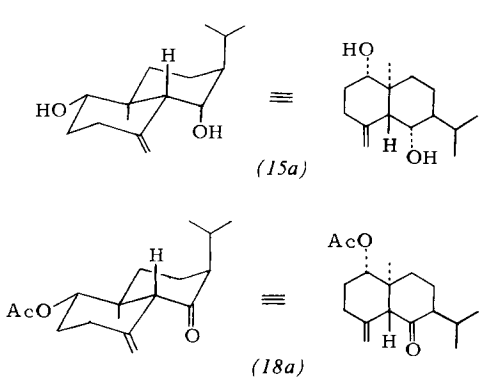
parative techniques. The molecular formula was established as $C_{15}H_{26}O_2$ by mass spectrometry. In keeping with the double bond rule we deduced a bicyclic system, which was substantiated by dehydrogenation with selenium to give eudalin *(14)*.



This indication of a sesquiterpene structure was supplemented by ^{1}H-NMR spectroscopy, which revealed the platambin molecule [*(15)*] to contain two secondary hydroxyl groups, an angular methyl group, an isopropyl group, and an



exocyclic double bond. The relative position of the double bond could also be deduced from the shift of the methyl proton signal after partial acetylation to *(17)* and oxidation of the hydroxyl group to give *(18)*; finally the complete constitution of platambin followed from a mass spectrum of *(16)* with a base peak at 123. Each half-molecule obtained on fragmentation accordingly contains only one carbonyl group.

The stereochemistry of platambin was determined by measurement of circular dichroism, which showed natural platambin to be the enantiomer 7α*H*,5β,10α-eudesm-4(14)-ene-1α,6α-diol *(15a)* (Fig. 3).

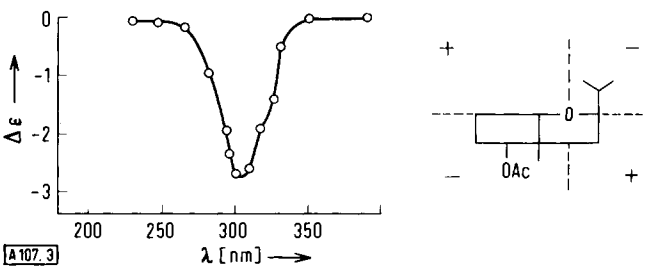


Fig. 3. Circular dichroism of the 1-acetoxy-6-ketone *(18a)* obtained from natural platambin (with octant projection).

We do not yet know anything about the physiological properties of platambin *(15)* since adequate amounts for a screening test only became available once it had been synthesized. However, we may justifiably expect that platambin is also an effective defensive substance against small mammals—such as shrews—since *Pl. maculatus* protects itself against attack by poikilothermal vertebrates with the steroid fraction of its prothoracic defensive secretion. Like all other beetles of the Dytiscidae family, *Pl. maculatus* is armed against attack by bacteria, fungi, and Campanularia with phenolic compounds, which it stores in high concentration in its pygidial defensive bladders. This antiseptic gland system produces mainly *p*-hydroxybenzaldehyde *(11)*, benzoic acid *(13)*, and methyl *p*-hydroxybenzoate *(12)*, which has never yet been absent in any of the water beetles we have studied, and finally also hydroquinone *(10)*.

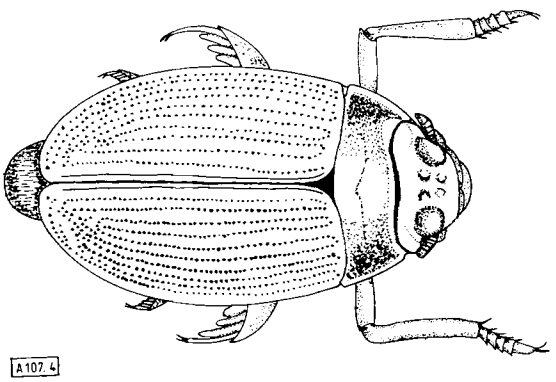
Let us now consider the chemistry of a water beetle which possesses only pygidial glands.

4. Chemical Ecology of Whirligig Beetles

On ponds and in places where a stream or river flows only sluggishly, and then mainly under bridges, the lustrous whirligig beetle *Gyrinus natator* (Fig. 4) can be seen carelessly tracing circles, loops, and spirals; up to one hundred of these gregarious little beetles are frequently observed in one place.

However, the Gyrinidae can also be highly nervous. The slightest cause for disquiet suffices to send them over the surface of the water at a speed of up to 1 m/s; and if they still feel threatened during their flight they will suddenly dive. Of the many water beetles we have so far observed, the whirligig beetles number among those which have adapted extremely well to their environment. Their bodies resemble boats in shape, their legs serve as oars for a highly refined swimming technique, and, according to *Nachtigall*, *Gyrinus* possess the best apparatus for forward motion yet to be found in the

animal kingdom[15]. When fleeing from predators, the beetle can follow a zig-zag course like a hare on land; the rowing frequency of its hind legs can reach 50 to 60 strokes per second. In spite of its high speed the beetle does not collide with solid obstacles since it locates them by means of V-shaped capillary waves which it utilizes after the manner of an echo-sounding device[16, 17]. Thus the whirligig beetle can be regarded as the counterpart of the bat in an aquatic environment.

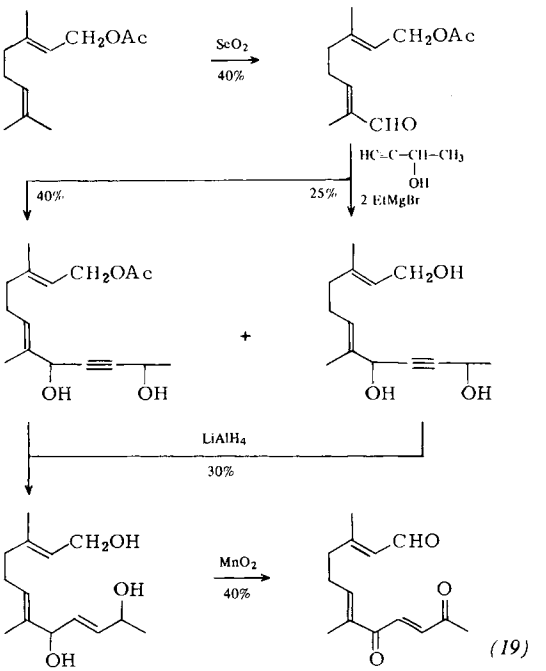


A107.4

Fig. 4. *Gyrinus natator.*

It would come as a surprise if this fantastically constructed "physical ecology" were not complemented by a highly advanced "chemical ecology", or if the former did not actually owe its existence to the latter. However, this would mean that the whirligig beetle possesses organs producing and secreting the necessary substances. Such organs are the pygidial defensive glands which had hardly been examined until a few years ago. They could be ascribed the same antiseptic function as the pygidial defensive bladders of the Dytiscidae; such a conclusion is justified by the cleaning ritual of the Gyrinidae. Like many other species of water beetles, the whirligig beetles soon climb up on to pieces of floating cork in an aquarium. After waiting until they have dried, the beetles then vigorously move their abdomen up and down and finally brush with their rear legs over the edge of their downward-arched abdomen, their belly, and sometimes under their elytra, most probably distributing the secretion of the pygidial defensive glands. This secretion is toxic to microorganisms living on the surface of water such as bacteria, flagellates, algae, amoebae, and ciliates[18]. Any of these organisms which may have attacked the elytra of the whirligig beetle are killed within minutes by the action of the secretion. In this connection, we were particularly interested to know whether the Gyrinidae use the same compounds for their bodily hygiene as the Dytiscidae, particularly since the Gyrinidae form a family of their own among the beetles.

The decomposable major component of the secretion, gyrinal, can be obtained under mild conditions by rapid high-pressure liquid chromatography[19] and crystallizes at 0 °C. Even the first preliminary experiments on gyrinal revealed the presence of an α,β-unsaturated keto aldehyde instead of a phenolic substance (cf. Fig. 2). A relative molecular mass of 234 (molecular formula $C_{14}H_{18}O_3$) was determined with a double focusing mass spectrometer; a 220-MHz ^{1}H-NMR spectrum confirmed the constitution of a norsesquiterpene bearing an acetyl group at the end of its chain. The positions of the two other double bonds and finally also that of the third carbonyl group followed from ^{1}H-NMR double resonance analysis[20]. The *trans* substitution of all three double bonds could only be confirmed by synthesis of gyrinal *(19)* from geranyl acetate which was performed independently in three laboratories[21–23].



(19)

The availability of synthetic gyrinal *(19)* allowed us to answer the remaining questions connected with the "whys and wherefores" of this sesquiterpenoid aldehyde. Tests with mice[*] showed gyrinal to be relatively toxic (DL_{50} *ca.* 45 mg/kg mouse); this means that every other mouse that has eaten ten beetles has to die because the pygidial defensive bladders, weighing about 200 µg, contain 80 µg of gyrinal. A critical examination of the defensive behavior of a typical aquatic species such as the whirligig beetle must of course also take account of predatory fish. Although the beetle can recognize its enemies in water just as quickly as above, possessing divided eyes, its underwater swimming speed is only about one-tenth of that on the surface.

Indeed, gyrinal is also toxic to fish[18]. This can readily be demonstrated with a small crucian carp (*Carassius carassius* L.) which is placed together with the contents of 20 pairs of glands in a beaker containing 140 ml of water; that corresponds to a gyrinal concentration of 10 mg/l. Initial disturbance of equilibrium gives way to a state of excitement, and the fish finally dies in a narcotic state after about an hour.

Thus gyrinal can be used as a defensive compound against both microorganisms and higher animals. This is supported by the following observation: whirligig beetles captured in spring after a long winter's rest nearly always have empty pygidial defensive bladders—perhaps because the beetles can only defend themselves against microorganisms by chemical means and hardly by mechanical measures—and that *Gyrinus*, like all other beetles equipped with defensive glands, possesses a characteristic "marking" for its enemies: a distinctive odor[24]. The odiferous substances are likewise located in

[*] We are indebted to Prof. *Lenke*, BASF AG, for the pharmacological screening.

the pygidial bladders and could be identified as isovaleraldehyde and isopentanol by coupled GC-MS analysis[25].

It remains to be established whether *G. natator* can more readily remain above water with the aid of the highly-surface-active compound gyrinal—they displace only half their total weight of water when floating on the surface[16]. In that case, gyrinal and the entire pygidial defensive gland secretion would have several functions and the whirligig beetles would be excellently established by virtue of their chemical ecology in the oldest biocenosis of living nature, that of the water. We see here an evolutionary peak, similar to that of the bombardier beetle, which is matched only by organisms whose development goes back further than that of the land beetles, namely ants.

5. Chemical Ecology of Myrmecine Ants

Apart from man, the only other animals founding highly organized colonies are the ants, the termites, and the bees. One can even speak of a cultural development in the case of the myrmecine ants. This subfamily contains tribes which reap and yet do not sow. These seed-gatherers are called harvester ants. A higher stage of development has been reached by the leaf-cutting ants, which have secured independence from a relatively uncertain food supply. They grow fungi on a mash of leaves and petals and sometimes even on refuse; only the hyphae of the fungi are taken as food for the ants and their brood. This "invention", dating back millions of years, has since been twice duplicated, namely by the macrotermitic termites and by a wood-boring beetle. According to *Martin*[26] this fungus-ant symbiosis has arisen *via* a complementary carbon-nitrogen metabolism of the participating organisms; however, in 1947 *Weber*[27] suspected a special

substance to be present in the ant secretions—a very reasonable hypothesis in view of the role played by the diverse glandular secretions especially in the chemical ecology of the colony-forming insects. The leaf-cutting ants possess mandibular and metathoracic glands (Fig. 5).

In 1959, *Butenandt et al.* found geranial *(21)* and neral *(22)* in the mandibular glands[29]. Since we maintain our own *Atta* colony in the laboratory[*], we were able to considerably extend *Butenandt*'s analytical results by working with 20000 freshly prepared ants' heads. So far we have found 16 further constituents (Table 1)[30], which were isolated by gas chromatography and identified mainly by mass spectrometry. Among them, citral [*(21)* + *(22)*] has been identified as an alarm pheromone of *A. sexdens*. The same effect was observed for 4-methyl-3-heptanone *(2)* and, to a lesser extent, with 6-methyl-5-hepten-2-one *(3)*, in accord with the findings of *Riley et al.*[31]. Some time will certainly elapse until the entire substance complement of the mandibular glands has been elucidated. Little progress can be expected, however, without thorough behavioral studies.

The metathoracic glands are organs occurring pairwise on the metapleura, whose secretion is distributed to the environment. Our studies on the composition and function of the secretion were directed by the idea that the metathoracic glands might be the organs responsible for controlling the fungus garden. This assumption was also supported by our observation that, in contrast to the larger soldiers, precisely the small animals of the worker caste—responsible for tending the fungus garden—have the best developed glands, always copiously filled with secretion.

The first component of the secretion which we isolated by thin-layer/gas chromatography was identified by UV, IR, and mass spectra as phenylacetic acid *(23)*. In addition, we could also detect a more readily decomposable carboxylic acid by thin-layer chromatography; it was isolated by column chromatography of the metathorax extract from 40 ants on Sephadex LH 20. Of several comparison samples, only 3-indolylacetic acid *(24)* gave the same R_f value, the color reaction with van Urk reagent, and the same UV absorption as the component isolated by gel chromatography. After esterification of the secretion we could identify the corresponding fraction isolated on a Sephadex column as the methyl ester of *(24)* by mass spectrometry[32].

Heteroauxin *(24)* is one of the most widely distributed plant growth substances and we thus had the first significant evidence confirming our assumption that the metathoracic gland secretion is involved in cultivation of the fungi. Phenylacetic acid *(23)* also fits in with this concept because it functions as a growth regulator, either alone or even more effectively in combination with the acid *(24)*[33]. It has long been known that plant growth substances play a role in the chemical ecology of insects. In 1965 *Kaldewey*[34] reported that the larva of the gall wasp *Cynips querusfolii* L. transforms a growth substance precursor, most likely tryptophan, into a growth substance which is probably *(24)* according to paper chromatography. And *Calam*[35] has unequivocally identified the acid *(24)* in the salivary glands of the gall gnats *Dasyneura urtucae* and *D. affinis*.

At that stage we had isolated the two growth-regulating carboxylic acids *(23)* and *(24)* but not identified the major

[*] We are grateful to BASF AG for providing this colony.

component. On thin-layer chromatography of the secretion drawn out of the metapleural sacs (Fig. 6) this component could only be rendered visible with concentrated sulfuric acid; however, on isolation, again as the methyl ester, it gives an interpretable mass spectrum. Accordingly, having a molecular formula of $C_{10}H_{20}O_3$ and showing the base peak $m/e = 103$ typical of methyl 3-hydroxycarboxylates, it must be 3-hydroxydecanoic acid *(25)*[36]. The natural compound, myrmicacin, is the levorotatory D-acid having $[\alpha]_D^{20} = -3°$ (in $CHCl_3$) (see Table 2).

Table 2. Concentration ranges of the acids from the the metathoracic gland of the leaf-cutting ant *Atta sexdens rubropilosa* Forel.

Acid	Content [µg/gland]
(23) C_6H_5—CH_2—COOH	1—2
(24)	0.04—0.1
(25) *n*-C_7H_{15}—CHOH—CH_2—COOH	1—10
(26) *n*-C_5H_{11}—CHOH—CH_2—COOH	0.5—5.0
(27) *n*-C_3H_7—CHOH—CH_2—COOH	<0.1

Myrmicacin *(25)* is accompanied by the lower homologs *(26)* and *(27)*, which are likewise very "everyday" compounds viewed both chemically and physiologically. It only occurred to us after a comparative biochemical study of the corresponding secretions from other myrmecine species that myrmicacin

Table 3. Plant growth substances from the metathoracic glands of myrmecine ants.

Species	Myrmicacin *(25)*	Phenylacetic acid *(23)*	3-Indolylacetic acid *(24)*
Atta sexdens	+	+	+
Messor barbarus	+	+	−
Myrmica laevinodis	+	+	+
Acromyrmex subterraneus Forel	+	−	+

(25) might be an inhibitor, because the grain-gathering species *Messor barbarus*, the harvester ant, does not possess the growth regulator 3-indolylacetic acid *(24)* but does produce myrmica-

cin (Table 3). Indeed, a simple experiment showed that plum pulp can be conserved with *(25)*. Quantitative determinations of the inhibition of sporulation[*] (Table 4) also indicate that the harvester ants prevent germination of grass seeds in their granaries and the leaf-cutting ants germination of undesirable fungal spores on cultivation of their fungal gardens by means of myrmicacin. The concentration of the three carboxylic acids *(23)*, *(24)*, and *(25)* in the secretion is high enough to exert such an effect.

Table 4. Inhibition of germination [a]; compounds tested: phenylacetic acid *(23)*, 3-indolylacetic acid *(24)*, and 3-hydroxydecanoic acid (myrmicacin) *(25)*.

[a] We are grateful to Farbwerke Hoechst AG for this test.

However, in the nest an average concentration of about 10^{-4} % is found. Ants are known to have excellent control over the conditions in their nests, and why should they not employ the same or a similar technique to lower the concentration of the constituents of their metathoracic secretion to such a level that all the carboxylic acids listed in Table 2, like true growth regulators, no longer act as inhibitors but as growth promoters? In any case, the three growth substances *(23)*, *(24)*, and *(25)* stimulate growth when present in concentrations of 10^{-4} %—as has been demonstrated by experiments with the ant fungus grown on agar[37] (cf. Table 5).

Table 5. Relative growth of the *Atta* fungus in 21 days; compounds tested: 3-indolylacetic acid *(24)*, phenylacetic acid *(23)*, and 3-hydroxydecanoic acid (myrmicacin) *(25)* [37].

We would hardly claim that the metathoracic glands of other ants also have to contain growth promoting substances; *Maschwitz*[38] has interpreted our work in that way, but concludes from the presence of a minor component, the bactericide phenylacetic acid *(23)*, which is, moreover, absent in the case of the leafcutting ant *Acromyrmex subterraneus* Forel (Table 3), that all metathoracic glands have a general bactericidal function. This generalization is not permissible, even though I would agree that every evolutionary series of defensive substances is based on substances active against the oldest enemy of all higher life forms, *i. e.* against microorganisms[1,2]. Like the long known heteroauxin *(24)*, myrmicacin *(25)* thus proved to be a plant growth regulator which should now be sought in higher or also in lower plants. However, it may be that the ants discovered myrmicacin as a growth promotor in a bygone age while it still played a role in plant metabolism, or that the fungus-growing ant is millions of years ahead of its time. While engaged in such considerations yet another thought occurred to me: might not the phenylacetic acid *(23)* be taken up by *Atta* fungus to form an antibiotic, as practiced in the case of *Penicillium* in industry. We did indeed find incorporation of ^{14}C-labeled phenylacetic acid in an antibiotic produced by the fungus[39,40], which inhibits the growth of *Staphylococcus aureus* just as well as the penicillins. It has yet to be established whether myrmicacin is also incorporated into a bactericidal and fungicidal compound.

There are probably few areas of chemical ecology where chemistry exerts such a profound influence as in the plant-fungus symbiosis just described; however, we also find another kind of co-existence in the ecology of the myrmecine ants, that of a parasite with its hosts, in which the chemistry of a Paussidae produces so much respect on the part of its host that it is allowed to feed on the most important component of the ant colony, *i. e.* on the brood. The smallest bombardier beetle that we have studied[41], *Paussus favieri*, is tolerated by the light brown ant *Pheidole pallidula* nyl. It is 4 mm long and brownish in color like its hosts. When stimulated it secretes quinones in the same way as its relatives; this can be accomplished, for example, in a glass vase and the volatile substances isolated in solution, as in our first experiments with black beetles, and concentrated by ice zone melting.

As with the Brachynidae, we again found the defensive substances *p*-benzo- und *p*-toluquinone; however, the Paussidae emit more toluquinone than benzoquinone. They accumulate the corresponding hydroquinones together with 15 % hydrogen peroxide in pygidial defensive bladders measuring only 0.3 to 0.4 mm. The myrmecophilic species *P. favieri* does not need to protect itself against external attack, that task being accomplished by the soldier caste of its hosts. Within the nest, it acquires respect by exploding quinone bombs and a certain degree of immunity lasting for a little while by virtue of the stubbornly disappearing quinone odor.

With regard to our study of the chemical ecology of insects, it is interesting that *P. favieri* is taxonomically closer to the bombardier beetles of the sub-family Brachynidae on account of its chemistry than *Arthropterus*, which *Moore* and *Wollbank* assign to the Paussidae. It remains an aim of further investigations to establish whether the Paussidae rather belong to the Brachynidae than to the Ozaenidae, or whether they even constitute a family of their own between the two. There would then be no need for the daring and improbable assumption that complicated and highly developed bombing mechanisms evolved independently in both the "Isochaeta" and the "Anisocheta" (according to *Janell*).

6. Chemical Ecology of the Araneids

We suspected a hitherto unknown antibiotic to be present in the adhesive of the mucous filaments in the webs of the

[*] We are indebted to Farbwerke Hoechst AG for this test.

garden spider (see Fig. 7), for in spite of its established protein character it resists attack by molds and bacteria for days and sometimes even for weeks even in warm and humid weather.

Fig. 7. Web of garden spider; the radial filaments are the adhesive ones.

We first found[42] the glue to be definitely acidic (pH *ca.* 4); we then noticed rhombic crystals in a droplet of glue located on a central double filament during spreading on a microscope slide. In order to analyze the spider glue we removed the surface-active glue proteins in a frothing column[43] and were then able to isolate two crystalline substances from the residue. They both displayed a paucity of IR bands typical for inorganic compounds. Accurate assignment was possible with the aid of reference spectra, according to which the first crystalline fraction is pure potassium nitrate. Its Debye-Scherrer diagram led to the same conclusion. The content of KNO_3 in the glue was determined gravimetrically as 6—8 % and that of KH_2PO_4 by colorimetry as 3 %. A third component was determined as pyrrolidone.

The trapping glue on the spiral adhesive surfaces holds the prey that has flown into the web and keeps the filaments themselves elastic. Most probably pyrrolidone, being hygroscopic, hinders drying out and KH_2PO_4 forms protons—the antibiotic sought—by dissociation, for many putrefactive bacteria avoid acidic media. However, the spiders can utilize this, the simplest of all antibiotics, to protect the protein glue against bacterial degradation only because they are able to keep the protein in solution by salting with KNO_3.

The research into chemical ecology described above was supported by grants from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, which I gratefully acknowledge. I also wish to express my special thanks to all my numerous co-workers.

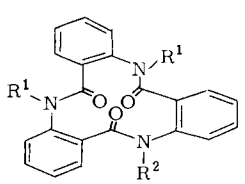
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

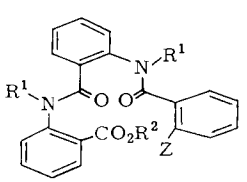
The Isolation of Conformational Diastereoisomers of *N,N',N''*-Tribenzyltrianthranilide

By *W. David Ollis, Julia Stephanidou Stephanatou, J. Fraser Stoddart*, and *Anthony G. Ferrige*[*]

Recently, we described the synthesis of *N,N',N''*-trimethyltrianthranilide *(1)*[1] and provided evidence that it crystallizes in a helical conformation, but in solution it exists in equilibrium with 5.5% of a propeller conformation[1]. We now wish to report the existence of two conformational diastereoisomers of *N,N',N''*-tribenzyltrianthranilide *(2)* as crystalline compounds.



(1), $R^1 = R^2 = CH_3$
(2), $R^1 = R^2 = CH_2C_6H_5$
(3), $R^1 = CH_2C_6H_5$; $R^2 = H$

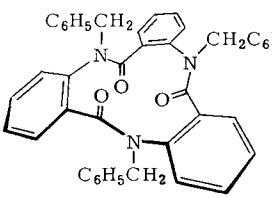


(4), $R^1 = R^2 = H$; $Z = NO_2$
(5), $R^1 = R^2 = CH_2C_6H_5$; $Z = NO_2$
(6), $R^1 = CH_2C_6H_5$; $R^2 = H$; $Z = NO_2$
(7), $R^1 = CH_2C_6H_5$; $R^2 = H$; $Z = NH_2$

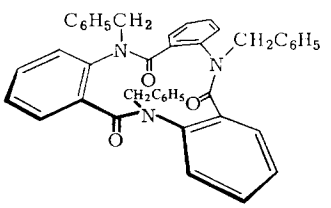
N-Benzylation ($C_6H_5CH_2Br$; NaH; THF) of *N*-[4-(2-nitrobenzoylamino)benzoyl]anthranilic acid *(4)*[2], m.p. 224°C (224°C[2]) afforded a mixture (yield >90%) of the ester *(5)* and the acid *(6)*. Reduction[3] of this mixture with $TiCl_3$ and completion of the de-esterification with LiOH yielded the *N,N'*-dibenzyl derivative *(7)* (64%, m.p. 177—179°C).

Cyclization (dicyclohexylcarbodiimide in CH_2Cl_2) of *(7)* gave *N,N'*-dibenzyltrianthranilide *(3)* (50%, m.p. 177—179°C; $\tau_{A1} = 5.00$, $\tau_{B1} = 5.54$, $J_{A1B1} = 14.7$ Hz; $\tau_{A2} = 5.17$, $\tau_{B2} = 5.33$, $J_{A2B2} = 14.8$ Hz in $CDCl_3$ for the constitutionally heterotopic benzylic-methylene protons[4, 5]). *N*-Benzylation ($C_6H_5CH_2Br$; NaH; THF) of *(3)* gave two diastereomeric products—*(2a)* and *(2b)*—with the constitution of *N,N',N''*-tribenzyltrianthranilide *(2)*. Preparative TLC on silica gel at +5°C using ethyl acetate/light petroleum (b.p. 60—80°C) (1:1) as developing solvent yielded *(2a)* (m.p. 134—144°C[6], 93% diastereomerically enriched) and *(2b)* (m.p. 260—263°C, >98% diastereomerically pure). Compound *(2a)* is the kinetically-controlled product and compound *(2b)* is the thermodynamically-preferred product.

When a ^{1}H-NMR spectrum of *(2a)* was recorded *immediately* after the crystals had dissolved in $CDCl_3$, three equal-intensity AB systems ($\tau_{A1} = 4.67$, $\tau_{B1} = 5.50$, $J_{A1B1} = 16.4$ Hz; $\tau_{A2} = 4.93$, $\tau_{B2} = 5.34$, $J_{A2B2} = 13.8$ Hz; $\tau_{A3} = 5.04$, $\tau_{B3} = 5.39$, $J_{A3B3} = 15.8$ Hz) were observed for the benzylic-methylene protons[4] of the 93% enriched diastereoisomer. In a similar experiment one AB system ($\tau_A = 3.96$, $\tau_B = 5.32$, $J_{AB} = 14.4$ Hz) was observed for the benzylic-methylene protons of *(2b)*. Diastereoisomers *(2a)* and *(2b)* interconvert slowly at room temperature in $CDCl_3$ giving eventually an equilibrium ratio [*(2a)*:*(2b)* = 41:59].



(8), Helix



(9), Propeller

The spectra of *(2a)* and *(2b)* can be rationalized in terms of two non-planar conformations, the Helix (H) *(8)* with C_1 symmetry and the Propeller (P) *(9)* with C_3 symmetry, which are formally interconverted by torsion about the Ar—N($CH_2C_6H_5$) and Ar—CO single bonds of *trans*-amide linkages. The interconversion between H and P conformations *(8)* and *(9)*, and their enantiomers (denoted as H* and P*) involves the following equilibrium: P⇌H⇌H*⇌P*.

It follows from the spectra that *(2a)* can be assigned to the Helix *(8)* with three diastereotopic benzylic-methylene groups and *(2b)* to the Propeller *(9)* with homotopic benzylic-methylene groups. The rate of diastereoisomerization of *(8)* to *(9)* was measured[7] in CD_3SOCD_3 at 63°C by monitoring the relative intensities of the benzylic-methylene proton signals in the ^{1}H-NMR spectrum as a function of time. An equilibrium constant of 0.59 and values for $\Delta G^{\ddagger}_{H\to P}$ and $\Delta G^{\ddagger}_{P\to H}$ of 24.3 and 24.8 kcal mol^{-1} were obtained for P⇌H interconversion at 63°C. The ^{1}H-NMR spectrum of the equilibrated sample of *(2)* showed temperature dependence. As the temperature is raised the signals for the Helix *(8)* decrease rapidly in relative intensity and are undetectable at 163°C. Between 163°C and 183°C the AB system for the Propeller *(9)* begins to undergo sufficient line broadening to permit line shape analysis and calculation of a value for $\Delta G^{\ddagger}_{P\rightleftharpoons P^*}$ of 26.2 kcal mol^{-1}.

The characterization of Helix *(8)* and Propeller *(9)* as crystalline diastereomeric conformational isomers is novel and represents the first example within this class of compound. It is also significant that the Helix *(8)* forms a 1:1 clathrate with ethanol[8].

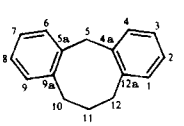
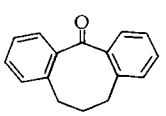
The Conformational Behavior of 5,10,11,12-Tetrahydrodibenzo[*a*,*d*]cyclooctene

By *Farouk Eltayeb Elhadi, W. David Ollis*, and *J. Fraser Stoddart*[*]

The conformational properties of 1,5-cyclooctadiene[1–4] and its derivative 5,6,11,12-tetrahydrodibenzo[*a*,*e*]cyclooctene[4–7] have been studied recently. Although the possibility of the existence of more than one conformation of 1,4-cyclooctadiene has been discussed[1] from a theoretical standpoint and the conformational behavior of some heterocyclic analogs of 5,10,11,12-tetrahydrodibenzo[*a*,*d*]cyclooctene *(1)* has been examined[8] by temperature-dependent ^{1}H-NMR spectroscopy and molecular mechanics, no experimental data are available for either of these hydrocarbons. We are now able to discuss in some detail the conformational behavior of the hydrocarbon *(1)*.



(1)



(2)

(1), m.p. 79—80 °C, was obtained by reduction ($AlCl_3$/$LiAlH_4$) of the ketone *(2)*[9], m.p. 145—148 °C (m.p. 148—149 °C[9]). At -5 °C, the ^{1}H-NMR spectrum of *(1)* in $CDCl_3$ showed an AB system ($\tau_{A1} = 5.72$, $\tau_{B1} = 6.32$, $J_{A1B1} = 12.5$ Hz) for the 5-CH_2 protons which exhibited selective broadening of the B portion of the spectrum. As the temperature was raised the unsymmetrical AB system coalesced to give a broad singlet above room temperature. Decreasing the temperature resulted in the AB system becoming well-resolved and assuming a symmetrical character. Although no signals were observed at -30 °C for a minor rapidly inverting conformation, line shape analysis with a program[8] suitable for simulating NMR line shapes of two AB systems (A1B1 and A2B2) undergoing exchange of nuclei between pairs of sites A1 and B1, A2 and B2, A1 and A2, and B1 and B2 was carried out (Table 1) successfully on selected spectra obtained between

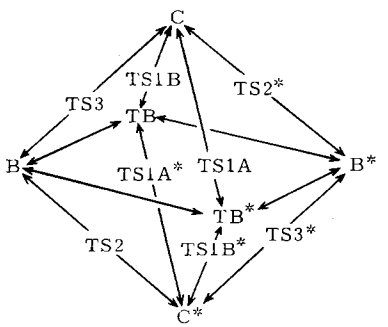

Fig. 1. Conformational changes in 5,10,11,12-tetrahydrodibenzo[*a*,*d*]cyclooctene *(1)*. The notation [7] for torsional angles refers in turn to the 12a-12, 12-11, 11-10, 10-9a, 5a-5, and 5-4a bonds.

from the temperature-dependent noise-decoupled ^{13}C-NMR spectra. The broad resonance ($\delta^{TMS}=37.6$ ppm) observed at +27 °C for C-10 and C-12 became a sharp singlet when the temperature was increased to +40 °C and also when it was decreased to −20 °C. At low temperatures no signal was observed which could be assigned to a minor conformation confirming its low population relative to that of the major conformation.

Table 2. Calculated strain energies of various conformations of the hydrocarbon *(1)*. The following energy terms have been used: E_r (bond length strain), E_θ (angle strain), E_ϕ (torsional strain), E_δ (out-of-plane strain in aromatic rings), E_{nb} (non-bonded interactional strain). Total strain energy, $E_T=E_r+E_\theta+E_\phi+E_\delta+E_{nb}$. For force constants and other empirical parameters, see Refs. [7] and [8].

Conformation	$\phi_{12,11}$ [°]	$\phi_{11,10}$ [°]	E_r	E_θ	E_ϕ	E_δ [kcal/mol]	E_{nb}	E_T
C *(3)*	− 91.8	+ 91.9	0.04	1.11	3.34	0.08	−0.57	4.00 [d]
B *(4)*	+ 75.0	− 75.0	0.15	7.80	0.83	0.08	0.44	9.30
TB *(5)*	− 58.3	− 59.6	0.08	2.75	0.54	0.39	0.25	4.01 [e]
TS1 *(6)* [a]	0.0	+ 60.8	0.36	14.99	3.03	0.06	1.13	19.57 [d]
TS2 *(7)* [b]	+108.0	−110.0	0.58	20.83	5.55	0.06	−0.08	26.94
TS3 *(8)* [c]	0.0	0.0	0.31	15.44	7.01	1.12	−0.29	23.59

[a] Defined by holding atoms 10, 11, 12, 12a, 4a, and 5, coplanar.
[b] Defined by holding atoms 12a, 4a, 5, 5a, and 9a coplanar.
[c] Defined by holding atoms 9a, 10, 11, 12, and 12a coplanar.
[d] If the difference in strain energies between the C conformation *(3)* and the TS1 conformation *(6)* is equated with $\Delta H^{\neq}$ then an approximate estimate for $\Delta G^{\neq}_{calc}$ of 15.2 kcal/mol follows from recognizing that the transition state is favored on entropy of mixing grounds by $R\ln 2$ cal K^{-1} mol^{-1} (*i.e.* there are two equivalent pathways for C→TB interconversion involving chiral transition states).
[e] The calculation on the TB conformation *(5)* allowed loss of C_2 symmetry during the energy minimization procedure. The values for $\phi_{12,11}$ and $\phi_{11,10}$ indicate that the minimum energy boat conformation corresponds to a slightly distorted TB conformation *(5)*.

Conformational analysis (Fig. 1) and strain energy calculations (Table 2) focus attention on the following conformations: (i) a rigid chair conformation [C, *(3)*, C_s symmetry], (ii) a boat conformation [B, *(4)*, C_s symmetry], (iii) a twist-boat conformation [TB, *(5)*, C_2 symmetry], and (iv) transition state conformations [TS1, *(6)*, C_1 symmetry], [TS2, *(7)*, C_s symmetry], and [TS3, *(8)*, C_s symmetry]. The calculations demonstrate that the C and TB conformations [*(3)* and *(5)*] correspond to ground state conformations and that relatively low energy transition states (B and B*) are associated with TB⇌TB* inversion while relatively high energy transition states (TS1 and TS1*) are associated with C⇌TB and C*⇌TB* interconversions necessary for C⇌C* inversion. On the basis of this analysis, the major conformation identified by NMR spectroscopy was assigned to the rigid chair conformation *(3)* and the minor conformation to the twist-boat conformation *(5)*.

The rate constants and free energies of activation for C⇌C* inversion and C→TB interconversion at various temperatures are given in Table 1. The fact that $k_{C\rightleftharpoons C^*}=0.5\,k_{C\rightarrow TB}$ is consistent with the presence of intermediate TB conformations *(5)* in the C⇌C* inversion process. The average free energy of activation ($\Delta G^{\neq}=14.9$ kcal/mol) for the C→TB interconversion is in very satisfying agreement with the calculated value (Table 2) of 15.2 kcal/mol between the C *(3)* and TS1 *(6)* conformations.

Crystal Structure of a Platinum Complex Containing NCl_2 Ligands: $[Pt(NH_3)_3(NCl_2)_2Cl]Cl$[**]

By *Mathias Zipprich, Hans Pritzkow*, and *Jochen Jander*[*]

Reaction of $[Pt(NH_3)_5OH]Cl_3$ with chlorine leads, according to *Kukushkin*[1], to orange-red $[Pt(NH_3)_3(NCl_2)_2Cl]Cl$ *(1)*. This compound can also be obtained in a crystalline form more suitable for X-ray structure analysis by chlorinating very dilute solutions of $[Pt(NH_3)_5Cl]Cl_3$[2]. Hitherto, only the structure of a complex containing one NCl ligand was known: Cl_3VNCl[3] contains a metal-nitrogen double bond; the V—N—Cl grouping is almost linear; the N—Cl distance of 159 pm is distinctly shorter than a N—Cl single bond. We have now solved the crystal structure of *(1)* in order to determine the geometry of the NCl_2 ligand and to compare the bonding of these two groups.

The intensities of 1550 reflections (390 classified as unobserved) were measured with an automatic Weissenberg diffractometer ($Mo_{K\alpha}$, graphite monochromator, ω scan). The structure was solved by Patterson and difference Fourier syntheses and refined with anisotropic temperature factors to an R value of 0.086, weighted R value 0.061. Unit cell: space group $P2_1/c$ (C_{2h}^5): $a=1352.9(1)$, $b=1080.0(1)$, , $c=860.1(1)$ pm; $\beta=114.33(7)°$; $d_{exp}=2.77$, $d_{calc}=2.77\,g\,cm^{-3}$; $Z=4$.

The crystal structure of *(1)* is built up from $[Pt(NH_3)_3(NCl_2)_2Cl]^+$ and Cl^- ions. A cation is shown in Fig. 1. No intermolecular interactions take place between the individual ions. The platinum atom is octahedrally coordinated (bond angles 90 ± 5 and 180 ± 7°). The two NCl_2 groups are arranged *cis* to one another. The distances in the cation correspond to those in similar structures. The distances from the platinum atom to the two *trans* nitrogen atoms N3 and N4 are somewhat shorter than the distance to the nitrogen atom N5, which is arranged *trans* to one of the NCl_2 groups.

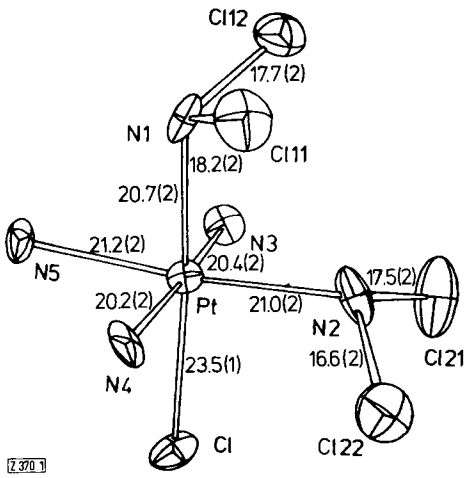

Fig. 1. Structure of the complex cation $[Pt(NH_3)_3(NCl_2)_2Cl]^+$; distances in [$10^1$ pm = 10^{-11} m].

The angles at the nitrogen atoms N1 and N2 of the two NCl_2 ligands are $108 \pm 6°$, thus indicating that the nitrogen atoms are sp^3 hybridized. The Pt—N distances to these two atoms lie in the same range as for NH_3 ligands. Hence, in contrast to the NCl group in Cl_3VNCl the NCl_2 groups here are linked to the central atom by a single bond.

The N—Cl distances scatter relatively largely (166—182 pm), but the values lie in the range which one would expect for a N—Cl single bond (NCl_3: 174 pm[4])[5].

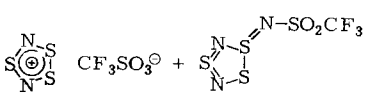
Synthesis of the $S_3N_2^+$ Radical Cation[**]

By *Herbert W. Roesky* and *Abbas Hamza*[*]

The metallic properties of the sulfur-nitrogen polymer $(SN)_x$ have recently attracted considerable attention[1]. Polythiazyl crystals of this kind are formed from S_2N_2, which is obtained by pyrolysis of S_4N_4; polymerization proceeds *via* a paramagnetic intermediate that has not yet been characterized. S_2N_2 is described as a highly explosive substance. By reaction of S_4N_4 with trifluoromethanesulfonic anhydride in methylene chloride we have now accomplished the first isolation of the SN radical cation as the trifluoromethanesulfonate *(1)* in an extremely facile and safe procedure[6]:

$$S_4N_4 + CF_3SO_2OSO_2CF_3 \longrightarrow$$



$CF_3SO_3^{\ominus}$ +

(1) *(2)*

[*] Prof. Dr. H. W. Roesky and A. Hamza
Anorganisch-chemisches Institut I der Universität
Niederurseler Hang, 6000 Frankfurt am Main 50 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In the reaction a small amount of $S(NSO)_2$ is also formed. The yellowish brown compound *(2)* which can be separated from the reaction mixture by sublimation or by digestion with light petroleum was found to be identical with the product of reaction between S_3N_2O and $CF_3SO_2—N=S=O$[2].

The blackish brown compound *(1)* can be purified by recrystallization from acetonitrile. Elemental analysis confirms the empirical formula. In the mass spectrum only $CF_3N_2O_3S_2$ is observed as ion of highest mass ($m/e = 241$) on fast heating because *(1)* does not volatilize without decomposition. The ESR spectrum shows the 1:2:3:2:1 quintet expected for two equivalent ^{14}N atoms ($a_N = 3.15$G, g factor 2.011)[3]. In the ^{19}F-NMR spectrum the pronounced effect of the spin density of the unpaired electron on the relaxation of the fluorine nucleus is manifested in the large half-width of the signal ($\delta_F = +76.7$ ppm, $CFCl_3$ as external standard). X-ray structure analysis of *(1)* is in progress[4].

Procedure:

Trifluoromethanesulfonic anhydride (7.6 g) is added dropwise with exclusion of moisture to a stirred suspension of S_4N_4 (5 g) in dry CH_2Cl_2. After refluxing (3 h) the solvent is removed *in vacuo*. The residue can be partly sublimed at 65 °C/0.02 torr (oil bath temperature); resublimation at 45 °C/0.02 torr affords 3.4 g of *(2)*. The nonsublimable portion is extracted with warm acetonitrile; on cooling to 0 °C lustrous blackish brown needles of *(1)* (1.8 g) precipitate[5].

Cyclobutadiene—A Square Singlet Molecule?[1][**]

By *Günther Maier*, *Hans-Georg Hartan*, and *Tugmac Sayrac*[*]

The matrix isolation technique, first successfully employed in the study of alkyl-substituted cyclobutadienes[2], also permits isolation and spectroscopic investigation of the unsubstituted parent compound *(2)* in monomeric form. Starting from the Corey lactone *(3)*, *Krantz*[3] and *Chapman*[4] were

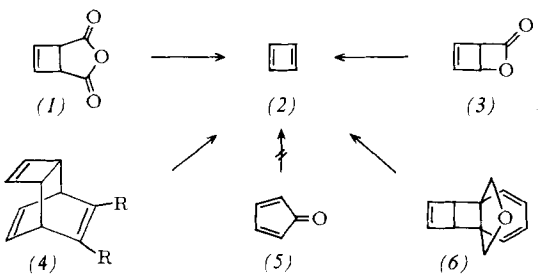
able to generate *(2)* in an argon matrix at 8K and to record its IR spectrum. *Masamune*[5] photolyzed the ether *(6)* and we[6] photocleaved the anhydride *(1)* in organic glasses at 77 K and also deduced the formation of monomeric cyclobutadiene.



(1) *(2)* *(3)* *(4)* *(5)* *(6)*

(4a), R = H *(4c)*, R = $COOCH_3$

(4b), R-R = -CH=CH-CH=CH- *(4d)*, R-R = -CO-O-CO-

The number of observed IR bands [square geometry (D_{4h}) allows four IR-active vibrations, and a rectangular geometry (D_{2h}) seven] requires that *(2)* has a square structure. However, most theoretical calculations predict that square cyclobutadiene should have a triplet ground state and that the energy content should increase in the order RS (rectangular singlet), ST (square triplet), SS (square singlet). On the other hand, the chemistry of *(2)* suggests a singlet molecule. On the basis of MINDO/3 calculations, *Dewar*[7] has proposed the following solution of this dilemma: Photocleavage of *(3)* should afford *(2)* in an excited triplet state which, owing to a barrier of 3.5 kcal/mol to the transition of ST to RS cyclobutadiene, is expected to be stable under matrix conditions.

In the present communication we shall demonstrate that the interpretation of the IR spectra of *(2)*[3,4] requires modification and that the tendency of cyclobutadiene to form complexes must also be considered in any discussion of its properties.

Irradiation of the anhydride *(1)* in an argon matrix at 7 K with a low pressure mercury lamp leads essentially to the same IR spectrum[3,4] as is observed on photofragmentation of *(3)*. There is, however, one striking difference: the band at 1240 cm^{-1} is now split into a doublet (1237, 1241 cm^{-1}) (Table 1).

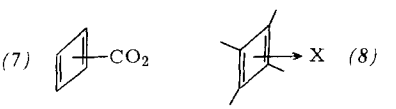
This finding is in itself rather odd, because more bands appear than would be permissible for a single D_{4h} species. The results of photofragmentation of compounds of type *(4)* give even more reason for scepticism.

Table 1. Comparison of the IR spectra [cm^{-1}] obtained on irradiation of the cyclobutadiene precursors *(1)*, *(3)*, and *(6)*. On cleavage of *(3)* the bands of CO_2 also appear (2340, 660 cm^{-1}) and in the case of *(1)* those of CO_2 and CO (2138 cm^{-1}).

(1)	*(3)*		*(6)*	calc. (D_{4h})
	[3]	[4]		
—	—	3040	—	3000 (E_u)
1241 + 1237	1238	1240	1240	1236 (E_u) [3b]
653	653	650	—	661 (E_u)
573	573	570	570	576 (A_{2u})

While the hydrocarbons *(4a)* and *(4b)* are photostable, the ester *(4c)* and the anhydride *(4d)* undergo cleavage on irradiation (argon, 7 K, 254 nm). The presence of only small amounts of cyclobutadiene can be deduced from the IR spectra (1240, 570 cm^{-1}). Nevertheless, it can be clearly seen that a "cyclobutadiene band" at 653 cm^{-1} is absent. The same peculiarity is also evident in the IR spectrum recorded on analogous photocleavage of the ether *(6)*[8] (Table 1). Only two intense absorptions are again observed at 570 and 1240 cm^{-1} which must be due to cyclobutadiene because they disappear in favor of the bands due to the *syn* dimer of *(2)* on thawing to 32 K. No band appears at 653 cm^{-1}.

How can these results be rationalized? We believe that photochemical cleavage of *(3)* affords neither free SS nor ST cyclobutadiene in the inert gas matrix but instead a species of type *(7)* associated with CO_2.



(7) *(8)*

The band at 653 cm^{-1} is not assignable to cyclobutadiene but to CO_2 functioning as a ligand whose deformation vibration splits into a doublet (660, 653 cm^{-1}) on destroying the degeneracy as a result of complex formation[9,10]. Confirmatory evidence comes from the observation that these two bands on complete photochemical secondary cleavage into two acetylene molecules do not disappear because a corresponding associate exists between acetylene and CO_2. Interestingly, the association has a fairly pronounced effect in the CO_2 ligand but is hardly noticeable in the substrate molecule cyclobutadiene.

In analogy to the preparation of "free" tetramethylcyclobutadiene from the tetramethyl derivative of *(6)*[11] formation of nonassociated cyclobutadiene would appear most likely on cycloreversion of the ether *(6)*. It may be deduced from the result of that cleavage that free cyclobutadiene *(2)* only gives two bands that are intense enough to be observed in the IR spectrum. In accord with calculations[3b], these can be assigned to the ring- and out-of-plane C—H deformation vibrations of a cyclobutadiene molecule having D_{4h} symmetry. In other words: the number of observed IR absorptions cannot

1240 cm^{-1} (E_u) 570 cm^{-1} (A_{2u})

serve for assignment to a square geometry. The only valid argument in favor of a square geometry is that the band at 1238 cm^{-1} must be split on deformation[3b]. The double band observed on irradiation of the anhydride *(1)* (1241, 1237 cm^{-1}) probably has a different origin. The difference of 4 cm^{-1} is too small. The splitting is presumably explained by the presence of two kinds of cyclobutadiene: cyclobutadiene associated with CO_2 together with free or CO-complexed cyclobutadiene. In order to examine the second possibility we have—in analogy to the preparation of tri-*tert*-butylcyclobutadiene[12]—generated cyclopentadienone *(5)* in an argon matrix[13] and attempted to cleave this product to *(2)* and CO. Under these conditions, however, cyclopentadienone is photostable.

The tendency of *(2)* to undergo association has its parallels in the excellent donor properties of tetramethylcyclobutadiene[11] [formation of charge-transfer complexes of type *(8)*] and in the strongly basic or nucleophilic behavior of tri-*tert*-butylcyclobutadiene[14]. The unsubstituted parent compound thus fits well into the pattern of the known properties of alkyl-substituted cyclobutadienes. All presently known properties of *(2)* are in accord with a recently published theoretical treatment by *Borden*[15] which states that cyclobutadiene, contrary to all previous predictions[2,7,16], can have a singlet

ground state even in a square or at least *effectively* square geometry.

[8] Prepared according to *H.-D. Martin* and *M. Hekman*, Synthesis *1973*, 667.
[9] The reports on partially deuterated cyclobutadienes [3b, 4b] and in particular the interpretation of the IR spectrum of monodeuterated *(2)* [3b] also have to be revised. If it is correct that a band appears at 655 cm^{-1} due to *(2)* on irradiation of pyridine in an argon matrix [4a] then this band cannot arise from CO_2 but must have its origin in the ability of simultaneously formed hydrogen cyanide to undergo complex formation. The additional absorption observed in the photocleavage of pyridine as well as of *(1)* or *(3)* should be assigned to a deformation vibration that becomes IR active on transition ($E_g \rightarrow E$) from *(2)* (D_{4h}) to a complex of type *(7)* (C_{4v}). We have attempted to repeat (Ar; 7 K; 254 or > 300 nm) the preparation of cyclobutadiene from pyridine (experiments by *U. Schäfer*) and found two bands of very low intensity at 570 and 1240 cm^{-1}, but none at 655 cm^{-1}.
The UV spectroscopic findings are not very informative: photocleavage (Ar, 7 K, 254 nm) of *(1)* and *(3)* gives no pronounced maxima (only end absorption, beginning at about 290 nm). On irradiation of *(6)* only the UV bands of phthalan (265, 272 nm) can be observed. UV-absorptions formerly (Refs. [2], [3a], [5], [6]) assigned to *(2)* therefore must arise from other species.
[10] We are indebted to Prof. *K. Dehnicke* for his help in the interpretation of the IR spectra.

[13] The existence of *(5)* has been established by rapid pyrolysis of suitable precursors and trapping of the pyrolysis products in an IR cell cooled to 77 K: *O. L. Chapman* and *C. L. McIntosh*, J. Chem. Soc. Chem. Commun. *1971*, 770. Pure cyclopentadienone is obtainable in the following way: *o*-benzoquinone is irradiated in an argon matrix at 7 K with light > 300 nm. Cleavage of the bond between the two carbonyl groups quantitatively affords the corresponding bisketene. Secondary irradiation with 254-nm light then yields CO and cyclopentadienone (IR: 1725, 1721, 1328, 1130, 970, 920, 815 cm^{-1}).

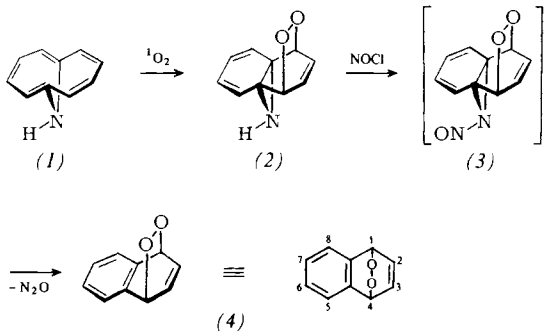
Naphthalene 1,4-Endoperoxide

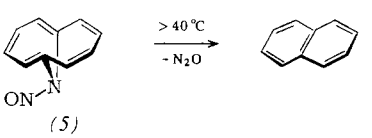
By *Maria Schäfer-Ridder, Ulrich Brocker*, and *Emanuel Vogel*[*]

In contrast to anthracene and higher members of the acene series[1], naphthalene shows hardly any tendency to react with singlet oxygen ($^1O_2$) to form a 1,4-endoperoxide[2]; it was estimated from kinetic data that naphthalene has a reactivity index for addition of $^1O_2$ which is several degrees of magnitude lower than that of the acenes[3]. In fact, the synthesis of the endoperoxide *(4)* from naphthalene and $^1O_2$ appears to be obstructed primarily by the high activation energy of the addition, and not at all by any great tendency of *(4)* to decompose, for we have now found an alternative entry to this compound.



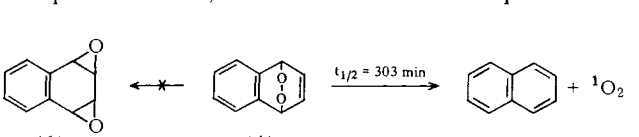
The *N*-nitrosoaziridine *(3)* of the 1,4-endoperoxide *(2)*[4] obtainable from 1,6-imino[10]annulene *(1)*[5] already eliminates N_2O at very low temperature[6]. Treatment of *(2)* dissolved in methylene chloride in the presence of triethylamine at −78 °C with an excess of liquid nitrosyl chloride (duration of reaction 1 h) affords *(4)*, which is isolated, after conventional workup with cooling (0–5 °C) and recrystallization from acetone (−20 °C), as colorless needles (rapid decomposition above room temperature); 50 % yield.

Attempts to prepare *(4)* by way of *N*-nitroso-1,6-imino[10]annulene *(5)* [pale yellow needles (from CH_2Cl_2/hexane), m.p. ≈70 °C (dec.); ^{1}H-NMR (CD_2Cl_2): multiplet at $\tau = 1.9$—2.9; UV (methanol): $\lambda_{max} = 250$ ($\varepsilon = 49000$), 295 (6350), 376 (240), 388 (380), 398 (630), 409 nm (720)], smoothly formed on reaction of *(1)* with nitrosyl tetrafluoroborate in acetonitrile, did not lead to the desired goal because *(5)* failed to react with $^1O_2$. In solution, *(5)* decomposes only above 40 °C to naphthalene and N_2O.



Structural proof for naphthalene 1,4-endoperoxide (1,4-epidioxy-1,4-dihydronaphthalene) *(4)* is provided mainly by the ^{1}H-NMR spectrum [(in $CDCl_3$, TMS as internal standard): AA'BB' system with $\tau = 2.70$ (H^5, H^8) and 2.76 (H^6, H^7) ($J_{5,6} = 7.34$, $J_{5,7} = 1.17$, $J_{5,8} = 0.52$, $J_{6,7} = 7.68$ Hz) and AA'XX' system at $\tau = 3.02$ (H^2, H^3) and 4.36 (H^1, H^4) ($J_{1,2} = 5.89$, $J_{1,3} = 1.66$, $J_{1,4} = 0.99$, $J_{2,3} = 8.08$ Hz)]. The UV spectrum [(cyclohexane): $\lambda_{max} = 205$ nm ($\varepsilon = 26100$)] of the 1,4-dihydronaphthalene type and the IR spectrum [(KBr): 1655 cm^{-1} (C=C)] are in accord with structure *(4)*.

Compound *(4)*, which can be handled without difficulty, undergoes thermal cleavage to naphthalene and oxygen with comparative ease[7]; in solution the reaction is quantitative.

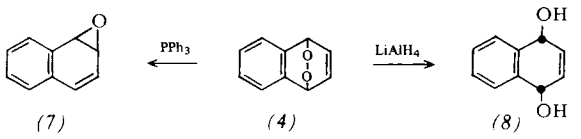


On insertion into the Arrhenius equation, the rate constants determined by NMR spectroscopy between 18 and 26 °C afford the activation parameters $E_A = 23.7 \pm 0.7$ kcal mol^{-1} and $\log A = 13.26 \pm 0.5$ ($\Delta H^{\neq} = 23.2 \pm 0.9$ kcal mol^{-1}, $\Delta S^{\neq} = 0.2 \pm 1.1$ cal deg^{-1} mol^{-1}) for fragmentation of *(4)*. The

[*] Prof. Dr. E. Vogel, Dr. M. Schäfer-Ridder, and Dr. U. Brocker
Institut für Organische Chemie der Universität
Greinstrasse 4, 5000 Köln 41 (Germany)

half-life of *(4)* at 20°C is 303 min. That the oxygen released by *(4)* is $^1O_2$ follows from the reaction of *(4)* with $^1O_2$ acceptors such as diphenylisobenzofuran or tetramethylethylene[8], which yields the products expected for $^1O_2$: for instance, 1 mmol of *(4)* and 0.5 mmol of 1,3-diphenylisobenzofuran in 10 ml of benzene at 20°C (24 h in the dark) furnish only *o*-dibenzoylbenzene and naphthalene in almost quantitative yield.

The temperature range in which the 1,4-endoperoxide *(4)* permits $^1O_2$ oxygenations (preferably 15—25°C) suggests a useful supplementary role alongside the known singlet oxygen sources of ozonide[9] and 1,4-endoperoxide type[1,2].



(7) *(4)* *(8)*

Reaction of *(4)* with triphenylphosphane (−78°C) leads to partial deoxygenation, the major product being *(7)*[10] (no indication was found for formation of the isomeric 1,4-epoxy-1,4-dihydronaphthalene). Reduction of *(4)* with $LiAlH_4$ in ether (0°C) gives *cis*-1,4-dihydroxy-1,4-dihydronaphthalene *(8)* [m.p. 106—107°C; NMR ($CDCl_3$): doublets at $\tau = 5.0$ (H^1, H^4) and 3.88 (H^2, H^3) and multiplet at $\tau = 2.2$—2.8 (H^5—H^8)], which has also been prepared in another way by *Jerina et al.*[11].

Compound *(8)* is a potential isolable secondary product of a biological oxidation of naphthalene to *(4)*, for which no firm evidence has yet become available. In view of the natural occurrence of 1,4-endoperoxides[12] it would hardly be surprising to find that living organisms can oxidize naphthalene not only to *(7)* but also to *(4)*. Our knowledge of the properties of *(4)* and *(8)* should facilitate solution of this problem.

syn- and *anti*-Naphthalene 1,2;3,4-Dioxide

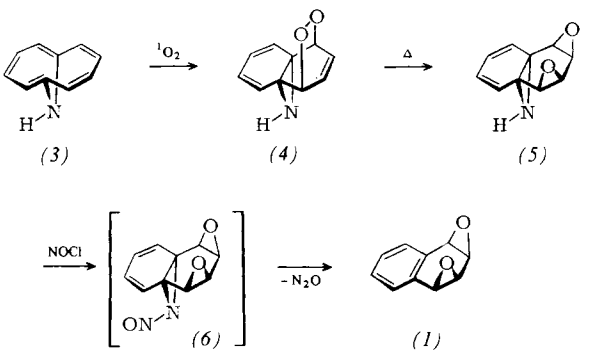
By *Emanuel Vogel*, *Hans-Helmut Klug*, and *Maria Schäfer-Ridder*[*]

Some time ago we reported the synthesis of *syn*-benzene dioxide[1] and proved that this arene oxide is in mobile equilibrium with its eight-membered ring valence tautomer 1,4-dioxocin above 50°C. Almost simultaneously, *Borders et al.*[2] described the isolation of an antibiotic having a benzene dioxide partial structure whose stereochemistry could only be elucidated by comparison with the stereoisomeric benzene dioxides[3] as involving a *syn* arrangement of the epoxide rings. The appearance of a benzene dioxide derivative as a metabolite of microorganisms suggests that nature may also produce naphthalene oxides, especially since naphthalene monoxide has already been detected as a product of enzymatic naphthalene degradation[4]. The search for such metabolites would doubtless be facilitated by a knowledge of the parent compounds, above all *syn*- and *anti*-naphthalene 1,2;3,4-dioxide [*(1)* and *(2)*]. We have now found methods of synthesizing these two arene oxides.

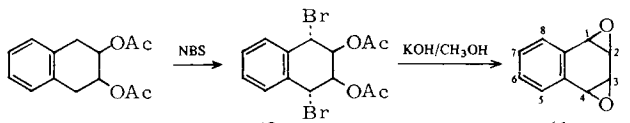
(1) *(2)*

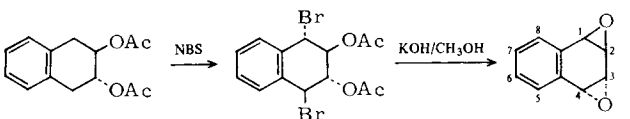
The synthesis of *(1)* exploits the photooxidation of 1,6-imino[10]annulene *(3)*. Irradiation of *(3)* with a sodium vapor lamp in the presence of methylene blue and oxygen [methylene chloride/methanol (100:1); 10—15°C; 36 h] yields the 1,4-endoperoxide *(4)*[5], which does not have to be isolated but, after removal of solvent, can be thermolyzed in boiling ethyl acetate (10 h). As may be predicted from the thermal behavior of 1,6-methano[10]annulene endoperoxide[6], *(4)* undergoes complete isomerization to the iminodioxatrishomobenzene derivative *(5)*[7] [m.p. 175—176°C (dec.); NMR ($CDCl_3$): AA'BB' systems, centered at $\tau = 3.58$ (olefin protons) and 6.53 (epoxide protons), singlet at $\tau = 10.7$ (NH proton); UV (CH_3CN): $\lambda_{max} = 255$ nm ($\varepsilon = 4650$); yield 25 % (36 % based on reacted *(3)*)]. To our knowledge, *(4)* and *(5)* are the first derivatives of the hitherto hypothetical benzene imine[8] which are unsubstituted at the aziridine nitrogen. Reaction of *(5)* with an excess of nitrosyl chloride in the presence of an equivalent amount of triethylamine in methylene chloride at −78°C leads to the unstable *N*-nitrosoaziridine *(6)* which transforms at very low temperature with elimination of N_2O into the desired *syn*-naphthalene 1,2;3,4-dioxide *(1)*. Recrystallization from ethyl acetate furnishes *(1)* as a remarkably stable colorless compound[9] (rhomboids) having m.p. 178—180°C (dec.); yield 50 %.

[*] Prof. Dr. E. Vogel, Dipl.-Chem. H.-H. Klug, and Dr. M. Schäfer-Ridder
Institut für Organische Chemie der Universität
Greinstrasse 4, 5000 Köln 41 (Germany)



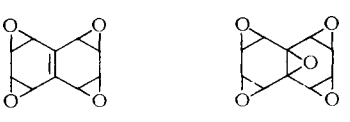
Apart from this route, *(1)* is also accessible conventionally from *(7)* *via* the naphthalene bisbromoacetate *(8)*. Compound *(8)* is a component of the complex bromination mixture arising in the reaction of *(7)* with *N*-bromosuccinimide (NBS) in boiling carbon tetrachloride. Treatment of an ethereal solution of the mixture, which was not resolved, at room temperature with 5% methanolic potassium hydroxide gives a low yield of *(1)* (5—8%).





anti-Naphthalene 1,2;3,4-dioxide *(2)* is obtained in analogous manner from *(9)* *via* the naphthalene bisbromoacetate *(10)*. After isolation by chromatography over silica gel [ether/hexane (1:1)], *(2)* crystallized as colorless needles, m.p. 99—100°C, from ether/pentane (9:1); yield 1—2%.

The NMR spectra of the naphthalene dioxides *(1)* [AA'BB' system at $\tau = 6.04$ (H^1, H^4) and 6.11 (H^2, H^3) ($J_{1,2} = 3.63$, $J_{1,3} = 0.30$, $J_{1,4} = 0.01$, $J_{2,3} = 2.97$ Hz) and AA'BB' system, centered at $\tau = 2.5$ (H^5—H^8); in [D_6]acetone] and *(2)* [AA'BB' system at $\tau = 6.06$ (H^2, H^3) and 6.34 (H^1, H^4) ($J_{1,2} = 4.22$, $J_{1,3} = 0.75$, $J_{1,4} = 0.10$, $J_{2,3} = 1.75$ Hz) and AA'BB' system, centered at $\tau = 2.6$ (H^5—H^8); in $CDCl_3$] are in full accord with those of *syn*- and *anti*-benzene dioxide, regarding the signal pattern and the coupling constants of the epoxide protons. Once more, only the vicinal coupling constant $J_{2,3}$ provides a reliable tool for distinguishing between the two stereoisomers by NMR spectroscopy. The $J_{2,3}$ coupling constants of 2.97 and 1.75 Hz, respectively, determined by analysis of the AA'BB' system of the epoxide protons, which are lower than suggested by the Karplus equation owing to the influence of the electronegative oxygen atoms[10], are almost identical with those of the corresponding benzene dioxides (2.83 and 1.75 Hz).



The photooxidation of *(3)* also proved to be a key reaction for the synthesis of a naphthalene 1,2;3,4;5,6;7,8-tetroxide *(11)* [m.p. 186°C (dec.)] whose configuration is not yet known with certainty. Starting from the intermediate *(5)* the reaction sequence of $^1O_2$ addition, thermolysis, and nitrosation leads to *(11)*. A naphthalene pentoxide *(12)* [m.p. 280°C (dec.)][11], probably *syn,syn,syn,syn*-1,2;3,4;5,6;7,8-*anti*-9,10-naphthalene pentoxide, was finally isolated as the product of "exhaustive photooxidation" of 1,6-oxido[10]annulene. The stereochemistry of *(11)* and *(12)* is currently being studied by X-ray structure analysis[12].

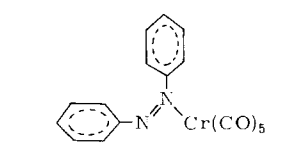
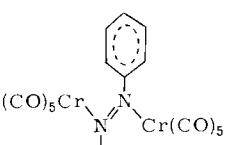
Carbonylchromium Complexes of Azobenzene[1]

By *Max Herberhold* and *Konrad Leonhard*[*]

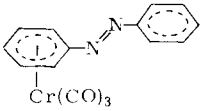
During investigations of the photo-induced and thermal reaction of azobenzene (azb) with hexacarbonylchromium we



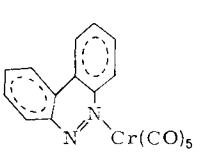
(1) (deep red)
ν(C≡O) 2063, 1984, 1941 and 1910 cm^{-1} (in THF)



(2) (blue-violet)



(3) (deep red)
ν(C≡O) 1972 and 1897 cm^{-1} (in THF)



(4) (red-brown)
ν(C≡O) 2065, 1983, 1927 and 1890 cm^{-1} (in THF)

[*] Doz. Dr. M. Herberhold and Dr. K. Leonhard
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, 8000 München 2 (Germany)

have been able to isolate—depending upon the reaction conditions—the three novel complexes *(1)*—*(3)*, and for the first time have observed a difference in behavior of *cis*- and *trans*-azobenzene in complex formation.

When *cis*-azobenzene is added to a photolyzed solution of $Cr(CO)_6$ in tetrahydrofuran (THF) the mononuclear complex *(1)* is formed:

$$Cr(CO)_6 \xrightarrow[-CO]{THF;\ h\nu} [Cr(CO)_5(THF)] \xrightarrow[-THF]{+\ cis\text{-azb};\ 25\,^\circ C} Cr(CO)_5(cis\text{-azb})$$
(1)

Benzo[*c*]cinnoline, which can be regarded as a rigidly fixed form of *cis*-azobenzene, reacts in an analogous way to give *(4)*[2]. *trans*-Azobenzene does not react under these conditions.

Compound *(1)* is stable in air, but sensitive to light. The mass spectrum shows the molecular ion $Cr(CO)_5(azb)^+$ ($m/e = 374$) and all the fragment ions $Cr(CO)_n(azb)^+$ ($n = 4$—0). In the electronic spectrum of *(1)* the characteristic $n \rightarrow \pi^*$ transition of *cis*-azobenzene (440 nm) is shifted to 505 nm; a new absorption appears at 390 nm.

Compound *(1)* is the first mononuclear azobenzene complex in which the azb ligand is present in the *cis* configuration[3a]. All azobenzene complexes studied so far by X-ray methods[3] always contain *trans*-azobenzene. In some cases catalyzed isomerization of *cis*- to *trans*-azobenzene was observed in the presence of metal complexes[3b].

Although *trans*-azobenzene—like *trans*-azocyclohexane[4]—does not react with a solution of $[Cr(CO)_5(THF)]$ in THF, subsequent removal of solvent and drying of the residue under high vacuum leads to formation of a dinuclear complex *(2)*, which is stable in the solid state up to *ca.* 65 °C. In the presence of solvents, *(2)* already decomposes at −40 °C with liberation of pure *trans*-azobenzene (λ_{max} 449 and 316 nm in *n*-hexane). At −20 °C a deep-red intermediate [presumably $Cr(CO)_5$(*trans*-azb)] can be observed. Decomposition of *(2)* in benzene affords solvent-stabilized $[Cr(CO)_5]$-fragments which are stable for a short period of time and can be used for the synthesis of pentacarbonylchromium complexes. The IR spectrum of *(2)* ($\nu(C\equiv O)$ 2053, 1963, 1924, and 1894 cm^{-1} in KBr) is almost identical to that of the (much more stable) tungsten complex (*trans*-azb)$[W(CO)_5]_2$ which precipitates on irradiation of a hexane solution of $W(CO)_6$ in the presence of *trans*-azobenzene.

Thermal reaction of azobenzene with $Cr(CO)_6$ in boiling diglyme at 160—170 °C leads with strong decomposition to the π-arene complex *(3)* (m.p. 121 °C) in *ca.* 1 % yield; anilinetricarbonylchromium[5] (6 %) is also formed. *(3)* is sublimable in a high vacuum above 90 °C. In the mass spectrum the molecular ion $Cr(CO)_3(azb)^+$ ($m/e = 318$) and successive loss of the three CO ligands followed by the fragmentation of the π-bonded azobenzene can be observed. The $\nu(C\equiv O)$ frequencies in the IR spectrum of *(3)* (1972 and 1897 cm^{-1} in THF) are surprisingly similar to those of benzenetricarbonylchromium (1972 and 1890 cm^{-1}); obviously the phenylazo substituent does not exert any considerable influence on the charge density in the π-bonded benzene ring. In the ^{1}H-NMR spectrum of *(3)* only the proton signals of the coordinated ring are shifted upfield (multiplets at $\tau = 3.55$ and 4.12 in $[D_6]$-acetone), while the signals of the free phenyl group occur, as in *trans*-azobenzene itself, at $\tau = 2.1$ and 2.4. *trans*-Azobenzene is liberated in the decomposition of *(3)* with bromine water.

Experimental[6]:

cis-Azobenzene-pentacarbonylchromium (1)

A solution of $Cr(CO)_6$ (0.22 g, 1 mmol) in THF (100 ml) is irradiated[7] until *ca.* 25 ml CO (= 1 mmol) have been evolved, and then treated with spectroscopically pure *cis*-azobenzene (0.20 g, 1.1 mmol). After 0.5 h the solvent is removed; unreacted $Cr(CO)_6$ and azobenzene can be sublimed from the residue at 30 °C in a high vacuum. The crude product is recrystallized from THF/hexane at −78 °C and dried in a high vacuum. Yield 0.20 g (53 %), m.p. 62—65 °C.

trans-Azobenzene-bis(pentacarbonylchromium) (2)

After evolution of gas has ceased, the irradiated solution of $Cr(CO)_6$ (0.44 g, 2 mmol) in THF is treated with commercial azobenzene (0.18 g, 1 mmol). The solvent is removed and the residue dried in a high vacuum. The bluish violet crude product is dissolved at −45 °C in a small volume of THF; on addition of pentane at −78 °C, *(2)* crystallizes out. After repeated washing with pentane at −78 °C the complex is dried in a high vacuum at room temperature. Yield 0.14 g (25 %).

μ-Bromo-μ-phenylmethylidynebis(tetracarbonylrhenium)[1]

By *Ernst Otto Fischer, Gottfried Huttner, Tassilo Lothar Lindner, Albin Frank*, and *Fritz Roland Kreissl*[*]

On reaction of phenylmethoxycarbenenonacarbonyldirhenium *(1)*[2] with aluminum bromide we observed expulsion of the CH_3O group, elimination of a CO molecule, and entry of a Br atom into the complex:

$$Re_2(CO)_9C(OCH_3)C_6H_5 + Al_2Br_6 \xrightarrow[-30\,^\circ C]{Toluene} Re_2(CO)_8(CC_6H_5)Br + CO + \{Al_2Br_5OCH_3\}$$
(1) *(2)*

Either the formation of a bromo- and a phenylcarbyne ligand with retention of the rhenium-rhenium bond or the linkage of two tetracarbonyl rhenium fragments *via* a bromo- and a phenylmethylidyne bridge appeared to account for the structure of the new compound *(2)*. X-Ray structure analysis

[*] Prof. Dr. E. O. Fischer, Doz. Dr. G. Huttner, Dipl.-Chem. T. L. Lindner, Dipl.-Chem. A. Frank, and Dr. F. R. Kreissl
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, 8000 München 2 (Germany)

[956 independent reflections ("Syntex P21"); solution with "Syntex XTL" ($R_1 = 0.057$)] of the complex confirmed the second alternative, and especially the bridging C_6H_5C ligand having sp^2-hybridized carbon (cf. Fig. 1). Cell parameters: space group P21/c; $a = 1330.9$, $b = 1083.9$, $c = 1817.1$ pm; $\beta = 134.6°$; $V = 1866.1 \times 10^6$ pm^3; $Z = 4$; $d_{calc} = 2.725$ g cm^{-3}.

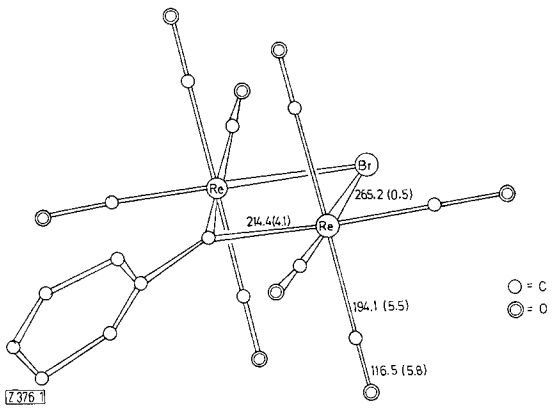

Fig. 1. Molecular structure of $Re_2(CO)_8(CC_6H_5)Br$ *(2)*.

The four-membered ReBrReC ring in *(2)* also differs from the MCMC rings found in the structures of the compounds bis(μ-trimethylsilylmethylidyne)tetrakis(trimethylsilylmethyl)-diniobium[3] and di-μ-ethoxycarbonylmethylidynebis(tetracarbonylmanganese)[4] in that the methylidyne bridge, discovered here to occur singly for the first time, between the two coordination centers contains a substituent devoid of a hetero atom. The Re—C bond length is 214.4 (4.1) pm, and is thus 14 pm shorter than a calculated Re—C single bond (covalent radii: Re = 151 pm[5], C = 77 pm). As expected, the Re—Br distance is longer than in Re_3Br_9 (254.3 pm, rhenium as Re^{3+}[6]); having a value of 265.2 (0.5) pm it corresponds to the sum of the single bond radii (Br = 114 pm). Both bridge atoms are located approximately in the plane of the equatorial carbonyl groups. The phenyl ring is twisted by 72° relative to this plane.

The results of total elemental analysis and IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectrometry are in accord with this finding.—In the IR spectrum (in *n*-hexane) of compound *(2)* four bands appear in the ν_{CO} frequency range at 2081 m, 2023 vs, 2013 s, and 1953 s cm^{-1}.—In the ^{1}H-NMR spectrum the phenyl protons are observed as two multiplets in the intensity ratio 3:2 at 7.50 and 6.84 ppm (in CD_2Cl_2, −20 °C, TMS as internal standard).—The proton noise decoupled ^{13}C-NMR spectrum (in CD_2Cl_2, −20 °C, relative to CD_2Cl_2 = 54.16 ppm) contains a total of seven signals: four in the carbonyl and three in the aromatic range. The signal at 201.20 ppm is assigned to the bridging carbon atom, the three signals at 186.85, 186.10, and 185.88 ppm to the carbonyl carbon atoms, and the remaining signals at 129.78, 127.84, 110.69 ppm to the phenyl carbon atoms.—In the mass spectrum the molecular peak appears at $m/e = 768$ (based on ^{187}Re and ^{81}Br, ion source TO 4, 50 eV).

Procedure:

All operations are to be performed under nitrogen with dried (Na, P_4O_{10}) and N_2-saturated solvents.—Compound *(1)* (1.00 g, 1.34 mmol) and Al_2Br_6 (0.72 g, 1.34 mmol) are stirred together in toluene (10 ml) at −30 °C for 30 min. Unconsumed Al_2Br_6 is decomposed at −70 °C with methanol and the solution decanted. Complex *(2)* in the residue is purified by chromatography in methylene chloride/pentane over silica gel and recrystallized from methylene chloride/diethyl ether: black crystals, decomposing above 108 °C; yield 0.5 g (49%).

Mechanism of the Thermal Conversion of 3,3′-Bicyclopropenyls into Benzene Derivatives[**]

By *James H. Davis, Kenneth J. Shea*, and *Robert G. Bergman*[*]

Possible mechanisms for the highly exothermic ($\Delta H_0 = -120$ kcal/mol) thermal conversion of 3,3′-bicyclopropenyls [*e.g. (1)*] into benzene derivatives fall into two general groups[1]. The first (which we shall refer to here as group A) postulates some sort of initial bonding interaction between the two cyclopropenyl rings (examples are concerted double ring expansion, the classical Breslow[1a] prismane mechanism, and the recently suggested tricyclic diradical mechanism offered by *Weiss* and *Köbl*[1g]). The other group (B) involves cyclopropene ring bond cleavage as the initial critical step[2]. Both *Weiss* and *Köbl*[1g] and *de Wolf et al.*[1c] have recently reported that, in addition to aromatization, substituted bicyclopropenyls also undergo Cope rearrangement[3]. 3,3′-Dimethyl-3,3′-bicyclopropenyl *(1)*, for example, rearranges to diastereomers *(2)* and *(3)* in competition with its conversion into xylenes[1e]. During a recent chemiluminescence study[4] of the aromatization of *(1)*, we, too, observed its conversion into *(2)* and *(3)*. It occurred to us that the stereochemical relationship of these two molecules was such that an examination of their aromatization might allow us to decide between the mechanisms A and B discussed above, since pathways involving initial ring cleavage (B) destroy the stereochemical distinction between *(2)* and *(3)*.

We have therefore (i) found methods to preparatively separate *(2)* and *(3)* from *(1)* and xylene products, (ii) carried out chemical correlations to determine which of these diastereomers is the DL and which the *meso* form, and (iii) determined

the zero-time (kinetic) ratio of xylenes formed from each diastereomer. Our results provide strong evidence for the ring-cleavage mechanism (group B).

Separation of *(2)* and *(3)* was achieved by preparative VPC at 25 °C on a 20′ × 1/4″ *glass* column packed with 30% SE-30 on chromosorb WAW (60/80). The stereochemistry of each diastereomer was determined by chemical correlation with DL- and *meso*-3,4-dimethyl-2,5-hexanediones, whose structures were assigned using chiral shift reagents[5a] and confirmed by asymmetric hydroboration of the DL-diketone[5b].

Pyrolysis of *(1)*, *(2)*, and *(3)*, in a 200-ml vessel made of lead-alkaline glass[6] (temperature range 160—200 °C), along with VPC analysis of *all three* xylenes at very low percentage conversion[7] provided information about both the Cope rearrangement and aromatization kinetic product distributions (Table 1). The chemical correlations confirmed earlier judg-

Table 1. Extrapolated zero-time xylene distributions formed in the gas phase pyrolysis [a] of dimethylbicyclopropenyls *(2)*, *(3)*, and *(1)* at 169.5 °C.

Compound	Xylene isomers [%]		
	p	*m*	*o*
(2) [b]	20±1	72±2	8±3
(3)	27±2	62±2	11±4
(1)	26±5	2±2	72±5

[a] Pyrolyses were carried out in a well-conditioned static system (see text) at a total pressure of *ca.* 150 torr (15 torr of substrate and 135 torr of pentane as bath gas). Samples were vaporized into the reaction vessel and removed using a conventional vacuum line system connected to the vessel. [b] Extrapolated from VPC data (see ref. [7]) taken at 4 points ranging from reaction times of 300 s (6.4% loss of starting material: 0.86% conversion to xylenes) to 1000 s (23.5% conversion of starting material, 1.50% conversion to xylenes). Data for *(3)* and *(1)* were taken over similar reaction times.

ments[1e,f] that the Cope process favors the chair transition state. The *(2)*/*(3)* ratio extrapolated to zero time (130±10) showed *no* variation with temperature[1e] and is very similar to that observed in acyclic systems[8] (one therefore needs no "special geometric and bonding effects"[1e] to account for it)[9]. Pyrolysis of isolated *(2)* and *(3)* (92% and 95% pure, respectively) demonstrated (i) that the diastereomers interconvert under the reaction conditions (by a pathway different from one involving reconversion into *(1)*) at rates (cf. Table 2) competitive with xylene formation, and (ii) the zero-time (kinetic) distributions of *o*-, *m*- and *p*-xylene formed from each diastereomer are very similar.

Table 2. Rate constants [a] (in s^{-1}, $\times 10^5$) for interconversion of bicyclopropenyls *(1)*, *(2)*, and *(3)* and for their conversion into xylenes.

Starting material \ Product	*(2)*	*(3)*	Xylenes [b]
(1)	18±2	0.14±0.02	3.6±1.0
(2)	—	25 ±2	1.7±0.5
(3)	25±2	—	1.9±0.5

[a] Determined by computer simulation of concentration-*vs.*-time curves (at both low and extensive conversion for *(1)*, *(2)*, *(3)* and total xylenes), using the MSIM4 program written by Ms. *Frances Houle* in collaboration with Professor *D. L. Bunker* at the University of California, Irvine. We are grateful to Ms. *Houle* and Professor *Bunker* for providing us with a copy of the program.
[b] Summation rate constants for appearance of all xylenes. For individual (relative) rates of formation, see Table 1.

