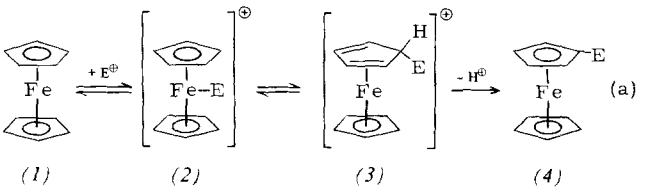
New Varieties of Sandwich Complexes[**]

By Helmut Werner[*]

Metal sandwich complexes of the classical type $M(C_nH_n)_2$ and related structural analogs are characterized by a sandwich-like coordination of *one* central atom by its ligands. This structural principle has been extended in recent years now that *di-* and *tri-nuclear* sandwich-type complexes have become accessible. The best-known representatives are the triple-decker sandwich complexes. A survey of this topical field is presented in this report, which also underlines the utility of kinetic and mechanistic studies for the development of new synthetic pathways in organometallic chemistry.

1. Introduction



The chemistry of sandwich complexes celebrates its 25th anniversary in these months. In its second December issue of 1951, the journal "Nature" contained a paper by *Kealy* and *Pauson* entitled "A New Type of Organo-Iron Compound", which reported the preparation of a compound of composition $FeC_{10}H_{10}$[1a]. Shortly afterwards, in the March issue of the Journal of the Chemical Society, *Miller*, *Tebboth*, and *Tremaine* described an independent but just as unexpected synthesis of "dicyclopentadienyliron"[1b]. The unusual (one could say provocative) properties of this substance prompted a unique development of epoch-making scale in organometallic chemistry. The first moves are common knowledge: just a few months after publication of the paper in "Nature" *Wilkinson*[2] and *Fischer*[3] proposed the correct structure of the new compound, *Woodward*[4] proved its "aromatic character" (thereby introducing the name "ferrocene"), and still in 1952 the first dicyclopentadienyl complexes of other transition metals were obtained[5].

Today, 25 years after the birth of ferrocene, the chemistry of $M(C_5H_5)_2$ complexes has become a well-established field of broad proportions. The first representative of these compounds, ferrocene, which displays exceptional thermodynamic stability and obeys the 18-electron rule, has been joined by the electron-deficient "metallocenes" with M = V, Cr, and Mn, on the one hand, and the electron-rich compounds with Co or Ni as central atom on the other. Although the prototype compound $Fe(C_5H_5)_2$ has retained pride of place among the metallocenes, especially in the general chemical literature, recent studies on the reactions of the formerly somewhat neglected compounds $Co(C_5H_5)_2$ and $Ni(C_5H_5)_2$ have provided entry to completely new types of organometallic complexes with sandwich structures. Some of the pathways leading through this new territory will now be considered.

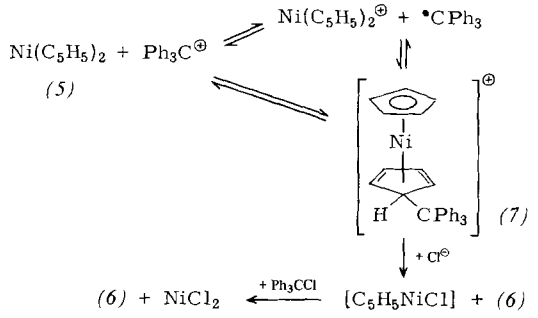
2. Triple-Decker Sandwich Complexes

2.1. Synthetic Studies

Ferrocene *(1)* is extremely susceptible to electrophilic substitution. The following mechanism is generally accepted for this reaction[6]:

[*] Prof. Dr. H. Werner
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

[**] Based on a main lecture delivered at the General Meeting of the Gesellschaft Deutscher Chemiker at Cologne, September 1975.



Initial attack by an electrophile accordingly takes place *at the metal*, and is followed by formation of a C—E bond and by expulsion of a proton to give the substituted complex *(4)*. The low stability of the intermediate *(3)* is explained in terms of the tendency of the iron atom, which has a 16-electron configuration, to complete its electron shell to give a species with 18 electrons.

If this interpretation is valid, a cation analogous to *(3)* containing Ni instead of Fe should be stable, since it would have 18 electrons in its valence shell. Owing to the failure of attempts to synthesize alkyl- or acyl-substituted nickelocenes starting from $Ni(C_5H_5)_2$[7], we first employed triphenylmethyl reagents in our studies instigated in 1970.

Nickelocene *(5)* reacts fast and quantitatively with Ph_3CCl[*] in nitromethane according to equation (b) to form *(6)*, an isomeric mixture of 1- and 2-triphenylmethylcyclopentadiene[8].

$$Ni(C_5H_5)_2 + 2\ Ph_3CCl \longrightarrow NiCl_2 + 2\ \text{(6)} \qquad \text{(b)}$$
(5)

We proposed the following mechanism for this reaction:

Scheme 1

The cation *(7)* was assumed to be kinetically very labile and should react further—even with weak Lewis bases—with cleavage of the nickel-diolefin bond.

In order to suppress such a reaction (and at the same time to trap the complex cation with a bulky anion) we treated nickelocene with $[Ph_3C]PF_6$. The result was more than surprising. Instead of the desired complex $[C_5H_5Ni(C_5H_5CPh_3)]PF_6$ we obtained a blackish brown compound *(8)* of remarkable stability. The yield was quantitative if the molar ratios given in eq. (2) were employed[9].

$$2\ Ni(C_5H_5)_2 + [Ph_3C]PF_6 \longrightarrow [Ni_2C_{15}H_{15}]PF_6 + \text{(6)} \qquad \text{(c)}$$
(5) *(8)*

An analogous product *(9)* is obtained from *(5)* and $[Ph_3C]BF_4$. The same compound [see eq. (d)] is also accessible starting from $[Ph_2CH]BF_4$, $[C_7H_7]BF_4$, $[OMe_3]BF_4$, and HBF_4.

$$2\ Ni(C_5H_5)_2 + [R]BF_4 \longrightarrow [Ni_2C_{15}H_{15}]BF_4 + C_5H_5R \qquad \text{(d)}$$
(5) *(9)*

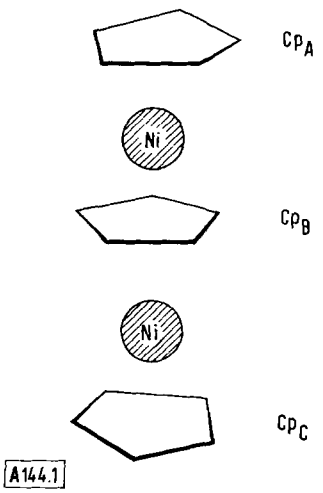
[*] Abbreviations: Me = CH_3, Et = C_2H_5, Pr = C_3H_7, Bu = C_4H_9, Cp = C_5H_5, Ph = C_6H_5, Tol = $C_6H_5CH_3$.

The HBF_4/propionic anhydride system has also proved very suitable for the synthesis of the methyl- and *tert*-butylcyclopentadienyl complexes *(10)* and *(11)*[10].

$$2\ Ni(C_5H_4R)_2 + HBF_4 \longrightarrow [Ni_2C_{15}H_{12}R_3]BF_4 + C_5H_5R \qquad \text{(e)}$$
(10), R = Me
(11), R = *t*-Bu

The ^1H- and ^{13}C-NMR spectra of *(8)* and *(9)* recorded in $[D_3]$nitromethane each contain two sharp singlets in the intensity ratio 2:1, which do not change on warming or cooling. This suggests that the cation $[Ni_2C_{15}H_{15}]^{\oplus}$ contains three symmetrically π-*(pentahapto)*-bonded cyclopentadienyl ligands of which two should be equivalent. The goal of constructing a complex having a triple-decker sandwich structure—already pursued by one of the fathers of sandwich compounds[11]—thus appeared to be fulfilled.

Final confirmation took more than a year. The exceptional reactivity of *(8)* and *(9)* towards Lewis bases ruled out most of the solvents suitable for such salt-like complexes, and only after many futile attempts were single crystals of *(9)* finally obtained from propionic anhydride. The result of crystal structure analysis confirmed the structure we had proposed for the $[Ni_2C_{15}H_{15}]^{\oplus}$ ion[12]. As shown by Figure 1 the two nickel atoms are located between three mutually parallel five-membered rings adopting neither a staggered nor an eclipsed conformation. The Ni-ring center distances to the outer rings Cp_A and Cp_C are 1.728 Å (average value) and are significantly shorter than those to the central ring Cp_B, which are 1.788 Å (average value).



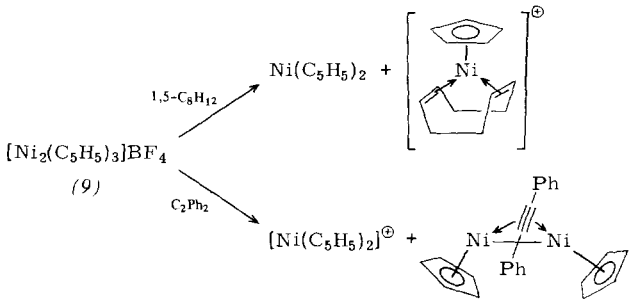


Fig. 1. Structure of the tris(η-cyclopentadienyl)dinickel cation, $[Ni_2(C_5H_5)_3]^{\oplus}$.

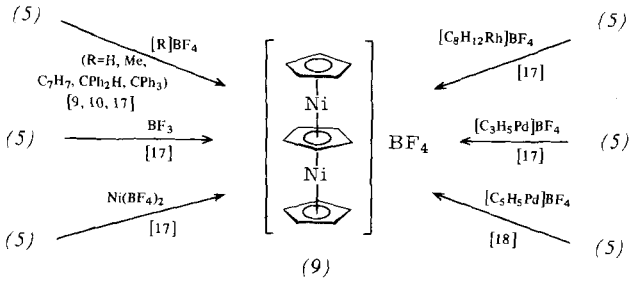
The reactions of compounds *(8)*—*(11)* are in full accord with this result. Reaction of one of the complex salts with a Lewis base L such as PR_3, $P(OR)_3$, AsR_3, or pyridine proceeds according to eq. (f) to give $Ni(C_5H_4R)_2$ and the salt of the corresponding cationic monocyclopentadienylnickel complex[13].

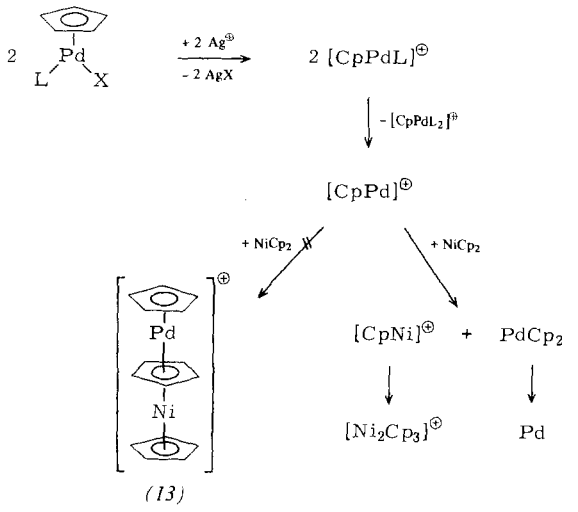


$$[Ni_2(C_5H_4R)_3]BF_4 + 2\ L \longrightarrow Ni(C_5H_4R)_2 + [C_5H_4RNiL_2]BF_4 \qquad \text{(f)}$$

The mechanism of this substitution reaction can be interpreted as follows: attack of the Lewis base L on one of

the nickel atoms removes a "storey" of the triple-decker sandwich and the resulting fragment $C_5H_4RNiL^{\oplus}$ is stabilized by addition of a further molecule L. Chelating ligands L—L (*e.g.* diphos = ethylenebis(diphenylphosphane) or bpy = 2,2'-bipyridine) give the compounds $[C_5H_4RNi(L—L)]BF_4$[13]. Using this approach, the first synthesis of cationic diolefin-nickel complexes $[C_5H_4RNi(diene)]^{\oplus}$ (diene = norbornadiene, 1,5-cyclooctadiene) has also been accomplished and their reactions with nucleophiles studied[14, 15]. Surprisingly, reaction of *(9)* with tolan does not give $Ni(C_5H_5)_2$ and $[C_5H_5Ni(C_2Ph_2)_2]BF_4$ or $[C_5H_5NiC_4Ph_4]BF_4$ but instead the tetrafluoroborate of the nickelocenium ion, otherwise difficult to prepare in pure form, and the previously described neutral complex *(12)*[16].

The synthetic procedure for *(9)* given in eq. (d) has meanwhile been supplemented by others (see Scheme 2). They also provide support for the idea that one of the two cyclopentadienyl rings of *(5)* can easily be liberated on interaction with a Lewis acid, and the resulting cation $C_5H_5Ni^{\oplus}$ readily reacts with $Ni(C_5H_5)_2$ to give the triple-decker sandwich.



Scheme 2

Special mention should be made of the reaction of nickelocene with the 12-electron species $[C_8H_{12}Rh]^{\oplus}$ and $[C_3H_5Pd]^{\oplus}$ and the 14-electron species $[C_5H_5Pd]^{\oplus}$. *Schrock* and *Osborn*[19] have prepared the first two cations *in situ* from the corresponding chlorides $[C_8H_{12}RhCl]_2$ and $[C_3H_5PdCl]_2$, respectively, by treatment with $AgPF_6$ in tetrahydrofuran and established their coordinatively highly unsaturated character by numerous reactions with Lewis bases. Although $Ni(C_5H_5)_2$ clearly acts as a Lewis base towards *e.g.* $H^{\oplus}$, $R^{\oplus}$, or BF_3, it does not build a new storey to form the desired cations $[C_8H_{12}RhC_5H_5NiC_5H_5]^{\oplus}$ and $[C_3H_5PdC_5H_5NiC_5H_5]^{\oplus}$, respectively, on reaction with $[C_8H_{12}Rh]^{\oplus}$ and $[C_3H_5Pd]^{\oplus}$. Instead, reaction proceeds *via* ring ligand transfer[20] to form the corresponding cyclopentadienylrhodium and -palladium complexes and $[Ni_2(C_5H_5)_3]^{\oplus}$[17].

$$C_8H_{12}Rh]^{\oplus} + 2\ Ni(C_5H_5)_2 \longrightarrow C_8H_{12}RhC_5H_5 + [Ni_2(C_5H_5)_3]^{\oplus} \quad (g)$$

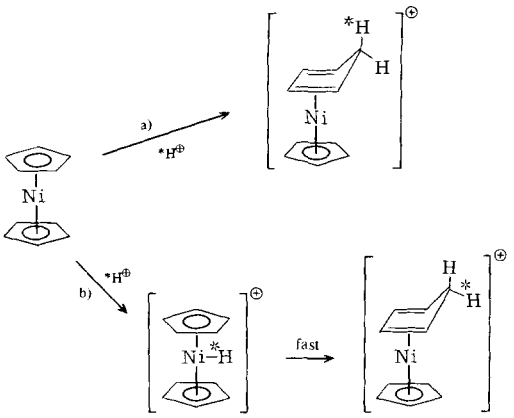
$$C_3H_5Pd]^{\oplus} + 2\ Ni(C_5H_5)_2 \longrightarrow C_3H_5PdC_5H_5 + [Ni_2(C_5H_5)_3]^{\oplus} \quad (h)$$

The synthesis of *(9)* from *(5)* and $[C_5H_5Pd]BF_4$ was discovered by accident. We had intended to produce a "mixed" triple-decker sandwich *(13)* by preparing $[C_5H_5Pd]^{\oplus}$ *in situ*, starting from $C_5H_5Pd(L)X$ (L = PR_3, $P(OR)_3$; X = Cl, Br, I), and subjecting it to reaction with *(5)*. NMR studies by *Turner*[18] show that the desired intermediate $[C_5H_5Pd]^{\oplus}$ is indeed formed, together with highly stable $[C_5H_5PdL_2]^{\oplus}$, but fails to undergo addition with *(5)*, rather reacting *via* ligand transfer and formation of $[Ni_2(C_5H_5)_3]^{\oplus}$[18].

Scheme 3

2.2. Reaction Mechanism

In view of the various synthetic approaches to the complex cation $[Ni_2(C_5H_5)_3]^{\oplus}$ the question occurs whether the reactions summarized in Scheme 2 (which all give practically *quantitative yields* of the triple-decker sandwich) proceed *via* a *common* intermediate or not. The most reasonable candidate would be the (electron-*deficient*) 14-electron species $[C_5H_5Ni]^{\oplus}$ which could react with the (electron-*rich*) $Ni(C_5H_5)_2$ according to eq. (i).



$$[C_5H_5Ni]^{\oplus} + Ni(C_5H_5)_2 \longrightarrow [C_5H_5NiC_5H_5NiC_5H_5]^{\oplus} \quad (i)$$

An *ion-molecule reaction* of this kind had already been detected by *Schumacher* and *Taubenest*[21] as the key step in the formation of the $[Ni_2C_{15}H_{15}]^{\oplus}$ ion in the mass spectrometer. We recently succeeded in isolating salts of the "single-decker" $[C_5H_5Ni]^{\oplus}$ by an unpredicted method. The impetus came from our continued interest in the mechanism of formation of the structurally so "simple" and long-sought complex $[Ni_2(C_5H_5)_3]^{\oplus}$.

In the proposal depicted in Scheme 1, we postulated a species $[C_5H_5Ni(C_5H_5CPh_3)]^{\oplus}$ as intermediate in the reaction of $Ni(C_5H_5)_2$ with $Ph_3C^{\oplus}$[8]. Use of $H^{\oplus}$ in place of $Ph_3C^{\oplus}$ should give $[C_5H_5NiC_5H_6]^{\oplus}$ (an analog of the complexes $[C_5H_5Ni(diene)]^{\oplus}$). All attempts to detect this cation on the action of HBF_4, HPF_6, HBF_3OH, or H_2SO_4 on *(5)* failed, even at −78 °C. Success came only when we used weaker acids. In anhydrous HF as solvent, nickelocene undergoes complete conversion into $[C_5H_5NiC_5H_6]^{\oplus}$, which is stable for several minutes under these conditions and can be unequivocally characterized by NMR spectroscopy[22]. Attempts to

precipitate the complex cation from HF solution as a stable salt $[C_5H_5NiC_5H_6]X$ ($X=BF_4$, SbF_6) by addition of a Lewis acid such as BF_3 or SbF_5 surprisingly led to the isolation of $[C_5H_5Ni]X$[22]. Conductivity measurements confirm the presence of a 1:1 electrolyte. $[C_5H_5Ni]BF_4$ reacts instantaneously and quantitatively with $Ni(C_5H_5)_2$ in nitromethane to form *(9)*, and $[C_5H_5Ni\{P(OPh)_3\}_2]BF_4$ is produced with triphenyl phosphite.

The site of proton attack on the sandwich compound *(5)* could also be elucidated. Two alternatives are possible in principle: (i) direct addition of $H^{\oplus}$ to one of the cyclopentadienyl ligands and (ii) attack of $H^{\oplus}$ on the metal followed by rearrangement with formation of a new C—H bond. In case (i) the proton added should assume an *exo* position in the CH_2 group of the cyclopentadiene, and in case (ii) an *endo* position. The former stereochemistry is found. In the frequency range of the alicyclic protons the ^{1}H-NMR spectrum of the cation $[C_5H_5NiC_5H_5D]^{\oplus}$ formed from *(5)* and CF_3COOD at -18 °C does not contain the signal of an AB system (as for $[C_5H_5NiC_5H_6]^{\oplus}$) but, instead, just a singlet broadened somewhat by H—D coupling, whose chemical shift agrees very well with that of the *endo*-methylene proton in the nondeuterated cation[23].

We therefore assume the following reaction sequence[24] to account for the formation of the triple-decker sandwich from *(5)* and HX (preferably HBF_4 in propionic anhydride[10]):

$$Ni(C_5H_5)_2 + H^{\oplus} \rightleftharpoons [C_5H_5NiC_5H_6]^{\oplus} \xrightarrow[-C_5H_6]{} [C_5H_5Ni]^{\oplus} \xrightarrow{+Ni(C_5H_5)_2} [Ni_2(C_5H_5)_3]^{\oplus}$$

(5)

It should be noted that nickelocene and ferrocene react *differently* with acids such as HBF_4. While attack of the proton is clearly directed at one of the *cyclic ligands* in the case of the nickel complex, reaction of the iron complex affords $[HFe(C_5H_5)_2]^{\oplus}$, *i.e.* attack occurs preferentially at the metal[17]. The latter statement accords with the course of electrophilic substitution formulated in eq. (a).

2.3. The 30-Electron/34-Electron Rule

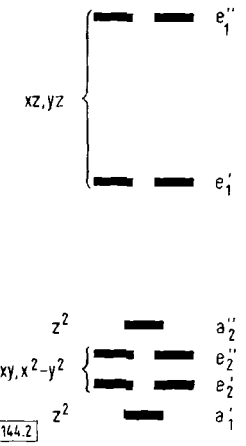
We have also invested considerable effort in attempts to prepare triple-decker sandwich complexes of other transition metals. In their well known experiments, *Schumacher* and *Taubenest* demonstrated[21] not only the formation of $[Ni_2(C_5H_5)_3]^{\oplus}$, but also that of $[Fe_2(C_5H_5)_3]^{\oplus}$ and $[FeNi(C_5H_5)_3]^{\oplus}$ in the mass spectrometer. *King*[25] and also *Müller* and *Fenderl*[26] were later able to supplement and confirm these results. In the consensus of opinion, the reactions leading to the ions $[MM'(C_5H_5)_3]^{\oplus}$ should be formulated thus:

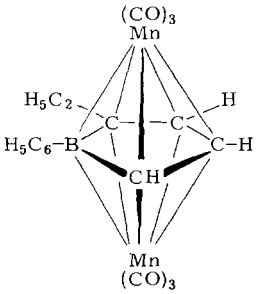
$$M(C_5H_5)_2 \xrightarrow{+e} [M(C_5H_5)_2]^{\oplus} \xrightarrow[-{}^{\bullet}C_5H_5]{} [C_5H_5M]^{\oplus}$$

$$\xrightarrow{+M'(C_5H_5)_2} [MM'(C_5H_5)_3]^{\oplus} \quad (M = M' = Ni, Fe, Cr; M = Ni, M' = Fe)$$

The corresponding reactions could not yet be reproduced in a Schlenk tube, except for that between $[C_5H_5Ni]^{\oplus}$ and $Ni(C_5H_5)_2$. When heated with $Cr(C_5H_5)_2$, the compound $[Cr(C_5H_5)_2]BF_4$ which is readily accessible from $Cr(C_5H_5)_2$ and HBF_4 in propionic anhydride[17], fails to give the desired dinuclear complex, and nor can a triple-decker sandwich be detected on thermolysis of a mixture of $[Fe(C_5H_5)_2]BF_4$ and $Fe(C_5H_5)_2$. The reaction of $[C_5H_5Ni]BF_4$[22] with $Fe(C_5H_5)_2$ does not afford $[FeNi(C_5H_5)_3]BF_4$ (although $[C_5H_5Ni]^{\oplus}$ reacts with $Fe(C_5H_5)_2$ in the mass spectrometer to give $[FeNi(C_5H_5)_3]^{\oplus}$[21]), but proceeds *via* oxidation of ferrocene to $[Fe(C_5H_5)_2]BF_4$.

An explanation for the failure of these attempted syntheses is provided by a very recent paper by *Hoffmann et al.*[27]. On the basis of EHT-MO calculations the authors conclude that triple-decker sandwich complexes of general composition $[C_5H_5MC_5H_5MC_5H_5]$ and $[(CO)_3MC_5H_5M(CO)_3]$ *having 30 and 34 valence electrons* should be stable. Part of the calculated MO scheme is reproduced in Figure 2.





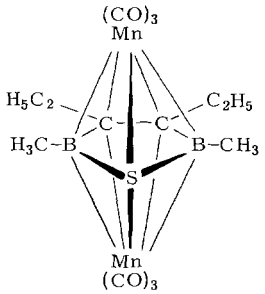


Fig. 2. Characteristic MO scheme for complexes of type $M_2Cp_3^{\oplus}$ and $(CO)_3MCpM(CO)_3^{\oplus}$ (section).

There result six low-lying orbitals (a'_1, e'_2, e''_2, and a''_2) and two pairs of degenerate orbitals (e'_1 and e''_1) of significantly higher energy. In the 34-electron species $[Ni_2(C_5H_5)_3]^{\oplus}$ the e'_1 orbital (which is weakly antibonding relative to the Ni—Cp_A and Ni—Cp_C bonds, and nonbonding relative to the Ni—Cp_B bonds, cf. Figure 1) is occupied by four electrons, while it is empty in the complexes $[C_5H_5Co(C_2B_3H_4R)CoC_5H_5]$ having a carbaborane bridge, which were discovered by *Grimes et al.*[28]. To the 30-electron species also belongs $[Fe_2(C_5H_5)_3]^{\oplus}$ or $[FeMn(C_5H_5)_3]$, whose synthesis is handicapped by the exceptional stability (*i.e.* the pronounced formation tendency) of ferrocene.

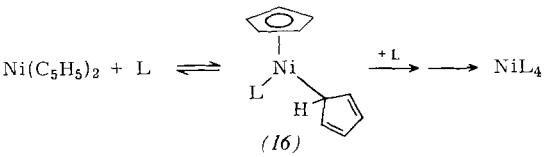
The calculations by *Hoffmann et al.*[27] on the preferred stability of triple-decker sandwich-like complexes having 30 and 34 valence electrons have also received support from the recently reported preparation of two $Mn_2(CO)_6$ compounds with boron-containing heterocycles as bridging ligands, *(14)*[29] and *(15)*[30].

(14)

(15)

Structurally analogous compounds containing three groups X in place of a bridging ring have been known for some time. *Hieber et al.*[31] prepared the complex anions $[(CO)_3M(OH)_3M(CO)_3]^{3\ominus}$ (M = Cr, Mo) as long ago as 1955; *White* and *Farona*[32] synthesized the corresponding halogeno and pseudohalogeno compounds $[(CO)_3MX_3M(CO)_3]^{3\ominus}$ (M = Cr, Mo, W; X = halogen, SCN, N_3, OEt) in 1972; and *Head* and *Nixon*[33] published an entry to the dinuclear complexes $[Ph_3P(L)ClRuCl_3RhCl(L)_2]$ (L = PPh_3, PBu_3, *etc.*) having two different metal centers in 1976. The interesting tris(μ-hydrido) complexes $[(CO)_3ReH_3Re(CO)_3]^{\ominus}$[34a] and [(triphos)-$FeH_3Fe$(triphos)]$^{\oplus}$ (triphos = $MeC(CH_2PPh_2)_3$)[34b] likewise belong to this series.

It is probably not too daring to predict that a whole range of similarly built 30-electron (and perhaps 34-electron) compounds will very soon exist and that the 30-electron/34-electron rule will then be as important for *dinuclear* complexes as the 18-electron rule for mononuclear complexes, especially with π-acceptor ligands.



3. Reactions with Lewis Bases: Unexpected Pathways to Di- and Trinuclear Complexes

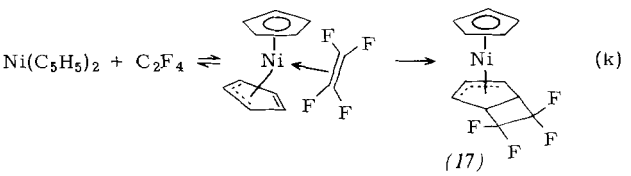
3.1. The Ambivalence of Nickelocene

As shown by the synthesis of the triple-decker sandwich complexes $[Ni_2(C_5H_5)_3]X$, nickelocene reacts with electrophiles or *Lewis acids* $R^{\oplus}$, by attack of the electrophile on *one of the cyclic ligands*. The charge distribution $(C_5H_5^{\delta-})$-$(Ni^{\delta+})(C_5H_5^{\delta-})$ deduced from PE spectra[35] appears to rationalize this behavior. In keeping with this charge distribution, *Lewis bases* L should react with nickelocene *via* attack of L on the metal. This also appears to be the case. Both the reactions of *(5)* with CO[36] and those of the sandwich complex with tertiary phosphanes or isocyanides[37] give very good yields of the nickel(0) compounds NiL_4 according to eq. (j).

$$\underset{(5)}{Ni(C_5H_5)_2} + 4\ L \longrightarrow NiL_4 + C_{10}H_{10} \qquad (j)$$

Ustynyuk et al.[38] have explained the mechanism of this ligand displacement reaction by assuming primary attack of L on the nickel to cause π-σ rearrangement of *one* cyclopentadienyl ligand, giving intermediate *(16)* which reacts with further L (possibly *via* subsequent cleavage of the Ni-σ-C_5H_5 bond) to give NiL_4.

(16)



Preliminary results of our independent kinetic studies on the reaction of nickelocene with tertiary phosphites $P(OR)_3$ seemed to confirm this proposal[39]. There resulted a third-order rate law which was interpreted by assuming steady-state conditions for *(16)*.

However, refinement of the experimental data raised doubts about the extremely simple mechanistic picture sketched out above. Photometric studies in the temperature range 0 to 40 °C (in which the reaction according to eq. (j) is very slow) showed the 1 : 1 adduct to be formed very fast; the equilibrium constant *K* is (R = C_2H_5) 0.9 ± 0.2 mol/l at 30 °C in dioxane[40]. The rate-determining process is not formation of the 1 : 1 adduct but the transformation of *(A)* into *(B)* and of *(B)* into *(C)*.

$$Ni(C_5H_5)_2 + P(OR)_3 \overset{K}{\rightleftharpoons} \underset{(A)}{[(C_5H_5)_2NiP(OR)_3]}$$

$$(A) + P(OR)_3 \overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}} (B) \xrightarrow[+\,P(OR)_3]{k_3} (C) \xrightarrow[+\,P(OR)_3]{fast} Ni[P(OR)_3]_4$$

A plausible proposal for the structure of the 1 : 1 adduct *(A)* is that of a *pentahapto*-cyclopentadienyl-*trihapto*-cyclopentadienylnickel phosphite complex. A corresponding change in coordination from η^5-C_5H_5 to η^3-C_5H_5 may also occur in the reaction of nickelocene with tetrafluoroethylene[41]; the complex *(17)* could arise by intramolecular, metal-catalyzed [2 + 2] cycloaddition of initially formed $(\eta^5$-$C_5H_5)Ni(\eta^3$-$C_5H_5)C_2F_4$.

(k)

(17)

The structure proposed for the adduct *(A)* obtained from $Ni(C_5H_5)_2$ and $P(OR)_3$ has not yet been unequivocally confirmed by spectroscopic measurements. With regard to the reaction mechanism, the precise structure of *(B)* also remains an open question. The most likely possibilities would be a $(\eta^5$-$C_5H_5)Ni(\eta^1$-$C_5H_5)[P(OR)_3]_2$ (formed by η^3-η^1 rearrangement of the π-allyl-type bonded five-membered ring) or a $(\eta^5$-$C_5H_5)Ni[P(OR)_3]_2$. Compounds of the type $(\eta^5$-$C_5H_5)Ni(PR_3)_2$ have already been isolated by *Uhlig et al.*[42].

We saw two possible ways of escape from the dilemma into which our kinetic and mechanistic studies had led us:

1) Using a *diamagnetic complex of similar structure* instead of *paramagnetic* nickelocene as starting material for the reaction with $P(OR)_3$ (or another Lewis base). This would provide a chance of gleaning some information about any intermediate(s) of the ligand displacement process by NMR studies (presumably at low temperature).

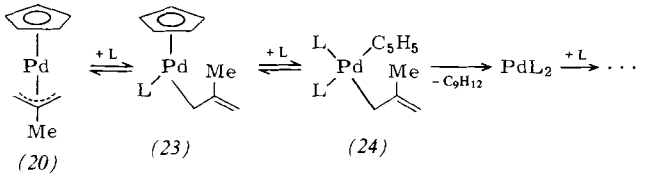
2) Reactions of a sandwich complex $M(C_nH_n)_2$ with a Lewis base L do not necessarily lead—as in eq. (j)—to cleavage of *both* ring-metal bonds; only *one* ring-metal bond may actually be broken (to form a compound $C_nH_nML_m$). Examples are known for $n=5$ or 6 and L=CO or PR_3[20,43]. Such a process would probably lead to a simpler rate law, and this could provide more precise information about the reaction mechanism.

3.2. Reaction of π-Allyl-π-Cyclopentadienylmetal Complexes

3.2.1. Mechanistic Studies

π-Allyl-π-cyclopentadienylnickel has a similar structure to nickelocene. The plane through the five C atoms of the cyclopentadienyl moiety and the plane through the three C atoms of the allyl ligand are parallel and enclose the metal in a sandwich fashion. Unlike nickelocene, $C_3H_5NiC_5H_5$ *(18)* is an 18-electron complex and hence *diamagnetic*.

Complete ligand displacement occurs in the reactions of *(18)* with excess phosphite, as in the reaction of *(5)* with $P(OR)_3$; $Ni[P(OR)_3]_4$ is formed[40]. The palladium complexes *(19)*—*(22)* react analogously.



$$(all)MC_5H_5 + 4\ P(OR)_3 \longrightarrow M[P(OR)_3]_4 + C_5H_5(all) \qquad (1)$$

M = Ni; all = C_3H_5: *(18)*

M = Pd; all = C_3H_5: *(19)*
$2\text{-}MeC_3H_4$: *(20)*
$2\text{-}t\text{-}BuC_3H_4$: *(21)*
$1,1,2\text{-}Me_3C_3H_2$: *(22)*

Under pseudo-first order conditions we found a rate law of second order for the reaction of *(19)* with $P(OPh)_3$, but one of third order for that of *(18)* with $P(OEt)_3$[44]. These results justify the assumption of a multi-step mechanism, with either $(\pi\text{-}C_5H_5)M(\sigma\text{-all})P(OR)_3$ or $(\pi\text{-all})M(C_5H_5)P(OR)_3$ (C_5H_5 = *trihapto-* or *monohapto*-cyclopentadienyl ligand) as primary intermediate.

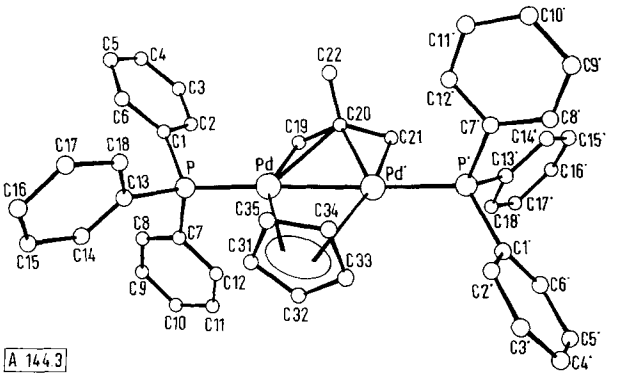
The former possibility was confirmed by NMR spectroscopy[45]. Compound *(20)* reacts at −50°C with L to give the σ-allyl complex *(23)*, whose kinetic stability is crucially dependent upon L. While further reaction to give PdL_4 is very fast for $L=P(OMe)_3$ above 0°C (probably *via (24)* as intermediate species), compound *(23)* can be isolated when $L=P(i\text{-}Pr)_3$[46]. The kinetics of its reaction with $P(i\text{-}Pr)_3$ to form $Pd[P(i\text{-}Pr)_3]_n$ is presently under investigation.

The organic product C_9H_{12} generated in this reaction is an allylcyclopentadiene[*]. NMR studies on the *(22)*/L system showed[45] that coupling of an allyl group with the cyclopentadienyl ring occurs at C_α. The initially formed 5-allylcyclopentadienes are highly labile and rearrange, like 5-alkylcyclopentadienes, *via* [1,5] H shift to give the 1-substituted isomers.

3.2.2. Unexpected Synthetic Results

Our efforts to isolate the primary intermediate *(23)* formed on reaction of *(20)* with L (initially with $L=P(OMe)_3$, $P(OPh)_3$, and PPh_3) led to a surprising result[47]. While the σ-allyl compound displays considerable kinetic stability at −50°C, *e.g.* in toluene, it reacts at higher temperature to give a new complex which can be recognized by a characteristic triplet for the cyclopentadienyl protons in the ^{1}H-NMR spectrum. Crystals of this product have the composition $(C_5H_5)(C_4H_7)Pd_2(PPh_3)_2$ *(26)* (for $L=PPh_3$).

The result of a crystal structure analysis performed on *(26)* is shown in Figure 3. The compound possesses an almost linear P—Pd—Pd—P arrangement with a Pd—Pd bond length of 2.679 Å, comparable with the interatomic distance in metallic palladium (2.74 Å). The mutually parallel cyclopentadienyl and 2-methylallyl ligands are coordinated to *both* palladium atoms and enclose the metal-metal bond in sandwich fashion. The Pd—C_{Cp} distances suggest that the five-membered ring may be bound as a *trihapto*-ligand *in the crystal* and two of the five carbon atoms participate only weakly in bonding to the metal atoms. Neither ^{1}H- nor ^{13}C-NMR spectra evidence nonequivalence of the CH groups of the cyclopentadienyl ring *in solution*; a single sharp resonance is still observed at −60°C for the ring carbon and hydrogen atoms. It would appear reasonable to attribute this observation to very fast rotation of the ring about an axis passing through its center and oriented perpendicular to the Pd—Pd bond, making the dinuclear complex a fluxional molecule in solution.



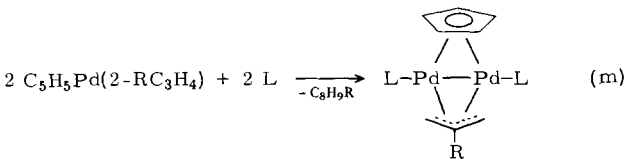


Fig. 3. Crystal structure of the dinuclear complex *(26)*.

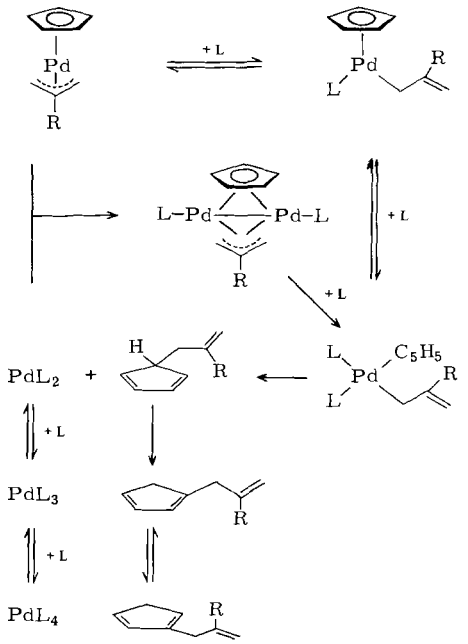
The complexes *(25)* and *(27)*—*(35)* analogous to *(26)* could also be synthesized according to eq. (m)[48]. Compounds *(20)* and *(21)* react with $P(i\text{-}Pr)_3$ to give the highly stable 1:1 adducts $(\pi\text{-}C_5H_5)Pd(2\text{-}RC_3H_4)L$ as initial products [see *(23)*]; at higher temperatures (only at 90°C for R = *t*-Bu) and in the absence of excess L they react further to give the dinuclear complexes *(28)* and *(34)*, respectively. The crystal structure of *(31)* is completely analogous to that of *(26)*[48]. Reactions of $C_5H_5Pd(2\text{-}ClC_3H_4)$ with L in the molar ratio 1:1 *exclusively* give σ-2-chloroallyl derivatives of type *(23)*, some of which eliminate allene at room temperature to form $C_5H_5Pd(L)Cl$[49]. Preparation of $(C_5H_5)(2\text{-}ClC_3H_4)Pd_2L_2$ has not yet been accomplished.

On the basis of detailed NMR studies we proposed[50] the mechanism summarized in Scheme 4 to account for the



[*] On reaction of *(22)* with an excess of L, the expected allylcyclopentadienes are accompanied by cyclopentadiene and 2,3-dimethylbutadiene, which probably arise from the intermediate analogous to *(24)*. The yields of these hydrocarbons are largely determined by the nature of L, the molar ratio *(22)*: L, and the temperature [45].

(m)

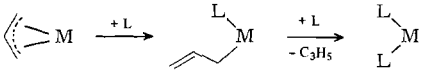
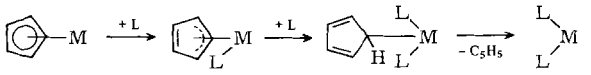
formation of the dinuclear complexes *(25)* to *(35)*. These are the first representatives of a class of compounds in which a C_5H_5 ligand is bound in sandwich fashion to a M_2 fragment.



Scheme 4

This proposal was based on the key assumption that under the reaction conditions chosen (room temperature, molar ratio of $C_5H_5Pd(2\text{-}RC_3H_4)$:L = 1:1) the second reaction step is considerably faster than the first one, and that PdL_2 is formed from the postulated intermediate $C_5H_5Pd(\sigma\text{-}C_3H_4R)L_2$ of type *(24)* on loss of the organic cyclopentadiene derivative. This 14-electron complex should react with the starting material to give $C_5H_5(2\text{-}RC_3H_4)Pd_2L_2$.

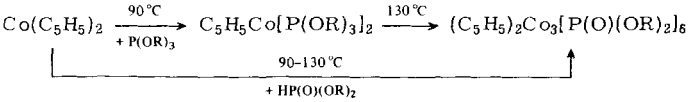


This hypothesis has recently been confirmed[46]. Both $Pd[P(i\text{-}Pr)_3]_2$[51] and $Pd[P(t\text{-}Bu)_3]_2$, which is accessible from *(20)*, yield the respective dinuclear complex *quantitatively* on reaction with *(20)* or *(21)*. Hence a new entry to this class of compounds has also become available, which is probably of potential utility for the synthesis of further complexes containing the L—M—M—L unit.

3.3. The "Supersandwich"

While studies on the reaction of complexes *(18)* to *(22)* with Lewis bases could provide no definite answer to the initial question of the mechanism of ligand displacement according to eq. (j), they nevertheless did show that cleavage of at least one (π-all)—M bond proceeds stepwise:

Evidence for a corresponding reaction course

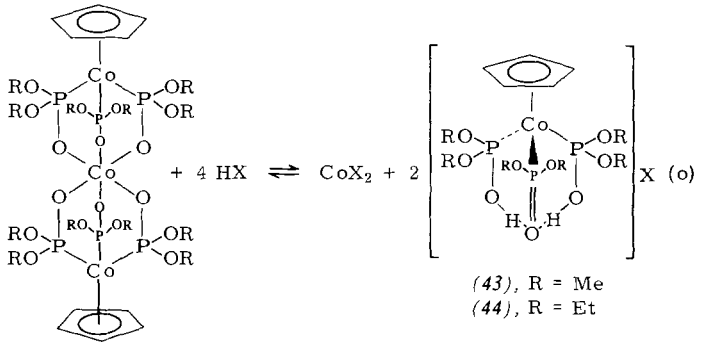


as described for the $Ni(C_5H_5)_2$/L system in Section 3.1, was only indirect in nature, and not necessarily conclusive. The question to be answered was whether a formally simpler reaction, such as

$$M(C_5H_5)_2 + n\,L \longrightarrow C_5H_5ML_n + \cdot C_5H_5 \qquad (n)$$

would give rise to a simpler and more readily interpretable rate law. We attempted to provide an answer by studying the ligand displacement reactions of cobaltocene with Lewis bases.

$Co(C_5H_5)_2$ *(36)* reacts according to eq. (n) with L = CO[52] or PF_3[53] to give $C_5H_5CoL_2$. An analogous reaction occurs with tertiary phosphites (which are better suited as reactants for kinetic studies than the volatile compounds CO and PF_3). Reaction with a 5 to 10-fold excess of phosphite at 90—120 °C gives very good yields of the complexes $C_5H_5Co[P(OR)_3]_2$ [R = Me: *(37)*, Et: *(38)*, Ph: *(39)*, *o*-Tol: *(40)*], which exhibit much greater stability than the carbonyl compound $C_5H_5Co(CO)_2$[54]. The rate of formation of the tri*alkyl* phosphite complexes *(37)* and *(38)* is considerably higher than that of the tri*aryl* phosphite complexes *(39)* and *(40)*. Hence, further studies concentrated on the reactions of cobaltocene with $P(OMe)_3$ and $P(OEt)_3$.



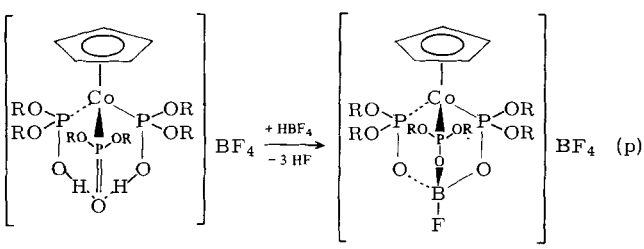
Although precise kinetic data have not yet been obtained (the NMR method of determining concentration changes cannot be applied because *(36)* is paramagnetic, and photometric measurements are difficult because *(36)*, *(37)*, and *(38)* are all intensely colored), an observation made during these experiments led to an interesting result. On prolonged reaction time or at elevated temperatures the $Co(C_5H_5)_2/P(OR)_3$ system (R = Me or Et) affords not only the compounds $C_5H_5Co[P(OR)_3]_2$ but small quantities of orange-yellow crystals were deposited on the wall of the reaction vessel. The crystals exhibit a number of properties unusual for organometallic complexes. They are completely stable towards air and do not decompose below about 350 °C. Elemental analyses and mass spectra confirm the composition $(C_5H_5)_2Co_3[P(O)(OR)_2]_6$ [R = Me: *(41)*, Et: *(42)*]. The novel trinuclear compounds are accessible in 50% yield by thermolysis of *(37)* and *(38)*, and almost quantitatively by reaction of *(36)* with $HP(O)(OR)_2$:

As shown by the crystal structure analysis[55] of *(41)* (known as the "supersandwich" in laboratory jargon), the two cyclopentadienyl ligands enclose the $Co_3[P(O)(OR)_2]_6$ fragment

in *sandwich* fashion. The three cobalt atoms are linearly arranged and bridged by the phosphonate groups. Two of the cobalt atoms are equivalent, while the third one is located at a center of symmetry. It is surrounded by six oxygen atoms occupying the corners of an octahedron in an almost ideal manner. This CoO_6 nucleus containing high-spin Co^{II} accounts for the paramagnetism of the trinuclear complexes. Assignment of the oxidation number +2 to the central cobalt atom and +3 to the other two is in accord with the results of ESCA studies[55].

Apart from their structure, the reactivity of complexes *(41)* and *(42)* towards Brønstedt acids also warrants particular attention. Conductivity measurements showed[56] that reaction with CF_3COOH in $(CF_3CO)_2O$ involves multiple protonation at the phosphonate oxygen atoms without complete destruction of the trinuclear structure. The complexes react according to eq. (o) with strong mineral acids such as H_2SO_4, H_3PO_4, or HNO_3.

+ 4 HX ⇌ CoX_2 + 2



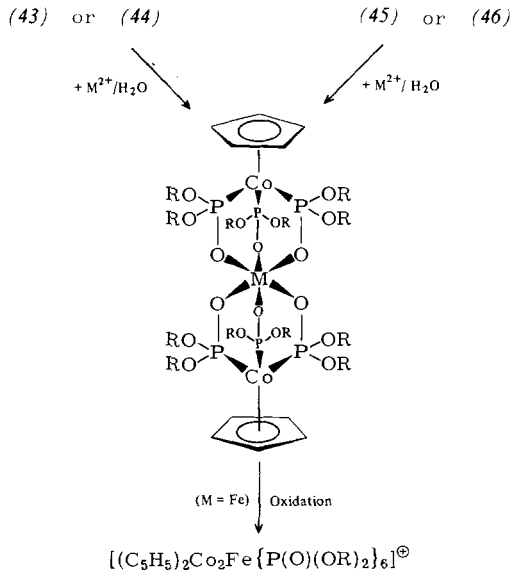
X (o)

(41), R = Me
(42), R = Et

(43), R = Me
(44), R = Et

Equilibration can be followed by NMR; the equilibrium lies entirely on the right-hand side in concentrated mineral acids. On use of a suitable solvent, either CoX_2 or the complex salts *(43)* and *(44)*, respectively, can be precipitated from the solutions[56]; the secondary phosphites $P(OH)(OMe)_2$ and $P(OH)(OEt)_2$, which are unstable in the free state, serve as ligands in these salts.

When performed with HBF_4 (in propionic anhydride) the reaction does not stop at *(43)* or *(44)*. Instead, complexes having the composition $[C_5H_5Co\{P(OR)_2O\}_3BF]BF_4$ [*(45)* and *(46)*, respectively] are obtained whose formation can be summarized as shown in eq. (p).



BF_4 $\xrightarrow[-3\ HF]{+\ HBF_4}$

BF_4 (p)

(45), R = Me
(46), R = Et

Crystal structure analysis of *(46)* shows that in addition to the cyclopentadienyl ring, a tris(diethoxyphosphito)boranate anion is coordinated to the cobalt as a tridentate chelate ligand[57]. Salts of such phosphitoboranate ions are, as yet, unknown in the free state and might be preparable by ligand displacement starting from *(45)* or *(46)*. The Co—C and Co—P bond lengths in *(46)* expectedly differ little from those in the trinuclear "supersandwich" complex.

The reverse reaction of eq. (o) has recently also been accomplished and the trinuclear complexes *(41)* and *(42)* prepared from the corresponding monocyclopentadienyl compounds *(43)* and *(44)* (X = BF_4) and CoX_2 (X = Cl, NO_3, $\frac{1}{2}$ SO_4)[58]. The phosphitoboranate complexes *(45)* and *(46)* can also be used for this purpose instead of *(43)* and *(44)*. The salts of various other transition metals react in the same way as CoX_2, thus providing a pathway to trinuclear complexes of general composition $(C_5H_5)_2Co_2M[P(O)(OR)_2]_6$ (M = Mn, Fe, Ni, Cu, Zn, Cd) having *two different metals as coordination centers in the same molecule* (see Scheme 5). The X-ray powder diagrams of compounds with R = Et reveal that they are all isotypic and therefore probably possess a structure very similar to *(41)*. Particular interest is warranted by the copper complex since the Jahn-Teller effect would be expected to lead to pronounced distortion of the CuO_6 octahedron. ESR studies at 4 K show that this is indeed the case at low temperature[59].

Scheme 5

4. Outlook

Sandwich complexes nowadays appear as veterans when viewed against the background of our hectic age, and yet their chemistry is just as topical as ever. The structural principle first demonstrated for ferrocene, formerly unknown but basically so simple, has time and time again fired the imagination of coordination and organometallic chemists and prompted countless synthetic experiments. As a result not only further "true sandwiches", such as dibenzenechromium and uranocene, but a whole variety of other sandwich-type or sandwich-like complexes have become accessible. Addition of another storey to a normal double-decker to give a triple-decker sandwich, long a mere pipe dream, has recently also been achieved in the preparation of the cation $[Ni_2(C_5H_5)_3]^{\oplus}$[9].

The chemist interested in molecular architecture will be tempted to construct a quadruple-decker or even higher "skyscrapers", and studies to this end are already in progress.

An attempt is made in Figure 4 to depict the trinuclear complexes *(41)* and *(42)*, and those of composition $(C_5H_5)_2Co_2M[P(O)(OR)_2]_6$ as variants of a quadruple-decker. Extension of these compounds of "supersandwich" type is also conceivable. Thus it has very recently been found, for example, that under the conditions of mass spectrometric degradation the compound $C_5H_5Ni[\{P(OMe)_2O\}_2H]$, characterized by a strong OHO hydrogen bond, yields the trinuclear complex $(C_5H_5)_2Ni_3[P(O)(OMe)_2]_4$ (possibly having a stability similar to that of *(41)*)[60]. The structure probably corresponds to that of the analogous cobalt compound.

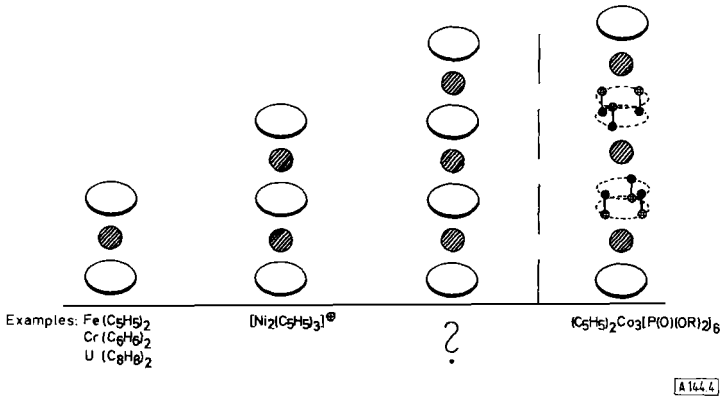


Fig. 4. Structural models of sandwich complexes.

Apart from the bidentate phosphonate ion, other typical bridging ligands—in the simplest case the CO group—should also be able to stabilize sandwich-like polynuclear structures. The calculations by *Hoffmann et al.* could signpost the way ahead. It would hardly come as a surprise if a further variant (ring)M(CO)$_3$M(ring) were to join the "true" triple-decker (ring)M(ring)M(ring) and the related type of compound (CO)$_3$M(ring)M(CO)$_3$; having 30 or 34 electrons in their valence shells they are predicted by *Hoffmann* to be stable.

Thanks should go first of all to those co-workers who participated in the work of the author's group: Ms. E. Deckelmann, Dr. T. L. Court, Dr. V. Harder, Dr. W. Kläui, Dipl.-Chem. A. Kühn, Dr. H. Neukomm, Dr. G. Parker, Dr. A. Salzer, Dr. M. Scotti, Dr. D. J. Tune, and Dr. G. K. Turner. I am also indebted to Prof. Dr. H. R. Oswald, Zürich, Doz. Dr. G. Huttner, München, and Dr. C. Krüger, Mülheim, as well as their colleagues, for performing the indispensable X-ray structure analyses. In conclusion, it should also be mentioned that the successful outcome of our studies would have been doubtful without the generous and unbureaucratic support of the Schweizerischer Nationalfonds.

Intramolecular [4+2] and [3+2] Cycloadditions in Organic Synthesis

New synthetic methods (18)

By Wolfgang Oppolzer[*]

Dedicated to Professor Vladimir Prelog on the occasion of his 70th Birthday

Numerous examples of intramolecular cycloaddition of 1,3-dienes, nitrones, and azomethine imines attest the preparative value of this variant for regioselective and stereoselective synthesis of annelated and bridged ring systems. The common features, differences, and limitations of these types of reaction are systematically reviewed.

1. Introduction

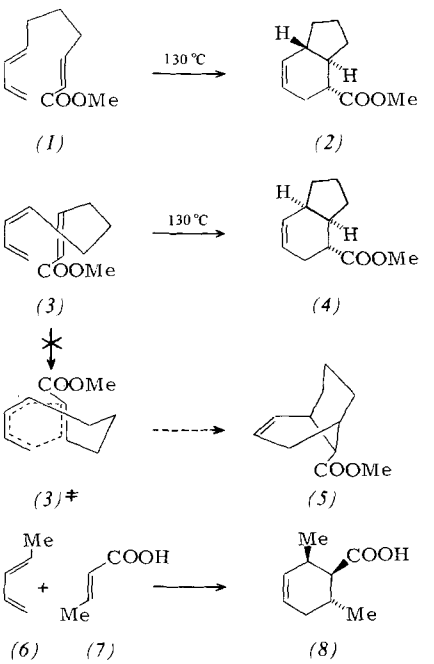
Thermally induced additions of 1,3-dienes and of 1,3-dipoles to multiple bonds clearly lead to six- or five-membered rings with the simultaneous formation of two σ-bonds, *via* a highly ordered aromatic transition state[1-3]. The stereochemical consequences of a reaction course of this type are paralleled by reactivity and orientation phenomena ascribed to frontier orbital interactions[4]. The great preparative importance of these features of the mechanistically related reactions is shown, *inter alia*, by a multitude of fascinating applications of the bimolecular Diels-Alder reaction to the synthesis of complex molecules[2].

From investigations carried out in recent years it follows that the synthetic potential of such cycloadditions is decisively increased by the principle of intramolecularity. Intramolecular additions of this type result not only in the simultaneous formation of *two* rings, but also in certain consequences which are superimposed on those of the classical bimolecular variants.

The aim of the present review is to collect the common characteristics of intramolecular additions of 1,3-dienes, nitrones, and azomethine imines and to indicate the possibilities and limitations of these processes. Entropy factors and problems of kinetically controlled regio- and stereoselectivity deserve special attention which justifies their detailed discussion. An attempt is made, with the aid of selected examples, to demonstrate the scope and utility of these reactions in the synthesis and biogenesis of structurally complex natural products.

2. Intramolecular Diels-Alder Reactions

Bimolecular [4+2] cycloadditions (type I), whose general applicability was recognized by *Diels* and *Alder* nearly 50

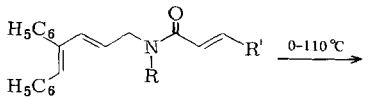


Scheme 1. [4+2]-cycloaddition of dienes.

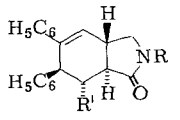
years ago[5], are today one of the most important types of reaction used in organic synthesis[2]. Although *Alder* had already indicated the possibility of intramolecular [4+2] additions (type II) as early as 1953[6], and other authors later found occasional examples[7], it was not until the last decade that the general utility of this reaction became apparent[8].

2.1. Acyclic Dienes

2.1.1. Construction of 5,6- and 6,6-Ring Systems

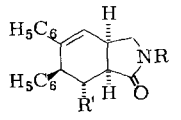


The first systematic investigation of this type of reaction, described by *H. O. House* in 1965[9], suffices to bring certain characteristic features to light. When heated to 130°C, the *trans*-diene unit in the triene *(1)* adds smoothly to the double bond of the acrylic ester linked to the diene by a bridge of three carbon atoms leading to the *trans*-annelated hydrindane derivative *(2)*. Surprisingly, under the same conditions the *cis*-substituted diene *(3)* reacts in a similar manner, but with exclusive formation of the *cis*-annelated product *(4)*. In view of the fact that *cis*-substituted open-chain 1,3-dienes usually undergo bimolecular Diels-Alder reactions only with difficulty, we are forced to the conclusion that the reaction *(3)*→*(4)* profits from entropy factors due to the spatial proximity of the reaction partners. (Examples given below show that nonactivated dienophiles smoothly undergo intramolecular cycloaddition for the same reason.)



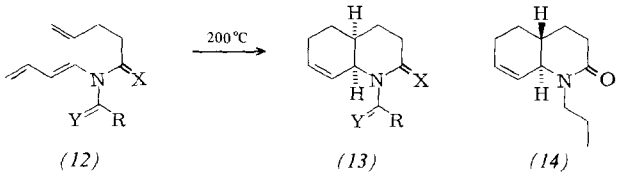
[*] Prof. Dr. W. Oppolzer
Département de Chimie Organique, Université de Genève
CH-1211, Geneva 4 (Switzerland)

A further notable feature of intramolecular [4+2] additions is the influence of orienting factors promoting the formation of annelated products. For example, the reaction of the *cis*-diene *(3)* gave no trace of the bridged positional isomer *(5)*; in this connection it should be remembered that the addition in the intramolecular reactions *(1)*→*(2)* and *(3)*→*(4)* takes place in the opposite direction to that strongly favored in the bimolecular reaction *(6)*+*(7)*→*(8)*[10].



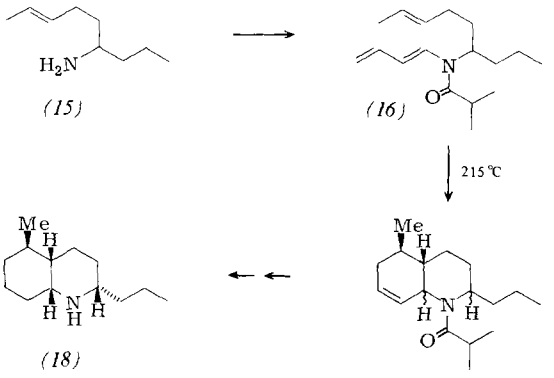
Consideration of models (see Section 2.6.2) shows that the formation of a bridged adduct from *(1)* is blocked by strain, whereas the formation of the transition state *(3)*$^+$ from *(3)* does not require any deformation of the bond angles; thus, the absence of *(5)* after thermolysis of *(3)* is due to other causes, presumably the (entropically favored) easier closure of a five-membered ring than that of a six-membered ring. The pronounced stereoselectivity of the conversion *(3)*→*(4)*, on the other hand, appears to be due to a strongly strained transition state, which would have to be overcome in the alternative reaction *(3)*→*(2)* (see Section 2.6.3). The *endo*-position of the ester group appears to be decisive for favoring the reaction *(1)*→*(2)* over the reaction *(1)*→*(4)*.

(9)



(10)

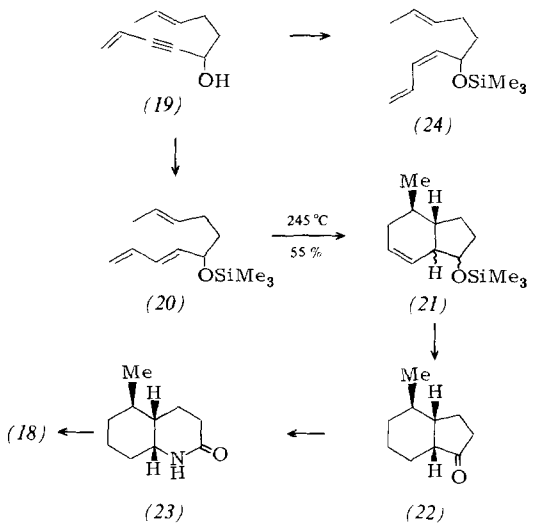
(11)



The results of kinetic and stereochemical studies[11] of the thermal reaction *(9)*→*(10)*+*(11)* are in accord with the above conclusions. For example, an activation entropy of $\Delta S^+ = -14.4$ cal K^{-1} mol^{-1} is found for the intramolecular addition of the acrylamides *(9)*, R = *tert*-butyl, R′ = H, whereas bimolecular Diels-Alder reactions have considerably more negative ΔS^+ values (between −30 and −40 cal K^{-1} mol^{-1}). Furthermore, the reaction *(9)*→*(10)*+*(11)* becomes increasingly slower as the size of the nitrogen substituent R decreases (probably for conformational reasons). The stereochemistry of these kinetically controlled additions reflects again the preferential *endo*-orientation of terminal π-substituents R′, *i.e.* the *trans*-fused adducts *(10)* are formed selectively from the amides *(9)*, R′ = COOEt or C_6H_5. This opens a simple route to polysubstituted perhydroisoindoles with stereochemical control of up to five chiral centers.

A close connection between systematic study and direct application of intramolecular Diels-Alder reactions to the synthesis of natural products is shown in the following example. Attempts to synthesize the physiologically active (but almost inaccessible) alkaloid pumiliotoxin C *(18)* in a stereoselective manner led to a study of the intramolecular additions of dienamides *(12)*, X or Y = O[12]. It transpired that the amide *(12)*, X = H_2, Y = O, R = CH_3, is converted at 200°C into the very nearly pure *cis*-fused octahydroquinoline *(13)*, whereas the amide *(12)*, X = O, Y = H_2, R = C_2H_5, affords, with lower but reversed selectivity, the *trans*-lactam *(14)* and its *cis*-isomer *(13)* in the ratio of 3:2. The different courses of the reaction can be due to a preferred coplanar arrangement of the amide and diene units in the corresponding transition states. Incidentally, this investigation provided the impetus for the development of a productive general synthesis of the then unknown *N*-butadienylamides[13].

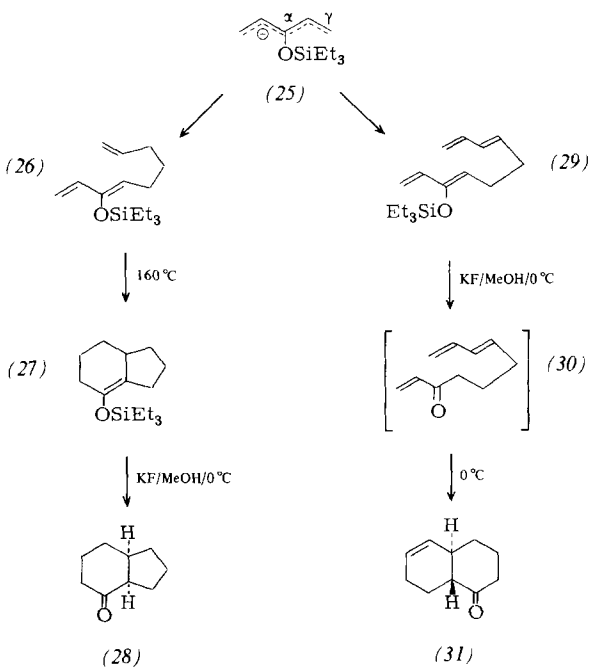
(12) *(13)* *(14)*



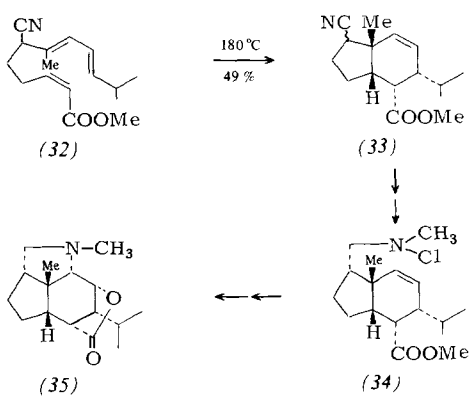
Using this process the readily available amine *(15)* could be converted in two stages into the dienamide *(16)*. When

(15) *(16)* *(18)* *(17)*

heated in toluene for 24 h at 215°C in a sealed, silylated glass tube, *(16)* undergoes efficient intramolecular cycloaddition[14a,14b]; the adducts *(17)* (isolated in 60 to 90% yield), when hydrogenated and hydrolyzed, finally afforded the racemic alkaloid *(18)* in 60% yield together with three stereoisomers (in yields of 17, 15, and 2%). The remarkable feature of this synthesis is the simultaneous control over all four chiral centers in the key step *(16)*→*(17)*, dictated by the *trans*-configuration of the dienophile and, presumably, by the double-bond character of the amide group.

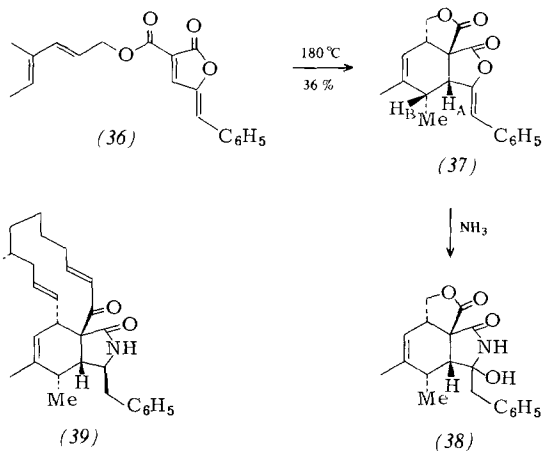


Another route to pumiliotoxin C[14c] is also based on an intramolecular [4+2] addition [*(20)*→*(21)*], which favors an *endo*-orientation of the three-carbon bridge; hydrogenation and oxidation of the adduct *(21)* lead thus to an easily separable 2:1 mixture of the *cis*-hydrindanone *(22)* and its *trans*-annelated isomer. After Beckmann rearrangement of the main product the carbonyl group of the perhydroquinolone *(23)*



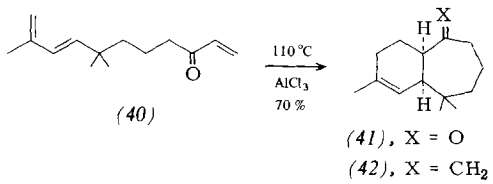
(19) *(24)* *(20)* *(21)* *(18)* *(23)* *(22)*

serves for simple and stereoselective introduction of the propyl group. For the preparation of *cis*-2,3,3a,6,7,7a-hexahydro-7a-methyl-1-indenone by thermolysis of *trans*-2-methyl-1,6,8-nonatrien-3-one, see Ref.[15].

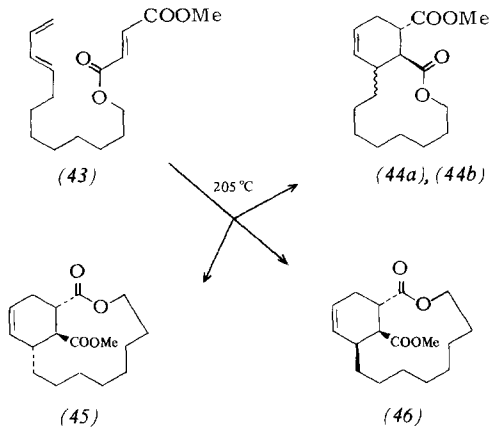


In the synthesis of carbocyclic systems by intramolecular Diels-Alder reactions there occasionally arose the problem of how to prepare the necessary polyene substrates by a rational route. In this connection the (triethylsilyloxy)pentadienyl anion *(25)* recently became available as a convenient building block for the construction and attachment of functionalized diene and dienophile units because of its reactivity toward electrophiles[16]. Thus, γ-alkylation of *(25)* led stereoselectively to (*Z*)-silyloxydienes, for example *(26)* or *(29)*. The triene *(26)* underwent an intramolecular cycloaddition at 160 °C and after ether cleavage afforded the hydrindanone *(28)* in an overall yield of 55 %. When, however, the tetraene *(29)* was treated at 0 °C with potassium fluoride, the *trans*-octalone *(31)* was produced directly (in 62 % yield) in an astonishingly smooth (kinetically controlled) *exo*-addition of the unisolable vinyl ketone *(30)*.

A recent attempt to synthesize the alkaloid dendrobine yielded its 8-*epi*-isomer *(35)*[17]. The *endo*-oriented addition *(32)* → *(33)* occurred with stereochemical control of all chiral centers except the center next to the nitrile group. It is assumed that *(32)* is formed by thermal isomerization from its (*Z*)-isomer (central double bond) prior to its conversion into *(33)*. In subsequent steps the newly formed double bond of the adduct *(33)* served as a bifunctional site to close the pyrrolidine and the lactone rings of *(35)*.



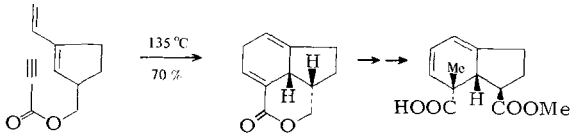
An elegant solution of stereochemical problems is also encountered in the thermal conversion of *(36)* into *(37)*, which was conceived as the key step for construction of the microbial metabolic product proxiphomine *(39)*[18]. The sole adduct obtained, *(37)*, apparently (concluded from the NMR coupling $J_{AB} = 7$ Hz) contains the correct relative configuration of the natural product *(39)* with respect to all four chiral centers. Treatment of *(37)* with ammonia led to the isoindole system *(38)*.



2.1.2. Construction of 6,7- and 6,12-Ring Systems

It can be assumed that bicyclic systems containing seven- or more-membered rings may be constructed by intramolecular addition if the distance between the diene and dienophile units is increased.

The validity of this assumption is demonstrated by the Lewis acid-catalyzed conversion of the triene *(40)* into the annelated cycloheptanone *(41)* (70 %), which was transformed by methylenation into the sesquiterpene α-himachalene *(42)*[19].



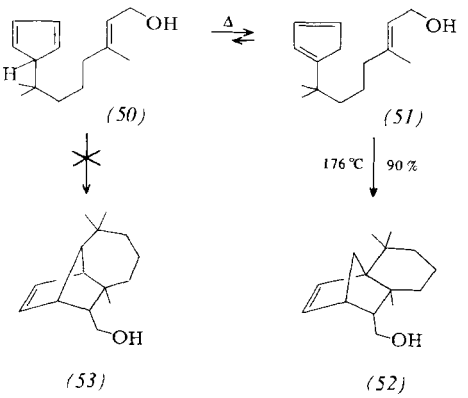
The fact that 12- and 13-membered rings can also be closed by intramolecular cycloaddition to *activated* dienophiles is exemplified by the thermolysis of *(43)*[20]. When low steady state concentrations are used (to suppress the undesired bimolecular addition), a 7:3:4:1 mixture of the stereo- and position-isomeric products *(44a)*, *(44b)*, *(45)*, and *(46)* is obtained in 80 % yield. This (kinetically and/or partially thermodynamically controlled) product ratio reflects the loss of the control over regio- and stereochemistry that characterizes the previously discussed construction of 5,6- and 6,6-ring systems.

2.2. Endocyclic Dienes

Intramolecular cycloadditions of 1,3-dienes which are partly or wholly incorporated in a ring may provide complicated ring systems which are accessible by other routes only with difficulty.

2.2.1. 1-Vinylcycloalkenes

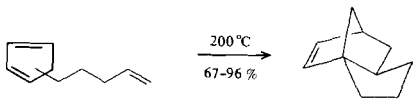
This is illustrated, *inter alia*, by a model study on the synthesis of gibberellic acid in which the cycloaddition *(47)*→*(48)* is the key step[21]. Stereoselective methylation



(47) *(48)* *(49)*

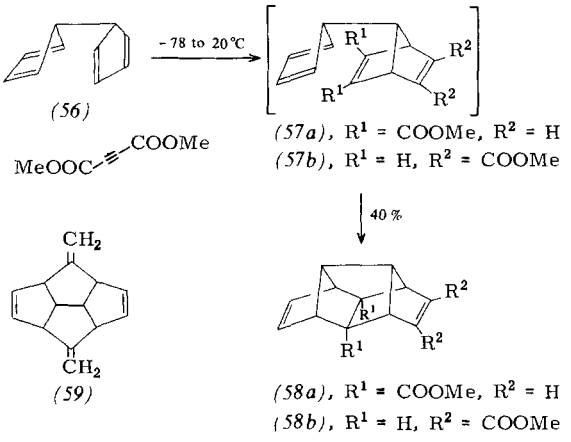
of the cyclohexadiene component in the adduct *(48)*, followed by modification of the lactone ring, leads to the indane derivative *(49)*. This compound has the correct spatial arrangement of functional groups for the construction of rings A and B of gibberellic acid.

2.2.2. Cyclopentadienes



Earlier work, whose objective was also the synthesis of a natural product, examined the thermal behavior of the mixture of cyclopentadienes *(50)* and *(51)*[22]. When

(50) *(51)* *(53)* *(52)*



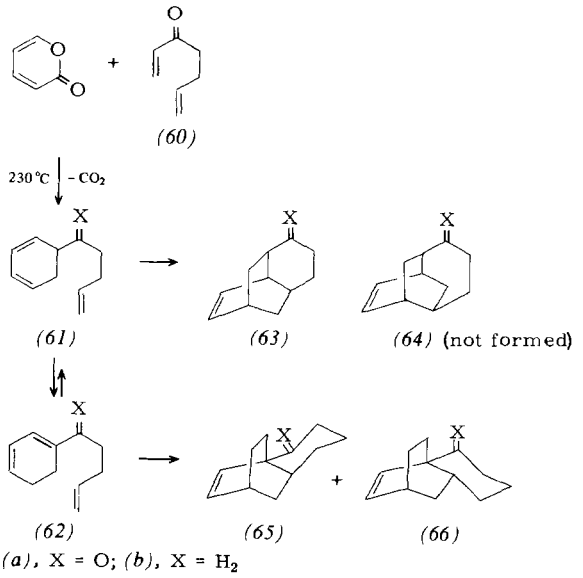
this mixture was heated at 176 °C for 48 h the norbornene *(52)* was the sole product, with no trace of the desired adduct *(53)* which could have served as a direct precursor of the sesquiterpene longifolene. Hence it can be concluded that *(50)* and *(51)* equilibrate (by a 1,5-hydrogen shift) and that the irreversible addition *(51)*→*(52)* proceeds faster than the expected reaction *(50)*→*(53)*, although here thermodynamic control cannot be completely ruled out.

Similar considerations apply for the reaction *(54)*→*(55)*[23].

(54) *(55)*

An interesting sequence of thermal inter- and intramolecular cycloadditions that leads in one synthetic operation to the formation of four C—C bonds (see also [7b]) is provided by the reaction of *(56)* with dimethyl acetylenedicarboxylate[24]. At low temperature (to avoid hydrogen shifts) a 3:2 mixture of *(58a)* and *(58b)* is immediately obtained *via* the intermediate bimolecular adducts *(57a)* and *(57b)*. The product *(58a)* was converted in several steps into *(59)*.

(56)



(57a), R^1 = COOMe, R^2 = H
(57b), R^1 = H, R^2 = COOMe

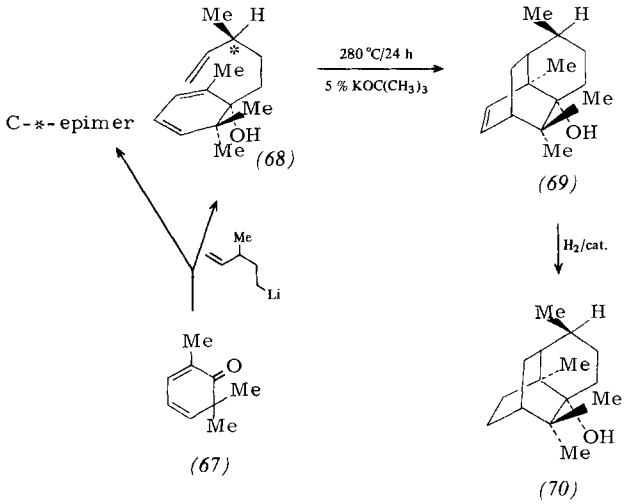
(59)

(58a), R^1 = COOMe, R^2 = H
(58b), R^1 = H, R^2 = COOMe

2.2.3. Cyclohexadienes

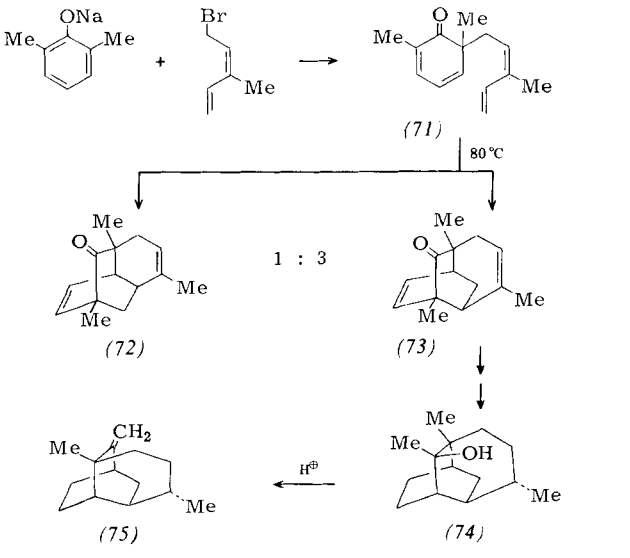
Another sequence of thermal (cycloaddition-cycloreversion and hydrogen-shift) reactions, involving participation of the intermediate compounds *(61a)* and *(62a)*, occurs when α-pyrone is heated with the dienone *(60)* at 230 °C[25]; the isomeric products *(63a)*, *(65a)*, and *(66a)*, are obtained directly in yields of 37, 43, and 11 %, respectively. Thermolysis of the pentenylcyclohexadiene *(61b)* is appreciably more selective, as it yields the adduct *(63b)* in 73% yield with small amounts of *(65b)* and *(66b)*; clearly the hydrogen shift *(61b)*→*(62b)* is slower than the addition *(61b)*→*(63b)*. Particularly noteworthy here is the fact that

(60)



(61) *(63)* *(64)* (not formed)

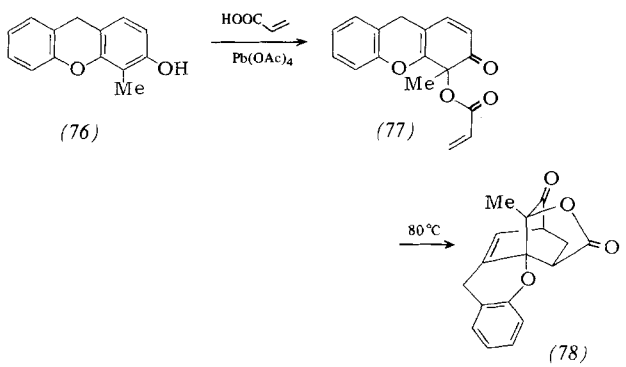
(62) *(65)* *(66)*



(a), X = O; *(b)*, X = H_2

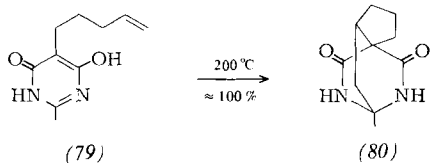
the thermal reactions of *(61a)* and *(61b)* yield no trace of the position-isomeric adduct *(64)*, although (owing to the *cis*-configuration of the diene with respect to the dienophilic chain) no strain opposes that reaction.

The same regioselectivity that we encountered earlier in the reaction *(3)*→*(4)* also characterizes the intramolecular cycloaddition *(68)*→*(69)*[*], which provides the complex skeleton of the sesquiterpene patchoulol *(70)* in a single step[26]; the racemic natural product *(70)* is obtained by simple hydrogenation of the adduct *(69)*. In comparison with several multistage syntheses of patchoulol[27], the reaction sequence *(67)*→*(68)*→*(69)*→*(70)* demonstrates the effectiveness of intramolecular cycloadditions.



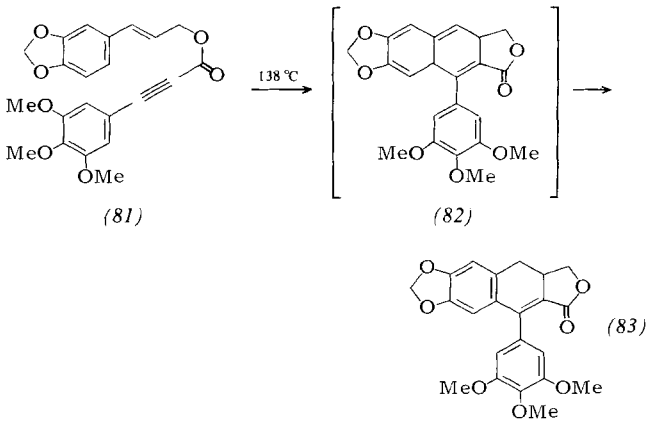
No less impressive is a route to the structurally related sesquiterpene seychellene *(75)*, in which a smooth intramolecular addition of the easily accessible cyclohexadienone *(71)* is used[28a]. Already at 80 °C a kinetically controlled reaction gives, as with the analogous alkenylcyclohexadienones[28b], the regioisomeric adducts *(72)* and *(73)* in a ratio of 1:3. The main product *(73)* was converted into the alcohol *(74)*, which on acid catalysis rearranged to the desired terpene *(75)*. Remarkably, the formation of *(73)* as the main product

[*] Addition of a strong base appears to be decisive for this addition to proceed successfully.



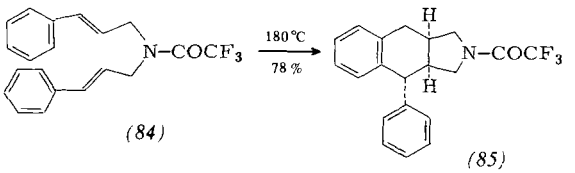
requires bond formation between the terminal dienophile center and the nearer end of the endocyclic diene system in *(71)*. This orientation, opposite to that in the examples mentioned above, is probably due to an overlap of the dienophile with the double bond conjugated thereto. In the formation of *(72)* such an overlap is impossible on the grounds of strain[28c].

A further application of intramolecular additions of cyclohexadienones exploits the easy preparation of *(77)* by Wessely oxidation of the phenol *(76)* in the presence of acrylic acid. On heating *(77)* in boiling benzene the lactone *(78)*[29] is formed, the ring system of which is a component of the natural products morellin and gambogic acid.



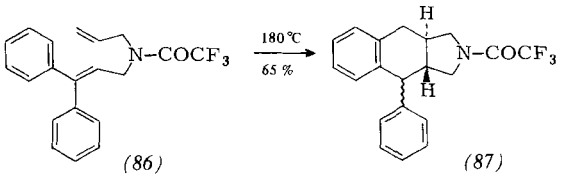
2.2.4. Endocyclic Heterodienes

The efficient intramolecular Diels-Alder addition of an isolated double bond to a 4,6-dihydroxypyrimidine has been demonstrated recently by the thermolysis *(79)*→*(80)*[30].



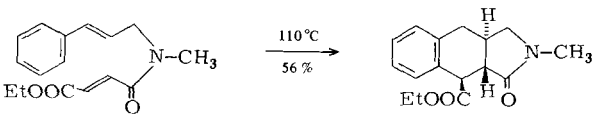
2.3. Styrenes as Diene Components

An extremely simple synthetic route to Podophyllum lignans[31], described by *L. H. Klemm*, may be taken as the first application of an intramolecular [4+2] cycloaddition to the synthesis of natural products. Thus, the natural lactone *(83)* is obtained by merely heating the arylpropargyl ester



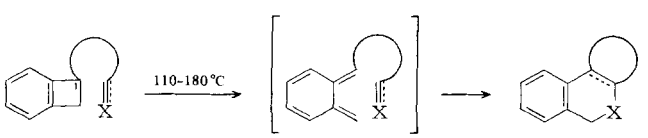
(81) in boiling acetic anhydride. In this reaction the styrene unit of *(81)* clearly reacts as the diene and the triple bond as the dienophile with the formation of an intermediate adduct *(82)* which aromatizes to *(83)* by a 1,3-hydrogen shift.

Furthermore, at higher temperatures (180 to 235 °C) olefinic double bonds that are relatively unreactive add intramolecularly to styrenes[32a]. For example, the *cis*-fused isoindoline derivative *(85)* is obtained exclusively by thermolysis of the *N,N'*-bis(cinnamyl)amide *(84)*, while the *trans*-system *(87)* is obtained selectively from the isomeric amide *(86)*. Steric



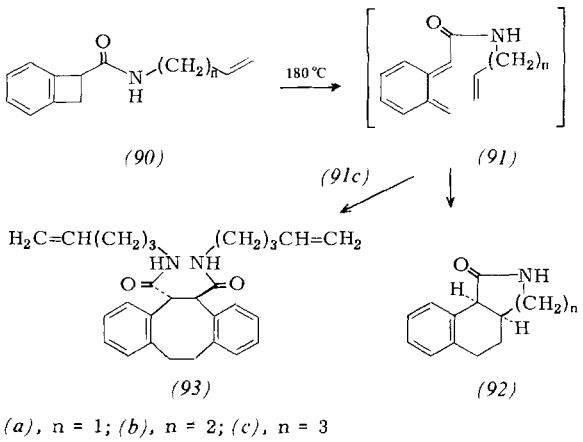
(84) *(85)*

(86) *(87)*



interactions of the phenyl substituents are probably responsible for this mutually exclusive steric control which disfavors on the one hand the *exo*-orientation of the chain in *(84)* and on the other the *endo*-addition of *(86)*. It is worth noting the exclusive formation of 1:1 adducts in the above cases, whereas bimolecular Diels-Alder reactions of styrenes often yield the (undesirable) 2:1 addition products[2a]. This difference underlines once more the preparatively advantageous influence of entropy factors on the reaction rate of intramolecular cycloadditions, as also shown by the smooth thermal transformation *(88)*→*(89)*[32b].

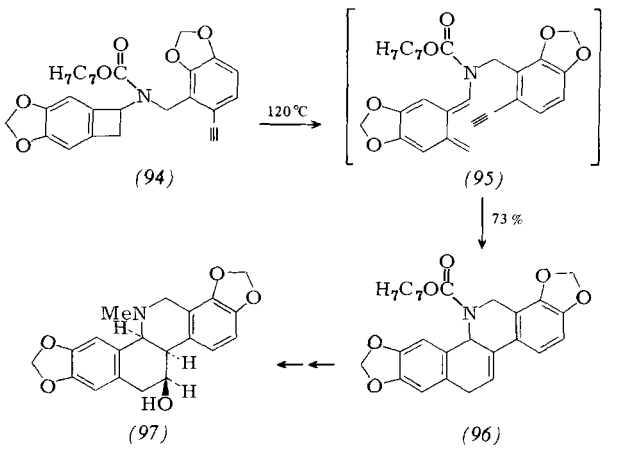
(88) *(89)*



2.4. *o*-Quinodimethanes

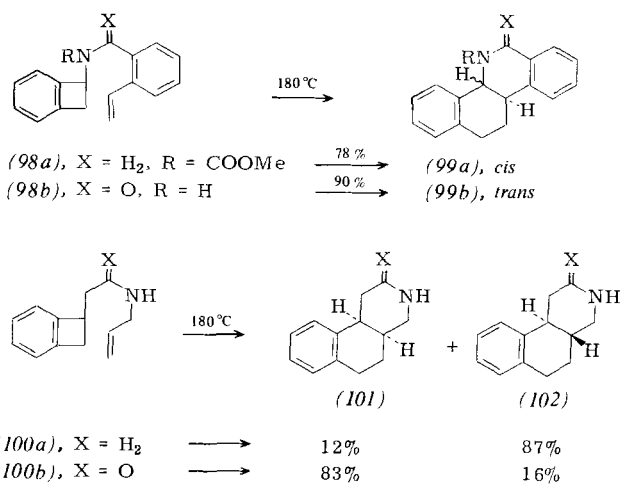
Another reaction sequence that is interesting from the preparative point of view and whose course involves participation of an aromatic system was developed in the laboratories of Sandoz Ltd.[33]. Accordingly, tricyclic systems of the type *(iii)* are obtained in excellent yield by heating the readily accessible benzocyclobutenes *(i)* that carry on C-1 a chain of five or six atoms with a terminal multiple bond. Here, according to stereochemical and kinetic findings[33b] we have a primary reversible opening of the four-membered ring to a nonaromatic intermediate (*E*)-quinodimethane *(ii)*, which undergoes irreversible cycloaddition to

i *ii* *iii*



the multiple bond in the chain (with concomitant formation of the arene system). This addition occurs smoothly even with unreactive dienophiles, *e.g.* with isolated C—C and C—N double or triple bonds[33c], presumably because of the entropic assistance resulting from the proximity of the reaction partner. (For intramolecular cycloadditions of nitriles to 1,3-dienes see [34].)

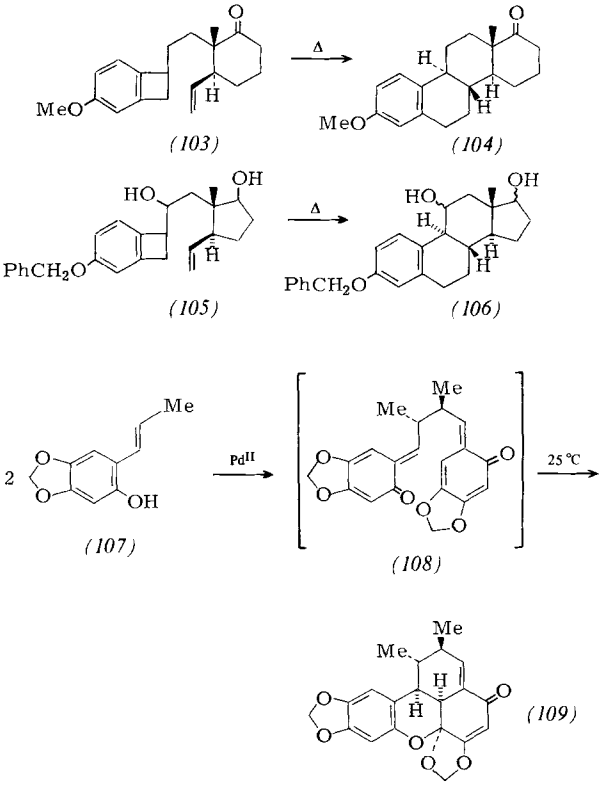
(90) *(91)* *(93)* *(92)*



(a), n = 1; *(b)*, n = 2; *(c)*, n = 3

The limits of this influence are revealed when one compares the efficient reactions *(90a)*→*(92a)* and *(90b)*→*(92b)* (both give an 80% yield) with the thermal behavior of the higher homolog *(90c)*[33a]; even at high-dilution the adduct *(92c)* is formed in drastically reduced yield (20%), together with the dimerization product *(93)* (6% yield).

(94) *(95)* *(97)* *(96)*

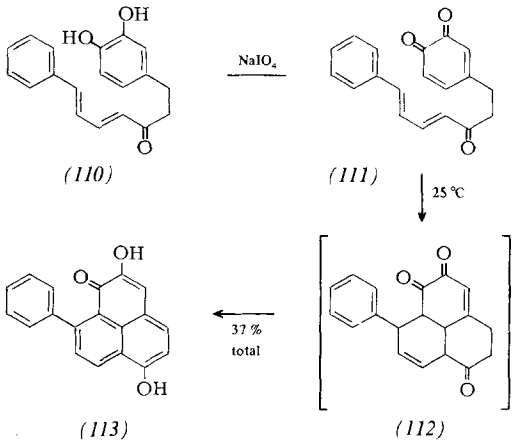


Of the numerous possible variations offered by the inclusion of heteroatoms and rings in the benzocyclobutene *(i)*, the

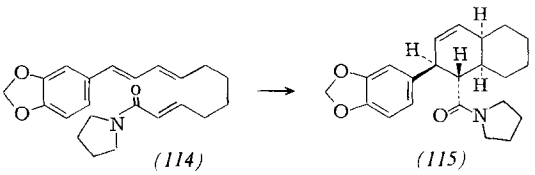
thermal reaction of *(94)* may be selected as an example; already at 120°C it provides *(69)* in 73% yield and forms the key step in the synthesis of the alkaloid chelidonine *(97)*[35].

The steric course of the related thermal transformations of *(98a)*, *(98b)*, *(100a)*, and *(100b)* may be cited as examples to illustrate how intramolecular cycloadditions can be directed toward *endo*- or *exo*-products merely by changing the conformation of the bridge[33d, 35].

High stereoselectivity was similarly observed in the key steps *(103)*→*(104)* and *(105)*→*(106)* of two independent steroid syntheses[36].



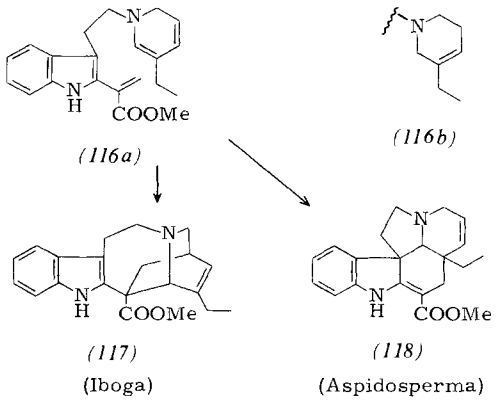
A similar concept is encountered in the elegant biomimetic synthesis of the lignan carpanone *(109)*[37a]. This route, which is characterized by remarkable control over five chiral centers, leads *via* phenol coupling of *(107)* to an intermediate bis-(quinodimethide) *(108)*; spontaneous intramolecular Diels-Alder reaction of this gives the lignan *(109)* in 46% yield.



2.5. Biogenesis of Natural Products

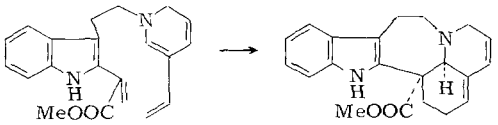
The striking utility of intramolecular [4+2]-cycloadditions for the synthesis of complicated natural products leads inevitably to the question whether this reaction principle is also used in nature. In answer to this, it may be recalled that the synthesis of carpanone was patterned along the lines of biogenetic ideas[37b]. The intermediacy of *(108)* in the biogenesis of *(109)* appears convincing in view of the mild conditions of the laboratory synthesis, the absence of optical activity in the natural alkaloid *(109)*, and the occurrence of the methyl ether of the precursor *(107)* in the same plant.

Considering an earlier hypothesis[38a] it was very recently suggested that the biogenetic pathway to the plant pigment



lanchnanthocarpone *(113)* also involves an intramolecular Diels-Alder reaction: *(111)*→*(112)*. In fact, the natural product *(113)* could be obtained in one synthetic operation by oxidation of the catechol *(110)* with $NaIO_4$; the ensuing cycloaddition *(111)*→*(112)* proceeds readily at 25°C[38b].

Similar facts apply to the racemic natural product cyclopiperstachine *(115)*[39]; this was isolated under mild conditions from *Piper trichostachyon* and to all appearances arises in nature by intramolecular cycloaddition of piperstachine *(114)*, which occurs in the same plant. This process was carried out in the laboratory, but required temperatures above 110°C to give stereochemically pure *(115)* in 33% yield.



It is considerably more difficult to prove the key role postulated for the dihydropyridineacrylic ester *(116a)* (dehydrosecodine, not yet either isolated or synthesized) in the biosynthesis of iboga and aspidoderma alkaloids[40].

Nevertheless, it seems reasonable to regard intramolecular Diels-Alder reactions of *(116a)* responsible for the natural occurrence of catharanthine *(117)* and tabersonine *(118)*. In favor of this assumption, for example, is the *in vivo* incorporation of secodine *(116b)* into the aspidosperma skeleton[41], whereas some *in vitro* experiments on indirect detection of the bio-intermediate *(116a)* are subject to debate[42]. However, this hypothesis provided the stimulus for a biomimetic total synthesis of the aspidosperma alkaloid minovine based

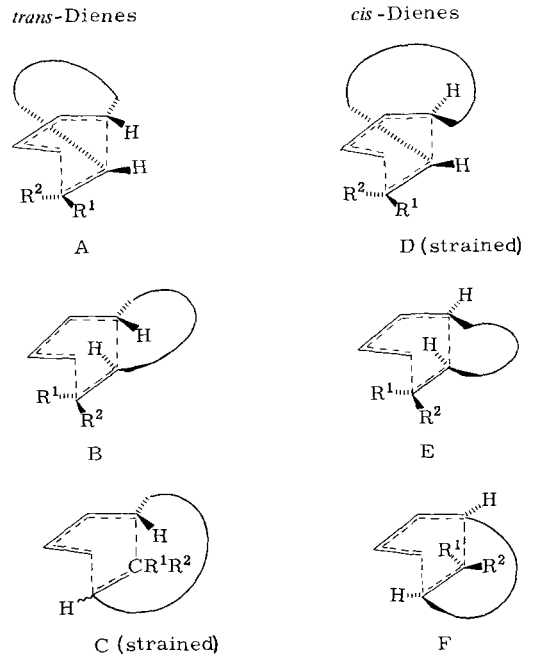
on a bimolecular [4+2]-addition (of a tetrahydropyridine to a 2-(2-indolyl)acrylic ester)[43].

Nature seems to follow similar principles in the synthesis of the alkaloid andraginine *(120)*[44]; both its racemic char-

(119) *(120)*

acter and its partial synthesis by thermolysis of precondylocarpine acetate find a reasonable interpretation in the intramolecular cycloaddition of the postulated secodine derivative *(119)*.

2.6. Discussion



It is anticipated that the above features relating to intramolecularity are in general limited to [4+2]-additions in which the diene and dienophile partners are linked by a bridge of three or four atoms. The longer and more flexible this bridge, the more the conditions resemble those for bimolecular addition, as is shown by the reactions of *(43)* and *(90c)*. It must also be stated that the regio- and stereoselectivity of intramolecular Diels-Alder reactions as discussed below rely on a kinetically-controlled reaction course. To avoid loss of this selectivity by the formation of thermodynamically controlled products it is recommended that such reactions be carried out at the lowest possible temperatures even if longer reaction times are necessary. These limitations apply equally to the [3+2]-additions discussed in Section 3.

2.6.1. Entropic Assistance

Intramolecular Diels-Alder reactions (type II in Scheme 1) take place under considerably milder conditions than are required for the analogous bimolecular reactions (type I in Scheme 1) [see, *inter alia*, the reactions of *(9)*, R=CH_3, R′=COOEt, *(30)*, *(57)*, *(108)*, and *(111)*]. The influence of entropy is illustrated by the $\Delta S^{\neq}$ values for the reactions of *(9)*, which are less negative than -20 cal K^{-1} mol^{-1}; their free activation energies ($\Delta G^{\neq}$) are thus lower by 5 to 7 kcal/mol than those for intermolecular [4+2]-additions. For the same reason, not only unactivated dienophiles, *e.g.* isolated olefins, oxime ethers, and nitriles but also unreactive (*e.g. cis*-substituted) 1,3-dienes undergo smooth intramolecular additions. [Catalysis of Diels-Alder reactions by Lewis acids has been used only to a limited extent in the intramolecular variants, *e.g.* in the reaction *(40)*→*(41)*.]

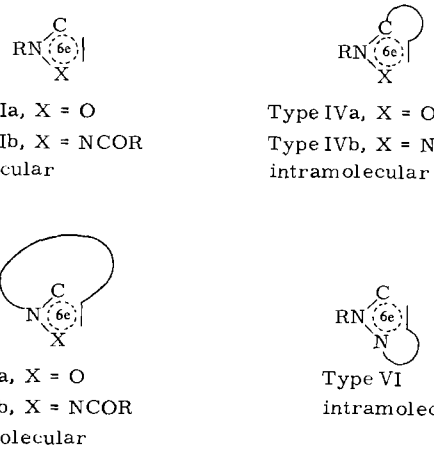
2.6.2. Direction of Addition

As follows from model considerations, intramolecular [4+2]-additions to *trans*-dienes are necessarily oriented in the direction A or B, since the orientation C is too strained (Scheme 2). Furthermore, from *cis*-dienes, *e.g. (3)*, *(24)*, *(61)*, *(68)*, and *(79)*, annelated rather than bridged adducts are generally obtained; the observed preference for direction E could here be ascribed to the fact that bond formation between the nearer ends of the diene and the dienophile is entropically more favorable than the orientation F. However, this influence can be overridden by other factors, as shown by the reaction *(71)*→*(73)*.

Scheme 2. Transition states of intramolecular [4+2]-additions. The bridge length is three or four atoms.

2.6.3. Stereochemistry

[4+2]-Additions I and II are synchronous multicenter processes with characteristic stereospecificity. Intramolecular additions II, however, exhibit supplementary features which differentiate between the *endo*- and *exo*-mode of addition (Scheme 2). On models it can be seen that in intramolecular addition of *cis*-dienes the dienophile chain is forced into the *exo*-position E, the transition state D being too strained. The *cis*-adducts thus arising with high stereoselectivity, *e.g. (4)*, *(21)* [from *(24)*], and *(63)*, can nevertheless be accompanied, or even outweighed, by products of competing sigmatropic or *cis*/*trans*-isomerization processes, *e.g.* in the formation of *(33)*.



In the thermally more stable *trans*-dienes the orientations A and B are both strain-free; as a result, the energy difference between these two transition states depends on the bonding and nonbonding interactions of the substituents and on other conformational influences that are less clearly predictable. For example, *trans*-dienophiles with *terminal* carbonyl or phenyl groups lead selectively to *trans*-fused adducts, *e.g. (2)* and *(10)*, which, as in the bimolecular Diels-Alder reaction, reflects the favored *endo*-position of sp^2 substituents. However, this is *not* so for dienophiles as soon as the sp^2 substituent forms an integral part of the bridge, as follows from the reactions *(9)*, R′=H, → *(10)*+*(11)*, *(30)*→*(31)*, *(36)*→*(37)*, and *(98b)*→*(99b)*. The repulsive forces due to the phenyl substituents appear to influence the spatial characteristics of the reactions of *(84)* and *(86)*. Other examples, such as the thermolyses of *(12)*, *(98b)*, and *(100b)*, show the stereochemical influence of amide groups built into the bridge. Quite generally, it should be possible, by conformational modification of the bridge, to direct intramolecular cycloadditions more or less completely in the direction of *trans*- or *cis*-anellated products.

Finally, it is of preparative importance to note the steric induction of chiral centers by centers already present in the bridge; here the conformational requirements of a highly ordered transition state come into play. For example, in the

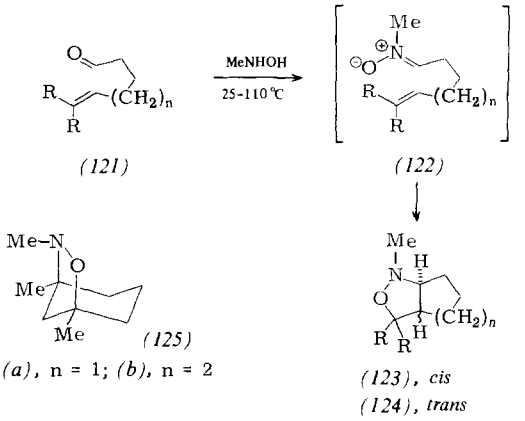
thermolyses of *(16)*, *(47)*, *(68)*, *(103)*, *(105)*, and *(108)* up to five chiral centers can be controlled simultaneously.

3. Intramolecular Cycloadditions of Nitrones and Azomethine Imines

It is due mainly to *Huisgen* and his school that the concept of [3+2]-cycloaddition and its general application to the synthesis of five-membered heterocycles has been visualized[3]. These reactions are closely related to the Diels-Alder reaction. Examples are, *inter alia*, the bimolecular additions of nitrones and azomethine imines to multiple bonds (Type IIIa and IIIb, respectively, in Scheme 3).

Scheme 3. [4+2]-Additions of nitrones (Types IIIa, IVa, Va) and azomethine imines (Types IIIb, IVb, Vb, VI).

Although intramolecular variants have recently been the subject of a review[45], it seems justifiable to consider their special features systematically in this article. However, the discussion will be limited to a small selection of reactions in which C—C double bonds are concerned (Types IV to VI in Scheme 3).

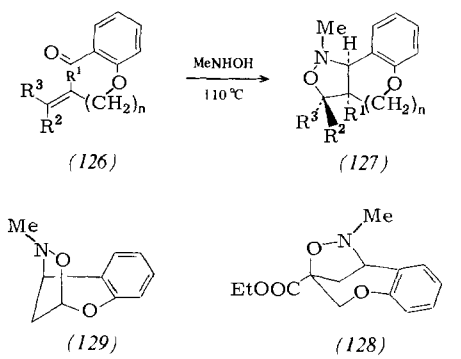


3.1. Nitrones

Nitrones occupy a special place among the 1,3-dipoles[46], not least because of their easy accessibility and the facility with which their adducts can be modified. Thus, *Beckmann* described cycloaddition of the nitrone *N*-benzylidenebenzylamine *N*-oxide to phenyl isocyanate as early as 1890[47], but the addition of nitrones to C—C double bonds was first reported—simultaneously by several groups of workers—only about 70 years later[48]. It seems remarkable that bimolecular and intramolecular nitrone-olefin additions were discovered at the same time.

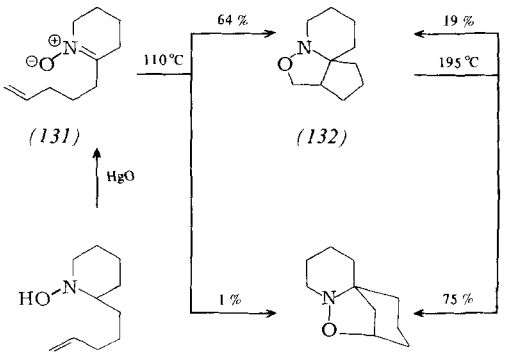
3.1.1. *C*-Alkenylnitrones (Additions of Type IVa)

Le Bel et al. showed[48c,49] that intramolecular additions of intermediate *C*-alkenylnitrones (Type IVa) can be easily effected if olefinic aldehydes *(121)* are condensed with *N*-alkylhydroxylamines; annelated isoxazolidines *(123)* and/or *(124)* are obtained in this way.



It is interesting that many of these additions to unactivated C—C double bonds take place smoothly at 25°C, whereas the bimolecular variant IIIa requires a higher temperature

and/or activation of the olefinic component[4]; this difference, which is useful for syntheses, again reflects the entropic influence in intramolecular reactions. It is also worth noting the regioselectivity of the addition of *(122)*, which leads mainly, if not exclusively, to annelated adducts (see Section 3.3.2). An exception is provided by the formation of bridged isoxazolidines such as *(125)* from *C*-alkenylketonitrones, probably owing to nonbonding interaction of the substituents.

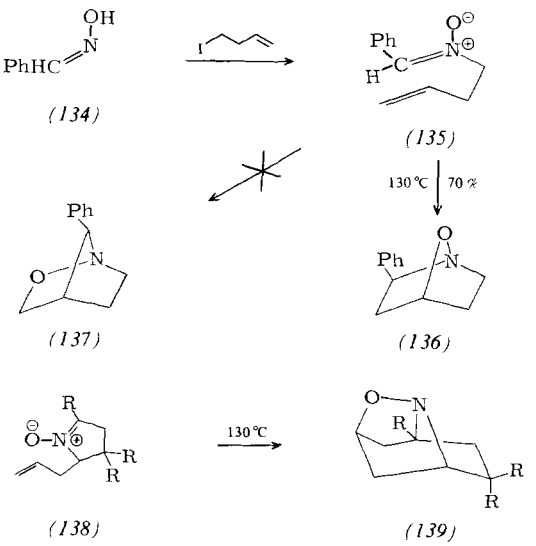


Concerning the stereochemical aspects (see Section 3.3.3) it appears that the *C*-(3-alkenyl)nitrones *(122a)* react highly selectively to give *cis*-condensed isoxazolidines *(123a)*. The kinetically controlled reaction of the homologous *C*-(5-alkenyl)nitrones *(122b)*[50] occurs less selectively; the *trans*-adducts *(124b)* are the main products, along with varying amounts of the *cis*-isomers *(123b)*. However, at higher temperatures (180—300°C) equilibration of the *trans*- and *cis*-adducts *(124b)* and *(123b)* occurs, presumably by 1,3-dipolar cycloreversion, to afford finally the thermodynamically more stable isomer *(123b)*.

Isoxazolidines that are *cis*-fused to a six-membered ring are, on the other hand, formed regio- and stereoselectively from ε,ζ-unsaturated aldehydes under kinetic control, provided that carbons α and β[51a,51b] (or γ and δ[51c]) are part of an aromatic ring. This is illustrated by the efficient reactions *(126a)*→*(127a)*, ($R^1=R^2=R^3=H$, 80% yield), which

nevertheless become less efficient with increasing distance between the reaction partners [*(126b)*→*(127b)*, $R^1=R^2=R^3=H$, 26% yield]. It was also not unexpected to find that ethoxycarbonyl or ether substituents (on the nearer end of the alkene unit) can direct the intramolecular addition partially towards bridged products, *e.g.* *(128)*, or *(129)*; this was also observed during model studies on the synthesis of tetracycline[51d]. The fact that the formation of annelated isoxa-

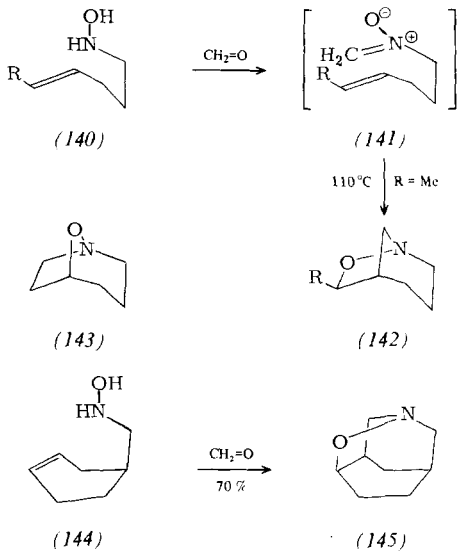
zolidines is generally dominant in additions of type IVa to nonpolarized C—C double bonds is shown particularly clearly in a model study for the synthesis of the alkaloid histrionicotoxin[52]. Namely, at 110 °C the endocyclic ketonitrone *(131)*,



(131) *(132)* *(130)* *(133)*

prepared by oxidation of the hydroxylamine *(130)*, gave mainly the annelated adduct *(132)*, and only a trace of the desired bridge isomer *(133)* which after cleavage of the N—O bond affords the histrionicotoxin skeleton. It should be noted that the conversion *(132)*→*(133)* could be accomplished at higher temperatures, apparently *via* 1,3-dipolar cycloreversion. It follows that the bridged adduct *(133)* is thermodynamically more stable than the annelated isomer *(132)*, whose formation is kinetically controlled.

3.1.2. *N*-Alkenylnitrones (Additions of Type Va)

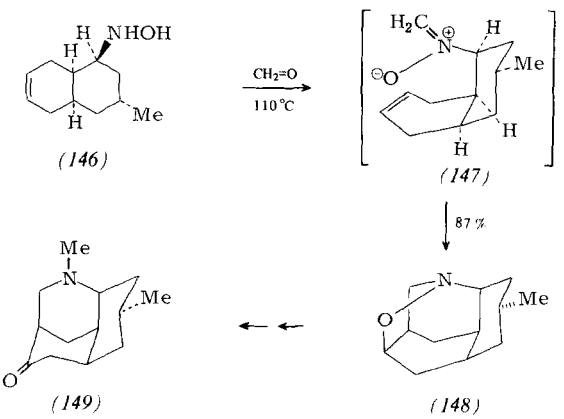


Intramolecular additions of Type Va, which necessarily lead to bridged isoxazolidines, attracted little attention until very recently. The first example was the thermolysis of the *N*-(3-butenyl)nitrone *(135)*, which was obtained by alkylation of benzaldehyde oxime *(134)*[53]; *(136)* was formed as the sole adduct, with no trace of the position isomer *(137)*. This result corresponds to a regiospecific formation of the C—C bond to the less substituted (terminal) alkene-carbon, as in most bimolecular additions of nitrones (Type IIIa) to monosubstituted olefins. The high stereochemical control of the intramolecular process indicates an *endo*-addition of the (*Z*)-nitrone *(135)*, the alternative *exo*-transition state being excluded by angular strain (see Section 3.3.3).

(134) *(135)* *(137)* *(136)* *(138)* *(139)*

The same direction of addition is followed by the reaction *(138)*, R = H, CH_3→*(139)*, which leads to the tropane skeleton[54] (after cleavage of the N—O bond).

In contrast, in the recently investigated intramolecular addition of *N*-(4-alkenyl)nitrones *(141)*[55], it is mainly the nearer alkene carbon that becomes linked to the nitrone-carbon. The nitrones *(141)* are formed *in situ* by condensation of formaldehyde with olefinic hydroxylamines *(140)*, which are readily accessible by reduction of oximes with sodium cyanoborohydride. On heating the non-isolated nitrones *(141a)*

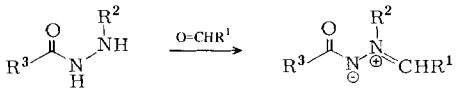


(140) *(141)* *(143)* *(142)* *(144)* *(145)*

(a), R = H; *(b)*, R = CH_3

at 110 °C, a 2:1 mixture of the two positional isomers *(142a)* and *(143)* was obtained in 75 % yield in a kinetically controlled reaction. Much higher directional selectivity was observed in the corresponding reaction of *(140b)* which gave exclusively the adduct *(142b)* in 90 % yield. Similarly the hydroxylamine *(144)*, which also contains a 1,2-disubstituted double bond, afforded *(145)* as the sole adduct.

The ready accessibility of *N*-(4-alkenyl)nitrones (from *N*-alkenylhydroxylamines) and the unequivocal direction of their intramolecular additions to nonconjugated "symmetric" C—C bonds recently allowed a simple[56a] and enantioselective[56b] synthesis of the lycopodium alkaloid luciduline *(149)*.



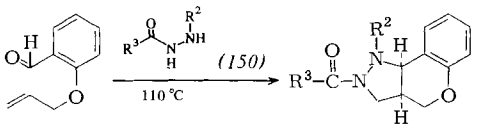
(146) *(147)* *(149)* *(148)*

Heating of the easily available hydroxylamine *(146)* with an excess of paraformaldehyde and molecular sieves in toluene furnished directly an 87 % yield of the isoxazolidine *(148)*, which on methylation, reduction and oxidation gave the alka-

loid *(149)* in high yield. Comparison with another, multistage, preparation of racemic *(149)*[56c] demonstrated for the first time in the synthesis of natural products a superiority of intramolecular nitrone additions over other types of reaction.

3.2. Azomethine Imines

The history of these dipoles is more recent than that of nitrones; the cycloadditions [type IIIb] of a few endocyclic azomethine imines to multiple bonds were described by *Huisgen et al.* in 1960[3a, 57]. Surprisingly, it was only a few years ago that convenient methods for the preparation of open-chain (unstable) azomethine imines, analogous to those for the preparation of nitrones, were found in the laboratories of Sandoz Ltd.

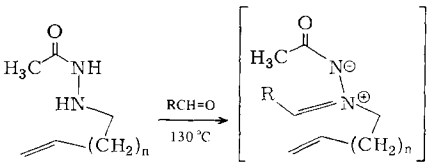


(150) *(151)*

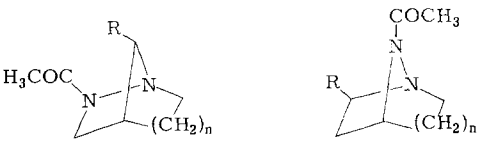
Azomethine imines *(151)* were then obtained *in situ* from *N*-acyl-*N'*,*N'*-dimethylhydrazines *via* mercury compounds[58] or preferably by condensation of aldehydes with *N*-acyl-*N'*-alkylhydrazines *(150)*[59]; subsequent trapping by bimolecular addition (Type IIIb) to dipolarophiles such as styrene, furnished pyrazolidines in high yields. The simple reaction *(150)*→*(151)* now allows olefinic substituents R^1, R^2, and R^3 to be introduced specifically into the three positions of the dipole; thus the intramolecular cycloadditions IVb, Vb, and VI may be easily realized.

3.2.1. *C*-Alkenylazomethine Imines (Additions of Type IVb)

C-Alkenylazomethine imines are conveniently accessible *in situ* by condensing olefinic aldehydes with *N*-acyl-*N'*-alkylhydrazines *(150)* and undergo a spontaneous, regioselective addition of Type IVb[60].



(152) *(153)*

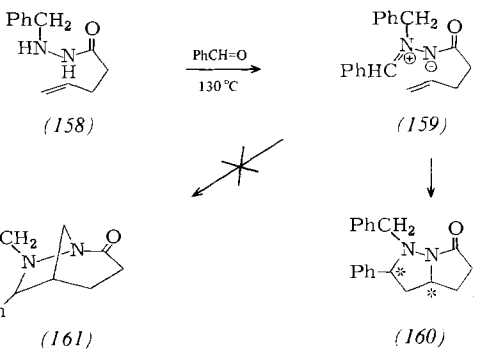


As shown by the example *(152)*→*(153)*, *cis*-annelated pyrazolidines are formed directly and preferentially (although the stereoselectivity is here less marked than for the analogous additions of nitrones). Remarkably, the reaction of *N*,*N'*-bis(*p*-methoxybenzyl)hydrazine does not produce isolable pyrazolidine derivatives on reaction under similar conditions with *(152)* or with paraformaldehyde in styrene[59, 60]; this is not in agreement with the postulate[3a, 61] that intermediate azomethine imines are formed when the last-mentioned hydrazine reacts with aldehydes in the presence of carbon disulfide (or acrylonitrile).

3.2.2. *N*-Alkenylazomethine Imines (Additions of Type Vb)

As expected, the condensation of *N*-acyl-*N'*-alkenylhydrazines with aldehydes leads to azomethine imines (with an alkenyl group on the central nitrogen of the dipole), which can undergo intramolecular additions of type Vb[62].

(154) *(155)*



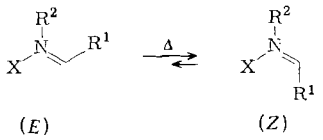
(157) *(156)*

(a), n = 1; *(b)*, n = 2

For example, the adduct *(156a)*, R = H, was formed regioselectively on treatment of *(154a)* with formaldehyde. Similarly to the analogous additions of nitrones of Type Va, the direction of the addition is reversed with the higher homologs *(154b)*, R = H; one obtains only the regioisomer *(157b)*, R = H. The same direction of addition is preferred on heating the hydrazide *(154b)* with benzaldehyde; the positional isomers *(156b)*, R = Ph, and *(157b)*, R = Ph are formed in the ratio of 1:7, in a total yield of 54%, together with smaller amounts of two stereoisomeric products. The stereochemistry observed in these reactions is consistent with predominant addition of the (*Z*)-dipole *(155b)*, R = Ph.

3.2.3. *N*-Alkenoylazomethine Imines (Additions of Type VI)

Finally, the third reaction type, VI, requires that the dipolarophile chain is attached to the terminal nitrogen of the dipole.



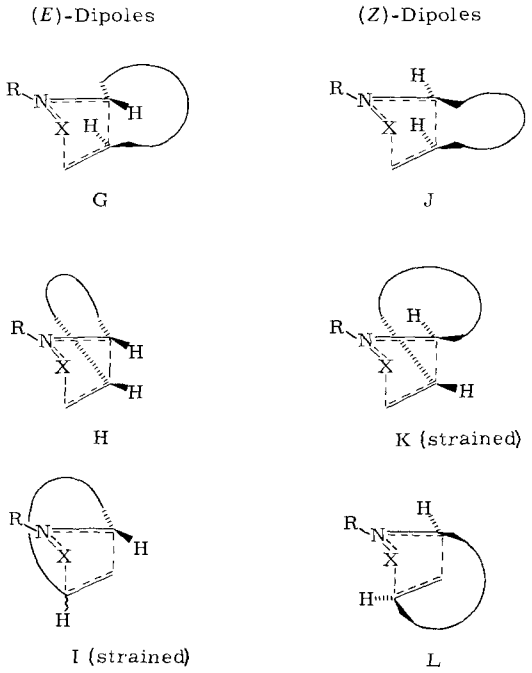
(158) *(159)* *(161)* *(160)*

A reaction of this type can be smoothly effected by heating *N*-alkenoyl-*N'*-alkylhydrazines together with aldehydes[62], as shown by the regio- and stereoselective conversion *(158)*→*(159)*→*(160)*. The sole product is the sterically homogeneously annelated adduct *(160)* (whose configuration has not yet been clarified) with no trace of the bridged isomer *(161)*.

3.3. Discussion

The mechanistic relationship between 1,3-dipolar addition and the Diels-Alder reaction makes it possible to discuss the features of their intramolecular variants on a common basis. However, nitrones and azomethine imines can add also intramolecularly to C—C double bonds that are linked by a short chain to the central atom of the dipole. In contrast,

the analogous Diels-Alder reaction would be blocked by the formation of a developing bridgehead double bond. A further difference concerns the rotation barriers of C—N and C—C double bonds (Scheme 4). It seems reasonable to assume that



Scheme 4. Rotation of acyclic nitrones and azomethine imines.

(*Z*)/(*E*)-isomerizations of acyclic nitrones and azomethine imines are comparable in rate with the cycloaddition process[46a, 63], which has been taken into account in the discussion of the orientation rules (Section 3.3.2). Furthermore, it must be remembered that, with the exception of strain, the proposed orienting forces may be overridden by other factors. As in the Diels-Alder reaction, cycloreversion can occur at higher temperatures with the formation of thermodynamically controlled products; this is occasionally of preparative use, as in the reaction *(132)*→*(133)*.

3.3.1. Entropic Assistance

In view of the strongly negative activation entropies of bimolecular additions of Type III[3b], there can be no doubt (despite the lack of data) that intramolecular reactions of Types IV, V, and VI are entropically favored. This is indicated by the smooth intramolecular addition of sensitive, unisolable dipoles to unreactive double bonds, which becomes less effective with increasing distance between the dipole and the isolated alkene unit [see the reaction *(126b)*→*(127b)*].

3.3.2. Direction of Addition

Scheme 5. Transition states of the additions IV (see Scheme 3).

Examination of models shows that in intramolecular additions of *C*-alkenyl-nitrones and -azomethine imines (Scheme 5) both (*Z*)- and (*E*)-dipoles are capable of forming annelated products. Bridged products, *e.g. (128)* and *(129)*, cannot arise by way of the strongly strained orientation I but only from (*Z*)-dipoles *via* the strain-free transition state L. However, in additions of Type IV to nonpolarized double bonds, the orientation L is disfavored compared with J and K, as is manifested by the predominant formation of annelated products. This kinetically controlled regioselectivity, which is illustrated by the reaction sequence *(131)*→*(132)*→*(133)*, may be due to the fact that bond formation between the nearer ends of the dipole and dipolarophile is entropically favored.

This may also apply for the regioselectivity of the addition *(159)*→*(160)*; in this case the dipolarophile is attached to the terminal nitrogen of the dipole.

Scheme 6. Transition states of additions V (see Scheme 3).

It is more difficult to predict the direction of the additions of type V. In these compounds the alkenyl chain is attached to the central nitrogen of the dipole (Scheme 6). Thus, the length of the chain as well as alkyl substituents on the alkene component may influence the preference between the orientations M and N. For example, transition state M predominates in intramolecular additions of *N*-(4-alkenyl)-nitrones and -azomethine imines.

3.3.3. Stereochemistry

For the kinetically controlled formation of *cis*- and/or *trans*-annelated adducts from *C*-alkenyl-nitrones and -azomethine imines the transition states G, H, J, and K may be considered (Scheme 5); however, a model of the (*Z*)-*endo*-transition state K proves to be strained. This strain clearly becomes more pronounced when the two reactants are separated from each other either by only three atoms or by a chain of four atoms two of which belong to one double bond. If (for reasons given below) we assume predominant addition of (*Z*)-dipoles, then this explains the selective formation of *cis*-annelated adducts in the reactions of *(121a)*, *(126)*, and *(152)* (also in the reaction of citral with *N*-methylhydroxylamine) by way of the strain-free (*Z*)-*exo*-transition state J. On the other hand, the observed formation of *trans*-fused addition products from the nitrones *(122b)* is consistent with the (*E*)-*exo*-transition state G, provided we assume that cycloaddition is now slower than the (*Z*/*E*)-isomerization. However, this does not preclude the participation of a (*Z*)-*endo*-transition state K, where angle deformation is diminished by the longer bridge.

In the intramolecular addition of *N*-alkenyl-nitrones and -azomethine imines we meet unequivocal steric relationships (Scheme 6). These reactions (Type V) can occur only through the *endo*-transition states M and/or N, since the alternative *exo*-orientations O require an inadmissible deformation of the bond angles. As a result, the stereochemistry of the additions of type V depend only on the configuration of the dipolarophile and the dipole; that the latter reacts preferably in the (*Z*)-form is probable in view of the observed conversions *(135)*→*(136)* and *(155b)*, R = Ph, → *(156b)*, R = Ph.

The stereochemistry of the additions of Type VI has not yet been investigated, although, as previously mentioned, the reaction *(159)→(161)* is known to take place stereoselectively.

4. Final Considerations

Intramolecular concerted cycloaddition reactions of 1,3-dienes, nitrones and azomethine imines have provided the organic chemist with the opportunity of synthesizing in one operation complex polycyclic molecules both in a regio- and stereoselective manner. The large number of the classical bimolecular variants indicates that the preparative wealth conferred by intramolecularity on these types of reaction is by no means exhausted. As a further possibility we may mention as an example the formation of more than two bonds by a controlled combination of successive pericyclic reactions. In the future it is to be hoped that new efficient routes to appropriately functionalized precursors, together with a better understanding of the theoretical implications will significantly increase the scope of these reactions.

Some of our own work mentioned in this article was carried out at Sandoz AG, Basle, and some at the University of Geneva. The latter investigations were kindly supported by the Fonds National Suisse de la Recherche Scientifique, Sandoz AG, Basle, and Givaudan SA, Vernier. I am indebted to Frau Kathrin Keller and to Roland Achini, Bartholomeus Bakker, Charles Fehr, Wolfgang Fröstl, Emil Pfenninger, Martin Petrzilka, Samuel Siles, Roger L. Snowden and Jochen Warneke for their valuable collaboration, and to my colleagues Prof. Charles W. Jefford and Dr. Roger L. Snowden for helpful suggestions during the writing of this manuscript.

Structural Rules for Globular Proteins

By Georg E. Schulz[*]

Is it possible to reach a detailed understanding of the complex three-dimensional structures of native polypeptide chains? In view of the wealth of common physicochemical and phylogenetic features discovered among proteins this question has become reasonable. The current state of discussion is presented in this report.

1. Introduction

The structure of a globular protein was first elucidated 16 years ago[1]. Meanwhile about 40 proteins have been analyzed at atomic resolution, and the polypeptide chain fold is known in about ten more cases. Thus the pioneering era has undoubtedly come to an end. Protein structure models have become everyday tools of the biochemist; with their aid he can design and interpret his experiments much more soundly than ever before.

The wealth of structural data available not only favors biochemical aspects, but also challenges us to understand the architecture of the observed structures and thus to trace biology back to its physical roots on a much more fundamental scale than was previously possible. Given an intimate knowledge of their architecture, a substantial increase in the number of analyzable proteins can be predicted because those proteins also become accessible which do not crystallize. Furthermore, the study of historical relationships, and especially very early stages of evolution, can be put on a firmer basis. Therefore, efforts invested in this field may be expected to yield considerable rewards.

2. Energy Balance

Globular proteins consist of linear polypeptide chains (Fig. 1), which are synthesized from 20 different amino acids[4]. During or after synthesis these chains fold spontaneously to an exact three-dimensional structure. The spontaneity of folding is regarded as a generally valid principle, because it could be demonstrated in renaturing experiments with several proteins[5–7]. Thus all information pertaining to three-dimensional structure is already implicit in the chemical structure of the chain, *i. e.* in the amino acid sequence. Folding is merely a transition to an energetically more favorable state of the chain.

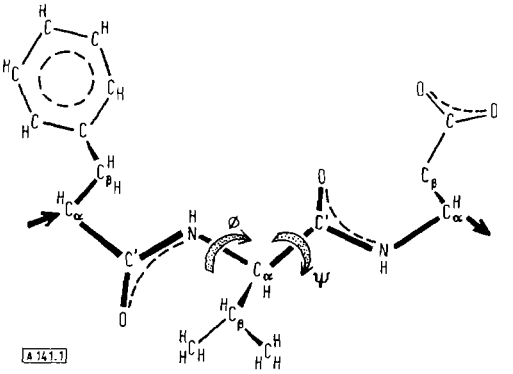

Fig. 1. Part of a peptide chain. Because of resonance the peptide bonds are planar [2]. Therefore the dihedral angles ϕ and ψ at the C_α atoms determine the chain fold. Steric hindrance permits adoption of only 15% of all possible ϕ, ψ orientations [3]. The relatively low mobility of the side chains should be noted.

The principal types of interactions involved in folding are: van der Waals forces between nonpolar groups, dipole forces between polar groups, in particular hydrogen bonds, and "hydrophobic forces" (a synonym for water entropy) which describe the tendency of the apolar side chains to form a separate hydrophobic phase—*i. e.* a kind of oil droplet[8]. In the free energy balance

$$\Delta G = \Delta H_{bond} - T \cdot \Delta S_{water} - T \cdot \Delta S_{chain} \quad (1)$$

the binding enthalpies and the water entropy together oppose the chain entropy term. Only when their contribution is sufficient can the chain entropy be overcome and the chain "immobilized", *i. e.* constrained to a definite structure. For chains containing about 100 residues a rough estimate yields values of several hundred kcal/mol for the opposing contributions. However, the resulting ΔG is of the order 10 kcal/mol[9]. Thus we are dealing with a delicately balanced system, which renders detailed understanding more difficult.

Hydrophobic nuclei are found in all structurally known proteins, confirming the importance of the water entropy term in eq. (1). The packing density of these nuclei is as high as in

[*] Dr. G. E. Schulz
Max-Planck-Institut für medizinische Forschung
Jahnstrasse 29, D-6900 Heidelberg (Germany)

the most densely packed crystals stabilized by van der Waals forces[10, 11], *i.e.* the number of van der Waals contacts and thus the corresponding bond enthalpy term are maximized. This is also reflected in the comparatively low compressibility of proteins[12, 13] ($\kappa_{oil}/\kappa_{protein} \approx 20$). However, the interior of proteins is not entirely apolar but contains about half of all the polar groups—in particular the C=O and N—H groups of the peptide bonds[14]. Being shielded from water 90% of these dipoles form hydrogen bonds with a relatively high energy contribution[15]. Thus although proteins are stabilized by the oil drop effect they bear little resemblance to a disordered and loosely packed oil droplet, rather they are similar to a densely packed crystal.

Equation (1) rationalizes the natural selection of α-amino acids and not β-amino acids, although the latter are produced in comparable quantities by experiments designed to simulate prebiotic synthesis[16]. A peptide chain made up of β-amino acids would exhibit almost free rotation about the $C_\alpha—C_\beta$ bond and thus have a much higher chain entropy content. Hence much greater bond enthalpies and/or water entropies would be necessary for stabilizing the three-dimensional structure. In contrast, a chain composed of α-amino acids is far less flexible (Fig. 1) can be immobilized much more easily. For analogous reasons the side chains used are also comparatively rigid (Fig. 1).

3. Folding Pathway

Folding of a chain of 100 α-amino acid residues requires the adjustment of about 300 parameters (Fig. 1). Even if each parameter is restricted to only two values, some 2^{300} conformations become possible. Random adoption of each conformation until the chain stumbles upon an energetically stable one would require a time exceeding the age of the earth, even if only 10^{-13} s were assumed for each trial. Hence the parameter values must be run through in a directed manner, *i.e.* there must be a folding pathway.

For pancreatic trypsin inhibitor the existence of such a pathway has been proved experimentally. This was done by tracing the sequence of S—S bridge formation on going from a random coil to the native state[17]. Of the $\binom{6}{2} = 15$ possibilities, initially one of the native bridges is formed with maximum yield (Fig. 2). The cysteines of the accompanying non-native bridges are proximate in the native three-dimensional structure (Fig. 2). Accordingly, the chain regions around residues 5, 30, and 53 approach each other in the first stage of folding. Various false linkages occur also in the ensuing stages (Fig. 2). The conformational mixture is therefore broad; folding is not absolutely "single tracked".

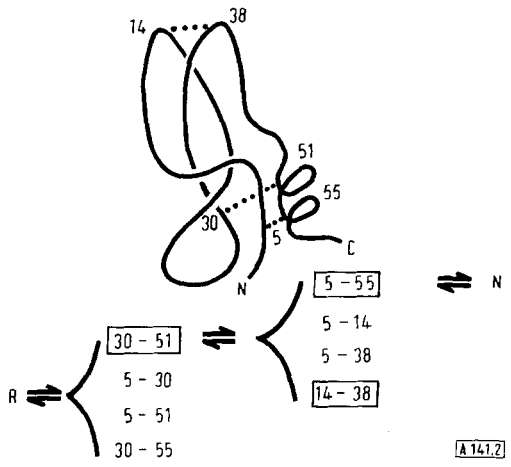

Fig. 2. Sequence of S—S bridge formation on renaturing of pancreatic trypsin inhibitor, according to *Creighton* [17]. The cysteine side chains are linked by disulfide exchange reagents. It is generally assumed that bridge formation is not necessary for chain folding; it only indicates the vicinity of the cysteines. The native bridges are shown in boxes. Premature formation of the native bridge 14–38 obstructs further folding. *Creighton*'s experiment shows unequivocally that a specific folding pathway is followed.—The chain fold is sketched according to *Huber et al.* [18]. R = random coil, N = native.

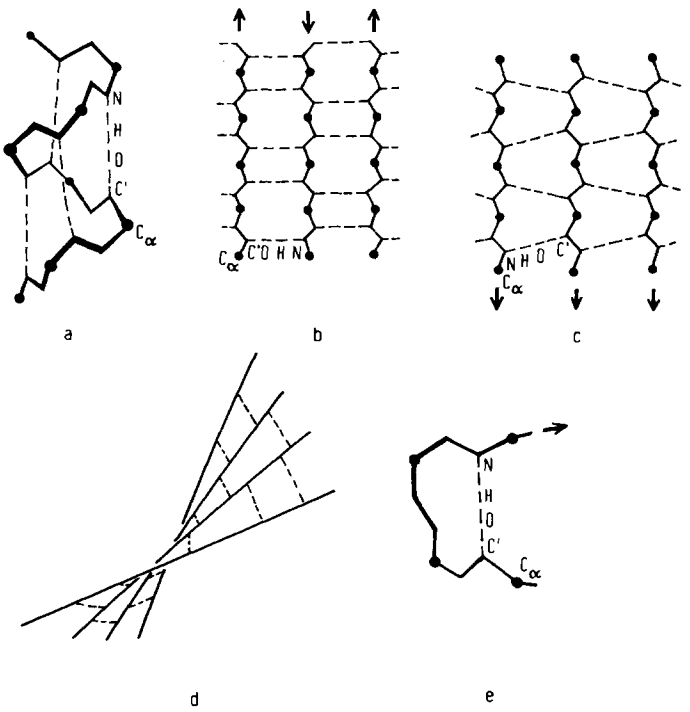
Renaturation experiments were performed with lysozyme at 84 °C[19]. Although this temperature exceeds by far the denaturation temperature of lysozyme (*ca.* 50 °C) a transient renaturation is observed. Hence, even at such high temperature folding is faster than thermal unfolding. However, fast folding is feasible only if a defined folding pathway exists and little time is lost with trial-and-error fitting. Since such a pathway greatly reduces the conformational space to be considered, there is hope that it can by elucidated and reproduced with theoretical models.



As the native three-dimensional structure is reached *via* a definite pathway it need not correspond to the absolute energy minimum in the entire conformational space. Extremely uneven energy surfaces with numerous local minima are to be expected for complicated structures[7]. Thus a defined pathway probably leads to a local minimum. However, it is fundamentally impossible to distinguish between a local and the global minimum because scrutinization of the entire conformational space would be required. Neither the chain itself nor any kind of computer simulation can do that. Moreover, all kinetically inaccessible minima are irrelevant even if they include the absolute minimum. Any discussion of this question[6, 7, 19] therefore resembles the arguments of the scholastics.

4. Hierarchy

Several degrees of organization are perceptible in the proteins of known structure (Table 1). The amino acid sequence represents the basis. As mentioned above, it implicitly contains the entire structural information. The next higher stage is seen in the secondary structures depicted in Figure 3. These are regular chain arrangements permitting optimal hydrogen bonding. Secondary structures are very common, extending over 75% of the chain in some proteins. This is probably related to the energetic necessity of compensating internal polar groups by forming hydrogen bonds.

Table 1. Levels of organization in proteins. The order is vertical and partially hierarchic, *i.e.* the structural elements of a particular level, *e.g.* α-helices (a secondary structure) are essentially determined only by the elements contained therein from the next lower level (*e.g.* amino acid residues).

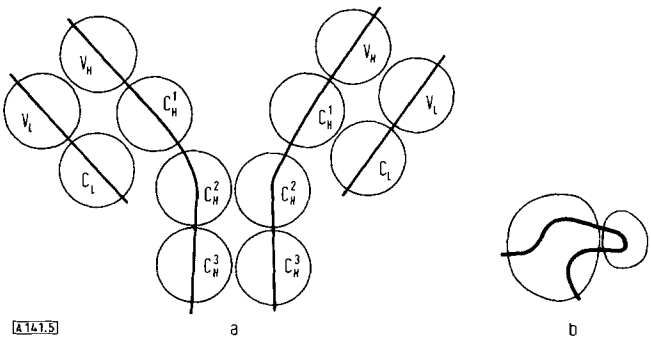
Fig. 3. Secondary structures in polypeptide chains. a) α-helix, b) antiparallel β-pleated sheet, c) parallel β-pleated sheet, d) twist found in all pleated sheets, e) β-bend. In all secondary structures hydrogen bonds are formed between the C=O and N—H groups of the peptide bonds.

In some cases, secondary structures form regular aggregates, so-called "supersecondary structures". One undisputed example is the double α-helix[20] in which the side chains of two α-helices are meshed together and the helices are wound around each other with a repeat distance of about 180 Å (Fig. 4).



A 141.4

Fig. 4. Secondary structure aggregates or "supersecondary structures". a) Double α-helix according to *Crick* [20], observed in paramyosin [21]; myosin [22], α-keratin [23], and tropomyosin [24]. Similar structures seem to occur in hemerythrin [25] and bacteriorhodopsin [26]. b) Pleated sheet/helix combination, consisting of three strands of pleated sheet and two α-helices, found in lactate dehydrogenase [27], malate dehydrogenase [28], alcohol dehydrogenase [29], and glyceraldehyde 3-phosphate dehydrogenase [30], adenylate kinase [31], flavodoxin [32, 33], subtilisin [34], phosphoglycerate kinase [35], and phosphorylase [36].

Another supersecondary structure is the pleated sheet/helix combination found in some dehydrogenases[27] and other proteins (Fig. 4). Apart from these clearly defined supersecondary structures there are several structural preferences to be regarded as less well-defined manifestations of the same principle. They are described below.

The next higher degree of complexity is encountered in the domain. Most of the proteins with more than about 150 amino acid residues can be structurally subdivided into two or more spatially separated regions or domains. This is seen most clearly in the immunoglobulins whose light and heavy chains, respectively, form two and four separate domains (Fig. 5). The domains appear to contain those regions of the chain which fold independently to their three-dimensional structure.

A 141.5

Fig. 5. Domain structure of globular proteins. a) The light (L) and heavy (H) polypeptide chains of immunoglobulins fold into two and four domains [37], *i.e.* spatially separated structural regions. b) Adenylate kinase forms one large and one small domain which are not linked in the usual manner by one, but by two strands. Consequently, the large domain shows a smaller neighborhood correlation than the small one.

Globular proteins with one or more domains (Table 1) are not always the ultimate stage of self-assembly. In many cases protein surfaces are constructed in such a way that globules combine into larger aggregates, *e.g.* enzyme complexes, ribosomes, virus coats, muscle fibers. If only one or two kinds of components join together the aggregates are usually symmetrical (*e.g.* subunits of glutathione reductase[38] or lactate dehydrogenase[39], regulatory and catalytic subunits of aspartate transcarbamylase[40], pentone and hexone subunits of the adenovirus coat[41], myosin forming a myosin filament[22]). Symmetry arises because surface contacts are optimized and everywhere the same.

Understanding of chain folding would be greatly facilitated if this vertical order were strictly hierarchic, *i.e.* if the structural elements of a given level (*e.g.* α-helix) were influenced only by the elements of the immediately preceding level contained therein (*e.g.* amino acid residues) and not by other parts of the protein or other structural levels. The folding could then be analyzed for each step separately, and the difficult overall problem resolved into several much easier problems. Fairly strict hierarchy is found between globular proteins and aggregates (Table 1) because in most cases the globular monomer is rather stable and hardly altered during association. If the monomer structure is known the structure of the aggregate can be derived from surface characteristics of the monomer. However, this does not apply for some ribosomal proteins with almost completely extended chains[42], the monomer being too flexible to assume a defined structure on its own. Its structure is determined only on association with other ribosomal components.—Hierarchy is also found between amino acid sequence and α-helices (Table 1) because the formation of α-helices is probably largely independent of the three-dimensional structure eventually adopted. The same applies to the association of domains to globular

proteins. Accordingly, while the vertical order of Table 1 is not strictly hierarchic it is nevertheless sufficiently hierarchic to provide an acceptable working hypothesis.

5. Separation of the Secondary Structure

Once the secondary structures postulated by *Pauling* and *Corey*[43,44] had been detected in several globular proteins, a test for hierarchy between secondary structure and amino acid sequence (Table 1) suggested itself. Assuming strict hierarchy, an α-helix, for example, should be determined exclusively by its constituent amino acids and by no other part of the chain; and the correlation function between helix formation and amino acid sequence should be deducible from experimental data. Knowing the correlation function, the amino acid sequences of structurally uncharacterized proteins could then be examined and helical regions predicted.

This approach has been pursued for some time by several research teams, who predicted α-helices, β-pleated sheet strands, and β-bends (Table 2). The purely statistical and readily applicable methods stem from early optimistic days. Meanwhile they have been overtaken by more elaborate systems. Furthermore, attempts have been made to improve the correlation by including other physical data. On the whole, readily applicable methods are far more popular than those which in effect can be used only by the authors themselves. However, their information content suffers as a result of their simplifying formulation.

Table 2. Classification of prediction methods for secondary structures.

	Purely statistical evaluation of structural data	Incorporation of further data: energy balance, structures of synthetic polymers, steric considerations
Applicable without computer program and data bank	References [44–47]	References [48–50]
Applicable only with computer program and data bank	References [51–54]	References [55]

For a long time predictions attracted little interest because they either determined known secondary structures *a posteriori* or, when dealing with proteins of unknown structure, were rather out on a limb. This situation changed with the test case of adenylate kinase where the object of study was a freshly determined but still generally unknown structure[56,57]. The results depicted in Figure 6 clearly demonstrate the success of an approach based on strict hierarchy (Table 3). However, a second test with T4 phage lysozyme[58] having less pronounced secondary structure revealed only slight correlations (Table 3). This modified the overall impression but did not efface it.

Table 3. Correlation coefficients between predicted and experimentally observed secondary structure [56, 58]. Because of the high helix content (54%) of adenylate kinase a relatively good helix prediction leaves only small regions for other secondary structures. This is one reason for their correlation coefficients being so high.

	α-Helix	β-Pleated sheet	β-Bend
Adenylate kinase	+0.44	+0.51	+0.49
T4 phage lysozyme	+0.28	+0.05	+0.13

In both tests α-helices were found much more exactly than β-pleated sheets and β-bends (Table 3). Since the data bases for all three types of secondary structures are of comparable size, this shows that the assumption of hierarchy (Table 1) is best fulfilled for α-helices. Thus, helix formation is least influenced by distant parts of the chain. Therefore helices are most likely to fold on themselves; they are candidates for nucleation sites, *i.e.* regions of initial chain folding. The better they can be predicted, the more likely candidates they are.

Conspicuously, in both tests the α-helices were detected better in the N-terminal than in the C-terminal region of

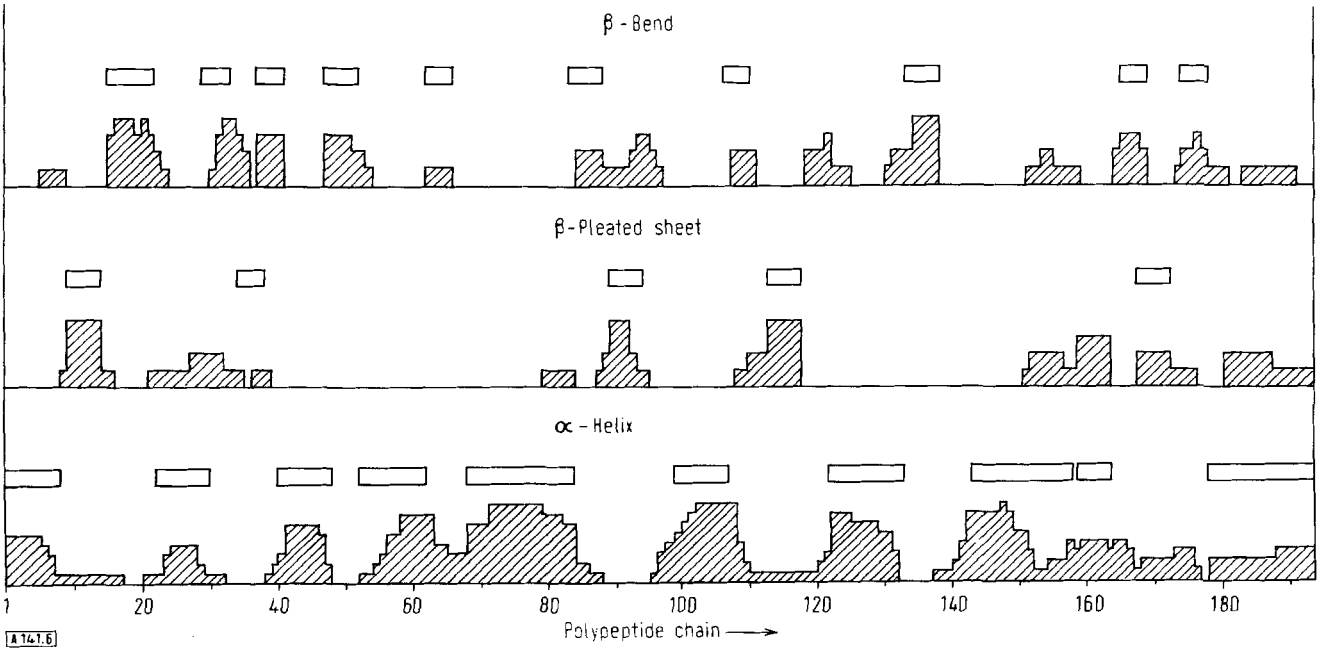


Fig. 6. Additive summary of all secondary structure predictions (hatched) for adenylate kinase [56]. Each method was given the same weight. The experimentally observed secondary structure (boxes) is included for comparison.

the chain, indicating that folding begins in the N-terminal region. Since on ribosomes the chain is synthesized from the N- to the C-terminal end folding may already start during chain production. Therefore, renaturation experiments using complete polypeptide chains may not simulate conditions *in vivo* and it is hardly surprising that some do not renature under these circumstances. In adenylate kinase three helices (residues 41—84) in the N-terminal half of the chain forming a small domain were fairly accurately recognized (Fig. 6). This indicates that folding may start by forming this domain.

The strands of β-pleated sheets may be widely separated along the polypeptide chain. They come together only when the connecting chain segment assumes particular conformations. With such a dependence upon other parts of the chain strict hierarchy cannot be expected. Accordingly, the accuracy of corresponding predictions is low (Table 3).

β-Bends are usually located on protein surfaces[59]. Energetically they are not much favored for they contain just a single hydrogen bond, which in many cases has to compete with the surrounding water; therefore they are best regarded as passive kink sites. Probably the kink position is defined not only by the local amino acid sequence but also by the folding of adjacent chain regions, giving rise to a rather ill-defined hierarchic order. β-Bends were predicted with considerable accuracy in adenylate kinase (Fig. 6) but with poor accuracy in T4 phage lysozyme (Table 3).

The varying success with these two proteins reflects the differences between their structures. While adenylate kinase contains a central pleated sheet surrounded by helices, and is therefore highly ordered, T4 phage lysozyme has less and hardly ordered secondary structure. Moreover, one has to expect that the folding mechanics differ greatly. Therefore it seems reasonable to classify proteins according to their secondary structure (Table 4), because the folding problem will probably have to be tackled differently in the individual classes.

Table 4. Structural classes of globular proteins.

Structural class	Examples
Proteins with few and hardly ordered secondary structures	Ribonuclease [60], lysozyme [61], ferredoxin [62]
Proteins with predominantly antiparallel pleated sheet	Immunoglobulins [63—66], superoxide dismutase [67], concanavalin A [68], prealbumin [69], chymotrypsin [70], bacteriochlorophyll protein [71]
Proteins with a central, generally parallel pleated sheet and surrounding helices	Malate dehydrogenase [28], lactate dehydrogenase [39], adenylate kinase [31], phosphoglycerate kinase [35], triose phosphate isomerase [72], carboxypeptidase [74], several glycolytic enzymes [73]
Proteins with predominant α-helix	Myoglobin [1], hemoglobin [75], hemerythrin [25], bacteriorhodopsin [26]

6. Structural Preferences

Secondary structures are very common in globular proteins. Among the helices, the α-helix having straight hydrogen bonds between the nth and $n+4$th residues predominates. To a slight extent one observes 3_{10}-helices with n and $n+3$, but never π-helices with n and $n+5$. The scarcity of the 3_{10}-helix can be explained by the energetic disadvantage of the bend in its hydrogen bonds. The π-helix does not exploit all the possible van der Waals contacts because it forms a large cavity around its axis. Therefore it is energetically disfavored in spite of its straight hydrogen bonds.

Among pleated sheets no preference for the parallel, antiparallel, or mixed type can yet be discerned (Fig. 3). It is, however, striking that no pleated sheet is flat; they all have a right-handed twist (Fig. 3). This is plausible because sheet twisting compensates for a twist of the individual chains around their axis (about 20° per residue) along a distance of about five residues; and the chain twist itself corresponds to an energetically favorable chain conformation, *i.e.* particularly low steric hindrance at the C_α atoms (Fig. 1). Energetically, the twisted sheet is about 0.5 kcal/mol per residue more favorable than the flat sheet[76]. This demonstrates again how important small energy contributions are in protein folding.

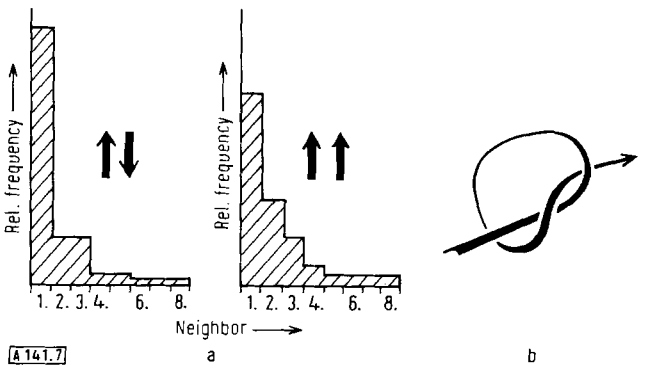

Fig. 7. Structural preferences in globular proteins. a) Observed neighborhood correlation in antiparallel and parallel β-pleated sheets, *i.e.* relative probability of a given strand of a pleated sheet to be connected in the chain direction to the 1st, 2nd, ... neighboring strand. b) Knots in a polypeptide chain; not yet observed.

The only undisputed secondary structure aggregate (Table 1) is the double α-helix. In addition, there are several less well-defined folding preferences of the chain. The individual strands in β-pleated sheets for instance display a very clear neighborhood correlation[67] which is even more pronounced for the antiparallel strands than for the parallel ones (Fig. 7). Regions occur close together in the three-dimensional structure which are not very distant from each other along the

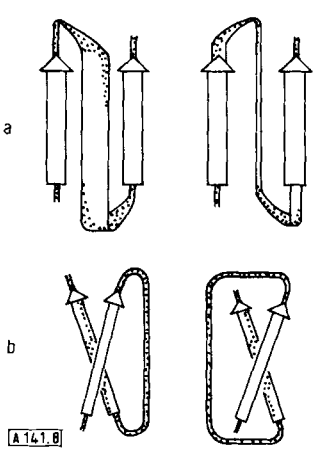

Fig. 8. Chirality of the β-strand-α-helix-β-strand group in parallel pleated sheets. The α-helix is shown as a smooth ribbon. The pleated sheet strands are not necessarily adjacent. The right-handed group has a much better neighborhood correlation than the left-handed one. a) frontal view, b) side view.

chain. In a crude approximation, the polypeptide chain behaves like a piece of string held vertically and allowed to fall onto a flat surface. The resulting coil is not random, it shows neighborhood correlation, it does not entangle, and it can easily be lifted up again. This picture is confirmed by the absence of "knots" in all the structures elucidated so far, the term knot not being used in a mathematical sense (mathematical knots exist only in closed threads), but in the everyday sense (Fig. 7).

Between strands of parallel pleated sheets the chain must go from the upper to the lower end of the sheet (Fig. 8). It thereby passes either over the front or over the back side of the sheet, forming a right- or a left-handed screw with the two pleated sheet strands (Fig. 8). In the known structures the right-handed screw predominates in a ratio of about 50:1[77]. Owing to the right-handed twist of pleated sheets, the right-hand screw permits a better neighborhood correlation than the left-handed screw (Fig. 8). Conversely, the observed predominance shows how important the neighborhood correlation is.

Other structural preferences are seen in the formation of domains, typical examples being immunoglobulin molecules (Fig. 5). Domains are usually joined together by a single strand of the peptide chain, and are therefore separated not only spatially but also along the chain[37]. This single chain linkage ensures a better neighborhood correlation within each domain than multiple chain linkages (Fig. 5). Since the neighborhood correlation within the domains is much greater than between domains, the domains are expected to fold separately. This is supported by the structure of chymotrypsin[70]. In the interior of the protein there are 13 water molecules between the two pleated sheet barrels, which can be regarded as domains (Fig. 9). The barrels are presumed to fold separately and capture the water molecules on association. The active center of chymotrypsin is located between the two domains. A similar location of the active center is observed in many other enzymes.

The limiting size of a domain is about 150 amino acid residues. As derived from the energy balance [eq. (1)] the formation of larger domains should be favored because in larger globules the surface/volume ratio is smaller, and the energy of the hydrophobic bonds (ΔS_{water}) and that of the internal hydrogen bonds can be increased. In spite of this fact long chains always fold to several smaller domains with high neighborhood correlation. Therefore, folding of several smaller domains seems to be much easier than folding of a single large and thus more complex domain.

As in the case of adenylate kinase there are often two linkages between smaller domains. With two linkages one domain has a higher neighborhood correlation than the other (Fig. 5). One has to expect that the domain with the higher correlation folds first and then serves as a support for construction of the remaining molecule. For adenylate kinase this assumption is corroborated by the great accuracy of secondary structure predictions in the domain with the higher neighborhood correlation (Fig. 6).

As described above, symmetric structures arise on aggregation of monomeric proteins when only few kinds of building units are utilized. This symmetry is also apparent in the aggregation of domains, particularly if they are structurally similar like those of the light and heavy chains of immunoglobulins[63-66], the domains of rhodanese[78], ferredoxin[62], dehydrogenases[79], and triose 3-phosphate isomerase[72] (Fig. 9). Not only domains, but also secondary structures appear

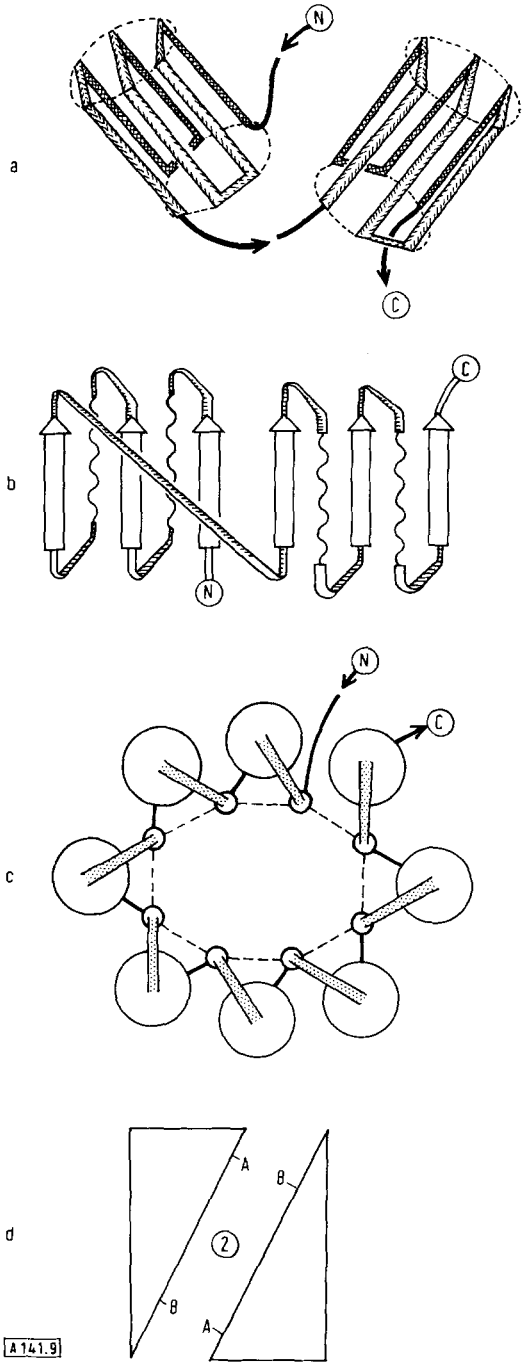

Fig. 9. Symmetry in chain folds (schematic representation). a) Chymotrypsin [70]. The pleated-sheet barrels correspond to one domain each; they are antiparallel and possess twofold internal symmetry. b) The double nucleotide-binding domain of lactate dehydrogenase and other proteins [39, 79, 93]. It contains a vertical twofold axis. c) The extremely symmetrical structure of triose phosphate isomerase [72], consisting of a parallel pleated-sheet barrel and eight surrounding α-helices. d) Optimization of contacts and symmetry: when the A-B contact is particularly favorable it is repeated, giving rise to twofold symmetry. In monomers, only twofold symmetry axes have so far been observed while the point groups 2, 3, 17 (protein of tobacco mosaic virus), 222, 32, 432 (apoferritin), 532 (spherical viruses) are found in aggregates.

to aggregate symmetrically, *e.g.* in parvalbumin[80, 81] and within the pleated sheet barrels of chymotrypsin (Fig. 9). The reason for symmetry lies in the optimization of contacts (Fig. 9). Obviously, this optimization is also important in very early stages of chain folding.

7. Structural Rules from Phylogenesis

The historical background of proteins is a great help in understanding their structures. In the course of biological evolution all these structures have continuously evolved either in parallel or by diverging from each other. Thus, nature has provided us with a wealth of completed experiments. We only need to interpret the results, *i.e.* extract information of general validity from common structural features.

The basic step in the evolution of proteins is the modification of a side chain. Others are insertions and deletions of amino acid residues which affect also the main chain and which can extend over long chain segments. Usually exchanges in the interior of proteins are conservative (apolar for apolar side chains, *etc.*), and the energy balance is hardly perturbed. Furthermore, any gaps that may arise (*e.g.* by omission of a methyl group on isoleucine→valine) are compensated by another exchange, *i.e.* the high packing density is retained. Apparently the packing density is of great importance for the energy balance.

The influence of amino acid exchanges on the folding process has been studied for the globin family[82]. It was found that all α-helices carry at their N-terminal end either a proline or a short polar side chain which can hydrogen-bond to the main chain (Asn, Asp, His, Ser, Thr). These hydrogen bonds and/or the proline, which fixes the dihedral angle ϕ (Fig. 1) to the α-helix value, are probably required for helix initiation because they limit the number of conformations at this site at an early stage of folding, *i.e.* form a miniature folding nucleus.

In the course of time the modifications accumulate; and when about 80% of the amino acids have been exchanged common features can be recognized only in special cases from the sequence. However, it was found, first on comparison of myoglobin[11] with hemoglobin chains[83] and later in cytochrome c[84] and the serine proteases[85] that the amino acids vary much faster than the chain fold. The course of the chain and the sites of prosthetic groups (*e.g.* hemes) are exceptionally well conserved. The observed chain fold conservation cannot be a consequence of keeping the delicate energy balance [eq. (1)] intact; because in meeting the energy requirements the amino acids utilized appear to be much more important than the chain fold. Therefore, chain fold conservation indicates that the folding mechanics and with it the folding pathway, impose stringent conditions on the protein.

Apart from continuous small evolutionary changes there are drastic discontinuous ones caused by gene fusion and gene duplication. A recent example of fusion is observed in the immunoglobulins where the genes of the variable chain regions are probably linked with those of the constant regions[86]. Gene separation and fusion must also have occurred in dehydrogenases because lactate dehydrogenase has the NAD-binding domain as N-terminal half, whereas an extremely similar domain is utilized in the C-terminal half of alcohol dehydrogenase[29]. Most gene duplications lead to separate chains and thus to proteins which develop separately[87]: globins, serine proteases, midbrain hormones, lysozyme, and α-lactalbumin, *etc.* However, some duplications double the chain length, *e.g.* in ferredoxin[62], rhodanese[78], chymotrypsin[88], parvalbumin[80, 81], troponin C[89], within the NAD-binding domains of dehydrogenases[79], in tropomyosin[90], *etc.* As described above, most such chains display internal symmetry. The folding mechanism is probably modified only insofar as now two nuclei fold similarly but separately and subsequently aggregate. The wealth of examples discovered show[87] these discontinuous modifications to play a considerable role in the production of new protein structures.

8. Phylogenesis on the Basis of Structures

The previous section demonstrated that the historical development of proteins permits deduction of structural rules. Conversely, structural analysis provides information about phylogenetic relationships. It becomes particularly important when proteins have diverged so much that there are no longer similarities between the amino acid sequences, but only between chain folds. Since chain folds are particularly well conserved, such resemblances indicate interrelationships in very early stages of evolution. Of special interest in this context is the evolution of metabolic pathways which are otherwise hardly accessible to study.

Structural similarity is not necessarily of phylogenetic origin, but may be an expression of a structural rule. For instance, nobody would think that α-keratin[23] is related to tropomyosin[24] merely because they both form a double α-helix structure (Fig. 4). This structural aggregate just happens to be energetically favored; therefore it is adopted independently by several proteins and the structural coincidence is not significant. A different situation is encountered in T4 phage lysozyme[91], hen egg white lysozyme[61], and α-lactalbumin[92], whose structures are complicated but nevertheless similar. Their chain folds are not unique in any particular way; for there are many other kinds of complicated protein structures. Consequently, the structural coincidence of these proteins is a significant event which can only be explained by assuming a phylogenetic relation. These examples show that the degree of significance is of decisive importance in structural resemblance and that this significance can only be established with a knowledge of structural rules.

This significance becomes extremely high when the amino acid sequences display common features. For example, 45 amino acids are common to hen egg white lysozyme and α-lactalbumin[92]. The probability of a random coincidence is $1:20^{45}$, giving rise to a significance of $20^{45}:1$. Admittedly, this value has to be reduced because 84 other amino acids are different, the sequences have been shifted relative to each other to achieve optimal fit, and the amino acids are not distributed randomly. Nevertheless the significance still remains so high that a phylogenetic relationship can be unequivocally concluded.

Significances based solely on three-dimensional structural features have been calculated for a group of proteins having central pleated sheets[93] which no longer display any similarity in the amino acid sequences (Fig. 9). The pleated sheet was defined as reference structure and the chain fold referred thereto. Viewed in such a way, an n-stranded pleated sheet can assume $M = 2^{n-2} \cdot n!$ different chain topologies. If two proteins have identical topologies the significance of this coincidence[93] is $M:1$ (Table 5). These values are reduced, however, by the observed predominance of the right-handed screw in connections between pleated sheet strands (Figs. 8 and 9)[77]. A further reduction arises from the neighborhood correlation in pleated sheets (Fig. 7) because in the case considered most of the

strands are proximate. If the symmetry in the pleated sheet is caused by gene duplication another reduction is necessary. On the other hand the significance is raised if not only the chain topology but also the location of active center and substrates is taken into account (Table 5). Moreover, it should be remembered that this comparison is restricted to a single structural class (Table 4). Extension of the comparison to all proteins enhances the significance. Some of these contributions are difficult to estimate. In conclusion, only within the dehydrogenases are the resulting significances large enough to indicate a phylogenetic relationship (Table 5); the other structural similarities can be of purely physical origin. In a similar way the β-pleated sheets of superoxide dismutase and immunoglobulin domains were subjected to a topological comparison[67]. Including neighborhood correlations a significance of about 3000:1 was found, which clearly indicates a phylogenetic relationship.

The calculations given above require the definition of a chain topology which is only possible if the chain fold is referred to a rigid substructure such as a pleated sheet. Comparisons are then restricted to the protein class containing this substructure (Table 4). In contrast, direct geometrical comparison of chain folds is a much more general approach. In this case, similarity is expressed in terms of the average distance of corresponding C_α atoms $\langle \Delta C_\alpha \rangle$, or by closely related indices. However, this comparison has the drawback that structure rules can be considered only with difficulty and no value can be derived for the significance, which eventually decides whether or not a resemblance is of phylogenetic origin.

In principle, a relationship between $\langle \Delta C_\alpha \rangle$ value, structure rules, and significance can be established by simulating chain folds with the aid of a random number generator on a computer and comparing them with one another[99]. In this procedure all known structural rules, such as neighborhood correlations, *etc.*, should be considered. The chain length should correspond approximately to that of a domain (Fig. 5). The initial task in the comparison is to find the relative orientation which corresponds to the minimal $\langle \Delta C_\alpha \rangle$ value. This would lead to a frequency distribution of minimal $\langle \Delta C_\alpha \rangle$ values resembling that sketched out in Figure 10. If we want to derive the significance of the similarity of two protein structures having, for example, $\langle \Delta C_\alpha \rangle = 3$ Å, then we are actually enquiring as to how many structures N there are with $\langle \Delta C_\alpha \rangle$ exceeding 3 Å, because this quantity N corresponds to the significance. To determine N it is by no means necessary to simulate all possible structures. One only has to randomly generate G structures and compare them with each other. This yields Z coincidences with $\langle \Delta C_\alpha \rangle \leq 3$ Å (Fig. 10). As in the counting

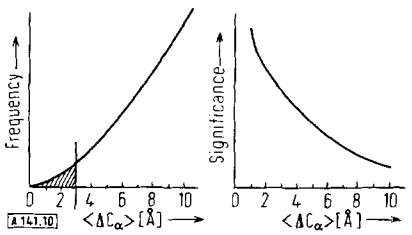

Fig. 10. Schematic frequency distribution of average C_α distances $\langle \Delta C_\alpha \rangle$ between all pairs taken from a set of G simulated chain folds. The significance N of a structural similarity between any two proteins having a given $\langle \Delta C_\alpha \rangle$ is derived from $N = G^2/Z$, where Z is the integral of the frequency distribution taken from zero to the $\langle \Delta C_\alpha \rangle$ value considered.

of radiation quanta[94] the simulated structures obey Poisson statistics, *i.e.* the coincidence ratio Z/G equals the average population G/N. Thus the total number N of different structures with $\langle \Delta C_\alpha \rangle \geq 3$ Å, *i.e.* the desired significance, can be determined from $N = G^2/Z$. Using the frequency distribution of $\langle \Delta C_\alpha \rangle$, the significance of a structural similarity between two proteins can be deduced for any mean C_α distance $\langle \Delta C_\alpha \rangle$, because the number of coincidences Z is known for any $\langle \Delta C_\alpha \rangle$ (Fig. 10).

9. Outlook: Determination of Protein Structures without Crystals

Usually, protein structures can only be solved if the proteins have been crystallized and subsequently analyzed by X-ray diffraction. However, one of the ultimate goals, determination of a three-dimensional structure from the amino acid sequence alone, has already been reached in a number of special cases. For example, the known three-dimensional structure of a given protein can be used in determining the structure of all its phylogenetic relatives once their sequences are known. For that purpose the sequence is fitted into the known chain fold. Remaining discrepancies are ameliorated by subsequent energy minimization[95]. Since the chain fold is extremely well conserved during evolution the method can be applied even to such distant relatives as thrombin and trypsin[88]. In the case of the muscle proteins parvalbumin and troponin C, not only the same chain fold but also internal molecular symmetry are postulated. Similarities between the sequences indicate that troponin C contains four of the substructures found in parvalbumin (one Ca^{2+} binding site and two neighboring α-helices)[89]. In parvalbumin, these substructures have aggregated symmetrically, forming a twofold axis. It therefore appears reasonable to assume that in troponin C the two other substructures are added with twofold symmetry, leading

Table 5. Significance of structural similarities on topological comparison of proteins with parallel pleated sheets.

	Significance including the location of the active center [93]	Significance after accounting for the preferred chirality of the β-α-β groups [77]
Adenylate kinase/subtilisin	2400:1	340:1
Adenylate kinase/flavodoxin	240:1	30:1
Adenylate kinase/any dehydrogenase	160:1	20:1
Subtilisin/flavodoxin	4800:1	350:1
Subtilisin/any dehydrogenase	2400:1	180:1
Flavodoxin/any dehydrogenase	4800:1	350:1
Any dehydrogenase/other dehydrogenase	115200:1	4420:1

to overall 222 (D_2) symmetry. Hence a structural model of troponin C can be built on the basis of the sequence[96]. Once again these examples demonstrate the utility of the phylogenetic relationships for solving protein structures.

Although the direct determination of a three-dimensional structure from an amino acid sequence is still a distant aim, the first steps in this direction have already been taken: an attempt was made to derive the known three-dimensional structures of myoglobin and pancreatic trypsin inhibitor *a posteriori* with the aid of simple rules. Strict hierarchy was assumed for the α-helices in both cases. In other words, it was assumed that they can be determined by secondary structure prediction methods and that they do fold first. The folding simulation then assumes ready-made α-helices. Since myoglobin contains practically only helices, in this case folding is merely helix association; the accessible conformational space is appreciably reduced. A simple scheme was postulated for calculating the packing energy of helices; and the folding pathway was determined as the direct route to the energy minimum[97]. At this minimum the native structure was obtained, confirming the validity of the method. However, this method is limited to purely helical proteins. Pancreatic trypsin inhibitor, on the other hand, contains only one short α-helix. In this case, the geometry of peptide bonds and side chains as well as the determination of the bond energies were simplified. Folding to reach the energy minimum was then simulated by an iterative energy minimization procedure. The most favorable simulation run yielded a structure with an average C_γ distance to the native structure of 6.3 Å[98].

These simulations and all the structural analyses of proteins described above nurture our hope that in the distant future three-dimensional structures can be derived merely from the amino acid sequence. In any case, they show how well the initial shock caused by the complexity of protein structures has been overcome. Moreover, some degree of order has already been established in the wealth of existing data. It may be expected that this order will become all the greater the more data become available, *i.e.* the more X-ray structure analyses succeed.

Experimental Electron Densities and Chemical Bonding

By Philip Coppens[*]

Some recent results of charge density analysis by X-ray and neutron diffraction are discussed. Problems that have been studied in a number of laboratories include the nature of single, double, and triple bonds, lone-pair hybridization, bonding in some metals, alloys, and organometallic compounds, and the derivation of physical properties from X-ray diffraction densities. At the present stage of development of methods studies of series of related compounds are feasible and expected to find widespread application.

Clearly a molecule is much more complicated than an atom. So the question arises: what happens to an atom when it becomes part of a molecule? [*C. A. Coulson,* Mem. Soc. R. Sci. Liege Collect 8° *6* (2), 143 (1971)].

1. Introduction

Part of the answer to this deceptively simple question can be provided by X-ray and neutron crystallography. Since X-ray scattering is primarily a result of the interaction between X-rays and electrons, it contains information on the electron distribution in the scattering material. As early as 1918, *Debye* and *Scherrer* discussed the determination of electron orbits[1], but for reasons more easily understood now their determination proved to be an elusive goal. Much pioneering work in the fifties and early sixties[2] was necessary before technical breakthroughs such as automatic diffractometry and high speed computing led to improvements in accuracy which made details of the electron distribution accessible to the experimentalist.

One of the problems to be faced has been that both the electron distribution and the positions and thermal vibrations of the atoms had to be deduced from the measurements. A significant step forward was therefore made possible with the advent of high-flux neutron beams at nuclear reactors which allowed an independent determination of the atomic parameters because neutrons interact with atomic nuclei (through nuclear forces) rather than with electrons. More recent developments in methodology described below have also been centered on obtaining the combined information from accurate low-temperature X-ray measurements alone so that the double effort and expense of measuring both X-ray and neutron data sets is not always necessary.

Today, charge density analysis with accurate diffraction methods is becoming increasingly sophisticated and applicable to crystals of sufficient complexity to be of chemical interest. Here, we will outline some typical chemical and physical information that can be obtained at the present stage of development, rather than attempt to describe all recent work in the field. A more comprehensive review (up to early 1974) and a comparison of experimental and theoretical results have been published elsewhere[3, 4].

1.1. Difference Densities and Experimental Considerations

The effect of bonding on the electron density is of a rather small magnitude when compared with the total number of electrons in a solid. This means that to a fairly good approximation the electron density ρ is equal to the sum of the densities the constituent atoms would have if all interactions with their neighbors were neglected. Since we are interested precisely in the small bonding effects it is most opportune to calculate the difference between the observed density and the density of the free atoms in their electronic ground state centered at the atomic positions in the crystal. This function may be called the deformation density $\rho_{\text{deformation}}$ because it represents the deformation that occurs when the atoms interact to form chemical bonds. Thus:

[*] Prof. Dr. P. Coppens
Chemistry Department
State University of New York at Buffalo
Buffalo, New York 14214 (USA)

$$\rho_{\text{deformation}} = \rho_{\text{observed}} - \sum_{\text{all atoms}} \rho_{\text{free atom}} \quad (1)$$

In other cases we may want to study the distribution of all the valence electrons involved in chemical bonding, in which case the inner shells (cores) of all atoms are to be subtracted to give the valence distribution ρ_{valence}:

$$\rho_{\text{valence}} = \rho_{\text{observed}} - \sum_{\text{all atoms}} \rho_{\text{inner shells}} \quad (2)$$

This second function will show bonding less clearly because it represents many more electrons, but is sometimes useful for comparison with theoretical results which are not always cast in the form of expression (1).

For both expressions (1) and (2) the observed density is evaluated by a Fourier summation of the observed X-ray amplitudes, while the calculated atomic part is obtained in a similar way from X-ray amplitudes *calculated* for the free atom functions. This latter calculation requires, of course, a knowledge of where the atoms are and how much their density is smoothed by thermal vibrations in the crystal. It is at this point that the neutron diffraction information becomes important.

It is common crystallographic practice to obtain the parameters describing the atoms by varying these parameters to obtain the least-squares fit between the calculated and the observed structure factors. But in the calculation of the structure factors the not entirely justified assumption is routinely made that the atoms have a spherical distribution as if they were not bonded. This corresponds to $\rho_{\text{deformation}}$ in expression (1) being zero everywhere! So when the least squares refinement is performed the incorrect assumption of spherical atoms will shift the atoms somewhat to make $\rho_{\text{deformation}}$ as close to zero as possible. In other words, X-ray diffraction bond lengths (and vibrational parameters) will be biased when atoms are in an asymmetric chemical environment, like terminal oxygen and nitrogen and especially hydrogen atoms. No such bias exists when the information is obtained with neutrons, which are scattered by the atomic nuclei rather than by the electrons in the crystal. As a result CH, NH, and OH bond lengths from X-ray analyses are typically less by 0.1—0.2 Å than spectroscopic or neutron diffraction values, while non-hydrogen atom shifts of up to 0.01 Å are not uncommon[5].

Because the neutron diffraction parameters are used in the calculated part that is subtracted out from the density observed with X-rays the label "X − N" (X minus N) is frequently used.

It is of great practical interest that good approximations to X − N densities can often be obtained when very many X-ray intensities have been collected. For this it is generally necessary to cool the specimen crystal which reduces the thermal vibrations of the atoms. This reduction may be considered as giving a higher degree of order in the crystal because the atoms are, on the average, closer to their equilibrium positions. The extra ordering especially increases the intensity of the X-ray reflection at high Bragg angles (see Fig. 1a) which are often too weak to be measured at room temperature. According to the theory of X-ray scattering the intensity of these high-angle reflections is almost exclusively determined by the distribution of the inner electron shells of the atoms and relatively unaffected by the valence density, which is the subject of chemical interest (Fig. 1b).

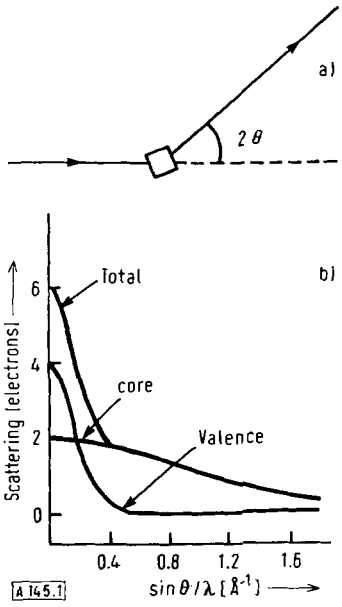

Fig. 1. a) Definition of the Bragg angle θ as half the angle between the incident and diffracted beams. b) Dependence of the scattering of the atomic core and valence shell of an isolated carbon atom on $\sin\theta/\lambda$. λ is the wavelength of the radiation used. The unit on the ordinate corresponds to the scattering of a classical point electron. In the direction of the incident beam (where $\theta = 0$) the scattering reaches the value for the total number of electrons.

This physical fact suggests a second way of separating the bonding effects on the valence density from the determination of atomic parameters by obtaining the latter from a least squares refinement of the high-angle data and the deformation density from a Fourier summation of the low-angle reflection. Electron densities obtained in this way will be referred to here as X − X densities because both the observed and the calculated densities in expressions (1) and (2) are now based on the X-ray data. Such X − X densities reproduce X − N results quite closely in bonds between non-hydrogen atoms, but are much less reliable in the vicinity of H atoms, which scatter little in the high angle region and can therefore not be well determined in a high-order refinement.

Some typical deformation densities are shown in Figures 2—8. Before discussing the chemical implication of these maps it is worthwhile to consider the magnitude of the experimental error in the density. As expressed by (1) and (2), the deformation and valence densities are both differences between an observed density and a calculated distribution. If the standard deviations in these are respectively $\sigma(\rho_{\text{obs}})$ and $\sigma(\rho_{\text{calc}})$ we get

$$\sigma^2(\rho_{\text{deformation}}) = \sigma^2(\rho_{\text{obs}}) + \sigma^2(\rho_{\text{calc}}) \quad (3)$$

with a similar expression for ρ_{valence}. It has been shown that the error function $\sigma(\rho_{\text{deformation}})$ in (3) is fairly constant in the crystallographic unit cell *except* near crystallographic symmetry elements and in the vicinity (< 0.3 Å) of the atomic nuclei[6]. The errors in the latter region are especially pronounced and prevent conclusions about the density near the atoms. They arise essentially because the deformation density here is the difference between two relatively large densities. On the other hand, the bond and lone-pair regions are relatively reliable with standard deviations of 0.05—0.07 e Å^{-3} or better reached in several accurate studies. As bond and lone pair peak heights are typically 0.3—0.7 e Å^{-3} the signal to noise ratio in the experimental maps is significant.

2. Density Maps

We shall proceed by describing a number of representative studies in which chemical information is derived from experimental charge densities.

2.1. The Electron Distribution in the Chemical Bond

A covalent chemical bond may be considered as resulting from the pairing of electrons of opposite spin, whose orbitals overlap in the bonding region. Theory indicates that the electron pairing leads to extra density in the bond compared to the density corresponding to the superposition of spherical atoms. This means that density should appear in the bonds in the deformation maps, a prediction which is readily confirmed on examination of the experimental results. For example, in CC, CN, and CO bonds peaks are found which typically have a height of 0.3 to 0.6 e Å^{-3}. There are also clear differences between single, triple, and double bonds which are most apparent when sections through the bond midpoints perpendicular to the bond axes are calculated. In these sections single and triple bonds appear as round, cylindrically symmetric density peaks, but double bonds are elongated in the direction of the p_π orbital axis[7,8], again as predicted by theory. The elongation of the double bond peaks is well demonstrated in the cumulene skeleton of tetraphenylbutatriene, where adjacent multiple bonds are mutually perpendicular, corresponding to a predominance of, respectively, p_x and p_y atomic orbitals in the π MOs of adjacent bonds (Fig. 2)[9].

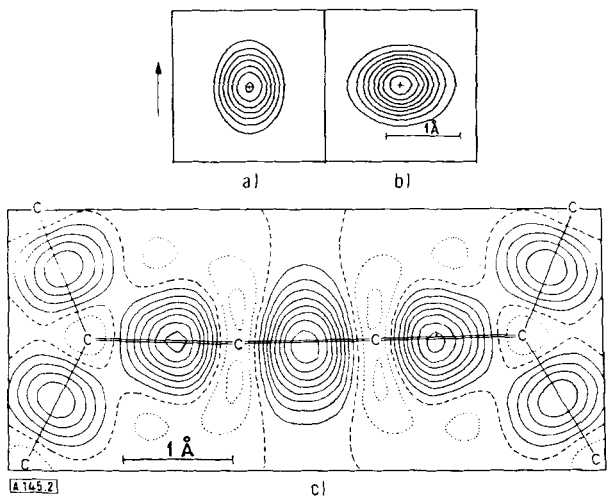

Fig. 2. Deformation density of tetraphenylbutatriene. Sections perpendicular to the outer (a) and inner (b) bonds of the butatriene chain through their midpoints. The arrow is perpendicular to the butatriene plane. c) Deformation density in the butatriene plane. Contours at 0.10 e Å^{-3}. Irregularities have been eliminated by fitting of smooth functions to the experimental data. From *Berkovitch-Yellin, Leiserowitz,* and *Nader* [9].

Unusual features occur in the maps of strained three-membered ring systems such as cyclopropane, ethyleneimine, and ethylene oxide[10], where the deformation density peaks are not exactly on the lines connecting the atoms, but located somewhat outside the nuclear triangles (Fig. 3). This observation provides experimental confirmation that the bonds in these small rings are bent. Such bending results from the geometrical constraint imposed by the three-membered ring: the 60° angle in the ring cannot be reproduced exactly by the atomic orbitals of the electron forming the bond, which are therefore pointing not exactly at the adjacent atoms. Such bonds are somewhat weaker than ordinary "straight" bonds and explain the strain energy which reduces the stability of small ring compounds.

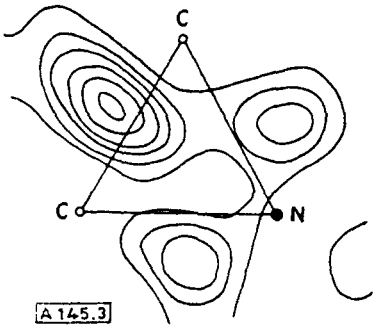

Fig. 3. Deformation density in the plane of the three-membered ring of 2,3:5,6-bisepimino-*p*-benzoquinone at 143 K. Contours at 0.05 e Å^{-3}. Negative contours omitted. Open circles represent carbon atoms. From *Ito* and *Sakurai* [10b].

In all the bonds discussed here, which are between first-row atoms, the deformation density peaks at or near the bond midpoint. But other density maps containing S—S and Ni—Ni bonds indicate that for heavier atoms changes nearer to the nucleus often dominate the deformation density, so that the peak may no longer be located at the midpoint of the bond.

2.2. Hybridization of Lone Pair Electrons

The concept of hybridization has been tremendously successful in explaining trends in molecular properties like bond strengths and distances, bond angles, force constants, and NMR coupling constants. More recently, atomic hybridization has also been related to the results of SCF molecular orbital theory through the use of truncated or localized molecular orbitals[11]. The measurement of the electron density provides a unique opportunity for directly obtaining information on atomic hybridization.

The wave function for the lone pair orbital may be written as a linear combination of 2s and 2p atomic orbitals $\phi(2s)$ and $\phi(2p)$:

$$\psi(\text{lone pair}) = a\phi(2s) + b\phi(2p) \qquad (4)$$

where a and b are constants, often referred to as the mixing coefficients. The corresponding electron density distribution is proportional to ψ^2 and therefore contains a cross-term equal to $2ab\phi(2s)\phi(2p)$ in addition to the terms depending on $\phi^2(2s)$ and $\phi^2(2p)$. As the function $\phi(2s)$ is positive in all directions from the nucleus the product $\phi(2s)\phi(2p)$ will be positive where $\phi(2p)$ is positive. Thus, the location of a lone pair peak near an atom gives evidence on the nature of the 2p orbital involved. For example, a lone pair peak is observed at the "back" of the nitrogen atom in the C≡N groups in tetracyanoethylene[8] (Fig. 4) and NaC≡N·2H$_2$O (Fig. 5)[12] and at the back of the oxygen atoms in benzene tricarbonylchromium[13] and hexacarbonylchromium[14] (Fig. 6). This indicates that the p orbital in (5) has its positive lobe in a direction opposite to the N—C (and O—C) vectors, while the fact that only one lone pair peak is observed leads, according to the arguments of valence bond theory, to the conclusion that an sp hybrid is involved in the bonding [*i.e.* $a=1$ and $b=1$ in expression (5)].

In these examples the lone pair belongs to an atom which participates in a triple bond. But when the terminal atom is doubly bonded such as the oxygen atom in the C=O group there are two lone pairs as found in a number of

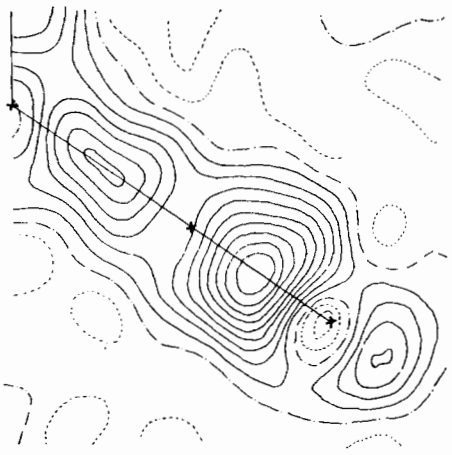

Fig. 4. X – N density in the molecular plane of tetracyanoethylene. Contours at 0.10 e Å^{-3}; negative contours (– – –); zero contour (–·–·–). Only one quarter of the molecule is shown as the remainder is related by symmetry to the part given. The cross to the right indicates the nitrogen atom, while the carbon atoms are to the left. From *Becker et al.* [8].

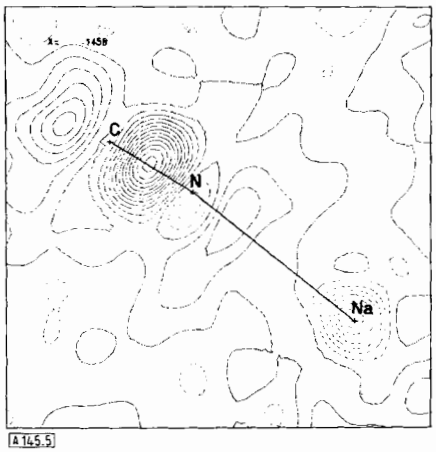

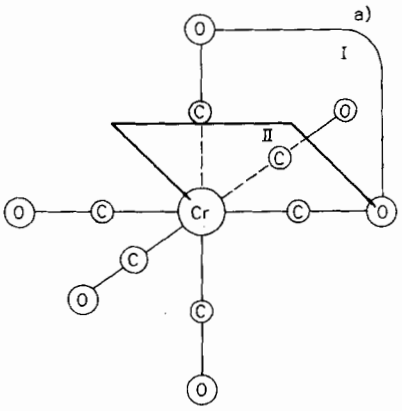

Fig. 5. Deformation density in $NaCN \cdot 2H_2O$ at 150 K. Contours at 0.05 e Å^{-3}. Negative contours broken. Lone pair electron density is especially pronounced at the carbon atom. From *Bats* [12].

compounds, including glycylglycine[15], glycine[16], cyanuric acid[17], and oxalic acid[18] (Fig. 7). All these have conjugated systems of double bonds and the lone pair peaks are found in the plane of the conjugated system at about 120° from the C=O bond axis. This arrangement corresponds to sp^2 hybridized lone pairs in the language of valence bond theory. Yet another type of hybridization is evidenced at the oxygen atom of the nitroxo group in *p*-nitropyridine *N*-oxide[19] (Fig. 8) where the density is again in the molecular plane, but at right angles to the bond axis. The interpretation is that the two oxygen lone pairs are unhybridized and described by s and p atomic orbitals respectively. The lone pair peaks seen in Figure 8 correspond to the latter orbital, because the s electrons have a spherical distribution as in the free atom and will not appear in the deformation density map, which is the difference between the observed and the free atom densities. The difference between the hybridization of

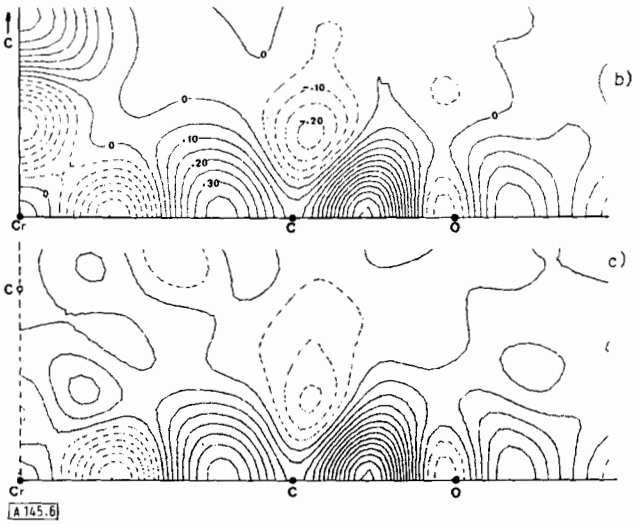

Fig. 6. Deformation density in $Cr(CO)_6$ at 78 K. a) Geometry of the molecule; b) section of plane I; c) section of plane II. Contours as indicated. From *Rees* and *Mitschler* [14].

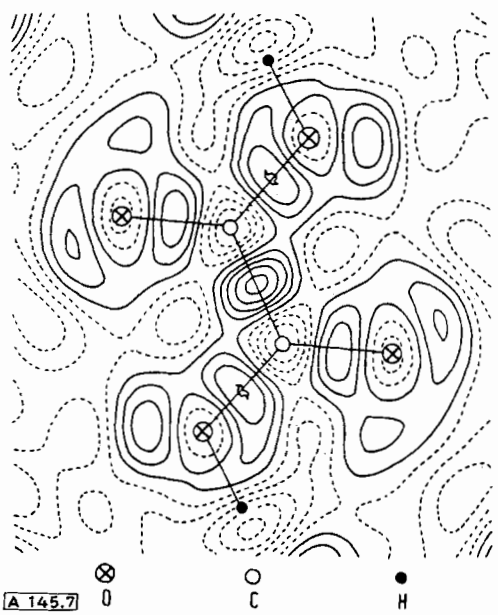

Fig. 7. Deformation density through the molecular plane of the oxalic acid molecule at room temperature. Contours at 0.05 e Å^{-3}. Zero and negative contours dashed. From *Coppens et al.* [18].

the oxygen atom in N—O and C—O may be related, as proposed by *Bent*[20], to the influence of the greater electro-

negativity of the nitrogen atom (compared with the carbon) on the electronic structure of the oxygen atom.

It is interesting to note that the excess density on the nitroxo oxygen in *p*-nitropyridine *N*-oxide is on the side of the bond and not towards the periphery of the molecule, yet a very

Fig. 8. Deformation density in the plane of *p*-nitropyridine *N*-oxide at 30 K. The NO_2 group is at the lower right, the NO part of the molecule at the upper left of the figure. Contours at 0.10 eÅ^{-3}. Negative contours broken. From *Wang et al.* and *Coppens* and *Lehmann* [19].

strong hydrogen bond exists between pyridine *N*-oxide and trichloroacetic acid[21]. The unanswered question arises whether the electron distribution in the nitroxo group in this complex is as observed in *p*-nitropyridine *N*-oxide or perhaps perturbed by the strong hydrogen bonding (O···O = 2.4 Å).

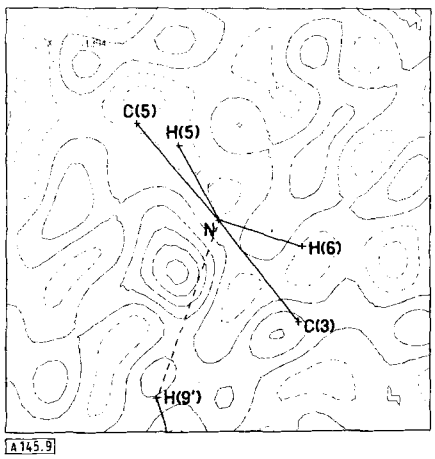

Fig. 9. Deformation density in sodium sulfanilate dihydrate at 78 K. The section shown is through the nitrogen atom of the NH_2 group perpendicular to the C—N bond. The carbon atoms indicate the projection of the benzene ring plane. The dotted line represents a hydrogen bond. Contours as in Fig. 5. From *Bats* [22].

