
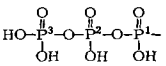
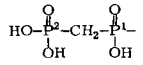
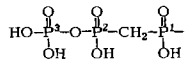
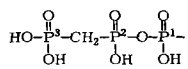
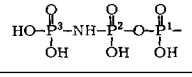
3.2. Substrate Analogs with Modified Phosphate Chains

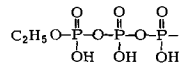


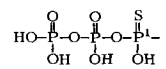


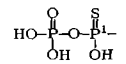


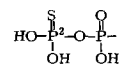


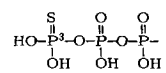












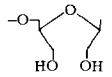
For carrier-specific binding of the adenine nucleotides ATP ($pK_a = 6.97$ for ATP^{4-}/ATP^{3-}) and ADP ($pK_a = 6.65$ for ADP^{3-}/ADP^{2-}) at least three negative charges are required[34]. Unlike adenosine 5'-*O*-di-, -tri-, and -tetraphosphate, therefore, adenosine 5'-*O*-monophosphate (AMP) is not

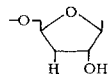
ments of the membrane integral carrier with respect to its substrate?

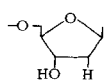
Modifications of the phosphate chain have only moderate influence on specific binding of the nucleotide to the carrier on the cytosolic side, provided that the number of negative charges remains unchanged. Structural changes in the adenine are tolerated as long as the adenine character of the hetero-

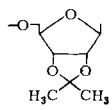
Table 4. Substrates and phosphate chain modified substrate analogs of type

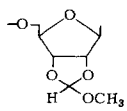
	Nucleotide Ⓟ	Structure of the phosphate chain	Translocator: Binding [%] [a]	Translocator: Rate of transport [b]	Remarks
(2)		P—O = 1.61 Å [47] ∢P—O—P = 130° [47]	100 [1, 2]	7 [1, 2]	
(16)		P—C = 1.79 Å [47] ∢P—C—P = 117° [47]	+ [73]	+ [73]	Neither is *(16)* phosphorylated by F1-ATPase [c] nor are *(17)* and *(18)* dephosphorylated [73]
(17)					
(18)					
(19)		P—N = 1.68 Å [47] ∢P—N—P = 127° [47]	+ [74, 75]	+ [74, 75]	*(19)* is not dephosphorylated by F1-ATPase, but inhibits competitively the dephosphorylation of ATP, no effect on ADP phosphorylation [76]
(20)		P—P = 3 Å [47]	+ [77]	+ [77]	*(20)* is not a substrate of F1-ATPase [77] [d]
(21)			+ [78]	− [78]	
(22)		van der Waals radii: O = 1.40 Å S = 1.83 Å electronegativities: O = 3.5 S = 2.5 thione thiol P=S > P—SH	+ [49, 79]	10 [49, 79]	*(22)* to *(24)* are not substrates of F1-ATPase [49, 80] or of ATP-P_i exchange [80]. Inhibition of mitochondrial respiration [49, 79] is due to inhibition of ATP synthetase [80—82] when coupled to complex IV of the respiratory chain [82]. Only the B isomer [e] of *(23)* is an inhibitor of oxidative phosphorylation of ADP. The A isomer of *(23)* is substrate of photophosphorylation in chloroplasts, whereas the B isomer of *(23)* as well as *(24)* is not a substrate for this reaction [66]
(23)					
(24)					
(25)					

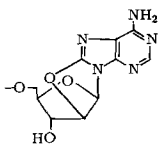


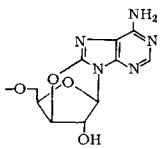


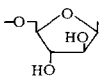


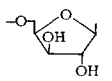


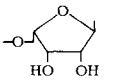












[a, b] Cf. footnotes to Table 3. [c] Possible explanation: In *(16)* P^2 is less electrophilic than in ADP; furthermore, in *(16)* the P—C bond is longer than the corresponding P—O bond in ADP. [d] Possible explanation: In *(20)* P^2 is less electrophilic than in ADP; furthermore, in *(20)* the P—P bond is shorter than the corresponding P—O bond in ADP. [e] The two diastereoisomers were separated enzymatically [46, 83] and by liquid chromatography [84]. The absolute configuration has so far not been determined.

cycle—including the amino group at C6—is retained, as can be concluded particularly from comparison of the structurally isomeric analogs *(6)* to *(9)* (Table 3). Thus, after substitution of the C8 hydrogen—as in *(12)* to *(15)* (Table 3)—the carrier specific binding is not lost, although the *syn*⇄*anti* isomerization of the nucleobase (Fig. 2) is prevented in favor of a sterically preferred *syn*-conformation[51, 57, 70, 71]. If, however, the sugar is covalently bound to the adenine base, as in *(36)* to *(39)* (Table 5), then the position of the nucleobase relative to the sugar is fixed. Because of this fixed position of the base, the hydrophobic interactions between nucleotide and active center of the carrier molecule are decreased in the case of *(36)* to *(39)* compared to *(12)* to *(15)*, so that the analogs *(36)* and *(37)* show only very weak specific binding while the analogs *(38)* and *(39)* display no specific binding at all. Replacement of the 3′- [*(28)* and *(29)*] or the 2′-hydroxyl group [*(30)* and *(31)*] by hydrogen has qualitatively as little effect on specific binding as an inversion of the *trans*-2′- or 3′-hydroxyl group of the ribose into the corresponding *cis*-configuration [*(40)* and *(41)*, *(42)* and *(43)*] or as cleavage of the C2′/C3′ bond of the ribose ring in *(26)* and *(27)*. If, however, both hydroxyl groups are chemically blocked [*(32)*

Table 5. Substrates and sugar-modified substrate analogs of type

$H-(PO_3H)_n-R$

Nucleotide R	n	Conformation (cf. Fig. 2)	Translocator: Binding [%] [a]	Translocator: Rate of transport [b]	Remarks
(26) 	2	N⇄S equilibrium abolished; neither the *syn*- nor the *anti*-orientation of the adenine base is favored; no hindrance to rotation around the C1′—C2′ or the C4′—C3′ axis [86]	15 [33, 62, 85]	– [33, 62, 85]	*(26)* is bound to CF1 coupling factor but is not photophosphorylated [87]
(27)	3				
(28) 	2	*anti*>*syn* [c] Distribution of rotamers: $gg \simeq tg \simeq gt$ [55, 56]	50 [88, 89]	3 [88, 89]	*(28)* is substrate of F1-ATPase [90] and of CF1 coupling factor [87]
(29)	3				
(30) 	2	*anti*>*syn* [c] N (29 %) ⇄ S (71 %) $gg < tg \simeq gt$ [55, 56]	30 [88, 89]	– [88, 89]	*(30)* is not a substrate of oxidative phosphorylation [90], but is photophosphorylated by CF1 coupling factor [87]
(31)	3				
(32) 	2	Restricted pseudorotation of the ribose [91, 92]	– [90]	– [90]	In equimolar concentrations *(32)* and *(34)* inhibit ADP induced state-3 respiration [93] to about 25 % [94] [d]
(33)	3				
(34) 	2				
(35)	3				
(36) 	2	Rigid fixation of the adenine base in the *syn*/*anti* boundary region "high" *anti* ($\phi = -122°$) [96] C2′-*endo*,*gt* favored	20 [89, 95]	– [89, 95]	
(37)	3	Rigid fixation of the adenine base in an *anti*-position ($\phi = -72°$) [98] C3′-*endo*, *gt* favored			
(38) 	2		– [89, 97]	– [89, 97]	
(39)	3				
(40) 	2	*anti*>*syn* [58, 99] *gt*>*gg*, *tg*	12 [89, 90]	– [89, 90]	
(41)	3				
(42) 	2	*anti*>*syn* [100] C3′-*endo*, *gt* favored	9 [89]	– [89]	
(43)	3				
(44) 	2	*anti*>*syn* [89] C2′-*endo*, *tg* favored	– [89]	– [89]	
(45)	3				

[a, b] Cf. footnotes to Table 3.

[c] The *anti*-conformation in *(28)* and *(29)* is stabilized by electrostatic attraction between C2′—OH and N3. Due to lack of stabilization in *(30)* and *(31)* the position of the adenine base is shifted toward *syn* ($\phi = -63°$) [58].

[d] Caused by incorporation into the lipophilic regions of the mitochondrial membrane due to the lipophilic character of *(32)* and *(34)*, thus reducing the activity of the translocator.

to *(35)*], or if there is an inversion at C4′ [*(44)* and *(45)*], the specific binding is completely lost.

Regarding the question how the binding step of a nucleotide is molecularly coupled to the second step of nucleotide transfer, following points of view can be taken into consideration:

Adenine nucleotide analogs existing in a (not covalently fixed) *syn*-conformation are bound to the carrier but do not

stimulate transfer across the membrane. The analogs *(36)* and *(37)* with covalently fixed adenine rings in the *syn/anti* boundary region are as little transferred after binding as are the analogs *(38)* and *(39)* containing a covalently fixed *anti*-conformation. For induction of the second step there must thus be a certain freedom of rotation around the C1′/N9 linkage in the *anti*-region ($-30° \pm 45°$, cf. Fig. 2).

The influence of the conformation on the transport of adenine nucleotides is demonstrated by analogs *(26)* and *(27)*. Chemically they are almost identical to the natural substrates, but differ markedly in their conformations. Ring-opening of the ribose prevents stabilization of the *anti-gauche*, *gauche*-conformation in which ADP and ATP preferentially occur (Fig. 3a). The analog *(27)* (Fig. 3b) is considerably more flexible in its structure; for energetic reasons the conformation equivalent to that of the natural substrate cannot be achieved in the carrier-nucleotide complex, and the transfer does not occur[33].

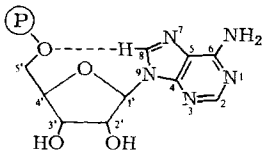


Fig. 3a. Conformation of ATP. Ⓟ = H—$(PO_3H)_3$.

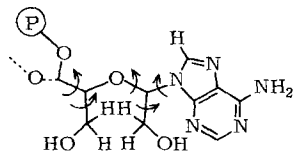

Fig. 3b. Conformation of *(27)*. Ⓟ = H—$(PO_3H)_3$.

A decisive function in establishing the transport is played by the 2′-hydroxyl group, very probably by means of hydrogen bridge formation to the complementary position in the carrier molecule. This group must be present in the *trans*-position; as *(40)* and *(41)* show, a 2′-hydroxyl group in the *cis*-position cannot fulfill this function. Replacement of the 3′-hydroxyl group by hydrogen, however, as in *(28)* and *(29)*, is tolerated.

We are indebted to all who have helped us by stimulation and criticism. We are grateful to the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung Nordrhein-Westfalen, and the Fonds des Verbandes der Chemischen Industrie for financial assistance. We thank Professor Walther Lamprecht for working facilities at the Medizinische Hochschule Hannover during the building operations at Paderborn.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Phase-Transfer Catalyzed Alkylation of Diphenylphosphinic Amide—A New Versatile Synthesis of Primary and Secondary Amines[**]

By *Andrzej Zwierzak* and *Iwona Podstawczyńska*[*]

Although wide applicability of Gabriel synthesis for the preparation of primary amines has been well documented, no general alkylative procedure for the synthesis of primary as well as secondary amines has so far been reported.

We have found that readily accessible diphenylphosphinic amide *(1)*[1] in contrast to dialkylphosphoramidates, can

be selectively mono- or dialkylated under the conditions of phase-transfer catalysis (for examples see Table 1). *N*-Alkyldiphenylphosphinic amides *(3)*, obtained by selective monoalkylation of *(1)* or prepared by conventional aminolysis of diphenylphosphinic chloride[2], can undergo further alkylation under the conditions similar to those reported for dialkyl *N*-alkylphosphoramidates[3] to give symmetrically *(5)* or unsymmetrically *(5')* *N,N*-disubstituted diphenylphosphinic amides. Possibilities of alkylation are, however, limited practically to primary alkyl halides as alkylating agents. Due to its remarkable acid lability the protecting diphenylphosphinic

group can be almost quantitatively removed from the alkylation product *(3)*, *(5)* or *(5')* by treatment of the latter with gaseous HCl in THF at room temperature[3].

The alkylation-deprotection two-step procedure can be utilized for the preparation of hydrochlorides of primary *(4)* and secondary *(6)* or *(6')* amines thus offering a substantial extension to conventional variants of the Gabriel synthesis. The use of diphenylphosphinoyl as protecting group for transformation of primary into secondary amines is superior to the previously described procedure[3].

Procedures

Monoalkylation of diphenylphosphinic amide *(1)* (Method (A)): A solution of alkyl bromide (0.02 mol) in benzene (15 ml) was added dropwise over a period of 1.5 h to the vigorously stirred and refluxed mixture of *(1)* (0.02 mol), 50% aqueous solution of NaOH (50 ml), benzene (50 ml), and tetra-*n*-butylammonium hydrogen sulfate (0.34 g, 5 mol%). Stirring was continued at the reflux temperature for 1.5 h. Benzene (50 ml) was then added, the organic layer separated, washed with water (3 × 30 ml), dried, and evaporated *in vacuo* to give crude *(3)*, which crystallized on cooling. Analytically pure samples of *(3)* were obtained by recrystallization from benzene/hexane.

Dialkylation of *(1)* (Method (B)): A mixture of *(1)* (0.02 mol), alkyl bromide (0.08 mol), toluene (50 ml), 50% aqueous solution of NaOH (50 ml), and tetra-*n*-butylammonium hydrogen sulfate (0.34 g, 5 mol%) was refluxed with vigorous stirring for 4 h. Toluene (50 ml) was then added and the product worked-up as in Method (A) to give crude *(5)*. The same procedure was applied for alkylation of *N*-alkyldiphenylphosphinic amides *(3)*. According to NMR data all crude products *(5)* and *(5')* did not contain any appreciable amounts of impurities.

$[\eta^5\text{-}C_5H_5Mo(CO)_3HgMo]_4$, a Metal Cluster with Cubane Structure

By *Josef Deutscher, Suheil Fadel*, and *Manfred L. Ziegler*[*]

In the synthesis of $C_5H_5Mo(CO)_3C_4H_7$ from the dimer $[C_5H_5Mo(CO)_3]_2$, 2-butenyl chloride and sodium amalgam by a procedure described in the literature[1], an as yet unknown by-product can be isolated under suitable conditions: to our knowledge tetrakis(tricarbonyl-η^5-cyclopentadienyldimolybdenummercury), $[C_5H_5Mo(CO)_3HgMo]_4$ *(1)*, is the first metal cluster with cubane structure to have a cubane framework composed only of metal atoms (Mo, Hg).

The novel compound *(1)* was characterized by elemental analysis, ^{1}H-NMR and IR spectra as well as by X-ray structure analysis. *(1)* shows three bands [CH_2Cl_2: 2020 (vs), 1943 (sh), 1930 (vs) cm^{-1}] in the region of the CO stretching frequencies. In the ^{1}H-NMR spectrum, only one signal is found at $\delta = 5.5$; this must be assigned to the cyclopentadienyl rings. Crystal structure analysis[2] provided the molecular structure shown in Figure 1. The corners of the slightly deformed cubic skeleton are occupied alternatively by molybdenum and mercury atoms; a $Mo(C_5H_5)(CO)_3$ group is found at each of the four Hg atoms.

The cluster-forming molybdenum is unusually coordinated, it merely forms three bonds with the mercury atoms. The possibility of a hydride ligand at the molybdenum can be ruled out on the basis of the ^{1}H-NMR spectrum. The molybdenum of the $Mo(C_5H_5)(CO)_3$ group obeys the 18 electron rule. The cyclopentadienyl rings are statistically arranged; since they are not subject to restrictions imposed by symmetry conditions or structural factors, free rotation would appear to be possible.

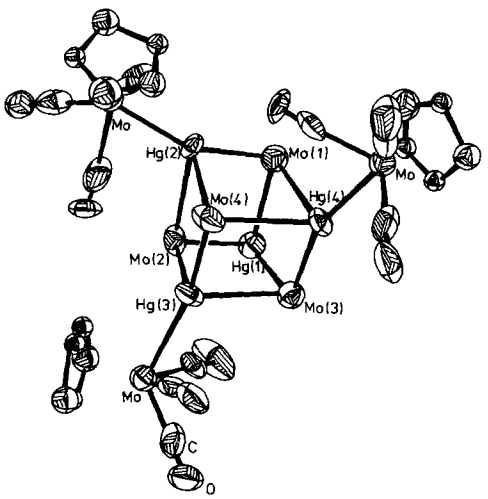

Fig. 1. ORTEP representation of the cubane *(1)*; the $Mo(CO)_3(C_5H_5)$ group at Hg(1) has been omitted for reasons of clarity. Only one position of the statistically distributed cyclopentadienyl rings is given. The thermal ellipsoids correspond to a probability of 50 %.

Bond lengths [pm]		Angles [°]

Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)

In describing the cluster it is also possible to postulate that there are two tetrahedra composed of either mercury or molybdenum atoms and with an identical center of gravity, which are displaced through an angle of 90° with respect to each other.

In the case of the known cubanes and dicubanes, non-metals as well as metals are involved in the formation of the cube (*e.g.* $[CH_3HgOSi(CH_3)_3]_4$[3] and $Zn_7O_8(CH_3)_{14}$[4]), but the cubane skeleton of *(1)* consists solely of mercury and molybdenum.

Experimental Procedure

5 g (≈ 10 mmol) $[C_5H_5Mo(CO)_3]_2$ is dissolved in 150 ml tetrahydrofuran and poured into a three-necked flask fitted with a draincock and containing sodium amalgam [15 ml (≈ 1 mol) Hg and 0.6 g (25 mmol) Na]. The contents of the flask are stirred for 12 h at room temperature. Unreacted sodium amalgam is removed and 17 g (0.2 mol) 2-butenyl chloride is added dropwise to the solution, which is then stirred for another 24 h. The color of the solution changes from yellow-green to red-brown. After removal of the solvent by evaporation, the remaining brown grease is taken up in 200 ml CH_2Cl_2, concentrated to 50 ml in a rotary evaporator and subjected to a column chromatographic separation (silica gel 0.05—0.2, 5 × 100 cm, eluting agent CH_2Cl_2). Yellow, orange ($C_5H_5Mo(CO)_3C_4H_7$) and red ($[C_5H_5Mo(CO)_3]_2$) bands are observed. A yellow crystalline solid can be isolated from the solution of the first yellow band, which is then recrystallized from CH_2Cl_2/CH_3Cl (1:3). Yield 10 % *(1)*, m.p. 200 °C (decomp.).—All operations must be carried out under a N_2 atmosphere.

Dicyanophosphide

By *Alfred Schmidpeter* and *Franz Zwaschka*[*]

According to the "cyano displacement principle"[1] the elements E, which precede the halogens by n places in the periodic system should, by taking up n cyano groups, form the pseudohalogens $E(CN)_n$. In the first short period this rule is obeyed up to $n = 3$, *e.g.* by the formation of pseudohalide ions $E(CN)_n^-$, but up to now the series in the second short period did not continue beyond $n = 1$.

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. F. Zwaschka
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

n =	3	2	1	0
	$C(CN)_3$	$N(CN)_2$	OCN	F
		$P(CN)_2$	SCN	Cl

The dicyanophosphide ion which continues this series has now been synthesized by reacting phosphorus tricyanide with dialkyl phosphites ($R=CH_3$, C_2H_5):

$$P(CN)_3 + HPO(OR)_2 + Et_3N \longrightarrow Et_3NH^+P(CN)_2^- + NCPO(OR)_2 \quad (1)$$

$$P(CN)_3 + NaPO(OR)_2 \longrightarrow Na^+P(CN)_2^- + NCPO(OR)_2 \quad (2)$$

However, neither its triethylammonium salt *(1)* nor its sodium salt *(2)* is stable in solution, but the salt of the crown ether-sodium complex *(3)* is stable as such and in solution.

In the reaction which we have found, phosphorus tricyanide behaves as an interpseudohalogen compound, NC—$P(CN)_2$, with "positive cyanogen" which is taken over nucleophilically by the dialkylphosphite anion (and the trialkyl phosphite, see below). With reverse polarity, however, phosphorus tricyanide reacts with the dialkylphosphite in the absence of a base:

$$P(CN)_3 + HPO(OR)_2 \longrightarrow HCN + (NC)_2P\text{-}PO(OR)_2 \quad (4)$$

The (dialkylphosphoryl)phosphorus dicyanide *(4)* [$\delta^{31}P=14$ (to low field, $PO(OEt)_2$, d) and -121 (to high field, $P(CN)_2$, d); $J_{PP}=88$ Hz] cannot be considered as an intermediate in the reaction formulated above since it is not cleaved by subsequent addition of CN^- to $P(CN)_2^-$ and $NCPO(OR)_2$.

The dicyanophosphide ion ($\delta^{31}P=-193$) is bent, as is the isoelectronic molecule $S(CN)_2$[2]; a transfer of charge into the cyano groups is however revealed by the lower CN and higher PC stretching frequencies as compared with those of $P(CN)_3$[3] and $CH_3P(CN)_2$[4] ($\nu_{as}PC=616$, $\nu_sPC=630$, $\nu_{as}CN=2097$, $\nu_sCN=2120\,cm^{-1}$).

$$N\equiv C-\overset{\ominus}{P}-C\equiv N \;\leftrightarrow\; N\equiv C-P=C=N^{\ominus} \xrightarrow{+CH_3I} CH_3P(CN)_2 \;\text{(}\not\rightarrow\text{ } CH_3NCPCN\text{)}$$

The dicyanophosphide ion could thus react ambivalently; the nucleophilicity at the σ^2P outweighs by far that at the σ^1N atom with the result that the anion reacts with methyl iodide to produce exclusively methylphosphorus dicyanide *(5)* (this corresponds to the *S*-methylation of the thiocyanate ion). The same compound is also formed directly from phosphorus tricyanide and trimethyl phosphite in a CN/CH_3 exchange accompanied by a Michaelis-Arbusov rearrangement:

$$P(CN)_3 + P(OCH_3)_3 \longrightarrow [NCP(OCH_3)_3^+P(CN)_2^-] \longrightarrow CH_3P(CN)_2 + NCPO(OCH_3)_2 \quad (5)$$

[18]Crown-6-sodium dicyanophosphide (3)

3.0 g $NaPO(OC_2H_5)_2$ and 5.0 g [18]crown-6 in 40 ml tetrahydrofuran were combined with 2.1 g $P(CN)_3$ in 20 ml tetrahydrofuran at room temperature and cooled to -20°C. The crystals which separated out were collected on a cooled frit under moisture-free conditions: 3.8 g (53 %).

Methylphosphorus dicyanide (5)

3.0 g $P(CN)_3$ and 3.4 g $P(OCH_3)_3$ in 30 ml CCl_4 are briefly warmed at 40 °C until the reaction starts and the suspension becomes clearer. After 30 min most of the solvent has evaporated off, the remaining oil is cooled and the crystals of *(5)* are removed. M.p. 70 to 72 °C (from CCl_4), $\delta^{31}P=-82$, cf. [4]; approximately 50 %. $NCPO(OCH_3)_2$[5] remains as the filtrate, $\delta^{31}P=-18$; it is contaminated by the residual $CH_3P(CN)_2$ which cannot be entirely removed by vacuum distillation.

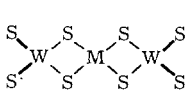
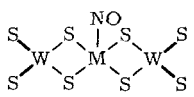
Thioheteroanions—Unusual Metal-Ligand Interaction and Reactions

By *Achim Müller* and *Sabyasachi Sarkar*[*]



Whereas heteropolyanions have been known for a long time[1], heteroanions of the type $[Ni(WS_4)_2]^{2-}$ were first reported only in recent years[1,2]. These complexes—which in contrast to heteropolyanions contain simple monomeric anions as ligands—are interesting because of their strong electron delocalization between the metal centers of different valence states[3]. From the strong reduction in electron density at the Co center[4], as *e.g.* in $[Co(WS_4)_2]^{2-}$ *(1)*, one should expect species of this type to react with free ligands such as NO, in spite of a nearly regular tetrahedral site symmetry of Co ($[Co(NCS)_4]^{2-}$ does not react!). This metal→ligand electron delocalization (pseudo intramolecular redox reaction) thwarted all previous attempts to isolate complexes like $[Fe^{II}(WS_4)_2]^{2-}$ and $[Fe^{II}(MoS_4)_2]^{2-}$ in a pure form[5], which contain the same or similar "heteroelements" as the nitrogenase[3]. Reactions of thioheteroanions were hitherto unknown.

The reaction products of the thioheteroanions, namely the brown-red derivatives $[Co(NO)(WS_4)_2]^{2-}$ *(2)*, $[Fe(NO)(WS_4)_2]^{2-}$ *(3)* and $\{Fe(NO)(MoS_4)_2\}^{2-}$ *(4)* as well as $[Fe(WS_4)_2]^{2-}$ *(5)* (green) and $\{Fe(MoS_4)_2\}^{2-}$ *(6)* (brown-violet, not pure) have now been isolated as the tetraphenylphosphonium salts and have been characterized by elemental analyses, powder diffractograms, IR-, VIS-, ESR-, PE(ESCA)-spectral studies, and by magnetic measurements. *(2)*, *(3)* and *(5)* are soluble in CH_2Cl_2.



The ν(WS)-bands of *(2)*, *(3)*, and *(5)* show the characteristic splitting pattern for *bidentate* thiometallato-complexes of the

[*] Prof. Dr. A. Müller, Dr. S. Sarkar [**]

[**] Alexander-von-Humboldt-Foundation Fellow.

degenerate vibrations of the free ligand (assignment confirmed by metal-isotope studies; see Table 1). These monomeric complex anions contain the structural units shown below[6]:

(M = Fe)

(M = Fe, Co)

(thick lines depict the stronger WS_{term}-bonds), whereas the stronger electron delocalization in the thiomolybdato complexes of iron (due to the lower lying unoccupied MO's in MoS_4^{2-} in comparison with those in WS_4^{2-})[2] causes weakening of the terminal MoS-π-bonds and thus a higher electron density at the terminal sulfur. Hence, the coordination ability of the terminal sulfur increases and consequently leads to "polymerisation" of the thioheteroanions. This can be recognized in the IR spectra of compounds *(4)* and *(6)*, which, in contrast to *(2)*, *(3)* and *(5)*, are X-ray amorphous [diffuse reflection (2θ) for Cu-K_α at 8.7, 12.7, 19.0 and 42.3° or 6.5, 12.5, 20 and 44°, respectively][7].

From our results one would expect that the thioheteroanions should also fix other interesting ligands. The strong electron delocalization in thioheteroanions compared to that in the other complexes with sulfur-containing ligands can be seen from the data listed in Tables 1 and 2. Extremely strong metal-ligand interactions also occur in ene-1,2-dithiolato complexes (the data of one have been given for comparison).

Experimental

$[(C_6H_5)_4P]_2[Co(NO)(WS_4)_2]$ *(2)*: NO (diluted with Ar in the ratio of *ca.* 1:10) was passed through a solution of tetraphenylphosphonium-bis(tetrathiotungstato)cobalt *(1)* (0.75 g) in CH_2Cl_2 (20 ml) for 10 min; the color of the solution changed from green to brown-red. After filtering this solution to remove traces of solid particles, the complex *(2)* was precipitated as a brown crystalline solid in almost quantitative yield by adding *n*-pentane (20 ml)[9].

$[(C_6H_5)_4P]_2[Fe(NO)(WS_4)_2]$ *(3)*: Prepared analogously to *(2)* from a solution of *(5)* (0.5 g) in oxygen-free CH_2Cl_2 (15 ml). The precipitate of *(3)* obtained on adding *n*-pentane (20 ml) was dissolved in CH_2Cl_2 and recrystallized as deep-red crystals in almost quantitative yield by adding methanol.

$[(C_6H_5)_4P]_2\{Fe(NO)(MoS_4)_2\}$ *(4)*: Prepared analogously to *(3)* (reaction time with NO 20 min!), but *n*-pentane was added after filtration of the reaction mixture and the process of reprecipitation was repeated by extracting the compound with CH_2Cl_2 and precipitating with *n*-pentane. Yield *ca.* 60 %.

$[(C_6H_5)_4P]_2[Fe(WS_4)_2]$ *(5)*: A solution of $(NH_4)_2WS_4$ (0.7 g) in H_2O (50 ml) was added slowly with stirring to an aqueous, O_2-free solution of $FeSO_4 \cdot 7H_2O$ (0.38 g), $[(C_6H_5)_4P]Cl$ (0.75 g) and $N_2H_4 \cdot 2HCl$ (50 mg). The resulting precipitate was filtered under Ar and washed with water, ethanol, and ether. Yield *ca.* 70 %.

$[(C_6H_5)_4P]_2\{Fe(MoS_4)_2\}$ *(6)*: Prepared analogously to *(5)* without adding $N_2H_4 \cdot 2HCl$, which reduces MoS_4^{2-}. Not isolated in pure form.

[4] The ESR-spectrum of *(1)* in $[(C_6H_5)_4P]_2[Zn(WS_4)_2]$ measured at 5.3 K shows only a small deviation from tetrahedral symmetry for CoS_4 ($g_1 = 2.054$, $g_2 = 2.035$, $g_3 = 2.002$) as well as a small value for the orbital reduction factor from the g_{av}-value (high electron delocalization!). The same conclusion results from the electron absorption spectrum (extremely high ε value for the pseudo d→d transition at 12400 cm^{-1}: *ca.* $5 \cdot 10^3$ l mol^{-1} cm^{-1}!) as well as from the μ_{eff}-values. The interesting band with high intensity (transition probably with L→M charge transfer character) will be assigned with a MO calculation.

Isodiazomethane Complexes[**]

By *Wolf Peter Fehlhammer, Peter Buračas*, and *Klaus Bartel*[*]

An "isomeric diazomethane" was first reported in 1934 by *Müller* and *Kreutzmann*[1a]. Its isocyanide character remained unrecognized for a long time. It was as late as 1968 before *Müller et al.* reported on the characterization of this species, which could not be isolated as a pure substance[1b].

We have now succeeded in the stabilization, in metal complexes, of this parent compound of the Bredereck *N*-isocyanodialkylamines[2a] which can also be regarded as the amide of the unknown isofulminic acid CNOH[2b].

1) Solid PdI_2 is suspended in a solution of isodiazomethane in ether[3] with cooling (−10°C). After filtration and concentration of the solution, diiodobis(isodiazomethane)palladium(II) crystallizes with 2 molecules of diethyl ether *(1)* in the form of orange-red platelets.

$$H_2CN_2 \xrightarrow[2)\ H_2O]{1)\ LiCH_3} CNNH_2 \xrightarrow[Et_2O]{PdI_2} I_2Pd(-C{\equiv}N-NH_2)_2 \cdot 2\ Et_2O \qquad (1)$$

The presence of an isocyanide complex with a metal-carbon bond is indicated by a weak IR absorption at 2240 cm^{-1} which we attribute to the ν_{NC} vibration of the coordinated isodiazomethane. The observed increase by $\approx +100\ cm^{-1}$ in the ν_{NC} frequency of isodiazomethane ($\nu_{NC} = 2140\ cm^{-1}$) on coordination to palladium(II) is of the usual order of magnitude for complexes of the type $Hal_2M(CNR)_2$[4a] and $Hal_2M(CNNR_2)_2$[4b] ($M = Pd^{II}, Pt^{II}$).

The solvent molecules in *(1)* apparently contribute to the stabilization of the compound. If they are removed by high vacuum, *(1)* decomposes to a dark brown powder which gives only unresolved peaks in the region of the ν_{NH} and ν_{NC} vibrations of the IR spectrum, presumably indicating the presence of separated cyano and ammine ligands[5]. *Müller et al.* isolated substances with analogous IR spectra while trying to incorporate isodiazomethane into Co^{II} and Ni^{II} complexes[6].

2) The isodiazomethane ligand in pentacarbonyl(isodiazomethane)chromium(0) *(3)* is generated at the protecting metal. Analytically pure *(3)* can be obtained in excellent yields [b) > 90 %] by protolysis of the Si—N bonds in *(2)*[7] and subsequent sublimation (50°C, high vacuum).

$$(OC)_5Cr-C{\equiv}N-N(SiMe_3)_2 \xrightarrow[b)\ CF_3CO_2H/CH_2Cl_2]{a)\ HCl/Benzene} (OC)_5Cr-C{\equiv}N-N\begin{matrix}H\\H\end{matrix}$$
(2) *(3)*

Embedded in this stable coordination compound isodiazomethane can be conveniently handled; this should be of benefit in the further investigation of its physical and chemical properties.

The signal of the molecular ion in the mass spectrum of *(3)* is of medium intensity (base line for $[CrCNNH_2]^+$). As expected, the ^1H-NMR spectrum ($CDCl_3$, TMS ext.) shows only a broad singlet at $\delta = 5.17$. The compound $(OC)_5Cr-N{\equiv}C-NH_2$ *(4)*, which is isomeric with *(3)*, was synthesized for comparison; in contrast to *(3)* (m.p. 91 °C), this compound proved to be extremely thermolabile (dec. pt. <40°C). The stabilities of the complexes are thus the reverse of those of the free ligands.

Trifluoromethylamine, CF_3NH_2[**]

By *Gerhard Klöter, Walter Lutz, Konrad Seppelt*, and *Wolfgang Sundermeyer*[*]

In spite of its instability, the hitherto unknown compound trifluoromethylamine has now been synthesized by two different pathways. The first pathway corresponds to the preparation of trifluoromethanol[1]: transformation of the known *N*-dichloro derivative[2] into the amine. The second pathway entails cautious cleavage of *tert*-butyl trifluoromethylcarbamate obtainable from trifluoromethyl isocyanate[3].

The amine can be liberated from the initially formed amine hydrochloride by the action of a base (quinoline, pyridine, diethylamine, or trimethylamine).

CF_3NH_2 is a colorless solid which melts with decomposition at -21 °C, but can be partly sublimed without decomposition. It was characterized by the mass spectrum [$m/e = 85$, $CF_3NH_2^+$, and numerous fragments], IR spectrum [gas; cm^{-1}: 3484 m ($\nu_{as}NH_2$), 3407 m (ν_sNH_2), 1611 s (δNH_2), 1310 vs, 1106 vs, 1038 s (νCF and νCN), *etc.*], Raman spectrum [solid; cm^{-1}: 1647 (15), 1372 (12), 1315 (7), 1272 (8), 914 (8), *etc.*], ^{1}H-NMR [broad quartet at $\delta = 6.73$, $J_{HF} = 10.6$ Hz and ^{19}F-NMR spectrum [sharp triplet at $\delta = 48.9$, $J_{HF} = 10.4$ Hz].

The compound has unexpected physical properties. While the recently discovered trifluoromethanol CF_3OH is more volatile than CH_3OH, CF_3NH_2 is less volatile than CH_3NH_2 (b.p. 50 °C, extrap.) and also has a notably high melting point. Hydrogen bonding can be ruled out on the basis of the gas phase IR spectrum. In fact, an HNH angle of 110.0° can be calculated with an approximation formula[4] from the splitting of the two very sharp NH_2 stretching vibrations. The fine structure of the NMR signals shows that the molecule also fails to associate in solution. Valuable information should come from crystal structure analysis which will, however, be complicated by the sensitivity of the substance.

Owing to the inductive effect of fluorine, CF_3NH_2 is a weaker base than CH_3NH_2. This has its parallels in the increase in acidity on going from CH_3OH to CF_3OH. Acidic properties like those observed for the related compound H_2NTeF_5[5] have not yet been found either for CF_3NH_2 or for H_2NSF_5[6].

The simplest primary perfluoroalkylamine decomposes at room temperature to give polymeric products of the general formula $(FCN)_x(CF_2NH)_y$ and hydrogen fluoride. In the gaseous state, on the other hand, decomposition leads to FC≡N and HF.

A Cobalt-Catalyzed One-Step Synthesis of Annelated Pyridines[**]

By *Alaric Naiman* and *K. Peter C. Vollhardt*[*]

The pyridine nucleus as incorporated into a more complex structural framework is ubiquitous in heterocyclic molecules of synthetic and medicinal interest. We wish to report a new approach to the synthesis of such moieties based on the cobalt-catalyzed cooligomerization of diacetylenes[1] with nitriles. This method allows in one step the formation of oligoheterocyclic systems with pronounced chemo- and regioselectivity, and it is tolerant of functional groups and medium sized (seven-membered) rings[2]. Thus, commercial cyclopentadienyl cobalt dicarbonyl under high dilution conditions catalyzes the cooligomerization of diynes *(1)* or *(8)* with a variety of substituted nitriles *(2)* to give heterocycles *(3)*—*(7)* with remarkable selectivity and in good yield[3]. The formation of the 5,6,7,8-tetrahydroisoquinolines *(4)* is particularly valuable, since this class of compounds is not otherwise easily accessible[4].

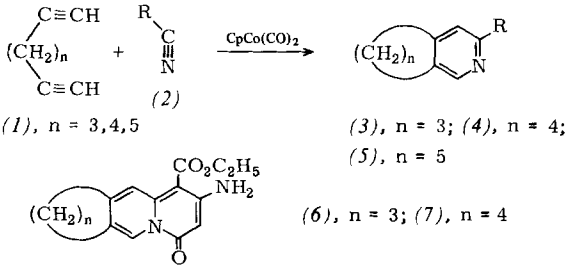

Table 1. Compounds synthesized.

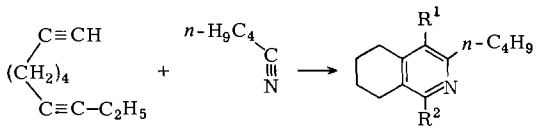

(2)	R	*(3)*—*(7)*	*n*	Yield [%]
(2a)	*n*-C_4H_9	*(3a)*	3	67
(2b)	C_6H_5	*(3b)*	3	56
(2a)	*n*-C_4H_9	*(4a)*	4	77
(2b)	C_6H_5	*(4b)*	4	70 [5]
(2c)	CH_3	*(4c)*	4	81 [6]
(2d)	CH_2OCH_3	*(4d)*	4	62
(2e)	$CO_2C_2H_5$	*(4e)*	4	5.9 [7]
(2f)	$CH_2CO_2C_2H_5$	*(4f)*	4	47
(2g)	CH_2CH_2CN	*(4g)*, *(4h)*	4	[a]
(2h)	C_6F_5	*(4i)*, *(4j)*, *(4k)*	4	2.7 [b, c] [8]
(2i)	$C(CH_3)_3$	*(4l)*	4	47
(2a)	*n*-C_4H_9	*(5a)*	5	43
(2b)	C_6H_5	*(5b)*	5	54
(2f)	$CH_2CO_2C_2H_5$	*(6)*	3	37 [d]
(2f)	$CH_2CO_2C_2H_5$	*(7)*	4	22 [d]

[a] Products *(4g)* and *(4h)* with R = CH_2CH_2CN (yield 30%) and CH_2CH_2-3-(5,6,7,8-tetrahydro)isoquinolyl (yield 19%).
[b] Mixture of the products *(4i)*, *(4j)*, and *(4k)* with R = C_6F_5, C_6F_4H and $C_6F_3H_2$ (3.5 : 5.5 : 1).
[c] Analyzed by GC/mass spectroscopy on a Du Pont 492-1 instrument interfaced with a Varian Aerograph Model No. 204 (linear temperature programmer) equipped with a 20′ + 0.03″ glass capillary column (*ca.* 600 cm × 0.1 cm) packed with 3% Dexsil 300 on 80/100 gas chrom Q.
[d] With excess *(2f)*.

Several results are particularly noteworthy. 1. In contrast to previous work[1, 2], large excess of any one reactant (in particular nitrile) is unnecessary and does not lead to improved yields. This permits the efficient utilization of starting materials. 2. Cyclization of *(1)*, $n = 3$ or 4, with excess cyanoacetic ester results in the novel 7,8-annelated 2-amino-4-oxo-4H-quinolizine-1-carboxylates *(6)* and *(7)*, respectively, formed *via* the 3-(tetrahydroisoquinoline)acetates [cf. *(4f)*] by condensation with a second equivalent of nitrile. 3. Pronounced regioselectivity is observed in the reaction of 1,7-decadiyne *(8)* with valeronitrile *(2a)* resulting in the preferred formation of product *(4m)*, at the expense of *(4n)* (17 : 1 ratio)[9]. 4. Despite the functional group tolerance of the reaction, strongly electron-withdrawing groups bound directly to cyano carbon appear to be disadvantageous.

[**] This work was supported by the National Institutes of Health (GM 22479), the National Science Foundation (CHE76-01783), (in part) by Cancer Research Funds of the University of California, and the A. P. Sloan Foundation. We thank Prof. *H. Rapoport* for useful discussions, and Dr. *R. P. Philp* and Mr. *S. C. Brown* for recording GC/MS data.

(8) *(2a)* *(4m)*, R^1 = H, R^2 = C_2H_5; 73%
(4n), R^1 = C_2H_5, R^2 = H; 4.1%

The pronounced chemospecificity of the reaction may derive from the ligand selectivity of a Co^{III} species, as it (formally) exists in an intermediate cobaltacyclopentadiene derived from *(1)* or *(8)*. Thus, whereas the better back-bonding Co^{I} nucleus in starting catalyst prefers complexation to the CC triple bonds of *(1)* and *(8)*, the subsequently formed metallocycle selects for the better σ-donor nitrile to give pyridine and not benzene as the final product.

Procedure

Ethyl 3-(5,6,7,8-tetrahydroisoquinoline)acetate (4f): A solution of 1,7-octadiyne *(1)*, $n=4$, (650 µl, 5.00 mmol), cyanoacetic ester *(2f)* (531 µl, 5.00 mmol) and $(C_5H_5)Co(CO)_2$ (63 µl, 0.50 mmol) in xylene (15 ml) was added over 117 h (by syringe pump) to *o*-xylene (15 ml) warmed to reflux under N_2 (all reagents deoxygenated).

After removal of solvent under reduced pressure, the reaction mixture was chromatographed on silica gel (60 g; ether elution). The crude product was microdistilled (85—105 °C/0.01 torr) to give a clear oil, analytically pure (510 mg = 47.1 %).

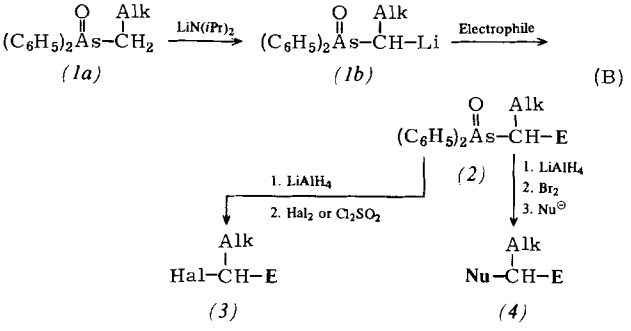
Versatile Principle for the Synthesis of Functionalized Hydrocarbons *via* Organoarsenic Compounds[**]



By *Thomas Kauffmann, Rolf Joussen*, and *Annegret Woltermann*[*]

Among the unattainable reactions of organic chemistry, that according to equation (A) would be extremely useful since the halogen in the final product could be replaced by a variety of other substituents[1]. The substitute reaction (B) described below utilizes the ability of organoarsenic groups to act as halogen equivalents.

(A)

Like *methyl*diphenylarsane oxide[2], the higher homologs *(1a)* preparable therefrom can be metalated in the methylene group α to the As atom by lithium diisopropylamide. The resulting compounds *(1b)* provide numerous entries to functionalized hydrocarbons: after reaction with electrophiles (Table 1), the diphenylarsane oxide moiety can be quantitatively reduced to the arsane and then replaced by halogen (Cl, Br, I) (Table 2). As demonstrated by two examples, the latter reaction can also be combined with nucleophilic substitution reactions in a one-pot procedure (Table 3). Sulfonyl chloride

Procedure: sec-Butyl phenyl sulfide from diphenylpropylarsane oxide

Transformation of diphenylpropyl arsane oxide into *sec*-butyldiphenylarsane oxide (72 %; m.p. 84 °C, from ether/THF 95:5) by methyl iodide and reduction to the arsane (not isolated) were accomplished by analogy with a recently published procedure[2]. A solution of bromine (16 g, 100 mmol) in chlorobenzene (50 ml) is added dropwise at room temperature to a solution of the arsane (15.0 g, 50 mmol) in chlorobenzene (125 ml). The reaction mixture is heated under reflux for 1.5 h, thiophenol (16.5 g, 150 mmol) and NaOH (6.0 g, 150 mmol) are added at room temperature, and heating under reflux then continued for 24 h. After removal of solvent in a rotary evaporator, fractional distillation affords *sec*-butyl phenyl sulfide [*ca.* 5.9 g (71 %); b.p. 104—105 °C/25 torr; lit. value 90—91 °C/4 torr[4]].

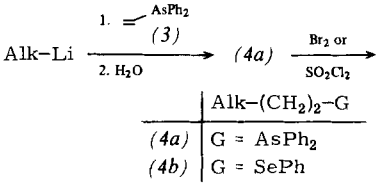
2C-Chain Elongation of Lithioalkanes with Diphenylvinylarsane and Phenyl Vinyl Selenide[**]



By *Thomas Kauffmann, Holger Ahlers, Hans-Joachim Tilhard,* and *Annegret Woltermann*[*]

Chain elongations of organolithium compounds according to the following scheme (Hal = Cl, Br) are precluded by the unattainability of step *(1)* → *(2)*:

(1) *(2)*

The addition of lithioalkanes to *diphenylvinylarsane (3)*[1] constitutes a replacement for *(1)* → *(2)*, for the diphenylarsanyl group of the resulting primary alkyl(diphenyl)arsanes *(4a)* can readily be replaced by Br or Cl atoms[2], which are in turn replaceable by lithium as shown in the reaction scheme[3]. In the case of the adduct *(4a)*, Alk = nC_4H_9, $As(C_6H_5)_2$/Br exchange is 96 % complete (heating with 1 mol. equiv. of Br_2 in chlorobenzene at 132 °C for 2.5 h) and $As(C_6H_5)_2$/Cl exchange is 90 % complete (mixing of reactants at room temperature in CCl_4, distillation of solvent, and heating to 185 °C for 2.5 h).

	Alk–$(CH_2)_2$–G
(4a)	G = $AsPh_2$
(4b)	G = SePh

We also succeeded in adding alkyllithium compounds to *phenyl vinyl selenide*. However, diphenylvinylarsane is greatly superior to phenyl vinyl selenide as an electrophilic chain elongation reagent since poorer yields are obtained, both in the addition step (Table 1) and on exchange of the C_6H_5Se group of primary alkyl phenyl selenides for a Br atom[4] (for Alk = nC_4H_9 reaction is 44 % complete after warming with 1 mol. equiv. of Br_2 in ethanol/H_2O (5:1) to 80 °C for 0.5 h)[5].

Table 1. Addition of lithioalkanes to *(3)* or H_2C=CH—SeC_6H_5.

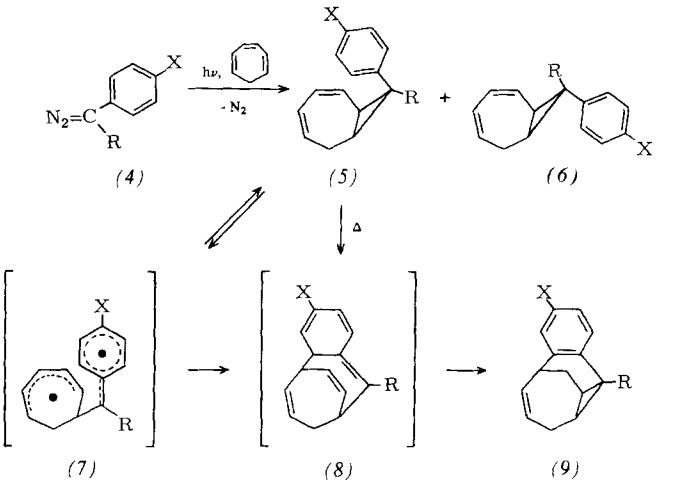
Carbo-Claisen Rearrangement of 8-*endo*-Phenylbicyclo[5.1.0]octa-2,4-dienes[**]



By *Gerhard Maas* and *Manfred Regitz*[*]

In contrast to the Claisen rearrangement of allyl phenyl ethers, the Cope rearrangement of a 1,5-hexadiene whose double bond belongs to an aromatic system as in *(1)*, known as the "carbo-Claisen rearrangement"[1], normally defies attempts at direct observation. This is because the only way in which the primary product *(2)* of the sigmatropic [3,3] shift can undergo rearomatization, apart from the reverse reaction to *(1)*, is by a thermally forbidden 1,3 hydrogen shift to form *(3)*. The isomerization *(1)* → *(3)* is therefore only observed in the presence of a strong base, which presumably catalyzes the step *(2)* → *(3)*[2].

(1) *(2)* *(3)*

We have found that the 8-*endo*-phenyl substituted bicyclo[5.1.0]octa-2,4-dienes *(5)*, formed together with minor amounts of the *exo* isomer *(6)* on photolytic decomposition of the diazo compounds *(4a)*—*(4e)*[3] in cycloheptatriene, isomerize to the tricyclic compounds *(9)* at as low a temperature as *ca.* 130 °C. Their structures are established by the ^{1}H-NMR spectra and X-ray structure analysis[4] of *(9b)*.

(4) *(5)* *(6)*

(7) *(8)* *(9)*

(a): R = $PO(OCH_3)_2$, X = H
(b): R = $PO(OCH_3)_2$, X = OCH_3
(c): R = CO_2CH_3, X = H
(d): R = $PO(C_6H_5)_2$, X = H
(e): R = C_6H_5, X = H

The transformation *(5)* → *(9)* can be interpreted as a carbo-Claisen rearrangement of *(5)* to *(8)*, which is subsequently stabilized in a thermally allowed 1,5-homodienyl hydrogen shift with regeneration of the aromatic system to give *(9)*.

The isomerization *(5a)* → *(9a)* was examined by ^{1}H-NMR spectroscopy in the temperature range 119.2—146.8 °C; it is found to be a first-order reaction with $k = (6.4 \pm 3.5) \times 10^{11} \exp[(29.3 \pm 0.4)RT]$ and $\Delta S^{\neq} = -7.1 \pm 0.9$ cal K^{-1} mol^{-1} (for a mean temperature of 133 °C). These data do not permit any decision whether the formation of *(8)* is concerted or proceeds *via* the diradical *(7)*; however, evidence favoring participation of *(7)* comes from the known ease of homolytic ring opening of vinylcyclopropanes[5] and from the observation that *(5e)* rearranges to the tricyclic about twice as fast as *(5a)*—*(5d)*.

Procedure:

A solution of *(4a)* (11.32 g, 50 mmol) in cycloheptatriene (180 ml) is irradiated for 22 h (Philips HPK 125 W). The excess of cycloheptatriene is distilled off, and the oily residue dissolved in ether (30 ml). Colorless *(5a)* (2.50 g) of m.p. 121 °C is obtained at 0 °C. Chromatography of the filtrate on silica gel (360 g, Woelm 0.2—0.5 mm) with ethyl acetate (3100 ml) and ethyl acetate/methanol 9 : 1 (800 ml) affords colorless compound *(6a)* (0.54 g, 4 %), m.p. 129 °C (ether), and a further crop of *(5a)* (1.31 g; total yield 3.81 g, 26 %).

A solution of *(5a)* (1.50 g) in xylene (10 ml) is heated under reflux for 9.5 h. The reaction mixture is evaporated down *in vacuo*, the residue treated with activated charcoal/chloroform, and after filtration the solvent is again removed and the residue recrystallized twice from ether/petroleum ether 30—75 °C (1 : 1): yield of *(9a)*, 1.0 g (67 %); m.p. 69 °C. IR (KBr): 3030, 3005, 2963, 2925, 2855 (CH/CH_2), 1655, 1607 (C=C), 1255 (PO), 1063, 1038, 1028 cm^{-1} (POC). ^{1}H-NMR ($CDCl_3$): $\delta = 1.70$—2.95 (CH_2 and CH-cyclopropane), 3.28—3.55 (CH-benzyl), 3.65 and 3.79 (each d, $^3J_{PH} = 10.8$ Hz, OCH_3), 5.39 and 5.98 (each dd, CH-olefin), 6.85—7.30 (m, 3 H-aromatic), 7.80—8.10 ppm (1 H-aromatic). A correct elemental analysis is obtained.

Thermal Rearrangement of Silylmethyl Acetates[1]

By *Manfred T. Reetz* and *Norbert Greif*[*]

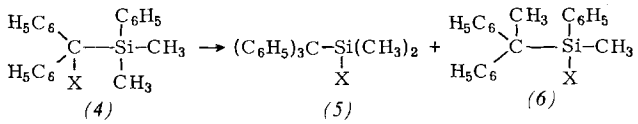
Two routes are formally open for dyotropic rearrangements[2] of compounds of type *(1)* to form a strong Si—O bond: a silyl-acyl or an acyloxy-methyl exchange[3] to the more stable valence isomers *(2)* and *(3)*, respectively. Heating of *(1a, b)* at 130—195 °C in inert solvents gives *(3a, b)* in almost quantitative yield.

(a): $R^1 = R^2 = C_6H_5$, $R^3 = CH_3$
(b): $R^1 = R^2 = C_6H_5$, $R^3 = CF_3$
(c): $R^1 + R^2$ = 2,2'-Biphenyldiyl, $R^3 = CH_3$

We attempt to interpret the mechanism of this smooth valence isomerization[4] with the aid of the following findings:

1) Crossover experiments prove that both the methyl and also the acetoxy groups undergo intramolecular migration to an extent exceeding 95%.

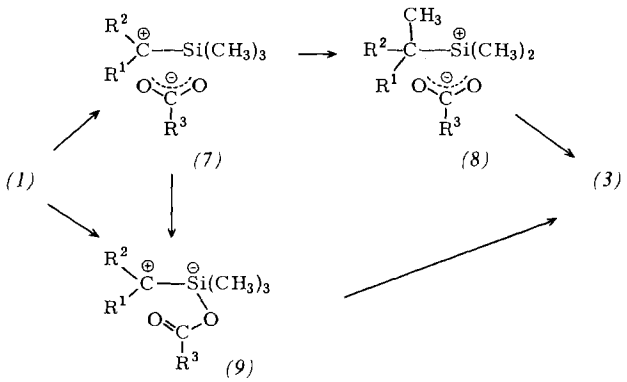
2) The rate of rearrangement is practically independent of solvent polarity: k_{rel} for *(1a)*→*(3a)*: 1.0 (benzene); 0.9 (acetonitrile); 1.3 (propylene carbonate).



3) The activation parameters for *(1a)*→*(3a)* in benzene are: $\Delta H^{\neq} = 33.1 \pm 0.8$ kcal mol^{-1}, $\Delta S^{\neq} = -5.3 \pm 1$ cal mol^{-1} K^{-1}; in acetonitrile they are: $\Delta H^{\neq} = 34.0 \pm 0.8$ kcal mol^{-1}; $\Delta S^{\neq} = -3.6 \pm 1$ cal mol^{-1} K^{-1}.

4) The trifluoroacetate rearranges faster than the acetate: $k_{(1b)}/k_{(1a)} = 564$.

5) The fluorene derivative *(1c)* is stable under the reaction conditions; only on raising the temperature (230 °C) does slow decomposition set in.



6) Replacement of the trimethylsilyl group in *(1a)* by a [D_9]-trimethylsilyl group leads to a secondary kinetic isotope effect of $k_H/k_D = 0.81 \pm 0.05$.

7) In the acetate *(4a)* both the methyl and the phenyl groups migrate to form *(5a)* and *(6a)* in the ratio 60:40 (yield >90%), while in the bromide *(4b)* only a quantitative migration of the methyl groups is observed to give *(5b)*[5].

(a): X = OC(O)CH$_3$
(b): X = Br

The entropy of activation for *(1a)*→*(3a)* and the unexpectedly high thermal stability of *(1c)* can be rationalized neither by a concerted dyotropic process nor by a two-step free-radical mechanism. An ionic mechanism involving contact ion pairs *(7)* and *(8)* also appears unlikely on account of the lack of solvent dependence. Without precedent, and yet in accord with our findings, is a rate-determining intramolecular migration of the nucleofugal group to the silicon to form an inverted ylide *(9)*, which transforms *via* a fast 1,2 shift into *(3)*. The differing behavior of *(4a)* and *(4b)* could be the result of stereoelectronic factors at pentavalent silicon. The results of solvent studies could be interpreted by assuming the formal positive charge at the cationic center of *(9)* to be delocalized as a result of hyperconjugation with pentacoordinate silicon. The question whether negatively charged hypervalent groups can stabilize carbenium ions has not previously been posed in general terms. However, it is known that compounds of pentacoordinate silicon are stable only if electronegative ligands effect a d-orbital contraction[7]. In this connection, carbenium ions are ideal substituents.

Two-step dyotropic mechanisms forming inverted ylides are therefore conceivable for related rearrangements[3, 5]—this working hypothesis is currently being tested.

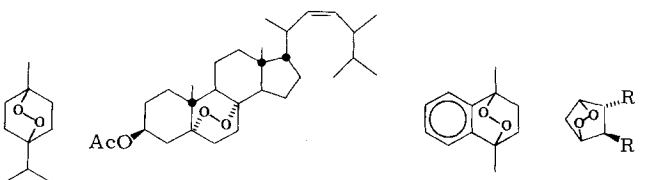
2,3-Dioxabicyclo[2.2.2]octane by Selective Reduction of Double Bonds with Azodicarboxylate[**]

By *Waldemar Adam* and *Henny J. Eggelte*[*]

The peroxide linkage is one of the most susceptible towards reductive cleavage by a variety of reductants. It is, therefore, not surprising that in the catalytic hydrogenation of unsaturated peroxides the peroxide bond as well as the double bond are reduced. If the problem of concurrent peroxide bond reduction could be circumvented in a general and efficient way, this would implement a novel entry into hitherto unknown saturated cyclic peroxides by reduction of the corresponding unsaturated precursors, which are readily available by singlet oxygenation[1] of suitable cyclic 1,3-diene substrates. Azodicarboxylate is a mild and double bond-specific reductant[2], ideally suited to solve the above synthetic problem. The strategy and execution is outlined below for the two-step conversion of 1,3-cyclohexadiene *(1)* into the previously unknown 2,3-dioxabicyclo[2.2.2]octane *(3)*.



(1) *(2)* *(3)*

On treatment of the unsaturated cyclic peroxide *(2)*, prepared by photo-oxygenation of *(1)*[3], with excess azodicarboxylate in methanol at 0°C[4], the saturated cyclic peroxide *(3)* was obtained in 48% yield (m.p. 117—118°C from hexane)[5]. On reaction with ethanolic potassium hydroxide the peroxide *(3)* is isomerized to the known 4-hydroxycyclohexanone in high yield, and on catalytic hydrogenation over Pd-C gives quantitatively the known *cis*-1,4-cyclohexanediol. It is important to mention that submission of pure *(3)* to the azodicarboxylate reduction conditions did not lead to reduction of the peroxide linkage to give the diol.

The generality of the azodicarboxylate reduction could be demonstrated by preparing dihydroascaridole *(4)*, epidioxyergosterol acetate *(5)*, and 1,2,3,4-tetrahydro-1,4-dimethyl-1,4-epidioxynaphthalene *(6)*. Thus, the known dihydroascaridole *(4)* was obtained quantitatively from ascaridole, and identified by its characteristic NMR and IR data.

Adam et al.*, to be published.

(4) *(5)* *(6)* *(7)*

Ascaridole is one of the few cyclic peroxides for which catalytic hydrogenation does not sever the peroxide linkage[6]. The previously unknown ergosterol derivative *(5)*[7a] with saturated Ring B has now been synthesized for the first time. Even the unstable 1,4-dihydro-1,4-dimethyl-1,4-epidioxynaphthalene, prepared by photo-oxygenation of 1,4-dimethylnaphthalene[8], could be reduced essentially quantitatively to the novel cyclic peroxide *(6)*[7b]. It is interesting to note that despite the excess azodicarboxylate that was used, the side chain double bond of *(5)* was not reduced. Strained double bonds show a greater reactivity towards azodicarboxylate reduction[2].

In the reduction of epidioxycyclopentene with azodicarboxylate only isomerization products could be isolated. Readily accessible peroxides of type *(7)* could simplify the prostaglandin synthesis.

General Reduction Method

To a 50 ml, round-bottom flask, provided with magnetic spinbar, are charged 5 mmol of the endoperoxide to be reduced and 15 mmol dipotassium azodicarboxylate in 10 ml absolute methanol. While stirring magnetically and cooling by means of an ice bath, a solution of 30 mmol acetic acid in 3 ml absolute methanol is added dropwise within 30 min. After stirring for 3 h at 30°C, the solvent is rotoevaporated (0°C/10 torr), and the residue taken up in 20 ml H_2O and extracted twice with 20 ml CH_2Cl_2. The combined CH_2Cl_2 extracts are washed once with saturated aqueous $NaHCO_3$ solution, dried over anhydrous $MgSO_4$ and rotoevaporated (0°C/10 torr). The crude product is purified by recrystallization.

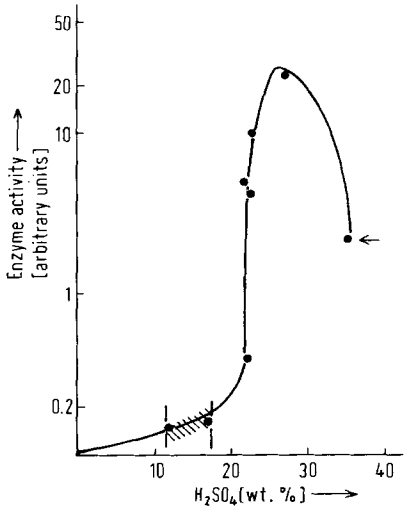
Binding of Urease to Anodized Sheet Aluminum

By *Peter Grunwald, Walter Gunsser,* and *Siegfried Scheer*[*]

The fixation of proteins to water-insoluble materials has become an important field of study in chemistry and related disciplines[1]. Preference is often given to inorganic carriers because they cannot be degraded by bacteria. The binding of an enzyme to the carrier may be covalent or adsorptive and usually entails a loss of activity. Criteria for the quality of such a preparation include not only the residual activity but, above all, the potential for repeated use and the thermal stability.

In our studies on the adsorption of proteins on inert metal oxides we found in the case of the enzyme urease that anodized sheet aluminum is very suitable for this application.

Figure 1 shows the dependence of enzyme activity on the conditions of anodization. While the reaction rate is still relatively low under the conditions of the well known G-S process (hatched area), the activity of the adsorbate increases by almost two powers of ten on surpassing a certain sulfuric acid concentration (current density). Scanning electron micrographs (Fig. 2) show the surface of an Al sheet before and after loading with urease. The structure of the aluminum hydroxide surface reveals the texture of the sheet aluminum used.



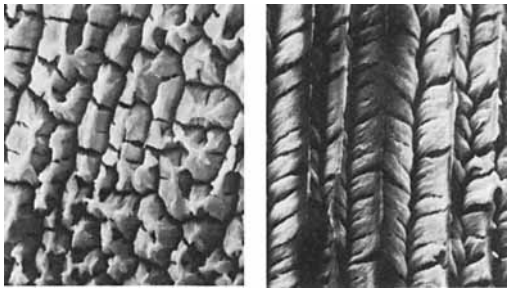


Fig. 1. Activity of anodized sheet aluminum as a function of the sulfuric acid concentration; the activities were determined by conductometry.

a) b)

Fig. 2. Scanning electron micrograph (magnification 2000 X) of an anodized layer a) before and b) after charging with urease from the region beyond the optimum activity (arrow in Fig. 1).

The thermal stability of urease fixed by adsorption to these anodization layers compared with that of the free enzyme in solution, whose optimum temperature is about 65 °C, is remarkable (see Fig. 3). Specific features of the temperature dependence of urease are apparently retained in the adsorbate, such as the anomalous course of urease-catalyzed hydrolysis of urea described by *Talsky*[2a] as well as different activation energies within different temperature ranges [50.8 kJ mol^{-1} (5—20 °C), 24 kJ mol^{-1} (20—41 °C), 45.1 kJ mol^{-1} (41—96 °C)]. The activation energies for hydrolysis of urea in the presence of dissolved urease are 49 kJ mol^{-1} (0—22 °C)[3] and 36.5 kJ mol^{-1} (20—40 °C)[2b]; we were able to confirm both values for the enzyme we used for absorption as 49 kJ mol^{-1} (0—21 °C) and 36.5 kJ mol^{-1} (20.5—50 °C). Relative to the free enzyme, the adsorbate has a significantly lower activation energy in the middle temperature range.

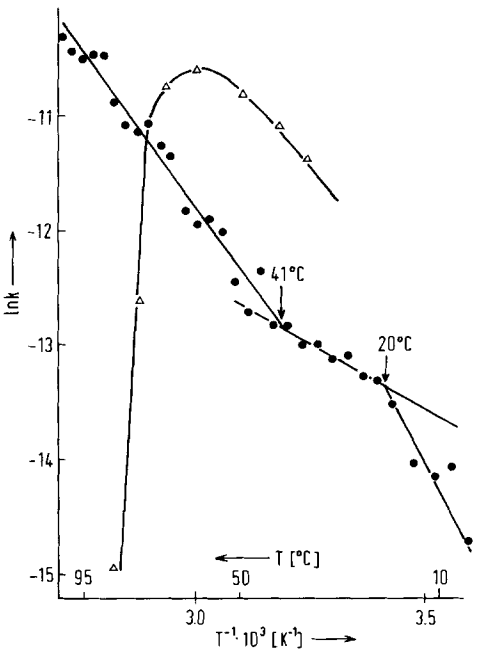

Fig. 3. Temperature dependence of the hydrolysis of urea for dissolved urease —△—△—△— and urease adsorbed on anodized aluminum —●—●—●—.

The temperature dependence of urea hydrolysis was determined over the entire temperature range of 2 to 98 °C (30 measurements) on the same preparation, thus adequately demonstrating the possibility of repeated use of this carrier-bound enzyme. If the supply of urease is not too high the adsorbed enzyme exhibits greater activity than that in the free state. Comparison with conventional inorganic carrier materials[4] shows that anodized sheet aluminum well satisfies the criteria initially mentioned.

Crystal and Molecular Structure of *cyclo*-Heptasulfur (δ-S_7)[1]

By *Ralf Steudel*, *Richard Reinhardt*, and *Fritz Schuster*[*]

Together with S_8, *cyclo*-heptasulfur is a principal component of molten[2] and gaseous[3] sulfur, and can be prepared by extraction of quenched sulfur melts[2] or by condensation of $(C_5H_5)_2TiS_5$ with S_2Cl_2[4]. An incomplete X-ray structure analysis (*xy* projection of the molecule) was interpreted in terms of a puckered seven-membered ring[5], and internuclear distances of 200—215 pm[6a] were deduced from the Raman spectrum. However, the precise molecular structure is not known.

We found by Raman spectroscopy that S_7 crystallizes in at least four modifications which differ significantly from one another primarily in their lattice vibrations, and also in the stretching and bending regions, with regard to the wave numbers and relative intensities of the lines. We have obtained single crystals of one of these modifications, which we call δ-S_7, by evaporation of a CS_2 solution at $-78\,^{\circ}C$[7] and subjected them to X-ray analysis at $-110\,^{\circ}C$. Since the modification is a low-temperature form, whose crystals rapidly disintegrate to a powder at 25 °C, the substance was handled at temperatures below $-50\,^{\circ}C$.

de Jong-Bouman and precession diagrams revealed the monoclinic space group $P2_1/n$ with $Z=8$, $a=1510.5(5)$, $b=599.8(7)$, $c=1509.6(5)$ pm, $\beta=92.15(5)^{\circ}$, $d_{calc.}=2.182\,g\,cm^{-3}$ ($-110\,^{\circ}C$). Using an automatic Siemens single crystal diffractometer, 2263 symmetry-independent reflections up to $\theta=25^{\circ}$ were recorded with $Mo_{K\alpha}$ radiation; 20 reflections were classified as unobserved ($I\leq 2\sigma$). The phase problem was solved by direct methods and the structure refined to an R value of 7.0 % with anisotropic temperature factors (absorption correction, $\mu=20.8\,cm^{-1}$).

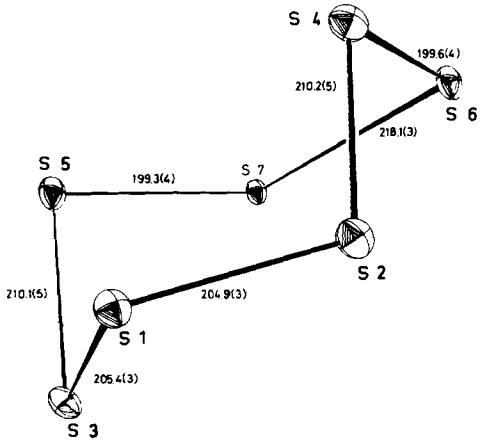

Fig. 1. Molecular shape, numbers of atoms, and internuclear distances [pm] of δ-S_7; standard deviations in parentheses (the values apply to molecule I).

One of the molecules in the asymmetric unit cell is depicted in Figure 1. Although the molecules occupy general sites, the molecular symmetry is approximately C_s. The internuclear distances are identical to within the simple standard deviation; among the angles, however, the differences are considerably greater (Table 1). The bond lengths deviate from the spectroscopically predicted values by at most 3 pm[6a] and thus confirm the theory of bond interaction in sulfur chains, explaining the alternancy of the internuclear distances[6], upon which the prediction is based.

Table 1. Valence and torsional angles [°] in δ-S_7; standard deviations in parentheses.

Valence angle at atom no.	Molecule I	Molecule II	Torsional angle at bond between atoms no:	Molecule I	Molecule II
1:	106.3(1)	105.9(1)	1—2:	−75.2	−74.4
2:	101.5(1)	102.8(1)	1—3:	75.8	75.4
3:	102.5(1)	102.1(1)	2—4:	107.6	107.2
4:	105.6(1)	105.0(1)	3—5:	−107.0	−108.0
5:	105.1(1)	105.4(1)	4—6:	−84.3	−85.6
6:	106.9(1)	106.5(1)	5—7:	83.6	82.5
7:	107.5(1)	107.5(1)	6—7:	−0.3	2.4

The shape of the δ-S_7 molecule resembles that of S_7I^+[8] and can be formally derived from that of S_8 by excision of one atom and connection of the resulting chain ends by an unusually long bond. The large internuclear distance of this bond is primarily due to the small S4-S6-S7-S5 torsional angle of *ca.* 1°, which normally corresponds to a maximum of the torsional potential[6b]. However, as a result of the bond weakening, the adjacent bonds are strengthened: they are the shortest ones in the molecule, the same effect having also been observed in other sulfur rings (S_8O, S_7I^+, S_7O). Simple MO considerations show that a four-center bond occurs between atoms 4 to 7, which is responsible for the almost coplanar arrangement of these atoms. This geometry, and hence C_s symmetry, are therefore also predicted for the free (gaseous) S_7 molecule. The average distance between atoms 4 and 5 is 335.5(3) pm.

As a consequence of the alternating bond lengths, the average SS distance of 206.8 pm is only slightly greater than that in S_6, S_8, and S_{12} (205 pm[6b]), so that the average bond energy can differ only slightly from that of the other rings. The average value of the bond angles (105.1°) lies exactly halfway between those of S_6 (102.2°) and S_8 (108.0°). The smallest intermolecular distances (339.7 pm) correspond to those found for other sulfur rings[9]. Particularly effective packing of the S_7 molecules in the lattice leads to a high density, which together with that of S_6 ($2.18\,g\,cm^{-3}$[9]) surpasses that in all other forms of sulfur (1.94—2.09 $g\,cm^{-3}$).

Bond Interaction in Sulfur Rings: Crystal and Molecular Structure of *cyclo*-Heptasulfur Oxide, S_7O[1]

By *Ralf Steudel*, *Richard Reinhardt*, and *Torsten Sandow*[*]

S_7O arises on oxidation of S_7 with CF_3CO_3H and forms orange-yellow crystals which are stable only at low temperatures[2]. In contrast to other sulfur rings (S_6, S_7, S_8, S_8O, S_9, S_{10}, S_{12}), S_7O fails to show any Raman lines in the stretching region of SS single bonds (410—500 cm^{-1}), *i.e.* all the bonds must be considerably longer or shorter than the SS single bond length (206 pm[3a]). In order to establish the reason for this unusual bonding we have carried out an X-ray structure analysis on a single crystal at −110 °C.

de Jong-Bouman and precession diagrams revealed the monoclinic space group $P2_1/n$ with $Z=4$, $a=1296.3(7)$, $b=872.3(9)$, $c=660.1(5)$ pm, $\beta=88.73(9)°$, $d_{calc.}=2.140\ g\,cm^{-3}$ (−110 °C). Using an automatic single-crystal diffractometer 4110 independent reflections up to $\theta=30°$ were measured with $Mo_{K\alpha}$ radiation and corrected in the usual way; 85 reflections were classified as unobserved ($I \leq 2\sigma$). The proposed structure (direct methods) could be refined with anisotropic temperature factors to $R=0.068$. An absorption correction ($\mu=19.25\ cm^{-1}$) has yet to be performed.

The asymmetric unit contains one molecule whose internuclear distances and bond and torsional angles are given in Figure 1 and Table 1. Exceptionally small intramolecular contacts are observed between atoms S4···S5 (332.8 pm) and S7···O1 (295.2 pm). The smallest intermolecular SO and SS distances are S5···O1 (288.6 pm) and S5···S7 (325.3 pm).

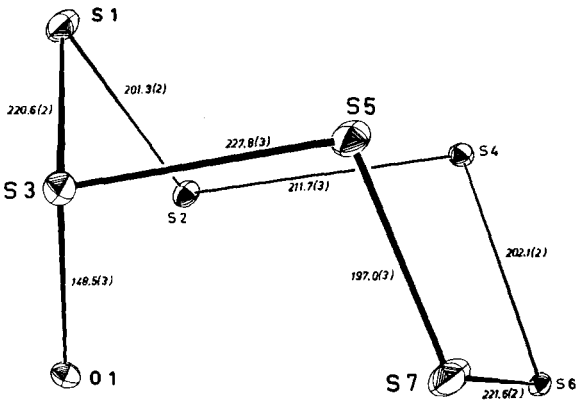

Fig. 1. Conformation, numbering, and internuclear distances [pm] of S_7O; standard deviations in parentheses.

Table 1. Valence and torsional angles [°] in S_7O; standard deviations in parentheses.

The conformation of the S_7O molecule corresponds to expectations based on comparison with S_7[1] and S_7I^+[4]. The average SS distance of 211.7 pm is larger than in S_7 (206.8 pm), which is attributable to bond weakening by the exocyclic oxygen atom as first observed in S_8O[5]. The torsional angles S4—S6—S7—S5 (−4°) and S7—S5—S3—O1 (−3°), which are energetically unfavorable for SS bonds[3a], lead to the extremely large internuclear distances of the S3—S5 and S6—S7 bonds. The bonds adjacent to the long ones are shortened by the influence of bond interaction[3], the shortest bond plainly lying next to the longest one, as also found in S_8O[5], S_7I^+[4], S_7[1], and S_{20}[6].

It is shown in Figure 2 that a relation exists between the internuclear distance between two divalent sulfur atoms d_2 in neutral sulfur rings[7] and the arithmetic mean of the

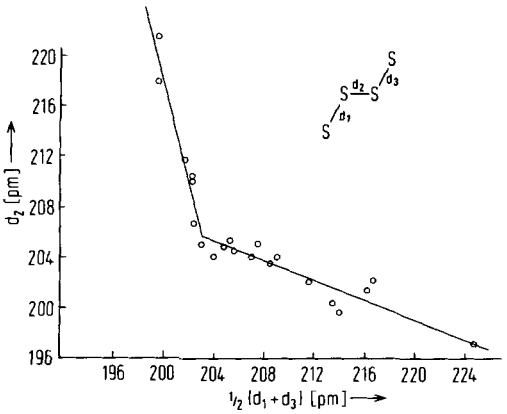

Fig. 2. Dependence of the internuclear distance d_2 of the SS bond upon the arithmetic mean of the internuclear distances d_1 and d_3 of the neighboring bonds in the compounds S_7, S_7O, S_8, S_8O, S_{12}, S_{20}, and $S_nO_6^{2-}$ ($n=4$—6). For large values of 0.5 (d_1+d_3), the distance d_2 approaches to 189 pm, the bond length in S_2.

internuclear distances d_1 and d_3 of the two adjacent bonds. The rings having bonds of equal length (S_6, S_8, S_{12}) lie near the discontinuity of the curve. On extrapolation of d_2 to the van der Waals distance of 340 pm[3a], *i.e.* for the case of homolytic cleavage of a bond in the S_n ring, it is seen that the internuclear distances d_1 and d_3 of the terminal bonds of the resulting diradical $\cdot S_n \cdot$ must be about 196 pm, *i.e.* correspond to multiple bonds. The resulting increase in bond energy facilitates homolysis and also explains why nonionic compounds with cumulated SS bonds are thermally very sensitive and often decompose at as low a temperature as 50—150 °C.

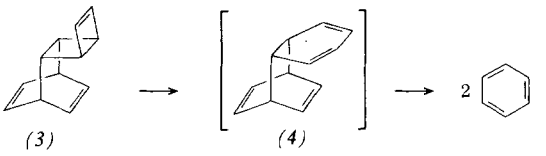
[7] The values for the S_4^{2+} and S_7I^+ ions are shifted towards the origin owing to the additional bond energy [3a]; however, an analogous relation apparently also applies to S_7I^+.

(3—6-η-Tricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene)-tricarbonyliron, a Stable Transition Metal Complex of "*o,p'*-Dibenzene"[**]

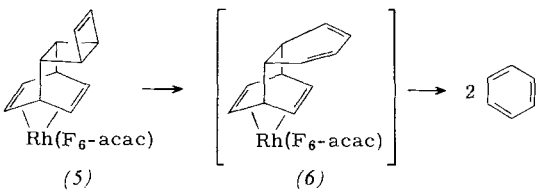
By *Wolfram Grimme* and *Ernst Schneider*[*]

[4+2]-Cycloreversions with elimination of benzene—favored by aromatic resonance in the transition state—proceed quite readily and are of synthetic importance[1]. In such reactions benzene can take on the role both of the diene as well as that of the dienophile[2]. In the Diels-Alder dimer of benzene, "*o,p'*-dibenzene" *(4)*[3a], it is present in both functions and consequently the rate of decomposition for this compound should, to a first approximation, increase quadratically. The preparation of *(4)* has hitherto been precluded by its low stability, whereas the dimer of the [2+2]-cycloaddition, "*anti-o,o'*-dibenzene"[3], could be isolated at 0°C.



Since their release from transition metal complexes at low temperature has proved a useful method for the liberation[4a] and isolation[4b] of labile olefins we have tried to synthesize π-complexes of *(4)*. To do this, a stable valence isomer of *o,p'*-dibenzene had to be bonded to a metal and subsequently thermally rearranged. The Dewar isomer *(3)*, which is readily accessible *via* a conventional route, appeared to be the most suitable candidate for this purpose:

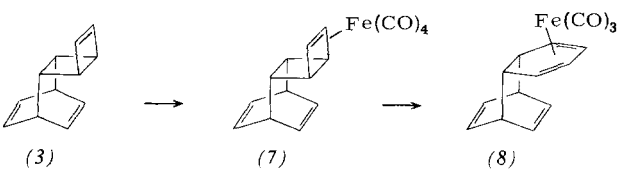
(1) *(2a)*, R = Cl, R^1–R^2 = O *(3)*
(2b), R = H, R^1–R^2 = O
(2c), R = R^1 = H, R^2 = OH
(2d), R = R^1 = H, R^2 = O_3SCH_3



Cycloaddition of dichloroketene[5a] to tricyclo[4.2.2.0^{2,5}]-deca-3,7,9-triene *(1)*[5b] affords the tetracyclic ketone *(2a)* [60%; m.p. 102°C; ^{1}H-NMR (CCl_4): δ=6.57—6.20 (m, H-9,10,11,12), 3.87 (m, H-1,8), 3.23 (dd, *J*=5 and 2.5 Hz, tgα=0.4[6], H-3), 2.70—2.42 (m, tgα=0.13, H-6,7), 2.15 (ddd, *J*=6.5, 4 and 2.5 Hz, tgα=0.26, H-2); IR (KBr): ν_{CO}=1807 cm^{-1}], whose partial dechlorination with tri-*n*-butylstannane in cyclohexane gives the monochloroketone *(2b)* [78%; m.p. 89°C; ^{1}H-NMR ($CDCl_3$): δ=6.63—6.23 (m, H-9,10,11,12), 5.03 (dd, *J*=8 and 2.5 Hz, H-5), 3.83 (m, H-1,8), 3.03 (m, H-3), 2.60 (m, H-6,7), 2.12 (m, H-2)]. In the subsequent reduction with sodium tetrahydridoborate in 80% dioxane at 0°C the base-sensitive chlorocyclobutanol *(2c)* is not purified but immediately esterified with methanesulfonyl chloride/triethylamine in ether to *(2d)*. The elimination reaction with sodium in liquid NH_3/ether[7] finally leads to the *anti*-tetracyclo[6.2.2.0^{2,7}.0^{3,6}]dodeca-4,9,11-triene *(3)*, which is purified by low-pressure chromatography on silica gel with pentane [43% from *(2b)*; ^{1}H-NMR (CCl_4); δ=6.30 (t, *J*=4.5 Hz, H-9,10,11,12), 6.07 (t, *J*=1.5 Hz, H-4,5), 3.47 (m, H-1,8), 2.62 (m, H-3,6), 2.18 (m, H-2,7); IR (in substance): $\nu_{C=C}$=1587 cm^{-1} (s), 1553 (s)].

On warming to 100°C *(3)* decomposes in a first-order reaction to benzene. The rate constant $k=(2.24\pm0.04)\times10^{-5}$ s^{-1} determined at 110.2°C is a little greater than that for the isomerization of bicyclo[2.2.0]hex-2-ene[8] and would suggest that the fragmentation is initiated by opening of the bicyclohexene moiety. Attempts to trap the intermediate *(4)* with maleic anhydride or tetracyanoethylene at 110°C have so far been unsuccessful.

(3) *(4)*



Boiling of *(3)* with dicarbonyl(hexafluoropentane-2,4-dionato)rhodium[9] in *n*-hexane for 1.5 h and subsequent sublimation (80°C/10^{-3} torr) yields orange needles of the complex *(5)* [83%; dec. pt. 132°C; ^{1}H-NMR (C_6D_6): δ=6.17 (s, F_6-acac), 5.99 (m, H-4,5), 3.42 (m, H-1,8,9,10,11,12), 2.55 (m, H-3,6), 1.45 (m, H-2,7); MS: *m/e*=466 (M^+), 388 ($M^+-C_6H_6$), 181 ($-F_6$-acac), 103 (Rh^+), 78 ($C_6H_6^+$)]. Heating of *(5)* to 110°C in degassed [D_6]-benzene leads to decomposition with formation of benzene. This reaction is not first-order, but proceeds autocatalytically; after 70 min no more complex *(5)* is present. Since tricyclo[4.2.2.0^{2,5}]deca-7,9-diene(hexafluoropentane-2,4-dionato)rhodium (m.p. 117°C) is stable up to 190°C under the same conditions it would appear that decomposition of *(5)* likewise begins with opening of the bicyclohexene moiety, but that stabilization of the ligand is inadequate in the initially formed *o,p'*-dibenzene complex *(6)*.

(5) *(6)*

Reaction of the Dewar dibenzene *(3)* with $Fe_2(CO)_9$ in hexane at 50°C does not lead to the expected η^4-tricarbonyliron, but exclusively to the η^2-tetracarbonyliron complex *(7)*, which can be purified by chromatography (alumina/pentane), recrystallization (pentane, −20°C) and sublimation (50°C/10^{-3} torr) [40%; m.p. 74°C; ^{1}H-NMR (C_6D_6): δ=6.35 (t, *J*=3 Hz, H-11,12), 6.11 (t, *J*=4.5 Hz, H-9,10), 3.42 (s, H-4,5), 3.37 (m, H-1,8), 2.12 (s, H-3,6), 2.05 (m, H-2,7); MS: *m/e*=324 (M^+), 268 (M^+-2CO), 240 ($-CO$), 212 ($-CO$), 134 ($-C_6H_6$), 78 ($C_6H_6^+$), 56 (Fe^+)].

Following the work of *Pettit et al.*[10] on the facilitated disrotatory opening of tricyclo[4.2.0.0^{2,5}]octenes in their tetracarbonyliron complexes, we heated *(7)* in degassed benzene to 100°C and found that complete transformation took place within one hour: the tricarbonyliron complex of the *o,p'*-dibenzene *(8)* was formed and some of the starting complex *(7)* was cleaved into the ligand *(3)* and $Fe(CO)_5$ by liberated CO. Recrystallization (pentane, −20°C) and sublimation (70°C/10^{-2} torr) afforded pure *(8)* [45%; dec. pt. 128°C; ^{1}H-NMR (C_6D_6): δ=6.30 (t, *J*=3.5 Hz, H-11,12), 6.20 (t, *J*=3.5 Hz, H-9,10), 4.35 (AA'XX' half spectrum, H-4,5), 3.03 (m, H-1,8), 2.70 (AA'XX' half spectrum, H-3,6), 1.50 (s, H-2,7); MS: *m/e*=296 (M^+), 268 (M^+-CO), 240 ($-CO$), 212 ($-CO$), 134 ($-C_6H_6$), 78 ($C_6H_6^+$), 56 (Fe^+)]. Oxidative cleavage with

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ceric ammonium nitrate in acetone at room temperature affords benzene as the sole organic product, thus proving the ease of decomposition of the primarily liberated *o,p'*-dibenzene.

The greater stability of *(8)* compared to that of the rhodium complex *(6)* and of norbornadienonetricarbonyliron[11] can be explained as follows: In the latter-mentioned complexes the metal fixes the bent bicyclo[2.2.*n*]diene moiety, which must be flattened in the transition state with scission of the bond to the metal. In *(8)*, on the other hand, the metal remains bound to the cyclohexadiene ring, with the result that the double bond that is formed does not gain the resonance energy of benzene[12].

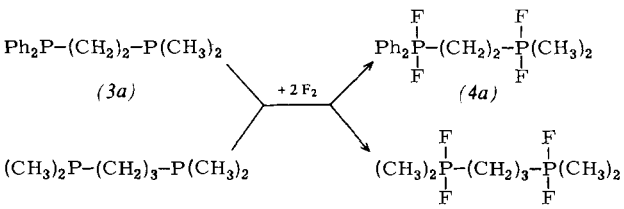
Oligo(difluorophosphoranes) by Direct Fluorination of Tertiary Phosphanes

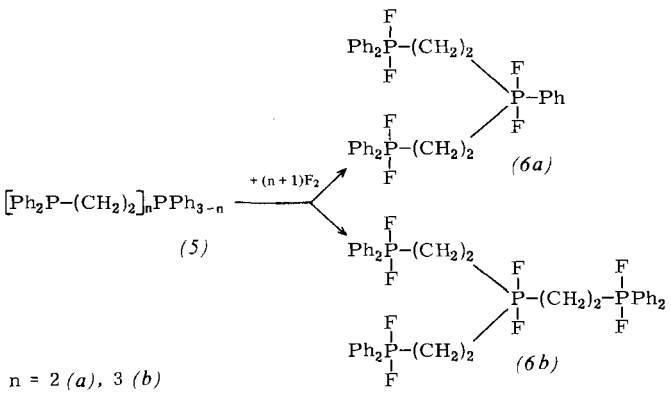
By *Ingo Ruppert* and *Volker Bastian*[*]

Although the first gas-phase chlorination of tertiary phosphanes was described as long ago as 1876[1], no such halogenation with fluorine has yet been reported. The reason may lie in the suspected failure of regioselective fluorination to compete successfully with cleavage of the PC and/or CH bond[2]. However, our preliminary experiments with triphenylphosphane showed quantitative conversion into the difluorophosphorane.



The general validity of direct fluorination will now be illustrated for the example of tertiary oligophosphanes whose difluorides were formerly accessible in isolated cases only by the action of SF_4[3a] or hydrofluorination of phosphoric imides[3b]. Passage of a current of fluorine (max. 20 ml/min) diluted with an inert gas (N_2, He, Ar; *ca.* 100 ml/min) through a suspension of perphenylated polymethylenebisphosphane *(1)* in $CFCl_3$ furnishes the bis(difluorophosphorane) *(2)* as reaction product in good yield, independently of the length of the methylene bridge.

(1) *(2)*



n = 1 *(a)*, 2 *(b)*, 3 *(c)*, 4 *(d)*

The concentration of fluorine given is an upper limit. If it is exceeded local ignition occurs at the gas inlet tube and decomposition of the substrate ensues. However, under the mild conditions chosen the methylene protons are not attacked even in the presence of an excess of fluorine. Phosphanes bearing terminal methyl groups such as *(3a)* and *(3b)* are likewise fluorinated mainly at the phosphorus[4], *i.e.* the procedure is not restricted to resistant phenyl substituents.

(3a) *(4a)* *(3b)* *(4b)*

The synthesis of the oligo(difluorophosphoranes) *(6a)* and *(6b)* constitutes a further impressive demonstration of the scope of oxidative direct fluorination[5].

(5) *(6a)* *(6b)*

n = 2 *(a)*, 3 *(b)*

The modest yields obtained in these cases are due less to side reactions during the actual fluorination than to greater sensitivity of the products to hydrolysis which interferes with their isolation and purification.

The constitution of the difluorophosphoranes is confirmed by correct elemental analysis and characteristic fragment ions[6], and above all by NMR studies. The $^{31}P\{^1H\}$ spectra exhibit an overall triplet pattern[7], showing that two fluorine atoms coordinate each λ^5-phosphorus atom and thereby ruling

[a] The ^{19}F- (Varian A 56/60, 56.4 MHz, $CFCl_3$ int.) and ^{31}P{^{1}H}-NMR spectra (Jeol C 60/HL, 24 MHz, H_3PO_4 ext.) were recorded in conc. $CHCl_3$ solution. Owing to pronounced multiplicity arising by PP coupling, ^{31}P{^{1}H}-PFT spectra with a more favorable signal to noise ratio were also recorded for *(4a)*, *(6a)*, and *(6b)* (Varian CFT 20, phosphorus head, 32 MHz).
[b] In sealed capillary with partial decomposition.
[c] Signal multiplicities in the usual notation, *e.g.* (td) = triplet with doublet fine structure.
[d] In alkyl-substituted difluorophosphoranes, HF-exchange (result of partial hydrolysis) leads, in some cases, to diffuse signal summits. However, this exchange phenomenon can be suppressed by low-temperature measurement.

out phosphonium structures; if nonequivalent phosphorus centers are present in the molecule then a significant fine structure of the individual triplet peaks is observed [^{3}J(PP), cf. Table 1]. The ^{19}F-NMR spectra show the complementary signal multiplicity: a quasi-doublet (dm) due to the λ^5-phosphorus atom with unresolved fine structure arising from long-range coupling with ^{1}H, ^{31}P, as well as ^{19}F *via* the methylene bridge.

Procedure

A current of diluted fluorine (max. 20 ml F_2 to 100 ml of Ar per minute, amount of fluorine determined by a rotameter system[9]) is passed into a magnetically stirred suspension or solution [*(3a)*, *(3b)*] of oligophosphane[8] (25 mmol) in $CFCl_3$ (150 ml, dried over P_4O_{10}) (Solidex glass flask with gas tube and low temperature cooler, −90 °C circulatory cooling with cryostat). Depending upon the solubility of the phosphane, reaction is complete after passage of 60—80 mmol of F_2 (excess), as checked by ^{31}P-NMR spectroscopy. In the case of *(2a)* and *(2b)* the product is recrystallized from boiling CH_3CN after filtration. Otherwise, the solids (oxide and/or HF adduct) are removed from the solution, $CFCl_3$ distilled off, and the residue recrystallized from hot *n*-heptane [*(2d)*], sublimed *in vacuo* [*(4b)*], or repeatedly frozen out of *n*-pentane/ether (5:1) [*(2c)*, *(4a)*, *(6a)*, and *(6b)*].

Dependence of the Calcium Isotope Effect upon the Electrolyte Concentration in Ion-Exchange Chromatography[**]

By *Klaus G. Heumann*, *Ferdinand Gindner*, and *Helmut Klöppel*[*]

Enriched stable calcium isotopes are of topical interest[1] primarily for labeling experiments in medical research. With the set aim of chemical pre-enrichment of calcium isotopes and elucidation of the origins of separation effects we have studied the dependence of the calcium isotope effect upon several parameters during ion exchange in inorganic electrolyte systems. Our previous findings suggested that the behavior of isotopes in electrolyte systems is comparable with that of a homologous series of elements—such as the alkaline earth metals[2].

All experiments were performed in a column packed with the strongly acidic sulfonic acid exchanger resin Dowex 50W-X12 (H^+ form, 200—400 mesh, Bio-Rad) at 20 °C. In each case a 60-mg sample of calcium of natural isotope abundance was applied in the form of $CaCl_2$ or $Ca(ClO_4)_2$ and eluted with HCl or $HClO_4$ of various concentrations (HCl: 3, 6, 9 M; $HClO_4$: 3, 5, 6 M) at a rate of about 15 ml/h. The calcium content of the eluate collected fractionwise was established

by atomic absorption spectrometry and the isotopic ratios $^{44}Ca/^{40}Ca$ and $^{48}Ca/^{40}Ca$ by thermal ionization mass spectrometry.

The equilibrium constant $K_c = 1 + \varepsilon$ (ε isotope effect of an equilibrium stage), *e.g.* for the isotope exchange reaction (resin: exchanger phase, sol: solution)

$$^{48}Ca^{2+}_{resin} + {}^{40}Ca^{2+}_{sol} \rightleftharpoons {}^{48}Ca^{2+}_{sol} + {}^{40}Ca^{2+}_{resin}$$

can be determined from the elution curve and the dependence of the measured isotopic ratio upon the amount of calcium eluted by a standard procedure[3].

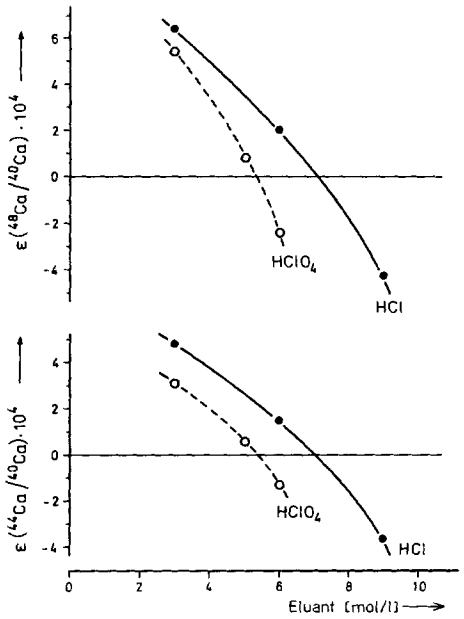

Fig. 1. Dependence of the calcium isotope effect ε upon the concentration and the anion of the eluant.

Figure 1 shows a pronounced dependence to exist between the isotope effect ε for the $^{44}Ca/^{40}Ca$ and for the $^{48}Ca/^{40}Ca$ ratio and both the concentration and the anion of the eluant. As the concentration increases, ε decreases—very high electrolyte concentrations can even effect inversion of the isotope effect. The inversion point lies at a concentration of *ca.* 5 M on use of $HClO_4$, and at 7 M for HCl. The dependence of the value of ε upon the concentration of the eluant is greater for the isotope pair $^{48}Ca/^{40}Ca$ than for the pair $^{44}Ca/^{40}Ca$. It is observed that $\varepsilon(^{48}Ca/^{40}Ca)$ is greater than $\varepsilon(^{44}Ca/^{40}Ca)$ by a factor of about $\sqrt{2}$ (corresponding to the square root of the ratio of the mass differences). Thus we have also found a drop in the ε value with increasing eluant concentration in the case of calcium, resembling that already detected in an analogous anionic system with the $^{37}Cl/^{35}Cl$ isotopic pair[2b]. However, an inversion of the isotope effect in the same system has not been reported before. The results of the calcium isotope study can be compared with those for alkali and alkaline earth metals obtained in similar exchange reactions. While the use of moderate electrolyte concentrations in the latter case leads to more selective binding of elements with increasing Pauling ionic radius—and hence decreasing radius of the hydrated ion—to a sulfonic acid exchange resin[4], an inversion of selectivity is observed with highly concentrated electrolyte solutions[5]. The results of our experiments are best compared with those of *Whitney* and *Diamond*[5b], who found an inversion of Cs^+/Na^+ selectivity on a sulfonic acid exchange resin at an HCl concentration of *ca.* 7 M but at an $HClO_4$ concentration of only 2 M. This inversion of selectivity can be explained in terms of more and more pronounced dehydration of the ions at high electrolyte concentrations and the consequent change in effective ionic radius. The point of inversion of Cs^+/Na^+ selectivity occurring at higher electrolyte concentrations in the HCl system is due to the greater anion-cation interaction of dehydrated Na^+ with the Cl^- ion as against the ClO_4^- ion.

The similarities between the isotopic series of calcium and the series of alkali metals demonstrate that—at least in the case of "hard" ions—isotopes in electrolyte systems behave in the same way as homologous elements. Hence it must be assumed that the isotopes have different effective ionic radii.

Our experiments show that it is fundamentally possible within certain limits to determine both the direction and the magnitude of an isotope effect by varying the concentration and the nature of eluant. This is of considerable significance for the preconcentration of stable isotopes. Furthermore, it should now be easier to understand some of the previously reported isotope effects whose direction and magnitude were not always perfectly clear.

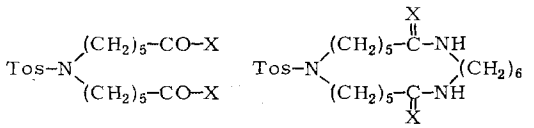
Inclusion of Anions in Macrotricyclic Quaternary Ammonium Salts[**]

By *Franz P. Schmidtchen*[*]

In contrast to the large variety[1] of compounds which form complexes with cations, there are only a few known synthetic host molecules (abiotic receptors[2]) for organic and inorganic anions[3]. Since at least two thirds of all enzymes act on negatively charged substrates or cofactors, the construction and complexation behavior of abiotic receptors for anions should provide interesting comparisons with substrate binding to enzyme pockets and to cell wall receptors.

The binding of anions to the host molecules *(12)* to *(14)* should be predominantly due to electrostatic attraction.

Whereas *(12)* is obtained by quaternization (methyl *p*-toluenesulfonate) of the known[4] aminopolyether, we synthesized the quaternary ammonium salts *(13)* and *(14)* by the following scheme: Alkylation of tosyl amide with the ε-bromo ester *(1)* (NaH/DMSO) and subsequent hydrolysis yielded the dicarboxylic acid *(2)* (50 %) which was converted to its acyl chloride *(3)* (95 %) by oxalyl chloride. Condensation of *(3)* with hexamethylenediamine under high dilution conditions



$$Br\text{-}(CH_2)_5\text{-}COOCH_3$$

(1)

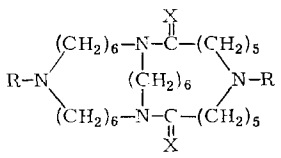
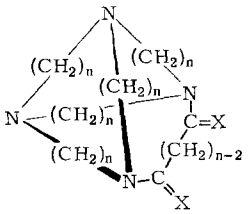
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



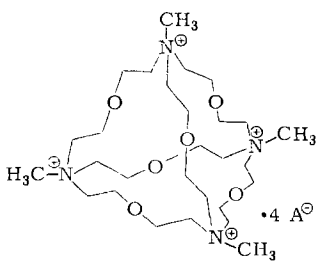
afforded the cyclic amide *(4)* (40 %) which was reduced to the amine *(5)* (95 %) with diborane in THF. Condensation of *(5)* with *(3)* at high dilution gave the bicyclic amide



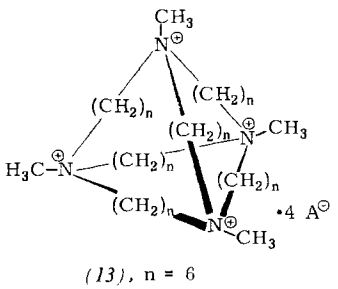
(2), X = OH
(3), X = Cl

(4), X = O
(5), X = H_2

(6) (50 %). The carboxamide groups were successively reduced with diborane [*(7)*, 90 %] and the tosyl groups split off with lithium in liquid ammonia [*(8)*, 90 %]. Ring closure between the two secondary amino groups of *(8)* was achieved by reaction with adipoyl chloride to give the tricyclic amide *(9)* (40 %) which could, in turn, be reduced with diborane/THF to the tetrahedral tetramine *(10)* (65 %). The tetramine *(11)* was obtained by the same method. The structure of these cage molecules was established by elemental analysis, ^{1}H-, ^{13}C-NMR, and mass spectra.



(6), X = O, R = Tos
(7), X = H_2, R = Tos
(8), X = H_2, R = H



(9), X = O, n = 6
(10), X = H_2, n = 6
(11), X = H_2, n = 8

Quaternization with methyl fluorosulfate or methyl *p*-toluenesulfonate in nitromethane converted *(10)* and *(11)* into the tetraammonium salts *(13)* and *(14)* which were obtained as crystals (fluorosulfates) or colorless oils (tosylates). Crystalline tetrafluoroborates were produced from the oils by anion exchange.

(12)
$A^{\ominus}$ = $^{\ominus}O_3S$–C$_6$H$_4$–CH_3

(13), n = 6
(14), n = 8
$A^{\ominus}$ = $FSO_3^{\ominus}$, $BF_4^{\ominus}$, $^{\ominus}O_3S$–C$_6$H$_4$–CH_3

The "cavity molecules" *(12)*, *(13)*, and *(14)* allow, for the first time, inclusion complex formation with anions to be studied independently of the configuration and protonation equilibria at the nitrogen atoms[3]. Examination of models shows that, with the maximum possible cavity radii [*(12)* 1.95 Å; *(13)* 2.3 Å; *(14)* 3.8 Å], compound *(12)* can bind, of the halides (ionic radii; Cl^- 1.81 Å; Br^- 1.96 Å; I^- 2.28 Å), chloride and bromide whereas *(13)* and *(14)* should also be able to take up iodide.

The 1:1 complexes were rapidly formed on addition of 100 mol-% alkali metal halide to solutions of the cage molecules *(12)*, *(13)*, and *(14)* in water or 95 % methanol. In the ^{1}H-NMR spectrum a downfield shift of the α and β methylene signals is observed, while the signals of the methyl groups experience a weak diamagnetic shift. However, the signals are not split, showing that the symmetry of the ligands is preserved in the complexed state. In aqueous solution, *(13)* also binds acetate ions and *(14)* binds the HPO_4^{2-} anion.

Comparison of the stability constants of the halide complexes (Table 1) demonstrates that the bromide and iodide complexes are considerably more stable than the chloride complexes. Since the solvation shell of the anion must be stripped off when it enters the cavity of the molecule, the more strongly solvated anion should form the more labile complexes. The observed order of stabilities thus agrees with these predictions. The same effect must also be partially responsible for the higher stability of the complexes in the more weakly solvating solvent (95 % methanol). On the other hand, it can be inferred from the low selectivity of bromide and iodide complex formation with *(13)* and *(14)*, that changes in ligand conformation also influence the stability. *(13)* and *(14)* are apparently not completely rigid cages and electrostatic attraction does not seem to be the sole force responsible for complex formation. If this were the case then the halide complexes of *(14)* should be weaker than those of *(13)*. Presumably, *(14)* is especially flexible, with the result that its equilibrium conformation will be drastically changed on transfer to a solvent having a lower polarity than water. The bromide and iodide complexes of *(13)* and *(14)* are, as yet, the most stable inclusion compounds of these two anions in aqueous solution.

Table 1. Stability constants ($\lg K_s$) of the inclusion complexes [a] of halides with *(12)*, *(13)*, and *(14)* in water and 95 % methanol.

Anion	Solvent	Complex with *(12)*	*(13)*	*(14)*

5-Methyl-5λ⁵-phosphaspiro[4.4]nonane—The Simplest Pentaalkylphosphorane Yet Obtained[**]

By *Hubert Schmidbaur*, *Peter Holl*, and *Frank H. Köhler*[*]

While there is still no evidence for the existence of unsubstituted phosphorane PH_5, stepwise progress is nevertheless being made towards the simplest pentaorganophosphorane systems PR_5[1]. Having successfully prepared pentamethylarsorane[2] and its alkoxy derivative[3] our search for monocyclic phosphoranes met with failure, although alkoxy compounds did prove to be accessible[4].

Meanwhile, by careful selection of the reaction conditions we have now been able to suppress the otherwise unavoidable formation of the ylide[6] on reaction of 5λ⁵-phosphoniaspiro[4.4]nonane chloride[5] with methyllithium and to force methylation of the phosphorus atom to give the pentaalkyl compound *(1)*:

(1)

Compound *(1)* is a colorless liquid which can be distilled unchanged and is hardly sensitive to air; in low concentration it gives off a blossom-like scent. The molecular mass was confirmed by the mass spectrum, which contains the molecular ion and also reveals fragmentation to *P*-methylphospholane. Pentacoordination of the phosphorus atom follows from the large ^{31}P-NMR upfield shift ($\delta = -91.7$). Owing to the complicated nature of the ^{1}H-NMR spectrum, which undergoes hardly any simplification in the $\{^{31}P\}$ version, particular importance attaches to the $^{13}C\{^1H\}$-NMR spectrum: at room temperature the doublet of the CH_3 group is accompanied by a doublet due to the four α-CH_2 groups and a doublet due to the β-CH_2 groups. Off-resonance experiments confirm this assignment by additional q,t,t splitting.

The molecular geometry of *(1)* is not expected to be that of an ideal trigonal bipyramid or a square pyramid because the two phospholane units have distinct angular preferences. Structural studies on related spirocyclic *oxa*phosphoranes nearly all indicate considerable deviations from these standard geometries[7]. It is therefore hardly surprising that low-temperature ^{1}H- and ^{13}C-NMR spectra of *(1)* fail to show any splitting of the CH_2 signals, in line with some kind of distribution between equatorial or axial positions, even at −105 °C. A decision in favor of a square planar structure, which appears somewhat more likely in the light of the above findings, or whether the activation energies of the polytopic rearrangement are extremely low, will have to await completion of the electron diffraction structural elucidation currently in progress.

Procedure:

5λ⁵-Phosphoniaspiro[4.4]nonane iodide is prepared according to ref. [5] and transformed into the chloride. $^{13}C\{^1H\}$-NMR (CD_2Cl_2, converted to TMS, 305 K): $\delta CH_2(\alpha)$ 22.6, d, J(PC) 46.4 Hz; $\delta CH_2(\beta)$ 25.4, d, J(PCC) 7.3[8].—To a suspension of the chloride (1.45 g, 8.1 mmol) in ether (20 ml) is slowly added dropwise at −60 °C a solution of methyllithium (10 mmol) in ether (25 ml), stirring is continued for 6 h at −40 °C, LiCl is filtered off after warming of the reaction mixture, and the solvent is removed at 0 °C/60 torr. Distillation at 46 °C/1 torr furnishes *(1)* (0.62 g (48 %), m.p. ≈ −40 °C).

^{1}H-NMR ([D_8]toluene, TMS ext., 305 K): δCH_3 1.44, d, 3H, J(HCP) 10.35 Hz; δCH_2(α and β) 0.88—1.83, m, 16H. The spectrum is almost unchanged at 180 K.—$^{13}C\{^1H\}$-NMR ([D_8]toluene, converted to TMS, 305 K): δCH_3 19.6, d, J(PC) 65.9; $\delta CH_2(\alpha)$ 33.3, d, J(PC) 41.5; $\delta CH_2(\beta)$ 23.0, d, J(PCC) 9.8 Hz. Off resonance: q,t,t. The spectrum is practically unchanged at 180 K.—$^{31}P\{^1H\}$-NMR (H_3PO_4 ext.): $\delta = -91.7$, s. MS (15 eV): m/e 158, M^+; 102, $(CH_2)_4PCH_3^+$ (100 %).

α-Thiolactones from Thioketenes

By *Ernst Schaumann* and *Ulrich Behrens*[*]

While the chemistry of α-lactams has been thoroughly studied[1] and α-lactones have been detected in solution[2], α-thiolactones *(3)* have not previously been reported. We have now found the oxidation of thioketenes *(1)*[3] bearing bulky substituents with nitrones of the 1-pyrroline 1-oxide type *(2)* to provide a facile entry to *(3)*.

(1) *(2)* *(3)*

(1a), *(3a)*: $R^1 = CH(CH_3)_2$, $R^2 = C(CH_3)_3$
(1b), *(3b)*: $R^1 = R^2 = C(CH_3)_3$
(1c), *(3c)*: $R^1 + R^2 = -C(CH_3)_2-(CH_2)_3-C(CH_3)_2-$

(2a): R = CH_3, R' = H
(2b): R = H, R' = CH_3

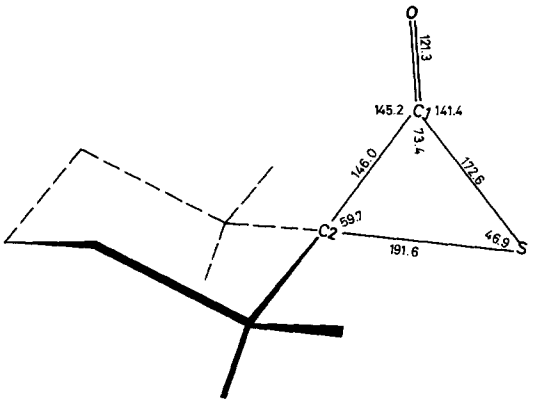
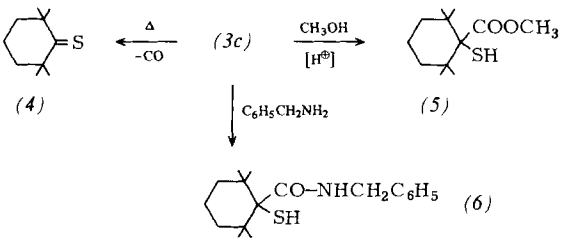
(3c)	20	3 h	ether [a]	92 [d]	107–111 (dec.)	1785 (C=O)
	20	4 h	ether [b]	84 [d]		
(4)	75	9 h	CCl_4	88	Oil [e]	1130 (C=S)
(5)	65	2 h	CH_3OH [c]	60	114–118	2590 (SH), 1720 (ester C=O)
(6)	20	3 h	ether	13 [d]	117–120	2550 (SH), 1635 (amide C=O)
(9)	35	14 h	ether [b]	59 [d]	56–58	1140, 1055 (S=O)

[a] Reaction with *(2a)*. [b] Reaction with *(2b)*. [c] Addition of a catalytic amount of conc. sulfuric acid. [d] Isolated by preparative layer chromatography on silica gel PF 254 [eluant dichloromethane/petroleum ether (1:9) or ethyl acetate/petroleum ether (1:9)]. [e] Red, b.p. 92°C/19 torr.

The thiolactones *(3)* clearly differ in all their data from the classical oxidation products of *(1)*, *i.e.* the thioketene *S*-oxides[4]. A C=O stretching vibration (Table 1) observed at high wave numbers and a carbonyl signal in the ^{13}C-NMR spectrum ($\delta = 186.9$ for *(3c)* in $CDCl_3$) are in full accord with structure *(3)*. Structural proof was provided by an X-ray structure determination[5] on *(3c)* (cf. Fig. 1). In keeping with their spiro-type connection the six-membered ring and the three-membered ring, which coincides with the crystallographic plane of symmetry, are at right angles to each other, with the sulfur in a quasi-equatorial position. The ring strain in the three-membered ring is apparently relieved to a considerable extent by the sulfur atom, as is demonstrated by the extremely long S—C^2 bond and the small bond angle at the sulfur.





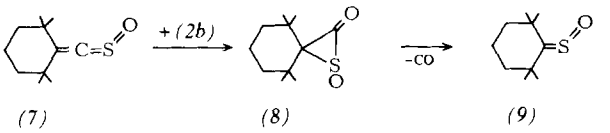


Fig. 1. Important bond lengths [pm] (standard deviation 0.8 pm) and angles [°] (standard deviation 0.7°) in *(3c)*.

On heating, compound *(3c)* (studied as a typical member of the class) underwent qualitative decarbonylation to the thioketone *(4)* (half-reaction time 1.5 h in acetonitrile, 2.9 h in tetrachloromethane at 75 °C). It is relatively stable to hydrolysis and solvolysis, probably as a result of the bulky alkyl group; only on heating is sulfur liberated to form derivatives of the ketene corresponding to *(1c)*. Addition products of *(3)* are obtained only with methanol and benzylamine: on the basis of their IR data (Table 1) and degradation reactions they are to be formulated as α-mercapto carboxylic acid derivatives *(5)* and *(6)*. Thus *(3)* reacts *via* 1,2 ring cleavage, whereas α-lactams[1] and the α-lactone corresponding to *(3b)*[2a] are preferentially attacked at the 1,3 bond by protic reagents.

The course of the reaction with the heteroallenes *(1)*, which differs from the usual behavior of the nitrones[6], is again observed in the reaction of the thioketene *S*-oxide *(7)*[4] with

(2b). However, the α-thiolactone *S*-oxide *(8)* cannot be isolated but, unlike *(3)*, eliminates CO to give the thioketone oxide *(9)* *in situ*.

Bis(trifluoromethyl)disulfane Oxide $CF_3S(O)SCF_3$[**]

By *Willy Gombler*[*]

Organyl disulfane oxides (-thiosulfinates) of the type RS(O)SR have been well documented[1], and since the disco-

[*] Dr. W. Gombler
Lehrstuhl für Anorganische Chemie II der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

[**] Experimental work performed at the Universities of Saarbrücken and Bochum.

very and characterization of allicin (R = allyl), the antibacterial component of garlic, the biological activities of dialkyldisulfane oxides have also been demonstrated[1]. All the previously synthesized disulfane oxides (and trisulfane oxides[2]) disproportionate at room temperature:

$$2\,RS(O)SR \rightarrow RSSR + RS(O)_2SR$$

Disulfane oxides containing perhaloalkyl groups could hitherto not be synthesized. Thus, reaction of $Hg(SCF_3)_2$ with $CF_3S(O)Cl$ did not afford the desired compound $CF_3S(O)SCF_3$ *(1)*, but CF_3SSCF_3 *(2)* and $CF_3S(O)_2SCF_3$ *(3)*[3]. The hydrolysis of CF_3SCl *(4)*[4] and the reaction of *(4)* with Ag_2O or Ag_2CO_3[5] led to the same result. All recent attempts to prepare compounds containing the $CF_3S(O)S$ group have also remained unsuccessful[6]. We have now been able to obtain *(1)* in 65 % yield by hydrolysis of $CF_3SF_2SCF_3$ *(5)*[7] at low temperature in the presence of KF as HF-trapping agent.

$$\underset{(5)}{CF_3SF_2SCF_3} \xrightarrow[-50\,^\circ C,\ KF]{H_2O} \underset{(1)}{CF_3S(O)SCF_3}$$

The product *(1)* is unexpectedly stable at room temperature (unchanged after 3 months in a sealed glass tube); it is a colorless liquid which solidifies at −138 °C whose vapor pressure is given by $\log p\,[\mathrm{torr}] = 7.5462 - 1605.98/T$ (extrapolated boiling point 71.1 °C, $\Delta H_v = 30.8$ KJ/mol, $\Delta S_v = 89.2$ J/mol·K). *(1)* disproportionates into *(2)* and *(3)* within 1—2 days in the presence of HF, and within about 3 weeks in the presence of *(4)*. Having characterized *(1)* it has now been possible to establish by NMR spectroscopy that the hydrolysis of *(4)* as well as the reaction of *(4)* with Ag_2CO_3 also proceed *via (1)*. Compound *(1)* was characterized spectroscopically (Tables 1 and 2) and by molecular weight determinations. The spectra were compared with those of *(3)*.

Table 1. ^{19}F- and ^{13}C-NMR data of *(1)*, *(2)*, and *(3)*.

Experimental

A fresh sample of *(5)* is prepared in a high vacuum apparatus. This is allowed to react with 8 g (59 mmol) *(4)* and 50 g (210 mmol) anhydrous HgF_2[7]. *(4)* and *(2)* are removed from the crude product at −78 °C by pumping until it is almost colorless (NMR spectroscopic identification of *(5)* at −50 °C). The yield of *(5)* with negligible contamination by residual *(2)* is *ca.* 5.8 g (24 mmol). *(5)*, which may not be warmed to more than −30 °C, is now condensed with the aid of liquid nitrogen into a glass condensation vessel [K] containing 6 g (103 mmol) finely ground KF and 0.6 g (33 mmol) H_2O. [K] is kept at −50 °C for 24 h and, if necessary, gently shaken. Any SiF_4 that is formed is then pumped off at −78 °C, [K] warmed to −50 °C and the product condensed into a receiver (−196 °C) except for the excess water. The separation of readily volatile *(2)* is achieved by batch removal of the gas phase, which is in equilibrium with the liquid at −50 °C (partial pressures at −50 °C: *(2)* 10.7, *(1)* 0.2 torr).

Yield of *(1)* 3.4 g (65 %), contamination with *(2)* 5 %. Molecular weight determination (Regnault): 217.5 (calc. 218.1).

Thiathione Radical Anions: Are $(—S)_2C{=}S$ Groups Electron Traps?[1, 2]

By *Hans Bock, Georg Brähler, Abbas Tabatabai, Andrzej Semkow*, and *Rolf Gleiter*[*]

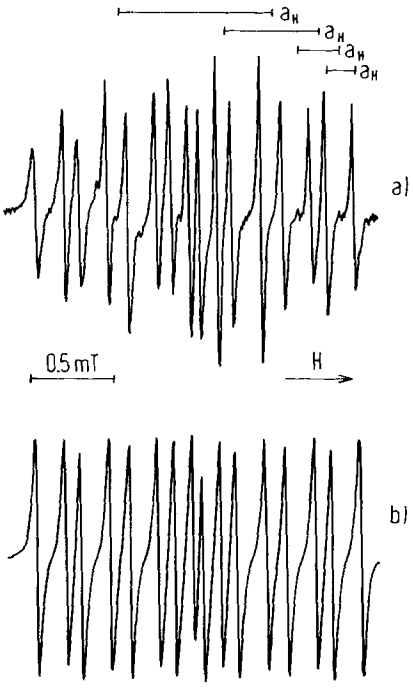
Dialkyl thioketones can be electrochemically reduced to their radical anions $R_2C{=}S^{\bullet\ominus}$[3,4]. We also succeeded in inserting an additional electron into electron-rich thia- and dithiathiones such as trithione[2]:

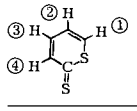
Our studies were prompted by the photoelectron-spectroscopic finding that thiocarbonyl difluoride $F_2C^{\oplus}—S^{\ominus}$ possesses a polar π_{CS} bond[5], as well as by the results of INDO open shell calculations[6], according to which thiapyran-α-thione, for instance, and its radical anion should exhibit the following total charge distribution:

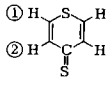
[*] Prof. Dr. H. Bock, Dipl.-Chem. G. Brähler, Dipl.-Chem. A. Tabatabai, Dr. A. Semkow
Institut für Anorganische Chemie der Universität
Theodor-Stern-Kai 7, D-6000 Frankfurt am Main 70 (Germany)
Prof. Dr. R. Gleiter
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

An electron hole is seen to be postulated at the thiocarbonyl carbon atom in the neutral molecule, and in the radical anion the additional unpaired electron should be located predominantly in the (SCS) region.

The ESR spectrum of the radical anion of thiapyran-α-thione (Fig. 1a) expectedly shows 16 lines of equal intensity for the 4 nonequivalent hydrogen atoms and can be simulated—except for the anisotropism arising in the mixture of solvents used at low temperature with the coupling constants given in Table 1 (Fig. 1b).







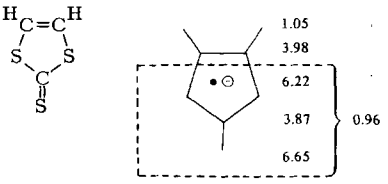


Fig. 1. a) ESR spectrum of the thiapyran-α-thione radical anion at 210 K in acetonitrile/dimethylformamide (DMF) and b) its simulation.

Table 1. Thiathione radical anions: recording temperature T of the ESR spectrum, measured ($a_{H,\mu}$) and calculated ($a_{H,\mu}^{INDO}$) coupling constants for the hydrogen atoms at the various centers μ.

Compound	T [K]	μ	$a_{H,\mu}$ [mT]	$a_{H,\mu}^{INDO}$ [mT]
	210	①	0.158	0.187
		②	0.246	0.437
		③	0.514	0.837
		④	0.861	1.052
	250	①	0.726	0.837
		②	0.241	0.410
	200	①	0.950	1.054
		②	0.274	0.481
	200	①	0.056	0.043

In view of the semiempirical INDO open shell calculation, the measured and calculated ESR coupling constants are in satisfactory agreement[7] and therefore permit spectral assignment (Fig. 1). The small coupling in the isotrithione radical anion is remarkable; according to the McConnell relation $a_{\pi,\mu} = |Q|\rho_{\pi,\mu}$ this corresponds to an only small spin population at the ethylene carbon atoms. The INDO open-shell total charges

also suggest that trithiocarbonate units in planar radical anions can act as "electron traps"[8].

Preparation of Thiocarbonyl Compounds Containing Isotopic Sulfur Labels[**]

By *Claus-Peter Klages* and *Jürgen Voss*[*]

The possibility of substituting the sulfur of a thiocarbonyl group by isotopes is of considerable utility in studies on the physical properties and chemical reactions of thiocarbonyl compounds by mass spectrometry, vibrational, NMR, and ESR spectroscopy, and by tracer methods. Conventional preparations of thiocarbonyl compounds[1] employ sulfur in the form of hydrogen sulfide, tetraphosphorus decasulfide, or carbon disulfide. Yields based on these reagents are generally low, making the incorporation of commercially available *elemental* sulfur isotopes extremely involved and very expensive.

We have now found a convenient method of preparing semimicro amounts of three classes of thiocarbonyl derivatives

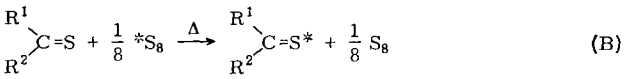
(A)

[*] Prof. Dr. J. Voss, Dipl.-Chem. C.-P. Klages
Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

(Table 1) in very good yield: the final step consists in exchange of selenium for elemental sulfur.

Our experiments were instigated in order to obtain ^{33}S-enriched compounds for ESR spectroscopic studies on their radical anions[2].



Transformation of selenocarbonyl compounds *(1)*[3] into the thiocarbonyl derivatives *(2)* is accomplished merely by heating with sulfur in the absence of solvent in an evacuated ampoule. After cooling the product is dissolved in a suitable solvent, the solution treated with activated charcoal and filtered through a layer of basic alumina. Amount of reactant *n*, reaction time *t*, reaction temperature *T*, solvent used for isolation S, and yields are listed in Table 1 (the data refer to a 1.4-fold excess of sulfur).

Table 1. Thiocarbonyl compounds *(2)* prepared by exchange of selenium.

	R^1	R^2	*n* [mmol]	*t* [min]	*T* [°C]	S	Yield [%]
(2a)	$C(CH_3)_3$	$C(CH_3)_3$	0.2	120	140	Hexane	80
(2b)	C_6H_5	OC_2H_5	0.6	180	140	CCl_4	95
(2c)	C_6H_5	$N(CH_3)_2$	0.5	20	120	CH_2Cl_2	90

The resulting products are pure according to NMR and IR spectroscopy. Possible contamination by elemental sulfur can be removed by chromatography if necessary. The excess of sulfur can be lowered; however, the reaction time for complete conversion at a given temperature will then increase [*e.g.* $t = 6$ h for *(1a)* with a 1.1-fold excess, $T = 140$ °C].