The data are clearly inconsistent with group A mechanisms[1a, 1g], since these should give dramatically different xylene distributions from diastereomers *(2)* and *(3)*. Initial (reversible) ring opening to diradicals *(4a)* and *(4b)* (or their vinylcarbene relatives[2]), however, nicely accounts for both the similarity of product distributions from *(2)* and *(3)* and for the competitive interconversion of these compounds, if one assumes that the relative rates of formation of *(4a)* and *(4b)* from *(2)* and *(3)* are very slightly different. This mechanism also accounts for the fact that the percentage of *m*-xylene formed directly from *(1)* at "zero time" is zero within experimental error. These results, taken together with the recent observation that Dewar benzenes are required intermediates in the aromatization[4], lead us to the overall mechanism outlined. We suggest that ring opening to diradicals (or carbenes) *(4)* followed by cyclopropenylmethyl ring expansion[10, 11], closure to Dewar benzenes, and subsequent concerted[12] ring opening of these intermediates, is the aromatization mechanism most consistent with presently available experimental evidence.

[9] Because of the unusual symmetry of *(1)*, the chair and boat transition states may be interconverted by a simple rotation rather than a ring flip, and the rigidity of the system prevents rearrangement by a number of other conformations available to the more flexible acyclic system [8b, c].

It therefore seems likely that the *(1)*→*(2)* and *(1)*→*(3)* $\Delta\Delta F^{\neq}$ of 4.3 kcal/mol (166 °C) reflects the true chair-boat transition state free energy difference for this system.

[10] This pathway is analogous to the ionic mechanism suggested by *Weiss et al.* [1b, 1c] for the silver-catalyzed conversion of bicyclopropenyls to Dewar benzenes, except that due to the extreme difficulty of generating charge-separated species in the gas phase, neutral diradicals rather than ionic intermediates are probably involved here; see, for example, a) *L. Salem* and *C. Rowland*, Angew. Chem. *84*, 86 (1972); Angew. Chem. Int. Ed. Engl. *11*, 92 (1972); b) *E. F. Hayes* and *A. K. Q. Siu*, J. Am. Chem. Soc. *93*, 2090 (1971); c) *L. Salem* and *W.-D. Stohrer*, to be published; d) *W. A. Goddard* and *J. H. Davis*, unpublished results.

[11] Interestingly, we have been unable to find a study in the literature of cyclopropenylcarbinyl radicals to use as a model for the ring expansion of *(4a)* and *(4b)*. It seems likely, however, that the strain relief and incipient allylic delocalization generated in the transition state for such an expansion would render it an extremely facile process.

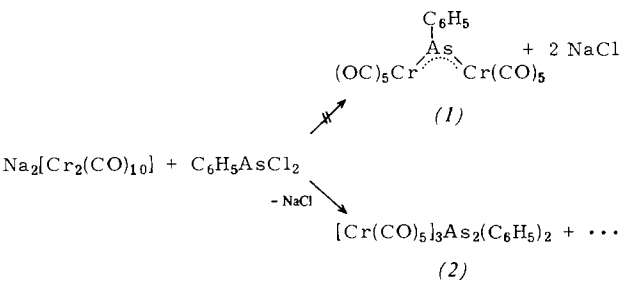
"Arsenobenzene", C_6H_5—As=As—C_6H_5, as a Bridging μ_3 Ligand in a Transition Metal Complex[**]

By *Gottfried Huttner, Hans-Georg Schmid, Albin Frank*, and *Olli Orama*[*]

In an attempt to synthesize the arsinidene complex *(1)*[1], according to:



we surprisingly isolated not *(1)* but instead the red complex *(2)*, m.p. 142 °C (dec.), among other hitherto unidentified products. The new compound *(2)* can also be prepared[2] according to:

The molecular ion of *(2)* does not appear in its mass spectrum; however, intense peaks are observed for the fragment ions $Ph_2As_2Cr(CO)_5$ (m/e = 496) and Ph_2As_2 (m/e = 304). The IR spectrum exhibits absorptions which are characteristic of phenyl groups; the band pattern in the ν_{CO} region indicates the presence of several differently coordinated $Cr(CO)_5$ units. The ^{1}H-NMR spectrum (solution in CD_2Cl_2) only shows signals due to phenyl protons.

X-Ray structure analysis[3] shows that arsenobenzene, Ph—As=As—Ph, which is homologous to azobenzene, is stabilized as a ligand in the complex *(2)*. The two arsenic atoms both form coordinative bonds to $Cr(CO)_5$ groups. In addition, the As=As double bond participates in π-interaction with a third $Cr(CO)_5$ group (cf. Fig. 1).

Arcisstrasse 21, 800 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

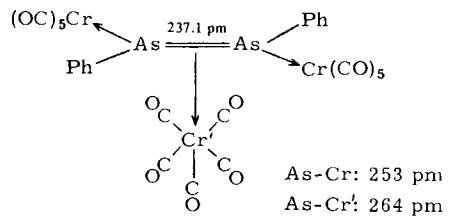

Fig. 1. Molecular structure of the arsenobenzene complex *(2)*.

In the only example of a R_2As_2 complex yet known, $(OC)_4Fe(C_6F_5As)_2$[4], the ligand is merely stabilized by π addition to a carbonylmetal fragment.

Evidence supporting formulation of the complex *(2)* with an As=As double bond is provided by the arsenic-arsenic interatomic distance (Fig. 1), which is 9 pm shorter than the As—As single bond in $C_5H_5(CO)_2Mn\{PhHAs\}_2Mn(CO)_2C_5H_5$ (246 pm)[5], in spite of the elongation due to coordination.

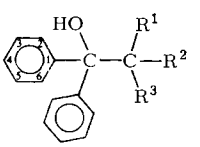
Magnetic Nonequivalence of the C Atoms of Prochiral Diphenylmethyl Groups in ^{13}C-NMR Spectroscopy

By *Hans Otto Kalinowski, Bernd Renger*, and *Dieter Seebach*[*]

The magnetic nonequivalence of diastereotopic groups manifested in ^{1}H-NMR spectra has proved to be of value in the elucidation of stereochemical problems[1]. Only very few comparable studies have so far been performed in ^{13}C-NMR spectroscopy[2–4]. We here report the magnetic nonequivalence of the C atoms of diastereotopic phenyl groups in tertiary alcohols of type *(1)*[5].



(1a-h)

Table 1 shows the chemical shift differences of the ^{13}C-NMR signals of the phenyl carbon atoms of these compounds. The relatively large difference of the signals for the ring C^1 atoms is not surprising since these atoms are located closest to the center of chirality (except in the case of *(1i)*); the magnitude of the difference remains practically constant within the classes of compounds *(1a–c)* and *(1d–h)*. The largest splittings are observed for the carbonyl-containing compounds *(1a–c)*, in which effective hydrogen bonding could be responsible for

(d)	H	—NH—$(CH_2)_4$—		146.6 144.4	2.2	0.6	0.5	0.8
(e)	H	—NH—$CH(CH_3)$—$(CH_2)_3$—		146.6 144.5	2.1	0.5	0.5	0.3
(f)	H	—NH—$(CH_2)_2$—$CH(CH_3)$—CH_2—		146.0 143.8	2.2	0.5	0.3	0.5
(g)	H	—NH—$(CH_2)_3$—$CH(CH_3)$—		147.4 145.0	2.4	0.7	—	0.3
(h)	H	—NH—$(CH_2)_3$—		148.3 145.5	2.8	0.3	0.3	—
(i)	H	$-\overset{\oplus}{N}H_2-(CH_2)_3-$ $Cl^{\ominus}$		145.0 [c] 144.6	0.4	0.7	0.3	0.3
(j)	H	SCH_3	C_6H_5	145.9 144.7	1.2	>0.1 [d]	>0.1 [d]	0.1

[a] The spectra were recorded with a CFT 20 Varian instrument (8K store, accuracy: 0.05 ppm).
[b] In dimethyl sulfoxide as solvent (to rupture the H bonds: cf. ref. [6]); dilution of the solution has no effect on the splitting and chemical shift of the signals.
[c] In dimethyl sulfoxide as solvent.
[d] In the phenyl region there are 12 signals of which only those for C^1 and C^4 can be unequivocally assigned. The splitting of the signals for C^2, C^6 and C^3, C^5 is in any case greater than 0.1 ppm since the lines are separated from each other by more than 0.1 ppm.

preference of a particular conformer (see Table 1, b). Comparison of the chemical shift differences observed for the signals of atoms C^2 and C^6, C^3 and C^5 and C^4, shows that, although significantly smaller than for C^1 except in the case of *(1i)*, they do not decrease with increasing distance from the center of chirality, as is claimed in the literature[1,2]. Instead, the magnitude of the difference alternates or (in one case) is observable only for the atom C^4. No explanation of this finding can yet be given. While there does seem to be a relationship between the magnitude of the chemical shift difference (compound *(1b,c,f,g)*) and the inductive and mesomeric substituent effect—the C atoms in positions 3 and 5 seem to be the least affected—this explanation appears unsatisfactory in view of the similarity of the compounds.

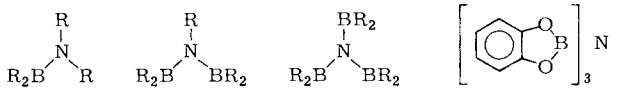
Tris(3-methylborolan-1-yl)amine, an Electron-Deficient Triborylamine

By *Wolfgang Storch* and *Heinrich Nöth*[*]

Dedicated to Professor J. Goubeau on the occasion of his 75th birthday

Alkyl-substituted borylamines *(1)* are stable, whereas diborylamines *(2)* readily decompose with elimination of BR_3[1] and tris(diorganylboryl)amines *(3)* were hitherto unknown[2].

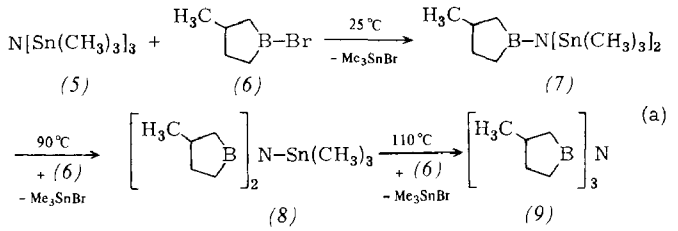


(1) *(2)* *(3)* *(4)*

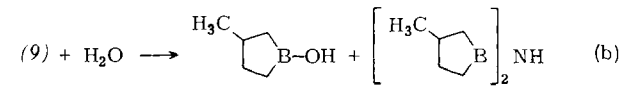
Existence of the predicted $N(BF_2)_3$ with D_{3h} symmetry[3a] has so far not been demonstrated experimentally[3b]. The B_3N skeletal unit of a triborylamine can be synthesized, however, if the boron atoms have substituents capable of π back-bonding and if 1,3 nucleophilic rearrangement is impeded by incorporation in a ring system[4]; the *electron-rich* compound *(4)* may be cited as example[4a]. Above 150°C the latter mentioned stabilization effect raises the decomposition threshold in bis(borolan-1-yl)amines compared to $[(CH_3)_2B]_2NCH_3$ to over 150°C[5]. This has now made it possible to synthesize also the *electron-deficient* triborylamine *(9)* of type *(3)* in accordance with Equation (a), where exact control of stoichiometry and temperature permits stepwise replacement of the $(CH_3)_3Sn$ groups of *(5)* by the 3-methylborolanyl group.

The higher temperature and longer reaction time required on progressive removal of $(CH_3)_3Sn$ groups reflects the expected decrease in basicity of the nitrogen in the series *(5)*—*(9)*.

[*] Prof. Dr. H. Nöth and Dr. W. Storch
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, 8000 München 2 (Germany)



The products *(7)*—*(9)* were characterized by elemental analysis and NMR, IR, and MS spectra. *(9)* slowly decomposes at 180°C. Traces of moisture lead to rapid reaction in accordance with Eq. (b). Compounds *(7)* and *(8)* are also sensitive to hydrolysis and oxidation.



The NMR data of the 3-methylborolan-1-ylamines *(7)*, *(8)*, and *(9)* [δ^{11}B: −59.2, −64.0, and −67.8 ppm, resp.; δ^{14}N: 286, 228, and 206 ppm, resp.][6] confirm the coordination number 3 for the B and N atoms. In spite of the electropositive character of the boron, the borolanyl group withdraws electron density from the N atom through BN π interactions, recognizable by the downfield shift of the ^{14}N-NMR signal and by the ^{1}H-NMR signal of the $(CH_3)_3Sn$ group [δ^{1}H: −0.16 *(5)*, −0.26 *(7)*, and −0.35 ppm *(8)*].

Because of the low π-electron density on the three boron atoms and the lability of the B—N bonds, *(9)* is a powerful boronating reagent[7].

Tris(3-methylborolan-1-yl)amine (9)

A solution of 1-bromo-3-methylborolane *(6)* (5 ml; 6.0 g, 37.2 mmol) in toluene (15 ml) is added dropwise at −20°C to a stirred solution of tris(trimethylstannyl)amine *(5)* (6.25 g, 12.4 mmol) in toluene (20 ml). The mixture is allowed to warm up slowly and then heated under reflux for 7 h. Fractional distillation (10 cm silver-mantle Vigreux column) of the residue remaining after removal of volatiles affords 8.4 g Me_3SnBr (93%; b.p. 28—30°C/10^{-2} torr) and 2.6 g *(9)* (81%; b.p. 73—74°C/10^{-2} torr). *(9)* is a water-clear, viscous liquid which is very sensitive toward hydrolysis and oxidation.

Analogous reactions of *(5)* with *(6)* in toluene under modified conditions [molar ratios 1:2 and 1:1, resp.; reaction at 90°C (4 h) and room temperature (2 h), resp.] afford the trimethylstannyl(3-methylborolan-1-yl)amines *(8)* (78%; b.p. 89—91°C/10^{-2} torr) and *(7)* (75%; b.p. 117—119°C/10^{-1} torr).

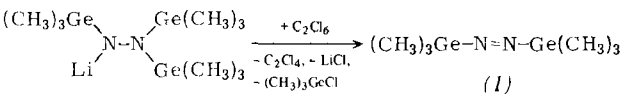
Bis(trimethylgermyl)diimine[1]

By *Nils Wiberg*, *Sham Kumar Vasisht*, and *Gerd Fischer*[*]

Bis(silyl)diimines (azosilanes) corresponding to the bis(alkyl)diimines (azoalkanes) have been known for several years[2]. However, all attempts to synthesize higher homologs of the type X—N=N—X (X = GeR_3, SnR_3, or PbR_3) have so far remained without success[3].

Adaptation of the oxidation of *N*-lithium tris(trimethylsilyl)-hydrazide[2], which affords bis(trimethylsilyl)diimine, to the preparation of bis(trimethylgermyl)diimine *(1)* was initially unsuccessful since the germyl hydrazide was not oxidized to *(1)* but further to nitrogen. However, in hexachloroethane we have now found an oxidizing agent providing access to the very easily oxidized azogermane *(1)* according to:



(Preparation of an azostannane—probably even more sensitive to oxidation—accordingly appears extremely difficult.)

The blue diimine derivative *(1)*, which can be sublimed at −45°C *in vacuo* (10^{-4} torr), expectedly gives only one signal in its ^{1}H-NMR spectrum ($\delta = -21.8$ Hz, TMS as internal standard, in C_6H_6). According to mass spectrometric studies the energy required for ionization of the highest occupied n_+ orbital of the nitrogen lone pairs is only 5.95 ± 0.05 eV; it is thus lower than the ionization energy of bis(trimethylsilyl)-diimine and much lower than that of bis(trimethylmethyl)diimine (cf. Fig. 1). The absorption maximum for the $n_+ \rightarrow \pi^*$ electronic transition responsible for the color of *(1)* on the other hand lies at 14310 cm^{-1} between the corresponding absorption maxima of the carbon and the silicon compound. This finding can be rationalized in a simplified manner in terms of inductive and—especially with regard to the π* orbital—mesomeric effects of the substituents attached to the azo group[4].

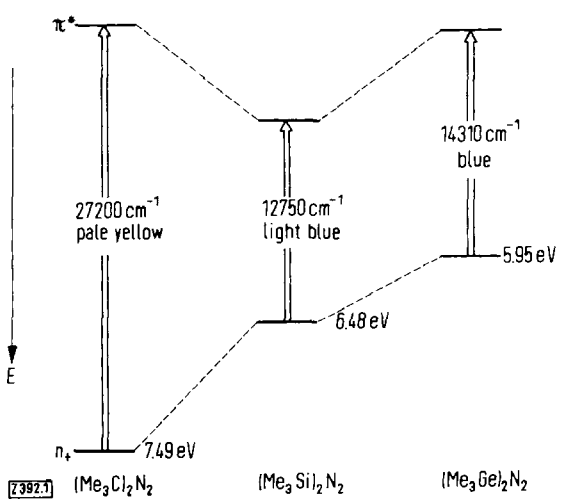


Fig. 1. Ionization energies of the n_+ orbital and wave numbers of the electronic transition between the highest occupied n_+ and the lowest unoccupied π* orbital of diimines $(CH_3)_3E—N=N—E(CH_3)_3$ (E = C, Si, Ge).

The azogermane *(1)*, which is readily hydrolyzed and extremely sensitive to oxygen[5], has a thermal instability resem-

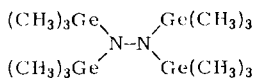
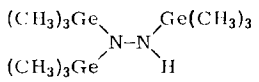
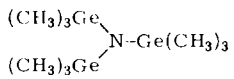
bling that of the corresponding azosilane (thermolysis occurring above *ca.* −35 °C). In analogy with $(Me_3Si)_2N_2$[6a] and $Me_3SiN_2GeMe_3$[6b], it decomposes at low temperatures almost exclusively *via* disproportionation to nitrogen and tetrakis(trimethylgermyl)hydrazine *(2)*, which is also accessible by another route[7]. At higher temperatures, increasing amounts of *(3)*–*(6)* and hexamethyldigermane *(7)*[8] are also formed.



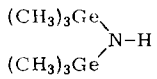
(2)



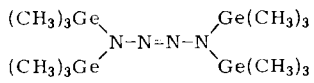
(3)



(4)



(5)



(6)

(7)

The yields of thermolysis products of *(1)* obtained at 80 °C in pentane, *e.g.*, amount to (the values in parentheses refer to the corresponding compound with Si in place of Ge): 50 (20)% *(2)*, 10 (25)% *(3)*, 10 (25)% *(4)*, 1 (10)% *(5)*, 20 (20)% *(6)*, 10 (0)% *(7)*.

Procedure:

A solution of hexachloroethane (6.0 mmol) in ether (50 ml) is added dropwise over 1 h to a stirred solution of *N*-lithium tris(trimethylgermyl)hydrazide[7] (10.0 mmol) in ether (100 ml) at −70 °C. After a reaction time of 1 h the solvent and trimethylgermyl chloride are removed as quickly as possible in the temperature range −70 to −50 °C and the product *(1)*, which volatilizes between −45 and −35 °C at 10^{-4} torr, is condensed in a cold trap at −60 °C (tetrachloroethane is not retained under these conditions). Repetition of this condensation affords *ca.* 2.0 mmol of pure *(1)*. All operations must be performed with rigorous exclusion of oxygen and moisture!

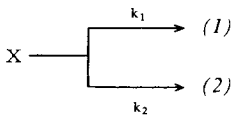
[8] Hexamethylazostannane should therefore already decompose preferentially to nitrogen and hexamethyldistannane.

Use of the Isoselectivity Principle for Distinguishing Cationic π- and σ Complexes[**]

By *Bernd Giese* and *Joachim Stellmach*[*]

Use of the kinetic selectivity principle which postulates a relationship between the competition constants $\varkappa$ and the structures of intermediates X has become subject to increasing criticism[1]. We were recently able to show that the differences in activation enthalpies $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ determined from the temperature dependence of $\varkappa$ provide a much better description of intermediates[2].



$$\varkappa = k_1/k_2$$

$$\log\frac{k_1}{k_2} = \frac{\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}}{2.303 \cdot R \cdot T} - \frac{\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}}{2.303 \cdot R}$$

As a result of that work we derived the isoselective relationship as a new criterion for distinguishing between intermediates[2].

$$\delta(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}) = T_{is} \cdot \delta(\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}) \qquad \text{(a)}$$

The subscripts 1 and 2 stand for the competing trapping reactions of X leading to the compounds *(1)* and *(2)*, respectively. The symbol δ indicates that only the changes in the activation parameters occurring on structural variation of X are related to each other.

The first application of the isoselectivity principle to radical halogen abstraction permitted a distinction to be made between π- and σ radicals[2]. In order to examine the general significance and scope of equation (a) we have now applied it to the ionic intermediates occurring on electrophilic additions to olefins. We have recently deduced that addition of halogens and benzenesulfenyl chloride to dimethyl norbornenedicarboxylate *(3)* involves intermediate formation of the π complexes *(4)* to *(6)*, *i.e.* bridged ions with electron deficient bonds, and complexes *(7)*, *i.e.* bridged onium ions without electron-deficient bonds[3,4]. Intramolecular *endo* attack of the ester groups on the carbon atoms C-6 and C-5 leads to the lactone esters *(8)* to *(15)*. The isomer ratios of *(8)*/*(12)* to *(11)*/*(15)* correspond to the selectivity values k_6/k_5 because the mixtures of isomers are formed in kinetically controlled reactions[5].

According to equation (b), which is obtained by subtraction of two Eyring relationships, the temperature dependence of the selectivity values k_6/k_5 yields the differences in activation

enthalpies $\Delta H_5^{\ddagger} - \Delta H_6^{\ddagger}$ and the entropies of activation $\Delta S_5^{\ddagger} - \Delta S_6^{\ddagger}$ for the competing *endo* attack at C-5 and C-6 of the intermediates *(4)* to *(7)*.

$$\log \frac{k_6}{k_5} = \frac{\Delta H_5^{\ddagger} - \Delta H_6^{\ddagger}}{2.303 \cdot R \cdot T} - \frac{\Delta S_5^{\ddagger} - \Delta S_6^{\ddagger}}{2.303 \cdot R} \qquad \text{(b)}$$

Measurements performed in chloroform from -60 to $+60$°C exhibit an average error of $\pm 10\%$ in the activation enthalpies and ± 0.3 e.u. in the entropies of activation[6].

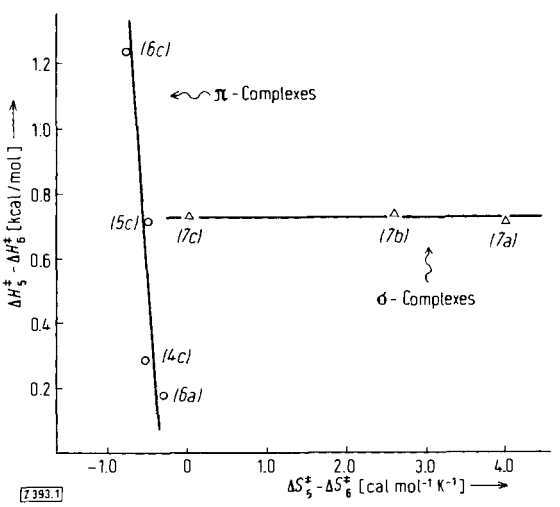

Fig. 1. Relationship between the activation parameters for competing attack of the ester on C-5 and C-6 of the intermediates *(4)* to *(7)* in chloroform.

Plotting the activation parameters gives one straight line for the halogen-bridged and another for the sulfur-bridged intermediates of electrophilic additions to *(3)* (Fig. 1). Their slopes correspond to the proportionality factors T_{is}. These are almost infinity for the halogen-containing intermediates *(4)* to *(6)* and zero for the intermediate *(7)*. Thus variations in the halogen-containing intermediates *(4)* to *(6)* predominantly affect the differences in activation enthalpies $\Delta H_5^{\ddagger} - \Delta H_6^{\ddagger}$, while changes in the intermediate *(7)* are reflected only in the differences in the entropies of activation $\Delta S_5^{\ddagger} - \Delta S_6^{\ddagger}$. These differences demonstrate that addition of halogen to *(3)* involves a different type of intermediate from that occurring in the addition of benzenesulfenyl chloride.

X-Ray Structure Analysis of 6-Methyl-6-oxo-3,5,7-triphenyl-6λ⁵-phosphatricyclo[3.3.1.0²,⁷]non-3-ene, the Product of Unusual Intramolecular Reactions

By *Werner J. Seifert*, *Ortwin Schaffer*, and *Karl Dimroth*[*]

Dedicated to Professor H. H. Inhoffen on the occasion of his 70th birthday

While investigating the rearrangement reactions of derivatives of λ⁵-phosphorin we found that the phospha-2,4-cyclohexadiene derivative *(2)*, formed *via* a $[3_s5_s]$ and a subsequent $[3_s3_s]$ rearrangement on heating of 1-allyloxy-1-methyl-2,4,6-triphenyl-λ⁵-phosphorin *(1)*, is itself transformed in boiling

toluene into the stable well-crystalline product of an intramolecular Diels-Alder reaction. Due to the complicated ^{1}H-NMR spectrum it could not be decided unequivocally if the five-membered or the four-membered ring derivative, *(3)* or *(4)*, had been formed[1]. Although postulated as intermediates of allyl phenyl ether rearrangements, intramolecular [4+2] cycloadducts have not yet been isolated[2]; such isolation has only been accomplished in the thermal rearrangement of propargyl phenyl ethers[3]. Thermolysis of 7-allyloxycycloheptatriene afforded a mixture of tricyclic reaction products of various ring sizes[4].

X-Ray structure analysis of the stable rearrangement product *(3)* or *(4)* has now permitted a decision in favor of the structural alternative *(4)*, and also confirmed that both rearrangement steps *(1)* → → *(2)* proceed suprafacially because the oxo group attached to phosphorus is located on the same side of the ring plane as the carbocyclic bridge newly formed from *(2)* by cycloaddition.

Compound *(4)* crystallizes in the triclinic space group $P\bar{1}$ with $a=9.940$, $b=12.164$, $c=10.660$ Å; $\alpha=82.11$, $\beta=115.25$, $\gamma=110.25°$; $Z=2$; $d_{calc.}=1.21\,g\,cm^{-3}$. A single crystal (*ca.* $0.5\times0.5\times0.2$ mm) was mounted on an automated Nonius four-circle diffractometer ($Mo_{K\alpha}$ radiation) and 2931 independent reflections registered, 2555 with detectable intensity, $Fo \geq \delta(Fo)$. The structure was solved by direct methods (MULTAN program[5]). The coordinates of all atoms (except H) could be deduced from an *E* Fourier synthesis with 350 phased reflections ($E \geq 1.60$). Refinement with anisotropic temperature factors for the P, O, and C atoms, and with isotropic temperature factors for the H atoms converged at $R=4.3\%$ (observed reflections).

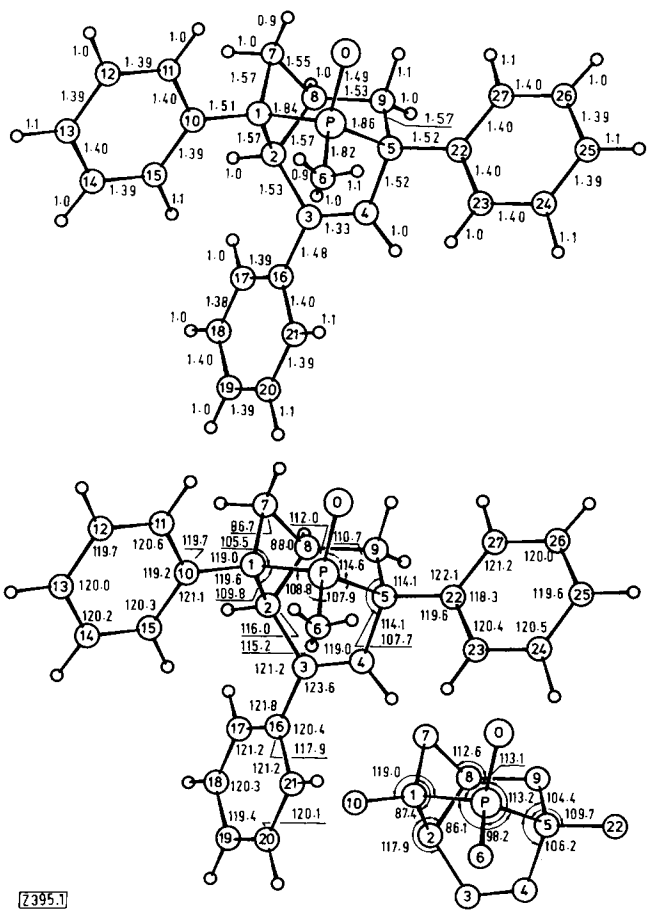

Fig. 1. Molecular structure of *(4)* with bond lengths [Å] (above) and angles [°] (below); mean standard deviations 0.004 Å (except for C—H: 0.04 Å) and 0.3°. The bond lengths are not corrected. Atoms designated by a number only are C atoms.

The tricyclic molecular skeleton of *(4)* is conformationally rigid. The bond lengths and angles (cf. Fig. 1) largely agree with the values obtained for analogous building units[6]. The bond angles in the four-membered ring are smaller than 90°; the pronounced folding (dihedral angle 35.6°) is attributable to the strained bridge between C-8 and C-5.

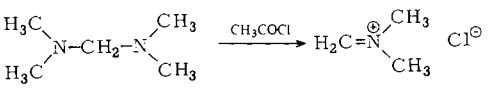
A New Variant of the Mannich Reaction[**]

By *Günther Kinast* and *Lutz-F. Tietze*[*]

The Mannich reaction is one of the most important methods available for the α-aminoalkylation of CH acidic compounds[1]. In general, a carbonyl component—usually formaldehyde—, a secondary amine, and a CH acidic compound are allowed to react together. Serious drawbacks of these reaction conditions include long reaction times, difficult optimization, poor reproducibility of the results, and the occurrence of side reactions.

We have now shown that *N,N*-dimethyl(methylene)ammonium chloride *(2)* is an inexpensive and extremely convenient reagent for α-aminoalkylation of ketones and aldehydes.



(1) *(2)*

The salt *(2)* is prepared from the aminal *(1)* and acetyl chloride in ether[2]. It crystallizes from the reaction solution and can be used without further purification. The compound can be stored indefinitely in the absence of moisture.

In order to perform the Mannich reaction, compound *(2)* (10 mmol) is suspended in anhydrous acetonitrile (5 ml) and stirred with a 10% excess of the aldehyde or ketone *(3)* for 2 min at 82 °C or 120 min at 20 °C, if necessary with cooling. The reaction time must be increased for less reactive ketones. In the course of the reaction, the reagent *(2)* dissolves and the α-aminoalkylated aldehydes or ketones generally crystallize spontaneously in the form of the hydrochlorides *(4)*. Yields are usually very good and the crystalline products often already analytically pure (Table 1).

[a] Yields of crystalline product; average values of several runs. Values in parentheses: overall yields after workup to give the amino ketone.
[b] Yields of amino ketone.

The data listed in Table 1 demonstrate the superiority of aminoalkylation with the iminium salt *(2)* over the "classical" Mannich reaction. In particular, the new method can also be employed for the reaction of sterically hindered ketones [*e.g. (3a)* and *(3b)*]. Unsymmetrical ketones [*e.g. (3i)*] are almost exclusively aminoalkylated at the more highly substituted C atom.

The Cyclohept[*a*]acenaphthylenylium Ion

By *Kagetoshi Yamamoto* and *Ichiro Murata*[*]

Among the many hydrocarbon cations so far studied the cyclohepta[*cd*]phenalenylium ion ($pK_{R^+} \approx 8.4$)[1] was found to be particularly stable. A recent study[2] revealed that the thermodynamic stability of the cyclopentadienyl anion is enhanced by annelation of the acenaphthylene system to give the anion *(1)*; this suggests the cyclohept[*a*]acenaphthylenylium ion *(2)* to be a highly stabilized hydrocarbon cation.

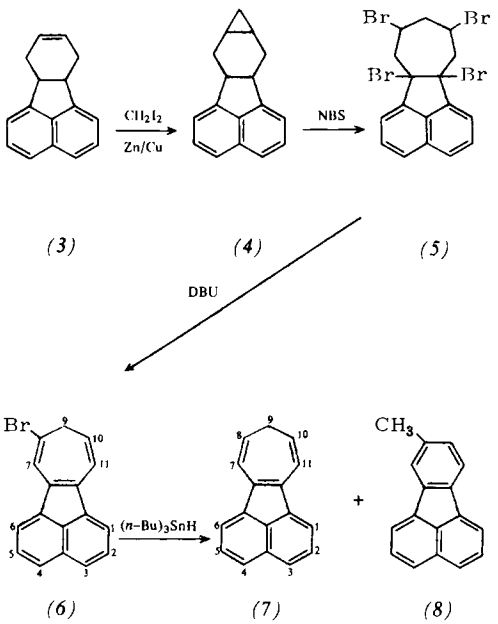
Toyonaka, Osaka 560 (Japan)

The pentaphenylcyclohept[*a*]acenaphthylenylium ion was first synthesized in 1963[3]. We have now synthesized the parent cation *(2)*, and believe it to be the most stable hydrocarbon cation yet known.



(3) *(4)* *(5)* *(6)* *(7)* *(8)*

The starting material for the synthesis was 6b,7,10,10a-tetrahydrofluoranthene *(3)*[4] which was cyclopropanated *via* the Harrison modification[5] of the Simmons-Smith reaction to produce the norcarane derivative *(4)*. Compound *(4)*, m.p. 67—68 °C, was purified by chromatography on a silver-nitrate-impregnated silica gel column with hexane (40—50 % yield). Treatment with four equivalents of NBS in benzene at room temperature afforded the crude tetrabromide *(5)* in 27 % yield, which was utilized in subsequent transformations. Dehydrobromination of *(5)* with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)[6] (in THF at ambient temperature, 12 h, under N_2) followed by chromatographic separation of the products (silica gel, hexane) gave the pure monobromide *(6)*, orange plates, m. p. 105—109 °C. The structure of *(6)* is clearly supported by its ^{1}H-NMR spectrum.

Reduction of *(6)* in refluxing toluene with tri-*n*-butyltin hydride leads to 9*H*-cyclohept[*a*]acenaphthylene *(7)* in addition to a small amount of unidentified hydrocarbon presumed to be 8-methylfluoranthene *(8)* in a ratio of 7 : 3[7]. Compound *(7)* showed the following ^{1}H-NMR characteristics after subtracting the spectrum of *(8)*: $\delta = 2.61$ (t, $J_{9,8} = J_{9,10} = 7.0$ Hz, 2 H-9), 5.58 (dt, $J_{8,7} = J_{10,11} = 9.0$, $J_{8,9} = J_{10,9} = 7.0$ Hz, H-8, H-10), 6.98 (d, $J_{7,8} = J_{11,10} = 9.0$ Hz, H-7, H-11), 7.4—7.9 ppm (m, H-1 to H-6).

Since we were unable to obtain *(7)* free of *(8)* by repeated chromatography, the final synthetic step was carried out with the mixture. Hydride abstraction from *(7)* was accomplished by treating the mixture in dry chloroform with trityl tetrafluoroborate. We obtained the cation *(2)* as the tetrafluoroborate [reddish orange crystals which decomposed at 163—170 °C; UV (acetonitrile): $\lambda_{max} = 263$ nm ($\log\varepsilon = 4.31$), 333 (4.44), 438 (4.23); 100-MHz ^{1}H-NMR (CF_3COOD): $\delta = 8.28$ (t, $J = 8.1$ Hz, H-2, H-5), 8.74 (d, $J = 8.1$ Hz, H-3, H-4), 9.04 (d, $J = 8.1$ Hz, H-1, H-6), 8.9—9.1 (m, H-8 to H-10), and 9.7 ppm (m, H-7, H-11)]. The NMR spectrum was consistent with the extensive charge delocalization into the naphthalene moiety. The species *(2)* is far more stable than other annulated tropylium ions[8]; its pK_{R^+} value is 8.7 (determined by a standard spectrophotometric method in 20 % aqueous acetonitrile). These results clearly indicate the effect of the acenaphthylene unit in delocalizing the positive charge of the tropylium ion.

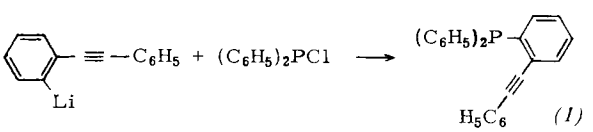
2,2″-Bis(diphenylphosphino)-2′,3′,5′,6′-tetraphenyl-*p*-terphenyl as an Arene Chelate Ligand for Rhodium(I)

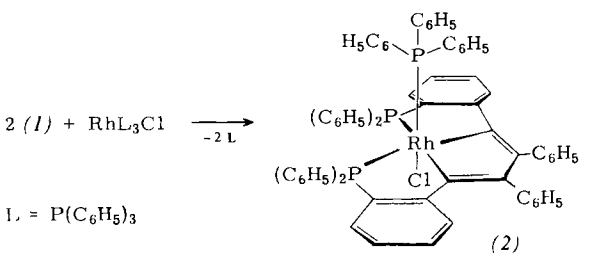
By *Werner Winter*[*]

Monoalkynylphosphanes react with transition metal compounds to give, *e.g.*, polynuclear complexes containing not only coordinated P atoms but also oligomerized "acetylene structures"[1]. Steric constraints preclude formation of a mononuclear chelate complex by the $R_2P{-}C{\equiv}C{-}R'$ group. However, this should be possible in the case of the vinylogous *o*-phenylethynyltriphenylphosphane *(1)*, preparable from *o*-lithiotolan and diphenylchlorophosphane as colorless crystals having melting point 93—94 °C (cyclohexane) [IR (KBr): $\nu(C{\equiv}C) = 2210\,cm^{-1}$ (w); FT-^{31}P{^{1}H}-NMR ($CHCl_3$, H_3PO_4 as external reference): $\delta = +8.4$ ppm; MS: $m/e = 362$ (M^+); yield 86 %].



(1)

Stirring of *(1)* and $RhCl(PPh_3)_3$ (molar ratio 2 : 1) in CH_2Cl_2 at room temperature for several minutes affords the octahedral rhodacyclopentadiene chelate complex *(2)* [obtained as orange-yellow needles, m.p. 230 °C, on slow precipitation with *n*-hexane, yield 80 %].



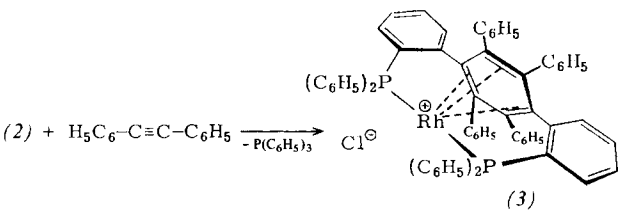
(2)

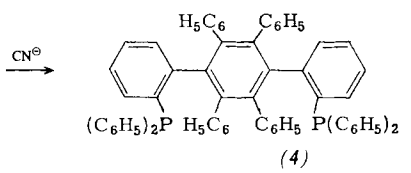
The composition and structure of the diamagnetic Rh^{III} complex follow from elemental analysis, osmometric molecular weight determination, conductivity measurements (nonelectrolyte!), and above all from the FT-^{31}P{^{1}H}-NMR spectrum

[*] Dr. W. Winter
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, 7400 Tübingen (Germany)

(CH_2Cl_2, H_3PO_4 as external reference): owing to anisotropic effects of the phenyl groups in a propeller-type arrangement on the apical triphenylphosphane ligands the equatorial chelate P atoms are found to give separate quadruplets at $\delta = -34.9$ and -28.6 ppm [$J_{RhP} = 115$, $^2J_{P(a)-P} = 29$, $^2J_{P-P} < 5$ Hz], whereas the apical P atom produces two triplets at $\delta = -8.7$ ppm [$J_{RhP(a)} = 94$, $^2J_{P(a)-P} = 29$ Hz]; in particular, the J_{RhP} values are typical for Rh^{III} complexes[2, 3].

The structure of *(2)* is also confirmed by the the IR spectrum (absence of ν(C≡C) vibrations) and by the reaction with tolan in boiling xylene: the ionic η^6-arene chelate Rh^I complex *(3)*, which is insoluble in xylene, appears almost instantaneously.





The orange-yellow, likewise diamagnetic "[4+2] cycloadduct" *(3)* [m.p. 370 °C; yield 87 %] can also be characterized by elemental analysis, molecular weight determination, conductivity measurement ($\Lambda_M = 71.4\ cm^2\ \Omega^{-1}\ mol^{-1}$, nitromethane, 1:1 electrolyte[4]) and the ^{31}P-NMR spectrum: $\delta = -48.9$ ppm, d, $J_{RhP} = 203$ Hz (typical for Rh^I complexes). The FT-$^{13}C\{^1H\}$-NMR spectrum contains the upfield shift of the new arene ligand at $\delta = 105$ ppm (narrow multiplet, coupling with ^{31}P and ^{103}Rh).

Heating of *(3)* with NaCN in aqueous ethanol affords the free ligand 2,2″-bis(diphenylphosphino)-2′,3′,5′,6′-tetraphenyl-*p*-terphenyl *(4)* [colorless crystals, m.p. 320—322 °C (benzene); ^{31}P-NMR ($CHCl_3$, H_3PO_4 as external reference): $\delta = +13.3$ ppm; MS: $m/e = 902$; yield 82 %].

The complexes *(2)* and *(3)* are extremely stable thermally and can be kept indefinitely in air. The possibility of *(3)* existing as a coordinatively unsaturated 16-electron system in the η^4-arene form is unlikely because this compound is completely inert towards CO in CH_2Cl_2[5].

The chelate function of the tertiary bisphosphane in *(2)* and *(3)* accounts for this, the first isolation of the Rh-arene intermediate[6] long suspected to occur in the Rh-catalyzed trimerization of acetylene. The reaction sequence *(1)* → *(4)* opens up a new entry to the hitherto unknown (*p*-terphenyl-2,2″-ylene)bisphosphanes, which hold promise as essentially rigid chelate ligands of fixed geometry.

Mustelan, the Malodorous Substance from the Anal Gland of the Mink *(Mustela vison)* and the Polecat *(Mustela putorius)*[**]

By *Hermann Schildknecht, Ingrid Wilz, Franz Enzmann, Norbert Grund*, and *Manfred Ziegler*[*]

We have taken advantage of the ready availability of mink posteriors to isolate from their anal glands the typical malodorous substance of species of the marten family (Mustelidae)[1]. Preparative gas chromatography of the yellow to green paste obtained from the secretion reservoir of similar size to a hazel nut in the anal sac yielded the penetratingly odorous compound mustelan as major component [255 mg from 450 anal sacs; 30 % loaded Apiezon L column (10″ × 3/8″); temperature program 136 to 236 °C].

Mustelan, b.p. 115 °C, is a mobile and colorless liquid, which according to elemental analysis and mass spectrometry has the molecular formula $C_5H_{10}S$. Absorption spectral studies and, in particular, the fragments obtained on electron pyrolysis[2], *viz.* 1-isopentanethiol, isopropyl alcohol, ethanol, and ethylene, suggested 2,2-dimethylthietane *(4)* to be the malodorous substance of the mink. This result was confirmed by desulfuration with Raney nickel to give isopentane. We found the 60-MHz ^{1}H-NMR spectrum ($CDCl_3$, TMS = 0) of mustelan to contain a singlet at 1.53 (6H) and two multiplets of an AA′BB′ system at *ca.* 2.68 and *ca.* 3.0 ppm (2H each); they are due to the ring methylene groups. Final proof of structure was provided by synthesis[3].

The best synthetic strategy appeared to involve the thietane 1,1-dioxide *(3)* which can easily be reduced to the thietane *(4)*. However, sufficient amounts of pure *(4)* for further tests only became available once we had succeeded in degrading the salt *(1)* with the less expensive PbO instead of Ag_2O. X-Ray structure determination of *(3)* expectedly showed that the thietane ring is nonplanar[4]. The new synthesis developed by *Mayer*[5] is particularly suitable for preparing larger quantities of mustelan.

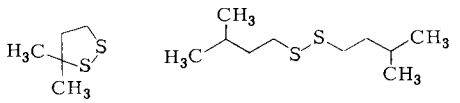
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Workup of the anal secretion of the mink by gas chromatography also gave 20 mg of a dark yellow, readily polymerizing oil whose IR spectrum closely resembles that of *(4)*, except for an additional band at 993 cm^{-1}. This fraction was shown to be 3,3-dimethyl-1,2-dithiolane *(5)*, mainly by mass spectrometric analysis, and in particular by the base peak at $m/e=69$ (M^+-65). The isomeric 4,4-dimethyl derivative could be ruled out by comparing the UV spectrum of *(5)* with those of five other dithiolanes.



(5)

(6)

In addition to *(4)* and *(5)* we also isolated a compound (retention time 14 min at 243 °C) having a mercaptane type odor, which we deduced to be diisopentyl disulfide *(6)* from its mass spectrum. Finally, we isolated a hydrocarbon $C_{10}H_{20}$, which was not further characterized, and indole.

The malodorous substances of the weasel (*M. erminea* L.) and of the polecat (*M. putorius* L.) were compared with those of the mink by gas chromatography. Indole and the hydrocarbon $C_{10}H_{20}$ were found in the weasel, and also *(4)*, *(5)*, and *(6)* in the polecat.

Enantioselective Wagner-Meerwein Rearrangement in Chiral Solvents under High Pressure[**]

By *Hans Plieninger* and *H. P. Kraemer*[*]

Dedicated to Professor Karl Freudenberg on the occasion of his 90th birthday

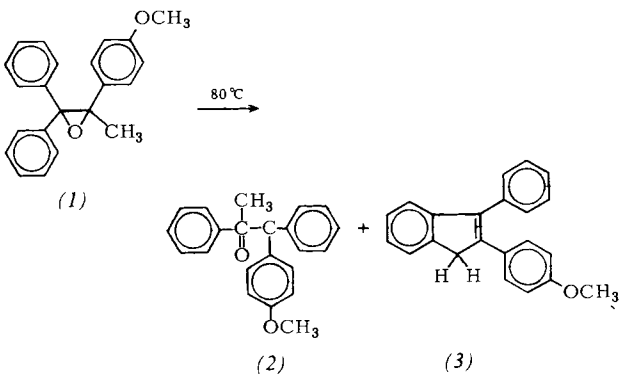
Only a few enantioselective reactions are known to take place in a chiral medium without the latter entering into reaction[1]. The object of our study was to establish whether enantioselective syntheses can be induced in a chiral medium by employing high pressures.

We based our investigations on the known fact that reactions in which at least partial charges occur in the transition state have a strongly negative activation volume under high pressure (*ca.* 10^4 bar)[2]. This "electrostriction" is due to increased interaction of the solvent molecules with the partially charged atoms of the molecules participating in the transition state. Use of a chiral solvent and a starting molecule having a prochiral functional group should give rise to two diastereomeric transition states under high pressure whose different energy content must be due only to interaction with the solvent and thus be a function of the pressure.

[*] Prof. Dr. H. Plieninger and Dipl.-Chem. H. P. Kraemer
Organisch-Chemisches Institut der Universität
Im Neuenheimer Feld, 6900 Heidelberg 1 (Germany)

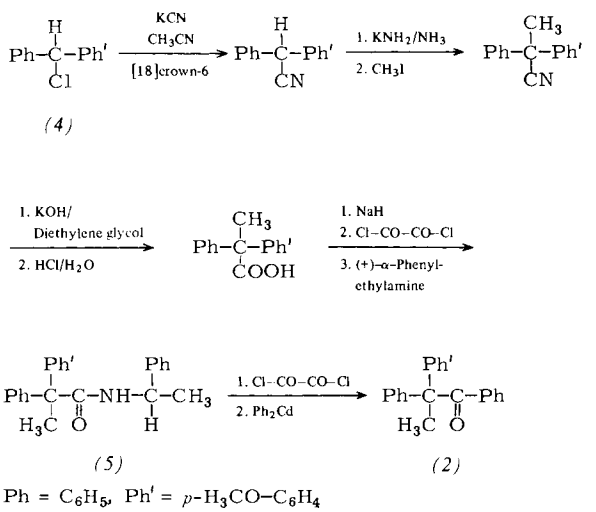
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

We have investigated the rearrangement of racemic 1-(4-methoxyphenyl)-1-methyl-2,2-diphenyloxirane *(1)* in L-(+)-diethyl tartrate at atmospheric pressure and at 10^4 bar. After hydrolysis of the L-(+)-tartrate, the main product 2-(4-methoxyphenyl)-2-phenylpropiophenone *(2)* could be easily separated chromatographically from any 2-(4-methoxyphenyl)-3-phenylindene *(3)* formed as by-product. The structures of *(2)* and *(3)* were confirmed by elemental analyses and ^{1}H-NMR and IR spectra. The ratio of *(2)* to *(3)* is shifted strongly in favor of *(3)* by pressure. Compound *(2)* (57 %) obtained under high pressure (10^4 bar) proved to be optically active; $[\alpha]_{436}^{25}=-1.1°$ ($c=3.5$; $CHCl_3$). The same reaction carried out at atmospheric pressure, however, affords optically inactive *(2)* (85 %). In order to confirm that the optical activity was not due to the optically active solvent, the compound *(2)* obtained at high pressure was recrystallized several times from different solvents (2 × ethanol, 2 × ligroin).



(1) *(2)* *(3)*

To determine the degree of asymmetric induction we prepared both enantiomers of *(2)* in optically pure form from racemic 4-(α-chlorobenzyl)anisole *(4)* [*(2)* could not be resolved]. Compound *(5)* (see Scheme) was separated by column chromatography into the diastereomers *(5a)* and *(5b)*, which on treatment with oxalyl chloride and diphenylcadmium furnished the enantiomers *(2a)* $[[\alpha]_{436}^{25}=+16.24$ ($c=1.52$, $CHCl_3$)] and *(2b)* $[[\alpha]_{436}^{25}=-16.10$ ($c=0.43$, $CHCl_3$)], respectively.



(4)

(5) *(2)*

Ph = C_6H_5, Ph' = p-H_3CO-C_6H_4

The asymmetric induction found in L-(+)-tartrate at high pressure corresponds to an optical yield of $p=6.7$ %. Highly optically active *(2)* is likewise formed in other chiral solvents, *e.g.* menthol or fenchone, but its purity still has to be checked.

To our knowledge this constitutes the first enantioselective synthesis effected by pressure in a chiral medium.

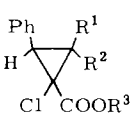
1-Cyclopropene-1-carboxylates from 1-Chloro-1-cyclopropanecarboxylic Acids[**]

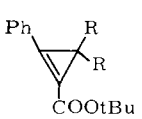
By *Volker Sander* and *Peter Weyerstahl*[*]

The isolation of a 1-cyclopropene-1-carboxylic acid has so far been accomplished in only one special case by lithiation and carboxylation of 1,3,3-trimethyl-1-cyclopropene[1]. Attempts to obtain such acids by basic HBr-elimination[2] or thermal cleavage of acetic acid[3] from cyclopropanecarboxylic acids have failed.

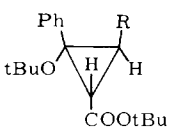
We have now synthesized the 1-cyclopropene-1-carboxylates *(5)* and *(6)* by removal of HCl from the 1-chloro-1-cyclopropanecarboxylates *(3b)* and *(4b)* with potassium *tert*-butoxide in THF. Few by-products are formed. We have already prepared other cyclopropene derivatives in this way[4]. The esters *(1b)*—*(4b)* were obtained from the carboxylic acids *(1a)*—*(4a)* by reaction with isobutylene. The acids themselves are readily accessible from the 1,1-dichlorocyclopropanes by halogen-metal exchange and carboxylation (Table 1).



(1) - *(4)*
(a), R^3 = H
(b), R^3 = tBu



(5), R = CH_3
(6), R = Ph



(7), R = H
(8), R = CH_3

Table 1. Synthesized acids *(1a)*—*(4a)*, R^3 = H, and esters *(1b)*—*(4b)*, R^3 = tBu. The ^{1}H-NMR and mass spectra are consistent with the given structures.

	R^1	R^2	*(a)* M.p. [°C]	*(b)* M.p. [°C] B.p. [°C/torr]
(1)	H	H	96	46
(2)	H	CH_3	147	60/0.05
(3)	CH_3	CH_3	151	80/0.02
(4)	Ph	Ph	190	141

As expected the 1-cyclopropene-1-carboxylic esters *(5)* and *(6)* (Table 2) are unusually strong Michael acceptors which can be isolated only if both sides of the ring bear bulky substituents.

Table 2. Physical properties of compounds *(5)*—*(8)*. All NMR spectra were recorded in CCl_4 [a].

[a] *(8)* in $CDCl_3$ (WH-270).

In elimination experiments with potassium *tert*-butoxide *(1b)* and *(2b)* gave, in addition to polymers, only the adducts *(7)* and *(8)*, respectively, in 25—30 % yield. Even with the sterically more demanding potassium 3-ethyl-3-pentanolate *(1)* afforded small amounts of *(7)* along with large amounts of polymer. The configuration of *(8)* follows from attack by the butoxide ion from the unhindered side and from the coupling constants for *trans* cyclopropane protons.

tert-Butyl 2,3,3-triphenyl-1-cyclopropene-1-carboxylate (6)

1,1-Dichloro-2,2,3-triphenylcyclopropane (10 mmol) in a mixture of THF, ether, and petroleum ether (4:1:1 v/v; 50 ml) is treated dropwise under pure N_2 at −105 °C with butyllithium (10 mmol) in hexane, and then with an excess of pulverized CO_2. After usual workup, the valeric acid that is always present is distilled off at 50 °C/0.01 torr and the residue crystallized from ether/petroleum ether; yield 55 % *(4a)*.—A solution of *(4a)* (10 mmol) in dry ether (10 ml) is heated at 50 °C for 16 h under N_2 in a bomb-tube with *ca.* 10 g isobutylene and 0.2 g conc. H_2SO_4. After usual workup the crude *(4b)* is chromatographed on silica gel with pet. ether/ether (9:1); yield 62 %.—A solution of potassium *tert*-butoxide (2 mmol) in THF (5 ml) is added dropwise to an ice-cooled solution of *(4b)* (2 mmol) in THF (5 ml) (reagents purified according to Ref. [4]) under purified N_2. The mixture is stirred for 30 min at 0 °C and then for a further 30 min at room temperature. After addition of 50 ml CCl_4 the mixture is washed twice with NH_4Cl solution, three times with ice-water, dried over $MgSO_4$ and finally concentrated by evaporation. The crude ester *(6)* is recrystallized once from CCl_4; yield 71 %.

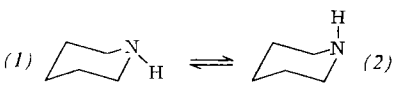
Reviews

Abstracts of selected progress reports and review articles

The conformation of piperidine is discussed in an article by *I. D. Blackburne, A. R. Katritzky,* and *Y. Takeuchi.* Whether the equatorial form *(1)* or the axial form *(2)* is preferred



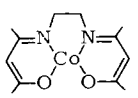
in the conformational equilibrium of piperidine has been the subject of considerable controversy (boat forms can be disregarded). In the analogous compounds with P, S^+, Se^+ or Te^+ instead of N the axial form is preferred. According to recent work it can be concluded that, for the gas phase and non-polar solvents, the piperidine equilibrium is displaced in favor of NH equatorial: $\Delta G^0 = 0.4 \pm 0.2$ kcal/mol. In hydrogen-bonding solvents, *e.g.* methanol, the position is less clear.—Piperidine derivatives with additional ring heteroatoms are also discussed. [Conformation of Piperidine and of Derivatives with Additional Ring Heteroatoms. Acc. Chem. Res. *8*, 300–306 (1975); 71 references]

[Rd 826 IE—L]

Synthetic oxygen carriers of biological interest are examined by *F. Basolo, B. M. Hoffman,* and *J. A. Ibers.* Oxygen carriers are systems forming 1:1 complexes with the O_2 molecule and in which neither the metal (M) nor the ligand (L) is oxidized irreversibly:

$$ML_n + O_2 \rightleftharpoons ML_nO_2$$

The starting point of the experiments were complexes between cobalt(II) and Schiff bases, *e.g. (1)*, which take up oxygen in the ratio 1:1. Studies on O_2—Co(porphyrin) complexes and the isolation of hemoglobin with Co in place of Fe fol-

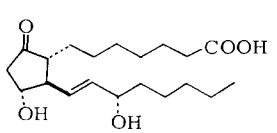


(1)

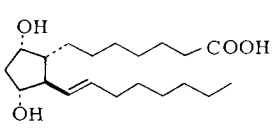
lowed. With the aid of these complexes it is possible to examine, *e.g.* the role of globin in oxygen transport. [Synthetic Oxygen Carriers of Biological Interest. Acc. Chem. Res. *8*, 384—392 (1975); 75 references]

[Rd 835 IE—L]

Prostaglandins are referred to as "Tomorrow's Drugs" in an article authored by *E. W. Horton.* The compounds prostaglandin E_1 *(1)* and $F_{1\alpha}$ *(2)* first isolated from sheep glands can be converted into many similar materials, most of which have



(1)

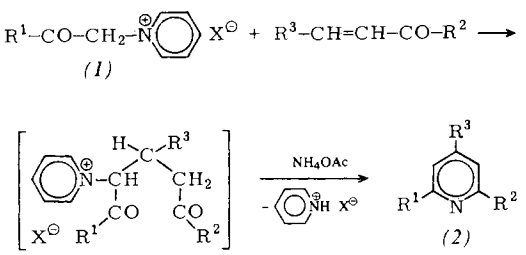


(2)

meanwhile also been found to exist in nature. They act on smooth muscle and have been used, *inter alia,* for the induction of birth, inhibition of gastric secretion, and for the relaxation of respiratory muscle. Postaglandin synthesis is blocked by aspirin and pharmacologically related substances. This effect appears to account for the action of aspirin, indomethacin, butazolidine, *etc.* Great efforts are presently being made to synthesize prostaglandins having selective activities. [Prostaglandins—Tomorrow's Drugs. Chem. Soc. Rev. *4*, 589–600 (1975); 44 references]

[Rd 839 IE—F]

The specific synthesis of substituted pyridines *(2)* **and oligopyridines** from (acylalkyl)pyridinium salts *(1)* and α,β-unsaturated ketones with ammonium acetate/glacial acetic acid or methanol is considered by *F. Kröhnke.* Individual representatives of this class of compounds are of interest for analytical applications. Bipyridine derivatives are of significance as herbicides (diquat, paraquat; some dialkylated bipyridines exhibit hypotensive, ganglion-blocking, or curare-type activity. The high reactivity of the *N*-methylene H atoms of many pyridinium salts, in particular those of type *(1)*, permit reaction with



(1) *(2)*

unsaturated ketones, or Mannich bases derived therefrom, in good yields. In place of *(1)*, 1,3-diketones and analogous compounds can be treated with α,β-unsaturated ketones; use of ammonium acetate/methanol permits ring closure to the 1,4-dihydropyridine derivative which can easily be dehydrogenated to the pyridine derivative. After a discussion of the nomenclature of the oligopyridines, the author considers the synthesis of bi-, ter-, quater-, quinque-, and septipyridines and annelated pyridines. [The Specific Synthesis of Substituted Pyridines and Oligopyridines. Synthesis *1976*, 1—24; 93 references]

[Rd 840 IE—M]

The search for life in the solar system is the title of a review by *N. H. Horowitz.* A prerequisite for life as we understand the term is the presence of complicated carbon compounds. In order to support life a planet should not be so hot as to decompose amino acids; moreover, it should also possess an atmosphere to ensure the circulation of material, including volatile metabolites. Thus living organisms could only exist on Mars and, even less likely, on Titan, the largest moon of Saturn. The Martian atmosphere is poor in water, and thus hostile to life. Much information is expected from the Martian probes Viking A and B launched in late 1975. They carry, *inter alia,* automated laboratories designed to perform biological experiments on the surface of the planet. [The Search for Life in the Solar System. Acc. Chem. Res. *9*, 1—7 (1976); 57 references]

[Rd 841 IE—L]

Several annual surveys are to be found in a volume of the Journal of Organometallic Chemistry. *C. Blomberg* has compiled the literature appearing on magnesium in 1974 (114 pp., 384 references); *G. O. Doak* and *L. D. Freedman* have authored three separate reviews of the 1974 literature on arsenic, antimony, and bismuth (102 pp., 326 references; 38 pp., 116 references; and 4 pp., 26 references). Articles on ferrocene published in the same year have been collected by *G. Marr* and *B. W. Rockett* (78 pp., 209 references). There follows a survey of the 1973 literature on nickel, palladium, and platinum by *E. Singleton*, *G. Cooke*, and *J. R. Moss* (124 pp., 463 references). The volume closes with an author index. [J. Organomet. Chem. *106*, 1—486 (1976)]

[Rd 842 IE—L]

Raw materials, as the basis of industry and primarily the chemical industry, provide the subject matter for an entire issue of the journal "Science". More than 30 authors express their ideas about future supplies of all kinds of raw materials and about possibilities of avoiding threatening shortages.—A brief introduction is followed by five articles on economic aspects and three about questions of energy and the environment and about the recovery of materials (and generation of energy) from household garbage. In the next four articles future requirements are estimated and suggestions made for action upon eventual exhaustion of, *e.g.*, mercury reserves. Production of chemicals from coal is another topic considered. There follow three contributions on prospecting for ores and new processes for extraction and recovery of metals, and three about materials for special purposes, *e.g.* in electronics. The final six articles are about wood and plant materials. These sources are the only ones capable of regeneration and therefore occupy a special position. [Materials. Science *191*, 631—776 (1976)]

[Rd 843 IE—L]

Rydberg states are considered in a review by *R. S. Mulliken*. A complete understanding of electronic spectra and the photochemistry of atoms and molecules requires a knowledge of the spectra of Rydberg states. Rydberg states are transversed during the ionization process and are also of importance for reactions in the upper atmosphere. In the case of atoms and molecules having high ionization energies the Rydberg spectra lie in the vacuum UV; for species with lower ionization energies they extend into the near UV. Particular attention is paid to H_2^+ as a prototype of a molecule and to Rydberg states in diatomic molecules such as N_2 and NO. [Rydberg States and Rydbergization. Acc. Chem. Res. *9*, 7—12 (1976); 13 references]

BOOK REVIEWS

Technische Chemie—Eine Einführung in die chemische Reaktionstechnik (Industrial Chemistry: Introduction to the Technology of Chemical Reactions). By *E. Fitzer* and *W. Fritz*. Springer Verlag, Berlin–Heidelberg–New York 1975. 1st Edit., xiii, 532 pp., 150 figures, 36 tables, paper, DM 44.—.

This book fills a gap that has been felt for many years in the German-language literature by chemistry students and teachers in universities.

The volume is divided into two parts. In the first 3 chapters (104 pp.), the economic factors affecting production are explained and the position of the chemical industry within the framework of world production is presented. The individual parameters affecting profits, such as the production output, the range of capacity, the site of the factory, *etc.* are discussed and the criteria for the choice of the raw materials and processes are described with the aid of examples. After the concepts important for reaction techniques have been explained, the industrial realization of batch, semibatch, and flow processes is related to the properties of reactor types important for single-phase and multiphase systems, as well as to the individual aspects of process optimization and the minimization of costs.

The second part (418 pp.) forms the bulk of the book, providing quantitative relationships for a mathematical treatment of the course of the reaction. The principles of chemical thermodynamics, microkinetics and heat and material transport are treated in Chapters 4 and 5. The behavior and the properties of ideal reactor types for batch and continuous operation in isothermal, adiabatic, and polytropic processes are presented in Chapters 6 to 10. Comparison of the residence-time distributions and back-mixing for ideal and real reactors and for the diffusion and the cell model, as well as calculations of the yield for real reactors are carried out in Chapter 11. Chapters 12 to 15 treat chemical reactions in multiphase systems, the special features of heat and material transport processes in reactions at the solid-liquid interface, and the principles of catalytic and non-catalytic heterogeneous reactions, including the relevant reactors; the various possible methods of carrying out such reactions are discussed. Chapter 16 (by *H. Gerrens*) is devoted to polymerization reactions and their industrial performance.

The book is written with didactic expertise, in readily understood, clear form, and with many illustrations and numerous examples of calculations taken from practice, together with their solutions; it can be recommended as a textbook, and that not only for chemistry students, since its readership should also include many chemists and economists.

Milos Ralek [NB 297 IE]

Environmental Chemistry. Vol. 1. Specialist Periodical Reports. Senior Reporter *G. Eglinton*. The Chemical Society, London 1975. 1st Edit., xii, 199 pp., numerous figs. and tables, bound, £ 7.—.

This is the first volume of a new series of "Specialist Periodical Reports" with the subtitle "Review of Recent Literature on the Organic Chemistry of the Environment up to the Middle of 1973"; the next volume, which should treat also inorganic problems, is expected by late 1976. The intended readership goes far beyond chemists. In the first chapter the biogeochemical cycles in undisturbed and stressed environmental regions are treated by the use of the stable isotopes of C, S, N, H, and O as examples; three chapters deal with ecotypes determined by water, with inclusion, when necessary, of sedimentary chemistry, material balances, and the microbiology of these areas. Two further chapters describe hydrocarbons in marine systems, including oil-spill accidents, as well as the behavior of DDT and PCB, with emphasis on metabolism, distribution, and analysis. In the final chapter 2,4-dichlorophenoxyacetate is discussed in detail. The text of the seven chapters is excellently documented with formulas, tables, and more than 900 references; the large number of diverse literature sources alone shows how much work of compilation has gone into this volume, which is a real mine of information for the user. The volume fulfills the function of a mediator

between the specialists and the large circle of other scientists who are, or may be compelled to be, interested in environmental problems.

Günther Siebert [NB 300 IE]

Elektrolytgleichgewichte und Elektrochemie (Electrolytic Equilibria and Electrochemistry). Fachstudium Chemie, Lehrbuch 5. By *G. Ackermann, W. Jugelt, H.-H. Möbius, H. D. Suschke*, and *G. Werner*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., 292 pp., 83 figs., 66 tables, paperback, DM 34.—.

This book contains ten chapters: solutions, electrolyte theory, electrochemical equilibria, electrochemical processes, acid-base equilibria, redox equilibria, precipitation equilibria, complex equilibria, extraction equilibria, and ion-exchange equilibria. The classical thermodynamics of ions in solution are treated in detail, the student being offered a good introduction; this is the strength of the book. The attached chapter "Electrochemistry" is, however, very short, with thermodynamics in predominance; thus, there is no discussion of modern electroanalytical methods or of industrial applications of electrochemistry. The Debye-Hückel theory is introduced in the form of its results only but is not derived.

Sections in small print provide the reader with additional information, some of it on still controversial topics. It is in particular here that the absence of literature references proves a great disadvantage. The indicative treatment of these fields—nonaqueous solvents and acid-base theories, for example—provides too little for the student.

The classifications of cations according to *Schwarzenbach, Ahrland, Chatt* and *Davies*, and *Pearson*'s concept of hard and soft acids and bases are not kept separate. In Table 8.2 Ga^{3+} is classified as soft but on p. 142 as hard.

The thermodynamic principles of extraction, of precipitation equilibria and ion-exchange equilibria are well treated, analytical and industrial processes being also indicated. To prevent mere reading without understanding, questions are built into the text and further problems are given at the end of each chapter, which is a help for independent study.

Gerhard Gritzner [NB 303 IE]

Auswertung und Analyse kinetischer Messungen (taschentext 37) (Evaluation and Analysis of Kinetic Measurements (pocketbook 37)). By *E. S. Swinbourne*. Revised and translated by *O. F. Olaj*. Verlag Chemie/Physik Verlag, Weinheim 1975. x, 166 pp., 36 figures, 47 tables, bound, DM 17.80.

The two middle chapters "Regularity and Order of Chemical Reading" (Chapter 3) and "Determination of the Rate Constants" (Chapter 4) of the book are concerned with the evaluation and analysis of kinetic measurements. In two general chapters the reader is familiarized with the numerical and graphical methods of data analysis and the most important prerequisites of error theory. The final chapter 5 provides stimulation and indicates special problems.

The book does not require any mathematical background beyond that taught in a Grammar School and that could not be mastered with the aid of the book itself. The many examples worked out for the reader are useful. The clear and simple structure of the book leads the beginner directly to the field of application, analysis of kinetic data with the aid of simple methods.

Josef Barthel [NB 304 IE]

Russian-English Chemical and Polytechnical Dictionary. By *Ludmilla I. Callaham*. John Wiley & Sons, New York—London 1975. 3rd Edit., xxviii, 852 pp., bound, £ 18.95.

This dictionary is the result of more than thirty years of involvement with Russian technical literature. In 852 pages printed in two columns it contains a wealth of carefully selected Russian terms (the number of entries is estimated at 80000—90000) from inorganic, organic, physical, analytical, and nuclear chemistry as well as from industrial chemistry (from the plastics, fiber, ceramic, paper, foodstuffs, dyes and varnishes, fertilizer, pest control, and pharmaceutical industries). Important terms from mineralogy, geology, metallurgy, electrical engineering, computer technology, nuclear engineering, agriculture, botany, medicine, zoology, physics, and mathematics are also included.

The contents of a dictionary can be investigated only by random sampling, and one looks first for terms not included in other similar works. The large majority of such tests were satisfactorily passed: in nearly all cases the dictionary gave an answer. Some reaction terms were missing, such as autoxidation, allyl rearrangement, amidolysis, protonation, as well as named reactions which present difficulties in back-transliteration since they appear phonetically in the Cyrillic ('Uoker'-=Walker). Trouble has been taken to give as many different English meanings as possible for each Russian word. What is particularly useful is that the singular and plural forms are given at their alphabetical places for those nouns that are declined in Russian in unusual ways. It is equally useful to find a table giving the customary endings of technical words in Russian and a collection of the possible methods of declining and conjugating Russian words.

In the Foreword the author emphasizes very modestly that her dictionary, like all others, cannot be complete. But the reviewer can confirm that the terms have been selected with great care and knowledge. All those concerned with Russian technical literature will certainly find this volume of great assistance.

Christian Weiske [NB 306 IE]

Techniques of Chemistry. Vol. VII: Membranes in Separations. By *Sun-Tak Wang* and *K. Kammermeyer*. Edited by *A. Weissberger*. John Wiley and Sons, New York—London 1975. 1st Edit., xxii, 559 pp., numerous figures and tables, bound, £ 17.50.

Although membranes have been the subject of scientific interest for more than a century, intensive research and development was not undertaken until a few years ago when it became apparent that they could be employed for large scale separations of molecular mixtures. Current interest in membranes and membrane separation processes has become so diversified that the voluminous literature is widely scattered in specialized journals and terminology tends to be inconsistent.

By compiling a comprehensive description of all currently known membrane separation processes and their applications, *Wang* and *Kammermeyer* have made a valuable contribution to this field. The need for such a work has long been recognized.

The first chapters present fundamental definitions and descriptions of membranes and membrane transport processes. Characteristic membrane constants are defined, together with experimental methods for their determination. In subsequent chapters individual membrane processes for material separation and the essential areas of their application are briefly discussed. The book particularly emphasizes aspects of membrane processes that have an industrial application, and there are extensive and numerous examples of their use in science and industry. The methods of preparing membranes and membrane systems, however, are treated in less detail. The book gains additional current interest owing to the detailed description and discussion of commercially available membranes and membrane filter systems and a list of membrane manufacturers.

This book will be especially helpful to anyone seeking practical solutions to material separation problems by membrane processes, irrespective of whether the specific application be in medicine, or industial or pure chemistry. By bringing a a description of all membrane processes into a single volume, even the reader previously unfamiliar with the subject can quickly become familiar with the most important basic concepts, and obtain a broad overview of possible applications. The more scientifically oriented reader interested in the theoretical aspects of membrane processes, however, will find this book of more limited value.

Heiner Strathmann [NB 298 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Nitrogen as Leaving Group: Aliphatic Diazonium Ions

By Wolfgang Kirmse[*]

Nitrogen is one of the best known leaving groups. Decomposition of aliphatic diazonium ions has rendered carbocations (carbon cations) accessible in cases where the solvolysis of halides or sulfonic esters follows different pathways. The limits of unassisted decomposition are seen in primary diazonium ions, where the participation of external nucleophiles and of neighboring groups in the elimination of nitrogen becomes noticeable. Cyclopropanediazonium ions occupy a position intermediate between aliphatic and aromatic diazonium ions. New versatile methods of generating aliphatic diazonium ions facilitate their preparative use.

1. Introduction

The pronounced stability and ready formation of molecular nitrogen have rendered numerous reactive intermediates of organic chemistry accessible by elimination of nitrogen. Diazeniates *(1)* afford carbanions in a step of the Wolff-Kishner reduction and related reactions[1]. Azo compounds *(2)* generate radicals; for instance, the readily accessible compound azoisobutyronitrile is frequently employed as an initiator of radical chain reactions[2]. Thermal or photochemical decomposition of diazo compounds *(3)* is indispensable for the generation of carbenes[3], and the decomposition of diazonium ions *(4)* often leads to carbocations (carbon cations)[4–7].

$$R{-}N{=}N{:}^{\ominus} \longrightarrow R{:}^{\ominus} + N_2 \quad (1)$$

$$R{-}N{=}N{-}R \longrightarrow 2\,R\bullet + N_2 \quad (2)$$

$$R_2C{=}N_2 \longrightarrow R_2C{:} + N_2 \quad (3)$$

$$R{-}\overset{\oplus}{N}{\equiv}N \longrightarrow R^{\oplus} + N_2 \quad (4)$$

The reactions of aliphatic diazonium ions and the way in which nitrogen differs from other leaving groups will be discussed in the present article.

The differences in stability between aromatic and aliphatic diazonium ions are impressive. Since their discovery by *Griess*[8], aromatic diazonium ions have found wide application in the synthesis of intermediates and dyes[9]. Some vinylic diazonium salts are also isolable[10]. But all we find about aliphatic diazonium salts in many textbooks is that they "spontaneously" decompose. The far greater ease with which the diazonium nitrogen is released from an sp^3 carbon as compared with an sp^2(aryl)carbon atom can be explained by several factors:

a) Aromatic diazonium ions are stabilized by interaction between the π-systems of the ring and the diazonium group. This effect is difficult to assess quantitatively. The thermodynamic data of the isoelectronic but uncharged nitriles indicate a stabilization of Ar—CN relative to R—CN of about 15 kcal/mol.

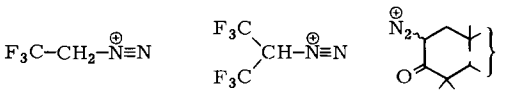
b) The high energy of aryl cations impedes the expulsion of nitrogen from aromatic diazonium ions. If the ionization potentials of the corresponding radicals are adopted as a measure for the stability of cations, then the phenyl cation assumes a position intermediate between the methyl and the ethyl cation[11]. A similar result is obtained from the heat of reaction of the hypothetical heterolysis

$$R{-}H \rightarrow R^{\oplus} \cdot H^{\ominus}$$

[*] Prof. Dr. W. Kirmse
Abteilung für Chemie der Universität
Universitätsstrasse 150, 4630 Bochum (Germany)

which is 314 kcal/mol for methane, 303 kcal/mol for benzene, and 280 kcal/mol for ethane[12]. (All these data apply to the gas phase.)

The few aliphatic diazonium ions that are detectable by spectroscopy, such as the 2,2,2-trifluoroethanediazonium ion *(5)*[13], the hexafluoropropane-2-diazonium ion *(6)*[14], and 2-oxocyclohexanediazonium ions *(7)*[15] bear powerfully electron-withdrawing substituents which destabilize the corresponding carbocation and oppose unimolecular decomposition.

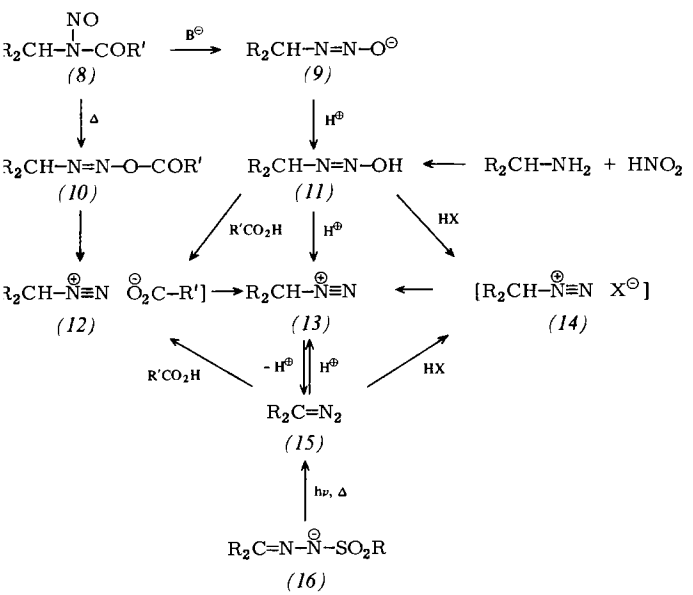


(5) *(6)* *(7)*

c) The difficult nature of bimolecular substitution of arenes stabilizes arenediazonium ions relative to their aliphatic analogs. Careful application of all the usual mechanistic criteria has confirmed that the decomposition of benzenediazonium ions leads to phenyl cations[16]. Methanediazonium ions are likewise stable in the gas phase (their decomposition to methyl cation and nitrogen is endothermic to the extent of 38 kcal/mol)[17], but not in solution. It seems an obvious conclusion that some aliphatic diazonium ions react with nucleophilic participation of solvent (cf. Section 4.1), especially when unimolecular decomposition would lead to a high-energy carbocation. This competition pathway is not open to aromatic diazonium ions.

2. Formation of Aliphatic Diazonium Ions

The most important pathways leading to aliphatic diazonium ions *(13)* are sketched out in Scheme 1.



Scheme 1

2.1. Nitrosation (Diazotization) of Primary Amines[18]

Amines are usually treated with nitrous acid (sodium nitrite) in acidic aqueous solution or glacial acetic acid. Reaction has to be performed in a relatively narrow pH range (pH 3–5 for alkylamines) since both the free amine and free nitrous acid must be present. The kinetics of nitrosation are usually complex; rates given by

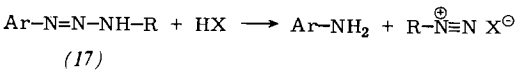
$$v = k[RNH_2][HNO_2]^2 \text{ and } v = k[RNH_2][HNO_2][H^+]$$

have been observed in limiting cases. In the former case N_2O_3 is regarded as the nitrosation reagent, and $H_2NO_2^+$ or NO^+ in the latter[18]. With long-chain amines the rate of nitrosation increases in the range of micelle formation[19].

A suitable reagent for diazotizations in weakly alkaline aqueous solutions is disodium pentacyanonitrosylferrate ("sodium nitroprusside") which transfers its nitroso group to amines at pH 9–11 but decomposes at higher pH values[20]. Nitrosation in aprotic solvents can be accomplished by reaction of the amine with an alkyl nitrite in the presence of one equivalent of acid[21]. Although it is more appropriate to speak of proton-deficient rather than aprotic solutions, product formation is influenced considerably by this variant of diazotization. Similar observations have been made in the reaction of amines with nitrosyl chloride[22,23] or with N_2O_4[24] in nonpolar solvents. These methods generate aliphatic diazonium ions in the form of ion pairs.

2.2. Acid Cleavage of Triazenes

3-Alkyl-1-aryltriazenes *(17)*, which are formed by azo coupling of aromatic diazonium ions with aliphatic amines, decompose into aliphatic diazonium ions and aromatic amines on acid catalysis[25]. The resulting diazonium ions react both with the anion of the acid and with the liberated amine[26]. On use of silica gel as "acid", the amine becomes the sole co-reactant[27].



(17)

2.3. Thermolysis of *N*-Nitrosoamides[28]

The slow preliminary step of the thermolysis of an *N*-nitrosoamide *(8)* (Scheme 1) consists in rearrangement to a diazo ester *(10)*. Aliphatic diazo esters decompose by a polar mechanism *via* diazonium-carboxylate ion pairs *(12)* whose fate largely depends upon the solvent. Whereas the thermolysis of *N*-nitrosoamides, nitrosation of primary amines, and protonation of diazoalkanes (cf. Section 2.5) lead to similar results in polar solvents, diazo esters furnish mainly products of ion pair recombination in nonpolar media; subsequent reactions (*e.g.* rearrangements) are suppressed[28,29].

2.4. Alkali Cleavage of *N*-Nitrosoamides

The initial step of alkali cleavage of *N*-nitrosoamides *(8)* (Scheme 1) is the removal of the acyl group by a base, forming alkanediazotates *(9)*. Bases attack the carbonyl group of *N*-nitrosoamides *(8)*, R′ = alkyl or aryl, and *N*-nitrosocarbamates *(8)*, R′ = OR″[30–32], but an N—H bond of *N*-nitrosoureas with elimination of cyanate[33,34]. The alkanediazotates *(9)* can be isolated from aprotic solvents in the form of their alkali metal salts[35–38]; they have a *Z* configuration[36]. In

protic solvents rapid protonation usually ensues to form the diazo hydroxide *(11)* and diazonium ion *(13)*; however, the diazotate intermediate can also be trapped intramolecularly by oxirane[39], allene[40], and alkyne functions[41].

Decomposition of the diazo hydroxide *(11)* in an ion pair process can afford alcohols. Evidence was obtained for such a course on hydrolysis of 2-octanediazotate with ^{18}O-labeled water[42] and on alcoholysis of 1-phenylethanediazotate[43, 44]. Viewed quantitatively this pathway is of minimal significance. The most important branching point of the reaction is the alkanediazonium ion *(13)*, which can undergo not only decomposition and substitution reactions but also deprotonation to give the diazo compound *(15)*. Insofar as this process is reversible[33], alkali cleavage of *N*-nitrosoamides here merges with the protonation of diazoalkanes (Section 2.5).