A final example of lone pair density is given in Figure 9. Low temperature X-ray diffraction shows the NH_2 group in sodium sulfanilate dihydrate to be slightly pyramidal[22]. The deviation from planarity is much less than in ammonia, the average angle at the nitrogen being 116°, so one may ask whether the non-planarity sufficiently influences lone pair hybridization to give excess density at the apex of the pyramid only rather than at both sides of the nitrogen atom. The section shown in Figure 9 is through the amine nitrogen atom perpendicular to the exocyclic C—N bond. The orientation of the molecule is indicated by the projection of two ring carbon atoms and two amine hydrogen atoms onto the section of the figure. The lone pair is at only one side of the nitrogen atom. A possible cause for this asymmetry is suggested by the hydrogen bond geometry shown in the figure by the broken line to a hydrogen atom belonging to the water molecule incorporated in the crystal lattice.

2.3. The Nature of the Hydrogen Bond

Theoretical charge density analyses of hydrogen bonded systems have emphasized the difference between the density in the hydrogen bonded dimer and the superposition of isolated molecules.

The comparison between theoretical density maps is hampered by lack of uniformity of the contour intervals in different studies. Often the height of a peak cannot be assessed because of lack of detail in the logarithmic contour scale which is commonly selected by theoreticians. But calculations on the water dimer by *Diercksen*[23] and by *Yamabe* and *Morokuma*[24] on $(HF)_2$ and $H_2O \cdot HF$ by *Kollman* and *Allen*[25], and on the formamide dimer by *Dreyfus* and *Pullman*[26] agree on a depletion of charge on the H-bond hydrogen atom and an increase in the covalent bond to this hydrogen. This change in density upon H-bonding is largest for the strongest hydrogen bonds and exceeds 0.02 ea_0^{-3} (0.14 eÅ^{-3}) in the $HF \cdot H_2O$ complex and the HF dimer. Such a change should be experimentally detectable where non-hydrogen bonded reference systems are available. But reference states like the superposition of spherical atoms must be used in experimental work because the non-hydrogen bonded monomers do generally not exist in the crystalline state. The difference between the two is negligible near the midpoint of the H···X bond, so in this region the effect of hydrogen bonding can be studied experimentally. Studies on glycylglycine[15], 2-amino-5-chloropyridine[27], and on cyanuric acid[17] and glycine[16] do not show any charge accumulation in the H···X hydrogen bond, in agreement with the theoretical work and supporting an electrostatic rather than a covalent interpretation of the XH···X interaction. The study of 2-amino-5-chloropyridine is of especial interest because only one of the two N—H bonds is involved in hydrogen bonding. There is a marked difference between the two N—H lengths which are 1.009(3) Å for the N—H bond participating in H-bonding and 0.980(3) for the second bond. The deformation density shows a much larger peak in the former bond, in agreement with theoretical calculations which predict that a pronounced change on H-bonding is exactly the enhancement of the density in the donor N—H bond[25, 26].

Above all in crystals containing molecules which are very strong acids much shorter hydrogen bonds occur which represent stronger interactions. For very short bonds the hydrogen may be exactly in the middle of the two adjacent atoms, so that the distinction between a hydrogen donor and a hydrogen acceptor group becomes meaningless. This may occur for example, when the O···O distance is less than 2.45 Å. A very early theoretical calculation on the FHF^- ion[28], which is a well known example of a species containing a

very short hydrogen bond, shows a general charge depletion on both sides of the proton suggesting an electrostatic nature of both H···F bonds. But recent experimental studies on 2,3-pyridinedicarboxylic acid (at room temperature) in which the two carboxylate groups are bridged by a strong hydrogen bond (with O···O = 2.398 Å)[27], and on sodium bisacetate (at 80 K)[29], in which two acetate ions are similarly linked, are more indicative of two at least partially covalent OH bonds (schematically represented by O—H—O) because density peaks are found in both O—H regions. A low temperature study of 2,3-pyridinedicarboxylic acid, as well as theoretical and experimental studies on other strong hydrogen bonded systems, are presently being undertaken[30, 31].

2.4. Compounds Containing 3d Transition Metals

Organometallic compounds are of great chemical interest from both fundamental and practical points of view. Much of what we know about the bonding in these compounds is based on the analysis of their varied geometry or deduced from spectroscopic measurements. Direct determination of the charge density distribution adds a completely new tool to existing techniques, but some caution is required because charge density studies become increasingly difficult as the number of electrons in the atomic cores increases. The atomic cores are very little affected by chemical bonding and their X-ray scattering is a strong signal on which the chemically interesting valence scattering is superimposed. For atoms with many electrons the deformation density according to expression (1) is the rather small difference between two functions (ρ_{observed} and $\rho_{\text{free atom}}$) with large values in the vicinity of the heavy atoms. As $\sigma(\rho)$ is in first approximation proportional to ρ, this means that the experimental errors according to (3) are larger for transition metal compounds than for the organic molecules we have discussed up to this point.

For this reason, early studies concentrated on crystals containing first and second row atoms only. More recently several research groups have made a serious start at studying compounds of 3d transition metals which are relatively light and therefore the most promising transition-metal compounds. A number of studies by *Saito et al.*[32, 33] and by *Rees* and *Mitschler*[14] on octahedral complexes of chromium, cobalt, and nickel indicate excess charge in the t_{2g} metal orbitals in $NiSiO_4$, $Co(NH_3)_6Co(CN)_6$, $Co(NH_3)_6Cr(CN)_6$, and $Cr(CO)_6$. The asymmetries in the deformation maps are reproduced in recent *ab-initio* calculations of MnO_4^-, CoO_6^{10-}, and $Ni(CH_3)_2$ by *Johansen*[34], though they appear at shorter distances from the metal atoms in these calculations. Since no single transition metal compound has been studied both experimentally and theoretically at this time it is not known whether the discrepancy is due to inadequacies in the calculation of differences between compounds.

The study of hexacarbonylchromium $Cr(CO)_6$ is an excellent example of what can be achieved in careful low temperature work. The molecule itself has octahedral symmetry but three out of the six CO groups are not related by crystallographic symmetry elements and therefore measured independently in the diffraction experiment. The planes shown in Figure 6 are averages over such chemically but not crystallographically independent parts of the molecule. The averaging is useful in eliminating the background noise in the experimental maps and correspondingly reducing the experimental errors. The section shown in Figure 6b contains the Cr atom and two CO groups, while the one of Figure 6c is inclined by 45° to the first plane (see Fig. 6a). The density in the CO ligand is very similar in the two planes but a significant difference occurs near the chromium atom where Figure 6b shows a peak along the diagonal of the drawing, interpreted as extra density in the t_{2g} orbitals of the chromium atom, which have their maxima in this direction[15]. A detailed analysis of these differences and a comparison with theoretical values for the chromium atom enabled *Rees* and *Mitschler* to conclude that the occupation of the two types of d orbitals which in the isolated atom is 40% and 60% for e_g and t_{2g} respectively, becomes 25% and 75% in the complex. Comparison of the density in the CO ligand with a theoretical result for the isolated CO molecule further suggested that antibonding π^* orbitals of the ligand are partially occupied by a donation of electrons from the metal orbitals into these ligand orbitals. This is in agreement with the "classical" Dewar-Chatt model of the metal-ligand bonding inferred earlier from less direct spectroscopic and structural evidence[35].

A binuclear metal-metal complex was the subject of a recent study of $(\eta^5\text{-}C_5H_5Ni)_2CH{\equiv}CH$[36]. The acetylene CC density was found to be displaced away from the Ni—Ni region as if the carbon bonding hybrids are bent away from the bond axis (Fig. 10) much like the distortion of the bonds in strained three-membered ring compounds discussed above. The analogy suggests a NiNiCC tetrahedron which is strained at the carbon atoms. The drastic effect on the density is not surprising because the geometry of the acetylene ligand is very different from that of the free acetylene molecule: The C—C bond length is lengthened from 1.21 Å to 1.341(6) Å while the CCH bond angle is changed from 180° to 148°. The lengthening of this CC bond again indicates that the bond is weakened by population of electrons in antibonding orbitals. Such antibonding orbitals have zero value in the plane perpendicular to the bond through its midpoint. This plane cuts the section shown in Figure 10 through the vertical line passing through the bond midpoint. The density along this line is indeed lower than elsewhere in the C≡C bond, in accordance with the explanation of the lengthening of the bond.

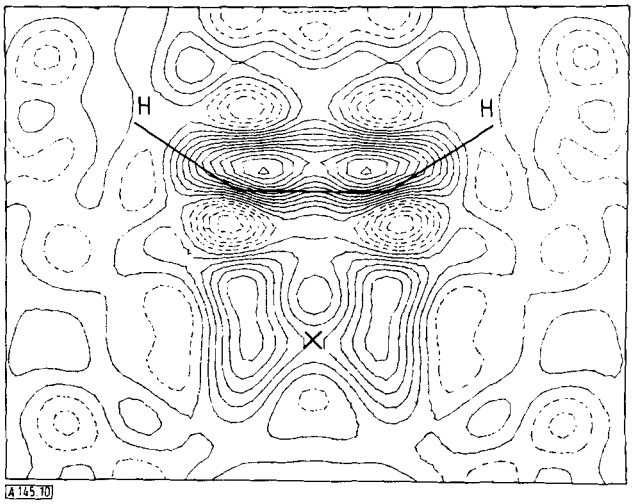

Fig. 10. Deformation density in μ-acetylenebis(η^5-cyclopentadienylnickel). The section shown contains the carbon and hydrogen atoms of the C_2H_2 ligand and is perpendicular to the Ni—Ni bond through its midpoint (indicated by X). Contours as in Fig. 5. From *Wang* and *Coppens* [36].

The changes in the structure of small molecules on coordination to a metal atom have been compared to the electronic excitation which occurs for example on absorption of a light quantum[37]. Such a drastic change will affect the chemical behavior of molecules and is therefore of importance in the study of catalysis of reactions by transition metal atoms.

2.5. Charge Density Studies of Covalent and Metallic Solids

Silicon is one of the very few solids of which perfect crystals are available. This allows unusually accurate measurement of the X-ray structure amplitudes[38]. The corresponding deformation density in the bonds has an estimated standard deviation of better than 0.01 $e\text{Å}^{-3}$ and agrees in peak height, but not in shape with an earlier pseudopotential calculation[39], the experimental density peak being elongated along, rather than perpendicular to the bond. But soon after the experimental results became available introduction of an additional parameter in the theoretical calculation effectively reduced the discrepancy (Fig. 11) and also lead to better agreement with photoemission and reflectance spectra[40]. This shows that semiempirical methods may be successfully parametrized using experimental densities.

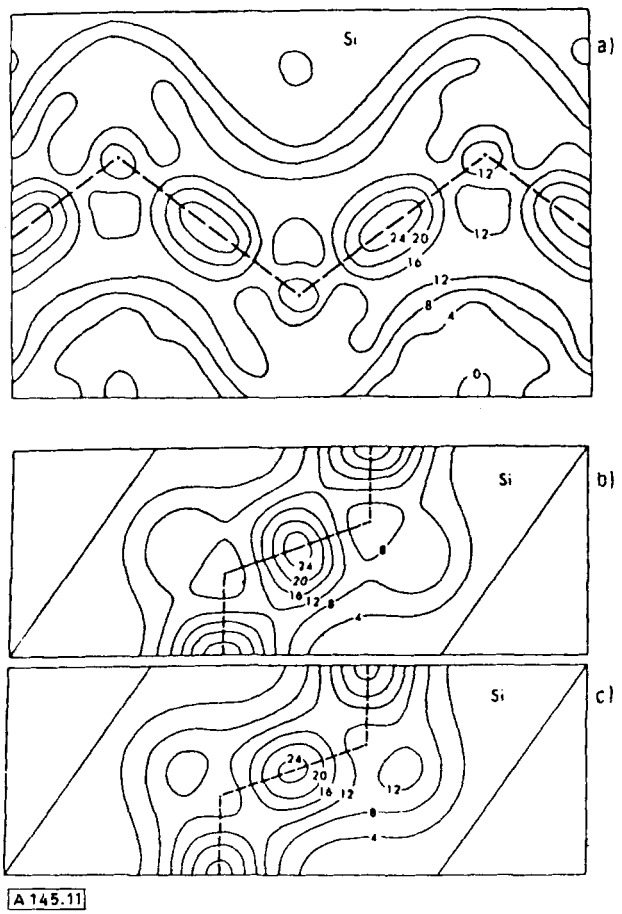

Fig. 11. Valence electron density in silicon. The broken lines indicate the bonds between the Si atoms which are at the corners of the zig-zag curve. Two other equivalent bonds to each atom are above and below the plane shown. a) Experimental density from *Yang* and *Coppens* [39]. b) Charge density from a local pseudopotential calculation [39]. c) Charge density according to a more recent energy-dependent non-local pseudopotential calculation by *Chelikowsky* and *Cohen* [40]. Contour units indicated are in 0.025 $e\text{Å}^{-3}$. The newer calculation is in better agreement with the experimental result.

No theoretical density has been calculated for the silicon containing alloy V_3Si which is a "high-temperature" ($T = 16.85$ K) superconductor. It contains linear chains of vanadium atoms which are more closely spaced, at 2.36 Å, than in vanadium metal where the nearest neighbor distances are 2.62 Å. The experimental X−X density at room temperature indicates accumulation of density between the vanadium atoms typical for covalent bonding (Fig. 12)[41]. There is no peak between nearest neighbor Si and V atoms and a general charge depletion of the region around the Si atom. A simple theoretical explanation of the superconducting properties of V_3Si and related compounds by *Labbe* and *Friedel*[42] is indeed based on a one dimensional (*i.e.* in the chain direction) band of electrons formed by the vanadium d-orbitals. The strong V-V interaction supports a one-dimensional analysis as a first approximation, but more detailed examination of the density maps shows a much lower than cylindrical symmetry of the density in the linear chains, which can only be explained by the effect of the crystal environment. A parallel study on the isomorphous compound Cr_3Si, which has no superconducting properties, shows a lower peak height and therefore less covalency between the Cr atoms[43]. Further variable temperature studies of these systems are presently being undertaken.

A certain degree of covalency has even been observed in Be metal where deformation density is observed within tetrahedra formed by four Be atoms, suggesting an electron deficient multicenter bond[44], comparable with the density observed within the triangle of two-electron three-center bonds in decaborane[45]. The analogy is perhaps not surprising as the number of nearest neighbors in metallic Be (12) far exceeds the number of available valence electrons per atom (2). Similar studies on Al metal are inconclusive due to lack of good single-crystal data on this solid[44b]. But it seems clear that careful charge density measurements will contribute to our understanding of metals and especially alloys which often crystallize in complicated structures with incompletely understood bonding arrangements.

3. Further Analysis of the Charge Density: Net Charges and Dipole Moments

The three-dimensional electron density distribution is the most detailed function obtainable from the X-ray data and it lends itself to rapid qualitative interpretation as discussed above. But we may want to proceed beyond qualitative results to the derivation of functions such as net charges, molecular dipole and quadrupole moments, or the electrostatic potential which are in principle known once the electron density has been obtained (within the limitations imposed by the experimental errors and the fact that the observed X-ray intensities correspond to the electron density averaged over the thermal vibrations of the crystal).

The simplest example of such a derived function is the total number of electrons n on an ion or molecule. If the electron density ρ is known as a function of the positional coordinates x, y, z the electron population in a volume of the crystal is obtained by a three dimensional integration:

$$n_{\text{electrons}} = \iiint_{\text{volume}} \rho(x,y,z)\,dx\,dy\,dz$$

Methods of evaluating such integrals are well-developed[46, 47], but the choice of the volume to be associated with an atom, ion, or molecule is more controversial. A meaningful definition of such a volume is really only possible when the constituents of the crystal are well separated. This occurs for example, when the electron density has a zero or very small value between the ions in an ionic crystal. In this case the boundary between the ions may be taken where the electron density is small and the exact choice of the position of the boundary will then have little effect on the results of the integration. Of course, such a surface of low density will in general not have the regular shape of, for instance, a sphere or an ellipsoid but rather be dependent on the detailed geometry of the crystal. One solution proposed by the author is to define a polyhedral boundary surface composed of planes perpendicular to the lines connecting atoms (see Fig. 13). By performing the integration for various positions of these boundary planes a curve of integrated electron population against plane-position is obtained which will have zero slope when the plane is located in a region of small electron population.

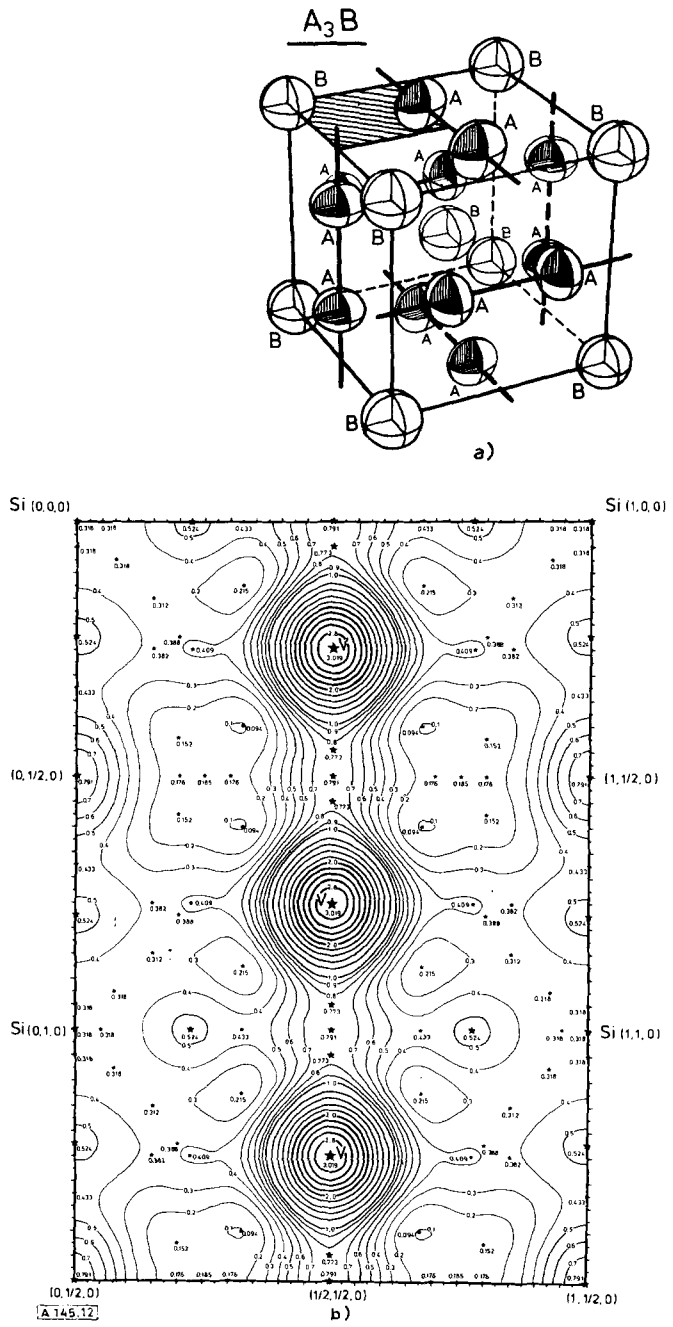

Fig. 12. a) Structure of V_3Si (A = V, B = Si). The hatched area indicates the plane shown in part b. b) Valence electron density in a plane containing a vanadium chain and silicon atoms (at the edges as indicated). The accumulation of density between the nearest neighbor vanadium atoms is characteristic for covalent bonding. Contours at 0.1 eÅ^{-3}. Lowest contour at 0.1 eÅ^{-3}. From *Staudenmann et al.* [41, 43].

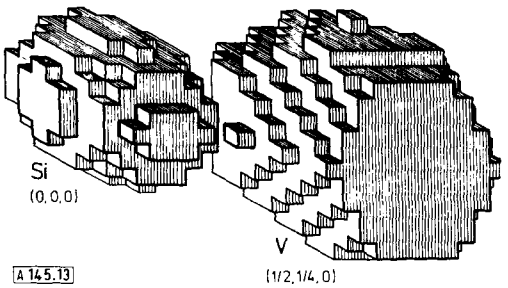

Fig. 13. Atomic volumes of integration in V_3Si type structures. The volumes touch even though they are shown separate here for illustration purposes. The steps are a necessity of the numerical integration method employed. They approximate boundary planes perpendicular to the inter-atomic lines. See text for further details. From refs. [41, 43].

A crystal which contains distinct entities to which this method has been applied is $NaCN \cdot 2H_2O$[22], in which the Na ions are found to have only very small positive charges (<0.15 electron units, the net charge being defined as the total electron population minus the nuclear charge). The result seems to be general as similar conclusions have been reached in studies of NaSCN[53] and the mineral kernite[48] ($Na_2B_4O_6(OH)_2 \cdot 3H_2O$). The sodium ions (or should we say atoms?) in $NaCN \cdot 2H_2O$ are each surrounded by four water molecules (which are in turn each shared by two Na ions) and as in kernite part of the positive charge is found on this hydration mantle in which each H_2O molecule is found to have a net charge of +0.23 units. Similar positive charges have been found on water molecules which are not coordinated to metal atoms as in oxalic acid dihydrate[49].

The volume of integration can be defined very well in molecular crystals in which molecules are held together by weak van der Waals interactions. A numerical integration of the charge density in the organic conductor TTF-TCNQ (tetrathiofulvalene-tetracyanoquinodimethane) indicates a charge transfer of a fraction of an electron (0.55 ± 0.15) from the TTF to the TCNQ molecule[47], in good agreement with less direct evidence from the sulfur chemical shift in the photoelectron spectrum of TTF[50]. This solid has a very high one-dimensional conductivity above 53 K at which temperature a phase transition to an insulating state occurs. Its properties and the mechanism of the phase transition are intricately linked to the number of electrons per molecule. *Comes et al.* concluded from the lattice periodicity in the insulating phase that 0.59 electrons are transferred[51], again in good agreement with the X-ray values. There are many related organic conductors in which the charge transfer is unknown and which would be fruitful subjects for further studies.

Very few examples are available in which a dipole moment has been evaluated from the charge distribution. For both the water molecules in $NaCN \cdot 2H_2O$ dipole moments of about 1.8D were obtained, in surprising agreement with the solution dipole moment of 1.84D. In a similar analysis

of the zwitterion NH_3SO_3 (sulfamic acid) the X-ray dipole moment of 6.5 D is much smaller than the solution value of 12.5 D[52]. This could mean that the dipole moment is markedly lowered upon crystallization, but such a conclusion is premature until error estimates are obtained and other compounds are studied[53]. Calculation of dipole moments represents one of the frontiers of charge density analysis and much further work is indicated.

4. Concluding Remarks

Charge density analysis is a new method for analyzing solids which has fairly general applicability. It requires an accurate X-ray data set, preferably recorded at low temperature, containing many multiple measurements to provide a check on data quality. This means that the great majority of existing data sets are inadequate for this purpose. But methods for interpretation of the data and for analysis of errors have now been developed and systematic analyses of bonding in related compounds is now possible. The technique is inherently slow with X-ray sources presently available, but the information obtained is unusually detailed and not otherwise accessible experimentally.

The author would like to thank several of his colleagues: Dr. J. W. Bats, Dr. B. Rees, Dr. J. L. Staudenmann, and Dr. Z. Berkovitch-Yellin for communicating results prior to publication. Financial support by the National Science Foundation for the part of the work done at SUNY/Buffalo is gratefully acknowledged.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Crown Ether Catalyzed Reduction of Aromatic Nitro Compounds to Give Amines[1]

By *Howard Alper*, *Daniel Des Roches*, and *Hervé des Abbayes*[*]

Aromatic nitro compounds are reduced to amines by refluxing with an equimolar amount of $Fe_3(CO)_{12}$ in benzene/methanol for 10 to 17 h[2]. We have found that this reaction is catalyzed by the crown ether [18]crown-6 *(1)* in the presence of 1 N KOH. Only half the amount of $Fe_3(CO)_{12}$ is needed, and the reaction proceeds within 1.5 to 2.5 h on stirring of the reactants in benzene at room temperature. Work-up is simpler and the yields are just as good (see Table 1).

(1)

$$ArNO_2 + Fe_3(CO)_{12} \xrightarrow[1\,N\,KOH,\ C_6H_6]{(1)} ArNH_2$$

Table 1. Reaction times and yields.

Amine formed	Reaction time [h]	Yield [%]
Aniline	2.5	60
p-Toluidine	1.5	65
p-Anisidine	2.0	78 [a]
p-Chloroaniline	2.5	79 [b]
2-Fluorenylamine	2.0	84 [c]

[a] 3% in the absence of *(1)*.
[b] 2% in the absence of *(1)*.
[c] 33% in the absence of H_2O.

The nitro compound was almost completely recovered when the reaction was repeated in the absence of the crown ether *(1)* (see Table 1), and the use of solid KOH, *i.e.* the absence of water, gave the amines in significantly lower yields.

[*] Prof. Dr. H. Alper [+], Dr. D. Des Roches, and Dr. H. des Abbayes [**]
Department of Chemistry, University of Ottawa
Ottawa, Ontario, Canada K1N 6N5
[+] To whom correspondence should be addressed.
[**] France-Canada exchange scientist.

We assume the reaction to proceed as follows: The crown ether *(1)* bonds the K^+ ion of KOH to give the unsolvated and highly reactive OH^- ion. This species attacks $Fe_3(CO)_{12}$ in the organic phase, affording $[Fe_3(CO)_{11}]^{2-}$[3] which yields the ions OH^- and $[HFe_3(CO)_{11}]^-$ with water. The latter ionic product reduces the nitro compound.

Procedure:

To a mixture of nitroarene (1.0 mmol), $Fe_3(CO)_{12}$ (0.5 mmol), and [18]crown-6 (0.1 mmol) in benzene (10 ml), is added 1 N KOH (10 ml). The solution was vigorously stirred at room temperature for 1.5—2.5 hours (N_2 atmosphere). The layers were separated and the aqueous layer was washed with ether; the washings are added to the separated organic layer, dried ($MgSO_4$), and evaporated *in vacuo*. The residue is chromatographed on a silica gel column using benzene or benzene/ether as the eluant.

Synthesis and Dynamic Behavior of Pentamethylcyclopentadienylboranes[**]

By *Peter Jutzi* and *Arnulf Seufert*[*]

The pentamethylcyclopentadienylboranes described here are the first representatives of this type of compounds in which boron is bound to the cyclopentadiene ring in the allyl position. The preferred vinyl isomers in all previously known cyclopentadienylboranes[1] cannot be formed here owing to the high activation energy of the 1,2-methyl shift.

Synthesis of the surprisingly thermally stable dichloro(pentamethylcyclopentadienyl)borane *(2)* has been achieved by

(1) *(2)* *(3)* *(4)*

[*] Doz. Dr. P. Jutzi and Dipl.-Chem. A. Seufert
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)
[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

reaction of trimethyl(pentamethylcyclopentadienyl)germane *(1)*[2] with boron trichloride. Reaction of *(2)* with dimethylamine affords the bis(dimethylamino)(pentamethylcyclopentadienyl)borane *(3)*, and with trimethylamine the adduct *(4)*[3].

These three compounds differ in their dynamic behavior, since the rate of migration of the boryl group depends on the Lewis acidity of the boron atom.

Compound *(2)* has a fluxional structure owing to very rapid degenerate sigmatropic rearrangements of the BCl_2 group. At 40°C a sharp ^{1}H-NMR signal is observed at $\delta = 1.81$ ppm (in CH_2Cl_2) for the three types of chemically non-equivalent methyl groups; cooling to −80°C leads to a slight broadening of the signal.

Compound *(3)* has a static structure at 40°C. The ^{1}H-NMR spectrum (in CH_2Cl_2) shows separate signals for vinylic and allylic methyl groups: δCH_3 vinyl.: 1.83 ppm S(12); δCH_3 allyl.: 1.15 ppm S(3); $\delta N{-}CH_3$: 2.55 ppm, broad (12). However, on increasing the temperature rearrangements also take place in the case of *(3)* and lead to coalescence of the signals of all methyl groups attached to the cyclopentadiene ring. In addition, the non-equivalence of the *N*-methyl groups effects a temperature-dependent hindrance to rotation.

Compound *(4)* is a static molecule at all temperatures. The ^{1}H-NMR spectrum still shows sharp separated signals for the various methyl groups attached to the cyclopentadiene ring, even at 100°C: δCH_3 vinyl.: 2.07 ppm S(6), 1.85 ppm, S(6); δCH_3 allyl.: 1.22 ppm S(3); $\delta N{-}CH_3$: 2.75 ppm S(9).

Experimental:

Compound *(2)*: A solution of *(1)* (6.6 g, 26 mmol) in CH_2Cl_2 (20 ml) is added dropwise and slowly at −30°C to a solution of BCl_3 (3.2 g, 27 mmol) in CH_2Cl_2 (20 ml). After one hour's stirring at room temperature *(2)* is isolated by fractional distillation *in vacuo* as a colorless liquid, b.p. 55°C/0.5 torr; yield 3.2 g (57 %); $M^{\oplus}$: *m/e* = 216 (0.5 %).

Compound *(3)*: A solution of *(2)* (3.2 g, 15 mmol) in pentane (20 ml) is added at −30°C to a solution of $HN(CH_3)_2$ (2.7 g, 59 mmol) in pentane (25 ml). After filtration, *(3)* is obtained by fractional distillation *in vacuo* as a colorless viscous liquid, b.p. 74°C/0.05 torr; yield 1.8 g (52 %); $M^{\oplus}$: *m/e* = 234 (1.5 %).

Compound *(4)*: $N(CH_3)_3$ (0.2 g, 3 mmol) is added at −20°C to a solution of *(2)* (0.4 g, 2 mmol) in pentane (35 ml). The precipitate is filtered off and recrystallized from methylcyclohexane; m.p. 135°C (dec.), yield 0.4 g (73%); $M^{\oplus}$: *m/e* = 275 (0.1 %).

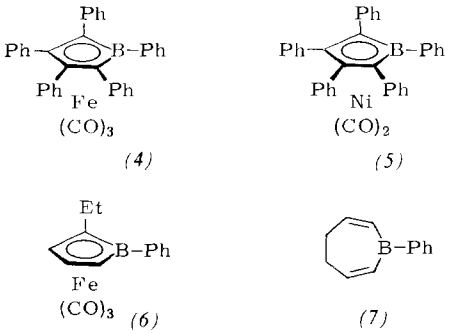
Two Routes to Complex Derivatives of Borole[1]



By *Gerhard E. Herberich*, *Joachim Hengesbach*, *Ulrich Kölle*, and *Wolfgang Oschmann*[*]

Unsubstituted borole *(1)* is unknown. The only non-complex derivative reported so far is pentaphenylborole *(2)*[2], and the only complex derivative the triple-decker complex *(3)*[3], a *closo*-metallocarborane. We report here on two extensions to borole chemistry which lead to complexes of the *nido* type.

(1) *(2)* *(3)*

Pentaphenylborole *(2)* reacts with $Fe_2(CO)_9$ to give tricarbonyl(η-pentaphenylborole)iron *(4)*[4], and with excess $Ni(CO)_4$ to give dicarbonyl(η-pentaphenylborole)nickel *(5)*[4].

(4) *(5)* *(6)* *(7)*

1-Phenyl-4,5-dihydroborepin *(7)*[5] tends to undergo ring contraction[3] in complexation reactions carried out under drastic conditions. Reaction with $Fe(CO)_5$ in boiling mesitylene leads to tricarbonyl[η⁵-(2-ethyl-1-phenylborole]iron *(6)*[4], and a mixture of stereoisomeric bis(2-methyl-1-phenylborinato)iron complexes which was not investigated any further.

The borole ligands in *(4)* to *(6)* are bound to the metal as pentahapto four-electron ligands. The boron-metal bond suppresses the cleavage of the phenyl group at boron in the mass spectra and in the case of *(6)* is directly detectable by the ^{11}B-shift of $\delta = +19.6$ ppm[6]. Further, in contrast to the extremely water-sensitive pentaphenylborole *(2)*, compounds *(4)* to *(6)* are stable towards water.

Table 1. Data for borole complexes *(4)* to *(6)*.

(4): MS (70 eV): *m/e* (from 10 % $I_{rel.}$) 584 (7; M^+), 556 (20; −CO), 500 (100; −3 CO), 322 (48; $C_2BPh_3Fe^+$), 264 (22; 322 $-H_2$, −Fe), 250 (14; $C_4BPh_5Fe^{2+}$), 178 (16; $C_2Ph_2^+$). The First Oxoferrate(III) Having a Ring Structure: $Na_{14}[Fe_6O_{16}]$[1]

By *Gerold Brachtel* and *Rudolf Hoppe*[*]

During our search for the hitherto unknown Na_3FeO_3, which in the meantime we have isolated in the form of yellow translucent crystals, a further phase was obtained as lustrous, yellow, single crystals which rapidly decompose in air. For the preparation, an intimate mixture of Na_2O_2 and FeO (Na : Fe = 2.2 : 1) was heated in a small Ni bomb (600°C, 5 d). The product was handled in an argon atmosphere and single crystals picked out under the microscope. According to Weissenberg and precession photographs $Na_7Fe_3O_8$ is seen to crystallize triclinically (diffractometer data): $a = 11.47_2$, $b = 8.33_7$, $c = 5.96_6$ Å, $\alpha = 109.3$, $\beta = 87.7$, $\gamma = 111.2°$, $Z = 2$. For the structure determination 2116 symmetry-independent reflections were measured[2] (Mo-K_α, graphite monochromator). The structure was solved by direct methods and interpretation of the Patterson synthesis[3]. Refinement of all particles with anisotropic temperature parameters gave an R-value of 4.8 % (space group $P\bar{1}$) for 1932 reflections with $F > 2.5\sigma(F)$.

The structural analysis reveals the following (see Fig. 1): *Primary structure:* iron is surrounded almost tetrahedrally by O (mean bond lengths: Fe—O (terminal) = 1.84 Å, Fe—O (bridge) = 1.91 Å. The coordination sphere of the sodium

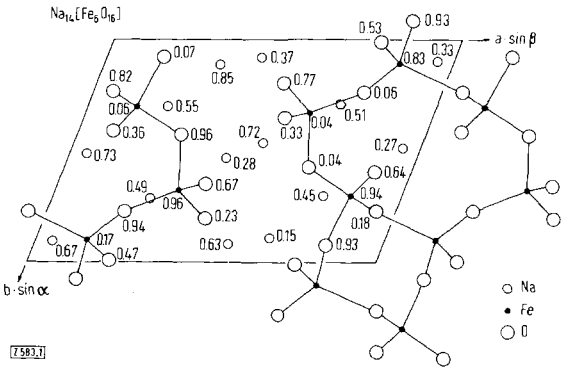

Fig. 1. Crystal structure of $Na_{14}[Fe_6O_{16}]$. Values of z in fractions of c.

particles is irregular. Calculation of the Effective Coordination Number (ECoN)[4] of Na towards O gives a value of 4 for the Na particles.

Secondary structure: Within the region of the unit cell the structure is predominated by six-membered rings of Fe: the Fe particles are bound to one another by O bridges.

Tertiary structure: Along [010] two thirds of the FeO_4 tetrahedra are coupled in the form of a "Dreier-Doppelkette", which has been proposed in the case of the silicate $Na_2Ca_3[Si_6O_{16}]$[5].

The compound described here illustrates once again the analogy between oxometalates with d^5 configuration and silicates[6]. This is also apparent in the compounds with island structure, Na_5FeO_4[7] and $Na_8Fe_2O_7$[8], previously prepared by us. However, the type of structure where two tetrahedra are coupled by a common edge, as has been observed in $K_6[Fe_2O_6]$[9] and $K_6[Mn_2O_6]$[10], has not yet been observed in the silicates.

The Madelung Part of the Lattice Energy, MAPLE[11] (8643.0 kcal/mol) is in excellent agreement with the sum of the MAPLE values of the binary oxides (8612.5 kcal/mol, $\Delta = 0.4$ %).

Stereoselective Hydride Elimination from Organo-Lithium and -Magnesium Compounds[**][1]

By *Manfred T. Reetz* and *Wilfried Stephan*[*]

In contrast to olefin formation by base-induced hydrogen halide elimination, little is known concerning hydride abstraction from carbanions. We report here on hydride acceptors which effect elimination of β-hydrogen atoms from organolithium and -magnesium compounds under mild conditions. Using triphenylmethyltetrafluoroborate[2], tricyclohexylborane, and tri(*sec*-butyl)borane[3] as hydride acceptors we were able to convert structurally different lithium and magnesium compounds *(1)* into olefins *(2)* with simultaneous formation of triphenylmethane and trialkylborohydrides, respectively (see Table 1).

(1) *(2)*

M = Li, Mg

Table 1. Olefins from organo-lithium and -magnesium compounds.

Metal compound	Hydride acceptor	Olefin [a]	Yield [%]
2-Hexylmagnesium chloride	Triphenylmethyltetrafluoroborate	1-Hexene (79) *trans*-2-Hexene (10) *cis*-2-Hexene (11)	74
Cyclohexylmagnesium chloride		Cyclohexene	75
1-Decylmagnesium chloride		1-Decene	28
1,1-Diphenyl-1-hexyllithium		1,1-Diphenyl-1-hexene	65
tert-Butyllithium	Tri(*sec*-butyl)borane	Isobutene	>95
1,1-Diphenyl-1-hexyllithium		1,1-Diphenyl-1-hexene	80
9,10-Dihydro-9-anthracenyllithium		Anthracene	86
2-Hexyllithium		1-Hexene (68) *trans*-2-Hexene (23) *cis*-2-Hexene (9)	60
1-Decyllithium		1-Decene	< 4
2-Hexyllithium	Tricyclohexylborane	1-Hexene (68) *trans*-2-Hexene (22) *ci*-2-Hexene (10)	62
1-Decyllithium		1-Decene	< 4

[a] Isomeric ratio given in brackets.

The good yields of olefin obtained with triphenylmethyltetrafluoroborate are surprising, since reaction of carbanions with carbenium ions should lead to C—C bond formation[4]. While this hydride acceptor promotes smooth eliminations within an hour already at −20 to −78 °C, the isoelectronic, but neutral trialkylboranes require longer reaction times (>16 hours) at 30 to 55 °C. It can been seen from Table 1 that the yields of olefin depend on the structure of the organometallic compound and increase clearly within the series primary < secondary < tertiary. This is due to the influence of steric factors on the competition between hydride elimination and carbanion addition[4]. Formation of the thermodynamically less stable Hofmann product is consistently favored. This selectivity may arise, not so very much from a possibly increased "hydride character" of the β-hydrogen atom on the alkyl residue, but rather from steric influences: the attack of the hydride acceptor on the lesser substituted alkyl residue is easier due to steric reasons[5]. The *cis/trans* ratios are more difficult to explain.

Experimental

To a solution of triphenylmethyltetrafluoroborate (3.3 g, 0.01 mol) in dry methylene chloride (40 ml) at −78 °C is added 0.01 mol of 2-hexylmagnesium chloride. The mixture is stirred at −78 °C for 1 h, allowed to warm to room temperature and hydrolyzed. The ethereal phase is analyzed gas-chromatographically (squalane, 90 m capillary column, 60 °C, 40 ml He/min): 74 % yield of hexene; isomer ratio see Table 1.

Nucleophilic Substitution of Vinylic Hydrogen Atoms by Carbanions[**][1]

By *Manfred T. Reetz* and *Dieter Schinzer*[*]

Hydride abstractions from carbanions are of preparative utility, since organometallic compounds are not only accessible *via* halogen-metal exchange or ether cleavage, but also by addition to activated olefins, by deprotonation, and by rearrangement. We report here on addition-elimination reactions which effect the substitution of vinylic hydrogen atoms by a variety of carbon residues in a one-pot reaction.

When activated olefins of type *(1)* were allowed to react with organolithium compounds, the lithium derivatives *(2)*[2] were obtained from which a hydrogen atom β to lithium could be eliminated as hydride ion by reaction with triphenylborane[3]. The end products were the olefins *(3)*.

(1) *(2)* *(3)*

Table 1 shows that these C—C bond formations with conservation of the olefin function proceeds smoothly even when

[b] Stereochemistry and composition of the *Z*/*E* mixture at present uncertain.

such sterically demanding groups as *tert*-butyl residues are incorporated. The applicability of the reaction to vinylsilanes is noteworthy, since these are readily modifiable and synthetically interesting[4]. Finally, it should be mentioned that double substitutions in one-pot reactions are also possible, as demonstrated by the preparation of *(5)* from *(4)* (61 % yield).

(4) *(5)*

Preparation of 1,1-diphenyl-1-hexene

13 ml of a 1.65 M solution of *n*-butyllithium in *n*-hexane is added dropwise at 0°C to a solution of 1,1-diphenylethylene (3.65 g, 0.02 mol) in anhydrous tetrahydrofuran (50 ml). The mixture is stirred for 85 min at room temperature and the resulting deep-red solution treated with 5 g (0.021 mol) triphenylborane[3] in 30 ml tetrahydrofuran; a gradual decolorization takes place. After 15 h the mixture is diluted with 50 ml petroleum ether (b.p. 40 to 60°C), the two phases that are formed are separated, and the lower phase is extracted twice with petroleum ether. The combined petroleum ether phases are washed with a 10 % sodium hydroxide solution and water and dried over sodium sulfate. Removal of solvent from the dried solution yields 4.2 g (89 %) of pure 1,1-diphenyl-1-hexene; ^{1}H-NMR spectrum identical with that of an authentic sample[5].

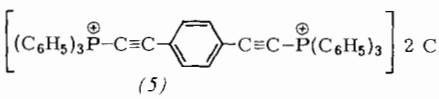
Simple Synthesis of (Arylethynyl)triphenylphosphonium Salts

By *Hans Jürgen Bestmann* and *Wolfgang Kloeters*[*]

Ethynylphosphonium salts are interesting synthetic building blocks[1]. We have now found a simple entry to the (arylethynyl)triphenylphosphonium salts *(4)*.



(1) *(2)*

(3) *(4)*

(a), Ar = C_6H_5; *(b)*, Ar = *p*-CH_3O-C_6H_4; *(c)*, Ar = α-$C_{10}H_7$

(5)

Reaction of aromatic acid chlorides *(1)* with hexaphenylcarbodiphosphorane *(2)*[2] leads initially to the compounds *(3)*, which on heating lose triphenylphosphane oxide and are converted into the phosphonium salts *(4)*. *(4a)*: m.p. 180°C, IR: 2175 cm^{-1} (C≡C), ^{31}P-NMR: δ = −6.52 ppm[3], yield 65 %.—*(4b)*: m.p. 183°C, IR: 2165 cm^{-1} (C≡C), ^{31}P-NMR: δ = −5.86 ppm[3], yield 68 %.—*(4c)*: m.p. 161°C, IR: 2170 cm^{-1} (C≡C), ^{31}P-NMR: δ = −6.45 ppm[3], yield 56 %.

When phthaloyl dichloride is used as starting compound the reaction furnishes the bisphosphonium salt *(5)*, m.p. 138°C; IR: 2175 cm^{-1} (C≡C), ^{31}P-NMR: δ = −6.52 ppm[3], yield 71 %[4].

In the ^{31}P-NMR spectra of the phosphonium salts *(3)*, both phosphorus atoms give a signal between δ = −18.5 and −20.0 ppm[3]. In the case of the ethynylphosphonium salts *(4)*, on the other hand, only one signal is observed at δ = −5.5 to −6.8 ppm, which can be ascribed to a strong interaction between the π-electron system of the triple bond and the phosphorus atom[5].

General procedure:

A solution of the freshly distilled acid chloride *(1)* (20 mmol) in anhydrous benzene (20 ml) is added dropwise under nitrogen to a solution of hexaphenylcarbodiphosphorane *(2)* (20 mmol)

[*] Prof. Dr. H. J. Bestmann and Dipl.-Chem. W. Kloeters
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (Germany)

in anhydrous benzene (100 ml). The white precipitate is filtered off, washed with benzene, and dried in a vacuum (1 torr) at 40 °C. A suspension of the recovered salt *(3)* in anhydrous toluene (100 ml) is boiled under reflux for 12 to 18 hours under nitrogen. The undissolved ethynylphosphonium salt *(4)* is filtered off, washed with benzene, and dried in a vacuum.

Synthesis of Protohypericin from Emodin[**]

By *Dietrich Spitzner*[*]

Apart from hypericin and pseudohypericin, *Hypericum perforatum* L. contains two further photodynamically active pigments, *viz.* protohypericin *(2)* and protopseudohypericin, which readily transform into the first-named compounds on exposure to light and oxygen[1]. *Brockmann et al.*[2] obtained *(2)* by oxidation of penicilliopsin or emodin anthrone.

We have now found that *(2)* is also formed on alkaline dimerization of emodin *(1)* by the method of *Steglich et al.*[3], provided that light is excluded during the reaction and work-up. The violet pigment isolated in 25% yield (color in acetone and alkaline solution violet) is identical with an authentic sample of *(2)*[4, 5] [paper chromatography; spectra (FD-MS: $M^+ = 506$ mass units; UV (MeOH): $\lambda_{max} = 540$ nm; ^{1}H-NMR ([D_5]pyridine): $\delta = 2.06$ (CH_3), 6.91 (2(7)-H), 7.13 (11(14)-H), 7.47 (4(5)-H)]. Irradiation in acetone quantitatively affords hypericin identical with authentic material in all its properties.

(1) *(2)*

Decoupling experiments on *(2)* [irradiation at the CH_3 frequency gives a doublet ($J = 1.5$ Hz) for H-2(7) and H-4(5); irradiation at the H-4(5) frequency gives a doublet ($J = 0.5$ Hz) for CH_3 and a suggestion of a quartet ($J = 0.5$ Hz) for H-2(7)] establish the aromatic protons *ortho* to the CH_3 group. Admixture of authentic *(2)* does not change the spectrum. Hence the orientation of the two emodin halves in *(2)* is confirmed.

Procedure:

Compound *(1)* is heated with 1.8 mol. equiv. of 0.6 N KOH and 1 mol. equiv. of hydroquinone under N_2 with exclusion of light for 20 d at 100 °C in a bomb tube. The violet mixture is acidified with 0.1 N HCl, the precipitate filtered off, washed, dried, and exhaustively extracted with ethyl acetate. The resulting crude pigment is chromatographed on cellulose with DMF/water/butyl acetate (1 : 1 : 2) in the absence of light. After an orange primary zone (anthraquinone components), compound *(3)* is eluted.

Synthesis of Hypericin and Related *meso*-Naphthodianthrones by Alkaline Dimerization of Hydroxyanthraquinones[**]

By *Gisbert Rodewald, Rüdiger Arnold, Johannes Griesler*, and *Wolfgang Steglich*[*]

In 1957 *Brockmann et al.* obtained hypericin *(4)*, the photodynamic component of *Hypericum perforatum*, in a multistep synthesis starting from 1-bromoemodin trimethyl ether[1]. One year later the preparation of *(4)* was accomplished in two steps from emodin-9-anthrone[2].

In 1973 we reported the alkaline condensation of emodin *(1)* to give a *meso*-naphthodianthrone which we assigned the formula of an isohypericin *(5)*[3]. On repeating the experiment it was found that hypericin *(4)* is actually formed[4].

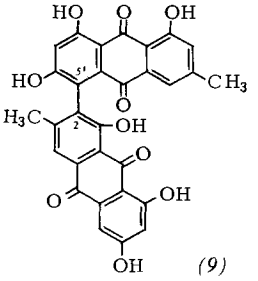
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



Compound *(1)* is heated with 1.5 mol. equiv. of hydroquinone and 2.5 mol. equiv. of potassium *tert*-butoxide in water (corresponding to 0.5 N KOH) under N_2 for three weeks in a sealed tube at 110 °C. Acidification of the reaction mixture, filtration, and washing of the filter cake neutral with water, followed by dissolution of the solid in ethyl acetate and chromatography of the filtered and concentrated solution on silica gel (ethyl acetate with acetone gradient) furnishes *(4)* in 29 % yield. The compound and its hexaacetate, m.p. 265 °C (dec.), agree in all their properties with authentic hypericin and its hexaacetate[5].

To *Spitzner*[6] as well as *Cameron*[4] goes the credit for the important observation that the reaction yields protohypericin if light is carefully excluded during the reaction and the product is worked up in the dark. Initially formed protohypericin is apparently transformed into *(4)* under the reaction conditions we employed.

The condensation reaction can also be applied to 1,3,8-trihydroxyanthraquinone *(2)* and emodic acid *(3)*. Bisdemethylhypericin *(6)*[7] and hypericindicarboxylic acid *(7)*[4] are obtained in 28 and 25 % yield, respectively, on workup in daylight. Under same conditions, 1,3-dihydroxyanthraquinone surprisingly affords a dark red product, the molecular weight of which (FD-MS: $M^+ = 460$ mass units) shows it to contain two H atoms less than the expected *meso*-naphthodianthrone. Since all attempts at cyclization to a *meso*-naphthodianthrone by irradiation were unsuccessful, the compound probably has the structure *(8)*, which is compatible with spectroscopic data (Table 1). In the absence of a 3-OH group, as in the case of 1,8-dihydroxyanthraquinone, no condensation occurs on heating with alkali.

(8)

(9)

Table 1. Spectroscopic properties of compounds *(6)* to *(9)*.

(6) $\lambda_{max} = 574$ nm ($\varepsilon = 30100$), 531 (16800), 497 (7600), 463 (11600), 440 (sh, 10100), 380 (8300), 334 (22600), 323 (21200), 281 (28100), 273 (28100), 245 (34900), 220 (55000) [in MeOH]	$\delta = 6.60$ (s); 7.36, 8.84 (each d, $J = 9$ Hz); 14.50, 14.78 (each s) [in D_6-DMSO/$CDCl_3$ = 7:3]
(7) $\lambda_{max} = 591$ nm ($\varepsilon = 20000$), 547 (10700), 508 (4400), 475 (6800), 380 (5900), 327 (15700), 280 (19400), 255 (sh, 23900), 230 (34100), 213 (41800) [in MeOH]	$\delta = 6.65$, 7.82, 14.22, 14.65 (each s) [in D_6-DMSO/$CDCl_3$ = 7:3]
(8) $\lambda_{max} = 535$ nm (sh, $\varepsilon = 5700$), 473 (12900), 342 (5380), 273 (24100), 247 (38400), 205 (27000) [in MeOH with one drop of HCl]	$\delta = 6.41$ (s); 7.25, 7.51 (each ddd, $J = 7.5$, 7.5, 1.5 Hz); 7.88, 8.44 (each dd, $J = 7.5$, 1.5 Hz) [in D_6-acetone]
(9) $\lambda_{max} = 446$ nm ($\varepsilon = 12200$), 276 (21000), 253.5 (sh, 18700), 220.5 (30000) [in EtOH]	$\delta = 2.18$ (d, $J = 0.8$ Hz) [3-CH_3]; 2.38 (t, $J = 0.8$ Hz) [3'-CH_3]; 6.39 (s) [7'-H]; 6.68 (d, $J = 2.5$ Hz [7-H]; 7.10 (broad) [2'-H]; 7.32 (d, $J = 2.5$ Hz) [5-H]; 7.35 (broad) [4'-H]; 7.74 (s, broadened) [4-H]; 10.2 [6- and 6'-OH]; 12.00, 12.20, 12.31, 12.78 [in D_6-acetone]

If the dimerization of *(1)* is performed without a protective gas and addition of hydroquinone, the yield of *(4)* obtained after three weeks is only 10 %. Workup after only 24 h reaction showed the reaction mixture to contain not only traces of *(4)* and 70 % of unreacted *(1)* but also 18 % of 2,5'-bisemodinyl *(9)* [no m.p., decomposition above 215 °C; MS: $m/e = 538$ (90 %, M^+), 523 (100), 521 (17), 510 (6), 270 (6), 269.5 (4), 269 (11); IR (KBr): 1670, 1610 (C=O) cm^{-1}]. The linkage of the two emodin halves follows from the ^{1}H-NMR spectra of the dehydro-dimer and its hexaacetate, m.p. 155 °C (dec.), and from the result of reductive cleavage of *(9)* with sodium dithionite in $D_2O/OD^{\ominus}$. In the ^{1}H-NMR spectrum of the resulting compound *(1)* the signal of 2-H is only half as intense as that of 4-H. Under the conditions of cleavage 7-H is exchanged completely, and 5-H to a large extent.

The formation of *(9)* on heating of *(1)* in alkali is remarkable, in that *Franck et al.*[8] always obtained 5,7'-bisemodinyl and only a little 5,5'-bisemodinyl (skyrin) on oxidative dimerization of *(1)*.

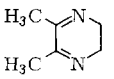
Heat of Hydrogenation of Compounds Containing Isolated and Conjugated C=N Double Bonds



Günter Häfelinger and *Ludger Steinmann*[*]

The heats of hydrogenation of compounds containing C=N double bonds have not previously been determined directly. We have now measured[1] the heats of hydrogenation of the imines *(1a)* to *(1c)*, the diimines *(2)* and *(3)*, and the pyrazine *(4)* in a heat of hydrogenation calorimeter based on the instrument of *Bretschneider* and *Rogers*[2].

R^1–CH=N–R^2 *(1)*

(a): $R^1 = n\text{-}C_3H_7$, $R^2 = n\text{-}C_4H_9$
(b): $R^1 = CH_3$, $R^2 = CH(CH_3)_2$
(c): $R^1 = CH_3$, $R^2 = C(CH_3)_3$

$(CH_3)_3C$–N=CH–CH=N–$C(CH_3)_3$ *(2)*

(3)

(4)

[*] Prof. Dr. G. Häfelinger and Dr. L. Steinmann
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

The results listed in Table 1 have been corrected for the heats of solution and dilution determined in a blank experiment.

Table 1. Heats of hydrogenation of compounds *(1)* to *(4)* in methanol with 5 % of Pd/active charcoal as catalyst.

	Heat of hydrogenation [kcal/mol]	[kJ/mol]	Number of independent determinations
(1a)	20.5±0.7	86.2±2.6	2
(1b)	21.9±1.0	91.6±4.1	3
(1c)	23.0±1.4	96.4±5.9	3
(2)	45.0±0.5	188.1±1.6	3
(3)	40.5	169.4	1
(4)	48.1±0.7	207.2±2.8	3

Compounds *(1a)* to *(1c)* give an average heat of hydrogenation of 21.8±1.3 kcal/mol (91.2±5.4 kJ/mol) for an isolated C=N bond. As the degree of branching of the substituent bonded to nitrogen increases (primary < secondary < tertiary) so do the heats of hydrogenation, indicating increasing steric hindrance. The average value is in good agreement with the average heats of hydrogenation of 20.9±1.6 kcal/mol (87.6±6.7 kJ/mol) determined indirectly by *Jackman* and *Packham*[3] from the reaction enthalpy of the reduction of five *N*-alkylaldimines with $LiAlH_4$, but lies below the value of 24.3±2.7 kcal/mol (101.7±11.3 kJ/mol) determined with less accuracy by combustion calorimetry for *N*-isobutylidenepropylamine[4].

The heat of hydrogenation of an isolated N=C double bond is therefore lower than that of an isolated C=C double bond [the values measured for *ca.* 50 monoolefins[1] lay between 25.2 and 32.8 kcal/mol (105.2 and 137.3 kJ/mol)] but is higher than the heat of hydrogenation of an isolated C=O double bond [14.3±2.4 kcal/mol (59.6±10 kJ/mol) for five compounds[5]].

As expected, the 1,4-diimines *(2)* and *(3)* show a slight empirical delocalization energy (eDE) of 1.0±1.4 and 0.5 kcal/mol relative to *(1c)* and *(1a)*, respectively.

Relative to the average heat of hydrogenation of two isolated C=N double bonds and to the heat of hydrogenation of dissolved cyclohexene (26.8 kcal/mol)[6] the eDE of the cyclically conjugated pyrazine *(4)* amounts to 22.3±3.3 kcal/mol (93.3±13.8 kJ/mol) and thus corresponds to only 62 % of the eDE value for benzene (36 kcal/mol). The eDE of *(4)* was calculated from bond energy increments as 16 kcal/mol[7], 18 kcal/mol[8], and 38 to 57.4 kcal/mol[9], and determined as 14 kcal/mol[7] and 24.3 kcal/mol[10] by combustion calorimetry.

α-Glycosidic Linkage of D-Ribofuranose[**]

By *Richard R. Schmidt* and *Peter Hermentin*[*]

The stereoselective formation of glycosides and oligosaccharides from halogenoses is attributable primarily to neighboring group participation of vicinal acyloxy groups in halogen substitution[1]. The formation of β-anomers is therefore favored for the best-known sugars owing to the configuration at C-2[1a, 2]. Methods for the selective synthesis of α-anomers are practically unknown in the case of furanoses.

The steric control of halogen substitution due to vicinal acyloxy groups should also be achievable with nucleophilic groups in other positions. We considered the α-directing effect of the carboxylate group in furanosid- and pyranosiduronic acids to hold considerable promise. Our first task was to design syntheses for methyl 1-deoxy-1-chloro- and 1-deoxy-1-bromo-2,3-*O*-isopropylidene-β-D-ribofuranosiduronate *(1)*

and *(2)*[3]. Reaction of these compounds with methanol under Koenigs-Knorr conditions affords the α- and β-methyl furanosides *(4a)* and *(5a)* in the ratio 8:1 to 9:1[4]; the overall yield is practically quantitative. The disaccharides *(4b)*, *(4c)*, *(5b)*, and *(5c)* were obtained in yields that were almost as good and with a likewise excellent stereochemical result. So were the trisaccharides *(4d)* and *(5d)* on reduction of

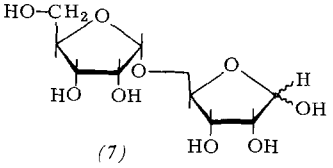
(4c)	83	93	−36.2 (2.150 [c])
(4d)	77	viscous oil	+ 9.2 (1.489 [c])
(6)	94	106	+20.8 (0.255 [c])
(7)	79	viscous oil	+64.8 (1.164 [d])



[a] All compounds gave correct elemental analyses.
[b] Isolated yield.
[c] Concentration in $CHCl_3$.
[d] Concentration in CH_3OH.

Since the anomeric ratios depend neither upon the halogenose used, nor upon the reaction temperature[5], nor upon the molar excess of the alcohol component[5], we assume the intermediacy of a dioxanorbornene *(3)* which is attacked mainly from the side facing away from the carboxylate group, *i.e.* from the α-side[6].

The carboxylate function serving as assisting and protecting group in this oligosaccharide synthesis can be reduced by $LiAlH_4$ to the hydroxymethyl group. In this way the protected trisaccharide *(6)* was obtained quantitatively from *(4d)*. However, the isopropylidene group can only be removed without

(6)

(7)

decomposition of the remaining compound if an α-glycosidic bond is present or the compound is unsubstituted at C-1. The unprotected α-linked disaccharide *(7)* is therefore accessible in good yield from *(4c)* by reduction of the carboxylate group, hydrogenolytic removal of the benzyl group, and acid-catalyzed removal of the isopropylidene group.

Fulvenes and Fulvalenes of a Heterocyclic System with 12π Electrons—Pseudophenafulvenes and Pentapseudophenafulvalenes[**][1]

By *Richard Neidlein* and *Arnold D. Kraemer*[*]

We recently reported the first synthesis of deeply colored cations[2] which we could prepare from 2-phenyl-5*H*-naphtho[1,8-*bc*]thiophen-5-one *(1)*[3]. We have now found an entry to deeply colored fulvenes *(3)* and fulvalenes [*(2)*, *(4)*] of this system.

(1)

(2)

(3): R = $R^1R^2C=$

(4): R =

Heating of *(1)* with 1,2,3,4-tetrachlorocyclopentadiene in acetic anhydride affords the deep blue crystalline fulvalene *(2)*. The compounds listed in Table 1 react analogously with *(1)* to form the fulvenes *(3a)* to *(3f)*.

Treatment of *(1)* in anhydrous benzene under nitrogen and at room temperature with an equivalent amount of diphenylketene gives compound *(3g)* with evolution of CO_2. Finally, *(1)* reacts with fluoreneketene to form the fulvalene *(4)* (spectroscopic properties given in Table 2).

Procedures

Syntheses of *(2)*: Compound *(1)* (2 mmol) and tetrachlorocyclopentadiene (2 mmol) are heated under reflux for 6 h in acetic anhydride (10 ml). The solvent is distilled off and the residue chromatographed with benzene on silica gel 60 (Merck). Recrystallization from benzene gives deep blue crystals; yield 21 %, m.p. 166 to 168°C.

Synthesis of *(3a)* to *(3f)*: Compound *(1)* (2 mmol) and one of the compounds listed in Table 1 (2 mmol) are heated under reflux for 10 min in acetic anhydride (7.7 ml) and glacial acetic acid (3.8 ml). Workup as described for *(2)*.

Synthesis of *(4)*: Compound *(1)* (2 mmol) is dissolved in anhydrous benzene (10 ml) under nitrogen. Fluoreneketene (2 mmol) is added and the mixture heated under reflux for 1 h. The residue obtained on removal of the solvent is chromatographed with benzene on silica gel 60 (Merck). Recrystallization from *n*-hexane gives blue-black needles with a metallic luster; yield 38 %, m.p. 169°C.

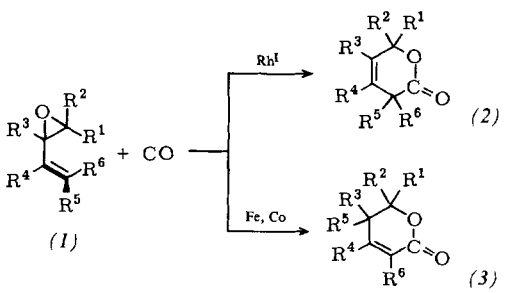
δ-Lactones by Carbonylation of Vinyloxiranes[1]



By *Rudolf Aumann* and *Horst Ring*[*]

No method is yet available for the direct linkage of carbon dioxide with 1,3-dienes after the manner of a Diels-Alder reaction to give δ-lactones[2].

However, transformation of 1,3-dienes into δ-lactones can be conveniently accomplished in two steps if the diene is first epoxidized and the epoxide *(1)* subsequently carbonylated in the presence of transition metals.

Fractional distillation gives the lactones in 10 to 75 % yield. Use of Rh^I catalysts affords β,γ-unsaturated lactones *(2)*, while Fe and Co catalysts lead predominantly to α,β-unsaturated lactones *(3)*. Competing reactions are: isomerizations to open-chain β,γ- and α,β-unsaturated ketones[3]; deoxygenation; and polymerization. R^3 = alkyl favors lactone formation; $R^5 = CO_2CH_3$ leads to almost quantitative deoxygenation with formation of CO_2; R^1 and R^6 = alkyl promotes formation of acyclic ketones.

(1) *(2)* *(3)*

5-Methyl-3,6-dihydropyran-2-one (2), $R^3 = CH_3$, $R^1 = R^2 = R^4$ to $R^6 = H$

Isoprene epoxide[4] (7.0 g, 83 mmol) and [1,5-cyclooctadiene-RhCl]$_2$[5] (0.2 g, 0.4 mmol) in anhydrous carbon tetrachloride (40 ml) are shaken under 150 atm of carbon monoxide for 50 h at 70 °C in a stainless steel autoclave. Fractional distillation of the yellow reaction mixture affords 5-methyl-3,6-dihydropyran-2-one (6.5 g, 75 %), b.p. 53—54 °C/0.1 torr, $n_D^{20} = 1.4762$. Reaction and workup must be performed with exclusion of air! ^{1}H-NMR (CCl_4): $\delta = 1.72$ ppm (br s, 3H), 2.88 (m, 2H), 4.64 (m, 2H), 5.26 (m, 1H). MS (70 eV): $m/e = 112$ (M^+, 72 %). IR (film): 1744, 1400, 1210, 1070, 796 cm^{-1}.

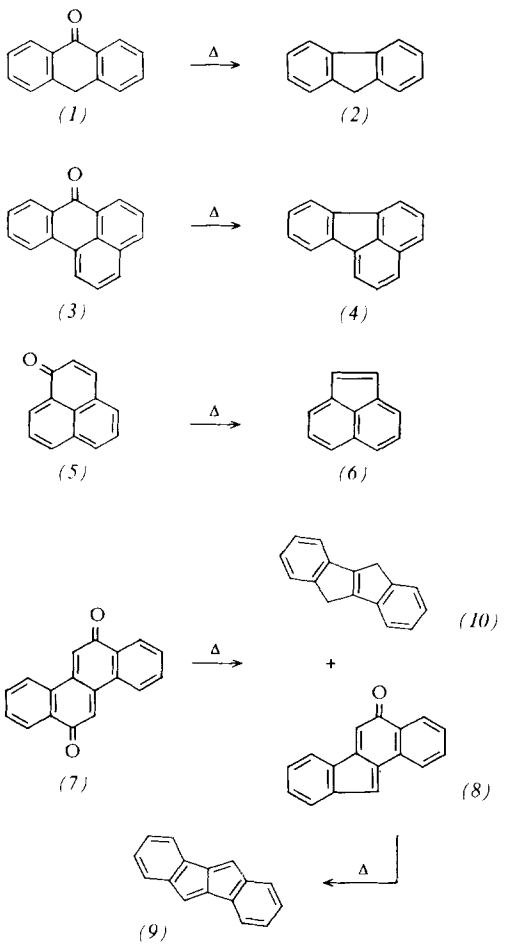
Elimination of CO from Cyclic Carbonyl Compounds by Flow Pyrolysis[1]



By *Gerhard Schaden*[*]

Some carbonyl compounds eliminate CO on heating, on electron impact, or in a glow discharge. In view of the facile mass-spectrometric elimination of CO from anthrone *(1)*, 7*H*-benz[*de*]anthracen-7-one *(3)*, 1*H*-phenalen-1-one *(5)*, and chrysene-6,12-dione *(7)*, thermal elimination of CO to give fluorene *(2)*, fluoranthene *(4)*, acenaphthylene *(6)*, and indeno[2,1-*a*]indene (dibenzopentalene) *(9)*, respectively, appeared to be promising.

Curie point pyrolysis at 900 °C and subsequent gas chromatography/mass spectrometry[2] demonstrated formation of the expected products. In order to produce larger amounts of material, *(1)*, *(3)*, *(5)*, and *(7)* were pyrolyzed in a high-vacuum flow apparatus. Compounds *(1)*, *(3)*, and *(5)* afforded *(2)*, *(4)*, and *(6)* in yields of 29 %, 42 %, and 41 %, respectively. The major product obtained on pyrolysis of *(7)*

[*] Priv.-Doz. Dr. R. Aumann and Dipl.-Chem. H. Ring

Orléansring 23, D-4400 Münster (Germany)

[*] Dr. G. Schaden
Fachbereich Pharmazie und Lebensmittelchemie der Universität
Marbacher Weg 6, D-3550 Marburg (Germany)

was found, by comparison of its UV, IR, and mass spectrum and of its gas chromatogram with those of authentic material[4], to be indeno[2,1-*a*]indene *(9)*. Small amounts of 5,10-dihydroindeno[2,1-*a*]indene *(10)* could also be detected. In addition, a slight amount of the primary pyrolysis product 5*H*-benzo[*a*]fluoren-5-one *(8)* was isolated. The compound likewise afforded *(9)* on Curie point pyrolysis.

Thus a simple entry is now available to indeno[2,1-*a*]indene (dibenzopentalene) *(9)*, which was formerly accessible only with difficulty. The method also suggests a new synthetic pathway to other molecules derived from pentalene or to the parent compound[5].

Procedure

Chrysene-6,12-dione *(7)*[6] (100 mg) was passed at 5×10^{-3} torr through a quartz tube (12 mm diameter, 70 mm length) filled with quartz wool and heated to 960 °C. The product was condensed in a trap cooled with liquid nitrogen[3]. Chromatography of the pyrolysis mixture (33 mg) on Al_2O_3 (activity grade 3, basic) with light petroleum/benzene afforded 12 mg (15 %) of pure *(9)*.

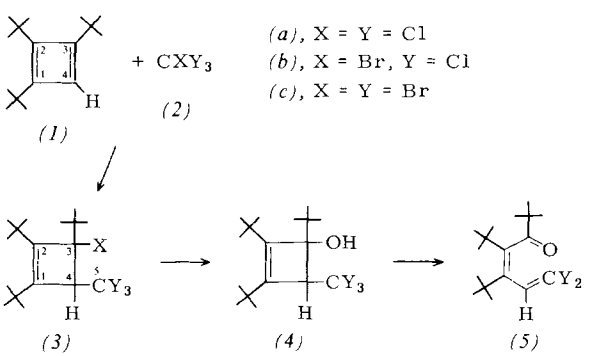
Diradical-Type Behavior of Tri-*tert*-butylcyclobutadiene[1][**]



By *Günther Maier* and *Wolfgang Sauer*[*]

The geometry of cyclobutadienes and the multiplicity of the parent hydrocarbon and its alkyl derivatives in the ground state have not yet been elucidated. The two aspects are interrelated, for most calculations require that square cyclobutadiene should have a triplet ground state, while a cyclobutadiene with a lower symmetry is predicted to have a singlet ground state.

The IR spectrum of unsubstituted cyclobutadiene suggests an "effectively square" structure[2]. Assuming a dynamic Jahn-Teller effect it becomes understandable why this molecule exhibits singlet character instead of the triplet character predicted on theoretical grounds[2].

In this communication we show for the first time that the converse behavior is also possible: tri-*tert*-butylcyclobutadiene *(1)*[3], for which a rectangular structure is to be assumed[4], can undergo reactions typical of a triplet molecule.

In spite of pronounced steric hindrance, tri-*tert*-butylcyclobutadiene *(1)* is capable of not only synchronous cycloadditions but also ionic additions in which it proves to be an exceptionally good nucleophile and a strong base[5]. We have classed the autoxidation of *(1)* to give an isolable dioxetane derivative[6] as a radical addition, but only with reservation because this unusually fast reaction does not appear to be affected by the necessary change of multiplicity. Meanwhile we have found that the autoxidation has parallels in the addition of tetrahalomethanes, which already proceeds at room temperature in the dark and without addition of radical initiators.

If cyclobutadiene *(1)*[3] prepared by matrix irradiation of 2,3,4-tri-*tert*-butylcyclopentadienone is allowed to react after thawing with an excess of carbon tetrachloride the product is found to contain no dimer of *(1)* but exclusively the adduct

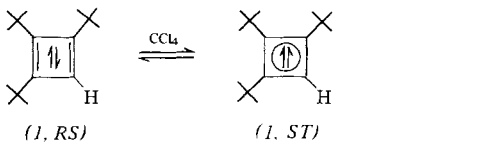
[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

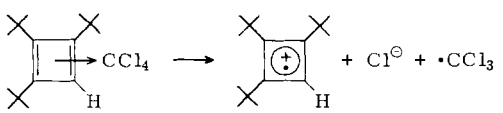
(3a) [^{1}H-NMR (CCl_4): $\tau = 6.09$ (1H), 8.60 (18H), 8.83 (9H); ^{13}C-NMR ($CDCl_3$): $\delta = 156.9$ ppm (C1 or C2), 149.5 (C1 or C2), 101.7 (C5), 82.2 (C3), 68.0 (C4, off resonance: d), 41.7, 34.5, 33.8, 31.4, 30.4, 28.4 (*tert*-butyl groups)].

The regiospecificity of the addition can be seen from the structure of the secondary products *(4a)* and *(5a)*. The alcohol *(4a)* is formed from *(3a)* on standing in air. Heating or chromatography of *(3a)* or *(4a)* leads to the stable end product *(5a)* [m.p. 96 °C; ^{1}H-NMR: $\tau = 3.68$ (1H), 8.69 (18H), 8.84 (9H); ^{13}C-NMR: $\delta = 213.5$ ppm, 149.8, 136.2, 133.2 (off resonance: d), 125.5, 44.5, 37.7, 34.4, 32.9, 32.3, 29.5; IR (CCl_4): 1680 cm^{-1}; correct elemental analysis].



The adducts formed by the action of bromotrichloromethane and tetrabromomethane[8] *(3b)* and *(3c)* are even more sensitive than *(3a)*[7]. On hydrolysis and subsequent ring cleavage, *(3b)* affords *(4a)* and *(5a)*. The CBr_4 adduct *(3c)* is transformed particularly readily *via* the alcohol *(4c)* into the acyclic ketone *(5c)* [m.p. 103 °C; ^{1}H-NMR: $\tau = 3.19$ (1H), 8.70 (9H), 8.73 (9H), 8.86 (9H); ^{13}C-NMR: $\delta = 213.3$ ppm, 149.3, 141.6 (off resonance: d), 138.5, 96.9, 44.7, 37.4, 34.4, 32.8, 32.5, 29.7; IR: 1680 cm^{-1}; correct elemental analysis].

Thus tri-*tert*-butylcyclobutadiene *(1)* undergoes reactions expected of a diradical. A possible mechanism, formulated for the reaction with CCl_4, is seen in the radical chain proceeding *via* the intermediate *(6)*.



(6)

Since the rectangular singlet and the square triplet state of *(1)* are of similar energy and CCl_4 can accelerate the interconversion of these species by a heavy atom effect[9], it is possible that the reactions observed might involve the triplet molecule *(1,ST)* in equilibrium with the rectangular singlet cyclobutadiene *(1,RS)*. However, the explanation may lie in the extremely good donor properties[5] of *(1)*. In analogy with similar reactions of amines[10] and electron-rich olefins[11], an electron transition in *(7)* with formation of the

(1, RS) *(1, ST)*

(7) *(8)*

radical *(8)* and the trichloromethyl radical is to be regarded as initiation reaction. Even if this explanation is valid, cyclobutadiene still occupies a special place since the electronic transition does not require additional excitation[12] by light or metal ions, in contrast to the case of amine/CCl_4 complexes[10].

Tetraaxial Conformation of 1,2,3,4-Tetra-*O*-benzoyl-β-D-xylopyranose[**]

By *Peter Luger*, *Gabriele Kothe*, and *Hans Paulsen*[*]

During our studies[1] on the conformation of β-D-xylopyranosyl halides in solution and in the crystalline state we had observed a 1,3-diaxial arrangement of two *O*-benzoyl groups to be particularly favorable from an energetic standpoint. The 1,3-diaxial interaction between two *O*-acyl groups is probably much smaller[2] than hitherto assumed[3]. Estimates[4] based on model compounds belonging to the 1,5-anhydropentitol series indicate the interaction between two *O*-benzoyl groups to be 0.2 to 0.6 kcal/mol smaller than that between two *O*-acetyl groups; the reason for this difference has yet to be explained.

[**] Conformational Analysis, Part 18.—Part 17: *P. Luger* and *H. Paulsen*, Carbohydr. Res., in press.

We have now examined the crystal structure of 1,2,3,4-tetra-*O*-benzoyl-β-D-xylopyranose, in which the $^4C_1$ form *(1b)* having four equatorial *O*-benzoyl groups coexists with the $^1C_4$ form having four axial *O*-benzoyl groups. In acetone the conformational equilibrium contains 28% of the $^1C_4$ form *(2a)* in the case of the tetraacetate but 50% of the $^1C_4$ form *(2b)* in the case of the tetrabenzoate[5].

The tetrabenzoate *(1b)*⇌*(2b)* crystallizes in the monoclinic space group $P2_1$ with four molecules in the unit cell. Two independent molecules are found in the asymmetric unit, so that 84 heavy atom positions have to be determined. The phase problem can be solved with the MULTAN program. Refinement is possible as far as an *R* value of 0.044. The two independent molecules are both seen to exist in the unusual tetraaxial conformation *(2b)*. The structure of one of the two molecules is shown in Figure 1.

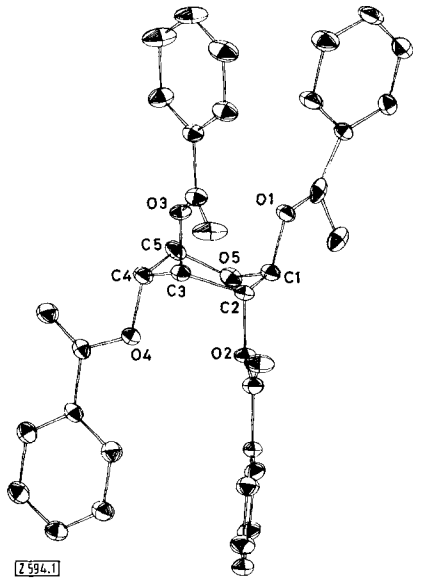

Fig. 1. Tetraaxial structure of 1,2,3,4-tetra-*O*-benzoyl-β-D-xylopyranose. Only one of the two independent molecules is shown.

Bond lengths and angles are very similar in the two molecules. Differences are observed in the orientation of the benzoyl groups relative to the ring. Thus the benzoyl groups at C2, C3, and C4 are twisted in a positive sense out of the normal position in one molecule but in a negative sense in the other. In the normal position the acylcarbonyl groups and the hydrogen atoms of the ring are orientated *syn*-parallel[1].

The distances between O1 and O3 and between O2 and O4 are 2.888 and 2.853 Å, respectively, corresponding to about twice the van der Waals radius of oxygen. The benzene rings of the benzoyl groups are not parallel but mutually inclined at various angles. Hence these groups will hardly be expected to exert attractive forces influencing the conformation.

Lithiomethyl(diphenyl)arsane Oxide, a New Reagent[**]

By *Thomas Kauffmann, Heinz Fischer,* and *Annegret Woltermann*[*]

Arsanes containing at least one alkyl group are cleaved by halogens (Cl_2, Br_2, I_2) at moderate temperatures according to equation (a) (halodemetalation); under these conditions, phenyl groups usually remain attached to the arsenic[1].

$$R_2As\text{–}Alk \xrightarrow{Hal_2} \begin{matrix} Hal & Hal \\ \diagdown & \diagup \\ & R_2As\text{–}Alk \end{matrix} \xrightarrow{\Delta T} \begin{matrix} Hal\text{–}Alk \\ + \\ R_2As\text{–}Hal \end{matrix} \qquad (a)$$

Since the $(C_6H_5)_2As$ is thus equivalent to Hal, the reaction of electrophilic organic compounds with lithiomethyl(diphenyl)arsane *(1)* followed by a dehalometalation should provide a method for the nucleophilic introduction of halogenated C atoms into organic compounds. Lithiomethyl(diphenyl)arsane oxide *(2)* could also be utilized in place of *(1)* because arsane oxides can easily be reduced to arsanes[1, 2].

$(C_6H_5)_2As\text{–}CH_2\text{–}Li$ *(1)*

$(C_6H_5)_2As(O)\text{–}CH_2\text{–}Li$ *(2)*

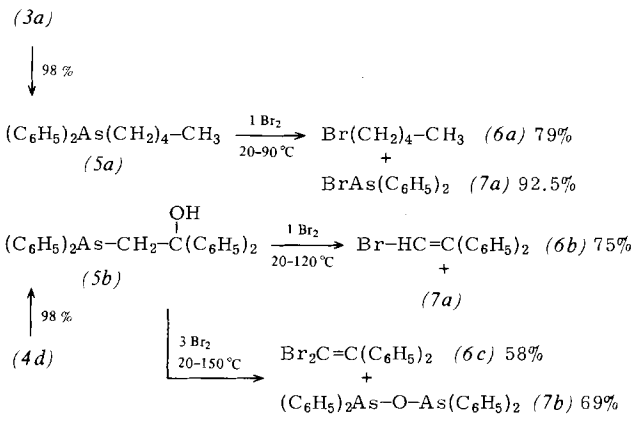
While attempts to synthesize *(1)* failed, the lithium compound *(2)*, which to our knowledge has likewise not been reported previously, is formed almost quantitatively on treatment of methyl(diphenyl)arsane oxide[3] with lithium diisopropylamide in THF at −40 °C for 30 min. Compound *(2)* reacts with organic halides or carbonyl compounds with CC linkage to give the products listed in Table 1.

$$(2) \xrightarrow{Hal\text{–}R} (C_6H_5)_2As(O)\text{–}CH_2\text{–}R \quad (3)$$

$$(2) \xrightarrow[2.\ H_2O]{1.\ R\text{–}CO\text{–}R'} (C_6H_5)_2As(O)\text{–}CH_2\text{–}C(OH)RR' \quad (4)$$

Table 1. Reaction of *(2)* with electrophilic compounds (molar ratio 1:1) in THF.

Reactant		Product	Yield [%]	M.p. [°C]
n-Butyl bromide [a]	*(3a)*,	R = $-(CH_2)_3CH_3$	72	84
Allyl bromide [a]	*(3b)*,	R = $-CH_2-CH=CH_2$	70	140–141
Benzyl bromide [b]	*(3c)*,	R = $-CH_2-C_6H_5$	61	139
n-Butyraldehyde [a]	*(4a)*,	R = H, R′ = $-(CH_2)_2CH_3$	60	141–142
Benzaldehyde [a]	*(4b)*,	R = H, R′ = $-C_6H_5$	82	159–160
Cyclohexanone [b]	*(4c)*,	R + R′ = $-(CH_2)_5-$	53	204–206
Benzophenone [a]	*(4d)*,	R = R′ = $-C_6H_5$	81	200–202



[a] Reaction temperature −40 to +65 °C; reaction time 1.25 h.
[b] Reaction temperature −40 to +20 °C; reaction time 1 h.

For the examples of compounds *(3a)* and *(4d)* we could demonstrate that $LiAlH_4$ reduction to the arsane [*(5a)*, oil, $n_D^{20} = 1.588$; *(5b)*, m.p. 94 to 96 °C] and subsequent bromolysis gives preparatively useful yields of organic bromides. Whereas

[**] New Reagents, Part 3.—This work was supported by the Fonds der Chemischen Industrie.—Part 2: *Th. Kauffmann, D. Berger, B. Scheerer,* and *A. Woltermann,* Chem. Ber., in press.

(3a) furnishes the expected pentyl bromide *(6a)*, compound *(4d)* affords either 1-bromo-2,2-diphenylethylene *(6b)* (m.p. 40 to 41 °C; lit. value[4] m.p. 41 to 42 °C) or 1,1-dibromo-2,2-diphenylethylene *(6c)* (m.p. 83 to 84 °C; lit. value[5] m.p. 83 °C), depending on the amount of bromine used.

Thus compound *(2)* can be utilized for stepwise chain elongation of alkyl halides by one C atom at a time. The available experimental data are not yet sufficient to provide a basis for general statements about the synthetic operations possible on carbonyl compounds with the aid of *(2)*.

The structures of the newly prepared compounds follow from the results of elemental analysis and from their spectroscopic data (MS, IR, ^{1}H-NMR).

Procedure for the chain elongation of n-butyl bromide

(All reactions performed in a nitrogen atmosphere and in anhydrous N_2-saturated solvents.)

a) *n*-Pentyl(diphenyl)arsane oxide: A freshly prepared solution of lithium diisopropylamide (17.6 mmol) in THF (40 ml) is added dropwise at −40 °C to a stirred solution of methyl(diphenyl)arsane oxide (4.16 g, 16.0 mmol)[3] in THF (250 ml). Methyl(diphenyl)arsane oxide precipitated at −40 °C dissolves during the reaction. After 30 minutes' stirring, *n*-butyl bromide (2.19 g, 16.0 mmol) in THF (10 ml) is added dropwise to the resulting clear yellow solution and the mixture warmed to 65 °C for 1 h. Water and chloroform are added to the almost colorless solution, the phases are separated, the aqueous phase extracted with chloroform, and the dried chloroform phases are evaporated down. The crystalline residue is worked up by column chromatography [silica gel, chloroform/ethanol (85:15)]: 3.6 g (72 %) of *(3a)* and 0.90 g (21 %) of methyl(diphenyl)arsane oxide are obtained.

b) *n*-Pentyl(diphenyl)arsane: After reduction of *(3a)* with $LiAlH_4$ (190 mg, 5.0 mmol) in THF (55 ml) at room temperature, work-up [by analogy with a), but without chromatography] affords 2.94 g (98 %) of the oily arsane which is homogeneous on chromatography.

c) *n*-Pentyl bromide: A solution of Br_2 (1.12 g, 7 mmol) in CCl_4 (5 ml) is added dropwise at room temperature to a solution of the arsane (2.10 g, 7 mmol) in CCl_4 (15 ml). A yellow solution is formed above a brownish red oil. The solvent is drawn off *in vacuo*, and the residue heated to 90 °C for 2 h. The resulting *n*-pentyl bromide (79 % according to gas chromatography) can be separated from chloro(diphenyl)arsane (92.5 %) by distillation.

Dipole Metathesis[**]

By *Klaus Burger*, *Helmut Schickaneder*, and *Claus Zettl*[*]

1,5 Dipoles of type *(1)*[1] are accessible by electrocyclic ring opening from 1,5-diazabicyclo[3.3.0]oct-2-enes[2]. The azomethinimine system present in *(1)* reacts with double bond systems by [3+2] cycloaddition. The cycloadducts fulfil the requirements necessary for a [3+2] cycloreversion. The initiation temperature depends upon the nature of the substituents at C-3 and C-4.

Reaction of *(1)* with ethylenetetracarbonitrile proceeds *via (2)* to give the stable 1,3 dipole *(3a)* and 4,4-bis(trifluoromethyl)buta-1,3-diene-1,1-dicarbonitrile *(4a)*. Reaction of *(1)* with fumaronitrile affords, apart from two stereoisomeric [3+2] cycloadducts [*(2b')*, *(2b'')*] and the cycloreversion products [*(3b)*, *(4b)*], a [3+2] cycloadduct *(5a)* derived from *(3b)* and fumaronitrile, which becomes the major product on use of an excess of fumaronitrile and at higher temperature. The reactions of *(1)* with dimethyl fumarate and maleate proceed in a similar manner; however, in these cases only one cycloadduct of structure *(2)* could, as yet, be isolated along with *(5)* in each case.

[a] Very weak. [b] In KBr. [c] As film.

The reaction sequence *(1)* → *(2)* → *(3)*, comprising a [3+2] cycloaddition and subsequent [3+2] cycloreversion, is a dipole metathesis. It provides a general entry to variously substituted azomethinimines *(3)* and a new 1,3-butadiene synthesis. The reaction *(1)* → *(2)* → *(3)* → *(5)* is a new variant of the dipolar cyclosynthesis.

General procedure

Compound *(1)* (4.10 g, 10 mmol) and a little more than an equimolar amount of a dipolarophile are heated in tetrahydrofuran (50 ml) under reflux for 2 to 5 d. After the solvent has been distilled off, any solids are removed and the remaining oil is fractionated by column chromatography with chloroform on silica gel.

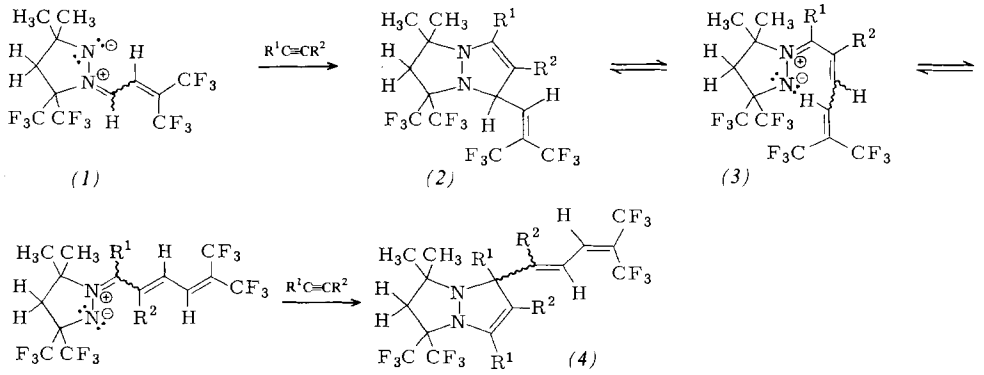
A General Procedure for Generating Conjugated 1,*x* Dipoles[**][1]

By *Klaus Burger, Helmut Schickaneder*, and *Claus Zettl*[*]

1,5 Dipoles of structure *(1)*[2] add substances with triple bonds to form 1,5-diazabicyclo[3.3.0]oct-2-enes *(2)*; with methyl propiolate the orientational isomers *(2a)* and *(2b)* are formed.

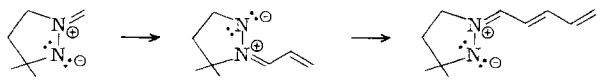


The cycloadducts *(2)* are able to undergo electrocyclic ring opening. The position of the equilibrium *(2)* ⇌ *(3)* depends upon the nature of the substituents R^1 and R^2[3]. While *(2a)* coexists with the 1,7 dipolar species *(3a)* in a 78:22 equilibrium at room temperature in $CDCl_3$, only the 1,7 dipolar species *(3b)* can be detected by ^{19}F-NMR spectroscopy in the case of the orientational isomer *(2b)*. The adduct of *(1)* with dimethyl acetylenedicarboxylate exists entirely as *(2c)* under the same conditions.

Table 1. Compounds *(2)* to *(4)* prepared. All compounds gave correct elemental analyses.

	R^1	R^2	Yield [%]	M.p. [°C]	IR [cm^{-1}]
(2a)	H	CO_2CH_3	49	107	1670 (br), 1572 [a]
(2c)	CO_2CH_3	CO_2CH_3	73	107	1752, 1690 (br), 1580 [a]
(3b)	CO_2CH_3	H	15	oil	1715, 1617 [b]
(4a)	H	CO_2CH_3	70	oil	1720—1670, 1650, 1587 [b]

[a] In KBr. [b] As film.



The 1,7 dipole *(3a)* likewise reacts with substances containing triple bonds as an azomethinimine; the major product *(4a)* can again undergo electrocyclic ring opening as a 1,5-diazabicyclo[3.3.0]oct-2-ene.

Repetition of the reaction sequence of [3+2] cycloaddition of an acetylene and electrocyclic ring opening permits construction of 1,*x* dipoles from 1,3 dipoles. During each extension step the dipole end shifts from one to the other nitrogen atom. The reaction is also a new type of oligomerization of acetylenes.

General procedure

Compound *(1)* or *(2a)*⇌*(3a)* (5 mmol) are heated under reflux for 3 d with an equimolar amount of a dipolarophile in anhydrous tetrahydrofuran (60 ml). After distilling off the solvent, the crude product is purified by column chromatography with hexane/chloroform (2:1) on silica gel. Further purification of *(3b)* was accomplished by preparative layer chromatography on ready-made plates (silica gel 60 F_{254}, Merck).

Preparation of Halogen-Bridged Cationic Dinuclear Complexes of Manganese and Rhenium[**]

By *Rüdiger Mews*[*]

While halogen-bridged anionic complexes of type *(1)*[1] and also neutral representatives of this type[2] are already known, the cations *(2)* isoelectronic with *(1)* have not previously been reported. To our knowledge a bridging function of individual halogens in cationic complexes has so far only been demonstrated for complexes of iron[3].

$[(CO)_5MXM(CO)_5]^-$ *(1)*, M = Cr, Mo, W

$[(CO)_5MXM(CO)_5]^+$ *(2)*, M = Mn, Re

We have now found that four possible pathways are available for the synthesis of complex cations of type *(1)*:

Reaction of the SO_2 complexes *(3)*[4] with carbonylmetal halides [eq. (a)] or with metal halides [eq. (b)].

$$[M(CO)_5SO_2]^+AsF_6^- + M'(CO)_5X \quad (a)$$
(3)

$$\xrightarrow[-SO_2]{} [(CO)_5MXM'(CO)_5]^+AsF_6^-$$
(4)

(a): M = M' = Mn, X = Cl
(b): M = M' = Re, X = Cl
(c): M = Mn, M' = Re, X = Br

$$2\,[M(CO)_5SO_2]^+AsF_6^- + X^- \quad (b)$$
(3)

$$\xrightarrow[-SO_2]{} [(CO)_5MXM(CO)_5]^+AsF_6^- + AsF_6^-$$
(4)

(d): M = Mn, X = I; *(e)*: M = Re, X = I

Reaction of carbonylmetal halides *(5)* with $AgAsF_6$ in SO_2 [eq. (c)]. Isolation of the intermediate SO_2 complexes is unnecessary in the synthesis of symmetrical cations.

$$2\,M(CO)_5X + AgAsF_6 \xrightarrow[-AgX]{SO_2} [(CO)_5MXM(CO)_5]^+AsF_6^- \quad (c)$$
(5) *(4)*

(f): M = Mn, X = Br; *(g)*: M = Re, X = Br

Exchange of bridging halogens in *(4)* with the aid of silver salts in SO_2 [eq. (d)].

$$(4f) + AgNCS \xrightarrow[-AgBr]{SO_2} [(CO)_5MnNCSMn(CO)_5]^+AsF_6^- \quad (d)$$
(4h)

Whereas reactions according to eq. (a) are complete within a few minutes, and those according to (c) and (d) within a few hours, it is difficult to obtain clean products according to eq. (b).

The strongly yellow manganese salts and their colorless rhenium counterparts are readily soluble in SO_2, but dissolve only sparingly with decomposition in organic solvents.

The complexes *(4)* are thermally stable up to more than 100°C. They were characterized by elemental analysis and their IR spectra. Although the spectra are complex in the CO stretching region, the absence of bands below 1900 cm^{-1} rules out bridging by carbonyl groups. The manganese compounds show a strong band at 700 cm^{-1} ($\nu_3AsF_6^-$). The splitting of this band observed with the rhenium compounds, and especially the chlorine derivative (715 m, 699 vs), indicates distortion of the AsF_6^- ion in the solid.

Procedure:

To a precisely stoichiometric mixture of the reactants (2 to 3 mmol each) at −196°C is condensed SO_2 (*ca.* 10 ml), and the reaction mixture is allowed to warm slowly. Reaction (a) is complete within a short time of reaching room temperature. A clear solution is obtained from which the pure products precipitate on evaporation of SO_2. In the case of reactions (b) to (d) the precipitated silver halide or alkali metal hexafluoroarsenate is filtered off before evaporation of the SO_2.

cis-Bis(dinitrogen)tetrakis(trimethylphosphane)chromium

By *Hans Heinz Karsch*[*]

Almost all transition metals are known to form complexes with molecular nitrogen, but in the case of some metals—nota-

[*] Dr. H. H. Karsch
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, D-8000 München 2 (Germany)

bly chromium—the examples are few and far between. The higher homologs, molybdenum and tungsten, on the other hand, readily bind nitrogen and can even coordinate two N_2-ligands[1, 2]. To our knowledge, such complexes with metals of the first transition series have not as yet been reported[3].

During investigations on the behavior of trimethylphosphane in the presence of low-valency metals[4] it was found that the complex *cis*-$[(CH_3)_3P)]_4Cr(N_2)_2$ *(1)* can be isolated on reduction of $CrCl_3$ with Mg in the presence of $P(CH_3)_3$ in tetrahydrofuran under nitrogen. Initially, reaction of $CrCl_3$ with $P(CH_3)_3$ in THF leads to an adduct *(2)*, which is crystallizable from ether as brown-violet needles (m.p. 144—147 °C).

$$CrCl_3 \xrightarrow{P(CH_3)_3/THF} [(CH_3)_3P]_3CrCl_3$$
(2)

On reduction of *(2)* with Mg in the presence of excess phosphane a deep blue solution is formed, from which crystalline *(3)*[5] (m.p. 51 °C) can be isolated.

$$(2) \xrightarrow{P(CH_3)_3/THF/Mg} [(CH_3)_3P]_3CrCl_2$$
(3)

(3) readily liberates $P(CH_3)_3$ in a vacuum at 25 °C and the crystals become brighter.

In the presence of $P(CH_3)_3$ under nitrogen, however, *(3)* can be reduced further to a deep brown solution:

$$(3) \xrightarrow[10\,^\circ C]{P(CH_3)_3/THF/Mg/N_2} \begin{matrix} (CH_3)_3P \\ (CH_3)_3P \\ (CH_3)_3P \\ (CH_3)_3P \end{matrix} \!\!\begin{matrix} \diagup \\ \diagdown \end{matrix}\!\! Cr \!\!\begin{matrix} \diagdown \\ \diagup \end{matrix}\!\! \begin{matrix} N\equiv N \\ N\equiv N \end{matrix}$$
(1)

After removal of volatile components, dark brown *(1)* can be extracted from the residue with pentane/$P(CH_3)_3$ and then isolated after removal of solvent at −30 °C. Complex *(1)* slowly decomposes at room temperature with liberation of N_2 and $P(CH_3)_3$. Its *cis*-octahedral structure is confirmed by spectroscopic findings.

The IR spectrum (Nujol) shows, in addition to the typical bands for coordinated $P(CH_3)_3$, two very strong bands of equal intensity at 1990 and 1918 cm^{-1} along with two weaker bands, also of equal intensity, at 562 and 513 cm^{-1}. The percentage decrease in frequency (P = 16.2) of $\nu_{N\equiv N}$ through fixation of the N_2 is twice as large as that in the known simple N_2-complexes of chromium, and thus about equally as large as in *cis*-$L_4M(N_2)_2$ with M = Mo[2] or W[1]. Since the isoelectronic carbonyl complexes *cis*-$L_4M(CO)_2$ (M = Cr,Mo,W)[6] prove to have corresponding P-values of the same order of magnitude, it is clear that there is an extensive analogy in the bonding of these complexes.

The *cis* array derived from the IR spectrum leaves the remaining positions of an octahedral configuration to the four phosphane ligands which is recognized in the $\{^1H\}$-^{31}P-NMR spectrum of *(1)* (24 MHz, toluene, −20 °C, H_3PO_4 ext.) as an A_2B_2 pattern ($^2J(AB)/(\nu_A - \nu_B) = 0.15$, similarly as, *e.g.* in *cis*-$[(CH_3)_3P]_4Fe(CH_3)_2$[7]) with $\delta P_A = +13.8$, $\delta P_B = +9.4$ ppm; $^2J P_A P_B \approx 16$ Hz. For $[(CH_3)_3]_4Cr(CO)_2$ two "signals" (1 : 1) were found at +16.5 and +5.4 ppm[6].

The bis(dinitrogen) complex *(1)* reacts with carbon monoxide to give $[(CH_3)_3P]_4(CO)_2$[6] *(4)* and $[(CH_3)_3P]_3Cr(CO)_3$[6] *(5)*.

$$L_4Cr(N_2)_2 + 2\,CO \xrightarrow[-2\,N_2]{} L_4Cr(CO)_2 \xrightarrow[-P(CH_3)_3]{CO} L_3Cr(CO)_3$$
(1) *(4)* *(5)*

L = $P(CH_3)_3$

Reduction of *(3)* with Mg at higher temperatures (above 15 °C) leads to a further brown, decomposable paramagnetic complex, which likewise contains nitrogen ($\nu_{N\equiv N}$ 1992 cm^{-1}) but, in addition, also a hydridochromium unit (νCrH: 1850 vs (br) cm^{-1}). The IR spectrum also shows bands for coordinated THF (1030 and 840 cm^{-1}) and $P(CH_3)_3$. Whether the CrH— function is formed by C—H cleavage of a $P(CH_3)_3$ ligand[4], as in the reduction of $FeCl_2/P(CH_3)_3$ with Mg, is still uncertain.

Electrochemical Reduction of 2,2,2-Trichloroethanols[**]

By *Andreas Merz*[*]

The reductive dehalogenation of vicinal dihalides has been studied very thoroughly[1]. In contrast, little is known about the concomitant reductive elimination of a halogen and an adjacent substituent bonded *via* an oxygen atom[2].

We have found that 2,2,2-trichloroethanols *(1)*, readily accessible for example by OH^- phase-transfer catalyzed addition of chloroform to aldehydes and ketones[3], can be reduced at a mercury cathode at −1.3 to −1.5 V in acidic electrolytes to give 1,1-dichloroolefins *(2)*; in some cases good yields are obtained (Table 1). 2,2-Dichloroethanols *(3)* arise as by-products. Suitable electrolytes are aqueous-organic solvent mixtures containing a mineral acid and an acidic supporting electrolyte, *e.g.* triethylammonium chloride. The low current yields due to competing evolution of hydrogen can be improved by admixture of tetraethylammonium *p*-toluenesulfonate.

The reaction also commands mechanistic interest on account of its analogy to the electrochemical dehalogenation of vicinal dihalides, which is regarded as a synchronous reaction because of its pronounced stereoselectivity[1b, 4].

$$\begin{matrix} R^1 \\ R^2 \diagup C\text{–}CCl_3 \\ \quad\; OH \end{matrix} \xrightarrow{2\,e^\ominus,\,-Cl^\ominus} \begin{matrix} R^1 \\ R^2 \diagup C{=}CCl_2 \end{matrix} + \begin{matrix} R^1 \\ R^2 \diagup C\text{–}CHCl_2 \\ \quad\; OH \end{matrix}$$
(1) *(2)* *(3)*

Since a C—O single bond is not attacked electrochemically at the working potentials employed[5], electron transfer must occur at the trichloromethyl group; in this case a dichloro-

[d] The compounds *(2)* prepared have been previously reported in the literature.

methyl anion [*e.g. (4a)*] is to be expected as reactive intermediate[6]. Protonation of *(4a)* by the solvent leads to *(3a)*, and nucleofugal elimination of the OH group—comparable with the second step of an E1cb elimination—to *(2a)*.

(1a) *(4a)*, X = OH *(4a')*, X = $OH_2^{\oplus}$ *(3a)* *(2a)*

Reduction of *(1a)* in a *neutral* medium (95% aqueous DMF, 0.1 M $Et_4N^+Br^-$, $E_{1/2}$ −1.76 V) leads exclusively to *(3a)*. Since H^+-catalyzed dehydration of *(3a)* to *(2a)* could be ruled out experimentally under the electrolysis conditions, the reduction must take a different course in an *acidic* medium: it appears that the protonated alcohol is then reduced, as also follows from the shift of the reduction potential by *ca.* 0.4 V towards positive values. The protonated OH group in *(4a')* is such a good leaving group that elimination to give *(2a)* greatly predominates. However, the existence of the zwitterion *(4a')* is unlikely in solution. Consequently, either a reaction from the adsorbed state on the electrode surface or a synchronous electron transfer and elimination not involving *(4a')* has to be assumed.

Procedure:

Electrolyte (1.5 M HCl, 0.1 M $Et_4N^+OTos^-$, 0.5 M $Et_3NH^+Cl^-$ in 95% ethanol) is transferred into the cathode and anode compartments of a divided electrolysis cell (*e.g.* according to ref. [1b]) fitted with a cooling jacket and having a magnetically stirred mercury cathode and a graphite anode. The cathode potential is adjusted[7] (cf. Table 1) and the resulting initial current is measured. After addition of *(1)* (*ca.* 0.35 M) electrolysis is continued until the electrolysis current falls below the previously measured initial current. After pouring the electrolyte from the cathode compartment into water the product is extracted with pentane and distilled.

[2+2]- and [4+2]-Cycloadditions of Arylazoalkenes to Diphenylketene[1]

By *Sven Sommer*[*]

It is known that (*E*)-azobenzenes react only very slowly with diphenylketene *(2)* to give 1,2-diazetidinones, even under drastic conditions (100 °C, in substance)[2]. Arylazocarbonyl compounds, on the other hand, react exothermally with *(2)* in solution to give [2+2]-[3], and in one case also [4+2]-cycloadducts[3c]. We have now investigated how an olefin bond conjugated to an arylazo group affects the reaction of arylazoalkenes *(1)*[4] with *(2)*.

In our studies, we found that compounds *(1a)*—*(1g)*, unlike the (*E*)-azobenzenes, react with *(2)* (1:1 in benzene) to give 1:1 cycloadducts within 2 h to a week, even at room temperature. The reactions of *(1a)*, *(1b)*, and *(1e)* with *(2)* lead exclusively to the [2+2]-cycloadducts *(3a)*, *(3b)*, and *(3e)* within the ^{1}H-NMR detection limit, while only the [4+2]-cycloadducts *(4f)* and *(4g)* are formed in the reaction of *(1f)* and *(1g)* with *(2)*. *(1c)* and *(1d)* each react with *(2)* to give two cycloadducts, namely *(3c)* and *(4c)* (67:33)[5] and *(3d)* and *(4d)* (83:17), respectively[5].

[a] $\nu_{C=O}$(ring), $\nu_{C=O}$, $\nu_{C=C}$. [b] $\nu_{C\equiv N} = 2215\ cm^{-1}$. [c] δ-value [ppm], in $CDCl_3$ rel. to TMS int. [d] δ_{CH_3}, $\delta_{5\text{-H}}$, $\delta_{6\text{-H}}$, δ_{OCH_3}. [e] $J_{5,6} = 13.4$ Hz. [f] $J_{5,6} = 13.8$ Hz. [g] $\nu_{C=O}$(ring), $\nu_{C=O}$, $\nu_{C\equiv N}$ (very weak). [h] Hidden by aromatic signals. [i] $\nu_{C\equiv N} = 2255\ cm^{-1}$. [j] $J_{5,6} = 4.6$ Hz. [k] $J_{5,6} = 4.1$ Hz. [l] $J_{5,6} = 4.0$ Hz.

If acetonitrile, which is more polar than benzene, is used as medium in the reaction of *(1c)* with *(2)* the adduct ratio is shifted in favor of the four-membered ring *(3c)* [*(3c)*:*(4c)* = 81:19][5]. Interconversion of the compounds *(3)* and *(4)* does not take place under the reaction conditions. However, on treatment with small amounts of trifluoroacetic acid in dichloromethane the four-membered rings *(3a)*—*(3d)* rearrange in high yields into the six-membered rings *(4a)*—*(4d)*.

It should be pointed out that the configuration at the C=C double bond of compound *(1)* in the adducts unaltered in [2+2]-cycloadditions of the (*E,Z*)-isomeric azoalkenes *(1d)* and *(1e)*[4] to *(2)*. On treatment with catalytic amounts of trifluoroacetic acid, compound *(3e)* rapidly isomerizes to *(3d)*, which subsequently rearranges slowly into the six-membered ring *(4d)*.

The structures of the cycloadducts follow from correct CHN-analyses and from IR-, ^{1}H-NMR-, and ^{13}C-NMR-data (Table 2). The regiochemistry of the four-membered ring adduct, which cannot be clarified by these techniques, follows from the hydrolysis of *(3b)* to the well-known 2,4,4-triphenyl-1,2-diazetidin-3-one[3a].

The above findings show that arylazoalkenes behave similarly to α,β-unsaturated carbonyl compounds[6] towards *(2)*. Both heterodiene systems are capable of forming [2+2]- and [4+2]-cycloadducts with *(2)*, six-membered ring formation predominating over four-membered ring formation with increasing donor capacity of the substituents on the C=C bond of the heterodiene. The cycloadditions described here render possible a simple entry to the previously unknown *N*-vinyl-1,2-diazetidinone system and to novel 4,5-dihydro-2*H*-pyridazin-3-one derivatives.

[4] With the exception of *(1d)* and *(1e)* all the azoolefins mentioned here have already been described in the literature. *(1d)* (m.p. 92—93°C, from methanol) and *(1e)* (m.p. 127—128°C, from methanol) were synthesized according to a general experimental procedure for the preparation of 3-arylazocrotononitriles[7]. Separation of the isomeric mixture [*(1d)*:*(1e)* = 82:18], which was obtained in 75% yield, was achieved by column chromatography on silica gel (hexane/ethyl acetate 3:1). The procedure cited here [7], contains no information about the stereochemistry of the azoalkenes thus prepared, nor about the occurrence of stereoisomers.
[5] The product ratio was determined from the integrals of the methyl signals in the ^{1}H-NMR spectrum of the crude solution.

Reviews

Abstracts of selected progress reports and review articles

Picosecond chemistry is the subject of a review by *G. E. Busch* and *P. M. Rentzepis*. A picosecond (ps) is 10^{-12} s. In most measurements the sample was irradiated with a laser pulse of a few ps duration, and investigated before, during, and after this excitation. Novel areas of application include, *inter alia*, the behavior of solvated electrons in solvents and of free electrons in water, the rapid relaxation of the triphenylmethane dyes crystal violet and malachite green, as well as the photobiochemistry of reaction centers in bacteriochlorophyll. The photosystems in chloroplasts and the primary processes of vision were also investigated by this technique. [Picosecond Chemistry. Science *194*, 276—283 (1976); 39 references]

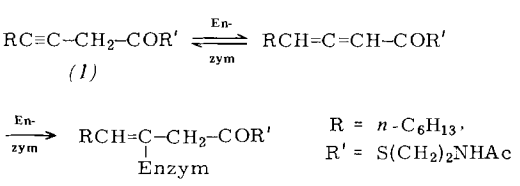
[Rd 902 IE—F]

Reviews of papers published during 1974 form the contents of a volume of the Journal of Organometallic Chemistry. *J. Boersma* deals with zinc and cadmium, *M. I. Bruce* reports on the structure of organotransition metal complexes, *P. M. Treichel's* themes are manganese, technetium, and rhenium, *D. J. Darensbourg* and *M. Y. Darensbourg* cover chromium, molybdenum, and tungsten, and *M. E. Howden* and *R. D. W. Kemmitt* report on cobalt, rhodium, and iridium. [Annual Surveys covering the year 1974. J. Organomet. Chem. *115*, 1—16, 17—176, 177—220, 221—325, 327—415 (1976); 47, 406, 153, 364, 377 references]

[Rd 903 IE—F]

Inorganic pyro-compounds of type $M_a[(X_2O_7)_b]$ are reviewed by *G. M. Clark* and *R. Morley*. Compounds with this stoichiometry exhibit an extraordinary variety of structures. Thus, $Ca_2Ta_2O_7$ is a complex with the continuous pyrochlorite structure, $Y_2Pb_2O_7$ has a continuous oxide structure of the defect fluorite type, $Na_2Mo_2O_7$ contains an infinite unidimensional $Mo_2O_7^{2-}$ chain. Especially interesting are the island structures, in which $X_2O_7^{2-}$ is a discrete pyroanion and for which those with X = As, Be, Cr, Ge, P, S, Si and V have been demonstrated. These pyro-compounds crystallize with structures like $Sc_2Si_2O_7$ or $K_2Cr_2O_7$. The review contains numerous informative diagrams of molecular and crystal structures as well as summarized data on pyro-compounds in which the island structure of the anion has been confirmed. [Inorganic Pyro-compounds $M_a[(X_2O_7)_b]$. Chem. Soc. Rev. *5*, 269—295 (1976); 144 references]

[Rd 904 IE—F]



Nuclear reactions with heavy ions are the subject of a review by *J. R. Huizenga*. Interest in these reactions evolved from the predicted increased stability of elements with atomic numbers between 110 and 126, which it was hoped could be generated with the aid of heavy ions. The article deals with the interactions that can take place between two large complex nuclei, with emphasis on the recently discovered strongly damped collision process. [Nuclear Reactions Revisited with Very Heavy Ions. Acc. Chem. Res. *9*, 325—333 (1976); 56 references]

[Rd 907 IE—L]

An effective method for designing synthetic approaches to natural products is afforded by studying degradation processes in the mass spectrometer. The method has been used successfully by *T. Kametani* and *K. Fukumoto* in the case of protoberberine, phthalideisoquinoline, spirobenzylisoquinoline and quinazolinocarboline alkaloids, as well as olivacine and yohimbine. The most important types of mass spectrometric fragmentations are CC bond cleavages, concerted cleavages of the retro Diels-Alder type, and cleavages involving heteroatoms; the reverse reactions carried out "chemically" were used in the alkaloid syntheses. [Total Synthesis of Natural Products by Retro Mass Spectral Synthesis. Acc. Chem. Res. *9*, 319—325 (1976); 39 references]

[Rd 906 IE—L]

Suicide inactivators for enzymes are a special type of inhibitors according to *R. H. Abeles* and *A. L. Maycock*. Unlike a classical inhibitor, which resembles the natural substrate of an enzyme, a suicide inactivator must be transformed by the enzyme into the active form. This binds covalently and irreversibly to the active site of the enzyme, which thus becomes

inactive.—An example is the suicide inactivation of β-hydroxydecanoyl thioester dehydrase by the ester *(1)*. Suicide inactivators are suitable for probing the structure and function of enzymes and ought to be useful in the development of drugs. [Acc. Chem. Res. *9*, 313—319 (1976); 28 references]

[Rd 905 IE—L]

"Uncommon" amino acids in plants forms the subject of a review by *A. Bell*. Such amino acids include all those which are not fragments of proteins and which do not occur in the "usual" metabolic pathways. More than 200 of them are already known; some make up a considerable portion of the plant material. Little is known about their biosynthesis, their metabolism and their biological importance. Only a part of them are directly related to the "usual" amino acids, many are formed in completely novel metabolic pathways. In contrast to the ubiquitous "usual" amino acids, the "unusual" types are suitable for phylogenetic studies. Several of them exhibit special biological, in part toxic action, which would indicate their usefulness in medicine. The "unusual" amino acids might serve as protective agents in the plant's growth, either as a deterrent against consumption by animals or against competing germinant seeds of other plants. ["Uncommon" Amino Acids in Plants. FEBS Lett. *64*, 29—35 (1976); 31 references]

[Rd 908 IE—R]

Immobilized enzymes form the theme of an article by *K. Mosbach*. The past few years have seen great progress in the coupling of biologically important substances, and of enzymes, to insoluble carriers. With such immobilized enzymes kinetic parameters can by investigated under conditions in

which the free enzymes undergo undesirable side reactions (association, self consumption). Furthermore, biologically relevant model systems can be constructed, for enzymes are not freely mobile in their natural environment but are bound to membranes or surrounded by a gel-like phase. In addition, immobilized enzymes are gaining increasing importance for preparative and analytical purposes. Immobilized coenzymes have general utility as affinity adsorbents. [Immobilized Enzymes. FEBS Lett. *62* (Suppl.), E80—E95 (1976); 84 references]

[Rd 909 IE—R]

DNA ligases of eukaryotes are reviewed by *S. Söderhäll* and *T. Lindahl*. These enzymes act together with the DNA polymerases in replication and the repair of strand breaks. Mammalian enzymes differ from the better known enzymes of microorganisms. Thus, only ATP has been detected as energy donor, whereas bacterial enzymes also use NAD^+. In contrast to microorganisms, mammalian cells contain two different DNA ligases. The dominating enzyme I is relatively large (175—200000 Dalton) and occurs mainly in dividing cells. It can couple growing DNA fragments *in vitro*. Enzyme II, with a molecular weight of 85000 Dalton, occurs only in small amounts (5—20%). It is less specific than enzyme I. A ligase similar to enzyme II has also been detected in mitochondria. [DNA Ligases of Eukaryotes. FEBS Lett. *67*, 1—8 (1976); 73 references]

[Rd 911 IE—R]

A review of methods for the analysis of kinetic data in biochemistry is given by *M. Markus, B. Hess, J. H. Ottaway*, and *A. Cornish-Bowden*. The review is based on discussions held at a conference devoted to this theme. The advantages and disadvantages of the total trace of the curve as well as the various methods for the linearization of kinetic functions are discussed. [The Analysis of Kinetic Data in Biochemistry. A Critical Evaluation of Methods. FEBS Lett. *63*, 225—230 (1976); 59 references]

[Rd 910 IE—R]

BOOK REVIEWS

Werkstoff Glas (Glass as a Material). By *K. Kühne*. Akademie-Verlag, Berlin 1976. 1st edit., 329 pp., various figs., paperback, *ca.* 12.50 DM.

The history of glass goes back many thousands of years. Scientific penetration into glass technology began at the end of the nineteenth century (*e.g.* by *Schott* at Jena), but one can validly speak of a science of glass only from about 1950. Today glass with almost any desired properties can be made.

After a short section of the history of glass the book discusses "the vitreous state", in which, *inter alia*, views on the structure of glass and its segregation are discussed. The following chapter describes the glass-forming systems and applications of glass, while Chapter 4 concerns the properties of glasses and the possibilities of their modification. The next (very extensive) chapter deals with the production and working of glass. Finally there is a short section on "Special Glasses", followed by literature references and several indexes.

The author has succeeded in giving a very good and easily readable review of the field. The presentation is perhaps a little too classical, and in some places one could have hoped for the latest results obtained by modern methods of investigation. Nevertheless, the book can be very warmly recommended to all interested in glass, *e.g.* to students at universities or technical colleges and to scientists in industry.

G. H. Frischat [NB 356 IE]

Reaktionen der organischen Chemie (Reactions of Organic Chemistry). By *H. Krauch* and *W. Kunz*. 5th, revised and extended edit. By *W. Kunz* and *E. Nonnenmacher*. Dr. Alfred Hüthig Verlag, Heidelberg 1976. xxxi, 875 pp., linen, DM 134.—.

The original "Named Reactions" title of "Krauch-Kunz" was generalized to "Reactions of Organic Chemistry" already in the 3rd edition (1966), when some important reactions not known by their discoverers' names were added, with brief descriptions and literature references. In the present 5th edition this tendency to broaden the scope has led to a changeover from the mode of arrangement by authors' names to arrangement by the description of content. For example, the degradation processes of carboxylic acids due to *Barbier-Wieland*, *Gallagher-Hollander*, *Krafft*, and *Mieschер* are no longer scattered all over the text but are treated one after the other (pp. 216ff.). Simultaneously with this rearrangement, the authors have tried to make the reaction terminology more standardized, with dubious success, judging by the lack of consistency in the descriptions selected. Thus, the degradation of carboxylic acids according to *Simonini* and to *Hunsdiecker-Borodin* is treated under "Decarboxylation of Silver Salts" (p. 700), and ring syntheses from α,ω-difunctional alkanes are discussed in one place as cyclization (*Gustavson-Hass*, p. 302) and in another as ring closure (*Ladenburg*, p. 687), and finally also as propane ring closure (*Freund*, p. 650), starting from the educt. Fortunately, the volume contains not only an extensive author and subject index but also an index of named reactions, so that "Krauch-Kunz" can still be used, as before, for reference to a reaction under its "trivial name(s)".

Along with the new principle of arrangement in the 5th edition, some of the descriptions of the reactions have been revised and the references have been extended, apparently to the end of 1974. Only 15 new reactions have been added among the present total of *ca.* 580. Even if we allow that the choices made by the authors must necessarily be subjective, we may surely ask whether the last ten years have not brought forth a larger number of "named" reactions which at the same time supersede older processes. In this respect the current revision has not always succeeded in eradicating the patina of age. This also appears in the often old-fashioned nomenclature, although actual errors, such as the description of the bicyclobutonium ion by mesomerism of two cations (p. 686), are refreshingly rare. In all, value of "Krauch-Kunz" as a revision text has decreased, but for rapid information about a reaction, and for gaining an entry into the primary and secondary literature, this volume remains irreplaceable.

Ernst Schaumann [Nb 357 IE]

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (dec.), and *W. M. Weigert*. Vol. 10: Dentalchemie bis Erdölverarbeitung. Verlag Chemie, Weinheim 1976. 4th edit., xvi, 714 pp., 345 figs., 228 tables, half-linen, subscription price DM 345.—; final price DM 385.—. Cumulative index to vols. 7 to 9; 133 pp., DM 38.—.

The present volume[*] of the new Ullmann is the fourth of the alphabetically arranged main Parts dealing with the products and processes of the chemical industry and of related important fields. A considerable proportion of this volume is devoted to Natural Gas [Erdgas], Petroleum [Erdöl], and Petroleum Processing [Erdölverarbeitung] (excluding formation, exploration, occurrence, and recovery, which are dealt with in volume 11; total 132 pp.), and to Iron and Iron Compounds [Eisen, Eisenverbindungen] (together 124 pp.); steels, steelmaking, iron alloys, and cast iron, however, are not dealt with here but separately under their own headings. Another extensive entry is Enzymes [Enzyme] (86 pp.), where one chapter deals with the immobilized enzymes, which are particularly important today; further chapters are devoted to, *inter alia*, the industrial use of enzymes, enzyme analysis, and enzyme therapy. Pharmacy in its wider sense is also represented, *viz.* by Dental Chemistry [Dentalchemie] (27 pp.), Dermatological agents [Dermatotherapeutica] (9 pp.), Disinfectants [Desinfektionsmittel] (18 pp.), Diagnostic agents [Diagnostica] (38 pp.) and Diuretics [Diuretica] (6 pp.). Among the entries on organic chemical precursors and intermediates included in this volume we may mention Dialkyl Sulfates [Dialkylsulfate] (12 pp.), Dicarboxylic Acids [Dicarbonsäuren] (9 pp.), Dioxane [Dioxan] (4 pp.), and Epoxides [Epoxidverbindungen] (18 pp.), and from the sector of dyes and precursors, we have Disperse Dyes [Dispersionsfarbstoffe] (11 pp.), Printing Inks [Druckfarben] (13 pp.), as well as Diazo Compounds and Diazo Reactions [Diazoverbindungen und Diazoreaktionen] (24 pp.). Under Fertilizers [Düngemittel] (56 pp.) are summarized mainly the various aspects of industrial application; the technology of the production of individual fertilizers is, however, described under the appropriate chemical keywords. Other applied fields dealt with in this volume include Thin Layers [Dünne Schichten] (12 pp.), Enamels [Email] (14 pp.), and Emulsions [Emulsionen] (25 pp.).

As in the previous volumes, the authors of the individual articles are experts mainly from industrial circles. What should be emphasized is the unfailing expertise of the editors in achieving a balanced and clearly arranged presentation of topics in spite of the by no means small number of authors. Especially useful are the numerous charts containing, *e.g.* material constants and economic data, as well as a list of uses, as in the chart of fertilizer types (with data on composition and application) and the two tables of radiopharmaceuticals (though here the half-lives and energies of the individual isotopes would also have been useful). The work is up to date too: in the entry on Noble Gases [Edelgase] (42 pp.) there is a 1975 reference according to which krypton difluoride and particularly $[KrF]^+[AuF]_6^-$ are extremely good fluorinating agents.

Alongside Volume 10 a cumulative index for the first alphabetical Volumes 7 to 9 has been published in German and English. It is planned to publish cumulative indexes immediately after the appearance of successive sets of three volumes, *i.e.* the next cumulative index (for Volumes 7 to 12) will be available with Volume 13. These cumulative indexes are most useful for cross-referencing, for they are subdivided in great detail; for example, the present index lists about 9000 entries.

Ulfert Onken [NB 361 IE]

Chiral Derivatives of Achiral Molecules: Standard Classes and the Problem of a Right-Left Classification

By Ernst Ruch[*]

Chemistry judging by its applications, physics according to its methods, and heavily reliant upon the tools of mathematics—that is what makes theoretical chemistry. And yet that is where its strength lies—in the variety of these sciences. It is quite natural that, in answer to specific problems, results and methods can sometimes be developed whose scope extends far beyond the original application. Rather it is a mark of quality if consequences can be found in chemistry and physics and the pathway leads *via* new mathematical procedures and concepts. Regrettably, any publication aiming to present such aspects will usually encounter little resonance since the linguistic confusion in science, its disciplines, and subdisciplines, lies like a veil over our understanding. The author nevertheless wishes to attempt to present, in a series of articles, results of research into chemical themes in a manner designed to appeal to the interest of chemists, without neglecting interdisciplinary aspects. All that is required to understand the argumentation is a lively interest.

The first two articles are concerned with the chirality of molecules, and in particular with questions relating to the chirality phenomenon of molecules in the framework of molecular classes. In view of the algebraic nature of the mathematical methods adopted, it is not surprising that precise statements result. It appears of primary interest to establish the degree to which such statements can be considered valid for molecular models or molecules themselves.

1. Chirality

The intuitive concept that we call symmetry refers to geometrical properties of an object. It can be mathematically defined in terms of a "symmetry group", *i.e.* by the entire set of rotation and reflection operations ("symmetry operations") leading to no visible change of the object and its spatial position.

An object that differs from its mirror image[**] is called chiral, otherwise it is achiral. In other words, it is termed achiral if only its position in space changes on reflection or rotation-reflection, but chiral if a different object is produced. Thus for achiral objects there are symmetry operations involving a reflection. Hence, chirality indicates the absence of certain symmetry elements—the symmetry of an object contains neither mirror planes, nor improper symmetry axes, nor a center of symmetry.

Our approach shows that it is reasonable to classify the symmetries themselves and accordingly to distinguish between chiral and achiral symmetries. Thus a symmetry shall be called chiral if the symmetry group contains no reflection operation, and shall otherwise be called achiral. An achiral symmetry will contain chiral subsymmetries; "no symmetry" is a special case of chiral symmetry.

The definition of chirality as a property of objects therefore simplifies to the trivial statement: *An object is called chiral*

[*] Prof. Dr. E. Ruch

Holbeinstrasse 48, D-1000 Berlin 45 (Germany)

[**] The "mirror image" of an object is once again an object generated from the original one by any reflection operation, *e.g.* by reflection in an arbitrarily chosen plane.

or achiral depending upon whether its full symmetry is chiral or achiral.

Molecules are objects which can be successfully studied experimentally and theoretically in terms of chirality. It proves advantageous to discuss various examples having common features, *i.e.* various kinds of molecules from suitably selected classes. It is hardly surprising that a phenomenon observable for various kinds of objects will, when referred to a suitably chosen set, provide conclusions and insights which will not be forthcoming from analysis of a single case.

Sections 2 to 4 of this article are concerned generally with the type of such sets. The principal factors determining the choice of set type are ready susceptibility to mathematical analysis and maximum applicability to chemical problems. These requirements are satisfied by sets of objects which we call "standard classes". There exists a—predominantly algebraic—theory of the chirality of standard classes[1, 2], of the related problems of classification[3], and of quantum mechanical models concerned with specific chirality phenomena on the pattern of the algebraic theory[4, 5]. The results of these studies increase in value when viewed against the background of an extensive area of application, and once it has been established to what extent the objects investigated serve as good models for molecules and that real molecules themselves can be objects of such sets. Preliminary applications will be considered in Sections 5 and 6[6].

2. Symmetry and Chirality of Objects of a Special Class

In order to pave the way for an understanding of the term "standard class" to be defined later, let us first consider a set of objects consisting of a uniform skeleton having the symmetry of a regular tetrahedron and spheres of varying sizes located at the tetrahedral corners (Fig. 1).

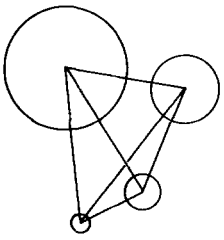

Fig. 1. An example taken from the set of objects having a regular tetrahedral skeleton.

The symmetry of the objects is that of the skeleton if all four spheres have the same diameter. Otherwise the symmetry of the objects will differ from that of the skeleton and depend upon the number of spheres having the same or different diameters; it does not depend upon the size of differences in the diameter of the spheres. In total there are five possible object symmetries which are depicted in Figure 2. The corresponding partition diagram, in which the boxes in a row each represent spheres of the same size, is shown alongside each picture.

The objects shown in Figure 2 are achiral if two or more spheres have the same diameter. Hence the only chiral object is seen at the bottom of the Figure. No two spheres are identical.

Symmetry operations on the tetrahedron subject the objects to rotations or rotation-reflections by which the skeleton is brought into coincidence with itself. When performed on a spatially rigid skeleton, such operations are manifested in an interchange of the spheres. These interchanges or permutations can therefore be used to describe the given rotations and rotation-reflections of the objects.

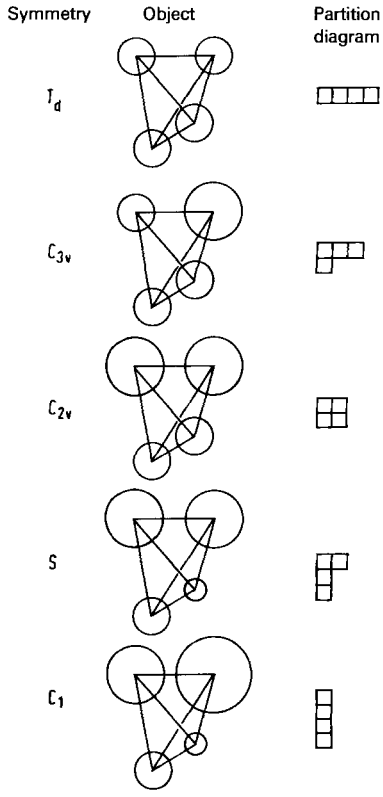

Fig. 2. The partitioning of sphere diameters is characteristic of the five possible object symmetries. It is depicted by partition diagrams in which boxes in the same row represent spheres of equal size and boxes in different rows correspond to spheres of differing size.

To what extent can the concept of the object be extended in the present case without falsifying conclusions about the symmetry of the objects?

The limitation to spheres of various sizes is certainly unnecessary; ligands such as circular cylinders, cones, trigonal prisms, *etc.*, can also be included. The symmetry of an object is then determined solely by the identity or non-identity of ligands at the various sites provided that the site symmetry is not impaired by the ligands, *i.e.* the mirror planes of each tetrahedral corner coincide with the mirror planes of the ligand located there. This condition defines the type of ligands permitted and the manner of their attachment. The partition diagrams of Figure 2 are still characteristic for the symmetry of the objects, the boxes in a given row not necessarily corresponding to spheres of equal size but to ligands of the same kind. However, the relation between object symmetry and ligand partition no longer applies if ligands are present which possess only one or two mirror planes or if ligands having C_{3v} symmetry are twisted out of the required orientation.

Ligands of the same and of different kinds located at the corners of a tetrahedron as a sufficient criterion for the symmetry of the objects in a class, in which the objects having

spheres of equal and different size are symmetry-determining, is what characterizes our class type. It is therefore reasonable to cast aside all prerequisites which are not necessary for this criterion. It may readily be seen that the required T_d skeletal symmetry for objects with ligands of one single type imposes a constraint upon the ligand type admitted that corresponds to the condition of site symmetry. If the attachment of the ligands is the same in all objects as in the objects having ligands of a single type the proper symmetry is guaranteed, also in any object of the class. However, to achieve this symmetry property the ligand attachment need not necessarily be the same in all objects. For the more general concept of a class the sufficient requirement is that the symmetry of an object remains unchanged on replacing ligands of different kinds by spheres of different sizes.

This formulation has many advantages. Referring neither to the ligands nor to the skeleton directly, it retains its validity even when a distinction between skeleton and ligand is not unequivocally possible or is to be avoided. It is applicable to classes of objects having an arbitrary achiral skeleton and then affords the necessary and sufficient condition for permitted ligands. It permits greater expression of specific peculiarities in the individual members of a class of objects. The first- and last-mentioned aspects, in particular, correspond precisely to the demands placed on good models for molecules.

Objects of the kind discussed having a rigid invariant skeleton are apparently suitable as grossly simplified models for methane and its derivatives, for particular adamantane derivatives, for inorganic tetrahedral complexes having a common central metal atom, or for other classes of molecules having a corresponding skeleton. The term skeleton can refer, as for methane, to an atom with four directed bonds, or, as for adamantanes, to a construction containing several atoms with four available valences in a regular tetrahedral arrangement (*e.g.* in positions 1, 3, 5, and 7 of tricyclo[3.3.1.1^{3,7}]decane). The permitted ligands include monoatomic ones, diatomic ones which can bind in the direction of their axis, tetraatomic groups such as CH_3, CCl_3, NH_3, *etc.*

Even if rigid constellations are accepted as models for real molecules, the above model concept must be viewed with reservations. For example, the skeleton will certainly not have the same shape in all methane derivatives, and ligands of the same kind are exposed to different neighboring group effects in different compounds; they deform in various ways. The occurrence of individual peculiarities is especially obvious in methane derivatives because the valence angles of the central carbon atom are components of the skeleton and very dependent upon interactions between the ligands.

The model concept can be improved to accommodate such corrections without necessitating any change in the symmetry of the "naive model". This can be demonstrated for the cases shown in Figure 2. A search through the field of chemistry for facts concerning the shape of compounds having tetrahedral molecular shape reveals the following empirical rule which is broken in only few cases[*]: *The symmetry of the molecules is determined by the ligand partition according to Figure 2 provided that this is not precluded by steric hindrance or the symmetry of the isolated ligands.*

This conclusion is not surprising since the geometry of molecules can be explained by naive models in which the symmetry is determined by the partitioning of the ligands and deforming intramolecular forces are at work. Such force fields generally have the symmetry of the native models and in the absence of special reasons will not lead to any symmetry-reducing deformations.

As a term applied to real objects, molecule refers to arrangements of atoms which are not rigid and frequently occur in several different conformations. Ascertainment of molecular symmetry is therefore usually a statement about an average value of geometrical possibilities. The result of such a symmetry ascertainment will of course depend upon the nature of the experiment, and the concept of symmetry has a well-defined meaning only in relation to experiment. In as much as molecular symmetry can be interpreted as an average value, real molecules can be objects of a class with the symmetry criteria according to Figure 2.

3. Standard Classes

Experience gained in the preceding example leads us to the general concept of a "standard class". It appears appropriate for the definition of this concept to use the usual concepts of chemistry independently of their application to molecules and to supplement them in an appropriate manner.

A "class of derivatives" should be taken to mean a set of objects which differ in the nature and distribution of ligands over given sites of a skeleton. The skeleton is the determining feature of a class of derivatives; however, it can exhibit geometric deviations in different derivatives of the same class. Ligands of the same kind can also have deviating shapes in a modified environment. Two derivatives having the same ligand assortment but differing distribution of the ligands over the sites are called "permutational isomers". Derivatives which are mirror images of each other are called "enantiomers". We call derivatives having ligands of a single kind "basis derivatives"[*].

To these derivatives we can assign models consisting of a rigid, simply constructed skeleton which is invariant within a given class and spheres of various sizes in place of ligands of different kinds. We term such models "standard models" and assume the skeleton to be achiral. The symmetry of the standard model is established once it is known where spheres of equal size are located on the skeleton. The symmetry operations of the skeleton subject the standard models to rotations and rotation-reflections which are interpretable as permutations of the spheres with reference to a spatially rigid skeleton. For a skeleton having n labeled sites the following sets of permutations can be distinguished:

S_N = group of all $n!$ permutations of the n ligands,
$\mathfrak{G}$ = group of those permutations which effect only rotations or reflections of the objects[**],
$\mathfrak{N}$ = group of those permutations which effect only rotations of the objects.

[*] A possible exception is the methane derivative CH_2Li_2 recently reported by *Schleyer* [13].

[*] According to this definition a molecule of the chemical parent compound methane is itself a derivative, being a basis derivative of the tetrahedral class!

[**] In the tetrahedral class of the preceding Section, S_N is identical to $\mathfrak{G}$.

Comparison of derivatives and standard models—on the one hand objects completely adapted to those occurring in nature such as molecules and on the other hand geometrical constructions without individual peculiarities in skeleton and ligands in the specific members—facilitates representation of a theoretical situation taken from an apparently complex chemical world: The principal reason is because the symmetry of standard models can also apply to the assigned derivatives without individual geometric features of the skeleton and ligands being eliminated.

Derivatives having the symmetry of the assigned standard models are called "standard derivatives" and a class of standard derivatives a "standard class". Thus, as for standard models, the symmetry of the derivatives of a standard class is determined by the distribution of like ligands. The symmetry of the "bare skeleton" and that of "isolated ligands" are to be found in the basis derivatives of a standard class. The fact that basis derivatives have the symmetry of the bare skeleton characterizes the ligands as permissible.

In standard derivatives a ligand permutation should designate a rearrangement, including the inherent deformations. Permutations effecting rotations or transition to the enantiomer in standard models have the same action on the standard derivatives, provided that the pertinent deformations are also considered.

The best rigid models of molecules which are conventionally described as derivatives of an achiral compound and whose ligands all belong to basis derivatives having the same achiral symmetry are generally the objects of a standard class. This is understandable because the intramolecular force field in a hypothetical molecule with the symmetry of a standard model normally also possesses the symmetry of the molecule, and therefore changes of geometry but not of symmetry may be expected. Since statements of symmetry may be referred to time-averaged values, chemical derivatives may themselves be members of a standard class. In a certain sense, standard classes represent the "pure case" or "standard case" upon which the discussion of other derivatives, which are not standard derivatives, is preferably based.

It can be demonstrated for cyclopropanone derivatives that the selection criterion for ligands in standard classes is generally not sufficiently formulated by the requirement of site symmetry of the ligands (cf. Section 2) but only by the symmetry requirement for basis derivatives (Fig. 3).

Fig. 3. Skeleton of cyclopropanone with specified sites (a) and a basis derivative (b), which shows that the effect of the environment can induce chirality in achiral ligands without destroying the overall symmetry of the ligand.

Cyclopropanone has C_{2v} symmetry. The requirement of site symmetry for ligands in cyclopropanone does not lead to any specification of the kind of ligand as the ligand sites do not lie in mirror planes or on axes of rotation. Accordingly, chiral ligands are also permitted. Derivatives having four chiral ligands of the same kind are chiral however; they do not possess the C_{2v} symmetry of the assigned standard models with four identical spheres and therefore do not belong to a standard class.

The C_{2v} symmetry required for basis derivatives of a standard class presupposes, for example, that the ligand at site 1 is the mirror image of the ligand at site 2 (Fig. 3). Since the two ligands in basis derivatives must be of the same kind by definition, they can only be deformed as object and mirror image and are achiral when not exposed to the effect of their environment ("isolated ligands"). Requirement of basis derivatives having C_{2v} symmetry therefore means that only achiral ligands are permitted. It may readily be demonstrated that the symmetry of the assigned standard models (C_{2v}, S, C_2, and C_1) is always possible in cyclopropanone derivatives with achiral ligands.

There are no standard classes having an achiral skeleton and chiral ligands, as follows from the achiral symmetry of the basis derivatives. Thus if the discussion is to include chiral ligands, then an extension of the concept of "standard classes" becomes essential. An adequate generalization consists in the somewhat less rigorous requirement that derivatives possess (at least) the full chiral subsymmetry of the standard models. Hence, a minimum symmetry of C_2 would be required for basis derivatives in the case of cyclopropanone. Almost all of what we shall discover later[6] about the chirality phenomenon in standard classes can be extended to the corresponding situation with chiral ligands. However, owing to the mathematical and conceptual complexity we shall not discuss this extension, but content ourselves with a reference to pertinent literature[7, 8].

4. Chirality Functions

The special theoretical importance of standard classes is based *inter alia* upon the simple relation between the symmetry of a standard derivative and the partition of its ligand system. It is thus fitting and proper to speak of "active ligand partitions" and thereby characterize the type of ligand systems which on suitable distribution over the skeletal sites give chiral derivatives. A simple criterion is also available for achiral classes: *i.e.* no chiral derivatives exist in a standard class if the two permutational groups $\mathfrak{N}$ and $\mathfrak{G}$ coincide ($\mathfrak{N}=\mathfrak{G}$). The standard derivatives of the benzene type are an apt example.

Owing to the equivalence of certain ligand permutations with rotations, properties independent of spatial position are invariant towards ligand permutations from the group $\mathfrak{N}$ in standard derivatives. A scalar property such as the energy changes neither on rotation nor on reflections and can be described as a function $f(l_1, l_2 \ldots l_n)$ of the ligands l_i located at the skeletal sites which remains unchanged if l_i is subjected to a permutation from group $\mathfrak{G}$. Pseudoscalar properties, on the other hand, such as optical activity or circular dichroism, are independent of rotations and change their sign on reflection. They can accordingly be described by a function $\varphi(l_1, l_2 \ldots l_n)$ which is invariant towards permutations from $\mathfrak{N}$ and its sign changes on permutations from $\mathfrak{G}$ which do not belong to $\mathfrak{N}$. We call such functions "chirality functions".

Chirality functions prove to be particularly successful tools for studying the phenomenon of chirality in standard classes. In order to correctly assess the relevance of such analyses it should be borne in mind that the above transformation

properties apply not only to standard models but also to standard derivatives. Hence it follows that the insights gained with the aid of chirality functions are frequently valid for the real world of molecules without any limitation by approximative hypotheses. The question of right-left classification of standard derivatives introduced in the next section serves as a first illustration of the utility of chirality functions.

5. Homochirality

Sets of objects can in principle be subdivided into three subsets, two containing exclusively chiral objects, but no enantiomers, and the subset of achiral objects. The membership of achiral objects is evident, but not that of chiral ones. Separating enantiomers generally does not mean collecting chiral objects which are geometrically or physically related in a certain sense. Thus, for example, any subdivision which arises from exchanging mirror images would be just as arbitrary as the one from which it arose. This uncertainty in the assignment can be eliminated in specific cases by recourse to a principle of classification which somehow naturally expresses a kind of chiral relatedness. However, there are sets for which natural classification criteria of this sort just do not exist: this situation corresponds to the general rule. Some examples will help to illustrate this state of affairs.

The task of dividing a set of shoes into two classes such that mirror images are separated leads—apparently without any further instructions—to a classification according to "right" and "left". Although right and left shoes may be very different in shape, size, color, material, *etc.*, there is clearly a principle which allows classification of "related" members according to chirality, necessarily separating mirror images. It is only specific reference to what our task does not require which shows classification according to the concept "right" and "left" to prescribe more that the mere separation of mirror images. The same applies to screws. Here, the classification can be carried out according to the direction in which a screw moves when twisted in a clockwise sense. This criterion constitutes a rule which is sufficient for unequivocal classification of any set of screws without need for any arbitrary decision.

A completely different situation is encountered when mirror image potatoes are to be separated and distributed among three boxes, two of them for chiral and one for achiral potatoes. This task cannot be performed without arbitrariness. Any potato being chiral but neither identical with nor a mirror image of one already allocated to a given box necessitates deciding an alternative for which no obligatory principle is available. Concepts like right or left are meaningless; nothing like chiral similarity can be introduced without very artificial definitions.

It is surprising and of significance for applications in stereochemistry that the analysis of the corresponding problem for standard classes with an achiral skeleton results in the statement that some classes are comparable with shoes, others with potatoes. One consequence, among others, is that a nomenclature for derivatives designed to distinguish enantiomers may be based on a natural classification for certain sets, but is necessarily an artifact for others.

A distinction between chiral objects which leads to assignment into two classes and thus to separation of mirror images is natural if objects belong to the same subset because they can be designated as "chirally equivalent" by reference to a geometrical or physical similarity. Similarity and chirality of standard derivative can be traced back to a concept of similarity of ligands. Standard derivatives are similar if similar ligands are located at corresponding sites of the skeleton, and are chiral if ligands of different kinds are located at various skeletal sites. It may therefore be expected that chiral equivalence in the above sense—if at all possible—is completely determined provided that a suitable concept is available for similarity of ligands. Such a classification would be rigorous, and natural provided that the concept of ligand similarity is natural. Of course, the existence of such a classification will not be affected by the nature of the ligands present, but is solely the consequence of specific skeletal characteristics. Therefore, we call skeletons whose derivatives are governed by the desired classification principle *type a* skeletons; and the others are termed skeletons of *type b*. Standard classes of type a and of type b, abbreviated as a- and b-classes, are distinguished accordingly.

In order to grasp the existence of standard classes of both types, it is necessary to delve into the mathematics of the problem. Our first task is to develop the similarity concept for ligands in more precise terms. We distinguish between the kinds of ligands by values of a continuously variable parameter and call two kinds similar if they are represented by points sufficiently close together on the parameter scale. Thus defined, the similarity concept may be natural, such as the similarity of spheres as an expression of only slightly different diameters; it may also relate to a particularly interesting property of the ligands, *e.g.* their dipole moment or their polarizability, or it may formally express an arbitrarily chosen proximity on a scale. In this way, a similarity definition is fundamentally always possible for any finite or infinite set of ligands. Under no circumstances is a similarity concept for ligands which is based on more than one parameter suitable for accomplishing the desired classification.

On describing kinds of ligands by *one* parameter, standard derivatives having n skeletal sites are represented by n parameter values, *i.e.* by points in an n-dimensional parameter space; it should be noted that points arising from each other by certain permutations of their coordinates denote the same derivatives (in a rotated position). We distinguish between "chiral" and "achiral points" according to whether they denote chiral or achiral derivatives. Since similar ligands have adjacent values on a parameter scale, similar derivatives are characterized by the proximity of representative points in the parameter space. A curve devoid of achiral points expresses a relationship based on "chiral similarity". We therefore describe chiral points as chirally connected if there is a connecting path which does not pass through achiral points. It may be appreciated that chirally connected points could designate chirally equivalent derivatives in the sense of our intended classification if it were established that this equivalence cannot exist between enantiomers. Whether that is the case is determined by the individual features of the skeleton, and leads to a distinction between a and b skeletons. In b-type standard classes there are chirally connected points representing enantiomers; this is not the case in a-type standard classes.

Only in a-classes is a separation of all chiral derivatives into two subsets with resolution of enantiomers explained

by the chiral connection of points in the parameter space. We call two chiral derivatives *homochiral* if they belong to the same subset, and otherwise *heterochiral*. Homochirality, membership of the same subset, is established with a one-parameter ligand similarity concept.

The difference between a-type and b-type skeletons is manifested in the existence of a kind of chirality functions limited to a-type classes. Chirality functions $\varphi(\lambda_1,\lambda_2\ldots\lambda_n)$, depending upon the values of a ligand-specific parameter λ at the various skeletal sites, vanish at all achiral points of the parameter space and possibly also at other places. The "achiral zeros" are the same for all functions φ, while the "chiral zeros" are not; rather they are accidental, *i.e.* different functions φ do not have the same chiral zeros. It is clear that a continuous chirality function must have at least one zero on any path between two "enantiomeric points" in the parameter space. Since in b-type skeletons enantiomeric points exist which by definition are chirally connected, it follows that there can be no relevant continuous chirality functions $\varphi(\lambda_1,\lambda_2\ldots\lambda_n)$ without chiral zeros. On the other hand, it can be proved that there are continuous chirality functions without chiral zeros for a-type classes, and we call them "homochirality functions". Their sign thus characterizes homochiral derivatives in a-type classes, and this classification is unequivocal once a convention has been agreed for the similarity of ligands. The following theorems have been rigorously proved[3], and appear reasonable in view of the above argumentation.

Theorem 1: Homochirality functions exist for standard classes with skeletons of type a, and only for such classes. Only then is classification according to the homochirality concept possible. Homochiral derivatives are characterized by the same sign, heterochiral derivatives by opposite signs of a homochirality function, and achiral derivatives by the value zero.

According to Theorem 1 homochirality functions are characteristic for skeletons of type a and can therefore be used for analysis of their geometric features. The result of such a study is summarized in Theorem 2.

Theorem 2: A skeleton having two skeletal sites[*] is always of type a. Skeletons having more than two sites are of type a if, and only if, they possess mirror planes and $n-2$ sites lie in each of these mirror planes (n=total number of sites).

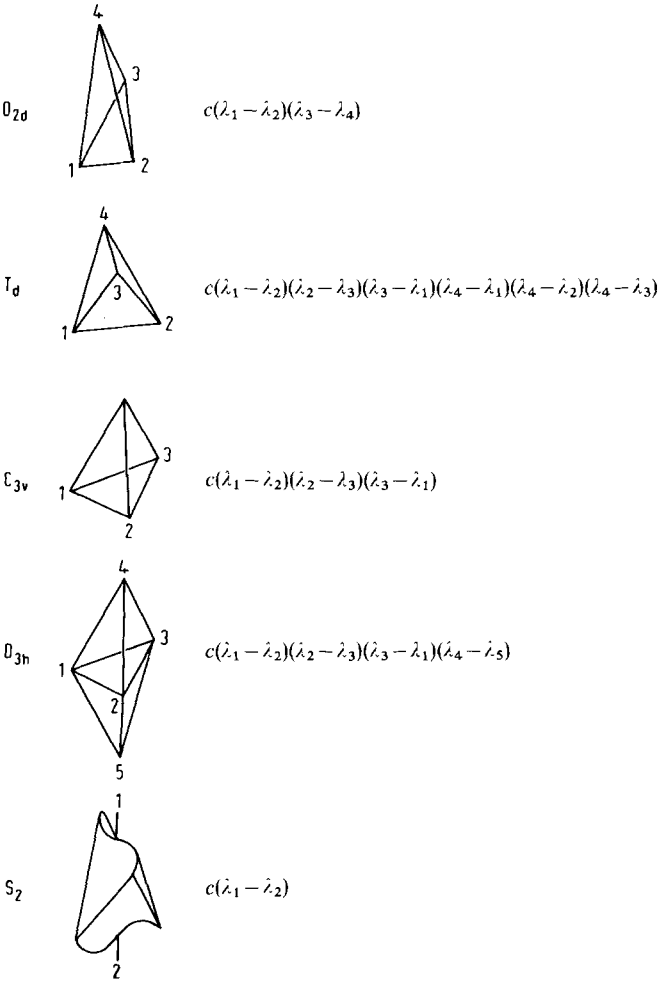
Chirality functions can be chosen in a variety of ways for any skeleton. Among such functions which vary continuously with a ligand-specific parameter λ_i at each skeletal site i, polynomials of the lowest degree in λ_i are distinguished by mathematical simplicity (the degree of the polynomial has a lower limit set by the required transformation properties). It can be demonstrated that for a-classes chirality polynomials of lowest degree in λ_i are homochirality functions. Theorem 3 shows that their construction is particularly facile.

Theorem 3: The homochirality polynomial of lowest degree can be written in the form:

$c(\lambda_1-\lambda_2)$ for skeletons with two skeletal sites (c=const.);

$c\prod_{i<k}(\lambda_i-\lambda_k)$ for skeletons with more than two sites (c=const.), the pair of subscripts of a factor referring to the two sites lying outside the mirror plane (the degree of the polynomial is thus equal to the number of mirror planes).

In Figure 4 a list is given of a-type skeletons together with the corresponding homochirality polynomials, which permits verification of Theorems 2 and 3 for specific examples. It may be proved that chirality polynomials for b-type skeletons cannot have the form of a product like the homochirality



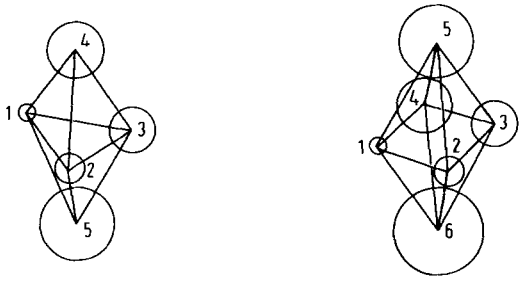


Fig. 4. Skeletons of type a and corresponding homochirality polynomials.

$c(\lambda_1-\lambda_2)(\lambda_2-\lambda_3)(\lambda_3-\lambda_1)(\lambda_4-\lambda_5)$

$c(\lambda_1-\lambda_3)(\lambda_2-\lambda_1)(\lambda_5-\lambda_6)(\lambda_6-\lambda_2+\lambda_3-\lambda_4)$

Fig. 5. Standard models having a trigonal and a tetragonal bipyramid as skeleton of type a and type b, respectively, together with the corresponding chirality polynomials.

[*] A site lying in the center of symmetry of a skeleton is not counted.

polynomials. Thus the mere form of the lowest degree chirality polynomial for the tetragonal bipyramid (Fig. 5) reveals the skeleton to be of type b. This result is also confirmed by Theorem 2, because mirror planes are present which contain only two, *i.e.* less than $6-2=4$ skeletal sites. The polynomial accordingly possesses chiral zeros: it vanishes, for example, when $\lambda_1=1$, $\lambda_2=2$, $\lambda_3=4$, $\lambda_4=3$, $\lambda_5=5$, $\lambda_6=6$.

Comparison of a tetragonal bipyramid with a trigonal bipyramid illustrates the idea of homochirality for a specific case. Working on the basis of standard models, the ligands are considered as spheres and the ligand-specific parameter is their diameter. Figure 5 depicts standard models for each skeleton in which all the spheres are different (their diameters were chosen as proportional to the site number). Both derivatives are chiral. We appeal to the imagination of the reader in following the subsequent argumentation.

In the case of the trigonal bipyramid, it is easily confirmed that transformation of a chiral derivative into its mirror image by a continuous change in sphere diameters necessarily leads *via* an achiral situation, *i.e.* two spheres on opposite sides of the skeleton mirror plane will inevitably become momentarily equal. Along any such transformation path the homochirality function has an achiral zero; it is readily seen from the form of the function to possess no other zeros. Non-zero values of the same sign denote homochiral derivatives.

The situation is completely different for the tetragonal bipyramid. Let us perform the transition from the derivative shown in Figure 5 to its enantiomer in two consecutive steps. The spheres at sites 1 and 2 are first continuously changed until the sphere at site 1 has a diameter of two units and that at site 2 a diameter of one unit. A corresponding operation involving the spheres at sites 3 and 4 finally leads to a sphere of four units in diameter at site 3 and one of three units in diameter at site 4. The result of this transformation is the mirror image of the original derivative. If the originally larger sphere is monotonically diminished and the originally smaller sphere monotonically enlarged in each step, then the overall transformation path cannot contain an achiral point. Hence the derivative shown in the figure and its enantiomer are chirally connected.

In its points the latter transformation path represents an arrangement of chiral derivatives corresponding typologically to similarity. Since the separation of enantiomers is an essential requirement of our intended classification, the connection between the endpoints must be broken at some place between them. No position along the transformation path is better suited as a separation point than any other. Therefore an arbitrary decision must be made, *i.e.* a decision which cannot be justified from arguments relating to chirality. As a corollary, continuous chirality functions must have at least one chiral zero somewhere along the transformation path—the position is not fixed and will generally be different for different chirality functions.

6. Chemical Aspects Summarized

A set of experimental data for derivatives of a standard class pertaining to a pseudoscalar phenomenon, such as experimental rotations for the optical activity at a particular wavelength, constitute a chirality function, *i.e.* they transform as a result of ligand permutation in the manner described. Theories relating to such experiments—whether classical, quantum mechanical, or semiempirical—also lead to chirality functions. Of course, chirality functions may also be purely mathematical constructions.

Every pseudoscalar property and every chirality function provides an opportunity of distinguishing between enantiomers on the basis of the sign. However, this does not apply to chiral derivatives for which the value zero happens to be measured or the chirality function vanishes (chiral zero).

As demonstrated in Section 5, any distinction between enantiomers which follows compellingly from a classification in compliance with a physically justifiable aspect of "similarity" is restricted to standard classes of type a. There are no homochirality functions for type b classes, *i.e.* no chirality functions which depend monotonically upon continuously variable properties of the ligands and do not possess chiral zeros. Any binary criterion distinguishing between enantiomers is necessarily arbitrary in the case of classes of type b, and is no more than a binary nomenclature symbol. The need for such a nomenclature for purposes of chemical systematization is not disputed—it is merely asserted that no physically relevant nomenclature can be found.

A completely different situation exists in standard classes with a skeleton of type a. Standard derivatives from an a-class are resolved into two heterochiral sets of homochiral members and into achiral derivatives according to the sign and zero, respectively, of a homochirality function. The concept of homochirality is based on a one-parameter specification of kinds of ligands. Classification "by homochiral derivatives" is unequivocal if the ligand specification is established.

The ligand-specific parameters may describe a physical or a geometrical property of the ligand or merely a formal sequence of kinds of ligands; the homochirality classification depends solely upon the physical or geometrical property, *i.e.* upon the sequence of parameter values. This assertion is confirmed as follows:

Two parameters λ and λ' can be taken as representing the same property if they admit the interpretation that the same situation can be measured on different scales. This is the case if one parameter is a monotonic function of the other one, *i.e.* if:

$$\lambda=\lambda(\lambda'); \quad \text{where} \quad \frac{d\lambda}{d\lambda'}>0 \tag{1a}$$

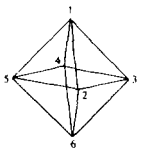
With reference to kinds of ligands l_A, l_B ... we can write:

$$\frac{\lambda(l_A)-\lambda(l_B)}{\lambda'(l_A)-\lambda'(l_B)}>0; \quad \text{for all } l_A \neq l_B \tag{1b}$$

The relation (1b) clearly shows that λ and λ' define the same sequence of ligands. Since homochirality polynomials are shown by Theorem 3 (Section 5) to be products of differences of the form $(\lambda_i-\lambda_k)$, the sign will therefore not change on replacing the ligand parameter λ by another one λ', which according to (1b) describes the same property or the same sequence of ligands.

In standard models of class a, a homochirality concept based on the size of the spheres affords a natural distinction between "right" and "left". It is immaterial for the sequence

of parameter values, and hence for the classification, whether the sphere diameter, or surface area, or volume is selected as parameter in the corresponding homochirality function.



Only in standard classes of type a are geometrically or physically relevant aspects of classification encountered, which provide an alternative for chiral derivatives. If such a classification exists which does not display the accidental features of a special case, then a fitting homochirality concept may be expected to lie at the root, *i.e.* there is a sequence of ligands for which the homochirality polynomial yields a corresponding sign distribution. "Accidental features" would be observed *e.g.* in the sign distribution of the optical rotation which is valid only for a narrow wavelength range. Accepting the hypothesis that a homochirality relation exists, an attempt can be made to determine the corresponding parameter sequence from the experimental data.

In the case of allene derivatives—the allene skeleton is of type a—we have used experimental optical rotation data[9, 10] to determine the values of a ligand parameter. The experimental data were assumed to be correctly represented by the homochirality polynomial (cf. the first polynomial in Fig. 4). Since the number of different allene derivatives is increasing faster than the number of available ligands, such a procedure is suitable for the prediction of optical rotatory values. The result of this investigation far exceeded our expectations; for the derivatives studied the agreement between theory and experiment lies within the limit of experimental error[9, 10]. This same is true of a recently concluded study on spirane derivatives[11]. This result reveals far more than a mere physical relevance of the homochirality concept; it testifies to the quality of our *Ansatz* with the homochirality polynomial for quantitative purposes. Against this background, confirmation of the correct prediction of the experimentally determined sign seems little more than a self-evident by-product.

Irrespective of the question of relevance of a classification, there is a need for a corresponding nomenclature. Any binary nomenclature for differentiating enantiomers within a standard class corresponds to the signs of a chirality function without chiral zeros. Homochirality polynomials are suitable for use in a classes, while discontinuous chirality functions are employed in b classes.

Adopting the ligand sequence due to *Cahn*, *Ingold*, and *Prelog*[12], the *R,S* nomenclature is obtained in a-classes in that the signs of the homochirality polynomial are represented by the symbols *R* and *S*.

In the case of b classes, of the many chirality functions without chiral zeros one must be chosen arbitrarily for purposes of nomenclature. For instance, a nomenclature is obtained for the octahedral skeleton with the signs of the following (discontinuous) chirality polynomial

$$(\lambda_1-\lambda_2)(\lambda_2-\lambda_4)(\lambda_3-\lambda_5)$$
$$(\mu_{12}-\mu_{64})(\mu_{14}-\mu_{62})$$
$$(\mu_{23}-\mu_{45})(\mu_{25}-\mu_{43})$$
$$(\mu_{31}-\mu_{56})(\mu_{51}-\mu_{36})$$

with

$$\mu_{ij}=\mu_{ji};\quad \mu_{ij}=\mu_{kl}\Leftrightarrow\lambda_i=\lambda_k,\lambda_j=\lambda_l \quad \text{or} \quad \lambda_i=\lambda_l,\lambda_j=\lambda_k$$

$$\mu_{ij}>\mu_{kl}\Leftrightarrow \left\{\begin{array}{l}\max(\lambda_i\lambda_j)>\max(\lambda_k,\lambda_l)\\ \min(\lambda_i\lambda_j)<\min(\lambda_k,\lambda_l),\ \text{if}\ \max(\lambda_i\lambda_j)=\max(\lambda_k,\lambda_l)\end{array}\right\}$$

Based on the *R,S* sequence of ligands the sign distribution of this polynomial does not represent the *R,S* nomenclature proposed by *Prelog* for the octahedron. It is very similar, however. *Prelog*'s nomenclature is described by the signs of the given polynomial if a different definition is given for the relation $\mu_{ij}>\mu_{kl}$ on the basis of a complicated case-to-case distinction. Viewed from the standpoint of mathematical simplicity this approach appears artificial and is therefore not pursued any further. This result confirms our assertion that there is no natural preference for any of the possible nomenclatures in the case of b-type skeletons.

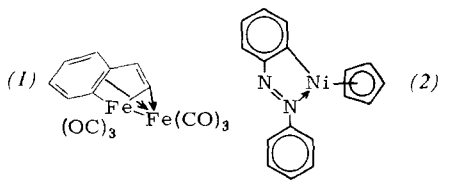
Cyclometalation Reactions

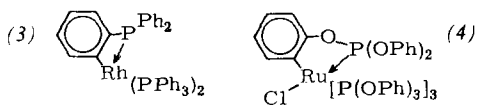
By Michael I. Bruce[*]

Reactions of transition metal complexes in which an organic ligand undergoes intramolecular metalation with formation of a metal-carbon σ bond are termed cyclometalation reactions. This article provides a general summary of our knowledge of these reactions, and discusses them in terms of their scope, mechanisms, and utility in organic synthesis, particularly of heterocyclic molecules.

1. Introduction



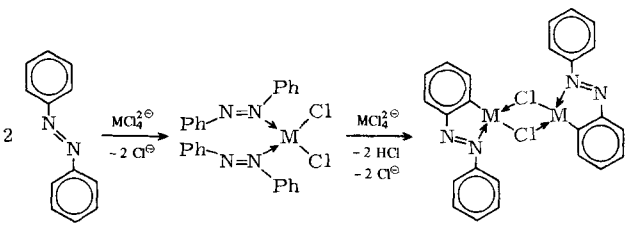
The term "cyclometalation" was introduced by *Trofimenko*[1] to describe those reactions of transition metal complexes in which a ligand undergoes an intramolecular (or more rarely, intermolecular) metalation with formation of a chelate ring containing a metal-carbon σ bond:



Scheme 1. Cyclometalation. E = donor atom, M = transition metal, X = leaving group.

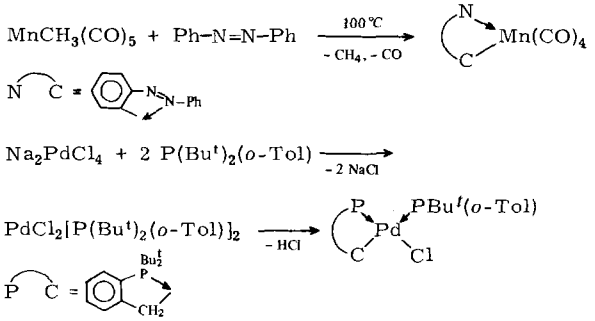
Metalations of phenyl-substituted ligands have been most frequently described, and termed *ortho*-metalation, but the wider scope of these reactions now recognized is covered by the term used in the title.

One of the earliest examples of an *ortho*-metalated complex is the "benzometallole" *(1)* obtained from reactions between carbonyliron compounds and diphenylacetylene[2]. Other related reactions appeared sporadically in the literature of the 1960's, including cyclometalations of azobenzene-nickel complexes to give *(2)*[3], of palladium and platinum[4] complexes, and of other complexes containing phenyl-phosphane *(3)*[5,6] and -phosphite *(4)*[7-9] ligands.



Attention was focused on this area in 1970 by *Parshall*[10], who has more recently considered the general problem of the activation of C—H bonds by transition metals[11]. The purpose of the present article is to summarize our present knowledge of cyclometalation reactions, to survey current ideas concerning the mechanism of formation of the metal-carbon σ bond, and to discuss the utility of these reactions in organic synthesis. Some earlier articles have described aspects of these reactions[12-14].

2. Formation and Detection of the Metal-Carbon σ Bond

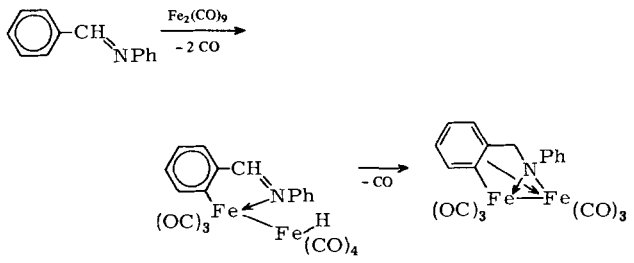


In general, formation of the metal-carbon σ bond occurs more or less readily by direct interaction of the ligand and metal substrate, and elimination of the hydrogen by combination with a suitable leaving group. In most cases, an intermediate ligand-metal complex without a metal-carbon σ bond is formed, which may or may not be isolable:

M = Pd, Pt

Scheme 2.

Many reactions occur on pyrolysis (50–200 °C) of the reaction mixture, an inert solvent often being used as the reaction medium and heat transfer agent (Scheme 3).



Scheme 3. A common method of indicating a metalated ligand is the symbol $\overset{\frown}{E\ C}$, where E is the donor atom, and C the metalated carbon atom (see also Scheme 1). Bu' = *tert*-butyl, *o*-Tol = *o*-tolyl.

The cyclometalation reaction is facilitated by choice of a good leaving group in the metal complex, which combines with the hydrogen atom displaced from the metalated carbon atom. Thus, the well studied cyclometalation reactions of alkyl(carbonyl)metal compounds with azobenzene[15] (see Scheme 3, top) involve loss of alkane.

[*] Prof. Dr. M. I. Bruce
Department of Physical and Inorganic Chemistry
University of Adelaide

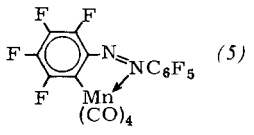
Addition of lithium acetate to a solution of $PdCl_2(PPh_3)_2$ affords the cyclometalated complex directly together with acetic acid and LiCl[16], and reactions involving the loss of a variety of small molecules are now known.



In some cases, notably with carbonyliron and -ruthenium compounds, dinuclear complexes are produced in which the formation of the cyclometalated complex is accompanied by hydrogen transfer (perhaps *via* a metal hydride) and interaction with a second metal atom (Scheme 4).

Scheme 4.

In this and related reactions, the dinuclear complex is stabilized by interaction of one metal atom with the aromatic π-electron system[17].

There are few reports of the loss of atoms or groups other than hydrogen from the metalated carbon atom. Consideration of the mechanisms of the metalation reactions of azobenzenes (see below) led us to examine the reactions of polyfluorinated derivatives with electron-rich metal complexes. Nucleophilic attack on $C_6F_5N{=}NC_6F_5$ by $Mn_2(CO)_{10}$ or $RuCH_3(PPh_3)_2(C_5H_5)$[83] afforded complexes [*e.g. (5)*] by elimination of a fluorine atom possibly as the metal fluoride, or as CH_3F.

(5)

The formation of cyclometalated, and particularly *ortho*-metalated, complexes, is generally revealed by conventional analytical and spectroscopic methods. The presence of an *ortho*-metalated ligand is shown in the infrared spectrum by extra bands (compared with the nonmetalated complex) characteristic of an *ortho*-disubstituted benzene nucleus, in the 700—800 and 1100 cm^{-1} regions[5, 8, 9]. Similarly, the appearance of multiplets upfield (for N-donor ligands) or downfield (for P-donor ligands) from the main aromatic proton signals, variously assigned to the proton *ortho* to the metal or donor atom group, has been indicative of the presence of a metalated ligand[9]. More recently, ^{13}C-NMR spectroscopy has been used to determine the presence of a metal-carbon σ bond in this type of complex[18]. If available, the mass spectrum provides strong evidence for the presence of the chelate group, as this appears to have some stability in the spectrometer. Care must be taken to ensure that the formation of such an ion is not a mass spectrometric reaction, as observed with certain molybdenum and ruthenium[19] complexes. In some cases, the observation of particularly intense (stable) ions of this type may indicate the ready macrochemical formation of cyclometalated complexes.

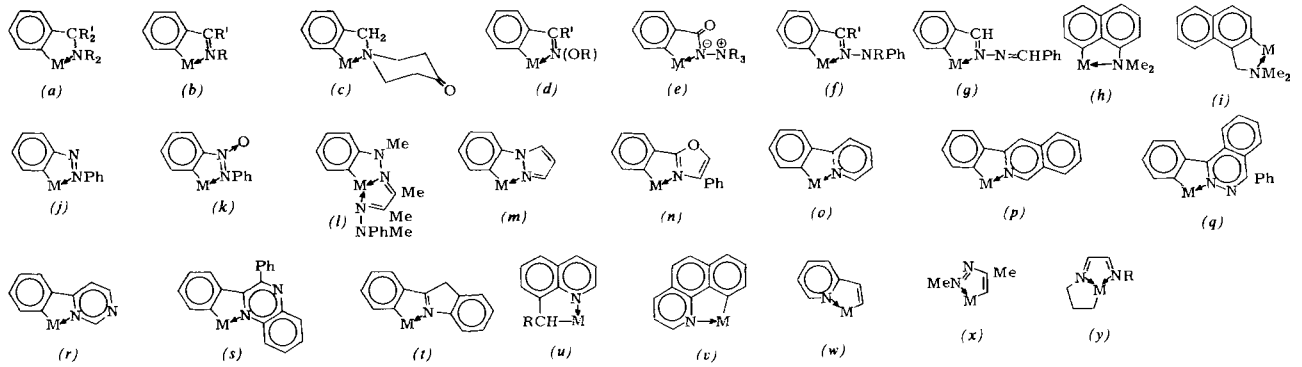
The final arbiter of the presence of the chelating metalated ligand is X-ray structure analysis, and numerous examples of such complexes have now been characterized in this way.

3. Scope of the Cyclometalation Reaction

Cyclometalated complexes will be considered from three points of view, namely those of the central metal atom, the type of carbon atom σ-bonded to the metal (or the system metalated), and the nature of the donor atom used to form the chelate ring.

3.1. Nature of the Metal

The majority of transition elements contained in Groups VI-VIII, with the exception of technetium, have been reported to form metal-carbon σ bonds. Complexes containing the $Ru(PPh_3)(C_5H_5)$ group are particularly prone to form cyclometalated derivatives[20]. The particular stereochemistry of the Group IB elements results in complexes containing formally metalated ligands being di- or poly-nuclear; complexes of this kind containing copper and silver have been obtained albeit indirectly (see Section 6.2). The elements of Groups IV and V are represented by $\eta^1{:}\eta^5$-cyclopentadienyl derivatives (Section 3.2), and a similar example is also known for thorium. Titanocene derivatives, such as $\overline{Ti[C_6H_4C(O)O]}(C_5H_5)_2$, have been obtained from reactions between $TiPh_2(C_5H_5)_2$ and CO_2, which may proceed *via* the phenylene intermediate $Ti(C_6H_4)(C_5H_5)_2$[20a].



3.2. Nature of the Metalated System

As mentioned in Section 1, most cyclometalated systems bear a phenyl group. Examples of *ortho*-metalated ligands containing nitrogen, phosphorus, or arsenic donor atoms are shown in Table 1, and the variety of nitrogen-containing ligands is noteworthy. A general stereochemical requirement for formation of a five-membered ring can apparently be met by many phenyl-substituted nitrogen-heterocycles, and numerous examples containing manganese or palladium have been reported[21, 22].

Examples of the metalation of polycyclic aromatic systems are being reported with increasing frequency, and it appears that the fused-ring metallocyclic systems so formed have considerable stability. Ligands which have been metalated in this way include naphthyl-amines[1], -phosphanes, and -arsanes[23], and benzo[*h*]quinoline, which forms tetracyclic derivatives with many metals[24] including the tricarbonylchromium complex *(6)*. The tendency for metalation in these systems is very high, and is further illustrated by the formation of *(7)* on heating the corresponding methyl(naphthylmethyl)platinum complex[25]. A general discussion of metallocyclic complexes and intermediates falls outside the scope of this article, however.

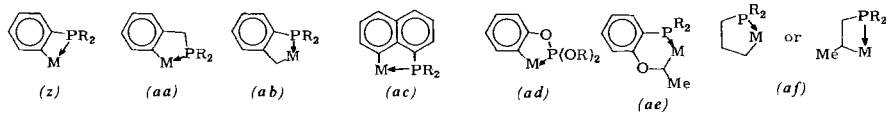


Table 1. Representative cyclometalated ligands containing nitrogen, phosphorus, or arsenic as donor atoms.

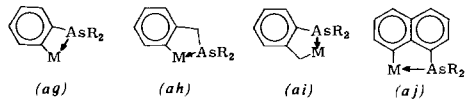
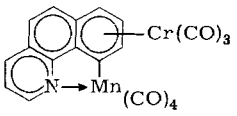
N-donor ligands:

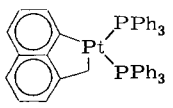


(a) *N,N*-disubstituted benzylamines [1, 30, 31, 33, 36], *(b)* Schiff bases [32], *(c)* *N*-benzyl-4-piperidone [33], *(d)* oximes (R = H) [34], oxime ethers, *(e)* *N*-ammoniobenzimidate [37], *(f)* phenylhydrazones [33, 35], *(g)* benzylideneazine, *(h)* *N,N*-dimethyl-1-naphthylamine [30], *(i)* 1-(*N,N*-dimethylaminomethyl)naphthalene [33], *(j)* azobenzene [13], *(k)* azoxybenzene [36, 38], *(l)* biacetylbis(*N*-methyl-*N*-phenyl)hydrazone [39], *(m)* 1-phenylpyrazole [1, 21], *(n)* 2,4-diphenyloxazole [21], *(o)* 2-phenylpyridine [21, 40], *(p)* 2-phenylisoquinoline [40], *(q)* 1,4-diphenylphthalazine [21], *(r)* 4-phenylpyrimidine [21], *(s)* 2,3-diphenylquinoxaline [21], *(t)* 2-phenyl-3*H*-indole [42], *(u)* 8-alkylquinoline [41, 43], *(v)* benzo[*h*]quinoline [24, 33, 41], *(w)* 2-vinylpyridine [44], *(x)* 2-(methylazo)propene [45], *(y)* *N*-alkyldiazadiene [45a]

P-donor ligands:

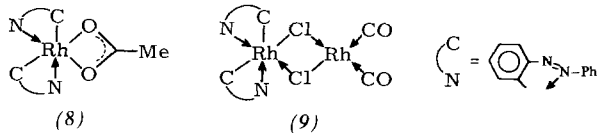


(z) phenylphosphanes [5, 6], *(aa)* benzylphosphanes [48], *(ab)* *o*-tolylphosphanes [49], *(ac)* 1-naphthylphosphanes [46], *(ad)* aryl phosphites [9], *(ae)* 2-alkoxyphenylphosphanes [47], *(af)* propylphosphanes [49]

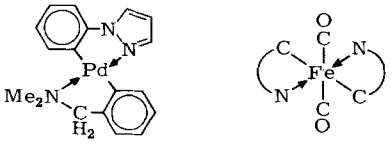


As-donor ligands:

(ag) phenylarsanes [5], *(ah)* benzylarsanes [48], *(ai)* *o*-tolylarsanes [50], *(aj)* 1-naphthylarsanes [46]

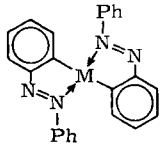


(6)



(7)

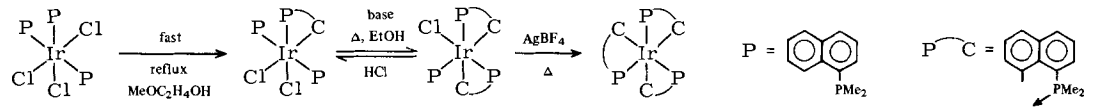
Complexes containing more than one metal-carbon σ bond [*(8)* and *(9)*] have been obtained directly from reactions between rhodium complexes and azobenzene[26, 27]. Treatment of halo complexes containing one cyclometalated ligand also



(8) *(9)*

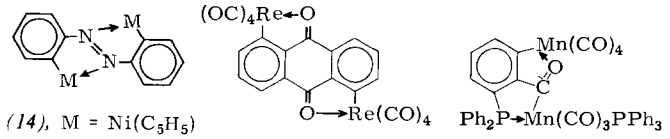
(10)

(11)



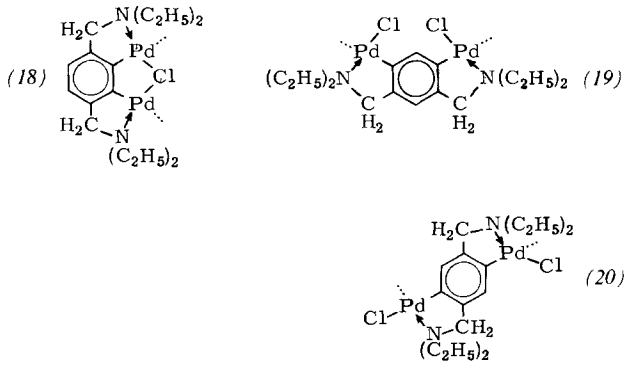
gives complexes of this type, such as *(10)*, obtained from $[Pd(2\text{-(pyrazolyl)phenyl})Cl]_2$ and *o*-$LiC_6H_4CH_2NMe_2$[1], while *(11)* is formed from $Fe(CO)_5$ and azobenzene in low yield[28]. Reactions between mercurated azobenzene and metal(0) complexes such as Pd_2(dibenzylideneacetone)$_3$ or $Pt(PPh_3)_4$, have given the spiro complexes *(12)* and *(13)*[29].

(12), M = Pd
(13), M = Pt



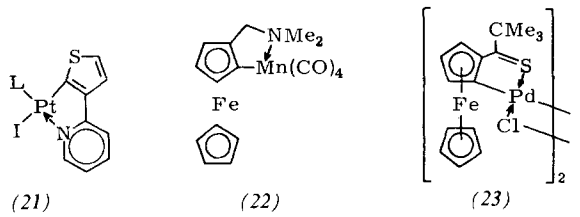
Using PMe_2(Nap) (Nap = 1-naphthyl), a series of mono-, di-, and tri-metalated derivatives of iridium has been prepared, by stepwise conversion of *mer*-$IrCl_3[PMe_2(Nap)]_3$[30] (Scheme 5).

Ligands with more than one donor site can form polynuclear complexes, and known examples include nickel and manganese derivatives of azobenzene *(14)* and *(15)*[51, 52], and complexes derived from anthraquinone [*(16)* and its "1,8"-isomer][53]. The formation of a cyclometalated complex may be accom-



Scheme 5.

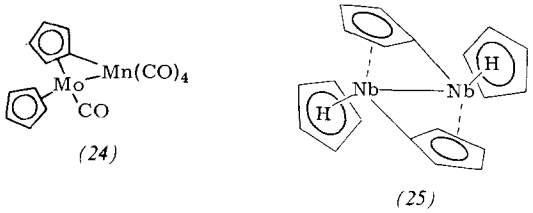
panied by insertion of a small molecule, *e.g.* CO, with generation of a second donor site. Examples of this are provided by products [*e.g. (17)*] isolated from high temperature reactions between $MnCH_3(CO)_5$ and PPh_3[54]. Other complexes



(14), M = $Ni(C_5H_5)$
(15), M = $Mn(CO)_4$ *(16)* *(17)*

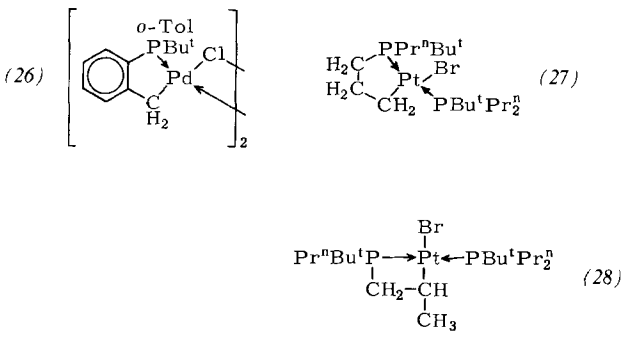
containing dimetalated aryl groups *(18)*—*(20)* have been obtained from tetraethylxylenediamines; the presence of the first palladium atom on the benzene ring activates the ring towards further substitution[11].

(18) *(19)* *(20)*



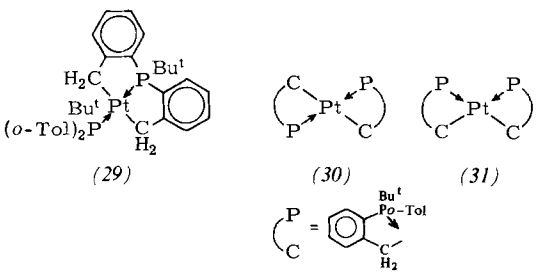
Metalation of other systems commonly thought to exhibit aromatic character has been achieved. Thus the reaction between 2-(2-thienyl)pyridine and K_2PtCl_4 affords *(21)*[55], while metalation of nitrogen and sulfur derivatives of ferrocene has given complexes such as *(22)*[56,57] and *(23)*[58].

(21) *(22)* *(23)*



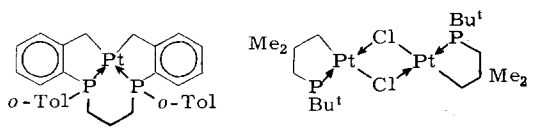
L = 2-(2-Thienyl)pyridine

The *inter*molecular metalation of η^5-cyclopentadienyl complexes to give new binuclear derivatives containing $\eta^1:\eta^5$-C_5H_4 ligands is related to the more conventional cyclometalation reactions. It was first described in the reaction between $MoH_2(C_5H_5)_2$ and $MnCH_3(CO)_5$, which afforded *(24)*[59]. Several related complexes of electron deficient transition metals such as thorium[60] or niobium [*(25)*][61] have since been described, and the transformation of $M(\eta^5\text{-}C_5H_5)$ moieties into $M(\eta^5:\eta^1\text{-}C_5H_4)_2M$ systems is an important reaction in low-valent transition metal chemistry.



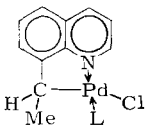
(24) *(25)*

Metalation of aliphatic carbon atoms has been reported by several groups. Typical of these reactions are those of complexes containing tertiary phosphanes containing sterically bulky groups, such as CMe_3. The elegant work of *Shaw et al.* has demonstrated that the steric effects of coordinating



(26) *(27)* *(28)*

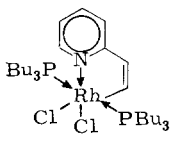
several of these ligands to one metal atom considerably enhance the tendency to form cyclometalated derivatives. Complexes containing metalated *o*-tolyl *(26)* or *n*-propyl *(27)* and *(28)*[49] groups were obtained. In one case the three isomeric complexes *(29)*—*(31)* were characterized[62], while pyrolysis of $PtMe_2[(o\text{-Tol})_2P(CH_2)_3P(o\text{-Tol})_2]$ afforded



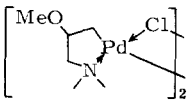
(29) *(30)* *(31)*

(32)[63]. Metalation of the aliphatic chain in $PBu^t_2(CH_2CMe_3)$ with $PtCl_2(NCPh)_2$ affords *(33)*, although $PBu^t_2Pr^n$ gives only P-donor complexes such as $[PtCl_2(PBu^t_2Pr^n)]_2$, a difference ascribed to favorable conformational and entropy factors arising from the presence of *gem*-di-*tert*-butyl and *gem*-dimethyl groups[64].

(32) *(33)*

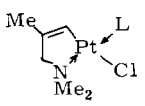


The metalation of alkyl groups has been observed with alkylquinolines. With 8-ethylquinoline, the metalated carbon is a chiral center, and ready resolution of the diastereoisomers



(34), L = (+)–PhCH(Me)–NH_2

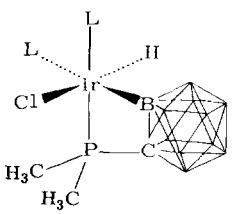
was achieved by crystallization of the (+)-1-phenethylamine derivative *(34)*[65]. Similar rhodium derivatives of 8-methylquinoline have been described[43].



Chelating ligands have also been formed by metalation of alkenyl carbon atoms; for example, 2-vinylpyridine gives *(35)*[44]. Alkylamines are cyclopalladated by Li_2PdCl_4 in methanol to give *(36)* but cycloplatination affords products of type *(37)*[66]. The complexes *(35)* may be formed

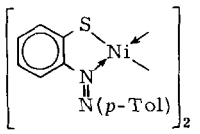
(35)

(36)



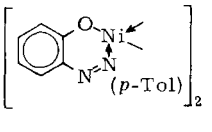
L = Amine, tert. Phosphane

(37)



by nucleophilic attack of alkoxide on an intermediate η-olefin-ammine complex, rather than by direct metalation. A number of related reactions leading to chelating ligands containing metal-carbon σ bonds and Group V donor atoms have been described by *Nyholm*[67] and *Bennett*[68].

Organolithium derivatives of a variety of dimethylaminomethyl substituted systems have been prepared, including benzene[69], thiophene[70], and ferrocene[71]. The preferred formation of an α-lithio derivative has been explained in terms of chelation of lithium by the donor atom. The precise relationship between this type of reaction and the cyclometalation by transition metal compounds has not been explored in detail. However, in 1-(dimethylaminomethyl)naphthalene palladation occurs in the 2-position, while lithiation occurs at the 8-position[72]. *Parshall*[10] has pointed out that the formal analogy between palladation and lithiation may not be valid mechanistically because lithiation of arenes is not an electrophilic reaction, but this may not be true for all cyclometalation reactions (see Section 7.3).

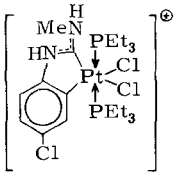


(38)

One example of a ligand metalated at an atom other than carbon in a reaction similar to those described above is *(38)*, resulting from the reaction between 1-Me_2P-1,2-$C_2B_{10}H_{11}$ and $[IrCl(C_8H_{14})_2]_2$[73]. This reaction is wholly comparable with the internal metalation of $IrCl(PPh_3)_3$, and further exemplifies the formal analogy between some carboranes and aromatic systems.

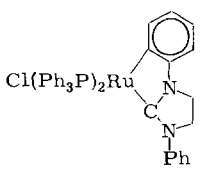
(39)

(40)



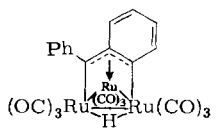
Reactions in which elements other than carbon are metalated are common in the chemistry of metal azo dyes[74], and generally fall outside the scope of this article. Recent examples include structural studies establishing ring sizes in the nickel complexes *(39)* and *(40)*[75]. Moreover, the various factors influencing *C*- and *O*-metalation of methoxy- and hydroxy-phenylphosphanes in reactions with platinum or iridium complexes have also been considered[47,76].

3.3. Effect of the Donor Atom



Systematic studies of the effect of the donor atom on the tendency for metalation are largely lacking, although the wide differences in types of complex formed with differing donor atoms is evident from the discussion already given. Qualitative observations on reactions between $PhCH_2EMe_2$ (E = N, P, As), or $PhCH_2XMe$ (X = O, S), and $MnR(CO)_5$ (R = Me or CH_2Ph) or $PdCl_2$ suggest that the ease of manganation decreases in the order N > P > As, and S > O, but only with $PhCH_2NMe_2$ were any palladated complexes obtained[48].

3.3.1. Carbon



Complexes containing cyclometalated ligands with carbon as the donor atom have been obtained in the course of other studies, and include derivatives of alkynes, such as *(1)*. Chlorination of *trans*-$[PtCl\{C(NHMe)(NHPh)\}(PEt_3)_2]ClO_4$ has

(41)

(42)

(43)

given the metalated carbene complex *(41)*[77], while reaction between $RuCl_2(PPh_3)_3$ and the imidazolidine derivative $[CH_2N(Ph)]_2C{=}C[N(Ph)CH_2]_2$ afforded *(42)*[78]. A low yield of *(43)* was obtained from LiPh and $Ru_3(CO)_{12}$[79]; this complex contains an *ortho*-metalated CPh_2 ligand, the structural features of which are similar to the cluster-bonded allyl complexes obtained from reactions between alkenes[80] or 1,5,9-cyclododecatriene[81] and $Ru_3(CO)_{12}$.

3.3.2. Nitrogen

The majority of studies of the metalation of N-donor ligands have been made with azobenzene and related compounds, although the palladation reactions first described by *Cope* have now been extended to many other nitrogenous ligands. Indeed there seem to be few restrictions on the latter reaction if a five-membered ring, containing both nitrogen and the *ortho*-carbon, can be formed. Structural studies[82] on the compounds Mn(C—N)$(CO)_2$ (C—N = metalated benzylideneaniline or *N*,*N*-dimethylbenzylamine) have compared the

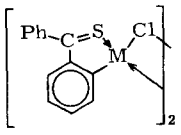
conformations of the five-membered chelate rings and the distortions resulting from the presence of CH=N and CH_2N units, respectively.

3.3.3. Phosphorus

The extensive use of triphenylphosphane as a P-donor ligand has resulted in the isolation of many *ortho*-metalated derivatives as by-products from reactions designed to proceed in other ways[82]. Where bulky alkyl groups are present, the metalation reaction predominates, especially where more than one *tert*-butyl group is present, for example. The ligands $PBu^t(o\text{-Tol})_2$ and $PBu^t_2(o\text{-Tol})$ are metalated in the tolyl methyl group, showing the preference for formation of a five-membered ring[49].

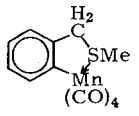
Similar reactions have been described for aryl phosphites, and *Robinson* has systematically examined the metalation of $P(OPh)_3$ or $P(OTol)_3$ ligands by metals of the second and third periods[84]. More recently, examples with the first period transition elements Mn[85], Fe[86], and Co[87] have been reported.

3.3.4. Arsenic and Antimony



Relatively few examples of metalated As and Sb donor ligands have been described. The iridium complexes $IrCl(EPh_3)_3$ (E = As, Sb) readily afford $IrHCl(E{-}C)(EPh_3)_2$ on heating[88], while elimination of toluene in the reaction between $Mn(CH_2Ph)(CO)_5$ and $AsMe_2(CH_2Ph)$ has given $Mn(C_6H_4CH_2AsMe_2)(CO)_4$[48].

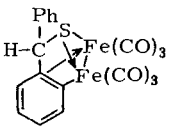
3.3.5. Oxygen



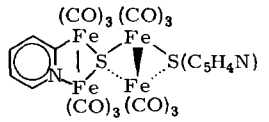
Some *ortho*-metalated derivatives of aromatic ketones have been obtained from reactions with $MMe(CO)_5$ (M = Mn or Re)[53], and *(17)* is formed in the reaction between $MnMe(CO)_5$ and PPh_3. The complex $Cr(C_6H_4OMe)_3$[88a] and a similar derivative of 2-phenyldioxolane[88b] are also known.

3.3.6. Sulfur

Thioketones or *O*-alkyl thioesters form dinuclear complexes when treated with carbonyl-iron or -ruthenium compounds (see Section 4), and mononuclear complexes such as *(44)* have been obtained with palladium and platinum[89]. Generally, however, S-donor ligands tend to form simple σ-donor complexes, and metalation occurs only with the more reactive metal substrates. Thus, $PhCH_2SMe$ forms only $MCl_2(PhCH_2SMe)_2$ (M = Pd, Pt) on attempted metalation[90, 91], although $MnR(CO)_5$ (R = Me or $PhCH_2$) reacts to give $Mn(C_6H_4CH_2SMe)(CO)_4$ *(45)*[92], characterized by an X-ray structure analysis of the PPh_3 derivative[93]. In the reaction between $Re_2(CO)_{10}$ and thiobenzophenones, the isolable intermediate $Re_2(CO)_9[SC(C_6H_4X)_2]$ can be converted into the *ortho*-metalated $Re[XC_6H_3C(S)C_6H_4X](CO)_5$, possibly by elimination of $ReH(CO)_5$[94].

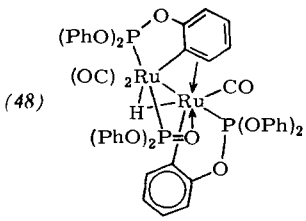


(44), M = Pd, Pt

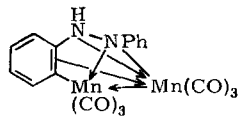


(45)

4. Metalation Involving Two or More Metal Atoms

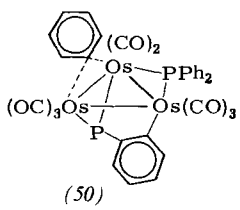


Many complexes of iron and ruthenium containing cyclometalated ligands are dinuclear, with the second metal atom interacting with an aromatic ring. Examples are *(1)*, and derivatives of sulfur ligands, such as *(46)*[95]. The reaction between pyridinethiol and $Fe_3(CO)_{12}$ has given *(47)*, containing a metalated pyridine ring[96], while a pyrolysis product of $Ru_3(CO)_9[P(OPh)_3]_3$ has structure *(48)*[97]. A solitary manganese example *(49)*, obtained from $MnPh(CO)_5$ and azobenzene, is also known[52].

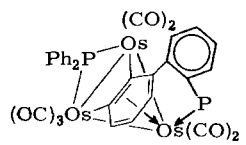


(46)

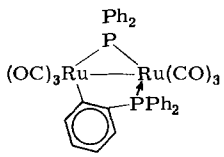
(47)



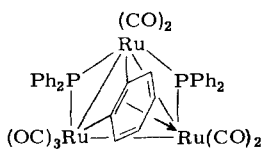
(48)



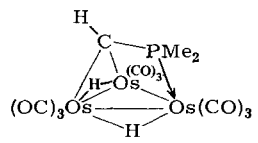
(49)



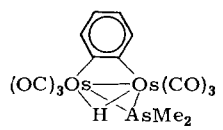
The propensity of metal clusters, particularly those containing ruthenium or osmium, to metalate aromatic compounds



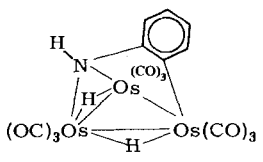
(50)



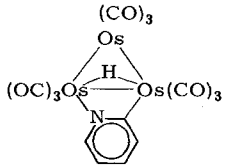
(51)



(52)



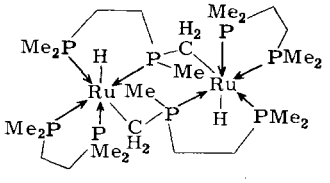
(53)



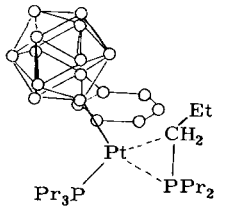
(54)

(55)

(56)



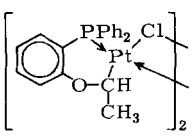
(57)



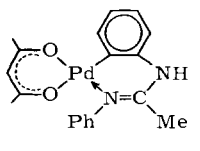
has been spectacularly demonstrated by their reactions with tertiary phosphanes. The reaction between $Os_3(CO)_{12}$ and PPh_3 gives a variety of products, including *(50)* and *(51)*[98], while pyrolysis of carbonylruthenium-tertiary phosphane clusters has given complexes such as *(52)* and *(53)*[99]. The stabilized dehydrobenzene group found in *(51)* can also be considered as a doubly-metalated phenyl group. A wide variety of polynuclear complexes containing singly- and doubly-metalated aromatic groups has been obtained and characterized *via* X-ray diffraction methods. These reactions are not limited to tertiary aryl phosphanes, complexes *(54)*—*(57)* being obtained from reactions using PMe_3, $AsMe_2Ph$, aniline, or pyridine, for example[100].