By analogy with reaction (A), sulfur-sulfur exchange is also possible (B). This was established for thiocarbonamides and thiocarboxamides by use of ^{35}S[4].

(B)

We found that 2,2,4,4-tetramethylpentane-3-thione *(2a)* can be substituted according to (B). A mixture of *(2a)* (0.32 mmol) and $^{34}S_8$ (0.15 mmol, 51.7 % enrichment) was heated to 140 °C. After 72 h, the thioketone was shown by its mass spectrum to contain 20 % of ^{34}S. A ^{34}S content of 19.2 % is calculated for complete equilibration. Thus it is possible, using a large excess of enriched sulfur, to label thioketones directly.

ESR Spectroscopic Studies on the Radical Anion of [^{33}S]-2,2,4,4-Tetramethylpentane-3-thione[**]

By *Claus-Peter Klages* and *Jürgen Voss*[*]

Radical anions of thioamides and thionic, as well as dithioic, esters generated by electrochemical means have long been studied by ESR spectroscopy. We have now also generated dialkyl thioketyls *(1)*[1] for the first time, and now report di-*tert*-butyl thioketyl *(1a)*, its ESR spectrum, and our conclusions regarding the electronic and geometrical structure of this species.

(1a), X = S, $R^1 = R^2 = C(CH_3)_3$
(1b), X = S, R^1, $R^2 = -C(CH_3)_2CH_2C(CH_3)_2-$
(2), X = O, $R^1 = R^2 = C(CH_3)_3$

Di-*tert*-alkyl thioketones can be reduced electrochemically to the radical anions in a reversible one-electron step in polar aprotic solvents in the presence of tetraalkylammonium supporting electrolytes.

As expected from the lower strength of the CS π bond, compared with the CO π bond, the negative half-wave potential $E_{1/2}$ for thioketones lies at lower values than for the analogous ketones: while the radical anion of 2,2,4,4-tetramethylpentan-3-one *(2)* cannot be generated in acetonitrile in the accessible range of potentials, the corresponding thioketyl *(1a)* is formed at $E_{1/2} = -2.25$ V (*vs.* 0.1 N $AgNO_3$ (CH_3CN)/Ag).

Figure 1 shows the ESR spectrum of [^{33}S]-di-*tert*-butyl thioketyl. The corresponding thioketone was prepared from the selenoketone and elemental [^{33}S]-sulfur (16.7 % ^{33}S) by a new procedure[2].

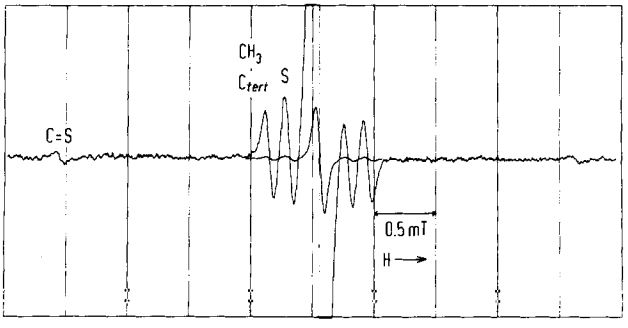

Fig. 1. ESR spectrum of radical anion *(1a)* with ^{13}C and ^{33}S satellites.

The satellite lines of the radical anions with a ^{33}S or ^{13}C atom can be recorded at higher amplification. The measured parameters are compared with those of *(2)* in Table 1.

Table 1. Coupling constants [mT] and *g* values of *(1a)* and *(2)*.

	(1a)	*(2)*
g	2.0061	2.003 [3]
$a^C_{C=X}$	4.19	5.27 [4]
$a^C_{C\text{-}tert}$	0.80	0.77 [4]
$a^C_{CH_3}$	0.80	0.77 [4]
a^X	0.16	−1.11 [4]
$a^H_{CH_3}$	—	0.012 [4]

[**] Thioketyls, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Owing to the greater anisotropism of the g tensor, the ESR signals of thioketyls are broader than those of the ketyls. Coupling of the methyl protons of *(1a)* is therefore not resolved under the given conditions. Assignment of the satellite signals is based upon intensities and comparison with the spectrum of the thioketyl having a natural isotopic abundance. Only the components with $m_I = \pm 3/2$ are visible in the quadruplet due to ^{33}S coupling.

A positive sign is deduced for $a^{C}_{C=S}$ from variations in line width in the thiocarbonyl ^{13}C doublet[5]. Our studies on *(1b)* yielded a sulfur coupling constant of $a^{S} \approx +0.2\,mT$[1]; by analogy we assume *(1a)* to have $a^{S} > 0$.

Comparison of the coupling constants $a^{C}_{CH_3}$ and $a^{C}_{C\text{-}tert}$ in *(1a)* with those in *(2)* and in some substituted di-*tert*-butylmethyl radicals[6] shows that the spin population at the thiocarbonyl C atom ρ^{π}_{C} is about 0.8 to 0.9. Hence di-*tert*-butyl thioketyl resembles an alkyl radical more closely than a thiyl radical. This result confirms an INDO calculation by *Ohno et al.*[7]. The measured coupling constants can be reproduced by known or plausible $\sigma-\pi$ parameters[1]. There is accordingly no need to postulate a pyramidal configuration for *(1)*, as assumed for ketyls[8a] and the *tert*-butyl radical[8b], even though this possibility cannot be entirely ruled out.

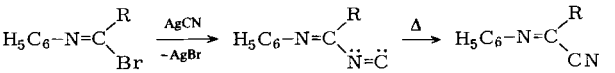
N-Imidoyl Isocyanides[**]

By *Gerhard Höfle* and *Bernd Lange*[*]



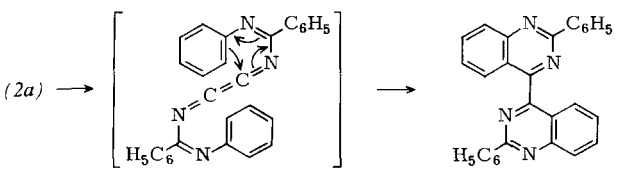
Successful preparation of the first *N*-acyl isocyanides from carboxylic acid iodides and silver cyanide[1] raised the question whether structurally related isocyanides could be prepared according to the same principle.

We have found that the *N*-phenylimidoyl bromides *(1a)* and *(1b)* undergo rapid reaction with silver cyanide in $CHCl_3$ to give the imidoyl isocyanides *(2a)* and *(2b)*, respectively.

[*] Priv.-Doz. Dr. G. Höfle, Dipl.-Chem. B. Lange
Institut für Organische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] Reactions of Organic Halogen Compounds with Silver Cyanide, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 3: [1].

The structures of the compounds are confirmed by their IR spectra, which show an intense isocyanide absorption at 2110 and 2100 cm^{-1} and a C=N absorption at 1632 and 1660 cm^{-1}, respectively. In the ^{13}C-NMR spectrum[2] of *(2a)* a signal for the isocyanide group is observed in the expected range at $\delta = 169.3$.



(1a), R = C_6H_5 *(2)* *(3)*
(1b), R = $C(CH_3)_3$

Compared to the *N*-acyl isocyanides, the *N*-imidoyl isocyanides are distinctly more stable in dilute solution; thus *(2a)* is transformed into the thermodynamically more stable imidoyl cyanide *(3)* only in the course of days, *(2b)* in several hours. However, if the solutions are concentrated at room temperature or reaction of the imidobromide is carried out in boiling chloroform formation of the imidoyl cyanides *(3)* predominates[3].

Isolation of an *N*-imidoyl isocyanide in pure form has so far been realized only in the case of the diphenyl derivative *(2a)*, which is obtained in 85 % yield in the form of yellow crystals on low-temperature crystallization from petroleum ether. It melts at 60 °C and has a weak aromatic isonitrile odor. It can be stored at room temperature for a few days, and at −20 °C indefinitely. On melting it decomposes, giving mainly *(3a)*. Hydrolysis with dilute HCl leads to benzanilide in good yields, and reaction with methanol affords mainly *N*-phenylbenzimino esters.

According to mass spectral data the expected trimerization of *(2)*, in analogy to the *N*-acyl isocyanides, does not take place, even under the most varied conditions. In contrast, in the thermal transformation of *(2a)* into *(3a)* varying amounts (10 to 30 %) of a by-product are observed which could be identified by an authentic synthesis as 2,2′-diphenyl-4,4′-bisquinazoline *(5a)*. We interpret its formation in terms of an initial head-to-head dimerization of *(2a)* to give the heterocumulene *(4a)*, which by double electrocyclic ring closure and subsequent oxidation can elude trimerization[5]. Attempts to transform β-styryl isocyanides into 2,2′-bisisoquinolines in the same way have so far failed.

(2a) *(4a)* *(5a)*

Experimental

Synthesis of *(2a)*: 1.34 g (5.15 mmol) *N*-phenylbenzimidoyl bromide is added to a solution of AgCN[1] (1.7 g, 12.7 mmol) in anhydrous CH_2Cl_2 (20 ml). After 10 minutes' stirring at 20 °C the silver salt is filtered off and the filtrate evaporated down at 0 °C/0.1 torr. The orange-red residue is extracted several times with petroleum ether. On cooling the concentrated petroleum extract from 0 °C to *ca.* −60 °C, 0.90 g (85 %) *(2a)* crystallized out, m.p. 60 °C.

Synthesis of *(5a)*: A solution of AgCN (1.34 g, 10 mmol) and *N*-phenylbenzimidoyl bromide (1.04 g, 4.0 mmol) in anhydrous benzene (25 ml) is heated under reflux for 4 h. The silver salts are separated by filtration and washed several times with hot benzene. The combined filtrates are concentrated and

then treated with petroleum ether. This affords 0.26 g (32 %) *(5a)*, m.p. 293–294 °C. 0.31 g (38 %) *(3a)* can be obtained from the petroleum ether solution by distillation.

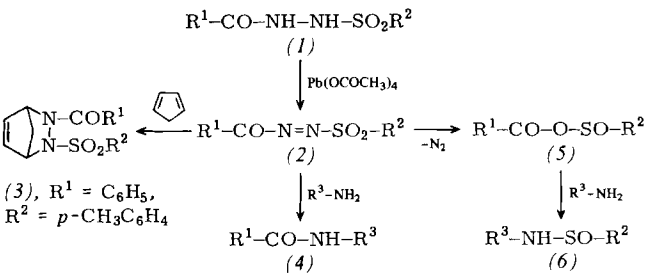
[1] *G. Höfle, B. Lange*, Angew. Chem. *89*, 272 (1977); Angew. Chem. Int. Ed. Engl. *16*, 262 (1977).

[2] Bruker WH 270 at 67.88 MHz in $CDCl_3$ at 30 °C; ^{13}C enrichment in the isocyanide group 90 %; halfwidth of signal 10 Hz at $\delta = 169.3$. On cooling, a coalescence of this signal at *ca.* −10 °C is followed at −50 °C by its replacement by two new signals of comparable intensity at $\delta = 146.3$ and 157.2, which can be assigned to the *E*- and *Z*-isomers. Unusual, however, is that *both* signals are shifted to higher field. The possibility that we observed the dimer *(4a)*, likely to be present in the equilibrium, is ruled out by the low-temperature IR spectrum.

[3] This thermolability casts doubt upon the isolation [4] of *N*-alkylformimidoyl isocyanides in admixture with the corresponding cyanides. The IR and ^{13}C-NMR data [4] (2120 cm^{-1} and $\delta_{-NC} = 157.7$, resp.) suggest that these compounds are actually alkyl isocyanides originating from base-catalyzed HCN elimination from the *N*-alkylformimidoyl cyanides.

[4] *J. H. Boyer, J. Kooi*, J. Chem. Soc. Perkin I, *1975*, 1743; *J. H. Boyer, J. Dunn, J. Kooi*, J. Am. Chem. Soc. *98*, 1099 (1976).

[5] A cyanide-catalyzed dimerization of *(2a)* by way of a 2-phenylquinazoline can be ruled out since added 2-(*m*-tolyl)quinazoline is neither consumed nor incorporated in *(5a)*.



N-Acyl-*N'*-arylsulfonyldiazenes; Detection and Use in the Synthesis of Amides

By *Hansjürgen Gölz, Bernd Glatz, Georges Haas, Günter Helmchen*, and *Hans Muxfeldt* (deceased)[*]

While *N,N'*-diacyldiazenes are in many cases stable and readily accessible, to our knowledge the *N,N'*-disulfonyl- and *N*-acyl-*N'*-sulfonyldiazenes (excepting azobissulfates) have so far not been reported[1]. Owing to the pronounced nucleofugal character of the sulfonylazo group[2] these compounds ought to represent an interesting new class of acylating agents.

We have now been able to demonstrate the existence of a compound of type *(2)*, *viz.* *N*-benzoyl-*N'*-tosyldiazene *(2a)* (cf. Scheme 1 and Table 1). Oxidation of the hydrazide *(1a)* with lead tetraacetate in the presence of cyclopentadiene at −78 °C leads to formation of the cycloadduct *(3)*[3] in 33 % yield, and on addition of boron trifluoride ether in 53 % yield[4] (cf. experimental procedure). In order to estimate the lifetime of *(2a)* the temperature and the interval of time between completion of oxidation and addition of cyclopentadiene were varied. Oxidation at −50 °C and addition of cyclopentadiene after 30 minutes leads to 40 % *(3)*, whereas oxidation at −30 °C and addition of cyclopentadiene after 10 minutes leads to only traces of *(3)*. Consequently, at temperatures below *ca.* −50 °C *(2a)* is sufficiently stable for its isolation.

Scheme 1

Table 1. Carboxamides *(4)* and sulfinamides *(6)* prepared (see experimental) from hydrazides *(1)* and benzylamine ($R^3 = CH_2C_6H_5$) by oxidation with lead tetraacetate.

Reactant	R^1	R^2	T [°C]	Products yield [%]			
(1a)	C_6H_5	*p*-$CH_3C_6H_4$	−60	*(4a)*	>98	—	
(1b)	C_6H_5	C_6H_5	25	*(4a)*	75	*(6a)*	5
(1c)	CH_3	*p*-$CH_3C_6H_4$	−60	*(4b)*	77	*(6b)*	2
(1c)	CH_3	*p*-$CH_3C_6H_4$	25	*(4b)*	51	*(6b)*	12
(1d)	$(CH_3)_3C$	*p*-$CH_3C_6H_4$	−80	*(4c)*	>98	—	
(1d)	$(CH_3)_3C$	*p*-$CH_3C_6H_4$	−50	*(4c)*	89	*(6b)*	9
(1d)	$(CH_3)_3C$	*p*-$CH_3C_6H_4$	25	*(4c)*	28	*(6b)*	42
(1e)	$(CH_3)_3C$	2,4,6-$(CH_3)_3C_6H_2$	−60	*(4c)*	92	*(6c)*	5
(1e)	$(CH_3)_3C$	2,4,6-$(CH_3)_3C_6H_2$	25	*(4c)*	9	*(6c)*	76

N-Acyl-*N'*-arylsulfonyldiazenes *(2)* can acylate amines. Thus, oxidation of the hydrazides *(1a)*—*(1e)* with lead tetraacetate in the presence of benzylamine below −60 °C leads to the carboxamides *(4)*[5] in good yields, together with small amounts of the sulfinamides *(6)* (cf. Table 1 and experimental procedure). The amount of *(6)* can reach significant proportions if the reaction is carried out at room temperature. It follows from our present studies and from numerous other data[6] that the ratio *(6)*/*(4)* increases with increasing temperature and increasing bulkiness of R^1 and R^2. Electronic effects have comparatively little influence in this respect[6].

The results can be interpreted in terms of Scheme 1. The diazenes *(2)* stable at −60 °C react cleanly with amines to give carboxamides; however, at higher temperatures competing elimination of nitrogen leads to the mixed anhydrides *(5)*. These are preferentially attacked at the sulfur atom by amines[7]. This is confirmed by predominant formation of the sulfinamide *(6e)* from *(1e)* at room temperature; in this instance the situation is especially sterically unfavorable for attack at the sulfur atom.

Experimental

2-Benzoyl-3-tosyl-2,3-diaza-5-norbornene (3): A solution of lead tetraacetate (4.0 mmol) in dichloromethane (25 ml) is added dropwise during 1 h at −78 °C to a solution of *(1a)* (880 mg, 3.03 mmol), cyclopentadiene (30.3 mmol), and boron trifluoride ether (1.54 mmol) in THF/acetonitrile (1/1) (50 ml). After a further 4 h at −78 °C the solution is allowed to warm over a period of *ca.* 20 h to room temperature. The crude product obtained after treatment with ether, extraction with sodium hydrogen carbonate solution, drying (sodium sulfate) and removal of organic phase by evaporation is chromatographed on 300 g silica gel (chloroform/acetone 95/5, 15 ml fractions). Fractions 64 to 80 yielded 564 mg (53 %) *(3)*, colorless crystals, m.p. 148—149 °C, after recrystallization from ethyl acetate/hexane.

Carboxamides (4): A solution of lead tetraacetate (1 mmol) in dichloromethane (10 ml) is added dropwise during 20 min to a solution of hydrazide *(1)* (1 mmol) and benzylamine (5 mmol) in THF (for temperature see Table 1). After 2 h

at the same temperature the reaction mixture is treated with ether and extracted with 1 N hydrochloric acid, 1 N sodium hydroxide, and water. The crude product obtained after drying and evaporation of the ether phase is recrystallized or chromatographed on silica gel for determination of the *(4)*/*(6)* ratio.

The Te-O-Fe System: $Te(OTeF_5)_6$[**]

By *Dieter Lentz, Hans Pritzkow*, and *Konrad Seppelt*[*]

The accidental discovery[1] and subsequent elucidation of the structure[2] of *trans*-$F_2Te(OTeF_5)_4$ *(4)* motivated interest in the directed synthesis of higher tellurium oxide fluorides utilizing the oxidative action of xenon(II) derivatives. It was essential, in the first place, to establish the ultimate steric accommodation of a tellurium atom and whether the octahedral construction remains valid. As will be demonstrated in the present communication, the covalent chemistry of tellurium can be developed quite extensively.

First of all, $Te(OTe_5)_4$ *(1)* was synthesized (m.p. 89 °C, subl. 110 °C/10^{-2} mbar, 99.5 % yield) and then oxidized with $Xe(OTeF_5)_2$[3] to $Te(OTeF_5)_6$ *(2)* (95 % yield).

$$3\ TeF_4 + 4\ B(OTeF_5)_3 \longrightarrow 4\ BF_3 + 3\ Te(OTeF_5)_4 \qquad (1)$$

$$(1) + Xe(OTeF_5)_2 \xrightarrow{100\,^\circ C} Xe + Te(OTeF_5)_6 \qquad (2)$$

(2) is the largest oxide fluoride of tellurium so far reported, and, with respect to its mass, one of the heaviest of all inorganic molecular compounds.

Compound *(2)* is a colorless solid having the extremely high melting melting point of 242 °C; nevertheless, despite its high relative molecular mass of 1559.2 it can be sublimed at 110 °C/10^{-2} mbar. It crystallizes in at least two forms [triclinic $P\bar{1}$, $a = 9.096(2)$, $b = 9.132(2)$, $c = 8.878(3)$ Å, $\alpha = 100.22(2)$, $\beta = 99.96(3)$, $\gamma = 115.41(2)°$, $Z = 1$; rhombohedral, $a = 10.524(2)$ Å, $\alpha = 50.09(2)°$, $Z = 1$], but in each case in a pure molecular lattice.

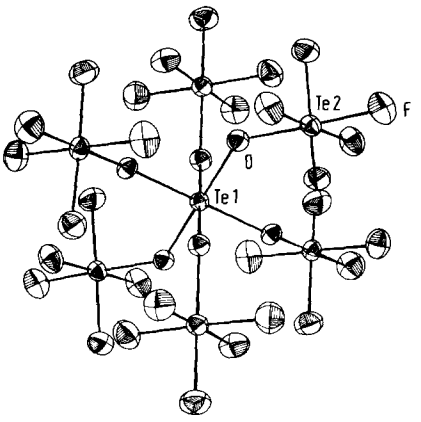

Fig. 1. Crystal structure of $Te(OTeF_5)_6$, triclinic modification, $R = 0.029$.

It can be seen in Figure 1 how the large $OTeF_5$ ligands perfectly occlude the central atom, due to the TeOTe angle of 138°. The high melting point naturally arises from the spherical shape of the molecule. Spatial compactness is much better here than in the case of $U(OTeF_5)_6$[4], since in the latter the U-O-Te angle reaches almost 180°.

On the other hand, $Te(OTeF_5)_4$ *(1)* reacts with XeF_2 and with F_2 to give a mixture of products.

$$(1) + XeF_2 \xrightarrow[-\,Xe]{20\,^\circ C} \begin{cases} cis\text{-}F_2Te(OTeF_5)_4 & (3) \\ FTe(OTeF_5)_5 & (5) \\ trans\text{-}F_4Te(OTeF_5)_2 & (6) \end{cases}$$

$$(1) + F_2 \xrightarrow{20\,^\circ C} \begin{cases} cis\text{-}F_2Te(OTeF_5)_4 & (3) \\ trans\text{-}F_2Te(OTeF_5)_4 & (4) \\ FTe(OTeF_5)_5 & (5) \end{cases}$$

The product *cis*-$F_2Te(OTeF_5)_4$ *(3)* (m.p. −12 °C, b.p. 63 °C/3 mbar) is shown by its ^{19}F spectrum to be the isomer of the already known *trans*-compound *(4)*: the spectrum shows two different pairs of $OTeF_5$ groups ($\delta_A = 51.5$, $\delta_{A'} = 51.6$, $\delta_{B_4} = \delta_{B'_4} = 39.7$). It is still unclear why only the *cis* isomer is formed in the reaction with XeF_2, while fluorination with elemental fluorine also gives the *trans* isomer.

The fivefold substituted compound $FTe(OTeF_5)_5$ *(5)* occurs as by-product (m.p. 48 °C, b.p. 90—100 °C/5 mbar), and, as expected, in the ^{19}F-NMR spectrum it shows different $OTeF_5$ signals in the intensity ratio 1:4 ($\delta_A = 48.0$, $\delta_{A'} = 48.1$, $\delta_{B_4} = \delta_{B'_4} = 36.9$).

Finally, an old structural problem could be solved by directed synthesis:

$$TeF_4 + Xe(OTeF_5)_2 \xrightarrow{20\,^\circ C} Xe + (trans)F_5TeO\text{–}TeF_4\text{–}OTeF_5\ (6)$$

$$+\ (cis)F_5TeO\text{–}\underset{\displaystyle O}{\underset{|}{TeF_4}}\ \ (7)$$
$$\qquad\qquad\qquad

be separated by fractional crystallization. In the ^{19}F-NMR spectrum the *trans* compound *(6)* shows equivalence of the four fluorine atoms ($\delta = 20.7$) while the *cis* compound *(7)* shows a typical A_2B_2 spectrum ($\delta_A = 27.7$, $\delta_B = 35.9$). Up to 150 °C the isomers do not transform into one other. Comparison of the physical data shows that *Robinson* in 1956 had indeed obtained exclusively the *cis* compound. The sulfur analog $F_5SO\text{-}SF_4\text{-}OSF_5$ is so far known only in the *cis* form[6].

All reactions proceed almost quantitatively, and we found no evidence for the frequently observed occurrence of polymeric $(TeOF_4)_n$[1, 7].

The new compounds are astonishingly stable toward hydrolysis. They have been unequivocally characterized (elemental analysis, mass spectrum, IR, Raman and NMR spectra); their data are in agreement with the given structures.

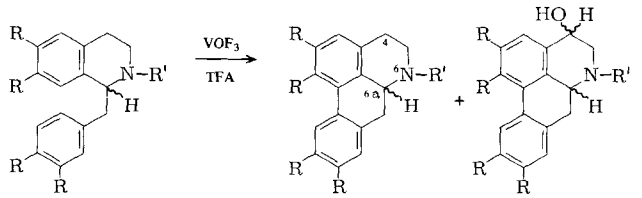
Diastereoselective Synthesis of the Aporphine Alkaloid (+)-Cataline. Hydroxylation with Vanadium(V) Trifluoride Oxide[**]



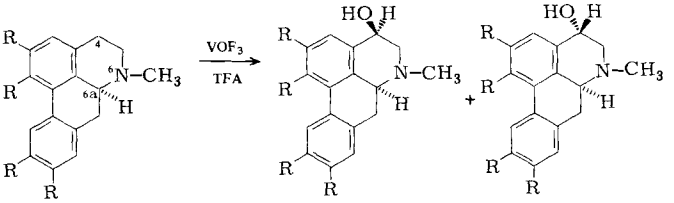
By *Johannes Hartenstein* and *Gerhard Satzinger*[*]

Dedicated to Professor Robert B. Woodward on the occasion of his 60th birthday

The use of vanadium(V) oxide compounds for the intramolecular oxidative coupling of benzylisoquinolines has recently claimed considerable preparative interest[1]. On oxidative coupling of (±)-laudanosine, (±)-*(1a)*, with VOF_3 (2 mol. equiv.) in trifluoroacetic acid (TFA) at −15 °C we surprisingly obtained racemic cataline (4-hydroxyglaucine), (±)-*(3a)*, in *ca.* 40 % yield: m.p. 152—153 °C; hydrobromide: m.p. 212—215 °C (dec.)[2, 3]. Small amounts of (±)-glaucine, (±)-*(2a)*, could also be identified[1].

Careful chromatographic investigation of the reaction product showed that practically only one of the two possible diastereomeric pairs of *(3a)* had been formed.

Similarly, in the reaction of (±)-tetrahydropapaverine, (±)-*(1b)* with VOF_3 in trifluoroacetic acid, after chromatography of the reaction product on basic aluminum oxide (Activity III) with chloroform/triethylamine (99/1, v/v) as eluent we obtained not only (±)-norglaucine, (±)-*(2b)* [yield *ca.* 30 %; hydrobromide: m.p. 252—253 °C (dec.)] but also (±)-*N*-norcataline, (±)-*(3b)*[2] [m.p. 93—95/152—160 °C (ether), yield



(±)-*(1a)*, (±)-*(1b)* (±)-*(2a)*, (±)-*(2b)* (±)-*(3a)*, (±)-*(3b)*

(a), R' = CH_3; *(b)*, R' = H
R = CH_3O

38 %, trifluoroacetate: m.p. 200—205 °C (dec.); *O,N*-diacetyl-(±)-*(3b)*: m.p. 194—196 °C (ether)].

Use of optically active (−)-tetrahydropapaverine, (−)-*(1b)*[4], led to (+)-*N*-norglaucine, (+)-*(2b)*, and (+)-*N*-norcataline, (+)-*(3b)*, (see Table 1).

Concerning the mode of formation of the 4-hydroxyporphines of type *(3)* under the reaction conditions mentioned we have carried out the reaction of (+)-glaucine, (+)-*(4)*, and of (−)-glaucine with VOF_3 (2 mol. equiv.) in trifluoroacetic acid between −15 °C and room temperature, and likewise *via* regio- and stereoselective reaction obtained (+)-cataline, (+)-*(5)*, and (−)-cataline, respectively, in *ca.* 50 to 60 % yield; $[\alpha]_D^{22} = +139.7$ and $-147.7°$, respectively ($c = 1$, $CHCl_3$) (see Table 1).

(+)-*(4)* (+)-*(5)* (+)-*(6)*

6a-H: α-Position
R = CH_3O

On chromatographic separation of the reaction product on basic aluminum oxide (Activity III) small amounts (< 2 % yield) of the respective diastereomeric *cis*-4-hydroxyaporphine, (+)-*(6)*, and its antipode could also be isolated and characterized (see Table 1).

In contrast to the smooth 4-hydroxylation with VOF_3, reaction of glaucine with $Pb(OAc)_4$ in glacial acetic acid at room temperature[6] leads mainly to the oxoaporphine *O*-methylatheroline.

Table 1. Some data for compounds (+)-*(2b)*, (+)-*(3b)*, (+)-*(5)* and (+)-*(6)* and their derivatives.

(+)-(6a*S*)-*(2b)*, NMR ($CDCl_3$): $\delta = 6.66$ (8-H, s), 6.80 (3-H, s), 8.19 (11-H, s); hydrobromide: m.p. 246—248 °C (248—250 °C [5a]), $[\alpha]_D^{22} = +97.3°$ ($c = 1$, MeOH) (+99° ($c = 1$, MeOH) [5a]); *N*-acetyl-(+)-*(2b)*: m.p. 185—186 °C (173—174 °C [5b]), $[\alpha]_D^{22} = +356.3°$ ([α]$_D$ = 367° ($c = 0.5$, EtOH) [5b])

(+)-(4*S*,6a*S*)-*(3b)*, NMR ($CDCl_3$): $\delta = 4.52$ (4-H, m, unresolved), 6.73 (8-H, s), 6.89 (3-H, s), 8.10 (11-H, s); m.p. 160—162 °C (EtOH), $[\alpha]_D^{22} = +106.7°$ ($c = 1$, $CHCl_3$); *O,N*-diacetyl-(+)-*(3b)*: m.p. 235—236 °C, $[\alpha]_D^{22} = +286.3°$ ($c = 1$, $CHCl_3$)

(+)-(4*S*,6a*S*)-*(5)*, NMR ($CDCl_3$): $\delta = 2.60$ (N—CH_3, s), 4.47 (4-H, dd, unresolved, X part of an AMX system), 6.72 (8-H, s), 6.92 (3-H, s), 8.03 (11-H, s), m.p. 180—182 °C

(+)-(4*R*,6a*S*)-*(6)*, NMR ($CDCl_3$): $\delta = 2.43$ (N—CH_3, s), 4.80 (4-H, dd, resolved, AMX system with $J_{AM} = 10.7$, $J_{AX} = 6.2$, $J_{MX} = 9.5$ Hz), 6.68 (8-H, s), 7.04 (3-H, s), 8.03 (11-H, s), m.p. 188—189 °C, $[\alpha]_D^{22} = +97.3°$ ($c = 1$, $CHCl_3$)

Experimental

(+)-Cataline, (+)-*(5)*: A solution of (+)-*(4)* (1 g) in trifluoroacetic acid (TFA) is treated dropwise with stirring at −15 °C with a solution of VOF_3 (0.7 g) in TFA (25 ml) (deep blue to red-violet coloration). The mixture is stirred for 2 h at −15 to −10 °C and, after removal of the cold-bath, for a further 1 h at room temperature. The TFA is then removed at 20 °C/70 torr and the residue treated with cold aqueous NH_3 solution and extracted with $CHCl_3$. After drying over Na_2SO_4 and removal of solvent the residue is taken up in ether and filtered. Subsequent crystallization affords 646 mg (61 %) (+)-*(5)*.

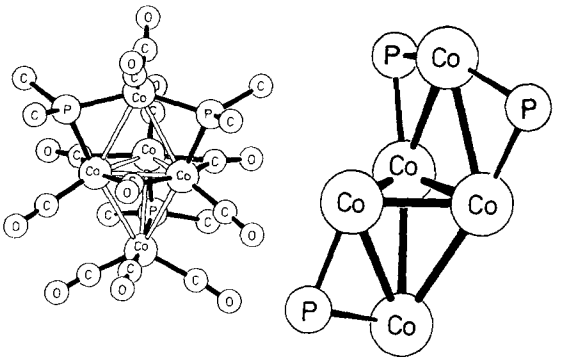
$Co_5(CO)_{11}(PR_2)_3$, A Novel Type of Pentanuclear Cluster[**]

By *Egbert Keller* and *Heinrich Vahrenkamp*[*]

The reaction of complexes of secondary phosphanes with π-allyl complexes involving elimination of propene has previously led to phosphorus-bridged dinuclear and trinuclear complexes containing metal-metal bonds[1]. We have now tried to utilize this reaction scheme for the synthesis of a compound containing a Co—Ni bond. On reacting η^3-$C_3H_5Co(CO)_3$ with $(CO)_3Ni—PMe_2H$ we surprisingly obtained the pentanuclear cobalt cluster $Co_5(CO)_{11}(PMe_2)_3$ *(1)*. The mechanism of formation of this product is unclear; its formation is, however, consistent with our observation[1] that the aggregation of polynuclear base-bridged complexes increases with decreasing number of terminal ligands.

The composition and structure of the new compound *(1)*[2] could be unequivocally determined only by a crystal structure analysis[3]. As seen in Figure 1, the arrangement of the cobalt atoms has to be described as an edge-bridged trigonal pyramid in which the lengths of the Co—Co bonds in the central $Co_3(CO)_6$ unit are 2.41—2.47 Å, of those bridged by phosphorus to the outer Co atoms 2.76—2.81 Å, and of the unbridged Co—Co bonds 2.89 and 2.92 Å. The nonbonding Co···Co distance is 3.21 Å.



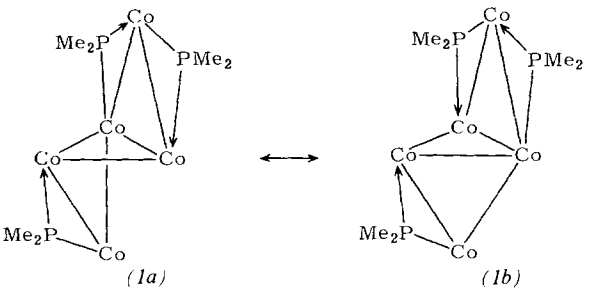


Fig. 1. Molecular structure (left) and heavy-atom skeleton (right) of $Co_5(CO)_{11}[P(CH_3)_2]_3$ *(1)*.

The structure and bonding of *(1)* are in many respects unusual. Firstly, *(1)* is the first Lewis-base-bridged cluster containing more than four metal atoms[4]. Further, such an edge-bridged trigonal pyramid in pentanuclear clusters is new; previously only the trigonal bipyramid[4, 5], the tetragonal pyramid[4, 6], and the double triangle[7] have been observed. Finally, the metal-metal bonds in *(1)* are explainable neither by simple application of the 18-electron rule nor by the skeleton electron counting method[8]. Only the valence bond notation with the two resonance formulas *(1a)* and *(1b)* provides a somewhat acceptable picture of the bonding. It gives all cobalt atoms the krypton configuration and assigns the bond order $^1/_2$ to the unbridged Co—Co bonds. It is then understandable that these two bonds are distinctly longer than normal unbridged Co—Co bonds.

The structure of *(1)* is a further example showing that phosphorus bridging leads to unusual polynuclear complex geometries[1, 9]. A systematization of these geometries, however, requires the discovery of further examples.

Experimental:

A mixture of $(CO)_3Ni—PMe_2H$ (4.0 g, 20 mmol) and η^3-$C_3H_5Co(CO)_3$ (3.7 g, 20 mmol) is stirred for 1 d without solvent. 280 ml of gas (propene, CO) is evolved. The highly viscous oil remaining after removal of 1.9 g of volatile reaction products (mainly $Ni(CO)_4$) is extracted with benzene (20 ml) and the extract chromatographed on a silica gel column (2 × 100 cm). Initial elution with benzene/hexane (1:4) gives a dark-green compound which has not yet been identified. Next, with benzene/hexane (1:2) a dirty-green fraction is obtained which after concentration by evaporation and subsequent slow recrystallization from benzene affords 220 mg (7 %) of black *(1)*, m.p. 166—167 °C (dec.).

ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

Polymerizations proceeding *via* free radicals and initiated by light have become increasingly important in recent years owing to their practical significance in the printing industry and in the production of printed circuits and coatings. *A. Ledwith* gives an account of the polymerizations of methyl methacrylate initiated by various amine-fluorenone combinations and light. [Photoinitiation of Polymerisation. Pure Appl. Chem. *49*, 431—441 (1977); 36 references]

[Rd 970 IE]

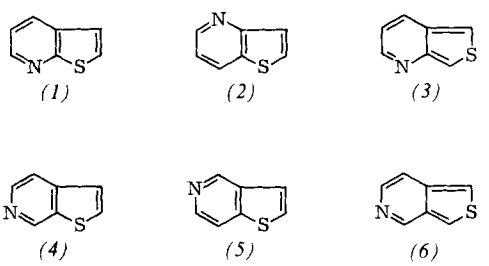
Thiols (mercaptans), as all chemists know, have an extremely unpleasant odor. This repulsive property may have precluded a thorough study of this class of compounds, although no organism is able to live without them. In a review, *A. Ohno* and *S. Oae* compare and contrast the physical properties of the thiols with those of their oxygen analogs, describe the syntheses and reactions of thiols, and discuss some of their biological functions. [Thiols in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 119—187; 250 references]

[Rd 964 IE]

Thiocarbonyl and carbonyl groups differ in the following properties: 1) The π electrons of a thiocarbonyl group are more strongly localized at the sulfur than the π electrons of a carbonyl group at the oxygen. The thiocarbonyl C atom therefore carries a greater positive charge than the carbonyl C atom.—2) Unpaired electrons on the thiocarbonyl sulfur are more readily removed than those on the carbonyl oxygen, *i.e.* the thiocarbonyl group is more easily ionized than the carbonyl group.—3) The thiocarbonyl group has a greater volume than the carbonyl group.—*A. Ohno* compares the reactions of thiocarbonyl and carbonyl compounds from this vantage point. [Thiones in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 189—229; 145 references]

[Rd 965 IE]

Tellurophene *(1)* and related compounds is the title of a survey by *F. Frinquelli, G. Marino*, and *A. Taticchi*. The term "related compounds" not only covers derivatives of tellurophene but also applies to furan, thiophene, and selenophene,



(1)

whose properties are compared quantitatively with those of tellurophene. [Tellurophene and Related Compounds. Adv. Heterocycl. Chem. *21*, 119—173 (1977); 109 references]

[Rd 976 IE]

Thienopyridines, *i.e.* compounds of type *(1)* to *(6)*, command theoretical interest as systems having one ring with a surfeit of π electrons and the other with a deficiency of π electrons. Numerous substances of this class have also been synthesized in the search for new pharmaceuticals; apart from derivatives of type *(1)* and *(2)*, which occur in high-sulfur oil shales,

(1) *(2)* *(3)*

(4) *(5)* *(6)*

thienopyridines have not yet been found in nature. *J. M. Barker* has written a review of the syntheses, reactions, and properties of these compounds. [The Thienopyridines. Adv. Heterocycl. Chem. *21*, 65—118 (1977); 150 references]

[Rd 975 IE]

Chronologie Chemie 1800—1970 (Chronology of Chemistry 1800—1970). By *S. Neufeldt*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., vii, 359 pp., 19 figs., 4 tables, linen, DM 78.—.

Neufeldt's "Chronology of Chemistry 1800—1970" will be welcomed both by chemists and by historians of science. It is a wide-ranging reference work standing half-way between a presentation of the history of chemistry and a chronological tabulation of findings and discoveries. It should be found in every school library, in every library of a chemical college or research institute, and on the desks of science historians, teachers and lecturers of chemistry.

Dates provide the main arrangement of the most important discoveries, theories, syntheses, processes, and apparatus (as well as occasionally the more important institutions), and they also serve for crossreferences. In each section arranged under a year the names of the innovators as subtitle are picked out in bold print, while the innovation itself is presented in three to eighteen lines of text and is emphasized within the text by an italicized keyword. The events described are "characterized by their content and nature, and are provided with references to previous knowledge as well as their importance; laws and rules are formulated, formulas and equations are written out wherever possible, and synthesis routes are indicated" (page V). There follow brief bibliographic references to the original publications, to previous work mentioned in the text, and to directly dependent subsequent innovations and further advances; but unfortunately only a few references to historical papers or books occur. Eighteen "highlights" have been extracted from the chronological arrangement, and for those Appendix I gives a detailed description with an illustration. "Important steps in the development of chemical nomenclature" are described in Appendix IV (why is *Cannizzaro*'s name missing from the item "1860 Karlsruhe Chemical Congress"?), which is divided into inorganic and organic chemistry; this gave the opportunity to mention *Lavoisier*'s contributions under the dates 1787 and 1789, whereas the date 1800 seems to have been a rather arbitrary choice for the starting point of chemistry proper.

Other Appendices contain the names of Nobel prizewinners for physics, chemistry, and physiology or medicine (each up to 1975) and the achievements for which the prize was awarded; the names of the scientists who bore or bear the order "Pour le mérite" for science and technology; chemical societies; a "Chronological list of a selection of the oldest scientific journals (up to 1900)", as well as a "Selection of (*s.c.* monographic) literature on the history of chemistry" (up to 1974).

No lexicological method is perfect, since it can never be applied to the whole material. It is somewhat confusing that the names of several persons are often given together as keywords under one date, persons who either made different contributions (*e.g.* 1800: *Ritter*, *Cruickshank*; electrolytic decomposition of water and cathodic separation of metals) or made advances that supplemented each other (*e.g.* 1934: *Butenandt*, *Marker* [1940], *Pincus* [1956]; isolation of crystalline progesterone, conversion of sapogenins into progesterone, and investigations on oral contraceptives, respectively). There are also other difficulties with the system, as in the organization of important institutions. For example, *e.g.* "1911: *A. v. Harnack* [the first President] and *O. Hahn* [the first postwar President after renaming]" as the keyword for the organization of the Kaiser-Wilhelm-Gesellschaft (Max-Planck-Gesellschaft).

The dating usually follows the date of appearance of the first publication, but here too there have been decisions that could lead to different dates and thus to confusion. X-Rays were discovered in December 1895; *Röntgen* submitted his work ("Vorläufige Mitteilung") on December 28th, and it was accepted by the Sitzungsberichte der Physicalisch-Medizinischen Gesellschaft in Würzburg of the year 1895, but the journal didn't appear before January 1896 (recorded in *Neufeldt*'s book under 1895); on November 19th, 1807 *Davy* reported the discovery of sodium and potassium before the Royal Society; the lecture was published as the first contribution in the Philosophical Transactions of 1808 (put by *Neufeldt* under 1808). In December 1938 *O. Hahn* and *F. Strassmann* discovered nuclear fission of uranium (why was *Strassmann*'s name not mentioned, especially since it was in fact he who provided the analytical proof?), but the paper appeared only on 6th January 1939 (listed by *Neufeldt* under 1939). Since *I. Noddack*'s paper of 1934 is listed in this section and recorded as the first reference to nuclear fission, the editorial comment in Naturwissenschaften 27 (No. 13) 1939 concerning her pretension printed there should have been noted together with this pretension itself.

The notions above are, however, minor criticisms that do not detract from the excellent total impression of this work, the contents of which are made accessible by author and subject indexes.

Fritz Krafft [NB 382 IE]

Atmospheric Chemistry. By *J. Heicklen*. Academic Press, London—New York 1976. 1st edit., xiv, 406 pp., numerous figures and tables, bound £ 27.00.

This book aims at giving a comprehensive account of the chemical processes taking place in the upper and lower atmosphere.

The structure of the atmosphere, its chemical composition in individual altitude zones, and the primary photochemical processes are first treated in the introductory chapter. The next two chapters deal with the chemical reactions in the upper atmosphere, *i.e.* the stratosphere, the mesosphere, and the ionosphere. Here the treatment follows essentially the view of the Brussels aeronomist *M. Nicolet*, with whom the author collaborated for many years. The theory is strongly emphasized, but unfortunately much less emphasis is given to the results of measurements, so that the impression is one of an uncritical treatment of the material.

The remaining two-thirds of the book deal with the problems of atmospheric pollution. After a chapter on the sources and the effects of atmospheric pollutants there is a section on the chemical processes taking place in the oxidation of hydrocarbons. Three chapters follow on the chemistry of chemical smog, on the reactions of ozone and singlet oxygen, and on the homogeneous oxidation of sulfur dioxide. Two concluding chapters treat very briefly the possible processes of aerosol formation and measures for limiting the emission of pollutants.

In the general representation of this material *Heicklen* writes overwhelmingly from the standpoint of reaction kinetics. This has the advantage that the reaction mechanisms are described in detail, but on the other hand a number of other important aspects are dealt with too briefly. The biochemical sources of trace atmospheric gases, the transport of trace constituents in the troposphere, and the chemical composition and distribution of atmospheric aerosols to mention only a few topics, are not treated. Furthermore, the author cannot be absolved from the charge of using some obsolete material. On the subject of the distribution of CO with geographic latitude more extensive and more reliable data are now available;

the (unpublished) first results from 1969, which are given on page 161, are therefore superseded.

The book contains remarkably few printing errors and can be recommended to all those who would like a detailed account of atmospheric gas reactions. The price is reasonable.

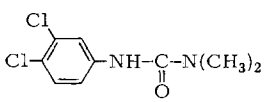
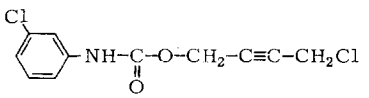
Fluorinated Isocyanates and Their Derivatives as Intermediates for Biologically Active Compounds

By Engelbert Kühle and Erich Klauke[*]



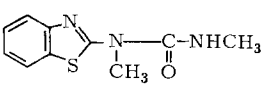
Dedicated to Professor Otto Bayer on the occasion of his 75th birthday

Fluorinated aromatic isocyanates are valuable intermediates for the production of herbicides and insecticides. Unexpected rearrangements during the synthesis of 2-(trifluoromethyl)phenyl isocyanates provide an entry to *N*-trifluoromethylaminobenzoyl fluorides, a novel class of compounds having fungicidal properties. Carbamoyl fluorides, the products of HF addition to isocyanates, undergo ready sulfenylation. Use of these intermediates for the synthesis of *N*-sulfenylcarbamate insecticides led to the discovery of the new principle of detoxification of carbamates by sulfenylation.



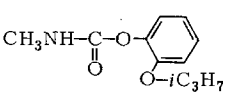
1. Introduction

The active constituents of modern pesticides are not all esters of phosphorus acids—derivatives of carbonic acid also play a considerable role. This very extensive class of compounds is dominated by those derived from aliphatic or aromatic isocyanates.

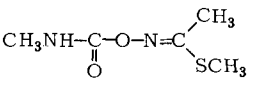


Examples of compounds having pronounced general or selective herbicidal activity[1] are found in the 3,4-disubstituted *N*-alkyl-*N'*-phenylurea derivative *(1)*, the *N*-phenylurethane *(2)*, and the urea *(3)* bearing heterocyclic substituents.

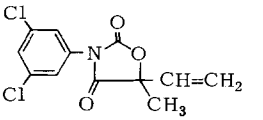
(1)



(2)



(3)

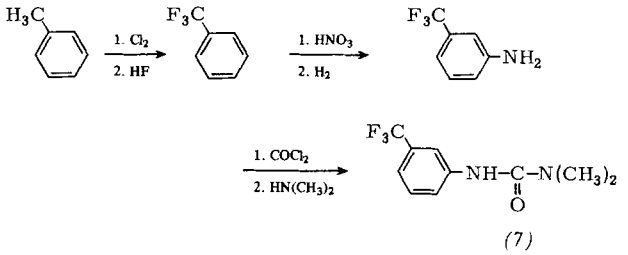


Like phosphoric esters, aryl *N*-methylcarbamates, *e.g. (4)*, and *O*-(*N*-methyl-carbamoyl)oximes *(5)* act as strong cholinesterase inhibitors and are used as insecticides because of this property[2].

(4)

(5)

(6)



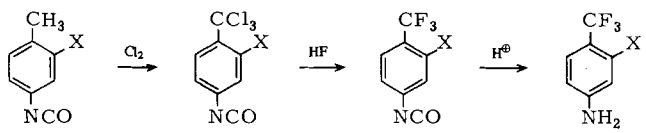
Finally, the existing range of fungicides has recently been extended by specific botrytis agents, such as *(6)*, which are all derived from 3,5-dichlorophenyl isocyanate[3].

2. Fluorinated Isocyanates as Intermediates for Herbicides

Several years ago *N*,*N*-dimethyl-*N'*-[3-trifluoromethylphenyl]urea (common name Fluometuron)*(7)* became known as a derivative of a fluorinated isocyanate and has meanwhile

[*] Dr. E. Kühle, Dr. E. Klauke
Bayer AG, Zentrale Forschung WHL
D-5090 Leverkusen (Germany)

become a market leader among cotton herbicides, particularly in the USA and the USSR. Compound *(7)* is accessible from toluene by classical methods[1].

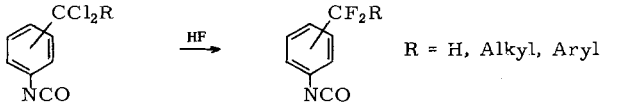


(7)

The isomers of the *para* and *ortho* series cannot be synthesized in this way.

The classical protecting group for a primary amine is an acyl group; the subsequent reactions will determine whether it should be an acetyl group (*e.g.* for nitration) or a phthaloyl group (*e.g.* for halogenations). In recent years the smallest possible "acyl group", *viz.* the carbonyl group, has found increasing application in chlorinations[4], *i.e.* the primary amine is protected in the form of the isocyanate on chlorination.

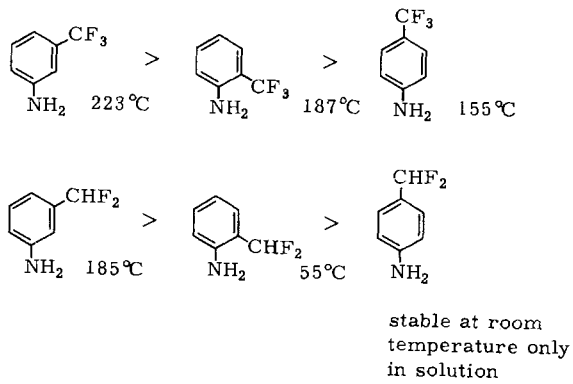
Starting from readily available 4-tolyl- or 3-chloro-4-tolyl isocyanate *(8)* side-chain chlorination affords the corresponding 4-trichloromethylphenyl isocyanate *(9)* and subsequent chlorine/fluorine exchange with anhydrous hydrofluoric acid furnishes the required 4-(trifluoromethyl)phenyl isocyanates *(10)*[5]. If desired, 4-trifluoromethylanilines *(11)* can be liberated from *(10)* by acid hydrolysis.



(8) *(9)* *(10)* *(11)*

X = H, Cl

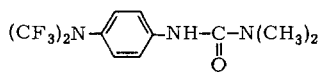
The reaction scheme is not applicable to the *ortho* series since the action of hydrofluoric acid then leads to rearrangement (cf. Section 3). 2-(Trifluoromethyl)phenyl isocyanate can be produced from the trichloromethyl compound by direct fluorination with SbF_3[6].



Side-chain fluorination with an excess of hydrofluoric acid proceeds very smoothly and almost quantitatively at temperatures between 0 and 60 °C, depending upon the other substituents present. Operation between definite temperature limits and appropriate dosing of the anhydrous hydrofluoric acid permit directed synthesis of intermediates of chlorine/fluorine exchange; products are the dichloromonofluoro- and monochlorodifluoro derivatives.

Apart from the CCl_3 group, the CCl_2R moiety with R = H, alkyl, or aryl can also be fluorinated with hydrofluoric acid[7].

Suitable starting compounds for these intermediates are substituted benzylidene chlorides or the products of reaction between benzaldehydes, acetophenones, and benzophenones with PCl_5[8].

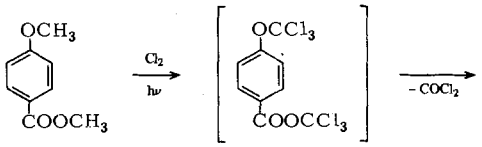


It is appropriate at this juncture to compare the stability of CF_3- and CHF_2-substituted anilines. The temperature of incipient decomposition is given in Scheme 1 as a measure of thermal stability (determined by differential thermal analysis).

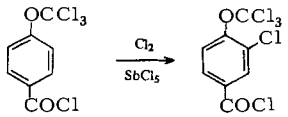
Scheme 1

Potential intermediates for herbicides are not limited to isocyanates having fluoroalkyl groups linked directly to the phenyl ring but also include those in which a heteroatom such as oxygen or sulfur is located between the fluoroalkyl and phenyl units.

N,N-Dimethyl-*N'*-[4-bis(trifluoromethyl)aminophenyl]-urea (with an inserted nitrogen atom) exhibits only slight herbicidal activity[8a].



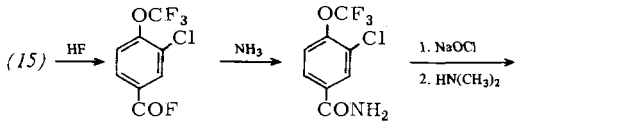
Among the trifluoromethoxyphenyl and trifluoromethylthiophenyl isocyanates, we have concerned ourselves primarily with the 3- and 4-substituted compounds containing, in some cases, a further chlorine atom in position 3 and 4, respectively.



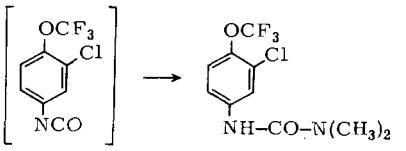
In the following Sections we shall consider the synthesis of three selected isocyanates whose dimethylureas exhibit a highly selective herbicidal action in various plant cultures.

2.1. Synthesis of *N'*-[3-Chloro-4-(trifluoromethoxy)phenyl]-*N,N*-dimethylurea *via* the Isocyanate

4-Hydroxybenzoic acid, readily accessible on an industrial scale by the Kolbe-Schmidt reaction, is converted directly into methyl 4-methoxybenzoate *(12)* by methylation. Per-



(12) *(13)*

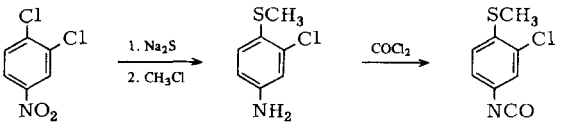


(14) *(15)*

chlorination of the side chain thence affords the thermally unstable ester *(13)* which undergoes stabilization to 4-trichloromethoxybenzoyl chloride *(14)* by elimination of phosgene[8b]. Subsequent ring chlorination in the presence of a catalyst then leads to the 3-chloro-4-(trichloromethoxy) derivative *(15)*. An appropriate catalyst is $SbCl_5$ which also has a catalytic action in the subsequent fluorination step.

Thus *(15)* affords 3-chloro-4-trifluoromethoxybenzoyl fluoride *(16)* which in turn cleanly gives the benzamide *(17)* with ammonia. Treatment of *(17)* with NaOCl in an alkaline medium at 10 to 20 °C is conducted as a one-pot reaction; the desired urea *(18)* is then formed directly in high purity *via* Hoffmann degradation in the presence of dimethylamine at about 40—50 °C. There is no need to isolate the isocyanate[9].

(16) *(17)*



(18)

The urea derivative *(18)*[10,11] shows very good selective herbicidal activity on pre-emergence or post-emergence application to cotton. At an application of 1 kg/ha this product is superior to other ureas, especially towards grasses. Moreover the compound shows good selectivity in corn, potatoes, sorghum, and peanuts.

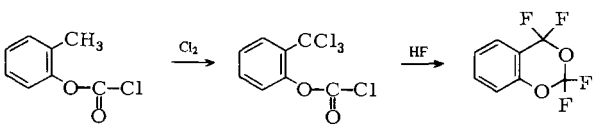
The acute toxicity of compound *(18)* can be regarded as low or insignificant. The LD_{50} values for oral application to rats is 797 mg/kg; maximum amounts and concentrations, respectively, were tolerated without symptoms on dermal and aerosol exposure. The compound is without irritant properties on skin and mucous membranes. No cumulative toxic effects were observed in subacute animal experiments on application with feed or as aerosols.

2.2. Synthesis of *N'*-[3-Chloro-4-chlorodifluoromethylthiophenyl]-*N*,*N*-dimethylurea *via* the Isocyanate

In a one-pot reaction, 3,4-dichloro-1-nitrobenzene *(19)* is first transformed into 3-chloro-4-mercaptoaniline by treatment

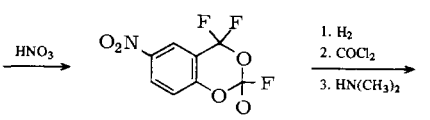
(19) *(20)* *(21)*

(22) *(23)*



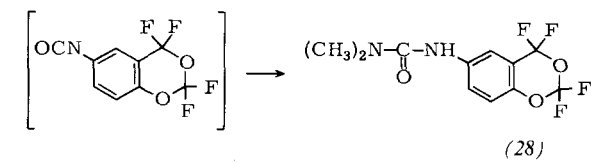
with sodium sulfide and methylated directly with methyl chloride to give the 4-methylthio compound *(20)*. The isocyanate *(21)* obtained therefrom is chlorinated in the side chain, fluorinated at room temperature to give the desired chlorodifluoromethylthio compound *(22)*, and converted into the urea *(23)* with dimethylamine.

The urea *(23)*[12], known as Thiochloromethyl, is used for weed control in sown and transplanted rice. It is well tolerated by the rice, being mainly active against Dicotyledoneae and algae. The product can be used in both the pre-emergence and the post-emergence modes. This urea is also very suitable for use as a component of commercially available grass herbicides based on thiolcarbamates (*e.g.* Benzthiocarb)[13]. The 4-trifluoromethylthio compound analogous to the urea *(23)* shows the same range of activity, but requires more involved production technology since the last chlorine atom can only be replaced by fluorine under pressure (side reactions)[14].



The active component *(23)* has a moderate acute oral toxicity in laboratory animals (*e.g.* LD_{50} oral, rat = 432 mg/kg). No symptoms were observed on application of 500 mg/kg to the skin of rats. High concentrations were tolerated without symptoms for exposure periods of four hours. The compound has no damaging effect on the skin of rabbit and man, or on the eye of a rabbit. No cumulative toxic effects were observed in subacute animal experiments on application with feed or as an aerosol.

2.3. Synthesis of *N*,*N*-Dimethyl-*N'*-(2,2,4,4-tetrafluoro-4*H*-1,3-benzodioxin-6-yl)urea *via* the Isocyanate



As the third example, a herbicidal urea will be presented which contains a phenyl group with a difluoromethyleneoxydifluoromethyleneoxy bridge. In order to synthesize the urea *(28)*, *o*-cresol is chlorinated in the form of its chloroformate *(24)* to give the trichloromethyl compound *(25)*. On subsequent fluorination *(25)* cyclizes to the stable benzodioxine derivative *(26)*, which can be cleanly nitrated in position 6 to give *(27)*[15]. Further steps of the process leading to the urea *(28)* are straightforward.

(24) *(25)* *(26)*

(27)

(28)

This urea also shows good selectivity in several crops, *e.g.* in potatoes (4 kg/ha) and in cotton (2—4 kg/ha)[16].

2.4. Other Fluorinated *N,N*-Dimethyl-*N'*-phenylureas Having Herbicidal Activity

Section 2 will now close with a brief characterization of other ureas, classified according to their fluorine-containing substituent.

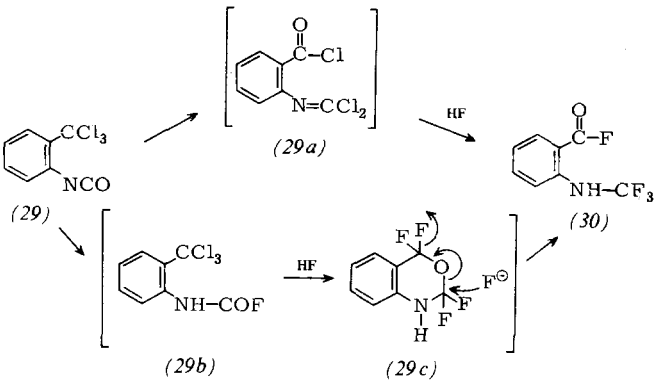
CF_3 Substitution[5]: The active compounds of this series, exhibiting a good selective action in cotton, should be viewed in relation to Fluormeturon *(7)*. The *para* isomer has roughly the same activity, while the 3-chloro-4-trifluoromethylphenyl derivative has a somewhat superior action against weeds.

CF_2H Substitution[7, 17]: In contrast to the above series, the 4-chloro-3-difluoromethylphenyl derivative occupies the leading position in the scale of herbicidal efficacy; selectivities are present in cotton, peanuts, corn, and potatoes. The 3-chloro-4-difluoromethyl isomer can be used as a selective agent in corn and grain. The herbicidal activity of the 4-difluoromethyl derivative is only modest, probably owing to its instability; the *m*-isomer on the other hand, can be used in rape.

CF_3O Substitution[10, 11]: Apart from the urea *(18)*, which is significantly more active and also more reliable in its cotton selectivity than Fluometuron *(7)*, only the 3-chloro-4-chlorodifluoromethoxy compound has an action comparable with that of Fluometuron in cotton and corn. Surprisingly, the chlorine-free representatives of this series develop only a weak herbicidal activity.

CF_2HO Substitution[17a, 17b]: Among the compounds substituted in this way, mention should be made of the 3-chloro-4-difluoromethoxy derivative, which is superior to *(7)*, but less active than *(18)*, and is also less selective than *(18)* in cotton.

CF_3S Substitution[12, 14]: In this series too, the ring-chlorinated compounds have greater biological activity than the unchlorinated derivatives. However, crops are also affected adversely, with the result that rice is the only crop for which practical application is feasible. The best product is the above-mentioned urea *(23)*.

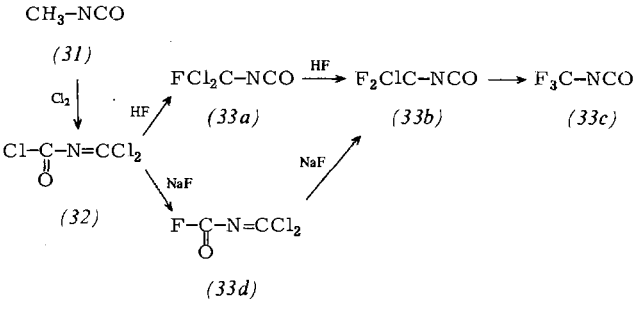


CF_2HS Substitution[17b]: The herbicidal activity of the 4-difluoromethylthio and the 3-chloro-4-difluoromethylthio compound is unusually strong; unfortunately their selectivities leave much to be desired.

Summarizing: in each of the series presented above, the compounds having the best herbicidal activity and greater selectivity are nearly always the ones bearing a chlorine atom in position 3 in addition to the fluorinated substituent in position 4.

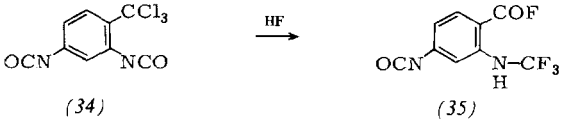
3. 2-[*N*-Trifluoromethylamino]benzoyl Fluorides as Intermediates for Fungicides and Bactericides

As already mentioned, attempts to synthesize trifluoromethylphenyl isocyanates from the trichloromethyl compounds with anhydrous hydrofluoric acid fail in the *ortho* series. For instance, in the case of *(29)* a novel rearrangement involving oxygen migration gives *N*-trifluoromethylanthraniloyl fluoride *(30)*[17c] (Scheme 2).



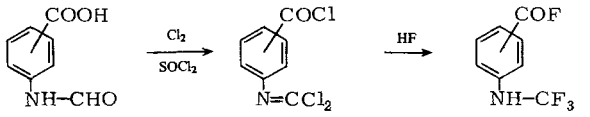
With regard to our discussion of Scheme 2, it should be mentioned that isomerization of *(29)* to *(29a)*, giving contents up to 50 %, can be accomplished merely by thermal treatment. Owing to the high temperatures employed in the production of *(29)*, there is always a certain amount of *(29a)* present

Scheme 2



in *(29)*. This isomeric structure provides a ready explanation for the fluorination product *(30)* formed by chlorine/fluorine exchange and subsequent HF addition to the N=C double bond. Another interpretation of the reaction course involves a primary HF/isocyanate adduct, the carbamoyl fluoride *(29b)* having a strongly polarized carbonyl bond, which cyclizes to *(29c)* on chlorine/fluorine exchange [cf. the synthesis of the stable compound *(26)*]. In HF as reaction medium, $F^{\ominus}$ addition leads to ring opening and stabilization to give *(30)*.

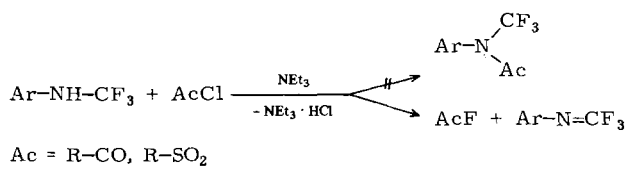
If compound *(29)* is regarded as the phenylog of trichloromethyl isocyanate, CCl_3NCO, then the rearrangement shown in scheme 2 appears particularly surprising. Perchlorination of methyl isocyanate *(31)* does not give an isocyanate but exclusively the chlorocarbonyl isocyanide dichloride *(32)*[4]. Only on preparing the corresponding fluorinated products does re-isomerization occur to give isocyanates *(33a)*—*(33c)*. The direction of isomerization is the opposite of that in the phenylogous series.



The monochlorinated compound should be mentioned as a curiosity—depending upon the fluorination reagent it can appear as *(33a)* or *(33b)*. Surprisingly, these two compounds are not in equilibrium with each other, and differ considerably in their physical properties.

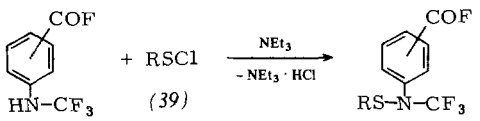
The rearrangement *(29)*→*(30)* proceeds unaffected by other ring substituents. Thus, even 4-trichloromethyl-1,3-phenylene diisocyanate *(34)* rearranges with retention of an NCO group to *(35)*.

What do we know about the *N*-trifluoromethylaminobenzoyl fluorides of the *meta* and *para* series which cannot be synthesized in the same way?



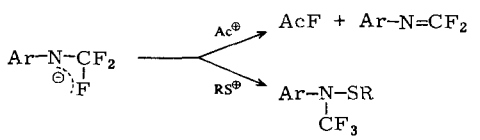
These isomers are accessible by a "classical" route starting from *m*- and *p*-aminobenzoic acids, which react in the form of their formyl compounds *(36)* with chlorine in thionyl chloride to form the chlorocarbonylphenyl isocyanide dichlorides *(37)*[18]. The products *(37)* yield the desired compounds *(38)* on treatment with hydrofluoric acid[19].

(36) *(37)* *(38)*



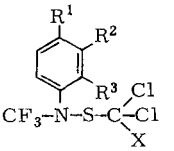
The basicity of the NH group in *N*-trifluoromethylaminobenzoyl fluorides is severely diminished by the electronegative CF_3 moiety. On the basis of their reactivity the compounds are better classified as "orthofluorides" of carbamic acids.

The *N*-trifluoromethylamino compounds form true salts with tertiary amines. However, they are of only very limited use as nucleophilic reactants. For instance, they can no longer be alkylated. On attempted acylation with acid chlorides of carboxylic and sulfonic acids in the presence of a tertiary amine they generally exert a fluorinating action. Acid fluorides are formed, while the *N*-trifluoromethylamines are transformed into isocyanide difluorides or their dimers[20].



Ac = R–CO, $R–SO_2$

In contrast *N*-trifluoromethylaminobenzoyl fluorides *(38)* and sulfenyl chlorides *(39)* give the desired sulfenamides *(40)*[21] under the same conditions.

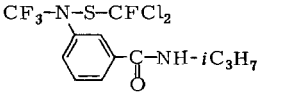


(38) *(39)* *(40)*

The remarkable behavior of the sulfenyl chlorides in this reaction can be adequately explained in terms of the concept of hard and soft acids and bases. The soft sulfenyl cation attacks the soft nitrogen atom of the *N*-trifluoromethylamine while hard acyl cations preferably react with the hard fluoride ion.

In view of the expected biological, and especially fungicidal activity of the reaction products, we have treated *N*-trifluoromethylaminobenzoyl fluorides with trichloromethane- and, in particular, dichlorofluoromethanesulfenyl chloride[22]. A selection of these intermediates is presented in Table 1[21].

Table 1. *N*-Sulfenylated aminobenzoyl fluorides of type *(40)*.

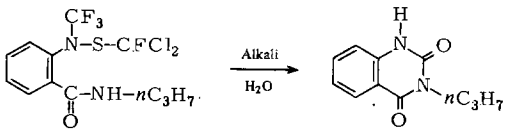


(40)

R^1	R^2	R^3	X	[°C/torr]
H	H	COF	Cl	148—151/13
H	H	COF	F	132—136/13
CF_3	H	COF	F	116—124/13
H	COF	H	F	118—125/11
Cl	COF	H	F	142—147/13
CH_3	COF	H	F	140—145/15
OCH_3	COF	H	F	160—167/13
COF	H	H	F	123—128/11
COF	Cl	H	F	155—158/27
COF	NO_2	H	F	128—129/0.15

These novel sulfenylaminobenzoyl fluorides *(40)* can be transformed into numerous acid derivatives. They can be readily hydrolyzed to the free carboxylic acids with formic acid while retaining the sulfenamide structure[23]. Moreover, a wide range of esters[24], thioesters, amides[25] and hydroxamic acids[26] have been examined since practically all the reaction products possess fungicidal, and in some cases also antimycotic and bactericidal properties.

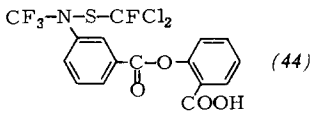
In this context, attention should be directed to *N*-isopropyl-3-[*N*-dichlorofluoromethylthio-*N*-trifluoromethylamino]-benzamide *(41)*, which has a pronounced biological activity and a wide spectrum of fungicidal action[27]. The biological activity is directed predominantly towards Peronosporaceae. Field tests conducted over several years under conditions close to those encountered in practice revealed not only a high acute efficacy, but also certain eradicating action and a relatively long duration of action. Within the phytopathologically important group of the Peronosporaceae, compound *(41)* is active both towards Phytophthora species and towards fungi of the Bremia, Peronospora, Pseudoperonospora, and Plasmopara genera. Furthermore, several trials have also shown it to exhibit acaricidal side effects. Potential applications are shown in Table 2.



(41)

Table 2. Activity of compound *(41)* towards Peronosporaceae and other harmful fungi.

Fungus	Culture	Amount of *(41)* [kg/ha]	[%]
Phytophthora infestans	Potatoes	1.25	
	Tomatoes		0.05—0.1
Phytophthora parasitica	Eggplant (Aubergine)		0.08
Bremia lactucae	Lettuce		0.05—0.1
Peronospora destructor	Onions		0.15
Pseudoperonospora cubense	Cucumbers		0.05—0.1
Pseudoperonospora humuli	Hops		0.05—0.1
Plasmopara viticola	Grapevine		0.075—0.1
Alternaria spp.	Apples, Pears Tomatoes, Cabbage		0.075—0.1
Colletotrichum spp.	Vegetables, Coffee		
	Wine		0.05—0.1
Venturia spp.	Apples, Pears		0.075



The oral LD_{50} of compound *(41)* is 3086 mg/kg for male rats. Application of 500 mg/kg to the skin of rats is tolerated without symptoms. The LC_{50} for four hours' exposure to an aerosol is 250 mg/m³ air. Compound *(41)* does not irritate the skin of rabbits, but does cause significant damage to the mucous membranes of the eye. No cumulative toxic effects were observed in rats after repeated oral administration or repeated aerosol exposure.

The isomer *(42)* shows the same spectrum of biological activity as compound *(41)*. Depending upon the quality of the active component, however, *(42)* may cause crop damage in the field. Combined gas chromatography/mass spectrometry showed that this compound can easily be degraded to 2,4-dioxo-3-propyltetrahydroquinazoline *(43)* by alkali. Admixture of only 2% of compound *(43)*[28], already known as a herbicide, to pure *(42)* has a phytotoxic effect.

(42) *(43)*

Surprising biological activity is found in aryl esters of *N*-sulfenylated *N*-trifluoromethylaminobenzoic acid whose aryl group contains an additional carboxyl group, *i.e.* derivatives of hydroxybenzoic acids. These compounds have a high fungicidal and also bactericidal efficacy on use in organic materials[29]. The reaction product *(44)* obtained from 3-[*N*-dichlorofluoromethylthio-*N*-trifluoromethylamino]benzoyl fluoride and salicylic acid (Eulan Asept P®) has proved of considerable value.

(44)

This product[30] is used for antimicrobial finishing of textiles. Owing to its broad spectrum of activity towards fungi and bacteria and to its ease of application, compound *(44)* is used for hygienic finishing of fabrics to suppress the spread of pathogenic microbes on the textile and in its soil phase. Such treatment is employed mainly on textiles (carpeting, rugs, upholstering, fabrics, *etc.*) used by many people (in hotels, hospitals, homes) and not frequently laundered.

A concentration of 0.5—0.75% of compound *(44)* suffices for general applications, while 1—1.5% is recommended for floorcovering material in hospitals in order to provide an added safety factor against pyogens (Pseudomonas pyocyanea). The antimicrobial action of *(44)* is still present in polyamide fibers and wool even after several washings or shampooings.

A biological application has also been found for the same compound *(44)*, *i.e.* for maintaining the freshness of cut flowers[31]. It is active towards microorganisms which block the channels of the plant stem by slime formation; moreover, it also inhibits the growth of microorganisms in vase water. The compound exhibits a good conserving effect in numerous plant species (roses, carnations, chrysanthemums, *etc.*) over a long period of time. Good results have also been obtained with branches from flowering shrubs (*e.g.* forsythia).

The active ingredient *(44)* has an oral LD_{50} of 882 mg/kg in rats. On cutaneous application to rats, 500 mg/kg were tolerated without symptoms. In a four-hour exposure of rats to aerosols, LC_{50} was found to be 135 mg/m³ air. Applied neat, the compound irritates the skin and mucous membranes of rabbits.

4. *N*-Sulfenylated Carbamic Esters as Insecticides and Fungicides

If the *N*-trifluoromethylamino compounds described in Section 3 are considered as adducts of HF to isocyanide difluorides then corresponding addition compounds should be preparable from isocyanates and isothiocyanates.

$$R{-}N{=}CF_2 + HF \longrightarrow R{-}NH{-}CF_3$$

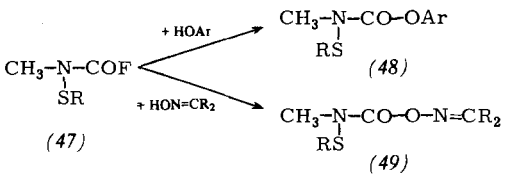
$$R{-}N{=}C{=}O + HF \longrightarrow R{-}NH{-}\underset{\underset{O}{\|}}{C}{-}F \qquad (45)$$

$$R{-}N{=}C{=}S + HF \dashrightarrow R{-}NH{-}\underset{\underset{S}{\|}}{C}{-}F$$

While no thiocarbamoyl fluorides can be prepared by reaction of hydrofluoric acid with isothiocyanates[31a], isocyanates and hydrofluoric acid do afford carbamoyl fluorides *(45)*[32] which exhibit considerable thermal stability in contrast to monosubstituted carbamoyl chlorides.

In their reactivity, the carbamoyl fluorides resemble *N*-trifluoromethylamines, at least as far as acylation reactions are concerned. The action of acyl or sulfonyl chlorides on carbamoyl fluorides *(45)* in the presence of a *tert*-amine merely leads to cleavage of the carbamoyl fluoride to the isocyanate. In contrast, sulfenyl chloride reacts under the same conditions to give *N*-sulfenylated carbamoyl fluorides *(46)*. A selection is shown in Table 3.

$$\underset{(45)}{R{-}NH{-}COF} + AcCl \xrightarrow[-\,NEt_3\cdot HCl]{NEt_3} R{-}N{=}C{=}O$$



$$\underset{(45)}{R{-}NH{-}COF} + R'SCl \xrightarrow[-\,NEt_3\cdot HCl]{NEt_3} \underset{\underset{R'S}{|}}{R{-}N{-}}COF \qquad \underset{(46)}{}$$

Table 3. *N*-Sulfenylated carbamide fluorides of type *(46)* [33, 34, 34a].

	R—N(R'S)—COF	*(46)*

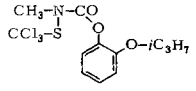
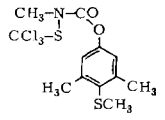
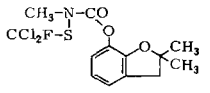
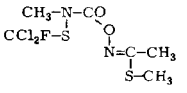
CH_3	$N(CH_3)_2$	55—57/5	
CH_3	Morpholino		48—50









As is apparent from Table 3 we have concerned ourselves primarily with sulfenylation products of *N*-methylcar-

bamoyl fluorides *(47)*, because these intermediates are suitable for the production of highly active insecticides, *viz.* *N*-sulfenylated aryl carbamates *(48)* and carbamoyl oximes *(49)*.

Like the *N*-trifluoromethylamines described in Section 3, *N*-methylcarbamoyl fluoride was treated preferably with trichloromethane- or dichlorofluoromethane-sulfenyl chloride with a view to obtaining biologically active end products. Only those representatives were subjected to reaction with phenols or oximes, whose *N*-methylcarbamates are known to be insecticides. Some examples are presented in Table 4.

Table 4. *N*-Sulfenylated carbamates *(50)* to *(52)* [of type *(48)*] and carbamoyloximes *(53)* [of type *(49)*] and their parent compounds without the *N*-(trihalomethylthio)-substituents. The LD_{50} values refer to the rat.

N-Sulfenylation product	LD_{50} [mg/kg]	Parent compound "common name"	LD_{50} [47] [mg/kg]
(50) 	2000	Propoxur	100
(51) 	500	Methiocarb	100
(52) 	200	Carbofuran	5
(53) 	250	Methomyl	25

The biological data of compounds *(50)* to *(53)* cannot be discussed at length in this article. The following features have been established[35–38]:

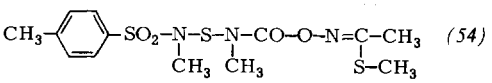
a) The sulfenylated products *(50)* to *(53)* show about the same insecticidal activity as their parent compounds listed in Table 4.
b) The sulfenyl compounds are significantly stronger acaricides than the parent compounds.
c) Possible phytotoxic activity of the parent compounds in various crops is reduced in the case of the sulfenyl derivatives.
d) Particular importance attaches to the fact that the toxicity of the sulfenylated products towards warm-blooded animals is generally lower than that of the parents by a factor of 5 to 20 (see Table 4)[38a].

Despite their advantages, we have turned our attention away from this particular class of compounds, which were subsequently also studied by other research teams[38], because all these trihalomethansulfenyl-substituted *N*-methylcarbamates have some degree of irritating action on the skin or mucous membranes.

Our continued studies on other sulfenyl chlorides, particularly aromatic sulfenyl chlorides and those belonging to the sulfonamide series, have confirmed the general principle of "detoxification by sulfenylation".

Meanwhile, other workers have also successfully introduced a sulfenyl group into known biologically active groups, *e.g.* in formamidines[39] and ureas[40].

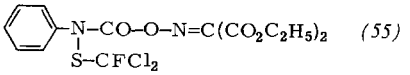
Whereas sulfenylated *N*-methylcarbamates based upon *N*-trihalomethanesulfenyl chlorides are accessible only *via* the fluorides of type *(47)*, an alternative synthetic pathway is open for other sulfenylated *N*-methylcarbamates, *i.e.* direct sulfenylation of *N*-methylcarbamates proceeding under analogous conditions[41,42,42a].



$$CH_3–NH–CO–OR + R'SCl \xrightarrow[-NEt_3 \cdot HCl]{NEt_3} CH_3–\underset{\underset{SR'}{|}}{N}–CO–OR$$

R = Aryl or $-N=CR_2''$
R' ≠ Trihalomethyl
(48), (49)

Although direct sulfenylation of *N*-methylcarbamates with trichloromethanesulfenyl chloride is claimed in an earlier patent, the reaction could not be repeated[43].

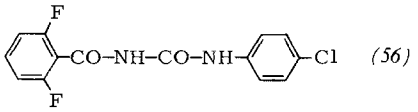


The sulfenylated *N*-methylcarbamates obtained from arene or sulfonamidesulfenyl chlorides show essentially the same biological behavior as observed in trihalomethylsulfenyl compounds (roughly equal insecticide activity but better acaricidal action than with the parent compounds having the CH_3NH instead of the $CH_3N(SR)$ group, disappearance of possible damage to crops, greatly diminished toxicity to warm-blooded animals). However, in contrast to the sulfenyl compounds described above, the new compounds do not act as skin irritants.

The biological action will be considered in greater detail for the example of compound *(54)*[44]. Compound *(54)*

(54)

(LD_{50} = 843 mg/kg rat, per os) has much more favorable toxicological data than its parent compound Methomyl (see Table 4). The spectrum of action of *(54)* is shifted relative to that of Methomyl; the principal application of *(54)* lies in the protection of cotton and vegetable crops against attack by various caterpillars. Its initial action is established somewhat slower, but its long term action is very good. Like Methomyl, *(54)* also exhibits a systemic action. It is better tolerated by plants than Methomyl.



In the further course of our studies we also discovered sulfenylated carbamates having pronounced microbicidal or fungicidal properties[45]. Thus compound *(55)* is suitable as a wood preservative or for use in paints.

(55)

5. Outlook

The acylureas have been found to have a completely new mode of insecticidal action. They are not cholinesterase inhibi-

tors, but interfere with molting of the insects, stopping chitin formation and thus inhibiting development. An example taken from this series is Diflubenzuron *(56)*[46].

(56)

This field of study is undergoing rapid development, and once again underlines the significance of fluorinated isocyanates as starting materials for the synthesis of biologically active materials.

In addition to all the ladies and gentlemen at Bayer AG whose names appear in the literature references, we wish to thank the following colleagues for their cooperation: Dr. H. Tarnow for chemical engineering contributions, Dr. Oehlmann for spectroscopic studies, and Dr. I. Hammann, Dr. L. Eue, Dr. H. Kaspers, Dr. J. Niggemann, and Ing. A. Fuss for a comprehensive discription of the biological results used in this article. The toxicological data were kindly supplied by Dr. G. Kimmerle.

Synthesis and Reactions of *N*-Chlorocarbonyl Isocyanate

By Hermann Hagemann[*]

Dedicated to Professor Otto Bayer on the occasion of his 75th birthday

Cl—CO—N=C=O (*N*-chlorocarbonyl isocyanate) is prepared in 90% yield by partial hydrolysis of the addition product of phosgene and cyanogen chloride. Many derivatives of the iminocarboxylic acid parent compound can be obtained from this highly reactive species. Both the acid chloride and the isocyanate group are amenable to reactions exhibiting overall selectivity, and this opens the way, *inter alia*, to a simple preparative synthesis of isocyanates from alcohols, phenols, thiols, and thiophenols. Combination of the two functional groups and their peculiar symmetry, which becomes evident, *e.g.* in the HCl adduct, facilitates ready cyclization of *N*-chlorocarbonyl isocyanate under very mild conditions.

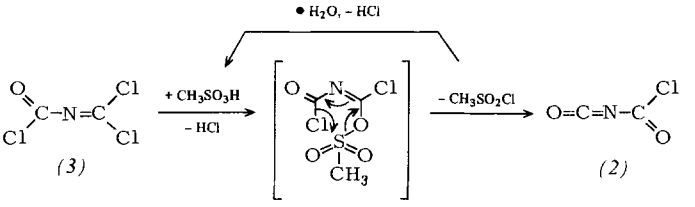
1. Introduction

Following several publications in which modes of formation[1] and reactions[1a, 2] of *N*-chlorocarbonyl isocyanate were described, the present article deals with our syntheses, already patented in 1968[3], and with the diverse chemistry of this C_2-compound which has meanwhile become available on a technical scale.

2. Preparation of *N*-Chlorocarbonyl Isocyanate from Cyanogen Chloride, Phosgene, and Water

The addition products of cyanogen chloride and strongly electrophilic reagents are in some cases formed under very mild conditions[4]. The best known example is probably chlorosulfonyl isocyanate *(1)*, which can be prepared from sulfur trioxide and cyanogen chloride[5].

$$ClCN + SO_3 \rightarrow ClSO_2{-}NCO \quad ClCO{-}NCO$$
$$(1) \qquad (2)$$

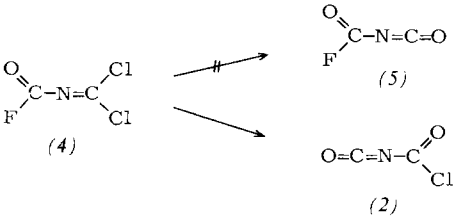


The analogous reaction to yield *N*-chlorocarbonyl isocyanate *(2)* does not, however, occur because the electrophilic character of carbon dioxide is too weak. A detour by way of the more strongly electrophilic carbonic acid derivative phosgene provides a simple access to the desired compound.

If phosgene and cyanogen chloride are passed at 150°C and 55 bar over an active charcoal catalyst the addition product *N*-chlorocarbonyl isocyanide dichloride *(3)* is formed[6], a compound that had been obtained earlier by chlorination of methyl isocyanate[7].

$$CH_3{-}NCO \xrightarrow[-3\,HCl]{+3\,Cl_2} \underset{Cl}{\overset{O}{\overset{\|}{C}}}{-}N=\underset{Cl}{C}{<}^{Cl} \xleftarrow[55\,bar]{150\,^\circ C} COCl_2 + ClCN$$
$$(3)$$

Addition over the active charcoal catalyst is carried out in a plant operating semicontinuously, an excess of phosgene being used to suppress as far as possible the trimerization of the cyanogen chloride and the formation of a product from two moles of cyanogen chloride and one mole of phosgene.

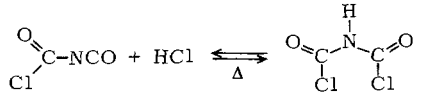


Partial hydrolysis of *(3)* by methanesulfonic acid leads to *N*-chlorocarbonyl isocyanate *(2)* in 90% yield[8], although this product reacts rapidly and irreversibly with methanesulfonic acid.

By suitable temperature control the partial hydrolysis can be largely resolved into two partial steps, so that the reaction between methanesulfonic acid and *N*-chlorocarbonyl isocyanate *(2)* is suppressed. The first step occurs already at 20°C with elimination of hydrogen chloride. The hypothetical intermediate *(3a)* is cleaved at a slightly higher temperature into *(2)* and methanesulfonyl chloride; the latter can be recovered in >90% yield and after conversion into methanesulfonic acid can be returned to the cycle.

Whether, in the partial hydrolysis, *(3)* reacts by way of a four-membered transition state as the isocyanide dichloride[9] or as *N*-(chlorocarbonyl)imidoyl chloride[8], as formulated above, cannot be decided from the formation of *(2)*. The six-membered ring transition state *(3a)* is favored by the fact that *N*-chlorocarbonyl isocyanate *(2)* and not *N*-fluorocarbonyl isocyanate *(5)* is formed from *N*-fluorocarbonyl isocyanide dichloride *(4)* under the same conditions.

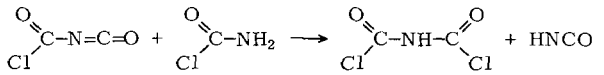
The isocyanate group is thus apparently formed from the *N*-fluorocarbonyl group and not from the isocyanide dichloride grouping[10].



[*] Dr. H. Hagemann
Wissenschaftliches Hauptlaboratorium der Bayer AG
D-5090 Leverkusen (Germany)

The product *(2)* is a water-clear liquid that can be stored indefinitely in the absence of moisture; it boils at 64°C (63.6°C[1a]).

3. Reactions of *N*-Chlorocarbonyl Isocyanate

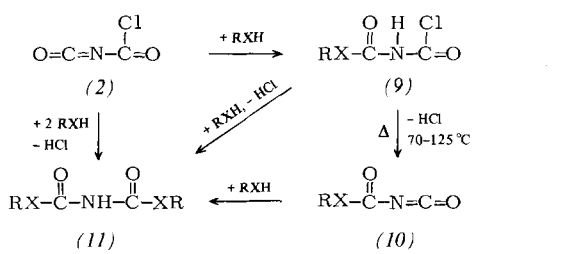


3.1. General Considerations

The diversity of the chemical reactions of *(2)* arises on the one hand from the combination of two functional groups known to be especially reactive and, on the other hand, from the inherent symmetry of the molecule, which is manifested in its adduct with hydrogen chloride, *viz.* *N*-(chlorocarbonyl)carbamoyl chloride *(6)*. Compound *(6)*, the dichloride of iminodicarboxylic acid, redissociates on melting at 88—89°C.

(2) *(6)*

Because of this symmetry one cannot conclude, for instance from product analysis, whether *(2)* reacts with weak nucleophiles such as water or alcohol primarily at the acid chloride or at the isocyanate grouping.



(2) *(7)* *(6)* *(8)*

Furthermore, the formation of *N*-(chlorocarbonyl)carbamoyl chloride *(6)* from *(2)* and an excess of water, and the absence of carbamoyl chloride *(7)* from reaction products, do not justify the conclusion that there could not have been primary addition of water to the isocyanate group[1a]. Carbamoyl chloride *(7)* is known[11] to eliminate HCl even at room temperature, whereas under these conditions *(2)* adds HCl in a strongly exothermic reaction, so that in the presence of *(2)* the chloride *(7)* escapes detection owing to formation of *(6)* and *(8)* (→cyanuric acid).

3.2. Reaction with Alcohols, Thiols, Phenols, Thiophenols, Secondary Amines, and Sulfonamides

The preparation of the *N*-carbonyl-substituted carbamoyl chlorides *(9)* is effect by the reaction of the above nucleophiles (RXH) with a supply of *(2)*. Here again, however, it is not immediately necessary to assume that the apparently plausible selective addition of the nucleophile to the isocyanate group has in fact initially occurred, since the hydrogen chloride arising on substitution of the acid chloride group would be trapped at once by the isocyanate group under the reaction condition (*ca.* 20°C), and the same products would be obtained.

(2) *(9)* *(11)* *(10)*

R,R' = Alkyl, Aryl

a, RX = RO; *b*, RX = RS; *c*, RX =  ; *d*, RX = 

The primary products *(9)* lose hydrogen chloride at 70—125°C, thus being transformed into the relevant isocyanates *(10)*[12]. Some examples of the reaction *(2)*→*(10)* are collected in Table 1.

Table 1. Isocyanates of type *(10)* from *(2)* and nucleophiles [a].

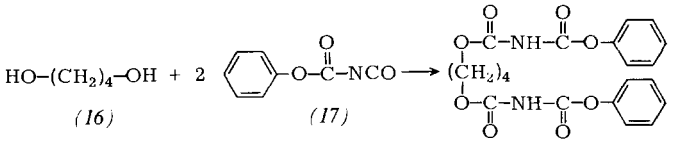
[a] The structures of the isocyanates *(10)* are proved by elemental analyses, spectra, numerous solid iminodicarboxylic acid derivatives, and comparison with authentic samples.
[b] The yields, which in many cases are not optimized, refer to the product isolated by distillation.

The primary products from *(2)* and some secondary amines show partially divergent behavior. Whereas mixed aliphatic-aromatic allophanoyl chlorides *(9c)*, R = alkyl, R' = aryl, afford the isocyanates *(10c)* with elimination of hydrogen chloride as described above, on thermolysis of purely aliphatic allophanoyl chlorides *(9c)*, R = R' = alkyl, fission into HNCO and dialkylcarbamoyl chlorides *(12)* to the extent of about 50% is observed.

The isocyanates *(10c)* from *(2)* and secondary amines have a further peculiarity that has been described by *Zinner* and *Isensee*[12e]. Unlike the other isocyanates of general formula *(10)*, they dimerize very readily to 1,3,5-oxadiazinediones *(13)* without the addition of a catalyst. This [4+2]-cycloaddition is reversible even under very mild conditions, and thus the well-crystallizing dimers permit a simple separation of

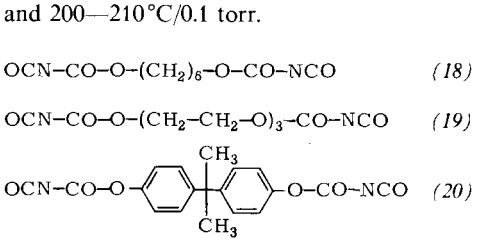


(9c) *(12)* *(10c)* *(10c)* *(13)*

the isocyanates *(10c)* from the carbamoyl chlorides *(12)* that boil at almost the same temperatures.

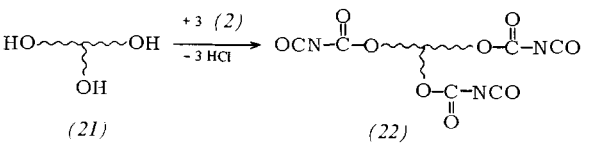
The symmetrical iminodicarboxylic acid derivatives *(11)* can be obtained in one step from *(2)* and the nucleophile RXH reacted in a molar ratio of 1:2. Almost any desired asymmetric compound of general formula *(14)* can be prepared by treating the primary products *(9)* or the isocyanates *(10)* with a second nucleophile.

RX—CO—NH—CO—XR′ *(14)*



Polyfunctional mixed aliphatic-aromatic iminodicarboxylic esters *(15)* are phenol-capped highly reactive polyisocyanates that are suitable for thermal crosslinking of polymeric lacquers containing hydroxyl groups[13]; these esters *(15)* are prepared, *e.g.*, by the reaction of polyhydroxy compounds *(16)* with the phenyoxycarbonyl isocyanate *(17)*, a compound of type *(10a)* that is readily accessible from *(2)* and phenol.

(16) *(17)* *(15)*

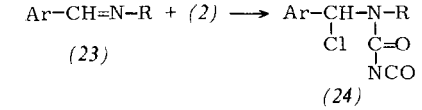


3.3. Reaction with Diols and Polyols

1,6-Hexanediol, triethylene glycol, and α,α-dimethyl-4,4′-methylenediphenol (bisphenol A) lead on reaction with *(2)* to the diisocyanates *(18)*—*(20)*. The yields are 90, 85, and 90%, and the boiling points 123°C/0.09 torr, 170°C/0.1 torr, and 200—210°C/0.1 torr.

(18), *(19)*, *(20)*

The reaction *(2)* → *(10)* proceeds very smoothly even with polyethers *(21)* containing several hydroxyl groups and opens a particularly simple route to high-molecular (molecular weight *ca.* 2000), very reactive polyisocyanates *(22)*. By analogy with polyurethane chemistry, polyiminodicarboxylic



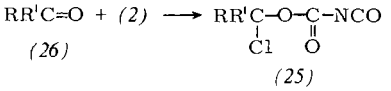
(21) *(22)*

esters of very widely variable properties are obtainable from the di- and polyisocyanates by reaction with polyol systems[14]. Here one needs as starting material for the isocyanate component only a di- or polyhydroxy compound and no di- or polyamine as in the preparation of the isocyanate components for polyurethanes.

3.4. Reaction with Azomethines, Aldehydes, Ketones, Vinyl Esters, Cyanates, and Epoxides

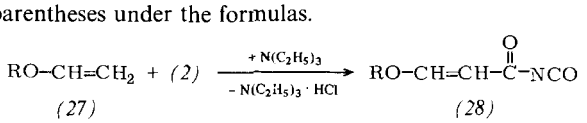
A selective reaction of the chlorocarbonyl group of *(2)* can be achieved with some polar π-bonds and with the C—O bond of epoxides.

From azomethines of general formula *(23)* there thus arise carbamoyl isocyanates with an *N*-(chloroalkyl)amide partial structure *(24)*[15].



(23) *(24)*

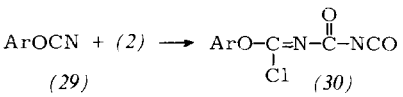
Ar = C_6H_5; R = CH_3, *i*-C_3H_7, *c*-C_6H_{11}, C_6H_5
Ar = *p*-Cl-C_6H_4; R = CH_3



The basic character of the amide-nitrogen is weakened by the neighboring chlorine atom, and this is probably why the isocyanates *(24)* do not have any tendency to dimerize comparable with that of the chlorine-free *N*,*N*-disubstituted carbamoyl isocyanates of type *(10c)* (cf. Section 3.2).

The adducts *(25)* of carbonyl compounds *(26)* and *N*-chlorocarbonyl isocyanate *(2)* can be isolated in yields of between 25 and 80%. This reaction has been carried out with chloral and benzaldehyde as aldehydes and with acetone, ethyl methyl ketone, and cyclohexanone as ketones[2b].

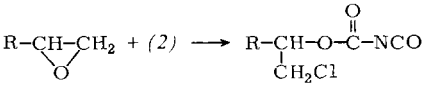
(26) *(25)*



The 1:1 adducts of vinyl ethers *(27)* and *(2)* can be converted by triethylamine into 3-alkoxyacryloyl isocyanates *(28)* with elimination of hydrogen chloride[2a]; the yields are given in parentheses under the formulas.

(27) *(28)*

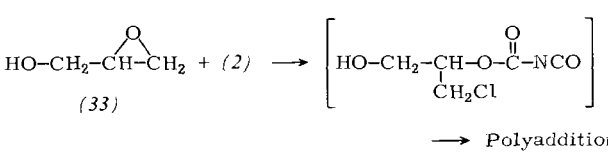
R = C_2H_5(36%), *i*-C_3H_7(39%), C_4H_9(43%)



Aryl esters *(30)* of *N*-(isocyanatocarbonyl)chloroformimidic acid are accessible by the addition of the acid chloride group of *(2)* to the CN triple bond of aromatic cyanates *(29)*[2c]; the yields in the examples cited under the formulas are 55—60%.

(29) *(30)*

Ar = C_6H_5, *p*-CH_3-C_6H_4, *p*-Cl-C_6H_4

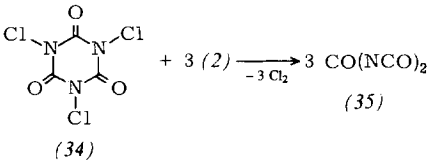


1-(Chloromethyl)alkoxycarbonyl isocyanates *(31)* are formed in 55—60% yield by the ring-opening addition of *(2)* to epoxides *(32)*[16].

(32) *(31)*

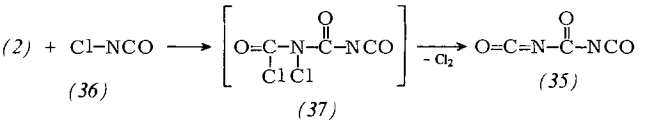
R = H, C_6H_5, CH_3, C_2H_5, $ClCH_2$

Epoxides containing an additional hydroxyl group in the molecule, such as *(33)*—the simplest representative of this series, undergo polyaddition on reaction with *(2)*.



(33)

3.5. Reaction with *N,N',N''*-Trichloroisocyanuric Acid

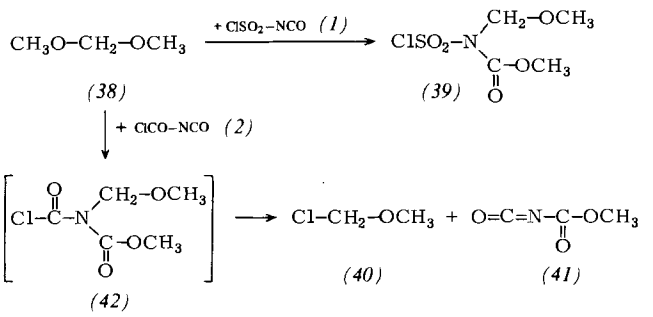


Compounds with negatively polarized chlorine, *e.g.* acid chlorides, and compounds with positively polarized chlorine, *e.g.* *N*-chloro compounds, can react with each other *via* elimination of chlorine. However, high temperatures and often also Friedel-Crafts catalysts are required for this purpose[17].

One of the most readily accessible and easily handled *N*-chloro compounds is trichloroisocyanuric acid *(34)*, which can also be regarded as a trimer of *N*-chloro isocyanate *(36)*. Unlike all other acid chlorides, *(34)* can be induced to react with *(2)* at as low a temperature as *ca.* 40 °C *via* elimination of chlorine; at somewhat higher temperature the reaction gives carbonyl diisocyanate *(35)* in 86 % yield[18].

(34) *(35)*

The special position of *(2)* among acid chlorides with respect to its reactivity must presumably be explained by the participation of the isocyanate group, as described above for the reaction of *(2)* with alcohols. The initial step would then be addition of the *N*-chloro compound *(34)* to the isocyanate group of *(2)*, affording *(37)* (formulated for the sake of clarity with $^1/_3$ trichloroisocyanuric acid = *(36)*).

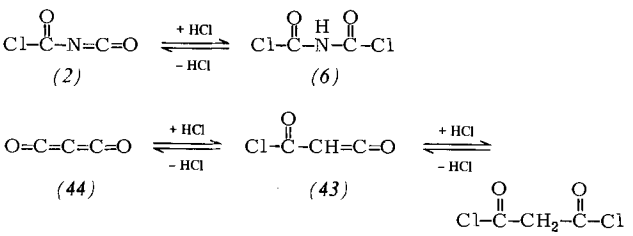


(36) *(37)* *(35)*

On reaction of *(2)* with alcohols, a new isocyanate group arises from the primary product *(9)* by elimination of hydrogen chloride; in the present case, it is formed with the elimination of chlorine.

3.6. Reaction with Dimethoxymethane

It seems reasonable to compare additions to *N*-chlorocarbonyl isocyanate *(2)* with the extensively investigated additions to *N*-chlorosulfonyl isocyanate *(1)*[5]. The primary step is similar in both cases, but the properties of the carbonyl group permit surprising, stabilizing, secondary reactions that are not open to compounds containing the sulfonyl group.

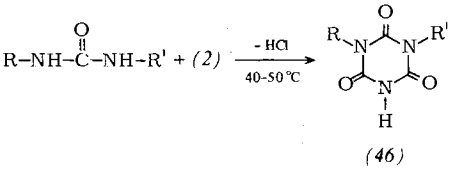


(38) *(39)* *(42)* *(40)* *(41)*

Compound *(1)* gives an insertion product *(39)* with dimethoxymethane (methylal) *(38)*. The reaction of *(2)* with *(38)* leads, however, to chloromethyl methyl ether *(40)* and methoxycarbonyl isocyanate *(41)*; once again *(2)* probably undergoes an initial insertion reaction [to give *(42)*]; however, this primary product achieves stability by fission to *(40)* and *(41)*.

3.7. Syntheses of Heterocycles

In spite of the great reactivity of both functional groups in chlorocarbonyl isocyanate *(2)*, reaction may occur at one or other of these groups, depending on the nature of the other reactant, thus making the compound particularly suitable for heterocycle syntheses.



N-(Chlorocarbonyl)carbamoyl chloride *(6)* can be regarded as azamalonyl dichloride. The formal close relationship with the reactive malonic acid derivatives leads us to expect that *(6)* will also be suitable as a building block in heterocycle syntheses. Compound *(2)* is the aza analog of the hitherto unisolated chlorocarbonyl ketene *(43)*, the adduct of carbon suboxide *(44)* and hydrogen chloride[19].

(2) *(6)* *(44)* *(43)*

3.7.1. Heterocycles from *(2)* and R—NH—$(X)_n$—NH—R'

One of the best known heterocycle syntheses, the preparation of barbiturates from malonic acid derivatives and ureas, can readily be adapted for *(2)*. *N,N'*-Disubstituted ureas *(45)* cyclize with *(2)* even in boiling dichloromethane with thermal elimination of hydrogen chloride, to yield disubstituted isocyanurates *(46)* (Table 2). The synthesis conditions are so mild that even thermally sensitive substituents such as *tert*-butyl survive the reaction unaltered[20].

(46)

Whereas in the cyclization to *(46)* hydrogen chloride is eliminated under very mild conditions even without the aid of an acid-binding material, hydrogen chloride elimination does not occur under similar conditions in the reaction of *N,N'*-disubstituted thioureas *(47)*. However, the initial products *(48)* can easily be converted into monothioisocyanurates *(49)* (Table 3) by water or an alcohol/water mixture. The

Table 2. Disubstituted isocyanurates of type *(46)* from *(2)* and *(45)* [20a].

R	R'	M.p. [°C]	Yield [%]
3,4-Cl_2—C_6H_3	CH_3	233	94

c-C_6H_{11}	CH_2=CH—CH_2	140	36
C_6H_5	CH_3	217	42

For reaction with still more strongly basic cyclization components *(50)* it is preferable to use derivatives of *(2)* such as *(17)* in order to have a better leaving group. Five-, six-, and seven-membered heterocycles *(51)* recorded in Table 4 are obtained from hydrazines *(50)*, $n=0$, aminals *(50)*, $n=1$, and ethylenediamines *(50)*, $n=2$, respectively.

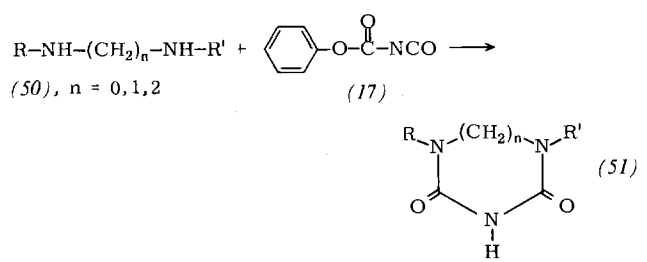

Table 4. Heterocycles of type *(51)* from the *(2)*-derivative *(17)* [or similar compounds *(10a)*] and *(50)* [21].

C_4H_9	C_4H_9	2	140—142	80

3.7.2. Heterocycles from *(2)* and ArOH, ArNHR, or $ArNR_2$

If the two acylatable centers in the cyclization components for *(2)* have very different nucleophilicities, then in many cases intermediate products can be isolated. Examples of especially stable intermediates are the adducts of phenols and *(2)* mentioned in Section 3.2, namely the phenyl ester chlorides of iminodicarboxylic acid of type *(9a)*. However, these compounds cyclize at higher temperatures in the presence of catalytic amounts of iron(III) chloride in an intramolecular Friedel-Crafts reaction that yields benzoxazinediones *(52)* (Table 5). The isocyanate *(10a)*, R = R′ = R″ [≡ *(17)*], obtained without $FeCl_3$ from *(9a)*, R = R′ = R″ = H, is thermally stable but is smoothly cyclized by iron(III) chloride.

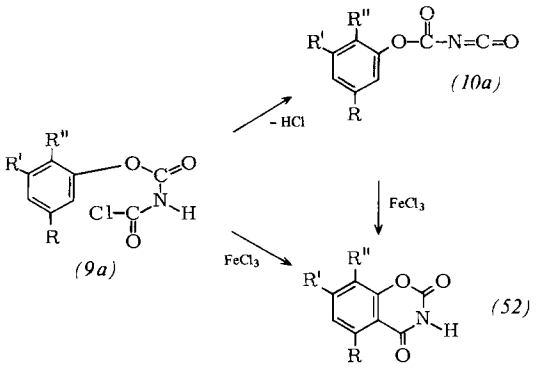

Table 5. Benzoxazinediones of type *(52)* from *(2)* and phenols [22].

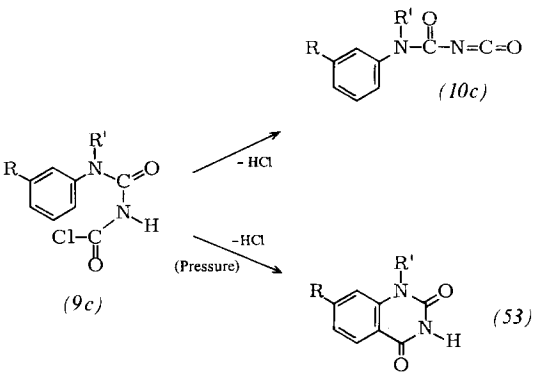
R	R′	R″	M.p. [°C]	Yield [%]
H	H	H	226—227	89
CH_3O	H	H	216—217	86
CH_3	CH_3	CH_3	257—259	84
H	—(CH=CH)$_2$—		280	76
H	H	Br	243	22

A similar situation arises with the addition products of mixed aliphatic-aromatic secondary amines and *(2)*, *viz.* allophanoyl chlorides *(9c)* (see Section 3.2). They can be converted as desired into either the carbamoyl isocyanates *(10c)* or (under pressure in autoclaves) into the quinazolinediones *(53)* isomeric therewith (Table 6).



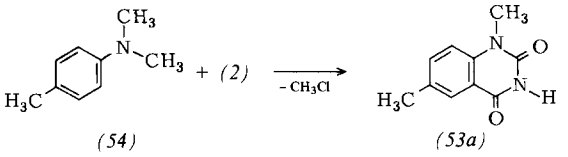


Table 6. Quinazolinediones *(53)* from *(2)* and mixed aliphatic-aromatic secondary amines [22].

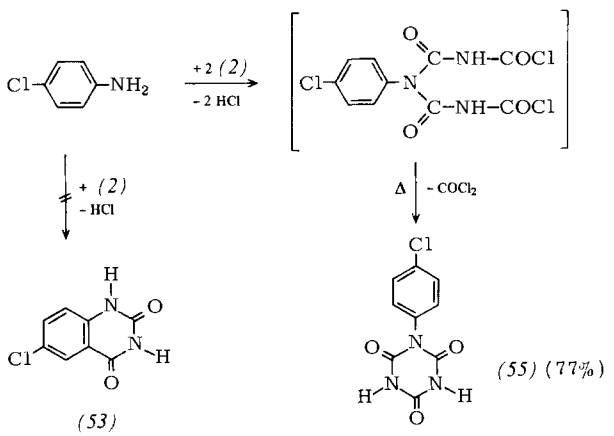
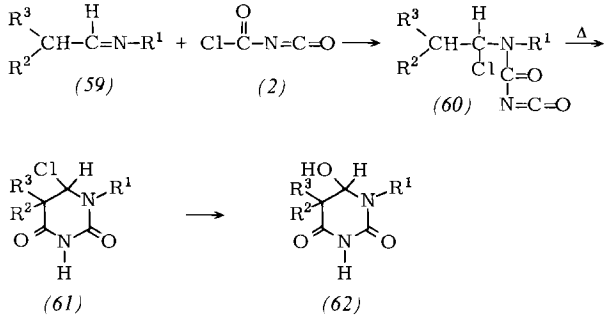
R	R′	M.p. [°C]	Yield [%]
H	CH_3	243—244	34
H	C_2H_5	215	62
H	n-C_4H_9	125—128	62
H	i-C_4H_9	160	45
CH_3	n-C_4H_9	159—163	60



The same type of heterocycle *(53)* is obtained from *N*,*N*,4-trimethylaniline *(54)*. In place of hydrogen chloride, methyl chloride is eliminated from this tertiary amine in a kind of von Braun degradation. *(53a)* is formed in 80% yield and melts at 275 °C. The yields are good only from *p*-substituted dimethylanilines.

The reaction of primary aromatic amines with *(2)* does not give the heterocycles of type *(53)*, but instead leads,

(54) (53a)



with addition of two moles of (2) and elimination of phosgene, to monosubstituted isocyanurates (55).

(53) (55) (77%)

Like their open-chain analogs[24], such cyclic *N*-(chloroalkyl)amides are readily substituted by nucleophiles at the C-6 atom: heating with water or water/ethanol leads to (62).

If *N*,*N'*-disubstituted amidines (63) are used in place of the azomethines (59), then compounds (64) with salt-like character are formed; replacement of $A=CR^2R^3$ by $A=NR^1$

(59) (2) (60) (61) (62)

makes it possible for the resonance-stabilized cation to be formed in the cyclization with (2).

Particularly stable salts of this type are obtained when trisubstituted cyclic thioureas (65) are used as the reactants

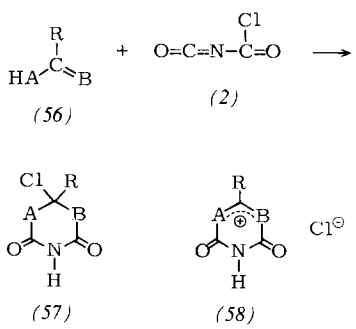


Table 7. 6-Chloro-5,6-dihydropyrimidine-2,4-diones (61) from (2) and azomethines (59) as well as hydroxy-compounds (62) from (61) [23].

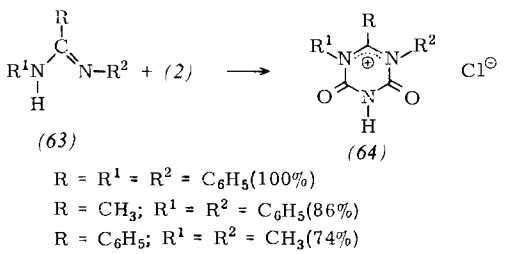
			(61)		(62)	
R^1	R^2	R^3	M.p. [°C]	Yield [%]	M.p. [°C]	Yield [%]
c-C_6H_{11}	CH_3	CH_3	198	92	213	92
c-C_6H_{11}	$-CH_2-CH=CH-(CH_2)_2-$		211	91	213	98
CH_3	CH_3	CH_3	205—207	57	180	66
CH_3	$-CH_2-CH=CH-(CH_2)_2-$		190	44	192	60
$C_6H_5-CH_2$	CH_3	CH_3	86—88	70	204	39
i-C_3H_7	CH_3	CH_3	161—163	78	203	92

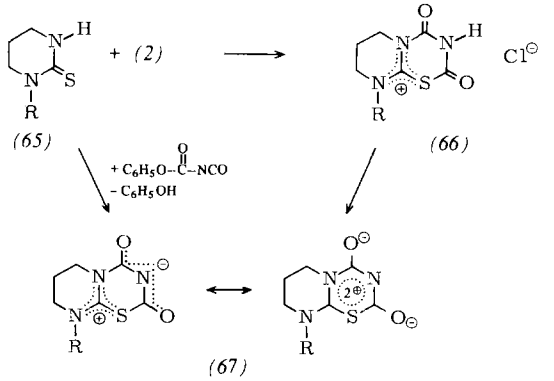
The yields are also good from aliphatic primary amines if the hydrochlorides are used instead of the free amines to suppress the formation of biuret that might easily occur.



3.7.3. Heterocycles from (2) and HA—CR=B

In the cyclization of (2) with compounds of the general formula (56) two types of product can be expected: 1) the cyclic chloroalkylamides (57) with activated but still predominantly homopolar-bonded chlorine; and 2) the salt-like compounds (58) in which the positive charge is particularly well delocalizable.

(56) (2) (57) (58)

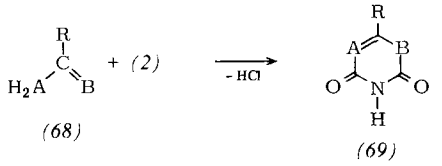


The addition of (2) to azomethines (59), which are derived from disubstituted acetaldehyde [(56), $A=CR^2R^3$; $B=NR^1$], does not stop at the isocyanate stage (60); instead rapid cyclization to 6-chloro-5,6-dihydropyrimidine-2,4-diones (61) occurs at *ca.* 90°C (Table 7).

(63) (64)

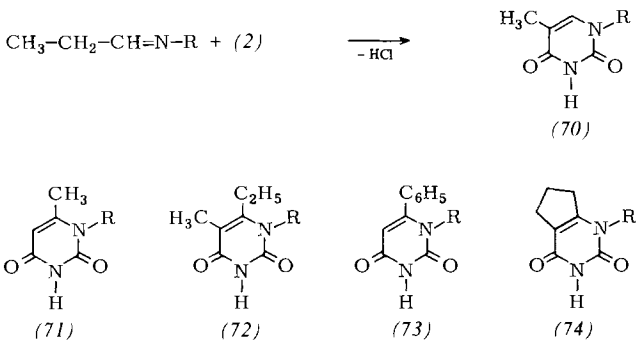
R = R^1 = R^2 = C_6H_5(100%)
R = CH_3; R^1 = R^2 = C_6H_5(86%)
R = C_6H_5; R^1 = R^2 = CH_3(74%)

HA—CR=B. The salts (66) can be dehydrochlorinated to six-membered mesionic "arenes" (67). Such mesoionic heterocycles can here, as in the amidine series, be prepared in a single step by treating compounds (65) or (63) with isocyanates RO—CO—NCO (10a) (see Table 1)[25]. Examples of (67) are the compounds



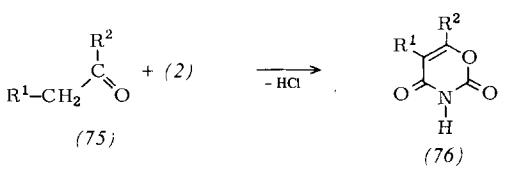
(65) (66) (67)

with R = CH_3, i-C_3H_7, n-C_4H_9, and c-C_6H_{11}; they melt at 210—211, 190, 114, and 208 °C, respectively.



3.7.4. Heterocycles from (2) and H_2A—CR=B

The generalized reaction (68)→(69) describes the most widely variable type of cyclization. Unlike compounds HA—CR=B (56), in compounds (68) there are two H atoms in the position α to the double bond. Thus, the cyclization products corresponding to (57) can react further with β-elimination of hydrogen chloride and the formation of a double bond, so affording (69). In such reactions A may represent nitrogen or a substituted carbon atom, and B oxygen, sulfur, or a substituted nitrogen; A and R, or B and R, may together belong to a common ring system. Compounds (68) include, for example, azomethines, amidines, ketones, amides and thioamides, isoureas and isothioureas, β-dicarbonyl compounds, pyrazolones, iminoethers, oxazolines, and thiazolines.

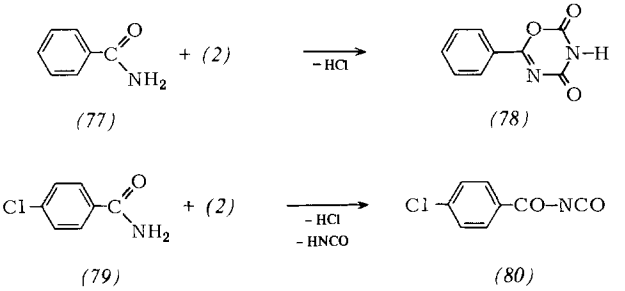


(68) (69)

Among the most interesting from the preparative point of view are the azomethines with two or three hydrogens in the β-position to the nitrogen atom. By their use one obtains, even at room temperature, very good yields in the series of biologically highly active uracils. For example, the use of propionaldehyde as the starting material for the azomethine components leads to thymines (70), the use of acetone leads to the isothymines (71), diethyl ketone to the 6-ethyl-5-methyluracils (72), and acetophenone to the 6-phenyluracils (73). Bicyclic uracils (74) are obtained from azomethines and cyclic ketones.

(70) (71) (72) (73) (74)

Such reactions provide an exceedingly simple route to a large number of uracil derivatives, some of which are too difficult to prepare in other ways; in two German patent applications, Nos. 2126148 and 2142317, over a hundred examples are listed together with yields and melting points[26].



(75) (76)

Table 8. Disubstituted 1,3-oxazine-2,4-diones (76) from (2) and ketones (75).

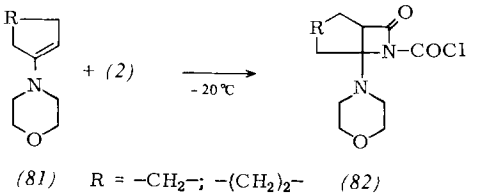
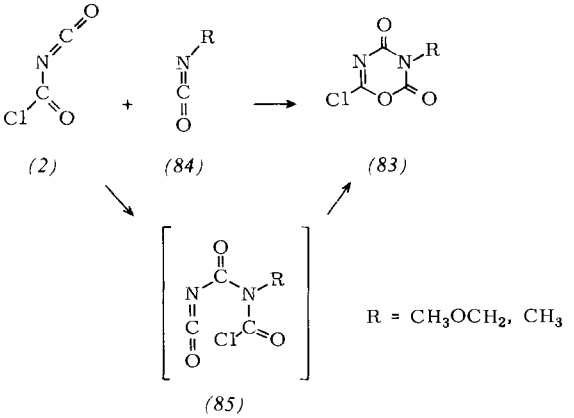
H	p-Cl—C_6H_4	244—246 (dec.)	50
H	C_6H_5—CH=CH	265—267	56
H	C_6H_5	229—230	55
CH_3	C_6H_5	177—178	47
n-C_3H_7	C_6H_5	146.5—148	54
H	$(CH_3)_3C$	193—194	50
C_2H_5O—CO	CH_3	99—100	77
CH_3	C_2H_5	146—147	51
CH_3CO	CH_3	122—124	68

Ketones of general formula (75) can be treated in a similar way, yielding 1,3-oxazine-2,4-diones (76) (Table 8)[27].



A small change in the nucleophilic character of the centers controlling the ring formation can completely transform the course of the reaction; while benzamide (77) and (2) cyclize smoothly to the phenyloxadiazinedione (78) (m.p. >360 °C, yield >90 %), p-chlorobenzoyl isocyanate (80) is almost the sole product when p-chlorobenzamide (79) is used. The nucleophilicity of the carboxamide group is apparently so weakened that the expected primary product decomposes before it can cyclize.



(77) (78) (79) (80)

3.7.5. Cycloadditions Involving (2)

The marked tendency of N-chlorosulfonyl isocyanate (1) to undergo cycloadditions with even relatively apolar olefinic double bonds has not yet been observed with (2). On use of the strongly polar double bond of enamines (81), however, the [2+2]-cycloadducts (82) have recently been obtained[2d].

(81) R = $-CH_2-$; $-(CH_2)_2-$ (82)

(2) (84) (83) (85) R = CH_3OCH_2, CH_3

Formation of adducts *(83)*[28], corresponding in result to a [2+4]-cycloaddition between *(2)* and aliphatic isocyanates *(84)*, can also be explained by assuming intermediates *(85)*. The addition of acid chlorides to the C=N double bond of isocyanates is a known reaction[29].

Entanglement of Thread Molecules and Its Influence on the Properties of Polymers

By Martin Hoffmann[*]

Dedicated to Professor Otto Bayer on his 75th birthday

This article shows the extent to which the entanglement of threadlike molecules can influence many of the properties of deformable polymers and of solutions of macromolecular substances. Thus, the molecular concept of entanglement leads to quantitative predictions of the dependence of the entanglement number on the nature of the polymer, its concentration, and extension. Experimental values of the relaxation modulus confirm these predictions for melts and solutions. The influence of entanglement on relaxation and flow processes leads to very simple relationships for the magnitudes of the structural viscosity and the shear stress at which the structural viscosity starts to become measurable. Osmotic pressures, light scattering intensities, and diffusion coefficients of concentrated solutions can be derived quantitatively from the conformational constraints due to entanglement. Entanglement is effective above a concentration at which the three-dimensional coils fill the solution volume, and probably also at lower concentrations. At very high concentrations entangled structures may be formed which drastically reduce the number of possible conformations. The swelling and extension behavior of cross-linked deformable polymers can be understood only if entanglement is taken into account.

1. Introduction

In dilute solutions[1] and in melts[2] long threadlike molecules demonstrably assume a conformation resembling a three-dimensional coil: for a polystyrene sample of molecular weight $M=1\times10^6$ in toluene solution the diameter of the coil is about 100 nm. Such coils are approximately spherical and in this case have a volume V of about 3×10^8 ml per mole. The polymer concentration in the coil is M/V and here amounts to about 0.3 wt-%. In solutions containing more than 0.3 wt-% of such a polymer the coils may interpenetrate or escape interpenetration by shrinkage. The coils are energetically preferred, *i. e.* stable, conformations; they rapidly return to their original shape after deformation (rubber-elasticity[3]). As a result, they shrink only little on concentrating the solutions, and they are so large in melts that, with such threadlike molecules and because of the high polymer concentration in the melt, the number of molecules contained in the volume of one coil must be of the order of 10^2. If several coils interpenetrate with retention of the coil conformation, then chain fragments must touch one another during the continual movement of the chains (conformational changes); in some cases the movement is such that one chain twines round the other so that further movement is hindered. Such contact between two chains acts briefly as a chain junction made by main valences.