2.5. Protonation of Diazoalkanes[45]

The sensitivity of diazo compounds *(15)* to acids (Scheme 1) is very dependent upon substituents. While diazoalkanes are even protonated in alkaline solution, diazo ketones, diazo esters, and diazo sulfones only react at low pH values. Cases are known of rate-determining proton transfer (which is slow compared with the subsequent reactions of the diazonium ion), as are examples in which a reversible diazo-diazonium equilibrium precedes diazonium decomposition. These cases can be distinguished by H-D exchange experiments and solvent isotope effects. Which mechanism predominates depends upon the structure, but also on the pH value. Primary diazo ketones ($RCO—CHN_2$)[46], diazo esters ($N_2CH—CO_2R$)[47], and diazo sulfones ($RSO_2—CHN_2$)[48] display predecomposition equilibria, whereas secondary diazo ketones ($RCO—CR'N_2$)[49] and diazo esters ($N_2CR—CO_2R'$)[50], like diphenyldiazomethane[51, 52], undergo rate-determining protonation. 1-Diazobutane exhibits irreversible protonation in acidic solution, but reversible protonation in alkaline solution[53].

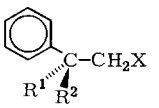
A convenient method of generating diazonium ions in alkaline solution is photolysis of sulfonyl hydrazones or their anions *(16)* (Scheme 1). In this photochemical variant of the Bamford-Stevens reaction[54], initial elimination of sulfinate gives the diazo compound *(15)*[55] which is then protonated by solvent. With secondary diazo compounds (R_2CN_2, R = alkyl) in particular, protonation at room temperature is fast compared with photochemical or thermal decomposition so that the reaction products of carbenes occur in only small amounts, if at all.

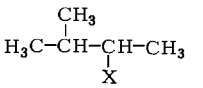
Reaction of diazoalkanes with acids in nonpolar solvents leads to ion pairs[29, 52, 56, 57], like the thermolysis of *N*-nitrosoamides (Section 2.3).

3. Carbocations as Intermediates of Diazonium Decomposition

3.1. "Hot" Cations?

Identical intermediates give identical products. According to this criterion, the carbocations generated in different ways are not identical, since the product distribution usually depends upon the genesis of those species. Admittedly, cases are known where the S_N1 reactions of halides or sulfonic esters and decomposition of diazonium ions lead to corresponding results, and a common intermediate appears to be proven[58, 59]; generally speaking, however, the intermediates of diazonium decomposition are more prone to rearrangement and are less selective than those of S_N1 solvolyses. For instance, the deamination of 2-arylalkylamines *(18)* is accompanied by competing 1,2-shifts of all groups (aryl, alkyl, hydrogen) attached to the β-C atom[60–62]. Only the aryl group migrates in the solvolysis of corresponding sulfonic esters *(19)*[62, 63].





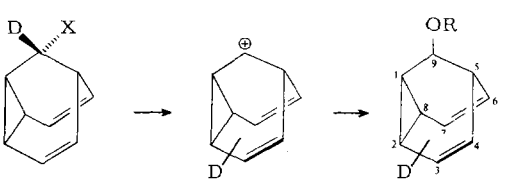
(18), X = NH_2
(19), X = OSO_2R
R^1, R^2 = Alkyl, H

(20), X = NH_2
(21), X = OSO_2-C_6H_4-CH_3 (*p*)

Similarly, deamination of 3-methyl-2-butylamine *(20)* involves not only a hydrogen shift but also a methyl shift (although the latter, as a "degenerate" rearrangement, does not lead to any gain in energy and can only be detected by isotopic labeling)[64]. Solvolysis of the *p*-toluenesulfonate *(21)* proceeds almost exclusively with H shift[65].

The reason for this and similar findings[4, 5] is no doubt to be found in the lower activation energy of the (exothermic) decomposition of diazonium compounds compared to that for compounds having poorer leaving groups. It is a matter of dispute just how these differences in the ionization step affect product formation. According to *Young*[66], elimination of nitrogen from aliphatic diazonium ions should lead to high-energy, "hot" carbocations. This hypothesis constantly recurs in various forms right up to the very latest publications, although its original foundation—product ratios in the substitution of allyldiazonium ions—has since collapsed (cf. Section 4.1).

The term "hot" carbocation means an intermediate still possessing excess energy arising from its exothermic mode of formation and not in thermal equilibrium with its environment. Transformation of heat of reaction into excitation energy of a product ("chemical activation") is well known for gas phase reactions[67], but there are no unequivocal examples of such reactions occurring in solution[68]. The following test for excess energy in intermediates of diazonium decomposition has recently been reported[69]: On solvolysis of tricyclo[3.3.1.$0^{2,8}$]nona-3,6-dien-9-yl ("barbaralyl") toluenesulfonate a D label on C-9 is initially distributed over positions 3, 7, and 9. In less nucleophilic media and after repeated formation of the barbaralyl cation the label is scrambled over all positions[70]. The barbaralyl cation accordingly experiences two distinct degenerate rearrangements which differ only slightly in their activation energies (for mechanism see

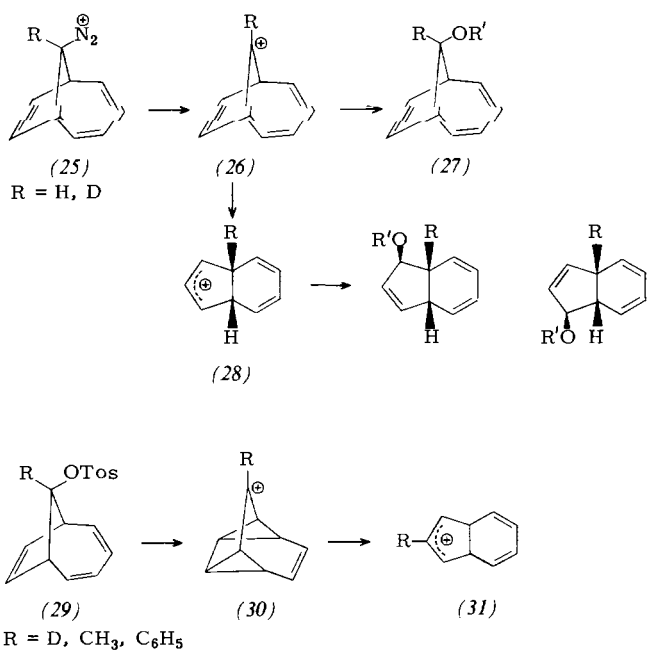


(22), X = OTos
(23), X = $N_2^{\oplus}$

(24)

ref. [70]). If decomposition of the barbaralanediazonium ion *(23)* were to give a cation *(24)* having excess energy then the redistribution of the deuterium would be more extensive than that observed on solvolysis. However, the distribution of deuterium was found to depend solely upon the solvent nucleophilicity and not upon the mode of formation of the cation *(24)*[69]. Thus solvolysis and diazonium decomposition generate the same ("cold") barbaralyl cation.

In the light of such findings, use of the rather confusing term "hot" in connection with the intermediates of diazonium decomposition should be abandoned. Of more significance than *energy* differences are differences in the *structure* of transition states and intermediates of the various cation-forming reactions. The facile process of diazonium decomposition requires far less assistance from neighboring groups or external nucleophiles than the dissociation of halides or sulfonic esters. The above differences in behavior of *(18)/(19)* and *(20)/(21)* can be rationalized in this way. *Skell*[4] therefore describes the intermediates of diazonium decomposition as "free" cations, while poorer leaving groups afford "encumbered" cations. But this mode of expression places too much emphasis on the influence of external factors (gegenion, co-reactant). It is often precisely intramolecular effects (neighboring group participation) which account for the differences between deamination and solvolysis, as exemplified in Scheme 2.



Scheme 2

Decomposition of bicyclo[4.2.1]nona-2,4,7-triene-9-diazonium ions *(25)* leads to the cation *(26)* which is partly trapped by substitution to give *(27)* and partly transformed by an alkyl shift into the 3a,7a-dihydroindenyl cation *(28)*. A substituent at position 9 of *(25)* expectedly reappears at the bridgehead of the dihydroindene skeleton[69]. Solvolysis of the toluenesulfonate *(29)* does not afford *(27)*; the only products obtained are dihydroindene derivatives bearing the substituent R at position 2, being derived from the cation *(31)*[71, 72]. Formation of this cation, an isomer of *(28)*, is explained with the aid of the intermediate *(30)*, *i.e.* by intramolecular Diels-Alder reaction. Whether this diene reaction occurs before ionization or simultaneously has yet to be decided, but in any case it leads to a stabilized dicyclopropylcarbenium ion *(30)*. Formation of *(26)* is possible only because of the excellent leaving group nitrogen.

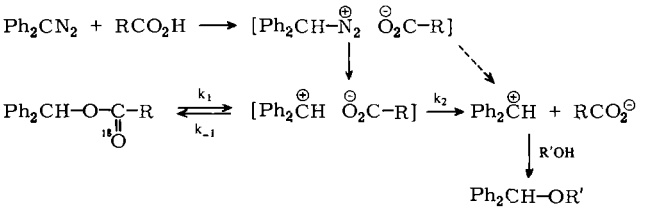
The pair of compounds *(25)/(29)* provides an impressive example for the production of "free" carbocations by diazonium decomposition. Nevertheless, only few diazonium ions react in manners completely independent of their environment. The "limits of freedom" are critically examined in the following sections.

3.2. Ion Pairs

In media of low polarity, the reactions of aliphatic diazonium ions will be influenced by the spatial proximity of the gegenion. The following observations are rationalized by the occurrence of ion pairs.

3.2.1. Product Ratios

Reaction of diphenyldiazomethane with carboxylic acids in ethanol yields a greater proportion of benzhydryl esters (60—70 %) than would be expected from the modest nucleophilic character of the carboxylate ion[45]. The product ratio depends only little on the nature of the acid[52] and remains unchanged on addition of its salts. It appears likely that the benzhydryl esters arise from diazonium-carboxylate ion pairs, whereas benzhydryl ethers are formed from the dissociated diazonium ions or the carbenium ions (Scheme 3). Comparison with the solvolysis of benzhydryl esters supports this concept. (internal return from the ion pair is measured by the distribution of ^{18}O): similar values of k_{-1}/k_2 are found for both reactions[73].



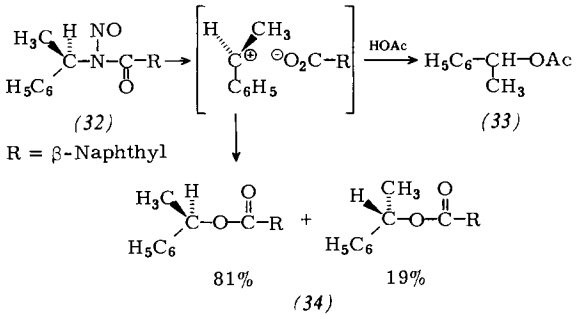
Scheme 3

Both 1-diazo-2-butene and 3-diazo-1-butene afford the corresponding ester without allylic rearrangement on treatment with 3,5-dinitrobenzoic acid in ether, while identical mixtures of the isomeric butenols are obtained in aqueous perchloric acid[45]. The formation of *sec*- and *tert*-butyl derivatives on thermolysis of *N*-isobutyl-*N*-nitroso-3,5-dinitrobenzamide increases with increasing solvent polarity[74]; a similar trend occurs in *n*-propyl→isopropyl rearrangements[29]. In the thermolysis of *N*-nitrosoamides, ion-pair orientation can reach such an extent that complete equilibration of the carboxylate oxygen atoms even becomes impossible[75].

3.2.2. Stereochemistry

Substitution of the diazonium nitrogen in polar media occurs with racemization and inversion (cf. Sections 3.3 and 4.1). In ion-pair processes, however, the configuration is largely retained. Decomposition of the optically active *N*-nitrosoamide *(32)* in the presence of acetic acid gives the "ion-pair product" *(34)* exhibiting 81% retention (19% inversion); the

acetate *(33)* which is also formed in the reaction is largely racemic[29, 75]. Extensive retention can also be achieved by reaction of the hydrochlorides of optically active amines with pentyl nitrite in benzene or light petroleum[76]. Even the nitrosation of aliphatic amines in aqueous acetic acid displays a transition from inversion to retention as the concentration of acetic acid increases, indicating formation of diazonium-acetate ion pairs[19, 77–80].



(32) *(33)* *(34)*

R = β-Naphthyl

The question whether ion-pair effects are operative only in direct substitution or also at the origin of rearrangements has still to be settled. A particular source of disagreement is whether the stereochemical preferences of bicyclic cations ("memory effects") are due to conformational barriers, delocalized bonds, or ion pairs[81, 82].

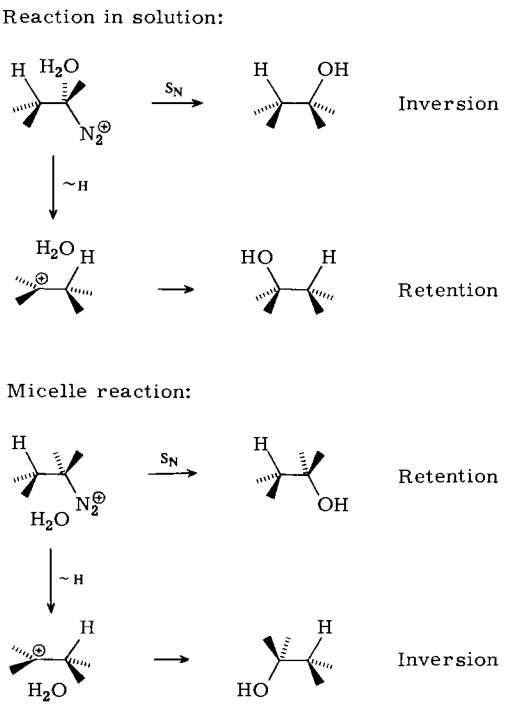
3.3. Micelle Effects

Under the conditions of diazotization with nitrous acid (pH 3—5) alkylamines exist mainly as alkylammonium ions. On exceeding a critical micelle concentration (cmc), the alkylammonium ions begin aggregating to micelles. The hydrophobic alkyl groups point to the interior of the micelles, while the polar ammonium groups are oriented on the surface[83]. Acid-base equilibration between free amine and ammonium ions is fast compared with mass transfer between the micelle and solution. Hence above the cmc, diazotization and diazonium decomposition also partly occur within the micelles. This has an effect on the product distribution and stereochemistry[19, 84]: in solution substitution of the diazonium nitrogen proceeds with partial inversion (and racemization). Micelle formation impedes back-side attack by the solvent; thus the inversion decreases with increasing concentration until retention is finally observed[19]. A linear relationship exists between the micelle content of the solution

$$F_m = (c_i - \text{cmc})/c_i$$

(c_i = initial amine concentration) and the stereochemistry of the product; this demonstrates that the overall reaction is made up of a solution component and a micellar component[19]. The stereochemistry of the products of 1,2-hydrogen shifts also depends upon micelle formation[84]. Since the migrating hydrogen assumes an antiplanar position relative to the leaving group[64, 85] it is replaced with retention in dilute solution and with inversion in the micelle (Scheme 4).

Furthermore, the lower effective concentration of water in the micelle also favors increased elimination and rearrangement at the expense of direct substitution[84]. The structure of the micelles and hence the course of micellar reactions depends upon the gegenion; the above effects are especially pronounced for poorly hydrated ions such as ClO_4^- and BF_4^- which favor dense micelle packing[19].



Scheme 4

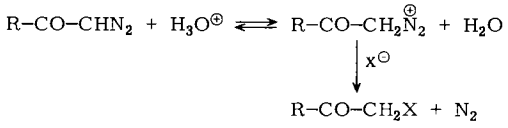
4. Participation of Nucleophiles in Diazonium Decomposition

4.1. Intermolecular Reactions

The product-determining step can be studied by kinetic methods only for stable diazonium ions and diazo-diazonium equilibria. Bis(trifluoromethyl)diazomethane *(35)* is completely protonated in fluorosulfuric acid at −70 °C. Decomposition of the diazonium ion *(6)* at −5 to +5 °C obeys second-order kinetics [first order in *(6)* and first order in fluorosulfate][14]. Since *(6)* would afford an extremely unstable cation by unimolecular decomposition it even reacts with the weak nucleophile fluorosulfate according to an S_N2 substitution.

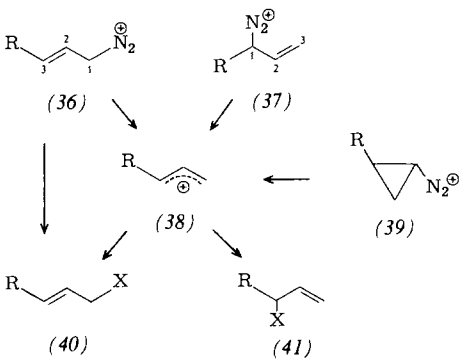
$$\underset{(35)}{(CF_3)_2CN_2} + FSO_3H \longrightarrow \underset{(6)}{(CF_3)_2CH\text{–}\overset{\oplus}{N}_2\ {}^{\ominus}OSO_2F} \xrightarrow{k_2} (CF_3)_2CH\text{–}OSO_2F + N_2$$

The rate of decomposition of diazoacetic ester[47, 86] and of diazoacetone[87] in acid solution depends not only upon the acid strength (Hammet acidity function H_0) but also upon the acid anion. With chloride, bromide, and iodide a linear relationship is obtained between $\log k$ and the nucleophilicity parameters n of *Swain* and *Scott*[88] ($\log k_x/k_{H_2O} = n \cdot s$; $s = 0.43$ for diazoacetic ester and $s = 0.36$ for diazoacetone). The kinetic data are a convincing argument for participation of nucleophilic anions—and even of water—in the decomposition of primary oxodiazonium ions (Scheme 5).



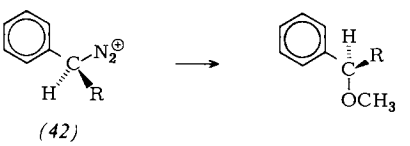
Scheme 5

Secondary diazoketones cannot be studied by this method because the protonation is rate determining (Section 2.5). However, the product distributions obtained in competition reactions also permit derivation of reaction parameters of the Swain-Scott type ($s = 0.37$ for 3-diazo-2-butanone; $s = 0.33$ for 1-diazo-1-phenylacetone)[89]. The good agreement of these parameters and those obtained above suggest the occurrence of S_N2 substitution even with secondary oxodiazonium ions.



Product analysis also throws some light on the reactions of allyldiazonium ions. This is a classical problem of diazonium decomposition which led to the hypothesis of "hot" cations (Section 3.1). If 1- and 3-substituted allyldiazonium ions react *via* an allyl cation as common intermediate then they should give identical mixtures of products. However, product mixtures are usually obtained in which the structure of the starting material predominates[66]. In order to draw the correct conclusions from these results it must be known in what ratio the delocalized allyl cation *(38)* forms the two isomeric allyl derivatives *(40)* and *(41)*. This important fact is obtained from ring opening of the cyclopropanediazonium ion *(39)*. Falsification of the product ratios by direct substitution is impossible in this case. The dependence of the product ratio upon the base concentration (*e.g.* methoxide in methanol) was employed as a further criterion. The species *(38)* should yield *(40)* and *(41)* in a constant ratio, whereas a direct substitution in *(36)* or *(37)* should be favored by the strongly nucleophilic methoxide. Series of experiments with $R = C_6H_5$[90], CH_3[91], $C(CH_3)_3$[92], and D[93] showed that the ratio of products *(40)* and *(41)* obtained from *(37)* and *(39)* is independent of base and approximately constant. Thus it is established that secondary allyldiazonium ions of type *(37)* largely react *via (38)* as intermediate. On starting with *(36)* the ratio *(40)*/*(41)* was much higher and increased with increasing base concentration. Participation of the nucleophile in nitrogen elimination accordingly appears likely in primary allyldiazonium ions such as *(36)*; its significance increases with decreasing stabilization of the allyl cation *(38)* ($R = C_6H_5 < CH_3 < C(CH_3)_3 < D$)[93].

Similar conclusions are drawn from the stereochemistry of substitution in benzyldiazonium ions *(42)* (Table 1). In 1-phenylethanediazonium ions ($R = CH_3$) the extent of inversion is independent of the base concentration[44] (pure S_N1 mechanism), while in deuterated α-toluenediazonium ions a slight increase in inversion suggests incipient participation of the nucleophile[94]. Unfortunately, the stereochemistry of alkanediazonium ions cannot be studied in alkaline solution since the diazo-diazonium equilibrium (see Sections 2.4 and 2.5, and Scheme 1) then leads to racemization. It should be pointed out, however, that deamination of optically active [1-D_1]-butylamine with nitrous acid is accompanied by 68% inversion[95], whereas secondary amines display only 20 to 25% inversion[19].



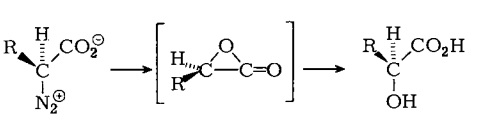
(42)

Table 1. Methanolysis of the 1-phenylethanediazonium ion *(42)*, $R = CH_3$, and the [α-D]-toluenediazonium ion *(42)*, R = D.

Base	$R = CH_3$	R = D
	Inversion [%]	
$CH_3OH/NaHCO_3$	20.6	26
CH_3OH/Na_2CO_3	20.4	32
CH_3OH/0.1 N $NaOCH_3$	19.6	40
CH_3OH/1 N $NaOCH_3$	18.6	42
CH_3OH/3 N $NaOCH_3$	20.6	

4.2. Neighboring Group Effects

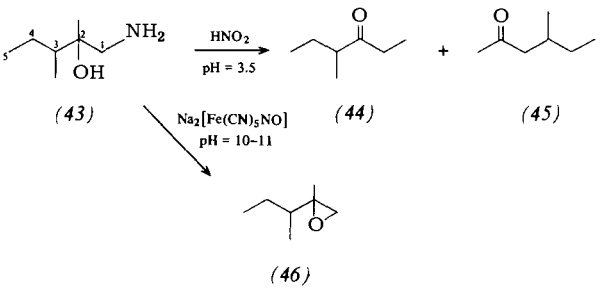
The effect of a nucleophile is often enhanced if it is located in the same molecule in the proximity of the leaving group. At least one neighboring group effect has long been known to occur in diazonium ions: diazotization of α-amino acids affords α-hydroxy acids with retention of configuration (Scheme 6)[96, 97]. The stereospecificity (*ca.* 95%) can be determined particularly easily from the formation of diastereomeric products from isoleucine[98]. The stereochemical findings are explained by double inversion: intramolecular substitution of the diazonium group by carboxylate leads to an α-lactone which is opened by water in a back-side attack. If the diazonium group is located on a tertiary C atom then neighboring carboxylate can no longer hinder formation of a carbocation; the stereospecificity falls to *ca.* 30% retention[99].



Scheme 6

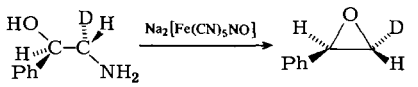
The alkoxide function can also act as a neighboring group, albeit only in primary diazonium ions. Deamination of 1-amino-2,3-dimethylpentanol *(43)* proceeds like a pinacol rearrangement in acid solution to give the ketones *(44)* (methyl shift) and *(45)* (*sec*-butyl shift). Diazotization in alkaline solution, however, gives exclusively the oxirane *(46)*[100]. As shown by the example of the amino alcohol *(47)*, the diazonium nitrogen is displaced with inversion on oxirane formation[101]. If the leaving group is attached to a secondary C atom, how-

ever, then the pinacol rearrangement cannot be avoided by working in an alkaline medium[98, 101]. Exceptions to this rule are encountered with conformationally rigid systems in which the relative position of the leaving and neighboring groups is fixed[102].



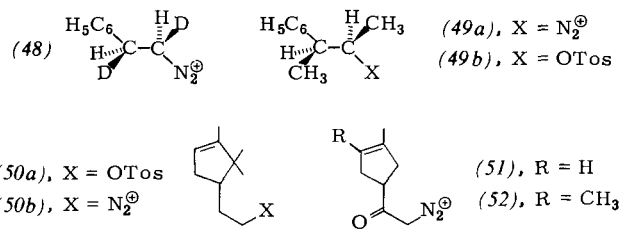
(43) (44) (45)

(46)



(47)

The reactions of the 2-phenylethanediazenium ion *(48)* can be analyzed by ^{14}C- and D-labeling[103, 104]. Migration of the phenyl group in *(48)* proceeds with complete inversion[104]. Far less stereospecificity is shown by the 3-phenylbutane-2-diazonium ion *(49a)*[105a] (leaving group on a secondary C atom), in contrast to the toluenesulfonate *(49b)* which reacts in a highly stereospecific manner[105b]. Similar differences are found between the toluenesulfonate *(50a)*, which like numerous 2-(3-cyclopentenyl)ethyl toluenesulfonates[106] reacts completely with double-bond participation to give norbornane derivatives, whereas the diazonium ion *(50b)* furnishes only 15–20 % bicyclic products[107]. If the alkanediazonium group in *(50b)* is replaced by the more reluctantly decomposing oxodiazonium function (cf. Section 4.1) then the yield of norbornane derivatives rises to 90 % in the case of *(51)* and 100 % with *(52)*[108].

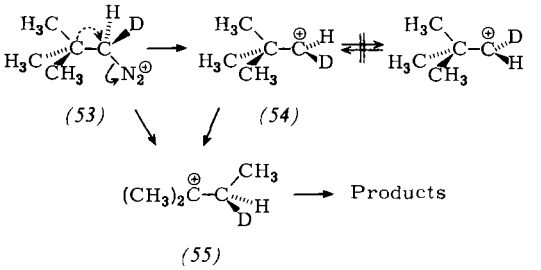


(48) (49a), X = $N_2^{\oplus}$ (49b), X = OTos

(50a), X = OTos (50b), X = $N_2^{\oplus}$ (51), R = H (52), R = CH_3

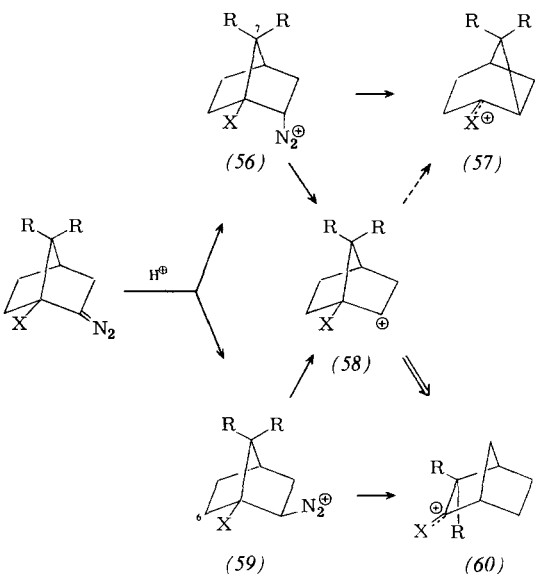
Stereochemical studies and product analyses can only hint at the occurrence of neighboring group effects. Since kinetic data are generally not available for diazonium decomposition, alternative interpretations cannot be definitely ruled out—*e.g.* very short-lived intermediate cations showing no (or only incomplete) rotation about C—C bonds. Decomposition of the optically active [1-D_1]-neopentanediazonium ion *(53)* affords products derived from *(55)* with 85% inversion[109]. This result is compatible with both a synchronous reaction of *(53)* and a very short lifetime of the primary cation *(54)*.

The behavior of norbornanediazonium ions permits a clearer distinction between these alternatives. In the *exo*-diazonium ion *(59)*, C-6 is suitably oriented for participation



(53) (54) (55)

in elimination of nitrogen; a synchronous reaction leads to the norbornane derivative *(60)*. X is a cation-stabilizing substituent (OR, NHR, *etc.*), which prevents further rearrangements. In the *endo*-diazonium ion *(56)* steric constraints merely permit participation of C-7 in nitrogen elimination; the rearrangement leads into the bicyclo[3.1.1]heptane series *(57)*. In principle both rearrangements are available to the norbornyl cation *(58)* as a possible intermediate; however, it preferably forms the less strained norbornane derivative *(60)*. In favorable cases (X = NH_2, R = CH_3) almost complete rearrangement to *(57)* is observed; the ratio *(57)*/*(60)* increases with increasing donor character of X and R[110]. These results strongly suggest



(56) (57) (58) (59) (60)

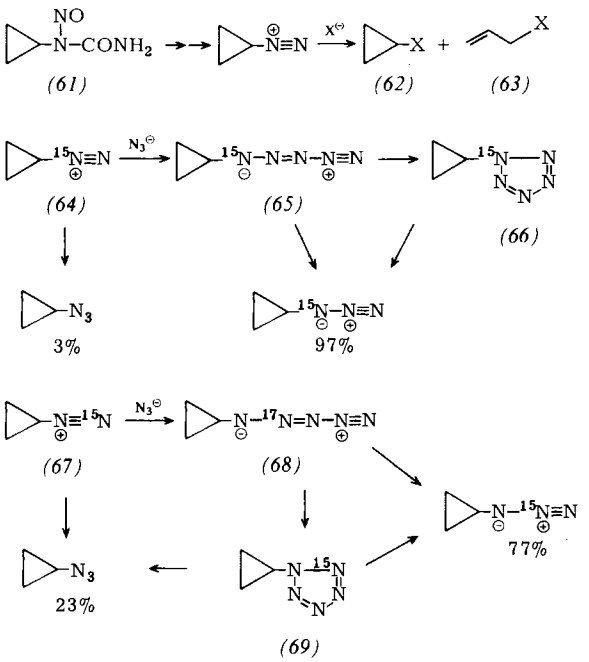
a synchronous reaction of the *endo*-diazonium ion *(56)*. Acceptor substituents in position 3 have a similar but less pronounced effect[111, 112].

5. Cyclopropanediazonium Ions

5.1. Azo Coupling

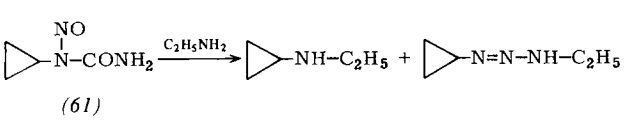
In weakly nucleophilic media, cyclopropanediazonium ions predominantly give allyl derivatives such as *(63)*. In the presence of strong nucleophiles cyclopropane derivatives of type *(62)* are also obtained; alkaline cleavage of *N*-cyclopropyl-*N*-nitrosourea *(61)* provides almost ideal conditions for this reaction[113]. While iodide ions give *(62)* and *(63)* (X = I) in the ratio 0.2 : 1, the ratio of the azides formed *(62)*/*(63)* (X = N_3) in the presence of azide ions is about 15 : 1. These drastic differences suggest that azide reacts *via* a mechanism not open to iodide. Starting from the [1-^{15}N]-labeled cyclopropanediazonium ion *(64)*, 97 % of the label reappears in the

cyclopropyl azide; it is formed almost exclusively by azo coupling and subsequent decomposition of the pentazene *(65)* and/or the pentazole *(66)*[114]. In contrast, the cyclopropyl azide formed from the [2-^{15}N]-labeled diazonium ion *(67)* contains only 77 % of the ^{15}N[114, 115]. Comparison with *(64)* indicates reaction branching at the pentazene *(68)*, which



partly (60 %) decomposes directly and partly (40 %) cyclizes to pentazole *(69)*. Compound *(69)* gives equal amounts of labeled and unlabeled cyclopropyl azide. Very similar results are observed in the reaction of aromatic diazonium ions with azide[116].

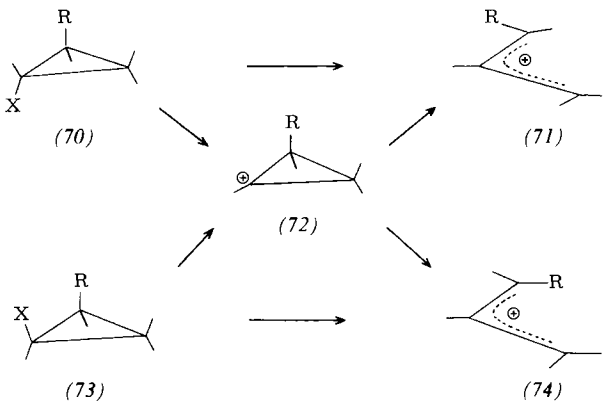
The reaction of *(61)* with ethylamine gives not only the substitution product *N*-ethylcyclopropylamine but also the coupling product 3-ethyl-1-cyclopropyltriazene (30%)[115, 117]. Coupling of cyclopropanediazonium ions with phenols has not yet been accomplished.



Such coupling reactions show the cyclopropanediazonium ions to occupy a position intermediate between purely aliphatic and aromatic diazonium ions. The only other example known is the coupling of a bridgehead diazonium ion[118]; here, too, the hybridization of the C atom probably prevents easy elimination of nitrogen.

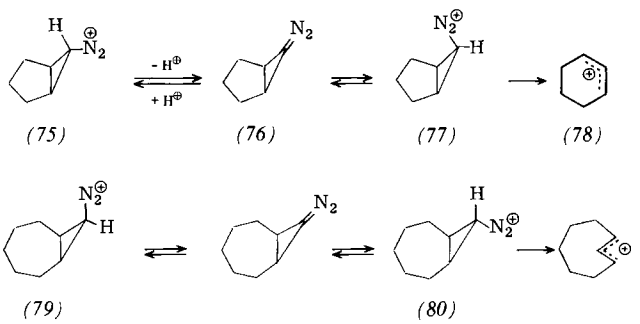
5.2. Ring Opening

One-step and multistep reaction mechanisms are conceivable for the transformation of cyclopropanediazonium ions into allyl derivatives. Does ring opening occur in a cyclopropyl cation or synchronously with elimination of nitrogen from the diazonium ion? In all cyclopropyl halides and toluenesulfonates kinetic and stereochemical criteria unequivocally support a synchronous process[119]. Substituents located *trans* to the leaving group will rotate outwards [forming a *trans*-allyl cation *(71)*] and those situated *cis* to the leaving group will turn inwards [forming a *cis*-allyl cation *(74)*][120]. Cyclo-



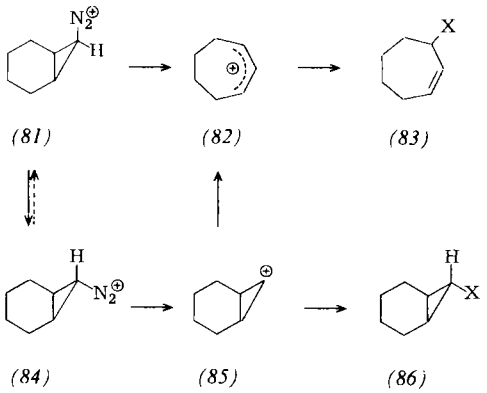
propanediazonium ions behave in a complicated way. *cis*- and *trans*-2-Phenylcyclopropane-1-diazonium ions *(73)* and *(70)*, R = C_6H_5, X = N_2^+, afford identical product mixtures, derived mainly from *(71)*, R = C_6H_5[113]. This supports a cyclopropyl cation *(72)*, R = C_6H_5, as common intermediate.

In the case of bicyclo[*n*.1.0]alkanediazonium ions, on the other hand, there are indications of a synchronous ring opening. *exo*- and *endo*-Bicyclo[3.1.0]hexane-6-diazonium ions *(75)* and *(77)* react to form cyclohexenes derived from *cis*-allyl cation *(78)*[121]. The species *(75)* only appears to contravene the Woodward-Hoffmann rules. Experiments in deuterated solvents show that the conversion *(75)*→*(78)* is accompanied by complete exchange of H-6 for deuterium, *i.e.* *(75)* initially isomerizes *via* the diazo compound *(76)* to the *endo* isomer *(77)* which can synchronously transform into *(78)*. The opposite situation is found in the bicyclo[5.1.0]octane series where the *endo*-diazonium ion *(79)* reacts with complete H/D exchange, while the *exo* isomer *(80)* give a deuterium-free product. In both cases *trans*-cyclooctene derivatives are obtained exclusively[121].



The norcarane-7-diazonium ions *(81)* and *(84)* behave in a remarkable way[122]. "Allowed" opening of the *endo*-diazonium ion *(81)* to give the cycloheptenyl cation *(82)* is only observed in acidic solution. Even in weakly alkaline media, the isomerization *(81)*→*(84)* becomes faster than the decomposition of *(81)*; norcarane and cycloheptene derivatives are then formed with complete exchange of H-7 for deuterium. The products *(83)* and *(86)* are obtained in the same ratio directly from *(84)*, then being (partly) free of deuterium, however. Accordingly, the transformation

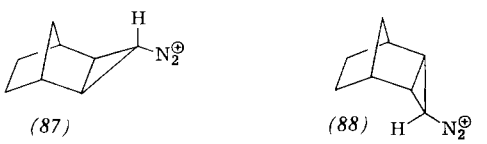
(84) → *(83)* does not proceed *via (81)* but most likely *via (85)*. Decomposition of *(84)* provides no indication for the formation of a *trans*-cycloheptenyl cation—as was obtained



(81) *(82)* *(83)*

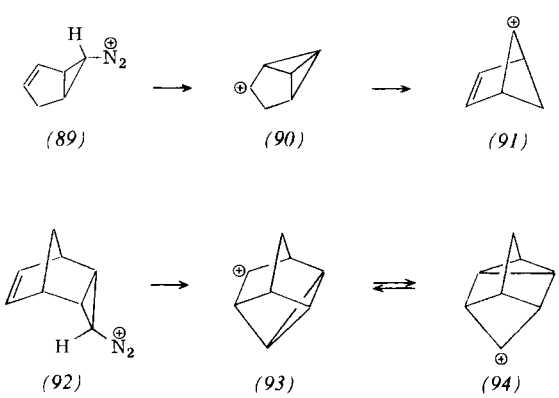
(84) *(85)* *(86)*

on solvolysis of *endo*-7-norcaryl toluenesulfonate[119]. Observations on norcarane-7-diazonium ions suggest a conformational destabilization of the *endo* isomer *(81)*. The significance of conformational effects is underlined by comparison of *(87)*, which reacts like *(75)*, and *(88)*, which behaves analogously to *(84)*[123].



(87) *(88)*

The relatively slow decomposition of some *exo*-bicycloalkanediazonium ions permits participation of double bonds. Thus *exo*-bicyclo[3.1.0]hex-2-ene-6-diazonium ions *(89)* afford products derived from tricyclo[3.1.0.$0^{2,6}$]hexyl cation *(90)* or from bicyclo[2.1.1]hex-2-en-5-yl cation *(91)*, depending on the nucleophilicity of the reactant[124]. *(92)* furnishes derivatives of the equilibrating (or mesomeric) cations *(93)* and *(94)*[125, 126]. It is essential for the success of these reactions, which provide an entry to highly strained ring systems,



(89) *(90)* *(91)*

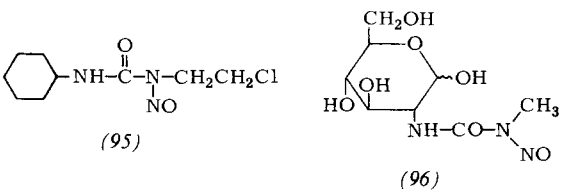
(92) *(93)* *(94)*

that the pH value lies between 7 and 8. In stronger alkaline solution isomerization yields the *endo*-diazonium ions, which then undergo (synchronous) ring opening. Rearrangement of the sensitive reaction products threatens to occur in more strongly acid solution. As in this example, preparative use of aliphatic diazonium ions is frequently a matter of optimum reaction conditions.

6. Outlook

Twenty years ago *Huisgen* summarized the latest findings in the chemistry of aliphatic diazonium ions in a excellent review[127] and greatly stimulated further development. Ion pairs were then the center of attraction; development of the ion-pair concept in the following years facilitated the interpretation of numerous, formerly incomprehensible phenomena. The discovery and application of micelle effects permitted modification of the environment of the diazonium ions in a fundamentally different way. At the same time it became increasingly clear that numerous aliphatic diazonium ions decompose with the assistance of an external or intramolecular co-reactant. *Primary* alkanediazonium ions behave like *secondary* alkyl toluenesulfonates as borderline cases between S_N1 and S_N2. As expected, the change in mechanism is shifted to less stable cations in the case of the better leaving group.

The details of diazonium decomposition possess not only theoretical and preparative interest, but also have biological implications. On the one hand, the carcinogenic and mutagenic action of nitrosamines is due to alkylation of cell components by alkanediazonium ions arising from the nitrosamines by α-oxidation and aldehyde elimination[128–130], while on the other hand cytostatics such as *N*-(2-chloroethyl)-*N'*-cyclohexyl-*N*-nitrosourea *(95)*[131] and antibiotics such as streptozotocin *(96)*[132] number among the nitrosamides and probably function by similar mechanisms.



(95) *(96)*

In vivo and *in vitro* studies have shown that heavy metal ions can intervene in this action[133]. Model experiments on the generation and decomposition of aliphatic diazonium ions in the ligand sphere of metals are still in their infancy. Perhaps they will provide new tools for modifying the leaving group properties of the nitrogen. Each addition to our knowledge about aliphatic diazonium ions will enhance their attraction as a source of carbocations and further their use in organic synthesis.

I am indebted to my co-workers named in the references for their support in our own work cited in this article. Generous support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, particularly in the initial phase of our work, is gratefully acknowledged. Limitations of space necessitated a subjective choice in the publications cited, trusting that this will meet with the understanding of all those colleagues whose work is not mentioned.

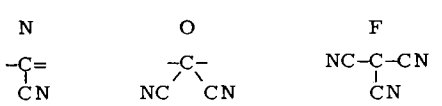
The Analogy between O and $C(CN)_2$

By Kurt Wallenfels, Klaus Friedrich, Jürgen Rieser, Werner Ertel, and Herbert K. Thieme[*]

The compounds of oxygen, *i.e.* OH acids, ethers, quinones, aldehydes, ketones, carboxylic esters and amine oxides, sulfoxides, and phosphane oxides, are compared and contrasted with those compounds which contain a $C(CN)_2$ moiety in place of the characteristic O atom. In their typical properties the pairs of analogs frequently display surprising agreement. The purpose of such analogy studies lies primarily in the estimation of reactivities; their limits are reached where specific properties of the structural components become effective.

1. The Cyano Group as a Substituent Imparting Electronegative Properties

An early attempt to characterize the behavior of atoms in an atomic assembly by a parameter was the concept of electronegativity formulated by *Pauling* in 1932[1]. This parameter affords a measure for the attraction exerted by an atom on bonding electrons. It has long been known to the organic chemist that the magnitude of this attraction depends



Scheme 1

not only on the nature of the atom itself but also on the atoms or groups of atoms to which it is bonded. One of the most powerful electronegativity-enhancing groups is the cyano group. The more CN groups a carbon atom bears, the greater will be its attraction for electrons. A kind of electronegativity series can therefore be drawn up for CN-substituted carbon atoms, resembling that of the atoms N, O, and F, and correlated with them as shown in Scheme 1.

We have developed this heuristic concept[2] in recent years, synthesizing a large number of CN-substituted compounds by analogy with those containing N and O and studying their properties. This report will compare compounds which differ solely in the presence of the $C(CN)_2$ component in place of an oxygen atom. It can be linked by double or single bonds to carbon or hydrogen, or also to nitrogen, sulfur, and phosphorus. The $C(CN)_2$ compounds are thus analogs of alcohols, ethers, quinones, aldehydes, ketones, carboxylic acids and their derivatives, and of amine oxides, sulfoxides, and phosphane oxides.

As the simplest case of an analogous reaction we shall consider the dissociation of a proton from O and from $C(CN)_2$. We see (Table 1) that the pK_a values of the $C(CN)_2$—H acids are 3.7 to 4.5 units smaller than those of the corresponding O—H acids. This difference in pK_a values is still greater in series of compounds in which two or even three oxygen atoms have been replaced by $C(CN)_2$ groups. Within a given

[*] Prof. Dr. K. Wallenfels, Doz. Dr. K. Friedrich, Dr. J. Rieser, Dr. W. Ertel, and Dr. H. K. Thieme
Chemisches Laboratorium der Universität
Albertstrasse 21, 7800 Freiburg (Germany)

series of comparable compounds, however, the same gradation of acidity is registered. Thus, as shown by *Rappoport*[7], unknown pK_a values of analogous compounds can be estimated from known pK_a values of O—H or $C(CN)_2$—H acids.

Table 1. pK_a values of O—H and $C(CN)_2$—H acids.

O—H acids	pK_a		$C(CN)_2$—H acids
H_2O	15.7 [3]	11.25 [3]	$CH_2(CN)_2$
CH_3CO—OH	4.76 [4]	1.0 [3]	CH_3CO—$C(CN)_2H$
C_6H_5—OH	9.92 [5]	5.8 [6]	C_6H_5—$C(CN)_2H$

Protonation reactions of anions of O—H acids are very fast diffusion controlled processes. Carbanions of $C(CN)_2$—H acids (malononitrile and derivatives) are protonated at a similar rate. Doubts have recently been expressed concerning the initially assumed diffusion control[8]. In any case, the high rates suggest that the pronounced C—H acidity of CN-substituted compounds are more probably due to polar field effects or inductive effects rather than to stabilization of the carbanions by electron delocalization as in the case of acidic nitroalkanes[8].

The principal application of the analogy principle is already apparent from this example: the estimation of reactivities. Analogous is by no means synonymous with identical, as becomes especially clear when specific properties of the two structural components play a particular role, *e.g.* ability of oxygen to form associates *via* hydrogen bonds with the aid of its lone pairs, or the ability of the nitrile group to stabilize an adjacent negative charge[8].

Table 2. Vertical PE ionization energies of $O/C(CN)_2$ analogs.

O compound	Vertical PE ionization energy [eV]		$C(CN)_2$ compound
H_2O	12.67 [9]	12.68 [10]	$H_2C(CN)_2$
O_2	11.55 [11]	11.78 [12, 13]	$(NC)_2C{=}C(CN)_2$
O_3	12.53 [14]	12.9 [15]	
$H_2C{=}O$	10.88 [9]	11.35 [13]	$H_2C{=}C(CN)_2$

That the two structural components do have a quantitatively similar influence in an assembly of atoms follows from a comparison of the vertical PE ionization energies (Table 2).

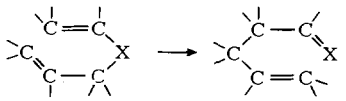
2. Ether/$C(CN)_2$ Compounds

Linkage of the $C(CN)_2$ group with two alkyl- or cycloalkyl groups affords compounds which are highly stable and chemically inert like the corresponding ethers. Reactive compounds may be expected when the structural component O or $C(CN)_2$ is incorporated into a delocalizable electron system. In such cases mainly rearrangements are observed. Classical examples are the valence tautomerism in the 7-oxanorcaradiene-oxepin *(1a)*[16] and the 7,7-norcaradienedicarbonitrile-cycloheptatriene-1,1-dicarbonitrile system[17], and the sigmatropic 3,3-shifts of the Cope and Claisen rearrangements. The thermal

(1)

(a), X = O
(b), X = $C(CN)_2$

rearrangements of allyl vinyl ether *(2a)*[18] and allylvinylmalononitrile *(2b)*[19] are entirely analogous.



(2)

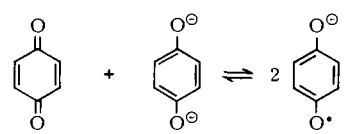
(a), X = O
(b), X = $C(CN)_2$

The decisive role of the change in electronegativity of the C atom due to substitution in the Cope rearrangement is seen in the kinetic studies by *Cope et al.* on compounds of type *(2)* with $X{=}C(CN)_2$, C(COOR)(CN), and $C(COOR)_2$[19]. The rates of these first order reactions decrease considerably along the given series.

In spite of intense effort, *Cope* was unable to carry out the classical Claisen rearrangement of aryl allyl ethers with compounds containing the $C(CN)_2$ group in place of oxygen[20]. The limitations of the analogy are again seen: it appears that the lone pairs of the oxygen in resonance with the π electrons of the aromatic ring can provide a stabilizing contribution when the low energy aromatic system is eliminated in the transition state. This is impossible in the $C(CN)_2$ "ethers".

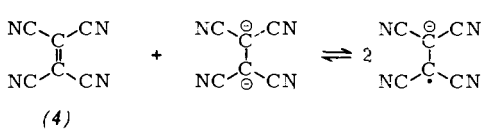
3. Quinones/Tetracyanoquinodimethanes

Both structural components are able to stabilize unpaired electrons in suitable systems. This is already apparent for oxygen from the electronic arrangement in the O_2 molecule and from the pronounced stability of the semiquinones. These radical anions arise on mixing of benzoquinone *(3)* with hydroquinone at a suitable pH value.

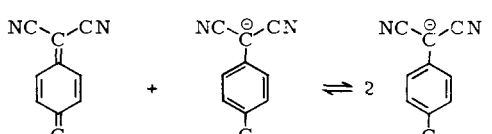


(3)

Tetracyanoethylene *(4)* accordingly reacts with the dianion of tetracyanoethane[21] and tetracyanoquinodimethane *(5)* with the dianion of tetracyano-*p*-xylene[22].



(4)

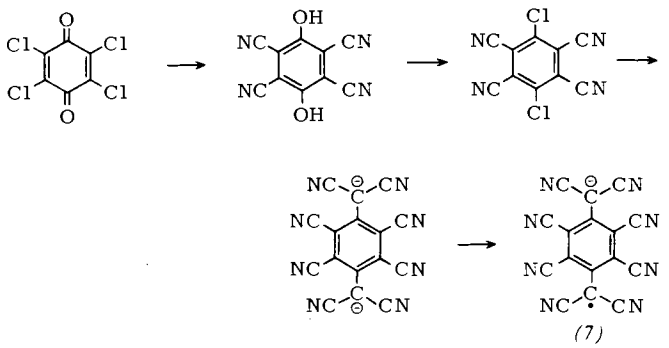


(5) *(6)*

In both cases the equilibrium lies on the side of the radical anions. The radical anion *(6)* of tetracyanoquinodimethane has recently gained great popularity because its complexes

with tetrathiafulvalene are the prototype of organic metals[23], *i.e.* organic compound with a metallic-type conductivity; they have even been ascribed superconductivity at 57 K.

In 1965 we prepared tetracyanobenzoquinone *(9)* (Table 3)[24] and pointed out its exceptional oxidizing power. Attempts have also been made to synthesize the $C(CN)_2$ analog of this quinone (Scheme 2)[25].



(7)

Scheme 2

Octacyano-*p*-xylene has so far only been prepared as the dianion (dipyridinium salt). Two polarographic waves are recorded during its anodic oxidation; they can be assigned to oxidation to the radical anion *(7)* and to octacyano-*p*-quinodimethane *(10)*, the half-wave potentials being 661 and 1290 mV respectively[25].

The radical ion *(7)* is sufficiently stable to be prepared in solution. It is obtained by oxidation of the dipyridinium salt with bromine. The completely resolved ESR spectrum affords the ^{14}N coupling constants for two sets of equivalent nuclei; $a_{N'}=1.09$ and $a_{N''}=0.125$ gauss. HMO calculations indicate a high spin density at the dicyanomethylene groups and a low spin density at the ring-bonded cyano groups[25].

4. Carbonyl Compounds/Alkylidenemalononitriles

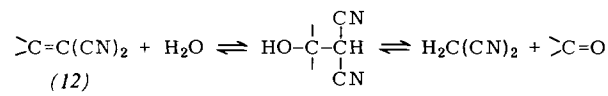
Two types of reactions dominate the chemistry of carbonyl compounds: In one type they are the passive partner of a nucleophilic addition at the carbonyl carbon atom. It is characterized by addition and—after subsequent elimination—substitution. In the other type initial abstraction of an α-proton transforms carbonyl compounds into the active agent of such an addition or addition-elimination reaction. As seen in Table 4, alkylidenemalononitriles fulfill nearly all expectations of this kind.

4.1. Hydration

The reversible hydration of aldehydes and ketones is one of the most thoroughly studied reactions of carbonyl compounds[42]. Both the forward and the reverse reaction can be catalyzed by acid or base. However, the nucleophilic character of water usually permits reaction without addition of catalyst. The degree of hydration is highly dependent upon structure. Thus, for instance, formaldehyde is almost completely hydrated in aqueous solution, acetaldehyde to the extent of about one half, and other aldehydes and ketones such as acetone hardly at all.

Addition of water nevertheless also occurs with these carbonyl compounds *(11)*; it is just that elimination of water from the adduct is a much faster process, as shown by studies

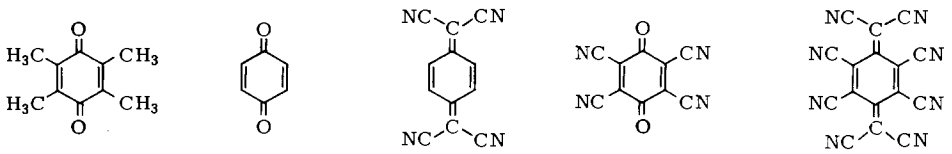
(11)



(12)

on ^{18}O-labeled water. The $C(CN)_2$ compounds *(12)* react in the same way[27, 28, 34]. Analogies in reactivity are seen to apply both to carbonyl compounds and alkylidenemalononitriles and to water and malononitrile. We have employed the reaction for preparation of aldehydes[34]; however, it is also suitable for synthesis of alkylidenemalononitriles[28].

Table 3. Polarographic data of quinones and cyano-substituted quinodimethanes [a].



(8) *(3)* *(5)* *(9)* *(10)*

	Quinone/semiquinone				Semiquinone/dianion					
	$E^1_{1/2}$ [mV]	s	C_L [mol/l]	I_1 [μA]	$E^2_{1/2}$ [mV]	s	I_2 [μA]	$\Delta E_{1/2}$ [mV]	log K	I_2/I_1
(8) [26]	− 760				−1635			875	15	
(3) [26]	− 400				−1340			940	16	
(5)	303	63	$19.3 \cdot 10^{-4}$	108	− 348	82	86	651	11	0.80
(9)	995	68	$7.57 \cdot 10^{-4}$	67	174	69	53	821	14	0.79
(10)	1209	53	$6.28 \cdot 10^{-4}$	61	661	63	56	548	9	0.92

[a] $E_{1/2}$ = half-wave potential measured *vs.* Ag/AgCl (benzonitrile) saturated with $(CH_3)_4NCl$; s = slopes of logarithmic analysis curves; C_L = molar concentration of solutions; I = normalized limiting current $I = I_d(\omega^{1/2} C_L)^{-1}$; ω = rate of revolution; K = semiquinone formation constant; $\Delta E = E^1_{1/2} - E^2_{1/2}$.

Under analogous conditions, tetracyanohydroquinone also gives the radical anion[25]. Polarographic comparison of a series of quinones with the cyano-substituted quinodimethanes is seen in Table 3. The potentials of the $C(CN)_2$ analogs lie at much more positive values than those of the O compounds.

Table 4. Analogous reactions of carbonyl compounds and alkylidenemalononitriles.

	Carbonyl compound	Alkylidenemalononitrile	Ref.
Reagent	$>C=O$	$>C=C(CN)_2$	
H_2O	Hydrate formation	Addition of water	[27, 28, 34]
$CN^{\ominus}$	Cyanohydrins	(1-Cyanoalkyl)malononitriles	[28]

Thermolysis	Isocyanate reaction products	Ketenimine reaction products	[41]

4.2. Cyanohydrin Formation

Addition of hydrogen cyanide to aldehydes or ketones affords cyanohydrins. The reactions are known to be strongly accelerated by small amounts of bases. The effective nucleophile appears to be the cyanide ion. Alkylidenemalononitriles react analogously and form anions of (1-cyanoalkyl)malononitriles *(13b)*[28].

$$>C=X + CN^{\ominus} \rightleftharpoons -\underset{CN}{\overset{|}{C}}-X^{\ominus} \quad (13) \qquad (a),\ X = O \qquad (b),\ X = C(CN)_2$$

The (1-cyanoalkyl)malononitriles are strong acids and accordingly form stable salts. This is doubtless the reason why no condensation reaction ensues in the case of alkylidenemalononitriles bearing aromatic substituents. A reaction analogous to the benzoin condensation could not be observed.

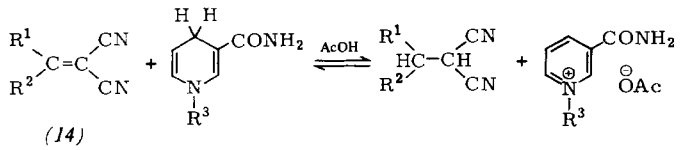
4.3. Reduction

Reduction of aldehydes and ketones usually involves transfer of a proton and of two electrons from the reducing agent to the carbonyl carbon atom. The resulting alkoxide ion is protonated to the alcohol, usually by water. Meerwein-Ponndorf-Verley reduction is formulated as a hydride transfer, and the mechanisms considered are: a cyclic process with participation of one mole of alkoxide per mole of carbonyl compound and a non-cyclic course with participation of two moles of alkoxide per mole of carbonyl compound[42].

We have subjected alkylidenemalononitrile to the conditions of the Meerwein-Ponndorf-Verley reduction[33]; progress of the reaction can easily be monitored with the aid of the amount of acetone formed. The yields of alkylmalononitrile are relatively low however (*p*-nitrobenzylidenemalononitrile gives 15 %, and benzylidenemalononitrile 35 % of the benzyl compound). We suspect that the coordination of the carbonyl oxygen atom with the metal leads to a significantly greater enhancement of positive charge on the adjacent carbon atom than, for example, coordination of the nitrogen atoms in the $C(CN)_2$ compounds. The latter should have relatively little effect on the incorporation of the weakly nucleophilic hydrogen in aluminum isopropoxide. In contrast, complex hydrides with strongly nucleophilic hydrogen, such as sodium tetrahydridoborate, reduce alkylidenemalononitriles in good yields similar to those for aldehydes or ketones[34].

The reduction of carbonyl compounds to alcohols with the aid of dihydropyridines as reducing agent plays a central role in the most varied metabolic pathways of all biological systems. It is essential for the regulation of degradation and synthesis in living cells that these hydrogen transfers are subject to such kinetic hindrance that they can only proceed with the aid of catalyzing proteins (dehydrogenases). It was therefore surprising to find that some alkylidenemalononitriles *(14)* are easily reduced by NADH or model compounds such as 1-benzyl-1,4-dihydronicotinamide without any need for a catalyst, apart from the promotion they may receive from weak acids[31]. Thus the $C(CN)_2$ analogs of certain aldehydes and ketones behave like the quasi-carbonyl compound thiobenzophenone[43] and some carbonyl compounds such as trifluoroacetaldehyde[44] and hexachloroacetone[45] which are highly polarized by halogen substitution. Depending upon the substituents R^1 and R^2 the yields of the reaction lie between 40

and 95%. Remarkably, benzhydrylidenemalonitrile *(14)*, $R^1 = R^2 = C_6H_5$, is not reduced[31], in contrast to the thioanalog of benzophenone.



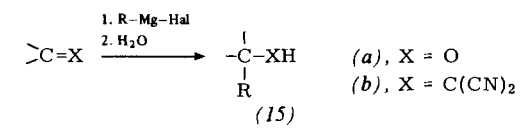
(14)

R^1, R^2 = H, Alkyl, Aryl
R^3 = Benzyl, 2,6-Dichlorobenzyl

The reaction is characterized by a direct transfer of hydrogen from dihydropyridine to the activated olefin, as in biochemical hydrogen transfers and most of the model reactions. Hence no exchange takes place between the dihydropyridine hydrogen and protons of the reaction medium, not even on working in 20% alcoholic acetic acid. This was proved by use of [4,4'-D_2]-1-benzylnicotinamide as reducing agent[31]. The solvent dependence of the isotope effect (H/D = 5—9) is in accord with the concept that transfer of a proton and two electrons takes place in a molecular complex formed from donor and acceptor.

4.4. Reactions with Grignard Compounds

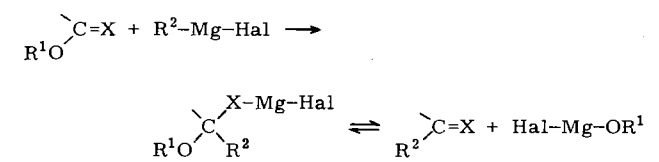
A close similarity exists between the behavior of carbonyl compounds and their $C(CN)_2$ analogs towards Grignard compounds. Thus aldehydes and ketones generally give the alcohols *(15a)* in high yields, and alkylidenemalononitriles the alkylmalononitriles *(15b)*[39].



(15)

(a), X = O
(b), X = $C(CN)_2$

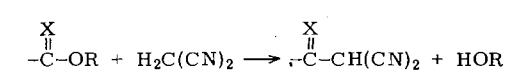
The reaction of Grignard reagents with the $C(CN)_2$ ester analogs has also been investigated[39]. As in the reaction of esters, the labile primary adduct *(16b)* releases an alkoxide ion; reaction to form compounds of type *(15b)* usually follows.



(16)

(a), X = O; *(b)*, X = $C(CN)_2$

This analogous reaction behavior is understandable since Grignard reactions are largely initiated by nucleophilic attack of a potential carbanion on the positively charged carbon atom and the electronegativities of the two structural components therefore play a crucial role in the early phase of the reaction.



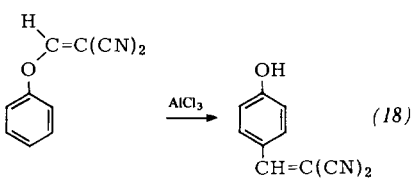
(17)

(a), X = O; *(b)*, X = $C(CN)_2$

Carbonyl compounds and their $C(CN)_2$ analogs also resemble each other in their reactions with CH acids or their carbanions[40, 46]; the reaction leading to *(17a)* or *(17b)* is an appropriate example.

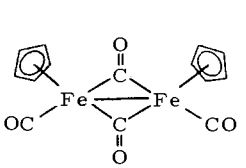
4.5. The Fries Shift

The Fries shift is preferred over direct acylation for the synthesis of aromatic hydroxy ketones. Analogous preparation of aromatic hydroxy aldehydes starting from phenyl formate has been examined by *Olah et al.*[47]. However, instead of rearrangement products they obtained complex condensation products whose formation is rationalized by secondary reactions of the phenol which can arise on acid-catalyzed decarbonylation of both the starting material and the rearrangement product. In spite of this negative result we attempted the analogous reactions[34] starting from *O*-dicyanovinylated phenol, assuming that the elimination of dicyanomethylenecarbene would be less likely, owing to its instability, than the O-analogous decarbonylation. We did indeed obtain a rearrangement product, albeit in only 5% yield, *viz.* *p*-hydroxybenzylidenemalononitrile *(18)*.

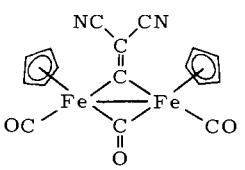


(18)

Free dicyanomethylenecarbene, the $C(CN)_2$ analog of carbon monoxide, has not yet been prepared. The carbene does act as ligand in transition metal complexes such as *(20)*, however, just like carbon monoxide in the complex *(19)*[48, 49].



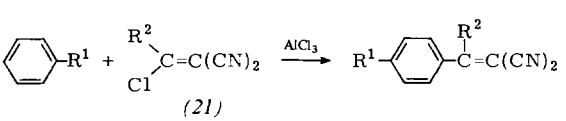
(19)



(20)

4.6. Reactions with Arenes

On proceeding as in the Friedel-Crafts synthesis of ketones, and treating arenes with (1-chloroalkylidene)malononitriles *(21)* in the presence of aluminum chloride, smooth reaction ensues to give the analogous products[35].

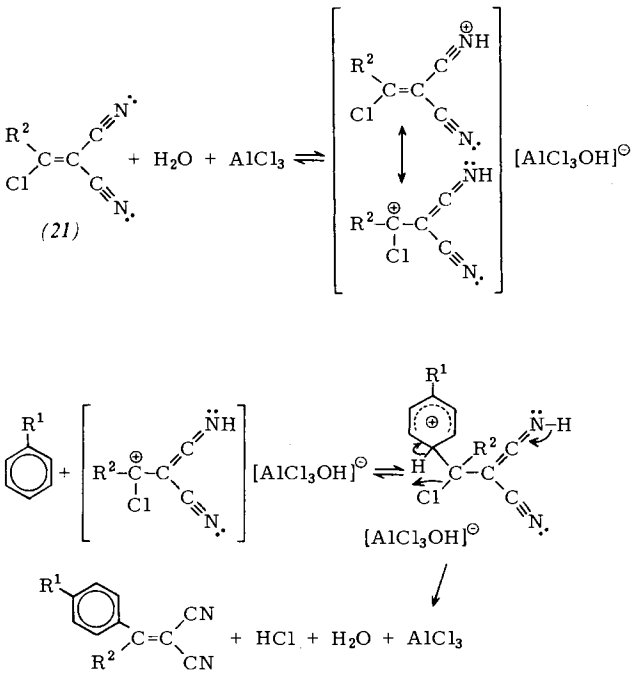


(21)

R^1 = H, CH_3, Cl, OCH_3, OH, also thiophene and naphthalene
R^2 = H, CH_3

We have examined the reaction of numerous arenes with activated olefins, sometimes varying the reaction conditions

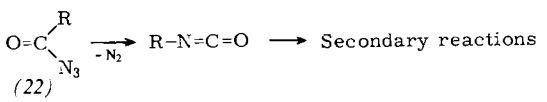
(solvent, temperature, amount of catalyst), and found this reaction to have a wide preparative scope[33-35]. Characteristically, the reaction fails to start in an anhydrous medium. We therefore propose the mechanism depicted in Scheme 3, which is corroborated by spectroscopic evidence[33].



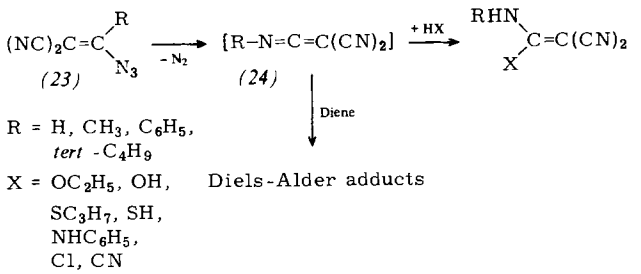
Scheme 3

4.7. Pyrolysis of (1-Azidoalkylidene)malononitriles

By analogy with acyl azides *(22)*, (1-azidoalkylidene)malononitriles *(23)* can be prepared from the corresponding vinyl chlorides[41]. In contrast to most vinyl azides, compounds *(23)* also behave like acyl azides *(22)* on pyrolysis and undergo a Curtius-analogous rearrangement. The ketenimine *(24)* can be detected by trapping reactions.

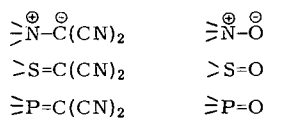


The analogous pyrolysis of the vinyl azides *(23)* is also of broad preparative utility. Its scope is further extended by application to vinyl azides bearing other electron-withdrawing substituents such as COR or COOR in place of the cyano group[36,38,41].



5. Heteroatom Oxides/Heteroatom Dicyano Ylides

The numerous examples of Sections 1 to 4 have shown that the $C(CN)_2$ group, when linked to C or H, imparts the relevant compounds with a close similarity to those of oxygen. This prompted us to consider whether the $C(CN)_2/O$ analogy could also be extended to compounds in which the oxygen is bonded to the heteroatoms N, S, or P (Scheme 4).

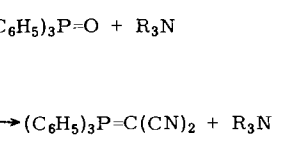


Scheme 4

Although dicyano ylides have been known for several years, until recently the only reports about them in the literature were of a physico-chemical nature; these include dipole moments, X-ray structural data, and spectroscopic data. The reason was probably that the dicyano ylides are far more stable than other ylides and there was therefore little incentive to subject them to the usual ylide reactions[50]. In their reactions they resemble oxides more closely than other ylides, as is immediately apparent from their stability.

5.1. Amine Oxides and Nitrogen Dicyano Ylides

On comparison of the reactions of nitrogen dicyano ylides *(26)* with those of the amine oxides *(25)* it is instructive to consider the reaction with triphenylphosphane.



(25)

(26)

Aliphatic amine oxides transfer their oxygen almost quantitatively to triphenylphosphane in boiling glacial acetic acid[53]. In contrast, aromatic amine oxides prove to be very inert towards triphenylphosphane; they only react above 200 °C and then in low yields[54]. The $C(CN)_2$ group is transferred analogously from nitrogen dicyano ylides to triphenylphosphane. We have investigated this transylidation with six different nitrogen dicyano ylides[51,52]; they were all less reactive than the oxides. An analogy is noted, however, in the gradation of reactivity. For instance, trimethylammoniodicyanomethanide *(26)*, R = CH_3, reacts at lower temperature (160 °C) and faster (16 h), giving far better yields (60 %) of triphenylphosphoniodicyanomethanide than pyridiniodicyanomethanide (210 °C/24 h/8.5 %).

5.2. Sulfoxides and Sulfur Dicyano Ylides

Numerous reports about physico-chemical studies on the structure of sulfoxides and sulfur dicyano ylides are encountered in the literature. Together with our findings the following picture can be drawn[51]:

1) Sulfoxides and sulfur dicyano ylides are not planar but pyramidal molecules, whose apices are occupied by two C

atoms, the S atom, and the O atom or the $C(CN)_2$ group (X-ray structure analysis, NMR spectra).

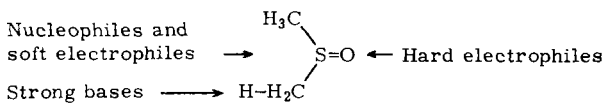
2) The S atom in sulfoxides and sulfur dicyano ylides is sp^3 hybridized; there is a polar $d\pi$—$p\pi$ bond between S and O or between S and $C(CN)_2$ (X-ray structure analysis, dipole moment, basicity).

3) Both in sulfoxides and in sulfur dicyano ylides interaction exists between the sulfur lone pair and the π-electron systems of unsaturated substituents (X-ray structure analysis, UV spectra).

4) Sulfoxides and sulfur dicyano ylides are only weakly basic. The pK_{BH^+} lie between those of the phosphane oxides (around -2) and that of acetone (-7.0).

5) X-Ray structure analysis and IR spectra indicate interactions between the carbanion electron pair and the CN groups in sulfur dicyano ylides.

A suitable reference substance for chemical reactions was dimethyl sulfoxide (DMSO) whose properties as solvent and reactant have attracted so much attention that there is nowadays hardly any other organic compound so thoroughly studied and for which such a broad range of applications has been discovered. Scheme 5 shows the reactive sites of the DMSO molecule[55].

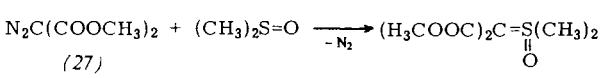


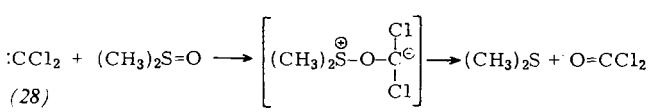
Scheme 5

We have carried out detailed comparisons of thermal decomposition, basicity and salt formation, as well as the reactions with diazomalononitrile, sodium hydride/benzyl chloride, chlorinating agents, acyl chlorides, methyl iodide, and triphenylphosphane with the corresponding reactions of the ylides.

5.2.1. Reaction with Diazomalononitrile

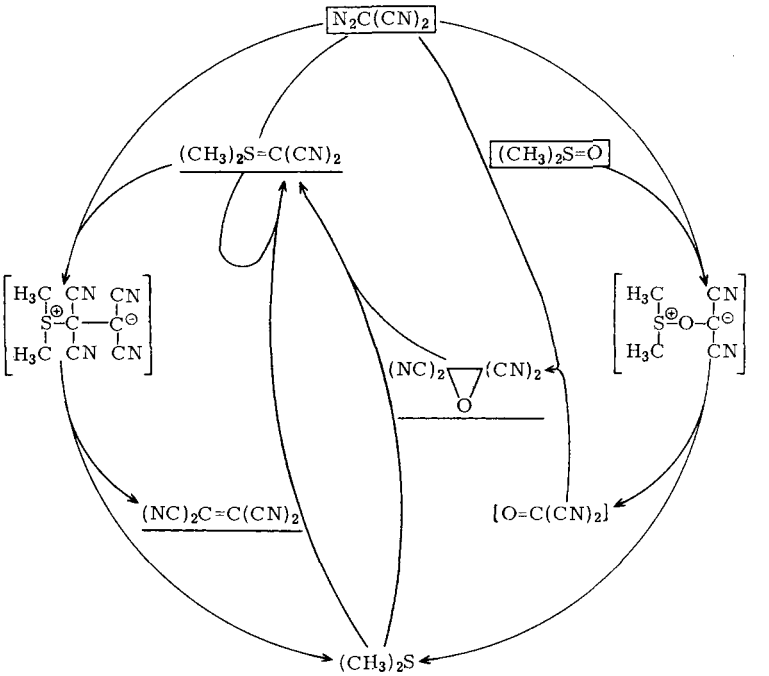
Sextet intermediates of carbene type are trapped by DMSO to form sulfoxonium ylides, *e.g.* in the reaction with dimethyl diazomalonate *(27)*[56], or oxidized, *e.g.* dichlorocarbene *(28)* to phosgene[57].





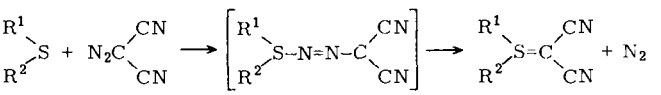
The reaction of DMSO with diazomalononitrile leads to dimethylsulfoniodicyanomethanide, dimethyl sulfide, tetracyanoethylene, and tetracyanoethylene oxide (and nitrogen). This finding supports the reaction course shown in Scheme 6[58].

The secondary reaction of the sulfide with diazomalononitrile shown in Scheme 6 is frequently the method of choice for preparing sulfur dicyano ylides *(29)*, particularly those bearing aryl substituents[51, 58].

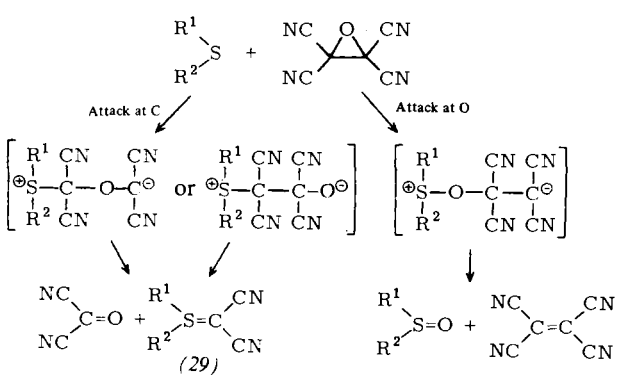


Scheme 6. Starting materials are shown in boxes, intermediates enclosed in brackets, and isolated products underlined.

Tetracyanoethylene is obtained as by-product (as in Scheme 6). This compound and sulfide were invariably isolated when we carried out the direct reaction of sulfur dicyano ylides with diazomalononitrile[51, 58]. The reaction of the sulfide with



tetracyanoethylene oxide can likewise be utilized for the preparation of sulfur dicyano ylides[51, 59, 60]. Sulfides containing bulky aryl or aralkyl substituents also attack the oxygen; the product ylide *(29)* is then accompanied by the sulfoxide (Scheme 7)[51, 59].



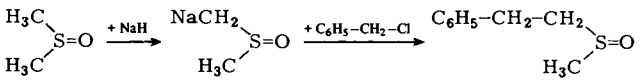
Scheme 7

Thus in this reaction both the oxygen and the $C(CN)_2$ group of tetracyanoethylene oxide are transferred to a sulfur atom.

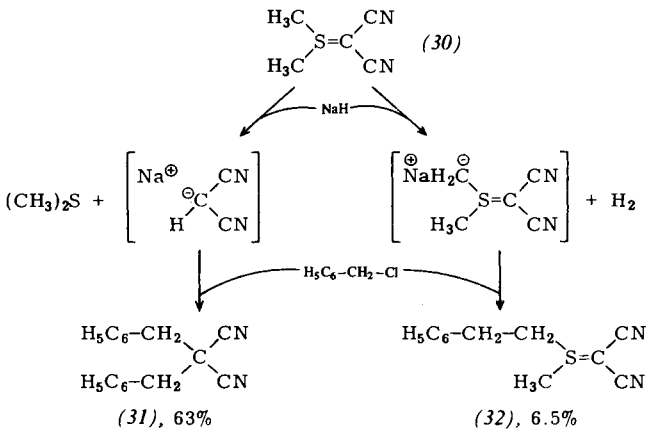
5.2.2. Reaction with Sodium Hydride and Benzyl Chloride

One of the best known reactions of dimethyl sulfoxide is deprotonation by strong bases, leading to the methylsulfinyl

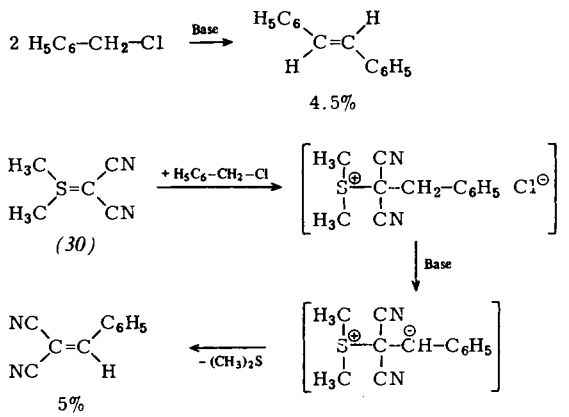
carbanion which can undergo numerous further reactions. For purposes of comparison we chose benzylation after prior treatment with sodium hydride[61].



Reaction with dimethylsulfoniodicyanomethanide *(30)* gives only low yields of the analogous reaction product, *viz.* methylphenethylsulfoniodicyanomethanide *(32)*. The principal reaction is cleavage of the ylide bond with subsequent benzylation giving dibenzylmalononitrile *(31)*.

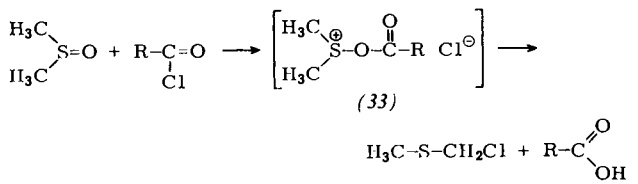


Further products obtained are *trans*-stilbene, which also occurs as by-product of reaction with DMSO[61], and benzylidenemalononitrile, which is probably formed by analogy with the Kornblum aldehyde synthesis with DMSO[62].

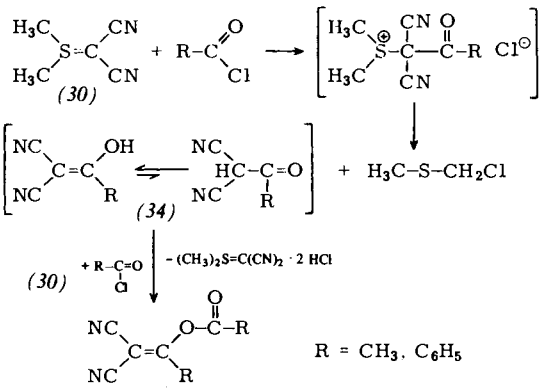


5.2.3. Reaction with Acyl Chlorides

DMSO reacts with acyl chlorides *via* the acyloxysulfonium salts *(33)* as intermediates to give carboxylic acids and chloromethyl methyl sulfide[63,64].

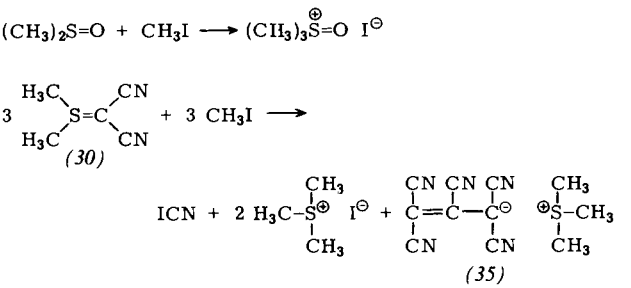


We assume that the primary step of the reaction of the ylide *(30)*[51,58] is acylation of the cyano-substituted carbon atom, as in the reaction with DMSO. The acylation product then decomposes to chloromethyl methyl sulfide and acylmalononitrile *(34)*. The latter, which preferably exists as the enol, is once again acylated as such, with the ylide *(30)* acting as a base. Support for this reaction comes from formation of the same product on acylation of the corresponding potassium enolates.

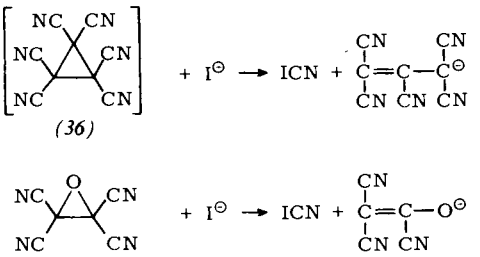


5.2.4. Reaction with Methyl Iodide

Reaction with methyl iodide leads to trimethylsulfoxonium iodide in the case of DMSO[65], and to trimethylsulfonium iodide, cyanogen iodide, and trimethylsulfonium pentacyanopropenide *(35)* in the case of dimethylsulfoniodicyanomethanide *(30)*[51,58].



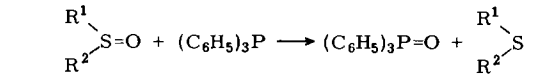
The initial product is most likely a salt analogous to that formed in the DMSO reaction, whose decomposition affords trimethylsulfonium iodide and unites three $C(CN)_2$ fragments. Hexacyanocyclopropane *(36)* is a conceivable intermediate which would doubtless react immediately with iodide ions to give pentacyanopropenide and cyanogen iodide; the analogous reaction of tetracyanoethylene oxide is known[66].

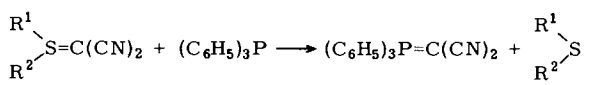


5.2.5. Reactions with Triphenylphosphane

The reaction of sulfoxides with phosphanes involves transfer of oxygen from sulfur to phosphorus. The mechanism of the

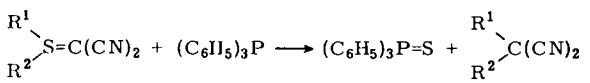
actual oxygen-transfer step is strongly dependent on the nature of the substituents attached to the two heteroatoms and on the reaction conditions such as temperature, catalyst, and solvent[67–69]. Most investigations employed the least reactive phosphane, triphenylphosphane; triphenylphosphane oxide and the relevant sulfide are obtained.