5. Chelate Ring Size

It has been noted above (Section 3.3.2) that metalation of nitrogen-donor ligands does not occur if the chelate ring produced has fewer than five atoms, while the metalation of tertiary phosphanes, arsanes, or stibanes may produce complexes containing four-membered rings. Metalation of aryl phosphites gives five-membered rings, as do reactions with the bulky phosphanes containing Bu^t or *o*-tolyl groups. The five-membered ring is sterically favored, and is formed where there is a choice, with $\overline{PtCl[CH_2C_6H_4PPh(o\text{-}Tol)][PPh(o\text{-}Tol)_2]}$[49] or $\overline{RuCl(CO)[MeC_6H_3OP(o\text{-}Tol)_2][P(o\text{-}Tol)_3]}$[8].



(58)



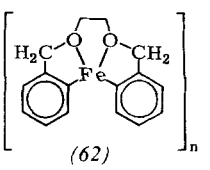
(59)

Reduction of $FeCl_2(PMe_3)_2$ with sodium amalgam affords monomeric $H\overline{Fe(CH_2PMe_2)}(PMe_3)_3$, containing a three-membered ring[101]. In contrast, internal metalation of $Ru(dmpe)_2$ [dmpe = $Me_2P(CH_2)_2PMe_2$] affords the dinuclear derivative *(58)*[102]. The presence of an $\overline{IrPC}$ ring has been established crystallographically in *(59)*, for which the phosphorus-ylide ($P{=}CH_2$) formulation is favored[102a].

(60)

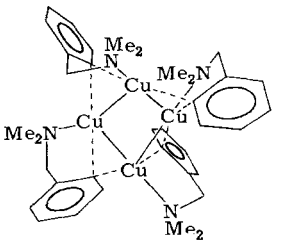
(61)

Six-membered rings have been obtained from 2-alkoxyphenylphosphanes in the case of *(60)*[47], and by palladation of *N*-aryl-amidines or -amides *(61)*, for which the usual five-membered ring cannot be formed[103].



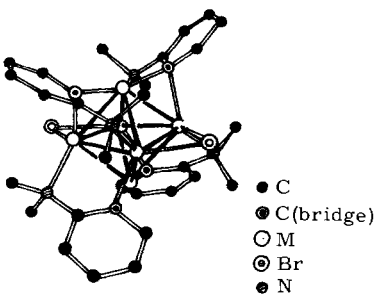
6. Other Reactions Leading to the Formation of Cyclometalated Products

6.1. Ligand Exchange



Treatment of $[\overline{PdCl(C_6H_4N{=}NPh)}]_2$ with carbonylmetalates, such as $[Re(CO)_5]^-$ or $[Co(CO)_4]^-$, affords the corresponding carbonyl(phenylazophenyl)metal complexes[104]. In contrast, reaction with $[Fe(CO)_4]^{2-}$ gave only bis(phenylazophenyl)palladium[28]. More recently, the preparation of $HgCl(C_6H_4N{=}NPh)$ by direct mercuration of azobenzene[105] has allowed the synthesis of several transition metal complexes[106].

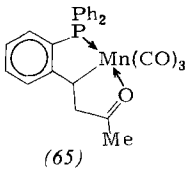
6.2. Reaction with Organo-lithium or -magnesium Reagents



Reactions between the appropriate organolithium or Grignard reagent and metal halide have been used to prepare several complexes containing *ortho*-metalated ligands. This type of reaction is especially useful for ligands containing weak donor atoms, and for obtaining complexes in unusual oxidation states. Thus, $Co(\overline{C_6H_4CH_2NMe_2})_3$[107] and *(62)*[108] can be obtained from the appropriate mono- and

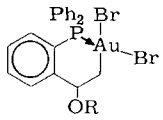
(62)

(63)



(64), M = Cu, Ag

dilithio derivatives. *Chini et al.* have described the syntheses of complexes containing $C_6H_4CH_2NMe_2$ ligands from *o*-$LiC_6H_4CH_2NMe_2$ and appropriate nickel, palladium, or platinum precursors[109], and of similar complexes derived from $KCH_2C_6H_4PPh_2$[110].

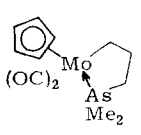


Reactions between copper(I) or silver(I) halides and *o*-$LiC_6H_4CH_2NMe_2$ or di- and tri-methoxyphenyllithium reagents have given polynuclear complexes [*e.g. (63)*] containing metalated ligands bridging the Group IB metals. These compounds are thermally stable, and contain tetranuclear clusters. Hexanuclear complexes such as *(64)* are formed on further reaction with the Group IB metal halide[111].

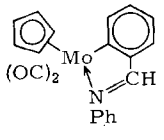
6.3. Insertions and Reactions with CC Double Bonds

The formation of metal-carbon σ-bonds by attack of nucleophiles on coordinated double bonds has been briefly alluded to already. An alternative route is the insertion of an unsaturated center into a metal-hydrogen or metal-carbon bond to give new examples of chelating metalated ligands. The reactions of alkenylphosphanes with $HMn(CO)_5$ or $MeMn(CO)_5$

(65)



(66)

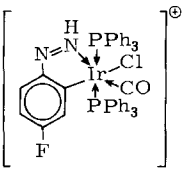


provide examples of these reactions, affording complexes such as *(65)*[112]. Similarly, electrophilic attack on complexes containing alkenyl-phosphanes or -arsanes has given derivatives such as *(66)* containing stable chelate rings having metal-carbon σ-bonds. Extensive studies of these reactions by *Bennett et al.*[68] have given a variety of related complexes, while the occurrence of this type of heteroatom chelating group has been documented elsewhere[53,113]. A detailed discussion of these interesting and novel complexes falls outside the scope of the present review.

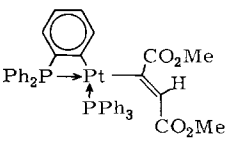
6.4. Miscellaneous Reactions

Other complexes containing cyclometalated ligands have been obtained from a wide variety of unrelated reactions, and the precise way in which they are formed is not obvious in all cases. Thus dehalogenation of $MoI(CO)_2[Me_2As(CH_2)_3Cl](C_5H_5)$ with sodium amalgam forms *(67)*[114], while reaction between *o*-$BrC_6H_4CH{=}NPh$ and $[Mo(CO)_3(C_5H_5)]^-$ afforded *(68)*, also obtained directly from $MoCl(CO)_3(C_5H_5)$ and the Schiff base, and separable into optical isomers[115]. The reaction between $LiC_2B_{10}H_{10}$ and $PdCl_2(bpy)$ gives $Pd(C_6H_4C_2B_{10}H_{10})(bpy)$, which oxidatively

(67)



(68)



adds bromine to give stable palladium(IV) complex containing two Pd—C σ-bonds[116], while a similar reaction with $IrCl(PPh_3)_3$ has given $Ir(C_6H_4PPh_2)(PPh_3)_2$[117].

One of the products from the reaction between *Vaska*'s complex and *p*-$FC_6H_4N_2^+$ BF_4^- contains the *ortho*-metalated cation *(69)*, which can be readily hydrogenated to give the hydrazine complex[118]. Spontaneous cyclometalation of other aryldiazoiridium complexes occurs in chloroform[119]. Oxidative addition of azobenzenes or *o*-bromoazobenzene to *Vaska*'s complex gives iridium(III) complexes, *e.g.* $Ir(C_6H_4N{=}NPh)HCl(PPh_3)_2$[120].

Photolysis of the species $Pt(C_2O_4)(PPh_3)_2$ furnishes $[Pt(C_6H_4PPh_2)(PPh_3)]_2$ in moderate yields[121]. Attempted

(69)

(70)

carbonylation of the oxidative adduct of $Pt(PMePh_2)_4$ with $CF_2{=}CFBr$ afforded the platinum(IV) derivative $HBrPt(C_6H_4PMePh)(CF{=}CF_2)(PMePh_2)$[121a]. Pyrolysis of the η^2-alkyne complex $Pt[C_2(CO_2Me)_2](PPh_3)_2$ gives *(70)* *via* a two-step sequence in which oxidative addition of the aryl C—H bond to platinum is followed by insertion of the alkyne into the resulting Pt—H bond[122].

7. Mechanisms of Cyclometalation Reactions

7.1. Effect of Leaving Groups

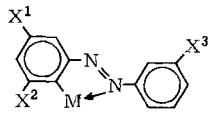
The metalation of aromatic substrates proceeds with the elimination of the *ortho*-hydrogen together with the group leaving the metal. Some representative small molecules eliminated are indicated in Table 2.

Using a variety of precursors, the relative ease of metalation of azobenzene by $MnR(CO)_5$ has been qualitatively established as R = $PhCH_2$ > Et > Me > $CH_2C_6Me_5$[48], the pronounced ease of metalation with the benzyl complex probably being related to the thermodynamic stability of toluene. On use of PdX_2L_2 (L = hindered tertiary phosphane) the order is

Table 2. Influence of leaving group on cyclometalation.

$2\,PdCl_2$	+	$2\,PhN{=}NPh$	→	$[PdCl(C_6H_4N{=}NPh)]_2$	+	$2\,HCl$			[4]
$MnCH_3(CO)_5$	+	$PhN{=}NC_6F_5$	→	$Mn(C_6H_4N{=}NC_6F_5)(CO)_4$	+	CH_4	+	CO	[16]
$Mn(CH_2Ph)(CO)_5$	+	$C_6H_5CH_2SMe$	→	$Mn(C_6H_4CH_2SMe)(CO)_4$	+	$PhCH_3$	+	CO	[92]
$2\,Pd(OAc)_2$	+	$2\,PhCH{=}NPh$	→	$[Pd(C_6H_4CH{=}NPh)(OAc)]_2$	+	$2\,HOAc$			[32]
$Pt(NO_3)[CH_2C_6H_4PBu^t(o\text{-}Tol)][PBu^t(o\text{-}Tol)_2]$			→	$Pt[CH_2C_6H_4PBu^t(o\text{-}Tol)]_2$	+	HNO_3			[123]
$Pt(C_3H_5)(C_5H_5)$	+	$PhN{=}NPh$	→	$Pt(C_6H_4N{=}NPh)(C_5H_5)$	+	C_3H_6			[19]
$Ni(C_5H_5)_2$	+	$PhCH{=}NPh$	→	$Ni(C_6H_4CH{=}NPh)(C_5H_5)$	+	C_5H_6			[42]
$Mn_2(CO)_{10}$	+	$PhN{=}NPh$	→	$Mn(C_6H_4N{=}NPh)(CO)_4$	+	$MnH(CO)_5$	+	CO	[15]
$IrHCl(C_{10}H_6PMe_2)[PMe_2(Nap)]_2$			→	$IrCl(C_{10}H_6PMe_2)_2[PMe_2(Nap)]$	+	H_2			[124]

Cl < Br < I. In contrast, with tertiary phosphites, the reverse order was established, suggesting that different mechanisms are operative in these cases.



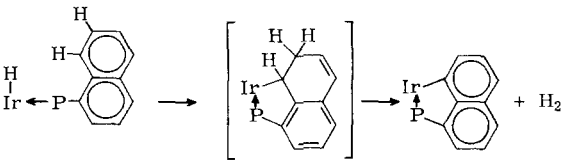
In several instances, the metalation of ligands by loss of hydrogen has been reported: *e.g.*, complex $IrHCl(P{-}C)(P)_2$ [P = PMe_2(naphthyl); P—C = $C_{10}H_6PMe_2$] is reported to melt with gas evolution, resolidifying to give $IrCl(P{-}C)_2P$[124]. In contrast, metalation of azobenzene with $Mn_2(CO)_{10}$ does not give greater than 50% yields of $Mn(C_6H_4N{=}NPh)(CO)_4$, with the balance probably forming $MnH(CO)_5$, which does not react further. The complex $RuH(PPh_3)_2(C_5H_5)$ is stable for days in refluxing dibutyl ether. In some cases, therefore, it would appear that formation of H_2 in the metalation reaction is a relatively difficult process.

7.2. Steric Factors

In a series of complexes of tertiary phosphanes, the presence of bulky groups promotes the metalation reaction, and a five-membered chelate ring is favored. If this is a thermodynamic effect, *Shaw*[125] has proposed that metalation results in a decrease of steric interaction, and thus formation of stronger M—P bonds. He further suggests that the change in entropy on metalation of a bulky phosphane (which has already lost much of its entropy, for example by constraints on rotation) would be considerably less than for a freely rotating tertiary phosphane ligand of low bulk. This argument can be extended to account for palladation of $PhCH_2NMe_2$, but not of the analogous P and As ligands, although, as pointed out above, a suitable choice of leaving group can markedly affect the course of these reactions.

7.3. Electronic Effects

A variety of qualitative evidence is available in the literature which gives some insight into mechanism. Thus, palladation of *para*-substituted azobenzenes gives results consistent with an electrophilic attack of the ring, palladation of the substituted ring occurring more easily along the series: Cl < H < Me < OMe[126]. Similarly *para*-tolylphosphanes show an increased tendency (over the phenyl derivatives) to be metalated by platinum(II). For $IrClL_3$ [L = $P(C_6H_4X\text{-}p)_3$], the rate of metalation increases in the order X = F < H < OMe < Me[88].



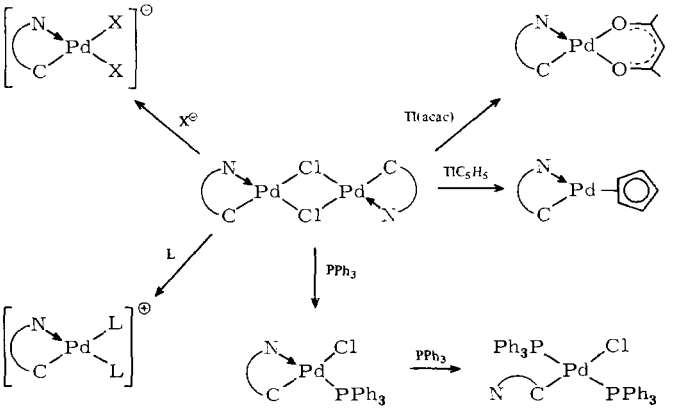
(71), M = $Mn(CO)_4$
(72), M = $Pd(C_5H_5)$

	X^1	X^2	X^3
a	H	F	H
b	H	H	F
c	F	H	H

We used *meta*-substituted azobenzenes. The substituent will therefore be *ortho* or *para* to the metalated carbon in the resulting complex. In this way we have shown that reactions of substituted azobenzenes with $MnCH_3(CO)_5$ or $PdCl_2$ proceed in a manner which is consistent with a nucleophilic reaction of the electron-rich manganese complex, or an electrophilic reaction of the palladium complex[127]. Thus, with *m*-fluoroazobenzene, $MnCH_3(CO)_5$ affords 80% *(71a)* and 20% *(71b)*, while palladium(II) chloride reacts to produce < 1% *(72a)*, 80% *(72b)*, and 20% *(72c)*.

Two possible mechanisms have been considered for the metalation of tertiary phosphane or phosphite ligands: *viz.* electrophilic substitution and oxidative addition, which may be followed by reductive elimination of a small molecule. In some reactions, *e.g.* the metalation of iridium(I) complexes $IrCl(EPh_3)_3$ (E = P, As, or Sb), or the reaction between $IrCl(CO)(PPh_3)_2$ and azobenzene, the product is the iridium(III) complex. Similarly, the rate of metalation of some platinum complexes with bulky phosphanes, which increases in the order Cl < Br < I, agrees with oxidative addition to form a platinum(IV) complex, which then eliminates hydrogen halide. On the other hand, with tertiary aryl phosphite complexes of palladium(II) or platinum(II), the ease of metalation shows the opposite trend, *i.e.* I < Br < Cl.

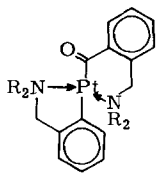
The rate of iridiation of PMe_2(Nap) is enhanced by replacement of Cl by H in the iridium complex. Although this argues against an electrophilic reaction, the iridium is coordinatively saturated in these complexes, so that metalation probably does not proceed by oxidative addition. A hydrogen addition-elimination mechanism has been suggested[124] (Scheme 6).



Scheme 6.

These results suggest that cyclometalation reactions may proceed *via* different mechanisms, according to metal and substrate, or more probably, the balance of steric and electronic factors in each case determines the nature of the final product. Certainly, this is one aspect of the cyclometalation reaction which requires further detailed and careful study.

8. Reactions of Cyclometalated Complexes



The metal-carbon σ bond in cyclometalated complexes is remarkably robust, and a variety of conventional reactions can be successfully carried out, for example on the halide complexes which leave it intact. Scheme 7 illustrates a selection

Scheme 7.

of reactions reported for some palladium derivatives, and involve the formation of anionic and cationic, as well as neutral, derivatives[128-131]. The replacement of halide by β-dionate or η^5-C_5H_5 ligands has often been used to facilitate the characterization of rather intractable halide complexes.

The donor atom of many cyclopalladated nitrogen-containing ligands can be readily displaced by other donor ligands, such as tertiary phosphanes, with formation of substituted phenylpalladium complexes[129]. Similar reactions have been found with platinum compounds, and phosphane exchange proceeds by intramolecular nucleophilic reactions in these complexes[132]. The chelate ring in $[Ru(C_6H_4N{=}NPh)Cl(CO)_2]_2$ can be opened by treatment with TlC_5H_5 or K[HB(pyrazolyl)$_3$], and subsequently reformed by thermal or photochemical reactions[133].

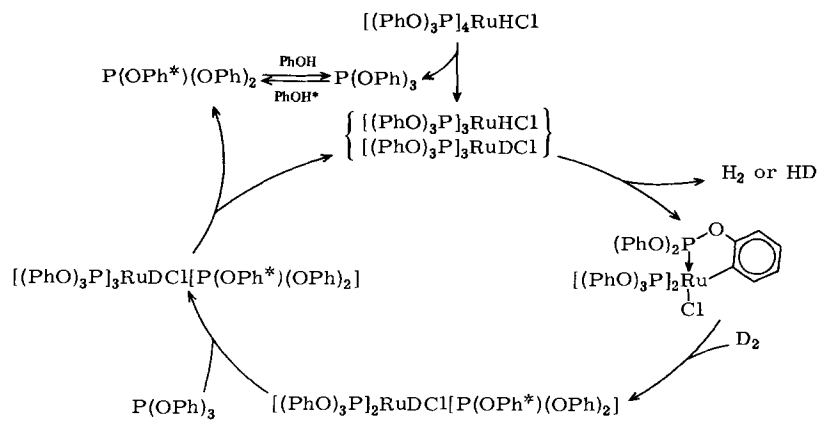
(73)

Platinum derivatives of *N,N*-dialkylbenzylamines react with CO with displacement of the coordinated nitrogen and migration of the aryl group to form the acyl complex *(73)*[109].

9. Cyclometalated Complexes in Synthesis

9.1. Hydrogen/Deuterium Exchange

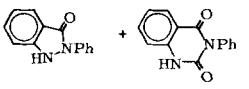
In several cases, the cyclometalation reaction can be reversed by hydrogenolysis of the metal-carbon σ-bond. The activation of molecular hydrogen by transition metal complexes is a well-known reaction, and many examples of H_2/D_2 exchange catalyzed by such complexes are known. Of particular interest in the present context is the specific *ortho*-hydrogen/deuterium exchange observed on treatment of complexes such as $RhCl[P(OPh)_3]_3$ or $RuHCl(PPh_3)_3$ with D_2[134], a reaction which may be extended to the catalytic *ortho*-deuteration of phenol using $RuHCl[P(OPh)_3]_4$. In this case a catalytic cycle involving consecutive metalation-demetalation reactions can be constructed (Scheme 8).

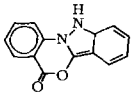


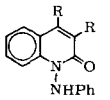
In addition to *ortho*-hydrogen exchange, olefin deuteration studies using $RuHCl(PPh_3)_3$ or $CoH[P(OPh)_3]_4$ (giving deuterated ethylenes and ethanes)[10], hydrogenation of olefins by $NiBr_2(PPh_3)_2$ in the *absence* of hydrogen[135], and the formation of *trans*-(*o*-DC_6H_4)CH=CDPh [catalyzed by $RhCl_3(py)_3/NaBH_4/HCONMe_2$][136] all implicate intermediate *ortho*-metalated complexes.

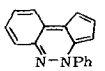
9.2. Synthesis of Heterocycles

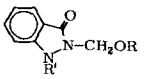
Simple ring-closure of metalated complexes with elimination of the metal group from the chelate ring, with or without replacement by small molecules, offers a simple synthesis of many unusual heterocyclic molecules. Indeed the formation of heterocycles by "hydroformylation" of azobenzenes and Schiff bases in the presence of cobalt carbonyl catalysts[137] has been rationalized by CO insertion into the Co—C bond of an intermediate metalated species[104]. *Rosenthal*[138] has provided an excellent summary of early accounts of reactions of this type, and Table 3 lists some heterocyclic systems that have been obtained from cyclometalated intermediates.

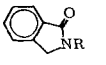


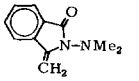


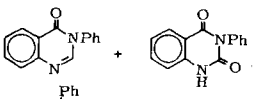






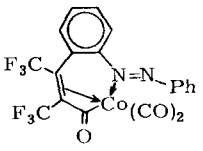






Mechanistic patterns in the carbonylation of cyclopalladated ligands have been determined, and enable products from these reactions to be predicted[22]. Similarly, carbonylation of metalated sulfur ligands has proved to be a convenient route to benzo[*c*]thiophenes[95], and similar treatment of Schiff bases in the presence of rhodium complexes afforded isoindolones[140].

These carbonylation reactions generally correspond to the replacement of the metal atom in the chelate ring by a molecule of CO. The arylcyclopenta[*c*]cinnolines formed from reactions between $Ni(C_6H_4N{=}NPh)(C_5H_5)$ and derivatives with *o*-chloro- or *o*-bromo-azobenzene contain the azobenzene fragment from the original complex, and correspond to a formal replacement of the metal atom by a double bond of the C_5 ring[141]. A C_3 unit replaces cobalt in the reaction between $Co(C_6H_4N{=}NPh)(CO)_3$ derivatives and $C_2(CF_3)_2$, when an



Scheme 8. OPh* = OC_6H_4D-*o*.

Table 3. Some heterocyclic syntheses involving cyclometalated complexes.

Ligand	Metal	Small molecule	Heterocycle		Ref.

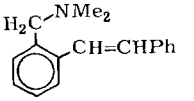
anilinoquinolone can be isolated. Formation of this heterocycle proceeds *via* the unusual complex *(74)*[142]. These heterocyclic syntheses often proceed in high yield, to give products which are otherwise only available *via* many-step syntheses.



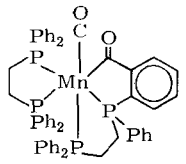
(74)

10. Other Reactions of the Metal-Carbon Bond

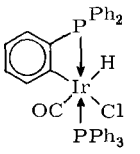
The metal-carbon σ-bond in cyclometalated complexes may be cleaved by a variety of reagents to give other organic products. Thus reductive cleavage of metalated azobenzene with $LiAlD_4$ affords *o*-deuterioazobenzene[4], while halogenation of azobenzene in the presence of $PdCl_2$ affords a mixture of *o*-haloazobenzenes, prolonged reaction affording good yields of 2,2',6,6'-tetrahaloazobenzenes. All these products are formed *via* the intermediate cyclopalladated complexes[143].

In contrast, chlorination of $\overline{PdCl(C_6H_4PPh_2)}(PPh_3)$ affords only $PdCl_2(PPh_3)(o\text{-}ClC_6H_4PPh_2)$[116]. Carbonylation of $\overline{[RhCl(C_6H_4N{=}NPh)_2]_2}$ causes linkage of the two azobenzene moieties to form 2,2'-bis(phenylazo)biphenyl[26].

Other reactions in which cyclometalated complexes are known or suspected to be intermediates include reaction of anilines, CCl_4, and CO in the presence of a cobalt complex to give quinazolinones and -diones[144], of *o*-lithiated *N,N*-dimethylbenzylamine with carbonyliron or -nickel compounds, followed by addition of organic halides (RX) to give ketones $Me_2NCH_2C_6H_4COR$[145], and carbonylation of the product from $Me_2NCH_2CH{=}CH_2$ and $PdCl_2$ to give esters 4-(*N,N*-dimethylamino)-3-methoxybutyric acid. Cyclopalladated complexes react with α-olefins, to give *e.g. (75)*[146], or substituted acrylic esters[72].



(75)

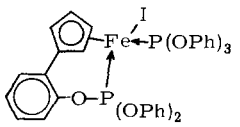


11. Other Cyclometalated and Related Complexes

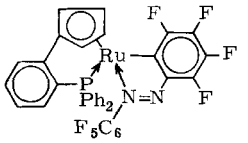
The ready ring enlargement that can occur in reactions between internally metalated complexes containing a four-membered ring and small molecules such as CO or alkynes have been mentioned in Section 9. In cases where a chelating

bis-tertiary phosphane is metalated, the resulting bicyclic system of fused four- and five-membered rings would be expected to have greater reactivity. Reactions between $Mn_2(CO)_{10}$ and $Ph_2P(CH_2)_2PPh_2$(dppe) afford small amounts of *(76)* formed by insertion of CO into an initial cyclometalated intermediate[147].

(76)



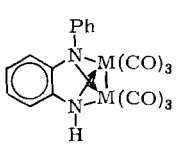
(77)



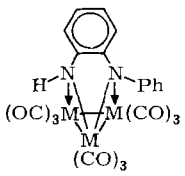
In the older literature, there are several reports of metal complexes of apparently unusual stoichiometry, which have been shown subsequently to be *ortho*-metalated complexes. Examples include $M[P(OPh)_3]_4$ (M = Rh or Ir)[148] and $\{Fe[P(OPh)_3]_2(C_5H_5)\}_2$, now known to be $\overline{M[(C_6H_4O)P(OPh)_2][P(OPh)_3]_3}$[7] and $\overline{Fe[(C_6H_4O)P(OPh)_2][P(OPh)_3](C_5H_5)}$[86], respectively.

An isomer *(77)* of *Vaska*'s complex, $IrCl(CO)(PPh_3)_2$, has been obtained by briefly heating $IrCl(N_2)(PPh_3)_2$ in Me_2SO, followed by reaction with CO. Surprisingly, *(77)* reverts to *Vaska*'s complex on standing or brief warming in benzene[149].

The interaction of *ortho*-C—H atoms with transition metals has been found in several complexes, by X-ray diffraction studies in $RuCl_2(PPh_3)_2$[150] and $[Ir(dppe)_2(S_2)]Cl$[151] for example, and by ^{1}H-NMR measurements on several other dppe complexes[152].

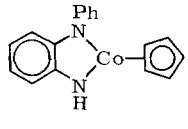


(78)



(79)

In two instances, complexes containing ligands formed by interaction of aryl groups with η^5-C_5H_5 groups have been characterized. One of the "isomers" of $FeI[P(OPh)_3]_2(C_5H_5)$ is *(78)*[153], and the reaction between $RuMe(PPh_3)_2(C_5H_5)$ and $C_6F_5N{=}NC_6F_5$ affords *(79)*[83]. The new ligands, containing substituted phenylcyclopentadienyl groups formed by formal elimination of hydrogen, may proceed by activation of the *ortho*-C—H bond by the metal.



(80)

M = Fe, Ru

(81)

(82)

The activation of the *ortho*-C—H bond in azo compounds does not always result in the formation of a cyclometalated complex. Thus, reactions between azobenzenes and carbonyliron[28] or -ruthenium[154], or $M(CO)_2(C_5H_5)$[140, 155] (M = Co or Rh) afford complexes *(80)*—*(82)* containing rearranged ligands derived from *o*-semidine. Formally, the reaction consists of cleavage of the N=N bond, migration of the *ortho*-hydrogen to a nitrogen, and attachment of the nitrene to the *ortho*-carbon, the metal remaining σ-bonded to the nitrogens. The precise mechanism of this reaction remains obscure.

Cleavage of the N=N bond in azobenzenes, or the CH=N bond in Schiff bases, by rhodium complexes, gives the corresponding amines, isolated as the metal derivatives[156, 157].

12. Outlook

The foregoing account shows that cyclometalation reactions form a large and growing area of transition metal complex chemistry, and that the original *ortho*-metalation reaction is but one aspect of this field. It is also evident that chelation of ligands to induce specific *ortho*-H activation is but a specific example of the more general problem of the homogeneous catalytic activation of C—H bonds by transition metal complexes. We may expect that studies of cyclometalated intermediates will provide further clues to the ways in which C—H bonds may be induced to react with a variety of reagents under mild conditions.

Other exciting developments are occurring with studies directed toward the involvement of transition metals in organic synthesis. We must be ready to consider transition metals complexes as stoichiometric reagents in the synthesis of unusual organics, particularly heterocycles, in one- or two-step reactions. In these cases, the costs of the transition metal reagents, many of which are available commercially, are more than offset by savings in time and materials used in more conventional but tedious multi-step syntheses.

To these ends, much more detailed knowledge about the course of cyclometalation reactions is required, and the study of the reactions of the cyclometalated products is still in its infancy. It is likely that with enough foresight, three or four-component reactions proceeding to give products without the necessity for isolation of the cyclometalated intermediate will be developed. Further investigation of the reactions of cluster compounds with organic materials will serve to delineate the hydrogen-abstraction reactions which are becoming characteristic of these materials, and draw parallels with reactions of metal surfaces, which in turn may then be used to catalyze some of the reactions described above.

It is a pleasure to acknowledge the help and encouragement of Professor Gordon Stone, F. R. S., without whom this work would not have been started. Thanks are also extended to Drs. Zafar Iqbal and Brian Goodall, for their essential contributions, to my other coworkers mentioned in the references, and to Dr. Michael Green for stimulating discussions.

Early History of the Quantum Mechanical Treatment of the Chemical Bond[**]

By Friedrich Hund[*]

Formulation of the Schrödinger equation (1926) laid the foundation for a theory of the electronic structure of molecules, and thus for a physically sound theory of the homopolar chemical bond. Physicists reached a qualitative understanding of the bond in diatomic molecules during the ensuing years 1927 to 1929, and of stereochemistry by 1931.

1. Survey

The history of a scientific discipline usually advances in a series of small steps. Any account of this history, however, must trace lines of development; their evaluation is subjective. Anybody who has been actively involved in such a history is in danger of presenting developments as he understood them at the time. It is hoped that trap has been largely avoided in the present article.

In the early days of "quantum chemistry" interest was focused not so much on calculation of physical quantities but rather on acquiring a qualitative understanding of chemical phenomena; that is, an understanding in terms of physical concepts. The topic of my account could equally well be: How did physicists understand chemistry? The chemist's idea of the atom, the periodic system, and rules for valence, saturation, bond angles were a challenge to physicists; the physicist's response was the quantum mechanics of atoms and molecules. If we regard quantum mechanics as the doctrine of mutual demarcation between a corpuscular and a wave or field view of matter, then the chemical bond appears as a manifestation of the field aspect of matter in the atomic shell, but the integral number laws as a manifestation of the corpuscular aspect, *i.e.* of electrons. Both aspects found expression in the Schrödinger equation formulated in 1926, even if this was only appreciated somewhat later. Although a "wave equation", it was also an equation for a system with one electron, with two electrons, *etc.*

The situation had been incompletely expressed in the provisional atomic dynamics developed between 1913 and 1924. It had led to an "Aufbauprinzip" for atoms, in which 1s, 2s, 2p, 3s, *etc.* electrons were consecutively added, their total number per "electron shell" being limited by a maximum eventually decided upon as 2, 6, 10... for s, p, d shells respectively. A vector model in which an angular momentum vector S (units: $h/2\pi$) of the total spin was combined with an angular momentum vector L of the orbits to give a resultant J, L being made up of the angular momentums $l_1, l_2 \ldots$ of the individual electrons, in conjunction with the Pauli exclusion principle permitted extensive understanding of atomic spectra. Attempts to treat molecular spectra in similar manner met with only partial success.

The formation of a molecule from (initially) two atoms could not be understood with these tools. An explanation of sorts was available for the rotational and vibrational components of the terms of molecular spectra. The "electronic terms" then had to correspond to states of the electron shell in the field of two atomic nuclei, and formation of a molecule from two atoms to the change in the ground state on transition from distant nuclei to proximate nuclei. A satisfactory treatment of such a system only became possible with the advent of the Schrödinger equation. Within a short time of its formulation, there began a rapid development of the theory of molecular structure and of interpretations of chemical valence, starting with diatomic molecules and progressing to polyatomic ones. The following steps are discerned with comparative ease: *molecular structure in analogy to atomic structure* (1925/26), *first understanding of the electronic structure of a diatomic molecule* (1926), *interpretations of valence (1927–1929)*, *understanding of stereochemistry* (1930/31). As already mentioned, this understanding was primarily qualitative. Those were the happy days in which "der Rahm noch nicht abgeschöpft war".

2. The Schrödinger Equation as a Tool

An essential requirement for any understanding of the chemical bond was that the structure of a molecule be understood. Prior to the formulation of the Schrödinger equation molecular structure was understood only fragmentarily in analogy with the contemporary understanding of atomic structure. The terms of atomic spectra exhibited "multiplicities"; these were even (doublets, quartets, *etc.*) for odd numbers of electrons, and odd (singlet, triplets, *etc.*) for even numbers of electrons. A similar situation was found in the electronic terms of diatomic molecules (*Mecke*, *Birge*, *Mulliken* 1924/25); analogous fundamental structures were also discovered in the electronic terms of molecules having the same number of electrons. Thus doublets resembling those for the Na atom were found in the series BO, CN, CO^+, N_2^+, and singlets and triplets like those for the Mg atom were found in the series CO, N_2, NO^+. *Mulliken* introduced a notation expressing these analogies: the form later adopted was: $^1\Sigma$, $^2\Sigma$, $^3\Sigma$, $^1\Pi$, $^2\Pi$, $^3\Pi$.

The vector model had to be modified to accommodate symmetry about the molecular axis instead of the spherical symmetry of the atom; the angular momentum quantum number L was replaced by the quantum number of the angular momentum about that axis, later to be called Λ. The combination of S and Λ with the angular momentum of rotation

[**] Based on a lecture delivered at the A-76 Conference: "Exploring the Chemical Bond—New Developments" held by the Chemical Physics Section of the Atomic Physics Division, European Physical Society at Amsterdam (August 30—September 1, 1976).

was newly introduced for the molecule. Depending upon the conditions, this led to different "coupling cases" (*Hund* 1926) which proved useful in distinguishing band types corresponding to the transitions later known as $\Sigma \rightarrow \Sigma$, $\Pi \rightarrow \Sigma$, and $\Pi \rightarrow \Pi$ transitions. While work was progressing on this "term zoology"—in which aspects of proven value in atomic spectra were applied to molecular spectra (*Mulliken* was particularly successful)—there was born the Schrödinger equation.

The equation appeared to be a reliable and, compared to the quantum mechanics developed by *Heisenberg*, *Born*, *Jordan*, and *Dirac* in 1925, conveniently manipulated basis for calculating the electronic states of a molecule, or more precisely the energies of electrons in the force field between two nuclei as a function of the distance between these nuclei. This energy function was then approximately the potential energy for the vibration of the nuclei. Immediately upon publication of the Schrödinger equation, *Burrau* performed an approximate calculation for the ground state of the simplest molecule H_2^+[1].

In general, the Schrödinger equation permitted a number of qualitative statements which were not forthcoming from the provisional atomic dynamics. Even in the simple case of a single electron in a one-dimensional potential $V(x)$ the "correspondence principle", *i. e.* the key concept of this provisional atomic dynamics, furnished approximate information about the energies $E(n)$ of the quantum states only for a relatively smooth function $V(x)$. It failed with potentials like that of Figure 1, the simplified model of a diatomic molecule.

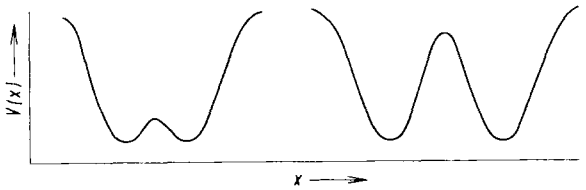

Fig. 1. Model of a diatomic molecule.

The Schrödinger equation, which is an ordinary differential equation in the one-dimensional case, is solvable (graphically for instance). Thus it was possible to interpolate between the case of widely separated potential troughs and the case of adjacent or united troughs. In particular, starting with equal troughs at a distance and bringing them together led to a splitting; considered in three dimensions, the splitting of an atomic term into two terms of the dinuclear system. In this way qualitative energy level schemes could be obtained for the H_2^+ molecule ion and the H_2 molecule as an interpolation between He^+ and $H+H^+$ and between He and H+H respectively[2]. Only later were these considerations utilized as a model of the chemical bond (although they might well have served as such).

The two new features of quantum mechanics, as compared with classical mechanics, *viz.* the indivisibility of the action quantum h (wave-particle dualism, uncertainty relation) and the indivisibility of elementary particles and indistinguishability of like elementary particles found characteristic and highly pictorial expression in the Schrödinger equation. It was the wave concept that was responsible for the wave function's bursting over the boundaries of classical motion. This feature was exploited in the interpolation between states of the two-center system with widely separated centers and with proximate centers, and provided the first instance of the tunnel effect. The indistinguishability of like elementary particles, initially electrons, was expressed by the symmetry properties of the wave function. Only those solutions of the Schrödinger equation corresponded to reality which were antisymmetrically dependent upon the coordinates of the electron. Thus in 1926 *Heisenberg* explained the singlet and triplet system (para- and ortho-system) of the He spectrum: in the former the spin component of the eigenfunction was antisymmetric but the orbit component symmetric; the situation was reversed in the latter case. Similar reasoning applied to the H_2 spectrum. Correspondingly, for like nuclei: assumption of a proton spin (1/2) and suitable spins for other nuclei explained the differences in intensity observed in the rotational bands of molecules with two identical nuclei.

This was all very useful in the interpretation of band spectra, which was diligently pursued at the time (1926/27). However, the first interpretation of the chemical bond was obtained in 1927 from a somewhat different application of the Schrödinger equation.

3. Interpretation of Valence

The inaugural step of "quantum chemistry" was made in 1927 when *Heitler* and *London* applied the Schrödinger equation and a seemingly very crude approximative procedure to the H_2 molecule[3]. They approximated the eigenfunction of the two electrons (1, 2) in the expression

$$u(1,2) = a(1)b(2) \pm b(1)a(2) \qquad \text{(I)}$$

by the eigenfunctions a, b of electrons in two H atoms. In the crudest approximation of the energy of the two states as a function of the internuclear distance r

$$E(r) = C(r) \pm A(r) \qquad \text{(II)}$$

the contribution $A(r)$ was understandable only in the light of the new quantum mechanics as the consequence of encroachment of the wave function of one atom on the other. A was negative; hence the combination with the plus sign was that of lower energy. A could now be regarded as a measure of the chemical bond. It was comforting for those physicists who initially felt this interpretation to be too formal that the shape of the eigenfunctions (I) qualitatively afforded the result (II) with $A<0$. As a one-dimensional reduction, the left-hand side of Figure 2 represents the lowest-lying states of the molecule and the right-hand side the eigenfunctions

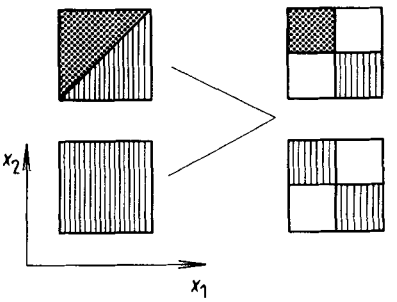

Fig. 2. One-dimensional model of the H_2 molecule.

for one electron each per atom in separate atoms, each belonging to the same lowest energy.

The procedure of *Heitler* and *London* was significant for two reasons: it led to a model of chemical valence and provided a pattern for similar crude approximations in which the eigenfunctions were approximated, not by a complete orthogonal system of functions, but by a very incomplete system of functions which were generally not orthogonal. Before long, physicists ventured to approximate functions of an electron in a symmetrical diatomic molecule in the form $a \pm b$ and to attempt a crude quantitative description of the splitting of an atomic term into two molecular terms mentioned in Section 2.

Heitler and *London* now framed a simplified model of chemical valence[4, 5]. In the case of H_2, a $^1\Sigma$ state of the molecule arose from the ^2S states of the H atoms with the plus sign in equation (I), and a higher, non-bonding $^3\Sigma$ state with the minus sign. Operation of the valence corresponded to the transition:

$$^1\Sigma \leftarrow {}^2S + {}^2S$$

and non-operation of the valence to:

$$^3\Sigma \leftarrow {}^2S + {}^2S.$$

No valence could operate on formation of a hypothetical HeH molecule:

$$^2\Sigma \leftarrow {}^2S + {}^1S.$$

In the ground state of the N_2 molecule

$$^1\Sigma \leftarrow {}^4S + {}^4S$$

three valences were saturated, and in higher states

$$^3\Sigma,\ ^5\Sigma,\ ^7\Sigma \leftarrow {}^4S + {}^4S$$

two, one, or none. Disregarding anything that happened in P, D,... Π... states, a simple scheme was available; in

$$^{m-n+1}\Sigma \leftarrow {}^{m+1}S + {}^{n+1}S; \quad m \geq n$$

one atom of valence m combines with one of valence n, with saturation of all n valences; in

$$^{m+n+1}\Sigma,\quad {}^{m+n-1}\Sigma,\quad {}^{m+n-3}\Sigma \ldots$$

0, 1, 2... valences are saturated.

This scheme conceived by *Heitler* and *London* in 1927/28 could also be applied to the combination of molecules with additional atoms. *It was a picture of the rules of chemistry concerning valence and saturation impressed upon expressions of quantum mechanics.* Hence it was a *model of valence*, albeit a greatly simplified model for it was overtaxed as soon as P, D... atomic terms occurred. Thus the true ground state of the O_2 molecule corresponded to the scheme

$$^3\Sigma \leftarrow {}^3P + {}^3P$$

According to the rules of the valence model this would mean saturation of only one valence for two divalent O atoms.

In 1929 *Heitler* introduced the designation "*orbit valence*" for the possibility of bonding relating to $L > 0$; its origin was elucidated two years later. The simple scheme shown above then corresponded to the "*spin valence*".

4. "Aufbau" Principle for Diatomic Molecules

The Schrödinger equation was used in the theory of molecular structure to develop a more exact idea about the relationship of rotation, vibration, and electron motion (*Born* and *Oppenheimer*, *Kronig* 1927). An understanding of electronic structure of diatomic molecules was sought with the aid of an Aufbau principle, resembling that used for atoms by *Bohr* to rationalize the periodic system of the elements. He had accomplished the conceptual jump from one atom to the next with an atomic number 1 unit higher by increasing the nuclear change by 1 and inserting one electron into an incomplete orbit, *i.e.* adding 1s, 2s, 2p, 3s, 3p, *etc.* electrons in turn. Corresponding to the symmetry about one axis diatomic molecules now required allocation of (in a later notation) σ, π, δ electrons, and a molecule with two identical nuclei σ_g, σ_u, π_u, π_g, electrons. In 1928 *Mulliken* deduced such an interpretation by states of individual electrons from the electronic term types ($\Sigma, \Pi, \ldots$) of the empirical molecular spectra of several molecules[6]. In so doing he noticed that on reducing the internuclear distance certain electronic states increased in energy—he called them "promoted electrons"—and thus did not contribute to bonding of the atoms.

Interpolation between the limiting case of proximate nuclei and the limiting case of distant nuclei held promise of revealing the energetic sequence in the addition of electrons, which was dependent upon the internuclear distance. There resulted, initially in tabular form, a kind of normal energy level scheme (*Hund* 1928[7])—nowadays known as a correlation diagram. For two identical nuclei it finally took the form shown in Figure 3.

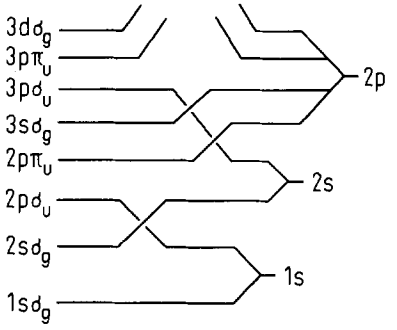

Fig. 3. Electronic states in a diatomic molecule having identical nuclei.

The diagrams of electronic energy levels which could be produced therefrom were not entirely unequivocal since it remained to be established whether, for variable internuclear distance, only the strictly fulfilled symmetries had to be considered or also the approximately fulfilled ones. *Herzberg* and *Lennard-Jones* showed in 1929 that the real conditions were best satisfied by the assignment which conserved all the symmetry quantum numbers of the individual electrons[8, 9].

These preliminary steps of a theory of the electronic structure of diatomic molecules also furnished aspects of the chemical bond complementing those put forward by *Heitler* and *London*. Introduction of an electron according to the Aufbau principle could strengthen or weaken the binding of the molecule. Thus interpolation along the series

$$\begin{array}{l} He^+ \text{ —— } H_2^+ \text{ —— } H + H^+ \\ He \text{ —— } H_2 \text{ —— } H + H \end{array}$$

showed that, owing to the high ionization energy of the atom, the ionization energy of H_2 was expected to be higher than that for H, *i.e.* the second electron in H_2 reinforces the bond already present in H_2^+. In contrast, the interpolations

$$\begin{array}{l} Li^+ \text{ —— } HeH^+ \text{ —— } He + H^+ \\ Li \text{ —— } HeH \text{ —— } He + H \end{array}$$

suggested a lower ionization energy for the hypothetical molecule HeH than for H, *i.e.* weakening of the bond possibly present in HeH^+[7]. The Aufbau principle of the molecule used by *Herzberg* in 1929 together with the interpolation of the states of the individual electrons led him to a very simple and convincing view of the chemical bond. On approach of two identical atoms the energies of the individual electrons split as shown in Figure 3. Occupation of a molecular state from the lower half of the resulting states by an electron strengthens a bond, while occupation of a state from the upper half weakens it. Its wave function has acquired a new nodal plane between the two atoms. On formation of N_2 from N + N just the states in the lower half (π_u, σ_g) are occupied: of the three p electrons belonging to each N atom, two go into the bonding π state and one into the bonding σ state, thus saturating three valences. On formation of O_2, a bond-weakening state (π_g) is also occupied; of the four p electrons belonging to each O atom, three enter bonding states and one enters a bond-weakening state, thus saturating two valences. *The valence of an atom is the number of electrons which can enter bonding states minus the number of electrons which have to enter bond-weakening states.* Similar arguments could be developed for molecules having non-identical atoms.

The relationship between the two interpretations of the chemical bond—the Heitler-London approach and that based upon the states of individual electrons—which had been rather poorly understood at the 1928 Bunsen Conference was soon to be better appreciated. If the lowest state σ_g of an individual electron of the H_2 molecule in the form $a+b$ is approximated by the states a, b in the atoms, then the expression for the ground state of the molecule

$$[a(1)+b(1)][a(2)+b(2)] = [a(1)b(2)+b(1)a(2)] + [a(1)a(2)+b(1)b(2)]$$

is seen to be a mixture of a state formed from atomic states according *Heitler* and *London* with a state arising from ionic states H^+ and H^-. Compared with reality, the contribution of the ions was overemphasized in the description by states of individual electrons of the molecules (soon to be called "molecular orbitals" by *Mulliken*); it was completely neglected by *Heitler* and *London*. Both procedures could be regarded as the starting point for a continuable approximation procedure. Their various aspects were complementary. The Heitler-London approach was certainly superior as an approximation for distant nuclei, *i.e.* for the transition to separated atoms, and hence for quantification of bonding. Perhaps the molecular

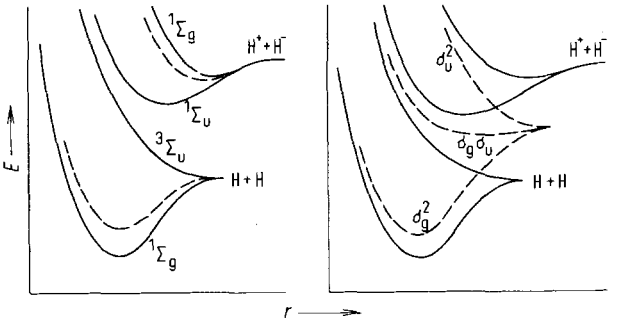

Fig. 4. H_2 molecule according to *Heitler-London* (left) and with states of individual electrons (right).

orbital approximation was better for proximate nuclei; the influence of interaction between electrons could easily be introduced in the same way as for atoms (in the case of $\sigma_g\sigma_u$ of H_2 as a splitting into a lower $^3\Sigma$ and an upper $^1\Sigma$ state). Figure 4 shows the qualitative course of the energy values as functions of the internuclear distance r—the Heitler-London procedure is shown on the left-hand side and the molecular orbital approach on the right (the first approximation is shown as a dashed curve in each case).

5. Stereochemistry

The tetravalence of carbon so important for chemistry could not be readily accommodated by either the Heitler-London scheme of spin valence or the Herzberg scheme of bonding and antibonding electrons. As early as 1928, however, *Pauling* suggested four electrons would become available for bonding if the energy gap between s and p electrons were regarded as small relative to the energy of a bond in a molecule[10].

Double bonds frequently occur in carbon compounds, *e.g.* in ethylene $H_2C{=}CH_2$. On replacement of one or more H atoms by another atom, then twisting about the double bond gives a molecule having different properties, whereas twisting about a single bond does not give a new isomer. Rotation is possible about a single bond, but not about multiple bonds. The reason was discovered by *Hückel* in 1930[11]. Single bonds are σ bonds (based on a bonding σ^2 state, two electrons in states whose eigenfunctions are symmetrical about the line joining the participating atoms). Double bonds contain a (somewhat stronger) σ bond and a (somewhat weaker) π bond; the eigenfunction of the two π electrons has a nodal plane containing the line joining the atoms. If the molecule has a distinct plane then twisting about the $\sigma\pi$ bond will require expenditure of energy.

Rules exist governing the bond angles, *e.g.* angle at the O atom, tetrahedral arrangement at the C atom, in polyatomic molecules. The explanation was found by *Slater*[12] and *Pauling*[13] in 1930/31: A strong bond is favored by pronounced overlapping of the eigenfunctions of the two participating atom electrons; if one atom supplies two p electrons they can contribute to two σ bonds if two mutually orthogonal p functions of this atom can engage in extensive overlapping,

i.e. the lines joining it to other atoms are roughly perpendicular to each other. The approximation procedure was worked out by *Slater*[12]: the eigenfunctions of the molecule were formed as a combination of products of functions of the individual electrons in the separate atoms, and of the many such combinations possible those were preferred for which the one-electron functions could overlap particularly effectively, *i.e.* which correspond to valence structures.

An understanding of the special situation in aromatic compounds, starting with benzene, was reached by *Hückel* in 1931[14] when he accommodated three of the four valence electrons of each C atom in σ bonds, and the fourth one for reasons of symmetry not in a π bond localized between two adjacent C atoms but in a state belonging to the whole ring. For this purpose *Hückel* employed two approximate procedures, *viz.* Slater-type combinations of eigenfunctions of individual electrons in separate atoms and Mulliken-type "Aufbau" from functions of individual electrons in the multicenter system.

Two starting points or procedures were now available for a qualitative explanation of the valence rules of organic chemistry, and their mutual relationship was appreciated. Thus it seemed an obvious step to classify the valences as s, p, p^2, p^3—on regarding the energy difference between s and p electrons as small, sp^2 and sp^3 valences were also available; an sp^3 valence led to a nonplanar system and an sp^2 valence to a planar one; p^4 and p^5 valences were similar to p^2 and p valences, respectively. Bonds were classified as σ, $\sigma\pi$, $\sigma\pi^2$ bonds (*e.g.* N_2), σ defect bonds (F_2), $\sigma\pi$ defect bonds (O_2) ("defect" meant an electron missing from a closed shell).

Apart from "spin valence", which was a very simple model of limited validity, *two concepts of the chemical bond* were also current for polyatomic molecules as from 1931. One of them corresponded to approximation of the eigenfunctions by functions of individual electrons in separate atoms, and hence took into account the interaction of the electrons at the same level of approximation as the effect of bonding to another atom. The other one corresponded to approximation by eigenfunctions of individual electrons in the multicenter system, and thus accounted primarily for the effect of bonding and relegated the interaction of the electrons to second place. The first concept is better suited for treating the transition from the molecule to separate atoms (in which the interaction of the electrons is particularly important, the difference between $H+H$ and $H^+ + H^-$ in the case of H_2 serves to illustrate this point). However, the second one is easier to manipulate and not inferior to the first when applied to the real interatomic distances encountered in a molecule. *Both concepts were known to be models* in the sense that effects were neglected not because they were small in magnitude but because they did not appear typical for the chemical bond. The models neglected these effects in different ways. Such was the vein of discussion about concepts of the chemical bond at the Physicist's Congress held at Bad Nauheim in 1932, and presumably also elsewhere in the world.

6. Conclusion

Meanwhile, highly sophisticated quantum mechanical techniques have grown up from the humble models of 1926 to 1931. The qualitative or crude quantitative beginnings nowadays appear fairly simple; after all, the convenient Schrödinger equation was available with the illustrative eigenfunctions. Let us briefly summarize those first steps:

1926: The Schrödinger equation permitted simple calculations and interpolation of molecular states between known atomic states.
1927: A simple interpretation of chemical valence appeared.
1928: The electronic structure of a diatomic molecule could be understood with the aid of an "Aufbau" principle.
1929: The chemical bond was also explained as contribution of the individual electrons.
1930: The special nature of the π bond was recognized.
1931: The valence rules of stereochemistry were understood.

The Surface Chemical Bond[**]

By Gabor A. Somorjai[*]

Adsorbed particles can be bound chemically to the surface of a solid (chemisorption). Modern variants of electron diffraction and electron spectroscopy now enable us to gain an insight into the nature of such surface chemical bonds, which play a key role in heterogenous catalysis and many other technically important phenomena such as adhesion, lubrication etc. Predominantly localized surface bonds can be compared to the covalent bonds in cluster compounds.

1. Introduction

The nature of the surface chemical bond that forms between adsorbed atoms and/or molecules on the surface of a solid has been the subject of extensive speculation over the past several decades. The formation and breaking of these bonds are controlling processes in heterogenous catalysis and play an important role in adhesion and lubrication, to name only a few of the many important phenomena that take place at surfaces. Only over the past decade have techniques become available that permit investigation of the surface bond on the molecular level: a) surface crystallography by low-energy electron diffraction (LEED), whereby the location, bond distance and bond angles of the adsorbates are determinable and b) electron spectroscopic techniques (ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS), and electron absorption spectroscopy), which permit studies of the electronic structure of the substrate and adsorbate and the vibrational frequencies associated with the various surface bonds. These techniques are still under development and have been applied to only a few adsorbate systems. Nevertheless, as a result of these few studies a model of the surface chemical bond emerges. It appears that the bonding in the solid surface-adsorbed molecule (atom) system is localized among a few neighboring atoms that can be viewed as a cluster. The adsorbed species are bound to one or several of the nearest surface atoms in well-defined configurations corresponding to maximized bond energy. Correlations between chemical bonding at the surface and bonding in multinuclear clusters of atoms have been found and will be discussed later.

In this paper we shall first discuss the structure and charge density of solid surfaces as revealed by low-energy electron diffraction and electron spectroscopic studies. These surface properties determine primarily the nature of the surface bond. We shall then review the adsorbate systems where information about the bonding has already become available.

2. Atomic Structure of Clean Solid Surfaces

Surface atoms are in an asymmetric environment. They are surrounded by atoms in and below the surface layer, but there are no atoms above them. This surface environment has also lower symmetry than that for atoms in the bulk. The structural asymmetry experienced by atoms at the surface can lead to surface reconstruction: atoms in the surface may move into new equilibrium positions that provide higher symmetry or greater overlap of available bonding orbitals.

2.1. Surface Reconstruction

There are several types of surface reconstruction observed for clean solid surfaces. Many surfaces have atomic structures that are different from that expected from the projection of the X-ray bulk unit cell. The surface atoms assume new equilibrium positions by out-of-plane buckling or by relaxing inward (contraction), which often results in entirely different ordered surface structures. An example of this is shown in Figure 1. The LEED pattern (a) and schematic representation (b) shown here are characteristic of the surface structure of the (100) crystal face of platinum. This surface exhibits the so-called (5×1) surface structure[1, 2]. There are two perpendicular domains of this structure and there are 1/5, 2/5, 3/5 and 4/5 order spots between the (00) and (10) diffraction beams.

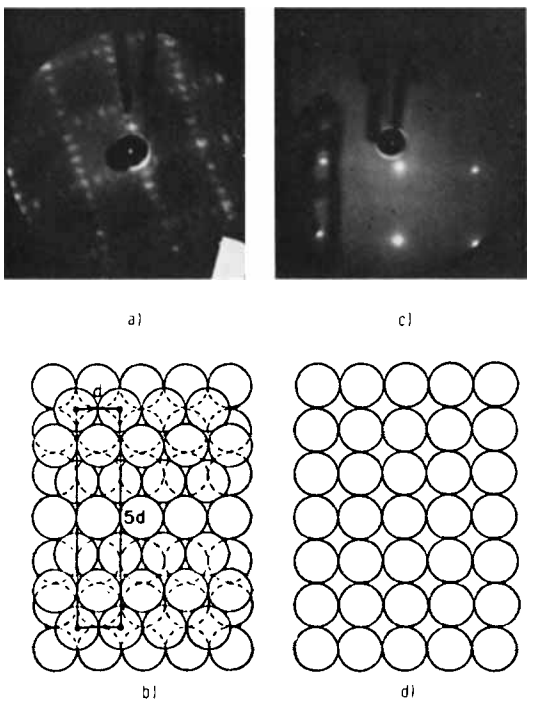

Fig. 1. a) Diffraction pattern of the Pt (100)-(5×1) structure; b) schematic representation of the (100) surface with a hexagonal overlayer; c) diffraction pattern of the Pt (100)-(1×1) structure; d) schematic representation of the (100) surface.

[**] Based on a lecture delivered at the conference "A-76: Exploring the Chemical Bond—New Developments" of the Chemical Physics Section of the Atomic Physics Division, European Physical Society, Amsterdam (August 30—September 1, 1976).

The surface structure appears to be stable at all temperatures from 25 °C up to the melting point, although at elevated temperatures impurities from the bulk can come to the surface and cause a transformation of the structure into the impurity stabilized (1 × 1) surface structure (Fig. 1, c and d).

Preliminary calculations by *Clark et al.*[3] and in our laboratory favor a model for Pt (100) in which the surface atoms assume a distorted hexagonal configuration by out-of-plane buckling. The apparent (5 × 1) unit cell is then formed as a result of coincidence of the positions of the atoms in the surface, *i.e.* of the atoms in the distorted hexagonal layer with those in the undistorted second layer below. The (100) crystal faces of gold[4] and iridium[5], which are neighbors of platinum in the periodic table, exhibit the same surface reconstruction and the same surface structure as that of platinum (cf. Fig. 1). The (110) crystal faces of these three elements are also restructured[6] and exhibit different unit cells than that expected from the bulk x-ray structure. On the other hand, the (111) crystal faces of these three metals appear to have the same surface structure as that indicated by the bulk unit cell.

For semi-conductors, most crystal planes that have been studied show reconstruction[7]. Numerous monatomic and diatomic semi-conductor surfaces have already been investigated and surface reordering has been observed for most of them. Frequently there are changes of surface structure with temperature that are often irreversible.

For many metal surfaces, the distance between the uppermost two layers, *i.e.* the *z*-spacing, is equal to that of the bulk value to within the estimated accuracy of about five percent. However, the Al (110)[8], Mo (100)[9] and W (100)[10] surfaces seem to show substantial contraction in the upper layer *z*-spacing with respect to the bulk while retaining the (1 × 1) surface unit cell. A simple contraction or expansion of the interplanar *z*-spacing of this kind is usually termed a "relaxation".

For many binary solids non-stoichiometry occurs in the surface layer: the surface composition may be different from that in the bulk[7]. Non-stoichiometry is apparently a major contributary factor in the observed reconstruction of the polar faces of the 3B-5B semi-conductors such as gallium arsenide, GaAs. The (111) face, for example, would ideally have all gallium atoms at the surface bonded to arsenic atoms immediately beneath the surface while the reverse would be true of the $(\bar{1}\bar{1}\bar{1})$ face. However, the $(\bar{1}\bar{1}\bar{1})$ surface has been found to lose arsenic at elevated temperatures and this is associated with the appearance of a new surface structure, while at low temperature another surface structure is arsenic stabilized[11]. Similarly, phosphorus is found to preferentially desorb at high temperatures from the gallium phosphide's $(\bar{1}\bar{1}\bar{1})$ surface[12]. On the other hand, the gallium arsenide (110) surface, which contains an equal number of gallium and arsenic surface atoms, does not exhibit reconstruction. A number of studies have also pointed to possible non-stoichiometry in alkyli-metal halide crystal surfaces upon cleavage[13]. On oxide surfaces, such as aluminum oxide[14] and vanadium pentoxide[15], changes in chemical composition and valency of surface atoms have been related to the formation of new surface unit cells.

Molecular crystals constitute a large and important group of materials that include most organic solids, but only very recently have the surface structures of some of these materials been investigated on an atomic scale by low-energy electron diffraction. Ice and naphthalene crystals have been grown by vapor-phase deposition[16] and ordered surface structures of crystals of many other organic solids such as benzene, trioxane, *n*-octane, cyclohexene and methanol have been grown on metal substrates at low temperatures[17]. Phthalocyanine crystals have been grown from the vapor-phase on ordered metal surfaces[18]. These high molecular weight, large size organic crystals exhibit a different kind of surface reconstruction. When copper phthalocyanine was grown on the Cu (111) surface, the surface structure of the growing organic crystal layer did not resemble the structure of any of the simpler crystal planes in the bulk structure of the organic crystal. It appears that the ordered metal substrate predetermined the orientation and packing of the phthalocyanine monolayer, which in turn controlled the orientation and packing of the organic layer deposited on top of it. For large molecules, such as phthalocyanine, restructuring into a more stable crystallographic arrangement requires molecular rotation and diffusion processes that are too slow under conditions of crystal growth. Thus the molecules are frozen into a surface structure that is predetermined by the structure of the substrate and the first adsorbed organic monolayer.

2.2. Surface Irregularities

As shown schematically in Figure 2, the surfaces of real solids are atomically heterogeneous and not smooth. There are several atomic sites present simultaneously that are distinguishable by their number of nearest neighbors. The symmetry of these low coordination number sites and their charge density are different from that of the sites on the smooth surface and are different from each other. As a result, large variations in chemical bonding of adsorbates at these different sites could occur. Indeed, there is an increasing body of experimental evidence indicating that atomic steps and kinks behave as different chemical entities at transition metal[19, 20] and semi-conductor surfaces[21], forming chemical bonds of different strengths compared to those formed by atoms on the terraces.

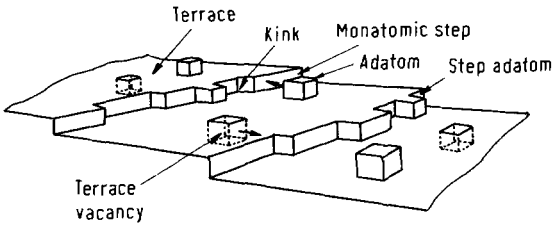

Fig. 2. Model of a solid surface on an atomic scale.

Surfaces with a large concentration of stable and ordered irregularities (steps and kinks) can be prepared by cutting crystal faces along directions having high Miller indices[22]. Stepped surfaces of metals[23], semi-conductors[24] and oxide surfaces[25] have been prepared in this way.

In order to study the surface chemical bond it is essential to carry out the investigation of structurally well-characterized solid surfaces. For this purpose single crystals of various orientations are used. Low Miller index crystal faces, *e.g.* the (111), (100) and (110) orientations of face-centered cubic metals, certainly have a high density of surface atoms and minimal

surface free energy. Under suitable conditions, these surfaces can be prepared in such a way that most of their atoms are terrace atoms. The density of steps or other irregularities are orders of magnitude lower than the total surface concentration (approximately 10^{15} atoms/cm^2). At the present stage of development, studies of adsorbate structure and bonding are carried out on atomically smooth and homogeneous surfaces such as are provided by the already mentioned low Miller index surfaces of cubic solids. One face of a single crystal of a clean solid provides the best surface to carry out these experiments. Hence, in this paper we shall not discuss the structural properties and adsorption characteristics of high Miller index surfaces that exhibit a large concentration of surface irregularities.

3. Charge Density at Clean Solid Surfaces

Let us consider an atomically smooth surface where each atom is in the same structural environment. The surface atoms have fewer nearest neighbors as compared to atoms in the bulk. As a result, electronic orbitals that participate in bonding of atoms in the crystal are available at the surface, where they give rise to increased charge density. These localized unsaturated bonding orbitals are frequently called dangling bonds and the angular distribution of their charge density largely depends on the structural arrangement (packing of atoms, orientation) at the surface. The excess free electron density at metal surfaces that is not localized on any particular atom gives rise to an induced surface dipole. The presence of this dipole is responsible for changes in the work function of metals from crystal face to crystal face. The formation of the surface dipole can be rationalized and demonstrated using the so-called jellium model. There are strong exchange correlation forces which act on the electrons in the solid due to many-body coulomb interactions. In the metal interior each electron lowers its energy by pushing others away to form an exchange-correlation "hole". This repulsive interaction is lost when the electron leaves the solid so there is a steep potential barrier at the surface. In the jellium model the positive charge density from the ion cores is smeared out over the atomic volume and the conduction electrons are free to respond to the surface barrier potential. At the surface, however, the electrons are not totally trapped and there is a small probability for them to leak out into the vacuum. Such a charge leakage creates a dipole effect which modifies the self-consistent surface barrier potential. This dipole creates an additional electrostatic barrier, V_{dipole}, for the electrons in the solid, so that the total barrier is, $V_{total} = V_{exchange} + V_{dipole}$. This gives the work function, $\phi = V_{exchange} + V_{dipole} - E_F$, where E_F is the energy at the Fermi level. Variations of the work function from crystal face to crystal face are well documented.

Surface irregularities, for example steps of atomic height, exhibit different work functions, as have recently been determined experimentally by *Wagner et al.*[26]. Theoretical studies provide firm foundation of the effect of surface heterogeneity and irregularities on the density of states at the Fermi level[27] and on the angular distribution of charge densities[28] at these low coordination number surface sites. Structural heterogeneity at the surface leads to chemical heterogeneity, *i.e.* the ability of the surface to carry out complex chemical rearrangements involving the simultaneous forming and breaking of surface bonds of varied strength at the various atomic surface sites.

4. Techniques for Studying the Surface Chemical Bond

4.1. Surface Crystallography by LEED Spectroscopy[29, 30]

A typical apparatus used for low-energy electron diffraction experiments is illustrated in Figure 3. Ultra-high vacuum conditions (base pressure approximately 10^{-9} torr) are maintained to ensure surface cleanliness. The backscattered electrons are post-accelerated onto a fluorescent screen and the diffraction pattern so produced is observed through a glass viewport. The condition of the surface under study is immediately apparent from the diffraction pattern. Sharp spots are indicative of long-range order (200 Å) on the surface. Diffuse and large spots probably signal poor ordering or the presence of adsorbed impurities. Extra diffraction spots, *i.e.* those not expected on the basis of simple termination of the bulk lattice structure along the surface plane, indicate either a reordering, reconstruction of the lattice in the surface region, or ordered structures of impurities. Electron spectroscopy—mainly Auger electron spectroscopy (see Section 4.2.1)—is routinely used to identify impurities that may be present in amounts of up to about one percent of a monolayer before, during and after low-energy electron diffraction studies.

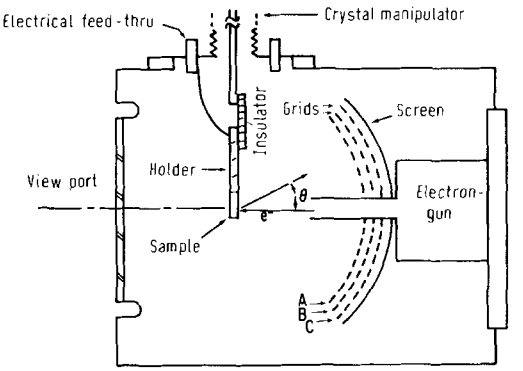

Fig. 3. A low-energy electron diffraction (LEED) apparatus of the post-acceleration type. Grids A and C are at ground potential for shielding purposes, and a voltage nearly equal to the gun accelerating potential is applied to grid B so that only the elastically backscattered electrons may pass through it. These electrons are then post-accelerated to a phosphor screen for observation through the viewport.

The electron energy range of 15 to 200 eV provides optimal surface sensitivity. Electrons of this energy range do not penetrate more than a few atomic layers before they undergo inelastic scattering events (absorption) and are lost from the diffracted (elastically backscattered) portion of the beam. Furthermore, they are rather strongly scattered in an elastic fashion by the attractive coulomb forces of the atomic nuclei and may traverse very complex trajectories (multiple or dynamical scattering) before leaving the crystal. These considerations are, or course, quite general and also have some bearing on the quantitative interpretation of various methods of electron spectroscopy.

As outlined above, the dimensions of the surface unit cell are readily found from observations of the diffraction pattern geometry. We cannot in this manner, however, discover the arrangement of atoms or molecules in the basis of the unit cell or obtain information concerning the spacings of atoms perpendicular to the surface plane. This essential information is obtained by analysis of the dependence of the intensity I of the diffraction spots on the incident beam energy V, from the so-called I/V profiles. These profiles exhibit pronounced peaks and valleys which are indicative of constructive and destructive interference of the electron waves scattered from planes parallel to the surface as the electron wavelength is varied. A rather complete quantum-mechanical description of this scattering has been achieved through the efforts of a number of theorists in recent years, but the details are outside the scope of this discussion. It suffices here to state that an accurate description of the I/V profiles generally requires consideration of several orders of multiple scattering and absorption due to inelastic events and vibrational effects. The diffraction beam intensities are measured by photographing the fluorescent screen or by using other means of detection of the elastically scattered electron flux[31]. The intensities are then calculated on the basis of a scattering model in which the essential parameter to be adjusted is the atomic geometry. The assumed geometry is varied until the best fit between theory and experiment is reached. Fortunately, the calculated I/V profiles are very sensitive to geometrical spacings, so that an accuracy of 0.1 Å in atomic positions have been obtained in the better calculations. This procedure has already been applied to numerous clean surfaces and has also provided quantitative information about bonding for atomic and molecular adsorbates. Alternates of this rather indirect method of analysis have not as yet proven viable.

4.2. Electron Spectroscopy Techniques

The methods of electron spectroscopy that are used to determine the surface composition and bonding may be divided into two groups: (i) The techniques of core-level electron spectroscopy, which enable chemical identification on the basis of the characteristic energies of atomic core states. Variations of surface chemical bonding are observed as chemical shifts of the core levels. (ii) The techniques of valence-level spectroscopy, which are also sensitive to chemical structure. Here an electron is excited from the valence band or the bonding orbital of the surface atom or adsorbate; from its energy, information can be obtained about chemical bonding and structure at surfaces.

4.2.1. Core-level Electron Spectroscopy

There are four processes involving core levels that are of importance in surface studies.

1. Incident X-rays excite electrons from a core level into a vacuum. The energy distribution of the emitted electrons is observed. This is the principle of *X-ray photoelectron spectroscopy* (XPS)[32].

2. Incident electrons cause electron excitation from a core level to a final level above the Fermi level and in so doing suffer a detectable loss in energy. The technique used for measurements in this case is called *energy-loss spectroscopy* (ELS)[33].

3. After initial excitation of the core level by incident X-rays, electrons, ions *etc.*, an Auger deexcitation process occurs. The core hole is filled by an electron transition from a higher occupied level and the transition energy is transferred to another electron (Auger electron) in the same atom or in a neighboring atom which is then emitted. In *Auger electron spectroscopy*, the energy distribution of emitted electrons is observed[34].

4. After excitation of an electron from a core level by an incident electron, the core hole is filled by a transition from a higher occupied level and X-rays or Auger electrons are emitted. In *appearance potential spectroscopy* (APS) the derivative of the intensity of emitted X-rays or Auger electrons is measured as a function of the incident electron energy[35]. At each threshold value of the incident electron energy, at which the energy is just sufficient to excite a core electron to vacant levels above the Fermi level (E_F), the intensity of emission suddenly increases. This is recorded as a peak in the derivative curve of the emission intensity.

4.2.2. Valence Electron Spectroscopy

In ultraviolet photoelectron spectroscopy (UPS)[36] an ultraviolet photon is absorbed by a valence electron whose energy is increased by $\hbar\omega$, making it possible for the excited electron to leave the crystal. The final state energy E_2 of the excited electron is measured, thus also enabling determination of the initial state energy E_1: $E_1 = E_2 - \hbar\omega$. Currently, surface studies are carried out at photon energies in the range of 10 to 45 eV.

4.2.3. Electron Absorption Spectroscopy[37]

In this technique the energy losses suffered by incident electrons of 1—10 eV energy are monitored with a resolution of ± 7 to 20 meV. Monochromatized incident electron beams and high energy resolution electron detectors are employed for such studies. Exploitation of the fact that the energy losses in this energy range are due to vibrational excitations of the surface bonds provided a means of detection and distinguishing C—C, C=C, C≡C, C—H and M—C bonds. Moreover, adsorbed hydrogen atoms, whose scattering cross sections are very small compared to those of other atoms and which are therefore not readily detectable by either electron spectroscopy or by LEED techniques, are detectable by electron absorption spectroscopy through their stretching and bending modes of vibration relative to the atoms in the solid surface (M—H). Recent investigations by *Ibach et al.* and by *Willis et al.* have illustrated the high sensitivity of this technique in the study of the surface chemical bond.

5. The Surface Crystallography of Adsorbed Monolayers of Atoms

The structural asymmetry and excess charge of the atoms at the surface have an important effect on the structure of the adsorbate/substrate system. In the presence of adsorbates, bonds are formed that make optimum use of the available bonding orbitals. For small adsorbed atoms and molecules

this often leads to the formation of a close-packed adsorbate structure in which the adsorbate occupies the high symmetry atomic sites that correspond to a continuation of the bulk structure. We shall review several examples of such chemisorbed structures below.

For most of the 200 and more surface structures of adsorbed monolayers that have been studied so far, only the two-dimensional symmetry of the diffraction pattern has been determined[29]. Hence, only the size and shape of the two-dimensional surface unit cell are known. Determination of the actual positions of the adsorbed atoms requires analysis of the intensity of the diffraction beam and has been performed only on a small number of systems—in almost all cases for atomic adsorption and low Miller index surfaces of face-centered cubic metals. The first of these analyses was carried out by *Anderson* and *Pendry*[38], who examined sodium adsorption on the nickel(100) crystal face and reported that the sodium atoms occupy fourfold coordinated sites at a distance of 0.87 Å above the topmost nickel layer. *Demuth et al.*[39] have examined the overlayer structures of oxygen, sulfur, selenium and tellurium on the nickel (100) surface, where each of the adsorbed atoms also occupy fourfold coordinated bonding sites; the displacements from the center of the top nickel layer are 0.9, 1.3, 1.45 and 1.9 Å, respectively. Results are also reported for the nickel (111) and nickel (110) surfaces. *Forstmann et al.*[40] reported iodine adsorbed on the Ag (111) surface to occupy threefold coordinated sites at a distance of 2.5 Å above the topmost layer. The adsorption of oxygen on tungsten[41] and of nitrogen on tungsten[42] and other body-centered cubic metals have also been studied.

Several general observations appear to be emerging from this work. Chemisorbed atoms seek an adsorption site which allows them to maximize their coordination. The substrate-adsorbate bond length, at least for the strongly chemisorbed systems studied thus far, can be reproduced rather well by adding the metallic radius of the substrate and the single bond covalent radius of the adsorbate. This is shown in Table 1, which lists the experimentally determined bond lengths and the predicted bond lengths obtained by summing the covalent radii. In most cases the difference is within the 0.1 Å accuracy claimed for the experimental determination, in no case is the discrepancy greater than ten percent. This result suggests that the chemisorption bond of the small adsorbate atoms studied so far is basically covalent in character, which means that theoretical treatment in terms of localized surface complexes and clusters should be applicable to their chemisorption.

Table 1. Adsorbate-substrate bond lengths [Å] determined by LEED.

Substrate	Adsorbate	Bond Length (experimental)	Ref.	Bond Length (predicted) [18]
Ni(001)	O	1.97	[a]	1.90
	S	2.18	[a]	2.28
	Se	2.27	[a]	2.41
	Te	2.58	[a]	2.61
	Na	3.37	[b]	3.10
Ni(110)	O	1.91	[c]	1.90
	S	2.17	[d]	2.28
Ni(111)	S	2.02	[d]	2.28
Ag(001)	Se	2.80	[e]	2.61
Ag(111)	I	2.75	[f]	2.77
Al(100)	Na	3.52	[g]	3.32
Mo(001)	N	2.02	[h]	2.08
W(110)	O	2.08	[i]	2.05

The small adsorbate atoms that are listed in Table 1 invariably occupy sites of the highest symmetry. These sites would also be the location of the next layer of metal atoms if we were to continue building up the solid layer by layer. The adsorbate-metal atom bond distance is equal, within the limits of experimental accuracy, to the sum of the covalent radii of the two atoms being bonded. There are other types of surface bonding, however, that are not readily rationalized using simple chemical arguments. Thus, in the case of oxygen on nickel (110), the best agreement with experiment is obtained if it is assumed that adsorbed oxygen atoms lie in a twofold bridge site between 1.41 and 1.51 Å above the nickel layer[43]. This is clearly not the highest coordination site on the surface. The fact that bridge bonding is preferred suggests that atomic oxygen is bonded *via* the p_x and p_y atomic orbitals to two adjacent nickel atoms. The bond angles and atomic distances are very close to what one would expect in compounds of the type X_2O, where X is the metal atom.

Another example of unusual bonding was recently discovered during studies on the adsorption of hydrogen to the nickel (110) surface. A new surface structure forms and surface crystallography studies indicated that this unit cell is a consequence of the restructuring of the nickel (110) surface as a result of hydrogen chemisorption and is not due to ordering of the hydrogen adsorbate[43]. The surface structure model giving the best fit to experimental data involves distorting the nickel surface atoms so as to produce the new (1×2) periodicity. This is achieved by simple depression or raising of every alternate row of nickel atoms in one direction, or a pair-wise distortion of every alternate row of nickel atoms in the plane of the surface. The optimal agreement with experimental curves is obtained by a 0.1 Å compression of the surface layer and a 0.1 Å alternate displacement of the rows of nickel atoms in the $[1\bar{1}0]$ direction.

Studies on the titanium/oxygen system also provided another example of unusual structure. It has recently been reported[44] that after chemisorption, oxygen atoms are located *below* the first layer of titanium atoms in the (0001) surface. There is little doubt that future studies will throw more light on the variety and complexity of surface bonding and will reveal many unexpected bonding configurations.

6. Studies on the Bonding of Hydrocarbons to Metal Surfaces

6.1. The Surface Crystallography of Acetylene on Pt(111)

Acetylene forms a (2×2) overlayer on the platinum (111) crystal surface. In recent experimental studies we have identified, on the basis of LEED I/V profiles for the platinum/acety-

lene system[45,46], two different (2 × 2) structures of adsorbed acetylene, which we refer to briefly as stable and metastable states. They have been interpreted as involving different chemical bonding. Exposure to small amounts [1 L (Langmuir) = 10^{-6} torr·sec) of C_2H_2 at room temperature leads initially to formation of the metastable (2 × 2) structure, which upon gentle heating (to 100°C, 1 h) is transformed into the stable (2 × 2) structure. Both structures are characterized by the same (2 × 2) surface unit cell and involve the same carbon coverage as determined by Auger electron spectroscopic analysis. However, they are readily distinguishable by their different *I/V* profiles.

Let us examine the various modes of bonding of acetylene to platinum in the context of high symmetry bonding sites available on the (111) face of a face-centered cubic crystal. As illustrated in Fig. 4, we distinguish four sites designated as: a) singly π-coordinated; b) doubly σ-bonded; c) μ_2-bridging; and d) μ_3-bridging (triangular complexes). For each site we have indicated only those surface metal atoms expected to have significant metal-carbon interaction. It is natural to discuss these surface geometries in terms of structural analogies to organometallic complexes. In these terms, the singly coordinated π complex (a) typically involves the interaction of one or both π orbitals of the acetylene molecule with a single metal surface atom. In the μ_2-bridging site (c) both π orbitals are utilized for bonding with two surface atoms. In principle, both (a) and (c) should entail little rehybridization of the C_2H_2 molecule since essentially undistorted π orbitals would be involved. On the other hand, the di-σ bond (b) implies sp→sp² rehybridization and the formation of two carbon-metal σ bonds accompanied by considerable bending of the CCH angle (*ca.* 120°, *cis*). This possibility has received serious consideration in the catalysis literature. Finally, the triangular structure (d), commonly found in trinuclear alkynemetal complexes, illustrates a mode of bonding loosely referred to in terms of both σ and μ bonds. We find this triangular geometry to be the favored arrangement in the (2 × 2) stable structure of acetylene on platinum (111).

In Table 2 are cited various organometallic compounds demonstrating the four geometries we have considered. It should be noted that we have examined only highly symmetric structures having the C-C axis parallel to the platinum surface. Large deviations from planarity, *e.g.* end-on bonding characteristic of metal carbonyls, are unlikely to occur in chemisorbed acetylene as they would lead to minimum overlap of bonding molecular orbitals. Furthermore, in previous work it was shown that a rather closely packed layer of planar acetylene molecules is consistent with the observed (2 × 2) unit cell. The possibility of dissociation of acetylene into CH fragments bound to the surface in a (2 × 2) configuration was ruled out on the basis of experimental findings.

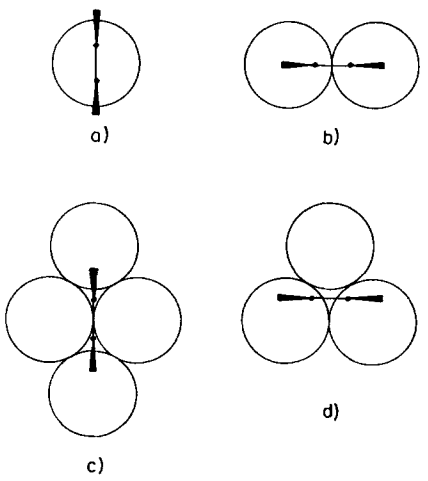

Fig. 4. Schematic diagram indicating various high-symmetry local bonding sites for acetylene on the (111) face of a face-centered cubic crystal: a) singly π-coordinated; b) doubly σ-bonded; c) μ_2-bridged; d) μ_3-bridged.

Table 2. Bonding structures and bond lengths in some transition-metal complexes with alkyne ligands RC≡CR.

Compound	Coordination geometry	M—C (Average) [Å]	C≡C [Å]
$(Ph_3P)_2Pt(C_2Ph_2)$ [a]	π (single)	2.04	1.32
$(CO)_6Co_2(C_2Ph_2)$ [b]	μ_2-bridge	1.97	1.46
$(\eta^5\text{-}C_5H_5)_2(CO)_2Rh_2(CF_3C_2CF_3)$ [c]	σ (double)	2.04	1.29
$(CO)_{10}Os_3(C_2Ph_2)$ [d]	μ_3-bridge	2.22	1.29

In Figures 5 and 6 we compare selected results for di-σ, μ_2, and μ_3 structures. On the (111) surface of a face-centered cubic crystal (abc stacking) there are two inequivalent triangular sites distinguished by the presence or absence (hole site) of a second layer substrate atom located beneath the center of the triangle formed by substrate atoms in the topmost layer. The hole site corresponds to the site that would be filled in the formation of an additional substrate layer and

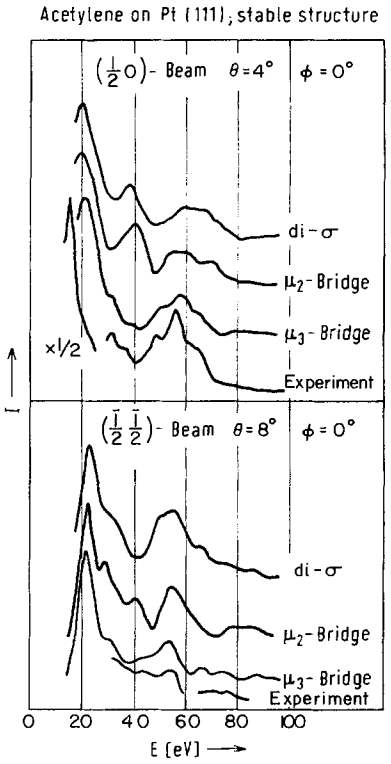

Fig. 5. Comparison of calculated *I/V* profiles for various model geometries ($z = 1.9$ Å) with experiment (stable acetylene overlayer) for two fractional-order beams.

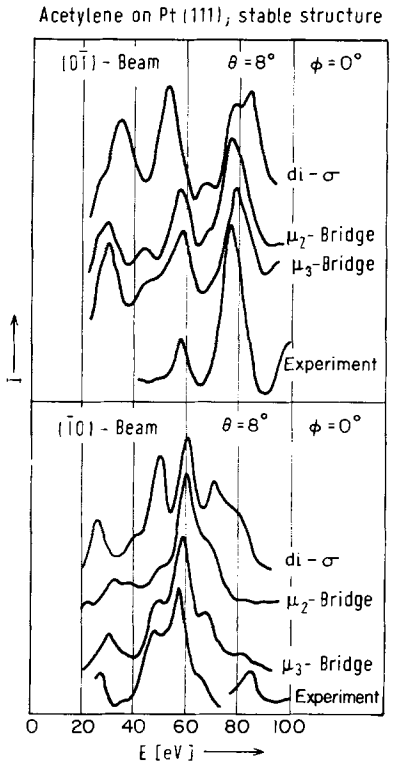

Fig. 6. Comparison of calculated I/V profiles for various model geometries ($z = 1.9$ Å) with experiment (stable acetylene overlayer) for two integral-order beams.

this is also found in the calculations to be the particular triangular site giving the optimum agreement for the location of C_2H_2 molecules in the acetylene overlayer. The z-distance of 1.9 Å employed in these comparisons was the optimum value to within ± 0.1 Å—for all three structures and all diffraction angles.

Analysis of Figures 5 and 6 shows that the triangular geometry gives consistently better agreement than either the μ_2-bridging or di-σ geometries. The singly coordinated π complex can be readily ruled out as well. We should also note the effects of scattering by the hydrogen atoms in a trial calculation for the μ_2-bridging structure at normal incidence.

The intensity profiles also indicate that no major $sp \rightarrow sp^2$ rehybridization of acetylene occurs. The CCH bond angle appears to be greater than 150° for acetylene in the adsorbed state; if rehybridization were to occur, a CCH bond angle of 120° would be expected. For a z-distance of 1.9 Å, the C—Pt distance is found to be 2.2 Å for C_2H_2 centered on the triangular site. This value is very close to the predicted covalent bond distance of 2.16 Å.

Using a dynamical analysis of low-energy electron diffraction intensity profiles we have been able to distinguish between various proposed bonding models for the chemisorption of acetylene on the Pt (111) surface. We have found that bonding of acetylene in a triangular site on the Pt (111) surface is the stable and preferred configuration. It is interesting to note that this same bonding geometry is exhibited in trinuclear alkynemetal clusters; moreover, the average C—Pt distance is similar to that determined for the corresponding distance in the trinuclear osmium cluster (Table 2), the covalent radius of osmium being only 0.04 Å shorter than that of platinum. Although we cannot detect a small change in C—C bond length we anticipate a C—C bond stretching of about 0.1 Å to occur for acetylene adsorption judging from the C—C length found in X-ray structure determinations on alkynemetal clusters.

We have also found encouraging evidence that bending of the CCH angle may be studied by such dynamical techniques despite the fact that electron scattering by hydrogen is relatively weak.

6.2. Studies of Other Hydrocarbons by Electron Spectroscopy

The bonding and composition of ethylene on the nickel (111) crystal face were studied by UPS[47]. At 100 K, the organic molecule adsorbs by bonding *via* its π orbitals to the metal surface. On heating to 230 K, C_2H_4 dehydrogenates to form C_2H_2 that is bound with even stronger π bonds to the nickel surface. With UPS the changes in bonding caused by the activated dehydrogenation that occurs could be monitored as a function of temperature. The chemisorption involved predominantly π-d bonding, so it would seem that rehybridization of the adsorbed molecule does not occur.

Similar studies carried out with C_2H_4 adsorbed on the W (110) crystal face have already been reported[48]. At 300 K, the adsorbate dehydrogenates to form C_2H_2 that π bonds to the metal. As the surface temperature is increased to 500 K, breaking of the carbon-hydrogen bond occurs and the C_2 fragments are identified by UPS by way of their C—C and C—W bonds. On heating to 1100 K, the C—C bond breaks and carbon atoms remain on the surface in a disordered state.

One of the striking features of the adsorption process is the existence of small (of the order of kT) activation energy barriers in the reaction paths leading to various bond breaking reactions. As a result an organic molecule may be adsorbed intact even on the most reactive metal surface at sufficiently low surface temperatures. On increasing the temperature electron spectroscopy can be used to identify the different bond breaking processes, which seem to occur in readily distinguishable steps.

6.3. Results of Electron Absorption Spectroscopy Studies

Surface vibrational modes have been detected in high-resolution energy spectra of backscattered low-energy electrons. In such an experiment, the energy loss of the incident electrons is determined by measuring the energy distribution of the electrons scattered from the surface or from the adsorbates. *Propst* and *Piper* observed characteristic energy losses due to adsorption of a number of simple gases on W (100)[49]. In their paper they list the vibrational bands observed for H_2, N_2, CO and H_2O. The energy resolution of 50 meV in these experiments did not permit the measurement of peak shift as a function of coverage. However, the authors concluded from the absence of molecular vibrational bands for strongly bound CO on tungsten (100) that this molecule undergoes dissociation.

More recently *Ibach et al.*[50, 51, 52] have developed a much more sensitive technique in which the energy resolution is ± 7 meV. They have confirmed that CO does in fact adsorb dissociatively on tungsten surfaces. They have also observed surface modes of lattice vibrations on both zinc oxide and silicon surfaces. In addition, vibrational modes of adsorbed oxygen were observed on silicon (111). Electron adsorption

studies were also carried out on platinum surfaces. Hydrogen was detected on metal surfaces by the stretching modes of vibration of its bonds to the metal atoms. This technique appears to be one of the most promising for studies on the surface chemical bonds of hydrogen, since it detects this atom in the adsorbate states very well indeed. Other techniques of electron scattering have failed to detect hydrogen directly because of its extremely small scattering cross section.

7. Studies on the Bonding of CO to Metal Surfaces

The chemisorption of carbon monoxide has been studied on several metal surfaces by electron spectroscopy. Using synchrotron radiation, *Shirley et al.* have found that CO adsorbs in a bridge structure bound through the carbon to the metal on the platinum (111) crystal face, while the oxygen end of the molecule points away from the surface[53]. Using the high Miller index (775) surface, which has a large concentration of kink atoms of low coordination number, *Mason et al.* found that CO dissociates at the kink sites[54], whereas it does not on atoms in terrace sites. These studies were carried out using UPS and XPS techniques. The concentration of carbidic carbon corresponded to the kink concentration and arose during the initial stages of CO chemisorption. It can be concluded therefore, that the adsorption of CO takes place first at kink sites, where the molecule dissociates. Once the kinks are blocked by carbon, CO further chemisorbs in the molecular state on other atomic sites of the heterogeneous platinum surface. CO adsorbs on tungsten crystal surfaces in several bonding sites, some of them molecular, some of them dissociated[55].

8. Conclusion

Several important findings have been made by LEED and electron spectroscopic studies on the chemical bonding of adsorbates on solid surfaces. Surface crystallography has revealed that many small atoms (O, S, Se, Na) occupy high symmetry surface sites at atomic distances characteristic of a covalent bond to the nearest neighbor metal atoms. Acetylene forms π-d bonds and occupies high symmetry sites at atomic distances that are similar to those found in organometallic cluster compounds. Surface irregularities, steps and kinks at surfaces of many solids display distinctly different bonding characteristics and chemical reactivities as compared to atoms on surface terraces. Both the bonding characteristics of adsorbates and the marked changes of chemical activity with coordination numbers of surface atoms, point to the predominance of localized bonding of adsorbates. The surface bond may be regarded as being localized between the adsorbed species and its nearest neighbor surface atoms and, to a first approximation, interactions with more distant metal atoms can be neglected. Adsorbed atoms or molecules can thus be looked upon as part of a surface molecule or surface cluster that forms between the adsorbed species and its nearest neighbor surface atoms. Consequently, good correlations between the chemistry of polynuclear clusters and that of adsorbed surface species are to be expected. Future studies will certainly verify the validity of this physical picture of the surface chemical bond.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Substituted Phenylcyclohexanes—A New Class of Liquid-Crystalline Compounds

By *Rudolf Eidenschink*, *Dietrich Erdmann*, *Joachim Krause*, and *Ludwig Pohl*[*]

We have found that 4-[*trans*-4-alkylcyclohexyl]benzonitriles *(4)* form nematic phases with higher clearing points and wider temperature intervals than those of the industrially important 4'-alkylbiphenyl-4-carbonitriles[1]. This means that the effect of a short-range order[2] of steric origin on the stability of nematic phases must be much greater than hitherto assumed.

Compounds *(4a)* to *(4e)* (Table 1) are obtained as follows: The *cis/trans* isomeric 4-alkyl-1-phenylcyclohexanols *(2)* and *(2')* formed in approximately equal amounts on reaction of 4-alkylcyclohexanone *(1)* with phenylmagnesium bromide in diethyl ether are separated on a column packed with silica gel (Kieselgel 60, Merck). Light petroleum (boiling range 50 to 70 °C) containing an amount of diethyl ether increasing up to 15 vol-% was used as solvent. *(2)* is hydrogenated with retention over Raney nickel in ethanol, and *(2')* with inversion over palladium/activated charcoal (10 % Pd) in ethanol. The nitrile group is introduced into the common product *(3)* in known manner (Friedel-Crafts acetylation, haloform reaction to give the carboxylic acid, conversion into the amide, and dehydration with $POCl_3$).

The structures of the products *(4a)* to *(4e)* are in accord with the results of elemental analysis and the IR and ^{13}C-NMR spectra. Since the formation of a nematic phase requires an elongated molecular shape[3], compound *(4)* probably exists in the equatorial *trans* form.

Table 1. Properties of compounds *(4)*.

	R	Yield [a] [%]	M.p. [°C]	Clearing point [°C]
(4a)	n-C_3H_7	36	36	46
(4b)	n-C_4H_9	30	41	41
(4c)	n-C_5H_{11}	42	31	55
(4d)	n-C_6H_{13}	25	42	47
(4e)	n-C_7H_{15}	38	30	59 [b]

[a] Based on amount of *(1)* weighed in.
[b] *(4e)* has a smectic-nematic transition at 17 °C.

Compounds *(4)* have viscosities of about 20 cP at 20 °C. These low values are advantageous for their application in electro-optical devices. The absorption maxima at 235 nm suggest use of eutectic mixtures as solvents in the study of anisotropic molecular properties. The optical anisotropy lies between 0.12 and 0.13, and the DC anisotropy is around +10.

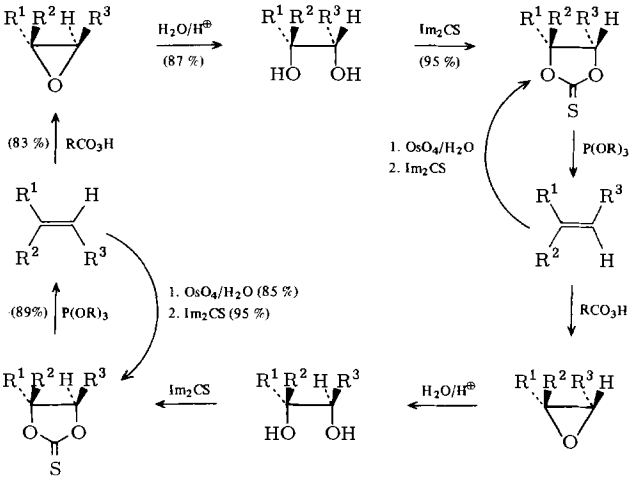
Assignment of Configuration of Olefins, Diols, and Epoxides. Quantitative Analysis of Their Stereoisomeric Mixtures



By *Alain Krief*, *László Hevesi*, *János B. Nagy*, and *Eric G. Derouane*[*]

We report here on a new method, extensively tested by us[1], for the assignment of the configuration of di- and trialkyl-substituted olefins, diols, and epoxides, as well as for

the quantitative analysis of mixtures of their stereoisomers. No simple general method has hitherto been available for these compounds[2].

Scheme 1. Stereospecific transformation of olefins into epoxides, diols, and thionocarbonates. The values in parentheses refer to approximate yields. Im = imidazolyl. Procedure: see ref. [6].

Our method is based on the ^{1}H-NMR chemical shift differences in stereoisomeric cyclic thionocarbonates[3], which are easily stereospecifically derived from the olefins[4] as described in Scheme 1. The significant chemical shift differences concern the proton or methyl substituents of the five-membered thionocarbonate ring. For example, the protons on the *cis (erythro)* disubstituted thionocarbonates generally appear at lower applied field ($\delta \approx 4.8$ to 4.9 ppm) than those on the corresponding *trans (threo)* isomer ($\delta \approx 4.4$ to 4.5 ppm)[5].

In the case of trisubstituted derivatives the differences are less pronounced (see Table 1). However, when a methyl substituent is present on the five-membered ring the corresponding shifts complement those of the ring protons. As a general rule, a methyl group *cis* to the hydrogen resonates at lower field ($\Delta \approx 0.1$ ppm). Consequently, in most cases a quantitative analysis can be carried out with NMR precision.

This is illustrated for two mixtures having known ratios of (*Z*)- and (*E*)-2-octene [*(1a)* and *(1b)*]. Mixture a [*Z*/*E* = 28.5/71.5] and mixture b [*Z*/*E* = 95.3/4.7] have been transformed into the corresponding mixtures of thionocarbonates according to the reaction sequence shown in Scheme 1 [1) OsO_4—H_2O/$NaHSO_3$; 2) thiocarbonyldiimidazole]. Integration of the ^{1}H-NMR signals centered at 4.84 and 4.39 gave *erythro/threo* ratios of a) 29/71 and b) 94.5/5.5 for the mixtures of thionocarbonates. Furthermore, pure *erythro*-thionocarbonate *(2b)* (ring protons at 4.84 ppm) and pure *threo*-thionocarbonate *(2c)* (ring protons at 4.39 ppm) have been mixed together in known proportions (*erythro/threo* = 9.4/90.6 and 49.6/50.4). NMR analyses of these mixtures were correct to within 1–2% error. Similar precision was obtained with mixtures of trisubstituted olefins [*(1q)* and *(1r)* in Table 1] when they were subjected to olefin → epoxide → diol → thionocarbonate transformation according to Scheme 1[3].

The interest of our method is further enhanced by the possibility of stereospecific synthesis of both thionocarbonate isomers from each of the two olefin isomers.

[2] The utility of VPC is limited by separation difficulties and the necessity for calibration by means of authentic samples. NMR has been already used as a powerful direct method on the olefins. Nevertheless, except for those carrying functional groups as substituents, this method is not easily applicable. For a review, see *G. J. Martin* and *M. L. Martin*, Progr. Nucl. Magn. Reson. Spectrosc. *8*, 163 (1972).

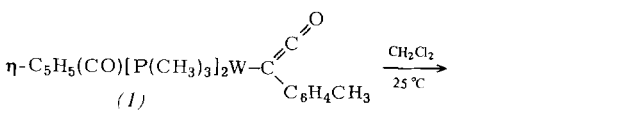
[5] All the ^{1}H-NMR measurements have been carried out on a routine MH100-JEOL 100 MHz instrument.



[6] The epoxides are prepared by rapid addition at 0°C (on a small scale) of a dichloromethane solution of the olefin to a solution of 1.2 equiv. of *m*-chloroperbenzoic acid in the same solvent. Diols are obtained by a) hydrolysis at room temperature of the epoxides in dimethoxyethane/water (2:1 v/v) catalyzed by $HClO_4$ (70% in water), or b) adding a slight excess (5%) of OsO_4 solution in anhydrous pyridine to a pyridine solution of the olefin at 10°C. After reaction for 4 h at room temperature, 10 equiv. of $NaHSO_3$ in water-pyridine (2:3 v/v) is added and reaction continued for 17 h.—The thionocarbonates [1a, 3, 4] are formed by heating 1 equiv. of diol with 2 equiv. thionocarbonyldiimidazole (Im_2CS) in dry toluene under N_2 at 100°C.—The conversion of thionocarbonates into olefins has been effected according to [4a]. In all the cases studied and especially for quantitative analysis of mixtures, care must be taken to conduct the reactions to completion (TLC monitoring) and not to remove one or part of one isomer if present.

p-Tolylketenyl as Novel *dihapto* 3-Electron Ligand[**]

By *Fritz R. Kreissl, Peter Friedrich*, and *Gottfried Huttner*[*]

Carbonyl(η-cyclopentadienyl)(*p*-tolylketenyl)bis(trimethylphosphane)tungsten *(1)*[1], formed by reaction of dicarbonyl(η-cyclopentadienyl)(*p*-tolylcarbyne)tungsten[2] with trimethylphosphane, rapidly liberates a phosphane ligand in solution at room temperature and forms a novel, stable ketenyl complex *(2)*.

(2) can also be prepared by direct reaction of η-$C_5H_5(CO)_2W{\equiv}C{-}C_6H_4CH_3$ with an equimolar amount of

(1) *(2)*

$P(CH_3)_3$ in dichloromethane; at low temperatures *(2)* adds a phosphane molecule and is reconverted into *(1)*[3].

The complex *(2)* can be isolated as brick-red crystals (m. p. 138°C) which are readily soluble in dichloromethane but insoluble in ether or pentane. Composition and structure of the ketene derivative[4] were confirmed by elemental analysis, molecular weight determination, IR, ^{1}H-, ^{13}C- and ^{31}P-NMR spectral data, and by an X-ray structure analysis.

The IR spectrum (KBr) shows two bands in the carbonyl region—one for the CO ligands (1878 cm^{-1}, vs) and one for the stretching vibration of the ketenyl group (1684 cm^{-1}, s).—The ^{1}H-NMR spectrum[5] (CD_2Cl_2) contains four signals of relative intensities 4:5:3:9, which are assigned to the aryl ($\delta = 7.75$ and 7.38 ppm), cyclopentadienyl (5.81), methyl (2.35), and *P*-methyl protons (1.43). The signals at 5.81 and 1.43 ppm are split into doublets as a result of spin-spin interaction with the phosphorus nucleus ($J = 1.2$ and 10.5 Hz, resp.).—The $\{^1H\}$-^{13}C-NMR spectrum[6] (CD_2Cl_2) shows the ten expected signals (chemical shifts rel. to $CD_2Cl_2 = 54.2$ ppm; ^{31}P-^{13}C coupling constants [Hz]): W—CO (229.6; 7.4), CO-ketene (203.7), C-ketene (197.6; 5.9), C_6H_4 (138.6, 138.4, 130.2, 126.7), C_5H_5 (93.3), CH_3 (21.9), and PCH_3 (21.6; 35.3).—The ^{31}P-NMR spectrum[6] contains a singlet accompanied by satellites at −13.0 ppm with $^1J(^{183}W$-$^{31}P) = 405.9$ Hz.

All spectral data of *(2)* are consistent with the results of an X-ray structure analysis[7] (Fig. 1).

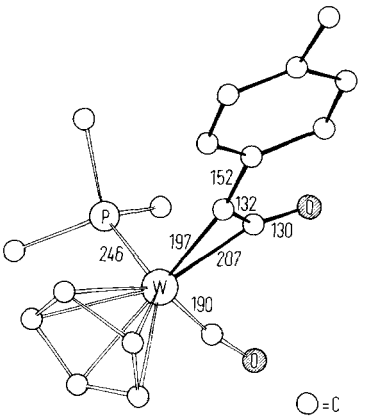


Fig. 1. Structure of the ketenyl complex *(2)* (distances in pm).

The ketenyl group, which is σ-bonded as a *monohapto* 1-electron ligand in *(1)*, has also 2 electrons of the C=C bond available for the metal in *(2)*; this π interaction leads to shortening of the distance between the metal atom and the σ-bonded carbon atom from 227(2) pm in *(1)* to 197(3) in *(2)*. The lengths of the C=C and C=O bonds increase from 124(3) and 121(3) pm, respectively, in *(1)* to 132(4) and 130(4) pm, respectively, in *(2)*. The length of the complexed double bond in *(2)* is consistent with the length of the corresponding bond in dicarbonyl(η-cyclopentadienyl)(diphenylketene)manganese (135 pm)[8].

Experimental:

All operations are carried out under nitrogen in dried (Na, P_4O_{10}) N_2-saturated solvents.—*(1)* (1.12 g, 2.0 mmol) is

dissolved in dichloromethane (20 ml) at 25 °C, whereupon the color of the solution rapidly changes from yellow to dark red. Solvent and liberated trimethylphosphane are removed from the stirred solution in a vacuum. This procedure is repeated several times and the residue finally washed twice with 10 ml ether and then 10 ml pentane. After drying in a high vacuum, *(2)* is obtained as analytically pure, brick-red crystals; yield 0.80 g (83 %).

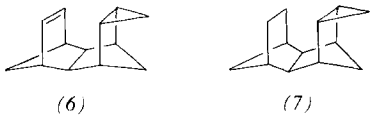
Geometrical Dependence of [2π+2σ]Photocycloaddition[**]



By *Horst Prinzbach, Gottfried Sedelmeier*, and *Hans-Dieter Martin*[*]

Photochemical cycloadditions of type *(1)* → *(2)* ([2π+2σ]) are even more dependent upon the relative orientation of the participating bonding orbitals than the analogous [2π+2π] reactions[1]. The β parameter as determined by

PE spectroscopy can be considered as an experimental criterion for the assessment of these geometrical requirements; the transannular overlap present in the "vertical" radical cations is assumed to be typical of the photoreactivity of the excited states. With this in mind we have investigated

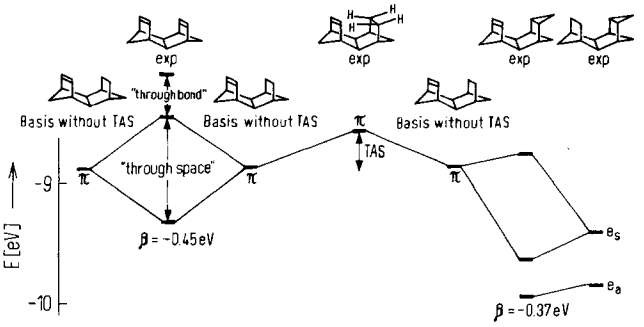
[**] Photochemical Transformations, Part 57. Part 56: *H. Prinzbach* and *H. Sauter*, Tetrahedron Lett. *1974*, 3049. Also: Small Rings, Part 21.—Part 20: *H.-D. Martin, C. Heller*, and *R. W. Hoffmann*, Chem. Ber., in press.

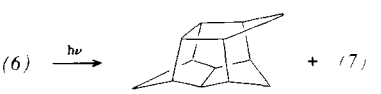
the correlation between β values and photochemistry in the cases of pentacyclo[6.3.1.1^{3,6}.0^{2,7}.0^{9,11}]tridec-4-ene *(6)*[2] and *endo*-tetracyclo[5.2.1.0^{2,6}.0^{3,5}]dec-8-ene[3].

The orbital energies ($\varepsilon=-IP_{i,v}$) shown in Figure 1 are derived, with the usual assumptions, from the vertical ionization potentials of *(3)*—*(7)* (Table 1). In the reference compound *(5)*, the transannular interaction (TAS = transannular strain) between the π- and C—H bonds lowers $IP_{1,v}$ by 0.3 eV (cf. $IP_{2,v}=8.90$ eV in *(3)*[4]). The β value in *(4)* (−0.45 eV)[4] hardly differs from that of norbornadiene (−0.4 eV)[5] and is lowered by a similarly small amount on replacement of a double bond by a three-membered ring (*(6)*: $\beta=-0.37$ eV; cf. *exo*-tricyclo[3.2.1.0^{2,4}]oct-6-ene: $\beta=-0.3$ eV)[5]. A similar lowering by *ca.* 0.1 eV relative to the already smaller value of the corresponding diene *(8)* (−0.2 eV)[3] makes the β value of the homodiene *(9)* (−0.1 eV) very small.

Table 1. Vertical ionization potentials ($IP_{i,v}$ [eV]) of the hydrocarbons *(3)*—*(7)* (values rounded off to the nearest 0.05 eV).

	(3)	*(4)*	*(5)*	*(6)*	*(7)*
IP_1	8.45	8.10	8.60	8.80	9.45
IP_2	8.90	9.35	9.70	9.70	9.90
IP_3				10.00	





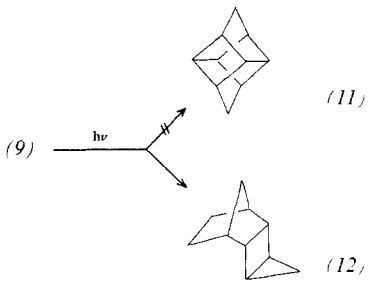


Fig. 1. Orbital correlation diagram for compounds *(4)*—*(7)*.

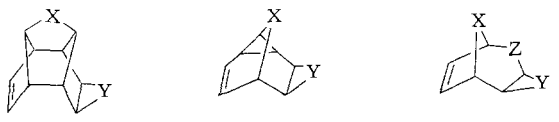
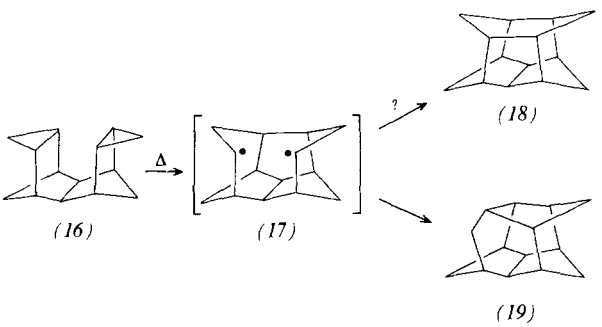
Direct irradiation of a *ca.* 3×10^{-3} M CH_3CN solution of *(6)* [$\varepsilon_{212\,nm}=2950$; −35 °C, 150 W Hg high pressure lamp, quartz vessel, 70 % conversion (96 h)] leads, according to GC, to a mixture (*ca.* 65 %) of hexacyclo[5.5.1.0^{2,6}.0^{3,11}.0^{5,9}.0^{8,12}]-tridecane *(10)* (colorless crystals, m.p. 222 to 223 °C)[6] and the hydrogenation product *(7)* (m.p. ≈ −20 °C) which was freed by chromatography (Al_2O_3, 20 % $AgNO_3$) from residual *(6)* and polymeric material and isolated by GC (SE 30/10 %, 100 °C; 27 and 23 % isolated, respectively, based on reacted *(6)*).



Under the same conditions, the conversion of *(9)* [$\varepsilon_{220}=700$] is comparably slow; in addition to polymeric product, TLC and GC give no indication of *(11)*[7] but only the progressive formation of the dihydro product *(12)*; the

latter is isolated in *ca.* 55 % yield after complete consumption of *(9)*.

The course of photolysis of *(6)* and *(9)* corresponds to expectation in that at the very short wavelength of excitation necessary $[2\pi+2\sigma]$ cycloaddition becomes effective against the major competing reaction, hydrogenation, only under very favorable overlap conditions, *i.e.* given a large β parameter.



We expect to gain a more detailed insight from studies of homodienes of type *(13)*—*(15)* with systematic variations in distances and angles between the π/σ bonds.

(13) *(14)* *(15)*

X, Y, Z = $-(CH_2)_n-$, O, NR

In compound *(16)*[2] formed as co-product on preparation of *(6)* the stereochemistry is favorable for $[2\sigma+2\sigma]$ cycloaddition to form *(18)*, a reaction already attempted on earlier occasions. On gas phase pyrolysis, *(16)* is stable up to *ca.*

500 °C but polymerizes and chars above 750 °C. However, between 630 and 670 °C the reaction affords an hydrocarbon isomeric to *(16)* in 60—70 % yield together with a small amount of side products [*(18)*?]. According to spectroscopic data the hydrocarbon is not the highly symmetrical cycloadduct *(18)* but hexacyclo[6.5.1.$0^{2,6}$.$0^{3,12}$.$0^{5,10}$.$0^{9,13}$]tetradecane *(19)* (m.p. 199 to 200 °C)—probably formed from the intermediate *(17)* by hydrogen migration.

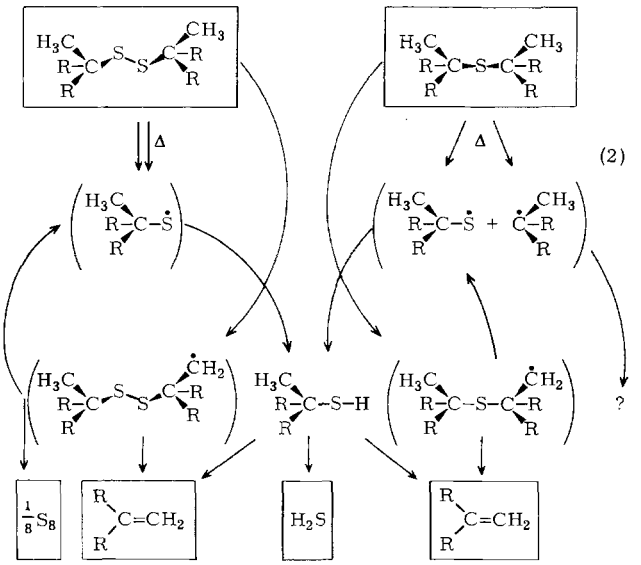
reactions: With 100 to 200 mg of compound the temperature dependence of a reaction at 0.1 torr can be monitored, *e.g.*, between 300 K and 1500 K at intervals of 50 K within a day.

An example[3] is the pyrolysis of di-*tert*-butyl disulfide in a 0.5m-long, furnace-heated quartz tube: the continuously recorded PE spectra show that decomposition commences at 650 K (Fig. 1: a/b) and is complete at a furnace temperature of 690 K, and that H_2S[4] and isobutene[4] are the sole gaseous products formed (Fig. 1: c). In addition, sulfur is deposited on the tube wall outside of the furnace zone.

Like di-*tert*-butyl disulfide, numerous organic and inorganic compounds decompose under PE spectrometer conditions at relatively low temperatures *via* "reaction channels" which lead quantitatively to uniform reaction products (cf. Fig. 1: c). In most cases thermodynamically favorable "leaving molecules" such as hydrogen halides, nitrogen, hydrogen sulfide, sulfur dioxide, carbon monoxide, *etc.* are split off[1,3]. On the contrary, stronger "heating up" to higher temperature frequently leads to a "splattering" in fragments which are energetically favored under these conditions; thus the PE spectrum of the decomposition products of di-*tert*-butyl disulfide at 1400 K confirms the presence of species such as CS_2, H_2S, $HC{\equiv}CH$, CH_4, or H_2[4] (Fig. 1: d).



All the dialkyl sulfides or disulfides listed in (1) eliminate quantitatively hydrogen sulfide and, in the latter case, sulfur at 0.1 torr and at the given temperatures, forming the corresponding alkenes:

=	1090		970	920	[K]
	R^1	CH_3	CH_2CH_3	CH_3	CH_3
	R^2	H	H	CH_3	CH_3
	R^3	H	H	H	CH_3
=	840	790		770	690 [K]

(1)

Disulfides decompose at temperatures which are about 200 K lower than those for the sulfides; the decomposition temperature decreases further with increasing methyl substitution and increasing chain branching. The experimental results (1) are consistent *e.g.* with the expectation that a SS bond ($\Delta Hb \approx 226$ kJ/mol) ought to cleave more readily than a CS bond ($\Delta Hb \approx 272$ kJ/mol), and in part, suggest a common product formation scheme for the $(CH_3CR_2)_2S_n$ pyrolyses ($n=1, 2$; R = H, CH_3):

(2)

Assuming that a chain reaction proceeds *via* alkylthio radicals, the PE spectroscopically investigated thermolytic reactions of ethyl hydrosulfide and dimethyl sulfide[5]

$$H_3C{-}CH_2{-}SH \xrightarrow{820\ K} H_2C{=}CH_2 + H_2S \qquad (3)$$

$$H_3C{-}S{-}S{-}CH_3 \xrightarrow{890\ K} H_2C{=}S + H_3C{-}SH \qquad (4)$$

seem to support the hypothetical product formation scheme (2)[6].

[6] *Note added in proof:* According to *G. Martin* and *N. Barroeta*, J. Chem. Soc. Perkin II *1976*, 1421, thermal decomposition of di-*tert*-butyl disulfide proceeds *via* a first-order elimination of isobutane.

Unstable Intermediates in the Gaseous Phase[1]: The Thermal Decomposition of Acyl Chlorides RCOCl[2]

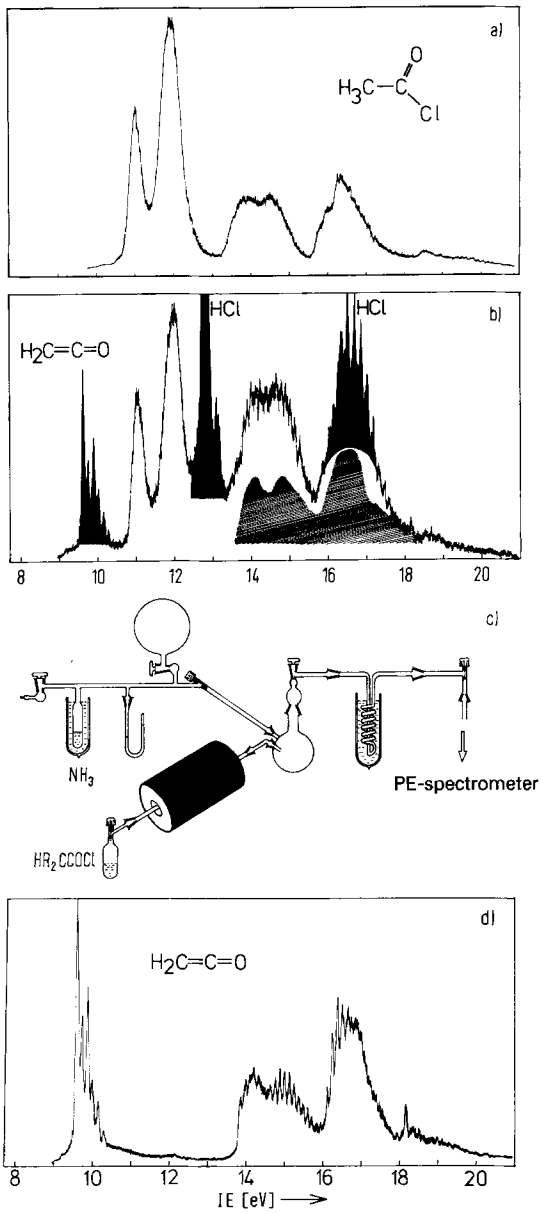
By *Hans Bock, Takakuni Hirabayashi, Shamsher Mohmand*, and *Bahman Solouki*[*]

Ketene is obtained on an industrial scale by thermal cleavage of water from acetic acid or by thermal removal of methane from acetone[3]; of the numerous laboratory methods[4] known, the one involving elimination of HCl from acyl chlorides is the most suitable for a PE spectroscopic analysis of ketene formation reactions in the gaseous phase.

(1)

[*] Prof. Dr. H. Bock, Dr. T. Hirabayashi, Dipl.-Chem. S. Mohmand, and Dr. B. Solouki
Institut für Anorganische Chemie der Universität
Theodor-Stern-Kai 7, D-6000 Frankfurt am Main 70 (Germany)

The hydrogen chloride formed shows a simple and strikingly characteristic PE spectrum[5] with two fine-structured vibrational bands at 12.8 and >16.2 eV, and can be removed from the reaction mixture by injection of ammonia gas[6] (Fig. 1).



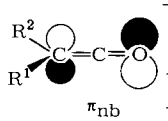


Fig. 1. PE spectra of acetyl chloride (a), of the pyrolysis mixture at 650 K (b), and, after injection of NH_3 (c) at 820 K (d). (H_3CCOCl, white; HCl, black; H_2CCO, hatched.)

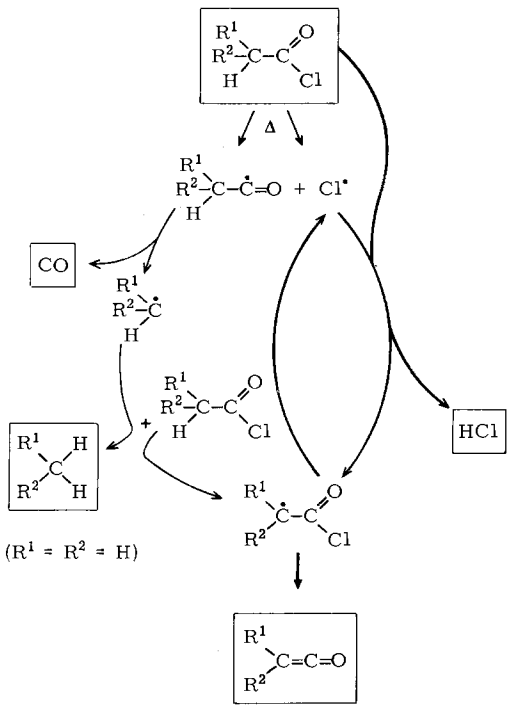
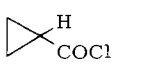


Numerous ketene derivatives can be generated in the gaseous phase at 0.1 torr from the corresponding substituted acyl chlorides according to (1) and characterized PE spectroscopically. The substituent-dependent changes enable assignment of the PE bands—*e.g.* the first ionization leads to a radical-cation state of type π_{nb}—and can be described within a MO model by hyperconjugative interaction.

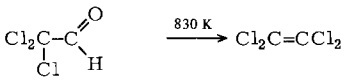
	R^1	H[5]	CH_3	CH_3	C_6H_5	Cl
	R^2	H	H	CH_3	H	H
	IE_1 [eV]	9.60	8.95	8.38	8.17	9.35

(2)



Indications of a possible reaction mechanism (3) for the smooth gas-phase elimination of HCl from acyl chlorides are given by a PE spectrum of the H_3CCOCl decomposition which was recorded after incorporation of a cold trap (−190 °C) between the furnace and PE spectrometer (Fig. 1: c), and from which the bands of CO and CH_4 in the unfrozen residual gas can be recognized.

(3)



According to the hypothetical reaction scheme (3) the C—Cl bond is the weakest ($\Delta Hb \approx 327$ kJ/mol) and will presumably be cleaved first. This initiation reaction would yield Cl• atoms as radical chain carriers; the ketenes could be formed *via* $R_2\dot{C}COCl$ radicals.

Detailed PE spectroscopic investigations[7] show that the HCl elimination is often accompanied by loss of CO. Examples are:

(4)

$$H_2C{=}CH{-}COCl \xrightarrow{910\ K} HC{\equiv}CH + HCl + CO \quad (5)$$

(6)

On elimination of (HCl + CO) from trichloroacetaldehyde *(6)*, the major product of the pyrolysis is tetrachloroethylene—presumably formed by dimerization of dichlorocarbene.

Alkylation of Diethyl Phosphoramidates – A Simple Route from Primary to Secondary Amines[**]

By *Andrzej Zwierzak* and *Janina Brylikowska-Piotrowicz*[*]

The methods commonly employed for the transformation of primary into secondary amines involve the synthesis and subsequent catalytic hydrogenation of the corresponding Schiff bases. Procedures for direct alkylation frequently afford mixtures of secondary and tertiary amines or necessitate the use of expensive and difficultly accessible reagents.

We have found that the diethyl esters *(2)* of the *N*-alkyl- or *N*-arylphosphoramidic acids, which are accessible in high yields from primary amines *(1)*[1] or their hydrochlorides, can be readily alkylated under the conditions of phase-transfer catalysis.

Applicability of this procedure is limited, however, to primary alkyl halides as alkylating agent. The protecting diethoxyphosphoryl group is removed from the alkylation product *(3)* by treatment of the latter with gaseous HCl in THF at room temperature[2].

Procedure:

A mixture of *(2)*[1] (0.05 mol), alkyl bromide (0.075—0.1 mol), toluene (30 ml), 50% aqueous solution of NaOH (25 ml), and tetra-*n*-butylammonium hydrogen sulfate (0.85 g, 5 mol%) was refluxed with vigorous stirring for 4 h. Toluene (50 ml) was then added, the organic layer separated, washed with water (20 ml), dried, and evaporated *in vacuo* to give crude *(3)* as an oil. For the degradation a solution of crude *(3)* (2.0 g) in THF (10 ml) was saturated with gaseous HCl and set aside at room temperature for 12 h. Solvent was then evaporated, the residue diluted with ether (15 ml), and refrigerated. The precipitated crystals of *(4)* were filtered off, washed with ether, and dried over P_2O_5.

Isolation and Vibrational Spectra of Bond-Isomeric Hexakis(thiocyanato-isothiocyanato) Complexes of Ruthenium(III) and Osmium(III)

By *Hans-Joachim Schwerdtfeger* and *Wilhelm Preetz*[*]

Since the first preparation of $(TBA)_3[Ru(NCS)_6]$ and $(TBA)_3[Os(NCS)_6]$ (TBA^+ = tetrabutylammonium) it was doubtful whether the ambidentate SCN^- group is bonded as a "soft" ligand *via* S (thiocyanato) or as a "hard" ligand *via* N (isothiocyanato) to the trivalent central ion[1, 2]. IR spectra are compatible with both possibilities, and exchange reactions with $S^{14}CN^-$ yield evidence supporting both *N*-bonded and *S*-bonded groups[3]. Using high voltage electrophoresis[4] we have now been able to show unequivocally that both products are actually mixtures consisting of at least four or three, respectively, bond isomers of the type

$(TBA)_3[Ru(NCS)_n(SCN)_{6-n}]$, $n = 1, 2, 3, 4$

and

$(TBA)_3[Os(NCS)_n(SCN)_{6-n}]$, $n = 2, 3, 4$

Since the rate of migration of the complex anions in an electric field increases stepwise by 5—10% with increasing *n*, sharply separated zones of different colors are obtained. After elution the stable TBA salts are precipitated. They give distinctly different UV, VIS, IR, and Raman spectra, but identical analyses. They are therefore the first bond isomers to be isolated which have exclusively *N*- or *S*-bonded SCN ligands. All the isomers previously described contain other ligands in addition to one or two SCN groups[3]. Equilibration between several hexakis(thiocyanato-isothiocyanato) complexes shows that Ru^{III} and Os^{III} are borderline cases between hard and soft acids, and the kind of bonding of the ligand is therefore largely adopted at random.

In accord with data reported in the literature[5], the assignment of the individual species is based mainly upon the intensity ratios of the $\nu_{CS(N)}$, $\nu_{CS(S)}$, δ_{NCS}, δ_{SCN}, ν_{M-N}, and ν_{M-S} vibrations (Table 1). Interpretation of the vibrational spectra is difficult because the complexes having $n = 2, 3, 4$ are presumably mixtures of the two stereoisomeric forms.

Procedure

$(TBA)_3[Ru(NCS)_n(SCN)_{6-n}]$, $n = 1, 2, 3, 4$
$(TBA)_3[Os(NCS)_n(SCN)_{6-n}]$, $n = 2, 3, 4$:

$K_2[RuCl_6]$ (1 g) or $K_2[RuBr_5(OH)]$ (1 g) and KSCN (3 g) are dissolved in water (20 ml) and allowed to stand at room temperature for 4 d; $K_2[OsCl_6]$ (0.5 g) or $K_2[OsBr_6]$ (0.5 g) or $K_2[OsI_6]$ (0.5 g) and KSCN (6 g) are refluxed in water (30 ml) for 18 h. After centrifuging off the small amount of decomposition products formed in either case, the solutions are evaporated in a high vacuum at 0 °C. Extraction with ether/alcohol (1 : 1) furnishes, respectively, deep blue or orange solutions of the complex mixtures which contain only little KSCN. After removal of solvent in a rotary evaporator the residues are dissolved in a small volume of water and small portions subjected to high voltage electrophoresis[4]. The complexes eluted from the cut out zones with a small volume of ice-cold water can be isolated as voluminous precipitates with a few drops of 1 M (TBA)Br solution. The yields lie between 25 and 60 mg for each of the bond-isomeric complexes.

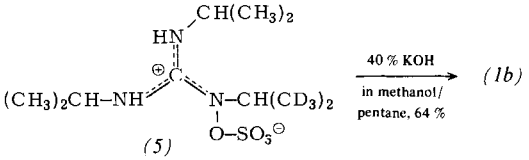
Cycloaddition of Phenyl Isocyanate to a Diaziridinimine[**]

By *Helmut Quast* and *Erwin Spiegel*[*]

Cycloadditions to hetero analogs of methylenecyclopropanes are steadily gaining in preparative and mechanistic importance. We now report the [3+2] cycloaddition of phenyl isocyanate to triisopropyldiaziridinimine *(1a)*[1].

Already at low temperature equimolar amounts of the two components react in ether to give a 1:1 adduct in 82% yield, which is shown by its spectra, degradation reactions, and independent synthesis from 1-anilino-1,2,3-triisopropylguanidine and phosgene to have the 1,2,4-triazolidine structure *(2a)*. The highly substituted triazolidine ring proved to be surprisingly stable. After refluxing in concentrated hydrochloric acid for 3d only the isopropyl group attached to C-1 had been lost. The triazolinone *(3)* isolated in 77% yield was obtained by an independent pathway from 1-anilino-2,3-diisopropylguanidine and phosgene. Only on prolonged heating of *(2a)* with KOH in water/methanol (1:1) in a sealed tube at 100°C does ring opening and hydrolysis occur to give isopropylamine (84% as the picrate) and 2,4-diisopropyl-1-phenylsemicarbazide *(4)* (yield 60%), which is readily accessible from 1-isopropyl-2-phenylhydrazine and isopropyl isocyanate.



Like other guanidine derivatives[2] *(2a)* can exchange the imino group with an isocyanate. Heating of *(2a)* with phenyl isocyanate gives quantitative yields of isopropyl isocyanate and *(2d)*.

	R^1	R^2
(a)	$CH(CH_3)_2$	$CH(CH_3)_2$
(b)	$CH(\overset{*}{C}D_3)_2$ [a]	$CH(\overset{*}{C}D_3)_2$ [a]
(c)	$CH(\overset{*}{C}D_3)_2$ [a]	$CH(CH_3)_2$
(d)	$CH(CH_3)_2$	C_6H_5

[a] $CH(\overset{*}{C}D_3)_2$ corresponds to 50% deuterium labeling of the methyl groups.

In order to determine which N atoms are involved in the [3+2] cycloaddition of phenyl isocyanate *(1a)*, we synthesized the hydroxyguanidine-*O*-sulfonic acid *(5)* from [D_6]isopropylhydroxylamine-*O*-sulfonic acid and diisopropylcarbodiimide. In accord with the general diaziridinimine synthesis[1] the product of *(5)* was *(1b)*, in which only the two ring isopropyl groups were labeled (50% each).

^{1}H- and ^{13}C-NMR spectra of the adduct *(2)* formed from *(1b)* and phenyl isocyanate provided direct evidence that only two of the isopropyl groups were labeled, and thus ruled out mechanisms requiring symmetrization of the N atoms. However, which of the groups were labeled in the addition product could not be determined from the chemical shifts. On prolonged heating (2—3 weeks, 80°C) of the labeled adduct in an excess of isopropyl isocyanate one of the labeled isopropyl groups was exchanged in a reaction corresponding to that between *(2a)* and phenyl isocyanate. If both this product and the original adduct of *(1b)* and phenyl isocyanate are subjected to the degradation reactions described for *(2a)*, then unequivocal assignment of the structures *(2b)* and *(2c)* becomes possible.

Information about the course of hydrolysis of the triazolidines *(2)* could be obtained using *(2b)*. While *(2b)* remained completely unchanged after 10d at 80°C in [D_6]benzene or [D_4]methanol, the action of 2N KOH in methanol (3d, 90°C) led to exchange of the isopropyl group at N-4 and at the imino group, indicating reversible ring opening after addition of a nucleophile to C-3. The label of the iminoisopropyl group of *(2b)* is accordingly distributed evenly over the resulting isopropylamine and the isopropyl group at N-4 of the semicarbazide *(4)* on alkaline degradation.

1,2-Di-*tert*-butyldiaziridinone, which is related to the diaziridinimines, reacts in a completely different way with heterocumulenes[3]. The same is true of postulated ring-opened diaziridinimine equivalents[4]. The above cycloaddition of phenyl isocyanate can readily be applied to other diaziridinimines.

Procedure

Phenyl isocyanate (6.50 g, 54.6 mmol) is added at −78°C to *(1a)*[1] (10.0 g, 54.6 mmol) in anhydrous ether (15 ml). The mixture is allowed to warm to 20°C over a period of 15 h, the crystals filtered off under vacuum, and washed with pentane. Concentration of the mother liquor yields a second fraction of the same melting point. Yield: 13.5 g (82%) *(2a)* as colorless crystals of m.p. 89—90°C.

Resolution of a Chiral Olefin by Complexation Chromatography on an Optically Active Rhodium(I) Complex[**]

By *Volker Schurig*[*]

Chromatographic resolution of racemic substrates on optically active stationary phases[1] is an elegant method for the absolute determination of chirooptical properties such as optical purity and optical rotation. While the resolution of racemic amino acid derivatives on optically active dipeptides[1] or host crown ethers[2] is attributed to diastereomeric interactions between hydrogen bonds and dipoles, that of the inherently asymmetric helicenes on optically active aromatic acceptor molecules[3] is due to selective diastereomeric charge-transfer complexation.

We have now accomplished the first gas chromatographic resolution of enantiomers on optically active metal complexes, postulated by *Gil-Av*[4], in an olefin/rhodium(I) system which commands interest in connection with asymmetric homogeneous catalysis.

R-(1) *S-(1)* *1R-(2)*

A high-resolution capillary column (200 m) was loaded with optically active dicarbonylrhodium(I) 3-trifluoroacetyl-(1*R*)-camphorate[6], *1R-(2)*, in squalane solution which is highly selective for alkenes[5a] and isotopically labeled ethylenes[5b]. Using this column, chiral 3-methylcyclopentene *(1)* was resolved quantitatively into its antipodes within 3 h at 22 °C (Fig. 1).

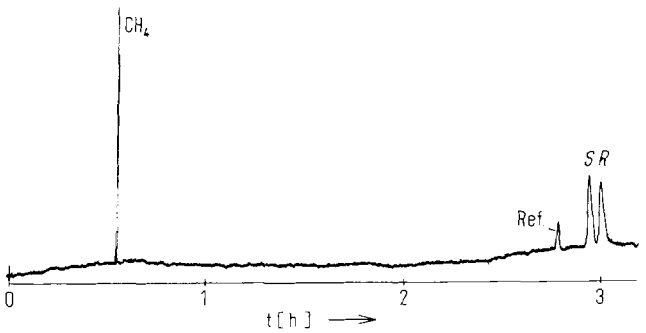

Fig. 1. Resolution of *(1)* by complexation gas chromatography on *1R-(2)* in squalane (0.15 m) at 22 °C; $\alpha = 1.025$, peak area ratio 1 : 1. For chromatographic conditions see ref. [5b]. Reference standard: methylcyclohexane [$r_R = 1.095$, $r_S = 1.07$, $r_{o(R,S)} = 0.26$ (pure squalane)].

[*] Univ.-Doz. Dr. V. Schurig
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

[**] This work, which was partly carried out at the Department of Chemistry, Weizmann Institute of Science, Rehovoth (Israel), was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Resolution is attributed to differences in π-complexation strength K between the enantiomers *R-(1)* and *S-(1)* with the rhodium complex *1R-(2)*. The difference in free energy of association $\Delta_{R,S}(\Delta G^0)$ calculated from the relation $Km_{Rh} = r/r_0 - 1$[5a] is −19 cal/mol (295 K).

The assignment of the antipodes (cf. Fig. 1) was deduced by preparation of enriched *R*-(+)-3-methylcyclopentene, *R-(1)* by acid dehydration of *R-cis,trans*-3-methylcyclopentanol which is accessible from *R*-3-methylcyclopentanone by reduction with $LiAlH_4$. Complexation chromatography of the olefin mixture permitted resolution of the positional isomers (1-methylcyclopentene, 15 %; 4-methylcyclopentene, 40 %) as well as determination of the optical purity of *R-(1)* (69 %)[7].

Unequivocal proof of the successful resolution of *(1)* is provided by use of the rhodium complex of opposite configuration, *1S-(2)*. Peak inversion was then observed for the olefin fraction *(1)* enriched in the *R* antipode. Moreover, peak coalescence was seen with the racemic complex *1S,1R-(2)*[8].

In principle the method described should be applicable to all conceivable ligand-metal interactions.

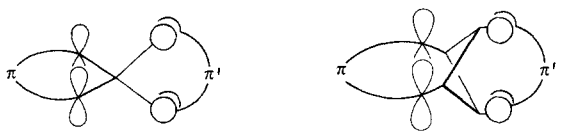
[8] Prepared according to ref. [6]. In contrast to *1R-(2)* and *1S-(2)* (yellow crystals) the racemic complex *1R, 1S-(2)* is dark red in the solid state. We call this interesting phenomenon "chirodichroism".

Through-Bond Interaction between Two Mutually Perpendicular π Systems—A New Possibility of Conjugation[**]



By *Peter Bischof, Rolf Gleiter,* and *Rudolf Haider*[*]

The physical and chemical properties of classically conjugated π systems can be explained by the concept of direct π-π interaction. In cases of homo- and spiro-conjugation, on the other hand, the interacting systems are separated by more than one C—C bond length. This leads to a smaller overlap integral and thus to a smaller interaction.

We shall now demonstrate that the interaction between two mutually perpendicular π systems linked by a spiro center *(1a)* becomes considerably stronger on replacing the spiro center by a four-membered ring *(1b)*. The spiro interaction between the two π systems is then replaced by a through-bond interaction[1]. The Walsh orbitals[2] of the four-membered ring act as a "relay".

(1a) (1b)

On comparing (1a) ($\pi=\pi'$, D_{2d}) with (1b) ($\pi=\pi'$, D_{2d}) we expect the following consequences[3] (see Table 1[4] and Fig. 1):

1) The splitting between the a_2 and b_1 orbitals should become larger.

2) The sequence of the a_2 and b_1 orbitals should be reversed.

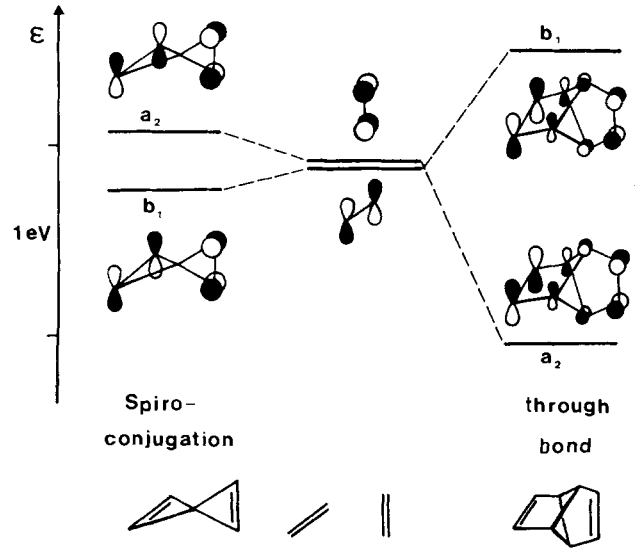

Fig. 1. Interaction diagram for two mutually perpendicular π* orbitals in spiropentadiene (left) and tricyclo[3.3.0.0^{2,6}]octa-3,7-diene (right). The π orbitals remain degenerate and are not shown.

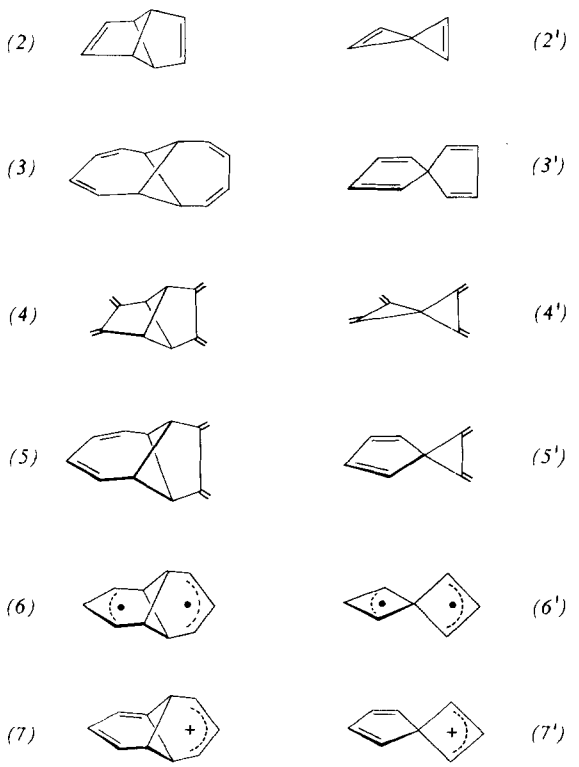
We have calculated the orbital energy differences for the spiro compounds (2') to (6') and for the analogs (2) to



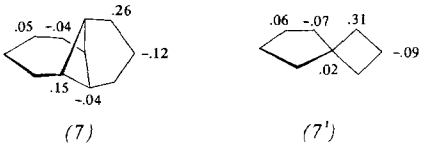


Table 1. Orbital energy differences, calculated by the MINDO/3 [5] and EH (extended Hückel) method [6].

Compound and symmetry	Energy difference of orbitals	Calculated by EH	Calculated by MINDO/3
(2), D_{2d}	$2b_1-1a_2$	1.59	1.06
(2'), D_{2d}	$1b_1-1a_2$	−0.32	−0.14
(3), D_{2d}	$2b_1-1a_2$	1.00	1.24
	$3b_1-2a_2$	0.81	0.23
(3'), D_{2d}	$1b_1-1a_2$	−0.55	−0.63
	$2b_1-1a_2$	−0.60	−0.25
(4), D_{2d}	$2b_1-1a_2$	0.45	0.77
	$3b_1-1a_2$	1.44	0.90
(4'), D_{2d}	$1b_1-1a_2$	−0.08	−0.08
	$2b_2-2a_2$	−0.31	−0.10
(5), C_{2v}	$3a_2-2a_2$	0.69	1.08
	$5a_2-4a_2$	1.07	0.76
(5'), C_{2v}	$2a_2-1a_2$	0.46	0.73
	$4a_2-3a_2$	0.84	0.24
(6), D_{2d}	$2b_1-1a_2$	1.71	6.23
(6'), D_{2d}	$1b_1-1a_2$	−0.66	−5.33

(6) with a four-membered ring. Comparison of the values in Table 1 confirms our hypothesis.

In contrast to the examples (2) to (5) we expect for (6) and (7) a stabilization of the ground state by the through bond interaction. This stabilization can be seen in the case of (6) from the large HOMO-LUMO splitting (see table). It is considerably larger than in (6'). In the case of (7) the distribution of the positive charge over the whole frame, as in (7') (see below), can be taken as an indication of its stabilization.

(7) (7')

Of the compounds listed in Table 1, (2)[7] and a tetramethyl derivative of (4)[8] are known. The unusual electronic spectrum of (2) suggests a strong interaction between the double bond and the four-membered ring[9]. Further confirmation of our hypothesis comes from recent photoelectron spectroscopic studies[10].

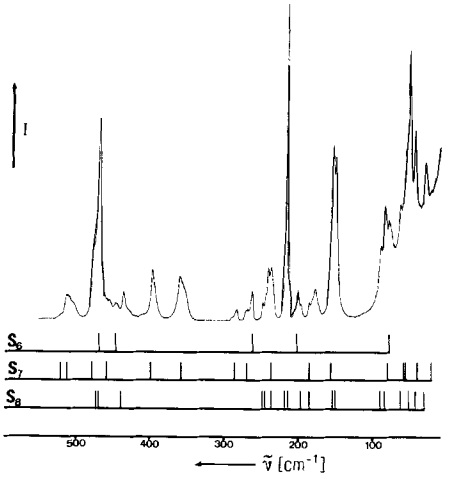
Detection of S_6 and S_7 in Molten Cyclooctasulfur[1]

By *Ralf Steudel* and *Hans-Joachim Mäusle*[*]

Despite numerous experimental and theoretical studies the molecular composition of molten cyclooctasulfur remains controversial. Some authors assume that not only S_8-rings (S_8^R) and (above 160°C) larger chain- or ring-molecules (S_μ) but also S_8-chains (S_8^C) or "complexes" between S_8^R and S_8^C ($S_8^C \cdot nS_8^R$) exist, others postulate a mixture of ring molecules S_6, S_7,...S_{30} or S_9, S_{10},...*etc.* Furthermore, S_3- and S_4-molecules of unknown structure are considered as being responsible for the change in color from yellow to dark red-brown observed on increasing the temperature.



Since the IR and Raman spectra of S_6[2], S_7[3], S_8[4], S_{10}[3b], and S_{12}[5] rings and of the chain shaped polysulfide ions S_n^{2-} ($n=3$ to 8)[6] are known, all conditions are satisfied for qualitative analysis of the sulfur melt by vibrational spectroscopy.

We have examined the spectra of melts of ultrapure sulfur (S_8^R), which had been heated under nitrogen for 5 h at a constant temperature between 120–160°C in an aluminum vessel and then allowed to flow through a small hole in the bottom of the vessel into stirred liquid nitrogen and quenched within 1 to 2 s. These samples (A), which were handled only with cooling (< −50°C) and in the absence of light, were yellow powders having a maximum particle size of 1 mm at −196°C. Extraction of these samples at 25°C with CS_2 (intense yellow solution B) or *n*-pentane or *n*-hexane (light yellow solution C) afforded "π-sulfur solutions"[8]. The largest portion of S_8^R could be crystallized from B at −78°C (solution E remained). Freezing of C at −78°C or treatment of E with hexane until the onset of clouding at 25°C and cooling to −78°C afforded honey-like sulfur (D). Raman spectra of A, D, and E were recorded at −70 to −100°C with krypton laser excitation (647.1 nm), which does not destroy even unstable sulfur rings under these conditions. IR spectra (200 to 700 cm^{-1}) of D and E were recorded at 25°C[9].

Apart from S_8^R, S_6^R and S_7^R were detectable by the following IR absorptions or Raman lines:

S_6 IR: 313 (a_{2u}); Raman: 265 (a_{1g}), 203 (e_g) cm^{-1}
S_7 IR: 516, 481, 400, 270; Raman: 518, 481, 402, 360, 239 cm^{-1}

There is no interference of these frequencies by coincidences with bands due to S_8^R, a large excess of which is often present. With low S_8 contents, further S_6- and S_7-bands were found. Agreement of the wave numbers, of the relative intensities, and of the band shapes were taken into consideration on assignment of the spectra by comparison with those of the pure compounds. As Figure 1 shows, even Raman bands lying very close to each other can be resolved quite well at low temperature and small spectral slit widths (1.5 cm^{-1}), thus enabling detection of S_6 with its line-deficient spectrum.

S_6 and S_7 were detectable in all samples. In A their content referred to S_8 at a melt temperature of 160°C was greater than at 120°C and was estimated to be a few percent, in agreement with the value of 5.5% determined for the π-sulfur content from the melting point depression[8a].

Sulfur D, prepared by treatment of E with hexane, contained about equal amounts of S_7 and S_8 along with smaller amounts of S_6, as was shown by comparison with spectra of test mixtures from S_7 and S_8.

S_{10} and S_{12} were not detected in A (the region from 110 to 140 cm^{-1}, in which both exhibit stronger Raman lines, was free from any lines). The content of these rings in the melt at 120 to 160°C is thus estimated to be <0.2% in each case.

Several spectra contained IR absorptions at 265 and 250 cm^{-1} and Raman lines at 460, 188 and 117 cm^{-1} which are assigned to S_{12} and $S_{12} \cdot 2CS_2$, respectively. Since the average molecular mass of π-sulfur corresponds to *ca.* 8 atoms[8a], at least one larger ring must be present besides S_6, S_7, and S_8. There was no indication of S_8^C being present, which ought to show Raman active vibrations at 300 to 330 cm^{-1}[6] independent of the conformation.

According to these results numerous experimental and theoretical investigations on the problem of the composition of sulfur melts must be newly interpreted, since there is no more need for the assumption of S_8^C or $S_8^C \cdot nS_8^R$, and the concentration of small rings S_n ($n \neq 8$) is in no way negligibly small, as has been assumed on many occasions.

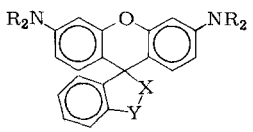
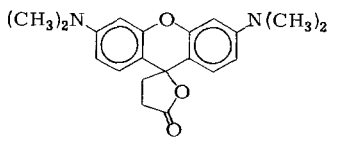
Photochromism of Rhodamine Derivatives[**]

By *Karl-Heinz Knauer* and *Rolf Gleiter*[*]

The use of photochromic compounds, *e.g.* as photoswitches or in data processing technology depends upon the reversibility and magnitude of the photochromic effect[1].



Although triarylmethyl cyanides ("leukonitriles") display a marked photochromic effect[2], the photoinduced reaction is not strictly reversible because the cyanide ion can be replaced by solvent.



$$R_3CCN \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} R_3C^{\oplus} + CN^{\ominus} \qquad (1)$$

R = Aryl

This serious drawback is absent for geometrical reasons in the case of triarylmethane derivatives which have a spiro-type leuko form.

Flash photolysis of the colorless solutions of such rhodamine derivatives *(1a)* to *(4a)*[3] [*(1a)* in CH_3CN; $\lambda_{max}=314$ ($\log\varepsilon=4.11$), 274 (4.52), 239 (4.74) nm] in protic and aprotic solvents between 10 and 60°C reveals a transient having a maximum at $\lambda=558$ nm for *(1a)* and *(2a)*, 545 nm for *(3a)*, and 542 nm for *(4a)*.

(1a)	C_2H_5	NC_6H_5	CO
(2a)	C_2H_5	*p*-NC_6H_4Br	CO
(3a)	CH_3	NH	SO_2

The absorption spectrum of the photoproduct of *(1a)* is identical with that of the corresponding protonated zwitterion *(1b)* obtained in acidic solution.

The activation parameters (Table 1) for the thermal reverse reaction of the photoproduct of *(1a)* are very similar to those of Malachite Green[4].

Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

Table 1. Kinetic data for the thermal reverse reaction *(1b)*→*(1a)*.

Solvent	$k_{25°C}$ [s^{-1}]	$E^{\neq}$ [kcal·mol^{-1}]	$\Delta G^{\neq}_{25°C}$ [kcal·mol^{-1}]	$\Delta S^{\neq}_{25°C}$ [cal·mol^{-1} K^{-1}]
Ethanol	1.01	10.35	16.07	−21.16
Acetonitrile	$2{,}33\cdot10^{-3}$	13.89	21.02	−25.97

On the basis of these findings we deduced the following reaction sequence:

(1a)-(4a) *(1b)-(4b)* (2)

The half-reaction times for the thermal reverse reaction are listed in Table 2.

Table 2. Half-reaction times for the thermal reverse reaction *(2)*.

Compound	Solvent	T[°C]	$\tau_{1/2}$ [s]
(1b)	Acetonitrile	25	297
(1b)	Ethanol	25	0.067
(2b)	Acetonitrile	29	317
(3b)	Acetonitrile	25	1.7
(4b)	Ethanol	25	5.6

The relative quantum yield of *(1a)*→*(1b)* is independent of the oxygen concentration, but dependent upon the solvent: $\Phi_{rel}=1.0$ (dioxane), 0.88 (*n*-butyronitrile), 0.47 (acetonitrile), and 0.06 (ethanol). A similar solvent dependence is found for the fluorescence quantum yield of *(1a)*. In contrast, the phosphorescence quantum yield is independent of the solvent.

Hence we conclude that the photoreaction *(2)* proceeds from the singlet state (S_1). In the S_1 state the C—X bond is considerably weaker than in the S_0 or T_1 state[5].

Synthesis of Cyclodepsipeptides by Cyclooligomerization[**]

By *Manfred Rothe* and *Wolfgang Kreiss*[*]

A common feature of numerous biologically active cyclodepsipeptides is their repeating structure. Cyclooligomerization

[*] Prof. Dr. M. Rothe, Dr. W. Kreiss
Lehrstuhl Organische Chemie II der Universität
Oberer Eselsberg, D-7900 Ulm (Germany)

[**] Cyclic Peptides, Part 23. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF, Ludwigshafen.—Part 22: *M. Rothe, D. Mühlhausen*, Angew. Chem. *88*, 338 (1976); Angew. Chem. Int. Ed. Engl. *15*, 307 (1976).

of the basic repeating unit[1, 2] appears promising as a synthetic approach for these compounds since the laborious preparation of open chain precursors is then limited to that of subunits.

We have investigated the solvent-dependent formation of cyclic homologs of valinomycin. Cyclooligomerization was accomplished by the phosphite method[3].

Valinomycin partial sequences H(Val-D-Hyv-D-Val-Lac)$_n$OH[4], $n=1$, 2, and the complete sequence with $n=3$ served as linear subunits. The pronounced lipophilic character of these precursors permitted use of apolar solvents as well as the usual reaction medium diethyl phosphite. In the case of the tetradepsipeptide ($n=1$) cyclooligomerization was detectable up to the heptamer ($m=7$,84 ring atoms) by gel chromatography. The octadepsipeptide ($n=2$) gave di- and trimerization products ($m=4$ and 6, with 48 and 72 ring atoms, respectively) together with cyclic monomer, while the dodecadepsipeptide ($n=3$) yielded only the cyclic monomer (valinomycin, $m=3$). A significant influence of the solvent polarity was apparent in the relative amounts of the cyclic homologs obtained (Table 1).

Table 1. Solvent-dependent formation of cyclooligomers. DEP = diethyl phosphite, Tol = toluene.

H(Val-D-Hyv-D-Val-Lac)$_n$OH			cyclo(Val-D-Hyv-D-Val-Lac)$_m$ Yield [%]				
n	Solvent	c [mol/l]	$m=1$	2	3	4	6
1	DEP	0.05	48	14	2	—	—
1	Tol	0.05	4	13	7	2	—
2	DEP	0.01	—	30	—	4	1
2	Tol	0.01	—	23	—	10	2
3	DEP	0.001	—	—	24	—	—
3	Tol	0.001	—	—	56	—	—

Both partial sequences ($n=1$, 2) yielded greater amounts of the macrocyclic oligomers in the apolar reaction medium toluene. The large drop in intramolecular ring closure for the tetradepsipeptide in toluene is particularly striking. Possible explanations are loss of chain mobility of the linear monomer as a result of more extensive solvation as well as enhanced association. Association of the linear octa- and tetradepsipeptides in toluene could actually be detected by vapor pressure osmometry. However, it could not be correlated directly with the occurrence of cyclic oligomers.

The series of oligomeric cyclic peptides obtained could readily be interpreted as the result of linear polycondensations, which are concentration dependent. In this case cyclization is to be regarded as competing with chain growth.

Our attempts to oligomerize the aminoacyl hydroxy acids H-MeVal-D-Hyv-OH and H-D-Val-Hyv-OH to give higher-molecular members of the enniatin series led exclusively to cyclic monomers. The reason is to be seen in the marked formation tendency of the six-membered morpholinediones. The low solubility of the linear precursors precluded exploitation of the favorable influence of apolar solvents on oligomer formation observed in valinomycin series.

The preparative potential of cyclooligomerization is illustrated by the first synthesis of the macrocyclic valinomycin dimer [$m=6$, 72 ring atoms, molecular weight 2223 (mass spectrum)][5]. This depsipeptide is of significance as a model substance in studies on the ionic permeability of lipid membranes.

General procedure

The free linear depsipeptides were subjected to reaction under the usual conditions of phosphite cyclizations[3, 2]. The resulting reaction solutions were evaporated to dryness. On use of diethyl phosphite as reaction medium the residue was dissolved in dichloromethane and freed from acidic contaminants by extraction with $NaHCO_3$ solution. The crude products obtained in toluene were separated without further extractions by gel chromatography (Sephadex LH 20/methanol; 200 × 2.4 cm column; $EHTP_{acetone} = 0.0205$ cm).

Determination of Reaction Enthalpy in the Ion-Exchange of Chlorine Isotopes[**]

By *Klaus G. Heumann* and *Rainer Hoffmann*[*]

In a recent communication we reported on the chlorine isotope effect in ion-exchange chromatography[1]. We have now succeeded in determining the first set of thermodynamic data for an isotope exchange equilibrium of anions by measuring the temperature dependence of the chlorine isotope effect. Knowledge of such data is of fundamental importance for an understanding of isotope effects, in the development of chromatographic methods for the chemical enrichment of chlorine isotopes.

A column ($d=1.5$ cm, ht. of packing 80 cm) filled with the strongly basic anion exchanger AG1-X10 (NO_3^- form, 200—400 mesh, Bio-Rad) was used in the experiments. In each run 200 mg of chloride of natural isotopic composition was applied to the column in the form of NaCl and then eluted with 1 M $NaNO_3$ solution at an elution rate of *ca.* 0.35 ml/min. The temperature-dependence was determined by carrying out the runs at 0, 5, 7.5, 10, 15, 20, 30, 45, and 60 °C. The eluate was collected in fractions and the isotopic ratio $^{35}Cl/^{37}Cl$ determined by measurement of the negative thermions in a mass spectrometer.

The equilibrium constant K_c of the isotope exchange reaction

$$^{37}Cl(H_2O)_x^-R^+ + {}^{35}Cl(H_2O)_y^- \rightleftharpoons {}^{37}Cl(H_2O)_y^- + {}^{35}Cl(H_2O)_x^-R^+ \quad (1)$$

[R^+ = quaternary ammonium group of the anion exchanger]

can be determined according to a method described by *Glueckauf*[2]. The number of equilibrium steps in the column is determined from the elution curve, and the isotope effect ε of an equilibrium step ($K_c = 1+\varepsilon$) from the dependence

[*] Prof. Dr. K. G. Heumann, Dr. R. Hoffmann
Institut für Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. *K. H. Lieser*, Technische Hochschule Darmstadt for allowing us to carry out the mass spectrometric measurements in his Institute.

of the measured isotopic ratio on the amount of eluted chloride. The elution curve must correspond to a Gaussian distribution, a prerequisite that is fulfilled on elution with 1 M $NaNO_3$ solution. K_c decreases with increasing temperature, thus indicating that the reaction from left to right in Eq. (1) is exothermic.

If the logarithm of K_c is plotted against the reciprocal of the absolute temperature, the reaction enthalpy can be determined according to the van't Hoff reaction isobar from the slope of the curve.

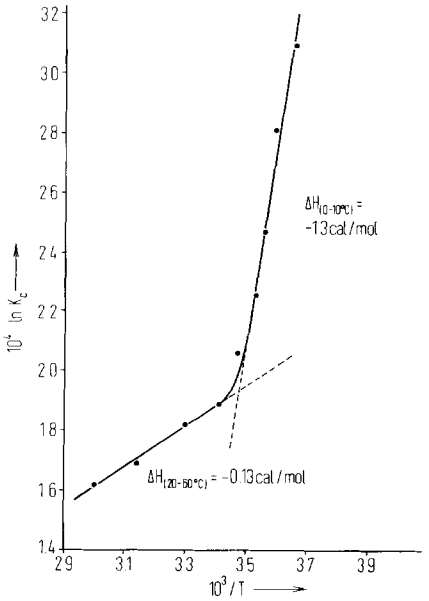

Fig. 1. Determination of ΔH for the Cl^- isotope exchange reaction from the temperature-dependence of the K_c value.

Figure 1 shows that two reaction enthalpies differing by one power of ten, $\Delta H(0—10\,°C) = -1.3$ and $\Delta H(20—60\,°C) = -0.13$ cal/mol are found in the temperature range investigated. Using these for the calculation of entropy values gives *e.g.* for 5 °C $\Delta S = -4.1 \times 10^{-3}$ cal/K·mol, and for 30 °C $\Delta S = -0.07 \times 10^{-3}$ cal/K·mol.

We interpret the unexpected change in the value of ΔH between 10 °C and 20 °C in terms of modification of the ionic structure of the reaction partners. Owing to partial dehydration of the ions on passage of the solution through the ion exchanger, $y > x$ for the hydration numbers in Eq. (1). Since changes of the ionic structure in such systems have hitherto not been observed in solution it would appear that the change of structure is due to either the Cl^- ions in the exchange resin or to the fixed ions of the exchanger. Such ion-exchange equilibria can therefore possibly serve as indicators for structural changes in ions of low energy.

So far reaction enthalpies for isotopic exchange reactions analogous to those studied by us have been determined only in the case of two isotopic pairs of cations in systems with a strongly acidic cation exchanger. Thus, *Glueckauf*[2] has obtained a value of $\Delta H(5.5—25\,°C) = -0.41$ cal/mol for $^{22}Na/^{24}Na$ using the experimental results of *Betts et al.*[3], whereas *Lee*[4] obtained $\Delta H(3—59\,°C) = -2.26$ cal/mol for $^6Li/^7Li$. Negative ΔS values were also calculated in both cases. Since the thermodynamic data for the $^{22}Na/^{24}Na$ pair were determined from only two measurements, really only the values for the lithium isotopes (four measurements) can be compared with our results: in contrast to Cl^-, in the case of Li^+ there is no change of ΔH value in the temperature range investigated. The enthalpy of $\Delta H(0—10\,°C) = -1.3$ cal/mol for the ion-exchange reaction of chloride agrees, within one order of magnitude, with that of lithium; the difference is probably due to the smaller difference in the ionic radii of the chloride isotopes[5].

Serious Detonation during the Preparation of *tert*-Butyloxycarbonyl Azide (Boc-Azide)

By *Peter Feyen*[*]

tert-Butyloxycarbonyl azide (Boc-azide) is frequently employed as a reagent for the protection of amino groups. During its preparation we recently witnessed a serious explosion, which fortunately only resulted in damage to equipment.

Boc-azide was prepared by reaction of *tert*-$C_4H_9OCO—NH—NH_2$ with HNO_2 in ether according to the method described in Ref.[1]. The ether was distilled off at a water-bath temperature of 50 °C through a 30-cm Vigreux column. After about half of the ether had been distilled off, *i.e.* before actual distillation of the product, which normally occurs at 73 to 74 °C/70 torr and at a water-bath temperature of 90 to 95 °C, a detonation took place. According to Ref. [1] heavy metal azides may be responsible for the detonation, not Boc-azide itself. How this particular detonation could have arisen remains unanswered, since all the reagents and the ether employed were of proven high purity according to the manufacturer's analyses.

Differential thermal analysis[2] of the pure Boc-azide showed that practically no decomposition takes place on heating it in a closed glass vessel for 3 h at 80 to 90 °C. After 3 h at 100 °C the amount of decomposition had increased to about 50 %, and after 3 h at 110 °C it was almost complete. The heat of decomposition is 46 kcal/mol. At a heating rate of 5 °C/min maximum decomposition is reached at 138 °C.

Distillation of Boc-azide in ether containing 0.1 vol-% peroxides or additives such as Cu ions did not bring about premature detonation[3].

In view of this inexplicable incident and the fact that the Aldrich company has discontinued production of Boc-azide[4], it is urgently recommended that other reagents[5] be employed for introduction of the *tert*-butyloxycarbonyl protecting group.

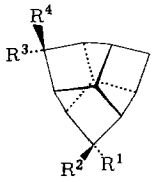
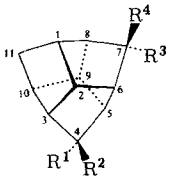
Synthesis and Absolute Configuration of Enantiomerically Pure D_3-Trishomocubanes (Pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane) and Trishomocubanones[**]



By *Günter Helmchen* and *Gerhard Staiger*[*]

Rigid chiral hydrocarbons and ketones are of special interest as test cases for chiroptic theories. Outstanding representatives are the enantiomeric trishomocubanes *(2f)* and *(3f)*, in that they are apparently the smallest stable organic molecules of the point symmetry group D_3[1].



While racemic trishomocubane is very readily accessible *via* rearrangement of the alcohols *(1a)* and *(1b)* to the stereoisomeric 4,7-diiodotrishomocubanes with hydriodic acid and their subsequent reduction with zinc, only relatively tedious methods exist for the synthesis of derivatives appearing suitable for separation of the enantiomers[2]. We have how found that 4-hydroxy-7-iodotrishomocubanes are formed in good yields as intermediates in the first mentioned reaction and that these can be easily resolved into their enantiomers. The structures and properties of the new compounds are summarized in Table 1[3].

(1)

(2)

(3)

(a): X = Y = OH, Z = H
(b): X = Z = OH, Y = H
(c): X, Y = O, Z = H

Complete separation of the enantiomers *(2a)* and *(3a)* was achieved by liquid chromatography of their diastereomeric esters *(2c)* and *(3c)* with (−)-camphanic acid[4] [silica gel columns, petroleum ether/ethyl acetate (92:8), separation factor: 1.1]. Pure *(2c)* can also be obtained in 30% yield by crystallization of the mixture from ethyl acetate. Like the (−)-camphanic acid, which was prepared from natural (+)-camphor, *(2c)* and *(3c)* and their secondary products described below were enantiomerically pure. Reduction of *(2c)* with zinc/glacial acetic acid and hydrolysis of the product with ethanolic potassium hydroxide solution yielded (−)-4-trishomocubanol *(2d)*, which in turn furnished (−)-trishomocubanone *(2e)* by Jones-Kiliani oxidation (97% yield in each case). Wolff-Kishner reduction of *(2e)* afforded the readily volatile, camphor-like smelling (−)-trishomocubane *(2f)* in

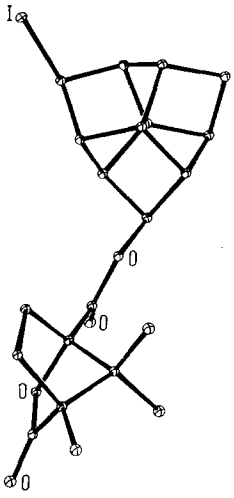


Fig. 1. Molecular structure of the ester *(2c)*.

Table 1. Configuration and physical properties of trishomocubane derivatives *(2)* and *(3)*.

	R^1	R^2	R^3	R^4	Abs. configuration [a] of *(2)*	M.p. [°C] *(2, 3)*	M.p. [°C] *(2)*	M.p. [°C] *(3)*	$[\alpha]_D^{20}$ [b] *(2)*	$[\alpha]_D^{20}$ [b] *(3)*	
(a)	H	OH	H	I	3*S*,4*R*,7*S*	132	116		− 65.4°		(*c*=2, ethanol)

(f)	H	H	H	H	3*S*		149		−164°		(*c*=1.3, *c*-hexane)
(g)	H	$OCOR^6$ [d]	H	I	3*S*,4*R*,7*S*						

[a] All the compounds have further chirality centers besides those specified; their configurations follow logically.
[b] Determined according to the Drude equation from measured values at 578 and 546 nm.
[c] R^5—COOH = (−)-camphanic acid.
[d] R^6—COOH = (+)-(*S*)-2-phenylbutyric acid.

Heating a mixture of the diols *(1a)* and *(1b)*[2] with concentrated hydriodic acid at 70°C (15 h) followed by chromatographic separation of the reaction products affords *(2, 3a)* and *(2, 3b)* in 54% and 13% yield, respectively. Assignment of configuration—confirmed in the case of *(2, 3a)* *(vide infra)*—was based on the fact that under the same conditions these compounds are also formed from the cyclic ether *(1c)* in a constant ratio of 6.5:1 independent of the reaction time and that *(2, 3a)* does not isomerize to *(2, 3b)*.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

80% yield. The compounds of the enantiomeric series were prepared analogously from *(3c)*.

An extraordinarily reliable and simple ^{1}H-NMR method recently developed by us[5] was used for determination of the absolute configuration: (−)-*(2a)*, obtained by hydrolysis of the ester *(2c)*, was esterified with (*S*)-2-phenylbutyryl chloride to give *(2g)*. The ^{1}H-NMR spectrum ($CDCl_3$) of this compound shows a signal at $\delta = 3.88$ ppm for 7-H. The corresponding signal of the (*R*)-2-phenyl butyrate occurs at $\delta = 3.82$ ppm, which was inferred from the spectrum of a mixture of the esters *(2g)* and *(3g)*. From these data it follows[5] that (−)-*(2a)* has the (3*S*,4*R*,7*S*) configuration. This result was confirmed by an X-ray structure analysis of *(2c)* (cf. Fig. 1)[6].

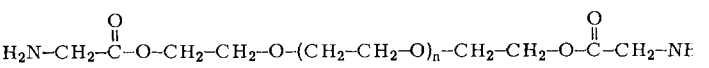
Synthetic Hemopolymers for Reversible Binding of Molecular Oxygen[**]

By *Ernst Bayer* and *Gunter Holzbach*[*]

Dedicated to Professor Hans-Joachim Bielig on his 65th birthday

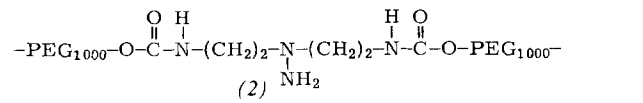
Myoglobin and hemoglobin number among the most thoroughly studied biologically active proteins. Although the structure of these metalloproteins and their mode of action have been largely elucidated it has so far proved impossible to synthesize analogous heme complexes which reversibly bind oxygen under physiological conditions (20 to 40 °C; aqueous solution); such substance would play a very important role in the development of blood substitutes. Reversible oxygenation of model complexes containing heme has been observed only at low temperatures or in nonphysiological media[1]. Replacement of the protein component of an enzyme or an oxygen carrier appears to be difficult, even in well investigated biopolymers. Since protein synthesis is still too complicated or unreliable by presently available methods, and proteins are too unstable for practical use in catalyst systems, attention should be directed to synthetic polymers functionalized in suitable manner.

We have now synthesized heme-containing functionalized polymers for the reversible transport of oxygen which share the following properties with the natural oxygen carriers hemoglobin and myoglobin:



1) good solubility in water in order to achieve high concentrations of O_2;

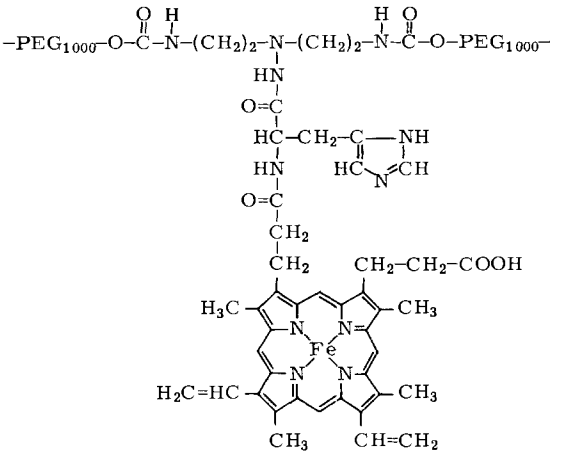
2) hindrance of irreversible oxidation of the oxygen complex by the functionalized polymer;



3) imitation of the distal imidazole.

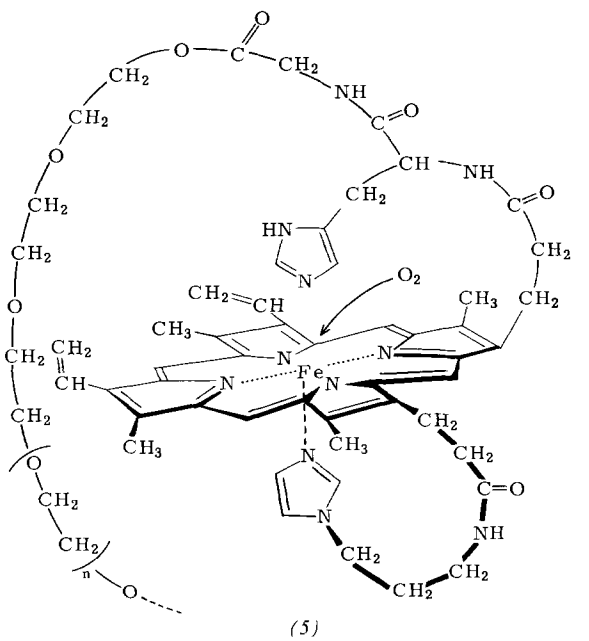
Polyvinylpyrrolidinone, poly[ethylene glycol bis(glycine ester)][2a], *(1)*, and polyurethanes of structure *(2)* from polyethylene glycols (PEG) and diisocyanates[2b] were used as the basic polymers. Di-*tert*-butyloxycarbonylhistidine[3] is coupled to the free amino groups of polymers *(1)* and *(2)* in compliance with the procedures of liquid phase peptide synthesis with dicyclohexylcarbodiimide (DCCI)[4]. The amino protecting group of the histidine is then removed with trifluoroacetic acid/CH_2Cl_2 (1:1) and the amino group coupled with DCCI to a carboxy group of hemin. The hemin content of poly[ethylene glycol bis(glycylhistidylhemin)] *(3)* is 73 %, that of the histidylhemin derivative of the polymeric urethane *(4)* 100 %, based on the amino groups of the starting polymer *(1)* and *(2)*, respectively.

In the two functionalized polymers *(3)* and *(4)*, histidine is linked with the carboxy group of a propionic acid residue of hemin to form the amide. This arrangement prevents optimum coordinative fixation of the imidazole nitrogen of the histidine residue to the iron of heme for steric reasons. The histidine bound in this way can therefore be compared with



(1)

(2)



Heme–His–Gly–PEG–Gly–His–Heme

(3)

(4)

the distal histidine in myoglobin. The only other requirement for synthesis of an oxygen carrier is an imidazole ligand corresponding to the proximal histidine of natural oxygen carriers. This approach was adopted in the case of polymer *(4)* by addition and coordinative bonding of imidazole or imidazole derivatives. It is better however, to introduce an additional covalent bond between the proximal imidazole and the polymer. In the case of *(3)*, 3-(5-imidazolyl)propylamine[5] was therefore coupled to the second propionic acid group—once again using the methods of liquid phase peptide synthesis with DCCI/hydroxybenzotriazole. In the polymeric product *(5)* this imidazole group can undergo optimal coordination with the iron.

(5)

[*] Prof. Dr. E. Bayer, Dipl.-Biochem. G. Holzbach
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The structural units of the active site of myoglobin or hemoglobin which are essential for binding oxygen are all present, albeit in a different arrangement, in the two polymers. The oxygen coordination site is shielded both by histidine and by the synthetic polymer. Nothing is known about the conformation of *(5)* in solution, especially in the vicinity of the active site. In the solid state, however, the hemin polymer *(5)* shows the same X-ray reflections ($d_1 = 3.794$ Å; $d_2 = 4.611$ Å) as are characteristic of the helix structure of poly(ethylene glycol) and poly(ethylene glycol peptide esters).

After synthesis the iron is present as Fe^{III} in both polymers *(4)* and *(5)*; they must therefore be reduced with sodium dithionite prior to oxygenation. An excess of reducing agent can be removed by chromatography on Sephadex. The O_2-free hemopolymers prepared in the above way are highly soluble in water. On oxygenation the typical spectral shifts occur (Table 1) which also accompany formation of the oxygen complexes of myoglobin and hemoglobin.

Table 1. Absorption maxima [nm] of various complex types of polymers *(4)* and *(5)*.

Polymer	Reduced	Oxygenated	Oxidized	CO complex
(4)	421	412	408	412
	529	526	540	537
	560	556		564
(5)	418	410	405	414
	527	524		535
	558	554		560

Oxygen can be reversibly removed from the dioxygen complexes, *e.g. in vacuo* (0.01 to 0.04 torr; 5 min). The process can be repeated several times. Addition of carbon monoxide to form a CO-hemopolymer is also possible (Fig. 1). The O_2 complex can be obtained therefrom by prolonged passage of oxygen. After repeated reversible oxygenation the complex shows increasing signs of irreversible oxidation to the hemin polymer, detected by the unstructured spectrum in VIS region and the shifts in the UV spectrum (Fig. 1). In the blood, the irreversibly oxidized hemoglobin which is also slowly formed is reduced to oxygenatable hemoglobin by an enzyme, *viz.* methemoglobin reductase[6]. The synthetic hemin polymers are also reduced to the Fe^{II} state by methemoglobin reductase and can then react once more with O_2 to form the oxygen complex.

The oxygen sorption curve for complex *(4)* is reproduced in Figure 2. The O_2 partial pressure for semi-saturation of our fully synthetic models [*(4)*, 0.21; *(5)*, 0.10 torr] is in good agreement with the values for myoglobin [0.2 to 1.2 torr[7]]. The sigmoid shape of the curve (Fig. 2) is indicative of a cooperative effect in oxygen binding, as in the case of hemoglobin[8].

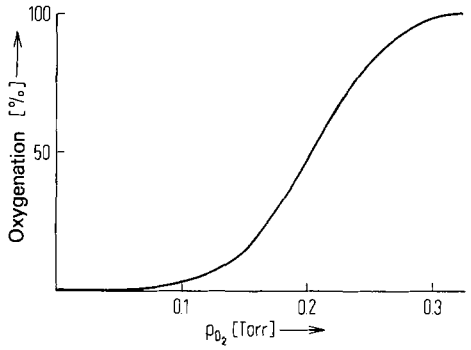


Fig. 2. Oxygen sorption curve of polymer *(4)* at 25 °C in 0.05 M phosphate buffer pH = 8.1.

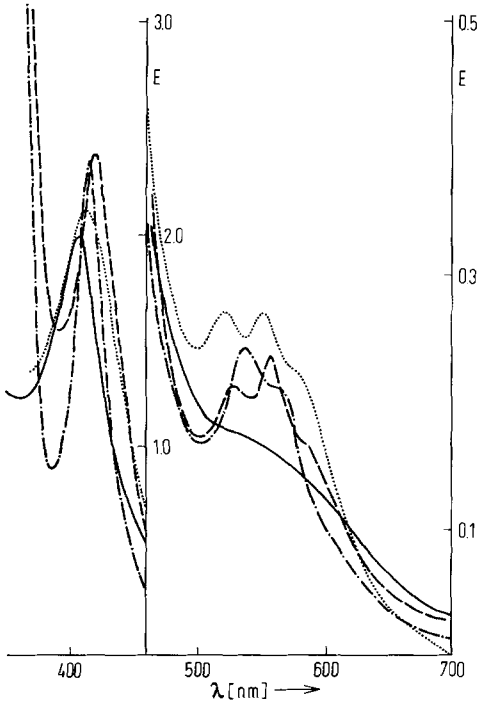

Fig. 1. Absorption spectra of polymer *(5)* in 0.05 M phosphate buffer pH = 7 (concentration: 4.5 ppm hemin iron): ..... oxygenated; ----- reduced; ——— oxidized; -·-·-·-CO complex.

The synthetic hemopolymers have properties closely resembling those of natural oxygen carriers, although the basic polymer is completely different. This demonstrates that specificity and reactivity are by no means privileges of naturally occurring polymers. This is confirmed for reactions of preparative and industrial interest by the development of homogeneous catalysts on the basis of synthetic, non-crosslinked polymers[9].

Extension of the Scope of Anionic Cycloadditions by Activating Organoelement Groups[**]

By *Thomas Kauffmann, Holger Ahlers, Angelika Hamsen, Herbert Schulz, Hans-Joachim Tilhard,* and *Annemarie Vahrenhorst*[*]

[$_\pi$2+$_\pi$4]-Cycloadditions to isolated unstrained CC double bonds usually require the presence of an activating group in the olefin. Carbonyl groups of proven value in Diels-Alder reactions and 1,3 dipolar cycloadditions are unsuitable for anionic 1,3 additions owing to the pronounced nucleophilic character of the anionic reagents; nor can cyano groups be used[1]. The choice was limited to aryl groups, *i.e.* to groups which are practically impossible to remove and hardly suitable for subsequent synthetic steps (CC linkages).

We have now found that S—C_6H_5, Se—C_6H_5, $P(C_6H_5)_2$, and $As(C_6H_5)_2$ groups permit the cycloaddition of 1,3-diphenyl-2-azaallyllithium *(1)* to a vinyl group (see reaction scheme and Table 1). The utility of $Si(C_6H_5)_3$ and $Si(CH_3)_3$ groups, which can be removed from sp^3 C atoms only with difficulty, for this purpose was already known[2]. With one exception, cycloadducts could also be obtained with 1,1-

diphenyl-2-azaallyllithium *(2)*. With *(2)* only one of the two possible regioisomeric cycloadducts could be detected in each case, *i.e.* structure *(4a)*. $P(O)(C_6H_5)_2$ and $P(S)(C_6H_5)_2$ do not act as activating groups; nor does $Sb(C_6H_5)_2$[3].

Since C—S, C—Se, and C—As bonds can be cleaved with relative ease and the $P(C_6H_5)_2$ should permit CC linkages to the cycloadducts after oxidation or quaternization, the scope of anionic 1,3-cycloadditions appears to have been considerably extended.

The structures of the newly prepared compounds are in accord with the results of elemental analysis and their spectra (MS, IR, ^{1}H-NMR). The stereochemistry at the chiral centers has not yet been elucidated.

Procedure:

Synthesis of *(3a)*: A solution of *cis*-2,3-diphenylaziridine (3.90 g, 20 mmol) in anhydrous THF (150 ml) is stirred under N_2 and treated at room temperature with an equimolar amount of *n*-butyllithium. The solution is heated under reflux for 2 h. The dark red reaction mixture is cooled to −60 °C and treated dropwise with phenyl vinyl sulfide (2.72 g, 20 mmol) in THF (20 ml), and then stirred for ½ h at −60 °C and 1 h at +20 °C. After addition of H_2O (20 ml) the mixture is extracted three times with $CHCl_3$ (3 × 100 ml). The oily residue obtained on evaporation of the dried organic phases crystallizes on addition of ether/light petroleum (30 to 60 °C) (1 : 2). Crystalline *(3a)* (4.5 g, 68 %) is obtained; its melting point does not increase on recrystallization from methanol.

Collision Activation Mass Spectrometry with Novel Analysis Technique

By *Richard Robbiani, Thomas Kuster,* and *Joseph Seibl*[*]

The analysis of collision induced degradation reactions of ions in the gas phase (CA-mass spectrometry[1]) has acquired increasing importance recently as a means for investigating ion structures. Ion cyclotron resonance (ICR) is preferably employed for such measurements, especially if ions of long lifetimes are the subject of interest. Otherwise double focusing mass spectrometers of Nier Johnson geometry are used in the so called DADI mode of operation[2], whereby the collision gas is admitted to the field free region between magnetic and electric sector. This mode of operation requires reversal of the instrument's conventional configuration, as the magnetic sector must precede the electric sector and therefore is not easily applicable to existing instrumentation. In addition under these conditions the principle of double focusing (mutual compensation of energy dispersion of electric and magnetic field) is not operative for ions generated in this region. The peaks appear broadened by collisional scattering and tend to overlap, often in a quite disturbing manner.

We would like to point out that collision induced degradations can be investigated with double focusing mass spectrometers in their usual configuration (the electric sector preceding the magnetic sector) while simultaneously avoiding the above mentioned drawbacks of the DADI method. If the collision gas is admitted to or just behind the ion source, the products formed by collisional processes in the first field free region can be analyzed by the newly established "linked scan technique"[3]. The operating principle of this method consists essentially of giving daughter ions m_2^+, m_3^+ ... arising from a freely selectable parent ion m_1^+ so much additional kinetic energy (velocity) that they acquire the same momentum as their precursor m_1^+. Having the same momentum they are recorded at the same place as m_1^+ at the collector site without altering the magnetic field. The required additional kinetic energy is imparted by increasing the accelerating voltage V. Thereby the ion trajectory in the electric sector is stretched and in order to focus the beam on to the intermediate slit the electric sector voltage E must be changed simultaneously ("linked") in such a way that E/V remains constant. A continuous linked scan of this sort produces a daughter ion spectrum of m_1^+ much like a DADI scan, save that now the principle of double focusing is operative. The signals are sharp and do not overlap. The measurement takes place earlier with respect to formation of the investigated ions than in the DADI configuration, reducing the probability of their isomerization before collision.

We tested the method by examining the ion $C_{12}H_{10}O^+$ (*m/e* 170) formed from diphenyl carbonate by decarboxylation under electron impact. *McLafferty et al.*[4] have determined the DADI-CA spectrum of this product and compared it with the spectra of diphenyl ether and the isomeric phenylphenols which were determined under identical conditions.

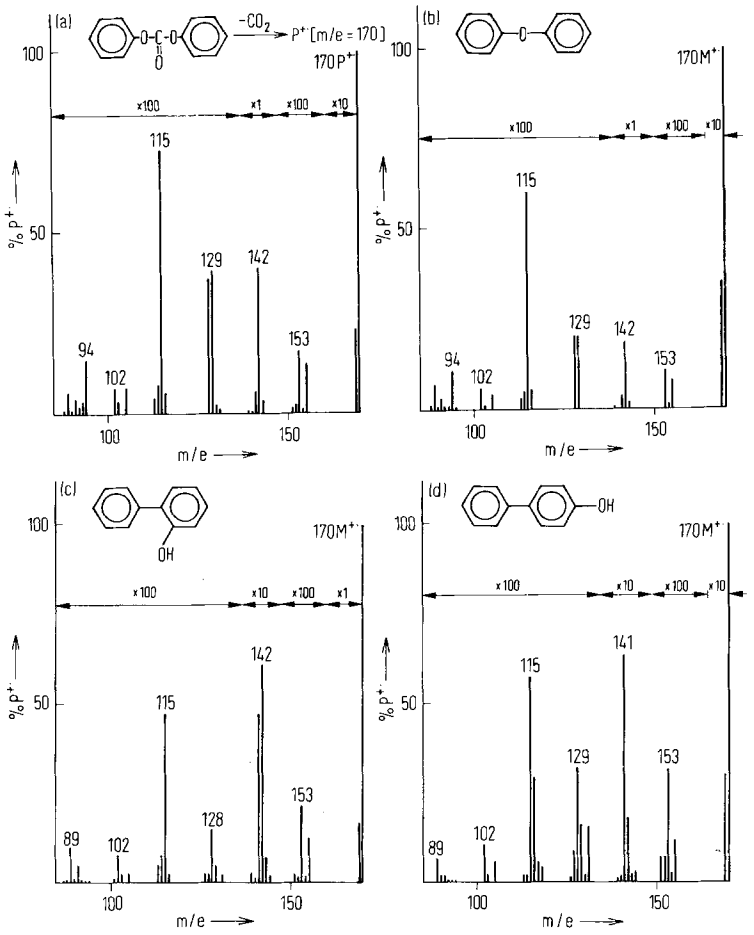

Fig. 1. Collision activation spectra of *m/e* = 170 from diphenyl carbonate (a), diphenyl ether (b), *o*-phenylphenol (c), and *p*-phenylphenol (d). Pure CA spectra, monomolecular components have been eliminated by substraction.

[*] Prof. Dr. J. Seibl, Dr. R. Robbiani, Dr. T. Kuster
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule
Universitätstrasse 16, CH-8092 Zürich (Switzerland)

The authors found that the decarboxylation product gave a spectrum similar to that of the diphenyl ether but different from those obtained from the phenylphenols and concluded, that a diphenyl ether structure must be attributed to the fragment of diphenyl carbonate. The conclusion is of course somewhat relativized by the statement that the spectra of the isomeric phenylphenols are mutually identical. Our LS-CA spectra of the diphenyl carbonate fragment, of diphenyl ether, and of two of the isomeric phenylphenols are shown in Figure 1. Corroborating the results reported in [4] the spectra of fragment (a) and diphenyl ether (b) are virtually identical and are taken to indicate identical structures. In accordance with expectation, it appears that differences in internal energy of the decomposing ions of different origin do not influence their behavior under CA conditions to any significant extent, at least not in this case. The spectra of the isomeric phenylphenols (c) and (d) are again different from (a) and (b), in line with the finding in [5], but in contrast to the DADI results they are by no means identical. The differences are absolutely sufficient for structural identification of the respective isomer. These opposing results of DADI-CA *versus* LS-CA suggests that the molecular ions of phenylphenols can isomerize completely to a common structure within the short period of time required to travel from the first to the second field-free region of the instrument. To move the observational window closer in time to the ion production process seems to be a suitable way for analyzing ion processes preceding the collisional activation step.

The described method is applicable to other modes of operation like linked scan of sector- and magnet field as well, and is suited for a further shift of the observational window to even shorter time lags between ion formation and collision process, as for example in combination with field-desorption ionization.

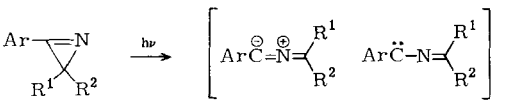
ABSTRACTS

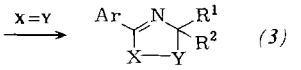
Reviews

Abstracts of selected progress reports and review articles

Stabilized vinyl cations are reviewed in article by *M. Hanack*. Classically stabilized cations of this type are α-arylvinyl *(1)*, dienyl *(2)*, and allenyl cations *(3)*; the nonclassically stabilized vinyl cations include cyclopropylvinyl *(4)* and cyclopropylidenemethyl cations *(5)*. Vinyl cations can be readily generated



(1) *(2)* *(3)* *(4)* *(5)*



by solvolysis, particularly if the "super leaving groups" $F_3C-SO_3^{\ominus}$ and $F_9C_4-SO_3^{\ominus}$ are employed. The more stable the intermediary vinyl cation the less the rearrangement that takes place in the solvolysis. [Stabilized Vinyl Cations. Acc. Chem. Res. *9*, 364—371 (1976); 44 references]

[Rd 915 IE—L]

The photochemistry of 2*H*-azirines *(1)* is dealt with in an article by *A. Padwa*. 2*H*-Azirines—cyclic amines—are versatile substrates which can serve as precursors for other heterocycles. They react both with electrophiles as well as with nucleophiles and can participate as dienophiles or dipolarophiles in thermally allowed $[_4\pi_s + _2\pi_s]$ cycloadditions. On electronic excitation 2*H*-azirines undergo irreversible ring opening to give reactive nitrile ylides *(2a)* and/or *(2b)*, which react, for example, with dipolarophiles to form five-membered

(1) *(2a)* *(2b)*

(3)

heterocyclic compounds *(3)*. Further possible reactions of *(1)* include photochemical dimerization and intramolecular reactions, when R^1 = vinyl or allyl. [Azirine Photochemistry. Acc. Chem. Res. *9*, 371—378 (1976); 61 references]

[Rd 916 IE—L]

The biological activity of sesquiterpene lactones forms the theme of an article by *E. Rodriguez, G. H. N. Towers*, and *J. C. Mitchell*. These compounds are characteristic components of most Compositae, but are also occasionally found in other angiosperms and even in liverworts. The bitter substances often contain an α,β-unsaturated γ-lactone ring, which according to recent findings could be responsible for their activity towards tumors and microorganisms as well as their cyto- and phytotoxicity. Sesquiterpene lactones poison cattle, protect plants from being eaten by insects and in the case of man give rise to allergic dermatitis on contact. [Biological Activities of Sesquiterpene Lactones. Phytochemistry *15*, 1573—1580 (1976); 75 references]

[Rd 920 IE—R]

Fast reactions of carbanions and carbocations in solution are reported on by *L. M. Dorfman*, *R. J. Sujdak*, and *B. Bockrath*. These species can be generated and investigated by pulse radiolysis. Absolute rate constants were determined for a number of reactions. The benzyl anion ($PhCH_2^{\ominus}$) was prepared both unpaired and as the ion pair ($PhCH_2^{\ominus}$, $Na^{\oplus}$) in solvents such as tetrahydrofuran:

$$e_s^{\ominus} + (PhCH_2)_2Hg \rightarrow PhCH_2^{\ominus} + PhCH_2Hg^{\bullet}$$

The benzyl anion shows a UV band at 362 nm; the ion pair absorbs at 355 nm. The reactions of these species with alcohols were studied in detail. Carbocations, *e.g.* the benzyl cation ($PhCH_2^{\oplus}$), were obtained by pulse radiolysis in hydrocarbon halides:

$$e^{\ominus} + RCl \rightarrow RCl^{\bullet\ominus} + 2e^{\ominus}$$

$$RCl^{\bullet\ominus} + (PhCH_2)_2Hg \rightarrow RCl + PhCH_2^{\oplus} + PhCH_2^{\bullet} + Hg$$

The carbocation $PhCH_2^{\oplus}$ shows an absorption band at 363 nm. The lifetime of some of these cations is longer than 1 μs. Investigations were carried out, *inter alia*, on their reactions with halide ions and tertiary amines. [Fast Reactions of Carbanions and Carbocations in Solution. Acc. Chem. Res. *9*, 352—357 (1976); 42 references]

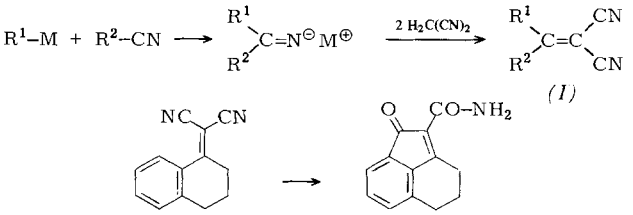
[Rd 914 IE—L]

The surface of titanium dioxide is the subject of a review by *G. D. Parfitt*. The rutile and anatase forms are considered separately; whenever possible the conditions of preparation and the origin of the samples are given. Most samples were obtained by oxidation or hydrolysis of titanium tetrachloride or by hydrolysis of titanium sulfate; the surface properties of the products depend strongly upon whether they still contain anions. Particle size must be taken into account. Particularly worthy of note is the comprehensive chapter on the hydroxylation of the surface. [The Surface of Titanium Dioxide. Progr. Surf. Membr. Sci. *11*, 181—226 (1976); 130 references]

[Rd 919 IE—F]

Elucidation of structure and specificity of chromatin by immunological methods is reported on by *M. Bustin*. Chromatin, a complex of DNA, RNA, histones and non-histone proteins, is responsible for regulation of the expression of the genetic information stored in the DNA. Studies on the individual chromosome proteins during the life of the cell suffer in that these proteins cannot be determined in a simple way. Antibodies that can be prepared for various components of the chromatin offer one possibility for specific detection. Unfortunately such determinations have so far not afforded any quantitative values; these are to be expected as soon as the methods for preparation of components of the nucleus have been refined. [Chromatin Structure and Specificity Revealed by Immunological Techniques. FEBS Lett. *70*, 1—10 (1976); 71 references]

[Rd 921 IE—R]

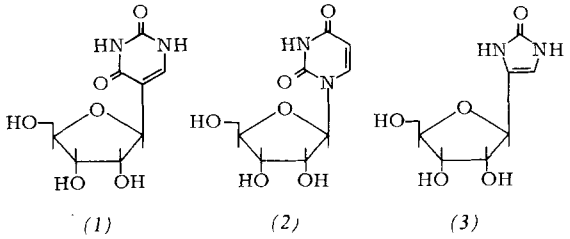


Pineal gland biorhythms form the theme of an article by *S. Binkley*. Particular emphasis is laid on the serotonin *N*-acetyltransferase which plays a role in the biosynthesis of melatonin from serotonin. This enzyme was investigated in chicken and rats. It is subject to circadian fluctuations, which are not only connected with the light-dark cycle but also persist in permanent darkness; however, on permanent illumination they disappear. In rats light reception is *via* the eyes, in chicken *via* extraretinal photoreceptors. [Pineal Gland Biorhythms: *N*-Acetyltransferase in Chicken and Rats. Fed. Proc. *35*, 2347—2352 (1976); 43 references]

[Rd 922 IE—R]

The synthesis and function of prostaglandins in the heart are reported on by *P. Needleman*. The isolated perfused heart of the rabbit can rapidly synthesize, liberate, and inactivate prostaglandins. Prostaglandins influence the resistance of the coronary vessels of the heart and thus the ability of the heart to work. The biosynthesis starts from arachidonic acid, which is converted into prostaglandin-like substances in a single passage through the heart. Arachidonic acid and bradykinin together effect a drop in resistance of the coronary vessels; this effect is directly connected with the synthesis and liberation of prostaglandin-like substances. The phenomenon can be increased by injection of a peptide type inhibitor of bradykinin degradation. Indomethacin, an inhibitor of prostaglandin biosynthesis, on the other hand, reduces the effect of bradykinin and arachidonic acid on the resistance of the coronary vessels. [The Synthesis and Function of Prostaglandins in the Heart. Fed. Proc. *35*, 2376—2391 (1976); 45 references]

[Rd 923 IE—R]



The use of malononitrile for annelation reactions *via* intermediary alkylidenemalononitriles *(1)* is dealt with in an article by *E. Campaigne* and *S. W. Schneller*. Compounds *(1)* can be prepared by base-catalyzed Knoevenagel condensation of carbonyl compounds and malononitrile or, much more advantageously, from an organometal compound, a nitrile, and malonitrile. The alkylidenemalonitriles *(1)* are a valuable system for the annelation of carbocyclic or heterocyclic rings, electronic effects and steric conditions decisively influencing

the reaction course. Five- or six-membered carbocycles (indenones, indanones, naphthalenes) or aromatic heterocycles (lactones, coumarins) can be obtained by cyclization in acid media. [Cyclization of Ylidenemalononitriles. Synthesis *1976*, 705—716; 32 references]

[Rd 912 IE—M]

The chemistry and biochemistry of C-nucleosides are reviewed by *G. D. Daves, Jr.* and *C. C. Cheng*. In the C-nucleosides, *e.g. (1)*, the carbohydrate component is linked to the base by a CC bond which is hydrolytically stable. Some C-nucleo-

sides can serve as enzyme substrates; thus pseudouridine *(1)* is recognized as uridine *(2)* at the nucleotide and polynucleotide level. In the meantime more than ten natural C-nucleosides

have been discovered; six of these, *e.g.* showdomycin *(3)*, are antibiotics. [The Chemistry and Biochemistry of C-Nucleosides. Progr. Med. Chem. *13*, 303—349 (1976); 265 references]

[Rd 918 IE—F]

Disguised chemical selectivities are the subject of a review article by P. Rys. That several chemical reactions can compete with one another is a well known phenomenon. Kinetic chemical selectivity is defined as the ratio of the rate constants of two competing reactions, and thermodynamic chemical selectivity as the ratio of their equilibrium constants. If diffusion or adsorption effects alter the rate of at least one of the reactions, the selectivity is disguised. In specific cases it can be shown that the product pattern depends *e.g.* on the precursor complexes of the reaction partners, the spatial orientation of the reaction partners in these complexes, or on the diffusion conditions. [Disguised Chemical Selectivities. Acc. Chem. Res. *9*, 345—351 (1976); 58 references]

[Rd 913 IE—L]

The influence of prostaglandins on the behavior of blood vessels is reported on by *J. C. McGiff, K. U. Malik*, and *N. A. Terragno*. Prostaglandins are tissue hormones which manifest their effect in the immediate neighborhood of the site of formation. Endogenous prostaglandins, *e.g.* PGE_2, counteract vasoconstriction and the anti-sodium diuretic activity of circulating, hypertensive hormones, and control the release of noradrenalin. This is demonstrated by the increased sensitivity of vessels having low or inhibited rates of prostaglandin synthesis to stimulation by hypertensive hormones and inhibition of the activity of these hormones by exogenous prostaglandin. [Prostaglandins as Determinants of Vascular Reactivity. Fed. Proc. *35*, 2382—2387 (1976); 53 references]

[Rd 924 IE—R]

BOOK REVIEWS

Grundlagen der analytischen Chemie. Unter besonderer Berücksichtigung der Chemie in wäßrigen Systemen. (Principles of Analytical Chemistry. With Special Reference to Chemistry in Aqueous Systems). By *F. Seel*. Verlag Chemie, Weinheim—New York 1976. 6th improved edit., 387 pp., 49 figs., 53 tables, bound, DM 42.—.