This concept of physical cross-linking by entanglement was first formulated several decades ago (for a review see [4]), but was accepted only slowly as a basis for theoretical interpretation of the properties of polymers and their solutions[4–6]. Such conformational interaction of polymer molecules does not arise from any specific interaction by secondary valence forces between them and therefore occurs generally in solutions and melts, as well as in partly crystalline and cross-linked polymers. Since entanglement influences many of the properties of high-molecular substances and their solutions, the underlying principles and effects will now be surveyed and formulated quantitatively for noncrystalline systems.

2. The Molecular Model

The shape of long molecules essentially resembles a random flight path, being formed by joining rigid chain fragments of given length (segments) to one another in such a way that the direction of the last segment is completely independent of the direction of the previous one and all directions occur with equal probability[7]. These segments of length l replace equally long chain fragments regarded as rigid (straight or possibly curved). The distance h between the ends of a sufficiently long chain of Z segments is then on average a vector of length $l\sqrt{Z}$. If Z is large, the chain can be divided into subchains each with Z_i members, and each subchain obeys chain statistics (*i. e.* $h_i=l\sqrt{Z_i}$). The vectors h_i at the junctions are on average perpendicular to one another, as is easily appreciated by considering the case of $Z=2Z_i$; here $h=l\sqrt{Z}$ and $h_i=l\sqrt{Z/2}$, so that $h=\sqrt{2}\cdot h_i$ is the diagonal of a square of side length h_i.

For the description below, which is correct to an order of magnitude, the segment model can be simplified to the string-of-beads model; thus, we assume that the segments are compact balls that in a melt adopt a close packing and become deformed so as to eliminate empty spaces. The segment molecular weight M_S can then be employed to calculate how many segments are contained in 1 cm³ of the melt of density ρ ($N_A\approx6\times10^{23}$);

$$N_S=\frac{\rho N_A}{M_S} \tag{1}$$

[*] Dr. M. Hoffmann
Bayer AG, Zentrale Forschung, Wissenschaftliches Hauptlabor
5090 Leverkusen (Germany)

On estimating how many bonds are required for the direction of a polymethylene chain to be continued with equal probability in each spatial direction (a requirement of the segment model), one obtains a segment molecular weight M_S of around 170, in agreement with estimates from measured coil dimensions[8]; thus for polyethylene N_S is approximately 3×10^{21}.

Next, we can calculate how many contacts between different chains occur in 1 cm^3 of this melt. Figure 1 shows two macromolecules A and B in a melt, the two chains being in contact at segment a of chain A. The segment a has twelve nearest neighbor sites, of which two are occupied by neighboring portions of chain A. In addition, back-coiling of chain A causes further p nearest neighbor sites of segment a to be occupied by chain A.

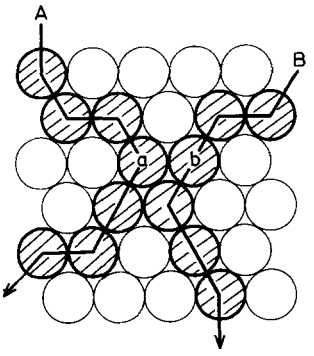

Fig. 1. Two thread molecules A and B whose spherical segments in the melt adopt close packing (represented two-dimensionally).

When estimating the back-coiling number p, it must be remembered that the third segment (counting from a) can occupy, out of the twelve possible places, those four that are adjacent to a, so that $4/12=0.33$ neighboring sites of a are occupied. This treatment can be continued for further segments, considering then the positions of the third segment. The residence probability P of a more distant segment at a site adjacent to a can be calculated by the known statistical function[10] for chain-end separations (α is *Flory*'s expansion factor[10]):

$$P(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z = \left(\frac{3}{2\pi Z l^2 \alpha^2}\right)^{3/2} \exp\left[-\frac{3}{2Z l^2 \alpha^2}(x^2+y^2+z^2)\right]\mathrm{d}x\mathrm{d}y\mathrm{d}z \qquad (2)$$

For $l=1$ each of the twelve neighboring sites has the volume $\mathrm{d}x\mathrm{d}y\mathrm{d}z=1$ and in eq. (2) the exponent $-3/(2Z\alpha^2)$. The summation over all values of $12P(Z_i)$, leading to p, should already be stopped, however, when Z_i is still small: entanglements are continually being untied and new ones formed; the network chains of the entanglement network, *i.e.* the portions of the chain between entanglement points, contain in the melt relatively few segments [see eq. (17)], of which certainly only a small proportion can be attached at segment a without severely straining the residual part of the network chain. Contact of chain A at segment a with distant segments of the same chain should therefore be regarded as contact between different chains. In solutions the network chains comprise many more segments than in melts, so that p can then be greater than in melts; $p\approx1$ has been estimated for the latter.

If one considers that chain A coils back to segment a from two directions, one finds that, of the twelve neighboring sites of segment a in the melt, $2+2p\approx4$ sites are occupied by segments of the neighboring portions of chain A. The remaining $12-4=8$ sites adjacent to segment a can now be occupied by segments of other chains. If chain B occupies such a position with segment b, then a and b have four nearest neighbors in common, of which on average $4\times4/12$ are occupied by chain A and the same number by chain B. Chain B thus occupies $1+(4/3)=2.3$ of the sites adjacent to a. The eight sites at a which are free for contact with other chains can thus be occupied by $8/2.3=3.5$ foreign chains. On counting all N_K contacts of the various chains in 1 cm^3 of the melt, each contact refers to two segments and is therefore counted twice, giving the contact number N_K as[9]:

$$N_K = \frac{3.5}{2} N_S \qquad (3)$$

For polyethylene therefore, in conjunction with eq. (1), $N_K=5\times10^{21}$.

It still remains to be shown which of these contacts should be regarded as entanglements. Entanglements should be contacts that withstand many changes of chain conformation and thus are so long-lived that they act as cross-linking sites, permitting rubber-elastic deformations of the melts. Figure 2 shows such a contact position of chains A and B. In this presentation[9] the chains are symbolized only by the vectors h_i of the subchains, which here have the designations A_1, A_2, B_1, and B_2. In the outer part of Figure 2, these vectors end in further entanglements of the chains A and B. Had the contact of chains A and B taken the form shown in Figure 1, it would have been rapidly broken by the usual conformational changes. On average, such changes leave unaltered the length of the vectors A_1, A_2, B_1, B_2 and angle α (on average a right angle) between A_1 and A_2 and the angle β between B_1 and B_2. Having fixed the lengths of the vectors A_i and B_i, as well as α and β, the allowed conformational changes thus correspond to rotating chain A (or B) around the vector h_A (or h_B). It is now simple to formulate the conditions under which contact between chains A and B is not destroyed by such rotations. In so doing, it must be borne in mind that h_A and h_B can assume any position in space. The contact is not destroyed if the following geometric conditions are fulfilled (for $\alpha=\beta=90°$):

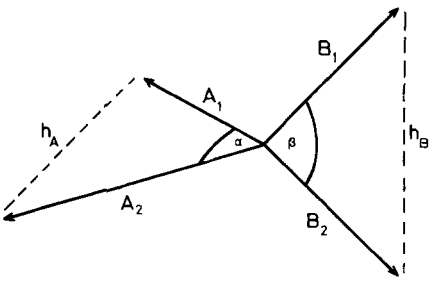

Fig. 2. Two thread molecules A and B touch at one point. Their subchains are symbolized by the vectors A_1 and B_1. The vectors h_A and h_B join the end points of two chain fragments that are themselves situated at further entanglement points [9].

a) Chain B touches chain A in the internal angle of the vectors A_1 and A_2. This happens with a probability $W_a=1/4$ ($=90°/360°$).

b) Vector B_1 lies above and vector B_2 below the plane of the vector A_1 and A_2: $W_b = 1/2$.

c) In cases where the plane containing A_i is at right angles to that of B_i: B_1 points in directions in space that correspond to the octant lying diagonally "opposite" the internal angle between A_1 and A_2: $W_c = 1/4$. W_c is not changed when the plane of A_i is not at a right angle to that of B_i.

The fraction $W = W_a \times W_b \times W_c = 0.031$ of all N_K contacts is therefore long-lived. Such contacts are entanglements that are only destroyed when neighboring contacts are also released in a cooperative process.

This argument can be extended to all cases in which the angles α and/or β are not 90°.

If $\beta = 90°$, then W_2 is always 1/2 and $W_1 = \alpha/360$, and further $W_3 = (180-\alpha)/360$. The probability $W_{\alpha\beta}$ then amounts to:

$$W_{\alpha\beta} = \frac{8}{360^4}[\alpha(180-\alpha)\cdot\beta(180-\beta)] \tag{4}$$

α and β can assume any values between 0 and 180°, so that the probabilities are proportional to $\sin\alpha$ and $\sin\beta$, respectively, the maximum of the frequency distribution of statistical conformations lies at 90°, and half of all cases have angles between 60 and 120°. If $W_{\alpha\beta}$ is multiplied by the corresponding values of the frequencies of α and β and averaged, the result is $W_R = 2/\pi^4 = 0.021$. Furthermore, W_R is not changed when the vectors A_1, A_2, B_1, B_2 are allowed to have different lengths. If, however, the entanglements are sufficiently long-lived, then A_i and B_i "forget" to which chain they belong and thus on average point to the corners of a tetrahedron. The frequency distribution of the angles then has a maximum at 109.5°, so that the probability $\bar{W}$ falls to $\bar{W}_{109.5} = 0.018$[9]. The entanglement number N_v is then:

$$N_v = 0.018\, N_K \tag{5}$$

For polymethylene eqs. (4) and (3) give $N_v = 9 \times 10^{19}$.

The preceding derivation neglects the effect of end groups and thus assumes infinitely long molecules. If the network chains of the entanglement network have a molecular weight M_c and the molecules have a molecular weight M, then networks can be formed[3] only if the condition known for cross-linking polymerizations[11] is fulfilled for the construction of a continuous network:

$$2M_c \leq M \tag{6}$$

In the derivation of eq. (5) it was also considered unimportant that some of such entanglements are more easily broken than others. Thus, the entanglement number calculated according to eq. (5) includes entanglement for which the pair of values α and β or the position of chain A relative to chain B only just fulfil the geometric requirements for entanglement. Even small diffusion movements of neighboring entanglement points can break such entanglements, so that they will certainly be shorter-lived than the others.

Furthermore, no consideration was given to how easily the chains could slide over one another and to how far the end of the chain is separated from the entanglement of interest. Diffusion of a chain end could break an entanglement near to this end faster than a more distant one[9]. Such considerations will be taken up in Section 4 below.

We would add here that, even in the absence of any long-term relaxation, the entanglement number N_v given by eq. (5) is lowered if the entanglement network is subjected to shear or deformation[12]. Deformation causes changes in the angles α and β and thus in the geometric requirements for entanglement. The tetrahedral entanglement (Fig. 3) is broken if sufficiently strong uniaxial stretching occurs in directions that do not lie in the part of the spherical shell drawn in the figure (or in the opposite direction), for then the stretching directions make an angle smaller than 90° with one or more of the relevant chain vectors. Thus, purely geometrically and in a very short time, a large stretch reduces the number of entanglement points per unit volume to the fraction X:

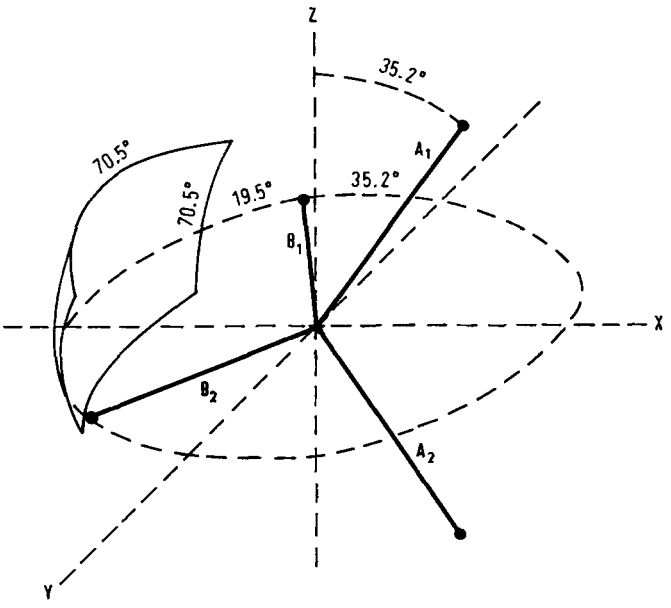

Fig. 3. As a result of stretching the spatial directions and lengths of the vectors at a (tetrahedral) contact of two chains are deformed, so that the entanglement no longer has the same probability $W_{\alpha\beta}$ [see Eq. (4)] as before the stretching [12].

$$X = \frac{\alpha}{180}\sin\left(\frac{180-\beta}{2}\right) \tag{7}$$

If one averages over all α and β corresponding to their frequency, one obtains[12] for a maximum of the frequency distribution 90° $\bar{X} = 0.33$ and for 109.5° an almost identical value. If one now permits even a slight relaxation or slip of the sometimes very unevenly stretched network chains at the entanglement points, then the number of residual entanglement points decreases almost to zero.

Furthermore, it is important to know how small extensions reduce the entanglement number N_v. The ends of the vectors A_1, A_2, B_1, and B_2 can occupy any desired point on the surface of a sphere of radius $|A|$. On deformation (extension ratio $\lambda = L/L_0$) such a sphere is transformed into an ellipsoid of rotation ($a = |A|\cdot\lambda$, $b = |A|/\sqrt{\lambda}$), so that on average each vector assumes a greater length $|A_\lambda|$[3]:

$$|A_\lambda|^2 = |A|^2\left(\frac{\lambda^2}{3} + \frac{2}{3\lambda}\right) \tag{8}$$

The coordinate x (in the stretching direction) and y of each vector end-point have thus changed into $x' = x \cdot \lambda$ and $y' = y/\sqrt{\lambda}$, so that an angle γ formed initially by the x-axis and such a vector ($\tan\gamma = y/x$) changes to γ' ($\tan\gamma' = y'/x' = \tan\gamma/\lambda^{1.5}$). If one puts the length $|A_\lambda|$ into the equation for the ellipsoid of rotation one obtains the relevant angle α' between two vectors as $\tan(\alpha'/2) = \pm 1/\lambda^{1.5}$. Before the stretching, the angles α and β amount on average to 90° and are transformed into smaller or greater angles α' and β'. As a result, $W_{\alpha\beta}$ [eq. (4)] decreases to $W_{\alpha'\beta'}$, *i.e.* the entanglement number N_v falls to N'_v. The factor f_λ ($= W_{90,90,\lambda}/W_{90,90,\lambda=1}$) gives the fraction of entanglements that are still present at λ (relative to the number at $\lambda = 1$) (Fig. 4a). The elastic restoring force of an entanglement network (referred to the cross section of the stretched specimen) is therefore not, as in main-valence networks, proportional to $\lambda^2 - 1/\lambda$ [see eq. (9)], but is instead proportional to $f_\lambda(\lambda^2 - 1/\lambda)$. Figure 4b shows the course of this function. Above a certain extension the restoring force should decrease on further extension. The entanglement network thus breaks on deformations around $\lambda = 2$. The experimentally observed extension law for non-cross-linked, very slowly relaxing polymers confirms that the entanglement number N_v decreases with λ in the manner derived here[12]. Moreover, the shear stress at which structural viscosity occurs shows that entanglement networks break at specific extensions (see Section 5).

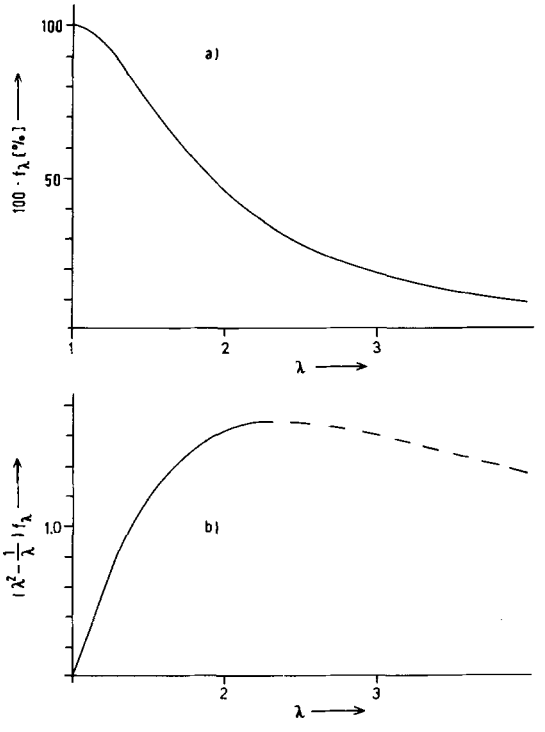

Fig. 4. a) The percentage of active entanglements as a function of the extension ratio λ. $f_\lambda = W_{90,90,\lambda}/W_{90,90,\lambda=1}$ is not exactly $1/\lambda$ as required by the Mooney-Rivlin equation [19]. b) The restoring force σ_r of an entanglement network divided by the relaxation modulus G_r (at $\lambda = 1$) in dependence on the extension ratio λ [cf. eq. (9)]. If λ is larger than corresponds to the curve maximum, an equilibrium retractive force is no longer established: the sample flows by a mechanism different to the usual one, where the conformational changes destroy and rebuild entanglements even at low τ. The relationship applies for all polymers.

The above considerations neglect the fact that in entanglement networks of undiluted polymers (and in very concentrated solutions) the network chains lead to a network junction that, although a neighbor along the chain, is not the junction nearest in space but in fact one further removed (Fig. 5) (see also Section 8). If such a network is stretched, volume elements of interest become more remote in the stretching direction.

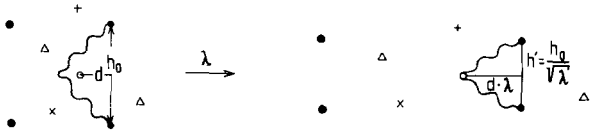

Fig. 5. At high concentrations the distances between the entanglement points are smaller than those between the ends of the network chains. Then several simple networks seem to interpenetrate (different point symbols for each network). If such a system is deformed, contacts are established that were not previously present; these contacts are not broken during extension, thus acting as additional entanglement points [12].

Since the contour length of the network chains remains unchanged, the network chain finally contacts a spatially close network junction[12] (Fig. 5). Even a small extension can lead in this way to larger entanglement numbers, estimated[11] as $(5/3)N_{v,\lambda=1}$. After a small extension, therefore, the $N_{v,\lambda=1}$ in eq. (5) should be replaced by $(5/3)N_{v,\lambda=1}$.

3. Conclusions from the Molecular Model and Their Experimental Testing with the Aid of the Relaxation Modulus

Equation (5), the result of the molecular model, can be tested by investigating whether melts have highly elastic properties. As shown in Figure 6, it is in fact found experimentally that above the softening temperature a rapid deformation is followed by restoring forces σ that remain constant for a longer time (plateau of the relaxation modulus in the rubber region of the relaxation). Use of the extension ratio $\lambda = L/L_0$ permits calculation of the relaxation moduli E_r or $G_r = 3E_r$ (G_r = shear modulus in experiments with $f_\lambda \approx 1$)[3]:

$$\sigma_r = G_r\left(\lambda^2 - \frac{1}{\lambda}\right) = 2N_v kT\left(\lambda^2 - \frac{1}{\lambda}\right)\left(1 - \frac{2M_c}{M_n}\right) \qquad (9)$$

At sufficiently high molecular weights G_r is proportional to $2N_v$, the number of network chains per cm³ of the melt, and it has a finite value only when the molecular weight M_n (M_n = number-average molecular weight of the polymer) of the polymer exceeds $2M_c$ (Fig. 6).

However, at appreciably larger M, G_r is independent of M. This result is to be expected from the description of entanglement given above, because at $M < 2M_c$ the known requirement for network formation [see eq. (6)] is not fulfilled. On the other hand, if $2M_c \ll M$, the entanglement number does not depend on the molecular weight because the small number of chain ends does not influence the relaxation modulus.

For polyethylene melts at 120°C one obtains according to eq. (9) a modulus G_r of about 1.1×10^6 Pa, and thus an entanglement number $N_v = 8 \times 10^{19}$ at 25°C. The agreement of this value with that estimated from eq. (4) is much too good in view of the uncertainty in the segment size, the crude approximations of the molecular model used here, and the uncertainty in the conversion from 120 to 25°C. The experiment thus confirms the molecular model at least to within

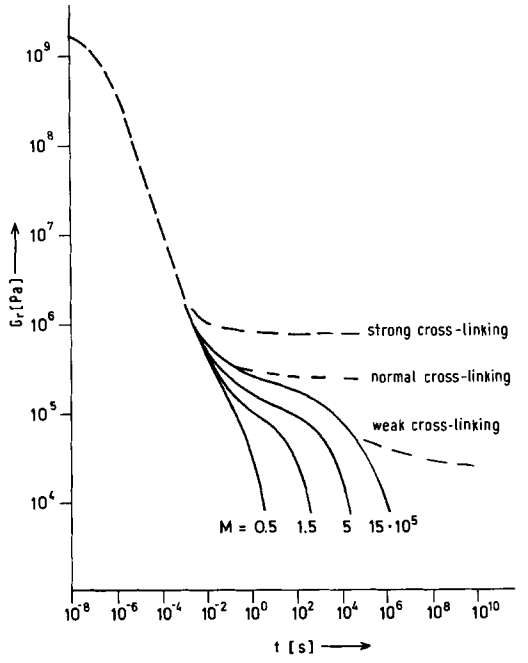

Fig. 6. Restoring forces σ_r arise after momentary stretching of *cis*-1,4-polyisoprene, which decrease as the load-application time is increased. In non-cross-linked samples of molecular weight $M > 2 \times 10^4$ it is observed that G_r (the relaxation modulus calculated from the restoring force) remains nearly constant for a certain time (the plateau of the modulus in the rubber elastic region of the relaxation). G_r is there almost independent of the molecular weight and of weak cross-linking by main valences [14].

an order of magnitude and encourages us in our search for further conclusions.

In proceeding further it must be remembered that the segment model correctly represents the conformations of a chain of CH_2 groups linked together at the usual valence angles. The auxiliary quantity "segment" is used only to simplify the statistics. In reality the spheres considered here are the CH_2 groups of the polymethylene chain and these are joined together with specific valence angles. If to a polymethylene melt we add oligomers or solvent molecules having the size of one segment (or the size of the CH_2 groups), not changing the chain conformation by special interactions with the polymer, then the solvent molecules will occupy some neighboring sites of each segment and thus reduce the number of contacts between different chains (contact number N_K). The probability of pairs of segments from different chains occurring is known to be proportional to the square of the volume fraction φ of the polymer, provided that the back-coiling number p is not dependent on φ:

$$N_{K,\varphi} = N_{K,1} \cdot \varphi^2 \tag{10}$$

Since, furthermore, the geometric conditions of chain conformation at entanglement points are not changed by the presence of solvent molecules, it follows from eq. (10) and (5) that the entanglement number is[9]:

$$N_{v,\varphi} = N_{v,1} \cdot \varphi^2 \tag{11}$$

Table 1. Relaxation moduli G_r, critical shear stresses τ_w (see text), molecular weights for network chains M_c, and molar volumes V_g of the repeating unit for the entanglement networks in linear polymers, in dependence on the volume fraction φ and temperature.

Table 1 shows that the relaxation modulus G_r, which according to eq. (9) is a measure of the entanglement number N_v, does in fact depend on the square of the volume fraction φ of the high-molecular components in solutions and polymer mixtures[9]. The same result can be derived from the right-hand side of Figure 7 ($f_t \sim G_r$). Fractions with molecular weights $M < M_{c,\varphi=1}$ thus lower the entanglement density of a polymer.

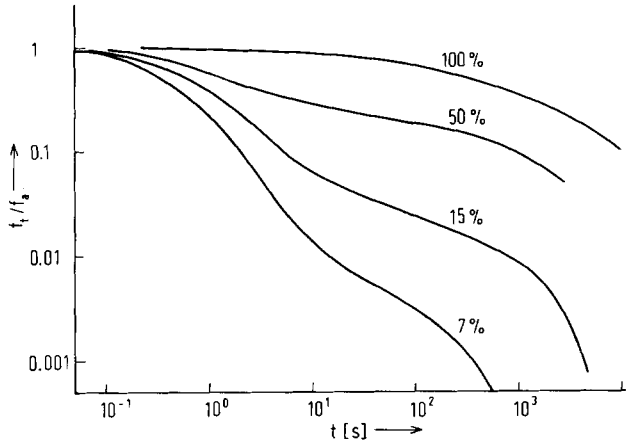

Fig. 7. Restoring forces arising after momentary (5 ms) deformation of mixtures of two molecularly homogeneous ($U_M < 0.02$) polyisoprenes (Li) ($M_1 = 2 \times 10^6$, $M_2 = 1.4 \times 10^5$) plotted as a function of the load-application time at 22 °C. f_t/f_a has the following meaning: $f = \sigma/\lambda$ is the restoring force referred to the initial cross-section of the sample, and f_a is the same for all samples (3.0 bar $= G_r$; eq. (9)). According to eq. (9), $\sigma_r \sim G_r$. The components relax at different rates, which leads to the stepwise nature of the relaxation curves of such mixtures [9]. The numbers on the curves are the proportions of M_1 in the mixtures.

When we next consider melts of chains whose side groups are so large that they occupy neighboring sites of a segment, and thus decrease the entanglement number N_v, we see that, as in eq. (11), the square of the volume fraction of backbone chains determines the entanglement number. If $V_{g,PE}$ is the molar volume of an ethylene unit and V_g that of the repeating unit of a vinyl polymer with side groups, then we should find that[9]:

$$N_v = 8 \times 10^{19} \left(\frac{V_{g,PE}}{V_g} \right)^2 = \frac{0.75 \cdot 10^{23}}{V_g^2} \tag{12}$$

Figure 8 and Table 1 show that eq. (12) is also confirmed by experiment[9]. In these calculations we used the molar volume V_g of the repeating unit of the polymers or the molar volume of a chain fragment of constant length, this fragment corresponding to a repeating unit in the case of vinyl polymers. In eq. (12) it is assumed that the backcoiling number p does not depend on the structure of the polymer; special hindrance to rotation is also disregarded.

In place of the number N_v of entanglement points in 1 cm^3 we may use M_c, the molecular weight of the network chains in the entanglement network (ρ = density of the polymer). From equations (9), (11), and (12):

$$G_{r,\varphi} = 2 N_{v,\varphi} kT \left(1 - \frac{2 M_{c,\varphi}}{M_n} \right) = \frac{\rho \varphi RT}{M_{c,\varphi}} - \frac{2 \rho \varphi RT}{M_n}$$

$$= \frac{2.1 \times 10^6 \times T \times \varphi^2}{V_g^2} - \frac{2 \rho \varphi RT}{M_n} \text{ [Pa]} \tag{13}$$

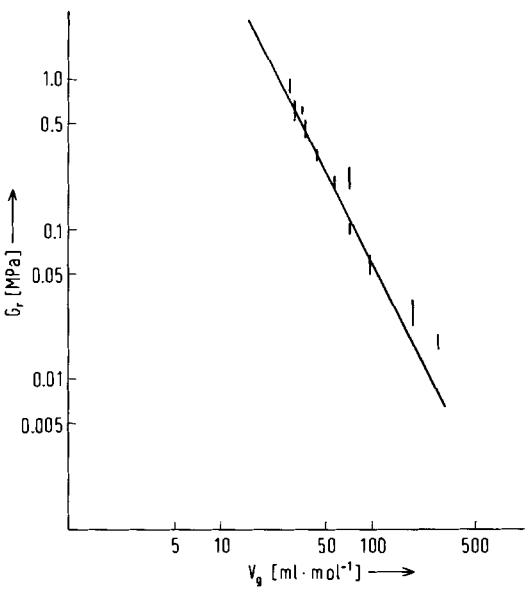

Fig. 8. Relaxation moduli G_r, measured according to Fig. 6, of various polymers (for individual values see Table 1) plotted as a function of the molar volume V_g of a chain fragment whose length corresponds to a repeating unit of the vinyl polymers [9].

$$M_{c,\varphi} = \frac{\rho \varphi N_A}{2 N_{v,\varphi}} = \frac{4.1 \times \rho V_g^2}{\varphi^2} = \frac{M_{c,1}}{\varphi} \tag{14}$$

A proportionality between $M_{c,\varphi}$ and $1/\varphi$ was earlier derived by *Bueche* by a different route and was tested experimentally[5].

At this point we should turn to yet another consequence of the molecular model, concerning the segment size. Eq. (3) shows the relation between the segment number N_S and the contact number N_K in chains without side groups. According to eq. (12) side groups reduce the contact number proportionally to $(V_{g,PE}/V_g)^2$. It is now possible to define an apparent segment size by assuming spherical segments (larger than in polyethylene because the spheres now contain the side groups) and apply eq. (3) for the calculation of the segment number. The segment number in melts is then given by:

$$N_{S,m} = \frac{N_K}{1.75} = \frac{N_{K,PE}}{1.75} \cdot \left(\frac{V_{g,PE}}{V_g} \right)^2 = \frac{1.67 \times 10^{24}}{V_g^2} = \frac{N_A}{V_{S,m}} \tag{15}$$

It follows that the molecular weight of the segment $M_S = V_S \rho$ in melts is:

$$M_{S,m} = 0.36 \times \rho \times V_g^2 \tag{16}$$

Experimentally, it has been found that eq. (16) is confirmed, although the factor 0.36 is better replaced by 0.2[9].

Now, since according to eq. (13) the molecular weight $M_{c,1}$ of the network chain in the melt is also proportional to V_g^2, the network chains of different polymers in the melt all contain the same number of segments[9]:

$$\frac{M_{c,1}}{M_{S,m}} = \frac{4.1}{0.36 \text{ to } 0.2} = 11 \text{ to } 21 \tag{17}$$

For nonideal solutions eq. (14) must be modified when the distance h between the ends of a molecule in such solutions is greater by the Flory expansion factor[13] α than in ideal

solutions (denoted by a subscript θ): $h=h_\theta\cdot\alpha$. The volume occupied by a chain fragment of molecular weight M_c in the form of a coil is then increased by the factor α_c^3 over that in ideal solvents, so that correspondingly more foreign chains pass through this coil and form entanglements. Moreover, in each volume element there are α_c^3 as many chains, because at a given total concentration the more coils must overlap, *i.e.* interpenetrate, the greater the coils are at a given molecular weight, so that the total concentration may everywhere be attained. Finally, the segment length also increases, under the usual assumptions ($Z_0 l_0^2 \alpha^2 = Z l^2$ and $Z_0 l_0 = Z l$) by the factor α_c^2. The segment molecular weight M_S thus similarly increases by about α_c^3, so that N_K and hence N_v should decrease by α_c^3. In all, α_c thus changes eq. (14) to[14]:

$$M_{c,\varphi} = \frac{M_{c,\theta,\varphi}}{\alpha_{c,\varphi}^3} = \frac{M_{c,\theta,1}}{\varphi \times \alpha_\varphi^3} = \frac{M_{c,1}}{\varphi}\cdot\left(\frac{\alpha_{c,1}}{\alpha_{c,\varphi}}\right)^3 = \frac{M_{c,1}}{f(\varphi)} \tag{18}$$

$$\left(\frac{\alpha_{c,\varphi}}{\alpha_{c,1}}\right)^3 = \frac{f(\varphi)}{\varphi} = \frac{G_{r,\varphi} + \dfrac{2\rho\varphi RT}{M_n}}{\left(G_{r,1} + \dfrac{2\rho\varphi RT}{M_n}\right)\varphi^2} \tag{19}$$

The experimental relaxation moduli confirm (see Table 1 and Figs. 9 and 19) the influence of the efficiency of the solvent and thus the influence of α_c.

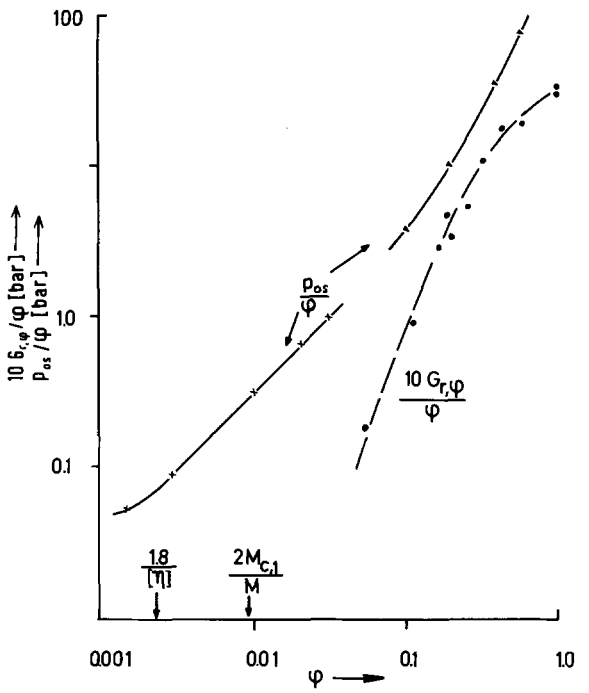

Fig. 9. Relaxation moduli $G_{r,\varphi}$ divided by the concentration φ (=volume fraction) plotted as a function of the concentration for mixtures of polyisoprene (Cariflex IR 305, $M_w = 1.7\times10^6$, $U_M < 0.1$) and toluene, as measured from the relaxation behavior 15—3000 ms after momentary (5 ms) compression or shear and extrapolated to $t=0$ (Hottinger technique, display oscillograph). The osmotic pressures p_{os}, also plotted were measured with an automatically compensating osmometer [14] (left-hand branch of the curves) or taken from the literature [29].

According to experimental investigations of structural viscosity[15] and relaxation modulus (see Table 1) in a temperature interval of about 100°C, the temperature dependence of $M_{c,1}$ is negligibly small. The modulus plateau can therefore hardly be due to an equilibrium between association and dissociation of the polymer chains[31].

4. Influences of Entanglement on Relaxation and Flow Processes

All the investigations described so far show that the entanglement number is an intrinsic property of each polymer and is thus independent of time. Since, however, according to Figure 7 restoring forces disappear in the course of time and melts or solutions can flow, it must be assumed that the entanglement numbers measured correspond to a dynamic equilibrium between disentanglement and renewed entanglement. The underlying processes are not specific associations and dissociations of the polymer chains but the usual conformational changes of the chains, diffusion of chain ends through entanglement loops[6], and cooperative and nearly simultaneous conformational changes at several neighboring entanglement points[4-6]. It is found that polystyrene powder ($M_w \approx 10^5$), produced by spraying of dilute solutions into vacuum, has the usual flow behavior immediately after pressing in vacuum, *i.e.* about 40 min after the spraying. Thus, the entanglement network must have formed in the course of this time. Other experiments show that large dissolved molecules diffuse away from one another in milliseconds after instantaneous fission; then the fragments display the usual light scattering[16]. The conformations clearly change so fast that even complicated structures such as entanglement networks are formed sufficiently rapidly. Further information on this is provided by a study of strain relaxation and of flow.

Figure 7 shows relaxation measurements made on mixtures of polyisoprenes with a heterogeneity index of about 1.1. It is evident that these mixtures form two kinds of entanglement networks. At short times one finds moduli that correspond to the usual moduli for polyisoprenes (Fig. 6), independently of the composition of the mixture or its molecular weight M_w (weight average molecular weight). This means that the two types of molecules have formed a common network whose network density is independent of the composition of the mixture. At long times, however, there is a second plateau of the relaxation moduli that shows much smaller moduli and depends strongly on the concentration of the high-molecular fraction and can therefore be assigned only to entanglement of the larger molecules. At this time all the entanglement positions in which short molecules take part have changed their conformation, their contribution to the restoring force being lost because the chains have formed an equal number of new entanglements with the use of undeformed chain fragments. The entanglements of the larger molecules remain; these are broken only after longer times, because there must be a cooperative process involving many entanglement points simultaneously—or at least coordinated in time and space—and this cooperation requires the more points, the larger is the molecule concerned.

Bueche[5] and others (for a review see [4]) have used the concept of entanglement in theories of flow. Accordingly, the maximal relaxation time t_r in the rubber-elasticity region of the relaxation and the viscosity η proportional to it depend extensively on the molecular weight M and the concentration φ (volume fraction)[17]:

$$t_r = \text{const.}\,\eta = \text{const.}\; M^{3.5}\cdot\varphi^4 \tag{20}$$

Figure 7 gives the times in which the entanglement networks of molecules of various sizes undergo strain relaxation to one-tenth of its original value; these times are approximately in the ratio $(M_2/M_1)^{3.5}$, thus confirming eq. (20). Furthermore, the step heights obey approximately the expected law, namely eq. (13). On the other hand, concentration dependence of t_r in this experiment appears to be considerably weaker than predicted by eq. (20); the reason for this is that the process cannot be described by a single relaxation time, and the maximal relaxation times t_r for disappearance of the last traces of a restoring force cannot yet be measured with accuracy.

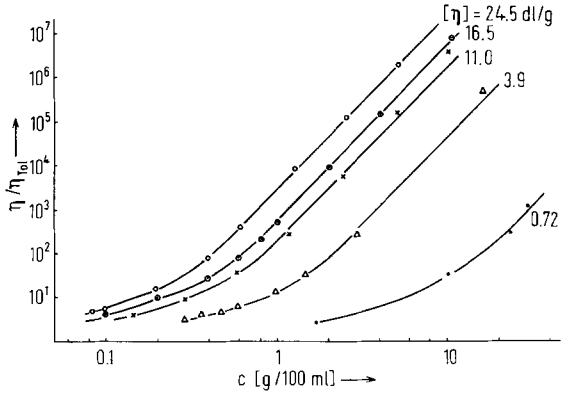

Fig. 10. Relative viscosity η/η_{tol} (from flow curves extrapolated to shear stress $\tau = 0$) plotted as a function of the concentration for polystyrene fractions of various molecular weights. $[\eta]$ = limiting viscosity in [dl/g] in toluene at 25 °C. Above a critical concentration the viscosity of the solutions increases with c^4. The critical concentration decreases with increasing molecular weight.

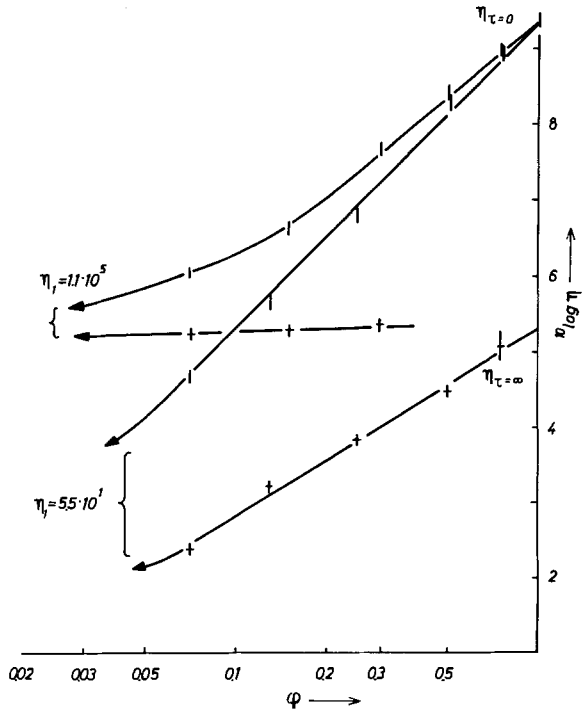

Fig. 11. Flow curves for mixtures of two polyisoprenes (Li, $M_1 = 1.4 \times 10^5$ or 1.2×10^4; $M_2 = 2 \times 10^6$, $U_M < 0.1$) give viscosities $\eta_{\tau=0}$ and $\eta_{\tau=\infty}$ extrapolated to shear stresses $\tau = 0$ and $\tau = \infty$, respectively, which are here plotted as a function of the concentration (= volume fraction φ) [17]. The $\eta_{\tau=\infty}$ is extrapolated as if the viscosity η_1 of the lower-molecular component were independent of τ and at sufficiently small η_1 is proportion to φ^2. At sufficiently small η_1, however, $\eta_{\tau=0}$ is proportional to φ^4. $\eta_1 = 1.1 \times 10^5$ refers to $M_1 = 1.4 \times 10^5$; $\eta_1 = 5.5 \times 10^1$ refers to $M_1 = 1.2 \times 10^4$.

However, many investigations of the flow of solutions confirm the concentration dependence expressed in eq. (20) (Figs. 10 and 11). Naturally, this is only so if the prerequisites for eq. (20) are satisfied, *i.e.* if the expansion factor α and the back-coiling number p as well as the segment mobility are none of them strongly dependent on φ[9, 17].

The flow behavior of melts and solutions containing entangled molecules also shows other effects of entanglement. It is found that the molecular volume V_g of the repeating unit of the vinyl polymers has an appreciable influence[17]:

$$\eta_v = f(T - T_g) \times \frac{M^{3.5} \cdot \varphi^4}{V_g^{7.5}} \cdot 1.7 \times 10^{-5} \text{ [Pa·s]} \quad (21)$$

The factor $f(T - T_g)$ describes the influence of the strongly temperature-dependent segment mobility. In the absence of entanglement the viscosity is far less influenced by M, φ, and V_g[17]:

$$\eta = f(T - T_g) \times \frac{M^{1.45} \cdot \varphi^2}{V_g^{3.5}} \cdot 2.5 \times 10^{-4} \text{ [Pa·s]} \quad (22)$$

Thus, eq. (21) holds for the dependence of the viscosity on molecular weight at molecular weights M that fulfil the network-formation condition [eq. (6)], whereas eq. (22) applies if M is smaller. This kink or transition in the $\log\eta - \log M$ relationship has been shown to appear in many polymers and solutions[4, 5, 17, 21].

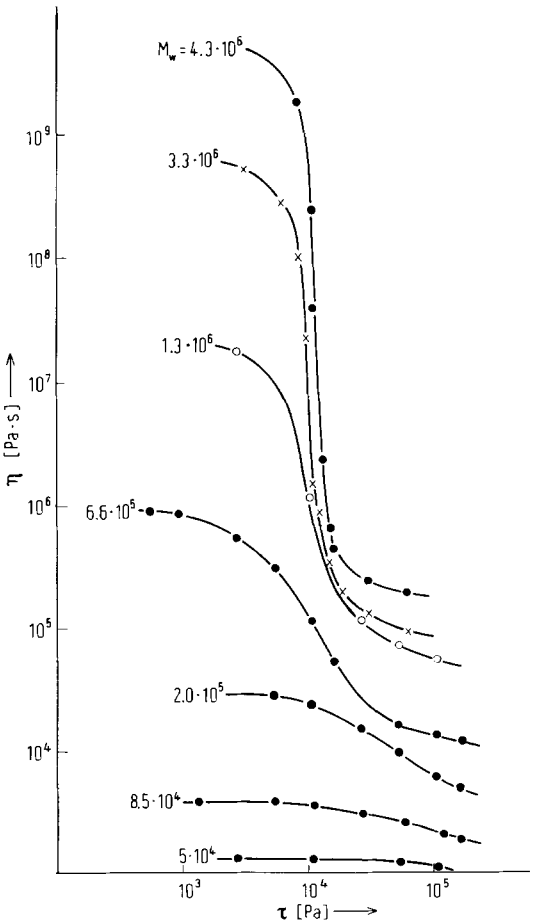

Fig. 12. Flow curves of unbranched polydodecyl methacrylates at 25 °C. The flow curves of these polymers can be measured down to the vicinity of the second Newtonian region without fracture of the melt [17].

A further consequence of entanglement is the appearance of a structural (non-Newtonian) viscosity that is much stronger than in systems where the thread molecules do not entangle. If melts or solutions that follow eq. (21) are made to flow under higher shear forces, their viscosity decreases with increasing shear stress τ (Fig. 12). At very high shear stresses the viscosity reaches values that correspond to those of eq. (22)[17], so long as the melt does not previously collapse (melt fracture). The quotient of the viscosities η_v and η constitutes a suitable measure of the magnitude of the structural viscosity:

$$\frac{\eta_{\tau=0}}{\eta_{\tau=\infty}} = \frac{\eta_v}{\eta} = 1.54 \times 10^{-2} \frac{M^2 \varphi^2}{V_g^4} = \left(\frac{M}{M_{c,\varphi}}\right)^2 \tag{23}$$

Figure 13 shows flow curves for polyisoprene mixtures[9] at low shear stresses. Measurements on solutions[18] and on the mixtures of Figure 13 are shown in Figure 14 to conform, at least approximately, to eq. (23) which, as previously, is formulated for constant expansion factors α_c and constant back-coiling numbers p. The influence of the basic molar volume V_g is not clearly visible for the few polymers studied,

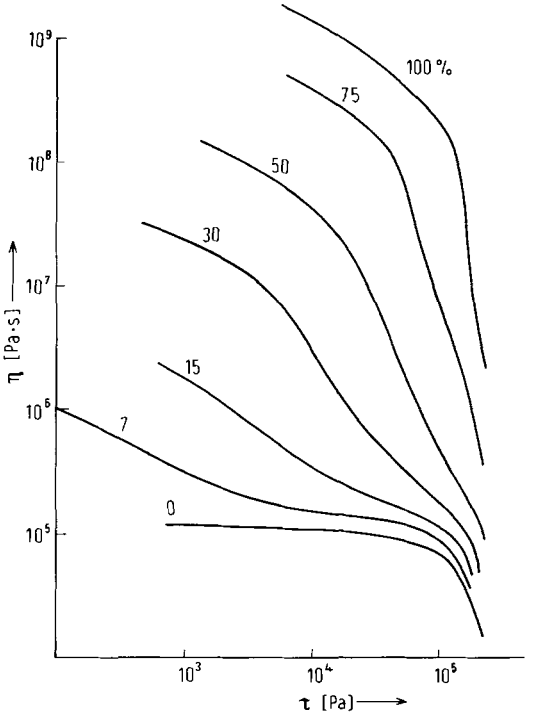

Fig. 13. Flow curves of mixtures of homogeneous ($U_M < 0.1$) polyisoprenes ($M_1 = 1.6 \times 10^6$; $M_2 = 1.4 \times 10^5$) at 25 °C. Addition of the component with a high molecular weight raises the viscosity $\eta_{\tau=0}$ and produces a structural viscosity and an inflection point in the flow curves in the region of $\tau < 10^5$ Pa, this inflection not being observed with homogeneous polymers [9]. The numbers on the curves give the proportion (percentage) of M_1.

apparently because other factors such as differences in *Bueche*'s slipping factor[5] may play a part. The constants derived experimentally[17] for eq. (23) agree with the constants obtained differently for eq. (14), in fact much too well in view of the large limits of error in the construction of eq. (23). The size $\eta_{\tau=0}/\eta_{\tau=\infty}$ of the structural viscosity is thus simply equal to the square of the number of network chains per molecule, which is a clear indication of a cooperative process. The experimental result does not confirm other theoretical claims so well[4, 5].

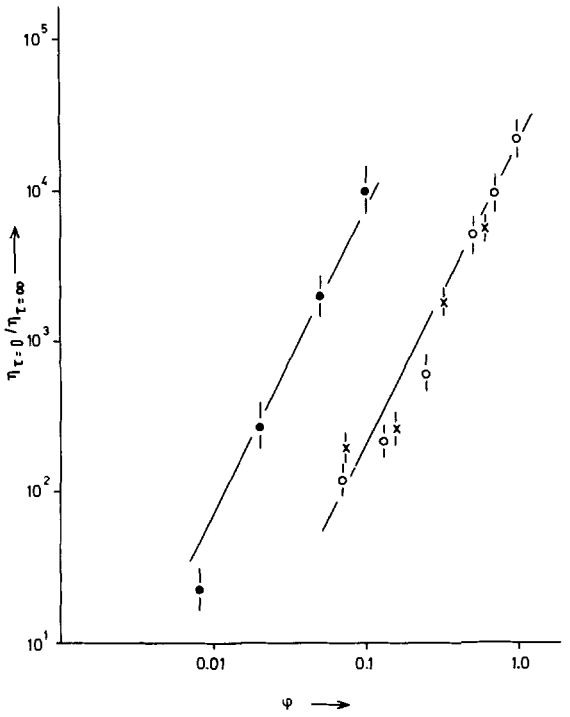

Fig. 14. $\eta_{\tau=0}/\eta_{\tau=\infty}$ as a measure of the magnitude of the structural viscosity plotted against the concentration φ for polystyrenes ($M = 1.4 \times 10^7$, $U_M \leq 0.3$) in toluene (●), and for polyisoprene ($M = 1.7 \times 10^6$, $U_M \leq 0.1$) in polyisoprenes of lower molecular weight (○; see Fig. 13) as well as in toluene (+) at 25 °C. The concentration dependence sufficiently confirms eq. (23).

To obtain a visible structural viscosity of the melts it is necessary to use various shear stresses, suited to the individual polymer. For a more precise discussion we use the shear stress τ_w found at the inflection point of the plots of $\log\eta$ *versus* $\log\tau$. Figure 12 shows that the τ_w are almost independent of M, so that τ_w may be regarded as a property of entanglement networks. Furthermore, the τ_w follow laws similar to those for G_r[9, 17]. Eq. (24) summarizes the results for several polymers at various concentrations (see also Table 1):

$$\tau_w = \frac{5.5 \times 10^8 \cdot \varphi^2}{V_g^2} \approx G_r\,[\mathrm{Pa}] \tag{24}$$

This finding can be interpreted as showing that the same distortion of the entanglement network is always sufficient to reduce its effect on viscosity by a certain fraction, confirming the considerations of the dependence of the number of active entanglements on the extension, which lead to the assumption that $\tau_w \approx 1.6\,G_r$ (see Fig. 4). The collapse of the entanglement network becomes evident when, at high shear stresses, melt fracture occurs. Consequently, these critical shear stresses are proportional to φ^2/V_g^2[17, 18] so long[32] as no stretch crystallization occurs.

Moreover, it can be assumed that under the influence of an applied load, *i.e.* deformation of the chain fragments taking part in entanglement, the diffusion steps or conformational changes leading to a removal of the load are preferred to others and so accelerate the disentanglement of the stressed network chains[6, 4], but leave the process of new entanglement unaffected. A gradual decrease of entanglement could therefore occur during relaxation after large deformations.

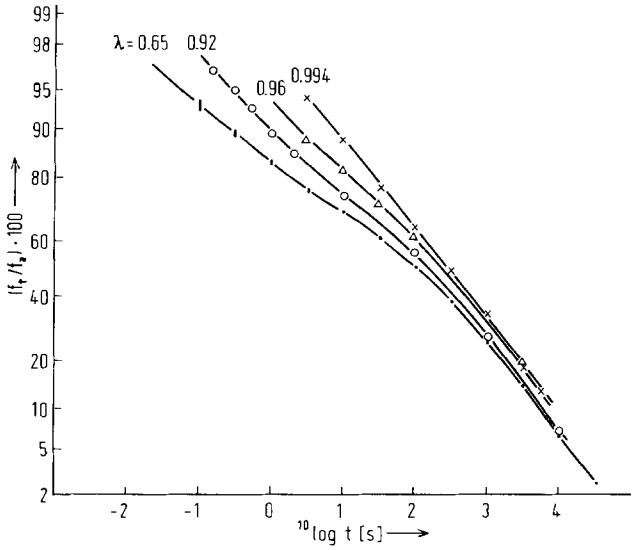

Fig. 15. Rate of strain relaxation (as a percentage) in a non-crosslinked polyisoprene ($M/M_0 \approx 130$) after momentary (5 ms) compression increases with increasing deformation as a result of the nonlinear form of eq. (9) and for the same reason as causes structural viscosity (see text). λ = extension ratio. $f_a = \sigma_a/\lambda$ can be calculated for $\lambda \geq 0.92$ by means of eq. (9) with $G_{r,a} = 3.0$ bar·cm^{-2}.

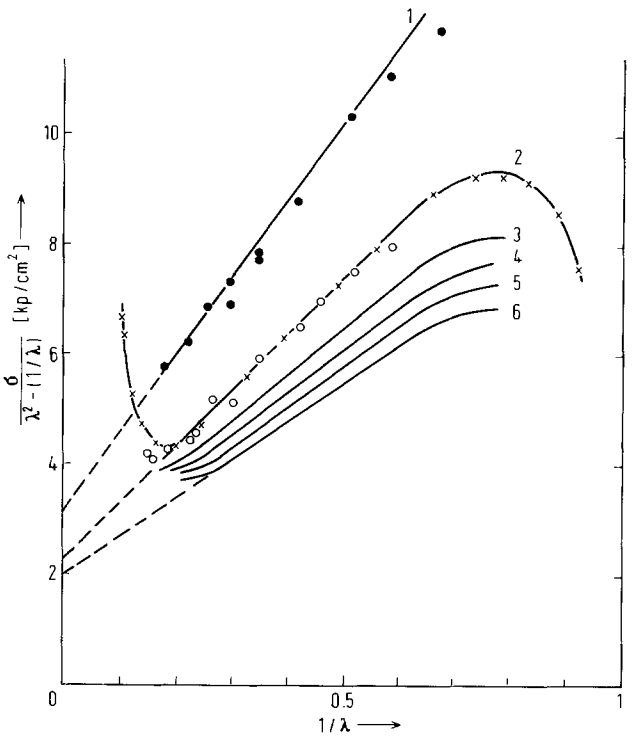

Fig. 16. As described by Mooney-Rivlin-Saunders [19], the quotients of the stress σ (referred to the cross-section of the stretched sample) and $\lambda^2-(1/\lambda)$ (λ = extension ratio) are plotted against $1/\lambda$. The intercept $2C_1$ on the left-hand ordinate is a measure of the main-valence cross-linking; that on the right, $2C_2$, is a measure of the concentration of entanglements active under the measurement conditions. $2C_2$ decreases with increasing duration of stress [12]. Curves 1 to 6: $d\lambda/dt = 13$, 1.25, 0.12, 0.025, 6.25×10^{-3}, 1.25×10^{-3}.

The same causes as lead to the appearance of structural viscosity lead to the fact that the relative rate of stress relaxation is greater after large than after small elongations: According to Figure 15, the halflife of mechanical relaxation decreases with increasing deformation[9].

5. Influence of Entanglement on the Extension of Cross-Linked Materials

The fact that the effective entanglement number depends on the extension is also important for the properties of materials such as rubber[12] that are cross-linked by main valences. Figure 6 shows their relaxation behavior in comparison with that of non-cross-linked material. With slightly to medium cross-linked samples we find, at short loading times, relaxation moduli that correspond to those of non-cross-linked polymers. Only after prolonged loading times does cross-linking by main valences become noticeable, so that analytic stretching experiments are often carried out with extended loading times. On the other hand, in chemically weakly cross-linked samples and with brief and slight (*e.g.* periodic) deformations, restoring forces are found that arise only from the entanglement network and, according to Figure 6, are usually greater than expected on the basis of the weak main-valence cross-linking. Since, however, according to Fig. 4, entanglements are made ineffective by strong deformations, even with short-lasting load applications one can, by using strong deformations, recognize the restoring forces that arise from the main-valence cross-linking. At large extensions one then finds the extension behavior predicted by the theory for main-valence networks[12]. With medium extension rates and deformations one must divide the restoring forces by the Mooney-Rivlin-Saunders procedure[19] into $2C_1$, the fraction due to the main-valence network, and $2C_2$, the fraction due to the entanglements (Fig. 16).

The ordinate intercept of the straight part of the curve at $\lambda = 1$ is $2C_2$, and that at $\lambda = \infty$ is $2C_1$. The fraction $2C_2$ decreases, as expected, when the loading times are increased, and also if the sample is swollen, as would be expected from the strong concentration dependence of the entanglement number shown by eq. (13). The experiments confirm the following law[12]:

$$\frac{2C_{1,\varphi}}{\varphi^{1/3}} + \frac{2C_{2,\varphi}}{\varphi^2} = \frac{5}{3} G_{r,\varphi=1} \tag{25}$$

In the rubber region of relaxation behavior the breaking stresses and maximal extensions also rise with increasing rate of extension, because with short loading times (rapid stretching) the restoring forces affect more contacts and entanglements than with long times.

Finally, the maximum degree of swelling of cross-linked samples is influenced by entanglement of the thread molecules because entanglement changes the thermodynamic properties of the solutions. In the usual swelling equations a value of the interaction parameter (Flory-Huggins parameter) χ_1 should then be used[14], which is influenced by the effects of entanglement, as will now be shown.

6. Significance of Entanglement for the Thermodynamic Properties of Solutions

If melts or solutions become rubber-elastic by the entanglement of thread-like molecules and thus possess an entropy-determined memory, and if the entanglement density depends

on the concentration, then on dilution of such a network an entropy change ΔS occurs that differs from the entropy change for unentangled dissolved polymers[20, 14]. This can have a considerable bearing on the thermodynamic properties of such systems and will be formulated here, because previous formulations[21] of statistical thermodynamics cannot yet be used for experimental testing.

If a chain comprising b bonds or Z segments (of bonding number b_s and length $l=1$) is fastened at one end in such a way that the orientation of the first segment with respect to the anchoring is defined, then that chain can assume ω_0 conformations, which can be calculated when the rotation potential has three minima and thus each bond can be oriented in a total of three spatial directions[3]:

$$\omega_0 = 3^b = 3^{b_s Z} \tag{26}$$

If such a chain is fastened at both ends, *e.g.* at entanglement points, then only a fraction of the previously permissible conformations is possible. This can easily be understood by considering a chain of two segments. The end points of the second segment mark out evenly the surface of a sphere of radius l. On average, the first and the second segment make an angle of 90° to each other. If we specify that this angle is strictly retained, so that the chain ends always maintain the statistical mean value of their separation, then the end of the second segment can occupy only positions on an arc and no longer on the whole surface of the sphere.

If the separation h of the ends of the chain considered in eq. (26) has the statistical mean value, then $h_0^2 = Z l^2$; and with $l=1$ and eq. (2) the conformation number ω_e of the chain fixed at both ends[3] is given by:

$$\omega_e = \omega_0 \cdot \left(\frac{3}{2\pi Z \alpha^2}\right)^{3/2} \cdot e^{-3/2} = \frac{\omega_0 \cdot 0.074}{Z^{1.5} \cdot \alpha^3} \tag{27}$$

In the case of greater entanglement each polymer molecule with its Z segments is divided into $m+1=(M/M_c)+1$ parts, of which $m-1$ parts are network chains with Z/m segments and two parts are end fragments with $Z/2m$ segments. The total number of conformations of such a chain is ω_m:

$$\omega_m = \left(\frac{3^{Zb_s/m} \cdot 0.074}{(Z/m)^{1.5} \cdot \alpha_c^3}\right)^{m-1} \cdot (3^{Zb_s/2m})^2 = \omega_0 \cdot \left(\frac{0.074}{(Z/m)^{1.5} \cdot \alpha_c^3}\right)^{m-1} \tag{28}$$

For calculating the dependence of ω_m on concentration we require the concentration dependences of m and α_c. According to eq. (18) we have:

$$m_\varphi = \frac{M}{M_{c,\varphi}} = m_1 \times \left(\frac{\alpha_{c,\varphi}}{\alpha_{c,1}}\right)^3 \times \varphi = m_1 \cdot f(\varphi) \tag{29}$$

The concentration dependence of $\alpha_{c,\varphi}^3$ follows according to eq. (19) from that of $G_{r,\varphi}$, φ, and $f(\varphi)$:

$$\frac{d\alpha_{c,\varphi}^3}{d\varphi} = \frac{\alpha_{c,\varphi}^3}{\varphi}\left(\frac{\varphi f'(\varphi)}{f(\varphi)} - 1\right) = \frac{\alpha_{c,\varphi}^3}{\varphi}\left(\frac{d\ln G_{r,\varphi}}{d\ln\varphi} - 2\right) \tag{30}$$

The entropy S_φ of the network of N_2 polymer molecules and N_1 solvent molecules can now be obtained[14]:

$$S_\varphi = k N_2 \ln \omega_{m,\varphi}$$
$$= k N_2 \{b_s Z \ln 3 + (m_\varphi - 1)[\ln 0.074 - 1.5 \ln(Z/m_\varphi) - \ln \alpha_{c,\varphi}^3]\} \tag{31}$$

At least in the case where $\alpha_{c,\varphi}=1$, eq. (31) agrees with other formulations for network-formation entropy[21].

In addition to the entropy of mixing $S_\varphi - S_1$ derived from eq. (31), a further term $-kN_1\ln(1-\varphi)$ must be introduced into the equation for the free energy of mixing (subscript M), since this describes the amount of entropy that should be assigned to a giant molecule containing $N_2 \cdot Z$ segments (the entanglement network)[22]:

$$\Delta G_M = \Delta H_M - T\Delta S_M = k T_1 N_1 \varphi - T[S_\varphi - S_1 - k N_1 \ln(1-\varphi)] \tag{32}$$

The osmotic pressure p_{os} can now be calculated by substituting eq. (31) into eq. (32) and by partial differentiation[22]:

$$p_{os} = -\frac{N_A}{V_1} \cdot \left(\frac{\partial \Delta G_M}{\partial N_1}\right)_{N_2} \tag{33}$$

V_1 is the molar volume of the solvent, $N_A = 6 \times 10^{23}$, and k is Boltzmann's constant. To carry out the differentiation we need $d\alpha_{c,\varphi}^3/d\varphi$ [eq. (30)], $\alpha_{c,\varphi}^3$ [eq. (19)], and finally the quantity $(\partial\varphi/\partial N_1)_{N_2}$:

$$\left(\frac{\partial \varphi}{\partial N_1}\right)_{N_2} = -\frac{N_1}{V_2 N_2}\varphi^2 \tag{34}$$

We now obtain a relationship for p_{os} that involves not only the known term containing the Flory-Huggins parameter χ_1[22], but also a further term that depends on the relaxation modulus $G_{r,\varphi}$ of the solution, *i.e.* on its entanglement number N_v [see eq. (9)]. $f(\varphi)$ is the experimentally determinable function defined in eq. (18).

$$\begin{aligned} p_{os} = \frac{RT}{V_1}[&-\ln(1-\varphi) - \varphi - \chi_1 \varphi^2] + \\ &+ G_{r,\varphi}\left[\frac{d\ln G_{r,\varphi}}{d\ln\varphi} - 1\right]\left\{1.5 \ln \frac{M_{c,1}}{M_S} - \ln 0.074 - 1.5\ln\varphi\right. \\ &- 0.5 \cdot \ln\left(\left[\frac{G_{r,\varphi} + 2\rho\varphi RT/M_n}{G_{r,1}\cdot\varphi^2}\right] \cdot \alpha_{c,1}^3\right) \\ &\left. - 0.5\left[1 + \frac{1}{1 + (2\rho\varphi RT/M_n G_{r,\varphi})}\right]\left[2.5 - \frac{(1 + 2\rho\varphi RT/M_n G_{r,\varphi})}{[(d\ln G_{r,\varphi}/d\ln\varphi) - 1]}\right]\right\} \end{aligned} \tag{35}$$

In the last term the part beginning with $1/(1+\cdots)$ describes the usually small influence of the unentangled end fragments of the network. Eq. (35) is valid only for the case of an entanglement network and must not be extrapolated to $\varphi = 0$, *i.e.* to a very dilute solution.

With the experimental value of $G_{r,\varphi}$ we can calculate, by means of eq. (35) the portion of the osmotic pressure that corresponds to the term with $G_{r,\varphi}$. This pressure differs little at $\varphi < 0.1$ from the experimentally measured pressure (see Tables 2 and 3), so that we must conclude that at concentrations below 10% the first term on the right in eq. (35) is appreciably smaller than the term with $G_{r,\varphi}$. The parameter χ_1 must therefore have values of around 0.50, *e.g.* 0.51 for polystyrene in toluene and 0.57 for polystyrene in decalin.

Table 2. Osmotic pressures of concentrated solutions at 25°C, given as rise heights d of the solvent at 25°C [η] = viscosity.

A theoretical formulation[24], corresponding to the lattice theory[23], presumes that at high concentrations and with a homogeneous segment distribution the osmotic pressure is independent of the molecular weight and is proportional to the square of the concentration, but with these corrected χ_1 values this theory gives pressures that are much too low. For the same reason, the excluded-volume theory cannot explain the experimental values, especially as according to this theory the pressures would be expected to depend on the molecular weight. Experiment[20] shows (Fig. 17) that above a critical concentration φ^* the concentration dependence can no longer be described by the virial coefficients of this theory.

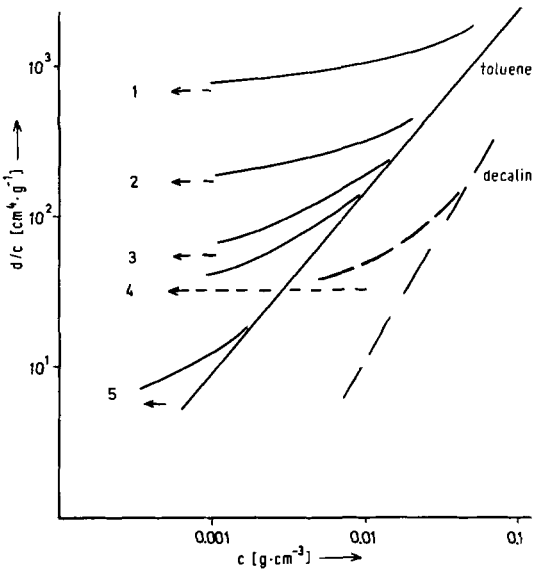

Fig. 17. Osmotic pressure p_{os} (represented as the rise height d of the solvent for $\rho = 0.87$) plotted against the concentration c in toluene (polymers 1 to 5) [20] and in decalin (*cis-trans* mixture) (polymer 5) at 25 °C for the following polystyrenes: 1, $M_w = 4.1 \times 10^4$, $U_M < 0.02$; 2, $M_w = 1.7 \times 10^5$, $U_M < 0.02$; 3, $M_w = 4.7 \times 10^5$, $U_M < 0.02$; 4, $M_2 = 9 \times 10^5$, $U_M < 0.02$; 5, $M_w = 1.4 \times 10^7$, $U_M \leq 0.3$. At sufficiently high concentrations the values reach the limiting straight line with all molecular weights.

The term including $G_{r,\varphi}$ in eq. (35) is almost proportional to φ^2. The same is true of $\chi_1 \varphi^2$, so that the two terms can be treated together by means of an effective parameter $\chi_{1,eff}$. The $\chi_{1,eff}$ measured at high concentrations thus contain an entropy component that is derived from the entanglement network and in nonideal solutions is dependent on concentration, because there $G_{r,\varphi}/\varphi^2$ is not quite constant but decreases with increasing concentration. $\chi_{1,eff}$ thus increases.

Eq. (35) is also important for light scattering R_0 (in the direction of the primary beam) and for diffusion in concentrated solutions, as shown by the following relationships[25, 26] (K^* = light scattering constant):

$$\frac{K^* \cdot c}{R_0} = \frac{1}{RT} \cdot \left(\frac{\partial p_{os}}{\partial c}\right)_T \tag{36}$$

$$D = \frac{M}{f} \cdot \left(\frac{\partial p_{os}}{\partial c}\right)_T \tag{37}$$

Since according to eqs. (35) and (13) p_{os} is independent of M and is proportional to the square of the concentration, it follows that $K^* c/R_0$ is independent of M and proportional to c, *i.e.* R_0 is independent of both M and c[20, 14] (Fig. 18). Then the diffusion coefficient D measured in concentrated solution is also proportional to c, whereas the value obtained by measurement in the supernatant dilute solution in an overlaying experiment is almost independent of c[20]. Thus, the

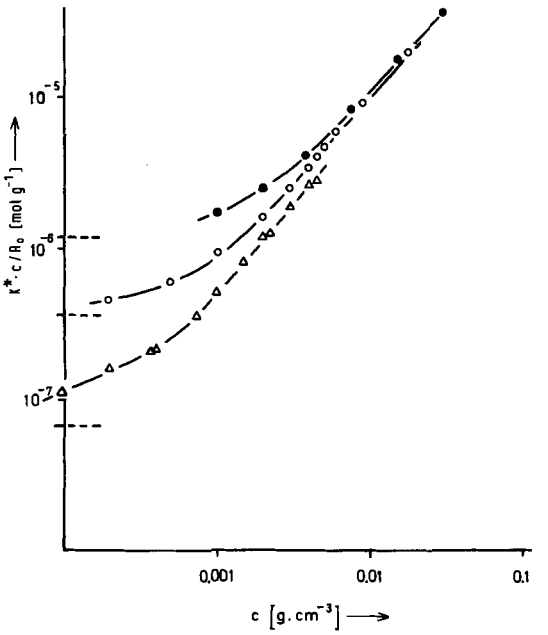

Fig. 18. Light scattering R_0 (extrapolated to the direction of primary beam) as a function of the concentration c for polystyrenes of various molecular weights ($U_M \leq 0.3$) in toluene at 25 °C. At sufficiently high concentrations the scattering becomes independent of the molecular weight and of the concentration [20].

concentrated solution increases its volume, *i.e.* it swells like a cross-linked polymer. Permeation of low-molecular substances through polymers, diffusion in melts (adhesion), and sedimentation are also altered by the formation of an entanglement network, as can be recognized from the preceding discussions. Finally, the effects of entanglement on the demixing behavior of concentrated solutions, *e.g.* on concentration of the concentrated phase and on swelling of substances cross-linked by main valences, can also be formulated by means of the equations given above. In an approximate manner, an effective interaction parameter $\chi_{1,eff}$ can be used for this purpose[14].

7. Effects of Entanglement at Medium and Low Concentrations

It now remains to demonstrate at what concentrations φ^{**} a solution begins to form an entanglement network. Figures 9 and 19 show that an osmotic pressure independent of the molecular weight can be observed already at small concentrations where one cannot detect the very small rubber elastic modulus arising from an entanglement network. The limiting concentration for the formation of an entanglement network follows from equations (9) and (18):

$$\varphi^{**} = \frac{2 M_{c,1}}{M_n} \cdot \left(\frac{\alpha_{c,1}}{\alpha_{c,\varphi}}\right)^3 \tag{38}$$

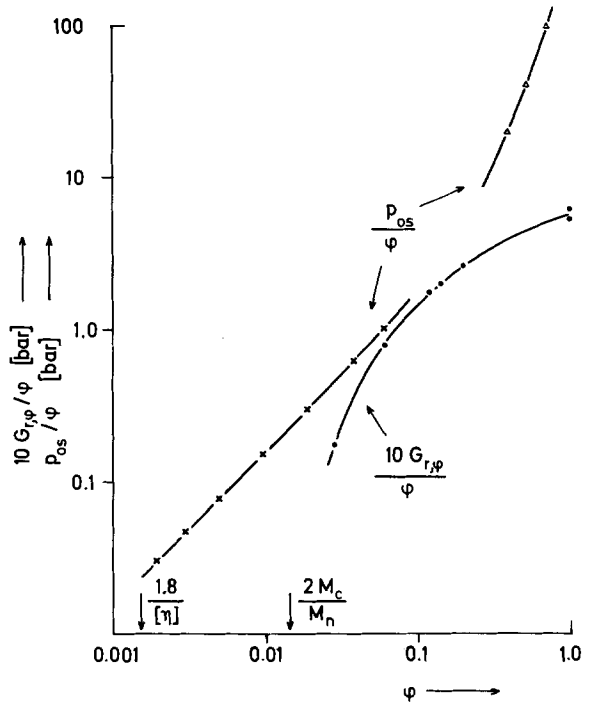

Fig. 19. Diagram plotted analogously to Fig. 9, showing $G_{r,\varphi}/\varphi$ and p_{os}/φ for polystyrene ($M_w = 8 \times 10^6$, $M_n = 5.5 \times 10^6$) in toluene at 25 °C. The left-hand branch of p_{os}/φ was determined as in Fig. 9; the right-hand branch comes from the literature [30] ($M_n = 2.9 \times 10^5$).

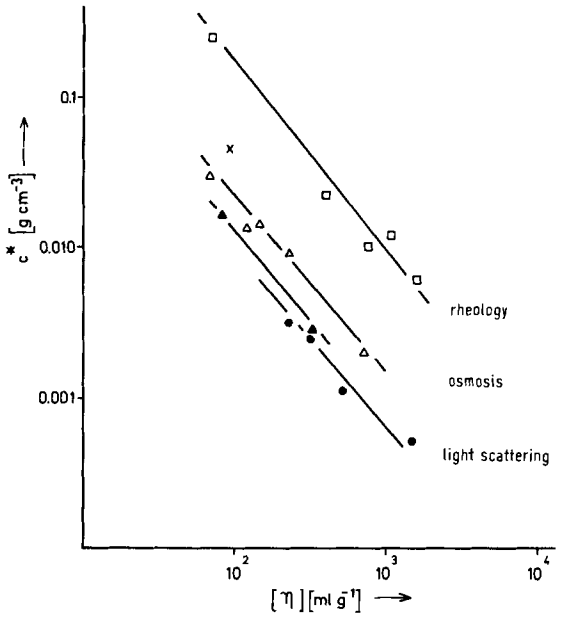

Fig. 20. Critical concentrations c^* above which the osmotic pressure p_{os} or the light scattering R_0 is independent of M, or the viscosity of the solutions rises with φ^4, plotted against the limiting viscosity $[\eta]$ for polystyrenes in toluene at 25 °C (△, ●, □), in cyclohexane at 35 °C (▲), and in decalin (*cis-trans* mixture) at 25 °C (×).

If then in accordance with eq. (13) $G_{r,\varphi}/\varphi$ is plotted against φ, one observes that, for polystyrene with $M_n \approx 6 \times 10^6$ in toluene or decalin, $G_{r,\varphi}$ disappears at $\varphi^{**} \approx 0.02$. The critical concentrations following from measurements of elasticity (see Fig. 19 for $G_{r,\varphi} \to 0$) correspond well with those from rheology (Fig. 10). Their value is somewhat higher than expected and could be explained by $\alpha_{c,\varphi} < 1$ (see below), but in any case it is far above the critical concentrations measured osmotically or by light scattering (see Figs. 9, 19, and 20). Furthermore, the critical concentrations measured osmotically are inversely proportional to $[\eta]$ according to Figure 20 and thus contrary to eq. (38). The value corresponds to a state of the solution where the coils just fill the volume of the solution. For spherical coils of diameter h this concentration would be:

$$\varphi^* = 0.74 \times \frac{2.5}{[\eta]} = \frac{1.85}{[\eta]} \tag{39}$$

The values obtained in good solvents follow this relationship very closely. Clearly mere mutual contact between the coils causes disturbances that raise the osmotic pressure above the value calculated by the excluded-volume theory (second virial coefficients dependent on the molecular weight) and, contrary to this theory, make the osmotic pressure independent of the molecular weight.

The cause of the disturbances is that at the concentrations in question the coils begin to interpenetrate; during this process entanglements occur between the end fragments of the chains, which may be found mainly in the outer regions of the coils[27]. Such entanglements are not subject to the statistics that led to eq. (9), so that M_c, the molecular weight of the network chains, is larger, and φ^* is smaller, than expected. At this stage the entanglements need not lead to a complete network but may only bind several coils together, thereby considerably restricting the number of possible conformations. The molecules can reduce these disturbances by shrinkage, so long as the increase in free energy due to shrinkage does not exceed the increase due to entanglement. Presumably some shrinkage occurs in the neighborhood of φ^*, which in the neighborhood of φ^{**} is largely superseded by stronger entanglement. On shrinkage, the free energy of the N_2 molecules in the network increases[28]:

$$\frac{\partial \Delta G}{\partial \alpha_K} = -6 c_M kT \left(\frac{1}{2} - \chi_1\right) \frac{\sqrt{M} N_2}{\alpha_K^4} + \frac{\partial \Delta G_{el}}{\partial \alpha_K} = 3 N_2 kT \left(\alpha_K - \frac{1}{\alpha_K} - \frac{\alpha_0^5 - \alpha_0^3}{\alpha_K^4}\right) \tag{40}$$

In expression (40) c_M is a constant, $\alpha_K = \alpha/\alpha_0$ is a relative expansion factor (<1) in the shrunken molecule and α_0 is the expansion factor (>1) before the shrinkage, the latter factor depending on interactions with the solvent. From the assumption $\alpha_K^3 = \varphi^*/\varphi$ that is arguable in the vicinity of φ^*, the pressure can be calculated as:

$$p_{os} = \frac{RT}{M} c \left[2 - \left(\frac{\varphi^*}{\varphi}\right)^{2/3} + (\alpha_c^5 - \alpha_0^3) \cdot \frac{\varphi}{\varphi^*}\right] + \frac{RT}{V_1} [-\ln(1-\varphi) - \varphi - \chi_1 \varphi^2] \tag{41}$$

According to Table 3 this expression agrees sufficiently well with the experimental values for polystyrene in toluene, polyisoprene in toluene, and polystyrene in decalin in the neighborhood of φ^* for $\chi_1 = 0.5$. The $\alpha_{c,\varphi} < 1$ discussed in respect of eq. (38) also supports this hypothesis.

Thus for a quantitative interpretation of the experimental pressures the relationship $\alpha_K = \varphi^*/\varphi$ must be assumed, *i.e.*

a strong dependence of α on concentration. As the usually assumed decrease of α over the whole concentration range to $\alpha=1$ in the melt is much smaller, this concentration dependence does not suffice to explain the osmotic pressure.

It is possible that entanglements exert their effect even at concentrations below φ^* thus influencing the second virial coefficients A_2 of the osmotic pressure. Specifically, it is remarkable that, according to Table 2 and Figure 17 (where it is designated by d/c), the reduced osmotic pressure p_{os}/φ is greater than $\lim_{\varphi\to 0} p_{os}/\varphi$ by the same percentage, independently of the solvent efficiency at the same φ/φ^*. In fact, theories of the excluded volume do not take into account the conformation restrictions due to contacts between two chains or distant chain fragments, at least not explicitly. The parameter χ_1 derived from A_2 or from the expansion factor α_0 (in dilute solutions) may therefore contain an entropy contribution due to conformational disturbances.

8. Abnormal Effects of Entanglement at Very High Concentrations

At concentrations above 20 % conformational changes may be subject to hindrance[114], which has not been discussed above. At large entanglement numbers N_v the distance of the ends of the network chains of the entanglement network is greater than the distance between spatially neighboring network junctions, in polystyrene for example 1.4×10^{-6} cm as opposed to 0.45×10^{-6} cm (see Fig. 5). Consequently, the $m-1$ subchains of a chain cannot be arranged as freely as is assumed in eq. (27).

It is not easy to calculate the hindrance[21c], so it must be estimated[114]. Starting from one entanglement (network junction) a network chain (Z_c segments) passes through several (namely n) lattice planes of such disturbing network junctions. The twelve nearest neighbors divide the totality of spatial directions into g groups of directions of almost equal size. The network chain decides in favor of one of them and thus reduces the number of its possible conformations to the fraction $1/g$. It carries out this limitation $n=(M_c/M^*)-1$ times, so that the numerator in eq. (27) must be increased by the factor g^n. M^* is the molecular weight of a coiled chain fragment whose ends have the same distance as the spatially neighboring network junctions.

Reckoning that network junctions acting in this way may include both the entanglement points N_v and, to a smaller degree (factor $j<1$), the $n/2$ quasi-network points assigned to the n segments of the network chains, we obtain

$$N_{v,\mathrm{eff}}=N_v(1+jn/2) \tag{42}$$

and the distance separating the ends of the chain fragments of molecular weight M^* becomes:

$$h^*=K_{h,\theta}M^{*1/2}=\frac{l}{N_v^{1/3}(1+jn/2)^{1/3}} \tag{43}$$

For $j\ll 1$, therefore:

$$n=M_{c,1}{}^{1/3}\times(\rho N_A/2)^{2/3}\times K_{h\theta}^2\times\frac{\varphi^{2/3}}{[f(\varphi)]^{1/3}}=n_1\times\frac{\varphi^{2/3}}{[f(\varphi)]^{1/3}} \tag{44a}$$

and for $j=1$:

$$n=\frac{M_{c,1}\times(\rho N_A/2)^2\times K_{h,\theta}^6\times\varphi^2}{(j/2)^2 f(\varphi)}=n_1\times\frac{\varphi^2}{f(\varphi)} \tag{44b}$$

The number n is then introduced into eq. (31), giving:

$$S_\varphi=kN_2\{\ln\omega_0+(m\varphi-1)[\ln 0.074-1.5\ln(Z/m\varphi)-\ln\alpha_{c,\varphi}^3-n\ln g]\} \tag{45}$$

The bracket at $G_{r,\varphi}$ in eq. (35) then receives for $jn/2\ll 1$ a term proportional to

$$\varphi^{2/3}/[f(\varphi)]^{1/3}\approx\varphi^{1/3}$$

and for $jn/2\gg 1$ a term that is proportional to φ[114].

As a result, p_{os} now increases more steeply with φ than the second term in eq. (35) would lead us to expect. In addition, at high φ the first term in eq. (35) has a large influence on p_{os}, independently of the value of the parameter χ_1.

The n portions of the network chains which may disturb the conformational changes of the chains need not also act elastically, at least not at small deformations where the number n is not altered by deformation. Figures 9 and 19 show that at very high concentrations the experimentally determined relaxation modulus has an almost normal dependence on concentration, and thus it is not possible to draw any conclusions about the conformational hindrance considered here from measurements of elasticity.

9. Final Remarks

The concept of entanglement of thread molecules is confirmed by many experimental findings and lucidly explains some important properties of melts and concentrated solutions, *i.e.* of noncrystalline systems.

Chain entanglement certainly also occurs in partially crystalline polymers. This explains why polymers that have been stretched, *i.e.* deformed in the crystalline state, shrink on melting: the sample regains the form that it had before being stretched. The entanglement network has clearly withstood the crystallization and the deformation of the partially crystalline material and on melting appears as a deformed network with a restoring force corresponding to its modulus G_r [see eq. (13)] and the deformation due to stretching.

Some effects of entanglement still remain to be treated more precisely—*e.g.* those occurring in phase separation, in intramolecularly cross-linked molecules (the effect of cross-linking so far observed for such cases is surprisingly small[120]), and in the chemical reactivity of the groups and structure components (*e.g.* double bonds) situated at entanglement positions.

In any event, in discussions of the properties of polymers it should always be borne in mind that entanglement can strongly affect the properties of soft polymers and solutions.

Flexible Drug Molecules and Dynamic Receptors[**]

By R. J. P. Williams[*]

When a small flexible drug molecule binds to its likewise mobile receptor (protein, membrane *etc.*) the shape and function of both can change. The study of the nature and extent of these changes by several independent methods gives an insight into the mode of action of drugs. The static lock and key model will most probably have to be revised or be replaced by the nebulous concept of dynamic states.

1. Introduction

The basic problem of drug action in biological systems is easily formulated. In order to interact with a biological system any drug must first bind and may then react, whence a comprehensive minimal two-stage reaction path can be written

$$D + L \underset{k_b}{\overset{k_f}{\rightleftarrows}} DL \xrightarrow{k_{DL}} D^1L^1 \ldots \quad (1)$$

where D is the drug which undergoes a rapid reversible binding to a biological receptor L, *i.e.* a protein, DNA, RNA or a membrane *etc.*, giving DL. This reaction has an equilibrium binding constant

$$\frac{k_f}{k_b} = K_{DL} = [DL]/[D][L]$$

and there can be many successive steps of this kind before the 'final' binding condition is reached. The second step in the above simplified scheme [eq. (1)], which may or may not be a required part of action, is an irreversible chemical combination of D in the form D^1 with a part of the biological system L^1, where L^1 may be a protein, RNA, DNA, a membrane *etc.* which has incorporated D (or D^1). L and L^1 could be the same receptor site of course. The reaction rate constant in its simplest form is a first order rate constant, k_{DL}, but again many such steps could be involved.

My analysis of drug action will be based upon the structural features of these reaction paths starting from the structures of D and L themselves. By structural features I imply the whole series of conformational states through which the two species D and L must go in order to reach some final state DL or D^1L^1. Recently the nature of such pathways has been stressed by *Feeney, Roberts* and *Burgen*[1], who were motivated by their observations, using nuclear magnetic resonance (NMR) spectroscopy, on the mobility of certain drug and hormone molecules. My independent and parallel interest in the problem of conformational mobility has arisen through studies of both small and large molecules in solution also using sophisticated NMR methods for conformational analysis. In the past the solution structures of D and L (which

[**] This article is based on the Merck, Sharp and Dohme Scientific Lecture 1976 given in London. It was also given in outline at the Belgian Chemical Society Meeting in Namur, 1976.

are the ones to be discussed in a drug/receptor interaction) have often been assumed to be known once X-ray *crystal* structures had been completed. This approach ignores the statistical occupancy and the time dependencies of many different conformations of a molecule in solution and may well have led to over-precise thinking about the general need for structural fitting, *e.g.* as in the notions of lock-and-key and induced fit. Examples illustrate the point.

The study of different penicillins in the crystalline state by X-ray crystallography showed that there were two possible ring conformers and that different substituents on the four-membered ring led to a switch from one conformation to the other (Fig. 1). We have studied the conformation of some of the same penicillins in aqueous solution by NMR probe

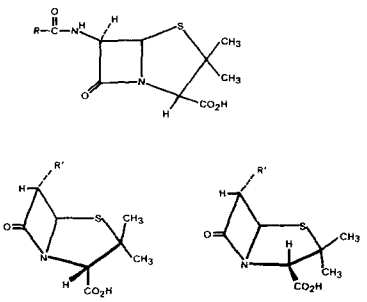

Fig. 1. General formula of penicillins; spatial arrangement of the atoms in crystalline penicillin G and ampicillin.

methods[2] but our results show clearly that there is little if any dependence of structure of the penicillins in solution on substitution of its rings (see Fig. 1). We also noted that the data suggested that although one conformation was dominant there was a smaller percentage of the other conformation in fast equilibrium with it. In principle the rate constants for conformational flipping of the molecules could have been determined too. We are forced to ask which particular structure if any is important for drug action and, has the nature and rate of conformational mobility an importance of its own?

A rather general inspection of drug molecules shows in fact that only a limited number of drugs have rigid frames and obviously their conformations in the bound state are easily described from crystal or solution studies (but see below). In all other cases there are different conformations open to the drug molecule and these may well be in rapid equilibrium, as in the case of the penicillins. We need to consider the relative energies of these different conformations (open to the drug in the unbound state) since, presuming that only a limited set of the conformational forms are bound by the receptor, there is a population bias against the drug being bound in these forms in direct proportion to the probability of achieving the limited conformation set in the free state. Drug design might then be based partly on fitting, but if we are dealing with a conformationally mobile drug, partly on the restriction of conformational freedom of the (free) drug. However, this last approach could fail too for the very flexibility of the drug might also be an unavoidable requirement in order to achieve final binding or reaction, and in this case a knowledge of the conformational mobility of the drug would be essential in an understanding of action. In the above Scheme [eq. (1)] certain steps, k_f, would represent necessary movements on the way to a final binding site—a wriggling of the drug to a 'best' site. Drug design might have to be based on selected dynamic properties of a molecular frame as well as upon the possibility of providing a particular structure to fit a supposedly rigid receptor. Finally it will be shown in this article that the large molecules which form receptors are not necessarily more rigid than the small molecule drugs, and the same statistical fluctuations and time-dependent changes must be analyzed for them. This motion also has an influence upon the constants in eq. (1).

The obvious need for a careful analysis of the mobilities of drugs and receptors before indulging in a discussion of their interaction leads me to turn away from drug action for a while and to describe recently obtained knowledge of structures in solution and of the dynamics of these molecular conformations.

2. General Comments about Rigidity of Small Molecules in Solution

Apart from the conformations of penicillins in solution we have examined the conformations of a series of amino-acids, some small peptides, some sugars, and a series of nucleotides, where there is obviously a much greater variety of possible mobility[3,4]. The general impression gained from these studies is that even though there must be mobility in the small molecules (rotation about single bonds with limited steric hindrance) certain "conformational families" or a very small set of families peculiar to each group of molecules in turn are overwhelmingly favored, possibly through the solvation by water. A family of conformations is to be thought of as a relatively small group of structures related to one another by minor changes in bond angles. We can illustrate the point by reference to the simple nucleotides but rather than making direct reference to the deduced nucleotide conformations, derived from NMR spectroscopic data, I shall use a comparison of the experimental NMR information so that experiment and interpretation are not confused.

Our experimental procedure starts from an examination and an assignment of the NMR spectrum of a molecule in solution in as much detail as possible. This means that each ^1H, ^{13}C, ^{31}P, ^{19}F nucleus in the molecule is studied as far as is possible, but here I shall describe ^1H-NMR data in large part. These spectra in themselves contain coupling constant data derived from spectral fine structure and the coupling constants are related to the relative position in space of coupled protons. For example, in such a system of atoms as $C(H^1)$—$C(H^2)$ the geometric relationship of H^1 and H^2 can be uncovered. Restrictions upon free rotation about C—C bonds are then obvious in a qualitative and sometimes in a semi-quantitative way. Again proton relaxation times of the spectral signals can be used to calculate the non-bonded H—H distances and further data on small local regions of the conformation comes from the study of the nuclear Overhauser effect. All these methods have been used for some time by a large number of research workers. The considerable extension of the conformational analysis which we have made is to examine the NMR spectra of the small molecule in the presence of bound (in fast exchange) paramagnetic ions (see Fig. 2). The NMR spectra are found to be perturbed in two ways: 1) shifts of absorption lines (δ) arise if the paramagnetic center has

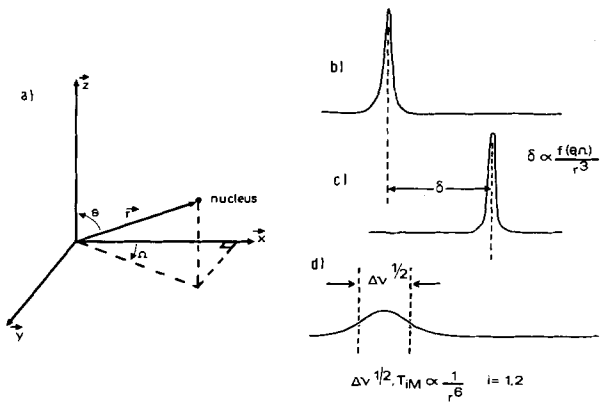

Fig. 2. The effect of a paramagnetic reagent placed at the origin of space (a) upon the line position (shift b→c) and line of width (broadening b→d) of an NMR spectrum (see ref. [3]). The broadening of lines is directly related to T_{2m}, and the shift is given as δ for the most general rhombic field case. In an axial field, $\Omega = 0$.

a fast electron relaxation time; 2) changes in relaxation time, *e.g.* broadening of lines *(B)* arise when the paramagnetic center has a long electron relaxation time. The equations

$$\delta = A(3\cos^2\theta - 1)/r^3 \tag{2}$$

$$B = C\ \frac{1}{r^6} \tag{3}$$

show that δ is a vector quantity depending upon the distance, r, of the nucleus under inspection from the paramagnetic probe atom, and upon the angle θ between the principal axis of the paramagnetic probe and the direction from probe to the nucleus (see Fig. 2), while B is a scalar quantity. In the equations A and C are constants independent of the nucleus under study. (The above shift equation [eq. (2)] assumes that the bound paramagnetic ion generates an axially symmetric magnetic field. Details of the methods and measurements which allow the field to be so defined are given elsewhere[3].) Let us assume that the site of binding of the paramagnetic ion to the molecule under study can be determined (which is the case), then these shift and relaxation measurements give directly a set of conformational parameters, δ and B, just as coupling constants are conformational parameters and they can be used empirically as comparative molecular conformation data on very many different atoms which are separated by considerable distances. Of course all the different NMR methods add together to give the largest number of conformational parameters, and together should be used in the definition of structure[*].

[*] All NMR methods provide data which refer to the average conformation. It is a matter of convenience whether we search to describe the average in terms of a single conformation with non-idealized bond-lengths and bond angles [2, 3, 5] or in terms of combinations of two, or three, or four idealized conformations *etc.* It has often been the case that averaged conformations have been analyzed using sums of two or three conformers where the contributing conformers introduced are those suggested by theoretical energy calculations in the gas phase. As shown by *Feeney et al.* [7] it is always possible to fit NMR data by such a procedure. Even though it is certain that better fits of experimental parameters can be obtained by using such semi-theoretical approaches, since larger numbers of variables are introduced, than using single conformation fitting the fit must be suspect as the theory does not apply to solvated species. Thus it is essential that many *independent* methods are used to check structural representations of molecules in solution, *e.g.* coupling constants, relaxation data, shift data, and nuclear Overhauser effects, using first *one* and only later combinations of *two* conformations.

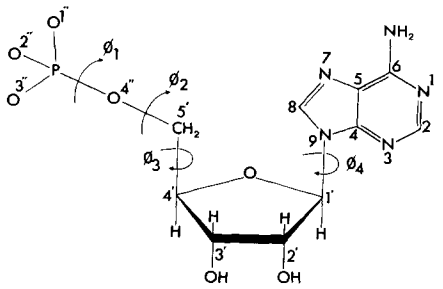

Fig. 3. 5'-Adenosine monophosphate (5'-AMP); bonds about which there is apparent free rotation are indicated by arrows.

Table 1. NMR shifts (δ) of nucleotide sugar protons by lanthanoid(III)-containing probes given as the ratio $R = \delta(i\text{-H})/\delta(5'\text{-H})$ [9] [see Fig. 2, Fig. 3 and Eq. (2)].

Nucleotide	pH	$R = \delta(i\text{-H})/\delta(5'\text{-H})$			
		i = 1'	i = 2'	i = 3'	i = 4'
5'AMP	2.0	0.09	0.24	0.40	0.32
	7.6	0.09	0.26	0.38	0.34
5'-GMP	9.0	0.11	0.27	0.38	0.33
5'-CMP	2.0	0.10	0.20	0.40	0.32
	7.6	0.08	0.21	0.38	0.31
5'-UMP	2.0	0.07	0.20	0.38	0.32
	7.6	0.08	0.25	0.37	0.32
5'-d-TMP	2.3	0.08	0.30	0.37	0.35

Table 1 gives shift data for the protons of some nucleotides (Fig. 3). The observed shift δ(*i*-H) of the NMR signal of a proton *i*-H due to presence of a bound lanthanide(III) ion is expressed by the ratio R of this observed shift relative to the shift of a chosen proton, here δ(5'-H) of the 5'-H proton (see Fig. 2). The paramagnetic lanthanide ions have been used to generate the shifts but a wide variety of reagents can be employed. A striking result is that, almost within experimental error limits, all the nucleotides give the same set of conformation parameters. Broadening (relaxation) and coupling constant data are also almost invariant which can only mean that independent of the base (pyrimidine or purine) and of the sugar (oxy- or deoxyribose), the general conformational outline of nucleotide (including mobility averaging) is fixed, and it is surprisingly closely related to the single conformation observed in crystals. (As an aside we observed that although the crystal structures of deoxy- and oxy-uracil monophosphate were different from that of deoxy- and oxy-cytidine monophosphate this difference was not seen in solution and it may well be that the difference seen is an "artefact" of crystallization as in the case of the penicillin.) These results were deduced independently from coupling constant data alone by *Sundaralingam*[6] who has gone so far as to state that the nucleotides must be relatively rigid in solution.

As there is clearly a high degree of constraint in the mobility of these molecules the relative stability of the observed (averaged) set of conformations seen in these nucleotides must be due in part to the nature of water as a solvent. If we change solvent we observe a different stable conformational family. In dimethyl sulfoxide the (average) conformation of the nucleotide monomers is different from that found in water, and in some aqueous systems we find that even salt and denaturants such as urea also affect the conformations of small molecules, as indicated by probe measurements[3]. We

note that receptor sites may be very unlike water in their "solvation" properties and may prefer energetically a quite different conformational family from that found in aqueous solution. All these data tell us nothing about the nature of other non-preferred conformations or the rate of flipping to lowly populated conformational states, although we may presume this flipping is fast since we see no separate signals for different states (but of course we do not know that such states of low probability exist). In fact many conformations widely different from those determined by NMR methods of analysis could be reached and for 1 % of the time almost any conformation X could be present and it would go undetected by these solution methods. However, if X is the desired conformation for action there is then a factor of 100 against its formation for this particular molecule and it must be possible to build a better molecule, drug, for binding alone where this mobility factor is considerably reduced.

The implications of these findings for the study of drugs is simple but has not been clearly stated before:

1. Only for those drugs which have *rigid* frames (Table 2), are we able to neglect mobility, but even here we must consider the aqueous (or other) solvation environment. For example our study of cyclic 3',5'-adenosine monophosphate (3',5'-cAMP) gave the same structure for the two rings containing the phosphate and the sugar (X-ray structure analysis), and we may assume that this frame is relatively rigid[8]. The

Table 2. Rigid and flexible drug molecules [a].

Relatively rigid	Flexible	Moderately flexible
Quinine (Many alkaloids)	Straight-chain alcohols	Penicillins Chloramphenicol
	Nitrogen mustards (*N*-methylbis(2-chloroethyl)amine) and derivatives	
Sulfonamides		Streptomycin
	Linear polypeptides	
Steroids		Mepacrine
Tetracyclines		Phenothiazine
Morphine		Nicotine
Cocaine		

[a] It is of great interest to make molecular models of drugs and attempt to visualize the number of different static and dynamic modes of action which they could have.

receptor could bind exactly this frame, but just because the hydration remains unknown it is conceivable that it is the hydrated form of the molecule which generates action when the stereochemistry of the receptor site can *not* be deduced from the solution or crystal structure studies of the small molecule.

2. Other drug molecules may be much more mobile (Table 2); for example, we have been unable to determine a "structure" for 2',3'-cAMP by our methods, a fact which suggests that the NMR data can not be represented by a single conformation family[9]. For such a molecule (drug) which has considerable mobility between two or more rather different conformational families knowledge of the conformations observed in crystals or in solution is of much more limited value for we do not know not only the hydration but which or how many conformationally different steps are required in each of the steps of equation (1), and we do not know which are the important conformations in the final condition. The problem becomes even more serious as we turn to molecules of increasing size, and we note that it is not just a problem of drug binding alone but is perhaps a general feature of biological activity.

3. From our studies, the orientation of the base in 3',5'-cAMP is clearly not fixed relative to the two rings of the cyclic system to the same degree as was found in the simple nucleotides 5'- or 3'-AMP[8]. Thus it may be easy for this part of 3',5'-cAMP to wriggle or corkscrew its way to a required binding site, receptor. Thus, whether a molecule binds or not can depend upon whether it can reach a certain site or not, for the receptor site need not be on an open surface[**]. Impressions as to the importance of molecular dynamics for drug action are strongly supported by the inspection of hormones.

2.1. Hormones and Peptide Hormones

On first inspection it is surprising that small molecules such as adrenaline, 5-hydroxytryptamine, and acetylcholine should be used as hormones and transmitters, for these molecules contain only a very small rigid unit—if they contain a rigid unit at all—and rather few sites (*e.g.* —OH or $-NH_2$ groups) by which they can be recognized selectively. The molecules also contain some bonds about which rotation is relatively easy. Given the requirement for virtually specific action of a hormone a much more rigid molecule would seem to be appropriate. However, if we consider that a molecule has to "wriggle" to reach its site of action then rapid on/off reactions using a series of different conformations could be required[1]. Thus as above a compromise may be reached between a good match of hormone and binding surface in some final state and a mobility required in order to reach the site. This compromise will include a loss of some binding capability which is governed by the adverse statistical weighting of conformers in free and bound forms. It is not easy to work out an optimum system for such fast and selective binding but, as it may be that the actual binding site is closely related to the heavily weighted conformation in solution, it will still pay in designing drugs which compete with hormones or transmitters to try first conformational matching with these states.

It is remarkable too how many larger hormones are not like 3,5'-cAMP or sterols, which must have very limited conformational mobilities. Instead many of them are apparently disordered linear polymers ranging from tripeptides to higher peptides such as glucagon, which have molecular weights

[**] A change of attitude may now be required on the part of chemists who are engaged in the design of drug molecules. The outline "shape" of a molecule, at 0 K, when examined by instantaneous methods (time constant $< 10^{-13}$ s) will conform to bond angle and bond length predictions based upon our knowledge of simple molecules such as methane. However for a mobile molecule/mobile receptor interaction it could well be that a rather different space-filling model would be more appropriate: for example, methane would become a simple ball and an indole ring would be represented by a flattened spinning disc. Dynamics in these cases involves rotational movement about various axes, but no translation. However, translation could also be important and perhaps we should seek for tunnels and channels in receptors which may have gates at which "wriggling" motions may be involved in site interactions. The shape of these channels must be such that given wriggling the whole molecule can pass through, but such a shape is clearly not closely related to any single molecular structure.

of >10000. These molecules must be flexible to a very high degree, and in fact this mobility has been confirmed by NMR measurements. The longer the chain of these hormones the smaller the probability of a correct matching between the hormone and receptor assuming that the receptor recognizes all the hormone. It would seem that fast action should then belong to small or rigid hormone molecules while slower action, but perhaps very highly selective control, should belong to longer flexible molecules, all static and dynamic ways of achieving selectivity having then been found (Table 3).

Table 3. Naturally occurring rigid and flexible small molecules and hormones [a].

Relatively rigid	Flexible	Moderately flexible
Alkaloids	Spermine	Vassopressin
Sterols	Glutathione	Oxytocin
Auxins	Corticotropins (ACTH)	Nucleotides
Thyroxine	Releasing hormone	Vitamins E and K
Trypsin inhibitor	Many lipids	Bacetracin
Heme	Glucagon	Folic acid
Coenzyme B_{12}	Melanocyte-stimulating hormones	Polysaccharides ATP

[a] It is assumed that steric hindrance as in thyroxine, ring formation as in vasopressin, and cross-linking as in the trypsin inhibitor make a part of a molecule effectively rigid.

Particularly interesting in this respect is the recent work on insulin, which illustrates conformational mobility of at least one tenth of the peptide[10]. Here it is the cooperative effect of metal ion and anion binding, at different sites, which causes a rearrangement of the peptide. Using NMR methods we have confirmed that a corresponding conformational switch of insulin occurs in solution with addition of the same reagents[11]. The changes are anion-, cation- (*i. e.* salt) and temperature-dependent. This result throws doubt again on the detailed use of crystal structures in the discussion of the action of such hormones—except for the regions of immobilized (rigid) surface (see the trypsin inhibitor in Section 2.2). The observations can also be used to describe the synergism of two small-molecule "drugs", here X^+ (Zn^{2+}) and Y^- (Cl^- or I^-), on a receptor surface (insulin) when it is seen that there can be large conformational effects in some regions of the large molecule and that also general changes may occur to a smaller degree over larger regions of the molecule (see Section 2.2).

2.2. Small Molecules: Summary

Table 3 lists a variety of molecules found in biological systems. Apart from peptides and polynucleotides[9,12] we have looked at such molecules as adenosine triphosphate (ATP)[13] and vitamin B_{12}[14] by the same conformational methods using paramagnetic probes. In the last two cases the structures found in solution are again relatively closely related to those in the solid state and we class these molecules as largely rigid. Other molecules such as polyamines and long chain fatty acids must have a much greater mobility and Table 3 puts them into a different group. Not all control peptide molecules of higher molecular weight are of the mobile kind such as is glucagon. The nature of the trypsin inhibitors which are quite large peptides but not simple linear polymers and which must act rapidly, suggest that they are rather rigid, for their —S—S cross-links and internal β-pleated sheet restrict the conformation very greatly[15,16]. The rigidity of the trypsin inhibitor is shown too by the fact that even some of the aromatic residues of amino-acid side chains do not flip freely despite the fact that this is a small molecule[16]. We stress that the possible combinations of rigid and flexible elements can lead to all kinds of intermediate behavior and different parts of large molecules can behave differently.

3. The Receptor Site: Introduction

The approach in the discussion of the structure of the receptor must be the same as that used in the study of small molecules. We must go from an examination of constrained molecules in crystals or free molecules in the solution phase to a semi-speculative knowledge of a receptor geometry and dynamics. Now we suspect that receptor sites are particular regions of proteins, DNA, RNA, membranes or polysacchar-

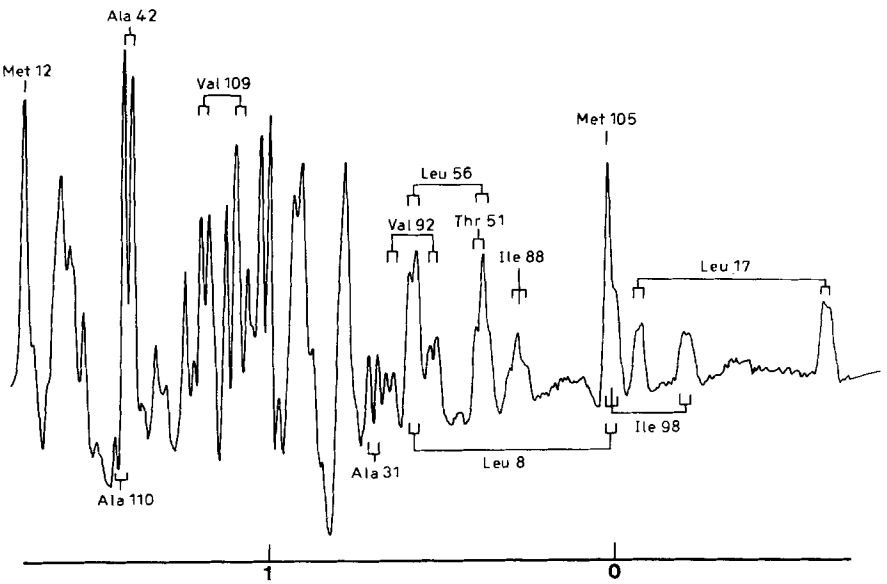

Fig. 4. Part of the ^{1}H-NMR spectrum of lysozyme with assignments (methyl groups in the given amino acids).

ides. What can we say about the structure of such large molecules in biological systems? First we turn to the examination of the nature of these large molecules in solution.

3.1. Proteins as Flexible Molecules

In the last few years, 1974—77, a change away from rigid pictures of the conformation of macromolecules has developed. We pioneered these studies in so far as the use of high resolution ^{1}H-NMR spectroscopy on proteins was concerned[17] (Fig. 4), while parallel work by *Sykes* and by *Wüthrich*[16] was underway on peptides, and many authors were carrying out ^{13}C-NMR studies. In other work a variety of techniques[18, 19] have been employed which also demonstrate motion, such as oxygen quenching of fluorescence and hydrogen exchange, but this work is restricted to the general discussion of the protein and it has not been possible to locate the mobility within the protein sequence. Our work shows clearly the nature of the motions and how they are distributed within proteins. The types of motion observed are:

1. Rotation and libration (sometimes restricted) about certain single bonds internal to the protein.
2. High mobility of protein side-chains on the surface.
3. General mobility of (hydrophobic) groups internal to proteins (breathing).
4. Occasional segmental movements of the main chain.
5. Some proteins are quite generally mobile *i.e.* close to random coil polymers. Table 4 gives some details of these motions.

Table 4. Protein motion.

Type of Motion	Observation
Expansion (Vibration)	Temperature dependence of ring current shifts relaxation times
Fast segmental motion	Insulin: transitions Heme: resonances (hemoglobin)
Surface motion	Lysine: correlation times
Slow motion of side chains	Tryptophan: oscillation Phenylalanine and tyrosine: flip Temperature dependence of resonance positions
Random coil motions	Relaxation times

3.2. Segmental Motion: Summary

In some proteins we must suppose that a part of the protein may be mobile while another part is not and that these parts can be of quite diverse sizes for different proteins[20–22]. *Vallee et al.* have stressed the mobility of the active site region of carboxypeptidase in solution[23] and it would appear that the effect is seen even in the crystals. This mobility effects a relatively small back-bone change, comparable with the type of change which occurs on the binding of oxygen to hemoglobin when the FG region undergoes perturbation. In the meantime quite a number of proteins have been examined and they would appear to fall into very different classes of behavior. Lysozyme, peroxidases, peptidases, carbonic anhydrase and cytochrome c show least conformational change of the main frame; kinases, concanavalin A, colicin Ia, and hemoglobin show rather larger changes; histones, chromagranin A, and phosvitin are very adaptable, flexible, chains (Table 5). Thus it seems that large molecules (receptors) show the same range of flexibility as small molecules. There must be some very rigid systems and some very mobile ones and all intermediate behavior patterns will emerge.

Table 5. Rigid and flexible large molecules [a].

Relatively rigid	Flexible	Moderately flexible
Cytochrome c	Phosvitin	Insulin
Neurotoxins [b]	Chromogranin A	DNA-binding proteins
Lysozyme	Histones	t-RNA
Peptidases	Glucagon	Kinases (?)
Nucleases	Myelin protein A. 1.	Antibodies (?)
	Vesiculin	Lipases

[a] Generally, extracellular proteins are rigid and are often crosslinked by S—S bridges. Intracellular proteins are more mobile especially if they are required to equilibrate between bound and unbound states involving DNA, RNA or membrane surfaces.
[b] Personal communication from Prof. *G. Petsko.*

The case of cytochrome c is of great interest[21]. Although it is known that the two oxidation states of cytochrome c have different physical properties *e.g.* solubility and chromatographic mobility we have been unable to detect differences in the interior of the molecule in the two oxidation states in solution. A similar result has been found in crystals. However we do observe that the binding of various anionic and cationic reagents on the surface of cytochrome c is different in the two oxidation states which proves that their surface energies are changed by the change in charge on the iron. Change in surface energy will be reflected by change in charge, conformation, and hydration, but present methods do not detect the surface states readily. Even so it is these surface states which will be important in protein/protein and at least initially in drug/protein interactions.

4. Small Molecule/Protein (Drug/Receptor) Combination

This article has stressed dynamic features of both drugs and receptors where drugs have been likened to many types of small molecules and receptors to many types of large polymers or assemblies. In discussing the combination of drug with receptor it is the dynamic features which we wish to keep to the forefront, although we realize that static matching has a very important and proven role to play. The discussion will proceed through examples, but before proceeding to these examples the states of the receptor and small molecule must be visualized as they approach one another. All the evidence provided above indicates that the small molecule will be fluctuating very rapidly between at best a small number of similar conformations and at worst a complete spectrum of very different states. The receptor surface may be equally mobile—especially in the case of sugars and lysines—but in other regions, pockets and grooves, may show limited mobility. An agonist drug might bind and then pass through these mobile regions, in some cases going to a site much deeper in the receptor while other, antagonist, molecules may just block access of the agonist to the deep-seated site. From here on we examine the bound drug/receptor sites.

4.1. Lysozyme-Saccharide Reactions

The "receptor site" of lysozyme is the enzyme binding groove for substrate. It is lined with readily recognizable (by NMR) tryptophan residues (Fig. 5), and it is these groups which we can follow most readily during the binding of the saccharide[24,25]. The NMR method is fast enough to follow steps which occur with time constants of $\leq 10^{-4}$ s, and its specificity allows a precise statement as to which groups move and, if sufficient care is taken, the movement itself can be defined with some precision (Fig. 6).

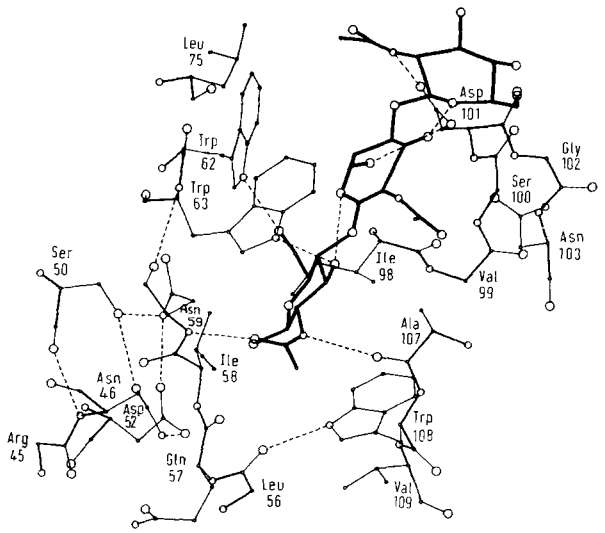

Fig. 5. The lysozyme pocket showing the binding of a trisaccharide (after [25]).

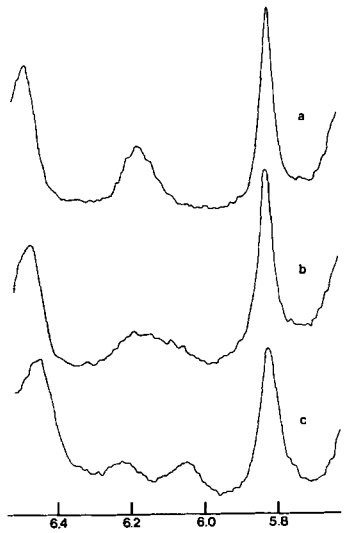

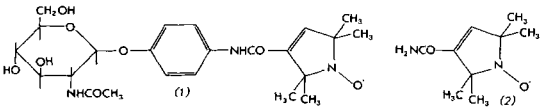

Fig. 6. Aromatic ^{1}H-NMR spectral region of hen lysozyme (3 mmol/l) at pH 5.3 in the presence of tris(*N*-acetylglucosamine) (4 mmol/l) showing the effect of temperature on the tryptophan $>$NH resonances at a) 37 °C, b) 45 °C, c) 55 °C.

In the initial state there is present say the disaccharide bis(*N*-acetylglucosamine), which is a semi-mobile molecule but which may well be largely constrained by interaction with water, so that perhaps 95 % of the molecules belong to a small family of conformers. The protein lysozyme has a groove which is undergoing some dynamic motion including fast motion of side chains such as valines and the slow movement of the tryptophans (see Fig. 10). In other words the two molecules generate a set of geometries, some compatible and some incompatible, and on binding they settle down into the final energetically most favorable bound state, which—as we have shown—has rather less mobility. The overall binding reaction path is then a succession of conformational states

$$E+S \rightarrow \sum ES(1) \rightarrow \sum ES(2) \rightarrow$$
$$\text{final state } (\textstyle\sum \text{ final conformations})$$

where the sum sign, Σ, covers all the dynamic states of a species. It is the dynamic nature of the initial and intermediate states of the reaction sequence which allows all the steps to the final condition to be rapid[24]. The observed greater rigidity in the last step (or stages) means that the reverse process, the first dissociation step, may have a slow step as its initial step. Ignoring the consequences of this description as far as enzyme action is concerned we note here that an inhibitor of the enzyme could be a molecule which reaches states $\Sigma ES(1)$ or $\Sigma ES(2)$ but cannot go through to the final state for reaction, when the inhibitor need not be a very good match for a substrate so long as it binds. As an almost trivial example CN^- is a very strong poison (drug) when it replaces O_2 in heme proteins. Sulfonamides do not match CO_2 or HCO_3^- very well but they bind in the pocket of carbonic anhydrase in place of CO_2. Thus the match of enzyme and substrate is not highly restricted and we visualize a series of poor, moderate and good matches to different states of the enzyme groove. A very interesting test of this situation has been observed by accident.

We wished to study the surface of lysozyme using the spin-labeled substrate 3-[4-(2-deoxy-2-acetylamino-1-glucosyloxy)-phenylcarbamoyl]-2,2,5,5-tetramethyl-3-pyrrolin-1-oxyl *(1)*[26]. However, we found that the binding was not through the *N*-acetylglucosamine moiety, which is a portion of the natural substrate, but was directly to the spin-label itself which binds in site C. The fit can not be perfect but the binding of the spin-label molecule *(2)* by itself, which was tested as a result of the above finding, showed that it is bound better than *N*-acetylglucosamine! Thus by accident a potential inhibitor (drug) has been uncovered which is chemically unlike the substrate but binds better than the substrate analog. No examination of the spin-label molecule *(2)* and the *N*-acetylglucosamine would have suggested the parallel. Detailed inspection of possible protein surfaces and the geometry of a molecule such as *N*-acetylglucosamine or even more so a steroid reveals how difficult it is for an enzyme to match precisely the space-filling and bonding capabilities of a substrate or a drug. Restricted mobility of the surface then becomes a very great advantage in assisting good (not excellent) matching. In fact I believe the matching has been rather over-stressed, for all that is required is good, relatively specific, *binding* and that the *kinetics* of this binding should be under control. In both respects mobility is highly valuable (Fig. 7).

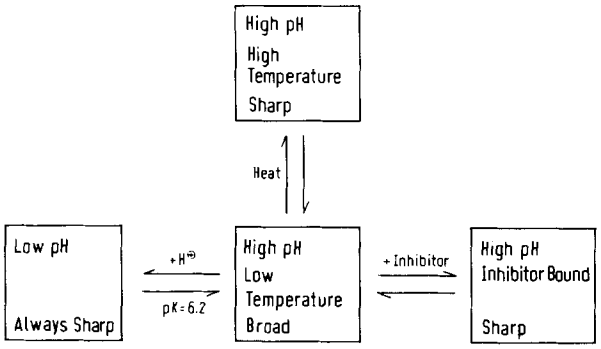

Fig. 7. Active center of lysozyme [25]. Overall survey of the conformational states of lysozyme in solution. Each block represents a conformational state and the linewidths referred to are those of the ^{1}H-NMR spectrum.

A somewhat more extensive rearrangement is seen on binding saccharides to concanavalin A[27]. Here binding results in such changes to the protein structure that two complete crystal structure analyses (protein with sugar and protein without sugar) were required. No evidence is available about the dynamics of the protein in this case. Note that here too a carefully labeled reagent, 1-(*o*-iodophenyl)-β-D-glucopyranoside, designed to find the sugar binding site, actually became bound to an abnormal site.

Another example of mobility at a receptor site has been uncovered by *Burgen et al.*[28]. They observed that the absorption spectrum of carbonic anhydrase (as the cobalt(II) enzyme) was changed by the addition of sulfonamides. The change is consistent with the reaction

$$\underset{\text{distorted geometry}}{\text{Co(II)(base}^-\text{)}} + \text{sulfonamide} \rightarrow \underset{\text{tetrahedral geometry}}{\text{Co(II)(sulfonamide}^-\text{)}}$$

for the 3- and 4-substituted sulfonamides; but the 2-substituted sulfonamide complex has an absorption spectrum lying between these extremes and thus indicating an "intermediate" geometry at the cobalt. There is general agreement that the metal site in carbonic anhydrases can flick between different coordination states. Although only a small change is apparent this metalloenzyme is comparable with such enzymes as peroxidase and cytochrome P-450 in that the coordination sphere of the metal is sensitive to drug binding (see also Table 6).

Table 6. Changes in metalloenzymes due to drug binding.

Enzyme	Metal	Drug	Change
Cytochrome P-450	Iron(III)	Sterol	Low-spin ⟷ high-spin
Peroxidase	Iron(III)	3-Indolepropionic acid	*g*-value changes
(Myoglobin	Iron(III)	HgI_3^-	Low-spin ⟷ high-spin)
(Hemoglobin	Iron(III)	Xe 1,3-di-phosphoglycerate	Low-spin ⟷ high-spin)
Carbonic anhydrase	Cobalt(II) [Zinc(II)]	Sulfonamides	Distortion of tetrahedral coordination

4.2. Peroxidase-Substrate Complexes

The complexes of peroxidase with substrates can be readily studied since some of the substrates—indoles and phenols—have NMR spectra which are easy to interpret. The indole ring is a rigid frame and we have examined such frames extensively in simple complexes, showing for example how they form plane-to-plane stacked molecular complexes with porphyrins[29]. We then used these methods in the study of peroxidase complexes[30].

Peroxidases are very large glycoproteins which have some obvious mobile features such as the saccharide side chains. In the native state they are high-spin Fe^{III} enzymes. Reaction with cyanide converts them into the low-spin state, whereas reaction with azide gives a mixture of the two forms (low-spin ⇄ high-spin) in equilibrium. *On the NMR time-scale* all these states

$$\text{Native (largely high-spin)} \rightleftharpoons \text{Azide (high-spin)} \rightleftharpoons \text{Azide (low-spin)}$$

are rapidly in equilibrium so that both the on/off reactions of azide and the spin-changes are very fast. In fact there is probably present some 5% of low-spin state in the native enzyme, as is the case in myoglobin and hemoglobin. As shown in Figure 8, high-spin and low-spin Fe^{III} heme complexes have rather different structures. We must suppose that iron(III) oscillates rapidly between the different states and that the protein chain linked directly to the iron through the proximal histidine also undergoes rapid changes[22, 31].

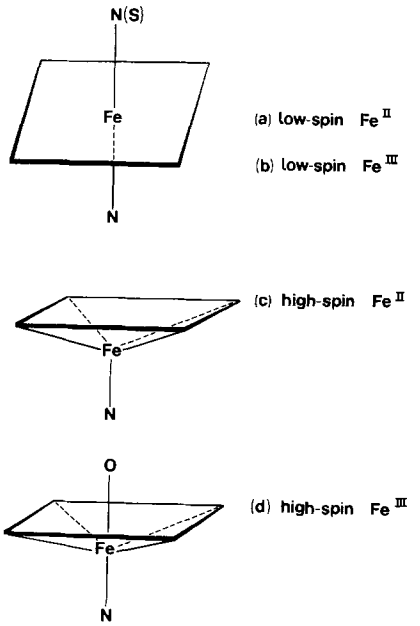

Fig. 8. Stereochemistry of the heme iron spin-states.

When an aromatic substrate binds to the protein it does not form a plane-to-plane stacked molecular complex like in the model reactions with porphyrins. Taking peroxidase complexes of 3-indolepropionic acid as an example we find that the indole system lies as is shown in Figure 9[30]. The indole derivative is bound only by weak Van der Waals interactions in the pocket of the enzyme. Binding of other substrates is in the same pocket but the relationship between these substrates and their binding sites and between the indoles and their binding sites differ considerably. We conclude that the site of binding is more like a small *mobile* oily pool than a lock and key fit. Thus it is anticipated that a large number of organic chemicals can act as inhibitors of these

enzymes. Maybe enzymes for detoxification behave in this rather general way, for similar features can be seen in the binding sites of cytochrome P-450 and of alcohol dehydrogenases.

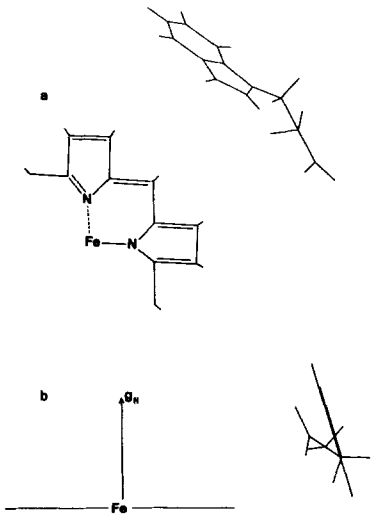

Fig. 9. The peroxidase complex of indolepropionic acid showing the disposition of heme and substrate, (a) and (b) are orthogonal views.

Now these oily pools in the proteins for taking up substrates need not be immediately accessible to the small molecules and it would be very interesting to observe exactly the time course of approach to the final state of binding. An inhibitor or a drug could act at any of the approach stages, or it could act indirectly by preventing the conversion of one form of a protein into another. Again it does not appear that the mobility within the oily drop is much altered by the insertion of the substrate even though the substrate binding affects the iron(III) site somewhat.