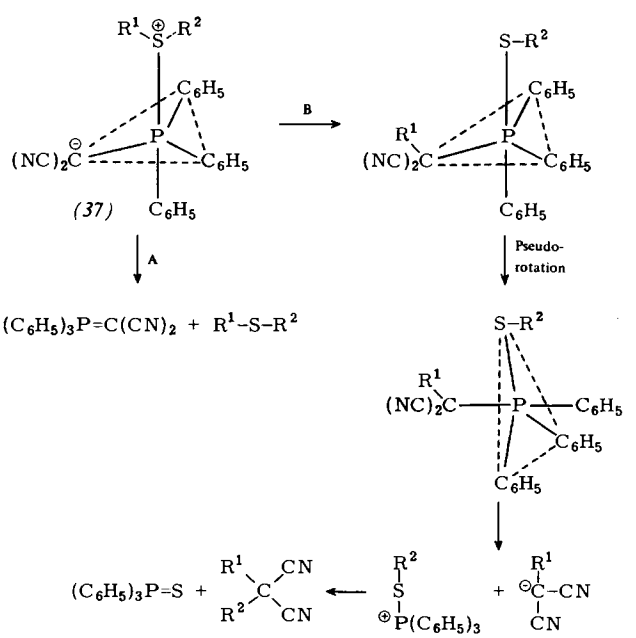


We have treated a series of sulfur dicyano ylides carrying various substituents on the sulfur with triphenylphosphane in the melt and in all cases observed the analogous $C(CN)_2$-transfer reaction giving the phosphorus dicyano ylide[51, 70].

Thus transylidation is the sole or predominant reaction on use of sulfur dicyano ylides bearing aromatic substituents on the sulfur. With dialkyl- and diaralkylsulfoniodicyanomethanides, however, it occurs only as a side reaction; the major reaction is then transalkylation, in which the substituents migrate from sulfur to the dicyano-substituted carbon atom while the sulfur is taken over by the phosphorus to form triphenylphosphane sulfide[71].



In order to interpret the reactions (Scheme 8)[70], we assume that the initial step is addition of triphenylphosphane to the ylide bond giving adducts *(37)* with five ligands on the phosphorus atom. Elimination of the sulfide from the apical position then gives the transylidation products by route A. The alkyl shift from the apical sulfonium sulfur to the equatorial carbanion center according to path B modifies the electronega-



Scheme 8

tivity gradation of the ligands. This leads to a rearrangement of the pseudorotation type[72]. Rupture of the P—C bond, which is now the weakest linkage, leads after subsequent alkylation of the fragments as a secondary reaction to the transalkylation products.

6. Conclusion

Strict classification of organic reactions according to the elemental composition of the compounds, to the type of bonding, and to the functional groups present is unable to cater for a large number of "anomalous" reactions. There are poorly defined boundaries between O—H and C—H acids, between carbonyl compounds and olefins, between heteroatom oxides and ylides. Comparisons of reactivity as described above serve to help us understand the finer points of the way in which "normal" and "anomalous" reactions proceed. Moreover, our thinking within the framework of this analogy permitted the discovery and interpretation of several novel reactions. The utility of this conceptual approach largely depends upon our remembering that no comparison is perfect.

Our own work cited in this article was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are also indebted to Dr. Stafast, Frankfurt, for compiling the PE data, some of which have yet to be published. Gifts of chemicals from Hoechst AG, and microanalyses by Sandoz AG are also gratefully acknowledged.

New synthetic methods (15)

The Synthetic Utility of 2-Oxazolines[**]

By A. I. Meyers and E. D. Mihelich[*]

The oxazoline ring system, first prepared in 1884, has only in the last five years been shown to possess considerable utility in the synthesis of a variety of functionalized organic compounds. By appropriate metalation of the 2-alkyl substituent it is possible to prepare a variety of homologated carboxylic acid derivatives, both chiral and achiral. Various other manipulations of the oxazoline ring lead to aldehydes, ketones, lactones, amino acids, thiiranes, and olefins. Due to the inertness of the oxazoline ring system to various reagents (RMgX, $LiAlH_4$, CrO_3, mild acid or alkali) it may be utilized as a protecting group for carboxylic acids during the transformations involving the above reagents. Two major new developments in oxazoline chemistry involve a) the use of a chiral oxazoline as a reagent for asymmetric syntheses of chiral carboxylic acids, lactones, alcohols, thiiranes, and olefins and b) a new mode of aromatic substitution in which the aryloxazolines act as nucleophilic or electrophilic reagents. This behavior has led to a variety of polysubstituted benzenes and biphenyls which would be inaccessible by classical routes. A variety of examples illustrating the utility of oxazolines indicated above are presented so that the reader may appreciate the vast potential of this simple ring system in synthesis.

1. Introduction

As organic chemists attempt syntheses of increasingly complex molecules, the need for efficient, mild, and selective functional group transformation and elaboration becomes ever more apparent. The ability of a heterocycle to meet these requirements is not a new idea[1]. In general, however, this concept has not been generally accepted for synthesis. The introduction and rapid acceptance of dithianes[2], oxazines[3], isoxazoles[4], and other heterocycles as versatile tools of the synthetic chemist result predominantly from their ability to 1) remain inert to a variety of commonly used reagents, 2) perform a desired transformation efficiently and under mild conditions, and 3) be available for further modification *via*

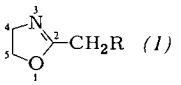
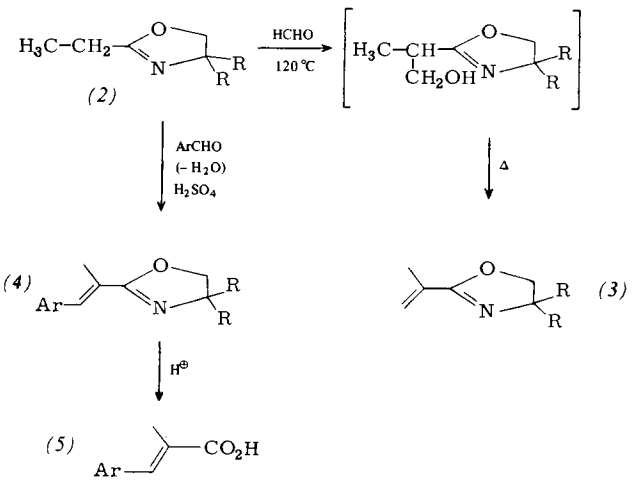
[**] Abbreviations: Me = methyl, Et = ethyl, Pr = propyl, Bu = butyl, Pent = pentyl, Hex = hexyl, Ar = aryl, Ph = phenyl, Tos = *p*-toluenesulfonyl, LDA = lithium diisopropylamide, DME = dimethoxyethane, HMPA = hexamethylphosphoric triamide.

mild or neutral "releasing" conditions. These properties, commonly identified with "latent functionality"[5], provide a flexibility which is both rare and extremely valuable to the chemist involved in synthesis.

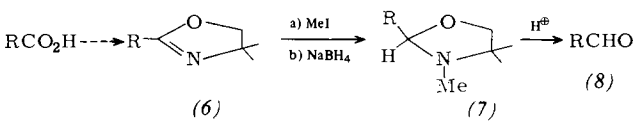


(1)

2-Substituted 2-oxazolines *(1)*, although well-known compounds[6], are newcomers to this elite group of molecules. Earlier reviews[6] emphasized the industrial importance of monomeric and polymeric 2-oxazolines since few uses in synthesis had been reported. The 2-substituted 2-oxazoline ring was recognized, however, as having a number of potentially useful properties. The α-hydrogen in *(1)* was shown to be labile and to undergo aldol-type condensation with formaldehyde[6a] and aromatic aldehydes[7] leading to oxazolines *(3)* and *(4)*, respectively, bearing an unsaturated side chain. Compounds *(4)* are hydrolyzed in aqueous acid to unsaturated carboxylic acids *(5)*. *Nordin*[8] found that carboxylic acids may be transformed into aldehydes *(8)* *via* the oxazoline *(6)* if it is first methylated and then reduced with sodium tetrahydridoborate to *(7)*.



Research in oxazoline chemistry has been greatly aided by their ready availability. The classical methods[9,10] utilizing α-amino alcohols and carboxylic acids provide ready access to 2-alkyl- and 2-aryloxazolines. More recent preparations

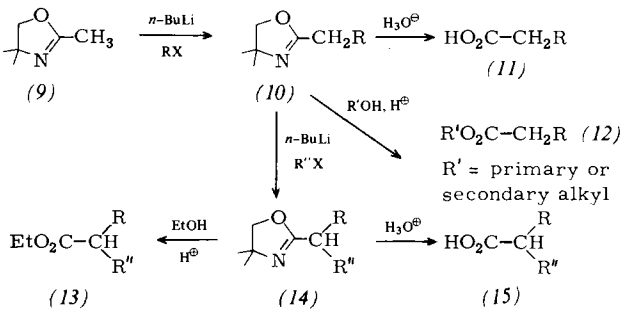


(6) *(7)* *(8)*

involve the condensation of α-amino alcohols with isocyanides[11], nitriles[12], cyanoallenes[13], and propargylphosphonium salts[14]. These preparations foreshadowed the explosion in oxazoline research over the past five years which has led to a multitude of functionally diverse products through suitable manipulations of the oxazoline nucleus. A summary of this work by product type is presented below.

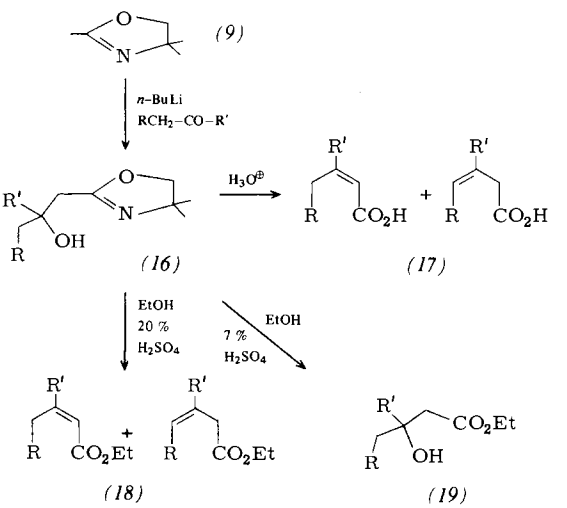
2. Aliphatic Carboxylic Acids and Esters

The simple oxazoline *(9)*[15] may be metalated with a variety of lithio bases [butyllithium, phenyllithium, lithium diisopropylamide (LDA), and lithium bis(trimethylsilylamide) at −78 °C and treated with alkyl iodides or bromides to afford the elaborated oxazoline *(10)* in excellent yields (93—99 %). Acidic hydrolysis affords the homologated acetic acid *(11)*, whereas alcoholysis provides the homologated esters *(12)* in yields of 77—98 %. Dialkylations (but not trialkylations) are also feasible by metalation of the 2-alkyloxazoline *(10)* followed by addition of a second equivalent of alkyl halide furnishing the 2-(dialkylmethyl)oxazolines *(14)*. Hydrolysis or alcoholysis once again leads to the dialkyl acetic acids *(15)* or the corresponding esters *(13)*. In this fashion, a number of carboxylic acid derivatives were prepared in good yield[16].



(9) *(10)* *(11)* *(12)* *(13)* *(14)* *(15)*

Unsaturated acids or esters were also prepared *via* this technique by utilization of carbonyl compounds. Thus, the 2-methyloxazoline *(9)*, when metalated and treated with various carbonyl compounds, gave high yields of the hydroxy derivative *(16)* which may be cleaved in aqueous acid to a "thermodynamic" mixture of α,β- and β,γ-unsaturated acids *(17)*. Alternatively, use of 20% H_2SO_4/ethanol provided good yields of the unsaturated esters *(18)*. Of further interest was the fact that cleavage of the oxazoline ring in *(16)* could be readily accomplished without loss of the β-hydroxy group by heating in 7% H_2SO_4/ethanol. In this way, good (80—87 %) yields of β-hydroxy esters *(19)* were obtained. This last result should be a useful alternative to the Reformatsky reaction and more recent routes to this class of compounds[17].



(9) *(16)* *(17)* *(18)* *(19)*

2.1. Optically Active Carboxylic Acids

An efficient asymmetric synthesis of 2-alkyl carboxylic acids *(24)* in 51—86% enantiomeric excess (ee) was recently developed based upon the synthetic properties of 2-alkyloxazo-

lines[18]. The readily available (+)-amino diol *(20)*[19] was transformed into the chiral 2-alkyloxazoline *(21)*[19b,c] which was metalated, using lithium diisopropylamide, to the lithio derivative *(22)*. Alkylation with a wide variety of alkyl halides gave *(23)* which was then hydrolyzed in 4 N sulfuric acid to either the (*R*) or (*S*) carboxylic acid *(24)*. The method, in addition to high optical yields, allows one to *predictably prepare either enantiomer* by proper introduction of R and R′ (Table 1). The methoxyamino alcohol *(25)* was also efficiently recovered and could be reused to prepare the starting oxazoline *(21)*.

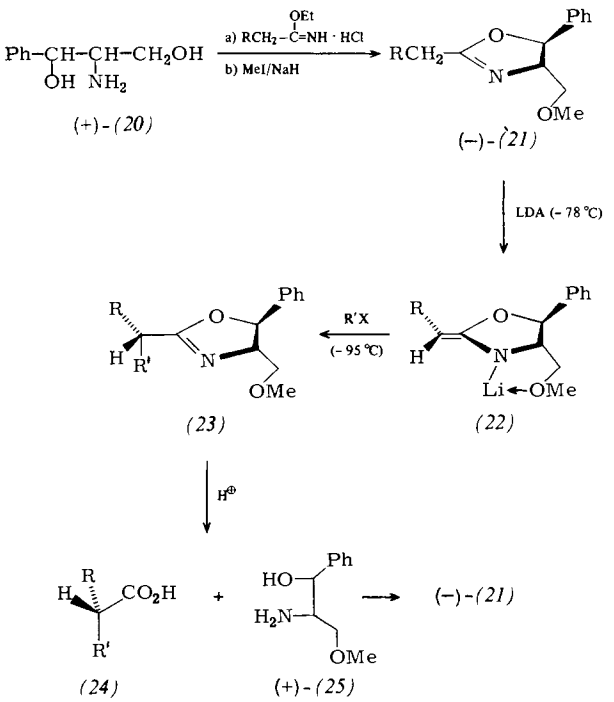


Table 1. Optically active 2-alkyl carboxylic acids *(24)* from chiral oxazolines *(21)*. Alkyl halides or sulfates were added at −98 °C.

R	R'X	Overall yield [%]	ee [%] [a]	Configuration

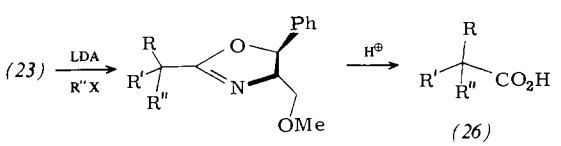
Ph	*i*-PrI	22	65 [b]	*R*

[a] ee = enantiomeric excess.
[b] Accompanied by 8—10 % racemization due to increased acidity of benzyl protons.

An attempt to prepare chiral trialkylacetic acid from *(23)* gave trialkylacetic acids *(26)*, but the products were nearly



racemic[20]. It is important to note that 2-trialkylmethylated oxazolines could not be prepared from simple oxazolines *(9)*. The presence of the methoxyl group in the chiral oxazolines serves to stabilize the lithio derivative *(22)* and presumably allows metalation to occur.

2.2. Kinetic Resolutions

The chiral oxazoline *(27)*, when transformed into its lithio derivative *(28)*, was capable of chiral recognition with respect to racemic alkyl iodides[21]. In a variety of examples, the (*S*)-enantiomer of 2- and 3-iodoalkanes was alkylated faster by *(28)* leaving the (*R*)-enriched halide enantiomer to be recovered (30—49% ee). The (*R*)-enriched 3-alkyl carboxylic acid *(31)* was also recovered (30—47 % ee) after hydrolysis of the alkyloxazoline *(30)*. In most cases the enantiomeric excess for halide and acid differed by less than 8 % (Table 2). This method therefore allows a) establishment of absolute configuration of alkyl halides and 3-alkyl carboxylic acids without the need for any optically active materials except *(27)*, b) prediction of the maximum rotation of either alkyl halide or acid as long as one of them is reliably known,

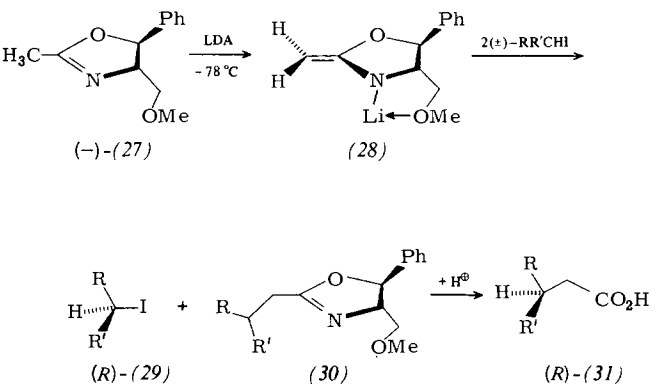


Table 2. Kinetic resolution of alkyl iodides and synthesis of the optically active 3-alkyl carboxylic acids *(31)*. The alkyl iodides were added to *(28)* between −50 and −70 °C; the reaction time was 8 to 30 h. The values given in parentheses are our own; the optically active compounds were hitherto unknown.

		Alkyl iodide recovered			Acids *(31)*		
R	R'	Yield [%]	ee [%] [a]	Config.	Overall yield [%]	ee [%] [a]	Config.
Me	Et	41	34	*R*	86	34	*R*
Me	Pr	60	31	*R*	89	39	*R*
Me	Bu	43	49	*R*	85	47	*R*
Me	Hex	83	31	*R*	81	39	*R*
Et	Pr	50	(31)	*R*	71	31	*R*
Et	Bu	125 [d]	46 [b]	*R*	48	20 [b]	(*R*)
Et	Pent	120 [d]	(58)	*R* [c]	54	(58)	*R*

[a] ee = enantiomeric excess.
[b] Both halide and acid were known but the large variance in optical purity suggests that one or both $[\alpha]_D$ values for the pure compounds are incorrect.
[c] Configuration assigned based on the configuration of the acid.
[d] Yield defined here as amount of halide recovered in excess of 50%.

c) confirmation of the rotation of pure enantiomers as long as one is reliably known. Thus, failure to achieve comparable percentage enantiomeric excesses for halide or acid clearly indicates that the reported values are unreliable.

2.3. Optically Active 3-Alkyl Carboxylic Acids

Chiral 2-(1-alkenyl)oxazolines *(32)* undergo 1,4-addition with organolithium reagents at −78 °C to form the adduct *(33)* which, after hydrolysis (3—6 N H_2SO_4, reflux, 3—6 h), leads to the 3-alkyl carboxylic acids *(34)* in exceedingly high optical yields (Table 3).

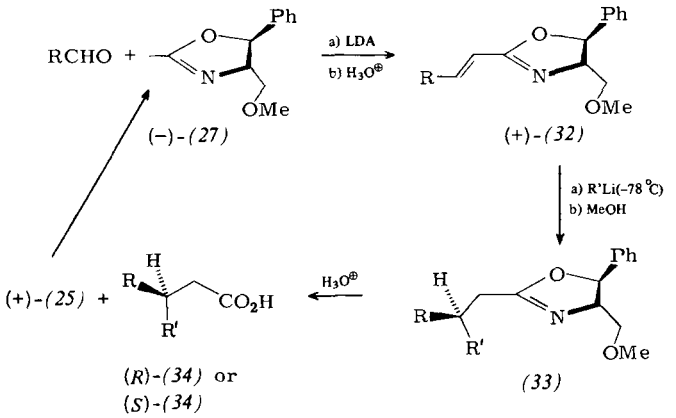

Table 3. Optically active 3-alkylalkanoic acids *(34)*.

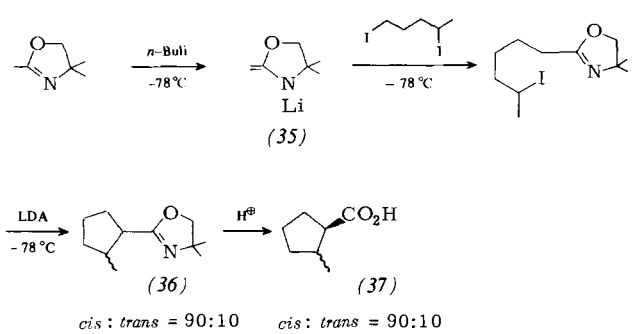
R	R' [a]	Overall yield [%]	ee [%] [b]	Config.
Me	Et	30	92	*R*
Me	*n*-Bu	38	91	*R*
Me	Ph	34	98	*S*
Et	*n*-Bu	49	(61) [c]	*R*
Et	Ph	31	92	*S*
Ph	Et	66	97	*R*
c-Hexyl	Et	75	99	*R*
c-Hexyl	*n*-Bu	76	99	*R*

[a] To date, methyllithium has not been added to (+)-*(32)*. [b] ee = enantiomeric excess. [c] The literature value is questionable and thus this may not reflect the true enantiomeric purity.

Once again, either enantiomer may be formed by appropriate choice of the R and R'[22]. The chemical yield for this process is sometimes low and this is due mainly to competing allylic proton abstraction from *(32)*. However, when R is phenyl or contains only a tertiary proton, this side reaction becomes less serious.

2.4. Cyclic Carboxylic Acids

A stereoselective synthesis of *cis*-2-methylcyclopentanecarboxylic acid *cis-(37)* was achieved by successive treatment of the lithiooxazoline *(35)* with 1,4-diiodopentane furnishing a 90:10 mixture of the oxazolines *(36)* (NMR and VPC).



Hydrolysis gave *(37)* as the major product[23] (70 % overall yield). Note that this reaction leads to the thermodynamically less stable isomer.

3. Butyrolactones

The reaction of lithiooxazolines *(35)* with a variety of epoxides *(38)* results in nucleophilic ring opening to the adducts *(39)* in good yield. Hydrolysis in aqueous acid furnished the butyrolactones *(40)* in overall yields of up to 76% (Table

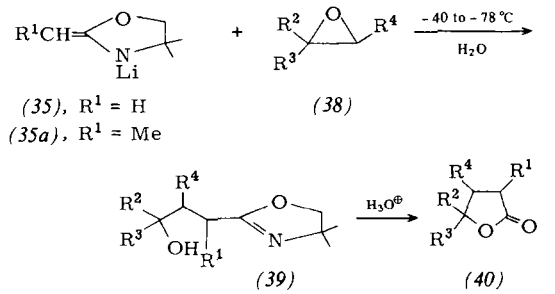


Table 4. Butyrolactones *(40)* from 2-oxazolines.

R^1	R^2	R^3	R^4	Overall yield [%]
n-Pent	H	H	H	72
n-Pent	H	Et	H	76

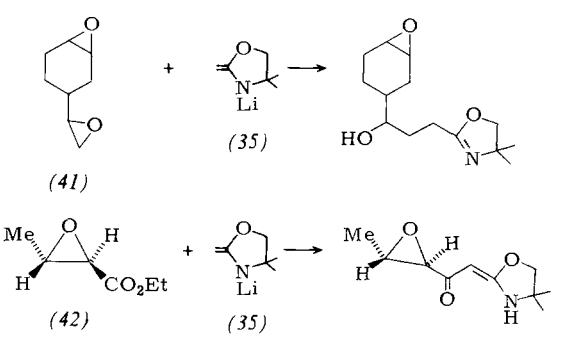
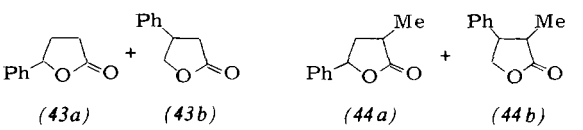
H	H	Me	Me	16

4)[24]. The efficiency of the epoxide ring opening was sensitive to substituents present, and it was observed that 1,2-disubstituted epoxides containing bulky group reacted poorly if at all under the conditions employed. Thus, cyclooctene oxide failed to react whereas compounds containing two epoxy functions could be selectively alkylated [*e.g. (41)* and *(42)*].



Styrene oxide gives a mixture (94:6) of two isomeric lactones *(43a)* and *(43b)* whereas the lithio-α-methyloxazoline *(35a)* gives a 60:40 mixture with styrene oxide [*(44a)* and *(44b)*]. (For reactions of other lithiated heterocycles with styrene oxide see ref. [25].)



3.1. Optically Active Butyrolactones

The use of a chiral oxazoline *(27)* for the asymmetric synthesis of chiral α-alkylbutyrolactones *(47)* was also demonstrated and gave the latter in 65—75 % enantiomeric excess[26] (Table 5). This can be regarded as a routine extension of the asymmetric synthesis of 2-alkyl carboxylic acids (see Section 2). Alternatively, the optical antipode of *(47)* can be prepared by reversal of the introduction of electrophiles. Since ethylene oxide reacts too slowly at −78 °C, it is necessary to use an equivalent unit and 2-iodoethyloxytrimethylsilane *(48)* was employed. Alkylation of the chiral lithiooxazoline

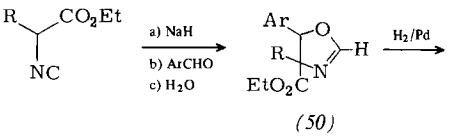
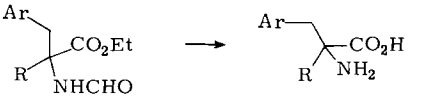
4. Amino Acids

Schöllkopf[28] has demonstrated the use of oxazolines *(50)* in an efficient synthesis of α-amino acids *(52)*. The yields



(50)



(51) *(52)*

of the *N*-formyl precursor *(51)* were very high (95—99 %) in this sequence.

5. Optically Active 2-Chloro and 2-Methoxy Carboxylic Acids

Chiral oxazolines *(53)* and *(54)* have been employed to prepare optically active 2-chloro acids *(55)* and 2-methoxy acids *(56)* in 50—65 % overall yield[29]. The percentage enantiomeric excesses for these products were not unusually high and further work is required. This method may also have potential for an efficient synthesis of these classes of compounds using achiral oxazolines.

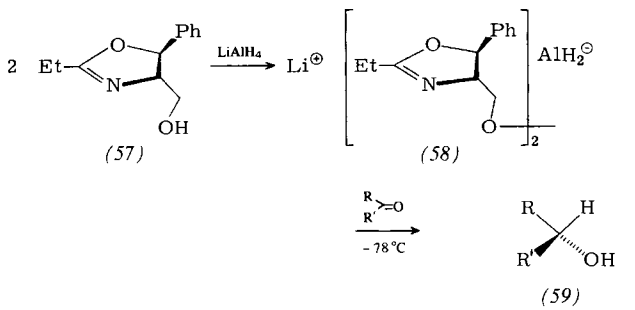
6. Optically Active Alcohols

The unusual stability of 2-oxazolines toward Grignard compounds and lithium tetrahydridoaluminate[48] was also put to use in a study of asymmetric additions to prochiral carbonyl compounds[30]. Treatment of *(−)-(57)* with 0.45 equiv. of $LiAlH_4$ gave an alkoxide *(58)* of undetermined structure and when treated with a variety of prochiral carbonyl compounds (−78 °C, THF) gave chiral alcohols of 4—65 % ee (Table 6). The chiral oxazoline was recovered for further use in 88—91 % yield. As seen from Table 6, aryl ketones gave reasonable degrees of asymmetric reduction (except α-tetralone) whereas alkyl ketones produced the corresponding alcohols in poor enantiomeric excess. Although these results, using a chiral oxazoline, are still far from perfect, they indicate that *(57)* mediates asymmetric reduction of ketones as well as a variety of other chiral systems (Table 7). To date, the asymmetric



(57) *(58)* *(59)*

reduction of ketones to chiral alcohols in an efficient and general manner still eludes synthetic methodology.

Table 6. Asymmetric reductions of ketones with $LiAlH_4 \cdot 2$ *(57)* at −78 °C in tetrahydrofuran.

reagent [to give *(62)*] and treated with various carbonyl compounds at different temperatures. The resulting alcohols *(64)* were obtained in good yield (80—90 %) but in only low enantiomeric excess (0.5—17 %). On the other hand, the methyloxazolinol *(61)* was treated with 1.7 equiv. of RMgBr [to form *(63)*] and added to carbonyl compounds under various conditions. Once again, the addition proceeded in 80—95 % yield but the optical efficiency of the reactions was only 9—25 % ee (Table 8). It is interesting to note, however, that the Grignard reaction using *(60)* gave 1-phenylethanol of opposite configuration to that utilizing *(61)*. Once again the asymmetric induction is somewhat disappointing but compares favorably with other reported attempts to prepare chiral alcohols from Grignard complexes[37, 38].

7. Aldehydes

A one-carbon homologation of Grignard reagents to aldehydes has been reported using 3,4,4-trimethyloxazolinium iodide *(66)*[39]. Addition of the Grignard reagent previously complexed with hexamethylphosphoric triamide gave the adduct *(67)* which was hydrolyzed to the aldehyde *(68)* in 50—90 % yield (Table 9). The starting oxazoline *(65)* was also transformed into its 2-deuterio derivative *(69)* and, after performing the same sequence of reactions, gave the C^1-deuterated aldehyde *(70)*. Unfortunately, alkyl Grignard reagents react poorly with *(66)*; the major side reaction is proton abstraction from C^2-H and the *N*-methyl group.

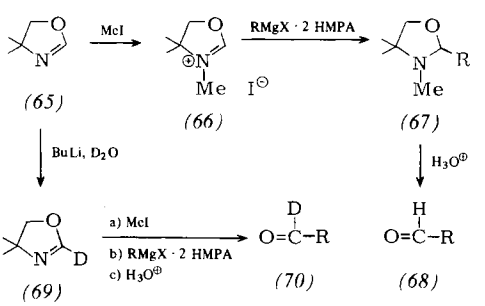

Table 9. Aldehydes *(68)* and *(70)* from Grignard addition to *N*-methyloxazolinium salts.

RMgX	Aldehyde	Yield [%]

$PhCH_2MgCl$	*(68)*, Phenylacetaldehyde	87

A novel synthesis of 4-ethoxy-2-oxazolines *(71)* has led to a facile preparation of 2-hydroxy aldehydes *(72)* in monomeric form (Table 10)[40]. In this instance, the oxazoline ring serves as a "formyl anion" equivalent *(73)*[41].

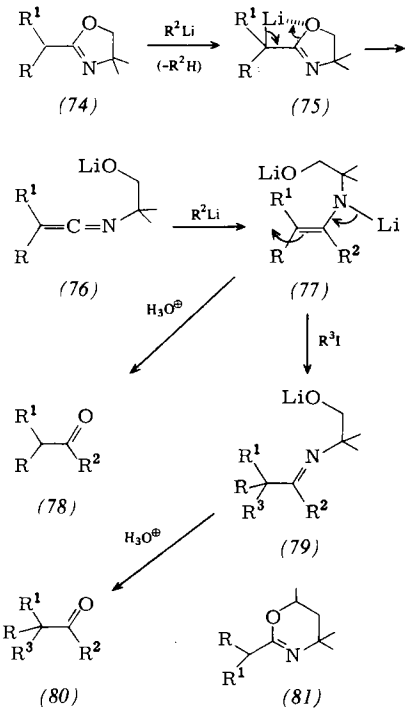
8. Ketones

The ready availability of 2-substituted oxazolines prompted *DuBois* and *Lion*[42] to develop a facile synthesis of hindered ketones based on previous studies with the dihydro-1,3-oxazine system *(81)*[43]. Advantage was taken of the reported[43] fact (since it is a lithioenamine) and undergoes alkylation once more to give *(79)*. Hydrolysis of the latter provides α-(quaternary alkyl) ketones *(80)* which may contain four different alkyl groups. A representative series of ketones is given in Table 11.



(74) *(75)* *(76)* *(77)* *(78)* *(79)* *(80)* *(81)*

Table 11. Unsymmetrical ketones from 2-oxazolines *(74)* [42] or dihydro-1,3-oxazines *(81)* [43].

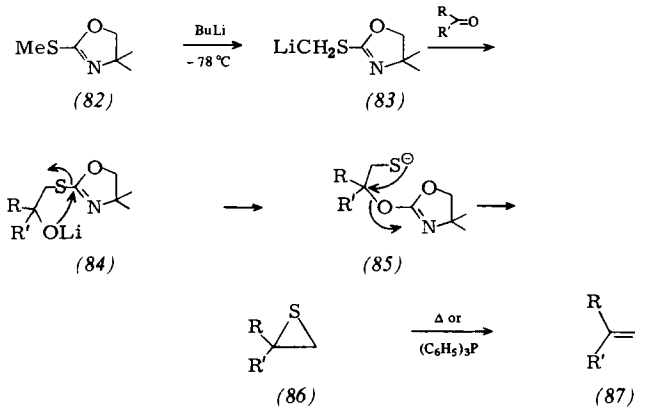
Me	*neo*-Pent	Et	Me		*(80)*	65	[43]

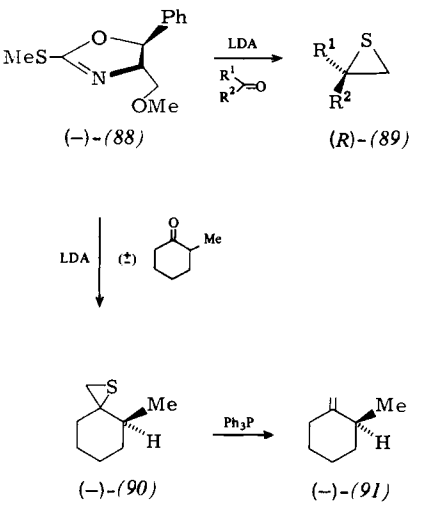
that tertiary lithium compounds of type *(75)* are unstable and readily rearrange to the ketenimines *(76)*. Addition of organolithium or Grignard reagents gave *(77)* which could be hydrolyzed to the unsymmetrical ketones *(78)* (Table 11). Alternatively, the intermediate *(77)* reacts with alkyl halides

9. Thiiranes and Olefins

A one-carbon homologation of carbonyl compounds to thiiranes *(86)* has been effected using the 2-(methylthio)oxazolines *(82)*[44]. The reaction leading to thiiranes is a "one-pot"

reaction which does not involve the isolation of intermediates *(84)* and *(85)* which can be converted directly into olefins *(87)*. Since the fragmentation-rearrangement sequence *(84)* → *(85)* → *(86)* does not take place until the reaction temperature exceeds −20 °C, it is possible to trap *(84)* with trimethylchlorosilane. Representative thiiranes and olefins are given in Table 12[46]. A similar reaction of thiazolines gave only poor yields[45].





fins were also shown to be obtainable when (±)-2-methylcyclohexanone was treated with the lithium salt of *(88)*. The resulting thiirane *(90)* ($[\alpha]_D^{25} = -0.42$) was desulfurized with triphenylphosphane to give the chiral olefin *(91)* in 30% ee.

Table 12. Thiiranes *(86)* and olefins *(87)* from 2-(methylthio)oxazolines *(82)* and carbonyl compounds.

Carbonyl cpd.	Thiirane	Yield [%]	Olefin	Yield [%]

	[a]			48
	[a]			40

[a] The thiirane decomposes spontaneously to the olefin during workup.

9.1. Optically Active Thiiranes and Olefins

Application of the thiirane synthesis to chiral derivatives *(89)* has also been successfully implemented[47]. The oxazoline *(88)* was subjected to the same conditions as the achiral derivative and gave chiral thiiranes of 19—32% ee [examples: *(R)*-*(89)*, $R^1 = H$, $R^2 = n$-hexyl, ee = 21%; $R^1 = H$, R^2 = cyclohexyl, ee = 32%; $R^1 = H$, R^2 = phenyl, ee = 19%]. Chiral ole-

10. Aromatic Carboxylic Acids

10.1. *Via* Metalated Aryloxazolines

Since oxazolines react only poorly with Grignard reagents, a series of bromobenzoic acids *(92)* was converted into their oxazoline derivatives *(93)* and then transformed into the corresponding Grignard reagents *(94)*. Treatment with a variety

of electrophiles (E) was shown to give the elaborated benzoic acids *(95)* in good overall yield (Table 13)[48]. The reaction appears to be insensitive to steric effects and *ortho*-substituted benzoic acids are formed in good yields.

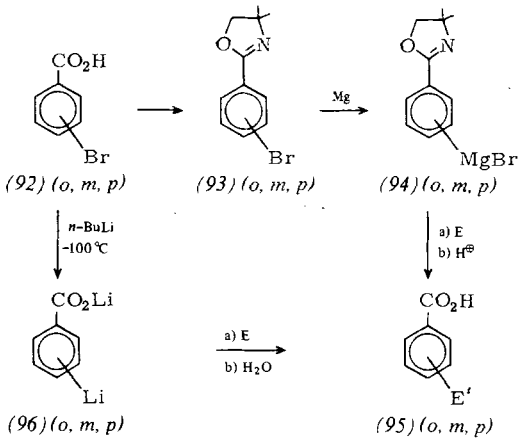

Table 13. Substituted aromatic acids *(95)* from aryloxazolines *(93)*. Yields are based on *(93)*.

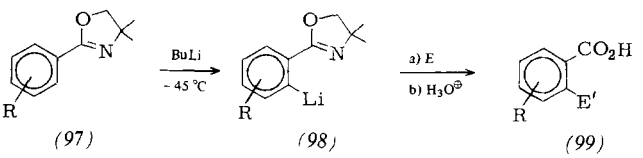
Isomer of *(93)*	Electrophile E	Product	Yield [%]
para	Benzonitrile		81
para	Allyl bromide	 [a]	68
para	Styrene oxide		83
para	Cycloheptanone		80
meta	D_2O		86
ortho	D_2O		85
ortho	Cycloheptanone		80
ortho	*p*-Anisaldehyde		78

[a] Hydrolysis of *(94)* performed in 1.5 N H_2SO_4 in ethanol.

Recently *Parham*[49] described a similar technique. After successful metalation of bromobenzoic acids with *n*-butyllithium at −100 °C to their lithio derivatives *(96)*, addition of electrophiles also gave the substituted benzoic acids. Although the yields for both reaction types were good, their generality is limited by the availability of the appropriate bromo acids.

It has been recently observed by two research groups[50, 51] that aryloxazolines *(97)* are efficiently metalated to their *ortho*-lithio derivatives *(98)* which, as expected, may also be elaborated to substituted benzoic acids *(99)*. Some representative examples are given in Table 14. This metalation is very highly



(97) (98) (99)

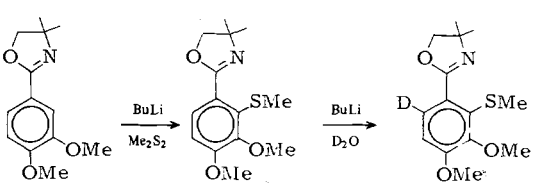
No.	*(97)*, R	E	*(99)*	Yield [%]
1	4-D	D_2O		76
2	2,4-D_2	D_2O		74
3	3,4-$(MeO)_2$	D_2O		71
4	4-Cl	MeI		71 [a]
5	4-MeO	DMF		70 [a]
6	3,4-$(MeO)_2$	NCS		90
7	3,4-$(MeO)_2$	Me_2S_2		93

[a] Yields of oxazolines after addition of electrophile. These compounds were not hydrolyzed to the acids[50], although they would be expected to give benzoic acids in good yield.

regioselective in that *ortho*-lithiation occurs only at the position adjacent to the *meta* methoxy groups (examples 3, 6, and 7). Of particular significance is the fact that treatment of *(100)* with *n*-butyllithium followed by addition of dimethyl disulfide provides *(101)* in 94 % yield whereas a second equivalent of butyllithium now may be used to metalate the 6-position and another electrophile may be added, giving *(102)*[27]. This sequence illustrates the immense versatility of lithiated aryloxazolines and should provide a welcome addition to the classical approach to aromatic substitution.

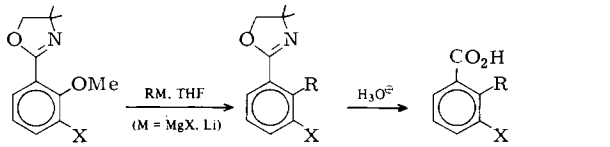


(100) (101) (102)

10.2. *Via* Methoxyaryloxazolines

The above description of the synthetic utility of aryloxazolines has also been extended to nucleophilic additions. Thus,

2-(methoxyaryl)oxazolines, when treated with an organolithium reagent (−45 °C) or a Grignard reagent (25 °C), undergo facile methoxyl displacement giving substituted aryl oxazoline



(103), X = H, MeO *(104)* *(105)*, X = H, MeO

Table 15. Nucleophilic aromatic substitution of 2-(methoxyaryl)oxazolines *(103)* to give substituted benzoic acids *(105)*.

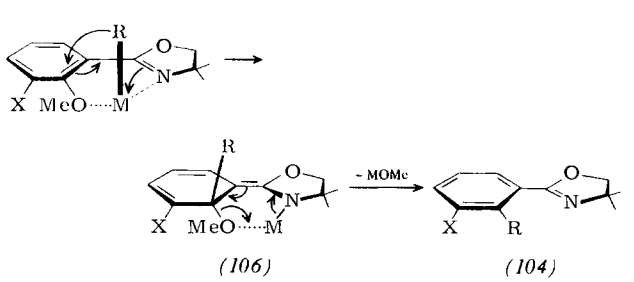
MeO	*p*-Ph—PhLi	73		48
MeO		95		78

(104) in excellent yields. Hydrolysis provides the newly substituted alkyl (or aryl) benzoic acids *(105)* (Table 15)[52]. Although only a preliminary report has appeared concerning this method, further studies should demonstrate the novel and versatile approach to aromatic compounds so difficult or tedious to prepare by conventional routes[53]. The synthesis of unsymmetrical biaryls has always been a difficult task[54, 55]

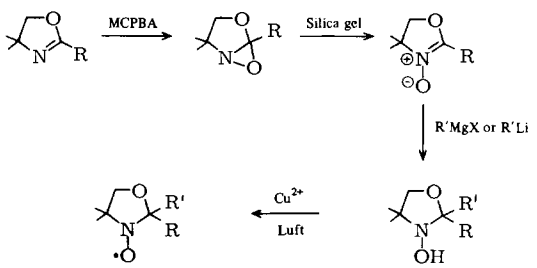


(106) *(104)*

and this new sequence may prove to be the method of choice in many instances. The nucleophilic substitution may be envisioned as occurring through a chelate-assisted addition of the organometallic to the aromatic ring furnishing the "metalated enamine" *(106)*. Elimination of metal methoxide provides the substituted aryloxazoline *(104)*.

11. Oxazolines as Spin Labels

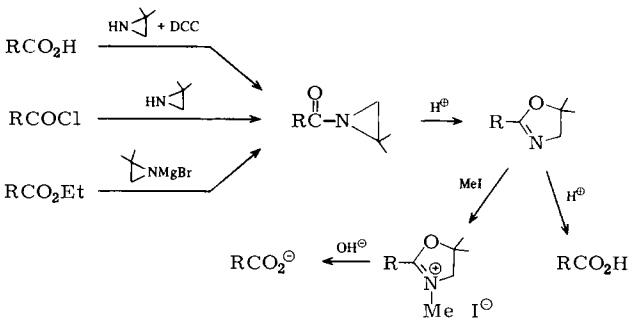
An elegant route to a series of useful biological probes was recently reported by *Keana*[56]. The process is outlined in Scheme 1. The flexibility of this approach allows the preparation of a large number of currently important compounds in yields comparable to other, less general methods.



Scheme 1. R = *n*-pentyl, R' = methyl, ethyl, or vinyl, MCPBA = *m*-chloroperbenzoic acid.

12. Oxazolines as Protecting Groups

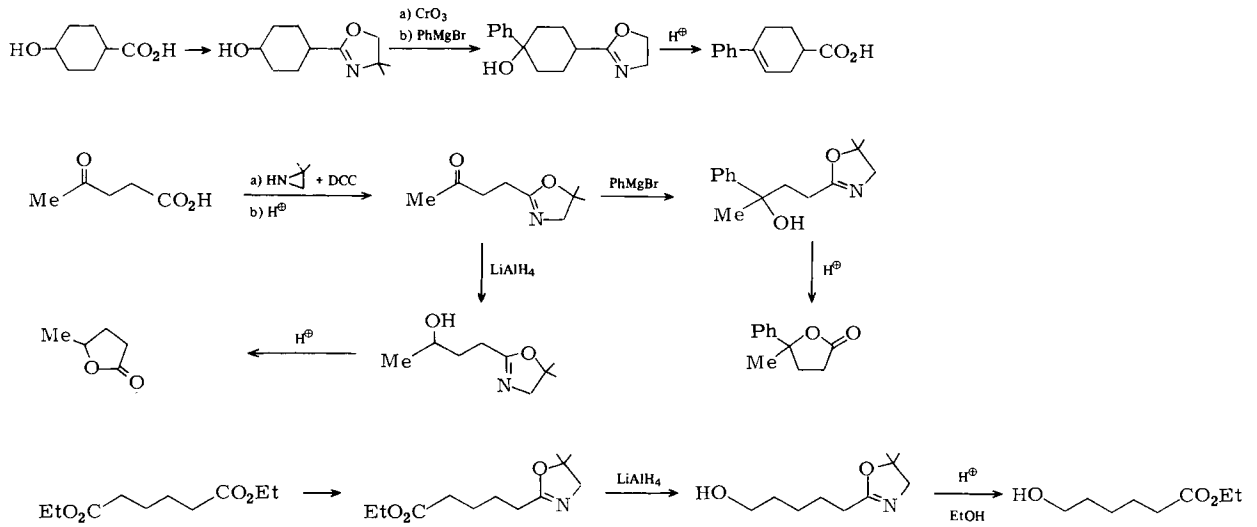
An examination of the preceding sections reveals a number of properties of the oxazoline ring that suggest it to be a valuable protecting group. It is inert to Grignard reagents,



Scheme 2. DCC = dicyclohexylcarbodiimide.

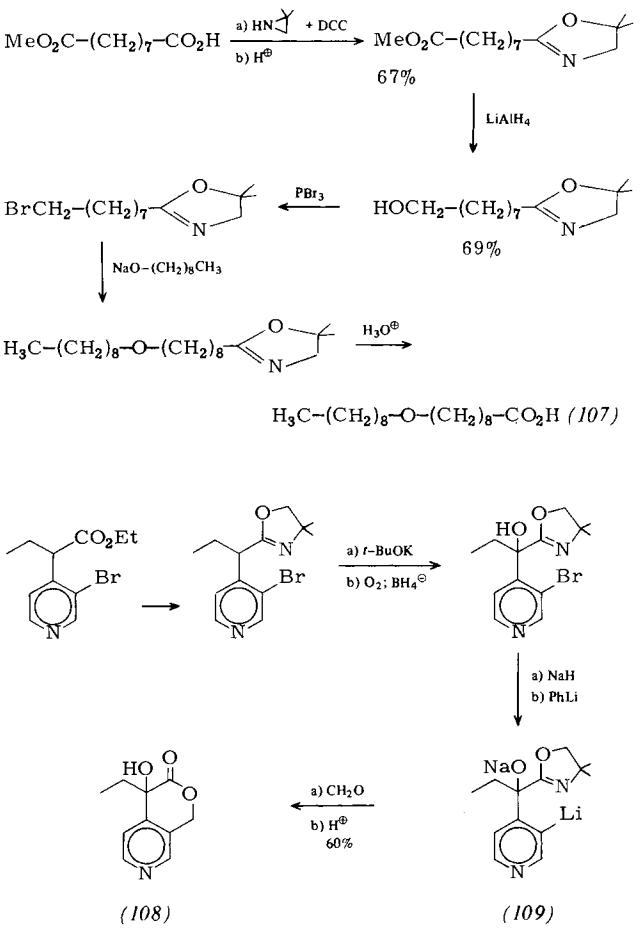
lithium tetrahydridoaluminate, organolithium reagents (when no α-protons are present on the 2-substituent), mild alkali, and mild acid. Furthermore, it may be hydrolytically removed under stronger acidic or basic conditions[48]. The remaining necessary condition for a protecting group, *i. e.* mild formation, is also fulfilled. Thus, a carboxyl function (acid, acid chloride, or ester) may be masked as the oxazoline by use of 2,2-dimethylaziridine. The various ways in which a carboxyl function may be protected and released are given in Scheme 2. Several examples of the use of the oxazoline as a protecting group are given in Scheme 3.

Recently, a structure proof for an unusual fatty acid *(107)* was performed using an oxazoline protecting group[57]. Application of the oxazoline masking group was reported in an



Scheme 3

approach to the CD-ring of the alkaloid Camptothecin *(108)*[58]. The presence of the oxazoline ring allowed the lithiopyridine derivative *(109)* to form cleanly and subsequent reaction with formaldehyde and acid produced the desired product.



13. Summary and Conclusions

The versatility of the simple heterocyclic system known as 2-oxazolines has been demonstrated by surveying the existing literature to date (October 15, 1975). It is difficult to imagine how so many years could have elapsed since the compounds were initially prepared[59] (1884!) before their synthetic usefulness was appreciated. One must therefore wonder how many other useful chemical properties are hidden in this and other well-known heterocyclic systems.

We thank the National Science Foundation, The National Institutes of Health, the ACS-Petroleum Research Fund, and Hoffmann-La Roche for their generous support of the author's (A.I.M.) research program since this work began in 1970.

Electro-Deprotection— Electrochemical Removal of Protecting Groups[**]

By V. G. Mairanovsky[*]

The reactions of electrochemical splitting may be successfully used for removal of protecting groups. Theoretical and preparative aspects of the method of electro-deprotection are discussed, and examples of its use are given. The removal often requires high potentials. The use of modified protecting groups ("inner activation") or of catalysts (electron carriers) which facilitate electron transfer against the standard potential gradient ("external activation"), can greatly increase the scope of the electrochemical method.

1. Introduction

Temporary blocking (protecting) of definite centers of a molecule which prevents them from undesirable change in the course of the reaction is a widely adopted method in many syntheses, especially in peptide and carbohydrate chemistry[2]. Removal of the protecting groups is usually carried out by more or less severe chemical treatment, frequently at higher temperatures and in the presence of acids or bases which may cause degradation or racemization.

As shown by recent investigations many protecting groups used in the synthesis of organic compounds can be removed by electrochemical reactions. Mild reaction conditions and the possibility of smooth variation in the strength of reagent (electrode) by merely changing its potential makes electrolysis a very attractive method for such conversions. In principle all reactions for the cathodic cleavage (electroreduction) of chemical bonds could be used.

[*] Dr. V. G. Mairanovsky
All-Union Institute for Vitamin Research
117246, Moscow (USSR)

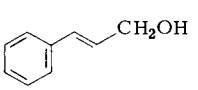
[**] Based on a report to the VIII All-Union Conference on Organic Electrochemistry (cf. also Ref. [1]).

2. Electrolysis Conditions—Influence of Solvent and pH Value

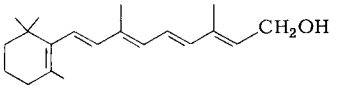
Although the first instances of cathodic bond cleavage (C—O in hydroxyketones[3], C—N in aminoketones and aminonitriles[4, 5], C—S in thiones[6]) were observed in solutions with a high content of proton donors, in many cases aprotic solvents seem to be more suitable[*]. Their high stability toward electroreduction permits working at as highly negative potentials as are required for the removal of most protecting groups. In addition, the low content of proton donors in the solution helps to decrease the rate of competitive protolytic reactions.

The possibility of competition between two chemical reactions—bond cleavage and protonation after an electron transfer—was apparently first noted in the reduction of β,γ-unsaturated alcohols: sorbyl alcohol *(1)*, cinnamyl alcohol *(2)*, and vitamin A *(3)*[8].

$H_3C-CH=CH-CH=CH-CH_2OH$ *(1)*

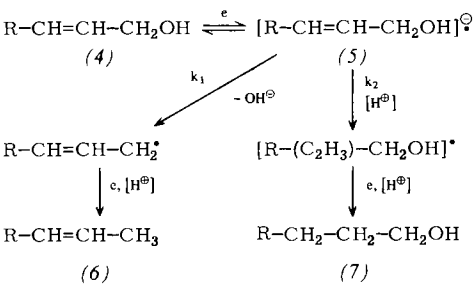


(2)



(3)

The negligible difference in half-wave potentials for the cathodic reduction of unsaturated alcohols of type *(4)* and the unsaturated hydrocarbons $R-CH=CH_2$ led us to the conclusion that the two reactions have a common intermediate product—namely, the radical anion *(5)* [Eq. (a)][8].



(a)

(6) *(7)*

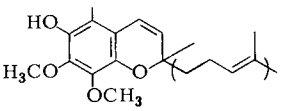
Predominant formation of the hydrocarbon *(6)* in the electrolysis of *(4)* in dimethylformamide (DMF) was ascribed to the higher rate of C—O bond cleavage in radical anion *(5)* compared to the rate of protonation under these conditions (DH = proton donor):

$$V_1 = k_1\,[(5)]$$
$$V_2 = k_2\,[(5)]\,[DH]$$

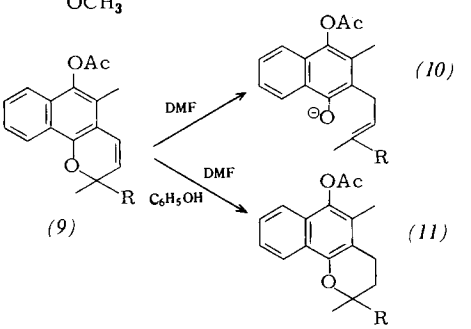
It was natural to expect that the increase of protonic activity of the solution be accompanied by an increase in V_2 and therefore that the yield of the desirable ("cleaved") product *(6)* would decrease: when $V_2 > V_1$ the formation of the saturated alcohol *(7)* should predominate.

[*] Apparently, *Given* and *Peover* were the first to observe the cleavage of a C—O bond in an aprotic medium during the electroreduction of 9,10-anthracenediol in dimethylformamide [7].

Such a mechanism, in fact, was found to be of common occurrence (see also Ref. [9]). Thus, in the electroreduction of ubichromenol *(8)* (inner ether of a substituted cinnamyl alcohol—cyclic isomer of ubiquinone) or naphthochromenol *(9)* [a similarly derived vitamin K derivative; reaction (b)] in DMF a corresponding hydroquinone derivative is formed in exceedingly large amounts, while the chromanol derivative was the main product of the electroreduction in the presence of proton donors; this could also be obtained in high yield[12].



(8)

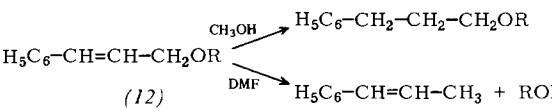


(b)

(9) *(10)* *(11)*

α,β-Unsaturated sulfones[13, 14], pyridine carbonitriles[15], benzoin and furoin[16], chloromaleic and chlorofumaric acids[17], 2,2-dichloronorbornane and its chloro-bromo analogs[18], as well as 4-(chlorostyryl)pyridines[19] and other compounds, were also reduced in this way.

A direct indication that the use of aprotic solvents is preferable in electroremoval of the protecting groups follows from a comparison of the reduction of cinnamyl ethers *(12)* in methanol[20] and in DMF: in methanol the cinnamyl moiety evidently cannot be used as a protecting group (hydrogenation of the ethylene bond is to be expected instead of C—O bond cleavage) but it can in DMF[21, 22].



(c)

(12)

It should be noted however that in some cases (for example in the removal of tosyl or benzoyl protecting groups) the use of an aprotic medium is not necessary. Protonation and cleavage reactions do not compete with each other here (see Sections 3.1 and 3.2). In contrast electroreduction of the C—N bond in α-aminoketones requires previous protonation of the nitrogen atom[23–27].

An important condition is maintaining the proper acidity (basicity) of the medium during electrolysis. For example, an increase in pH in the catholyte may not only change the direction of the reaction but also result in the undesirable removal of a protecting group, racemization *etc.* Monitoring and control of the pH during the electrolysis are beset with difficulties. Since the pH-meter reading can change by a few hundred mV after the current is switched on either the electrolysis must be interrupted during the pH-measurements[28] or a complicated arrangement must be resorted to which allows electrical isolation of the solutions in the electrolyzer and in the pH-meter cell[29].

Assuming that this effect is for the most part brought about by the drop in potential (iR) between the pH-meter electrodes we decreased the distance between them. We succeeded in almost completely eliminating the interferences, even in non-aqueous solvents, by using a special pH-meter sender. This differed from the usual arrangement in that one end of the electrolyte bridge of the reference electrode was in direct contact with the membrane of the glass electrode (Fig. 1).

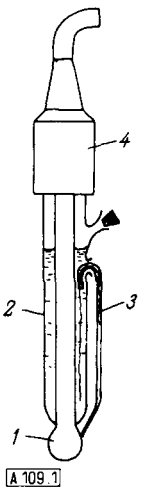


Fig. 1. Electrode sender for pH control during electrolysis. 1: glass electrode; 2: calomel electrode casing; 3: electrolytic bridge; 4: holder.

A pH-stat system[30] constructed with such a sender was used in most of our experiments on electro-deprotection; the working point mostly corresponded to the solvent (DMF) acidity. Moreover, the consumption of acid and current was recorded automatically, so we were able to determine continuously the number of electrons and protons consumed during the process. (A detailed description of the arrangement and examples of its use in studying the mechanism of electroorganic reactions is given in Ref. [30].)

Effective maintenance of the pH value necessitated vigorous stirring of the solution. Sometimes buffer components (*e.g.* phenol) were added to the solution to raise the efficiency of the system.

In other respects the conditions of electrolysis did not differ from those usually employed (mercury or lead cathode, glass frit or alundum diaphragm, potentiostat, bubbling of inert gas *etc.*). In some cases we were able to dispense with a diaphragm; it was found that performing the electrolysis under these conditions was not accompanied by large changes of pH, probably because of partial neutralization of the basic and acidic products formed at cathode and anode, respectively. To prevent alkalinization of the catholyte during electrolysis in a nonaqueous medium, *Saveant* and *Su Khac Binh*[111] have suggested carrying out the electrolysis without a diaphragm at a platinated Pt anode with hydrogen bubbling.

3. Electrochemical Removal of Protecting Groups

3.1. Removal of the Tosyl Group

In 1965 *Horner* and *Neumann*[31] discovered that the reduction of esters or amides of *p*-toluenesulfonic acid (TosOH) at a mercury cathode in methanol in the presence of tetramethylammonium chloride led to free alcohols (or amines) and toluenesulfinic acid in good yields (55—98 %). The process was carried out without control of potential; S—O and S—N bond cleavage was explained by the action of tetramethylammonium amalgam formed at the cathode. In later work[32, 33] a direct electrochemical reduction was proposed [Eqs. (d) and (e)].

$$p\text{-}H_3C\text{-}C_6H_4\text{-}SO_2\text{-}OR \xrightarrow{2\,e,\,[H^{\oplus}]} p\text{-}H_3C\text{-}C_6H_4\text{-}SO_2^{\ominus} + ROH \quad (d)$$

$$p\text{-}H_3C\text{-}C_6H_4\text{-}SO_2\text{-}NR'R'' \xrightarrow{2\,e,\,[H^{\oplus}]} p\text{-}H_3C\text{-}C_6H_4\text{-}SO_2^{\ominus} + R'R''NH \quad (e)$$

Contrary to the usual methods of tosyl cleavage the process was not complicated by side reactions and did not cause a marked decrease in optical purity, as observed in the cases of menthol, borneol and cholesterol derivatives.

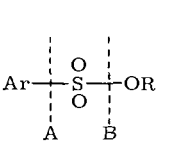
According to our investigations[34] the tosyl protecting group (Tos) in amino acids and aromatic or aliphatic amines and alcohols can also be cleaved in 70—90 % yield in an aprotic solvent (solution of $(Alkyl)_4NI$ in DMF). The ease of S—O and S—N bond cleavage decreases in the following sequence: Tos—O—Ar > Tos—O—Alkyl, Tos—NH—Ar > Tos—NH—Alkyl > Tos—NH—CH(Alkyl)—COOH[*].

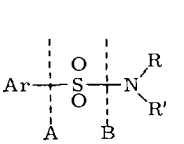
All these experiments show that it is possible to remove *O*-tosyl groups by electrolysis without affecting *N*-tosyl groups of amino acids and aliphatic amines. *Mann et al.* reported the possibility of using another aprotic solvent (acetonitrile) in the detosylation reactions[35, 36].

The formation of identical products during electrolysis in different solvents does not mean that the mechanisms of the reactions are identical. The demonstrated correlation between substituent constants and polarographic half-wave potentials in different media (DMF, dimethyl sulfoxide, acetonitrile[37] pyridine, benzonitrile[38], DMF in aqueous alcohol[39]) does not seem to be sufficiently informative.

On the contrary there are data indicating a significant influence of the experimental conditions (including the nature of the anion in the supporting electrolyte, and of the cathode material[35]) on the course of the electroreduction of arenesulfonates; the mechanism of the reaction evidently cannot be concluded with absolute certainty.

Detection of toluene during electroreduction of alkyl tosylates in acetonitrile led the authors[35] to conclude that two parallel reactions occur: the S—O bond cleavage (final products are alcohol and sulfinic acid) and C—S bond cleavage (the final products may be alcohol and toluene). The latter reaction was predominant when arenesulfonamides were reduced in aqueous, buffered solutions[40] [**].





[*] The $-E_{1/2}$ values (*vs* SCE) within the groups of substances mentioned fluctuated between 1.99 ± 0.03; 2.20 ± 0.06; 2.55 ± 0.08, 2.67 ± 0.04 V. In the case of *N*-tosyl-α-amino acids a "hydrogen" wave was observed in the polarogram, its $-E_{1/2}$ value lies between 2.1 and 2.3 V (cf. also *V. G. Mairanovsky* and *N. F. Loginova*, Bioorg. khim., in press).

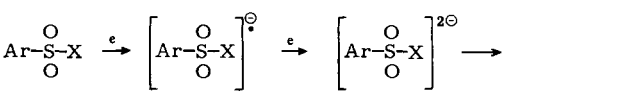
[**] There is evidence available that electroreduction of *N*-tosylamino acids in acid/alcohol medium does not lead to free amino acids [41].

Two such parallel reactions (routes A and B) can also be demonstrated in the case of homogeneous electron transfer to arenesulfonates and arenesulfonamides; thus, *e.g.* in the reduction of *N*-tosylamino acids or -peptides by Na in liquid ammonia[42], in the reduction of tosylates by naphthalenesodium[43] or in the reduction of tosylamides by arene radical anions in dimethoxyethane[44].

No cleavage of the C—S bond has been observed, however, in the electroreduction of ditosylates (Tos—O$(CH_2)_n$—O—Tos, $n=2$–6) in DMF[45] and of arenesulfonamides in acetonitrile[36]. Formation of toluene, which would indicate that the reaction followed "route A", was also not observed in our experiments on electroreduction in DMF[34].

We do not wish to dwell on the possible reasons for the above mentioned differences[*] but rather to discuss in more detail the frequently occurring case where the reaction proceeds predominantly *via* "route B"[31,34,36,45,46].

It is usually accepted that the S—X bond in arenesulfonates, arenesulfonamides and arylalkylsulfones is cleaved after the transfer of a second electron [eec mechanism Eq. (f)][**].

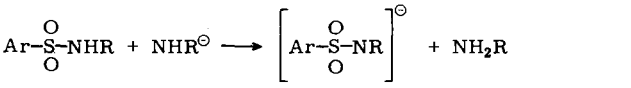


$$Ar\text{–}SO_2^{\ominus} + X^{\ominus} \qquad (f)$$

$$X^{\ominus} + DH \longrightarrow HX + D^{\ominus}$$

where X = OR [46], NR'R'' [36], Alkyl [47]
DH = proton donor (solvent or supporting electrolyte)

This equation also explains the formation of only one one-electron wave in the reduction of NH-tosylamides[36]; the decrease in wave height is attributed to deactivation of 50% of the initial compound (NH-acid) as a result of acid-base interaction with the anion $X^{\ominus}$ that is formed (here $NHR^{\ominus}$).

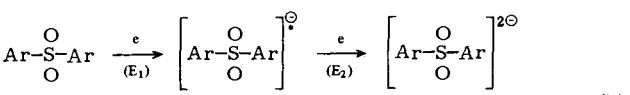


Nevertheless Eq. (f), which demands that the two electrons be transferred at exactly one and the same potential[46,47] (a common two-electron wave in a polarogram) does not seem convincing. In fact, proceeding from Eq. (f) it is difficult to explain why two separate one-electron transitions occur[46] in the case of diarylsulfones (when X = Ar) but not in the case of arylalkylsulfones (X = Alkyl). At the same time Eq. (f) predicts insufficient negative values of $E_{1/2}$ for the reduction of the radical anions $[Ar\text{—}SO_2\text{—}Alkyl]^{\ominus}$. Thus it gives $E_{1/2} = -2.36$ V[47] (or even still less negative values) *vs* SCE for $[H_5C_6\text{—}SO_2\text{—}CH_3]^{\ominus}$, while for $[H_5C_6\text{—}SO_2\text{—}C_6H_5]^{\ominus}$, which should be more easily reducible, a value of $E_{1/2} = -2.52$ V was measured[***]. The data obtained in the experiments on delayed homogeneous electron transfer against a standard potential gradient provide further evidence against Eq. (f) (see Section 4.2 and Table 1).

The following scheme of reduction [Eq. (g)] seems the more likely (ece mechanism):

$$(g)$$

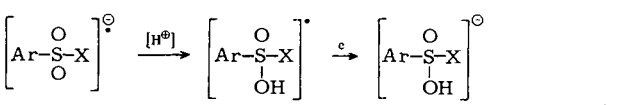
Here $E_2 > E_1$[*]; accordingly a two-electron wave is to be expected in the polarogram. The radical anion $[Ar\text{—}SO_2\text{—}X]^{\ominus}$ quickly dissociates when X = OR, NR'R'' or Alkyl; when $X = C_6H_5$ dissociation does not take place on the polarographic time scale:



$$(h)$$

In Eq. (h) $E_2 < E_1$; one can observe two one-electron waves in the polarogram.

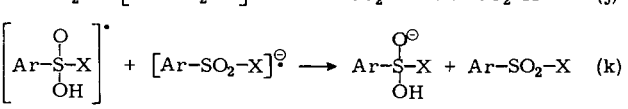
In contrast to a number of other cases [see Section 2, Eqs. (a)—(c)] electroreduction of tosyl derivatives in a protonic medium (methanol[31]) leads exclusively to formation of cleavage products, because the stepwise protonation of the radical anion $[Ar\text{—}SO_2\text{—}X]^{\ominus}$ (contrary to Eq. (a)) likewise leads to cleavage [Eq. (i)].



$$(i)$$

In addition one should take into consideration volume reactions such as (j) and (k).

$$Ar\text{–}SO_2^{\bullet} + [Ar\text{–}SO_2\text{–}X]^{\ominus} \longrightarrow Ar\text{–}SO_2^{\ominus} + Ar\text{–}SO_2\text{–}X \qquad (j)$$



$$(k)$$

The electrolytic method of removing tosyl groups has already been applied to the synthesis of *cis*- and *trans*-4-mercapto-L-prolines[48]. Sensitivity of the pyrrolidine ring in proline towards acid media and the instability of the protecting group on sulfur under conditions of catalytic hydrogenolysis limited the use of chemical methods to remove a tosyl group. Recently, Japanese authors[49,50] showed the possibility of reducing the cost of the procedure (a mercury electrode was replaced by a lead electrode and $K^{\oplus}$ and $Na^{\oplus}$ cations were used instead of tetraalkylammonium cations) and conducted the electrolysis of *N*-tosyl amino acids in aqueous methanol on a 10^1-gram scale[50]. The necessity of strictly maintaining a pH value of 11 during the experiment was especially emphasized; the authors used an automatic titrator for this purpose. When the electrolysis was performed without pH control the yield dropped by more than half and racemization took place[50].

Cox and *Ozment*[112] and *Horner* and *Meyer*[113] have demonstrated for the case of diarylsulfones a reaction mechanism which differs from the mechanism proposed by us [Eqs. (g) and (i)] in that it does not include cleavage of the radical anion.

[*] *R. Gerdil* [46] recently attempted to explain the different contributions of processes "A" and "B" by their dependence on the proton donor properties of the medium.

[**] e = electron transfer, c = chemical stage (cleavage).

[***] This $E_{1/2}$ value is taken from Ref. [46] and calculated relative to SCE.

[*] $E_2 > E_1$ means that potential E_2 is less negative than E_1.

3.2. Removal of the Benzoyl Group

Information on the polarographic activity of the amides and esters of benzoic acid (Bz—NH_2 and Bz—OR) first appeared in the late fifties[51, 52]. In connection with the problem of removing protecting groups *Horner et al.* pointed out the possibility of reducing benzoyl derivatives electrochemically[31, 33]. Electrolysis of esters and amides in 1 M tetramethylammonium bromide in methanol afforded alcohols or amines in 60—90% yield and benzyl alcohol (in approximately equivalent amounts).

$$H_5C_6{-}CO{-}NR'R'' \xrightarrow{4\,e,\,4\,[H^{\oplus}]} H_5C_6{-}CH_2OH + R'R''NH \qquad (l)$$

$$H_5C_6{-}CO{-}OR \xrightarrow{4\,e,\,4\,[H^{\oplus}]} H_5C_6{-}CH_2OH + ROH \qquad (m)$$

It has been found that benzoyl derivatives are slightly more difficult to reduce than tosyl derivatives[33][*]; Eq. (n) shows the possibility of selectively removing the tosyl protecting group in presence of the *p*-anisoyl (*p*-methoxybenzoyl) group[33].

$$p\text{-}H_3CO{-}C_6H_4{-}CO{-}NH{-}(CH_2)_4{-}\underset{\displaystyle -2.4\ V}{\underset{\uparrow}{CH}}{-}NH{-}\underset{\displaystyle -2.15\ V}{\underset{\uparrow}{Tos}} \xrightarrow[-\,Tos^{\ominus}]{2\,e,\,[H^{\oplus}]} \begin{matrix} COOH \\ | \\ p\text{-}H_3CO{-}C_6H_4{-}CO{-}NH{-}(CH_2)_4{-}CH{-}NH_2 \end{matrix} \qquad (n)$$

Horner's data for the electrochemical cleavage of C—N bonds confirms the results recently obtained in a polarographic study of benzamide and its derivatives in protonic media[53–57].

In contrast to literature data[58] we established that methyl benzoate and benzamide can also be reduced in aprotic media, the first stage being a one-electron transfer[21] leading to relatively highly stable radical anions[59]. Nevertheless, during the electrolysis of β-D-methyl-2-benzoyl-4,6-*O*-benzylidene-galactopyranoside *(13)* [see Eq. (q)] in DMF at the potential of the first wave (generation of a benzoyl radical anion), it was observed that the second benzoate wave gradually disappeared, thus indicating transformation of the radical anion in the solution. Such a behavior is typical for ece-processes. Formation of the debenzoylated carbohydrate *(14)* during the electrolysis indicates that one of the chemical stages is cleavage of a C—O bond [Eq. (o)].

$$Bz{-}OR \xrightarrow{e} [Bz{-}OR]^{\ominus\bullet} \longrightarrow RO^{\ominus} + Bz^{\bullet} \longrightarrow \cdots \qquad (o)$$

$$Bz = H_5C_6{-}CO \qquad\qquad RO^{\ominus} \xrightarrow{[H^{\oplus}]} ROH$$

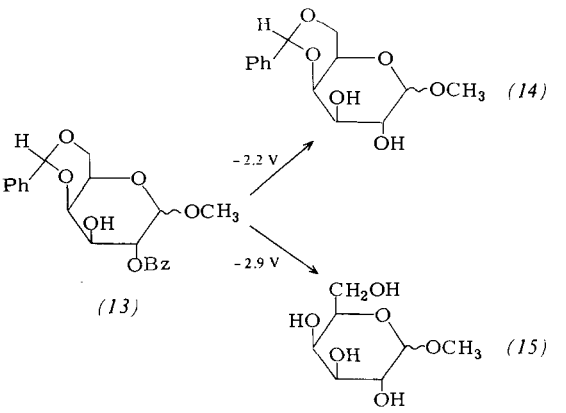
Like the tosyl radical, on electroreduction the benzoyl radical Bz$^{\bullet}$ can accept an electron either from the electrode or from the benzoate radical anion $[BzOR]^{\ominus\bullet}$; in principle the radical can still also undergo other reactions (dimerization, abstraction of H$^{\bullet}$ from the medium, *etc.*). The reactions of the benzoyl derivatives, like those of the tosyl derivatives, do not change on going over to the use of protonic media (cf. Ref. [33]). This means that the C—O bond may also cleave after the protonation [cf. Eq. (p) and Eqs. (i) and (k)].

[*] We have found that this is not the case in DMF (see Table 2).

$$[H_5C_6{-}CO{-}OR]^{\ominus\bullet} \xrightarrow{[H^{\oplus}]} \left[H_5C_6{-}C(OH)(OR)\right]^{\bullet} \xrightarrow{e} \left[H_5C_6{-}C(OH)(OR)\right]^{\ominus} \qquad (p)$$

$$\xrightarrow[-\,RO^{\ominus}]{} H_5C_6{-}CHO \xrightarrow{2e,\,2\,[H^{\oplus}]} H_5C_6{-}CH_2OH$$

Electrochemical removal of the benzoyl protecting group from the carbohydrate *(13)* in DMF proceeds in good yield and without attack at the benzylidene group[60]. If both groups are to be removed simultaneously from the carbohydrate, then a more negative potential must be chosen for the electrolysis[60].



(q)

3.3. Removal of Trityl, Benzhydryl, Benzyl, Phenyl, and Cinnamyl Groups

The trityl (triphenylmethyl), benzhydryl (diphenylmethyl), benzyl, and phenyl groups are used for the protection of hydroxyl, amino, and carboxyl groups as well as phosphoric

$$H_{31}C_{15}{-}CO{-}NH{-}CH_2{-}CH_2{-}O{-}Cin \xrightarrow{2e,\,2\,[H^{\oplus}]} H_{31}C_{15}{-}CO{-}NH{-}CH_2{-}CH_2OH + Cin{-}H \qquad (r)$$

(16)

$$H_{27}C_{13}{-}CH{=}CH{-}\underset{\displaystyle Cin{-}O}{CH}{-}\underset{\displaystyle NH{-}CO{-}C_{15}H_{31}}{CH}{-}CH_2{-}O{-}Cin \xrightarrow{4\,e,\,4\,[H^{\oplus}]} H_{27}C_{13}{-}CH{=}CH{-}\underset{\displaystyle OH}{CH}{-}\underset{\displaystyle NH{-}CO{-}C_{15}H_{31}}{CH}{-}CH_2OH + 2\ Cin{-}H \qquad (s)$$

(17)

$$H_{31}C_{15}{-}CO{-}NH{-}CH_2{-}CH_2{-}O{-}Trt \xrightarrow{2\,e,\,2\,[H^{\oplus}]} H_{31}C_{15}{-}CO{-}NH{-}CH_2{-}CH_2OH + HTrt \qquad (t)$$

(16)

$$(Bzl{-}O)_3PO \xrightarrow{2\,e,\,[H^{\oplus}]} (Bzl{-}O)_2\overset{\displaystyle O}{\overset{\|}{P}}{-}O^{\ominus} + H_5C_6{-}CH_3 \qquad (u)$$

$$(o\text{-}H_3C{-}C_6H_4{-}O)_3PO \xrightarrow{2\,e,\,[H^{\oplus}]} (o\text{-}H_3C{-}C_6H_4{-}O)_2\overset{\displaystyle O}{\overset{\|}{P}}{-}O^{\ominus} + H_5C_6{-}CH_3 \qquad (v)$$

$$H_{31}C_{15}{-}CO{-}O{-}Bzl \xrightarrow{2\,e,\,2\,[H^{\oplus}]} H_{31}C_{15}{-}COOH + H_5C_6{-}CH_3 \qquad (w)$$

(18)

$$AcNH{-}CH_2{-}CO{-}O{-}C_6H_5 \xrightarrow{2\,e,\,2\,[H^{\oplus}]} AcNH{-}CH_2{-}COOH + C_6H_6 \qquad (x)$$

(19)

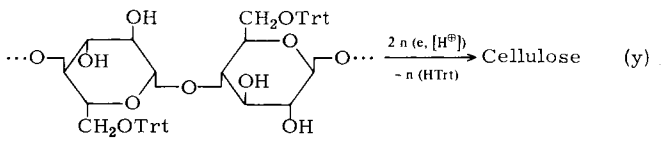
Cin = $H_5C_6{-}CH{=}CH{-}CH_2$; Bzl = $H_5C_6{-}CH_2$; Trt = $(C_6H_5)_3C$

acid esters; we suggested the cinnamyl group (Cin, see Section 4.1) be used for the blocking of the hydroxyl group[61].

According to polarographic measurements cinnamyl[21,8] and trityl ethers[62], benzyl and phenyl phosphates[63,64], as well as trityl, benzhydryl, benzyl, and phenyl esters of carboxylic acids[65,66] are electrochemically active in the supporting electrolyte (0.04 M tetraethylammonium iodide in anhydrous or 95% aqueous DMF). All of these protecting groups can be removed under the conditions of preparative electrolysis.

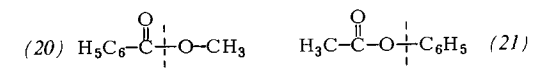
Several examples of such transformations, *e.g.* with derivatives of *N*-(2-hydroxyethyl)palmitamide *(16)*, *erythro*-*N*-palmitoylsphingosine *(17)* are given in equations (r)—(x); the yields of the products were 70—90%[61-65].

The preparation of cellulose from 6-*O*-tritylcellulose[1] can also serve as an example of electrochemical removal of the trityl protecting group [Eq. (y)]. The electrolysis was carried out with 0.1 M tetraethylammonium iodide in DMF. Free cellulose, which is very sparingly soluble in this solvent, precipitated out immediately it was formed; no decomposition products were observed. Electro-deprotection is very promising for use in the synthesis of modified polysaccharides.



(y)

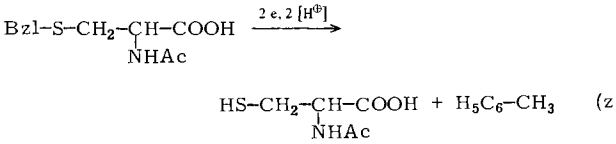
The reduction of ethers (Eqs. (r)—(t)) proceeds according to the mechanism given in Eq. (a) (see Section 2). It must be pointed out however that the residues of other unsaturated alcohols investigated in Refs. [8, 9] may be also be used as protecting groups.



(20) *(21)*

Interest attaches to the difference in behavior of the esters of aromatic and aliphatic carboxylic acids, *e.g.* isomeric methyl benzoate *(20)* and phenyl acetate *(21)*[66]. The sites of cleavage are indicated. Compound *(21)* is reduced at a potential *ca.* 0.6 V more negative than that at which *(20)* is reduced and without separation of the one-electron stage (formation of the radical anion) from the following stages. The different behavior of *(20)* and *(21)* can be rationalized on a quantum mechanical basis (position of the LUMO, degree of charge delocalization in the radical anion, *etc.*). As an estimation of the bond energies shows[66], the site of bond cleavage in *(21)* does not coincide with the least stable bond of the molecule in the ground state.

Benzyl derivatives of aliphatic alcohols are not reduced below the discharge potential of tetraethylammonium iodide in DMF (*ca.* −2.9 V *vs* SCE)[*]. At the same time we found that alkylbenzyl sulfides[68] are polarographically active due to the electrochemical cleavage of the C—S bond[**]. Thus electrolysis of *N*-acetyl-*S*-benzylcysteine results in formation of *N*-acetylcysteine in good yield (82%) [Eq. (z)].



(z)

The electrochemical method for removal of the *S*-benzyl protecting group is especially promising for preparation of complicated peptides, as chemical methods often lead to undesirable side reactions (see *e.g.* Ref. [71]).

According to *Horner*'s and *Neumann*'s findings[31], which have been confirmed by other authors[48,49], the *S*-benzyl protecting group is not removed by electroreduction in methanol. Evidently other reactions of type (t)—(y), which require high cathodic potentials, cannot be carried out in this solvent. In the reactions (r) and (s) there is the danger of possible competitive protonation of an intermediate radical anion in methanol in accordance with Eq. (a).

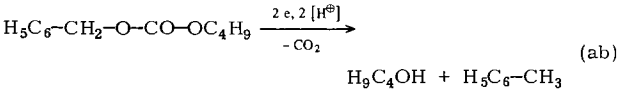
3.4. Removal of the Benzyloxycarbonyl Group

The benzyloxycarbonyl group (Z) is one of the most important groups for blocking the amino function, *e.g.* in peptide syntheses[72]. Chemical methods cannot always be used for its removal; this is so *e.g.* in the synthesis of some complicated polyfunctional compounds (*vide infra*).

It has already been reported that the *N*-benzyloxycarbonyl group cannot be removed by electrolysis in methanol solution[31,48,49]. We succeeded in removing this protecting group in good yield (70—80%) however by electroreduction in DMF at a high negative potential[73]. The reaction, which is revealed in the polarogram by a rise in current before discharge of the supporting electrolyte, can be formulated as in Eq. (aa) (CO_2 reduction is not included in the equation of the reaction).

(aa)

Electrolysis can also be used for removal of the Z protecting group from hydroxyl and thiol groups. Thus, in the reduction of Z-protected butanol equivalent amounts of butanol (70%) and toluene are obtained[68].