If we consider modern analytical chemistry to be a science whose aim is to provide correct information about chemical systems—a view generally accepted today in professional circles—then we must agree that it is impossible to write a textbook of 387 pages covering the "Principles of Analytical Chemistry" (chemical, physical, and biochemical analysis) with Prof. *Seel*'s specific extreme precision. Accordingly, the phrase "With Special Reference to Chemistry in Aqueous Systems" is an important part of the title of the "new Seel".

This was certainly the author's reasoning. In his own words, "The present book presents a collection of the most important principles of general chemistry insofar as these are relevant to the analytical work that the student carries out in his basic inorganic practicals". This presumably means "qualitative" and "quantitative" analysis in the classical sense. Opinion as to whether processes such as colorimetry, polarography, potentiometry with ion-selective electrodes, chromatography, statistical evaluation of the methods, and assessment of analytical methods and results should nowadays be included in these basic courses will not be discussed here.

What is certain is that the author intentionally rejected treatment of specialized processes on this occasion in order to be able, within the given limits, to describe the physicochemical principles of classical analytical chemistry in his usual demanding manner.

It should be emphasized that the book succeeds in the attempt to "derive the variety of analytically important (chemical) reactions from a very small number of fundamental reactions types (dissolution and precipitation processes, complexation, acid-base reactions, and redox reactions). It is repeatedly stated, and proved by the application of the law of mass action, that the course of many analytical reactions can be explained only by a combination of such fundamental model reaction types. Indication of the formal relationship between acid-base and redox reactions is also important for the student. The didactic value of the book is enhanced by the use of logarithmic diagrams for the description of dissociation equilibria in the basic chapters and by their application to practical problems in hydrogen sulfide separation processes.

Partly as an understatement and partly self-critically, the author claims that his work "... is no textbook of analytical chemistry". A better description would be "... an excellent textbook on special chapters in analytical chemistry". The author does not simplify but explains in detail and requires the reader's intelligent participation.

Robert Kellner [NB 358 IE]

Handbook of Analysis of Organic Solvents. By *V. Šedivec* and *J. Flek*. Ellis Horwood Ltd., Chichester 1976. 1st edit., 455 pp., various figs., numerous tables, bound, £ 18.00.

In this monograph the authors limit themselves mostly to "classical" analysis of solvents, whilst often admitting a very wide interpretation of what a solvent may be. Gas chromatography receives very brief mention and spectroscopic methods none at all. The first part gives general principles—sampling, determination of physical constants, separation, and quantitative analysis of two- and three-component systems; in the second part individual groups of compounds are discussed. However, alkyl aryl and diaryl ethers are not included among the ethers, nor are alkyl aryl ketones among the ketones. Among other shortcomings we may note: Peroxides and water can often be excellently removed by Al_2O_3 (pp. 16 and 20). There is no mention of the determination of water by *Karl Fischer*'s method (p. 18). Is not a sample for tasting superfluous (p. 32)? In the distillation of CS_2 there is no "Caution" notice (p. 41). Cumene and *p*-cymene form hydroperoxides very readily (p. 124). The expression "nascent hydrogen" should be finally allowed to die (pp. 286/287). As a whole, the book can be recommended, especially because of its numerous tables which make it superfluous to refer to the handbooks that often provide the information less readily. The book is suitable for the practising chemist but can also be used for teaching. The production is good.

Basis and Limitations of the Reactivity-Selectivity Principle

By Bernd Giese[*]

The reactivity-selectivity principle (RSP), which describes a linear relationship between the decrease in selectivity and increase in reactivity of molecules X_m in their reactions with Y_1 and Y_2, has been much criticized during the last few years. The present paper shows the kind of reactions where the RSP does not hold and reveals how the individual types of reaction can be distinguished by varying the solvent. The dependence of molecule selectivity on temperature produces a further effect. An isoselective relationship (ISR) can be deduced when this dependence is taken into account. This relationship is not concerned with the connection between the temperature-dependent rate and competition constants, but with the connection existing between activation enthalpies and activation entropies, which are temperature-independent over wide ranges. The application of the ISR to different types of reactions makes it possible to characterize and distinguish between short-lived intermediates and underlines the significance of the isoselective temperature (T_{is}) in interpreting the reaction parameters of linear free energy relationships and in planning syntheses.

1. Introduction

The aim of preparative chemistry is quick and uniform synthesis of desired compounds. Formation of inconvenient side-products is caused by the ability of initial substances and/or intermediates X_m to react in different ways, *e.g.* with Y_1 and Y_2:

$$; \quad \varkappa_X = \frac{k_1}{k_2}$$

If the reactions proceed with the rate constants k_1 and k_2, the product ratio P_1/P_2 depends on the concentration of the reaction partners Y_1 and Y_2 and on the competition constant $\varkappa_X$. Thus, in planning a synthesis, competition constants of possible branched reaction pathways should be approximately known.

A different problem can arise in studies of reaction mechanisms: more often than not, it is impossible to identify postulated short-lived intermediates, *e.g.* X_m, by their physical properties. In many cases, however, such intermediates can be detected chemically by competitive trapping with suitable reaction partners, *e.g.* Y_1 and Y_2[1]. The reactivity-selectivity principle (RSP) is applied in order to obtain information on the rate constants of the intermediates k_1 and k_2 from the competition constants $\varkappa_X$:

If molecules X_1, X_2, X_3 ... X_m react with Y_1 and Y_2, selectivity ($\log \varkappa_X$)[2] decreases proportionally to increasing reactivity ($\log k_X$).

This linear relationship is described by proportionality relationship (a) or by equation (b).

$$\delta \log \varkappa_X \sim -\delta \log k_X \quad \text{(a)}$$
$$\log \varkappa_X = a - b \cdot \log k_X \quad \text{(b)}$$

[*] Priv.-Doz. Dr. B. Giese
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

The symbol δ indicates that only changes of reactivities and selectivities on varying molecules X_m of the reaction series in question are compared. The constants a and b, *i.e.* the intercept and the slope of linear equation (b), are larger than zero (cf. Section 3). The RSP can be checked graphically by a $\log\varkappa_X/\log k_X$ plot (Fig. 1).

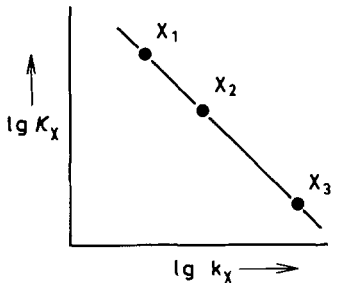

Fig. 1. Graphical check of the RSP [Eq. (a)] in a selectivity-reactivity plot.

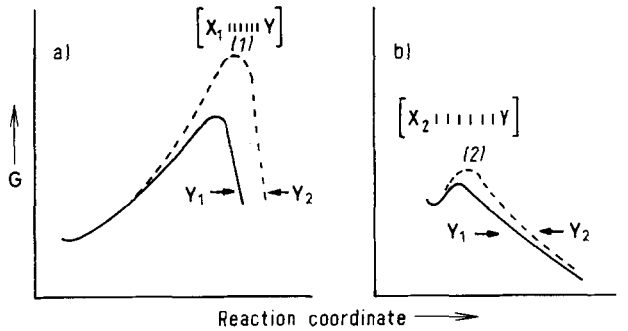
If the various molecules X_m give a straight line with a negative slope as in Figure 1, the reaction complies with the RSP: in this case the more reactive molecule X_2 is less selective than molecule X_1.

2. Basis of the Reactivity-Selectivity Principle (RSP)

2.1. Variation of Substituents

The connection between changes in reactivity and changes in selectivity, which is supplied by the RSP, certainly appears plausible, for the differences in the free activation enthalpies $\Delta G_1^{\neq} - \Delta G_2^{\neq}$ are large in the case of large activation enthalpies of the individual reactions: when a less reactive molecule X_1 reacts with Y_1 or Y_2 it has to overcome a larger free activation enthalpy than the more reactive molecule X_2. Variation of the reaction partners (Y_1 and Y_2) has greater influence on the free activation enthalpy of the less reactive particle X_1, as can be shown by the Hammond postulate[3] according to which the slower reaction has a "later" transition state than the faster reaction. Reorientation of electron distribution and atom location is further advanced in a "late" transition state than in an "early" transition state (Fig. 2).



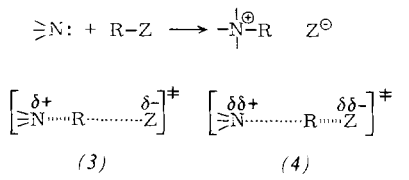


Fig. 2. Reaction profiles for reaction of Y_1 and Y_2 with a) less reactive molecule X_1 and b) more reactive molecule X_2.

Bond lengths and angles have changed to a greater extent in the activated complex *(1)* than in the activated complex *(2)*. Where partial charges occur at transition states, such as in amine alkylation, the charge separation is more advanced on the activated complex *(3)* of the slower reaction than on that of the faster reaction [*(4)*].

A change to a reaction partner which stabilizes or destabilizes charges has greater influence on transition state *(3)* than on transition state *(4)*, because formation of the charges is further advanced in *(3)* than in *(4)*. This is exemplified by the methylation of α-substituted pyridines *(5)*[4].

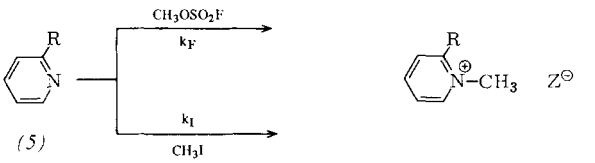

Figure 3 demonstrates how the selectivity of the competing reactions with methyl fluorosulfonate/methyl iodide decreases with increasing reactivity of the pyridine derivative *(5)* (varying substituents R). The fluorosulfate leaving group effects a better stabilization of the negative charge than iodide, and this is more noticeable in the "later" transition state of the slower reaction than in the "earlier" transition state of the faster reaction, where charge separation is comparatively small.

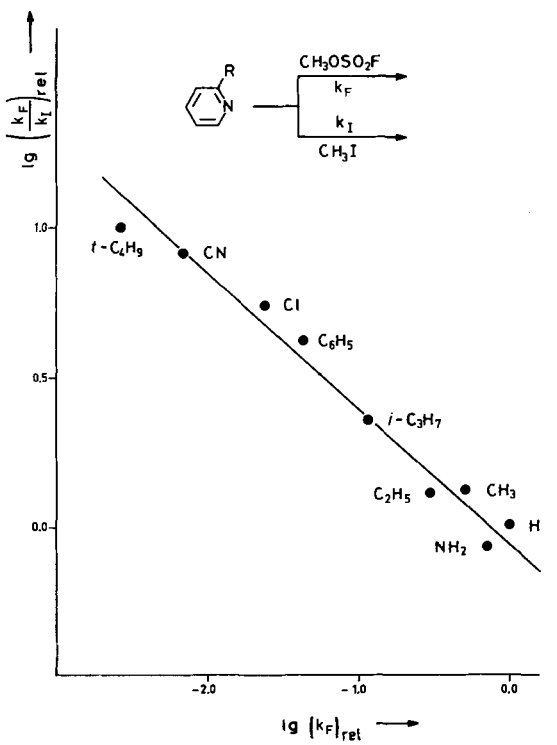

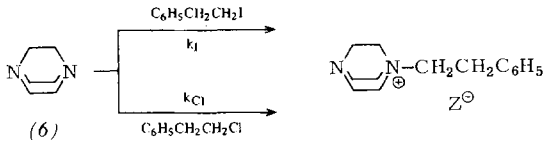

Fig. 3. Checking the reactivity-selectivity principle by reaction of various substituted pyridines *(5)* with methyl fluorosulfonate and methyl iodide in nitrobenzene at 30°C.

2.2. Variation of the Solvent

If the RSP holds, changing the solvent should have similar effects on reactivity and selectivity as varying substituents:

An increase in reactivity caused by changing the solvent is accompanied by a proportional decrease in selectivity of molecule X_m reacting with Y_1 and Y_2.

The oppositely directed influence of solvents on reactivity and selectivity can also be exemplified by the alkylation of tertiary amines.

(6)

Figure 4 demonstrates how the selectivity of 1,4-diazabicyclo[2.2.2]octane (6) decreases and the reactivity increases in the competition system phenethyl iodide/phenethyl chloride as the solvent is changed[5].

The considerable scatter of the experimental values in Figure 4 is typical of interaction between solvents and dissolved substances, which is dependent on several parameters[6]. Therefore, application of the selectivity principle is admissible only if the reaction is examined in a sufficient number of solvents. In spite of frequently poor correlations, a greater influence of the solvent is observed on slower reactions than on faster reactions[7] provided that similar reactions are considered.

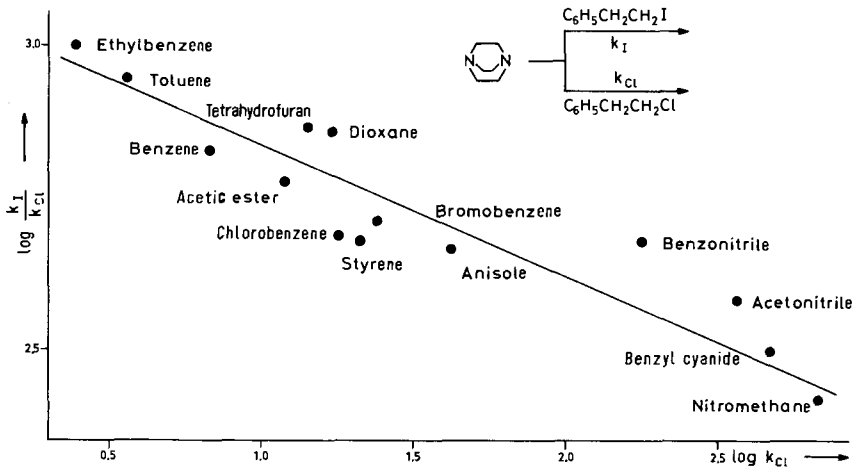

Fig. 4. Checking the reactivity-selectivity principle by reaction of tertiary amine (6) with 2-phenethyl iodide and 2-phenethyl chloride in various solvents at 54.4 °C.

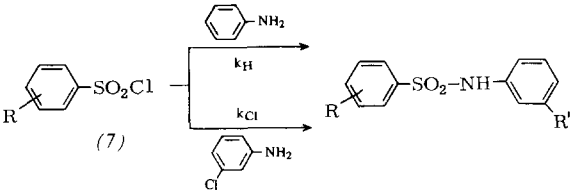
3. Limitations of the Reactivity-Selectivity Principle

The connection between changes in reactivity and selectivity expressed in equation (b) can be reformulated as equation (c) on substituting competition constant $\varkappa_X$ by rate constants k_{X,Y_1} and k_{X,Y_2}.

$$\log \varkappa_X = \log k_{X,Y_1} - \log k_{X,Y_2} = a - b \cdot \log k_{X,Y_1} \quad \text{(b)}$$



$$(b+1)\log k_{X,Y_1} = a + \log k_{X,Y_2} \quad \text{(c)}$$

Thus, the proportional connection between reactivity and selectivity is valid if a linear relationship exists between the reactivities of the individual reaction series. The selectivity principle therefore turns out to be a specific form of linear free energy relationship and therefore holds only for limited variations of molecules X_m and reaction partners Y_1 and Y_2[8]. The positive sign of b, a result of the application of the Hammond postulate (cf. Section 2.1), limits the validity range still further: only those linear free energy relationships in which variations of substituent and solvent exert a greater influence on the slower reaction series comply with the RSP.

When testing the reactivity-selectivity principle numerically or graphically, care must be taken that the competition constants are greater than unity, otherwise the sign of b must change for the RSP to remain valid. On the other hand, either k_{X,Y_1} or k_{X,Y_2} can be inserted, for the rate constants are related according to equation (c).

3.1. Opposing Influence of Substituents on Bond Cleavage and Bond Formation

In the last few years the RSP has been much criticized because there are reactions in which selectivity does not change in spite of increasing reactivity, or even increases proportionally to increasing reactivity[9]. One example is the reaction of arenesulfonyl chlorides (7) in the competition system aniline/3-chloroaniline.

The positive slope in a selectivity-reactivity plot of experimentally determined values[10] (Fig. 5) shows that the most reactive sulfonyl chloride, nitrobenzenesulfonyl chloride, is also the most selective in this particular competition system.

This finding is completely opposed to the prediction of the selectivity principle.

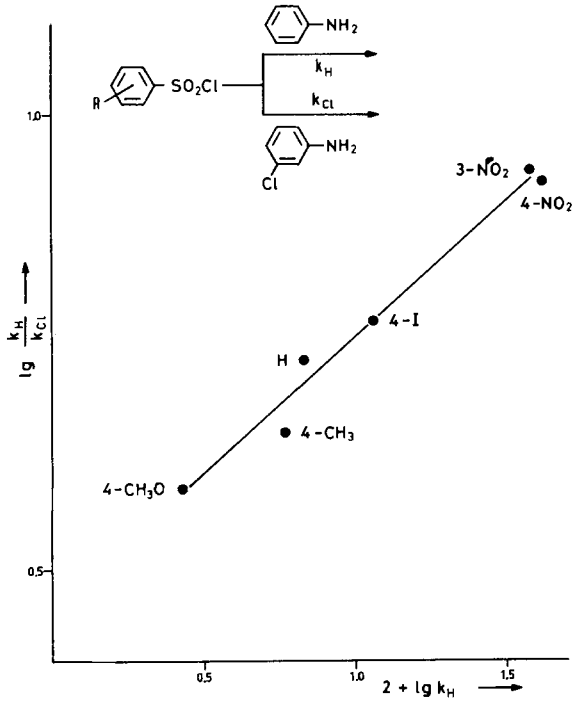


Fig. 5. Failure of the RSP for reaction of various substituted benzenesulfonyl chlorides *(7)* with aniline and 3-chloroaniline in methanol at 25 °C.

The influence of the solvent on the reaction of benzenesulfonyl chloride with aniline/3-chloroaniline, however, gives an entirely different picture from that of varying substituents. The selectivity is seen to fall and individual reaction rates to rise when the solvent is changed (Fig. 6)[11].

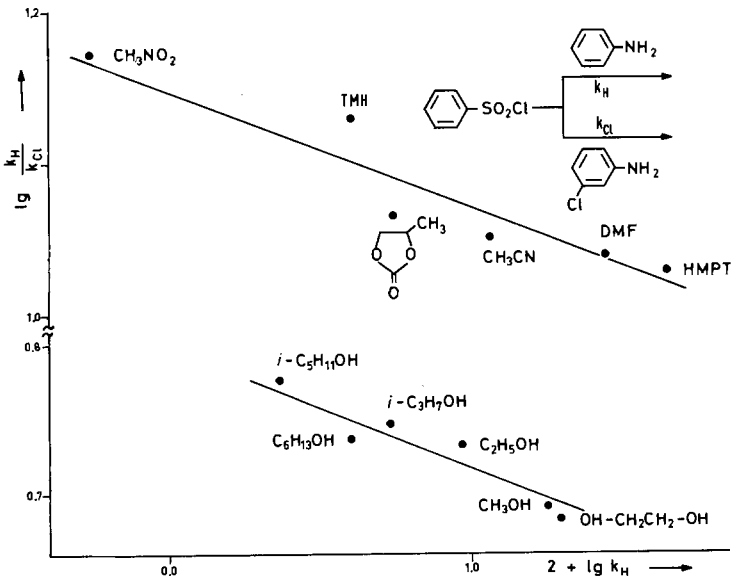

Fig. 6. Checking the RSP by reaction of benzenesulfonyl chloride with aniline and 3-chloroaniline in aprotic and protic solvents at 45 °C. TMH = tetramethylurea, DMF = dimethylformamide, HMPT = hexamethylphosphoramide.

Why should the reactivity-selectivity principle fail for substituent variation and yet remain valid for solvent variation?

This apparent discrepancy is resolved when the various types of interaction between substituents and individual atoms of reacting molecules are taken into consideration. Reactivity changes (that is, selectivity) estimated in a competition system when substituents are varied represent only a partial view of the entire reaction. If reaction of A with BC consists in bond formation A—B and bond cleavage B—C, the free energy of activation $\Delta G^{\neq}$ can be formally split up into two partial values, *viz.* for bond formation ($\Delta G^{\neq}_{AB}$) and bond cleavage ($\Delta G^{\neq}_{BC}$) in the transition state [Eq. (d)].

$$A + B{-}C \longrightarrow [A\cdots B\cdots C]^{\neq} \longrightarrow A{-}B + C$$

$$\Delta G^{\neq} = \Delta G^{\neq}_{AB} + \Delta G^{\neq}_{BC} \qquad (d)$$

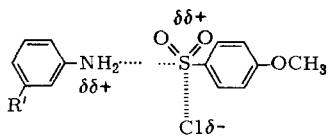
Only if partial values $\Delta G^{\neq}_{AB}$ and $\Delta G^{\neq}_{BC}$ change proportionally to $\Delta G^{\neq}$ when substituents R are varied, does each of the formal "partial reactions" describe stereoelectronic reorientation of the entire reaction [Eq. (e)]. Relationships (f) and (g) are derived from (d) and (e). Equation (g) shows that proportional change of $\Delta G^{\neq}$, $\Delta G^{\neq}_{AB}$, and $\Delta G^{\neq}_{BC}$ is possible only if the ratio of bond formation and bond cleavage in the transition state of the reaction is independent of substituents R.

$$\Delta G^{\neq}_{R} \sim \Delta G^{\neq}_{AB,R} \sim \Delta G^{\neq}_{BC,R} \qquad (e)$$

$$\frac{\Delta G^{\neq}_{1}}{\Delta G^{\neq}_{2}} = \frac{\Delta G^{\neq}_{AB,1}}{\Delta G^{\neq}_{AB,2}} = \frac{\Delta G^{\neq}_{BC,1}}{\Delta G^{\neq}_{BC,2}} \qquad (f)$$

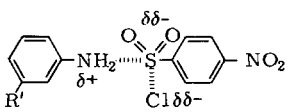
$$\frac{\Delta G^{\neq}_{AB,1}}{\Delta G^{\neq}_{BC,1}} = \frac{\Delta G^{\neq}_{AB,2}}{\Delta G^{\neq}_{BC,2}} \qquad (g)$$

This condition, a constant ratio of bond formation to bond cleavage, is met for reaction of α-substituted pyridines *(5)* with the competition system methyl fluorosulfonate/methyl iodide. If formation of a N—C bond is facilitated, as in the case of unsubstituted pyridine compared with the 2-*tert*-butyl derivative, the energy maximum (transition state of the reaction) is already reached while the C—Z bond (Z = OSO_2F, I) is only slightly stretched. Bond formation and bond cleavage are both slight in the transition state *(8)* but extensive in the transition state *(9)*. The ratio of bond formation and bond cleavage turns out to be almost independent of substituent variation in *(5)*.



Slight bond formation | Slight bond cleavage | Extensive bond formation | Extensive bond cleavage

(8) (9)



$$\frac{\text{bond formation}}{\text{bond cleavage}} \approx \text{const.}$$

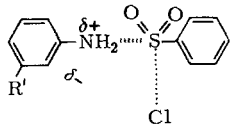
On the other hand, the ratio of bond formation and bond cleavage is not constant when arenesulfonyl chlorides *(7)* react with an aniline/3-chloroaniline system, because substituent variation on sulfonyl chlorides influences bond formation and bond cleavage in opposite directions: a methoxy group at position 4 of the arenesulfonyl chloride impedes formation of a negative charge at the sulfur atom, but facilitates the expulsion of the chloride ion. A nitro group on *(7)*, however, promotes formation of the N—S bond and impedes cleavage of the S—Cl bond. The ratio of bond formation and bond cleavage is smaller in the transition state *(10)* than in the transition state *(11)*. Therefore, the nitrogen atom of *(11)* will bear a higher charge than that of *(10)*, so that the more reactive nitrobenzenesulfonyl chloride is more selective than the less reactive methoxybenzene sulfonyl chloride in the competition system aniline/3-chloroaniline (Fig. 5).

Slight bond formation | Extensive bond cleavage

(10)

Extensive bond formation | Slight bond cleavage

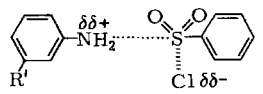
(11)



$$\frac{\text{Bond formation}}{\text{Bond cleavage}} = \text{variable}$$

The Hammond postulate indeed holds for these reactions (the faster reaction has an "earlier" transition state), but the RSP is not valid (the more reactive particle is also the more selective one).

Therefore, great care should be taken when interpreting competition measurements, if "central atom B" is varied. Only an analysis of the influence of substituents[12] on bond formation and bond cleavage[13] can supply information on selectivity behavior.



Compared with variation of substituents on arenesulfonyl chloride *(7)*, varying the solvent has quite a different effect on the reaction, because solvents stabilize both the positive charge on the aniline nitrogen and the negative charge on the leaving chloride ion. Transition state *(13)* is reached "earlier" in the more polar ethylene glycol than transition state *(12)* in less polar isoamyl alcohol because of favorable interaction between charges and ethylene glycol.

Isoamyl alcohol:

(12)

Ethylene glycol:

(13)

The RSP holds if varying the solvent influences bond formation and bond cleavage in the same direction: the selectivity of benzenesulfonyl chloride decreases as reactivity increases (Fig. 6).

3.2. Dominating Influence of Frontier-Orbital Interaction

With a number of reactions, however, it seems that other reasons are responsible for simultaneous increase of reactivity and selectivity: if reactions of molecules X_m and Y_n pass through "early" transition states, and energy differences E_I and E_{II} (Fig. 7) between the highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO) of the same symmetry are small, the course of the reaction can be described in a satisfactory manner by means of stabilization energies ΔE_I and ΔE_{II}[16]. The smaller the orbital differences E_I and E_{II}, the greater are the subsequent stabilizing interactions ΔE_I and ΔE_{II}, and the faster are such reactions. This point of view neglects, for instance, repulsive energy resulting from the mutual approach of molecules X_m and Y_n. Therefore, this model should only be applied to reactions with "early" transition states, in which reacting molecules are still comparatively far apart[16,17].

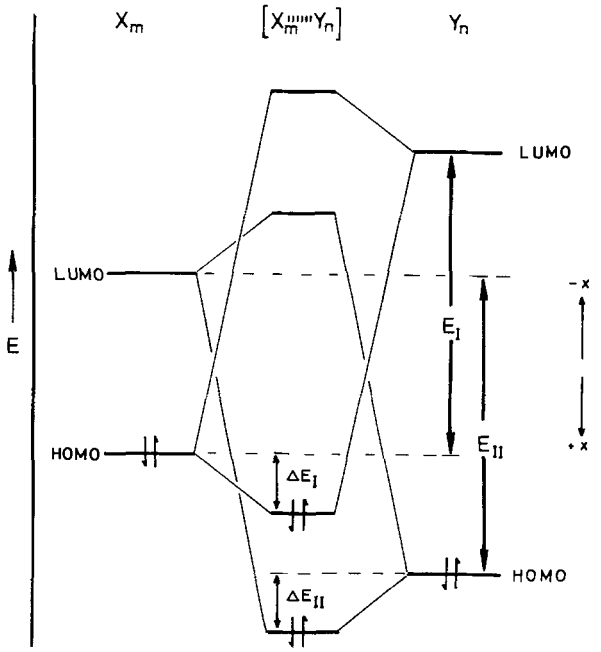


Fig. 7. Interaction between frontier orbitals (HOMO and LUMO) of reacting molecules X_m and Y_n.

Assuming that substituent variation on X_m and Y_n produces a greater effect on the position of frontier orbitals, and subsequently on stabilizing interaction, than on repulsive energy, relationship (h) was derived for cycloadditions[18].

$$\delta \log k = K \cdot \beta^2 \left[\frac{1}{E_I + x} + \frac{1}{E_{II} - x} \right] \qquad \text{(h)}$$

In equation (h), E_I and E_{II} are the differences between HOMO and LUMO (Fig. 7), x is the effect of the substituents on the frontier orbitals, energy-decreasing $(+x)$ and energy-increasing $(-x)$, respectively, β is the resonance integral and K specifies the products of the atomic orbital coefficients (β and K are assumed to be constant for this simplified consideration). The inversely proportional relationship between reactivity and frontier orbital differences shows that the influence of substituents is greater, the smaller the energy differences E_I and E_{II} of the reacting molecules. The selectivity increases with increasing reactivity of molecules X_m and Y_n[18,19].

According to equation (h), plotting reactivity against any parameter varying proportionally to the energy of the frontier orbitals, produces hyperbolas. If the frontier orbitals are arranged in a symmetrical manner, as in Figure 7, a point of intersection of two hyperbolas is obtained. This intersection is attained for the Diels-Alder reaction of bis(dimethylamino)-cyclopentadienone *(14)*, $X = N(CH_3)_2$, with unsubstituted styrene[20] (Fig. 8). Any substitution of styrene causes an increase in reactivity.

Like substituents, solvents influence the energy of the frontier orbitals[22], an effect due to the appropriate "donicity"[23] of the solvents. Thus, according to equation (h), selectivity

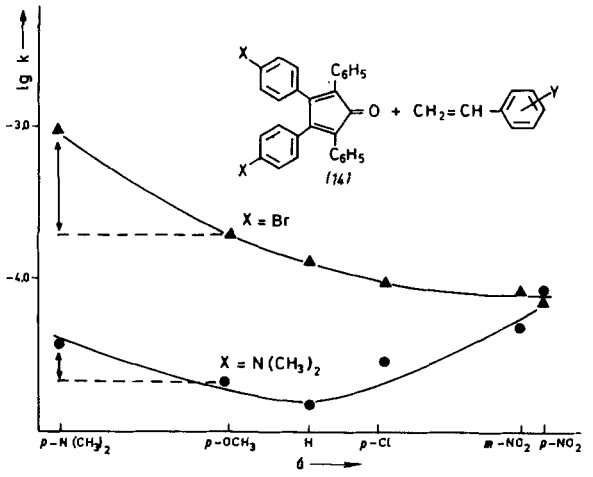

Fig. 8. Reactivities of cyclopentadienones *(14)*, $X = Br$, $N(CH_3)_2$, plotted against σ-parameters of styrene substituents Y.

should increase with increasing reactivity for such cycloadditions if the solvent is changed. This is indeed the case, as is shown by the solvent influence on reactivity values of some Diels-Alder reactions[24] and 1,3-dipolar cycloadditions[25]. A simultaneous increase of selectivity and reactivity was also observed in [2+2]-cycloadditions of diphenylketene and enol ethers (Fig. 9)[26].

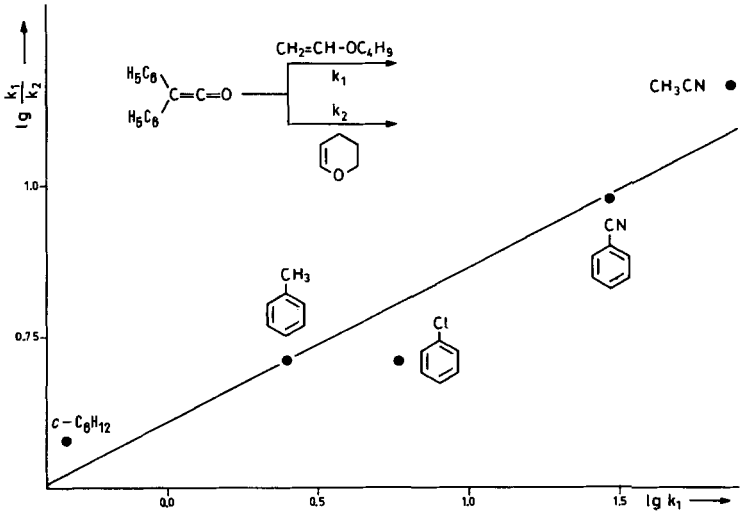

Fig. 9. Solvent influence on reactivity and selectivity of reaction of diphenylketene with butyl vinyl ether and 2,3-dihydropyran.

Varying the substituents on the diene shifts the minimum, according to equation (h). Dibromocyclopentadienone *(14)*, $X = Br$, with lower electron density, reaches minimum reactivity only with styrene derivatives of low electron density. In 4-dimethylaminostyrene/4-methoxystyrene as competition system, selectivity of the fast reacting dibromo compound *(14)* is higher, because reactivity is determined at a steeper part of the hyperbola[21] (Fig. 8).

On the other hand, reaction of tetracyanoethylene (TCNE) with the same competition system shows decreasing selectivity values on increasing reactivity of TCNE due to a change of solvent (Fig. 10)[27].

In contrast to the one-step cycloaddition of diphenylketene[26], tetracyanoethylene and enol ethers form zwitterionic intermediates[27], the formation rates of which are no longer governed by the stabilizing interaction of frontier orbitals.

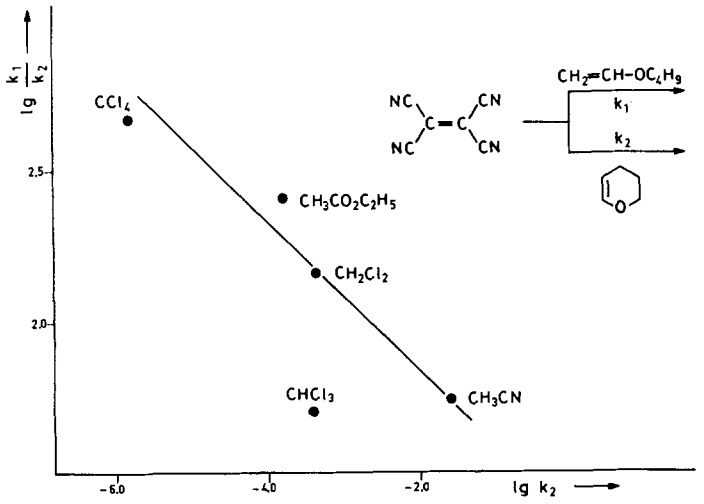

Fig. 10. Solvent influence on reactivity and selectivity of reaction of tetracyanoethylene with butyl vinyl ether and 2,3-dihydropropane.

Therefore, application of the reactivity-selectivity principle to solvent variations can help to distinguish between one-step reactions and formation of zwitterionic intermediates.

4. Dependence on Temperature

4.1. Temperature Dependence of Selectivity Values

Classification of chemical reactions according to the reactivity-selectivity principle as dealt with in Sections 2 and 3 completely ignores the temperature dependence of selectivity values.

However, the selectivity (that is, difference in reactivity[2]) will depend on temperature according to equation (i) if the competing reactions have different activation enthalpies.

$$\log\frac{k_1}{k_2}=\frac{\Delta H_2^{\ddagger}-\Delta H_1^{\ddagger}}{2.303\cdot RT}-\frac{\Delta S_2^{\ddagger}-\Delta S_1^{\ddagger}}{2.303\cdot R} \qquad \text{(i)}$$

Whereas the order of rate constants of reaction series does not change when the temperature is varied[28], the temperature has such a drastic influence on competition constants that selectivity values coincide within a narrow temperature range, the isoselective temperature T_{is}, and reverse their order above this temperature. Halide formation of alkyl radicals R· in the competition system $BrCCl_3/CCl_4$ was the first example of this selectivity behavior to be thoroughly examined[29]. Plotting radical selectivity measured between 0 and 130 °C against the reciprocal temperature produces straight lines as shown in Figure 11. Their position corresponds to the expected gradation of selectivity at 0 °C: the methyl radical, most reactive in CCl_4[30], is less selective than primary, secondary, and tertiary radicals; the most selective is the bulky *tert*-undecyl radical. Between 40 and 80 °C selectivities have similar values and above 80 °C the order is reversed. Thus at 130 °C the methyl radical is the most selective, while the *tert*-undecyl radical is the least selective. A further surprising result is the increase of selectivity differences with increasing temperature above the isoselective temperature (Fig. 11).

The methyl radical remains the most reactive radical in spite of reversal of selectivity, as shown in Figure 12, where

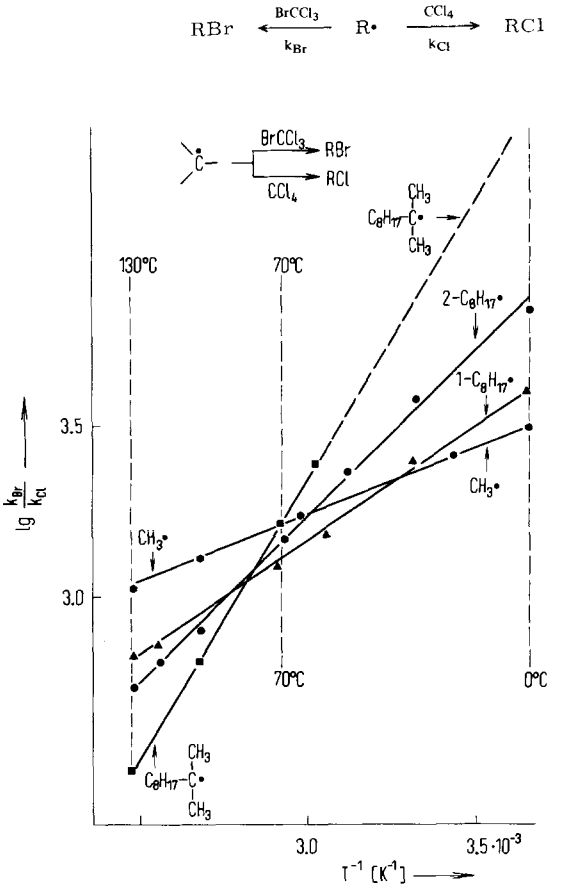

Fig. 11. Reaction of alkyl radicals (π-radicals) in the competition system $BrCCl_3/CCl_4$ between 0 and 130 °C.

selectivity[29] of halogen abstraction in competition system $BrCCl_3/CCl_4$ is plotted against reactivity[30] of chlorine abstraction in CCl_4 for methyl and cyclohexyl radical at various temperatures. Reversal of selectivity is not accompanied by reversal of reactivity.

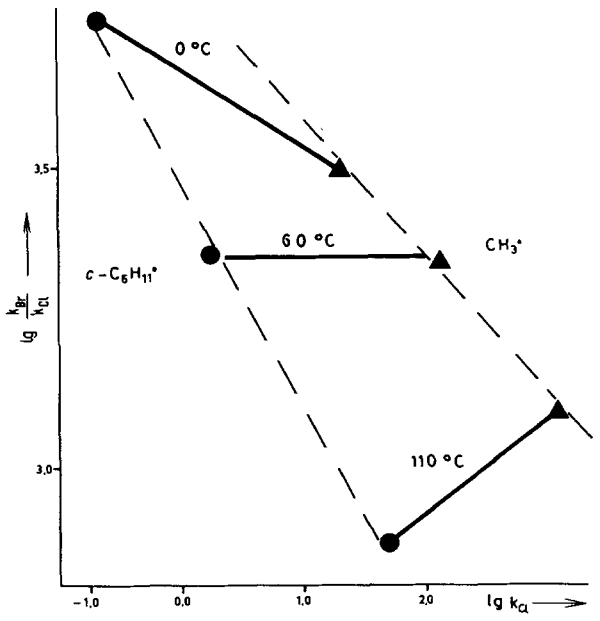

Fig. 12. Selectivity-reactivity plot for reaction of methyl and cyclohexyl radicals in the competition system $BrCCl_3/CCl_4$ at three temperatures.

Like π-radicals[31], σ-radicals also reverse their order[29] (Fig. 13). In this case T_{is} is in the region of 60 °C.

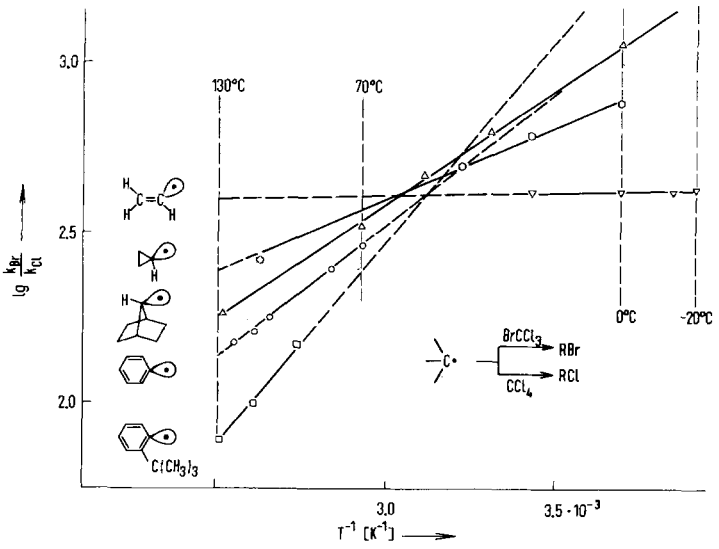

Fig. 13. Reaction of σ-radicals in competition system $BrCCl_3/CCl_4$ between −20 and +130 °C.

Temperature also has a pronounced influence on the selectivities of primary, secondary, and tertiary alkyl radicals in their addition reaction with the 3-chlorostyrene/4-methylstyrene competition system[32]. Distinct differences in selectivity exist at −20 °C, but at +40 °C the radicals have almost identical competition constants (Fig. 14).

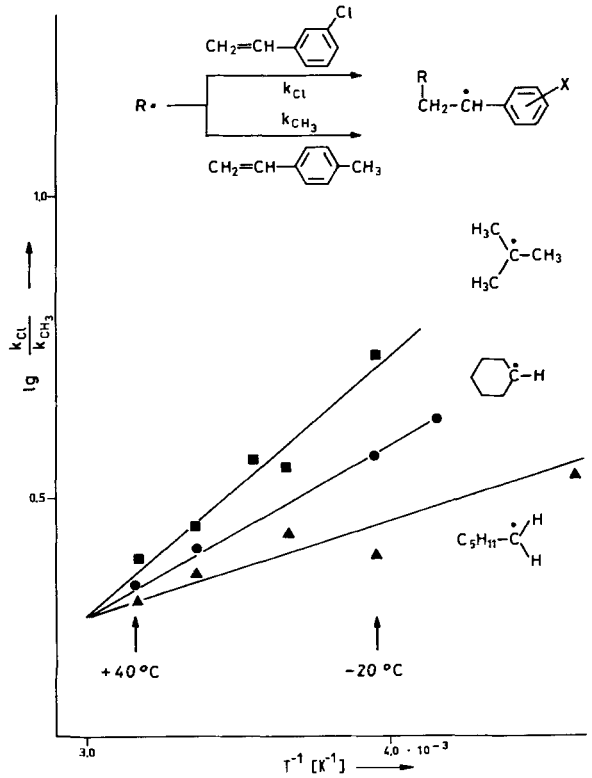

Fig. 14. Reaction of primary, secondary, and tertiary radicals with competition system 3-chlorostyrene/4-methylstyrene between −55 and +40 °C.

Diels-Alder reaction of substituted anthracenes with *N*-arylmaleimide[17] also shows a reversal of selectivity at about 110 °C (Fig. 15). As in radical halogen abstraction (Fig. 11 and 13) the more reactive anthracenes with higher electron density are more selective above the isoselective temperature than the less reactive anthracenes (with lower electron density).

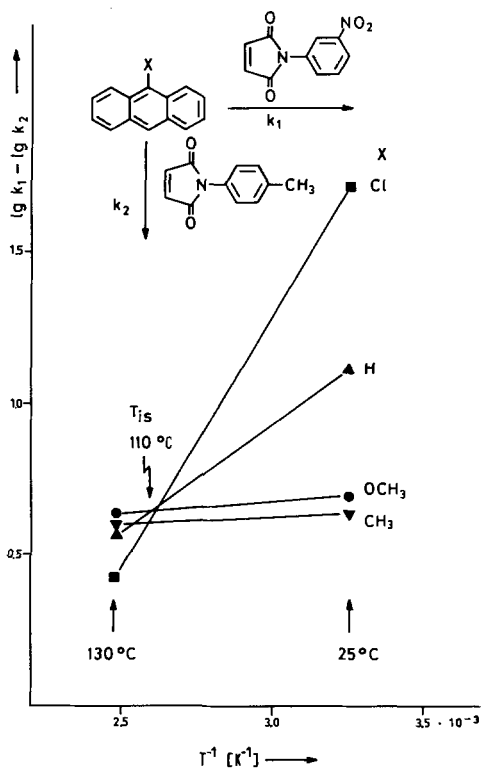

Fig. 15. Temperature dependence of selectivity of anthracene derivates reacting with the competition system *N*-(3-nitrophenyl)maleimide/*N*-(*p*-tolyl)maleimide between 25 and 130 °C.

These examples demonstrate how the temperature dependence of selectivity values may falsify discussions of competition data if T_{is} lies within or below the range of measurement.

4.2. Temperature Dependence of Reaction Parameters in Linear Free Energy Relationships

Equation (j) is the general form of a linear free energy relationship.

$$\log \frac{k_X}{k_0} = p_r \cdot p_s \qquad \text{(j)}$$

Linear free energy relationships describe the effect of substituents (variation of X) on the rate constant k_X of a reaction series. The substituent constants p_s determined in standard reactions and the experimentally determined reactivity differences ($\log k_X - \log k_0$) afford the characteristic reaction parameters, which are dependent on temperature, being typical selectivity values[34]. If variation of reactants X_m or their partners Y_n can be described by substituent parameters of linear free energy relationships, the reaction parameters of the individual series of reactions are essentially equal at the isoselective temperature (T_{is}). This temperature dependence of reaction parameters can be exemplified by the reactions discussed in Section 4.1.

The Taft-Hancock equation (k) has proved its value for halogen abstraction by π-radicals *(15)—(22)*[35]:

$$\log \frac{k_X}{k_{CH_3}} = \delta_X \cdot E_s^c \qquad (k)$$

where δ_X (X = Br, Cl) are the reaction parameters[36] and E_s^c the steric substituent constants[37].

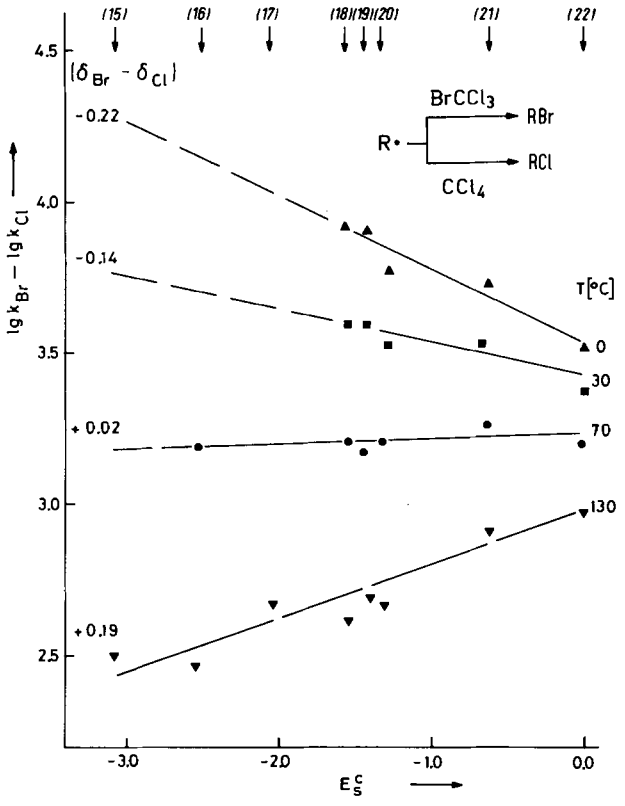

Fig. 16. Dependence of differences in reactivity ($\log k_{Br} - \log k_{Cl}$) for alkyl radicals *(15)—(22)* on steric E_s^c constants between 0 and 130°C. *(15)*, $CH_3\dot{C}(C_2H_5)_2$; *(16)*, $C_8H_{17}\dot{C}(CH_3)_2$; *(17)*, $C_4H_9C(CH_3)_2\dot{C}H_2$; *(18)*, *c*-$\dot{C}_7H_{13}$; *(19)*, *c*-$\dot{C}_6H_{11}$; *(20)*, 2-$\dot{C}_8H_{17}$; *(21)*, 1-$\dot{C}_7H_{15}$; *(22)*, $\dot{C}H_3$.

The various slopes of the straight lines in Figure 16 indicate that the differences of reaction parameters ($\delta_{Br} - \delta_{Cl}$) change their signs at about 60°C. This value accords with the isoselective temperature (Fig. 11). Plotting the differences ($\delta_{Br} - \delta_{Cl}$) directly against $1/T$ affords a straight line. ($\delta_{Br} - \delta_{Cl}$) becomes zero at the isoselective temperature (Fig. 17).

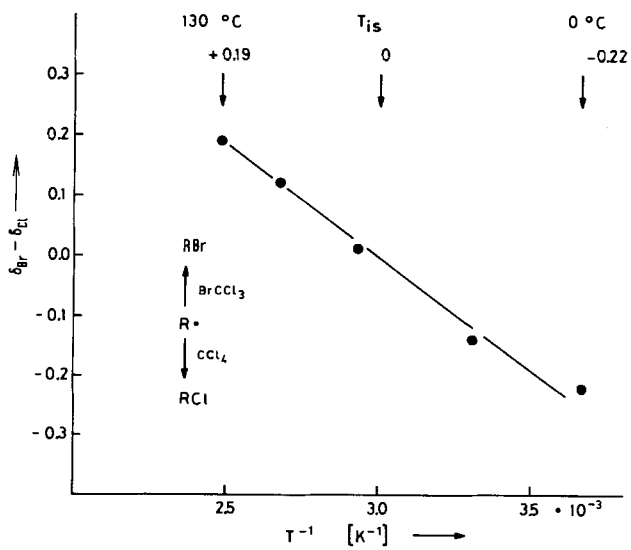

Fig. 17. Temperature dependence of reaction parameter differences ($\delta_{Br} - \delta_{Cl}$) for halogen abstraction by radicals *(15)—(22)* in the competition system $BrCCl_3/CCl_4$.

Addition of alkyl radicals to alkenes (Fig. 14)[32,38] and Diels-Alder reaction of anthracene derivatives with *N*-arylmaleimides[17] (Fig. 15) can be described by the Hammett relationship (l):

$$\log \frac{k_X}{k_H} = \rho \cdot \sigma \qquad (l)$$

In equation (l) the ρ-values are the temperature dependent reaction parameters, the σ-values are the substituent constants[39]. Plotting dienophile selectivity against σ_I-parameters affords almost straight lines, their slopes being of opposite sign at 25 and at 130°C (Fig. 18).

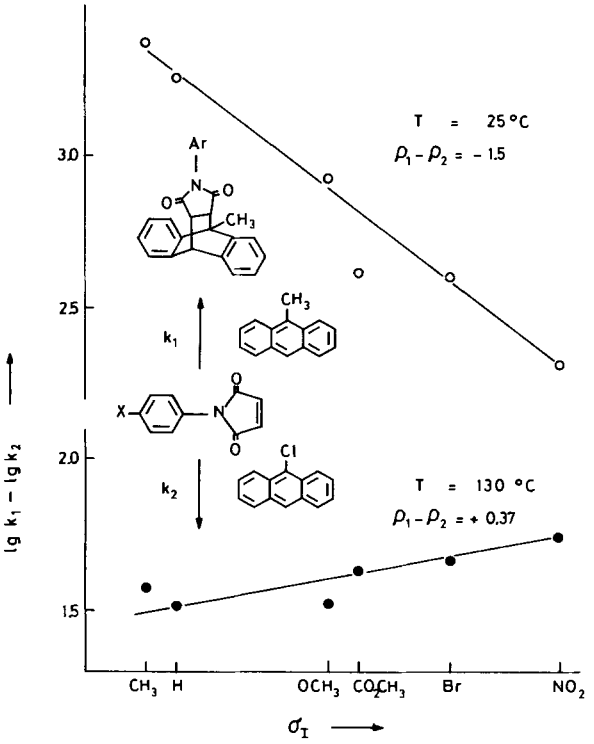

Fig. 18. Dependence of differences in reactivity ($\log k_1 - \log k_2$) on σ_I-parameters for reaction of substituted *N*-arylmaleimides with 9-methylanthracene and 9-chloroanthracene at 25 and 130°C.

This temperature dependence of reaction parameters makes it evident that comparative interpretation of linear free energy relationships is only possible with at least qualitative knowledge of their temperature dependence.

5. The Isoselective Relationship

5.1. Deduction of the Isoselective Relationship

The reactivity-selectivity principle (RSP) is applicable only above or below the isoselective temperature because of the temperature dependence of selectivity values. Which equation, then, is suitable for correct description of the behavior of molecules X_m reacting with Y_n over the entire temperature range?

The temperature dependence of selectivity for every individual particle X_m is described according to the Eyring relationship, equation (i). If boundary condition (m), accounting for coincidence of selectivity values within the immediate vicinity of T_{is}, is introduced, equation (n) evolves, which can be rewritten as the isoselective relationship (o)[40].

$$T_{is}\colon\ 0 \equiv \delta \log \frac{k_1}{k_2} \tag{m}$$

$$0 = \frac{\delta\Delta H_2^{\ddagger} - \delta\Delta H_1^{\ddagger}}{2.303 \cdot R\, T_{is}} - \frac{\delta\Delta S_2^{\ddagger} - \delta\Delta S_1^{\ddagger}}{2.303 \cdot R} \tag{n}$$

$$\delta(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}) = T_{is} \cdot \delta(\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}) \tag{o}$$

The isoselective relationship (ISR) signifies the proportional alteration of the differences of activation parameters $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ and $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ when particles X_m are varied. δ indicates variation of molecules X_m, the isoselective temperature (T_{is}) is the proportionality factor of the ISR.

Equation (o) is formally very similar to the isokinetic relationship (p), derived from the temperature dependence of reactivity ($\log k$) of a series of reactions (varying X_m and constant Y)[41].

$$X_m \xrightarrow[k]{Y} P$$

$$\delta\Delta H^{\ddagger} = \beta \cdot \delta\Delta S^{\ddagger} \tag{p}$$

In contrast to selectivity, coincidence of reactivity values at a certain temperature (in this case the isokinetic temperature β) and reversal of order of reactivity above this temperature has not yet been observed unequivocally for simple series of reactions[42]. Statistically correct evaluation of results of measurement affords β-values as computational quantities, the physical significance of which is a matter of dispute[28, 43].

5.2. Application of the Isoselective Relationship to Elucidation of Reaction Mechanisms

The RSP relates temperature dependent reactivity and selectivity values, the ISR on the other hand compares activation enthalpies and activation entropies, which are temperature-independent over wide ranges. If, for instance as in the examples of Figures 16 to 18, the large temperature dependence of selectivity values makes interpretation of reaction parameters of linear free energy relationships dubious, the problem can be evaded by plotting differences of activation enthalpies against substituent parameters (Fig. 19).

In Figure 19 the reaction parameters of Taft-Hancock and Hammett relationships for radical halogen abstraction and Diels-Alder reaction are constant quantities with no temperature dependence over wide ranges.

A further application of the ISR makes it possible to distinguish between intermediates with different bonding properties. It was shown that π- and σ-radicals afford two straight lines in $\Delta\Delta H^{\ddagger}/\Delta\Delta S^{\ddagger}$ diagrams[40]. As activation enthalpy and activation entropy are evaluated from the same experiments according to the Eyring relationship and are thus mutually dependent[28, 43], the selectivity of π- and σ-radicals was plotted against $1/T$ in Figure 20. This representation

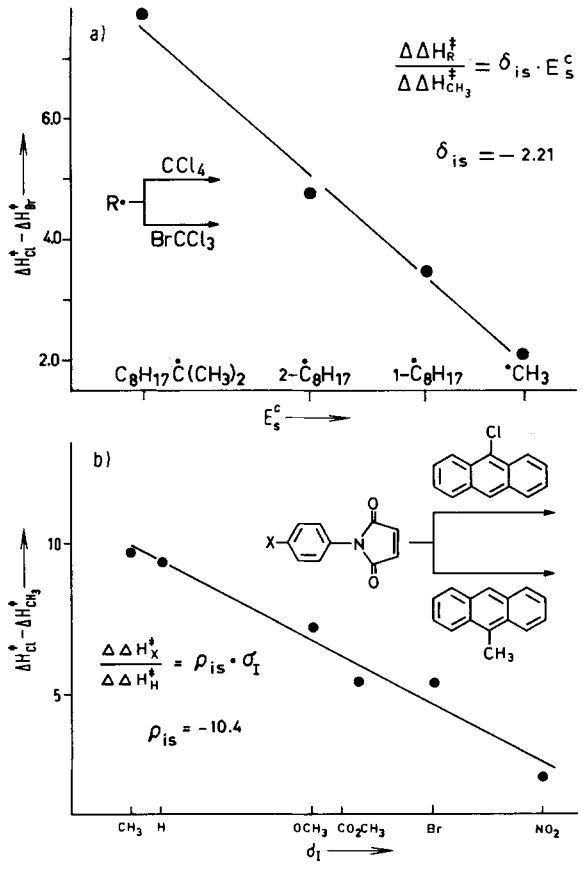

Fig. 19. Linear free energy relationships between activation enthalpy differences and substituent parameters for a) radical halogen abstraction, b) Diels-Alder reaction.

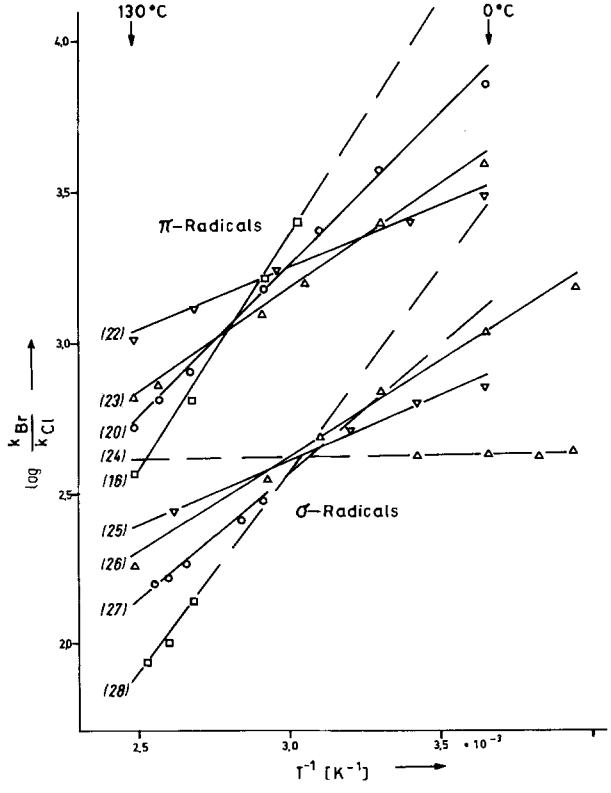

Fig. 20. Temperature dependence of selectivities of π- and σ-radicals for halogen abstraction in competition system $BrCCl_3/CCl_4$.
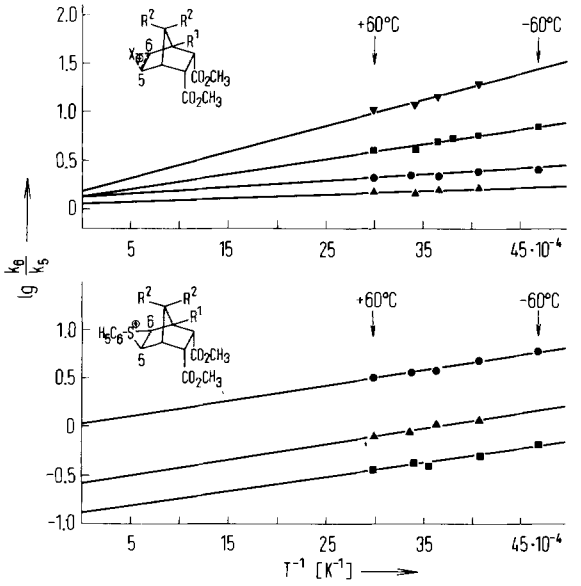
(23), 1-$\dot{C}_8H_{17}$; *(24)*, $CH_2{=}\dot{C}H$; *(25)*, c-$\dot{C}_3H_5$; *(26)*, 7-norbornyl; *(27)*, $\dot{C}_6H_5$; *(28)*, 2-*t*-$C_4H_9{-}\dot{C}_6H_4$.

is statistically sound, for selectivity and reaction temperature are independent variables[28]. The two fans of straight lines in Figure 20 confirm the existence of two separate isoselective relationships corresponding to π-radicals and σ-radicals, respectively. Thus estimation of competition constants in a $BrCCl_3/CCl_4$ system allows distinction of these types of radical[44].

Similarly, it was possible to distinguish[47] between different types of intermediate[46] occurring when halogens and benzenesulfonyl chlorides are added to alkenes. Figure 21 shows the different changes in selectivity for norbornene derivatives bridged by X=Cl, Br, I or by a phenylthiyl group for intramolecular *endo* trapping reactions with the adjacent ester groups, the temperature ranging from −60 to +60 °C[47].



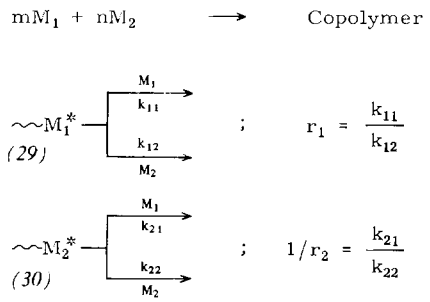


Fig. 21. Different dependence of selectivity of intermediates bridged by halogen (X=Cl, Br, I) or a phenylthiyl group for intramolecular trapping reaction with adjacent ester groups.

The ISR could develop into a diagnostic criterion for distinguishing between different structures of reactive intermediates.

5.3. Use of the Isoselective Relationship for Planning a Synthesis

When the occurrence of several intermediates leads to branching of reaction pathways, the different temperature dependence of selectivity values influences the yields and structures of reaction products. This is shown for example by copolymerization, an extremely important synthetic reaction: the structure of the polymer material is essentially dependent

on copolymerization parameters r_1 and r_2. The values of r_1 and r_2 describe the ability of growing nuclei *(29)* and *(30)* to react competitively with monomers M_1 and M_2[48].

Thus copolymerization parameters are competition constants. The course of copolymerization is specified by the absolute values of r_1 and r_2 and their product $(r_1 \cdot r_2)$. It has been shown for various radicals[32,38] how selectivities in olefin mixtures change to different extents when temperature is varied and become equal at relatively low temperatures (Fig. 14). In the case of radical copolymerization, therefore, copolymerization parameters are temperature-dependent to different extents[49]. Reaction behavior in the vicinity of the isoselective temperature where "ideal copolymerization"[48] is possible, should prove interesting.

6. Conclusion

The fact that the RSP does not hold for many series of reactions does not necessarily render the Hammond postulate useless, as frequently presumed[9,50]. If substituents influence bond cleavage as well as bond formation, a more reactive particle can be more selective than a less reactive molecule in spite of an "earlier" transition state (see Section 3.1). If the Hammond postulate is valid, the RSP is also not applicable at temperatures near or above the isoselective temperature (T_{is}) (see Section 4). This substituent and temperature dependence of selectivity values and reaction parameters must be taken into account when interpreting kinetic data and planning syntheses.

An unsolved problem is the question, for which series of reactions the isoselective temperature might lie within the range of measurement. According to equation (o), T_{is} is low if the activation entropies of reaction series $X_m + Y_1$ and $X_m + Y_2$ differ widely. It was concluded from studies on addition of carbenes to alkenes that variation of reactants in reactions with low activation enthalpies (slight mutual approach of molecules in the transition state) can have greater influence on activation entropy than on activation enthalpy[51]. Adopting this concept, low isoselective temperatures are to be expected in particular for reactions with "early" transition states. T_{is} is actually low for radical addition to styrenes (Fig. 14), for radical halogen abstraction in the competition system $BrCCl_3/CCl_4$ (Fig. 11 and 13), and for Diels-Alder reaction of anthracenes and maleimides (Fig. 15), *e.g.* between 40 and 110 °C; these are reactions with low activation enthalpies. However, temperature dependence of further series of reactions must be determined in order to allow reliable predictions of the types of reaction for which low isoselective temperatures are to be expected.

I wish to express my gratitude to my co-workers Dipl.-Chem. Klaus Heuck, Dipl.-Chem. Jürgen Meister, Dipl.-Chem. Joachim Stellmach, and Mrs. Karla Keller. I owe special thanks to my teacher Professor Rolf Huisgen and to Professor Christoph Rüchardt, whose advice and discussion contributions were of great assistance for this work. Our research was supported by the Deutsche Forschungsgemeinschaft.

Organic Fluorescence Reagents in the Study of Enzymes and Proteins

By Yuichi Kanaoka[*]

Studies designed to elucidate life processes require close cooperation between various scientific disciplines. A pertinent example is seen in the application of fluorescence spectroscopy to biological studies, where biological sciences, physical and organic chemistry, and technical innovations complement one another. This report reviews the application of fluorescence probes which bind covalently to certain sites of proteins. The major organic fluorescence reagents used in this field are tabulated.

1. Introduction

Fluorescence probes have been defined by *Edelman* and *McClure*[1] as "small molecules which undergo changes in one or more of their fluorescence properties as a result of noncovalent interaction with a protein or other macromolecules." In general there are three types of fluorescent chromophores in proteins—intrinsic, coenzymic, and extrinsic. The side chains of aromatic amino acid residues are intrinsic chromophores. Studies on intrinsic and coenzymic chromophores have afforded important information about the structure and function of proteins. However, "Nature does not always provide the right chromophore at the right place in a protein" *(Stryer)*[2]. In fact, a variety of extrinsic fluorescence labels, now commonly referred to as fluorescence probes, have been devised and employed for the study of biopolymers. The relative merits and drawbacks of extrinsic labeling techniques, with covalent or noncovalent bonding, depend in complex fashion on the particular system being studied and the type of information desired.

In this article the discussion is mainly confined to the *extrinsic* fluorescence probes which *covalently* combine with enzymes and proteins, since studies with noncovalently bound and naturally occurring labels have been extensively reviewed elsewhere[3]. Instead of encyclopedic coverage of a large number of related papers, we attempt to focus our attention on surveying what fluorogenic groups are employed and what methodologies are applied, since we have been concerned with the development of new approaches in biological studies on the basis of novel organic fluorescence reagents. Our principal interest centers upon specific and preferential labeling of functional sites of proteins; however, some nonspecific and coenzymic examples are referred to where appropriate.

2. Basic Principles of Fluorescence[4–15]

Some of the basic concepts of fluorescence spectroscopy are briefly summarized in this Section. As shown in Figure 1, a molecule that has been excited to an upper singlet energy level (S_2) rapidly goes (in $<10^{-10}$ s) to the lowest excited state (S_1). From S_1 the molecule may go to any of the rotational and vibrational levels of the ground state (S_0), either by fluorescence or by internal conversion, or it may go to the triplet state (T_1) by nonradiative processes referred to as intersystem crossing. The lifetime of a molecule in S_1 may range between 0.1 and 100 nanoseconds (10^{-9} s) depending on the chromophore, seemingly short but still sufficiently long for a variety of chemical and physical interactions to take place, which include rotational motion, solvent reorientation, complex formation, proton transfer, and energy transfer. The processes important for fluorescence spectroscopy are those involving the S_1 state, for they determine the fluorescence spectrum as well as the quantum yield, lifetime, and polarization of

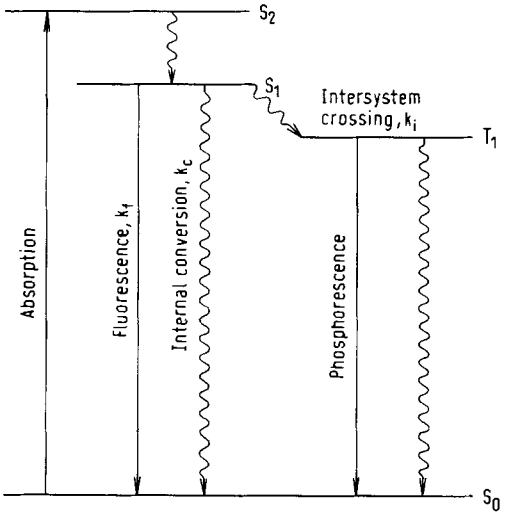

Fig. 1. Energy level diagram of a fluorophore, schematic (see text). Straight and wavy arrows denote radiative and nonradiative processes, respectively.

fluorescence. The fluorescence spectrum represents the intensity of fluorescence at different wave lengths. The fluorescence quantum yield Φ_f is the fraction of excited molecules which fluoresce; it is related to kinetic parameters by Eq. (a)

$$\Phi_f = \frac{k_f}{k_f + k_c + k_i} \qquad (a)$$

where k_f, k_c, and k_i represent the rate constants of fluorescence from S_1, of nonradiative energy loss from S_1, and of intersystem crossing, respectively (see Fig. 1). The fluorescence lifetime τ is defined by Eq. (b), which describes the decay

$$F(t) = F_0 e^{-t/\tau} \qquad (b)$$

of fluorescence intensity following excitation, and is the time required for the intensity F to decay to e^{-1} of its initial value F_0. Eqs. (c) and (d) hold. For a process to compete

[*] Prof. Dr. Y. Kanaoka
Faculty of Pharmaceutical Sciences
Hokkaido University
Sapporo, 060 (Japan)

$$1/\tau = k_f + k_c + k_i \quad (c)$$

$$\Phi_f = k_f \tau \quad (d)$$

effectively with the radiative processes, it must have a rate constant greater than the decay rate of the excited state from which it occurs as shown in Eq. (e), where k is the rate constant of the process.

$$k > 1/\tau \quad (e)$$

When a molecule absorbs plane-polarized light, the emitted light is also plane-polarized. For a randomly labeled, rigid ellipsoidal protein Eq. (f) is obtained, where P and P_0 are the polarization in the presence and absence of rotation, respectively, and ρ_h is the harmonic mean of the rotational relaxation times. It is desirable that 3τ and ρ_h be

$$\frac{1}{P} - \frac{1}{3} = \left(\frac{1}{P_0} - \frac{1}{3}\right)\left(1 + \frac{3\tau}{\rho_h}\right) \quad (f)$$

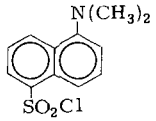
of similar magnitude. These spatial and polarization properties of emission, studied by fluorescence polarization techniques, allow the rotational motion of macromolecules to be measured in solution and hence permit studies of size, shape, and rigidity of proteins.

3. Molecular Structures and Fluorescence—Strategy of Designing Fluorescence Reagents

For fluorescence to dominate, the rate constant for the fluorescence transition (k_f) must be large relative to those for other competing processes. Strongly fluorescing molecules usually have the following characteristics: (a) The absorption transition of lowest energy is intense (large ε_{max}). Generally the fluorescence spectrum of ($S_1 \rightarrow S_0$) of a molecule is similar to the "mirror image" of its absorption spectrum ($S_0 \rightarrow S_1$). (b) The molecule should not contain structural features or functional groups that enhance the rates of radiationless transitions (k_c, k_i).

In solution, most unsubstituted arenes exhibit fluorescence for they possess low-lying π, π^* singlet states as a result of highly favored π, π^* transitions ($\varepsilon_{max} \approx 10^4$). In molecules with excitable nonbonding (n) electrons, the energy of the n,π^* transition will usually be lower than that of the π,π^* transition. Since n,π^* transitions are less intense ($\varepsilon \approx 10^2$) and have longer lifetimes, k_i is larger starting from an n,π^* state than from a π,π^* state. Generalizing, it may be said that *ortho-para*-directing substituents often enhance fluorescence, whereas *meta*-directing groups repress it[16]. Many of the common *meta*-directing substituents possess low-lying n,π^* states. For example, introduction of nitro groups usually leads to total quenching, while carbonyl substituents (ketone, aldehyde, carboxylic acid derivatives) repress fluorescence. By contrast, some *ortho-para*-directing substituents such as amino, hydroxy, or methoxy tend to enhance the fluorescence of arenes. The diminishing influence of heavy atoms such as bromo- and iodo-substituents is termed the "heavy-atom effect." Some unsaturated nitrogen heterocycles with a lowest n,π^* state do not fluoresce.

In addition, fluorescent properties are also sensitive to environmental factors including solvent, pH, and presence of other chemical species[4, 5]. Notably it is this sensitivity of the fluorescence parameters to the environment of the chromophore which makes the fluorescence labeling a useful tool in the study of conformation and dynamics.



Although the principles of fluorescence of organic molecules outlined above are oversimplified, let us briefly consider the rational approaches to the design of a fluorescence probe (F)-X for proteins, where (F) and X represent a fluorophore (fluorescent chromophore) and a reactive group, respectively. The first requirement for the probes is that they have suitable fluorescent properties: Their emission maxima should be distinct from those of the proteins. The fluorescent characteristics should either be sensitive to the structures and dynamics of the environment if (F) is to be used as a reporter, or relatively insensitive to them if (F) is to serve as a tracer or marker, and as an analytical tool. Their fluorescence lifetimes should be sufficiently long for the proposed application. Secondly, the structure of the probe should allow covalent attachment to the protein at a unique location. Thirdly, it is generally desirable that the probe be soluble in water to some extent, since it is to act on aqueous solutions of protein. Finally, an "all or none" nature greatly facilitates spectroscopic determination, *i.e.* the probe should be nonfluorescent but the protein-conjugate fluorescent, or *vice versa*.

These criteria lead to the following strategy. (a) To compromise between the two contradictory requirements, namely aromatic and hence hydrophobic compounds on the one hand, and water-solubility on the other, aromatic systems having two or three rings are preferred as a fundamental fluorophore. (b) Auxiliary chromophores are necessary, *e.g.* heteroatoms in the ring. Such an addition of polar groups may also favor the solubility. (c) If a reporter is required, the fluorescent properties must be sensitive to polarity and other factors of the environment. (d) It may also be necessary to bear in mind that the absorption and emission maxima may be affected by donor-acceptor interactions with the other chromophores, including tryptophan residues in proteins. (e) For specific labeling, special structural characteristics (*e.g.*, substrate-like or hapten-like) must be present. (f) For covalent bonding suitable organic functional groups must be selected which can react by any mechanism, whether heterolytic, homolytic, or photochemical. (g) Since general rules are not available for the "all or none" nature or the structure-fluorescence lifetime relationship, systematic screening has to be undertaken.

4. Covalent and Random Fluorescence Labeling

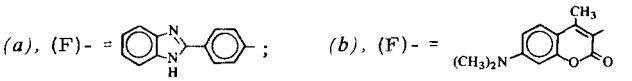
If a fluorophore covalently attached to a protein is excited with a polarized light, the fluorescence will also be polarized to a degree that is inversely related to the amount of Brownian motion occurring during the interval between absorption and emission. Since *Weber*'s pioneering work[17], 5-(dimethylamino)-1-naphthalenesulfonyl chloride (DNS-Cl or dansyl chloride) (*1*) is the fluorophore of choice in most polarization studies. DNS-conjugates have usually been assumed to have fluorescence lifetimes τ of 11 to 14 ns regardless of the protein,

and to have a polarization P_0 of about 0.4[18]. Hence DNS-Cl *(1)* is well suited to the polarization studies of modified globular proteins that have hydrodynamic properties corresponding to those of rigid spherical particles with molecular weights of 10000 to 200000. Solvent effects on the fluorescence of DNS-OH and its derivatives have recently been reported[19].

(1), DNS-Cl (or dansyl chloride)

Polarization studies of proteins modified with *(1)* or other reagents have furnished considerable data on rotational motion and on mutual orientation of molecules, showing whether a given molecule is rigid or flexible and indicating its size and shape. Many procedures are available for covalent attachment of the probes[20, 21]. If the method is to be used on very large proteins with long relaxation times, then long fluorescence lifetimes τ are desirable. Anthracene-, pyrene-, and fluorene-conjugates were prepared and indeed shown to have greater τ values than derivatives of *(1)*. Unfortunately, however, the advantage is partly offset by their inherently lower P_0 values[18].

The use of Eq. (f) to determine the rotational relaxation time ρ_h is permissible assuming that fluorophores are randomly distributed on proteins and rigidly attached. In many cases, however, labeling reagents attach preferentially to particular sites. Moreover, the fluorophores may be in different microscopic environments, resulting in heterogeneous emission. Actually many observations suggest that side-chains are mobile, and flexible segments and subunits rotate. Fluorescence spectra, polarization, quantum yields, and lifetimes have been examined as a function of the degree of labeling and the kind of reagent using bovine serum albumin and γ-globulin[22].

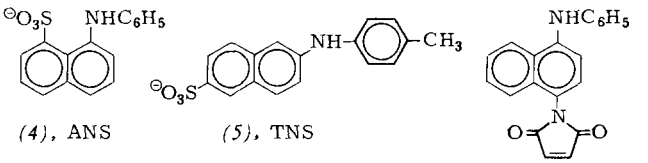


5. Preferential Fluorescence Labeling: Design of a Series of Maleimide Reagents for Thiols[23]

The thiol group is an exceedingly important functional center in biological systems. A wide range of biological phenomena is believed to be somehow dependent on thiols and thiol derivatives[25]; an extensive methodology has been developed for their study. Maleimides generally undergo facile addition to thiols. As thiols are chemically the most active groups found in cells, this reaction is expected to be preferential if not specific for thiols. In earlier work we had found that certain *N*-substituted maleimides *(2)* which are themselves nonfluorescent react readily with various thiols to form fluorescent addition products *(3)*[23a]. This finding led us to develop the reaction shown in Scheme 1 as an empirical "all or none" process[23d] for fluorometric studies on thiol groups.

After careful studies of the reactivity, hydrolytic behavior, and fluorescence properties of a series of maleimides and succinimides, which are their hydrogenation products[23p], we reached the conclusion that it is possible to design thiol reagents carrying a variety of fluorophores (F) yet having similar

(2) nonfluorescent — *(3)* fluorescent



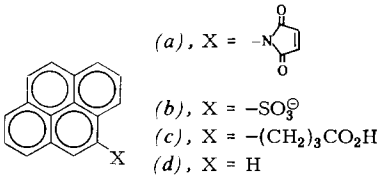
(a), (F)- = ; *(b)*, (F)- =

(2a), BIPM; *(2b)*, DACM

Scheme 1.

reactivities. A systematic search for fluorophores, starting from substituted naphthalenes as the smallest bicyclic system[23o], led us ultimately to *N*-(7-dimethylamino-4-methyl-2-oxo-3-chromenyl)maleimide (DACM) *(2b)*, as a promising reagent of this type which fluoresces at longer wavelengths and is more soluble in water than the others[23l]. In the design of DACM, solubility was enhanced by use of the polar auxochromes coumarinyl and dimethylamino.

Among the initially examined maleimides, *N*-[*p*-(2-benzimidazolyl)phenyl]maleimide (BIPM) *(2a)* turned out to be the first practical reagent in this series. Thus a very sensitive fluorometric determination of thiol compounds has been developed with *(2a)*[23f]. The detection limit is of the order of 0.01 μg of reduced glutathione. BIPM reacts specifically with thiol groups of egg albumin to give fluorescent adducts, confirming the suitability of this type of reagent for protein modification[23k]. On the basis of these results the reactivity of thiol groups in proteins was subjected to kinetic analysis. By comparing parameters for thiol groups in Takaamylase A and myosin A, the states of the thiol groups in the protein molecules were studied[23j]. BIPM inhibits cell-free synthesis of polyphenylalanine in a *E. coli* system, thus providing chemical proof of the involvement of thiol groups of the ribosomal protein[23e]. By virtue of its improved fluorescence properties, DACM is expected to find extensive application[23r].



(4), ANS — *(5)*, TNS

(6), ANM

N-Arylaminonaphthalenesulfonates such as ANS *(4)* and TNS *(5)* are used as sensitive probes for the polarity of their environment because the quantum yield increases and the emission maximum shifts toward the blue as the environmental polarity decreases[1-3, 24]. The emission properties appear to be most strongly influenced by reorientation of the solvation sheath during the lifetime of the excited state. The relaxation process depends on the excited state dipole moments of these fluorophores which are large compared to the ground state dipoles, as well as the dipole moment and mobility of the solvent[3, 24]. One of the limitations of the use of hydrophobic probes which are not covalently bound to the protein is that it is often not possible to identify which sites are involved. A more useful approach may well be the

use of fluorophores which are covalently incorporated into the protein. Although chlorides of *(4)* and *(5)* may be such reagents, they are not specific and will react with all nucleophilic sites in a protein.

N-(4-Anilino-1-naphthyl)maleimide (ANM) *(6)* is a reagent which combines the selective reactivity of maleimide toward thiols with the spectral properties of arylaminonaphthalene[23g]. As expected, ANM is a useful hydrophobic probe for thiol groups in proteins. The remarkable solvent-dependence of the fluorescence spectra of the ANM-conjugates was described in terms of *Kosower*'s *Z* values. For example, the environmental hydrophobicity of the reactive thiol in egg albumin was estimated to be 74—79 *Z*[23g, 23p]. The differential hydrophobic nature of the thiols of the elongation factors in protein synthesis was elucidated by means of this reagent[26], while the calcium ion-induced conformational change in a muscle contraction system, *e.g.* the actin-tropomyosin-troponin complex, was analyzed by labeling F-actin or tropomyosin with ANM[23h, 23i, 23n]. A novel technique for the study of the orientation of proteins in membranes has been developed, in which analysis of angular distribution of polarization was applied to ANM-labeled samples of muscle membranes[23s].

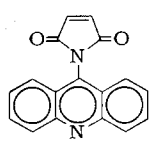
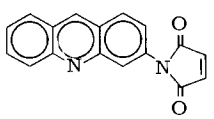
(b), X = $-SO_3^{\ominus}$

(c), X = $-(CH_2)_3CO_2H$



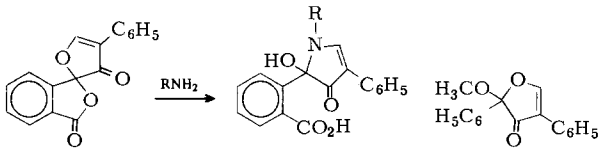
(d), X = H

(7)



(8), FAM

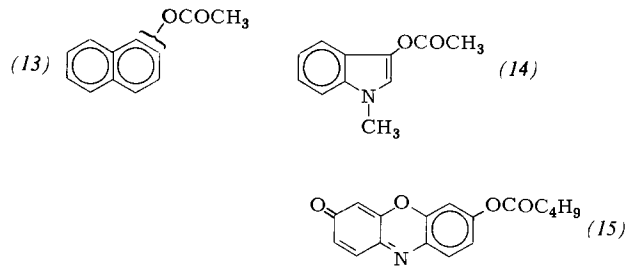
The fluorescence lifetimes of the adducts of proteins with the above reagents are less than 10 ns, and are thus too short for studies of complex biological systems involving large proteins[23r]. On the basis of the empirical rule (see Section 5) *N*-(4-pyrenyl)maleimide *(7a)* was synthesized whose adducts with proteins had fluorescence lifetimes around 100 ns[28]. After screening polycondensed arenes, we have recently extended the list of reagents by a new "medium lifetime" clock, *N*-(4-fluoranthyl)maleimide (FAM) *(8)*, whose adducts display fluorescence lifetimes of around 20 ns[23m]. Efforts are still continuing to find useful fluorophores like the acridine derivatives *(9)* and *(10)*[23q, 27].



(9)

(10)

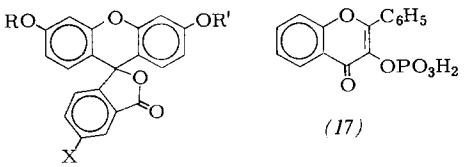
Notable advances have been recently made in the preferential labeling of amines. Nonfluorescent hydroxyfuranones react with amino groups to give the highly fluorescent pyrrolin-4-ones[29a, b] (Scheme 2). 4-Phenylspiro[furan-2,1′-phthalan]-3,3′-dione *(11)* has been successfully used for fluorometric assay of proteins in the nanogram range[29c] and sensitive amino acid analysis[29d, 29e], while *(11a)* was utilized for fluorescent labeling of proteins[29b].



(11) nonfluorescent *(12)* fluorescent *(11a)*

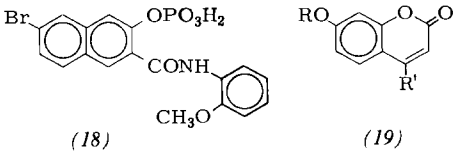
Scheme 2.

6. Specific Fluorescence Labeling; Enzyme Assay



In fluorescent molecules for enzyme research (see Section 3), fluorophores must be introduced into substrate molecules without affecting the activity as substrates and the spectroscopic response. This is feasible: many enzymes can accommodate the extra bulk, without blocking the active site, which must satisfy specific structural requirements[30, 31]. Those substrates which react to form covalently bound intermediates, transient or long-lived, are mainly considered; in addition some of the fluorescent equilibrium inhibitors which exhibit noncovalent interaction are also briefly mentioned.

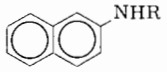
Because fluorometric methods are generally several orders of magnitude more sensitive than chromogenic ones, a large increase in the sensitivity of measurement is expected ($\approx 10^{-9}$ mol/l). Thus fluorometry has been successfully applied to many enzyme assays[32–35]. The all or none approach is particularly useful: fluorogenic substrates are nonfluorescent but are transformed by enzymatic action into a fluorescent product. Utilizing the enzyme-catalyzed hydrolysis of a nonfluorescent ester to a highly fluorescent alcohol, the method has been extensively

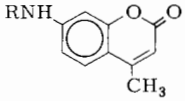


(13) *(14)* *(15)*

used for the determination of hydrolytic enzymes. For example, naphthyl acetates *(13)*[35a], *N*-methyl-3-indolyl acetate *(14)*[35a], and resorufin butyrate *(15)*[35a] were used for determination of cholinesterases. Dibutyrylfluorescein *(16a)*, R = R′ = butyryl, was used for lipases[35a, 36] while the bis(β-D-galactopyranoside)[37] and the 3-*O*-methyl phosphate[38, 39]

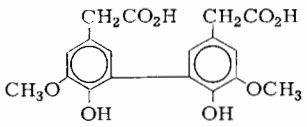
(16a), X = H
(16b), X = NCS





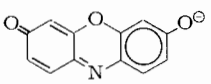
(17)

(18) *(19)*



were used for galactosidase and phosphatases, respectively. The phosphates *(17)*[39] and *(18)*[35d] can also be used for determining phosphatases. Riboflavin 5-phosphate served the same purpose in a histochemical procedure[40].

Coumarin is one of the most versatile of the fundamental fluorophores. Thus esters of umbelliferone (7-hydroxycoumarin) *(19)* or its 4-methyl derivative *(19)*, $R'=CH_3$, are frequently employed as fluorogenic substrates for various hydrolytic enzymes. The phosphate[35f] is excellently suited for determination of phosphatases, and many other esters have been used for carbohydrate hydrolases[33-34]. Likewise, assays for peptidases and proteases make use of the similar fundamental fluorophores, naphthalene and coumarin. The β-naphthylamides *(20)* of phenylalanine[41], L-leucine[42], and cystine[42]

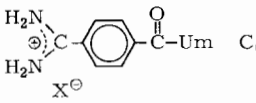


(20)   *(21)*

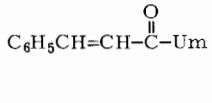
R = CO–CHR–NR_2

were used for aminopeptidase, leucineaminopeptidase, and oxytocinase, respectively. Assays for carboxypeptidase made use of *N*-(β-naphthyloxycarbonyl)phenylalanine[43,44]. We have recently found that the L-leucine derivative of *(21)* is the substrate of choice for leucineaminopeptidase[45]. The benzoyl-L-arginine derivative of *(20)* was used for trypsin[46a]. Further improvements are expected from corresponding derivatives having the coumarin skeleton [*(21)*][46b]. The following examples illustrate the applications to assays for oxidative enzymes. Nonfluorescent homovanillic acid was oxidized enzymatically to the fluorescent dimer *(22)*[35f]. Dehydrogenases can be determined on the basis of the conversion of resazurin (resorufin *N*-oxide) to the resorufin anion *(23)* with participation of the NAD-NADH or NADP-NADPH system[35a].

(22)

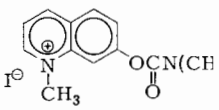


(23)

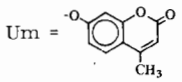


The typical reaction course of some hydrolytic enzymes (E) is formulated in terms of the acyl-enzyme model [Eq. (g)], where $X^{\ominus}$ is a leaving group and E—COR is the intermediate acylenzyme.

$$E + R{-}COX \underset{}{\overset{K_m}{\rightleftharpoons}} E{\cdot}R{-}COX \xrightarrow[-X^{\ominus}]{k_2} E{-}COR \xrightarrow[+H_2O]{k_3} E + R{-}CO_2H \quad (g)$$



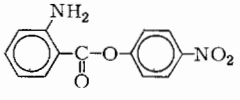
For quantitative enzyme studies the necessity of determining the concentration of active sites instead of using arbitrary activity units is becoming increasingly clear[47]. Important characteristics in assessing usefulness as a "titrant" are: large k_2, small k_3, and small K_m. In compound *(24)*, the protonated *p*-amidinobenzoyl moiety which has a strong affinity for the trypsin active site[48a] and a 4-methylumbelliferyl moiety are combined. The burst [formation of $X^{\ominus}$ in Eq. (g)] titration by fluorometry and the steady state kinetics revealed that *(24)* is a good fluorescent titrant for trypsin, while the cinnamic ester *(25)* can be used as a titrant for chymotrypsin[48b]. The analogous esters of protonated *p*-guanidinobenzoic acid



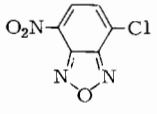
(24)

(25)

(26)



and *p*-trimethylaminocinnamic acid are titrants for trypsin and chymotrypsin, respectively[49]. (7-Dimethylcarbamoyloxy)-1-methylquinolinium iodide *(26)* was used for acetylcholinesterase[50].

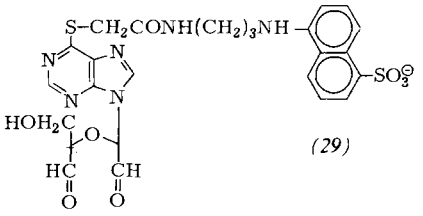


7. Studies on Enzyme Mechanisms

Conformational changes associated with proteolytic zymogen activation have been studied with DNS-substituted peptides [see *(1)*] for chymotrypsinogen[51], with 6-(*N*-methylanilino)-2-naphthalenesulfonyl-(MANS)-peptides for pepsinogen[52a,52b] and with fluorescein-labeled prothrombin[53]. It was suggested that the substrate-binding site is already present in chymotrypsinogen[51]. A change in the emission was observed when disulfide bonds of DNS-substituted Taka-amylase were reductively cleaved[54]. In trypsinogen an amino group was introduced into a tyrosine residue. After labeling with DNS-Cl, the activation process was examined by the fluorescence of DNS[55]. DNS-Cl was in turn an affinity label for the localization of the thyroxine binding site on prealbumin[56].

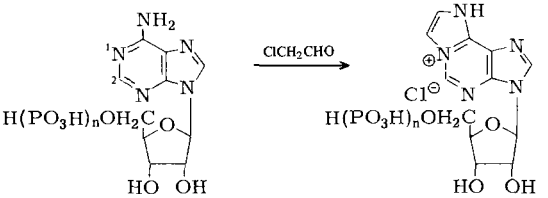
p-Nitrophenyl anthranilate *(27)* irreversibly inhibits α-chymotrypsin by reacting with the active site[57], while it does not react with chymotrypsinogen. The fluorescent spectra show that the environment of the active site is polar. A determination of the fluorescence polarization and emission kinetics in the nanosecond range indicated that the active site of the acylen-

(27)



(28)

zyme is rigid and the chromophore has no independent rotational mobility[2,57]. 4-Chloro-7-nitro-2,1,3-benzooxadiazole *(28)*, a fluorescence reagent for thiol groups[58a,b], reacts with cysteine-25 at the active site of papain[59]. *(28)* was also employed as a probe for the coenzyme-induced structural changes in glyceraldehyde 3-phosphate dehydrogenase[58c]. We have recently found that certain esters possessing a cationic site in the leaving group are efficiently hydrolyzed by trypsin to form acyltrypsin[60a]. Using this "inverse substrate" technique, fluorescence reporters can be specifically introduced into the active site of trypsin[60b].

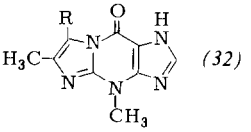


A fluorescent nucleotide analog having the partial structure *(29)* was used for affinity labeling of the initiation site of

E. coli ribonucleic acid polymerase, and covalently reacted with the β-subunit[61]. The inactive labeled enzyme still retains the ability to bind DNA and nucleoside triphosphates. Energy transfer measurements (see Section 8) indicate that initiation site and rifampicin binding site are at least 37 Å apart.

(29)

Possible methods of increasing the fluorescence of purines and pyrimidines consist in extending the conjugated system by addition of fused unsaturated rings and quaternization of heterocyclic nitrogen atoms (cf. Section 3). Fluorescent modification of nucleotide-containing coenzymes was thus performed as shown in the transformation (Scheme 3) of adenosine triphosphate (ATP) *(30)*, $n=3$[62a]. This finding made a set



(30), ATP *(31)*

Scheme 3.

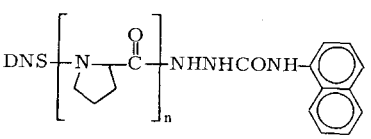
of coenzyme derivatives available for fluorescence studies. For example, ε-ATP *(31)*, $n=3$, was inactive as a substrate for firefly luciferase. However, chemically synthesized luciferyl-ε-AMP is oxidized by luciferase and light is emitted[62b]. Although ε-ATP binds to aspartate transcarbamylase, unlike ATP, it inhibits the enzyme suggesting that the N^1 in the purine ring is crucial for ATP activation[62c]. The adenylylation of a tyrosine residue in the subunits of glutamine synthetase plays an important role in regulation of this enzyme in *E. coli*. ε-Adenylylated glutamine synthetase served as an "internal" fluorescence probe for enzyme conformation and subunit interactions[63].

Kinetic methods[64] have found increasing application in fluorescence studies. Three "clocks" may be considered: electronic transitions (S_1 lifetimes), diffusion (rotational relaxation times), and chemical reaction (chemical relaxation times)[64a]. A compilation of reagents for fluorescent labeling has been attempted in Table 1 (Section 9); although noncovalent probes are not our major subject some recent examples are also mentioned in which stopped-flow ($>10^{-4}$ s) and temperature-jump ($>10^{-6}$ s) techniques are employed. The mode of binding to allosteric sites was examined in relation to enzyme regulation[65]. Observation of transient intermediates showed that NAD^+ binding to liver alcohol dehydrogenase causes a conformational change probably coupled with proton release[66]. By monitoring the fluorescence of naturally occurring Y-base *(32)*, the binding of $tRNA^{Phe}$ (yeast) to the cognate synthetase was studied[67]. The preequilibrium kinetics of L-isoleucine activation catalyzed by Ile-tRNA synthetase was analyzed

(32)

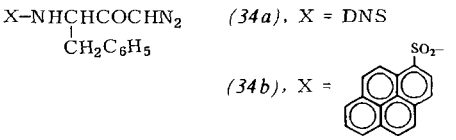
with TNS [see *(5)*]; of all the reactants isoleucine binds slowest to the enzyme[68]. The action of papain was examined with *N*-MANS-oligopeptides as fluorescent peptide substrates[52c] (MANS = 6-(*N*-methylanilino)-2-naphthalenesulfonyl). The observed biphasic reaction indicates that an initial enzyme-substrate complex is converted in a first-order process to another complex, which undergoes cleavage to form products.

8. Energy Transfer and Other Methods



The use of long-range nonradiative transfer of excitation energy for the measurement of distance within molecules has attracted much attention in biopolymer studies. According to *Förster*, singlet-singlet transfer occurs by a resonance interaction of the dipole pair between the energy donor and acceptor chromophores[2, 6, 8, 13, 69]. The distance R_0 (at which transfer is 50 % efficient) is related to spectroscopic and geometric parameters and given by Eq. (h), where n is refractive index, k_f is the rate constant for fluorescence of donor [Eq. (c)], J is the spectral overlap integral, and τ_{D^0} is the lifetime of the donor in the absence of acceptor. K is an orientation factor of the donor and acceptor. A general requirement for excitation transfer is that the donor fluorescence spectrum overlaps the acceptor absorption spectrum, and Eq. (h) applies

$$R_0=(8.71\times10^{23}\,JK^2k_f\tau_{D^0}n^{-4})^{1/6}\ [\text{Å}] \qquad \text{(h)}$$

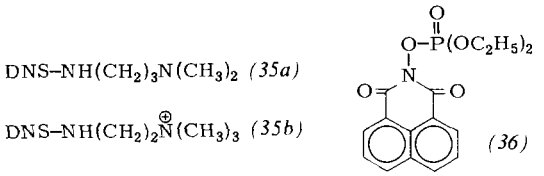


at distances of approximately 10 to 70 Å. The experimental determination of the parameters has been discussed elsewhere[8, 69]. The distance r between a donor and acceptor is given by Eq. (i) where E is the efficiency of transfer.

$$E=\frac{r^{-6}}{r^{-6}+R_0^{-6}} \qquad \text{(i)}$$

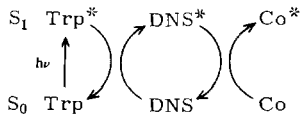
The validity of *Förster*'s theory has been well established. Several systems containing donor and acceptor pairs were synthesized and the distances estimated on the basis of the theory[70]. Flexible models with the indole group of tryptophan (Trp) as a donor and DNS as an acceptor were found in *N*-DNS—Trp[69b, 71] and DNS—$NH(CH_2)_nCO$—Trp ($n=1$ to 10)[71]. The distance r increased with n. Several experimental techniques were compared with DNS^{21}—ACTH(1—24)tetra-

(33)



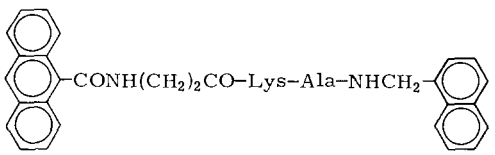
(34a), X = DNS

(34b), X =



kosapeptide containing Trp in position 9[69b, 73]. Typically, oligomers of poly-L-proline *(33)* served as rigid spacers, in which a donor (α-naphthyl) and an acceptor (DNS) are separated by distances ranging from 12 to 46 Å[72]. The results were in excellent agreement with the r^{-6} dependence predicted by Eq. (i).

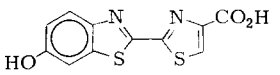
Pepsin substrate analogs such as *(34)*, which contain acceptor fluorophore, were covalently introduced into the active site[74] and the energy transfer phenomena were studied. *(35a)* was an active-site-directed, equilibrium probe for the anionic subsite of cholinesterase, while maretin *(36)* was a probe for the esteratic subsite. Kinetic and distance studies on the



(36)

enzyme were conducted with these probes[75]. A three-component energy transfer relay system consisting of cobalt carboxypeptidase, its DNS-peptide substrates [DNS-(Gly)$_n$-Trp;

Scheme 4.



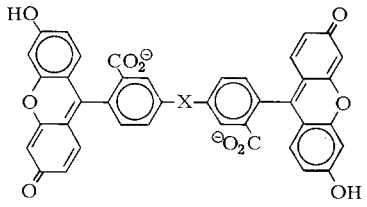
$n=1$ to 3], and tryptophan residues of the enzyme was devised[76]. As shown in Scheme 4, the DNS group served both as an acceptor of Trp excitation energy and as a donor to the cobalt atom. Energy transfer between Trp and DNS rapidly indicates the formation and breakdown of enzyme-substrate complexes; subsequent energy transfer from the bound DNS to the cobalt atom allows calculation of the distance between these moieties. This interesting system suggests far-reaching applications of energy transfer techniques to mechanistic studies of enzymes.

(37)

Tryptic digestion of *(37)* in which the Lys-Ala bond is cleaved was followed by monitoring the increase in fluorescence of a donor (naphthalene) since the transfer of energy to the acceptor (anthracene) is interrupted during the reaction[77]. Aspartate transcarbamylase is feedback regulated by nucleotides. The substrates bind to six catalytic sites and the nucleotide effectors bind to six regulatory sites per enzyme molecule. With the tryptophan residues on the catalytic subunit acting as donor groups, either pyridoxamine phosphate (covalently bound to an amino group at the active site) or ANS (noncovalently bound) is the acceptor[78b]. The pyridoxamine label serves in turn as a donor with mercurinitrophenol bound to the thiol of the catalytic subunit as the acceptor. The observed energy transfer was used to measure the distances between these specific sites.

Refinement of topological studies of proteins on the basis of energy transfer is still in progress[79]. Measurement of the decrease in depolarization during energy transfer to estimate K^2 [see Eq. (h)] values has been reviewed[80] (see Section 9). Circular polarization is related to conformational asymmetry of emitting molecules[81]. Furthermore, interactions of dehydrogenases with ε-ADP [cf. *(31)*] were investigated by the technique in order to analyze various structural changes occurring on coenzyme binding[81c, 81d]. One of the most fundamental as well as promising methods pertinent to fluorescence studies is the nanosecond time-resolved technique[13]. For example, a protein-dye complex of bovine serum albumin and TNS [see *(5)*] has been studied, as has a complex of cystathionase and its coenzyme with pyridoxylamino acids[82]. Decay of fluorescence anisotropy was recently reviewed[83]. The rates of excited state ionization can be directly measured

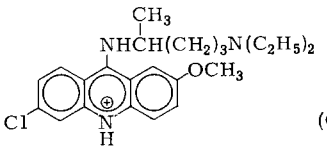
(38)



by the time-resolved method. Thus proton transfer rates of dehydroluciferin *(38)* and its complex with luciferase have been studied[84a]. Novel fluorescent probes which undergo excited state ionization have been suggested; they can be used both for the characterization of microenvironments and as sensitive detectors of conformational changes[84b].

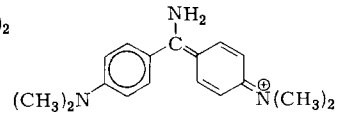
9. Applications of Fluorescence Labeling to Studies on Antibodies, Membranes, and Other Complex Systems

Fluorometric techniques have been employed to interpret the immune reaction: quenching of antibody fluorescence by haptens, quenching or enhancement of hapten fluorescence by antibody, and polarization could be observed[81]. However, most of these studies on antibody-hapten interaction use the noncovalently bonded fluorescence reagents. For example anti-DNS antibodies were titrated with ε-DNS-Lys[85], and production of anti-MANS antibodies has recently been reported[86]. The potential scope of nanosecond time-resolved fluorescence spectroscopy in studies of large protein systems, was demonstrated by work on the DNS-Lys/anti-DNS-antibody complex[13, 87]. The emission anisotropy experiments of the DNS bound to the active site of immunoglobulin G (IgG) and to F(ab')^2 and Fab fragments showed that the antibody displays a discrete mode of flexibility consistent with the model of a flexible joint between the heavy chain and the Fab fragment[13, 87]. Circular and linear polarization investigations on a complex of DNS derivatives and anti-DNS antibodies indicated that the asymmetry is induced by complex formation[88]. Kinetic studies of reactions between fluorescein (FLC) and antifluorescein antibody were carried out utilizing polarization measurements in the static (≈ 5 s) and in the stopped-flow (≈ 5 ms) modes[89]. It is the rate of dissociation which largely determines the stability of the hapten complex.

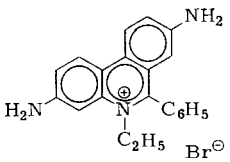


In order to study the shape of the IgG molecule in solution, a hybrid antibody was prepared in which one site specifically bound to the donor, ε-DNS-Lys, and the other site bound

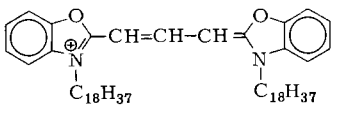
to the acceptor, FLC[85b, 90]. On the basis of the energy transfer theory the distance between the two hapten binding sites as well as the angle between Fab moieties were estimated to reveal that the molecules have an open Y- or T-shaped configuration[90a]. Furthermore, the acceptor FLC was covalently attached by disulfide interchange with the FLC-cystine derivative *(39a)*[90a] to both of the thiols generated by selective reduction of the inter heavy-chain disulfide bond of whole anti-DNS antibody and the $(Fab')_2$ fragments, and of the light-heavy interchain disulfide bond of the Fab fragment. Distance measurements with these systems using nanosecond decay kinetics allowed location of these interchain disulfide bonds, ultimately giving a general idea of the dimensions of IgG.



(39a), X = –NHCO–Cys–Cys–CONH–
(39b), X = $-NHCSNH(CH_2)_2S-S(CH_2)_2NHCSNH-$

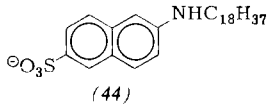


Although a number of fluorescent probes have been employed for studying membranes and macrostructures, the majority of them are noncovalently bound ones. Membranes are assemblies of highly complex chemical entities not confined to proteins. Since several reviews are available[3, 91], only typical fluorophores will be considered. Membrane surface charges were studied with anions; lipid components were examined with anions which are located in the lipid portion; organic anions such as ANS *(4)* and TNS *(5)*[92] and cations

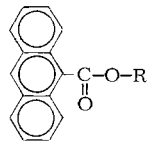


(40)

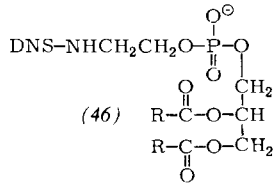
(41)



(42)



(43)



were employed as "energy probes" in excitable membranes. Compound *(35b)* was used for studying membrane-bound cholinergic receptor[93]. From the aminoacridines used, the quinacrine derivative *(40)*[94a] is shown. Other examples of cationic probes are auramin O *(41)*[94b], ethidium bromide *(42)*[95a], and the polymethine compound *(43)*[91c].

Examples of anions are: 6-(octadecylamino)-2-naphthalenesulfonate *(44)*[91b, 96], 12-(9-anthroyl)stearic acid

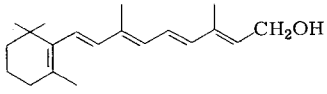
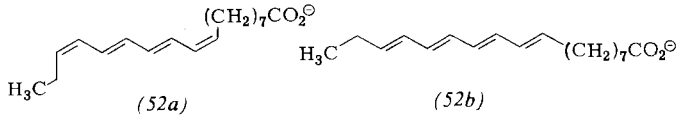
(47)

(48)

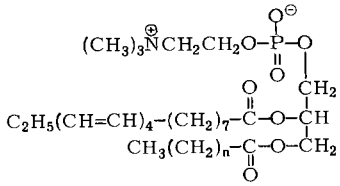


(49)



(50)

Neutral molecules are: *p*-bis(4-methyl-5-phenyl-2-oxazolyl)-benzene *(47)*[91c], the bisbenzoxazole derivative *(48)*[96], 7,12-dimethylbenz[*a*]anthracene *(49)*[97b], and 2-methylanthracene *(50)*[97a].



Fatty acid derivatives carrying a polyene fluorophore have also been employed: retinol *(51)*[91d], 9,11,13,15-octadecatetraenoic acids *(52a)* and *(52b)*[95c], and compound *(53)*, a lecithin-type derivative of *(52a)*[95c]. These various probes were chosen for their differences in charge, lipophilicity, rigidity, shape, and size. Pyrene excimer fluorescence was used as probe for micelles[98a] and vesicles[98b, 98c]. 5-(Iodoacetyl-

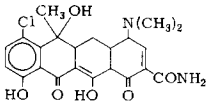
(55)

aminoethylamino)-1-naphthalenesulfonate *(54)*[99a, 99b] and *(28)*[78c] are examples of covalently bonding reagents used for membranes. Motion of proteins in excitable membranes was studied with covalently attached DNS by nanosecond anisotropy[100a], while interacting enzymes were also examined[100b]. A multienzyme complex was analyzed by the energy transfer method[78a]. Proximity relationships in rhodopsin were studied similarly with *(54)*, di-DNS-cystine *(55)*, and difluoresceinisothiocarbamidocystamine *(39b)* as covalently bound fluorophores, from which energy is transfered to retinal[101].



The structures of fluorescence reagents, including those not mentioned in the text, are compiled in Table 1.

10. Closing Remarks

Fluorescent spectroscopy is among the most sensitive, and one of the most versatile of the methods available for studying structure and dynamics of macromolecules. Application of fluorescence probes to obtain a better understanding of a wide spectrum of biological systems is making rapid advances. In addition to steady-state techniques, advances in nanosecond fluorescence spectroscopy have made it possible to measure directly time-dependent phenomena which will provide a wealth of information about the structure and function of macromolecules. One of the important strategies will be to develop more useful fluorescence probes which can be directed at specific sites of proteins as desired and satisfy specific spectroscopic requirements. For example, there is a need for well-defined systems as appropriate donor-acceptor pairs, a range of compounds with desired gradations of excited-state lifetimes, reagents suitable for fluorescence microscopic use, multifunctional probes with the other kinds of reporters, and biosynthetically incorporated probes.

I am grateful to Professors T. Sekine and M. Machida and to other collaborators involved in our own work cited. Financial support of these studies by the Ministry of Education, Science and Culture, Japan, is gratefully acknowledged.

Poly(organophosphazenes)—Unusual New High Polymers

By Harry R. Allcock[*]

An inorganic-backbone high polymer system based on alternating phosphorus and nitrogen atoms promises to solve many of the problems hitherto associated with conventional organic polymers. The chemistry, structure, biomedical, and technological aspects of these polymers are reviewed.

1. Introduction

Synthetic organic polymers are the basic raw materials for the manufacture of a vast range of articles used in technology and in ordinary daily life. Indeed, the multiplicity of organic polymers discovered in the last 40 years is responsible for much of the technical sophistication of modern life. However, in recent years there has been a decline in the number of new polymer systems used in technology. To a large degree this situation has arisen because new materials are now needed with properties that conventional organic polymers just cannot provide.

A few examples will illustrate this point. Most synthetic polymers burn. When used as textile fibers or as objects in the home, their flammability can only be corrected by the introduction of labile and sometimes toxic flame retardant compounds. Thus, a real need exists for synthetic polymers that are non-flammable and, ideally, will not decompose when heated to elevated temperatures.

Rubber and many synthetic elastomers harden and degrade in the atmosphere, swell and soften in contact with oils, hydrocarbon fuels, and solvents, and lose their elasticity when cooled below -20 or -30°C. A clear need exists for elastomers that do not possess these deficiencies.

In the biomedical field, the construction of replacement body organs, such as artificial heart pumps, replacement blood vessels, artificial skin, replacement tendons, *etc.* has been severely hampered by the incompatibility of many synthetic

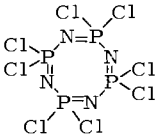
polymers with body tissues, blood, and lymph. Also in the medical field, considerable advances in chemotherapy are envisaged if drug molecules could be bound to water-soluble macromolecules in order to bring about a slow, controlled release of the drug. Unfortunately, nearly all synthetic organic polymers are insoluble in water, and most of those that are soluble are also toxic or resistant to biodegradation.



It was with these facts in mind that, several years ago, we undertook to design and synthesize a polymer system that could overcome many of these problems. The system chosen was one based on a polymer skeleton of alternating phosphorus and nitrogen atoms. These polymers are called polyphosphazenes. Only one other inorganic backbone system is currently in broad technological use—the silicone system. As will be illustrated, phosphazene high polymers are considerably more versatile from both a chemical and a potential applications point of view than are the silicones. Moreover, they show striking advantages over most organic polymer systems for the properties and applications mentioned above.

2. Background to Phosphazene Chemistry

The chemistry of *cyclic* (*i.e.* non-polymeric) phosphazenes has a long and distinguished history which extends back for over a hundred and forty years. *Liebig* and *Wöhler*[1] are usually credited with the first synthesis, in 1834, of hexachlorocyclotriphosphazene *(1)* [2,2,4,4,6,6-hexachlorotri(λ^5-phosphazene)] by the reaction of phosphorus pentachloride with ammonia.

(1)

(2)

By 1900 the cyclic tetrameric chlorophosphazene *(2)* had been isolated, the correct structure of *(1)* and *(2)* had been deduced[2–7], their hydrolytic behavior had been studied[8–13], and their thermal conversion to a hydrolytically unstable rubbery material, now known to be a crosslinked form of poly(dichlorophosphazene) *(3)* had been described[8–13]. An improved synthesis of *(1)* and *(2)* was described by *Schenck* and *Römer* in 1924, and this method remains today the basis of the modern manufacturing method[14].

The chemistry of the *cyclic* phosphazenes has been studied intensively since 1955, mainly in Britain, Germany, and the United States. Three main lines of research have been evident. Firstly, the direct synthesis of phosphazenes from halophosphoranes or halophosphanes has received considerable attention. Such reactions are summarized by equations (a)—(d).

$$PCl_5 + NH_4Cl \xrightarrow[-\ HCl]{} (NPCl_2)_{3\ to\ \approx\ 10} \quad [14\text{-}24]\ (a)$$

$$Ph_2PCl_3 + NH_4Cl \xrightarrow[-\ HCl]{} (NPPh_2)_{3\ or\ 4} \quad [25, 26]\ (b)$$

$$Ph_2PCl + NaN_3 \xrightarrow[-\ NaCl,\ -\ N_2]{} (NPPh_2)_{3\ or\ 4} \quad [27]\ (c)$$

$$Me_2\overset{\oplus}{P}(NH_2)_2Cl^{\ominus} \xrightarrow[-\ NH_4Cl]{} (NPMe_2)_{3\ or\ 4} \quad [28]\ (d)$$

It is important to note that none of these direct synthesis reactions yields high polymers. The products are low molecular weight cyclic species. The mechanisms of reactions of types (a) and (b) have been studied in detail[15–23], and it seems clear that the stepwise chain growth mechanism precludes the synthesis of long chains.

The second area of *cyclo*phosphazene research has attracted by far the most activity. It involves the nucleophilic and electrophilic replacement of halogen atoms in halocyclophosphazenes by organic residues, as illustrated by equations (e)—(g).

$$\underset{(1)}{(NPCl_2)_3} \xrightarrow[-\ NaCl]{NaOR} [NP(OR)_2]_3 \quad [29, 30]\ (e)$$

$$\underset{(2)}{(NPCl_2)_4} \xrightarrow[-\ NaCl]{H_2NR} [NP(NHR)_2]_4 \quad [31\text{-}33]\ (f)$$

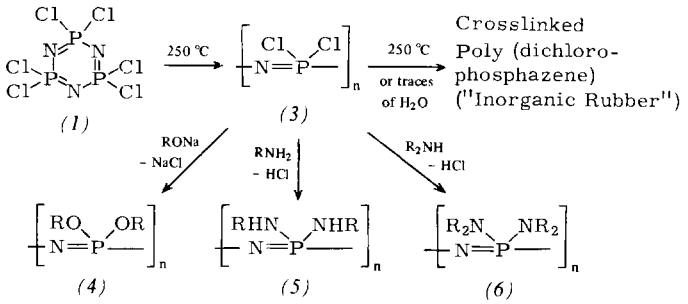
$$\underset{(1)}{(NPCl_2)_3} \xrightarrow[-\ HCl]{C_6H_6/AlCl_3} (NPPh_2)_3 \quad [25, 34, 35]\ (g)$$

Considerable reaction mechanistic work has taken place, designed to elucidate the *cis/trans*, or geminal/non-geminal characteristics of the reactions.

Thirdly, single crystal X-ray and other techniques have been used extensively to determine the molecular parameters of the cyclic derivatives, mainly for the testing of alternative bonding theories. X-ray work has also been carried out on the clathrate inclusion adducts formed by some cyclotriphosphazenes. All these developments have been reviewed elsewhere[36–41].

Surprisingly, apart from the clathrate adducts[42] and a few cyclophosphazene flame retardant additives, relatively few practical or technological developments have emerged from this earlier research on *cyclic* phosphazenes. However, this work has provided a firm fundamental background for the current emergence of useful phosphazene high polymers. The rest of this review will be concerned exclusively with this polymeric aspect.

3. The Polymer Synthesis Route



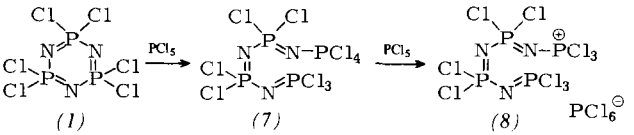
The thermal conversion of hexachlorocyclotriphosphazene *(1)* to the rubbery poly(dichlorophosphazene) has been known for over 80 years[11]. The high polymer is a transparent elastomeric material which has excellent stress-relaxation behavior. It is often called "inorganic rubber". Before 1965 a number of investigators had examined this material for possible use as a technological elastomer. In every case these investigations failed because the polymer is hydrolytically unstable. In contact with a moist atmosphere it degrades slowly to a crusty, crystalline conglomerate of ammonium chloride and ammonium phosphate, with the concurrent evolution of hydrogen chloride.

When we began our investigations, it seemed clear that this material could form the basis of a broad range of new and useful polymers if only the hydrolytic instability could be overcome. The rubbery elasticity of the material, in particular, provided the proof that an inorganic backbone could give rise to properties hitherto associated mainly with organic macromolecules.

In view of the fact that the cyclic trimers and tetramers, such as $(NPCl_2)_3$ *(1)* and $(NPCl_2)_4$ *(2)*, undergo nucleophilic substitution reactions with alkoxides or amines, our strategy was to attempt similar substitution reactions on the high polymer, $(NPCl_2)_n$. The initial experiments were disappointing. The poly(dichlorophosphazene) proved to be swellable, but insoluble, in all organic solvents. Even when the swollen polymer was emulsified in an organic solvent and then treated with nucleophiles, the halogen replacement was incomplete and the resultant polymers remained hydrolytically unstable.

A solution to this problem was provided by a fundamental study of the polymerization of $(NPCl_2)_3$ *(1)* carried out by *Allcock* and *Kugel*[43]. It was reasoned that a polymer which is swelled by but is nevertheless insoluble in a variety of solvents is probably crosslinked. It seemed plausible that the crosslinked modification could be formed from an uncrosslinked species which should be completely soluble in organic media. This was indeed found to be the case. A careful control of the reaction conditions allowed the uncrosslinked polymer to be isolated at an intermediate stage in the polymerization reaction. Subsequent reaction led to crosslinking.

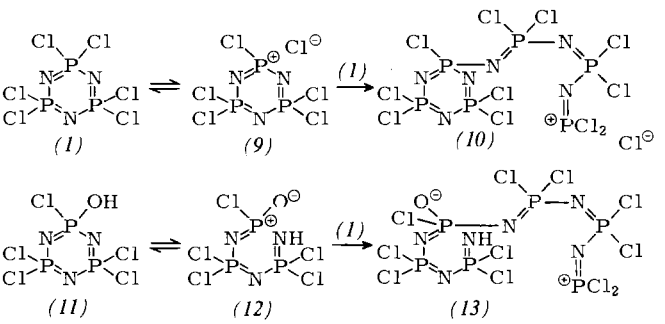
The uncrosslinked poly(dichlorophosphazene) was soluble in benzene or tetrahydrofuran to form highly viscous solutions. *Allcock*, *Kugel*, and *Valan*[43-45] treated such solutions of the polymer with alkoxides, such as sodium methoxide, ethoxide, or phenoxide[43,44] or with amines, such as aniline, piperidine, or dimethylamine[45]. Complete halogen replacement occurred. The substituted products were hydrolytically stable elastomers or flexible thermoplastics. The physical properties changed with each different substituent group. It was clear even from the initial experiments that, given the broad range of available alcohols, phenols, and primary or secondary amines, the system provided a route to the synthesis of an almost unprecedented range of different high polymers. The over-all synthesis route is summarized in Scheme 1.



Scheme 1.

4. The $(NPCl_2)_3$ Polymerization Problem

With these facts in mind, it is instructive to ask why these developments did not take place earlier and why the crosslinked form of high polymeric poly(dichlorophosphazene) was apparently not isolated in the preceding 70 years. The answer lies in the complexity of the chlorophosphazene polymerization process. Unlike many organic polymerizations, this is a highly unpredictable reaction that is unusually sensitive to the presence of trace impurities. These function as accelerators, inhibitors, or crosslinking agents.



Two examples will illustrate this point. First, phosphorus pentachloride is a powerful polymerization inhibitor. It functions mainly by the cleavage of rings to give non-polymerizable, inhibitory chains[46-48] [see *(7)* and *(8)*] by the end-capping of active chain ends[46].

Since phosphorus pentachloride is a reagent for the synthesis of *(1)*, it can be carried through the trimer purification process in trace amounts sufficient to totally block polymerization.

Secondly, traces of water function as a catalyst at low concentrations (≈ 0.1 %) and as an inhibitor or crosslinking agent at higher concentrations[46]. Clearly, rigorous and standardized purification and polymerization procedures are needed before uncrosslinked polymer can be isolated. Even in the apparent absence of impurities, crosslinking of the polymer takes place after about 75 % of the trimer has been consumed[43,44].

The detailed mechanism of the polymerization is still not fully understood. It is known that the electrical conductivity of the molten trimer rises dramatically at temperatures where polymerization also takes place (>230 °C)[49]. This suggests that ionization of the phosphorus-chlorine bond occurs during initiation or propagation [see *(9)* and *(10)*]. The catalytic effect of water implies either that this reagent facilitates removal of chloride ion from phosphorus, or that hydroxyphosphazenes *(11)* are the true initiators [see *(12)* and *(13)*]. Speculative mechanisms based on these observations are shown in Scheme 2.

Scheme 2.

The mechanism of crosslinking is similarly complex. Traces of water can definitely crosslink the chains[46]. However, if an ionization of the type shown in *(9)* can occur, it seems probable that initiation of *branching* could take place at middle units of the polymer. It appears that non-hydrolytic crosslinking does not occur until a deficiency of trimer exists in the polymerization system. Hence, an attack by active chain ends on other chains would appear to provide a plausible crosslinking mechanism. Nevertheless, this remains an important area for future research.

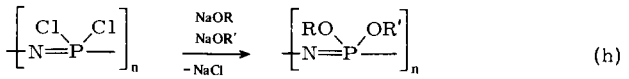
5. Alkoxy- and Aryloxy-Substituted Polymers

In organic polymer chemistry the modification of existing polymers by substitution reactions can only rarely be used

as a synthesis route. The coiling of polymer chains in solution and the relatively low reactivity of, for example, halogen atoms bonded to a hydrocarbon-type chain, place severe limitations on the degree to which organic polymers can be modified. The same is true of methylsiloxane polymers. The methyl group cannot be replaced effectively by other ligands; hence, each polymer must be made by polymerization of the corresponding "monomers". Obviously, this is not the case with halophosphazene high polymers. The phosphorus-chlorine bond has a very high reactivity in nucleophilic substitution. Hence, the poly(organophosphazene) synthesis route makes use of a chemically unstable polymeric species as an intermediate for the preparation of a multiplicity of stable derivatives.

The introduction of alkoxy or aryloxy groups into a polyphosphazene structure can be performed quite readily. A solution of poly(dichlorophosphazene) *(3)* in benzene or tetrahydrofuran is added dropwise to a stirred solution of a slight excess of sodium alkoxide or aryloxide, usually in an ethereal solvent[43, 44]. After completion of the reaction, the polymer is freed from sodium chloride, reprecipitated, and usually solution-cast as a film, or solution-extruded into fibers.

With the exception of the methoxy- and ethoxy-derivatives, which are elastomers at 25 °C[43, 44], most known alkoxy- or aryloxyphosphazene high polymers are colorless, flexible, film-forming thermoplastics at room temperature[43, 44]. The properties of some typical homopolymers are listed in Table 1. It is important to note that some have very low glass transition temperatures (T_g), and many are microcrystalline materials. All are stable to moisture and, indeed, most can be stored in contact with strong aqueous base or aqueous acid without decomposition. Concentrated sulfuric acid is one of the few reagents that causes degradation[44]. Polymers that contain fluoroalkoxy side groups are also highly water- and oil-repellent. Very few of the polymers examined to date will burn, and many are flame-retardants for organic polymers, such as cotton.



The high torsional mobility of the phosphazene backbone is indicated by the low T_g values. Low T_g values are often associated with elastomeric properties, but in most alkoxy- or aryloxyphosphazene homopolymers, the microcrystallites tend to function as labile "crosslink" sites that impart toughness to the polymer but prevent the facile molecular

Table 1. Properties of Selected Poly(organophosphazenes). T_g = glass transition temperature; T_m = microcrystalline melting point; T_l (in brackets) = additional melting point-like transitions; T_g temperatures quoted in brackets are approximate values or secondary transitions.

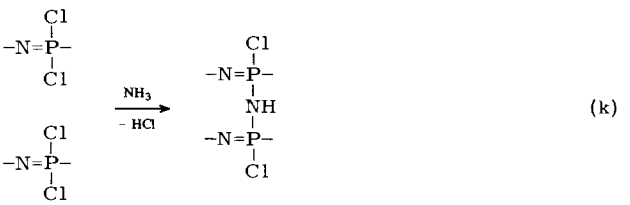
conformation changes needed for elasticity. Microcrystallites are formed only if the symmetry and regularity of the chain geometry is high enough to allow adjacent chains to pack together in a regular manner. Hence, the introduction of asymmetry or irregularity should allow the elastomeric characteristics to emerge.

This can be accomplished by the *random* introduction of two or more different alkoxy or aryloxy substituent groups. Two methods are available to achieve this end. Firstly, as demonstrated by *Rose*[50], poly(dichlorophosphazene) can be allowed to react simultaneously with two or more different alkoxides [eq. (h)]. If the reactivities of the two nucleophiles are similar, their introduction into the polymer will be random. Mixed substituent polymers made in this way are essentially non-crystalline, and they form an unusual and valuable series of elastomers[50, 52, 54]. This process is now used on a manufacturing scale to produce technological elastomers[61-64] (see Section 13).

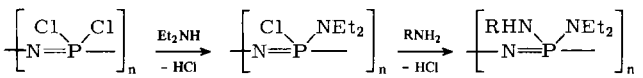
(h)



(i)

An alternative way to accomplish the same end is illustrated in equation (i). Treatment of an alkoxyphosphazene homopolymer with the alkali metal salt of a second nucleophile permits a metathetical ligand exchange process to take place[62]. Elastomers made in this way are similar to those prepared by the direct competition route.

Finally, it should be noted that poly(di*chloro*phosphazene) is not the only substrate that can be used to prepare alkoxy- or aryloxyphosphazene polymers. Similar polymers can be made from poly(difluorophosphazene)[65], and presumably poly(dibromophosphazene) behaves in the same way.

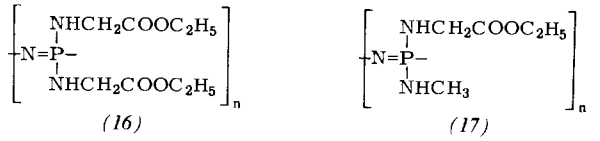


6. Aminophosphazene High Polymers

The aminolysis of poly(dichlorophosphazene) is usually accomplished in the presence of an excess of the amine, which functions both as a nucleophile and a hydrohalide acceptor[45, 57-59]. Completely substituted poly(aminophosphazenes) can be synthesized readily with the use of ethylamine, propylamine, butylamine, aniline, piperidine, dimethylamine, *etc.*[45, 57]. However, ammonia cannot be used as a nucleophile since this reagent crosslinks the chains [eq. (k)][45, 57], and the crosslinking process leads to insolubilization and incomplete substitution. Methylamine behaves similarly at room temperatures or above, but gives fully substituted linear polymers at low temperatures[57]. Obviously, the crosslinking reaction is retarded by increasing steric bulk in the amine.

(k)

However, beyond a certain size, the bulkiness of the *N*-substituent is disadvantageous. For example, *N*-methylaniline does not replace all the halogen atoms in poly(dichlorophosphazene)[57]. Diphenylamine causes decomposition rather than simple substitution. Diethylamine replaces exactly half of the available chlorine atoms[57, 58]. In fact, diethylamine replaces one chlorine atom on each phosphorus to yield a surprisingly stable elastomeric polymer *(14)*, which can itself be subjected to further nucleophilic substitution to yield mixed substituent derivatives *(15)*[57, 58]. These fully substituted polymers are non-crystalline, transparent, film-forming thermoplastics, very similar to cellophane in appearance.



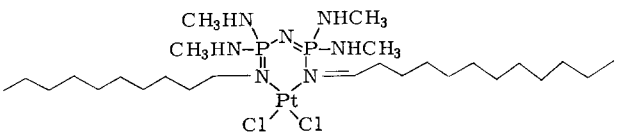
(3) *(14)* *(15)*

All the fully substituted aminophosphazene polymers are film-forming thermoplastics rather than elastomers. Their T_g values tend to be higher than those of related alkoxy- or aryloxy-derivatives, especially when primary amino residues are present. Presumably this reflects the influence of inter- and intramolecular hydrogen bonding in lowering the torsional mobility of the chains[45]. A second difference from alkoxy- or aryloxy-substituted polymers is found in the surface properties and solubility characteristics. Aminophosphazene polymers tend to be hydrophilic rather than hydrophobic, and some are soluble in aqueous rather than organic media. Again, these properties are probably connected with the ease of hydrogen bonding. Some of the properties of typical aminophosphazene polymers are summarized in Table 1.

7. Amino Acid Derivatives

As mentioned earlier, a need exists for polymers that will be either biocompatible or biodegradable to harmless, excretable or metabolizable small molecules. Biodegradable polymers could be used as surgical sutures, temporary tissue-reinforcement films or meshes, or as water-soluble or hydrolyzable carrier molecules for chemotherapeutic drugs or birth control agents.

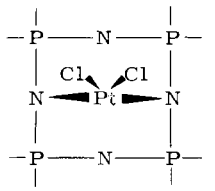
With these applications in mind, a series of flexible polymers that contain amino acid ester units as substituent groups have recently been synthesized[60]. The amino acid residues are bound to the polymer through the amino component. Polymers have been made which contain either amino acid ester residues only, or both an amino acid ester and a second, water solubilizing group, such as methylamino. Two typical polymers are shown in formulas *(16)* and *(17)*. Other polymers have been prepared which contain esters of alanino, leucino, and phenylalanino groups as substituents on the polymer chain.



(16) *(17)*

Polymers of this type are designed to degrade hydrolytically to phosphate, ammonia, and the amino acid. This they do.

However, all the polymers synthesized to date also degrade by a second mechanism which causes spontaneous shortening of the chains by a depolymerization process. At temperatures between about 25° and 50°C, this chain shortening reaction leads to a loss of the polymeric properties over a period of days or weeks, depending on the amino acid ester group employed. The reaction can be inhibited by storage at low temperatures. Hence, polymers of this type would "self-destruct" in the body at a rate needed for the absorption of sutures or the release of chemotherapeutic reagents.



8. Platinum and Heme Complexes

Considerable recent interest has been generated by the use of square planar platinum complexes as anticancer drugs[66]. One problem with the chemotherapeutic use of these compounds is the rapidity with which they are excreted, and the consequent damage to the kidneys that results from this process. Water-soluble high polymers cannot pass through semi-permeable membranes. Hence, they would be expected to be retained within the circulatory system and not be excreted. A drug molecule bound to the polymer should be similarly retained until decomposition of the polymer permitted its slow controlled release. With this objective in mind, *Allcock, Allen* and *O'Brien* have prepared polymeric complexes of type *(18)*[67-69]; these have proved in initial tests to be

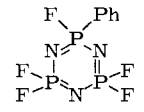
(18)

effective antitumor agents. Evidence that the platinum is bound to the *skeletal* atoms of the phosphazene chain comes from model compound studies with the cyclic tetramer, $[NP(NHCH_3)_2]_4$. This compound forms a complex of formula $[NP(NHCH_3)_2]_4PtCl_2$[68,69], which is also active in antitumor tests. An X-ray diffraction analysis of this complex indicates that the square planar platinum is bound to the skeletal atoms in a transannular fashion *(19)*[69]. Since complexes *(18)* and *(19)* have similar spectral properties, the binding of platinum to the polymer is believed to involve the skeletal rather than the side group nitrogen atoms.

(19)

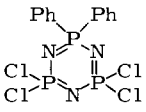
A second utilization of water-soluble phosphazenes is as models for biological polymers, such as proteins. For example, it is well-known that the oxygen-carrying capability of hemoglobin and myoglobin in aqueous media depends on the presence of both the iron(II)-porphyrin component (heme) and the protein unit (globin). If the heme unit is separated from the protein, the Fe^{II} atom is irreversibly oxidized to Fe^{III} in the presence of oxygen. Some investigators have attempted to modify the porphyrin molecule itself to prevent oxidation[70-72]. We have used a polyphosphazene chain to achieve the same end. Strong evidence exists that at least one function of the protein is to separate porphyrin residues and to prevent μ-oxo-dimer formation[73,74], since dimerization is believed to facilitate oxidation. Polyaminophosphazenes contain coordination sites in the skeleton and in the side groups, and they form a logical class of compounds for the binding of heme units. If the heme concentration along each chain were sufficiently low, porphyrin dimerization should be inhibited. Hence, such complexes might form reversible oxygen binding systems, perhaps with long-range uses as blood transfusion substitutes.

Poly[bis(methylamino)phosphazene], $[NP(NHCH_3)_2]_n$, forms a complex with iron(III) porphyrin complexes, such as hemin chloride. Reduction of Fe^{III} to Fe^{II} yields complexes which, in concentrated solution or in thin films, will absorb and release oxygen[75].



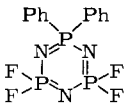
9. Polymerization and Ring-Ring Equilibration of Organocyclophosphazenes

The synthesis methods outlined earlier for the preparation of poly(organophosphazenes) from poly(dichlorophosphazene) are highly effective and permit an almost unparalleled range of different polymers to be made. Nevertheless, the prospect that poly(organophosphazenes) might be accessible by the *direct* polymerization of cyclic organophosphazene trimers and tetramers remains a tantalizing prospect. It is, therefore, instructive to examine the behavior of organo-substituted cyclic trimers at high temperatures with a view to establishing which factors inhibit or facilitate polymerization.

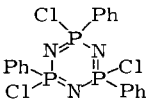


No conditions have yet been found which permit the homopolymerization of fully organic substituted cyclic trimers or tetramers. Although halogeno or pseudohalogeno derivatives, such as $(NPCl_2)_3$, $(NPF_2)_3$, $(NPBr_2)_3$, $[NP(NCS)_2]_3$ polymerize thermally to yield high polymers, compounds such as $[NP(CH_3)_2]_3$, $[NP(C_6H_5)_2]_3$, $[NP(OCH_2CF_3)_2]_3$, or $[NP(OC_6H_5)_2]_3$, do not. However, it is known that organic derivatives, such as these can equilibrate to yield species with large rings. For example, $[NP(CH_3)_2]_3$, when heated forms a mixture of the cyclic trimer and tetramer[76]. Similarly, the trifluoroethoxy derivative yields tetramer, pentamer, and higher cyclic compounds, but no high polymer[77]. Some evidence exists that $[NP(C_6H_5)_2]_3$ behaves in the same way[78]. The important point is that the *mechanism* of the equilibration is clearly accessible to these systems. If the mechanisms of ring-ring equilibration and chain propagation are similar (and this seems likely), the question remains of why chain propagation is inhibited when the organic substituent groups are present.

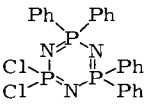
An attempt has been made to answer this question by the synthesis and attempted polymerization of phosphazene cyclic trimers that contain *both* halogen atoms and organic substituent groups. Two series of compounds have been examined—those in which phenyl groups were present[78], and those which contained trifluoroethoxy groups[77]. It was found that $N_3P_3F_5C_6H_5$ *(20)* polymerizes thermally, but derivatives *(21)* to *(26)* do not. However, compounds *(20)*—*(23)* form copolymers with $(NPCl_2)_3$, whereas species *(24)*—*(26)* do



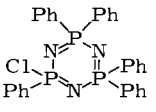
not. Hence, increasing numbers of phenyl groups lower the tendency for polymerization.



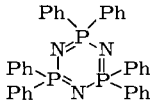
(20)



(21)

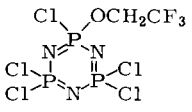


(22)

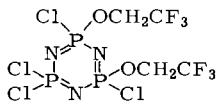


(23)

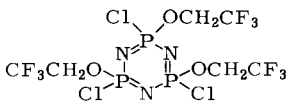
(24)



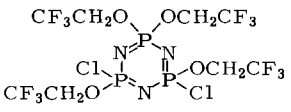
(25)



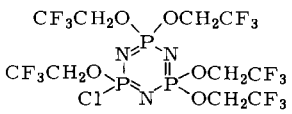
(26)



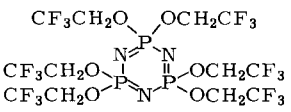
Similarly, compounds *(27)*—*(29)* polymerize at 200 °C to yield linear polymers, but derivatives *(30)*—*(32)* do not. At higher temperatures, side reactions result in the elimination of CF_3CH_2Cl from compounds *(27)*—*(31)*. Compound *(32)* copolymerizes with $(NPCl_2)_3$.



(27)



(28)



(29)

(30)

(31)

(32)

The progressive inhibitory effect of organic substituent groups probably results from a steric influence by these groups[36, 37, 79]. An open-chain phosphazene is subject to more severe side group-side group and side group-chain repulsions than is a cyclic trimer or tetramer. In a small ring cyclic phosphazene, the side groups point away from each other to minimize steric interactions. In a chain they do not. Hence, the steric influence of the side groups would be expected to be especially serious in the chain propagation steps[77–79]. The enthalpy of a chain species would be higher than that of a cyclic species, and cyclization would be preferred to linear chain propagation. Further evidence in favor of this viewpoint comes from polymer depolymerization studies[80, 81].

10. Polymer Decomposition and Depolymerization

Aminophosphazene polymers decompose at high temperatures to yield side group fragments, with concurrent crosslinking of the chains. Alkoxy- and aryloxy-substituted polymers behave differently. At elevated temperatures (especially above 250 °C) they *depolymerize* to yield small cyclic phosphazene molecules that have the same basic repeating structure as the high polymers[80, 81]. Poly(dichlorophosphazene) behaves similarly, but at higher temperatures (above 350 °C)[11, 13, 82–89].

Depolymerization is a response to thermodynamic influences. At high temperatures, the $T\Delta S$ term in the usual equation $\Delta G = \Delta H - T\Delta S$ becomes increasingly important, favoring systems in which many small molecules are formed at the expense of a few long chain molecules. This factor is responsible for the high temperature depolymerization of organic polymers, such as poly(methyl methacrylate), to their vinyl monomers. Poly(dimethylsiloxane) depolymerizes for the same reason.

However, in poly(organophosphazenes) an additional factor is superimposed onto the entropic influence. Bulky organic groups, when present as substituents on the polymer chain, can raise the enthalpy of the polymer relative to that of the cyclic trimer or tetramer. Hence, both the entropic and the enthalpic terms now favor depolymerization[79]. Presumably, the enthalpic term is so serious for some poly(organophosphazenes), (aryloxy derivatives, for example), that the polymers may be stable at moderate temperatures only because the mechanism of depolymerization is not accessible.

Figure 1 shows the behavior of $[NP(OCH_2CF_3)_2]_n$ after 30 h at various temperatures, as illustrated by gel permeation chromatography curves. The high molecular weight peak moves to progressively lower molecular weight values as thermal depolymerization proceeds[80].

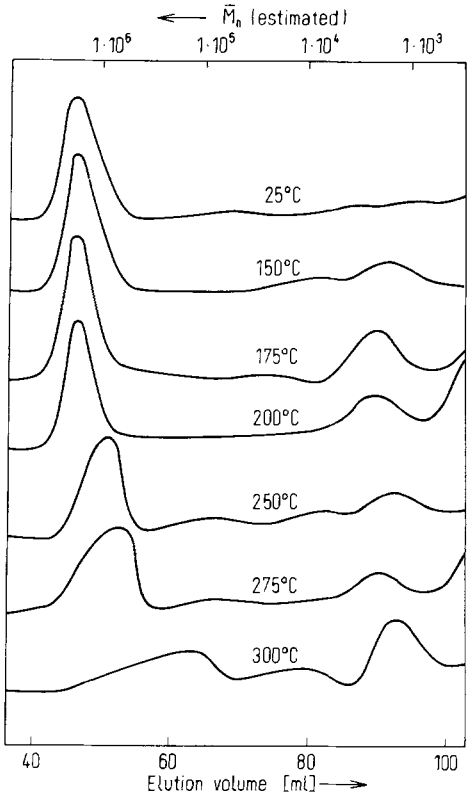


Fig. 1. Changes in the gel permeation chromatography curves of $[NP(OCH_2CF_3)_2]_n$ after heating of the polymer for 30 h at different temperatures.

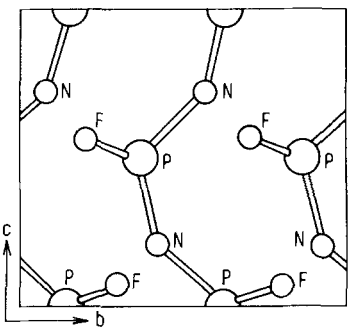
In practice, this thermal instability is no worse than it is for silicones or most organic polymers. Moreover, crosslinking of the chains, or the introduction of discontinuities, such as phenyl substituents in an alkoxy or aryloxyphosphazene, serve to lower the "unzipping" chain length and raise the thermal stability.

11. X-Ray Structure Analysis of Polyphosphazenes

The rapid expansion of synthetic activity in polyphosphazene chemistry has naturally raised questions about the structure and conformational characteristics of these polymers. An early X-ray diffraction analysis of poly(dichlorophosphazene) by *Meyer, Lotmar*, and *Pankow*[90] indicated the presence of a chain structure, but the resolution of the data was insufficient to correctly deduce the chain conformation. Later work by *Giglio, Pompa*, and *Ripamonti*[91], using the optical transform technique, suggested a *cis-trans* planar conformation.

More recently, the structures of $(NPF_2)_n$, $(NPCl_2)_n$, $[NP(OCH_2CF_3)_2]_n$, and $[NP(OC_6H_5)_2]_n$ have been studied by *Allcock, Kugel, Stroh*, and *Arcus*, with the use of X-ray fiber diagram techniques[44, 92, 93]. Firstly, it was found that $(NPF_2)_n$ exists in two different microcrystalline modifications at temperatures below 25 °C. At temperatures near −56 °C,



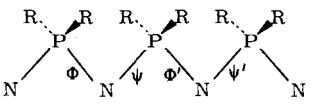


Fig. 2. Projection of the atoms in part of the unit cell of poly(difluorophosphazene) (conformer B), viewed down the *a* axis.

the structure is that of a *cis-trans*-planar chain (Fig. 2)[92], but above −36 °C the conformation apparently changes to that of a spiral helix. Secondly, it has been shown that $(NPCl_2)_n$ also assumes an almost *cis-trans* planar conformation when the elastomer is stretched at temperatures of 25 °C or below[93]. Thirdly, the fiber diagrams of $[NP(OCH_2CF_3)_2]_n$ and $[NP(OC_6H_5)_2]_n$ can also be interpreted in terms of a *cis-trans* planar chain[44]. Recently, the structure of $[NP(OC_6H_5{-}Cl\text{-}p)_2]_n$ has been examined, and the main chain conformation again appears to be *cis-trans*-planar[94].

Two questions arise from these results. Firstly, why do the chains assume a *cis-trans*-planar conformation? Secondly, what structural features of these molecules are responsible for the conformational mobility, especially at low temperatures? Attempts have been made to answer these questions by conformational analysis experiments as described in the next section.

12. Conformational Analysis

The chain conformation assumed by a microcrystalline polymer normally represents a minimum energy conformation in terms of the *intra*molecular non-bonding interactions. These interactions involve side group-side group and side group-chain repulsions and attractions. Inherent skeletal bond barriers may also influence the conformation, especially if double bonds are present. *Inter*molecular packing forces can also exert an influence on the conformation. However, in principle, it is possible to predict or rationalize the preferred chain conformations from calculations of the non-bonding intramolecular forces. The calculation of such energies for a long polymer molecule would be a formidable problem, and the simplified assumption is normally made that the conformation of a short chain segment, such as *(33)*, represents the conformation of the whole chain.

(33)

Once such calculations have been made, the results may be plotted as an energy surface, the coordinates of which represent the effects of 360° torsion of bonds φ and ψ in *(33)*. An energy surface of this type not only permits identification of energy minima, but also provides information about the barriers to torsion of individual skeletal bonds and the breadth of the principal energy wells. Such features can, in theory, be correlated with physical properties, such as skeletal flexibility, glass transitions, elasticity, *etc.*

Calculations of this type have been performed for a number of polyphosphazenes, including $(NPF_2)_n$, $(NPCl_2)_n$, $(NPBr_2)_n$, $[NP(OCH_3)_2]_n$, $[NP(OCH_2CF_3)_2]_n$, and $[NP(OC_6H_5)_2]_n$[95, 96]. Lennard-Jones 6:12-type energy potentials and a Coulombic term were used to calculate the energies of each interaction within the short chain segment for a wide range of different conformations. Typical energy surfaces are shown in Figure 3.

Firstly, the surfaces generate minima near the *cis-trans* planar conformations. ($\varphi = 0$, $\psi = 180$) detected for $(NPF_2)_n$, $(NPCl_2)_n$, $[NP(OCH_2CF_3)_2]_n$, and $[NP(OC_6H_5)_2]_n$ from the X-ray analysis. Secondly, the barriers to individual bond torsion are calculated to be surprisingly low for the polymers with the lowest glass transition temperatures, such as $(NPF_2)_n$, $(NPCl_2)_n$, $[NP(OCH_3)_2]_n$, $[NP(OC_2H_5)_2]_n$, and $[NP(OCH_2CF_3)_2]_n$. Thus, it appears that the low-temperature flexibilities of these polymers are a consequence of the absence of serious bon-bonding intramolecular interactions as the backbone bonds undergo broad torsional motions. Even for $[NP(OC_6H_5)_2]_n$, the bulky phenoxy residues can undergo subtle avoidance motions that permit a low energy pathway for backbone bond torsion.

It should be pointed out that these calculations did not take into account the possibility that an inherent barrier could exist in this system due to the presence of $d\pi$-$p\pi$ backbone bonding. However, the *experimental* evidence from X-ray diffraction work and spectroscopy with small phosphazene mole-

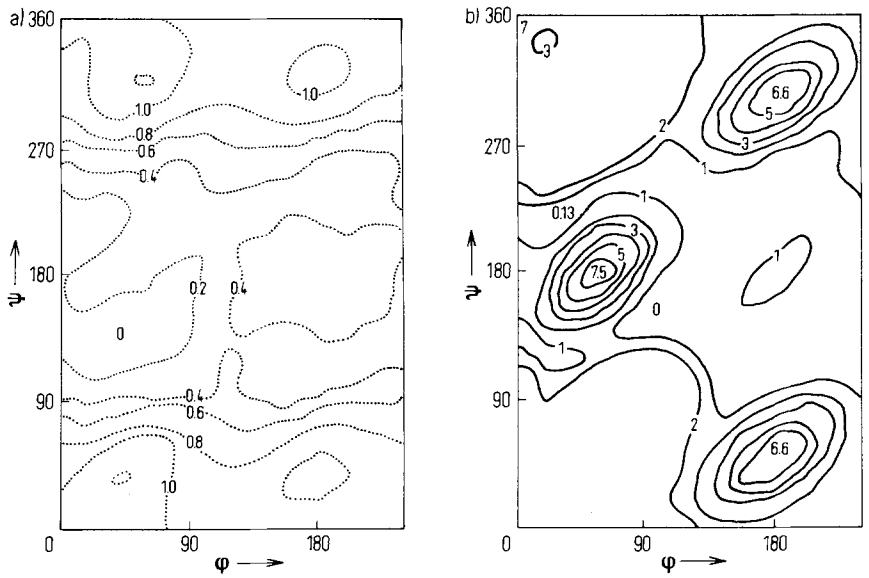

Fig. 3. Conformational energy surfaces calculated for (a) $(NPF_2)_n$ and (b) $(NPCl_2)_n$ [104]. The important features are the extreme flatness of the surface in (a), the low energy pathway for conformational changes in (b), and the presence of low energy minima near the *cis-trans* planar conformation ($\varphi = 0$, $\psi = 180$). The contour designations are in kcal/residue. For these calculations, bonds φ' and ψ' were allowed to assume minimum energy conformations as bonds φ and ψ were varied.

cules favors the view that such bonding, if it exists, exerts only a miniscule influence on the conformational behavior.

13. Possible Applications

The poly(organophosphazenes) that have been synthesized to date have generated considerable interest from an applications point of view. The following are the main areas of current interest and activity.

Firstly, most polyphosphazenes do not burn, and many are flame retardants for other polymers. Fabrication into fibers is relatively easy. Hence, textiles form a logical area for the future uses of polyphosphazenes. Added to this is the fact that specific polyphosphazenes (such as, $[NP(OCH_2CF_3)_2]_n$) are highly water- and oil-repellant and can be dyed or substituted with dye molecules. Thus, their long-range potential in textile technology becomes obvious. However, at the present time, polyphosphazenes are expensive, and the most logical initial developments are as fibers for fire-resistant fabrics or for co-weaving with conventional organic polymer fibers.

Secondly, as discussed in Section 5, mixed substituent poly(organophosphazenes) are elastomers, often with very low glass transition temperatures. It is these materials that have received the most intense technological attention as oil-resistant, low temperature elastomers for high performance applications in the aircraft, automobile, and oil technology areas[52, 55, 56, 62, 63]. One company in the United States[61] is currently producing seals, gaskets, flexible hoses, and expanded foams based on a variety of polyphosphazene formulations, and this area of application is expected to grow.

Thirdly, the film-forming polyphosphazenes offer some advantages over conventional organic films. Again, they are fire-resistant and can be carefully designed to have specific surface characteristics, adhesion properties, or solvent insolubility. Because the polyphosphazene backbone is essentially transparent to ultraviolet light at wavelengths longer than about 200 mμ, the weathering stability of some polyphosphazenes is expected to be higher than that of organic polymers. Other possibilities exist as electrical insulators or flexible wire coatings, but no actual products have yet been marketed in this area.

Finally, the strong possibility exists that polyphosphazenes will be used either to fabricate or to coat biomedical replacement devices, such as artificial heart pumps. The extreme water-repellency, coupled with high elasticity and low fat absorption that can be achieved with polyphosphazenes, makes them ideal candidates for this type of application. In initial *in vitro* blood compatability tests, they appear to be superior to silicone rubber or conventional organic polymers. From a long-range point of view, the water soluble polyphosphazenes may prove valuable as chemotherapeutic drug carrier molecules, and this aspect is receiving considerable attention in our own research group at the present time.

The polyphosphazene research in our group has been generously supported by grants from the U.S. Army Research Office, Office of Naval Research, N.A.S.A., The Firestone Tire and Rubber Company, and the National Heart and Lung Institute of N.I.H.

Fully Automatic Potentiometric Titrations

New analytical methods (9)

By Siegfried Ebel and Angelika Seuring[*]

Fully automatic titration systems consist of at least two units: the sample-changing system and the measuring system, the latter including addition of the reagent. These systems are preferably coupled to a computer. The possibilities of fully automatic titration can be best utilized if the sources of error are taken into account and the evaluation procedure optimal for the specific analysis is selected.

1. Introduction

Potentiometric titrations are nowadays used routinely in many laboratories for the control of raw materials, intermediates, and end products. Whereas until a few years ago their range of application was restricted mainly to acid/base, redox, and a few precipitation reactions, the introduction of ion-sensitive electrodes has enabled this range to be greatly extended. From a historical point of view, purely manual titration with color indicators was followed by potentiometrically indicated titrations in which the measurements were made stepwise and noted individually, later there came automatic recording by potentiographs, and finally digital potentiometric titrations with on-line coupled computer systems. Further, the use of sample changers made it possible to provide fully automatic procedures, except for preparation of the sample.

At first sight each improvement in apparatus appears to be accompanied by an increase in accuracy and reproducibility, but in reality typical systematic errors arise with each new development. In the present review we shall look critically at current possibilities afforded by automated titration with potentiometric indication of the end point, attention being directed mainly at the sources of error and the evaluation. So far as is necessary for an understanding of systematic errors we shall make some remarks on the problems of measurement and on the general character of titration curves.

Since in most cases only commercially available titration systems will be of interest to the reader, we have intentionally refrained from reporting on special apparatus described in the literature[1–5]. Moreover, only the potentiometric end-point indication will be discussed, despite considerable interest in colorimetric titration because of its use on a microscale[6] and despite the development of computer-controlled systems[7]. The theoretical principles, general outlines, and literature reviews of the fields of potentiometry, potentiometric titrations, and automation are provided in the cited monographs [5, 8–19] and review articles[20–23].

2. Problems of Measurement

In manual titrations the operator can interfere at any time in the analytical procedure and prevent mistakes or compensate for interference; very often this is done unconsciously. In fully automatic systems, however, any disturbances or even conditions that could lead to systematic errors must be recognized in advance and removed. We shall therefore discuss here some general problems of measurement. In some cases further interferences can occur, including in particular changes of the potential difference of the measuring circuits due to the "matrix"[*].

The potential difference ΔE between an indicator electrode and a reference electrode, which depends on the volume of reagent added, is the measured quantity that constitutes the basis of all potentiometric titration curves. In most measuring circuits the reference electrode is separated by a diaphragm from the solution being measured. According to the Nernst equation, there is a direct relationship between the potential of the measuring electrode and the logarithm of the activity a_x of the ion to be determined. The overall valid relationship is given by equation (1), which includes the constant potential of the reference electrode $E^{\ominus}_{Ref}$ and the diffusion potential E_j at the diaphragm, the latter being often responsible for major disturbances.

$$\Delta E = -\frac{RT}{nF} \ln a_x + E_j + E^{\ominus}_{Ref} \qquad (1)$$

If the activity of the ion to be measured is changed by the addition of a further definite amount of this ion (the standard addition method, especially with ion-selective electrodes) or by reaction with the added reagent (titration), then the potential difference of the measurement circuit will also change. Important problems arise at this point: all time-dependent phenomena falsify the course of the titration curve from that expected on the basis of thermodynamic constants (acidity constant, solubility product, *etc.*). There are six main points that warrant special attention in automated titrations.

2.1. Mixing Effects

Provided that stirring is vigorous no difficulty worth mentioning arises when titrations are carried out with solvents of low viscosity, with large volumes of the solution under analysis, and with none to great a difference in concentration between this solution and the reagent. However, in solvents such as nitrobenzene, chlorobenzene, and methylcellosolve the mixing times can be considerable. With rapidly responding electrodes this can result in increased noise, which may upset the end-point titration, or—at least shortly before reaching

[*] Prof. Dr. S. Ebel, A. Seuring

Marbacher Weg 6, D-3550 Marburg (Germany)

[*] By "matrix" is meant all the accompanying components of the sample under analysis.

the equivalence point—in extreme cases in "overshooting" of the electrode potential (cf. Fig. 8).

2.2. Kinetics of the Chemical Reaction

Acid-base reactions occur so fast that kinetically-determined effects should have no influence on their course. However, in precipitation reactions, especially in highly dilute solutions, considerable systematic errors can arise. Supersaturation effects appear in the early part of the titration, and there follows a region where supersaturation recedes. Near the equivalence point adsorption phenomena can lead to additional errors. The kinetics of precipitate formation[24, 25] are not yet understood in all their details. Appreciable errors due to kinetics can also arise in the titration of organic substances; examples are the determination of primary aromatic amines by diazotization, titanometric titration of nitro groups, and bromometric determination of aromatic compounds, where accurate matching of the rate of titration to the specific analytical problem is essential.

2.3. Response Time of the Measurement Electrode

In aqueous solutions glass electrodes usually have a very short response time. Appreciably longer response times are, however, found in mixed solvent systems (*e.g.* methanol/water), in protic solvents (*e.g.* alcohols, glacial acetic acid) and above all in aprotic solvents (*e.g.* dioxane, sulfolane)[26, 27]. These longer times cause a noticeable flattening of the titration curves, and thus lead to excessive consumption of reagent. Particular attention must be paid to relaxation effects due to concentration differences when working with ion-selective electrodes. The response of such electrodes has been studied in detail[28–31]; in particular, in the case of liquid-exchanger and gas-sensitive electrodes the response times are usually appreciably lengthened owing to the phase transitions occurring before establishment of the potential.

2.4. Diffusion Potential Relaxation

The reference electrode is always in a solution of constant defined composition and thus does not give rise to time-dependent phenomena. However, diffusion phenomena can alter the diffusion potential at the diaphragm and thus lead to systematic errors (Fig. 1). In view of the large throughput of samples to be analyzed, *i.e.* short times of analysis, sought for in automatic titration systems, this source of error should never be completely neglected.

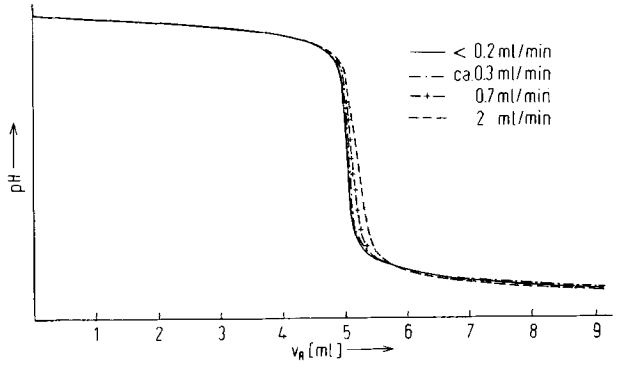

Fig. 1. Influence of the diffusion potential at a combined glass electrode on a titration curve [32]. The rate of addition of a strong acid to base is shown. v_R = reagent volume.

2.5. Potential Drifts

Over longer periods of time the potential difference of a measuring system can be affected by external influences. Such potential drifts may not only be in one direction but also fluctuate about some mean value. For example, glass electrodes in aqueous and above all in nonaqueous solvent systems may show potential drifts caused by changes in the gel structure of the swollen outer layer; here reconditioning in water may prove helpful. With ion-selective electrodes potential drifts are sometimes caused by the matrix. Finally, with platinum electrodes uncontrolled changes in the potential difference may occur; these are often caused by oxidative processes or adsorption phenomena.

It should also be noted that the potential of the Ag/AgCl reference electrode depends measurably on the intensity of the light; this effect is seldom of importance in the case of normal titrations, but it may cause serious disturbances during prolonged operation of fully automatic sample changers, particularly when reducing substances can diffuse into the reference electrode system (SO_2 electrodes[33]).

2.6. Electrostatic Charges

In solvents of low dielectric constant charged particles are present mainly as ion pairs and not in free form. Such solutions are thus very poor conductors of electricity. As a further consequence, occasional electrostatic charges cannot drain fast enough from the reference electrode that is at zero potential. The result is a change in the potential difference of the measurement circuit, which under certain circumstances may only slowly regain the value determined solely by the electrochemical reaction. Taking data for the potential recorded at the moment where an electrostatic potential is superimposed on the measurement potential, will in many cases (*e.g.* end-point titration) lead to faulty analysis.

3. Titration Curves[15, 35–41]

Potentiometric titration curves give the relationship between the potential difference ΔE of the measurement circuit and the added volume v_R of the reagent. The following definitions are of importance regarding the evaluation of titration curves.

Equivalence point: This is defined by the stoichiometry of the chemical reaction forming the basis of the titration and by the initial and the reagent concentrations (c_A, c_R).

Point of inflection: On a typical potentiometric titration curve there is usually a point of inflection in the vicinity of the equivalence point. This point can be calculated from the fundamental set of equations of the titration curve.

End point: Evaluation of a titration curve leads to an end point subject to random and synthetic errors and dependent on the method employed.

In this review we shall not go further into the theory of titration curves, but it must be noted that in volumetry there

is not a single case of a symmetrical titration curve. Even the titration curves of strong acids or bases or of isovalent precipitations show at least slight asymmetry. This is also immediately apparent from the set of equations for the titration curve (the fundamental set of equations; here for the titration of a strong acid with a strong base):

$$a_{H_3O} \cdot a_{OH} = K_w \tag{2}$$

$$[H_3O^+] + c_T = [OH^-] + c_B \tag{3}$$

$$c_T = \frac{c_R \cdot v_R}{v_A + v_R} \tag{4}$$

$$c_B = \frac{c_A \cdot v_A}{v_A + v_R} \tag{5}$$

c_A initial concentration, c_R concentration of reagent, v_A initial volume, v_R volume of reagent

Apart from the fact that the mean activity coefficient $f_\pm$ and thus the combination of $[H_3O^+]$ and a_{H_3O} (and of $[OH^-]$ and a_{OH}) changes during the titration, the asymmetry of the titration curve is caused mainly by the change in volume. Moreover, eq. (3) is not symmetrical with respect to $[H_3O^+]$ and $[OH^-]$. Consequently, the equivalence point and the point of inflection cannot be identical, as was already demonstrated by *Roller*[34] as early as 1928. However, the steeper the titration curve in the vicinity of the equivalence point, the smaller is the error if the point of inflection is regarded as the end point of the titration. The error can be considerable ($> 1\ \%$) in strongly asymmetric titrations (heterovalent redox or precipitation titrations).

4. Sample Changer

The phrase "automatic titration" has changed its meaning appreciably in recent years. Whereas about 15 years ago a potentiograph with automatic cut-off at the equivalence point was regarded as an automatic titrator[5, 19], today it is expected that at least sample transport and delivery of reagents be fully automated. Ideally the mechanization should go so far as to include automation of sample preparation and treatment (*e.g.* warming, boiling under reflux); this is quite possible in industrial automatic systems, but no laboratory device of this kind that functions on a really routine basis has as yet been described.

At least a certain degree of flexibility is required of automated laboratory systems, *i.e.* they should be designed for use on a multipurpose basis. Two variants of such systems can be employed. In one of them a large number of samples are processed simultaneously, *i.e.* for each individual sample there must be a mechanical buret[1]; the mechanical demand is enormous, since each sample also requires its own electrode; and further problems arise with the multiple high-impedance changeover switches. In the second type the sample is transported to the titration site; for this purpose a transport system such as is used for column chromatography suffices[3]. A disadvantage of such sample changers (and of commercial systems with exclusively linear sample transport) is that strictly speaking only one definite working position is available, and thus no mechanizable step can be carried out before the actual titration. Magazine changers are much more versatile (cf. Fig. 2)[42, 43]. Each magazine contains a definite number

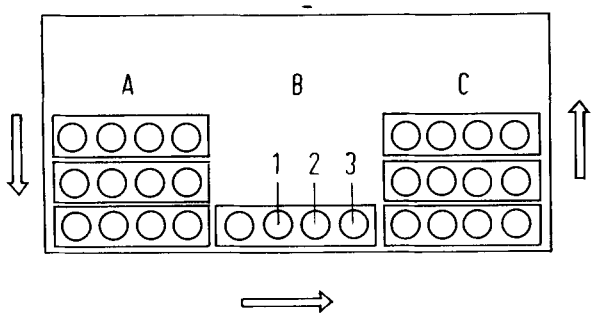

Fig. 2. Principle of Metrohm E 503 sample changer [42, 43]. A: magazines awaiting use; B: magazine in use; 1 addition of auxiliary solutions, covering of titration vessel, *etc.*, 2 delivery of solutions in back-titration; 3 titration; C: magazine previously used. Arrows indicate the direction of movement of the magazine.

of samples forming one mechanical unit. Thus, the samples can be prepared individually or together at a determined place in the sample changer. Moreover, such a system enables additional manipulations to be effected before the titration (addition of auxiliary solutions, *e.g.* TISAB solution when working with ion-sensitive electrodes, or buffer solutions in complexometric titrations; addition of standard solutions in back-titration).

Furthermore, all sample-changing systems should be so designed that rinsing processes can be incorporated in the system, so that memory effects can be reduced to a minimum.

At the Achema 1976 exhibition a further very interesting possibility was demonstrated: a sample-changing system with a multiburet titrator. The individual titration vessels are transported under computer control to their appropriate places preselected for a particular titration process. Here, addition of auxiliary reagents and the actual titration can be carried out. It is thus possible to automate small series of analyses or even repeated successive single analyses[44].

In the simplest set up the sample is identified by its serial number, but systems involving active sample identification by magnetic or optical coding of the magazine are also available[43, 44]. Weighing of the sample can also be incorporated in the system by way of an electronic digital balance with identification of the individual samples[45].

5. Fully Automatic Titration Systems

By fully automatic titration systems we mean here those apparatus that automatically titrate a certain number of samples. Other operations (*e.g.* dilution, addition of auxiliary solutions) may be integrated within the system. Selection and treatment of the sample are generally not included in the automation. In this section we shall try, on admittedly subjective examples, to describe the various types of fully automated titration systems. Such systems must fulfil all the demands—instrumentally or electronically—arising from the problems outlined in Sections 2 and 3.

5.1. Automatic Analog Recording Systems

In the simplest case with fully automatic titration systems one can start with the analog recording titration curves and evaluate them manually by one of the known graphical methods[46] (tangent method[47], Tubbs' circle method[48], intersection method[49]). It follows that the control unit then has to deal only with sample transport and the actual titrator (Fig. 3). Such a system may at first sight seem antiquated in this era of digital readouts and computerization, but it has two advantages that should not be overlooked. In the first place, when the titration is complete the whole titration

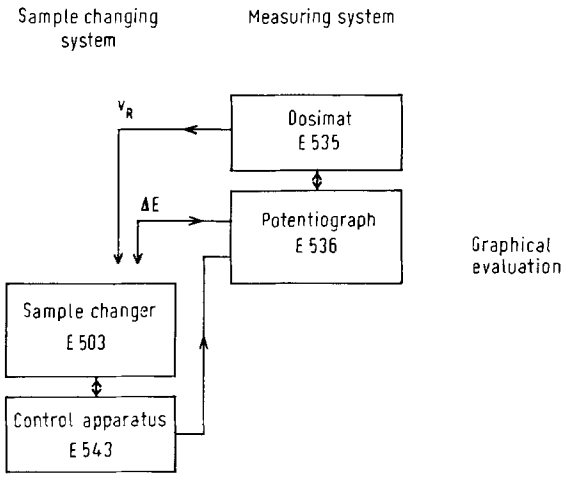

Fig. 3. Block diagram of the Metrohm fully automatic analog recording titration system E 553/12.

curve is available as a record from which an experienced analyst can deduce more information than, for example, just

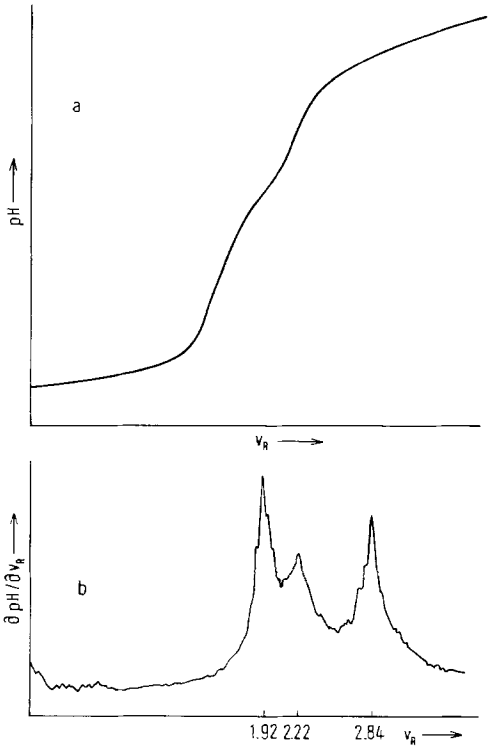

Fig. 4. Titration curve of an acidimetric simultaneous titration: HCl ($c_A = 0.01$ mol/liter), acetic acid ($pK_a = 4.75$, $c_A = 0.033$ mol/liter), and 4-nitrophenol ($pK_a = 7.15$, $c_A = 0.017$ mol/liter); titration with 0.1 N NaOH; Metrohm E 536 potentiograph; combined glass electrode. a) Normal titration curve, b) differentiated titration curve.

the end point. The second advantage is that direct recording of titration curves differentiated with respect to the reagent volume can now be simply effected, the volume of reagent added being matched to the change in potential difference, *i.e.* time-dependent phenomena can be largely eliminated from differentiated titration curves. In complicated titrations, *e.g.* in the simultaneous determination of similar components (Fig. 4) or of components present in very different concentrations (Fig. 5), evaluations can often be made only from the differentiated titration curve.

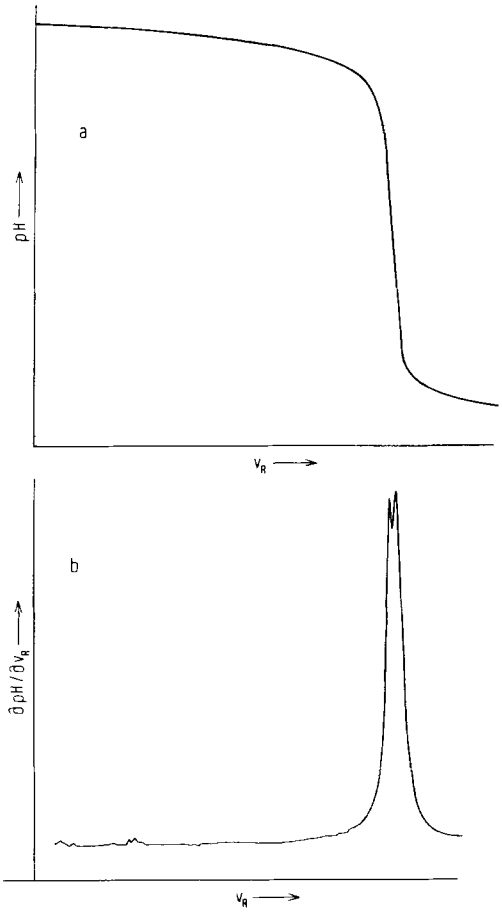

Fig. 5. Titration curve for 0.1 N NaOH containing carbonate *vs.* 0.1 N HCl. Metrohm E 536 potentiograph; combined glass electrode. a) Normal titration curve, b) differentiated titration curve. Both titration curves with the addition of reagent matched to the change of potential difference.

5.2. End-point Titrators

In routine analyses titrations are often carried out up to a prescribed potential difference in the measurement circuit, *i.e.* subject to certain criteria the control mechanism adds reagent solution until this specified value has been reached. Such titration systems with corresponding sample changers for fully automatic operation with a prescribed number of samples are available from several different manufacturers (Metrohm, Herisau/Switzerland (Fig. 6); Mettler, Greifensee (Fig. 7); Radiometer, Copenhagen).

Any deviation of the true end-point potential of the titration from the preselected end-point potential involves an error that is the greater the flatter is the titration curve in the vicinity of the end point. The errors caused by such deviations can be calculated[50–56], but they can also be very simply

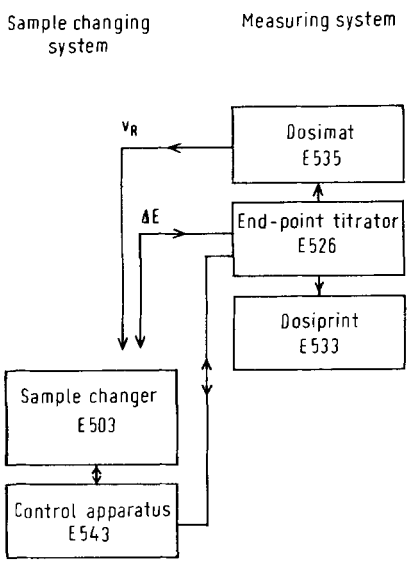

Fig. 6. Block diagram of the Metrohm end-point titrator E 553/9 (without data processing). The result of the titrations can be printed out.

determined by experiment: one first titrates to a defined potential (deviating *e.g.* −10 mV from the theoretical value) and then continues titrating, after alteration of the pre-selected end-point potential, up to the theoretically correct value; the error can be easily determined from the respective amounts of reagent consumed on these two occasions.

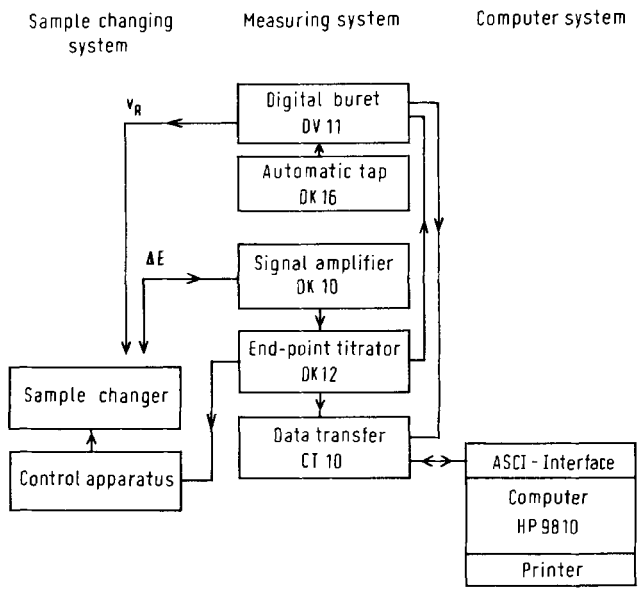

Fig. 7. Block diagram of the Mettler end-point titrator (with on-line data processing).

Errors due to potential drift (cf. Section 2) become very evident with end-point titrations. Potential drift can readily occur in long series of measurements, particularly with fully automatic sample exchange, and thus leads to a systematic succession of errors. In addition, changes arise in the real end point owing to temperature differences (particularly during overnight operation) or to evaporation of solvent and absorption of CO_2 during long intervals between sample preparation and titration if the sample containers are not closed (remedy: penetrable foils or stoppers, removable caps).

Furthermore, the end-point potential depends not only on the substance to be determined and on the reagent but also on the total matrix. In this respect special mention should be made of the influence of foreign salts on the activity coefficients and the alteration of thermodynamic parameters by high concentrations of inert substances. The almost uncontrollable influence of the diffusion potential at the diaphragm of the reference electrode should also be noted. It is therefore absolutely essential to determine the end-point potential with a sample that is identical with or at least very similar to those to be analyzed; it is also advisable to use the same end-point titrator for this determination and all subsequent analyses, since no additional parameter due to a different instrument can then interfere[57].

It is very important to match the rate of addition of the reagent to the course of the titration curve; if the titration is too fast, there is a danger of overtitrating, especially when the curve is very steep; on the other hand, the analysis time should be as short as possible, especially when working with sample changers. Several solutions to these problems have been described.

In the simplest case the difference between the actual and the true value can be used to match the pulse repetition frequency of a variable-speed motor-driven piston buret to the titration curve; or the analog-produced derivative of the potential curve can be used to control the buret. In addition, good commercial systems have reversible matching stages which facilitate optimum adjustment of the control mechanism to suit the titration.

For slow redox titrations (*e.g.* diazotization, reduction by $TiCl_3$) a special regulatory mechanism was proposed[58] and has been realized commercially (Redoxomat; Colera, Lorch). The typical potential/time relationship of incremental redox titrations exhibits the following peculiarity: after addition of reagent the potential at first changes more than would correspond to the actual course of the reaction and then, after consumption of an intermediary excess of reagent, readjusts itself to the true value.

This secondary potential change is utilized for addition of the reagent by means of a relay system. At the end point there is no further change of potential, no more reagent is added, and after a certain delay time the titration is broken off. Thus, the relay system takes over both matching the rate of the titration and recognition of the end point. Since the potential behavior of platinum electrodes is not always completely reproducible, this system should in some cases be superior to end-point titration.

We should, however, mention one essential disadvantage of all end-point titrators: the result is, after all, just one single value, namely the volume v_E of reagent needed to reach a prescribed end point. This provides no possibility of drawing conclusions about interferences or any properties of the sample or about the cause of a deviation.

5.3. Digital Titration Systems

In automatic titration systems titration curves or titration data are generally obtained digitally, *i.e.* one obtains a series of measurements from data on the volume of reagent added and the corresponding potential difference of the measuring circuit employed. In principle, all the commercial systems operate in such a way that the volume of reagent dispensed

increases by constant predetermined amounts. The principal elements of the digital titrator are the buret unit for reagent addition and the control unit that supervises the system and at the same time, as its most important function, takes over the elimination of time-dependent phenomena. The control unit for the sample changer is separate. In all cases the digital titration data must be evaluated by computer, *i. e.* fully automatic digital titration systems with sample changers are whenever possible, connected on-line to a computer.

5.3.1. Reagent Addition

Most of the modern titration systems, whether commercially available or described in the literature (see *e.g.*[59]) make use of variable-speed motor-driven piston burets. Delivery of the exact amount of titrant with defined volume increments is considerably simpler with this driving system than with piston burets operated by a synchronous motor or mechanically—the latter have now been largely abandoned. A further advantage is the easy digitalization by means of counters. Addition of the reagent is probably the part of the whole system that leads to the smallest number of errors in analysis. The usual commercial piston burets (*e.g.* Metrohm Dosimat E 535) attain reproducibilities of $<0.01\,\%$ and accuracies of $<0.04\,\%$[60] ($<0.01\,\%$[61]).

One other, very unconventional, method of adding the reagent should be mentioned: micro drops are produced by means of a micromagnetic valve and a mechanical chopper; these drops are controlled by strong electric fields and finally counted[2, 62–64]. However, calibration is rather troublesome, so that this method of adding the reagent is hardly likely to be suitable for routine operation.

5.3.2. Exclusion of Time-dependent Phenomena

Time-dependent phenomena can falsify a titration curve and thus lead to considerable systematic errors. Several technical possibilities have been proposed for excluding these effects to the maximum possible extent. In the simplest case one can operate with a time control, as in the Metrohm Titroprint E 475[64]. A delay time between addition of the reagent and measurement of the result is pre-set on the apparatus; this interval must be adjusted to suit the titration at hand. A disadvantage of this method is that the same interval must be retained throughout the whole titration, whereas the potential is set up at rates that vary during a titration—here we need only mention the longer times for the establishment of the potential near the equivalence point.

Another possibility is to use the variation of electrode signal with time after addition of the reagent to decide the moment when data shall be recorded. In the simplest case the analog produced derivative of the change in potential (Fig. 8) is used to control the data rate: transfer of the measurement to the read-out unit (computer, punched paper tape, print-out device) is carried out when the variation rate is smaller than a set threshold (*e.g.* 1 mV/min). One then waits until the chemical and thus also the electrode equilibrium has been established (to within a small error of time) (Mettler Equilibrium Titrator DK/DV system[65]). A similar system was used by *Boldt* and *Lackner* in 1963[66] for very slow redox titrations, for which a relay-controlled analog memory was used. In computer-controlled titration systems the computer

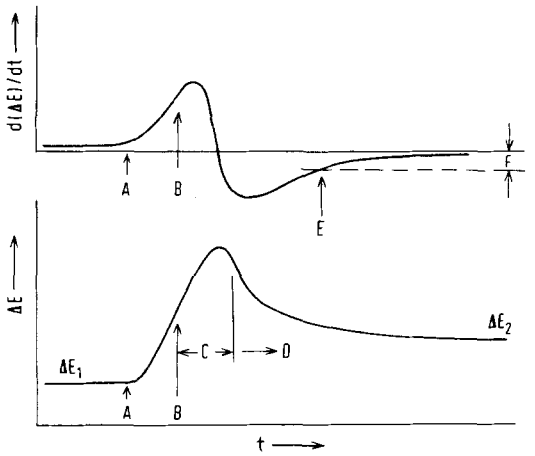

Fig. 8. Time-dependence of the potential in discontinuous titrations. Bottom: normal signal; top: signal differentiated with respect to time. A Beginning of addition, B end of addition, C overshooting of the cell potential (does not occur in all types of titration); waiting time to avoid incorporation of false potential, D adjustment phase of the cell potential (and its registration) on the equilibrium potential, E transfer of the potential to the computer or memory, F switch threshold, ΔE_1 equilibrium potential before reagent addition, ΔE_2 equilibrium potential after reagent addition.

can also take over the function of equilibrium titrator. *Anfält* and *Jagner*[1] described such a system, in which appropriate averaging leads to a decrease in statistical fluctuations and an improvement in the signal-to-noise ratio. In our experience such systems are especially useful when working with ion-selective electrodes[67]. Fig. 9 shows the block diagram of a system

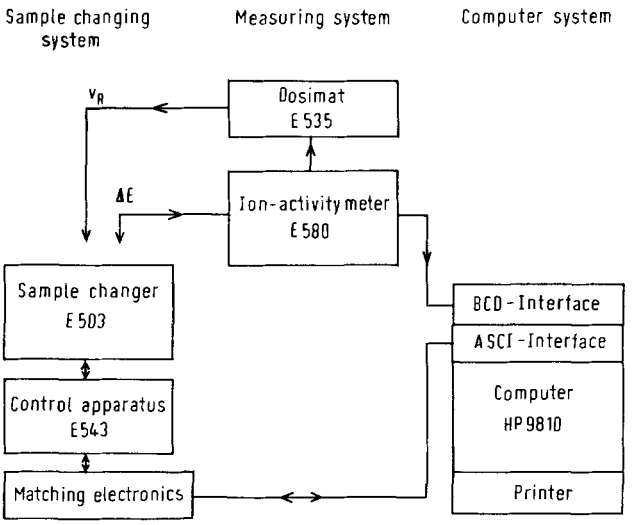

Fig. 9. Block diagram of a fully automatic system, made up of commercially available components, for direct potentiometry with ion-selective electrodes [69].

constructed almost wholly of commercially available units (only logic matching of computer pulse to input signal of controller is required[68]).

5.3.3. Data Processing

Digital titrations require numerical calculation of the end point. With fully automatic titration systems the output of data is so large that data processing is essential. It has long been a subject of dispute, or rather of philosophy, whether to work with an on-line computer or first transfer all the data onto an intermediate tape or punched cards. From the

point of view of the price/performance ratio direct data processing with a very efficient desk calculator (*e.g.* Hewlett-Packard HP 9810, 9815, 9830) is considered optimal, since a calculator with the necessary interface costs almost exactly as much as a punched paper tape or even magnetic tape unit with the necessary interface. The block diagrams in Figs. 10 and 11 show fully automatic digital titration systems built up exclusively of commercially available components and which have proved satisfactory in our laboratory.

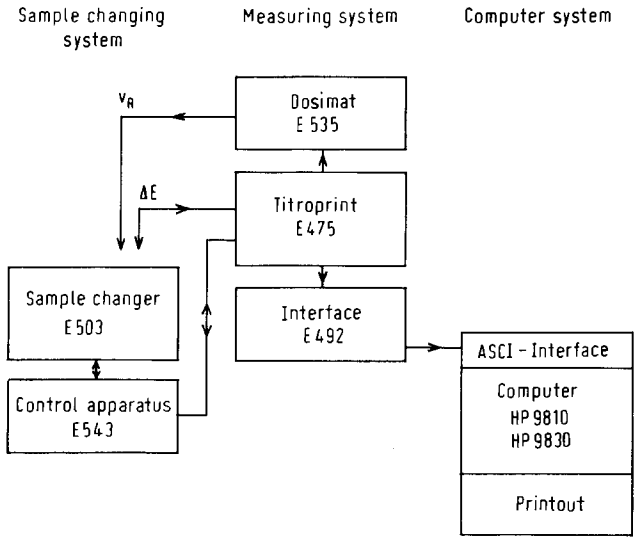

Fig. 10. Block diagram of a fully automatic digital titration system based on the Metrohm Titroprint E 475.

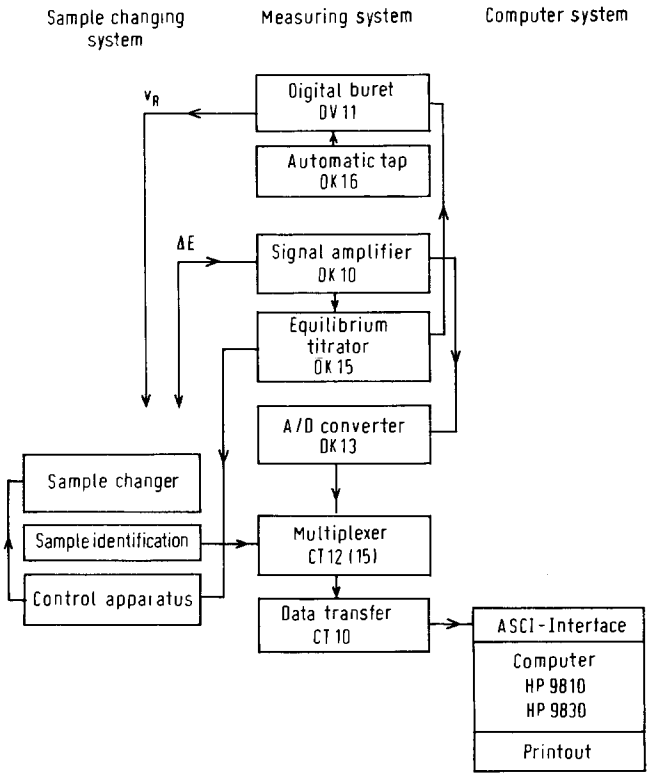

Fig. 11. Block diagram of a fully automatic digital titration system based on the Mettler equilibrium titrator (DK/DV system).

5.4. Systems Controlled by a Microprocessor

In 1976 the Radiometer company introduced a titration system controlled by a microprocessor[70]. In this system five collected values are averaged (digital suppression of noise), and the mean is recognized as a measured point if the potential change is less than 0.4 mV/s or if 45 s have elapsed since the last addition of reagent. The magnitude of the next volume increment is calculated according to eq. (7) from the titration curve differentiated with respect to reagent volume

$$\frac{\partial \Delta E}{\partial v_{R(n,n-1)}} \approx \frac{|\Delta E_n - \Delta E_{n-1}|}{\Delta v_{R(n,n-1)}} \tag{6}$$

$$\Delta v_{R(n,n+1)} = \frac{a}{b + \frac{2\partial \Delta E}{\partial v_{R(n,n-1)}} - \frac{\partial \Delta E}{\partial v_{R(n,n-2)}}} + c \tag{7}$$

a, b, c are empirically derived constants.

Furthermore, after each addition of reagent a test is carried out to see whether an inflection point in the titration curve has been passed through. If so, the inflection point is calculated by *Hahn-Weiler* or *Kolthoff-Furmann* procedures, modified to account for unequal increments in volume of reagent. The titration curve may show several inflection points, *i.e.* simultaneous titrations can also be carried out.

6. Evaluation of Digital Titrations[71]

Many processes have been described for the determination of the end point of a digital titration; they can be divided into three groups:

1. Simple approximation methods. These generally use only three points near the equivalence point.
2. Mathematical methods. These use all the measurements and require knowledge of the mathematical course of the titration curve.
3. Exhaustive approximation methods. These use all the measurements, approximate the titration curve by a selected function, and determine the inflection point.

This classification gives no indication of the accuracy attainable, the liability of the method to occasional error, or the sensitivity to time-dependent phenomena.

6.1. Simple Approximation Methods

The first methods for the evaluation of digital titrations were described as early as 1926. This is not surprising, since potentiometric titration curves initially had to be recorded manually and stepwise. *Hahn* and *Weiler*[72] started from the crude simplification that the equivalence point and the inflection point coincide, *i.e.* that the titration curve is symmetrical up to that point. In a further simplification difference quotients were used in place of the differentiated titration curve to determine the inflection point. The same procedure was described by *Kolthoff* and *Furmann*[73] in a more general formulation.

On the basis of experimental work and theoretical considerations, *Hahn*[15, 74] arrived at some improved methods. The starting point of his considerations was that the "outer zone" of the titration shows only slight potential change, while the "inner zone" harbors nearly all of the potential jump. The

nomogram method described by *Hahn*[75] as early as 1928 is the most interesting; it was later published again by *Fortuin*[76] in similar form and in fact only then became well known. Numerous variations based on it have been published by *Wolf*[77] and by *Keller* and *Richter*[78] for use with automated titrations. The last-named procedure in particular, which was based on systematic considerations of approximations[79], yields exceptionally good results without involving very much mathematical effort. Error simulation calculations show that it is far superior to all other simple approximation methods[80–82] and often even more reliable than the considerably more demanding mathematical procedure. It should also be mentioned that all simple approximation methods are actually valid only for titrations of strong acids or for isovalent precipitation titrations, although they can be readily used also for titrations of weak acids or titrations in anhydrous glacial acetic acid[77, 83]. Unsymmetrical titration curves (from, *e.g.* heterovalent precipitation titrations) can be evaluated if the asymmetry is taken into account by heterovalence equalization arising directly from the stoichiometry[84].

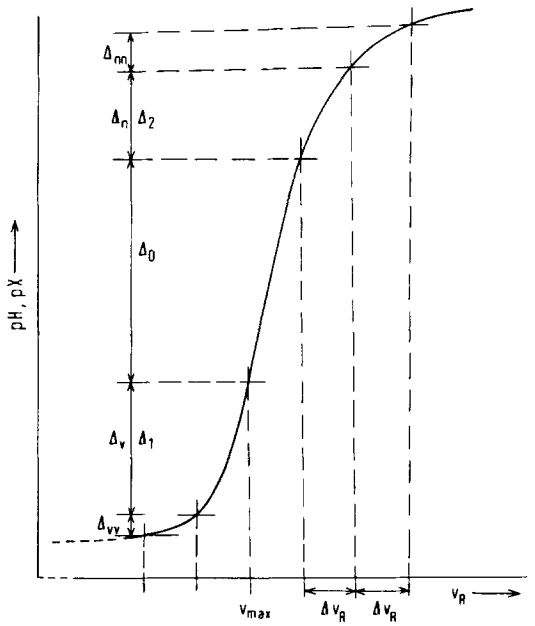

Fig. 12. Evaluation of digital potentiometric titrations by the simple approximation method. The indices v and n refer to volume increments respectively before and after the largest potential jump. $\Delta_0 > \Delta_1 > \Delta_2$.