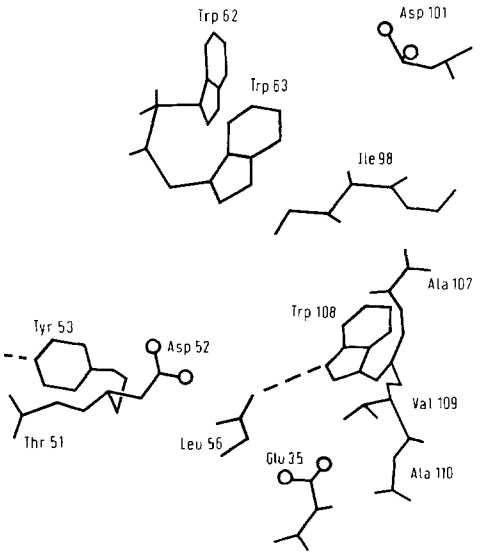
A good example of the wriggling of a group to reach such an "oily-drop" binding site is the uptake of the hydrophobic anion HgI_3^- into myoglobin. The binding site as observed by X-ray crystallography is at the back of the heme. There are gross restrictions to movement in this region of the protein and even quite small ligands cannot bind to the iron itself for this region of space is designed to accept oxygen only. We have studied the effect of the uptake of HgI_3^- on the properties of the Fe(III) form of myoglobin and have shown that there is a small change in the spin-state equilibrium (high-spin $\rightleftarrows$ low-spin) on binding. Thus the binding group (drug), here HgI_3^-, has to wriggle through the protein to its binding center where it alters the conformation of the protein slightly. Uptake of xenon (a very large atom) must take place by similar wriggling. Again the effects of oxygen on the fluorescence of proteins demand a similar conformational mobility allowing access by wriggling.

It is of interest to see how such binding could adjust the chemistry of the receptor. In the β-chains of hemoglobin[32] there is a sulfydryl group FG (β-93) which is on the helix which carries the Fe-linked histidine (proximal). *Perutz* has shown that the degree to which this sulfydryl is exposed depends upon the spin-state of the iron, for change of spin-state causes rotation of the helix. Thus we have the following dependencies: a) drug bound—more low-spin Fe, exposed —SH; b) drug absent—more high-spin Fe, hidden —SH.

The *effect* of a drug can occur (i) at its immediate site which may be a long way from the iron, *i.e.* 1,3-diphosphoglycerate, (ii) at the iron by way of the spin-state change—a considerable relay, (iii) at the —SH group which is an even greater distance away. Antagonists could block these processes while agonists could potentiate them in a quite different way. Moreover, there are several very different reagents which can act on the same process, *i.e.* O_2 uptake by hemoglobin, by binding at totally different sites, *e.g.* 1,3-diphosphoglycerate, xenon, HgI_3^-, CO, and sulfydryl reagents. The very different chemical behavior of these reagents as compared with O_2, the substrate which the drug challenges, shows that drug design can be quite impossibly difficult. Note too that it is the mobility of the receptor, here hemoglobin, which is responsible for all these different "drug" effects.

4.3. Wriggling and Gating

Another illustration of this "wriggling" principle can be given by examining again the mobility exhibited by the binding groove of lysozyme (Fig. 10). This groove contains two aminodicarboxylate residues, Glu 35 and Asp 52, of which Glu



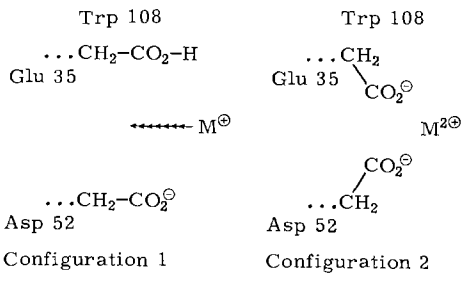


Fig. 10. The active site region of lysozyme; section of the crystal structure. *All* the amino acid residues can be detected in the NMR spectrum.

35 is held in the protonated form, against Trp 108. If a cation is bound in this region of the groove it may interact with sufficient strength that Glu 35 is ionized, and the resulting carboxylate group moves away from Trp 108 (configuration 2 in Scheme 1). In the case of weakly interacting cations this movement does not occur (configuration 1). We can therefore distinguish strongly interacting and weakly interacting cations. Now let us suppose that exactly the same structural relationship of two carboxylate groups occurs, not in lysozyme, but in a region of space *behind* which there is a second binding site for the cation. In the case of strong interaction (configuration 2) the actual binding at the two carboxylate centers would prevent (gate) access to this site. In the case of weak interaction (configuration 1) binding at the rear site would occur as the gate would remain open. Clearly the cations could act in very different ways. Gated reactions will always be associated with wriggling paths. Of course the same pattern can be imagined for the action of a cation such as acetylcholine.

Scheme 1

Another example concerns the passage of an ion, *e.g.* Li^+, through a membrane using an ionophore. There is a binding on/off reaction of metal and ionophore followed by a release. There is also an outward directed ion pump and we may suppose a site of action for Li^+ say in competition with Ca^{2+} or Mg^{2+}. It must be seen that the ionophore-governed steps are very important in the overall effect of lithium.

As we have stated above the mobility of the surfaces of proteins is much greater than that of the internal regions. Our measurements show that surface lysine and sugar side chains (in glycoproteins) have motions with correlation times of 10^{-9} s, *i.e.* as fast as collision diffusion rates. In an assembly of proteins there must be a pathway between the protein molecules which is diffusion restricted by the constraints imposed by the packing of the mobile side chains. The general point can be visualized from an examination of packing of proteins in crystals. Examination of these crystals shows that between protein molecules there are large channels of "disordered" solvent and protein side chains. Inhibitors and other quite large groups such as heavy atom labels diffuse down these channels quite readily to binding sites. But quite clearly there are restrictions on this diffusion which can be of almost any degree of selectivity. Thus only certain molecules will be able to reach particular regions of proteins in an assembly. It is possible to describe this as a "gating" of (drug) action, and the actual motion as "wriggling" to a site. The importance of this mobility of proteins extends to the binding reaction when an antibody combines with an antigen. *Huber et al.*[15] have suggested that the Fc fragment of the antibody is relatively mobile so that it changes conformation on receiving the antigen.

4.4. More Complicated Receptors

A protein or a group of proteins may or may not be the receptor site of a drug. Rather a drug may act on a similar type of large molecule, *e.g.* RNA or DNA, or it could act at a membrane or similar condensed phase. The effect of small molecules on a condensed phase should now be examined in the same way as we have examined their effect on large molecules. The parallels between these problems has been described in a recent review on phases in biological systems[33]. We use lipid phases, membranes, as an example.

4.5. Membranes

Fast tumbling of groups such as we have described in proteins is observed in artificial vesicle membranes of most lipids. For example lecithin vesicles give a high resolution NMR spectrum which shows that motion must be fast for the $-N(CH_3)_3^+$ group on the head and the methyl group on the tail of the fatty acid chains but is somewhat slower for the region around the glycerol group. When the size of the vesicle is changed or other molecules incorporated into it, or the temperature changed, or ions bound to the surface, these mobilities can undergo quite considerable changes. Turning to biological membranes we and others have observed that the ^{1}H-NMR spectrum of almost all *cell* membranes is very broad, even for membranes which contain a high percentage of lecithin, and it is not possible to detect in the NMR spectrum either the choline group on the head or the methyl group on the tail of the fatty acid chains. It is readily shown that inclusion of such molecules as cholesterol in the bilipid layer will cause a general reduction of the motion of the lipid sections of the molecule but the head-group remains free. We are therefore left with the problem that there are gross restrictions on mobility in real biological membranes which are not seen in vesicles. This restriction could be related to size, curvature of membrane surface, or to the binding of the head-groups.

The membrane lipids are also in rapid lateral motion, *i.e.* in the plane of the membrane. Inversion of lipids is however relatively slow; hence the membrane retains its asymmetry. The time scale for lateral movement is not vastly different from diffusion and it has frequently been supposed that drugs can influence this motion. The inversion has a time constant in the range of minutes. Thus although inversion is not important in any steady-state change and return, which takes place within seconds, the steady-state itself can change in response to ambient conditions. We proposed some years ago that it would be interesting to study this asymmetry with the paramagnetic binding probes, but the first actual study was made independently in Russia[34, 35]. A major problem—as in the study of proteins—was (and still is) the question of the structure and the structural dynamics of the membrane and what chemical factors control the dynamics. To this end we looked at the binding of probe ions to a variety of phosphate esters including phosphatidylcholines.

The first feature of binding is that the metal ions do not bind to the phosphate of a membrane phosphatidylcholine in the same way as they bind to phosphate esters such as phosphoglycerolcholine in water. If we use our standard procedures for the study of biological molecules we obtain the structure shown in Figure 11, in which the choline head-group stretches away from the bilipid membrane to a large degree. The result need not be analyzed in great detail, for there is surely much motion, but it is important to observe that the head-group of a lipid in a membrane does not behave in the same way as the dissociated free head-group, say phosphoglycerolcholine, behaves in aqueous solution. Secondly, the binding strength of cations at the two membrane surfaces (inside and outside) is not equal. Thirdly, as the cations bind selectively to different phospholipids they generate asymmetry in the membrane if their concentrations are different on the two sides of the membrane[36]. The effect of the metal binding on the mobility of the membrane has not yet been assessed. However, it will be recognized immediately that the action of a chemical (drug) on such a system is not likely to be dependent upon any one simple factor. Thus as with protein receptors we anticipate that an extremely complicated story

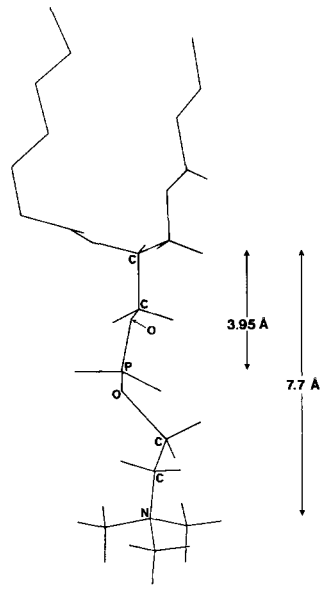

Fig. 11. The structure of phosphatidylcholine. Note that this structure has considerable mobility, and is for a cation-bound condition.

lies behind the drug action. Though it may be possible to follow drug-protein binding atom by atom, this possibility does not really exist in a membrane phase and we may have to be content with a more phenomonological functional thermodynamic approach. This would mean that drug design would remain very empirical. For example, fluidity in a cooperative liquid is open to a phase change of the sol ⇄ gel kind and it could be that a small quantity of an impurity could shift the sol ⇄ gel equilibrium and thus change the dynamics of the phase dramatically.

4.6. Mobility of Bound States

The conclusion seems inevitable that just as all degrees of molecular motion are to be found in drugs (small molecules) and in receptors (proteins, RNA, membranes) so in their combination we shall find all kinds of mobilities (Fig. 12), for the binding site of a drug can vary from a condition in which the best model is a molecule held on a rigid crystalline material to one in which the drug has partitioned from water into an organic medium. There cannot be a general theory of drug action, for this description covers the whole of solid state and solution chemistry with its wide variety of interactions which are expressed quantitatively only in terms of free energy changes. Recently we have been using NMR to examine whole organs and have found a remarkable variety of mobilities in different phases[37]. However, these features of cells cannot be discussed at length here; but in conclusion it should be pointed out that we must contend with many new problems when dealing with added chemicals (drugs) which can affect mobility, and static solid state models of fitting the geometry and chemistry of one surface to another may have to be supplanted by the more nebulous concepts of dynamic (solution) states.

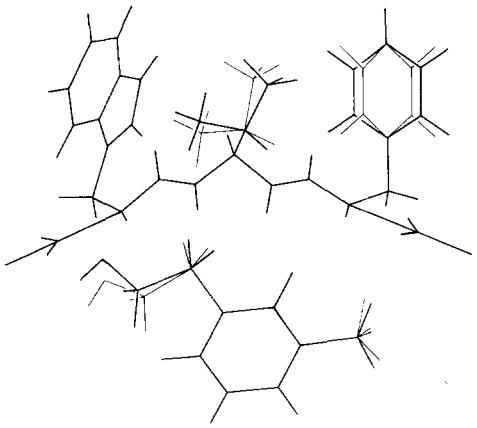

Fig. 12. Schematic diagram for a mobile protein (linked by arrows)—mobile drug interaction.

The work described in this article was made possible by grants from the Science and Medical Research Councils, England. The author wishes to acknowledge the great help he has received from fellow members of The Oxford Enzyme Group and from his students.

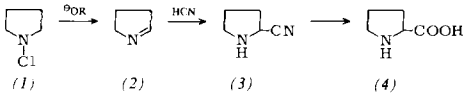
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



Simple Synthesis of Racemic Proline

By *Ulrich Schmidt* and *Hans Poisel*[*]

Dedicated to Professor Engelbert Broda on the occasion of his 65th birthday

Racemic proline has so far only been accessible by time-consuming multi-step syntheses[1]. We have now found a simple synthetic pathway starting from pyrrolidine:

N-Chlorination, preferably with *tert*-butyl hypochlorite, leads to *N*-chloropyrrolidine *(1)* which is not isolated but instead reacted directly with sodium methoxide to give 1-pyrroline *(2)*. This product trimerizes even in solution within a few hours and cannot be isolated[2]. However, we found it to be sufficiently stable in dilute solution to add reactive compounds. Hydrogen cyanide adds smoothly to 1-pyrroline to form the nitrile *(3)* whose hydrolysis affords racemic proline

(1) *(2)* *(3)* *(4)*

(4) in about 45% yield (based on pyrrolidine).

Hydrogen chloride must be eliminated from the *N*-chloropyrrolidine *(1)* prior to addition of hydrogen cyanide; direct reaction of *(1)* with cyanide in alkaline solution yields *N*-pyrrolidinecarbonitrile. For large scale preparations it is recommended that chlorination of the pyrrolidine be carried out in the two-phase system: ether (or toluene)/aqueous hypochlorite solution.

Racemic proline (4)

Pyrrolidine (7.1 g, 0.10 mol) and *tert*-butyl hypochlorite (12.0 g, 0.11 mol) are simultaneously added dropwise to stirred, ice-cooled ether (100 ml). After 5 min the colorless solution is extracted once with dilute HCl and twice with a small volume of water. The mixture is dried with sodium sulfate, treated with sodium (2.76 g, 0.12 mol) in methanol (70 ml) and refluxed for 25 min, whereupon NaCl is precipitated. After cooling, a solution of anhydrous hydrogen cyanide (10 ml, 0.26 mol) in ether (10 ml) is added and reaction allowed to continue overnight at room temperature. The solvent is removed in a rotary evaporator and the residue dissolved in methylene chloride, washed twice with water, and dried with sodium sulfate. Vacuum distillation yields 5.6 g (58%) of *(3)*, b. p. 77 °C/12 torr.—Compound *(3)* (5.5 g) is heated with 19% aqueous hydrochloric acid (100 ml) for 14 h at 100 °C in a bomb tube. After evaporation of the acid the residue is dissolved in water and decolorized with animal charcoal. After concentration the product is dried over sulfuric acid. Esterification of the salt mixture by *Fischer*'s method with HCl/ethanol affords 6.6 g (81%) of D,L-proline ethyl ester which is allowed to stand overnight with 20 ml of water. Removal of solvent leaves 5.0 g [76% based on *(3)*] of D,L-proline *(4)*.

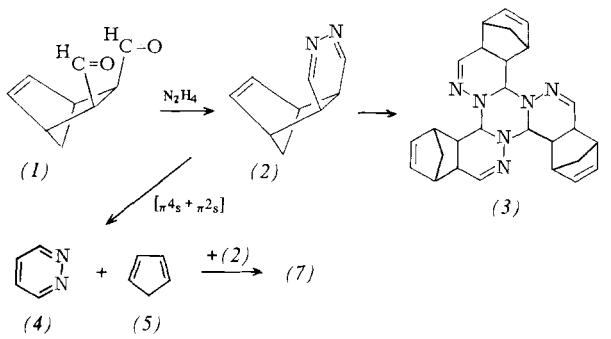
Photochemical [2+2] Cycloaddition between Parallel CC and NN Double Bonds[**]



By *Wilfried Berning* and *Siegfried Hünig*[*]

Rigid polycyclic compounds containing two parallel C=C bonds are well known and their chemistry, particularly photochemical [2+2] cycloaddition to cage compounds, has been

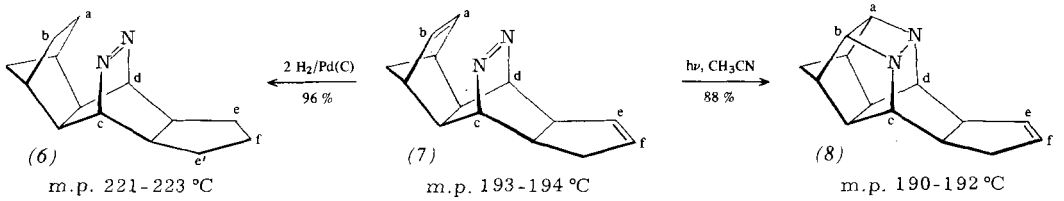
[**] From the dissertation by *W. Berning*, Universität Würzburg 1977. This work was supported by the Fonds der Chemischen Industrie and the BASF AG, Ludwigshafen.



the subject of numerous investigations[1]. We now wish to report on the rigid molecule *(7)*, in which a C=C bond and an N=N bond are oriented parallel and spatially very close to each other. *(7)* is formed in 91 % yield according to the stoichiometry $2(1)+2N_2H_4 \rightarrow (4)+(7)$. Addition of hydrazine hydrochloride to a solution of the aldehyde *(1)*[2]

in 1 % acetic acid leads to almost instantaneous precipitation of *(7)* as colorless crystals. The expected amount of pyridazine *(4)* can be isolated from the concentrated filtrate. The reaction most likely proceeds as follows: The initially formed azine *(2)* suffers a $[\pi 4_s+\pi 2_s]$ cycloreversion generating cyclopentadiene *(5)* and *(4)*. Related cycloreversions proceed under similarly mild conditions[3]. In a Diels-Alder reaction with inverse electron demand further available *(2)* then adds to *(5)*, a particularly active dienophile in this case[4], to give the product *(7)*. Protonation of *(2)* could increase its activity still further. Evidence for this is provided by the fact that under neutral conditions the cleavage $(2) \rightarrow (4)+(5)$ does not take place and *(2)* trimerizes to the hexahydrotriazine *(3)*[5], which is transformed into *(7)* only in an acidic medium.

(7) can be smoothly hydrogenated to the saturated azo compound *(6)*. In *(6)* the *cis* azo group shows UV data resembling those of 2,3-diazabicyclo[2.2.2]oct-2-ene[6], whereas in *(7)* an interaction typical for parallel CC double bonds[1] is observed to take place between the two unsaturated groups (Table 1). The strong π-π interaction between parallel C=C and N=N bonds is also clearly discernable in the photoelectron spectrum[7a]. As is usual in the case of alicyclic azo compounds[8], *(6)* liberates nitrogen on heating or irradiation, giving unidentified products. In contrast, *(7)*, which is thermally stable up to *ca.* 250 °C, undergoes ring closure almost quantitatively on irradiation in acetonitrile to give *(8)*, and the typical UV absorption of the azo group disappears. Thus, not only a new type of cage compound has been formed but also the first $[\pi 2_s+\pi 2_s]$ photocyclization between non-activated C=C and N=N bonds has been accomplished which previously always failed because of rapid elimination of nitrogen.

A detailed analysis of the ^{1}H- and ^{13}C-NMR spectra[7b] confirms the structure and configuration of *(6)*—*(8)*[7c]. The signals for the positions a through f in *(6)*—*(8)* are especially characteristic (Table 1): In *(7)* the resonances of H_c, H_d and C_c, C_d appear in the typical region for NMR absorptions of H and C atoms in the α-position to an azo group[9a]; and as expected for an asymmetric compound two signals appear for each of these atoms. The anisotropy effect of the azo group gives rise to a distinct upfield shift for H_a, H_b (cf. norbornene: $\delta = 5.95$[9b]), while H_e, H_f are influenced to a somewhat lesser extent (cf. cyclopentene: $\delta = 5.60$[9b]). After elimination of the intramolecular interactions in the cage compound *(8)* the signals of H_e, H_f appear at lower field. Consistent with the required C_s symmetry of the hydrogenated compound *(6)* H_c, H_d and C_c, C_d respectively show only one signal; magnetic equivalence of C_a, C_b and C_e, $C_{e'}$ is likewise observed. The ^{1}H-NMR spectrum of *(8)* exhibits a new signal at $\delta = 4.2$ which is assigned to the diazetidine protons H_a, H_b (best comparable example in the literature: 4.35[10]). Furthermore, in *(8)* the signals of C_a, C_b appear at lower field in the aliphatic region, thus indicating their close proximity to the nitrogens.

A New Synthesis of Pyrimidines and Pyrimidinones[**]

By *R. L. N. Harris* and *J. L. Huppatz*[*]

N-Alkyl-2-cyanamides *(1)* undergo self-condensation on prolonged heating in $POCl_3$ to give the pyrimidines *(3)*. An intermediate in this reaction was thought to be the α-chloroenamine *(2)*[1]. We have now found that these intermediates are suitable substrates for an alternative pyrimidine synthesis in which the other component is itself an amide-acid chloride adduct *(5)*, generated from an *N,N*-dialkylamide *(4)* and $POCl_3$. Thus, reaction of a mixture of the amides *(1)* and *(4)* with $POCl_3$ at 100°C leads to pyrimidines *(6)*. Depending on the nature of R^2, pyrimidinones *(7)* may also be isolated. When the R^2 is a primary alkyl group, it is only partially lost during the condensation and a mixture of pyrimidines and pyrimidinones results. When R^2 is a secondary alkyl group, loss is usually complete and good yields of pyrimidines are obtained (Table 1).

Most conveniently, *N*-cyclohexylamides are used as component *(1)* since they are readily prepared in high yield by gently refluxing together the appropriate ethyl 2-cyanoalkanoate and a slight excess of cyclohexylamine. The esters themselves are obtained by reductive alkylation of ethyl cyanoacetate[2].

The reaction appears to depend for its success on the simultaneous generation of intermediates *(2)* and *(5)*; when the highly reactive amides *(4b)* or *(4c)* are used the reaction fails unless compound *(1)* is heated at 100°C with $POCl_3$ for 5 min before their addition.

Yields are best when R^3 is aryl, when the synthesis complements the usual base-catalyzed routes[3] to compounds *(6)* and *(7)*. The principal limitation is that an alkyl or aryl substituent must be present at the α-carbon of the precursor amide *(1)* (and thus at C-5 of the products) to avoid alternative self-condensation of *(1)*[4].

Experimental:

4,6-Dichloro-2-phenyl-5-propylpyrimidine (6d): Ethyl 2-cyanopentanoate[2] (31 g, 0.2 mol) and cyclohexylamine (21 g, 0.21 mol) were heated under gentle reflux for 5 h. After removal of ethanol and excess cyclohexylamine *in vacuo* (rotary evaporation) the mixture was allowed to cool and the resulting solid amide *(1e)* (40 g, 96 %) used without further purification in the following step. A portion crystallized for analysis from ethanol as colorless needles, m.p. 90—92°C. The foregoing amide *(1e)* (2.1 g, 0.01 mol) and *N,N*-dimethylbenzamide *(4a)* (1.5 g, 0.01 mol) were dissolved in $POCl_3$ (5 ml) and the mixture heated on a steam-bath overnight. The mixture was poured

A Novel Heteroaromatic System: 2,1,3-Benzothiadiazinylium Derivatives[**]

By *Wolfgang Kosbahn* and *Helmut Schäfer*[*]

Analogously to pairs such as benzene/tropylium or thiophene/thiopyrylium, formal ring expansion of the well documented and extremely stable heterocycle 2,1,3-benzothiadiazole ("piazthiol")[1] affords the 2,1,3-benzothiadiazinylium ion *(2)*. We have now succeeded in preparing the first derivatives of this ring system from the benzothiadiazinones *(1)* by directed alkylation at the oxygen:

(1) *(2)*

	X	Y	R
(a)	H	H	CH_3
(b)	H	H	C_2H_5
(c)	Cl	H	C_2H_5
(d)	Cl	Cl	C_2H_5
(e)	NO_2	H	C_2H_5

[*] Dr. habil. W. Kosbahn, Dr. H. Schäfer

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Leibniz-Rechenzentrum München. The results were delivered in part in a lecture at the Chemiedozententagung in Marburg on March 25, 1977.

Like the already known unsubstituted compound *(1ab)*[2], the educts *(1c)* to *(1e)* are obtainable from the corresponding substituted 2-aminobenzamides by reaction with *N,N'*-bis(*p*-toluenesulfonyl)sulfur diimide in chloroform. The reaction with oxonium salts in dichloromethane proceeds at room temperature within a few minutes in the case of *(1ab)*, within a few days in the case of *(1d)*. The products *(2)* can be purified by dissolution in acetone and precipitation with diethyl ether [yields between 13% *(2e)* and 85% *(2a)*]. Their structure follows from the IR, ^{1}H-NMR and, in particular, from the ^{13}C-NMR spectra. Noteworthy is the strong deshielding influence of the N_2S^+ group on the atom C-6 located in the *p*-position; the substituent increment with about +15.5 ppm has almost the same value as the diazonium group[3].

The finely crystalline 2,1,3-benzothiadiazinylium salts *(2)* have decomposition points between 111 and 165 °C; they react slowly with water with evolution of SO_2.

(2b) reacts smoothly at room temperature with 1,3-dienes such as 2,3-dimethylbutadiene, 1,3-pentadiene or isoprene, whereby the double bond between N-1 and S functions as dienophile. The structure of the adducts (isolable in yields of *ca.* 65%) follows above all from the ^{13}C-NMR spectra. The ease of addition and its pronounced regioselectivity can be explained in terms of the frontier orbitals of the reactants: According to PPP and CNDO/S calculations[4] the lowest unoccupied molecular orbital (LUMO) of *(2)*, a π orbital, is almost completely localized on the atoms N-1 and S; this localization, a nodal plane between both atoms and the low energetic state of the LUMO enable optimum interaction with the highest occupied orbital (HOMO) of the diene in the sense of a normal Diels-Alder reaction[5].

Evidence for the "aromaticity"[6] of the new heterocyclic system *(2)* can be gained from its resonance energy. Resonance energies on an HMO basis have recently been re-defined[7]. For *(2)* calculation according to this definition yields a distinctly large resonance energy of 0.313 β (for comparison: naphthalene 0.389 β); the ring system *(2)* can therefore be regarded as being heteroaromatic.

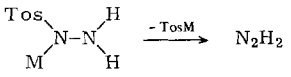
cis- and *trans*-Diazene (Diimine)[1]

By *Nils Wiberg, Gerd Fischer*, and *Heinz Bachhuber*[*]



According to experimental findings[1] and quantum mechanical calculations[2] N_2H_2 can exist in two constitu-

[*] Prof. Dr. N. Wiberg, Dr. G. Fischer, Dr. H. Bachhuber
Institut für Anorganische Chemie der Universität
Meiserstr. 1, D-8000 München 2 (Germany)

tionally isomeric forms, diazene (diimine) and isodiazene (isodiimine); for the diazene two configurationally isomeric forms are conceivable, *trans*- and *cis*-diazene.

As shown by mass spectrometric investigations, in the thermolysis of alkali-metal tosylhydrazides[3] according to

two constitutionally isomeric species N_2H_2[1] are formed depending upon the nature of M and the pretreatment of the tosylhydrazide: lithium, sodium, potassium, and aged cesium tosylhydrazide lead to formation of an energy-poor, yellow N_2H_2 (diazene), which above *ca.* −180 °C mainly disproportionates into nitrogen and hydrazine; freshly prepared cesium tosylhydrazide leads to a colorless N_2H_2 species (isodiazene) which is richer in energy by about 13 kcal/mol (54 kJ/mol), readily isomerizes, and decomposes above *ca.* −240 °C into nitrogen, hydrogen and ammonia. Thermolysis of rubidium tosylhydrazide affords both sorts of N_2H_2.

According to IR spectroscopic measurements the energy-poorer diazene itself occurs in two configurationally isomeric forms. Thus, as we have previously observed, in the thermal decomposition of potassium tosylhydrazide mainly one N_2H_2 form (*cis*-diazene) is produced which on contact with cold surfaces transforms into the other form (*trans*-diazene). If the N_2H_2 gas is passed through a glass tube cooled with 'dry-ice' (−78 °C) onto an IR window cooled with liquid nitrogen (−196 °C) then—according to the IR spectrum—a mixed condensate of both isomers is obtained which, given a short cooling tube, chiefly contains *cis*-diazene, and given a long cooling tube exists mainly as *trans*-diazene. The temperature of the window also plays a role: at lower temperatures the *cis*-diazene is obtained, at higher temperatures the *trans*-diazene.

A typical IR spectrum of the N_2H_2 mixed condensate, which generally contains hydrazine[4] shows—besides bands of N_2H_4 and two further absorptions at 2935 and 2870 cm^{-1} that are possibly due to hydrogen bridge vibrations—two groups of bands which according to number and position[5] are evidently due to vibrations of *trans*- and *cis*-diazene. The intensity of the band for the *trans* isomer increases at the expense of the absorptions of the *cis* isomer if a long cooling tube (up to 10 m)[6] and/or a relatively warm IR window[6] is used (the spectrum of a mixed condensate containing mainly *trans*-diazene is illustrated in [3]), and *vice versa*. Should the changes in the IR spectrum arise merely as a result of differences in molecular aggregation of a configurational isomer then only the condensation temperature, but not the length of the cooling tube, could influence the spectrum of the N_2H_2 condensate.

IR vibration bands of solid diazene and dideuteriodiazene. The underlined wave numbers [cm^{-1}] are assigned to the *trans* form, the remainder to the *cis* form.

N_2H_2: 3116, 3109, 3025, 1347, 1333, 1304
N_2D_2: 2305, 2275, 1517, 1084, 989

Our interpretation of the data is supported by investigations on dideuteriodiazene, which on the grounds of the kinetic isotope effect should have a lower reactivity, *i.e.* a higher thermostability and stability towards isomerization. In fact the thermolysis gas from lithium [D_2]-tosylhydrazide contains astonishingly little N_2D_4[4]; also the low-temperature condensate consists of only one sort of N_2D_2, even after flowing through a longer glass tube cooled to −78 °C: The IR spectrum of the condensate shows only one group of relatively sharp bands, which according to number and position correspond to the *cis* form.

The two configurationally isomeric diazenes are distinguishable only on the basis of the IR spectra, but not the UV or mass spectra. Their electronic structure ought, therefore, to be very similar (cf.[2] and the almost identical electron spectrum of *trans* and *cis* azomethane[7]). Since no difference in the appearance energies of the molecular and fragment ions of the isomers can be detected mass spectrometrically (limit of error: ±1.5 kcal/mol) their energy content might be almost equal. The observed *cis*→*trans* isomerization would of course indicate that the *trans*-diazene is somewhat more stable than the *cis*-diazene. This is consistent with calculations[2], according to which isodiazene is considerably richer, but *cis*-diazene only slightly richer in energy than *trans*-diazene.

[3] *N. Wiberg, G. Fischer, H. Bachhuber*, Chem. Ber. *107*, 1456 (1974).
[4] Owing to the high decomposibility of diazene the thermolysis gas of alkali-metal tosylhydrazides always contains the disproportionation product hydrazine, which can be separated from N_2H_2 only if the gas mixture is passed through very long glass tubes cooled with 'dry ice'.
[5] Considering vibration spectroscopic selection rules, 3 IR active absorptions are expected for *trans*-diazene, 5 for *cis*-diazene.
[6] Because of the decomposibility of diazene the temperature of the IR window should not exceed −180 °C; also the cooling tube should not be too long.

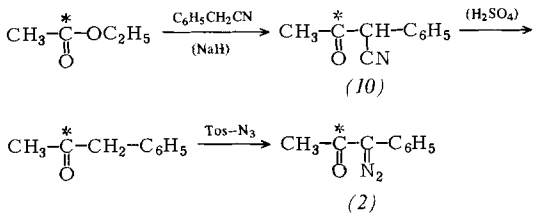
α-Oxocarbene-Oxirene Isomerization: Photolysis of [1-^{13}C]-2-Diazo-1-phenyl-1-propanone and [2-^{13}C]-1-Diazo-1-phenyl-2-propanone[**]

By *Klaus-Peter Zeller*[*]

The carbene-carbene rearrangement of α-oxocarbenes *via* potential antiaromatic oxirenes[1] has been demonstrated on numerous acyclic systems by carbon labeling[2] or competing carbene reactions[3]. Scheme 1 outlines the individual steps on using the labeling technique and the Wolff rearrangement as demonstration reactions.

[*] Priv.-Doz. Dr. K.-P. Zeller
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.



Scheme 1. The α-oxocarbene-oxirene equilibrium as accompanying reaction for the Wolff rearrangement.

If an α-diazoketone labeled on ① or ② [*(1)*, *(2)*] is used as starting compound, a carbene-carbene rearrangement *(3)*⇌*(4)*⇌*(5)* is confirmed when the labeling is distributed over both carbon atoms in the Wolff rearrangement product.

For closer examination of the kinetic model (Scheme 1) both entries to the α-oxocarbene-oxirene equilibrium by photolysis of the isomers, ^{13}C-labeled α-diazopropanones [1-^{13}C]-*(1)* and [2-^{13}C]-*(2)* ($R^1=C_6H_5$, $R^2=CH_3$) have now been monitored.

The diazoketone *(1)* can be obtained from [carbonyl-^{13}C]-benzoyl chloride and excess diazoethane solution[4]: $M^{+\bullet}=m/e$ 161, 84.5% ^{13}C in ①; IR $\tilde{\nu}$ [cm^{-1}]: 2075 (NN), 1570 (^{13}CO). For the synthesis of the isomeric compound *(2)*, [carbonyl-^{13}C]-ethyl acetate is first condensed with benzyl cyanide to give the nitrile *(10)*. Hydrolysis of *(10)* with sulfuric acid affords phenylacetone[5], which reacts with tosyl azide to give the labeled diazoketone *(2)*[6]: $M^{+\bullet}=m/e$ 161, 60.8 % ^{13}C in ②; IR $\tilde{\nu}$ [cm^{-1}] 2070 (NN), 1655 (CO).

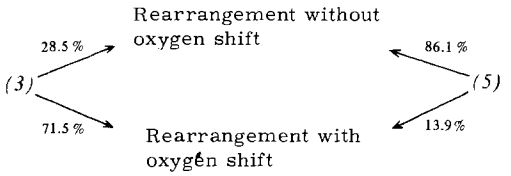
(10)

(2)

Photolysis of *(1)* and *(2)* in aqueous dioxane leads to ^{13}C-labeled 2-phenylpropionic acid *(8)* and *(9)*, respectively, ($R^1=C_6H_5$, $R^2=CH_3$) in which the distribution of ^{13}C over the carboxy group and the tertiary C atom can be determined from the ^{13}C-NMR spectrum and the mass spectrometric fragmentation.

The PFT ^{13}C-NMR spectrum of unlabeled 2-phenylpropionic acid contains signals at δ (rel. TMS)=180.8 (CO_2H), 139.7, 128.6, 127.5 (C_{ar}), 45.3 (CH) and 17.9 (CH_3). The spectrum of the acid obtained from *(1)* shows that *ca.* 60% (irradiation with pyrex-filtered radiation from a Hanovia 450 watt medium-pressure lamp) or 68 % (mercury low-pressure burner) of the label has migrated from ① to ②. The same values are obtained from the intensities of the pronounced $[M-CO_2H]^+$ ions in the mass spectrum (*m/e* 105, C_8H_9 and *m/e* 106, $C_7{}^{13}CH_9$). In the acid obtained from *(2)* the proportion of the label migrating from ② to ① borders on the limit of detection of the two analytical methods.

Table 1. Photolysis of 1.3×10^{-2} M solutions of *(1)* and *(2)* in dioxane/water (13:2) at room temperature and on purging with pure nitrogen.



α-Diazoketone	^{13}C-Labeling	λ [nm]	Proportion of migrated labeling [%] [a]
(1) $R^1=C_6H_5$, $R^2=CH_3$	84.5 % in ①	>290	60.2
		254	68.3
(2) $R^1=C_6H_5$, $R^2=CH_3$	60.8 % in ②	>290	2.8
		254	4.4

[a] Mean value of three ^{13}C-NMR and five mass spectrometric measurements; mean deviation *ca.* ±2.

Consequently, the Wolff rearrangement product formed from *(1)* does not predominantly orginate from the primarily generated α-oxocarbene *(3)* but from the isomeric α-oxocarbene *(5)* formed by oxygen migration. On the other hand, in the photolysis of *(2)* the oxygen atom largely remains on the original carbon atom ②.

This finding points to a complicated dependence of the carbene-carbene rearrangement of α-oxocarbenes on the partial steps k_1 to k_6. The preferred formation of *(7)* [and subsequently of *(9)*], irrespective of whether the α-oxocarbene-oxirene equilibrium proceeds *via* *(1)*→*(3)* or *(2)*→*(5)*, is explained in part by the pronounced migration ability of the methyl group (R^2) compared to the phenyl group (R^1) in the photochemical Wolff rearrangement[1a, 7]. The drastic difference in the proportion of migrated oxygen, however, is only understandable if it is also assumed that the equilibrium *(3)*⇌*(4)*⇌*(5)* is strongly shifted towards *(5)*.

If k_1 and k_2 are summed to $k_{(3)\rightarrow(5)}$ and k_4 ad k_2 to $k_{(5)\rightarrow(3)}$ a kinetic evaluation from the 254 nm photolysis[8] yields the ratio $k_{(3)\rightarrow(5)}/k_5=2.5$ and $k_{(5)\rightarrow(3)}/k_6=0.16$ (cf. Scheme 1). Thence for the carbenes *(3)* and *(5)* we have the following proportions for rearrangement with and without oxygen shift:

An Imino-Bridged Triaza-λ^5-phosphetine[**]

By *Edgar Niecke* and *Hans-Günther Schäfer*[*]

Reaction of *tert*-butyliminodi(isopropyl)aminophosphane[1] *(1)* with *tert*-butyl azide does not lead to the completely alkylated aminodiiminophosphorane *(2)*, but to a thermostable adduct *(3)* having a bicyclic structure.

We presume that *(3)* is formed by intramolecular [2+2] cycloaddition from an intermediate *(4)* corresponding to the Staudinger adducts of tertiary phosphanes and organic azides[2]. Formation of a four-membered ring transition state[3] leading to N_2 elimination is evidently suppressed by electronic and steric effects of the *N*-alkyl substituents.

The imino-bridged triaza-λ^5-phosphetine *(3)* is a yellow crystalline solid (m.p. 78 °C) which is practically insensitive to moisture. The composition and the monomolecularity of the compound in the liquid and gaseous phase are confirmed by elemental analysis, molecular weight determination, and mass spectrum[4]. The bicyclic structure of the adduct with phosphorus-nitrogen double bond in the ring is supported by[5]:

1) the equivalence of the two *tert*-butyl groups in the ^{1}H- and $\{^1H\}^{13}$C-NMR spectrum (Table 1);
2) the chemical shift of the ^{31}P-NMR signal ($\delta = +23.9$; ext. H_3PO_4) in the expected region for nitrogen-substituted phosphorus compounds of coordination number 4;
3) the P=N absorption at 1225 cm^{-1} in the IR spectrum, because of its characteristic position, intensity, and contour.

Temperature dependent ^{1}H- and $\{^1H\}^{13}$C-NMR measurements show that the two isopropyl groups are already anisochronic at room temperature ($T_c = 28$ °C). Model considerations suggest that this finding, evidencing hindered rotation about the phosphorus-nitrogen bond, results from a steric interaction with the *tert*-butyl groups bound to the ring.

Table 1. ^{1}H- and ^{13}C-NMR data [a] of *(3)*.

[**] Part 13 of Investigations on Phosphazenes of Coordination Number 2 and 3. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 12: *E. Niecke, G. Ringel*, Angew. Chem. *89*, 501 (1977); Angew. Chem. Int. Ed. Engl. *16*, 486 (1977).

Procedure

tert-Butyliminodi(isopropyl)aminophosphane *(1)* (4 g, 19.8 mmol) is added dropwise with stirring to a solution of *tert*-butyl azide (4 g, 40.4 mmol) in 20 ml CS_2 under N_2 as protecting gas. The solution turns pale yellow. It is allowed to boil under reflux for 2 h, whereupon it becomes dark-yellow in color. After cooling to room temperature it is stirred for 40 h before the solvent and unconsumed azide are removed by distillation at 0 °C/10 torr. The remaining yellowish brown residue is taken up in 15 ml toluene and recrystallized twice at −78 °C. After 2 hours' drying at 40 °C/0.1 torr an analytically pure product *(3)* is obtained (5.8 g, 95 %).

Simple *de-novo* Synthesis of Reactive Pseudoglycals (Hex-2-enopyranosides)—Stereospecific α-Glycoside Coupling[**]

By *Richard R. Schmidt* and *Rolf Angerbauer*[*]

Pseudoglycals (hex-2-enopyranosides) are valuable key compounds for the synthesis of modified sugars and oligosaccharides[1]. While α-*erythro*-hex-2-enopyranosides and corresponding disaccharides *(1)* are readily accessible by alkoxylating allyl rearrangement of tri-*O*-acetylglucal, the α-*threo* compounds *(2)* can be obtained from tri-*O*-acetylgalactal only in poor yield[2]. We report here on a facile *de-novo* synthesis of compounds of type *(2)* *via* the reactive acetylated α-*threo*-hex-2-enopyranosyluronic acid esters *(3a)*, which can be conveniently converted with alcohols into α-glycosides, *e.g. (3b)* to *(3f)*.

Diels-Alder reaction of *trans,trans*-1,3-butadienylene diacetate[3] with *n*-butyl glyoxylate affords a 1:1 mixture of *(3a)*[4] and *(4a)*[4, 5] in a total yield of 75 %. The β-anomer of *(3a)*, initially formed according to the *cis*-addition principle, com-

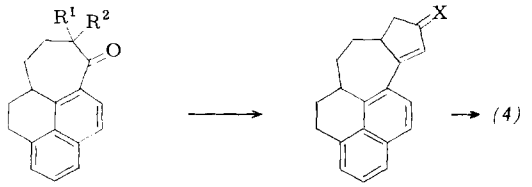
Azuleno[4,5,6-*cd*]phenalene; A Novel Nonalternant Isomer of Benzo[*a*]pyrene[**]

By *Kazuhiro Nakasuji, Eishiro Todo*, and *Ichiro Murata*[*]

Polycyclic arenes such as benzo[*a*]pyrene *(1)*[1] are an important class of carcinogenic compounds. Our interest lies in the area of comparative studies on the properties of *(1)* and its nonalternant isomers. Azuleno[5,6,7-*cd*]phenalene *(2)*[2] is a carcinogen[3], while its nonalternant isomer, azuleno[1,2,3-*cd*]phenalene *(3)*[4], exhibits only weak carcinogenicity[5]. We have now synthesized azuleno[4,5,6-*cd*]phenalene *(4)*, which on account of the topology of its π-electron system [similar to that of *(2)*] and its molecular geometry [which closely resembles that of *(1)*] can be expected to display substantial biological activity.



We selected the pentacyclic alcohol *(10)* as a precursor for our synthesis, reasoning that it might be converted to

Ethoxycarbonylation of the tetracyclic ketone *(5)*[6] ($(C_2H_5O)_2CO$, NaH, diglyme, reflux 2 h) furnished 89% of the oxo ester *(6)*. Reaction of *(6)* with propargyl bromide ($NaOC_2H_5/C_2H_5OH$, reflux 2 h) gave the alkyne *(7)*, which was subjected to hydration in the usual way ($HgSO_4$, H_2SO_4, HOAc, 95 °C, 3 h) to give the diketo ester *(8)* in quantitative yield. Intramolecular aldol condensation (5% aq. KOH, dioxane, reflux 6 h) yielded a mixture of the stereoisomeric cyclopentenones *(9)* which on chromatographic separation (Al_2O_3, benzene) afforded the isomers *(9a)* and *(9b)* in 28% and 43% yield, respectively. Reduction of the mixture *(9)* with $LiAlH_4$ provided a mixture of the cyclopentenols *(10)* in 95% yield. Final conversion of *(10)* into *(4)* was achieved in 18% yield by heating *(10)* with sulfur in trichlorobenzene at 210—220 °C (for properties of intermediates see Table 1).

(11)·CF_3COO^-, ^{1}H-NMR: $\delta = 4.82$ (br. s, 2H), 7.70 (dt, $J = 5.5$ and 1.2 Hz, 1H), 7.75 (dt, $J = 5.5$ and 1.7 Hz, 1H), 8.66—9.62 (m)

(12)·CF_3COO^-, ^{1}H-NMR: $\delta = 4.51$ (br. s, 2H), 7.6—7.9 (m, 2H), 8.66—9.62 (m)

[a] Assignment of previously enumerated signals by double resonance experiments. Irradiation at $\delta = 9.15$ (11-H) and 8.65 (7-H) converted the signals at $\delta = 8.11$ and 7.83, respectively, into singlets. Irradiation at $\delta = 8.35$ (10-H) converted the double doublet at $\delta = 7.66$ into a doublet with $J = 4.0$ Hz.
[b] The stereochemistry has not been investigated.

Azuleno[4,5,6-*cd*]phenalene *(4)* crystallizes as stable green leaflets. Its structure was confirmed by elemental analysis and spectroscopic properties (Table 1). In the electronic spectrum three major bands can be discerned, as in the spectra of *(2)*[2] and *(3)*[4]. Due to the lack of a symmetry axis in *(4)* complete analysis of the ^{1}H-NMR spectrum could not be made.

The diamagnetic susceptibility of *(4)* (measured with a Cahn balance) is $\chi_M = 147 \pm 7$[7] which is comparable with the value found in the case of *(3)*[4].

(11) *(12)*

As would be expected for a compound containing an azulene moiety, *(4)* is markedly basic and is protonated reversibly in degassed trifluoroacetic acid to a mixture of the cations *(11)* and *(12)* in the ratio of 4:1. The preferential formation of *(11)* can be explained by the postulation that relief of the strain associated with a nonbonded interaction between hydrogens H-10 and H-11 of *(4)* provides the driving force for protonation at C-10. The pronounced basicity of *(4)* is attributed to the substantial thermodynamic stability of the cyclohepta[*cd*]phenalenium ion[8].

Studies on the carcinogenicity and mutagenicity of *(4)*, which will provide insight into the biological properties of polycyclic arenes, are currently in progress[9].

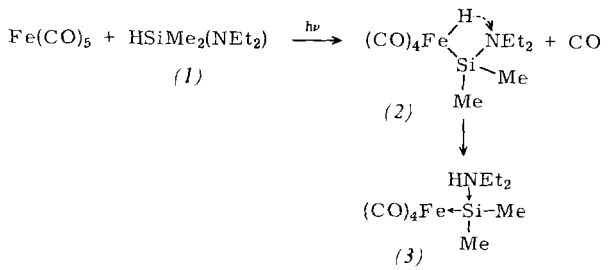
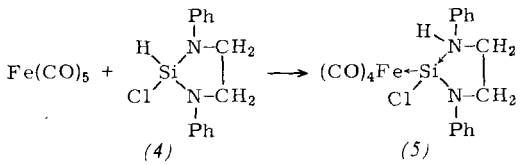
Base-Stabilized Silyleneiron Complexes[1]



By *Günter Schmid* and *Eckhard Welz*[*]

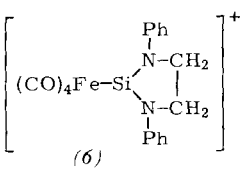
While germylene, stannylene, and plumbylene complexes can be prepared with comparative ease, attempts to synthesize

[*] Prof. Dr. G. Schmid, Dipl.-Chem. E. Welz
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg (Germany)



monomeric silylene complexes have so far met with only very limited success. The instability of divalent silicon and its tendency to assume the coordination number 4 led in most cases to formation of dimeric or trimeric complexes in which the silicon atoms bridge two metal atoms each and therefore fail to show silylene character. The dimeric complex $[(CO)_5WSiI_2]_2$ appears to deviate from this structural principle in that the iodine atoms are responsible for the bridging[2]. Although this complex is monomeric in basic solvents such as tetrahydrofuran, it was not possible to isolate stable $(CO)_5WSiI_2 \cdot B$ (B = basic solvent).

We have now succeeded in isolating the first base-stabilized silylene complexes *via* aminosilyl(carbonyl)iron hydrides.



The silylated tetracarbonyliron hydride *(2)*, accessible from $Fe(CO)_5$ and diethylamino(dimethyl)silane *(1)*, is unstable under the reaction conditions and is transformed into the silylene complex *(3)*. This compound is stable for prolonged periods only at temperatures below −20 °C. The reason for the proton shift from iron to nitrogen in *(2)* lies in the greater basicity of the nitrogen atom compared with the iron.

The reaction can be applied to other aminosilanes, as demonstrated by the formation of the silylene complex *(5)* from $Fe(CO)_5$ and 2-chloro-1,3-diphenyl-1,3-diaza-2-silacyclopentane *(4)*.

Complex *(5)* is likewise stable for extended periods only below −20 °C.

The presence of NH bonds is established by a sharp NH stretching vibration at 3220 cm^{-1} in *(3)* and at 3185 cm^{-1} in *(5)*. In the ν(CO) region there appear [as also in the case of base-stabilized stannylene complexes $(CO)_4FeSnR_2 \cdot B$[3]] essentially three bands, of which that at longest wavelengths is split in the case of *(5)*: *(3)*: 1996 (s), 1900 (s, sh), 1868 cm^{-1} (vs, br.); *(5)*: 2050 (s), 1966 (s), 1925/1896/1880 cm^{-1} (vs). The mass spectrum of *(5)* shows, in addition to the molecular ion at $m/e = 442$ ($I_{rel} = 33.7\,\%$), two characteristic degradation series, one of which corresponds to stepwise elimination of CO as far as FeL^+ (97 %) (L = silylene ligand). The second degradation series begins with the

(6)

elimination of HCl from *(5)* to form the complex ion *(6)* [$m/e = 406$ (26.8 %)] which then likewise undergoes successive loss of CO as far as FeL'^+ (L' = 1,3-diphenyl-1,3-diaza-2-silacyclopent-2-yl) [$m/e = 294$ (97 %)]. The final product of both series is the free silylene cation L'^+ at $m/e = 238$ (100 %). The formation of the fragment $(CO)_4FeL'^+$ and the apparent high stability of the silylene cation L'^+ suggested preparative removal of HCl from *(5)* to form the 1,3-diaza-2-silacyclopentyl complex $(CO)_4FeL'$; however, reaction with amines and with butyllithium merely led to the decomposition of *(5)*.

Procedure

Synthesis of *(3)*: To an ice-cooled solution of Me_2SiHCl (10.5 g, 111.0 mmol) in light petroleum (300 ml) is added dropwise a solution of $HNEt_2$ (16.1 g, 220.1 mmol) in light petroleum (80 ml). After completion of addition, $[Et_2H_2N]Cl$ is filtered off and washed with light petroleum (2 × 40 ml), and the combined filtrates are then reacted with $Fe(CO)_5$ (22.0 g, 109.6 mmol). Upon UV irradiation (150 W mercury vapor immersion lamp) evolution of CO starts immediately. After 3 h, compound *(3)* (3.26 g) could be scratched off the lamp housing and a further crop of *(3)* (1.18 g) could be frozen out of the solution (−20 °C). Total yield: 4.44 g (13 %) of pale yellow, wax-like crystals.

Synthesis of *(5)*: One proceeds as for *(3)*, except that 2-chloro-1,3-diphenyl-1,3-diaza-2-silacyclopentane[4] (27.5 g, 100.0 mmol) is used instead of Me_2SiHCl. Yield: 57 % of *(5)* as a yellow product that is sparingly soluble in light petroleum.

The compositions of *(3)* and *(5)* were confirmed by elemental analyses and molecular weight determinations.

New Aliphatic Thioacylating Reagents; Preparation of *tert*-Butyl Esters of Aliphatic Dithiocarboxylic Acids *via* Bis(thioacyl) Sulfide

By *Shinzi Kato, Takashi Takagi, Tomonori Katada*, and *Masateru Mizuta*[*]

Sterically hindered esters of carboxylic or thiocarboxylic acids are best prepared by reaction of alkali metal alkoxides or thioalkoxides with acyl halides or anhydrides. However, application of this method for the preparation of the dithiocarboxylic acid analogs, particularly esters of type *(1)* (R = alkyl), was limited because of the difficulty of synthesizing aliphatic thioacyl chlorides and the unavailability of the aliphatic bis(thioacyl) sulfides *(3)*. We have now succeeded in preparing compounds *(1)*, like the aromatic analogs[1], from the aliphatic dithiocarboxylic acid and dicyclohexylcarbodimide, but at temperatures below −5 °C (see Table 1).

R = Alkyl

With the thioanhydrides *(1)* and the thiolates *(2)* it was possible to synthesize the sterically hindered esters of type *(3)*. Examples are listed in Table 1. The structures of compounds *(1)* and *(3)* are in accord with the results of elemental analysis, IR, UV, and ^{1}H-NMR spectroscopic data. The $n \rightarrow \pi^*$ band of *(3)* is shifted bathochromically by *ca.* 17—18 nm compared to that of sterically unhindered aliphatic dithioesters.

Experimental

Synthesis of *(3b)*: A solution of *(2)* (2.24 g, 20 mmol) in 10 ml of anhydrous ethanol was added dropwise over 30 min to an ice-cold solution of *(1b)* (cf. [1]) (2.06 g, 10 mmol) in 70 ml of dry n-hexane. After addition, the solution was stirred at room temperature for 5 h, washed with cold water, dried over Na_2SO_4, and then the solvent removed. Distillation of the resulting residue gave analytically pure *tert*-butyl dithioisobutyrate *(3b)*, an orange liquid, in 20% yield.

2,4-Diisopropyl-1,3-dithietane-2,4-diyl Bis(dithioisobutyrate), a Dimeric Form of Bis(thioacyl) Sulfide

By *Shinzi Kato, Akira Hori, Takashi Takagi*, and *Masateru Mizuta*[*]

In a previous paper[1] we described the isolation of bis(thioacyl) sulfides *(1)* (Scheme 1, Route A), which are considered as important intermediates in the cyclization of dithio acids to hexathiaadamantanes *(3)*[2].

We now wish to report the synthesis of 2,4-diisopropyl-1,3-dithietane-2,4-diyl bis(dithioisobutyrate) *(2a)* from dithioisobutyric acid and *tert*-butyl isocyanide (Route B) *via* the thioanhydride *(1a)* and its dimerization. *(2a)* could likewise be an intermediate in thiaadamantane synthesis.

(a), R = i-C_3H_7

Scheme 1

An equimolar amount of *tert*-butyl isocyanide (1.29 g) is added dropwise over 5 min to an ice-cold solution of freshly distilled dithioisobutyric acid (1.86 g, 15.5 mmol) in anhydrous n-hexane (10 ml). The purple reaction mixture turns yellow within 10 min. Fractional recrystallization of the reaction mixture with n-hexane or ether affords an almost quantitative yield (95%) of *N-tert*-butylthioformamide; it was identified by comparison with authentic material. 0.36 g of yellow crystals (m.p. 145—146 °C) could also be isolated, and were shown to be *(2a)* [IR (KBr): $\tilde{\nu} = 1200\ cm^{-1}$; UV (cyclohexane): $\lambda_{max} = 323$ ($\varepsilon = 9600$) and 465 nm ($\varepsilon = 18$); ^{1}H-NMR ($CDCl_3$): δ = 1.05 (d, 6H, CH_3), 1.25 (d, 6H, CH_3), 2.75 (m, 1H, CH), 3.15 (m, 1H, CH); MS: $m/e = 412$ (M^+), 293 (M − i-Pr—CS), 206 (M/2), 174 (M − i-Pr—CS—S), 119 (i-Pr—CS—S), 87 (i-Pr—CS)].

It is interesting that the same yellow compound *(2a)* was obtained in 12.5% yield on stirring bis(dithioisobutyryl) sulfide *(1a)* (2.06 g, 10 mmol) in n-hexane (10 ml) for 5 h at room temperature. This finding and the observation[3] that the UV and visible spectra (in cyclohexane, $\lambda_{max} = 351$ and 517 nm) of the purple solution formed on reaction of dithioisobutyric acid with *tert*-butyl isocyanide were consistent with those of *(1a)*[1a] provide supporting evidence for the formation of *(2)* *via* *(1)*.

Dichloro(porphyrinato)molybdenum(IV)—Synthesis and Structure

By *Tharcis Diebold*, *Bernard Chevrier*, and *Raymond Weiss*[*]

Most of the known porphyrinatomolybdenum derivatives are oxo compounds whose chemistry is dominated by the presence of very strong Mo=O bonding[1]. We now report the synthesis and structural characterization of the non-oxo dichloro(porphyrinato)molybdenum(IV) compounds $MoCl_2(P)$, where P = *meso*-tetra(*p*-tolyl)porphyrinate(2−) (TTP) or octaethylporphyrinate(2−) (OEP). Both compounds represent useful starting materials for the synthesis of other porphyrinatomolybdenum derivatives with a low valency central atom.

Gaseous hydrogen chloride was bubbled into a stirred benzene solution of Mo=O(P) (P = TTP or OEP) under scrupulously oxygen free conditions and at ambient temperature[1b,1c,2]. The dichloro compounds $Mo(Cl)_2P$ were then crystallized from the resulting brown solution by addition of pentane and identified by elemental analysis and by IR and NMR spectroscopy.

The far IR spectra each revealed an intense band at 330 cm^{-1} for the TTP complex and at 268 cm^{-1} for the OEP complex. These bands are ascribed to the asymmetric Mo—Cl vibration; when the dichloro compounds are allowed to react with potassium thiocyanate these bands are replaced by strong absorptions at 2020 cm^{-1} (TTP complex) and 2060 cm^{-1} (OEP complex).

Both dichloro(porphyrinato)molybdenum(IV) compounds are paramagnetic, as evidenced by the fact that their NMR spectra ($CDCl_3$, under argon) show large chemical shifts relative to tetramethylsilane: for the TTP derivative, a singlet (methyl-H) at $\delta = 2.46$, two doublets (phenyl-H) centered at $\delta = 7.71$ and 10.06 ($J = 8$ Hz) and a singlet (pyrrole-H) at $\delta = 17.54$; for the OEP derivative, a singlet (methine-H) at $\delta = -3.70$, a triplet (methyl-H) centered at $\delta = 3.26$ ($J = 7.3$ Hz), and a quadruplet (methylene-H) centered at $\delta = 14.61$ ($J = 7.3$ Hz).

Paramagnetic susceptibilities were measured at room temperature by the NMR method described by *Evans*[3]. The resulting moments μ_{eff}^{corr} of 2.90 μ_B for the TTP derivative and of 2.88 μ_B for the OEP derivative are consistent with a high-spin d^2 molybdenum configuration.

In CH_2Cl_2 each of the two compounds gave four visible absorptions: the TTP complex, at 550 nm ($\varepsilon \times 10^{-3} = 10$), 488 (28), 429 (105), and 360 (42); the OEP complex, at 574 (24), 530 (30), 406 (143), and 354 (57).

Well-formed crystals of the benzene solvate $Mo(Cl)_2TTP \cdot C_6H_6$ were obtained on allowing benzene/pentane solutions of the TTP complex (under argon) to stand for several weeks. These enabled an X-ray structure analysis to be carried out[4], the results of which are shown in Figure 1.

The two chlorine atoms are mutually *trans* relative to the porphyrin ligand, and the Cl(1)—Mo—Cl(2) bond angle is

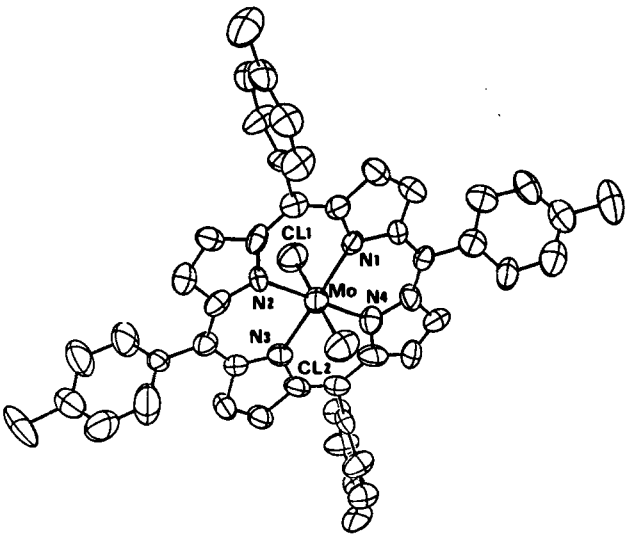

Fig. 1. Crystal structure of dichloro[*meso*-tetra(*p*-tolyl)porphyrinato]molybdenum(IV), $MoCl_2$ (TTP).

178.4(2)°. The mean plane of the four coordinating pyrrole nitrogen atoms contains the molybdenum atom. Coplanarity of molybdenum and nitrogens is also reflected in the angles at the molybdenum atom: ∢ N(1)—Mo—N(3) = 178.4(5)°, ∢ N(2)—Mo—N(4) = 179.3(5)°. The four Mo—N bond lengths are equivalent (2.07 ± 0.02 Å) and compare well with those in $Mo(O_2)_2TTP$[5] [2.096(4) Å] and in $(O{=}MoTTP)_2O$[1d] [2.094(3) Å]. The average bond angles are 90.0(5)° for N(1)—Mo—N(2), 89.6(3)° for Cl(1)—Mo—N, and 90.4(3)° for Cl(2)—Mo—N. Although the chlorine atoms are chemically equivalent, the two Mo—Cl distances appear to be slightly different. Thus the Mo—Cl(1) distance of 2.347(4) Å is longer than the Mo—Cl(2) distance of 2.276(4) Å. We cannot as yet offer a reasonable explanation for this finding.

The bond parameters for the porphinato core are in good agreement with those reported for several metalloporphyrins[6]. The individual pyrrole rings are almost planar. Their planes make dihedral angles of 2.9° (N-1), 3.7° (N-2), 1.6° (N-3) and 4.2° (N-4), respectively, with the mean plane of the four nitrogens. Also small angles of 4—5° occur between adjacent pyrroles. The departures from planarity observed here closely resemble those found in the so-called planar porphyrins and metalloporphyrins[7].

The tolyl groups are tilted with respect to the plane of the three neighboring carbons of the bridge positions between pyrroles; the angles are 83.9°, 78.3°, 85.0° and 65.5°.

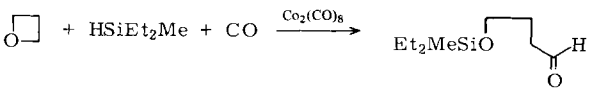
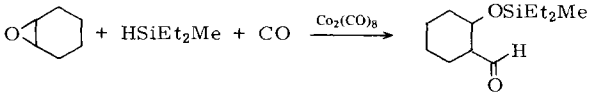
$Co_2(CO)_8$ Catalyzed Reactions of Cyclic Ethers with Hydrosilanes and Carbon Monoxide[1]

By *Yoshio Seki, Shinji Murai, Iwao Yamamoto*, and *Noboru Sonoda*[*]



We recently reported a new reaction of olefins with hydrosilanes and carbon monoxide which leads to enol silyl ethers[2], and resembles that of hydroformylation. To test the applicability of the new hydrosilane reaction to compounds other than olefins, we have studied the reaction of cyclic ethers with hydrosilanes and carbon monoxide.

Hydroformylation of cyclic ethers is known to give hydroxyaldehydes as initial products[3]. The reaction, however, frequently suffers from undesirable side reactions or further reactions, since the hydroxyaldehydes are very labile compounds. For example, hydroformylation of tetrahydrofuran did not afford the expected 4-hydroxybutanal but yielded various products arising from further carbonylation[4], and the hydroformylation of cyclohexene oxide gave only a condensation product of the expected 2-hydroxycyclohexanecarbaldehyde[5].



We have found that the reaction of tetrahydrofuran, oxetane, or 1,2-epoxycyclohexane with diethyl(methyl)silane and carbon monoxide in the presence of a catalytic amount of $Co_2(CO)_8$ gives the silyl-protected hydroxyaldehydes *(1)*—*(3)*, respectively, in reasonable yields[6].

(1), 53%

(2), 40%

(3), 51%

It is interesting to note that *Chalk*[7] has already reported the polymerization of tetrahydrofuran catalyzed by $Co_2(CO)_8$ and triethylsilane (1:2) and proposed opening of the tetrahydrofuran ring by a carbonyl(silyl)cobalt for the initiation step. No polymerization, however, was observed in the present reaction.

Experimental

Synthesis of *(1)*: A solution of 4 ml (50 mmol) of tetrahydrofuran, 1.02 g (10 mmol) of diethyl(methyl)silane, and 0.068 g (0.2 mmol) of $Co_2(CO)_8$ in 20 ml of benzene was placed in a 100 ml stainless steel autoclave. The autoclave was flushed with N_2 (60 kg/cm^2) and CO (60 kg/cm^2), then charged with CO (60 kg/cm^2) and heated at 140°C with stirring. After 20 h, the autoclave was cooled and depressured. Analysis of the reaction mixture by GLC (Silicon OV-1, 5%, on Uniport KS, 3 m × 3 mm, 135°C) with *n*-tetradecane as an internal standard showed it to contain *(1)* in 53% yield. An analytical sample of *(1)* was obtained by fractional distillation (b.p. 120—130°C/30 torr) followed by preparative GLC (Silicon OV-1, 5%, on Uniport KS, 3 m × 8 mm, 140°C).

Tris(*tert*-butylimino)sulfur(VI) and Bis(*tert*-butylimino)(silylimino)sulfur(VI); The "Y-triene" Structure[**]

By *Oskar Glemser, Siegfried Pohl, Frank-M. Tesky*, and *Rüdiger Mews*[*]

Compounds containing tricoordinate sulfur(VI) have only rarely been reported. The only representatives of proven structure are SO_3 and its aza analogs $(R_3SiN{=})_3S$[1] and $(R_3SiN{=})_2S{=}O$[2]. As shown by these examples, the trimeth-

ylsilyl group can be used to stabilize small coordination numbers; the bulky *tert*-butyl group has the same effect[3].

We have now found that while the reaction of NSF_3 with $LiN(SiR_3)R'$ ($R=CH_3$, $R'=CH_3$, *i*-C_3H_7, C_6H_5) leads to polymeric products, that with $LiN(CR_3)SiR_3$ affords compounds of tricoordinate sulfur.

If the reaction is conducted at -70°C then only *(2)* can be isolated. At higher temperature and given an excess of $LiN(CR_3)SiR_3$ transamidation occurs to form the tris(*tert*-butyl) derivative *(3)*.

(2) + LiN(CR$_3$)(SiR$_3$) ⟶ S(=NCR$_3$)$_3$ + LiN(SiR$_3$)$_2$

(3)

The colorless compounds *(2)* (m.p. 11 °C) and *(3)* (m.p. 52.5 °C) could be characterized by their IR and Raman spectra [ν_{as} and ν_{sym} are tentatively assigned to the bands at 1215 and 1074 cm^{-1} for *(2)* and 1210 and 1059 cm^{-1} for *(3)*][4], mass spectra [*(2)*: E.I. (70 eV, principal fragments only): 261 M^+ (8.1), 246 $M-CH_3^+$ (57), 191 $M-R_3CN+H^+$ (99), 73 R_3Si^+ (100), 57 R_3C^+ (91); *(3)*: E.I.: 245 M^+ (1.3), 230 $M-CH_3^+$ (5.0), 175 $M-NCR_3+H^+$ (28.6), 174 $M-NCR_3^+$ (13.5), 57 CR_3^+ (100), F.I.: 245 M^+ (100), 174 $M-NCR_3^+$ (6.2)], ^{1}H-NMR spectra [*(2)*: $\delta(CH_3)_3Si=+0.18$, $\delta(CH_3)_3C=+1.33$; *(3)*: $\delta(CH_3)_3C=+1.34$], and the results of elemental analyses.

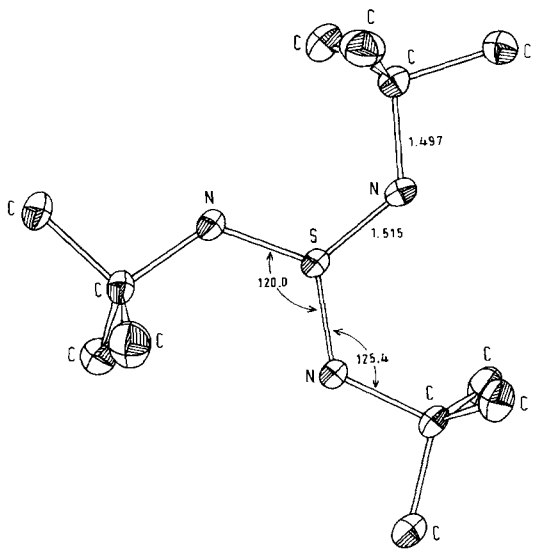

Fig. 1. Molecular structure of *(3)* with mean bond lengths (in Å) and bond angles (in °) (without H atoms, vibrational ellipsoids corresponding to 50% probability distributions).

Information about the crystal structure of the molecules is provided by an X-ray analysis performed on *(3)* at -130 °C[5] (see Fig. 1). It afforded the first proof of a trigonal planar coordination of sulfur(VI) in a solid. The S—N bond lengths are 1.508(4), 1.517(4), and 1.519(4) Å. The σ bonds between the sulfur and the nitrogen atoms are practically coplanar. This steric arrangement thus favors formation of $3p_\pi$(S)—$2p_\pi$(N) bonds. Similar bonding has been observed in the SN_3 skeleton of $(R_3SiN=)_3S$ ($R=CH_3$)[1], which is a liquid under normal conditions; its structure was also determined at -130 °C (S=N bond lengths: 1.504(3) Å)[6]. The C—C bond lengths in *(3)* have an average value of 1.522 Å, lying between 1.513(6) and 1.537(6) Å. The positions of all 27 H atoms could be determined.

Procedure

A solution of $LiN(CR_3)SiR_3$ with $R=CH_3$ (15.1 g, 0.1 mol) in tetrahydrofuran (200 ml) is added to a solution of NSF_3 (11 g, 0.106 mol) in tetrahydrofuran (50 ml) at -70 °C over a period of 2 to 3 h. After removal of volatile products, fractional distillation (oil-pump vacuum) affords *(2)* (2.0 g, 7.2% yield).

In contrast, passage of NSF_3 (31 g, 0.3 mol) into a suspension of $LiN(CR_3)SiR_3$ with $R=CH_3$ (99 g, 0.65 mol) in *n*-hexane (700 ml) at -15 °C within 2 to 3 h affords compound *(3)* (10 g, 19% yield). $(R_3Si)_2NH$, $R_3SiNHCR_3$, $(R_3CN)_2S$, $(R_3CN)_2C$, $R_3CN{=}SF_2{=}NSiR_3$, and $(R_3SiN)_2SF_2$ (R always CH_3) were identified as by-products.

Infrared Rotatory Dispersion of Liquid-Crystalline Solutions of Chiral Molecules[**]

By *Ernst-Heiner Korte, Bernhard Schrader, Sauvarop Bualek*, and *Hans Jürgen Krabbe*[*]

In nematic phases the longitudinal axes of rod-shaped molecules are parallel. When a chiral "guest substance" is dissolved in such a phase the arrangement of molecules becomes twisted in the form of helices[1]. Such a solution exhibits the properties of cholesteric phases. These are distinguished by the fact that they selectively reflect circularly polarized light of wavelength λ_0 in the direction of their screw axis. λ_0 is proportional to the pitch *z* of the helical structure ($\lambda_0=n\cdot z$;

n = refractive index), and the circular polarization corresponds to the handedness of the helix[2]. Inversely circularly polarized light of the same wavelength is transmitted. In the surrounding range of wavelengths a strong anomaly in the optical rotation occurs with the center at λ_0: a Reflection Cotton Effect. A positive Reflection Cotton Effect indicates a left-handed helical structure (M-helix) of the cholesteric phase, a negative effect a right-handed structure (P-helix). In induced cholesteric solutions the Reflection Cotton Effect usually lies in the IR region.

In order to test whether information about the molecular structure of chiral substances can be gained with the aid of this effect we have measured and evaluated the infrared rotatory dispersion of *ca.* 150 chiral compounds in the spectral region 2.5...50 μm[3f].

As solvent we used an equimolar mixture of MBBA and EBBA [*N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline and *N*-(*p*-ethoxybenzylidene)-*p*-*n*-butylaniline] and the nematic phase Licristal®IV [*p*-methoxy-*p'*-*n*-butylazoxybenzene, eutectic mixture of both isomers]. The concentration of chiral substance was in the region of *ca.* 1...10 mol percent, the sample temperature varied in the range within which the mesophase exists (*ca.* 15...75 °C). The infrared rotatory dispersion spectra were measured in NaCl or CsI cuvettes with an IR spectropolarimeter[3a]; a typical spectrum is shown in Figure 1. The essential characteristics of the method are:

1. Molecules with chiral centers or axes and helical molecules transform nematic into cholesteric phases[3b,c].
2. Enantiomers produce cholesteric phases having equal pitches but with opposite helical sense.
3. At low concentration ($x = 0.01...0.1$) the pitch z is inversely proportional to the mole fraction x of the chiral guest substance[3e]: $\lambda_0/n = z = 1/xP$; the proportionality factor P is called the "Helical Twisting Power"[4].
4. The quantity P is proportional to the optical purity[3e].
5. The pitch, but not the induced handedness, depends upon the temperature[3c].
6. A chiral substance (which does not form a liquid-crystalline phase), always induces the same handedness in a "host substance"[3c].
7. Besides the Reflection Cotton Effect, whose wavelength—as mentioned under 3—changes with the concentration, sharp dispersion anomalies appear at fixed positions in the region of the absorption bands of the host molecules[3d,5], so-called Absorption Cotton Effects. If the Reflection Cotton Effect does not lie in the accessible spectral region its position and sign can be deduced from the sign of the above Absorption Cotton Effect[3c,d].
8. The absolute configuration of dissolved chiral molecules can be elucidated from the infrared rotatory dispersion of the induced cholesteric solutions.

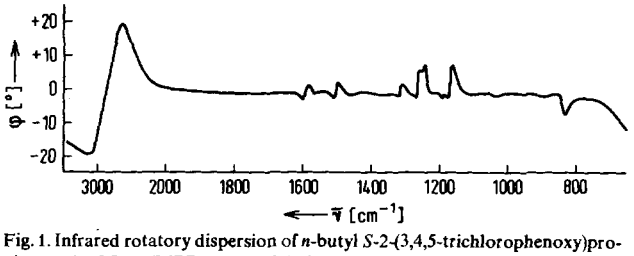

Fig. 1. Infrared rotatory dispersion of *n*-butyl *S*-2-(3,4,5-trichlorophenoxy)propionate in EBBA/MBBA ($x = 0.07$), layer thickness *ca.* 25 μm. A positive Reflection Cotton Effect appears at *ca.* 2900 cm^{-1}; a series of Absorption Cotton Effects in the region between 800 and 1600 cm^{-1} has a negative sign, all others have positive signs.

The infrared rotatory dispersion of induced cholesteric solutions indicates primarily properties of the helical molecular arrangement. Conclusions about the guest molecules are therefore independent of the previously known chiroptic methods, which are determined by electron excitation (ORD, CD) or normal vibrations (Raman circular intensity difference[6], vibrational circular dichroism[7]) of the chiral molecules.

The use of this new chiroptic method for the determination of absolute configurations is reported in the following communication[8].

Relationship between the Infrared Rotatory Dispersion of Liquid-Crystalline Solutions of Chiral Molecules and Their Absolute Configuration[**]

By *Hans Jürgen Krabbe, Heinrich Heggemeier, Bernhard Schrader*, and *Ernst-Heiner Korte*[*]

In the preceding communication the characteristics of the infrared rotatory dispersion of induced cholesteric solutions were outlined[1]. We shall now demonstrate how conclusions about the absolute configuration of molecules having a chirality center can be drawn from the sign of the observed Reflection Cotton Effect.

The absolute configuration of chiral molecules was characterized by a sequence of ligand parameters in analogy to the Cahn-Ingold-Prelog nomenclature[2]. Various systems of ligand parameters were then investigated to establish whether a relationship existed between the absolute configuration

defined thereby and the helical sense induced, which would enable prediction of the absolute configuration of compounds of unknown structure. The ordering by atomic number used in the Cahn-Ingold-Prelog system is unsuitable in this respect. Using the "effective volume" of ligands as a basis we have empirically worked out a system for the interpretation of our measurements on substances having one chirality center. Table 1 shows the priority scheme of the ligands in previously investigated molecules. The determination of the absolute configuration proceeded as follows:

1. The four ligands a, b, c, d of a chirality center might according to Table 1 have the order of priority a > b > c > d. If a molecular model is oriented in such a way that the ligand d is furthest away from the observer then the molecular model is assigned the absolute configuration R_v when the sequence a, b, c is clockwise, otherwise the symbol S_v.

2. Molecules having the absolute configuration R_v give rise to a positive Reflection Cotton Effect in liquid-crystalline solution, those having configuration S_v a negative effect.

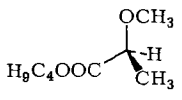

Table 1. Priority scheme for determination of the absolute configuration from the Reflection Cotton Effect.

Fig. 1. Absolute configuration according to a) the Cahn-Ingold-Prelog system, b) R_v, S_v system, and c) the signs of the Reflection Cotton Effect for molecules with one chirality center.

So far over 100 compounds having a chirality center fit into this scheme[3]. The handedness of the induced helical structures for guest substances extrapolated by *Gottarelli et al.*[4] from measurements in the visible region can also be interpreted by a modified scheme corresponding to Table 1. Molecules with chirality centers in rings or with several chirality centers, and those with branched ligands or ligands which resemble the host molecules, cannot as yet be definitely classified by a systematic sequence.

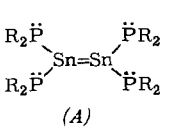
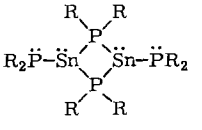
Dimeric Bis(di-*tert*-butylphosphino)stannanediyl: A Cyclic Phosphorus-Tin Ylide[**]

By *Wolf-Walther du Mont* and *Heinz-Jürgen Kroth*[*]



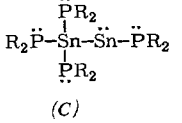
Reports on the stabilization of carbene-analogous stannylenes (stannanediyls) by bis(trimethylsilyl)methyl- and trimethylsilylamino substituents have evoked lively and in part controversial discussion on how and whether such stannylenes associate in solution or in the solid state, and whether the color of such compounds is caused by monomeric species[1].

We have now succeeded in synthesizing bis(di-*tert*-butylphosphino)stannanediyl *(1)*, the first stannylene substituted only with R_2P groups[2], by reaction of potassium di-*tert*-butyl phosphide with stoichiometric amounts of ethylphosphanedichlorostannanediyl[2] in toluene at −78 to −40 °C[3]:



$$2\ KP(CMe_3)_2 + Et_3PSnCl_2 \longrightarrow 2\ KCl + Et_3P + [(Me_3C)_2P]_2Sn \qquad (1)$$

(1) readily dissolves in toluene, ethers and aliphatic hydrocarbons with deep red coloration of the solution. The pure compound is obtained as orange-red crystals in *ca.* 40 % yield on crystallization from pentane at −25 °C. Cryoscopic molecular weight determinations in benzene show that *(1)* is dimeric in this solvent (calc.: 409.1 (monomer), obs.: 765)[4].



There are three possible alternative structures *(A)*–*(C)* for the dimeric compound:

(A)

(B)

(C)

[*] Dr. W.-W. du Mont, Dr. H.-J. Kroth
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The formulation *(A)*, corresponding to the structure of dimeric $[(Me_3Si)_2CH]_2Sn$[5] in the solid state, is ruled out since two main signals with quite different chemical shifts and coupling constants $^1J(^{31}P^{117,119}Sn)$ appear in the ^{31}P-NMR spectrum of *(1)*. A distinction between the structure *(B)* and *(C)* is made possible by the ^{119}Sn-NMR spectrum of *(1)*, in which only *one* group of signals with doublet-of-triplet splitting is observed [$\delta(^{119}Sn)=328$, triplet $^1J(^{119}Sn^{31}P)=1800$ Hz, doublet $^1J(^{119}Sn^{31}P=1086$ Hz][6]. This splitting pattern is obviously compatible only with the structure *(B)* and at the same time enables a correct assignment of the ^{31}P resonances: $\delta(P_{ring})=19.1$, $^1J(^{31}P^{117/119}Sn)=1707/1782$ Hz; $\delta(P_{terminal})=67$, $^1J(^{31}P^{117/118}Sn)=1035/1071$ Hz. The ^1H-NMR signal of the terminal $(t\text{Bu})_2P$ groups appears as a sharp doublet [$\delta(^1H)=0.9$, $^3J(HP)=10.0$ Hz], superposing the group of signals of the $(t\text{Bu})_2P$ groups in the diphosphadistannetane ring [$(AX_n)_2$ spin system].

Assuming that the nonbonding electron pairs on the tin in *(1,B)* are stereochemically active, then there should still be the possibility of formation of *cis* and *trans* isomers for the R_2P ligands on the four-membered ring. In repeated syntheses of *(1)* we always obtained the same product. The kinetic stability of *(1)*, even in the presence of triethylphosphane or dimethoxyethane, shows that there are no rapid exchange equilibria. Evidence for the remarkable stability of the phosphorus(III)-tin(II) four-membered ring in *(1)* is also provided by the fact that attempts to introduce three di-*tert*-butylphosphino groups at tin(IV) have so far failed—presumably for steric reasons—while nucleophilic attack of the third phosphino group at the tin(II) in the dimerization of bis(di-*tert*-butylphosphino)stannanediyl to diphosphadistannetane apparently even proceeds with gain in energy.

Procedure

A 1 M solution of Et_3PSnCl_2 in toluene (4.5 ml) is added at -78 °C to a suspension of $KP(t\text{Bu})_2$ (1.88 g, 10 mmol) in toluene (50 ml) in the absence of oxygen and moisture and the mixture stirred for *ca.* 4 h at -40 °C. The resultant deep-red solution is filtered and the filtrate concentrated under reduced pressure to about a third of its original volume. For crystallization of *(1)* the solution is treated with 20 ml pentane and cooled to -25 °C. The crude product is recrystallized from pentane. Yield *ca.* 1 g (45%) orange-red, *(1)*, m.p. 148—150 °C (dec.).

A Novel Transformation of Diphenylcyclopropenone: Double Bond Cleavage in the Reaction with Platinum Complexes[**]

By *W. Eamon Carroll, Michael Green, Judith A. K. Howard, Michel Pfeffer*, and *F. Gordon A. Stone*[*]

Although cyclopropenone-metal complexes have been postulated[1] as intermediates in certain metal-catalyzed co-oligomerizations of acetylenes and carbon monoxide, relatively little has been reported on reactions of this important class of small-ring molecules with transition metal compounds. One interesting reaction involving zero-valent tertiary phosphane complexes of platinum results in the formation of platinacyclobutenone compounds *via* initial formation of an η^2-adduct between the metal and the carbon-carbon double bond of the cyclopropenone[2]. We now report a novel activation of diphenylcyclopropenone resulting in ring-opening *via* cleavage of the carbon-carbon double bond of the three-membered ring.

Reaction (toluene solution, 25 °C) of diphenylcyclopropenone with the trinuclear platinum complex $[Pt_3(t\text{BuNC})_6]$[3] gives a yellow crystalline diplatinum compound $[Pt_2\{\mu_2\text{-}(PhC)_2CO\}(t\text{BuNC})_4]$ *(1)* [ν_{max}(NC) 2168 and 2140 cm^{-1}]. The molecular structure was established by a single crystal X-ray diffraction study (Fig. 1)[4].

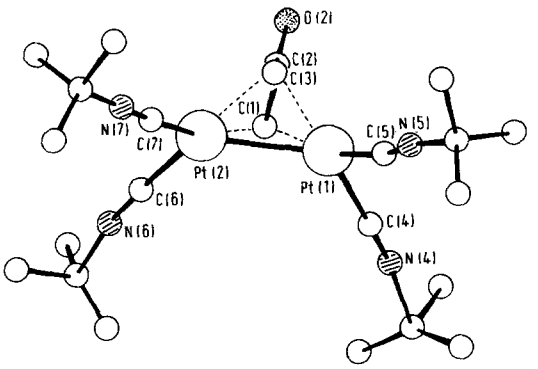

Fig. 1. Molecular structure of $[Pt_2\{\mu_2\text{-}(PhC)_2CO\}(t\text{BuNC})_4]$ *(1)*; the two phenyl groups are omitted for clarity.

The ring-opened fragment C(1)C(2)C(3) lies perpendicular to the Pt—Pt vector, with the carbon C(1) and C(3) atoms originally involved in the ring CC double bond now separated by 2.18(2) Å[5]. The two platinum atoms are in essentially square planar environments equidistant from C(1) and C(3) (mean Pt—C = 2.11 Å)[6]. The distance of C(2) from the platinum atoms (mean 2.50(2) Å) exceeds the sum of the covalent radii (1.99 Å) but some degree of bonding appears to be involved because ^{13}C-NMR studies reveal substantial coupling $J(^{195}Pt\text{-}^{13}C)$ between C(2) and the metal nuclei[7]. Moreover, the C(2)O(2) distance (1.26(2) Å) is unusually long and this lengthening is reflected in an abnormally low ν_{max}(CO) band at 1556 cm^{-1}.

Several other complexes similar to *(1)* have been synthesized. Treatment of $[Pt(cod)_2]$ (cod = cycloocta-1,5-diene)[8] with

methyl vinyl ketone at −50°C in diethyl ether followed by addition of diphenylcyclopropenone gives yellow crystalline $[Pt_2\{\mu_2\text{-}(PhC)_2CO\}(cod)_2]$ *(2)*, $\nu_{max}(CO)$ 1570 cm^{-1}, m.p. 206°C (decomp.). Complex *(2)* reacts with *tert*-butyl isocyanide to give *(1)*, while treatment with HBF_4 gives the salt $[Pt_2\{\mu_2\text{-}(PhC)_2COH\}(cod)_2]BF_4$ *(3)*. Compound *(1)* can also be readily protonated at the oxygen atom yielding $[Pt_2\{\mu_2\text{-}(PhC)_2COH\}(tBuNC)_4]BF_4$ *(4)*.

Mechanistically it is interesting to contrast the CC double bond cleavage process observed in this study with the previous results which gave platinacyclobutenones[2]. It seems likely that an η^2-complex $[Pt\{\eta^2\text{-}PhC{=}C(Ph)C(O)\}L_2]$ ($L = Ph_3P$[2]; *t*BuNC, cod/2) is also initially formed in the reactions here described but with the weaker σ donors (*t*BuNC or cod) the rearrangement of the η^2-complex is slowed down sufficiently to permit attack by a second PtL_2 group on the bent σ orbitals of the C_3-ring with simultaneous breaking of the CC double bond and formation of a bridged dinuclear system[9].

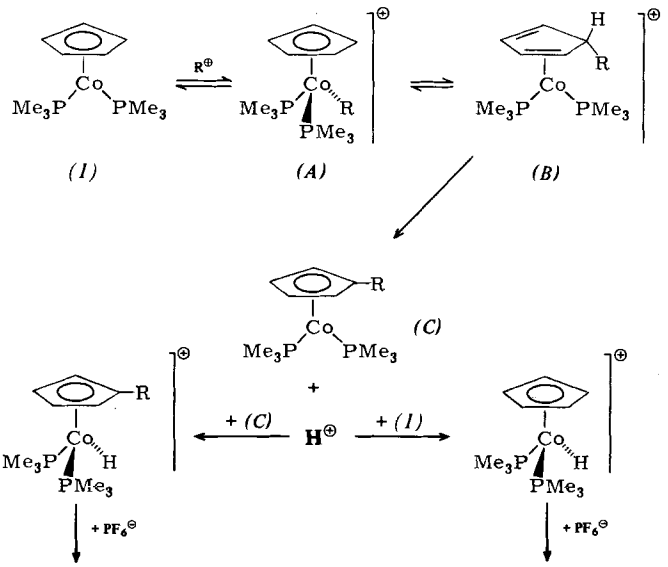
An Unusually Facile Electrophilic Substitution at the Cyclopentadienyl Ring in a Half-Sandwich Complex[1]

By *Helmut Werner* and *Werner Hofmann*[*]



Concepts on the mechanism of electrophilic ring substitution in η-cyclopentadienylmetal complexes are still controversial. For reactions of ferrocene and of cyclopentadienyltricarbonylmanganese—the two compounds whose "aromatic behavior" has so far been investigated in most detail—initial attack of the electrophile E^+ at the metal center with subsequent linking of a C—E bond and elimination of H^+ has been most frequently postulated[2].

We have now been able to establish that this postulate is in fact correct in the case of ring substitution of a half-sandwich complex of type $C_5H_5ML_2$, namely $C_5H_5Co(PMe_3)_2$ *(1)*.

Compound *(1)* contains an extraordinarily nucleophilic metal center[3,4]. It reacts with MeI to give the salt $[C_5H_5(PMe_3)_2CoMe]I$, whose cation possesses a very stable methylcobalt bond[3]. On reaction with EtI, $[C_5H_5(PMe_3)_2\text{-}CoEt]I$ is formed. In contrast, reactions of *(1)* with alkyl halides RX (X preferably Br) which carry at least two methyl or ethyl groups on the C_α atom leads to *cationic hydridocobalt complexes containing an alkyl-substituted cyclopentadienyl ring.* They are isolated as PF_6 salts *(3)*—*(5)*. Depending upon the molar ratio *(1)*: RX, formation of $[C_5H_4R(PMe_3)_2CoH]^+$ can be accompanied by formation of the corresponding cation with an unsubstituted five-membered ring (isolated as PF_6 salt *(2)*)[5]. On using *equimolar* amounts of *(1)* and RX (in ether as solvent) a product ratio $[C_5H_4R(PMe_3)_2CoH]^+ : [C_5H_5(PMe_3)_2CoH]^+ = 70:30$ results when RX = *i*-C_3H_7Br, and a ratio of 50:50 when RX = *t*-C_4H_9Br. With a *threefold* excess of *i*-C_3H_7Br or *t*-C_4H_9Br, the ring-substituted cation is the *only* reaction product.

Scheme 1.

(3), R = *i*-C_3H_7
(4), R = *t*-C_4H_9
(5), R = $C(CH_3)_2C_2H_5$

The mechanism of the reaction of *(1)* with RX is outlined in Scheme 1. The initially formed intermediate *(A)* (which can be isolated when R = Me or Et[3]) rearranges to a 5-R(*endo*)-cyclopentadiene complex *(B)* if the alkyl groups R are bulky, and $C_5H_4RCo(PMe_3)_2$ is formed with elimination of a proton.

[*] Prof. Dr. H. Werner, Dipl.-Chem. W. Hofmann
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

The proton can then react either with this compound or with *(1)* in an oxidative addition, the latter reaction applying only if the initially formulated equilibria are not shifted completely to the side of the cationic species because of the selected molar ratio *(1)*:RX. That *steric* and not electronic effects are actually decisive for the rearrangement of *(A)* to *(B)* is evidenced by the observation that the cation $[C_5H_5(PMe_3)_2CoSnMe_3]^+$ formed from *(1)* and Me_3SnCl is kinetically completely inert[4], although the stability of Me_3Sn^+ (which would be a likely migrating particle) is distinctly greater than that of Me_3C^+.

Two alternative mechanisms—namely a direct attack of RX at the ring as well as formation of HX by β-elimination from RX—are ruled out on the following grounds:

1. Addition of R^+ to the ring would lead to initial formation of a cationic cyclopenta*diene* complex in which the group R assumes an *exo* position at the sp^3 hybridized C atom. Owing to the favorable steric conditions for interaction of the metal with the *endo*-H atom in such an intermediate the cation $[C_5H_4R(PMe_3)_2CoH]^+$ should be formed—even at a molar ratio of *(1)*:RX = 1:1. But this is not the case.
2. On formation of HX from RX (possibly catalyzed by *(1)*) the product ratio $[C_5H_4R(PMe_3)_2CoH]^+:[C_5H_5(PMe_3)_2CoH]^+$ should not be dependent upon the concentration of RX in the manner observed. The cation $[C_5H_5(PMe_3)_2CoH]^+$ would then have to be formed even with an excess of RX, but this is also not the case.

Reaction of *(1)* with Me_3SiCl leads to a paramagnetic product. Use of $Me_3SiOSO_2CF_3$ as silylating reagent leads to formation of the cation $[C_5H_4SiMe_3(PMe_3)_2CoH]^+$, which can be precipitated as the PF_6 salt *(6)*. The NMR data of *(6)* are listed—together with those of *(3)*–*(5)*—in Table 1.

Table 1. ^{1}H-NMR data of $[C_5H_4R(PMe_3)_2CoH]PF_6$ in CD_3NO_2 (δ values, TMS int.; *J* in Hz).

(9)	3.49 m	4.61 m	0.98 vt	C—CH_3: 1.21 s; CH_2: 1.57 q [J_{HH} = 7.0]; CH_2—CH_3: [a]
(10)	3.61 m	4.88 m	0.99 vt	CH_3: 0.30 s

[a] Masked by signal of the PMe_3 protons.

A quantitative transformation of the cationic hydrido complexes *(3)*–*(6)* into the corresponding neutral compounds *(7)*–*(10)* (Table 2) is possible with NaH in tetrahydrofuran.

$$[C_5H_4R(PMe_3)_2CoH]^+ + H^- \rightarrow C_5H_4RCo(PMe_3)_2 + H_2$$

(7), R = *i*-C_3H_7
(8), R = *t*-C_4H_9
(9), R = $C(CH_3)_2C_2H_5$
(10), R = $Si(CH_3)_3$

The extraordinarily mild reaction conditions for the ring substitution of *(1)* differ markedly from those which are necessary for the electrophilic substitution of $Fe(C_5H_5)_2$ or $C_5H_5Mn(CO)_3$. We attribute this to the *considerably higher basicity of the metal atom* of *(1)*, which at the same time also explains why a stable secondary product with a C_5H_4RM—H bond can be isolated in the reaction of this complex but not in the reactions of ferrocene and cyclopentadienyltricarbonylmanganese with RX.

Procedure

(3)—*(5)*: A threefold excess of alkyl bromide is added dropwise at −78°C to a solution of *(1)* (1 mmol) in ether (5 ml). On slowly thawing out, a light-brown precipitate forms which is extremely air-sensitive and is therefore dried directly in the reaction flask. Addition of NH_4PF_6 (2 mmol) to the solid residue followed by methanol (5 ml) leads to formation of light-yellow crystals, which are filtered off and washed with cold ethanol and ether. Recrystallization from acetone/ether affords the analytically pure PF_6 salt; yield 85–95 %.

(6): Preparation analogous to that above except that the ester $Me_3SiOSO_2CF_3$ is used instead of RBr; yield >95 %.

(7)—*(10)*: To the corresponding salt *(3)*—*(6)* (1 mmol) in a little THF (3—5 ml) is added NaH (*ca.* 3 mmol). After spontaneous evolution of gas has subsided the solvent is removed *in vacuo* and the residue extracted with pentane. Filtration and removal of the pentane affords a dark brown oil which is extremely air-sensitive. The yield is quantitative.

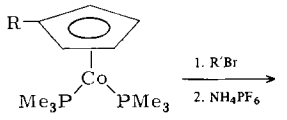
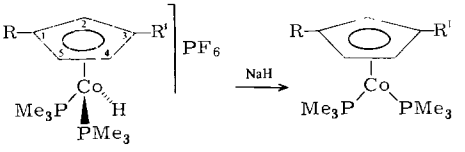
Detection of Rigid Rotamers in Disubstituted Cyclopentadienylcobalt Complexes[1]



By *Werner Hofmann, Wolfgang Buchner*, and *Helmut Werner*[*]

In general, the barrier to rotation about the metal-to-ring bond in bis(η^5-cyclopentadienyl)metal complexes is very small;



[*] Prof. Dr. H. Werner, Dr. W. Buchner, Dipl.-Chem. W. Hofmann
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

for ferrocenes it is 2—5 kcal/mol[2]. Estimated values for other metallocenes and for cyclopentadienylmetal carbonyls are of the same order of magnitude. In the case of substituted monocyclopentadienyl complexes $C_5H_{5-n}R_nML_m$ it should be possible by choice of sufficiently bulky substituents R and voluminous (especially not rod-shaped) ligands L to hinder rotation about the metal-to-ring bond to such an extent that certain conformers can be frozen. We have now succeeded in demonstrating the first such frozen conformation for half-sandwich complexes of cobalt.

Monosubstituted derivatives of cyclopentadienylbis(trimethylphosphane)cobalt such as *(1)* and *(2)* are accessible *via* the intermediate $[C_5H_4R(PMe_3)_2CoH]X$[3]. The *disubstituted* cationic complexes *(3)*—*(5)* and the neutral compounds *(6)*—*(8)* can be obtained in an analogous way.

(1), R = *i*-C_3H_7
(2), R = *t*-C_4H_9

(3) - *(5)* *(6)* - *(8)*

(3), *(6)*: R = R' = *i*-C_3H_7
(4), *(7)*: R = *i*-C_3H_7, R = *t*-C_4H_9
(5), *(8)*: R = R = *t*-C_4H_9

In the case of *(3)* and *(6)* no fixed rotamers are detectable. In the temperature range from −60 to +25°C the ^{1}H- and ^{13}C-NMR spectra each show the very characteristic virtual triplet of spectral type $X_nAA'X'_n$ for protons[4] and AA'X for ^{13}C of the PMe_3 groups (X = ^{1}H or ^{13}C; A = ^{31}P), which is also observed for the complexes $C_5H_4RCo(PMe_3)_2$ and $[C_5H_4R(PMe_3)_2CoH]PF_6$ (R = H, *i*-C_3H_7, *t*-C_4H_9 *etc.*)[3] and whose appearance requires chemical equivalence of the two A nuclei. The triplet splitting of the signals of the cyclopentadienyl ring in *(3)* and in *(6)* by the two phosphorus atoms likewise affords proof of the equivalence of the phosphane ligands and thus of unhindered rotation about the metal-to-ring bond.

By way of contrast, the NMR data of *(5)* and *(8)* prove the presence of *rigid rotamers*—even at 100°C. Thus a typical AB pattern is observed for the two phosphorus ligands in the ^{31}P-NMR spectrum at −60°C which at higher temperature is no longer resolved owing to the quadrupole moment of cobalt. At 25 to 100°C, however, the non-equivalence of the PMe_3 ligands is very clearly revealed in the ^{1}H- and ^{13}C-NMR spectra: in no case is a virtual triplet observed, since the condition for a spectrum of the type $X_nAA'X'_n$ or AA'X is no longer fulfilled owing to the dissimilarity of the phosphorus atoms. On the contrary, the ^{1}H-NMR spectra show two doublets ($^4J_{PCoPCH}$ is very small) for PMe_3 protons, while the ^{13}C-NMR spectra show two doublets of doublets for the corresponding C atoms, each due to simple PH and PC coupling. The rigid structure of *(5)* and *(8)* (Table 1 and 2) is most evident from the different, no longer time averaged, phosphorus coupling constants of the ^{13}C- and ^{1}H-NMR signals of the corresponding ring atoms. From these data and the fact that two chemically non-equivalent *tert*-butyl groups are detectable for *(5)* it follows without doubt that *(A)* and *(B)* are the rotamers of *(5)* and *(8)* obtained in the synthesis, and are probably the most stable ones.

[a] PC coupling not resolved; [b] masked by signal of the solvent.

The complexes *(4)* and *(7)* with mixed substituents fit into the series between *(3)*/*(6)* (freely rotating) and *(5)*/*(8)* (rigid). Two different types of phosphorus atoms are recognizable in the ^{31}P-NMR spectrum of *(7)* at -60 °C, thus indicating a frozen conformation (analogous to *(B)*). Above -10 °C a "thawing" of this arrangement and a slow rotation about the cobalt-to-ring axis is observed (change in the splitting of the NMR signals of the phosphane H and C atoms). Below -10 °C, for example, a doublet of doublets is observed in the ^{13}C-NMR spectrum at $\delta = 24.62$ with $^{1}J_{PC} = 17.3$ and $^{3}J_{PCoPC} = 5.5$ Hz, which at higher temperature converts into a virtual triplet ($\delta = 25.14$ with $|^{1}J_{PC} + {}^{3}J_{PCoPC}| = 22.8$ Hz, 50 °C, in [D$_6$]acetone). In the case of *(4)* no definite conclusions can be drawn from NMR data regarding hindered or restricted rotation about the cobalt-to-ring axis, since the two phosphorus atoms are bonded, as a result of unsymmetrical ring substitution, to a prochiral cobalt atom and are therefore non-equivalent in any case.

The question why two *tert*-butyl substituents (in *(5)* and *(8)*) hinder rotation of the cyclopentadienyl ring, whereas two isopropyl substituents (in *(3)* and *(6)*) do not, might be explained in terms of a "gear mechanism". When a 1,3-(t-C$_4$H$_9$)$_2$C$_5$H$_3$ ring is present it is obviously impossible on rotation about the metal-ring axis for the *tert*-butyl groups

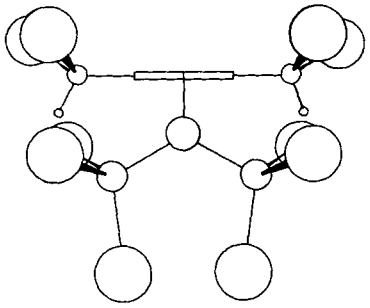

Fig. 1. Steric requirements for rotation according to the "gear mechanism" in compound *(6)* (schematic).

to get past the trimethylphosphane ligands—despite rotation about the C—CMe$_3$ bond. However, if one of the three methyl groups is replaced by an H atom (*i.e.* i-C$_3$H$_7$ instead of t-C$_4$H$_9$) then it appears possible that the two ring substituents are so oriented during the rotation that at the moment of sliding past a trimethylphosphane the H atom of the isopropyl group is directed inwards (cf. Fig. 1).

Synthesis of Bridged 1,3,2λ^3,4λ^3-Diazadiphosphetidines

By *Rodney Keat* and *David G. Thompson*[*]

1,3,2λ^3,4λ^3-Diazadiphosphetidines of type *(1)* have recently attracted considerable attention[1]. Geometrical isomers of these heterocycles are characterized by exceptionally large ^{31}P chemical shift differences[1a–c, 4] and by differences in chemical reactivity[2].

We have now succeeded in "bridging" the 1,3-di-*tert*-butyl-2,4-dichloro-1,3,2λ^3,4λ^3-diazadiphosphetidine *(1)* to give the new crystalline bicyclic compounds *(4)*, *(5a)* and *(5b)*. The compounds were characterized by elemental analyses, mass spectra, and the spectral data shown in Table 1. Variable amounts of polymeric materials are also formed, but generally the proportion is much less than in the condensation of aromatic diols with 1,3,2λ^5,4λ^5-diazadiphosphetidines, where they are the exclusive products[3]. No bicyclic compound of type *(4)* was isolated on reaction of *N*,*N*′-dimethyltrimethylenediamine with *(1)*.

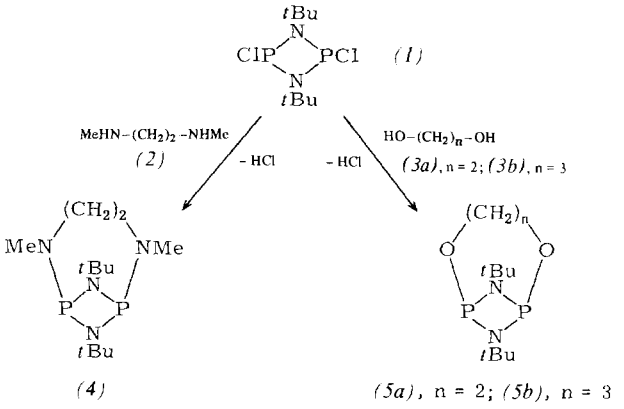

Table 1. Selected physical properties of the bicyclic compounds *(4)*, *(5a)* and *(5b)*.

	(4)	*(5a)*	*(5b)*
M.p. [°C]	36–38	65–67	182
B.p. [°C/torr]	73/0.1		
Yield [%]	20	23	20
δ_P (in CDCl$_3$)	155.0	177.5	135.4
δ_{ZCH_2} (in CDCl$_3$) [a]	3.12	4.17	3.97
$\lvert J_{PZCH_2} + J_{PNPZCH_2}\rvert$ [Hz] [a]	5.6 [b]	9.1	6.6
ν(P—N—P) asymm. [cm^{-1}] (in Nujol)	846	861	899

[a] Z = O or N.
[b] $|J_{PNCH_3} + J_{PNPNCH_3}| = 13.8$ Hz.

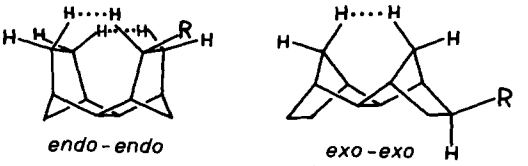
It is not clear what causes the large ^{31}P shift differences between geometrical isomers of diazadiphosphetidines of type *(1)*[4], but conformational changes within the diphosphetidine ring and the exocyclic (or bridging) groups are clearly implicated, especially when the difference in shift between *(5a)* and *(5b)* is considered.

Experimental

7,8-Di-tert-Butyl-2,5-dimethyl-2,5,7,8-tetraaza-1λ^3,6λ^3-diphosphabicyclo[4.1.1]octane (4): A solution of *(2)* (2.75 g, 31.2 mmol) in ether (30 ml) is slowly added with stirring at ambient temperature to a solution of *(1)* (4.30 g, 15.6 mmol)

[*] Dr. R. Keat, D. G. Thompson
Department of Chemistry, University of Glasgow
Glasgow G12 8QQ (U.K.)

in ether (120 ml). Removal of the precipitate and solvent affords a colorless oil which is purified by vacuum distillation.



(5a): A mixture of *(3a)* (0.7 g, 11 mmol) and triethylamine (2.4 g, 12 mmol) in chloroform (30 ml) is added slowly to a solution of *(1)* (3.2 g, 12 mmol) in light petroleum (200 ml) at 0 °C. After removal of the salt and solvent the product is purified by two vacuum sublimations (*ca.* 50 °C/0.1 torr).

(5b) was prepared similarly to *(5a)* and recrystallized from pentane.

The structures of two racemic derivatives each of *(1)* and *(2)* have been determined [*(3)*—*(6)*; Table 1, Fig. 1][4].

(1), R = H
(3), R = 3,5-dinitrobenzoate
(4), R = hydrogenphthalate

(2), R = H
(5), R = 3,5-dinitrobenzoate
(6), R = *p*-nitrobenzoate

Unreasonable bond lengths and thermal motion parameters are obtained for the hydrocarbon residue of the poorly refinable structural model *(4)* (*R* = 0.131; Table 1). Similar effects, though less extreme are observed in *(6)*, while in the case of *(3)* normal thermal motion but again questionable bond lengths are obtained. In each case the aromatic substituents behave normally. Difference Fourier syntheses reveal partial disorders, presumably because the asymmetric units contain a random mixture of both enantiomers ("enantiomeric disorder"[5]). No disorder effects are perceptible in the *exo-exo* derivative *(5)*, which crystallizes non-centrosymmetrically.

Table 1. Crystallographic data of the structure analyses: cell constants and intensities measured on four-circle diffractometers (N_{tot}, number of independent reflections measured); space groups of *(3)* and *(6)* assumed centrosymmetric; determination of the structure of *(4)* by direct, otherwise by vector methods; heavy atoms anisotropically refined with N_{ref} reflections [$F_0 > 4\sigma(F_0)$ for *(3)* and *(4)*, $F_0 > 3\sigma(F_0)$ for *(5)* and *(6)*], H atoms isotropically with additional exclusion of reflections with $\sin\theta/\lambda > 0.45$ Å^{-1} (H atoms of *(4)* not refined); conventional *R* values for the N_{ref} reflections.

Structure of Two Highly Strained Tetracyclododecanes[**]

By *Otto Ermer*[*]

More than 15 years ago *Winstein et al.* prepared a series of highly strained polycyclic hydrocarbons and attempted to interpret abnormally high CH stretching modes by means of very simple force field considerations[1]. These compounds also represent suitable candidates for testing the much more refined force field calculations presently in use. We report here on crystal structure analyses of derivatives of *endo-endo*- and *exo-exo*-tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodecane [*(1)* and *(2)*, resp.] and compare the results with force field calculations[2]. Compounds *(1)* and *(2)* consist of fused norbornane moieties[3] and display unusually large C—C—C angles as a result of non-bonded repulsions between H atoms. The two angles C(1)—C(2)—C(3) and C(6)—C(7)—C(8) in the *endo-endo* isomer *(1)* exceed the tetrahedral angle by about 18° (Fig. 1a, b).

Universitätsstr. 150, D-4630 Bochum (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

With respect to bond angles and torsion angles the *endo-endo*-tetracyclododecane framework in the crystals of *(3)* has, to a good approximation, C_2 symmetry—but without greatly deviating from the higher C_{2v} symmetry. In view of substituent and crystal packing effects the agreement with the results of the force field calculations (Fig. 1a, b) is not self-evident, since the calculated C_{2v} conformation (transition state between enantiomeric C_2 minima) is only 0.08 kcal·mol^{-1} richer in energy than the C_2 minimum. The lowering of symmetry leads to a favorably "staggered" arrangement of the four inner H atoms on C(4), C(5), C(9), and C(10), enabling a slight closing-up of these C atoms accompanied by a reduction of angle strain. The small energy difference between the C_2 and C_{2v} geometries is expressed by a calculated smallest vibrational frequency of only 63 cm^{-1} for the C_2 minimum. As expected, the atomic displacements of the respective normal coordinate point towards the C_{2v} transition state (Fig. 1e).

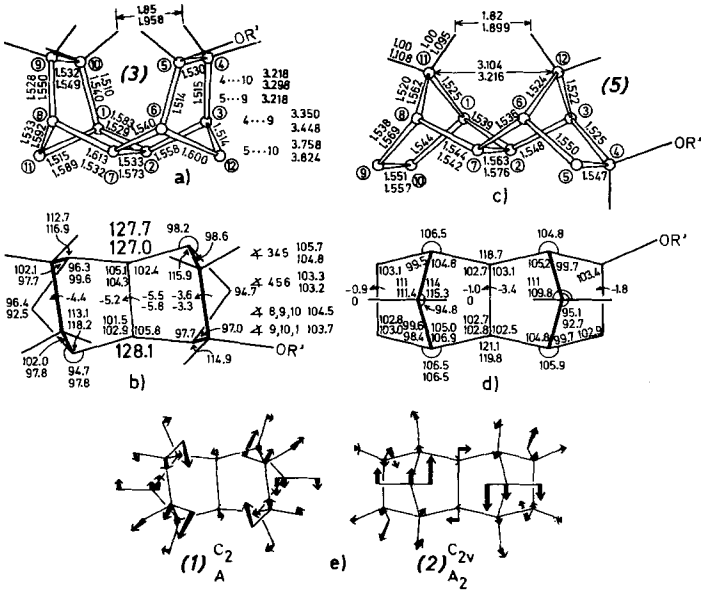

Fig. 1. a, c) Observed and calculated bond lengths [Å], and b, d) bond angles and torsion angles [°] for the tetracyclododecane moieties in *(3)* and *(5)*; the lower calculated values apply for gaseous *(1)* and *(2)* of symmetry C_2 and C_{2v}, respectively (only symmetry independent values given); estimated average standard deviations for *(5)*: CC 0.005, CH 0.04, HH 0.06 Å, CCC 0.3, CCH 2, HCH 3, CCCC 0.4°; observed geometrical parameters including H atoms represent C_2 and C_{2v}-averages, respectively; R' = 3,5-dinitrobenzoyl. e) Normal coordinates of the calculated smallest vibrational frequencies of *(1)* and *(2)* (63 and 69 cm^{-1}, respectively); atomic displacements drawn to scale apart from an arbitrary overall scale factor.

The *exo-exo*-tetracyclododecane framework in the crystals of *(5)* has, to a good approximation, C_{2v} symmetry. Once again the agreement with the calculations is remarkable, since a lowest frequency of 69 cm^{-1} is calculated for *(2)*, along whose normal coordinate (Fig. 1e) the distance between the two inner H atoms on C(11) and C(12) increases (corresponding frequency of norbornane 166 cm^{-1}). The deformation is similar to that in *(1)*, but the one inner H...H repulsion in *(2)* does not quite suffice for a lowering of symmetry.

The partial disorder in *(3)* does not allow a conclusive discussion of the geometric parameters in the *endo-endo*-tetracyclododecane skeleton. For example, the bond lengths C(3)—C(12) and C(6)—C(12), which are expected to be similar, differ by 0.086 Å. On the other hand, there is good agreement between the particularly interesting widely opened angles C(1)—C(2)—C(3) and C(6)—C(7)—C(8) with values of 127.7 and 128.1°, respectively, and the calculated value 127.0° (Fig. 1a, b). The angle deformation potentials of our force field are simple quadratic functions. As in the case of C—C=C angles[6] it would appear that also at sp^3 C-atoms harmonic potentials can be applied to the description of angle opening up to the high value of *ca.* 18°. Final clarification should be provided by the planned study of optically active derivatives of *(1)*, whose crystal structures we expect to be ordered.

The shortest inner H...H distances in *(3)* are 1.85 Å (C_2-average; Fig. 1a, b; calculated for *(1)*: 1.958 Å; also the more accurately observed distances C(4)...C(10) and C(5)...C(9) are shorter than calculated). *Winstein et al.* roughly estimated the very small value of 1.58 Å for *(1)* in order to explain an abnormally high νCH band at 3031 cm^{-1}[1]. We calculate 2976 cm^{-1} for the highest vibrational frequency of *(1)*. The above mentioned short H...H distances decrease markedly along the respective normal coordinate. The same applies for the normal coordinate of the highest calculated CH_2 angle deformation frequency of 1571 cm^{-1} (mainly deformation of the CH_2—CH_2 groups; corresponding frequency in norbornane 1465 cm^{-1}).

The results for the ordered crystals of *(5)* enable a more informative comparison with the calculations than in the case of *(3)*. The angles C(1)—C(2)—C(3) and C(6)—C(7)—C(8) with values of 118.7° and 121.1° are not opened to the extent they are in *(3)* (Fig. 1c, d; calculated for *(2)* 119.8°). The smallest inner H...H distance is 1.82 Å and again is shorter than the calculated value (1.899 Å; estimated[1] 1.50 Å). The same applies for the very short distance C(11)...C(12) of 3.104 Å. As for *(1)*, the observed highest vibrational frequency of 3052 cm^{-1}[1] is larger than our calculated value of 3007 cm^{-1}. The respective normal coordinate has similar character as in *(1)*, *i.e.* the two inner C—H bonds at C(11) and C(12) stretch synchronously. The largest CH_2 deformation frequency is calculated to be very high, 1686 cm^{-1} (the normal coordinate is characterized by simultaneous opening of the two H—C—H angles at C(11) and C(12) accompanied by substantial shortening of the inner H...H distance; analogous frequency of norbornane 1532 cm^{-1}).

The C—C bond lengths calculated for *(2)* are not in complete agreement with those observed in *(5)*. The C—C bonds emanating from C(11) and C(12) in *(5)* are on average 0.04 Å shorter than calculated for *(2)*, while the CCC angles at these atoms are somewhat larger (Fig. 1c, d). The four measured bond lengths of type C(1)—C(2) are also systematically shorter than calculated, albeit to a lesser extent. Apparent bond shortening by strong thermal motion can essentially be ruled out. Similarly as in norbornane the C—C bond lengths in *(1)* and *(2)* depend strongly on "stretch-bend" cross terms[3]. However, calculations with modified such terms did not lead to satisfactory results, so that further investigations are necessary which also should include experiments for a more accurate determination of the hydrogen positions. The comparison of the experimental findings with the partly deviating calculated results is important in a future re-optimization of our force field.

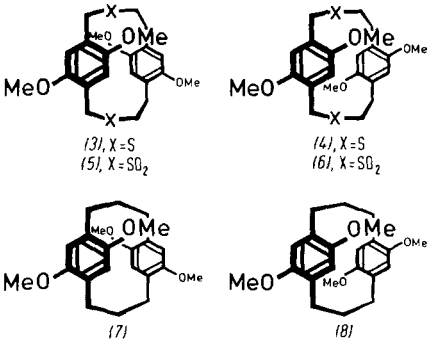
Diastereoisomeric [3.3]Paracyclophane Quinhydrones[1]

By *Heinz A. Staab* and *Claus P. Herz*[*]

Considerable differences in charge-transfer (CT) interactions have become apparent on comparing diastereomeric quinhy-

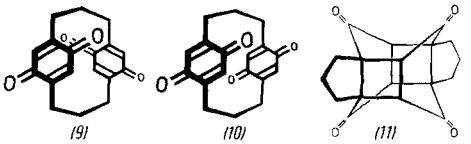


[*] Prof. Dr. H. A. Staab, Dr. C. P. Herz
Max-Planck-Institut für medizinische Forschung, Abteilung Organische Chemie
Jahnstrasse 29, D-6900 Heidelberg (Germany)

drones and other donor-acceptor systems of the [2.2]paracyclophane series[2]. Due to the strong deviations from ring planarity and the short transannular distances in [2.2]paracyclophanes, these results give only limited evidence for the orientation dependence of CT interactions in regular CT complexes. Donor-acceptor cyclophanes of the [3.3]paracyclophane series are better models for intramolecular simulation of normal CT interactions since their donor and acceptor units are almost planar and the distance between them (around 3.2 Å) is closer to the donor-acceptor distance in CT complexes. We report here the syntheses of the two diastereomeric [3.3]paracyclophane quinhydrones *(1)*/*(2)* and a comparison of their CT absorptions.

(1) *(2)*

6,9,16,19-Tetramethoxy-2,13-dithia[4.4]paracyclophane was obtained by cyclization of 1,4-bis(bromoethyl)-2,5-dimethoxybenzene[3] with the disodium salt of 1,4-bis(mercaptomethyl)-2,5-dimethoxybenzene[2] [*tert*-butanol/ethanol (1:1), dilution principle, 65% yield, ratio of diastereomers *(3)* and *(4)* about 1:1[4]]. Oxidation of the *(3)*/*(4)* mixture (3-chloroperbenzoic acid, chloroform, 24 h, 20°C, 90%) yielded the corresponding disulfones *(5)*/*(6)* which, on gas phase pyrolysis[5] (600°C, 0.01 torr), afforded the tetramethoxy[3.3]paracyclophanes *(7)* and *(8)* (ratio 2:1, total yield 40%)[6] together with the compounds *(12)* and *(13)* mentioned below. The separation of the diastereomers *(7)* and *(8)* was achieved by fractional crystallization from *n*-hexane. *(7)*[7]: m.p. 104–105°C (from ethanol); ^{1}H-NMR ($CDCl_3$): δ = 1.8—3.2 (m, 12H, methylene), 3.71 (s, 12H, methoxy), 6.40 (s, 4H, aromatic); *(8)*[7]: m.p. 224—225°C (from *n*-hexane); ^{1}H-NMR ($CDCl_3$): δ = 1.6—3.3 (m, 12H, methylene), 3.66 (s, 12H, methoxy), 6.21 (s, 4H, aromatic). The assignment to the pseudo-*ortho*-structure *(7)* and the pseudogeminal structure *(8)*, respectively, is based on the ratio of yields, and on the differences in the melting points and δ-values for the aromatic protons (cf. [2]).



(3), X = S
(5), X = SO_2

(4), X = S
(6), X = SO_2

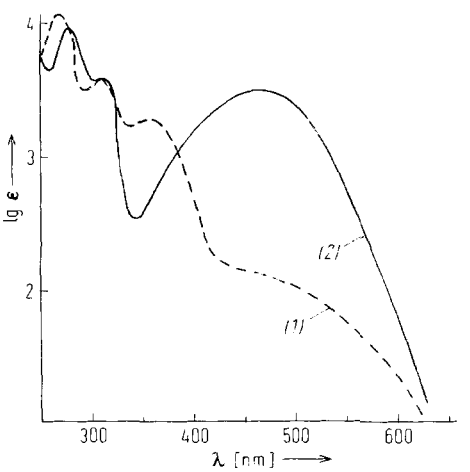
(7) *(8)*

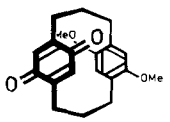
By ether cleavage of *(7)* with methylmagnesium iodide (25 min, 170°C, under argon) and subsequent oxidation of the tetrahydroxy[3.3]paracyclophane with lead(IV) acetate (acetic acid, 10 min, 55°C) pseudo-*ortho*-[3.3](2,5)-*p*-benzoquinonophane *(9)*[7] was obtained [pale yellow crystals, m.p. 264—266°C (dec.), 72% yield; ^{1}H-NMR ($CDCl_3$): δ = 1.9—3.1 (m, 12H, methylene), 6.29 (s, 4H, ring). Analogously, ether cleavage of compound *(8)* and subsequent lead(IV) acetate oxidation yielded pseudogeminal [3.3](2,5)-*p*-benzoquinonophane *(10)*[7] [yellow crystals, dec. >300°C; 65% yield; ^{1}H-NMR ($CDCl_3$): δ = 1.5—3.3 (m, 12H, methylene), 6.46 (d, *J* = 1.5 Hz, 4H, ring)]. The assignment of the diastereomers *(9)* and *(10)*, based on that of *(7)* and *(8)*, is confirmed by the photochemistry of these compounds: on irradiation (solid state, 300 W Osram Ultra-Vitalux) *(10)* underwent almost complete conversion within minutes into an isomer which was obtained from dioxane as colorless crystals (dec. >250°C; 83% yield). According to ^{1}H-NMR [in $CDCl_3$: δ = 1.6—2.2 (m, 12H, methylene), 3.32 (s, 4H, methine), no olefinic or aromatic absorptions], IR, and UV spectra this compound has the cage structure *(11)* resulting from *(10)* by double intramolecular cycloaddition of the two pairs of coplanar quinone double bonds. In agreement with the results obtained for the [2.2](2,5)-*p*-benzoquinonophanes[8] the pseudo-*ortho*-compound *(9)* does not undergo intramolecular cycloadditions due to the unfavorable orientation of the double bonds.

(9) *(10)* *(11)*

Catalytic hydrogenation of *(9)* (Pd/C, dioxane, 20°C) yielded the quinhydrone *(1)*[7] as brown microcrystals, m.p. (dec.) 272—274°C (from benzene/acetone), yield 74%; MS: M^+ calc. for $C_{18}H_{18}O_4$ 298.1205, obs. 298.1212; ^{1}H-NMR ([D_6]-DMSO): δ = 1.6—3.0 (m, 12H, methylene), 6.10 (s, 2H, ring), 6.26 (s, 2H, ring), 8.52 (s, 2H, hydroxyl); IR (KBr): ν(C=O) 1638, ν(OH) 3400 cm^{-1}. Under the same conditions the pseudogeminal quinhydrone *(2)*[7] was obtained in 67% yield from *(10)*: glittering black crystals (from dioxane), dec. >300°C; MS: M^+ calc. for $C_{18}H_{18}O_4$ 298.1205, obs. 298.1212; ^{1}H-NMR ([D_6]-DMSO): δ = 1.4—3.0 (m, 12H, methylene), 5.96 (s, 2H, ring), 6.17 (s, 2H, ring), 8.54 (s, 2H, hydroxyl); ν(C=O) 1620, ν(OH) 3230 cm^{-1}.

The electronic spectra of *(1)* and *(2)* (Fig. 1) resemble those of the respective quinhydrones of the [2.2]paracyclophane series. The differences in the absorptions due to the different donor-acceptor orientations are, however, much more pronounced for the diastereomer pair *(1)*/*(2)*: Whereas a strong CT absorption is observed for *(2)* in the 350—630 nm region [λ_{max} = 462 nm (ε = 3210)], *(1)* shows only a weak absorption shoulder around 500 nm with ε = 105; however, in contrast to *(2)*, a strong CT absorption at λ_{max} = 346 nm (ε = 1904) is found for *(1)*.





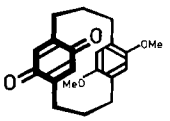


Fig. 1. Electronic spectra of the [3.3]paracyclophane quinhydrones *(1)* and *(2)* (in dioxane).