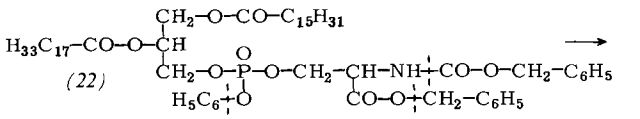
(ab)

The reduction of *S*-benzyloxycarbonylcysteine gives cysteine; the ease of removal of the protecting group increases in the series: amine < alcohol < thiol ($E_{1/2}$ of the Z-derivatives of *n*-butylamine, *n*-butanol and cysteine are −2.9, −2.7 and −2.62 V, resp., *vs* SCE). The removal of the *N*-benzyloxycarbonyl group from amino acids in DMF was not accompanied by marked racemization[1].

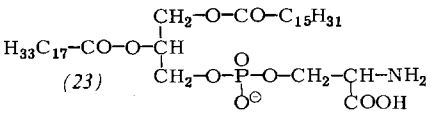
The electrochemical method for removal of the benzyloxycarbonyl group was used in the synthesis of glycerol phosphatides containing residues of unsaturated acids[64,74], which naturally do not permit removal of the protecting group by catalytic hydrogenolysis. An example is the preparation of

[*] In DMF with $(n\text{-}C_4H_9)_4N^{\oplus}ClO_4^{\ominus}$ as supporting electrolyte, alkyl benzyl ethers are first reduced shortly before discharge of the electrolyte [67]; thus *e.g.* butyl benzyl ether has a half-wave potential of *ca.* −3.1 V in this solution.

[**] The electrochemical reduction of diaryl-, arylalkyl-, dibenzyl- [69], and arylbenzhydryl sulfides [70] has also been reported.



(22) (ac)



(23)

the phosphatidylserine derivative *(23)* from compound *(22)*[74], in which all three protecting groups were removed by electroreduction at −2.9 V in the final stage of the synthesis.

3.5. Removal of the Benzylidene Group

This group, which is widely used in carbohydrate chemistry for blocking hydroxyl groups, is usually removed by acid hydrolysis or catalytic hydrogenation. We found that benzylidene derivatives of carbohydrates can be reduced polarographically in DMF at a potential at which discharge of the supporting electrolyte (0.04 M tetraethylammoniumiodide) begins. Preparative electrolysis of β-D-methyl-4,6-*O*-benzylidene-galactopyranoside *(14)* yielded the methylgalactoside *(15)* and toluene [Eq. (ad), cf. Eq. (q)].

(ad)

It is interesting to note that C—O bond cleavage during the electroremoval of protecting groups from carbohydrates occurs at rather less negative potentials than in the case of protected aliphatic alcohols[60].

4. Electro-deprotection with Activation

As can be seen from the previous Sections electrochemical removal of protecting groups requires rather high cathodic potentials (from *ca.* −2.0 to *ca.* −3.0 V *vs* SCE). It should be possible to extend the working range to less negative potentials and thus increase the scope of the method.

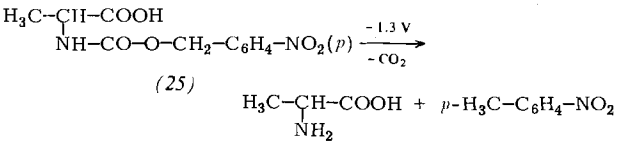
4.1. Directed Modification of Protecting Groups ("Inner Activation")

This problem could be solved in principle by increasing the electron affinity of the protecting group by introduction or elongation of a conjugated chain. If the reaction proceeds *via* formation of a relatively stable radical anion $[R—CH{=}CH—X]^{\ominus}$ [Eq. (a)], the ease of removal of the protecting group should compare to a first approximation with the ease of reduction of the corresponding unsaturated hydrocarbon. The dependence of the ease of reduction of unsaturated hydrocarbon on the parameters of the π-electron system (aromatic[75,76] or linear conjugated[77]) is described by known quantum mechanical correlations. An example is the use of the cinnamyl moiety $C_6H_5CH{=}CHCH_2$ instead of the benzyl moiety $C_6H_5CH_2$[61] for blocking the hydroxyl group: the former is removed smoothly at −2.5 V (*vs* SCE) while the latter remains secure until discharge of the supporting electrolyte (see however Footnote [*] in Section 3.3).

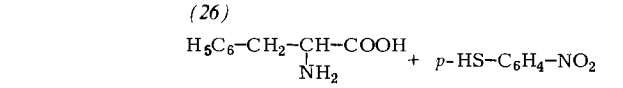
A variant of this activation method is the introduction of electron acceptors (A) at definite sites of the protecting group[78]. Taking into consideration the activating effect of a nitro group on the reductive splitting of halogen, as was observed in nitrohaloalkanes[79] and later in nitrohalobenzenes[80–85], we tested the nitro group[78,86] as activating substituent A.

The possibility of removing nitro-substituted protecting groups by reduction at the potentials of the first polarographic wave of the nitro group was first established in the case of the *p*-nitrobenzyl ester of *N*-acetylglycine *(24)*, *p*-nitrobenzyloxycarbonylalanine *(25)*, and *N*-(*o*-nitrophenylsulfenyl)-phenylalanine *(26)*. In order to avoid decomposition of the substance by attendant bases the electrolysis was carried out with pH-control at the "pH" of DMF. In all cases the protecting group could be removed and the corresponding amino acid was formed in good yield [Eqs. (ae)—(ag)][78].

(24) (ae)



(25) (af)



(26) (ag)

A similar effect was also demonstrated in the case of the *O*-benzyl group[1,67]. As in the activation by lengthening of a conjugated system (benzyl → cinnamyl, *vide supra*) introduction of a *p*-nitro substituent shifts the potential necessary for removal of the protecting group into an accessible range; in the case of the butyl derivative *(27)* $E_{1/2}$ is shifted more than 1.8 V. The yield of butanol is 60%. The electrolysis was performed at the "pH" of DMF.

(27) (ah)

In principle the mechanism of reactions (ae)—(ah) does not differ from the previously studied reduction of nitrohaloarenes[81,82]. However, our experiments on the use of cyclic voltammetry showed that the radical anions $[X—Ar—NO_2]^{\ominus}$ formed here are much more stable (rate constant of decomposition $<0.1\ s^{-1}$). The slow decrease in current during electroreduction of nitro compounds at the potentials of the first wave of the nitro group should be noted. It is evidently connected with the participation of radical anions [*e.g.* $[H_3C—C_6H_4—NO_2]$ in Eq. (ah)] in homogeneous electron transfer reactions which regenerate a neutral compound (nitrotoluene). The starting substance *(27)*, oxygen, and any other impurities present in the solution, can all serve as electron acceptors in such a catalytic conversion.

Besides the nitro group other electron accepting substituents (carbonyl, nitrile, halogen, *etc.*) can also be used as activating groups. The activating effect of a nitrile group manifests itself

by the easier removal of halogen from haloarenecarbonitriles; for instance, $E_{1/2}$ of chlorobenzene in DMF is *ca.* −2.8 V, and that of *p*-chlorobenzonitrile is −1.93 V (*vs* SCE; calculated from the data described in Ref. [87]). Similarly the *p*-cyanotoluenesulfonyl protecting group is removed at a much less negative potential than the toluenesulfonyl group[36].

The activating effect of halogens is particularly well revealed in the haloethoxy and haloethoxycarbonyl groups[88]. Examples of the ready removal of such protecting groups by electroreduction in methanol with 0.1 M $LiClO_4$ are given in Equations (ai)—(ao). The potentials are referred to SCE; the yields are 50—100 %[88].

$$H_5C_6{-}CO{-}O{-}CH_2{-}CHCl_2 \xrightarrow{-1.85\ V} H_5C_6{-}COOH \qquad (ai)$$

$$H_5C_6{-}CO{-}O{-}CH_2{-}CCl_3 \xrightarrow{-1.65\ V} H_5C_6{-}COOH \qquad (aj)$$

$$H_5C_6{-}CO{-}O{-}CH_2{-}CBr_3 \xrightarrow{-0.7\ V} H_5C_6{-}COOH \qquad (ak)$$

$$p\text{-}H_3C{-}C_6H_4{-}NH{-}CO{-}O{-}CH_2{-}CCl_3 \xrightarrow{-1.7\ V} p\text{-}H_3C{-}C_6H_4{-}NH_2 \qquad (al)$$

$$p\text{-}H_3C{-}C_6H_4{-}NH{-}CO{-}O{-}CH_2{-}CHCl_2 \xrightarrow{-2.15\ V} p\text{-}H_3C{-}C_6H_4{-}NH_2 \qquad (am)$$

$$H_5C_6{-}CH_2{-}O{-}CO{-}O{-}CH_2{-}CCl_3 \xrightarrow{-1.50\ V} H_5C_6{-}CH_2OH \qquad (an)$$

$$H_5C_6{-}CH_2{-}S{-}CO{-}O{-}CH_2{-}CCl_3 \xrightarrow{-1.50\ V} H_5C_6{-}CH_2SH \qquad (ao)$$

In these cases activator and protecting group are removed together. It must be pointed out that transformations (ai)—(ao) are similar to the electroreduction of vicinal haloethanes with different halogens[89] and of haloalcohols[90]. The homogeneous reduction of 2,2,2-trifluoroethyl ethers with naphthalenesodium proceeds in much the same way[91].

$$RO{-}CH_2{-}CF_3 \xrightarrow{C_{10}H_8^{\ominus},\ [H^{\oplus}]} ROH + H_2C{=}CF_2 + F^{\ominus} \qquad (ap)$$

One can consider that the scheme of "conjugated cleavage of halogens" proposed by *Feoktistov et al.*[89] may also be applied to the reactions (ai)—(ao), *i.e.* they may proceed *via* a concerted mechanism.

In a detailed interpretation of the reaction mechanism the formation of small amounts of dichloro from trichloro compounds [6% and 26%, reactions (aj) and (an)] observed by *Semmelhack* and *Heinsohn*[88] must be taken into consideration. The content of dichloro compounds changes slightly depending on the solvent (MeOH or DMF) and type of acid employed (acetic or trifluoroacetic).

$$\begin{array}{l} H_5C_6{-}CO{-}O^{\ominus} + H_2C{=}CCl_2 \qquad (aq) \\ \uparrow\ 2\ e,\ -Cl^{\ominus} \\ H_5C_6{-}CO{-}O{-}CH_2{-}CCl_3 \\ \downarrow\ 2\ e,\ [H^{\oplus}],\ -Cl^{\ominus} \\ H_5C_6{-}CO{-}O{-}CH_2{-}CHCl_2 \qquad (ar) \end{array}$$

These data indicate that here the cleavage of the C—O bond [Eq. (aq)] and protonation of the radical anion [Eq. (ar)] are not competitive reactions with participation of one and the same species [cf. Eq. (a)]. On the contrary, in view of the results of an investigation by *Feoktistov et al.* on the electrochemical[92–95] reduction of polyhaloethanes an alternative explanation can be suggested: whether the reaction proceeds according to Eq. (aq) or (ar) depends on the conformation of the participating species. [According to Refs. [92–94] Eq. (ar) can be ascribed to the reduction of the *gauche* conformer.]

Independently of the method (introduction of a conjugated system or electron acceptor) modification of a protecting group presents an opportunity to decrease the potential necessary for the bond cleavage. The opening of the bond should be practically irreversible and proceed rapidly in comparison to the competing deactivation of the radical anion by protonation *etc.* If these conditions are not fulfilled the protecting group may not be removed at all on account of its increased electron-acceptor properties. Thus the *p*- and *o*-nitrotoluenesulfonyl derivatives of glycine and *n*-butanol could not be split electrochemically on the preparative scale with pH control (at "pH" of DMF)[1]. As comparative experiments have shown (storage of the substance in basic DMF solution) the formation of small amounts of butanol (up to 20 %, GLC) during the electrolysis of butyl *p*-nitrotoluenesulfonate without pH-control is connected with the action of strong bases formed in the cathodic space during the electrolysis.

The electroreduction of *p*-nitrobenzenesulfonamides in DMF has recently been studied in detail by *Asirvatham* and *Hawley*[96]. S—N bond cleavage was found not to occur either, and the authors suggested that removal of a hydrogen atom takes place in the case of primary and secondary amides:

$$p\text{-}O_2N{-}C_6H_4{-}SO_2{-}NHR \overset{e}{\rightleftharpoons} \left[p\text{-}O_2N{-}C_6H_4{-}SO_2{-}NHR\right]^{\ominus\bullet} \xrightarrow[-H^{\bullet}]{} p\text{-}O_2N{-}C_6H_4{-}SO_2{-}NR^{\ominus} \quad \text{etc.} \qquad (as)$$

The polarographic activity of trifluoroacetates could be ascribed to cleavage of a C—O bond with formation of trifluoroethanol and free alcohol in a four-electron process[86]; however, preparative electrolysis at the "pH" of DMF showed it not to be connected with the removal of a trifluoroacetyl protecting group but rather with partial defluorination[1,97].

$$F_3C{-}CO{-}O{-}C_4H_9 \xrightarrow{4\ e,\ 2\ [H^{\oplus}]} H_2FC{-}CO{-}O{-}C_4H_9 + 2\ F^{\ominus} \qquad (at)$$

Thus the introduction of a substituent A which facilitates electron transfer to a molecule can simultaneously lower the rate of bond cleavage since the negative charge no longer prefers this bond. Another reaction takes place instead of removal of the protecting group.

Utley et al. have demonstrated the cathodic cleavage of the methoxycarbonyl-activated *O*-benzyl protecting group[114]. An ESR study of the structure and kinetics of decomposition of radical anions in reactions (ae)–(ah) and (as) is reported in Ref. [115]. The rate constants for bond cleavage are decreased by introduction of the electron-acceptor substituent A. A quantum mechanical description of the effect is proposed in Ref. [116].

4.2. Use of Catalysts as Electron Carriers ("External Activation")

The role of an "inner activator" *i.e.* of an electron-acceptor substituent is first of all that it facilitates transfer of electrons to the system. The ensuing process may be regarded as a very fast (up to 10^{-12}—10^{-14} s) intramolecular transfer (redistribution) of charge, which provides the prerequisite high electron density on the R—XA bond prior to its cleavage.

In analogy to the above case (see Section 4.1) we investigated the feasibility of homogeneous electron transfer from an external activator A. This must have a high electron affinity for the substrate S but not form any chemical compound with it. Obviously the rate of charge transfer should decrease significantly, for it now depends on the difference of the standard potentials $\Delta E_0 = E_0^S - E_0^A$ of substrate S and activator A and its upper limit is diffusion controlled. If the bond cleavage is irreversible and both the electron transfer and the bond cleavage are fast compared to the competitive transformations of the radical anion $A^{\ominus\bullet}$, the reaction is both thermodynamically and kinetically favorable (cf. Refs. [1, 98]).

We carried out electro-deprotection of the substrate (S), *N*-(*p*-nitrobenzyloxycarbonyl)alanine *(25)*, using 4-nitrobiphenyl in the form of its radical anion $A^{\ominus\bullet}$ as activator. The transformation, which proceeds analogously to Eq. (af), was performed at $\Delta E_0 = -0.1$ V ($E_{1/2}^S = -1.14$ V, $E_{1/2}^A = -1.05$ V) in the absence of current and obtained the free amino acid in quantitative yield[1]. When the current was switched on (*i.e.* with continuous generation of $A^{\ominus\bullet}$) a catalytic current should appear similarly to that observed in the systems quinone/hydroquinone/H_2/Pd, nitro compound/camphor/$IO_4^{\ominus}$ *etc.* (see review given in Ref. [99]).

This phenomenon predicted by us in 1973[1], has in the meantime been confirmed by three groups of investigators working independently[100-102, 98, 67]; it evidently also occurred[98] in the experiments described by *Margel* and *Levy*[103][*].

$$A + e \rightleftharpoons A^{\ominus\bullet} \qquad \text{(au)}$$

$$A^{\ominus\bullet} + S \overset{k_3, K_3}{\rightleftharpoons} S^{\ominus\bullet} + A \qquad \text{(av)}$$

$$S^{\ominus\bullet} \overset{k_4, K_4}{\rightleftharpoons} P^{\ominus} + R^{\bullet} \qquad \text{(aw)}$$

$$A^{\ominus\bullet} + R^{\bullet} \overset{k_5, K_5}{\rightleftharpoons} R^{\ominus} + A \qquad \text{(ax)}$$

$$R^{\ominus} + DH \longrightarrow RH + D^{\ominus} \qquad \text{(ay)}$$

$$A^{\ominus\bullet} \xrightarrow{k_6} I \qquad \text{(az)}$$

The transformation of substrate S can be described by Equations (au)—(az)[1, 98, 100, 101].

A and $A^{\ominus\bullet}$ are, respectively, the electroneutral and radical anion forms of the activator, $P^{\ominus}$ and RH are products, DH is a proton donor (solvent, electrolyte, *etc.*), and I the product of a competitive deactivation of $A^{\ominus\bullet}$. When

$$\Delta E_0 = E_0^S - E_0^A = \frac{RT}{F} \ln K_3 < 0$$

the equilibrium constant K_3 is small, and the value K_4 (thermodynamic factor) must be high; besides the kinetic condition $k_3 > k_6$ must be fulfilled.

In principle the catalytic current allows determination of the rate constant of the rate-determining step—this is either the cleavage of the bond (k_4) or the electron transfer against the standard potential gradient (k_3). *Koutecky*'s solution[104], for which a convenient analytical function was recently developed[105], can be used to find k_3 (if k_3 is large, but very much smaller than k_4). *Britton* and *Fry* recently solved the problem in an analogous case (one irreversible step of type (av)+(aw), $k_3 \ll k_4$) using the method of chronoamperometry with stepwise change of potential[106]. We recently discussed the whole process (au)—(az) for arbitrary ratios of k_3 and k_4 and various values of K_3[107]. The solution for average polarographic currents was obtained with the help of a computer which provided plots of $(\bar{i}_k/\bar{i}_d) = F(k_3, k_4, K_3)$ ($\bar{i}_k$ = kinetic limiting current, $\bar{i}_d$ = diffusion current). We shall not go into an analysis of the individual results[107] here, but it must be noted that the solutions quoted previously[104, 105] are not suitable for the determination of k_3 and k_4 when these constants are of comparable order of magnitude.

Not only the cleavage of a bond [Eq. (aw)] can function as a fast irreversible step but also protonation, for instance in the activated hydrogenation of a difficultly reducible conjugated hydrocarbon S with the help of the easily reducible activator A [Eqs. (ba)—(bf)][98]:

$$A + e \rightleftharpoons A^{\ominus\bullet} \qquad \text{(ba)}$$

$$A^{\ominus\bullet} + S \rightleftharpoons S^{\ominus\bullet} + A \qquad \text{(bb)}$$

$$S^{\ominus\bullet} + DH \rightleftharpoons SH^{\bullet} + D^{\ominus} \qquad \text{(bc)}$$

$$A^{\ominus\bullet} + SH^{\bullet} \rightleftharpoons SH^{\ominus} + A \qquad \text{(bd)}$$

$$SH^{\ominus} + DH \longrightarrow SH_2 + D^{\ominus} \qquad \text{(be)}$$

$$A^{\ominus\bullet} + DH \longrightarrow I + D^{\ominus} \qquad \text{(bf)}$$

Several different aspects of such reactions have been discussed in the literature[98, 100-102].

Data on homogeneous catalytic electron transfer against the standard potential gradient for the removal of different protecting groups are listed in Table 1. Electro-deprotection is carried out at the reduction potentials of the activator; the required potential can be lowered (by more than 0.6 V) and the process essentially facilitated.

$$n\text{-}H_9C_4\text{–}O\text{–}CH_2\text{–}C_6H_5 + H_5C_6\text{–}C_6H_5 \xrightarrow[-2.65\ V]{2e,\,2\,[H^{\oplus}]} n\text{-}C_4H_9OH + H_3C\text{–}C_6H_5 + H_5C_6\text{–}C_6H_5 \qquad \text{(bg)}$$

The use of inner activation by introduction of a conjugated double bond was discussed in Section 4.1 for the removal of the *O*-benzyl protecting group. Table 1, No. 11, demonstrates the use of external activators for this purpose. The transformation [Eq. (bg)] proceeds according to first order kinetics and gives butanol and toluene in good yields (100% and 90% resp.)[67]. Thus one can succeed in carrying out electron transfer in a potential range lying beyond the discharge potential of the supporting electrolyte. Another example is illustrated in Fig. 2.

The possibility is revealed (see examples 6 and 7 in Table 1) of using the "chemical factor", *i.e.* the different stability of the radical anions $S^{\ominus\bullet}$ [that is the difference between constants k_4, Eq. (aw)] for the selective cleavage of protecting groups in addition to the electrochemical factor (the difference in reduction potentials). In fact, despite the higher half-wave potential (Table 2) the *N*-tosyl protecting group (−2.6 V) is

[*] It is possible that *Sease* and *Reed* considered an analogous process in 1970 (see reference to the author's report of *Reed*'s thesis in Ref. [100]). Unfortunately the works [101] and [102], were first accessible to us after contributions [98] and [67] had already been submitted for publication.

Table 1. Electron transfer reactions against potential gradient for the removal of protecting groups (in DMF, for conditions see original literature). $Z(NO_2)$ = *p*-nitrobenzyloxycarbonyl, Z = benzyloxycarbonyl, Tos = toluenesulfonyl, Bzl = benzyl.

2,2,2-Tribromethoxy				0.7 [d]	

[a] In methanol.
[b] No removal of protecting group up to the discharge potential of the supporting electrolyte.
[c] Reduction of molecule without removal of protecting group.
[d] In methanol. The given potential is that at which the electroreduction was carried out.

removed *earlier* in DMF than the *O*-benzoyl group (−2.3 V), since it is cleaved faster from the corresponding radical anion $S^{\ominus}$. It is interesting that *Horner* and *Singer* observed the same order in deprotection during electroreductions performed in methanol[33] (*N*-tosyl, $E_{1/2} = -2.2$ V; *N*-benzoyl, $E_{1/2} = -2.3$ V), but in this case the electrochemical factor was apparently determining [cf. Eq. (n)].

The directed modification of protecting groups and utilization of activators (electron carriers) permit variation of the potential at which electro-deprotection takes place. This opens new prospects for the use of electrochemical methods in preparative organic chemistry.

Different aspects of electron transfer reactions are touched upon in Refs. [117–119].

5. Conclusion

A great number of protecting groups (see Table 2) can be removed by electrolysis. The essential advantages of the method are:

a) mild conditions in the electrochemical cleavage;
b) high degree of selectivity; the required potential can be shifted into a favorable range by "inner" or "external" activation;
c) uniform experimental technique in contrast to chemical methods, *i.e.* the technique is the same for all protecting groups to be removed. It permits removal of several different protecting groups at one and the same time during the last stage of the synthesis (compare Section 3.4) and furnishes the prerequisites for working out standard methods.

The range of potential for removal of various protecting groups extends from *ca.* −1 to *ca.* −3 V (*vs* SCE). A general regularity may be noted—the removal of one and the same protecting group (Y) is facilitated along the series N—Y < O—Y < S—Y < C(O)O—Y, *i.e.* according to increasing nucleophilicity of the blocking group. By "external activation" the potential of deprotection may be essentially decreased (by at least 0.5—0.7 V) compared to the potentials listed in Table 2.

The protecting groups listed in Table 2 are universal. An example of a special protecting group is the nitro group sug-

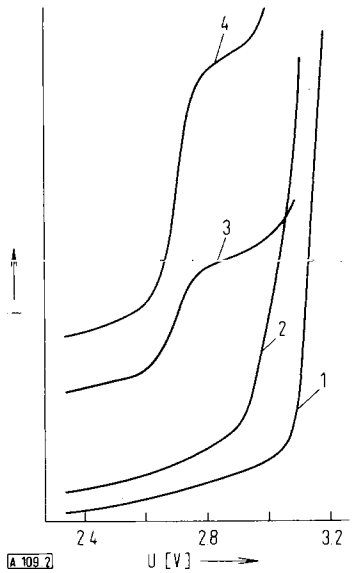

Fig. 2. Catalytic polarographic current in a system with electron transfer against potential gradient beyond the supporting electrolyte discharge range. 1: 0.04 M $(C_4H_9)_4N^{\oplus}ClO_4^{\ominus}$ in DMF; 2: 1.6×10^{-3} M benzyl-*N*-butylcarbamate (*N*-benzyloxycarbonyl-*n*-butylamine) (S); 3: 4.1×10^{-4} M biphenyl (A); 4: mixture of A and S (schematic); see Table 1, No. 3. Potentials referred to SCE.

gested here for blocking the guanidine residue of arginine[108] and which can likewise be removed by electroreduction[109]. The possibility of using not only cathodic but also anodic reactions for the removal of protecting groups can so far be illustrated by only a few examples: The electrooxidative cleavage of benzyl and benzhydryl ethers[110].

$$H_5C_6{-}CH_2{-}O{-}C_8H_{17} \xrightarrow[-2e,\,-2\,H^{\oplus},\,+H_2O]{Pt,\,CH_3CN} H_{17}C_8OH + H_5C_6{-}CHO \qquad \text{(bh)}$$

$$(H_5C_6)_2CH{-}O{-}C_{12}H_{25} \xrightarrow[-2\,e,\,-2\,H^{\oplus},\,+H_2O]{Pt,\,CH_3CN} H_{25}C_{12}OH + (C_6H_5)_2CO \qquad \text{(bi)}$$

The yields of free alcohols are 60—70 %.

Weinreb et al. have discussed the anodic cleavage of the benzyl protecting group[120].

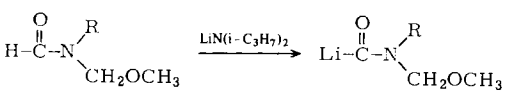
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

α-Hydroxycarboxamides from *N,N*-Bis(methoxymethyl)carbamoyllithium and Carbonyl Compounds

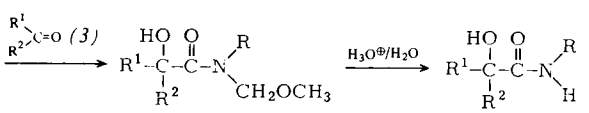
By *Ulrich Schöllkopf* and *Heiko Beckhaus*[*]

α-Hydroxycarboxamides of type *(6)* are versatile intermediates in preparative chemistry. Hitherto, the method used for their synthesis from carbonyl compounds *(3)* involved initial conversion of the latter to cyanohydrins; this method, however, failed in many cases owing to the instability of the cyanohydrin. We have now found an alternative method which also permits synthesis of the *N*-alkyl derivatives *(7)*.

When the *N*-methoxymethylformamides *(1a)* and *(1b)* protected at the amino group[1] are used as starting material, reaction with lithium diisopropylamide affords the *N*-methoxymethylcarbamoyl derivatives *(2a)* and *(2b)*, which are converted *in situ* with the carbonyl compound *(3)* into the *N*-substituted α-hydroxycarboxamides *(4)* and *(5)*, respectively[2]. Compounds *(4)* and *(5)* can be readily converted into the carboxamides *(6)* and *(7)*, respectively, by acid hydrolysis[1].



(1a), R = CH_2OCH_3 *(2a)*, R = CH_2OCH_3
(1b), R = CH_3 *(2b)*, R = CH_3



(4), R = CH_2OCH_3 *(6)*, R = H
(5), R = CH_3 *(7)*, R = CH_3

	R^1	R^2	*(4)* Yield [%]	*(4)* B.p. [°C/torr] M.p. [°C]	*(5)* Yield [%]	*(5)* B.p. [°C/torr] M.p. [°C]
a	H	C_6H_5	74	142—143/0.05	76	49
b	—$(CH_2)_5$—		44	119/0.01	39	107/0.01
c	C_6H_5	C_6H_5	88	85—86	85	110—112
d	H	C_6H_5—CH=CH	—	—	40	62—63

N,N-Bis(methoxymethyl)formamide (1a)

A solution of freshly distilled formamide (22.5 g, 0.5 mol) in tetrahydrofuran (50 ml) is added dropwise to a stirred suspension of sodium hydride (24 g, 1 mol) in tetrahydrofuran (400 ml) such that the temperature of the reaction mixture never exceeds 30 °C. After 10 minutes' stirring at room temperature chloromethyl methyl ether (80.5 g, 1 mol) is added dropwise (also at room temperature) over a period of 30 min to the mixture, which is then stirred for a further 12 hours, filtered (under nitrogen), and the solvent removed by distillation in a rotary evaporator at 14 torr (bath temperature 50 °C). 43.3 g (65% yield) of *(1a)* (b.p. 58—59 °C/0.1 torr; 20 cm-Vigreux column) is obtained. The product is sometimes contaminated with a little formaldehyde. ^{1}H-NMR (CCl_4): τ = 1.72 (s, CHO), 5.33 (d, N—CH_2—O, coalescence temperature 130 °C), 6.78 (s, CH_3).—*(1b)* was prepared in the same way as *(1a)* with the exception that 59 g (1 mol) of *N*-methylformamide was used; yield 80.5 g (78 %), b.p. 73—75 °C/15 torr.

N,N-Bis(methoxymethyl)-1-hydroxycyclohexanecarboxamide (4b)

A solution of lithium diisopropylamide (40 mmol) [prepared from 1.6 N butyllithium (25 ml) and diisopropylamine (4.04 g) in tetrahydrofuran (40 ml) at 0 °C] previously cooled to −60 °C is added dropwise at −75 °C over a period of 20 min to a stirred solution of *(1a)* (5.3 g, 40 mmol) and cyclohexanone (3.93 g, 40 mmol) in tetrahydrofuran (100 ml). After 3 h the mixture is allowed to warm to room temperature, poured into 200 ml of saturated ammonium chloride solution, and the organic phase separated off and dried over sodium sulfate. The dried solution is then distilled in a rotary evaporator at 14 torr (bath temperature 60 °C). The residue of crude *(4b)* is purified chromatographically on *ca.* 500 g silica gel (Merck; 0.2—0.5 mm) with ether as eluent. 4.1 g (44 %) of *(4b)* is obtained. ^{1}H-NMR ($CDCl_3$): τ = 5.05 (s, N—CH_2—O), 6.37 (s, OH replaceable by D with D_2O, 6.7 (s, O—CH_3), 8.0—8.8 (m, —CH_2—).

N-Methylmandelic acid amide (7a) from (5a)

Concentrated hydrochloric acid (1 g) is added dropwise to a solution of *(5a)* (3 g) in ethanol (50 ml). After 12 hours' stirring at room temperature the reaction solution is concentrated in a rotary evaporator (bath temperature 60 °C); the residue is taken up in ether and washed with sodium bicarbonate solution. The washed ethereal phase is finally worked up in the usual way *(vida supra)*. *(7a)* (m.p. 97—98 °C) is obtained in 92 % yield (2.18 g).

Continuous Electrocatalytic Synthesis of Phenol from Benzene and Hydrogen Peroxide[1]

By *Eberhard Steckhan* and *Josef Wellmann*[*]

Despite the well established methods of synthesizing phenol there has long been interest in the realization of a practicable synthesis of phenol from benzene and hydrogen peroxide.

All previous results however have been unsatisfactory, since the reaction usually affords only poor yields and is not very selective. This applies also for the reaction with iron(II) as catalyst[2]. Under the usual reaction conditions mixtures of phenol, hydroquinone, pyrocatechol, as well as higher oxidation products and biphenyl are formed; the yields of phenol are less than 10% based on consumed hydrogen peroxide[2, 3]. Recent analytical investigations[4], on the other hand, show that phenol formation is preferred if the following conditions are maintained: a large excess of benzene and iron(III) or copper(II) salts, a hydrogen peroxide concentration not greatly exceeding the concentration of iron(II), pH *ca.* 1, *T* *ca.* 25 °C.

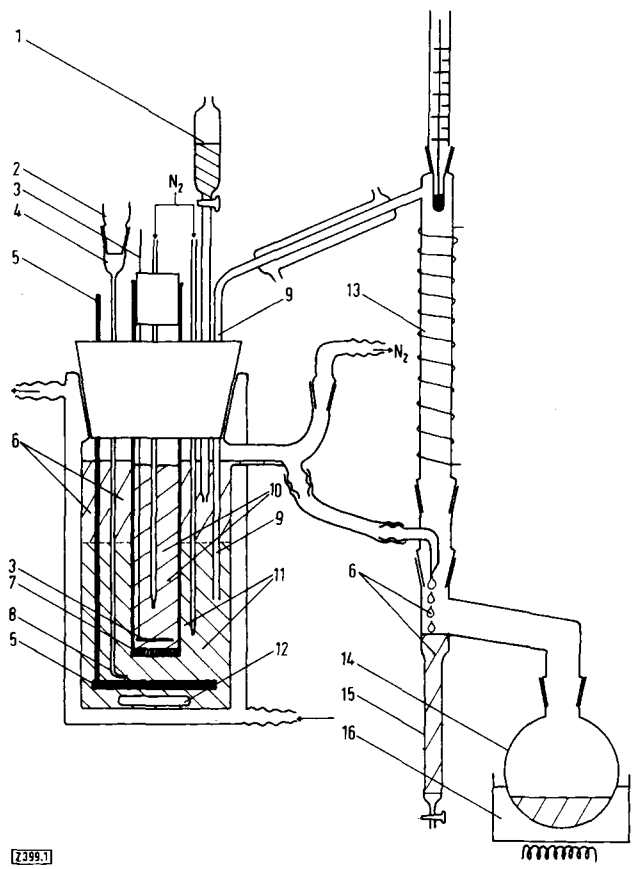

Fig. 1. Glass cell for electrolytic synthesis of phenol. 1, dropping funnel with 30% H_2O_2; 2, reference electrode; 3, anode (platinum); 4, salt bridge; 5, cathode (graphite); 6, benzene phase enriched with phenol; 7, glass cylinder with frit as anode compartment; 8, luggin capillary; 9, benzene inlet tube; 10, anolyte; 11, catholyte: aqueous phase with suspended benzene; 12, magnetic stirrer; 13, heated column for distillation of benzene; 14, receiver for enriched benzene/phenol mixture; 15, water separator; 16, thermostatic heating bath.

Orléans-Ring 23, 4400 Münster (Germany)

These optimum conditions must be maintained throughout the whole duration of the reaction. This can be achieved with the "electrocatalytic" method, for it permits maintenance of a constant iron(II) concentration by continuous replenishment of the iron(II) consumed in side-reactions at the electrode. The ratio of iron(II) to iron(III) and copper(II) thus remains unchanged. Furthermore, the consumption and replacement of hydrogen peroxide can be controlled by monitoring the cathodic working potential. Of great importance is the continuous extraction of oxidation-labile phenol[5] and other organic products from the aqueous catalyst phase into the supernatant benzene. The two-phase system also allows continuous operation since the benzene can be recycled and readily separated from the products.

Procedure

A solution of iron(III) sulfate (3.5 mmol), copper(II) sulfate (7 mmol), and 60% perchloric acid (1.17 g) in water (70 ml) was transferred to the cathode compartment of a glass cell (beaker) (see Fig. 1) and covered with a layer of benzene. The anode compartment contained an aqueous solution 0.1 M w.r.t. perchloric acid and 0.2 M w.r.t. sodium perchlorate. After preliminary electrolytic generation of 2 mmol iron(II) a constant current of 50 mA was maintained and 30% hydrogen peroxide was added dropwise with stirring and passage of nitrogen at 25 °C whenever the working potential of the cathode reached its original value. The overflow of phenol-enriched benzene was continuously distilled and the benzene recycled into the reaction vessel. After addition of 20.4 mmol H_2O_2 and consumption of 7 mF, the products were determined quantitatively on a Tenax column against tetradecane as internal standard. 13.0 mmol of phenol and 0.1 mmol of biphenyl were obtained, *i.e.* 64% and 0.24%, respectively, based on H_2O_2.

Synthesis of α,β-Dehydro Amino Acid Esters and *N*-*tert*-Butoxycarbonyl α,β-Dehydro Amino Acids[**]

By *Hans Poisel* and *Ulrich Schmidt*[*]

α,β-Dehydro amino acids have been claiming increasing attention in the past few years as components of antibiotic peptides and intermediates in biosyntheses[2]. We recently described the transformation of amino acids into *N*-acyl dehydro amino acid esters and amides by *N*-chlorination and dehydrochlorination[3]. By using *N*-*tert*-butoxycarbonyl amino (Boc-amino) acid derivatives as starting compounds this reaction sequence can also be employed for the synthesis of the *free* dehydroamino acid esters and Boc-dehydro amino

[*] Prof. Dr. U. Schmidt and Dr. H. Poisel

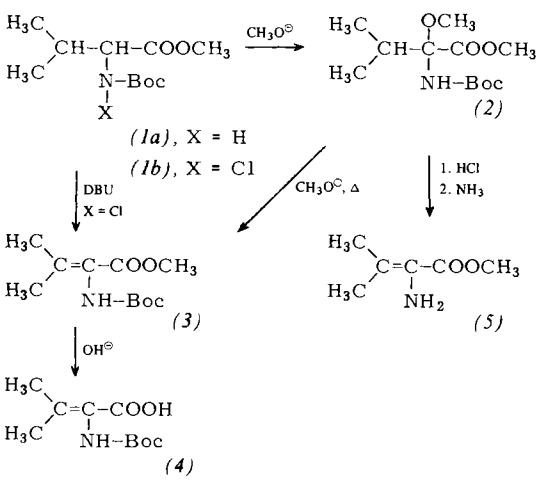
[**] Amino Acids and Peptides, Part 19.—Part 18: ref. [1].—Also: Dehydro Amino Acids, Part 6.—Part 5: ref. [1].

acids, which are of importance for the synthesis of dehydropeptides.

The method is demonstrated for the case of Boc-valine methyl ester *(1a)*: *N*-chlorination [to *(1b)*] and reaction with methoxide to achieve subsequent dehydrochlorination and addition of methanol, without isolation of intermediates, affords good yields of the Boc-α-methoxy amino acid ester *(2)*, which on reaction with hydrogen chloride in ether suffers loss of the *tert*-butoxycarbonyl group and methanol with formation of dehydrovaline ester hydrochloride. The free amino acid ester *(5)*[4] is easily accessible from the hydrochloride by reaction with ammonia. This reaction sequence can also be extended to the preparation of dehydrophenylalanine ester and dehydroleucine ester[5]. The NMR spectrum of the latter also shows signals of the tautomeric imino acid ester; the dehydrophenylalanine ester and dehydrovaline ester *(5)*, on the other hand, are present exclusively as enamines.



Base-catalyzed elimination of methanol from the methoxy compound *(2)* yields the Boc-dehydrovaline ester *(3)* which can be hydrolyzed to Boc-dehydrovaline *(4)*. More favorable, and especially more suited for the synthesis of Boc-dehydroaminobutyric acid, however, is the dehydrochlorination of the corresponding *N*-chloro compound *(1b)* with diazabicycloundecene (DBU) and hydrolysis of the resulting Boc-dehydro amino acid ester *(3)*. Dehydroaminobutyric acid has been found to be present in various antibiotic peptides (nisin, subtilin[6]).

α,β-Dehydrovaline methyl ester (5)

A solution of sodium (1.30 g, 56.5 mmol) in methanol (100 ml) is slowly added dropwise to an ice-cooled solution of *(1a)* (9.24 g, 40.0 mmol) and *tert*-butyl hypochlorite (6.0 g, 55.6 mmol) in anhydrous ether (200 ml). When the addition is complete, the ice-bath is removed and the mixture stirred for 1 h. The solvent is then removed by distillation *in vacuo* and the residue taken up in dichloromethane and shaken with 0.01 N HCl followed by a saturated $NaHCO_3$ solution. After removal of the dichloromethane the residue is distilled in a bulb-tube under high vacuum (bath temp. 120°C). 9.8 g (94 %) of *(2)* is obtained as colorless crystals, m.p. 52—55°C (petroleum ether); ^{1}H-NMR ($CDCl_3$): δ = 0.92 (d, 3H); 1.00 (d, 3H); 1.48 (s, 9H); 2.22—2.70 (m, 1H); 3.34 (s, 3H); 3.80 (s, 3H); 5.48 (br. s, 1H).

An ice-cooled solution of *(2)* (3.0 g) in anhydrous ether (50 ml) is saturated with dry HCl. The solution is allowed to stand overnight and then evaporated to dryness under vacuum. The crystalline residue [*ca.* 1.9 g *(5)*·HCl] is treated several times with anhydrous ether and dried under vacuum. To liberate *(5)*, 1.8 g of the hydrochloride is dissolved in 15 ml dichloromethane, and the ice-cooled solution saturated with dry ammonia; the ammonium chloride formed is removed by filtration and the filtrate concentrated by evaporation *in vacuo*. The oily residue is distilled in a bulb-tube. 1.2 g (86 %) of *(5)*, b.p. 76°C/11 torr is obtained; ^{1}H-NMR ($CDCl_3$): δ = 1.76 (s, 3H); 2.06 (s, 3H); 3.24 (br. s, 2H); 3.76 (s, 3H).

Methyl N-tert-butoxycarbonyl-α,β-dehydro-α-aminobutyrate

Methyl Boc-α-aminobutyrate (1.76 g, 8.1 mmol) is dissolved in anhydrous ether (40 ml). The ice-cooled solution is treated first with *tert*-butyl hypochlorite (1.40 g, 13.0 mmol) and then dropwise with 1 ml of a 1 % solution of Na in methanol. After 15 min the reaction mixture is examined by thin-layer chromatography (silica gel plates, chloroform). If any starting material is found, the mixture is treated with a further 0.70 g *tert*-butyl hypochlorite and 0.50 ml of the methoxide solution. The reaction solution is concentrated *in vacuo*, the residue taken up in chloroform, washed twice with a small volume of water, and dried. After removal of chloroform by evaporation, 1.95 g (96 %) of the oily *N*-chloro product [of type *(1b)*] is obtained; ^{1}H-NMR ($CDCl_3$): δ = 1.0 (t, 3H); 1.51 (s, 9H); 1.60—2.22 (m, 2H); 3.76 (s, 3H); 4.6—4.82 (m, 1H).

1.90 g (7.6 mmol) of the crude oil is dissolved in ether (50 ml) and, after addition of 1.15 g (7.6 mmol) of diazabicycloundecene (DBU), is heated to boiling. When no more *N*-chloro compound is present on examination by thin-layer chromatography (2—3 h), DBU·HCl is separated off by filtration, the ether replaced by chloroform, and the resulting solution washed first with dil. HCl and then a saturated solution of $NaHCO_3$. After drying and removal of solvent the residue is distilled under high vacuum in a bulb-tube (bath temp. 120°C). The oily product of type *(3)* (1.15 g, 75 %) crystallizes on being rubbed with petroleum ether; m.p. 70—72°C; ^{1}H-NMR ($CDCl_3$): δ = 1.48 (s, 9H); 1.80 (d, 3H); 3.78 (s, 3H); 6.20 (br. s, 1H); 6.66 (q, 1H).

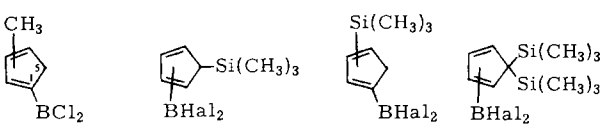
for the transfer of cyclopentadienyl ligands to other elements under mild conditions[1, 2]. We report here on the use of this synthetic principle for the preparation of cyclopentadienylboranes; the extremely few compounds of this type so far reported were prepared by comparatively complicated methods[3].

Reaction of trimethylsilyl-substituted cyclopentadienes[4, 5] with boron trihalides leads *via* cleavage of trimethylhalosilane to formation of the corresponding dihaloboryl-substituted cyclopentadienes:

$$R\text{—}CpSi(CH_3)_3 + BHal_3 \rightarrow R\text{—}CpBHal_2 + (CH_3)_3SiHal$$

To demonstrate the preparative scope of this method we have so far synthesized the compounds *(1)*—*(7)*; they are colorless liquids and extremely sensitive to air.

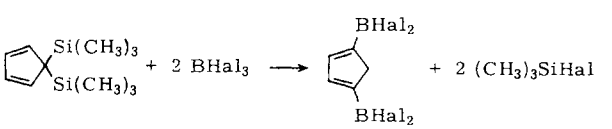


(1) *(2), (3)* *(4), (5)* *(6), (7)*

Hal = Cl in *(2)*, *(4)*, *(6)*; Hal = Br in *(3)*, *(5)*, *(7)*

In most cases the reactions proceed almost quantitatively under very mild conditions. A loss in yield only occurs during distillative workup of some compounds due to their thermolability.

Polyborinated cyclopentadienes could not be prepared by the previously known methods for the synthesis of monoborylcyclopentadienes, since the B—C bond is cleaved on attempted metalation[3a, 6]. With the present method, however, diborylcyclopentadienes can also be very easily synthesized. Thus, on reaction of 5,5-bis(trimethylsilyl)cyclopentadiene with 2 equivalents of boron trihalide the crystalline compounds *(8)*, *(9)*, and *(10)*, which are very sensitive to air, are formed.



Hal = Cl in *(8)*, Br in *(9)*, I in *(10)* *(8), (9), (10)*

The structures of compounds *(1)*—*(10)* were confirmed by analytical as well as mass spectrometric and NMR spectroscopic data (see Table 1). The dihaloboryl group and the methyl group are always bound to a vinylic C atom of the cyclopentadiene system. The trimethylsilyl ligand is usually fixed to an allylic C atom and is thus responsible for the fluctional structure ([1,5] sigmatropic rearrangement) of the compounds *(2)*, *(3)*, *(6)*, and *(7)*. No dynamic behavior is exhibited by compounds *(1)*, *(4)*, *(5)*, *(8)*, *(9)*, and *(10)* at room temperature.

Experimental:

Compounds *(1)*—*(8)*: The respective reactants are stirred together for 2 h at the temperatures quoted in Table 1. The products *(1)*—*(8)* are isolated from the reaction solution by fractional distillation.

Compounds *(9)* and *(10)*: To a solution of 5,5-bis(trimethylsilyl)cyclopentadiene in pentane are added concentrated pentane-solutions of BBr_3 and BI_3 respectively; the additions are carried out slowly and with stirring at the temperatures given in Table 1. The precipitated crystals are filtered off and recrystallized from methylcyclohexane [*(9)*] and dichloromethane/pentane (2:1) [*(10)*], respectively.

Low-Temperature X-Ray Structure Analysis of 1-Benzothiepin

By *Noritake Yasuoka, Yasushi Kai, Nobutami Kasai, Toshio Tatsuoka*, and *Ichiro Murata*[*]

Structural data of the thiepin ring have hitherto been unavailable because of its thermal instability; on the other hand, its stable dioxide derivatives have been fully investigated[1, 2]. Here we wish to report the molecular structure of 1-benzothiepin at low temperature (−140 °C).

1-Benzothiepin *(1)* (for synthesis, see Ref. [3]) was chromatographed on alumina (deactivated with 5% water, hexane, −20 °C) and subsequently recrystallized from hexane at −60 °C. The resulting pale yellow platelets, m.p. 23.5—24.5 °C, were examined on a Rigaku automated single crystal diffractometer with $Mo_{K\alpha}$ radiation; the low temperature being attained by the gas-flow technique with liquid nitrogen.

Compound *(1)* is monoclinic, $a=12.403(9)$, $b=6.187(3)$, $c=10.856(5)$ Å, $\beta=107.45(4)°$, space group $P2_1/n$ (No. 14), $d_{calc.}=1.34\,g\,cm^{-3}$ for $Z=4$.

The structure was solved by the direct method with the MULTAN program. At the earlier stage of the refinement, the larger values of isotropic temperature factors observed in the thiepin ring than the benzo ring indicated the presence of disorders. According to difference Fourier syntheses a minor contribution (15%) of a mirror image form of the molecule is plausible. This partially disordered model of the structure could be refined successfully including hydrogen atoms (with isotropic temperature factors) to a final R value of 0.069 (1586 observed reflections).

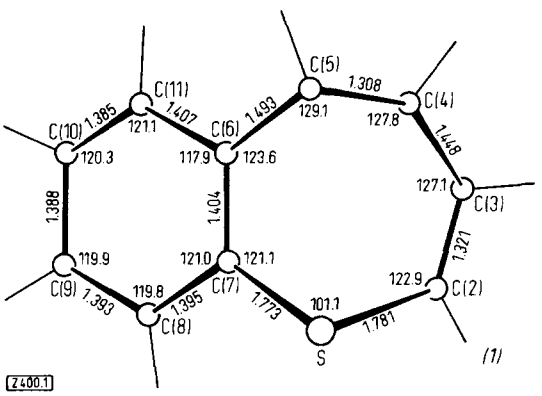

Fig. 1. Bond lengths and angles in 1-benzothiepin *(1)*. Maximum errors ±0.005 Å and ±0.3°, respectively.

The molecular structure projected onto the plane passing through C(2), C(3), C(6), and C(7) is shown in Figure 1 with bond lengths and angles. It is remarkable that the molecular geometry is quite similar to that of 1-benzothiepin 1,1-dioxide already reported by the present authors[2]. The thiepin ring is in a boat conformation with angles of 49.1 and 30.0° between the base plane and the "bow" [C(2)—S—C(7)] and "stern" [C(3)—C(4)—C(5)—C(6)] planes, respectively.

Total Synthesis of Methionine-Enkephalin

By *Wolfgang Voelter, Claus Bürvenich, Hans Horn, Hubert Kalbacher*, and *Emanuel Pietrzik*[*]

On the 18th of December 1975, *Hughes et al.*[1] reported the identification of two pentapeptides isolated from pig brains: in the vas deferens of the mouse, methionine-enkephalin (H-Tyr-Gly-Gly-Phe-Met-OH) was found to be twenty times more active, and leucine-enkephalin (H-Tyr-Gly-Gly-Phe-Leu-OH) ten times more active compared to normorphine. We now present a preliminary report of a classical total synthesis of the "endogenous opiate" methionine-enkephalin[2].

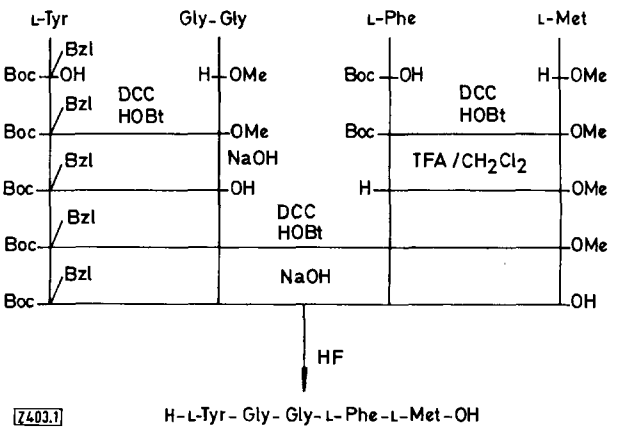

Fig. 1. Synthetic strategy for the preparation of methionine-enkephalin.

The synthetic strategy is shown in Figure 1. The following starting materials were synthesized for the preparation of the peptide: Boc-L-Tyr(Bzl)-OH[3] (m.p. 109 °C; $[\alpha]_D=+5°$, $c=1$, CH_3COOH), H-Gly-Gly-OMe·HCl[4] (prepared from H-Gly-Gly-OH and thionyl chloride/CH_3OH (1.2:12), m.p. 122 °C), Boc-L-Phe-OH[3] (m.p. 83—84 °C, $[\alpha]_D=-4°$, $c=1$, CH_3COOH), and H-L-Met-O-Me·HCl[4] (m.p. 144 °C; $[\alpha]_D=+26.3°$, $c=1$, H_2O).

Twelve hours' coupling of Boc-L-Tyr(Bzl)-OH (1.02 g, 2.75 mmol) and H-Gly-Gly-OMe·HCl (0.50 g, 2.75 mmol) with dicyclohexylcarbodiimide (DCC) (0.6 g, 2.90 mmol) and 1-hydroxybenzotriazole (HOBt) (0.37 g, 2.75 mmol) in DMF affords Boc-L-Tyr(Bzl)-Gly-Gly-OMe which is hydrolyzed at pH 12.5 (adjusted with 1 N NaOH) in dioxane/water (1:1) (yield 1.0 g = 75 %).

The protected C-terminal peptide fragment H-L-Phe-L-Met-OMe is obtained *via* Boc-L-Phe-L-Met-OMe by reaction of Boc-L-Phe-OH (5.3 g, 20 mmol) and H-L-Met-OMe·HCl (3.99 g, 20 mmol) with DCC (4.12 g, 20 mmol) and HOBt (5.4 g, 40 mmol) in DMF; the *tert*-butyloxycarbonyl protecting group

[*] Prof. Dr. W. Voelter, Dipl.-Chem. C. Bürvenich, Dipl.-Chem. H. Horn, Dipl.-Chem. H. Kalbacher, and Dipl.-Chem. E. Pietrzik
Chemisches Institut der Universität
Auf der Morgenstelle, 7400 Tübingen (Germany)

is removed with trifluoroacetic acid (TFA/CH_2Cl_2, 1:1; yield 5.9 g = 70 % as TFA derivative).

In analogy to the above two peptide linkages the protected pentapeptide Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-L-Met-OMe (1.2 g, 77 % yield) was obtained from Boc-L-Tyr(Bzl)-Gly-Gly-OH (1 g, 2 mmol) and H-L-Phe-L-Met-OMe·CF_3COOH (0.85 g, 2 mmol). Twelve hours' hydrolysis of the methyl ester at room temperature in methanol/water (1:1) at pH 12.5 (adjusted with 1 N NaOH), neutralization with 1 N HCl, and evaporation was followed by removal of the remaining protecting group with HF in the presence of anisole, and precipitation of the peptide with ether. An aqueous solution of the peptide was then stirred for 90 min with Dowex 1×8 (OH form). After the resin had been filtered off the peptide was recrystallized from ether/alcohol mixtures (yield 540 mg = 61 %): The purity was established by thin layer chromatography (silica gel plates (F_{254}) from Merck, mobile phase: *n*-butanol/glacial acetic acid/water (3:1:1), $R_f = 0.42$).

Methionine-enkephalin melts and decomposes at 195 °C; its rotatory power $[\alpha]_D^{25}$ is +31.5° ($c = 0.96$, MeOH).

Oxidation of Alkylidenetriphenylphosphoranes with Phosphite-Ozone Adducts

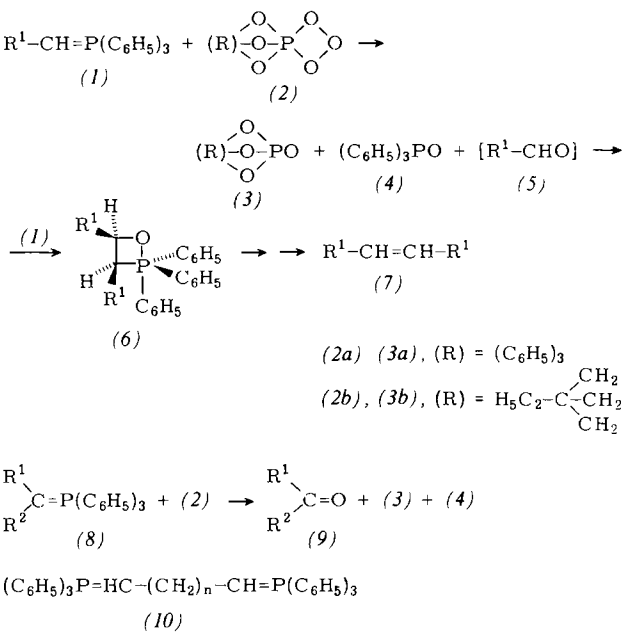
By *Hans Jürgen Bestmann, Lothar Kisielowski,* and *Werner Distler*[*]

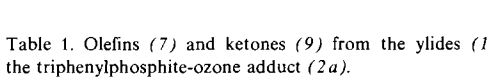
Alkylidenetriphenylphosphoranes *(1)* and *(8)* are oxidized by phosphite-ozone adducts[1] such as *(2a)* and *(2b)*. Ylides of the general structure *(1)* afford olefins *(7)*, phosphates *(3)*, and triphenylphosphane oxide *(4)*, while those of type *(8)*, R^1, $R^2 \neq H$, give ketones *(9)*. The reaction of *(1)* with *(2)* presumably proceeds *via* aldehydes *(5)* (Table 1).

Bifunctional ylides *(10)*, $n > 4$, react with *(2)* to form macrocyclic polyolefins; thus the bis(alkylidenetriphenylphosphorane) *(10)*, $n = 8$, accessible from 1,10-bromodecane furnishes a mixture of 20-, 30-, 40-, 50-, and 60-membered rings having two to six double bonds[2].

The preparative advantages of the new method of oxidation compared with autoxidation[3] lie (a) in accurate dosing of the oxidizing agent, (b) in the considerably milder reaction conditions (reaction temperature −75 °C), (c) in the possibility of converting stable ylides which are not attacked by oxygen into 1,4-diacylethylenes or 1,2-diketones, and (d) in the higher yields; thus the ylide derived from axerophthene gives a 75 % yield of β-carotene on treatment with *(2a)*[4].

In contrast to other oxidations with *(2)*[1b,1c] the oxygen is not transferred from *(2)* to *(1)* or *(8)* in the form of





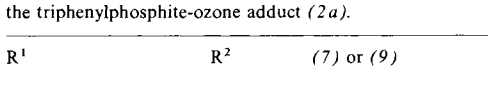


Table 1. Olefins *(7)* and ketones *(9)* from the ylides *(1)* and *(8)* and the triphenylphosphite-ozone adduct *(2a)*.

R^1	R^2	*(7)* or *(9)*	Yield [%]
n-$C_{11}H_{23}$		12-Tetracosene	61
C_6H_6		Stilbene	89
p-CH_3O—C_6H_4		4,4'-Dimethoxystilbene	48
p-NO_2—C_6H_4		4,4'-Dinitrostilbene	72
$C_{19}H_{27}$ [a]		β-Carotene	75
CH_3—CO		1,2-Diacetylethylene	87
C_6H_5—CO		1,2-Dibenzoylethylene	62
CH_3O—CO		Dimethyl fumarate	83
C_6H_5	C_6H_5	Benzophenone	73
C_6H_5	CH_3	Acetophenone	77
C_6H_5CO	CH_3	Methyl phenyl diketone	81
C_6H_5CO	C_6H_5	Benzil	46

[a] R^1—CH_3 = axerophthene.

singlet oxygen ($^1O_2$)[5]. Decomposition of *(2a)* to triphenylphosphate *(3a)* and $^1O_2$ is shown by ^{31}P-NMR spectroscopy to proceed at a detectable rate only above −30 °C[1c], and that of the adduct *(2b)* of ozone and 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane at 0 °C[1c] [^{31}P-NMR (toluene): *(2a)*: δ = +63.0; *(2b)*: +42.5; *(3a)*: +18.1; *(3b)*: +9.5; *(4)*: 24.1 ppm[6].

On combination of a salt-free solution of butylidenetriphenylphosphorane *(1)*, $R^1 = C_3H_7$, with *(2a)* or *(2b)* at −75 °C the ^{31}P-NMR spectrum recorded at that temperature contains no signal for *(2a)* or *(2b)*. Instead the signals of the phosphate *(3a)* or *(3b)* and of triphenylphosphane oxide *(4)* appear alongside those of a new compound containing pentavalent phosphorus at δ = +59.5 ppm[6] which we consider to be the initial cycloadduct formed in the Wittig reaction between *(1)* and *(5)* ($R^1 = C_3H_7$ in each case)[7] and to which we assign the structure of the oxaphosphetane *(6)*. In accord with this postulate a signal appears at the same position when *(1)*, $R^1 = C_3H_7$, is allowed to react with butyraldehyde *(5)*, $R^1 = C_3H_7$, at −75 °C. In both cases the intensity of the signal decreases as the temperature slowly rises until it has completely disappeared at 0 °C. The signal of *(4)* increases simultaneously.

General procedure:

A solution of *(2a)*[1a] in toluene or dichloromethane cooled to −70 to −80 °C is added dropwise to a stirred solution

[*] Prof. Dr. H. J. Bestmann, Dipl.-Chem. L. Kisielowski, and Dr. W. Distler
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, 8520 Erlangen (Germany)

of the ylide *(1)* or *(8)* (preferably free from lithium) in toluene[8] (strongly basic ylides with R^1, R^2, R^3 = alkyl or aryl) or dichloromethane ("stable" ylides with R^1, R^2, or $R^3 = COR^4$), respectively, at the same temperature. The reaction mixture is then allowed to warm up to room temperature, any sodium halide that may have precipitated out is filtered off, and the solvent removed by distillation. Further workup depends on the properties of the olefins *(7)* or ketones *(9)*.

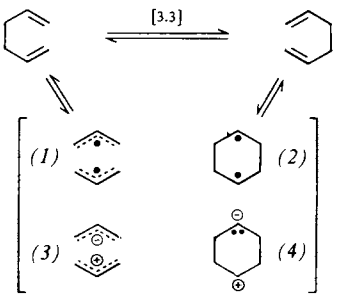
Cope Rearrangement with Dipolar Intermediates[**]

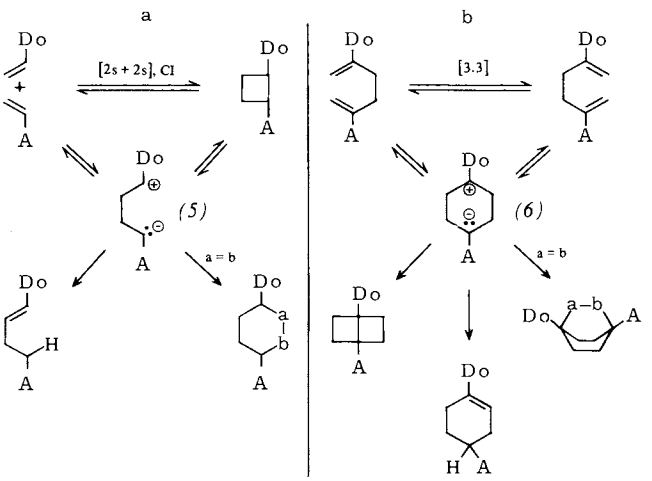
By *Rudolf Gompper* and *Wolf-Rüdiger Ulrich*[*]

The Cope rearrangement can be described either as a sigmatropic [3,3] rearrangement[1] or as a two-step process involving the intermediates *(1)*[2], *(2)*[3], *(3)*[4], or *(4)*.

In connection with our studies on dipolar intermediates *(5)* in cycloadditions[5] we have attempted to stabilize intermediates of type *(4)* in Cope rearrangements by donor and acceptor groups and to detect them in the form of their derivatives *(6)* by means of typical reactions (Scheme 1b) such as are known for the (isolable) intermediates *(5)* in [2+2] cycloadditions (Scheme 1a). Polar Cope rearrangements according to Scheme 1b would provide a further entry to 1,4-dipoles and also document the significance of substituent



effects by the appearance of intermediates in symmetry-allowed pericyclic processes too. The α,α'-annelation of cyclic ketones[6] can be rationalized by the intermediacy of zwitterions of type *(6)*.



Scheme 1. Abbreviations: A = acceptor group; Do = donor group, CI = configurational interaction.

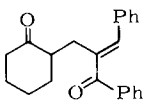
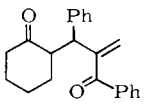
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Reaction of *N*-(1-cyclohexenyl)pyrrolidine *(7)* with β-bromo-α-benzylidenepropiophenone *(8)* yields the salt *(9)* (m.p. 186—187 °C). Treatment of *(9)* with triethylamine (path A) provides an 80 % yield of the bicyclic immonium salt *(12)* (containing 1 mol of CH_2Cl_2: m.p. 237—239 °C), from which the ketone *(13)* (m.p. 104—105 °C) is obtained by acid hydrolysis.

Heating of the salts *(9)* and *(12)* with NaH in THF (path B) affords the enamino ketone *(14)* in both cases (yields *ca.* 80 and *ca.* 60 %, respectively). Treatment of *(14)* in THF with 70 % perchloric acid and subsequently with water produces the diketone *(15)* (b.p. 170 °C/10^{-3} torr).



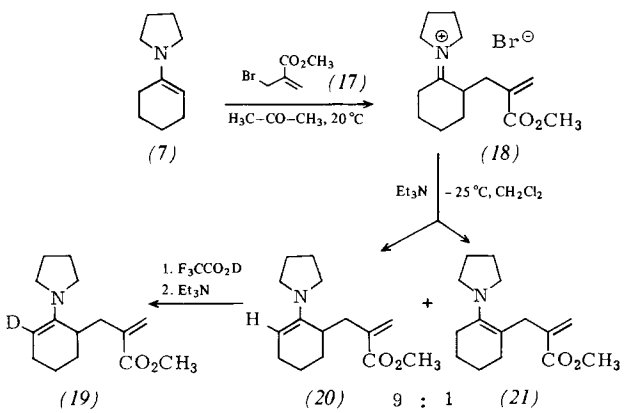
(15)



(16)

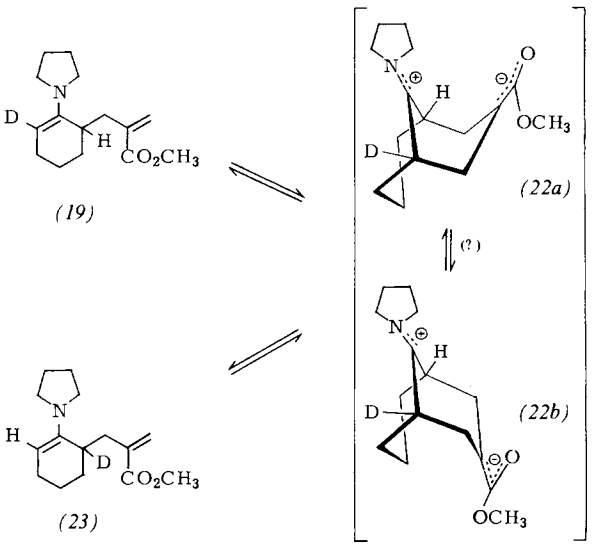
The isomeric diketone *(16)* (m.p. 120 °C) arises on acid hydrolysis of *(9)*.

Conversion of *(9)* into *(14)* by path B shows that the initially formed enamino ketone *(10)* has undergone a Cope rearrangement. The intermediacy of the zwitterion *(11)* in this rearrangement of *(10)* into *(14)* follows from formation of the bicyclic *(12)* from *(9) via* path A and of *(14)* from *(12) via* path B. This scheme of a two-step ("polar") Cope rearrangement is also compatible with the finding that the diketone *(13)* can be detected on treatment of *(14)* with water (path C).

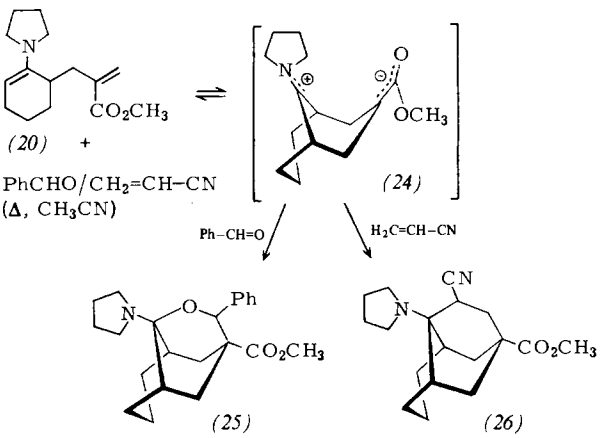


Since the enamino ketone *(10)* cannot be isolated we have attempted to synthesize similar polar Cope systems. The reaction of *(7)* with methyl bromomethacrylate *(17)* affords the salt *(18)* (m.p. 129—131 °C) in 75 % yield. On treatment of *(18)* with triethylamine a mixture of the enamines *(20)* and *(21)* is obtained in 80 % yield. Compound *(20)* can be purified by crystallization form *n*-pentane at −60 °C.

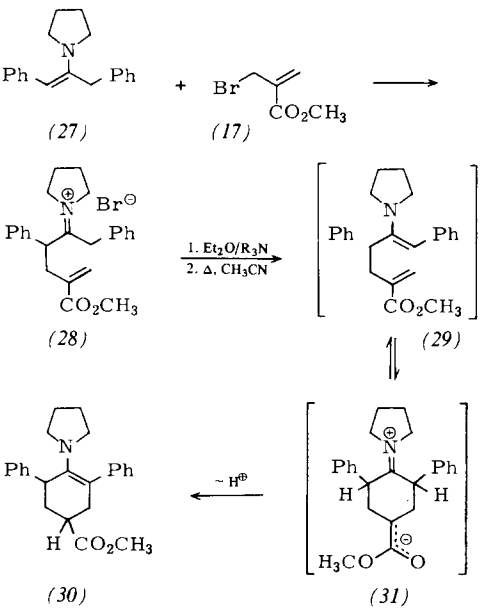
Deuteration of *(20)* is accomplished by treatment of its solution in dichloromethane at −20 °C (this temperature should not be exceeded throughout the entire operation) with an equimolar amount of deuteriotrifluoroacetic acid, addition of triethylamine after 30 min, removal of the solvent *in vacuo*, and dissolution of the residue in *n*-pentane. After filtration under N_2 the solvent is again removed *in vacuo*. The ^{1}H-NMR spectrum of the residue (in $[D]_8$-toluene) shows a drop in intensity of the triplet due to the ring vinyl proton at $\delta = 4.3$ ppm to 54 % relative to the signals of the other two vinylic protons at $\delta = 6.08$ and 5.3 ppm. On repetition of the procedure the intensity falls to 26 %, thus showing that *(19)* now predominates.



The Cope rearrangement can be detected in the 3 : 1 mixture of *(19)* and *(23)*. After 15 minutes' heating of a 1 % benzene solution the intensity of the triplet at $\delta = 4.3$ ppm has again risen to 45 %, and after four days' standing at room temperature to 55 %.



Proof of the dipolar intermediate *(22)* and the nondeuterated form *(24)* is obtained on heating of *(20)* with benzalde-



hyde and acrylonitrile. There result the cycloadducts *(25)* (yield 90%; m.p. 144—145°C) and *(26)* (yield 48%; m.p. 84—85°C).

A further possible reaction of intermediate *(6)* shown in Scheme 1 can be demonstrated by the action of tertiary amines in the immonium salt *(28)* obtained from *(17)* and *(27)* in ether at room temperature; yield 65%. Treatment of an ethereal solution of *(28)* with Hünig base (diisopropylethylamine) followed by decantation of the hydrobromide, evaporation of ether, and heating of the residue in acetonitrile permits isolation of the cyclic enamine *(30)* (yield 72%; m.p. 114—115°C), the species *(29)* and *(31)* presumably occurring as intermediates.

Hetero Cope Rearrangements with Dipolar Intermediates[**]

By *Rudolf Gompper* and *Wolf-Rüdiger Ulrich*[*]

Cope rearrangements of 1,5-hexadienes bearing a donor group in position 2 and an acceptor group in position 5 are much faster than the rearrangements of compounds with "neutral" groups in these positions, and 1,4-dipolar intermediates can be detected[1]. The rate of hetero Cope rearrangements is also enhanced by the presence of donor-acceptor groups (cf. ref. [2]): The thioamides *(1)* and the allyl bromides *(2)* afford (ether, reflux) the salts *(3)* in excellent yields [*(3ad)*: m.p. 98—100°C; *(3bd)*: m.p. 113—114°C; *(3cd)*: m.p. 93—94°C; *(3ae)*: m.p. 103—105°C (dec.); *(3be)*: m.p. 126—127°C]. Treatment of solutions of *(3)* in acetonitrile (−40°C) or their suspensions in ether (20°C) with diisopropylethylamine (NaH in THF can also be used) furnishes the thioamides *(4)* in 60—80% yield [*(4ad)*: m.p. 18—20°C; *(4bd)*: b.p. 94—95°C/0.5 torr; *(4cd)*: b.p. 75°C/0.5 torr; *(4ae)*: m.p. 77—79°C; *(4be)*: m.p. 126—127°C].

	R^1	R^2
a:	H	H
b:	H	CH_3
c:	CH_3	CH_3

	R^3	R^4
d:	CO_2CH_3	H
e:	$COCH_3$	C_6H_5

Proof of the intermediacy of dipolar species in these thia Cope rearrangements has been obtained in the reactions of *(1)* with α-chloromethylacrylophenone *(7)*: reaction at room temperature in acetone (path A) gives the cyclic salts *(10)* [*(10a)*: yield 50%; m.p. 150—152°C; *(10b)*: yield 65%; m.p. 96—98°C; *(10c)*: yield 60%; m.p. 175—176°C]. Under otherwise identical conditions in the presence of diisopropylethylamine (path B) one obtains the thioamides *(13)* [*(13a)*: yield 40% based on *(7)*; b.p. 150°C/10^{-3} torr; *(13b)*: yield 60%; b.p. 150°C/10^{-3} torr; *(13c)*: yield 70%].

	R^1	R^2
a:	H	H
b:	H	CH_3
c:	CH_3	CH_3

These results can be interpreted by assuming *(1)* and *(7)* to initially form the quaternary salts *(8)* which are transformed by deprotonation into the thia Cope systems (ketene *S,N*-acetals) *(9)*. "Cope cyclization" of *(9)* affords the 1,4-dipoles *(11)*, which in the absence of a strong base are trapped by the hydrogen chloride present in the reaction mixture to form *(10)*. Protonation of *(11)* fails to occur in the presence of diisopropylethylamine; instead the ring is opened to give *(13)*.

This scheme is compatible with the finding that the action of bases (*e.g.* diisopropylethylamine) on *(11c)* also leads to *(13)*. Thus it is established that the 1,4-dipoles *(11)* occur as intermediates in the thia Cope rearrangement of *(9)* to *(13)*.

[*] Prof. Dr. R. Gompper and Dipl.-Chem. W.-R. Ulrich
Institut für Organische Chemie der Universität
Karlstrasse 23, 8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

It is remarkable that the deprotonation of *(10)* can also follow a different route. Treatment of the solutions of *(10a)* and *(10b)* in ether with diisopropylethylamine gives good yields of the cyclic ketene *S,N*-acetals *(12)* [*(12a)*: b.p. 150°C/10^{-3} torr; *(12b)*: b.p. 125°C/10^{-3} torr].

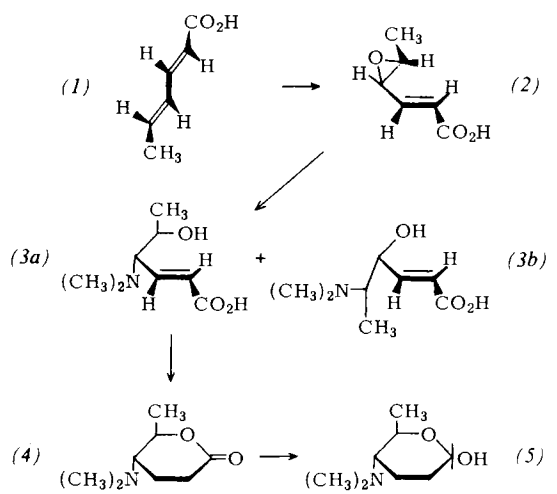
Synthesis of D-Forosamine, the 4-Dimethylamino Sugar from Spiramycin[1][**]

By *Ingolf Dyong, Rainer Knollmann*, and *Norbert Jersch*[*]

Little is known about the biological function of the often rather unusual sugars present in antibiotics[2]; a prerequisite for model studies is to be seen in the availability of productive syntheses.

Forosamine, the 4-dimethylamino-2,3,4,6-tetradeoxy-D-*erythro*-hexose *(5)* which occurs alongside mycarose and mycaminose in spiramycin, a therapeutically employed macrolide antibiotic complex from *Streptomyces ambofaciens*[3], is accessible only with great difficulty *via* two earlier syntheses each involving thirteen steps in yields of 0.1[4] and 1%[5], respectively.

We have found an alternative synthetic pathway of general significance for the preparation of neutral and basic polydeoxyhexoses[6] which provides a ready entry to *(5)*.



Epoxidation of sorbic acid *(1)* with 40% peracetic acid affords the enantiomeric *trans*-4,5-epoxy-*threo*-2-hexenoic acids (yield 76%) of which the D-isomer *(2)* crystallizes from ether (yield 90%) with D-(+)-phenylethylamine. Compound *(2)* [m.p. 82—84°C, $[\alpha]_D^{22} = +7.6°$ ($c = 1.0$, $CHCl_3$), yield 98%], liberated on treatment of the ammonium salt with dilute acid, reacts with 40% aqueous dimethylamine at room temperature to give a 4:1 mixture of 4-dimethylamino-5-hydroxy-D-*erythro*-2-hexenoic acid *(3a)* and 5-dimethylamino-4-hydroxy-L-*erythro*-2-hexenoic acid *(3b)* (yield 87%), from which the 4-dimethylamino lactone *(4)* [$[\alpha]_D^{25} = +116.2°$ ($c = 1.2$, benzene), yield 61%] can be isolated with acetone/benzene/dioxane (1:1:1) after catalytic hydrogenation and lactonization with acetic anhydride. Reduction of *(4)* with diisobutylaluminum hydride in tetrahydrofuran at −30°C furnishes forosamine *(5)*, obtained as a syrup from acetone. It rapidly crystallizes [m.p. 58—60°C, $[\alpha]_D^{25} = +86.1°$ ($c = 0.9$, methanol), yield 70%[7]].

Apart from M^+ (14%), a key fragment in the mass spectrum of *(5)* is the K_1 ion $[(CH_3)_2N{-}CH{=}CH{-}CH_3]^+$ (14%).—The yield of *(5)* from *(1)* is 25%, considering only the D-isomer *(2)*.

Stereospecific Synthesis of β-Bromoamines by Ionic Addition of Diethyl Dibromophosphoramidate to a Double Bond[**]

By *Andrzej Zwierzak* and *Krystyna Osowska*[*]

While free-radical addition of various *N,N*-dihaloamides to double bonds has been extensively studied over the past decade[1], the available information about ionic reactions of such systems with unsaturated compounds remains scarce and inadequate[2].

In the course of our studies on the possible application of diethyl dibromophosphoramidate *(1)* for regiospecific functionalization of a double bond[3] we have found that this reagent readily adds to unsaturated hydrocarbons such as styrene or cyclohexene. When the reaction is carried out in carbon tetrachloride at −20°C in the presence of stoichiometric amounts of trifluoroborane-ether it affords *N*-bromo-*N*-(β-bromoalkyl)phosphoramidates which can be readily reduced

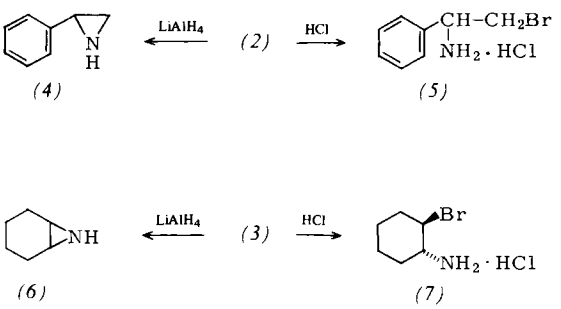
with 20% aqueous sodium hydrogen sulphite to the *N*-(β-bromoalkyl)phosphoramidates *(2)* and *(3)*.

Compound *(2)* [92% yield, m.p. 90—91 °C (*n*-hexane)], which evidently was formed by ionic, Markovnikov addition, was found to be uncontaminated by other regioisomers[4]. The structure of *(3)* [m.p. 79—81 °C (*n*-hexane)] was deduced from its IR and ^{1}H-NMR spectra and also the spectra of its degradation product *(7)*. From the spectra of *(7)* it would appear that both ring substituents are located in *trans*-diequatorial positions. The observed stereospecificity of the addition is fully consistent with the ionic course predicted for this reaction.

Both adducts *(2)* and *(3)* can be readily transformed into the corresponding aziridines *(4)* and *(6)*[5] in 79 and 72% yield respectively[6] by the action of lithium aluminum hydride in ether.

(2) and *(3)* are easily converted into the corresponding β-bromoamines *(5)* and *(7)* by the action of gaseous hydrogen chloride in THF at room temperature (24 h, yields 95 and 90%, respectively).



The reaction sequence: olefin → *(1)*-adduct → β-bromoamine hydrochloride, which can be realized in excellent overall yield, offers an attractive approach to functionalization of a double bond on account of its simplicity, mild reaction conditions, lack of side-products, and predictable regio- and stereospecificity.

Procedure:

Trifluoroborane-ether (7.1 g, 0.05 mol) was added dropwise with stirring to a solution of *(1)*[3a] (15.5 g, 0.05 mol) in CCl_4 (100 ml) at −20 °C. The olefin (0.05—0.06 mol) was then added and the mixture heated slowly to 20 °C. 30 ml of a 20% aqueous solution of $NaHSO_3$ was added dropwise at this temperature and the organic layer separated, washed with water (2 × 50 ml), dried and evaporated *in vacuo* to give crude adduct *(2)* or *(3)* as a hard, crystalline mass. For the degradation a solution of *(2)* or *(3)* (0.03 mol) in THF (25 ml) was saturated with gaseous HCl and set aside at room temperature for 24 h. The crystals of *(5)* or *(7)* were then filtered off, washed with ether, and recrystallized from ethanol/ether (2:1).

Correlation between the β-Effect of Methyl Groups on $\delta(^{13}C)$ and the C_α—C_β π-Bond Order[**][1]

By *Ludger Ernst*[*]

A knowledge of the influence of substituents on chemical shifts is often the most important prerequisite for an unambiguous interpretation of ^{13}C-NMR spectra. We report here on the β-effect of methyl groups on $\delta(^{13}C)$, *i.e.* on the change, $\Delta\delta_\beta$, of the shift of C_β in going from *(1)* to *(2)*.

(1) $H-C_\alpha=C_\beta \longrightarrow CH_3-C_\alpha=C_\beta$ *(2)*

In an investigation of the ^{13}C spectra of the isomeric monomethylcoumarins[2] we suggested for the first time, that a relationship existed between $\Delta\delta_\beta$ and the bond order P_π between the $2p_z$ orbitals of atoms C_α and C_β, which we had calculated by the INDO-MO method[3] (cf. Table 1, cases 10, 11, 16, 21). In the meantime we have been able to substantiate the correlation between $\Delta\delta_\beta$ and P_π. Regression analysis of the data in Table 1 affords the relationship

$$\Delta\delta_\beta\ [\text{ppm}] = 12.6 - 18.6\,P_\pi \qquad \text{(a)}$$

(correlation coefficient −0.985, rms deviation 0.68 ppm). Since introduction of a methyl group has only a slight influence on the bond orders, it is irrelevant whether equation (a) is derived from the bond orders of *(1)* or from those of *(2)*[4].