All simple approximation methods for the evaluation of digital potentiometric titrations use only the three largest potential steps and assume constant increments of the reagent volume. With the aid of the factor ρ [see eqs. (11) to (17)] the end point can be calculated for all procedures by means of eq. (8) (for explanation of the symbols see Fig. 12; v_E is the volume of reagent required to reach the equivalence point).

$$v_E = v_{max} + a\Delta v_R + b \cdot \rho \cdot \Delta v_R \quad (8)$$

$$a = \begin{cases} 0 \text{ for } \Delta_v > \Delta_n;\ \Delta_1 \text{ before } \Delta_0 \\ 1 \text{ for } \Delta_v < \Delta_n;\ \Delta_1 \text{ after } \Delta_0 \end{cases} \quad (9)$$

$$b = \begin{cases} +1 \text{ for } \Delta_v > \Delta_n;\ \Delta_1 \text{ before } \Delta_0 \\ -1 \text{ for } \Delta_v < \Delta_n;\ \Delta_1 \text{ after } \Delta_0 \end{cases} \quad (10)$$

$$\rho = \frac{\Delta_0 - \Delta_1}{2\Delta_0 - \Delta_1 - \Delta_2} \quad [72, 73] \quad (11)$$

$$\rho = \frac{\Delta_2}{2\Delta_1} \quad [15, 74] \quad (12)$$

conditions: $\Delta_1 \leq 2\Delta_2;\ \rho \geq \frac{\Delta_1}{\Delta_0};\ \rho \geq 0.3$

$$\rho = 1.58 \cdot \lg \frac{\Delta_2}{\Delta_3} \quad [15, 74] \quad (13)$$

conditions: $\Delta_2 < 1.5\Delta_3$ [a]

$$\rho = \frac{\Delta_2}{2\Delta_1} - 0.35 \cdot \left(0.3 - \frac{\Delta_2}{2\Delta_1}\right) \quad [15, 74] \quad (14)$$

conditions: $0.3 \geq \frac{\Delta_2}{2\Delta_1} \geq 0.15$

$$\rho = 0.5 \cdot R_2 - 0.2 \cdot R_1^2 \quad [75, 76] \quad (15)$$

$$\rho = [0.5 \cdot R_2 - 0.3 \cdot R_1^2(1 - R_2)](1 - R_1^6) \quad [77] \quad (16)$$

$$\rho = \frac{18R_2 - 5R_2^2 - 10R_1^2R_2 - 3}{20 - 20R_1^2R_2} \quad [78] \quad (17)$$

conditions: $\rho \geq 0.1$

$$R_1 = \frac{\Delta_1}{\Delta_0};\ R_2 = \frac{\Delta_2}{\Delta_1}$$

[a] Δ_3 is defined in analogy to Δ_1, Δ_2 as the fourth largest potential step.

Some methods are applicable only under certain conditions; if these are not fulfilled, the desired result can be achieved by combining two potential steps, so that $\Delta_0 + \Delta_1$ becomes the new Δ_0.

A disadvantage of all simple approximation methods is that only three measured points near the equivalence point are used for the evaluation. Precisely these points however, are liable to be subject to errors due to the time-dependent phenomena mentioned above (adjustment of electrode potential, kinetics of the titration reaction, time constant of the measuring system, *etc.*). The error in the analytical result due to these causes can be estimated[80, 81] (cf. Fig. 13). It

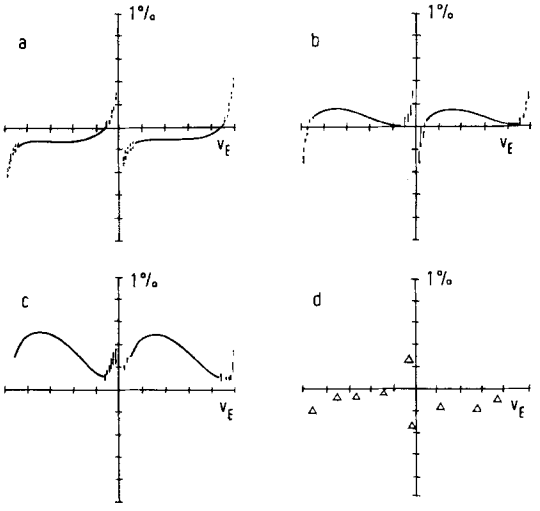

Fig. 13. Error of the *Keller-Richter* numerical version [78] of the *Hahn-Fortuin* [75, 76] simple approximation method for different magnitudes of the potential transfer error caused by time-dependent phenomena [80, 81], and practical results [86]. a) Without time-dependent error, b) potential recording 98% of the theoretical value, c) potential recording 95% of the theoretical value, d) practical results. Titration of a weak acid: $c_A \approx 0.02$ mol/liter, $c_R \approx 0.1$ mol/liter, $pK_a \approx 6$.

can then be seen that a potential transfer error of, *e.g.*, 1 or 2 % can occur precisely at the end point, *i.e.* the largest potential difference becomes too small by this amount. This difference then appears in the next potential difference as a positive systematic error. It is, however, also possible to calculate titrations carrying time constants[85] and to determine the evaluation error therefrom.

6.2. Mathematical Methods

This general heading is intended to cover all methods of evaluation that start directly from the mathematical expression for the titration curve. Here must be noted on the one hand the methods based on *Gran*'s work[87,88] and on the other the nonlinear regression or multiparametric curve fitting calculations. The calculation involved is often a formidable task, but the advantage is that the individual measurement points are weighted differently according to their susceptibility to error. Furthermore, in these methods it is the equivalence point and not the inflection point of the titration curve that is determined. A disadvantage is that the fundamental mathematics of the titration curve to be evaluated must be known, and that each type of titration must be handled differently.

In 1952 *Gran*[88] published a graphical method for the determination of the equivalence points of potentiometric titrations; this depended on a linearization of the titration curve. The formulas given [eq. (18)—(22)] in Table 1 are, however, only approximate expressions; these were later improved[60,89,90]. The main error in an evaluation by *Gran*'s method is the assumption that the resulting function is linear. Since all multiplicative factors (slope of the electrode characteristic, activity coefficient) produce a slight curvature[60,91], attempts have been made to eliminate these factors by iterative calculation[92,93].

In titrations of weak acids some authors merely evaluate partial regions, which may be suitably linear[94] or carry only small errors of measurement[32]; in these cases the first measured points and those in the immediate neighborhood of the equivalence point are not included. Others have suggested linear adjustment of observations (based on simple expressions)[95–97] or linear adjustment with systematic testing for a linear relationship[40], as well as adjustment by means of polynomials[60,92] (orthogonal polynomials[98] of the 3rd and 4th order).

Whereas the *Gran* method for acidimetric titrations can be handled with precision starting from the law of mass action, from the condition of electroneutrality, and from equilibrium constants[60,89,92], this has not yet been demonstrated in practice for other types of titrations. It is true that the complete formula for isovalent precipitation titrations has been de-

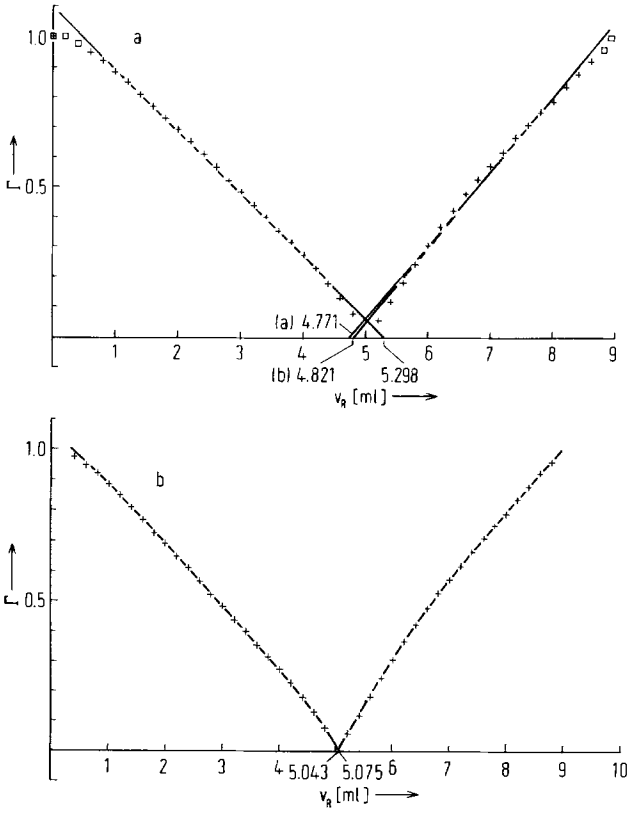

Fig. 14. *Gran* function Γ of an isovalent precipitation titration ($AgNO_3$ + NaCl). a) Iterative procedure according to [93], b) approximated by orthogonal polynomials [100]. $AgNO_3$, $c_A = 0.0168$ mol/liter, $v_A = 30.0$ ml; titration with 0.1 N NaCl.

Table 1. Calculation of the Gran function Γ for various types of titration. σ "electrode steepness" (correction factor), $f_\pm$ activity coefficient, K_L solubility product, K_w ionic product of water, K_a acidity constant, x stoichiometric factor, k selected favorable arbitrary constant for the evaluation.

	Approximate formula [a]		Exact formula [b]	
Titration of a strong acid	$\Gamma = \frac{v_A + v_R}{c_R} \cdot 10^{-pH}$	(18)	$\Gamma = \frac{v_A + v_R}{c_R}\left[\frac{1}{f_\pm} \cdot 10^{-pH} - \frac{K_\omega}{F_\pm} \cdot 10^{pH}\right]$	(23)
$H_3O^+ \xrightarrow{OH^-} H_2O$	$\Gamma = \frac{v_A + v_R}{c_R} \cdot K_\omega \cdot 10^{pH}$	(19)		
Titration of a weak acid	$\Gamma = \frac{v_R}{K_a} \cdot 10^{-pH}$	(20)	$\Gamma = \frac{v_R}{K_a} \cdot 10^{-pH} + \frac{v_A + v_R}{c_R \cdot K_a}\{10^{-pH} + K_a \cdot 10^{-pH} + K_\omega \cdot K_a \cdot 10^{pH} - K_\omega\}$	(24)
$HAc \xrightarrow{OH^-} H_2O + Ac^-$	$\Gamma = \frac{v_A + v_R}{c_R} \cdot K_\omega \cdot 10^{pH}$	(19)		
Precipitation titration	$\Gamma = (v_A + v_R) \cdot 10^{\{(x/\sigma)\cdot(\Delta E - k)\}}$	(21)	$\Gamma = (v_A + v_R)\left[x \cdot \frac{a_x}{f_x} - x \cdot \frac{1}{f_A} \cdot \left(\frac{K_L}{a_x}\right)^{\frac{1}{x}}\right]$	(25)
$xA^{a\pm} \xrightarrow{aX^{x\pm}} A_xX_a$	$\Gamma = (v_A + v_R) \cdot 10^{\{(x/a)\cdot(x/\sigma)\cdot(k - \Delta E)\}}$	(22)	with $a_x = 10^{\{-(x/\sigma)(\Delta E - E^\ominus)\}}$	(26)

[a] In each case the upper formula refers to the front branch and the lower formula to the back branch of the titration curve.
[b] A single formula describes the whole course of the titration curve.

scribed[93], and that there should be a linear connection when activity coefficients are used in the calculation, but real titration curves almost invariably give slightly curved *Gran* functions[99, 100] (cf. Fig. 14).

No systematic study of redox titrations has yet been made. Here linearization may be beset above all with problems concerning the indicator electrode.

Acidimetric titrations in mixed solvent systems and titrations of weak bases in anhydrous glacial acetic acid with 0.1 N $HClO_4$ can be evaluated by modified *Gran* functions[83, 101] and adjustment by polynomials.

Nonlinear regression analysis or multiparametric curve fitting also starts from the mathematical expression of the titration curve. The object of the numerical process is to determine a function $Y_{calc.}$ in dependence on several parameters P_i (*e.g.* for acid/base titrations, c_A, K_a, $E_*^\ominus$) from experimental data Y_i, in such a way that the sum S of the squared errors is a minimum.

$$Y_{calc} = f(p_1, p_2, p_3 \ldots x) \tag{27}$$

$$S = \sum (Y_i - Y_{calc})^2 \stackrel{!}{=} \min \tag{28}$$

Methods of this kind have been described for the determination of the stability constants of mixed complexes (Legatrop computer program[102]) and have also been used for the evaluation of titration curves[103]. *Meites* has also published programs (Curfit[104], CFT3[105]) that can be applied to the evaluation of titration curves[106]. An alternative approach to these more general methods of curve fitting involves methods of calculation employing truncated Taylor series and partial differentiation of the equation of the curve with respect to all the parameters (for a general introduction see, *e.g.*, [107]). This approach has been described for multiple standard mixing methods with ion-selective electrodes[108], for acidimetric titrations[100, 109], for precipitation titrations[100], and for titrations in anhydrous glacial acetic acid[83].

6.3. Exhaustive Approximation Methods

A middle role is played by the evaluation methods that can be collected under the heading of Exhaustive Approximation Methods. Like the simple approximation methods, these do not start with a mathematical equation for the titration curve, *i.e.* they are independent of the type of titration and thus determine not the equivalence point but the point of inflection. On the other hand, like the mathematical methods in principle, they utilize all the measured points in the evaluation and thus do not depend so heavily on the potential transfer errors in the vicinity of the end point. Here the first citation should be of a graphical method going back to *Kohn* and *Zitko*[110], which was later elaborated for digital titrations[111]. In this method the end point v_E is obtained when the surface area of the trapezium F_T equals the area F_P of the polygon series (see Fig. 15). The evaluation can be improved, especially for slightly unsymmetrical titration curves, because it is easy to incorporate an asymmetry correction[83, 112]. The method is thus particularly suitable for titrations in anhydrous glacial acetic acid.

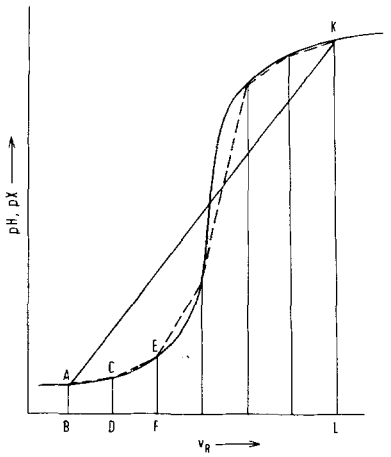

Fig. 15. Principle of the evaluation of digital potentiometric titrations by *Kohn-Zitko*'s method [110] (according to [111, 112]). v_E is defined as: $F_T = F_P$, Area of trapezium F_T: ABLK, Polygon series area F_P: Sum of the trapeziums ABCD, CDFE *etc.*

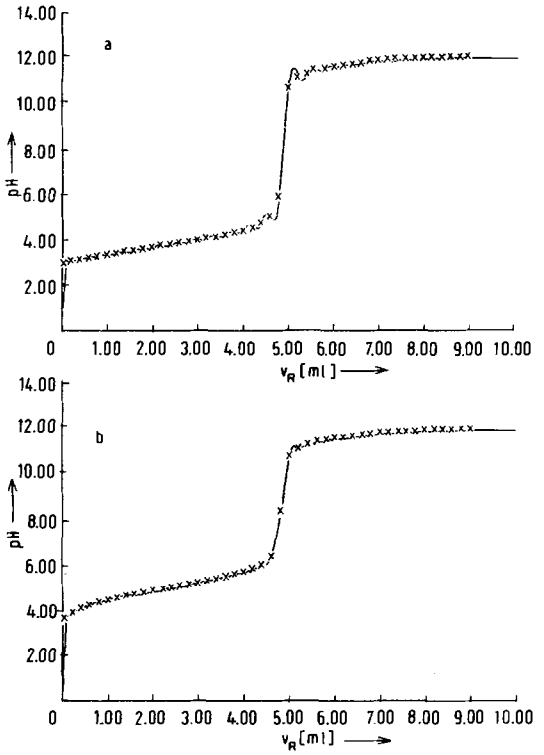

Fig. 16. Fourier approximation of a digital potentiometric titration curve [113]. a) No supporting point near the equivalence point, b) supporting point near the equivalence point. Solutions: a) ≈ 25 ml of 0.02 N mandelic acid, b) ≈ 25 ml of 0.02 N acetic acid.

Evaluation of digital potentiometric titration curves by Fourier series seems very promising[113]. The end point is obtained from the point of inflection with maximum slope (cf. Fig. 16). The error depends on the magnitude of the reagent volume increment.

7. Examples of Application

7.1. Direct Potentiometry

A series of analytical problems is solved relatively easily by means of ion-selective electrodes[114]. If the whole response range of such electrodes must be used, it is still best to determine the calibration function for the electrode under defined

conditions and to analyze the sample under conditions as similar as possible. In a fully automatic system (Fig. 9) the calibration plot is first established with *e.g.* four samples (*e.g.* $c_A = 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}$); then several analyses follow. Because of potential drift it is advisable (depending on the nature of the analysis and on the electrode) to repeat the calibration after a certain number of analyses[69]. The computer must know the positions of the standard solutions in the sample changer. Such self-calibration systems operate with fairly high sample frequencies (*e.g.* for the determination of chloride in drinking water and service water: about 40 samples/hour[115]). By extension of the system (a second operational stage on the sample changer with an attached Dosimat) the TISAB solution (Total Ionic Strength Adjustment Buffer) can be added immediately before the measurement (important *e.g.* for the determination of Na^+ by means of nitrilotriethanol because of the absorption of CO_2 from the air) (cf. Fig. 17).

7.2. Simple Standard Addition Method

The standard addition method[116, 117] is often used in work with ion-selective electrodes. In this method the concentration of the ion to be measured is changed by adding defined quantities of that ion. The systems shown in Figures 9 and 10 are suitable for this method of measurement. Only two points, at $v_R = 0.0$ and, *e.g.*, $v_R = 10.0$ ml, are used for the evaluation; all other measurements are rejected by the computer. There is no need for a calibration function for the evaluation, but instead the electrode slope σ must be known. Potential drift is little in evidence, since the standard potential of the measuring cell employed need not be known. The potential difference $\Delta(\Delta E)$ between the two selected points affords the required concentration c_x in the volume v_x from the concentration c_s and the volume v_s of the standard solution added:

$$c_x = c_s \cdot v_s \cdot \frac{\beta}{v_x + v_s + v_x \cdot \beta} \tag{29}$$

$$\beta = 10\uparrow\left\{-\frac{\Delta(\Delta E)}{\sigma}\right\} \tag{30}$$

A TISAB solution must be added to ensure that the conditions (pH, ionic strength) remain constant during the measurement. The accuracy of the method is determined mainly by the accuracy of the measurement; the errors are acceptable only within limited concentration ranges (for consideration of the error see, *e.g.*, [118]).

7.3. Multiple Standard Addition Method

In the simple standard addition method every error in the determination of potential is carried directly into the result. Proposals have therefore been made to monitor a series of measurement points and to determine the desired concentration by a balancing calculation. The following relationship between the cell potential and the concentration of the potential-determining ion is valid for every measurement point (provided that here too the analysis is carried out at constant ionic strength):

$$\Delta E_i = E_*^{\ominus} + \sigma \cdot \lg\left\{\frac{c_x v_x + c_s v_s}{v_x + v_s}\right\} \tag{31}$$

The problem of evaluation can be solved by nonlinear regression analysis (multiparametric curve fitting)[108] or by transformation and linearization[119] with subsequent adjustment of the straight lines (cf. also [120]). The programmable desk calculators shown in the block diagrams (Hewlett-Packard 9810 and 9830) work so fast that a fully automatic arrangement is justified and the time between two samples suffices for the evaluation.

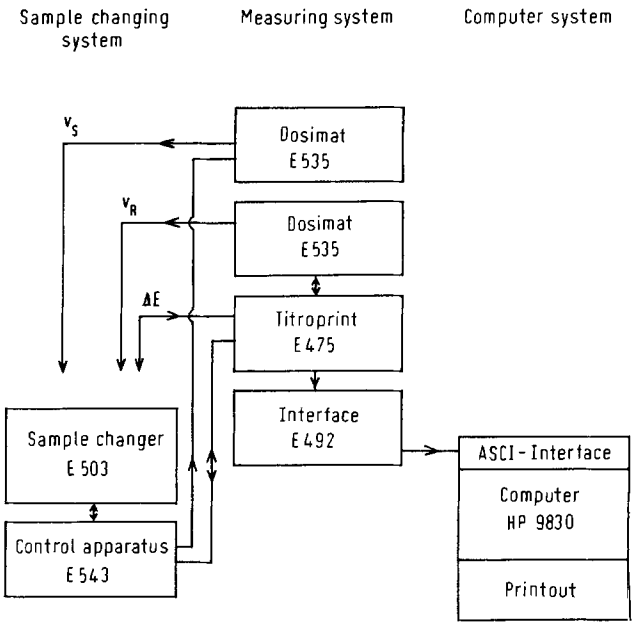

Fig. 17. Fully automatic system for indirect determination [69]: the upper Dosimat adds an excess of reagent at the first transport station, this excess being back-titrated at the second transport station. The system is also suitable for indirect determinations with ion-selective electrodes.

If the system shown in Figure 10 is slightly modified (Fig. 17) indirect determinations can also be carried out. For example, sulfate can be determined by adding a definite volume of a lead salt solution at the first transport station, thus precipitating the sulfate; the excess of lead is then determined by one of the two methods of evaluation described, involving the multiple standard addition method; the standard solution is added at the second transport station.

Rather large deviations must be expected in the multiple standard addition method if the concentration of the reagent used is not optimal for the concentration of the ion to be determined[115, 121].

7.4. End-point Titrations

In end-point titrations involving fully automatic methods (particularly in precipitation titrations), it should be noted that, in addition to the problems mentioned in Section 5.2, a systematic error can occur that is dependent on the consumption of the reagent. Under certain circumstances this error is reproducible and can be accounted for in the evaluation. We investigated this problem in the determination of chloride in drinking water and service water[115].

7.5. Digital Titrations

The problems of evaluation were outlined in Section 5.3. The methods mentioned are suitable for acidimetric titrations

(also when glacial acetic acid is employed as the solvent), for precipitation titrations, and for some redox titrations. In this last case it is particularly important that the methodology should be well planned out for fully automatic systems. Some demanding evaluation procedures (*e. g.* nonlinear regression analysis, *Gran* procedure with optimization calculations) require long calculation times with desk calculators. The calculation time is, however, limited by the time required by the control mechanism of the sample changer between two samples (the system in Fig. 10 has only passive data transfer). Nevertheless, as it is not the interface that transmits the data but the computer that calls the data from the interface (Fig. 11), in systems involving active data transfer the time between samples does not play the primary role[122, 123].

We are indebted to the Deutsche Forschungsgemeinschaft for supporting our work as reported in this review by material and personal means, to the Fonds der chemischen Industrie for materials, to instrument manufacturers for provision of apparatus, and in particular to U. Bethge, Dr. A. Binder, Dr. C. P. Christiansen, E. Glaser, Dr. S. Kalb, E. Koch, Dr. R. Krömmelbein, Dr. W. Parzefall, and P. Surmann for their fruitful collaboration in the field of evaluation and automation of electroanalytical processes.

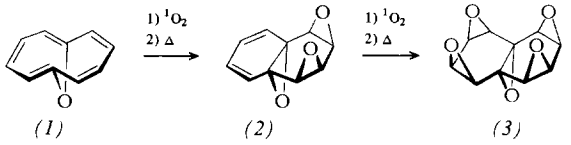
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



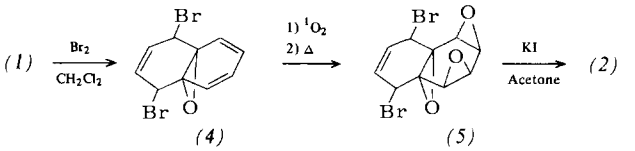
Synthesis and Structure Analysis of a Naphthalene Pentoxide

By *Emanuel Vogel, Arthur Breuer, Claus-Dieter Sommerfeld, Raymond E. Davis,* and *Ling-Kang Liu*[*]

Photooxidation of 1,6-bridged [10]annulenes with oxygen ($^1O_2$) affords 1,4-endoperoxides, which can be readily isomerized thermally to *syn*-diepoxides[1]. In the case of the 1,6-imino[10]annulene this reaction sequence has proved to be synthetically very useful, for it opens a simple route to *syn*-1,2;3,4-naphthalene dioxide[2].

We have now found that 1,6-epoxy[10]annulene can be converted into a naphthalene pentoxide by two successive $^1O_2$-addition/thermolysis sequences.

On irradiation with a sodium-vapor lamp in the presence of methylene blue and oxygen (methylene chloride; 10 to 15°C) 1,6-epoxy[10]annulene *(1)* shows little tendency to take up $^1O_2$[3]; the 1,2;3,4;9,10-naphthalene trioxide *(2)* [m.p. 119—120°C (needles from ethyl acetate); NMR ($CDCl_3$): sing-



(1) *(2)* *(3)*

let (degenerate AA'BB' system) at τ=3.50 (olefin protons) and AA'BB' system centered at τ=6.49 (epoxide protons); UV (acetonitrile): λ_{max}=265 nm (ε=3200)], originating from a labile 1,4-endoperoxide, can be isolated in only *ca.* 1% yield, even after 120 h[4].

That the trioxide has the *anti* configuration *(2)*, and that, accordingly, attack of the singlet oxygen proceeds from the side of the molecule opposite to the oxygen bridge, could only be clarified later by an X-ray structure analysis of the pentoxide *(3) (vide infra)*.

In order to obtain *(2)* on a preparative scale it is advantageous not to photooxidize the annulene *(1)* itself, but rather its dibromo adduct *(4)*[5] (reaction with $^1O_2$ complete within 1 h). Photooxidation of *(4)* leads smoothly *via* an unstable 1,4-endoperoxide to the trioxide *(5)* [m.p. 189 to 190°C (dec); NMR ($CDCl_3$): singlets at τ=4.2 (olefin protons) and 5.0 (CHBr protons) and AA'BB' system at τ=6.35 (epoxide protons)], which on treatment with potassium iodide in acetone (40°C; 20 h) furnishes *(2)* in 50% yield. In contrast to *(1)*, compound *(2)* reacts relatively readily with $^1O_2$ (complete conversion after 120 h) with formation of a non-peroxidic oxidation product having the molecular composition $C_{10}H_8O_5$ [m.p. 280°C (dec); colorless platelets (from acetonitrile); yield 55%; 100-MHz ^{1}H-NMR (CD_3CN): AA'BB' system at τ=6.55 (H_1,H_4 / H_5,H_8) and 6.62 (H_2,H_3 / H_6,H_7); $J_{1,2}$=3.78 Hz, $J_{2,3}$=3.69 Hz, $J_{1,3}$=0.15 Hz, $J_{1,4}$=−0.15 Hz; ^{13}C-NMR (CD_3CN, TMS): δ(C_9/C_{10})=61.5, δ(C_1,C_4 / C_5,C_8)=50.2, δ(C_2,C_3 / C_6,C_7)=48.0].

The NMR spectra of this compound are consistent with the presence of a sterically uniform naphthalene pentoxide. It follows from the ^{1}H-NMR spectrum and the 3-line ^{13}C-NMR spectrum that the pentoxide is symmetrical with respect to the central epoxide ring (C_{2v} symmetry). The stereochemistry has been elucidated by X-ray structure analysis carried out by the American co-authors[6].

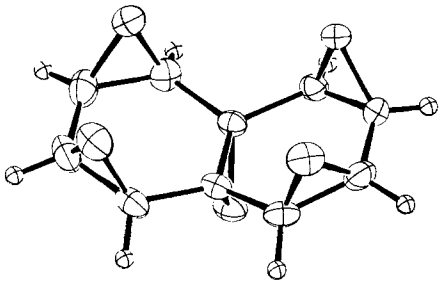

Fig. 1. *syn,syn,syn,syn*-1,2;3,4;5,6;7,8-*anti*-9,10-naphthalene pentoxide *(3)*, computer drawing.

The investigations showed that the naphthalene pentoxide has almost unperturbed C_{2v} symmetry in the crystal and that the compound has the *syn,syn,syn,syn*-1,2; 3,4; 5,6; 7,8-*anti*-9,10 configuration *(3)* (Fig. 1). The bond lengths and some of the angles are given in Figure 2. Each of the two "cyclohexane rings", *i.e.* C(1) to C(4), C(9), C(10) and C(5) to C(10), is planar (maximum deviation of the C atoms from planarity ±0.02 Å); the dihedral angle between the ring planes is 155.6°.

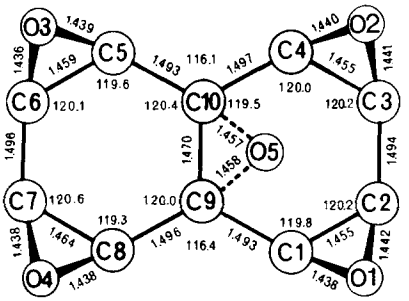

Fig. 2. Bond lengths [Å] and bond angles [°] in *syn,syn,syn,syn*-1,2; 3,4; 5,6; 7,8-*anti*-9,10-naphthalene pentoxide *(3)*. Maximum error ±0.003 Å and ±0.2°, respectively.

The angles between the central epoxide ring and the planes of the two six-membered rings are 102.3° and 102.1°, while the four outer epoxide rings form angles of 106.7°, 105.6°, 103.6° and 106.3° (counting according to Figure 2), respectively, with "their" six-membered rings. In the light of the molecular structure of *syn*-benzene trioxide, recently reported by *Littke* and *Drück*[7], the data found for *(3)* are consistent with expectation.

[2] *E. Vogel, H.-H. Klug*, and *M. Schäfer-Ridder*, Angew. Chem. *88*, 268 (1976); Angew. Chem. Int. Ed. Engl. *15*, 229 (1976); *syn*-1,2;3,4-naphthalene dioxide has in the meantime also been obtained by thermolysis of the 11,11-difluoro-1,6-methano[10]annulene 2,3;4,5-dioxide (from 11,11-difluoro-1,6-methano[10]annulene and $^1O_2$)—unpublished work carried out with *R. Müller*.

[3] The resistance of *(1)* toward attack by singlet oxygen might mainly be due to the (−*I*) effect of the bridge oxygen atom. This explanation is further supported by the observation that 1,6-methano[10]annulenes containing electronegative bridge substituents, particularly 11,11-difluoro-1,6-methano[10]annulene, undergo photooxidation only very slowly.

[4] The major proportion of *(1)* employed is recovered unchanged.

syn-4,13;6,11-Dimethano[15]annulenone, a 14π-Analog of Tropone—Synthesis and X-Ray Structure Analysis

By *Wolfgang Wagemann, Klaus Müllen, Emanuel Vogel, Tullio Pilati*, and *Massimo Simonetta*[*]

The recently reported[1] bicyclo[5.4.1]dodeca-2,5,7,9,11-pentaene-3,5-dicarbaldehyde, for which an equilibrium between *syn* and *anti* conformers *(1a)* and *(1b)* is to be assumed, ought to undergo a Knoevenagel condensation with acetone dicarboxylic ester to give the 4,13;6,11-dimethano[15]annulenone as *syn* and/or *anti* stereoisomers *(2a)* and *(2b)*.

Prediction of which of the two [15]annulenone isomers is preferentially formed is difficult. The dialdehyde is surely present almost entirely as the conformer *(1a)* capable of more effective conjugation; but it cannot be ruled out that *(1a)* undergoes ring closure slower than *(1b)* for steric reasons (increase in the conformational strain of the internal CH_2 hydrogen atoms) and thus that *(2b)* is preferentially formed.

Condensation of *(1)* with dimethyl acetonedicarboxylate in benzene in presence of piperidineacetate as catalyst (3 h, 80°C) leads, as expected, to dimethyl 2-oxo-5,14;7,12-dimethano[15]annulene-1,3-dicarboxylate, which can be readily separated as a sterically uniform compound by chromatography on alumina (ether) [orange prisms (from chloroform/ether), m.p. 244 to 245°C, yield 28%]. Treatment of the diester with 10% methanolic potassium hydroxide (reflux, 1 h) and subsequent heating of the crude dicarboxylic acid liberated on acidification with HCl in boiling dimethylformamide (30 min) furnishes the 4,13;6,11-dimethano[15]annulenone [air-stable, red rhombic crystals (from chloroform/*n*-hexane), m.p. 235 to 236°C, yield 80%] sterically corresponding to the diester.

The 360-MHz ^{1}H-NMR spectrum[2] (CD_2Cl_2) of the 4,13;6,11-dimethano[15]annulenone led to the following assignments: $\tau = 2.59$ and 2.65 (H_8,H_9 and H_7,H_{10}, resp.; AA'BB' system with $J_{7,8} = 7.5$ and $J_{8,9} = 9.2$ Hz), 2.61 (H_5,H_{12}; s), 2.79 and 3.85 (H_3,H_{14} and H_2,H_{15}; AB system with $J_{2,3} = 12.3$ Hz), 7.28 and 8.31 ($H_{16\,endo}$ and $H_{16\,exo}$; AB system with $J = 15.8$ Hz), 7.64 and 10.92 ($H_{17\,endo}$ and $H_{17\,exo}$; AB system with $J = 13.0$ Hz).

On recording the spectrum in CF_3COOH the signals of the annulenone- and bridge-protons experience drastic down- and up-field shifts, respectively, from which it can be concluded that protonation to a delocalized 13-hydroxy-1,10;3,8-dimethano[15]annulenium ion has taken place. Also consistent with formation of the annulenium ion are the changes in the UV spectrum on going from ethanol to ethanol/perchloric acid as solvent, and the relatively high pK_a value of the annulenone of -0.4 ± 0.2 (tropone: $pK_a = -0.6 \pm 0.3$).

These findings prove the 4,13;6,11-dimethano[15]annulenone stereoisomer to be a 14-π analog of tropone and of the 4,9-methano[11]annulenone[3]. This makes the presence of *(2a)* likely, for *(2b)* could hardly be capable of forming a delocalized annulenium ion for steric reasons[4]. Final clarification of the stereochemistry was possible from an X-ray structure analysis carried out by our Italian colleagues[5].

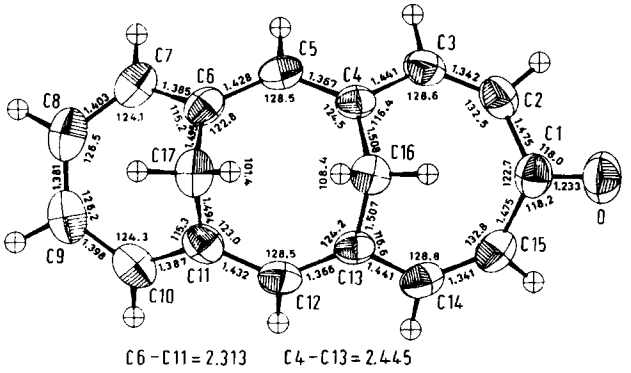

Fig. 1. Bond lengths [Å] and bond angles [°] in the *syn*-4,13;6,11-dimethano[15]annulenone *(2a)*. Maximum error ±0.003 Å and ±0.2°, respectively.

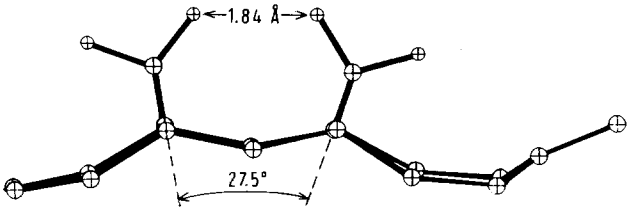

Fig. 2. Side view of *syn*-4,13;6,11-dimethano[15]annulenone *(2a)*

The analysis confirmed the assumption that the 4,13;6,11-dimethano[15]annulenone stereoisomer has the *syn* configuration *(2a)*. More detailed information about the molecular structure is given in Figures 1 and 2. It follows, in particular from the side view of the molecule shown in Fig. 2, that the internal bridge hydrogen atoms are relatively strongly compressed, and that the bending of the annulenone ring is thus limited. Interestingly, according to Fig. 1 the degree of alternation of single and double bonds decreases with increasing distance of the bonds from the CO group[7]. The cause of this, which is also reflected in a certain equalizing of the vicinal coupling constants of the ring protons H(7) to H(10), is currently under investigation.

[7] The same trend, albeit in weaker form, is observed in the case of 4,9-methano[11]annulenone: *D. W. Hudson* and *O. S. Mills*, Chem. Commun. *1971*, 153.

A Complementary Route to *anti*-1,2:3,4-Naphthalene Dioxide; Direct Oxidation of Arenes with *m*-Chloroperbenzoic Acid[**]

By *K. Ishikawa* and *G. W. Griffin*[*]

Widespread attention has recently focused on arene oxides and particularly epoxy diols related to arene dioxides as the possible ultimate mutagens and/or carcinogens[1]. Such metabolites of exogenous aromatic hydrocarbons have been found to interact with cell nucleophiles and produce malignant transformations of cells *in vitro*. Some time ago the synthesis of benzene dioxide was reported by *Vogel et al.*[2] and its possible significance from a biochemical standpoint became evident when shortly thereafter *Borders et al.*[3] found that a naturally occurring substance with antibiotic properties incorporates a benzene dioxide moiety.

As a consequence of our continuing interest in arene oxides[4] and in particular the *direct* epoxidation of polycyclic hydrocarbons[5] we have investigated the oxidation of naph-

[**] This investigation was supported by Grant Number 1-RO1-CA-18346-01, awarded by the National Cancer Institute, DHEW, and also by Grant Number MPS75-14831, awarded by the National Science Foundation, which the authors wish to acknowledge. We also wish to thank Dr. *E. Elder* and Ms. *J. Thompson* for assistance in the preparation of the manuscript.

thalene *(1a)* with *m*-chloroperbenzoic acid (*m*-CPBA). Under carefully controlled reaction conditions and workup procedures it has been possible to achieve the direct synthesis and isolation of *anti*-1,2:3,4-naphthalene dioxide *(3a)*[6] using *m*-CPBA in the presence of water as the oxidant.

A solution of *(1a)* (0.04 M) in methylene chloride containing *m*-CPBA (2.25 equiv.) was stirred with saturated sodium bicarbonate at 25°C for 14 h and the organic phase washed with aqueous sodium thiosulfate to remove excess *m*-CPBA. The organic phase is dried over anhydrous sodium sulfate, concentrated and chromatographed on a column packed with silica gel which has been previously deactivated by stirring with ethanol[7]. The elution was conducted with benzene-hexane (0—40%). The *anti*-dioxide *(3a)* (15—20%) emerges after *(1a)* and is followed by a by-product whose structure remains to be established, although it is not the *syn* isomer *(4a)* or a trioxide or diol epoxide, as evidenced by NMR analysis. The melting point (99–100°C) and spectral data for *(3a)* compare favorably with that described by *Vogel et al.*[6]. The NMR spectrum exhibits the complicated pair of AA'BB' signals at $\tau = 6.0$—6.5 ($CDCl_3$) reported previously for *(3a)*. It is of interest that *(3a)* is not deoxygenated with thiourea in methanol, which is generally effective in reducing K-region arene oxides[8].

It is important to note that the concentration of *(1a)* and *m*-CPBA be maintained at a low level and the isolation procedures used for *(3a)* are critical. For example, if the concentration of *(1a)* is increased to 0.2 M, by-product formation increases to the point where isolation of *(3a)* is difficult.

That the technique has general application is apparent from the fact that 2-methylnaphthalene *(1b)* also undergoes oxidation under conditions similar to those described for *(1a)*, albeit at a faster rate (3 h); however, in this case both the *anti* and *syn* isomers [*(3b)* and *(4b)*, respectively] are obtained, presumably because initial oxidation occurs at the activated 1,2-bond to give *(2b)*, and the differential steric factors responsible for the stereocontrol observed in the subsequent step in the comparative oxidation of *(2a)* are reduced. Techniques similar to those used with *(3a)* were employed for the isolation of the unstable dioxides (40%) and also partial separation of the two stereoisomers *(3b)* and *(4b)*. Assignment of stereochemistry in the case of *(3b)* and *(4b)* is complicated by the absence of a proton at C-2 precluding utilization of the $J_{2,3}$ coupling constant which provides the sole method reported to date for the differentiation of *(3a)* and *(4a)*[6]. The NMR spectra of *(3b)* and *(4b)* are nearly identical and bear an obvious resemblance to those of *(3a)* and *(4a)* [$\tau = 8.33$ s, (CH_3); 6.50 br s (H^1); 6.27 dd (H^3, H^4) ($CDCl_3$)]. The major isomer after recrystallization from CH_2Cl_2/hexane melts at 67—68°C, with partial decomposition.

As expected, anthracene upon treatment with *m*-CPBA in the manner described gives primarily anthraquinone. If, however, positions 9 and 10 are blocked by aryl substituents, as is the case in 9,10-diphenylanthracene, oxidation occurs to give a dioxide. The oxidation in this case was conducted most efficiently by adding 4 equiv. of *m*-CPBA in two equal portions during a twelve hour period. In this manner the resulting dioxide, m.p. 188—190°C (dec), $M^+ = 362$, was obtained in 16% yield. The NMR spectrum [$\tau = 6.39$, 6.14 AA'BB' m] is very similar to that of *(3a)*; by analogy with the oxidation of naphthalene *(1a)* the oxidation of 9,10-diphenylanthracene should lead to the 9,10-diphenyl-1,2:3,4-anthracene dioxide, which is probably in the *anti* configuration.

[6] Elegant, albeit multistep, procedures have very recently been reported by *Vogel et al.* for the synthesis of the diastereomeric dioxides *(3a)* and *(4a)*. While synthesis of the *syn* isomer *(4a)* was achieved in high yield (50%) from naphthalene-1,4-endoperoxide, the *anti* isomer, was obtained in only 1–2%; the procedure described herein is thus complementary. See *E. Vogel, H.-H. Klug, M. Schäfer-Ridder*, Angew. Chem. *88*, 268 (1976); Angew. Chem. Int. Ed. Engl. *15*, 229 (1976). We are indebted to Prof. *Vogel* for a spectrum of *(3a)*, contained in the doctoral thesis of *H.-H. Kluge* (Universität Köln, Germany, 1976) for purposes of comparison.

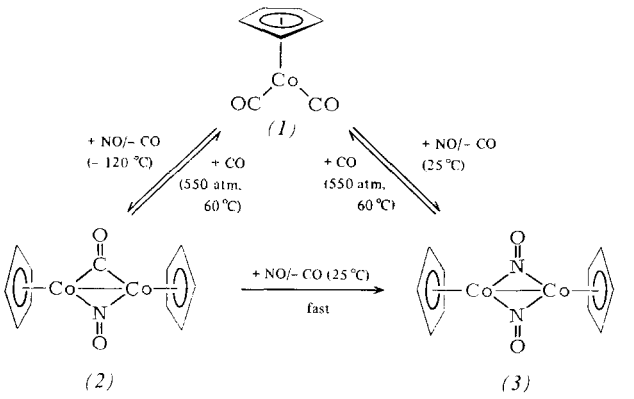
Partial Nitrosylation of Dicarbonyl(η-cyclopentadienyl)cobalt[**]



By *Wolfgang A. Herrmann* and *Ivan Bernal*[*]

Dicarbonyl(η-cyclopentadienyl)cobalt *(1)* reacts at room temperature with nitrogen monoxide with complete substitution of CO; apart from the stable dinuclear complex $(\eta\text{-}C_5H_5CoNO)_2$ *(3)* no other products are isolated[1].

Partial nitrosylation of *(1)* has now been accomplished by drastically reducing the reaction temperature or by using organic NO-transfer agents: Rapid formation of μ-carbonyl-μ-nitrosyl-bis(η-cyclopentadienylcobalt) *(Co—Co)* *(2)*[2] takes place on treating an *n*-pentane solution of *(1)* for a short period of time with NO gas at −120°C. With an excess of NO, *(2)* is converted slowly at −120°C, and quantitatively within a few seconds at room temperature, into the dinitrosyl complex *(3)*. From this finding we conclude that *(2)* is an intermediate in the synthesis of *(3)*[1]. Both compounds can be recarbonylated under pressure (550 atm, 60°C, 3 h in THF) to the mononuclear starting complex *(1)*.

paramagnetic

ν_{NO}: 1543 cm^{-1};
ν_{CO}: 1819 cm^{-1}(KBr)

diamagnetic

ν_{NO}: 1585,
1525 cm^{-1}(KBr)

N-Methyl- and *N*-ethyl-*N*-nitrosourea react with *(1)* in boiling benzene to give exclusively the partially nitrosylated product *(2)*, even when used in twofold excess. This large difference in reactivity in comparison to NO underlines the preparative importance of these two nitrosourea derivatives as very mild nitrosylating reagents for metal carbonyls. They are readily accessible and thermally relatively stable (m.p./dec >100 °C). This also applies for *N*-nitroso-*p*-toluenesulfonamide, which is employed for a similar purpose in complex chemistry; its use in the case described here, however, leads only to mixtures of the difficultly separable complexes *(2)* and *(3)*.

The structure of *(2)*, confirmed by an X-ray structure analysis to be a dinuclear complex containing a Co—Co single bond[3], is consistent with its paramagnetism (1.86 μ_B[2]), which we were also able to detect ESR spectroscopically. The 15-line system ($a_{Co}=47.4$, $a_N \leq 14$ Oe; *g*-factor 2.0539) evidences uniform charge distribution over both Co nuclei ($I=7/2$); were the unpaired electron to reside preferentially on the bridge ligand, as in the μ-peroxobis(pentamminecobalt) ion[4], a_{Co} would be much smaller.

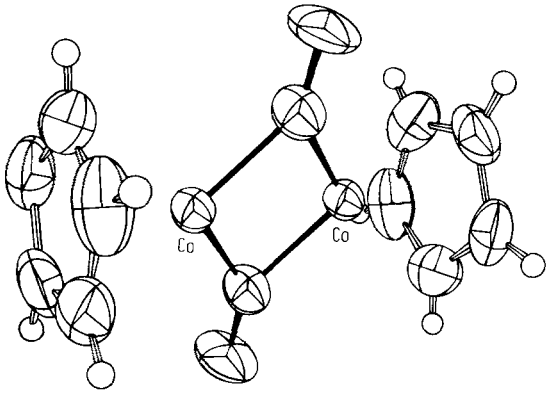

Fig. 1. ORTEP diagram of *(2)*. The $Co_2(NO)(CO)$ fragment is coplanar (max. deviation from the plane ±0.4 pm). Bond lengths: Co—Co 237.0 pm (single bond), Co—Co = Co—NO 182.9 pm; angle CoNCo (= ∢CoCCo) 80.7°.

Experimental[5]:

a) Nitrogen monoxide variant: A slow stream (0.5 mm capillary) of dry NO gas is passed through a magnetically stirred solution of *(1)*[6] (1.80 g, 10 mmol) in *n*-pentane (100 ml) at −120 °C. After 10 minutes, the solvent is first removed under high vacuum at −40 °C and then any unconsumed *(1)* at room temperature. The brown residue crystallizes from diethyl ether/methylene chloride (2:1, −35 °C); yield 410 mg (27 %) of *(2)*.

b) *N*-Alkyl-*N*-nitrosourea variant: A mixture of *(1)* (1.80 g, 10 mmol) and *N*-methyl-[7a] or *N*-ethyl-*N*-nitrosourea[7b] (15 mmol, 1.55 and 1.76 g resp.) in benzene (40 ml) is heated under reflux for 8 h. The solution is evaporated down in a high vacuum and the residue chromatographed (20 × 3 cm column; +15 °C) with benzene on silica gel (0.063—0.200 mm, Act. II—III). Recrystallization (diethyl ether/methylene chloride 2:1; −35 °C) of the substance obtained from the brown zone yields 918 g (61 %) of analytically pure *(2)*.

Isolation of Halohydroborates of Type $[B_{10}H_{10-n}X_n]^{2-}$

By *Klaus-Georg Bührens* and *Wilhelm Preetz*[*]

Electrophilic substitution reactions on hydrodecaborate ions *(1)* with chlorine, bromine, or iodine in aqueous or alcoholic solution lead to the corresponding halohydroborates *(2)*[1].

$$\underset{(1)}{B_{10}H_{10}^{2-}} + nX_2 \longrightarrow \underset{(2)}{B_{10}H_{10-n}X_n^{2-}} + nHX$$

X = Cl, Br, I; n = 1-9,10

Only the terminal members ($n=10$) of the three homologous series *(2)* have as yet been confirmed, while it was not ruled out for the few intermediates isolated—*e.g.* $B_{10}H_2Cl_8^{2-}$, $B_{10}H_3Br_7^{2-}$, $B_{10}H_8I_2^{2-}$[1]—that mixtures of several of the very similar species had actually been obtained.

By means of electrophoresis[2] we have now detected all the substituted species *(2)*, of which the compounds listed in Table 1 were isolated in pure form. They were characterized by elemental analysis and vibrational spectra of the sparingly soluble tetramethylammonium salts.

The rate of reaction decreases along the series $Cl_2 > Br_2 > I_2$. It is very high for the initial reaction steps and diminishes with increasing degree of halogenation. The solutions invariably contain 3 to 5 successive components, of which those in the middle are present in the highest concentration. The maximum shifts systematically towards higher values of n as the halogenation time increases. The ion mobilities decrease with increasing degree of halogenation. The difference in mobility therefore becomes progressively smaller and the ions having $n > 6$ can no longer be completely separated. The pherogram of a mixture of all radioactively labeled chlorohydroborates and the relevant activity profile are shown in Figure 1.

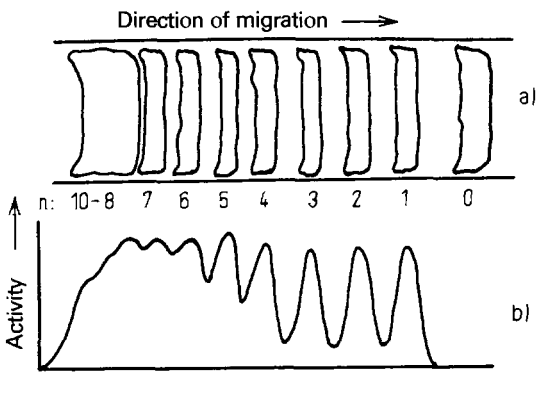

Fig. 1. a) Pherogram and b) activity profile of compounds $B_{10}H_{10-n}Cl_n^{2-}$ labeled with ^{36}Cl.

In the vibrational spectra, the BH stretching frequencies are seen in the 2470—2560 cm^{-1} region, the skeletal frequencies in the 1000—1300 cm^{-1} region, and the B—X stretching frequencies in the 700–895 cm^{-1} region. In the more extensively halogenated species in particular, characteristic splitting patterns are observed which are especially pronounced in the Raman spectra recorded on saturated acetonitrile solutions. Presumably, several geometrical isomers coexist in the solutions. The intensity of the BH stretching vibrations steadily diminishes with increasing halogenation while the center of gravity of the bands shifts to higher frequencies. The increase in strength of the BH bond manifested in this shift is paralleled by an increase in stability of the products.

Procedure:

A current of N_2 carrying a very small amount of Cl_2 or Br_2 is passed through ice-cooled solutions of $(NH_4)_2B_{10}H_{10}$ (1.5 g, 0.01 mol) in water (50 ml) (only a few minutes for preparation of species with $n < 3$, and up to an hour for more highly halogenated compounds). Iodination is performed by shaking the aqueous solution with a few ml of CCl_4 in which iodine is dissolved until the iodine color disappears, the procedure being repeated if necessary. After filtering off resinous side-products the mixtures *(2)* are precipitated from the aqueous solutions as the tetramethylammonium salts which are recrystallized from acetonitrile/water. They are treated with a cation exchanger to give the more soluble NH_4^+ or Na^+ salts, which are subjected to high voltage electrophoresis. On spraying of the pherograms with a dilute acridine hydrochloride solution the separated colorless halohydroborates give yellow zones which are cut out, collected, and eluted with 0.01 M NaOH. After concentration the ions *(2)* can be precipitated with tetramethylammonium chloride. Recrystallization from water/alcohol (almost pure alcohol for $n = 1$, almost pure water for $n = 6$) gives the colorless finely crystalline salts $[(CH_3)_4N]_2B_{10}H_{10-n}X_n$ in yields between 20 and 60 mg.

The Reaction of Olefins with Silane and Carbon Monoxide Catalyzed by $Co_2(CO)_8$[1]

By *Yoshio Seki, Akihiko Hidaka, Shinji Murai*, and *Noboru Sonoda*[*]

Hydrosilylation, the catalyzed addition of $R_3Si—H$ to an olefin, is formally analogous to catalytic hydrogenation. The well-known hydroformylation reaction involves addition of hydrogen and carbon monoxide to olefins [Reaction (a)]. Addition of a silane and carbon monoxide to olefins, however, has not been reported apart from in a very complex reaction described almost a decade ago[2].

[*] Y. Seki, A. Hidaka, Prof. Dr. S. Murai [+], and Prof. Dr. N. Sonoda
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University
Suita, Osaka 565 (Japan)
[+] Author to whom correspondence should be addressed.

We have studied the reaction of olefins (cyclopentene, cyclohexene, cycloheptene, and cyclooctene) with diethyl(methyl)silane *(1)* and carbon monoxide in the presence of $Co_2(CO)_8$. Instead of the products of type *(2)*, expected by direct formal analogy with hydroformylation, the enol silyl ethers *(3)* were obtained. The yields were: *(3a)* 48 %, *(3b)* 71 %, *(3c)* 74 %, *(3d)* 69 %. Isomeric products were not formed.

(a)

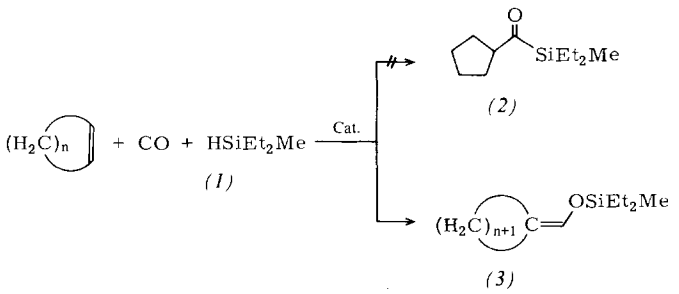

Table 1. Physical properties of the compounds *(3a)* to *(3d)*.

	n	B.p. [°C/Torr]	IR [a] (C=C) $\tilde{\nu}$ [cm^{-1}]	^{1}H-NMR [b] (s, HC=C) δ [ppm]
(3a)	3	98—100/15	1685	6.04
(3b)	4	130—138/28	1680	5.88
(3c)	5	155—165/50	1660	5.92
(3d)	6	126—135/25	1660	5.94

[a] Without solvent. [b] In CCl_4.

Numerous synthetic reactions are known in which enol silyl ethers are used as starting materials and in which these substances are prepared from carbonyl compounds[3]. The reaction described here affords direct access to enol silyl ethers from olefins. Its scope and limitation is at present under investigation.

The reaction does not proceed *via* aldehydes or acylsilanes as intermediates, for reaction of these compounds with *(1)* does not lead to enol silyl ethers.

Experimental:

Synthesis of *(3b)*: A solution of 2.52 g (30 mmol) of cyclohexene, 1.02 g (10 mmol) of diethyl(methyl)silane, and 0.068 g (0.2 mmol) of $Co_2(CO)_8$ in 20 ml of benzene was placed in a 100 ml stainless steel autoclave. The autoclave was flushed with N_2 (80 kg/cm^2) and CO (50 kg/cm^2), then charged with CO (80 kg/cm^2) and heated at 140 °C with stirring. After 20 h, the autoclave was cooled and depressurized. Distillation of the cooled reaction mixture furnished pure *(3b)*.

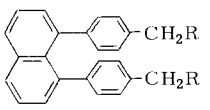
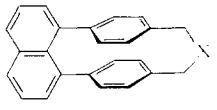
Synthesis and Stereochemistry of Strained Naphthalenophanes[**]

By *Wolfgang Bieber* and *Fritz Vögtle*[*]



Deformed benzene rings and transannular electronic effects between spatially interpenetrating π-electron clouds can best be studied on helicenes and phanes. While numerous publications are concerned with the extreme [2.2]paracyclophane system[1a], the naphthalenoparacyclophanes *(1)* and *(2)*, which are hardly less strained, have not hitherto been reported. Related to the [3.2]paracyclophane system yet containing additional stiffening, they are profitable synthetic objectives on account of the particular features of steric interactions in the *peri* position of the naphthalene system[2] and the parallel and orthogonal orientations of the π systems. Moreover, they also offer an opportunity of studying additional effects due to bracketing in isolation, since the two phenylene rings are already in a "face-to-face"[3] arrangement in the open-chain precursor *(3)*.

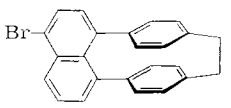


(1) *(2)*

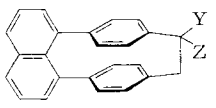
Synthesis: Reaction of di-*p*-tolyllithium cuprate with 1,8-diiodonaphthalene leads to 1,8-di-*p*-tolylnaphthalene *(3)*[4], which affords *(4)* in 80 % yield on NBS bromination in CH_2Cl_2[5]. Intramolecular ring closure to give the phane *(1)* occurs in 65 % yield on treatment with phenyllithium in THF, being favored by the rigid structure.

The geometry of the 1,8-diarylnaphthalenes also facilitates the alternative synthesis of *(1)* *via* desulfuration of the sulfide *(5)*, which is obtained on reaction of *(4)* with Na_2S in *tert*-butanol/benzene. The corresponding sulfone *(6)* (H_2O_2 oxidation of *(5)* in glacial acetic acid/benzene) transforms spontaneously and practically quantitatively into the hydrocarbon *(1)* with elimination of SO_2 above its melting point (317 °C)[6].

(3), R = H
(4), R = Br



(5), X = S
(6), X = SO_2



NBS bromination of *(1)* displays a remarkable solvent dependence: in CH_2Cl_2 bromination occurs exclusively in the aromatic ring to form the phane *(7)*, while in CCl_4 the monobromide *(8)* required for preparation of *(2)* is formed alongside the *gem*-dibromide *(9)*. Elimination of HBr from *(8)* with *tert*-butoxide in THF gives *(2)* in 55 % yield.

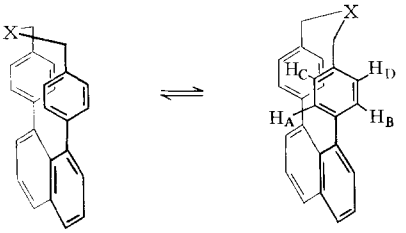
Institut für Organische Chemie und Biochemie der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.



(7)

(8), Y = H, Z = Br
(9), Y = Z = Br

Stereochemistry: Comparison of ^{1}H-NMR absorptions (Table 1) shows that a characteristic *upfield shift* of 0.2 ppm occurs on going from the open-chain species *(3)* to the bracketed compound *(1)*; the shift is attributed to enhancement of the anisotropic effect by the forced mutual approach of the *p*-phenylene rings.

Low temperature ^{1}H-NMR spectra [90 MHz; in CD_2Cl_2/D_6-acetone/$CFCl_3$ (1:5:5)] show the 14-membered rings of the sulfide *(5)* and the sulfone *(6)* to possess a conformational mobility (shown by models to be hindered mainly by ring strain) which is reminiscent of ring topomerization in the cyclohexane system:

(A) (B)

The conformations *(A)* and *(B)* interconvert rapidly at room temperature on the NMR time scale: the *p*-phenylene protons give a time-averaged AA'BB' system. Below the coalescence points of −75 °C and −65 °C, respectively, an ABCD system (A ≈ B) is observed for the sulfide and the sulfone. In the sulfone the singlet of the bridge CH_2 protons splits to give the AB system ($T_c = -65$ °C), while in the sulfide only a broadening of the methylene singlet is observed down to −140 °C. $\Delta G_c^{\neq}$ for ring inversion is about 9.6 kcal/mol (40.2 kJ/mol) for *(5)*, and 10.0 kcal/mol (41.9 kJ/mol) for *(6)*.

Table 1. Melting points and ^{1}H-NMR data of the new naphthalenophanes [a]; the data for [2.2]- *(11)* and [3.2]paracyclophane *(13)* [1b] are given for sake of comparison.

Cpd.	M.p. [°C]	CH (bridge) [b]	CH (phenylene) [b]
(1)	245—246	3.07	6.51
(2)	249—251	7.35	6.69
(3)	179—179.5	2.15	6.72
(5)	215—218.5	3.84	6.70
(6)	317	4.46	6.98
(11)	285—287	3.05	6.37
(13)	148—149	2.10 2.71 2.97	6.48

[a] Correct elemental analyses and mass spectra were obtained for all compounds.
[b] ^{1}H-NMR (90 MHz; in $CDCl_3$): δ-values [ppm].

While the NMR data reveal additional transannular π interactions between the phenylene rings for *(1)*, interpretation of the UV absorptions (Fig. 1) is impeded by conjugation which still comes about in spite of the near orthogonality of the naphthalene and phenylene rings[7]. The red shift of the maximum lying at shorter wavelength on going from the cyclic systems to the open one *(3)* is striking; it can be interpreted in terms of the greater mobility of the non-bracketed phenylene rings which facilitate conjugation with the naphthalene nucleus. In analogy to the [2.2]paracyclophane system a diminution of intensity of the shorter wavelength maxima is observed for the olefin *(2)*.

The red shift of *ca.* 15 nm observed in the UV spectra of the *tetracyanoethylene adducts* on going from the monoarylated naphthalene[8] to the 1,8-ditolylnaphthalene adduct would correspond to an increase in the π basicity in the open chain system[9a]. Interpretation[9b] of the short wave absorptions of the TCNE adducts of *(1)*, *(2)*, and *(5)* is not easy because the role of the naphthalene nucleus as π base in the phanes is difficult to estimate.

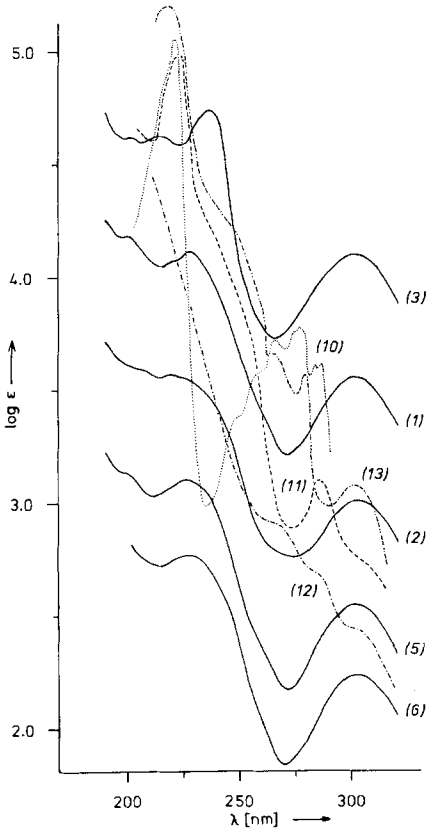


Fig. 1. UV spectra of the compounds *(1)*, *(2)*, *(3)*, *(5)*, and *(6)* (in cyclohexane); the spectra of naphthalene *(10)*, [2,2]paracyclophane *(11)* and its diene *(12)* [10a], and [3.2]paracyclophane *(13)* [10b] (in ethanol) are given for comparison. Compounds *(1)*, *(2)*, *(5)*, and *(6)* are progressively displaced downwards by 0.5 ordinate units (log ε) compared to *(3)*, and *(11)* and *(13)* upwards compared to *(10)* and *(12)*.

The similarity of the UV spectra of the cyclized and noncyclic 1,8-diarylnaphthalenes, which is striking in view of the significant difference in the ^{1}H-NMR results indeed shows the open chain system to be more closely related to the bracketed one than in other examples reported so far: 1,8-diarylnaphthalenes can be described as "open-chain cyclophanes"—a consequence of the stereochemical peculiarity of the *peri*-position.

Spiro Compounds Having a Nonplanar 1,4-Dihydropyridine Ring from Diaziridinimines and Dimethyl Acetylenedicarboxylate[**]

By *Helmut Quast, Karl-Heinz Ross, Erwin Spiegel, Karl Peters*, and *Hans Georg von Schnering*[*]

The pronounced reactivity and versatility of dimethyl acetylenedicarboxylate *(1)* make it an interesting but frequently unpredictable reagent[1]. This is seen in the number of its products whose structure could only be elucidated by X-ray structure analysis. We have discovered further examples in our studies on the cycloadditions of diaziridinimines[2].

Reaction of the diaziridinimine *(2a)* and *(1)* at 20°C in benzene/pentane produces the 1:3 adduct *(3a)* as deep red crystals (yield 27%). The two isomers *(2b)* and *(2c)*[3] behave differently when subjected to the same reaction: While *(2b)* and *(1)* give a 1:3 adduct resembling *(3a)* in its properties, reaction of *(2c)* with *(1)* affords only a 1:2 adduct of unknown structure in 4% yield.

	R^1	R^2
(a):	CH_3	CH_3
(b):	$C(CH_3)_3$	CH_3
(c):	CH_3	$C(CH_3)_3$

E = CO_2CH_3

The 270 MHz ^{1}H-NMR spectrum[4] and the ^{13}C-NMR spectra of the adduct of *(2a)* recorded in [D_6]benzene[4] and in [D]chloroform[5] indicate a symmetrical molecule. On cooling, however, all the ^{1}H-NMR signals undergo broadening which in the case of the NCH_3 signal leads to coalescence and splitting at −60°C [CD_2Cl_2, 60 MHz, $\Delta\nu = 13.5$ Hz (−88°C), $\Delta G_c^{\neq} = 10.8$ kcal/mol]. The symmetry observed at room temperature and the ^{13}C-NMR signal of a quaternary C atom at 86.0 ppm suggest structure *(3a)* having a nonplanar, flexible 1,4-dihydropyridine ring[6]. Final proof was provided by X-ray structure analysis, which showed *(3a)* to crystallize monoclinically in $P2_1/n$ (No. 14) with $a = 16.304(3)$, $b = 13.334(3)$, $c = 13.109(3)$ Å; $\beta = 99.02(2)°$; $Z = 4$. The structure was solved by direct methods and refined to $R = 0.096$ for 3066 reflections with $I > 2\sigma(I)$ [SYNTEX P$\bar{1}$ diffractometer; $Cu_{K\alpha}$; ω scan; $2\theta \leq 110°$; extended SYNTEX XTL system; MULTAN[7]; 40 independent atoms C, N, O with anisotropic B_{ij}; calculation neglecting the 33 H atoms].

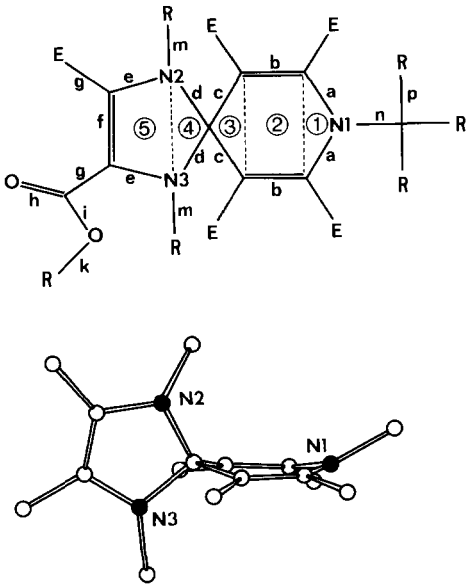

Fig. 1. Top: Designation of bonds and planes (numbers in circles) in *(3a)*. The designations g to k apply to all ester groups E.—Bottom: Spiro system of *(3a)*. Only the atom attached directly to the ring is shown for each of the substituents.

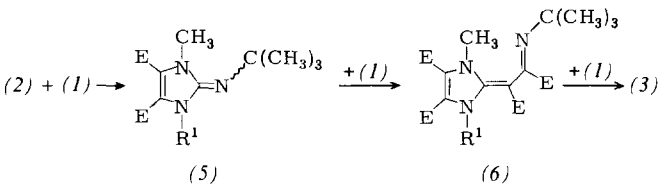

Figure 1 shows the structure of *(3a)*. The 1,4-dihydropyridine ring is distinctly bent; the planes 1 and 2 as well as 2 and 3 are mutually inclined by 11.3 and 15.0°, respectively. The double bonds b do not lie exactly in plane 2, as in a twisted boat. In the five-membered ring the planes 4 and 5 are mutually inclined by 4.4°; the planes 3 and 4 enclose an angle of 87.6°. The average bond lengths are (Å): a = 1.393, b = 1.358, c = 1.513, d = 1.480, e = 1.396, f = 1.337, g = 1.486, h = 1.200, i = 1.326, k = 1.469, m = 1.463, n = 1.554, p = 1.549; (σ = 0.009). Marked deviations from the average values occur only in d and e (different orientation of N-2 and N-3 to the six-membered ring). The lengths of c and d correspond to single bonds. The lengths a and b as well as e and f indicate extensive conjugation of the bonds in the two rings. Except for N-1, N-2, and the spiro C atom, the atoms of both rings lie in the plane defined by their three neighboring atoms. N-1 and N-2 project from this plane by 0.2 Å. The ester groups are practically identical, the average value of the angle between g and i being 111.8°.

The adducts *(3a)* and *(3b)* liberate isobutene very readily in the presence of traces of acid. The structure *(4)* of the yellow products formed in quantitative yield is based on ^{1}H-

NMR, ^{13}C-NMR, and IR spectra. The IR absorption at 3320 cm^{-1}, which is independent of the state of aggregation, solvent, and concentration, indicates an intramolecular hydrogen bond.

(5) *(6)*

The unexpected formation of *(3)* can be rationalized in terms of a primary [3+2] cycloaddition of *(1)* to *(2)*, giving *(5)*, a [2+2] cycloaddition of *(1)* to the C=N bond of *(5)*, subsequent opening of the azetine ring to give *(6)*, and a [4+2] cycloaddition of *(1)* to *(6)*. Analogous spirodihydropyridines were accordingly also obtained from other heterocyclic imines and guanidine derivatives[8]. A reaction corresponding to *(6)*+*(1)*→*(3)* has recently been observed on formation of similar spirodihydropyridines from benzothiazoletriazenes[9].

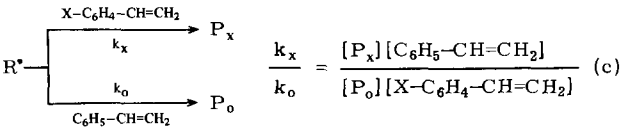
Polar Effects in the Addition of Alkyl Radicals to Olefins[**]

By *Bernd Giese* and *Jürgen Meister*[*]

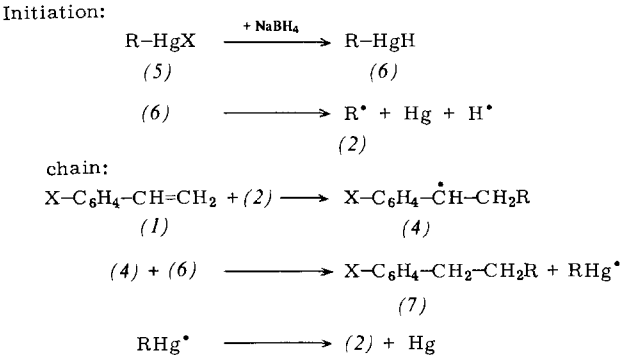
Alkyl radicals *(2)* add faster to electron-deficient olefins[1a] and aromatic compounds[1b] than to electron-rich π systems. These differences in reactivity have been interpreted in terms of stabilization of the transition states due to polar effects[1c]. Experimental determination of the Hammett ϱ values[2] represents a quantitative method of establishing the extent of charge separation in *(3)*.

$$\log(k_X/k_0) = \varrho \cdot \sigma \qquad \text{(a)}$$



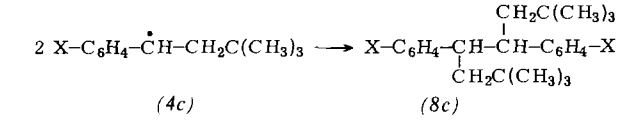
According to eq. (a) the reaction parameter ϱ reproduces the effect of the substituent X on the rate constant k_X in eq. (b). k_0 applies to X=H.

(1) *(2)* *(3)* (b)



(4)

If the subsequent reactions of the adduct radicals *(4)* can be quantitatively determined (formation of products P_X), then the selectivity values ($\log k_X - \log k_0$) can be calculated according to eq. (c) on working in an excess of *(1)*[3].



(c)

A suitable method for generating the radicals *(2)* and for trapping the adduct radicals *(4)* consists in the reaction of organomercury salts *(5)* with $NaBH_4$ in the presence of substituted styrenes *(1)*[4a]. The hydrides *(6)* should act as radical generators[4a,4b]. The resulting radicals *(2)*, which can undergo typical radical reactions[4], add to the olfins *(1)*. Subsequent H capture leads to the 1:1 adducts *(7)*.

Product analysis by gas chromatography showed that on reaction of ethanolic solutions of 1-hexyl- *(5a)* and of cyclohexylmercury acetate *(5b)* with $NaBH_4$ in the presence of the styrenes *(1)*, the 1:1 adducts *(7)* are formed as secondary products of *(4)*. Only *tert*-butylmercury chloride *(5c)* gave the dimer *(8c)* from the adduct radicals *(4c)*, alongside *(7c)*, in yields exceeding 5%. No disproportionation products could be detected[5].

(4c) *(8c)*

Plotting of the relative reactivities ($k_{styrene} \equiv 1$) of 4-chloro- *(1a)*, 3-chloro- *(1b)*, 4-methyl- *(1c)*, and 4-methoxystyrene *(1d)* *versus* the σ^+ parameters[6] for 14 reaction series gave straight lines each having a correlation coefficient *r* of about 0.95. The positive reaction parameters ϱ obtained for primary, secondary, and tertiary radicals *(2)* between −56 and +42 °C

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

(Fig. 1) establish the presence of a negative partial charge on the benzylic carbon atom in the transition state *(3)*. Thus, as in H abstractions from toluene derivatives[7], the alkyl radicals display nucleophilic properties in additions to olefins.

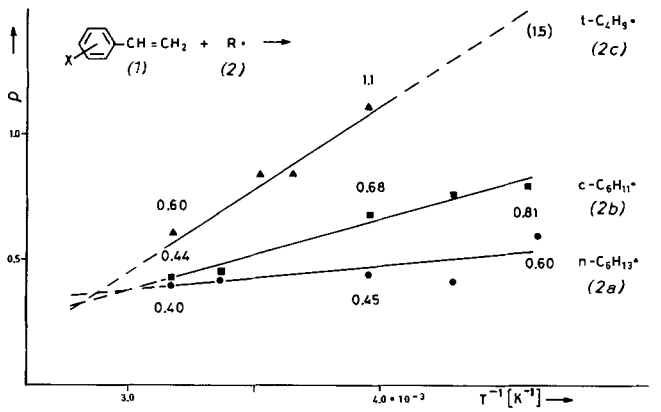

Fig. 1. Temperature dependence of the ϱ values (−56 to +42 °C) for the addition of alkyl radicals *(2a)*—*(2c)* to the styrenes *(1a)*—*(1d)* in ethanol.

The gradation of ϱ values for tertiary, secondary, and primary radicals warrants interest: The *tert*-butyl radical *(2c)* has a much larger ϱ value (1.1) at −20 °C than the cyclohexyl radical *(2b)* ($\varrho = 0.68$) and the 1-hexyl radical *(2a)* ($\varrho = 0.45$). In contrast, the values hardly differ from one another at +42 °C (0.60, 0.44, and 0.40, respectively) (Fig. 1). The reaction parameter of 0.51 determined for benzylic radicals at +60 °C in copolymerizations[8] is in good agreement with these results.

Like the steric reaction parameters for radical halogen abstractions[9] the values for additions of radicals to olefins are highly dependent upon temperature.

X-Ray Structure Analysis of *N*-Phenyl-*N'*-sulfinylhydrazine

By *Alfred Gieren* and *Bernhard Dederer*[*]

In order to gain further insight into the nature of the S=N double bond of tetravalent sulfur with the coordination number 2, having already solved the structure of sulfur diimides of the type RN=S=NR[1], we have performed to our knowledge the first X-ray structure analysis of an isoelectronic compound of the type RN=S=O. The compound investigated, *N*-phenyl-*N'*-sulfinylhydrazine *(1)*[2], crystallizes from

(1a) *(1b)*

anhydrous ethanol in the monoclinic space group $P2_1/a$ with eight molecules in the unit cell (2 molecules per asymmetric unit). Lattice constants: $a = 10.50_5$, $b = 15.75_1$, $c = 8.45_9$ Å, $\beta = 94.4_9°$; $d_{calc} = 1.47$, $d_{exp} = 1.45\ g \cdot cm^{-3}$. Using an automatic single crystal diffractometer 2642 independent reflections were recorded with Cu-K_α radiation (5 point measurement, $\theta/2\theta$ scan); 300 reflections were unobserved ($I \leq 2\sigma_I$). The structure was solved by direct methods. Least squares refinement (H atoms with isotropic temperature parameters, all other atoms with anisotropic ones) converged at an R value of 4.2 % (observed reflections). All the hydrogen atoms were located in a difference Fourier synthesis at $R = 8.5$ %.

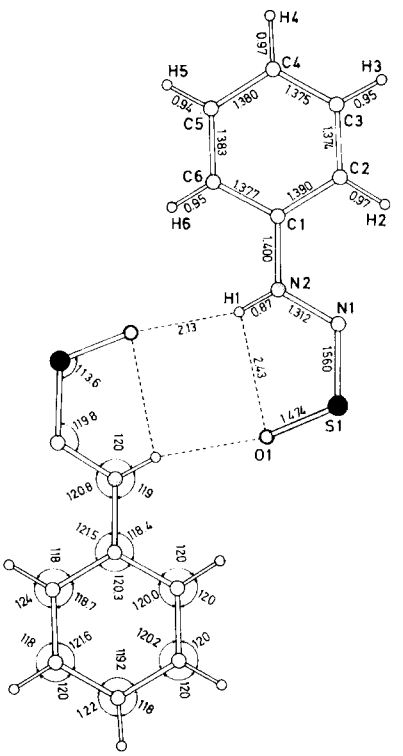

Fig. 1. Structure of dimeric *N*-phenyl-*N'*-sulfinylhydrazine. The bond lengths and angles are averaged over the two molecules. The mean standard deviations of the non-averaged values are 0.006 Å for the bond lengths (except C—H and N—H: 0.05 Å), and 0.4° for the angles (except those including H: 3°).

[*] Dr. habil. A. Gieren, Dipl.-Chem. B. Dederer
Max-Planck-Institut für Biochemie, Abt. Strukturforschung I
Am Klopferspitz, D-8033 Martinsried (Germany)

Compound *(1)* is roughly planar and in the crystalline state forms a dimer with approximate 2/m symmetry: the two molecules of the dimer (asymmetric unit) are linked by two (N)—H···O=(S) hydrogen bonds (2.13 Å). In addition, *(1)* contains an intramolecular bridge of the same kind (H···O 2.43 Å). Hence the hydrogen and the oxygen atom function as twofold donor and acceptor, respectively (Fig. 1).

The S=N bond length is 1.56 Å, and the S=O bond length 1.47 Å. Both bonds are thus significantly longer than the corresponding S^{IV}=N distances in sulfur diimides (*ca.* 1.53 Å)[1] and 2,5-diphenyl-1-phenylimino-1λ^4,2,5-thiadiazolidine-3,4-dione (1.51 Å)[3] on the one hand, and the S^{IV}=O distance in sulfur dioxide (1.43 Å)[4], on the other. The N—N bond length indicates a significant double bond character (N=N double bond length 1.24 Å[5]). Both nitrogen atoms are sp^2 hybridized, as shown by the bond angles at N-1 and N-2 and by the trigonal-planar configuration at N-2. The formal S=N double bond is *cis*-configurated, this being favored by formation of the H-chelate ring.

It may be deduced from the bond lengths and the sp^2 hybridization of N-2 that the mesoionic resonance formula *(1b)* makes a considerable contribution to the ground state. The formation of hydrogen bonds also evidences *(1b)* since the acidity of the NH proton and the basicity of the sulfinyl oxygen are thus enhanced.

(Chloromethylene)triphenylphosphorane

By *Rolf Appel* and *Wolfgang Morbach*[*]

Having recently isolated (dichloromethylene)triphenylphosphorane *(3c)*[2], a reactive compound fittingly described as "moderated"[1] we have attempted to synthesize (chloromethylene)triphenylphosphorane which is to be assigned an intermediate position between methylenetriphenylphosphorane *(3a)* and *(3c)*. The first indication of the existence of this ylide was provided by dehydrochlorination experiments on (chloromethyl)triphenylphosphonium chloride *(1b)* with

$$\underset{(1b)}{[Ph_3P{-}CH_2Cl]^{\oplus}Cl^{\ominus}} + \underset{(2)}{C(=PPh_3)_2} \rightleftharpoons \underset{(3b)}{Ph_3P{=}CHCl} + \underset{(4)}{[Ph_3P{=}C(H){=}PPh_3]^{\oplus}Cl^{\ominus}} \quad (a)$$

$$\underset{(1c)}{[Ph_3P{-}CHCl_2]^{\oplus}Cl^{\ominus}} + \underset{(5)}{P[N(CH_3)_2]_3} \longrightarrow \underset{(3b)}{Ph_3P{=}CHCl} + \underset{(6)}{PCl_2[N(CH_3)_2]_3} \quad (b)$$

[*] Prof. Dr. R. Appel, Dipl.-Chem. W. Morbach
Anorganisch-chemisches Institut der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

bis(triphenylphosphoranylidene)methane *(2)*[2a]; however, the ylide could not be obtained on a preparative scale according to eq. (a) owing to an inadequate difference in basicity between the two ylide systems. Dechlorination of (trichloromethyl)-triphenylphosphonium chloride with tri(dimethylamino)phosphane which was successful in the case of *(3c)* failed to give a uniform product on application to *(1c)* according to equation (b) because dechlorination is accompanied by dehydrochlorination, thus precluding isolation of a pure product.

We have now succeeded in isolating pure *(3b)* by a systematic application of the reaction termed transylidation by *Bestmann*[3], which is based on the graduated basicity of the ylide systems *(3a—c)*. If the phosphonium salts *(1a—c)* are regarded as Brønstedt acids and the corresponding alkylenephosphoranes as bases, then the strengths of the corresponding acid/base pairs will depend upon the number of H and Cl atoms attached to the ylidic C atom.

Acidity:

$$\underset{(1a)}{[Ph_3PCH_3]^{\oplus}Cl^{\ominus}} < \underset{(1b)}{[Ph_3PCH_2Cl]^{\oplus}Cl^{\ominus}} < \underset{(1c)}{[Ph_3PCHCl_2]^{\oplus}Cl^{\ominus}}$$

Basicity:

$$\underset{(3a)}{Ph_3PCH_2} > \underset{(3b)}{Ph_3PCHCl} > \underset{(3c)}{Ph_3PCCl_2}$$

The electron-withdrawing effect of chlorine enhances the acidity of the phosphonium salts proceeding from *(1a)* to *(1c)*, while the basicity increases in the opposite direction from *(3c)* to *(3a)*. Owing to the considerable differences in the basicity of the ylides *(3a—c)* "transylidations" according to eqs. (c) to (e) proceed smoothly and adequately to permit isolation of the missing member in the series *(3b)* in good yield.

$$Ph_3PCH_2 + [Ph_3PCH_2Cl]^{\oplus}Cl^{\ominus} \longrightarrow [Ph_3PCH_3]^{\oplus}Cl^{\ominus} + Ph_3P{=}CHCl \quad (c)$$

$$Ph_3PCH_2 + [Ph_3PCHCl_2]^{\oplus}Cl^{\ominus} \longrightarrow [Ph_3PCH_3]^{\oplus}Cl^{\ominus} + Ph_3P{=}CCl_2 \quad (d)$$

$$Ph_3PCHCl + [Ph_3PCHCl_2]^{\oplus}Cl^{\ominus} \longrightarrow [Ph_3PCH_2Cl]^{\oplus}Cl^{\ominus} + Ph_3P{=}CCl_2 \quad (e)$$

(Chloromethylene)triphenylphosphorane (3b):

Compound *(3a)* (13.8 g, 0.05 mol)[4] is added to *(1b)* (21 g, 0.06 mol) in anhydrous THF (300 ml). After stirring for 20 to 30 min the precipitated salt *(1a)* and excess *(1b)* are filtered from the ylide present in solution. The initial crystal deposit obtained on concentrating the orange solution is dried in a high vacuum; further yields are purified by recrystallization from THF. Yield 10.9 g (70 %) of analytically pure yellow substance, decomp. 95 to 98 °C. ^{31}P-NMR: $\delta_{(THF)} = 14.3$ ppm (85 % H_3PO_4 as ext. standard); ^{1}H-NMR $\delta_{([D_8]THF)} = 2.64$ ppm (doublet, TMS int. standard, $J_{PCH} = 24$ Hz); ^{13}C-NMR: $\delta_{(C_6D_6)} = 25.73$ ppm (doublet, TMS int. standard, $J_{PC} = 64.4$ Hz).

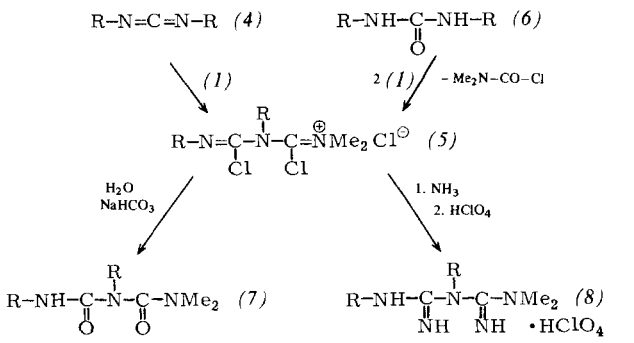
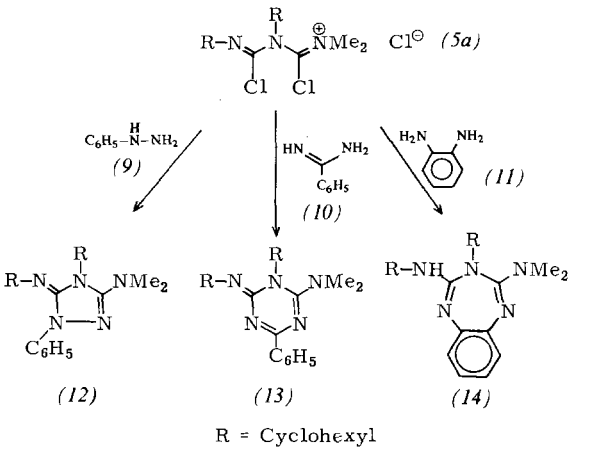
New Reagents for Synthesis of Heterocyclics from Carbodiimides and Phosgeniminium Salts[1]



By *Asher Elgavi* and *Heinz Günter Viehe*[*]

(Dichloromethylene)dimethylammonium salts ("phosgeniminium salts") *(1)* are stable electrophilic reagents of the Mannich-Böhme and Vilsmeier-Haack-Arnold type[2]. These salts add readily to electron rich multiple bonds: with cyanamide *(2)*, for example, they yield the versatile azatrimethinecyanine *(3)*[3].



(1) *(2)* *(3)*

It is now found that carbodiimides *(4)* form the adducts *(5)* with *(1)*. The same products arise also from *(1)* and *N,N'*-disubstituted ureas *(6)*. Biselectrophiles *(5)* being isomeric with *(3)* are in fact trichlorides of 1,1,3,5-tetrasubstituted biurets *(7)*, which they yield upon hydrolysis. Aminolysis or ammonolysis of *(5)* afford the corresponding biguanides *(8)* (Table 1).

(a), R = Cyclohexyl; *(b)*, R = CH_3

The synthetic potential of (1,3-dichloro-2,4-dicyclohexyl-2,4-diaza-3-butenylidene)dimethylammonium chloride *(5a)* in heterocyclization reactions is demonstrated by the synthesis of triazolinimine *(12)*, triazinimine *(13)*, and benzotriazepine *(14)* (see Table 1).

R = Cyclohexyl

Procedures:

(5a): A mixture of dicyclohexylcarbodiimide *(4a)* and *(1)* (molar ratio 1 : 1) in chloroform is stirred at room temperature until *(1)* has dissolved. The solvent is partially evaporated and ether is added to precipitate *(5a)* as a white hygroscopic solid.

(5b): 1,3-Dimethylurea *(6b)* and *(1)* (molar ratio 1 : 2) are refluxed in chloroform for about 1 h until all *(1)* has dissolved; work-up is the same as for *(5a)*.

(14): A refluxing mixture of *(5a)* (3.68 g) and *o*-phenylenediamine *(11)* (10.8 g) in methylene chloride (40 ml) is stirred overnight. The solution is then concentrated and dry ether is added to precipitate the hydrochloride of *(14)* (4.6 g, 87 %). The free base *(14)* is obtained by treatment with concentrated KOH at 0 °C, and recrystallization from ethanol/water.—Compounds *(12)* and *(13)* were prepared analogously.

Table 1. Properties of the new compounds.

Cpd.	R	Yield [%]	M.p. [°C]	IR [cm^{-1}] (in $CHCl_3$)	^{1}H-NMR (δ values) [a]

Reactions of Acyl Chlorides/Triethylamine or Ketenes with Phosgeniminium Salts[1]

By *Heinz Günter Viehe, Brigitte Le Clef*, and *Asher Elgavi*[*]

α-Chloro-β-(chlorocarbonyl)enamines *(3)* are known to arise from the addition of phosgene to ynamines[2] or from the condensation of phosgene with monosubstituted acetamides in the presence of bases[3, 4].

We have now found that *(3)* can be obtained in good yields from the reaction of monosubstituted acetyl chlorides and (dichloromethylene)dimethylammonium salts ("phosgeniminium salts") *(2)*[5] (Table 1).

(1) *(2)* *(3)*

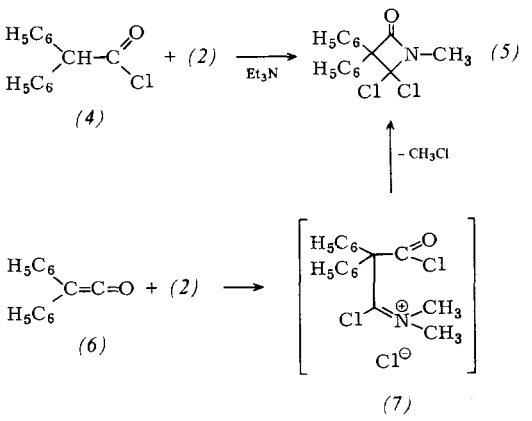

Table 1. α-Substituted β-chloro-β-(dimethylamino)acryloyl chlorides *(3)*.

Cpd.	R	Yield [%]	B.p. [°C/torr]	IR [cm^{-1}] (in $CHCl_3$)	^{1}H-NMR (δ value) [a]
(3a)	C_6H_5	70	dec.	1700, 1555	3.18 (6H, s), 7.32 (5H, s)
(3b)	Cl	75	70—75/0.1	1685, 1550	3.17 (s)
(3c)	CH_3	70	70—74/0.1	1715, 1555	2.20 (3H, s), 3.10 (6H, s)
(3d)	C_2H_5	60	75—80/0.3	1710, 1550	1.14 (3H, t), 2.60 (2H, q), 3.08 (6H, t)

[a] In $CDCl_3$, TMS = 0.

Thus phenylacetyl chloride *(1a)* condenses with *(2)* in the presence of triethylamine to yield *(3a)*. No reaction occurs in the absence of a base, which indicates that either phenylketene, the corresponding acylammonium salt, or the acyl chloride enolate[6] is the reactive intermediate.

If the starting material is diphenylacetyl chloride *(4)*, the new dichloro β-lactam *(5)* is obtained instead of the adduct *(3)*. This heterocycle arises alternatively and equally well from diphenylketene *(6)* and *(2)*.

(4) *(5)* *(6)* *(7)*

The intermediate *(7)* can be detected by NMR spectroscopy. When diphenylketene *(6)* and *(2)* are heated to 45 °C, broad peaks appear at δ = 4.25 and 7.45 ppm which correspond most probably to the *N*-dimethyl and phenyl signals. These absorptions disappear on the formation of *(5)*.

Compounds *(3)*, being reactive derivatives of malonamic acid, are well established reagents, particularly for the synthesis of heterocycles[4, 7]. *(5)* as the first representative of the reactive class of 4,4-dichloroazetidin-2-one merits further synthetic interest[8].

Experimental:

(3a): Triethylamine (2.02 g, 0.02 mol) is added dropwise at room temperature to a stirred suspension of *(2)* (1.65 g, 0.02 mol) in a dry chloroform solution containing phenylacetyl chloride (1.54 g, 0.02 mol). Stirring is continued until *(2)* is completely dissolved. The solvent is then evaporated and the product is extracted with refluxing ether. After filtration and evaporation of the solvent *(3a)* is recrystallized from ether/petroleum ether.

(5): Compounds *(2)* (1.62 g, 0.01 mol) and *(6)* (1.94 g, 0.02 mol) are added to dry chloroform (30 ml). The stirred solution is refluxed until *(2)* has completely disappeared. The solvent is evaporated and *(5)* is recrystallized from cyclohexane [colorless needles, m.p. 152—153 °C, yield 72%; IR ($CHCl_3$) 1775 cm^{-1} (C=O); NMR ($CDCl_3$/TMS = 0): δ = 3.0 (3H, s), 7.1—7.75 ppm (10H, m)]. The *N*-ethyl analog of *(5)* was obtained analogously [m.p. 138—139 °C, yield 73%; IR ($CHCl_3$): 1775 cm^{-1}; NMR ($CDCl_3$/TMS = 0): δ = 1.4 ppm (3H, t), 3.45 (2H, q), 7.1—7.7 (10H, m)].

Halogenonitrosylmolybdates—Simple, Monomeric Mo^{II} Complexes

By *Sabyasachi Sarkar* and *Achim Müller*[*]

In general the complexes of bivalent molybdenum are still poorly understood[1]. It is assumed that several strong π-acceptors as ligands are necessary to stabilize the Mo^{II}-d^4-system (as *e.g.*, in $[Mo(CO)_2(diars)I_2]$ or $[Mo(diars)_2Cl_2]$[1,2]. Classical mononuclear coordination compounds with simple ligands (as in Cr^{II}) were hitherto unknown[3]. We report here on the first of such complexes, which can also be used for the preparation of other molybdenum(II) complexes.

The complexes $Cs_2[Mo(NO)Cl_5]$ *(1)* (orange) and $Cs_2[Mo(NO)Br_5]$ *(2)* (deep red) as well as $[(C_6H_5)_4P][Mo(NO)Cl_4]$ *(3)* (yellow) and $[(C_6H_5)_4P][Mo(NO)Br_4]$ *(4)* (red) can be isolated as diamagnetic and stable crystals at room temperature. They were characterized by elemental analysis, molecular weight measurements [*(3)* and *(4)* in CH_2Cl_2], magnetic measurements as well as by X-ray powder diffraction diagrams (for the interconversion of *(1)* to *(3)* and of *(2)* to *(4)* see experimental part). *(1)* and *(2)* as well as *(3)* and *(4)* are isostructural, respectively. The magnetic properties and vibrational spectra proved the existence of monomeric complex anions (C_{4v}-symmetry) with d^4-configuration of the central atom (four electrons in two d(e)-orbitals)[4]. All vibrational frequencies lie in the expected region. Accurate measurements of ν(NO) and ν(MoN) showed (Table 1) that the π-backbonding effect of NO in the chloro complex *(1)* is smaller than that in the bromo complex *(2)*; this can be explained by the higher electronegativity of the halogen ligand in the *trans* position in *(1)*. The *trans*-effect of the NO-group in *(1)* and *(2)* gave $\nu(MoX_4) > \nu(MoX)_{trans}$.

hydrochloric acid *in air* for *ca.* 2 h to get a clear solution. After addition of 2 g of CsCl, dissolved in 20 ml concentrated hydrochloric acid, *(1)* precipitated as orange crystals which were filtered, washed several times with concentrated hydrochloric acid and dried in a vacuum over KOH. The preparation of *(2)* (HBr and CsBr), *(3)* (HCl and $[(C_6H_5)_4P]Cl$) and of *(4)* (HBr and $[(C_6H_5)_4P]Br$) was carried out analogously. *(1)* and *(3)* are interconvertible in hydrochloric acid according to the following equation (see[6]):

$$Cs_2[Mo(NO)Cl_5] \underset{CsCl}{\overset{[(C_6H_5)_4P]^+}{\rightleftharpoons}} [(C_6H_5)_4P][Mo(NO)Cl_4]$$

The corresponding equation is valid for *(2)* and *(4)*.

(3)	1694.5±2(vs)	616±1(w)	638±2(w)	323*br*(s)	[a]	—
(4)	1691.5±2(vs)	615±1(w)	640±2(w)	230*br*(s)	[a]	—
	A_1	A_1	E	E	A_1	A_1

[a] overlapped by $\nu_{as}(MoX_4)$.

The MoNO moiety is so stable (the π-accepting ability of one NO ligand is large enough to stabilize the Mo-d^4-system!) that in the case of addition of other ligands, *e.g.*, CN^- or OH^-, only an exchange of Cl^- and Br^- is observed. Therefore, the complexes *(1)*–*(4)* can be used to synthesize other Mo^{II} complexes and also to study the ligand exchange reactions on Mo^{II} systems.

Experimental:

A saturated solution of 2 g $K_4[Mo(NO)(CN)_5]\cdot 2H_2O$[5] in water was refluxed after addition of 30 ml concentrated

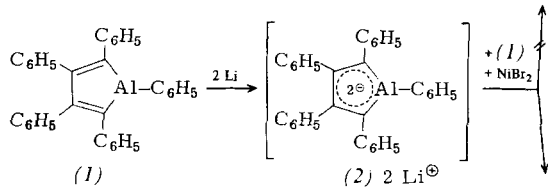
Novel Organonickel Compounds from (Pentaphenyl)aluminacyclopentadiene

By *Heinz Hoberg*[*] and *Reinhild Krause-Göing* and *Carl Krüger*[**] and *Janine C. Sekutowski*[***]



Acting as a cyclic diene, (pentaphenyl)aluminacyclopentadiene *(1)*[1] forms olefin complexes with transition metals. We have obtained a 1:1 complex from *(1)* and $(COD)_2Ni$[2]. The hitherto unknown 2:1 compound *(3)* should be accessible

[*] Priv.-Doz. Dr. H. Hoberg, Dipl.-Chem. R. Krause-Göing, Dr. C. Krüger, Dr. J. C. Sekutowski

by reduction of $NiBr_2$ with the dilithiated Al-five-membered ring *(2)* in the presence of *(1)*.

(3)

(1) *(2)* 2 $Li^{\oplus}$

$C_5(C_6H_5)_5NiC_3(C_6H_5)_3NiC_4(C_6H_5)_4$

(4)

+

$C_4(C_6H_5)_4NiC_4(C_6H_5)_4$

(5)

However, on performing the reaction of $NiBr_2$ with *(2)* in the presence of *(1)* in the molar ratio 1:1:1 we did not obtain compound *(3)* but instead the Al-free Ni complexes *(4)* and *(5)*.

IR and ^{1}H-NMR analyses reveal only phenyl groups. The mass spectrum of the deep violet compound *(4)* contained both the molecular ion and characteristics ions of the ligands at *m/e* 1184 $[C_{12}(C_6H_5)_{12}Ni_2]$, 446 $[C_5(C_6H_5)_5H]$, 356 $[C_4(C_6H_5)_4]$, 268 $[C_3(C_6H_5)_3H]$.

The structure of *(4)* could be established by X-ray analysis[3]. Cell data: $a=13.253(1)$, $b=21.310(1)$, $c=23.4775$ (6) Å, space group $P2_12_12_1$, $Z=4$, $R=0.075$ for 4473 reflections, of which 1378 were unobserved ($I \leq 2\sigma I$). The molecule (see Fig. 1 and 2) contains two non-identical nickel atoms, of which one (Ni-2) is complexed to pentaphenylcyclopentadiene, and the other one to a tetraphenylcyclobutadiene unit. Ni-1 and Ni-2 are bridged by a 1,2,3-triphenylallyl unit, which bonds as a π-allyl group to Ni-1[4] and *via* two σ bonds to Ni-2. The distance Ni-2—C-6 is 2.44(2) Å. Both nickel atoms achieve a stable 18-electron configuration by forming an additional Ni—Ni single bond[5]. Thus compound *(4)* is characterized both by an unusual mode of synthesis and by a remarkable structure, in which three dissimilar olefinic ligands are bonded to a Ni—Ni system and the bridging C_3 unit engages in both σ and π bonding.

It cannot yet be decided whether the $C_3(C_6H_5)_3$ and $C_5(C_6H_5)_5$ units present in *(4)* have arisen from the $C_4(C_6H_5)_4$ group of the Al-five-membered ring *(1)* as a result of a dichotomy[6].

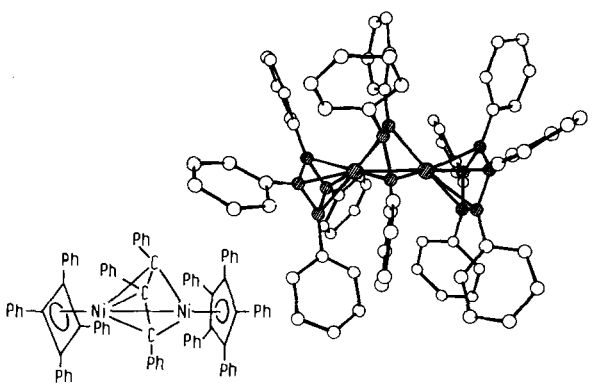

Fig. 1. Complete molecular structure of *(4)*.

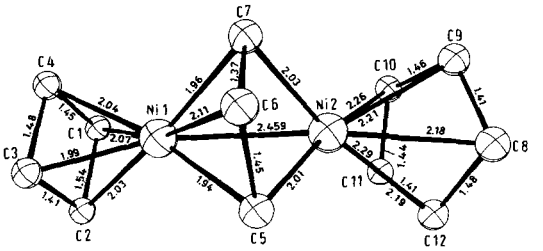

Fig. 2. Molecular structure of *(4)* and numbering of the atoms. The 12 phenyl groups have been omitted for the sake of clarity.

Elemental and MS analyses of *(5)* provide evidence that it is a compound in which two $C_4(C_6H_5)_4$ units are bonded to a nickel atom, *i.e.* possibly a derivative of the hitherto unknown bis(cyclobutadiene)nickel. Further studies, and in particular X-ray structure analysis, should substantiate this conclusion.

Procedure:

A suspension of $C_4(C_6H_5)_5Al \cdot O(C_2H_5)_2$ *(1)* (4.83 g, 9.0 mmol) and Li powder (73 mg, 10.5 mmol) in diethyl ether (350 ml) is stirred for 4 d at 20°C. The resulting red mixture is filtered and the filtrate allowed to react at −10°C with $NiBr_2$ (1.0 g, 4.6 mmol). The temperature of the stirred mixture is permitted to rise to 20°C, and after standing for *ca.* 48 h a gray precipitate is filtered off (*ca.* 0.4 g). From the intensely green filtrate fractional crystallization gives *(5)* (0.15 g, 4.2%; blue crystals, m.p. >300°C) and *(4)* (0.19 g, 7%; m.p. 270°C (dec.)). The yields are based on $NiBr_2$.

Quantitative Field Desorption Mass Spectrometry; Stable Isotope Dilution and Cationization[**]

By *W. D. Lehmann* and *H.-R. Schulten*[*]

Field desorption mass spectrometry (FD-MS) has been used for the qualitative analysis of polar organic and inorganic compounds[1]. One of the principal applications is the determination of the molecular ion $[M]^{\ddagger}$. In FD-MS attachment of a cation $[Cat]^+$ to a neutral molecule M (cationization)[2] leads to particularly stable ions of the type $[M+Cat]^+$ which can be utilized in molecular weight determinations[3]. Quantitative FD-MS with ions of type $[M]^{\ddagger}$ has already been de-

[+] To whom correspondence should be addressed.

scribed[4]. We now report the first quantitative results of FD-MS obtained by exploiting cationization.

Field desorption mass spectrometry and similar mass spectrometric methods give spectra for numerous organic compounds which consist predominantly of the ion $[M]^{\ddagger}$ or $[M+Cat]^+$. These methods are particularly suitable for quantitative determinations because:
structurally significant fragments are not required,
interference due to impurities in the sample is reduced, and
the molecular ion or the cationized molecule carries almost the entire ion current, thus leading to maximum possible sensitivity.

A drawback of the FD-MS method is that it gives lower ion currents showing greater fluctuations than electron impact and chemical ionization. For this reason
the sensitivity was increased by cationization with alkali metal cations,
the precision improved by an isotopically labeled internal standard, and
the value determined for $[M+Cat]^+$ was averaged over a large number of repetitive scans.

Figure 1 shows a section of five scans recorded in the quantitative determination of a non-derivatized monosaccharide, glucose, on a microgram scale.

The extent of labeling of the internal standard [1-^{13}C]-glucose was determined by comparison of the attachment-FD spectra A and B (Table 1). Taking account of the intensity of the peak at *m/e* 202 of unlabeled glucose, it was calculated that C-1 of the [^{13}C]-glucose is 86.7% ^{13}C. Use of monoisotopic $[^{23}Na]^+$ for cationization greatly simplifies quantitative evaluation of the spectra. The quantitative data obtained are supported by determination of the intensity distribution of the $[M+H]^+$ group by the normal field desorption procedure (spectrum D, Table 1).

The spectra were evaluated by making the simplifying assumption that only $[M+Na]^+$ and $[M+H]^+$ ions are formed. For spectrum C($[M+Na]^+$ group) a molar ratio

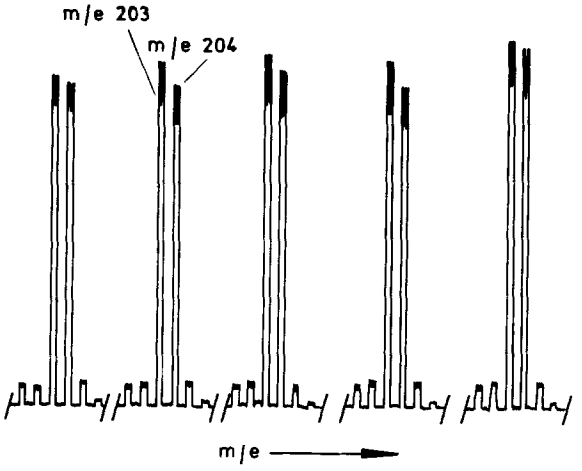

Fig. 1. Five scans from a series of measurements comprising 105 consecutive FD scans over the $[M+Na]^+$ group of a mixture of glucose and [1-^{13}C]-glucose (86.7% ^{13}C) in the presence of $[Na]^+$. According to the amount of sample weighed out the molar ratio was 1:1.17. Cationization was ensured by dissolution of glucose and NaI in the approximate molar ratio 1:1 in water. The solution was applied to a high-temperature activated FD emitter with a microliter syringe. The emitter heating current was about 10 mA while the spectrum was being recorded. The spectra were recorded at low resolution (plateau peaks) by variation of the accelerating potential with a Varian MAT 731 mass spectrometer (see also Table 1, spectrum C).

of 1:1.184 (error +1.1%) was obtained, and for spectrum D ($[M+H]^+$ group) a molar ratio of 1:1.191 (error + 1.7%).

Table 1. Relative intensities of the $[M+Na]^+$ group (spectra A to C) and the $[M+H]^+$ group (spectrum D) in the FD mass spectrum of glucose in the presence and absence, respectively, of $[Na]^+$. In order to record the sodium attachment spectra the sample was dissolved together with NaI in the approximate molar ratio of 1:1 in H_2O; for recording the normal FD mass spectrum pure H_2O was used as solvent. The amounts of sample applied were in the microgram range.

m/e	202	203	204	205
	Relative intensity [%]			
Spectrum A	2.3	100	8.9	
Spectrum B		17.5	100	6.3
Spectrum C	3.4	100	96.1	7.1
m/e	180	181	182	183
	Relative intensity [%]			
Spectrum D	10.5	100	96.5	9.8

Spectrum A: $[M+Na]^+$ group of glucose + NaI, 60 consecutive scans, 5 mA emitter heating current.
Spectrum B: $[M+Na]^+$ group of [1-^{13}C]-glucose (86.7% ^{13}C) + NaI, 60 consecutive scans, 10 to 15 mA emitter current.
Spectrum C: $[M+Na]^+$ group of a mixture of glucose and [1-^{13}C]-glucose (molar ratio 1:1.17) + NaI, 105 consecutive scans, 10 to 15 mA emitter heating current, mean error of the individual measurements of relative intensity of *m/e* 204: ±7.2%; mean error of average value: ±0.7% (see also Fig. 1).
Spectrum D: $[M+H]^+$ group of a mixture of glucose and [1-^{13}C]-glucose (molar ratio 1:1.17), 210 consecutive scans, 18 to 20 mA emitter heating current, mean error of the individual measurements of the relative intensity of *m/e* 182: ±6.8%; mean error of the average value: ±0.47%.

In the quantitative determination of glucose by field desorption mass spectrometry the mean error of the individual measurement is about 7%. On evaluation of 100 scans the mean error of the average value is ±0.7%, and this value decreases accordingly as more scans are recorded. No isotope effects were observed in these series of measurements. Our investigations show that field desorption mass spectrometry in conjunction with the isotopic dilution method possesses good sensitivity and precision for quantitative analysis and can be regarded as a promising method for biochemical and medical analysis (*e.g.* pharmakokinetic studies).

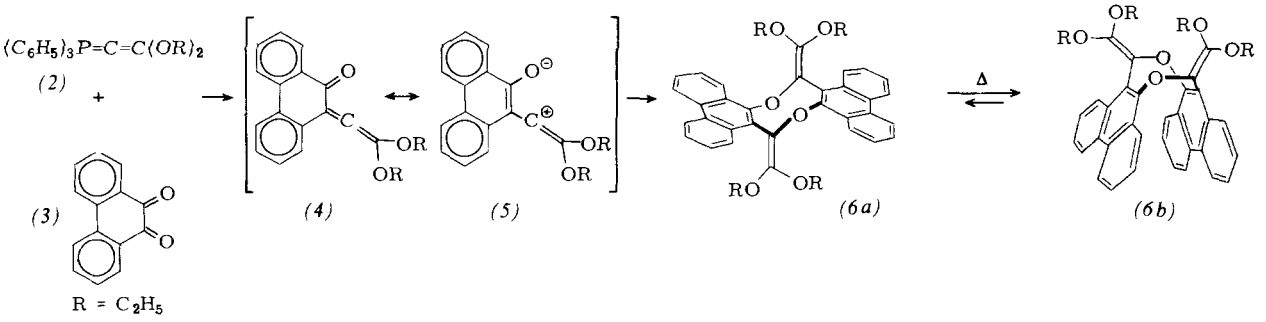
Chair and Boat: Stable Conformers of an Eight-Membered Ring System[**]

By *Rolf W. Saalfrank*[*]

Eight-membered ring systems of type *(1)* can in principle assume a rigid chair-like conformation or a flexible boat-like



[*] Priv.-Doz. Dr. R. W. Saalfrank
Institut für Organische Chemie der Universität
Erlangen-Nürnberg (Germany)
[**] Based on a lecture delivered at the V. International Conference of Organic Chemistry, Gdansk (Poland), September 1974.

conformation[1]. α-Disalicylide [*(1)*, X=Z=O; Y=W=CO] exists exclusively in the boat conformation[2]. In the case of 5,6,11,12-tetrahydrodibenzo[*a,e*]cyclooctene [*(1)*, X=Z=Y=W=CH_2], however, both the chair and the boat conformations are present in almost equal proportions in solution[3], whereas in the crystalline state only the chair conformation is known[4]. In the following communication the synthesis and isolation of the chair and boat conformers of an eight-membered ring system is reported for the first time.

(1)

Wittig reaction of the (2,2-diethoxyvinylidene)triphenylphosphorane *(2)* with 9,10-phenanthrenequinone *(3)* leads, probably *via* [4+4] cycloaddition[6] of the 1,4-dipole *(5)* and the "*o*-quinonoid" allene *(4)*[5], to the cyclooctane derivative *(6)*, whose chair and boat conformers *(6a)* and *(6b)* can be separated by fractional crystallization.

Identification of the conformers follows from the temperature dependent ^{1}H-NMR and ^{13}C-NMR spectra (Table 1).

On the basis of their molecular symmetry [C_i for *(6a)*, C_2 for *(6b)*] one would expect the ^{1}H-NMR spectra of both conformers at room temperature to show two triplets for the methyl groups together with a multiplet, since the methylene protons in both molecules are diastereotopic. A molecular model shows that in the chair conformers *(6a)* two ethoxy groups are more remote from the phenanthrene residues than the other two. Hence two CH_3 groups are more strongly shielded and, as a consequence, their signals appear at higher field in the ^{1}H-NMR spectrum. In the flexible boat conformer *(6b)*, on the other hand, no ethoxy group is outstandingly oriented. Hence the two CH_3 triplets differ only slightly in their chemical shift.

Heating of the chair boat conformer in 1,2-dichlorobenzene leads to an equilibrium mixture. The position of the equilibrium (chair : boat ≈ 1 : 2) is practically independent of temperature between 30 and 90°C.

All conformers of the boat family are chiral. Their racemization ensues by flipping of the eight-membered rings. As shown by the multiplet of the diastereotopic methylene protons, the racemization at room temperature is slow with respect to the ^{1}H-NMR scale. With increasing temperature it becomes more rapid, and at about 100°C the methylene protons are magnetically equivalent.

The temperature dependence of the ^{1}H-NMR spectra of the chair conformer *(6a)* is surprising: Above 120°C its CH_3 triplets begin to broaden, at about 160°C they coalesce, and at 180°C a new triplet of double intensity appears exactly in the middle of the two original triplets[7]. This would indicate that free rotation about the exocyclic C=C double bond is possible in the chair conformer under these conditions[8].

Evidence for the isolated substances being conformers is also provided by the fact that the differences between corresponding ^{13}C-NMR signals do not exceed 1.5 ppm (see Table 1).

Experimental:

A hot benzene solution of 8.3 g (40 mmol) 9,10-phenanthrenequinone is added with vigorous stirring under nitrogen to a benzene solution of (2,2-diethoxyvinylidene)triphenylphosphorane *(2)*, prepared from 18.0 g (40 mmol) (2,2-diethoxyvinyl)triphenylphosphonium tetrafluoroborate[9]. The mixture is allowed to stand overnight; the solvent is then removed by evaporation and the residue treated with methanol. After 2 to 3 hours the precipitate (yellow crystals) is filtered off and dried (orange-red crystals). Recrystallization from methylene chloride/methanol (1 : 10) affords the boat conformer *(6b)* in the form of shiny-red platelets. The mother liquor is allowed to stand for 2 to 3 days at room temperature. The precipitated yellow chair conformer *(6a)* is recrystallized as above (yellow

Observed and Calculated Electron-Density Distribution in the Bonds of a Rectangular Cyclobutadiene[**]

By *Hermann Irngartinger, Hans-Lothar Hase, Karl-Wilhelm Schulte*, and *Armin Schweig*[*]

According to the results of photoelectron spectroscopy[1a] and X-ray structure analysis[1b] the cyclobutadiene derivative *(1)*[1c] has a rectangular four-membered ring structure and a singlet ground state. In order to study the distribution of the bonding electrons for this structure and this state we have determined the difference electron density[2,3] for *(1)*

(1)

from the experimental X-ray data (4615 reflections up to $\sin\theta/\lambda = 0.663$ Å^{-1}; Mo-K_α radiation) and we have theoretically calculated the static ("double-ζ"[4] *ab initio*[5] quality) and dynamic (by a newly developed method[6]) difference electron densities for cyclobutadiene[7]. Figure 1 shows three sections through each of the resulting densities (*stat* = static, *dyn* = dynamic, *exp* = experimental density). Section *A* is in the plane of the four-membered ring, *B* at right angles through the center of the double bonds, and *C* is analogous but through the center of the single bonds).

As shown by the diagram, the density maxima (and minima) of the dynamic densities are considerably reduced (by about 70% for the C=C bond, and by about 60% for the C—C bond) relative to the maxima of the static densities. Therefore

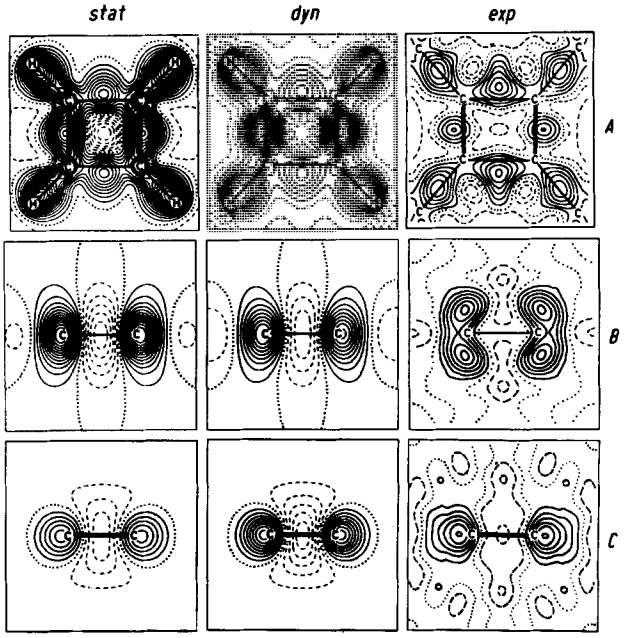

Fig. 1. Calculated static (*stat*), dynamic (*dyn*), and experimental (*exp*) difference electron densities in the four-membered ring of the cyclobutadiene system in three planes: *A*, section within the plane of the four-membered ring; *B*, section perpendicular to the plane of the four-membered ring through the centers of the double bonds; and *C*, section perpendicular to the four-membered ring through the centers of the single bonds. In all cases the contours indicate differences of 0.04 e/Å^3. The zero contour is dotted, the positive (negative) values being shown as solid (dashed) lines. The calculated densities were obtained for cyclobutadiene and the measured ones for *(1)*. In the *B* sections the line of view is parallel to the C=C bonds in the direction of a C—C bond and *vice versa* in the *C* sections.

the calculated dynamic densities are now in general agreement with the experimentally determined densities. It is particularly remarkable that both theory and experiment give density maxima for the four-membered ring compound which lie significantly off the lines joining the C atoms. Thus bent bonds are to be assumed for the four-membered ring of *(1)*, and also for cyclobutadiene, such as are known for three-membered rings[8] and have recently also been found for cyclobutane[9]. In contrast, the density maxima of the exocyclic C—C bonds of *(1)* and C—H bonds of cyclobutadiene lie in the center of the bond axes. The sections perpendicular to the bonds clearly show the elongation of the electron distribution in the π bonds, whereas the density distribution in the σ bonds is axially symmetric. More precise quantitative statements will require low temperature measurements and extension of the basis set in the calculations[10].

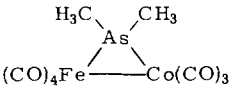
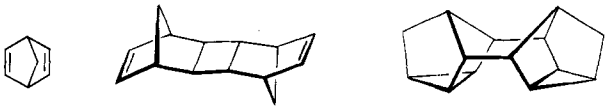
[10] The experimental results of Figure 1 were derived from a conventionally refined structure analysis at room temperature. The resulting possible errors in the atomic parameters (positional and temperature factors) and scale factor can lead to inaccuracies of the derived experimental difference electron densities. A theoretical estimate of the inaccuracies by conventional temperature factors in the case of tetracyanoethylene (TCNE) showed that they do not exceed 0.1 e/Å^3 in this system. Moreover, an exact comparison between calculated and measured difference electron densities for TCNE and smaller model systems has also shown that the difference densities calculated in "double ζ" quality are not falsified by more than 0.15 to 0.2 e/Å^3 (*H.-L. Hase, K.-W. Schulte, A. Schweig*, unpublished results). These experiments suggest that the observed and calculated results are already essentially correct.



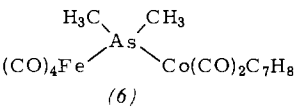
Catalytic Activity by Opening of Metal-Metal Bonds[**]

By *Hans Joachim Langenbach, Egbert Keller*, and *Heinrich Vahrenkamp*[*]

The metal-metal bonds in complexes *(1)* and *(2)* are so reactive that they are readily opened by phosphanes at room temperature[1]. Compounds *(1)* and *(2)* may therefore be regarded as complexes having latent free coordination sites capable of being exploited for catalytic reactions.



(1)



(2)

As an example of such a reaction we describe here the catalyzed dimerization of norbornadiene *(3)* with *(1)* and *(2)* which permitted the first characterization of a catalytically active intermediate formed by opening of a metal-metal bond of a polynuclear complex. Norbornadiene *(3)* is converted exclusively into the *exo-trans-exo* dimer *(4)* on reaction with *(1)* in benzene at 60°C, whereas reaction with *(2)* at 80°C leads to a 1:1 mixture of *(4)* and the dimer *(5)*. If the reaction with *(1)* or *(2)* is carried out unter milder conditions (CH_2Cl_2, room temperature) using equimolar amounts of catalyst and BF_3-etherate, very rapid and exclusive formation of *(5)* takes place. Compounds *(1)* and *(2)* surpass other catalysts[2] for the dimerization of norbornadiene in their accelerating effect on the reaction. Moreover, unlike *(1)*, other catalysts afford the dimer *(4)* always in admixture with other dimers[3].

(3) *(4)* *(5)*

Reaction of norbornadiene with *(2)* in benzene at 55°C affords the isolable complex *(6)*, which directly catalyzes the same reactions as *(2)* without any induction period. The structure of *(6)* has been determined by X-ray crystallography[4]. It confirms the opening of the metal-metal bond and loss of a CO group at cobalt as the activating step (Fig. 1).

(6)

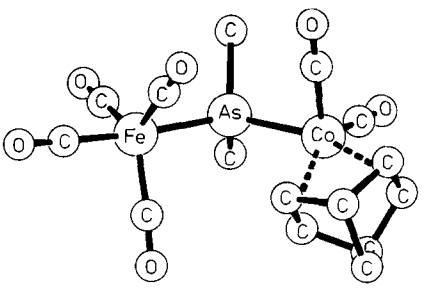


Fig. 1. Molecular structure of complex *(6)*. Important parameters: Fe—As=2.385 (1) Å, Co—As=2.379 (1) Å, Co—C (norbornadiene)=2.09, 2.10, 2.17, and 2.18 (1) Å.

In our opinion only one of the metal atoms of *(1)* and *(2)* can be considered as the catalytically active center of the reaction. The unaltered presence of the $(CO)_4Fe—As(CH_3)_2$ group in *(6)* and the inertness of $(CO)_4Fe—L$ complexes toward CO substitution, rule out participation of this part of the molecule in the dimerizing process. It would appear, therefore, despite the use of dinuclear complexes, that the monomolecular mechanism *via* a metallacyclic intermediate[5] is favored over the π-complex multicenter mechanism[1]. Accordingly, like *(1)*, $Fe(CO)_2(NO)_2$ preferably dimerizes norbornadiene to *(4)*[3], and formation of *(5)* is mainly achieved with cobalt catalysts[6,7]. Thus the essential property of the complexes *(1)* and *(2)* is not their polynuclear character but the functionality of their metal-metal bonds.

Experimental:

Synthesis of *(6)*: A mixture of *(2)* (930 mg, 2.0 mmol) and norbornadiene (2.00 g, 22 mmol) in benzene (15 ml) is stirred for 48 h at 55°C under nitrogen. After removal of all volatile components in a vacuum the residue is taken up in 1 ml of benzene. Dropwise addition of 10 ml hexane affords *(6)* as a brown-violet, air-sensitive precipitate [270 mg (27%), m.p. 89—90°C], which is washed with a little hexane and dried in a vacuum.

A Model of Internal Monooxygenase Catalyzed Reactions: Copper-Catalyzed Autoxidation of Bis(1-methylbenzimidazol-2-yl)methane[**]

By *Charles A. Sprecher* and *Andreas D. Zuberbühler*[*]

While dioxygenase activity, *e.g.* the oxidative cleavage of aromatic rings, can be mimicked closely in low molecular weight systems[1], no model studies seem to have been reported for internal monooxygenases[2], a group of enzymes catalyzing the four electron oxidation (a) of organic substrates.

$$RH_2+O_2\rightarrow RO+H_2O \qquad (a)$$

Here we wish to present evidence for internal monooxygenase behavior in the copper catalyzed autoxidation of bis(1-methylbenzimidazol-2-yl)methane *(1)* to bis(1-methylbenzimidazol-2-yl)ketone *(2)*.

(1) *(2)* + H_2O

Compound *(1)* (m.p. 211—213 °C from methanol), was obtained by condensation of 1-amino-2-(methylamino)benzene with diethyl malonate[3]. Copper(II) perchlorate (8 μmol) was added to a solution of *(1)* (3.6 mmol) in 200 ml anhydrous ethanol and the solution stirred for 30 min at room temperature and atmospheric pressure under pure O_2. An O_2 uptake of 81 ml (3.3 mmol) indicated a 1:1 substrate to O_2 stoichiometry, as required by eq. (a). On addition of H_2O containing some EDTA to complex Cu^{2+}, *(2)* was precipitated in nearly quantitative yield [m.p. 191—192 °C (from CH_3CN); NMR: loss of methylene protons at 4.65 ppm relative to TMS in $CDCl_3$); IR: carbonyl stretching at 1649 cm^{-1}; mass spectrum: molecular ion at $m/e=290$].

The redox stoichiometry was checked using an oxygen-analyzer. In 10 runs under different conditions the consumption of O_2 was 90±2% of the theoretical value. The origin of the carbonyl oxygen was tested with $D_2{}^{18}O$. The methylene compound was oxidized in the presence of an 80-fold excess of 64% $D_2{}^{18}O$ and *(2)* isolated immediately after completion of the reaction. Only a slight increase (8%) of the (M^++2) peak, corresponding to 13% exchange, was observed in the mass spectrum, excluding water as the source of the carbonyl oxygen. A considerable exchange (43%) is observed only if *(2)* is treated with $D_2{}^{18}O$ for 3 weeks. The concomitant shift of the carbonyl frequency by 28 cm^{-1} compares well with the shift of 29 cm^{-1} for the ^{16}O-^{18}O exchange in benzophenone[4].

The autoxidation of *(1)* is absolutely dependent on metal ion impurities. In commercial *p.a.* ethanol, $CHCl_3$, or acetonitrile a slow, irreproducible uptake of dioxygen takes place. This uptake is completely blocked by traces of strong chelators like dithizone or EDTA. Equimolar amounts of acid (H_2SO_4) or base (NaOH), and surprisingly, excess Cu^{2+} strongly inhibit the reaction. In 60% ethanol with dilute acetate buffer ($[CH_3COOH]=[CH_3COO^-]=0.0005$ mol/liter) at an ionic strength of 0.1 ($NaNO_3$) the rate of the reaction is first order with respect to $[O_2]$ and $[Cu^{2+}_{tot}]$ and independent of the substrate concentration, so long as $[substrate]/[Cu^{2+}_{tot}]>3$. According to potentiometric measurements, the formation of a partially deprotonated species $[CuL\cdot(L-H^+)]^+$ with $L=$ *(1)* is essentially complete under these conditions. *(1)* is probably deprotonated at the methylene group before reaction with the oxygen sets in.

Of the other metal ions tested, only Co^{2+} showed catalytic activity comparable to Cu^{2+}; Fe^{2+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, and Mg^{2+} did not significantly increase the rate of dioxygen uptake. Methyl 2-(1-methylbenzimidazol-2-yl)acetate and 2-(1-methylbenzimidazol-2-yl)acetonitrile are oxidized at rates comparable to those found with *(1)* in the presence of Cu^{2+}. With the second substrate and using ethanol as the solvent, one of the carbon atoms is lost in the process. 1,2-Dimethylbenzimidazole and higher bis(1-methylbenzimidazol-2-yl)alkanes, do not show any reactivity. We therefore suggest that the sequence —N=C—CH_2—X (X indicating an unsaturated, electron-withdrawing group) may be essential for the catalyzed autoxidation.

The system described here fulfils all the basic requirements for internal monooxygenase activity: Dioxygen is used as an oxidant, one atom of O_2 is incorporated into the substrate, no external reducing agent is needed, and the oxidation is absolutely dependent on the presence of a suitable catalyst.

Reactions of Phosgeniminium Salts with Nitriles, Imino Ethers and Imidoyl Chlorides—Synthesis of 4,6-Dichloro-2-(dialkylamino)pyrimidines[1]

By *Bernard Stelander* and *Heinz Günter Viehe*[*]

Phosgeniminium salts *(1)* react with nitriles, depending on their substituents, either by addition to the CN triple bond [Equation (a)][2,3] or by condensation with the CH_2 group alpha to the CN group, if this is activated by a further substituent [Equation (b)][3]. Thus, acetonitrile *(2a)* does not condense with *(1)*, even in the presence of bases such as tertiary amines.

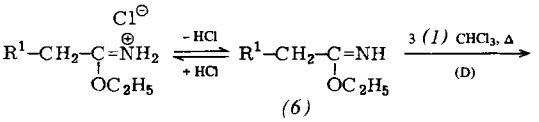
Laboratoire de Chimie Organique de l'Université de Louvain
Lavoisier C3, Place L. Pasteur, 1
B – 1348 Louvain-la-Neuve (Belgium)

Table 2. Physical properties of compounds *(7)*.

	R	R^1	Yield [%]	M.p. [°C] (b.p. [°C/torr])	^{1}H-NMR ($CDCl_3$) TMS = 0 δ[ppm]	UV (CH_2Cl_2) λ_{max} [nm]
(7a)	CH_3	H	33	53	3.33 (6H, s), 6.78 (1H, s)	246, 249, 308
(7b)	CH_3	C_6H_5	90	82—83	3.17 (6H, s), 7.18 (5H, m)	254, 260, 319
(7c)	CH_3	CH_3	84	60—61	3.10 (6H, s), 2.25 (3H, s)	246, 250, 320
(7d)	C_2H_5	C_6H_5	61	(115/0.1)	1.23 (6H, t), 3.60 (4H, q), 7.25 (5H, m)	259, 320

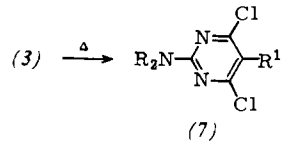
We have now found that acetonitrile, like its monoalkyl and monoaryl derivatives, reacts with two mols of *(1)* in the presence of hydrogen chloride to give the new 2,4,6-trichloro-1,3,7-triazaheptatrienium chlorides *(3)*[4] (Table 1).



(2) *(1)* *(3)*

Compound *(3b)* is also formed in 95% and 85% yield, respectively, on reaction of *(1)* with compounds *(4)*[5] or *(5)*[6], thus suggesting the possible intermediacy of the latter in the synthesis of *(3)* from *(2)* and *(1)*.

(4) *(3b)* *(5)*



The imino ethers *(6)* react with *(1)* much faster than the nitriles *(2)*, forming compounds *(3)* in excellent yields (see Table 1).

(6)

(3) + $(H_3C)_2N$–COCl + C_2H_5Cl

The 2,4,6-trichloro-1,3,7-triazaheptatrienium chlorides *(3)* are hygroscopic solids, stable in a dry atmosphere, soluble in dichloromethane and chloroform, and insoluble in ether. They are characterized by their spectral data (Table 1) and by their pyrolysis to 4,6-dichloro-2-(dialkylamino)pyrimidines *(7)*. In each case only the symmetric isomer *(7)* is formed (see Table 2).

(7)

We have confirmed the structures of the products by two alternative unambiguous syntheses[6]. To our knowledge, only one representative *(7a)* of this class of pyrimidines is known[7]. Compounds *(7)* are chemically characterized by the two reactive chlorine atoms. Hydrolysis or aminolysis leads to barbituric acid derivatives[6].

Table 1. Physical properties of compounds *(3)*.

	R	R^1	Method	Time [h]	Yield [%]	^{1}H-NMR ($CDCl_3$) δ[ppm] (TMS = 0)	UV (CH_2Cl_2) λ_{max} [nm]

Experimental:

Synthesis of *(3)* according to method A: 0.01 mol of *(1)* and 0.02 mols of *(2)* (excess) are refluxed in dry chloroform under a stream of gaseous hydrogen chloride until complete disappearance of *(1)* (24—72 h). The yellow solution is then concentrated in a vacuum and the residue washed three times with dry ether. The yellow solid *(3)* thus obtained is practically pure.

Synthesis of *(3)* according to methods B and C: 0.01 mol of *(1)* and 0.01 mol of *(4)* or *(5)* are refluxed in dry chloroform for three hours. Work-up is identical as for method A.

Synthesis of *(3)* according to method D: 0.03 mol of *(1)* and 0.01 mol of *(6)* are refluxed in dry chloroform for 3—4 hours. The work-up is identical as for method A.

Synthesis of *(7)*: 0.01 mol of *(3)* is heated in a bulb tube at 100—160 °C/0.1—0.01 torr. An oil is formed which readily solidifies [*(7d)* excepted]. The solid mass is recrystallized from aqueous methanol. *(7d)* can be further purified either by distillation or by column chromatography (silica gel 60/benzene).

[2.2.2.2](1,2,3,5)Cyclophane[1]

By *Walter Gilb, Klaus Menke*, and *Henning Hopf*[*]

Boekelheide and *Gray* recently described[2] the synthesis of [2.2.2.2](1,2,4,5)cyclophane, the first phane in which two benzene rings are linked by four ethano bridges. Using an analogous method we have now prepared an isomer, the hydrocarbon[2.2.2.2](1,2,3,5)cyclophane *(6)*, the first cyclophane to have a consecutive arrangement of three ethano bridges. Multiply bridged cyclophanes are of interest because they should display a stronger transannular π-electron interaction than [2.2]paracyclophane. Such an enhancement of π-electron interaction should manifest itself in modified chemical and spectroscopic properties. Moreover, the geometry of the (non-planar) benzene rings should also be influenced by additional bridges, especially if they are directly adjacent to one another.

(1), R = $COOCH_3$, R' = H — *(6)*
(2), R = $COOCH_3$, R' = CH_2Cl (62%)
(3), R = CH_2OH, R' = CH_3 (42%)
(4), R = CHO, R' = CH_3 (82%)
(5), R = CH=NNHTs, R' = CH_3

The diester *(1)*[3] was alkylated with chloromethyl ethyl ether/aluminum trichloride at 70°C to give the dichloride *(2)*[4] (colorless platelets from chloroform/ether, m.p. 142°C), which was reduced with diisobutylhydridoaluminum in benzene at room temperature to the diol *(3)*[5] (colorless prisms from ethyl acetate, m.p. 197°C). Compound *(3)* was subsequently oxidized with activated manganese dioxide[6] in chloroform at room temperature to the dialdehyde *(4)*[4] (colorless prisms from carbon tetrachloride, m.p. 188°C). In a one-pot reaction, *(4)* was first transformed by treatment with tosyl hydrazide in tetrahydrofuran in the presence of catalytic amounts of hydrochloric acid into the bis-tosylhydrazone *(5)*, the sodium salt of which (addition of sodium methoxide to the reaction solution) could be directly converted into *(6)* by 22 hours' irradiation with a daylight lamp (Osram Vitalux, 300 W). Column chromatography on neutral silica gel and recrystallization from chloroform/carbon tetrachloride afforded analytically pure *(6)* (overall yield of cyclization reaction 35%) as platelets having a silky luster (m.p. 286°C, sealed tube)[4].

In its ^{1}H-NMR spectrum ($CDCl_3$/int. TMS) [2.2.2.2](1,2,3,5)cyclophane *(6)* gives sharp singlets for the bridge protons H_2 at $\delta = 2.67$ (4H) and H_5 at $\delta = 2.88$ (4H), whereas the protons of the "flanking" bridges (H_1 and H_3) give rise to an AA'BB' multiplet (8H) between $\delta = 3.33$ and 2.55. The signal of the aromatic protons H_{ar} ($\delta = 5.96$, 4H, s) corresponds to that for the 1,2,4,5 isomer[2], but is shifted upfield relative to the H_{ar} signals of [2.2]paracyclophane ($\delta = 6.46$) and [2.2.2](1,2,4)-cyclophane ($\delta = 6.41$ to 6.08)[1]. Whether it is permitted to conclude that *(6)* possesses stronger cyclohexatriene character on the basis of these findings can only be decided after study of the chemical behavior of *(6)*. The cyclophane strongly resembles the 1,2,4,5 isomer in its vibrational [KBr; 3020 (w), 2955 (s), 2926 (s), 2890 (s), 2857 (s), 900 (m), 626 (m), and 610 cm^{-1} (m)] and electronic spectrum [ethanol; $\lambda_{max} = 308$ ($\varepsilon = 195$) 287 (sh, 370), 248 (sh, 2030), 222 (sh, 14100), and 207 nm (71300)][2,7].

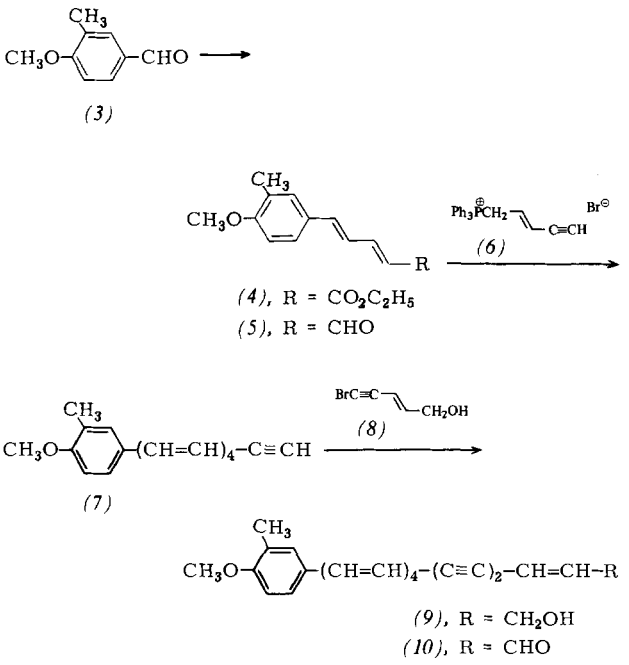
Total Synthesis of Flexirubin Dimethyl Ether[**]

By *Hans Achenbach* and *Joachim Witzke*[*]

Flexirubin *(1)* the pigment of the "gliding bacterium" *Flexibacter elegans*, which was formely regarded as having a carotenoid structure, is the first member of a new class of bacterical pigments[1] which have meanwhile also been detected in the related genus *Cytophaga*[2]. The structure of the flexirubins is characterized by non-isoprenoid ω-phenylpolyenecarboxylic acids in ester type linkage with dialkylated resorcinols[3].



(1), R = H

[**] Studies on the Metabolic Products of Microorganisms, Part 14. This work was supported by the Fonds der Chemischen Industrie.—Part 13: ref. [3c].

In particular, the fact that structurally similar ω-phenyl-analogous polyenoic acids of the vitamin A series display anti-tumor activity[4] prompted us to undertake the total synthesis of flexirubin dimethyl ether *(2)*.

Starting from 4-methoxy-3-methylbenzaldehyde[5] *(3)*, Wittig reaction with the phosphonium salt prepared from ethyl γ-bromocrotonate[6] initially gave the pentadienoic ester *(4)* [m.p. 92—94 °C; lit.[5] 91—93 °C] which was transformed by reduction ($LiAlH_4$) and oxidation (MnO_2) into the aldehyde *(5)* [m.p. 69—70 °C; λ_{max} 354 nm (EtOH)]. A second Wittig reaction with the phosphonium salt *(6)* derived from 1-bromo-2-penten-4-yne (from 2-penten-4-yn-1-ol[7] and Ph_3PBr_2) provides access to the decatetraenyne *(7)* [m.p. 76—79 °C; M^+ 250.1365; λ_{max} 370 nm (hexane)] which we have converted by Chodkiewicz coupling with *(8)* (from penten-4-yn-1-ol and NaOBr) into the diyne *(9)* [m.p. 158—163 °C; M^+ 330.1617; λ_{max} 397 nm (hexane); ^{1}H-NMR (180 MHz): $\delta = 2.22$ ppm (3H, s), 3.83 (3H, s), 4.2 (2H, br), 5.5—7.5 (13H, m)].

Wittig reaction of the aldehyde *(10)* [M^+ 328.1451; λ_{max} 419 nm (hexane)] (from *(9)* and MnO_2) with the phosphonium salt *(11)* yielded *(12)* [mixture of isomers: M^+ 658.4032; λ_{max} 411 nm (hexane)], thus completing the carbon skeleton of flexirubin. Compound *(11)* is accessible by esterification of bromoacetic acid with the sodium salt of the previously described compound 2-dodecyl-3-methoxy-5-methylphenol[3b] and subsequent reaction with triphenylphosphane. Catalytic

hydrogenation of *(12)* over a Lindlar catalyst and isomerization with iodine led to *(2)*[3b].

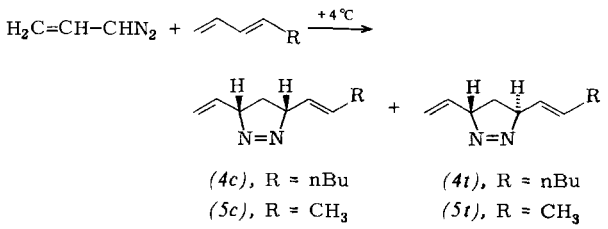
Models for the Biosynthesis of Naturally Occurring Divinylcyclopropanes and Cycloheptadienes[**]



By *Manfred Schneider* and *Angelika Erben*[*]

Dictyopterenes A *(1)* and C′ *(3)* were isolated from the gametes of brown algae (Dictyopteris)[1]. The biosynthesis of *(3)* presumably proceeds *via* the *cis*-divinylcyclopropane *(2)*, which does not occur in nature. *(1)* and *(2)* are probably

formed by introduction of a methylene group from active methyl (*S*-adenosylmethionine)[2] into the corresponding 1,3,5-decatriene (from fatty acids), *(2)* being then converted by Cope rearrangement into *(3)* under the conditions of the biosynthesis (*ca.* +15 °C). *(1)* cannot be the precursor of *(3)* since it is thermally stable up to 150 °C[3].

Like *(1)* and *(3)*, monosubstituted *cis*-divinylcyclopropanes of type *(2)* ought to be readily accessible by decomposition of suitably substituted 3,5-divinyl-1-pyrazolines[4]. Participation of the Cope rearrangement in the biosynthesis of *(3)* could thus be studied on a model.

The 1,3-dipolar cycloaddition of 3-diazo-1-propene to *trans*-1,3-octadiene[5] affords the *cis*- and *trans*-3-(*trans*-1-hexenyl)-5-vinyl-1-pyrazolines *(4c)* and *(4t)*. The *cis*- and *trans*-3-(*trans*-1-propenyl)-5-vinyl-1-pyrazolines *(5c)* and *(5t)* are formed

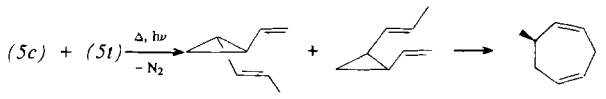
Postfach 106, 7000 Stuttgart 70 (Germany)



[**] We thank Dr. *W. Pickenhagen* (Firmenich & Cie., Geneva) for the spectra of *(1)* and *(3)*.—This work was supported by the Deutsche Forschungsgemeinschaft.

analogously by addition to *trans*-1,3-pentadiene. The cycloaddition proceeds exclusively as shown below, affording the 1-pyrazolines in the isomeric ratio 1:1 (NMR integration).

(4c) and *(4t)* decompose thermally (30—60 °C) and photochemically (0 °C, *n*-pentane, Pyrex filter, Hanau TQ 150) with formation of *trans*-1-(*trans*-1-hexenyl)-2-vinylcyclopropane *(1)* and 6-butyl-1,4-cycloheptadiene *(3)*. *trans*-1-(*trans*-1-Propenyl)-2-vinylcyclopropane *(1a)* and 6-methyl-1,4-cycloheptadiene *(3a)* are obtained in an analogous way from *(5c)* and *(5t)*.

Δ	41.5%	58.5%
hν	55.5%	44.5%

	(1a)	*(2a)*	*(3a)*
Δ	35%		65%
hν	60%		40%

All spectroscopic data of the natural products *(1)* and *(3)*, readily accessible in this way, were identical with those of the compounds isolated and obtained by multistep synthesis[6,7]. *(1a)* and *(3a)* have been unequivocally identified[4]. Low-temperature photolysis of *(4c)*+*(4t)* at −45 °C[7] affords exclusively *(1)* and *cis*-1-(*trans*-1-hexenyl)-2-vinylcyclopropane *(2)*. In an analogous way the low-temperature photolysis of *(5c)*+*(5t)* leads to *(1a)* and *cis*-1-(*trans*-1-propenyl)-2-vinylcyclopropane *(2a)*. The novel compounds *(2)* and *(2a)* are stable for several hours up to −20 °C, and rearrange quantitatively at 0—20 °C into the 1,4-cycloheptadienes *(3)* and *(3a)*, respectively. Both reactions can be followed directly by ^{1}H-NMR spectroscopy by observing the allylic protons of *(3)* (δ=2.18 and 2.86 ppm) and *(3a)* (δ=2.25 and 2.83 ppm).

Experimental:

A solution of *N*-allyl-*N*-nitrosourea *(6g)* in triethylene glycol (50 ml) is added dropwise with stirring at 20 °C and 15 torr to a solution of sodium *(6g)* in triethylene glycol (100 ml). The 3-diazo-1-propene that is formed (*ca.* 10 mmol, 0.7 g) is condensed at −78 °C in a cold trap containing 30 mmol *trans*-1,3-octadiene or -pentadiene. The resulting deep-red mixture is stored at +4 °C until completely decolorized (*ca.* 4 days), taken up in *n*-pentane and washed with ice-water to remove the pyrazole. After drying, all volatile components are distilled off at 0 °C/15 torr. The pyrazolines *(4c)*+*(4t)* (1.5 mmol) or *(5c)*+*(5t)* (1.4 mmol) so obtained are photolyzed at 0 °C without further purification in a forced circulator (Hanau T 150, pyrex filter) or thermolyzed in *n*-heptane at 30—60 °C. After distillation, the products *(1)* and *(3)*, or *(1a)* and *(3a)*, are isolated by gas chromatography (3 m 10% OV17 on Chromosorb W).

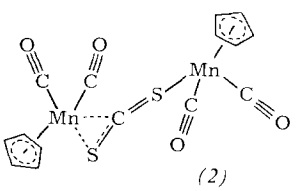
Intramolecular Mobility in CS_2 Complexes of Manganese[**]

By *Max Herberhold, Margot Süss-Fink*, and *Cornelius G. Kreiter*[*]

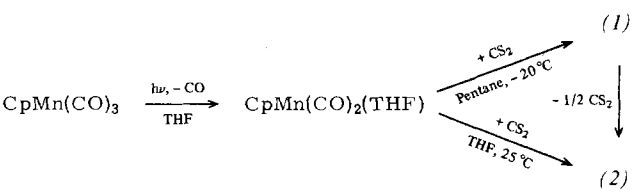
Considerable speculation still surrounds the coordinative bonding of carbon disulfide in transition metal complexes[1] since the structures of only few molecules are known. We have made the surprising observation that the two cyclopentadienylmanganese complexes $CpMn(CO)_2(CS_2)$ *(1)* and $[CpMn(CO)_2]_2(CS_2)$ *(2)* give temperature-dependent NMR spectra. Thence it is concluded that:



1) The mononuclear complex *(1)* possesses an η^2-coordinated CS_2 ligand which undergoes hindered motion in solution.

2) The dinuclear complex *(2)* contains a new kind of CS_2 bridge and is a fluxional molecule.

(1)



ν(C≡O) 2012,1957 cm^{-1} (THF)

(2)

ν(C≡O) 2021,1969; 1928,1871 cm^{-1} (THF)

Compounds *(1)* and *(2)* can be prepared by photolysis of $CpMn(CO_3)$ in tetrahydrofuran solution (THF) and subsequent reaction of the labile THF complex $CpMn(CO)_2(THF)$ with CS_2[2]:

In solution *(1)* slowly loses CS_2 to form *(2)*. Contrary to earlier reports[3], we were unable to observe the reverse reaction.

The compositions of *(1)* and *(2)* are confirmed by elemental analysis and mass spectra. Their structures follow from NMR

and IR spectra, which indicate a pronounced acceptor capacity of the CS_2 ligand[4]. We assume that CS_2 is coordinated like an olefin *via* a C=S double bond in *(1)*; on complexation, the molecule which is linear in the free state should experience bending, such as has been detected by X-ray analysis of $(Ph_3P)_2M(CS_2)$ (M = Pt, Pd)[5].

[a] In [D_6]-acetone; δ values [ppm] *vs.* TMS int.
[b] In [D_6]-acetone/THF.

A rigid molecule having the structure *(1)* must contain two non-equivalent CO ligands; however, only one CO signal is observed down to 220 K in the ^{13}C-NMR spectrum. The expected signal splitting confirming structure *(1)* is not observed until below *ca.* 200 K. This reversible splitting can be explained in terms of a hindered rotation of the CS_2 ligand about the axis of the coordinative bond which becomes slower with decreasing temperature ($\Delta G^{\ddagger}_{190} = 9.5 \pm 0.1$ kcal/mol; $\Delta G^{\ddagger}$ values of 8 to 12 kcal/mol are characteristic for the analogous rotation of monoolefin ligands in $CpMn(CO)_2L$ complexes[6]).

In addition to two C≡O bands which are shifted slightly relative to those of *(1)*, the IR spectrum of the dinuclear complex *(2)* contains two additional C≡O stretching absorptions. It may be deduced from their relatively low frequency that *(1)* is bonded as a donor ligand *via* a lone pair of the non-coordinated sulfur atom to another $[CpMn(CO)_2]$ fragment. In contrast to the dithiocarboxylato-bridged complexes *(3)*[7a] and *(4)*[7b], *(2)* appears to contain a true carbon disulfide bridge.

(3)

(4)

At room temperature the two differently coordinated $[CpMn(CO)_2]$ moieties cannot be distinguished in the ^{1}H- and ^{13}C-NMR spectra of *(2)*: only one signal each is registered for the Cp and CO ligands (Table 1). An intramolecular motion is clearly taking place in which the two $[CpMn(CO)_2]$ fragments rapidly exchange their sites and functions. This "degenerate σ/π bond isomerization" is completely frozen at 210 K, and line shape analysis of the ^{1}H-NMR cyclopentadienyl signals affords $\Delta G^{\ddagger}_{250} = 12.4 \pm 0.1$ kcal/mol. At even lower temperature (*ca.* 180 K) the rotation of the $CpMn(CO)_2(CS_2)$ "ligand" is also seen to be frozen in the ^{13}C-NMR spectrum, only the CO signal of the $CpMn(CO)_2$ fragment engaged in olefinic complexation undergoing splitting.

In contrast to *(2)*, the iron complex *(3)* does not give a temperature-dependent ^{1}H-NMR spectrum. Two cyclopentadienyl signals are always observed, until the complex decomposes into $[CpFe(CO)_2]_2$ and CS_2 at *ca.* 370 K.

Procedure[8]:

(Carbon disulfide)dicarbonyl(η-cyclopentadienyl)manganese (1)[2]:

To $CpMn(CO)_2(THF)$[9] (1.5 mmol) at −20°C is added cooled pentane (80 ml). After addition of CS_2 (2 ml) the solution is slowly warmed to room temperature and stirred for 5 min. The solvent is drawn off at −20°C and $CpMn(CO)_3$ sublimed off at room temperature under high vacuum. The residue is taken up in cooled pentane; after filtration (G3 frit) the solvent is drawn off at −20°C and compound *(1)* dried *in vacuo* at −10°C. Orange-red crystals, dec. at *ca.* 65°C (under argon); yield 0.10 g (27%).

(μ-Carbon disulfide)bis[dicarbonyl(η-cyclopentadienyl)manganese] (2)[2]:

CS_2 (2 ml) is added to the red solution of $CpMn(CO)_2(THF)$ formed on photolysis of $CpMn(CO)_3$ (0.306 g, 1.5 mmol) in THF and the mixture stirred for 2 h. $CpMn(CO)_3$ and *(1)* are washed out of the residue of the reaction solution. Recrystallization from ether gives dark red *(2)*, dec. at *ca.* 118°C (under argon): yield 0.13 g (40%).

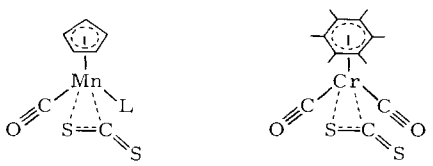
Acceptor Function of η^2-Bonded CS_2 Ligands[**]



By *Max Herberhold* and *Margot Süss-Fink*[*]

Carbon monoxide is regarded as the prototype of all "acceptor ligands". There are only few two-electron ligands which surpass CO in its ability to withdraw charge from a central metal; apart from CS and PF_3 these also include dienophilic olefins such as tetracyanoethylene (TCNE) and maleic anhydride (MA). We have now discovered that η^2-coordinated carbon disulfide is also a stronger acceptor than CO. This follows from the IR and ^{1}H-NMR spectra of the cyclopentadienylmanganese complexes $CpMn(CO)_2(CS_2)$ *(1)*[1],

[*] Doz. Dr. M. Herberhold, Dipl.-Chem. M. Süss-Fink
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *M. Süss-Fink* is indebted to the Cusanus Foundation for a graduate study grant.

$[CpMn(CO)_2]_2(CS_2)$ *(2)*[11], $CpMn(CO)(PMe_3)(CS_2)$ *(3)*, and the arenechromium complexes $(ar)Cr(CO)_2(CS_2)$ *(4)* and *(5)*.

(1), L = CO
(3), L = $P(CH_3)_3$

(4), ar = Hexamethylbenzene
(5), ar = Mesitylene

The IR spectra of the complexes *(1)*—*(5)* (Table 1) display a characteristic $\nu(C{=}S)$ absorption of the CS_2 ligand in the region from 1150 to 1220 cm^{-1} (cf.[12]). The frequency of this band is significantly lower than that of the $\nu(C{\equiv}S)$ absorption of the thiocarbonyl complexes formed from *(1)* and *(3)*—*(5)* by desulfuration with a tertiary phosphane[13] (PPh_3, PMe_3).

Procedure[8]:

(Carbon disulfide)carbonyl(η-cyclopentadienyl)trimethylphosphanemanganese (3): A solution of $CpMn(CO)_2(PMe_3)$[9] (0.25 g, 1 mmol) and CS_2 (2 ml) in pentane (80 ml) is irradiated for 1 h. The crude product *(3)* is recrystallized from THF/hexane. Red-brown crystals, dec. 132 °C (under argon); yield 0.045 g (15%).

Arene(carbon disulfide)dicarbonylchromium (4) and (5): Several hours' irradiation of a pentane solution (100 ml) of arenetricarbonylchromium (1.5 mmol) and cyclooctene (2 ml) affords the intermediate complex $(ar)Cr(CO)_2(C_8H_{14})$. After addition of CS_2 (2 ml) the mixture is stirred until $(ar)Cr(CO)_2(CS_2)$ is deposited as a sparingly soluble precipitate. Recrystallization from THF/hexane furnishes $(C_6Me_6)Cr(CO)_2(CS_2)$, *(4)*, rust-colored crystals, dec. 140 °C (under argon); yield 0.06 g (12%), or $(C_6H_3Me_3)Cr(CO)_2(CS_2)$, *(5)*, dark brown, dec. 101 °C (under argon), yield 0.19 g (40%).

$[C_6H_3Me_3]Cr(CO)_2(CS)$	1950 1900	14.97	1188	5.40	2.24

[a] In THF solution, calibration with polystyrene film.
[b] Cotton-Kraihanzel force constant [4], calculated from the CO stretching frequencies in THF solution.
[c] In KBr.
[d] In $[D_6]$-acetone, *vs.* TMS int.; JEOL C-60 HL, range 1080 Hz.
[e] In CS_2 solution [3].
[f] $^3J(P,H)$ 2.2 Hz.
[g] $^2J(P,H)$ 8.9 Hz.
[h] $^3J(P,H)$ 1.9 Hz.
[i] $^2J(P,H)$ 10.1 Hz.

The expected number of C≡O stretching vibrations is observed in each case. However, comparison of the force constants[14] k(C≡O) shows that replacement of a CO ligand by CS_2 always leads to an increase of the k(C≡O) values of the remaining CO ligands. This means that CS_2 withdraws more charge from the metal than the originally coordinated CO group. A further criterion for the greater acceptor capacity of the CS_2 ligand relative to CO is provided by the ^{1}H-NMR spectrum: the singlet of the aromatic ring protons experiences a downfield shift on replacement of a CO ligand by CS_2. This effect can be explained by assuming that CS_2 reduces the charge density between the metal and the π-bonded ring. Thus CS_2 is a better acceptor ligand than CO, and in this respect proves to be comparable, for instance, with the ligands L=CS[3], PF_3[5], TCNE[6], or MA[7] in the series of $CpMn(CO)_2L$ complexes.

The pronounced acceptor strength of the CS_2 ligand in *(1)* to *(5)* is a convincing argument in favor of η^2-olefin-type coordination of CS_2 *via* a C=S double bond (cf.[11]).

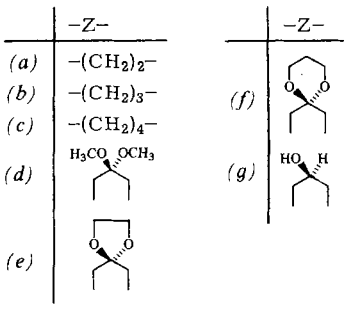
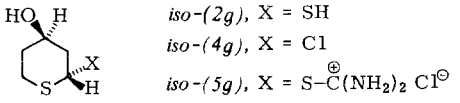
Cyclic Dithiohemiacetals—Synthesis and Properties[**]



By *Hans-Joachim Gais*[*]



Whereas ring-chain tautomerism and the anomeric effect in cyclic hemiacetals *(1)* have long been recognized as fundamental phenomena—*e.g.* in carbohydrate chemistry[1]—nothing has yet been reported about the behavior of the sulfur analogs of *(1)*, the cyclic dithiohemiacetals *(2)*[2].

We report here on the synthesis and properties of the cyclic dithiohemiacetals *(2a)* to *(2g)* and *iso-(2g)*. They are the first representatives of this new class of compounds[3], for whose synthesis the reaction sequence *(3)*→*(4)*→*(5)*→*(2)* has proven the most advantageous.

iso-(2g), X = SH
iso-(4g), X = Cl
iso-(5g), X = S–C(NH$_2$)$_2$ Cl$^\ominus$

The α-chlorosulfides *(4a)* to *(4g)* and *iso-(4g)*, which are readily accessible from the sulfides *(3a)* to *(3g)* by reaction with *N*-chlorosuccinimide (NCS) in carbon tetrachloride[4,5], are converted by thiourea into the stable isothiouronium salts *(5a)* to *(5g)* and *iso-(5g)*. From these the dithiohemiacetals *(2a)* to *(2g)* and *iso-(2g)* can be obtained in satisfactory yields (Table 1) as colorless, liquid or crystalline compounds having a characteristic odor; they are stable over prolonged periods of time, both in substance and in solution, and only slightly sensitive to oxidation[6].

The ^{1}H-NMR spectra (Table 1), providing proof of the cyclic structure of the dithiohemiacetals *(2)*, give no indication of a ring-chain tautomerism with the open-chain mercaptothioaldehyde- *(6)* and mercaptovinylthiol-form *(7)*.

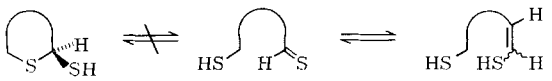
(2d): Yield: 38%; b.p. 125°C/0.2 torr; ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 1.30$—3.00 (m, 6H), 2.15 (d, $J = 9.5$ Hz, 1H), 3.12 (s, 3H), 3.20 (s, 3H), 3.95 (ddd, $J_{AX} + J_{BX} = 14.5$ Hz, $J_{SH} = 9.5$ Hz, 1H); MS: M^+ 194 (7), 163 (27), 162 (100), 133 (38), 129 (96), 128 (95), 127 (24), 103 (27), 101 (60), 97 (48), 88 (12), 87 (11), 86 (10), 85 (55), 75 (18), 74 (16), 73 (100), 59 (53), 58 (15), 57 (20), 55 (29), 45 (58).

(2e): Yield 69%; m.p. 55—56°C (benzene/ether); ^{1}H-NMR (100 MHz, C_6D_6): $\delta = 1.55$—1.85 (m, 3H), 197 (d, $J = 9.3$ Hz, 1H), 2.11—2.57 (m, 2H), 2.83 (ddd, 1H), 3.56 (sm, 4H), 3.92 (ddd, $J_{AX} + J_{BX} = 14.5$ Hz, $J_{SH} = 9.3$ Hz, 1H); MS: M^+ 192 (27), 159 (72), 132 (15), 131 (25), 130 (12), 99 (100), 87 (11), 86 (22), 72 (20), 59 (11).



(2f): Yield 41%; m.p. 80°C (ether); ^{1}H-NMR (60 MHz, C_6D_6): $\delta = 1.05$—2.40 (m, 6H), 2.04 (d, $J = 10$ Hz, 1H), 2.60—3.20 (m, 2H), 3.50 (sm, 4H), 4.05 (ddd, $J_{AX} + J_{BX} = 14.5$ Hz, $J_{SH} = 10$ Hz, 1H); MS: M^+ 206 (33), 173 (78), 172 (35), 146 (45), 145 (50), 144 (16), 115 (60), 113 (100), 100 (29), 85 (50), 86 (22), 73 (30), 71 (10), 59 (30), 58 (17), 55 (43), 45 (35).

(2g): Yield 28%; b.p. 120°C/0.3 torr; ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 1.29$—2.90 (m, 6H), 2.26 (d, $J = 9$ Hz, 1H), 3.36 (s, 1H), 3.57 (tt, 1H), 3.86 (ddd, $J_{AX} + J_{BX} = 14.8$ Hz, $J_{SH} = 9$ Hz, 1H); MS: M^+ 150 (25), 117 (100), 99 (15), 97 (10), 89 (25), 88 (10), 87 (10), 75 (40), 73 (55), 61 (15), 60 (15), 59 (15), 58 (11), 57 (15), 45 (25); IR (CCl_4): 3500, 3595 cm^{-1}.

iso-(2a): Yield 41%; b.p. 120°C/0.3 torr; ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 1.70$—3.20 (m, 6H), 2.18 (d, $J = 8$ Hz, 1H), 3.00 (s, 1H), 4.15 (sm, 1H), 4.42 (sm, 1H); MS: M^+ 150 (4), 117 (100), 99 (10), 89 (25), 75 (32), 73 (63), 61 (15), 59 (15), 58 (10), 45 (30); IR (CCl_4): 3500, 3595 cm^{-1}.

[a] Yields w. r. t. *(3a)* to *(3g)*; b.p. on bulb-tube distillation; mass spectra: relative intensity in %.

In accordance with this finding, and in contrast to *(1)*, the diastereomeric 2-mercapto-1-thia-4-cyclohexanols *(2g)*

and *iso-(2g)* are configurationally stable[7] and do not undergo mutual transformation, even in the presence of acids or bases. Preliminary ^{1}H-NMR investigations of the conformational equilibrium in *(2a)* to *(2g)* and *iso-(2g)* provide evidence of an anomeric effect comparable in magnitude to that found in cyclic dithioacetals[8]. Interestingly, however, *(2d)* to *(2g)* exist almost exclusively in the conformation with equatorial arrangement of the mercapto group.

Experimental:

(2e): *N*-Chlorosuccinimide (0.17 mol) is added with stirring to a solution of *(3e)* (0.16 mol) in carbon tetrachloride (400 ml) at 0°C. After 2 h at 0°C—a ^{1}H-NMR spectrum of the reaction solution indicates the almost quantitative formation of *(4e)* [(60 MHz, CCl_4): $\delta = 1.74$–2.40 (m, 4H), 2.56–3.00 (m, 2H), 3.96 (s, 4H), 4.98 (dd, $J_{AX} + J_{BX} = 14$ Hz, 1H)]—the reaction mixture is filtered and treated at 0°C with a solution of thiourea (0.17 mol) in anhydrous acetone (300 ml). Filtration and washing with acetone yields 34.1 g (79%) of crystalline *(5e)*, m.p. 115–116°C, which is dissolved in 100 ml water and treated dropwise at 0°C with a solution of sodium hydroxide (0.36 mol) in water (80 ml). After 2 h at 0°C the solution is acidified with ice-cold 2 N sulfuric acid, extracted with di-

chloromethane, and the organic phase washed with saturated $NaHCO_3$ solution and evaporated to dryness. The residue is dissolved in a little dichloromethane and filtered with dichloromethane/*n*-hexane (1:1) over silica gel 60 (Merck). Evaporation to dryness and recrystallization of the residue from benzene/ether affords 21 g (87%) of colorless crystals, m.p. 55—56 °C.

Site of Protonation of Dimethyl Sulfoxide.—Raman Spectroscopic Data[**]

By *Manfred Spiekermann* and *Bernhard Schrader*[*]

To understand the mechanism of acid catalyzed reactions of sulfoxides, both the position of the acid-base equilibrium as well as the location of the proton in the first step of the reaction must be known[1].

Dimethyl sulfoxide *(1)* contains two potentially basic centers in the S=O group. Consequently a protonation of the oxygen atom *(1a)* or the sulfur atom *(1b)* would be possible:

(1a) *(1b)*

Investigations into the actual location of the proton in protonated *(1)* with the aid of NMR spectroscopy have led to contradictory findings[2,3].

Analysis of the vibrational spectra ought to further clarify the problem. IR spectroscopy would be better suited for the detection of OH groups and Raman spectroscopy for the detection of SH groups[4]. Great experimental difficulties are met with in recording the IR spectra of superacids; added to this the superacid itself contains OH groups.

We have investigated the Raman spectra of *ca.* 30 mol% solutions of *(1)* and of dimethyl sulfide *(2)* in 100% magic acid (HSO_3F—SbF_5, 1:1) (Raman spectrometer Coderg PHO with low-temperature measuring cell, −40 to +20 °C, argon-ion laser 5145 Å[5]). The spectra of the protonated species show new bands and/or band shifts compared to those of the pure compounds *(1)* and *(2)* and those of the pure superacid (Fig. 1). Their interpretation in the region of the skeletal vibrations below 1500 cm^{-1} is rendered difficult, since the signals of the protonated species in this region are superposed by bands of the pure superacid and of the complex ions in solutions of this type[6]. For compounds with SH groups the signal of the S—H stretching vibration appears above 1500 cm^{-1} at 2550 to 2600 cm^{-1}.

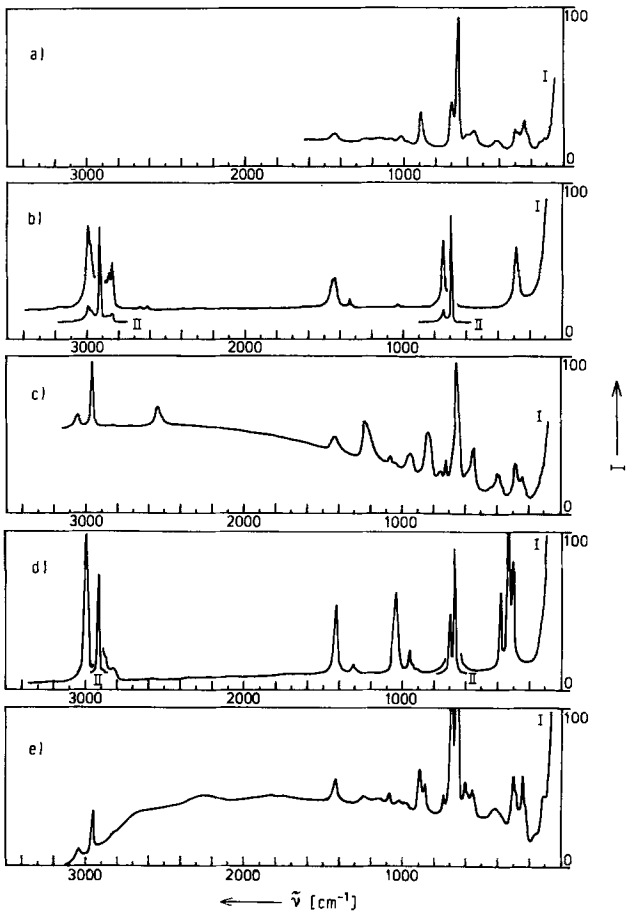

Fig. 1. Raman spectra of a) magic acid (MA), HSO_3F (100%); b) $(CH_3)_2S$ *(2)*; c) 30 mol% *(2)* in MA; d) $(CH_3)_2S{=}O$ *(1)*; e) 30 mol% *(1)* in MA [I = amplification × 1; II = amplification × 0.2].

In the spectrum of the protonated sulfide *(2)* the band is observed quite clearly at 2550 cm^{-1} (Fig. 1c), whereas in the spectrum of the protonated sulfoxide *(1)* this region is free of bands (Fig. 1e). In our opinion this affords a sure indication of the absence of SH groups in the protonated dimethyl sulfoxide and thus proof of the structure *(1a)*.

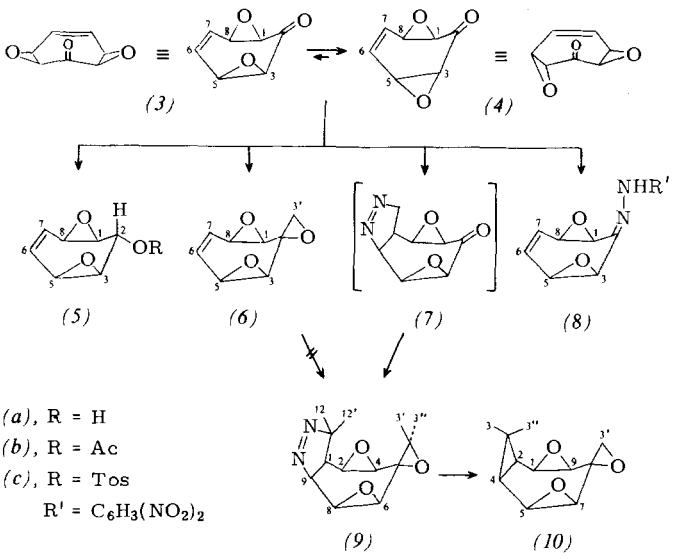
2,3:6,7-Dioxa-bis-σ-homotropones. Synthesis and *cis*⇄*trans*-Isomerization[**]

By *Horst Prinzbach*, *Wolfgang Seppelt*, and *Hans Fritz*[*]

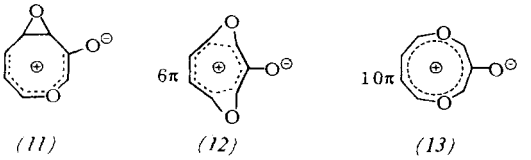


Substituted hetero-bis- *(1)* and hetero-tris-σ-homotropilidenes *(2)* are of interest as homologous hetero-σ-homobenzenes[1]—and, in this connection, also as intermediates in the preparative route to polyfunctional cycloheptanes[2] and to potential heteroaromatic cations. Since all attempts to substitute the methylene groups of tropilidene oxides *(1)* and *(2)* (X,Y,Z = O, R = H) and to epoxidize 7-hydroxytropilidene derivatives[3] have so far failed, the synthesis and *cis*⇄*trans*-isomerization of the tropone dioxides *(3)*/*(4)* described here constitute a versatile entry to compounds of type *(1)*[4] and possibly also *(2)*.

(1) X, Y, Z = CR'_2, O, NR' *(2)*

The acid-sensitive tropone reacts in alkaline medium with excess hydrogen peroxide (*e.g.* 2.0 g, 90 ml methanol, 5.6 ml 8% aqueous NaOH, 5 ml 85% aqueous H_2O_2, 3 h, 5°C, conditions not optimized), reaction terminating after *ca.* 70% conversion. According to TLC and ^{1}H-NMR investigations the crude product contains 45—50% of a chromatographically [ethyl acetate/CCl_4 (1:1)] isolable mixture of *(3)* and *(4)*, whose initial 1:1 composition continually changes in favor of *(4)*. After brief warming of a mixture of *(3)*/*(4)* in acetone or acetonitrile [$t_{1/2}$ (50°C) *ca.* 40 min] *(3)* is no longer chromatographically detectable alongside *(4)*. Compounds *(3)* and *(4)* are sparingly soluble in apolar solvents. According to ^{1}H-NMR analysis of the components separated by fractional crystallization *(3)* [$J_{5,6} \approx 0$ Hz, $\nu_{C=O} = 1688$ cm^{-1}] has a comparatively rigid open-boat configuration (C_s), *(4)* [m.p. 105°C, $(J_{5,6} + J_{5,7}) = 6.3$ Hz, $\nu_{C=O} = 1684$ cm^{-1}] a very flexible boat configuration (C_2).

Reversal of the *cis*→*trans* isomerization *(3)*→*(4)* cannot be observed ^{1}H- and ^{13}C-NMR spectroscopically on account of the strong thermodynamic disadvantage of *(3)*, but appears likely on the basis of the following experiments designed to utilize the kinetic preference of *(3)*. Reaction of the *trans*-dioxide *(4)* with $NaBH_4$ (ethanol, 0°C) affords exclusively the *cis*-alcohol *(5a)* [m.p. 102°C, $J_{5,6} \approx 0$ Hz, acetate *(5b)*: m.p. 120°C, tosylate *(5c)*: m.p. 93°C], with diazomethane

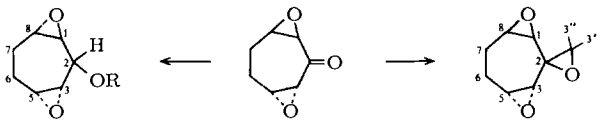


(a), R = H
(b), R = Ac
(c), R = Tos
R' = $C_6H_3(NO_2)_2$

(9) *(10)*

(*ca.* 5 equiv., ether/THF, −15°C, 50 h) a mixture (90%, *ca.* 1:1) of the *cis*-products *(6)* (m.p. 127°C, $J_{5,6} \approx 0$ Hz) and *(9)* (m.p. 90°C, $J_{1,2} = J_{8,9} = 4.5$ Hz), and with 2,4-dinitrophenylhydrazine only the *cis*-hydrazone *(8)* (>146°C dec., $J_{5,6} \approx 0$ Hz). The easier accessibility of the *endo* side in *(3)*, possibly supported by a *cis*-directing effect of the oxirane oxygen[5], as cause for the overwhelming kinetic preference is reflected in the stereochemistry of *(5)*, *(6)*, and *(9)*. Characteristic for *(5)* is the $J_{1,2}$-value (6.3 Hz), for *(6)* the [J(C-3', 1-H) + J(C-3', 3-H)]-coupling (5 Hz) and the relatively high chemical shift of the CH_2 protons [$\tau_{3'-H} = 7.17$ ($CDCl_3$); cf. $\tau_{3'-H(3''-H)}$ in *(16)*], and for *(9)*, in addition, the $J_{1,2}$- and $J_{8,9}$-coupling. Further structural information is provided by *(10)* [97%, m.p. 98°C, $\tau_{3'-H} = 6.91$ ($CDCl_3$), (C_s)], obtained from *(9)* by direct irradiation (CH_3CN, ether, 0°C, Pyrex filter), whose H,H couplings [*inter alia* $(J_{1,2} + J_{1,4}) = 5.2$ Hz] are in good agreement with those of two well known compounds, which according to X-ray structural analysis are *cis*-tris-σ-homotropilidenes[3].

Compounds *(3)* to *(6)* are of limited preparative utility for syntheses in the series *(2)*: the C=C double bond is shielded so effectively that it does not undergo addition with a variety of partners (*inter alia* CH_2N_2, peracids). Consequently *(6)* is not a precursor of *(9)*; the likely intermediate is *(7)*, but this cannot be enriched even in the presence of a substoichiometric amount of CH_2N_2.



Mechanistically, the equilibrium *(3)*⇄*(4)* is noteworthy in connection with the role of heteroatoms in the [$\pi 2_s + \sigma 2_s + \sigma 2_s$]- and [$\sigma 2_s + \sigma 2_s + \sigma 2_s$]-cycloreversions of *cis*-hetero-bis- and *cis*-hetero-tris-σ-homobenzenes[1]. In both directions—insofar as catalysis is excluded—the activation barrier for cleavage of the C—C bond in the oxirane ring is remarkably low[6]. This situation most closely resembles the valence tautomerism between highly-substituted cyclopentadienone oxides and pyrylium 3-oxides[7]. Thus, several delocalized ylide intermediates are conceivable, *e.g.* *(11)* to *(13)*; however, we have so far failed to trap any one of them with methyl acetylenedicarboxylate (20—140°C, up to 5 d), tetra-

cyanoethylene (20—60 °C), or *N*-phenyltriazolinedione (20—40 °C). Observations favoring delocalized ylide intermediates are the steric integrity of the *cis/trans*-tropilidene dioxides *(1)* (X=Y=O, R=H)[3] and of the *cis*-hydrazone *(8)*, as well as the finding that *trans*-dioxide *(15)* ($\nu_{C=O}$ = 1713 cm^{-1}) reacts with $NaBH_4$ and with diazomethane without *trans*→*cis* isomerization to give the alcohol *(14a)* [acetate *(14b)*: m.p. *ca.* 20 °C, τ_{2-H} = 4.69; $J_{1,2}$ = 4.6; $J_{2,3} \approx 0$ Hz] and *(16)* [m.p. 34 °C, $\tau_{3'-H}$ = 6.87; $\tau_{3''-H}$ = 7.11], respectively.

Demonstration of the Ionic Structure of the Intercalation Compound $TaS_2 \cdot NH_3$

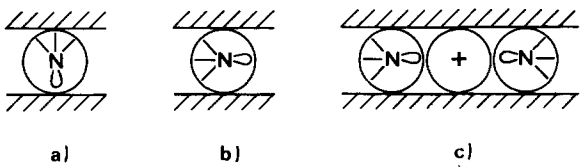
By *Robert Schöllhorn* and *Hans-Dieter Zagefka*[*]

Intercalation compounds of layer chalcogenides MX_2 (M = transition metal, X = S, Se) with neutral molecules have acquired increasing interest on account of their marked structural anisotropy and consequent special chemical and physical properties; the nature of the host lattice-guest molecule interaction, however, is still largely unclear even in the case of simple guest molecules. *Gamble et al.*[1] were recently able to demonstrate by ^{1}H-NMR measurements that the three-fold symmetry axis of the NH_3 molecule in the superconducting compound $TaS_2 \cdot NH_3$ is, contrary to previous assumptions, oriented parallel to the MX_2 layer plane; they postulated a charge-transfer interaction $NH_3 \rightarrow MX_2$, even though the position of the lone-pair orbital is unfavorable.

We have now found that the MX_2 layers act as oxidizing agent in the reaction of ammonia with 2H-TaS_2 (25 °C) and part of the NH_3 is oxidized to elemental nitrogen; N_2 could be detected both gas-chromatographically and mass-spectrometrically (using $^{15}NH_3$). The ratio Ta:N reached a value of 18 to 20. Only small amounts of H_2 are formed in the reaction, so that a catalytic decomposition, as is known for metal interfaces, can be ruled out. If the electrons liberated during N_2 formation according to eq. (1) are taken up by the conduction band of the TaS_2 layer [eq. (2)], then

$$2\,NH_3 \longrightarrow N_2 + 6\,H^+ + 6e^- \quad (1)$$

$$xe^- + TaS_2 \longrightarrow [TaS_2]^{x-} \quad (2)$$



$$H^+ + NH_3 \longrightarrow NH_4^+ \quad (3)$$

the concomitant protons can be transferred to NH_3 molecules [eq. (3)]; the composition of the solid phase would thus be $(NH_4^+)_x(NH_3)_{1-x}[TaS_2]^{x-}$. In analogy with the reactions of solvated ternary compounds[2] detection of NH_4^+ ions ought to be possible by exchange in electrolyte solutions. In ion exchange reactions of $TaS_2 \cdot NH_3$ with KBr in liquid ammonia (—40 °C) we obtained, after careful washing with NH_3, the bromide-free potassium compound *(1)*: determination of the potassium content of this phase, which agreed with the content of nitrogen found in the extracted salt (NH_4Br), gave the value $x = 0.1$; the value of x calculated from the Ta/N ratio is likewise *ca.* 0.1.

$$(NH_4^+)_x(NH_3)_{1-x}[TaS_2]^{x-} + K^+ \longrightarrow (K^+)_x(NH_3)_{1-x}[TaS_2]^{x-} + NH_4^+ \quad (4)$$

(1)

The formation of $TaS_2 \cdot NH_3$ is thus coupled with a redox reaction in which a part of the guest molecules is chemically modified. The resulting compound $(NH_4^+)_x(NH_3)_{1-x}[TaS_2]^{x-}$ is to be regarded as a polyelectrolyte system consisting of $[TaS_2]^{x-}$ layers with delocalized negative charges; the interlayer spacings are populated by readily mobile and exchangeable NH_4^+ cations solvated by NH_3 molecules.

a) b) c)

Fig. 1. Models of the arrangement of the NH_3 molecules between the metal sulfide layers in $TaS_2 \cdot NH_3$: a) C_3 axis perpendicular to layers, b) C_3 axis parallel to the layers, c) ionic model.

This ionic structural model provides a simple explanation of the unusual arrangement of the NH_3 molecule (C_3 axis parallel to the layer)[1]. With a ratio of $NH_4^+/NH_3 = 1:9$, each NH_4^+ aquires a complete two-dimensional solvation sphere: the solvate molecules must—as is known from crystal structure investigations on ammonium halide-ammoniates[3]—be arranged with the lone pair directed to the positive charge centers (Fig. 1c); the isometric NH_4^+ ions themselves cannot contribute to the observed anisotropic effect of the spin-lattice relaxation. The X-ray crystallographic result[4] that the center of gravity of the N atoms lies in a plane midway between

[*] Prof. Dr. R. Schöllhorn, Dipl.-Chem. H. D. Zagefka
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

the layers is also in agreement with this model. The host lattice-guest phase bonding is therefore largely due to electrostatic interaction between the solvated NH_4^+ ions and the negatively charged layers. Measurements on the H/D exchange in the system $TaS_2 \cdot ND_3/NH_3$ at 25 °C[5] can now be explained in terms of a rapid proton transfer between NH_3 and NH_4^+ ions, resulting in a dynamic reorientation of the solvate molecules. The redox reaction also explains the kinetic results of *Dines et al.*[6]: only solvate molecules can be easily and reversibly removed from the lattice; above *ca.* 100 °C an irreversible decomposition of the NH_4^+ ions takes place, similarly as in layer silicates[7]. The sigmoidal shape of the initial intercalation curve and the temperature dependence can be interpreted by adsorption- and redox-equilibria.

N_2 formation was also demonstrated in the reaction of NbS_2 or $TaSe_2$ with NH_3. From the above observations and our earlier investigations on ion formation[2] it can be concluded that intercalation reactions of layer chalcogenides are fundamentally connected with redox reactions and ion formation. These conclusions also explain the NH_3-analogous position of pyridine in $TaS_2 \cdot (py)_{0.5}$[8]. Demonstration of the presence of discrete cations in intercalation compounds $MX_2 \cdot B_y$ is of considerable importance for interpretation of the physical properties of these phases, particularly of superconducting phenomena.

ABSTRACTS

Reviews

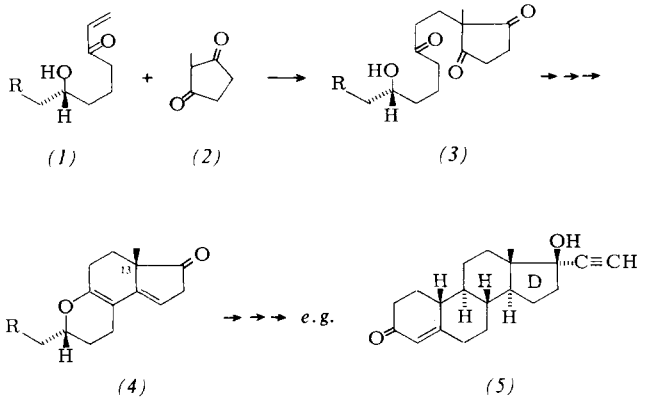
Abstracts of selected progress reports and review articles

Aspects of the photochemistry of organo-transition metal compounds are reviewed in an article by *E. A. Koerner von Gustorf, L. H. G. Leenders, I. Fischler*, and *R. N. Perutz*. The authors deal *inter alia*, with, the methods of photochemical generation and characterization of unstable short-lived intermediates, photosynthesis of novel organometal compounds, photochemical rearrangements of organic compounds on metal templates, mechanistic studies by photochemical methods, and the use of photoreactions of organometal compounds as models for biological processes. [Aspects of Organo-Transition-Metal Photochemistry and Their Biological Implications. Adv. Inorg. Chem. Radiochem. *19*, 65—183 (1976); 632 references]

[Rd 929 IE—F]

The dependence of translation on the 5′-terminal methylation of m-RNA is dealt with in an article by *A. J. Shatkin, A. K. Banerjee, G. W. Both, Y. Furuichi*, and *S. Muthukrishnan*. The m-RNAs of numerous animal viruses and of eukaryotes have methylated 5′-terminal groups. Only methylated m-RNA allows a translation, unmethylated m-RNA is inactive. It can however be methylated by *S*-adenosylmethionine and wheat germ extract and thus become capable of translation. This reaction is inhibited by *S*-adenosylhomocysteine. The binding of the m-RNA to ribosomes depends on the methylation. [Dependence of Translation on 5′-Terminal Methylation of m-RNA. Fed. Proc. *35*, 2214–2217 (1976); 17 references]

[Rd 925 IE—R]

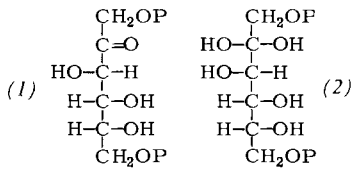


The effect of vitamins on drug metabolism is the subject of a report by *V. G. Zannoni* and *P. H. Sato*. There is mounting evidence that the enzyme system of drug metabolism in liver microsomes is influenced by the vitamins ascorbic acid, riboflavin, and tocopherol. In the case of ascorbic acid deficiency lower cytochrome P-450, NAPDH-cytochrome and other enzyme activities are found. After administration of ascorbic acid it takes 3 to 7 days for the enzyme activity to readjust to its original level. Cytochrome P-450 can also be readjusted to its normal level by administration of δ-aminolevulinic acid, a precursor in heme synthesis. Riboflavin deficiency is effective only in adult animals after prolonged periods of time; the recuperation time is 10 to 15 days after administration of riboflavin. Tocopherol deficiency affects only the *N*-demethylase; an effect on cytochrome P-450 is still controversial. [The Effect of Certain Vitamin Deficiencies on Hepatic Drug Metabolism. Fed. Proc. *35*, 2464—2469 (1976); 36 references]

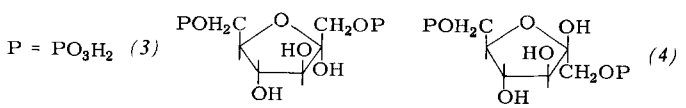
[Rd 931 IE—R]

The role of hemin in the regulation of protein synthesis in erythroid cells is the subject of a review by *I. M. London, M. J. Clemens, R. S. Ranu, D. H. Levin, L. F. Cherbas*, and *V. Ernst*. It has long been known that iron ions promote heme synthesis, serving not only as substrate but also as cofactor in the synthesis of δ-aminolevulinic acid. Heme itself inhibits its own synthesis by feedback but simulates the synthesis of globin. Since this synthesis takes place in the reticulocytes which contain no nucleus stimulation must act at the translation level. The globin synthesis is inhibited by a high-molecular protein which impairs the binding of met-t-RNA_F to the 40S subunits of the ribosomes. [The Role of Hemin in the Regulation of Protein Synthesis in Erythroid Cells. Fed. Proc. *35*, 2218—2222 (1976); 37 references]

[Rd 926 IE—R]



Asymmetric induction in the total synthesis of 19-norsteroids such as *(5)* is the subject of a report by *N. Cohen.* It is known that the useful biological properties of most steroids are confined to only one enantiomer; however, resort to classical resolution procedures ought to be avoided wherever possible. Many syntheses of 19-norsteroids start from prochiral precursors of ring D, *e.g. (2).* This is allowed to react with chiral compounds such as *(1)* (which are later transformed into



the rings A and B); ring closure of the intermediate *(3)* affords optically active products having wholly, [like *(4)*], or partly the required 13β configuration. Besides this intramolecular induction of chirality an intermolecular variant (with amino like acids) is also known. [Asymmetric Induction in 19-Norsteroid Total Synthesis. Acc. Chem. Res. *9*, 412—417 (1976); 38 references]

[Rd 927 IE—L]

The structure of ketones and their biologically important phosphate esters in solution is reported on by *G. R. Gray.* Is, for example, D-fructose-1,6-biphosphate present in the acyclic keto form *(1)*, as its hydrate *(2)*, in the cyclic α- *(3)* or

β-furanose form *(4)* or also in the corresponding furanose form? In solution the biphosphate is present in amounts of up to 1.7% (IR; 25°C) in form *(1)*, 18% in form *(3)*, and 80% (both ^{13}C-NMR, 30°C) in form *(4)*. Such findings are interesting as regards the question of whether enzymes can utilize all or only specific forms of the sugar. [Solution Structures of the Keto Sugars and Their Biologically Important Phosphate Esters. Acc. Chem. Res. *9*, 418—424 (1976); references]

[Rd 928 IE—L]

The drug-metabolizing enzyme systems of liver microsomes are reported on by *A. Y. H. Lu.* These enzyme systems consist of the protein components cytochrome P-450 and NADPH-cytochrome-c reductase and a phospholipid. Cytochrome P-450 binds oxygen and substrate, the reductase transfers electrons from NADPH to the cytochrome. Electron transfer is facilitated by the phospholipid. Numerous cytochromes P-450, exhibiting different spectral, catalytic, and immunological properties and different molecular weights, have been isolated. This variety probably accounts for the differences in drug metabolism found in various species, tissues, sexes, age groups, and under differing induction and dietary conditions. [Liver Microsomal Drug Metabolizing Enzyme System: Functional Components and Their Properties. Fed. Proc. *35*, 2460—2463 (1976); 56 references]

[Rd 930 IE—R]

The effect of dietary lipids on drug metabolizing enzymes forms the theme of a review by *A. E. Wade* and *W. P. Norred.* Rats fed on a diet of corn oil metabolize hexobarbital, aniline, and heptachlor more rapidly than do control animals. In particular, the activity of cytochrome P-450 is increased. Besides these quantitative changes, there would appear to be qualitative changes in the enzyme system by dietary lipids. [Effect of Dietary Lipid on Drug-Metabolizing Enzymes Fed. Proc. *35*, 2475—2479 (1976); 44 references]

[Rd 932 IE—R]

Structure-activity relations of antagonists of the renin-angiotensin system are reviewed in an article by *G. R. Marshall.* The inhibition of renin and renin-forming enzyme (a dipeptidyl carboxypeptidase) and suppression of renin-receptor interaction are considered from the mechanistic point of view. In addition questions bearing upon the future synthetic strategies for inhibitors are discussed. [Structure-Activity Relations of Antagonists of the Renin-Angiotensin System. Fed. Proc. *35*, 2494—2501 (1976); 68 references]

[Rd 933 IE—R]

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (dec.), and *W. M. Weigert*. Volume 11: Erdöl und Erdgas bis Formazanfarbstoffe. Verlag Chemie, Weinheim 1976. 4th edit., xvi, 718 pp., 307 figs., 212 tables, half-linen, subscription price DM 345.—; final price DM 385.—.

This volume continues the alphabetical series of volumes in the new edition of Ullmann[*]. A large part of the volume (219 pp.) is taken up by the major heading Fibers [Fasern, with entries on Structure, General Production methods, Individual Synthetic (Organic, Inorganic) Fibers, Testing and Analysis, and including a highly instructive tabular comparison of fiber properties. Another special commercial form of polymers is described under Films [Folien] (14 pp.). Under Synthetic Dyes [Synthetische Farbstoffe] (10 pp.) the reader finds useful reviews of the classification of dyes and the various steps generally used in dye manufacture, with data on production quantities and values together with export and import figures for various countries. A further general entry covers the Investigation of Dyes, including color measurement and calculation of formulations (48 pp.). The individual dye classes are treated under their own keywords, *e.g.* in this volume under Natural Dyes [Natürliche Farbstoffe] (36 pp.) and Formazan Dyes [Formazanfarbstoffe] (8 pp.). Entries on petroleum formation, exploration, occurrence and production (40 pp.) supplement those on Natural Gas [Erdgas] and Petroleum [Erdöl] which were dealt with largely in the preceding volume. Mention must also be made of Natural Fats and Oils [Natürliche Fette und Öle] (70 pp.), Fatty Acids [Fettsäuren] (24 pp.), Aliphatic Alcohols [Fettalkohole] (19 pp.), Aliphatic Amines [Fettamine] (6 pp.), Acetic Acid and Vinegar [Essigsäure und Essig] (34 pp.), Formaldehyde [Formaldehyd] (16 pp.), Formamide [Formamid] (8 pp.), Fluorine and Inorganic Fluorine Compounds [Fluor und anorganische Fluorverbindungen] (44 pp.), and Organic Fluorine Compounds [Organische Fluorverbindungen] (26 pp.). Entries covering applied fields occur also in this volume, *e.g.* Ferroelectrics [Ferroelektrika] (11 pp.), Flameproofing [Feuerfeste Erzeugnisse] (17 pp.), Fire Extinguishers [Feuerlöschmittel] (9 pp.), and Liquid Crystals [Flüssigkristalle] (15 pp.).

About the present volume we need only say that its quality matches that of the previous volumes in every respect. Thus, the extensive sections, like the 200 plus pages devoted to Fibers, are so concentrated as to be complete monographs standing up to comparison with separate specialist works. This over-all impression is not diminished by occasional unevenness (*e.g.* a somewhat more detailed description of the methods of preparation of organic fluorine compounds would be welcome, though it is realized that the size of the whole work and thus also of the individual sections is necessarily limited). As regards this last point, some space could have been saved if the vapor-liquid equilibria (*e.g.* for acetic acid/acetic anhydride) had been presented as tables rather than as diagrams, and thus even more informatively.

As far as new developments are concerned one of the most outstanding sections in this volume is that on Liquid Crystals, where the majority of the references are to publications from 1970 onward. Clearly, this volume can only enhance Ullmann's reputation, not only as a valuable source of information for practically-oriented scientists working in the chemical and allied industries but also as an excellent work of reference providing the chemist with reviews of important new developments. The work is a must for all chemical libraries.

Ulfert Onken [NB 362 IE]

Die Giftliste (List of Poisons). By *L. Roth*. Verlag Moderne Industrie, Munich 1976. 1st edit., 347 pp., ring-bound, DM 148.—.