(12)

(13)

The dimethyl ethers (12) and (13), corresponding to (1) and (2), were formed unexpectedly (5% yield each) on gas phase pyrolysis of (5)/(6) and were separated by chromatography (silica, benzene): (12)[7] forms dark red needles (from methylcyclohexane), m.p. 202—203 °C; MS: M^+ calc. for $C_{20}H_{22}O_4$ 326.1518, obs. 326.1522; ^{1}H-NMR ($CDCl_3$): δ = 1.8—3.3 (m, 12H, methylene), 3.73 (s, 6H, methoxy), 6.16 (s, 2H, ring), 6.29 (s, 2H, ring). (13)[7] crystallizes from methylcyclohexane as brick-red needles, m.p. 218—219 °C; MS: M^+ calc. for $C_{20}H_{22}O_4$ 326.1518, obs. 326.1522; ^{1}H-NMR ($CDCl_3$): δ = 1.65—3.3 (m, 12H, methylene), 3.67 (s, 6H, methoxy), 6.00 (s, 2H, ring), 6.35 (s, 2H, ring). The electronic spectra of (12) and (13) agree very well with those of the respective quinhydrones (1) and (2): in the 350—650 nm region (13) shows a strong CT absorption [λ_{max} = 475 nm (ε = 3000), in chloroform] having about 30-fold greater intensity than (12) for which, on the other hand, an additional CT absorption at shorter wave-length is observed [λ_{max} = 367 nm (ε = 1740), shoulder 500 nm (ε = 100), in chloroform]. For (13) it was shown by the concentration independence (10^{-3}—10^{-5} M) that intermolecular donor-acceptor interactions do not contribute detectably to the CT absorption.

Comparison of the electronic spectra of the pairs of diastereomers (1)/(2) and (12)/(13) reveals an even stronger orientation dependence of the CT absorption for the quinhydrones of the [3.3]paracyclophane series than was found in the [2.2]paracyclophane group. For the reasons mentioned in the introduction, we think that the results now obtained provide a general description of the orientation dependence of CT interactions in donor-acceptor complexes of the quinhydrone type.

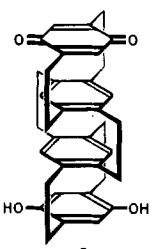
Indirectly Transmitted Charge-Transfer Interactions: Multilayered [2.2]Paracyclophane Quinhydrones[1]

By *Heinz A. Staab, Udo Zapf*, and *Anneliese Gurke*[*]



Intramolecular fixation of donor-acceptor systems in the rigid skeleton of cyclophanes led to information regarding orientation and distance dependences of charge-transfer (CT) interactions which is inaccessible by the investigation of regular intermolecular CT complexes[1,2]. Using the same concept an attempt was made to answer the question whether an indirect transmission of CT interactions occurs if donor and acceptor are not in direct spatial contact but are separated by intercalated aromatic π-electron systems. For this purpose donor-acceptor cyclophanes were to be synthesized where the donor and acceptor units are in the external positions of a multilayered [2.2]paracyclophane. Interesting representatives of this group of compounds would be quinhydrones of triple- or quadruple-layered [2.2]paracyclophanes like (1) or (5). As in the case of quinhydrones of simple [2.2]- and [3.3]paracyclophanes[1,2a], for these multilayered quinhydrones pairs of stereoisomers with different donor-acceptor orientation are to be expected ((1)/(2), for example). The electronic spectra of these compounds were expected to provide evidence about the problem of indirect transmission of CT interactions and its orientation dependence.

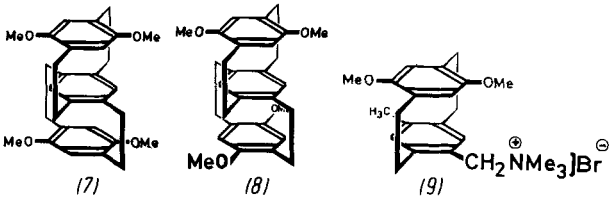
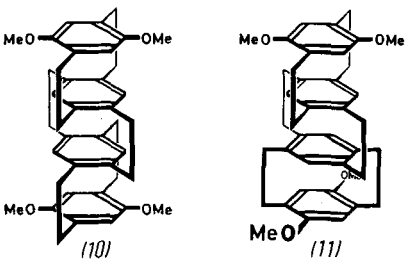
(5)



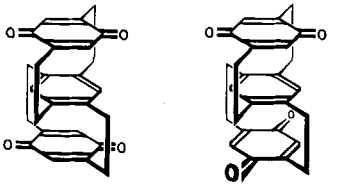
(6)

As in the previous syntheses of cyclophane quinhydrones[1,2a,3], the corresponding tetramethoxy compounds (7) and (8) were key intermediates for the preparation of (1) and (2). By analogy with the syntheses of other multilayered cyclophanes[4], crossed 1,6-Hofmann elimination of (2,5-dimethoxy-4-methylbenzyl)trimethylammonium bromide[2b] and pseudo-*ortho*-4,7-dimethoxy-12-methyl-15-trimethylammoniomethyl[2.2]paracyclophane bromide (9) seemed to be a suitable approach for the syntheses of (7) and (8). The reaction of pseudo-*ortho*-4,7-dimethoxy-12,15-dimethyl[2.2]-



[*] Prof. Dr. H. A. Staab, Dipl.-Chem. U. Zapf, A. Gurke
Max-Planck-Institut für medizinische Forschung
Abteilung Organische Chemie
Jahnstrasse 29, D-6900 Heidelberg (Germany)

paracyclophane[5] with *N*-bromosuccinimide (90% of the equivalent amount, CCl_4) resulted in pseudo-*ortho*-4-bromomethyl-7-methyl-12,15-dimethoxy[2.2]paracyclophane which yielded *(9)*[6] (dec. >230°C, about 50% overall yield) with trimethylamine in ether. Equimolar amounts of *(9)* and (2,5-dimethoxy-4-methylbenzyl)trimethylammonium bromide were converted into the hydroxides (silver oxide, water) which were heated 12 h in boiling xylene (water separator, addition of phenothiazine). The reaction product separated from insoluble polymers yielded, by chromatography (silica, benzene), a mixture of the two diastereomeric tetramethoxy[2.2]paracyclophanes[2a,b] and the quadruple-layered tetramethoxy[2.2]paracyclophanes *(10)* and *(11)* (total yields 14,5%) and subsequently in 15.5% yield *(7)*/*(8)* which were separated by fractional crystallization from acetone or by chromatography (silica, benzene, *n*-hexane, 3:2): *(7)*[6] forms colorless needles, m.p. 204—205°C (from methanol), *(8)*[6] colorless needles, m.p. 226—228°C (from acetone). The assignment to *(7)* and *(8)*, respectively, is possible on the basis of ^{1}H-NMR: Whereas for the pseudo-*ortho*/pseudo-*ortho* linked *(7)* all four methoxy groups and all four protons of the two external rings are equivalent, this is not true for *(8)* since here the pseudo-*ortho*/pseudogeminal linkage leads for the methoxy groups and the protons of the two external rings to different orientations with regard to the methylene bridges between the neighboring [2.2]paracyclophane unit. Indeed, for *(8)* a doubling of the ^{1}H-NMR signals for the methoxy groups and the protons for the external rings is observed: *(7)*: $\delta = 2.15$—3.6 (m, 16H, methylene), 3.32 (s, 12H, methoxy), 5.51 (s, 4H, external ring), 6.13 (s, 2H, internal ring); *(8)*: $\delta = 2.1$—3.65 (m, 16H, methylene), 3.30 (s, 6H, methoxy), 3.33 (s, 6H, methoxy), 5.45 (s, 2H, external ring), 5.50 (s, 2H, external ring), 5.61 (s, 2H, internal ring); in C_6D_6[7] (80 MHz).



(7) *(8)* *(9)*

The quadruple-layered tetramethoxy[2.2]paracyclophanes *(10)*/*(11)* were also obtained when *(9)* alone was subjected to 1,6-Hofmann elimination (14% yield). The separation of the diastereomers which would be necessary for the syntheses of the quinhydrones *(5)* and *(6)* has not yet proved possible by chromatography because of the extremely similar properties of *(10)* and *(11)*; a partial separation has been achieved by fractional crystallization from acetone/carbon tetrachloride (3:1).

(10) *(11)*

Ether cleavage of *(7)* with methylmagnesium iodide (1 h, 160—190°C, under nitrogen) and subsequent oxidation with silver oxide in acetone led, after chromatography on silica from chloroform, in 60% yield to the benzoquinonophane *(12)*[6]: orange needles, dec. >250°C; MS: M^+ calc. for $C_{26}H_{22}O_4$ 398.1518; obs. 398.1517; ^{1}H-NMR ($CDCl_3$): $\delta = 2.0$—3.3 (m, 16H, methylene), 5.70 (s, 4H, quinonoid), 6.26 (s, 2H, internal ring). Analogously, compound *(8)* gave the diastereomeric benzoquinonophane *(13)*[6]: orange needles, dec. >260°C; yield 40%; MS: M^+ calc. for $C_{26}H_{22}O_4$ 398.1518, obs. 398.1517; ^{1}H-NMR ($CDCl_3$): $\delta = 2.05$—3.15 (m, 16H, methylene), 5.69 (s, 2H, quinone), 5.74 (s, 2H, quinone), 6.18 (s, 2H, internal ring). In contrast to the preparation of the simple [2.2]- and [3.3]paracyclophane quinhydrones[1,2], catalytic hydrogenation of *(12)* and *(13)* gave mixtures of the tetrahydroxy compound and unreacted benzo-

(12) *(13)*

quinonophane—probably due to the smaller stabilization of the quinhydrone stage—together with quinhydrone which could not yet be isolated from these mixtures.

The dimethyl ethers *(3)* and *(4)* of the quinhydrones *(1)* and *(2)*, however, were obtained—obviously due to incomplete demethylation—as by-products (*ca.* 2% yields) of the syntheses of *(12)* and *(13)*, respectively, and were separated by chromatography (silica, chloroform): *(3)* forms red needles, m.p. 224—226°C (from methanol); MS: M^+ calc. for $C_{28}H_{28}O_4$ 428.1987, obs. 428.1960; ^{1}H-NMR ($CDCl_3$): $\delta = 2.0$—3.5 (m, 16H, methylene), 3.61 (s, 6H, methoxy), 5.60 (s, 2H, external ring), 5.66 (s, 2H, external ring), 6.16 (s, 2H, internal ring); *(4)* forms dark red crystals (from ethanol, dec. >260°C); MS: M^+ calc. for $C_{28}H_{28}O_4$ 428.1987, obs. 428.1981; ^{1}H-NMR ($CDCl_3$): $\delta = 1.8$—3.5 (m, 16H, methylene), 3.58 (s, 6H, methoxy), 5.56 (s, 2H, external ring), 5.65 (s, 2H, external ring), 5.85 (s, 2H, internal ring).

In the 350—550 nm region *(3)* and *(4)* show a broad CT absorption [*(3)*: $\lambda_{max} = 437$ nm ($\varepsilon = 2270$); *(4)*: $\lambda_{max} = 415$ ($\varepsilon = 2010$), chloroform]. Since this band is concentration-independent it must be due to an intramolecular CT transition which in "vertical conjugation" is transmitted through the π-system intercalated between donor and acceptor[8]. As is shown by comparison of *(3)* and *(4)*, however, the orientation dependence of CT absorptions, observed for simple donor-acceptor [2.2]paracyclophanes, is almost completely lost in this type of CT interactions.

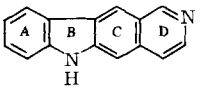
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

Thioethers (sulfides) have attracted increasing interest as reagents for organic syntheses in recent years, for they are stable towards acids and bases, can form sulfur-stabilized carbanions, and can be transformed into compounds having different substitution patterns by reductive or oxidative cleavage of the C—S bond. A comprehensive survey of methods of synthesis of thioethers, the physical and chemical properties of these compounds, and their reactions has been written by *W. Tagaki*. [Sulfides in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 231—302; 210 references]

[Rd 966 IE]



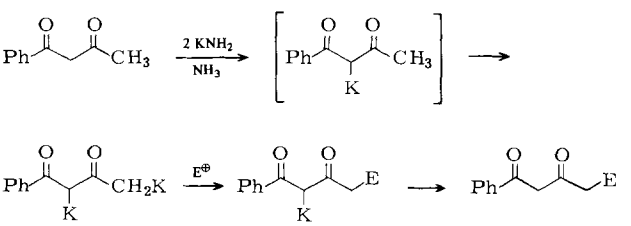
Control at the level of substrate supply in the synthesis of phenylpropanoids in plants is proposed by *U. Margna*. This offers an alternative to regulation at the level of enzyme activity. The activity of the key enzyme, phenylalanine ammonia lyase, often bears no relationship to the accumulation of phenylpropanoids; the actual enzyme activity usually exceeds by far that which is necessary for the measured rate of synthesis. Addition of exogenous phenylalanine also causes the synthesis of phenylpropanoids to increase. Protein metabolism and the synthesis of flavonoids and cinnamic acid derivatives in plants are however in a well balanced ratio. [Control at the Level of Substrate Supply—an Alternative in the Regulation of Phenylpropanoid Accumulation in Plant Cells. Phytochemistry *16*, 419—426 (1977); 120 references]

[Rd 982 IE]

The coordination of lipid degradation with the Krebs cycle is discussed by *P. W. Hochachka, J. R. Neely*, and *W. R. Driedzic*. The essential links between these two metabolic pathways are their mutual requirements for coenzyme A, NAD^+ and the oxidation capacity of $FADH_2$. The cell can thus maintain a precise coordination between fatty acid activation in the cytosol, the β-oxidation of fatty acids in the mitochondria, and the complete oxidation of acetyl coenzyme A to CO_2 *via* the Krebs cycle for a wide range of energy requirements and oxygen supply. [Integration of Lipid Utilization with Krebs Cycle Activity in Muscle. Federation Proc. *36*, 2009—2014 (1977); 57 references]

[Rd 983 IE]

The synthesis of 6*H*-pyrido[4,3-*b*]carbazole *(1)* and its derivatives is treated in a review by *M. Sainsbury*. *(1)* is the basic molecular framework of the alkaloids (*e.g.* ellipticin, olivacin, guatambin) which are found in the plant family *Apocyanaceae*. These substances are of biogenetic interest and their derivatives seem to be promising drugs for the treatment of cancer. The already known routes for the synthesis of the skeleton *(1)*



(1)

can be divided into three groups: 6-isoquinolone derivatives (rings C and D) are reacted with arylhydrazines according to the Fischer indole synthesis to give arylhydrazones which are subsequently cyclized. The framework *(1)* is synthesized from carbazoles (rings A, B and C) by *Vilsmeier* formylation, condensation with 2,2-diethoxyethylamine, hydrogenation, cyclization, and dehydrogenation. Other syntheses start with indoles, *e.g.* gramin derivatives, (rings A and B) which are condensed with substituted pyridines. Derivatives of *(1)* are formed by cyclization (ring C). [The Synthesis of 6*H*-Pyrido[4,3-*b*]carbazoles. Synthesis *1977*, 437—448; 33 references]

[Rd 984 IE]

Di- and polyalkali metal derivatives of organic compounds with functional groups are treated in a review by *E. M. Kaiser, J. D. Petty*, and *P. L. A. Knutson*. Di- and polyalkali metal derivatives, which give valuable compounds with electrophilic reagents, are formed from numerous organic compounds by the action of two or more equivalents of strong alkali metal bases (alkali metal amides, organolithium compounds). The

multiple metalation proceeds according to the following scheme: metalation of the most strongly acidic proton to give a weakly nucleophilic intermediate, subsequent metalation of a second proton producing a more strongly nucleophilic compound which usually reacts regiospecifically in the condensation with the electrophile at this anionic center. [Di- und Polyalkali Metal Derivatives of Heterofunctionally Substituted Organic Molecules. Synthesis *1977*, 509—550; 306 references]

[Rd 985 IE]

Mechanisms of polymerizations in the solid state are discussed by *G. Wegner* for the example of the four-center polymerization of diolefins, which lead to polymers with cyclobutane rings in the main chain, and the polymerization of diacetylenes. Both processes afford highly crystalline products, and in some cases it is possible to obtain macroscopic crystals practically devoid of defects. The reaction course as well as the crystal and molecular structure of the product depend upon the packing of the monomer molecules in the starting crystal. [Solid-State Polymerization Mechanisms. Pure Appl. Chem. *49*, 443—454 (1977); 36 references]

[Rd 971 IE]

Literature available about di- and polysulfides is extremely extensive. A survey of this field by *L. Field* lists 282 publications to have appeared up to 1973. About one third of them are review articles. Papers on disulfides and their oxidation products predominate, but surprisingly few of them are concerned with disulfides of biological importance. S—S bridges are of importance for the spatial structure, and hence for the physiological activity, of numerous proteins. The report deals with the physical properties and reactions of disulfides and methods for the synthesis of these compounds. [Disulfides and Polysulfides in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 303—382; 282 references]

[Rd 967 IE]

The photolysis of saturated alcohols, ethers, and amines is considered in a survey by *C. von Sonntag* and *H.-P. Schuchmann*. These compounds are transparent in the near ultraviolet, only beginning to show significant absorption (except the amines) in the region of 200 nm. Although this spectral region is readily accessible experimentally, only little is known about the photolytic behavior of saturated alcohols, ethers, and amines, and the present report was written with the intention of stimulating research in this area. [Photolysis of Saturated Alcohols, Ethers, and Amines. Adv. Photochem. *10*, 59—145 (1977); 195 references]

[Rd 977 IE]

Protein inhibitors of α-amylase in wheat are reviewed by *V. Buonocore, T. Petrucci,* and *V. Silano*. Their localization, molecular properties, and biological significance are discussed. Further topics are their specificities of inhibition, the structural requirements necessary for an interaction between the enzyme and the inhibitor, and the significance of the presence of the inhibitors in foodstuffs. The article finally deals with the genetic aspects of inhibitor synthesis and the possibility of improving the nutritional value and insect resistance of wheat by the cultivation of new varieties. [Wheat Protein Inhibitors of α-Amylase. Phytochemistry *16*, 811—820 (1977); 87 references]

[Rd 980 IE]

The influence of drugs and hormones on lipolysis in heart is the subject of a report by *J. J. Lech, G. J. Jesmock,* and *D. N. Calvert*. In contrast to the lipase from adipose tissue, which has been shown to be directly influenced by cyclic AMP, hormonal control of the heart enzyme has so far only been indirectly inferred. The activation of lipolysis in heart muscle by hormones, drugs or physical exertion is thus possibly due to a mechanism which generally comes into action when endogenous substrates have to be used because of an increased energy requirement. [Effect of Drugs and Hormones on Lipolysis in Heart. Federation Proc. *36*, 2000—2008 (1977); 76 references]

BOOK REVIEWS

Analysis with Ion-Selective Electrodes. By *P. L. Bailey*. Heyden, London—New York—Rheine 1976. 1st edit., xii, 228 pp., various figures and tables, bound, DM 43.50.

This is an interesting addition to the literature that has already appeared in this field, since it differs somewhat in its organization and in the selection of material from other comprehensive accounts of ion-selective electrodes. While it gives very exhaustive and clear information on all practical aspects, the theory must be said to be cut short to some extent. For example, a systematic presentation of potential-formation mechanisms would be welcome, and the beginner has to refer to other books in this field to understand the electrode processes.

The arrangement of the material is clear. In addition to sections on the general properties of ion-selective electrodes and on methods of measurement, each electrode type is treated in an independent chapter, the following classification having been selected: glass electrodes with the exception of pH electrodes, solid-state electrodes based on inorganic salts, electrodes based on organic ion exchangers and neutral complexing agents, and gas-sensitive electrodes. There is also a section on special types such as enzyme electrodes and tenside electrodes, and a detailed treatment of reference electrodes. Finally, general constructional principles are treated briefly and directions are given on the construction of ion-selective electrodes.

Since the book was conceived primarily as a practical introduction to the technique of potentiometric analysis, great value is placed on a critical account of electrode properties. This applies to the downright optimistic data published by many electrode manufacturers, to the various perturbing influence, and to the basic limits of sensible application of ion-selective electrodes. The term "selectivity" is treated as is customary in English-language literature: selectivity *coefficients* referred to specified conditions are used, and the value of selectivity *constants* for characterizing electrodes is fundamentally questioned. However, this concept is not undisputed.

In the measurement techniques, all methods including the continuous processes are described in real detail and the advantages and disadvantages of each are very realistically compared. This provides the beginner with a useful guide. In this connection a discussion is also given of the conditions under which ion-selective sensors, more sensitive than glass electrodes, can be used for the severe conditions of plant supervision.

Original papers up to 1975 have been taken into account and are abundantly cited, so that the book constitutes the most up to date literature review available at the present

time. It is this in particular that makes it valuable for an analyst already familiar with the field. For the beginner it is a useful practical introduction.

Handbook of Marine Science. Compounds from Marine Organisms. Vol. I. By *J. T. Baker* and *V. Murphy*. CRC Press, Inc., Cleveland 1976. 1st edit., 226 pp., bound, $ 29.95.

This book closes a large gap in the literature of this field. The authors review very comprehensively the investigations up to 1973 (445 references, 504 compounds isolated from marine organisms) and give tables showing molecular formulas, structural formulas, trivial names, and the biological activities of these compounds, arranged in order of increasing number of carbon atoms. This is followed by a section in which some of these compounds are discussed; here the compounds are arranged according to their structural characteristics. In these respects this book is valuable and the work that has gone into it must be applauded.

Unfortunately, it is impossible to avoid errors in a book of this kind. The reason for this is largely the long production time of three years; for example, the structural formula of saxitoxin has meanwhile been revised. There is also another shortcoming that should be avoided in the next edition: alongside the chemical classification it should be possible to find the substances according to the organism in which they occur (this is in fact most important for marine chemists and marine biologists). For example, on page 53 the constituents of the sponge *Phakellia flabellata* are mentioned and the relevant paper is cited in the bibliography. If, however, one wishes to work in reverse, *i.e.* to find what substances have been isolated from a given species, this appears to be impossible. One looks in vain in the index under "Phakellia"; under "Sponges" too there is nothing to be found, and yet pages have been devoted to sponge substances. The same is true for the keyword "Starfish" and the species names "Asterias" and "Acanthaster". Names are, however, given for species from which fewer substances have been isolated. Again, surugatoxin cannot be found under "S", but under "M", where it is included as a "mydriatic parasympatholytic agent"; the same situation occurs with tetrodotoxin, which is found under "H" ("hypotensive") and not under "T". This unreliable index considerably reduces the usefulness of the book which is a pity since so much trouble and labor has gone into it.

Nevertheless, the marine chemist will welcome the appearance of this Handbook; in spite of the above failings, its purchase will be worthwhile to all working in the field of marine chemistry.

The Selectivity of Chemical Reactions Disguised by Diffusion. Part I: Chemical Selectivity Disguised by Mixing[**]

By Paul Rys[*]

A mixing-reaction model (MIRE) is used to develop criteria, readily accessible by experiment, which permit the chemist to decide whether and when mixing effects influence the product distribution in competitive consecutive or parallel reactions. The validity of these criteria is demonstrated by comparison of prediction and experiment in the examples used.

1. Prologue

"Wissen allein ist nicht Zweck des Menschen auf der Erde; das Wissen muss sich im Leben auch betätigen." (H. Helmholtz)

Biological processes are probably the most interesting selective reactions: we meet them every day. Study of their fascinating specificity has led to numerous model representations by means of which we can now understand and explain some of the selectivity phenomena in the living and the nonliving environment. As successful as these *analyses* of selective biochemical partial processes may prove to be, they still cannot satisfy a *synthetically* oriented scientist, who will feel himself challenged by the difficult but exciting demand that he should apply his knowledge of selectivity principles to develop highly selective syntheses and industrial processes[1]. Setting this goal opens up to industrial chemistry a wide and promising field of research, inasmuch as more selective industrial chemical syntheses promise a better utilization of chemical raw materials and minimization of the byproducts burdening the environment.

It seems that the selectivity principle of enzymatic processes is based on an optimal combination of three partial processes, namely *diffusion*, *intermolecular adsorption* (complex formation), and *chemical change* (the making and breaking of bonds). In order to predict and understand the specificity of such complex reaction systems, it is not, however, sufficient to analyze these partial processes individually. It is rather their behavior on interaction that causes the observed selectivity effects and which therefore we must investigate.

In the present article and in Part II, which will follow later, we shall discuss one of these mutual relationships, namely the coupling of the diffusion processes with chemical changes. With the aid of the "engineering approach"—a model suitable for our purpose—simple criteria have been derived that allow the experimental chemist to decide, without much mathematics, *whether* and *when* diffusion processes will influence the product distribution in a chemical process. To provide a simpler overview, only reactions in solution are treated here, but, except where specifically stated otherwise, the selectivity criteria derived apply also to gas-phase reactions. Finally, no distinction is made here between "homogeneous" and "heterogeneous" reactions, as the fundamental principles discussed do not depend on the resolution of any measuring

[**] Part II (Selectivity Determining Properties of Encounter Complexes) will shortly appear in this journal.

instrument used. The discussion is limited to isothermal reaction systems.

2. Basic Concepts of Reactivity and Selectivity

"*A clear statement of the problem requires clear definitions*".

The concept of chemical selectivity is intimately linked to the concept of chemical reactivity, and it can therefore be defined only in connection with the latter. The rate constant of the chemical reaction may serve as an experimental measure of the reactivity. This reaction consists either of a single chemical step or of a sequence of several events. In the former case we shall speak of an *elementary* reaction, while in the latter we are dealing with a *complex* reaction.

What is the information that can be deduced from the rate constant of an elementary reaction? In principle, an answer could be provided by a rigorous description of the chemical dynamics by means of quantum mechanics: Solution of the *time-dependent* Schrödinger equation would first of all yield not only information about the energy states of all the molecules present in the system but also predictions about the rate of physical processes in which energy is transferred between degrees of freedom and between molecules. The chemical transformation of molecules in the various energy states could be treated correspondingly. Statistical averaging of the rates of all these elementary steps over all possible energy states would lead to the mean measurable reaction rates. The mathematical complexity unfortunately prevents this procedure from being usable.

To be able, nevertheless, to calculate approximate relative reactivities of elementary reactions we nowadays use simpler methods. These start from the simplifying assumption that the pre-equilibrium energy-transfer processes are much faster than the actual chemical reaction. This assumption makes it possible, at least in principle, to use the solution of the *time-independent* Schrödinger equation to correlate the "static" properties of the molecules with the energetic and structural differences between the reacting molecules in the ground and the transition state and thus with the rate constants of elementary reactions. Static properties of the reactant or intermediate molecules, projected to the rate-limiting transition state, are described as reactivity indices, examples being free valence, localization energies, charge densities, *Brown*'s Z values, and *Dewar* reactivities. Finally, there are more modern models by means of which it is possible to predict even the influence that the reactants may mutually exert on their reactivity indices[2].

Before going any further, however, it is essential to take note of the following points:

1. The assumption that the calculated reactivity indices can be correlated with the measured rate constants is valid only for reactions whose rate is independent of the rate of diffusion of the reactants.
2. The rate constant determined by kinetic measurements is a macroscopic quantity. As such, it is a measure of the free activation enthalpy of the *over-all* chemical process. This process can be either an elementary or a complex reaction. A measured rate constant can never be referred with certainty to an elementary reaction or to the reactivity index calculated from it. It is true that a complex reaction can be traced by kinetic determination of consecutive, quasistationary intermediate products[3], but this is possible only in the most favorable cases. If no intermediate can be detected, then there is still no proof that an elementary reaction is in fact occurring. Here arises the critical question as to how conclusive kinetic measurements can be. How long must the lifetime of a species be for the species to be considered as a potential consecutive intermediate in a chemical reaction? Is it reasonable, for example, to postulate also rotamers or even certain solvation states and solvent structures as quasistationary intermediates? If so, then what is actually a chemical elementary step in solution?

All these questions will be treated in greater detail in Part II.

Kinetic chemical selectivity can be defined as the ratio of the rate constants of two competing elementary or complex chemical reactions. Correspondingly, thermodynamic selectivity would be defined as the ratio of the equilibrium constants of the competing reactions. For known kinetic orders of the competing reactions the chemical selectivity can be determined experimentally from the product distribution. This, however, gives the *intrinsic* (actual) chemical selectivity only if the rate constants compared refer solely to the events of bond making and breaking. If, on the other hand, diffusion or adsorption effects influence the measured reaction rates and the product distribution, then we speak of the selectivities as *disguised by diffusion* or *disguised by adsorption*[4].

3. Partial Processes in a Chemical Reaction

In a chemical process the reactants may pass through partial processes that precede the chemical change before the actual chemical event (bond formation and bond opening) can occur. For a clear discussion of the possible diffusion effects it will

1. Macroscopic mixing process (convection)

BBAABBAA	BABABABA
BBAABBAA ⟶	ABABABAB
AABBAABB	BABABABA
AABBAABB	ABABABAB

3. Encounter process (diffusion)

AB ⟺ (A, B)

Encounter complex

4. Chemical event

(A, B) ⟶ P

Scheme 1. Partial processes of a bimolecular unidirectional reaction in solution.

be useful to distinguish the partial processes outlined in Scheme 1.

At the beginning the two reactants A and B are mixed. During or after this mixing a diffusion process on the "molecular level" occurs, which leads to the encounter complex. This complex can either decompose or can undergo the chemical event that leads to the product P.

Such division into partial processes reminds us that discussions of reaction mechanisms are generally confined strictly to the event occurring within the solvent cage of the encounter complex. Therefore, the kinetics and product distribution provide access to reaction mechanisms only if the preceding diffusion step is much faster than the chemical event. If this condition is not fulfilled—and that is commoner than is generally assumed—then the *measured* kinetic data and selectivities are disguised by diffusion effects[*]. It is most important to distinguish two situations, each of which can lead to such diffusion effects, namely:

1. The observed kinetics of a reaction can be influenced by the *rate of mixing of the reacting solutions* (mixing-disguised kinetics).
2. The kinetics can be disguised by the *rate of formation of the encounter complex* (encounter-disguised kinetics).

It should be noted in this connection that in mixing-disguised reactions the encounter process (Scheme 1) may be considerably faster than the chemical event. Moreover, we cannot assume, as is often wrongly done, that every encounter-disguised reaction is also disguised by mixing. In the present Part I we shall discuss the influence of the mixing processes on the product distribution of consecutive and parallel reactions. Later, in Part II, we shall deal with the selectivity-determining influence of the encounter process.

Substrate selectivity:

$$A + B \rightleftarrows (A,B) \rightarrow A{-}B$$
$$C + B \rightleftarrows (C,B) \rightarrow C{-}B$$

The product distribution (A—B)/(C—B) can be influenced by diffusion effects

Positional selectivity:

$$A{-}X + C \rightleftarrows (A{-}X,C) \begin{cases} \nearrow A{-}X{-}C \\ \searrow C{-}A{-}X \end{cases}$$

The product distribution (A—X—C)/(C—A—X) is not influenced by diffusion effects

Scheme 2. Possible influence of preceding diffusion processes on the measured substrate and positional selectivity.

[*] The rate of an over-all process is *described* by its kinetics and is *determined* from the rates or the equilibrium positions of individual partial processes. Rate-*describing* partial processes are considered to be all those whose rate equations (differential equations) must be taken into account in the formulation of the over-all kinetics. It should be noted that, if rapidly established, equilibria are taken into the rate equation of the process because of the position of the equilibrium and not because of its kinetics. These equilibria are rate-*determining* and not rate-*describing*. If the kinetics of the total process are described by the kinetics of *one single* partial process, then that partial process is rate-*controlling*. If, however, two or more partial steps are rate-describing, the kinetic behavior of the over-all process is made up of a coupling of these rate-describing steps. The kinetics of one of these partial steps are then *disguised* by the others.

It is important to take account of the fact that, whatever their origin, diffusion effects can influence the measured substrate selectivity but not the positional selectivity (Scheme 2).

Let us consider *substrate*-selectivity first. We speak of this kind of selectivity when a reagent B can react with either compound A or compound C. We recognize that in this case each of the two reactions forms *its own* encounter complex and thus that the product ratio can be influenced by diffusion effects. In contrast to substrate selectivity we have *positional* selectivity, which, for example, determines the *ortho/meta/para*-isomer ratios in substitution reactions of arenes, these being largely independent of preceding diffusion effects. The isomers, which are represented in Scheme 2 as A—X—C and C—A—X, are all formed from the *same* encounter complex. Their ratio thus depends on the likelihood of success in the collisions *within* this encounter complex, and thus not directly on preceding diffusion processes.

To explain the positional selectivities of diffusion-controlled reactions, we must briefly discuss the difference between gas-phase chemical reactions and those in the liquid phase. Whereas the encounter complex in gas-phase reactions lasts essentially for only one collision between the reactants, it can be estimated[5,6] that in general the corresponding encounter complex in the usual solvents at room temperature survives some 10 to 1000 collisions (cage effect). The consequence is that in liquid-phase encounter-controlled reactions isomers are formed in various amounts, which are determined by the chemical reactivities of the various positions; within 10 to 1000 collisions a "selection" of reaction positions according to the chemical reactivities is quite possible. Indeed, it is only in the extreme case, when *every* collision within the encounter complex leads to the chemical event (*collision*-controlled reaction), that a statistical distribution of isomers according to the number of reaction positions can be observed. This is what occurs in the collision-controlled events in the gas phase.

4. Mixing-Disguised Chemical Reactions in Solution

"*Measured kinetics is not what it seems*". (*J. Wei*[7])

A comprehensive mathematical description of the mixing process between two liquids is extremely complicated. It would not be useful to discuss here the numerous model representations, especially as many of them define indices that, although they do in fact characterize the mixing process, are not so far accessible experimentally. To develop, for mixing-disguised reactions, selectivity criteria that will be readily applicable by, and useful to, experimental chemists we shall here make use of a simple *MI*xing-*RE*action model (MIRE)[8,9]. This permits us to describe clearly the coupling between the partial processes displayed in Scheme 1 and to determine the influences that result from this coupling upon the product distribution. The discussion will first be confined to wholly miscisble reaction solutions. Immiscible reaction solutions could be treated similarly, but including consideration of the corresponding solubility parameters of the reactants. Reviews should be consulted for an exhaustive treatment of mixing processes[10,11].

4.1. The Concept of a Simple Mixing-Reaction Model

When two solutions are mixed together they first of all form small liquid elements. The size of the resulting *eddies*, *i.e.* the "segregation length" of the reaction mixture, depends on the turbulence, which is produced *e.g.* by mechanical stirring. If one assumes that, to a first approximation, these eddies are spherical droplets, then their average[*] radius $\mathscr{R}$ can be estimated from turbulence theory[10, 11].

Values of $\mathscr{R} = 10^{-2}$ to 10^{-3} cm are found for the usual solvents such as water, ethanol, or hexane, and this corresponds to an agglomeration of 10^{12} to 10^{15} molecules. In general, the mean size of these liquids elements increases with increasing viscosity of the reaction medium. The stirring imposes on the eddies a convective transport, namely eddy diffusion or dispersion, which leads to a "macroscopic homogeneity" of the reaction mixture (first partial process in Scheme 1). In this state further mixing takes place, but now mainly by diffusion on the molecular level[**] (second partial process in Scheme 1[***]).

The relaxation time of this diffusion process is obtained from the lifetime τ_D of the eddy, which in turn can be estimated from the $\mathscr{R}$ values and the mean diffusion coefficients D of the dissolved molecules (10^{-5} to 10^{-6} cm^2/s) by the relation $\tau_D \approx 0.05\,\mathscr{R}^2/D$. τ_D is in the region of 0.01 to 1 s. Hence it must be concluded that every chemical event that can occur in a time shorter than 0.01—1.0 s may be hindered by mixing processes.

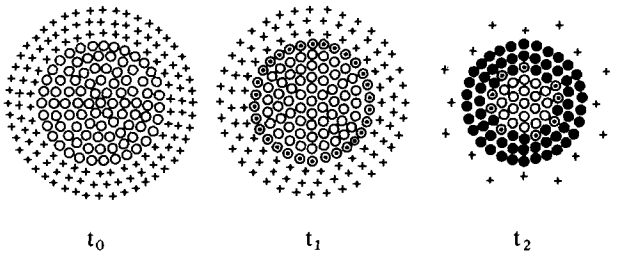
4.2. Competitive Consecutive Reaction Disguised by Mixing

In what follows we shall derive mixing criteria for a competitive consecutive reaction (Scheme 3) that

1. is *first*-order with respect to the reactants A, B, and R and
2. is not encounter-disguised. The latter is the case when the chemical event (Scheme 1) takes place more slowly than the dissociation of the encounter complex formed in a low, quasistationary concentration.

$$A + B \underset{k_{d1}}{\overset{k_{a1}}{\rightleftharpoons}} (A,B) \xrightarrow{k_{r1}} R \qquad \text{Primary reaction}$$

$$R + B \underset{k_{d2}}{\overset{k_{a2}}{\rightleftharpoons}} (R,B) \xrightarrow{k_{r2}} S \qquad \text{Secondary reaction}$$



$k_1 = k_{a1} k_{r1}/k_{d1}$: second-order rate constant of the primary reaction
$k_2 = k_{a2} k_{r2}/k_{d2}$: second-order rate constant of the secondary reaction

Scheme 3. Competitive consecutive second-order reaction.

Furthermore, a reaction system with very efficient mechanical stirring is assumed, in which the eddy diffusion, *i.e.* the mutual displacement of the eddies, is much faster than molecular diffusion into or out of the eddies. In Scheme 1 this would mean that the macroscopic mixing process occurs faster than the microscopic mixing. If this condition is fulfilled, we can make the simplifying assumption that the concentration on the eddy surface at any one time corresponds to that in the surrounding solution.

4.2.1. A Qualitative Description[8]

For a clear qualitative understanding of the effect of mixing on the product distribution in a competitive consecutive reaction, it is assumed in the schematic representation of the mixing process (Scheme 4) that the reactant B, being the mobile reactant, diffuses into the liquid eddy in which the molecules A, R, and S are dissolved as immobilized reactants or products[*]. For the sake of simplicity these eddies are represented as spherical liquid elements of constant radius. A simplification of this kind does not detract from the validity of the qualitative conclusions.

Scheme 4. Schematic representation of a mixing-disguised competitive consecutive second order reaction (cf. Scheme 3). Reaction times: $t_0 < t_1 < t_2$. Mobile component: reactant B (+). Immobile components: substrate A (○); primary product R (⊙); secondary product S (●).

In a competitive consecutive reaction *one* molecule A can "bind" *two* molecules of the reactant B in two reactions steps. After a first time interval A and B will have reacted at the periphery of an eddy to produce the primary product R. In a further time interval a molecule B can react with a further molecule A to form R, but only if it succeeds in diffusing through the peripheral zone of R molecules already formed without being trapped there by the substance R in a reaction affording the secondary product S. This succeeds less often, the longer the relaxation time of the diffusion process is in comparison to the relaxation time [**] of the secondary reaction. In the extreme case a mixing-controlled reaction will convert all the R into S before the molecule B finds a further molecule A. Thus, at the end of the reaction practically only the secondary product S is present and no primary product R can be detected. In this case the selectivity k_1/k_2 loses its influence on the product distribution.

4.2.2. The Quantitative Description[8, 9]

The mathematical description of a mixing-reaction system can be arrived at from a mass balance for the components

[*] Practical limits to subdivision of the eddies is set by the energy uptake of the mixing system: $\mathscr{R}$ is inversely proportional to only the 4th root of the stirring energy taken up [11].

[**] Further mixing could conceivably occur by repeated coalescence and re-formation of the eddies. However, on the basis of present knowledge of the dependence of coalescence frequency on turbulence [12], and on the basis of an estimated maximal possible rate of redispersion, it can be assumed that this process plays only a minor role in the mixing of reaction solutions.

[***] This microscopic mixing is characterized by the degree of segregation. It can have values between 1 for unmixed and 0 for completely mixed reaction solutions.

[*] In reality all the reactants are mobile. This has been taken into account in the quantitative description (Section 4.2.2), as far as it proved necessary.

[**] The relaxation time is the time that elapses until a significant quantity in the process has achieved the $(1 - 1/e)$-th part ($= 63.2\,\%$) of the change from the initial value ($t = 0$) to its final value ($t = \infty$).

i in a differential volume element that is fixed in space. This procedure leads to the continuity equation (1), which describes the change in the concentration of the component i with respect to time at a fixed point in space. This change results from the motion of species i and its chemical reaction:

$$\frac{\partial[\mathrm{i}]}{\partial t} = -(\nabla \cdot \vec{N}_\mathrm{i}) + \mathbf{r}_\mathrm{i} \tag{1}$$

([i] = concentration of the component i; ∇ = "del" or "nabla" operator; $\vec{N}_\mathrm{i}$ = the flux vector of the component i; t = time; $\mathbf{r}_\mathrm{i}$ = rate of formation of the component i).

If the flux $\vec{N}_\mathrm{i}$ results only from concentration gradients of the components i, *i.e.* the influence of temperature and pressure gradients as well as of field forces can be neglected, we arrive at equation (2):

$$\frac{\partial[\mathrm{i}]}{\partial t} = -(\nabla \cdot [\mathrm{i}]\vec{v}) + (\nabla [\sum_\mathrm{i}] D_\mathrm{i} \nabla x_\mathrm{i}) + \mathbf{r}_\mathrm{i} \tag{2}$$

([$\sum_\mathrm{i}$] = sum of the concentrations of all components in the system (including the solvent); D_i = diffusion coefficient of the component i; $\vec{v}$ = mean velocity[*], x_i = mole fraction of the component i).

If now, for the diffusion in the eddy, it is valid to assume that [$\sum_\mathrm{i}$] and the diffusion coefficient are constant, and that in dilute solutions the molar mean velocity is zero, then it follows from equation (2) that:

$$\frac{\partial[\mathrm{i}]}{\partial t} = D_\mathrm{i} \nabla^2 [\mathrm{i}] + \mathbf{r}_\mathrm{i} \tag{3}$$

(∇^2 = the Laplacian operator).

For spherical eddies of constant radius equation (3) can be rewritten in polar coordinates:

$$\frac{\partial[\mathrm{i}]}{\partial t} = D_\mathrm{i}\left(\frac{\partial^2[\mathrm{i}]}{\partial r^2} + \frac{2}{r}\frac{\partial[\mathrm{i}]}{\partial r}\right) + \mathbf{r}_\mathrm{i} \tag{4}$$

In the competitive consecutive reaction according to Scheme 3 the following relations can be derived for the rates of formation $\mathbf{r}_\mathrm{i}$[**]:

$$\mathbf{r}_\mathrm{A} = -k_1[\mathrm{A}][\mathrm{B}] \tag{5}$$
$$\mathbf{r}_\mathrm{B} = -k_1[\mathrm{A}][\mathrm{B}] - k_2[\mathrm{R}][\mathrm{B}] \tag{6}$$
$$\mathbf{r}_\mathrm{R} = k_1[\mathrm{A}][\mathrm{B}] - k_2[\mathrm{R}][\mathrm{B}] \tag{7}$$
$$\mathbf{r}_\mathrm{S} \doteq k_2[\mathrm{R}][\mathrm{B}] \tag{8}$$

For the calculation of the reaction behavior and the product distribution of this mixing-reaction system the initial conditions and the boundary conditions must be laid down. The initial conditions are taken when the eddies are built ($t = 0$) assuming that no diffusion and reaction in the eddy have taken place until this moment. If the reaction is carried out batchwise, and hence discontinuously, *i.e.* if one of the reactant solutions is first prepared and the other is mixed into it, the initial conditions depend on the rate at which the two solutions are united. If the addition is *slow*, each eddy encounters new initial conditions set up by the reaction behavior of its predecessors. This is a situation that the experimental chemist meets daily in the laboratory. For the model calculations considered here the simplifying assumption was made that the reactant solutions are united *instantaneously*. The same initial conditions then apply to all the eddies formed (see below). The conditions in a continuously operated stirred vessel are again quite different. In comparison with the conditions under discontinuous operation, we note that the entering reactant stream of B molecules now meets fewer A but more of already formed R and S molecules. Furthermore, the initial conditions depend on the macroscopic mixing state in the stirred vessel, and hence on the site of addition of the reactant stream.

The boundary conditions are obtained from the symmetry of the eddy that is assumed to be spherical: at first there is no concentration gradient at the center of the eddy, and thus also no material flux [eq. (9)].

$$\left(\frac{\partial[\mathrm{i}]}{\partial r}\right)_{r=0} = 0 \tag{9}$$

A further boundary condition is obtained by applying the mass balance of all the mobile components to the eddy and to the solution around it [eq. (10)].

$$V_\mathrm{s}\left(\frac{\partial[\mathrm{i}]}{\partial t}\right)_{r \geq \mathscr{R}} = -S_\mathrm{e} D_\mathrm{i}\left(\frac{\partial[\mathrm{i}]}{\partial r}\right)_{r=\mathscr{R}} \tag{10}$$

(V_s = volume of outer solution; S_e = eddy surface; $\mathscr{R}$ = eddy radius)

The left-hand side of equation (10) gives the time variation of the concentration of i in the outer solution around the eddy. The right-hand side describes the flow of the component i through the eddy surface. Rearranging, we obtain the boundary condition (11).

$$\left(\frac{\partial[\mathrm{i}]}{\partial t}\right)_{r \geq \mathscr{R}} = -3\frac{V_\mathrm{e} D_\mathrm{i}}{V_\mathrm{s} \mathscr{R}}\left(\frac{\partial[\mathrm{i}]}{\partial r}\right)_{r=\mathscr{R}} \tag{11}$$

(V_e = eddy volume)

The system given by equations (4) to (8) and also the initial and boundary conditions can be normalized by using the following dimensionless quantities:

$$\mathbf{X} = \frac{r}{\mathscr{R}};\ \mathbf{T} = \frac{Dt}{\mathscr{R}^2};\ \mathbf{A}_\mathrm{A} = \frac{[\mathrm{A}]}{[\mathrm{A}]_0};\ \mathbf{B}_\mathrm{B} = \frac{[\mathrm{B}]}{[\mathrm{B}]_0};\ \boldsymbol{\Omega}_\mathrm{A} = \frac{[\mathrm{R}]}{[\mathrm{A}]_0}$$
$$\mathbf{E} = \frac{[\mathrm{A}]_0}{[\mathrm{B}]_0};\ \boldsymbol{\varphi}^2_{\mathrm{B},1} = \frac{\mathscr{R}^2 k_1 [\mathrm{B}]_0}{D};\ \boldsymbol{\varphi}^2_{\mathrm{B},2} = \frac{\mathscr{R}^2 k_2 [\mathrm{B}]_0}{D};\ \boldsymbol{\alpha} = \frac{V_\mathrm{A}}{V_\mathrm{B}} \tag{12}$$

(V_A and V_B = reaction volumes of the substrate A and the reactant B; the subscript 0 denotes the initial concentrations before mixing)

For this normalization it is permissible to use the simplifying assumption that all the components A, B, R, and S have the same diffusion coefficient ($D_\mathrm{i} = D$). This leads to the system of equations (13) to (15). Since the concentration distribution of the secondary product S has no direct influence on the selectivity behavior of the reaction system, the corresponding continuity equation for S is superfluous when it comes to

[*] This term denotes the velocity caused by the bulk motion within the eddy.

[**] If all the quantities in equations (4) to (8) are expressed in cgs units, the k_1 and k_2 must be divided by 10^3 to obtain the usual dimensions of $1\ \mathrm{mole}^{-1}\ \mathrm{s}^{-1}$.

calculating the product distribution. The total amount of S is obtained from the mass balance for the whole system.

$$\frac{\partial \mathbf{A}_A}{\partial \mathbf{T}} = \frac{\partial^2 \mathbf{A}_A}{\partial \mathbf{X}^2} + \frac{2}{\mathbf{X}} \frac{\partial \mathbf{A}_A}{\partial \mathbf{X}} - \varphi^2_{B,1} \mathbf{A}_A \mathbf{B}_B \tag{13}$$

$$\frac{\partial \mathbf{B}_B}{\partial \mathbf{T}} = \frac{\partial^2 \mathbf{B}_B}{\partial \mathbf{X}^2} + \frac{2}{\mathbf{X}} \frac{\partial \mathbf{B}_B}{\partial \mathbf{X}} - \mathbf{E}\mathbf{B}_B(\varphi^2_{B,1} \mathbf{A}_A + \varphi^2_{B,2} \Omega_A) \tag{14}$$

$$\frac{\partial \Omega_A}{\partial \mathbf{T}} = \frac{\partial^2 \Omega_A}{\partial \mathbf{X}^2} + \frac{2}{\mathbf{X}} \frac{\partial \Omega_A}{\partial \mathbf{X}} + \mathbf{B}_B(\varphi^2_{B,1} \mathbf{A}_A - \varphi^2_{B,2} \Omega_A) \tag{15}$$

If we assume that the eddy consists of the solution of reactant B, then for batchwise operation with instantaneous unification of the reactant solutions and instantaneous dispersion we obtain the following initial and boundary conditions:

Initial conditions: $\mathbf{T}=0$

$\mathbf{X}<1$: $\mathbf{A}_A=0$; $\mathbf{B}_B=1$; $\Omega_A=0$
$\mathbf{X}=1$: $\mathbf{A}_A=1$; $\mathbf{B}_B=1$; $\Omega_A=0$

Boundary conditions: $\mathbf{T}>0$

$$\mathbf{X}=0\text{: } \frac{\partial \mathbf{A}_A}{\partial \mathbf{X}}=0;\ \frac{\partial \mathbf{B}_B}{\partial \mathbf{X}}=0;\ \frac{\partial \Omega_A}{\partial \mathbf{X}}=0$$

$$\mathbf{X}=1\text{: } \frac{\partial \mathbf{A}_A}{\partial \mathbf{T}} = -\frac{3}{\alpha}\frac{\partial \mathbf{A}_A}{\partial \mathbf{X}};\ \frac{\partial \Omega_A}{\partial \mathbf{T}} = -\frac{3}{\alpha}\frac{\partial \Omega_A}{\partial \mathbf{X}};\ \frac{\partial \mathbf{B}_B}{\partial \mathbf{T}} = -\frac{3}{\alpha}\frac{\partial \mathbf{B}_B}{\partial \mathbf{X}}$$

It follows from equations (13) to (15) and from the boundary conditions that the product distribution of a completely reacted (100% conversion) competitive consecutive reaction with given initial and boundary conditions is determined unambiguously by the four quantities $\mathbf{E}$, α, $\varphi^2_{B,1}$ and $\varphi^2_{B,2}$. The φ^2 values are proportional to the ratio of the relaxation times of the microscopic mixing processes and the chemical reaction. They show how strongly a step in the chemical reaction is hindered by preceding mixing processes. This hindrance by diffusion is represented quantitatively in Figure 1[*]. The smaller $\varphi^2_{B,2}$ is, the closer will the relative yields X_S of the secondary product S approach the values for the reaction-controlled case. X_S is defined as the fraction of B molecules that has reacted to give S after 100% conversion:

$$X_S = \frac{2(S)_\infty}{2(S)_\infty + (R)_\infty} \tag{16}$$

($(R)_\infty$ and $(S)_\infty$ = total amounts of R and S formed after infinite time)

As the $\varphi^2_{B,2}$ values increase, X_S becomes increasingly strongly disguised by diffusion effects and approaches the value of 1. The more marked this disguise by mixing, the smaller becomes the influence of the intrinsic selectivity $\varphi^2_{B,1}/\varphi^2_{B,2}$ (or k_1/k_2) on the product distribution.

[*] For the model calculations in Figures 1 to 9, B was taken as an immobile reactant, *i.e.* the diffusion term in equations (14) and (24) was neglected. Analysis of the cost-evaluation for MIRE calculations showed that this simplifying procedure has negligibly little influence on the calculated predictions but that it reduces decisively the time of the calculation.

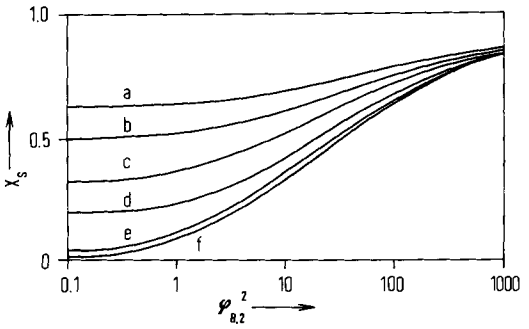


Fig. 1. MIRE model for a competitive consecutive second-order reaction: Calculated relative yields X_S as a function of the mixing modulus $\varphi^2_{B,2}$ for several (a—f) intrinsic selectivities $\varphi^2_{B,1}/\varphi^2_{B,2}$ (a = 1; b = 2; c = 5; d = 10; e = 10^2; f = 10^4). Assumptions: spherical eddy; $\mathbf{E}=1$; $\alpha=1$.

As Figure 2 shows, the influence of the ratio of the reaction volumes α on X_S is not particularly strong. The dependence of the product distribution in mixing-disguised reaction systems on $\mathbf{E}$ can be seen in Figure 3.

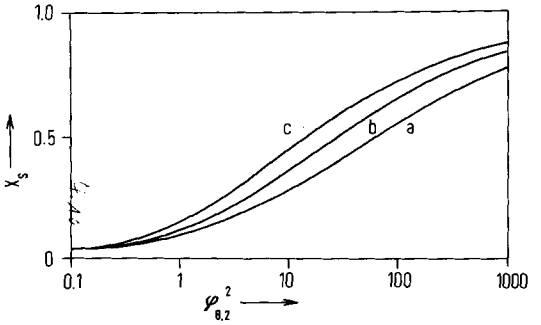

Fig. 2. MIRE model for a competitive consecutive second-order reaction: Calculated relative yields X_S as a function of the mixing modulus $\varphi^2_{B,2}$ for several ratios (a—c) of the reaction volumes α (a = 0.1; b = 1.0; c = 10). Assumptions: spherical eddy; $\alpha\mathbf{E}=1$; $\varphi^2_{B,1}/\varphi^2_{B,2}=100$.

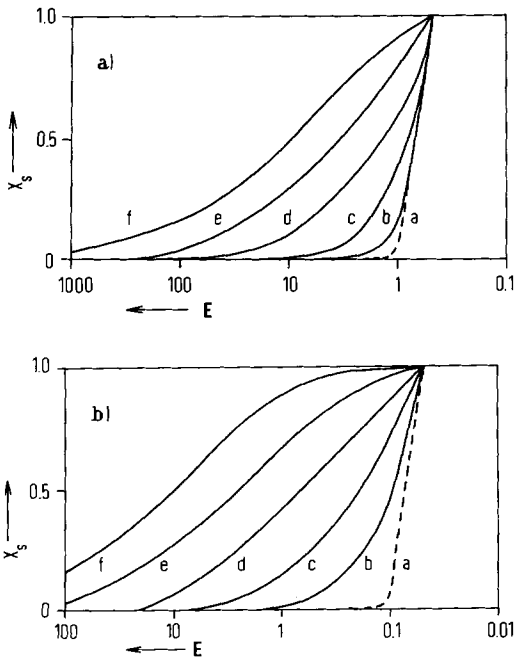

Fig. 3. MIRE model for a competitive consecutive second-order reaction: Calculated relative yields X_S as a function of $\mathbf{E}$ for several (a—f) values of $\mathbf{E}\varphi^2_{B,2}$ ($a \ll 1$; reaction-controlled; b = 1; c = 10; d = 10^2; e = 10^3; f = 10^4). Assumptions: spherical eddy; $\varphi^2_{B,1}/\varphi^2_{B,2}=100$; $\alpha=1$ (Fig. 3a), $\alpha=10$ (Fig. 3b).

The curves in Figure 3, calculated for $\varphi^2_{B,1}/\varphi^2_{B,2}=100$, also characterize the behavior of the reaction at $\varphi^2_{B,1}/\varphi^2_{B,2}>100$ to a good approximation. An indication in that direction was given already by the curves in Figure 1: the selectivity curves e and f for $\varphi^2_{B,1}/\varphi^2_{B,2}=10^2$ and 10^4 lie close together.

Summarizing, the following simple mixing criteria are obtained for the experimenter when, for example, the molar ratio has the value of $\alpha\mathbf{E}=1$:

$\varphi^2_{B,2}<0.1$: mixing effect negligible
$\varphi^2_{B,2}\approx 1$: mixing effect possibly present
$\varphi^2_{B,2}>10$: mixing effect certainly present

4.2.3. Experimental Results

Although chemists in the laboratory and in production plants have to deal daily with diffusion effects that can be traced back to mixing processes, there are relatively few experimental investigations[13-18] that can be used for comparison with MIRE calculations. Moreover, it is precisely for mixing-disguised rapid reactions that the intrinsic (undisguised) kinetics essential for this comparison are so often unknown. Many of the previous models are not amenable, or only difficultly so, to experimental testing[19].

Mixing-disguised product distributions have long been suspected in aromatic nitrations. In many studies the remarkable observation has been reported that on equimolar nitration of durene (1,2,4,5-tetramethylbenzene) mainly dinitrodurene and unchanged durene were found, but hardly any mononitrodurene[20-22,14]. Similar observations have been made with other substrates[23,28]. These experimental results are in apparent contradiction to the general knowledge of the mechanism of electrophilic aromatic substitution, according to which the second nitration should be slower than the first by a factor of $>10^6$ because of the deactivating effect of the first nitro group. *Willstätter* and *Kubli*[24], and also *Olah*[25], sought to explain the apparently faster second nitration by reaction mechanistic considerations. Many other authors, however, pointed to mixing effects as the possible cause[14,21,22,26-29]. The product-determining influence of such mixing effects was questioned particularly by *Olah*[30].

The MIRE model presented above permits mixing effects and their influence on the product distribution to be investigated in systematic experiments. The necessary information is provided by the mixing modulus $\varphi^2_{B,2}$ derived as above: if the intrinsic selectivities exceed about 100 (in aromatic nitration they usually exceed 10^6), then the product distribution and thus the relative yield X_S are almost wholly determined by the $\varphi^2_{B,2}$ values; this is true for constant $\mathbf{E}$ and α, for given initial conditions (Fig. 1). X_S is expected to be most sensitive for $\varphi^2_{B,2}$ values between 1 and 10^3. Experimentally, these values can be easily varied by means of the quantities $\mathscr{R}$, $[B]_0$, k_2, and D:

1. The mixing modulus $\varphi^2_{B,2}$ is most influenced by the eddy radius $\mathscr{R}$ which is applied as its square. If the other reaction conditions are unchanged, $\mathscr{R}$ can be varied by the stirring speed or by the method of mixing (mixing chamber). This dependence of the product distribution on the stirring system has been demonstrated experimentally, for example in the nitration of durene[22]. Since it is not yet possible to determine $\mathscr{R}$ exactly by independent measurements, the values of $\varphi^2_{B,2}$ cannot be calculated[*]. Thus, a *quantitative* comparison of the experimentally determined and the calculated X_S values is not feasible.
2. Such a comparison is, however, possible under constant stirring conditions. The selectivity curves can be determined for given values of α by corresponding variations of $[A]_0$, $[B]_0$, and thus of $\mathbf{E}$ and $\varphi^2_{B,2}$ and can then be compared with the calculated predictions[14,15,17]. Figure 4 shows a comparison of such curves for five arenes, *i.e.* for five k_2 values. From the relative positions of these curves the relative k_2 values have been determined as follows: prehnitene/durene/mesitylene/*m*-xylene[**]/*p*-xylene = 300/100/20/3/1. If it becomes possible to determine even one of these values under reaction-controlled conditions, then the rate constants k_2 of the other arenes can be obtained from the relative values[15].

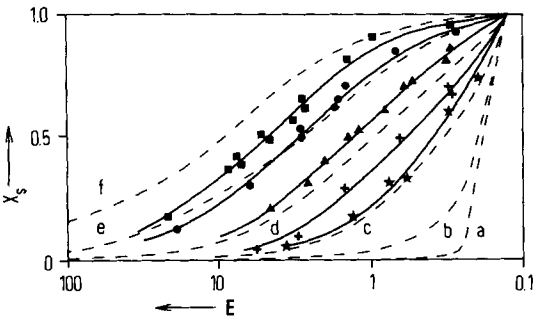

Fig. 4. Mixing-disguised nitration of aromatic compounds (A) by $NO_2^+PF_6^-$ (B) in nitromethane (20°C) [15]. $\alpha=4$. Experimental results: ⋆ *p*-xylene; + *m*-xylene; ▲ mesitylene = 1,3,5-trimethylbenzene; ● durene = 1,2,4,5-tetramethylbenzene; ■ prehnitene = 1,2,3,4-tetramethylbenzene. Calculated curves (broken curves) for several (a—f) values of $\mathbf{E}\varphi^2_{B,2}$ ($a\ll 1$, reaction-controlled; $b=1$; $c=10$; $d=10^2$; $e=10^3$; $f=10^4$). $\varphi^2_{B,1}/\varphi^2_{B,2}=100$. The curves calculated for $\varphi^2_{B,1}/\varphi^2_{B,2}=100$ also represent to a good approximation the predictions for $\varphi^2_{B,1}/\varphi^2_{B,2}>100$ (cf. Fig. 1).

This comparison of the experimental data with the MIRE calculations is, strictly speaking, possible only because the intrinsic kinetics of the chemical reaction are known: the second nitration by nitronium salts is of first order in both R and B[15].

Azo coupling is another reaction that is often disguised by mixing. For the interpretation of its product distribution one must take into account not only the mixing processes discussed above but also the following effects[17]: First, the primary coupling in the competitive consecutive reaction (Scheme 3) generally consists of two (or more) parallel reactions, and they in turn may be mixing-disguised. For example, in the coupling of 1-naphthol derivatives (A) the reaction may occur in position 2 or 4. The bisazo product (S) is then formed from two monoazo products (R) that themselves differ in reactivity. Secondly, it must be remembered that azo-coupling liberates protons which, even with macroscopic buffering, lead to *local* pH gradients in the reaction zone. In mixing-disguised reactions in which these pH gradients cannot be sufficiently rapidly evened out this leads to a shift in the preceding

[*] The $\mathscr{R}$ values can in fact be calculated by turbulence theory [10, 11, 16], but the results cannot be tested experimentally and must be regarded only as approximate.

[**] Interpretation of the results for *m*-xylene is made difficult by the fact that more than one mononitro compound is formed in the first nitration step.

acid-base equilibria of the reactants in the reaction zone and thus influences the reaction rates. Thirdly, the primary or secondary reaction may generally be base-catalyzed. In this case the rate of each reaction step is influenced by the *local* concentration gradient of bases in the eddy.

For a test of the usefulness of the MIRE model for characterizing the reaction behavior of mixing-disguised azo couplings it proved possible to find conditions[17] that avoided the complications mentioned above. As Figure 5 shows, the agreement between the experimental results and the calculated predictions is remarkable. The calculated values were fitted to the experimental data by using the characteristic time $\mathscr{R}^2/D = 1$ s. Thence it can be concluded that, for the reaction conditions used, the eddies have a mean radius $\mathscr{R} = ca.\ 3\times10^{-3}$ cm and a lifetime τ_D of about 5×10^{-2} s.

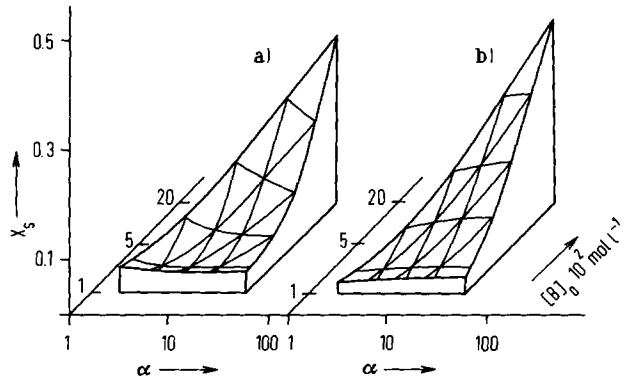

Fig. 5. Mixing-disguised azo coupling of 5-hydroxy-2-naphthalenesulfonic acid with diazotized aniline at pH 10.8 (22°C; $I = 0.2$) [17]. a) Experimental results: $\alpha E = 2$; $k_1/k_2 = 1850$. b) Calculated behavior $\alpha E = 2$; $\varphi^2_{B,1}/\varphi^2_{B,2} > 1000$ (I is the ionic strength).

On the assumption that the preceding acid-base equilibria of the coupling components and of the diazonium ion in the reaction zone are set up very rapidly in comparison with the mixing process, a mixing criterion [eq. (17)] can be set up for azo coupling under conditions close to practice[17].

$$\varphi^2_{B,2} = \frac{\mathscr{R}^2[B]_{tot,0}k_2}{D}\left(\frac{K_R}{K_R+[H_3O^{\oplus}]_l}\right)\left(\frac{[H_3O^{\oplus}]_l^2}{K_1K_2+[H_3O^{\oplus}]_l^2}\right) \qquad (17)$$

($[B]_{tot,0}$ = total concentration of the diazo component at time $t = 0$; K_R = acidity constant of the monazo dye; K_1 = equilibrium constant of the diazonium-diazohydroxide equilibrium; K_2 = acidity constant of the diazohydroxide; $[H_3O^{\oplus}]_l$ = local $H_3O^{\oplus}$ concentration)

The *local* $H_3O^{\oplus}$ concentration is a complex function of the rates of the primary and secondary coupling and of the local (microscopic) buffer capacity of the reaction system. It is, however, smaller than the macroscopically measurable $H_3O^{\oplus}$ concentration and could be calculated by means of equation (4). The rate constant k_2 may also be a function of the local concentration of general bases, in cases where the proton abstraction from the σ-complex is the rate-limiting step in the second coupling[31].

3. The $\varphi^2_{B,2}$ values and thus X_S can be influenced by change in the viscosity of the reaction medium. The change in D and $\mathscr{R}$ due to viscosity can be calculated with the aid of equations given by *Kolmogoroff*[11] and by *Wilke* and *Chang*[32]. The expected effect of viscosity on X_S has been confirmed experimentally for the case of a mixing-disguised azo coupling[16].

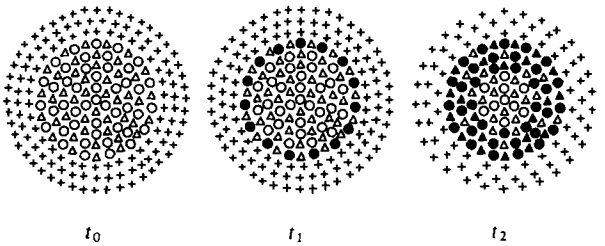
4.3. Competitive Parallel Reaction Disguised by Mixing

For competitive parallel reactions (Scheme 5) assumptions should apply that are analogous to those made for competitive consecutive reactions (Scheme 3), namely that the reactions

1. are each of *first*-order with respect to the reactants A, B, and C, and
2. are not encounter-disguised.

Furthermore, for this reaction system too, the condition should be fulfilled that the microscopic mixing process is the rate-limiting part of the mixing process.

$$A + B \underset{k_{d3}}{\overset{k_{a3}}{\rightleftharpoons}} (A,B) \xrightarrow{k_{r3}} P$$



$$C + B \underset{k_{d4}}{\overset{k_{a4}}{\rightleftharpoons}} (C,B) \xrightarrow{k_{r4}} Q$$

$k_3 = k_{a3}k_{r3}/k_{d3}$ and $k_4 = k_{a4}k_{r4}/k_{d4}$: second-order rate constants

Scheme 5. Competitive parallel second-order reaction.

4.3.1. A Qualitative Description[8]

The qualitative effect of the microscopic mixing process on the product distribution in competitive parallel reactions can be illustrated (Scheme 6) in a manner analogous to that used for the competitive consecutive reaction (Scheme 4).

Scheme 6. Schematic representation of a mixing-disguised, competitive parallel second order reaction (cf. Scheme 5). Reaction times: $t_0 < t_1 < t_2$. Mobile component: reactant B (+). Immobile components: substrate A (○); substrate C (△); product P (●); product Q (▲).

Here the substrates A and C compete for the same reactant B. If the reaction with A is faster than that with C, then in the first time interval more of the product P will be formed in the boundary zone of the eddy. At a later point in time a B molecule must, in order to react with another A molecule, penetrate a zone that has become enriched in the compound C which is less reactive than A. For this reason the reactivity of C appears at this time to be greater than predicted from the selectivity k_3/k_4. In the extreme case of a mixing-*controlled* reaction the measured product distribution becomes 1:1. In this case the selectivity k_3/k_4 loses its influence.

4.3.2. The Quantitative Description[8,9]

The mathematical description of competitive parallel reactions is carried out similarly to that for the competitive con-

secutive reactions. The following relationships for r_i are introduced into equation (4):

$$r_A = -k_3[A][B] \quad (18)$$
$$r_B = -k_3[A][B] - k_4[C][B] \quad (19)$$
$$r_C = -k_4[C][B] \quad (20)$$
$$r_P = k_3[A][B] \quad (21)$$
$$r_Q = k_4[C][B] \quad (22)$$

The same general remarks apply for the initial conditions here as for the consecutive reaction. The boundary conditions are set by equations (9) to (11). If the same assumption ($D_i = D$) applies for normalization, and if we use the dimensionless quantities defined above but supplement them with the quantities:

$$\Gamma_C = \frac{[C]}{[C]_0}; \quad M = \frac{[C]_0}{[A]_0}$$

$$\varphi^2_{B,3} = \frac{\mathscr{R}^2 k_3 [B]_0}{D}; \quad \varphi^2_{B,4} = \frac{\mathscr{R}^2 k_4 [B]_0}{D},$$

then we arrive at the system (23) to (25) for the components A, B, and C. Since the concentration distribution of the products P and Q has no direct influence on the selectivity behavior of the reaction system, the corresponding continuity equations for P and Q are superfluous for calculating the product distribution. The total yields of the products are obtained from the mass balance over the whole system.

$$\frac{\partial A_A}{\partial T} = \frac{\partial^2 A_A}{\partial X^2} + \frac{2}{X}\frac{\partial A_A}{\partial X} - \varphi^2_{B,3} A_A B_B \quad (23)$$

$$\frac{\partial B_B}{\partial T} = \frac{\partial^2 B_B}{\partial X^2} + \frac{2}{X}\frac{\partial B_B}{\partial X} - E B_B(\varphi^2_{B,3} A_A + \varphi^2_{B,4} \Gamma_C M) \quad (24)$$

$$\frac{\partial \Gamma_C}{\partial T} = \frac{\partial^2 \Gamma_C}{\partial X^2} + \frac{2}{X}\frac{\partial \Gamma_C}{\partial X} - \varphi^2_{B,4} \Gamma_C B_B \quad (25)$$

If here too we assume that the eddies are composed of the solution of the reaction component B, then for batchwise operation with instantaneous union of the reaction solutions we obtain the following initial and boundary conditions:

Initial conditions: $T = 0$

$X < 1$: $A_A = 0$; $\Gamma_C = 0$; $B_B = 1$
$X = 1$: $A_A = 1$; $\Gamma_C = 1$; $B_B = 1$

Boundary conditions: $T > 0$

$$X = 0: \quad \frac{\partial A_A}{\partial X} = 0; \quad \frac{\partial \Gamma_C}{\partial X} = 0; \quad \frac{\partial B_B}{\partial X} = 0$$

$$X = 1: \quad \frac{\partial A_A}{\partial T} = -\frac{3}{\alpha}\frac{\partial A_A}{\partial X}; \quad \frac{\partial \Gamma_C}{\partial T} = -\frac{3}{\alpha}\frac{\partial \Gamma_C}{\partial X}; \quad \frac{\partial B_B}{\partial T} = -\frac{3}{\alpha}\frac{\partial B_B}{\partial X}$$

The product distribution from a completely reacted competitive parallel reaction system is determined, for given initial and boundary conditions, by the five quantities **E**, **M**, α, $\varphi^2_{B,3}$, and $\varphi^2_{B,4}$. The φ^2 criteria here again show how strongly the chemical event is hindered by mixing processes. The hindrance due to diffusion is presented quantitatively in Figures 6 to 9[*]. The relative yield X_Q of the product Q is defined as the proportion of the B molecules that, after 100 % conversion, have reacted to form Q. In general, one can apply the same remarks as in the discussion of the reaction behavior for the competitive consecutive reactions; the Figures speak for themselves.

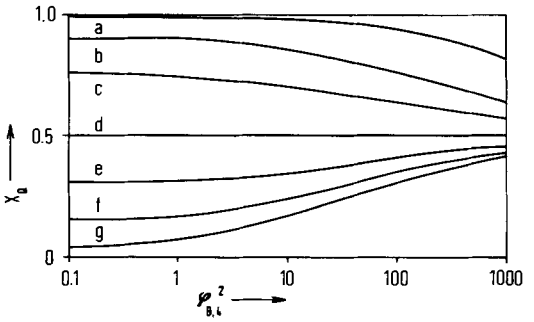


Fig. 6. MIRE model for a competitive parallel second-order reaction: Calculated relative yields X_Q as a function of the mixing modulus $\varphi^2_{B,4}$ for several (a—g) intrinsic selectivities $\varphi^2_{B,3}/\varphi^2_{B,4}$ (a = 0.01; b = 0.1; c = 0.3; d = 1.0; e = 3; f = 10; g = 100). Assumptions: spherical eddy; **E** = 1; **M** = 1; α = 1.

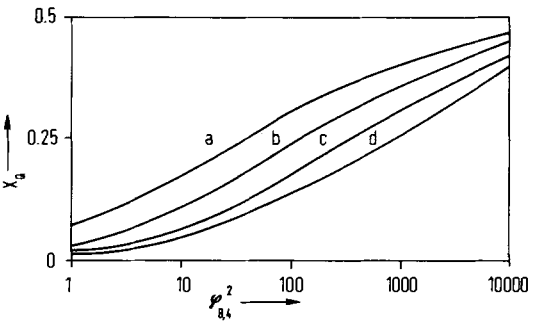

Fig. 7. MIRE model for a competitive parallel second-order reaction: Calculated relative yields X_Q as a function of the mixing modulus $\varphi^2_{B,4}$ for several (a—d) values of **E** (a = 1; b = 2; c = 5; d = 10). Assumptions: spherical eddy; $\varphi^2_{B,3}/\varphi^2_{B,4} = 100$; **M** = 1; α = 1.

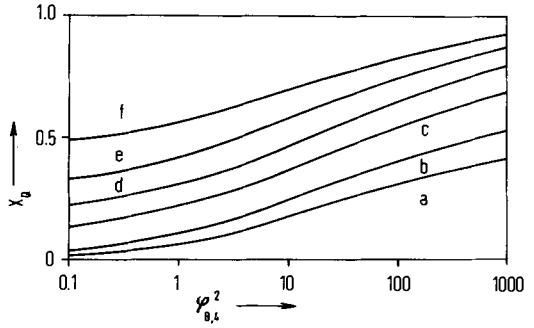

Fig. 8. MIRE model for a competitive parallel second-order reaction: Calculated relative yields X_Q as a function of the mixing modulus $\varphi^2_{B,4}$ for several (a—f) values of **M** (a = 1; b = 2; c = 5; d = 10; e = 20; f = 50). Assumptions: spherical eddy: $\varphi^2_{B,3}/\varphi^2_{B,4} = 100$; **E** = 1; α = 1.

[*] Cf. footnote on p. 812

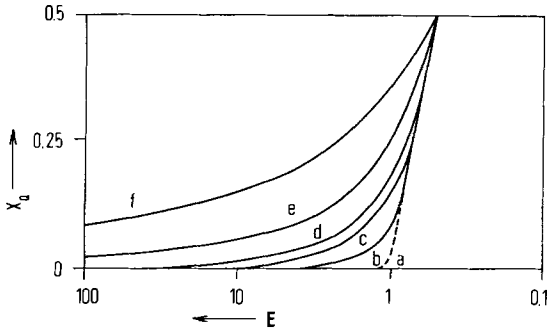

Fig. 9. MIRE model for a competitive parallel second-order reaction: Calculated relative yields X_Q as a function of **E** for several (a—f) values of $\mathbf{E}\varphi^2_{B,4}$ ($a \ll 1$, reaction-controlled; $b = 0.1$; $c = 1$; $d = 10$; $e = 10^2$; $f = 10^3$). Assumptions: spherical eddy; $\varphi^2_{B,3}/\varphi^2_{B,4} = 100$; $\mathbf{M} = 1$; $\alpha = 1$.

4.3.3. Experimental Results

The results of MIRE calculations (Figs. 6 to 9) lead to the question of how much, if any, importance attaches to the countless relative reactivities that have been determined by means of competitive parallel reactions. This method is used just for those cases in which the reaction to be studied is too fast for direct kinetic measurements[33]. It was *Tolgyesi*[29] who first drew attention to the limitations of this competitive method.

Unfortunately, none of the available experimental results are suitable for direct comparison with the MIRE calculations[*].

Finally, we shall consider the numerous aspects of mixing-disguised product distributions also in the case of bromination of resorcinol: If resorcinol in methanol is treated with an equimolar amount of molecular bromine, the monobromo isomers are formed, as well as the dibromo isomers and 2,4,6-tribromoresorcinol[35, 36]. As expected the degree of substitution decreases when the rate of stirring is increased, *i.e.* with more effective mixing. If one investigates the isomer ratio of the dibromo products one finds that the relative proportion of the 2,4-isomer increases with increasing intensity of stirring; this is shown in Figure 10.

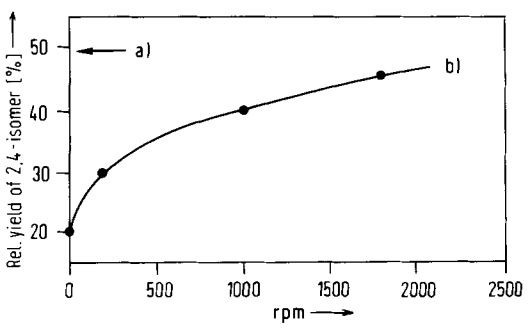

Fig. 10. Bromination of resorcinol (A) with molecular bromine (B) in methanol (22 °C) [35]. Dependence of the relative yield of 2,4-dibromo isomer on the stirring speed $[A]_0 = [B]_0 = 5 \times 10^{-2}$ mol l^{-1}; $\alpha = 1$. a) Stopped-flow mixing chamber; b) propeller stirring.

This result may at first seem surprising, for we have established that positional selectivity does not depend on diffusion effects (Scheme 2). In this result, therefore, it cannot be a matter of positional selectivity that determines the isomer distribution. In fact, it could be shown[35] that the 2,4-dibromo isomer is formed *via* the resorcinolate or monobromoresorcinolate, whereas the 4,6-dibromo isomer is formed from resorcinol derivatives. Thus, the isomer ratio is, exceptionally, a function of substrate selectivity and can be influenced by diffusion effects. The substrate ratio resorcinol/resorcinolate, and hence also the isomer ratio of the dibromo products, depends on the pH of the reaction solution. Since protons are liberated during the bromination, the pH in the reaction zone decreases. The consequence is that on the eddy surface the 4,6-dibromo isomer is formed in preference as the reaction continues. With intensive stirring the pH gradient is more rapidly destroyed, shifting the isomer ratio in favor of 2,4-dibromoresorcinol. This pH effect is superposed by the rate-reducing action of the bromide ion formed, which with bromine forms the tribromide ion. This product inhibition finally leads to a decrease in the disguising effect of mixing.

[*] Investigations are in progress [34].

5. Concluding Remarks on Mixing-Disguised Selectivity

In the above considerations the pride of place was given to chemical processes whose rates and product distributions were influenced by microscopic mixing processes. In Part II we shall start with microscopically mixed reaction systems in which encounter processes between the reactants may disguise the selectivity.

Because of its simplicity, the model presented here is suitable also for the experimental chemist; it can be adapted to any other form of kinetics. The model is, however, capable of refinement, if that should prove necessary. For example, the simplifying assumption of a "constant" eddy radius could be given up, and instead the size of the liquid element as a function of time could be built into the model. Such refinements do not at present promise any essentially new aspects. At the present state of knowledge it is interesting to speculate what influence local product concentration gradients due to mixing might have on the reaction behavior in autocatalytic systems. The insight gained into the behavior of mixing-disguised reaction systems is not just of interest to the synthetic chemist; it also shows the possibility of measuring the mixing state indirectly at any desired place in a reaction vessel.

This excursion into a hitherto neglected area of chemical kinetics was made possible by the collaboration of an expert and enthusiastic group of associates. The experimental basis of the studies reported was provided in particular by Drs. F. Pfister, P. Eugster, E. Crivelli, F. Nabholz and M. Aellen. Model presentation of the results was first made possible by Dr. R. J. Ott's creative and skilled assistance. The author is deeply indebted to all these colleagues and to Professor J. R. Bourne for many valuable ideas and discussions. Some of our own investigations were financially supported by the Swiss National Science Foundation (Project No. 2.62072) and by Ciba-Geigy AG, Basel.

Titanium Tetrachloride in Organic Synthesis

New synthetic methods (21)

By Teruaki Mukaiyama[*]

Titanium tetrachloride can accelerate numerous organic reactions. Valuable syntheses of, *e.g.*, allyl sulfides, amides, enamines, and ketones are based upon transformations of functional groups with $TiCl_4$. Particular mention should also be made of carbon-carbon linkage with $TiCl_4$ which permits the synthesis of hydroxy ketones and carbonyl compounds of the Michael adduct type. $TiCl_4$ reduced *in situ* is suitable for the reduction of chloroarenes or the linkage of two aldehyde molecules to give an alkene.

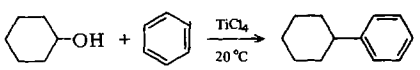
1. Introduction

During the decade that has elapsed since the widespread introduction of strong bases such as alkyllithium and potassium hydride into organic chemistry, much effort has been devoted to the generation of carbanions from various types of compounds; this has led to a revolution in the field of organic synthesis. On account of their many interesting reactions, the carbanions of sulfur compounds and the dianion of ethyl acetoacetate have frequently been employed in synthetic work.

Apart from the development of reactions carried out under basic conditions, it would also appear important to explore new reactions executed in acidic media. For example, if active electrophiles were to be generated by the use of acid new synthetic reactions could then be developed as very welcome alternatives to existing procedures, especially in arranging efficient synthetic schemes for preparations of complex molecules.

[*] Prof. Dr. T. Mukaiyama
Department of Chemistry, Faculty of Science
The University of Tokyo
Hongo, Bunkyo-ku, Tokyo 113 (Japan)

From this standpoint, the promotion of organic reactions by Lewis acids was re-examined in our laboratory, and titanium tetrachloride was found to be useful in developing synthetic reactions. The chemistry of low-valent titanium compounds has already made remarkable advances in the field of polymer chemistry; typically, in olefinic polymerization according to *Ziegler* and *Natta*, these compounds have been recognized as indispensable. Although titanium compounds are considered as unique reagents, there has been no systematic research. Titanium tetraalkoxides have been utilized as catalysts of transesterification[1], and $TiCl_4$ has been effectively employed in various dehydration reactions[2].



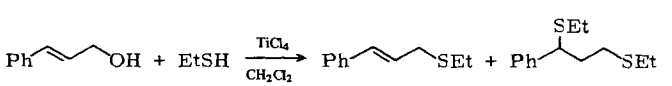
In this review, recent advances in synthetic reactions using titanium tetrachloride will be described, with particular emphasis on our recent work in the following three fields: 1) transformation of various organic functional groups by the use of titanium tetrachloride; 2) carbon-carbon bond formation using titanium tetrachloride; and 3) synthetic reactions utilizing low-valent titanium compounds generated *in situ* from titanium tetrachloride.

2. Transformations of Organic Functional Groups with Titanium Tetrachloride

Titanium tetrachloride is known as one of the typical Lewis acids, and it has a strong affinity for organic oxygenated compounds. Furthermore, $TiCl_4$ has a powerful dehydrating action; these typical characteristics of $TiCl_4$ are manifested in the following functional group transformations.

The condensation reactions of alcohols with aromatic compounds or thiols proceed rapidly in the presence of $TiCl_4$. For example, cyclohexylbenzene *(1)* is obtained in 91% yield when cyclohexanol is treated with $TiCl_4$ in benzene[3].

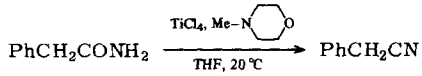
Similarly, an important synthetic intermediate, allyl phenyl sulfide *(2)*, is prepared in fairly good yield by the reaction of 2-hexen-1-ol and thiophenol in the presence of $TiCl_4$ in nitromethane[3].



(1), 91%

(2), 63%

When dichloromethane is employed as a solvent in the preparation of allyl sulfides, addition of thiol to carbon-carbon double bond takes place to give bis-sulfides, *e.g.* 1,3-bis(ethylthio)-1-phenylpropane *(3)*, as a minor product[3].

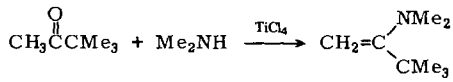


56% *(3)*, 23%

Hence $TiCl_4$ promotes the addition of thiol to the alkene; details of the addition reaction of thiols to other alkenes will be discussed later.

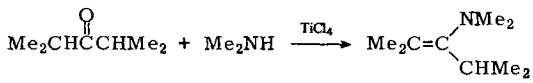
Further, $TiCl_4$ is used as a dehydration reagent in the formation of carboxamides *(4)* from carboxylic acids and amines[2a], and in the transformation of primary amides into nitriles[2b].

(4), 82%



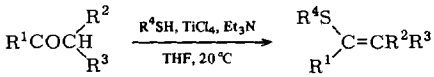
(5), 83%

In contrast to the above transformation of phenylacetamide into the nitrile *(5)*, various nitriles are converted to the corresponding carboxamides *(6)* by $TiCl_4$-promoted hydrolysis in acetic acid, and none of the corresponding carboxylic acids can be detected[4]. The yield of hydrolysis of benzonitrile (R = Ph) or pivalonitrile (R = *t*-Bu) can be increased to 64% or 87%, respectively, by conducting the reaction in highly concentrated solution. Butyramide (R = *n*-Pr) and isobutyramide (R = *i*-Pr) are formed in 88 and 65% yield, respectively.



(6)

Ketones are rapidly transformed into the corresponding enamines, *e.g. (7)* and *(8)*, by reaction with stoichiometric amounts of $TiCl_4$ and secondary amines, and highly hindered as well as ordinary enamines are prepared by this way[2c]. Examination of the effect of several other metal halides on enamine formation shows the following halides to be active: $AlCl_3$, $SnCl_4$, $FeCl_3$, and $AsCl_3$, but none of them appears better than $TiCl_4$.

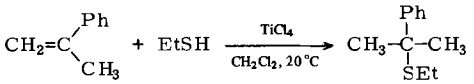


(7), 94%

(8), 72%

A similar concept is utilized in a convenient synthesis of various vinyl sulfides of type *(9)* directly from carbonyl compounds[5]. Relatively little work has been reported on the direct preparation of vinyl sulfides from carbonyl compound except for the elimination of thiols from thioacetals by acid catalyst and dehydration of hindered hemithioacetal.

The yield of vinyl sulfides on use of $TiCl_4$ markedly depends on reaction condition, *i.e.*, order of addition of reagents



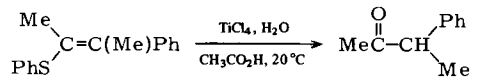
(9)

Table 1. Synthesis of vinyl sulfides of type *(9)*.

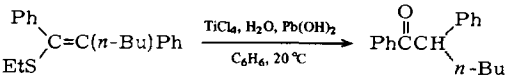
R^1	R^2	R^3	R^4	Yield [%]
Ph	Ph	H	Et	91
Ph	H	Me	Ph	72
$PhCH_2$	H	Me	Et	87
H	—$(CH_2)_4$—		Et	79

(ketone, thiol, $TiCl_4$, and triethylamine). The most favorable result is obtained when a THF solution of thiol and triethylamine is added dropwise to a solution of $TiCl_4$ and ketone with vigorous stirring.

As mentioned in the preparation of the sulfides *(2)* and *(3)* from alcohol and thiol, $TiCl_4$ activates not only oxygen functions but also carbon-carbon double bonds. Accordingly, thiols add to various alkenes in excellent yields in the presence of $TiCl_4$[6], *e.g.* to the alkenes *(10)* and *(11)*.

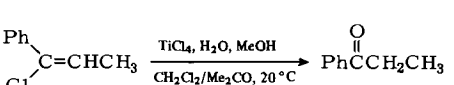


(10) quant.

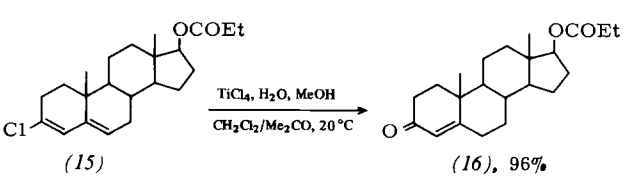


(11) 94%

Addition of thiols to alkenes suggests that vinyl sulfide is sufficiently activated by $TiCl_4$ to react with water, forming ketones. Hydrolysis of vinyl sulfides generally needs rather drastic conditions; an exception is the mercury(II)-promoted hydrolysis[7] reported by *Corey et al.* Titanium tetrachloride has a remarkable effect on the hydrolysis of vinyl sulfides; the corresponding ketones *(12)* and *(13)* are obtained in high yields without any by-products under mild conditions[8]. Even 2-aryl vinyl sulfides, for which Hg^{II}-promoted hydrolysis requires an elevated temperature, are hydrolyzed almost quantitatively at room temperature. In the case of ethyl vinyl sulfide, the yield of ketone is increased by the addition of $PbO/Pb(OH)_2$ to remove resulting ethanethiol simultaneously; with phenyl vinyl sulfide such a measure has no significant effect.



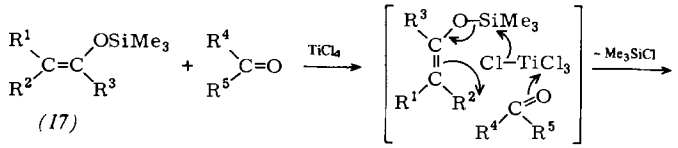
(12), 97%



(13), 91%

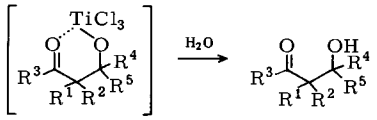
Vinyl chloride derivatives are regarded as useful carbonyl equivalents in organic synthesis, but the hydrolysis of vinyl chlorides remains a problem because the reaction must be carried out under drastic conditions, *i.e.*, in excess concentrated sulfuric acid or in a mixture of sulfuric acid and acetic acid[9]. Like vinyl sulfides, vinyl chlorides undergo ready hydrolysis on combined use of $TiCl_4$ and CH_3OH-H_2O in dichloromethane/acetone; the corresponding ketones are produced in excellent yields[10]. For example, the chlorosteroid *(15)* is smoothly converted at room temperature into testosterone propionate in 96% yield without hydrolysis of the ester function.

(14), 85%



(15) *(16)*, 96%

3. Carbon-Carbon Bond Formation with Titanium Tetrachloride



3.1. Synthesis of β-Hydroxy Ketones and Related Reactions

Aldol condensation has long been recognized as one of the most versatile synthetic tools in organic chemistry. The reaction is usually carried out under basic condition, and dimers, polymers, or self-condensation products or α,β-unsaturated carbonyl compounds are invariably formed as by-products. These undesirable side reactions frequently limit the utility of this otherwise efficient reaction. In order to alleviate these difficulties, useful synthetic procedures have been developed, especially under basic conditions, by *Wittig et al.*[11] using lithio derivatives of imines and by *Corey et al.*[12] using lithio derivatives of hydrazones. In addition, *Stork et al.*[13] and *House et al.*[14] reported the selective formation of lithium enolates which in the presence of metal salts lead to cross aldols under almost neutral condition. Vinyloxyborane has been successfully used in our laboratory for the preparation of cross aldols under neutral condition[15].

Powerful activation of carbonyl groups by $TiCl_4$ led to the assumption that silyl enol ethers of type *(17)* could readily attack carbonyl compounds to form trimethylsilyl chloride and the titanium salt of the aldol-type product. In this case, undesirable dissociation of the adduct would be inhibited by the formation of a stable titanium chelate *(18)* whose hydrolysis would yield the desired β-hydroxy ketone *(19)*.

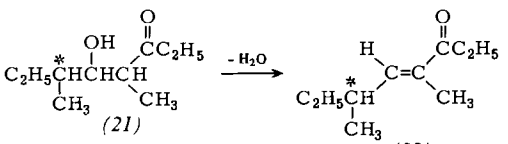
(17)

(19)

Table 2. Synthesis of β-hydroxy ketones of type *(19)*.

	R^1	R^2	R^3	R^4	R^5	T [°C]	Yield [%]
a	H	Ph	Me	$PhCH_2CH_2$	H	−78	95
b	H	—$(CH_2)_3$—		$PhCH_2CH_2$	H	−78	95
c	H	H	Ph	Me	Me	20	73
d	H	—$(CH_2)_4$—		*i*-Pr	H	−78	92

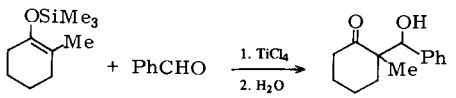
In fact, the aldol-type product *(19)* is selectively obtained in excellent yield, without accompanying self-condensation products, when the silyl enol ether *(17)* is treated with stoichiometric amounts of ketone or aldehyde and $TiCl_4$ in dichloro-



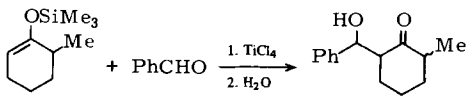
methane[16]. With aldehydes, the reaction proceeds even at −78 °C, whereas in the case of ketone, a reaction temperature of 0 °C or room temperature is required (Table 2).

The synthesis of β-hydroxy ketones is also promoted by various other metal salts, including $SnCl_4$ and $BF_3 \cdot OEt_2$; however, $TiCl_4$ is greatly superior to both these reagents with regard to product yield.

(+)-Manicone *(22)*, one of the alarm pheromones, is readily synthesized from (+)-1-methylbutanal *(20)* *via* the β-hydroxy ketone *(21)*[17].

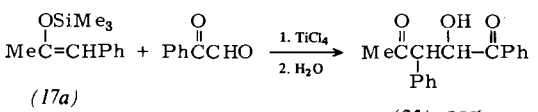


(20)

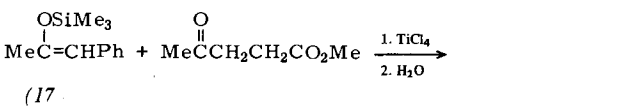


(21) *(22)*

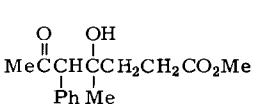
The regiospecificity of the above syntheses is proved by the reactions of two structurally isomeric silyl enol ethers, namely 1-methyl-2-trimethylsiloxy-1-cyclohexene *(23)* and 6-methyl-1-trimethylsiloxy-1-cyclohexene *(24)*[16b]. The reaction of *(23)* with benzaldehyde affords two stereoisomers of 2-(α-hydroxybenzyl)-2-methyl-1-cyclohexanone, whereas *(24)* reacts with benzaldehyde to give four stereoisomers of 2-(α-hydroxybenzyl)-6-methyl-1-cyclohexanone. Accordingly, the addition reaction appears to take place regiospecifically at the double bond of the silyl enol ether.



(23) 58%

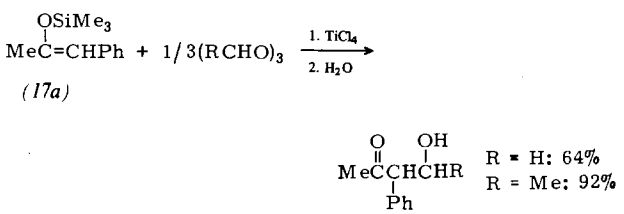


(24) 81%

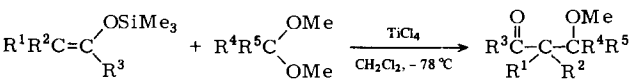


Furthermore, a high functional group selectivity is observed when two different kinds of carbonyl group, such as aldehyde, ketone and ester, are present in the same molecule. If phenylglyoxal is treated with the silyl enol ether *(17a)* at −78 °C, the α-hydroxy γ-diketone *(25)* is obtained exclusively, and no addition products to the ketone function are detected. The reaction of methyl levulinate with *(17a)* also affords the 4-hydroxy 6-oxo ester *(26)* as sole product at room temperature[16b].

(17a) *(25)*, 83%



(17)

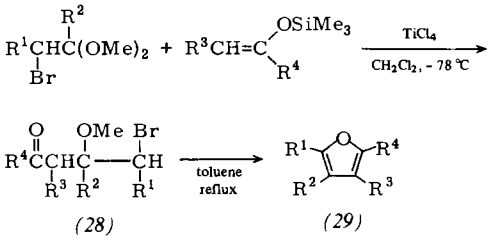


(26), 53%

In general, condensation reactions of ketones with formaldehyde give not only compounds with one CH_2OH group but also unsymmetrical bis- and poly(hydroxymethyl) products, and hence it is difficult to prepare a desired mono(hydroxymethyl) compound exclusively. However, *(17a)* reacts with 1,3,5-trioxane or paraaldehyde in the presence of $TiCl_4$ to give exclusively 1:1 adducts in good yields[16b].

(17a)

Trimethylsilyl enol ethers also react with acetals or methyl orthoformate in the presence of $TiCl_4$ to give β-alkoxy ketones or β-oxo acetals, respectively, at low temperature (Table 3)[18]. In the case of methyl orthoformate, only the β-oxo acetal is obtained; β-alkoxy δ-diketone which is formed on subsequent reaction with silyl enol ether is not isolated.



(17) *(27)*

Table 3. Synthesis of β-methoxy ketones and acetals of type *(27)*.

R^1	R^2	R^3	R^4	R^5	Yield [%]
H	H	Ph	$NCCH_2CH_2$	H	60
Ph	H	Me	$-(CH_2)_5-$		91
H	$-(CH_2)_4-$		H	OMe	71

Various substituted furans *(29)* are readily prepared by application of the $TiCl_4$-promoted reaction of α-halo acetals with silyl enol ethers[19]. For instance, β-alkoxy γ-bromo

(28) *(29)*

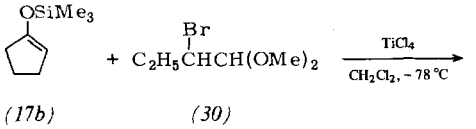


Table 4. Synthesis of furan derivatives *(29)*.

R^1	R^2	R^3	R^4	Yield [%]
H	H	Ph	Me	69

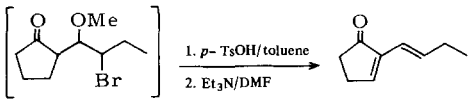
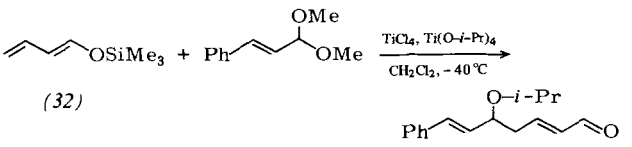
Et	H	Ph	Me	82
$-(CH_2)_4-$		H	Ph	77



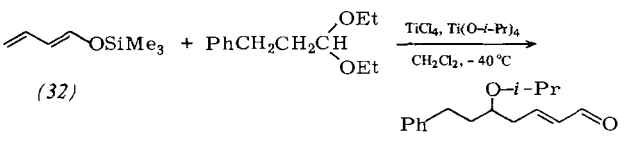
ketones *(28)*, prepared from α-bromo acetals and silyl enol ether, are readily converted into the corresponding furans *(29)* by refluxing in toluene (Table 4).

Many of the reported syntheses of furan derivatives involve several reaction steps and the yields are not always satisfactory. With the present method a general route is now available for preparation of substituted furans.

Cyclopentenone derivatives *(31)* are obtained in good yields instead of the furan compound when 2-(1-alkoxy-2-bromoalkyl)cyclopentanones, derived from the silyl enol ether *(17b)* and acetals *(30)*, are heated in the presence of *p*-toluenesulfonic acid[20].

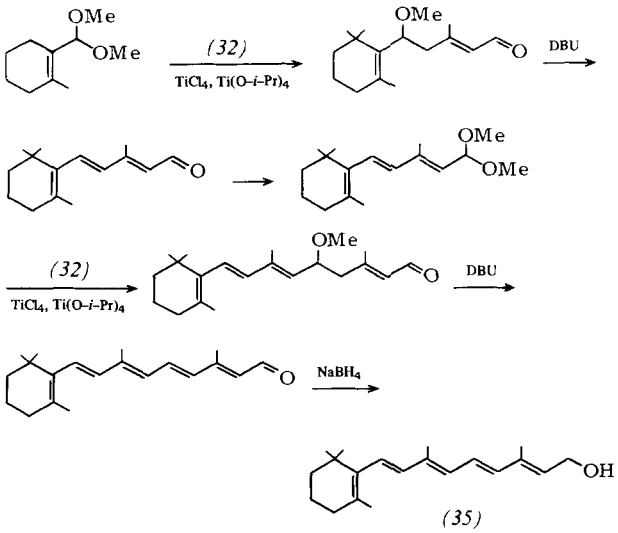


(17b) *(30)*



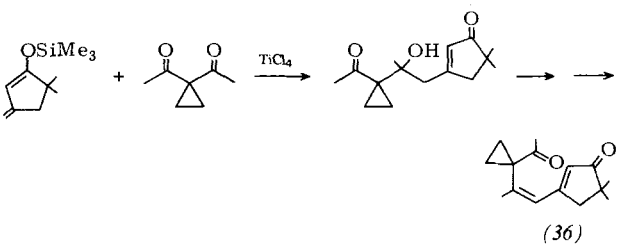
(31), 70%

δ-Alkoxy α,β-unsaturated aldehydes such as *(33)* and *(34)*, which are valuable synthetic intermediates because of their polyfunctionality, are prepared in good yields from dienyloxysilanes such *(32)* and acetals[21]. Reaction of acetals and *(32)*, prepared from crotonaldehyde or dimethylacrolein and chlorotrimethylsilane, in the presence of $TiCl_4$ alone gives only polymers. However, the desired aldehydes *(33)* and *(34)* are obtained in good yields by treating acetals and the silane *(32)* at −40 °C in the joint presence of $TiCl_4$ and $Ti[O—CH(CH_3)_2]_4$. Under these conditions undesirable side reactions are suppressed.



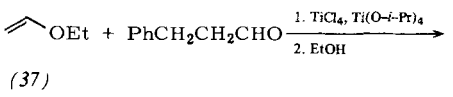
(32) *(33)*, 80%

(32) *(34)*, 79%



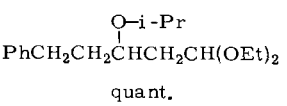
A similar reaction for the preparation of polyenic acetals is reported by *Krasnaya et al.* using 1-ethoxyisoprene and $ZnCl_2$, but the reaction is not so clear-cut and gives the desired product in lower yield than the present method[22].

δ-Alkoxy α,β-unsaturated aldehydes of type *(33)* and *(34)* are easily converted into polyenic aldehydes by elimination of alcohol. This can be accomplished by treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) or 1,5-diazabicyclo-[4.3.0]non-5-ene in the presence of molecular sieves 3 Å or 4 Å[23]. The syntheses of some natural products such as

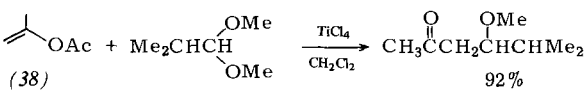


(35)

vitamin A *(35)*[24a], variotin[24b], and hypacrone *(36)*[25] are readily accomplished with dienyloxysilanes.

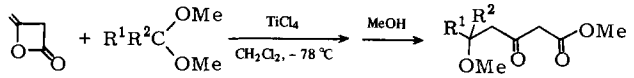


(36)



Similarly, enol ethers[26] and enol esters[27] can also be employed as nucleophiles in the aldol reaction. Ethyl vinyl ether *(37)* or isopropenyl acetate *(38)* reacts with an acetal or aldehyde in the presence of $TiCl_4$ or a mixture of $TiCl_4$ and $Ti[O—CH(CH_3)_2]_4$ and the addition product is obtained in good yield.

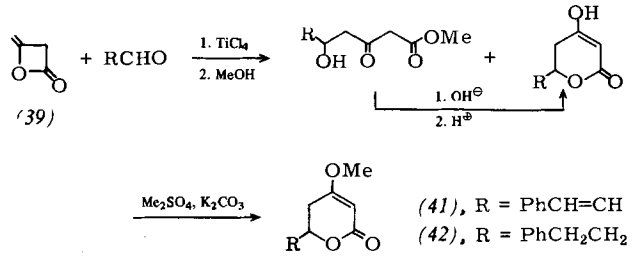
(37)



quant.

(38) 92%

Diketene *(39)* is also employed as a nucleophile in place of silyl enol ethers or isopropenyl acetate in the $TiCl_4$-promoted reaction. *Kucherov et al.* reported that the reaction of diketene with acetaldehyde diethyl acetal in the presence of Lewis acid, *i.e.* $BF_3 \cdot OEt_2$, affords ethyl α-(1-ethoxyethyl)-acetoacetate[28]. Contrary to the above result, δ-alkoxy β-oxo esters of type *(40)* (Table 5) are obtained exclusively by the treatment of diketene with acetals at −78 °C or −20 °C in dichloromethane, while no α-(1-alkoxyalkyl)acetoacetate is isolated[29].

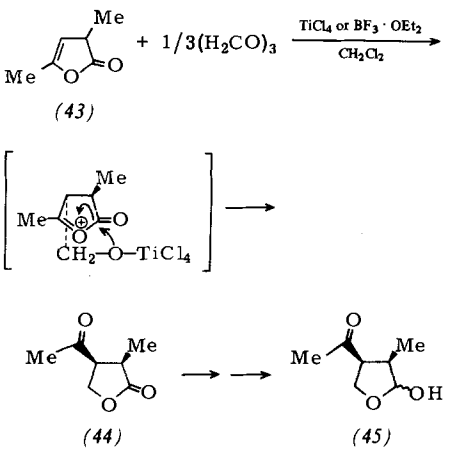


(39) (40)

Table 5. Synthesis of δ-methoxy-β-oxo carboxylic acids of type *(40)*.

R^1	R^2	Yield [%]
i-Pr	H	77
$PhCH_2CH_2$	Me	87
$CH_3COCH_2CH_2$	Me	76
H	OMe	68

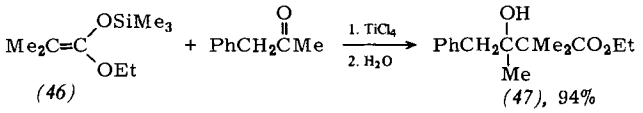
Likewise, δ-hydroxy β-oxo ester and dihydropyrone are prepared by the $TiCl_4$-promoted reaction of diketene with various aldehydes at −78 °C, and the reaction has been applied to the synthesis of kawain *(41)* and dihydrokawain *(42)*[30].



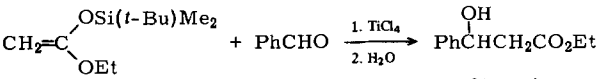
(39)

(41), R = PhCH=CH
(42), R = $PhCH_2CH_2$

The dianion of acetoacetic ester is known as an invaluable reagent for the introduction of the —CH_2—CO—CH_2—CO— unit into carbonyl compounds. Whereas this reaction requires basic conditions, on use of diketene and $TiCl_4$ the same unit is introduced in good yield under acidic conditions.

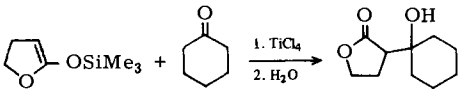


2-Methyl-β-angelicalactone *(43)*, an enol acetate, reacts with trioxane in the presence of $TiCl_4$ or $BF_3 \cdot OEt_2$ to afford β-acetyl-α-methyl-γ-butyrolactone (*cis*:*trans* = 85:15) in 73% yield[31]. Preferential formation of the *cis*-isomer may be due to the steric effect of the methyl groups of angelicalactone. This *cis*-lactone *(44)* has successfully led to antibiotics such as botryodiplodin *(45)*[32].



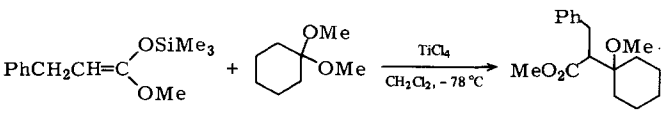
(43) (44) (45)

The synthesis of β-hydroxy esters such as *(47)*, *(49)*, and *(51)* is accomplished by the $TiCl_4$-promoted reaction of ketene alkyl trialkylsilyl acetals *(46)*, *(48)*, and *(50)* with carbonyl compounds[33].

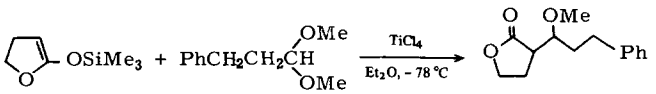


The Reformatsky reaction usually employed for preparing such esters is generally carried out under drastic conditions and is often accompanied by formation of an α,β-unsaturated ester. Recently, several investigators reported that β-hydroxy esters are obtained by employing the α-metalated carboxylic esters. Furthermore, it was recently shown in our laboratory that β-hydroxy esters are obtained in high yields under neutral conditions by treating a vinyloxyborane with carbonyl compounds[15]. The present $TiCl_4$-promoted reaction carried out under acidic conditions affords various β-hydroxy esters, including β-(1-hydroxyalkyl)-γ-butyrolactones such as *(51)* in excellent yields without formation of α,β-unsaturated esters.

(46) (47), 94%

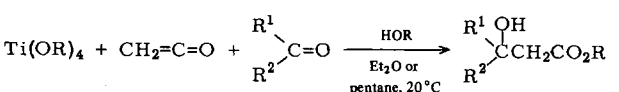


(48) (49), 84%



(50) (51), 88%

Similarly, β-alkoxy esters like *(52)* and lactones like *(53)* are prepared in good yields by the reaction of ketene alkyl trialkylsilyl acetals with various acetals of aldehydes and ketones in the presence of $TiCl_4$ under mild conditions[34].

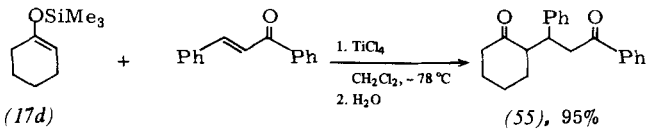


(52), 92%

(50) (53), 75%

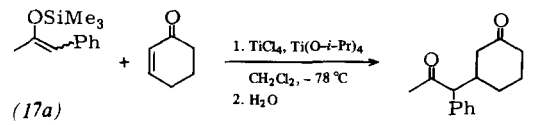
The preparation of β-hydroxy esters by the reaction of titanium tetraalkoxide, ketene, and ketone has been reported[35] by *Vuitel et al.* However, in the case of aldehyde,

(54)



a considerable amount of hydroxy diester is formed along with a normal product *(54)*.

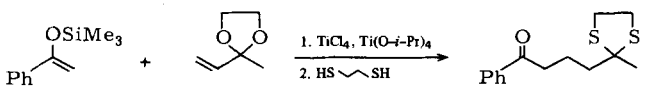
3.2. Michael Addition



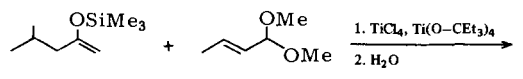
The $TiCl_4$-promoted reaction of α,β-unsaturated ketones with silyl enol ethers of type *(17)* results in the formation of 1,5-dicarbonyl compounds (Michael adducts) such as *(55)*

and *(56)* in fairly good yields instead of the aldol-type product[36].

In general, the Michael reaction of α,β-unsaturated carbonyl compounds and ketones is carried out under basic condition. The resulting 1,5-dicarbonyl compounds frequently undergo further transformation, and self-condensation of starting material is also observed. In contrast, the $TiCl_4$-promoted Michael reaction proceeds under very mild conditions (−78 °C); the side reactions are therefore largely suppressed and the 1,5-dicarbonyl compounds are formed in good yields. In some cases, when highly $TiCl_4$-sensitive compounds such as isopropenyl trimethylsilyl ether, 2-cyclohexen-1-one, or isopropenyl methyl ketone are employed, the reaction must be carried out in the joint presence of $TiCl_4$ and $Ti[O—CH(CH_3)_2]_4$.

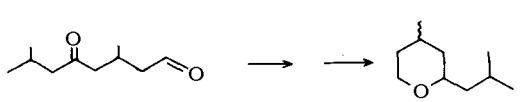


(17d) *(55)*, 95%



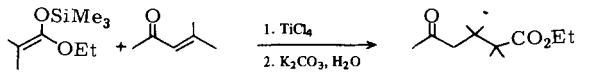
(17a) *(56)*, 70%

The combined use of $TiCl_4$ and $Ti[O—CH(CH_3)_2]_4$ is also applicable to the Michael reaction of α,β-unsaturated acetals such as *(57)* with silyl enol ethers; subsequent treatment of the reaction mixture with ethanedithiol gives the corresponding δ-oxothioacetals[36b].

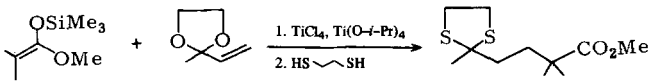


(17c) *(57)*

However, when crotonaldehyde dimethyl acetal *(58)* is treated with silyl enol ether in the presence of $TiCl_4$/$Ti[OCH(CH_3)_2]_4$, the desired Michael product is not formed but a β-alkoxy ketone. In such cases, the acetal is treated with $TiCl_4$ and $Ti[O—CEt_3]_4$ prior to addition of silyl enol ether in order to replace at least one of the methoxy groups by the bulky Et_3CO group and thus introduce steric hindrance around the acetal group. Subsequent treatment of the mixture with silyl enol ether gives the Michael product almost exclusively, and dihydro rose oxide *(59)* is readily synthesized by this reaction[36b].

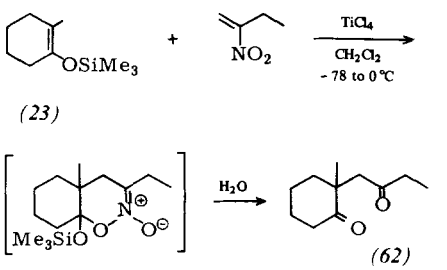


(58)



(59)

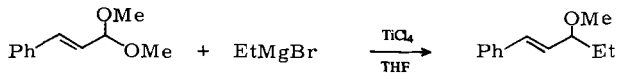
Ketene alkyl trimethylsilyl acetals also react with α,β-unsaturated ketones or their acetals in the presence of $TiCl_4$, in some cases together with $Ti[O—CH(CH_3)_2]_4$, to give the Michael products, δ-oxo esters *(60)*, in good yields[37].



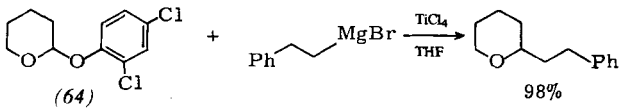
(60), 72%

Ethylene thioacetals *(61)* arise on treatment of ketene alkyl trialkylsilyl acetals with acetals of α,β-unsaturated ketones in the presence of $TiCl_4$ and $Ti[O—CH(CH_3)_2]_4$ and subsequent reaction with ethanedithiol[37].

(57) *(61)*, 90%



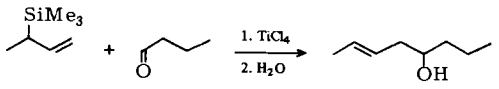
Similarly, *Yoshikoshi et al.* reported that the Michael reaction of nitroolefins and silyl enol ethers also proceeds in the presence of $TiCl_4$ or $SnCl_4$, and affords the Michael product, which is easily hydrolyzed to the 1,4-diketone *(62)* without having to be isolated. The high regiospecificity observed in the selective formation of 1,4-diketones demonstrates that no double bond migration of silyl enol ethers takes place during the reaction[38].



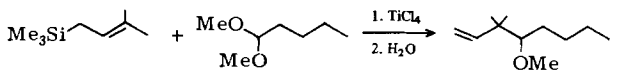
(23) *(62)*

3.3. Other Carbon-Carbon Linkages

Alkylation of acetals with Grignard reagent is accomplished by the use of $TiCl_4$. While acetals derived from α,β-unsaturated aldehydes such as *(63)* react smoothly with Grignard reagent, those derived from aliphatic aldehydes and ketones do not react at all. However, good yields of alkylation products can be obtained in the latter case if mixed acetals, in particular alkyl 2,4-dichlorophenyl acetals, are employed in place of the above mentioned acetals[39].



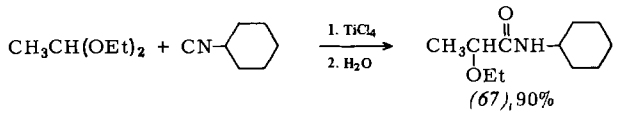
(63) 83%



(64) 98%

Another alkylation reaction is reported by *Sakurai et al.*, *i.e.* the treatment of carbonyl compounds or acetals with allylsilanes in the presence of $TiCl_4$ to give β,γ-unsaturated

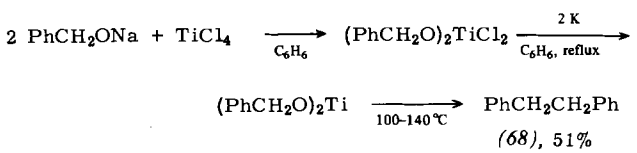
alcohols or ethers such as *(65)* and *(66)*. The synthetic utility of the reaction lies in the regiospecific transformation of the allylic group into a carbonyl or an acetal function, attack occurring exclusively at the γ-position of the allylsilanes[40].



(65), 89%

(66), 80%

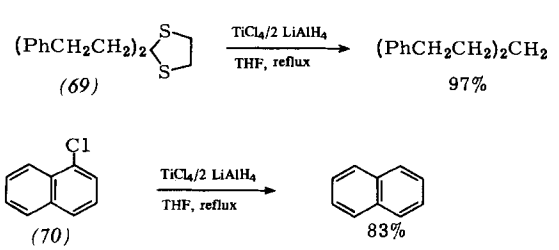
Acetal-$TiCl_4$ complexes immediately react with isocyanides at −70°C, and α-alkoxy carboxamides like *(67)* are formed in better yields than in the Passerini reaction[41].



(67), 90%

Sato et al. reported that $TiCl_4$ exhibits a remarkable effect on the photochemical reaction of α,β-unsaturated ketones with methanol. Two types of reaction are observed under these conditions: a) cyclization to form dihydrofuran, and b) replacement of the carbonyl function by a dimethoxymethyl group[42]. In both cases an additional carbon atom is introduced.

4. Syntheses with Titanium Tetrachloride Reduced *in situ*

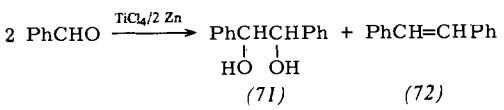


In the present Section an attempt is made to survey synthetic reactions utilizing low-valent titanium compounds accessible from $TiCl_4$ and reducing reagents. The reactions of $TiCl_3$ are not included (for review, see [43]).

The pioneering work by *van Tamelen* on reductive coupling of allylic or benzylic alcohols to form hydrocarbons such as *(68)*[44] demonstrated the fascinating potential of low-valent titanium compounds in organic synthesis.

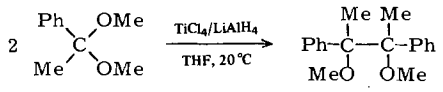
(68), 51%

Sulfides and haloarenes, *e.g. (69)* and *(70)*, are easily reduced to the corresponding hydrocarbons in good yields



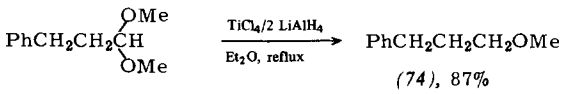
(69) 97%

(70) 83%



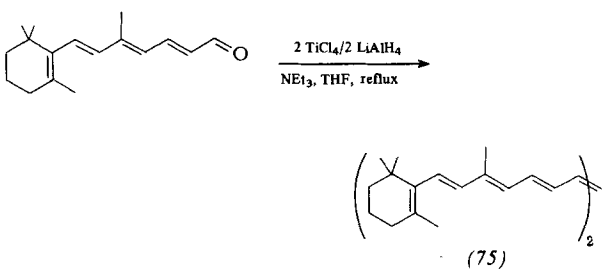
by the low-valent titanium compounds obtained from $TiCl_4$ and two equivalents of $LiAlH_4$[45].

When aldehydes or ketones are treated with low-valent titanium compounds produced from $TiCl_4$ and Zn, reductive coupling readily proceeds and, depending on the reaction conditions, the diol *(71)* or the alkene *(72)* is obtained in excellent yield[46]. In THF at room temperature 98 % of *(71)* and 1 % of *(72)*, are formed, and in boiling dioxane 98 % of *(72)* and no *(71)*.



(71) *(72)*

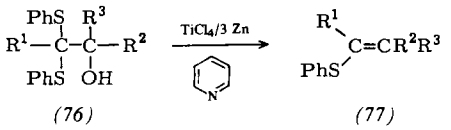
On combined use of $TiCl_4$ and $LiAlH_4$ instead of Zn, reductive coupling of acetals derived from aromatic aldehydes or ketones also affords the diol ether *(73)*. However, when acetals of aliphatic aldehydes or ketones are treated with $TiCl_4$ and two equivalents of $LiAlH_4$, one of the alkoxy groups is reduced to afford the ether, *e.g. (74)*[47].



(73), 97%

(74), 87%

The reduction by the $TiCl_4/LiAlH_4$ reagent is applicable to the preparation of symmetrical polyalkenes. In the presence of a tertiary amine as proton sponge, polyenic ketones or aldehydes are readily converted into the polyenes by treatment with equimolar amounts of $TiCl_4/LiAlH_4$. β-Carotene *(75)* has been synthesized in this way from retinal in good yield[48].

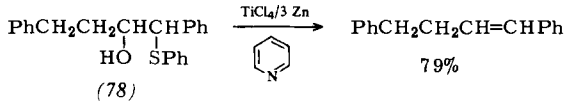


(75)

Similar reductive couplings of carbonyl compounds have also been reported independently by *Tyrlik et al.*[49] and by *McMurry et al.*[50] (see ref. [43]); they used combinations of $TiCl_3$ and reducing reagents.

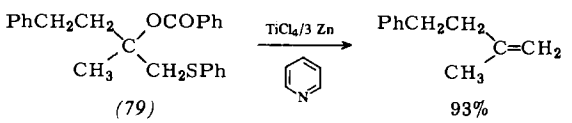
The use of low-valent titanium compound has also been applied to the reduction of β-hydroxy sulfides to alkenes such as vinyl sulfides, styrene derivatives, and *exo*-methylene compounds. β-Hydroxy thioacetals of type *(76)*, which are easily prepared from carbonyl compounds and α-lithio thioacetals, are reduced by $TiCl_4/Zn$ in the presence of tertiary amines to give the corresponding vinyl sulfides *(77)* in good yields (Table 6)[51]. As mentioned before, the resulting vinyl sulfides are easily hydrolyzed to ketones with $TiCl_4$. Hence a combination of these two reactions provides a con-

venient route for joining two carbonyl compounds to form a new one.



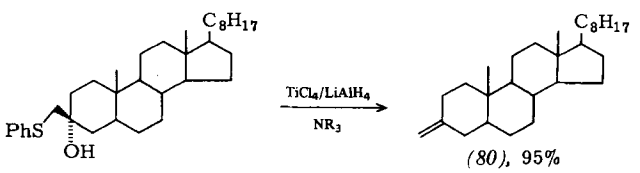
(76) (77)

Table 6. Synthesis of vinyl sulfides of type *(77)*.