Qualitatively, equation (a) implies that a high C_α—C_β π-bond order results in a large shielding β-effect of the methyl group (cf. propene/ethylene) and that low bond orders cause large deshielding β-effects, whereas only small β-(=*ortho*-) effects occur in the case of intermediate π-bond orders (cf. toluene/benzene).

In terms of the Karplus-Pople theory of ^{13}C shifts[5], whose very approximate nature ought to be borne in mind, the observed relation could be interpreted in such a way that

[**] This work was supported by the Ministry of Research and Technology (BMFT) of the Federal Republic of Germany within the Technology Program.—I thank Dr. *A. Gossauer*, Braunschweig, for the gift of 2- and 3-methylpyrrole, and Prof. *H. Günther*, Köln, for communicating unpublished results.

of the applicable parameters (ΔE, $\langle r^{-3}\rangle_{2p}$, $\sum_B Q_{AB}$) mainly the latter is affected by the replacement of H by methyl. This parameter is a summation of bond order terms, in which the change of P_π (C_α—C_β) should play the principal role in going from *(1)* to *(2)*. In order to arrive at an equation of type (a), the change of P_π must, moreover, be proportional to the magnitude of P_π in *(1)*. For the time being we wish to emphasize the empirical nature of the relationship.

Table 1. Comparison of experimental and calculated [Eq. (a)] β-effects [ppm] of methyl groups on $\delta(^{13}C)$.

[a] The Case Numbers refer to the following methyl compounds; the C-atom in the β-position to the methyl groups is given in brackets. 1: methylcyclopropane (C-2); 2: propane (C-1); 3: 3-methylcyclopropene (C-1); 4: 2-methylanthracene (C-3); 5: *N*-methylpyrrole (C-2); 6: 2-methylnaphthalene (C-3); 7: 3-methylpyrrole (C-4); 8: 4-methylpyridinium ion (C-3); 9: 3-methylpyridinium ion (C-4); 10: 7-methylcoumarin (C-6); 11: 6-methylcoumarin (C-7); 12: 4-methylpyridine (C-3); 13: 3-methylpyridine (C-4); 14: 3-methylpyrazole (C-4); 15: toluene (C-2); 16: 7-methylcoumarin (C-8); 17: 3-methylpyridine (C-2); 18: 2-methylpyridine (C-3); 19: 4-methylpyrimidine (C-5); 20: 2-methylpyrazine (C-3); 21: 6-methylcoumarin (C-5); 22: 2-methylpyridinium ion (C-3); 23: 3-methylpyridinium ion (C-2); 24: 2-methylnaphthalene (C-1); 25: 2-methylpyrrole (C-3); 26: 3-methylpyrrole (C-2); 27: 2-methylanthracene (C-1); 28: 2-methylfuran (C-3); 29: crotonaldehyde (C-2); 30: crotonic acid (C-2); 31: methacrylic acid (C-3); 32: propene (C-1).
[b] Own measurements are given to two decimal places; the other values are from Ref. [6].

The usefulness of equation (a) for signal assignments is obvious. The relationship is certainly most useful for the interpretation of the ^{13}C spectra of molecules with bonds of widely differing double-bond character, *e.g.* of polycyclic or heterocyclic aromatics, even if quantitative predictions cannot be expected (see Table 1). Recently, the difficulty of assigning the signals of C-2 and C-5 in the spectrum of 3-methylfuran was reported[7]. Depending on how these signals are assigned, a β-effect of the methyl group on δ_2 with a value of +0.1 or of −3.2 ppm would result. For an unequivocal decision, rather involved double-resonance experiments had to be carried out. Equation (a) would have predicted −3.21 ppm for $\Delta\delta_2(P_\pi^{2,3}$ in furan: 0.85) and would thus have easily distinguished between the two possibilities.

When interfering steric effects are present, *e.g.* in *ortho*-substituted methyl aromatics, equation (a) is no longer a good approximation; the discrepancies which then occur demand further investigation.

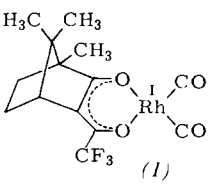
Separation of Deuteriated Ethylenes $C_2H_{4-n}D_n$ by Complexation Chromatography on a Rhodium(I) Complex[**]

By *Volker Schurig*[*]

Separations of deuteriated or ^{11}C and ^3H doubly-labeled alkenes have been carried out gas chromatographically on $AgNO_3$/ethylene glycol[1]. However, despite extreme conditions (75 m-long packed columns, recycling[1]) the separation of isotopes differing by only one mass unit was only partly successful. Moreover, $AgNO_3$ phases prove to have only a limited lifetime.

We have observed a considerably greater secondary isotope effect for $[D_4]/[D_0]$-ethylenes on the highly alkene-selective rhodium(I) β-diketonate phases previously described by us, *e.g.* dicarbonylrhodium(I) 3-trifluoroacetylcamphorate *(1)*[2]



(1)

in squalane, than on silver(I)[3]; their quantitative separation is already possible with a 2 m-long packed column. In contrast to $AgNO_3$, *(1)* is also suitable for the coating of high-resolution capillary columns having high separation efficiency and stability[4].

We have now been able to separate all deuteriated ethylenes $C_2H_{4-n}D_n$ under simple experimental conditions by complexation chromatography on rhodium(I) in 75 min at 22 °C (Fig. 1). The logarithmically additive separation factors $\alpha = t_D/t_H$

Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, 7400 Tübingen (Germany)

[**] This work, which was partly carried out at the Department of Chemistry, Weizmann Institute of Science, Rehovoth (Israel), was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

measured at several temperatures [α (22 °C) = (1.055)^n, α (42 °C) = (1.050)^n, and α (63 °C) = (1.042)^n, n = number of deuterium atoms] and the thermodynamic parameters of the π-complexing of [D_4]-/[D_0]-ethylene with *(1)* [$K_D/K_H = 1.28$ (22 °C), 1.24 (42 °C) and 1.21_5 (63 °C), $(\Delta H_D - \Delta H_H) = -0.24 \pm 0.01$ kcal/mol and $(\Delta S_D - \Delta S_H) = -0.34 \pm 0.04$ cal K^{-1} mol^{-1}] are the highest values observed so far for "inverse" ($K_D > K_H$) secondary isotope effects.

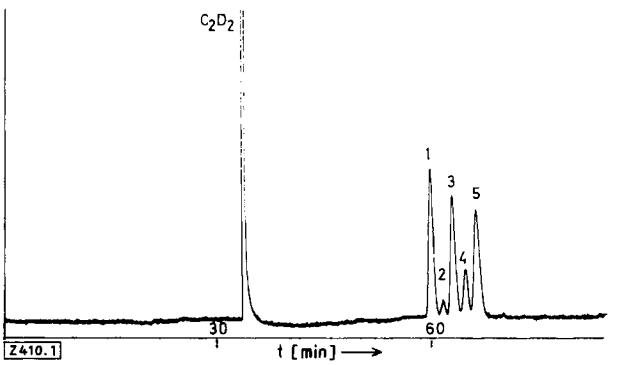

Fig. 1. Complexation chromatogram of the deuteriated ethylenes $C_2H_{4-n}D_n$ on *(1)* at 22 °C. 1: C_2H_4, 2: C_2H_3D, 3: $C_2H_2D_2$ (all isomers), 4: C_2HD_3, 5: C_2D_4.

Similarly selective separations are to be expected for deuteriated propenes or isomeric butenes. A doubling of the separation factors can be anticipated in the case of tritiated alkenes.

Procedure:

A 200 m × 0.5 mm steel capillary column (previously cleaned with HNO_3) is coated with a solution of *(1)*[2] (4 mg) in squalane (250 mg) diluted with CH_2Cl_2 (5 ml) at 1.75 atm N_2 (pure) and then conditioned for 150 h at 3 atm N_2 (n = 160000, isooctane) in the gas chromatograph (Carlo-Erba, Fractovap 2101). To avoid peak-tailing the separation is carried out at the highest sensitivity (output × 2), 1 µl gas mixture, split 1:100, column throughput 1.2 ml N_2/min, FID (100 °C, externally heated). The phase remains active over a period of months in absence of oxygen.

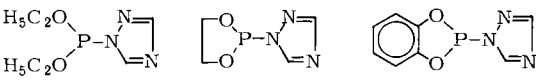
Synthesis of (Poly-)Peptides with Phosphorous Diester Triazolides[**]

By *Hans R. Kricheldorf, Martin Fehrle,* and *Jürgen Kaschig*[*]

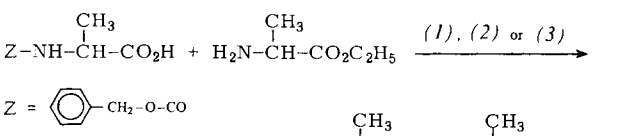
Reaction of 1-(trimethylsilyl)-1,2,4-triazole[1] with the phosphorous chlorides diethyl phosphorochloridite, 2-chloro-1,3,2-dioxaphospholane, and 2-chloro-1,3,2-benzodioxaphosphole leads to the phosphorous diester triazolides *(1)*, *(2)*, and *(3)*, respectively. They react readily with water, alcohols, carboxylic acids, and amines, are easy to isolate, and can be stored in a dry place.

N-Protected amino acids and amino acid alkyl esters can be condensed with *(1)*, *(2)*, or *(3)* to give peptides, *e.g.* *(4)*, in 70—80% yields. No crystalline products could be



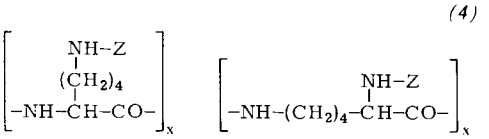
(1) *(2)* *(3)*

obtained in experiments on the esterification of Z-alanine with 4-nitrobenzyl alcohol or of Z-β-alanine with *tert*-butyl glycolate. Unlike many other condensation reagents, the triazolides *(1)*—*(3)* also react smoothly in polar solvents with free amino acids or oligopeptides to yield polypeptides and polyamides. Thus N^{ε}-Z-lysine affords the polypeptide *(5)*, which, like the polymers mentioned here, was characterized by elemental analysis, IR spectroscopy, and NMR spectroscopy (220 MHz in CF_3CO_2H). In addition, *(5)* was compared with a polymer which had been obtained by amine-catalyzed polymerization of N^{ε}-Z-lysine-N^{α}-carboxylic acid anhydride. Both polymers exhibited comparable rotations, thus indicating that no appreciable racemization takes place in the polycondensation with *(1)*—*(3)* below 80 °C.

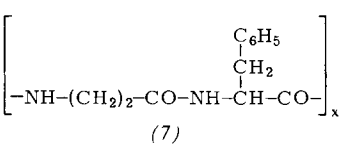


Z = Z-O-CO

(4)



(5) *(6)*



(7)

$[-NH-A-CO-NH-CH_2-CO-NH-CH_2-CO-]_x$

(8), A = $-CH(CH_2C_6H_5)-$; *(9)*, A = $-CH_2-CH_2-$;
(10), A = $-CH(CH_3)-$

N^{α}-Z-isopolylysine *(6)* and poly[β-Ala-Phe] *(7)* prepared with *(1)* were likewise identified by comparison with polypeptides which had been obtained by polycondensation of N^{α}-Z-lysine- and β-Ala-Phe-pentachlorophenyl ester trifluoroacetates, respectively. The sequence polypeptides *(8)*, *(9)*, and *(10)* could also be prepared from Phe-Gly-Gly, β-Ala-Gly-Gly and Gly-Gly-D,L-Ala, respectively, with *(1)*.

The crude products of the polycondensation with *(1)*—*(3)* had to be freed from attendant phosphorous acid derivatives. In the case of water-insoluble polymers [*(5)*—*(9)*] this was accomplished by boiling with 5% ammonia solution and methanol, and in the case of the water-soluble polypeptide

(10) by boiling with ammonia followed by dialysis. Compound *(3)*, which proved to be especially reactive in polycondensations, gave rise to most contaminants; consequently, *(1)* and *(2)* are to be preferred. As comparative experiments for the synthesis of *(6)* have shown, the same problem of purification occurs in the case of the less reactive condensation agents such as triphenyl phosphite or diphenyl phosphite.

Phosphorous diester triazolides (1)—(3)

1-(Trimethylsilyl-1,2,4-triazole (1.0 mol) and the corresponding phosphorous diester chloride of *(1)—(3)* (1.0 mol) are mixed in dry benzene (100 ml) and heated to boiling for 10 min. The major portion (*ca.* 60 %) of trimethylchlorosilane and benzene is then slowly distilled off *via* a Claisen head filled with glass wool, and any residual volatile products removed in a vacuum. *(1)* and *(2)* are isolated by distillation; the oily crude *(3)* is washed with a fivefold amount of warm petroleum ether and then cooled to 0 °C, whereupon it crystallizes almost completely.—1-(Diethoxyphosphino)-1,2,4-triazole *(1)*, yield 91 %, b.p. 75—77 °C/0.01 torr, $n_D^{20} = 1.4710$; 1-(1,3,2-dioxaphospholan-2-yl)-1,2,4-triazole *(2)*, yield 81 %, b.p. 74—76 °C/0.01 torr, $n_D^{20} = 1.5263$; 1-(1,3,2-benzodioxaphosphol-2-yl)-1,2,4-triazole *(3)*, yield 91 %, m.p. 55—57 °C.—*(3)* could not be subjected to elemental analysis because of its sensitivity to hydrolysis. In the case of *(2)* spontaneous ignition of the residue occurred within a few minutes of opening the warm distillation apparatus.

N-Benzyloxycarbonylalanylalanine ethyl ester (4)

A mixture of Z-L-Ala (0.1 mol) and *(1)* (0.1 mol) in dry dimethylformamide (50 ml) is stirred for 30 min. Addition of 0.1 mol L-alanine ethyl ester hydrochloride is followed by dropwise addition of 0.1 mol *N*-methylmorpholine. After about 12 h the reaction mixture is stirred together with a mixture of 250 ml water, a few drops of hydrochloric acid, and 300 ml ethyl acetate; the organic phase is separated off, dried, and evaporated to dryness. The product *(4)* crystallizes out on treatment with carbon tetrachloride and petroleum ether under cooling; yield 76 % [with *(2)*: yield 79 %; with *(3)*: yield 73 %], m.p. 113—115 °C (ref. [2]: 116 °C).

Poly β-Ala-L-Phe (7)

A mixture of finely powdered β-Ala-L-Phe (0.05 mol) in dry dimethylformamide (50 ml) is warmed with stirring to 80 °C, whereupon a part of the dipeptide goes into solution; after 30 min the polymer *(7)* begins to precipitate out. After four days at 80 °C the reaction mixture is stirred with 300 ml 1 N HCl; the precipitated polypeptide *(7)* is boiled for 4 h with a 5 % ammonia solution and 1 h with methanol; yield 50 %. ^{1}H-NMR (CF_3COOH): δ = 2.64, 3.11, 3.53, 4.82, 7.18, 7.30, 7.77, 8.00 ppm (2:2:2:1:2:3:1:1).

Regioselective Chlorination of Centered Methylene Groups in Dicarboxylic Acids[**]

By *Friedhelm Kämper, Hans J. Schäfer*, and *Heinrich Luftmann*[*]

We are presently studying the feasibility of regioselectively functionalizing unactivated C—H bonds remote from functional groups by electrostatic orientation of the reagent.

According to *Deno*[1] 1-hexanol, hexyl methyl ether, and hexanoic acid are chlorinated up to more than 90 % in the (ω − 1) position when treated with *N*-chlorodiisopropylamine in sulfuric acid (concentration: 72 %, 84 %, and 84 %, respectively). We have found that the C_6- to C_{12}-diacids are photochlorinated regioselectively at methylene groups situated in the middle of the chain with this reagent in sulfuric acid (Table 1).

In this radical chain substitution[3] the protonated CO_2H groups[4] could conceivably direct the H-withdrawing diisopropylamine radical cation electrostatically into the middle of the dicarboxylic acid.

Table 1. Chlorination of dicarboxylic acids with *N*-chlorodiisopropylamine in sulfuric acid.

	H_2SO_4 conc. [wt. %]	Distribution of isomers of the monochlorinated dicarboxylic acids [%] [a] α	β	γ	δ	ε	Conversion [%] [b]	Polychlorinated dicarboxylic acids [%] [a]

meric chlorodicarboxylic acids were converted into the dimethylamino derivatives in order to obtain a specific fragmentation. For example, the methyl esters of the isomeric dimethylaminodecanedioic acids cleave into the characteristic fragments: *m/e* 158, 172 (δ), 186, 144 (γ), 200, 130 (β). The CHCl proton of the dimethyl ester of the predominantly occurring chlorodecanedioic acid shows the same shift as the δ-CH_2 proton of unsubstituted dimethyl decanoate at various $Eu(fod)_3$ concentrations.

Experimental:

A solution of *N*-chlorodiisopropylamine (50 mmol) and decanedioic acid (50 mmol) in 85 % sulfuric acid (80 ml) under nitrogen is irradiated (Hg high-pressure lamp TQ 150, Hanau) at room temperature for 2.5 h; thereafter no more active chlorine was detectable with potassium iodide/ammonium acetate/starch. The reaction solution is finally poured into 150 ml ice-water; the precipitated product (11.2 g after drying in a vacuum) is filtered off and washed twice with cold dilute hydrochloric acid. Extraction of the combined aqueous phases for one day with ether affords (after drying in a vacuum) a further 0.6 g of the crude mixture of isomers.

Macrocyclic Peptides in Anionic Polymers of Amino Acid *N*-Carboxylic Anhydrides[**]

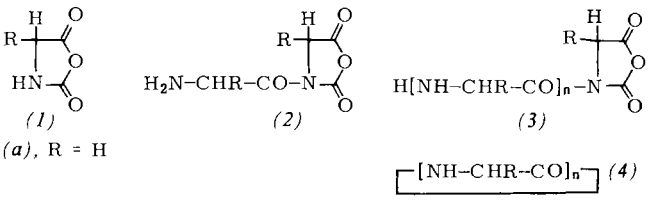
By *Manfred Rothe* and *Dietger Mühlhausen*[*]

Dedicated to Professor Werner Kern on the occasion of his 70th birthday

Amino acid *N*-carboxylic anhydrides (NCA) *(1)* can be polymerized anionically with tertiary bases or inorganic halides (LiCl, NaI)[1]. Reaction of NCA and the NCA anion according to a mechanism resembling that of the anionic lactam polymerization[2, 3] should give rise to initial formation of an *N*-aminoacyl-NCA *(2)*, which then undergoes reaction with further NCA molecules with loss of CO_2 to give poly-α-amino acids having a C-terminal NCA moiety *(3)*.

The isomerization of *(2a)* to 1-hydantoin acetic acid and the cyclization of *(3a)*, $n=5$, to cyclohexaglycyl *(4a)*, $n=6$, are known chain termination reactions.

We have found that glycine-NCA *(1a)* can also give rise to other macrocyclic peptides which could not be indentified previously because of their similarity to polyglycine (sparing solubility, high decomposition points, in part amorphous character). Extraction of anionic polymers with hot water and removal of linear peptides and inorganic salts with ion-



(1) *(2)* *(3)*

(a), R = H

(4)

exchangers afforded a ninhydrin-negative mixture of cyclopeptides which could be separated by gel-permeation chromatography on Merckogel PGM 2000 in water; the peaks were detected by differential refractometry.

Evaluation of the gel chromatograms presented difficulties in the case of cyclic glycine peptides, since the first members of the series up to cyclopentaglycyl deviate from normal chromatographic behavior—evidently owing to their conformations. Only from cyclohexaglycyl onwards is the dependence of the elution volume on log MW approximately linear. This could be demonstrated with ring peptide mixtures obtained by cyclization of linear oligoglycines at moderate concentrations using the phosphite method[4]. In each case the "monomeric" rings are accompanied by cyclic dimers, trimers, and tetramers, *i.e.* diglycine gives cyclotetra-, cyclohexa-, and cyclooctaglycyl along with glycine anhydride and triglycine gives cyclononaglycyl along with cyclohexaglycyl, while cycloocta- and cyclododecaglycyl or cyclodecaglycyl, respectively, are formed as higher ring oligomers from tetra- and pentaglycine.

Combination of the results so obtained together with molecular weight determinations enabled definite assignment of the peaks of all the cyclooligoglycyls mentioned.

Identification of the ring peptides obtained in the anionic polymerization of *(1a)* was accomplished by gel- and thin-layer chromatography and in particular by mass spectrometry (molecular peaks and fragmentation patterns) and comparison of the isolated crystalline products with authentic cyclopeptides synthesized from the linear oligoglycines and 2-chloro-1,3,2-benzodioxaphosphole (*o*-phenylene chlorophosphite) using the dilution technique[4] (cyclotetra-, cyclopenta-[5], cyclohexaglycyl: in each case colorless needles, m. p. (dec) >330 °C, >330 °C, and >350 °C, respectively; yields 35, 18 and 46 %, respectively]. In this way small amounts of cyclotetraglycyl ($m/e=328$) and the new compounds cycloheptaglycyl ($m/e=399$), cyclonona-, and cyclododecaglycyl could be detected in the NCA polymerization. The molecular peaks of the higher, unusually difficultly volatile cyclopeptides had hitherto not been detected; here the ring size is deduced from gel chromatograms. Cyclodi-, cyclotri-, and cyclopentaglycyl were not detected. The type and number of rings formed afford information about the previously largely unknown tendency to form many-membered cyclic peptides and about ring-chain equilibria in polypeptides.

Triorganophosphane-dichloro- and -dibromo-germanediyl and -stannanediyl: Phosphane-Stabilized Ge^{II} and Sn^{II} Halides

By *Wolf-Walther du Mont, Brigitte Neudert, Gero Rudolph,* and *Herbert Schumann*[*]

Silylene-, germylene-, and stannylene-phosphoranes corresponding to methylenephosphoranes are hitherto unknown. Only some phosphane-germanediyls and -stannanediyls formally analogous to methylenephosphoranes have been reported[1,2]. We have found that triorganophosphane-dichloro- and -dibromogermanediyls *(2)* can be obtained by α-elimination reactions from trihalogermylphosphanes *(1)*[3]:

$$[(CH_3)_3C]_2PGeX_3 + R_3P \longrightarrow [(CH_3)_3C]_2PX + R_3PGeX_2$$

(1)

(2a), R = C_6H_5, X = Cl
(2b), R = $(CH_3)_3C$, X = Cl
(2c), R = C_6H_5, X = Br

The fact that this reaction proceeds under very mild conditions—at 20°C in benzene—and the considerable thermal stability of the phosphanedihalogermanediyls indicate a surprisingly high formation tendency of the P—Ge bond in *(2)*. Thus organophosphanes readily displace dioxane from $GeCl_2 \cdot$ dioxane, leading to compounds *(2)* in high yield [*(2a)*: 87%; *(2b)*: 95%]:

$$[GeCl_2 \cdot C_4H_8O_2] + R_3P \longrightarrow R_3PGeCl_2 + C_4H_8O_2$$

Tri-*tert*-butylphosphane even undergoes a corresponding reaction with tin dichloride and dibromide:

$$[(CH_3)_3C]_3P + SnX_2 \longrightarrow [(CH_3)_3C]_3PSnX_2$$

(3a), X = Cl
(3b), X = Br

The adducts *(2)* and *(3)* are obtained as colorless crystals which are moderately soluble in benzene and only sparingly soluble in pentane. The coordination of the phosphorus is shown by ^1H- and ^{31}P-NMR spectra (Table 1).

Formulation of the phosphane-dihalogermanediyls and -stannanediyls as base-stabilized "germylenes" and "stannylenes" *(A)* and not as germylene- and stannylenephosphoranes *(B)* is supported by the following properties of compounds *(2)* and *(3)*: hydrogen chloride immediately cleaves the P—Ge and P—Sn bonds in *(2b)* and *(3a)*, giving phosphonium

$R_3P{:}\rightarrow\ddot{E}X_2$ *(A)* $\qquad R_3P{=}EX_2$ *(B)*

salts of the type $R_3PH^+ECl_3^-$. Fast exchange reactions already occur at room temperature with an excess of phosphane. Thus mixtures of tri-*tert*-butylphosphane with *(2b)*, *(3a)*, or *(3b)* give ^{31}P-NMR spectra invariably showing only one signal whose chemical shift is the average between that for the phosphane [$\delta^{31}P = 62.5$ ppm] and that of its adducts with EX_2. The ^1H-NMR spectra contain only a doublet with "coupling constants" $^3J(^1H^{31}P)$ between 9.8 Hz [tri-*tert*-butylphosphane] and the values for *(2b)*, *(3a)*, or *(3b)* (cf. Table 1).

If the phosphorus in *(2a)* or *(2b)* possesses a further reactive function then dichlorogermanediyl can insert into that bond in a subsequent reaction step, *e.g.*:

$$[GeCl_2 \cdot C_4H_8O_2] + R_2PCl \xrightarrow[-C_4H_8O_2]{} R_2P(GeCl_2)Cl \longrightarrow R_2PGeCl_3$$

R = $C(CH_3)_3$ *(4)* *(1)*

The transformation *(4)*→*(1)* is the first example of germylene insertion into a phosphorus-halogen bond. It demonstrates that α-eliminations of trichlorogermylphosphanes can be reversible. Since the insertion reaction *(4)*→*(1)* is much slower than formation of *(4)* we have been able to identify di-*tert*-butylchlorophosphane-dichlorogermanediyl *(4)* by spectroscopy [$\delta^1H = 1.29$ ppm, $^3J(HP) = 13.6$ Hz; $\delta^{31}P = 127.1$ ppm; $\nu(PGeCl_2) = 330$ and 275 cm^{-1}] and thus confirm the electrophilic attack of the germylene on the phosphorus-chlorine bond.

Tri-tert-butylphosphane-dichlorostannanediyl (3a)

$[(CH_3)_3C]_3P$ (2.0 g, 10 mmol) is added to a suspension of $SnCl_2$ (2.1 g, 11 mmol) in benzene (50 ml). After 2 h, unreacted $SnCl_2$ is separated off and the solution evaporated to dryness under reduced pressure. The colorless residue is dried at 1 torr; yield 3.5 g (90%) of *(3a)*.

Novel Redox Reactions of Tri-*tert*-butylphosphane with Tetrahalides of Germanium and Tin

By *Wolf-Walther du Mont, Brigitte Neudert,* and *Herbert Schumann*[*]

In combination with a tetrahalomethane, tertiary phosphanes are versatile reagents in preparative chemistry. In the absence of substrates triphenylphosphane and CCl_4, for ex-

[*] Prof. Dr. H. Schumann, Dr. W.-W. du Mont, and B. Neudert
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, 1000 Berlin 12 (Germany)

ample, undergo a complicated redox reaction to give dichlorotriphenylphosphorane and (triphenylphosphoranediylchloromethyl)triphenylphosphonium chloride[1]. In contrast, the reaction of phosphanes with the tetrachlorides of silicon, germanium, tin, or titanium has hitherto only been found to yield 1:1 or 2:1 adducts.

We have disovered that tri-*tert*-butylphosphane *(1)*, of which complexes with transition metals in low oxidation states are known, does not form stable addition compounds with element(IV) tetrahalides. Instead, *(1)* is oxidized by the tetrahalides of germanium and tin in benzene solution to give tri-*tert*-butylhalophosphonium salts *(2)*[2].

$$[(CH_3)_3C]_3P + EX_4 \longrightarrow [(CH_3)_3C]_3PX^+EX_3^-$$

(1)

(2a), E = Ge, X = Cl
(2b), E = Ge, X = Br
(2c), E = Sn, X = Cl
(2d), E = Sn, X = Br

Compounds of type (2) have also been formulated for the reaction of phosphanes with tetrahalomethanes (E=C) as ion-pair intermediate but have so far defied detection. The halophosphonium salts *(2a)*—*(2d)* however, are stable compounds open to identification by analysis and spectroscopy. Nevertheless, on variation of the stoichiometry formation of *(2)* may be followed by secondary reactions. Thus the anions $SnCl_5^-$ and $SnCl_6^{2-}$ are formed from $SnCl_4$ and *(2c)*. In the presence of an excess of *(1)* the halophosphonium salts are accompanied by tri-*tert*-butylphosphane-dichloro- and -dibromogermanediyls and stannanediyls which are poorly soluble in benzene[3]:

$$[(CH_3)_3C]_3PX^+EX_3^- + [(CH_3)_3C]_3P \rightleftarrows$$

(2) *(1)*

$$[(CH_3)_3C]_3PX^+X^- + [(CH_3)_3C]_3PEX_2$$

(3a), X = Cl — *(4a)*, E = Ge, X = Cl
(3b), X = Br — *(4b)*, E = Ge, X = Br
(4c), E = Sn, X = Cl

The ionic character of compounds *(2a)*—*(2d)* and *(3)* was established by comparison of vibrational and NMR spectra and of their conductivity with those of tri-*tert*-butyldihalophosphoranes, which also exist in ionic form, and by independent preparation of the chlorophosphonium salts (*e.g. (2c)* from *(3a)* with $SnCl_2$)[4]. The IR spectra of the tri-*tert*-butylhalophosphonium ions display remarkable analogies with those of the isoelectronic tri-*tert*-butylhalosilanes[5]. Two to three stretching vibrations between 500 and 620 cm^{-1} are to be assigned to the inner molecular framework C_3PX (C_{3v}) undergoing coupled vibrations. In keeping with the positive charge and the electronegative substituents at phosphorus the ^{31}P-NMR signals appear at very low field, and variation of the anions expectedly effects slight changes (Table 1).

Table 1. Properties of tri-*tert*-butylhalophosphonium salts *(2)* and *(3)*.

tBu_3PI_2 [2]	145—150 (dec.)	600, 562, 508	92.5	16.55

[a] Composition confirmed by elemental analysis.
[b] In sealed capillaries (Cu block).
[c] Varian XL 100 (40.5 MHz); positive values correspond to downfield shifts relative to 85% H_3PO_4, solutions in CH_2Cl_2/C_6D_6.

The relatively low sensitivity of the cations *(2)* and *(3)* to hydrolysis can be rationalized by stereochemical arguments. The fact that the tetrahalides of germanium and tin behave not only as Lewis acids but also as oxidizing agents towards bases such as R_3P warrants attention.

Tri-tert-butylchlorophosphonium trichlorogermanate(II) (2a):

Compound *(1)* (2.0 g, 10 mmol) is added dropwise to a stirred solution of $GeCl_4$ (2.14 g, 10 mmol) in benzene (20 ml). Two liquid phases appear and the mixture exhibits slight warming. The lower phase is separated and freed from solvent at 0.1 torr/50 °C. Compound *(2a)* (4 g, 95%) is obtained as colorless crystals. The conductivity of a 0.01 M solution of *(2a)* in CH_2Cl_2 is $0.41 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$.

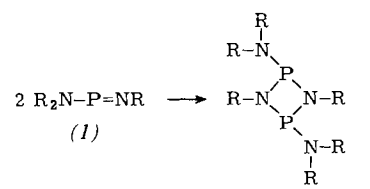
A Phosphorus(III) Derivative with Sterically Fixed Bis(trimethylsilyl)amino Groups[1]

By *Edgar Niecke, Wilhelm Flick*, and *Siegfried Pohl*[*]

According to present knowledge aminoiminophosphanes, phosphorus nitrogen ylides with a doubly coordinated P^{III} atom, are capable of existence in the monomeric form if there are sterically bulky substituents on the amine and imine nitrogens[2].

Especially interesting steric relations were to be expected if a [2+2]-cycloaddition product is observed besides a relatively stable monomer. We report here on the structural investigation of a compound of this type.

Pure bis(trimethylsilyl)aminotrimethylsilyliminophosphane *(1)* cyclizes slowly under inert gas at 25 °C to give 1,3-bis(trimethylsilyl)-*trans*-2,4-bis[bis(trimethylsilyl)amino]-1,3,2λ^3,4λ^3-diazadiphosphetidine *(2)*[3]. The crystalline product (m.p. 204—206 °C) can be obtained in pure form by separation from



the liquid monomer and subsequent repeated washing with small quantities of absolute cyclohexane.

[*] Dr. E. Niecke and Dipl.-Chem. W. Flick

Tammannstrasse 4, 3400 Göttingen (Germany)
Dr. S. Pohl
Fakultät für Chemie der Universität
Universitätsstrasse, 4800 Bielefeld (Germany)

Composition and structure of *(2)* were proved by chemical analysis, mass spectrum, NMR data (^{31}P[4], ^{1}H, ^{29}Si) and by complete X-ray structure analysis.

The ^{1}H-NMR spectrum (10% solution in CH_2Cl_2; TMS int.[5], 25°C) shows three groups of signals with equal intensity—$\{^{31}P\}$: three singlets—which indicate sterically fixed bis(trimethylsilyl)amino groups.

$\delta(>NSiH) = -0.08$ ppm (t), $^{4}J_{HP} = 0.55$ Hz
$\delta(-N<^{SiCH}_{SiCH}) = -0.26$ ppm (t) [6], $|^{4}J_{HP} + {}^{6}J_{HP}| = 3.80$ Hz
$\delta(-N<^{SiCH}_{SiCH}) = -0.52$ ppm (s)

High-temperature ^{1}H-NMR measurements (10% solution in HMPT) do not show significant changes in the spectrum up to 240°C (decomposition) and indicate an extremely high barrier of rotation around the phosphorus-nitrogen bond ($\Delta G^{\ddagger}_{Tc} > 27$ kcal/mol).

In the ^{29}Si-$\{^{1}H\}$-FT NMR spectrum (10% solution in C_6F_6; TMS int.[5]) the different stereochemistry of the two trimethylsilyl groups on the exocyclic nitrogens becomes evident from two differentiated multiplets with pseudo triplet structure[7] as well as from strongly different absolute values of the ^{29}Si-^{31}P interactions.

$\delta(>NSi) = 0.6$ ppm (t), $^{2}J_{SiP} = 7.8$ Hz
$\delta(-N<^{Si}_{Si}) = 1.5$ ppm (t) [6], $|^{2}J_{SiP} + {}^{4}J_{SiP}| = 3.4$ Hz
$\delta(-N<^{Si}_{Si}) = -6.1$ ppm (t) [6], $|^{2}J_{SiP} + {}^{4}J_{SiP}| = 31.0$ Hz

The X-ray structure analysis substantiates the NMR spectroscopic findings. *(2)* crystallizes in the monoclinic space group $P2_1/c$ with $a = 9.370$, $b = 16.348$, $c = 12.985$ Å; $\beta = 119.87°$; $V = 1725$ Å^3; $Z = 2$. The refinement with the structure factors of 2877 observed reflections converged to an R value of 4.5%.

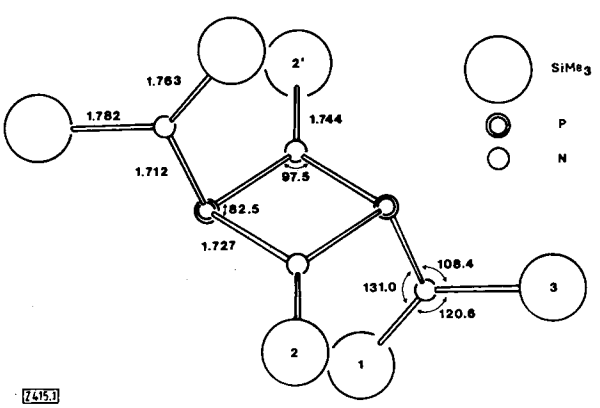

Fig. 1. Molecular structure of the diazadiphosphetidine *(2)*; bond lengths [Å] and bond angles [°].

In the crystal the molecule has C_i symmetry. Consequently, the P_2N_2 ring is exactly planar and the $(Me_3Si)_2N$ groups are *trans* to each other. The Si atoms bonded to the endocyclic nitrogen atoms are also in the plane of the ring. The bonding in the four-membered ring (Fig. 1) is similar to that in other known diaza-λ^3-diphosphetidines[7]. However, the two P—N—Si bond angles on the exocyclic N show an unusually high difference (108.4 *vs.* 131.0°). The abnormally high value of one of them is caused by steric hindrance and fixation of $SiR_{3(1)}$ between $SiR_{3(2)}$ and $SiR_{3(2')}$, the same hindrance leading to the high barrier of rotation within the free molecule in solution. This stereochemistry explains the unusually high difference of the J_{SiP} values in the $PNSi_2$ skeleton, the smaller bond angle belonging to the larger absolute value of the ^{29}Si-^{31}P coupling[8]. As a consequence, there is stronger interaction with the Si atom in ecliptic configuration to the "free" electron pair of the phosphorus atom; this is in agreement with investigations on aminophosphanes with restricted rotation[9].

The results indicate that in *(2)* the limit of steric strain by bulky substituents is evidently reached within the class of [2+2]-cycloaddition products of aminoiminophosphanes. This is in accord with the earlier observation that no cyclization ensues on replacing the trimethylsilyl groups in *(1)* by the sterically still more voluminous *tert*-butyl substituents[2].

Interaction of the Walsh Orbitals in Bicyclopropyl[1]

By *Peter Asmus* and *Martin Klessinger*[*]

The extent of conjugative interaction between the Walsh orbitals of bicyclopropyl has been the topic of numerous studies[2]. Sterically fixed bicyclopropyls, in which the first four PE bands can be assigned to the combinations ω_{as}^{-}, ω_{s}^{-}, ω_{s}^{+}, and ω_{as}^{+} of the Walsh orbitals of the two cyclopropane units[1,3], afford values for the interaction from which it is impossible to estimate to what extent they are modified relative to the values for unsubstituted bicyclopropyls by substituent effects and steric effects. That these effects can reach considerable magnitudes is apparent from the results obtained for the analogous *exo*-dimethylene compounds where $\beta \approx -1.90$ eV compares with the value of $\beta = -2.40$ eV for unsubstituted butadiene[4].

Investigation of unsubstituted bicyclopropyl by photoelectron spectroscopy is difficult because eight ionizations from combinations of the Walsh orbitals of the *trans*- ($\phi = 180°$) and *gauche*-conformation ($\phi = 35$—$40°$) present in a ratio of about 40:60 in the gas phase[5] are predicted to occur in the comparatively narrow range of *ca.* 9—11 eV. Nevertheless, we have now succeeded in analyzing the PE spectrum of unsubstituted bicyclopropyl[6] by comparison with the spectra of sterically fixed bicyclopropyls and the results of MINDO/2 calculations. In this way it can be demonstrated that the strongly conformationally dependent conjugative interaction of the Walsh orbitals measured by the orbital splitting in

[*] Prof. Dr. M. Klessinger and Dipl.-Chem. P. Asmus
Organisch-chemisches Institut der Universität
Orléans-Ring 23, 4400 Münster (Germany)

bicyclopropyl ($\Delta I_{as} = 2.3$—2.5 eV) is of approximately the same magnitude as the interaction of the orbitals of the double bonds in butadiene ($\Delta I = 2.45$ eV), while the substituent effects in the 1,1′-disubstituted sterically fixed bicyclopropyl derivatives considerably reduce this interaction.

It follows from the energies of the Walsh orbitals of unsubstituted bicyclopropyl and 1,1′-dimethylbicyclopropyl calculated as functions of the dihedral angle ϕ by the MINDO/2 method[7] (i) that in unsubstituted bicyclopropyl the splitting $\Delta I_{as} = I(\omega_{as}^{+}) - I(\omega_{as}^{-})$ should be somewhat larger for the *cis*-conformation than for the *trans*-conformation, (ii) that for dihedral angles between 0 and 80°, in keeping with the angular dependence of the resonance integral β, the splitting is given by the relation

$$\Delta I_{as} = \Delta I_{as}^{0} \cos\phi$$

and (iii) that in the *cis*-conformation alkyl substitution, as in the butadiene system, effects both a general destabilization of all orbitals and a reduction of ΔI_{as} by about 0.4 eV.

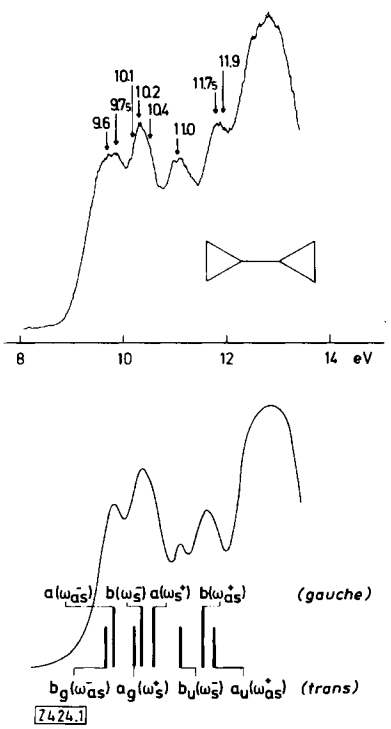

Fig. 1. PE spectrum of bicyclopropyl: above, recorded with a Perkin-Elmer PS 16 instrument (Xe/Ar calibration); below, calculated for *gauche/trans* ≈60:40.

In Figure 1 the spectrum predicted on the basis of MINDO/2 results and the assumption of Lorentz curves of 0.5 eV half-width for a mixture of conformers having the given composition is compared with the measured PE spectrum. Agreement is so good as to apparently justify the assignments given. These data yield a splitting of $\Delta I_{as}(trans) = 2.32$ eV for the *trans*-conformation of unsubstituted bicyclopropyl, corresponding to a HMO resonance integral $= -1.74$ eV, which fits very well into the series of values of $\beta = -2.45$ eV for *trans*-butadiene[8a] and $\beta = -2.1$ eV for the *trans*-form of vinylcyclopropane[8b]. With the aid of the cosine relation the value $\Delta I_{as}(cis) \approx 2.5$ eV is calculated from $\Delta I_{as}(gauche) = 2.00$ eV; the corresponding value of β is *ca.* -1.9 eV. Comparison with the sterically fixed 1,1′-disubstituted bicyclopropyls shows that, as for the *exo*-dimethylene compounds[9], the magnitude of β is reduced by a total amount of about 0.45 eV by the inductive effect of the substituents and by a lengthening of the central CC bond. As in the case of substituted butadienes[8a], a perturbational treatment of the substituent effect accordingly fails to give consistent results[10].

It is striking that in contrast to butadiene the interaction energies $H_{RS} = c_{\rho}^{R} c_{\sigma}^{S} \beta_{\rho\sigma}$ determining the orbital splitting are different for the *cis*- and *trans*-forms of bicyclopropyl: $H_{RS}(cis) = -1.25$ eV and $H_{RS}(trans) = -1.16$ eV (for comparison: $H_{RS} = -1.23$ eV for butadiene).

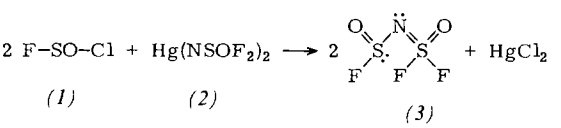
Fluorosulfinylimidosulfur Oxide Difluoride[**]

By *Hans-Joachim Krannich* and *Wolfgang Sundermeyer*[*]

Sulfinyl pseudohalides tend to disproportionate into the corresponding sulfenyl and sulfonyl compounds, which are in turn frequently unstable[1,2]. In contrast, halosulfinyl pseudohalides appear to resist decomposition of this kind[3]. From the hitherto unknown series of the halosulfinylimidosulfur oxide difluorides, X—SO(NSOF$_2$), we have now prepared the fluorine compound *(3)*, X=F, as the first representative by reaction of sulfinyl chloride fluoride *(1)*[4] with mercury bis(imidosulfur oxide difluoride) *(2)*[5].



In a vacuum system, compound *(1)* (12 g) is condensed onto *(2)* (6.5 g) and the suspension stirred for 1 h at room temperature. The volatile components are again condensed onto the same quantity of *(2)* and the mixture once more allowed to react for 1 h. Distillation of the volatile components drawn off affords *(3)* (8.5 g, 78 %) as a water-clear liquid boiling at 64 °C.

[*] Prof. Dr. W. Sundermeyer and Dipl.-Chem. H.-J. Krannich

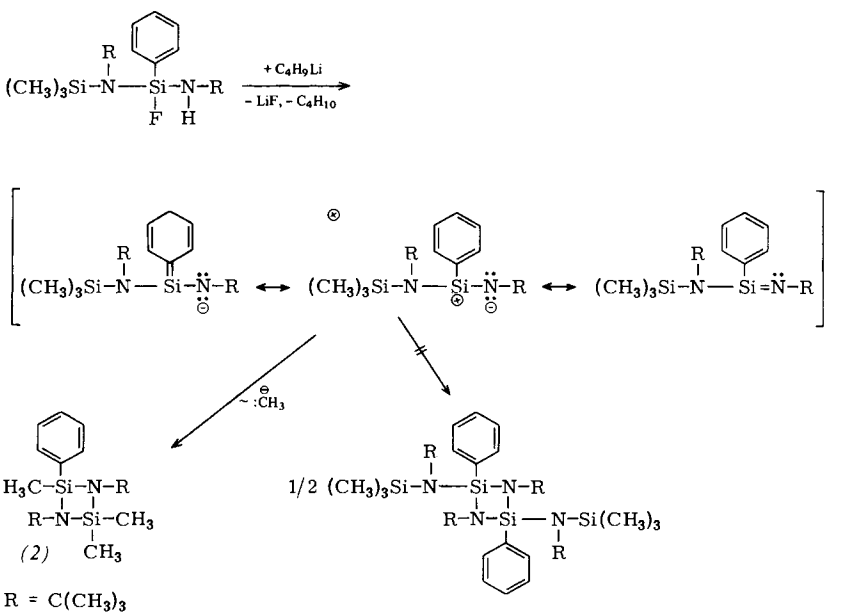
However, if a fluorine atom of *tert*-butylaminodifluorosilane is replaced by an aryl group[4] the reaction takes an unusual course: The product obtained is an unsymmetrically substituted cyclic system whose formation can be attributed to a nucleophilic 1,3-rearrangement at silicon (comparable with the known methyl shift in a carbon skeleton) and also be regarded as evidence for generation of a silicon ylide. The absence of oligomerization products of type *(1)* shows the steric influence of the nitrogen atoms alone to provide insufficient stabilization of such a species with silicon having the coordination number 3[5]. Instead, the expected extremely high reactivity of this intermediate leads to intramolecular nucleophilic substitution with migration of a methanide ion and ring closure to give *(2)*.

Procedure:

C_4H_9Li (0.11 mol, as 15 % solution in hexane) is added dropwise at room temperature to monoalkylaminofluorosilane (0.1 mol) with stirring. An exothermic reaction ensues, liberating lithium fluoride and butane, which is condensed in a cold trap. After boiling for 12 h the hexane is distilled of *in vacuo* and the residue vacuum sublimed.



Nucleophilic 1,3-Rearrangement at Silicon—Indirect Evidence for a Silicon-Nitrogen Ylide[**]

By *Uwe Klingebiel* and *Anton Meller*[*]

Apart from bimolecular ring closure reactions of halosilanes with amines or ammonia[1], stable monoalkylaminofluorosilanes[2] can be cyclized directly by the action of *n*-butyllithium[3], the reaction mechanism being interpretable in intramolecular or intermolecular terms:

Synthesis of an *N*-Lithioaminofluorosilane[**]

By *Uwe Klingebiel* and *Anton Meller*[*]

Although fluorosilanes differ from other halosilanes in their reaction with amines, they nevertheless undergo analogous substitution reactions with the lithium salts of amines[1]. The action of *n*-butyllithium on monoalkylaminofluorosilanes leads *via* loss of lithium fluoride and butane to ring closures of various kinds[2]. With the aim of suppressing such cyclizations and of stabilizing an intermediate silicenium ylide[2] we have prepared the aminofluorosilane *(1)*, exhibiting optimal steric shielding, by reaction of di-*tert*-butyldifluorosilane[3] with lithium *tert*-butylamide:

$$[(CH_3)_3C]_2SiF_2 \xrightarrow[-\,LiF]{+\,LiNHC(CH_3)_3} [(CH_3)_3C]_2\underset{F}{\overset{}{Si}}-\underset{H}{\overset{}{N}}-C(CH_3)_3 \qquad (1)$$

As expected, *(1)* shows little tendency to react with *n*-butyllithium relative to other aminofluorosilanes. Evolution of butane is only observed on raising the temperature, whereupon a colorless solid crystallizes which proves to be the first aminofluorosilane lithiated on the nitrogen atom *(2)*:

$$(1) \xrightarrow[-\,C_4H_{10}]{+\,C_4H_9Li} [(CH_3)_3C]_2\underset{F}{\overset{}{Si}}-\underset{Li}{\overset{}{N}}-C(CH_3)_3 \qquad (2)$$

The ready hydrolysis of *(2)* and its solubility in organic solvents correspond to those of other lithium amides. However, the thermal stability of this compound is remarkable: it only sublimes above 125 °C with partial decomposition and formation of polymeric products. The unusually large upfield shifts of the ^{19}F-NMR signals of *(1)* and *(2)* is explained by the electron pressure of the *tert*-butyl groups. Molecular weight determination and the spatial structure of the compound rule out association of *(2)*. Elemental analysis and vibrational spectra support the structures given.

Procedure:

C_4H_9Li (0.1 mol, 15 % solution in hexane) is added dropwise at room temperature under N_2 to compound *(1)* (0.1 mol) with stirring. Warming of the reaction mixture to *ca.* 50 °C effects liberation of butane which is condensed in a cold trap. The metalation is driven to completion by boiling for another 2 h. The product *(2)* can be purified by recrystallization from hexane or by sublimation at 120 °C/0.1 torr.

Di-tert-butyl(tert-butylamino)fluorosilane (1)

Yield 85 %; b.p. 80 °C/8 torr; MS (70 eV): *m/e* = 233 (rel. int. 1 %, M^+); ^{1}H-NMR (in C_6H_6, TMS int. standard): −1.05 (tBuSi; J_{HF} = 1.0 Hz), −1.20 ppm (tBuN; J_{HF} = 0.8 Hz); ^{19}F-NMR (in C_6H_6, $CFCl_3$ ext. standard): +168.09 ppm, J_{HNF} = 8.0 Hz; ^{29}Si-NMR (in C_6F_6, TMS int. standard; ^{1}H-noise decoupled): −0.7 ppm, J_{SiF} = 300.3 Hz.

N-Lithiodi-tert-butyl(tert-butylamino)fluorosilane (2)

Yield 80 %; m.p. >125 °C (dec.); MW (osmometric in $CHCl_3$): 252; ^{1}H-NMR (in C_6H_6, TMS int. standard): −1.20 (tBuSi), −1.23 ppm (tBuN); ^{19}F-NMR (in C_6H_6, $CFCl_3$ ext. standard): +162.41 ppm.

Nucleophilic Aminoalkylation. Lithiated *N,N*-Dimethylthiopivalamide[1][**]

By *Dieter Seebach* and *Winfried Lubosch*[*]

In the search for activating groups X in *(1)* which permit metalation to *(2)* (CH acidification of amines) several derivatives have been examined. The group X should be such that it is neither attacked by the deprotonating reagent employed (as with X = CN[2], CHO[3], and CHS[4]) nor undergo facile departure from *(2)* as LiX (as with X = NO_2[5] and Tosyl[2]); nor should self-condensation with the precursor *(1)* occur on generation of *(2)* (as with X = benzoyl[6] and $\overset{\oplus}{C}(C_6H_5)_2$[7]),

$$\left[\begin{array}{c} X \\ | \\ R-N-CH_3 \end{array} \longleftrightarrow \begin{array}{c} X^{\ominus} \\ \| \\ R-\overset{\oplus}{N}-CH_3 \end{array}\right] \xrightarrow{\text{Base}} \begin{array}{c} X \\ | \\ R-N-CH_2Li \end{array}$$

(1) (2)

(a), X = NO; (b), X = $(CH_3)_3C-\overset{S}{\overset{\|}{C}}$

and finally the extent of acidification by X should be sufficient to obviate any need for additional stabilization of the carbanionoid center of *(2)* (as with $X = POX_2$[8]). So far only the nitrosamines *(1a)* have proved to be aminomethylation agents of broad scope[2].

We have now found the thiopivaloyl group to be another substituent permitting quantitative metalation to give stable derivatives (up to −50 °C) of type *(2)*. Thus conversion of *(3)* into the organolithium compound *(4)* can be accomplished under the conditions given in the reaction scheme. Reaction of *(4)* with alkyl halides and carbonyl compounds proceeds *via* C—C linkage to form the products *(5)* (Table 1). Alkylations are more successful than hydroxyalkylations;

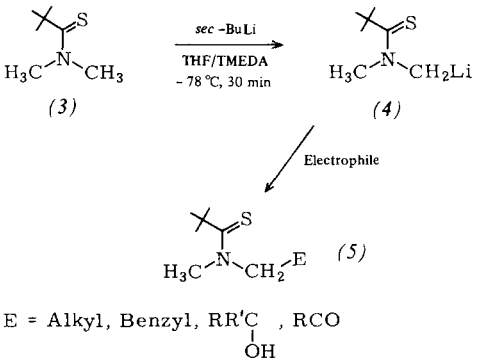

Table 1. Reactions of *(4)* with electrophiles to form products of type *(5)* [a, b].

Electrophile	Yield % spectr. [c]	pure [b]	^{1}H-NMR [d] δ [ppm]
CH_3I	95	80	3.97 (q)

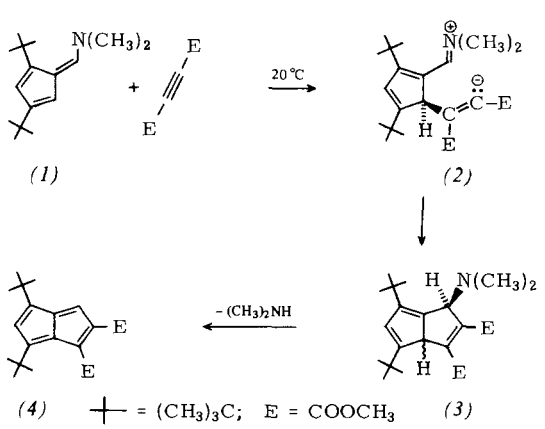
[6+2] Cycloadditions of Pentafulvene. A Facile Pentalene Synthesis[**]

By *Klaus Hafner* and *Minoru Suda*[*]

The hitherto known syntheses of pentalene and its derivatives require several reaction steps and frequently the isolation of rather unstable intermediates[1]. We have found that the [6+2]cycloaddition[2] of 6-dimethylaminofulvenes with electron-deficient acetylene derivatives offers a facile synthesis of pentalenes which can be carried out as a "one batch procedure" at 20 °C.

While 6-dimethylaminofulvene undergoes a Michael addition with dimethyl acetylenedicarboxylate at 20 °C in benzene[3], 1,3-di-*tert*-butyl-6-dimethylaminofulvene *(1)*[4] combines with the alkyne under the same reaction conditions, presumably *via* the dipolar intermediate *(2)* and its cyclization product *(3)*, to give the thermally- and air-stable dimethyl 4,6-di-*tert*-butylpentalene-1,2-dicarboxylate *(4)*.



[*] Prof. Dr. K. Hafner and Dr. M. Suda
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 15, 6100 Darmstadt (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The electronic spectrum of *(4)* (in *n*-hexane) resembles that of 1,3,5-tri-*tert*-butylpentalene[1], except for a bathochromic shift of the longest wavelength maximum by 70 nm [$\lambda_{max}=259$ ($\log\varepsilon=4.29$), 357 (3.71), and 668 nm (2.36)] due to the ester groups. The 60-MHz ^{1}H-NMR spectrum of *(4)* (in $CDCl_3$), which provides proof of structure, consists of six singlets, of which two are assigned to the two ring protons [$\tau=3.85$ (H-3) and 5.07 (H-5)], two to the ester methyl protons ($\tau=6.24$ and 6.36), and two to the *tert*-butyl protons ($\tau=8.96$ and 9.02). The relatively high upfield shift of the H-5 signal indicates the presence of a paramagnetic ring current in *(4)*. The ^{13}C-NMR spectrum of *(4)* (in $CDCl_3$) shows one signal each for the eight ring C atoms at $\delta=129.3$ (C-5), 134.7 (C-3), 135.1, 135.9 (C-1, C-2), 141.6, 143.7 (C-6a, C-3a), 161.7 and 162.9 (C-4, C-6), four signals for the *tert*-butyl C atoms at $\delta=27.9$ and 28.6 (CH_3), 33.0 and 34.9 (quat. C), and four for the ester C atoms at $\delta=51.3$ and 51.9 (CH_3O) and 167.4 and 173.0 (C=O). In contrast to pentalene and its simple alkyl derivatives[5], compound *(4)*, like 1,3,5-tri-*tert*-butylpentalene[1], shows no tendency to dimerize even at elevated temperatures[6].

(5) *(6)*

┼ = $(CH_3)_3C$; R = $COOCH_3$, CHO

Treatment of *(1)* with methyl propiolate or propiolaldehyde affords a *ca.* 40 % yield of the pentalene derivatives *(5)* which are in equilibrium with their dimers *(6)* at room temperature. A study of this equilibrium reaction is in progress.

Dimethyl 4,6-di-tert-butylpentalene-1,2-dicarboxylate (4)

To a solution of *(1)* (1.17 g, 5.0 mmol) in anhydrous benzene (50 mol) is added dimethyl acetylenedicarboxylate (1.50 g, 10.6 mmol) at room temperature. After 2 h, the solvent is removed from the green reaction solution *in vacuo* and the residue chromatographed over silica gel (Kieselgel 60, Merck) with *n*-hexane/ether (10:1). The eluate of the leading blue zone is extensively concentrated at room temperature *in vacuo* and the residue cooled to −70 °C. The fine blue crystals precipitated are filtered off. Compound *(4)* (0.73 g, 44 %) is isolated analytically pure; it is obtained as blue plates, m.p. 120—121 °C, by recrystallization from *n*-hexane.

(Dichloromethylene)triphenylphosphorane

By *Rolf Appel*, *Fritz Knoll*, and *Harald Veltmann*[*]

(Dichloromethylene)triphenylphosphorane *(3)* is obtained from triphenylphosphane and dichlorocarbene, which is generated from chloroform and potassium *tert*-butoxide[1] during the reaction. On reaction of triphenylphosphane with carbon tetrachloride the species *(3)* also arises as a short-lived intermediate[2], which resists isolation—just as in the preparation according to ref. [1]—and can only be detected by Wittig reaction with carbonyl compounds.

The first indications of a possible isolation were provided by attempted preparations of *(3)* by dechlorination of (trichloromethyl)triphenylphosphonium chloride *(1)* and dehydrochlorination of (dichloromethyl)triphenylphosphonium chloride *(5)* with an excess of bis(triphenylphosphoranylidene)methane according to equations (a) and (b), respectively[3].

$$\underset{(1)}{[Ph_3P{-}CCl_3]^{\oplus}\,Cl^{\ominus}} + \underset{(2)}{C(=PPh_3)_2} \longrightarrow \quad (a)$$

$$\underset{(3)}{Ph_3P{=}CCl_2} + \underset{(4)}{[Ph_3P{=}CCl{=}PPh_3]^{\oplus}\,Cl^{\ominus}}$$

$$\underset{(5)}{[Ph_3P{-}CHCl_2]^{\oplus}\,Cl^{\ominus}} + \underset{(2)}{C(=PPh_3)_2} \longrightarrow \quad (b)$$

$$\underset{(3)}{Ph_3P{=}CCl_2} + \underset{(6)}{[Ph_3P{=}CH{=}PPh_3]^{\oplus}\,Cl^{\ominus}}$$

During the reactions, which were performed in acetonitrile and dichloromethane, respectively, a singlet appeared in the ^{31}P-NMR spectrum (85 % H_3PO_4 as external standard) at −21.6 ppm which was not observed in any of the other preparations; it disappeared immediately upon addition of benzaldehyde. Thereafter triphenylphosphane oxide and β,β-dichlorostyrene could be detected.

This signal also gradually disappears in the absence of benzaldehyde, thus suggesting a deprotonation reaction of the ylide *(3)* with solvents. In order to record the ^{13}C-NMR spectrum the salt *(5)* bearing a ^{13}C label at the alkyl carbon atom was therefore treated with *(2)* in a deuteriobenzene suspension. The signal of the ylidic C atom which is split into a doublet by phosphorus coupling is seen at $\delta=-73.9$ ppm ($J_{P,^{13}C}=72.3$ Hz; minus sign indicates downfield shift). It was established by ^{13}C-NMR spectroscopy that hydrolysis of *(3)* affords only dichloromethane and triphenylphosphane oxide (TMS as internal standard).

Preparative scale isolation of the pure salt-free ylide *(3)* synthesized according to eq. (b) depends crucially upon the use of an aprotic solvent with which the strongly basic ylide is unable to form a corresponding acid-base pair. A suitable solvent system proved to be a mixture of chlorobenzene and toluene in which *(3)* displays adequate solubility. On removal of the solvent it remains behind as a yellow substance decomposing between 115 and 122 °C, which can be stored for several days. In contrast, solutions of *(3)* can only be stored for limited periods; they turn darker and darker while depositing a coating on the wall of the vessel. Apart from the ^{13}C-NMR spectrum, elemental analysis and cryoscopic molecular mass

[*] Prof. Dr. R. Appel, Dr. F. Knoll, and Dipl.-Chem. H. Veltmann
Anorganisch-Chemisches Institut der Universität
Max-Planck-Strasse 1, 5300 Bonn (Germany)

determination (calc. 345.2, exp. 335) confirm the existence and the monomeric structure of *(3)*. The mass spectrum contains the molecular peak ($m/e = 344$), accompanied by satellites due to the two chlorine atoms, at an ionization voltage of 13 eV.

Dehydrochlorination of (chloromethyl)triphenylphosphonium chloride *(7)* with an excess of *(2)* affords the (chloromethylene)phosphorane *(8)* whose ^{31}P-NMR signal is observed at -16.9 ppm. In contrast, the reaction according to eq. (d) is found on monitoring by ^{31}P-NMR spectroscopy to lead merely to a broadening of the signals of the starting compounds, which is probably attributable to comparable basicities of the two ylide systems coupled with a fast proton exchange.

$$\underset{(7)}{[Ph_3P{-}CH_2Cl]^{\oplus}\,Cl^{\ominus}} + \underset{}{(2)} \longrightarrow \underset{(8)}{Ph_3P{=}CHCl} + \underset{}{(6)} \qquad (c)$$

$$\underset{(9)}{[Ph_3P{-}CH_3]^{\oplus}\,Cl^{\ominus}} + \underset{}{(2)} \rightleftharpoons \underset{(10)}{Ph_3P{=}CH_2} + \underset{}{(6)} \qquad (d)$$

(Dichloromethylene)triphenylphosphorane (3)

Compounds *(5)*[4] (3.81 g, 0.01 mol) and *(2)*[5] (6.7 g, 0.0125 mol) are stirred together at room temperature for 6 h in chlorobenzene (10 ml) and toluene (15 ml). After filtration (glass frit) and washing (3×10 ml of toluene) of the residue consisting of *(6)* and excess *(2)* the clear filtrate is gently evaporated to dryness in a vacuum. Compound *(3)* (1.9 g, 55 %) is obtained as a yellow powder which can be redissolved as the monomer in toluene.

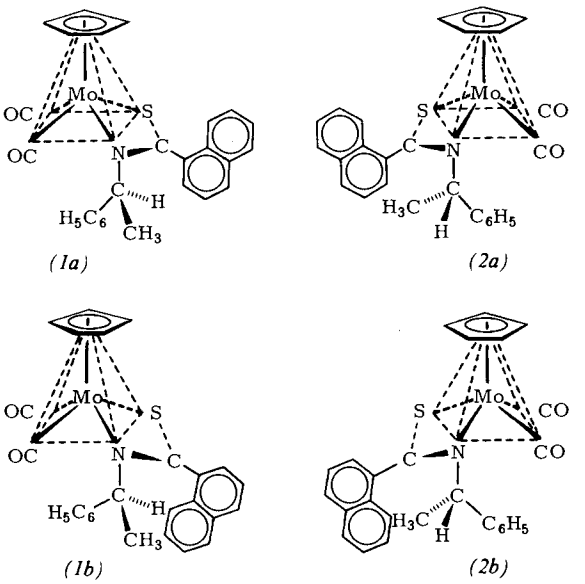
1-Naphthyl Rotation and Metal-Centered Rearrangement in Square-Pyramidal Molybdenum Complexes[1]

By *Henri Brunner* and *Joachim Wachter*[*]

In the thioamide complexes $C_5H_5(CO)_2MoSC(R)NR^*$ the Mo atom is a center of asymmetry[2]. Resolvable diastereoisomeric pairs are obtained with $R^* = (S)$-α-phenylethyl[2, 3]. At elevated temperatures the diastereomers undergo mutual interconversion *via* first-order intramolecular reactions[2, 4].

While the ^{1}H-NMR spectra of complexes with R = H, CH_3, and C_6H_5 show only two C_5H_5 singlets and two CH_3 doublets for each pair of diastereomers[5], twice as many signals are observed for the compound with R = 1-naphthyl. This is because each Mo configuration *(1)* and *(2)* forms two atropisomers *(1a)/(1b)* and *(2a)/(2b)* with the 1-naphthyl groups in different orientations[6].



The four isomers arise on reaction of $C_5H_5Mo(CO)_3Cl$ with (*S*)-(−)-*N*-(α-phenylethyl)-1-naphthothioamide in pyridine at 130 °C. The configurational isomers *(1)* and *(2)* can be obtained optically pure by fractional crystallization from ether/pentane (10:1)[5]. The sparingly soluble isomer *(1)* ($[\alpha]_{365}^{20} = -4035°$; 0.3 mg/ml in toluene) gives a ^{1}H-NMR spectrum (90 MHz, $CDCl_3$, −10 °C) containing two C_5H_5 signals at $\tau = 4.38$ and 4.46 (isomer ratio *(1a)*:*(1b)* = 81:19). The C_5H_5 signals of the readily soluble isomer *(2)* ($[\alpha]_{365}^{20} = +3135°$; 0.5 mg/ml in toluene) lie at $\tau = 5.05$ and 5.08 (isomer ratio *(2a)*:*(2b)* = 64:36). The splitting and intensities of the methyl signals resemble those for the C_5H_5 signals.

In $CDCl_3$ solution at 25 °C the intensity of the C_5H_5 signals of optically pure *(2)* gradually diminishes; a concomitant growth of the C_5H_5 signals of *(1)* progresses up to equilibration at *(1)*:*(2)* = 13:87. The time-dependence of the integrals (51 measurements)[7] affords the rate constants $k_{(1)\rightarrow(2)} = 5.36 \times 10^{-5} \pm 0.66 \times 10^{-6}$ s^{-1} and $k_{(2)\rightarrow(1)} = 9.19 \times 10^{-6} \pm 0.23 \times 10^{-6}$ s^{-1} as well as the activation energies $\Delta G^{\ddagger}_{(1)\rightarrow(2)} = 23.3 \pm 0.1$ kcal/mol and $\Delta G^{\ddagger}_{(2)\rightarrow(1)} = 24.3 \pm 0.1$ kcal/mol. The half-life of 184 ± 2 min for the equilibration *(1)* ⇄ *(2)* is comparable with the epimerization rates of other thioamide complexes[5]. Hence the observed process is ascribed to a configurational change at the Mo atom.

On heating of *(1)* or *(2)* in toluene solution the epimerization equilibrium is rapidly established ($\tau_{1/2}$ at 60 °C *ca.* 1.5 min, extrapolated). The C_5H_5 signals exhibit concomitant broadening. At 63 °C the dominant isomer *(2)* exhibits coalescence; at 80 °C the C_5H_5 signals of *(1)* and *(2)* are singlets, and the methyl signals doublets. The rate constants $k_{(2a)\rightarrow(2b)} = 2.31 \pm 1$ s^{-1} and $k_{(2b)\rightarrow(2a)} = 4.32 \pm 1$ s^{-1} and the activation energies $\Delta G^{\ddagger}_{(2a)\rightarrow(2b)} = 19.2 \pm 0.3$ kcal/mol and $\Delta G^{\ddagger}_{(2b)\rightarrow(2a)} = 18.8 \pm 0.3$ kcal/mol were calculated with the aid of the following parameters[8]: coalescence temperature $T_c = 336 \pm 0.3$ °K; linewidth $b_E = 0.6$ Hz; chemical shift $\Delta\nu = 2.63$ Hz (extrapolated to the coalescense temperature); equilibrium constant $K = 0.55 \pm 0.05$. This process is assigned to 1-naphthyl rotation in *(2)*. The much lower intensity of

[*] Prof. Dr. H. Brunner und Dipl.-Chem. J. Wachter
Institut für Chemie der Universität
Universitätsstrasse 31, 8400 Regensburg 2 (Germany)

the C_5H_5 signals precludes accurate determination of the values for *(1)*.

In contrast to the 1-naphthyl complexes *(1)*/*(2)*, the corresponding 2-naphthyl complex does not appear to display any barrier to rotation. Each diastereomer gives only one C_5H_5 signal, which fails to split even on cooling to −80°C in [D_8]-toluene.

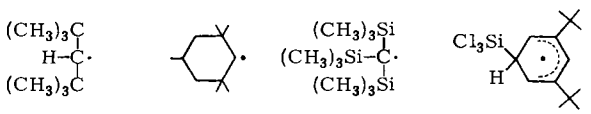
Reviews

Abstracts of selected progress reports and review articles

Persistent carbon-centered radicals are the theme of an article by *D. Griller* and *K. U. Ingold*. The authors suggest this term to symbolize radicals whose lifetime in solution is considerably longer than that of the methyl radical. Under certain experimental conditions the persistence of a radical can be expressed by the rate constant of its decomposition. Triphenylmethyl is a persistent radical; benzyl, vinyl, *tert*-butyl, *etc.*



(1) *(2)* *(3)* *(4)*

are transient radicals. The thermodynamic stabilization or destabilization of a radical must be considered apart. After it had been shown that steric and non-electronic factors play the principal role in persistence, several persistent radicals were synthesized; examples are *(1)*—*(4)*. [Persistent Carbon-Centered Radicals. Acc. Chem. Res. *9*, 13—19 (1976); 46 references]

The distinction between concerted and nonconcerted eliminations is the subject of review by *E. H. Saunders, Jr.* A few years ago there was a certain amount of doubt that concerted reactions, especially E2 eliminations [Eq. (1)], are of frequent occurrence[*]. Instead, it was proposed that eliminations proceed according to the irreversible carbanion mechanism $(E1cB)_i$ [Eq. (2) and (3)] or the ion-pair mechanism $(E2)_{ip}$, [Eq. (4) and (5)]:

(3)

(4)

(5)

In an E2 process the β H atom is partly detached and the C—X bond partly opened in the transition state of the rate-determining step. It can be concluded from eliminations on β-deuteriated compounds and other experiments that almost all second order eliminations of simple primary and secondary derivatives follow the E2 mechanism. In tertiary and allylic derivatives or α-arylalkyl compounds it is still undecided whether or not the ion-pair mechanism is at issue in many cases. The stereochemical consequences of correlated rotation in propeller molecules are dealt with in an article by *K. Mislow*. Examples are compounds of type *(1)*—*(3)* ($a \neq b \neq c$), whose substituents contain no stereoisomeric elements. Each rotation of a ring about the B-aryl or CH-aryl bond is accompanied by rotation of the other rings; this coupled motion is referred

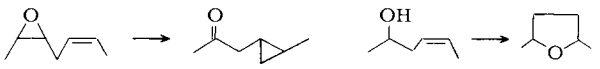
(1) *(2)* *(3)*

to as correlated rotation. Both the static and the dynamic stereochemistry of these molecules are first discussed. Three further sections of the article are devoted to stereochemical agreements, residual stereoisomerism, and residual stereotopism. [Stereochemical Consequences of Correlated Rotation in Molecular Propellers. Acc. Chem. Res. *9*, 26—33 (1976); 23 references]

[Rd 847 IE—L]

Some new chemical properties of unsaturated C_{18} acids are described by *F. D. Gunstone*. Particularly interesting are the

reactions involving neighboring group participation. Examples are the BF_3-induced transformation of epoxyalkenoic esters *(1)* into cyclopropane oxoesters *(2)* and the acid-catalyzed



(1) *(2)* *(3)* *(4)*

cyclization of polyhydroxy acids *(3)* to tetrahydrofuran derivatives *(4)*. (Only partial structures are given in each case.) [Some New Chemical Properties of Unsaturated C_{18} Acids. Acc. Chem. Res. *9*, 34—40 (1976); 26 references]

[Rd 848 IE—L]

A survey of hormone-receptor interactions has been written by *E. J. M. Helmreich*. It is not yet known how the hormone-receptor reaction is transformed into biological action. An important, though not universal, mechanism involves the activation of adenyl cyclase which generates the "second messenger" 3',5'-cyclic AMP. Hormone-receptor complexes are extremely long-lived; half-lives of 15 to 40 min have been measured for the complex of insulin. This tends to rule out any regulatory function of the complex in the overall process. It must therefore be asked how the interaction between hormone and receptor is modulated. One proposal is that of a negative cooperativity facilitating dissociation of the complex, and another one, applying in cases of positive cooperativity or none at all, assumes that regulation occurs beyond the stage of hormone-receptor interaction, say in an interaction between hormone-receptor complex and adenyl cyclase. [Hormone-Receptor Interactions. FEBS Lett. *61*, 1—5 (1976); 25 references]

[Rd 850 IE—R]

The bioenergetics of mitochondria in brown adipose tissue is considered by *D. G. Nichols*. In these cell organelles, found mainly in hibernating animals, a cold stimulus leads to generation of heat by oxidation of fatty acids. A mechanism must therefore exist for circumventing the coupling of oxidation rate to ATP production occurring in normal cells. This mechanism is seen in a nucleotide-dependent enhanced proton conductance by the membrane whose characteristics are in accord with *in vivo* thermogenesis. Uncertainty still surrounds the modulation of proton conduction *in vivo*. [The Bioenergetics of Brown Adipose Tissue Mitochondria. FEBS Lett. *61*, 103—110 (1976); 43 references]

[Rd 851 IE—R]

The legume storage proteins legumin and vicilin are the topic of an article by *E. Derbyshire, D. J. Wright*, and *D. Boulter*. Their localization and distribution in the seeds are described and methods for their extraction, purification, and characterization viewed in the light of modern biochemical practice. The physical, chemical, and immunological properties of the "classical" preparations from *Pisum sativum* are surveyed and compared with those of similar legumin and vicilin preparations from other leguminous plants. [Legumin and Vicilin, Storage Proteins of Legume Seeds. Phytochemistry *15*, 3—24 (1976); 271 references]

BOOK REVIEWS

Molekülgeometrie. Elektronenpaar-Abstossung und molekulare Struktur (Molecular Geometry. Electron Pair Repulsion and Molecular Structure). By *R. J. Gillespie*. Translated by *J. Grobe*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., xiii, 232 pp., 153 figs., 62 tables, paper, DM 29.80.

The Gillespie-Nyholm model concept of the consequences, to molecular geometry, of electron pair repulsion in the valence shell of molecules (*V*alence *S*hell *E*lectron *P*air *R*epulsion theory, VSEPR model) have proved extremely useful for systematizing the existing structural data and for predicting previously unknown structures. The simplicity of the model's principles promotes its use in teaching and study and makes the "theory" an important didactic and heuristic aid. It is therefore good to see this book by one of the model's founders, on the evolution and successes of the VSEPR concept, in a German translation. Thus, in an externally attractive form and at a reasonable price, teachers and students in the widest sense can discover for themselves the breadth of a concept whose beginnings go back to *G. N. Lewis*, but which has now been thought through afresh on the basis of much more extensive factual material. In so doing one is astonished to find how many structural details, often puzzling when looked at in isolation, can now be fitted in with very little difficulty.

This last phrase "with very little difficulty" must, however, be looked at more carefully for in spite of the very clear explanations and the many and successful illustrations, one cannot avoid the impression that things really cannot be quite so simple. The striking appeal of the model must not be allowed to overshadow the fact that much can indeed now be systematized anew, but fundamentally is not better "understood". This becomes clear on the introduction of ideas such as the "secondary valence shell" which is essential *e.g.* for the interpretation of the bonding state in the oxygen molecule. Here one would like to see some mention of the MO model which in its time was able to give a convincing answer to this problem. For such a courageous comparison of the capabilities of the relevant models one must wait until the last 15 pages, and then it is too late. It is hoped that the reader will not succumb to the temptation of this little book and willingly throw overboard all that he had previously learnt about bonding and structural matters: he may still need it.

Hubert Schmidbaur [NB 307 IE]

Biochemie (Biochemistry). By *A. L. Lehninger*. Translated by *K. Fischer* and *R. Ries*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., xv, 747 pp., 468 figs., 94 tables, paperback DM 68.—, bound DM 78.—.

Since the first edition appeared four years ago, *Lehninger*'s "Biochemistry" has set a standard as the most comprehensive one-man textbook of biochemistry that is also modern in conception. This standard is confirmed by the almost universal agreement in reviews and has been exceeded by hardly any other textbook. Lehninger has rightly become the favorite textbook for the advanced biochemist, since it presents the coordinated filigree work of the functional interactions between cell components, *i.e.* the "molecular logic of the

organism", in an easy, readable, and nearly always correct manner. Verlag Chemie have taken the risk of bringing a translation of this compendium onto the much more limited German market, and have succeeded technically and linguistically, for one sees many students carrying the monster book and finds the fat blue volume in numerous libraries.

The advantage of the German translation is obvious, even for one who believes he gets on passably with English, for one can complete a search faster if one is not chasing linguistic details. The translation is consistently successful, even if a little lifeless; it misses the sparkling spirit and the rhythm of the original. On the other hand, the translators have also carefully but silently managed to remove many of the factual errors in the original and to extend the reference lists by numerous easily accessible reviews in the German literature and international monographs, thereby providing a real service to the German reader. The conversion of calories into joules is often carried out with excessive confidence in numbers, but the priggish and unspeakable "katal" is not yet included. The weaknesses of the original in the thermodynamic chapters, in the stereochemistry, and in the set problems naturally appear also in the translation, but these minor failings can be overlooked in view of the extraordinary didactic and factual merits of the book. Nevertheless, the avoidable externals are really disturbing: the oversize format of a pulpit bible—still harder to handle than the English edition—the poor contrast of the colors in many illustrations that are more vividly colored in the original, and above all the shiny yellow paper on which the whole book is printed; no one can work with it at night without troublesome and continuous adjustment, and anyone who likes to underline as an aid to memory will have no joy with this book. Finally, the purchaser will feel slightly cheated when he discovers that simultaneously with this translation an improved and expanded English edition has appeared at about half the price. All this hardly decreases the value of this textbook for the student, who will find in it much more than he is generally able to assimilate. In any case, the German Lehninger will undoubtedly become as greatly liked by students and teachers in Germany as its counterpart is in America, and that with complete justification.

L. Jaenicke [NB 308 IE]

Allgemeine und Anorganische Chemie (General and Inorganic Chemistry). By *V. Gutmann* and *E. Hengge*. Verlag Chemie, GmbH, Weinheim 1975. 2nd revised and expanded edit., xi, 397 pp., 160 figs., 124 tables, paperback DM 39.—.

In spite of all the enthusiasm with which "general chemistry" was introduced in recent years into various universities, this textbook also shows that general chemistry should not be taught in isolation from experimental chemistry. Accordingly, the material is divided into two parts: general chemistry and inorganic chemistry. The chapters in the first part describe: 1) atomic structure and the periodic system; 2) the nature of chemical reactions with new sections on free energy and reaction kinetics; 3) the chemical bond; this chapter has been extensively reworked from the first edition; 4) states of matter (such as gases, liquids, and solids) and crystal structure; 5) a newly arranged chapter on electron-acceptor-donor interactions which underlie the known concepts of redox reactions, coordination-chemical interactions, solubility, and ion formation. There follow: 6) acid-base considerations; 7) electrochemistry; 8) magnetochemistry, and 9) the structure of complexes (VB methods, ligand field theory, π-complexes).

The second part provides in terse form basic knowledge on the chemistry of the main-group and subgroup elements. To each section in the second part are added problems whose answers can be discovered from the text. Although some sections, *e.g.* those on the hydrogen spectrum, electronegativity, ion-exchangers, and magnetochemistry, are treated very briefly, this textbook contains much to stimulate the student and the teacher and can be recommended as a text to accompany a course on general and inorganic chemistry. Clear illustrations and carefully chosen tables aid understanding, particularly since the publishers have been able to improve the printing of the second edition.

Hk. Müller-Buschbaum [NB 310 IE]

Analysis of Water. By *J. Rodier*. Translated from the 5th French edition. Israel Program for Scientific Translations, John Wiley & Sons, New York—Toronto, and Keter Publishing House Ltd., Jerusalem 1975. 1st Edit., xvii, 926 pp., numerous figs. and tables, bound $ 76.50.

This analytical handbook is divided into the following main sections: analysis of natural waters (447 pp.), of waste waters (108 pp.), and sea water (by *Laporte* and *Kovacsik*, 42 pp.), bacteriological analysis (*Geoffray* and *Vial* 82 pp.), biological quality of fresh water (*Verneaux*, 23 pp.), and interpretation of results (78 pp.). In addition, there is an appendix (138 pp.), with sections on, *inter alia*, instrumental methods, statistical control and evaluation procedures, sediment analysis, degradation of detergents (not the OECD test), and numerous ancillary tables. The main chapters devoted to the three types of water are subdivided in the same way and consider sampling, immediate evaluation of a sample and determination of its physicochemical characteristics, and determination of the constituents and typical sum and action parameters by classical and modern methods (*e.g.* polarography, atomic absorption spectroscopy, use of ion-sensitive electrodes), including radioactive measurements. With respect to the bacteriological investigations, questions of collecting and handling the samples are treated, as well as testing for bacteria that indicate fecal pollution and important pathogens, while for the assessment of the water quality consideration is given to methods based on Saprobia systems, various fish tests, and biocenotic analysis.

The choice of the methods considered naturally shows individual streaks. Thus, the main weight is beyond doubt placed on the study of drinking water. The methods discussed there cannot, however, always be so simply applied to waste waters as is made to appear in Chapter 2. Furthermore, evaluation of the results of chemical analysis is restricted to one parameter and hardly at all concerned with comparable interpretation of several analytical values; this is unavoidable for usable and waste water in order to obtain information not directly measurable on the water under study. On looking through the book an error of translation—and a serious one—was noticed: "une eau résiduaire urbaine fraîche" for obtaining inoculation material for the BOD determination became "fresh urban tap water".