The author, already known from his "Sicherheitsfibel Chemie" (Chemical Safety Primer), has now completed the laborious task of collecting information about the nearly 7000 substances that are poisonous, corrosive, irritant, or otherwise dangerous to health, insofar as they are contained in the German or Swiss Poisons Lists, the EEC guidelines for the labeling of dangerous materials, or the German MAK list.

Tables occupying 291 pages contain the details of labeling directions taken from the above-named regulations and guidelines. Particularly valuable is the inclusion of data from the Swiss Poisons List, as these are little known in Germany. Further indications of the special dangers in handling these materials or destroying them are collected under specially worked out codes. However, the "Immission Classes" listed for several substances in column 1 could lead to misunderstandings, because this refers to the classes in the Technical Guide for Cleanliness of the Air of 28. 8. 1974 for limiting *emissions* from industrial plants, controlled by § 4 of the Federal Immission Protection Law (previously § 16 of the Trade Order).

The introductory text gives not only explanations for the tables but also a literal transcription of the law on poisons and plant protection agents of the Land Baden-Württemberg, the law on dangerous working materials of 8. 9. 75, and a list of occupational diseases. There is also a table of radioactive nuclides. The section on first aid in cases of poisoning and the provision of the addresses of Poison Information Centers in the German Federal Republic and in other European countries will be found to be particularly valuable.

E. Quellmalz [NB 369 IE]

Angewandte Elektrochemie. Grundlagen der elektrolytischen Produktionsverfahren. (Applied Electrochemistry. Principles of Electrolytic Production Processes.) By *A. Schmidt*. Verlag Chemie, Weinheim—New York 1976. 1st edit., xv, 322 pp., 135 figs., 72 tables, bound, DM 98.—.

The most recent comprehensive standard work on electrochemistry in the German language appeared in 1933, edited by *Engelmann* in collaboration with numerous electrochemists.

After many years' activity in industry, *Alfred Schmidt* has now undertaken the task of writing a book on "Applied Electrochemistry" in line with the current state of knowledge and providing both the student and the specialist with a comprehensive review of the whole field in clear and modern form. In doing so the author supplements technical details with a treatment of economic aspects.

Section 1 presents the fundamental concepts and principles of electrochemical processes. After an introduction into the structure of matter and the problems of current conduction and distribution, electrode processes are treated in detail. Brief but clear definitions of the concepts customary in modern electrochemistry will be useful to students and above all to the practical worker.

In Section 2, dealing with the principles of industrial electrolytic processes, the apparatus and materials used in industry

are described, *e.g.* electrolysis cells, electrodes, electrolytes, cell connections, and power distribution. The latest knowledge about bipolar cells, coated titanium anodes, and the importance of regular current distribution is presented. Description of the generation of direct current is followed by a discussion of the economic principles involved: here the important questions of current yield, specific power consumption, and optimization of electrolysis plant are treated with reference to the increasing shortage of raw materials and increasing energy costs.

Presentation of the advantages and disadvantages of electrochemical processes, not given previously, enables these processes to be compared critically with other methods of industrial production. Ecological problems and the environment are also not forgotten.

In the section on industrial production processes considerable space is devoted to the electrolysis of water and to the preparation of chlorine and chlorine-oxygen compounds. The industrially less important products, peroxo compounds, permanganate, manganese dioxide, chromic acid, and fluorine are treated more briefly.

The production of metals by electrolysis of aqueous solutions and by fusion electrolysis is described in detail. A section on organic electrochemistry has been added, the importance of this field being expected to increase in the future.

Carefully chosen references at the end of each chapter, together with a collection of important bibliographies, facilitate ready reference to specific problems. Numerous surveys and tables in the appendix make this volume an important handbook not only for electrochemists but also for all who are concerned with electrochemical processes, and thus especially for engineers in many sectors of industry.

Karl Hass [NB 359 IE]

Lehrprogramm Statistik. Mit Beispielen und Ausgaben aus den Naturwissenschaften (Teaching Program Statistics. With Examples and Problems from the Natural Sciences). (Pocketbook 46) By *W. Schmidt*. Verlag Chemie/Physik Verlag, Weinheim 1976. 1st edit., vii, 137 pp., 51 figs., 1 table, paperback. DM 18.80.

This book arose from the material accompanying the practical course for physics students in their fourth semester.

The aim of the first three chapters is to provide sufficient grounding for further study of user-oriented specialist works on statistics. Starting from the basic principles of probability calculus, the author describes normal, binomial and Poisson distributions, treating in the third chapter simple statistical processes for the evaluation of experiments, *e.g.* formation of the mean or calculation of the standard deviation. The fourth chapter concerns some applications in the field of natural sciences.

For physics students conversant with the theory of sets and its symbolism the book provides a valuable extension of the practical work and the lectures. The interaction between the material learnt on the one hand and the questions, exercises, and problems on the other is very successful, the latter closing each teaching section; the reader can thus run a continuous check on his progress. The whole is supported by illustrations which in many cases make the point clear without any need to study the text. Since in spite of its extensions the book retains its character as an auxiliary aid to a lecture course, it is not especially suited for independent study without subsidiary material explaining the most commonly used symbols, abbreviations, and signs (no table of these is included). Furthermore, there are no literature references.

Karl Hans Simmrock [NB 364 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Ullmanns Encyklopädie der technischen Chemie, Band 12: Fungizide bis Holzwerkstoffe. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (dec.), and *W. M. Weigert* (dec.). Verlag Chemie, Weinheim 1976. 4th revised and expanded edition. xv, 727 pp., bound, DM 430.—.—ISBN 3-527-20012-6

DMS Raman/IR Atlas organischer Verbindungen, 3. Lieferung. Edited for the Institut für Spektrochemie und Angewandte Spektroskopie, Dortmund, by *B. Schrader* and *W. Meier*. Verlag Chemie, Weinheim 1977. Loose-leaf collection DM 265.—.—ISBN 3-527-25542-7

Handbuch der Textilhilfsmittel. Edited by *A. Chwala* (dec.) and *V. Anger* in collaboration with *Ch. Chwala*. Verlag Chemie, Weinheim 1977. xxiv, 1374 pp., bound, DM 440.—.—ISBN 3-527-25367-X

Atomic Absorption Spectroscopy. By *B. Welz*. Verlag Chemie, Weinheim 1976. xii, 267 pp., bound, DM 68.—.—ISBN 3-527-25668-7

Coordination and Catalysis. By *G. Henrici-Olivé* and *S. Olivé*. Vol. 9 of "Monographs in Modern Chemistry". Edited by *H. F. Ebel*. Verlag Chemie, Weinheim 1977. xii, 310 pp., bound, DM 98.—.—ISBN 3-527-25686-5

Praktische Nomographie. By *C. Bliefert, G. Dehms*, and *G. Morawietz*. Verlag Chemie, Weinheim 1977. x, 204 pp., paperback, DM 42.—.—ISBN 3-527-25685-7

Vom Wasser, Band 47, 1976. Lectures presented at the 1976 Anniversary Conference of the Fachgruppe Wasserchemie at Kiel. Issued by the Fachgruppe Wasserchemie in the Gesellschaft Deutscher Chemiker. Responsible for text: *W. Husmann*. Verlag Chemie, Weinheim 1976. viii, 484 pp., bound, DM 144.—.—ISBN 3-527-25668-7

Utilization of Microbes—Modern Developments in Biological Technology[**]

By Paul Präve[*]

Until recently microbiology had found use only in the foodstuffs sector and in the production of antibiotics; however, the production of biomass should be regarded as the key development of the new science of biotechnology. The biomass consists of fatty and protein-rich microorganisms that can be used for example in animal feeds. The microorganisms grow not only on cellulose waste and other biological substrates but also, for example, on petroleum and methanol. Their energy demand is comparatively low. It is being realized more and more that inflexible technologies pose problems for our civilization and that biotechnology, which utilizes the cyclic metabolic pathways of microorganisms and often recycles waste materials, shows great promise for the future.

1. Introduction

Microbiology is a relatively young science; it is concerned with small living organisms whose size lies in the micrometer region. Although man has used microorganisms for thousands of years it was only about a hundred years ago that he recognized them as capable of encroaching upon his life by causing disease or damaging crops. Names such as *Koch*, *Pasteur*, *Ehrlich*, and *Behring* are connected with extraordinary advances in our knowledge of the actions of harmful and often deadly microorganisms.

Almost simultaneously, however, it was realized that Nature's cycle could not be maintained without the participation of microorganisms, and slowly it became clear that microorganisms take part in a host of processes. Man uses them directly, *e.g.* in the production of foodstuffs.

In recent years the term biotechnology has come increasingly into use to denote applied microbiology; it denotes that biological reactions have been carried out by "technical" processes—a combination of biology and technology[1–3]. The underlying basis of biotechnology is microbiology, for microorganisms are used in all these processes. Biotechnology occupies a key position in the present spectrum of disciplines; one of its chief aims is to conduct the reactions of microorganisms under the conditions prevailing in reactors in such a way that the natural process can be carried out and the desired product obtained.

2. Biotechnology

Microorganisms are the small forms of life ranging from bacteria through yeasts and fungi to algae. Work with such "material" requires many specialized laboratory methods, technical processing methods, and large-scale industrial plant. Many different types of reactors or fermenters have been introduced, and stirring techniques, aeration, separation, drying, extraction, and other methods have been applied. Special technologies have been further developed for specific purposes.

Microbiological processes have a long history. In the first place, developments in other scientific disciplines, *e.g.* microscopy or the determination of biochemical metabolic pathways, led to the elucidation of processes that had previously been

[**] Based on a lecture given at the 109th Meeting of the Gesellschaft Deutscher Naturforscher und Ärzte, on September 21, 1976, in Stuttgart, Germany.

used on an empirical basis. Even today use is made of some processes whose scientific foundations are still unknown.

One could philosophize as to which were the first biotechnological processes. Accident certainly played a decisive role. It can be assumed that microbiological transformations of foods were utilized very early. Man also knew that food could be preserved, *e.g.* when dried. It would also be worth considering whether partial predigestion did not play a part even before the use of fire; it would have been advantageous for natural selection to provide protein in a more readily digestible form.

The preparation of mead, bread, wine, sauerkraut, cheese, and other dairy products covers a group of microbiological processes that have been known from antiquity.

Unlike most modern technologies, which start from natural raw materials and finally produce waste, biotechnology can often bring a waste product back into the natural cycle. For example, biological purification of waste water is often the decisive method by which a water system is brought back to a natural state. Furthermore, many examples of fermentation (as the principal process of biotechnology is called) use mainly surplus products of agriculture or the food industry.

The value of the cyclic metabolic processes occurring in the microorganisms themselves is supplemented by the advantages of the industrial technology. For example, biotechnological processes occupy little space, are often independent of climate, and can be carried out either where the substrate occurs or where the product is used; they thus fulfil present and future needs.

3. Microbiological Processes—Survey of the Most Important Processes[4, 5]

3.1. Production of Foodstuffs

The classical use of microorganisms is for the production of foodstuffs. Processes of this type convert the available starting substrates into an edible, stable form that tastes well and/or can be readily digested.

A selection of such processes is shown in Table 1. The ripening of cheese can be used to illustrate the potency of microbial processes. The action of the microorganisms taking part includes the oxidation of lactose, lactic acid, other acids, alcohols, and ketones; the proteins present in the milk are converted by hydrolysis into peptides and amino acids; fats are hydrolyzed to fatty acids. These very diverse processes can at the moment be carried out only by using the enzyme systems present in microorganisms.

Similar reactions occur in the production of alcohol, involving processes that are inconceivable without the aid of microorganisms. They are a good example of age-old processes that yield first-class products only through the experience of the brewer or winemaker.

In Asia there are special foods that are hardly known in the rest of the world, although they play a major role in their homelands. In their preparation the substrates are so improved that products of high value are obtained. Such enrichment is a strong motive for many microbiological processes.

Table 1. Selected microbiological processes—production of foodstuffs.

Products	Microorganisms
Milk products	
Yoghurt	*Streptococcus thermophilus*
Kephir	*Streptococcus lactis*
Rocquefort cheese	*Penicillium rocquefortii*
Gouda cheese	*Bacterium sp.*
Tilsiter cheese	*Bacterium sp.*
Alcoholic products	
Beer	*Saccharomyces cerevisiae* *Saccharomyces carlsbergensis*
Rum	*Saccharomyces cerevisiae* yeasts
Whisky	*Saccharomyces cerevisiae*
Wine	*Saccharomyces ellipsoideus*
Soya (also wheat)	*Aspergillus oryzae* (koji mold),
Miso, tofu	also yeasts and bacteria
Fatty and proteinaceous products (biomass)	
Fat	Algae
Protein	Yeasts, bacteria
Agricultural processes (silage, rotting)	
Silage for feed	Lactobacteria
Flax	Decomposing bacteria

The direct production of fat or protein (biomass) by means of microorganisms is a development of the last few decades (see Section 4.1).

Silage plays a large part in agriculture: fresh greenstuffs are subjected to a souring process with lactobacteria and can then be stored and used as feed throughout the year.

The actual course of the reactions always starts from two components—microorganisms and substrate—and leads to three products—microorganisms, residual substrate, and product. The reactions are usually carried out in vats, tanks, or fermenters. The processes discussed in this section normally require only very simple reactors, such as simple wooden vessels, fermentation vats, or stainless steel stirred-tank fermenters. Centrifugation, distillation, and precipitation are among the methods used for isolation of the product.

3.2. Preparation of the Primary Metabolites

Among the products obtained from the metabolism of microorganisms are vitamins and ethanol, amino acids, and solvents. Microbiological processes have for some decades provided an important method of preparing a number of solvents such as acetone, butanol, acetic acid, and glycerol. Since the starting substrates have always been materials that are renewable, *e.g.* molasses, wood, and grain, an industrial process was in principle simply tacked onto the end of the agricultural process, so that a final utilization of the residual, intermediate, or waste product was achieved. Under special conditions (*e.g.* high price of oil) such processes could stage a comeback.

Thus, production of ethanol at economic prices is today possible in many countries because these countries produce the initial substrate at a low cost. Together with a few specialities, this is one of the few important processes of foodstuff production that is carried out microbiologically at the present time.

Table 2 lists further products, among which citric acid occupies a special position. This is used for many purposes,

Table 2. Selected microbiological processes—primary metabolites.

Products	Microorganisms	Uses
2,3-Butanediol	*Bacillus polymyxa*	Solvent
Ethanol	*Saccharomyces cerevisiae*	Beverages, solvent
Citric acid	*Aspergillus spp.*	Food, beverages
Lysine	*Micrococcus glutamicus*	Food and feed additives
Vitamin B_{12}	*Propionibacterium freudenreichii*	Food and feed additives

e.g. as an additive to lemonades, fruit juices, sweets, jellies, ice cream, auxiliary baking materials, as a complex-former in the fats industry, as a pH regulator, as a polishing and etching material, and for removing calcium carbonate deposits. Citric acid production from molasses or *n*-paraffin[6] cannot only compete with agricultural production but moreover is independent of the available land and of climate and is thus a good example of the advantages of specialized biotechnology.

The possibility of preparing natural amino acids is a development of the last twenty years; thanks especially to Japanese work almost any desired amino acid can today be synthesized by microorganisms. This is achieved in particular by the use of mutant strains, but often the desired L-amino acid is produced in a two-stage process using two different microorganisms.

From the wealth of other possibilities we shall mention here only the preparation of vitamins. These are already very complicated substances, but they can often be easily produced by biotechnological processes. An important future field of application will certainly be the biosynthesis of larger and more complicated molecules, whose chemical production would be accompanied by many difficulties.

Most of the processes described in this section require a developed biotechnology in which the stirred-tank fermenter is used as a reactor. In the production of the substances, refinement is also very demanding, since the desired product must be removed from the viscous and chemically complex nutrient solution used to maintain the microorganism.

In modern processes the various procedures are carefully controlled so as to keep, *e.g.*, the pH constant throughout the reaction.

3.3. Preparation of Secondary Metabolites

Secondary metabolites are substances formed by microorganisms under special conditions. These metabolites are rarely essential for normal industrial use or for intracellular processes. There are indications that the production of such substances is one method of removing waste material from the cells.

Table 3. Selected microbiological processes—secondary metabolites.

Products	Microorganisms	Uses
Amylase	*Bacillus subtilis*	Textile smoothing
Dextran	*Leuconostoc mesenteroides*	Plasma expanders
Protein-toxin	*Bacillus thuringiensis*	Insecticide
Penicillin	*Penicillium chrysogenum*	Drugs

Some selected products including enzymes, are listed in Table 3. Most of these are used on an industrial scale, as additives to washing powders, as smoothing materials, as digestion aids, for the clarification of fruit juices, *etc.* These exoenzymes are amylases, proteases, hemicellulases, pectinases, invertases, *etc.* None of them requires a coenzyme. They are not the enzymes of normal metabolism, which play a special role in the fine chemicals sector, although they are also obtained by biotechnological processes.

Furthermore, biopolymers are prepared by biotechnological processes and have special possible fields of application in chemistry and medicine (*e.g.* dextran).

Antibiotics constitute the best known and the most important group. Today it is inconceivable that we should have to treat infectious diseases without the help of antibiotics. Research in this area still leads to interesting products. They are all prepared from streptomycetes, molds, or bacteria in batches in aerated stirred-tank fermenters. The reactor size may exceed $100\,m^3$. Recently the precursors for antibiotics have also been prepared, *e.g.* 6-aminopenicillanic acid, and from these, special antibiotics have been synthesized that are active against some resistant strains.

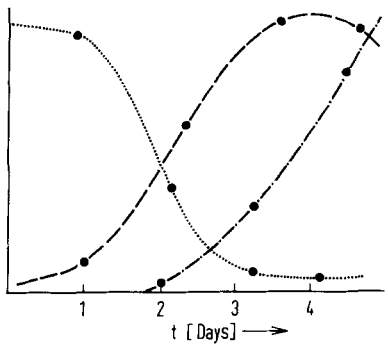

Fig. 1. Production of an antibiotic (schematic). – – – Cell growth (increase in the dry substance of the cell mass), ... Concentration of the carbon source in the nutrient medium, –·–·– Concentration of the antibiotic.

Taking antibiotic production as an example of a biotechnological process, the principle underlying a typical batchwise fermentation (Fig. 1) can be illustrated. The S-shaped curve of cell growth, with its lag, its logarithmic, and its stationary phase corresponds to an inverse of the concentration of the carbon source in the nutrient medium. Synthesis of the desired antibiotic starts at the end of the logarithmic phase of growth.

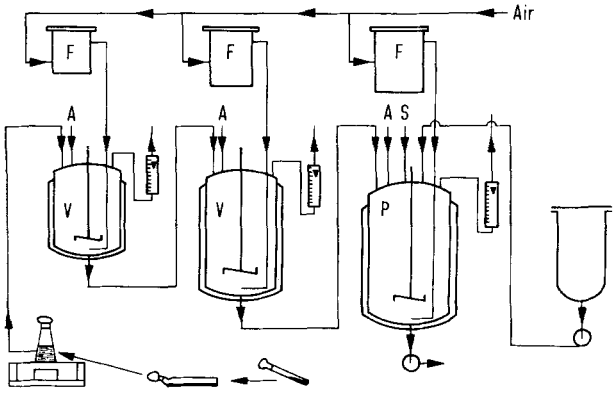

Fig. 2. Scale-up of the fermentation (slant culture—shaking culture—fermenter). A = antifoaming agent; F = filter; P = production fermenter; S = substrate; V = prefermenter; storage vessel on extreme right. For reaction route see text.

The first step of submerged fermentation is the transfer of the organism from an agar slant to a shake-culture in a conical flask (Fig. 2). The culture is then inoculated into a small prefermenter (*e.g.* 20 l). It is customary at this stage and on transfer to a second prefermenter (200 l) to arrange the growth times in such a way that the inoculation occurs during the logarithmic growth phase. In the present example, therefore, the production fermenter must contain 2000 l. This scale-up of about 1 : 10 is typical of the processes under consideration.

The preparation of *Bacillus thuringiensis* spores gives a product not considered harmful to the environment. These spores are sprayed onto cabbage plants and are eaten by pests, in particular by caterpillars. In the caterpillars a toxic product is liberated by the spores. The result of this method is a correction of the mass of special bacilli in the soil; it regenerates the balance that has been disturbed by monoculture.

3.4. Conversion Reactions

Apart from the fact that all the processes described above are conversions of substrates, particular importance must be paid to "biotransformations". Many microorganisms can act as biocatalysts for one-stage reactions of specific substances, thus effecting, *e.g.* an oxidation, methylation, or decarboxylation. These microbial intermediate syntheses are used especially in steroid chemistry to avoid difficult and demanding chemical operations.

3.5. The Economic Importance of Microbiological Processes

For a correct assessment of the importance of biotechnology it is necessary to examine the economic significance of some types of reactions.

Thus, 556000 tons of fresh cheese, in addition to hard, sliced, and soft cheese, with a value of 1.98 thousand million DM, was prepared in 1974 in West Germany alone; in addition, 178000 tons was imported (value 0.936 thousand million DM). In Germany in 1972 breweries and malthouses employed 95000 people in 756 establishments and had a turnover of 9.9 thousand million DM[7]. From the primary metabolites more than 200000 tons of citric acid were prepared worldwide by fermentation (excluding the socialist countries)[8]. Antibiotics are prepared in large quantities; the production of penicillin in the USA rose from 75 tons in 1949 to *ca.* 4500 tons in 1975; the present-day world production is estimated at 10000 tons p.a., the production of all antibiotics totalling 25000 tons p.a.

4. Recent Developments of Biotechnological Processes

Living things are subject to selection and mutation, *i.e.* to evolution. In microorganisms the changes can already be directed to some extent: for example, the yield of an antibiotic can be increased or the microorganisms can be adapted to a different substrate.

Microbiological-biochemical-genetic development work of this type often has sufficient technical consequences to cause economic changes. Antibiotics are a well known example, having been first prepared in small glass vessels they are now produced in highly specialized fermenters; antibiotics were once expensive luxuries, now they are accessible to everyone.

There are also many interesting possibilities from the industrial point of view. New fermenters have come to take their place besides the old types: according to *Rehm*[2, 9] three groups can be distinguished—stirred-tank fermenters (*e.g.* suitable for multiphase fermentation as required for *n*-paraffin substrates), airlift reactors (no mechanical stirring needed), and special types of reactors. This last group includes reactors in which explosive gas mixtures are handled, as is necessary for microorganisms utilizing oxyhydrogen or methane; also, among others, falling-film, fluidized-bed, multistage, and surface reactors[10].

4.1. Biomass Production

Production of biomass is one of the key developments in the whole of biotechnology. This term denotes the production of a mass of cells of microorganisms.

4.1.1. The Substrate

Like other living cells, microorganisms as a rule require a source of carbon and nitrogen for growth, and in addition phosphate and other salts must be present.

Organic compounds serve as a source of carbon and often of nitrogen too. This means that many microbiological processes are based on primary or secondary products of agriculture: milk in the production of yoghurt, barley in brewing, molasses in the production of citric acid, soya in production of antibiotics. A further possibility is to use waste products from human civilization: industrial plants for biological purification of sewage are already indispensable.

There are many substances besides those just mentioned that can act as substrates for the growth of microorganisms, although they appear to be unrelated to life and some of them are even poisonous to cells. Oil, natural gas, *n*-paraffin, methanol, CO_2, CO, and also cellulose are such substances. From the point of view of evolution it is difficult to understand why some bacteria and fungi can use methanol as a source of carbon, and yet can be isolated from soil and water or from flowers and fruits. An explanation could be the presence of pectinesterases[11], which liberate methanol from pectin. It is easier to understand that molds can decompose cellulose, although special species are required for this.

The normal annual growth of cellulose throughout the world is of the order of 10^8 tons; one could not imagine the world situation with respect to cellulose without the activity of microorganisms.

Methanol and cellulose are two very different carbon substrates. Methanol can be obtained from coal, natural gas, or oil and will very probably be one of the most important and cheapest raw materials for chemistry in the future. Cellulose, on the other hand, is a basic material for human civilization (heating, building of ships and houses), and moreover it is renewable. Both substrates are available for biotechnological processes. Some culture media for bacteria which utilize methanol or cellulose[12] are shown in Table 4.

Table 4. Nutrient media for bacteria using methanol and cellulose [12].

Methanol	Added continuously
NH_4OH (25 % soln.)	Initially 2.8 ml/l
H_3PO_4 (85 % soln.)	Initially 2.0 ml/l
$MgSO_4 \cdot 7H_2O$	0.9 g/l
Na_2SO_4	0.24 g/l
$Fe_2(SO_4)_3 \cdot 3H_2O$	85 mg/l
$CaCO_3$	0.14 g/l
and tap water	
Cellulose	5 %
KH_2PO_4	1 %
NaCl	0.1 %
$(NH_4)_2SO_4$	1 %
$MgSO_4 \cdot 7H_2O$	0.3 %
$CaCl_2$	0.1 %
Trace elements and water	

Conversion of methanol into biomass is occurs in a wholly synthetic culture medium, *i.e.* here the microorganisms are in the position that plants occupy in the natural life cycle. Processes based on cellulose accelerate the very slow decomposition of cellulose which takes place in nature. In both cases biomass is produced by a fermentation process from readily accessible raw materials. This biomass consists of cells that often exceed standards, *e.g.* for protein content, for animal feeds or human consumption.

4.1.2. Biotechnology

A characteristic feature of biotechnological processes is that they work batchwise; each batch requires hours, days, or perhaps weeks for completion. After the harvest a new batch is started. In contrast, biomass production is continuous; this means that biomass can be continually removed from the reaction vessel over a period of weeks, months or longer; at the same time fresh supplies of the nutrient medium must be added. The course of such a process, which is a common one in chemical technology, can be changed, by *e.g.* genetic changes in the cells, but it has many advantages (*e.g.* economic).

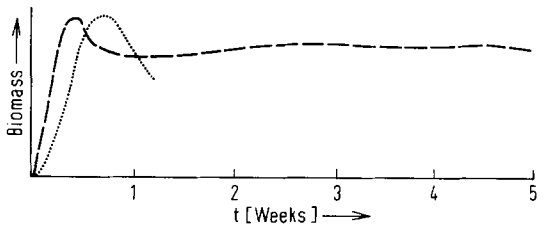

Fig. 3. Growth curves in batch (·····) and continuous (– – –) culture.

In Figure 3 a batch process for the production of biomass from methanol is compared with a continuous process. This refers to a process developed by Hoechst-Uhde and based on methanol, using bacteria of a *Methylomonas* sp.[13], which is obligatorily methylotropic. A fully synthetic medium and modern reactors are used.

Figure 4 shows a representative of the old generation of fermenters together with a new type. The route from the rotting of flax in a cool shelter *via* a fermenting vessel or a cabbage tub led by way of the continuously stirred and aerated tank fermenter to a number of new systems[10, 14–16] that were often influenced by highly developed chemical process technology. The basis of this development can be seen in Table 5.

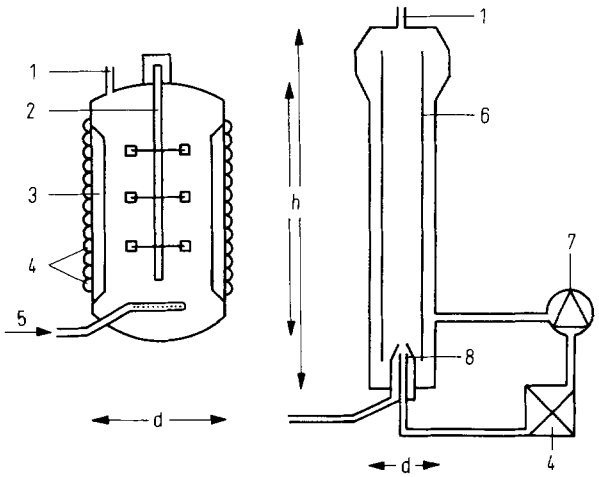

Fig. 4. Comparison of a small classical stirred-tank (left) and a modern injection nozzle loop reactor (right). 1 = Exhaust gas; 2 = multivane paddle; 3 = baffle plate; 4 = cooling; 5 = air; 6 = insertion tube; 7 = circulating pump; 8 = jet.

Table 5. Comparison of reactors (example: production of biomass).

Conventional stirred vessels	Modern loop reactor
High energy costs	Low energy costs
10 kW/m³	2 kW/m³
Internal cooling (jacket)	External cooling (plate exchanger)
Limited scale-up	Unlimited scale-up
Indefinite mixing—	Defined mixing—
irregular residence times	regular residence times
Large air demand	Low air demand
10—20 % oxygen yield	40—50 % oxygen yield
Batch operation	Continuous operation

A comparison of the data, in particular the energy consumption, shows what advantages can be obtained by optimization of the reaction vessel.

In this connection attention should be drawn to the gathering of data during the course of a reaction or cell growth in the fermenter. The computer displays very clearly the wealth of biological data and assists in the choice of appropriate biological developments, provided that two prerequisites are achieved: One is that the data measured must refer to the process in the fermenter, which is relatively easy with synthetic nutrient media but much harder to achieve with complex organic media. The second is that the metabolic state of the microorganism must be known. On this basis we can now begin to arrange for biological processes to take place optimally[3].

4.1.3. Economics

Economic considerations are an important factor in industrial processes. As a rule it is not sufficient to make a new product in a new way. The process as a whole must be able to compete with others and originality is often an insufficient advantage—the old process may provide almost the same product at a lower price.

The fate of new biological and technological developments also depends on economic considerations. However, the processes described here for biomass production have so many

advantages that at least a part of the new biotechnology will probably find application in large-scale practice.

Emphasis should first be placed on the continuous nature of the process. With this method fermentation plants can be designed to be smaller, or with larger vessels they can produce more product than those of batch operation. In a highly automated plant the personnel requirements are also lower. The economical output of plants which produce biomass is around 60000 to 100000 tons p.a.; this quantity of biomass or SCP (Single Cell Protein) can be produced by about 100 men.

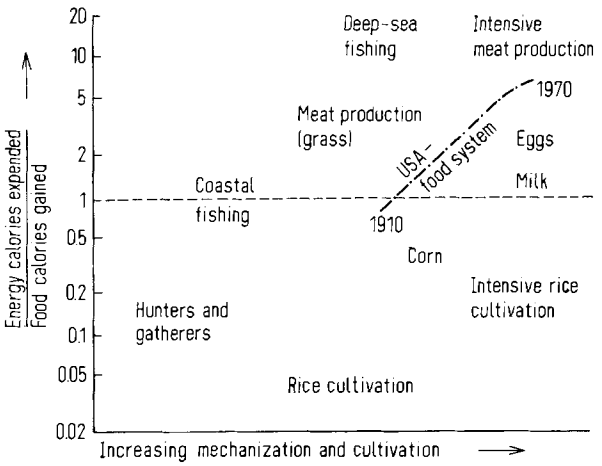

Fig. 5. Energy demand for food production (after [20, 21]). The ratio of energy calories to nutritional calories is shown.

In addition, SCP manufacture requires little land (*ca.* 1000 m^2), is independent of climate, and gives a product that always has the same composition. This product can be prepared almost anywhere in the world in the same quality. If one adds that many countries are greatly dependent on imports of soya and grain, it is clear that some hundred thousand tons of SCP will be produced every year. Such products may also affect the price of protein[17]. A considerably more important aspect of this biotechnology is, however, the energy demand.

Even before that great increase in the cost of energy it had been realized that the costs of power are of decisive importance for any process. This knowledge was, however, not considered seriously because primary energy was so cheap. Only the shock effect of publications about a possible collapse of world resources[18, 19], followed by the price rise, made a critical review of the whole situation imperative.

Thinking in terms of energy consumption there is a disquieting trend especially when one considers food production. A human requires *ca.* 1 million kcal p.a.; from this energetic viewpoint the world harvest ought to be sufficient to supply the requirements of 5.6 billion people p.a. However, 50—90% of the energy in grain is lost if carbohydrates are used for the animal feeds. Moreover, up to 34% of the world harvest is spoilt. On the other hand, the seas are still full of promise—at present only 1% of its potential is utilized. Figure 5 shows how many calories must be expended to provide one nutritional calorie.

One starts with a ratio of 1.0 for coastal fishing *i.e.* 1 calorie of energy is required to obtain 1 calorie of food. Our ancestors, the hunters and gatherers, lived energetically more favorably; with a ratio of 0.1 to 0.05 simple rice culture is in the same region. The modern methods of obtaining or producing food are much more energy-demanding: for normal production of meat or eggs 2—5 calories of energy must be provided, for intensive meat production 10 calories, and for fish caught in the open sea 20 calories or even more. Since biomass from microorganisms is characterized especially by its high protein content—of the same order as that of the richest protein sources—it is not surprising that SCP processes are being developed throughout the world. Presuma-

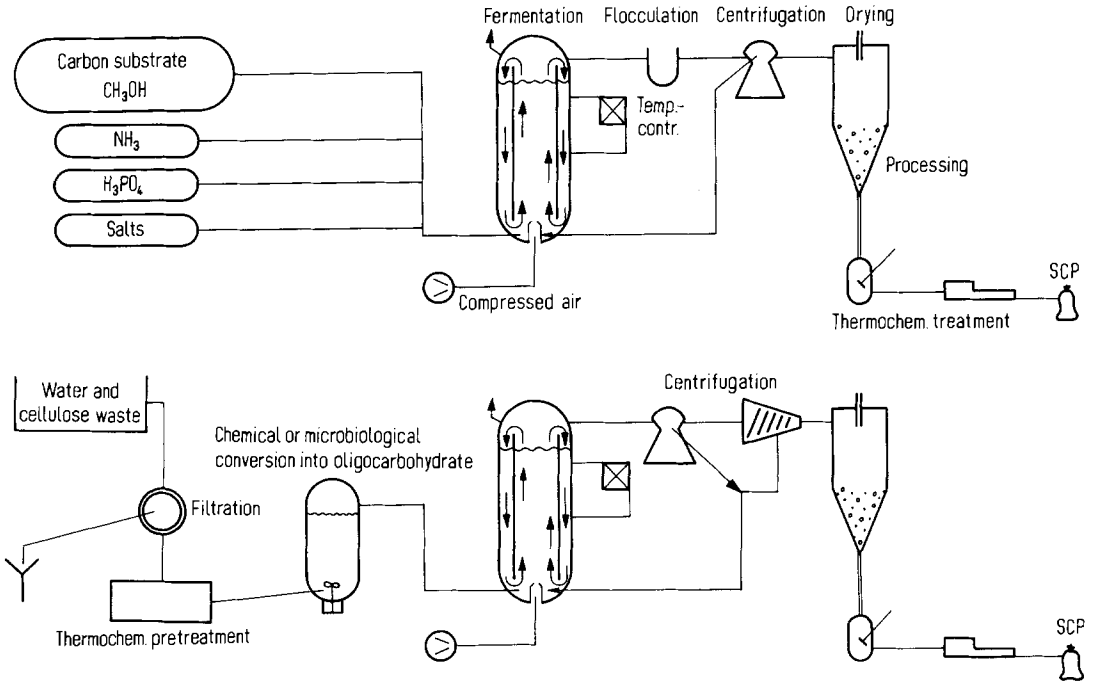

Fig. 6. Two SCP (single cell protein) processes, top for a methanol, bottom for a cellulose substrate [3].

bly such products will in the not too distant future be processed into human food, since the route *via* animals results in an average energy loss of 85 %[22]. A different calculation[23] starts from the fact that 4000 kg of grain are harvested from 1 hectare, and that such a crop used as animal feed yields 85 kg of protein (beef); fermentative utilization of the grain would, in contrast, yield 680 kg of protein!

4.1.4. Biomass Processes

Out of the many processes for the production of biomass two will be considered here from the aspect of their possible utilization. Figure 6 illustrates one process based on methanol and one based on cellulose.

Much interest attaches to use of a symbiotic mixed culture in a process starting from cellulose[25]; in this process a type of population such as occurs in nature is used for inoculation. Utilization of this substrate will certainly be locally restricted; in contrast, processes based on methanol can be used globally. The quality of the product is also an important positive argument (Table 6).

Table 6. Composition of some protein sources.

	FAO Standard [24]	Soya meal [24]	SCP yeast [24]	SCP bacterium [13]
Crude protein content [%]		45	60—62	80—85
Essential amino acids [g/16 g N]				
Ile	4.2	4.8	5.3	4.3
Leu	4.8	6.1	7.8	7.4
Lys	4.2	6.1	7.8	6.5
Met + Cys	4.2	2.9	2.5	2.5
Phe + Tyr	5.6	8.4	8.8	7.1
Thr	2.8	4.0	5.4	4.6
Val	4.2	5.0	5.8	5.6
Trp	1.4	1.3	1.3	1.5

4.2. Other Types of Processes

4.2.1. Enzymes

The step from the production of cells to their content is a short one. Enzymes may well be one of the most interesting groups among the cell constituents; they are biological catalysts that play a key role in the biosynthesis of, *e.g.* carbohydrates, proteins, fats, and steroids.

The major industrial users of enzymes are the starch, leather, foodstuffs, and detergent industries and medicine, but enzymes also play a part in the fine chemicals sector.

Enzymes produced by microorganisms have achieved great importance in the last few decades. For example, microbiological production of the rennin enzymes has already been developed, since it is difficult in certain countries to obtain rennin in amounts sufficient for cheesemaking. The most interesting development is, however, that of immobilized enzymes[26, 27]. Enzymes can be immobilized in water-insoluble material without any loss of their catalytic activity. Their uses are obvious and there are already many processes for this purpose; for example penicillin-cleaving amidases immobilized in a column or in a reactor yield 6-aminopenicillanic acid, the starting point for many important semisynthetic penicillins.

The food and beverage industries are also users of such enzyme preparations, and in the technical field enzyme treatment is especially valuable for making waste waters harmless.

4.2.2. Secondary Metabolites

Among the secondary metabolites we find, for example, new antibiotics, substances with pharmacological activity, and other natural products. The microbiological preparations of food colors, insecticides, and inhibitors are other interesting developments.

Here too belong biopolymers such as the dextrans. The future of this group seems very promising. As auxiliaries in drilling they confer on the drilling mud the viscosity needed for transporting rock. The properties of these natural but fermentatively prepared polymers for special purposes are very favorable[17].

4.2.3. Leaching

The capabilities of microorganisms can also be exploited for metal extraction. Thus, in leaching processes crystalline copper sulfide or uranium compounds can be solubilized by bacteria. It has long been known that microorganisms take part in weathering, soil formation, mineral deposition, *etc.*, but it is still astonishing to find that toxic heavy metal compounds can be dissolved by special microorganisms such as *Thiobacillus* and *Ferrobacillus* species. In this way it becomes possible to rework old mine dumps, and in a few cases the process is already used on a large scale (Sweden, Canada) to enrich low-grade ores.

4.2.4. Waste Disposal

Our industrial society must be concerned more with the problems posed by residues and wastes.

Waste water usually requires biological purification. Biotechnology is also used in the removal of refuse tips; in more recent processes the material is mixed with waste water and composted. Processes of this kind must be suited to the type of waste arising from a specific town, industry, or agricultural system, and thus a large field of work can be envisaged for the future. Only the microorganisms made available by mutation and adaptation and a corresponding advanced technology will finally enable the waste materials to be recycled.

There are processes by which waste is retransformed into basic raw materials. Thus, in many large towns methane is produced from waste in fermentation or decomposition towers with the aid of microorganisms. This methane is fed into the town's gas distribution network, burnt in small power plants, or used in the operation of the decomposition towers. The process is anaerobic, the organic material being first converted into hydrogen and fatty acids which are then decomposed by Methanobacteria into methane and CO_2.

4.2.5. Other Possibilities of Using Microorganisms

Nitrogen fixation by microorganisms for agricultural purposes cannot yet be exploited at will. Bacteria exist which can fix atmospheric nitrogen by means of a nitrogenase (*e.g.*

Clostridium, Azotobacter); in these organisms N_2 is converted by way of NH_3 into amino acids and proteins. The old three-field crop rotation system was based partly on nitrogen enrichment of the land by N_2-fixing microorganisms. Symbionts should also be cited; nodules on the roots of leguminous plants in particular contain bacteria (*Rhizobium* species) that bind molecular nitrogen during symbiosis; in this way some 100—200 kg of nitrogen are bound per hectare each year. The current manufacture of fertilizers by the Haber-Bosch process is essential to our civilization but requires a large expenditure of energy. Since there are other microorganisms that bind atmospheric nitrogen, there is a prospect that this economical energy-saving process will one day find greater application.

Another group of microorganisms must also be mentioned, namely those that react with inorganic compounds (the leaching process has been discussed in Section 4.2.3 above). *Desulfovibrio*, for example, forms acetic acid and hydrogen sulfide from sulfate and hydrogen; denitrifiers reduce NO_3 and NO_2, for example, liberating N_2 and water. For many microorganisms the energy source is light, required for example so that H_2S can be used as an H-donor. These phototrophic and many C-autotrophic microorganisms require carbon, but this carbon is derived from atmospheric CO_2 and not from carbohydrates, fats, or proteins. This carbon autotrophy shows the relationship between the microorganisms and plants. Utilization of these possibilities by biotechnology is only just beginning; but, for example, foul-smelling gases that also contain CO_2 can be subjected to fermentation in which the microorganisms transform the harmful material, use the CO_2 as a source of carbon, and in so doing also provide biomass.

Possibilities of a very different kind should now be added to the above examples. A wide variety of starting materials for chemical reactions can be prepared microbiologically: acetone, butanol, isopropanol, ethanol, glycerol, acetic acid, and many others can be produced by special microorganisms on media that are usually substrates of vegetable origin. Such substrates are renewable. Processes of this kind are not generally economic, but in the developing countries a given process may serve as the sole source of material; for example, ethanol production from sulfite lye, maize, whey, molasses, and nearly all fruits and grains is widely practised in the developing countries and to some extent also in the industrialized world. The use of such processes is likely to increase greatly in the future, when other starting materials become either unavailable or too expensive.

5. Cycles and Adaptation—Biotechnological Possibilities

5.1. Utilization of Natural Cycles

Looking at the carbon cycle[28] in Figure 7 makes it clear that the processes used today for treating dumps and purifying waste water are only a beginning. Microorganisms play a role in the essential synthetic and degradative processes taking place in the biosphere and cells of microorganisms and in

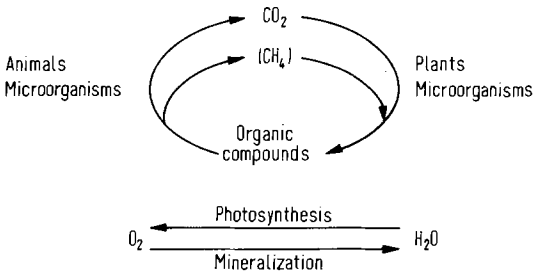

Fig. 7. The carbon cycle [28].

biotechnology. *Cramer*[29] compared biological metabolism with a cyclic function to cultural metabolism with a linear function; it became clear that exponential growth of one parameter in a closed system rapidly leads to stagnation values; any growth curve, whether of microorganisms or of man, confirms this conclusion, which is not contradicted by the statement that "growth is the sole proof of life" (Cardinal *Newman* 1864[30]). Biological reactions are balanced processes, which have a high degree of efficiency. This high efficiency is achieved through evolution. The performance of muscle cells is an example: it is believed that their efficiency averages 60%. Combustion engines reach maximum values of 30% or more, but the average is a bare 10%. Intensive animal breeding, deep-sea fishing, and intensive grain production have efficiencies between 5 and 20%. The biotechnological process for the production of biomass reaches 20% or more (see Fig. 5), so that it would seem wise to include such processes in considerations of how to remove waste and produce food or, in general, how to introduce biological cycles in place of the linear consumption processes.

5.2. Adapted Processes

Large-scale biotechnological processes require much capital, extensive know-how, and a highly skilled labor force, but

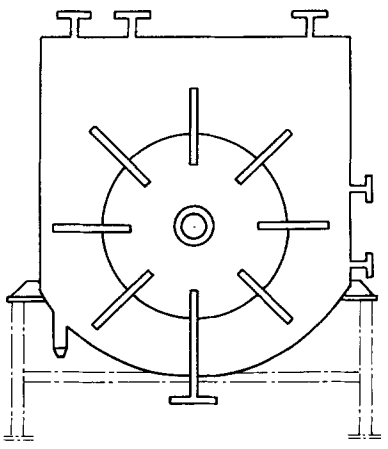

Fig. 8. Paddle wheel reactor for the production of biomass on a small scale.

they could be supplemented by small-scale processes that function with little capital, little know-how, and a relatively

untrained labor force. Biotechnological processes in particular must often be adapted to serve specific localities. The waste water of a town in Central Europe must be handled differently from ditch water in Africa. Processes for the production of biomass can be run in special small plants which provide a small population with biomass for use, *e.g.* as a component of animal feeds[31]. Figure 8 shows such a reactor[34]. An area with many intensive animal feeding units must, however, be served by a large plant.

However, it is not only a question of large plants—plants can be adapted to special needs. The basis for this lies in the possibility of cell adaptation: mutation, selection, or merely the suitability of the substrate may enable a particular problem to be solved. In this way, for example, application of the astonishing results coming from molecular biology in the last 15 years has started: by plasmid transfer the degradative metabolic route characteristic of one bacterium was transferred to another where it was, so to speak, collected, and the resulting "supermicrobe"[32, 33] could then degrade compounds such as camphor, octane, salicylate, and naphthalene. Biotechnological processes are important in that it may be possible to bring our civilization back into equilibrium with their aid.

6. Conclusion

The microbial cell had hitherto been utilized only accidentally and sporadically. In the past its possibilities were often neglected in favor of more economic processes. Today we have become aware of the darker side of our civilization, but microbiology and technology offer a possible way out. Microbiology brings with it the natural principle of cyclic processes, the simplest of cells are capable of many varied tasks, and the opportunities for these smallest of living forms include all the reactions known in the living organism. The technology of today is highly developed and offers a wealth of processes for which we can thank our level of civilization. *Claude*[35] speaks of the coming age of the cell; *Spinks*[23] puts his trust in technology but is politically and economically pessimistic.

It seems reasonable to except the union of biology and technology that we call biotechnology to play a decisive role in the future.

Secondary and Tertiary Structure of Polysaccharides in Solutions and Gels

By David A. Rees and E. Jane Welsh[*]

Many polysaccharide chains can adopt ordered helical and ribbon-like secondary structures. It seems however that these chains are often so stiff and extended that the cooperative interactions necessary for stability in the solvent environment can only be achieved when inter-chain as well as intra-chain interactions are favorable. Hence we commonly find two- or more-stranded associations of helices, of ribbons, or of helices with ribbons. These can be regarded as tertiary and higher levels of structure. The ordered secondary structure characteristically requires a regular repeating sequence of sugar residues, and the termination of this sequence by insertion of a residue of different type may also terminate the secondary structure and hence the association in which it is involved. This is the mechanism by which native polysaccharides may link up to form three dimensional networks, or gels, in which state they perform their natural roles in maintaining the hydration and integrity of biological tissues. For several polysaccharides there is evidence that the mechanism of biological control over the fine topology and properties of the gel network is mediated by enzymes which modify sugar residues at the polymer level to change the pattern of "interrupting" sugar residues.

1. Introduction

The idea of primary, secondary, and tertiary structure has essentially the same meaning for polysaccharides as for proteins and other biopolymers; it provides a convenient way of distinguishing different levels of structural organization. The primary structure describes the covalent sequence of monomer residues in the chain; the secondary structure defines any geometrically regular arrangement in space that this sequence might adopt; and the tertiary structure defines the way in which these arrangements pack together in a compact whole. In polypeptides and proteins, the α-helix and the β-sheet structure are familiar examples of secondary structure, whereas the tertiary structure is, for example, the overall form of a globular subunit. Similarly, various helical and ribbon-like secondary structures of polysaccharides are known and some of these are described later in this article. They can pack in more elaborate arrangements such as double helices and aggregates of helices and ribbons, which we can regard as tertiary and higher levels of structure.

In this article, we shall focus attention on structure in solution because this is usually expected to be most relevant to the understanding of physical and biological properties. However, the characterization of solution conformations does ultimately depend on comparison with ordered structures defined in the condensed phase by X-ray diffraction. Very many solid state conformations have been elucidated in the last five years—far more than have so far been studied in solution—but we do not have space to describe and discuss them systematically here.

In any discussion of polymers in solution, we cannot of course take it for granted that conformations are necessarily ordered. In all polymer systems there is an entropic drive to the disordered (random coil) state, which must be outweighed by sufficiently favorable non-bonded interactions before an ordered form can be adopted. For polysaccharides, the relevant interactions are hydrogen bonding, dipole and ionic interactions, and solvation terms. Contributions from hydrophobic and charge transfer interactions, which are so important for proteins and nucleic acids, probably have little relevance here. The secondary interactions are individually so weak that conformational stability can be achieved only when a large number of them is simultaneously favorable—that is, when they act cooperatively. In polysaccharides it rarely seems to be possible for such stabilization to exist within a single chain; on the contrary, it requires the alignment and interaction of two or more chain segments, usually with long regions of regular covalent sequence. Often, such regions are terminated by changes in sequence which are incompatible with the ordered association. There are obvious analogies here with helix-breaking residues, such as proline, in proteins. The interruptions can be provided by the introduction of one or more different sugar units, by chain branching, or other altered substitution.

A further important consequence of interruptions in secondary and tertiary structure of polysaccharides is that a single chain can pass through several regions of tertiary structure, that is through several chain associations, each involving a different partner with the result that a three-dimensional network, or gel structure, is set up. In such systems, the interruptions clearly have an important function in controlling the density and distribution of cross-linking and hence the hydration and detailed pore structure of the gel. These features seem to be under enzymic control at a late stage in polysaccharide biosynthesis; after polymerization, the regions of regular chain-associating residues are "unmasked" in ways that will be described for several examples, inviting analogy with the secretion of many proteins in an inactive form which is later converted by covalent modification to an active form.

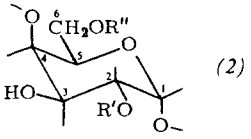
Other aspects of this subject, including solid state conformations and the implications of conformation for binding, were reviewed in 1973[1].

2. Double Helices in Solutions and Gels

2.1. Double Helices in Solution: Carrageenans and Agarose

Double helix conformations have been characterized in the solid state[2,3] for a number of algal polysaccharides of types

1,3-linked β-D-galactose — 1,4-linked 3,6-anhydro-D-galactose



(1a), R = $SO_3^{\ominus}$: ι-carrageenan
(1b), R = H: κ-carrageenan

(1) and *(3)* (see Section 2.1.3). These are alternating copolymers of 1,3-linked β-D-galactose and 1,4-linked 3,6-anhydro-D- or L-galactose[4–7]. Individual members of the family carry different amounts of sulfate ester and/or other substituent groups. It appears that the polysaccharides containing 3,6-anhydro-D-galactose form threefold right handed helices whereas those containing 3,6-anhydro-L-galactose form threefold left handed helices.

2.1.1. ι-Carrageenan

ι-Carrageenan *(1a)* is the most highly sulfated member of the double helix-forming polysaccharide family and it is also the member for which the double helix conformation is most thoroughly characterized, both in the solid state and in solution. One influence that stabilizes the double helix is a hydrogen bond between O-2 and O-6 of D-galactose residues on different strands. It will be observed that these two positions represent the only unsubstituted hydroxy groups in the covalent structure and therefore that this one hydrogen bond, repeated along the chain by helical symmetry, provides a fully hydrogen bonded structure.

Native ι-carrageenan does not consists entirely of a regular, alternating sequence of sugar residues; interruptions exist at various points in the chain and appear to terminate the double helical regions. We shall first describe the properties of ι-carrageenan after processing to remove these interruptions which are of the types shown in formula *(2)*.

(2)

R' = H: split by periodate
R' = H, R'' = $SO_3^{\ominus}$ } undergo reaction with $NaBH_4$
R' = R'' = $SO_3^{\ominus}$ }

This is achieved by using the Smith periodate degradation sequence[8] to split the 4-linked residues in the C1 chair form that are not 2-sulfated, then converting the other residues into 3,6-anhydride with $NaBH_4$[9]. The result is that the native, long chains with interrupted sequence are converted to short chains of regular sequence which we call "ι-carrageenan segments".

That the ι-carrageenan segments can exist in the double helical conformation in solution, is supported by a variety of measurements on the reversible "melting" of this structure. Light-scattering and osmometry measurements show that the expected change by a factor of two occurs in the molecular weight[10]. The accompanying optical rotation change[11] shows (at constant temperature and pressure) a concentration-dependence which corresponds to a dimerization process[12] (see Fig. 2).

The sign and magnitude of this shift can be related by a semi-empirical treatment of optical activity to the conformation angles of the polysaccharide backbone[13]; it emerges that there is excellent agreement with the sign and magnitude to be expected from the double helix geometry shown to exist in the solid state[14]. In addition corroborative evidence of an order-disorder transition has been obtained by high resolution and relaxation NMR techniques. ^{13}C-NMR studies have shown that, as expected, the mobility of residues in the form believed to be the helix is severely restricted since a marked decrease occurs in the spin-spin relaxation times (T_2) for the carbon nuclei (Fig. 1).

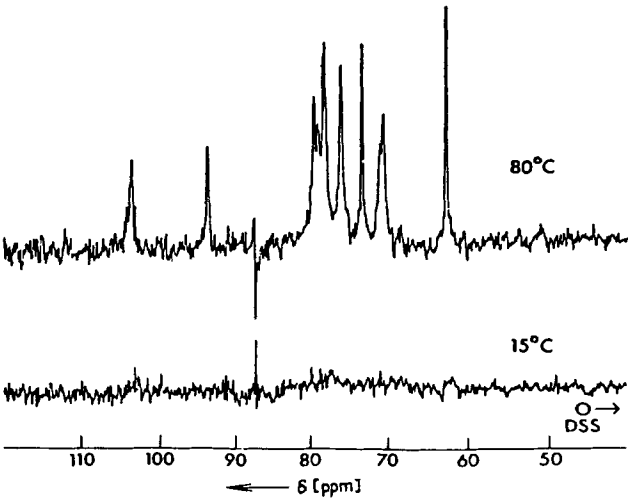


Fig. 1. Comparison of ^{13}C-NMR spectra for ι-carrageenan segments at 80°C (upper spectrum) and 15°C (lower spectrum). Concentration 6 % (w/v); solvent 0.1 M sodium chloride; standard DSS (DSS = sodium 2,2-dimethyl-2-silapentane-5-sulfonate).

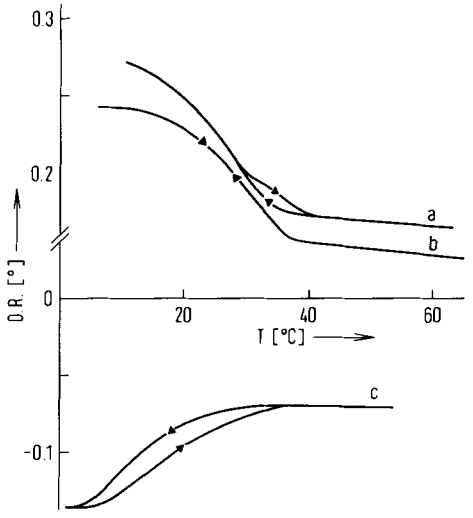
This results in linewidth broadening to such an extent that the peaks are lost from the high resolution spectrum[15]. A similar progressive disappearance of intensity without other changes in the high resolution spectrum has been seen with ^{1}H-NMR spectra and has been interpreted in essentially the same way. The changes are paralleled by the appearance of a microsecond T_2 component in the pulse spectrometer concomitant with the optical rotation change.

A thermodynamic description has been obtained by determination of the enthalpy of the transition by calorimetry and from the van't Hoff isochore[16]. Again the model accounts adequately for the observations and the results show further that the interconversion is two state all or none. Finally,

small angle X-ray scattering shows rod-like molecules in solution with dimensions which correspond to the double helix.

2.1.2. Other Carrageenans

κ-carrageenan *(1b)* has essentially the same covalent structure as ι-carrageenan except that only one sulfate group is present on each disaccharide repeating unit, this being on O-4 of the D-galactose residue[17]. This change modifies not only the conformation in the solid state but also the solution properties. Although the X-ray diffraction evidence is not as well defined as ι-carrageenan, it has been interpreted in terms of a right handed three-fold double helix with the pitch somewhat shortened and the relative positions of chains shifted[2].



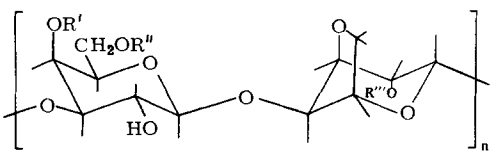


Fig. 2. Comparison of the optical rotation variations with temperature for segments of (a) κ-carrageenan, (b) ι-carrageenan, and (c) agarose sulfate. Heating and cooling curves are distinguished by arrows. $\lambda = 546$ nm; concentration 3 % (w/v); solvent distilled water.

Short chains of regular sequence can be obtained from κ-carrageenan in the same manner as described for ι-carrageenan. Optical rotation measurements on this product show a concentration-dependent, temperature-induced cooperative transition which provides good evidence that the double helix can persist in solution[18,19]. The curve shows hysteresis in formation and "melting" of the ordered conformation which is enhanced by the addition of univalent salt (Fig. 2, curve a). The extent of this effect appears to parallel the extent of aggregation of the double helices—hence its enhancement in salt solution when electrostatic repulsions are screened. The high charge density of the ι-carrageenan double helix limits aggregation and hence hysteresis is not observed in that system (Fig. 2, curve b).

Furcellaran, a third member of the carrageenan family, has an even lower content of sulfate ester with only 40 % of the 3-linked residues being substituted. Less is known about its solid state and solution conformations but the optical rotation and other properties strongly suggest analogous behavior[20]. As we would expect from its lower charge density, aggregation and hysteresis effects are still more pronounced than for κ-carrageenan.

2.1.3. Agarose and Derivatives

A recent X-ray diffraction investigation on fibers of agarose and a number of derivatives of type *(3)* (Table 1) from natural sources and chemical modification, has led to a family of related double helical models[3]. As mentioned earlier, the presence of the anhydro sugar in the L-configuration reverses the screw sense of the helix but still retains the threefold symmetry. The pitch of the helix (1.96 nm) is still shorter than for ι-carrageenan (2.66 nm) and κ-carrageenan (2.46 nm), following the trend of changing sulfate content. Within the agarose series the helix geometry is not fundamentally altered by introduction of substituents on O-2 of the 3,6-anhydride and on O-4 and O-6 of the D-galactose residue. This changed substitution does however alter the stability of the solution tertiary structure, particularly where aggregation of these helices is pronounced.

(3)

1,3-linked β-D-galactose

1,4-linked 3,6-anhydro-L-galactose

Table 1. Compilation of substituted agaroses of type *(3)*.

Name	R'	R''	R'''
Native agarose	H	H	H
Naturally occurring *O*-methylated agaroses	H	50—75 % H 25—50 % CH_3	H
	H	H	50 % H 50 % CH_3
Chemically hydroxyethylated agarose	CH_2CH_2OH, partially and irregularly substituted on all positions		
Naturally occurring agarose sulfate (used in optical rotation studies)	H	13 % CH_3 87 % $SO_3^{\ominus}$	80 % H 17 % $SO_3^{\ominus}$, 3 % CH_3
Agarose sulfate, also naturally occurring	H	$SO_3^{\ominus}$	80 % H 20 % $SO_3^{\ominus}$
Agarose naturally substituted with pyruvic acid	*ca.* 12 % 4,6-*O*-carboxyethylidene		H

As with carrageenan, the disaccharide repeating unit represents an idealized extreme of primary structure, because interruptions usually exist along the chain. Again these are helix-incompatible and can be modified to yield a structurally regular polysaccharide product. Unfortunately, it is not possible to follow the complete order-disorder transition with this product because the segments associate and separate rapidly from solution at the onset of helix formation[19]. This behavior is to be expected for a chain molecule which is not solubilized by ionic substituents because much of the drive to solution is associated with conformational entropy and this is lost when the molecule becomes conformationally rigid. Agarose segments substituted with sulfate ester on C-6 of the 3-linked sugar and partially on C-2 of the anhydride do remain in solution after formation of the ordered state. The optical rotation behavior is then consistent with double helix formation and, like κ-carrageenan, shows a hysteresis loop on heating and cooling[21] (Fig. 2, curve c).

2.2. Double Helices in Gels

As we indicated in the introduction, one consequence of interruptions in the covalent sequences in polysaccharides which undergo chain association is that individual polysaccharide chains are forced to combine with a large number of partners and, if the resulting complex is hydrophilic, the result is a swollen gel. This is shown schematically for ι-carrageenan in Figure 3.

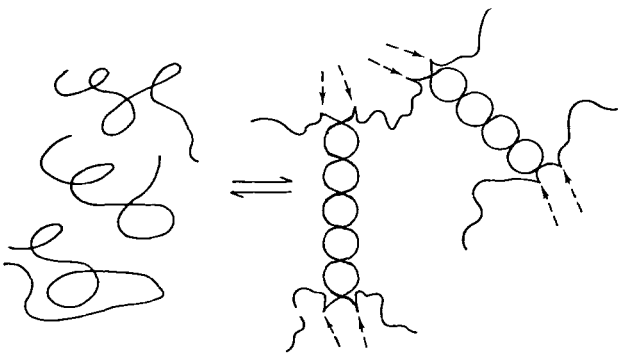

Fig. 3. Model for the molecular basis of gel formation by ι-carrageenan: The helix-breaking kinks are shown by arrows.

These gels show optical rotation changes analogous to those that accompany double helix formation and melting in the segments, and the midpoint for the transition is usually close to the temperature for sol-gel conversion[19]. This remains true even when the transition temperature is altered by changing the concentration of polysaccharide or salt, and in systems which show hysteresis in the heating and cooling curves. All this provides good evidence that the chain association in helix formation is the actual mechanism of cross-linking in the gel network.

The mechanism of gelation is further substantiated by competitive inhibition studies[22]. Introduction of ι-carrageenan segments into an ι-carrageenan gel is expected to lead to double helix formation between short and long chains which will be unproductive from the point of view of cross-linking into a continuous network. In contrast, in systems in which the double helices aggregate when formed as in κ-carrageenan, incorporation of segments should no longer prevent cross-linking (Fig. 4).

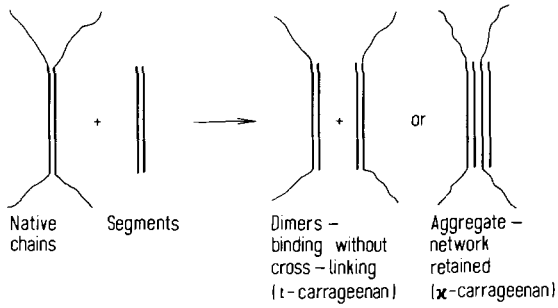

Fig. 4. Incorporation of segments into the gel network—proposed molecular interpretation.

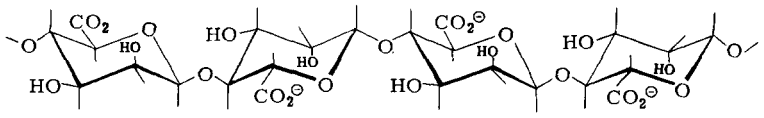
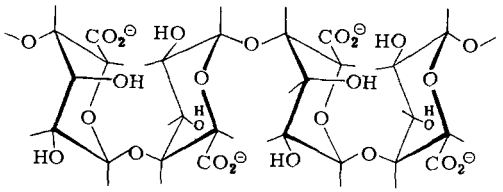
These effects are indeed seen in gel strength measurements where incorporation of segments markedly decreases ι-carrageenan gel strength and κ-carrageenan gel strength is actually enhanced by addition of the corresponding segments. This competitive inhibition method therefore distinguishes between chain association by dimerization and chain association which involves the formation of larger aggregates.

Calorimetry[16] and optical rotation[15] measurements indicate that the extent of helix formation is as high as 80% of the theoretical maximum, or even higher, in carrageenan and agarose gels. This is surprising when we consider the topological constraints that must exist on the formation of double helices in these highly tangled systems.



The detailed pore structure of the gel is evidently a consequence of the number and distribution of double helical sections which is in turn determined by the extent to which the covalent structure contains regular alternating sequences longer than the critical size for double helix formation. The knowledge we have of biosynthesis of these polysaccharides, suggests that these variables are under control through regulation of appropriate enzyme levels. As in the biosynthesis of most other polysaccharide types, these carbohydrate chains appear to be built up by transfer of glycosyl residues from nucleotide disphosphate donors. Very probably the sugar residues are polymerized in their unsubstituted form and then modified afterwards by the introduction of sulfate ester and the formation of anhydride and other derivatives. Very little detailed information is available on these stages but, in the agarose series, it seems likely that the nucleotides involved are uridine diphosphate D-galactose and guanosine diphosphate L-galactose[23].

For both the agarose series and the carrageenan series an enzyme has been detected in the parent alga which will convert 4-linked 6-sulfated residues to anhydride at the polymer level[24, 25]. This is presumed to represent a stage in natural biosynthesis, a view that is supported by the identification of precursor residues and in some cases precursor polysaccharide fractions; in principle these are convertible to agarose, κ-carrageenan, or ι-carrageenan respectively by the action of the appropriate enzyme. Because the stereochemical influence of an isolated 4-linked 6-sulfated residue in a chain otherwise composed of alternating 3-linked β-D-galactose and 4-linked 3,6-anhydride residues is to introduce a "kink", this enzyme can be considered to "de-kink" the chain and it has accordingly been given the trivial name "dekinkase".



3. Ordered Ribbons in Solution and Gels: Alginates and Pectins

3.1. Alginates

Another group of algal polysaccharides which can adopt ordered solution conformations, primarily by a dimerization process, are the alginates. These are linear polymers of 1,4-linked β-D-mannopyranosyluronate residues and 1,4-linked α-L-gulopyranosyluronate residues, containing homopolymeric sequences[26,27,28] and also regions in which the two sugars alternate although perhaps not in strictly regular fashion[29,30]. The relative proportions of these types of sequence, or "blocks", alters with the botanical source, with the state of maturation of the plant, and with the morphological origin of the polysaccharide within it. It is possible to obtain naturally occurring polymers consisting almost exclusively of polymannuronate sequences and others in which guluronate represents over 70% of the residues present.

1,4-linked β-D-mannuronate

1,4-linked α-L-mannuronate

Fiber diffraction studies on alginate samples of these two extremes have given insight into conformations of two of the individual blocks. In the solid state polymannuronic acid adopts a flat ribbon-like twofold conformation[31] similar to that of other β-1,4 di-equatorially linked hexosans, such as cellulose, chitin, and mannan. In the salt form the helix can be modified to a threefold conformation[32] which is still extended and ribbon-like. In polyguluronic acid[33], as a consequence of the residues being linked di-axially and 1,4-, rotation about the glycosidic bonds is even more restricted and a buckled twofold conformation is adopted which is maintained in all the salt forms so far studied[32].

To study the ability of the various block structures to maintain secondary and tertiary structure in solution it is possible to split out the three types of sequence by partial acid hydrolysis[27,28]. Polyguluronate segments show an enhanced and at first unexpected Ca^{2+}-binding property when the chain length exceeds a critical value of 20 or so residues[34,35]. This observation of a threshold for strong calcium binding suggests a cooperative mechanism. Such effects are not seen for the corresponding polymannuronate oligomers. By other criteria also, it can be shown that polyguluronate sequences show cooperativity in their calcium binding behavior, whereas polymannuronate and the alternating sequences do not[34]. Such cooperativity implies that the binding of each ion facilitates the binding of the next, *i.e.* that these sites exist in ordered arrays which, in view of the stiff and extended nature of the chain (see above), are formed between chains rather than within an isolated chain. Physical and mathematical model building[36] using criteria based on crystal structures of analogous salts including calcium sodium D-galacturonate[37] and the strontium salt of a disaccharide derived from pectic acid[38], leads to a plausible model in which the chain conformation is similar to that already characterized by fiber diffraction for polyguluronic acid. The array of co-ordination sites is formed by the alignment of two polyguluronate chains; because of the buckled shape of these chains, cavities remain between them which happen to be of the right size to accommodate a calcium ion and moreover are lined with carboxylate and other electronegative oxygen atoms which are favorable ligands. For obvious reasons this model (Fig. 5) is known as the "egg-box model"[36].

A further distinctive feature of the calcium binding behavior of polyguluronate sequences is that large circular dichroism changes are seen when this occurs. A much smaller change is observed for alternating sequences with virtually no effect for polymannuronate blocks. The change is confined to the $n\rightarrow\pi^*$ transition region of the carboxylate spectrum, consistent with the n orbitals in the polyguluronate sequences being specifically involved in the chelation of calcium ions. The egg-box model provides a convincing basis for explanation of these changes because it places the ion in the correct position for coordination by carboxylate n-orbitals and in the same region of symmetry space as O-4 and O-5 which normally determine the sign of the $n\rightarrow\pi^*$ band.

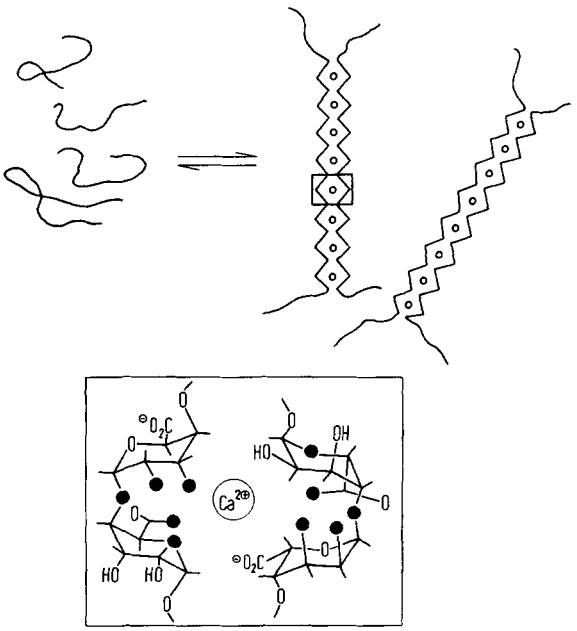


Fig. 5. Schematic representation of association of polyguluronate sequences by chelation of Ca^{2+}: "egg-box model". Below: Section; oxygen atoms coordinated to calcium are shown as filled circles.

This association of polyguluronate sequences by cation binding is believed to be the principal mechanism of cross-linking in alginate gelation. The characteristic CD spectral changes on gelation, particularly for alginates rich in polyguluronate

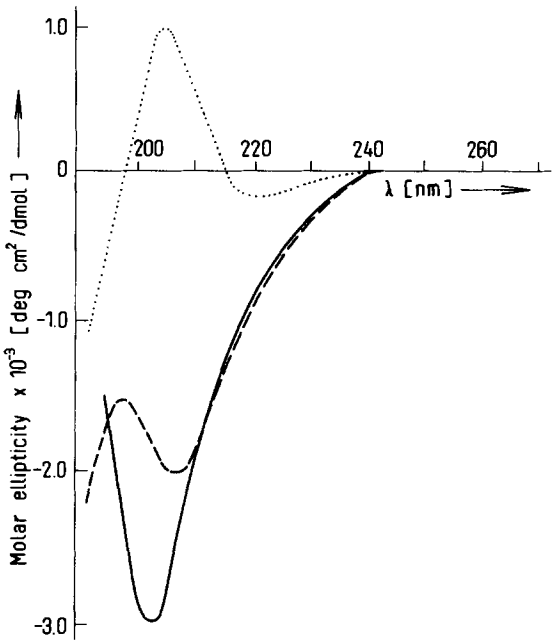

Fig. 6. Characterization of calcium binding to alginate by circular dichroism. Spectral changes with the diffusion of Ca^{2+} to a final concentration of 6 mmol into a solution of alginate (0.1 %) having mannuronate and guluronate residues in the ratio 29:71. Broken and dotted lines show spectra before and after this process, and the full line shows the difference spectrum.

sequences (Fig. 6) provide the same confirmation that this is so[39]. At first sight, there might seem no reason why the egg-box structures should not be layered structures involving many chains. However, the stoichiometry of binding as studied by equilibrium dialysis[40] and also by reinterpretation of earlier binding studies by a cation exchange method[41] points quite clearly to dimerization. By both approaches, it is found that competitive inhibition is observed at all, points to a dimeri-calcium ion for every four guluronate residues as expected on a dimerization model, rather than to one calcium ion for every two guluronate residues as would be expected on an infinite sheet model. The reason why the process tends to stop at the dimer may be that much of the electrostatic driving force for association has been neutralized by this stage: this would be analogous to the reasons why dibasic acids usually have two separate dissociation constants. It may also be that the polyguluronate chain undergoes the conformational adaptation to optimize coordination of the first set of calcium ions in a way that inhibits further associations.

Competitive inhibition studies[22] in which the influence of added "blocks" was studied on the bulk properties of alginate gels provide further confirmatory evidence. The fact that competitive inhibition is observed at all, points to a dimerization mechanism (compare with evidence of the same type discussed above for carrageenans). They also confirm that polyguluronate sequences rather than either of the other two types are mainly involved in the cross-linking mechanism. A marked decrease is seen in gel strength when polyguluronate blocks are added, less change with alternating blocks, and virtually no effect with the polymannuronate. These results are entirely consistent with the spectroscopic evidence and ion binding studies.

The extent to which ordered solution conformation can occur, and hence gelation, is therefore limited by the number and length of polyguluronate sequences. Biosynthetic studies suggest that, as for analogous features in agar and carrageenans, these are under enzymic control at the polymer level. Original studies with bacterial alginates (*Azotobacter vinelandii*) showed that the polymer chains were synthesized first as polymannuronate sequences, and that guluronate residues were introduced subsequently by epimerization at C-5[42,43]. Similar epimerase activities have now been demonstrated in brown algae, capable of producing regions of alternating sequence and of polyguluronate[44]. Work with algae has also suggested that the nucleotide precursor is guanosine diphosphate mannuronate[45].

3.2. Pectin

Pectin is a major constituent of the cell wall of higher plants, and like alginate is involved in the maintenance of structural integrity. It again illustrates how stiff, buckled chains can pack together under conditions of extensive hydration. It occurs naturally as the partial methyl ester of 1,4-linked poly-(α-D-galacturonic acid)[46,47]. These chains are geometrically similar to polyguluronate blocks in alginates in that the sugar residues are linked di-axially. In pectin, the polygalacturonate sequences are interrupted by 1,2-linked L-rhamnose residues which can introduce a severe kink into the backbone geometry[48]. Unlike alginate, pectin usually contains a proportion of branch chains which are composed mostly of various neutral sugar residues and which are expected to limit possible chain associations. Different types of chain associations occur depending on whether the chains are methyl-esterified and to what extent. These various modifications offer mechanisms of biological control over the secondary and tertiary structures that will be discussed later.

Fiber diffraction studies have shown that 1,4-linked polygalacturonate chains show a similar projected residue rise as polyguluronate, although the sodium salt which is the only form to have been examined experimentally in any detail does appear to be threefold in contrast to the twofold symmetry of polyguluronate[49]. We conclude that the stereochemical analogies between polygalacturonate and polyguluronate, like the covalent analogies, are close but limited.

The calcium binding behavior of (de-esterified) polygalacturonate chains shows strong similarities to that of polyguluronate. Binding is greatly enhanced at chain lengths above a critical value of around 20 residues[41], and large circular dichroism changes occur in the $n \rightarrow \pi^*$ region of the same type as with polyguluronate[36]. Moreover there are similarities in cation exchange behavior. All this leads us to expect that gelation and calcium binding by pectins of low methyl ester content will proceed by an "egg-box" mechanism which is broadly similar to that which we have described for polyguluronate. Differences in detail include the fact that these regions of ordered association are terminated by covalent features of a different character.

For pectins with higher degrees of methyl esterification, interactions with cations are relatively weak because the chains are uncharged and hence gelation does not occur under the same conditions as for the polyanion. However pectin can be induced to gel by addition of a large amount of a cosolute such as sucrose to lower the water activity and hence to favor polymer-polymer interaction rather than polymer-solvent interaction[47]. For samples which are incompletely esterified, chain association is further facilitated by a low pH to suppress residual ionized residues and thus to minimize electrostatic repulsion between chains. This gelation is accompanied by an *increase* in amplitude of the $n \rightarrow \pi^*$ band in the circular dichroism, greater than that over the same temperature range for solutions of nongelling polysaccharide[36]. Thus pectin has two very different mechanisms for chain association depending on the extent of methyl esterification and on the aqueous environment. In natural situations, it is to be expected that both of these mechanisms will occur to relative extents that depend on the amount and distribution of methyl ester as well as on other covalent features.

The extent and distribution of methyl esterification in native pectins would appear to be under enzymic control at the polymer level, although the relative importance of control at the esterification step relative to the de-esterification step is not clear. It would appear that polygalacturonate chains are synthesized by polymerization from uridine diphosphate D-galacturonate which is then esterified by transfer of the methyl group from *S*-adenosyl-L-methionine[50, 51]. Subsequently, de-esterification may occur under the influence of pectin esterase[52], the action pattern of which is such as to generate consecutive sequences of de-esterified galacturonate residues—in contrast to chemical treatments which cause de-esterification in a more irregular way[53].

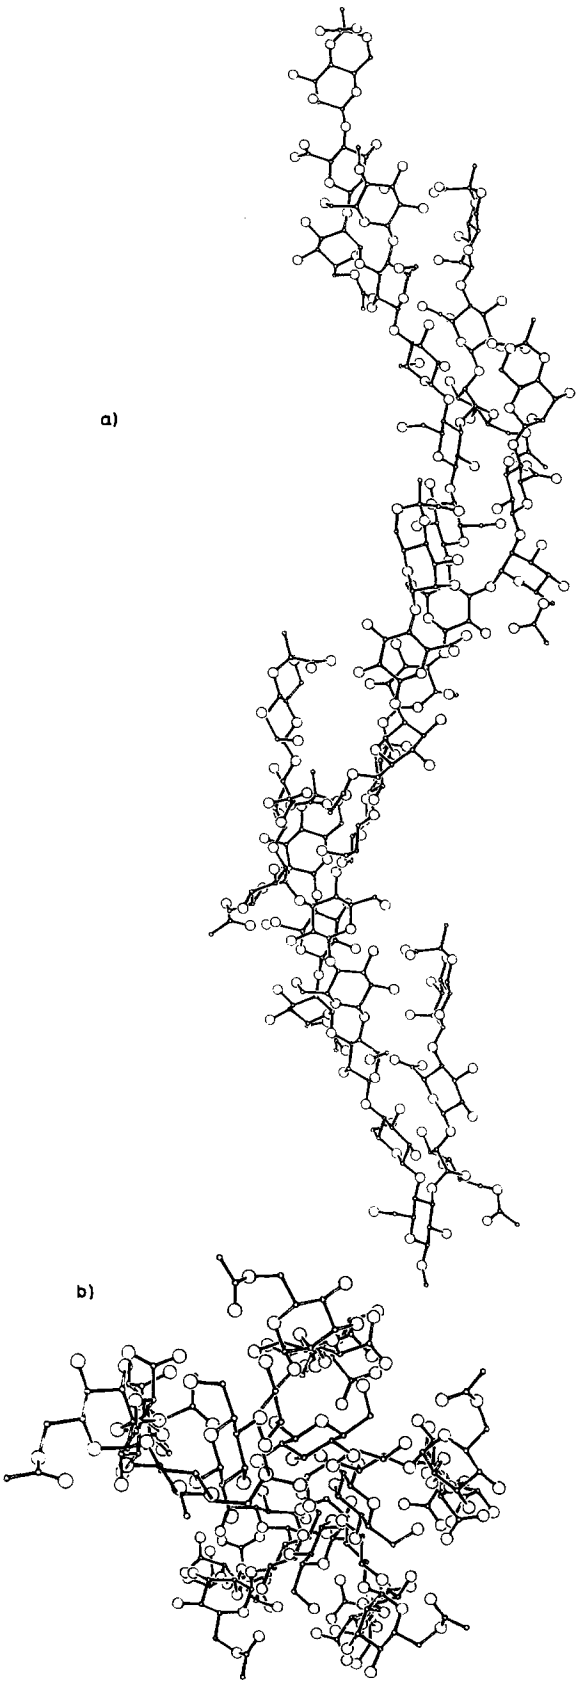
Some of the natural differences in pectin covalent structure in the plant cell walls may correlate with stages in cell growth. In tissues having a potential for rapid growth there appears to be a high proportion of L-rhamnose residues to prevent alignment of chains and hence gelation[54, 55]. Regular packing may be further limited by side-chains typically based on β-D-galactopyranose and/or α-L-arabinofuranose. The combined effect on physical and mechanical properties of the cell wall may then be to facilitate stretching and hence cell elongation.

4. Native Order in Solution: Xanthan

Xanthan, the extracellular polysaccharide from *Xanthomonas campestris*, has a pentasaccharide repeating unit[56, 57] in which trisaccharide side chains occur on alternate glucose residues of a cellulose-like backbone, giving rise to a highly branched molecule of type *(4)*. All the sugar residues are present in the pyranose form.

Actually the structure may not be quite as regular as depicted here; pyruvate substitution, which occurs in less than stoichiometric proportions, could be distributed irregularly or according to some type of regular pattern. Some departure from a strict alternating pattern of side-chain distribution is also possible in principle, although the evidence available from chemical degradation studies does not support this at present.

X-ray diffraction studies on oriented xanthan fibers[58] have shown that the chain describes a fivefold helix with a pitch of



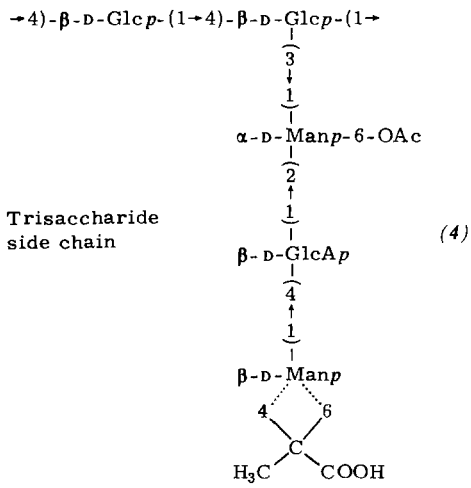


Fig. 7. Xanthan fivefold helix; computer generated diagram showing a likely interpretation of present X-ray diffraction evidence. a) Projection perpendicular to the helix axis; b) projection along the helix axis.

Cellulose-type backbone

Trisaccharide side chain

(4)

about 50 Å. Several alternative models can be built; a very likely possibility is shown in Figure 7. In this single helical conformation the trisaccharide side-chains fold down to align with the main chain and form noncovalent interactions which presumably stabilize the overall conformation. Evidence for the existence of an ordered form in solution has come from a variety of physical measurements[59, 60]. Optical rotation, NMR relaxation measurements, and low shear viscosity measurements each show a sigmoidal change with temperature (Fig. 8). Analogous results are found in circular dichroism studies on the carboxylate chromophore[59]. The temperature of the order-disorder transition is found to be independent of polysaccharide concentration at constant ionic strength. Since the transition is too broad to indicate a highly cooperative phase change, this concentration independence is taken as evidence for a unimolecular reaction which implies a coil to single helix transition. It seems likely that the xanthan single helix is stabilized in solution by associations between the side chain and the backbone similar to those in the model (Fig. 7) for the solid state. This is the first example of secondary structure stabilized within a single polysaccharide chain, and can be considered to be analogous to the α-helix in polypeptides and proteins.

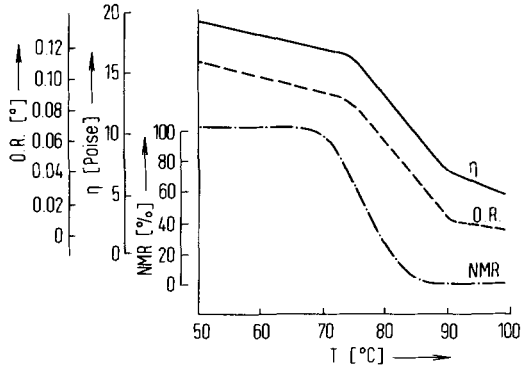

Fig. 8. Influence of temperature on optical rotation (O.R.), slow shear ($\dot{\gamma} = 14\ s^{-1}$) viscosity ($\eta$), and high resolution nuclear magnetic resonance relaxation (NMR) for 1% (w/v) aqueous solutions of *Xanthomonas* polysaccharide.

5. Helix-Ribbon Associations

Although xanthan adopts an ordered conformation in solution, it does not gel; this is of course expected if the order-disorder transition does not require the cross-linking of chains. However, a rubbery gel can be formed by addition of certain β-1,4-linked polysaccharides of a type which normally exist in solution as random coils and in the condensed phase as stiff, extended ribbons[61]. This gelling interaction implies a cross-linking between the unlike polysaccharide chains. The gel-sol transition is sharp enough to indicate cooperative character—that is, that the two polysaccharides interact in ordered conformations.

One example of this gelling interaction is between xanthan and the galactomannan from *Ceratonia siliqua* (also known as locust bean gum or carob gum). Analogous behavior is seen in mixtures of this and certain other galactomannans when mixed with the double helical algal polysaccharides. For example, concentrations of κ-carrageenan or agarose that are too low to gel alone will gel in the presence of this galactomannan[19]. Likewise the short chain segments derived from these polysaccharides and which will not gel alone, will do so in mixtures with galactomannan. All these mixed gels show sharp melting and setting behavior consistent with cooperative transitions and hence the networks would appear to be cross-linked by ordered non-covalent associations. Comparison of the gelling interactions of galactomannans with different degrees of substitution would suggest that the unsubstituted mannose residues are the effective ones in binding. In view of the chemical evidence[62] that these can occur in long consecutive "blocks", the likely mechanism for cross-linking involves helix-ribbon associations of the type shown schematically in Figure 9. The stoichiometry of this association, and whether it exists only as a subunit of some larger aggregate, remains to be determined.

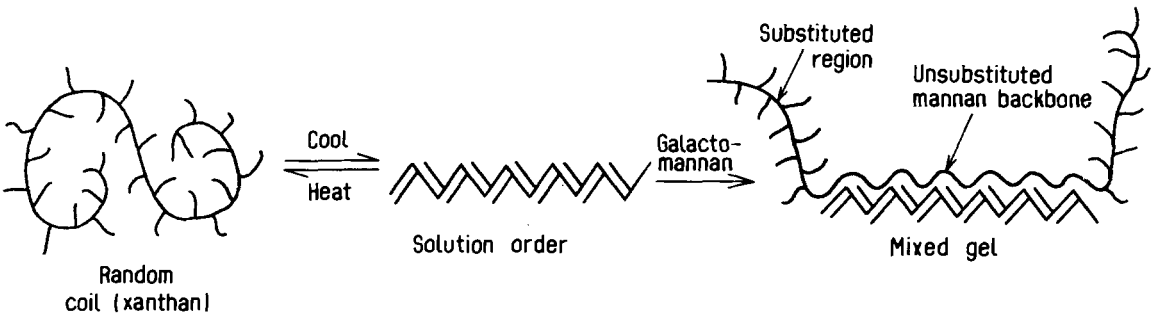

Fig. 9. Model proposed for the interaction between the xanthan helix and the unsubstituted backbone regions of galactomannans. (By courtesy of Dr. *E. R. Morris.*) Similar models in which galactomannan-double helix interactions occur have been proposed for interactions involving agarose and carrageenan[19].

The general features of this model are confirmed by optical rotation measurements[19]. The helix-coil transition for κ-carrageenan segments is perturbed by galactomannan, confirming an interaction between the two polysaccharides (Fig. 10). The cooling transition is shifted in a way that suggests that nucleation of the carrageenan double helix is facilitated by this interaction—that is, presumably by binding of the galactomannan. Likewise, on the heating curve the helix melts at higher temperature pointing to its stabilization by binding.

The optical rotation behavior of agarose in the presence of galactomannan can be interpreted in similar terms, although some of the observations are actually different. Once again, the cooling transition is shifted to slightly higher temperature

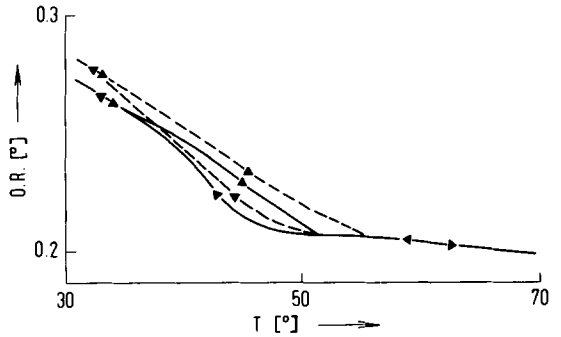

Fig. 10. Comparison of the variations in optical rotation (O.R.) with temperature for segmented κ-carrageenan (——) and a mixture of segmented κ-carrageenan and galactomannan from *Ceratonia siliqua* (– – –). Concentration of κ-carrageen and galactomannan 4 % and 1 %, respectively.

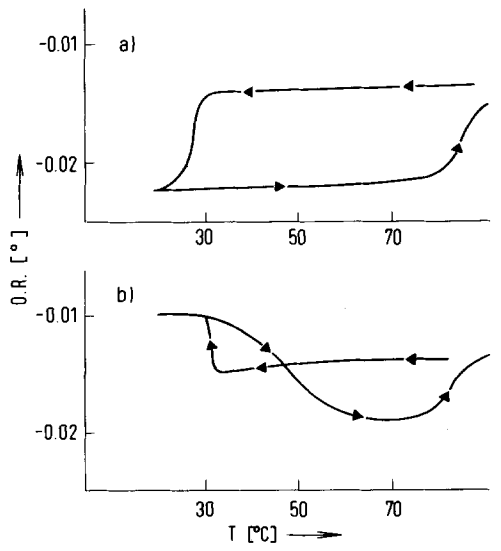
indicating an involvement of galactomannan in the nucleation event. On heating however, the optical rotation changes follow a complex form which strongly indicates that the galactomannan can be removed from its association before the double helix itself melts (Fig. 11). This dissociation of the galactomannan shows as a sigmoidal optical rotation change pointing to a cooperative process and hence confirming that the galactomannan chain is itself present in an ordered conformation in the bound state.



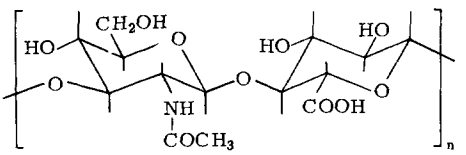


Fig. 11. Comparison of the variations in optical rotation (O.R.) with temperature a) for agarose and b) for a mixture of agarose and galactomannan from *Ceratonia siliqua*. Concentration of agarose and galactomannan 0.05 % and 0.1 %, respectively.

To varying extents, xanthan, agarose, and κ-carrageenan interact with other β-1,4-linked ribbon-like polysaccharides such as cellulose derivatives, xylans and glucomannans[61,63]. These interactions can be considered to be analogous to quaternary structure in proteins, and the specificity of interactions of this sort may well be important in the structural integrity of plant tissues. For the particular instance of xanthan, it might be significant that the bacterial species from which this polysaccharide derives is a pathogen which colonizes plant tissue by invasion through intercellular regions. Possibly the polysaccharide-polysaccharide interactions which we describe could play a role in host-pathogen recognition.

6. Animal Polysaccharides: Glycosaminoglycans

The glycosaminoglycans are matrix polysaccharides of animal origin. Most of them are alternating copolymers of type *(5)* formed from β-1,4-linked uronic acid and β-1,3-linked *N*-acetylhexosamine, and either residue may carry sulfate ester groups[64]. *(5)* is hyaluronic acid. An exception is keratan sulfate[65] in which the 4-linked residue is *N*-acetyl D-glucosamine and the 3-linked residue is D-galactose. Heparin is also different from other members of this group of polysaccharides[66]; although its structure has an alternating arrangement of uronic acid and *N*-acetylhexosamine residues, there are major differences in the configurations and positions of linkage.

(5)

1,3-linked *N*-acetyl-D-glucosamine — 1,4-linked D-glucuronic acid

Those polysaccharides which have an alternating arrangement of 1,3 and 1,4 linkages could be considered to be analogous to the agarose and carrageenan family in their general backbone stereochemistry [compare *(1)* and *(5)*] and also in that the 4-linked residue occurs naturally in both possible ring chair conformations. In glycosaminoglycans this residue may be D-glucuronate in the Reeves C1 conformation or L-iduronate which, at least in solution, exists in the Reeves 1C conformation[67]; in the agarose-carrageenan series, the analogous residue may be 3,6-anhydrogalactose or galactose 6-sulfate. Interconversion of the alternate forms would appear to occur at the polymer level in biosynthesis of glycosaminoglycans[66,68,69], just as (see above) the corresponding transformation exists in the agarose and carrageenan series.

In recent years, glycosaminoglycans have been very extensively studied by X-ray diffraction of oriented fibers and a variety of single-helical conformations have been characterized. All of these appear to be left-handed helices which differ in their states of extension. The threefold helices are most common[70–73], but fourfold forms are known for hyaluronic acid[74,75], twofold forms for keratan sulfate[76] and for some other polysaccharides in the acid form, and 8_5 helices for chondroitin 6-sulfate[77] and dermatan sulfate[78]. Although

the stereochemical analogies with agarose and carrageenans might lead us to expect the existence of double helical conformations, such forms have not yet been authenticated.

The polysaccharide of this family whose solution conformation has been most fully investigated is hyaluronic acid *(5)*. Many hydrodynamic studies have shown that, to a good first approximation, the molecule can be described as a random coil[79–81]. At the same time, however, evidence exists for intermolecular interactions which are difficult to explain merely in terms of entanglements of flexible chains[82, 83]. Hyaluronate solutions show coupling of coil domains at a concentration that is an order of magnitude lower than would be necessary for entanglement of most polymers—that is, hyaluronate molecules "stick" where they touch[84]. Further, hyaluronate behavior is untypical of random coil polysaccharides when the hydroxy groups are ionized by exposure to high pH; a random coil is expected to expand with consequent increase in molecular rigidity and solution viscosity. Both NMR relaxation studies[85] and viscosity measurements[86] show that sodium hyaluronate becomes more flexible and compact at high pH suggesting a reversible disruption of some form of association whose precise molecular origin is as yet unknown.

The inter-chain association of hyaluronate can be enhanced by diminishing the electrostatic charge by adjusting to pH 2.5; under these conditions and in the presence of a lower concentration of sodium chloride, the solution shows pronounced elastic character even at low polysaccharide concentration[81]. It is not strictly a gel because the inter-molecular contacts break and reform (*e.g.* when the material is cut, it "heals") indicating a fleeting association of chain segments in a state of dynamic equilibrium. The material has therefore been called a "viscoelastic putty". The properties become still more elastic when the water activity is reduced, for example by dialysis against a low concentration of ethanol. All these phenomena invite analogy with the systems discussed earlier in the article, where ordered polysaccharide secondary and tertiary structures were involved in cross-linking processes. However, the molecular origin of the effects for hyaluronate has still to be characterized.

7. Conclusions

The polysaccharide systems described in this review show enough common features to suggest general principles in the formation and interactions of secondary and tertiary structures in solutions and gels.

In all known examples, ordered conformations in polysaccharides require long regions of regular repeating covalent structure. When the regular covalent pattern is interrupted, the conformational ordering is usually (though not invariably) terminated. This terminating influence of changed sequence is more pronounced than it is in proteins and nucleic acids because the typical, natural variations in covalent structures of polysaccharides are more fundamental in their stereochemical implications. The polypeptide or polynucleotide backbone is not altered in general contour when one monomer residue is exchanged for another; whereas substitution of one sugar residue for another in a polysaccharide can involve change of glycosidic configuration, of position and configuration of the aglycon linkage and even of the sugar ring conformation. Hence an α-helical or β-sheet region in a globular protein may incorporate amino acid residues of a number of different types and, similarly, all four types of nucleotide residues can be accommodated within a single double helical region in a nucleic acid. In a polysaccharide helix or ribbon however, the insertion of a new sugar residue often introduces a sharp kink or at least changed packing requirements.

A further difference between polysaccharide and other biopolymer chains is that model building calculations[1] show that polysaccharides are much stiffer structures. Chain folding within a confined volume as seen in globular proteins does not generally occur for polysaccharides and many polysaccharides are extended ribbons or helices which need inter-chain packing to accumulate enough favorable non-bonded interactions for stability. In this article, we have given examples of this in two-stranded helical structures, two-stranded ribbon-ribbon associations, and multi-stranded helix-ribbon associations. We know only one example of a structure which may be stabilized intramolecularly, namely xanthan. Actually, even the model described, being highly branched, combines a number of separate strands within the same molecule so that the conformation can be considered to be intramolecularly multi-stranded.

We suggest two main conclusions about the relation between polysaccharide secondary and tertiary structure and biological function. Firstly, the formation of ordered conformations, even in very highly hydrated environments, usually involves intermolecular associations; no doubt this reflects the biological function of polysaccharides in structural integrity at the outer surfaces of cells and in the organization of cells into tissues. Secondly, these ordered states and hence their associations are often under the fine control of enzymes which modify sugar residues at the polymer level.

We are grateful to Dr. E. R. Morris for valuable discussions during the writing of this article.

Analytical Applications of Chemiluminescence

By G. D. Mendenhall[*]

Most organic compounds react very slowly with atmospheric oxygen at room temperature. The weak chemiluminescence accompanying this autoxidation can be amplified and measured by sensitive instruments. Emission of light from many materials can also be induced mechanically and photochemically. The intensity-time curves are so characteristic that they can be used to establish whether the composition and history of two samples are identical. Moreover, numerous physical properties can be correlated with emission and thus measured.

1. Introduction

Chemiluminescence, light emitted from a chemical reaction, was first observed in biological sources such as the firefly and luminescent bacteria and marine organisms[1]. In 1727, *Swift* described a fictional, 16-year effort in one laboratory to isolate sunbeams from cucumbers[2]. The recognition of the advantages of a controlled source of light other than fire thus anticipated the progress of science and technology by a considerable margin.

There were in fact a number of attempts to use luminescent bacteria for lighting purposes from the Middle Ages up into the present century. In recent decades a number of intense sources of chemiluminescence have been discovered, and some of them indeed have been modified to provide useful lighting devices (*e.g.* the Cyalume® light marker developed by *Rauhut*[3]), and for more specialized purposes as described below.

It is not widely appreciated, however, that chemiluminescence is a virtually universal property of oxidizable organic substances. This discovery was made only after the advent of photomultipliers that were sufficiently sensitive to detect the faint emission from papers, plastics, rubber, edible materials, resins, cloth, and most articles of nonmetallic nature that undergo some degree of oxidative decay. If the emission from a reprint of a recent article in Angewandte Chemie is representative, for instance, the page on which this article appears is emitting about 10^2 photons per second at room temperature. The light is probably associated with the dynamic changes that contribute to the disintegration of the paper over the span of decades to centuries. The most extensive studies to date of faint chemiluminescence of this sort have been carried out by *Vassil'ev* and *Shlyapintokh*[4].

2. Instrumentation and the Nature of Measurements

Compared with many other spectral techniques, the apparatus for measurement of chemiluminescence is relatively simple. A sample container must eliminate background sources of light and not chemiluminescence itself. Usually provision is made for temperature and atmosphere control. The detected light must be recorded in some convenient way, either with a strip chart or by computerized data collection. Spectral distributions may be measured with cut-off or interference filters, or with conventional grating or prism dispersion. The former methods are more suitable with faint chemiluminescence from natural sources and have been included in an apparatus constructed at Battelle-Columbus (Fig. 1). Less sensitive equipment is available commercially, including fluorimeters that can be operated purely in the emission mode.

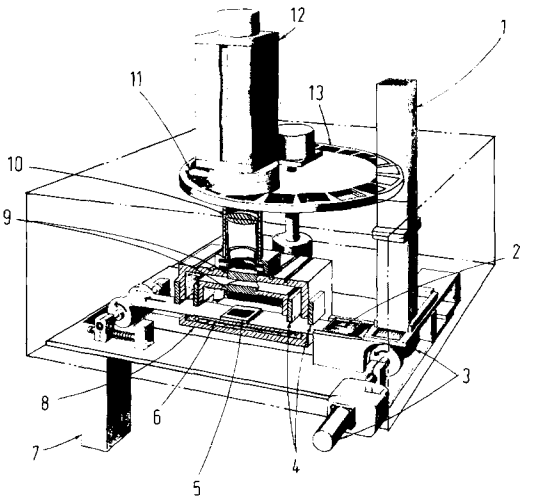

Fig. 1. Apparatus constructed at Battelle-Columbus (Ohio, USA) for measuring chemiluminescence. 1, sample bank and charger; 2, liquid sample; 3, sample conveyor and drive; 4, automatic doors; 5, solid samples (external dimensions *ca.* 50 × 50 mm²); 6, sample oven; 7, sample bank; 8, water-cooled oven shield; 9, quartz windows; 10, collector lens; 11, manually operated shutter; 12, photomultiplier; 13, filter wheel with 20 filters.

The apparatus depicted in Figure 1 is particularly suited for examination of thin sheets of material at elevated temperatures. The samples are mounted on glass or aluminum backing onto 35-mm aluminum slide holders, which ensure that a constant surface area is exposed to the photomultiplier. The samples are carried on a conveyer belt into an inner, heated compartment; a second compartment surrounding the first is water-cooled to avoid heating the entire apparatus, which is enclosed with 1/4-inch aluminum panels. The temperature, atmosphere, and position of the filter wheel in the apparatus are controlled from an adjacent room where the recording facilities are also located.

When emission from a sample is low (10—10^3 counts/s), a correction is made by subtracting the counting rate observed from the oven without the sample. Noise in the associated electronics, small sources of emission in the oven compartment, and cosmic radiation contribute to this background, which is temperature-dependent but rarely exceeds 10^3 counts/s with our particular apparatus.

Battelle-Columbus Laboratories
505 King Avenue, Columbus, Ohio 43201 (USA)

At a given instant, the chemiluminescence from a sample is defined by an intensity and an energy (spectral) distribution. One usually measures these parameters *versus* time, temperature, composition, or other variables. In some cases the quantity of interest is the integrated intensity, *i.e.*, the total chemiluminescence emission, or still more complicated functions of the intensity (see, *e.g.* Section 9).

3. Chemiluminescence for Analysis of Trace Materials

One way that chemiluminescence analysis can be made particularly useful is by modification of a *highly efficient* light-producing reaction so that one reagent is rate limiting. Trace amounts of the reagent then can be determined in samples once the proportionality between chemiluminescence and its concentration has been established. This method has been applied to the determination of trace metals in solution by their catalytic effect on the rate of luminol oxidation[5, 6], and for measurement of the concentration of atmospheric hydrocarbons by their chemiluminescent reaction with oxygen atoms[7], among other examples.

Another approach along these lines involves the use of coupled enzymatic reactions to produce light. In one such example, low concentrations of lactic dehydrogenase (LDH) can be measured from the chemiluminescence emitted from the following reaction sequence[8]:

$$CH_3CH(OH)COOH + NAD \xrightarrow{LDH} NADH + CH_3COCOOH \quad (1)$$

$$O_2 + NADH + FMN + RCHO \xrightarrow{Luciferase} FMNH + RCOOH + NAD + Light \quad (2)$$

There are a number of ways in which such sequential reactions have been carried out. For detection of a small amount of substrate (here lactic acid), for instance, the sample may be passed through a column containing bound enzyme, and converted entirely into products [eq. (1)] that subsequently undergo reaction according to eq. (2) with luminescence.

Another variation of this method involves the use of classes of enzymes which oxidize substrates with concomitant formation of hydrogen peroxide. The latter can be detected, *e.g.*, by its chemiluminescent reaction with oxalate esters [eqs. (3) and (4)]. (Fl. is a fluorescing compound.)

$$Glucose + O_2 \xrightarrow{Glucose\ oxidase} \longrightarrow H_2O_2 \quad (3)$$

$$H_2O_2 + ROCOCOOR \longrightarrow \xrightarrow{Fl.} 2\ ROH + 2\ CO_2 + Light \quad (4)$$

Two reviews of the rather extensive analytical applications of these types of reactions are available[9].

4. Chemiluminescence from Autoxidation

A very different approach to the utilization of chemiluminescence takes advantage of the weak light emission that accompanies the autoxidation of organic materials. The autoxidation sequence is presented in Scheme 1 (eqs. (5) to (12)] in a somewhat simplified form that neglects β-scission of alkoxy groups, induced decomposition, cage recombination of radicals, and the relatively slow terminations involving tertiary peroxy radicals. The species P* is a ketone in an excited singlet or triplet state. We assume activity coefficients of unity for all species.

From the kinetic evidence and on thermodynamic grounds, it is believed that the electronic excitation occurs in the termination step [eq. (9)] which produces a small proportion of excited states [eq. (10)]. In most simple hydrocarbons and derivatives, one photon is emitted per 10^8 to 10^{10} terminations[10]. This inefficiency arises in part because the excited ketones P* are usually quenched by oxygen and other solutes before they can emit.

$$\left.\begin{array}{l} \text{a) ROOR} \\ \text{or b) ROOH + Catalyst} \\ \text{or c) RH + } [O_2]_{const.} \end{array}\right\} \xrightarrow{2\ R'H} 2\ R'^{\bullet} \quad (5)$$

$$\text{or } 2\ ROOH \longrightarrow RO^{\bullet} + RO_2^{\bullet} + H_2O \xrightarrow{2\ R'H} 2\ R'^{\bullet} \quad (6)$$

$$R'^{\bullet} + O_2 \longrightarrow R'O_2^{\bullet} \quad (7)$$

$$\left.\begin{array}{l} R'O_2^{\bullet} + R'H \longrightarrow R'^{\bullet} + ROOH \\ \text{or } R'O_2 + R'H \longrightarrow\longrightarrow ROOR + R'^{\bullet} \end{array}\right\} \quad (8)$$

$$2\ R'O_2^{\bullet} \longrightarrow R'OH + R''_2C{=}O + O_2 \quad (9)$$

$$2\ R'O_2^{\bullet} \longrightarrow P^* \quad (10)$$

$$P^* + Q \longrightarrow P + Q \quad (11)$$

$$P^* \longrightarrow P + h\nu \quad (12)$$

Scheme 1. R = alkyl site on polymer chain, lipid, hydrocarbon, *etc.*; R'H = olefin; P* = electronically excited state of ketone; Q = quenching species, *e.g.* oxygen.

The detectable chemiluminescence is reduced further by self-absorption in opaque materials, and by a geometrical factor $f_{geom} = A/4\pi r^2$, where r is the distance from the sample to the photomultiplier, and A is the effective area of the sensing head. For $r = 20$ cm and $A = 4$ cm^2, for instance, $f_{geom} \approx 10^{-3}$. These factors do not present a particular handicap in most measurements, since photomultipliers are available which respond even to single photon events. A modest counting rate of $1000\,s^{-1}$ from a sample, for instance, corresponds to about 10^{12} terminations per second, or to an initiation rate of 10^{-11} mol/s.

The mathematical treatment of the set of reaction in Scheme 1 is rather complicated, although a number of equations have been derived based on certain initial conditions. At temperatures below about 50°C, for instance, the oxidation of most materials is sufficiently slow that the concentrations of all species remain essentially constant during times adequate to measure the chemiluminescence emission. In this low-temperature case,

$$v_{init} = k_{init}[Initiator] = v_{term} \approx \text{constant} \quad (13)$$

For initiation according to (5)

$$d(h\nu)/dt = k_{12}[P^*] = \frac{k_{10}k_{12}k_{init}[Initiator]}{k_9(k_{12} + k_{11}[Q])} \quad (14)$$

Usually $k_{11}[Q] \gg k_{12}$, so that

$$d(h\nu)/dt = \frac{k_{10}k_{12}k_{init}}{k_9k_{11}[Q]}[Initiator] \quad (15)$$

The activation energy for chemiluminescence is then

$$E_I \approx E_{10} + E_{12} + E_{init} - E_9 - E_{11} \tag{16}$$

If $E_9 \approx E_{10}$, then $E_I \approx E_{init}$, since the other terms are usually small. The quantum yield, Φ_{CL}, per radical chain is

$$\Phi_{CL} = \frac{d(h\nu)}{d[\text{Initiator}]} = \frac{k_{10}k_{12}}{k_9(k_{12}+k_{11}[Q])} \tag{17}$$

For a bimolecular mode of initiation according to eq. (6), the expression corresponding to eq. (15) is

$$d(h\nu)/dt = \frac{k_{10}k_{12}k_6[\text{ROOH}]^2}{k_9(k_{12}+k_{11}[Q])}, \tag{18}$$

$$\text{with } E_I \approx E_{10} + E_{12} + E_6 - E_9 - E_{11} \approx E_6 \tag{19}$$

Another set of equations can be derived to predict the chemiluminescence from a sample during the *autocatalytic period* of oxidation when the rates of oxygen uptake and light emission both increase rapidly. If the initiation is first-order or pseudo-first order, the doubling time for the chemiluminescence intensity is given by eq. (20):

$$t_{1/n} - t_{1/2n} = \frac{2}{k_{init}} \ln \frac{n^{1/2} - (1/2)^{1/2}}{n^{1/2} - 1} \qquad (n > 1) \tag{20}$$

where $t_{1/n}$ refers to the time required to reach $1/n$ of maximum chemiluminescence (I_{max}) in the sample. In this derivation the maximum chemiluminescence is assumed to correspond to a chain length of unity.

At low degrees of conversion (large n), the doubling time for the unimolecular case approaches zero.

If the autocatalytic buildup occurs with bimolecular initiation [eq. (2)], the doubling time for the chemiluminescence is given by a more complicated function:

$$t_{1/n} - t_{1/2n} = \left(\frac{k_9}{k_6}\right)^{1/2} \frac{1}{k_8[\text{R'H}]} \left[\ln \frac{n^{1/2} - (1/2)^{1/2}}{n^{1/2} - 1} + 1/2 \ln 2\right] \tag{21}$$

At very low conversions the doubling time from eq. (21) is predicted to become independent of n and approach a constant value of $0.347\, k_9^{1/2}/(k_6^{1/2} k_8[\text{R'H}])$.

A third set of equations apply when a steady-state rate of oxidation has been achieved, the radical chain length is unity, and a *limiting rate* of oxygen uptake obtains[11]. Under these conditions

$$2k_8[\text{R'O}_2^\cdot][\text{R'H}] = k_{init}[\text{Initiator}] \text{ (unimolecular)} \tag{22}$$

$$2k_8[\text{R'O}_2^\cdot][\text{R'H}] = k_6[\text{ROOH}]^2 \text{ (bimolecular)} \tag{23}$$

$$\text{and } I_{max} = \frac{k_8^2 k_{10} k_{12}[\text{R'H}]^2}{k_9(k_{12}+k_{11}[Q])} \text{ (unimolecular)} \tag{24}$$

In the bimolecular case, eq. (24) applies with an additional factor of four. The activation energy $E_{I_{max}}$ obtained from an Arrhenius plot of I_{max} is represented as follows:

$$E_{I_{max}} \approx 2E_8 + E_{10} + E_{12} - E_{11} - 2E_9 \approx 2E_8 - E_9 \tag{25}$$

The basic form of these expressions is not altered by the presence of fluorescers that may accept energy from P*, (within limits) by specifying the precise origin or fate of P*, or (within limits) by inclusion of mechanistic details described above. The general mechanism for the autoxidation sequence shown is widely accepted[4, 11, 12], although the nature(s) of the individual species clearly will depend on the substrate and individual rate constants will be influenced by medium effects.

In many materials, particularly in fabricated mixtures, a substantial effort would be required to elucidate the detailed steps of the autoxidation and chemiluminescence emission, even in simple systems. We emphasize, therefore, that there is rarely any rigorous justification for applying these equations in any given case, and the examples presented here are simply an attempt to treat the subject from a basis beyond mere empiricism. As progress is made in understanding both autoxidation and chemiluminescence, our approach may become more sophisticated. At the same time, the reader should not be intimidated by this mathematical format into abandoning an empirical approach in the application of this technique, which is often quite fruitful.

5. Oxidation of Simple Hydrocarbons

Lundeen and *Livingston*[13], as well as *Nathan* and *Mendenhall*[14, 15] have applied some of the above equations to the chemiluminescence arising from hydrocarbon oxidation. The light emission from tetralin containing 9,10-diphenylanthracene, for instance, rose from zero at the beginning of an oxidation to a constant rate, at which point the rate of O_2

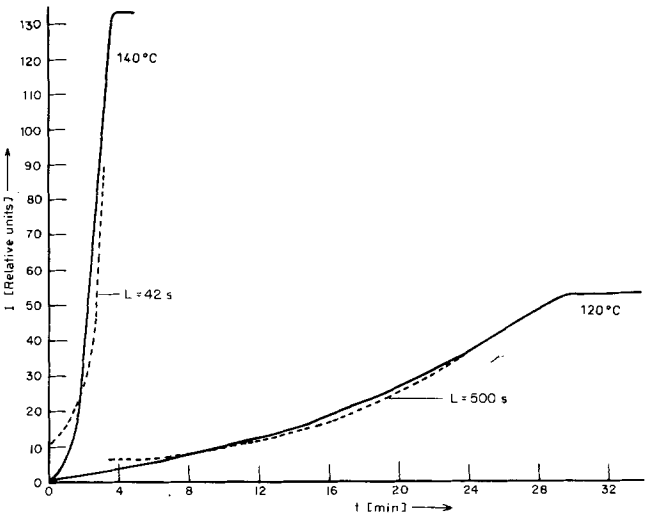

Fig. 2. Chemiluminescence from autoxidation of tetralin in the presence of 10^{-3} mol/l of 9,10-diphenylanthracene. (——) experimental curve, (– – –) curve calculated according to eq. (21).

uptake was also approximately constant (Fig. 2). Treatment of the data[15] according to eqs. (20) and (21) gave plots shown in Figure 3. The quantity L is defined as follows:

$$L \equiv (t_{1/n} - t_{1/2n}) \left[\ln \frac{n^{1/2} - (1/2)^{1/2}}{n^{1/2} - 1} + 1/2 \ln 2\right]^{-1} \tag{26}$$

There is excellent agreement of the data with the equations based on bimolecular initiation [eq. (21)], although studies of this system by other workers indicate that the oxidation

products include phenolic inhibitors[16], and that the maximum rate of oxygen absorption is far less than that predicted from other experimental evidence[17]. Even if the system is considerably more complicated than suggested by our reaction scheme, the shape of the chemiluminescence *versus* time plot at a given temperature can be described quite well over a limited range by a single parameter (Fig. 2).

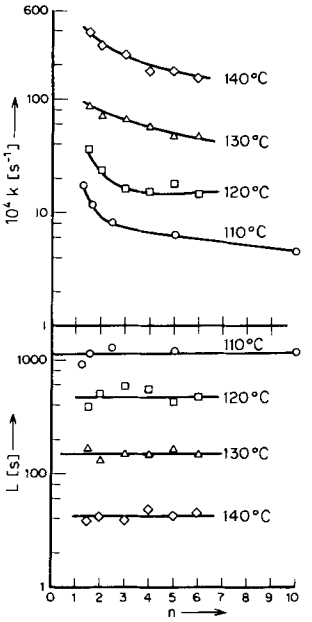

Fig. 3. Test for molecularity of the initiation step in the autoxidation of tetralin according to eqs. (20) and (21). L is defined by eq. (26).

For tetralin $E_{I_{max}}$ [eq. (24)] has been measured as 20.8[13] and 22.7[14] kcal/mol. These values are reasonable, since under these conditions $E_{I_{max}} \approx 2E_8 - E_9$, and from other studies[18, 19] $E_8 \approx 12$ kcal/mol and $E_9 \approx 3$ kcal/mol. The chemiluminescence from films of purified *cis*-1,4-polyisoprene and related elastomers in oxygen has also been studied in these laboratories[20]. In the initial stages eq. (21) describes the chemiluminescence from polyisoprene fairly well, although a plot of $f(\lambda)$ values,

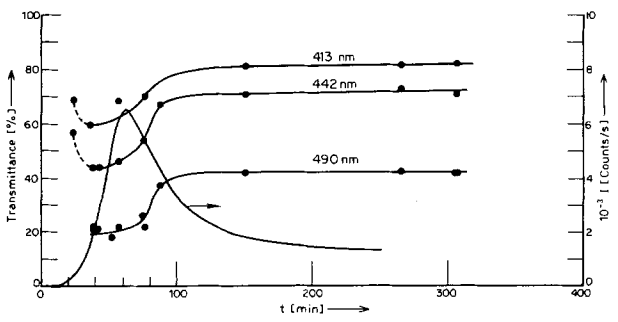

Fig. 4. Chemiluminescence (right-hand ordinate) and $f(\lambda)$ values (left-hand ordinate) from *cis*-1,4-polyisopropene in oxygen at 116°C. The $f(\lambda)$ values were determined by measuring the chemiluminescence after passage through filters which were opaque to light of shorter wavelengths than those given.

the fractions of chemiluminescence transmitted through a filter eliminating wavelengths shorter than λ, show that the nature of the emitting state changes as oxidation proceeds (Fig. 4).

At elevated temperatures the oxidation of a number of straight-chain hydrocarbons shows nonlinear behavior in a plot of I_{max} *versus* $1/T$ (*e.g.* Fig. 5). This result indicates a

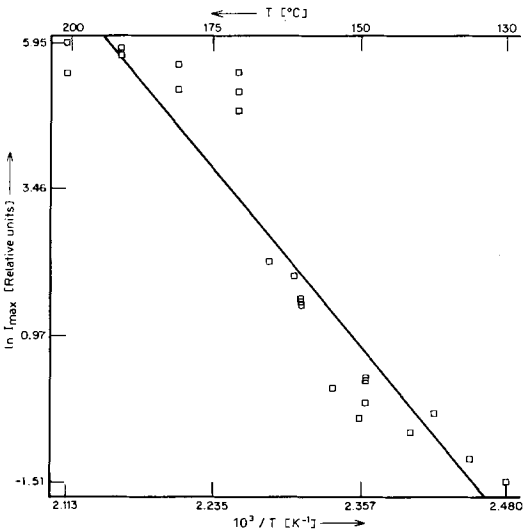

Fig. 5. Arrhenius plot of maximum chemiluminescence on autoxidation of *n*-dodecane containing 10^{-3} mol/l of 9,10-diphenylanthracene in oxygen.

change in the mechanism for producing chemiluminescence at the temperature corresponding to the change in slope, and the experiment was suggested to bear on the validity of accelerated aging tests carried out at high temperatures with hydrocarbons such as jet fuels[14].

6. Chemiluminescence Studies of Complicated Materials

Most nonmetallic materials that are of practical significance do not have a simple composition. The chemiluminescent behavior of such materials, on the other hand, often is surprisingly simple and a sensitive indicator of subtle changes in the samples.

At moderate temperatures up to 45°C two samples of a well-known breakfast cereal gave fairly linear Arrhenius plots

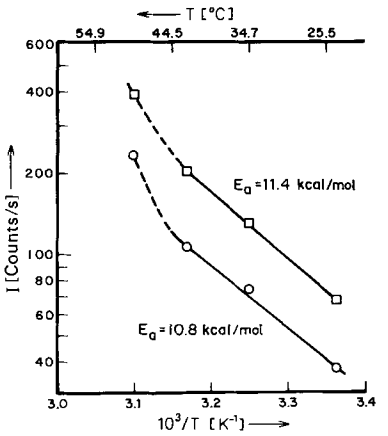

Fig. 6. Arrhenius plot of chemiluminescence from samples of two breakfast cereals in oxygen. □, laboratory cereal; ○, plant cereal; E_a activation energy.

of chemiluminescence emission up to about 45°C, but measurements at a higher temperature gave values that did not fall on the line determined by the other three points (Fig. 6).

Although the result is complicated by an enhanced chemiluminescence from the effects of room lights, the shape of the plot is consistent with the manufacturer's experience that accelerated aging tests carried out above 45 °C did not give valid results. The lab-prepared cereal was known also to be much less stable than the plant product. All other factors being equal, one expects a faster rate of initiation to produce a proportionately higher chemiluminescence intensity [eq. (19)].

On the other hand, linear activation energies have been found for chemiluminescence emission from most commercial polymers in oxygen between 25 and 100 °C or higher. Whether this result validates accelerated aging tests on these materials remains to be seen.

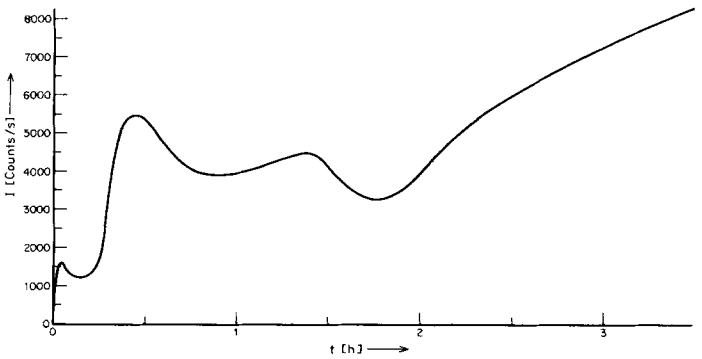

Fig. 7. Chemiluminescence from edible oil sample at 118 °C in oxygen.

Many materials do show complicated chemiluminescent behavior that cannot be related to the limiting cases for which we have semiempirical equations. One such example, which is typical of edible oils, is shown in Figure 7. The curve is interesting, although the oscillatory behavior may result from a number of possible changes in the material, whose nature might be elucidated only with other techniques. Complicated curves such as these are useful, however, for assessing uniformity among samples of material because the time *versus* intensity plots are highly reproducible. In one study at Battelle, for instance, we received two allegedly identical samples of an uncured potting compound. The products made from the two compounds did not show similar long-term stability, however, and this difference apparently was reflected in the markedly different chemiluminescence spectra (Fig. 8). The problem was later traced to a deficiency of one component in the material which showed less chemiluminescence.

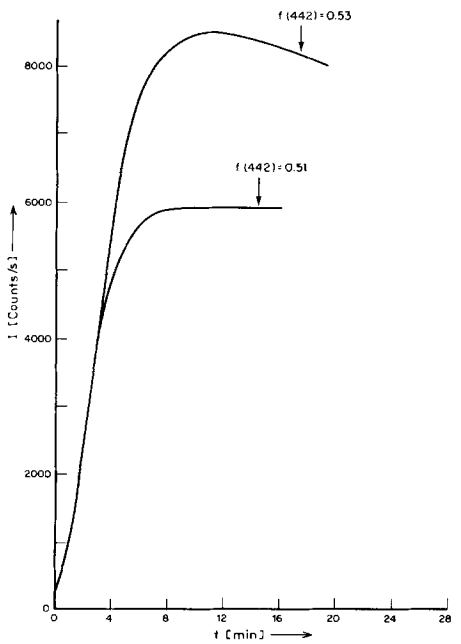

Fig. 8. Chemiluminescence from two potting compound samples at 80 °C in oxygen.

Simplified chemiluminescence spectra can be obtained by measuring the emission in an inert atmosphere. Under these circumstances the light probably results from preformed peroxides and hydroperoxides, whose decomposition gives radicals which can terminate to give excited states in the same way as they do in the presence of oxygen. Chemiluminescence from an edible oil under argon at 155 °C is shown in Figure 9, along with the enhancement brought about by addition of 9,10-diphenylanthracene. Such a procedure can detect peroxidic materials below the limits of conventional methods for their measurement.

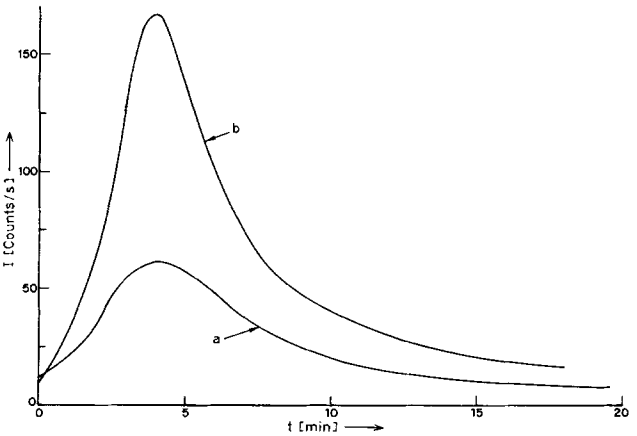

Fig. 9. Chemiluminescence from edible oil under argon at 155 °C. The oil had been aged for five weeks in air. a) pure oil; b) with addition of 0.6 mg of 9,10-diphenylanthracene/ml.

Another method of extracting useful information about a sample is to calibrate the chemiluminescence by dispersing in it a measured amount of free-radical initiator. The enhancement of the chemiluminescence is predicted to be proportional to the added initiator according to eq. (27), where v_0 is the initiation rate in the pure material. Preliminary results with a small sample of an edible oil were encouraging (Fig. 10), although the conditions of the experiment were not optimal.

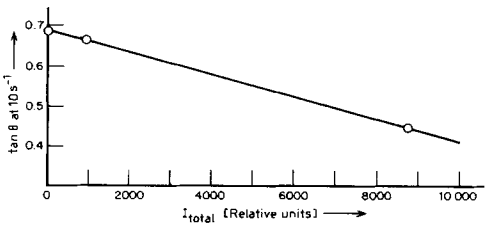

Fig. 10. The added-initiator technique. Example: addition of azoisobutyronitrile (AIBN) to edible oil at 55 °C.

$$\frac{d(h\nu)}{dt} = \frac{k_{10}k_{12}}{k_9(k_{12}+k_{11}[Q])}[v_0 + k_{init}[Initiator]] \quad (27)$$

In some cases we have used chemiluminescence techniques to measure changes in a material that are brought about by nonoxidative reactions. In Figure 11 emission curves are

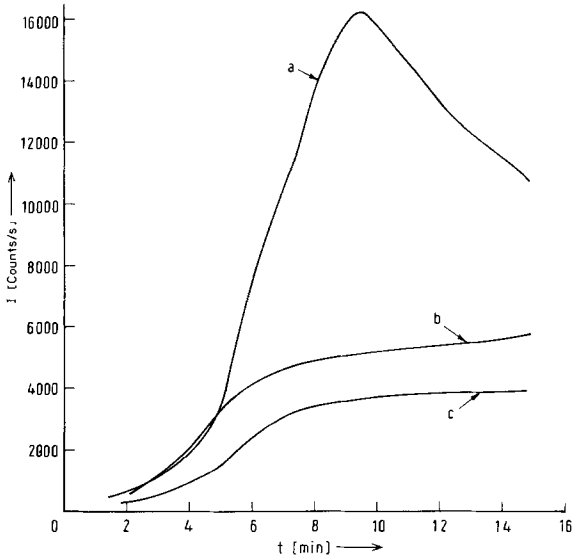

Fig. 11. Effect of curing time on chemiluminescence from an epoxy coating on steel. The samples were examined in an oxygen atmosphere at 200 °C. a) undercured (2.5 min at 246 °C); cured normally (5 min at 246 °C); overcured (10 min at 274 °C).

given for samples of steel bearing a protective epoxy coating that has been cured at high temperature for different times in each sample. A much smaller total emission was observed in properly cured material, although the curing reactions are almost certainly ionic in nature. In a related study of photoinduced degradation, we found that samples of polyethylene pipe showed twice as much chemiluminescence from the outer surface after outdoor exposure of the pipe for several months. Both inner and outer surfaces of unweathered pipe gave identical results under these conditions.

7. Effect of Antioxidants

In an early classic paper on polymers, *Ashby*[21] pointed out the progressive decrease of chemiluminescence from polypropylene with increasing antioxidant concentrations. Figure 12 reproduces the results from his study of synergism between two antioxidants. We and others have repeated *Ashby*'s experiment with other systems; however, the shape of the chemiluminescence *versus* time curves have been found to depend on the particular polymer-antioxidant combination. In preliminary experiments we have shown results similar to those in Figure 12 with antioxidant-edible oil combinations.

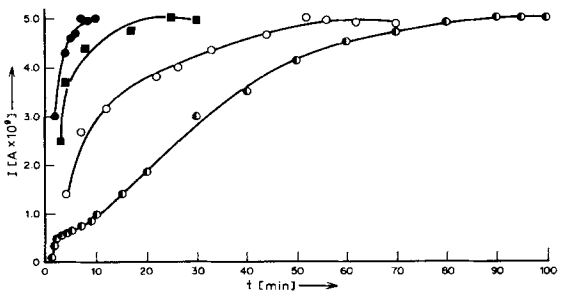

Fig. 12. Illustration of synergistic effects of antioxidants in polypropylene (Hercules 6501) at 143 °C by chemiluminescence emission (from *Ashby* [21]). ●, without antioxidant; ■, with dilauryl-3,3'-thiodipropionate (0.01 %); ○, with 6,6'-di-*tert*-butyl-4,4'-thiodi(*o*-cresol) (0.01 %); ◐, with dilauryl-3,3'-thiodipropionate (0.01 %) plus 6,6'-di-*tert*-butyl-4,4'-thiodi(*o*-cresol) (0.01 %). Reprinted with permission of the author and publisher.

In general terms, the reduced emission in the presence of antioxidants can result principally from: 1) quenching of the excited states (P*); 2) alternate termination pathways involving the antioxidant that compete with formation of P*; and 3) reduction of the number and length of free-radical chains through destruction of initiators and peroxy radicals, which then prevents autocatalysis. A number of techniques for determining inhibitor efficiencies in fluid solutions have been described[4f].

8. Mechanically and Photochemically Induced Chemiluminescence

It is well known among polymer chemists that mechanical damage to rubbers and other materials results in bond scission and free-radical reactions. We were not surprised to find that increased chemiluminescence from many polymers results from abrading or beating them, or from milling. *Grabec*[22] recently reported emission of light on stretching of a sample of a polymer, although the phenomenon was ascribed to triboluminescence rather than to oxidation reactions.

During our studies we noticed that room lights caused an enhanced luminescence emission from edible oils, cereals, and resins, among other materials. The decay of chemilumines-

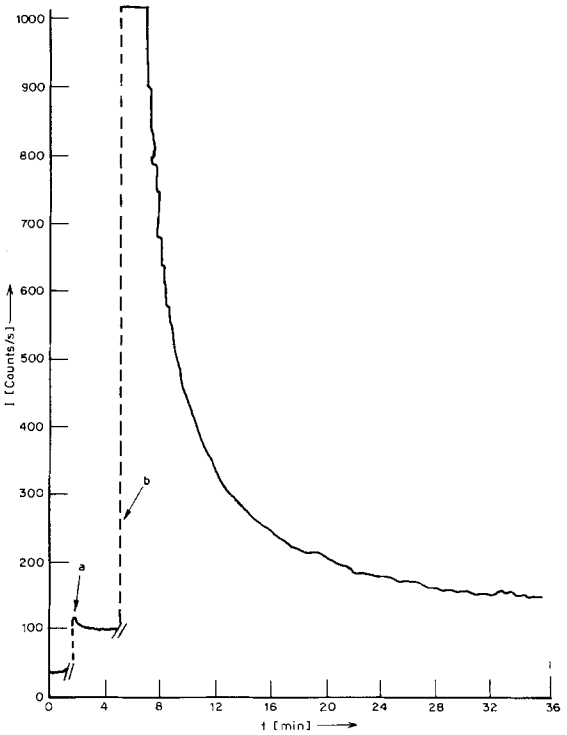

Fig. 13. Light-induced chemiluminescence from a soda cracker at 25 °C in air. a) sample introduced into apparatus; b) sample irradiated.

cence from a soda cracker is typical and is shown in Figure 13. The cracker was irradiated by means of a photographer's flashbulb immediately before examination. The light probably causes bond scission in some components of the samples and results in a free-radical chain reaction as in Scheme 1. In terms of this scheme, the decay curve for chemiluminescence arising from momentary light or mechanical action is described by eqs. (28) and (29) if the emission falls from an initial (I_0) to a constant value (I_∞) after irradiation[4f]. The final value is assumed to result from residual initiators in the sample. Equation (29) describes curves such as the one in Figure 13 fairly well in the later stages of decay, although in deriving this expression we assumed that the radicals are dispersed homogeneously in the portion of the sample from which we can detect light.

$$\frac{d(RO_2^\bullet)}{dt} = -2k_9(RO_2^\bullet)^2 + 2k_5[\text{Initiator}] \tag{28}$$

$$t = \frac{1}{4k_9k_5[\text{Initiator}]} \ln \frac{(I_\infty^{1/2} + I^{1/2})(I_\infty^{1/2} - I_0^{1/2})}{(I_\infty^{1/2} - I^{1/2})(I_\infty^{1/2} + I_0^{1/2})} \tag{29}$$

9. Correlations of Chemiluminescence with Physical Properties; Service Life Predictions

The importance of methods for determining the useful service life of fabricated materials has increased rapidly in recent years, due partly to the growing numbers and variety of synthetic products on the market. In many cases the new synthetic material or formulation is preferred on economic grounds over the product currently in use, although there is an associated risk on replacement because the behavior of the new product over long periods is not known. A large number of empirical tests have evolved throughout the manufacturing industry to determine long-term properties of new items, and of products made routinely by batch processes. Many of these tests are not entirely satisfactory, even though decisions of enormous economic significance sometimes must be based on their outcome.

One way in which such tests themselves may benefit from chemiluminescence is through Arrhenius plots that can reveal discontinuities between the service and the accelerated aging temperatures. This was known in advance of our study of the breakfast cereal (Figure 6), although our results were obtained more conveniently and in far less time. Uniformity among a collection of samples undergoing an aging test, on the other hand, can be studied by monitoring the chemiluminescence during the test itself. Batch-to-batch differences, including uniformity of product processing (Figures 8 and 11) can be revealed after short observation times in many cases.

A different approach, on the other hand, was adopted in experiments at Battelle with use of chemiluminescence to study degradation of a polyurethane sample. We assumed that a bimolecular mode of initiation [eq. (6)] occurred, that the effective concentration of abstractable hydrogens remained constant in the polymer, and that autoxidation products did not interfere. Rewriting eq. (18), we obtain

$$[\text{ROOH}] = (k_9 I)^{1/2}/(q_1 k_6)^{1/2}, \text{ where } q_1 = k_{10}k_{12}/(k_{12} + k_{11}[Q]) \tag{30}$$

From steady-state relations we can shown that

$$-d[O_2]/dt \equiv v_{O_2} = k_8(k_6/k_9)^{1/2}[\text{ROOH}][R'H] \tag{31}$$

and from (18), (30), and (31) we obtain

$$v_{O_2}/v_{hv} = \frac{k_8(k_9/k_6)^{1/2}[R'H]}{q_1[\text{ROOH}]} = \frac{k_8[R'H]}{q_1^{1/2} I^{1/2}} \tag{32}$$

$$\text{or } v_{O_2} = \frac{k_8[R'H] I^{1/2}}{q_1^{1/2}} = q_2 I^{1/2} \tag{33}$$

For a constant value of I

$$E_a(v_{O_2}/v_{hv}) \approx E_8 - 1/2\, E_{q_1} \tag{34}$$

This equation allows us to correct chemiluminescence data obtained at different temperatures for differences in radical chain length. We estimate $E_8 \approx 12 \pm 1$ kcal/mol and $E_{q_1} \approx 0$ kcal/mol, which give $E_a(v_{O_2}/v_{hv}) \approx 12$ kcal/mol.

Since oxygen uptake was calculated to depend on $I^{1/2}$, we plotted this value as a function of time over several days' accelerated aging at 60°C (Fig. 14). At 40°C, I_0 was 6.5 ± 1 counts/s, and from the chemiluminescence behavior at higher temperatures we inferred that this value was relatively constant for long periods. The area under the 60°C curve (for 7d) in Figure 14 was 39 (relative units). This value corresponds

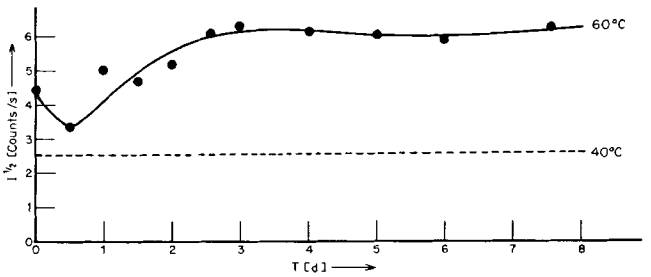

Fig. 14. Chemiluminescence (given as $I^{1/2}$) from a polyurethane sample in air at 40 and 60°C.

to 124 units at 40°C [after correction for the activation energy according to eq. (34)]. An equivalent area under the curve of a plot of $I^{1/2}$ *versus* time is realized at 40°C after

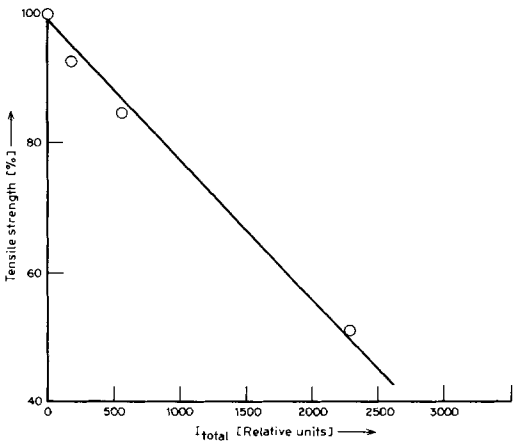

Fig. 15. Demonstration of proportionality between chemiluminescence and tensile strength of Malaysian natural rubber at 125°C. The aging data were kindly provided by *S. C. Teo*. The samples were examined at 70°C after 0, 6, 24, and 48 h at 125°C. I_{total} is total chemiluminescence emission.

$124/(6.5\pm1)^{1.2}=49\pm4$ days. That is, our treatment predicts that the same extent of oxygen uptake occurs in 7 days at 60 °C as in 49 days at 40 °C. We should emphasize, however, that this approach involves a number of assumptions about the oxidation mechanism that remain unproven.

We have carried out preliminary studies also to correlate physical properties of polymers with chemiluminescence emission. The oxidation of many polymeric materials is accompanied by both cross-linking and chain scission. The extent of either is proportional to the number of free-radical chains, and hence to the total chemiluminescence emission from the sample. This approach ignores completely the detailed morphological changes that can be observed by other techniques, but under certain conditions (Figs. 15 and 16) smooth relationships are observed between total chemiluminescence and physical changes in the sample that are probably caused by free-radical reactions.

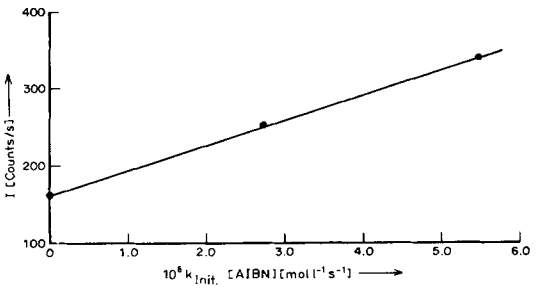

Fig. 16. Correlation between chemiluminescence emission and loss factor ($\tan\delta$) of General Electric Silicone W-96. Points correspond to aging in oxygen at 193 °C for 0, 0.45, and 6 h. I_{total} is total chemiluminescence emission.

10. Summary

The wide versatility of chemiluminescence techniques can readily be seen from the rather limited number of examples we have presented. The instrumentation for chemiluminescence is relatively simple and reliable, highly sensitive, precise over many orders of magnitude, and there is generally no associated art of sample preparation. The technique can be applied with equal success as a sophisticated research tool for mechanistic studies or for quality control of fabricated products in a nondestructive manner.

The application of chemiluminescence to the study of changes in materials (polymer degradation, flavor reversion, *etc.*) is largely a matter of discovering conditions under which the light emission will relate to properties of interest. This discovery is often done in a highly empirical way, aided by reasonable assumptions about the nature and behavior of the material under investigation. In spite of the limitations frequently imposed by a lack of detail about a given sample, the results of chemiluminescence studies of this sort have usually exceeded our expectations.

The Battelle chemiluminescence program has been assisted during the past five years by support from the Battelle Institute Program, the National Aeronautics and Space Administration, the Naval Air Systems Command, and from numerous industrial firms, some of whom gave permission to disclose details of current and past projects. Individuals at Battelle during this time who have made principal contributions in this effort include Dr. Albert H. Adelman, Dr. Gerald W. Lundeen, and Dr. Richard A. Nathan.

New Developments in the Field of Vitamin B_{12}: Enzymatic Reactions Dependent upon Corrins and Coenzyme B_{12}

By G. N. Schrauzer[*]

Simple corrins such as vitamin B_{12} and vitamin B_{12} coenzyme catalyze a variety of unusual enzymatic reactions of which some are still without analogy in organic or organometallic chemistry. The mechanisms of these reactions are currently the subject of lively discussion. The present review focuses attention on new ideas about the mode of action of vitamin B_{12} coenzymes in enzymatic reactions.

1. Introduction

The first article of the present series described some of the more important reactions of the cobalt atom in corrins and in vitamin B_{12} model compounds[1]. In this article we shall discuss corrin-dependent enzymatic reactions with particular emphasis on questions concerning the mechanism of action of corrinoid coenzymes. Details dealing with the biological sources, properties, and isolation of the respective enzymes will not be given, nor will we mention purely medical aspects such as vitamin B_{12} deficiency syndromes, physiological transport mechanisms and the like, as these topics are adequately treated elsewhere[2, 3]. Moreover, the complexity of the corrin-dependent enzymatic reactions necessitated further limitations of coverage, as it turned out to be impossible to discuss all enzymatic reactions in full detail and to include historical developments within the available space. The view can be taken that proposed mechanisms of enzymatic reactions can be considered as valid only after they have been simulated, at least in principle, in suitable model systems under nonenzymatic conditions. Following the discovery of vitamin B_{12} model compounds in our laboratory, we as well as other workers have attempted to elucidate the mechanisms of corrin-dependent enzymatic reactions along these lines. In spite of considerable effort, there is still much controversy and uncertainty concerning the mode of action of corrinoid coenzymes. I believe that this is in part a consequence of insufficient communication between the workers in this highly interdisciplinary field. Moreover, new results of enzymological studies continue to appear in the biochemical literature, which in part necessitate a modification of current mechanistic ideas. It is therefore important to summarize the present status of this intriguing area of research.

1.1. Outline

The known corrin-dependent enzymes may be placed in two major groups. The first group comprises enzymes in which simple corrins, *e.g.* vitamin B_{12} itself, are utilized as cofactors. These are shown in Table 1. Enzymes which require vitamin B_{12} coenzymes such as 5'-deoxyadenosylcobalamin as cofactors fall into the second group (see Table 2). It is therefore reasonable to treat the reactions of the enzymes of the two groups separately.

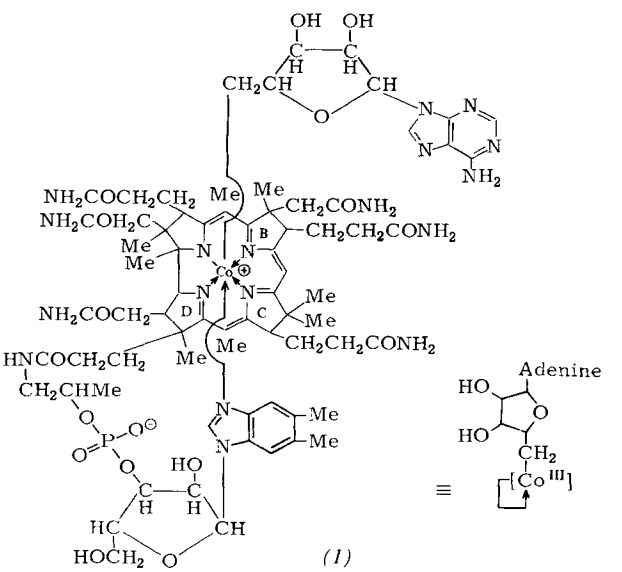

Table 1. Enzymes dependent on simple corrins [4].

Enzyme	Source(s)	Reaction catalyzed [a]	Cofactors
Methane synthetase	*e.g. Methanosarcina barkeri, Methanobacterium M. o. H.*	$C_1 \longrightarrow CH_4$	Reductant (H_2) (ATP, H_2, "coenzyme M")
Methylarsane synthetase	*Methanobacterium M. o. H.*	$C_1 \xrightarrow{+As^{3+}} AsH_{3-n}(CH_3)_n$	ATP, H_2, "coenzyme M" (?)
Acetate synthetase	*Clostridium thermoaceticum*	$C_1 + CO_2 \longrightarrow CH_3CO_2^{\ominus}$	Reductant
Methionine synthetase	*Escherichia coli*	5-CH_3-THFA + Homocysteine $\longrightarrow$ THFA + Methionine	Adenosylmethionine (reducing conditions)

[a] C_1 denotes one-carbon precursors of the methyl group, also including compounds which already possess a reactive methyl group, *e.g.* 5-CH_3-THFA [=5-methyltetrahydrofolic acid, see eq. (k) for formula].

1.2. Nomenclature

We shall use the same abbreviated nomenclature as outlined in Ref. [1]. 5'-Deoxyadenosylcobalamin *(1)* (Fig. 1) is simply

(1)

Fig. 1. Structure of coenzyme B_{12} *(1)* [43, 44]. In place of the 5'-deoxyadenosyl group, vitamin B_{12} bears a cyano group at the cobalt atom and vitamin B_{12a} a hydroxyl group.

ATP, pyridoxal phosphate
Ornithine aminomutase	*Clostridium sticklandii*	$\overset{\oplus}{N}H_3\ \overset{\oplus}{N}H_3 \rightleftharpoons \overset{\oplus}{N}H_3\ \overset{\oplus}{N}H_3$ ($CH_2(CH_2)_2\overset{\ominus}{C}HCO_2^{\ominus} \rightleftharpoons CH_3{-}\overset{\oplus}{C}HCH_2\overset{\oplus}{C}HCO_2$)	(I) (II)	*ca.* 60000 160000	none (?)

[a] Two components; protein II binds coenzyme B_{12}.

denoted as "coenzyme B_{12}". All other abbreviations are either readily understood or explained in the text. The typical vitamin B_{12} model compounds are called cobaloximes.

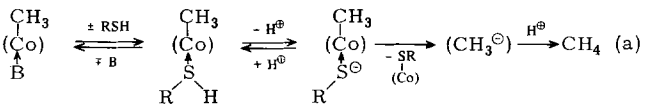
2. Enzymatic Reactions Dependent on Simple Corrins

The enzymes listed in Table 1 occur in the presence of simple corrins such as *e.g.* vitamin B_{12a} (hydroxocobalamin). Certain methane-producing bacteria utilize corrin derivatives in which bases other than 5,6-dimethylbenzimidazole are present in the molecule, *e.g.* "Factor III", which contains 5-hydroxybenzimidazole, or corrins in which no axial base is present, *e.g.* "Factor B" (cobinamide)[5]. The formation of methylarsanes presumably does not require an independent enzyme and may be considered as a by-product of methanogenesis in the presence of added arsenic.

2.1. Methane Biosynthesis

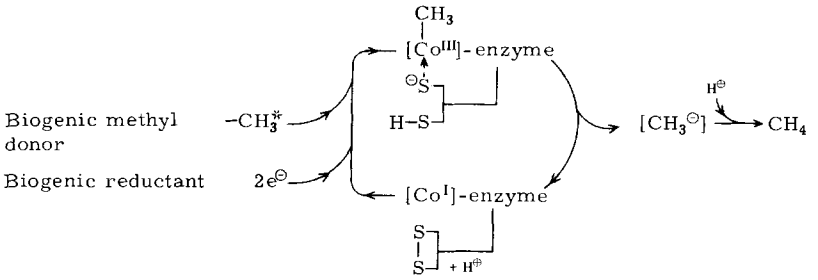
A number of bacterial species produce methane as the terminal product of the metabolism of cellulose, sugars, fatty acids, alcohols, formaldehyde, serine, but also from CO_2. These organisms are as a rule difficult to cultivate. Among the best-known are *Methanosarcina barkeri* and *Methanobacterium M. o. H.* Other methane-producing bacteria that may be mentioned in this context are those of the genus *Methanococcus* as well as *Methanobacterium ruminantium*, *Methanospirillium*, and *Methanobacterium formicium*. To illustrate the difficulties of isolation and cultivation of some of these organisms we quote the example of *Methanococcus vanneillii*, which was isolated from San Francisco Bay sludge but subsequently became lost. A deep-frozen tube of cells, stored for over 12 years was still available, however, from which *Stadtman* was able to obtain viable cells for renewed cultivation[5].

Considerable amounts of methane are produced from sewage sludge, a source of combustible gas that could in future become commercially interesting. Prior to World-War II, 2×10^6 cubic meters of methane were collected per year in the disposal plant of Stuttgart, Germany. This amount was sufficient to provide fuel for 110 municipal motor vehicles[6]. Methane is also formed in the rumen of cows and other animals. A fully grown cow may generate as much as 200 liters of methane per day[5]. This is considered to be an undesirable side-reaction during the digestive process as it lowers the feed-efficiency. Methane is produced in the human intestine too, in amounts which depend on the type and quantity of food ingested.



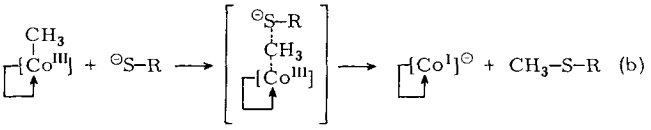
2.2. Methane-Biosynthesis *in Vitro*

Methane bacteria can be cultivated in media containing ammonia as the source of nitrogen; B-vitamins as well as rumen fluid are added to promote growth. CO_2, methanol, ethanol, formate, or acetate can be employed as sources of C_1, while hydrogen is commonly used as the reducing agent. The pure methane synthetases have not yet been isolated; they appear to be extremely sensitive, and most of the available information on methanogenesis *in vitro* was obtained from experiments with intact cells or cell-free extracts[5]. A variety of compounds contain reactive methyl groups or precursors of the methyl group for methane production. These include: serine, pyruvate, 5-methyltetrahydrofolic acid (5-CH_3-THFA), 5,10-methylene-tetrahydrofolic acid, methylcobalamin, other co-methylated corrins and even methyl-derivatives of vitamin B_{12} model compounds[7]. Extracts from *Methanobacterium M. o. H.* require catalytic amounts of ATP for methane production. Additional cofactors are presumably also necessary; most interestingly, 2-mercaptoethylsulfonate, $HS{-}CH_2CH_2SO_3^-$, has been found to be one such factor. This compound was shown by *Wolfe et al.*[8] to possess the properties of a coenzyme and was for this reason named "coenzyme M". In the absence of ATP, this compound is *S*-methylated by methylcobalamin; the product is reductively demethylated by a different enzyme

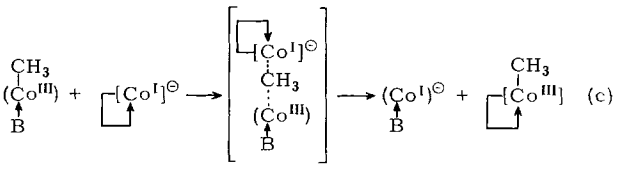


to yield methane. The reductive demethylation, which regenerates coenzyme M, is inhibited by tripolyphosphate[8]. It is not yet known if methane is formed exclusively *via* methylated coenzyme M or whether the *S*-methylation-demethylation is not a side-reaction. On the other hand, there can be no doubt that methylated corrins are formed in the terminal stages of methanogenesis. A corrin-containing protein present in cell-extracts of *Methanobacterium omelianskii*, which is actually a symbiotic association of *Methanobacterium M. o. H.* with a hydrogen-producing organism[9], can be converted into a propylated derivative on reaction with propyl iodide. This causes inhibition of methane formation, but exposure of the protein to light restores activity. It thus may be assumed that the enzyme-bound corrin is converted into the *n*-propyl-derivative and that the Co—C bond in the latter is cleaved on irradiation with light. Methanogenesis is also inhibited by a variety of halogenated hydrocarbons, including freon and DDT[10–12]. Chloromethylcobalamins act as competitive inhibitors of methane formation. How methane is produced from the methylated corrin cofactor does not follow clearly from any of these experiments. It was assumed for some time that the reaction occurs *via* free methyl radicals[13], but such a mechanism must now be considered as unlikely.

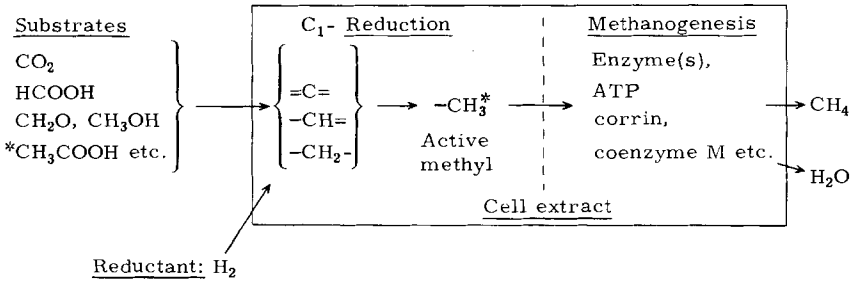
2.3. Mechanism of Methane Synthesis



Scheme 1 surveys the most important reactions which occur in cell extracts of methane-producing bacteria. A fully satisfying mechanism of methanogenesis cannot be formulated on the basis of the available enzymological evidence. We considered the possibility that methane is formed from the methylated corrin through the reductive cleavage of the Co—C bond[14]. This reaction occurs readily under nonenzymatic conditions; thiols and dithiols are some of the reductants that can be used for this purpose (see [1]). The reaction occurs as shown in eq. (a), it thus involves an axial attack of cobalt by the thiol:



A mechanism of enzymatic methane production was formulated along these lines and is schematically represented in Scheme 2[14]. At the time of this proposal, little was known about coenzyme M. Since coenzyme M is a thiol, we expected it to react with methylcobalamin according to eq. (a). This has since been confirmed[15], but we cannot say, of course, whether coenzyme M reacts in this manner under enzymatic conditions as well.



Scheme 2. Proposed mechanism of methane biosynthesis.

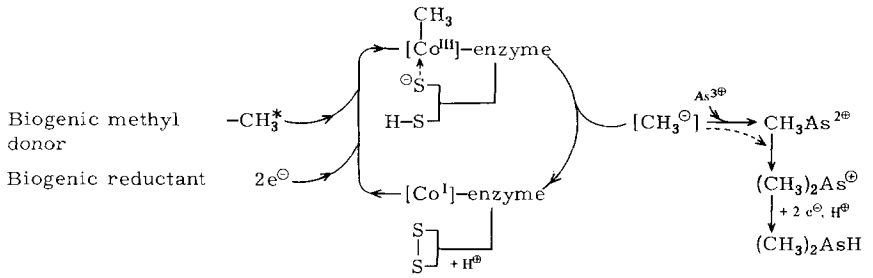
The *S*-methylation of coenzyme M, which has been observed under enzymatic conditions, can also be formulated, as methylcobalt complexes react with thiolate ions according to eq. (b)[1].

Eq. (b) could thus be considered as an acceptable model of the enzymatic demethylation of methylcobalamin by coenzyme M.

Scheme 1. Enzymatic methane synthesis.

The fact that methylcobaloximes are demethylated to yield methane in functional cell-extracts of *Methanobacterium M. o. H.* is of considerable interest. Methane is produced under these conditions only if catalytic amounts of a corrin and ATP are added[7]. This suggested a mechanism in which the

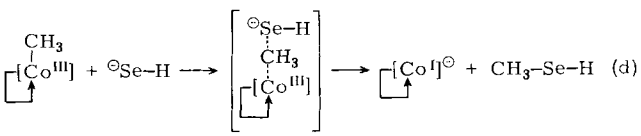
cobaloxime-bound methyl group is first transferred to the corrin cofactor, followed by the actual enzymatic demethylation process. A reversible exchange of methyl groups in terms of eq. (c) occurs readily under nonenzymatic conditions[16].



However, this interpretation leads to mechanistic difficulties. Thus, if a transfer of the methyl group were the main reaction, the rates of methane evolution from different methylcobaloxime substrates should either all be the same or should at least be related to the relative tendency of methylcobaloximes to undergo transfer of the methyl group according to eq. (c). However, this is not the case. It was observed instead that the relative rates of methane production depend on the nature of the axial bases. Other authors suggested that this was mainly due to differences in the solubilities of the different cobaloximes studied[17], *but a more detailed comparison of the solubilities of the model compounds in polar solvents did not reveal any significant correlation with the rates of methane production*[16]. A statistically significant *direct association* ($P=0.05$) between the relative rates of enzymatic methane production and the nonenzymatic reaction according to eq. (a) was observed using experimental data for 13 different compounds. The linear correlation coefficient increases to $r=0.87$ ($P<0.01$), if the calculations are restricted to methylcobalamin and methylcobaloximes (7 data points)[18]. These results suggest that methane may well arise from methylcobalamin after the manner of Scheme 2 and that methylcobaloximes are reductively demethylated under the enzymatic conditions by way of a reaction which occurs with a displacement of the axial base by a biogenic reductant, possibly a thiol or dithiol.

Thus methane biosynthesis is seen to be a relatively complicated process. It at least seems clear why corrins are utilized for such a comparatively simple biochemical reaction: It is now well established that the Co(I) supernucleophiles of vitamin B_{12} (vitamin B_{12s}) are perhaps the most effective scavengers of activated methyl groups in nature. On the other hand, corrin-independent mechanisms of methanogenesis may exist as well, as is suggested by the reductive demethylation of methylated coenzyme M[19], but these processes are not yet understood. Further details of methane biosynthesis will not be discussed, particularly those concerning the reduction of CO_2 to active methyl groups. Such reactions are part of the metabolism of C_1-compounds and are corrin-independent processes.

2.4. Methylarsane Biosynthesis



The addition of arsenate to cell extracts of *Methanobacterium M. o. H.* yields derivatives of methylarsanes, *i.e.* $AsH(CH_3)_2$ and $AsH_2(CH_3)$[20]. The methylation of arsenic was also observed with intact cells of this organism under conditions of methanogenesis. The reaction is inhibited by added selenite. Methylcobalamin acts as the donor of the methyl group[20], and obviously has little if anything in common with the methylation of arsenic by certain fungi, *e.g. Penicillium glaucum.* The corrin-dependent formation of methylarsanes must be closely related with methane biosynthesis, as methane is always formed as well. Methylcobalamin and methylcobaloximes methylate arsenic under the conditions of reductive Co—C bond cleavage[16]. The reaction is inhibited by selenite, but the latter is of course reduced to selenide and ultimately forms methyl selenide. Ethylcobalamin, on the other hand, does not give rise to ethylarsane, under neither enzymatic[20] nor nonenzymatic conditions[16].

With ethylcobaloximes, only traces of ethylarsane are formed[16]. There thus exist plausible model reactions for methylarsane biosynthesis as represented in Scheme 3.

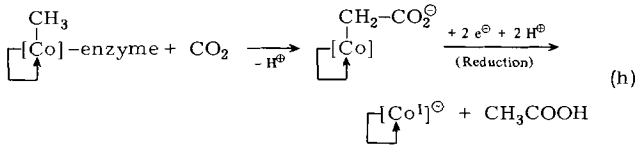
Scheme 3. Postulated mechanism of enzymatic methylarsane synthesis.

The inhibitory effect of selenide on arsenic methylation is attributed to a competition between the methylation of arsenic and a nucleophilic displacement of the cobalt-bound methyl group in terms of eq. (d).

The conversion of arsenic to methylarsanes under conditions of methanogenesis may be regarded as a bacterial detoxification process. The observed *methylation of mercuric ion* should also be mentioned in this context. Hg^{2+} ion reacts with methylcobalamin rapidly to produce $Hg(CH_3)^+$[21–23], a process which may have some toxicological significance[24].

2.5. Acetate Biosynthesis

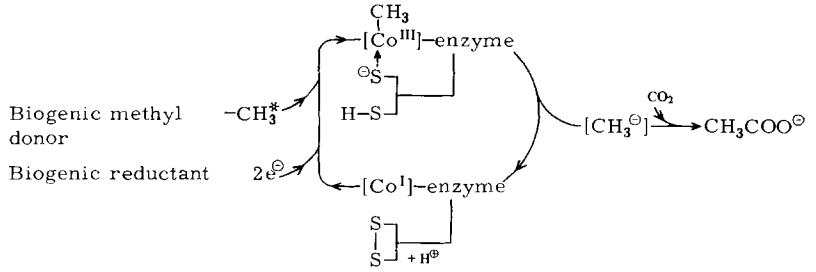
Acetate (or acetic acid) is formed as terminal product of the fermentation of glucose, cellulose, *etc.* by *Clostridium thermoaceticum*[25]. The net reactions which occur are summarized in eqs. (e) to (g)[26].



$$C_6H_{12}O_6 + 2\ H_2O \longrightarrow 2\ CH_3COOH + 2\ CO_2 + 8\ H \quad (e)$$

$$8\ H + 2\ CO_2 \longrightarrow CH_3COOH + 2\ H_2O \quad (f)$$

$$C_6H_{12}O_6 \longrightarrow 3\ CH_3COOH \quad (g)$$

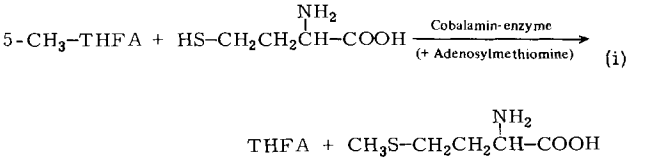


Cell-free extracts of *Cl. thermoaceticum* convert the methyl group of added methylcobalamin to acetate *as a whole, i.e.* the reaction occurs without loss or exchange of hydrogen atoms of the methyl group[27]. This reaction thus represents

a rare example of a bacterial CO_2 assimilation. It occurs under reducing conditions and is inhibited by SH-blocking reagents. The conversion of methylcobalamin to acetate was first assumed to occur as shown in eq. (h)[28].

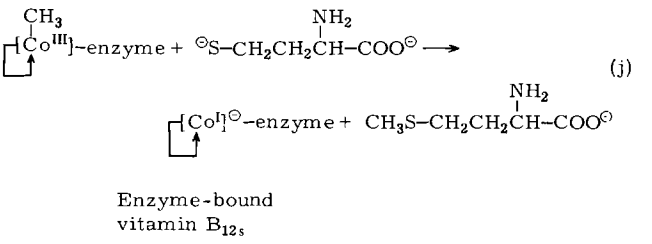
(h)

However, a reaction of this type is unlikely as it assumes the removal of a proton from the cobalt-bound methyl group, in contrast to the observations mentioned above. A methylation of CO_2 by methylcobalamin in analogy to known reactions of Grignard reagent also does not occur, since methylcobalamin or related organocobalt complexes are insufficiently reactive. However, the formation of acetate from methylcobalt complexes was demonstrated under conditions of reductive Co—C bond cleavage. This led to the proposal of acetate biosynthesis shown in Scheme 4[16,29].



Scheme 4. Postulated mechanism of acetate biosynthesis from methylcobalamin.

Hence, acetate biosynthesis, the enzymatic methylation of arsenic, and methanogenesis appear to be closely related reactions. The reaction of CO_2 with CH_3^- must occur in an essentially proton-free enzymic environment, for otherwise methane would be formed preferentially. It would be of interest to examine if *Cl. thermoaceticum* methylates arsenic or produces methane under certain conditions.

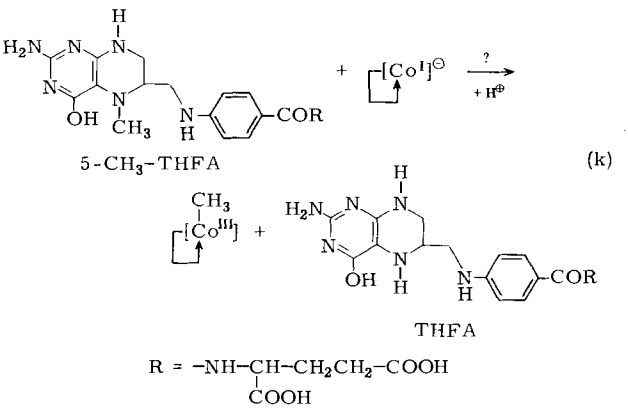


2.6. Methionine Synthesis by *Escherichia coli*

E. coli contains an enzyme which transfers the methyl group from 5-methyltetrahydrofolic acid (5-CH_3-THFA) to homocysteine according to eq. (i)[30–36].

(i)

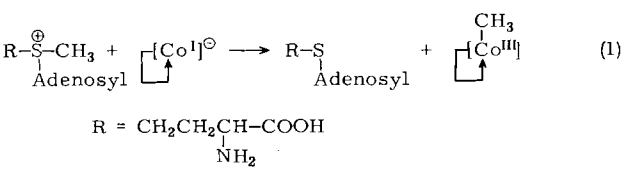
Corrin-dependent methionine synthesis also occurs in animal tissues but not in plants. *S*-Adenosylmethionine (AMe) also appears to be a cofactor and was shown to methylate enzyme-bound vitamin B_{12s} more rapidly than 5-CH_3-THFA. The terminal step of methionine biosynthesis is assumed to occur according to eq. (j), a reaction which has also been simulated under nonenzymatic conditions using methylcobaloxime as the donor of the methyl group.



(j)

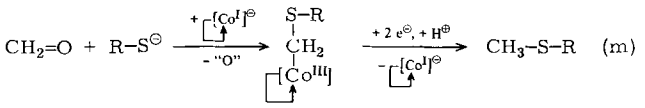
Enzyme-bound vitamin B_{12s}

Alkaline conditions are required for the nonenzymatic synthesis of methionine from methylcobaloxime and homocysteine, since a nucleophilic displacement according to eq. (j) occurs only in the presence of the homocysteinyl dianion. In neutral solution, homocysteine causes reductive cleavage of the Co—C bond [see eqs. (a) and (b)].



On the other hand, attempts to demonstrate the formation of methylcobalamin from 5-CH_3-THFA and vitamin B_{12r} or B_{12s} have thus far not been successful under nonenzymatic conditions [eq. (k)].

It must be assumed that reaction according to eq. (k) can only occur after a specific activation of the 5-CH_3 group,

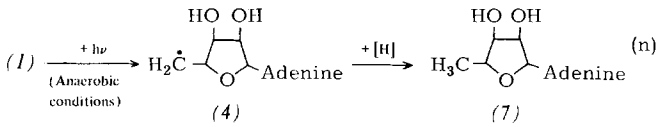


(k)

or that the methylation of the enzyme-bound corrin by 5-CH_3-THFA is an indirect reaction. The question how reaction (k) occurs is one of the unresolved problems in all corrin-dependent methyl group transfer reactions. The role of adenosylmethionine in methionine biosynthesis has also not been fully elucidated, even though reaction (l) occurs nonenzymatically with no difficulty.

(l)

It should be mentioned in passing that thiols are reductively methylated on reaction with formaldehyde in the presence of catalytic amounts of vitamin B_{12s} [eq. (m)][37,38].



(m)

It would be of interest to demonstrate a corrin-dependent enzymatic methylation of homocysteine in analogy to eq. (m), utilizing substrates such as 5,10-methylene-tetrahydrofolic acid, which contains the C_1-unit at the oxidation level of formaldehyde.

3. Coenzyme B_{12}-Dependent Enzymatic Reactions

3.1. Properties and Reactions of Coenzyme B_{12}

At least nine enzymes are presently known in which coenzyme B_{12} is a required cofactor (see Table 2). The structure of the coenzyme (see Fig. 1) does not provide any clue as to how it functions in enzymatic reactions. It is commonly assumed that a cleavage of the Co—C bond occurs if the coenzyme is bound to the apoenzymes, but how this activation takes place is a matter of controversy. Coenzyme B_{12} or 5'-deoxyadenosylcobalamin *(1)* is stable in the solid state and in neutral aqueous solution. An irreversible decomposition into hydroxocobalamin (vitamin B_{12a}), adenine, and D-*erythro*-2,3-dihydroxypent-4-enal *(2)* occurs on reaction with acids[39]. In alkaline solution, the Co—C bond is cleaved by way of an elimination reaction, giving rise to the formation of vitamin B_{12s} and of 4',5'-anhydroadenosine *(3)*[40]. On irradiation, vitamin B_{12r} and the 5'-deoxyadenosyl radical *(4)* are formed, indicating that the Co—C bond is cleaved homolytically. The radical *(4)* terminates under anaerobic conditions to yield the cyclic adenosinoid *(5)*[41]. In the presence of air, *(4)* is oxidized primarily to *(6)*[42]. A reductive cleavage of the Co—C bond on reaction of *(1)* with thiols or dithiols, gives

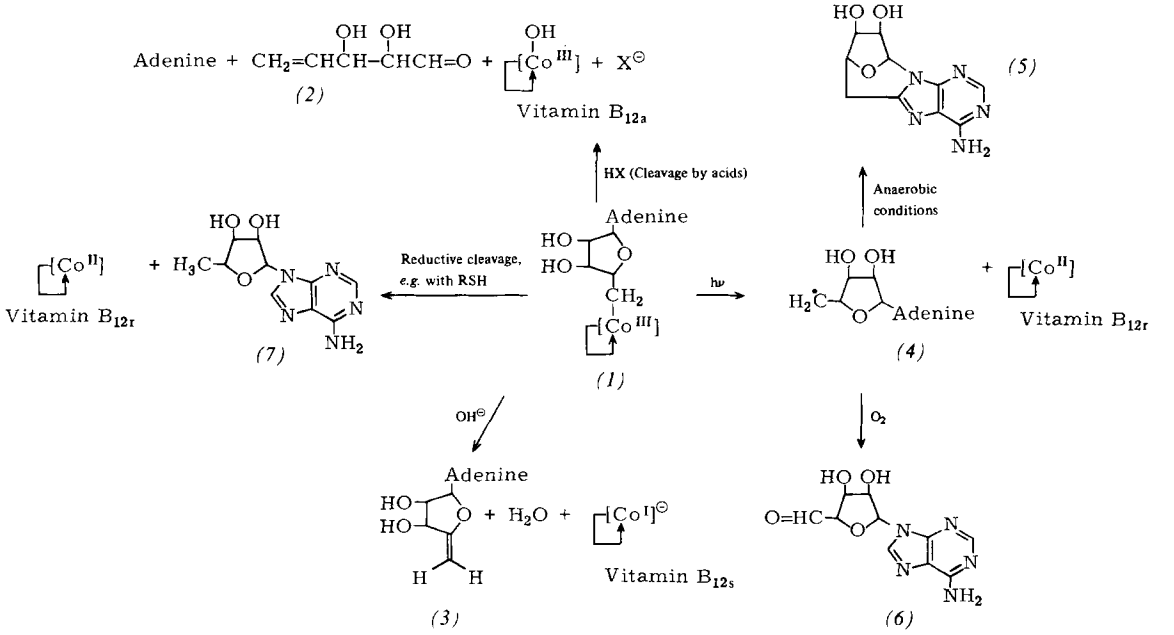
(n)

rise to 5'deoxyadenosine *(7)* (see Scheme 5)[16]. The same compound *(7)* can also be formed from *(4)* in solvents containing labile hydrogen atoms, *e.g.* in alcohols [eq. (n)].

Coenzyme B_{12} is also decomposed by alkaline cyanide. Most Co—C bond cleavage reactions of *(1)* are irreversible, except the recombination of vitamin B_{12r} with *(4)* and, possibly, the base-induced elimination to give vitamin B_{12s} and *(3)*[40].

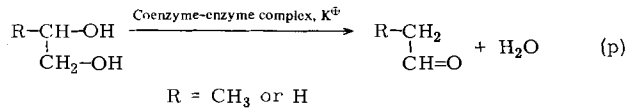
3.2. Coenzyme B_{12} Biosynthesis

Coenzyme B_{12} *(1)* is synthesized by a variety of microorganisms and was first isolated by *Barker et al.* from extracts of *Cl. tetanomorphum*[41,42]. In the terminal step of the biosynthesis of *(1)*, the adenosyl residue from ATP is transferred to the cobalt atom under reducing conditions with attendant formation of tripolyphosphate [eq. (o)][45,46].



(o)

Reaction according to eq. (o) could not yet be verified under nonenzymatic conditions. The enzymatic reaction presumably involves a specific activation of the C—O—P bond of ATP. In laboratory syntheses of *(1)*, vitamin B_{12s} is reacted with 2',3'-protected derivatives of adenosine, usually the tosylates and the protecting groups are subsequently removed under mildly acidic conditions.

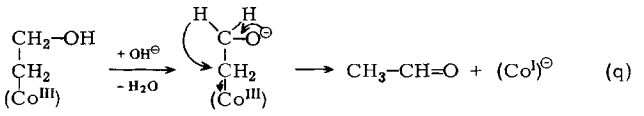


3.3. Dioldehydrases

In cell extracts of *Aerobacter aerogenes* an enzyme was discovered by *Abeles et al.*[47] which catalyzes the conversion

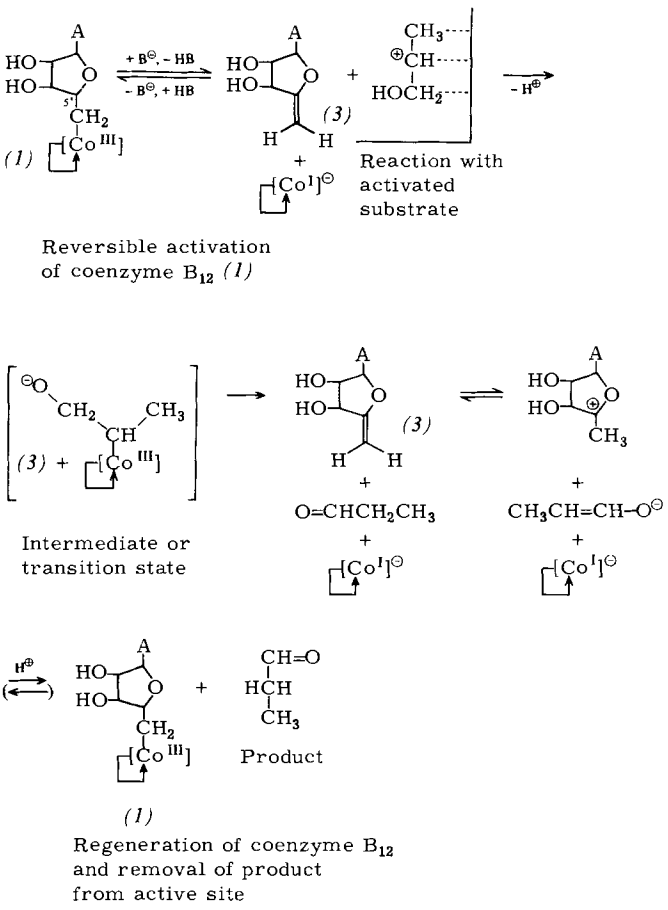
Scheme 5. Reactions of coenzyme B_{12} *(1)* (see also Fig. 1).

of D,L-1,2-propanediol and of ethylene glycol to propionaldehyde and acetaldehyde, respectively [eq. (p)].



(p)

A *Lactobacillus* contains a related enzyme which causes the conversion of glycerol into hydroxypropionaldehyde[48]. This reaction may occur during alcohol fermentation and is undesirable as it gives rise to the formation of acrolein on subsequent distillation. Dioldehydrase from *A. aerogenes* has since been isolated in relatively pure form. The apoenzyme is known to contain thiol groups, some of which are presumably located in the vicinity of the coenzyme binding site. It was observed only a short time ago, however, that the enzyme also converts 1,2-butanediol into butyraldehyde and 2,3-butanediol into 2-butanone, for example[49]; these substrates were previously considered to be inhibitors. The functional holoenzyme is inactivated by oxygen. The relative oxygen-sensitivity depends on the pretreatment of the apoenzyme. If solutions of the apoenzyme are prepared and stored under careful exclusion of oxygen, more highly oxygen-sensitive holoenzyme samples are obtained than when the apoenzyme is dissolved and maintained aerobically. We assume[50] that the apoenzyme can exist in at least two active modifications, which differ from each other in their content of free SH groups. Exposure of the apoenzyme to air seems to cause an oxidation of free SH groups to disulfide, giving rise to the formation of a the less oxygen-sensitive holoenzyme. This view is supported by the fact that the oxidized modification may be in part converted back into the reduced form on reaction with mild reducing agents[50].

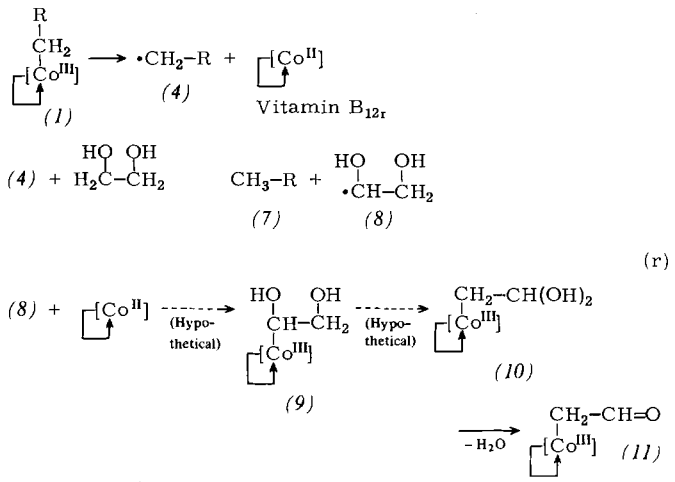


3.3.1. Mechanism of Enzymatic Dehydration of Diols

1,2-Diols can be converted into aldehydes or ketones quite easily on reaction with acids. Thus, phenylglycol is converted to phenylacetaldehyde simply by steam-distillation of a solution of the diol in 12% aqueous H_2SO_4. But what is the mechanism of the coenzyme B_{12}-catalyzed dehydration of glycol to acetaldehyde? β-Hydroxyethylcobaloximes were found to decompose into acetaldehyde and cobaloxime(I) in alkaline solution. This led us 10 years ago to propose that an analogous reaction occurs in the enzymatic dehydration of diols [see eq. (q)][51].

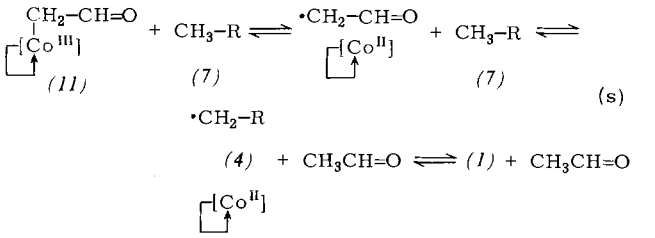
(q)

Since glycols as such do not react with vitamin B_{12s} or cobaloximes(I), the assumption was made that the diol substrates are specifically activated on interaction with the enzyme[29]. We furthermore suggested that enzyme-bound vitamin B_{12s} is generated from coenzyme B_{12} by way of a base-induced elimination. The 4′,5′-anhydroadenosine *(3)* formed during this activation of the coenzyme was assumed to remain in the vicinity of the active site. To explain the demonstrated exchange of substrate protons with the hydrogen atoms at the 5′-position of the coenzyme, we proposed that the product aldehyde exchanges protons with the enzyme-bound *(3)* as shown in Scheme 6. According to this mechanism, the coenzyme-substrate hydrogen exchange is thus considered to be



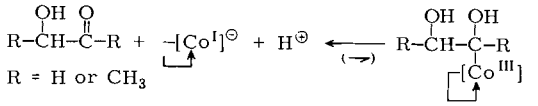
Scheme 6. Suggested mechanism for enzymatic conversion of D,L-1,2-propanediol into propionaldehyde [29].

independent of the actual catalytic conversion of diols to aldehydes and is instead assumed to occur between the 4′-protons of *(3)* and the labile β-protons of the product aldehyde generated at the active site. Such ionic proton-exchange reactions can be readily simulated in model systems[29]. In Section 3.3.2 we shall discuss an alternative mechanistic proposal in which the same processes are formulated *via free radicals.*



The mechanism in Scheme 6 is supported by the fact that the oxygen-sensitive modification of dioldehydrase-holoenzyme is inactivated by N_2O almost as efficiently as by O_2[50]. In the first part of this series, we already pointed out that N_2O is a specific oxidant of vitamin B_{12s}. Thus, the inactivation of the holoenzyme by N_2O demonstrates the presence of enzyme-bound vitamin B_{12s}. We recently also obtained evidence for the presence of *(3)* in the functional holoenzyme[52]. In spite of these observations, the proposed mechanism in Scheme 6 has thus far not been accepted by other workers in the field. It has been argued, that our mechanism does not fully explain the observed hydrogen-isotope exchange effects[53], but these and other objections will not be discussed here in view of more extensive counterarguments presented in Ref. [54]. We still consider the mechanism in Scheme 6 to be correct *in principle*, but since an alternative mechanism has been proposed which is based on different assumptions, we shall discuss this mechanism as well.

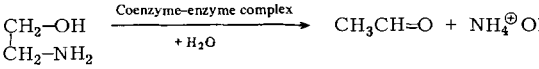
3.3.2. Alternative Mechanism



Abeles and other workers believe that the diol dehydration occurs by way of free radicals[55]. The assumption is made that coenzyme B_{12} *(1)* is converted into the active form by *homolysis* of the Co—C bond. The resulting 5′-deoxyadenosyl radical *(4)* in turn abstracts a hydrogen atom from the glycol substrate and is converted into 5′-deoxyadenosine *(7)*. The glycol radical *(8)* is subsequently assumed to react with vitamin B_{12r} to yield 1,2-di-hydroxyethylcobalamin *(9)*, an intermediate which is postulated to rearrange into the hydrate of formylmethylcobalamin *(10)* or formylmethylcobalamin *(11)*, respectively [eq. (r). The enzyme has been omitted from the formulas].

In the terminal step of the reaction, formylmethylcobalamin *(11)* was suggested to yield acetaldehyde by a reaction involving *homolysis* of the Co—C bond and a hydrogen abstraction reaction between the resulting acetaldehyde radical and a 5′-hydrogen atom of 5′-deoxyadenosine *(7)*. This hypothetical reaction sequence is outlined in eq. (s).

This radical mechanism was assumed in order to explain the observed appearance of ^3H-labeled acetaldehyde in the reaction of unlabeled glycol with the holoenzyme containing ^3H in the 5′-position of the coenzyme[56]. If the view is taken, that this exchange of hydrogen involves the coenzyme and the *substrate* glycol, it would indeed be necessary to consider radical reactions of the type shown in eq. (r) or (s). However, there is in fact evidence that ^3H-exchange reactions also occur between enzyme-bound coenzyme and *product* aldehyde. This would mean that the hydrogen-exchange reactions are reversible even though the glycol dehydration is irreversible. Attempts to verify the hypothetical reactions (r) and (s) met with little success. Model experiments indicated that compounds of type *(9)* are either extremely unstable or incapable of existence; the postulated rearrangement of *(9)* into *(10)* thus could not be demonstrated. Compound *(9)* could be regarded as a "*corrinohydrin*" of glycolaldehyde. However, we have previously shown that the equilibrium in reaction (t) is far on the left side, over a wide pH range[57a].

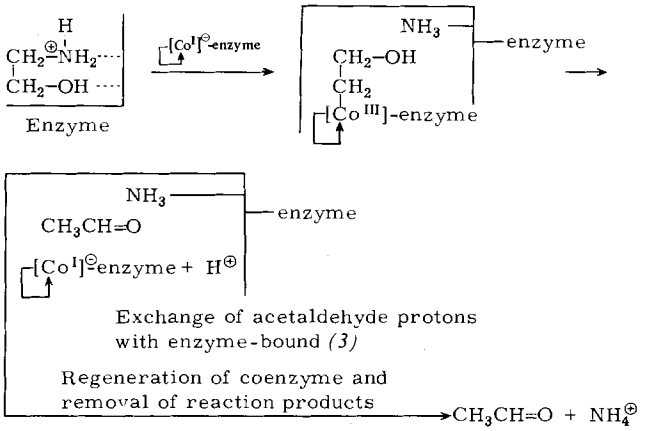


Glycol radicals generated by a radiolysis reaction of glycols were in addition shown to have no tendency to form *(9)* on reaction with vitamin B_{12r}[57b]. Another argument against the free-radical mechanism of glycol dehydration was obtained in attempts to verify reaction eq. (s). Formylmethylcobalamin *(11)* decomposes thermally as well as on irradiation in solution to yield acetaldehyde and hydroxocobalamin *without the intermediate appearance of vitamin* B_{12r}[58] [see eq. (q) in the first part of this series]. Thus it is not possible to support this alternative mechanism of enzymatic diol dehydration by means of direct experimental studies. This is not to say that free-radical rearrangements of glycol radicals to acetaldehyde radicals cannot occur. Acetaldehyde is formed, for example, in the reaction of glycol with Fenton's reagent. It has also been reported that traces of acetaldehyde are generated if methylcobaloxime is photolyzed in the presence of glycol, provided that the reaction is performed in acidic solution[59]. We studied the same reaction in neutral media. Under these conditions, the glycol radicals generated seem to dimerize to yield erythritol and related compounds[57a]. Since a homolysis of the Co—C bond of coenzyme B_{12} was considered to represent the mechanism of its enzymatic activation, it should also be pointed out that such a process is improbable for energetic reasons. Traces of *(7)* have been detected after the work-up of enzyme solutions incubated with radioactively labeled *(1)*. This was interpreted to suggest that *(7)* participates in the catalytic process of glycol dehydration. However, since the same compound is formed as the product of a reductive cleavage of the Co—C bond of *(1)* and dioldehydrase contains thiol groups, *(7)* may also be the by-product of a side-reaction rather than a catalytic intermediate [see eq. (n) and Scheme 5].

ESR measurements, finally, have been performed on functional dioldehydrase. Under certain experimental conditions, paramagnetic species were observed, but the signals are not very characteristic and could not be identified unambiguously.

3.4. Ethanolamine-Deaminase (Ethanolamine-Ammonia Lyase)

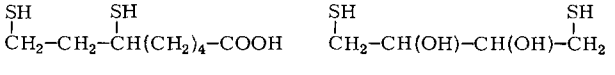
An enzyme which catalyzes the conversion of ethanolamine into acetaldehyde and ammonia [eq. (u)] was discovered in *Clostridium sp.*[60] and shown to require *(1)* for activity. The



enzyme was studied in detail by *Babior*[61]. The apoprotein has a MW of 520000 and on treatment with 5 M guanidinium hydrochloride is cleaved into inactive subunits of MW 51000. The oxygen atom of ethanolamine becomes the oxygen atom of product acetaldehyde and remains associated with the same carbon atom. The enzyme appears to be related to some

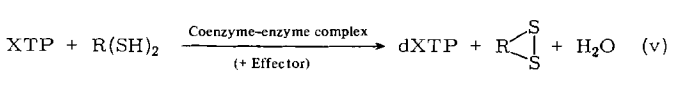
extent with dioldehydrase, especially since glycol can function as a stoichiometric substrate. If [^{3}H]-2-aminoethanol is employed as the substrate, ^{3}H enters into the 5'-position of the coenzyme. For reaction (u), both ionic and free-radical mechanisms were therefore postulated as will be outlined below.

3.4.1. Mechanism of Enzymatic Deamination of Aminoethanol



We found in our laboratory[62] that ethanolamine-ammonia lyase is inactivated by oxygen as well as by N_2O, and hence concluded that the active enzyme contains a bound Co(I)-corrin. Using ^{14}C-labeled coenzyme B_{12} we were also able to detect traces of labeled *(3)* on careful work-up of preparations of the functional holoenzyme, while *(7)* could not be seen. Accordingly, a mechanism was postulated for the enzymatic reaction which is shown in Scheme 7[62]. We see no possibility to support a free-radical mechanism on the basis of model experiments.

Scheme 7. Proposed ionic mechanism of enzymatic deamination of ethanolamine by ethanolamine deaminase (abbreviated version)[62].

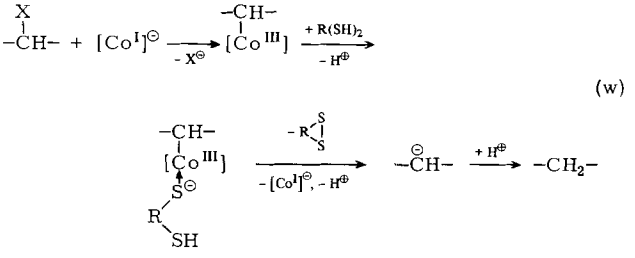


3.5. Ribonucleotide Reductase

An enzyme in *Lactobacillus leichmannii* catalyzes the reduction of ribonucleotides to deoxyribonucleotides[63, 64]. 5'-

(12) *(13)*

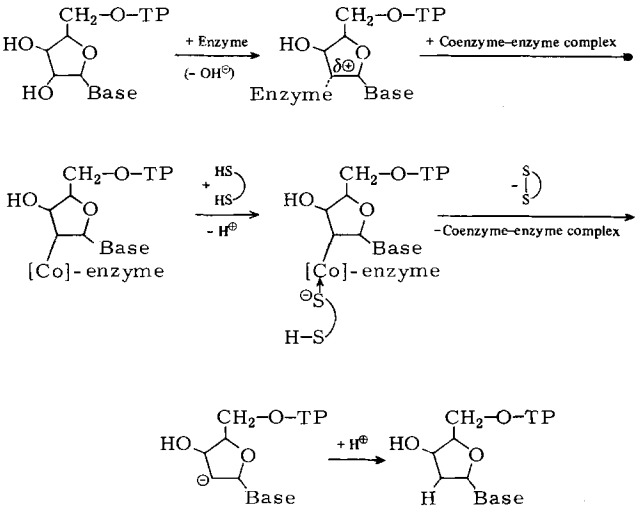
Deoxyadenosylcobalamin is the coenzyme, a thioredoxin-system the reductant, but for *in vitro* experiments, the latter may be replaced by dithiols such as dihydrolipoic acid *(12)* or dithioerythritol *(13)* [eq. (v)].



(v)

Certain deoxyribonucleotides accelerate the reduction of the substrates and are for this reason considered to act as effectors. A similar enzyme was detected in *Lactobacillus acidophilus* and *Rhizobium melioti*; it is possibly also present in a variety of other organisms[65, 66]. The enzyme is non-specific with respect to the nucleotide base component. However, minor modifications of the ribose moiety have a pronounced effect on the ability of the substrates to be reduced. The added effector is assumed to be bound by the apoenzyme but probably not in the vicinity of the active site. It is believed to induce a conformational change of the protein which in turn enhances substrate binding and/or reduction. Incubation of the enzyme with 5'-^{3}H-labeled coenzyme B_{12} causes the appearance of tritium in the water solvent during substrate reduction[67]. At low enzyme concentrations the amount of tritium released is proportional to the yields of reduced product. If the reaction is carried out in ^3H_2O, tritium is found both in the enzyme-bound *(1)* as well as in the product deoxyribonucleotide. The displacement of the OH group by H in the C'-2 position of the ribose moiety occurs with net retention of configuration. The apoprotein appears to contain thiol groups in the vicinity of the coenzyme binding site. Vitamin B_{12a} does not exhibit coenzyme activity but is reduced to vitamin B_{12r} upon the addition of a thiol and an effector. The resulting solution shows ESR signals of vitamin B_{12r} with highly resolved ^{14}N-superhyperfine splitting[68], indicating that the 5,6-dimethylbenzimidazole remains attached to cobalt under these conditions. In functional ribonucleotide reductase holoenzyme ESR-acetive species have been observed as well[69]. The signals show a certain degree of similarity to those observed in other coenzyme B_{12}-dependent enzymes but could not yet be identified.

3.5.1. Mechanism of Enzymatic Reduction of Ribonucleotides



For the mechanism of ribonucleotide reduction, schemes have been put forward which involve free radicals [*e.g. (4)*] and in which 5'-deoxyadenosine *(7)* is assumed to be an intermediate carrier of hydrogen. It has been suggested, for example, as a working hypothesis, that *(4)* abstracts a hydrogen atom from the dithiol reductant[64], but since thiols are known to be efficient scavengers of radicals it would seem to be unlikely that such mechanisms can be part of the catalytic process. An ionic mechanism was proposed on the basis of our own experiments[16], however, which appears to be in accord with most of the available experimental evidence. This mechanism was deduced from observations made in the study of the reductive cleavage of alkylcobalt complexes by thiols and dithiols[16]. These reactions may be regarded as prototypes of corrin-catalyzed reductions of substrates [eq. (w)].

(w)

Along these lines, the mechanism given in Scheme 8 was proposed. It has not been possible as yet to demonstrate the presence of enzyme-bound vitamin B_{12s} in the functional holoenzyme[70] using N_2O, since the enzymatic reduction of ribonucleotides is also not greatly inhibited by oxygen. However, a surprising observation was made in a subsequent study

on the effects of buffers in reductive Co—C bond cleavage reactions. *Jacobsen* and *Huennekens* reported in 1969 that the rate of enzymatic ribonucleotide reduction is dependent on the type and concentrations of the buffers employed[71]. The authors interpreted their results by assuming chaotropic effects of the buffer anions on the enzyme protein. We in turn investigated the effects of buffer-type and -concentration on the rates of methane production from methylcobaloxime in the presence of dithioerythritol *(13)* and dihydrolipoate *(12)*. *A surprising similarity between the nonenzymatic rates of methane production and the enzymatic rates of ribonucleotide reduction was observed*[16], the results are shown in Figure

Scheme 8. Postulated mechanism of enzymatic ribonucleotide reduction [16]. TP = triphosphate.

2. The observed relative rates of the reductions occurring in both systems are directly and significantly correlated [$r = 0.71, P < 0.01$][18]. This remarkable similarity between two reactions which cannot be immediately recognized as having

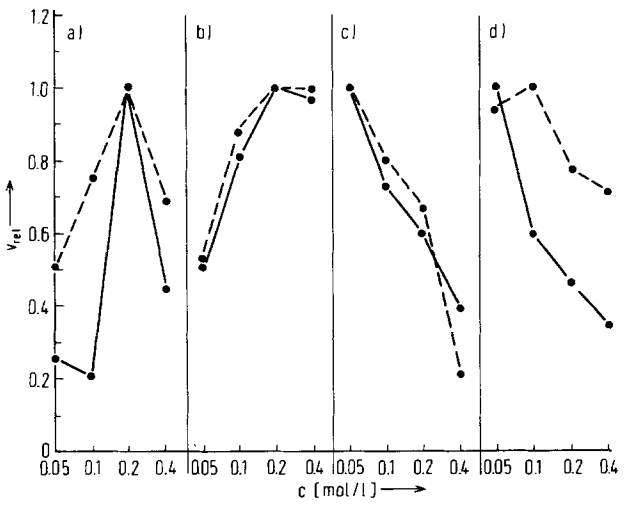


Fig. 2. Relative rate profiles of enzymatic reduction of ribonucleotide (----) and of methane formation from methyl(aquo)cobaloxide (——) in tris and phosphate buffer with dithioerythritol *(13)* and dihydrolipoic acid *(12)* as reductant [16]. v_{rel}, relative reaction rate; c, concentration of buffer. a) Tris buffer + *(13)*; b) phosphate buffer + *(13)*; c) tris buffer + *(12)*; d) phosphate buffer + *(12)*. Kind of ribonucleotide: GTP; amount of thiols 0.17 M.

anything in common becomes plausible if it is assumed that the same processes are rate-determining in both systems. Presumably, the axial coordination of the thiols is a concentration- and buffer-dependent step and responsible for the observed results. We again assume that the activation occurs by way of a β-elimination to yield enzyme-bound vitamin B_{12s} and *(3)*, respectively, although direct evidence is not yet available.