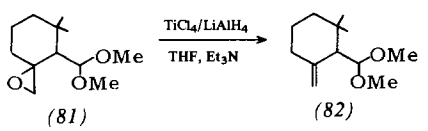
R^1	R^2	R^3	Yield [%]
H	n-C_5H_{11}	H	84
H	Ph	Me	91
H	—$(CH_2)_5$—		90
n-Bu	n-C_5H_{11}	H	82

Styrene derivatives can be synthesized by reduction of β-hydroxy sulfides *(78)*, prepared from aldehydes or ketones and the α-lithio benzyl phenyl sulfides, with $TiCl_4$ and Zn[52].



(78)

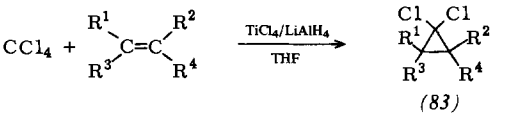
A general synthetic method for the synthesis of terminal alkenes from ketones proceeds *via* β-hydroxy sulfides which are readily available from ketones and phenylthiomethyllithium. Reductive elimination of β-hydroxy sulfides leads to the terminal alkenes in fairly good yields according to *Coates et al.* by acylation of β-hydroxy sulfides and subsequent reduction with Li/NH_3[53]. The same reductive elimination takes place even at room temperature when β-arylthioalkyl benzoates *(79)* are treated with $TiCl_4$/Zn in pyridine[54].



(79) 93%

When $TiCl_4/LiAlH_4$ is employed as reducing reagent, the reaction of β-hydroxy sulfides in the presence of a tertiary amine directly affords the corresponding terminal alkenes in high yields, and the benzoylation step becomes unnecessary[55]. The steroid derivative *(80)* is synthesized in benzene/dioxane.

(80), 95%



Another preparative entry to terminal alkenes starts from epoxides. For example, the epoxy acetal *(81)* is reduced to the *exo*-methylene acetal *(82)* with $TiCl_4/LiAlH_4$ in the presence of triethylamine[56].

(81) (82)

The same reduction with $TiCl_3$ was also recently reported by *McMurry*[57].

All the alkene syntheses mentioned above proceed as β-eliminations. In addition, reductive α-eliminations of polyhalogenated compounds can also be accomplished with low-valent

(83)

Table 7. Synthesis of 1,1-dichlorocyclopropane derivatives *(83)*.

R^1	R^2	R^3	R^4	Yield [%]
—$(CH_2)_4$—		H	H	79
—$(CH_2)_6$—		H	H	82
Me	Me	Me	Me	65
—$O(CH_2)_3$—		H	H	79

titanium compounds, and have been applied for the preparation of *gem*-dichlorocyclopropanes *(83)* in good yields by treatment of carbon tetrachloride and alkene with a low-valent titanium compound prepared from equimolar amounts of $TiCl_4$ and $LiAlH_4$ (Table 7)[58]. This method is useful in view of its facile execution and the ready availability of the starting materials.

5. Conclusion

Titanium tetrachloride is a valuable reagent promoting various synthetic reactions, both in cases requiring a stoichiometric amount of $TiCl_4$ and on use of a catalytic amount of $TiCl_4$ together with other metal salts.

In order to synthesize complex molecules, exploration of new reactions proceeding smoothly under almost neutral conditions without any assistance of acids or bases is urgently required. When exploring such reactions, it is often profitable to make use of characteristic properties of various elements such as phosphorus and sulfur which are prone to undergo "oxidation-reduction condensation"[59]. Furthermore, a combination of first row elements could also become an important tool for developing new synthetic reactions.

Spontaneous Alternating Copolymerization *via* Zwitterion Intermediates

By Takeo Saegusa [*]

This article describes a new concept of copolymerization which occurs spontaneously without any added catalyst. A nucleophilic monomer (M_N) combines with an electrophilic one (M_E) to generate a zwitterion $^{+}M_N—M_E^{-}$, which is responsible for the initiation and propagation of copolymerization. Twenty-three novel copolymerizations have been explored on the basis of the new concept. M_N monomers which have been investigated are five- and six-membered cyclic imino ethers, dihydro-2(3*H*)-furanimine, an azetidine, a cyclic phosphinic acid ester and a Schiff base; the M_E monomers include β-propiolactone, a cyclic dicarboxylic acid anhydride, a sultone, acrylic acid, acrylamide, a β-hydroxyalkyl acrylate and ethylenesulfonamide. In most combinations, alternating 1:1 copolymers were produced. In addition to the above-mentioned combinations, the alternating 1:1 copolymerization of cyclic phosphite with α-keto acid was discovered.

1. General Scheme

Induction of a polymerization reaction usually requires a catalyst, an initiator or high energy radiation. This article describes a new concept of copolymerization without the addition of an initiator. Interaction of two monomers affords a zwitterion, which is the responsible species for the copolymerization.

In organic chemistry, the reaction between a nucleophile and an electrophile is a typical example of a reaction which takes place without added catalyst. The nucleophile-electrophile reactions are classified into three categories according to the charge of the reactants:

1. both reactants are charged [*e.g.* eq. (a)],
2. one reactant is charged and the other is neutral [*e.g.* eq. (b) and (c)],
3. both reactants are neutral [*e.g.* eq. (d)].

$$Me_4\overset{\oplus}{N}OH^{\ominus} + Et_3\overset{\oplus}{O}BF_4^{\ominus} \longrightarrow EtOH + Et_2O + Me_4\overset{\oplus}{N}BF_4^{\ominus} \quad (a)$$

$$Me_3N + Me_3\overset{\oplus}{S}Cl^{\ominus} \longrightarrow Me_4\overset{\oplus}{N}Cl^{\ominus} + Me_2S \quad (b)$$

$$\overset{\oplus}{Na}CN^{\ominus} + EtI \longrightarrow EtCN + Na^{\oplus}I^{\ominus} \quad (c)$$

$$Me_3N + MeI \longrightarrow Me_4\overset{\oplus}{N}I^{\ominus} \quad (d)$$

[*] Prof. Dr. T. Saegusa
Department of Synthetic Chemistry
Kyoto University, Kyoto 606 (Japan)

The concept of spontaneous alternating copolymerization described here is based upon the reaction pattern of the third category[1]. Thus, a monomer having nucleophilic reactivity (M_N) is admixed with an electrophilic monomer (M_E) to produce a zwitterion *(1)*, which is called a "genetic zwitterion".

$$M_N + M_E \longrightarrow {}^{\oplus}M_N\text{–}M_E^{\ominus} \quad (e)$$
(1)

The genetic zwitterion is responsible for initiation as well as for propagation of the chain. Two molecules of *(1)* react with each other to produce the first propagating species *(2)* [eq. (f)], which continues to grow by successive reactions with *(1)* [eq. (g)]. Hereafter, the propagating species, *(2)* and *(3)*, are called "macrozwitterions".

$$(1) + (1) \longrightarrow {}^{\oplus}M_NM_E\text{–}M_NM_E^{\ominus} \quad (f)$$
(2)

$$(2) + n(1) \longrightarrow {}^{\oplus}M_N\text{–}(M_EM_N)_{n+1}\text{–}M_E^{\ominus} \quad (g)$$
(3)

The reaction between two macrozwitterions *(3)* leads to a sharp increase in the degree of polymerization of the propagating species [eq. (h)].

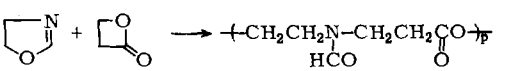
$${}^{\oplus}M_N\text{–}(M_EM_N)_m\text{–}M_E^{\ominus} + {}^{\oplus}M_N\text{–}(M_EM_N)_n\text{–}M_E^{\ominus} \longrightarrow {}^{\oplus}M_N\text{–}(M_EM_N)_{m+n+1}\text{–}M_E^{\ominus} \quad (h)$$

The contribution of the reaction of eq. (h) to the total reaction becomes substantial at the stage of high conversions, where the concentration of *(3)* is quite high.

Intramolecular reactions between the cationic and anionic sites in a single macrozwitterion can produce so-called "macrocycles" [eq. (i)]. However, the contribution of this reaction is usually small.

$${}^{\oplus}M_N\text{–}(M_EM_N)_n\text{–}M_E^{\ominus} \longrightarrow \boxed{\text{–}(M_NM_E)_{n+1}\text{–}} \quad (i)$$

A series of consecutive reactions—shown in equations (g), (h) and (i)—leads to formation of a copolymer with the alternating structure $\cdots M_NM_EM_NM_E\cdots$. Besides the above mentioned elementary reactions, the reaction between a free monomer and one of the ionic sites (cationic or anionic) of the zwitterion (genetic or macro) can also occur in some cases [eqs. (j) and (k)].



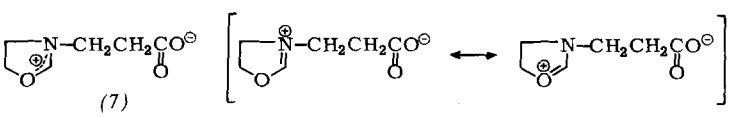
$${}^{\oplus}M_N\text{–}(M_EM_N)_n\text{–}M_E^{\ominus} \xrightarrow{M_N} {}^{\oplus}M_NM_N\text{–}(M_EM_N)_n\text{–}M_E^{\ominus} \quad (j)$$

$${}^{\oplus}M_N\text{–}(M_EM_N)_n\text{–}M_E^{\ominus} \xrightarrow{M_E} {}^{\oplus}M_N\text{–}(M_EM_N)_n\text{–}M_EM_E^{\ominus} \quad (k)$$

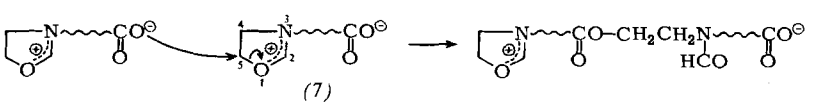
The above homopropagations disturb the alternating arrangements of M_N and M_E units in the product. Alternating propagation [eqs. (e) and (f)] and homopropagation [eqs. (j) and (k)] compete with each other. Whether homopropagation is excluded or not depends upon the reactivity characteristics of the monomers. Alternating copolymer is produced when a dipole-dipole reaction between M_N and M_E monomers producing *(1)* occurs in preference to ion-dipole reactions between ionic centers of zwitterions and monomers.

2. Alternating Copolymerization between 2-Oxazoline and β-Propiolactone[2]

Alternating copolymerization of 2-oxazoline *(4)* with β-propiolactone *(5)* is described first in order to illustrate the general character of this new type of copolymerization.



(4) *(5)* *(6)*



When a solution of an equimolar mixture of *(4)* and *(5)* in an aprotic polar solvent such as DMF was kept at room temperature, the solution gradually became viscous, and after one day the alternating copolymer *(6)* was formed in almost quantitative yield[2].

In this copolymerization, *(4)* behaves as M_N and *(5)* as M_E. A zwitterion *(7)* is the key intermediate for the polymerization. The onium ring derived from *(4)* is opened by nucleophilic attack of the carboxylate anion at C-5 [eq. (l)].

Figure 1 shows the variation of two parameters during the course of copolymerization; the solid line shows the relation between the molecular weight of the copolymer and the percent conversion, while the broken line shows the change of the quotient of the amount of copolymer divided by its

(7)

(7) (l)

molecular weight. This quotient is proportional to the number of copolymer molecules. The number of macrozwitterions, *i.e.* copolymer molecules, increases at the beginning (points 1—3), then reaches a maximum (point 4), and finally decreases as the conversion becomes higher (points 5—7). The shapes

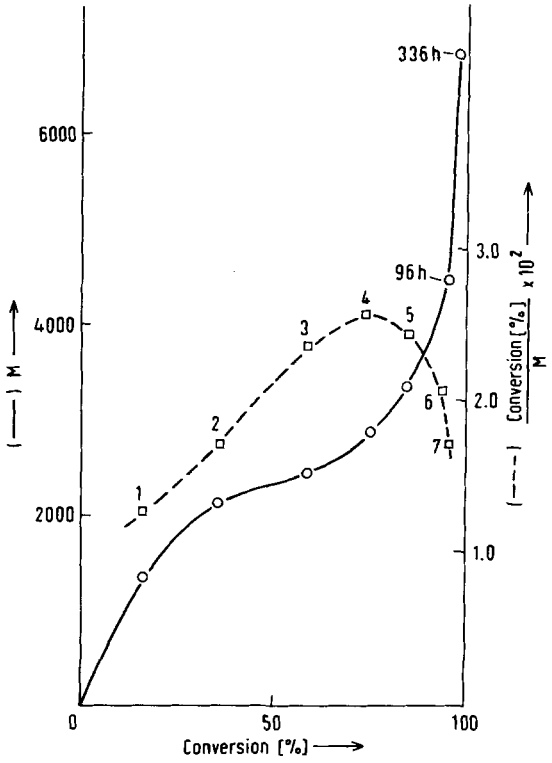


Fig. 1. Copolymerization of 2-oxazoline *(4)* with β-propiolactone *(5)* in DMF at 40°C [2]. 1 to 7, see text.

of the curves reflect the ratio of formation and consumption of the macrozwitterions [eqs. (f) and (h), respectively]. Before point 4, the reaction according to eq. (f) is faster than that according to eq. (h) because the concentration of both monomers is high and formation of the genetic zwitterion *(7)* is favored. This relationship is reversed after point 4, since the concentration of macrozwitterions becomes higher,

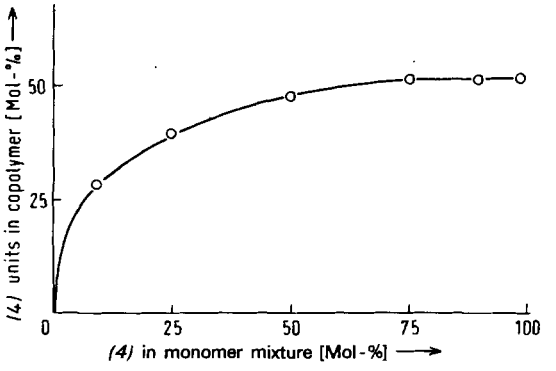

Fig. 2. Copolymerization of 2-oxazoline *(4)* with β-propiolactone *(5)* in acetonitrile at 25°C [1a].

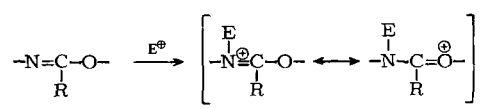
the monomer concentration decreases, and the macrozwitterions preferably react with each other. At the transition stage (points 3—5), where the polyaddition reaction according to eq. (g) predominates, the change in number of macrozwitterions is small.

Figure 2 shows the change in copolymer composition with varying monomer feed ratios. When the mole fraction of 2-oxazoline *(4)* in the monomer mixture is less than 50% (and correspondingly the fraction of β-propiolactone *(5)* is greater than 50%), the carboxylate end-group of the zwitterion reacts not only with cyclic onium sites of the zwitterions but also with free β-propiolactone *(5)* to produce copolymers consisting of more than 50% of β-propiolactone units. The reaction of carboxylate anions with *(5)* corresponds to the propagation of the anionic polymerization of *(5)*, which is quite possible under the conditions of alternating copolymerization, *i.e.* at room temperature in a polar aprotic solvent. In mixtures with more than 50% *(4)*, however, the cationic homopropagation of 2-oxazoline *(4)* is very slow under these conditions[3, 4]; consequently the propagation of a genetic zwitterion leads exclusively to an alternating copolymer.



Copolymerizations of 2-oxazoline *(4)* with α-methyl-β-propiolactone and with α,α-dimethyl-β-propiolactone proceeded in a similar way[5]. The overall rates of copolymerization follow the sequence *(5)* > α-methyl- > α,α-dimethyl-β-propiolactone. This sequence is consistent with the order of reactivity of the β-lactones towards nucleophiles[6].

3. Scope of Copolymerization

So far six monomers of type M_N and seven monomers of type M_E have been examined as reactants for this novel copolymerization. Thus, the number of possible combinations of copolymerization is six times seven, *i.e.*, forty-two. Of these, 23 have been examined. Table 1 summarizes the results. In all 23 combinations, copolymerization took place as expected, without any added catalyst.

As mentioned above, the character of copolymerization, *i.e.* alternating or non-alternating, depends upon the reactivity characteristics of the monomers. In Table 1, a letter A in parentheses indicates that alternating copolymerization is possible under a wide variety of reaction conditions, a letter B means that an alternating copolymerization is possible under suitable reaction conditions, and a letter C indicates those cases in which alternating copolymerization has not yet been realized.

Of the monomers of type M_N, 2-oxazolines *(8)*, 5,6-dihydro-4*H*-1,3-oxazines *(10)*, 4,5-dihydro-2(3*H*)furanimine *(12)* and 2-phenyl-1,3,2-dioxaphospholane *(16)* are quite reactive. The responsible functional group in *(8)*, *(10)* and *(12)* is the imino ether group (imidate group) *(32)*, which reacts with electrophiles to give a cation *(33)* stabilized by ammonium-oxonium resonance. Thus, cyclic imidates are highly polarizable and reactive nucleophiles.

(32) *(33)*

Table 1. M_N and M_E monomers, cationic and anionic groups and combinations. Empty fields: not examined. (A): alternating copolymerization under almost all conditions, (B) alternating copolymerization under certain conditions, (C) no alternating copolymerization.

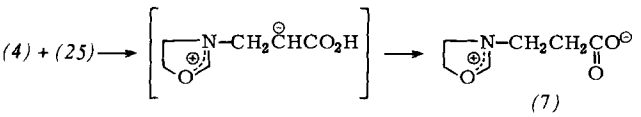
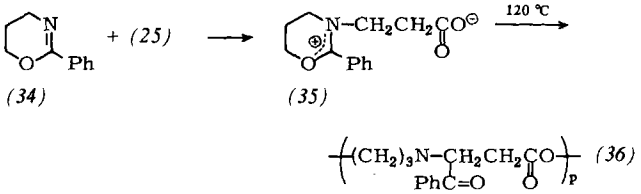
Trivalent phosphorus compounds such as *(16)* are also known to be strong nucleophiles of high polarizability. In other words, M_N monomers of type *(8)*, *(10)*, *(12)* and *(16)* are soft nucleophiles and they prefer soft electrophiles to hard electrophiles of the onium-zwitterion type. It is seen in Table 1 that the combinations of copolymerizations between soft M_N monomers [*(8)*, *(10)*, *(12)* and *(16)*] and soft M_E monomers [*(25)*, *(26)*, *(28)* and *(30)*] have a strong tendency to form alternating copolymers. Dipole-dipole reactions are favored in these combinations.

Studies carried out on M_N and M_E monomers have led to new findings which are of importance not only for polymer chemistry but also for preparative organic chemistry. The following sections deal with these new developments.



4. Copolymerization of Acrylic Monomers with Nitrogen-Containing Nucleophilic Monomers

An equimolar mixture of 2-oxazoline *(4)* and acrylic acid *(25)* in acetonitrile was heated at 60°C in the presence of a small amount of *p*-methoxyphenol as radical inhibitor. The reaction mixture became viscous, and the alternating copolymer *(6)* was formed[9].



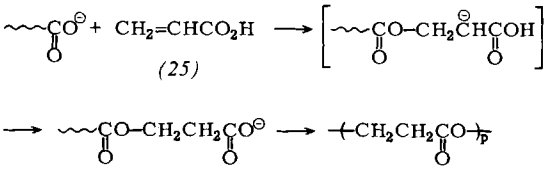
(4) + $CH_2=CHCO_2H$ *(25)* → $-(CH_2CH_2N(HCO)-CH_2CH_2CO)_p-$ *(6)*

The structure of the product *(6)* is the same as that of the 2-oxazoline/β-propiolactone copolymer, *i.e.* acrylic acid is converted into the same repeat unit as that formed in the ring-opening of β-propiolactone *(5)*. A reaction scheme leading to a zwitterion *(7)* has been suggested, which involves nucleophilic attack of *(4)* on the acrylic acid *(25)* followed by proton migration.

(4) + *(25)* → [N–CH_2–$\overset{\ominus}{C}$HCO_2H] → N–$CH_2CH_2CO^{\ominus}$ *(7)*

Indeed, from an equimolar mixture of 2-phenyl-5,6-dihydro-4*H*-1,3-oxazine *(34)* and acrylic acid *(25)* in acetonitrile at 5°C, a zwitterion *(35)* was in fact isolated as a crystalline solid[19]. *(35)* is very hygroscopic, but can be converted into a less-hygroscopic form which contains one mol of water of crystallization and melts at 145–146°C. When heated in bulk at 120°C *(35)* polymerizes to *(36)*, which corresponds to the alternating copolymer of *(34)* with *(25)*. These findings support the reaction scheme involving intermediary zwitter-

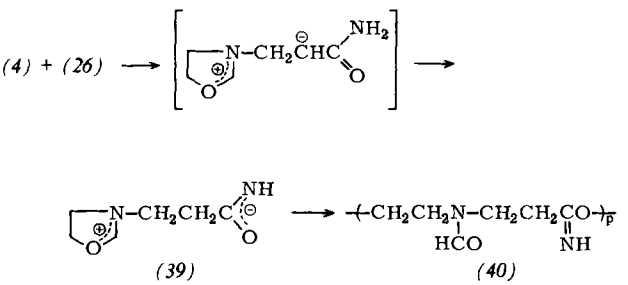
(34) + *(25)* → *(35)* (120 °C) → $-(CH_2)_3N(PhC{=}O)-CH_2CH_2CO-_p$ *(36)*



ions.—The copolymerization of acrylic acid with cyclic phosphorus compounds is described in Section 5.

The above observed reaction pattern of acrylic acid, *i.e.* addition of a nucleophile to the electron-deficient double bond and subsequent proton migration, was hitherto not so familiar. A series of our studies, however, have shown it to be quite a general reaction pattern. For example, reaction of pyridine and acrylic acid affords the zwitterion *(37)* which is usually prepared from pyridine and β-propiolactone *(5)*[20].

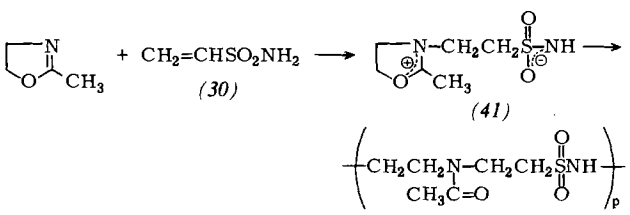
(37)



More interesting is the polymerization of acrylic acid, in which proton migration leads to formation of poly-β-propiolactone *(38)*. This reaction is initiated by phosphane, pyridine and other basic catalysts, including even alkali metal hydroxides[21]. The propagation involves repeated addition of a carboxylate anion to the double bond of the monomer followed by migration of a proton.

(25) *(38)*

Interestingly, the reaction pattern of the acrylic acid polymerization described above is also observed in the formation of poly-β-alanine from acrylamide *(26)*[22].



Copolymerizations of acrylamide *(26)* with cyclic imino ethers proceed similarly[10], *i.e.* addition of the cyclic imino ether monomer to the olefinic bond of *(26)* followed by proton migration. Thus, for example, the zwitterion *(39)* is the key intermediate in the copolymerization of *(26)* with *(4)*[10].

(4) + *(26)* *(39)* *(40)*

The anionic moiety of *(39)* is ambifunctional, *i.e.* depending upon the nature of electrophile, it may react either at the oxygen or at the nitrogen atom. Analysis of the copolymers has established that reaction takes place at the oxygen atom in this case.—The copolymerization of acrylamide with cyclic phosphorus compounds is described in Section 5.1.

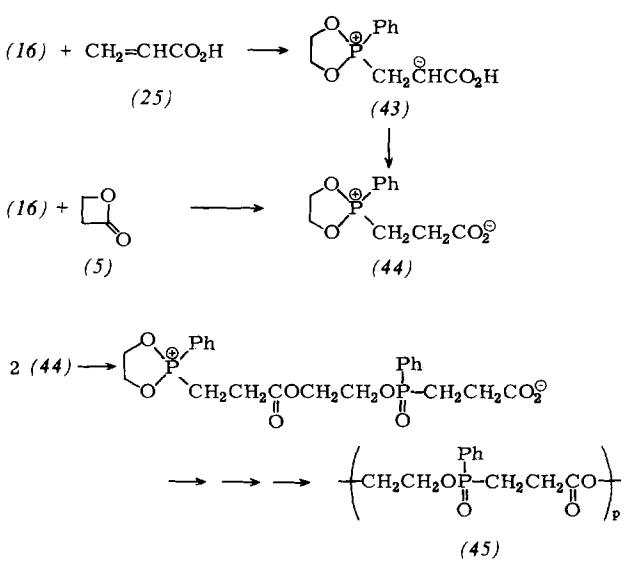
In this connection, the scheme for copolymerization of ethylenesulfonamide *(30)* with 2-methyl-2-oxazoline is also outlined[12]. In this case, an ambifunctional anionic group of the zwitterion reacts at the nitrogen atom.

(30) *(41)*

The reactions of the anionic groups, both in *(39)* and in *(41)* (and the corresponding macrozwitterions), are regiospecific, although the reaction sites are completely different. An understanding of this regiospecificity requires further studies to be carried out.

Copolymerizations of β-hydroxyalkyl acrylates with cyclic imino ethers proceed similarly. Here too, the genetic zwitterion is formed first by nucleophilic addition of cyclic imino ether to the CC double bond of the acrylate; this is followed by transfer of the proton from the hydroxyl group to the transient carbanion site[11].

5. Copolymerization of Cyclic Phosphorus Compounds with Electrophilic Monomers

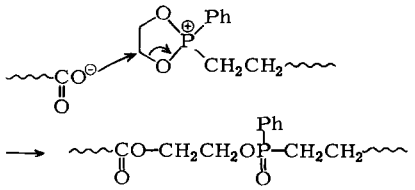


The reaction of two cyclic phosphorus compounds, 2-phenyl-1,3,2-dioxaphospholane *(16)* and 2-phenoxy-1,3,2-dioxaphospholane *(42)*, with several M_E monomers led to novel copolymerizations. Interesting patterns of polymerization as well as of synthetic organic reactions of phosphorus compounds were discovered.

(16) *(42)*

5.1. Copolymerization of the Dioxaphospholane *(16)* and Related Synthetic Reactions

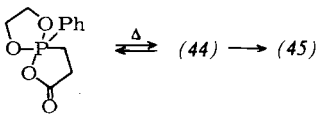
2-Phenyl-1,3,2-dioxaphospholane *(16)* has been successfully copolymerized with the electrophilic monomers *(5)*[16], *(23)*[17], *(25)*[16], *(26)*[16], *(30)*[17], acrylic esters[23], vinyl



(16) + *(25)* *(43)* *(16)* + *(5)* *(44)* 2 *(44)* *(45)*

ketones[23], and *o*- and *p*-formylbenzoic acids[24] to give the respective 1:1 alternating copolymers.

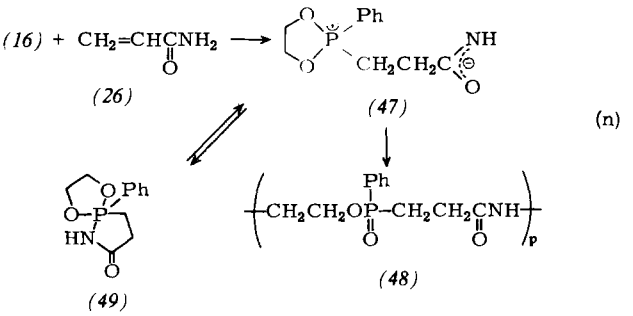
The copolymerization of *(16)* with β-propiolactone *(5)* and with acrylic acid *(25)* afforded the same alternating copolymer *(45)*[16]. The zwitterion *(44)* is the key intermediate in both cases.



In the reaction with *(5)*, *(44)* is formed directly by ring-opening. In the case of acrylic acid *(25)*, the carbanionic zwitterion *(43)* is first formed and is then rapidly converted into *(44)* by migration of a proton. An analogous reaction scheme for the acrylic acid component has already been mentioned in Section 4. The reaction between phosphonium ring and carboxylate anion, which is responsible for the propagation of genetic and macrozwitterions, proceeds according to the Arbuzov reaction [eq. (m)].

(m)

It should be noted that the trivalent phosphorus in *(16)* is converted into the pentavalent state during copolymerization.

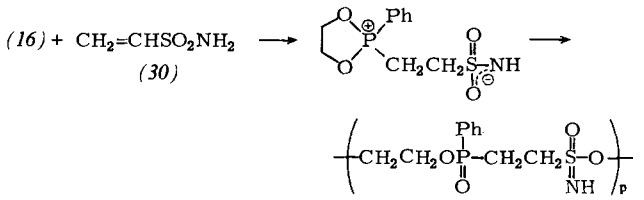


The above copolymerizations take place only at 100°C or higher temperatures[16]. At room temperature, reaction of an equimolar mixture of *(16)* and *(25)* in ether afforded a crystalline material (m.p. 80°C) having structure *(26)* in an almost quantitative yield[25].

(46)

It is reasonably assumed that *(46)* is formed by covalent bonding between the phosphonium and the carboxylate groups in *(44)*; the reaction is probably reversible. Heating of *(46)* to 150°C in DMF or in substance leads to the copolymer *(45)*[16]. At higher temperatures, the P—OC(O) bond in *(46)* undergoes heterolytic cleavage to give the zwitterion *(44)*, which promotes the polymerization. Thus, this reaction is a novel type of ring-opening polymerization which is initiated thermally and proceeds *via* zwitterion intermediates.

A similar copolymerization of *(16)* is observed also with acrylamide *(26)* [eq. (n)][16].

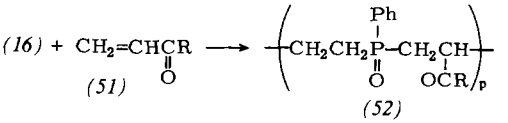


(n)

As in the above case, the pentavalent compound *(49)* (m.p. 158°C) could be isolated at lower temperatures, *e.g.* 50°C, and polymerized at 120°C[16]. This is the second example of a "thermally-induced ring-opening polymerization *via* zwitterion intermediates".

The ambifunctional anionic group of the zwitterion *(47)* in the above copolymerization (namely, of *(16)* with *(26)*) reacts exclusively at nitrogen. In contrast, in the copolymerization of *(4)* with *(26)* (Section 4) the reaction occurs at oxygen.

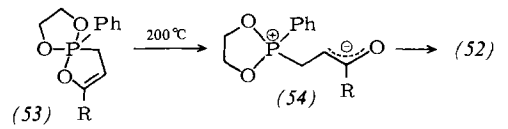
Copolymerization of *(16)* with ethylenesulfonamide *(30)* produces an alternating copolymer *(50)*; here the sulfonamide anion reacts at the oxygen atom[17].



(50)

Table 2 summarizes the reaction sites of two ambifunctional anions for reaction with the oxonium ring from cyclic imino ethers and the phosphonium ring. Regiospecificity was quite high in all cases. Elucidation of these phenomena may represent an interesting problem for future studies.

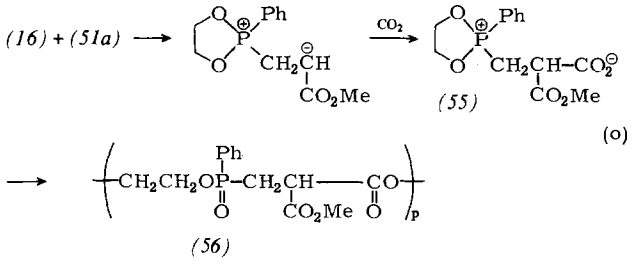
Table 2. Reactive sites in the reaction of ambifunctional anions with cations.



Anion \ Cation		
	oxygen	nitrogen
	nitrogen	oxygen

Alternating copolymerization of *(16)* with methyl acrylate *(51a)* and with the vinyl ketones *(51b)* and *(51c)* occurred at 130°C to give alternating copolymers *(52)* having lower molecular weights (700—1600)[23].

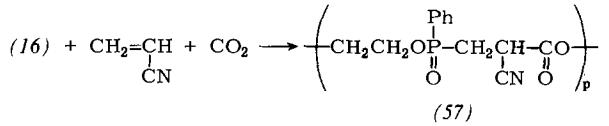
(a), R = OMe; *(b)*, R = Me; *(c)*, R = Ph



At room temperature or 50°C, pentavalent phosphorus compounds *(53a)* and *(53b)* were isolated from equimolar mixtures of the combinations *(16)*/*(51a)* and *(16)*/*(51b)*, respectively[23]. On heating to 200°C, *(53a)* and *(53b)* give the polymers *(52a)* and *(52b)*, respectively. Thus, these are additional examples of a "thermally-induced ring-opening polymerization". Zwitterions *(54)* having an enolate anion partial structure are assumed to be the intermediates in the 1:1 alternating copolymerizations of *(16)* with *(51a)* to *(51c)* and in the homopolymerization of *(53a)* and *(53b)*.

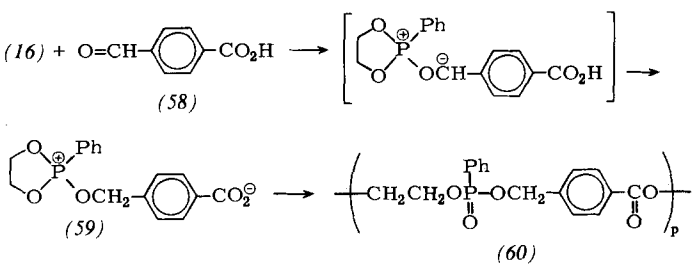
(53) R

(a), R = OMe; (b), R = Me



When the copolymerization of (16) with (52a) is carried out under CO_2 (atmospheric pressure) a 1:1:1 alternating terpolymer (56) is formed[26]. The following scheme [eq. (o)] explains this novel alternating terpolymerization, in which a zwitterion (55) is the key intermediate.

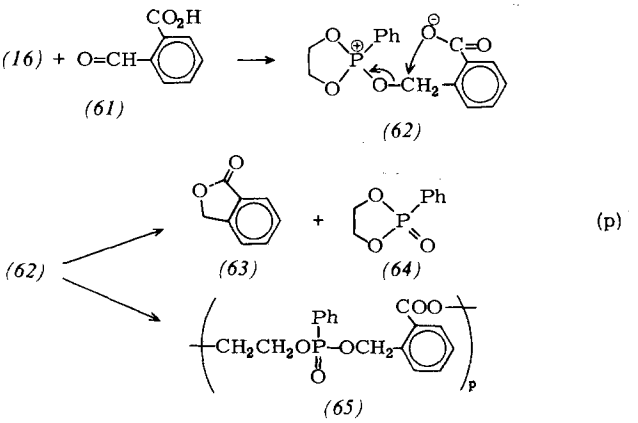
(o)



(56)

Two outstanding findings must be pointed out here, namely the incorporation of carbon dioxide into terpolymer without the aid of any added catalyst, and the production of a 1:1:1 alternating terpolymer. An isolated sample of (53a) dissolved in acetonitrile was readily copolymerized with CO_2 at room temperature to give the product (56). Moreover, combination of (16) and acrylonitrile under CO_2 atmosphere also gave an alternating terpolymer (57).

(57)

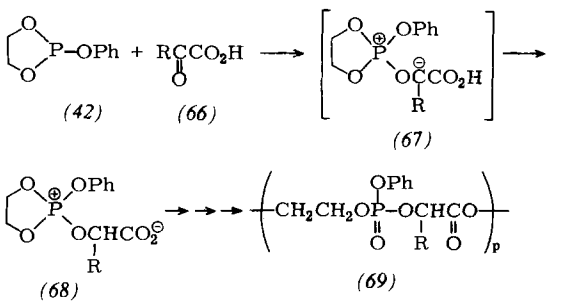


Another interesting copolymerization is that of (16) with *p*-formylbenzoic acid (58), in which an alternating copolymer (60) was produced[24]. The genetic zwitterion (59) is the responsible key intermediate; it is formed by bonding of the phosphorus atom of (16) to the formyl oxygen of (58) and subsequent hydrogen transfer.

(58) (59) (60)

In the reaction of (16) with *o*-formylbenzoic acid (61), however, a lactone (63) was the major product. The linear alternating copolymer (65) was merely a minor product.

Formation of the lactone (63) is ascribed to the intramolecular cyclization of the zwitterion (62) [as indicated by an arrow in (62)]. The cyclic phosphonate (64) could indeed be isolated in an amount corresponding to that expected according to



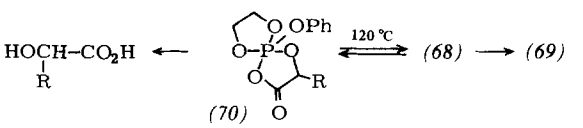
(61) (62) (63) (64) (65)

(p)

eq. (p). Copolymerizations of (16) with (58) and with (61) are closely related to the copolymerization of (42) with α-keto acids described in Section 5.2.

5.2. Copolymerization of the Dioxaphospholane (42) with α-Keto Acids and Related Synthetic Reactions

2-Phenoxy-1,3,2-dioxaphospholane (42), which is not listed in Table 1, displays an interesting polymerization behavior: it is readily copolymerized with α-keto acids (66) at temperatures higher than 120°C without addition of catalyst[27].

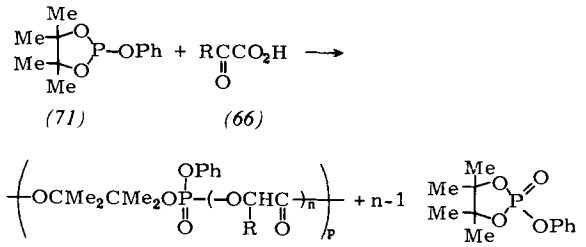


(42) (66) (67) (68) (69)

(a), R = Me; (b), R = Ph

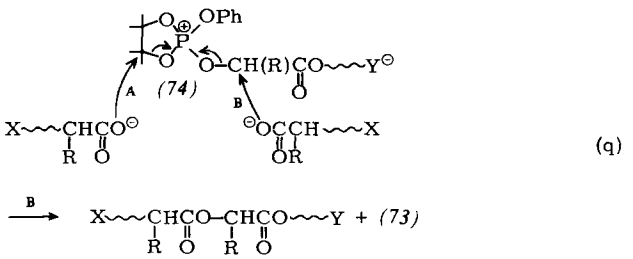
It must be mentioned that the trivalent phosphorus in monomer (42) is oxidized to the pentavalent state in the copolymer repeat unit; correspondingly the α-keto acid (66) is incorporated in the copolymer (69) in the reduced form as α-hydroxylic acid. In addition, this is the first instance of an α-keto acid being polymerized through bond-opening of the carbonyl double-bond.

At lower temperatures, *e.g.* −20°C in diethyl ether, the pentaoxyphosphoranes (70a) and (70b) (m.p. 87 and 60—62°C, respectively) could be isolated[28]. On heating (70a) in substance to 120°C the polymer (69a) was formed. This is also an example of a "thermally-induced ring-opening polymerization *via* zwitterions". A reversible interconversion of (70) and (68) is assumed to take place.



(70)

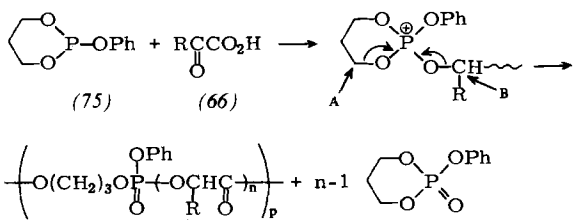
(a), R = Me; (b), R = Ph



The synthesis of pentaoxyphosphoranes *(70)* is very important not only from the point of view of polymer chemistry but also in the sector of phosphorus chemistry. *(70)* readily undergoes hydrolysis to give the corresponding α-hydroxylic acid. Thus, this reaction constitutes a new synthetic method for the reduction of α-keto acids to α-hydroxylic acids under very mild conditions. For preparative purposes, the isolation of *(70)* is unnecessary[29]. Furthermore, *(70)* can be regarded as a mixed anhydride linkage and as such comes into the category of so-called "high-energy" compounds, which play an important role in biological reactions. Reactions of *(70)* with nucleophilic and electrophilic reagents have led to several novel syntheses[30]. In addition, *(70)* is readily homopolymerized at room temperature in presence of an anionic catalyst[31].

When a fully substituted cyclic phosphite such as *(71)* is subjected to reaction with α-keto acids, a copolymer *(72)* consisting mainly of the α-hydroxylic acid ester unit is obtained[32].

(71) *(66)* *(72)* *(73)*



This result can be explained as shown in eq. (q). The carboxylate anion attacks mainly the carbon atom located outside of the phosphonium ring of the zwitterion *(74)* (reaction course B), for attack at the ring carbon atoms (course A) is greatly hindered by the methyl groups.

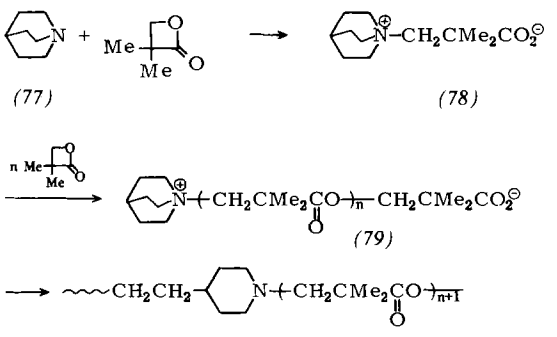
(q)

Polymerization *via* course B represents the first example of a novel type of polymerization which may appropriately be termed as a "reductive polymerization of a α-keto acid".

In the copolymerization of six-membered cyclic phosphites *(75)* with α-keto acids *(66)*, the propagation corresponding to course B [see eq. (q)] occurs concurrently. The copolymer

(75) *(66)* *(76)* (n > 1)

(76) thus obtained contains an excess amount of α-hydroxylic acid ester units[33].



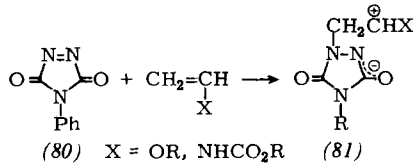
Since the six-membered phosphonium ring does not very readily undergo ring-opening, propagation according to course B can not be suppressed.

6. Related Copolymerizations

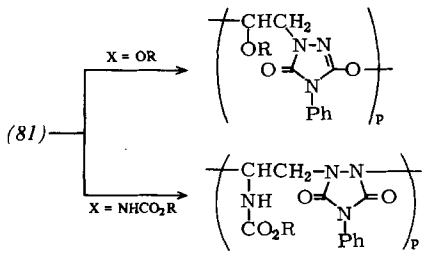
In this connection mention must first be made of spontaneous copolymerization between two kinds of vinyl monomers. Examples of spontaneous copolymerizations between electron-accepting and electron-donating monomers include the combinations of vinylidene cyanide/vinyl ether[34], 2,4,6-trinitrostyrene/4-vinylpyridine[35] and acrylonitrile/vinyl ether[36]. These copolymerizations are assumed to involve a free radical mechanism which proceeds *via* the charge-transfer complex species formed by interaction between two kinds of monomers. Furthermore, *Hayashi et al.*[37] recently reported the spontaneous copolymerization of nitroethylene and vinyl ether, involving three elementary reaction processes:

1. cycloaddition between two monomers,
2. anionic polymerization of nitroethylene induced by the cycloadduct, and
3. ring-opening polymerization of the cycloadduct.

Before completing our studies on spontaneous copolymerizations *via* zwitterion intermediates, several copolymerizations have been reported which are closely related to the concept presented in this article. *Wilson* and *Beaman*[38] have reported on the polymerization of pivalolactone initiated by cyclic amines such as quinuclidine *(77)*, *N*-substituted aziridines, and *N*-methylazetidine. These authors observed that more than one molecule of the cyclic amine employed as initiator was incorporated in each polymer molecule. This finding was explained in terms of participation of the cyclic amine in the copolymerization. For example, zwitterions *(78)* and *(79)* were postulated in the case of *(77)*.

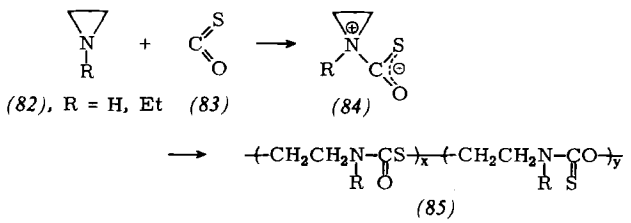


(77) *(78)* *(79)*



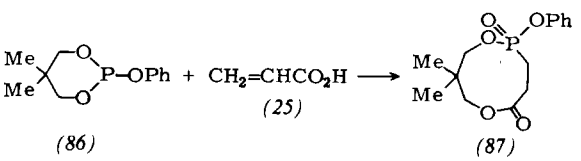
Butler et al.[39-41] have described the alternating copolymerizations of 4-phenyl-1,2,4-triazoline-3,5-dione *(80)* with vinyl ethers and with vinyl carbamate. Zwitterions of type *(81)* are assumed to be the key intermediates.

The anionic part of the zwitterion *(81)* is ambifunctional. Which of the two reaction sites reacts, depends upon the nature of the electrophilic monomer (see also Table 2).



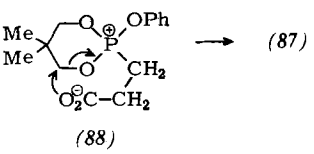
The spontaneous alternating copolymerization between aziridines *(82)* and carbonyl sulfide *(83)* is also interesting[42].

(80) X = OR, $NHCO_2R$ (81)



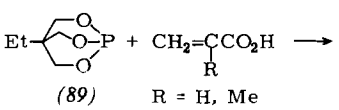
A zwitterion of structure (84) may be assumed as the key intermediate species. The anionic site of (84) is ambifunctional; the COS repeat unit having two different isomeric structures is formed.

(82), R = H, Et (83) (84)



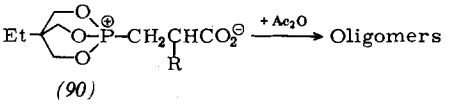
(85)

The reaction of 5,5-dimethyl-2-phenoxy-1,3,2-dioxaphosphorinane (86) with acrylic acid to give the nine-membered cyclic phosphonate (87) should also be mentioned[43] here, since this reaction proves to be related to the copolymerization of cyclic phosphorus compounds (16), (42) and (75) with electrophilic monomers.



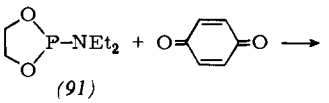
(86) (25) (87)

The formation of (87) can be explained in terms of an intramolecular reaction of a zwitterion of structure (88).

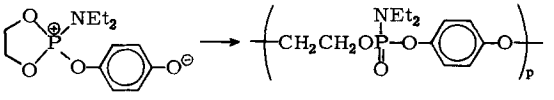


(88)

The spontaneous copolymerization of cyclic compounds containing trivalent phosphorus is described in two patents. One of the patents[44] deals with the preparation of co-oligomers by reaction of bicyclic phosphites (89) with acrylic or methacrylic acid in the presence of acetic anhydride. *Inter alia*, the zwitterion (90) was postulated as the key intermediate. The products were proposed as potential flame retardants.



(89) R = H, Me



(90)

The other patent[45] describes the alternating copolymerization of the cyclic phosphorus compound (91) with *p*-benzoquinone. This copolymerization may well be explained by the intermediacy of the zwitterion (92).

(91)

(92)

7. Conclusion

In this article a new concept of spontaneous copolymerization has been described, on the basis of which various new copolymerizations have been discovered. This new concept has also proven very useful in the exploration of organic synthetic reactions. The discovery of new M_N and M_E monomers is essential for further development in this sector of polymer chemistry; and it is to be hoped that some unique applications might be discovered on the basis of this new concept of copolymerization.

Thermal and Photochemical Cycloelimination of Nitrogen

By Herbert Meier and Klaus-Peter Zeller[*]

Cyclic azo compounds including heteroaromatics with a N=N bond of strong double-bond character can eliminate molecular nitrogen on addition of sufficient thermal energy or on electronic excitation. Some substrates decompose spontaneously, others are moderately or even extremely resistant to N_2-elimination. From a preparative point of view this type of reaction opens a variety of interesting possibilities, *e.g.* the synthesis of small carbocycles or heterocycles, strained bi- and polycycles, as well as cage compounds. From a theoretical mechanistic viewpoint, current importance attaches to the primary fragments such as carbenes, diradicals, trimethylene, trimethylenemethane, dipoles, ylides, antiaromatic 4π-systems, unstable cycloalkynes, and arynes.

1. Introduction

Cycloelimination is the reverse reaction of cycloaddition[1-3]. Cycloeliminations of nitrogen constitute a particularly interesting and extensive section of this field[4-8]. The structural basis for the elimination of molecular nitrogen is provided by the cyclic azo compound *(1)* and its isomer *(2)*.

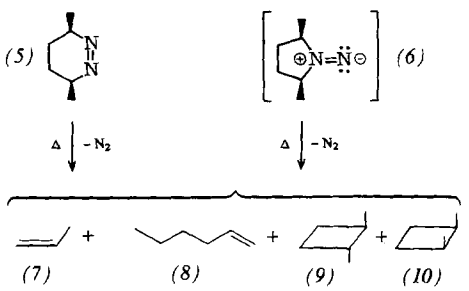

Table 1. Thermal decomposition of the equivalent systems *(5)* [type *(1)*] and *(6)* [type *(2)*] at 306°C in the gas phase. *(6)* was produced *in situ* from the *N*-methanesulfonamide. Compound *(7)* is formed by $[\pi 2_s + \pi 2_s + \pi 2_s]$-cycloreversion, compound *(8)* by [1.5]-H-shift, compounds *(9)* and *(10)* by stereoselective ring closure [10].

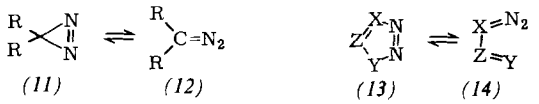
Yield [%]	*(7)*	*(8)*	*(9)*	*(10)*
From *(5)*	74.7	0.5	8.5	16.3
From *(6)*	74.0	0.7	9.1	16.2

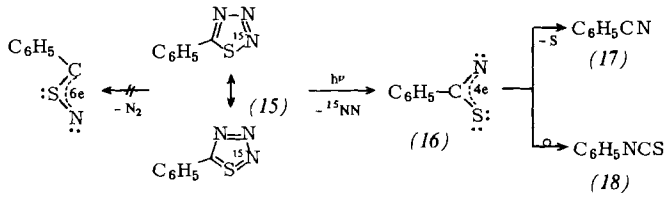


[*] Prof. Dr. H. Meier, Doz. Dr. K.-P. Zeller
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

Compounds *(2)* occur only as short-lived intermediates; their decomposition is, for example, a subject of the theory of chelotropic reactions[9]. The equivalent systems *(5)* and *(6)*, corresponding to *(1)* and *(2)*, undergo a very similar decomposition[10] (Table 1).

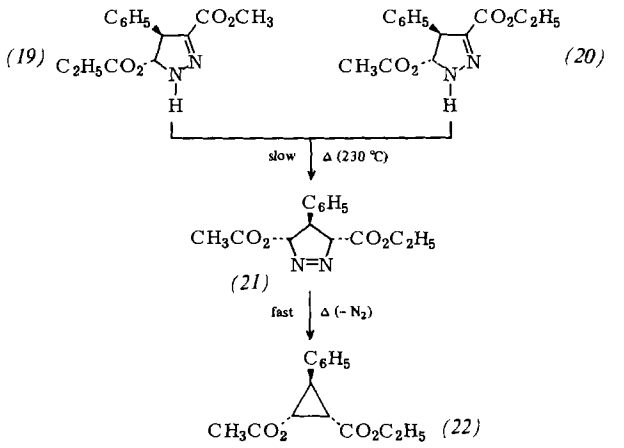
Cyclic azo compounds exist in large numbers, ranging from three-membered rings to macro-rings, and among them we include systems *(1)*, where X and/or Y = N, O, S, Se, CR_2, *etc.*, that contain N=N bonds with strong double-bond character.

In open-chain compounds and in large rings the *trans*-configuration of the azo group is thermodynamically more stable than the *cis*-configuration, whose higher energy content is due mainly to repulsion of the free electron pairs. In analogy to cyclooctene, 1,2-diaza-1-cyclooctene is the smallest azo-ring system existing in a stable *trans*-form[11, 12]. The ring strain in smaller rings prevents their existence as free *trans*-isomers under normal conditions.



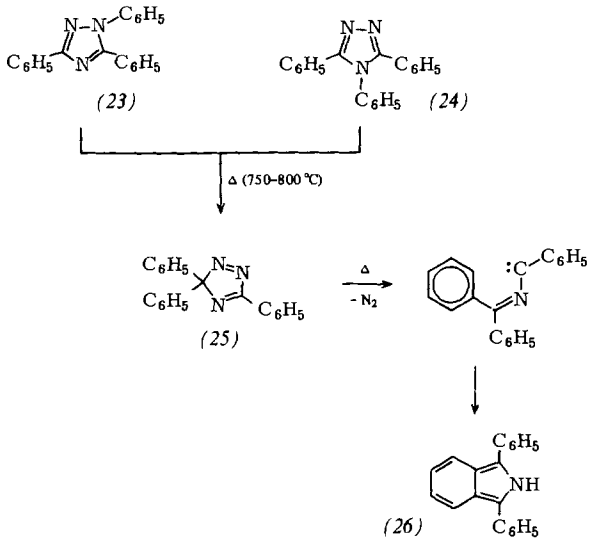
As a further structural characteristic, the ring-chain valence isomerism of some 1,2-diaza-heterocycles should be noted, especially for three-membered *(11)*[13, 14] and five-membered rings *(13)*.

(11) *(12)* *(13)* *(14)*



For the system *(13)* ⇄ *(14)* with X, Z = CR, N and Y = CR_2, NR, O, or S, 16 isomers are to be expected; some of these are unknown, in other cases only the cyclic or only the open-chain structure is so far known, *e.g.* in the 1,2,3-thiadiazoles and the α-diazocarbonyl compounds respectively[15]. To a further category belong systems in which *(13)* and *(14)* exist in thermal equilibrium, as in suitably substituted 1,2,3-triazoles[16–18]. In principle, it should be noted that nitrogen can be eliminated from a diazo, diazonium, or an azide structure.

Unlike cyclic azo compounds, but like all systems with an N—N bond of weak double-bond character, the cyclic azines are incapable of eliminating nitrogen. Isotopic labeling shows *(15)* to eliminate $^{15}N{\equiv}N$ selectively, in accord with the higher order of the N^2—N^3 bond[19].

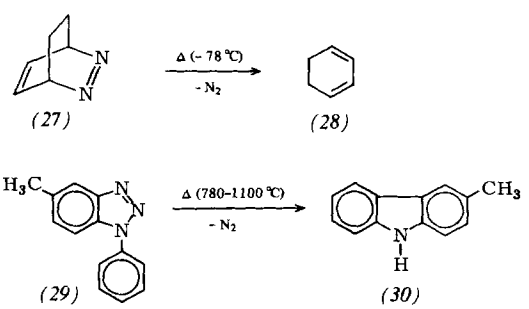


(15) *(16)* *(17)* *(18)*

However, compounds not at first containing an azo function can eliminate nitrogen if a suitable substrate can be formed in a preceding isomerization; a current example is the thermolysis of 2-pyrazolines *(19)* and *(20)* initiated by proton migration[20].

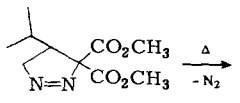
(19) *(20)* *(21)* *(22)*

Under drastic thermal or photolytic conditions larger groups may migrate or ring structures may isomerize, for which 1,2,4-triazoles *(23)* and *(24)* may be cited as examples[21].



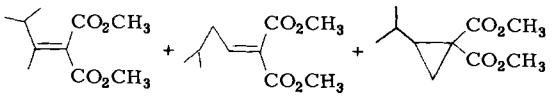
(23) *(24)* *(25)* *(26)*

2. Performance of the Reaction



2.1. Thermolysis

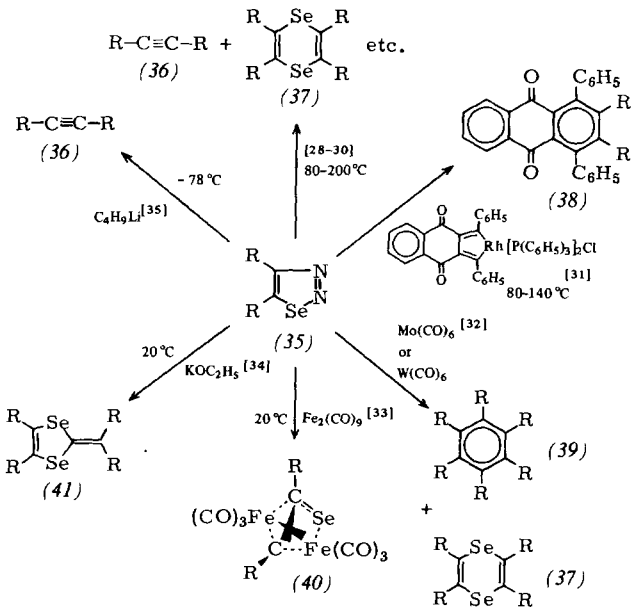
Thermal cycloelimination of nitrogen can be effected from a substrate in solution, in a purely liquid phase, or in the gaseous state. The observed decomposition temperatures vary between −78 °C for spontaneous decomposition of 2,3-diazabicyclo[2.2.2]octa-2,5-diene *(27)*[22–24] and up to 1100 °C for the gas-phase pyrolysis of benzotriazole *(29)*[25].



(27) *(28)* *(29)* *(30)*

Most of the experiments are carried out at atmospheric pressure, but thermolyses have also been effected in high vacuum and at pressures up to 5000 atm[26]. The activation barrier to N_2-elimination and thus the decomposition temperature can sometimes be considerably depressed; in this connection heterogeneous or homogeneous catalysts must be distinguished from agents incorporated in the product. Substances investigated for this purpose include metals (Cu, Pt, Pd), metal salts (Cu^+, Cu^{2+}, Ag^+), metal complexes (Fe, Rh), organometallics (C_4H_9Li), aluminum oxide, bases, and Lewis acids. Table 2 gives the change in the thermodynamic activation parameters and the influence of the catalyst on the nature of the products obtained in the pyrolysis of 1-pyrazoline *(31)*[27].

(31)



(32) *(33)* *(34)*

Table 2. Thermal decomposition of 1-pyrazoline *(31)*. Yields in *n*-butanol at 105 °C with and without $CuCl_2 \cdot 2H_2O$ as catalyst (cat.); activation parameters at 35 °C with and without catalyst.

Yield [%]		*(32)*	*(33)*	*(34)*
Without cat.		24.6	44.3	31.1
With cat.		15.5	5.3	79.2
Activation parameter	E_a [kcal/mol]	ΔH [kcal/mol]	ΔS [cal K^{-1} mol]	ΔG [kcal/mol]
Without cat.	24.0 ± 0.5	23.3	−10.3 ± 1.4	27.1
With cat.	13.2 ± 0.7	12.6	−29.3 ± 2.3	21.9

The synthetically valuable ability to induce decompositions yielding a variety of products can be demonstrated on the

example of 1,2,3-selenadiazoles *(35)*, occurring between −78 °C and +200 °C with or without catalysts.

2.2. Photolysis

On considering the local symmetry of *cis*- and *trans*-azo groups[36, 37], it can be recognized that the longest-wave transition in the *trans*-configuration is parity-forbidden (see Fig. 1). Even for the *cis*-isomer its intensity is relatively low ($\lambda_{max} \approx 360$ nm, $\varepsilon_{max} \approx 100$—760), since the transition moment resulting from the weak overlap of n_- and π^* is small. Nevertheless, this intensity suffices to effect efficient photolysis.

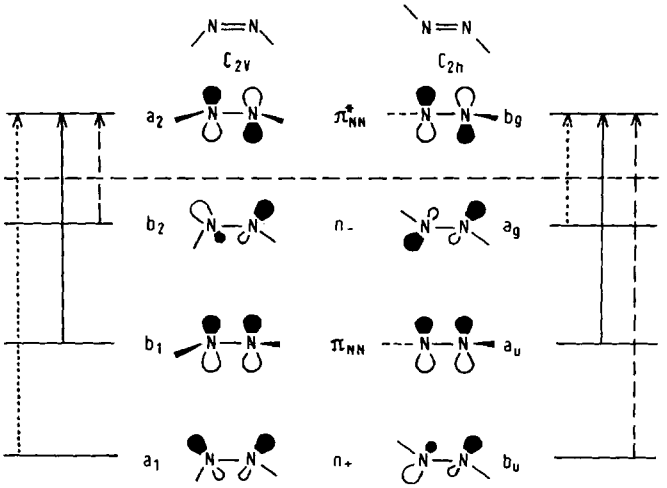


Fig. 1. Electron transitions in *cis*- and *trans*-azo compounds.

The situation exactly the opposite for the $n_+ \rightarrow \pi^*$ transition, which is hard to assign in the UV spectra.

Intense absorptions with $f \geq 0.3$ correspond to $\pi\pi^*$-excitations. Conjugation shifts them bathochromically from the vacuum-UV region. 1,2-Diazaheteroarenes show characteristic $\pi \rightarrow \pi^*$ transitions for this system. The influence on the π^*-excitation is smaller.

Direct or triplet-sensitized photolyses of cyclic azo compounds are known for all three states of aggregation. Singlet energy transfer has also been observed[37]. The quantum yields Φ for the evolution of nitrogen in the gas phase are often around 1, but in solution they are generally considerably lower; examples are shown in Table 3.

Table 3. Quantum yields Φ of the elimination of N_2 in the photolysis of compounds *(42)* to *(48)*.

Substrate	 *(42)*	 *(43)*	 *(44)*	 *(45)*	 *(46)*	 *(47)*	 *(48)*
Φ	1.0	0.022	0.88	0.12	0.002	0.45	0.012
Ref.	[38]	[39]	[40]	[40]	[41]	[40]	[40]

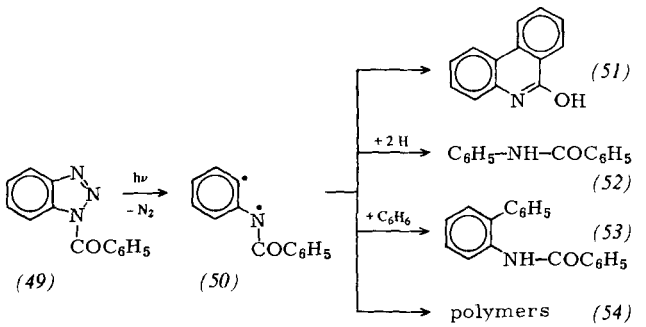
The reactivity, in particular the tendency to eliminate N_2, may differ markedly between $n\pi^*$ and $\pi\pi^*$ excitation states[41a].

2.3. Influence of the Reaction Conditions

The choice of the reaction conditions (medium, substrate concentration, temperature, wavelength region) can have a

Note: Due to a pagination error by the printer, p. 837 is followed by p. 840. This omission is without effect on the text of the present article.

decisive influence on product formation, as may be illustrated by some examples. 1-Benzoylbenzotriazole *(49)* forms photochemically a fragment *(50)* and this can stabilize itself by ring closure, reaction with the solvent, or polymerization. Table 4 shows the product pattern obtained under various conditions[42].



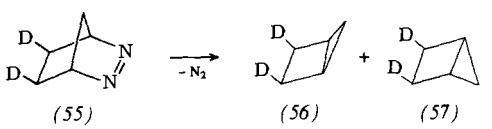


Table 4. Relative yields in the photolysis of 1-benzoylbenzotriazole *(49)* with variation of concentration, solvent, and wavelength (filter).

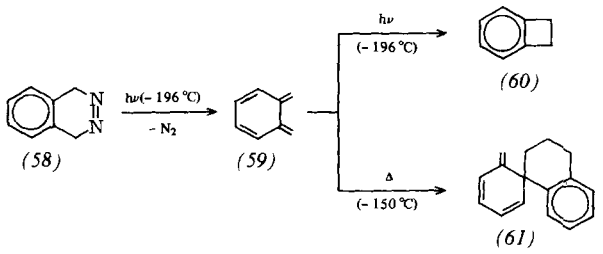
Initial concn. [mol/l]	Solvent	Filter	Rel. yield [%] (51)	(52)	(53)	(54)
$0.9 \cdot 10^{-3}$	$C_6H_6/CHCl_3$ 1:1	Quartz	—	7	81	12
$1.0 \cdot 10^{-1}$	$C_6H_6/CHCl_3$ 1:1	Quartz	18	5	11	66
$1 \cdot 10^{-2}$	C_6H_6	Corex	8	—	65	27
$1 \cdot 10^{-2}$	$CHCl_3$	Corex	15	18	—	67
$1 \cdot 10^{-2}$	$C_6H_6/CHCl_3$ 1:1	Pyrex	9	10	57	24
$1 \cdot 10^{-2}$	$C_6H_6/CHCl_3$ 1:1	Quartz	5	6	39	50

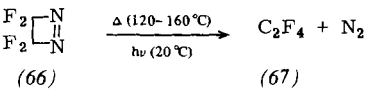


There are often extremely striking differences between thermolysis, direct photolysis, and sensitized photoreaction, arising as a result of the different conditions, possible modes of deactivation, or excitation processes of the primary fragments. This may be illustrated by the following examples.

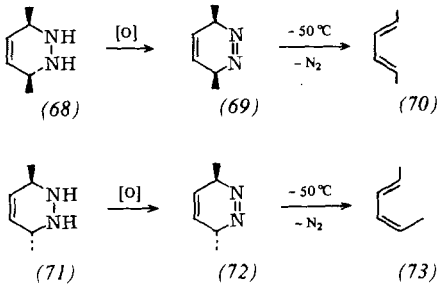
In *(55)*[43], the degree of double retention or inversion, and thus the stereoselectivity, changes according to the methods, as shown by the figures for *(56)* and *(57)*:

	(56):(57)		(56):(57)
180°C, 100—200 torr	1:3	hν, in benzene	1:1.5
Gas phase, 1—2 torr	1:1	hν, solid −70°C	1:1.05
Gas phase, 350—760 torr	1:1.5		

For the photolysis of *(58)*[44] the secondary thermal or photochemical activation is of decisive importance.

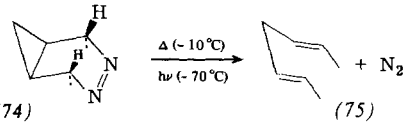


Whereas on direct photolysis *(62)* affords a mixture *(63)*:*(64)*:*(65)* = 48:24:28, only *(65)* is produced on triplet sensitization[45].



3. Primary Fragments and Subsequent Reactions

3.1. Stable Primary Fragments



The primary fragments arising on the elimination of nitrogen are only rarely stable, isolable compounds. Examples are provided by 3,4-dihydro-1,2-diazetes such as *(66)*[46-48]

and 3,6-dihydropyridazines such as *(69)* and *(70)*. The latter compounds decompose in the sense of a symmetry-allowed,

concerted $[\pi 4_s + \pi 2_s]$-cycloreversion[49]. The place of the C=C double bond in *(69)* may be taken by a cyclopropane ring, which is equivalent to it in many respects[49, 50].

Bicyclic and polycyclic compounds also readily eliminate nitrogen if they contain this structural unit. Compounds in which the cyclopropane ring is not *anti* but *syn* to the azo bridge behave like ordinary 3,4,5,6-tetrahydropyridazines: they eliminate N_2 only photochemically or at elevated temperatures[51].

1,2,4-Triazines and 1,2,4,5-tetrazines react with alkenes, ketene acetals, or 2*H*-azirines to form [4+2]-cycloadducts that contain respectively, a 3,6-dihydro-1,2,4-triazine or 3,6-

dihydro-1,2,4,5-tetrazine structural component and also eliminate nitrogen *in situ*[52,53].

3.2. Unstable Primary Fragments

Cycloelimination of nitrogen generally leads first to unstable intermediates. Thus, diazirines *(11)* afford carbenes R_2C: *(4a)*, directly or by way of the valence-isomeric diazoalkanes *(12)*. Diradicals or dipolar species *(4)* are formed from larger ring systems *(1)* (Table 5).

The primary fragments stabilize themselves by subsequent intra- or intermolecular reactions; the most important of these are treated in Sections 3.3 to 3.8.

Table 5. Summary of primary fragments *(4)* from azo compounds *(1)* containing five or six ring members.

3.3. Ring Closures

Species of type *(4b)* to *(4f)* and larger fragments of this type can undergo ring closure immediately.

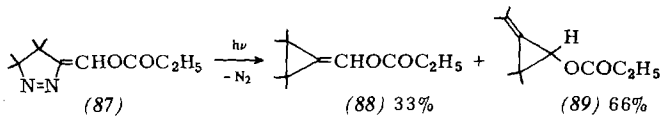
Three-membered ring compounds *(76)* are obtained from *(4b)* in this way, specifically cyclopropanes from *(4b1)* to *(4b3)*, oxiranes from *(4b6)*, thiiranes from *(4b7)*, aziridines from *(4b9)* and *(4b12)*, and diaziridines from *(4b11)*, *(4b13)*, and *(4b14)*.

(4b) → *(76)*

However, most of the investigations were carried out on 4,5-dihydro-3*H*-pyrazoles (1-pyrazolines), the first thermolysis having been recorded as early as 1888[54]. The product pattern depends markedly on the reaction conditions. In general, the proportion of three-membered ring compounds in the products is larger on photolysis than on thermolysis. Cycloelimination of nitrogen has proved particularly useful for the preparation of strained bicyclic and polycyclic compounds (for the synthesis

(77) → *(78)* → *(79)*

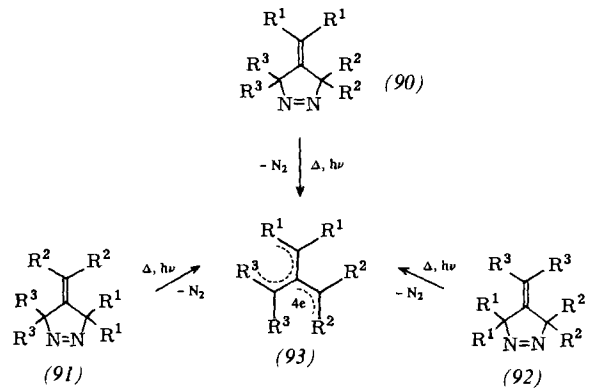
of bicyclo[*n*.1.0]alkanes *(78)*, $n=1$ to 6, see *e.g.*[43,55–59]). It was by this method that, *inter alia*, the first synthesis of unsubstituted prismane *(82)* was successfully accomplished[60].



(80) → *(81)* → *(82)*

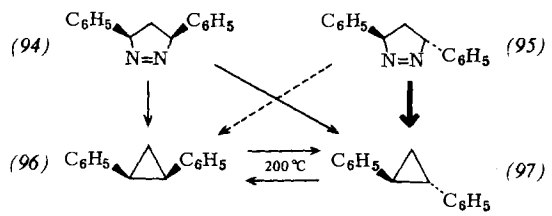
Bispyrazolines such as *(83)* yield biscyclopropanes, *e.g. (86)*, in a series of steps[61].

(83) → *(84)* + *(85)* → *(86)*



(84) : *(85)* = 85 : 11

Elimination of nitrogen from 1-pyrazolines containing an *exo*-methylene group in position 3 or 4 leads to methylenecyclopropanes; as shown by the example of *(87)*, this may also involve rearrangement of the original σ-bonded skeleton[62].

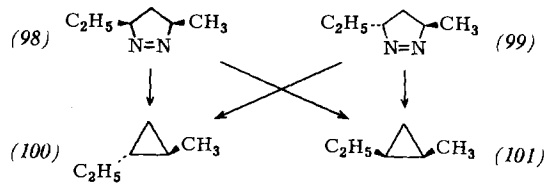


(87) (88) 33% (89) 66%

The primary fragment from the normal 1-pyrazolines yields trimethylene, which is a π-type 1,3-diradical, but a substituted trimethylenemethane is obtained from 4-methylenepyrazolines, as shown in formulas *(90)* to *(92)*; both intermediate stages can exist and react in sterically distinguishable singlet and triplet states.

(90) (91) (93) (92)

The stereochemistry of product formation is particularly important. Depending on the substrate, method, and medium, all possible types of process can be observed, from stereospecific through stereoselective to purely random; for example, the *trans*-isomer *(95)* of 3,5-diphenyl-1-pyrazoline shows high stereoselectivity both photochemically and thermally[63], while the *cis*-isomer *(94)* does not (Table 6).



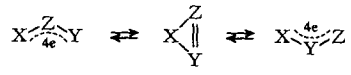
(94) (95) (96) (97)

Table 6. Steric course of the cycloelimination of nitrogen from 1-pyrazolines *(94)* and *(95)*.

Substrate	Method	Rel. Yield [%] (96)	(97)
(94)	Δ (45 °C)	44	56
(94)	*hν*	51.5	48.5
(95)	Δ (45 °C)	8	92
(95)	*hν*	14.5	85.5

By way of contrast, the stereoselectivity of methyl 3,5-dimethyl-1-pyrazoline-3-carboxylate is independent of the configuration but specific for the method, namely photolysis[64].

Two recent papers[65,66] report the stereochemical course of the reaction based on the absolute configuration of the 1-pyrazolines used. Thermolysis of the stereoisomeric 3-ethyl-5-methyl-1-pyrazolines *(98)* and *(99)*, for example, gave the results collected in Table 7[66].



(98) (99) (100) (101)

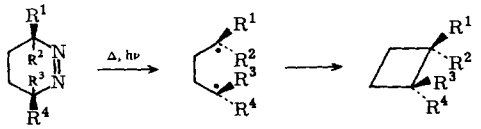
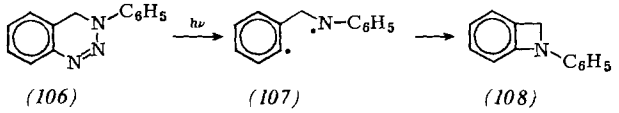
(101)		
Yield [%]	32.1	70.6
Dominant stereochemistry	Double inversion	Rotation at C-3
Retention of configuration [%]	36.5 ± 2.9	0.85 ± 0.02



Cyclization of the species *(4c)*, X = CR_2, Y = Z = CR, makes possible the very valuable photochemical synthesis of cyclopropenes *(102)* from 3*H*-pyrazoles by way of vinyldiazo compounds and vinylcarbenes *(4c1)*.

(4c) *(102)* *(4c')*

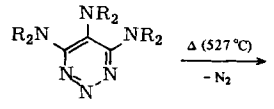


From the heteroanalogous fragments *(4c2)* to *(4c8)* having X = NR, S, or Se there arise cyclic conjugated 4π systems with potential antiaromatic character. Like the oxirenes *(102)*, X = O, Y = Z = CR[15], these three-membered rings *(102)* can be detected only by the establishment of the equilibrium *(4c)* ⇄ *(4c')* or by isomerizations such as the conversion of 1*H*-azirines into 2*H*-azirines[67–70].

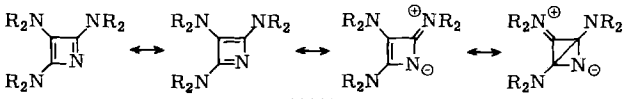
1,4-Diradicals *(4d1)* cyclize to give four-membered rings. On thermal or direct photochemical fragmentation of 3,4,5,6-tetrahydropyridazines of type *(103)* with aliphatic substituents, cyclobutanes *(105)* are formed with retention of configuration[71,72]; however, on triplet-sensitized decomposition or in the case of aryl-substituted substrates the stereoselectivity decreases as a result of the longer lifetime of the diradicals.

(103) *(104)* *(105)*

Among the cyclizations of the compounds *(4e1)* to *(4e5)* special mention should be made of the synthesis of the first stable benzazetine *(108)*[73].



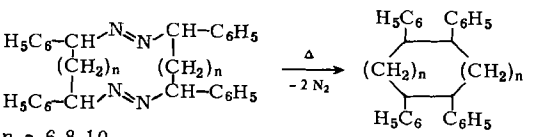
(106) *(107)* *(108)*



X-Ray structure analysis and theoretical calculations show that the bond between the two nitrogens of pyridazines *(109)* has mainly single-bond character[74]. The small contribution from the limiting structure *(109b)* is in line with the drastic conditions needed for elimination of the nitrogen as N_2.

(109a)  *(109b)*

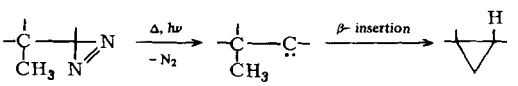
Cyclization of the fragments *(4f)* leads to the cyclobutadiene system. This could be realized experimentally by high-temperature pyrolysis of the benzo[*c*]cinnolines to biphenylenes[75] and by vacuum flash-thermolysis of 4,5,6-tris(dimethylamino)-1,2,3-triazine *(110)* to the resonance-stabilized tris(dimethylamino)azacyclobutadiene, compound *(111)*, which is stable at $-80\,^{\circ}C$[76,77].



(110)

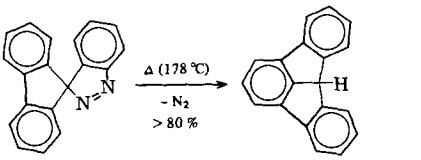
(111)

R = CH_3



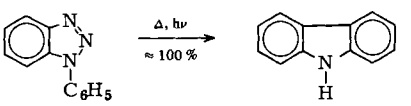
Diradicals produced from seven-, eight- and higher-membered rings also undergo ring closure reactions[78–81]; macrorings of structure *(112)* decompose thermally in steps to *(113)*[11,82].

n = 6,8,10 *(112)* *(113)*



3.4. Ring Closures Involving Substituents

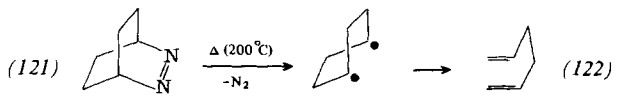
In certain substrates the direct cyclization of the primary fragment *(4)* may be replaced in whole or in part by involvement with a substituent leading to a larger ring. The reactive center X attacks the β- or γ-position of Y, removing a hydrogen atom which undergoes a [1.3]- or [1.4]-shift to become attached to Y. This type of reaction includes the formation of cyclopropanes *(116)* from diazirines *(114)*[83,84], of the



(114) *(115)* *(116)*

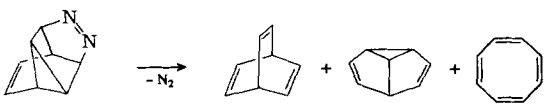
fluorenes, *e.g.* fluoradene *(118)*[85], from 3*H*-indazoles *(117)*, and especially the formation of carbazole *(120)* or related systems from 1,2,3-triazoles *(119)*[86,87].

(117) *(118)*



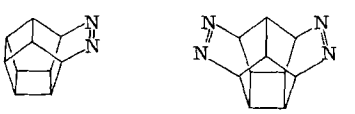
(119) *(120)*

In 1-benzoyl-1,2,3-triazoles both the phenyl group[42,88] and the carbonyl oxygen[89] may take part in the cyclization. Attacks at the β- and γ-position have been observed in the fragmentation of 1,2,3-triazines[76,90].



3.5. Rearrangements (Valence Isomerizations)

In contrast to the synchronous cycloeliminations of nitrogen from 3,6-dihydropyridazines (Section 3.1), 3,4,5,6-tetrahydropyridazines such as *(121)*[91] undergo a two-stage decomposition which is terminated by ring-closure (Section 3.3) or ring-opening reactions. The ring opening should often be regarded not as direct stabilization of the primary fragment but as due to thermal or photochemical valence isomerization of the initially formed cyclization product. The compound *(123)*



(121) *(122)*

may be instanced here as undergoing a complicated valence isomerization[92]: on thermolysis only *(124)* is formed, on direct photolysis a mixture *(124)*, *(125)*, and *(126)* in the proportions of 24:73:3, and on sensitized photolysis only *(125)*.

(123) *(124)* *(125)* *(126)*

The cage structures *(127)* and *(128)* provide access to the $(CH)_{10}$ hypersurface[93].

(127) *(128)*

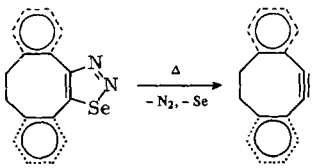
The most commonly observed rearrangement of the primary fragments is a [1.2]-shift of hydrogen atoms or of alkyl or aryl groups. The carbenes formed from diazirines are thus converted into alkenes[83]. Special mention must be made in this connection of the tetrazoles, which by double elimination of the nitrogen afford carbenes that are prone to rearrangement[94–96].

The primary products *(4b1)* and *(4b9)* formed from 4,5-dihydro-3*H*-pyrazoles and 4,5-dihydro-1,2,3-triazoles are con-

verted by 1,2-shifts into, respectively, alkenes and azomethines of type *(129)*.

(4b1), (4b9) $X=\overset{R_2}{\overset{|}{C}}-CR_2 \longrightarrow X=CR-CR_3$

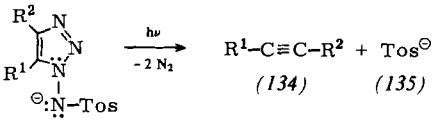
X = CR_2, NR *(129)*



Systems *(130)* containing cumulated double bonds are formed analogously from *(4c)*, specifically ketenimines from *(4c2)*[68,87], thioketenes from *(4c3)*[97-100], selenoketenes

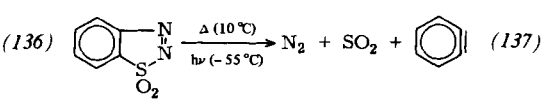
(4c) $X=\overset{R}{\overset{|}{C}}-Y \longrightarrow X=C=YR$ *(130)*

from *(4c4)*[101], carbodiimides from *(4c5)*[102-104], and isothiocyanates from *(4c7)*[103,105-107].



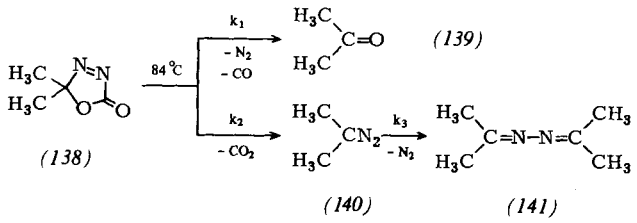
3.6. Fragmentations

Further cleavage of the primary fragments is particularly favorable if energy-deficient species such as S, Se, CO, CO_2, N_2, or SO_2 are thereby eliminated. 1,2,3-Thiadiazoles and 1,2,3,4-thiatriazoles can be converted into alkynes or nitriles respectively by way of *(4c3)* and *(4c7)* with loss of sulfur. The preparation of alkynes[108-110] and particularly of the highly reactive and often unstable cycloalkynes[28-30,35,111-114a] by thermolysis of 1,2,3-selenadiazoles such as *(132)* from *(131)*[113,114] is of special synthetic value.



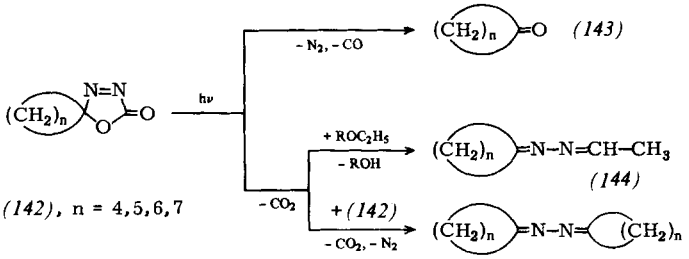
(131) *(132)*

Double N_2 elimination with the formation of alkynes *(134)* occurs on starting from 1-(tosylamino)-1,2,3-triazole anions *(133)*[115-117].

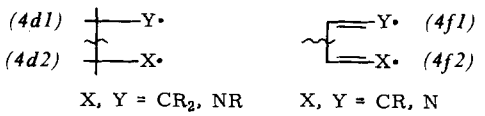


(133) *(134)* *(135)*

1,2,3-Benzothiadiazole 1,1-dioxide *(136)* is a suitable precursor of dehydrobenzene *(137)*, since it loses both nitrogen and sulfur dioxide[118,119].

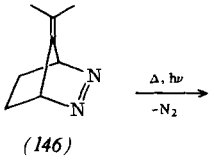


Of special interest is the fragmentation of 5*H*-1,3,4-oxadiazol-2-ones *(138)*. Nitrogen, carbon monoxide, and carbon dioxide are expected as gaseous products. On thermolysis, formation of ketones *(139)*, diazo compounds and azines *(141)* was observed, the decomposition always obeying first-order kinetics[120,122a].

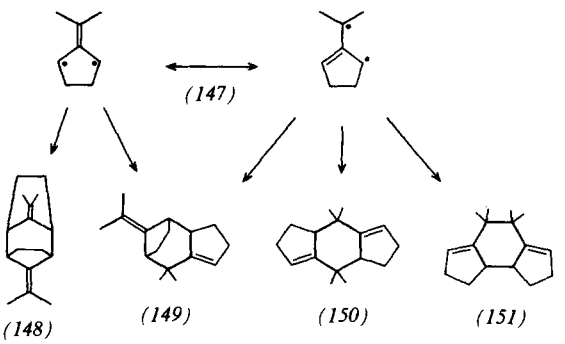


CCl_4: $k_1 = 10^4\ s^{-1}$, $k_2 = 0.25 \times 10^4\ s^{-1}$; *(139)*:*(140)* = 8:1.
CH_3OH: $k_1 = 0.9 \times 10^4\ s^{-1}$, $k_2 = 4 \times 10^4\ s^{-1}$; *(139)*:*(140)* = 1:2.

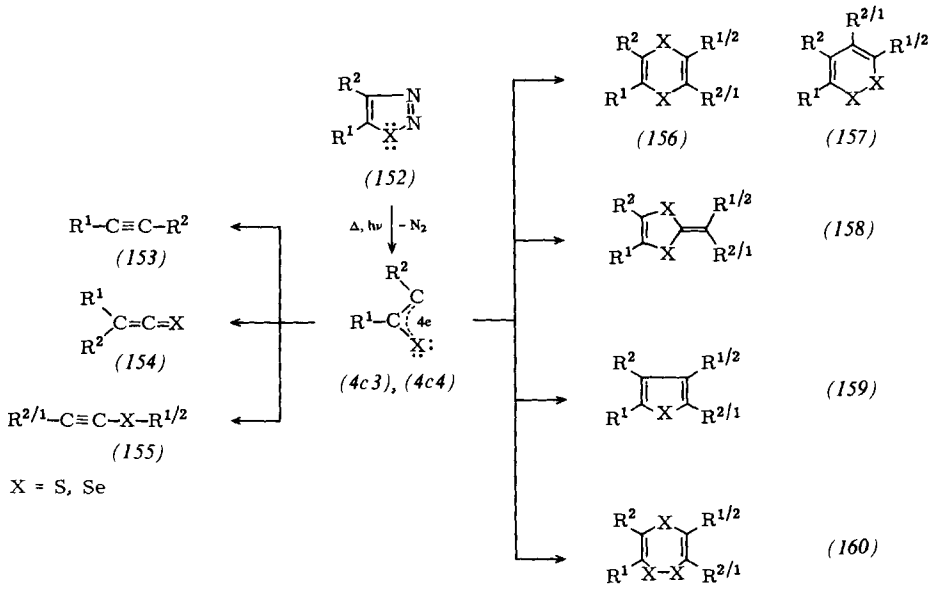
Photochemically in benzene, N_2 and CO were eliminated almost completely (quantum yield 0.6)[121,122]. In ethers a considerably more complex reaction sets in, with, additionally, the elimination of CO_2; the ether acts both as solvent and as reactant[121,122,122b,122c].



The primary fragments *(4d)* to *(4f)* formed from six-membered rings can undergo cleavage into alkenes, azomethines, alkynes, or nitriles as possible modes of stabilization.



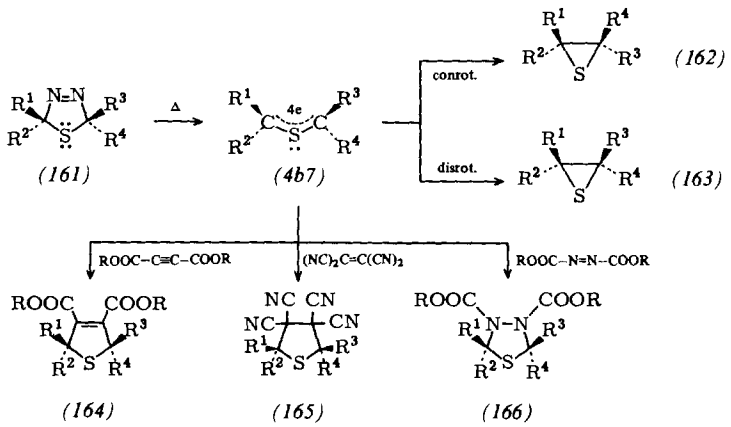
X, Y = CR_2, NR X, Y = CR, N



3.7. Cyclodimerizations

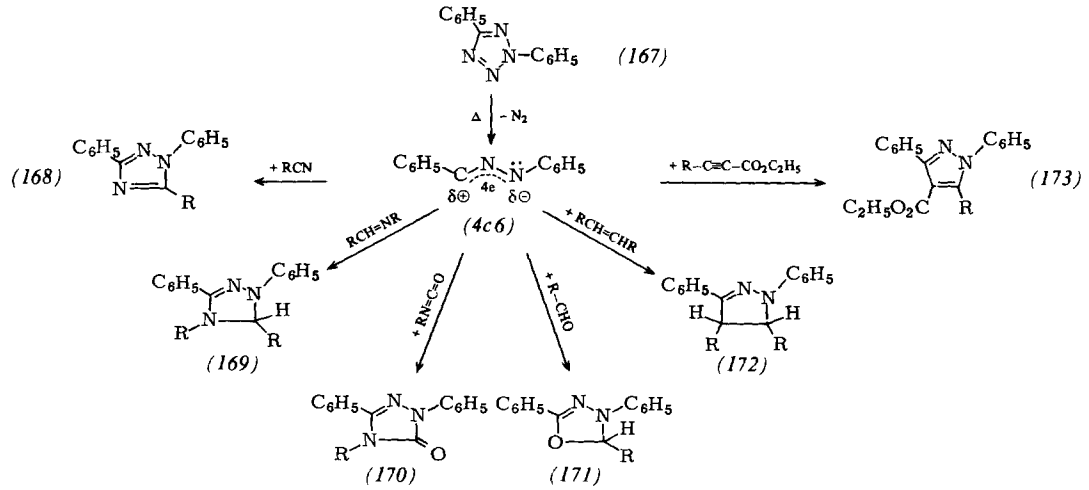
Diradicals or dipolar primary fragments can readily stabilize themselves by dimerization into rings of twice the size. Numerous examples of this type of reaction are known in the formation of alkenes from carbenes up to the synthesis of eight-membered rings[73]. Here we have selected the cyclodimerization of trimethylenemethane *(147)*[123].

(146)



Cyclodimerizations may be accompanied by eliminations, additions, and rearrangements. Elegant examples of this are provided by the 1,2,3-thiadiazoles and 1,2,3-selenadiazoles *(152)*, which in very simple manner yield five-, six- and seven-membered heterocycles with one, two, or three heteroatoms[29,30,97–100,111,112,124–128].

Nitrile imines *(4c6)*, the primary fragments from tetrazoles, dimerize to dihydrotetrazines which are readily converted into 1,2,4,5-tetrazines with loss of hydrogen[129,130].



3.8. Trapping Reactions and Reactions with the Solvent

The intermolecular reactions relevant for "saturation" of the primary fragments are abstraction of hydrogen and insertion into solvent molecules. Particularly interesting are the directed capture reactions leading to cycloadducts. Photochemical or thermal denitrogenation of 3*H*-diazirines in the presence of alkenes leads to stereospecific cycloaddition of the intermediate singlet carbene to give cyclopropane derivatives[131,132].

1,3-Diradical species of type *(4b)* can occasionally be trapped by alkenes[123], isocyanates[133,134], enamines[135], *etc.* Special interest attaches to the stereochemical course of this cycloaddition. The thiocarbonyl ylides of type *(4b7)* formed from 2,5-dihydro-1,3,4-thiadiazoles *(161)* by $[_{\pi}4_s+_{\pi}2_s]$-cycloreversion have been selected as specific examples[136–138a]. They can be trapped as the heterocycles *(164)*—*(166)*.

A number of trapping reactions are known for the more unsaturated species of type *(4c)*. Thus, vinylcarbenes *(4c1)* with furan or benzene give 1,1-cycloadducts and with buta-

diene or *N*-phenylmaleimide they give 1,3-cycloadducts[85,139–141]. *(4c3)* can be trapped by carbon disulfide[124,125]. Trapping reactions for the nitrile imines *(4c6)* that are accessible from tetrazoles *(167)* are particularly numerous[129,142,143].

4. Reaction Mechanisms

4.1. Elimination Processes

Table 8 gives a review of the kinetic parameters of thermal N_2-evolution from some of the compounds in the classes considered in this article. The various possibilities for the cycloelimination of nitrogen on addition of thermal energy in the form of translational or vibration energy have been collected in Figure 2. As a first step the substrate can cleave

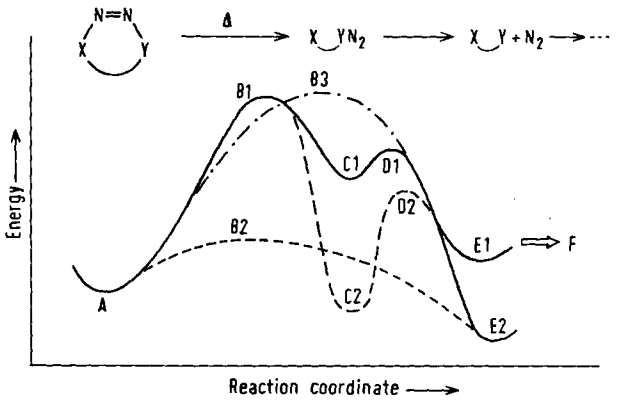


Fig. 2. Course of the thermal cycloelimination of nitrogen. (Substrate A; products E_2; F; intermediates C_1, C_2, E_1; transition states B_1 to B_3, D_1, D_2.)

a single bond of the azo function either homolytically or heterolytically, giving rise to a generally energy-rich diradical or dipolar species (route $A \rightarrow B_1 \rightarrow C_1$). With diazirines or maximally unsaturated five-membered ring systems, however, the open-chain valence isomer may be obtained (cf. Section 1), whose formation may indeed be exothermic (route $A \rightarrow B_1 \rightarrow C_2$). Nitrogen is eliminated when a second activation barrier is overcome, and the primary fragment namely a carbene, a diradical or a dipole is formed (route $C_1 \rightarrow D_1 \rightarrow E_1$, or $C_2 \rightarrow D_2 \rightarrow E_1$). Besides such short-lived species which stabilize themselves in subsequent reactions ($E_1 \rightarrow F$) (cf. Section 3), stable molecules may also occur as primary fragments. This is especially common in symmetry-allowed synchronous reactions (route $A \rightarrow B_2 \rightarrow E_2$). Finally, the synchronous though symmetry-forbidden process is described by route $A \rightarrow B_3 \rightarrow E_1$ or E_2.

The photochemical elimination of nitrogen can be effected by direct irradiation, usually in the longest-wave absorption band (cf. Section 2) and, in contrast to the situation with open-chain azo compounds, often also by triplet-sensitization. It is rarely possible to reach the T_1 level by intersystem crossing (ISC) without a sensitizer. As shown in Figure 3,

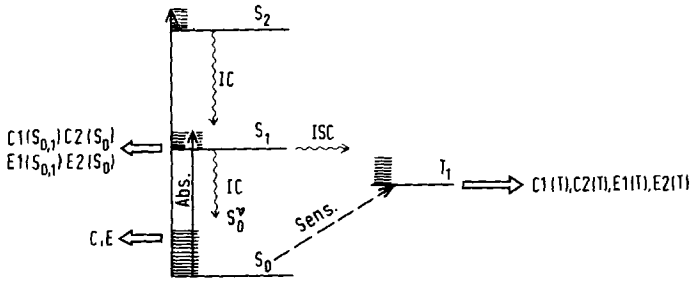

Fig. 3. Course of the photochemical cycloelimination of nitrogen.

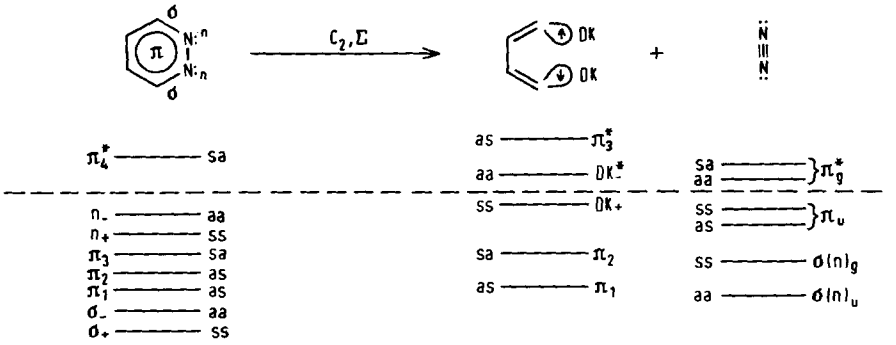
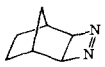
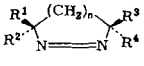
N_2-elimination occurs on attainment of the dissociation limit at S_1 or T_1, by crossing of a repulsion term (predissociation), or by internal conversion (IC) to a highly vibrationally excited electronic ground state S_0^v. If the nonadiabatic photoreaction at C_1 or C_2 (Fig. 2) does not lead back to the energy hypersurface of the ground state, then a second (thermal or electronic) activation is necessary. From spectroscopic findings and differences in reactive behavior it can be concluded that the intermediate species C_1 and E_1 can appear in various electronic or spin states, depending on the method used. (For examples of elimination processes see Sections 2 and 3.)

4.2. Synchronous Elimination of Nitrogen

Symmetrical substrates that have equivalent single bonds to the azo group have the possibility of eliminating nitrogen synchronously. This is particularly relevant in retention of orbital symmetry. Pyridazine (Fig. 4) and its 3,6-dihydro derivative (Fig. 5) may be used as examples.







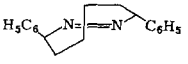


Fig. 4. Orbital correlation for the fragmentation of pyridazine.

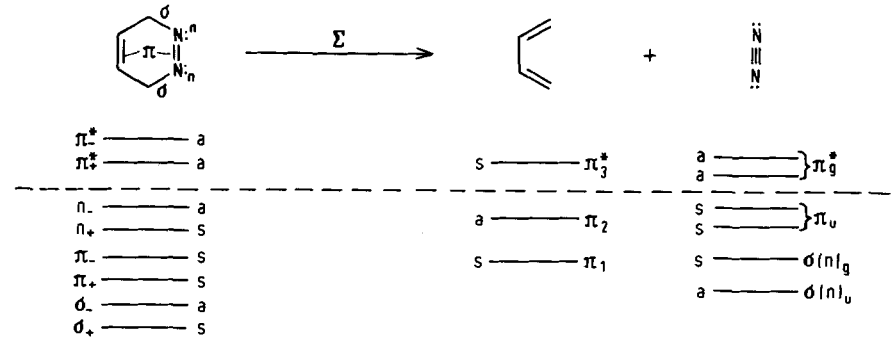

Fig. 5. Orbital correlation for the fragmentation of 3,6-dihydropyridazine.

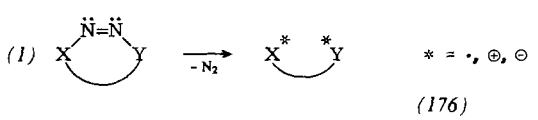
Whereas the transition in the ground state

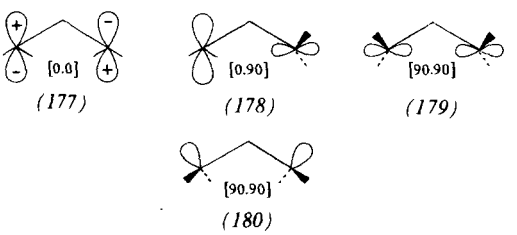
$$(\sigma_+)^2(\sigma_-)^2(\pi_+)^2(\pi_-)^2(n_+)^2(n_-)^2 \rightarrow (\pi_1)^2(\pi_2)^2/(\sigma_u)^2(\sigma_g)^2(\pi_u)^4$$



for 3,6-dihydropyridazine is symmetry-allowed, such a correlation is not possible for pyridazine. As can be deduced from Figures 4 and 5, energy-deficient photoprocesses are symmetry-forbidden for both systems.

4.3. Intermediates

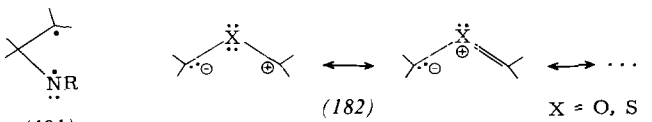
Ejection of an N_2 molecule from diazirines affords derivatives of bivalent carbon[157]. The many theoretical[158] and spectroscopic contributions to the electronic structure of carbenes provide a fascinating chapter in the chemistry of reactive intermediates. It has now been established that the parent substance has a triplet ground state *(174)* with an equilibrium angle H—C—H of about 136°. The triplet methylene and its mono- and di-deuterated derivatives can be produced by photolysis of diazirine[159] or deuterated diazirines[159, 160] in solid xenon and then observed by ESR spectroscopy (zero field parameters: $D/hc = 0.6881\ cm^{-1}$, $E/hc = 0.00346\ cm^{-1}$). In spite of the triplet ground state, the lowest singlet *(175)* with an energy minimum at an H—C—H angle of *ca.* 105°[158, 161] is the reactive species in thermolyses and direct photolyses[162].



On ejection of molecular nitrogen from five- or higher-membered rings one obtains, at least formally, intermediates *(176)* with terminal reaction centers (X, Y), that can be considered either as diradicals or as dipoles and whose nature is determined by whether conjugative interactions are possible between X and Y.

(176)

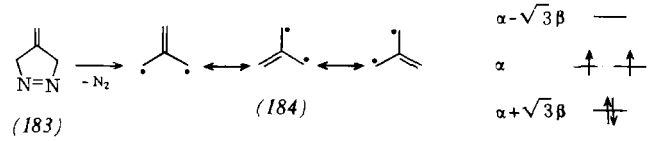
Whereas the structure of these intermediates of type *X—Z—Y* in some [5→3+2]-processes has been provided by spectroscopic and quantum-mechanical investigations, final conclusions about the homologous species, *e.g.* 1,4-diradicals, have so far been drawn mainly indirectly, mostly from the stereochemistry of the cyclization products.



Cycloelimination of nitrogen from 1-pyrazolines has led to an extremely wide variety in the stereochemistry of the reaction products, depending on the way the reaction is carried out, the degree of substitution, and the nature of the substituents (see Section 3.3). This phenomenon may have its origin in the occurrence of stereochemically different trimethylenes in singlet or triplet states. Of the many spatial structures of trimethylene *Hoffmann*[163] has calculated the [0,0]-*(177)*, [0,90]-*(178)*, and [90,90]-geometry *(179)* of the π-diradical as extreme cases.

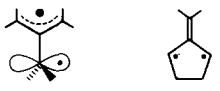
(177) *(178)* *(179)* *(180)*

According to this work, the antisymmetric [0,0]-trimethylene, which can form cyclopropane by the conrotatory route, is the most stable form at angles above 120°; at angles below 120° the [90,90]-form, which easily passes directly into cyclopropane, is certainly more stable. It is interesting that *Jean* and *Salem*[164] find [90,90]-trimethylene *(180)* with pyramidal terminal methylene groups to be still more energy-deficient than the singlet *(179)* by about 6.2 kcal/mol. *(180)* owes its relative stability mainly to 1,3-zwitterion admixtures. EHMO calculations[163] favor the existence of a mobile excited singlet trimethylene whose presence is deduced from the product pattern after direct photolysis[165]. Ketone-sensitized photolysis probably gives triplet trimethylene, which is identical with the adduct of $^3CH_2$ to alkenes[165]. On substitution by electronegative groups the chances of the appearance of 1,3-zwitterions in place of the 1,3-diradicals are increased. The very small solvent effect, however, speaks against this[166]. Nevertheless, it must finally be mentioned that, especially in some bicyclic compounds, the experimental findings can be explained in terms of a two-stage mechanism[167, 168]. Yet, for most of the 1-pyrazolines the mechanism of synchronous elimination of nitrogen with the formation of the trimethylene intermediate appears to be proved by the course followed by the activation energy on stepwise alkylation[147] or arylation[63] and particularly conclusively by kinetic deuterium



isotope effects[169]. N_2-elimination from 4,5-dihydro-1*H*-1,2,3-triazoles produces a molecule *(181)* that is comparable with trimethylene, if we allow for replacement of a methylene group by NR[170].

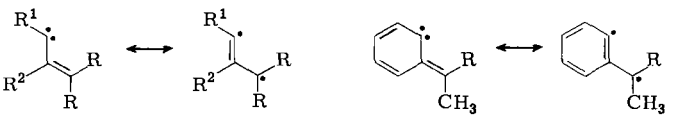
(181) *(182)* X = O, S



In contrast to the trimethylenes, the primary fragments *(182)* from 2,5-dihydro-1,3,4-oxadiazoles and -thiadiazoles contain terminal reaction centers conjugated with each other *via* the heteroatom. Carbonyl ylides and thiocarbonyl ylides[136–138] that are isoelectronic with allyl anions and accordingly cyclize in conrotatory manner are thus derived.

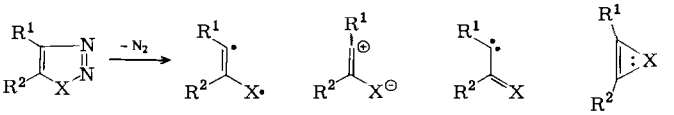
The liberation of nitrogen from 4-methylene-1-pyrazoline *(183)* leads to trimethylenemethane *(184)*, which is one of the molecules of greatest theoretical interest[171]. Its central carbon shows the maximal bond order (N = 1.732) and minimal free valence (F = 0) that can be associated with an sp^2-carbon. Trimethylenemethane serves as a model for the calculation of HMO bond orders and negative spin densities in the triplet state.

(183) *(184)*



Even simple MO considerations give for *(184)* a triplet ground state[171]. This is supported by more recent calculations[172], according to which the lowest singlet state is alleged to lie 18—21 kcal/mol above the triplet ground state. In contrast to planar triplet trimethylenemethane, a geometry corresponding to *(184a)* was assumed for this state; the planar singlet trimethylene is separated from it only by a few kcal/mol[172,172a].

(184a) *(185)*



According to the conclusions from correlation diagrams[173], the thermal decomposition of pyrazolines in a concerted reaction should not lead directly to the triplet ground state. This can, however, be attained by $n\pi^*$ excitation followed by ISC and elimination of nitrogen. The ESR detection of triplet trimethylenemethane *(184)* on photolysis *(183)* in Fluorolube[174] is in excellent agreement with this. The signal intensity changes with temperature (20—80 K), the Curie law being strictly obeyed, whereby it is proved that the triplet molecule does in fact represent the ground state[175]. The calculated triplet-singlet separation for unsubstituted trimethylenemethane is so large that the triplet character of the ground state remains intact even after severe disturbance by substituents[176,177]. Thermally produced trimethylenemethane can reach the ground state only by ISC, but this process must compete with both conrotatory and disrotatory permitted ring closure to methylenecyclopropane; if the excess of vibrational energy is easily given up, it is possible that in this manner the methylene groups never become equivalent in the course of the reaction. For the trimethylenemethane derivative *(185)* *Berson et al.*[178] were able to prove the existence of at least two reactive states, only one of which is a triplet state. A nonplanar geometry analogous to *(184a)* was proposed for the reactive singlet molecule because of the stereo- and regiospecificity of the alkene adducts. Experimental results indicate an upper limit of 3.5 kcal/mol for the singlet-triplet energy gap in the trimethylenemethane derivative *(185)*[188].

3*H*-Pyrazoles undergo photochemical ring opening to yield vinyldiazoalkanes which form vinylcarbenes in a second photochemical step. Although the reaction products presumably arise in the singlet state[179], these carbenes have a triplet ground state characterized by an ESR spectrum[85,139,180–182,189]. The zero field parameters of *(186)* (*e.g.* $R^1 = R^2 = C_6H_5$, $R = CH_3$: $D/hc = 0.358\ cm^{-1}$. $E/hc = 0.0206\ cm^{-1}$) are in accord with a considerable contribution from the vinylcarbene limiting structure *(186a)*[180]. In systems of the type *(187)* strong delocalization of one electron over the π-system must be assumed; the other electron is localized in a σ-orbital on the benzene ring ($R = CO_2CH_3$: $D/hc = 0.111\ cm^{-1}$, $E/hc = 0.0069\ cm^{-1}$)[181,139].

(186a) *(186b)* *(187a)* *(187b)*

The primary fragments produced on N_2-elimination from heteroarenes *(152)* are formulated as 1,3-diradicals *(188)*, 1,3-dipoles *(189)*, and heteroanalogous α-oxocarbenes *(190)*[42,68,87,125,126].

(152) *(188)* *(189)* *(190)* *(191)*

X = S
X = NR

Radical intermediates but no triplet 1,3-diradicals could be detected[183] on photolysis (−170 °C) of 1,2,3-thiadiazoles *(152)*, X = S, in the crystalline state or in solidified hexafluorobenzene. All three structures could be utilized to explain the formation of the reaction products isolated.

Meanwhile, there has been proof of the appearance of the potentially antiaromatic thiirenes *(191)* X = S, and 1*H*-azirines *(191)*, X = NH, as further intermediate stages. The participation of such "symmetrical" species follows from the product composition, from the low-temperature matrix photolysis of deuterated[184] and ^{13}C-labeled[185] 1,2,3-thiadiazoles, from the formation of 2-phthalimido-2*H*-azirine in the photolysis of 1-phthalimido-1,2,3-triazole[68,10], and from the distribution of ^{13}C in the thermolysis products of ^{13}C-labeled 1,2,3-triazoles[69]. The antiaromatic character of the three-mem-

bered rings *(191)* has been supported by *ab-initio*[186] and MINDO[187] calculations.

Considerations similar in principle to those outlined above probably apply to the nature of the primary fragments derived by the elimination of nitrogen from other heteroaromatic five-membered rings; many of these primary fragments have not been investigated either theoretically or experimentally.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Quantitative Trace Analysis of Metals by Field Desorption Mass Spectrometry[**]

By *Wolf Dieter Lehmann* and *Hans-Rolf Schulten*[*]

The great sensitivity of field desorption mass spectrometry (FD-MS)[1] for the detection of metal cations became clear in the first studies on organic and inorganic salts[2a]: the signals for sodium and potassium were several orders of magnitude more intense than those of the organic ions[2b]. By means of FD-MS, cesium has been quantitatively determined in the picogram range in a number of solvents, body fluids, and environmental samples[3]. The detection limit for cesium by the FD technique lies in the lower femtogram region (10^{-15} g). Quantitative determination of metal cations—as in the case of organic ions[4]—requires integrating recording owing to the fluctuations of the FD ion currents.

In order to put the quantitative trace analysis of metals on a firm methodological footing, we have coupled a magnetic mass spectrometer with a multi-channel analyzer. Using this approach we have made the first FD-MS determinations of the distribution of the lithium isotopes ^{6}Li and ^{7}Li (natural abundance 7.5 % and 92.5 % respectively[5]) in some commercial lithium salts and an environmental sample.

The measurements were performed with a double focusing mass spectrometer (Varian MAT 731) with a mono FD ion source of our own construction and indirect heating of the FD emitter by a tunable argon laser (Spectra Physics, Model 166). The ion currents were recorded electrically and accumulated by a multi-channel analyzer (C-1024, Varian). The magnetic scan of the spectrometer controlled the multi-channel analyzer externally during the accumulation. Integrating electrical recording of low-intensity FI and FD ion currents with a multi-channel analyzer has already been described[6].

The determination of the isotopic distribution of the metals presented in this communication is a facile analytical procedure because the ion currents are powerful, because the emitter quality plays only a subordinate role, because the coupling of the mass spectrometer and the multi-channel analyzer can be quickly modified to accommodate a variety of analytical problems, and because the averaging of several hundred scans requires only 10 to 30 min. An experimental accuracy of several tenths of a percent was achieved by accumulation of several hundred scans (Table 1).

Table 1. Determination of the isotopic ratio of ^{6}Li and ^{7}Li by FD-MS with a multi-channel analyzer.—Compounds *(1)*—*(5)* were purchased from Merck AG, Darmstadt (Art. No. 5686, Suprapur; 5675, Erg. B. 6; 5668, Suprapur; 5688, molten; 5663, Suprapur), ^{6}Li-enriched compound *(6)* from Rohstoff-Einfuhr GmbH, Düsseldorf. The sample of Rhine water *(7)* was taken at the bank of the river, Kilometer 625 (August 25, 1977).—Over 300 scans were averaged in each case. The mean experimental error was 0.3 %.

Sample		^{6}Li [%]	^{7}Li [%]
(1)	LiF	10.6	89.4
(2)	LiCl	10.2	89.8
(3)	LiBr	5.8	94.2
(4)	LiI	2.9	97.1
(5)	$LiNO_3$	9.3	90.7
(6)	^{6}LiF	91.7	8.3
(7)	Rhine water	7.4	92.6

The data show that the distribution of the lithium isotopes in the salts examined deviates considerably from the mean natural distribution. The large variations observed are probably due to isotopic fractionation processes occurring during the production and purification of the products since the natural variation in the distribution of the lithium isotopes is much smaller[7]. The molecular weights of *(1)*—*(5)* calculated with the experimentally determined lithium distribution differ by 0.12 to 0.02 % from the values calculated with the natural isotopic abundances. However, much greater differences could occur if $[Li]^+$ is attached to a neutral molecule M (cationization[2a, 8]). Thus, for instance, the isotopic ratios found on analysis of $[M+Li]^+$ groups deviated from the mean natural lithium distribution, corresponding instead—within the limits of experimental accuracy—to the distribution in the salts used for cationization[9]. Deviations of the same magnitude are to be expected if the metal is incorporated into a product by chemical synthesis and a direct isotope analysis is performed on the new compound.

The LiF sample *(6)* shows a high degree of enrichment of ^{6}Li and is therefore suitable as internal standard for a quantitative determination of lithium. In a sample of Rhine water *(7)*, approximately the mean natural distribution was found. Knowledge of these two distributions permits quantitative determination of the lithium content of Rhine water by the method of isotopic dilution (Fig. 1).

Evaluation of the experimental data from Figure 1 gives a value of 8.3 µg Li/l for the water sample. The total error of this determination does not exceed 5 %.

This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. We are indebted to Dr. *D. Haaks*, Gesamthochschule Wuppertal, for his help in the laser experiments, to Dr. *H. M. Schiebel*, Technische Universität Braunschweig, for his help in measurements with the multi-channel analyzer, and to Prof. Dr. *H. J. Meyer*, Universität Bonn, for a sample of ^{6}Li-enriched lithium fluoride.—Part 6: *W. D. Lehmann, H.-R. Schulten, H. M. Schiebel*, Z. Anal. Chem., in press.

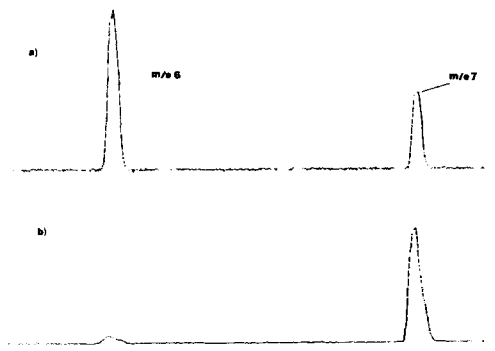

Fig. 1. Lithium isotopic distribution in Rhine water [2 µl; 100 scans were accumulated in each case]: a) with addition of 36.0 pg of Li *(6)*: ^{6}Li 67.5 %, ^{7}Li 32.5 %; b) original sample: ^{6}Li 7.4 %, ^{7}Li 92.6 %.

The results clearly demonstrate that field desorption mass spectrometry in conjunction with a multi-channel analyzer represents a powerful method for the trace analysis of metals. By use of the isotope dilution technique quantitative determinations of high sensitivity and accuracy can be accomplished without prior treatment of the original biological or environmental sample.

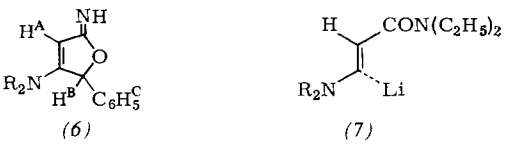
Functional Vinyl Carbanions—Deprotonation of β-(1-Pyrrolidinyl)acrylonitrile[1]

By *Richard R. Schmidt* and *Jörg Talbiersky*[*]



Highly selective reactions of polyfunctional systems are of great importance in synthetic chemistry. *trans*-β-(1-Pyrrolidinyl)acrylonitrile *(1)*, a derivative of the polyfunctional species formylacetonitrile, can react with strong bases or nucleophiles by Michael addition, addition to the carbonitrile group, and deprotonation at the α and β position[2]. We have now found that deprotonations with lithium diisopropylamide in tetrahydrofuran are very selective and temperature dependent; no significant competition from addition reactions is observed.

Thus, below −105 °C, kinetically controlled deprotonation occurs exclusively at the β position. The functional vinyllithium derivative *(2)* is of great preparative utility as a β-acylvinyl anion equivalent[2, 3]. Retention of stereochemistry is observed on reaction with electrophiles to give the cyano-enamines *(4a)*—*(4d)*; *(4d)* equilibrates with the cyclic isomer *(6)*. The lithiated acrylonitrile *(2)* is unstable at room temperature, unlike the corresponding acrylamide *(7)*. At temperature above −100 °C *(2)* already rearranges very slowly, and at higher temperatures fast and almost quantitatively, into the thermodynamically more stable vinyllithium derivative *(3)*[4]. At −15 °C *(3)* can be obtained directly from *(1)*, albeit in somewhat lower yield; at this temperature there is still no serious competition from addition reactions. Transition of the vinyllithium derivative into the mesomeric imine anion *(3b)* probably plays an important role in the conversion of *(2)* into *(3)*[4], for the analogous reaction was not observed under comparable conditions in the case of *(7)* owing to pronounced interaction between the lithium atom and the carboxamide group[2].

Compound *(3)* is an equivalent of the monoanion of formylacetonitrile; it reacts with electrophiles with retention to give the cyano-enamines *(5a)*—*(5d)*. In this way it proves possible to monosubstitute the very reactive compound α-formylacetonitrile at the α position conveniently, specifically, and in high yield[5].

(a): E = D; *(b)*: E = CH_3^B; *(c)*: E = CH_3^C–CH_2^B; *(d)*: E = $C_6H_5^C$–CH^B(OH)

Experimental

Compound *(1)* (0.74 g, 6 mmol) is dissolved under N_2 in dry THF (10 ml) and added dropwise within 3 min to a vigorously stirred and cooled mixture (temperature *T*, Table 1)

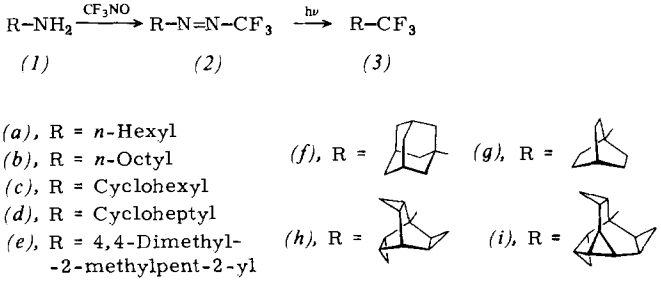
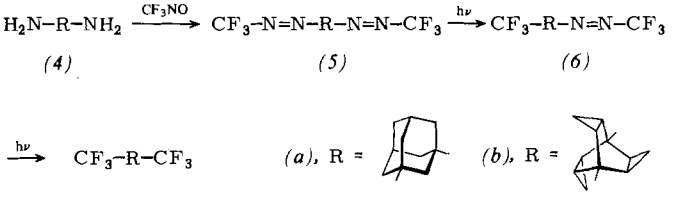
A New Method for the Introduction of Trifluoromethyl Groups[**]



By *Peter Gölitz* and *Armin de Meijere*[*]



The strongly negative inductive effect of the CF_3 substituent endows it with the ability of stabilizing otherwise unstable molecules, making them isolable as trifluoromethyl derivatives[1]. Moreover, many trifluoromethyl derivatives display an enhanced pharmacological activity relative to the unsubstituted analogs[2].

Several methods are known for the trifluoromethylation of arenes[3]; however, they are unsuitable for the preparation of corresponding aliphatic compounds[4] or are successful only in special cases[2, 5].

We have now found a method for the mild introduction of the CF_3 group into primary, secondary, and tertiary positions by photolysis of trifluoromethylazo compounds, which are readily accessible from the corresponding amines by reaction with trifluoronitrosomethane[6].

The pale yellow azo compounds *(2)* are far more stable thermally and towards acids than the corresponding methylalkyldiazenes[7]. However, they readily undergo photochemical cleavage with liberation of nitrogen. In highly viscous solvents such as *tert*-butyl alcohol or hexadecane, the resulting radicals afford the trifluoromethyl derivatives *(3)* in good yields by "cage recombination" (Table 1).

An undesired side reaction occurs in some cases, in which stable olefins can be formed by hydrogen abstraction from the position α to the radical center (Table 1, examples *(1c)*, *(1d)*, *(1e)*). The extremely mild reaction conditions also permit the trifluoromethylation of highly sensitive polycyclic systems (Table 1, examples *(1h)*, *(1i)*). The same procedure can be used to prepare bis-trifluoromethyl derivatives *(7)* from diamines *(4)* (Table 1); in these cases, however, the intermediate trifluoromethylazo(trifluoromethyl) derivatives *(6)* are also isolated besides the desired product.

Experimental

I. Trifluoromethylazo compounds: Trifluoronitrosomethane is passed into a stirred solution of the amine (10 mmol) in methanol (50 ml) maintained at −70 °C in a 250-ml three-necked round-bottom flask fitted with a gas inlet tube, gas exit, and low-temperature thermometer until a persistent blue color appears (11 mmol). The solution is allowed to warm to room temperature within 1 h, water (100 ml) is then added and the mixture extracted with pentane (3 × 30 ml). The combined extracts are dried over magnesium sulfate and concentrated on a rotary evaporator (with compounds containing more than 10 C atoms) or by means of a 30-cm packed column. The residue is purified by gas chromatography (1-m column, 10 % SE 30 on Chromosorb W-AW DMCS/60—80 mesh, gas flowrate 100 ml/min).

II. Trifluoromethyl compounds, method A: A solution of the trifluoromethylazo compound *(2)* (5 mmol) in hexadecane (40 ml) is irradiated in a cylindrical photolysis vessel with a 450-W medium pressure mercury vapor lamp (Hanovia 679 A-36) through a Pyrex immersion well at room temperature for 24—96 h (cf. Table 1). The volatile components of the reaction mixture are distilled off at 0.1 torr and 80 °C oil-bath temperature (250-ml flask) and condensed into a receiver cooled with liquid N_2. The condensate, consisting of the product *(3)* and starting material *(2)*, is separated into its components by gas chromatography (5-m column, 10 % SE 30 on Chromosorb W-AW DMCS/60—80 mesh, gas flowrate 100 ml/min).—*Method B:* A solution of *(2)* or *(5)* (5 mmol) in *tert*-butyl alcohol is irradiated at 25 °C as described for method II A. After addition of water (100 ml) the mixture is worked up with pentane, as described for method I. The residue consisting of the product *(3)* (or *(6)* and *(7)*) and starting material *(2)* (or *(5)*) with solvent, which is obtained on evaporation of the pentane, is separated into its components by preparative gas chromatography (conditions as for A).