Considered as a whole, the book is a collection of prescriptions of wide range and notable completeness, in which, as the references cited show, the complete technical literature of the Western hemisphere has been considered, even if in particular German-language literature is not always given equal weight. Unfortunately, the work is not as up to date as would be desirable: the few citations from the 1970's are almost all from French sources, and very few of them are original papers. Thus, the book does not contain some important new developments, *e.g.* nitrification inhibition in the BOD determination; at the same time, it contains some data that have been revised, *e.g.* the table of temperature corrections for measurements of the electrical conductivity.

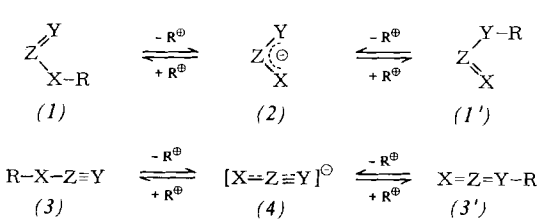
The Concept of Allopolarization. Effects of Substituents on the Reactions of Ambifunctional Anions

By Rudolf Gompper and Hans-Ulrich Wagner[*]

The chemistry of ambifunctional anions is of great importance in organic preparations. Planning of syntheses requires a set of rules correlating structure and selectivity. The concept of allopolarization permits a description of substituent effects on kinetically controlled reactions: the change in selectivity is a function of the change in polarity of the ambifunctional anions. The relative charge density $P = l_X/l_Y$ serves as "polarity index"; X and Y are the potential sites of reaction. An attempt is made to illustrate the utility of this principle by means of examples taken from various classes of compounds.

1. Introduction

Owing to their great preparative significance in all areas of chemistry, the reactions of ambifunctional (ambident[11]) compounds have always posed a mechanistic challenge to the chemist (cf. refs. [1–14]). The term "ambifunctional" cannot easily be defined unequivocally; the following statements are restricted to conjugated systems of the general formulas *(1)*, *(1')* and *(3)*, *(3')*, and in particular to the



anions *(2)* and *(4)*. Compounds *(1)* to *(4)* characteristically react with electrophiles in positions 1 *or* 3, *i.e.* at X *or* Y.

A concept common to all theories of ambifunctional reactivity is that two factors are primarily responsible for product formation, *viz.* the polarity (charge, "hardness") of the two reactants on the one hand, and their polarizability (frontier orbital coefficients, "softness") on the other. This dualism has been expressed particularly clearly in the concept of hard and soft acids and bases (HSAB concept)[13] and in the idea[9, 10, 12, 14] that the chemical reactivity results from the interplay of "charge control" and "orbital control".

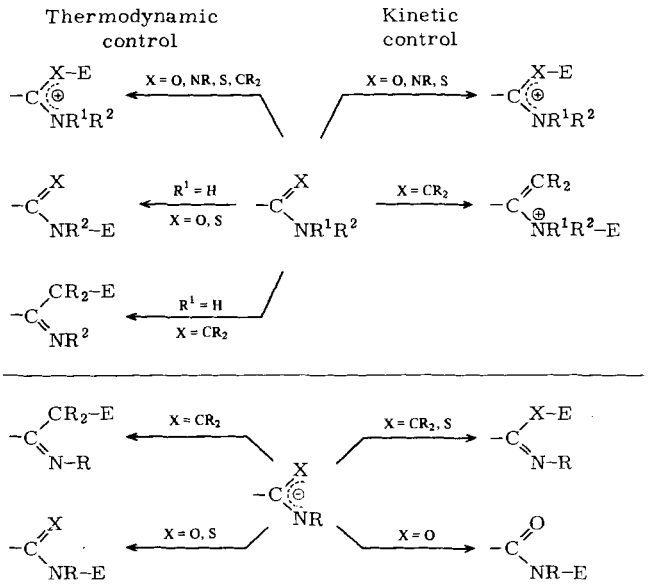
Apparently limited in scope, the HSAB concept, which reflects the formal distinction between covalent and heterovalent bonds, has its champions[15] and its critics[16]. The problems encountered in applying it to the reactions of ambifunctional compounds are clear from Scheme 1 (substituent effects being neglected).

a) The HSAB concept makes no distinction between kinetic and thermodynamic control, although different products are formed in many cases.

b) The "hardness" of the site X has a differential effect upon the reactions of the uncharged compounds and their anions (amides, for instance, are *O*-alkylated on kinetic control, while amide anions are *N*-alkylated).

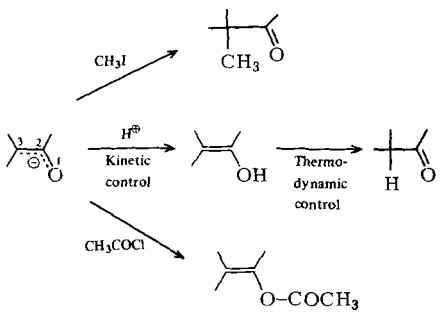
Similar difficulties are seen on examining the "perturbational treatment of chemical reactivity"[9, 10, 12, 14] for its applicability to the planning of syntheses. Any decision whether charge or orbital control predominates in a reaction is usually reached

[*] Prof. Dr. R. Gompper and Dr. H.-U. Wagner
Institut für Organische Chemie der Universität
Karlstrasse 23, 8000 München 2 (Germany)



Scheme 1. Reactions of some ambifunctional systems with electrophiles ($E^{\oplus}$).

a posteriori on the basis of experimental results. At best, crude predictions of reactivity are possible for entire classes of compounds, for instance, the enolate ions shown in Scheme 2.



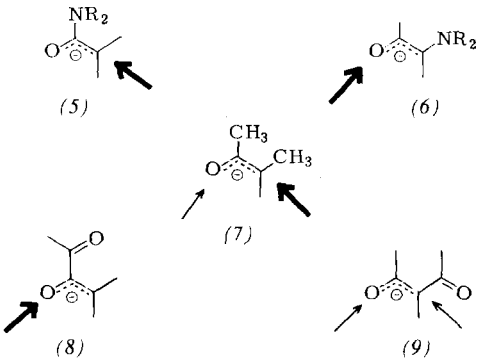
Scheme 2. Reactions of the enolate ion. Frontier orbital coefficients: $c^2_{3,\mathrm{HOMO}}=0.543$, $c^2_{1,\mathrm{HOMO}}=0.349$; charge densities $l_3=-0.301$, $l_1=-0.785$.

Formation of enols on kinetically controlled protonation (ketones usually have the greater thermodynamic stability) and occurrence of enol esters on acylation with acyl chlorides and carboxylic anhydrides[17] can be interpreted by the hardness of HX and RCO—X as electrophiles; they consequently undergo charge-controlled reaction with the enolate O atom which bears the major part of the negative charge.

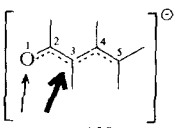
In comparison with HX and RCO—X, methyl iodide is a "soft" nonpolar reagent. Since C-3 of the enolate ion has the greatest frontier orbital coefficient we would expect *C*-methylation in this case.

Owing to the electronegativity difference between O and C, the gradation of reactivity indices (charge l and frontier orbital coefficient c^2_{HOMO}) corresponds in all enolate ions without exception to the values given in the legend of Scheme 2. However, variation of the substituent as in the enolate ions *(5)*—*(9)* (Scheme 3) drastically alters their mode of reaction under comparable conditions (the arrows symbolize the relative yields and the site of alkylation). The frequently assumed correlation[18] between increase of *C*-alkylation and decrease in acidity of the keto compound is not evident.

Another result[17] difficult to reconcile with the "charge-orbital concept" is that dienolate ions *(10)* of electrophiles are attacked mainly at C-3, occasionally at the O atom, but never at C-5 under kinetic conditions, regardless of the nature of the electrophile.



Scheme 3. Reactions of substituted enolate ions.



(10)

Position	l	c^2_{HOMO}

3	−0.230	0.301
5	−0.186	0.356

Attractive as the HSAB concept, and the related perturbational charge-orbital concept, may appear for the interpretation of chemical bonding in the ground- and transition state, its application to the reactions of ambifunctional compounds, and particularly to the treatment of the substituent effects in anions, is beset with difficulties. It is precisely in the interpretation of substituent effects on the course of chemical reactions, however, that theoretical concepts reveal their heuristic value to the preparative chemist.

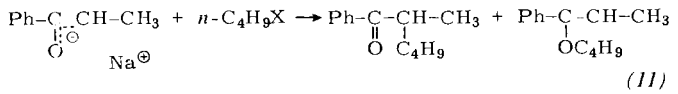
2. Derivation of the Concept of Allopolarization

The difficulties attending application of two-parameter models to the chemistry of ambifunctional systems sharply contrast with the resounding success of orbital symmetry rules for concerted reactions (*Woodward-Hoffmann*[19], *Fukui*[20], *Klopman*[21], *Dewar*[22], *Zimmerman*[23]). Subsequent refinements or additions (cf., *e.g.* ref. [24]) have not detracted from the significance of the original concept which utilizes a single parameter. Astonishing as it may seem, substituent effects can even be neglected in many cases.

Assuming that orbital interactions occur preferentially over short distances between reacting centers while Coulombic interactions predominate at greater distances, it might be expected that the majority of bimolecular reactions of polar systems—and such are the reactions of ambifunctional compounds—will be charge-controlled. This should be all the more true for reactions of charged species.

Might there not therefore be some set of rules governing the reactions of ambifunctional anions (and cations), comparable in simplicity to the Woodward-Hoffmann rules, which are based on the control of product formation by charge interaction instead of on the principle of orbital-symmetry control in concerted reactions? Such rules would not be required to give any detailed "explanation" for the formation of chemical bonds. The possibility of predicting with their aid how the product composition of a kinetically controlled reaction would alter on changing the substituents in the reactants and solvent would be entirely sufficient.

The basis for a set of rules permitting the description of the chemical behavior of ambifunctional anions can be taken from Table 1: The course of butylation of propiophenone anion depends upon the solvent and upon the alkylating agent[34].



(11)

Table 1. *C*- and *O*-alkylation of the propiophenone anion with *n*-butyl derivatives in various solvents. (HMPT = hexamethylphosphoric triamide, DMSO = dimethyl sulfoxide, THF = tetrahydrofuran.) Yields Q_O [%] of enol ether *(11)* are given.

X	HMPT	DMSO	THF	Diglyme	Et_2O
I	15	10	3	4	1
Br	40	23	5	5	5
Cl	67	46	31	13	18
OSO_3CH_3	83	—	—	—	11
OTos	85	44	—	—	20
OPO_3Bu_2	93	78	40	—	36

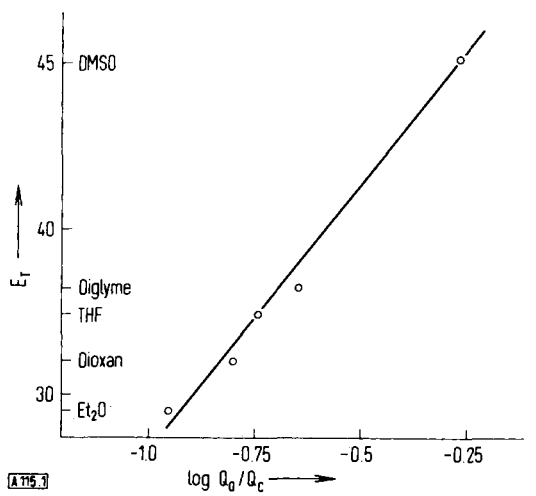


Fig. 1. Relationships between the yield Q_O of enol ether *(11)*, the yield Q_C of *C*-butylated propiophenone, and the solvent parameter E_T (see Table 1). $\log Q_O/Q_C = 0.06532 \times E_T - 3.1783$. $\log Q_O/Q_C$ is also designated the selectivity factor S_f.

The yield of enol ether *(11)* correlates well with the solvent parameter E_T (see Fig. 1). Increasing solvent polarity increases the yield of *(11)*. Hence it may be deduced that increasing solvent polarity enhances charge control which in turn favors electrophilic attack at the O atom of the enolate ion. Similar observations have been made with other enolate alkylations[17,25-30]. The solvent affects the rates of *O*- and *C*-alkylation not only *via* the change in solvation of starting materials and transition states but also *via* the change in bonding in the metal enolates (covalent bond/contact ion pairs/solvent separated ion pairs/free ions)[30-32]. *LeNoble*[29] summarized his findings for salts of acetoacetic esters in a single sentence: "The freer the anion, the larger the O/C ratio".

A similarly drastic change in the yield of enol ether is observed on use of different alkylating agents. In all solvents the yield of enol ether increases in the order R—I < R—Br < RCl < R—OY ≤ (R—F): the yields differ relatively slightly for the compounds R—OY; the main requirement appears to be that an O function is bound to the group R.

In keeping with the interpretation of the solvent effect, the effect of the alkylating agent could be explained in terms of an increasing polarization of the C—X bond in R—X raising the partial positive charge at the α-C atom, as a result of the increasing electronegativity, and thus enhancing the effect of charge control.

Other research groups have also reported high yields of enol ethers on reaction of enolates with dialkyl sulfates and triethyloxonium tetrafluoroborate[17,26,28,33]. However, the assumption[28] that the *O*/*C*-alkylation ratio increases with increasing reactivity of the alkylation finds no confirmation. The reactivity decreases rapidly along the series Bu—I > Bu—Br > Bu—Cl > Bu—F, but the yield of enol ether increases (see Table 1). Reaction of the propiophenone anion with the highly inert compound *n*-butyl fluoride in HMPT affords *ca.* 96% of the enol ether[34], *i.e.* more than with the very reactive triethyloxonium tetrafluoroborate. The relation between reactivity of the alkylating agent and the selectivity of their reaction with enolate ions is apparent from Table 2. Thus the energy of the transition and the heat of reaction[36] appear to be of minor importance for the selectivity of reactions of ambifunctional anions. The change in the *C*/*O*-alkylation ratio has also been explained as arising from the change in "hardness" of the electrophile due to the leaving group[35,37].

Table 2. Reaction of Na-acetoacetic ester with C_2H_5—X in dimethoxyethane [35].

X	I	Br	TosO	$EtOSO_3$	CF_3SO_3	FSO_3
$k \times 10^5$ [l mol^{-1} min^{-1}]	500	8	1.3	40	6.1×10^5	17.8×10^5
Q_C/Q_O	>100	60	6.6	4.8	3.5	3.7

The essence of all the previous arguments is that increasing the polarity of the solvent on the one hand, and of the electrophile on the other, enhances charge control on alkylation of enolate ions and hence favors attack by the alkylating agent on the O atom as the site of greater negative charge. Development of this idea implies that an increase in polarity of the enolate ion should also lead to an enhancement of charge control. It then remains to be defined what the "polarity" of an ambifunctional anion actually signifies. We propose the use of the relative charge density *P* or the relative charge difference *P'* as a polarity index (the HMO charges are employed in the following discussions, generally being the easiest to calculate[37a]):

$$P = l_X/l_Y$$
$$P' = (l_X - l_Y)/(l_X + l_Y)$$

X and Y are the potential reactive sites [see *(2)* and *(4)*].

The utility of this proposal is confirmed by Figure 2[38]: the extent of *O*-methylation increases with increasing polarity index $P = l_O/l_C$ of the *para*-substituted propiophenone anions.

Donor- and acceptor substituents appear to modify the polarity (polarity index *P*) of ambifunctional anions and thus affect the product ratio of reactions with electrophiles (kinetic control).

The reaction of the ambifunctional anion *(2)* with the electrophile E is illustrated in Scheme 4. The ratio of the yields of the two products *(12)* and *(13)* affords the selectivity factor S_f. Replacement of the anion *(2)* by the substituted anion *(2')* modifies the polarity index $[P_{(2)} - P_{(2')}]$. The crux of the allopolarization concept is that the *change*

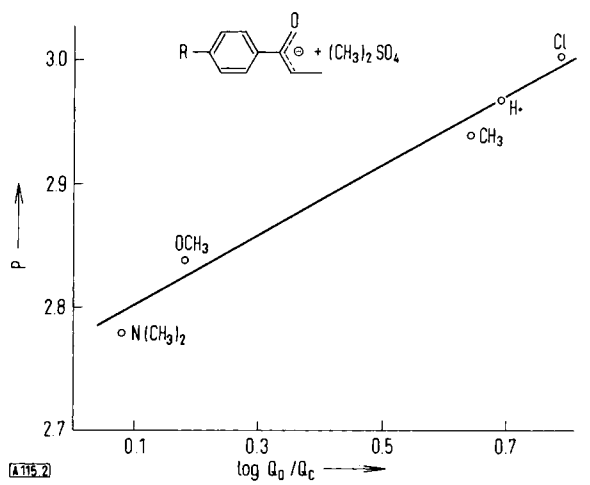

Fig. 2. Relationships between the yield Q_O of enol ether, the yield Q_C of *C*-methylated *p*-propiophenone and the polarity index $P = l_O/l_C$ of *p*-substituted propiophenone anions. $\log Q_O/Q_C$ is also designated the selectivity factor S_f.

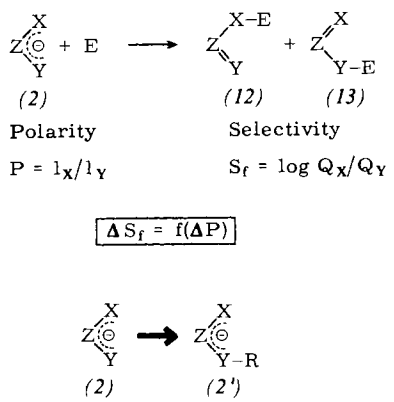


Scheme 4. Concept of allopolarization of ambifunctional anions.

in selectivity is a function of the change in polarity. If P increases on substitution $[P_{(2)} < P_{(2')}]$ then the charge control is enhanced and attack by the electrophile at the center of greater negative charge (X or Y) is favored. If P becomes smaller $[P_{(2)} > P_{(2')}]$ then charge control is diminished and electrophilic attack is favored at the site bearing the smaller charge.

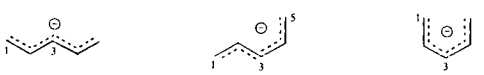
Table 3 gives an impression of the way in which donor and acceptor substituents affect the distribution of charge in ambifunctional anions (cf. ref. [39]). It should be noted that a) the influence of strong acceptors on the amidine anion system (X,Y = NR) differs from that on the allyl anion system and b) donor and acceptor groups can modify the polarity index in the same way.

3. Application of the Allopolarization Concept

The allopolarization principle will now be illustrated with the aid of examples. The sheer mass of experimental data precludes our consideration of finer details.

3.1. Allyl Anions

The reactions of allyl anions can be excellently described in terms of charge distribution: the charge densities in the pentadienyl anions *(14)*—*(16)* accord with the course of



Pople-π-SCF:			
l_1	−0.40	−0.42	−0.34
l_3	−0.36	−0.38	−0.39
l_5		−0.39	

protonation and reactions with methyl iodide and ethylene oxide[17,40–47]. Hydrolysis of the anions *(17)*[48] and *(18)*[49] also complies with the charge distribution (Table 4).

Considerable preparative significance attaches to the reactions of 1-substituted allyl anions with electrophiles. As shown in simplified manner in Scheme 5, the site of electrophilic attack corresponds to the points of greatest charge density according to Table 3: donor substituents direct electrophiles into position 3, and acceptor substituents into position 1. Deviations from this scheme are usually attributable to steric

Table 3. Charge distribution (positions 1 and 3) in ambifunctional anions (HMO, $\alpha_R = \alpha + 1.0\ [\beta]$). To save space all zeros preceding the decimal points have been omitted.

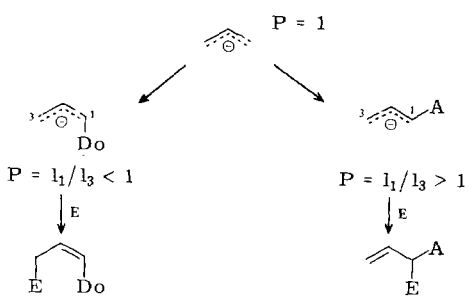
hindrance. Apart from that, ion pair effects (see, *e.g.*, refs.[50–52]) may also be operative as a result of "blocking" of the more highly charged C atom by the metal ion (cyclic concerted alkylations with RX, however, are unfavorable[53]).

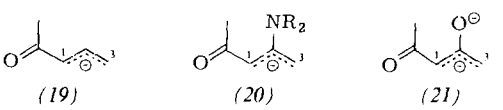


Scheme 5. Reactions of 1-substituted allyl anions with electrophiles. Do = donor = $CR_2^{\ominus}$ [54], $O^{\ominus}$ [55], $S^{\ominus}$ [56], NR_2 [57–62], OR [63–65], CH_3 [57, 66]; A = acceptor = BR_2 [67], SiR_3 [68, 69], SR [70–72], SOR [71, 72], SO_2R [73], $PO(OR)_2$ [74], COR [17, 75], CO_2R [76], CN [17], C_6H_5 [77, 78].

The reactions of allyl anions with carbonyl compounds often take a different course from those with alkylating and acylating agents. Alkyl-substituted allyl anions, for example, are preferentially attacked at the alkyl-substituted C atom in the absence of steric hindrance[50]. 1,1-Dichloroallyllithium reacts with aldehydes and ketones in the α- and/or γ-position[79]. The exceptional situation in the case of carbonyl compounds probably arises from their tendency to undergo multicenter processes on the one hand and thermodynamically controlled reactions on the other.

γ-Alkylation of 1-acylallyl anions can be accomplished under kinetic conditions in two different ways:

1-Acylallyl anions are employed which bear a donor substituent in position 2. In the allylic component of the anions (19) the greater negative charge is located at C-1, but at



(19) (20) (21)

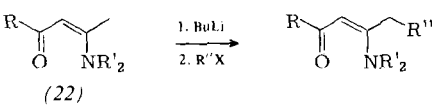
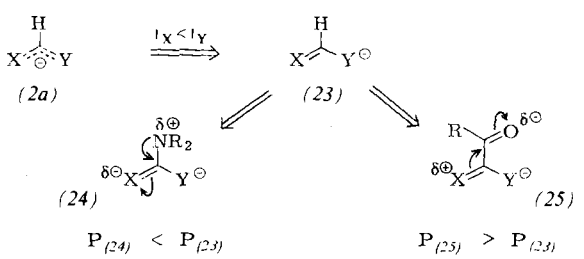
C-3 in the allylic part of the anions (20) and (21). According to the concept of allopolarization, dianions of β-dicarbonyl compounds corresponding to type (21) undergo γ-alkylation[80, 81]. Reaction of enamino ketones (22) *via* (20) follows the same pattern[82–85].



(22)

The influence of 2-substituents on the polarity of (2a) can be deduced without explicit calculation (see Scheme 6).



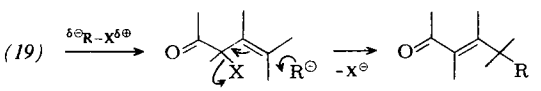
Scheme 6. Effect of 2-substituents on polarity (polarity index P) of anions (see text for details).

The starting point is that resonance structure of *(2a)* which best represents the charge distribution; *i.e.* *(23)* in the case of $l_X < l_Y$. Introduction of a donor substituent (NR_2) into position 2 of *(23)* yields the formula *(24)* in which X is assigned a negative partial charge. Thus $P_{(24)} < P_{(23)}$; weaker charge control and an enhanced proclivity to undergo reaction at X are the consequences. The reverse applies on going from *(23)* to *(25)*: charge is withdrawn from X by the acceptor substituent (COR), *i.e.* $P_{(25)} > P_{(23)}$. The increase in charge control then results in a comparatively greater tendency to react at Y.

It should be noted in this context that the reactions of anions of type *(19)* can also be described with the aid of formula *(26)* (similar alternatives are also available for other systems). *(26)* is a vinyl-substituted enolate ion. Since the

vinyl group is only a weak acceptor, *(26)* will be expected to display reactions similar to those of the unsubstituted enolate ion, *i.e.* mainly *C*-alkylation (see Section 3.4). The preparative problem at hand will determine which of the formulas is to be preferred; the predictions are essentially the same.

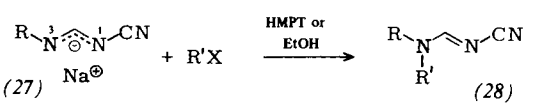
The use of allofunctionalized alkylating agents ("umpolung") also permits γ-alkylation of anions of type *(19)*[86].



2-Azaallyl anions react similarly to allyl anions. Mention should be made of the reactions of anions of 5-oxazolones[87] and the alkylation of metalated *N*-[bis(alkylthio)methylene]-α-amino carboxylic esters[88].

3.2. Amidine Anions

With respect to the active sites, amidine anions have the same symmetry as allyl anions. However, strong acceptor substituents have a different polarizing effect in the two systems (Table 3). Since N-3 bears the greater negative charge in 1-acceptor substituted amidine anions, electrophiles should attack preferentially at that site. This is indeed the case, as demonstrated by the reactions of the Na salts *(27)* of cyano-

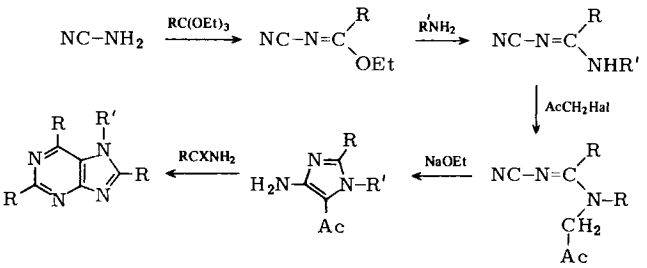


R = $C_6H_5CH_2$, *i*-C_3H_7, *t*-C_4H_9, C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, *p*-$EtO_2CC_6H_4$, β-$C_{10}H_7$, 2-pyridyl

R'X = CH_3I, $(CH_3)_2SO_4$, $PhCH_2Cl$, $PhCOCH_2Br$, $NCCH_2Br$, EtO_2CCH_2Br

formamidines—only the cyanamidines *(28)*[38,39] are produced. Selective formation of *(28)* can be exploited for a facile synthesis of 4-amino-5-acylimidazoles and purines[89] (see Scheme 7).

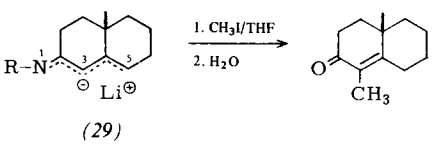
Methylations of the Na salts of phosphorus compounds $(EtO)_2PNHAryl(=NAryl)$[90] follow the same pattern as the reactions of *(27)*.



Scheme 7. Synthesis of imidazoles and purines *via* amidines. R = H, alkyl, aryl, SR, NR_2. Conversion of 4-amino-5-acylimidazole into purine can also be accomplished with RNCX or H_2N—CX—NH_2; X = O or S.

3.3. Enamine and Hydrazone Anions

Like enolate ions, simple enamine anions undergo preferential *C*-alkylation[91-94]; the extent of *N*-alkylation can be greatly increased by use of especially polar alkylating agents such as triethyloxonium fluoroborate[93]. Alkylations of anions of 5,6-dihydro-2,4,4,6-tetramethyl-4*H*-1,3-oxazine[95,96] and of 2-methyloxazolines[97] possess particular preparative importance. Dienamine anions[98] such as *(29)* are only α-alkylated in the same way as dienolate ions *(10)*.

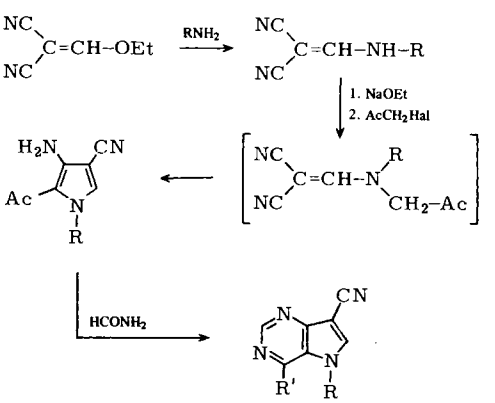


(29)

The presence of donor and acceptor substituents at C-3 raise the polarity of the enamine anions (see Table 3). Alkylation of the dianion *(30)* can be regarded as an example of the donor case[99].

(30)

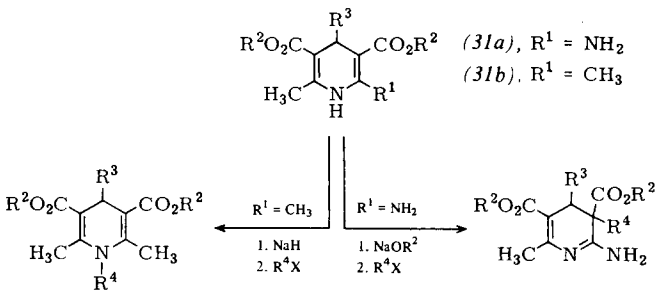
3-Acceptor substituted enamine anions are obtained, *e.g.* from aminomethylenemalononitriles. Their exclusive *N*-alkylation can be utilized for synthesizing aminopyrroles and pyrrolo[3,2-*d*]pyrimidines[89], as shown in Scheme 8.



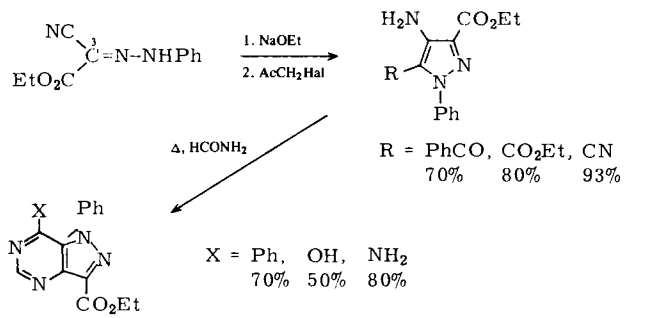
Scheme 8. Synthesis of aminopyrroles and pyrrolo[3,2-*d*]pyrimidines *via* enamines. R' = C_6H_5, 2-thienyl, CH_3, OH.

The effect of a change of substituent at position 2 of the enamine anion to be expected from the general scheme is

confirmed by the reactions of the anions of *(31a)*[100] and *(31b)*[101–103].

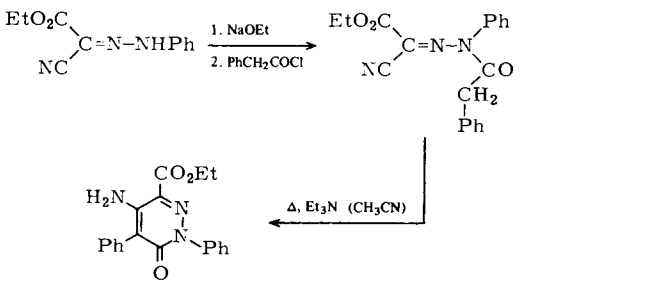


The principle of the aminopyrrole synthesis shown in Scheme 8 can also be employed for production of aminopyrazoles and pyrazolo[4,3-*d*]pyrimidines from hydrazone anions according to Scheme 9[104] (1-alkylation; further reactions of hydrazone anions, see Section 3.6).



Scheme 9. Synthesis of aminopyrazoles and pyrazolo[4,3-*d*]pyrimidines from hydrazones.

Acylation of hydrazone anions (see Scheme 10) corresponds to their alkylation; pyridazine derivatives can be synthesized in this way[104].



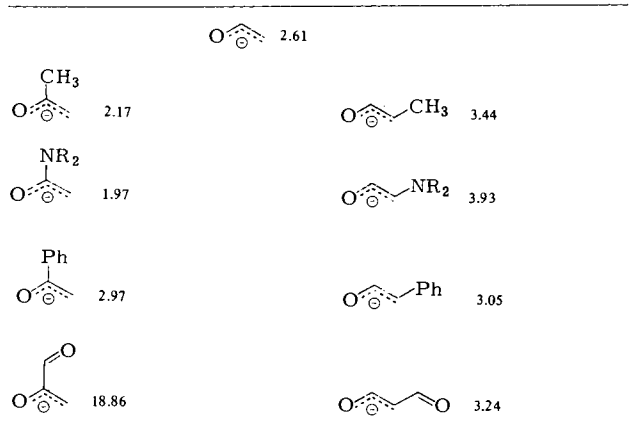
Scheme 10. Synthesis of pyridazines from hydrazones.

3.4. Enolate Ions

Apart from the reactions of allyl anions, those of enolate ions[17] (see also Sections 1 and 2) provide considerable material for discussions of the substituent effect. Table 5 conveys an impression of the polarity indices of typical enolate systems. Unfortunately, only little is known about aldehyde anions[91c, 105]. Since the Na salt of phenylacetaldehyde is only *O*-methylated in DMSO[28], *O*-alkylation should generally predominate with aldehyde anions in dipolar aprotic solvents according to the polarity indices.

Expectedly, the reaction of all enolate ions with trimethylchlorosilane only affords enol derivatives[106–111].

Table 5. Polarity indices $P = I_O/I_C$ of some enolate systems.



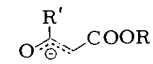


Table 6. Influence of substituents in position 2 of 3-alkoxycarbonyl enolate ions on the reaction with ethyl iodide and with ethyl *p*-toluenesulfonate (both in HMPT). Yields of OEt derivative are given. $P = I_O/I_C$. R = alkyl.

[a] With dimethyl sulfate.

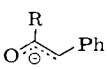

Table 7. Influence of substituents in position 2 of 3-phenyl enolate ions on the reaction with dimethyl sulfate in HMPT. $P = I_O/I_C$; Q_O = yield of OCH_3 derivative, Q_C = yield of CCH_3 derivative.

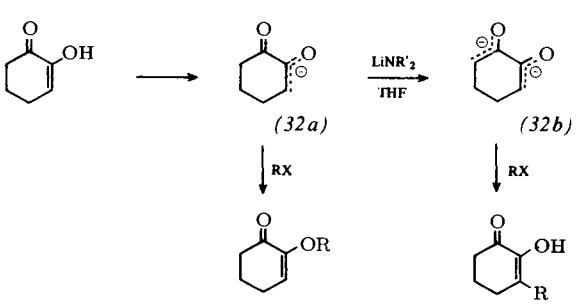
R	P	Q_O/Q_C
C_6H_5	3.55	> 10
H	3.05	> 10
CH_3	2.55	0.7
OCH_3	2.49	< 0.1
$O^{\ominus}$	2.22	< 0.1

The influence of substituents in position 2 of enolate ions follows from Tables 6 and 7. The relationship between polarity and selectivity is also impressively demonstrated by the fact that the monoanions [*e.g. (32a)*] of 1,2-cycloalkanediones are *O*-alkylated[112, 113], while the dianions [*e.g. (32b)*] are *C*-alkylated[114].



The situation is not so clear-cut for substituents in position 3, probably due mainly to steric factors. Table 8 surveys methylations of anions of substituted acetophenones. The difference in yield between R = *i*-C_3H_7 and $N(CH_3)_2$, which have the same steric bulk, reflects the more pronounced donor effect of the amino group. Exclusive *O*-methylation in the case of the two *N*-substituted compounds can be explained by an increase in polarity of the enolate ion caused by donor and acceptor substituents. However, a considerable difference in reactivity exists between R = $\overset{\oplus}{N}(CH_3)_3$ and $\overset{\oplus}{P}Ph_3$ on the one hand and R = $\overset{\oplus}{S}(CH_3)_2$ on the other (it should be borne in mind that among these three substituents only that containing sulfur still possesses a lone pair)[115].

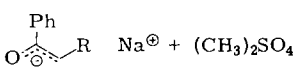


Table 8. Influence of substituents in position 3 of acetophenone anions on the reaction with dimethyl sulfate in HMPT at 25°C. Substituents of comparable bulk are shown linked together.

[a] K salt.
[b] With C_2H_5I [116].

In other systems *C*-alkylations of the anions of α-mercapto ketones are also possible[118–120]; dimethylsulfonium benzoylmethanide is *O*-methylated by trimethyloxonium tetrafluoroborate[121].

A certain degree of uncertainty surrounding some reactions of *S*- and *P*-substituted enolate ions prompts us to ask the question whether it might not be more appropriate to use an "orbital index" $F = c^2_{C,\,HOMO}/c^2_{O,\,HOMO}$ (cf. ref. [122]) instead of the polarity index $P = l_O/l_C$. The changes in the two indices are compared in Figure 3. The *P* value is seen to be highly sensitive to a change of substituent, whereas the *F* value appears relatively insensitive. The same applies to allyl anions (see Fig. 4). Hence the *P* value appears to be better suited than the *F* value for demonstrating relations between structure and reactivity/selectivity.

The influence of aromaticity can also be regarded as a "substituent effect". Table 9 lists some anions in which the enolate moiety is incorporated into (anti)aromatic/bicycloaromatic systems. Aromatic systems predictably have large polarity indices, and antiaromatic systems small ones (phenolate ions are generally *O*-alkylated and *O*-acylated). The fact that the anions of anthrone[123a] and of phloroglucinol[123b] can be *O*- and/or *C*-alkylated is reflected in the decrease in polarity indices upon annelation of a benzene ring on the α-naphtholate ion or upon introduction of a *m*-hydroxy group into the resorcinol monoanion.

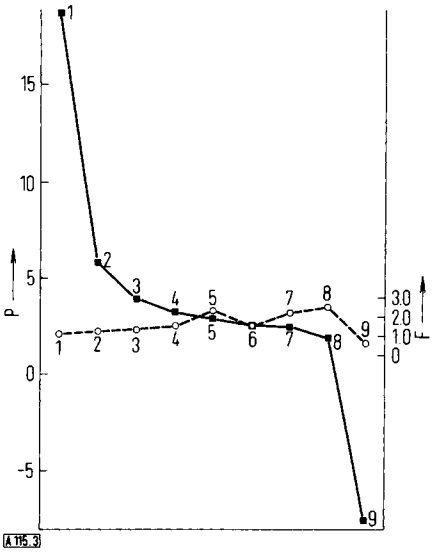

Fig. 3. Comparison of the polarity index $P = l_O/l_C$ (——) and the "orbital index" $F = c^2_{C,\,HOMO}/c^2_{O,\,HOMO}$ (– – –). The indices compared are those for substituted enolate ions of the type

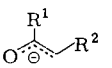

1: $R^1 = CO_2R$, $R^2 = H$; 2: $R^1 = R^2 = CO_2R$; 3: $R^1 = H$, $R^2 = NR_2$; 4: $R^1 = H$, $R^2 = CO_2R$; 5: $R^1 = NR_2$, $R^2 = CO_2R$; 6: $R^1 = R^2 = H$; 7: $R^1 = R^2 = NR_2$; 8: $R^1 = NR_2$, $R^2 = H$; 9: $R^1 = CO_2R$, $R^2 = NR_2$.

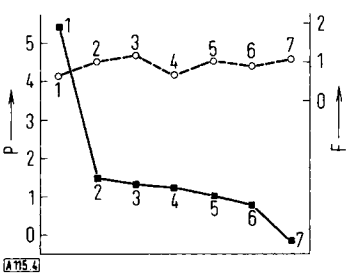

Fig. 4. Comparison of the polarity index $P = l_1/l_3$ (——) and the "orbital index" $F = c^2_{3,\,HOMO}/c^2_{1,\,HOMO}$ (– – –). The indices compared are those for substituted allyl anions of the type

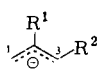
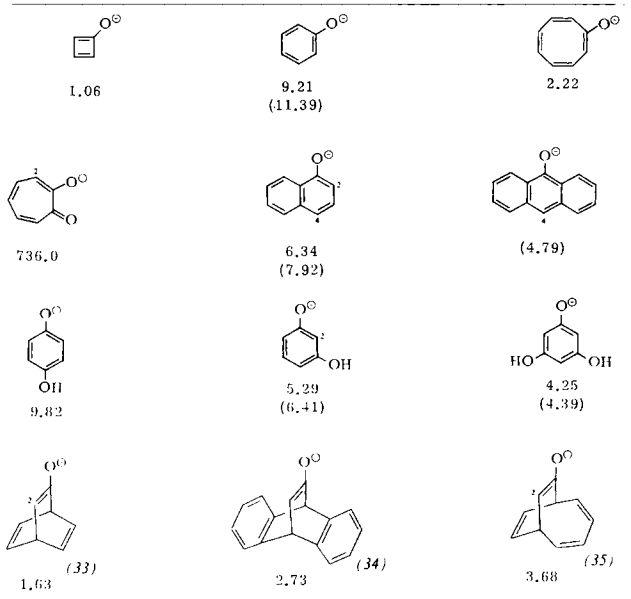


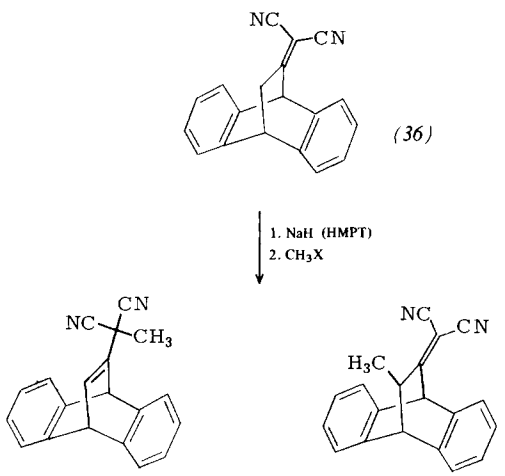
1: $R^1 = CO_2R$, $R^2 = NR_2$; 2: $R^1 = H$, $R^2 = NR_2$; 3: $R^1 = R^2 = NR_2$; 4: $R^1 = NR_2$, $R^2 = CO_2R$; 5: $R^1 = R^2 = H$; 6: $R^1 = H$, $R^2 = CO_2R$; 7: $R^1 = R^2 = CO_2R$.

It is remarkable that the anion *(35)* possesses a higher polarity index than the anions *(33)* and *(34)*. This is in accord with the finding that *(35)* is only *O*-methylated (Na salt + dimethyl sulfate in DMSO)[124]. In the case of *(34)*, on the other hand, *C*-methylation predominates (Li salt + dimethyl sulfate in ether; the ion-pair effect may be significant

Table 9. Polarity indices of "aromatic" enolate ions. The values given are $P = I_O/I_{C-2}$ and I_O/I_{C-4} (in parentheses).



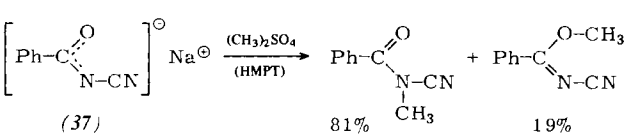
here)[125]. With the Na salt of *(36)*[125], too, methylation proceeds less selectively than is normally found with 1,1-dicyanoallyl anions (see Section 3.1).



X = OSO_3CH_3	95%	5%
X = I	75%	25%

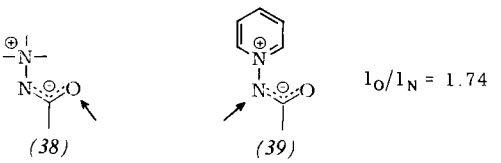
3.5. Amide and Thioamide Anions

Judging by the electronegativities of C, N, and O, the reactions of amide anions would be expected to follow a similar pattern to enamine anions. Thus instead of the *C*-alkylation prevailing with the simple enamine anions, *N*-alkylations should be observed for amide anions. This is indeed the case[126, 126a] when alkali metal salts are employed; silver salts lead to exclusive or partial *O*-alkylation (alkylation of α-pyridone has been studied particularly thoroughly[127]).



(37) 81% 19%

The enhancement of polarity by acceptor substituents at the N atom is manifested on methylation of *(37)*[38] and alkylations of the zwitterions *(38)*[128, 129] [the reasons for the deviating behavior of the pyridinium derivatives *(39)*[128] are unclear].

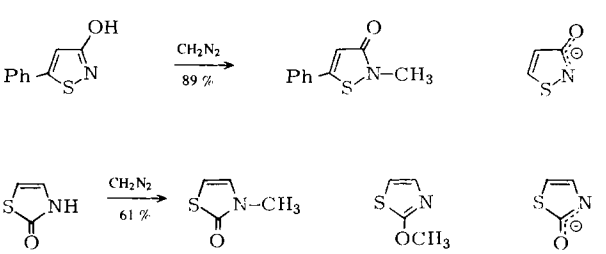


The polarity indices of amide anions in lactam systems show wide variation (cf. Table 10). However, no comparative studies of alkylations and acylations under standard conditions have been reported. That the polarity indices in Table 10 point in the right direction is shown, *inter alia*, by the almost invariable *N*-alkylation of imide anions of type *(40)* (formation of an *O*-substituted derivative on reaction of Ag maleimide with 1-bromoadamantane in benzene[130] is an exception), as against the pronounced tendency of cyclic hydrazide anions of type *(41)* to undergo *O*-alkylation and *O*-acylation[131].

Table 10. Polarity indices $P = I_O/I_N$ of some amide anions.

	I_O	I_N	P
(40)	−0.540	−0.502	1.076
	−0.720	−0.517	1.393
	−0.625	−0.375	1.666
	−0.743	−0.407	1.826
	−0.799	−0.291	2.746
	−0.799	−0.269	2.970
(41)	−0.809	−0.214	3.780
	−0.820	−0.191	4.293

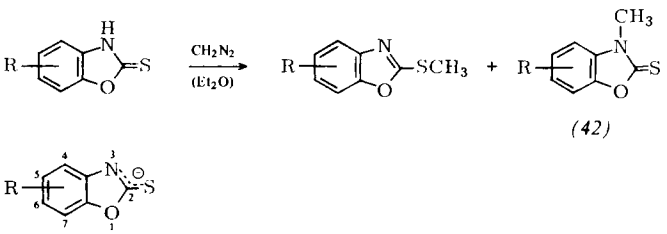
The differences in reaction conditions also preclude a general correlation of the reaction between amide systems and diazomethane[132] with polarity indices. Nevertheless, notable relationships between the course of methylation and polarity can be detected with closely related compounds, *e.g.* 3-isothiazolone and 2-thiazolone (see Scheme 11); concerning the *N*-benzylation of 3-isothiazolone cf. ref. [135]).



Scheme 11. Methylation of 5-phenyl-3-isothiazolol (for the anion $P = I_O/I_N = 1.98$; $I_O = -0.737$ and $I_N = -0.373$) [133] and methylation of 2-thiazolone (for the anion $P = I_O/I_N = 2.30$; $I_O = -0.724$ and $I_N = -0.322$) [134].

Although 7-azabicyclo[4.2.2]deca-2,4,9-trien-8-one is to be regarded as the N-analog of *(35)* (Table 9), it is only *N*-methylated (NaH, DMF, dimethyl sulfate)[136].

Thioamide anions are usually *S*-alkylated[126]. However, in the case of *N*-acylthioamide anions *N*-alkylation also occurs (5-alkylidenerhodanines[137], 2-thio- and 2,4-dithiohydantoins[138], 2-thio-6-azauracil[139], 4-thioxothiazolo-[3,2-*a*]-*s*-triazin-2-one[140]). The relation between *N*-methylation and increasing polarity index of thioamide anions is evident from Table 11.



(42)

Table 11. Methylation of substituted 3*H*-benzoxazole-2-thiones [141]. Yields of NCH_3 derivative are given *(42)*. $P = I_N/I_S$.

5-NO_2	−0.366	−0.520	1.421	6.1
7-NO_2	−0.355	−0.511	1.439	8.0
6-NO_2	−0.209	−0.345	1.651	17.6
4-NO_2	−0.199	−0.332	1.688	64.7

3.6. Other Anions

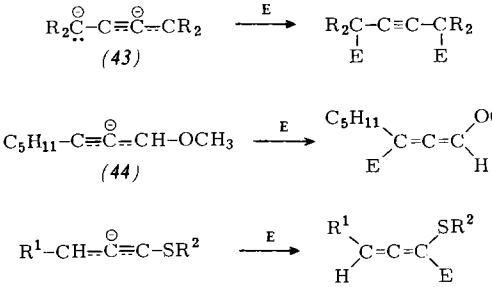
A number of ambifunctional anions are summarized in Table 12. Comparing the reactions of those anions which contain the same reactive sites (O/C and O/N) once again reveals the relation between polarity and selectivity (the arrows symbolize product formation). Oxime anions[142]—nitrone

Table 12. Polarity indices of some ambifunctional anions. $P = I_O/I_X$.

Anion		I_O	I_X	P
	Amide	−0.720	−0.517	1.39
	Enol	−0.785	−0.301	2.61
	Nitroalkane	−0.805	−0.037	21.76
	Nitrosamine	−0.677	−0.384	1.76
	Oxime	−0.778	−0.111	7.01
	Nitramine	−0.703	−0.379	1.85

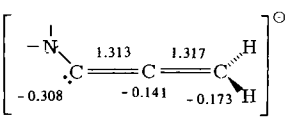
formation[143–145] is excluded from our present discussion since only reactions at the sites X and Y of anions of type *(2)* are being considered—and especially nitroalkane anions[146] have much greater polarity indices than enolate ions[146], and it is therefore hardly surprising that oxime anions are exclusively *O*-alkylated. Hydrazone anions (see Section 3.3) are accordingly 1-alkylated[147–154]. In contrast, amide anions, nitrosamine anions[155–157], and nitramine anions[158–160] exhibit relatively low polarity indices of similar size, and *N*-alkylation accordingly predominates.

It might be expected that the substituent effects observed with the anions *(2)* will also occur with the anions *(4)*. The simplest case is that of the propargyl anions. The reactions of *(43)*[162], *(44)*[162–165], and *(45)*[166,167] correspond to the pattern already established for the allyl anions (see Section 3.1).



(43) *(44)*

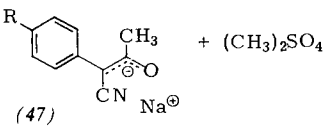
The situation is different in the case of the anions of ynamines[168] and alkoxyallenes[169]. MINDO/3 calculations have shown that such anions have structures resembling *(46)*, *i.e.* are not planar, and react like vinyl anions. (The bond lengths [Å] are given above the formula, and charge densities below.)



(46)

Alkynethiolates[170] behave in similar manner to enethiolates on alkylation; with lithium phenylethynolate[171] the tendency to react at the C atom appears even more pronounced than with enolate ions.

The concept of allopolarization is based upon the assumption of a relatively early transition state. Although this assumption is problematic, the reactivity generally has no influence on the selectivity (see Table 2). However, if anions bearing different kinds of substituents happen to have the same polarity, the reactivity can decide the selectivity. Table 13 illustrates such a case[38]. The anions[47] with R=H and R=Cl have the same polarity index but different reactivity. The larger



(47)

Table 13. Influence of the reactivity on the selectivity in compounds having equal polarity indices. $P = I_O/I_C$; the enol/ketone ratio given refers to the starting material.

R	P	Q_O/Q_C	ε_{HOMO} [β]	Enol/Ketone
CH_3	3.341	1.8	0.307	0.67
H	3.328	1.2	0.346	0.98
Cl	3.327	2.4	0.381	3.20

yield of enol ether in the case of *(47)*, R=Cl, can be explained by the "later" appearance of the transition state than for

(47), R = H, so that the bonding in the product also affects the selectivity [the greater enol content of the starting material suggests that for *(47)*, R = Cl, the enol ether is more stable than in the other two cases].

4. Conclusion

With regard to synthetic strategy the following summary rules can be drawn up for the reactions of ambifunctional anions:

1) By starting from the known reactions of an ambifunctional parent system of type *(2)* the "selectivity factor" $S_f = \log Q_X/Q_Y$ is established (see Scheme 4). The influence exerted by a perturbation due to substituents on the parent system is then examined. The change in the "polarity index" $P = l_X/l_Y$ is taken as a measure of the perturbation.

An increase (decrease) in P indicates enhancement (diminution) of charge control. The result is an increased tendency to undergo reaction at that site (X or Y) of the anion which bears the greater (smaller) partial negative charge.

2) The statement of expected selectivity in the reactions of a (substituted) anion, as derived according to 1), has to be modified in special cases (equal polarity of two anions) by taking into account the change in reactivity due to the perturbation (early/late transition state).

3) Polarity and reactivity of the electrophilic reactants according to 1) and 2) are included.

4) The solvent effect is taken into consideration (empirical solvent parameter).

The rules of the allopolarization concept cannot be applied to reactions in which π-complexes or ion pairs occur as intermediates since their subsequent reactions cannot be directly deduced from the properties of the starting materials. Formation of such intermediates is to be expected above all in reactions of cyclic π-systems. Examples are the reactions of pyrrole- and imidazole anions to form heterofulvalenes[172] and the acylation of 5-oxazolones in the presence of pyridine[87, 173].

One of us (R. G.) wishes to thank his collaborators Dipl.-Chem. K. H. Etzbach, G. Heywang, Dr. F. Saygin, Dr. W. Schmidt, and H. H. Vogt. We are indebted to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Leibniz-Rechenzentrum der Bayerischen Akademie der Wissenschaften for support of our work on ambifunctional compounds.

Hydrozirconation: A New Transition Metal Reagent for Organic Synthesis

New synthetic methods (16)

By Jeffrey Schwartz and Jay A. Labinger[*]

Hydrozirconation has recently been developed as a procedure for functionalizing alkenes, alkynes, and 1,3-dienes *via* organozirconium(IV) intermediates. These intermediates react with a variety of electrophilic reagents to give organic products in high yield. Mechanisms of reactions involved in these sequences are discussed.

1. Introduction

Because of the scope of reactions found in transition metal organic chemistry, there is much current interest in the development of transition metal complexes as reagents for organic synthesis. Transition metal hydrides constitute one class of compounds presently under study, since by selective hydrometalation readily available starting materials, olefins or acetylenes, can be converted specifically into reactive σ-bonded organometallic intermediates, at least in theory; upon C—M cleavage these intermediates give the desired organic product. Hydrides of main group elements (*e.g.*, boron[1], aluminum[2], or tin[3]) have become commonly used stoichiometric reagents for accomplishing this type of synthetic transformation, and transition metal hydrides find use as catalysts for reactions of unsaturated hydrocarbons such as hydrogenation, hydroformylation, hydrosilation, and isomerization[4].

To develop transition metal hydrides as useful reagents of general applicability, it is necessary to find such complexes which will react with ordinary "unactivated"[**] alkenes or alkynes to give alkyl- or alkenyl-metal derivatives in high yield. The presence of electron-withdrawing substituents on the unsaturated organic molecule seems to favor this reaction. For this reason the study of the formation of transition metal-carbon σ-bonds by β-hydride addition to unsaturated organic molecules has heretofore centered around the chemistry of transition metal hydrides and olefins or acetylenes containing electron-withdrawing substituents such as tetrafluoroethylene[5,6], hexafluoro-2-butyne[7], dimethyl acetylenedicarboxylate[8], acrylonitrile[7,9], and fumaronitrile[7]. Unfortunately, whereas these substrates do provide important mechanistic information, they are not generally useful precursors of desired organic products.

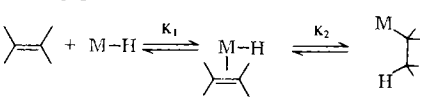
[**] By "unactivated" we mean acetylenes or olefins which are substituted with alkyl or proton substituents only.

The conversion of an unactivated alkene or alkyne into a transition metal alkyl or alkenyl involves two steps (Scheme 1):

1) Coordination of the olefin or acetylene to the transition metal atom;
2) "β-M-H addition" to the coordinated unsaturated molecule.

Scheme 1.



For a variety of transition metal complexes the magnitude of the equilibrium constant K_1 has been found[10] to depend on the number and size of alkyl substituents attached to the double bond; as these increase, K_1 decreases rapidly. β-Hydride addition or elimination in transition metal complexes (K_2) has been studied in numerous cases[6,11–14], and *Hoffmann* has recently proposed[15] that the position for this equilibrium (K_2) should depend on the availability of electron density on the metal to stabilize the alkene complex; its increase favors the hydrido-alkene species. Similar arguments are applicable to alkyne chemistry.

The reaction between ethylene and certain transition metal hydrides which are catalytically active can result in the formation of an isolable ethyl derivative[6,16–20]. Although alkyl-metal derivatives cannot usually be observed in reactions between higher alkenes and transition metal hydrides used as homogeneous catalysts, there is evidence for their formation as intermediates[6,19]. Even though the concentration of an alkyl-transition metal compound thus formed is too low to be detected directly, several types of catalytic sequences involving such intermediates are known. In catalytic hydrogenation, for example, even though K_1 and K_2 can be relatively unfavorable, the reagent that ultimately effects C—M bond cleavage in the intermediary alkylmetal species, *viz.* H_2, does not destroy the metal hydride catalyst; it can react *reversibly* with H_2 to give a metal trihydride[4,21]. A different situation exists when the cleavage reagent chosen is not H_2 (or is any other species that reacts irreversibly with the metal hydride). Here,

consumption of the metal hydride reagent can occur to give a low yield of desired product unless

- a) The alkyl compound is disfavored relative to either hydride species at equilibrium (Scheme 1), but the cleavage reagent attacks it preferentially;
- b) β-hydride addition is fostered by attack of the cleavage reagent on a metal hydride species;
- c) the alkyl compound is favored relative to both hydride species at equilibrium (Scheme 1) and the cleavage reagent can react with any of these complexes with comparable facility.

Hydrozirconation, a process permitting the selective and high-yield conversion of unactivated alkenes and alkynes into a variety of types of organic products *via* isolable σ-bonded organozirconium intermediates, was developed as a result both of the mechanistic considerations discussed above and of synthetic studies using hydrides of various other transition metals. This evolution is traced in brief below.

2. Hydroacylation

Preliminary studies indicated practical limitations for sequences involving condition (a) described in Section 1. Ethylene can be converted into an ethyl ketone *via* an ethylrhodium or ethylcobalt complex generated by reaction with $HRh(CO)L_3$ or $HCo(N_2)L_3$ ($L=PPh_3$)[22]. In this sequence ketone is formed by oxidative addition of acyl halide to the alkyl-transition metal intermediate followed by reductive elimination of the product[23,24]. However, the use of higher olefins results in diminished yield of ketone. Meager success with these substrates can be attributed to unfavorable factors associated with the equilibrium constant K_1 (Scheme 1) and the observation that many acyl halides react irreversibly with $HRh(CO)L_3$ or $HCo(N_2)L_3$ to give halometal complexes. Although the equilibrium concentration of alkyl is not high even for ethylene, the reaction of ethylrhodium or ethylcobalt is faster than that of the hydride with acyl halide; hence for ethylene the concentration of alkylmetal is sufficiently large to give yields of ketone as high as 86% (based on starting metal hydride). With long chain alkyl substituents on the double bond the concentration of the alkylmetal drops so that most of the starting hydride is consumed by the acyl chloride.

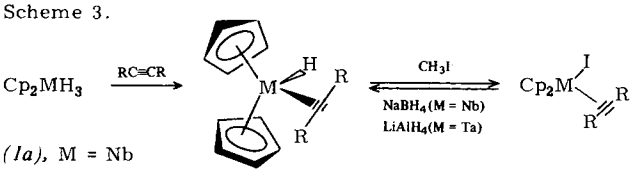
H	C_6H_5	86	75
$CH_3CH_2CH_2$	CH_3	2	20

3. Alkenyl-tantalum(III) and -niobium(III) Complexes

Parshall et al. have reported[20] that Cp_2NbH_3 *(1a)* ($Cp=\eta^5$—C_5H_5) coordinates ethylene with loss of H_2 to give $Cp_2NbH(C_2H_4)$ *(2)* and that further treatment of *(2)* with ethylene results in the formation of an isolable ethylniobium(III) species. Study of the reaction between Cp_2MH_3 *(1)* (M = Nb, Ta) and dialkylacetylenes was initiated in light of these results[25,26]. Few complexes of dialkyl-substituted acetylenes are known[27,28]; however, it was found that treatment of *(1)* in benzene with such alkynes gave in high yield the first known examples of hydrido-alkyne complexes, $Cp_2MH(C_2R_2)$ *(3)* (Scheme 3), compounds which can be used as models to explain the selectivity of the hydrozirconation process (see below). These compounds *(3)* (M = Nb) could not be prepared by displacement of the phosphane ligand from $Cp_2NbH(L)$[29].

Scheme 3.



(1a), M = Nb
(1b), M = Ta

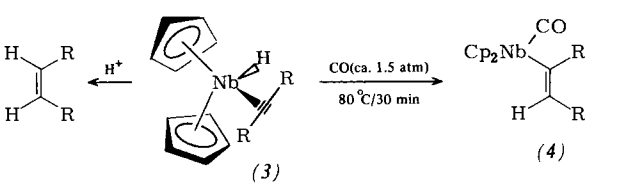
(3)

Crystallographic studies[30] on $Cp_2Nb(C_2H_4)C_2H_5$ indicate that Nb is pseudotetrahedrally coordinated and that the two carbon atoms of the ethylene ligand lie in a plane which also contains the niobium atom and the α-carbon atom of the ethyl chain. NMR evidence obtained for the related species *(3)* indicates that the acetylene unit in these complexes is deployed in the same fashion: the hydrido ligand, the metal atom, and both carbons of the acetylenic unit all lie in one plane. In this geometry one substituent on the triple bond is in a relatively uncrowded environment near the sterically small hydrido ligand while the other substituent on the triple bond resides in a more congested surrounding near the two cyclopentadienyl rings (Scheme 3). Two consequences of this mode of coordination are notable:

1) Coordination of a symmetrically substituted acetylene renders the two ends of the alkyne ligand non-equivalent;

2) coordination of an unsymmetrically substituted acetylene gives rise to two isomers which differ only in the orientation of the alkyne ligand in the plane containing the M—H bond. If the substituents on the triple bond differ in steric size, that isomer should predominate in which the largest substituent lies nearer the small hydrido ligand.

Scheme 4.

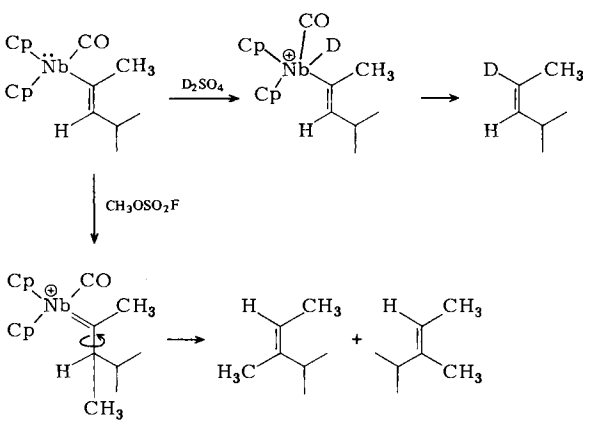


(3) *(4)*

Protonation of *(3)* (M = Nb, Ta) yields *cis* olefins as does its reaction with H_2[26] [see condition (b) in Section 1]. Treatment of *(3)* (M = Nb) with CO as shown in Scheme 4 converts it into the alkenylcarbonyl species *(4)*. This σ-bonded organometallic species is formed with (C=C) *cis* stereochemistry[8] by β-Nb—H addition to the triple bond. It is interesting to note that for 4-methyl-2-pentyne greater regioselectivity is observed in *(4)* than was found in its precursor *(3)*: quantitative NMR analysis demonstrates that all of *(3)* is converted into *(4)*. This observation can be explained by a process in which the alkyne ligand is free to rotate about the metal-ligand bond axis, as has been demonstrated in another system[31]. Since the steric requirements of the alkenyl ligand

are different from those of the alkyne one, the selectivity displayed by the starting material is different from that shown by the σ-bonded product. Carbon monoxide traps the coordinatively unsaturated alkenyl complex. Note that in both *(3)* and *(4)* a lone pair of electrons is present which is formally associated with the Nb^{III} (d^2) metal center. Such a pair of electrons associated with a metal center can be protonated or alkylated[32,33]. The formation of *cis* olefin upon protonation of *(4)*[25] can be envisioned as proceeding through such a protonation of niobium(III) followed by reductive elimination of olefin from the resulting cationic niobium(V) intermediate (Scheme 5). Labeling studies with D_2SO_4 support the proposed mechanism for protonation: in the olefinic product deuterium replaces the niobium. A parallel synthesis of a trialkyl-substituted olefin from *(4)* was therefore attempted. However, although a trialkyl olefin *is* formed upon treatment of *(4)* with CH_3OSO_2F, the product observed[25] was *not* the one predicted by this mechanism. Rather, a mixture of isomeric olefins was formed. This mixture probably arises from alkylation at the β-carbon of the alkenyl ligand followed by proton migration and reductive elimination of olefin (Scheme 5). The cationic carbene complex intermediate contains a single C—C bond and rotation about this bond prior to proton transfer leads to the *cis-trans* mixture of product observed. This pathway is not unprecedented: *Casey* has shown[34] that deprotonation of a transition metal alkyl carbene complex occurs at the β-carbon to yield a species best described as an alkenyl complex, and that protonation or alkylation of this alkenyl compound also occurs at the β-carbon to regenerate a carbene complex.

Scheme 5.



Cp = η^5-C_5H_5

4. Organozirconium(IV) Chemistry

Results with the niobium(III) and tantalum(III) systems described in Section 3 indicate that the system Cp_2MHX can be used to selectively functionalize unsymmetrically substituted acetylenes. However, with these d^2 metals cleavage of the organometallic intermediate was found to be non-specific. Using a d^0 metal in Cp_2MHX (*e.g.* $M = Zr^{IV}$), specific C—M cleavage as well as specific activation of an olefin or an acetylene could be possible. Arguments described earlier also suggest that for a formally d^0 metal the alkyl complex should predominate over the hydrido (alkene) species at equilibrium (K_2 in Scheme 1).

4.1. Background

A variety of stable zirconium(IV) alkyls have been prepared by conventional alkylation of $ZrCl_4$ with Grignard, lithium, or aluminum reagents[35]. Several of these compounds demonstrate appreciable thermal stability, including tetraneopentylzirconium(IV)[36], tetranorbornylzirconium(IV)[37], and tetra(trimethylsilylmethyl)zirconium(IV)[38]. Tetrabenzylzirconium(IV) is also known[39] and has shown limited use as a hydrogenation catalyst. However, none of these organozirconium compounds has seen extensive use as a reagent in organic synthesis. Alkylchlorobis(cyclopentadienyl)zirconium(IV) complexes have been prepared from Cp_2ZrCl_2 and lithium[40] or Grignard[41] reagents. These compounds have been briefly investigated with regard to NO[40] and SO_2[40] insertion into the C—Zr bond[41,42]; their hydrolytic lability has also been noted[40].

The preparation of alkylzirconium compounds has now been accomplished by reaction of Cp_2ZrHCl with a variety of unsaturated organic molecules. This reaction, named "hydrozirconation", is described in detail below.

4.2. Hydrozirconation

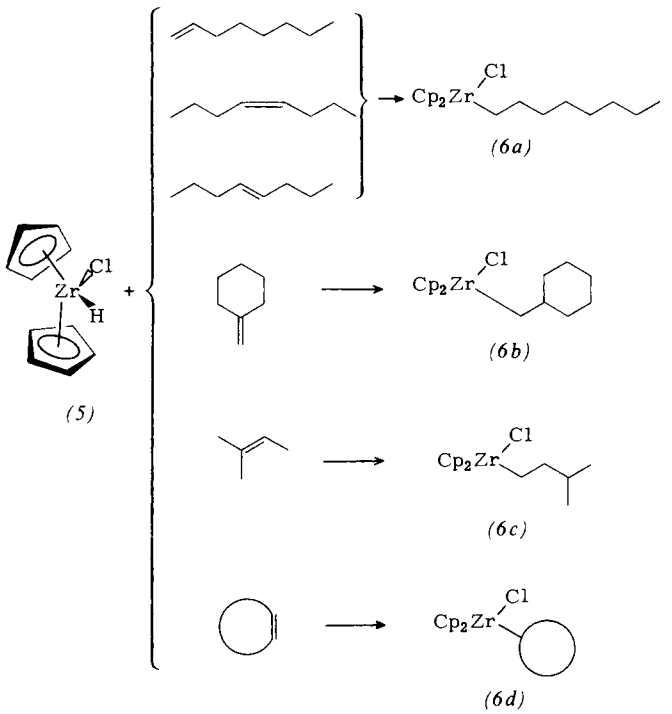
The zirconium hydride $Cp_2Zr(H)Cl$ *(5)* was first prepared by *Wailes et al.*[42] from Cp_2ZrCl_2 and $LiAlH_4$. It is also easily prepared by treatment of the dichloride in tetrahydrofuran with a stoichiometric amount of $NaAlH_2(OR)_2$. Both procedures result in the high yield precipitation of *(5)*[43].

4.2.1. Hydrozirconation of Alkenes

Wailes briefly studied the reactions of *(5)* with several olefins[42]; the resulting alkyl complexes were not identified. This hydride was later found[43] to react under mild conditions with a variety of olefins to generate isolable alkylzirconium(IV) complexes $Cp_2Zr(R)Cl$ *(6)*. Hydrozirconation of olefins proceeds to place the zirconium moiety at the sterically least hindered position of the olefin chain as a whole[43] (cf. Scheme 6). Formation of this product involves either the regiospecific addition of Zr—H to a terminal double bond or Zr—H addition to an internal double bond followed by rapid rearrangement *via* Zr—H elimination and readdition to place the metal in each case at the less hindered position of the alkyl chain. In contrast to *(5)* other transition metal hydrides are known[19] to catalyze the conversion of α-olefins into thermodynamically more favored isomers having an internal double bond but do not form isolable alkyl complexes. Although this observation represents the first instance in which a stable alkylzirconium compound is formed by rearrangement of an unisolated precursor, the migration of a Zr moiety from a secondary carbon to the terminal position of an internally functionalized starting material is not totally unprecedented. Thus Zr^{IV} and Ti^{IV} salts are known to catalyze the isomerization of secondary Grignard[44] and aluminum[45] reagents to give primary ones and these isomerization procedures most likely involve the intermediacy of Zr^{IV} or Ti^{IV} alkyl derivatives. Isomerization here too probably occurs through reversible β-hydride elimination and readdition. In the case of alkylzirconium(IV) complexes prepared from *(5)*, the migration of these metallic moieties proceeds rapidly at room temperature in contrast to analogous organoboron[46] or -aluminum com-

pounds[47], which rearrange only slowly at elevated temperature.

Scheme 6.

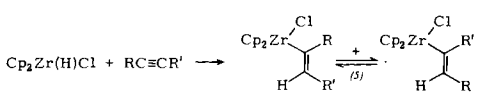


Relative rates[43] for hydrozirconation of alkenes with *(5)* (at room temperature) are α-olefin > *cis* internal olefin ≈ *trans* internal olefin > exocyclically functionalized olefin > cyclic olefin; terminal olefin > disubstituted olefin > trisubstituted olefin. Tetrasubstituted olefins such as tetramethylethylene fail to react with the hydride after many hours at room temperature, as do trisubstituted cyclic olefins such as 1-methylcyclohexene. Competition studies indicate that an α-olefin (*e.g.*, 1-octene) reacts about seventy times faster than do either *cis* or *trans* disubstituted olefins (*e.g.*, 2-octene).

4.2.2. Hydrozirconation of Alkynes

Wailes et al. have reported[48] that hydrozirconation of terminal alkynes proceeds with (C=C) *cis* stereochemistry to place the metal at the terminal carbon atom. Hydrozirconation of various unsymmetrically disubstituted acetylenes occurs[49] readily to give mixtures of alkenylzirconium derivatives in which the relative steric bulk of the alkyl substituents on the C≡C bond dictates the preferred direction of Zr—H *cis*-β addition. The composition of such a mixture of vinylzirconium(IV) compounds does not appreciably change as a function of time if *(5)* is not present in excess. However, with added *(5)*, isomerization to an equilibrium mixture takes place at room temperature (Table 1). The composition of this mixture displays higher regioselectivity than that observed in hydroboration of unsymmetrical acetylenes with hindered boranes[50]. In no case were products derived from allylic rearrangements detected[51].

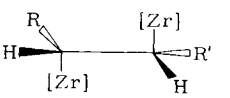
Table 1. Hydrozirconation of unsymmetrically disubstituted acetylenes.



Alkyne R	Alkyne R'	Product ratio (*A*:*B*) [a] initially observed	Product ratio (*A*:*B*) [a] after treatment with *(5)*
H	n-C_4H_9	>98:2	
CH_3	CH_3CH_2	55:45	89:11
CH_3	$CH_3CH_2CH_2$	69:31	91:9
CH_3	$(CH_3)_2CHCH_2$	55:45	>95:<5
CH_3	$(CH_3)_2CH$	84:16	>98:<2
CH_3	$(CH_3)_3C$	>98:2	

[a] Determined by NMR analysis [49].

Isomerization probably occurs through the intermediacy of doubly metalated alkyl derivatives *(7a)* analogous to the one isolated *(7b)*[48] from the reaction between *(5)* and diphenylacetylene. Since metal hydride addition and elimination both occur stereospecifically *cis*, there is no loss of (C=C) stereochemistry in the isomerization process.

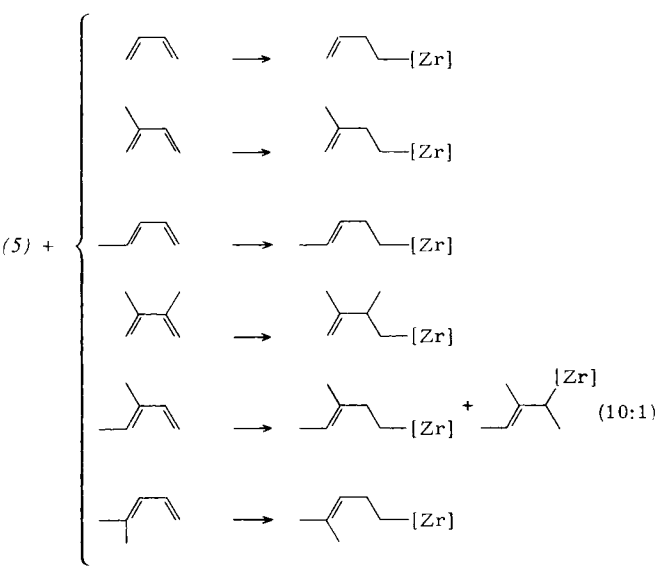


(7a), R, R' = Alkyl
(7b), R = R' = Phenyl

4.2.3. Hydrozirconation of 1,3-Dienes

While the overall mode of addition of *(5)* to alkenes and alkynes parallels reactions known for several main group or transition metal hydrides, the course of addition of *(5)* to 1,3-dienes is significantly different. In contrast to boron-[52] or aluminum hydrides[53], which often doubly metalate 1,3-dienes or give a mixture of products, or to most transition metal hydrides which undergo 1,4- or 1,2-addition to yield allylic complexes[54], *(5)* reacts with a variety of 1,3-dienes by 1,2-addition to the sterically less hindered double bond to give γ,δ-unsaturated alkyl complexes in high yield (see Scheme 7)[55]. However, 2,4-dienes do not behave analogously. Rather, they react with three equivalents of *(5)* (as confirmed by [D]-labeling studies) to give *saturated* alkylzirconium compounds[61]. The mechanism of this unusual transformation has not yet been established.

Scheme 7.



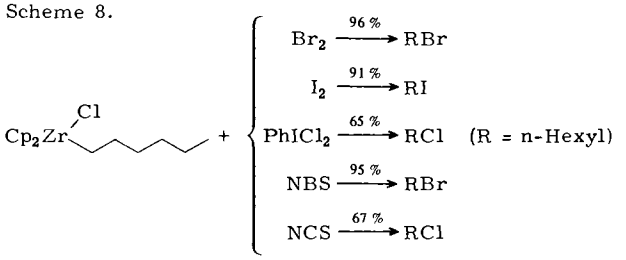
[Zr] = $(\mu^5\text{-}C_5H_5)_2ZrCl$

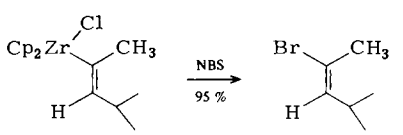
4.3. Cleavage of the Carbon-Zirconium Bond

4.3.1. Alkyl and Alkenyl Halides

Electrophilic halogenation reagents (*e.g.*, Br_2, I_2, *N*-bromo- or *N*-chloro-succinimide, or iodobenzene dichloride) react with alkyl-[43,55] or alkenylzirconium(IV)[49] complexes to yield the corresponding organic halides (Scheme 8). In contrast to reactions involving electrophilic attack upon alkenylniobium(III) complexes[25] (see Section 3), the isomeric composition of the vinyl halide product closely duplicates that of its alkenylzirconium precursor and no *cis-trans* isomerization in the vinyl halide obtained is detectable.

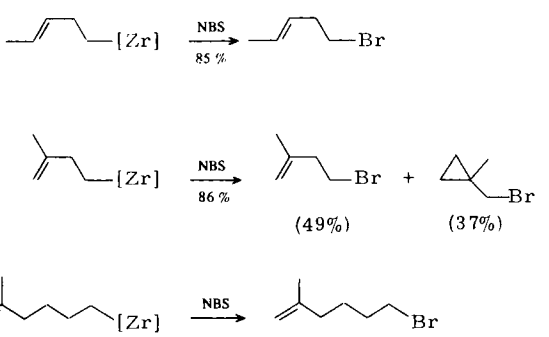
Scheme 8.





For γ,δ-unsaturated alkylzirconium(IV) complexes[55] yet another mode of carbon-metal bond cleavage is also possible. For the compounds shown in which there is a methyl group on the 3-position of the original 1,3-diene, electrophilic attack on the remote double bond can occur to eventually generate (1-methylcyclopropyl)methyl halide (Scheme 9). Noteworthy here is the observation that only properly alkyl-substituted γ,δ-unsaturated alkylzirconium precursors undergo cyclization; the alkyl derivative prepared from 2-methyl-1,5-hexadiene reacts with NBS to yield only the acyclic compound, 6-bromo-2-methylhexene.

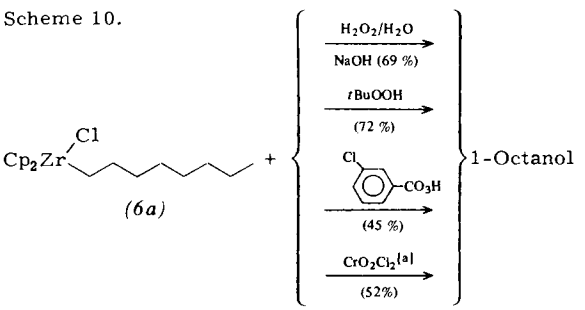
Scheme 9.

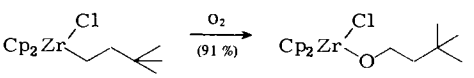


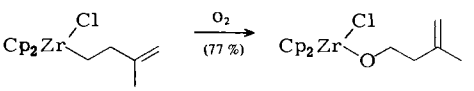
4.3.2. Alcohols[56]

Oxidation of the alkyl carbon-zirconium bond can be effected by O_2 or by various electrophilic oxidizing reagents such as hydrogen peroxide, *tert*-butyl hydroperoxide, *m*-chloroperbenzoic acid, or chromyl chloride. When protic reagents are used, reaction with the alkylzirconium species yields the corresponding alcohol directly. For O_2 or chromyl chloride an alkoxide species is produced which on hydrolysis gives the alcohol. Reaction with chromyl chloride is complicated by the formation of some by-product alkyl chloride. The reaction of alkylzirconium(IV) complexes with O_2 is very slow and requires several hours to attain completion. γ,δ-Unsaturated alkyl derivatives can be oxidized using O_2 to give γ,δ-unsaturated alcohols (Scheme 10). However, attempts to oxidize alkenylzirconium(IV) compounds to give ketones (after hydrolysis) have met with only moderate success; oxidation with O_2 fails completely and only a low yield of ketone is produced with *tert*-butyl hydroperoxide.

Scheme 10.





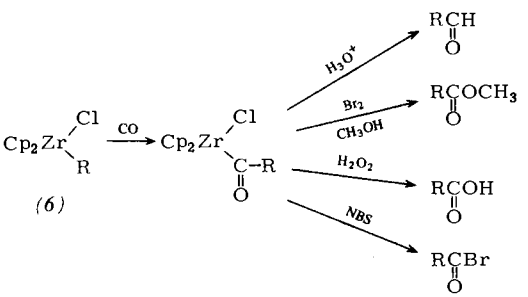


[a] some 1-chlorooctane is also formed.

4.3.3. Insertion Reactions

Carbon monoxide does not insert into the benzyl-zirconium bond of $Cp_2Zr(CH_2C_6H_5)_2$ even under forcing reaction conditions (100°C, 40 atm)[57], and $Cp_2Zr(CH_3)_2$ reacts with CO under pressure (20°C, 40—80 atm) to give an unstable acyl-alkyl species which rapidly loses CO at 1 atm[58]. In contrast to these, CO undergoes clean and high-yield insertion (20°C, 1.5 atm) into the C—Zr bond of many alkyl, alkenyl, or γ,δ-unsaturated alkylzirconium(IV) complexes to generate isolable acylzirconium(IV) species which do not lose CO even under vacuum[59]. Relative rates for CO insertion[60] into the C—Zr bond depend on the nature of the organic substituent: cyclohexyl > *n*-alkyl ≈ alkenyl. These acyls can in turn be converted, depending on subsequent procedures, into aldehydes, carboxylic acids, esters, or acyl halides (Scheme 11). An aldehyde is produced by hydrolysis of the RC(O)—Zr bond with dilute aqueous acid. Treatment of the zirconium acyl with

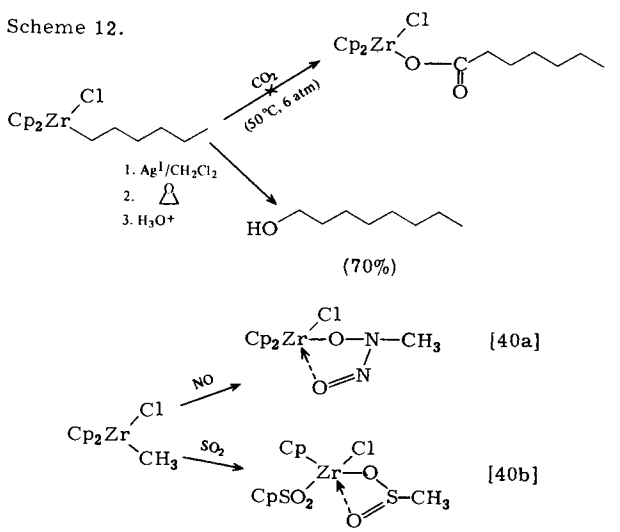
Scheme 11.