3.6. Coenzyme B_{12}-Dependent Mutase Reactions

The presently known coenzyme B_{12}-dependent mutases[72–81] are shown in Table 2. They exhibit high substrate-specificity, the reactions are reversible and take place without proton-exchange with the solvent. However, an exchange between protons of the substrate and hydrogen at the 5'-position of the coenzyme has been demonstrated. It has also been shown that hydrogen migrates between two neighboring carbon atoms, and all reactions may be *formally* considered to involve the reversible removal and attachment of a substituent R to positions 3 and 2 of propionic acid [eq. (x)].

$$\underset{\text{R}}{\text{CH}_2\text{–CH}_2\text{–COOH}} \rightleftharpoons\rightleftharpoons\rightleftharpoons \underset{\text{R}}{\text{CH}_3\text{–CH–COOH}} \qquad \text{(x)}$$

R = –CO–CoA, –CH(NH_2)COOH, CH_2=C(–)–COOH etc.

We considered a mechanism in which an organocobalt intermediate undergoes isomerization according to eq. (y)[4] as a part of the overall rearrangement process.

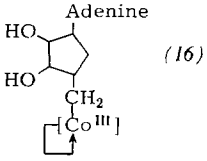
$$\underset{[\text{Co}^{\text{III}}]}{\text{CH}_2\text{–CH}_2\text{–R'}} \rightleftharpoons\rightleftharpoons\rightleftharpoons \underset{[\text{Co}^{\text{III}}]}{\text{CH}_3\text{–CH–R'}} \qquad \text{(y)}$$

Reactions of this type have been observed in model systems [see eq. (h) in the first article]. However, it would have to be assumed that C—C bonds of the substrates are reversibly broken or at least labilized to yield complexes of the type assumed in eq. (y), and no good examples are known to date for such reactions. As early as 1964 *Ingraham* considered that the rearrangement of methylmalonyl-CoA occurs *via* organocobalt intermediates of type *(14)*[82]. We studied complexes of type *(15)* as possible models for the reverse conversion of succinyl-CoA into methylmalonyl-CoA but were unable to observe a reaction of this type [eq. (z)][83, 83a]

$$\underset{[\text{Co}^{\text{III}}]}{\text{CH}_2\text{–CH(–C(=O)–CoA)–COOH}} \;\not\rightleftharpoons\; \underset{[\text{Co}^{\text{III}}]}{\text{CoA–C(=O)–CH–CH}_2\text{–COOH}} \qquad \text{(z)}$$

(14) *(15)*

Lowe and *Ingraham* succeeded in 1971 in performing at least one reaction which could be considered a possible model for the rearrangement of *(14)* to *(15)*[84]; however, even this reaction cannot be fully compared with enzymatic process (see, *e.g.*[4]). It is particularly difficult to formulate a mechanism for the reverse reactions, *i.e.* the conversion of succinyl-CoA into methylmalonyl-CoA. In spite of more recent encouraging reports from other workers[85, 86], it is necessary to treat all attempts to explain the mechanisms of these intriguing reac-



tions with caution, until more evidence becomes available and the role of the enzyme in the reactions is better known.

3.7. Aminomutases

Extracts of *Cl. sticklandii* catalyze the reversible conversion of α-lysine into β-lysine. Analogous isomerizations were observed with arginine and ornithine. In all reactions an amino group and a hydrogen atom appear to migrate simultaneously between two carbon atoms. All known aminomutases consist of two protein components (see Table 2). In some cases, enhanced activity is observed upon the addition of bivalent metal cations, *e.g.* Mg^{2+} or Mn^{2+}, or by catalytic amounts of ATP. At least one aminomutase also requires pyridoxal phosphate as cofactor. In view of the complexity of these enzymes, possible mechanisms will not be discussed.

3.8. Coenzyme B_{12} Analogs

It is obvious that our understanding of the mechanism of action of coenzyme B_{12} *(1)* is closely linked to the question of how the coenzyme is activated by the enzyme. Only two alternatives remain to be considered: Does the activation occur *via* a homolytic or heterolytic cleavage of the cobalt-carbon bond? To obtain additional experimental information that might prove useful toward the solution of this problem various analogs of coenzyme B_{12} have been synthesized[87] and tested for coenzyme activity. It was soon found that even minor modifications of the structure of *(1)* cause a loss or diminution of activity. The behavior of only one coenzyme B_{12} analog, *(16)*, will be described here. The substitution of the ribose oxygen by a CH_2 group causes a significant diminution of coenzyme activity in the dioldehydrase system[53], which has been attributed to the greater stability of the Co—C bond in *(16)* as compared to *(1)*. However, *(16)* also undergoes Co—C bond cleavage on reaction with strong bases[88].

(16)

We have recently observed that the activity of *(16)* in dioldehydrase can be increased by exposing the pseudoholoenzyme to light[88]. The effect was attributed to a light-induced heterolytic cleavage of the Co—C bond of enzyme-bound *(16)*. In alkaline aqueous solution, *(16)* was found to yield vitamin B_{12s}[89] on irradiation with strict exclusion of air. We suggested that the Co—C bond of the coenzyme in dioldehydrase is not necessarily closed after each substrate turnover[88], in accord with the general features of the mechanism in Scheme 6.

4. Concluding Remarks

This review shows that we may eventually come to understand all the details of the mechanism of action of vitamin B_{12} coenzymes in enzymatic reactions. It also indicates, however, that serious problems remain to be solved even in the simpler systems. Although model studies seem to lead in the right direction, it cannot be denied that there are still wide gaps between the current biochemical and organometallic interpretations of the available experimental data. The most important difference of opinion concerns the function of coenzyme B_{12} itself: The biochemical studies led to the conclusion that the coenzyme promotes free-radical reactions of the substrates and that its adenosyl moiety acts as an intermediate carrier of substrate hydrogen. Model work, as performed by the author, has produced mechanistic proposals in which free radicals are avoided and the hydrogen-exchange phenomena are formulated as ionic processes which are not directly associated with the actual conversion of the substrates to the products. A decision between the two divergent views is left to the reader.

[70] The detection of vitamin B_{12s} or of Co(I) derivatives of the model compounds in the presence of thiols is difficult due to the formation of thiolates of cobalamins or cobaloximes. These cobalt-sulfur compounds can be regarded as cobalt(I) nucleophiles *in situ*, for the cobalt atom is easily alkylated in complexes of this type even if the nucleophilic Co(I) derivatives are not detectable spectroscopically.

[89] In addition to vitamin B_{12s}, vitamin B_{12r} is formed in the photolysis of *(16)*; the photolysis must be performed in specially vacuum-degassed cuvettes to eliminate traces of oxygen. If this is done carefully, the major photolysis product is vitamin B_{12s}. The photolysis of diolde-hydrase incubated with *(1)* does not produce any stimulation, but instead a slight diminution of enzymatic activity. The irradiation experiments with the enzyme must also be conducted as strictly anaerobically as possible [88].

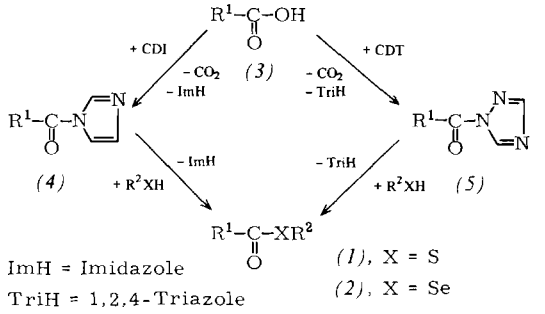
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis of Thiol and Selenol Esters from Carboxylic Acids and Thiols or Selenols, respectively[**]

By *Hans-Joachim Gais*[*]

Dedicated to Professor Robert B. Woodward on the occasion of his 60th birthday



In contrast to their O-analogs, thiol esters *(1)* and selenol esters *(2)* frequently exhibit toward nucleophiles a higher and more selective reactivity, which is enhanced even further by activation with heavy metal ions or oxidizing agents. These properties make *(1)* and *(2)* valuable acyl transfer agents and permit selective transformations in complex molecules.

[*] Dr. H.-J. Gais
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] Support of this work by Professor *K. Hafner* is gratefully acknowledged.

In particular, the total synthesis of macrolide antibiotics and cytochalasanes and the synthesis of acyl-coenzyme A demand simple, mild and general methods for the preparation of *(1)* and *(2)*.

Carboxylic acid-imidazolides *(4)* or -1,2,4-triazolides *(5)* are accessible in almost quantitative yields from carboxylic acids *(3)* and carbonyl di-imidazole (CDI) or -1,2,4-triazole (CDT)[1], respectively. We have found that *(4)* and *(5)* react with aliphatic[2] and aromatic thiols or selenols to give *(1)* and *(2)* in excellent yields (Tables 1 and 2)[3].

The activation of *(3)* with CDI or CDT and acylation of the thiols or selenols are carried out without isolation of *(4)* or *(5)* in inert anhydrous solvents at or below room temperature under almost neutral reaction conditions. In the case of aromatic thiols and selenols the reactions are complete within a few minutes, and in the case of aliphatic thiols within a few hours. The imidazole or 1,2,4-triazole formed along with *(1)* or *(2)* is readily removed by extraction with water. In the case of *N*-benzyloxycarbonyl-L-phenylalanine, activation and acylation are accompanied by only very slight racemization (Table 2).

The selective activation of carboxyl groups with CDI[4] important for synthesis of a macrocyclic lactone from thiol esters of ω-hydroxycarboxylic acids is demonstrated by the formation of *(1ag)*, *(1ah)*, and *(1ai)* from ricinelaidic acid (Table 1).

Experimental

N-Benzyloxycarbonyl-L-phenylalanine phenylthiol ester *(1aj)*: A mixture of CDI (1.71 g, 10.5 mmol) and *N*-benzyloxycarbonyl-L-phenylalanine (2.99 g, 10.0 mmol) in anhydrous DMF (50 ml) is stirred for 2 h at −10 °C under exclusion of moisture (evolution of CO_2!). The reaction mixture is then treated with thiophenol (1.08 ml, 10.5 mmol) and stirred for 30 minutes at −10 °C. After addition of ethyl acetate (50 ml) the mixture is washed with saturated NaCl solution, dried over $MgSO_4$, and the solvents evaporated *in vacuo*. The crystalline residue is chromatographed on silica gel 60 (Merck) with CH_2Cl_2/*n*-hexane (3 : 1). Yield of crude product 3.71 g (95 %). Recrystallization from ethyl acetate/*n*-hexane furnishes 3.48 g (89 %) of colorless needles. Evaporation of the aqueous phase *in vacuo* and extraction of the residue with hot ethyl acetate affords

Selective Monofunctionalization of Non-Conjugated Dienes by Nitrogen Dioxide/Iodine Monoaddition[**]

By *Volker Jäger* and *Hans Jürgen Günther*[*]

Dedicated to Professor Robert B. Woodward on the occasion of his 60th birthday

The selective transformation of one of two or more identical functional groups that are separated by two or more saturated carbon atoms represents a synthetic problem which is generally solved statistically[1] or by carrying out heterogeneous reactions[2], or circumvented[1].

In the case of simple 1,5-, 1,6- and 1,7-dienes selective monofunctionalization can be effected by reaction with stoichiometric amounts of dinitrogen tetroxide in the presence of iodine[3]. In this way the unsymmetrical monoadducts *(2)* are obtained selectively from symmetrical dienes *(1)*[4]. The bis-adducts *(3)* are formed in minor amounts only[4a] (see Table 1).

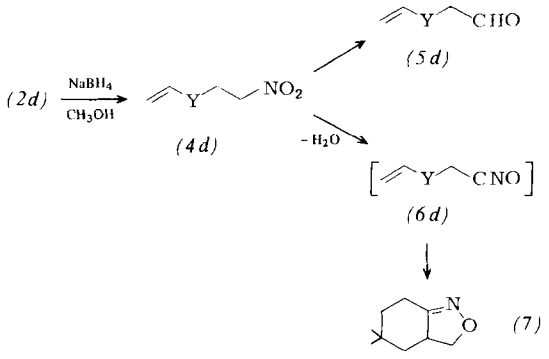
[c] B.p. ≈80°C/0.005 torr.
[d] The compound can be isolated using an excess of NO_2/I, longer reaction time, and warming (0→20°C; 12 h)
[e] M.p. 111°C.
[f] M.p. 92°C (dec.)
[g] 0.24 mol *(1)*, 0.51 ether, addition period 6.5 h.
[h] 0.7 mol *(1)*, 1.51 ether, addition period 7 h.

Steric effects[5] or the transmission of inductive (polar) effects[6] especially of the nitro group through the carbon chain should hardly be responsible for the reduced reactivity of the remaining C=C double bond. Possible intramolecular interactions of the iodine/nitro function with the C=C double bond or with intermediates have yet to be clarified.



ω-Nitroalkenes *(4)*, ω-unsaturated aldehydes *(5)*, and ω-unsaturated nitrile oxides *(6)* are readily accessible (the latter *in situ*) from compounds *(2)* by modifications of known procedures. These products are of interest, *e.g.*, as starting materials for intramolecular 1,3-dipolar cycloadditions[7]. The inherent preparative possibilities are illustrated by some reactions start-

ing with *(2d)*[4b]: Reaction of *(2d)* with sodium borohydride in methanol at 0 to 20°C affords 4,4-dimethyl-7-nitro-1-heptene *(4d)* in 72% yield; *(4d)* is then converted in a modified Nef reaction[8] into the aldehyde *(5d)* (77% yield, b.p. 80°C/15 torr). Dehydration of *(4d)* with phenyl isocyanate/triethylamine/benzene under reflux[9] in a dilution set-up furnishes [*via* the ω-unsaturated nitrile oxide *(6d)*] the cycloadduct *(7)* (91% yield, m.p. 61°C).

Experimental

NO_2/iodine addition to 1,*n*-dienes[3]: A solution of the diene and iodine in ether (0.15 to 0.6 mol diene/l ether) is prepared at 0°C in a three-necked flask (acetone/dry-ice condenser, gas inlet tube, magnetic stirrer). Dinitrogen tetroxide (dried with P_2O_5, weighed after cooling in a sealable cold trap) is then transferred into the flask by means of an argon stream at a rate of 0.01 to 0.05 mol (0.9 to 4.6 g) per hour. The reaction mixture is then extracted [in the case of *(1e)* after filtering off the precipitated bis-adduct *(3e)*] with 10% sodium thiosulfate solution until disappearance of the iodine color, washed with sodium hydrogen carbonate solution and water, and dried over $CaCl_2$. Solvent and any residual diene are then removed in a rotary evaporator (oil-pump vacuum at the end). The remaining yellow to brown liquids are not very stable at room temperature and should be stored at −20°C (Care: skin irritants).—Spectral data for *(2a)*: ^{1}H-NMR (CCl_4): δ = 6.2—5.4 (1H, m, —CH=), 5.3—4.2 ppm (5H, $=CH_2$, —CHI—CH_2NO_2); IR (film): ν_{NO_2} = 1560, 1375 cm^{-1}.

Bis(trimethylsilyl)magnesium—The First Organosilylmagnesium Compound Isolated[**]

By *Lutz Rösch*[*]

Reaction of cyclohexylmagnesium bromide and triphenylchlorosilane affords hexaphenyldisilane whose formation is explained in terms of the intermediacy of an organosilylmagnesium compound[1]. Other reactions involving silyl transfer in the presence of magnesium are also assumed to proceed *via* organosilylmagnesium compounds as intermediates[2], and evidence has recently been obtained for their existence in solution[3].

We have now been able to isolate the first representative of this class of compounds, *viz.* bis(trimethylsilyl)magnesium, and thus to prove the existence of organosilylmagnesium compounds. Stirring of bis(trimethylsilyl)mercury with an excess of magnesium powder in dimethoxyethane (DME) at room temperature furnishes an intensely wine-red solution within a few hours. The red color disappears in the course of several days and a dark-colored reaction mixture is obtained. Filtration, removal of volatile components, and sublimation of the residue gives a colorless substance which ignites spontaneously on exposure to air. Well defined colorless needles are obtained on recrystallization from pentane. In the ^{1}H-NMR spectrum recorded in benzene the signals of coordinated dimethoxyethane are accompanied by just one sharp signal in the vicinity of TMS. Decomposition of the compound with water or D_2O gives trimethylsilane or trimethyldeuteriosilane. Elemental analysis indicates the composition

$$Mg[Si(CH_3)_3]_2 \cdot C_4H_{10}O_2 \quad (1)$$

Conclusive proof of this composition is provided by the mass spectrum, which displays the molecular peak $[(Me_3Si)_2Mg \cdot DME]^+$ with the expected isotope splitting, and signals for the expected fragmentation products. Decomposition occurred only at 80°C on determination of the melting point.

Procedure

All operations were carried out with rigorous exclusion of air and moisture under argon as protective gas. Sublimed $(Me_3Si)_2Hg$ (8 g) is dissolved in dry DME (30 ml) and stirred with magnesium powder (10 g) until the initial red coloration has disappeared (*ca.* 8 d). The solution is filtered through a glass frit, volatile constituents removed at oil-pump vacuum and room temperature, and the residue sublimed at 50°C/10^{-5}

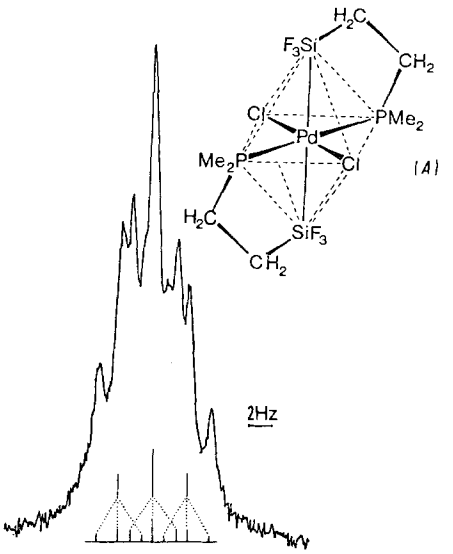
A Novel 3z-2e Bond System[**]

By *Joseph Grobe*, *Roland Martin*, and *Uwe Möller*[*]

Investigations on the M→L back-bonding in transition metal complexes have indicated a Fe→Si interaction in the case of the carbonyliron derivatives $Fe(CO)_4[PMe_2CH_2CH_2SiX_3]$ (X=F, Cl)[1]. For the d^8 electron configuration of Fe^0 this effect is most simply described in terms of a Lewis base-acid interaction with $Fe(CO)_4PMe_2CH_2$ as base and the CH_2SiX_3 moiety as acid. It is still uncertain, however, whether such a σ back-bonding is reinforced by (d-d)π back bonding.

Transition metal compounds having Lewis base properties are already known. Thus, for example, the anion $[Mn(CO)_5]^-$ isoelectronically related to $Fe(CO)_5$ forms an adduct with "BH_3"[2]. This tendency is even more strongly pronounced in planar d^8 systems, as demonstrated by the existence of $(Ph_3P)_2Rh(CO)Cl \cdot BX_3$ (X=Cl, Br)[3] and $(Ph_3P)_2Ir(CO)Cl \cdot nBF_3$ ($n=1, 2$)[4]. Corresponding adducts of d^{10} complexes with Lewis acids are also known; *e.g.*, $(Ph_3P)_2Pt \cdot 2BX_3$ (X=F, Cl) or $(Ph_3P)_2Pt \cdot SiF_4$[5].

We have now made attempts to exploit the pronounced basicity of planar d^8 systems for a more accurate study of M→Si interaction. Reaction of bis(benzonitrile)dichloropalladium(II) *(1)* with the oligomeric donor-acceptor ligand *(2)* ($n \approx 6$)[1b, 6] in benzene afforded the yellow-orange complex *(3)* in quantitative yield; on the basis of spectroscopic findings, *(3)* was assigned the structure *(A)* (see Fig. 1).



$$\underset{(1)}{trans\text{-}(PhCN)_2PdCl_2} + \frac{2}{n}\underset{(2)}{(Me_2PCH_2CH_2SiF_3)_n} \rightarrow$$

$$\underset{(3)}{(F_3SiCH_2CH_2PMe_2)_2PdCl_2} + 2\ PhCN$$

The composition and molecular size of the new compound follow from the mass spectrum ($M^+=526$ for ^{108}Pd and ^{35}Cl). The spectroscopic investigations were rendered difficult by the sparing solubility of *(3)* in inert organic solvents and the alteration of the complex in the dissolved and in the solid state.

A planar arrangement of the two chlorine and the two phosphane ligands in the *trans*-position seems plausible:
1) The complex is formed from *trans*-$(PhCN)_2PdCl_2$.
2) In the ^1H-NMR spectrum of *(3)*, the "triplet" with broadened inner signal typical for *trans*-isomers is found for the methyl groups on phosphorus. It is a higher order spectrum of type $X_6AA'X'_6$[7] with large AA' coupling, from which only the signal position $\tau=9.05$ ppm and the magnitude $|^2J_{PH}+{}^4J_{PH}|$ can be taken exactly as the distance between the two outer lines with 7.0 Hz. This value is comparable with that for *trans*-$PdCl_2(PMe_3)_2$ (7.4 Hz) and suggests $^2J_{PP'}$ and $^4J_{PH}$ couplings of about 600 and 3 Hz, respectively, as were determined for *trans*-$PdX_2(PMe_3)_2$ complexes[8].

This necessitates the *trans* arrangement for the two SiF_3 groups if they are included in the coordination sphere of the palladium. The bonding Pd→Si interaction responsible for the formulation *(A)* can be recognized in the ^{19}F-NMR spectrum (Fig. 1). It shows a strong coupling with two equivalent ^{31}P- and two ^1H nuclei (CH_2 group bound to Si) [$^3J_{PF}=1.88$ Hz; $^3J_{HF}=2.88$ Hz] and can be characterized as a triplet of triplets. Assignment of the couplings is confirmed by double resonance experiments.

(A)

Fig. 1. ^{19}F-NMR spectrum and constitution of the complex *(3)* (FT spectrum at 84.66 MHz, 1000 scans).

If strong fixation is assumed for the coordination of the SiF_3 groups to the palladium, a distorted trigonal-bipyramidal environment of three fluorine atoms, one carbon atom and one palladium atom is expected. Such structures have very low pseudorotation barriers, even on incorporation of two atoms into a ring system[9]. The equivalence of the fluorine atoms observed in the ^{19}F-NMR spectrum of *(3)* is thus understandable; the mobility of the system is so great that the equivalence is still preserved at −60°C.

For interpretation of the bonding in complex *(3)* we presuppose that the $4d_{x^2-y^2}$, 5s, $5p_x$, $5p_y$ orbitals of the palladium participate in the planar unit $PdCl_2P_2$. Only one electron pair of the Pd center is available for the bonding of the two SiF_3 groups *via* the $4d_{z^2}$ or a $(4d_{z^2}-5p_z)$ hybrid orbital. Each Pd—Si bond is thus formally effected by only one electron, which in our opinion can best be described by a "coordinative 3z-2e bond".

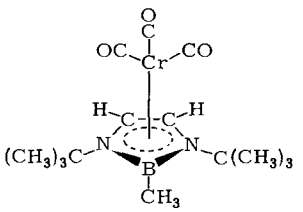
Δ^4-1,3,2-Diazaborolines as Complex Ligands



By *Günter Schmid* and *Joachim Schulze*[*]

Diazoborolines of type *(1)*, accessible by dehydrogenation of diazoborolidines[1a] or from α,β-diimines and haloboranes[1b], are isoelectronic with the cyclopentadienide ion and should therefore also have good ligand properties. This assumption is further supported by ^{11}B- and ^{14}N-NMR, UV, and photoelectron spectroscopic investigations[1,2], which provide evidence for a delocalized 6π-electron system.

(1a), $R^1 = R^3 = C(CH_3)_3$, $R^2 = CH_3$, $R^4 = R^5 = H$

We have now been able to isolate the tricarbonylchromium complex *(2)* as the first coordination compound containing such a heterocyclic ligand, namely 1,3-di-*tert*-butyl-2-methyl-Δ^4-1,3,2-diazaboroline *(1a)*.

(2)

Reaction of *(1a)* with $(CH_3CN)_3Cr(CO)_3$ in dioxane at 85 °C affords *(2)* in 91 % yield; *(1a)* can also be used in excess without solvent, but without any increase in the yield of product. *(2)* crystallizes as yellow needles which are soluble in various ethers. The air-stable crystals decompose above *ca.* 170 °C.

The mass spectrum of *(2)* shows the molecular ion at $m/e = 330$ (I_{rel} 14.5 %) along with $LCrCO^+$ (7.2) [L = *(1a)*], LCr^+ (100) and the free heterocycle itself (21.4) as characteristic fragments. The stability of the completely decarbonylated fragment LCr^+ seems surprising. In accord with the local C_{3v} symmetry of the $Cr(CO)_3$ group the IR spectrum of *(2)* displays two very strong νCO bands at 1929 and 1813 cm^{-1}, thus showing the diazaboroline *(1a)* to be a very strong donor ligand. The vibrations of the coordinated and of the free diazoboroline do not differ very largely from each other; only the band at 1628 cm^{-1} to be assigned to the C=C double bond in *(1a)* is no longer observed in *(2)*. In accord with the finding that increasing donor ability of the aromatic ligand in (ar)$Cr(CO)_3$ effects strong deshielding of the C-atoms in the carbonyl groups[3], in *(2)* $\delta^{13}C(CO)$ (234.6 ppm, Table 1) is shifted noticeably downfield as compared to $Cr(CO)_6$ (212.5 ppm)[3]. Thus the ligand strength of *(1a)* corresponds to that of the mesitylene in (π-mesitylene)$Cr(CO)_3$ with $\delta^{13}C(CO) = 235.1$ ppm[4].

Table 1. NMR-spectroscopic data [a] of *(1a)* and *(2)*.

(1,3-Di-tert-butyl-2-methyl-Δ^4-1,3,2-diazaboroline)tricarbonylchromium (2)

A mixture of $(CH_3CN)_3Cr(CO)_3$ (2.26 g, 8.7 mmol) and *(1a)* (5.82 g, 30.0 mmol) in dry dioxane saturated with nitrogen is heated in the absence of air for 6 h at 85 °C. Liberated acetonitrile is repeatedly removed from the equilibrium by suction into a cold trap. The brown-yellow reaction solution is filtered hot and cooled to 10 °C. The resulting precipitate is separated by filtration and washed with petroleum ether (b.p. 40—60 °C). Extraction with ether affords additional *(2)*; total yield 2.56 g (91 %). The composition of the product was confirmed by elemental analysis and molecular weight determination.

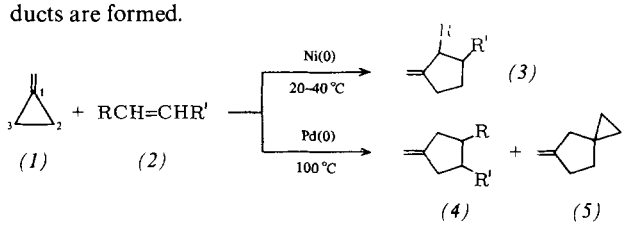
Palladium(0)-Catalyzed [2σ+2π] Cycloadditions of Methylenecyclopropane to Alkenes

By *Paul Binger* and *Ulf Schuchardt*[*]



Catalyzed codimerizations of methylenecyclopropane *(1)* with alkenes to give [2π+2π] and [2σ+2π] cycloadducts has hitherto been accomplished only with nickel(0) compounds[1,2]. Besides cyclobutane derivatives[2] methylenecy-

[*] Dr. P. Binger, Dr. U. Schuchardt
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

clopentane derivatives of type *(3)*[1] are formed with opening of the three-membered ring in the neighborhood of the double bond.

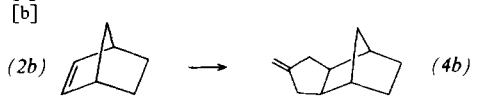
Exclusive $[2\sigma+2\pi]$ cycloaddition of *(1)* with alkenes *(2)* has now been found on palladium(0) catalysts, where, in contrast to the nickel(0) catalyzed reactions, the three-membered ring is opened between C-2 and C-3.

At 100—115 °C the methylenecyclopentane derivatives *(4)* are obtained (cf. Table 1), up to 300 mol *(1)* being converted per 1 mol Pd. The codimerization always has to compete with cyclodimerization of *(1)*, which affords the 5-methylenespiro[2.4]heptane *(5)*. Only negligible amounts of other products are formed.

Methylenecyclopentane (4c)

(1) (40 g, 0.74 mol) is added to a solution of bis(pentanedionato)palladium (0.61 g, 2 mmol), triisopropylphosphane (0.32 g, 2 mmol), and ethoxydiethylaluminum (0.52 g, 4 mmol) in benzene (20 ml) in a 200 ml-V2A steel autoclave at −78 °C. Ethylene *(2c)* (120 atm) is fed into the autoclave at room temperature. After 6 hours' shaking the pressure drops from a maximum of 630 atm to 380 atm. 29 liters of excess ethylene (GC) is drawn off and the content of the autoclave distilled. 55.3 g of a colorless liquid of b.p. up to 25 °C/14 torr is obtained; GC analysis: 29.6 % benzene, 22.6 % *(4c)*, 46.4 % *(5)*, 3.3 g black viscous residue.

Dimethyl cis- and trans-4-methylene-1,2-cyclopentanecarboxylate (4f)



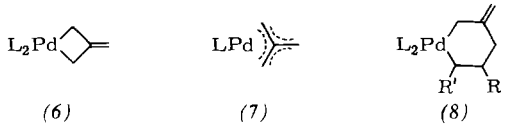
(1) (6.5 g, 0.12 mol) is added to a solution of bis(pentanedionato)palladium (0.3 g, 1 mmol), triisopropylphosphane (0.16 g, 1 mmol), and ethoxydiethylaluminum (0.26 g, 2 mmol) in dimethyl maleate *(2f)* (17.25 g, 0.12 mol) at −78 °C in a bomb-tube fitted with a threaded seal. The sealed bomb-tube is then heated to 100 °C for 18 h, whereupon a contraction in volume of 4 ml occurs. The bomb-tube is opened at −78 °C and the content (24.5 g yellow solution) fractionally distilled. This affords 1.7 g of a fraction of b.p. up to 25 °C/0.02 torr with (GC) 73.8 % *(5)* and 17.6 % *(2f)* [residue (8.8 %), seven unknown peaks] and 18.7 g of a fraction of b.p. 51—55 °C/0.02 torr with (GC) 5.6 % *(2f)*, 51.1 % *trans-(4f)* and 33.7 % *cis-(4f)* [residue (9.6 %), ten unknown peaks].

Table 1. Palladium(0)-catalyzed $[2\sigma+2\pi]$ cycloadditions of *(1)* to alkenes *(2)* to give methylenecyclopentane derivatives *(4)*, 5-methylenespiro[2.4]heptane *(5)*, and oligomers. The catalyst was prepared from bis(pentanedionato)palladium, triisopropylphosphane and ethoxydiethylaluminum (1 : 1 : 2) in benzene *(a—d)* or in the alkene concerned *(e—g)*. Experiments were carried out in a bomb-tube [molar ratio of *(1)* : *(2)* = 1 : 1]; conversion of *(1)*: > 90 %.

	(2) R	R'	Reaction Temp. [°C]	Time [h]	Rel. Yield [%] *(4)* [a]	*(5)*	Oligomer	Remarks
a	*(2a)* ≡ *(1)*		100	4	—	94	6	
b	[b]		100	1	78	21	1	*(4b)*: only *exo*
c	H	H [c]	115	≈ 6	23	72	5	
d	H	CO_2CH_3 [d]	100	3	51	3	46	
e	CH_3	CO_2CH_3 *trans*	100	18	43	50	7	*(4e)*: probably *trans*
f	CO_2CH_3	CO_2CH_3 *cis*	100	18	77	23	—	*(4f)*: 60 % *trans*, 40 % *cis*
g	$CO_2C_2H_5$	$CO_2C_2H_5$ *trans*	100	18	88	4	—	*(4g)*: 88 % *trans*, 12 % *cis*

[a] All codimers *(4)* were identified spectroscopically (MS, IR, ^{1}H-NMR).

[b]



[c] With excess ethylene in a 200 ml V2A steel autoclave.

[d] Terminated after 20 % conversion of *(1)*, since *(2d)* polymerizes.

1- or 2-Alkenes (with the exception of ethylene) and cycloalkenes not containing a strained double bond, *e.g.* cyclopentene, are not suitable for this new codimerization with *(1)*.

Besides 1 : 1 mixtures of bis(dibenzylideneacetone)palladium[3] and a trialkylphosphane, especially triisopropylphosphane, palladium(0) compounds obtained *in situ* are particularly suitable as palladium(0) catalysts (see Table 1).

The catalytic cycloadditions described here might proceed *via* palladacyclobutanes of type *(6)*[4] and palladacyclohexanes of type *(8)*.

As experiments with 1-methyl-2-methylenecyclopropane have shown, *(6)* is transformed at a detectable rate into a complex of type *(7)* at 120 °C. Only above this temperature are methylene and ethylidenecyclopentane derivatives formed[5].

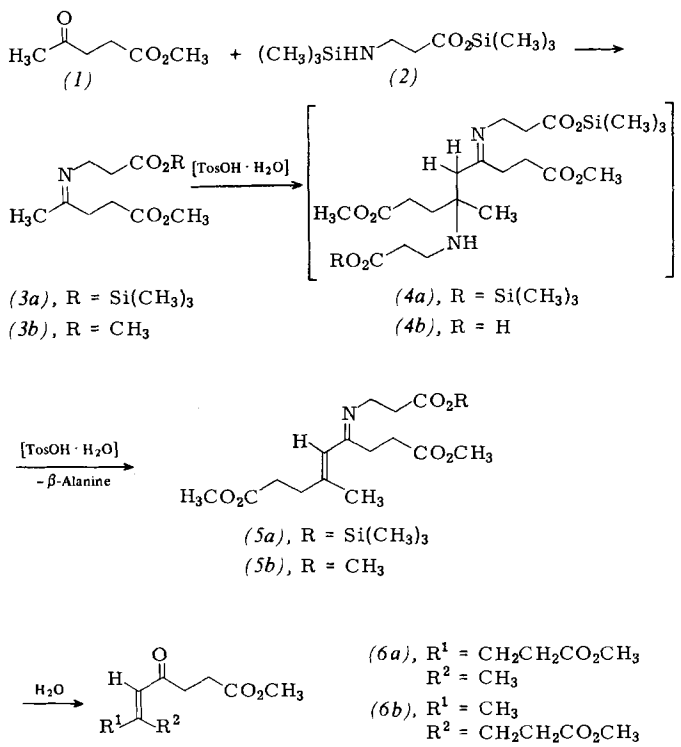
N-(Trimethylsilyl)amino Acid Trimethylsilyl Esters as Reagents for Directed Self-Condensation of Methyl Ketones under Mild Conditions[**]

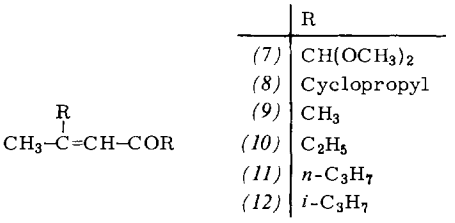


By *Günter Schulz* and *Wolfgang Steglich*[*]

Self-condensation of methyl ketones to α,β-unsaturated dimers generally requires strongly alkaline or acid conditions[1]. On use of secondary amines several days' boiling in benzene is necessary even with *n*-alkyl methyl ketones[2]. We have found that the reaction proceeds under extremely mild conditions with *N*-(trimethylsilyl)amino acid trimethyl silyl esters.

On addition of *N*-(trimethylsilyl)-β-alanine trimethylsilyl ester *(2)*[3] (1.5 equiv.) and a few grains of *p*-toluenesulfonic acid monohydrate to methyl levulinate *(1)*, β-alanine (0.5 equiv.) is soon precipitated in an exothermic reaction. According to the ^{1}H-NMR spectrum quantitative formation of the ketimine *(3a)*[4] also takes place [in CCl_4: $\delta = 0.26$ ppm (s, 9H); 1.86 (s, 3H); 2.47 (s, 4H); 2.53 (t, 2H); 3.40 (t, 2H); 3.58 (s, 3H)].

If *p*-toluenesulfonic acid monohydrate (0.1 equiv.) is now added and the mixture heated to 80 °C for 5 h the signals of unreacted *(3a)* and hexamethyldisiloxane are accompanied only by those of the condensation product *(5a)* [in CCl_4 $\delta = 1.63$ ppm (s, 3H) and 5.63 (broad s, 1H) are characteristic for *(5a)*].



After stirring with water the α,β-unsaturated ketone can be isolated as a 4:1 mixture of the stereoisomers *(6a)* and *(6b)* in 58% yield [b.p. 140 °C/0.05 torr (bulb-tube distillation); IR (CCl_4): 1740 (broad), 1695, 1630 cm^{-1}; ^{1}H-NMR (CCl_4) of (a): $\delta = 2.14$ ppm (d, 3H); 2.78 (s, 4H); 2.81 (dd, 2H); 3.01 (dd, 2H); 3.64 (s, 6H); 6.07 (broad s, 1H); ^{1}H-NMR (CCl_4) of *(6b)*: $\delta = 1.91$ ppm (d, 3H) instead of 2.14 (d, 3H) as for *(6a)*].

The reaction proceeds in regioselective manner and with exclusive participation of the acetyl group. In contrast, the ester group of *(1)* reacts with basic condensation reagents such as sodium methoxide[5].

The above self-condensation is not the result of a simple acid-catalyzed ketimine dimerization[2] since protonation of the ketimine *(3a)* with anhydrous *p*-toluenesulfonic acid, which can be reversed with triethylamine, does not lead to the condensation product *(5a)*. Apparently, expulsion of the silyl group from *(4a)* to form *(4b)* is of importance since the amine component required for condensation can subsequently be released as a low energy betaine. This concept finds support in the reaction of *(1)* with *N*-(trimethylsilyl)-β-alanine methyl ester to form the ketimine *(3b)*, which also shows no tendency to form the dimer *(5b)* in the presence of *p*-toluenesulfonic acid monohydrate.

Methylglyoxal dimethyl acetal and cyclopropyl methyl ketone can also be condensed to form the unsaturated ketones *(7)* and *(8)* respectively in 49 and 23% yield with the aid of *(2)*. The ratios of (*Z*) and (*E*) isomers are 1:20 and 1:3. The condensation can also be accomplished with pertrimethylsilylated α-amino acids[6]. Thus *N*-(trimethylsilyl)glycine trimethylsilyl ester yields exclusively the α,β-unsaturated ketones *(9)* to *(12)* in yields of 30 to 70% (not optimized) with acetone, methyl ethyl ketone, methyl *n*-propyl ketone, and methyl isopropyl ketone; the (*E*) isomer always predominates in the product.

	R
(7)	$CH(OCH_3)_2$
(8)	Cyclopropyl
(9)	CH_3
(10)	C_2H_5
(11)	n-C_3H_7
(12)	i-C_3H_7

Procedure

Synthesis of *(7)*: Methylglyoxal dimethyl acetal (2.03 g) is stirred with *(2)* (6.00 g) in anhydrous $CHCl_3$ (5 ml). Within a short time the mixture warms and β-alanine precipitates. After 5 min, *p*-toluenesulfonic acid monohydrate (0.14 g) is added and the mixture heated to 85 °C (bath temperature) for 3 h. After partitioning between water and CH_2Cl_2 the dehydrated organic phase is evaporated down and the residue distilled in a bulb-tube (110 °C/0.05 torr). Yield 0.92 g (49%), colorless oil; IR (CCl_4): 1705, 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$), (*E*)-*(7)*: $\delta = 2.12$ ppm (d, $J = 2$ Hz, 3H); 3.31 (*s*, 6H); 3.43 (s, 6H); 4.52 (s, 1H); 4.64 (broad s, 1H); 6.68 (quintuplet, $J = 2$ Hz, 1H); (*Z*)-*(7)*: $\delta = 1.92$ ppm (d, $J = 2$ Hz, 3H) instead of 2.12 (d, $J = 2$ Hz, 3H).

Condensation of α-Acylaminoalkyl Methyl Ketones to Give *N*-Acylpyrroles[**]

By *Günter Schulz* and *Wolfgang Steglich*[*]

We have reported *N*-(trimethylsilyl)-β-alanine trimethylsilyl ester *(2)* as a novel reagent for the self-condensation of methyl ketones[1]. We have now also established that this reagent is suitable for preparation of *N*-acylpyrroles from α-acylaminoalkyl methyl ketones *(1)* which are readily accessible from α-amino acids with acetic anhydride/4-(dimethylamino)-pyridine[2].

Compound *(1)* is suspended in *(2)* (1.5 equiv.) and a catalytic amount of *p*-toluenesulfonic acid monohydrate is added. After brief warming *(1)* goes into solution and β-alanine is precipitated. Further *p*-toluenesulfonic acid monohydrate is added and the mixture heated to 80 °C for several hours[1]. The resulting *N*-acylpyrroles *(5)* are freed from unreacted starting material by filtration over silica gel.

(4a), R = $Si(CH_3)_3$
(4b), R = H

	R^1	R^2	Yield [%]	M.p. [°C]
(5a)[4]	H	CH_3	55	95
(5b)	CH_3	CH_3	60	139
(5c)	CH_3	C_6H_5	75	121
(5d)	i-C_3H_7	CH_3	40	oil

The constitution of the acylpyrroles *(5)* follows from elemental analyses, mass spectra, and the IR and ^{1}H-NMR spectra [IR in KBr[3]: ν_{CO} = 1700—1690 and 1640—1630 cm^{-1}, ν_{NH} = 3280—3260 cm^{-1}; ^{1}H-NMR ($CDCl_3$) of *(5a)*: δ = 1.94 ppm (s, 3H); 2.03 (s, 3H); 2.51 (s, 3H); 4.47 (d, J = 6 Hz, 1H); 6.13 (broad s, 1H); 6.4—6.9 (broad, 1H); 6.79 (broad s, 1H).

The acetyl group can be removed from the pyrrole nucleus by hydrolysis with 2 N NaOH (1 h, room temperature).

Procedure:

Synthesis of *(5b)*: 3-Acetylaminobutan-2-one (1.11 g) and *(2)* (3.00 g) are united in an argon-purged flask and warmed with stirring to 80 to 90 °C (bath temperature), the acetylamino ketone being dissolved. β-Alanine is precipitated within a few minutes of adding a catalytic amount of *p*-toluenesulfonic acid monohydrate. Further *p*-toluenesulfonic acid monohydrate (0.1 equiv.) is added and the mixture diluted with anhydrous $CHCl_3$ (1 ml). After 24 h, the mixture is stirred with CH_2Cl_2, β-alanine is filtered off, the filtrate evaporated down, and the residue recrystallized from ether or sublimed *in vacuo*. Yield: 0.57 g (60 %) of colorless crystals; m.p. 139 °C; IR (KBr): 3260, 1692, 1639 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ = 1.39 ppm (d, J = 6.5 Hz, 3H); 1.93 (s, 6H); 2.29 (broad s, 3H); 2.58 (s, 3H); 5.43 (broad m, 1H); 6.07 (broad s, 1H); 6.67 (very broad d, J = 9 Hz, 1H).

Control of the Direction of Addition in the Nickel-Catalyzed 2:1-Cooligomerization of Butadiene with Monoolefins by Perturbation of the Monoolefin[**]

By *Paul Heimbach, Achim Roloff*, and *Hartmut Schenkluhn*[*]

It has often been observed that the formation of different products in metal-catalyzed reactions depends on the nature of the ligand on the catalyst (ligand control), *e. g.* in the cyclooligomerization of butadiene[1], in the dimerization of propene on Ni catalysts[2], and in the oxo synthesis on Rh catalysts[3]. In order to investigate the corresponding substrate control, systems are required which are not subject to ligand control. In the cooligomerization of butadiene with propylene on nickel catalysts[4], we found that the direction of addition during the insertion of the monoolefin into the metal-allyl bond is independent of the nature of additional ligands[5]. However,

the direction of addition is influenced by a perturbation (St) of the monoolefin in which either a substituent is introduced *(1)* or a sp^2-carbon atom is replaced by nitrogen *(2)* (Fig. 1).

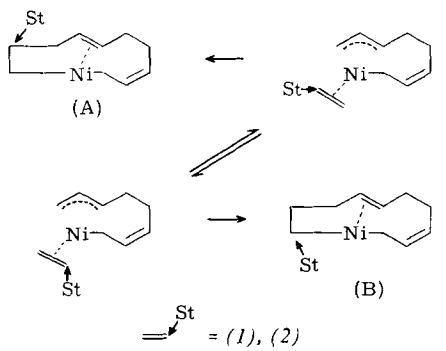

Fig. 1. Insertion of *(1)* or *(2)* into the metal-allyl bond in the cooligomerization of *(1)* or *(2)* with butadiene. The preferred direction of addition (A) or (B), is determined by the electron densities in the LUMOs of the atoms of *(1)* and *(2)* which participate in the double bond (see Table 1). The orbital coefficients [7] are given below the formulas.

We have used the monoolefin substrates listed in Figure 1 as reactants for butadiene. It can be seen from Table 1 that the direction of addition depends on the nature of the perturbation. Indeed exclusive addition in either one of the two directions can be achieved.

Table 1. Dependence of the direction of addition on the nature of the modification of the olefin (cf. Fig. 1). Reaction temperature: 40 °C.

Olefin	Direction of addition	Type of addition [a]
(1a)	B	100 % M→C^s
(1b)	A	76 % M→C^p
	B	24 % M→C^s
(1c)	B	100 % M→C^t
(2)	B	100 % M→N

[a] M→C^p = Addition of the metal to the primary C atom of the olefin.
M→C^s = Addition of the metal to the secondary C atom of the olefin.
M→C^t = Addition of the metal to the tertiary C atom of the olefin.
M→N = Addition of the metal to the N atom of the azaolefin.

The reaction step shown in Figure 1 proceeds irreversibly. Changing the solvent does not have any significant effect on the reaction rate. It should therefore be possible to establish rules for the substrate control of the insertion step similar to those already discussed for concerted reactions[6] (*e.g.* Diels-Alder and ring-closure reactions).

We found that the predominant directions of addition of all four compounds listed in Table 1 could be explained by assuming interaction to take place between the lowest unoccupied molecular orbital of the olefin and the highest occupied molecular orbital (ψ_2) of the allyl group. The terminal C-atom of the allyl group then bonds with the center of highest electron deficiency in the monoolefin. Figure 1 shows the orbital coefficients of the frontier orbitals of compounds *(1)* and *(2)*; the squares of these coefficients are measures of electron density. It can be seen from Figure 1 and Table 1 that in each case, the C atom of *(1)* or *(2)* which reacts predominantly with the terminal C atom of the allyl group is the one which has a larger absolute orbital coefficient in the LUMO.

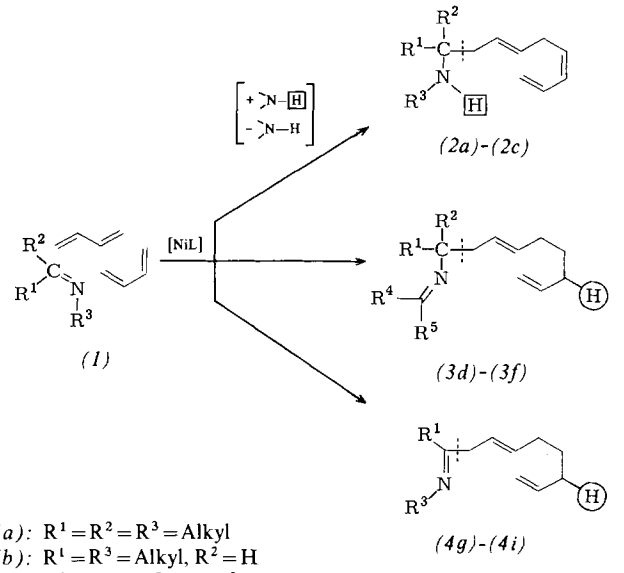
Control of the Nickel-Catalyzed Cooligomerization of Butadiene with Schiff Bases by Cocatalysts[**]

By *Paul Heimbach, Bernard Hugelin, Erich F. Nabbefeld, Dieter Reinehr, Achim Roloff*, and *Eduard Troxler*[*]



Di- and trisubstituted Schiff bases *(1)* can, like ethylene[1,2], be converted with butadiene into 2:1 adducts on Ni-ligand catalysts[3,4]. Three 2:1 adducts [*(2)* to *(4)*] can be formed with yields of up to 88 % [based on *(1)*].

Octadienylated Schiff bases of types *(3)* and *(4)* are only formed if very pure reactants are used. Type *(4)* Schiff bases are produced if the substituent R^3 in the α-position with respect to nitrogen does not contain hydrogen and if $R^2 = H$. If a hydrogen atom is in the α-position in R^3, then a type *(3)* Schiff base can be synthesized. Addition of very weak

amines of type *(2)* are not nearly so effective for this switch-over as morpholine. Nevertheless, an auto-cocatalysis must also be taken into consideration.

We think that the intermediates important for the branching of the reaction can be described by structures *(5)* and *(6)*[7]. The C=N double bond of *(1)* is inserted into one of the nickel-allyl bonds of the C_8-chain formed from two butadiene molecules. Migration of hydrogen from one of the two positions which are α with respect to the nitrogen, to the 3-position of the second allyl group leads to the formation of *(3)* or *(4)*. Association of an amine permits transfer of a hydrogen atom to the amide nitrogen [see *(6)*]. The subsequent β-elimination of a hydrogen atom from the diene chain with regeneration of the amine >N—H leads to compound *(2)*.

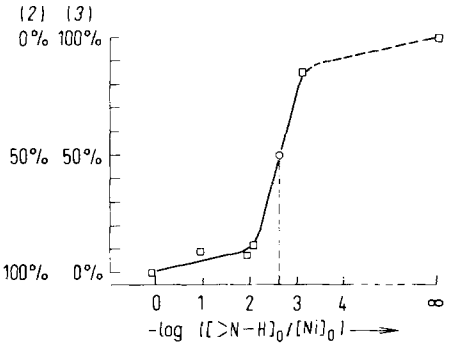

Fig. 1. Products of the catalyzed cooligomerization of *N*-(benzylidene)propylamine with butadiene as a function of the negative logarithm of the molar ratio morpholine : nickel. The sum of the type *(2)* and *(3)* isomers was taken as 100%; molar ratio nickel : Schiff base = 1:50; molar ratio Schiff base : butadiene = 1:2; reaction temperature 40°C [5].

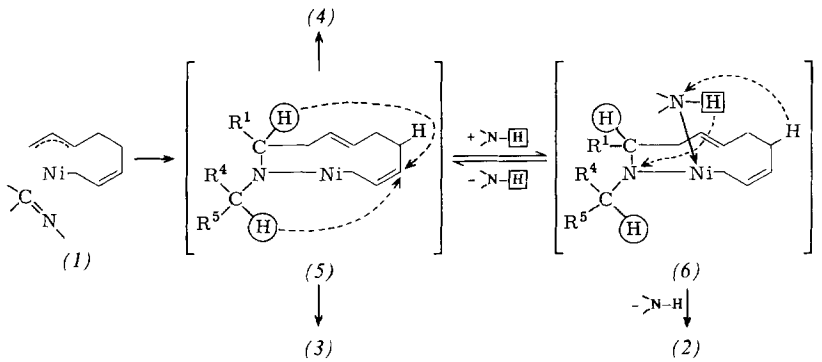

Table 1. Yields and properties of some type *(2)* and *(4)* products. Reaction conditions: 40°C; molar ratio $Ni^{(0)}$: triphenylphosphane = 1:1; butadiene : Schiff base *(1)* = 2:1; Ni : Schiff base *(1)* = 1:50.

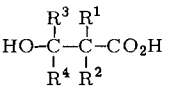
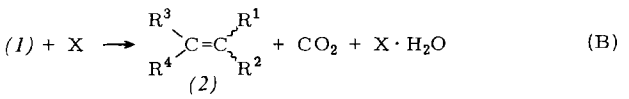
Decarboxylative Dehydration of β-Hydroxycarboxylic Acids by Redox Condensation: A Novel Olefin Synthesis

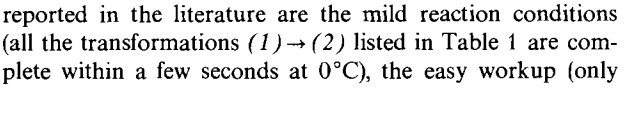


By *Johann Mulzer* and *Gisela Brüntrup*[*]

By addition of carbonyl compounds to the dilithium salts of carboxylic acids a wide variety of β-hydroxycarboxylic acids *(1)* can be obtained in good yields[1]. The decarboxylative dehydration of *(1)* according to eq. (B) leads to the olefins *(2)*, the combination of (A) and (B) being an attractive alternative to the Wittig reaction.



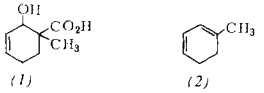
Depending on the nature of the dehydrating reagent X eq. (B) can be realized in two variations I or II. Thus, with X = dimethylformamide acetal, for example, olefin formation and elimination of H_2O and CO_2 proceeds in *one* step (variation I[2]). Alternatively, if X = arenesulfonyl chloride, *(1)* is first converted into its β-lactone, from which *(2)* is subsequently obtained by thermal elimination of CO_2 (variation II[3]). We report here on a novel method for variation I utilizing the principle of the redox condensation[4]. The reagent X we use is the adduct of triphenylphosphane and ethyl azodicarboxylate[5]. This adduct is capable of binding the H_2O which is formed according to eq. (B) in an exergonic process [eq. (C)].



(A)

(1)

(B)



(C)

The advantages the new method has over those already reported in the literature are the mild reaction conditions (all the transformations *(1)* → *(2)* listed in Table 1 are complete within a few seconds at 0°C), the easy workup (only nonvolatile and hence easily separable byproducts are formed), and the low cost of the reagents employed (azodicarboxylate can be readily prepared on a large scale from hydrazine, chloroformates and an oxidizing agent[6]). The full scope, the stereochemistry and the mechanism of the reaction are currently under investigation.

Experimental:

To a stirred solution of *(1a)* (3.0 mmol) in anhydrous THF (3 ml) is added a solution of $P(C_6H_5)_3$ (3.0 mmol) in THF (2 ml) under a nitrogen atmosphere. The resulting mixture is treated dropwise with a solution of 3.0 mmol of ethyl azodicarboxylate in THF (2 ml). The rapid progress of the reaction is indicated by the slight warming of the mixture and the instantaneous decoloration of the azoester. After the evolution of CO_2 has ceased, the resulting mixture is stirred for an additional 10 min. The solvent is then evaporated under reduced pressure and the residue triturated with ether/pentane. The triphenylphosphane oxide and the hydrazoester crystallize and are removed by filtration. The filtrate, after stripping

Ionization Barrier of Trityl Chloride in Sulfur Dioxide[1]

By *Martin Feigel* and *Horst Kessler*[*]

Rate constants for ionization and dissociation of a compound RX *via* ion pairs into free ions according to the following simplified Winstein scheme

$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underbrace{R^{\oplus}X^{\ominus}}_{\text{ion pair}} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underbrace{R^{\oplus} + X^{\ominus}}_{\text{free ions}}$$

have so far been studied by two different methods: (i) determination of the solvolytic behavior of RX[2] and (ii) examination of the kinetics of recombination of $R^{\oplus}$ and $X^{\ominus}$ by flow methods[3a] or relaxation techniques[3b]. All these methods use time-dependent changes in concentrations in order to determine kinetic parameters. We now report a study of the ionization kinetics of triphenylmethyl chloride in SO_2 under equilibrium conditions by NMR spectroscopy.

When a solution of trityl chloride in SO_2 is cooled down, the center of gravity of the ^{1}H-NMR signals migrates downfield, indicating a shift of the equilibrium from covalent to ionic species. In addition, the signals exhibit broadening below -40 °C and ultimately split into a spectrum of ionic and covalent trityl chloride. In order to allow a quantitative evaluation of the ^{1}H-NMR spectra we used trityl chloride deuterated in the *ortho* and *para* positions[4] which at low temperatures only gives rise to singlets at $\delta = 7.37$ (covalent trityl chloride) and 7.93 ppm (all ionic forms). Line shape analysis of the coalescence of these two signals (Fig. 1) results in temperature-dependent values of the average lifetimes τ_{ion} (all ions) and τ_{cov} (covalent form). The rate constant k_1 can easily be calculated from τ_{cov} according to

$$k_1 = \frac{1}{\tau_{cov}}; \quad k_{-1} = \frac{1}{\tau_{ion}}\left(1 + \frac{k_2}{k_{-2}\, a_{Cl^{\ominus}}}\right)$$

$a_{Cl^{\ominus}}$: activity of free chloride ions

[*] Prof. Dr. H. Kessler, Dipl.-Chem. M. Feigel
Institut für Organische Chemie der Universität, Laboratorium Niederrad
Theodor-Stern-Kai 7, D-6000 Frankfurt am Main 70 (Germany)

Since the calculation of k_{-1} requires knowledge of the equillibrium constant of dissociation, only the temperature dependence of $k'_{-1} = 1/\tau_{ion}$ (the reciprocal lifetime of all ionic forms) was considered in the compilation of kinetic data (Table 1) for recombination.

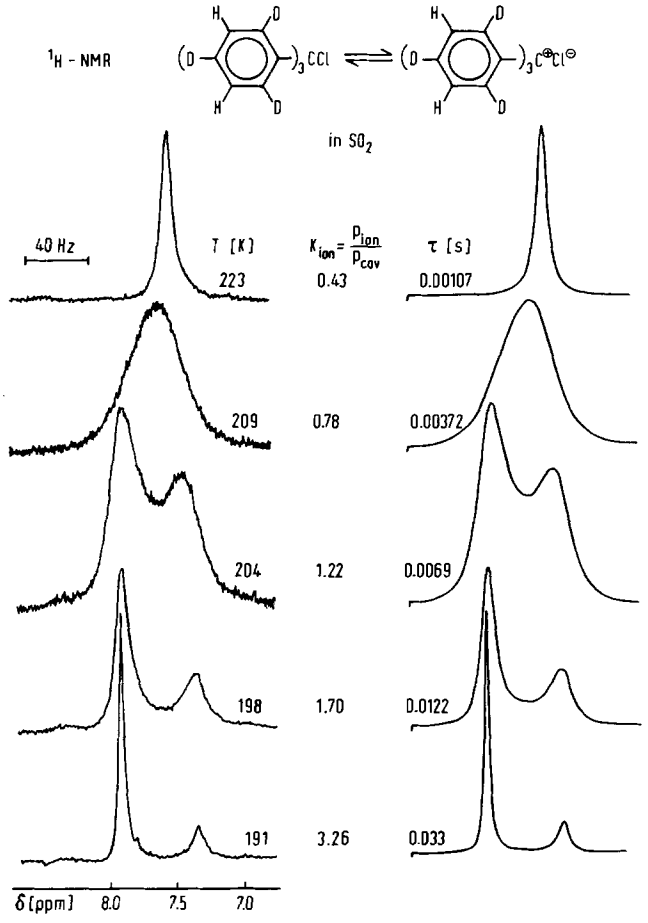

Fig. 1. Line shape analysis (right) of the FT-^{1}H-NMR spectra (left) of nonadeuteriotrityl chloride in SO_2 (0.1 M). The individual mean lifetimes of the ionic and covalent species are given by $\tau_{ion} = \tau/p_{cov}$ and $\tau_{cov} = \tau/p_{ion}$; p_s = population of the species S; $K_{ion} = p_{ion}/p_{cov}$.

Table 1. Activation parameters for trityl chloride in SO_2 (0.1 M).

	Ionization (k_1)	Recombination (k'_{-1}) [a]
$\Delta G^{\neq}_{209}$ [kcal/mol]	10.12 ± 0.05	10.06 ± 0.05
$\Delta H^{\neq}$ [kcal/mol]	5.34 ± 0.5	10.6 ± 0.5
$\Delta S^{\neq}$ [cal/mol·K]	−22.9 ± 3	+ 2.6 ± 3

[a] Recombination pseudo first order, see text.

Whereas enthalpy contributions are mainly responsible for the recombination barrier, the ionization barrier is largely determined by the strong negative activation entropy (Table 1). The higher order of the solvent molecules around the ions than around covalent RX lowers the entropy. It follows from our data that in the transition state the solvation is comparable with that of ion pairs[5].

Regarding the results obtained in less polar solvents the value of $\Delta G^{\neq}_1$ in SO_2 appears high. For example the barrier was estimated to be lower than 4 kcal/mol from S_N1 reactions of trityl chloride in benzene[7]. Furthermore, in dichloroethane the recombination of trityl cations with chloride anions is diffusion controlled[3b]. Since the population of ions and covalent compound are similar in SO_2 (measureable populations p_s are an essential condition for kinetic NMR measurements

at equilibrium; cf. Fig. 1), according to the Hammond postulate the transition state in our case is more similar to the covalent compound than on collapse of the high-energy system of dissociated ions in dichloroethane[8]. Dynamic NMR measurements therefore permit the study of barriers of ionization equilibria, and should thus provide a deeper insight into the transition state of ion recombinations in solution.

Comparison of Calculated and Experimental Electron Difference Densities of Tetracyanoethylene[**]

By *Hans-Lothar Hase, Karl-Wilhelm Schulte*, and *Armin Schweig*[*]

It is assumed[1] that electron difference densities[2] in the region of chemical bonds can be determined with an accuracy[3] of 0.05 e/Å^3. We now report quantum chemical *ab initio* results which cast doubt upon this expectation[4] for the standard example tetracyanoethylene (TCNE)[5].

For this purpose the static and dynamic electron difference densities were calculated in "4—31 G" quality[6]. Figure 1 shows sections through the resulting static *(stat)* and dynamic *(dyn)* densities and also through the experimental *(exp)* densities [in the molecular plane *(A)*, perpendicular thereto through the C=C *(B)*, C—C *(C)*, and C≡N bonds *(D)*]. As shown by the figure, overall agreement between the calculated and the experimental difference densities is surprisingly good. However, some considerable discrepancies (0.5 e/Å^3 for C≡N and 0.4 e/Å^3 for C—C) are found for the difference densities in the bonds (Table 1).

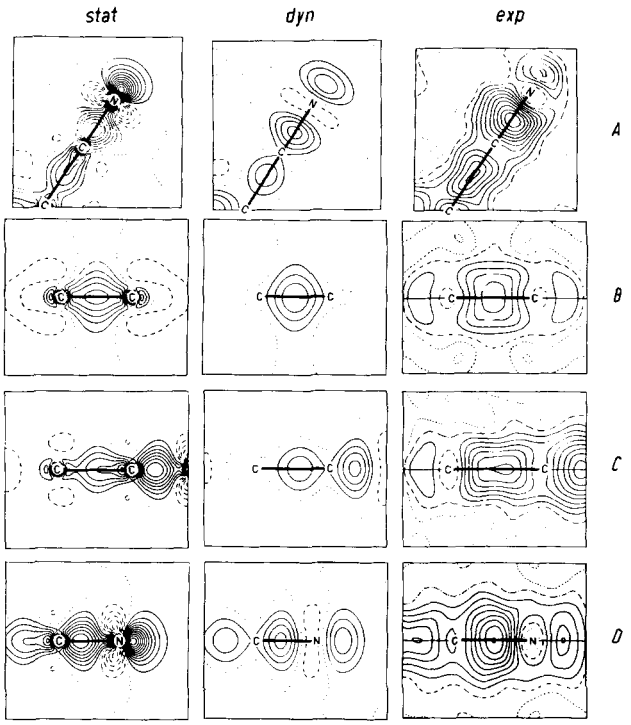

Fig. 1. Calculated ("4—31 G" basis) static *(stat)* and dynamic *(dyn)* and experimental *(exp)* electron difference densities in the molecular plane *(A)* and perpendicular to the molecular plane through the C=C *(B)*, C—C *(C)*, and C≡N bonds *(D)* of tetracyanoethylene (TCNE). The contour lines mark differences of 0.1 e/Å^3 in all cases; positive lines (——), negative lines (– – –), zero line (···· calculated and ·–·– experimental).

The deviations of the calculated values to be expected as a result of using the incomplete "4—31 G" basis have been estimated for the model compound cyanogen (NCCN). For

Table 1. Peak heights in the difference densities of tetracyanoethylene (TCNE).

[**] Part 3 of "Comparison of Observed and Calculated Electron Densities", DFG-Sonderforschungsbereich 127 ("Crystal Structure and Chemical Bonding"). Presented in part at the "Sagamore V" conference, Killjava (Finland), August 16—20, 1976.—Part 2: *H. Irngartinger, H. L. Hase, K.-W. Schulte, A. Schweig*, Angew. Chem. *89*, 194 (1977); Angew. Chem. Int. Ed. Engl. *16*, 187 (1977).

this molecule the static difference density is known in "near HF" quality[7]. As shown by comparison of the corresponding dynamic difference densities in the bonds with the corresponding "4—31 G" values[8] (Table 2) the mutual deviation between the two calculations does not exceed 0.16 (C—C) or 0.18 e/Å^3 (C≡N). "4—31 G" calculations thus prove to be surprisingly reliable for calculations of difference densities.

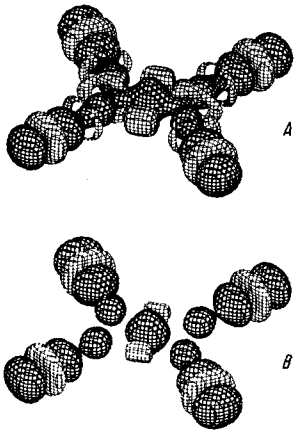

Fig. 2. Perspective representation of the three-dimensional static *(A)* and dynamic *(B)* "4—31 G" difference electron densities of tetracyanoethylene (TCNE) for the values 0.1 e/Å^3 (——) and −0.1 e/Å^3 (——).

These results suggest that the "4—31 G" bond difference densities of Table 1 are falsified by no more than 0.2 e/Å^3 in the critical bonds C≡N and C—C. Thus, the corresponding experimental densities are probably more erroneous than hitherto assumed (0.07 e/Å^3). The large experimental values may possibly be explicable in terms of erroneous scaling[8].

Our results pose the challenge to compare calculated and experimental difference electron densities for other compounds in order to better appreciate their accuracy. The present demonstration of the very good (if not yet optimum) quality of the "4—31 G" difference densities attainable with reasonable effort is an encouraging step in this direction. These densities (static and dynamic) are shown in perspective[9] for TCNE in Figure 2. Corresponding representations of experimental difference densities have not so far been employed in any case.

[2] The electron difference density of a molecule is defined as the difference between the total molecular electron density and the superposed atomic densities of the atoms of which the molecule considered is composed.
[3] Standard deviation in the electron difference densities resulting from statistical errors (in the structure factors, the positional and temperature factors of the atoms, and in the scale factor). Systematic errors (due to approximation corrections of the experimental values or to crystal forces) are not considered.
[4] A somewhat greater standard deviation (0.07 e/Å^3) was estimated for TCNE [5].
[5] *P. Becker, P. Coppens, F. K. Ross*, J. Am. Chem. Soc. *95*, 7604 (1973).
[6] *R. Ditchfield, W. J. Hehre, J. A. Pople*, J. Chem. Phys. *54*, 724 (1971). The total static electron density was calculated with the POLYATOM program system (QCPE, No. 199) on the basis of the experimental geometry [5]. The atomic densities were determined with the RHF program section using the same basis set. In order to determine the dynamic difference electron density according to *H.-L. Hase, H. Reitz*, and *A. Schweig*, Chem. Phys. Lett. *39*, 157 (1976), an orthorhombic unit cell was constructed with the dimensions $a=8$, $b=9$, $c=5$ Å, into which a molecule of TCNE just fits. The temperature factors obtained by neutron diffraction were used [5].
[7] *A. D. McLean, M. Yoshimine*: Tables of Linear Molecule Wave Functions, IBM 1967; *F. L. Hirshfeld*, Acta Crystallogr. *B 27*, 769 (1971).
[8] *P. Coppens*, Acta Crystallogr. *B 30*, 255 (1974). According to this method the maximum bond densities in NCCN are represented by a Gaussian function $\rho = A\exp(-\alpha r^2)$ perpendicular to the bonds and subsequently "smeared out" in simple manner. Our "4—31 G" difference densities give $A=0.8$, 0.4, and 1.1 e/Å^3 and $\alpha=6.365$, 7.354, and 12.237 Å^{-2} for C≡N, C—C, and the lone pair, respectively.

An Economic Basis for Electron Difference Density Calculations[**]

By *Hans-Lothar Hase* and *Armin Schweig*[*]

Experimental electron difference densities are already available for large polyatomic molecules. RHF (Restricted Hartree-Fock) calculations have so far proved impossible for such systems, and calculations with drastically limited basis sets are therefore unavoidable. In this communication we propose such a basis which leads to results of "near RHF" quality and therefore appears very promising for difference density calculations on large molecules.

As shown by a comparison[1], the "4—31 G"[2] difference densities of cyanogen (NCCN) are of surprisingly high quality relative to the "near RHF" densities[3]. However, discrepancies do occur in the peak heights in the difference densities (0.2 e/Å^3) and in the detailed shape of the densities (cf. Fig. 1). As a corrective measure we have tentatively extended the "4—31 G" basis by admixture of limited sets of atomic or bond polarization functions (henceforth abbreviated as AP or BP). Four basis sets were tested explicitly: STO-3G[4] *(A)*; 4—31 G *(B)*; 4—31 G+AP [AP: six d functions at each atom[5]] *(C)*; and 4—31 G+BP [BP: one s and two p functions in the middle of each bond][5] *(D)*.

Table 1. Peak heights in the difference densities of cyanogen (NCCN).

Basis sets		Peak heights in the difference densities [e/Å^3]		
		C≡N	C—C	lone pair
A	STO-3 G	0.1	0.1	1.0

[5] The set of six d functions (d_{xx}, d_{yy}, d_{zz}, d_{xy}, d_{xz} and d_{yz}) contains only five actual d functions, the sixth one ($d_{xx}+d_{yy}+d_{zz}$) being an additional s function. The exponents were taken from a publication by *B. Roos* and *P. Siegbahn*, Theor. Chim. Acta *17*, 199 (1970).—The two p functions used are the p_x and the p_y function. The exponents of the CC bond functions originate from a publication by *R. J. Buenker* and *S. D. Peyerimhoff*, Chem. Phys. 9, 75 (1975). The exponents of the CN bond functions were estimated on the basis of the CC exponents and the average 2s- or 2p carbon α(C) and -nitrogen exponents α(N) according to α(CN) = [α(CC) + α(NN)]/2 and α(NN) = [α(N)/α(C)] · α(CC).—All calculations were performed with the POLYATOM program system (QCPE, No. 199) using the experimental geometry [*C. K. Moller, J. P. Stoicheff*, Can. J. Phys. *82*, 635 (1954)]. We gratefully acknowledge mention of the utility of bond polarization functions by Prof. *W. H. E. Schwarz*, Bonn.
[6] The basis sets *A*, *B*, *C*, *D* contain 60 (20), 80 (36), 104 (60), 89 Gaussian functions (contracted to 45 basis functions).

Isocyanide Synthesis with Diphosgene[**]

By *Giselher Skorna* and *Ivar Ugi*[*]

Elimination of water from *N*-alkyl- or *N*-arylformamides *(1)* is the method of choice for preparation of isocyanides *(3)*[1]. Phosgene in the presence of tertiary amines has proved particularly effective as dehydrating agent[1, 2]. In general, higher yields of isocyanides are obtained with phosgene than with other dehydrating agents; however, phosgene is volatile and highly toxic. Outside production plants, phosgene is no longer readily available owing to the safety legislation concerning its transport. Hence a dehydrating agent is required which is as effective as phosgene in the isocyanide synthesis and yet less dangerous to handle.

We have found that isocyanides *(3)* can be prepared in excellent yields from *N*-monosubstituted formamides *(1)* with diphosgene [perchloro(methyl formate)] *(2)*[3] as dehydrating agent (cf. Table 1).

$$\underset{(1)}{2\,R{-}NH{-}CHO} + \underset{(2)}{Cl{-}CO{-}O{-}CCl_3} + 4\,NEt_3 \rightarrow$$

$$\underset{(3)}{2\,R{-}N{\equiv}C} + 2\,CO_2 + 4\,NEt_3 \cdot HCl$$

Table 1. Synthesis of isocyanides *(3)* with diphosgene *(2)*.

Isocyanide *(3)*	Yield [%] with *(2)*	Yield [%] with $COCl_2$
(3a) Methyl isocyanide [a]	47	37 [1]
(3b) *tert*-Butyl isocyanide [b]	97	82 [1]
(3c) Cyclohexyl isocyanide	98	88 [1]
(3d) Benzyl isocyanide	95	82 [1]
(3e) *p*-Methoxyphenyl isocyanide	95	64 [4]
(3f) Methyl isocyanoacetate	82	47 [5]
(3g) *N*-(L-α-Isocyano-β-phenylpropionyl)-L-phenylalanine methyl ester [c]	75	51 [6]

[a] Tri-*n*-butylamine is used as base and *o*-dichlorobenzene as solvent. On completion of the reaction dry NH_3 is passed through the mixture. Crude *(3a)* is distilled at *ca.* 150 torr/50 °C bath temperature into traps cooled with Dry Ice (cf. [1]).
[b] *o*-Dichlorobenzene is used as solvent. On work-up the mixture is extracted with a phosphate buffer (pH *ca.* 5) and then with 0.5 N NaOH solution.
[c] Reaction performed at −30 °C with *N*-methylmorpholine as base.

Diphosgene has a good chance of becoming the reagent of choice for the synthesis of isocyanides for it is easier to handle and gives higher yields than phosgene. The two-phase phosgene method[8] was found to be more productive only in the synthesis of isocyanomethylpolystyrene[7].

General procedure:

N-Monosubstituted formamide *(1)* (0.10 mol), anhydrous triethylamine (29.0 ml, 21.3 g, 0.21 mol), and anhydrous CH_2Cl_2 (100 ml) are introduced into a three-necked flask fitted with a reflux condenser maintained at −30 °C. Diphosgene *(2)* (6.03 ml, 9.69 g, 0.05 mol) dissolved in anhydrous CH_2Cl_2 is added with stirring at 0 °C over one hour. After stirring for 25—30 min, the temperature is allowed to rise to *ca.* 20 °C and the solution extracted with water (50 ml) and 7.5 % $NaHCO_3$ solution. The organic phase is separated and dried over a 4-Å molecular sieve. The solvent is evaporated *in*

Diastereoisomers with Differing Bond Lengths: Structure Analysis of the Diastereomeric Forms of μ-(1,2-Dichloro-1,2-diphenyldiphosphane)bis(pentacarbonylchromium)[**]

By *Gottfried Huttner, Peter Friedrich, Heinrich Willenberg,* and *Hans-Dieter Müller*[*]

The distances between covalently bonded phosphorus atoms deviate only slightly from an average value of 222 pm, regardless of the nature of the substituents attached to the phosphorus and its formal charge[1]. It therefore appears surprising that the P—P distance in P_2F_4 has recently been determined as 228.1(6) pm[2]. We have now found even longer P—P distances in transition metal complexes of 1,2-dichloro-1,2-diphenyldiphosphane, which can be interpreted at least in part as the result of steric interactions, as demonstrated by structural comparison of two diastereomeric diphosphane complexes.

The symmetrically substituted diphosphane $Ph_2P_2Cl_2$ forms the dinuclear complexes *(1)* with $(CO)_5Cr$[3]. The structures of the *meso* form *(1a)* and of the racemate *(1b)* were determined by X-ray analyses[4] (Fig. 1).

The P—P distance in the *meso* form *(1a)* is 229.0(1) pm and thus lies at the upper limit of the range hitherto observed for the P—P bond lengths of diphosphanes[2, 5] and their complexes[6].

In the racemic form *(1b)* the P—P distance is increased by 3.7 pm to 232.7(6) pm; thus *(1b)* exhibits the longest P—P distance so far reported for diphosphanes.

Since *(1a)* and *(1b)* bear the same substituents at the phosphorus, the difference in the P—P bond lengths can only arise from steric interactions between the substituents which have to adopt a less favorable arrangement in the racemate *(1b)* (C_2 symmetry) than in the centrosymmetric *meso* form *(1a)* (Fig. 1).

To our knowledge the compounds *(1a)* and *(1b)* constitute the first pair of diastereoisomers for which significant differences have been observed in the central bond lengths.

A Monothiooxalato-*O,S*-oxo Complex of Molybdenum Containing Two S_2^{2-} Ligands

By *Karl Mennemann* and *Rainer Mattes*[*]

During studies on the reactivity of mono- and dinuclear halogeno- and oxalato-oxomolybdates(V) towards thiooxalates[1] we isolated from aqueous solution dark red crystals of a molybdenum compound having an unexpectedly high sulfur content. The IR spectrum revealed the presence of *O,S*-coordinated monothiooxalate[2] and of terminal oxygen [ν(MoO): 930 cm^{-1}]; a band at 530 cm^{-1} could not initially be assigned.

X-Ray structure analysis[3] showed the molybdenum atom to be heptacoordinated in the form of a pentagonal bipyramid (cf. Fig. 1): the equatorial plane contains only sulfur atoms, *viz.* the S atom of the monothiooxalate ligand [*d*(MoS): 253(2) pm] and, surprisingly, two S_2 groups with a mean Mo—S distance of 238(2) pm and an S—S distance of 203(2) pm; a terminal oxygen atom and an O atom belonging to the carboxyl group of the monothiooxalate form the two apices of the bipyramid [*d*(MoO): 170(4) and 231(4) pm]. Thus the geometry

[*] Prof. Dr. R. Mattes, Dipl.-Chem. K. Mennemann
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

is analogous to that of the sulfur-free peroxo complex $K_2[MoO(O_2)_2(C_2O_4)]$[4].

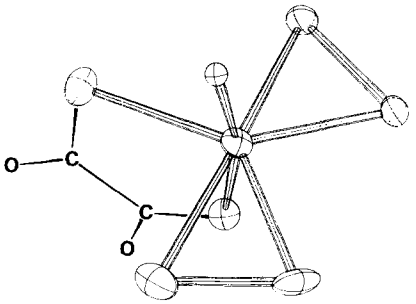

Fig. 1. Structure of the complex anion in cesium bis(disulfido)monothiooxalato-*O,S*-oxomolybdate(VI) *(1)*.

Compounds containing S_2 groups as ligands have hitherto only been found in the case of iridium and rhodium[5], niobium[6], *e.g.* $(\eta^5\text{-}C_5H_5)_2Nb(S_2)X$ with X=Cl, Br, I, SCN, and molybdenum[7], *e.g.* $MoO(S_2)[S_2CN(C_3H_7)_2]_2$. In all cases the IR spectrum contains a band at 520 to 560 cm^{-1} which, as for the new molybdenum complex *(1)*, is to be assigned to an S—S stretching frequency. In the earlier publications cited it is emphasized that the S_2 molecule is bound to the metal center and the metal atom is assigned the resulting oxidation number (*e.g.* Nb^{III}, Mo^{IV}). We are not of this opinion and consider that the niobium and molybdenum compounds, including *(1)*, are better formulated as disulfido complexes (with S_2^{2-} ligands), *i.e.* as sulfur analogs of the peroxo complexes of niobium(V) and molybdenum(VI)[8]. Our reasons are as follows: the structure of the anion of *(1)* corresponds to that of a diperoxomolybdate(VI)[4]; assumption of neutral S_2 ligands would lead to an oxidation number of +2 for molybdenum; however, reduction of Mo^{V} to Mo^{II} is impossible under our reaction conditions. Passage of O_2 through the solution during the reaction actually increases the yield of $Cs_2[MoO(S_2)_2(COS—CO_2)]$. A terminal Mo—O bond with double bond character is not to be expected for Mo^{II}[9].

Procedure:

$Cs_2[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (3 g) is dissolved in H_2O (80 ml) and $Cs_2(C_2O_2S_2\text{-}1,2)$ (6.05 g) is added portionwise to the hot solution. On passage of O_2 it rapidly changes color from dark red *via* dark green to blue. After removal of a yellowish green crystalline precipitate (*ca.* 2 g) which also contains a few red crystals and a red amorphous precipitate, the solution once again turns red. $Cs_2[MoO(S_2)_2(COS—CO_2)]$ precipitates in the cold as dark red to black crystals; yield 350 mg.

Identification of the other products provides important clues about the reaction path; thus the yellowish green crystals are shown by analysis and structural elucidation to be $Cs_2[Mo_2O_2(\mu\text{-}S)_2(C_2O_2S_2\text{-}1,2)_2]$ and the remaining products are likewise sulfur- or oxygen-bridged dimeric dithiooxalato-oxo complexes of molybdenum(V)[10].

Asymmetrical Bridge Complexes of Type $\eta^3\text{-}C_7H_7(CO)_2Mo(OR)_3Mo\text{-}\eta^7\text{-}C_7H_7$ with Two Mo Centers of Different Oxidation Number[**]

By *Basil Kanellakopulos, Dietrich Nöthe, Klaus Weidenhammer, Henning Wienand*, and *Manfred L. Ziegler*[*]

The symmetrical dinuclear complexes $(\eta^7\text{-}C_7H_7)\text{-}MoX_3Mo(\eta^7\text{-}C_7H_7)$ *(1)* with X=Cl, Br, I, OCH_3 were recently synthesized[1] and characterized on the basis of NIR and ESCA investigations as "mixed-valence" compounds[2].

We have now prepared the complexes $(\eta^3\text{-}C_7H_7)(CO)_2Mo\text{-}(OR)_3Mo(\eta^7\text{-}C_7H_7)$ *(2)* [R=CH_3 *(2a)*, C_2H_5 *(2b)*, C_6H_5 *(2c)*, $C_6H_4CH_3$ *(2d)*, C_6H_4Cl *(2e)*][3] by reaction of $(\pi\text{-}C_7H_7)Mo(CO)_2Br$ with sodium alkoxides or phenoxides. Compounds *(2)*—to our knowledge the first asymmetric "mixed-valence" complexes having π-acids as ligands—were identified by elemental analysis, IR and mass spectra, ESR measurements, and by an X-ray structural analysis[4] on *(2a)*. It follows from Figure 1 that the compounds are dinuclear complexes in which the two Mo centers are coupled by three OR bridges; one Mo atom is completely coordinated by a 1—3-η-cycloheptatrienyl and two carbonyl ligands, the second by a 1—7-η-cycloheptatrienyl ligand.

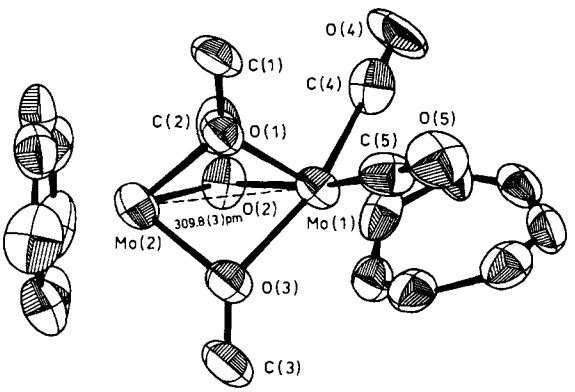

Fig. 1. ORTEP plot of a molecule *(2a)*. The thermal ellipsoids correspond to a probability of 50%; all atoms are drawn true to scale.

As expected, the IR bands in the CO stretching vibration region are shifted to lower wavelengths as compared to the

mononuclear bromide[5]. In the mass spectrum (Varian MAT CH7, 70 eV, ion source 150 °C, vaporization temperature: 175 *(2a)*, 145 *(2b)*, 185 *(2c)*, 198 *(2d)*, 185 °C *(2e)*) only the molecular ion (M^+) can be observed in the case of alkyl derivatives; in the aryl derivatives the lines of highest mass correspond to the fragment ions ($M^+ - 2CO$).

Since no utilizable ^{1}H-NMR spectra of compounds *(2)* could be obtained, ESR investigations were carried out on *(2a)*, *(2b)* and *(2e)*. The species prove to be paramagnetic. Susceptibility measurements (Faraday method) at room temperature yielded a value of $\mu_{eff} = 1.735\,\mu_B$, corresponding to one unpaired electron. The paramagnetic susceptibility remains field-independent from 4.2 up to 300 K for six magnetic fields (between 3.50 and 13.1 kG) and obeys the Curie-Weiss law ($C = 5$ K).

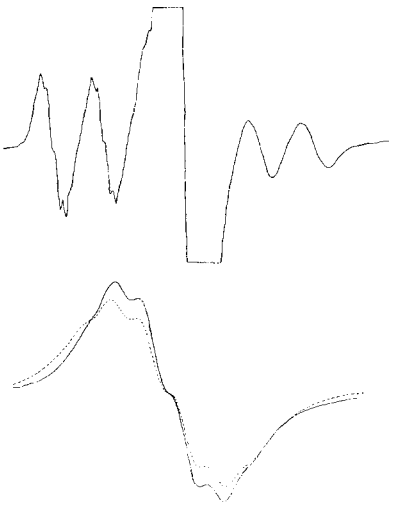

Fig. 2. (Above) ESR total spectrum of *(2a)*. (Below) central line (—— measured, ---- simulated).

As Figure 2 shows, the unpaired electron is located at only one molybdenum nucleus (^{92,94,96,98,100}Mo (75 %), $I = 0$ and ^{95,97}Mo (25 %), $I = 5/2$), otherwise an 11-line spectrum should occur in the case of equivalent Mo atoms, a 36-line spectrum in the case of non-equivalence. The superhyperfine structure points to additional interaction of the electron with magnetically active nuclei; the number of lines and intensity ratios prove the presence of seven magnetically equivalent protons ($a_H = 5.2$ G). No interaction with the bridge ligands is detectable, since there is no alteration in the spectrum on substitution of OCH_3 by OC_2H_5 and OC_6H_4Cl ($g = 1.9537$, $a_{Mo} = 46.4$ G *(2a)*; $g = 1.9529$, $a_{Mo} = 46.7$ G *(2b)*; $g = 1.9530$, $a_{Mo} = 48$ G *(2e)*).

Experimental:

To a solution of π-$C_7H_7Mo(CO)_2Br$ (1.6 g, 5 mmol) in methanol (150 ml) is added 5 mmol $NaOCH_3$ at room temperature. After 48 h the initial green, later yellow-green, solution is evaporated to dryness, the residue taken up in 30 ml CH_2Cl and treated with pentane/petroleum ether (300 ml, 1 : 1). *(2a)* remains in solution and can be isolated as black crystals on removal of solvent by evaporation.

N-Acyl Isocyanides[**]

By *Gerhard Höfle* and *Bernd Lange*[*]

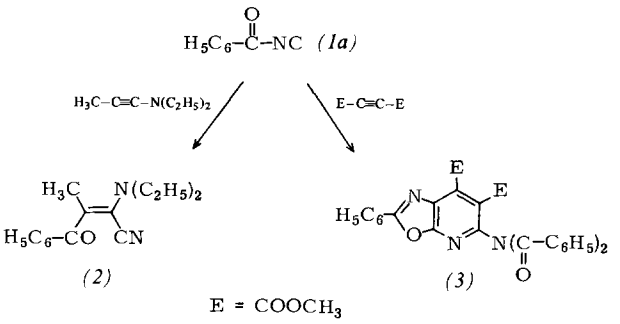
Whereas acyl cyanides were first reported as long ago as 1832 and have since been thoroughly investigated[2], the isomeric *N*-acyl isocyanides *(1)* have so far been neither detected nor synthesized[3]. These compounds should—in contrast to the alkyl and aryl isocyanides—be also capable of reacting as electrophilic carbenes, which would make them attractive reaction partners in cycloadditions.

(1)

We have now succeeded in preparing aliphatic and aromatic compounds of the type *(1)* in a surprisingly simple way by reaction of carboxylic acid iodides with silver cyanide.

R = Aryl, Alkyl

If secondary reactions of *(1)* are interrupted immediately after consumption of the acid iodide by cooling to *ca.* −30 °C then *e.g. N*-benzoyl *(1a)* and *N*-pivaloyl isocyanide *(1b)* can be detected in solution by IR and ^{13}C-NMR spectroscopy. In $CHCl_3$, both compounds show an intense isocyanide band at 2100 cm^{-1} and carbonyl bands at 1738 cm^{-1} [*(1a)*] and 1758 cm^{-1} [*(1b)*]. The ^{13}C-NMR spectrum[4] of *(1a)* shows a carbonyl signal at 154.8 ppm and a signal for the isocyanide group at 165.0 ppm. This finding and the coupling constants $^1J_{^{13}CO,\,^{14}N} = 6$ Hz and $^2J_{^{13}CO\,^{13}CN} = 7$ Hz confirm the postulated structure. It follows by comparison with spectroscopic data of other isocyanides[5] that the acyl moiety in *(1)*, contrary to expectation, only slightly influences the electron distribution in the isocyanide group.



Isolation of *(1a)* is best achieved by low-temperature sublimation in a high vacuum; colorless crystals having a distinct odor of isocyanide are obtained in 73 % yield. *(1a)* is transformed within a few minutes at its melting point of 14 °C into the well-known trimer[6], but is capable of existing for several hours in very dilute solutions[7].

Reaction with methanol gives methyl benzoate in good yield, while reaction with dilute HCl yields benzoic acid and

[**] Reaction of Organic Halogeno Compounds with Silver Cyanide. Part 3. This work was supported by the Deutsche Forschungsgemeinschaft. Part 2: Ref. [1].

N-formylbenzamide. The high carbonyl activation also manifests itself in the rapid rearrangement into benzoyl cyanide with the acyl transferring agent 4-pyrrolidinopyridine[8] and the acylation of 1-diethylaminopropyne to *(2)*. With electron-deficient acetylenedicarboxylates on the other hand the tendency to undergo cycloadditions comes into play. The 1:3 adduct *(3)* is formed in a multistep reaction[3].

Experimental:

Synthesis of *(1a)*: Benzoyl iodide (1.2 g, 5.2 mmol) is added to a solution of AgCN (1.7 g, 12.7 mmol) (precipitated from aqueous solutions of $AgNO_3$ and KCN, washed with methanol and ether without pressing, and dried at 110 °C over P_2O_5) in 25 ml anhydrous CH_2Cl_2. After ten minutes' stirring at 20 °C the silver salts are rapidly separated and the solvent removed by evaporation at −35 °C/0.1 torr. On slowly warming the residue to 0 °C at 10^{-4} torr *(1a)* sublimes and is collected on a cold finger cooled with liquid N_2; yield 0.50 g (73 %), m.p. 14 °C.

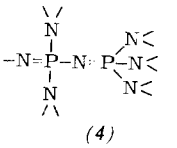
A Diazadiphosphetidine with Ring-Stabilized "Pentaamidophosphorus"[1]



By *Rolf Appel* and *Mechthild Halstenberg*[*]

The cycloaddition of aminobis(imino)phosphorane *(1)*[2] to methyliminotriphenylphosphorane[3] can be applied to numerous other alkyl- and silyl-substituted iminophosphoranes[4]. Of particular interest is the reaction of *(1)* with tris(dimethylamino)methyliminophosphorane *(2)*. The phosphanimide *(2)* contains a phosphorus atom already bonded to four nitrogen atoms. During addition of *(1)* it increases its coordination number and is ultimately surrounded by five nitrogen ligands.

To our knowledge the only phosphorus compound hitherto found to contain a PN_5 unit is the azide $P(N_3)_5$ which was understandably not isolated[5]. In spite of its very modest stability, however, compound *(3)* can be isolated in good yield.

The composition and molecular size of *(3)* have been established by elemental analysis and molecular weight determination. The structure proposed is in accord with ^1H-, ^{13}C-, and ^{31}P-NMR and IR data. The chemical shift of the pentacoordinated phosphorus atom in *(3)* which at −38.3 ppm lies outside the upfield region typical of many pentavalent phosphorus compounds could initially be interpreted as indicating a linear structure *(4)* resulting from silyl group migration.

However, the ^1H-NMR spectrum of *(3)* opposes this alternative: the dimethylamino protons appear as a doublet but an *N*-methyl group as a double doublet. Such strong coupling with the two phosphorus atoms is not to be expected for the linear isomer but is compatible with the cyclic structure *(3)*[9]. Isolation of the PN_5 derivative in this case is probably made possible by the pronounced tendency to form diazadiphosphetidines.

Tris(dimethylamino)methyliminophosphorane (2)[6]:

A solution of hexachloroethane (71.1 g, 300 mmol) in CH_2Cl_2 (200 ml) is added dropwise over a period of 2 h to a stirred solution of tris(dimethylamino)phosphane (48.9 g, 300 mmol) in CH_2Cl_2 (250 ml) at room temperature. Stirring is continued for 2 h and a solution of methylamine (23.3 g, 750 mmol) in CH_2Cl_2 (100 ml) is added dropwise, also over 2 h at room temperature. Stirring, filtration to remove precipitated methylamine hydrochloride, and removal of solvent affords an oil which crystallizes within a day at room temperature. The crude product is digested in ether (500 ml) with exclusion of moisture and after vacuum filtration freed from traces of solvent. The spectroscopically pure[7] solid (69.0 g, 300 mmol = 100 %) is added portionwise at −40 °C to a suspension of sodamide in liquid ammonia prepared from 6.9 g (300 mmol) of sodium. After stirring for 1 h the mixture is allowed to warm to room temperature and the NH_3 evaporated off completely. The residue is taken up in ether (250 ml). Filtration to remove NaCl, concentration of the filtrate, and

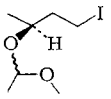
Synthesis and Determination of the Absolute Configuration of Pyrenophorin and Vermiculin[**]

By *Dieter Seebach, Bernhard Seuring, Hans-Otto Kalinowski, Winfried Lubosch*, and *Bernd Renger*[*]



(−)-Pyrenophorin *(1a)* (fungicidal)[1] and (−)-vermiculin *(2a)* (antibiotic)[2] are two simple macrocyclic dilactides ("dilides") with cytotoxic activity. Both have already been synthesized as *d,l* compounds[3]; the absolute configurations (*R,R* or *S,S*) at the C atoms marked with an asterisk in the formulas are so far unknown. We report here on alternative productive syntheses of these two natural products. The starting materials are the optically active building blocks *(S)-(3)* and *S-(4)*[4], from which the hydroxy acids *(1c)* and *(2c)*, respectively, are synthesized. "Dimerizing cyclization" leads respectively to *(1b)* and *(2b)*, which on hydrolysis afford the enantiomerically pure pyrenophorin *(1a)* and vermiculin *(2a)*, respectively. Since the chiral educts were prepared from β-hydroxybutyrate [→ *(3)*] and malic acid [→ *(4)*] ("chiral pool"[5]) of known absolute configuration[4] and since the stereochemistry of the synthesic step at the asymmetric center is known *(vide infra)*, the total syntheses described here also permit assignment of the absolute configurations of the natural products.

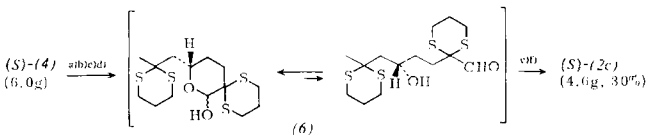
(S)-(4)

"Semipyrenophorin" derivative (1c) (cf. Scheme 1): C—C coupling of acetal-protected iodoalcohol *(3)* by the dithiane method in a one-pot reaction affords the aldehyde *(5)*[6], which is transformed by a Wittig reaction into the α,β-unsaturated ester; hydrolysis of the acetal and ester groups furnishes *(1c)*.



Scheme 1. Synthesis of the hydroxy acid *(1c)*.

a) Addition of *(3)* (opt. purity 90 %) to 2-Li-1,3-dithiane in THF at −100 °C, warmed within 3 h to −78 °C, then within 12 h to +10 °C;
b) *n*-BuLi addition (−40 °C), 30 h at −25 °C (freezer);
c) Addition of dimethylformamide at −78 °C, addition to NaCl solution after warming to −20 °C.
d) Crude product *(5)* heated under reflux with $Ph_3P{=}CH{-}CO_2Me$ in benzene for 30 h, filtration over SiO_2;
e) $HCl/H_2O/THF$, 3 h, room temperature;
f) $LiOH/CH_3OH/H_2O$, 5 h, room temperature, washing of alkaline phase, then $H_2O/H^{\oplus}$, extraction and crystallization of *(1c)*

"Semivermiculin" derivative (2c) (cf. Scheme 2): Three successive C—C coupling reactions by the dithiane method are also carried out here in a one-pot process without workup[6].

Scheme 2. Synthesis of the hydroxy acid *(2c)*.

a) Addition of *(4)* ($[\alpha]_D = -23.9°$ ($c = 4.8$; $CHCl_3$), >95 % opt. purity) to 2-Li-dithiane in THF, 2 d between −78 and −5 °C;
b) 2-Li-2-methyl-1,3-dithiane solution, 1 d between −30 and 0 °C;
c) Metalation with *n*-BuLi/TMEDA; 1 d at −20 °C;
d) Addition of dimethylformamide at −70 °C, warming to −10 °C, workup and isolation of *(6)*.
e) Olefination of crude product *(6)* with $PH_3P{=}CH{-}CO_2Me$, dioxane, 50 h reflux;
f) $LiOH/CH_3OH/H_2O$ analogous to Scheme 1.

[**] Part of the planned dissertation by *B. Seuring*, Universität Giessen. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *H. Gerlach* (ETH Zürich) and Dr. *J. Fuska* (University of Bratislava) for samples.

At low temperature the difunctional electrophile *(4)* reacts only at the "bromine end" with Li-dithiane; subsequent opening of the epoxide with methyldithiane anion and formylation at the initially introduced dithiane center affords the aldehyde *(6)*, which is present almost exclusively as the cyclic semiacetal. The subsequent steps are once again a Wittig reaction with methoxycarbonylmethylenephosphorane and hydrolysis of the resulting ester to the acid *(2c)*, which crystallizes after extractive purification.

Owing to the high yields of all steps and the high stability of the dithiane group towards acids, bases, and strong nucleophiles no workup and/or purification is needed in either synthesis up to the stage where the crystalline 7-hydroxy acid *(1c)* or *(2c)* is obtained (cf. Table 1)[6] and—as can be seen from Schemes 1 and 2—large amounts can be readily synthesized. This demonstrates the advantage of employing 1,3-dithianes for the C—C coupling and nucleophilic acylation, particularly in multistep syntheses.

The only method we have so far used successfully for dimerizing cyclization of *(1c)* and *(2c)* to the dithiane derivatives *(1b)* and *(2b)* of the desired molecules is the azodicarboxylate/triphenylphosphane method[7] [10^{-2} M, toluene, 2d, −25 to +20°C; 60% *(1b)* and 25% *(2b)*, respectively, after preparative thin-layer chromatography, cf. Table 1]. In this reaction—as in intermolecular esterifications[8a]—inversion occurs at the carbinol C-atom[8b]. Hence the "dilides" *(1b)* and *(2b)* and also the samples of (−)-pyrenophorin *(1a)* and (+)-vermiculin *(2a)* (70 and 60% resp.) obtained from them by hydrolysis of the dithiane groups with HgO/$BF_3 \cdot Et_2O$[9] must be (*R*,*R*) configurated and not (*S*) configurated like the precursor. This means that the natural product pyrenophorin has the (*R*,*R*) configuration and natural vermiculin the (*S*,*S*) configuration.

$[Zn_2Cr(OH)_6]X \cdot 2H_2O$, New Layer Compounds Capable of Anion Exchange and Intracrystalline Swelling

By *Hanns-Peter Boehm, Johann Steinle*, and *Carmen Vieweger*[*]

Layer structures with negatively charged layers and intercalated exchangeable cations are well known. They frequently exhibit unidimensional intracrystalline swelling[1]. In contrast, apart from graphite salts, compounds having cationic layers and exchangeable anions have rarely been described[2]. The inadequate interpretation of the observation[3] that zinc oxide turns pink on spraying with an alcoholic solution of chromium(III) nitrate prompted us to study the reaction of ZnO with solutions of Cr^{III} salts. In so doing we obtained a new layer compound in which exchangeable anions are intercalated between brucite-type layers.

ZnO reacts with aqueous solutions of hexaaquachromium(III) or tetraaquadichlorochromium(III) ions at room temperature within several days, and at 60 to 80°C within a few hours, to form a voluminous gray- to pink-violet precipitate which gave a characteristic X-ray powder photograph. Using an excess of chromium, the reflections due to ZnO can no longer be recognized after completion of the reaction.

Analysis of the products dried at 110°C indicated the empirical formula $Zn_2CrO_3X \cdot 5H_2O$ ($X = Cl^-$, NO_3^-, or $^1/_2 SO_4^{2-}$). Since the occurrence of O^{2-} is unlikely under the reaction conditions, we assign the new compounds the formula $[Zn_2Cr(OH)_6]^+X^- \cdot 2H_2O$ by analogy with $[Ca_2Al(OH)_6]^+X^- \cdot 2H_2O$[2a]. Their gray-violet color is compatible with an octahedral arrangement of OH^- ions surrounding the Cr^{3+} ions in brucite-type layers. The coordination number of 7 found for the Ca ions in $[Ca_2Al(OH)_6]^+$ compounds[4] appears unlikely for the smaller Zn ions, which presumably occupy octahedral or tetrahedral sites in the hydroxide double layers.

The reflections observed in the relatively simple X-ray powder diagram (Cu-Kα radiation) could be interpreted as (00*l*) reflections and broadened two-dimensional (*hk*) reflections of a turbostratically perturbed layer lattice. The basal spacings (in the *c* direction) depend upon the kind of anion intercalated (cf. Table 1). The (*hk*) reflections were indexed as (11), (20), (30), and (22) of a two-dimensional lattice of hexagonal symmetry with $a_0 = 0.536$ nm. This corresponds to the diameters of two OH^- in a dense triangular packing. The equivalent area per unit layer charge of 0.249 nm^2 is very similar to that in micas. Some samples exhibited weak

[*] Prof. Dr. H. P. Boehm, C. Vieweger

Meiserstrasse 1, D-8000 München 2 (Germany)
Dr. J. Steinle
Present address: AEG-Telefunken AG, D-4788 Warstein 2 (Germany)

and diffuse (*hkl*) reflections. The densities determined by pyknometry indicate the presence of one formula unit per unit cell, which contains in the *c* direction two hydroxide layers and one anion layer. The X-ray densities are only slightly lower than those calculated from *Biltz* spatial increments[5] for the components. All attempts to age the finely divided precipitates (specific surface area 5 to 22 m^2/g) to give better crystallized substances were unsuccessful.

The chloride initially dried at room temperature had a slightly greater basal spacing (0.776 nm) which fell irreversibly at 110°C to the value given in Table 1 (weight loss 11.49% corresponding to 2.27 H_2O per formula unit). No change in basal separation was observed on drying of the nitrate, although it irreversibly lost 4.32 H_2O per formula unit at 110°C.

The X^- anions of the compounds are exchangeable. Thus after the action of 2 M $NaNO_3$ solution on the chloride for 1 h the Cl^- could be detected quantitatively in the solution (after 15 min at 60°C); the layer separation of the reaction product corresponds to that of the directly synthesized nitrate. Complete exchange was also accomplished with solutions of NaF, $NaHCO_3$, and Na_2SO_4; with $NaClO_4$ only 50% of the anions were exchanged in the first step. Likewise, only 90% exchange took place in the first step between the nitrate and 1 M NaCl solution, only 52% with bromide solution, and only 41% with iodide. Especially large basal separations were measured after treatment with sodium alkyl sulfates (Table 1). Deviations in the last decimal place of the given values were observed on repeating the experiments. This phenomenon, which may be due to additional inclusion of water or to irregularities in the conformation of the alkyl chains[6], was also observed with *n*-alkylammonium layer silicates[7].

$^1/_2\,HPO_4^{2-}$	1.090		

The compounds having inorganic anions in the intercalated layers do not display unidimensional swelling in water or other polar solvents. In contrast, we found the compounds with X^- = alkyl sulfate to undergo unidimensional swelling under *n*-alkyl alcohols or *n*-alkylamines (Table 2). This behavior is analogous to that of alkylammonium layer silicates[1, 7]; the basal spacing after inclusion of dodecyl sulfate and dodecanol corresponds very closely to the value calculated for alkyl double layers (4.13 nm).

Experiments designed to prepare similar layer compounds of the same type in which Zn^{2+} and Cr^{3+} are replaced by other di- and trivalent cations have so far only been successful in the CuO/Cr^{III} salt system.

Table 2. Swelling of $[Zn_2Cr(OH)_6]^+C_{12}H_{25}SO_4^- \cdot nH_2O$ in *n*-alkanols and *n*-dodecylamine.

Swelling agent	*d* [nm]	Swelling agent	*d* [nm]
C_3H_7OH	2.83	$C_{12}H_{25}OH$	4.11
C_4H_9OH	2.92	$C_{14}H_{29}OH$	4.24
$C_6H_{13}OH$	3.08	$C_{16}H_{33}OH$	4.49
$C_8H_{17}OH$	3.37	$C_{12}H_{25}NH_2$	4.17
$C_{10}H_{21}OH$	3.82		

Procedures:

ZnO (2 to 3 g) is stirred with a little water to give a smooth suspension to which is added a *ca.* 1 M solution of a chromium salt (10 ml; pH ≈ 4). The decolorized solution is replaced by fresh solution after 1 d. After repeating the procedure twice the solution is no longer decolorized even after 14 d. The isolated precipitate is washed with water and dried at 110°C.

In order to perform ion exchange, the Cl^- or NO_3^--containing substance (250 mg) is shaken with a 1 N, 2 N, or 5 N solution of alkali metal salt (10 ml). After a given time halide is determined by potentiometric titration of aliquot portions of the solution. The exchange solution is renewed if necessary.

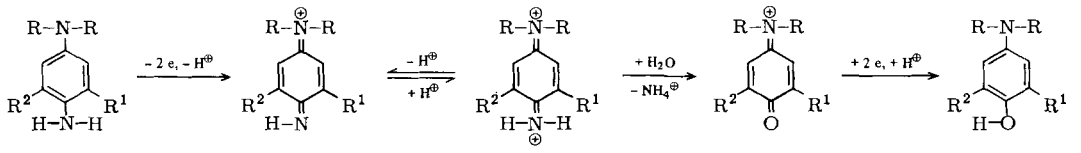
Synthesis of Substituted *p*-Aminophenols from *p*-Phenylenediamines[**]

By *Ulrich Nickel* and *Klaus Kemnitz*[*]



In connection with studies on the mechanism of oxidation of *p*-phenylenediamine derivatives[1] we have also investigated the deamination of the oxidation products. It was found that the unsubstituted imino group is cleaved from oxidation products of type *(2)* at pH ≤ 6 with formation of substituted *p*-quinonemonoimines *(3)*[2].

This reaction offers a facile entry to the often difficultly accessible *N*-substituted *p*-aminophenols from the corresponding derivatives of the *p*-phenylenediamine *(1)*. These must be oxidized rapidly and quantitatively to the quinonediimines *(2)* and then, after a time interval at pH ≤ 2 which is sufficient for complete conversion of the quinonediimine into the quinonemonoimine *(3)*, reduced once again.

In order to avoid side reactions the oxidizing agent must be added before the oxidation, the reducing agent before the reduction. After reduction of *(3)* the pH value is increased

(1) *(2)* *(3)*

(4a): R = C_2H_5, R^1 = R^2 = H
(4b): R = C_2H_5, R^1 = CH_3, R^2 = H
(4c): R = CH_3, R^1 = R^2 = H
(4d): R = R^1 = R^2 = CH_3

for formation of the free *p*-aminophenol *(4)*, which is extracted from the aqueous phase with a suitable solvent.

So far the *p*-aminophenols *(4a)* to *(4d)* have been prepared (as hydrochlorides) in yields of at least 80% and identified on the basis of their UV, NMR, and IR spectra.

$Ce(SO_4)_2$ and iodine are suitable oxidizing agents, and $SnCl_2$ or iodide can be used as reducing agent; so there are several variants for the preparation.

Experimental:

1. *(4a)*, *(4b)*, *(4c)*, *(4d)*: An aqueous solution of *(1)* (10 mmol)[3] is added with vigorous stirring to a solution of $Ce(SO_4)_2$ (22 mmol) in approximately 1 N H_2SO_4 and the mixture poured after *ca.* 5 seconds into an acidified solution of $SnCl_2$ (12 mmol). Cerium and zinc are precipitated as the hydroxides with NaOH, the pH of the filtrate adjusted to about 8 and the resulting solution extracted three times with *n*-amyl alcohol or diethyl ether. The extract is dried over Na_2SO_4 and then evaporated down. The product *(4a)* can be precipitated as the hydrochloride. A slight red coloration of the solution after addition of alkali is due to partial oxidation of the *p*-aminophenol by atmospheric oxygen; this can be avoided by working under nitrogen.
2. *(4a)*, *(4c)*: Oxidation is carried out as described under 1, but after *ca.* 5 seconds the reaction mixture added to an aqueous solution of about 60 mmol KI. The iodine formed is reduced with thiosulfate, the pH adjusted to 8 and the solution then treated as described under 1. This procedure involves one more working step, but less hydroxide is precipitated. Part of the iodine can be recovered by extraction with CCl_4 before the reduction with thiosulfate.
3. *(4d)*, *(4c)*: A particularly elegant procedure is oxidation with iodine[1, 4] and subsequent reduction with the iodide formed, but this is only applicable in dilute solutions: A solution of *(1)* (2 mmol) in semi-concentrated phosphate buffer (about 100 ml) is oxidized with 2.1 to 2.2 mmol KI_3 in H_2O (about 100 ml). The solution is poured after about 30 seconds into 50 ml *ca.* 1 N HCl, whereupon the quinonemonoimine *(3)* is reduced by the iodide formed during the oxidation to the *p*-aminophenol, the iodine being recovered. The solution is then worked up as described under 2.
4. *(4b)*, *(4d)*: If the *p*-phenylenediamine derivatives *(1)* must be first prepared *via* the corresponding *p*-nitroso compounds they need not be isolated. All that is necessary is to reduce the nitroso compound, *e.g.* with hydrazine hydrochloride in the presence of Raney nickel, pour the reaction solution after separation from solid phase directly into the acidic solution of the oxidizing agent, and then continue as in 1.

Resynthesis of Phalloidin and Phallisin from the Seco-Compounds[1]

By *Eisuke Munekata, Heinz Faulstich*, and *Theodor Wieland*[*]

The peptide bond between the dihydroxy amino acid and alanine of phalloidin *(1a)* and phallisin *(1b)*, two constituents of the green deathcup toadstool *Amanita phalloides*[2], can be cleaved by relatively mild proton catalysis owing to the neighboring group effect of the γ-hydroxyl group. There result the nontoxic seco-compounds which appear as lactones *(2a)* and *(2b)*, respectively. They are transformed into the anions *(3a)* and *(3b)* by hydroxide ions. We regard the resynthesis of the toxins *(1a)* and *(1b)* from *(3a)* and *(3b)*, respectively, as a key reaction since (i) it could represent the final step of the total synthesis of the natural phallotoxins and (ii) it would provide an entry to analogs if the N-terminal alanine of *(2a)* were removed in an Edman degradation step and replaced by any desired amino acid. Internal peptide linkage is unsuccessful with slowly acting methods (azide-, carbodiimide-, and imidazolide method, as well as activated ester methods) because they regenerate the lactone ring. Nor did we succeed in producing quantities of *(1a)* detectable by paper chromatography from a sample of *(3a)* obtained on an earlier occasion, even upon use of the rapidly acting method of mixed anhydrides which proved successful in the case of secoketophalloidin[3].

We have now found a particularly mild method of executing the hydrolytic cleavage of *(2a)* and *(2b)* and obtaining the anions *(3a)* and *(3b)* in extremely pure form. To this end we ran a solution of *(2a)* or *(2b)* in 4×10^{-3} N aqueous NH_4OH (in which hydrolysis proceeds very slowly) through a column packed with Sephadex LH-20. Compound *(3a)* or *(3b)* appearing as a sharp fraction could be cyclized by the method of mixed anhydrides (cf. [4]). *(1a)* or *(1b)* could be isolated in about 10% yield from the reaction mixture.

(1)

(a), R = H
(b), R = OH

aHyp = *allo*-Hydroxyproline

(2)

(3)

Both the resynthesized toxins were identical with the starting compounds *(1a)* and *(1b)* in all the properties examined: CD spectra as in [5], R_F [TLC on Merck 60 F_{254} silica gel plates in chloroform/methanol/water (65:25:4 v/v)]: *(1a)* = 0.31, *(1b)* = 0.24, UV difference spectra in the presence of actin as in [6], toxicity in white mouse (LD_{50}) of *(1a)*: 2 mg/kg, and of *(1b)* 2.5 mg/mg[2].

Procedures:

Production of *(2a)* and *(3a)* from *(1a)*: A solution of *(1a)* (1.0 g, 1.27 mmol) in trifluoroacetic acid (250 ml) + water (250 ml) is stirred for 15 h at 20 °C and then evaporated down *in vacuo*. The residue is chromatographed on Sephadex G-15 (column 5.5 × 184 cm) with 0.1 N acetic acid. Of the 27.0 ml fractions, Nos. 118—190 afford 780 mg (78 %) of the trifluoroacetate of *(2a)*. No *(1a)* could be detected with cinnamaldehyde-HCl in the TL chromatogram of a sample applied in concentrated form. Conversion into *(3a)* was accomplished by passing *(2a)*-trifluoroacetate (500 mg, 0.63 mmol) dissolved in 0.004 N ammonium hydroxide through Sephadex LH-20 (column 2.2 × 245 cm). On elution with the same solvent *(3a)* appears in Nos. 33—80 of the 6.5 ml fractions; evaporation *in vacuo* affords *(3a)* (418 mg, 82 %) which is homogeneous on electrophoresis.

Cyclization of *(3a)*: To a stirred solution of *(3a)* (390 mg, 0.48 mmol) in dimethylformamide (DMF) (51 ml) + tetrahydrofuran (THF) (38 ml) at −10 °C are added a 1 % solution of trifluoroacetic acid in THF (3.51 ml) and 5 min later a 1 % solution of isobutyloxycarbonyl chloride in THF (6.63 ml). After 25 min the solution is rapidly poured into a mixture of DMF (194 ml) and a 1 % solution of *N*-methylmorpholine in THF (13.3 ml) cooled to 0 °C. The mixture is stirred for 2 h at 0 °C and for 12 h at 20 °C. After evaporation *in vacuo* the residue is chromatographed with 0.2 % NH_4OH on Sephadex LH-20 (column 2.2 × 245 cm) with collection of 6.0 ml fractions. The last third of the first UV absorbing peak (Nos. 121—170) is chromatographed once more on Sephadex LH-20 (column 1.8 × 147 cm) in the same solvent. Compound *(1a)* (33 mg = 8.7 %) appears in Nos. 38—54 of the 7.3 ml fractions; it is identical with the original sample of *(1a)* in each of the above-mentioned properties.—Both procedures can be applied to the phallisin series.

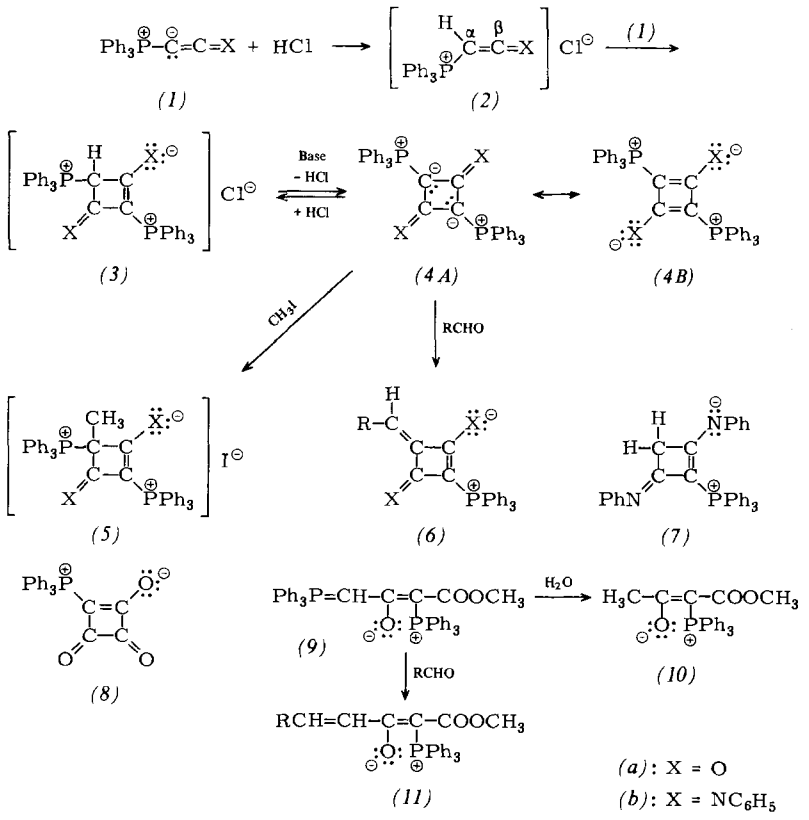
Dimers of Ketenylidene- and *N*-Phenylketeniminylidene-triphenylphosphorane



By *Hans Jürgen Bestmann, Günter Schmid, Dieter Sandmeier*, and *Lothar Kisielowski*[*]

Ketenylidenetriphenylphosphorane *(1a)* and the *N*-phenylketeniminylidenetriphenylphosphorane *(1b)* are monomeric[1], strongly nucleophilic ketene derivatives that do not dimerize. Their dimers *(4)*, which can be described by the resonance formulas *(4A)* ↔ *(4B)*, are therefore of interest, since their mesomeric form *(4B)* represents yet another type of "push-pull" cyclobutadiene[2]. We have been able to synthesize the compounds *(4)* *via* the route shown in the following reaction scheme.

Slow addition of ½ equivalent of HCl to a solution of the heterocumulene ylides *(1a)* or *(1b)* leads *via* protonation at the ylidic C-atom to their transformation into the phosphonium salts *(2a)* or *(2b)*, which are now "real" ketenes or ketenimines having ambident dipolar character, *i.e.* nucleophilic at C_α and electrophilic at C_β[3]. They undergo spontaneous cycloaddition with non-protonated *(1)* to give the 1,3-cyclobutanedione derivatives *(3a)* and *(3b)*, respectively[4]. *(3a)*: m.p. 270 °C (sinters); ^{1}H-NMR[5] ($CDCl_3$): τ = 3.85 (d, J_{PH} = 8 Hz, $P^\oplus$−CH); ^{31}P-NMR[5] ($CDCl_3$): δ = −18.95 (d, $P^\oplus$−CH), +1.36 ppm (d, $P^\oplus$−C<, J_{pp} = 5.72 Hz); IR: 1760, 1645 cm^{-1} (CO); yield 96 %. *(3b)*: m.p. 236 to 238 °C; ^{31}P-NMR[5] (d_6-DMSO): δ = −22.04 (d, $P^\oplus$−CH, J_{pp} = 5 Hz), +4.08 ppm (broad s, $P^\oplus$−C<); IR: 1608, 1572 cm^{-1} (C=N); yield 82 %.

Reaction of the phosphonium salts *(3)* with bases, particularly sodium bis(trimethylsilyl)amide[6], leads to the bisylides *(4)*, which can be regarded as dimers of *(1)*. Evidence of participation of the cyclobutadiene resonance formula *(4B)* is afforded by the position of the CO frequencies in the IR spectrum of *(4a)* at 1650 and 1610 cm^{-1} and that of the C=N bands of *(4b)* at 1563 and 1527 cm^{-1}.

[*] Prof. Dr. H. J. Bestmann, Dr. G. Schmid, Dipl.-Chem. D. Sandmeier, Dipl.-Chem. L. Kisielowski
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestr. 42, D-8520 Erlangen (Germany)

(4a): yellow crystalline powder, m.p. 278 to 280 °C (charring) ^{31}P-NMR[5] ($CDCl_3$): $\delta = +9.48$ ppm (s); yield 83 %. *(4b)*: yellow crystalline powder, m.p. 178 °C (dec.); MS: $m/e = 754$ (M^+), 492 [$M^+ - 262$ (Ph_3P)]; yield 63 %.

The following, in part preparatively useful reactions confirm the structure of the compounds *(4)*: Reaction with HCl regenerates the phosphonium salts *(3)*. Reaction of *(4a)* and *(4b)* with methyl iodide affords the known phosphonium salts *(5a)* and *(5b)*[7a]. On reaction of *(4a)* and *(4b)* with *p*-nitrobenzaldehyde the phosphoranes *(6a)*[7a] and *(6b)*[7b] are formed (R = *p*-$NO_2C_6H_4$). Hydrolysis of *(4b)*[8a] in aqueous methanol affords the monoylide *(7)* [m.p. 221 °C, ^{1}H-NMR (d_5-pyridine): $\tau = 8.18$ (s, CH_2); MS: $m/e = 494$ (M^+); yield 52 %]. Oxidation of *(4a)* with the adduct of ozone and triphenylphosphite[8b] leads to the cyclobutanetrione derivative *(8)* [m.p. 258 °C (dec.); ^{31}P-NMR[5] ($CDCl_3$): $\delta = -7.60$ ppm (s), IR: 1769, 1651, 1629 cm^{-1} (CO)], which reacts with benzylidenetriphenylphosphorane to give *(6)*, R = C_6H_5, [m.p. 192 °C; ^{31}P-NMR[5] ($CDCl_3$): $\delta = -0.43$ ppm]. *(4a)* reacts with methanol with ring opening to give the bisylide *(9)*[9] [m.p. 247 °C; yield 79 %], whose two ylide functions differ in reactivity. *(9)* is hydrolyzed by water to the acetylmethoxycarbonylmethylenetriphenylphosphorane *(10)*[10] and reacts with *p*-nitrobenzaldehyde to give the phosphorane *(11)* (R = *p*-$NO_2C_6H_4$) [m.p. 205 °C; yield 69 %].

(1a), R = CH_3, R' = C_6H_5
(1b), R = CF_3, R' = C_6H_5

In contrast to the known, relatively stable acyl-phosphonates and -dialkylphosphane oxides[2], compounds *(1)* are extremely sensitive towards nucleophiles, especially water. *(1a)* and *(1b)*, which can be stabilized by small amounts of $(CF_3CO_2)O$, are also obtained according to

$$(RCO)_2O + HP(O)R'_2 \longrightarrow \underset{(2)}{(1a, b)} + RCO_2H$$

as colorless oils that decompose with loss of CO above 120 and 80 °C, respectively. They were characterized by elemental analysis, IR(phase: film), ^{31}P-NMR (in C_2Cl_4), and mass spectra (Table 1).

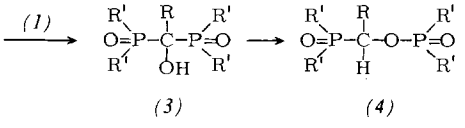

Table 1. IR [cm^{-1}], ^{31}P-NMR (rel. 85% H_3PO_4 ext.) and MS data of the acyldiphenylphosphane oxides *(1)*.

	ν(>C=O)	ν(P=O)	δ^{31}P [ppm]	*m/e* (M^+)
(1a)	1720 s	1200 vs	−21.1	244
(1b)	1781 vs	1215 vs [+ν(CF_3)]	−30.4	298

In comparison with the acyldiarylphosphanes $RC(O)PR'_2$, in *(1)* ν(>C=O) is shifted by *ca.* 45 [*(a)*] and 80 cm^{-1} [*(b)*] to shorter wavelengths. In the $^{31}P\{^1H\}$-NMR spectra only one singlet occurs in each case, as in $CH_3C(O)P(C_6H_5)_2$ ($\delta = -16.6$ ppm; CCl_4); in the spectrum of $CF_3C(O)P(C_6H_5)_2$, on the other hand, a quartet occurs at $\delta = -17.6$ ppm ($J_{PCCF} = 16$ Hz).

With the isolation of the phosphane oxide *(1)* we are now able to explain completely the course of the oxidation of acyldiarylphosphanes[3] to [1-diarylphosphoryl-1-H(perfluoro)alkyl]diaryl phosphinates *(4)*:

$$RC(O)PR'_2 \xrightarrow{O_2} (1) \xrightarrow[-RCO_2H]{H_2O(D_2O,\ H_2{}^{18}O)} (2)$$

(3) *(4)*

The initially formed acylphosphane oxide *(1)* is very readily hydrolyzed to phosphane oxide *(2)* and the free acid RCO_2H. *(2)* reacts with excess *(1)* to give the alcohol *(3)*, which rearranges irreversibly into the thermodynamically more stable phosphinate *(4)*. The hydrogen atom in *(2)*, *(3)* and at the chirality center of *(4)* can be exchanged quantitatively for deuterium by employment of D_2O. It can be shown with $H_2{}^{18}O$ that the ^{18}O isotope is situated as expected in carboxylic acid after the transformation step *(1)* → *(2)*. The elimination of CO_2 and CF_3H observed earlier[4] in the oxidation of $CF_3C(O)P(C_6H_5)_2$ is due to a competing reaction, which predominates on rapid introduction of O_2 into an ethereal solution of the acylphosphane.

Experimental:

(1a,b): The reaction vessel is first treated with $(CH_3)_3SiCl$ to render its surface hydrophobic. Dry oxygen is passed into a solution of acyldiphenylphosphane (16 mmol) in diethyl ether (50 ml) until decoloration of the solution. Introduction of gas must be so regulated that the oxygen is completely absorbed. After removal of the solvent in a high vacuum *(1a,b)* remains behind in quantitative yield.

(3a,b): An ethereal solution (100 ml) of water (5 mmol D_2O or $H_2{}^{18}O$) is added to a solution of *(1a)* or *(1b)* (10 mmol) in anhydrous diethyl ether (100 ml) at room temperature. After a few minutes *(3a,b)* separates out as a colorless precipitate; this is filtered and dried in a high vacuum. Yield *ca.* 85%.

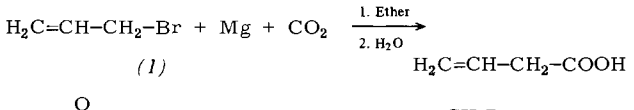
Reviews

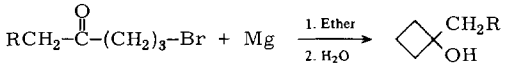
Abstracts of selected progress reports and review articles

***O*-Mesitylenesulfonylhydroxylamine *(1a)* and related aminating reagents** such as *(1b)* and *(1c)* are summarized in a review by *Y. Tamura, J. Minamikawa*, and *M. Ikeda*. Reaction of *(1a)* with the —N= group of nucleophilic heteroaromatic tertiary amines leads under mild conditions to formation of salts of type *(2)* in good yield. With tertiary amines hydrazinium salts are formed, whereas secondary amines react less smoothly. Anionic N-systems such as amides, imides, and pyrroles can be *N*-aminated with *(1)*. *S*-Aminosulfonium salts, valuable intermediates for organic syntheses, are readily accessible directly from *(1a)* and sulfides. Phosphane reacts with the *O*-substituted hydroxylamines *(1)* to give *P*-aminophosphonium salts. Some carbanions are aminated by *(1a)* or *(1c)* to primary amines. On reaction with electrophiles aldehydes and acetones give the *O*-substituted oximes, which are useful for characterization and for further reactions. *(1a)* reacts with Schiff bases to give diaziridines, with acylating

(1a) (1b)



(1c) (2)

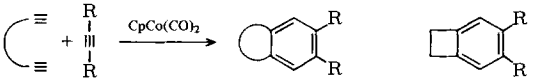


reagents to give *N*-acyl derivatives, and with organoboranes to give primary amines. [*O*-Mesitylenesulfonylhydroxylamine and Related Compounds—Powerful Aminating Reagents. Synthesis *1977*, 1—17; 107 references]

[Rd 934 IE—M]

The Barbier reaction—a one-step alternative for syntheses *via* organomagnesium compounds—is dealt with in an article by *C. Blomberg* and *F. A. Hartog*. In contrast to the two-step Grignard reaction it consists in reaction of organic halides with Mg, in some cases also with Zn, Ca, or Li, in the presence

(1) $H_2C{=}CH{-}CH_2{-}COOH$



(2)

of a substrate in a suitable solvent. Sometimes the Barbier reaction is superior to the Grignard reaction, *e.g.* in the case of allyl halides *(1)*. With CO_2 in ether (preferably with addition of hydrocarbon) they form carboxylic acids, with aldehydes and ketones secondary and tertiary alcohols, respectively. Other aliphatic halides, *e.g.* (substituted) 1-bromo-4-pentanones *(2)*, 5-iodopentane nitriles and 6-iodohexane nitriles may also be employed, whereupon cyclobutanols, cyclopentanones, and cyclohexanones, respectively, are formed. Benzyl halides also undergo the Barbier reaction. Reaction of diiodomethane with carbonyl compounds in the presence of Mg-amalgam affords unsaturated hydrocarbons, *e.g.* cyclohexanone → methylenecyclohexane, *p*-chlorobenzaldehyde → *p*-chlorostyrene. Spirosilanes can be prepared by reaction of butadiene with Mg and a halosilane. [The Barbier Reaction—A One-Step Alternative for Syntheses *via* Organomagnesium Compounds. Synthesis *1977*, 18—30; 80 references]

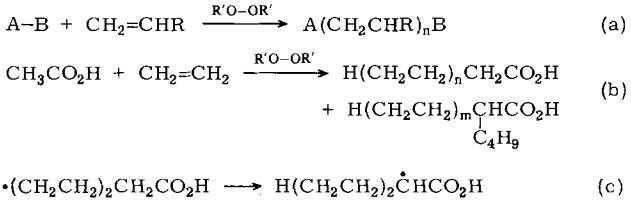
Transition metal-catalyzed cyclizations of acetylenes form the theme of a report by *K. P. C. Vollhardt*. Indanes and tetralins, for example, can be synthesized from 1,6-heptadiynes or 1,7-octadiynes and monoacetylenes according to the scheme *(1)* + *(2)* → *(3)*. $CpCo(CO)_2$ has proved useful as catalyst. In addition, strongly strained molecules of type *(4)*, anthraquinones, *etc.* are also accessible according to this scheme.



(1) (2) (3) (4)

Compound *(2)*, $R=(CH_3)_3Si$, affords trimethylsilyl-substituted products *(3)* and *(4)*, which can be converted into numerous other compounds. Polycycles and heterocycles are likewise obtainable from *(1)* and *(2)* by cooligomerization. [Transition-Metal-Catalyzed Acetylene Cyclizations in Organic Synthesis. Acc. Chem. Res. *10*, 1—8 (1977); 54 references]

[Rd 936 IE—L]

Free-radical rearrangements in telomerization forms the subject of a report by *R. Kh. Freidlina* and *A. B. Terent'ev*. Telomerization can formally be described by equation (a). However, products are also observed [see *e.g.* reaction (b)], which arise from hydrogen shifts in the growing chain [equation (c)].

(a)

(b)

(c)

α,α-Dialkylcarboxylic acids are accessible by a related one-step reaction from unbranched acids. These products are of interest in the varnish industry. [Free-Radical Rearrangements in Telomerization. Acc. Chem. Res. *10*, 9—15 (1977); 48 references]

[Rd 937 IE—F]

Recent developments in heterogeneous catalysis, especially catalysis by metals, are summarized in a review by *J. H. Sinfelt*. An outline of the progress made in the characterization of the degree of dispersion of a metal catalyst on a carrier material is followed by an account of the catalytic activity of a metal in the hydrogenolysis of ethane in relation to its position in the periodic system. The review concludes with a report on catalysis with alloys and related bimetallic clusters. Such clusters are prepared by impregnating a carrier with aqueous solutions of salts of the two metals and reducing the salts with hydrogen. These clusters are often distinguished by their increased catalytic selectivity. [Heterogeneous Catalysis: Some Recent Developments. Science *195*, 641—646 (1977); 38 references]

BOOK REVIEWS

Analytische Methoden zur Prüfung gesundheitsschädlicher Arbeitsstoffe (Analytical Methods for the Testing of Hazardous Working Materials). Edited by *D. Henschler*. Verlag Chemie, Weinheim 1976. Vol. 1: Luftanalysen. 1st edit., xiii, 515 pp., 163 figs., loose-leaf edit., DM 124.—. Vol. 2: Analysen im biologischen Material. 1st edit., xiii. 378 pp., 99 figs. Loose-leaf edit., DM 104.—.

The Deutsche Forschungsgemeinschaft, through its Senate Commission for the Testing of Hazardous Materials, has published, in loose-leaf format, two sets of recommendations for

the determination of harmful materials present in industrial premises (MAK values), namely those in the atmosphere and in biological materials. In the selection of methods for such determinations it is important to have a representative understanding of the action profile, and in this connection special attention is paid to the labor-medicine relevance. The more laborious methods are also recommended when necessary.

The two volumes are structured strictly according to the same scheme. Following an explanation of the basic analytical concepts such as the material to be measured, the measurement quantities, sampling, sample preparation, analytical procedures, single- or multicomponent determinations, attainment and quality (accuracy) of the analytical result, detection limits, specificity, *etc.*, the application and performance of general analytical methods are discussed. The latter are the spectroscopic methods, in particular atomic absorption spectroscopy, gas chromatography, and the electrochemical methods in which ion-selective electrodes are used. The volume on air analyses contains preliminary remarks about the specific sampling methods for this type of work.

About two-thirds of each volume then deals with the specific methods recommended. All those proposed have been carefully checked, especially ones taken from the literature. Where no satisfactory methods had been known, new methods were worked out and were then recommended if they passed experimental testing in an independent laboratory. Particular emphasis is placed on the following features: evaluation of the analytical method, statistical testing of the results, specificity, and detection limits.

The two volumes are perfect examples of careful preparation and recommendation of analytical methods for industrial analyses of materials in air and in biological materials. They constitute a worthwhile enrichment of collected methods, stimulate comparable analytical exercises, and can be recommended without any qualification.

Hermann Kienitz [NB 365 IE]

Einführung in die Chemie und Technologie der Kunststoffe (Introduction to the Chemistry and Technology of Plastics). By *F. Runge* and *E. Taeger*. Akademie-Verlag, Berlin 1976. 4th revised and expanded edition, xiv, 682 pp., 91 figs., 70 tables, 4 charts, bound, *ca.* DM 88.—.

Comparison of the first (1952) with the present fourth edition of this work shows merely by the almost fourfold increase in size the rapid strides that have been made in macromolecular chemistry and its practical applications. There is thus certainly a need for a modern introduction into this academically and industrially important field. Since this is a textbook for a deeper study of the subject, there is a very broad general discussion of the principles of synthesis and states of polymers. The description of the syntheses is based on division into chain and step polymerizations—a principle not yet in general use, but nevertheless a very practical one and into which not merely the classical polycondensations and polyadditions but also the newer "nonclassical" polyreactions such as radical coupling can be readily fitted in. This part of the book provides an excellent introduction into the synthetic methods of macromolecular chemistry. However, the subsequent section on the solid state of polymers and its dependence on structure is distinctly less successful; it is largely restricted to a general discussion of questions connected with properties of direct importance for industrial application.

The chapters "From polymers to industrial materials" and "processing of plastics" are relatively short and purely qualitative; it is true that they contain much about the most important processes and the necessary auxiliary materials, but there is no mention of *e. g.* the methods of testing or of the quantities important for industrial applications and their determination; the elasticity modulus is only very briefly mentioned, and important concepts such as bending strength, elongation, or melt viscosity are completely absent.

The special part of the book is concerned with the most important aspects of industrial polymerization and with the raw materials, manufacturing processes, and the processing of plastics produced industrially. The subdivision is based largely on the structure of the basic skeleton (carbon chains, chains with heteroatoms *etc.*); the individual sections differ greatly from one another in arrangement and depth. The literature references and the tradenames mentioned are also often chosen rather arbitrarily, but to be fair it must be remembered that an introduction of this kind to high-polymeric materials always requires a certain amount of selection, and this naturally emphasizes the authors' point of view more than does treatment of general chemical principles. It should be noted that new developments are covered extensively.

A broad presentation of this kind of an area of chemistry so diverse in raw materials and industrial applications cannot be free from simplifications, but in some places a more precise formulation would have been desirable (for example on page 81, in the treatment of the relationships between the polymerization rate and conversion, where Fig. A 6 is certainly not correct in the general form given); in a later edition at least a few references to further comprehensive works should be added to the general section. In spite of a certain imbalance between the general and the special parts, the book can be recommended as an introduction into the chemical principles of plastics, particularly as hardly anything comparable is available in this form in German-language literature; for information about the actual raw materials the reader must, however, turn to an additional textbook.

The Biochemistry of Sphingolipid Storage Diseases

By Konrad Sandhoff[*]

Sphingolipids are components of animal membranes that are made up of a hydrophobic ceramide and a hydrophilic moiety (phosphorylcholine, oligosaccharides or their derivatives). Several enzymes are required for the step-by-step degradation of the sphingolipids. If one of these enzymes is deficient or totally lacking, then its substrates accumulate in the body and cause severe damage, especially when storage occurs in the nervous system. The enzyme defects are inherited in a recessive manner.

1. Introduction

Up until 1975 over 2300 human hereditary disorders had been described[1]. As early as 1909 it was suggested by *Garrod*[2] that "inborn errors of metabolism" were responsible for these diseases but biochemical lesions have as yet been demonstrated for only 176 of them[1]. If the activity of an enzyme is greatly diminished or totally absent, then the normal flow of metabolism is interrupted at a certain point. If biosynthesis continues uninhibited up to the point of biochemical lesion a pathological accumulation of the substrate of the defective enzyme can result; such accumulations are observed in disorders of numerous metabolic pathways (*e.g.* in the degradation of glycogen, mucopolysaccharides, amino acids, and sphingolipids). Various pathological symptoms, often including mental and neurological disturbances, are observed depending on the nature and importance of the accumulated substances. Unfortunately, in most cases the precise relationship between the biochemical causes and the neurological effects has not yet been elucidated. A connection between the accumulation of a substance and the resulting neuropathological changes can, however, be recognized in the sphingolipid storage diseases which primarily affect the central nervous system. Clinically, the course of several of these disorders is very similar, and it is only as a result of the analysis of the pathologically increased sphingolipids and the identification of the specific enzyme defects that it is possible to distinguish clearly between the individual diseases.

2. Sphingolipids

The membrane-forming lipids of mammals are essentially glycerol phosphatides, cholesterol, and sphingolipids. Although the glycerol phosphatides are the most important quantitatively, no disease is known which is caused by a primary storage of such a phosphatide. It is remarkable however, that almost every sphingolipid can be accumulated pathologically in humans; these storage diseases are called the sphingolipidoses. Historically speaking, the investigation of these diseases led to the discovery of several sphingolipids such as the gangliosides[3–9] and glucocerebroside, also known as glucosylceramide[10].

Ceramide, the hydrophobic part of the molecule, is characteristic of all the sphingolipids: it consists of sphingosine (*trans*-(2*S*,3*R*)-2-amino-4-octadecene-1,3-diol) or a sphingosine analog as base with a fatty acid moiety bound to its amino group (Fig. 1). The sphingolipids are differentiated by the nature of their hydrophilic groups which are bound to the primary hydroxyl group of the sphingosine. In the case of

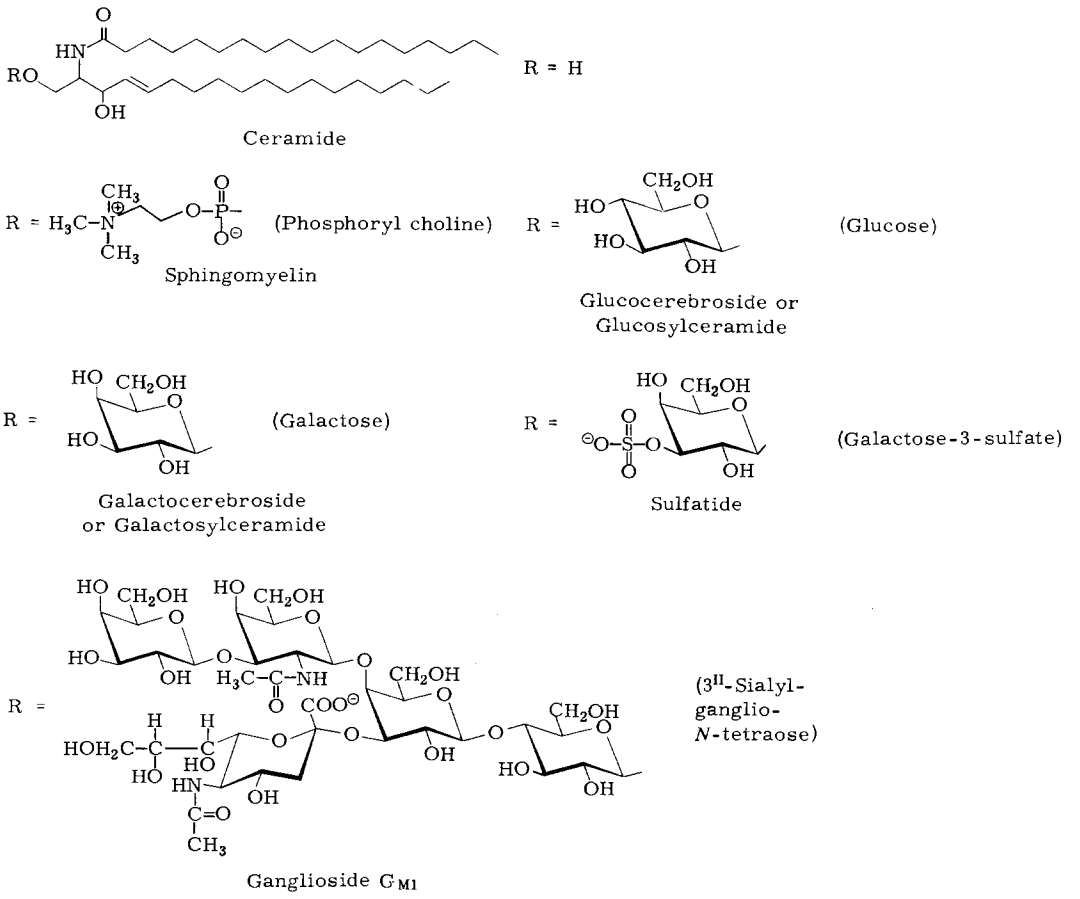

Fig. 1. Structure of some sphingolipid storage substances.

the most common sphingolipid, sphingomyelin, the hydrophilic component is phosphorylcholine. In the glycosphingolipids the hydrophilic component is either a sugar residue, as in the cerebrosides, or an oligosaccharide chain which, in the case of the gangliosides, contains sialic acid (*N*-acylneuraminic acid) as a characteristic structural unit[11]. The "pure" sphingolipids which have so far been prepared are rarely homogeneous in terms of their hydrophobic components, but contain only one type of hydrophilic residue. It is the latter which is mainly responsible for the different chemical and physiological behaviors of the complex lipids. Variations in the hydrophobic ceramide component play only a minor role in large molecules such as the gangliosides. In addition to sphingosine, dihydrosphingosine and a sphingosine analog with 20 instead of 18 carbon atoms are also found[11,12]. The fatty acid component of the ceramide is also heterogeneous; one fatty acid is always found in especially high concentrations (*e.g.* stearic acid in brain gangliosides) but its nature depends on the source of the ganglioside.

3. Localization and Function of the Sphingolipids

Sphingolipids, in particular the glycosphingolipids, are constituents of cell membranes[13]. The glycosphingolipids, in contrast to the ubiquitous sphingomyelin, are found predominantly as membrane components in nervous tissue. The neuronal plasma membrane is especially rich in gangliosides[14] whereas galactocerebrosides and sulfatides are mainly present as structural components of myelin (*i.e.* in the white matter of the brain)[15]. However, sphingolipids are also found in all other animal tissues although in smaller quantities than in nervous tissue. The comparative studies of *Klenk* and *Yamakawa* on erythrocyte membranes have led to the present concept that every animal cell type can have a specific glycosphingolipid pattern which exhibits species differences (cf.[16,17]). Differentiated cells exhibit a more complex pattern than undifferentiated cells. Thus a simplification of the glycosphingolipid pattern is also observed in cells which have been transformed by virus infection (cf. [13]).

These findings indicate that glycosphingolipids play a specific role in the formation of individual cell types but little is known about their function. Their oligosaccharide residues and those of the glycoproteins influence the properties of the cell surface. In addition, the gangliosides create negative charges on the cell membrane and serve as receptors for numerous substances (*e.g.* cholera toxin[18–23], enterotoxin[24,25], α-toxin[26–28], interferon[29], thyrotropin[30], and possibly tetanus toxin[31,32]). According to *Roseman*[33,34], the glycosphingolipids might be important for the mutual recognition and adhesion of cells.

4. Formation and Degradation of the Sphingolipids

The biosynthesis of the sphingolipids always begins with the formation of their hydrophobic component, the ceramide. The structural units of the hydrophilic component are then attached step by step to the primary hydroxyl group[33,35–39]. Each monosaccharide is transferred onto the end of the grow-

ing oligosaccharide chain from an activated form, a sugar nucleotide, depending on the specificity of cell-specific transferases (Fig. 2). For the formation of the sulfatides, sulfate is transferred from 3′-phosphoadenosine 5′-phosphosulfate to a galactocerebroside. In the case of sphingomyelin synthesis, phosphorylcholine is transferred from cytidine diphosphate choline or phosphatidylcholine[40] to a ceramide.

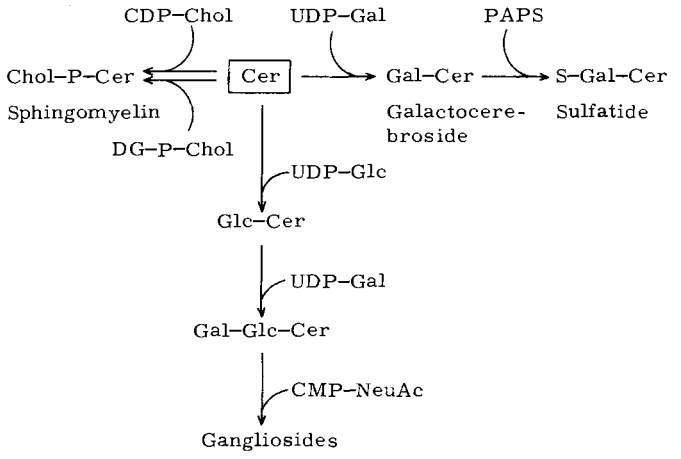

Fig. 2. Biosynthesis of sphingolipids. Abbreviations: CDP = cytidine diphosphate, Cer = ceramide, Chol = choline, CMP = cytidine monophosphate, DG = diacylglycerol, Gal = D-galactose, Glc = D-glucose, NeuAc = *N*-acetylneuraminic acid, P = phosphate, PAPS = 3′-phosphoadenosine 5′-phosphosulfate, UDP = uridine diphosphate, S = sulfate.

The biological degradation of the sphingolipids is catalyzed by hydrolases[12,37] which display their optimal activities in the acid pH range. They are stored intracellularly in membrane-bound sacs, the lysosomes, and are thus separated from the cytosol of the cell. In general, their specifity is directed towards certain types of bonds rather than towards individual substrates. Together, they can cleave a range of macromolecules (*e.g.* proteins, nucleic acids, polysaccharides, and complex lipids) into their structural units. The degradation of sphingolipids (Fig. 3 and Table 1) begins at the hydrophilic end of the molecule. The oligosaccharide chain is shortened step-by-step by removal of the terminal residues. Sphingomyelin is split up directly into phosphorylcholine and a ceramide which is subsequently cleaved to give sphingosine and a fatty acid. The question of how the sphingolipids are enclosed within the lysosomes is still largely unexplained.

5. Disorders of Degradation

Inherited disorders of sphingolipid metabolism have so far been observed almost exclusively in their degradation[41–44]. The resulting accumulation of lipids shortens the lives of the patients to a greater or lesser extent. In contrast, only one case is known of a possible hereditary disorder of sphingolipid synthesis (cf. Section 10.6). It seems reasonable to assume that genetically linked disorders of synthesis and the associated deficiencies in certain sphingolipids and their functions are

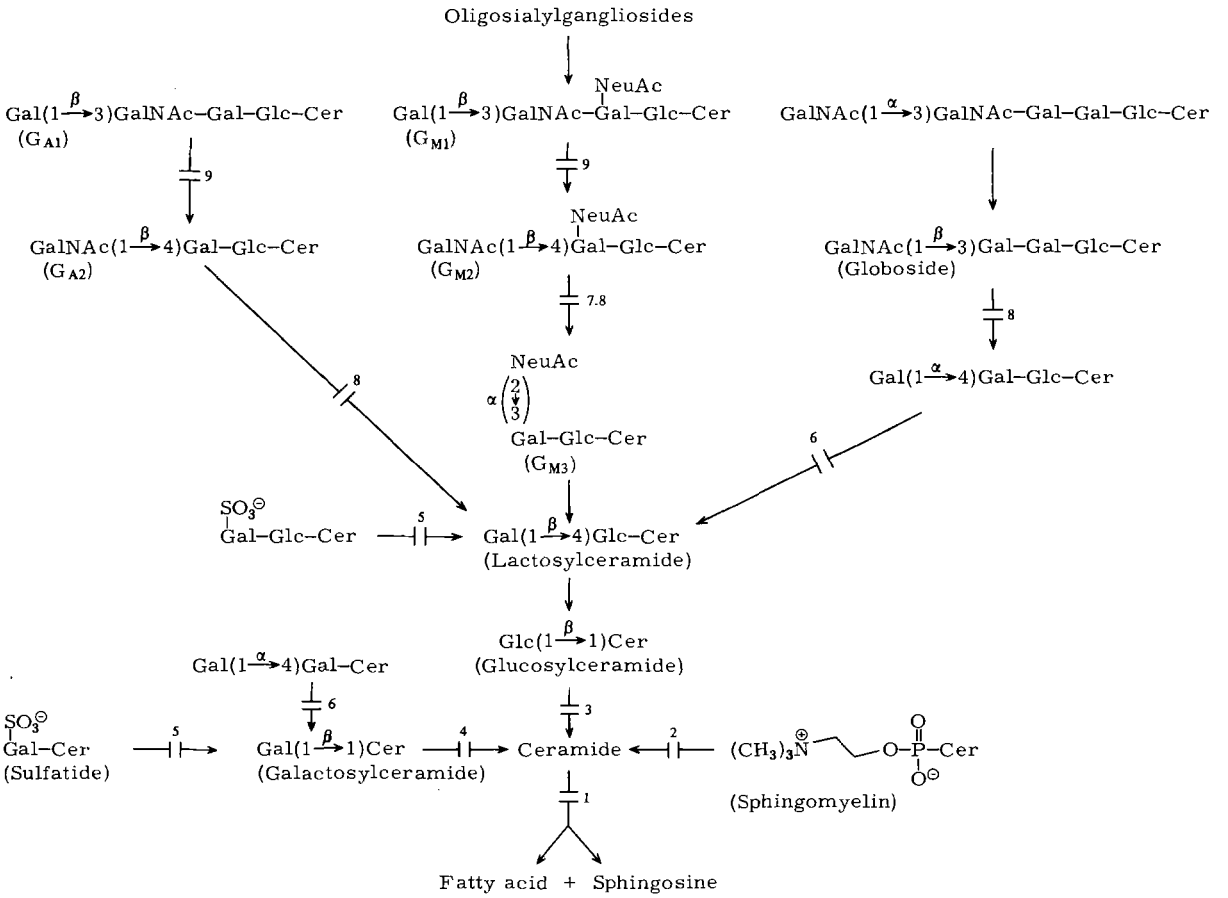

Fig. 3. Degradation of sphingolipids. The positions at which the degradation is interrupted by hereditary enzyme deficiencies are indicated by numbers which correspond to those in Table 1.

Table 1. Degradation of sphingolipids. The numbers in Fig. 1 refer to inherited enzyme defects leading to the storage diseases named.

No.	Disease	Defective enzyme	Stored substance; principal storage site
1	Farber's disease (ceramidosis)	Ceramidase	Ceramide; viscera and brain
2	Niemann-Pick s disease (sphingomyelinosis)	Sphingomyelinase	Sphingomyelin; viscera and brain in Type A
3	Gaucher's disease (glucocerebrosidosis)	Glucocerebroside β-glucosidase (glucosylceramide β-glucosidase)	Glucosylceramide; viscera and brain in infantile form
4	Krabbe's disease (galactocerebrosidosis)	Galactocerebroside β-galactosidase	Galactosylceramide; brain (white matter)
5	Metachromatic leucodystrophy (sulfatidosis) and Austin's disease	Sulfatide sulfatase (arylsulfatase A)	Sulfatides; brain and kidney
6	Fabry's disease	α-Galactosidase A	α-Galactosylgalactosylceramide and α-galactosyllactosylceramide; visceral organs
7	G_{M2} gangliosidosis, variant B (Tay-Sachs' disease)	Hexosaminidase A	Ganglioside G_{M2}; brain (gray matter)
8	G_{M2} gangliosidosis, variant 0	Hexosaminidases A and B	Gangliosides G_{M2} and G_{A2}; brain Globoside; viscera
9	G_{M1} gangliosidosis	Ganglioside G_{M1} β-galactosidase	Ganglioside G_{M1}; brain Keratan sulfate [a]; visceral organs

[a] Keratan sulfate is a linear mucopolysaccharide containing the disaccharide unit: [D-galactopyranosyl(β1→4)2-acetamido-2-deoxyglucopyranosyl 6-sulfate (β1→3)].

much more detrimental to life than the storage of these substances in disorders of degradation. Almost every step in degradation can be inhibited by an enzyme deficiency. These enzyme defects, which are schematically represented in Figure 3, are passed on in a recessive manner according to the laws of Mendelian genetics.

Usually, every cell of the human body has two allelic genes at each locus which code for the synthesis of a peptide chain—one gene is from the father and one is from the mother. If one of these genes has mutated and then produces a functionally inactive polypeptide chain or no polypeptide chain at all, this defect is usually not detrimental to the health of the carrier; this is because the second allelic gene synthesizes functional gene products although in only half the normal amount. A person can thus be a carrier of a mutated allele without suffering any damage to his health. A disease is, however, observed if two carriers of a defective allele pass this on to their child; the child therefore has a locus with two defective alleles which do not code for a functional enzyme protein.

The genetically controlled defects of sphingolipid hydrolases occur very rarely with a gene frequency of approximately 0.002 *i.e.* from 1000 genes in the average population which code for an enzyme, two are mutants. In certain population groups much higher values are observed, *e.g.* Tay-Sachs disease has a gene frequency of approximately 0.01 among Jews of East European origin (Ashkenazi)[45].

The lack of an enzyme activity in the lysosomes leads to an intralysosomal build-up of all its substrates[46]; an increase in concentration of more than a hundred-fold is no exception. Storage granules are formed in the cell cytoplasm: these are pathologically transformed lysosomes which are no longer able to digest their contents.

The enzyme defects shown in Figure 3 and Table 1 which block the normal degradation of sphingolipids, occur in all tissues and body fluids which contain lysosomal enzymes—thus they are also found in leucocytes, cultured fibroblasts, and amniotic cells. However, storage only takes place in the tissues in which the lipid substrates of the deficient enzyme are also synthesized. The accumulation of sulfatides in metachromatic leucodystrophy is thus seen mainly in the brain and kidney. In the brain this leads to the destruction of the white matter whereas storage in the kidney is tolerated without any significant injury. In gangliosidoses, the gangliosides G_{M1} and G_{M2}, typical of nervous tissue, are mainly stored in the neurons. Multilaminated bodies containing, in addition to gangliosides, phospholipids, and proteins are found in the cytoplasm of these cells (Fig. 4)[47,48]. The enormous deposition of lipids leads to balloon-like swelling of the nerve cells and ultimately to their destruction.

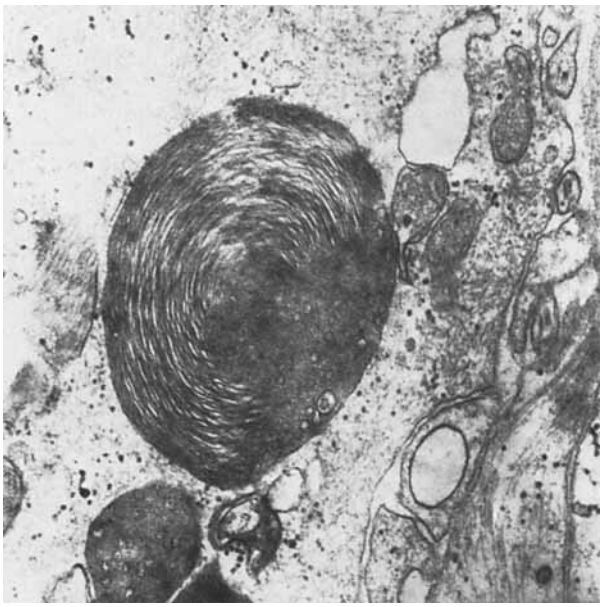

Fig. 4. Multilaminated bodies (MCB) in the cytoplasm of a nerve cell from a Tay-Sachs patient. (Magnification × 54000: micrograph by *E. Sluga*, Wien).

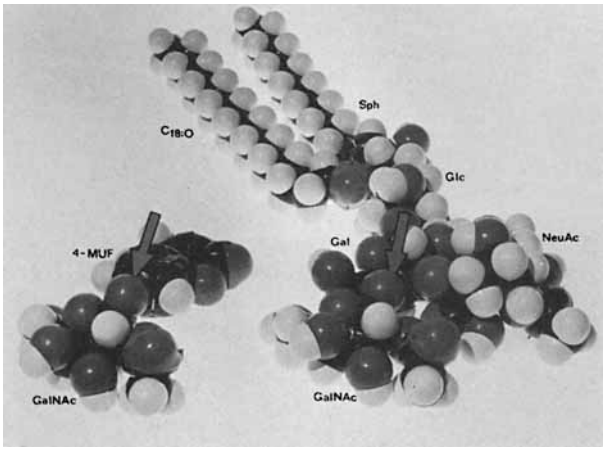
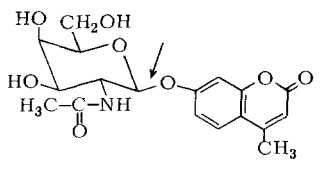
6. Measurement of Sphingolipid Hydrolases

The identification of the relevant enzyme defect is critical for the diagnosis of the storage diseases. Since the lysosomal hydrolases usually have only a low substrate specificity, their activity can be measured not only with natural substrates but also with synthetic, water-soluble substrates. The activity of these enzymes can be most simply determined with fluoro-

genic or chromogenic substrates. 4-Methylumbelliferyl (Fig. 5) and *p*-nitrophenyl derivatives are widely used[49]. In the investigation of tissue extracts with synthetic substrates it often remains uncertain whether it is really only the activity of the enzyme catalyzing the degradation of the relevant, natural lipid that is being measured. Investigation with the natural substrate is therefore often necessary for diagnostic purposes.

Sphingolipids are cleaved very slowly by hydrolases *in vitro*, and it is only when detergents or natural activators are added that easily measured reaction rates are obtained. The inert behavior of these lipids is due to their characteristic solubility properties in aqueous media. They dissolve in a monodisperse form only below a certain concentration known as the critical micelle concentration (CMC). Above the CMC they form micelles (like gangliosides and many detergents) or liposomes which are made up of multilamellated double layers (like the sphingomyelins). Micelles and liposomes are attacked only very slowly or not at all by the hydrolases *in vitro*. The addition of a detergent, usually in concentrations above the CMC, leads to the formation of mixed detergent-lipid micelles; in such a complex the substrate can react with the enzyme.





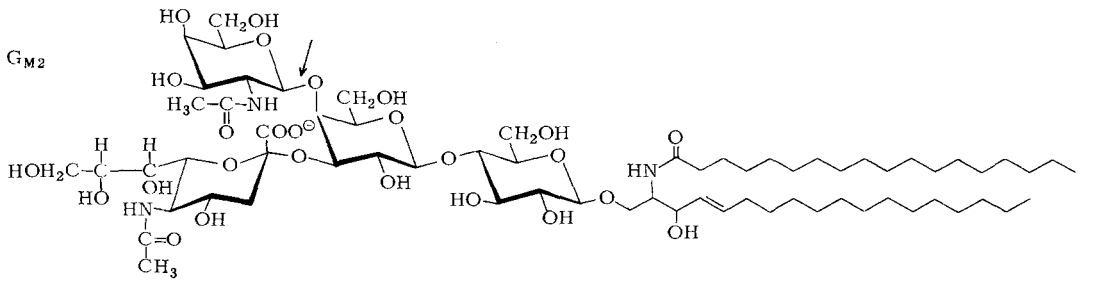


Fig. 5. Comparison between the synthetic and natural substrates of hexosaminidase A (cf. Fig. 3 and Table 1, No. 7), 4-methylumbelliferyl-β-*N*-acetyl-D-galactosaminide (4-MUF-GalNAc) and ganglioside G_{M2}. The β-glycosidic bonds split by the enzyme are indicated by arrows.

4-MUF–GalNAc

G_{M2}

However, the nature of the interaction between lipid, detergent, and enzyme and hence the true substrate concentration remain unknown, and the specification of kinetic parameters (*e.g.* apparent Michaelis constants) is therefore of only limited value.

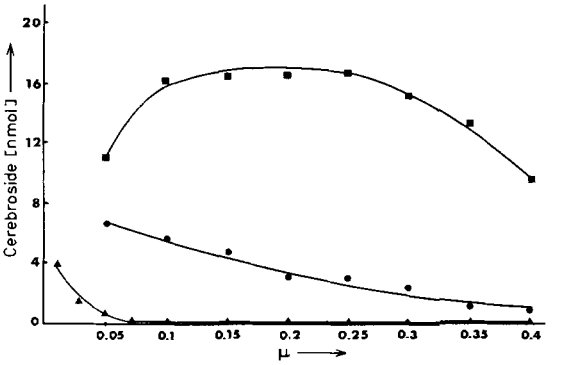

Fig. 6. Influence of ionic strength (μ) and addition of sodium taurodeoxycholate or protein activator on the activity of arylsulfatase A (cf. Fig. 3 and Table 1, No. 5). The samples contained 20 nmol of sulfatide and sodium acetate buffer (pH 4.8) at the given ionic strength in a volume of 100 μl. Additions: 0.1 unit sulfatase A (▲—▲); 0.1 unit sulfatase A and 11 μg (≙0.55 nmol) protein activator (●···●); 0.025 unit sulfatase A and 200 nmol sodium taurodeoxycholate (■—■). The samples containing sodium taurodeoxycholate were incubated for 15 min at 37 °C, the others for 60 min at 37 °C. The liberated cerebroside was then determined (*G. Fischer* and *H. Jatzkewitz*, unpublished). The ionic strength $\mu = \frac{1}{2}\sum c_i \cdot z_i^2$ is given in ½ mol of monovalent ions/l (c_i = concentration of the ion i; z_i = charge of the ion i).

The enzymatic cleavage of sphingolipids can also be accelerated in the absence of detergents by natural protein activators. The addition of an acid, low molecular weight protein (MW 22000) from liver stimulates the enzymatic degradation of sulfatides (Fig. 6)[50, 51]. According to the investigations of *Fischer* and *Jatzkewitz*[52], activator and sulfatide form a complex in a molar ratio of 1:1 and it is probably in this form that the lipid acts as a substrate for hydrolysis *in vivo*.

A similar protein activator (MW 22000) stimulates the splitting of gangliosides by hexosaminidase and β-galactosidase by an as yet unknown mechanism[53–55]. The requirement for the activator suggests that there is also an interaction between lipid and activator in these cases. On the other hand, the activator (MW 22000) for the cleavage of glucocerebroside forms an active complex with the enzyme glucocerebrosidase[56–61].

The physiological role of the protein activators is still unexplained. Changes in their concentrations could, for example, regulate the activity of the hydrolases in the lysosome. An activator deficiency disease has not yet been described. The sphingolipidoses which have so far been biochemically characterized are caused by deficiencies in enzyme activities. The most thoroughly investigated enzyme deficiencies (*i.e.* in β-galactosidase, arylsulfatase, and hexosaminidase) will now be considered in more detail.

7. β-Galactosidase Deficiencies

β-Galactosidase deficiencies are responsible for two completely different hereditary disorders. G_{M1}-Gangliosidosis is primarily a disease of the grey matter of the brain while Krabbe's disease leads to damage of the white matter.

7.1. G_{M1}-Gangliosidosis

G_{M1}-Gangliosidosis (cf. Fig. 3 and Table 1, No. 9) occurs as a result of a β-galactosidase deficiency which can be demonstrated with synthetic substrates[62]. The natural substrate of this enzyme and thus the main storage substance of this disease, is the ganglioside G_{M1}[63,64]. The ganglioside-G_{M1} β-galactosidase (a monomeric protein of molecular weight 72000) splits, in addition to the ganglioside, other β-galactosides—the sialic acid free residue of ganglioside G_{M1}, called G_{A1}[65], and a range of glycoproteins and mucopolysaccharides containing a terminal galactose bound by a β-glycosidic bond[66,67]. All these substrates are deposited in different organs depending on their site of synthesis. The enormous storage of gangliosides in the neurons leads to progressive damage of the nervous system while the deposition of acidic mucopolysaccharides[68–73] in the cells of the reticuloendothelial system[*] causes an enlargement of the liver and spleen and also changes in the bones.

Clinically, several forms of the disease can be distinguished. In Type 1, generalized G_{M1}-gangliosidosis, the symptoms of the disease appear within the first six months of life and lead to death after about two years with progressive mental and physical deterioration[62]. Type 2, the late infantile form[62,74], with slight disturbance of bone growth, and the adult forms[62,74–76] are milder in comparison. Cerebral symptoms become apparent after the first year of life at the earliest. In the late infantile form death occurs at about ten years of age. Intermediate types have also been described[67].

In neither the infantile nor the late infantile diseases is the lack of enzyme activity due to a disappearance of the enzyme protein; this can be immunologically detected in approximately normal quantities in both forms of the disease[77], *i.e.* a defective enzyme with very low activity is present in each case. The fact that the residual activity in Type 2 is higher than in Type 1 could be the reason for the considerably milder course of Type 2. In a Type 2 patient, a change in the electrophoretic mobility of the enzyme and an increase in its Michaelis constants for 4-methylumbelliferyl-β-D-galactoside and ganglioside G_{M1} have been demonstrated[77] (see also Fig. 5). Similar changes in the electrophoretic and kinetic properties of the residual β-galactosidase were also observed in Type 1[78]. These observations speak in favor of a mutation in the structural gene of the enzyme.

7.2. Krabbe's Disease

Globoid cell leucodystrophy or Krabbe's disease (cf. Fig. 3 and Table 1, No. 4) primarily attacks the white matter of the central nervous system. Early clinical symptoms are seen in the first year of life. As a result of progressive psychomotor deterioration, overexcitability to external stimuli, increasing spastic paralysis, convulsions, blindness and deafness the patients seldom survive beyond the age of two years[79].

This disease is caused by the lack of the enzyme, galactosylceramide β-galactosidase[80–82], which can be distinguished from ganglioside-G_{M1} β-galactosidase since it does not precipitate with antibodies against the latter, it remains active in G_{M1}-gangliosidosis and shows a different substrate specificity. In addition to galactocerebrosides, this enzyme can also split galactosylsphingosine, lactosylceramide, and monogalactosyldiglyceride[82–87]. Strictly speaking Krabbe's disease is not a storage disease. In the degenerating white matter of the brain only a slight increase of the undegradable metabolite, galactosylceramide, is found[88,89]. The population of cerebroside- and myelin-synthesizing cells (the oligodendroglia) declines sharply[79]. Multinuclear globoid cells (macrophages—migratory cells—of mesodermal origin) infiltrate the white matter and take up the storage material (Fig. 7). Toxic galactosylsphingosine (psychosine) resulting from the enzyme defect could play a pathogenetic role[90].

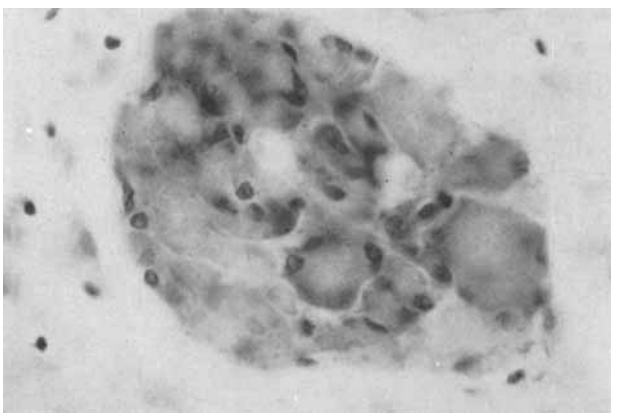

Fig. 7. In Krabbe's disease numerous, usually multinucleated, globoid cells are seen under the light microscope in the white matter of the brain; they are frequently most abundant around the blood vessels. These macrophages (migratory cells) of mesodermal origin take up the lipids (Nissl staining; magnification approximately × 250; photograph: *P. Mehraein*, München).

8. Arylsulfatase Deficiencies

Arylsulfatase deficiencies are responsible for metachromatic leucodystrophy, Austin's disease, and the Maroteaux-Lamy

[*] A functional unit of biologically very active mesenchymal cells characterized by phagocytosis, storage, and antibody production which form, as it were, the resorbing inner surface of the body (*Pschyrembel:* Klinisches Wörterbuch, de Gruyter, Berlin 1972).

syndrome (cf. Fig. 3 and Table 1, No. 5). In the Maroteaux-Lamy syndrome defects in arylsulfatase B[91-93] and *N*-acetylgalactosamine sulfatase[94,95] activities have been demonstrated; both activities are probably associated with the same enzyme. As the Maroteaux-Lamy syndrome belongs to the mucopolysaccharidoses it will not be discussed further here.

8.1. Metachromatic Leucodystrophy

The storage of sulfatides[96,97]—typical structural units of myelin in nervous tissue—in metachromatic leucodystrophy is correlated with a deficiency of cerebroside sulfatase[98,99] and arylsulfatase A (Fig. 3)[98,100,101] activities. Cerebroside sulfatase can be determined by the hydrolysis of cerebroside sulfate in the presence of a natural protein activator[51,102] or taurodeoxycholate[51] (Fig. 6); arylsulfatase activity is measured by the hydrolysis of nitrocatechol sulfate[103] or 4-methylumbelliferyl sulfate[104]. Both activities have been recognized as being properties of the same enzyme[50,105-107] and have very low values in all organs of patients with metachromatic leucodystrophy. An enzyme protein of very low activity can be identified; its kinetic and antigenic properties appear to be abnormal[108,109].

Human arylsulfatase A has a molecular weight of 107000 and consists of two subunits of approximately 50000[110]. At low pH values and high ionic strengths it forms dimers and tetramers. In addition to the sulfate esters of cerebrosides, the enzyme cleaves other sulfated lipids such as lactosylsulfatide[111] (which is also found in slightly increased amounts in metachromatic leucodystrophy[112]), psychosine sulfate[113], sulfogalactoglycerol lipid[114], and seminolipid[115,116].

Metachromatic leucodystrophy is, above all, a demyelinating disease of the central nervous system[117]. As a result of the cerebroside sulfatase deficiency, sulfatides and other sulfated lipids are stored, not only in nervous tissue, but also in the kidney. However, the neurological symptoms are clinically predominant and kidney function is only slightly impaired. The first difficulties in walking are seen at the age of 1 to $1\frac{1}{2}$ years in the late infantile form of the illness. Hypotonicity, deterioration of the reflexes, mental deficiency, failing sight, convulsions, and deficiencies in the motor system set in and lead to death within ten years[118]. Morphologically, a pathological degradation of the myelinated fibers in the nervous tissue is found. The small amount of myelin still detectable has an abnormal lipid composition with an especially high sulfatide content[119,120]. The juvenile and adult forms of the disease take a milder course[118]; here the severity of the course of the disease can be correlated with the extent of the enzyme defect, as *Kihara et al.* have demonstrated with cultured fibroblasts[121,122]. These cells incorporated the natural substrate, ^{35}S-sulfatide, from the medium and the rate of degradation of the labeled sulfatide decreased with the severity of the disease.

8.2. Austin's Disease

Austin's disease is a variant of metachromatic leucodystrophy[118,123,124] in which several sulfatases are deficient—the lysosomal arylsulfatases A and B[118], microsomal arylsulfatase[118], steroid sulfatase[125], heparan N-sulfatase[126], and iduronate sulfatase[126]. In this variant, sulfatide storage in the nervous tissue is also of greatest importance. However, increases in the amounts of mucopolysaccharides and sulfated steroids are also observed in the organs due to the multiple sulfatase deficiencies. In one case of the disease normal quantities of the arylsulfatase A protein were detected immunologically but in an enzymatically inactive form[127]. The reason for the common deficiency of the, in some aspects, very different lysosomal and microsomal sulfatases remains unknown. This multienzyme deficiency suggests that all the affected sulfatases have a common feature; a common subunit or factor necessary for the activity or biosynthesis of all these sulfatases could, for example, be missing or defective.

9. Hexosaminidase Deficiencies (G_{M2}-Gangliosidoses)

In 1881 *Warren Tay*[128] was the first to draw attention to the clinical characteristics of infantile amaurotic idiocy when he observed a cherry-red spot in the eye-ground region of most acute vision of a one year old child. The blood vessels become visible through the degenerating layer of ganglion cells and increasingly weak vision ends in blindness. The children suffering from this disease develop normally at first but lose abilities such as grasping and sitting up which they had already learned in their first months of life. Paralysis of the limbs, epileptic fits and convulsions set in. The disease leads to death within two to three years with progressive mental and physical deterioration[45,129,130]. Morphologically, a characteristic change in the ganglion cells of the nervous system is found. The cytoplasm of the cells is severely swollen, the cells are enlarged severalfold and their dendrites are distended. Under the electron microscope many oval, multilaminated granules can be seen in the cytoplasm of the neurons (cf. Fig. 4)[47] (as is also observed in G_{M1}-gangliosidosis). These granules contain the storage substance of this disease[48]—the ganglioside G_{M2}[131,132] (cf. Fig. 3 and Table 1, Nos. 7 and 8); the disease is therfore referred to as G_{M2}-gangliosidosis. Whereas ganglioside G_{M2} only occurs in traces as an interme-

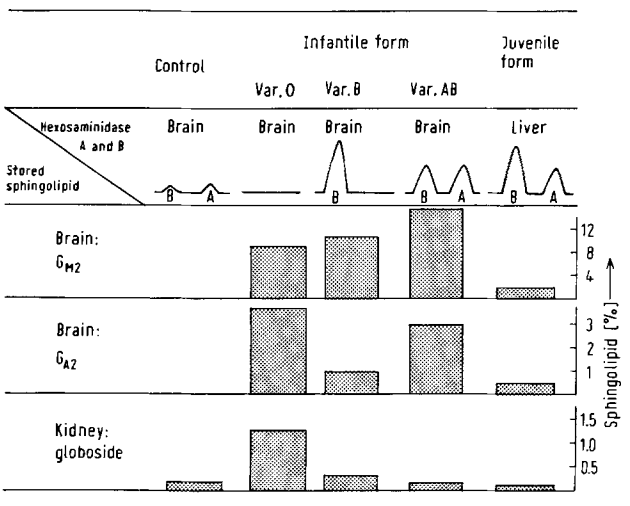

Fig. 8. Storage of glycolipids and hexosaminidase pattern in G_{M2}-gangliosidosis (infantile form with variants 0, B, and AB and juvenile form). The pattern of hexosaminidase activities was measured with synthetic substrates after the isoelectric separation of isoenzymes A and B. The quantities of the stored sphingolipids are given as percentages of the dry weight of the storage organ [134].—In the juvenile form of G_{M2}-gangliosidosis the level of hexosaminidase B in the liver is normal whereas the activity of hexosaminidase A only amounts to 50% of the normal value.

Table 2. Comparison of *N*-acetyl-β-D-hexosaminidases A and B.

Property	Hexosaminidase A		Hexosaminidase B		Ref.
Isoelectric point	5.0		7.3		[137]
Stability at 50 °C	−		+		[129]
Precipitation with antibodies to hexosaminidase B	+		+		[143, 145, 146]
Precipitation with antibodies to hexosaminidase A	+		+		[143, 145, 146]
Precipitation with specific antibodies to hexosaminidase A [a]	+		−		[145, 146]
Molecular weight	100000		100000		[160]
Proposed composition	$\alpha_2\beta_2$		$\beta_2\beta_2$		[160]
Activity in variant 0	−		−		[130, 133, 134]
Activity in variant B	−		+		[135, 141, 142]
Hydrolysis of ganglioside G_{M2} [μmol h^{-1} mg^{-1}] [b]	0.25		0.04		[159]
Hydrolysis of	K_m [mmol/l]	V_{max} [μmol $min^{-1} \cdot mg^{-1}$]	K_m [mmol/l]	V_{max} [μmol $min^{-1} \cdot mg^{-1}$]	
4-MUF-β-D-GalNAc [c]	0.09	14	0.05	35	[159]
4-MUF-β-D-GlcNAc [c]	0.8	160	0.6	280	[159]
Asialoganglioside G_{A2} [b]	0.05	0.15	0.03	0.65	[159]
Globoside [b]	0.20	1.1	0.26	4.7	[159]

[a] Antibodies to hexosaminidase A are freed from cross-reacting material by absorption with Sepharose-loaded hexosaminidase B.
[b] Hexosaminidases purified from human autopsy liver and tested in the presence of 2 mmol/l of sodium taurodeoxycholate.
[c] 4-MUF = 4-methylumbelliferyl.

diate product in healthy brain tissue, it forms about 6—12 % of the dry brain weight of patients with this disease[133, 134].

The enormous increase in ganglioside G_{M2} leads to the destruction of the nerve cells and therefore to myelin degeneration. The demyelinization is reflected in the lipid content of the diseased nervous tissue[134]. A drastic decrease of all typical myelin lipids such as cerebrosides, sulfatides, and C_{24}-sphingomyelin is observed. Similar secondary changes also occur in G_{M1}-gangliosidosis.

Three enzymatic variants of G_{M2}-gangliosidosis can be identified (Fig. 8)[135]. Defective isoenzymes of *N*-acetyl-β-D-hexosaminidase can cause the storage of glycosphingolipids. In human tissues mainly hexosaminidases A and B are found[136, 137]; both of them cleave β-*N*-acetylglucosaminides and β-*N*-acetylgalactosaminides as well as ganglioside G_{M2} and its sialic acid-free residue G_{A2} in the presence of detergent (Table 2)[138–140]. However, when the detergent is substituted by natural activator proteins, the ganglioside G_{M2} is hydrolyzed only by hexosaminidase A[159].

Tay-Sachs disease, which has been known for a long time, is caused by a complete lack of the hexosaminidase A enzyme[135, 141, 142]; inactive enzyme protein cannot be detected immunologically[143–146]. In contrast, the activity of the B enzyme is normal in most organs and in nervous tissue is even increased by as much as six-fold[133, 134, 141]. This disease is systematically denoted as variant B of infantile G_{M2}-gangliosidosis (Fig. 8).

A deficiency in both isoenzymes A and B is responsible for the occurrence of variant 0 of infantile G_{M2}-gangliosidosis[130, 133]. Inactive enzyme proteins have been immunologically detected in only one case[143, 144]. The additional storage of globoside in internal organs and the increase of glycosphingolipid G_{A2} in nervous tissue are typical in this form of the disease (Figs. 3 and 8)[130, 133, 134, 147–150].

It is also worth noting the rare variant AB in which an enormous storage of ganglioside G_{M2} and its sialic acid-free residue G_{A2} occurs although no enzyme deficiency can be detected with artificial substrates[134, 135, 151, 152]. However, the activity of the A enzyme towards the main storage substance, ganglioside G_{M2}, appears to be reduced *in vitro*[134]. The disorder in this form of the disease still remains to be elucidated. Is an activator, necessary for the degradation of ganglioside G_{M2}, missing or is there an abnormal hexosaminidase with an altered substrate specificity? A disorder in the organization of the lysosome, which prevents an ordered interaction between the lipid and the enzyme must also be considered.

In the juvenile form of G_{M2}-gangliosidosis (Fig. 8) it is possible that a hexosaminidase A with an altered substrate specificity is present. This form of the disease can be considered as a milder type of Tay-Sachs disease[129, 151, 153–156]. This is consistent with the fact that much less ganglioside G_{M2} is stored in the nervous tissue than is observed in the infantile form. With synthetic substrates, hexosaminidase A activity still amounts to 15 to 60 % of the normal level[129, 157]; with natural lipid substrates however, considerably lower activities have been found in the one case so far investigated[158].

Geiger and *Arnon*[160] have isolated the subunits of hexosaminidase A and B and proposed a model for the structure of the enzymes. According to this model, hexosaminidase A consists of two subunits, α_2 and β_2 (cf. Table 2) in each of which two peptide chains are linked by a disulfide bridge. The B enzyme is a homopolymer of composition $\beta_2\beta_2$. The common β_2 subunit of enzymes A and B could be changed or lacking in the 0 variant whilst the defect in the B variant would be in the α_2 subunit. The model explains why the trace enzyme S, which is made up of α_2 subunits, is only missing in the B variant[134, 145, 161, 162]. It also explains why hexosaminidase A ($\alpha_2\beta_2$) reappears in hybrids of skin cells of 0 and B variants[163–167] in which the A enzyme is missing; the cells must synthesize intact α_2 (variant 0) or β_2 (variant B) subunits which combine in the hybrids to form the A enzyme. The gene loci for the α and β chains lie on different chromosomes[168–171].

10. Further Enzyme Defects in Sphingolipid Metabolism

10.1. Fabry's Disease

Fabry's disease (cf. Fig. 3 and Table 1, No. 6) is a disorder of sphingolipid metabolism which does not primarily affect

the nervous system. In this disease the deposition of lipids leads to the appearance of skin eruptions (angiokeratoma), pains in the extremities, and renal failure which is often the cause of death in elderly patients. Lipids with terminal galactose residues bound by α-glycosidic bonds are stored—trihexosylceramide, digalactosylceramide (Fig. 3), and a complex lipid with blood group B specificity[172,173]. The cause is a deficiency in α-galactosidase A which, *in vitro*, cleaves the stored di- and trihexosylceramides[174-178]. In the patients examined so far, no immunologically crossreacting material has been found[178,179]. However, residual activity with synthetic substrates such as 4-methylumbelliferyl- and *p*-nitrophenyl-α-galactoside could still be detected. This residual activity can be attributed to another enzyme, α-galactosidase B, which is not deficient in patients with Fabry's disease and is immunologically unrelated to the A enzyme[178-182].

10.2. Gaucher's Disease

The storage of glucocerebroside (glucosylceramide) (Fig. 1), above all in the cells of the reticuloendothelial system, is characteristic of Gaucher's disease (cf. Fig. 3 and Table 1, No. 3). These storage cells (Gaucher cells) colonize spleen, liver, and lymph nodes and cause, in addition to bony changes, an enormous enlargement of these organs. The storage is due to a deficiency in β-glucosidase[183,184] which normally splits off the sugar residue from the storage substance, its fatty acid-free residue (*i.e.* β-glucosylsphingosine), and also from synthetic β-glucosides[185]. In the various forms of Gaucher's disease (infantile, juvenile, and adult), different degrees of deficiency in glucocerebrosidase activity have been observed[184]. The milder and more slowly progressing forms are reported to show higher residual activities than the infantile form in which neurological symptoms cause additional complications.

10.3. Niemann-Pick's Disease

It is striking that, in the course of the various forms of Niemann-Pick's disease (cf. Fig. 3 and Table 1, No. 2), the nervous system can be affected very differently. Recessively inherited sphingomyelinase defects give rise to storage of sphingomyelin in the infantile type A with neurological symptoms and in the juvenile type B without any effect on the brain[186-188]. According to *Callahan*[189,190] the lysosomal enzyme has several isoenzymes; in the juvenile type C, displaying neurological symptoms, one of these is reported to be missing. It still has to be explained why, in the juvenile and adult types D and E in which no enzyme defect has so far been found, sphingomyelin is stored. In addition to the lysosomal sphingomyelinase, a microsomal sphingomyelinase could be of importance, which is especially active in brain tissue[187,191]. It remains to be explained what role this enzyme might play in the different types of Niemann-Pick's disease, in particular to what extent it might be responsible for the quite different neurological symptoms observed in the various forms.

10.4. Fucosidosis

Fucosidosis is due to a deficiency in lysosomal α-fucosidase which leads to the storage of fucose-containing glycoproteins and glycolipids[192-197]. Enzyme protein could not be immunologically detected in a patient with the infantile form of the disease[198]. Lack of enzyme activity is also observed in the protracted, adult form of the disease[199]. α-Fucosidase shows a wide polymorphism[200,201]; the enzyme occurs in six forms which can be separated from one another[198,200,202] and which are all lacking in this disease.

10.5. Farber's Disease

Until now, Farber's lipogranulomatosis has been very rarely diagnosed (cf. Fig. 3 and Table 1, No. 1). According to *Sugita et al.*[203-205] a deficiency in ceramidase which, in acid solution, should split ceramides into sphingosine and fatty acids, is the cause of the observed storage of ceramide in several organs.

10.6. G_{M3}-Gangliosidosis

As has been described in the previous sections, hereditary defects of almost all sphingolipid hydrolases have been discovered in the last ten years. Until recently the exception was neuraminidase. In contrast to the other lysosomal sphingolipid hydrolases, this enzyme is found in the brain predominantly in the neuronal plasma membrane[206,207]. The enzyme releases sialic acid from its membrane-bound ganglioside substrates. The activity of neuraminidase (in this case probably of lysosomal origin) has now been reported to be considerably decreased in leucocytes or cultured fibroblasts from patients suffering from mucolipidoses, types I, II, and III[207a,207b,207c]. However, the chemical nature of the storage material has not yet been elucidated.

Storage of a neuraminidase substrate, ganglioside G_{M3}, has as yet only been observed in two patients. In the first patient the enzyme defect could not be identified as only formalin-fixed tissue was available for examination[208]. In the second patient *Brady et al.*[209,210] observed that, in addition to an increase in ganglioside G_{M3}, there was a lack of all the tetrasaccharide gangliosides present in healthy brain tissue. This abnormal ganglioside pattern is apparently not due to a disorder of degradation but of biosynthesis; whereas the neuraminidase activity in this patient appeared to be normal, the activity of *N*-acetylgalactosaminyl transferase, which extends ganglioside G_{M3} by one amino sugar and thus converts it to ganglioside G_{M2}, was greatly reduced[210].

11. Diagnosis of Homozygotes and Heterozygotes

On the basis of biochemical findings, the diagnosis of sphingolipidoses can now be obtained from a lipid analysis of the affected tissue or by measuring the enzyme defect in tissues or body fluids. The enzymatic analyses are used more widely as they can be carried out, not only with organ extracts, but also with extracts of leucocytes, cultured fibroblasts, or amniotic cells[45,49]. In addition, enzymatic analysis permits the identification of heterozygotes whose levels of enzyme activity usually lie between those of controls and patients[45,49,211-219]. The identification of disease carriers is a prerequisite for genetic counselling of affected families.

Enzyme analyses have confirmed the recessive mode of inheritance of the storage diseases. However, uncertainties arise in the diagnostic measurement of enzyme activities in cell cultures. The levels of activity of lysosomal enzymes from cultured cells of normal individuals vary widely and the activity also depends on the phase of the cell cycle[220]. Nevertheless, since there is no causal therapy for the sphingolipidoses, the enzyme analyses are of great importance, especially for prenatal diagnosis. Fetal cells taken from the amniotic fluid and maintained in culture contain a set of lysosomal enzymes which is very similar to that of cultured skin fibroblasts from children and adults[221-231]. These cells can therefore be used for prenatal diagnosis.

As a rule, enzyme measurements are carried out with synthetic substrates[49, 211-231]. Galactocerebroside β-galactosidase is an exception since its activity is measured towards radioactively labeled galactosylceramide[79].

The determination of specific enzyme defects in cultured amniotic cells and, in some cases, in the amniotic fluid itself allows in principle the prenatal diagnosis of all lipidoses with known enzyme defects. However, it remains questionable whether the identification of an enzyme defect with synthetic substrates is adequate as a diagnosis for a lipidosis. With synthetic substrates, the combined activities of several enzymes are often recorded which makes interpretation of the results difficult. As long as the enzyme deficiency is due to the absence of enzyme protein in the patient, it is also possible to use radioimmunological procedures for the diagnosis of the disease. This method has already been developed for Tay-Sachs disease by *Arnon et al.*[146].

12. Therapeutic Studies

The investigations carried out so far have supported the hypothesis that lipid storage in sphingolipidoses is caused by different deficiencies of degradative enzymes. It could thus be shown in model experiments that uptake of active enzymes by defective cells led to the degradation of the storage material. Defective fibroblasts take up lysosomal enzymes from the culture medium; the enzymes can have a considerable stability in the cells, with half lives of between a few days and several weeks[43, 44, 121]. On the basis of these experiments extremely pure enzymes have been infused into patients[44, 232, 233]. Encouraging short-term success was obtained, especially in forms of the disease which do not significantly affect the brain. The trihexosylceramide content of the plasma of patients with Fabry's disease decreased temporarily after the injection of ceramide trihexosidase; the glucocerebroside level in the erythrocytes of patients with Gaucher's disease falls after the injection of β-glucosidase[232]. Temporary improvements were also observed in patients with Fabry's disease after the transplantation of a healthy kidney which acts as a permanent source of the lacking enzyme, releasing it into the circulation[234-236]. However, in the case of lipidoses which mainly affect the brain therapeutic experiments have so far been unsuccessful[232, 233].

The infused enzyme is mainly taken up by the liver and degraded; it is apparently unable to penetrate the blood-brain barrier and reach the nervous tissue. Before enzyme replacement can be clinically used several problems still have to be solved. Since the infused enzyme is inactivated too quickly and eliminated from the organism, repeated doses are necessary; this can, in return, cause an undesirable immune response. These fundamental difficulties will not be overcome by methods in which the stability of the enzyme is increased by chemical modification[237, 238] or packing in the immunologically neutral erythrocyte ghosts[239, 240] or leucocytes[241] of the patient.

Theoretically there should be other means of therapy besides enzyme replacement. Among other methods which should be considered is the transfer of the genetic information for the defective or missing enzyme protein to the diseased organism by means of viral vectors. *Horst et al.*[242] recently reported an experiment with cell cultures which can be regarded as a model of this approach. They succeeded in transferring the genetic information for β-galactosidase from *E. coli* to cultured fibroblasts from a patient with G_{M1}-gangliosidosis by using the phage λ plac. At the moment, however, there is no evidence that such "genetic engineering" might be employed in the treatment of inherited illnesses.

13. Final Remarks

The biochemical investigation of sphingolipidoses has led to the identification of storage substances and enzyme deficiencies in most forms of these diseases. The gene mutations causing them can, however, only be determined when the protein chemistry of the enzymes involved is further advanced. The physiological function of the sphingolipids, above all in cell membranes, should also be more closely studied in order to obtain a better understanding of the pathogenesis of these diseases.

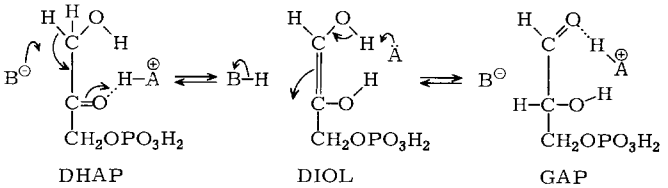
Efficiency and Evolution of Enzyme Catalysis



By W. John Albery and Jeremy R. Knowles[*]

A new function derived from kinetic data, the efficiency function, can be used to quantify the efficiency of a catalyst. For freely diffusing species the maximum efficiency is unity. The enzyme triose phosphate isomerase has an efficiency of 0.6 and is thus almost a perfect catalyst. The efficiency of the acetate ion as catalyst for the same reaction is 2.5×10^{-11}. This increase in catalytic efficiency is discussed in terms of three types of evolutionary improvement: the uniform binding of the substrate to the enzyme, changes in the internal thermodynamics of the bound states, and more effective catalysis of elementary steps. These concepts are illustrated for triose phosphate isomerase.

1. Introduction

Chemical kinetics without catalysis is like skiing without skis. Enzymes are nature's catalysts and every living system depends on the efficiency with which they mediate the flow of energy and material through the organism. During the last 10^9 years (1 G year) the different species have evolved in response to environmental pressures. Likewise we may expect that enzymes have improved and become better catalysts as a result of the pressures that select those organisms possessing a more efficient flow of energy and material.

For instance, the glycolytic enzyme triose phosphate isomerase catalyzes the reaction shown in Scheme 1 some 10^{10} times more effectively than does a simple catalyst like acetate ion[1].

Scheme 1. Isomerization of dihydroxyacetone phosphate (DHAP) *via* enediol (DIOL) to D-glyceraldehyde 3-phosphate (GAP). This reaction is catalyzed by triose phosphate isomerase.

We should not be too surprised that the enzyme is a far more efficient catalyst than the simple functional groups that comprise it. Clearly in order to control the flow of energy and material through the living system it is essential that the desired processes should take place much more rapidly than the random thermal reactions of the different metabolites. Hence there has to be a large difference in catalytic efficiency between the simple catalysts and the enzymes. Can we quantify this difference, and is there any limit to how efficient a catalyst can be? Is there such a thing as a "perfect" catalyst? The answer to both these questions is yes, and the first part of this paper is concerned with describing an "efficiency function" for catalyzed reactions in solution; in the second part the function will be applied to triose phosphate isomerase.

2. The Efficiency Function

Although the concepts presented below are general ones, in order to avoid too much algebra, we will apply them to the simple reaction shown in Scheme 2.

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EP \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E + P \qquad K$$

Scheme 2. E = catalyst, S = substrate, P = product.

This reaction involves a single substrate, a single product, a single step for their interconversion, and has an overall equilibrium constant

$$K=[P]_{eq}/[S]_{eq}$$

Although the letter E suggests an enzyme, Scheme 2 simply describes the interconversion of S and P in solution effected by *any* catalyst E. In this paper, however, we will refer to E as the enzyme, recognizing that this dignifies simple organic catalysts with a title they do not deserve.

The reaction in Scheme 2 may take place under "irreversible" or "reversible" conditions. Under "irreversible" conditions the back reaction of P to S does not take place to any significant extent. This may be because P is thermodynamically so stable that its chances of return are negligible, or it may be that P is removed by some subsequent reaction that is sufficiently rapid to prevent its return to S. Under "reversible" conditions, the net flux of material from S to P is small enough for the concentrations of S and P to be close to their equilibrium values. This would occur if the reaction catalyzed by E is flanked by two relatively slow processes:

$$\xrightarrow{\text{slow}} S+E \overset{\text{fast}}{\rightleftharpoons} E+P \xrightarrow{\text{slow}}$$

In an ordered sequence of enzyme-catalyzed reactions one step often controls the flux through the whole sequence. This step has to be an irreversible step. Control cannot be exercised through a reversible step, because the transition state between S and P is then of such low free energy that it does not influence the flux through either the earlier or the later steps. On the other hand it is much more efficient for steps which are *not* control steps to operate reversibly rather than irreversibly. This is because for a given flux less entropy is created under reversible conditions.