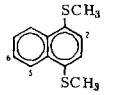
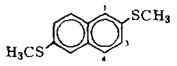
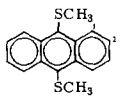
Oxidation and Reduction of Methylthio-Substituted π-Systems and the Electron Distribution in Their Radical Ions[1,2]







By *Hans Bock* and *Georg Brähler*[*]

So far, only few molecules M have so far been both reduced to the radical anion $M^{\bullet\ominus}$ and oxidized to the radical cation $M^{\bullet\oplus}$[3-5], although a comparison of the experimental spin densities $\rho^{\ominus}$ and $\rho^{\oplus}$, with one another and with calculated charge distributions for M, $M^{\bullet\ominus}$, and $M^{\bullet\oplus}$, is of topical interest[3]. In particular, two classes of compounds have proved to be suitable for such studies, *i.e.* large π-systems capable of adequate delocalization of ⊕ and ⊖ charges, and molecules containing both donor and acceptor regions[5], in which electron holes ⊕ are localized predominantly in the donor moiety and excess charges ⊖ largely in the acceptor moiety. In the following, methylthio-substituted π-systems are presented as examples of a further class of compounds able to form both radical cations and radical anions: characterized by suitable substituents which hardly affect the radical anion $M^{\bullet\ominus}$ while effecting considerable stabilization of the radical cation $M^{\bullet\oplus}$.

H_3CS-substituted derivatives of benzene, naphthalene, or anthracene[6] are conveniently prepared[2] by reduction of the corresponding sulfonyl chlorides with red phosphorus/iodine in glacial acetic acid and subsequent methylation. On disubstitution the first ionization energy lies below 8 eV[2,7] and, therefore[5a], oxidation with $AlCl_3$ in nitromethane affords radical cations which are generally stable at room temperature. Reduction to the radical anions is accomplished electrochemically at a Pt cathode in H_3CCN/DMF cooled to 200 K with $Bu_4N^{\oplus}\,ClO_4^{\ominus}$ as supporting electrolyte. The experimental data are compiled in Table 1, and two typical ESR spectra are reproduced in Figure 1.

		2	0.075	0.030		
		CH_3	0.220	<0.01		

[a] The coupling constants and their assignments are supported by deuterations, ESR spectral simulation, and INDO open-shell calculations [1].
[b] Degeneracy precludes more precise determination.

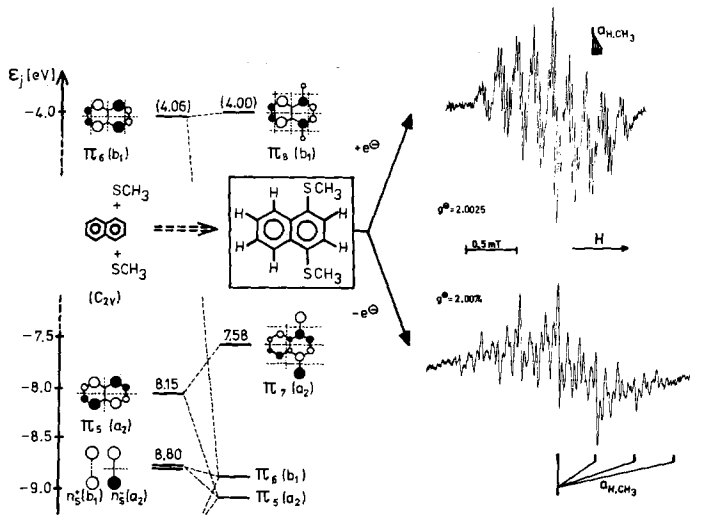

Fig. 1. Effects of H_3CS on cyclic π-systems can be satisfactorily predicted by HMO calculations with parameters determined by photoelectron spectroscopy [8]: 1,4-substitution of naphthalene raises the highest occupied orbital $\pi_7(a_2)$ by admixture of $n_s^-(a_2)$ components while the lowest unoccupied orbital $\pi_8(b_1)$ is hardly perturbed. Accordingly, the 1st ionization energy falls from 8.15 to 7.58 eV. In contrast to that of unsubstituted naphthalene, the radical cation is stable at room temperature, and yet a stable radical anion can also be generated. Furthermore, methyl proton coupling constants $a^{\oplus}_{H,CH_3} > a^{\ominus}_{H,CH_3}$ or values $g^{\oplus} > g^{\ominus}$ [4] confirm that the sulfur atoms accommodate a significant portion of the spin population only in the radical cation—as already suggested by the orbital diagrams.

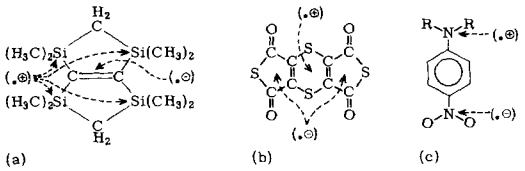
The experimental data for the isomolecular radical ions of methylthioarenes (Table 1) illustrate the MO prediction that energetically adjacent orbitals of like symmetry undergo pronounced mixing on perturbation of π-systems, while distant ones hardly interact[9] (Fig. 1): The 1st ionization energies decrease and the large *S*-methyl coupling constants and g values[4] clearly demonstrate the stabilizing influence of RS substituents in radical cations. Comparison with the radical ions of the parent compound naphthalene[4]

	$a^{\oplus}_H$[mT]	$a^{\ominus}_H$[mT]
H----------	0.554	0.495
H----------	0.206	0.183

shows that the alternancy $a^{\oplus}_{H,\mu} \approx a^{\ominus}_{H,\mu}$[4,9] is removed mainly due to deviations of the RS-substituted radical cations (Table 1): in the 1,4-derivative one observes, *e.g.* unequal constants $a^{\oplus}_{H,2} \neq a^{\oplus}_{H,6}$ or much too low a coupling constant $a^{\oplus}_{H,5}$, whereas comparable constants $a^{\ominus}_{H,2} \approx a^{\ominus}_{H,6}$ and a relatively large coupling constant $a^{\ominus}_{H,5}$ are still found for the radical anion.



The principle of stabilizing the radical cations of anion-forming systems by donor substituents at suitable sites is applicable to numerous compounds, including the 9,10-anthracene derivative in spite of the twisted *S*-methyl groups (Table 1)[2].

Ba_3As_{14}, The First Compound with the Cluster Anion As_7^{3-}[*]

By *Walter Schmettow* and *Hans Georg von Schnering*[*]

In the reaction of metallic barium with arsenic in the ratio Ba : As = 1 : 4 to 1 : 5 at temperatures between 1000 and 1100 K the polyarsenide Ba_3As_{14} is produced in the form of black prismatic crystals with a dull metallic luster. The compound is isotypic with Sr_3P_{14} and Ba_3P_{14}[1]. On treatment with hot dilute sulfuric acid Ba_3As_{14} decomposes with deposition of a reddish brown amorphous substance (polyarsane?).

Ba_3As_{14} crystallizes monoclinically in the space group $P2_1/n$ with $a = 1003.3(2)$, $b = 1363.9(2)$, $c = 685.4(1)$ pm, $\beta = 90.15(1)°$, $Z = 2$ formula units per unit cell[2]. The structural determination (Syntex $P\bar{1}$ diffractometer, $Mo_{K\alpha}$ radiation; 2072 reflections *hkl*; $R = 0.036$, anisotropic) gave the following values for the atomic positions [*x*; *y*; *z*]: Ba(1) in 2(a) [0;0;0]; in 4(e) the atom Ba(2) is located at [0.3722; 0.1557; 0.1939], As(1) at [0.1859; 0.5039; 0.8908], As(2) at [0.1385; 0.3574; 0.0987], As(3) at [0.8246; 0.5597; 0.4356], As(4) at [0.9743; 0.1868; 0.3272], As(5) at [0.8732; 0.0786; 0.5561], As(6) at [0.1308; 0.2216; 0.8733], As(7) at [0.7799; 0.2186; 0.1234].

The cluster anion As_7^{3-} has a heptaarsanortricyclic structure and is directly comparable in all respects with the polyanions P_7^{3-}[3] and Sb_7^{3-}[4] (Fig. 1). The As—As bond lengths depend, as in the other groups, on the function in the nortricyclic skeleton; on average they are: $A = 249.8$, $B = 239.9$, and $C = 243.2$ pm. The sequence $A > C > B$ is typical for all previously investigated heterosubstituted cluster anions having a nortricyclic structure[5]. Particularly noteworthy are the very short atomic distances of type B in comparison with the sum of the covalent radii. The most important bond angles are: $\alpha = 60$, $\beta = 105.2$, $\gamma = 99.0$ and $\delta = 101.2°$. The Ba atoms are bound to (8+2) or (7+3) As atoms. The bond lengths vary between 332.1 and 385.1 pm.

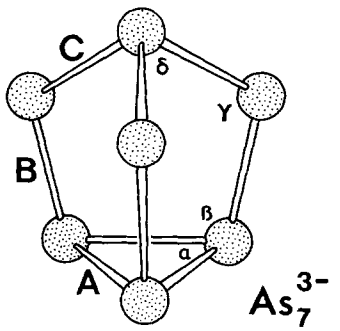

Fig. 1. Polyanion As_7^{3-} in Ba_3As_{14}; bond lengths and angles indicated (cf. text).

The description as a formal anion As_7^{3-} is justified not only in the sense of the Zintl-Klemm formalism[6], but is also supported in particular by the variation in the bond lengths and bond angles in comparison to neutral heteronortricyclic compounds[5]. Moreover, in the anion the distance between the formally negatively charged divalent bridging atoms is relatively large and the height of the cluster relatively small.

(η-Cyclopentadienyl)cobalt-μ-(η-diborolenyl)-(η-cyclopentadienyl)iron—A Triple Decker Sandwich Complex Containing Two Different Metals[1]

By *Walter Siebert* and *Manfred Bochmann*[*]

The difunctional Lewis acid 1,3-diborolene *(1)* ($R = C_2H_5$) reacts with nickelocene and with octacarbonyldicobalt to give the mononuclear complexes $(\eta\text{-}C_5H_5)Ni(\eta\text{-}C_3B_2R_4CH_3)$[2] and $(CO)_3Co(\eta\text{-}C_3B_2R_4CH_3)$[3], respectively, in which the ligand acts as a three-electron acceptor. If *(1)* is allowed to react simultaneously with carbonylcyclopentadienylmetal complexes of iron and cobalt as suppliers of one- and two-electron donor groups, then the green diamagnetic species *(2)* is formed.

(1) *(2)*

This dinuclear complex, which is stable to heat and air and highly soluble in apolar solvents, is assigned a place in the series of isoelectronic triple decker sandwich complexes[4] $(\eta\text{-}C_5H_5)M(\mu\text{-}B_nC_{5-n}R_5)M'(\eta\text{-}C_5H_5)$ between μ-borolebis(cyclopentadienyliron)[5] ($n = 1$) and μ-(1,2,4-triborolan-3,5-diyl)bis(cyclopentadienylcobalt)[6] ($n = 3$). In *(2)* three 6π-ligand systems are held together by two different d^6-metal ions. This is the first example of a "mixed metal" triple decker sandwich complex with 30 valence electrons[7]. If *(2)* is regarded as a metallacarbaborane then 16 skeletal electrons are required for bonding in the 7-atom C_3B_2CoFe cluster [(2*n*+2)-rule for *closo* compounds[8]], which are supplied by C (3 × 3), B (2 × 2), C_5H_5Co (2), and C_5H_5Fe (1).

The analytical and spectroscopic data of *(2)* confirm our structural proposal of a triple decker sandwich. In the ^1H-NMR spectrum [δ = 4.00 (S, 5), 3.33 (S, 5), 2.63 (Q, 4), 1.97 (S, 3), 1.78 ("S", 10), 1.52 (T, 6); in CS_2 rel. TMS int.] two Cp signals occur (Cp = C_5H_5), of which we assign the downfield signal to the CpCo group. In contrast to the *C*-ethyl protons,

[*] Prof. Dr. W. Siebert, Dipl.-Chem. M. Bochmann
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg 1 (Germany)

the *B*-ethyl protons show only one broad signal (apparent singlet). The ^{11}B-NMR signal [$\delta = 19.6$; in CS_2 rel. to $BF_3 \cdot OEt_2$] lies in the expected range and is shifted upfield by 49 ppm relative to *(1)*. Apart from the molecular ion Cp_2CoFeL^+ ($L = \{(1) - H\}$; $I_{rel} = 100\,\%$ rel. to $^{11}B_2{}^{59}Co^{56}Fe$), the mass spectrum contains only Cp_nM ions Cp_2Co^+ (6), Cp_2Fe^+ (3), $CpCo^+$ (2), and $CpFe^+$ (4).

(η-Cyclopentadienyl)cobalt-μ-(1,3,4,5-tetraethyl-2-methyl-1,3-diborolenyl)-(η-cyclopentadienyl)iron (2)

A mixture of *(1)*[9] (0.58 g, 3.05 mmol), $CpCo(CO)_2$ (0.56 g, 3.11 mmol), and $[CpFe(CO)_2]_2$ (0.71 g, 2.01 mmol) in $(EtOCH_2CH_2)_2O$ (1 ml) is heated to 180—200 °C under N_2 for 6 h. The solvent is removed, and the residue is taken up in hexane and filtered (G3 frit). After chromatography of the solution over dry silica gel (Woelm 100—200) hexane is drawn off and Cp_2Fe removed by vacuum sublimation. The deep green product crystallizes from Et_2O/CH_3CN (1:4) at −25 °C as long, highly intergrown leaflets. Compound *(2)* sublimes above 120 °C and slowly liquifies above 270 °C in a sealed tube. Yield 0.125 g (9.5 %).

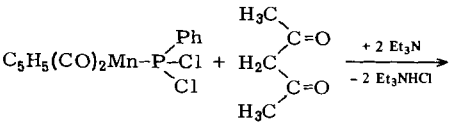
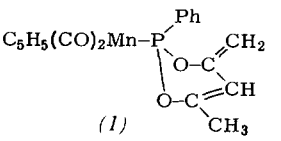
A New Coordination Form of Acetylacetone[**]



By *Joachim von Seyerl, Dietmar Neugebauer*, and *Gottfried Huttner*[*]



Acetylacetone (2,4-pentanedione) is one of the most thoroughly studied potentially bidentate ligands. Although it is coordinated in most cases as the enolate *(a)*, bonding as β-diketone *(b)*, as π-ligand *(c)*, or as σ-organyl groups *(d, e)* has also been observed on various occasions[1].

The alternative *(f)*, in which acetylacetone occurs as dienediolate, has not yet been described. We now wish to report the first example of this novel coordination.

Dicarbonyl(η-cyclopentadienyl)(phenyldichlorophosphane)manganese reacts with acetylacetone in the presence of triethylamine to give compound *(1)*:

(1)

Apart from the molecular ion $M^{\oplus}$ ($m/e = 382$) the mass spectrum of *(1)* contains the following characteristic fragments: $M^{\oplus} - 2CO$ (326), $C_5H_5Mn{-}PPh(O)^{\oplus}$ (244), and $C_5H_5Mn^{\oplus}$ (120).—The ^{1}H-NMR spectrum exhibits the signals expected for the *cis*-dienediolate group (δ values, TMS int., [D_8]toluene): H^a 3.75, H^b 4.32, H^c 4.58, H^d 1.25 (cf. Fig. 1). The structure of *(1)* was established by X-ray analysis[2]. The dienediolate group is strictly planar. The CC distances of this "ligand" do not show the alternation of bond length expected for the diene structure, since the *exo*-methylene group and the methyl group are subject to about the same degree of disorder in the crystal.

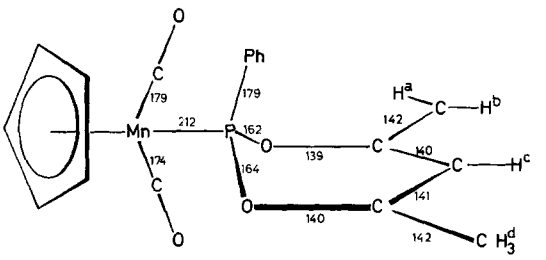


Fig. 1. Structure of complex *(1)* with interatomic distances [pm] and designation of the H atoms in the 1,3-diene-2,4-diolate group. The CC distances are averaged over single and double bonds since the methyl and methylene groups are disordered in the crystal.

The unusual double enolization of acetylacetone is probably induced by the possibility of forming two highly stable covalent P—O bonds.

Procedure

All operations are performed under N_2 with thoroughly dried reagents.—Triethylamine (2 ml) is added to a solution of $C_5H_5(CO)_2Mn(PPhCl_2)$ (1 g, 2.82 mmol) in freshly distilled acetylacetone (6 ml) and the mixture stirred at 10 °C for 16 h. Triethylammonium chloride is filtered off, and the filtrate chromatographed on silica gel (Merck, 0.06—0.2 mm; column 30 × 2.5 cm) at −15 °C. The first fractions (*n*-pentane/toluene 2:1) contain $C_5H_5(CO)_3Mn$ and a little of the starting material. The main fraction (toluene) gives analytically pure *(1)* (500 mg, 45 %) on removal of the solvent and recrystallization from toluene/pentane.

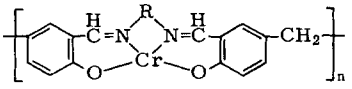
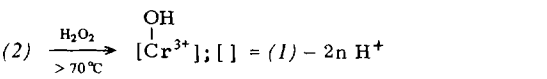
Addition Compounds with Polymeric Chromium(II)-Schiff Base Complexes



By *Wolfgang Sawodny* and *Manfred Riederer*[*]

The complex chemistry of chromium in oxidation state +2 is somewhat underdeveloped because most organic ligands are unable to resist the powerful reducing action of the Cr^{2+} ion. Only recently have such air-sensitive complexes been reported[1,2]. Complexes with Schiff base ligands have not previously been described.

We have now obtained stable Schiff base complexes *(2)* by reaction of the polymer *(1)* with Cr^{2+}.



(1)

(2a), R = $-(CH_2)_3N(CH_2)_3-$ (CH$_3$ on N)

(2b), R = 

The yellowish green compound *(2a)* and the green compound *(2b)* are formed in more than 90% yield and are insoluble in all the common solvents. They are surprisingly stable. No change can be seen after several weeks' exposure to air. Oxidation to the Cr^{3+} complex with equivalent amounts of hydrogen peroxide occurs only on heating:

(2) $\xrightarrow[>70\,^\circ C]{H_2O_2}$ [OH, Cr^{3+}]; [ ] = *(1)* − 2n H^+

The IR spectra of the complexes *(2)* contain the bands characteristic for coordinated Schiff bases (*(2a)*: 1615, 1525, 1320 cm^{-1}. *(2b)*: 1615, 1525, 1322 cm^{-1}). Magnetic measurements at room temperature indicate a low-spin configuration of the d^4 system (μ_{eff} for *(2a)* 2.97, for *(2b)* 2.93 μ_B) as also found for complexes of chromium(II) within *o*-phenylenebis(dimethylarsane)[2b].

Addition properties

The ability of monomeric Schiff base complexes to crystallize with one or several molecules of solvent has been known for some time[3]. However, it has hardly been the subject of directed studies. The first steps in this direction by *H. Krebs et al.*[4] for Cu^{2+} and Ni^{2+} have not yet been published.

We have now investigated the addition behavior of polymeric Schiff base complexes of a series of metal ions and found that the chelate complex *(2b)* can accept the largest number of guest molecules per coordination center. In order to produce the adducts the solid polymeric complex was exposed to a nitrogen atmosphere saturated with potential guest molecules at normal pressure (Table 1).

Table 1. Addition capacity of polymeric chromium(II) Schiff base complexes *(2b)*.

Guest molecule (G)	Molar ratio of G/Cr^{2+} in the adduct with *(2b)*
CH_3OH	4.81
Pyridine	4.00
Benzene	3.12
H_2O	2.87
CCl_4	1.77
Cyclohexane	1.54
Cumene	1.20
n-Pentane	1.16

In most cases equilibrium is reached within 2 h (thermal balance). The number of guest molecules that can be added apparently depends upon both the polarity and the size and shape of the guest. The addition compounds are stable only under equilibrium conditions. Slow liberation of the added component occurs on exposure to air. The guest compound can be removed quantitatively by heating; the process is reversible. For example, complete liberation of benzene added to *(2b)* in a benzene-saturated nitrogen atmosphere requires a temperature of 160 °C; slightly below this temperature significant addition can again be observed. The polymeric Schiff base complexes are characterized by a greater ability to undergo addition of a large number of neutral molecules, as compared with monomeric compounds. Addition even occurs above the boiling points of the guest molecules, with approximate retention of reversibility.

Procedure

All operations are performed under N_2 and with oxygen-free solvents. Polymeric Schiff base *(1)* (2 mmol) is dissolved in hot freshly distilled dimethylformamide (DMF) and sodium acetate (4 mmol) is suspended by stirring in the solution. Freshly prepared chromium(II) acetate (2 mmol) is dissolved in a minimum volume of DMF and added dropwise at 100 °C. Reaction is allowed to continue for 24 h at this temperature, the amorphous precipitate appearing on cooling is filtered off, washed with DMF and H_2O, then extracted for 24 h with methanol (Soxhlet) and dried in a high vacuum at 105 °C.

In order to prepare the addition compounds a dried current of N_2 is saturated with the guest molecules in an efficient washbottle and passed over the Schiff base complex for 2 d.

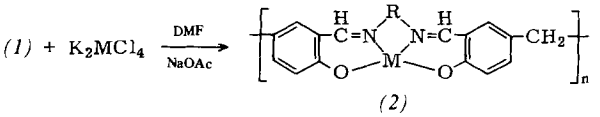
Palladium(II) and Platinum(II) Complexes with Polymeric Schiff Base Ligands

By *Manfred Riederer, Erna Urban*, and *Wolfgang Sawodny*[*]

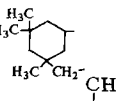


Although complexes of monomeric Schiff bases have been the subject of numerous studies, these ligands have hardly featured in the chemistry of the platinum metals[1]; in particular, only very few bridged coordination units have been described[2]. On the other hand, polymeric Schiff base complexes with ligands of type *(1)*

(1)

are known only for few metals[3, 4].

By means of the reaction



(2)

M = Pd^{2+}, Pt^{2+}

(a): R = $-(CH_2)_x-$; x = 2–8, 10, 12

(b): R = $-CH_2-CH(CH_3)-$

(c): R =

(d): R = $[-(CH_2)_3-\overset{\overset{CH_3}{|}}{N}-(CH_2)_3-]^+ I^-$ (CH_3)

we have now obtained the first palladium(II) and platinum(II) complexes of structure *(2)*. The polymeric ligands *(1a—d)* were prepared by polycondensation of 5,5'-methylenebis(salicylaldehyde) with the corresponding amines [*(1d)* was quaternized with CH_3I in a second reaction step]. The yields of the Pd^{2+} complexes were *ca.* 40% for MNRN rings with $m \leq 8$ members, and over 80% for $m \geq 9$; the yields of the Pt^{2+} complexes are lower in all cases (*ca.* 30%). The yellow, green, or brown compounds are insoluble in all the usual solvents.

The IR spectra exhibit characteristic bands at 1630—1618, 1535—1515, and 1319—1304 cm^{-1}, in agreement with findings for analogous monomeric palladium Schiff base complexes[2]. In the Pd^{2+} compounds *(2)* the bands of the free ligands at 1585 and 1278 cm^{-1} can no longer be observed, indicating together with the results of elemental analyses that all chelating centers of the polymeric ligand are occupied. In contrast, complete occupation of the coordination sites cannot be achieved for the Pt^{2+} compounds *(2)* with small rings ($m \leq 8$).

[*] Prof. Dr. W. Sawodny, Dipl.-Chem. M. Riederer, E. Urban
Abteilung für Anorganische Chemie der Universität
Oberer Eselsberg, D-7900 Ulm (Germany)

Since the ν(MCl) band of K_2PdCl_4 (335 cm^{-1}) or K_2PtCl_4 (325 cm^{-1}) is absent from the spectrum of the products *(2)*, as are the OH bands of *(1)*, fourfold coordination of the dianionic chelate ligand to the metal ion can be regarded as confirmed.

We have examined the thermal stability of the Pd^{2+} compound *(2a)* as a function of the size of the $MN(CH_2)_xN$ ring by simultaneous TG/DTA measurements (10°C/min, N_2 as inert gas). We find the expected stability maximum for the five- and six-membered rings; the stability of the larger rings is essentially independent of ring size (Fig. 1).

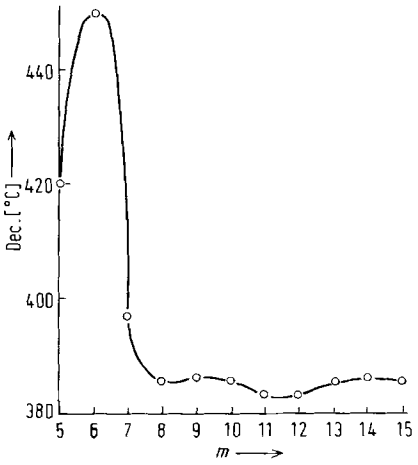


Fig. 1. Plot of thermal stability of the Pd^{2+} complexes *(2a)* *vs.* number of ring members *(m)* in the $PdN(CH_2)_xN$ system.

Like all polymeric Schiff base complexes of divalent metals, the Pd^{2+} and Pt^{2+} compounds are able to intercalate organic molecules[4].

Procedure

Preparation of (1): 5,5'-Methylenebis(salicylaldehyde) (10 mmol) is dissolved with stirring in freshly distilled dimethylformamide (DMF) (50 ml). After addition of amine (10 mmol) the resulting H_2O is removed with the aid of a water separator with toluene as entraining agent. Condensation is complete after 2—5 h. Compound *(1)* is precipitated from the cooled solution with ethanol, filtered off, and dried. *(1d):* the corresponding polymeric Schiff base is dissolved in DMF and heated under reflux for 18 h with an equivalent amount of CH_3I. After cooling and precipitation with glacial acetic acid the product is washed with ether and dried.

Preparation of (2): Sodium acetate (4 mmol) is suspended in a solution of compound *(1)* (2 mmol) in freshly distilled DMF. K_2MCl_4, M = Pd, Pt (2 mmol), dissolved in a minimum volume of dimethyl sulfoxide (DMSO), is added dropwise at 100°C. After cooling, the amorphous precipitate is filtered off, washed with DMF and DMSO, and dried in a high vacuum at 100°C.

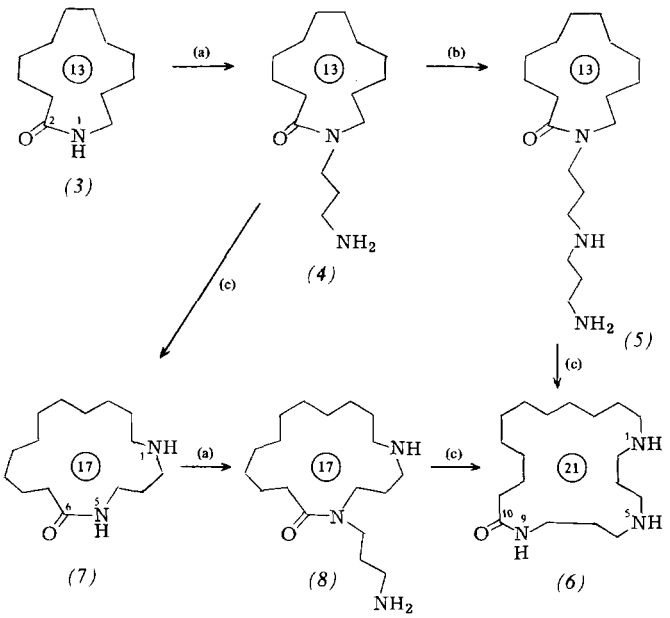
The "Zip" Reaction: A New Method for Ring Expansion; Synthesis of 17- and 21-Membered Polyaminolactams[1]



By *Urs Kramer, Armin Guggisberg, Manfred Hesse*, and *Hans Schmid* (deceased)[*]

Type *(1)* derivatives of trimethylenediamine, in which one of the amino groups is primary and the other is part of a *N,N*-disubstituted carboxamide, isomerize in the presence of a base[2]. The trimethylene derivative *(2)* is then formed which contains a secondary amino group and a monosubstituted amide.

If R^1 and R^2 of *(1)* are members of a lactam ring, then the reaction results in an expansion of the ring by four members. This type of reaction was first discovered in the structural elucidation of the *Oncinotis* alkaloids[3] (for a related reaction with substituted secondary amides cf. [4]).

If the sodium salt of 1-azacyclotridecan-2-one *(3)* is reacted with acrylonitrile and the resulting nitrile subsequently hydrogenated catalytically (C_2H_5OH/H_2SO_4, H_2/Pt, 4.2 atm), then 1-(3-aminopropyl)-1-azacyclotridecan-2-one *(4)* is formed in 82% yield. With *(4)* the same reaction sequence affords the 13-membered diaminolactam *(5)* in 78% yield. *(5)* reacts with potassium (3-amino)propylamide[5] in trimethylenediamine (30 min, 20°C) to give 1,5,9-triazacycloheneicosan-10-one *(6)* in 90% yield. This 21-membered diaminolactam was also synthesized by a stepwise ring expansion to verify its structure: the base catalyzed transamidation [potassium (3-amino)propylamide, 30 min, 20°C] of *(4)* yields 1,5-diazacycloheptadecan-6-one *(7)*. This 17-membered compound can, after tosylation of the basic amine nitrogen, again be alkylated with acrylonitrile and subsequently detosylated (electrolysis: 0°C, 24 V, 0.1 to 0.7 A, cathode: distilled Hg, anode: electrographite)[6]. After catalytic hydrogenation to *(8)*, *(6)* is produced under the previously described conditions for transamidation. The identity of the two preparations synthesized by different routes was confirmed by their IR and mass spectra, their behavior on thin layer chromatography and their reaction with the fluram fluorescence reagent[7]. The initial compounds were also characterized by IR and mass spectra, all compounds with at least one primary or secondary amino group were additionally characterized by means of their *N*-acetyl derivatives.

(a) Na salt of the amide + CH_2=CH–CN; H_2/Pt

(b) CH_2=CH–CN; H_2/Pt

(c) $K[NH(CH_2)_3NH_2]$; H_3O^+

The structurally isomeric bases *(5)* and *(6)* were distinguished by means of their IR spectra [*(5)*: 1625 cm^{-1}; *(6)*: 1650 + 1515 cm^{-1}; both in $CHCl_3$], by thin layer chromatography [Al_2O_3-GF 254 (Merck), $CHCl_3/CH_3OH$ (2:1): R_f value for *(5)*: 0.0, for *(6)*: 0.11], by the fluram test[7] [*(5)*: strong, light green fluorescence for primary amines; *(6)*: no fluorescence at 360 nm] as well as on the basis of their ^{1}H-NMR spectra.

It is remarkable that this novel ring expansion reaction proceeds using one, two or more trimethyleneamino expansion units and that in all cases very good yields are obtained[8]. One of the driving forces for this reaction is the formation of the resonance-stabilized amide anion of type *(1c)*. We describe this reaction as the "zip" reaction in analogy with the behavior of a zip fastener.

A Stable Acyclic Alkoxyhalosulfurane: Chlorotris(2,2,2-trifluoro-1-trifluoromethylethoxy)sulfurane[**]

By *Gerd-Volker Röschenthaler*[*]

As recently discovered[1], chloroalkoxysulfuranes are stable at room temperature, provided that the tetracoordinated sulfur(IV) atom is incorporated in a five-membered ring. An acyclic compound of type $ClS(OR)_3$ has now been prepared for the first time by the action of elemental chlorine on the sulfoxylic diester *(1)* of 2,2,2-trifluoro-1-trifluoromethylethanol in 85% yield according to the overall equation[2]

$$3\,S[OCH(CF_3)_2]_2 + 2\,Cl_2 \rightarrow 2\,ClS[OCH(CF_3)_2]_3 + SCl_2$$
$$\quad (1) \qquad\qquad\qquad (2)$$

The new sulfurane *(2)* is a colorless crystalline solid which is extremely sensitive to moisture and is rapidly hydrolyzed by an equivalent amount of water to HCl, $(CF_3)_2CHOH$, and the sulfurous diester $O{=}S[OCH(CF_3)_2]_2$[3]. The compound is stable for several days at 78 °C.

$$2\,(2) \xrightarrow{\Delta} \begin{cases} \longrightarrow (1) + SCl_2 + 2(CF_3)_2CHOH + 2(CF_3)_2CO \\ /\!/\!\longrightarrow 2\,O{=}S[OCH(CF_3)_2]_2 + 2\,ClCH(CF_3)_2 \end{cases}$$

Degradation resembling an Arbuzov reaction could not be observed.

In the same way as sulfur tetrafluoride can oxidize phosphorus(III) compounds to fluorophosphoranes[4], the sulfurane *(2)* is also able to transfer $(CF_3)_2CHO$ onto the phosphite $P[OCH(CF_3)_2]_3$[5] after the manner of a redox reaction to form a pentaalkoxyphosphorane[5].

$$2\,(2) + 2\,P[OCH(CF_3)_2]_3 \rightarrow (1) + SCl_2 + 2\,P[OCH(CF_3)_2]_5$$

The composition and structure of the new compounds *(1)* and *(2)* were confirmed by elemental analysis and mass and NMR spectra (^1H, ^{19}F). While the mass spectrum [70 eV, *m/e* (rel. int.)] of *(1)* exhibits the molecular ion at 366 (4%) [69 (100%), CF_3^+], the sulfurane *(2)* shows the fragment $[M-Cl]^+$ at 533 (100%) as the ion of highest mass[1,6] whose great intensity indicates that a sulfonium ion is favored in the degradation process.—The signals in the ^1H-NMR spectra (10% solution in $CFCl_3$, TMS int. standard) are expectedly split by HF coupling into septets [*(1)*: $\delta_H = -4.82$, $^3J_{HF} = 5.4$ Hz; *(2)*: $\delta_H = -4.71$, $^3J_{HF} = 5.2$ Hz] and in the ^{19}F-NMR spectra into doublets with the same coupling constants [*(1)*: $\delta_F = 75.0$; *(2)*: $\delta_F = 72.1$]. Nonequivalence of the $(CF_3)_2CHO$ groups[7] of *(2)*, which would apply in the case of a trigonal-bipyramidal structure, could not yet be detected as detailed studies are precluded by crystallization of the sulfurane from the solvents used at temperatures below 0 °C.

Procedure

Sulfur dichloride (5.15 g, 0.05 mol) is added dropwise with exclusion of moisture to lithium 2,2,2-trifluoro-1-trifluoromethylethoxide[8] (17.40 g, 0.1 mol) and stirred at room temperature for 2 h. Compound *(1)* is evaporated from the LiCl produced in a high vacuum and subsequently distilled (b.p. 51—52 °C/50 torr); yield 16.5 g (90%).

Chlorine (1.56 g, 0.22 mol) is condensed under high vacuum onto compound *(1)* (10.98 g, 0.30 mol) and maintained at 0 °C for 24 h. After removal of volatile reaction products, identified as excess Cl_2 (0.15 g) and SCl_2 (0.87 g), analytically pure *(2)* (9.60 g, 85%) is obtained.

Carbonyl Olefination with (Triphenylstannyl)methyllithium[**]

By *Thomas Kauffmann, Reinhard Kriegesmann*, and *Annegret Woltermann*[*]

Carbonyl olefination with trimethylsilylmethyllithium and its derivatives[1] (Peterson reaction) has gained increasing importance as an alternative to the Wittig reaction and its variants[2]. Analogous reactions are possible with triphenylstannylmethyllithium *(1)*[3]:

The reagent *(1)* was obtained almost quantitatively (see Experimental procedure) from the known triphenylstannylmethyl iodide *(3)*[4]. Reaction with one mol.-equiv. of aldehyde or ketone (benzophenone does not react) led to the previously unknown 2-triphenylstannylethanol derivatives *(2b)* (Table 1), which at 110—175 °C formed the given olefins in good yield. It is still unclear into which compounds the Ph_3Sn group is converted during the elimination processes.

[**] New Reagents, Part 8.—This work was supported by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie. Part 7: *Th. Kauffmann, U. Koch, F. Steinseifer, A. Vahrenhorst*, Tetrahedron Lett. *1977*, 3341.

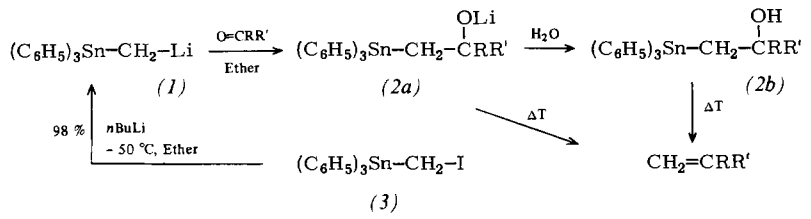

Table 1. 2-Triphenylstannylethanols of type *(2b)* and their thermolyses.

Carbonyl compound	Alcohol *(2b)* [a] R	R'	M.p. [°C]	Yield [%]	Thermolysis *t* [min]	*T* [°C]	Olefin	Yield [b] [%]
Benzaldehyde	H	C_6H_5	136	65	15	140 [c]	Styrene	84 (55)
					300	110 [d]		95 (62)
Butanal	H	C_3H_7	64—65	31	60	170 [c]	1-Pentene	100 (31)
					120	132 [e]		100 (31)
Heptanal	H	C_6H_{13}	75	26	180	132 [e]	1-Octene	71 (18)
Acetophenone	CH_3	C_6H_5	104	41	45	75 [c]	α-Methyl-	71 (29)
					90	110 [d]	styrene	70 (29)
Cyclohexanone	—(CH_2)$_5$—		100	37	45	170 [c]	Methylene-	95 (35)
					120	132 [e]	cyclohexane	96 (35)

[a] The structure is confirmed by elemental analysis, ^{1}H-NMR and mass spectra; the melting points are corrected.
[b] Referred to isolated pure *(2b)*; values in brackets based on carbonyl compound.
[c] Dry heating.
[d] In toluene.
[e] In chlorobenzene.

Table 2. Carbonyl olefination without isolation of *(2b)*.

Carbonyl compound	*t* [min]	Thermolysis *T* [°C]	Solvent	Olefin	Yield [a] [%]
Benzaldehyde	120	110	Toluene	Styrene	87 (48)
Butanal	90	132	Chlorobenzene	1-Pentene	75
Cyclohexanone	180	132	Chlorobenzene	Methylene-cyclohexane	86 (26)

[a] Referred to carbonyl compound; data in brackets: without hydrolysis of *(2a)*.

In order to avoid losses in preparative carbonyl olefinations with *(1)* (cf. Table 1 and Table 2) isolation of the sensitive alcohols *(2b)* should be circumvented, but not the hydrolysis of the lithium alkoxides *(2a)* which leads to considerable increases in yields (Table 2). Such olefinations and in all likelihood possible olefinations with analogous organotin compounds could in many cases offer advantages over corresponding reactions with silicon compounds, since the bond energy of the C—Sn bond is notably lower than that of the C—Si bond (52 and 70 kcal/mol, respectively[5]).

Experimental procedure

(Triphenylstannyl)methyllithium (1): A solution of *n*-butyllithium (5 mmol) in *n*-hexane (*ca.* 2 M solution) is added dropwise within 1 min to a solution of (triphenylstannyl)methyl iodide (2.45 g, 5 mmol) in anhydrous ether (50 ml) under N_2 at −50 °C, and the mixture stirred for 5 min (hydrolysis with D_2O and ^{1}H-NMR spectroscopic investigation of the product shows that *(1)* is formed in 98 % yield).

Styrene from benzaldehyde: A solution of benzaldehyde (5 mmol, 0.51 ml) in ether (10 ml) is added dropwise with stirring to the above mentioned ether solution of *(1)* under N_2 at −50 °C. After warming to room temperature the mixture is treated with 5 ml water and 20 ml toluene. The ether is then removed by distillation and the remaining mixture boiled under reflux for 2 h. Gas chromatographic analysis of the reaction mixture yields 453 mg (87 %) styrene.

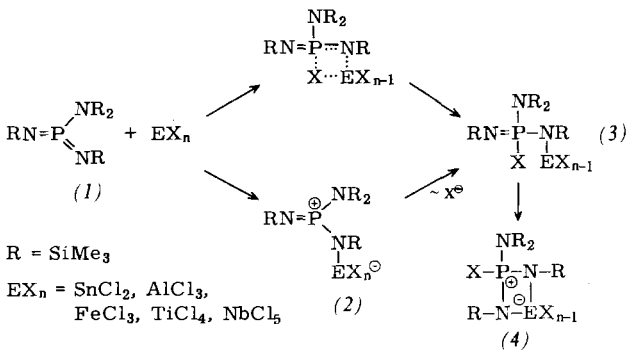
Four-Membered Phosphorus-Nitrogen-Metal Heterocycles with Zwitterionic Structure[**]



By *Edgar Niecke, Rainer Kröher,* and *Siegfried Pohl*[*]

The synthesis of four-membered heterocycles from aminesilylated aminoiminophosphanes and metal halides (a) is limited to a small number of elements due to the α-elimination of many of the Lewis acids (b)[1].

In the reactions of λ^5-phosphorus-nitrogen ylides with EX_n we observed cyclizing halosilane elimination[2] [in analogy with (a)] as well as adduct formation, in place of (b), to yield the cyclic zwitterions *(4)* which have a $\overset{\oplus}{P}N_2\overset{\ominus}{E}$ skeleton.

As is exemplified by the reaction of bis(trimethylsilyl)-aminobis(trimethylsilylimino)phosphorane *(1)* with main group and transition metal halides, this reaction allows access to novel phosphorus-nitrogen-metal heterocycles *(4c—e)*[9] and also the stabilization of rarely occurring coordination numbers of the metal atoms (Table 1: *(4a, d)*).

We suspect that the heterocycles are formed by intramolecular ring closure from the intermediates *(3)* which are themselves produced by a four-centered reaction. The first step of the reaction possibly involves a stage with a highly reactive phosphenium species having a triply coordinated phosphorus[3], the electrophilic phosphorus being then stabilized by chloride migration.

The composition and constitution of compounds *(4)* as four-membered PN_2E rings with zwitterion structure have been established by elemental analysis, molecular weight determinations, mass spectra[4], (^1H,^{31}P)-NMR and characteristic IR data (Table 1) and by X-ray structure analysis in the case of *(4d)*.

Whereas the coordination of the metals in *(4a,b,e)* (CN = 3, 4, 6) results, as expected[5], in magnetic equivalence of the trimethylsilyl groups bound directly to the ring, in *(4d)* these substituents are anisochronous. These findings, which were confirmed by the $^{13}C\{^1H\}$-NMR spectra of *(4d)*[6], are in accord with a trigonal-bipyramidal coordination of the titanium atom with one N atom being in the axial and the other in the equatorial position. ^1H- and $^{13}C\{^1H\}$-NMR measurements at high temperatures show that the two pertinent $SiMe_3$ groups equilibrate at 37(2) °C independently of the concentration of the solution[7]. This speaks in favor of an intramolecular process occurring at the titanium atom

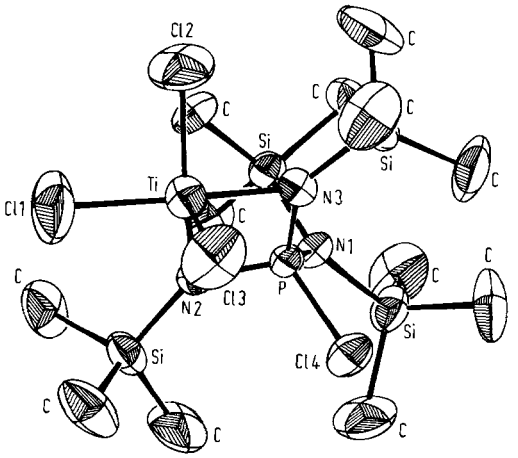


Fig. 1. Molecular structure of *(4d)* (without the H atoms; vibration ellipsoids are shown with a probability of 50 %).

(Berry pseudorotation or turnstile rotation) as has been suggested in the interpretation of exchange phenomena with pentacoordinated phosphorus[8].

The titanium compound *(4d)* crystallizes monoclinically, space group $P2_1/n$; $a = 943.9(1)$, $b = 1718.3(3)$, $c = 1724.2(3)$ pm; $\beta = 92.12(1)°$; $V = 2795 \cdot 10^6$ pm^3; $Z = 4$. Refinement with the structure factors from 3866 observed reflections $[I > 1.968\,\sigma(I)]$ gave an unweighted R value of 7.0 %

($R_w = 6.5\,\%$). Figure 1 represents the molecular structure of *(4d)* and shows the vibration ellipsoids of the atoms (the positions of the H atoms could not be localized).

The four-membered ring formed from the Ti, N2, P and N3 atoms is planar within the limit of error. The coordination of the titanium atom can be described as a distorted trigonal bipyramid. The two ring nitrogen atoms occupy different positions (axial and equatorial) which confirms the findings of NMR spectroscopy. The chlorine atoms bound to the titanium also have larger coefficients for the anisotropic temperature factors than the chlorine atom bound to the phosphorus; these findings are probably due to a dynamic defect as has been found in solution.

Experimental Procedure

A solution of 7.3 g (0.02 mol) *(1)* in 10 ml toluene is added dropwise with stirring under an atmosphere of N_2 to a suspension of 0.02 mol of the metal halide in 20 ml toluene at room temperature. The reaction mixture is then stirred for 5 h.

(4a, b): The solvent is evaporated off at 40 °C/0.1 torr and the residue is sublimed twice at 75 °C/0.1 torr *(4a)* or 85 °C/0.1 torr *(4b)*. Yields 7.8 g (70 %) *(4a)* and 4.5 g (45 %) *(4b)*.

(4c): The reaction solution is allowed to stand until crystallization occurs (*ca.* 80 h). A single recrystallization affords 7.6 g (72 %) *(4c)*.

(4d, e): The reaction solution is cooled to −20 °C when *(4d)* and *(4e)* crystallize out. Recrystallization gives 6.8 g (55 %) *(4d)* and 4.6 g (37 %) *(4e)*.

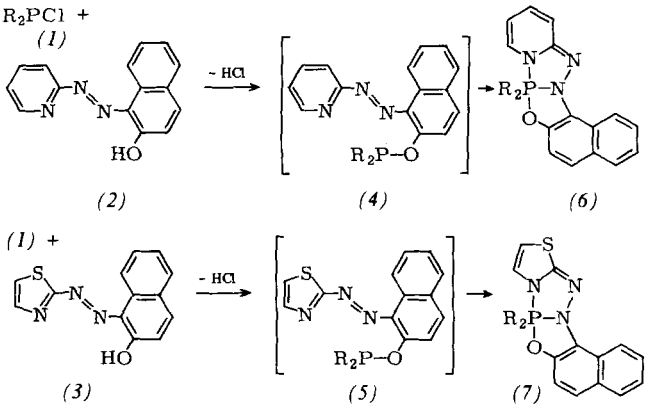
Intramolecular Oxidative Addition of Azopyridine to Phosphorus(III)[1]

By *Alfred Schmidpeter* and *Josef Helmut Weinmaier*[*]

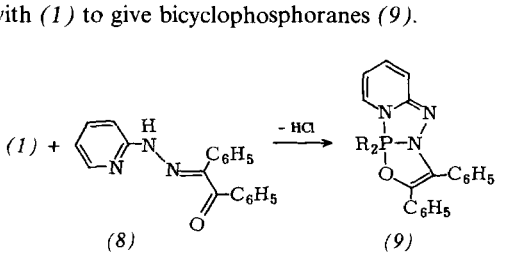


1-(2-Pyridylazo)- and 1-(thiazol-2-ylazo)-2-naphthol, *(2)* and *(3)*, called PAN and TAN, are used as indicators for complexometric titration and as reagents for solvent extraction and spectrophotometric determination of numerous metal ions. They act as monovalent tridentate chelate ligands. Their bonding to the metal ion might be largely determined by a synergic $d\rightarrow\pi^*$ electron transfer from the metal to the azopyridine system[2]. Expressed in terms of valence bonds, a redox relationship *(B)* is superposed upon the donor/acceptor relationship *(A)* between ligand and metal ion.

(A) *(B)*

M = Metal equivalent

Like metal ions, trivalent phosphorus can also simultaneously accept and donate electrons. Indeed, in principle, *(2)* and *(3)* react with chlorophosphanes *(1)* in the same way as with metal ions, *i.e.* as tridentate ligands. Owing to the higher reducing power of P^{III}, however, the oxidative addition in the sense of formula *(B)* is realized, and the bicyclophosphoranes *(6)* and *(7)* are formed.



(2) *(4)* *(6)*

(3) *(5)* *(7)*

The reactions most likely proceed *via* the substitution intermediates *(4)* and *(5)*. The second step is then [4+1] cycloaddition at P^{III}[3], which is normally restricted to certain heterodienes, but in this intramolecular version is also observed with the azopyridine system[4, 5].

N'-(2-Pyridyl)benzil monohydrazone *(8)* contains a seven-membered chain having the same functionality as in *(2)* but with a 1,5-shifted proton. Like *(2)* it forms metal chelates[6] and reacts with *(1)* to give bicyclophosphoranes *(9)*.

(8) *(9)*

The upfield shift of the ^{31}P-NMR signals (Table 1) confirms that the phosphorus in *(6)*, *(7)*, and *(9)* achieves pentacoordination. The bicyclic should be planar, *i.e.* meridionally incorporated in the trigonal-bipyrimidal configuration. This is supported by the fact that the substituents on the phosphorus when $R^1=R^2$ are equivalent in the ^1H-NMR spectrum and that their signals are split with $^{2,3}J_{PH}$ coupling constants

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. J. H. Weinmaier
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

(J_{PCH} = 13 to 15 Hz, $J_{P(N,O)CH}$ = 14 to 15 Hz) that are typical for the equatorial position. Exceptions are *(9i)* with non-equivalent methylene members in the dioxaphospholane ring and presumably also *(9j)*. Here the axial-equatorial position of the third ring forces the bicyclic into the facial position (cf. Ref.[7]). The two thiazole protons in *(7)* give ABX signals with $\delta^1H(4) = 6.0$ to 6.7; $J_{PNCH} = 1.0$ to 1.5 Hz and $\delta^1H(5) = 5.6$ to 5.0; $J_{PNCCH} = 1.4$ to 4.2 Hz.

Table 1. Color, melting point [°C] and $\delta(^{31}P)$ of the compounds *(6)*, *(7)*, and *(9)*. When no melting point is quoted the compound is an oil.

Experimental

A suspension of *(2)*, *(3)*, or *(8)* (20 mmol) and triethylamine (20 mmol) in anhydrous benzene (30 ml) is treated under N_2 with chlorophosphane *(1)* (20 mmol). After one hour's stirring at room temperature, the triethylammonium chloride is separated off by filtration, washed with benzene, and the combined filtrates concentrated by evaporation. The crude product is then chromatographed on Al_2O_3 and/or recrystallized from acetonitrile. In some cases the products could not be crystallized.

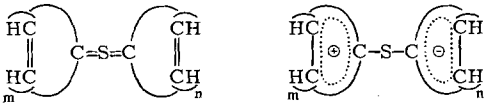
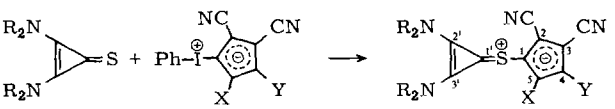
Stable Thiocarbonyl Ylides



By *Kazuhiro Nakasuji, Keitaro Nishino, Ichiro Murata, Hisanobu Ogoshi*, and *Zen'ichi Yoshida*[*]

Thiocarbonyl ylides *(1)* constitute a new class of compounds, conventionally represented by many resonance structures such as the 1,3-dipolar *(1b)*[1], the quadrivalent sulfur *(1c)*[2], and the biradical structure *(1d)*. Since the first report on clear-cut evidence for the intermediacy of the thiocarbonyl ylide by *Kellogg et al.*[3], much attention has been focused on the preparation of stable thiocarbonyl ylides[4].

(1a) *(1b)* *(1c)* *(1d)*



The thiocarbonyl ylide of general formula *(2)*, containing two odd unsaturated rings might be stabilized by participation of the aromatic dipolar structure *(2a)* in the ground state in which each of the two oppositely charged rings satisfies the Hückel rule. The simplest compound of this type is *(2)*, $m = 1$, $n = 2$. We now report the synthesis of the first example of this type of thiocarbonyl ylide.

(2) *(2a)*

Since the 1,2-bis(diisopropylamino)cyclopropenyl[5a] and the tricyanocyclopentadienyl[6] systems have been shown to give stable cations and anions, respectively, our attention turned to the reaction of bis(diisopropylamino)cyclopropenethione *(3)*[5a] with 1-phenyliodonium 2,3,5-tricyanocyclopentadienide *(4a)*[7] or 1-phenyliodonium 2,3,4-tricyanocyclopentadienide *(4b)*[7].

Reactions of equimolecular amounts of *(3)* and *(4a)* or *(4b)* in refluxing chloroform afford the expected thiocarbonyl ylides *(5a)* and *(5b)*, respectively[4d]. In both cases, no starting materials were left after 1.5 h and the products obtained essentially pure by chromatography (short column, Al_2O_3, CH_2Cl_2). *(5a)*, colorless needles from CH_2Cl_2/hexane, m.p. 248—250 °C, 86 % yield; *(5b)*, colorless prisms from CH_2Cl_2/hexane, m.p. 269—271 °C, 71 % yield. Both thiocarbonyl ylides appear to be quite stable under atmospheric condition. Their

Table 1. Selected physical properties of *(5a)* and *(5b)*.

	(5a)	*(5b)*
^{13}C-NMR (in $CDCl_3$, TMS internal)		
C-1	109.2	109.9
C—CN	97.4, 98.9, 102.0	97.7, 101.7, 102.5
C-4	108.9	
C-5		105.1
C-1′	124.5	124.8
C-2′, C-3′	131.1	130.9
IR (KBr) [cm^{-1}]		
C≡N	2210	2210
Cyclopropene [5]	1898, 1550	1900, 1550
UV (CH_3CN) λ_{max} [nm] (log ε)		
	240 (4.61), 278 (4.23)	223 (4.49), 243 (4.45) s, 285 (4.29), 295 (4.26)
^{1}H-NMR (100 MHz, $CDCl_3$, TMS internal)		
4-H	6.78 (1H, s)	
5-H		6.56 (1H, s)

structures were unambiguously established by their elemental analyses and spectra (Table 1).

The upfield shift of the C-1 signal in the ^{13}C-NMR spectrum of *(5a)* and *(5b)* is comparable with that of the cyclopentadienide ion (δ = 102.1)[8]; this indicates an enhanced electron density at this carbon atom and is consonant with the similar chemical shifts of 4-H in the ^{1}H-NMR spectrum of *(5a)* and 3-H of potassium 1,2,4-tricyanocyclopentadienide (δ = 6.67). On the other hand, the chemical shift noted for

C-1′ lies between those of the reference compounds *(6)*[9] and *(3)*[9]. These findings suggest a partial double bond character of the (C-1′)—S bond. Hence structure *(1a)* should play an important role in stabilizing the thiocarbonyl ylides *(5a)* and *(5b)*.

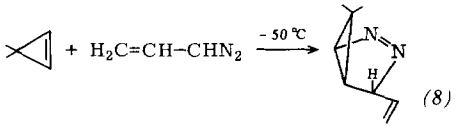
Formation of Diazo Compounds on Decomposition of 2,3-Diazabicyclo[3.1.0]hex-2-enes: [3+2]-Cycloreversions[**]

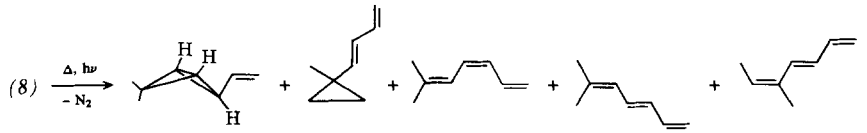


By *Manfred Schneider* and *Bernd Csacsko*[*]

The reaction products obtained on thermal or photochemical decomposition of *(1)* differ fundamentally from those of other bicyclic 1-pyrazolines[1]. Thus *(1a)* gives *trans*-1,3-pentadiene *(4a)*, and *(1b)* affords *cis*-1,3-pentadiene *(4b)*[2]. This was interpreted in terms of the intermediacy of carbenes. The first reaction step was formulated as a 1,3-dipolar retroaddition leading to a diazo compound *(2)*. The reaction products then arise from *(2) via* the carbene *(3)*. On the other hand, formation of bicyclo[1.1.0]butane *(7)* on decomposition of *(1c)* was regarded as evidence for the simultaneous occurrence of diazenyl and cyclopropyl diradicals *(5)* and *(6)*, respectively[3].

The isolation and identification of *(2)* as the principal or sole decomposition product of *(1)* would constitute unequivocal proof of the carbene mechanism and rule out the formation of diradicals *(6)*. This has not previously been accomplished[4]. We now report the first successful experiments in a typical series of compounds.

1,3-Dipolar cycloaddition of 3-diazo-1-propene to 3,3-dimethylcyclopropene[5] at −50 °C furnishes 6,6-dimethyl-4-*exo*-vinyl-2,3-diazabicyclo[3.1.0]hex-2-ene *(8)* in 70% yield, b.p. 58 °C/4 torr. Only the *exo* isomer is formed[6].



Compound *(8)* decomposes thermally (*n*-octane, 40—70 °C; $\Delta H^{\neq} = 24.8 \pm 1$ kcal/mol; $\Delta S^{\neq} = -1 \pm 2$ cal/mol K) and photochemically (*n*-pentane, 0 °C; Hanau TQ 150, Pyrex filter) with

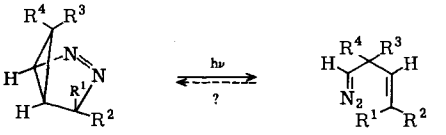
formation of 2,2-dimethyl-4-*exo*-vinylbicyclo[1.1.0]butane *(9)*, 1-(*trans*-1,3-butadienyl)-1-methylcyclopropane *(10)*, the *Z*- and *E*-6-methyl-1,3,5-heptatrienes *(11a)* and *(11b)*, and of *(11c)*, tentatively identified as *E*-5-methyl-1,3,5-heptatriene[7]. All the compounds are stable under the reaction conditions. The trienes *(11a—c)* can be separated by preparative gas chromatography, but polymerize rapidly at room temperature and must therefore be kept at −78 °C under N_2. Above 150 °C compound *(9)* quantitatively rearranges [$t_{1/2}$ (170 °C) = 60 min] to *(11b)* in a [$_\sigma2_s + _\sigma2_a$] process. The

	(9)	(10)	(11a)	(11b)	(11c)
photochemical [%]	24.0	21.8	12.1	35.3	6.8
thermal [%]	16.8	18.8	–	56.2	8.2

formation of all products can be explained as intramolecular secondary reactions of a carbene *(13)* formed from *(8)* *via* the diazo compound *(12)*.

This conclusion is also supported by the finding that only traces of *(9)*, *(10)*, *(11a—c)* are formed on photolysis of *(8)* in methanol *(14)*. Instead, the methyl ethers *(15)* and *(16)* are formed in 80 and 20 % yield, respectively[8].



Brief heating of *(8)* in *n*-octane to +80 °C gives a deep yellow solution whose IR spectrum displays the intense diazo group band at $\nu = 2060\,cm^{-1}$. The UV spectrum exhibits a broad band at $\lambda_{max} = 460$ nm ($\varepsilon \approx 8$) and a further maximum at $\lambda_{max} = 219$ nm ($\varepsilon \approx 17000$), and is practically identical with the spectrum of diazoethane in the visible region. Solutions obtained in this way (up to 0.5 M) likewise afford *(15)* and *(16)* with methanol and react with 2-naphthol and with 3,5-dinitrobenzoic acid with evolution of N_2 to form the corresponding derivatives.

UV irradiation of a solution of *(8)* in [D_8]tetrahydrofuran at −50 °C in the NMR spectrometer[9] leads to rapid disappearance of the signals of *(8)* and formation of *(12)*. On use of monochromatic light ($\lambda = 331 \pm 12$ nm) for excitation of the $n \rightarrow \pi^*$ band of *(8)* at $\lambda_{max} = 331$ ($\varepsilon = 370$) or on use of suitable filter solutions[9], it is possible to suppress the further reaction of *(12)* and to record its ^{1}H-NMR spectrum [in [D_8]THF: $\delta = 1.20$ (s, 6H), 3.72 (s, 1H), 4.70—5.40 (m, 2H), 5.70—6.50 (m, 3H)]. Apart from *(12)*, only traces of *(9)*, *(10)*, and *(11a—c)* are found. Hence the diazo compound *(12)* is the sole reaction product of photochemical (and most likely also thermal) decomposition of *(8)*. At room temperature it can be detected in solution for only *ca.* 2 h, and decomposes with formation of *(9)*, *(10)*, and *(11a—c)*.

In the same way we have studied the low-temperature photolysis of *(1a—i)* and were able to record the ^{1}H-NMR spectra of the diazo compounds *(17a—i)* formed practically exclusively in all cases.

It is clear from these results that the decomposition reactions of 2,3-diazabicyclo[3.1.0]hex-2-enes proceed *via* diazo compounds and carbenes and that 1,3-diradicals play only a minor role (if any) in product formation.

(i), $R^1 = H$, $R^2 = Vinyl$, $R^3 = C_6H_5$, $R^4 = CH_3$

The thermal decomposition reactions can be regarded as the [3+2] cycloreversion of a thermally allowed [$_\pi4_s + _\pi2_s$] addition. In no case were we able (within the limits of accuracy of the NMR method) to observe this reaction with formation of the starting compound *(1)* since the decomposition of the diazo compounds was faster.

Formation of the (*Z*,*E*)-1,3-Diphenylallyl Radical from the (*Z*,*E*)-1,3-Diphenylallyl Anion by Electron Transfer—Comparison of the Rotational Barriers of the Radical and the Anion[**]

By *Gernot Boche* and *Dieter R. Schneider*[*]

The rotational barriers of allyl radicals[1] and their relationship with allyl resonance[2, 3] are questions of topical interest. In addition, we were also interested in the rotational barriers of allyl systems having the same topology but differing in the number of π-electrons, and hence in their charge.

The preparation of the (*Z*,*E*)-1,3-diphenylallyl radical (*Z*,*E*)-*(2)* from the (*Z*,*E*)-1,3-diphenylallyl anion (*Z*,*E*)-*(1)* was accomplished by electron transfer[4]: addition of (*Z*,*E*)-*(1)* in tetrahydrofuran (THF) to nitrobenzene in THF[5] led, even at −82 °C, to immediate[6] oxidation. Work-up afforded the products of radical dimerization *(3cc)*, *(3ct)*, and *(3tt)*[7] in 97% yield. They were separated and isolated as mixtures of diastereomers by preparative thin-layer chromatography (silica gel; light petroleum : ether = 95 : 5).

Structural proof was provided by spectroscopy[8].

(3cc): NMR ($CDCl_3$): decoupling of the benzyl protons gave two AB systems of approximately equal intensity for the olefinic protons; $J_{cis} = 12.0$ and 12.2 Hz. IR (CS_2): no absorption between 920 and 1020 cm^{-1}. UV (dioxane): $\lambda_{max} = 246$ nm, $\varepsilon = 18490$. *(3tt)*[9]: NMR: decoupling of the benzyl protons gave two AB systems of approximately equal intensity for the olefin protons, with $J_{trans} = 15.8$ and 16.0 Hz. IR: bands at 950 and 959 cm^{-1}. UV: $\lambda_{max} = 253$ nm, $\varepsilon = 21380$. *(3ct)*: NMR: simultaneous decoupling of all benzyl signals was unsuccessful. IR: band at 952 cm^{-1}. UV: $\lambda_{max} = 253$ nm ($\varepsilon = 26490$).

The relative yields are of particular significance. While diffusion-controlled dimerization[10] of the allyl radical (*Z*,*E*)-*(2)* should give the ratio *(3cc)* : *(3ct)* : *(3tt)* = 25 : 50 : 25, we found the values listed in Table 1.

Table 1. Yields [%] of the dimers *(3cc)*, *(3ct)*, and *(3tt)*.

T [°C]	*(3cc)*	*(3ct)*	*(3tt)*
−82	10±5	20±10	70±10
−67	6±4	14±10	80±10
+25	0	10±5	90±5

Since the allyl radical (*E*,*E*)-*(2)* isomeric to (*Z*,*E*)-*(2)* leads exclusively to the dimer *(3tt)* and the anion (*Z*,*E*)-*(1)* is configurationally stable under the reaction conditions, the radical isomerization (*Z*,*E*)-*(2)* → (*E*,*E*)-*(2)* must compete with the diffusion-controlled dimerization of (*Z*,*E*)-*(2)* even at −82 °C. The deviation of the yields from the statistical values cannot be explained in terms of selectivity during the dimerization of the allyl radical (*Z*,*E*)-*(2)* because the diastereomers are formed in the ratio 1 : 1 in the case of *(3cc)* and *(3tt)* (see NMR data).

In accord with the above qualitative demonstration of a very low rotational barrier of the radical (*Z*,*E*)-*(2)*, approximate solution of the formal kinetics of competition between isomerization and dimerization with the aid of the dimerization rate constant $k_2 = 4.5 \times 10^8$ l/mol·s, determined from a viscosity measurement of the reaction medium at −67 °C[11], gives the value $k_{1(-67\,°C)} < 5 \times 10^8\ s^{-1}$. This value corresponds to $\Delta G^{\neq}_{-67\,°C} > 3.7$ kcal/mol. Comparison with the rotational barriers of other allyl radicals[1] shows that the upper limit for (*Z*,*E*)-*(2)* should lie at $\Delta G^{\neq}_{-67\,°C} \approx 9$ kcal/mol.

Thus, in contrast to the allyl anion (*Z*,*E*)-*(1)* of like topology [$k'_{1(-38\,°C)}$ (THF/HMPA) $= 1.9 \times 10^{-4}\ s^{-1}$, corresponding to $\Delta G^{\neq}_{-38\,°C} = 17.9$ kcal/mol], the allyl radical (*Z*,*E*)-*(2)* exhibits pronounced configurational lability[12]. This conclusion is in agreement with *Brauman*'s recently published result[3] that the resonance energy of the allyl radical is at least 4.9 kcal/mol lower than that of the allyl anion, and demonstrates afresh that uncharged π-systems are configurationally less stable than charged ones[13,14].

[14] *Note added in proof* (October 26, 1977): *Ab initio* 4-31-G calculations also indicate that the rotational barrier of the allyl radical (21.2 kcal/mol) is smaller than that of the allyl anion (27.6 kcal/mol); *G. Boche, H. U. Wagner*, unpublished results.

Bis(η^6-naphthalene)chromium(0)[**]

By *Christoph Elschenbroich* and *Reinhart Möckel*[*]

It is surprising that more than two decades after the original preparation of bis(η-benzene)chromium(0)[1] the corresponding naphthalene complex, the parent compound of bis(η-arene)metal complexes of fused six-membered ring aromatics, has still not been isolated. The sole representative of this class so far reported is the dicationic complex bis(η^6-naphthalene)ruthenium(II)[2]; its attempted reduction to the neutral complex was unsuccessful.

Among the few synthetic methods available for bis(η-arene)-metal complexes, the classical reductive Friedel-Crafts reaction[1] and its variants[3] lead to π-complexes of partially hydrogenated arenes when applied to fused six-membered ring systems, at least when the metal belongs to the first transition series[4]. The reaction of metal halide with arene radical anion merely appears suitable for obtaining ESR proof of the existence of the desired compounds[5]. We have now synthesized bis(η^6-naphthalene)chromium(0) *(1)* by cocondensation of metal atom and ligand[6].

(1)

After recrystallization from light petroleum, *(1)* is obtained as brown crystals of analytically confirmed composition $C_{20}H_{16}Cr$ which decompose with sublimation of naphthalene on exposure to air. The complex is readily soluble in tetrahydrofuran (THF) and toluene, but poorly soluble in dimethoxyethane and aliphatic hydrocarbons, and can be sublimed without extensive decomposition at 80 °C/10^{-4} torr.

The presence of a homogeneous bis(naphthalene) sandwich complex is confirmed *inter alia* by the mass spectrum (FD-MS: m/e=308, 100 %, M^+; 309, 12.3 % $[M+1]^+$). In particular, the absence of a mass line at m/e=312 and characterization of the ligand by gas chromatography after cleavage of *(1)* demonstrate that formation of the hydrogenation product bis(η^6-tetralin)chromium(0) can be suppressed on synthesis by the cocondensation technique.

In the ^{1}H-NMR spectrum of *(1)* (D_8-THF) the protons of the complexed ring appear as an A_2B_2 system [δ=4.50 m ($H_{2,3,2',3'}$), 5.40 m ($H_{1,4,1',4'}$)] whereas the protons on the free ring—as also in structurally closely related bis(η^5-indenyl)-iron[7]—give rise to a singlet [δ=6.98 s ($H_{5,6,7,8,5',6',7',8'}$)]. Air oxidation of *(1)* in solution leads to the radical cation $(1)^+$ with ESR data (THF, −80 °C): $\langle g\rangle$=1.986, $a(^1H_{1,4,1',4'})$ =3.65 G, $a(^{53}Cr)$=18.2 G.

The thermal stability of *(1)* (dec. 160 °C) is significantly lower than that of $Cr(C_6H_6)_2$ (m.p. 283—284 °C), possibly due to the greater gain in resonance energy on transition of naphthalene from the π-coordinated to the free state, as compared with benzene.

Drastic differences in reactivity are found for the complex cations: In contrast to $Cr(C_6H_6)_2^+$, which is stable for several days in aqueous solution (pH neutral, room temperature), the radical cation $(1)^+$ decomposes with a half-life of 25 min under these conditions (ESR measurements). In solvent THF decomposition is so fast that cooling to −80 °C is necessary for recording ESR spectra. To a lesser extent this lability is also manifested by the neutral complex. Thus *(1)* reacts instantaneously at room temperature in THF with 2,2'-bipyridine to give $Cr(bpy)_3$, recognizable by its intense reddish brown color, the color change red→blue→red→yellow upon controlled air oxidation and identified *via* ESR characterization of the cation $[Cr(bpy)_3]^+$ [8]. The mild conditions necessary for substitution of the π-bonded naphthalene are astonishing, for ligand exchange in bis(η-benzene)chromium(0) occurs only at high temperatures and pressures (substitution of C_6H_6 by CO, PF_3, bpy,tpy[9]) or with $AlCl_3$ catalysis (substitution by other arenes[10]).

Procedure

In a 1-liter flask (−196 °C, $<10^{-3}$ torr) Cr (0.664 g, 12.8 mmol) is evaporated within 2 h from a heatable Mo wire (diam. 1 mm) spiral (12 V, 40 A). Naphthalene vapor (*ca.* 40 g, 312 mmol) is simultaneously introduced *via* a heatable inlet. A condensate is formed which appears reddish brown as a thin layer. After warming to room temperature the condensate is dissolved in THF. Filtration and removal of solvent leave a residue which is placed in a high vacuum at +50 °C for 4 h to remove excess naphthalene. Recrystallization from light petroleum (−80 °C) gives dark brown crystals of *(1)* which are pyrophoric when finely divided (yield 0.68 g, 17.8 % based on evaporated Cr).

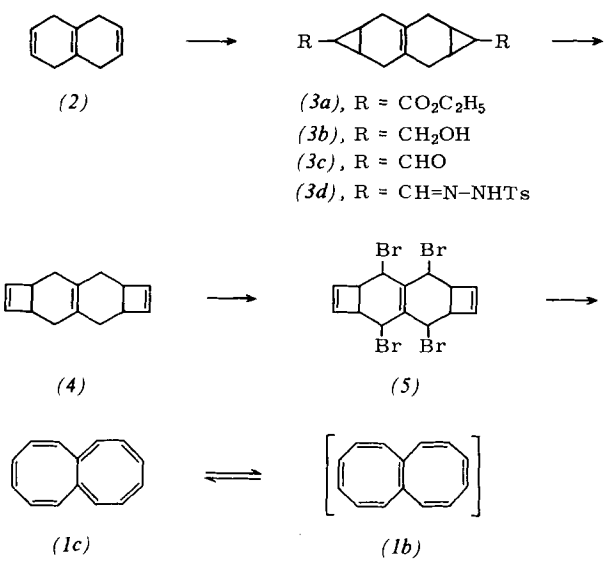
Octalene[**]

By *Emanuel Vogel, Hans-Volker Runzheimer, Frank Hogrefe, Bernd Baasner*, and *Johann Lex*[*]



Dedicated to Professor Otto Bayer on the occasion of his 75th birthday

Annulenoannulenes[1], bicyclic ring systems consisting of two *ortho*-condensed annulenes, are presently one of the main topics of interest in the field of "non-benzenoid aromatics". Of the various representatives of these annulene derivatives the [4*n*]annuleno[4*n*]annulenes made up of two [4*n*]annulenes are of special interest, since unlike their structural units they possess $(4n+2)$ π-electrons and thus possibly constitute a new class of aromatic compounds.

(1a) *(1b)* *(1c)*

The prototype of the [4*n*]annuleno[4*n*]annulenes is the 14π-system octalene *(1)* ([8]annuleno[8]annulene), the eight-membered ring homolog of naphthalene. All previous attempts to synthesize compound *(1)* have so far failed[2,3]. Hence the question whether *(1)* has an aromatic [*(1a)*] or an olefinic structure [*(1b)* and/or *(1c)*] has hitherto been dealt with merely on a theoretical basis[4]. According to recent calculations[4b-4f] the resonance stabilization of a planar octalene is not sufficient (deficit of *ca.* 50 kcal/mol)[4b] to overcome the strain on planarization of the two eight-membered rings. Consequently, a nonplanar olefinic structure is proposed for *(1)*. This prediction leaves the double-bond isomerism in *(1)*, which has hardly been dealt with in previous work[5], as the actual octalene structural problem.

(2) *(3a)*, R = $CO_2C_2H_5$; *(3b)*, R = CH_2OH; *(3c)*, R = CHO; *(3d)*, R = CH=N–NHTs

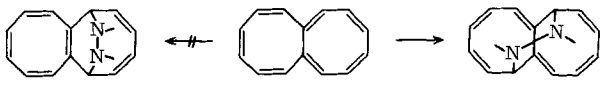
(4) *(5)*

(1c) *(1b)*

In this communication we wish to report the synthesis of octalene and some of its properties.

The concept of preparing *(1)* from the tetracycle *(4)* was the deciding factor for selection of the recently described 2:1 adduct *(3a)*[6] of ethyl diazoacetate to isotetralin *(2)* as starting compound. The dialdehyde *(3c)* required for the cyclopropane→cyclobutene ring expansion was most advantageously obtained by reduction of *(3a)* with lithium aluminum hydride in ether and oxidation of the resulting diol *(3b)* [m.p. 164—165 °C (from ethyl acetate); yield 95 %] with chromium trioxide/pyridine. Chromatographic work-up on silica gel (CH_2Cl_2) and subsequent recrystallization from ethyl acetate afforded colorless *(3c)* [m.p. 172—173 °C; yield 53 %; ^{1}H-NMR ($CDCl_3$): δ = 1.62—1.94 (m, 6 cyclopropyl-H), 1.94—2.54 (m, 8 allyl-H), 9.20 (d, 2 aldehyde-H); IR (KBr): 1680 cm^{-1} (C=O)].

Reaction of *(3c)* with *p*-toluenesulfonyl hydrazide in boiling ethanol smoothly afforded the ditosylhydrazone *(3d)* [m.p. 230—232 °C (dec.); yield 83 %]. On heating *(3d)* with sodium methoxide in 3-ethyl-3-pentanol at 140 °C (1 h), a mixture of the hydrocarbons *(4)*, *(2)*, and tricyclo[6.4.0.$0^{3,6}$]dodeca-1(8),4,10-triene was obtained, from which *(4)* crystallized out on addition of a little ethanol and cooling to −20 °C (15 hours' standing) [colorless needles (from ethanol), m.p. 74—75 °C; yield 15 %; ^{1}H-NMR (CCl_4): δ = 1.65—2.45 (m, 8 sec. allyl-H), 2.97 (m, 4 tert. allyl-H), 5.85 (s, 4 olefinic H); IR (KBr): 1620 cm^{-1} (cyclobutene C=C stretching vibration)].



(4) reacts relatively rapidly (15 min) with a 4.4-fold molar amount of *N*-bromosuccinimide in boiling carbon tetrachloride in the presence of azoisobutyronitrile to give a mixture of bromides, from which an oily fraction consisting essentially of tetrabromides [*(5)*] can be isolated by chromatography on silica gel (CH_2Cl_2). Since attempts to carry out a separation of isomers led to high losses, the crude tetrabromide fraction was directly dehalogenated with sodium iodide in acetone (reflux, 24 h) (this and the following operations were carried out with stringent exclusion of air). The dehalogenated product was taken up in pentane (yellow solution) and chromatographed on silica gel (pentane). On removal of solvent there remained a dark yellow liquid mixture of hydrocarbons, the main component (*ca.* 70 %) of which was isolated by preparative gas chromatography (SE 30 column, 170 °C) and subsequent short-path distillation. The pure hydrocarbon thus obtained, an extremely air-sensitive lemon-yellow liquid of b.p. 50—52 °C/1 torr and m.p. −5 to −4 °C [yield 8—10 % referred to *(4)*] was, as will be shown below, the desired octalene.

The ^{1}H-NMR spectrum (CCl_4) of the hydrocarbon shows only olefinic absorption, at δ = 5.65 (m, 10H) and δ = 6.30 [d with J = 12 Hz (A part of an AB system), 2H]. A similar absorption pattern (multiplet with a superposed 2-proton doublet) is observed in the spectrum of 7,8-dimethylenecyclooctа-1,3,5-triene[7]. This finding would suggest that octalene has the structure *(1c)*. In agreement with this the ^{13}C-NMR spectrum of the compound [($CDCl_3$/TMS): δ = 142.62, 136.34, 131.46, 131.43, 129.01, 127.59, 126.90] exhibits seven signals—a four-line spectrum would be expected for the double bond isomer *(1b)*—, of which one is due to quaternary C atoms. Since *(1c)* is chiral, implying the presence of 14 different carbon atoms, the room-temperature ^{13}C-NMR spectrum

[**] Based on a Plenary lecture delivered at the III. International Symposium on Novel Aromatic Compounds (ISNA), San Francisco, August 1977.

must represent an averaged spectrum arising by rapid conformational processes. Support for this explanation follows from the observed change in shape of the ^{13}C-NMR spectrum on lowering the temperature[8]. The remaining spectra of the hydrocarbon [UV (cyclohexane): $\lambda_{max} = 315$ nm ($\varepsilon = 3300$); IR (neat): 1600, 1621, 1660 cm^{-1} (C=C valence vibration); mass spectrum: $m/e = 180$ (M^+, 35 %), 179 (100 %), 178 (88 %), 165 (65 %), 153 (23 %), 152 (45 %)] though less informative are nevertheless consistent with the olefinic octalene structure *(1c)*.

(6) *(1c)* *(7)*

Independent proof of the presence of octalene has in the meantime been provided by an X-ray structural analysis carried out by *J. Lex*[9] on the 1:1 adduct [m.p. 165—166 °C (dec.); yield 30 %] obtained on reaction of the hydrocarbon with 4-phenyl-1,2,4-triazolinedione (PTAD) in acetone at room temperature. According to the analysis, the adduct does not have the structure *(6)* which could have been expected from the behavior of 7,8-dimethylenecycloocta-1,3,5-triene towards dienophiles (1,4-addition with participation of the exocyclic double bonds)[7b], but the structure *(7)*. An attractive possible explanation for the formation of *(7)* is provided by the assumption of a thermally allowed synchronous [8+2] cycloaddition[10] of PTAD to *(1c)*. Since PTAD is ascribed an electrophilic nature[11], there remains, however, the mechanistic alternative that *(7)* is formed from octalene *via* a zwitterionic homotropylium intermediate.

A representation of the three-dimensional structure of the adduct *(7)* is given in Figure 1. Remarkably, *(7)* is distinguished by a twofold symmetry axis. Also worthy of mention is the 90.3° torsion angle C6—C7—C7′—C6′, for this explains why *(7)* is colorless despite the presence of six conjugated double bonds.

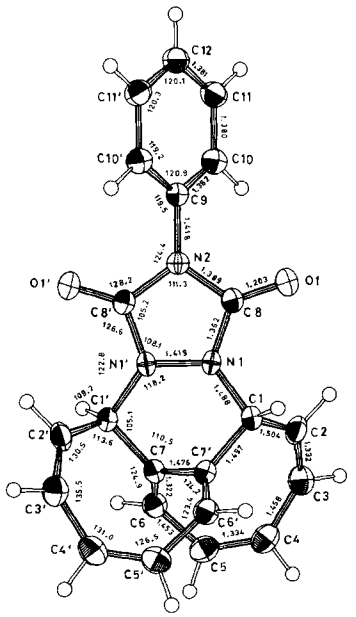

Fig. 1. Molecular structure of the 1:1-adduct *(7)* of octalene and 4-phenyl-1,2,4-triazolinedione.

The search for the double-bond isomer *(1b)* of octalene has so far met without success[12]. Obviously *(1b)* is so strongly disfavored energetically compared to *(1c)* that it does not play a significant role in the presumed equilibrium between the two double bond isomers.

Configuration, Conformation, and Dynamics of Octalene

By *Jean F. M. Oth, Klaus Müllen, Hans-Volker Runzheimer, Peter Mues*, and *Emanuel Vogel*[*]

We were recently able to demonstrate by ^{13}C-NMR spectroscopy that the 12π-system heptalene contains alternating

[*] Prof. Dr. J. F. M. Oth, Priv.-Doz. Dr. K. Müllen
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule
Universitätstrasse 16, CH-8092 Zürich (Switzerland)
Dipl.-Chem. H.-V. Runzheimer, P. Mues, Prof. Dr. E. Vogel
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

single and double bonds and undergoes a rapid isodynamic π-bond shift[1]. The method has also proved useful for gaining an insight into the π-bonding and conformational features in the case of the 14π-system octalene[2]. We report here on the double bond configuration, conformation, and dynamics of the octalene molecule[3].

(1a) *(1b)* *(1c)*

The room-temperature ^{13}C-NMR spectrum of octalene (Fig. 1b) shows seven signals, one of which is ascribed to quaternary C-atoms. This finding ruled out both the configuration with central double bond *(1b)*[4] (conformations with C_{2h} or C_{2v} symmetry[3]) as well as the aromatic structure *(1a)* with planar eight-membered rings[5], for in each of these cases only a four-line spectrum is to be expected.

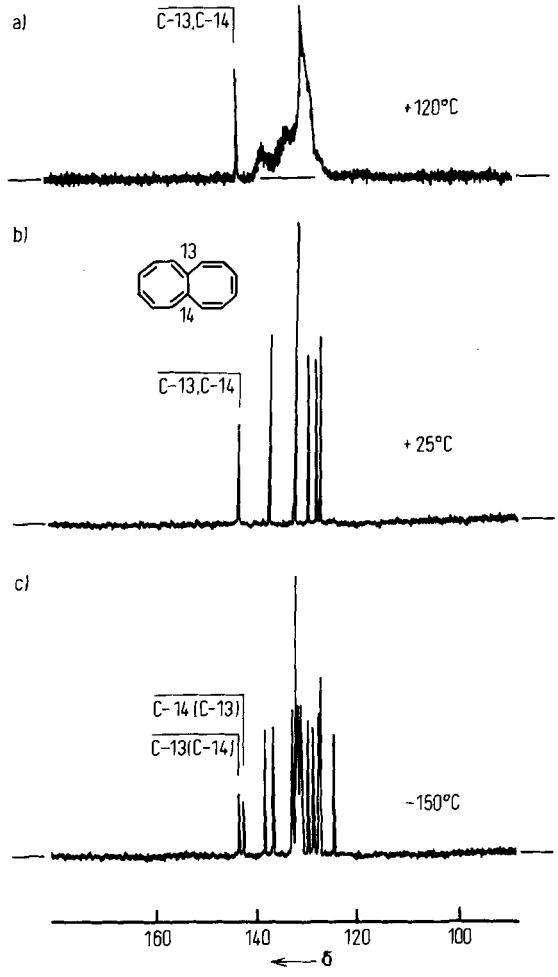

Fig. 1. ^{13}C-NMR spectra (25 MHz, ^{1}H-decoupled) of octalene at a) +120°C, b) +25°C (here coincidental overlapping of two signals occurs), c) −150°C.

At first sight the observed ^{13}C-NMR spectrum (and likewise the more recently analyzed 360-MHz ^{1}H-NMR spectrum[6]) is consistent only with a structure of type *(1c)*, in which no rapid π-bond shift takes place. This interpretation raises some problems, if the conformation of the molecule is considered. The most plausible conformation of *(1c)* is constructed from tub shaped cyclooctatetraene and cyclooctatriene fragments which have a common single bond. Such a three-dimensional structure with C_1 symmetry (Fig. 2) is chiral and should not show seven but 14 chemical shifts.

In this connection it is informative that the ^{13}C-NMR spectra are temperature-dependent: a broadening of all signals takes place below −100°C. Further lowering of the temperature leads to splitting. As expected, at −150°C a 14-line spectrum is obtained (Fig. 1c). This temperature dependence may be regarded as due to conformational processes, namely independent ring inversions of the cyclooctatetraene and cyclooctatriene fragments. The inversion of each of these rings is an isodynamic process, which effects the pairwise averaging of the 14 magnetic environments.

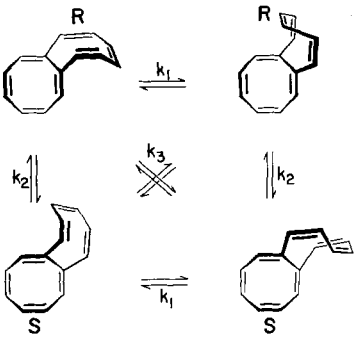

Fig. 2. Conformational mobility of octalene.

The presence of three consecutive single bonds in the cyclooctatriene ring would suggest that its inversion (k_1) proceeds much more rapidly than that of the cyclooctatetraene ring (k_2). As can be deduced from Figure 2 the same exchange is expected irrespective of which of the two rings inverts. An analysis of the NMR line shape thus will afford only the sum k_1+k_2 of the rate constants of the two inversion processes. A value of *ca.* 300 s^{-1} is obtained for k_1+k_2 from the ^{13}C-NMR spectrum at −115°C. Assuming $k_1 \gg k_2$ this affords a value of $\Delta G^{\neq}(k_1) \approx 8$ kcal/mol for the free enthalpy of activation for the inversion of the cyclooctatriene ring.

The conformational mobility of octalene includes a remarkable stereodynamic situation: while one enantiomeric form is converted into the other form (R⇌S) by inversion of the cyclooctatetraene ring, the stereochemistry remains unchanged after inversion of the cyclooctatriene ring. The synchronous inversion of both rings (k_3) would also lead to an enantiomer interconversion but would leave the magnetic environments of the nuclei (in achiral solvents) unaltered.

The dynamic process k_3 implicates a transition state with planarized perimeter. The occurrence of a peripheral π-bond shift in the octalene is coupled with the same geometrical prerequisite[7a,7b]. The possibility that such an isodynamic process could take place prompted us to investigate the high-temperature ^{13}C-NMR spectra. Above 80°C a broadening of the signals occurs in the spectra, from which the signal of the quaternary carbon is revealingly excluded (Fig. 1a). Apparently this change of shape is determined by an isodynamic peripheral π-bond shift *(v)*. The 4-line spectrum to be expected in the region of rapid exchange has so far defied observation since the compound polymerizes at higher temperatures. From the line shape of the ^{13}C-NMR spectrum at 120°C the rate constant of the π-bond shift is determined as $v \approx 200$ s^{-1}; it corresponds to a free enthalpy of activation of $\Delta G^{\neq}(v) \approx 20$ kcal/mol.

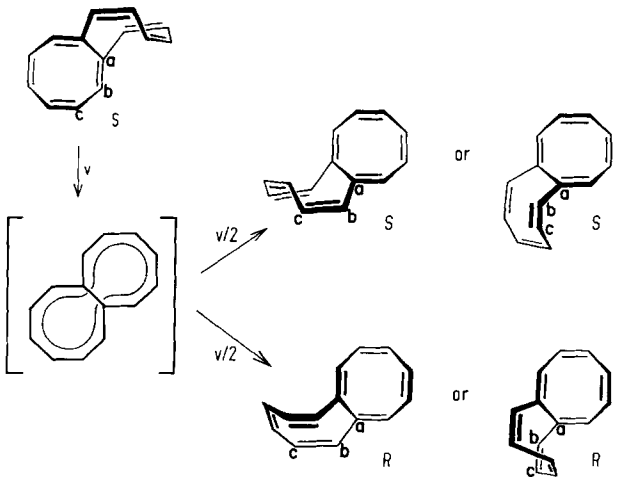

Fig. 3. π-Bond shift in octalene.

If one considers the planar structure *(1a)* with delocalized π bonds as the transition state of the π-bond shift, then $\Delta G^{+}(v) \approx \Delta H^{+}(v)$ corresponds to the difference of the enthalpy of formation of *(1a)* (planar) and *(1c)* (C_1 symmetry). This quantity is made up of the energy *demand*, ΔH_E, for planarization of both rings and the energy *gain*, ΔH_{STAB}, resulting from bond delocalization in the planar 14π-system. Since the experimentally inaccessible energy term ΔH_E can be estimated to be *ca.* 35 kcal/mol[8], a value of

$$\Delta H_{STAB} = \Delta H_E - \Delta H^{+}(v) \approx 15 \text{ kcal/mol}$$

is obtained for the stabilization energy.

That ΔH_{STAB} in the case of octalene with the planar structure *(1a)* is smaller than in the case of [14]annulene[9] must be attributed to the destabilizing effect of the central bond[10].

Eight isometric structures (4*R*, 4*S*) contribute to the dynamics of the octalene molecule. Each structure is interconvertible with any one of the other seven *via* one of the processes k_1, k_2, k_3 or v (Figures 2 and 3). The rate of enantiomer transformation is $k_2 + k_3 + v/2$. That the previously hypothetically assumed synchronous inversion of both rings (k_3) does in fact take place follows from the observed peripheral double bond migration v: the common transition state *(1a)* of the two processes reverts in the case of k_3 without effective π-bond shift into the ground state. The energy profiles of the dynamic processes by which an octalene structure is transformed into the seven other isometric structures are shown schematically in Figure 4.

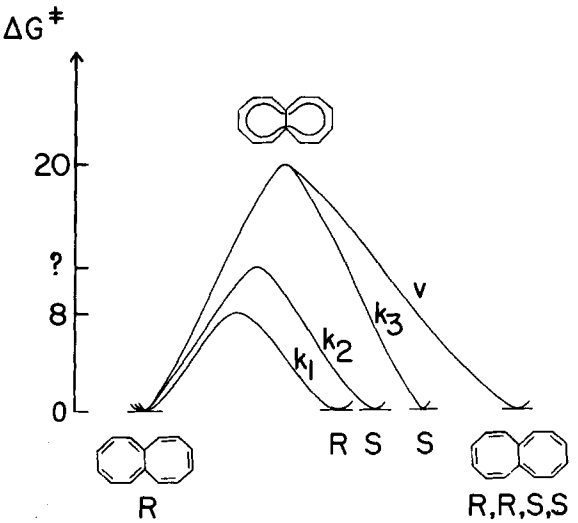

Fig. 4. Energy profiles for the transformations of octalene.

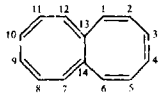

In the discussion of the energy hypersurface of octalene a structure of the type *(1b)* must also be taken into account. If the formation enthalpies of the octalene structures *(1c)* (C_1 symmetry) and *(1b)* (C_{2h} symmetry) are estimated on the basis of thermochemical group increments[11] the isomer *(1c)* would appear to be 5—6 kcal/mol more stable than *(1b)*[12]. The equilibrium between *(1c)* and *(1b)* which could adjust itself by a π-bond shift [again *via (1a)*], should therefore lie far over on the side of *(1c)*. At the same time it follows that a directed synthesis of *(1b)* is possible only at low temperature.

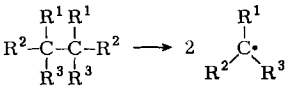
[6] The recording of the ^{1}H-NMR spectra at higher field strength (360 MHz) is made necessary by the small differences in the chemical shifts. The analysis of the room temperature spectrum, which is essentially simplified by decoupling experiments, affords six chemical shifts as well as some vicinal H,H coupling constants:

$\delta(H\text{-}1) = \delta(H\text{-}6) = 6.300$ ppm
$\delta(H\text{-}2) = \delta(H\text{-}5) = 5.706$ ppm
$\delta(H\text{-}3) = \delta(H\text{-}4) = 5.706$ ppm
$\delta(H\text{-}7) = \delta(H\text{-}12) = 5.693$ ppm
$\delta(H\text{-}8) = \delta(H\text{-}11) = 5.639$ ppm
$\delta(H\text{-}9) = \delta(H\text{-}10) = 5.780$ ppm



$J_{7,8} = J_{11,12} = 4.4$ Hz
$J_{8,9} = J_{10,11} = 13.3$ Hz
$J_{1,2} = J_{5,6} = 11.9$ Hz
$J_{9,10} = 7.0$ Hz.

[7] a) *J. F. M. Oth*, Pure Appl. Chem. *25*, 573 (1971); b) *K. Müllen*, Habilitationsschrift, ETH Zürich 1977.
[8] ΔH_E corresponds to the difference in the formation enthalpies of a hypothetical planar structure with localized double bonds and the real structure. The value of ΔH_E results from the activation enthalpy of the ring inversion in cyclooctatetraene (14 kcal/mol [7a]), from that for the inversion of the cyclooctatriene fragment (8 kcal/mol) and from that contribution which is due to the increased angular strain at the central bond and to the increasing non-bonding interaction of the hydrogen atoms.

[12] This value includes the gain in conjugation energy for a planar butadiene fragment in *(1c)* of 3.5 kcal/mol. It is further assumed that the ring strain is the same in *(1b)* (C_{2h} conformation) and *(1c)*.

Observation of a Linear Relationship Between Thermal Stability and Strain Energy of Alkanes[**]

By *Christoph Rüchardt, Hans-Dieter Beckhaus, Goetz Hellmann, Siegried Weiner*, and *Robert Winiker*[*]

C—C single bonds in hydrocarbons are cleaved homolytically between room temperature[1] and about 700 °C (ethane)[2], depending on the structure of the groups bound to the C atoms concerned.

This exceptionally high increase in thermolysis rate, corresponding to a factor of *ca.* 10^{30}, has, as yet, been explained only in an unsatisfactory qualitative manner[1]. Attempts at quantitative interpretation are almost completely lacking[3].

We have now found a linear relationship ($r = 0.98$) between free activation energies $\Delta G^{\neq}$ (300 °C)[4] of the thermolyses of a large number of aliphatic hydrocarbons[5] (see Tab. 1) and their strain energies E_s estimated by force-field calculations (see Tab. 1) according to *Engler-Schleyer*[6] (see Fig. 1).

$$\Delta G^{\neq} = -0.60(\pm 0.03)\,E_s + 65.6(\pm 1.0)\ \text{kcal/mol} \qquad \text{(I)}$$

This shows that the ground state strain energy of the alkanes is the crucial factor determining their thermal stability.

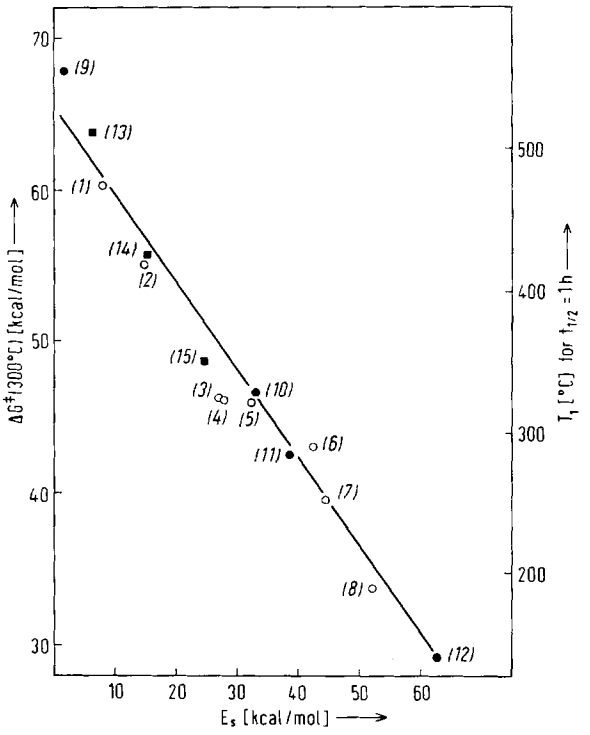

Fig. 1. Relationship between decomposition temperatures T_1 [°C] for $t_{1/2} = 1$ h [4], $\Delta G^{\neq}$ of thermolysis at 300 °C and strain energy E_s [6] of hydrocarbons mentioned in Table 1. ● = C_t—C_t series; ○ = C_q—C_q series; ■ = non-symmetrical bond cleavage.

Product analyses for compounds *(1)*—*(12)* show that bond cleavage occurs mainly at the central C—C bond; compounds *(13)*—*(15)* most likely lose a *tert*-butyl radical in the rate determining step of the thermolysis.

It is remarkable that this relationship is evidently independent of whether homolysis occurs between two quaternary C atoms [C_q—C_q series, *(1)*—*(8)* and *(15)*], between two tertiary C atoms [C_t—C_t series, *(9)*—*(12)*] or between a quaternary C atom and a tertiary [*(14)*] or a secondary

C atom [(13)]. On the other hand, the deviation of the thermal stability of ethane from this correlation does indicate that the type of bond can be significant. The remarkable difference in stability of diastereomers (10) and (11)[5c] also results in quite different bond lengths[8].

According to the above relationship, the C—C bond energy of a hypothetical strain-free alkane is calculated as $D \approx 76$ kcal/mol[9], which is of the expected order of magnitude[10].

The slope of the straight line in Figure 1 shows that only 60% of the change in strain energy E_s is reflected in activation enthalpy differences $\Delta\Delta G^{+}$ and $\Delta\Delta H^{+}$. It can be concluded that about 40% of strain energy prevails at the transition state of the thermolysis reaction, obviously largely independent of structure. Therefore, for radical recombination, *i.e.* the reverse reaction of thermolysis, an activation energy corresponding to 40% of the ground state strain energy E_s is required.

A New Lactone Synthesis

By *Helmut Vorbrüggen* and *Konrad Krolikiewicz*[*]

Dedicated to Professor Robert B. Woodward on the occasion of his 60th birthday

In the recently published cyclizations of ω-hydroxycarboxylic acids to medium or large lactone rings, activation of the carboxylic[1] or of the hydroxy groups[2] gives rise to polar intermediates in which the ends of the chains are attracted by opposite charges and thus react with each other[3].

Since the esterification of carboxylic acids with amide acetals[4,5] gives rise also to such a polar intermediate by activation of the alcoholic hydroxyl group, we have added slowly and simultaneously toluene solutions of ω-hydroxy acids[1] and *N,N*-dimethylformamide dineopentylacetal (2)[4] to boiling toluene. During this reaction the lactones (4) were formed *via* the polar intermediates (3) in yields of *ca.* 40—50% together with varying amounts of the oligomers (5) ($m = 2, 3, 4$)[6]. ω-Hydroxyoctanoic acid (1a) did not yield any monomeric lactone (4a) but only the oligomers (5a) ($m = 2, 3, 4$; cf. Table 1).

(1) (2) (3)

(4) (5)

$ClCH_2-(CH_2)_6-COO-CH_2CH_2Cl$

(6)

Table 1. Lactones (4) and (5) from ω-hydroxycarboxylic acids (1).

(1)	n	R	Reaction conditions	(4)	Yield [%] (5)		
					m=2	m=3	m=4
(a)	6	H	16 h/110 °C	—	14.3	10.8	9.2
(b)	10	n-C_6H_{13}	19 h/110 °C [a]	48.3	11.8	4.6	1.9
(c)	14	H	15 h/110 °C	40.0	16.6	3.9	1.4

[a] A concentrated solution of (1b) and (3) in methylene chloride gave on standing for 1 week at 24 °C some unreacted (1b) and a small amount of (4b) as well as a large amount of (5b) ($m = 2$).

As to be expected from intermediates of type (3), this lactonization occurs *via* a Walden inversion of a chiral center at the hydroxyl-carrying carbon atom. Optically active 12-hydroxystearic acid (1b) [$n = 10$, R = n-C_6H_{13}] thus afforded the lactone (4b) [CD (dioxane) $\lambda = 218$ nm, $\Delta\varepsilon = +0.589$] in 48% yield. Saponification of (4b) with methanolic KOH and a second lactonization with (2) gave the lactone (4b) [CD (dioxane) $\lambda = 218$ nm, $\Delta\varepsilon = -0.681$] with opposite configuration at C-12.

On using boiling 1,2-dichloroethane instead of toluene as solvent, the reaction of (1a) with (2) afforded the 2-chloroethyl ester (6) [$m/e = 161, 135, 122, 97$] as major product. The compound (6) is probably formed *via* attack of the carboxylate anion on 1,2-dichloroethane with formation of the β-chloroethyl ester and subsequent attack of the newly formed Cl^- on C-8 which is activated by reaction with (2)[7].

Procedure:

2.4 g (8 mmol) 12-hydroxystearic acid and 2.08 g (9 mmol) *N,N*-dimethylformamide dineopentylacetal were each dissolved in 100 ml anhydrous toluene and, using two special addition funnels (Normag No. 8056), added with stirring during 19 h to 100 ml boiling toluene. After two further hours' stirring at 130 °C the mixture was evaporated and the residue (3.0 g) chromatographed on 150 g Al_2O_3 (neutral, Woelm A III). After discarding the first 400 ml eluate, the next 1.5 l hexane afforded 1.092 g (48.3%) (4b) as colorless oil.

Preparation and Reactions of a Cyclic Phosphaallene Ylide

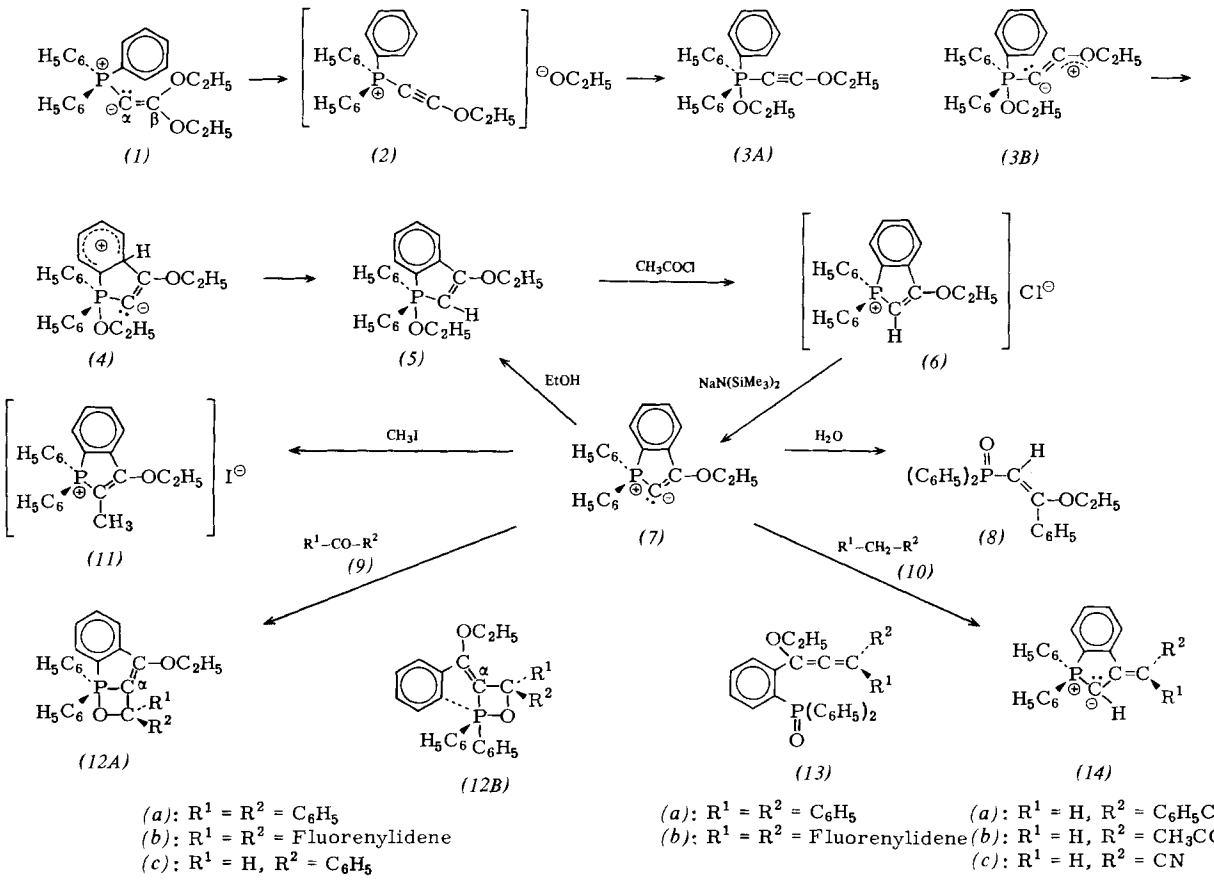
By *Hans Jürgen Bestmann, Kurt Roth*, and *Rolf W. Saalfrank*[*]

In the crystalline state diethoxyvinylidenetriphenylphenylphosphorane *(1)* has a bent structure ($\sphericalangle PC_\alpha C_\beta = 125.6°$); however, the ^{1}H-NMR spectrum of a toluene solution shows only one sharp triplet and quartet for the two C_2H_5 groups. Hence we conclude that a fast inversion of the triphenylphosphonio group takes place in solution[1]. The structure of *(1)* suggests that cyclic phosphaallene ylides should also be capable of existence in the case of small rings[2]. We now report the synthesis and reactions of the first representative of this class of compounds.

If a solution of *(1)* in toluene is refluxed for 3 d then the crystalline product 1,3-diethoxy-1,1-diphenyl-1λ^5-phosphaindole *(5)* can subsequently be isolated (m.p., ^{1}H- and ^{31}P-NMR data, and yields of all new compounds are listed in Table 1). We consider the following mechanism to account for the formation of *(5)* from *(1)*: the phosphaallene ylide *(1)* first rearranges to *(3)*; it has not yet been established whether the phosphonium alkoxide *(2)* occurs as intermediate[3]. Compound *(3)* can be described in terms of the two principal limiting structures *(3A)* and *(3B)* which differ in their geometry and electron distribution. Reaction proceeds from *(3B)* in which intramolecular electrophilic attack by the C_β atom on one of the phenyl groups furnishes the intermediate σ complex *(4)*, which stabilizes by proton migration to form *(5)*.

The action of acetyl chloride on *(5)* leads to ethyl acetate and the phosphonium chloride *(6)*. The latter can be converted by sodium bis(trimethylsilyl)amide[4] at −25 °C into the five-membered cyclic phosphaallene ylide *(7)*, which is isolable in crystalline form. The compound can be stored for a limited period with cooling. The strong negative shift of the phosphorus signal in the ^{31}P-NMR spectrum [$\delta = -38.5$] relative to that of *(1)* [$\delta = -2.8$] is particularly striking.

The following reactions of *(7)* provide proof of its structure: Ethanol is added to form *(5)*[3]. Hydrolysis in an aqueous medium leads to the phosphane oxide *(8)*, also formed from *(5)* under the same conditions. Compound *(7)* reacts with methyl iodide to form the phosphonium iodide *(11)*.



Particular interest attaches to the reaction of *(7)* with carbonyl compounds in connection with mechanistic considerations concerning the course of the Wittig reaction. The phosphaallene ylide *(7)* reacts with aldehydes or ketones which do not possess an acidic CH_2 group to form the crystalline primary products of the Wittig reaction *(12A)*. The given arrangement of ligands on the pentacoordinated phosphorus (^{31}P-NMR: $\delta = +52.0$ to $+57.6$) is based on the known rules concerning the entry and departure of nucleophilic groups in interconversion of tetra- and pentacoordinated phosphorus compounds[5] and on the X-ray structure analysis of the adduct formed from hexaphenylcarbodiphosphorane with hexafluoroacetone[6]. Rupture of the P—C bond in the 1,2-oxaphosphetanes *(12A)* should only be possible if a ligand rearrangement of *(12A)* directed towards *(12B)* becomes effective[5]. How-

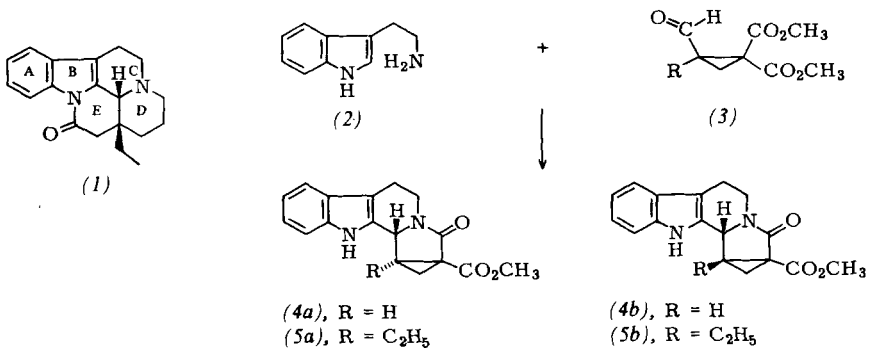
Simple Stereoselective Synthesis of Eburnamonine[**]



By *Friederike Klatte, Ulrich Rosentreter*, and *Ekkehard Winterfeldt*[*]

The regioselective ring-opening of cyclopropane derivatives with defined configurations can be used for the stereoselective synthesis of sp^3-hybridized centers[1]. In the intensively studied field of vincamines[2] we first chose to study the synthetic potential of eburnamonine *(1)* in which the *cis*-D,C linkage represents the critical stereochemical problem in this series.

We found a high degree of selectivity in the condensation of cyclopropanaldehyde *(3)*[3] with tryptamine *(2)*. When R = H, *(4a)* (*trans* isomer) is isolated exclusively as the kinetic product, and also when $R = C_2H_5$ the main product (85%) is *(5a)*—with only 15% of *(5b)* being formed. During the cyclization the indole residue thus attacks, in all cases, from the side which is turned away from the cyclopropane system. When R = H the configuration can easily be assigned with

the aid of the coupling constants of the crucial hydrogen atoms (*trans* coupling $J = 0$ Hz, *cis* coupling $J = 5.5$ Hz[4]); this is confirmed by the unusually large chemical shift of one of the cyclopropane protons of *(4b)* (obtained by the action of base on *(4a)*[5]) which is shielded by the indole aromatic ring in the *cis* position. Ring-opening reactions with *(5a)* proceed with excellent regioselectivity; with the Li salt of methyl cyanoacetate *(6)* is formed as the only reaction product. *(6)* can be converted to the lactam ketone *(7)* by two different routes (see formula scheme), with triethyloxonium hexafluorophosphate and subsequent hydrolysis *(7)* yields the β-ketoester *(8)*.

(5a') (5b') (6) (7) (8) (9) (10) (1)

Treatment of *(8)* with methoxide and subsequent reesterification affords the lactam ester *(9)* with a high degree of selectivity; *(9)* forms the dilactam *(10)* in trifluoroacetic acid at room temperature. Selective reduction according to the procedure of *Borch*[6] finally gives a good yield of eburnamonine *(1)* which shows identity with an authentic sample in all its properties[7].

[a] Very unpleasant smell. [b] Neat. [c] In cyclohexane.

We now wish to report the isolation and characterization of the acyl(thioacyl) sulfides *(2a)* to *(2e)* (see Table 1). They were obtained by reaction of sodium or piperidinium dithiocarboxylates *(3)* with acetyl chloride at 0°C. The structures were determined by UV, IR, ^{1}H-NMR spectroscopy and by elemental analysis. The UV absorption at 310 to 350 nm is due to the π→π* transition, and that at 570—585 nm to the n→π* transition of the thiocarbonyl group. The latter is shifted bathochromically much more strongly than in the bis(thioacyl) sulfides[1]. The acyl thioacyl sulfides are more sensitive to moisture than the bis(thioacyl) sulfides.

Synthesis of *(2a)*: To a stirred suspension of sodium 4-methyldithiobenzoate (380 mg, 2 mmol) in anhydrous *n*-hexane (20 ml) is added acetyl chloride (157 mg, 2 mmol) below 0°C and the reaction mixture stirred for 5 min under an argon atmosphere. The color of the solution changes from colorless to deep sky blue. The insoluble components are removed by filtration. Evaporation of the solvent under reduced pressure affords *(2a)* in almost quantitative yield.

The First Reaction of the N_2 Ligand with Bases; Reduction of Coordinated Dinitrogen by Nucleophilic Attack[1]

By *Dieter Sellmann* and *Woldemar Weiss*[*]

The following simplified reaction scheme [eq. (a)] is generally postulated for the reduction of N_2 ligands in transition metal complexes[2]:

$$[\overset{\ominus}{M}\text{–}\overset{\oplus}{N}\equiv N] \longleftrightarrow [\overset{\oplus}{M}\text{–}\overset{\cdot\cdot}{N}\text{=}\overset{\ominus}{N}:] \xrightarrow{2\,H^+} [\overset{\oplus}{M}\text{–}\underset{H}{\overset{\oplus}{N}}\text{=}NH]^{2+} \qquad (a)$$

[*] Professor Dr. D. Sellmann, Dr. W. Weiss
Laboratorium für Anorganische und Analytische Chemie der Gesamthochschule
Warburger Str. 100, D-4790 Paderborn (Germany)

A change in oxidation state of the metal M is accompanied by a transfer of electrons from the metal to the N_2 ligand, which then reacts with electrophilic reagents—*e.g.* H^+—or carbocations. The reactions of the complexes $[M(N_2)_2(diphos)_2]$ (M = Mo, W) with acids and alkyl or acyl halides and the reduction of N_2 in Ziegler-Natta systems are interpreted in this way[3,4].

We have now found that coordinated dinitrogen can be reduced in a fundamentally different and new way according to eq. (b):

$$[\overset{\ominus}{M}\text{–}\overset{\oplus}{N}\equiv N] \xrightarrow{X^-} [\overset{\ominus}{M}\text{–}\underset{X}{\overset{\oplus}{N}}\text{=}\overset{\ominus}{N}:]^- \xrightarrow{H^+} [\overset{\ominus}{M}\text{–}\underset{X}{\overset{\oplus}{N}}\text{=}NH] \qquad (b)$$

The oxidation state of the metal remains unchanged; the reduction of the N_2 ligand proceeds by external nucleophilic attack of $X^{\ominus}$—*e.g.* a carbanion—and subsequent protonation of the resulting diazenido complex. In the reactions investigated by us, both reaction steps can be observed separately. The reaction

$$C_5H_5(CO)_2Mn\text{–}N\equiv N + LiC_6H_5 \xrightarrow[-30\,°C]{THF} \underset{(1)}{Li[C_5H_5(CO)_2Mn\text{–}\underset{C_6H_5}{N}\text{=}N]}$$

affords the red-brown adduct *(1)*. The reaction can be monitored easily by IR spectroscopy; the ν_{N_2} absorption of $C_5H_5Mn(CO)_2N_2$ at 2165 cm^{-1} disappears and two new bands due to the ν_{CO} modes of *(1)* at 1868 and 1760 cm^{-1} can be observed. Concomitant partial decomposition and side reactions lead to acylate complexes, such as *e.g.* $Li[C_5H_5(CO)_2Mn\text{—}C(O)C_6H_5]$[5]. Addition of a stoichiometric amount of H_2SO_4 to the reaction mixture affords the deep red neutral phenyldiazene complex *(2)*, together with several side products, *e.g.* the hydroxyphenylcarbene complex $C_5H_5(CO)_2Mn\text{—}C(OH)C_6H_5$ [ν_{CO}(THF/Et_2O): 1954, 1887 cm^{-1}].

$$[C_5H_5(CO)_2Mn\text{–}\underset{C_6H_5}{N}\text{=}N]^- + H^+ \xrightarrow[0\,°C]{Et_2O/H_2O} \underset{(2)}{C_5H_5(CO)_2Mn\text{–}\underset{C_6H_5}{N}\text{=}NH}$$

(2) can be isolated chromatographically at −60°C [ν_{CO}(CH_2Cl_2, −62°C): 1955, 1885 cm^{-1}; ^{1}H-NMR (90 MHz, CD_2Cl_2, −62°C, rel. TMS): 14.50 (s, δNH), 7.55 (m, δC_6H_5), 4.65 (s, δC_5H_5); attempts to obtain a mass spectrum have so far failed[7]]. Addition of the tetrahydrofuran adduct $C_5H_5Mn(CO)_2THF$ to the reaction mixture leads to conversion of the deep red mononuclear complex *(2)* into the deep blue binuclear phenyldiazene complex *(3)*:

$$(2) + C_5H_5(CO)_2Mn(THF) \xrightarrow[-30\,^\circ C]{Et_2O} C_5H_5(CO)_2Mn-\underset{\underset{C_6H_5}{|}}{N}=\underset{|}{N}-Mn(CO)_2C_5H_5 + THF$$
$$(3)$$

(3) can be separated from decomposition products and any carbene complex still present by chromatography at −30 °C. Contrary to *(2)*, we were able to detect *(3)* also in the mass spectrum. [Spectroscopical data of *(3)*: $\nu_{CO}(CH_2Cl_2$, −62 °C): 1936, 1848 cm^{-1}; ^{1}H-NMR (90 MHz, $(CD_3)_2CO$, −62 °C, rel. TMS): 15.38 (s, δNH), 7.57 (m, δC_6H_5), 5.07 (s, δC_5H_5), 4.65 (s, δC_5H_5); MS (70 eV, T_Q 20 °C): M^+ at *m/e* 458]. Recrystallization from CH_2Cl_2 at −35 °C/−78 °C affords *(2)* and *(3)* as red-black and blue-black crystals, respectively. They are extremely sensitive towards oxidation, heat, acids and bases, and have to be handled at temperatures below −30 °C. Thermal decomposition of *(2)* in THF solution yields the starting N_2 complex:

$$C_5H_5(CO)_2Mn-\underset{\underset{C_6H_5}{|}}{N}=NH \xrightarrow[20\,^\circ C]{THF} C_5H_5(CO)_2Mn-N\equiv N + C_6H_6$$

The composition and structure of *(2)* and *(3)* have been confirmed by additional independent syntheses:

$$\underset{(4)}{C_5H_5(CO)_2Mn-\underset{\underset{C_6H_5}{|}}{N}H-NH_2} + H_2O_2 \xrightarrow[-78\,^\circ C]{THF/Cu^{2+}} 2\,H_2O + (2) + (3) + \text{decomposition products}$$

Oxidation of the phenylhydrazine complex *(4)*[6] yields a mixture of *(2)* and *(3)*. Separation and reaction of *(2)* with $C_5H_5(CO)_2MnTHF$ gives *(3)* again.

Our findings prove that ligating dinitrogen can be reduced by base addition under preservation of the N_2 coordination site. Addition reactions of $H^\ominus$-ions are under investigation to elucidate the relevance of the reaction for the mechanism of biological N_2 fixation.

Procedure

A solution of $C_5H_5Mn(CO)_2N_2$ (1450 mg, 7.1 mmol) in tetrahydrofuran (50 ml) is treated at −30 °C with a solution of LiC_6H_5 (7.1 mmol) in diethyl ether (16 ml). After 2 h the solvent is removed from the mixture by evaporation. The residue is dissolved in 40 ml of ether at −30 °C and neutralized by adding 18 ml 0.41 N H_2SO_4; the deep red ether phase is decanted off and dried over Na_2SO_4 at −30 °C. The solution is divided into two parts; the first part is evaporated, dissolved in toluene and chromatographed on SiO_2 at −60 °C. A yellow zone of $C_5H_5Mn(CO)_3$ is followed by a deep red zone, yielding after collection and evaporation 60 mg (5.9 %) $C_5H_5Mn(CO)_2N_2HC_6H_5$. The second part of the ether solution is allowed to react with 1240 mg (5 mmol) $C_5H_5Mn(CO)_2THF$ for 30 min at −30 °C. After evaporation and warming up to +20 °C for 3 min, the crude product is chromatographed on SiO_2 with toluene at −30 °C. After elution of $C_5H_5Mn(CO)_3$ and $C_5H_5Mn(CO)_2C(OH)C_6H_5$ a blue-black zone is eluted with toluene/THF = 1 : 1, which yields 70 mg (4.3 %) $[C_5H_5Mn(CO)_2]_2N_2HC_6H_5$. All reactions—including the synthesis of LiC_6H_5—are carried out under argon.

[6] Synthesis and proof of structure: *(4)* is obtained by reaction of $C_5H_5Mn(CO)_2THF$ with $C_6H_5N_2H_3$; the coordination of the C_6H_5NH group on the Mn center follows from the chemical shifts of NH and NH_2 protons on coordination.
[7] *Note added in proof* (11. 11. 1977): In the meantime a mass spectrum of *(2)* could be obtained: 15 eV, $T_S = -10$ °C, M^+ at *m/e* 282.

Catalyst-Dependent Product Distribution in the Reaction of 1-Hexene with a Hydrosilane and Carbon Monoxide[1]

By *Yoshio Seki, Shinji Murai, Akihiko Hidaka*, and *Noboru Sonoda*[*]

The $Co_2(CO)_8$-catalyzed reaction of cycloalkenes with hydrosilanes and carbon monoxide[2] gives only one product, a siloxymethylenecycloalkane, and the regioselectivity of this novel reaction type has yet to be elucidated. We now report the catalyst-dependent product distribution in the reaction of a linear *n*-alkene. Reaction of 1-hexene with diethyl(methyl)-silane and carbon monoxide affords four isomeric derivatives of siloxymethylene (regio- and stereoisomers); the effective catalysts found are listed in Table 1.

All of the effective catalysts are also known to be hydroformylation catalysts[3]. The total yields and the ratio of straight chain isomers (Table 1) are also similar to those observed in hydroformylation. A very good yield was obtained using $RhCl(PPh_3)_3/Et_3N$. The addition of triethylamine has already been reported to eliminate the induction period for hydroformylation of 1-pentene catalyzed by $RhCl(CO)(PPh_3)_2$[4]. A regioselectivity of 92 % was achieved by the addition of n-Bu_3P, as against 83 % for PPh_3, in the reaction using $Co_2(CO)_8$ (cf. Table 1; the corresponding proportions of straight chain

$Ru_3(CO)_{12}$ (0.4)	40	4	7	44	45	89
$RhCl(PPh_3)_3$ (0.4)	41	9	9	58	24	82
$RhCl(PPh_3)_3$ (0.4) + Et_3N (1.0)	88	8	13	56	23	79
$Co_2(CO)_8$ (0.4)	57	16	16	43	25	68
$Co_2(CO)_8$ (0.4) + nBu_3P (1.0)	18	2	6	70	22	92
$Co_2(CO)_8$ (0.4) + Ph_3P (1.0)	77	7	10	59	24	83

[a] Reaction conditions: 1-hexene (30 mmol), Et_2MeSiH (10 mmol), CO (50 kg/cm²), and catalyst in benzene (20 ml), 140 °C, 20 h.
[b] Determined by GLC.
[c] Proportion of straight-chain enol ethers (Z)-(2) plus (E)-(2) as determined by GLC in overall product.

isomers in the overall product of analogous hydroformylations of 1-hexene are 89.6 % and 62.4 %, respectively[5]).

These results clearly suggest that the new catalyzed reactions of olefins with hydrosilanes and carbon monoxide have basic features closely resembling those of hydroformylation.