NBS gives the acyl bromide. The acyl-zirconium bond can be cleaved by other oxidative procedures as well. Reaction with aqueous H_2O_2 followed by acidification gives the carboxylic acid, and with Br_2 in methanol yields the methyl ester.

Alkylchlorobis(cyclopentadienyl)zirconium(IV) complexes have not been observed to react with carbon dioxide[40, 61] in contrast to tetrabenzylzirconium(IV)[62], which undergoes facile reaction with CO_2 in the molar ratio 1:2. Ethylene oxide inserts slowly into the C—Zr bond of linear alkylzirconium(IV) complexes. This reaction is facilitated by treatment of the organometallic compound with Ag^I in CH_2Cl_2 solution prior to addition of the ethylene oxide. Nitric oxide[40] and sulfur dioxide[40] react with Cp_2ZrMe_2 to form insertion products comprising two equivalents of the electrophilic molecule.

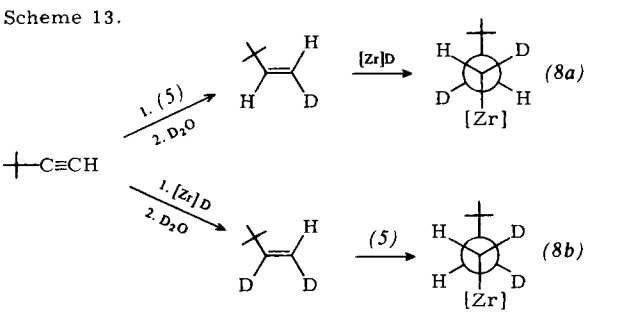
Scheme 12.



4.3.4. Mechanism of C—Zr Bond Cleavage in *(6)*

The mechanism of C—Zr bond cleavage in compounds prepared by hydrozirconation [*(6)*] has been studied[63] by determining the stereochemistry of these processes, employing the NMR technique developed by *Whitesides et al.*[64]. Diastereomerically pure dideuterated 3,3-dimethylbutylzirconium(IV) complexes *(8a)* and *(8b)* were prepared by successive hydrozirconation sequences as shown in Scheme 13. Treatment of 3,3-dimethyl-1-butyne with *(5)* yields the alkenyl derivative as shown, which with dilute aqueous D_2SO_4 gives the olefin indicated (no scrambling of the D label was detectable by NMR). Treatment of this olefin with $Cp_2Zr(D)Cl$ (prepared from Cp_2ZrCl_2 and $LiAlD_4$ in THF) gives the *erythro* alkyl derivative *(8a)* directly; formation of this diastereomer proves that Zr-H addition to an olefin proceeds stereospecifically *cis*.

Scheme 13.



[Zr] = $(\eta^5\text{-}C_5H_5)_2ZrCl$

Cleavage of an alkyl-transition metal bond by bromine proceeding with retention of configuration at carbon has been observed[64] when the metal atom can undergo oxidative addition. Cleavage of the C—M bond by Br_2 with inversion of configuration at carbon has been noted as well[64, 65], and has been interpreted in terms of initial oxidation of the metal complex followed by nucleophilic attack at carbon (with inversion) by Br^- to give the alkyl bromide. Reaction of bromine with *(8a)* or *(8b)* gives the alkyl bromide with retention of configuration at carbon. In the complexes *(8a)* or *(8b)* the metal is formally d^0: hence oxidative addition is not expected and further oxidation will be extremely difficult. A closed transition state such as that proposed for halogenation of organomercurials[66] reasonably accounts for retention at carbon as observed for electrophilic carbon-metal bond cleavage in these alkyl zirconium derivatives (see Fig. 1). Here the electrophilic reagent coordinates to zirconium by donation of a pair of electrons to its vacant low-lying orbital[67], facilitating frontside attack on the C—Zr bond.

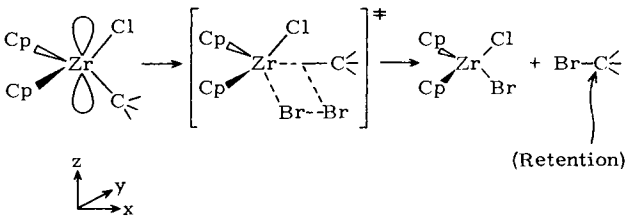


Fig. 1. Probable mechanism of C—Zr bond cleavage, for instance by Br_2.

Carbon monoxide inserts into the C—Zr bond with retention at carbon[63] as has been observed for all other alkyl-transition metal systems studied thus far[64]. Sulfur dioxide also inserts into the C—Zr bond with retention of stereochemistry[63]. It has been reported[40] that $Cp_2Zr(Cl)CH_3$ adds *two* equivalents of SO_2 to give an insoluble product. However, careful addition of *one* equivalent of SO_2 to a solution of *(8a)* or *(8b)* gives a monoinsertion product formulated[63] as $Cp_2Zr(Cl)[O_2S—CHD—CHD—C(CH_3)_3]$ with retention of stereochemistry. This result is in contrast to those[64, 68] obtained for other alkyl-transition metal compounds in which SO_2 insertion proceeds with inversion of configuration at carbon. Nitric oxide also causes electrophilic cleavage of the C—Zr bond with retention of configuration to give the *N*-nitrosylhydroxylamine compound[40]. Electrophilic oxygen reagents such as H_2O_2 or *tert*-C_4H_9OOH transform *(8a)* or *(8b)* into the alcohol with retention of configuration at carbon. These processes too can be accommodated by the closed transition state shown in Figure 1. The postulate that a nucleophilic interaction between the attacking electrophilic molecule and the Zr atom is necessary to effect C—Zr cleavage is supported by the observation that whereas poorly electrophilic (yet mildly nucleophilic) CO readily inserts into the C—Zr bond, the stronger electrophile (but poorer nucleophile) CO_2 does not react with *(6)* even under more stringent conditions.

Treatment of *(6)* with O_2 also gives the corresponding Zr alkoxide[56]. Here stereochemical results indicate that one half of the product is formed with retention at C, while the other half is formed with racemization. One possible mechanism[56] to account for O_2 oxidation is shown in Scheme 14, analogous to those proposed for the autoxidation of Grignard[69] or lithium reagents[70].

Scheme 14.

$$R^*[Zr] + O_2 \longrightarrow R\cdot + \cdot OO[Zr] \longrightarrow ROO[Zr]$$

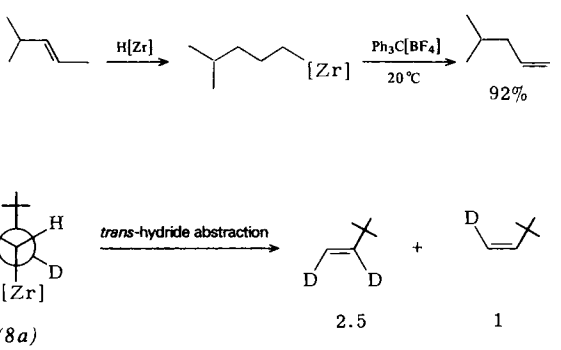
$$ROO[Zr] + R^*[Zr] \longrightarrow RO[Zr] + R^*O[Zr]$$

R^* = chiral alkyl group
R = racemized alkyl group
[Zr] = $(\eta^5\text{-}C_5H_5)_2ZrCl$

4.3.5. Recovery of an Olefin from *(6)*

Hydrozirconation of an alkene having an internal double bond by *(5)* yields the terminally functionalized alkyl complex *(6)* from which the terminal alkene can be obtained. Isomers of the starting olefins can be prepared from rearranged alkylboranes by treatment with a high-boiling terminal olefin and removal by distillation of the desired organic product[71]. This procedure has not yet been successful for *(6)*; the isomerized olefin can be freed neither by treatment with ethylene (even at high temperature and pressure) nor by donor ligands (such as pyridine or alkylphosphanes). However, it is possible to obtain isomerized olefin from *(6)* through β-hydride abstraction as has been observed in iron[72] or tin[73] chemistry. Thus treatment[74] of a solution of the rearranged alkylzirconium derivative with either trityl chloride or trityl tetrafluoroborate in methylene chloride or benzene at room temperature gives the corresponding terminal olefin (Scheme 15). The pattern of D labeling in olefins recovered from *(8a)* indicates that this reaction proceeds through β-hydride abstraction by Ph_3C^+ with *trans* stereochemistry.

Schema 15.



(8a)

4.4. Functional Group Compatibility

Hydride *(5)* can reduce several types of functional groups at a rate competitive with its reaction with an olefin. However, several common and convenient protecting groups have been found to be stable toward the new transition metal reagent. A brief tabulation of functional group reactivity is indicated in Table 2.

It has been reported[75] that Cp_2ZrH_2 reacts with acetone to give $Cp_2Zr[OCH(CH_3)_2]_2$. Hydride *(5)* also reduces free carbonyl groups to Zr alkoxides and nitrile compounds to zirconium imine complexes (similar species have been prepared from the corresponding lithium salts)[76]. These imine salts can be hydrolyzed with dilute aqueous acid to give the corresponding aldehydes[77].

Table 2. Compatibility of functional groups with the hydrozirconation reagent *(5)*; [Zr] = $(\eta^5\text{-}C_5H_5)_2ZrCl$. (An exhaustive study of functional group or protecting group compatibility has not yet been done.)

Reactant	Product with H[Zr]	Protecting group
R—OH	R—O [Zr]	—O—Si$(CH_3)_3$
R—C(O)H	RCH_2OH [a]	
R—C(O)R′	RR′CHOH [a]	
R—C(O)OH	R—CH_2OH [a]	
R—C(O)OR′	R—CH_2OH [a]	—
R—C≡N	R—CHO [a]	—

[a] Upon hydrolysis.

5. Conclusion

The development of *(5)* as a reagent for organic synthesis represents only *one* entry into organozirconium chemistry. For example, sterically congested hydride *(5)* reacts only slowly or not at all with hindered olefins; and, in *(6)*, migration of the metal moiety past a tertiary carbon center is very slow. Therefore, the development of sterically less-crowded zirconium hydrides is a worthwhile aim. Direct alkylation of *(6)* is not yet possible and the means to accomplish this transformation also represents an important goal of future research. Of course, finding new means to effect electrophilic cleavage of the C—Zr bond in *(6)* will continue to be of interest to demonstrate the versatility of these organometallic intermediates.

Apart from its utility as a technique, the development of hydrozirconation illustrates two important points:

1) That synthetically useful transition metal based organometallic reactions can be devised through consideration of organometallic mechanisms.

2) That the introduction of new such procedures will continue to be an exciting aspect of organic synthesis because of the broad scope and high reactivity of organometallic complexes.

Production of Oil by Hydrogenation of Coal[**]

By K. F. Schlupp and H. Wien[*]

A survey of coal hydrogenation processes revealed that, despite a wealth of experience gathered in Germany up to 1945 some of which served as a basis for further work in the USA, there is at present no process available anywhere in the world for the commercial production of oil from coal. Approaches suitable for further development are the noncatalytic one-step limited hydrogenation and catalytic hydrogenation. Under the most favorable conditions production of oil from coal should become technically feasible some time between the early and mid-1980's. In view of the price of heavy fuel oil the commercial prerequisites for production of synthetic fuel oil from coal are presumably fulfilled only in those countries with low coal prices.

1. Introduction

The energy crisis has shown that the industrial nations are in a vulnerable position owing to their great dependence upon oil imports, and will have to expect further increases in oil prices in the future. Enhanced recourse to coal supplies and liquefaction of this coal to give substitute oil products could alleviate the dependence upon imports and thereby help to ease the situation. Liquefaction of coal also has environmental advantages since the products are largely free from ash and sulfur.

For these reasons the liquefaction of coal is attracting growing interest in countries possessing coal deposits. Much positive efforts will, however, be required to develop the technologies necessary for coal liquefaction to commercial maturity.

2. Market Studies

The potential uses of synthetic fuel oil are determined by the amount of hydrogen added to the coal by the technological process adopted.

Modest addition of hydrogen affords extracts suitable as substitute heavy fuel oil. The synthetic oil could also serve as raw material for products normally obtained from tar or tar pitch, *e.g.* electrodes and binders.

More extensive addition of hydrogen can lead to light and middle distillates well suited as chemical feedstock on account of their aromatic, naphthenic, and aliphatic components.

In the fuel field, coal hydrogenation could provide substitutes for heavy and light fuel oil. The greatest consumers of heavy fuel oil in the Federal Republic of Germany are the heavy and manufacturing industries (58 %) and power stations (24 %).

Commercial production of oil from coal will not become technologically feasible until the early 1980's. A largely constant fuel oil market of about 30 million t/a has been predicted for that period in the Federal Republic. Any significant influence on this market will require production of about 6 to 10 million t/a of oil in large-scale plants, processing about 12 to 20 million t/a of coal.

[+] To whom correspondence should be addressed.

[**] Based on a joint study by Ruhrkohle AG and STEAG AG in collaboration with Bergbauforschung GmbH for the Minister für Wirtschaft, Mittelstand und Verkehr des Landes Nordrhein-Westfalen (Germany).

Accurate information is not yet available about the constituents of synthetic oil from coal. However, it may be assumed that important raw materials for the chemical industry will be produced from this source.

The oil produced by mild hydrogenation contains about 50 % of a substance resembling coal tar pitch, the rest being oil fractions of various boiling ranges.

The heavy fraction resembling coal tar pitch would be suitable for manufacture of valuable carbon products such as graphite, binding pitches, or special types of coke. Binding pitches are already produced mainly from coal products, while 80 % of the pitch required for producing special cokes is of petrochemical origin.

The oil fractions of the synthetic oil contain aromatic, naphthenic, and aliphatic components. The contents of cyclohexane, benzene, toluene, and xylene, and also of fused aromatics like naphthalene and anthracene, command particular interest for the production of important primary chemicals. Furthermore, tar acids and tar bases, as well as those fractions which may serve as carbon black oils, also possess economic significance.

The present-day contribution of coal chemistry to supplies of raw materials for the chemical industries is low, being estimated as about 10 % of petrochemical feedstock. In view of the expected growth in demand for chemical feedstocks, an additional market of about 1 million t/a of synthetic oil can be envisaged in the chemical industry of the mid-1980's.

3. Product Definition

Product definition for coal liquefaction arises from the objective of producing low-ash and low-sulfur products from coal ranging from heavy fuel oil to middle and light distillates which are stable when stored. Moreover, substitution of heavy fuel oil by the coal-based product should not require extensive adaptation of equipment and plant.

Table 1. Desired properties of oil obtained from coal.

Calorific value	*ca.*	10000 kcal/kg
Density (15 °C)	*ca.*	1.0 kg/dm^3
Flash point		>65 °C
Viscosity at 100 °C	max.	40 cSt
Sulfur content	max.	0.6 wt. %
Ash content	max.	0.1 wt. %

The desired properties of the synthetic oil are listed in Table 1. They largely correspond to those of heavy fuel oil. The values for sulfur and ash content are lower.

4. Survey of Contemporary Processes

4.1. Production of Liquid Products from Coal

Production of liquid products from coal was long accomplished exclusively by thermal treatment. The resulting lignite- and coal tars were the principal raw material of the chemical industry. Meanwhile, products of the petroleum industry have largely replaced tar derivatives.

Table 2. Molecular weights and hydrogen contents of various hydrocarbons.

	g H_2/100 g C	Molecular weight
Coal	6	>5000
Lignite	8	>5000
Petroleum	14	400
Light fuel oil	16	200
Gasoline	17	100
Methane	33	16

As shown in Table 2, high yield conversion of coal into liquid products requires degradation of the high-molecular coal and addition of hydrogen. Without addition of hydrogen, as in purely thermal processes, relatively low yields (5 to 25 % based on the initial amount of coal) of liquid products are obtained.

In 1910, *Bergius*[2] undertook the first industrially oriented investigations, and succeeded in producing petroleum-like products at 400 to 450°C and 150 bar. Experience gained by BASF at Ludwigshafen in the field of ammonia methanol synthesis (high-pressure engineering and catalyst production)[3] permitted development of the Bergius process to technical maturity[4]. The first large-scale experimental plant with a capacity of 100000 t/a of motor gasoline from coal was built at Leuna in 1926. Up till 1945, twelve further plant were commissioned for hydrogenation of tar, lignite, and hard coal, four of them on the territory of the present Federal Republic (Scholven, Gelsenberg, Welheim, and Wesseling). A total of about 15 million t of liquid fuel was produced on the basis of the Bergius process up to 1945. The plant were then either shut down or revamped for hydrogenation of petroleum residues.

Starting in about 1930, the Gewerkschaft Mathias Stinnes attempted to produce low-ash, solid extracts by extraction of coal with suitable solvents[5]. However, such extracts can be degraded to light liquid products only with great difficulty. They are ideally suited to the manufacture of electrodes. A commercial-scale plant producing 30000 t/a of extract was

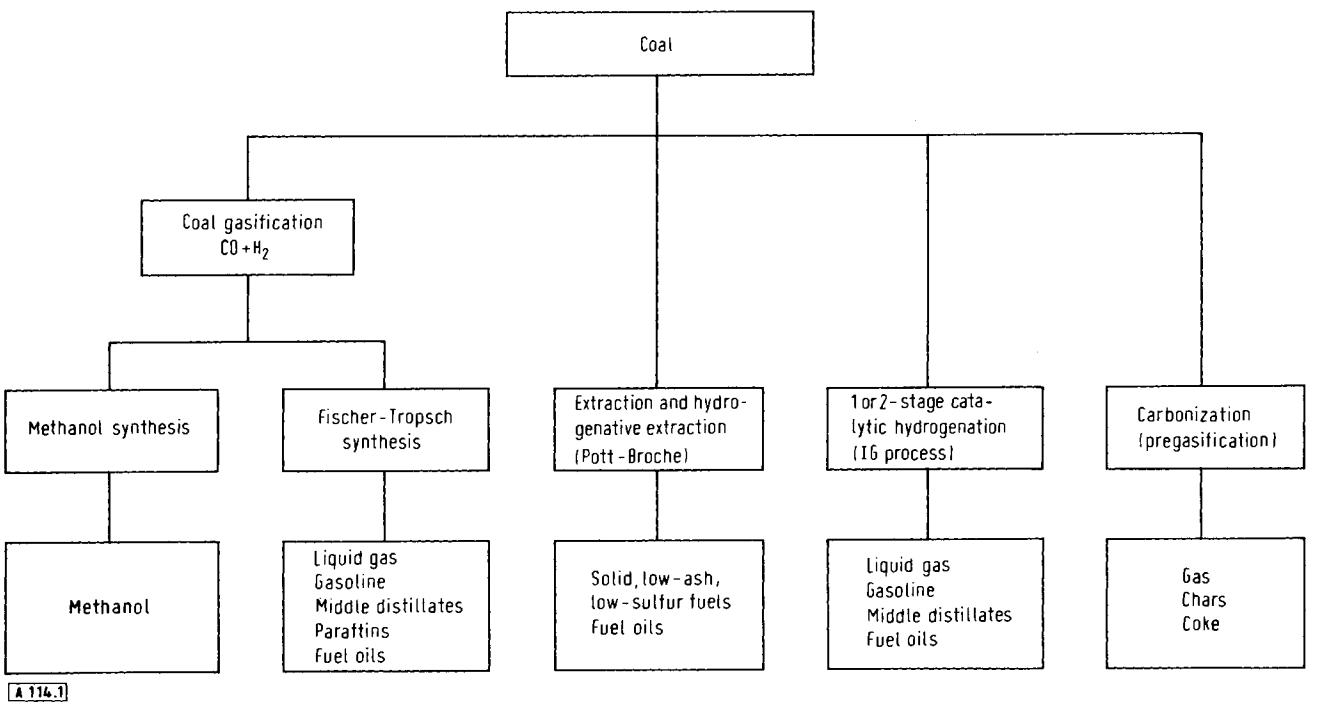

Fig. 1. Processes for liquefaction of coal.

Figure 1 depicts the processes yielding liquid products from coal. Only the carbonization process and the Fischer-Tropsch synthesis are still operating on an industrial scale. Production of methanol is included in the survey since increased efforts have recently been directed toward the use of methanol as a fuel (methyl fuel).

4.2. Historical Development

The first experiments on coal hydrogenation were performed by *Berthelot*[1] as long ago as 1869. They were without industrial significance but did demonstrate the basic feasibility of transforming coal, by addition of hydrogen, into liquid products.

operated by Ruhröl at Bottrop from 1938 to 1944. It was destroyed in the war and was never rebuilt.

In the Pott-Broche process only the solvent serves as hydrogen donor. By introducing a limited direct supply of hydrogen Uhde, and later also IG-Farben, attempted to produce extracts more susceptible to degradation to give liquid hydrocarbons. This Uhde-IG approach was not developed to commercial viability.

The development of coal liquefaction in Germany came to an end in 1945. The reasons were initially the restrictions imposed by the Military Government, and later the lack of

economic interest in the products. Up to about 1963 the remaining high-pressure plant were used for hydrogenation of petroleum residues.

Nevertheless, work was continued on coal liquefaction, above all in the USA and more recently in South Africa, Poland, and Great Britain. Utilizing German know-how, coal liquefaction was introduced in the USA for the production of fuels and chemical feedstocks. The intensity of these efforts lagged and operations were discontinued in the 1950's because the oil industry was marketing increasing quantities of crude oil at low prices. They were taken up anew by coal mining companies in the 1960's. The primary aim was to convert high-sulfur US coal into low-sulfur and low-ash products in order to obtain heating and motor fuels. This work received considerable financial support from the Office of Coal Research and led to the construction of several pilot units. Laboratory experiments were performed on direct conversion of coal into liquid products on fixed catalyst beds. Attempts were also made to operate carbonization processes leading to petroleum-like products in larger pilot plants.

4.3. Individual Processes[6]

4.3.1. The Pott-Broche Process

In the Pott-Broche process finely divided dry coal is extracted at 425 to 440°C and 150 bar with a solvent. Ash and unreacted coal are filtered off. The extract has a softening point of about 220°C and an ash content of <0.2 wt-%. The original solvent was a mixture of tetralin and cresol. Since it had to be rehydrogenated after recovery, later process variants employed a gas-oil fraction of pitch hydrogenation with similar results. Because of the considerable difficulties attending further processing to give lighter products, the extracts were used for manufacturing electrode carbon.

4.3.2. The Uhde-IG Process[4]

The Uhde-IG process is a hydrogenating extraction employing catalysts. The extract obtained at about 450°C and 300 bar has a softening point of 60 to 120°C and an ash content of <0.2 wt-%. Ash and unreacted coal are removed by filtration. The extract can be processed to light distillates in a hydrocracker. This process has so far only been tested on a pilot scale.

4.3.3. The Bergius-IG Process

In the Bergius-IG process coal is converted primarily into distillates in the gasoline boiling range by hydrogenolysis in the presence of catalysts. The process is conducted in two stages. In the first step (liquid phase process, 490°C, up to 700 bar) a slurry of pulverized coal in a solvent is transformed into a liquid product in the presence of a suspended catalyst and hydrogen. The liquid product boiling below 325°C is converted in the second stage (vapor phase process, 400°C, 300 bar) into light distillates over fixed catalysts in the presence of hydrogen. The solvent required for slurrying the coal is produced in the liquid phase and recycled to the process. About 15 million t of gasoline was produced by the process up to 1945. The plant capacity amounted to about 4 million t/a in 1943 and 1944.

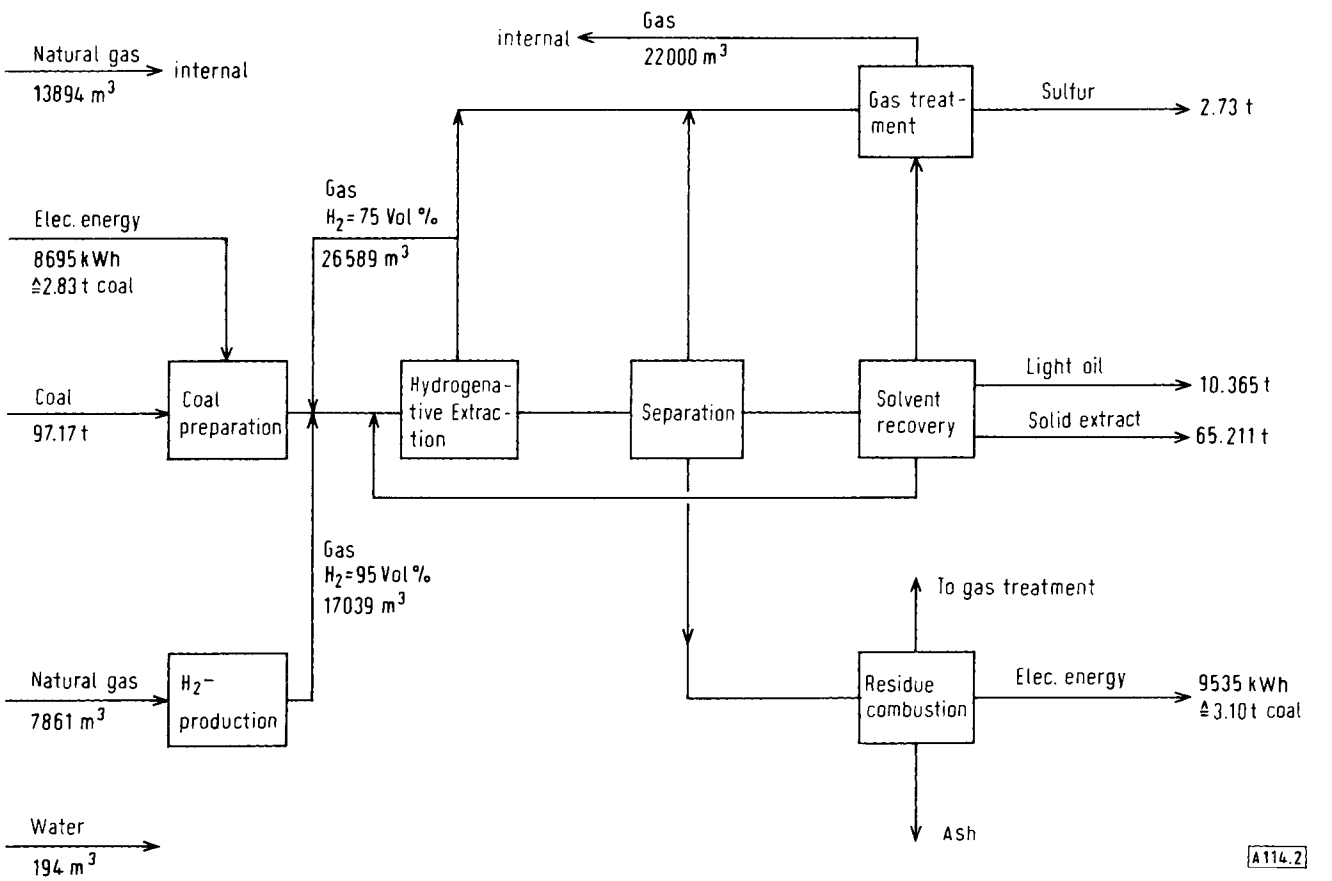

Fig. 2. Block flow diagram of the Gulf SRC-I process.

4.3.4. The Gulf-SRC Process[7]

This process resembles the Uhde-IG process. In the SRC-I process a solid, low-sulfur, low-ash extract is obtained by hydrogenating extraction. Ash and unreacted coal are separated off with the aid of drum filters. The softening point of the extract lies between 160 and 200 °C. Another variant, the SRG-II process, yields liquid products by hydrogenating extraction and destructive hydrogenation. The major product is a low-ash, low-sulfur heavy fuel oil. Production of the solid extract is carried out at 450 °C and 80 bar, and that of the liquid fuel at 450 °C and 140 bar.

Figure 2 shows a block flow diagram of the SRC-I process and its material and heat balance.

The SRC-I process for producing solid extracts has been tested in a 50 t/d pilot plant (Tacoma, Washington, USA). Meanwhile, the plant has been adapted for testing the SRC-II process, which should begin in 1976.

4.3.5. The Consol Synthetic Fuel Process (CSF)[8]

The CSF process of the Consolidated Coal Company was developed on the basis of the Pott-Broche process. It is a two-stage process.

In the first stage the coal is slurried with a solvent arising in the process and extracted at about 400 °C and 20 bar. After removal of ash and unreacted coal, the solid extract is subjected to destructive hydrogenation. A petroleum-like product is obtained.

A pilot plant having a capacity of 18 t/d was operated in Cresap, West Virginia, USA, but was shut down because of difficulties encountered in solids/liquid separation.

4.3.6. The H-Coal Process[9]

In the H-Coal process of Hydrocarbon Research Inc. the coal is converted in a single stage into liquid products in the presence of a cobalt-molybdenum catalyst. The catalyst is retained in the reactor where it is kept in random motion (ebullated bed reactor). Its hydrogenating capacity is maintained by constant removal and replenishment of spent catalyst. Maximum operating temperature and pressure are 460 °C and 200 bar. Depending on the reaction conditions the process can yield predominantly light distillates or fuel oils. A material and heat balance is shown in Figure 3.

The process has so far been tested in a pilot plant consuming 3 t/d of coal. With support from the Energy Research and Development Agency (ERDA) and several US companies, Hydrocarbon Research is currently planning a pilot plant for 600 t/d of coal.

4.3.7. The Clean-Fuel-from-Coal Process (CFFC)

In the Lummus CFFC process coal is subjected to destructive hydrogenation in a single stage with the aid of a cobalt-molybdenum catalyst. The catalyst remains in the reactor, and the process operates at about 440 °C and 200 bar.

Ash and undissolved coal are removed by sedimentation in settling tanks with addition of a flocculating agent (kerosine)[10]. Predominantly light products or fuel oils can be produced.

The process is being tested in a laboratory-scale plant with a coal throughput of 1 t/d.

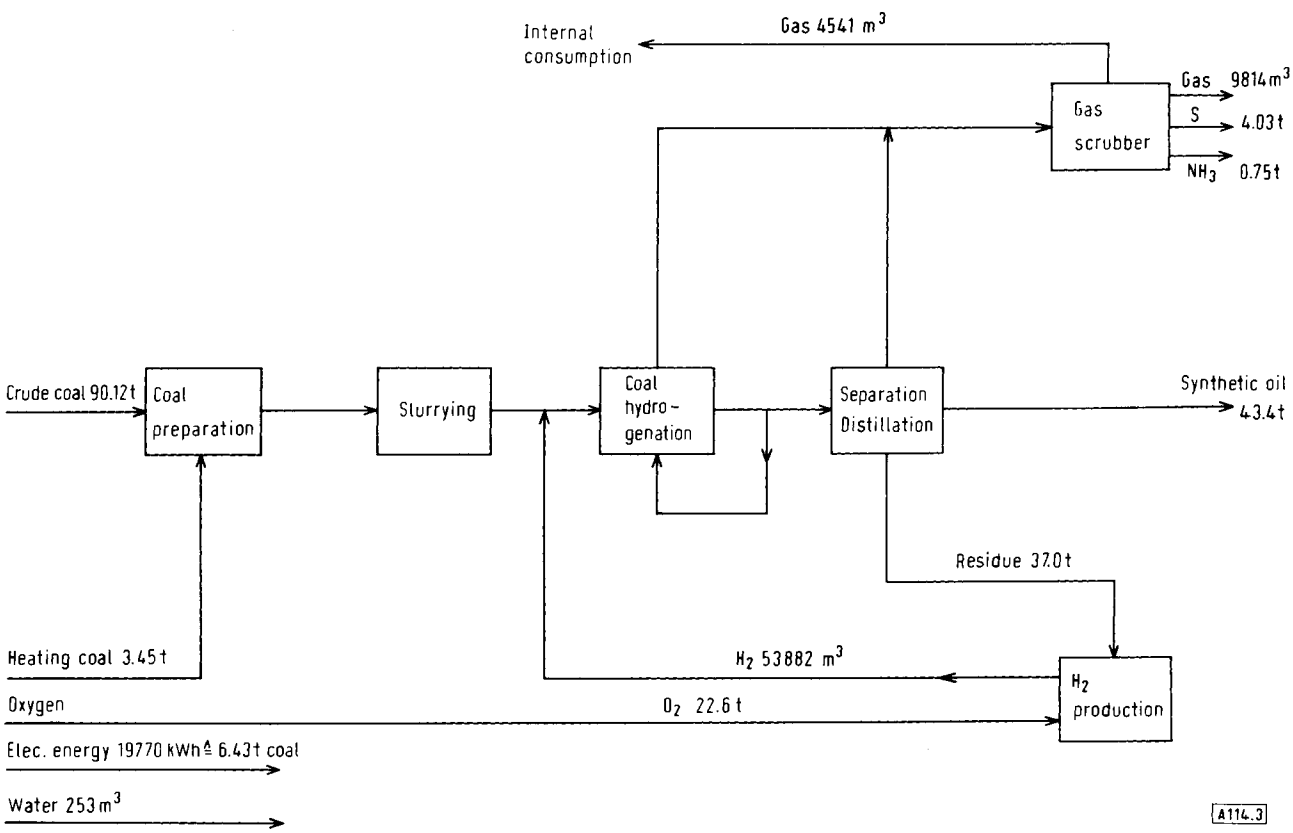

Fig. 3. Block flow diagram of the H-Coal process.

4.3.8. The Synthoil Process[11]

The Bureau of Mines Synthoil process involves destructive hydrogenation of coal slurried with solvent over a fixed bed catalyst at 425 to 450°C and 140 to 280 bar. The process is reported to be suitable for the manufacture of liquid low-sulfur and low-ash fuels for power stations. The technical feasibility of the process has been tested in pilot plant with a coal throughput of 500 kg/d. A pilot plant for a coal throughput of 8 t/d is planned.

4.3.9. The Donor Solvent Process (EDS)

Developed by Exxon, this process yields light distillates to heavy fuel oil. The hydrogen required is provided by the solvent and in the form of molecular hydrogen. The solvent is rehydrogenated catalytically in a second process step. The Exxon company plans to build a pilot plant with a coal throughput of 250 t/d.

4.3.10. Other Activities[12]

Apart from efforts to produce liquid products from coal by extraction or direct hydrogenation, work is also in progress on the conversion of coal into partly liquid products by carbonization. The initially formed low temperature carbonization tar must, however, be hydrotreated prior to further processing. These developments include the COED process (Char Oil Energy Development)[13] of the Food Machinery Company (FMC), the Toscoal process[4] of the Oil Shale Corporation, and the Hydrocarbonization process of the Coalcon Company. The last-mentioned approach utilizes hydrogenating carbonization in order to raise yields of liquid products. A Coalcon pilot plant is being built with the aid of ERDA, the cost being estimated as about 240 million $.

Mention should also be made of a dry hydrogenation of coal at 515°C and 140 bar over a tin chloride catalyst, as developed on a laboratory scale by Utah University[5]. The products are 35% of liquid products (gasoline, Diesel oil), 35% of gas (84% being methane), and 30% of coke. The experiments were carried out batchwise.

5. Technical Problems

5.1. Design Uncertainties

Experience has shown that the design of plant and components for extraction and hydrogenation of coal can be extremely unreliable when based only on analytical data. The consequences are design risks for product quality, functional ability, and capacity. Since the technical basis is uncertain, so are cost predictions. The reason for the uncertainty lies in the fact that the coal from each individual deposit is different. Its influence on the processes of extraction, hydrogenation, and filtration therefore must be experimentally verified.

5.2. Removal of Solids

The removal of solids (mineral components, undissolved coal) from the suspension after extraction or hydrogenation is problematic because the solid particles are very small and the difference in specific gravity between solids and liquid is slight. Furthermore, the adhesion between liquid and solid particles and the viscosity of the liquid are high.

A further obstacle to filtration may be presented by swelling of the primary transformation products of the coal on hydrogenation to form a kind of gel.

Filtration is accomplished mainly with rotary filters, the drums being precoated with a kieselguhr suspension. The layer of solids arising on filtration is continuously peeled from the drum by a doctor knife.

The efficiency and lifetime of the filters have hitherto been unsatisfactory. Filters will have to be developed which permit high-speed filtration and are reliable and easy to operate.

Removal of solids by sedimentation has the advantage of a low energy consumption. However, much space is required. The residence time in the large settling tanks is reduced by addition of flocculating agents. The principal development task consists in determination of the parameters determining the sedimentation process in large-scale plant for the particular kind of coal used. Moreover, the storage stability of the product must also be investigated. There is evidence that asphalts precipitate long after removal of the flocculating agent.

Use of distillation for liquid/solids separation can result in baking and blocking of the distillation column, thus impairing heat transfer. Wear of pumps, fittings, and other plant components by the enriched solids is also to be feared.

5.3. Utilization of Residues

Liquid/solids separation affords a sulfurous residue made up of oil, unreacted coal, and mineral components. Processing of this residue causes problems since dumping or combustion are ruled out by impaired efficiency or environmental pollution. A possible solution lies in heating of the residue to drive off the oil and subsequent gasification of the dry residue, provided that the ash content is not too high. Hydrogen generated on gasification can go some way to cover requirements for hydrogenation.

5.4. Catalyst Behavior

Problems encountered are attrition of the catalyst by the turbulence in the hydrogenation reactor and deactivation by solids deposited on the catalyst surface.

5.5. Performance of Materials of Construction and Plant Components

Plants for manufacture of synthetic liquid fuel from coal operate at temperatures between 450 and 500°C and pressures of 70 to 300 bar. Hydrogen used under these conditions as well as the presence of sulfur and other corrosion-promoting substances place stringent demands on materials. Problems are also raised by the conveying of coal/oil suspensions which can lead to erosion in pipework, fittings, and above all in the highly taxed pumps.

6. Further Developments

Development of a commercially viable process for producing heavy fuel oil and middle and light distillates as feedstock for the chemical industry should be pursued along two lines.

One of the principal paths worth following is the single-stage limited hydrogenation without catalyst. At the present state

of development this kind of process provides an opportunity of achieving the production of low-ash and low-sulfur heavy fuel oil in the fairly near future with relatively simple engineering and on a sound economic basis. Adaptation of the Gulf 50 t/d pilot plant at Tacoma to liquid product will provide the earliest opportunity for large-scale testing of this process variant.

The other main line of development is destructive hydrogenation with the aid of catalysts. This kind of process has greater inherent flexibility (production of heavy fuel oil and of middle and light distillates). It has been tested up to a pilot scale.

The double strategy outlined is necessary in the absence of any clear indication as to which approach offers the greater technical and economic promise. Moreover, it cannot yet be predicted when the processes will reach the goal of commercial viability. Nor can it be ruled out that one of the two approaches will have to be abandoned for technical or economic reasons prior to attainment of that goal.

Glass—A Continuing Challenge to Chemistry

By Marvin D. Britton[*]

This review of the modern chemistry of glass shows that silicate glasses are extremely reactive materials. Compositions, phases, surfaces, and structures can be manipulated in endless variety, and there is no foreseeable limit to the benefits of research in this area.

1. Introduction

1.1. The Structure of the Glass Industry

In the field of materials science, glass and ceramics are considered to be similar materials, both in respect to their properties and in many of their applications. However, the characteristic which truly distinguishes these materials is the process of forming. Typically, ceramic products are formed by powder compaction, while glass products are manufactured by chilling a completely fused silicate (for general reading, see refs. [1–10]).

This concept of isolating an industry for study on the basis of unique forming concepts can be carried further: the entire glass industry can be split into four major groups, all relying on the melting of mineral raw materials, but each depending on a characteristic forming process and product: the sheet glass industry, the container glass industry, the fiber glass industry, and the technical glass industry. The manufacture of art glass is a fifth branch, but of much less commercial importance. In the United States, containers account for about one-half the dollar volume, technical glass about one-fourth, and glass fibers and flat glass share the balance about equally[11].

1.2. The Economics of the Industry

While almost all elements of the periodic table are used in the glass industry, the oxides of silicon, calcium, and sodium form the "soda-lime glass" which accounts for 95% of the glass produced in the United States. Fortunately, there are no shortages of these raw materials, and given adequate fuel supplies in the future, glass will continue to be one of the most economical materials known to the architect, product engineer, or consumer.

The other 5% of the glasses encompass hundreds of specialty glasses, with several families of compositions developed especially for their optical properties, heat resistance, electrical resistance, ease of fabrication, or durability. Raw materials for such compositions are in generous supply, although economic and political factors have increasingly affected both costs and availability. For example, shortages of soda ash as produced by the Solvay process seriously affected container glass

[*] Dr. M. D. Britton
Corning Glass Works
Corning, New York 14830 (USA)

production as demand increased, but a 300 year underground supply of trona, a natural deposit, has been opened in Wyoming.

2. Glass Composition and Properties

2.1. The Structure of Glass

Glass should be considered as a state of matter, and is in no sense a unique composition. It is like a liquid in the sense that the composition is infinitely variable and the atomic structure is without long range order. However, there is a difference from a cooling or supercooled liquid: at some point, known as the transformation point, the volume *versus* temperature curve deviates from the straight line that would be followed by a supercooled liquid. The transformation temperature will vary according to the rate at which the liquid is being cooled, and the range of transformation temperatures associated with a particular composition is called the transformation range. The structural changes occurring at the transformation temperature are not known, since there is no definitive knowledge of the cold structure of glass. The difference in behavior from that of a supercooled liquid or a composition which crystallizes on cooling and melts on heating is shown in Figure 1.

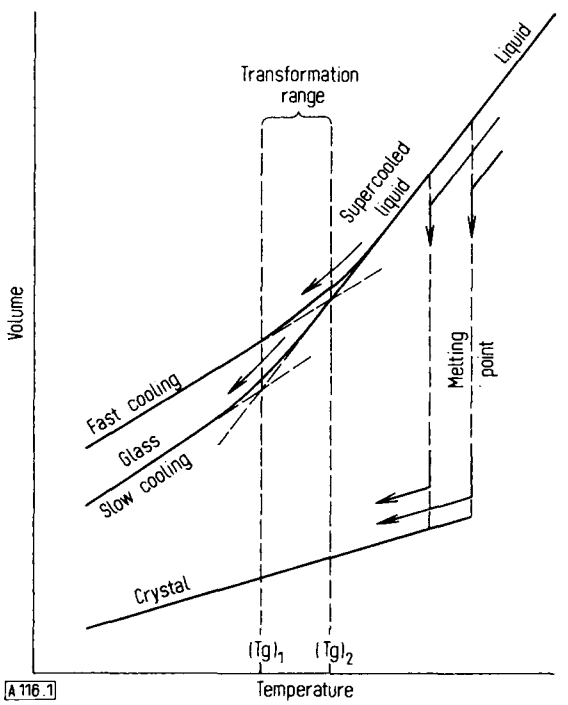

Fig. 1. Volume-temperature relationships for glasses, crystals, and supercooled liquids.

The most common concept of the structure of glass is of a random network of silicon atoms, each surrounded by a tetrahedrally arranged group of four oxygen atoms. This building block, the $[SiO_4]^{4-}$ tetrahedron, shares each of its oxygens with another silicon atom, which is at the center of an adjacent $[SiO_4]^{4-}$ tetrahedron, but the angle of contact between the several tetrahedra is not fixed in a glassy structure. Thus, there is a short range order: the 1.6 Å range of the Si—O couple; but within the distance of 17 Å, there is no longer any semblance of order, the structure being that of the liquid state. The two-dimensional schematic drawing (Fig. 2a) shows the irregularity of structure in contrast with the regular structure of a crystalline silica such as the mineral quartz (Fig. 2b).

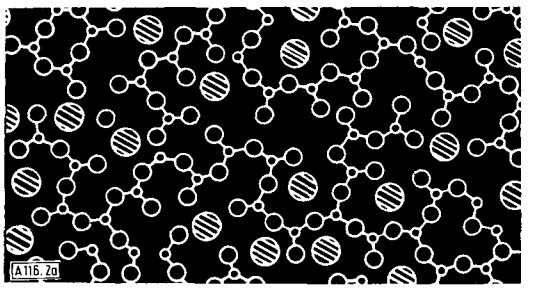

Fig. 2a. Schematic two-dimensional representation of a non-crystalline structure containing network modifying cations.

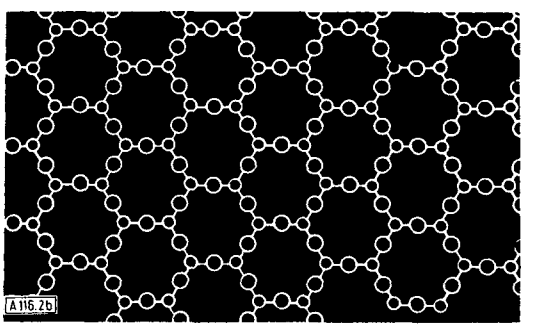

Fig. 2b. Schematic two-dimensional representation of a crystalline silica atomic structure.

Silicon is a network former because of its ability in conjunction with oxygen to maintain a random network on cooling to a solid. B_2O_3 and P_2O_5 behave similarly. The Si—O bond is covalent, and strong enough to make the network rigid even at high temperature. Thus, molten silica is extremely viscous even at 1800 °C, much above the 1713 °C melting point of the original phase, cristabolite. The network forming elements, B, Al, Si, Ge, and others fall in a group for which the E—O single-bond strength ranges from 80 to 120 kcal/mol. The modifying elements, *e.g.*, Mg, Ca, Li, K, Na, Cd, Cs are ionically bonded to oxygens, and this bond strength ranges from 10 to 60 kcal/mol. The network modifiers, being more loosely bonded are relatively free to diffuse through the structure, and this is especially true for the monovalent cations. These modifiers also rupture the continuous Si—O—Si network, and in thus limiting the degree of linkage, substantially reduce the viscosity of the glass at every temperature. Divalent ions act as a bridge between two oxygen ions, and while they break up the strong network structure they are less mobile and less effective fluxes than the univalent cations. The disruptive action of monovalent and divalent cations is illustrated in Figure 2a.

In addition to the network formers and modifiers, a third group, the intermediates, have bond strengths of 60—80 kcal/mol. Typical elements are Ti, Zr, Pb, and Al. Such ions are not usually capable of forming a glass, but can occupy either a glass forming or a glass modifying position, or both.

Relative amounts of the three types of elements can be varied to an almost infinite degree to achieve a particular set of properties. The only constraint is that a sufficient amount of network forming ions must be present to prevent crystallization. These base glasses then serve as a host for the coloring oxides, small quantities being adequate for rich, transparent colors. Examples of these coloring agents are: yellow, UO_2, CdS; green, Cr_2O_3, Fe_2O_3; blue, CoO, FeO; violet, NiO, Mn_2O_3; gray, Cr_3O_4-NiO; black, Mn_2O_3-Cr_2O_3; red, CdSe, colloidal Au or Cu.

2.2. The Homogeneous Glasses

Homogeneous glasses consist of a single phase. They vary widely in composition, but will fall into one of three classes: the "refractory" glasses[12] and the "hard" glasses, meaning that the melting, working, and use temperatures of the glasses are higher than those of the third type, the "soft" glasses. These terms refer to the viscosity-temperature behavior shown in Figure 3 rather than to abrasion resistance.

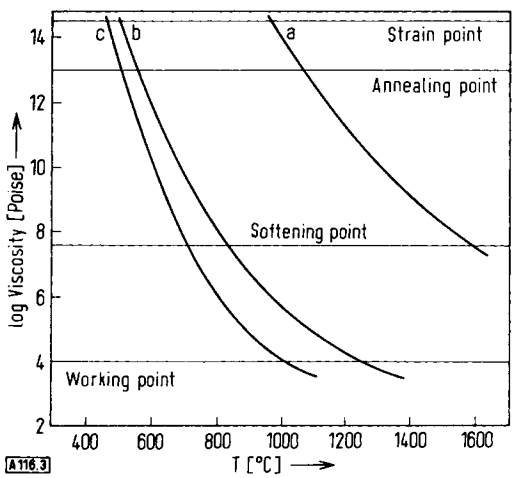

Fig. 3. Viscosity-temperature curves for (a) "refractory", (b) "hard", and (c) "soft" glasses. Compositions: (a) 99.9 % SiO_2; (b) 80.3 % SiO_2, 2.3 % Al_2O_3, 13.3 % B_2O_3, 4.0 % Na_2O; (c) 73.6 % SiO_2, 1.4 % Al_2O_3, 16.2 % Na_2O, 0.4 % K_2O, 3.4 % MgO, 4.8 % CaO, 0.2 % SO_3.

The refractory glasses include two main families: glasses having high silica contents and the aluminate and aluminosilicate glasses. Hard glass comprises the borosilicates. The soft glasses are made up of three families: the soda-lime, the lead, and most of the non-silicate glasses. It should be noted that the glasses are classified by application rather than by strict chemical type since there is no absolute correspondence between a glass composition and its utilization.

The refractory glasses can also be classed as those having an annealing point over 700 °C. This annealing point is defined as that temperature at which the viscosity is about 10^{13} poises, or as that temperature at which the internal stress is substantially relieved within 15 minutes. Thus, a hard glass such as that shown in Figure 3 (b), which is a sodium borosilicate, would not qualify as a refractory glass since its annealing point is 565 °C. An example of a soft glass, a soda-lime glass with an annealing point at 510 °C, is shown in Figure 3 (c). The refractory glasses include vitreous silica, reconstructed glass, high silica, aluminosilicate, and aluminate glasses (see Fig. 3 (a)).

Vitreous silica[13], the most refractory of commercially useful glasses, ranges in annealing point from 1020 to 1200 °C, depending on the raw material and manufacturing method. The significant variable is the OH^- content. If it is below 10 ppm, the annealing point is 1200 °C; but if the OH^- content is increased to 1000 ppm the annealing point drops by 150 °C. At the high temperatures for which vitreous silica is particularly appropriate there is a tendency for the glass to devitrify (crystallize), particularly around 1600 °C, although there is cristobalite growth throughout the temperature range of 1000 to 1723 °C. If Na_2O is present, even as little as ¼ %, the devitrification rate is increased 20- to 30-fold, and the temperature of maximum crystal growth rate drops from 1600 to 1400 °C. Because of its extreme viscosity, vitreous silica is very difficult to melt and to shape as the material tends to be reduced and to volatilize in the forming range.

If 7.5 % (by weight) of TiO_2[14] is added to vitreous silica the expansion coefficient drops from 5.3×10^{-7} cm/cm K to essentially zero. The annealing point remains at 1000 °C, compared to 1084 °C for vitreous silica.

Reconstructed glass of Vycor type is a 96 % SiO_2 material, described in Section 2.3 as a derivative of phase-separated glass. The properties are close to those of vitreous silica, although the decreased number of silicon-oxygen tetrahedra due to the presence of boron-oxygen triangles lowers the annealing temperature. If special efforts are made to reduce the OH^- content, the annealing point is raised, and the infrared transmittance is enhanced. The OH^- absorption band at 2.8 μm tends to reduce the optical transmission of silicate glasses to less than 10 % of the amount of incident light. With a nitriding treatment, *i.e.*, heat treatment of the porous silica residue in ammonia, the final glass will contain trivalent nitrogen in the structure. The annealing point is raised to 1214 °C. Adding 0.1—0.2 % alumina to vitreous silica will also raise the annealing point by as much as 100 °C.

The aluminosilicate glasses (containing, *e.g.*, 57.3 % SiO_2, 15.7 % Al_2O_3, 3.9 % B_2O_3, 0.1 % Na_2O, 6.6 % MgO, 9.4 % CaO, 5.9% BaO, 0.1% As_2O_3)[15], have high annealing points, but can be much more easily produced than the high silica glasses. Because of their relatively low or zero alkali content these glasses will have low expansion, high electrical resistivity, a steep viscosity curve, *i.e.*, a relatively large change in viscosity for a small temperature change, and lower permeability to gases. A principal use of these glasses is as a lower-cost substitute for high-silica glasses in discharge and halogen cycle lamps. Other uses result from the high annealing point: ignition tubes for chemical analyses, aerospace windows, and infrared transmitting applications.

The borosilicate glass family (hard glass type) balances the excellent properties of the vitreous silicas with the ease of manufacture of the soda-lime and lead glasses. Compared to lime or lead glasses, they have markedly superior resistance to chemical attack, a high annealing point, and excellent thermal shock resistance.

The soft glass families, such as the soda-lime, lead, and most of the nonsilicate glasses represent a predominant part of the glass industry. Soda-lime glass, for example, represents 90 % of the tonnage melted owing to its low cost, ease of melting, ease of forming, and excellent durability.

Lead glass is favored for electrical applications because of its high electrical resistivity and easy workability. Premium lead glasses are used for fine crystal ware because of the

high refractive index and for radiation shielding windows because of their radiation absorption.

The nonsilicate glasses contain GeO_2 or sulfur as one of their chief components. Lindemann glass is composed of light atomic weight materials, primarily B_2O_3, and is used as a transmitting medium for X-rays. Rare earth borate glasses have unusually low dispersion at high refractive index and, like phosphate glasses which have both low dispersion and low refractive index, are used for optical instruments. Germanate and arsenic trisulfide glasses are infrared transmitting glasses. The most remarkable property of the chalcogenide glasses is electronic, *i. e.*, these are semiconducting rather than ionically conducting materials. Recent research has shown that the glassy state can be achieved in very unusual systems such as nitrate, acetate, formate, and thiocyanate. Although no useful materials of this kind have yet been discovered, such systems are useful in the research on the structure of glass.

2.3. The Heterogeneous Glasses

Any account of the recent history of glass research must emphasize the importance of phase separation. These new materials, many of which are produced by chemical treatment or by alterations in the distribution of the various chemical species in the glass, can properly be called "heterogeneous glasses". It must be recognized that heterogeneity can exist at various levels: atomic, submicroscopic, microscopic, or even macroscopic. Each of these families will be now be discussed.

The phase separated borosilicate discussed in Section 2.2 is an example of separation on a scale below below the resolution of the optical microscope. It is a liquid-liquid system (Fig. 4).

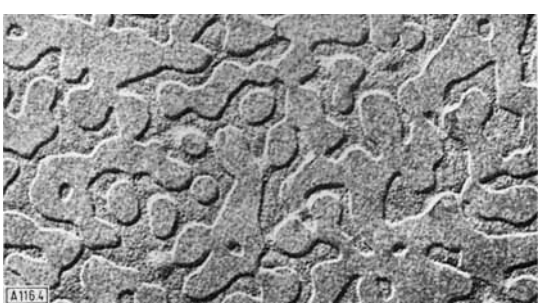

Fig. 4. Electron micrograph of phase separation in a sodium borosilicate glass (composition: see Fig. 3 (b)).

After the mixture has been leached, the residual phase containing 96 % SiO_2 can be reheated to form a condensed structure. In this state the structure is indistinguishable from that of a glass article of the same composition which has been melted and formed in the conventional manner. But there is an earlier stage, the open-structure stage, which is of interest in itself. The porous remains of the leaching process, the so-called "thirsty glass" has an average pore diameter of 40 Å, a surface area of 2×10^6 cm^2/g, a total pore volume of 35 %, and a water absorption of 25 %. The porosity is continuous, and the flow constant of water is 0.00065 ml/cm^2 atm h. While this ultra-fine filter has been experimentally useful in physical and chemical research, newer materials having larger pores have been developed (see Section 2.4). Pore diameters, increased by heat treatment followed by leaching the skeletal structure with mild NaOH or Na_2CO_3 solutions, can reach 2000 Å.

On reheating the 96 % SiO_2-glass skeleton, a shrinkage of 35 % in volume or about 14 % in linear dimension occurs. The properties of such a glass are comparable to those of a fused silica, and more refractory than those of the commercial heat-resistant glass (Table 1).

Table 1. Properties of some glasses.

Glass type	Thermal expansion (0—300 °C) cm/cm K	Softening point [°C]	Annealing point [°C]
Reconstructed [a]	7.5×10^{-7}	1530	1020
Borosilicate (see Fig. 3 (b))	32.5	821	560
Fused silica (see Fig. 3 (a))	5.5	1580	1084

[a] Composition: 96.6 % SiO_2, 0.3 % Al_2O_3, 3.0 % B_2O_3.

Because the glassy state is not a thermodynamically stable phase below the liquidus temperature, it is not surprising that separation of solid phases occurs. What is surprising is the diversity of the phases, the diversity of the mechanics of separation and the complexity of the separation processes. These processes may be studied because of the overriding effect of the high viscosity of glass on the reaction kinetics. That is, high temperature equilibrium states can be "frozen" by cooling the glass to a rigid state, so that expected reactions never occur, or occur at will by controlling the thermal history of the glass.

The first examples of crystal-separation in glass date back hundreds of years[16]. One type, the opal glasses, results simply from exsolution of crystals when the glass temperature drops below the liquidus temperature. Usually fluorides or phosphates of sodium and calcium are precipitated. The second type, gold or copper ruby glasses result from a far more complex reaction; these glasses are initially clear and colorless, and the color appears only after reheating, when colloidal precipitates of the metal are formed.

These processes are very sensitive to oxidation-reduction reactions involving copper in its various valence states. Multivalent ions such as tin, selenium, arsenic, and antimony act as reducing agents for Cu^+ at low temperatures. Cu^+ is generated by melting the glass in a controlled neutral atmosphere; on reheating below 1400 °C, at the lowest temperature at which diffusion can take place, the copper is reduced to the insoluble metal:

$$2\,Cu^+ + Sn^{2+} \rightarrow 2\,Cu + Sn^{4+}$$

If the concentration of reducing agent is decreased, the Cu^+ can absorb ultraviolet light at room temperature and disproportionate on reheating:

$$2\,Cu^+ + h\nu \rightarrow Cu + Cu^{2+}$$

In this photosensitive process a latent image consisting of photoelectrons trapped at Cu^+ ions is formed at room temperature, and the reaction is completed on reheating. With dissolved colorless gold ions, a sensitizer is needed to absorb ultraviolet light and thereby transfer electrons to reduce the gold ions to gold atoms. Cerium oxide is such a sensitizer; Ce^{3+} provides electrons which are trapped in the rigid glass.

While the photosensitive glasses are not commercially important, the concept of photosensitively precipitating metal crystals to act as nuclei for the subsequent crystallization of oxide or silicate phases is of great technical significance. The first development of this type was with lithium metasilicate crystals growing on nuclei of copper, silver, or gold. To act as a nucleus for lithium silicate, the silver or gold particle must have a minimum diameter of 80 Å. Barium disilicate is another separable phase. Sodium fluoride opalescent glasses will similarly separate if subjected to double heating, with a cooling cycle in between. Because the silicate crystals are more soluble in mineral acids than the surrounding glass regions, complex patterns can be developed photographically, then chemically etched into or even through the glass. These chemically machinable, intricately conformed materials have become commercially important. Figure 5 shows the parts for a fluidic control block. The upper sheet illustrates the crystallized portions of the glass; the lower sheet illustrates the residual material after the etching process has removed the crystalline portions of the material.

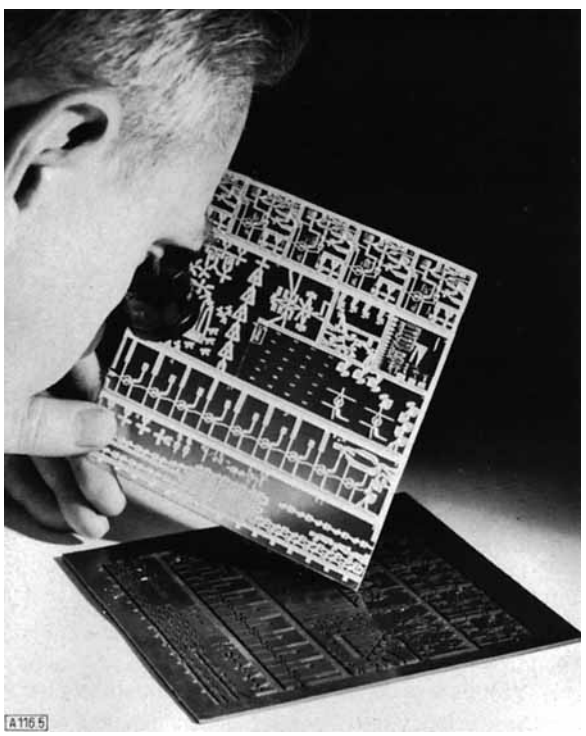

Fig. 5. Intricate glass products produced by photoinduced phase separation and subsequent selective etching (see text).

The concept of photosensitized nucleation and subsequent separation of silicate minerals can be more generally applied to a totally heat-sensitive process. This field of glass-ceramics[17] has developed into many applications, and research programs to discover new materials are being pursued all over the world. A number of substances are known to separate readily in colloidal-size particles in glass: fluorides, phosphates, TiO_2, ZrO_2, and others. TiO_2 is almost universally used as nucleating agent, being especially effective in MgO-Al_2O_3-SiO_2 and Li_2O-Al_2O_3-SiO_2 glasses. These are chemically complex systems, as shown in Scheme 1.

In the various glass ceramic systems it can be generalized that precipitation of β-spodumene, cordierite, and quartz solid solutions produces ultralow thermal expansion behavior; mullite and celsian produce more refractory materials, and mica produces a ceramic capable of being machined using steel tools. The advantages of such materials, characterized by a structure consisting of fine-grained, randomly oriented crystals with some residual glass, but no voids, microcracks, or other porosity, are:

Stage 1 Cordierite glass: $2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$ + TiO_2 catalyst

↓ Δ, 700 °C

Stage 2 Emulsion: colloidal droplets of low-SiO_2 glass in matrix of high-SiO_2 glass

↙ Low silica glass droplets ↘ High-SiO_2 glass matrix

↓ Δ, 800 °C

Stage 3 $MgTiO_3$ crystal nuclei and glass

↓ Δ, 900 °C

Stage 4 Quartz solid solution crystallites

↓ Δ, 1200 °C ↓ Δ, 1200 °C

Stage 5 Cordierite + TiO_2 crystallites Cristobalite

Scheme 1. Processes occurring on heating of a cordierite glass.

1) Flexibility and ease of forming, since all the normal glass-forming techniques can be used.

2) Feasibility of inspecting the transparent glass article for defects prior to crystallization.

3) Uniformity and reproducibility of properties in extremely fine-grained crystalline materials, *i.e.*, uniform thermal expansion.

4) Lack of porosity.

5) Feasibility of strengthening by chemical exchanges.

6) Economy of high volume manufacturing associated with conventional glass manufacturing operations.

If a molten silicate is cooled to a point that immiscible liquids form on a microscopic scale, the stage is set for further crystallization. This nucleation process is easily observed in the Al_2O_3-SiO_2 system in the composition range from silica to mullite ($3Al_2O_3 \cdot 2SiO_2$). The alumina-rich glass readily crystallizes upon heating the emulsion, but the siliceous glass ultimately crystallizes to cristobalite. Structural incompatibility is probably the reason for the separation into two liquids. At high temperature the liquid is composed of partially linked $[SiO_4]^{4-}$ and $[AlO_4]^{4-}$ tetrahedra. On cooling, the melt polymerizes towards a corner-shared tetrahedral array, requiring the coupling of an oxygen to three rather than the normal two tetrahedra. Apparently there is only limited tolerance for this array.

More complex aluminosilicate glasses avoid this anomaly because the interstitially placed alkali and alkaline earth ions provide a charge balance for the trivalent aluminum and normal coupling between tetrahedra is achieved at all temperatures. Thus, addition of another ion, such as titanium, which neither modifies the structure nor supplants the silicon in the structure, is necessary. Less than 10 mol% of TiO_2 induces separation of another glass phase. When the glass is reheated, titanates form from the TiO_2-rich phase, and then act as effective heterogeneous nuclei for the subsequent crystallization of the major aluminosilicate components. In the aluminosilicate glasses of commercial importance the nucleating agents are listed in Table 2.

The amorphous phase separates into particles less than 1000 Å in diameter, producing an enormous surface area on which the primary crystalline nuclei can form. Because the

Table 2. Nucleating agents for aluminosilicate glasses.

System	Nucleating agent	Primary crystalline nuclei	
SiO_2-Al_2O_3-Li_2O	TiO_2	$Al_2Ti_2O_7$	(metastable)
SiO_2-Al_2O_3-Li_2O	ZrO_2	ZrO_2	(metastable)
SiO_2-Al_2O_3-Li_2O	Ta_2O_5	$LiTaO_3$	
SiO_2-Al_2O_3-MgO	ZrO_2	ZrO_2	(metastable)
SiO_2-Al_2O_3-MgO	WO_3	$MgWO_4$	

major crystals also have a small particle size, local stresses due to differences in thermal expansion between phases, anisotropic expansion of crystals, and densification during crystallization are minimized. A major part of the crystallization occurs at viscosities of 10^{10} to 10^{14} poises, just above the annealing temperature, and distortion of the glass during crystallization is minimized.

The newest family of glass ceramics is based on the crystallization of mica-like sheet silicate structures[18]. The fluorine aluminosilicates (mica) have excellent cleavage because of weak crossbonding between the sheets. Fracture propagation across the sheets is very difficult so that fractures follow crystal boundaries. Individual crystals or small groups of crystals and enclosed glass regions thus break apart by pulverizing. These materials are machinable with metal tools and show less sensitivity to surface damage and greater resistance to brittle fracture than do most ceramics.

Now, glass ceramics containing more than two-thirds of mica by volume are normally machinable regardless of the morphology of the mica crystals, but if the mica component is as little as one-half of the volume, the material can be machined only if the aspect ratio of the crystals is high enough

Fig. 6a. Low aspect ratio phlogopite crystals.

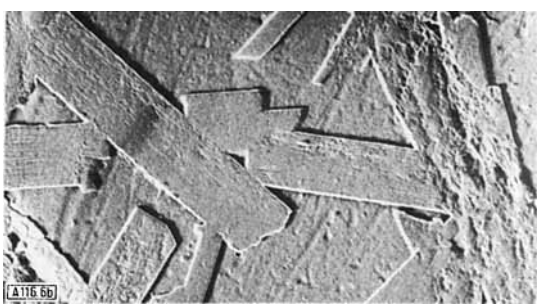

Fig. 6b. High aspect ratio interlocking crystals (flaky structure producing better machinability and thermal shock resistance).

to cause general contact on interlocking of the crystals. The two different microstructures typical of the glass ceramics with synthetic mica are shown in Figure 6a and 6b.

The aspect (diameter : thickness) ratio of the individual crystal can vary from two (thick books; Fig. 6a) to over ten (flakey sheets; Fig. 6b), and during the crystal growth stage depends on the cross-bonding in the crystal and the viscosity of the host glass. Weakly crossbonded micas grow more nearly two dimensionally. Crystals grown in a viscous host are more block-like in form simply due to the difficulties attending diffusion of the necessary ions over long distances.

These materials are composed of K_2O, MgO, Al_2O_3, B_2O_3, SiO_2, and F. They are melted at about 1450 °C, and are crystallized to 50—75 volume percent fluorophlogopite crystals by heating at 950—1050 °C for 2—4 hours. The nucleation step always necessary before crystallizing the glass ceramics occurs on cooling the glass without quenching or thermal soaking. Immiscible liquids are formed because Mg^{2+} ions combine with Al_2O_3, B_2O_3, and K_2O to form a low-SiO_2 matrix glass. Apparently the Mg^{2+} ions shift from a coordination number of 4 to a coordination number of 6. This is analogous to the 4 to 6 shift in the coordination number of titanium, a common nucleating ion for other glass ceramics. The process of crystallization is not a simple process, however. It involves the heterogeneous nucleation of chondrodite crystals and their dendritic growth in the matrix glass, followed by recrystallization of the chondrodite to norbergite, and subsequent grain growth of the phlogopite crystals into a highly interlocked microstructure.

While the glass ceramics are usually opaque, transparent varieties have also been discovered[19]. Either the crystallites of all species must be much smaller than the wavelength of visible light or the birefringence within the crystals and the refractive index difference between crystals and the host glass must be very small. These conditions are satisfied in several aluminosilicate systems containing β-quartz solid solutions, spinel, or mullite as the major crystalline phases. The β-quartz family produces materials that are refractory, of ultra-low expansion, and of high electrical resistivity. All members of the family have high thermal shock resistance, chemical durability, and crystallinity. The spinel and mullite glass-ceramic families contain considerable host glass, but still have excellent transparency, even after exposure to temperatures above 1000 °C for long periods. Such fine-grained materials are able to take an optical polish, permitting their use in reflective optic applications where the special property of an extremely low thermal expansion is desired.

Another aspect of nucleation and crystallization from glasses is demonstrated by the special family of photochromic glasses[20, 21]. Silver halide, the photosensitive phase, is precipitated from the host glass. Such materials, which darken when exposed to ultraviolet light and lighten when the ultraviolet is removed, do not seem to ever loose this capability, have high resolution capability, high darkening sensitivity, and a wide range of fading rates. Thus, special glasses can be designed for many applications because the physical properties are independent of optical properties, and optical bleaching (reversion) is independent of thermal bleaching.

The base glass of the most intensely studied photochromic system is an alkali boroaluminosilicate. Silver and halogen ions are dissolved in the glass and the halide crystallites are developed by holding the homogeneous glass at temperatures

between 500 and 700 °C for periods of 15 minutes to 4 hours. The most useful crystallite size is between 50 and 200 Å. If the crystals are smaller, the glass darkens poorly; if larger, the glass is hazy. The average spacing between particles is about 1000 Å.

A small amount of copper increases the darkening sensitivity by a factor of 100 or more, and the choice of halogen strongly affects the photochromic properties: as the atomic number of the halogen increases the fundamental absorption edge of the silver halide shifts to longer wavelength; thus the darkening sensitivity is extended. Furthermore, the solubilities of the various silver halides differ considerably in most base glasses. Obviously, the base glass composition, *i.e.*, the amount of lead, alkali, and boric oxide, affects the physical properties of the glass, but a most important function of the host glass composition is the temperature dependence of the silver halide solubility. In a good host glass, the solubility of the silver halide is high at the high temperature used to melt the glass, but low at intermediate temperature. Thus, the glass can be supersaturated with the halide and the excess solute can be precipitated out by heating at an intermediate temperature.

Heat treatment dictates the photochromic properties as much as composition, *e.g.*, the number and size of particles can be independently controlled by adjusting the nucleation and growth times. The fade rate constant decreases with increasing particle size, but particles less than a critical size will not darken.

The ultraviolet absorption is independent of particle size, and the darkening achieved is affected by the penetration of the light. Thus, while darkening and fading rates depend on the particle size distribution because the darkening and fading constants depend on particle size, the ultraviolet absorption depends on the total amount of silver halide precipitated. Furthermore, the photochromic absorption spectrum changes shape with the particle size: small particles make a glass appear pink while large particles make a glass appear blue-gray.

Composite structures of glass exist at all levels: macroscopic, microscopic, submicroscopic, and atomic. The complex array of lenses used in most cameras is made of different lens elements, each of which is a different composition and has different properties; at the microscopic level, a glaze on a porcelain or china dish will be of different composition and properties than the base material. At the submicroscopic level, liquid-liquid phase separation results in immiscible glasses which differ in composition and properties, and can be clearly recognized if one phase is etched and the material examined by the electron microscope. At the atomic level, glass is a composite in that it is composed of many different ions, but if the melt is well mixed, it is essentially homogeneous. This last condition can be altered to produce atomically composite structures of great utility. This process includes alteration either after forming or before forming the finished article.

There are two types of treatment applied after the glass article is formed: composition alteration at the surface by ion-exchange and phase alteration of the surface by crystallization. The first process results in surface compression or tension due to differential thermal expansion. For example, once lithium ions from a molten salt bath (*e.g.* lithium and sodium sulfate) are exchanged for sodium ions in the host glass at a temperature above the annealing point of the glass, the thermal expansion of the skin will be less than that of the core. On cooling, the shrinking of the higher expansion core will pull the skin into compression.

Ion exchange can also involve exchanging large ions, such as K^+ in the bath for smaller ions such as Na^+ in the glass. The skin, being expanded at the higher temperature will be stuffed, and will not shrink as much as the core. Again, the compressed surface greatly strengthens the glass. This process is done below the annealing point of the host glass, and thus the effect results from the inability of the glass to relieve the induced strain. The "stuffing" process is applicable to the replacement of Li^+ ions in the glass by Na^+ from a molten salt bath, but is less commonly used because of the high cost of lithium materials. Thus, the most satisfactory base glass is within the soda-alumina-silica system. The change in composition can be detected by an electron microprobe (Fig. 7).

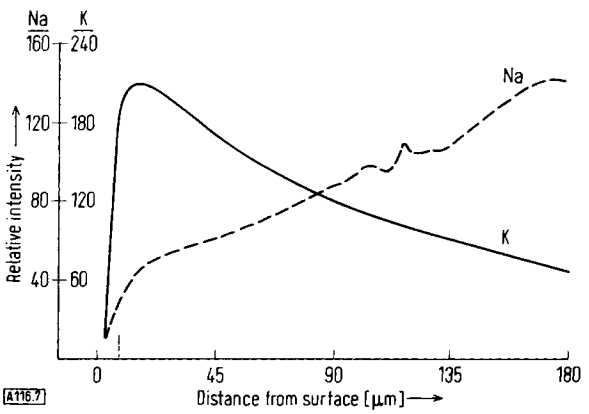

Fig. 7. Relative alkali ion concentration change of surface of sodium glass after immersion in a potassium salt bath.

While this stuffing is done at a temperature below the transformation range of the glass, long exposure to temperatures above 200 °C can result in substantial loss of strength because of ion migration. As was done with the case of multi-pane windows for the space capsules, such chemically strengthened glasses can be protected from transient high temperature by other panes of heat resistant, lower strength, refractory glasses.

Although the cost of the lithia-based glasses is more than that of the soda glasses, the more important difference is in their rates of ion exchange. At 400 °C, the Na^+ for Li^+ exchange rate using a $NaNO_3$ melt is ten times that of the K^+ for Na^+ exchange. To get adequate depth of penetration to produce an abrasion resistant skin the soda-alumina-silica glass must be treated in potassium nitrate at temperatures 100 to 150° higher than for the lithia-alumina-silica glass. The chemical durability of ion-exchanged glasses is better than that of the base glass, suggesting that leachability is a function of the stress level.

Surface strengthening is achieved by crystallization at the surface of materials having particular compositions, *e.g.*, 67 % SiO_2, 26 % Al_2O_3, and 5 % Li_2O with minor constituents: 0.1 % K_2O, 0.3 % Na_2O, 0.1 % B_2O_3, 0.8 % TiO_2, and 0.5 % As_2O_3. Some surface-crystallized specimens of compositions in the Li_2O-Al_2O_3-SiO_2 system achieved a modulus of rupture strength of over 70 kg/mm^2, compared to an uncrystallized glass strength of the order of 3 kg/mm^2. This finding can be rationalized as follows: in order for a quartz-like phase to precipitate, one Li^+ ion is needed for each Al^{3+} ion. Since

the glass is deficient in Li^+ ions, crystallization of the surface layer drains the adjacent interior region of Li^+ ions. Because the relative growth rate is proportional to the concentration of the Li^+ ions, the process ultimately becomes diffusion controlled.

The phenomenon common to all present-day modes of glass strengthening is surface compression. With the exception of thermal tempering, alteration is accomplished by a change in glass composition at the surface relative to the core. Production of laminates has been practiced for artistic purposes for many years, but Schott was probably the first to do this for technical purposes. The modern technique, unlike Schott's process of overlaying one gather of glass with another, is to simultaneously draw three ribbons, thus forming a sheet with two similar skins and a dissimilar core. The relative physical properties of such glass pairs are extremely important: the rheological properties for drawing the sheet and the expansion properties for establishing the ability of the laminate to remain bonded and yet achieve a high level of strength. Of most interest to the chemist is the nature of ion diffusion at the skin-core interface[22]. Diffusion distances for sodium and other ions can be readily estimated with the electron microprobe and are found to be substantial. For commercial laminates diffusion distances from less than 8 to as much as 30 μm have been found, and diffusion is, as would be expected, greater in the glass with the lower softening point.

Much has been written about the startling performance of optical waveguides for telephone systems, data transmission, and instrumentation. The usual cable has six step-index doped deposited silica optical waveguides with a maximum attenuation of 20 dB/km at the 820 nm wavelength. The individual fibers in a cable have an outside diameter of of 135 μm, and a core diameter of 85 μm. The fused silica family of glasses was chosen because of low intrinsic scattering and absorption loss and this functionally complex glass fiber is produced by an exacting chemical process to produce a material of extraordinary purity. Because of optical absorptivity, transition element contamination could not be tolerated beyond a few hundred parts per billion, thus the final choise of process involved vapor phase reaction using high purity vapors distilled from liquid starting materials. From this vapor, a highly reactive soot was condensed onto a mandrel to provide glass blanks for redrawing into a fiber. To raise the refractive index at the appropriate position in the glass blank, GeO_2 is added, again as a vapor phase addition. TiO_2 also had a favorable influence on refractive index and expansion, but at the high temperature required, the oxide was reduced and absorption losses increased.

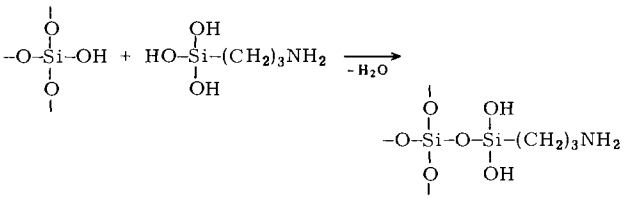
2.4. Surface-Active Glasses

Its use as a vessel for the storage of thousands of different liquids deludes us into thinking of glass as being chemically inert. This, while practically correct, is far from the truth, of course, and resistance to chemical attack on glass is an essential criterion for performance. Less well known is the surface activity of glass, and both organic and inorganic species can be chemically bonded.

Organic molecules are bound to glass by silane coupling. In the presence of water, a monomeric alkoxysilane having an organofunctional group will hydrolyze thus:

$$H_2N(CH_2)_3\text{-}Si(OC_2H_5)_3 \xrightarrow[-C_2H_5OH]{+H_2O} H_2N(CH_2)_3\text{-}Si(OH)_3$$

The hydrolyzed silane then reacts with the OH group on the glass surface to form an aminoalkyl-glass composite:



The activated glass surface can be reacted in standard organic fashion to directly couple biological molecules. Proteins[23] are readily coupled, *e.g.*, the enzymes commonly used to catalyze reactions in food processing. The advantage of fixing such agents is that on-line processes can supplant batch processes, with significant improvement in efficiency and in the useful life of the enzyme. Starch can be converted to glucose, whey can be converted to a useful milk solid. In one application, solid phase radioimmunoassay, controlled pore size glass is used as a substrate carrier. Antibodies are immobilized by silanization of the glass, using a glass particle of about 1 μm diameter and a pore surface of as much as 200 m^2/g. It is expected that this new branch of glass chemistry will find many applications in the field of food processing, medicine, chemical analysis, and pharmacy.

Inorganic species of most recent interest include iron oxide films and chromium films for photofabrication masks. The chromium masks are quite familiar, being a technology that with some refinement was put directly into use when the masking requirements arose in the late 1960's. Iron oxide masks[24] are manufactured by a similar process, *i.e.* high energy reactive sputtering, and at about the same cost. They have lower defect densities, and should supplant the chromium masks. The function of the glass is much more than simply a low expansion, transparent material. It can mean greater durability, increased scratch resistance, better ultraviolet transmission, improved flatness, reduced contamination from chipping of mask edges, and better pattern definition. The type of glass chosen plays an important role in mask performance. While durability is not a key point, scratch hardness is. Films on borosilicate glass are about $2\frac{1}{2}$ times more scratch resistant than those on a soda-lime glass.

The surface chemistry of glass is complex and depends on several factors, *e.g.* the initial pH of the corroding solution, the changes in pH which occur as the glass is leached, a film on the glass, or a film deposited as a reaction interface, ion exchange between the glass and the corroding solution, and phase separation within the glass which leads to nonuniform attack. As for the fundamental mechanism of attack, glass is not dissolved by water but is hydrolytically decomposed. Hydrolysis occurs preferentially at the Si—O—M (alkali or alkaline earth) bond rather than the Si—O—Si bond. The original Si—O—M element of structure is thus converted into Si—O—H and a hydroxide of M. A surface gel forms which contains both the original Si—O—M elements and the newly formed Si—OH elements. Penetration of the proton further into the glass structure is a diffusion process, but if the increasing quantity of alkaline hydrolysis products is not removed, a kind of alkaline attack will then occur and nullify the hydrolytic process. Below pH 7, alkali or

alkaline earth ions are replaced by H^+, but the Si—O—Si element of structure is unaffected. Alkali solutions will break the Si—O—Si elements to form both Si—O—M and Si—OH groups. Alkali attack then progresses linearly with time, and is more intensive than either water or acid attack[25].

Eutrophication and Wastewater Purification

By Dietrich Gleisberg, Joachim Kandler, Hansjörg Ulrich, and Peter Hartz[*]

One of the nuisance conditions brought about by the impact of civilization on some regions is the accelerated eutrophication of receiving waters, especially of stagnant waters, owing to the increased supply of plant nutrients from industrial and municipal wastes. To counteract this situation it is recommended that effective measures be taken to reduce the supply of phosphorus and, in part, nitrogen to such waters. Insofar as the supply of these elements stems from communal wastewaters this objective can be achieved by extensive purification. While the most suitable method for removal of nitrogen is nitrification and denitrification, that which recommends itself for the removal of phosphorus is the method of phosphate precipitation, a well established, economic technique which can be employed in existing plant. The success of the measures taken, however, depends to a large extent on achieving wastewater having a very low phosphorus content.

1. Causes and Effects of Eutrophication

1.1. Eutrophication Phenomena

By eutrophication is understood the enrichment of nutrients in surface waters. It also embraces the phenomena which are observed as a result of nutrient enrichment, particularly in stagnant and slowly running waters[1]. Eutrophication is a natural aging process, which, however, can be accelerated and altered by communal influences. The copious supply of nutrients leads primarily to increased growth of aquatic plants, especially of plankton algae. It can lead to extensive propagation of algae, to "lake blooms", having an unusually high algae density (number of algae per unit volume).