Experimental:

A solution of 1-hexene (3.7 ml, 30 mmol), diethyl(methyl)silane (1.02 g, 10 mmol), triethylamine (0.1 g, 1 mmol), and $RhCl(PPh_3)_3$ (0.37 g, 0.4 mmol) in benzene (20 ml) is placed in a 100-ml stainless steel autoclave. The autoclave is flushed with N_2 (50 kg/cm²) and CO (50 kg/cm²), then charged with CO (50 kg/cm²) and heated at 140 °C with stirring. After 20 h, the autoclave is cooled and depressured. Analysis of the reaction mixture by GLC (Silicon OV-1, 5 %, on Uniport KS, 6 m, 115 °C) with an internal standard (*n*-tetradecane, RRT (relative retention time) = 1) showed it to contain enol silyl ethers [(Z)-(1), RRT = 0.36; (E)-(1), 0.39; (Z)-(2), 0.45; (E)-(2), 0.60] and disiloxane [$(Et_2MeSi)_2O$, RRT = 0.19] in 88 % (total) and 11 % yields, respectively. The relative yields of the enol silyl ethers are shown in Table 1. Analytical samples were obtained by fractional distillation (b.p. 105—115 °C/12 torr) followed by repeated preparative GLC[6].

BOOK REVIEWS

Handbuch der Arzneimittel-Analytik (Handbook of Drug Analysis). By *S. Ebel*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., x, 417 pp., 3 figs., 354 tables, plastic binding , DM 118.—.

This new handbook differs from the earlier works on drug analysis in that first place has not been given to the analytical procedure with subsequent treatment of the substances appearing in the various fractions. Instead, extensive lists of analytically important data are provided for some 600 drugs. The division of the material into pharmacologically important groups is both novel and useful. In the first place the user can obtain an impression of the substance in question from the medical information that is almost always known for a drug, but he can also see, without a time-wasting search,

what method of identification or quantitative determination will be most useful in a given case. The number of important cross references could be increased; in the case of hypnotics, for example, there is no reference to benzodiazepines.

The clearly tabulated information about the drugs provides an unusual wealth of individual data. These range from the formula, name, salts, molecular weight, identification reactions, UV spectra, and solubilities to chromatographic behavior and possible methods of quantitative determination. In these tables the methods of chromatography (qualitative and quantitative TLC, GC, HPLC) are treated in special detail, in line with their importance.

Welcome too are the numerous indications of possible sources of error, *e.g.* the warning that identical R_f values of a sample and a reference substance do not constitute proof of identity.

The book leaves no room for criticism as regards its scope or its topicality. Its value in the future depends on how rapidly it can be updated in later editions to reflect the steadily changing range of products on the market. Already some of the materials included (*e.g.* Aminorex and Iproniazid) are no longer manufactured.

Supported by 2000 references to the literature, the work is a "Handbook" in the true sense. In spite of the high price it can be recommended without any reservations as a reference work in analytical laboratories and for supplementing the practical exercises in the study of pharmaceutical analysis.

Norbert Kreutzkamp [NB 392 IE]

Thermochemical Kinetics. Methods for the Estimation of Thermochemical Data and Rate Parameters. By *S. W. Benson*, John Wiley & Sons, Inc., New York 1976. 2nd edit., xi, 320 pp., 15 figs., bound, $ 28.50.

This is a considerably expanded second edition of the very condensed collection, first published in 1968, of formulas and approximation methods for estimating essential thermodynamic data and kinetic parameters for reactions taking place in the gaseous state.

In the intervening years the monograph has earned a place as a standard work. Its particular value lies mainly in the numerous and logically arranged examples of calculations and in the large number of numerical examples reproduced in the text and in a special Appendix.

In the new version the material of the second chapter (Methods for the Estimation of Thermochemical Data) is expanded into six new sections which deal with the compensation effect and with radicals. As reworked, the third chapter is devoted solely to unimolecular reactions, and a new section on the Arrhenius parameters for bimolecular and termolecular reactions has been added.

Chapter 5 (Analysis of Complex Reaction Systems) has been extended by a further section (Steady-State Hypothesis); in an Appendix there is a new table of ionic and atomic polarizabilities. With these additions the book constitutes a very useful source of information to all chemists who have to consider the thermal and kinetic parameters of gas reactions in their work.

The author has taken the trouble to work the large number of new experimental results in the field into his second edition. As an experienced practical chemist he has decided, for the time being, to retain the calorie as the unit of energy and to limit the recalculations into SI units to a brief indication. This will make it much easier for the user to evaluate the data in the literature.

The book is well produced. Its importance is such that, in spite of its price, it deserves the wider availability that would follow from a German translation.

Theodor Ackermann [NB 387 IE]

Römpps Chemie-Lexikon (Römpp's Chemical Dictionary). Vol. 6: T—Z. By *O.-A. Neumüller*. Franckh'sche Verlagshandlung W. Keller & Co., Stuttgart 1977. 7th edit., 660 pp., +16 pp. Appendix, 135 figs., bound, DM 160.—.

The present volume 6 of this lexicon, which begins with Θ and ends with zyto, completes the 7th edition. The author took a full five years to work through the 30000 key words, and it paid off. Right up to the last volume one can sense the editor's effort to bring the keywords into line with the most recent state of the art (it is by no means uncommon to find references from 1976). Many keywords appear for the first time; some such are transition state, overvoltage, twistane, trifluoromethanesulfonic acid, and triforine. Depending on its specific importance, text that has grown too large has been pruned to a sensible length, other parts have been adjusted to the state of the science. The transition elements are now given 3.5 columns, whereas previously 9 lines were considered sufficient. The contribution on ultrasound has been considerably expanded, as also has been the one on vinyl chloride that recently came into the news. Where useful, structural formulas have been added (*e.g.* for Xylenol Blue). Remarkable also are the changes among industrial products: many new names appear and many have vanished. The tabular review of the sources of vitamins is very clear.

The last volume contains additionally an Index Appendix. This consists of a formula index by the *Hill* method and an index of English and French expressions with their German equivalents, the French part being distinctly slimmer than the English with its *ca.* 8000 terms.

There is much evidence of the meticulous care taken by the author, the collaborators, and the publisher in this production. One would only like to know that these praiseworthy efforts have proved worthwhile, and the publisher and the author can only learn this if as many colleagues as possible use Römpp, collect suggestions for the next edition, and do not forget to send them to the publisher. In such a rapidly changing field as chemistry this must be considered well in advance.

Christian Weiske [NB 390 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Rare Gas Solids, Vol. II. Edited by *M. L. Klein* and *J. A. Venables*. Academic Press, London 1977. xi, 610—1252 pp., bound, £ 26.00.—ISBN 0-12-413502-1

Contemporary Quantum Chemistry. An Introduction. By *J. Goodisman*. Plenum Press, New York 1977. x, 375 pp., bound, $ 39.00.—ISBN 0-306-30947-5

DIN Deutsches Institut für Normung e. V.: English Translations of German Standards 1977. List Including the Announcement of December 1976 in "DIN-Mitteilungen". Beuth Verlag GmbH, Berlin 1977. 200 pp., paper.

Rechenmethoden und ihre Anwendung in Physik und Chemie. By *H. Horvath*. Vol. 78 of "BI Hochschultaschenbücher". Bibliographisches Institut, Mannheim 1977. 142 pp., paper, DM 9.90.—ISBN 3-411-00078-3

Steroidhormone. Biosynthese, Stoffwechsel, Wirkung. By *L. Träger*. Springer-Verlag, Berlin 1977. vii, 349 pp., bound, DM 58.—.—ISBN 3-540-08012-0

VDI-Berichte Nr. 290: Verfahrenstechnik 1976. Lectures at Annual Conference in Düsseldorf. VDI-Verlag, Düsseldorf 1977. 561 pp., paper, DM 198.—.—ISBN 3-18-090290-6

Chemistry of Natural Protein Fibers. Edited by *R. S. Asquith*. John Wiley & Sons, London 1977. xx, 417 pp., bound, £ 20.00.—ISBN 0-471-99518-5

Developments in Food Carbohydrate-1. Edited by *G. G. Birch* and *R. S. Shallenberger*. Applied Science Publishers Ltd., London 1977. x, 189 pp., bound, $ 25.00.—ISBN 0-85334-733-6

Electron Spectroscopy: Theory, Techniques and Applications, Vol. 1. Edited by *C. R. Brundle* and *A. D. Banker*. Academic Press, London 1977. xv, 459 pp., bound £ 24.00.—ISBN 0-12-137801-2

Der feste Zustand. Eine Einführung in die Festkörperchemie anhand sieben ausgewählter Beispiele. Für Studenten der Chemie und der Physik. By *W. J. Moore*. From the series "uni-text". Vieweg, Braunschweig 1977. viii, 164 pp., paper, DM 22.80.—ISBN 3-528-03026-7

The Chemistry of Pyrroles. By *R. A. Jones* and *G. P. Bean*. Vol. 34 of the series "Organic Chemistry". Edited by *A. T. Blomquist* and *H. H. Wasserman*. Academic Press, London 1977. ix, 525 pp., bound, £ 21.00.—ISBN 0-12-389840-4

Oxides and Oxide Films, Vol. 5. Edited by *A. K. Vijh*. From the series "The Anodic Behavior of Metals and Semiconductors". Edited by *A. K. Vijh*. Marcel Dekker, New York 1977. xi, 184 pp., bound, SFr. 84.—.—ISBN 0-8247-6580-X

Physik für Naturwissenschaftler II. Elektrizität und Magnetismus, Optik. By *H. Neuert*. Vol. 728 of "BI Hochschultaschenbücher". Bibliographisches Institut, Mannheim 1977. pp. 179—373, paper, DM 12.80.—ISBN 3-411-00728-1

Organometallic Chemistry Reviews; Annual Surveys: Silicon-Tin-Lead. Edited by *D. Seyferth* and *R. B. King*. Journal of Organometallic Chemistry Library 4. Elsevier Scientific Publishing Company, Amsterdam 1977. 547 pp., bound, Dfl. 134.00.—ISBN 0-444-41591-2

The Prostaglandins, Vol. 3. Edited by *P. W. Ramwell*. Plenum Press, New York 1977. xii, 359 pp., bound, $ 47.40.—ISBN 0-306-37793-4

Hard and Soft Acids and Bases. By *Tse-Lok Ho*. Academic Press, New York 1977. xii, 209 pp., bound, $ 19.50.—ISBN 0-12-3500-50-8

Corrigendum

The following corrections should be made to the article "Heinrich Wieland Centennial: His Lifework and His Legacy Today" by *B. Witkop*, Angew. Chem. Int. Ed. Engl. *16*, 559 (1977):

1) *Leipelt*'s middle name was not *Carl* but *Konrad*.
2) *Leipelt* was not hanged but beheaded. Hanging as carried out under the Nazi Regime was a particularly slow and painful method of execution, reserved for only the "worst offenders".
3) *Leipelt* had hardly any contact with *Kurt Huber*. Nor is he known to have had contact with Frau *Huber*, apart from attempting to collect money for her. No further information is to be found in *Clara Huber*'s publication cited in ref.[90].
4) The trial was not a mock trial but a normal, essentially open trial.
5) The President of the Court was not *Freisler* but "Volksgerichtsrat" *Diescher*, who conducted the proceedings in a more or less civilized way.
6) *Wieland* did not exchange a handclaps with *Leipelt*. That was impossible in the courtroom. He was only able, while the court was being held *in camera*, to shake hands with the accused not involved in that part of the case. This he did insofar as they were members of his Institute.

We are grateful to Professor *Valentin Freise* for pointing out these errors.

SUBJECT INDEX

FP = Full paper (review article) LA = Literature abstract
SC = Short communication
G.E. = Reference to Volume *89* (1977) of the German Edition of Angewandte Chemie.
References are given for Review Articles and Short Communications only.

ABSOLUTE configuration, Relationship between the infrared rotatory dispersion of liquid-crystalline solutions of chiral molecules and their ~ (SC) 791 [G.E. 831]
Acetylacetone, New coordination form (SC) 858 [G.E. 896]
Acetylene, 3,4-Bis(trimethylsilyl)benzocyclobutene—synthesis by ~ cotrimerization and conversion into 1,2-dihydrocyclobuta[c]benzyne (SC) 399 [G.E. 413]
Transition metal-catalyzed cyclizations (LA) 271
Transition metal catalyzed reactions of organic halides with carbon monoxide, olefins, and ~-s (LA) 335
Activation volume, Determination of ~ $\Delta V^{\neq}$ of simple molecular rearrangements by high-resolution ^{1}H-NMR spectroscopy at high pressures (SC) 331 [G.E. 340]
Acyl chlorides, Unstable intermediates in the gaseous phase: Thermal decomposition of ~ RCOCl (SC) 105 [G.E. 106]
Reactions of ~, triethylamine, or ketenes with phosgeniminium salts (SC) 182 [G.E. 189]
N-Acyl isocyanides (SC) 262 [G.E. 272]
Acyl thioacyl sulfides, Isolation (SC) 879 [G.E. 917]
Addition, Intramolecular oxidative ~ of azopyridine to phosphorus(III) (SC) 865 [G.E. 903]
Addition compounds with polymeric chromium(II)-Schiff base complexes (SC) 859 [G.E. 897]
Adenine nucleotides, Investigations of translocation of mitochondrial ~ by means of nucleotide analogs (FP) 695 [G.E. 717]
Alcohols, Photolysis of saturated ~, ethers, and amines (LA) 804
Aldehydes, Homologization of ~ and ketones to thiiranes or S-vinyl thiocarbamates via 2-alkylimino-1,3-oxathiolanes (SC) 462 [G.E. 478]
Alkali metal complexes, Kinetics of formation by bicyclic cryptates (SC) 538 [G.E. 567]
Alkali metal derivatives, Di- and poly-~ of organic compounds (LA) 803
Alkaloids, Diastereoselective synthesis of the aporphine alkaloid (+)-cataline. Hydroxylation with vanadium(V) trifluoride oxide (SC) 730 [G.E. 739]
Simple stereoselective synthesis of eburnamonine (SC) 878 [G.E. 916]
Alkanes, Observation of a linear relationship between thermal stability and strain energy of ~ (SC) 875 [G.E. 913]
Alkylation of diethyl phosphoramidates—A simple route from primary to secondary amines (SC) 107 [G.E. 109]
Alkyne complexes, Synthesis of alkyne-bridged dinuclear complexes by reaction of trans-halotetracarbonyl(methylcarbyne)tungsten with methylenebis(diphenylarsane) (SC) 465 [G.E. 481]
Allylacetophenone, Doubly deprotonated ~. First example of a "direct" E^5 synthon (SC) 320 [G.E. 333]
Allyl alcohols, C—C linkage of carboxylic acids with ~ using 2-phenylglycine as vehicle (SC) 394 [G.E. 408]
Alternating copolymerization, Spontaneous ~ via zwitterion intermediates (FP) 826 [G.E. 867]
Aluminacyclopentadiene, Novel organonickel compounds from (pentaphenyl)-~ (SC) 183 [G.E. 179]
Aluminum, Bindung of urease to anodized sheet ~ (SC) 714 [G.E. 761]
Aluminum compounds, Synthesis and properties of tris(trimethylsilyl)aluminum (SC) 480 [G.E. 497]
Synthesis and structure determination of a 1,4-dialuminacyclohexadiene (SC) 539 [G.E. 563]
Amides, N-Acyl-N'-arylsulfonyldiazenes; detection and use in the synthesis of ~ (SC) 728 [G.E. 742]
Aminating reagents, O-Mesitylenesulfonylhydroxylamine and related ~ (LA) 270
Amines, Crown ether catalyzed reduction of aromatic nitro compounds to give ~ (SC) 41 [G.E. 43]
Alkylation of diethyl phosphoramidates—A simple route from primary to secondary ~ (SC) 107 [G.E. 109]
Photolysis of saturated alcohols, ethers, and ~ (LA) 804
Amino acid esters, Facile synthesis of α,β-dehydro ~ (SC) 327 [G.E. 344]
Amino acids, Synthesis of N-protected ~ with the aid of stannyl azides (SC) 550 [G.E. 570]
"Uncommon" ~ in plants (LA) 60
p-Aminophenols, Synthesis of substituted ~ from p-phenylenediamines (SC) 266 [G.E. 273]
Aminophosphanes, Synthesis of a secondary aminophosphane (SC) 486 [G.E. 501]
Amino sugars and N-glycosides by oxyamination of unsaturated carbohydrate derivatives (SC) 553 [G.E. 565]
Ammonium salts, Vinylenedionium salts containing different onium groups (SC) 471 [G.E. 488]
Reactions of (2-dialkylsulfoniovinyl)trialkyl-~ (SC) 473 [G.E. 489]
Inclusion of anions in macrotricyclic quaternary ~ (SC) 720 [G.E. 751]
α-Amylase, Protein inhibitors of ~ in wheat (LA) 804
Analytical chemistry, Grundlagen der analytischen Chemie (Book Review) 123
Analytical methods, Fully automatic potentiometric titrations (FP) 157 [G.E. 129]
The electro-optical Kerr effect in conformational analysis (FP) 663 [G.E. 725]
Angiotensin, Structure-activity relations of antagonists of the renin-~ system (LA) 201
Annelation reactions, Use of malononitrile for ~ (LA) 122
[15]Annulenone, syn-4,13;6,11-Dimethano-~, a 14π-analog of tropone—Synthesis and X-ray structure analysis (SC) 170 [G.E. 176]
Anthracene radical cations, Radical cation of [2.2](9,10)anthracenophane as a model for dimeric ~ (SC) 657 [G.E. 666]
[2.2](9,10)Anthracenophane, Radical cation of ~ as a model for dimeric anthracene radical cations (SC) 657 [G.E. 666]
Anthraquinones, Synthesis of hypericin and related mesonaphthodianthrones by alkaline dimerization of hydroxy-~ (SC) 46 [G.E. 56]
Antibiotics, Macrolides. Recent progress in chemistry and biochemistry (FP) 585 [G.E. 602]
Some aspects of ~ research (FP) 687 [G.E. 696]
Arabinoadenosine 3'-phosphate, Facile synthesis (SC) 317 [G.E. 328]
Aromaticity, "Organic metals"—intermolecular migration of ~ (FP) 519 [G.E. 534]
Arsabenzene, 1-Aryl-4-methoxyarsacyclohexadiene→2-aryl-~ rearrangement—An organoelement analog of the cyclohexadienol→benzene rearrangement (SC) 637 [G.E. 670]
Arsanes, Phenyl-[2,2-dimethyl-1-(trimethylsiloxy)propylidene]arsane, an arsane with an isolated As=C bond (SC) 463 [G.E. 477]
Synthesis of alkyne-bridged dinuclear complexes by reaction of trans-halotetracarbonyl(methylcarbyne)tungsten with methylenebis(diphenylarsane) (SC) 465 [G.E. 481]
2C-chain elongation of lithioalkanes with diphenylvinylarsane and phenyl vinyl selenide (SC) 710 [G.E. 760]
Arsenic compounds, Lithiomethyl(diphenyl)-arsane oxide, a new reagent (SC) 53 [G.E 52]
Catalytic activity by opening of metal-metal bonds (SC) 188 [G.E. 197]
An organometallic five-membered ring with hetero-metal-metal bonding (SC) 332 [G.E. 341]
Versatile principle for the synthesis of functionalized hydrocarbons via organo-~ (SC) 709 [G.E. 759]
Ba_3A_{14}, the first compound to contain the cluster anion As_7^{3-} (SC) 857 [G.E. 895]
Arsonium ylides, Reaction with carbonyl compounds—Effect of substituents at arsenic (SC) 487 [G.E. 502]
Ascorbic acid, Reaction with dicyanocobyrinic heptamethyl ester (SC) 481 [G.E. 486]
Asymmetric induction in the total synthesis of 19-norsteroids (LA) 201
Atmosphere, Analysis of soil ~ by gas chromatography (LA) 419
Atmospheric chemistry (Book Review) 733
2H-Azirines, Nickel(II)-catalyzed synthesis of pyrroles from ~ and activated ketones (SC) 647 [G.E. 672]
Photochemistry (LA) 121
Azo compounds, [2+2]- and [4+2]-cycloadditions of arylazoalkenes (SC) 58 [G.E. 59]
Azodicarboxylates, 2,3-Dioxabicyclo[2.2.2]octane by selective reduction of double bonds with ~ (SC) 713 [G.E. 762]
Azuleno[4,5,6-cd]phenalene; a novel nonalternant isomer of benzo[a]pyrene (SC) 784 [G.E. 821]

BARBIER reaction—A one-step alternative for syntheses via organomagnesium compounds (LA) 271
Barium compounds, Ba_3A_{14}, the first compound to contain the cluster anion As_7^{3-} (SC) 857 [G.E. 895]
Barium disilicide, Crystal structure at high pressures (SC) 659 [G.E. 673]
Benzimidazole, Model of internal monooxygenase catalyzed reactions: copper-catalyzed autoxidation of bis(1-methylbenzimidazol-2-yl)methane (SC) 189 [G.E. 185]
Benzocyclobutene, 3,4-Bis(trimethylsilyl)-~—Synthesis by acetylene cotrimerization and conversion into 1,2-dihydrocyclobuta[c]benzyne (SC) 399 [G.E. 413]
Benzocyclobutenone, Formation by gas-phase pyrolysis (SC) 469 [G.E. 485]
Benzoin, 2,3,11,12-Tetraphenyl-1,4,7,10,13,16-hexaoxa-2,11-cyclooctadecadiene: A new crown ether from ~ (SC) 467 [G.E. 484]
Benzo[a]pyrene, Synthesis of perdeuterio-~ (SC) 656 [G.E. 667]
Azuleno[4,5,6-cd]phenalene; a novel nonalternant isomer of ~ (SC) 784 [G.E. 821]
5H-[1]Benzoselenino[2,3-b]pyridine—A novel heterocyclic ring system (SC) 319 [G.E. 329]
2,1,3-Benzothiadiazine, A novel heteroaromatic system: 2,1,3-Benzothiadiazinylium derivatives (SC) 780 [G.E. 826]

Bicyclo[3.2.0]heptanones, Uses (LA) 419
Bicyclo[5.1.0]octa-2,4-dienes, Carbo-Claisen rearrangement of 8-endo-phenyl-~ (SC) 711 [G.E. 763]
Bicyclophosphoranes, Intramolecular oxidative addition of azopyridine to phosphorus(III) (SC) 865 [G.E. 903]
Bilatriene-abc, A geometrically isomeric ~ (SC) 470 [G.E. 487]
Bile pigments, A geometrically isomeric bilatriene-abc (SC) 470 [G.E. 487]
Binding energy, entropy, and enzymic catalysis (FP) 449 [G.E. 456]
Biological technology, Utilization of microbes—Modern developments in ~ (FP) 205 [I.E. 211]
Biorhythms, Pineal gland ~ (LA) 122
Birth control, Role in the survival of the human race (FP) 506 [G.E. 513]
2,6-Bisazoniabicyclo[5.1.0]octa-2,5-diene, Degenerate Cope rearrangement of ~ dication (SC) 643 [G.E. 668]
Bis(thioacyl) sulfide, New aliphatic thiacylating reagents; preparation of tert-butyl esters of aliphatic dithiocarboxylic acids via ~ (SC) 786 [G.E. 820]
2,4-Diisopropyl-1,3-dithietane-2,4-diyl bis(dithioisobutyrate), a dimeric form of ~ (SC) 787 [G.E. 820]
Bis(trimethylsilyl)magnesium—The first organosilylmagnesium compound isolated (SC) 247 [G.E. 257]
Boc-azide, Serious detonation during the preparation of tert-butyloxycarbonyl azide (~) (SC) 115 [G.E. 119]
Bonding, Experimental electron densities and chemical ~ (FP) 32 [G.E. 33]
The surface chemical bond (FP) 92 [G.E. 94]
Early history of the quantum mechanical treatment of the chemical bond (FP) 87 [G.E. 89]
The Pauli principle and chemical ~ in molecules and solids (FP) 294 [G.E. 317]
Novel 3z-2e bond system (SC) 248 [G.E. 257]
Bond lengths, Diastereomers with differing ~: Structure analysis of the diastereomeric forms of μ-(1,2-dichloro-1,2-diphenyldiphosphane)bis(pentacarbonylchromium) (SC) 260 [G.E. 268]
Boranes, Synthesis and dynamic behavior of pentamethylcyclopentadienyl-~ (SC) 41 [G.E. 44]
New nido-carbaborane type by η^1—η^5 rearrangement of pentamethylcyclopentadienyl-~ (SC) 330 [G.E. 339]
Borates, Isolation of isomeric iodohydro-~ of type $[B_{10}H_{10-n}I_n]^{2-}$ (SC) 398 [G.E. 412]
Borole, Two routes to complex derivatives (SC) 42 [G.E. 43]
Boron compounds, Isolation of halohydroborates of type $[B_{10}H_{10-n}X_n]$ (SC) 173 [G.E. 195]
Δ^4-1,3,2-Diazaborolines as complex ligands (SC) 249 [G.E. 258]
Crystal structure of B_2S_3: Four-membered B_2S_2 rings and six-membered B_3S_3 rings (SC) 313 [G.E. 327]
μ-Thiadiborolene-bis(η-thiadiborolenecobalt)—A "homogeneous" triple-decker sandwich with three heterocyclic ligands (SC) 333 [G.E. 346]
Boron-nitrogen heterocycles, New pathways to four-membered ~ (SC) 478 [G.E. 494]
Bromine compounds, Difluorooxobromine(V) ion, $BrOF_2^+$ (SC) 461 [G.E. 476]
Butadiene, Control of the direction of addition in the nickel-catalyzed 2:1-cooligomerization of ~ with monoolefins by perturbation of the monoolefin (SC) 252 [G.E. 260]
Control of the nickel-catalyzed cooligomerization of butadiene with Schiff bases by cocatalysts (SC) 253 [G.E. 261]
tert-Butylation, Side reactions in peptide synthesis: ~ of tryptophan (SC) 317 [G.E. 330]
tert-Butyloxycarbonyl azide, Serious detonation during the preparation of ~ (Boc-azide) (SC) 115 [G.E. 119]
CALCIUM isotope effect, Dependence of ~ upon electrolyte concentration in ion-exchange chromatography (SC) 719 [G.E. 753]
Carbaboranes, New nido-carbaborane type by η^1—η^5 rearrangement of pentamethylcyclopentadienylboranes (SC) 330 [G.E. 339]
Carbanions, Nucleophilic substitution of vinylic hydrogen atoms by ~ (SC) 44 [G.E. 46]
Fast reactions of ~ and carbocations in solution (LA) 122
Carbene reactions, CIDNP studies on ~ (LA) 419
Carbenes, Thermal and photochemical cycloelimination of nitrogen (FP) 835 [G.E. 876]
Carbene addition to dicarbonyl(η-cyclopentadienyl)cobalt (SC) 555 [G.E. 557]
α-Oxocarbene-oxirene isomerization: Photolysis of [1-^{13}C]-2-diazo-1-phenyl-1-propanone and [2-^{13}C]-1-diazo-1-phenyl-2-propanone (SC) 781 [G.E. 827]
Carbocations, Fast reactions of carbanions and ~ in solution (LA) 122
Carbo-Claisen rearrangement of 8-endo-phenylbicyclo[5.1.0]octa-2,4-dienes (SC) 711 [G.E. 763]
Carbodiimides, New reagents for synthesis of heterocycles from ~ and phosgeniminium salts (SC) 181 [G.E. 188]
Silatautomeric organyl-~/cyanamides (SC) 311 [G.E. 336]
~ as source of isocyanide and carbonyl ligands (SC) 641 [G.E. 660]
"Carbodiphosphoranes" by a new rearrangement of phosphorus ylides (SC) 417 [G.E. 428]
Carbohydrates, α-Glycosidic linkage of D-ribofuranose (SC) 48 [G.E. 58]
Tetraaxial conformation of 1,2,3,4-tetra-O-benzoyl-β-D-xylopyranose (SC) 52 [G.E. 51]
Amino sugars and N-glycosides by oxyamination of unsaturated carbohydrate derivatives (SC) 553 [G.E. 565]
Simple de-novo synthesis of reactive pseudoglycals (hex-2-enopyranosides)—Stereospecific α-glycoside coupling (SC) 783 [G.E. 822]
Structure of ketoses and their biologically important phosphate esters in solution (LA) 201
Carbon disulfide, Intramolecular mobility in ~ complexes of manganese (SC) 193 [G.E. 191]
Acceptor function of η^2-bonded ~ ligands (SC) 194 [G.E. 192]
Carbon monoxide, Synthetic and mechanistic aspects of inorganic insertion reactions. Insertion of ~ (FP) 299 [G.E. 305]
Elimination of ~ from cyclic carbonyl compounds by flow pyrolysis (SC) 50 [G.E. 50]
Reaction of olefins with silane and ~ catalyzed by $Co_2(CO)_8$ (SC) 174 [G.E. 196]
$Co_2(CO)_8$ catalyzed reactions of cyclic ethers with hydrosilanes and ~ (SC) 789 [G.E. 818]
Catalyst dependent product distribution in the reaction of 1-hexene with a hydrosilane and ~ (SC) 881 [G.E. 919]
Transition metal catalyzed reactions of organic halides with ~, olefins, and acetylenes (LA) 335
Carbonylation, δ-Lactones by ~ of vinyloxiranes (SC) 50 [G.E. 47]
Carbonyl compounds, Elimination of CO from cyclic ~ by flow pyrolysis (SC) 50 [G.E. 50]
Carbonyl groups and thiocarbonyl groups (LA) 732
Carbonyl olefination with (triphenylstannyl)-methyllithium (SC) 862 [G.E. 900]
Carbonyl ylides, Electrocyclic ring opening reactions of ethylene oxides (FP) 572 [G.E. 589]
Carboxylic acids, C—C linkage of ~ with allyl alcohols using 2-phenylglycine as vehicle (SC) 394 [G.E. 408]
Carbyne complexes, Triphenylsilyl-~ of tungsten (SC) 401 [G.E. 416]
Carcinogens, Synthesis of perdeuteriobenzo[a]pyrene (SC) 656 [G.E. 667]
Azuleno[4.5,6-cd]phenalene; a novel nonalternant isomer of benzo[a]pyrene (SC) 784 [G.E. 821]
(+)-Cataline, Diastereoselective synthesis of the aporphine alkaloid ~. Hydroxylation with vanadium(V) trifluoride oxide (SC) 730 [G.E. 739]
Catalysis, Advances in phase-transfer ~ (FP) 493 [G.E. 521]
Titanium tetrachloride in organic synthesis (FP) 817 [G.E. 858]
Catalyst dependent product distribution in the reaction of 1-hexene with a hydrosilane and carbon monoxide (SC) 881 [G.E. 919]
Recent developments in heterogeneous ~, especially ~ by metals (LA) 271
Applications of Mössbauer spectroscopy to the study of heterogeneous ~ (LA) 335
Cationization, Quantitative field desorption mass spectrometry; stable isotope dilution and ~ (SC) 184 [G.E. 180]
Ceramics, Phosphates in ~ (LA) 490
Chain elongation, Titanium tetrachloride in organic synthesis (FP) 817 [G.E. 858]
Lithiomethyl(diphenyl)arsane oxide, a new reagent (SC) 53 [G.E. 52]
C—C linkage of carboxylic acids with allyl alcohols using 2-phenylglycine as vehicle (SC) 394 [G.E. 408]
2C-~ of lithioalkanes with diphenylvinylarsane and phenyl vinyl selenide (SC) 710 [G.E. 760]
Charge transfer interactions, Indirectly transmitted ~: Multilayered [2.2]paracyclophane quinhydrones (SC) 801 [G.E. 841]
Chemical dictionary, Römpps Chemie-Lexikon (Book Review) 883
Chemiluminescence, Analytical applications (FP) 225 [G.E. 220]
Chemisorption, The surface chemical bond (FP) 92 [G.E. 94]
Chirality, Chiral derivatives of achiral molecules. Standard classes and the problem of a right-left classification (FP) 65 [G.E. 67]
Chlorine isotopes, Determination of reaction enthalpy in the ion-exchange of ~ (SC) 114 [G.E. 118]
Chlorobenzenes, Formation of chlorophenols by microbial transformation of ~ (SC) 645 [G.E. 680]
N-Chlorocarbonyl isocyanate, Synthesis and reactions (FP) 743 [G.E. 789]
Chlorofluorocarbon/ozone theory—A scientific status report (FP) 513 [G.E. 507]
Chlorofluorocarbons, The chlorofluorocarbon/ozone theory—A scientific status report (FP) 513 [G.E. 507]
(Chloromethylene)triphenylphosphorane (SC) 180 [G.E. 203]
Chlorophenols, Formation by microbial transformation of chlorobenzenes (SC) 645 [G.E. 680]
Chlorotris(2,2,2-trifluoro-1-trifluoromethylethoxy)sulfurane, A stable acyclic alkoxyhalosulfurane: ~ (SC) 862 [G.E. 900]
Chromatin, Elucidation of structure and specificity (LA) 122
Chromatography, Column ~ on triacetylcellulose. Preparative separation of enantiomeric diaziridines (SC) 405 [G.E. 419]
Chromium complexes, cis-Bis(dinitrogen)tetrakis(trimethylphosphane)chromium (SC) 56 [G.E. 57]
Acceptor function of η^2-bonded CS_2 ligands (SC) 194 [G.E. 192]
Δ^4-1,3,2-Diazaborolines as complex ligands (SC) 249 [G.E. 258]
Synthesis of dinuclear complexes containing PCl_2 and PF_2 bridges (SC) 408 [G.E. 421]
$[C_5H_5(CO)_2Mn—N_2H_2—Cr(CO)_5]$, a complex with a diazene bridge and two different coordination centers (SC) 464 [G.E. 480]
μ-(η-Biphenyl)bis[(η-benzene)chromium(0)]—The arenechromium analog of biferrocene (SC) 479 [G.E. 497]
Pentacarbonyl(dimesitylgermanediyl)chromium(0) (SC) 639 [G.E. 675]
Addition compounds with polymeric chro-

mium(II)-Schiff base complexes (SC) 859 [G.E. 897]
Bis(η⁶-naphthalene)chromium(0) (SC) 870 [G.E. 908]
Chronology of chemistry, Chronologie Chemie 1800—1970 (Book Review) 733
Claisen rearrangement, Carbo-~ of 8-endophenylbicyclo[5.1.0]octa-2,4-dienes (SC) 711 [G.E. 763]
Cluster anion, Ba_3A_{14}, the first compound to contain the ~ As_7^{3-} (SC) 857 [G.E. 895]
Cobalt complexes, Partial nitrosylation of dicarbonyl(η-cyclopentadienyl)cobalt (SC) 172 [G.E. 186]
"Supersandwich"-type trinuclear complexes with a spiro center (SC) 324 [G.E. 332]
μ-Thiadiborolene-bis(η-thiadiborolenecobalt)—A "homogeneous" triple-decker sandwich with three heterocyclic ligands (SC) 333 [G.E. 346]
Carbene addition to dicarbonyl(η-cyclopentadienyl)cobalt (SC) 555 [G.E. 557]
Synthesis and reactivity of hetero dinuclear complexes containing a Mn—Co bond (SC) 649 [G.E. 656]
$Co_5(CO)_{11}(PR_2)_3$, a novel type of pentanuclear cluster (SC) 731 [G.E. 738]
$Co_2(CO)_8$ catalyzed reactions of cyclic ethers with hydrosilanes and carbon monoxide (SC) 789 [G.E. 818]
An unusually facile electrophilic substitution at the cyclopentadienyl ring in a half-sandwich complex (SC) 794 [G.E. 835]
Detection of rigid rotamers in disubstituted cyclopentadienylcobalt complexes (SC) 795 [G.E. 836]
(η-Cyclopentadienyl)cobalt-μ-(η-diborolenyl)(η-cyclopentadienyl)iron—A triple decker sandwich complex containing two different metals (SC) 857 [G.E. 895]
Cobalt compounds, Reaction of olefins with silane and carbon monoxide catalyzed by $Co_2(CO)_8$ (SC) 174 [G.E. 196]
Catalytic activity by opening of metal-metal bonds (SC) 188 [G.E. 197]
An organometallic five-membered ring with hetero-metal-metal bonding (SC) 332 [G.E. 341]
Cobalt-catalyzed one-step synthesis of annelated pyridines (SC) 708 [G.E. 758]
Cobyrinic heptamethyl ester, Reaction of dicyano-~ with ascorbic acid (SC) 481 [G.E. 486]
Coenzyme B_{12}, New developments in the field of vitamin B_{12}: Enzymatic reactions dependent upon corrins and ~ (FP) 233 [G.E. 239]
Collision activation mass spectrometry with novel analysis technique (SC) 120 [G.E. 115]
Complexation chromatography, Resolution of a chiral olefin by ~ on an optically active rhodium(I) complex (SC) 110 [G.E. 113]
Complexes, New varieties of sandwich ~ (FP) 1 [G.E. 1]
Complex ligands, New coordination form of acetylacetone (SC) 858 [G.E. 896]
Configuration, Assignment of ~ of olefins, diols, and epoxides. Quantitative analysis of their stereoisomeric mixtures (SC) 100 [G.E. 103]
Conformation, Tetraaxial ~ of 1,2,3,4-tetra-O-benzoyl-β-D-xylopyranose (SC) 52 [G.E. 51]
Configuration, ~, and dynamics of octalene (SC) 972 [G.E. 910]
Determination of ~ of hydrocarbon chains in solution by photochemical probes (LA) 557
Conformational analysis, The electro-optical Kerr effect in ~ (FP) 663 [G.E. 725]
Conformers, Chair and boat: stable ~ of an eight-membered ring system (SC) 185 [G.E. 185]
Conjugation, Through-bond interaction between two mutually perpendicular systems—A new possibility of ~ (SC) 110 [G.E. 122]
Contraception, Role of birth control in the survival of the human race (FP) 506 [G.E. 513]
Coordination, New ~ form of acetylacetone (SC) 858 [G.E. 896]
Cope rearrangement, Degenerate ~ of the 2,6-bisazoniabicyclo[5.1.0]octa-2,5-diene dication (SC) 643 [G.E. 668]
Carbo-Claisen rearrangement of 8-endophenylbicyclo[5.1.0]octa-2,4-dienes (SC) 711 [G.E. 763]
Copolymerization, Spontaneous alternating ~ via zwitterion intermediates (FP) 826 [G.E. 867]
Copper compounds, Model of internal monooxygenase catalyzed reactions: copper-catalyzed autoxidation of bis(1-methylbenzimidazol-2-yl)methane (SC) 189 [G.E. 185]
Corrinoids, (A→D)-Cyclization of a nickel(II) Δ^{18}-dehydro-1-methylidene-1,19-secocorrinate (SC) 459 [G.E. 475]
Reaction of dicyanocobyrinic heptamethyl ester with ascorbic acid (SC) 481 [G.E. 486]
Corrins, New developments in the field of vitamin B_{12}: Enzymatic reactions dependent upon ~ and coenzyme B_{12} (FP) 233 [G.E. 239]
(A→D)-Cyclization of a nickel(II) Δ^{18}-dehydro-1-methylidene-1,19-secocorrinate (SC) 459 [G.E. 475]
Crown ethers, Crown ether catalyzed reduction of aromatic nitro compounds to give amines (SC) 41 [G.E. 43]
"Noncyclic ~": The terminal group concept (SC) 396 [G.E. 410]
2,3,11,12-Tetraphenyl-1,4,7,10,13,16-hexaoxa-2,11-cyclooctadecadiene: A new crown ether from benzoin (SC) 467 [G.E. 484]
Cryptates, Kinetics of alkali metal complex formation by bicyclic ~ (SC) 538 [G.E. 567]
Noncyclic ~ (SC) 548 [G.E. 564]
Cubanes, Synthesis and absolute configuration of enantiomerically pure D_3-trishomo-~ (pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane) and trishomocubanones (SC) 116 [G.E. 119]
Hydrogenation (SC) 415 [G.E. 430]
Cubane structure, $[\eta^5\text{-}C_5H_5Mo(CO)_3HgMo]_4$, a metal cluster with ~ (SC) 704 [G.E. 746]
Cyanamides, Silatautomeric organylcarbodiimides/~ (SC) 311 [G.E. 336]
Cyclization, 4-Hydroxy-2-cyclopenten-1-ones from ketones and 3-nitropropionyl chloride. A facile method for the construction of five-membered rings (SC) 321 [G.E. 334]
Cycloadditions, Intramolecular [4+2] and [3+2] ~ in organic synthesis (FP) 10 [G.E. 10]
[2+2]- and [4+2]-~ of arylazoalkenes (SC) 58 [G.E. 59]
Geometrical dependence of [2π+2σ]photocycloaddition (SC) 103 [G.E. 111]
Cycloaddition of phenyl isocyanate to a diaziridinimine (SC) 109 [G.E. 112]
Extension of the scope of anionic ~ by activating organoelement groups (SC) 119 [G.E. 107]
Palladium(0)-catalyzed [2σ+2π]~ of methylenecyclopropane to alkenes (SC) 249 [G.E. 254]
Photochemical [2+2]-~ between parallel CC and NN double bonds (SC) 777 [G.E. 825]
Cyclobutadiene, Diradical-type behavior of tri-tert-butyl-~ (SC) 51 [G.E. 49]
Observed and calculated electron-density distribution in the bonds of a rectangular ~ (SC) 187 [G.E. 194]
Reversible transition between a [4]radialene and a ~ by electron transfer (SC) 410 [G.E. 424]
Cyclodepsipeptides, Synthesis by cyclooligomerization (SC) 113 [G.E. 117]
Cycloelimination, Thermal and photochemical ~ of nitrogen (FP) 835 [G.E. 876]
Cycloheptadienes, Models for the biosynthesis of naturally occurring divinylcyclopropanes and ~ (SC) 192 [G.E. 187]
Cyclohexanes, Substituted phenyl-~—A new class of liquid-crystalline compounds (SC) 100 [G.E. 103]
Cyclohexasilane, Preparation (SC) 403 [G.E. 417]
cis,trans-1,5-Cyclooctadienes (SC) 406 [G.E. 420]
Cyclooctasulfur, Detection of S_6 and S_7 in molten ~ (SC) 112 [G.E. 114]
Cyclopentadiene, An unusually facile electrophilic substitution at the cyclopentadienyl ring in a half-sandwich complex (SC) 794 [G.E. 835]
Cyclopentadienone, A trimeric ~ derivative by photolysis of 3,5-diphenyl-4H-thiopyran-4-one 1,1-dioxide with daylight (SC) 653 [G.E. 659]
Cyclopentadienylborane, Synthesis and dynamic behavior of pentamethyl-~ (SC) 41 [G.E. 44]
(η-Cyclopentadienyl)cobalt-μ-(η-diborolenyl)(η-cyclopentadienyl)iron—A triple decker sandwich complex containing two different metals (SC) 857 [G.E. 895]
2-Cyclopenten-1-ones, 4-Hydroxy-~ from ketones and 3-nitropropionyl chloride. A facile method for the construction of five-membered rings (SC) 321 [G.E. 334]
Cyclophanes, [2.2.2.2](1,2,3,5)cyclophane (SC) 191 [G.E. 177]
Cyclopropenes as vinylcarbenoids: intermolecular carbene-addition reactions of sulfinyl- and sulfonylcyclopropenes at room temperature (SC) 323 [G.E. 331]
Cyclopropenone, Novel transformation of diphenyl-~: Double bond cleavage in the reaction with platinum complexes (SC) 793 [G.E. 838]
Cycloreversion, Formation of diazo compounds on degradation of 2,3-diazabicyclo[3.1.0]hex-2-enes: [3+2]-cycloreversion (SC) 867 [G.E. 905]
Cyclotetra(λ^3-phosphazanes), $(RPNCH_3)_4$, — Synthesis and crystal structure analysis (SC) 407 [G.E. 423]

DECARBOXYLATIVE dehydration of β-hydroxycarboxylic acids by redox condensation: a novel olefin synthesis (SC) 255 [G.E. 265]
α,β-Dehydro amino acid esters, Facile synthesis (SC) 327 [G.E. 344]
Dehydro amino acids, Activation of double bonds in ~: A model for pyridoxal-containing enzymes in elimination-addition reactions (SC) 328 [G.E. 345]
Deprotonation, Doubly deprotonated allylacetophenone. First example of a "direct" E^5 synthon (SC) 320 [G.E. 333]
Functional vinyl carbanions—~ of β-(1-pyrrolidinyl)acrylonitrile (SC) 853 [G.E. 891]
Depsipeptides, Synthesis of cyclo-~ by cyclooligomerization (SC) 113 [G.E. 117]
Desalination, Principles of osmotic ~ (FP) 607 [G.E. 624]
Detergents, Micelles of ionic ~ in aqueous solutions (LA) 490
Detonation, Serious ~ during the preparation of tert-butyloxycarbonyl azide (Boc-azide) (SC) 115 [G.E. 119]
Deuteriobenzo[a]pyrene, Synthesis of per-~ (SC) 656 [G.E. 667]
1,4-Dialuminacyclohexadiene, Synthesis and structure determination (SC) 539 [G.E. 563]
Diastereoisomers with differing bond lengths: structure analysis of the diastereomeric forms of μ-(1,2-dichloro-1,2-diphenyldiphosphane)bis(pentacarbonylchromium) (SC) 260 [G.E. 268]
2,3-Diazabicyclo[3.1.0]hex-2-enes, Formation of diazo compounds on degradation of ~: [3+2]-cycloreversion (SC) 867 [G.E. 905]
Δ^4-1,3,2-Diazaborolines as complex ligands (SC) 249 [G.E. 258]
Diazadiphosphetidine, A ~ with ring-stabilized "pentaamidophosphorus" (SC) 263 [G.E. 268]
cis-2-Telluro-1,3,2λ^5,4λ^3-~—A fluxional redox system (SC) 486 [G.E. 500]
Synthesis of bridged 1,3,2λ^3,4λ^3—~ (SC) 797 [G.E. 829]
Diazene, N-Acyl-N'-arylsulfonyl-~-s; detection and use in synthesis of amides (SC) 728 [G.E. 742]

cis- and trans-~ (Diimine) (SC) 780 [G.E. 828]
Diazene complexes, $[C_5H_5(CO)_2Mn—N_2H_2—Cr(CO)_5]$, a complex with a diazene bridge and two different coordination centers (SC) 464 [G.E. 480]
Diazene derivatives, First reaction of the N_2 ligand with bases; reduction of coordinated dinitrogen by nucleophilic attack (SC) 880 [G.E. 918]
Diaziridines, Column chromatography on triacetylcellulose. Preparative separation of enantiomeric ~ (SC) 405 [G.E. 419]
Synthesis and chemistry of alkylidene-~ (SC) 475 [G.E. 492]
Diaziridinimine, Cycloaddition of phenyl isocyanate to a ~ (SC) 109 [G.E. 112]
Spiro compounds having a nonplanar 1,4-dihydropyridine ring from ~-s and dimethyl acetylenedicarboxylate (SC) 177 [G.E. 202]
Diazoacetate, Reaction of alkenylfurans with ethyl ~ (SC) 646 [G.E. 674]
Diazo compounds, α-Oxocarbene-oxirene isomerization: Photolysis of [1-^{13}C]-2-diazo-1-phenyl-1-propanone and [2-^{13}C]-1-diazo-1-phenyl-2-propanone (SC) 781 [G.E. 827]
Formation on degradation of 2,3-diazabicyclo[3.1.0]hex-2-enes: [3 + 2]-cycloreversion (SC) 867 [G.E. 905]
Diazomethane, Iso-~ complexes (SC) 707 [G.E. 752]
"o,p'-Dibenzene" (3—6-η-tricyclo[6.2.2.0^{2,7}]-dodeca-3,5,9,11-tetraene)tricarbonyliron, a stable transition metal complex of ~ (SC) 717 [G.E. 754]
1,3-Diborolenes, η-Cyclopentadienyl(η-diborolenyl)nickel—A diamagnetic nickelocene analog (SC) 468 [G.E. 483]
α-Dicarbonyl systems, Interaction between the nonbonding orbitals of ~ and π or Walsh orbitals (SC) 400 [G.E. 414]
Dichloronitronium ion, Dichloronitronium hexachloroantimonate, $ONCl_2SbCl_6$ (SC) 545 [G.E. 569]
Dichlorophosphoranes, Hydrogenolysis of trisubstituted ~—A new method for deoxygenation of oxophosphoranes (SC) 552 [G.E. 558]
Dicyanocobyrinic heptamethyl ester, Reaction with ascorbic acid (SC) 481 [G.E. 486]
Dicyanophosphide (SC) 704 [G.E. 747]
Dienes, Selective monofunctionalization of non-conjugated ~ by nitrogen dioxide/iodine monoaddition (SC) 246 [G.E. 253]
Imidazolidin-2-ones by anodic oxidation of conjugated ~ in the presence of dimethylurea (SC) 413 [G.E. 425]
Difluorooxobromine(V) ion, $BrOF_2^+$ (SC) 461 [G.E. 476]
1,2-Dihydrocyclobuta[c]benzyne, 3,4-Bis(trimethylsilyl)benzocyclobutene—Synthesis by acetylene cotrimerization and conversion into ~ (SC) 399 [G.E. 413]
2,3-Dihydro-1,4-dioxocin, 6,7-Diphenyl-~ (SC) 552 [G.E. 555]
1,4-Dihydropyridine, Spiro compounds having a nonplanar ~ ring from diaziridinimines and dimethyl acetylenedicarboxylate (SC) 177 [G.E. 202]
Diimine, cis- and trans-Diazene (~) (SC) 780 [G.E. 828]
Diimine complexes, $[C_5H_5(CO)_2Mn—N_2H_2—Cr(CO)_5]$, a complex with a diazene bridge and two different coordination centers (SC) 464 [G.E. 480]
syn-4,13;6,11-Dimethano[15]annulenone, a 14π-analog of tropone—Synthesis and X-ray structure analysis (SC) 170 [G.E. 176]
Dimethyl sulfoxide, Site of protonation of ~—Raman spectroscopic data (SC) 197 [G.E. 200]
Dinitrogen complexes, The first reaction of the N_2 ligand with bases; reduction of coordinated dinitrogen by nucleophilic attack (SC) 880 [G.E. 918]
Diols, Assignment of configuration of olefins, ~, and epoxides. Quantitative analysis of their stereoisomeric mixtures (SC) 100 [G.E. 103]
2,3-Dioxabicyclo[2.2.2]octane by selective reduction of double bonds with azodicarboxylate (SC) 713 [G.E. 762]
2,3:6,7-Dioxa-bis-σ-homotropones. Synthesis and cis ⇄ trans-isomerization (SC) 198 [G.E. 174]
Dioxacyclooctadiene, Chair and boat: stable conformers of an eight-membered ring system (SC) 185 [G.E. 185]
1,3,4-Dioxazolidine, Synthesis of a stable ~ (SC) 646, 882 [G.E. 675, 920]
1,3-Diphenylallyl anion, Formation of the (Z,E)-1,3-diphenylallyl radical from the (Z,E)-~ by electron transfer—Comparison of the rotational barriers of the radical and the anion (SC) 869 [G.E. 907]
1,3-Diphenylallyl radical, Formation of the (Z,E)-~ from the (Z,E)-1,3-diphenylallyl anion by electron transfer—Comparison of the rotational barriers of the radical and the anion (SC) 869 [G.E. 907]
6,7-Diphenyl-2,3-dihydro-1,4-dioxocin (SC) 552 [G.E. 555]
Diphosgene, Isocyanide synthesis with ~ (SC) 259 [G.E. 267]
1λ^5,3λ^5-Diphosphacyclobutadiene, Synthesis of a stabilized ~ (SC) 402 [G.E. 415]
Dipole metathesis (SC) 54 [G.E. 60]
Dipoles, General procedure for generating conjugated 1,x ~ (SC) 55 [G.E. 61]
Diradicals, Thermal and photochemical cycloelimination of nitrogen (FP) 835 [G.E. 876]
Disulfane oxides, Bis(trifluoromethyl)disulfane oxide $CF_3S(O)SCF_3$ (SC) 723 [G.E. 740]
1,3-Dithietane, 2,4-Diisopropyl-~-2,4-diyl bis-(dithioisobutyrate), a dimeric form of bis-(thioacyl) sulfide (SC) 787 [G.E. 820]
Dithiocarboxylic acids, New aliphatic thiacylating reagents; preparation of tert-butyl esters of aliphatic ~ via bis(thioacyl) sulfide (SC) 786 [G.E. 820]
Dithiohemiacetals, Cyclic ~—Synthesis and properties (SC) 196 [G.E. 201]
Divinylcyclopropanes, Models for the biosynthesis of naturally occurring ~ and cycloheptadienes (SC) 192 [G.E. 187]
DNA ligases of eukaryotes (LA) 61
Double bond cleavage, Novel transformation of diphenylcyclopropenone: ~ in the reaction with platinum complexes (SC) 793 [G.E. 838]
Double bonds, Activation of ~ in dehydro amino acids: a model for pyridoxal-containing enzymes in elimination-addition reactions (SC) 328 [G.E. 345]
Dodecahedrane, Symmetry and vibrational frequencies (SC) 411 [G.E. 431]
Drinking water, Soluble organic compounds present in ~ (LA) 335
Drug analysis, Handbuch der Arzneimittel-Analytik (Book Review) 882
Drug metabolism, Effect of vitamins (LA) 200
Drug-metabolizing enzyme systems of liver microsomes (LA) 201
Effect of dietary lipids on drug metabolizing enzymes (LA) 201
Drugs, Flexible drug molecules and dynamic receptors (FP) 766 [G.E. 805]
Influence of ~ and hormones on lipolysis in heart (LA) 804
EBURNAMONINE, Simple stereoselective synthesis (SC) 878 [G.E. 916]
Electrochemistry, Electrochemical reduction of 2,2,2-trichloroethanols (SC) 57 [G.E. 54]
Imidazolidin-2-ones by anodic oxidation of conjugated dienes in the presence of dimethylurea (SC) 413 [G.E. 425]
Angewandte Elektrochemie (Book Review) 202
Electrodes, Analysis with ion-selective ~ (Book Review) 804
Electron densities, Experimental ~ and chemical bonding (FP) 32 [G.E. 33]
Observed and calculated electron-density distribution in the bonds of a rectangular cyclobutadiene (SC) 187 [G.E. 194]
Comparison of calculated and experimental electron difference densities of tetracyanoethylene (SC) 257 [G.E. 263]
An economic basis for electron difference density calculations (SC) 258 [G.E. 264]
Electron distribution, Oxidation and reduction of methylthio-substituted π-systems and the ~ in their radical ions (SC) 855 [G.E. 893]
Electron transfer, Reversible transition between a [4]radialene and a cyclobutadiene by ~ (SC) 410 [G.E. 424]
Formation of the (Z,E)-1,3-diphenylallyl radical from the (Z,E)-1,3-diphenylallyl anion by ~—Comparison of the rotational barriers of the radical and the anion (SC) 869 [G.E. 907]
Electrophilic substitution, An unusually facile ~ at the cyclopentadienyl ring in a half-sandwich complex (SC) 794 [G.E. 835]
Electrophotography (FP) 374 [G.E. 386]
Emodin, Synthesis of protohypericin from ~ (SC) 46 [G.E. 55]
Enamines, N,N-Bis(trimethylsilyl)-~—Stereoselective synthesis from N,N-bis(trimethylsilyl)thioformamide (SC) 535 [G.E. 550]
Energy transfer, Electronic ~ (LA) 660
Enol ethers, Synthesis of α,β-unsaturated cyclic ketones by sensitized photooxidation of silyl ~ (SC) 413 [G.E. 426]
Chemistry of O-silyl ~ (LA) 335
Entanglement of thread molecules and its influence on the properties of polymers (FP) 751 [G.E. 773]
Entropy, binding energy, and enzymic catalysis (FP) 449 [G.E. 456]
Enzyme catalysis, Efficiency and evolution (FP) 285 [G.E. 295]
Entropy, binding energy, and enzymic catalysis (FP) 449 [G.E. 456]
Enzymes, Organic fluorescence reagents in the study of ~ and proteins (FP) 137 [G.E. 142]
Suicide inactivators for ~ (LA) 60
Immobilized ~ (LA) 60
Drug-metabolizing enzyme systems of liver microsomes (LA) 201
Effect of dietary lipids on drug metabolizing ~ (LA) 201
Epoxides, Assignment of configuration of olefins, diols, and ~. Quantitative analysis of their stereoisomeric mixtures (SC) 100 [G.E. 103]
ESR spectroscopy, Oxidation and reduction of methylthio-substituted π-systems and the electron distribution in their radical ions (SC) 855 [G.E. 893]
Ethers, "Noncyclic crown ~": The terminal group concept (SC) 396 [G.E. 410]
$Co_2(CO)_8$ catalyzed reactions of cyclic ~ with hydrosilanes and carbon monoxide (SC) 789 [G.E. 818]
Photolysis of saturated alcohols, ~, and amines (LA) 804
Ethylbenzene, Ortho-para protonation of toluene and ~ in super acids (SC) 315 [G.E. 323]
Ethylene oxides, Electrocyclic ring opening reactions (FP) 572 [G.E. 589]
Ethynylphosphonium salts, Simple synthesis of (arylethynyl)triphenylphosphonium salts (SC) 45 [G.E. 55]
FIELD desorption mass spectrometry, Quantitative ~; stable isotope dilution and cationization (SC) 184 [G.E. 180]
Quantitative trace analysis of metals by ~ (SC) 852 [G.E. 890]
Five-membered rings, 4-Hydroxy-2-cyclopenten-1-ones from ketones and 3-nitropropionyl chloride. A facile method for the construction of ~ (SC) 321 [G.E. 334]
Flash thermolysis of organic compounds (FP) 365 [G.E. 377]
Flexirubin, Total synthesis of ~ dimethyl ether (SC) 191 [G.E. 198]
Flow pyrolysis, Elimination of CO from cyclic carbonyl compounds by ~ (SC) 50 [G.E. 50]
Fluorescence reagents, Organic ~ in the study of enzymes and proteins (FP) 137 [G.E. 142]

Fluorination, Oligo(difluorophosphoranes) by direct ~ of tertiary phosphanes (SC) 718 [G.E. 763]
Fluorine compounds, Fluorinated isocyanates and their derivatives as intermediates for biologically active compounds (FP) 735 [G.E. 797]
Trifluoromethylamine, CF_3NH_2 (SC) 707 [G.E. 754]
The Te—O—Fe system: $Te(OTeF_5)_6$ (SC) 729 [G.E. 741]
Fluorocarbons, The chlorofluorocarbon/ozone theory—A scientific status report (FP) 513 [G.E. 507]
Force field calculations, Structures of two highly strained tetracyclododecanes (SC) 798 [G.E. 833]
Fulvalenes and fulvenes of a heterocyclic system with 12π electrons—Pseudophenafulvenes and pentapseudophenafulvalenes (SC) 49 [G.E. 48]
Fulvenes and fulvalenes of a heterocyclic system with 12π electrons—Pseudophenafulvenes and pentapseudophenafulvalenes (SC) 49 [G.E. 48]
Furans, Reaction of alkenyl-~ with ethyl diazoacetate (SC) 646 [G.E. 674]

GERMYLENE complexes, Pentacarbonyl(dimesitylgermanediyl)chromium(0) (SC) 639 [G.E. 675]
Glass, Werkstoff Glas (Book Review) 61
Glycosides, α-Glycosidic linkage of D-ribofuranose (SC) 48 [G.E. 58]
Amino sugars and N-~ by oxyamination of unsaturated carbohydrate derivatives (SC) 553 [G.E. 565]
Simple de-novo synthesis of reactive pseudoglycals (hex-2-enopyranosides)—Stereospecific α-glycoside coupling (SC) 783 [G.E. 822]

HALOGEN donors, Temperature dependence of the selectivity of the ~ $XCCl_3$ (SC) 466 [G.E. 482]
Halogen elimination, Electrochemical reduction of 2,2,2-trichloroethanols (SC) 57 [G.E. 54]
Hazardous materials, Analytische Methoden zur Prüfung gesundheitsschädlicher Arbeitsstoffe (Book Review) 271
Heat of hydrogenation of compounds containing isolated and conjugated C=N double bonds (SC) 47 [G.E. 48]
Helical hydrocarbons, New type of ~—Novel C—C coupling by sulfone pyrolysis (SC) 325 [G.E. 358]
Heme biosynthesis, Total synthesis of [^{14}C]- and [^{3}H]-labeled tripyrrole precursors for ~ (SC) 651 [G.E. 676]
Hemiacetals, Cyclic dithio-~—Synthesis and properties (SC) 196 [G.E. 201]
Hemin, Role in the regulation of protein synthesis in erythroid cells (LA) 200
Hemopolymers, Synthetic ~ for reversible binding of molecular oxygen (SC) 117 [G.E. 120]
cyclo-Heptasulfur, Crystal and molecular structure (SC) 715 [G.E. 756]
cyclo-Heptasulfur oxide, Bond interaction in sulfur rings: crystal and molecular structure (SC) 716 [G.E. 757]
Hereditary disorders, Biochemistry of sphingolipid storage diseases (FP) 273 [G.E. 283]
Heteroanions, Thio-~—Unusual metal-ligand interaction and reactions (SC) 705 [G.E. 748]
Heterocycles, Thermal and photochemical cycloelimination of nitrogen (FP) 835 [G.E. 876]
New reagents for synthesis of ~ from carbodiimides and phosgeniminium salts (SC) 181 [G.E. 188]
Four-membered phosphorus-nitrogen-metal heterocycles with zwitterionic structure (SC) 864 [G.E. 902]
Heterocyclic compounds, An introduction to the chemistry of ~ (Book Review) 558
1,4,7,10,13,16-Hexaoxa-2,11-cyclooctadecadiene,2,3,11,12-Tetraphenyl-~: A newcrown ether from benzoin (SC) 467 [G.E. 484]
1-Hexene, Catalyst dependent product distribution in the reaction of ~ with a hydrosilane and carbon monoxide (SC) 881 [G.E. 919]
Holography, Photodielectric polymers for holographic use (FP) 441 [G.E. 467]
Homotropones, 2,3:6,7-Dioxa-bis-σ-~. Synthesis and cis⇄trans isomerization (SC) 198 [G.E. 174]
Hormones, Influence of drugs and ~ on lipolysis in heart (LA) 804
Hydrazine, X-Ray structure analysis of N-phenyl-N′-sulfinyl-~ (SC) 179 [G.E. 190]
Hydride elimination, Stereoselective ~ from organo lithium and -magnesium compounds (SC) 44 [G.E. 46]
1,2-Hydride shift, Anomalous nucleophilic substitution in (chloromethyl)silane: ~ (SC) 639 [G.E. 678]
Hydrocarbons, Versatile principle for the synthesis of functionalized ~ via organoarsenic compounds (SC) 709 [G.E. 759]
Determination of the conformation of hydrocarbon chains in solution by photochemical probes (LA) 557
Hydrogen bond, The ~ (Book Review) 337
Hydrogenolysis of trisubstituted dichlorophosphoranes—A new method for deoxygenation of oxophosphoranes (SC) 552 [G.E. 558]
Hydrosilanes, $Co_2(CO)_8$ catalyzed reactions of cyclic ethers with ~ and carbon monoxide (SC) 789 [G.E. 818]
Hydroxylation, Diastereoselective synthesis of the aporphine alkaloid (+)-cataline. ~ with vanadium(V) trifluoride oxide (SC) 730 [G.E. 739]
Hypericin, Synthesis of ~ and related mesonaphthodianthrones by alkaline dimerization of hydroxyanthraquinones (SC) 46 [G.E. 56]

IMIDAZOLIDIN-2-ones by anodic oxidation of conjugated dienes in the presence of dimethylurea (SC) 413 [G.E. 425]
N-Imidoyl isocyanides (SC) 727 [G.E. 742]
Imines, Photochemistry (LA) 557
Imino ethers, Reactions of phosgeniminium salts with nitriles, ~, and imidoyl chlorides—Synthesis of 4,6-dichloro-2-(dialkylamino)-pyrimidines (SC) 189 [G.E. 182]
Inclusion compounds, Inclusion of anions in macrotricyclic quaternary ammonium salts (SC) 720 [G.E. 751]
7bH-Indeno[1,2,3-jk]fluorenide, Lithium ~, an organolithium compound having a "sandwich" structure (SC) 474 [G.E. 490]
η^5-Indenylrhodium(I) complexes, Reactivity; cyclocotrimerization of alkynes with alkenes (SC) 648 [G.E. 671]
Infrared rotatory dispersion, ~ of liquid-crystalline solutions of chiral molecules (SC) 790 [G.E. 830]
Relationship between the ~ of liquid-crystalline solutions of chiral molecules and their absolute configuration (SC) 791 [G.E. 831]
Inhibitors, Suicide inactivators for enzymes (LA) 60
Protein ~ of α-amylase in wheat (LA) 804
Inorganic chemistry, Anorganisches Grundpraktikum (Book Review) 420
Insertion reactions, Synthetic and mechanistic aspects of inorganic ~. Insertion of carbon monoxide (FP) 299 [G.E. 305]
Interaction orbital, Interaction between the nonbonding orbitals of α-dicarbonyl systems and π or Walsh orbitals (SC) 400 [G.E. 414]
Intercalation compounds, Demonstration of the ionic structure of $TaS_2 \cdot NH_3$ (SC) 199 [G.E. 193]
Internal monooxygenase, A model of ~ catalyzed reactions: copper-catalyzed autoxidation of bis(1-methylbenzimidazol-2-yl)methane (SC) 189 [G.E. 185]
Intramolecular cycloadditions, Intramolecular [4+2] and [3+2] cycloadditions in organic synthesis (FP) 10 [G.E. 10]
Iodine, Selective monofunctionalization of nonconjugated dienes by nitrogen dioxide/~ monoaddition (SC) 246 [G.E. 253]
Iodobenzenes, Regiospecific synthesis of mono- and polyiodo derivatives of benzene (SC) 488 [G.E. 502]
Iodohydroborates, Isolation of isomeric ~ of type $[B_{10}H_{10-n}I_n]^{2-}$ (SC) 398 [G.E. 412]
Ion exchange, Determination of reaction enthalpy in the ~ of chlorine isotopes (SC) 114 [G.E. 118]
Ion-exchange chromatography, Dependence of the calcium isotope effect upon the electrolyte concentration in ~ (SC) 719 [G.E. 753]
Ionization barrier of trityl chloride in sulfur dioxide (SC) 256 [G.E. 266]
Ion-selective electrodes, Analysis with ~ (Book Review) 804
Iron complexes, Two routes to complex derivatives of borole (SC) 42 [G.E. 43]
Phosphorus-bridged trinuclear complexes having contiguous metal-metal bonds (SC) 542 [G.E. 568]
(3—6-η-Tricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene)tricarbonyliron, a stable transition metal complex of "o,p′-dibenzene" (SC) 717 [G.E. 754]
Base-stabilized silylene-~ (SC) 785 [G.E. 823]
Iron compounds, The first oxoferrate(III) having a ring structure: $Na_{14}[Fe_6O_{16}]$ (SC) 43 [G.E. 45]
Catalytic activity by opening of metal-metal bonds (SC) 188 [G.E. 197]
An organometallic five-membered ring with hetero-metal-metal bonding (SC) 332 [G.E. 341]
Isocyanates, Fluorinated ~ and their derivatives as intermediates for biologically active compounds (FP) 735 [G.E. 797]
Synthesis and reactions of N-chlorocarbonyl isocyanate (FP) 743 [G.E. 789]
Cycloaddition of phenyl isocyanate to a diaziridinimine (SC) 109 [G.E. 112]
Catalyzed rearrangement of nitrile oxides to ~ (SC) 555 [G.E. 562]
Isocyanides, Recent applications of α-metalated ~ in organic synthesis (FP) 339 [G.E. 351]
Synthesis with diphosgene (SC) 259 [G.E. 267]
N-Acyl ~ (SC) 262 [G.E. 272]
Carbodiimides as source of isocyanide and carbonyl ligands (SC) 641 [G.E. 660]
N-Imidoyl ~ (SC) 727 [G.E. 742]
Isodiazomethane complexes (SC) 707 [G.E. 752]
Isoelectric focusing (Book Review) 420
Isothiocyanato complexes, Isolation and vibrational spectra of bond-isomeric hexakis(thiocyanato) complexes of ruthenium(III) and osmium(III) (SC) 108 [G.E. 108]
Isotope effect, Dependence of calcium ~ upon electrolyte concentration in ion-exchange chromatography (SC) 719 [G.E. 753]

KERR effect, The electro-optical ~ in conformational analysis (FP) 663 [G.E. 725]
Ketene derivatives, Dimers of ketenylidene- and N-phenylketeniminylidenetriphenylphosphorane (SC) 268 [G.E. 275]
Ketenes, [2+2]- and [4+2]-cycloadditions of arylazoalkenes (SC) 58 [G.E. 59]
Reactions of acyl chlorides, triethylamine, or ~ with phosgeniminium salts (SC) 182 [G.E. 189]
Ketene synthons, Reactions (LA) 490
Ketenyl complex, p-Tolylketenyl as novel dihapto 3-electron ligand (SC) 102 [G.E. 110]
Ketones, N-(Trimethylsilyl)amino acid trimethylsilyl esters as reagents for directed self-condensation of methyl ~ under mild conditions (SC) 251 [G.E. 255]
Condensation of α-acylaminoalkyl methyl ~ to give N-acylpyrroles (SC) 252 [G.E. 256]
4-Hydroxy-2-cyclopenten-1-ones from ~ and 3-nitropropionyl chloride. A facile method for the construction of five-membered rings (SC) 321 [G.E. 334]
Doubly deprotonated allylacetophenone.

First example of a "direct" E^5 synthon (SC) 320 [G.E. 333]
Synthesis of α,β-unsaturated cyclic ~ by sensitized photooxidation of silyl enol ethers (SC) 413 [G.E. 426]
Homologization of aldehydes and ~ to thiiranes or S-vinyl thiocarbamates via 2-alkylimino-1,3-oxathiolanes (SC) 462 [G.E. 478]
Nickel(II)-catalyzed synthesis of pyrroles from 2H-azirines and activated ~ (SC) 647 [G.E. 672]
Ketoses, Structure of ~ and their biologically important phosphate esters in solution (LA) 201
Kinetic data, Review of methods for analysis of ~ in biochemistry (LA) 61
Kinetics, Thermochemical ~. Methods for the estimation of thermochemical data and rate parameters (Book Review) 883
Krebs cycle, Coordination of lipid degradation with the ~ (LA) 803

LACTAMS, Reaction of monothiodicarboximides with phosphorus ylides: A new synthesis of ω-alkylidene-~ (SC) 418 [G.E. 429]
A new cis-stereospecific β-lactam ring closure (SC) 544 [G.E. 553]
The zip reaction: A new method for ring expansion; synthesis of 17- and 21-membered polyamino-~ (SC) 861 [G.E. 899]
Lactones, δ-~ by carbonylation of vinyloxiranes (SC) 50 [G.E. 47]
A new lactone synthesis (SC) 876 [G.E. 914]
Layer compounds, $[Zn_2Cr(OH)_6]X \cdot 2H_2O$, new ~ capable of anion exchange and intracrystalline swelling (SC) 265 [G.E. 259]
Lipid degradation, Coordination with the Krebs cycle (LA) 803
Lipids, Effect of dietary ~ on drug metabolizing enzymes (LA) 201
Lipolysis, Influence of drugs and hormones on ~ in heart (LA) 804
Liquid crystals, Substituted phenylcyclohexanes—A new class of ~ (SC) 100 [G.E. 103]
Selenol esters—A novel class of ~ (SC) 318 [G.E. 328]
Infrared rotatory dispersion of liquid-crystalline solutions of chiral molecules (SC) 790 [G.E. 830]
Relationship between the infrared rotatory dispersion of liquid-crystalline solutions of chiral molecules and their absolute configuration (SC) 791 [G.E. 831]
Lithium compounds, Stereoselective hydride elimination from organomagnesium compounds and organo-~ (SC) 44 [G.E. 46]
Lithiomethyl(diphenyl)arsane oxide, a new reagent (SC) 53 [G.E. 52]
Extension of the scope of anionic cycloadditions by activating organoelement groups (SC) 119 [G.E. 107]
Lithium 7bH-indeno[1,2,3-jk]fluorenide, an organo-~ having a "sandwich" structure (SC) 474 [G.E. 490]
2C-chain elongation of lithioalkanes with diphenylvinylarsane and phenyl vinyl selenide (SC) 710 [G.E. 760]
Quantitative trace analysis of metals by field desorption mass spectrometry (SC) 852 [G.E. 890]

MACROLIDES, Recent progress in chemistry and biochemistry (FP) 585 [G.E. 602]
Magnesium compounds, Stereoselective hydride elimination from organo-lithium compounds and organo-~ (SC) 44 [G.E. 46]
Bis(trimethylsilyl)magnesium—The first organosilylmagnesium compound isolated (SC) 247 [G.E. 257]
Malononitrile, Use for annelation reactions (LA) 122
Manganese complexes, Preparation of halogen-bridged cationic dinuclear complexes of manganese and rhenium (SC) 56 [G.E. 53]
Intramolecular mobility in CS_2 complexes of manganese (SC) 193 [G.E. 191]
Acceptor function of η^2-bonded CS_2 ligands (SC) 194 [G.E. 192]
$[C_5H_5(CO)_2Mn—N_2H_2—Cr(CO)_5]$, a complex with a diazene bridge and two different coordination centers (SC) 464 [G.E. 480]
Unsaturated organometallic intermediates: Electronic structure and structural dynamics of $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ (SC) 536 [G.E. 551]
Synthesis and reactivity of hetero dinuclear complexes containing a Mn—Co bond (SC) 649 [G.E. 656]
First reaction of the N_2 ligand with bases; reduction of coordinated dinitrogen by nucleophilic attack (SC) 880 [G.E. 918]
Marine organisms, Toxins (LA) 335
Marine science, Handbook of ~ (Book Review) 805
Mass spectrometry, Collision activation ~ with novel analysis technique (SC) 120 [G.E. 115]
Quantitative field desorption ~; stable isotope dilution and cationization (SC) 184 [G.E. 180]
Quantitative trace analysis of metals by field desorption ~ (SC) 852 [G.E. 890]
Effective method for designing synthetic approaches to natural products (LA) 60
Membrane bound processes, Investigations of mitochondrial adenine nucleotide translocation by means of nucleotide analogs (FP) 695 [G.E. 717]
Mercury compounds, $[\eta^5\text{-}C_5H_5Mo(CO)_3\text{-}HgMo]_4$, a metal cluster with cubane structure (SC) 704 [G.E. 746]
Metabolic regulation, Control at the level of substrate supply (LA) 803
Metalation, Cyclo-~ reactions (FP) 73 [G.E. 75]
Metal clusters, Study of ~ (LA) 557
Metathesis, Dipole ~ (SC) 54 [G.E. 60]
5-Methoxysemibullvalene (SC) 475 [G.E. 491]
Methylene complexes, Novel synthesis of μ-~ (SC) 334 [G.E. 342]
Methylenecyclopropane, Palladium(0)-catalyzed $[2\sigma+2\pi]$ cycloadditions to alkenes (SC) 249 [G.E. 254]
Micelles of ionic detergents in aqueous solutions (LA) 490
Michaelis-Arbuzov reaction, Phosphoranes as intermediates (SC) 477 [G.E. 493]
Microbial transformation, Formation of chlorophenols by ~ of chlorobenzenes (SC) 645 [G.E. 680]
Microbiology, Mikrobiologie (Book Review) 420
Microorganisms, Utilization of microbes—Modern developments in biological technology (FP) 205 [G.E. 211]
Microsomes, Drug-metabolizing enzyme systems of liver ~ (LA) 201
Mitochondria, Investigations of mitochondrial adenine nucleotide translocation by means of nucleotide analogs (FP) 695 [G.E. 717]
Mixing-reaction model, The selectivity of chemical reactions disguised by diffusion. Part I: Chemical selectivity disguised by mixing (FP) 807 [G.E. 847]
Molecular states and molecular orbitals (FP) 613 [G.E. 631]
Molybdates, Halogenonitrosyl-~—Simple, monomeric Mo^{II} complexes (SC) 183 [G.E. 189]
Molybdenum complexes, A monothiooxalato-O,S-oxo complex of molybdenum containing two S_2^{2-} ligands (SC) 260 [G.E. 269]
Asymmetrical bridge complexes of type $\eta^3\text{-}C_7H_7(CO)_2Mo(OR)_3Mo\text{-}\eta^7\text{-}C_7H_7$ with two Mo centers of different oxidation number (SC) 261 [G.E. 271]
Halogenonitrosylmolybdates—Isolation of the first classical Mo^I complex (SC) 468 [G.E. 479]
$[\eta^5\text{-}C_5H_5Mo(CO)_3HgMo]_4$, a metal cluster with cubane structure (SC) 704 [G.E. 746]
Dichloro(porphyrinato)molybdenum(IV)—Synthesis and structure (SC) 788 [G.E. 819]
Monofunctionalization, Selective ~ of non-conjugated dienes by nitrogen dioxide/iodine monoaddition (SC) 246 [G.E. 253]
Monothiooxalate, A monothiooxalato-O,S-oxo complex of molybdenum containing two S_2^{2-} ligands (SC) 260 [G.E. 269]
Mössbauer spectroscopy, Applications to the study of heterogeneous catalysis (LA) 335
Applications of ~ (Book Review) 420

anti-1,2:3,4-NAPHTHALENE dioxide, A complementary route to ~; direct oxidation of arenes with m-chloroperbenzoic and (SC) 171 [G.E. 181]
Naphthalene pentoxide, Synthesis and structure analysis (SC) 169 [G.E. 175]
Naphthaleno[2]paracyclophanes, Intramolecular quinhydrone of the [2](1,4)naphthaleno[2]paracyclophane series (SC) 394 [G.E. 407]
Naphthalenophanes, Synthesis and stereochemistry of strained ~ (SC) 175 [G.E. 199]
Stereoisomeric quinhydrones of the [2.2](1,4)naphthalenophane series (SC) 392 [G.E. 406]
Naphthodianthrones, Synthesis of hypericin and related meso-~ by alkaline dimerization of hydroxyanthraquinones (SC) 46 [G.E. 56]
Natural products, Effective method for designing synthetic approaches to ~ (LA) 60
Nervous system, Biochemistry of sphingolipid storage diseases (FP) 273 [G.E. 283]
Neutron activation tables (Book Review) 558
Neutron diffraction, Experimental electron densities and chemical bonding (FP) 32 [G.E. 33]
Nickel catalysts, Control of the direction of addition in the nickel-catalyzed 2:1-cooligomerization of butadiene with monoolefins by perturbation of the monoolefin (SC) 252 [G.E. 260]
Control of the nickel-catalyzed cooligomerization of butadiene with Schiff bases by cocatalysts (SC) 253 [G.E. 261]
Nickel complexes, Two routes to complex derivatives of borole (SC) 42 [G.E. 43]
"Supersandwich"-type trinuclear complexes with a spiro center (SC) 324 [G.E. 332]
(A→D)-Cyclization of a nickel(II) Δ^{18}-dehydro-1-methylidene-1,19-secocorrinate (SC) 459 [G.E. 475]
Nickel compounds, Novel organo-~ from (pentaphenyl)aluminacyclopentadiene (SC) 183 [G.E. 179]
Nickel(II)-catalyzed synthesis of pyrroles from 2H-azirines and activated ketones (SC) 647 [G.E. 672]
Nickelocene, η-Cyclopentadienyl(η-diborolenyl)nickel—A diamagnetic ~ analog (SC) 468 [G.E. 483]
Nitrile oxides, Catalyzed rearrangement to isocyanates (SC) 555 [G.E. 562]
Nitriles, Reactions of phosgeniminium salts with ~, imino ethers, and imidoyl chlorides—Synthesis of 4,6-dichloro-2-(dialkylamino)pyrimidines (SC) 189 [G.E. 182]
Nitro compounds, Crown ether catalyzed reduction of aromatic ~ to give amines (SC) 41 [G.E. 43]
Nitrogen complexes, cis-Bis(dinitrogen)tetrakis(trimethylphosphane)chromium (SC) 56 [G.E. 57]
Hexameric $KN_2Co[P(CH_3)_3]_3$—A novel potassium-dinitrogen cluster (SC) 485 [G.E. 499]
Nitrogen compounds, New pathways to four-membered boron-nitrogen heterocycles (SC) 478 [G.E. 494]
Detection of an orthonitrate by vibrational spectroscopy: $Na_3[NO_4]$ (SC) 534 [G.E. 567]
Dichloronitronium hexachloroantimonate, $ONCl_2SbCl_6$ (SC) 545 [G.E. 569]
Photochemical [2+2]-cycloaddition between parallel CC and NN double bonds (SC) 777 [G.E. 825]
Nitrogen cycloelimination, Thermal and photochemical cycloelimination of nitrogen (FP) 835 [G.E. 876]
Nitrogen dioxide, Selective monofunctionalization of non-conjugated dienes by ~/iodine monoaddition (SC) 246 [G.E. 253]

C-Nitroso compounds, Electrophilic ~ (LA) 490
Nitrosylation, Partial ~ of dicarbonyl(η-cyclopentadienyl)cobalt (SC) 172 [G.E. 186]
Nitrosylmolybdates, Halogeno-~—Isolation of the first classical Mo^I complex (SC) 468 [G.E. 479]
NMR-spectroscopy, Determination of the activation volume $\Delta V^{\neq}$ of simple molecular rearrangements by high-resolution ^1H-~ at high pressures (SC) 331 [G.E. 340]
Nuclear reactions with heavy ions (LA) 60
Nucleic acids, The dependence of translation on the 5'-terminal methylation of m-RNA (LA) 200
Stereoselectivity in the binding of transition-metal chelates to nucleic acid constituents (LA) 557
Nucleophilic substitution, ~ of vinylic hydrogen atoms by carbanions (SC) 44 [G.E. 46] ~ (LA) 557
Nucleosides, Chemistry and biochemistry of C-~ (LA) 122

OCTALENE (SC) 871 [G.E. 909]
Configuration, conformation, and dynamics of ~ (SC) 872 [G.E. 910]
Olefins, Assignment of configuration of ~, diols, and epoxides. Quantitative analysis of their stereoisomeric mixtures (SC) 100 [G.E. 103]
Resolution of a chiral olefin by complexation chromatography on an optically active rhodium(I) complex (SC) 110 [G.E. 113]
Reaction with silane and carbon monoxide catalyzed by $Co_2(CO)_8$ (SC) 174 [G.E. 196]
Polar effects in addition of alkyl radicals to ~ (SC) 178 [G.E. 178]
An olefin with unusually large C—C≡C angles (SC) 658 [G.E. 665]
Transition metal catalyzed reactions of organic halides with carbon monoxide, ~, and acetylenes (LA) 335
Olefin synthesis, Decarboxylative dehydration of β-hydroxycarboxylic acids by redox condensation: a novel ~ (SC) 255 [G.E. 265]
Orbitals, Molecular states and molecular ~ (FP) 613 [G.E. 631]
"Organic metals"—The intermolecular migration of aromaticity (FP) 519 [G.E. 534]
Organometallic chemistry, Reviews (LA) 60
Surveys of work published in 1975 (LA) 335
Orthonitrate, Detection of an ~ by vibrational spectroscopy: $Na_3[NO_4]$ (FP) 534 [G.E. 567]
Oscillation, Phenomena of ~ in biological systems (LA) 419
Osmium complexes, Isolation and vibrational spectra of bond-isomeric hexakis(thiocyanato) complexes of ruthenium(III) and osmium(III) (SC) 108 [G.E. 108]
Osmotic desalination, Principles (FP) 607 [G.E. 624]
Oxazolinones, C—C linkage of carboxylic acids with allyl alcohols using 2-phenylglycine as vehicle (SC) 394 [G.E. 408]
Oxirane ring opening, Facile synthesis of arabinoadenosine 3'-phosphate (SC) 317 [G.E. 328]
Oxirene, α-Oxocarbene-~ isomerization: Photolysis of [1-^{13}C]-2-diazo-1-phenyl-1-propanone and [2-^{13}C]-1-diazo-1-phenyl-2-propanone (SC) 781 [G.E. 827]
α-Oxocarbene-oxirene isomerization: Photolysis of [1-^{13}C]-2-diazo-1-phenyl-1-propanone and [2-^{13}C]-1-diazo-1-phenyl-2-propanone (SC) 781 [G.E. 827]
Oxoferrate(III), First ~ having a ring structure: $Na_{14}[Fe_6O_{16}]$ (SC) 43 [G.E. 45]
Oxometalates with planar coordination (FP) 674 [G.E. 704]
Oxophosphoranes, Hydrogenolysis of trisubstituted dichlorophosphoranes—A new method for deoxygenation of ~ (SC) 552 [G.E. 558]
Oxozincates, Coordination number 3 in ~: $Rb_8[OZnO_2ZnO_2ZnO_2ZnO]$ and $K_2[Zn_6O_7]$ (SC) 484 [G.E. 498]
Oxyamination, Amino sugars and N-glycosides by ~ of unsaturated carbohydrate derivatives (SC) 553 [G.E. 565]
Oxygen, Synthetic hemopolymers for reversible binding of molecular ~ (SC) 117 [G.E. 120]
Oxygenase, Model of internal mono-~ catalyzed reactions: Copper-catalyzed autoxidation of bis(1-methylbenzimidazol-2-yl)methane (SC) 189 [G.E. 185]
Ozone, The chlorofluorocarbon/~ theory—A scientific status report (FP) 513 [G.E. 507]

PALLADIUM(0)-catalyzed [2σ + 2π] cycloadditions of methylenecyclopropane to alkenes (SC) 249 [G.E. 254]
Palladium complexes, General method for the synthesis of sandwich-type complexes with a Pd—Pd or Pt—Pt bond (SC) 412 [G.E. 427]
Palladium(II) and platinum(II) complexes with polymeric Schiff base ligands (SC) 860 [G.E. 898]
Palladium compounds, Novel 3z-2e bond system (SC) 248 [G.E. 257]
Paracyclophane quinhydrones, Indirectly transmitted charge-transfer interactions: Multilayered [2.2]-~ (SC) 801 [G.E. 841]
Diastereomeric [3.3]-~ (SC) 799 [G.E. 839]
Pauli principle, The ~ and chemical bonding in molecules and solids (FP) 294 [G.E. 317]
Pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane, Synthesis and absolute configuration of enantiomerically pure D_3-trishomocubanes (~) and trishomocubanones (SC) 116 [G.E. 119]
Peptide synthesis, Side reactions in ~: tert-butylation of tryptophan (SC) 317 [G.E. 330]
Repetitive ~ with insoluble polymer-bound reagents and solubilizing macromolecular peptide carriers (SC) 642 [G.E. 681]
Peroxides, 2,3-Dioxabicyclo[2.2.2]octane by selective reduction of double bonds with azodicarboxylate (SC) 713 [G.E. 762]
Phallisin, Resynthesis of phalloidin and ~ from the seco-compounds (SC) 267 [G.E. 274]
Phalloidin, Resynthesis of ~ and phallisin from the seco-compounds (SC) 267 [G.E. 274]
Phase-transfer catalysis, Phase-transfer catalyzed alkylation of diphenylphosphinic amide—A new versatile synthesis of primary and secondary amines (SC) 702 [G.E. 737]
Phenethylamines and tryptamines; related compounds of plant origin (LA) 490
Phenylcyclohexanes, Substituted ~—A new class of liquid-crystalline compounds (SC) 100 [G.E. 103]
p-Phenylenediamines, Synthesis of substituted p-aminophenols from ~ (SC) 266 [G.E. 273]
2-Phenylglycine, C—C linkage of carboxylic acids with allyl alcohols using ~ as vehicle (SC) 394 [G.E. 408]
Phosgeniminium salts, New reagents for synthesis of heterocycles from carbodiimides and ~ (SC) 181 [G.E. 188]
Reactions of acyl chlorides, triethylamine, or ketenes with ~ (SC) 182 [G.E. 189]
Reactions with nitriles, imino ethers, and imidoyl chlorides—synthesis of 4,6-dichloro-2-(dialkylamino)pyrimidines(SC)189 [G.E. 182]
Phosphaallene ylide, Preparation and reactions of a cyclic ~ (SC) 877 [G.E. 915]
Phosphanes, Synthesis of acyldiarylphosphane oxides—Key compounds in the oxidation of acyldiaryl-~ with molecular oxygen (SC) 269 [G.E. 276]
Oligo(difluorophosphoranes) by direct fluorination of tertiary ~ (SC) 718 [G.E. 763]
$Co_5(CO)_{11}(PR_2)_3$, a novel type of pentanuclear cluster (SC) 731 [G.E. 738]
5λ^5-Phosphaspiro[4.4]nonane, 5-Methyl-~—The simplest pentaalkylphosphorane yet obtained (SC) 722 [G.E. 748]
Phosphate esters, Structure of ketoses and their biologically important ~ in solution (LA) 201
Phosphates in ceramics (LA) 490
β-Phosphatrimethinecyanine dye, Preparation (SC) 404 [G.E. 418]
Phosphazenes, Poly(organo-~)—Unusual new high polymers (FP) 147 [G.E. 153]
$(RPNCH_3)_4$, cyclotetra(λ^3-~)—Synthesis and crystal structure analysis (SC) 407 [G.E. 423]
Phosphonium salts, Simple synthesis of (arylethynyl)triphenyl-~ (SC) 45 [G.E. 55]
Phosphoramidates, Alkylation of diethyl ~—A simple route from primary to secondary amines (SC) 107 [G.E. 109]
Phosphorane, (Chloromethylene)triphenyl-~ (SC) 180 [G.E. 203]
Dimers of ketenylidene- and N-phenylketeniminylidene-triphenyl-~ (SC) 268 [G.E. 275]
~-s as intermediates in the Michaelis-Arbuzov reaction (SC) 477 [G.E. 493]
5-Methyl-5λ^5-phosphaspiro[4.4]nonane — The simplest pentaalkyl-~ yet obtained (SC) 722 [G.E. 748]
Intramolecular oxidative addition of azopyridine to phosphorus(III) (SC) 865 [G.E. 903]
Phosphorus compounds, Phosphacumulene ylides and phosphaallene ylides (FP) 349 [G.E. 361]
Diastereomers with differing bond lengths: structure analysis of the diastereomeric forms of μ-(1,2dichloro-1,2-diphenyldiphosphane) bis (pentacarbonylchromium) (SC) 260 [G.E. 268]
Diazadiphosphetidine with ring-stabilized "pentaamidophosphorus" (SC) 263 [G.E. 268]
Phenyl(trimethylphosphonio)methanidyl, a novel 3-electron bridge ligand (SC) 314 [G.E. 325]
Absolute configuration of the cancerostatic S(−)-cyclophosphamide (SC) 330 [G.E. 336]
Synthesis of dinuclear complexes containing PCl_2 and PF_2 bridges (SC) 408 [G.E. 421]
cis-2-Telluro-1,3,2λ^5, 4λ^3-diazadiphosphetidine—A fluxional redox system (SC) 486 [G.E. 500]
1,2,4,3λ^3-Triazaphospholes synthesized by reductive (σ^4→σ^2)-elimination at phosphorus (SC) 546 [G.E. 554]
Double ring-closure additions to o-(methyleneamino)-phenyl phosphites (SC) 549 [G.E. 558]
Hydrogenolysis of trisubstituted dichlorophosphoranes—A new method for deoxygenation of oxophosphoranes (SC) 552 [G.E. 558]
Phosphorus-bridged trinuclear complexes having contiguous metal-metal bonds (SC) 542 [G.E. 568]
Diphosphinomethanide/phosphoniumbismethylide: a novel ligand combination for transition metals (SC) 640 [G.E. 679]
Bis[trimethylphosphorio(-onio)]methanide, a "semi-ylidic" ligand in transition metal complexes (SC) 654 [G.E. 657]
Dicyanophosphide (SC) 704 [G.E. 747]
Phase-transfer catalyzed alkylation of diphenylphosphinic amide—A new versatile synthesis of primary and secondary amines (SC) 702 [G.E. 737]
An imino-bridged triaza-λ^5-phosphetine (SC) 783 [G.E. 817]
Synthesis of bridged 1,3,2λ^3,4λ^3-diazadiphosphetidines (SC) 797 [G.E. 829]
Phosphorus-tin ylide, Dimeric bis(di-tert-butylphosphino)stannanediyl: A cyclic ~ (SC) 792 [G.E. 832]
Phosphorus ylides, "Carbodiphosphoranes" by a new rearrangement of ~ (SC) 417 [G.E. 428]
Reaction of monothiodicarboximides with ~: A new synthesis of ω-alkylidenelactams (SC) 418 [G.E. 429]
Molecular structure of $[\eta\text{-}C_5H_5(CO)_2Re{=}C(C_6H_5)P(CH_3)_3][BCl_4]$ (SC) 543 [G.E. 553]
Photochemistry, Photochemical [2 + 2]-cycloaddition between parallel CC and NN double bonds (SC) 777 [G.E. 825]

α-Oxocarbene-oxirene isomerization: Photolysis of [1-^{13}C]-2-diazo-1-phenyl-1-propanone and [2-^{13}C]-1-diazo-1-phenyl-2-propanone (SC) 781 [G.E. 827]
The ~ of 2H-azirines (LA) 121
Aspects of the ~ of organo-transition metal compounds (LA) 200
The ~ of imines (LA) 557
Photochromism of rhodamine derivatives (SC) 113 [G.E. 116]
Photocycloaddition, Geometrical dependence of [2π + 2σ]-~ (SC) 103 [G.E. 111]
Photodielectric polymers for holographic use (FP) 441 [G.E. 467]
Photoelectron spectrometry, Unstable intermediates in the gaseous phase: The thermal decomposition of alkyl sulfides RS_nR (SC) 104 [G.E. 105]
Unstable intermediates in the gaseous phase: The thermal decomposition of acyl chlorides RCOCl (SC) 105 [G.E. 106]
Photolysis, A trimeric cyclopentadienone derivative by ~ of 3,5-diphenyl-4H-thiopyran-4-one 1,1-dioxide with daylight (SC) 653 [G.E. 659]
~ of saturated alcohols, ethers, and amines (LA) 804
Photooxidation, Synthesis of α,β-unsaturated cyclic ketones by sensitized ~ of silyl enol ethers (SC) 413 [G.E. 426]
~ of polymers (LA) 660
Picosecond chemistry (LA) 60
Pineal gland biorhythms (LA) 122
Planar coordination, Oxometalates with ~ (FP) 674 [G.E. 704]
Plastics, Einführung in die Chemie und Technologie der Kunststoffe (Book Review) 272
Platinum complexes, A general method for the synthesis of sandwich-type complexes with a Pd—Pd or Pt—Pt bond (SC) 412 [G.E. 427]
Novel monobridged dinuclear platinum species (SC) 482 [G.E. 495]
Novel transformation of diphenylcyclopropenone: Double bond cleavage in the reaction with ~ (SC) 793 [G.E. 838]
Palladium(II) and platinum(II) complexes with polymeric Schiff base ligands (SC) 860 [G.E. 898]
Poisons, Die Giftliste (Book Review) 202
Polar effects in the addition of alkyl radicals to olefins (SC) 178 [G.E. 178]
Polyethers, Noncyclic cryptates (SC) 548 [G.E. 564]
Polymeric carriers, Repetitive peptide synthesis with insoluble polymer-bound reagents and solubilizing macromolecular peptide carriers (SC) 642 [G.E. 681]
Polymerization, Crystallographic analysis of a topochemical ~ (SC) 416 [G.E. 432]
~ (LA) 732
Mechanism of ~ in the solid state (LA) 804
Polymers, Poly(organophosphazenes)—Unusual new high ~ (FP) 147 [G.E. 153]
Photodielectric ~ for holographic use (FP) 441 [G.E. 467]
Entanglement of thread molecules and its influence on the properties of ~ (FP) 751 [G.E. 773]
Photooxidation of ~ (LA) 660
~ which become electrical conductors on irradiation (LA) 660
Polyphosphazenes, Poly(organophosphazenes)—Unusual new high polymers (FP) 147 [G.E. 153]
Polysaccharides, Secondary and tertiary structure of ~ in solutions and gels (FP) 214 [G.E. 228]
Porphyrins, Dichloro(porphyrinato)molybdenum(IV)—Synthesis and structure (SC) 788 [G.E. 819]
Potassium-dinitrogen cluster, Hexameric $KN_2Co[P(CH_3)_3]_3$—A novel ~ (SC) 485 [G.E. 499]
Potentiometric titrations, Fully automatic ~ (FP) 157 [G.E. 129]
Proline, Simple synthesis of racemic ~ (SC) 777 [G.E. 824]
Propellanes (Book Review) 420
Prostaglandins, Synthesis and function in the heart (LA) 122
Influence on the behavior of blood vessels (LA) 123
Proteinase inhibitors of plants and microorganisms (LA) 419
Proteins, Structural rules for globular ~ (FP) 23 [G.E. 24]
Organic fluorescence reagents in the study of enzymes and ~ (FP) 137 [G.E. 142]
Protein synthesis, Role of hemin in the regulation of ~ in erythroid cells (LA) 200
Protohypericin, Synthesis from emodin (SC) 46 [G.E. 55]
Protonation, Site of ~ of dimethyl sulfoxide—Raman spectroscopic data (SC) 197 [G.E. 200]
Ortho-para ~ of toluene and ethylbenzene in super acids (SC) 315 [G.E. 323]
Pseudoglycals, Simple de-novo synthesis of reactive ~ (hex-2-enopyranosides)—Stereospecific α-glycoside coupling (SC) 783 [G.E. 822]
Pyrazine imines, Heat of hydrogenation of compounds containing isolated and conjugated C=N double bonds (SC) 47 [G.E. 48]
Pyrenophorin, Synthesis and determination of the absolute configuration of ~ and vermiculin (SC) 264 [G.E. 270]
Pyridines, Cobalt-catalyzed one-step synthesis of annelated ~ (SC) 708 [G.E. 758]
6H-Pyrido[4,3-b]carbazole, Synthesis (LA) 803
Pyridoxal-containing enzymes, Activation of double bonds in dehydro amino acids: a model for ~ in elimination-addition reactions (SC) 328 [G.E. 345]
(Pyridylazo)naphthol, Intramolecular oxidative addition of azopyridine to phosphorus(III) (SC) 865 [G.E. 903]
Pyrimidine nucleosides, Syntheses and rearrangements of 5-substituted ~ and pyrimidine nucleotides (LA) 556
Pyrimidines, New synthesis of ~ and pyrimidinones (SC) 779 [G.E. 816]
Pyrimidinones, New synthesis of pyrimidines and ~ (SC) 779 [G.E. 816]
Pyro-compounds, Inorganic ~ (LA) 60
Pyrometallurgy, Principles of ~ (Book Review) 491
Pyrroles, Condensation of α-acylaminoalkyl methyl ketones to give N-acyl-~ (SC) 252 [G.E. 256]
Nickel(II)-catalyzed synthesis of pyrroles from 2H-azirines and activated ketones (SC) 647 [G.E. 672]
Total synthesis of [^{14}C]- and [^{3}H]-labeled tripyrrole precursors for heme biosynthesis (SC) 651 [G.E. 676]
Pyrrolidine, Simple synthesis of racemic proline (SC) 777 [G.E. 824]
β-(1-Pyrrolidinyl)acrylonitrile, Functional vinyl carbanions—Deprotonation of ~ (SC) 853 [G.E. 891]
Pyrrolodiazines (LA) 661

QUANTUM chemistry, Early history of the quantum mechanical treatment of the chemical bond (FP) 87 [G.E. 89]
Quinhydrones, Stereoisomeric ~ of the [2.2](1,4)naphthalenophane series (SC) 392 [G.E. 406]
An intramolecular quinhydrone of the [2](1,4)naphthaleno[2]paracyclophane series (SC) 394 [G.E. 407]
Diastereomeric [3.3]paracyclophane ~ (SC) 799 [G.E. 839]
Indirectly transmitted charge-transfer interactions: Multilayered [2.2]paracyclophane ~ (SC) 801 [G.E. 841]

[4]RADIALENE, Reversible transition between a ~ and a cyclobutadiene by electron transfer (SC) 410 [G.E. 424]
Radical anions, Thiathione ~: Are (—S)$_2$C=S groups electron traps? (SC) 724 [G.E. 745]
ESR spectroscopy studies on the radical anion of [^{33}S]-2,2,4,4-tetramethylpentane-3-thione (SC) 726 [G.E. 744]
Radical cations, Radical cation of [2.2](9,10)anthracenophane as a model for dimeric anthracene ~ (SC) 657 [G.E. 666]
Radical ions, Oxidation and reduction of methylthio-substituted π-systems and the electron distribution in their ~ (SC) 855 [G.E. 893]
Radicals, Polar effects in the addition of alkyl ~ to olefins (SC) 178 [G.E. 178]
Reaction enthalpy, Determination of ~ in the ion-exchange of chlorine isotopes (SC) 114 [G.E. 118]
Formation of the (Z,E)-1,3-diphenylallyl radical from the (Z,E)-1,3-diphenylallyl anion by electron transfer—Comparison of the rotational barriers of the radical and the anion (SC) 869 [G.E. 907]
Reactions, Reaktionen der organischen Chemie (Book Review) 61
Reactivity, Basis and limitations of the ~-selectivity principle (FP) 125 [G.E. 162]
Rearrangements, Determination of activation volume $\Delta V^{\neq}$ of simple molecular ~ by high-resolution ^{1}H-NMR spectroscopy at high pressures (SC) 331 [G.E. 340]
Thermal rearrangement of silylmethyl acetates (SC) 712 [G.E. 765]
Free-radical ~ in telomerization (LA) 271
Receptors, Flexible drug molecules and dynamic ~ (FP) 766 [G.E. 805]
Redox condensation, Decarboxylative dehydration of β-hydroxycarboxylic acids by ~: A novel olefin synthesis (SC) 255 [G.E. 265]
Redox systems, cis-2-Telluro-1,3,2λ^5,4λ^3-diazadiphosphetidine—A fluxional ~ (SC) 486 [G.E. 500]
Reduction, Electrochemical ~ of 2,2,2-trichloroethanols (SC) 57 [G.E. 54]
Renin, Structure-activity relations of antagonists of the ~-angiotensin system (LA) 201
Rhenium, Molecular structure of [η-$C_5H_5(CO)_2Re{=}C(C_6H_5)P(CH_3)_3][BCl_4]$ (SC) 543 [G.E. 553]
Rhenium complexes, Preparation of halogen-bridged cationic dinuclear complexes of manganese and rhenium (SC) 56 [G.E. 53]
Phenyl(trimethylphosphonio)methanidyl, a novel 3-electron bridge ligand (SC) 314 [G.E. 325]
Molecular structure of [η-$C_5H_5(CO)_2$-$Re{=}C(C_6H_5)P(CH_3)_3][BCl_4]$ (SC) 543 [G.E. 553]
Rhodamine, Photochromism of ~ derivatives (SC) 113 [G.E. 116]
Rhodium(I) complexes, Resolution of a chiral olefin by complexation chromatography on an optically active ~ (SC) 110 [G.E. 113]
Reactivity of η^5-indenyl-~; cyclocotrimerization of alkynes with alkenes (SC) 648 [G.E. 671]
D-Ribofuranose, α-Glycosidic linkage (SC) 48 [G.E. 58]
Ribonucleic acid, Dependence of translation on the 5'-terminal methylation of m-~ (LA) 200
Ring expansion, The zip reaction: A new method for ~; synthesis of 17- and 21-membered polyaminolactams (SC) 861 [G.E. 899]
Ring opening reactions, Electrocyclic ~ of ethylene oxides (FP) 572 [G.E. 589]
Rotamers, Detection of rigid ~ in disubstituted cyclopentadienylcobalt complexes (SC) 795 [G.E. 836]
Rotational barriers, Formation of the (Z,E)-1,3-diphenylallyl radical from the (Z,E)-1,3-diphenylallyl anion by electron transfer—Comparison of the ~ of the radical and the anion (SC) 869 [G.E. 907]
Rotatory dispersion, Infrared ~ of liquid-crystalline solutions of chiral molecules (SC) 790 [G.E. 830]
Relationship between the infrared ~ of liquid-crystalline solutions of chiral molecules and their absolute configuration (SC) 791 [G.E. 831]
Rubber, Vulcanization of natural and synthetic ~ (LA) 660

Ruthenium complexes, Isolation and vibrational spectra of bond-isomeric hexakis-(thiocyanato) complexes of ruthenium(III) and osmium(III) (SC) 108 [G.E. 108]

SANDWICH complexes, New varieties of ~ (FP) 1 [G.E. 1]
(η-Cyclopentadienyl)cobalt-(η-diborolen-yl)(η-cyclopentadienyl)iron—A triple decker sandwich complex containing two different metals (SC) 857 [G.E. 895]
Schiff base complexes, Addition compounds with polymeric chromium(II)-~ (SC) 859 [G.E. 897]
Palladium(II) and platinum(II) complexes with polymeric Schiff base ligands (SC) 860 [G.E. 898]
Schiff bases, Control of the nickel-catalyzed cooligomerization of butadiene with ~ by cocatalysts (SC) 253 [G.E. 261]
Seawater analysis, Methods of ~ (Book Review) 491
Seaweeds, Volatile compounds from ~ (LA) 419
Selectivity, Basis and limitations of the reactivity-~ principle (FP) 125 [G.E. 162]
The ~ of chemical reactions disguised by diffusion. Part I: Chemical ~ disguised by mixing (FP) 807 [G.E. 847]
Temperature dependence of ~ of the halogen donors $XCCl_3$ (SC) 466 [G.E. 482]
Disguised chemical selectivities (LA) 123
Selenides, α-Halogenoalkyl ~ and α-(phenylseleno)alkanide anions (SC) 541 [G.E. 561]
2C-chain elongation of lithioalkanes with diphenylvinylarsane and phenyl vinyl selenide (SC) 710 [G.E. 760]
Selenium compounds, 5H-[1]Benzoselenino[2,3-b]pyridine—A novel heterocyclic ring system (SC) 319 [G.E. 329]
Selenoacetals, Synthesis of di-~ and O-(trimethylsilyl)mono-~ (SC) 540 [G.E. 559]
Selenoalkanide anions, α-Halogenoalkyl selenides and α-(phenylseleno)alkanide anions (SC) 541 [G.E. 561]
Selenol esters, Synthesis of thiol esters and ~ from carboxylic acids and thiols or selenols, respectively (SC) 244 [G.E. 251]
~—A novel class of liquid-crystal compounds (SC) 318 [G.E. 328]
Semibullvalene, 5-Methoxy-~ (SC) 475 [G.E. 491]
Sesquiterpene lactones, Biological activity (LA) 121
Silanes, Reaction of olefins with silane and carbon monoxide catalyzed by $Co_2(CO)_8$ (SC) 174 [G.E. 196]
Preparation of cyclohexasilane, Si_6H_{12} (SC) 403 [G.E. 417]
Anomalous nucleophilic substitution in (chloromethyl)silane: 1,2-hydride shift (SC) 639 [G.E. 678]
Catalyst dependent product distribution in the reaction of 1-hexene with a hydrosilane and carbon monoxide (SC) 881 [G.E. 919]
Silicates, $K_6[Si_2Te_6]$—Synthesis and structure of the first tellurodisilicate (SC) 554 [G.E. 566]
Silicides, Crystal structure of barium disilicide at high pressures (SC) 659 [G.E. 673]
Silicon compounds, A novel 3z-2e bond system (SC) 248 [G.E. 257]
Silatautomeric organylcarbodiimides/cyanamides (SC) 311 [G.E. 336]
Synthesis and some reactions of 1,1-dimethyl-2,2-bis(trimethylsilyl)-1-silaethane (SC) 328 [G.E. 343]
Silylaluminum compounds, Synthesis and properties of tris(trimethylsilyl)aluminum (SC) 480 [G.E. 497]
Silyl compounds, N-(Trimethylsilyl)amino acid trimethylsilyl esters as reagents for directed self-condensation of methyl ketones under mild conditions (SC) 251 [G.E. 255]
Silyleneiron complexes, Base-stabilized ~ (SC) 785 [G.E. 823]
Silyl enol ethers, Synthesis of α,β-unsaturated cyclic ketones by sensitized photooxidation of ~ (SC) 413 [G.E. 426]
Chemistry (LA) 335
Silylmethyl acetates, Thermal rearrangement (SC) 712 [G.E. 765]
Soil atmosphere, Analysis by gas chromatography (LA) 419
Solvents, Handbook of analysis of organic ~ (Book Review) 123
Spatial requirements, Steric interactions in organic chemistry: ~ of substituents (FP) 429 [G.E. 443]
Sphingolipid storage diseases, Biochemistry (FP) 273 [G.E. 283]
Spiro compounds having a nonplanar 1,4-dihydropyridine ring from diaziridinimines and dimehyl acetylenedicarboxylate (SC) 177 [G.E. 202]
Stability, Observation of a linear relationship between thermal ~ and strain energy of alkanes (SC) 875 [G.E. 913]
Stannyl azides, Synthesis of N-protected amino acids with the aid of ~ (SC) 550 [G.E. 570]
Statistics, Lehrprogramm Statistik (Book Review) 202
Stereochemistry, Synthesis and ~ of strained naphthalenophanes (SC) 175 [G.E. 199]
Stereoscopic pictures, Strukturen der Materie und ihre Symmetrie in Stereobildern (Book Review) 336
Stereoselective synthesis, Simple ~ of eburnamonine (SC) 878 [G.E. 916]
Steric accelerations, Steric enhancement of chemical reactivity. The molecular structure of tris(tert-butyl)methyl p-nitrobenzoate (SC) 654 [G.E. 658]
Steric interactions in organic chemistry: Spatial requirements of substituents (FP) 429 [G.E. 443]
Steroids, Asymmetric induction in the total synthesis of 19-nor-~ (LA) 201
Strain energy, Observation of a linear relationship between thermal stability and ~ of alkanes (SC) 875 [G.E. 913]
Structural rules for globular proteins (FP) 23 [G.E. 24]
Sulfanes, Bis(trifluoromethyl)disulfane oxide $CF_3S(O)SCF_3$ (SC) 723 [G.E. 740]
Sulfides, Unstable intermediates in the gaseous phase: Thermal decomposition of alkyl ~ RS_nR (SC) 104 [G.E. 105]
Thioethers (~) (LA) 803
Literature concerning di- and poly-~ (LA) 804
Sulfinylhydrazine, X-Ray structure analysis of N-phenyl-N'-~ (SC) 179 [G.E. 190]
Sulfone pyrolysis, New type of helical hydrocarbon—Novel C—C coupling by ~ (SC) 325 [G.E. 358]
Sulfonium salts, Vinylenedionium salts containing different onium groups (SC) 471 [G.E. 488]
Reactions of (2-dialkylsulfoniovinyl)trialkylammonium salts (SC) 473 [G.E. 489]
Sulfonyldiazenes, N-Acyl-N'-aryl-~; detection and use in the synthesis of amides (SC) 728 [G.E. 742]
Sulfoxides, Site of protonation of dimethyl sulfoxide—Raman spectroscopic data (SC) 197 [G.E. 200]
Sulfur, Detection of S_6 and S_7 in molten cycloocta-~ (SC) 112 [G.E. 114]
Crystal and molecular structure of cycloheptа-~ (δ-S_7) (SC) 715 [G.E. 756]
Bond interaction in ~ rings: crystal and molecular structure of cyclo-hepta-~ oxide, S_7O (SC) 716 [G.E. 757]
Sulfuranes, A stable acyclic alkoxyhalosulfurane: Chlorotris(2,2,2-trifluoro-1-trifluoromethylethoxy)sulfurane (SC) 862 [G.E. 900]
Elemental ~ and its reactions (LA) 660
Sulfur compounds, Cyclopropenes as vinylcarbenoids: intermolecular carbene-addition reactions of sulfinyl- and sulfonylcyclopropenes at room temperature (SC) 323 [G.E. 331]
New aliphatic thiacylating reagents; preparation of tert-butyl esters of aliphatic dithiocarboxylic acids via bis(thioacyl) sulfide (SC) 786 [G.E. 820]
2,4-Diisopropyl-1,3-dithietane-2,4-diyl bis-(dithioisobutyrate), a dimeric form of bis-(thioacyl) sulfide (SC) 787 [G.E. 820]
Tris(tert-butylimino)sulfur(VI) and bis(tert-butylimino)(silylimino)sulfur(VI): The "Y-triene" structure (SC) 789 [G.E. 829]
Sulfur labels, Preparation of thiocarbonyl compounds containing isotopic ~ (SC) 725 [G.E. 743]
Super acids, Ortho-para protonation of toluene and ethylbenzene in ~ (SC) 315 [G.E. 323]
Surface, The ~ chemical bond (FP) 92 [G.E. 94]
The ~ of titanium dioxide (LA) 122
Symmetry, Strukturen der Materie und ihre Symmetrie in Stereobildern (Book Review) 336
Synthetic methods, Intramolecular [4+2] and [3+2] cycloadditions in organic synthesis (FP) 10 [G.E. 10]
Recent applications of α-metalated isocyanides in organic synthesis (FP) 339 [G.E. 351]
Phosphacumulene ylides and phosphaallene ylides (FP) 349 [G.E. 361]
Flash thermolysis of organic compounds (FP) 365 [G.E. 377]
Advances in phase-transfer catalysis (FP) 493 [G.E. 521]
Titanium tetrachloride in organic synthesis (FP) 817 [G.E. 858]

TANTALUM disulfide, Demonstration of the ionic structure of the intercalation compound $TaS_2 \cdot NH_3$ (SC) 199 [G.E. 193]
cis-2-Telluro-1,3,2λ⁵,4λ³-diazadiphosphetidine—A fluxional redox system (SC) 486 [G.E. 500]
Tellurodisilicate, $K_6[Si_2Te_6]$—Synthesis and structure of the first ~ (SC) 554 [G.E. 566]
Tellurophene (LA) 732
Tellurium oxide fluorides, The Te—O—Fe system: $Te(OTeF_5)_6$ (SC) 729 [G.E. 741]
Tetracyanoethylene, Comparison of calculated and experimental electron difference densities of ~ (SC) 257 [G.E. 263]
Tetracyclododecanes, Structures of two highly strained ~ (SC) 798 [G.E. 833]
Textile auxiliary agents, Handbuch der Textilhilfsmittel (Book Review) 661
Thermolysis, Flash ~ of organic compounds (FP) 365 [G.E. 377]
μ-Thiadiborolene-bis(η-thiadiboroleneco-balt)—A "homogeneous" triple-decker sandwich with three heterocyclic ligands (SC) 333 [G.E. 346]
6aλ⁴-Thiapentalenes, New synthetic methods for ~ (SC) 403 [G.E. 420]
Thiathione radical anions: Are (—S)₂C=S groups electron traps? (SC) 724 [G.E. 745]
Thienopyridines (LA) 732
Thiiranes, Homologization of aldehydes and ketones to ~ or S-vinyl thiocarbamates via 2-alkylimino-1,3-oxathiolanes (SC) 462 [G.E. 478]
Thioacyl sulfides, Isolation of acyl ~ (SC) 879 [G.E. 917]
Thiocarbonyl and carbonyl groups (LA) 732
Thiocarbonyl compounds, Preparation of ~ containing isotopic sulfur labels (SC) 725 [G.E. 743]
Thiocarbonyl ylides, Stable ~ (SC) 866 [G.E. 904]
Thiodicarboximides, Reaction of mono-~ with phosphorus ylides: A new synthesis of ω-alkylidenelactams (SC) 418 [G.E. 429]
Thioethers (sulfides) (LA) 803
Thioformamide, N,N-Bis(trimethylsilyl)enamines—Stereoselective synthesis from N,N-bis(trimethylsilyl)-~ (SC) 535 [G.E. 550]
Thioheteroanions—Unusual metal-ligand interaction and reactions (SC) 705 [G.E. 748]
Thioketenes, α-Thiolactones from ~ (SC) 722 [G.E. 750]

ESR spectroscopy studies on the radical anion of [^{33}S]-2,2,4,4-tetramethylpentane-3-thione (SC) 726 [G.E. 744]
α-Thiolactones from thioketenes (SC) 722 [G.E. 750]
Thiol esters, Synthesis of ~ and selenol esters from carboxylic acids and thiols or selenols, respectively (SC) 244 [G.E. 251]
Thiols (mercaptans) (LA) 732
Thiocyanato complexes, Isolation and vibrational spectra of bond-isomeric hexakis-(thiocyanato) complexes of ruthenium(III) and osmium(III) (SC) 108 [G.E. 108]
4H-Thiopyran-4-one 1,1-dioxide, Trimeric cyclopentadienone derivative by photolysis of 3,5-diphenyl-~ with daylight (SC) 653 [G.E. 659]
Thread molecules, Entanglement of ~ and its influence on the properties of polymers (FP) 751 [G.E. 773]
Through-bond interaction between two mutually perpendicular systems—A new possibility of conjugation (SC) 110 [G.E. 122]
Tin compounds, Structure of the first four-membered cyclic diorganyltin chalcogenides (SC) 547 [G.E. 556]
Dimeric bis(di-tert-butylphosphino)stannanediyl: A cyclic phosphorus-tin ylide (SC) 792 [G.E. 832]
Titanium dioxide, Surface (LA) 122
Titanium tetrachloride in organic synthesis (FP) 817 [G.E. 858]
Titrations, Fully automatic potentiometric ~ (FP) 157 [G.E. 129]
Toluene, Ortho-para protonation of ~ and ethylbenzene in super acids (SC) 315 [G.E. 323]
p-Tolylketenyl as novel dihapto 3-electron ligand (SC) 102 [G.E. 110]
Topochemical polymerization, Crystallographic analysis of a ~ (SC) 416 [G.E. 432]
Toxins from marine organisms (LA) 335
Trace analysis, Quantitative ~ of metals by field desorption mass spectrometry (SC) 852 [G.E. 890]
Transition-metal chelates, Stereoselectivity in the binding of ~ to nucleic acid constituents (LA) 557
Transition metal complexes, Cyclometalation reactions (FP) 73 [G.E. 75]
Transition metal compounds, Aspects of the photochemistry of organo-~ (LA) 200
Triacetylcellulose, Column chromatography on ~. Preparative separation of enantiomeric diaziridines (SC) 405 [G.E. 419]
Triaza-λ^5-phosphetine, An imino-bridged ~ (SC) 783 [G.E. 817]
1,2,4,3λ^3-Triazaphospholes synthesized by reductive ($\sigma^4 \rightarrow \sigma^2$)-elimination at phosphorus (SC) 546 [G.E. 554]
Trifluoromethylamine, CF_3NH_2 (SC) 707 [G.E. 754]
Trifluoromethylation, A new method for the introduction of trifluoromethyl groups (SC) 854 [G.E. 892]
(Triphenylstannyl)methyllithium, Carbonyl olefination with ~ (SC) 862 [G.E. 900]
Tripyrroles, Total synthesis of [^{14}C]- and [^{3}H]-labeled tripyrrole precursors for heme biosynthesis (SC) 651 [G.E. 676]
Tris(tert-butyl)methyl p-nitrobenzoate, Steric enhancement of chemical reactivity. Molecular structure of ~ (SC) 654 [G.E. 658]
Trishomocubanones, Synthesis and absolute configuration of enantiomerically pure D_3-trishomocubanes (pentacyclo[6.3.0.0^{2,6}.-0^{3,10}.0^{5,9}]undecane) and ~ (SC) 116 [G.E. 119]
Trityl chloride, Ionization barrier of ~ in sulfur dioxide (SC) 256 [G.E. 266]
Trivial names, Trivialnamenkartei (Book Review) 336
Tryptamines, Phenethylamines and ~; related compounds of plant origin (LA) 490
Tryptophan, Side reactions in peptide synthesis: tert-butylation of ~ (SC) 317 [G.E. 330]
Tungsten complexes, p-Tolylketenyl as novel dihapto 3-electron ligand (SC) 102 [G.E. 110]
Triphenylsilylcarbyne complexes of tungsten (SC) 401 [G.E. 416]
Synthesis of dinuclear complexes containing PCl_2 and PF_2 bridges (SC) 408 [G.E. 421]
Synthesis of alkyne-bridged dinuclear complexes by reaction of trans-halotetracarbonyl(methylcarbyne)-tungsten with methylenebis(diphenylarsane) (SC) 465 [G.E. 481]
Tungsten compounds, Phenyl(trimethylphosphonio)methanidyl, a novel 3-electron bridge ligand (SC) 314 [G.E. 325]
Thioheteroanions—Unusual metal-ligand interaction and reactions (SC) 705 [G.E. 748]

ULLMANNS Encyklopädie der technischen Chemie (Book Review) 62, 202
Urease, Binding of ~ to anodized sheet aluminum (SC) 714 [G.E. 761]

VANADIUM(V) compounds, Diastereoselective synthesis of the aporphine alkaloid (+)-cataline. Hydroxylation with vanadium(V) trifluoride oxide (SC) 730 [G.E. 739]
Vermiculin, Synthesis and determination of the absolute configuration of pyrenophorin and ~ (SC) 264 [G.E. 270]
Vinyl carbanions, Functional ~—Deprotonation of β-(1-pyrrolidinyl)acrylonitrile (SC) 853 [G.E. 891]
Vinylcarbenoids, Cyclopropenes as ~: Intermolecular carbene-addition reactions of sulfinyl- and sulfonylcyclopropenes at room temperature (SC) 323 [G.E. 331]
Vinyl cations, Stabilized ~ (LA) 121
Vinylenedionium salts containing different onium groups (SC) 471 [G.E. 488]
Vinyloxiranes, δ-Lactones by carbonylation of ~ (SC) 50 [G.E. 47]
Vinylic hydrogen atoms, Nucleophilic substitution of ~ by carbanions (SC) 44 [G.E. 46]
Vitamin B_{12}, New developments in the field of ~: Enzymatic reactions dependent upon corrins and coenzyme B_{12} (FP) 233 [G.E. 239]
Vitamins, Effect on drug metabolism (LA) 200
Vulcanization of natural and synthetic rubber (LA) 660

WIELAND, Heinrich Wieland centennial: His lifework and his legacy today (FP) 559, 884 [G.E. 575, 922]
Wittig reaction, ~ in industrial practice (FP) 423 [G.E. 437]
Carbonyl olefination with (triphenylstannyl)methyllithium (SC) 862 [G.E. 900]

X-RAY diffraction, Experimental electron densities and chemical bonding (FP) 23 [G.E. 33]
β-D-Xylopyranose, Tetraaxial conformation of 1,2,3,4-tetra-O-benzoyl-~ (SC) 52 [G.E. 51]

YLIDES, Phosphacumulene ~ and phosphaallene ~ (FP) 349 [G.E. 361]
"Carbodiphosphoranes" by a new rearrangement of phosphorus ~ (SC) 417 [G.E. 428]
Reaction of monothiodicarboximides with phosphorus ~: A new synthesis of ω-alkylidenelactams (SC) 418 [G.E. 429]
Stable thiocarbonyl ~ (SC) 866 [G.E. 904]
Preparation and reactions of a cyclic phosphaallene ylide (SC) 877 [G.E. 915]

ZINCATES, Coordination number 3 in oxo-~: $Rb_8[OZnO_2ZnO_2ZnO_2ZnO]$ and $K_2[Zn_6O_7]$ (SC) 484 [G.E. 498]
Zinc complexes, "Supersandwich"-type trinuclear complexes with a spiro center (SC) 324 [G.E. 332]
Zinc compounds, $[Zn_2Cr(OH)_6]X \cdot 2H_2O$, new layer compounds capable of anion exchange and intracrystalline swelling (SC) 265 [G.E. 259]
Zip reaction: A new method for ring expansion; synthesis of 17- and 21-membered polyaminolactams (SC) 861 [G.E. 899]
Zwitterions, Spontaneous alternating copolymerization via zwitterion intermediates (FP) 826 [G.E. 867]
Four-membered phosphorus-nitrogen-metal heterocycles with zwitterionic structure (SC) 864 [G.E. 902]