Now, let us propose a function, y, that measures the efficiency of a catalyst[2]:

$$y=\frac{[E]_0(1-[P]/K[S])}{\vec{v}} \tag{1}$$

where $[E]_0$ is the total concentration of the enzyme and $\vec{v}$ is the velocity of the reaction from left to right. Under irreversible conditions $[P] \ll K[S]$ and y is then $[E]_0/\vec{v}$, which is simply the reciprocal of the turnover number of the enzyme. The term in brackets describes how far the system is perturbed from equilibrium and modifies the turnover number to cover the reversible cases.

How does y vary with each of the variables on the right hand side of equation (1)? First, if all the concentrations are held constant and the velocity of reaction, $\vec{v}$, is increased, y decreases. Secondly, if the velocity of reaction, [P], and [S] are all held constant, but the concentration of enzyme is decreased, y decreases. Thirdly, if for the same concentration of enzyme and the same velocity of reaction the perturbation of [S] and [P] from their equilibrium values is decreased, y decreases. All these three changes therefore lead to a decrease in y, but they are all changes in which the enzyme has become a more efficient catalyst. In the first case the velocity of reaction is larger; in the second the same velocity is maintained with less enzyme and in the third the same velocity is maintained closer to reversible conditions and with more product and/or less substrate present. In a metabolic pathway this is an advantage because S is itself a product and P a substrate for other enzyme-catalyzed reactions in the sequence. A lower concentration of S decreases the rate of the back reaction through the previous step or steps and a higher concentration of P increases the forward rate through the subsequent step or steps. Furthermore, the more reversible is the system the more efficient it is.

Table 1. Variation of y in equation (1).

	Less Enzyme $[E]_0$	Greater Flux $\vec{v}$	More Reversible $(1-[P]/K[S])$
Improved efficiency	↓	↑	↓
Change in y	↓	↓	↓

These arguments are summarized in Table 1. *Hence we can conclude that the lower the value of y the more efficient is the enzyme or catalyst.* This will be true whether we are concerned with maximizing the velocity of the reaction, or achieving a given velocity with as little catalyst as possible, or perturbing the system as little as possible from equilibrium. It is important to have such a general function, since in the biochemical environment the enzyme may operate under conditions of constant flux, or of constant metabolite pool concentrations, or neither.

We next find how the velocity of the reaction, $\vec{v}$, depends on the rate constants of Scheme 2, and so obtain

$$y=a/[S]+b+\theta c \tag{2}$$

where

$$a=\frac{\vec{K}_m}{\vec{k}_{cat}}=\frac{1}{k_1}+\frac{k_{-1}}{k_1k_2}+\frac{k_{-1}k_{-2}}{k_1k_2k_3} \tag{3}$$

$$b=\frac{1}{\vec{k}_{cat}}=\frac{1}{k_2}+\frac{k_{-2}}{k_2k_3}+\frac{1}{k_3} \tag{4}$$

$$c=\frac{1}{\overleftarrow{k}_{cat}}=\frac{1}{k_{-2}}+\frac{k_2}{k_{-1}k_{-2}}+\frac{1}{k_{-1}} \tag{5}$$

The value of θ is zero for the irreversible case and is unity for the reversible case; $\vec{K}_m$ is the Michaelis constant for the irreversible reaction from left to right. These equations describe how the function y is related to the free energy profile of the reaction. Each individual term in the expressions for a, b, and c is associated with a single free energy difference, as shown in Figure 1.

Under irreversible conditions ($\theta=0$) the c terms describing $\overleftarrow{k}_{cat}$ for the back reaction are not included in y at all [equation (2)]. The a and b terms between them describe every possible rate-limiting barrier that the system has to surmount in going from left to right. Under reversible conditions ($\theta=1$) we have in addition the c terms which 'mirror' the b terms for the back reaction. The a terms are not 'mirrored' in this way.

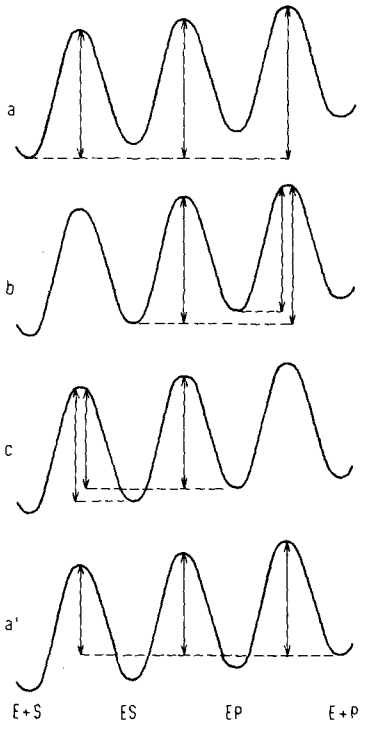

Fig. 1. The free energy differences associated with each term in the expressions for a, b, c, and a' in equations (3) to (6). Note that the k_{cat} terms in b and c involve the bound states ES and EP while the a terms and a' terms relate all three transition states to E+S and E+P respectively.

This is because the Haldane relation holds. This relation states that the overall equilibrium constant:

$$K = \frac{[P]_{eq}}{[S]_{eq}} = \frac{a'}{a}$$

where

$$a' = \frac{\overleftarrow{K}_m}{\overleftarrow{k}_{cat}} = \frac{1}{k_{-3}} + \frac{k_3}{k_{-2}k_{-3}} + \frac{k_2 k_3}{k_{-1}k_{-2}k_{-3}} \qquad (6)$$

$\overleftarrow{K}_m$ is the Michaelis constant for the irreversible reaction from right to left. The a' terms are also illustrated in Figure 1.

It can be seen that under reversible conditions

$$\frac{a}{[S]_{eq}} = \frac{a'}{[P]_{eq}}$$

and the *same* value of y will be obtained whether one considers the reaction to go left to right ($a/[S]_{eq}$) or right to left ($a'/[P]_{eq}$). Figure 1 shows that the only difference in the free energies of the a and a' terms lies in the base line from which they are measured.

Equation (2) and Figure 1 therefore allow us to see how the efficiency of a catalyst is related to the free energy profile of the catalyzed reaction.

While the right hand side of equation (2) contains lots of rate constants it also contains one variable; the concentration of S. This is inevitable since the steps E+S and E+P are second order reactions while the remaining steps are all first order reactions and so the free energy profile for the reaction must depend on the concentration of S.

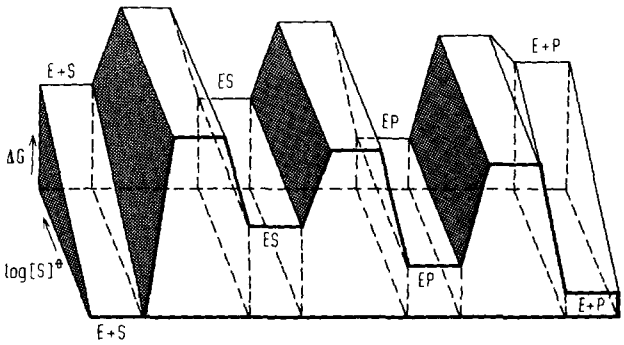

Fig. 2. Effect on the free energy profile of the choice of the standard concentration for the substrate, $[S]^\ominus$. The greater the $[S]^\ominus$ the greater the free energy of E+S and E+P with respect to the other states.

Figure 2 illustrates the effect of varying the concentrations of S and P on the free energy profile. At the back of the diagram the concentrations of S and P are high and ES and EP are more stable than E+S and E+P. Under these conditions the enzyme is saturated and the function y is dominated by the k_{cat} terms b and c. At the front of the diagram the concentrations of S and P are low, ES and EP are less stable than the unbound states and the function y is dominated by the $\vec{K}_m/\vec{k}_{cat}$ term, a.

If we followed the normal chemist's convention we would choose the slice of Figure 2 corresponding to $[S] \approx 1$ mol/liter. But this choice depends on Napoleon, the CGS system, and other historical accidents. The free energy profile at 1 mol/liter is *not* informative about what happens in the living cell, and if we wish to take a slice that is relevant to the *in vivo* situation then we must choose the same concentration of S, $[S]^\ominus$, as the enzyme actually experiences. This choice of S will serve for any sequence of reversible enzyme-catalyzed reactions and one could construct a single free energy profile for the whole sequence. After each irreversible reaction the product concentration is not related by thermodynamics to the substrate concentration and so a new standard state must be taken for the next sequence of reversible reactions.

Now physical organic chemists may say "but we can measure catalytic efficiency for Scheme 2 by means of the overall second order rate constant, k_{obs}. For instance, we plot these rate constants as measures of catalytic effectiveness in a Brønsted catalysis plot. Why do we need this function y?" The answer is that in catalysis by simple organic molecules the states EP and ES represent the caged reactants and products and are of higher free energy than E+S (or E+P) at the concentrations of S usually used. So for simple systems, the $[S]^{-1}$ term dominates the other terms in equation (2) and

$$y \approx \frac{a}{[S]} \approx \frac{1}{k_{obs}[S]}$$

Thus, as long as the free energy of the catalyst-substrate and catalyst-product complexes are high, one can measure catalytic efficiency with k_{obs}. But as soon as the free energies of ES and EP become relevant then we need the more general function y.

We have seen that as a catalyst becomes more efficient y decreases. Hence evolutionary pressure on an enzyme always

acts to reduce y. Just as Gibbs free energy is a measure of the approach to chemical equilibrium, so we can use y as a measure of the evolutionary improvement in catalytic efficiency. At chemical equilibrium the Gibbs free energy is at a minimum and we may ask, is there a minimum value of y which describes the perfect catalyst?

Returning to Figure 1 and equation (2) we can see that y will be reduced if the free energy barriers are reduced till they become kinetically insignificant. (The concept of kinetic significance was introduced by *Richard Noyes*. A kinetically insignificant transition state is one of such low free energy that it is in no way rate limiting for the overall process. Similarly a kinetically insignificant intermediate is one of such high free energy that, compared to the reactants or other more stable intermediates, very little material accumulates in the insignificant state.)

Which free energy barriers can the enzyme alter? It cannot change the outside levels (E+S and E+P) since these are fixed by the thermodynamics of the S-P system. It also cannot alter the rates (k_1 and k_{-3}) at which S+E and P+E find each other in the solution. The largest possible values of k_1 and k_{-3} are those corresponding to the diffusion controlled limit, and diffusion coefficients do not vary greatly with molecular structure. The free energies of these "external" states (E+S, E+P and transition states 1 and 3) cannot therefore be altered by the enzyme. By contrast, the "internal" states (ES, EP and transition state 2) will depend on how tightly the enzyme binds S and P and how well it catalyzes

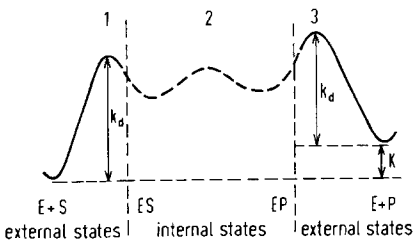

Fig. 3. The free energy profile for a perfect catalyst. The enzyme cannot improve the relative free energies of the external states, since they are fixed by thermodynamics (K) or by the rate at which molecules diffuse in solution (k_D). For the perfect catalyst all the other states, the internal states, are kinetically insignificant.

the reaction. If all these internal states become kinetically insignificant, the rate of the catalyzed reaction will reach a maximum and the free energy profile corresponding to the perfect catalyst will therefore have the form shown in Figure 3. The expression for y will then contain just two terms from a:

$$y_{min} = \frac{1}{k_D[S]} + \frac{1}{K k_D[S]}$$

where k_D is the diffusion controlled rate constant for E+S and E+P. The reaction catalyzed by the perfect catalyst is therefore limited only by the diffusion of the substrate *on* for a downhill reaction or by the diffusion of the product *off* for an uphill reaction. Since we now have a definition for y_{min}, we can define an efficiency function E_f which compares the efficiency of any catalyst to that of the perfect catalyst:

$$E_f = \frac{y_{min}}{y} = \frac{k_D^{-1}(1+K^{-1})}{a+[S](b+\theta c)} \tag{7}$$

For simple organic reactions we see that:

$$E_f = \frac{k_{obs}(1+K^{-1})}{k_D} \tag{8}$$

For an enzyme-catalyzed reaction, E_f can be written in terms of the usual Michaelis Menten parameters:

$$E_f = \frac{k_D^{-1}(1+K)}{\vec{K}_m/\vec{k}_{cat} + [S](\vec{k}_{cat}^{-1} + \theta\overleftarrow{k}_{cat}^{-1})} \tag{9}$$

When $\theta = 1$ for the reversible system the same value of E_f is obtained in terms of the product P:

$$E_f = \frac{k_D^{-1}(1+K)}{\overleftarrow{K}_m/\overleftarrow{k}_{cat} + [P](\vec{k}_{cat}^{-1} + \overleftarrow{k}_{cat}^{-1})}$$

3. Application to Triose Phosphate Isomerase

The free energy profile for the catalysis of the reaction in Scheme 1 by the enzyme triose phosphate isomerase is now largely known[3] and the non-enzymatic catalysis of the reaction has also been studied. So we can compare the values of the efficiency functions E_f for catalysis by the enzyme, and catalysis before the Garden of Eden by a base such as acetate ion. For the reasons discussed above we choose a concentration of S for the calculation of y corresponding to the *in vivo* concentration of triose phosphates in muscle, which is about 40 μmol/liter[4]. The results for E_f[2] are:

Triose Phosphate Isomerase: $E_f = 0.6$

Acetate Ion: $E_f = 2.5 \times 10^{-11}$

Since E_f for the perfect catalyst is unity, it is evident that triose phosphate isomerase is almost perfect. The free energy profiles for the reaction catalyzed by the enzyme and catalyzed by acetate are shown in Figure 4. The highest transition

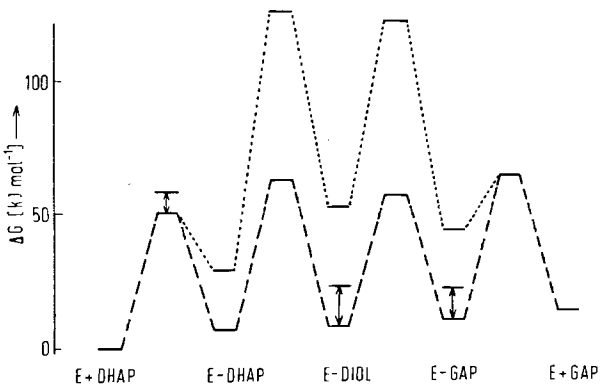

Fig. 4. The free energy profile for the reaction in Scheme 1 catalyzed by acetate ion (dotted line) and by the enzyme, triose phosphate isomerase (broken line). The vertical arrows indicate where the free energy profile for the enzyme is somewhat uncertain.

state for the enzyme reaction (going left to right) is diffusion *off* of the product and this is why the enzyme is almost perfect. How has the enzyme achieved this remarkable improvement?

3.1. Uniform Binding

The simplest answer to this question might be that, whereas for the simple organic catalyst ES and EP are only caged reactants and products, the enzyme binds the substrates, intermediates and transition states more tightly and the lower free energy of the transition states results in a faster reaction.

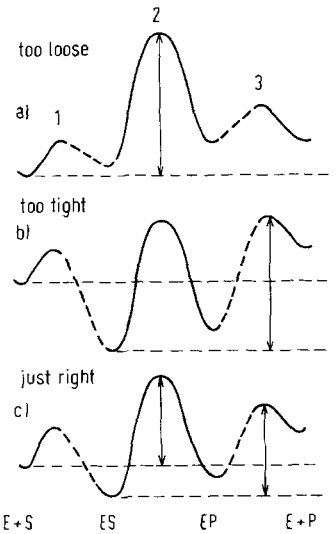

Fig. 5. The effect on the free energy profile of "uniform binding" of the substrate and product to the enzyme. In a) There is too little binding and transition state 2 is too "high"; in b) there is too much uniform binding and intermediate ES is too "low"; in c) the optimum profile is shown.

The effect of binding the internal states is shown in Figure 5. In Figure 5a we have the profile for a simple catalyst. In Figure 5b the catalyst binds S and P so tightly that transition state 2 now lies below transition state 3. Have we therefore already developed the perfect catalyst? Unfortunately the answer is no, because now the intermediates ES and EP are so stable that most of the enzyme becomes trapped in the ES valley. The dominant terms in y for the profiles in Figures 5a and 5b are shown. By differentiation one can prove that the *optimum condition* (*i.e.* the minimum value of y) *is when these two terms in y are equal.* This is shown in Figure 5c.

In making the changes in Figure 5 we moved *all* the internal states (ES, EP and transition state 2) up and down as a single block with respect to the external states. If we consider what changes random point mutations would cause in the free energy profile for an enzyme-catalyzed reaction, it is reasonable to suggest that those changes which do not discriminate amongst different internal states and which can use a variety of different interactions will occur more often than those changes which do discriminate and which require more particular and subtle alterations in enzyme structure. Thus the type of change considered in Figure 5 can arise from interactions with parts of the substrate molecule remote from the reaction center and by a variety of mechanisms such as hydrophobic interactions, hydrogen bonding, electrostatic interactions, and the rest. Changes in binding interactions some way from the reaction center will not discriminate significantly between the different bound states and we may expect the binding of all such states to be changed equally. Since for most enzyme substrates the reaction center is a relatively small part of the molecule, the random mutations that alter the binding are more likely to do it in a uniform fashion rather than discriminating (say) between ES and EP. Because changes in uniform binding are relatively the easiest type of change, we may expect that many enzymes will have achieved optimum profiles in this respect. As shown in Figure 6, triose phosphate isomerase is very close to the optimum condition illustrated in Figure 5c.

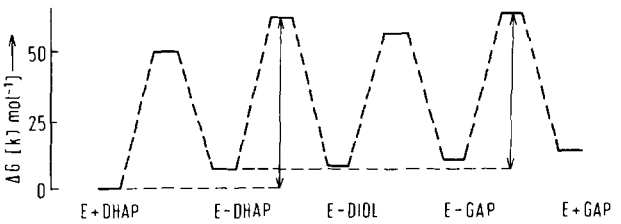

Fig. 6. The free energy profile for the triose phosphate isomerase catalyzed reaction in Scheme 1. It almost satisfies the optimum condition of uniform binding.

Now we may ask "Has triose phosphate isomerase achieved its high efficiency compared to acetate ion merely by using uniform binding?" Figure 7 shows the profile that one would obtain if one altered the acetate profile so as to optimize the uniform binding. The efficiency function for this profile has a value of $E_f = 3 \times 10^{-6}$. This is five orders of magnitude better than the simple acetate catalyst but it is still much less than the enzyme's actual value of 0.6.

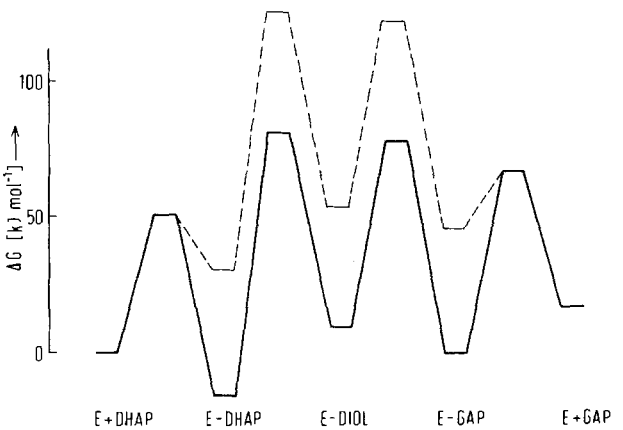

Fig. 7. The free energy profile for the reaction in Scheme 1 catalyzed by acetate ion (broken line) and the improved profile obtained after optimizing the uniform binding (full line). The relative free energies of all the internal states (E:DHAP to E:GAP) are the same in both profiles.

3.2. Differential Binding

We propose that the next easiest change the enzyme can make is to alter the internal thermodynamics of the bound intermediates. For instance, the optimized acetate profile (Figure 7) can be further improved if the enediol is bound more tightly compared to DHAP. This lowering of the free

energy of the enzyme : enediol complex will drive the proton abstraction from DHAP that much harder and hence improve the efficiency. To effect this change the enzyme has to discriminate in its binding of DHAP and of the enediol. There are still a number of mechanisms, *e.g.* hydrogen bonding, whereby this can be done, but this change is more localized and more specific; the enzyme must obviously interact discriminately with the substrate near the reaction center. Figure 8 shows the profile for the reaction where the internal thermodynamics has been optimized *and* the uniform binding readjusted to accommodate the new internal levels. Notice that the internal thermodynamics are optimized when DHAP and the enediol have the *same* free energy. This is because if one tries to drive the proton abstraction any harder by further lowering the enzyme:enediol complex then the efficiency drops because the enzyme : enediol complex is becoming too stable. The value of the efficiency function for this profile (Figure 8) is $E_f = 1.5 \times 10^{-4}$. The optimization of the internal thermodynamics has produced a smaller but still significant improvement.

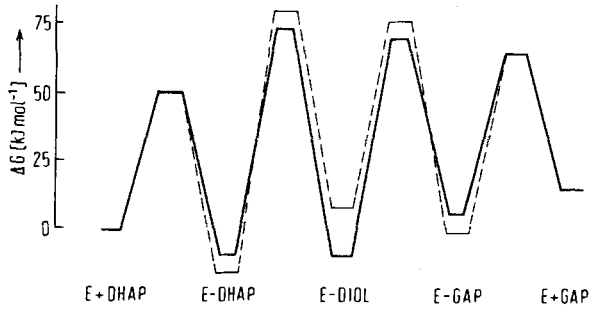

Fig. 8. The profile in Fig. 7 (broken line) is further improved (full line) by equalizing the free energies of the E : DHAP and E : DIOL complexes and then once again optimizing the uniform binding.

3.3. Catalysis of Elementary Steps

Having optimized both the uniform binding and the internal thermodynamics the only possible further improvement is to lower the free energies of the kinetically significant transition states *with respect to* the kinetically significant intermediates. That is, the free energy difference between the highest hill and the lowest valley must be reduced. Many wise angels have argued on the head of a pin whether this is done by binding the transition state more tightly with respect to the intermediates or by destabilizing the intermediates with respect to the transition state. We regard this distinction as irrelevant since after an improvement in the catalysis of a particular step, changes in uniform binding will optimize the level of the internal states with respect to the external states. As shown in Figures 6 and 8 this has happened for triose phosphate isomerase. The mechanism by which the catalysis of particular elementary steps can be improved must be the most subtle of all, since there are very few amino acid replacements that will result in a more rapid execution of the required covalency changes. As an example of such an improvement the enzyme might develop bifunctional rather than monofunctional catalysis. Indeed, triose phosphate isomerase seems to use an electrophilic group at the active site to polarize the carbonyl group of the substrate[5], thereby facilitating the abstraction of the enolate hydrogen by the active site base (Figure 9).

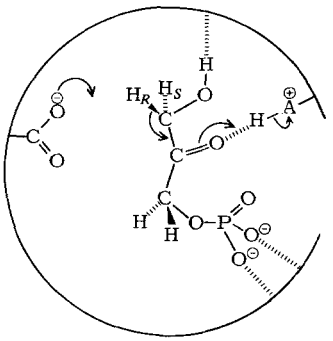

Fig. 9. Putative complex of dihydroxyacetone phosphate with triose phosphate isomerase. The carboxylate group of glutamic acid 165 abstracts the pro-*R* hydrogen assisted by an electrophilic group HA [5].

We cannot generalize about the ways in which the catalysis of individual steps of an enzyme reaction is improved. However, by using the efficiency function we can quantify *how much* of the improved performance of the enzyme is due to the relatively unsophisticated binding of the substrates and how much is due to the catalysis of elementary steps.

3.4. Variation of Efficiency with Substrate Concentration

In our discussion of triose phosphate isomerase we took the *in vivo* substrate concentration as our value of [S] in the calculation of the efficiency function. It is interesting to plot E_f for triose phosphate isomerase as a function of the substrate concentration according to equation (7). This is done in Figure 10. We find the enzyme on the edge of the plateau of perfection.

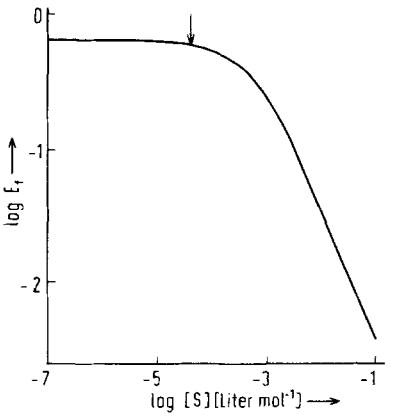

Fig. 10. Variation of efficiency function for triose phosphate isomerase with [S] according to equation (7). The arrow indicates the *in vivo* substrate concentration.

This is to be expected, since we have seen that the free energy profile of the enzyme is well tuned to the ambient substrate concentration. The enzyme has climbed out of the pit of the simple catalysts and has reached the plateau where there can be no further significant improvement in its catalytic effectiveness.

4. The Efficiency Surface

So far we have discussed separately the variation of efficiency with substrate concentration and with uniform binding. But uniform binding and substrate concentration are related, since uniform binding will be optimized for a particular ambient substrate concentration. To illustrate this behavior we can calculate a surface for the efficiency function. In order to construct a diagram that will fit into three dimensions we first assume that the E + S steps and the E + P steps are diffusion controlled:

$$k_1 = k_{-3} = k_D$$

Secondly, we describe the variation of uniform binding by the parameter β, where

$$\beta = \frac{k_2}{k_{-1}} + \frac{k_{-2}}{k_3} \tag{10}$$

Changing the uniform binding causes the same proportionate change in k_{-1} and k_3 while k_2 and k_{-2} remain constant. Increasing the binding of the internal states decreases k_{-1} and k_3 and increases β.

Most of the rest of the rate constants in the efficiency function can then be collected into a parameter γ where

$$\gamma = \frac{y_{min}}{k_2^{-1} + \theta k_{-2}^{-1}} = \frac{1 + K^{-1}}{k_D(k_2^{-1} + \theta k_{-2}^{-1})} \tag{11}$$

Thus γ is unaffected by changes in uniform binding, but any improvement resulting from changes in internal thermodynamics *or* in the catalysis of single steps that lead to larger values of k_2 or k_{-2}, will give a larger value of γ.

Then we obtain for the efficiency function:

$$E_f \approx \frac{1}{1 + \beta^{-1} + (1+\beta)[S]/\gamma} \tag{12}$$

This relation holds[*] for all reversible systems ($\theta = 1$), for all simple systems ($k_2/k_{-2} \approx K$), and all "uphill" systems ($k_2/k_{-2} \approx K \ll 1$). A slightly different expression is found for irreversible systems ($\theta = 0$) which are "downhill" ($K \gg 1$) and where the internal thermodynamics is more balanced than the external ($k_2/k_{-2} \ll K$):

$$E_f \approx \frac{1}{1 + \beta^{-1} + [S]/\gamma} \tag{13}$$

The difference is only the extra β/γ term in equation (12). Since equation (12) applies to a larger number of cases including the more efficient reversible systems we concentrate on equation (12).

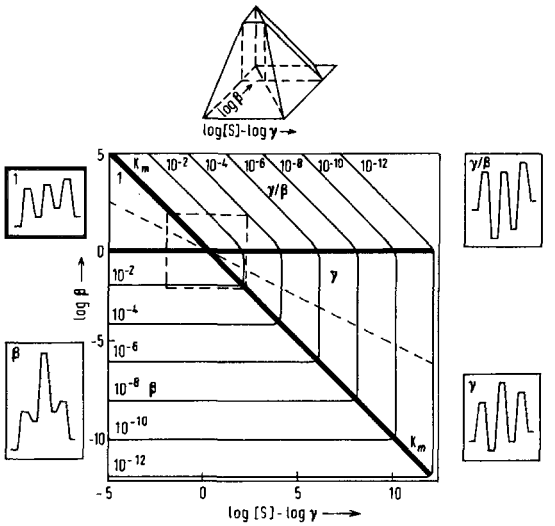

Fig. 11. Contour diagram showing the variation of the efficiency function from equation (12) with the uniform binding parameter β [eq. (10)] and the substrate concentration divided by γ [eq. (11)]. The shape of the surface is shown in the top inset. The other insets show typical free energy profiles for the four planes in the diagram. The line labeled K_m [eq. (15)] gives the [S] when the enzyme is half saturated. The broken line indicates the optimum value of β (see Fig. 5c). The area inside the broken square is shown in Fig. 12.

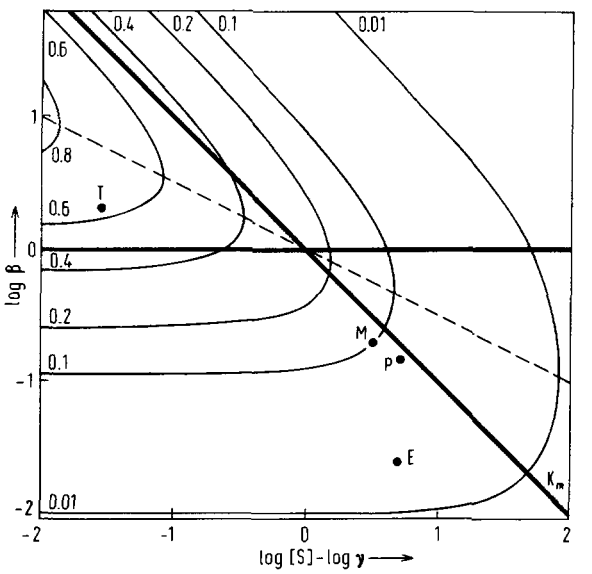

Fig. 12. The area near the origin in Fig. 11. The points T, M, P and E are the locations on the diagram for four glycolytic enzymes: T, triose phosphate isomerase; M, phosphoglycerate mutase; P, phosphoglucose isomerase; E, enolase.

Now since E_f depends on β and $[S]/\gamma$ we can plot equation (12) for E_f in the contour diagrams shown in Figures 11 and 12; Figure 12 shows the area around (0,0) in more detail. Depending on which term is dominant in the denominator of equation (12) we find four different planes in Figure 11. In the top left corner we have the "plateau of perfection", where E_f tends to unity. At the bottom of the diagram we have the β plane where $E_f \approx \beta$. On this plane the uniform binding is too weak and transition state 2 is always rate limiting. On both of these planes the efficiency function is

[*] The full expression for E_f is

$$E_f = \frac{1}{1 + \beta^{-1} + [1 + (1+\rho)\beta][S]/\gamma}$$

where

$$\rho = \frac{(k_2/k_{-2} - K)(1-\theta)}{(1+K)(1+\theta k_2/k_{-2})}$$

The parameter $\rho \approx 0$ for the systems discussed under equation (12) and $\rho \approx -1$ for the system discussed under equation (13).

independent of substrate concentration. Here the catalyst is unsaturated and the kinetic rate law has the form

$$v = k[S][E]$$

By contrast, when the other two terms in equation (12) are dominant, the efficiency function is inversely proportional to [S]. The efficiency falls off with increasing [S] and the rate law has the form

$$v = k[E]$$

These systems are saturated.

We now introduce a third Michaelis constant $K_{m,eq}$ (in addition to $\vec{K}_m$ and $\overleftarrow{K}_m$) which is appropriate for reversible systems reacting close to equilibrium conditions:

$$K_{m,eq} = \frac{\vec{K}_m}{1+\vec{k}_{cat}/\overleftarrow{k}_{cat}} = \frac{\overleftarrow{K}_m K^{-1}}{1+\overleftarrow{k}_{cat}/\vec{k}_{cat}} \qquad (14)$$

These systems become half saturated, when

$$[S] \approx [P]K^{-1} \approx K_{m,eq}.$$

To cover both reversible and irreversible cases we write

$$K_m = \frac{\gamma}{\beta} = \vec{K}_m/(1+\theta\vec{k}_{cat}/\overleftarrow{k}_{cat}) \qquad (15)$$

where K_m reduces to $\vec{K}_m$ for $\theta=0$ and to $K_{m,eq}$ for $\theta=1$[*].

This constant K_m defines the dividing line labeled K_m in Figure 11. Systems which cross this line as the substrate concentration is varied obey Michaelis Menten kinetics. To the right of the β plane we have the γ plane. Here the efficiency does not depend much on the uniform binding parameter because the main rate limiting process is the decomposition of a relatively stable ES or EP intermediate over transition state 2. Finally in the top right-hand corner we have the γ/β plane. Here the binding is too tight, and the rate limiting transition state for the decomposition of ES and EP is transition state 1 or 3. In the case of the downhill irreversible reaction where equation (15) holds, this plane is missing. It can be seen that the efficiency function can be applied to systems regardless of whether their biological role requires them to work under saturated or unsaturated conditions.

Having described the surfaces we can locate the area where simple systems are found. From equation (10):

$$\beta \approx \frac{k_2}{k_{-1}} = \frac{k_{obs}}{k_D} = E_f \approx 10^{-10}$$

and from equation (11)

$$\gamma \approx \frac{k_2}{k_D} = \frac{k_{obs}k_{-D}}{k_D^2} = \frac{\beta k_{-D}}{k_D} = 10\beta \approx 10^{-9}\ \text{mol/liter}$$

for a typical k_{obs} of 1 liter mol^{-1} s^{-1}, and $k_D/k_{-D}=0.1$ liter mol^{-1}. (The last quantity describes a typical association equilibrium constant for caged catalyst reactant or catalyst product pairs. In the absence of any specific interaction one can calculate such a constant for ES and EP from the chances of the two molecules, E and S or P, being nearest neighbors.) In Figure 13 we have therefore plotted the area in which the simple systems are found. They do not exhibit Michaelis Menten kinetics and the concentration of substrate is not large enough to take them across the dividing line between the β and γ planes.

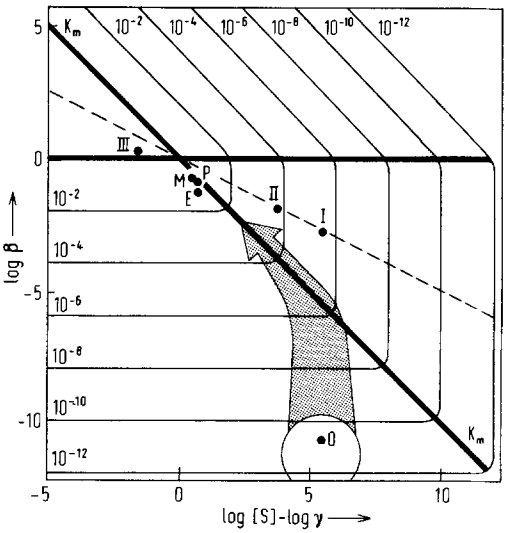

Fig. 13. The location of different systems on the efficiency surface. The circle indicates the area where simple organic systems are found and the point 0 is reaction 1 catalyzed by acetate ion. Points I and II are the same reaction after optimization of uniform binding with the profile (Fig. 7) and improvement in differential binding with the profile (Fig. 8). Point III is the location of triose phosphate isomerase. Three other glycolytic enzymes are shown by the points M, P and E: M, phosphoglycerate mutase, P, phosphoglucose isomerase and E, enolase.

The pressures of natural selection will first drive the evolving enzyme up towards the γ plane, since, as discussed above, there are many ways of adjusting uniform binding (*i. e.* increasing β). Once close to the K_m line further optimization of uniform binding is not too critical and catalytic efficiency now has to be improved by increasing k_2 or k_{-2} (*i. e.* increasing γ). Eventually the enzyme may cross the origin on to the plateau of perfection. We have shown in Figure 13 these steps for triose phosphate isomerase.

The enzyme will not move far onto the plateau of perfection. The reason for this is that the enzyme requires constant evolutionary pressure to maintain its foothold on the plateau. Most mutations will be disadvantageous to the enzyme and will tend to sweep it back down the hill. There can be no evolutionary pressure on the flat part of the plateau. Imagine an enzyme which by some good chance did become "super-perfect" with a very low transition state 2 as shown in Figure 3. The high

[*] The full expression for K_m is

$$K_m = \frac{\gamma/\beta}{1+\rho(1+\beta)^{-1}}$$

where ρ is defined in the previous footnote. Equation (15) holds when $\rho=0$ and equation (12) holds, or when $\beta \gg 1$.

proportion of disadvantageous mutations would undo the good work until transition state 2 was again partly rate limiting. Once this has occurred natural selection would then prevent further deterioration. For this reason we expect to find enzymes clinging to the edge of the plateau. The most accessible part of the plateau is near the origin and this is the region where we should find the enzymes. The conditions for the origin are $\beta=1$ and $\gamma=[S]^{\theta}$, where $[S]^{\theta}$ is the *in vivo* concentration of the substrate. Several authors[6-8] have suggested that for an efficient enzyme the Michaelis constant should match the ambient substrate concentration. We agree with this conclusion, since at the origin:

$$K_m=\gamma/\beta=[S]^{\theta},$$

but care must be taken about the reversibility of the system and K_m must be defined by equation (15). In addition, we can also describe the profile at the origin. As discussed there are some reasons for thinking that catalysis will be improved if $k_2\approx k_{-2}$. Assuming this equality and that $[S]=[S]^{\theta}$ we obtain the profile shown in Figure 14. It can be seen that

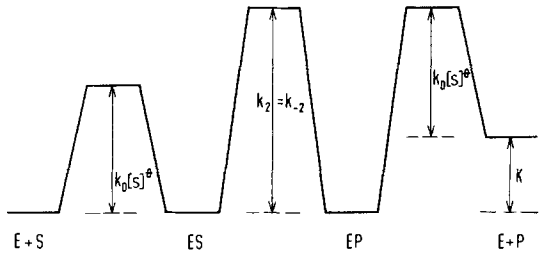

Fig. 14. The free energy profile for the almost perfect enzyme that is close to the origin in Figures 11, 12 and 13.

transition state 2 and transition state 3 are of equal free energy. This is because if transition state 2 were above 3 the enzyme would be inefficient and if it were much below 3 then there would be no evolutionary pressure to maintain an unnecessarily fast interconversion of ES and EP. We therefore expect that for enzymes on the edge of the plateau several transition states will be partly rate limiting. As in geological erosion the high peaks are worn away leaving a range of smooth hills.

Returning to Figure 14 we find that the intermediates ES and EP are of almost the same free energy as E+S. If the free energy of the intermediates were far below E+S, the enzyme would be inefficient, the catalyst being bogged down in the ES valley. But there is no evolutionary pressure to maintain the free energy of ES much above E+S. We therefore expect that the free energy profile for an enzyme will have several intermediates of much the same free energy as E+S when $[S]=[S]^{\theta}$ the ambient substrate concentration. For reversible downhill systems the relevant level will be E+P since it is of lower free energy than E+S.

Throughout this paper triose phosphate isomerase has been used as an example because we have a detailed knowledge of its free energy profile. However, we can plot other enzymes on our diagram using published values of k_{cat} and K_m. The relation between our variables and k_{cat} and K_m are:

$$\beta^{-1}\approx\frac{\vec{K}_m k_D}{\vec{k}_{cat}(1+K^{-1})}-1 \tag{16}$$

and

$$\gamma^{-1}\approx\frac{k_D(\vec{k}_{cat}^{-1}+\theta\overleftarrow{k}_{cat}^{-1})}{1+K^{-1}}-(1+\rho)K_m^{-1} \tag{17}$$

In Figure 13 we have plotted points for three other glycolytic enzymes for which data on k_{cat}, K_m, K and $[S]^{\theta}$ are available; these are the data required to calculate E_f, β and γ for a reversible system (for which $\rho=0$). These three enzymes (enolase, phosphoglucose isomerase and phosphoglycerate mutase) have no control function in glycolysis and it is gratifying to find them in Figures 12 and 13 close to the origin and close to the K_m line[*].

5. Conclusion

Finally we summarize our conclusions.

1. Our proposed efficiency function quantifies the efficiency of any catalyst for a reaction in solution under both reversible and irreversible conditions.
2. For freely diffusing species the maximum efficiency is unity.
3. We expect and find enzymes to have an efficiency somewhat less than unity (≈ 0.1).
4. Simple organic systems have efficiencies of very roughly 10^{-11}.
5. For triose phosphate isomerase about half the improvement in enzyme efficiency comes from binding the substrates, intermediates, and transition states by a non-discriminating interaction and about half by improved catalysis of covalency changes.
6. For an almost perfect enzyme the Michaelis constant matches the *in vivo* substrate concentration.
7. In the free energy profile of an almost perfect enzyme there will be several transition states that are partly rate limiting and several intermediates of comparable free energy to the free energy of free enzyme plus substrate or product.

The Pauli Principle and Chemical Bonding in Molecules and Solids[**]

By Laurens Jansen and Ruud Block[*]

The starting point of this contribution is a discussion of the concept of exchange interactions and its relation to chemical bonding and valence. Then, a class of phenomena characterized by weak chemical bonding ($\lesssim 1$ eV) in solids and molecules is analyzed in more detail, with "superexchange" in insulating solids with paramagnetic 3d-cations serving as prototype. A model of "effective electrons" is developed for weak bonding on the basis of exchange perturbation theory, taking full account of the Pauli principle. The model is applied to: i) magnetic interactions in solids (interaction energy 10^{-2} to 10^{-4} eV); ii) stability of noble-gas halides (binding energy ≈ 1 eV); and iii) rotational barriers in simple molecules (barrier heights of several 0.1 eV).

1. Introduction

Although the concept of a *chemical bond* between two atoms, A and B, denoted by A—B in the chemist's symbolism, is an old one, it is safe to say that, in spite of fifty years of quantum mechanics, we still do not know precisely what is meant by this concept. *Gassendi*, is his oeuvre "Syntagma Philosophicum" (1658), suggested that atoms could attach themselves to each other by means of "hooks" on their surface *(a)*; the number of hooks constituting what we call the "maximum valency" of the atom.

(a): 1658 *(b)*: 1931

For two-and-a-half centuries after *Gassendi*, no progress whatsoever was made in understanding the chemical bond; even in the era of *Kekulé*, towards the end of the nineteenth century, the picture of an atom still largely resembled a billiard ball with a certain number of fixed knobs on the surface, by means of which other atoms could be attached.

As we know, *Kossel* and *Lewis* in 1916 put an end to this romantic period by giving some structure to the bar between the atoms A and B. They implied that atoms strive towards attaining a noble-gas configuration for their electrons. This can be accomplished, energy permitting, either by transferring electrons from one atom to the other (as in Na^+Cl^-) or by "sharing" (as in H:H). In the first case we obtain the ionic bond *(Kossel)*, in the second case the homopolar electron-pair bond *(Lewis)*. The homopolar bond seemed to be vindicated as the archtype of chemical bonding through *Heitler* and *London*'s calculation[1] on the hydrogen molecule in 1927; instead of *Lewis*' naive electron sharing a complex chain of concepts emerged. The bonding in H_2 is the result of *exchange interactions* between the atoms. These, in turn, arise as a result of the Pauli principle, *i.e.*, the wave function describing the system must change its sign if any two electrons are interchanged.

As this is not readily formulated in terms of chemical concepts, however, chemists continued writing bars between atoms and kept on interpreting them in terms of electron-pair bonds. If the ground-state electron configuration of an atom could not account for a given number of pair bonds in molecules, then "valence structures" were constructed to explain observed facts. A highlight was *Pauling*'s sp^3-hybridization scheme[2] *(b)* for the carbon atom (1931). This, in fact, is *Gassendi* all over again, now with "lobes" of unpaired-electron density instead of the "hooks" of three centuries earlier.

Ingenious schemes of pair bonding are found in modern inorganic complex chemistry as well as in solid state chemistry; in the latter case, so-called "dangling bonds" are also implied at surfaces where complete saturation cannot occur. It should be realized that the interpretation of chemical bonding in terms of pairs of electrons with opposite spins has no direct connection with concepts of quantum mechanics. In fact, in this description quantum mechanics is essentially short-circuited and replaced by "chemical intuition" formulated as a number of *ad hoc* rules of assumed general validity, which live "their own lives", regardless of what quantum-mechanical theory can tell us.

The "message" of this article is, nevertheless, not that this is too primitive and that the only sensible alternative is to solve the Schrödinger equation exactly for a system of interacting atoms. What we do want to demonstrate is that the pair-bonding scheme, applied to a number of selected, yet simple, problems leads either to incorrect results, or, worse still, to no result at all. Instead, these problems can be dealt with effectively, without increasing their complexity, if one takes the Pauli principle really seriously and does not reduce it to a pairing principle. The problems selected all concern what may be called "weak chemical bonding", which we define to comprise phenomena with binding energies of about 1 eV or less. This limitation renders the use of perturbation techniques, starting from non-interacting atoms, plausible in principle. We will now discuss: i) magnetic interactions in 3d-solids (binding energies 10^{-2} to 10^{-4} eV); ii) stability of noble-gas halides such as XeF_2 and XeF_4 (binding energies about 1 eV per bond); and iii) rotational barriers in simple molecules (barrier heights of several 0.1 eV).

2. Effective-Electron Model for Weak Chemical Bonding

The model to be discussed for weak chemical bonding (weak exchange interactions) was first designed in order to analyze phenomena of coupling between electrons with unpaired spins on different paramagnetic 3d-cations in insulating solids such as solid MnS. The Mn^{2+} ion has a half-filled 3d-shell and the O^{2-} ion is diamagnetic. Let us consider the coupling between unpaired electrons on *two* neighboring Mn^{2+} ions in the presence of *one* O^{2-} ion. The reason why we must consider also at least one anion is that the distance between even nearest-neighbor cations is too large to explain the observed phenomena of *magnetic ordering* at low temperatures in such solids, *i.e.* the spins on different cations are all arranged in a certain pattern if the temperature is sufficiently reduced (below a few hundred K, depending upon the substance). It has become clear that the coupling arises through the anion; we call this phenomenon "indirect exchange", or "superexchange", a much studied subject in solid-state physics.

One remark before we come to the analysis of the phenomena under study. The Pauli principle is a *symmetry condition* on the wave function describing a system of an arbitrary number of electrons: if one *permutes* the labels of any two electrons, then the wave function must change its sign. Of course, there are in general many more conditions imposed by symmetries of a type different from permutations, namely rotations, reflections, translations (in a solid), *etc.* However, in order to avoid burdening the reader with abstract concepts, we shall refrain from a general discussion of the concept of symmetry; for this, the interested reader is referred to the literature[3].

Next, we discuss the assumptions of the model used in numerical calculations. First of all, we limit ourselves to phenomena of weak chemical bonding, implying that we may start from noninteracting atoms, ions, or molecules and may calculate their interaction as a perturbation of the initial state. Secondly, as stated earlier, we will consider the consequences of the Pauli principle as applied to the total system, not only to two electrons at a time on one-electron orbitals. We do, however, use localized orbitals for the description of the system, *i.e.* we do not smear out these orbitals over all atoms involved, as is the case in the "molecular orbital" method.

Perturbation theories taking into account the Pauli principle for interacting atoms (exchange perturbation theories), ions, or molecules have been developed in different versions; we here select a Rayleigh-Schrödinger type[4], most directly connected with standard perturbation theory in which effects of the Pauli principle on interactions are neglected. The usual treatment of van der Waals forces is an example of this latter category.

Let us now state explicitly the assumptions of the model. The validity of these assumptions is partly hypothetical, partly empirical; it must be ultimately established by comparison with experimental facts.

A) Weak exchange interactions may be evaluated by using perturbation methods, starting from free-ion wave functions.

B) The Pauli principle as applied to the whole system determines the essential characteristics of (weak) exchange interactions.

C) Properties of (weak) exchange interactions are not primarily dependent upon the number of unpaired electrons per atom or ion. As a consequence, we may replace, on each paramagnetic cation, its unpaired electrons by one "effective electron". The number of unpaired electrons is reflected indirectly in the "magnetic size" of the orbital of the effective electron.

Assumptions (A) and (B) have already been discussed. Assumption (C) may be made less *ad hoc* by observing that the stable magnetic patterns of insulating solids with 3d-cations are all antiferromagnetic; moreover, for solids with the B1 (NaCl) structure the patterns are all of the so-called second kind (except for CrN). In addition, the orders of magnitude of their Néel temperatures are the same (of the order of 100 K). Since the 3d-cations involved (Ni, Co, Mn, Fe, *etc.*) have varying numbers of unpaired electrons, this experimental fact indicates that the essential aspects of magnetic ordering may be described by assuming *one* "effective" unpaired electron per cation. In accordance with this assumption, we replace the electrons of the anion by *two*, spin-paired, effective electrons. For the simplest system affording superexchange of two cations and one anion, this then leads to the so-called "three-center, four-electron model" proposed by *Kramers*[5] as early as 1934. We note that the zero-order, free-ion, wave functions are necessarily *not orthogonal* to each other.

3. Applications of the Model

3.1. Indirect Exchange Interactions in Solids Containing Cations with an Incomplete 3d Electron Shell

Since the model adopted for weak chemical bonding has been devised to describe magnetic coupling in insulating solids, its first application[6, 7] must obviously deal with this class of phenomena. Consider two paramagnetic cations A and B, each with one effective electron, and one diamagnetic anion, C, with two spin-paired effective electrons. We start from an assignment of electrons 1, 2, 3, and 4 in which electron 1 is on cation A, 2 on cation B, and the electrons 3, 4 on anion C. Then, following standard methods, it is easy to construct a wave function for the state of three non-interacting ions which satisfies the Pauli principle. Note that there are two such functions, one for the case where the spins of the two unpaired electrons are parallel, one for the case where these spins are antiparallel. Next, the interactions between electrons on different ions are considered in first, second, *etc.* order of perturbation theory, very similar to a usual Rayleigh-Schrödinger perturbation analysis without exchange (*i.e.* neglecting the Pauli principle). An *ad hoc* assumption is here that we do not have to go beyond interactions of second order.

In view of the fact that there are only two unpaired electrons, the first-order interaction energy becomes particularly simple. It is, of course, different for the two spins of the unpaired electrons on the two cations parallel or antiparallel. This interaction energy $E^{(1)}$ can be written as

$$E^{(1)} = M + N \cdot \begin{cases} +\frac{1}{4} \text{ for parallel spins} \\ -\frac{3}{4} \text{ for antiparallel spins} \end{cases} \quad (1)$$

where M and N are spin-independent. We have evaluated (1) for Slater functions $r^{n-1}\exp(-pr)$ on each of the centers A, B, and C[8]. Actually, it turns out that the results are

very similar for $n=1$, 2, 3, and 4, so that we limit ourselves to 1s-functions ($n=1$). We only consider configurations of A, B, and C for which the distances AC and BC are the same. The opening angle θ at the anion C is varied from $\theta=40°$ to 180°; the choice of parameters is $p_A=p_B=1\,au^{-1}$,

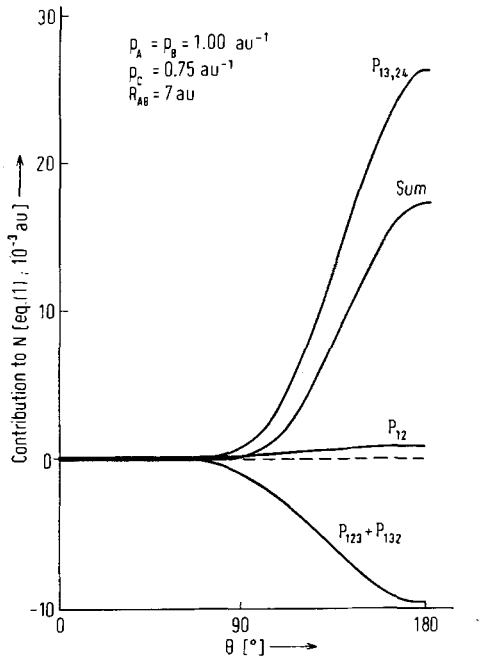

Fig. 1. Contributions to singlet-triplet splitting in the three-center, four-electron model, from permutations involving both electrons with unpaired spin (1, 2), as well as their sum, as a function of the opening angle θ at the anion. Parameters p_A, p_B (cations) and p_C (anion) of the 1s Slater orbitals are given. The unit of energy is 10^{-3} au (1 au $\approx 0.3\times10^6\,kT$). Positive values indicate singlet, negative values triplet stability.

$p_C=0.75\,au^{-1}$, $R_{AB}=7$ au. The results are given in Figure 1; from (1) we note that a positive contribution to N implies that the antiparallel (singlet) configuration is more stable, whereas negative contributions imply higher stability for parallel spins (triplet). The unit of energy is 10^{-3} au (1 au $\approx 0.3\times10^6\,kT$; T is given in K, k is Boltzmann's constant).

We see that first-order exchange favors antiparallel coupling of the cation spins, except for a region of weak ferromagnetic alignment around $\theta=80°$. The permutations $P_{13,14}$ and P_{12} always lead to antiferromagnetism, whereas $P_{123}=P_{132}$ always favors parallel spins. For large openings θ the coupling is strongly antiferromagnetic, in agreement with experiment.

Of particular interest for comparison with experiment is the narrow θ-range of weak ferromagnetic (*i.e.* parallel) coupling. Considering, in particular, the results for $\theta=85°$ (-0.078×10^{-3} au) and for $\theta=95°$ ($+0.178\times10^{-3}$ au) we see that in the first case the coupling is weakly ferromagnetic, in the second case weakly antiferromagnetic (*i.e.* antiparallel). Experimentally, it is known that the type of coupling does indeed sensitively depend on the opening θ just in this region. Note that the angle dependence of the exchange is due solely to the Pauli principle applied to a system of spherically symmetric atomic wave functions.

On the basis of the above simple model, 180°-indirect exchange in solids of composition XMF_3 and X_2MF_4 (X = K, Rb, Tl; M = Mn, Co, Ni) has been evaluated[9] and compared with experimental results. The available data show that the "exchange constants" $\mathcal{J}/k$ [where $\mathcal{J}$ is the same as $-N/2$ of eq. (1) and k is the Boltzmann constant] for Mn^{2+}, Co^{2+}, and Ni^{2+} are in the ratio 1:3.6:7.7 interpolated at the same distance $R=4.074$ au, and that they depend on R (cation-cation) as $|\mathcal{J}/k|\approx R^{-n}$, with $n\approx12$. Determining the values of the Slater p parameter for these cations from existing SCF calculations and diamagnetic susceptibilities, the effective-electron model yields 1:3.3:7.6 for this ratio and a value of n indeed close to 12. Very recent results for a number of other compounds, *e.g.* Cl in place of F, and also including the compound with M = Fe, are given in Table 1.

Table 1. Exchange constants $\mathcal{J}/k$ for 180°-superexchange in a number of compounds as predicted by the effective-electron model and compared with experiment. The numbers in parenthesis indicate experimental accuracy; R is the cation-cation nearest-neighbor distance. Note that in the first compound the anion is Cl^- and in the last compound the cation is Fe^{2+}.

Compound	R [Å]	$\mathcal{J}/k$ calculated	$\mathcal{J}/k$ experimental
Cs_2MnCl_4	5.130	− 5.0	− 5.0 (2)
$TlMnF_3$	4.250	− 3.1	− 3.0 (3)
$KCoF_3$	4.058	−17.6	−19.2 (20)
K_2NiF_4	3.992	−50	−51.5 (3)
Rb_2FeF_4	4.214	− 6.1	− 6.5 (15)

The results for 180°-superexchange are very much better than those produced by any other theoretical model. We have also applied[7] the effective-electron model to the three modifications of manganese(II) sulfide [B1 (NaCl lattice), B3 (sphalerite lattice), and B4 (wurtzite lattice)]. All three modifications are antiferromagnetically ordered at low temperatures, but of different kind. It is often supposed in the literature that different *covalent* character of the Mn—S bond is responsible for the different ordering. Application of the effective-electron model shows that *ionic* Mn—S bonding accounts very well for the phenomena if we take the differences in three-ion exchange properly into account.

3.2. Stability of Noble-Gas Halides: A Case of Selective Valence

Results bearing more directly on the concept of valence are obtained from applications of the model to bonding in molecules. We select the noble-gas halides as prime example, because their very existence seems to invalidate *Lewis'* octet rule and thus to attack the traditional interpretation of "valence" at one of its principal roots.

Since 1962 it has been known that XeF_2, XeF_4, XeF_6, KrF_2, and KrF_4 are stable molecules, with binding energies of about 30 kcal/mol for the Xe compounds, about 15 kcal/mol for the Kr compounds. Extensive first-principle theoretical analyses have not been very successful: an electron-pair description of bonding is practically hopeless from the outset since in the Xe compounds more and more electrons must be promoted from inner shells. Application of the molecular-orbital method does lead to stable molecules, but theoretical selectivity regarding stable geometric configurations is much too low to be convincing. In particular, it is difficult to explain why XeF_4 is square-planar and not tetrahedral, and why noble-gas compounds with Cl instead of F do not exist.

The three-atom exchange model used for the analysis of magnetic ordering in solids is also applicable[10, 11] to these molecules. A halogen atom has an open p shell of electrons

and spin 1/2, represented in the model by one effective electron. The rare-gas atom has closed shells, replaced by two spin-paired effective electrons. A complex XRX, with X a halogen atom, R a noble-gas atom, is then represented by the same three-center, four-electron model as we have already applied in the discussion of magnetic ordering. The extension to molecules RX_n with $n>2$, is straightforward. For the orbital parts of the effective-electron wave functions we chose a simple Gaussian form[12]:

$$\phi(r)=(\beta/\pi^{1/2})^{3/2}\exp(-\beta^2 r^2/2)$$

where r is the distance from the effective electron to its nucleus and β is a parameter characteristic for the size of the atom. If we denote the parameter for the noble-gas atom by β, that for the halogen atom by β', then $\gamma=(\beta'/\beta)^2$ is a measure for their relative size; for $\gamma<1$ the halogen atom is larger than the rare-gas atom, whereas for $\gamma>1$ the situation is reversed. The interaction energy for a complex XRX is evaluated in first- and second-order Rayleigh-Schrödinger type exchange perturbation theory[4]. In Figure 2 we demonstrate the selectivity of these three-atom exchange interactions. In the figure, the calculated binding energy (per bond) for linear symmetric noble-gas halides in the singlet state is plotted as a function of the relative-size parameter γ, for a value of the dimensionless parameter $\beta R_0=1.1$, where R_0 is the noble-gas-halogen atom distance. Estimated values[10] for γ are ≈ 2.5 for XeF_2, ≈ 1.8 for KrF_2, and ≈ 1 for $XeCl_2$. For other halides the γ values are still lower.

The curve agrees strikingly well with experimental findings in predicting XeF_2 and KrF_2 to be stable, $XeCl_2$ to be unstable, and other halides incapable of existence. Also, the binding

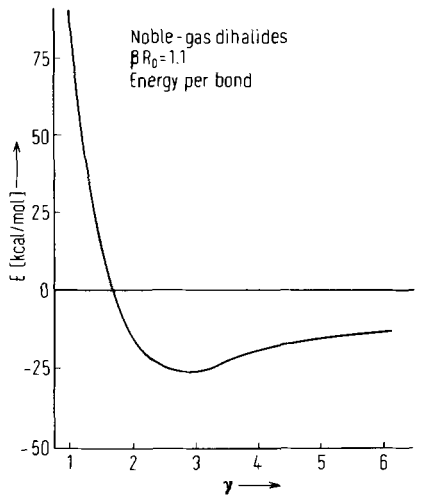

Fig. 2. Sum of first- and second-order interaction energies for xenon dihalides, as a function of the relative size γ of the xenon and the halogen atoms.

energy in KrF_2 is considerably lower than in XeF_2, again in agreement with experiment. The binding is found to be very stereospecific in that a XeF_2-molecule with a 90°-opening at the xenon atom exhibits no bonding at all. All dihalides are unstable in the triplet state.

In order to examine the configurations of noble-gas halides with coordination numbers >2, we carried out the calculations[11] for XeF_4 in both a square-planar and a tetrahedral geometry. Here, we have different states of total spin to consider; these are indexed in Figures 3 and 4 by different values of total spin S. Figure 3 gives the result for the square-planar, Figure 4 for the tetrahedral arrangement; the value of βR_0 is approximately 1.15.

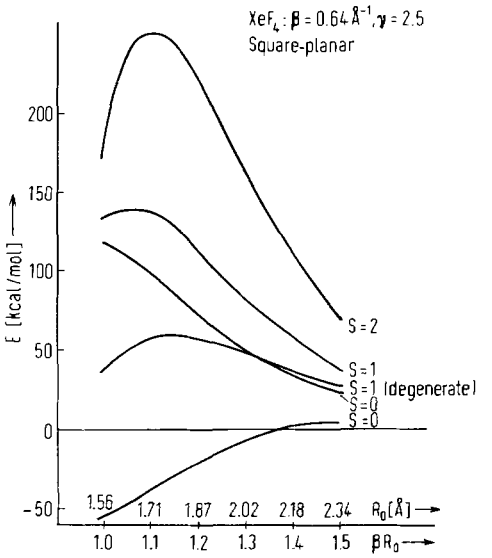

Fig. 3. Calculated energy per bond of the square-planar configuration for the molecule XeF_4, as a function of the dimensionless parameter βR_0, where R_0 is the Xe—F distance.

The results are seen to be in very good agreement with experiment, with regard both to stereospecificity and to binding energy (exp. ≈ 30 kcal/mol per bond). The introduction of a relative-size parameter as an important quantity in determining the possibility of chemical bonding is an old idea.

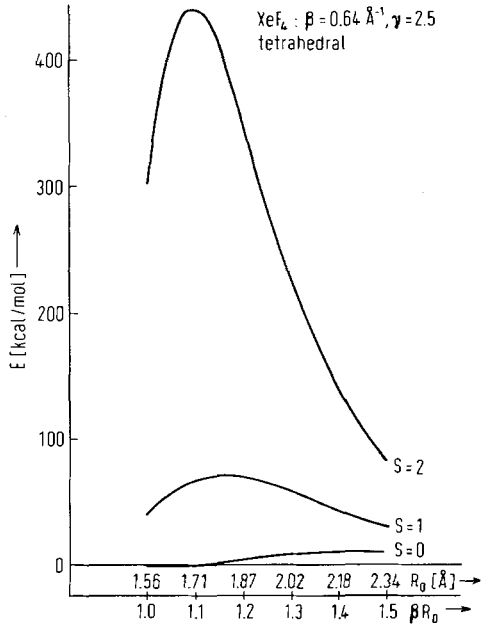

Fig. 4. Calculated energy per bond of the tetrahedral configuration for the molecule XeF_4, as a function of the dimensionless parameter βR_0 (see Fig. 3).

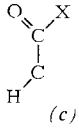
Stability of ionic crystals in the Goldschmidt model (1927) depends sensitively on the ratio R_+/R_- of cation and anion radii, the ions being considered as rigid spheres. This size



concept was also used extensively by *van Arkel* and collaborators in an analysis of properties of inorganic molecules and solids[13]. In a sense, therefore, introduction of three-atom exchange interactions seems to re-establish the significance of some old ideas regarding chemical bonding and valence.

3.3 Rotational Barriers in Simple Molecules

A last type of application of many-atom exchange interactions in the above model formalism concerns the evaluation of rotational barriers in simple organic and inorganic molecules. The subject of rotational barriers dates back to the early days of stereochemistry and to *Van 'tHoff* (1874); he postulated that rotation about a C—C single bond should be free, that around a C=C double bond should be restricted. Now, 100 years later, it can only be stated that these early views have been confirmed to a substantial extent by a great many experiments. Specifically, we now know that rotation around a carbon-carbon single bond, while not completely free, is hampered by a barrier of only a few kcal/mol, whereas the rotational barrier in *e.g.* ethylene is much higher, namely about 65 kcal/mol. Promising theoretical approaches date only from 1963, when *Pitzer* and *Lipscomb*[14] calculated a barrier in ethane of 3.3 kcal/mol, compared with an experimental value of 2.8 kcal/mol. *Pitzer, Kern, et al.* obtained interesting results for ethane[15] (1968) and methanol[16] (1974) on the basis of a bond-orbital concept, showing that exchange interactions are essentially responsible for the barrier. If the wave function is not antisymmetrized, then the barrier has the wrong sign.

We have carried out a model calculation of rotational barriers in about 40 simple molecules[17] including ethane, its halogen derivatives, as well as inorganic molecules such as B_2Cl_4, Si_2H_6, *etc.* The influence of the atoms on the axis of rotation was neglected. The electrons of the remaining atoms (H, or halogen) were replaced by one effective electron each, with parallel spins. The results are generally in good agreement with experiment; they will, however, not be reported here because in all these cases we have to do with so-called "repulsive dominant" barriers, *i.e.* the stable configuration is determined by a minimum in repulsive interactions between groups of atoms on different side of the axis of rotation.

Very different, and intriguing, are the phenomena involving barriers in molecules which contain a C=O double bond, of which the simplest representative is acetaldehyde. Acetyl halides were also considered[18]. The most stable molecular geometry is the *trans* configuration *(c)*, in which C—X is *trans*

(c)

to C—H, and C—X, C=O, and one C—H lie in the same plane. This preference cannot be explained on the basis of repulsive interactions between non-bonded atoms; thus, we speak here of an "attractive dominant" barrier. Attractive many-body exchange interactions, needed to explain the particular stability of the conformation *(c)*, can be taken over from the phenomenon of superexchange in insulating solids (cf. Section 3.1): the C=O bond replaces the diamagnetic anion, the atoms H and X (halogen) the two cations. We use again simple Gaussian functions for the orbitals of the four effective electrons, with β_{db} as characteristic parameter for the double bond.

We find, first of all, that the barrier is indeed sensitive to variations in β_{db}, and that it has the correct sign. For a series of molecules H_3C—COX (X=H, F, Cl, Br, I) the "best" value of β_{db} varies very little from molecule to molecule

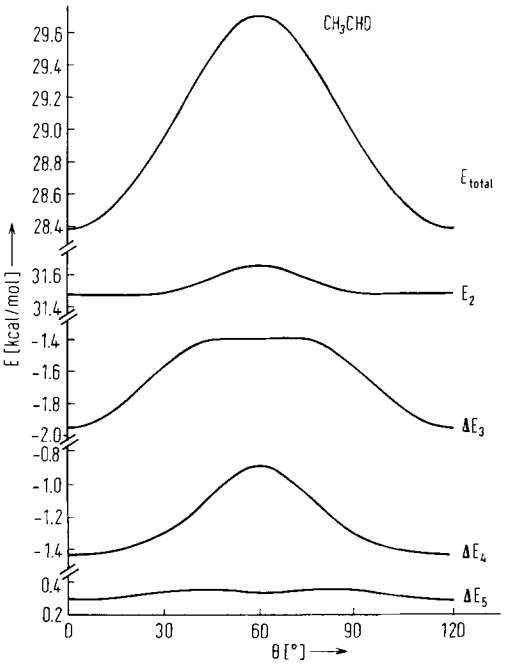


Fig. 5. Cluster expansion of the first-order energy for the molecule CH_3COH in terms of two-atom interactions (E_2), simultaneous interactions between three (ΔE_3), four (ΔE_4) and five atoms (ΔE_5), as a function of the dihedral angle θ (at $\theta=0°$ the C=O double bond eclipses one of the C—H bonds of the methyl group). Note the change of scale for each curve.

and gives good agreement with experiment (barrier 1—2 kcal/mol). Also, we undertook a cluster expansion of the first-order energy, *i.e.* we have split this energy into contributions due to interactions between two centers (E_2), three centers (ΔE_3), and, in order to include the methyl group, between four (ΔE_4) and five centers (ΔE_5). In Figure 5, these results are given as function of the angle of rotation θ ($\theta=0°$ denotes *cis* arrangement of C=O and C—H).

From the figure we see that E_2 is repulsive and varies little with θ; ΔE_3 is negative and most attractive at $\theta=0°$; the same applies to ΔE_4. The five-center interaction, ΔE_5, is very small and practically independent of θ. Further, we have found that ΔE_3 is indeed due to superexchange in the HC—COX unit.

All three examples we have analyzed can, therefore, be understood quantitatively in terms of a simple model in which the consequences of permutation symmetry of the wave function, *i.e.* the Pauli principle, are rigorously taken into account and in which no space-oriented one-electron orbitals and no covalency effects play a role.

Synthetic and Mechanistic Aspects of Inorganic Insertion Reactions. Insertion of Carbon Monoxide

By Fausto Calderazzo[*]

The synthetic potential and the mechanistic aspects of inorganic insertion reactions of carbon monoxide, especially into metal-carbon σ-bonds, are considered. Reactions of this type are encountered among most 3d, 4d, and 5d elements. In one case it has been demonstrated that the CO insertion proceeds by alkyl migration; this is likely to be a general feature of all such reactions. If an alkyl migration takes place, then insertion of CO into the M—C bond is governed kinetically by the cleavage of that bond. CO abstraction from RCO—M bonds most commonly proceeds by rate-determining vacation of a coordination position. Both CO insertion and abstraction are usually highly stereospecific.

1. Introduction

It is advantageous to define an insertion reaction in coordination chemistry solely on the basis of its stoichiometric result. For a metal complex M—L, therefore, we speak of an insertion reaction if the stoichiometric product results from the formation of new bonds by X to both the metal M and

$$X + M—L \rightarrow M—X—L \quad (1)$$

the ligand L [eq. (1)]. The classical example of an insertion reaction is the carbonylation of alkyl(pentacarbonyl)manganese by carbon monoxide, discovered almost twenty years ago [eq. (2)][11].

$$R—Mn(CO)_5 + CO \rightleftarrows R—CO—Mn(CO)_5 \quad (2)$$

The mechanism of inorganic insertion reactions is known in only few instances. In the great majority of cases the reaction mechanism is extrapolated from the experimental data (usually reaction kinetics or stereochemistry of reaction products) because no other necessary and complementary information is available.

The demands made of reagents M—L and X in eq. (1) can now be discussed. The species X to be inserted into the M—L bond is by definition "coordinatively unsaturated", since it increases its coordination number on forming new bonds. Its unsaturation is usually of the $p_\pi - p_\pi$ type (CO, SO_2, CO_2, *etc.*). Table 1 defines the insertion reactions which have been observed or may, at least in principle, become observable. The inserted group X can function in the end product as a monoatomic (C̲O, C̲NR, S̲nCl$_2$), a diatomic (>C=C<, —C≡C—, O_2), a triatomic (CS_2), or a polyatomic (S_n) bridge. Some of the groups X may be bidentate, *e.g.* CO_2 and CS_2 which insert into M—NR_2 bonds to give dialkylcarbamato- and dialkyldithiocarbamato complexes, respectively. Insertion of $SnCl_2$[21] is illustrated in eq. (3).

Table 1. Experimentally detected and theoretically possible insertions reactions.

Metal-ligand bond	Group inserted
M—C	CO, CNR, CR_2, >C=C<, —C≡C—, CO_2, O_2, SO_2, S_n, $SnCl_2$
M—H	CO_2, CNR, >C=C<, RNCO
M—N	CO_2, CS_2
M—O	RNCO, SO_2
M—S	CS_2
M—Cl	CNR, CR_2, $SnCl_2$
M—M	$SnCl_2$

$$CpFe(CO)_2Cl + SnCl_2 \rightarrow CpFe(CO)_2SnCl_3 \quad (3)$$
Cp = cyclopentadienyl

The present article will deal exclusively with insertions of carbon monoxide into transition metal compounds. (For insertions into compounds of nontransition elements see [3].) The most widely studied reaction is the insertion of CO into metal-carbon σ-bonds. An exhaustive and excellent review article was written on this subject four years ago[4]. However, considerable advances have been achieved since then.

The interest in carbon monoxide insertion reactions resides in the scope they offer for functionalizing hydrocarbons and other substrates to give more valuable organic compounds, such as aldehydes, acids, and esters. Catalytic reactions of this kind are hydroformylation[5], the reaction of methanol with CO to give acetic acid[6], the double insertion of CO and olefins within the coordination sphere of a metal to give acids or esters in the presence of water or alcohols[7], the synthesis of hydroquinone by carbonylation of acetylene in the presence of ruthenium catalysts[8], the synthesis of acrylic acid from acetylene in the presence of nickel catalysts[9] (catalytic aspects of carbon monoxide insertion are to be found in [10, 11]).

Also the Fischer-Tropsch reaction and its modifications[12], which amounts to a catalytic hydrogenation of carbon monoxide, has again attracted attention[13] as a tool for exploiting coal reserves.

It is interesting to note the case of a metal complex which is inserted into the X—Y bond of a covalent molecule (X—Y = H_2, alkyl halide, acyl halide) [eq. (4)][14, 15]. The reactions

$$L\text{–}M + X\text{–}Y \rightleftharpoons L\text{–}M\begin{matrix}X\\Y\end{matrix} \quad (4)$$

typified by eq. (4) are usually termed oxidative additions; the coordination number and oxidation number of the metal increase by two units. In insertion reactions of the classical type [eq. (1)] the metal alters neither its coordination nor its oxidation number. For example, in eq. (2) the manganese of the insertion product maintains its coordination number 6 and its oxidation state I. Accordingly, the stereochemical and electronic demands of the metal are seen to be less stringent in insertion reactions than in oxidative additions. Thus, it is not surprising that insertion reactions can be observed for nearly all transition elements.

2. General Considerations

The shaded areas of Figure 1 represent those transition elements for which carbon monoxide insertion reactions into σ-bonds have been reported. Generally speaking, an insertion reaction of this type is regarded as known when any one of the following stoichiometric reactions (or the reverse reactions) has been fully characterized:

$$R\text{—}M + CO \rightarrow RCO\text{—}M \quad (5)$$
$$R\text{—}M(CO) \rightarrow RCO\text{—}M \quad (6)$$
$$R\text{—}M(CO) + L \rightarrow RCO\text{—}M(L) \quad (7)$$
L = two-electron donor

Equations (5) to (7) specify three types of CO insertion reactions:

1) CO insertion into the metal-carbon σ-bond of a metal complex which may or may not contain coordinated carbonyl groups;

2) conversion of a coordinated CO group into an acyl (or aroyl) group (the reverse of this reaction has been observed, see Section 4);

3) CO insertion into a metal carbonyl complex promoted by a Lewis base L.

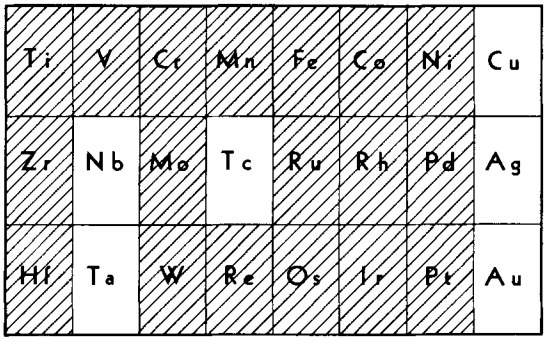

Fig. 1. CO insertion into transition metal-carbon σ-bonds. The hatched areas mean that CO insertions are known for the metal concerned. References: titanium [20], zirconium [21], hafnium [22], vanadium [23], chromium [24], molybdenum [25], tungsten [26], manganese [27], rhenium [28], iron [29], ruthenium [30], osmium [31], cobalt [32], rhodium [33], iridium [34], nickel [35], palladium [36], platinum [36a, 37].

The data of Figure 1 will now be considered. Only few metals are not yet known to give insertions of carbon monoxide into metal-carbon bonds. In the case of technetium, radioactive decay has probably discouraged an extensive research effort. However, CO insertion into a Tc—OR bond to give an alkoxycarbonyl compound has been reported[16].

The discovery of CO insertions also appears likely for other metals, especially considering that ethylene insertion is already known for niobium[17], that tetrafluoroethylene has been reported[18] to insert into the gold-methyl bond, and that isocyanides insert into copper-aryl bonds[19].

An important general observation is that relatively few kinetically stable CO inserted products are known for ruthenium, cobalt, rhodium, nickel and palladium. This is understandable in view of the comparatively low stability of both alkyl-(aryl-) and acyl (aroyl) derivatives of these metals. It is therefore not surprising to find that these metals are usually effective catalysts for the carbonylation of organic substrates.

A further point of interest comes from the observation *(vide infra)* that 5d metals are usually less inclined to undergo CO insertion reactions than the 3d and 4d metals of the same subgroup. It is now becoming plausible that the lower reactivity of 5d transition elements might be related to the higher strength of the metal-carbon bond.

Some thermochemically measured element-carbon bond dissociation energies are collected in Table 2. From these data it may be provisionally concluded that metal-carbon σ-bonds to alkyl and aryl groups are by no means weak bonds, and from the comparison between the manganese-methyl and the rhenium-methyl systems[40], it is evident that the 5d element forms stronger bonds to carbon then its 3d analog.

Since metal-carbon bond breaking is definitely an important step in carbonylation reactions, this may result in a slower

carbonylation of $Me—Re(CO)_5$ compared with $Me—Mn(CO)_5$. Unfortunately no quantitative data are yet available. In this connection it is, however, important to note that a considerable decrease in rates was found for the tungsten complex in the following reaction[26]:

$$R—MCp(CO)_3 + L \rightarrow RCO—MCp(CO)_2L \quad (8)$$
$$M = Cr, Mo, W;\ L = PR_3$$

Carbon monoxide insertion reactions are still unknown for organolanthanides[43] and organoactinides[44]. However, this may simply be due to the infancy of the chemistry of σ-alkyls and aryls of 4f and 5f elements.

3. Kinetic Studies on Manganese Compounds

Mechanistically speaking, insertion reactions have many points in common, independently of the metal to which the alkyl (or aryl group) is bonded. The kinetic and mechanistic results obtained for manganese will be discussed first, and then it will be indicated whether and how they can be applied to other systems.

The kinetic data for the CO insertion [eq. (2)] into $Me—Mn(CO)_5$[27a] and $Ph—Mn(CO)_5$[45] can be accommodated[27b] by a mechanism involving the formation of an acyl(tetracarbonyl) intermediate [eq. (9)].

$$R—Mn(CO)_5 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RCO—Mn(CO)_4] \underset{k_{-2}(-L)}{\overset{k_2(+L)}{\rightleftharpoons}} \begin{matrix} RCO—Mn(CO)_4L \\ L = CO \end{matrix} \quad (9)$$

This intermediate is suggested to be formed by alkyl migration in the original alkyl derivative to one of the terminal CO groups. This is in agreement with the mechanism of methyl migration found[27c] to be operative in the $Me—Mn(CO)_5/^{13}CO$ system by infrared spectroscopic methods. The acyl(tetracarbonyl) intermediate may be solvated, especially in solvents of high coordinating power. However, the structure of the intermediate is a difficult question to answer (see Section 4).

By applying the steady state approximation to the kinetic scheme [eq. (9)], and under the reasonable assumption that the term k_{-2} is comparatively small, the following kinetic equations are obtained [eqs. (10) and (11)].

$$k_{obs} = \frac{k_1 k_2 [L]}{k_{-1} + k_2 [L]} \quad (10)$$

$$1/k_{obs} = \frac{k_{-1}}{k_1 k_2 [L]} + \frac{1}{k_1} \quad (11)$$

The kinetic expression (10) predicts that when the term $k_2[L]$ is small (for example at atmospheric and lower pressure of carbon monoxide), the term k_{-1} may not be negligible, so that k_{obs} is finally a function of [L].

In contrast, at elevated CO pressure, under conditions such that k_{-1} may be small compared with $k_2[L]$, k_{obs} can become practically identical to k_1. The latter, within the validity of the assumptions, is the rate constant for the formation of the acyl(tetracarbonyl) intermediate.

The reaction of $Me—Mn(CO)_5$ with CO is first-order with respect to the metal complex, and dependent on the concentration of CO at atmospheric and lower pressure[27a]. On the other hand, the reaction of $Ph—Mn(CO)_5$ is independent of CO concentration[45] at the same CO pressure. Moreover, the rate of carbonylation of $Me—Mn(CO)_5$ becomes independent[27d,46] of CO concentration above 15 atm. In agreement with the kinetic expression (11), a good linear plot of $1/k_{obs}$ *vs.* 1/[CO] was obtained for the $Me—Mn(CO)_5$/CO system. From the intercept of the linear plot, k_1 can be calculated (see Table 3). Insertion of CO into the Me—Mn bond of $Me—Mn(CO)_5$ involving nucleophiles other than CO [eq. (12)] is found in several instances to be first order in metal complex concentration and independent of [L]. The kinetic scheme [eq. (9)] can also be applied to those cases.

$$Me—Mn(CO)_5 + L \rightarrow MeCO—Mn(CO)_4L \quad (12)$$

Table 3. Rate constants for the formation of the proposed acetyl(tetracarbonyl) intermediate from $Me—Mn(CO)_5$ and a ligand L [eqs. (9) and (12)].

Ligand L	$k_1 \times 10^4$ [s^{-1}]	Ref.
$P(OPh)_3$	9.9 [a]	[27b]
PPh_3	4.0 [b]	[27b]
$c\text{-}C_6H_{11}NH_2$	3.7 [b]	[27b]
PPh_3	6.6 [c]	[47]
CO	≈8	[46]

[a] In tetrahydrofuran at 25.5 °C.
[b] In 2,2'-diethoxydiethyl ether at 25.5 °C.
[c] In 2,2'-diethoxydiethyl ether at 30 °C.

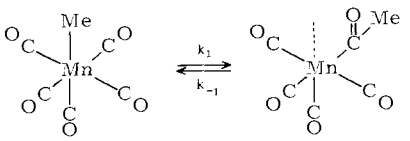
The validity of the experimental results is confirmed by the observation (see Table 3) that the rate constant k_1 for the $Me—Mn(CO)_5$/CO system is in satisfactory agreement with the $k_{obs} \approx k_1$ found for the $Me—Mn(CO)_5/PPh_3$ system under the same experimental conditions.

Since the rate for the carbonylation of $Ph—Mn(CO)_5$ by CO was found[45] to be independent of [CO], k_{obs} in this case is practically equal to the rate constant for the formation of the benzoyl(tetracarbonyl) intermediate.

The data for the reaction

$$R—Mn(CO)_5 + CO \rightleftarrows RCO—Mn(CO)_5$$

at 30°C in 2,2'-diethoxydiethyl ether, *i.e.* $10^4 \times k_1 = ca.$ 8 (R = Me) and 1.0 s^{-1} (R = Ph), lead to the conclusion that the Me—Mn bond is kinetically more labile than the Ph—Mn bond. These are believed to be the first comparative kinetic data available for transition elements. Phenyl derivatives are usually thermally more stable than the methyl ones[48]. Assuming other transition elements to resemble manganese, an order of magnitude difference between the kinetic lability of the two M—R bonds may well explain the empirical observations. Whether this is ultimately a purely kinetic effect or has its origin in thermodynamic stabilization of the aryl derivative is still an open question[49].



To conclude this section, mention should be made of a recent experiment[50] showing that acetyl migration, rather than methyl migration, is not a kinetically important pathway. Pyruvoyl(pentacarbonyl)manganese was synthesized by the conventional method [eq. (13)] and fully characterized (by X-ray analysis, too).

$$[Mn(CO)_5]^- + MeCOCOCl \rightarrow MeCOCO{-}Mn(CO)_5 + Cl^- \quad (13)$$

The pyruvoyl complex was shown to decarbonylate at a much slower rate than MeCO—$Mn(CO)_5$, thus excluding its intermediacy in CO abstraction from MeCO—$Mn(CO)_5$.

4. Mechanistic and Stereochemical Studies

It is now possible to specify the nature of the intermediate. If methyl migration is the mechanism of formation of acetyl(pentacarbonyl)manganese[27c], the rate constant k_1 refers to the process shown in eq. (14).

(14)

The vacant position may be occupied by the solvent. Considerable solvent effects were found for the reaction of Me—$Mn(CO)_5$ with CO[27a], Me—$FeCp(CO)_2$ with PPh_3[25a], and Me—$MoCp(CO)_3$ with PR_3 and $P(OR)_3$[25a]. In neat tetrahydrofuran (THF) Me—$Mn(CO)_5$ generates a band at about 1650 cm^{-1}[27a], suggestive of an adduct MeCO—$Mn(CO)_4$(THF). Dissolution of $PhCH_2$—$FeCp(CO)_2$ in dimethyl sulfoxide (DMSO) was reported[51] to result in a color change and the appearance in solution of a new band at 1600 cm^{-1}, suggesting the presence of $PhCH_2CO$—FeCp(DMSO)CO.

The kinetics of the carbonylation of d^6 iridium(III)[34a] and d^8 platinum(II)[37a] were interpreted as involving only little solvent assistance if any, although an acyl intermediate was considered to be operative also in these cases [eqs. (15) and (16)].

$$R{-}IrCl_2(CO)_2L + L' \rightarrow RCO{-}IrCl_2(CO)LL' \quad (15)$$

$$Et{-}PtCl(CO)L + L \rightarrow EtCO{-}PtClL_2 \quad (16)$$

No assistance by the solvent and the intermediacy of an acyl species were suggested by *Craig* and *Green*[25b, 25c] for CO insertion into some alkyl derivatives of d^4 molybdenum(II) complexes:

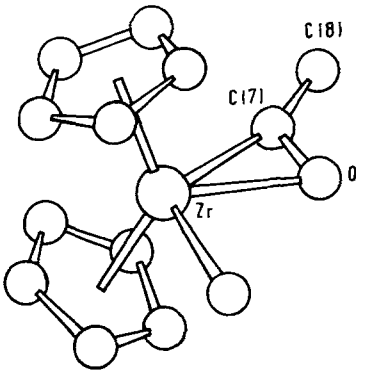
$$R{-}MoCp(CO)_3 + L \rightarrow RCO{-}MoCp(CO)_2L \quad (17)$$

L = PPh, $P(OR)_3$; R = Me, Et, σ-C_3H_5

It does not necessarily follow from the lack of kinetic evidence for solvent assistance that a coordinatively unsaturated, presumably highly energetic, complex is formed during these carbonylation reactions. It has recently been found[21] that the acetyl group of MeCO—$ZrCp_2Me$, obtained by carbonylation of Me_2—$ZrCp_2$ [eq. (18)], is bonded to zirconium through

$$Me_2{-}ZrCp_2 + CO \rightarrow MeCO{-}ZrCp_2Me \quad (18)$$

both the carbon and the oxygen atoms (see Fig. 2). The acetyl group in this zirconium(IV) complex of d^0 configuration can best be described as a four-electron donor, by which the central metal atom assumes the Xe inert gas electronic configuration.



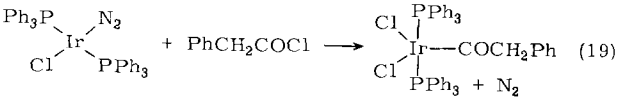


Fig. 2. Molecular structure of MeCO—$ZrCp_2Me$ [21]. Bond distances: Zr—C(7), 2.197(6); Zr—O, 2.290(4); C(7)—O, 1.211(8); C(7)—C(8), 1.492(10).

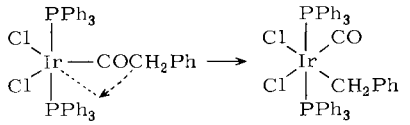
"Side-on" coordination of the acyl group to a transition element had been postulated[52a] for d^6 ruthenium(II) complexes of formula RCO—$RuCl(CO)(PPh_3)_2$ mainly on the basis of infrared spectroscopic results [ν_{CO}(acyl) = 1505—1510 cm^{-1}]. "Side-on" coordination of CO in dinuclear manganese complexes is also of interest in this connection[52b, 52c].



We shall now consider the ground-state structural features of alkyl- and acyl derivatives of transition elements, and it will be shown that the molecular arrangement found for the acetylzirconium complex does not represent an isolated example. The type of molecular arrangement found for the zirconium complex could, in certain cases, be close to the structure of the intermediate. The new finding shows that the metal may satisfy its electronic and stereochemical demands by binding the acyl group in a way different from that known *(vide infra)* in most acyl derivatives of transition elements. The acyl group is normally *C*-bonded to the metal ("end-on") with long nonbonding metal-O distances.

An important contribution to the problem of the nature of the intermediate in carbon monoxide insertion reactions has been provided by *Kubota et al.*[34b, 53]. Oxidative addition of phenylacetyl chloride to a dinitrogen complex of iridium(I) according to eq. (19) afforded an acyl derivative of iridium(III)[53a] (cf. also[53b]).

(19)

The phenylacetyl complex is monomeric in solution and probably has a trigonal-bipyramidal structure. Whatever may be the reason for the stabilization of this apparently coordinatively unsaturated species, its isolation and thermal transformation into the alkyl compound [eq. (20)] are very relevant experimental facts in connection with CO insertion. The acyl-

(20)

alkyl conversion may be assumed to take place *via* the rate-determining migration of the CH_2Ph group to give the stable hexacoordinate iridium(III) complex. The rate constants for the conversion have been determined[34b] for some *p*-substituted phenylacetyl derivatives (with R in place of Ph) at 30 °C in benzene:

R	*p*-$MeOC_6H_4$	*p*-MeC_6H_4	*p*-$O_2NC_6H_4$
$10^4 \times k(s^{-1})$	9.2	8.35	3.9

According to the assumption indicated in eq. (20), these are the rate constants corresponding to the cleavage of the C—C bond in the acyl group. The results found by *Kubota et al.* show that for iridium(III) complexes, and possibly for others too, alkyl migration from an acyl group to a vacant coordination site on the metal is not a particularly fast process. This is an interesting result because for manganese it was not possible to directly measure the same kind of process [*i.e.* k_{-1} of the kinetic scheme (9)]. The rate constant k_1 in Table 3 for $Me—Mn(CO)_5$ is that for methyl migration from the metal. We can only estimate k_{-1} by studying the process of CO abstraction from $MeCO—Mn(CO)_5$ to give $Me—Mn(CO)_5$ [reverse of equation (2), R = Me]. By the principle of microscopic reversibility both processes should have the same intermediate indicated in eq. (9) as $RCO—Mn(CO)_4$. The rates of CO abstraction from $RCO—Mn(CO)_5$ at 30 °C in 2,2′-diethoxydiethyl ether are[54]:

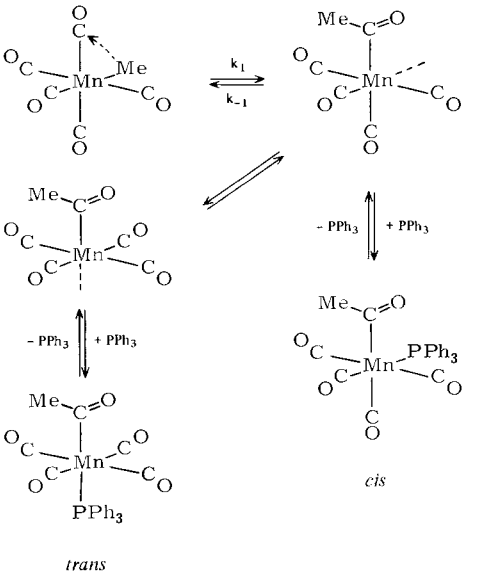
R	*n*-Pr	Et	Me	$PhCH_2$
$10^5 \times k(s^{-1})$	5.2	3.7	2.8	2.3

The observed differences are small, which is understandable only by assuming that these values are a measure of the rate of formation of the intermediate by CO dissociation from the metal.

To summarize the situation, and referring to the kinetic scheme (9) (R = Me), we can say that we know the rate constants for the formation of the intermediate $MeCO—Mn(CO)_4$ from $MeCO—Mn(CO)_5$ (k_{-2}) and from $Me—Mn(CO)_5$ (k_1), but we can only guess that k_{-1} (*i.e.* the rate constant corresponding to the cleavage of the C—C bond of the acetyl group) is larger than k_{-2}.

That $Me—Mn(CO)_5$ is formed from $MeCO—Mn(CO)_5$ by a relatively slow, rate-determining CO dissociation from the metal is supported by the results[27d] obtained in the reaction of PPh_3 with ^{13}C-labeled acetyl(pentacarbonyl)manganese [eq. (21)].

$$Me^{13}CO—Mn(CO)_5 + PPh_3 \rightarrow CO + Me^{13}CO—Mn(CO)_4PPh_3 \quad (21)$$



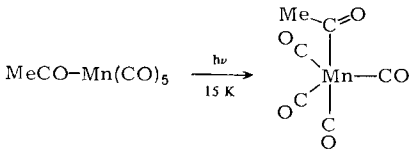
It is interesting to note that an acetyl iron system gives similar and complementary results[55]. ^{13}C-Labeled acetyl(dicarbonyl)cyclopentadienyliron(II) was photolyzed with a mercury lamp in heptane [eq. (22)] and the product of the reaction analysed by mass spectrometry. The labeling was found to be maintained in the product obtained, thus complementing the previous results for ^{14}C-[56] and ^{13}C-labeled $MeCO—Mn(CO)_5$[27c]. Moreover, photolyses of $Me^{13}CO—FeCp(CO)_2$ carried out in the presence of PPh_3 resulted in the formation of $Me^{13}CO—FeCp(CO)PPh_3$. It is reasonable to assume that the intermediate has originated from a Fe—CO bond fission. The competitive experiment with PPh_3 then shows that addition of PPh_3 is faster than methyl migration from the acetyl group to the metal.

$$Me^{13}CO—FeCp(CO)_2 \xrightarrow{h\nu} Me—FeCp(^{13}CO)(CO) + CO \quad (22)$$

$$Me^{13}CO—FeCp(CO)_2 \xrightarrow{h\nu} CO + [Me^{13}CO—FeCp(CO)] \quad (23)$$

$$Me—Mn(CO)_5 + PPh_3 \rightarrow \underset{cis + trans}{MeCO\quad Mn(CO)_4PPh_3} \quad (24)$$

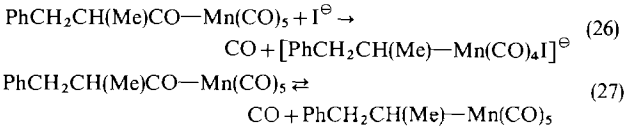
Some additional details can be given concerning the acyl intermediate $MeCO—Mn(CO)_4$ in the manganese case. The reaction of $Me—Mn(CO)_5$ and PPh_3 [eq. (24)] has been found[27d] to give initially the *cis* isomer, which subsequently transforms into the *trans* isomer (Scheme 1).



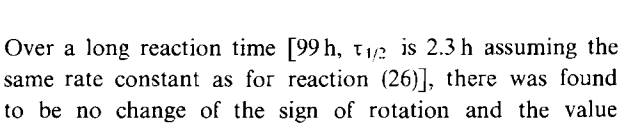
Scheme 1

Scheme 1 contains a further relevant suggestion about the nature of the acyl intermediate, *i.e.* that it may exist in two different structures, which have been tentatively indicated to approximate a trigonal bipyramid and a square pyramid. Interconversion between the two structures does not appear to arise from Me migration. The existence of two different intermediates interconverting with an energy barrier between them is required by the observation[27d] that the two geometrical isomers arising from reaction (24) are not initially present in the final equilibrium ratio, as would be the case if they

originated from a common intermediate or from two rapidly interconverting intermediates.



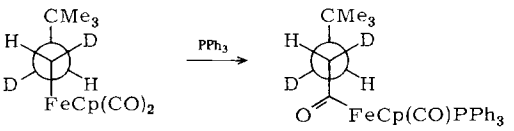
Relevant to this point is the recent[57] photolysis of MeCO—$Mn(CO)_5$[57], which produced, *inter alia*, a species suggested to be a trigonal bipyramidal MeCO—$Mn(CO)_4$ on the basis of infrared spectroscopic results [eq. (25)].



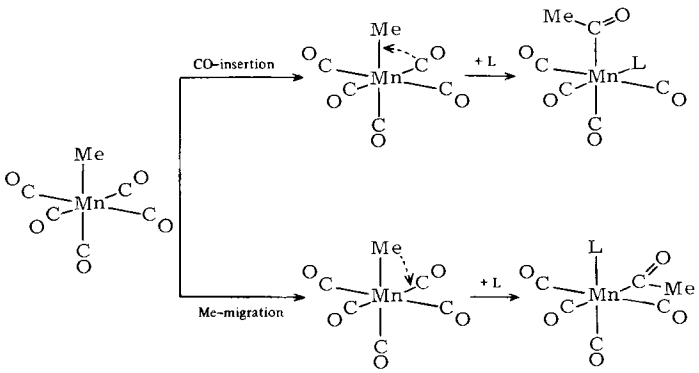
(25)

CO insertions into metal-carbon σ-bonds and related reactions are highly stereospecific, both at carbon and at the metal. The following preliminary experiments have been carried out[58]:

1) Reaction of an optically active acyl(pentacarbonyl)manganese with $I^{\ominus}$ (at 30.0°C in 2,2'-diethoxydiethyl ether, $k = 8.5 \times 10^{-5}\,s^{-1}$) [eq. (26)], and 2) thermal treatment of the same acyl complex to give the equilibrium mixture with the corresponding alkyl [eq. (27)].



(26)



(27)

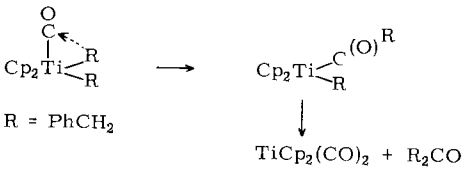
Over a long reaction time [99 h, $\tau_{1/2}$ is 2.3 h assuming the same rate constant as for reaction (26)], there was found to be no change of the sign of rotation and the value of the specific rotation changed slightly after a conversion of about 10%. Despite the low conversion, the experiment shows that the equilibrium is maintained under highly stereospecific conditions, although it was not possible to establish whether there was retention or inversion at the carbon.

More recent work[59a, 59b] on the reaction of *threo*-$Me_3CCHDCHD$—$FeCp(CO)_2$ with PPh_3 has established that the *threo*-acyl derivative is formed with more than 95% retention of configuration.

High stereospecificity was also found at iron[29, 60–62].

Scheme 2

To conclude this section, it should be recalled that alkyl migration to form an acyl group has been demonstrated in the case of the Me—$Mn(CO)_5$/CO system[27c]. Scheme 2 shows that both possible mechanisms, *i.e.* insertion of a coordinated CO group into the M—Me bond or alkyl migration, would give stereochemically equivalent, although not identical, products.

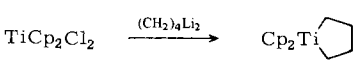


5. Studies on Titanium, Zirconium, Hafnium, and Vanadium Compounds

Having discussed the kinetic and mechanistic work which has been carried out mainly on manganese and iron, we now wish to consider CO insertion reactions of titanium, zirconium, hafnium, and vanadium compounds.

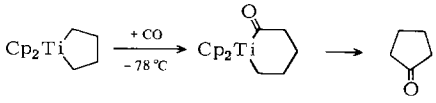
$(PhCH_2)_2TiCp_2$ reacts with carbon monoxide to give dibenzyl ketone [eq. (28)][63].

$$(PhCH_2)_2TiCp_2 + 3\,CO \rightarrow TiCp_2(CO)_2 + (PhCH_2)_2CO \qquad (28)$$



This reaction may be regarded as a reductive elimination assisted by carbon monoxide and provides an alternative route to $TiCp_2(CO)_2$[64–66]. It was suggested[63] that ketone formation, which requires a CO insertion into the benzyl-titanium bond, could take place *via* precoordination of CO to titanium, followed by benzyl migration (assumed) to form the unstable acyl intermediate [eq. (29)].

(29)



Precoordination of CO to titanium(IV) is regarded as a necessary reaction step. It is important to note in this connection that formation of ketone was predominant in heptane[63], whereas in the weakly basic benzene extensive thermal decomposition took place. Binding of CO to titanium(IV) is presumably very weak and competition by the solvent may easily occur. (Coordination of CO to other Group IVB elements in the oxidation state IV has been discussed[67].)

A thermally unstable metallocyclic titanium(IV) derivative was obtained[68] by reaction (30).

(30)

The cyclic derivative is stable at low temperature only [in contrast to the moderate stability of the dibenzyl compound, see eq. (29)] and reacts with CO to give cyclopentanone through the probable intermediacy of a metallocyclic acyl derivative [eq. (31)].

(31)

The possibility of inserting CO into a titanium-carbon σ-bond was definitely confirmed by the reaction of CO with alkyltitanium(IV) halides under ambient conditions in hydrocarbon solvents[20]:

$$R{-}TiCp_2X + CO \rightarrow RCO{-}TiCp_2X \quad (32)$$
$$X = Cl,\ R = Me,\ Et,\ CH_2Ph;\ X = I,\ R = Et$$

The complexes are characterized by strikingly low ν values for the acyl CO stretching vibration, thus suggesting a change of structural arrangement with respect to the known bonding situations for other transition elements. An X-ray investigation[69] of MeCO—$TiCp_2Cl$ shows that the "side-on" arrangement of the acetyl group already encountered for the zirconium derivative MeCO—$ZrCp_2Me$[21] is not an isolated case and may be much more common than previously thought, at least in this area of the Periodic Table (cf. Fig. 3).

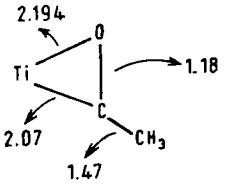


Fig. 3. Section of structure of MeCO—$TiCp_2Cl$, schematic. Bond lengths in Å [69].

Structural data for numerous acyl-(aroyl-) and alkyl-(aryl-) derivatives of transition elements are compiled in Table 4. The (O)C—C distances in the acetyl derivatives of titanium(IV) and zirconium(IV) are remarkably short, which may be an additional reason for the stability of these compounds. It has also been noted that the Fe—C distances in an acetyl[80] and in a benzoyl derivative[79] are somewhat shorter than in a corresponding phenyl-iron derivative[74], thus suggesting some kind of metal-carbon interaction in the benzoyl (and acetyl) complex. Of particular importance is the structure determination of $[cis\text{-}(MeCO)(PhCO){-}Mn(CO)_4]^{\ominus}$[77], which provides an opportunity of comparing structural parameters for two different RCO groups in the same molecule (see Section 6).

Like the titanium analogs [eq. (31)] alkylzirconium halides undergo CO insertion[82] [eq. (33)].

$$Me(CH_2)_5{-}ZrCp_2Cl + CO \rightarrow Me(CH_2)_5CO{-}ZrCp_2Cl \quad (33)$$

Acyl derivatives of zirconium(IV)[21] and hafnium(IV)[22] have been characterized only very recently [eq. (34)]:

$$R_2MCp_2 + CO \rightleftarrows RCO{-}MCp_2R \quad (34)$$

Isolation of the carbonylated products was possible for M = Zr, R = Me, CH_2Ph, Ph and for M = Hf, R = Ph; in addition, gas-volumetric and spectral data established that carbonylation also takes place similarly for M = Hf, R = Me, CH_2Ph. Moreover, in these latter cases, the position of the equilibrium was such that gas-volumetric measurements permitted determination of the formation constants and some thermodynamic parameters. ^{1}H-NMR and IR measurements established conclusively that only one R group was involved in CO insertion. The thermodynamic parameters for carbonylation of the hafnium complexes and some R—$Mn(CO)_5$ complexes are listed in Table 5[53]. These thermodynamic data may be considered assuming that the other bonds in the molecule are not affected by the insertion and that the ΔH^0 and ΔS^0 values predominantly reflect modifications occurring in the metal-carbon bond region. One point deserves special comment in connection with the data for the methyl derivatives Me—$HfCp_2Me$ and Me—$Mn(CO)_5$, which are particularly reliable. The ΔH^0 values are substantially identical, despite the considerable difference in bonding presumably existing in the two cases. The structure of the acetyl-hafnium species is not known, but the zirconium and hafnium species MeCO—MCp_2Me have substantially identical ν_{CO}(acetyl) values [1540 and

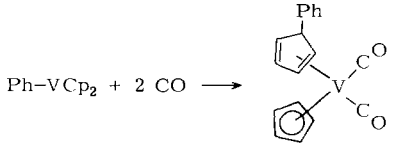
1550 cm^{-1} in CH_2Cl_2 solution, respectively, to be compared with the value of 1664 cm^{-1} known[83] for the acetyl group in MeCO—$Mn(CO)_5$]. Similar structures are therefore assumed. It is to be noted, however, that the thermodynamic parameters for the two Me—Zr/MeCO—Zr and Me—Hf/MeCO—Hf systems may be sensitive to solvent and they are therefore not directly comparable. The larger K value for the manganese complex is to be attributed, in view of the similar value of ΔH^0, to a less unfavorable entropy effect.

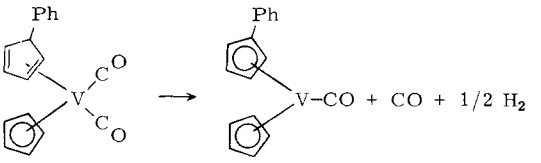
CO insertion into vanadium-carbon σ-bonds is also a recent achievement. VCp_2I reacts with CO to give an equilibrium mixture with $VCp_2I(CO)$ [eq. (35)][84] ($\Delta H^0 = -13.1$ kcal/mol, $\Delta S^0 = -34.6$ eu). The system does not evolve further, although one might expect a species such as $VCp_2(COI)CO$ to have a sufficient stability.



$$VCp_2I + CO \rightleftarrows VCp_2I(CO) \qquad (35)$$

Having established the possibility of labile coordination by CO to the coordination sphere of vanadium(III), the conditions necessary for CO insertion were determined. Alkylbis(cyclopentadienyl)vanadium(III) complexes were then shown[23] to react with CO to give acyl derivatives.

$$R—VCp_2 + 2CO \rightarrow RCO—VCp_2(CO) \qquad (36)$$
$$R = Me,\ CH_2Ph$$



Both complexes obtained by reaction (36) show rather low ν_{CO}(acyl) values (R = Me: 1605 cm^{-1}; CH_2Ph: 1615 cm^{-1}), similar to those of the acyl derivatives of zirconium and hafnium. This may suggest that the acylvanadium(III) complexes have an unusual type of acyl coordination to the metal.

A completely different reactivity was observed[23] with the phenyl derivative [eq. (37)].

(37)

The diolefinic derivative of vanadium(I), which clearly originates from phenyl migration to the cyclopentadienyl ring, could be isolated. However, the complex decomposes according to eq. (38), both in the solid state and in solution to give CO, H_2, and a phenyl-substituted bis(cyclopentadienyl)-vanadium(II) derivative.

(38)

There is no obvious explanation for such a dramatic effect of the group R on this CO insertion reaction. The decision between insertion into the Ph—V bond to give the still hypothetical PhCO—VCp_2 or migration to the cyclopentadienyl ring to give the observed reaction product must be the result of a very delicate balance of bond energies, the latter being dependent on the nature of R in a way which is still very difficult to predict.

6. Studies on Compounds of Other Transition Elements

A comparative study was reported of CO insertions and CO abstractions for the metals of the chromium triad[26].

$$Me—MCp(CO)_3 + PR_3 \rightarrow MeCO—MCp(CO)_2PPh_3 \qquad (39)$$
$$M = Cr,\ Mo,\ W$$

Tungsten is reluctant to undergo either reaction (39) or CO abstraction [eq. (40)].

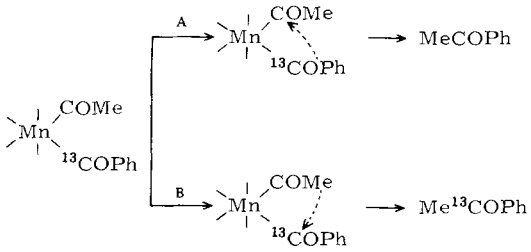
$$MeCO—WCp(CO)_2PPh_3 \rightarrow CO + Me—WCp(CO)_2PPh_3 \qquad (40)$$

Assuming a kinetic behavior similar to that encountered with manganese, it may be suggested for reactions (39) and (40) that a decisive factor is the strength of the W—Me and W—CO bonds, respectively. In the $M(CO)_6/^{14}CO$ exchange process[85] tungsten has a much higher activation energy (40.4 kcal/mol) than the molybdenum compound (30.8 kcal/mol).

CO abstraction from acyl derivatives of molybdenum and iron has been carried out[86] with $RhCl(PPh_3)_3$ as decarbonylating agent. In the reaction of the trifluoroacetyl-molybdenum complex

$$CF_3CO—MoCp(CO)_3 \xrightarrow{RhCl(PPh_3)_3} CF_3CO—MoCp(CO)_2PPh_3 + CF_3—MoCp(CO)_3 \qquad (41)$$

the trifluoroacetyl product was predominant, suggesting that CF_3 migration occurs more slowly than addition of PPh_3.



Similar to the attack by methyllithium on a terminal CO group of $W(CO)_6$ to give the $[MeCO—W(CO)_5]^{\ominus}$ anion[87], PhCO—$Mn(CO)_5$ was found[77] to be methylated at one of the terminal carbonyl groups. The bis(acyl) anion [eq. (42)],

$$PhCO—Mn(CO)_5 + Me^{\ominus} \rightarrow [cis\text{-}(PhCO)(MeCO)—Mn(CO)_4]^{\ominus} \quad (42)$$

was isolated as the tetramethylammonium salt. This anion has some peculiar features. It is the first bis(acyl) derivative carrying two different acyl groups. Only two other examples of kinetically stable, isolable bis(acyl) complexes are known, namely the complexes *cis*-$(EtCO)_2Os(CO)_4$[31] and $[cis\text{-}(MeCO)_2Mn(CO)_4]^{\ominus}$[88]. The X-ray investigation of the dianion obtained by reaction (42) (see also Table 4) has shown that the Mn—$C_{benzoyl}$ distance is 2.091 Å, and Mn—C_{acetyl} 2.045 Å. Hence the acetyl group is bonded much more strongly. This is consistent with the data of Table 5, which shows that the formation constant for MeCO—$Mn(CO)_5$ is larger than for PhCO—$Mn(CO)_5$ and that insertion into Me—$Mn(CO)_5$ is more exothermic than into Ph—$Mn(CO)_5$. In agreement with this is the observation that thermal decomposition of the anion ^{13}C-labeled at the benzoyl position gives unlabeled acetophenone [eq. (43)].

$$NMe_4^{\oplus}[cis\text{-}(Ph^{13}CO)(MeCO)—Mn(CO)_4]^{\ominus} \rightarrow MeCOPh \quad (43)$$

This experiment shows that phenyl migration to the coordinated MeCO group occurs more rapidly than methyl migration to the coordinated PhCO group.

(44)

In eq. (44), phenyl migration is faster than methyl migration in step A, while the situation is reversed in step B. There appears to be no necessity for R migration in a coordinatively unsaturated species resulting from loss of a terminal CO group, as implied in reference[77]. The reaction sequence (44) predicts the formation of the $[Mn(CO)_5]^{\ominus}$ anion: unfortunately no details about the fate of manganese were reported. This study is very important because is the only one existing in the literature establishing the relative rates of R migration from coordinated RCO groups in a truly competitive experiment. The reader may recall that the rate of methyl migration from manganese is greater than that of phenyl.

Moreover it was shown[77] that the results of the thermal decomposition [eq. (43)] were strongly affected by the nature of the counterion: the $Li^{\oplus}$ derivative gave some ^{13}C-enriched acetophenone. This was suggested to be due to specific coordination of $Li^{\oplus}$ to the acyl oxygens. Binding of alkali metals to oxygen atoms of coordinated structures is now a well established fact. It has been found between $Na^{\oplus}$ and Schiff base metal complexes[89] and, more recently[90], even terminal carbonyl groups have been found to interact with $Na^{\oplus}$ in $Na_2Fe(CO)_4 \cdot 1.5$ dioxane.

Nucleophilic attack by methyllithium on a terminal carbonyl group of MeCO—$Mn(CO)_5$ was also reported by *Lukehart et al.*[88], according to a reaction similar to (42). Treatment of the resulting bis(acetyl)anion, $[cis\text{-}(MeCO)_2Mn(CO)_4]^{\ominus}$ with anhydrous $AlCl_3$ gave a neutral derivative of formula $[Mn(CO)_4(COMe)_2]_3Al$.

CO insertions into rhenium-carbon bonds have been comparatively little studied. Several CO abstractions, usually occurring at temperatures higher than those employed for the corresponding manganese complexes, have been reported. For example, acetyl- and benzoyl(pentacarbonyl)rhenium were decarbonylated[28] according to eq. (45).

$$RCO—Re(CO)_5 \rightarrow CO + R—Re(CO)_5 \quad (45)$$
$$R = Me,\ T \geq 80°C;\ R = Ph,\ T = 120°C$$

However, no quantitative data on these systems are available.

Manganese and iron have much in common, as far as CO insertions are concerned. An ion-pair effect, similar to that reported[77] by *Casey* and *Bunnell*, has been found for the reaction of acyliron anions with tertiary phosphanes[91]. Small cations such as $Li^{\oplus}$ and $Na^{\oplus}$ favor the formation of the acyl derivative.

$$M[R—Fe(CO)_4] + PR_3 \rightarrow M[RCO—Fe(CO)_3PR_3] \quad (46)$$
$$M = Li^{\oplus},\ Na^{\oplus},\ \text{and others}$$

Synthetic applications of reactions possibly related to carbon monoxide insertions have been reported, aimed at the preparation of aldehydes[92], ketones[93–95], carboxylic acids, esters and amides[96], by making use of the $[Fe(CO)_4]^{2\ominus}$ anion as carbonylating agent.

In contrast to iron, only few CO insertions are known for ruthenium. This is certainly connected with the enhanced kinetic lability of ruthenium-carbon σ-bonds in general. In this respect the iron subgroup metals probably resemble the chromium triad. The 4d element ruthenium is generally speaking more reactive than osmium *(vide infra)*. Acyl derivatives of ruthenium(II) have been obtained[97] by the usual method of treating the alkyl derivatives with tertiary phosphanes, *e.g.* according to eq. (47). Protonation of the acetyl group afforded salts of the $[MeC(OH)RuCp(CO)PR_3]^{\oplus}$ cations, to which a carbene-like type of structure was assigned.

$$Me—RuCp(CO)_2 + PR_3 \rightarrow MeCO—RuCp(CO)PR_3 \quad (47)$$

Kinetic evidence for the formation of the protonated intermediate $[MeC(OH)Mn(CO)_5]^{\oplus}$ was gathered in studies[98] of acid-catalyzed solvolysis of the acetyl-manganese complex.

Insertions into alkyl-osmium bonds have also been reported[31]. The dialkyl derivatives $R_2—Os(CO)_4$ (R = Me, Et) are stable compounds at room temperature, which is very surprising for dialkyl derivatives of the iron triad.

$$[Os(CO)_4]^{2\ominus} + 2RI \rightarrow cis\text{-}R_2—Os(CO)_4 + 2I^{\ominus} \quad (48)$$

The dimethyl derivative, a colorless solid sublimable at room temperature, decomposes at 120°C to ethane and $Os(CO)_5$ in the presence of CO, with no indication of insertion products.

$$Me_2Os(CO)_4 + CO \xrightarrow{THF} Os(CO)_5 + C_2H_6 \quad (49)$$

The diethyl derivative, on the other hand, undergoes carbonylation, the main product of the reaction being *cis*-$(EtCO)_2Os(CO)_4$, identified spectroscopically in solution [eq. (50)].

$$cis\text{-}Et_2Os(CO)_4 + 2CO \xrightarrow[100\,atm]{110\,^\circ C,\ C_6H_6} cis\text{-}(EtCO)_2{-}Os(CO)_4 \quad (50)$$

This is the first case of double insertion into a dialkyl derivative.

Similar to the reactions mentioned earlier with PhCO—$Mn(CO)_5$[77] and $W(CO)_6$[87], *cis*-$OsBr_2(CO)_4$ undergoes methylation by methylmagnesium bromide at the terminal carbonyl groups[99].

$$cis\text{-}OsBr_2(CO)_4 + 2Me^{\ominus} \rightarrow [(MeCO)_2OsBr_2(CO)_2]^{2\ominus} \quad (51)$$

According to spectroscopic data, the anion has the all-*cis* stereochemistry.

CO insertions into alkyl(tetracarbonyl)cobalt compounds (or corresponding rhodium compounds) are important, being related to the hydroformylation reaction[100]. The most commonly accepted mechanism for this reaction requires: i) reaction of a metal hydride with an olefin to give the appropriate alkylmetal complex; ii) CO insertion; and iii) hydrogenolysis of the acyl derivative to give the aldehyde. Applied to ethylene this can be outlined as follows:

i) $L_nM{-}H + C_2H_4 \rightarrow L_nM{-}Et$
ii) $L_nM{-}Et + CO \rightarrow L_nM{-}COEt$
iii) $L_nM{-}COEt + H_2 \rightarrow L_nM{-}H + EtCHO$

In hydroformylations with 1-octene, infrared spectra typical of $C_8H_{17}CO{-}Co(CO)_4$ and $Co_2(CO)_8$[101] were recorded. In contrast, spectra measured during hydroformylation of diisobutylene (2,4,4-trimethyl-1- and -2-pentene) or cyclohexene show the presence of $H{-}Co(CO)_4$ and $Co_2(CO)_8$, thus suggesting that a relatively slow addition of olefins to the hydride takes place in this case.

Both $R{-}Co(CO)_4$ and $RCO{-}Co(CO)_4$ are unstable species thermally but they become more stable on substitution with a tertiary phosphane. CO insertion into such substituted compounds has been reported [eq. (52)][32b].

$$Me{-}Co(CO)_3P(n\text{-}Bu)_3 + CO \rightarrow MeCO{-}Co(CO)_3P(n\text{-}Bu)_3 \quad (52)$$

A benzyl derivative has been treated[32c] with labeled CO.

$$PhCH_2{-}Co(CO)_3PPh_3 + {}^{13}CO \rightarrow PhCH_2CO{-}Co({}^{13}CO)(CO)_2PPh_3 \quad (53)$$

This confirms the labeling experiments mentioned earlier and suggests that the mechanism of formation of the acyl could be alkyl migration.

Heck[32a] has studied the decarbonylation of acyl(tetracarbonyl)cobalt compounds by triphenylphosphane.

$$RCO{-}Co(CO)_4 + PPh_3 \rightarrow CO + RCO{-}Co(CO)_3PPh_3 \quad (54)$$

The reactions were found to be zero-order in tertiary phosphane concentration and first-order in cobalt complex concentration, thus suggesting dissociation of a terminal CO group to be rate-determining, as in the manganese system (cf. Section 4). For selected groups R in eq. (54) one obtains the following rate constants:

R	*n*-C_5H_{11}	Me	$PhCH_2$
$10^3 \times k[s^{-1}]$	1.07	0.97	1.32

Within the range of alkyl groups indicated, the effect is small, as expected. All the aroyl systems react much faster[32a].

In the course of the stoichiometric reaction of $Rh_4(CO)_{12}$ with olefins to give aldehydes [eq. (55)], *Chini et al.*[33b] have isolated anionic acyl cluster compounds of formula $[RCO{-}Rh_6(CO)_{15}]^{\ominus}$. This appears to be the sole example of an acyl-metal group in a metal cluster[102].

$$3Rh_4(CO)_{12} + 4MeCH{=}CH_2 + 4H_2 \rightarrow 2MeCH_2CH_2CHO + 2Me_2CHCHO + 2Rh_6(CO)_{16} \quad (55)$$

Oxidative addition of acyl- or aroyl halides to $RhCl(PPh_3)_3$ yields RCO complexes of rhodium(III)[33a].

$$RhCl(PPh_3)_3 + RCOCl \rightarrow PPh_3 + RCO{-}RhCl_2(PPh_3)_2 \quad (56)$$

Like the iridium(III) complexes reported by *Kubota*[53], these rhodium(III) complexes readily convert thermally into the corresponding alkyl or aryl derivatives of hexacoordinated rhodium(III).

$$RCO{-}RhCl_2(PPh_3)_2 \rightleftharpoons R{-}RhCl_2(CO)(PPh_3)_2 \quad (57)$$

Carbonyliridium complexes are less reactive than rhodium and cobalt analogues. *Whyman*[105] studied the behavior of the hydride $H{-}Ir(CO)_3P(i\text{-}Pr)_3$[103,104] towards ethylene, CO, and H_2 [eq. (58)].

$$H{-}Ir(CO)_3P(i\text{-}Pr)_3 + C_2H_4 \xrightarrow[14\,atm]{50\,^\circ C} Et{-}Ir(CO)_3P(i\text{-}Pr)_3 \quad (58)$$

On replacing ethylene with CO, an infrared spectrum consistent with the formation of an acyl derivative was measured, whereas substituting H_2 for ethylene yielded an infrared band assignable to the aldehyde. The experimental evidence supports the hydroformylation scheme also in the case of iridium.

Isolable products arising from the CO insertion into nickel-carbon σ-bonds have been reported only recently[35a,35b]

$$trans\text{-}Me{-}NiX(PMe_3)_2 + CO \rightarrow trans\text{-}MeCO{-}NiX(PMe_3)_2 \quad (59)$$
X = Cl, Br, I, O_2CMe

The complexes have one strong infrared absorption at 1635—1650 cm^{-1}, depending on the halogen.

Palladium(II) and platinum(II) complexes likewise undergo carbon monoxide insertion[36a].

$$trans\text{-}R{-}PdX(PEt_3)_2 + CO \rightarrow trans\text{-}RCO{-}PdX(PEt_3)_2 \quad (60)$$
X = Cl, Br, I; R = Me

$$trans\text{-}R{-}PtX(PEt_3)_2 + CO \rightarrow trans\text{-}RCO{-}PtX(PEt_3)_2 \quad (61)$$
X = Cl, Br, I; R = Me, Ph

$$Me{-}Pt(PP)Me + CO \rightarrow MeCO{-}Pt(PP)Me \quad (62)$$
PP = $Et_2PCH_2CH_2PEt_2$

Reaction (62) is one of the few examples of CO insertion into dialkyl (or diaryl) complexes of transition metals. Single insertion of CO takes place in this case, similar to the zirconium and hafnium cases[22] and contrary to the osmium case[31].

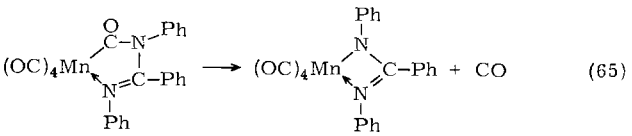
A coordination position of the RCO derivative must be vacated to initiate the CO abstraction (with retention of both R and CO in the coordination sphere of the metal). This can be accomplished photolytically as mentioned earlier[55,57], and also chemically[106]. Expulsion of Cl from the coordination sphere of RCO-platinum(II) derivatives was carried out with silver ions.

$$RCO{-}PtCl(PPh_3)_2 + Ag^{\oplus} \rightarrow AgCl + [R{-}Pt(CO)(PPh_3)_2]^{\oplus} \quad (63)$$
$$R = Me, Et, Ph, Me_2CH, p\text{-}XC_6H_4$$

Reaction (63) was observed in acetone, whereas in the effective donor acetonitrile isolable RCO-complexes of formula $[RCO{-}Pt(PPh_3)_2(NCMe)]^{\oplus}$ were isolated.

Although CO insertion reactions into copper-carbon σ-bonds are still unknown, there is experimental evidence available that suggests the intermediacy of acyl-copper derivatives[107]. Ketones have in fact been obtained by treatment of $[Bu_2Cu]^{\ominus}$ with CO.

7. CO Insertions into Other Metal-Ligand Bonds



The possibility of isolating products of CO insertions into a metal-ligand bond M—L is bound closely with the thermodynamic stability of the M—CO—L system *vs.* M—L + CO (L = H, NR_2, OR, SR, Cl, Br, I). In many cases, we are dealing with a less favorable thermodynamic situation, compared to acyl- or aroyl compounds, as far as the C(O)—L bond is concerned. On the other hand, several compounds containing the M—$CONR_2$ or M—COOR groupings as obtained by preparative methods other than the CO insertion, have been described as kinetically stable substances. It should also be mentioned that reaction paths are known that require or suggest the transient formation of M—CO—L bonds. This kind of CO insertion plays a very important role in catalytic carbonylations of organic substrates[108].

Despite considerable research efforts, CO insertion into M—H bonds still appears an elusive reaction. Pentacarbonyl(hydrido)manganese does not react appreciably with carbon monoxide under conditions suitable for the formation of the acyl derivatives from the corresponding alkyls[45]. This is consistent with the observation that no formyl groups were detected spectroscopically during photolytic treatment[109] of $H{-}Mn(CO)_5$ in an argon matrix.

On the other hand, an anionic formyl derivative of iron has been prepared from formic acetic anhydride, and reported[110] to undergo slow decomposition to the corresponding hydride.

$$(MeCO)(HCO)O + [Fe(CO)_4]^{2\ominus} \rightarrow [HCO{-}Fe(CO)_4]^{\ominus} + MeCOO^{\ominus} \quad (64)$$

The problem of CO insertions into metal-nitrogen bonds has been recently reviewed[111]. The complexes $MCpX(CO)_2$ [M = Mo, W; X = —N=CR_2, —$N(CR_2)_2$, —N(R)C(=N)—R'] did not give CO insertion products. On the other hand, thermal

(65)

treatment of a carbamoylmanganese complex resulted in the carbonyl abstraction product [eq. (65)], which however, failed to regenerate the starting material on treatment with CO under drastic conditions (125 °C, $p_{CO} = 200$ atm).

$$M{-}NR_2 + CO \rightleftharpoons MCONR_2 \quad (66)$$

Although CO insertion into metal-nitrogen bonds, for example into metal-dialkylamide bonds [eq. (67)], is not known as yet, carbamoyl complexes[112] are believed to be intermediates in some metal-catalyzed carbonylations of amines[113] and in reactions of CO with nitrogen-containing compounds in general[114].

1,1-Diphenylurea exchanges with ^{14}CO in the presence of $Co_2(CO)_8$ at elevated temperature[114]. This may suggest the transitory formation of Co—NPh_2 and Co—$CONPh_2$ bonds.

For an example of CO insertion into a metal-alkoxide bond, see reference [16].

A reaction which does not appear to have been reported as yet for a kinetically stable isolable complex is CO insertion into a metal-halogen bond. However, evidence does exist for the transitory formation of M—CO—X bonds in transition metal carbonyl chemistry. Some years ago *Noack*[115] used low temperature infrared spectroscopic methods to study the reaction between $Fe(CO)_5$ and Br_2 and I_2. In $CHCl_3/CH_2Cl_2$ a band was observed at about 1650 cm^{-1}, which was attributed to an intermediate species $FeBr(CO)_4(COBr)$ that rapidly collapses to $Fe(CO)_4Br_2$ on increasing the temperature. No acyl bands could be detected in CH_2Cl_2[116].

M—CO—Cl species are important intermediates for the reduction of anhydrous metal halides by CO. Anhydrous gold(III) chloride, prepared from tetrachloroauric acid in thionyl chloride[117], reacts further with CO in the same solvent to give almost quantitative yields of AuCl(CO) [eq. (67)].

$$\tfrac{1}{2}\,Au_2Cl_6 + 2CO \rightarrow COCl_2 + AuCl(CO) \quad (67)$$

A systematic investigation of the reaction between anhydrous gold(III) chloride and AuCl(CO) under nitrogen or argon has revealed[118] the existence of a soluble unstable carbonyl derivative of gold, characterized by $\nu_{CO} = 2180\ cm^{-1}$. This is higher than the carbonyl stretching vibration of AuCl(CO) in the same solvent (2162 cm^{-1}). In addition, a black moisture-sensitive substance of analytical composition $AuCl_2$ was isolated, whose yield was optimized when the $AuCl_3$: AuCl(CO) molar ratio was 3 : 1. No evolution of carbon monoxide was observed in any of the reactions and it was established spectroscopically that the CO initially coordinated to gold(I) in AuCl(CO) was transformed into $COCl_2$. The molecular structure of the analytical product $AuCl_2$ has now been established by X-ray analysis[119]. The structure is that of a covalently bonded gold(III)-gold(I) mixed-valence compound of formula Au_4Cl_8. Within the molecule the two gold(III) centers and the two gold(I) centers have the expected planar and linear coordinations, respectively. The existence of a compound of composition

$AuCl_2$ was a subject of considerable dispute in the literature[120].

Au_4Cl_8 reacts very rapidly with CO, even in the solid state, to give AuCl(CO). The soluble transient carbonyl species (ν_{CO} at 2180 cm^{-1}) of probable formula $Au_2Cl_4(CO)$, similar to the mixed-valence olefin complexes described by *Hüttel et al.*[121], plays an important role in the formation of Au_4Cl_8. Since the fate of coordinated CO is known, the formation of Au_4Cl_8 can best be represented by eq. (68).

$$Au_2Cl_4(CO) + Au_2Cl_6 \rightarrow Au_4Cl_8 + COCl_2 \quad (68)$$

Transfer of chlorine from Au_2Cl_6 to coordinated CO, and hence formation of kinetically unstable Au—CO—Cl bonds, are required by the results obtained in this study.

The author wishes to thank the National Research Council (C.N.R.), Rome, and Snam-Progetti S.p.A., Milan, for support of the work carried out at the University of Pisa, and to express his gratitude to all his past and present collaborators.

COMMUNICATIONS

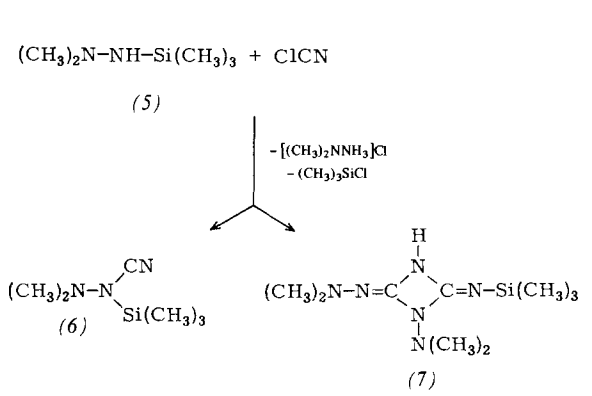
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Silatautomeric Organylcarbodiimides/Cyanamides

By *Ingo Ruppert*[*]

Various reports have recently been published about the synthesis of *tert*-butyl-[1a] and phenyl-substituted[1b] monosilylcarbodiimides, which can be employed not only for a variety of addition reactions[2a] but also for condensations involving elimination of halosilane[2b]. A particularly facile entry to these compounds with free choice of organyl substituent is provided by the action of cyanogen chloride on secondary silylamines[3].

R = CH_3 *(a)*, C_2H_5 *(b)*, $(CH_3)_2CH$ *(c)*, $(CH_3)_3C$ *(d)*, C_6H_5 *(e)*



If a slight excess of ClCN is passed into an ethereal solution of the silylamines *(1a—e)* the progress of the reaction can be followed by observing the amount of amine hydrochloride precipitated. Prior metalation of the silylamines[4] with butyllithium did not raise the yield of organylsilylcarbodiimides *(3a—e)*. In contrast, the disilylated amine *(4)*, unfortunately readily accessible only as the methyl derivative[5], can be used to advantage for condensation.

$$CH_3–N[Si(CH_3)_3]_2 + ClCN \longrightarrow (3a) + (CH_3)_3SiCl$$
(4)

Attempts to prepare an amino-substituted carbodiimide by using *N,N*-dimethyl-*N'*-trimethylsilylhydrazine *(5)* as amine component were unsuccessful.

Instead only the cyanohydrazine *(6)*, an aminocyanamide isomeric to the corresponding carbodiimide, could be isolated

[*] Dr. I. Ruppert
Anorganisch-chemisches Institut der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

as a by-product. The major reaction product is *(7)*, which is assigned the structure of a 1,3-diazetidine on the basis of analytical and spectroscopic data. Its formation *via* [2+2]-cycloaddition of an NH- and a silyl-functional carbodiimide appears reasonable to say the least.

Whereas freshly distilled samples of *(3a—c)* give only NMR signals specific for silylcarbodiimides with largely constant chemical shifts (*e.g.* about −130 ppm for the central ^{13}C atom[6]) the stored substance exhibited a slow doubling of all signals at the expense of the original intensities both in ^1H- and $^{29}Si\{^1H\}$- and in the $^{13}C\{^1H\}$-NMR spectrum; the changes occur much faster on dilution with $CDCl_3$. In particular, the ^{13}C study reveals a new singlet in the range of chemical shifts characteristic of cyanamides[7]. No change in average molecular weight determined by osmometry could be detected, thus ruling out oligomerization.

These results can only be explained by a silatropic rearrangement to the corresponding organylsilylcyanamides *(2a—c)*. Equilibration is found to be dependent upon substituents. As follows from the ^1H-NMR spectra, equilibration (25 °C) in $CDCl_3$ solution is complete for *(3a)* [*(b)*, *(c)*] within *ca.* 7 h (3, 4 d) at 62 (45, 31) mol-% of *(2a)* [*(b)*, *(c)*]. Fresh distillation leaving practically no residue again yields the pure carbodiimides. For this reason an attempted separation of isomers by gas chromatography failed. The fact that only the carbodiimide isomer is observed even after several months' storage of the *tert*-butyl and phenyl derivatives *(3d)* and *(3e)* can be explained, at least in the former case, by the unfavorable accumulation of bulky groups on the cyanamide nitrogen in *(2d)*. Further evidence for the stability of *(3e)* comes from the observation that even mild silylation of the corresponding phenylcyanamide with trimethylchlorosilane/triethylamine leads only to the rearrangement product *(3e)*.

The joint appearance and interconversion of the two constitutional isomers in the carbodiimide/cyanamide system could be established for the first time with the above silatautomers[8].

Procedure:

N-Organyl-N'-trimethylsilylcarbodiimides (3a—e) and organyltrimethylsilylcyanamides (2a—c): Cyanogen chloride (*ca.* 6.2 g, 100 mmol) which has been precondensed in a cold trap is slowly passed into a solution of silylamine (100 mmol) in ether (75 ml) with magnetic stirring in a closed apparatus (Hg pressure valve). The reaction temperature is −20 °C only in the case of *(1a)*; compounds *(1b—d)* are treated at room temperature, and *(1e)* at 50 °C in an autoclave. When precipitation is complete the mixture is filtered, solvent and trimethylchlorosilane are distilled off at normal pressure, and the product fractionated in the absence of moisture *in vacuo* (cf. Table 1).

Crystal Structure of B_2S_3: Four-Membered B_2S_2 Rings and Six-Membered B_3S_3 Rings[**]

By *Harald Diercks* and *Bernt Krebs*[*]

Characterization of boron chalcogenides runs into the obstacle that crystalline phases are difficult to prepare. Crystalline B_2S_3 has been available since 1962 by a variety of methods[1]; however, the quality of the crystalline material was in no case sufficient for a structure determination. The same applies to all other binary boron chalcogenides.

According to a preliminary report by *Chen, Conard*, and *Gilles*[2] B_2S_3 forms monoclinic crystals (C2, Cm, or C2/m) with $a=4.048$, $b=37.09$, $c=10.73$ Å, $\beta=90.0°$, $Z=14.1$; an attempted complete structure analysis was unsuccessful.

During studies on the synthesis of heavy metal thioborates we obtained single crystals of B_2S_3 suitable for X-ray structure determination by thermal decomposition of ternary phases (cf. also [1b]). For example, if the stoichiometric reaction mixture for preparation of $Ag_3B_5S_9$[3] (closed graphite crucible in an evacuated sealed quartz glass tube) is subjected to a temperature gradient of 800 to 600°C for *ca.* 10d, then apart from silver thioborate the extremely moisture sensitive colorless compound B_2S_3 is obtained as 0.3 mm long column shaped single crystals which are microtwinned [B:S = 1:1.49(2); monoclinic ($P2_1/c$) with $a=4.039(1)$, $b=10.722(2)$, $c=18.620(4)$ Å, $\beta=96.23(3)°$, $Z=8$, $V=801.6$ Å^3; $d_{calc}=1.952$, $d_{exp}=1.93(3)$ g/cm^3]. The crystal structure was determined for a twin along ($\bar{2}01$) from four-circle diffractometer data[4] and refined to $R=5.7\%$.

The structure is made up of planar B_3S_3 six-membered rings and B_2S_2 four-membered rings linked by S bridges to almost planar infinite two-dimensional high-polymer layers. The projection of two unit cells perpendicular to the plane of the layer is depicted in Figure 1. Zig-zag chains of six-membered rings run through the layers parallel to *b*; each six-membered ring is bonded *via* a four-membered ring (situated at an inversion center) to a six-membered ring of the adjacent chain. All the boron atoms exhibit trigonal-planar coordination. While the B_3S_3 ring corresponds to those of trimeric metathioboric acid $(BSSH)_3$ and its alkali salts in structure and bonding[3, 5], the 1,3,2,4-dithiadiboretane ring is of particular interest because the four-membered ring skeletons of $[BSN(C_2H_5)_2]_2$[6], $(BSSH)_2$, and $(BSSC_2H_5)_2$[7] could not previously be characterized structurally or spectroscopically. The very short transannular B...B (2.237 Å) and S...S distances (2.878 Å) in the strained four-membered ring warrant attention; the average B—S bond length (1.823 Å) differs but slightly from the average value taken over all B—S bonds in the structure (1.808 Å).

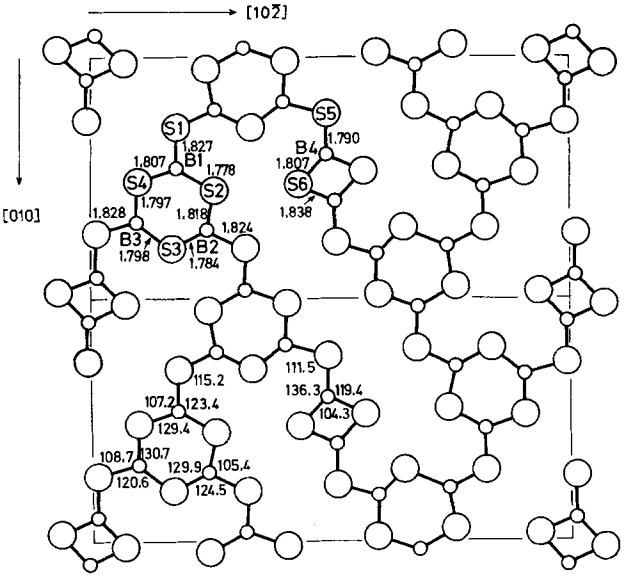

Fig. 1. Layer structure of B_2S_3 with bond lengths [Å] and angles [°].

Only van der Waals forces act between the $(B_2S_3)_n$ layers (S...S distances $\geq 3.814(2)$ Å); the perpendicular interlayer spacing is 3.55 Å. Overall, the packing of the S atoms can be regarded formally as a distorted ..ABAB.. closest packing. The extensive angular distortions in the trigonal-planar BS_3 groups (Fig. 1) are mainly due to the influence of S...S repulsive forces within the layers (shortest S...S distances within the BS_3 groups: S1...S2 2.898, S1...S4 2.926, S4...S5 2.945(2) Å; between S atoms within the layers not belonging to the same BS_3 polyhedron: S2...S3 3.194, S3...S6 3.256(2) Å).

The structure of B_2S_3 bears no resemblance to the three-dimensionally linked B_2O_3 crystal structure[8].

Phenyl(trimethylphosphonio)methanidyl, A Novel 3-Electron Bridge Ligand[**]

By *Fritz R. Kreissl, Peter Friedrich, Tassilo L. Lindner*, and *Gottfried Huttner*[*]

Reaction of trimethylphosphane with *trans*-halogenotetracarbonylcarbyne complexes of chromium and tungsten leads to metal-substituted ylides[1], whereas reaction with dicarbonyl(η-cyclopentadienyl)arylcarbyne complexes of tungsten affords metal-substituted ketenes[2a,c] and η^2-ketenyl complexes[2b,c]. A novel reaction behavior has been observed on treatment of pentacarbonylrheniotetracarbonyl(phenylcarbyne)tungsten *(1)*[3] with trimethylphosphane. μ-Carbonyl-μ-phenyl(trimethylphosphonio)methanidyltetracarbonylrheniotetracarbonyltungsten *(2)* could be isolated as a yellow, diamagnetic crystalline product. *(2)* is soluble in dichloromethane

$$(CO)_5Re{-}(CO)_4W{\equiv}C{-}C_6H_5 + P(CH_3)_3 \xrightarrow{Et_2O}$$

(1)

(2)

and acetone, but not in ether or *n*-pentane. Composition and structure of the ylide derivative were confirmed by IR and ^{1}H-, ^{13}C-, ^{31}P-NMR spectra and by an X-ray structure analysis.

The IR spectrum (KBr) of *(2)* shows seven bands in the carbonyl region for the terminal CO ligands (2092 s, 2042 s, 2003 s, 1960 vs, 1945 sh, 1930 s, 1920 sh cm^{-1}); we assign the absorption at 1842 s cm^{-1} to the bridge CO group. The ^{1}H-NMR spectrum (CD_2Cl_2) exhibits two multiplets at δ = 7.60 and 7.25 ppm for the phenyl group and a doublet at δ = 1.64 ppm, which is assigned to the *P*-methyl protons. The PCH_3 signal with a coupling of $^2J_{PH} = 11.3$ Hz proves the presence of a fourfold coordinated phosphorus atom with positive charge[4]. The $\{^1H\}$-^{13}C-NMR spectrum [CD_2Cl_2; δ values rel. to CD_2Cl_2 = 54.2 ppm (J_{PC} [Hz])] displays the eleven signals expected for *(2)*: CO 199.48, 197.86, 193.00, 191.49, 187.39; C_6H_5 158.37, 139.66 (7.3), 128.06 (4.9), 126.98 (4.9); W—C 80.37 (9.8); PCH_3 18.83 (56.2). Chemical shifts and coupling constants of the ylide-C and *P*-methyl signals agree with the values observed for ylide complexes[5]. The $\{^1H\}$-^{31}P-NMR spectrum shows a sharp singlet at δ = 41.3 ppm.

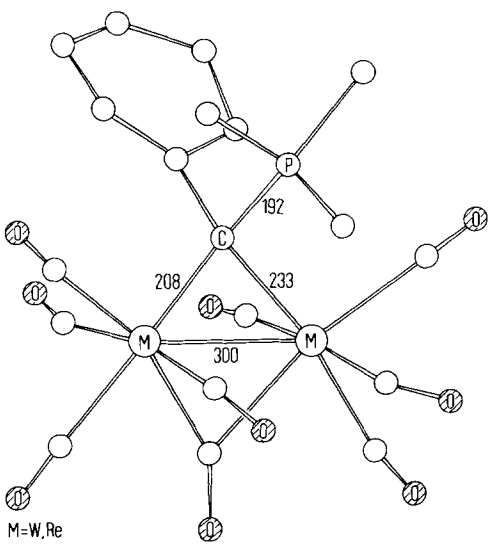

Fig. 1. Structure of the ylide bridge complex *(2)* (bond lengths in pm).

The constitution of *(2)* derived from spectroscopic data was confirmed by an X-ray structure analysis[6] (Fig. 1).

According to the noble gas rule complex *(2)* ought to possess a metal-metal bond; the W—Re distance of 300 pm complies with this assumption. The metal atoms W and Re cannot be distinguished by X-ray analysis owing to the small difference in their scattering power. However, the structure shows no pseudosymmetry[7].

The distances of the bridge C atoms of the methanidyl ligand from the two metal centers are markedly different, having values of 208 and 133 pm. It is suggested that the shorter distance be assigned to the tungsten-carbon bond of the carbyne complex component and that the bridge lacks symmetry due to the tendency towards charge delocalization between the metals[8].

Experimental

All operations should be carried out under nitrogen in dry (Na, P_4O_{10}) and N_2-saturated solvents.—Trimethylphosphane (0.1 g, 1.32 mmol) is added with stirring to a solution of *(1)* (0.71 g, 0.1 mmol) in diethyl ether (50 ml) at −60 °C. After 5 hours' further stirring the supernatant liquor is decanted off and the residue washed 5 times with 10 ml pentane. After drying in a high vacuum at −30 °C, *(2)* is obtained analytically pure as yellow crystals; yield 85 %.

Crystal Structure of As_2O_5

By *Martin Jansen*[*]

Although As_2O_5 numbers among the longest known oxides[1], its crystal structure is still unknown. Attempts to

[*] Dr. M. Jansen
Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Lahn-Giessen (Germany)

grow single crystals suitable for X-ray structure analysis have hitherto been thwarted by the poor thermal stability (loss of oxygen and sublimation of As_4O_6 above 300°C) and the ease of hydrolysis of As_2O_5.

Single crystals of this arsenic oxide have now been obtained by annealing of amorphous As_2O_5 under positive oxygen pressure with careful exclusion of moisture. Space group: $P2_12_12_1$ with $a = 8.64_6$, $b = 8.45_0$, $c = 4.62_6$ Å; $Z = 4$[2]. For the structure analysis, 1085 symmetry-independent reflections were measured (Philips PW 1100 automatic four-circle diffractometer, MoK_α, graphite monochromator, $\omega/2\theta$ scan). The structure was solved with Patterson and Fourier syntheses[3]; refinement of the positional and anisotropic temperature factors converged at an R value of 5.3 %. The positional parameters and the AsO bond lengths are shown in Table 1.

Table 1. Positional parameters of As_2O_5 and AsO bond lengths.

	x	y	z
As(1)	0.1515	0.4025	0.1284
As(2)	0.5336	0.7826	0.1340
O(1)	0.2903	0.4334	0.8451
O(2)	0.4953	0.1439	0.6171
O(3)	0.5824	0.2655	0.0817
O(4)	0.4990	0.4757	0.4612
O(5)	0.2757	0.2561	0.3000

As(1) – [O(1), O(1), O(2), O(3), O(4), O(5)] = (1.78, 1.80, 1.83, 1.82, 1.83, 1.82 Å)
As(2) – [O(2), O(3), O(4), O(5)] = (1.67, 1.66, 1.71, 1.69 Å)

The structure of As_2O_5 resembles that of β-Ga_2O_3[4] in that the two oxides both exhibit cations in adjacent tetrahedral and octahedral oxygen environments (ratio 1:1). The composition M_2O_5 which for exclusively octahedral coordination can only be attained by edge and corner linking of the octahedra is achieved in As_2O_5 by equal contributions of the coordination and linkage principles of ReO_3 and the SiO_2 modifications stable under normal pressure, as expressed in the formula $(AsO_{6/2})(AsO_{4/2})$.

Thus all the polyhedra are linked by corners: along [001] there are strands of octahedra which are linked by tetrahedra in such a way that tubular cavities are formed in the direction of [001].

The strongly crosslinked crystal structure explains the crystal form and is in agreement with the findings of *Thilo* and *Winkler* that only half the As can be replaced at most by P and Sb, respectively, on formation of mixed crystals of As_2O_5 with P_2O_5 and Sb_2O_5[5]. It could also account for the reluctance of the compound to crystallize.

Experimental:

H_3AsO_4, prepared from sublimed As_4O_6[6], is completely dehydrated first in a dessicator and then in high vacuum. The finely powdered As_2O_5 is placed in a steel autoclave under protective gas (corundum crucible, loosely closed with a corundum stopper). The autoclave (volume 14 ml, sample volume including corundum crucible 5 ml) is charged with 5 ml of liquid oxygen and heated to 600°C for 4 weeks. After prolonged cooling down (50°C/h) the sample was isolated, once again with careful exclusion of moisture. In this way As_2O_5 is obtained as homogeneous glass clear, largely agglomerated crystalline needles; maximum dimensions: 0.2 × 0.05 × 0.03 mm.

Ortho-para Protonation of Toluene and Ethylbenzene in Super Acids

By *Dan Fărcaşiu, M. T. Melchior*, and *Lynne Craine*[*]

Reports on the protonation of monoalkylbenzenes *(1)* in super acids indicate an overwhelming preference for *para* protonation to *(2)*[1]. Fast intramolecular exchange of the aromatic hydrogens implied a small equilibrium concentration of *meta* and *ortho* protonated isomers *(2)*⇌*(3)*⇌*(4)*[1a, 2]. On cooling below −97°C only the ^{1}H-NMR spectrum of the *para* protonated isomer was "frozen out" in each case[1a, b]; no detectable amount of *ortho* protonated species *(4)* in equilibrium with *2* was evidenced. On the other hand, a study of the protonation of alkylbenzenes in the gas phase[3] indicates that a measurable amount of *(4)* should be present in the mixture. We report here a reinvestigation of the protonation of toluene *(1a)* and ethylbenzene *(1b)* in two super acid media [acid A: HF-SbF_5 (1:1) containing SO_2FCl; acid B HF-TaF_5 (30:1)], by ^{13}C-NMR spectroscopy[4].

(1) *(2)* *(3)* *(4)* *(5)*

(a), R = CH_3; *(b)*, R = $^{\gamma}CH_2$–$^{\beta}CH_3$

Solutions of ethylbenzene *(1b)* in both acids at low temperature exhibited the spectrum expected[1a, c] for *para* protonation to *(2b)*. However, the spectrum in acid A exhibited also the signals of *ortho* protonated ethylbenzene *(4b)* at the locations to be expected on the basis of spectra of *(2b)* and of protonated *m*-diethylbenzene *(5)*[1c] (Table 1 and Fig. 1).

Characteristic changes of the spectrum were observed on warming in either acid. The pattern of change, as well as the fact that very similar chemical shifts were recorded at the same temperature in both acids of significantly different strength[5], unambiguously established the interconversion of *para (2b)* and *ortho* protonated *(4b)* isomers as the source

[a] Acid A: $HF/SbF_5/ArH$, 7/7/1, with 1.5 vol. SO_2FCl per vol. of acid; acid B: $HF/TaF_5/ArH$, 30/1/0.33. [b] From external (co-axial) TMS. [c] Values for *(2b)*. [d] Values for *(4b)*. [e] Assignment based on the observation that the ring carbon atoms *ortho* to the CH_2 group resonate generally at lower field than the ring atoms *para* to the CH_2 group. [f] Assignment might be reversed. [g] The spectra at higher temperature were measured from the signal for C-β, assumed of constant chemical shift.

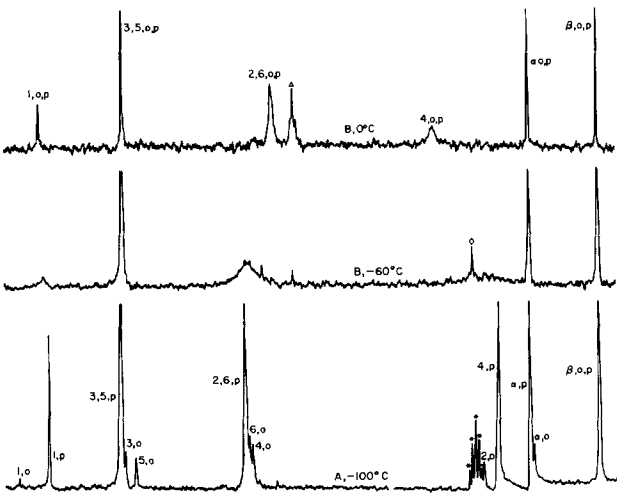

Fig. 1. ^{13}C-NMR spectra of protonated ethylbenzene. A: acid A; B: acid B. External standard: * $CDCl_2$; ◇ CH_2Cl_2; △ CD_3CN. The numbers on the signals signify carbon atoms, o and p indicate *ortho*- *(4b)* and *para*-protonated isomer *(2b)*.

of the observed exchange process, which was reversible on cooling. In the weaker acid B, the peaks are still somewhat broadened at the lowest temperature which could be attained (−75 °C)[6], but the signal for C-1 in *(4b)* could be seen (Table 1). In this acid the peaks for C-2 and C-4 disappear around −50 °C and the coalesced peaks can be observed above −30 °C. Interestingly, the coalescence temperature is about 30 °C higher in acid A[7], thus indicating that isomer interconversion *(2b)*⇌*(4b)* is faster in the weaker acid. The intramolecular hydrogen shift *(2)*⇌*(3)*⇌*(4)* should have the same rate in both cases. On the other hand, the published ^{1}H-NMR study of toluene *(1a)* in $DF-SbF_5-SO_2FCl$[1a] indicated that the concurrent proton exchange with the solvent is slow in that system. It appears then that the mechanism of isomerization *(2)*⇌*(4)* involves an intermolecular proton transfer from the protonated to the unprotonated alkylbenzene (*i.e.* *(1)*+*(2)*⇌*(4)*+*(1)*)[2a, c]. Alternatively, the exchange might occur by different mechanisms in the two media: intramolecular in acid A and intermolecular in acid B. It must be noted that within the detection limits of the ^{13}C-NMR method, protonation is virtually complete in the $HF-TaF_5$ acid system (B) as well. This leads to the possibility that the exchange process observed for a protonated aromatic substrate less basic than *(1)* (*e.g.* benzene[1a, 2e]) might occur intermolecularly even in $HF-SbF_5$.

The equilibrium ratio *(2b)*/*(4b)* could be determined by the integration of the low temperature spectra (*ca.* 6 % *(4b)* in acid A at −100 °C, 14 % *(4b)* in acid B at −75 °C), and from the chemical shifts measured for C-2 and C-4 in the region of fast exchange (0 °C to 10 °C for acid A[7], −30 °C to 10 °C for acid B) giving the values of $\Delta H^0 = -1.3$ kcal/mol, $\Delta S^0 = -2.7$ cal K^{-1} mol^{-1}. The equilibrium constant at 0 °C, calculated from the regression line is 3.0 [25 % *(4b)*]. All the values are approximate, in view of errors in the measurement of chemical shifts and especially in determining and maintaining constant the temperature during the long intervals required for spectra accumulation. (Discarding the experimental value obtained at −100 °C results in values $\Delta H^0 = -0.9$ kcal/mol, $\Delta S^0 = -1.0$ cal K^{-1} mol.) In any event, the ΔH^0 value is very close to that reported for toluene [*(2a)*⇌*(4a)*] in the gas phase[3] and somewhat lower than the result of *ab initio* calculations[3].

For protonated toluene the same behavior was seen (Table 1), but the poorer solubility in acid B limited the scope of investigation. Nevertheless, an estimate of the *para*/*ortho* protonation equilibrium constant *(2a)*/*(4a)* could be made from the chemical shifts for C-2 and C-4 at −10 to +10 °C[6, 7], using chemical shifts for the *ortho* protonated isomer *(4a)* calculated from those of *(4b)* and *(2a)*. The value [20—25 % *(4a)* in the mixture at 0 °C) is very similar to that found for ethylbenzene.

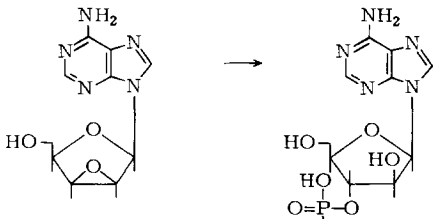
[4] The NMR spectra were obtained in the Fourier transform mode, at 25.2 MHz, using a Varian XL-100 instrument with a variable temperature probe.
[5] Acid A is well over 10^3 times stronger than acid B.
[6] The solution in acid B partially froze at lower temperature.
[7] The peaks are still broad in acid A at +10°C.



Facile Synthesis of Arabinoadenosine 3'-Phosphate[**]

By *Rudolf Mengel* and *Harald Wiedner*[*]

Only few examples of oxirane ring opening by phosphate ions are known in nucleoside chemistry[1]. We demonstrated that adenosine can be transformed into its lyxo-epoxide *(1)*[2] and that this product can be opened with mineral acid or alkali halide in the presence of boron trifluoride-etherate to give predominantly 3'-substituted halonucleosides[3].

We have now examined the cleavage of the oxirane ring of *(1)* with phosphoric acid in hexamethylphosphoric triamide. Fourteen hours' heating to 100°C affords arabinoadenosine 3'-phosphate *(2)* which can be precipitated as the barium salt. On electrophoresis[4a] and chromatography[4b] the salt behaves in a manner resembling adenosine 5'-monophosphate and is cleaved by alkaline phosphatase[5a] to arabinoadenosine together with traces of xyloadenosine[4c]. After reprecipitation of the salt and treatment with phosphatase, xyloadenosine can no longer be detected. Treatment with 5'-nucleotidase[5b] (18 h) has no effect on *(2)*, while 3'-nucleotidase[5c] cleaves the compound to the extent of 90% within 18 h.

The 90 MHz ^{1}H-NMR spectrum of *(2)* was measured against sodium 2,2-dimethyl-2-silapentanesulfonate as internal standard in D_2O to which had been added one drop of trifluoroacetic acid (to shift the HOD signal away from the signals due to the sugar protons). It showed signals at

(1) *(2)*

$\delta = 8.6$ (s, 1, H_8), 8.46 (s, 1, H_2), 6.5 (d, $J_{1'-2'} = 5.2$ Hz, 1, $H_{1'}$), 4.86 (m, 1, $H_{3'}$), 4.74 (q, $J_{2'-3'} = 4$ Hz, 1, $H_{2'}$), 4.29 (quart, 1, $H_{4'}$), 3.95 ppm ("d", 2H, $H_{5'a}$, $H_{5'b}$). The chemical shift of the H atom attached to C-3' (shifted downfield by 0.5 ppm relative to adenosine) and the coupling constant between ^{31}P and 3'-H, show the phosphate group to be located in position 3'.

Arabinoadenosine 3'-phosphate *(2)* could serve as an "arabino" building block in oligonucleotide synthesis and as starting material for the synthesis of arabino-cAMP[6]. Compound *(2)* also warrants interest in connection with the fact that arabinoadenosine has an inhibitory action on DNA polymerase, ribonucleotide reductase, adenyl cyclase, various viruses, and various animal tumors.

Procedure

A solution of adenosine lyxoepoxide *(1)* (100 mg, 0.4 mmol) and phosphoric acid (crystalline, 98%; 200 mg, 1.7 mmol) in hexamethylphosphoric triamide (2 ml) is stirred for 14 h at 100°C. After neutralization with conc. ammonia most of the solvent is removed *in vacuo* at 100°C. After addition of 10% barium acetate solution (6 ml), triethylamine (0.4 ml), and ethanol (12 ml) a precipitate is formed. The mixture is allowed to stand for 12 h at 4°C and then centrifuged; the residue is washed with ethanol (3 × 10 ml), and then with water (7 × 10 ml). The combined aqueous extracts are evaporated to 10 ml, treated with ethanol (10 ml), and left to stand for 10 h at 4°C. The precipitate formed is filtered off and applied to a Sephadex DEAE A 25 column (2.3 cm × 35 cm). Elution is performed with a gradient of triethylammonium hydrogen carbonate (0.05 to 0.2 M; 2 liter); 25-ml fractions are collected. Fractions 33 to 47 contain 0.153 mmol of *(2)* (yield 38%). They are concentrated and freeze dried.

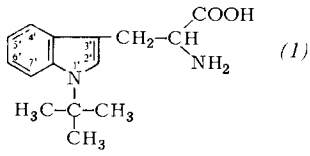
Side Reactions in Peptide Synthesis: *tert*-Butylation of Tryptophan

By *Erich Wünsch*, *Ernst Jaeger*, *Lajos Kisfaludy*, and *Miklos Löw*[*]



Indole and its derivatives are known to be very reactive. The amino acid tryptophan contains an indole ring as a third function, thus incorporating a relatively reactive moiety into the peptide chain. Side reactions due to indole have been described and postulated in peptide chemistry, *e.g.* also under conditions of acidolytic removal of protective groups from

synthetic peptide derivatives. *Alakhov et al.*[1] have detected such a side-reaction, *i.e.* an electrophilic substitution at an indole ring, by mass spectroscopic investigations on mixtures of dipeptide derivatives. However, the nature and extent of this side reaction on the indole side chain in peptide synthesis have so far not been demonstrated.

(1)

In 1972 in the Munich laboratory, changes at tryptophan were established during the synthesis of Leu[15]-human gastrin I, which contains two tryptophan residues[2]. Later, in the "artificial" preparation of Leu[11]-human minigastrin I containing only one tryptophan residue a byproduct containing modified tryptophan could be isolated[3]. The product concerned was 10-(N_{in}-*tert*-butyltryptophan)-11-leucine-minigastrin I; after enzymatic digestion, N_{in}-*tert*-butyltryptophan [1′-*tert*-butyltryptophan; H-Trp(1′-*t*Bu)-OH] could by isolated and characterized. Other *tert*-butylated peptide derivatives were also detected.

In the Budapest laboratory similar substitution processes were presumed to take place in ACTH synthesis. In a simple model reaction tryptophan was subjected to relatively drastic *tert*-butylation conditions; *tert*-butyl groups were incorporated in the indole ring. In particular, crystalline 2′,5′,7′-tri-*tert*-butyltryptophan [H-Trp(2′,5′,7′-tri-*t*Bu)-OH] could be obtained.

Further collaborative work by the two groups led to the following findings:

1) When tryptophan derivatives are subjected to a *tert*-butylation reaction, *e.g.* etherification or esterification with isobutene/acid or "simulated" demasking reactions of *tert*-butyl esters and ethers with trifluoroacetic acid, the indole ring is singly or multiply alkylated depending on the conditions. The use of liquid HF leads to unusually high yields of alkylation products (up to 50%).

2) On the basis of model processes it has been established that N_{in}-*tert*-butyltryptophan *(1)* is formed as main product of the alkylation[4]. *(1)* was obtained in pure form independently in both laboratories; it proved to be identical with the tryptophan derivative isolated from the byproduct of synthetic Leu[11]-human-minigastrin I *(vide supra)*. H-Trp(1′-*t*Bu)-OH *(1)* (from methanol/ether): m.p. 177—178°C (dec.); $[\alpha]_D^{20} = -31.2 \pm 0.5°$ ($c = 1.7$; in 80% ethanol); $[\alpha]_{546}^{20} = -34.7 \pm 0.5°$; *(1)*·$H_2O$ (after lyophilization from dil. acetic acid): m.p. 170—172°C (dec.); $[\alpha]_D^{20} = -30.4 \pm 0.5°$ ($c = 1.7$; in 80% ethanol); $[\alpha]_{546}^{20} = -34.0 \pm 0.5°$; ^{1}H-NMR [$(CD_3)_2SO/CD_3COOD/D_2O$ (3:1:1), TMS = 0]: $\delta = 1.70$ ppm [s, 9H, $>NC(CH_3)_3$], no indole NH signal [in $(CD_3)_2SO$]; MS (70eV): $m/e = 260$ (4%; $M^{\oplus}$); 186 (30%; $M-74 \rightarrow C_9H_7N{-}C_4H_9$), 130 (100%; $186-56 \rightarrow C_9H_7N{-}H$; $m^* = 90.9$); IR (KBr): 1220 (ν_{C-C}, *t*Bu), 2970 cm^{-1} (ν_{C-H}, *t*Bu), ν_{N-H} (indole) absent; UV (H_2O): $\lambda_{max} = 286$ nm ($\varepsilon = 5640$).

3) Alkylation products other than N_{in}-*tert*-butyltryptophan *(1)* are formed. Besides 2′,5′,7′-tri-*tert*-butyltryptophan, the 2′-, 3′- *(vide infra)*, 5′- and 7′-*tert*-butyltryptophans as well as the 1′,5′-disubstitution product were detected. H-Trp(2′,5′,7′-tri-*t*Bu)-OH (from 50% ethanol): m.p. 229—230°C (dec); $[\alpha]_D^{26} = +38.8 \pm 0.4°$ ($c = 1$; in acetic acid); ^{1}H-NMR [$(CD_3)_2SO/CD_3COOD/D_2O$ (3:1:1), TMS = 0]: $\delta = 1.40$ (s, C-5′-*t*Bu), 1.51 (s, C-2′-*t*Bu), 1.53 ppm (s, C-7′-*t*Bu); MS (70eV): $m/e = 372$ (3%; $M^{\oplus}$); 328 (3%; M − 44), 298 (100%; $M-74 \rightarrow C_{21}H_{32}N$), 268 (15%; $298-2\times15$), 130 (only 1%!); IR (KBr): 2960 (ν_{C-H}, *t*Bu), 3520 (ν_{N-H}, indole), 1250 cm^{-1} (ν_{C-C}, *t*Bu); UV (0.01 N HCl in 50% ethanol): $\lambda_{max} = 274$ ($\varepsilon = 7880$), 281—284 sh, 293 nm sh.

4) Peptides have been synthesized with 1′-*tert*-butyl- *(1)* and 2′,5′,7′-tri-*tert*-butyl-tryptophan. The same compounds are formed as when the unsubstituted tryptophan peptides are treated by one of the above mentioned *tert*-butylation methods.

5) Characteristic of the mono-N_{in}-*tert*-butylation of tryptophan is a ^{1}H-NMR singlet at $\delta = 1.60$ to 1.72 ppm (substance- and solvent-dependent differences have been observed within this range). N_{in}-*tert*-butyltryptophan *(1)* can be identified by this signal in higher oligopeptides too. The same is true of the other *tert*-butylation products: in the case of 2′- and 7′-substitution the singlets lie between 1.40 and 1.55 ppm (usually separated if both substitutions are present at the same time), in 5′-substitution between 1.28 and 1.40 ppm, and in 3′-substitution (on a 3*H*-indole isomer) between 0.92 and 0.98 ppm.

6) All these findings have been confirmed by mass spectrometry and by IR and UV spectroscopy on both the model compounds and the derivatives of the free amino acids.

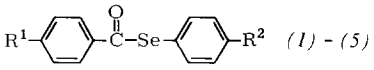
Selenol Esters—A Novel Class of Liquid-Crystal Compounds[**][1]



By *Gerd Heppke, Jürgen Martens, Klaus Praefcke*, and *Helmut Simon*[*]

Low-melting liquid crystals are of interest on account of their utility in electrooptic display systems[2]. Of the classes of compounds so far investigated, the esters of aromatic carboxylic acids with phenols have acquired importance because of their chemical and photochemical stability, low viscosity, and achromatism[3]. The corresponding thiol esters often show an extended mesophase region[4].

P.* thanks Dr. *D. Erdmann*, E. Merck, Darmstadt, for helpful discussions and the supply of chemicals.

In continuation of our work on photo- and electron collision-induced reactions of thiol-[5] and selenol-esters[1,6] we have now synthesized the selenocarboxylic *Se*-aryl esters *(1)–(5)* as first examples exhibiting liquid crystal properties. The positions of their carbonyl absorptions are typical for this class of compounds[7].

(1) - (5)

	R^1	R^2	Yield [%] [a]	M.p. [°C]	Clear point [°C]	$\nu_{C=O}$ ($CHCl_3$) [cm^{-1}]

[a] All compounds gave correct elemental analyses.

Under the polarizing microscope the new selenol esters *(1)—(5)* exhibit a nematic phase. Even these first examples show favorable transition temperatures, which should be further improved by variation of the substituents.

Experimental:

Finely powdered selenium (7.1 g, 0.09 g-atom), previously dried over conc. sulfuric acid in a dessicator, is added portionwise over 5 min to a solution of 4-methyl- or 4-methoxyphenylmagnesium bromide (0.1 mol) in boiling diethyl ether (100 ml) in the absence of moisture and air (purest argon) in accordance with a procedure[8] improved by us as regards protective gas, exclusion of light, amounts of reagents, reaction temperatures and times. The mixture is cooled, protected from light by wrapping the flask in Al foil, and treated dropwise at 0 to 5 °C (internal temperature of flask) with a solution of chloroformic acid (0.1 mol) [in the case of *(5)* 0.05 mol] in ether (100 ml). The mixture is stirred for 5 min and then extracted twice with a total of 400 ml saturated aqueous $NaHCO_3$ solution and then twice with water. The ethereal phase is dried with $MgSO_4$, evaporated down at a maximum temperature of 30 °C, and the resulting crude product purified by recrystallization: *(1)* from light petroleum (b.p. 30 to 70 °C)/ether, *(2)—(4)* from light petroleum (b.p. 30 to 70 °C), and *(5)* from ether.

5*H*-[1]Benzoselenino[2,3-*b*]pyridine—A Novel Heterocyclic Ring System[**][1]

By *Behrouze Pakzad, Klaus Praefcke*, and *Helmut Simon*[*]

Azathioxanthones[2] are formed from thionicotinic *S*-aryl esters by photorearrangement. We have now found that UV irradiation[3] of the isoelectronic 2-(chloro)selenonicotinic acid *Se*-(*p*-tolyl) ester *(1)*[4] in benzene leads *via* loss of hydrogen chloride to a mixture of products, from which 57 % di-(*p*-tolyl) diselenide *(2)* and 25 % 7-methyl-5*H*-[1]benzoselenino[2,3-*b*]pyridin-5-one *(3)* can be isolated by column chromatography in the above order.

Compound *(3)* is yellow and melts at 128 to 130 °C. The quoted structure is consistent with spectroscopic data: IR ($CHCl_3$): $\nu_{C=O} = 1630\,cm^{-1}$; MS (vaporized at room temperature; exact mass determinations for the following signals): $m/e = 275$ (100 %, M^+, $C_{13}H_9NOSe$), 247 (22 %, $C_{12}H_9NSe$), 195 (16 %, $C_{13}H_9NO$), 167 (32 %, $C_{12}H_9N$); ^{1}H-NMR ($CDCl_3$): $\delta = 8.84$ (4-H, dd, $J_o \approx 8$, $J_m \approx 2$ Hz), 8.69 (2-H, dd, $J_o \approx 4.7$, $J_m \approx 2$ Hz), 8.48 (6-H, broad s, halfwidth 4 Hz), 7.21 to 7.63 (3-H, 8-H, 9-H, m), 2.46 ppm (CH_3, s).

Doubly Deprotonated Allylacetophenone. First Example of a "Direct" E^5 Synthon[**]

By *Manat Pohmakotr* and *Dieter Seebach*[*]

Doubly unsaturated conjugated carbonyl compounds such as the ketone *(1)* react at the terminal C-5 atom with nucleophiles (N^5 attack)[1]. We have now found that this reactivity is reversed—as with N^1 and N^3 attack[2]—on use of the dianion derivative *(2)*. We obtained this derivative by double deprotonation of the allylacetophenone *(3)* containing two hydrogen atoms more. An α-carbonyl proton was first abstracted with potassium hydride (THF/45 min/0 °C) to give *(4)*[3], which was treated with *sec*-butyllithium (2 equiv. TMEDA/4 h/−78 to 0 °C)—a deep violet-red solution of *(2)* was obtained. Addition of an equimolar mixture of electrophile and hexamethylphosphoric triamide in a little THF (3 to 5 h/−78 °C to room temperature) permitted, after aqueous workup, isolation of product *(5)* or *(6)* (newly formed bonds appear bold in the formulas) which could be obtained pure in yields between 25 and 80 % by chromatography on silica gel (see Table 1). The configuration of these β,γ-unsaturated ketones is determined by the nature of the electrophile: pro-

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

tonation, alkylation with halides and epoxide, and α-hydroxyalkylation with aliphatic aldehyde and ketone gave exclusively the *cis* compound *(5)*[4], whereas the reaction of *(2)* with aromatic carbonyl derivatives (benzaldehyde, allylacetophenone, benzophenone) furnished only *trans* adducts *(6)* (see Table 1, NMR coupling constants). In no case did we observe mixtures of configurational isomers *(5)*/*(6)*; structural isomers resulting from attack of the electrophile on an atom other than C-5 in *(2)* were not detected either on chromatographic analysis of the products. Apart from *(5)* or *(6)*, most of the product mixtures were also found to contain the dimer *(6j)* (5—10 %) of the starting ketone *(3)* and a mixture (15 to 45 %) of 1-phenyl-2-, -3-, and -4-penten-1-ones, *i.e.* of *(3)* and its isomers.

Treatment of the adducts of *(2)* to aldehydes and ketones or isobutylene oxide in 0.1 M solution [THF:CH_3OH (1:1)/6 h/room temperature] with 1 equivalent of sodium

Table 1. Products *(5)*, *(6)*, and *(7)* from the dianion *(2)* and electrophiles. All IR and ^{1}H-NMR spectral data are compatible with the structures given. The *cis* and *trans* coupling constants in *(5)* and *(6)* were determined in decoupling experiments. All compounds gave elemental analyses correct to within 0.3 %. *(7f)*, *(7g)*, *(7i)*, and *(7j)* are obtained as mixtures of two diastereoisomers (according to ^{13}C-NMR analysis).

methoxide followed by workup with aqueous acid gives the tetrahydrofurans or pyrans (7) in high yields (see Table 1). The double bond apparently shifts into conjugation with the carbonyl group, whereupon the HO group undergoes intramolecular addition.

Compound (2) is the first "direct" carbonyl derivative with reactivity umpolung at C-5. The only E^5 building blocks known hitherto have a protected carbonyl group[5] or their use depends upon a thio-Claisen rearrangement[6].

merically pure form from carbonyl compounds (1) via 6-nitro-1,3-dicarbonyl compounds (2). Corresponding 5-nitro diketones (4) should cyclize to five-membered rings (5). We now describe an entry to the derivatives (4) and the first examples of their conversion into the products (5), (6), or (7), which are formed depending upon the structure of the precursors and upon the reaction conditions.

Slow addition of cooled amine-free solutions of the Li enolates of the ketones (1) to a stirred THF solution of an equimolar amount of β-nitropropionyl chloride[2] at −80 to −100°C furnishes the diketones (4) in 65 to 90% yield[3] (see Table 1, above). Cyclization was initially conducted under the conditions worked out for the reaction (2) → (3)[1] (variant A): Pouring of the dilithium salt (4'), dissolved in THF, into a large volume of water and slow neutralization with

(2) (3) (1) (5) (4) (6) (4') (7)

acetic acid. We have meanwhile discovered a simplified procedure (variant B), according to which a THF solution of the nitro diketone (4) is added to a buffer solution (pH = *ca.* 8.5). After a short reaction time, there result the hydroxycyclopentenones (6), which rearrange completely to the isomers (7) if the reaction is allowed to run over a prolonged period of time[4]. In only one case could we isolate the nitrocyclopentanone (5) (see Table 1), certainly formed as intermediate in all the reactions. The derivatives (5) and (6) are preferentially formed in one diastereomeric isomer; assignment has yet to be performed.

The IR, ^{1}H-, ^{13}C-NMR, and MS spectra, and elemental analyses of the new compounds (4) to (7) are in accord with the given structures. Thus the β-hydroxy ketone structure of these rearrangement products follows from the "coupled" ^{13}C-NMR signals of the carbonyl C atoms of (7) (splitting

by two geminal H atoms). As shown by the newly formed bonds emphasized by bold print in formula *(7)*, β-nitropropionyl chloride represents the synthetic building block

$$(HO)\overset{\ominus}{C}H—CH_2—\overset{\oplus}{C}O$$

None of the numerous other methods known for the construction of five-membered rings according to a (C_3+C_2) pattern gives derivatives having the same functionality as the above sequence of two readily executed steps. The cyclization step requires further optimization. Syntheses of jasmonoids, rethrolonoids, prostanoids, and other natural products containing five-membered rings are currently under investigation.

Procedure

3a-Hydroxy-4,5,6,7,8,8a-hexahydroazulen-1(3a*H*)-one *(6c)* and 3-hydroxy-3,4,5,6,7,8-hexahydroazulen-1(2*H*)-one *(7c)* from 2-(3-nitropropionyl)-1-cycloheptanone *(4c)*: A mixture of *(4c)* (2.13 g), diisopropylamine (3.1 ml), THF (80 ml), *n*-hexane (13 ml), and hydrochloric acid/borate buffer solution (200 ml, pH = 8) is vigorously stirred at room temperature for 2.3 h and then acidified with 10% aqueous acetic acid. The mixture is extracted three times with CH_2Cl_2, the organic phases are washed with 2.5% $NaHCO_3$ and H_2O, and dried over Na_2SO_4; 1.69 g of crude product is obtained on stripping off the solvent. Chromatography (SiO_2, ether/CCl_4 4:1) affords 1.46 g (88%) of *(6c)*, m.p. 68—70°C (from $CHCl_3/C_6H_{14}$). Reaction for 18 h under otherwise identical conditions (including work-up and purification) gives 0.99 g (60%) of *(7c)* as an oil, b.p. 180°C bath temperature/8 torr.

Trifluoromethanol, CF_3OH[**]

By *Konrad Seppelt*[*]

Very little is known about perfluorinated alcohols, except $(CF_3)_3COH$ and *c*-$(CF_2)_3CFOH$[1]. The reason for this is that primary and secondary perfluoroalcohols generally eliminate hydrogen fluoride with formation of carbonyl compounds. Methanol is stable towards hydrogen elimination, just as trifluoromethyl oxyfluoride is stable towards fluorine elimination[2]; but, as expected, the simplest perfluoroalcohol, CF_3OH, is unstable towards HF cleavage.

$$CH_3OH \longrightarrow \begin{matrix} H \\ \diagdown \\ C{=}O \\ \diagup \\ H \end{matrix} + H_2;\ \Delta H = +20.3\ \text{kcal/mol}$$

$$CF_3OF \longrightarrow \begin{matrix} F \\ \diagdown \\ C{=}O \\ \diagup \\ F \end{matrix} + F_2;\ \Delta H = +27.3\ \text{kcal/mol}$$

$$CF_3OH \longrightarrow \begin{matrix} F \\ \diagdown \\ C{=}O \\ \diagup \\ F \end{matrix} + HF;\ \Delta H \approx -20\ \text{kcal/mol}$$

It has now been possible, however, to isolate this compound as a product of the reaction of trifluoromethyl oxychloride with hydrogen chloride.

$$CF_3OCl + HCl \xrightarrow{-120\,^\circ C} Cl_2 + CF_3OH$$

The reaction principle is recombination of partially positively charged and partially negatively charged chlorine. The reaction temperature must be kept as low as possible, an inert solvent, *e.g.* CF_3Cl, being employed to take up the

heat of reaction. Excess HCl as well as CF_3Cl and Cl_2 can be pumped off completely at $-110°C$.

The colorless trifluoromethanol melts at $-82°C$ and has an extrapolated boiling point of $-20°C$. It was characterized by nuclear magnetic resonance spectra (^1H: singlet at $\delta = 8.65$ ppm *vs.* TMS; ^{19}F: singlet at $\delta = +54.5$ ppm *vs.* $CFCl_3$; ^{13}C: quartet at $\delta = +118$ ppm *vs.* TMS, $J_{CF} = 256$ Hz), mass spectrum ($m/e = 86$, CF_3OH^+), IR vapor phase spectrum 3675 (PQR, νOH), 1401, 1364, 1283, 1187, 1117 cm^{-1} and by controlled decomposition to CF_2O and HF at room temperature.

Although the decomposition of CF_3OH is thermodynamically much more strongly favored than that of the recently prepared $HOSF_5$[3], the alcohol is more stable; it decomposes slowly at $-20°C$, while $HOSF_5$ already starts to decompose at $-60°C$. This kinetic effect can be explained in terms of the larger intramolecular H···F distance, which has been estimated to be 2.2 Å in CF_3OH, and 1.9 Å in $HOSF_5$.

Because of this distance no intramolecular H···F bridge is observed in the IR vapor phase spectrum. Intermolecular bridges can be ruled out on the basis of the high vapor pressure of the alcohol: the boiling point of CF_3OH is about 85 °C lower than that of CH_3OH. A further explanation for the relative stability of CF_3OH can be that the HF elimination is not allowed as a synchronous reaction. In the case of $HOSF_5$ this can be cancelled on account of the d orbitals.

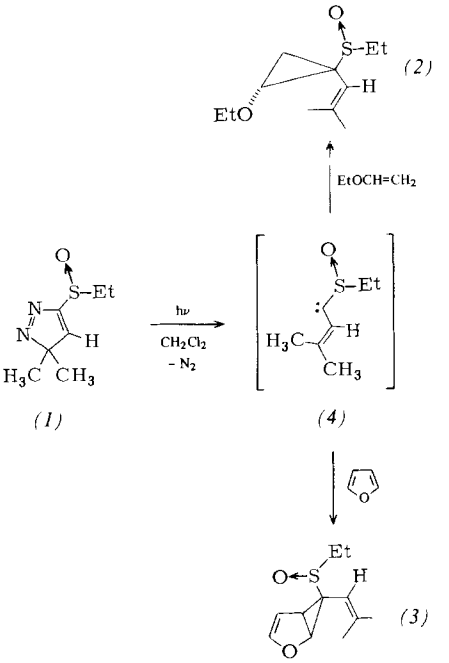
Cyclopropenes as Vinylcarbenoids: Intermolecular Carbene-Addition Reactions of Sulfinyl- and Sulfonylcyclopropenes at Room Temperature[**]

By *Michel Franck-Neumann* and *Jean-Jacques Lohmann*[*]



The interrelation between vinylethylene[1] and vinylcarbenes[2] on the one hand and cyclopropenes on the other has been the subject of numerous studies in recent years. In particular, the thermolytic (>150 °C) or photolytic ring-opening of cyclopropenes would appear to proceed *via* vinylcarbenes[3], which, however, are usually stabilized by intramolecular reactions.

We have now been able to demonstrate an isomerization of sulfinyl- and sulfonylcyclopropenes to the corresponding vinylcarbenes and found that the carbene forms react as intermolecular cycloaddition partners with nucleophilic olefins.

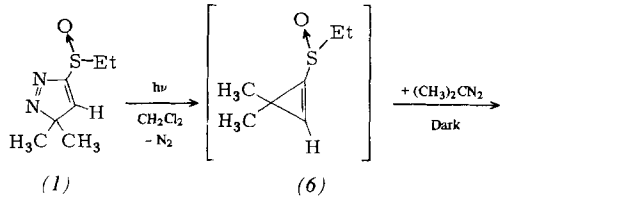
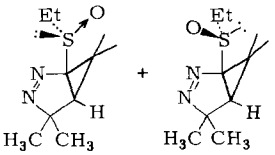
Irradiation[4] of the sulfinyl-3*H*-pyrazole *(1)*[5] in ether or methylene chloride leads to rapid and stoichiometric loss of one mol of nitrogen. After removal of the solvent at room temperature there remains a complex mixture of products. On irradiation in vinyl ether or furan, however, the products *(2)* and *(3)*, respectively, are formed smoothly and stereospecifically.

Compound *(2)* is isolated in the form of its *E*-*Z* isomers in 75 % yield[6]. IR and NMR spectra of the liquid product are consistent with the proposed structure[7]. The *trans*-divinylcyclopropane compound *(3)* (m.p. 76 °C, colorless) can be isolated in 95 % yield[6]. It remains unchanged an heating for two hours at 90 °C. Its IR and NMR spectra are in agreement with the given structure[7]. The NMR spectrum contains, in particular, the signals characteristic for similar dihydrofuran derivatives[8].



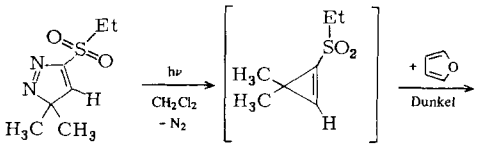
Apparently, photolysis of 3*H*-pyrazole *(1)* leads to formation of the carbene *(4)* which in the absence of reactive cycloaddition partners ought to cyclize to a cyclopropene.

In order to check this with the aid of a Diels-Alder trapping reaction the 3*H*-pyrazole *(1)* was irradiated in methylene chloride at $-25°C$ until complete extrusion of nitrogen, the UV irradiation switched off, and the irradiated solution immediately treated with cyclopentadiene. After several hours' standing at 5 °C and removal of solvent, however, no Diels-Alder adduct of a cyclopropene was detectable, but only polymers along with the carbene addition product *(5)* [*trans*-divinylcyclopropene structure, stability, compatible IR and NMR spectra], which could be isolated pure in *ca.* 30 % yield[6]. If the same experiment is carried out with furan instead of cyclopentadiene again only the carbene addition product *(3)* is formed, and in almost the same yield as in the irradiation in furan.

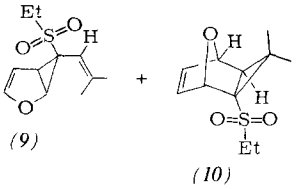


The "carbenoid" or its precursor involved thus has a relatively long lifetime in dilute solution in this temperature range which permits its direct identification: A solution of *(1)* in $CCl_4/DCCl_3$ solution was irradiated at −30°C and the 90-MHz Fourier NMR spectrum recorded immediately after complete extrusion of N_2. It shows the signals of the ethylsulfinyl group along with singlets at δ = 1.33 (3H), 1.36 (3H), and 8.07 ppm (1 H). This spectrum is compatible with the dimethyl-(ethylsulfinyl)cyclopropene structure *(6)*.

Subsequently we were also able to trap this intermediate chemically: Irradiation of *(1)* in methylene chloride, immediately followed by treatment of the solution with an excess of dimethyldiazomethane and then allowing the reaction mixture to stand for a few hours affords the diastereomeric products *(7a)* and *(7b)*, isolable in yields of 23% and 31%, respectively.



(1) *(6)*



(7a) *(7b)*

Compounds *(7a)* and *(7b)* form colorless crystals (m.p. 35°C and 53°C resp.), are photolabile, and can be separated by thin-layer chromatography[6]. They have very similar IR, UV, and mass spectra [1520 cm^{-1} (azo group), 1060 cm^{-1} (sulfoxide group); $\lambda_{max} = 340$ nm, $\varepsilon = 145$ *(7a)* and 125 *(7b)*], but different NMR spectra [four CH_3 singlets and a 1-H singlet between δ = 0.9 and 2.0 ppm, Et—SO group in the case of *(7a)* as ABX_3 spectrum with $J_{AB} = 12.5$ Hz and an AB non-equivalence of 10 Hz, in the case of *(7b)* as AMX_3 spectrum with $J_{AM} = 12.5$ Hz and an AM non-equivalence of 60 Hz].

That the photolysis of *(1)* leads to a cyclopropene which can react further as vinylcarbene is also shown by the photolytic investigation of the sulfone *(8)*[9]: here the reactivity of the cyclopropene as dienophile is sufficiently great to compete with ring opening to the vinylcarbene and correspondingly the products *(9)* [m.p. 40°C, colorless] and *(10)* [exocyclopropane $J_{HH} < 0.4$ Hz] are isolated in the ration 1:5[10] in the irradiation in methylene chloride followed by addition of furan.

(8)

(9) *(10)*

Whether real equilibrium between cyclopropenes and vinylcarbenes is involved here is still an open question. The cyclopropenes do at least react with nucleophilic olefins similarly to carbenes, in the dark and even below room temperature. The cause for destabilization of the cyclopropene structure in favor of the vinylcarbene structure would appear to lie in the sulfur-oxygen grouping, for corresponding studies on a (ethylthio)-3*H*-pyrazole gave other results.

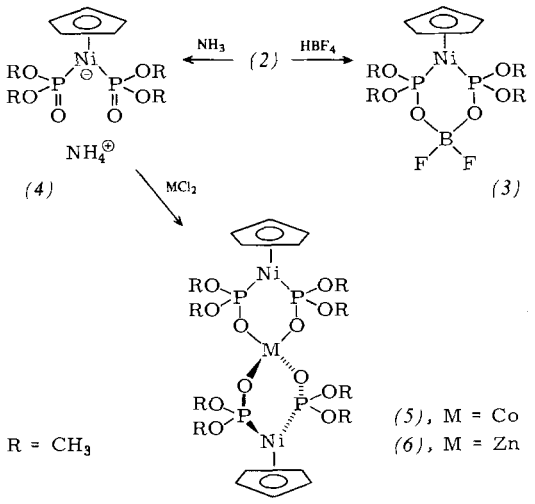
"Supersandwich"-Type Trinuclear Complexes with a Spiro Center[1]

By *Helmut Werner* and *Tri Ngo Khac*[*]

Bis(η-cyclopentadienyl)cobalt reacts with $HPO(OCH_3)_2$ *(1)* to form the trinuclear complex $(C_5H_5)_2Co_3[PO(OCH_3)_2]_6$ possessing a sandwich-type structure[2]. The reaction of bis(η-cyclopentadienyl)nickel with *(1)* gives the mononuclear compound *(2)*.



(2)

The equivalence of the CH_3 protons in the ^{1}H-NMR (pseudotriplet, sharp singlet after ^{31}P decoupling at 3.53 ppm[3]) and the phosphorus atoms in the ^{31}P-{^{1}H}-NMR spectrum (singlet at −147.0 ppm[4]) suggests that the bridging H atom

[*] Prof. Dr. H. Werner, Dipl.-Chem. Tri Ngo Khac
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

in *(2)* is probably bonded symmetrically to the two PO oxygen atoms as in the platinum complexes $Pt[(PR_2O)_2H]_2$ ($R = C_6H_5$[5], OCH_3[6]).

Reaction of *(2)* with HBF_4 leads to *(3)*, a complex containing the bis(dimethylphosphito)difluoroborate ion hitherto unknown in the free state. Compound *(2)* reacts with NH_3 to give the ammonium salt *(4)* shown by conductivity measurements and NMR data to coexist in equilibrium with *(2)* in dimethyl sulfoxide. Treatment of *(4)* in methanol with $CoCl_2$ and $ZnCl_2$ affords the trinuclear complexes *(5)* and *(6)*, respectively, having two different metals as coordination centers, which can be regarded as "supersandwich" complexes like $(C_5H_5)_2Co_2M[PO(OR)_2]_6$[7]. The spirocyclic structure around the central metal atoms is confirmed by the magnetic moments.

Preparation of the complex $(C_5H_5)_2Ni_3[PO(OCH_3)_2]_4$ analogous to *(5)* and *(6)* from *(4)* and NiX_2 (X = Cl, Br) could not be accomplished although the corresponding molecular ion was observed in the mass spectrum of *(2)*[7]. On reaction of *(2)* with $[Ni(NH_3)_6]Cl_2$ in ether the highly stable complex $[C_5H_5Ni\{P(OCH_3)_2O\}_2]_2Ni(NH_3)_2$ *(7)* is obtained, which does not loose ammonia on heating *in vacuo*. In the mass spectrum of *(7)* $[M-2NH_3]^+$ is observed as the fragment ion of highest *m/e* value.

Table 1. Data of the spirocyclic trinuclear complexes *(5)* and *(6)*.

(5): MS (70 eV): *m/e* (from 2% I_{rel}) 741 (3; M^+), 342 (3; $(2)^+$), 232 (2; $-HPO(OCH_3)_2$), 188 (100; $Ni(C_5H_5)_2^+$), 123 (92; $NiC_5H_5^+$). IR (KBr): $\nu(PO) = 1135\,cm^{-1}$. Magnetic moment (20 °C): $\mu_{eff} = 5.67\,\mu_B$ [8].
(6): MS (70 eV): *m/e* (from 3% I_{rel}) 746 (3; M^+), 342 (29), 232 (50), 188 (60), 123 (100). IR (KBr): $\nu(PO) = 1120\,cm^{-1}$. ^{1}H-NMR (δ-values, in C_6D_6 at room temp., 60 MHz): 5.12 (10H; s), 3.4 (24H; pseudotriplet).

Procedures

(2): $Ni(C_5H_5)_2$ (3.0 g, 15.9 mmol) and dimethyl phosphonate *(1)* (10 ml, 109.1 mmol) are heated under reflux for 30 min. After removal of the excess of *(1)* (10^{-3} torr) there remains an oily red substance which is dissolved in acetone. Filtration, removal of solvent, and crystallization from toluene/hexane (−30 °C) gives pale red crystals, m.p. 83 °C; yield 2.07 g (38%).

(3): HBF_4 (3 ml, 35%) is added dropwise to a stirred solution of *(2)* (1.0 g, 2.92 mmol) in propionic anhydride (5 ml). After addition of ether (10 ml) and cooling to −30 °C there appear red, air-stable crystals, m.p. 116 °C; yield 0.9 g (78%); M^+: *m/e* = 390 (83%).

(4): Dry NH_3 is passed into a stirred solution of *(2)* (353 mg, 1.03 mmol) in acetone (5 ml). The pale red precipitate is filtered off and washed with acetone; yield 340 mg (92%).

(5): A solution of *(4)* (435 mg, 1.21 mmol) in CH_3OH (10 ml) is added to a suspension of $CoCl_2$ (108 mg, 0.83 mmol) in CH_3OH (2 ml). After stirring for 2 h at room temperature, the solvent is removed, and the residue extracted with toluene. After filtration, evaporation, and cooling to −78 °C, bluish green crystals of *(5)* are obtained, m.p. 106 °C (dec.); yield 389 mg (82%).

(6): Preparation as for *(5)*. Pale red crystals, m.p. 115 °C; yield 89%.

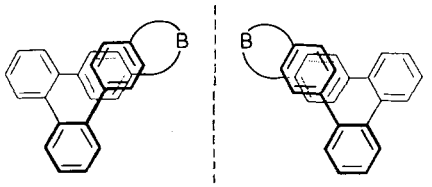
A New Type of Helical Hydrocarbon—Novel C—C Coupling by Sulfone Pyrolysis[**]

By *Fritz Vögtle, Manfred Atzmüller, Winfried Wehner*, and *Joachim Grütze*[*]

Apart from a series of [*n*]helicenes[1] very few molecules having helical structure have so far been reported[2]. In planning the synthesis of a new type helicoidal molecule we logically started from the heptahelicene skeleton *(1)*:

(1)

(2)



(3): R = H
(4): R = CH_3
(5): R = CH_2Br
(6): R = CH_2SH

Formal removal of the etheno bridges indicated by broken lines in *(2)* leads to the carbon skeleton of *o*-quaterphenyl *(3)*, whose conformational mobility can be prevented by a bridge between the terminal phenyl nuclei; this results in helix *(7)* fixed by clamping the ends[3], which should exhibit the com-

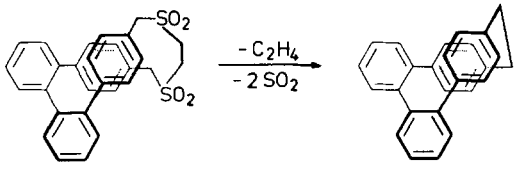
bined properties of the helicenes (helicity[4]) and the cyclophanes (transannular steric and electronic interactions[5]).

(7) (7')

We were able to synthesize the first representatives of the new structural type (7) using the bis(bromomethyl) compound (5), obtained by bromination of 4,4'''-dimethyl-*o*-quaterphenyl (4), and the dithiol (6) as starting materials.

Since (7a) could not be isolated on reaction of (5) with Na_2S under dilution conditions (small amounts of the dimeric product are obtained[6]), longer bridges were chosen: (7b) to (7i), see Table 1. Double sulfur extrusion from (7d) and (7h) by the sulfone pyrolysis method[7] led *via* ring contraction to the desired hydrocarbons (7p) and (7q) with shorter bridges.

trum of the *o*-quaterphenylophane (7o) with the shortest bridge affords particularly impressive proof of fixation of the many-membered ring: at room temperature an AA'BB' system is observed for the CH_2 groups and, at remarkably high field, an AB system for the *p*-phenylene protons ($\delta_A = 5.84$, $\delta_B = 6.60$ ppm) lying in the anisotropic region of the oppositely placed benzene ring[9]. The sulfide (7b) having a longer bridge also provides some indication of a helical structure: the AA'BB' system of the $(CH_2)_2$ protons is retained at temperatures in excess of +200 °C; the free energy of activation $\Delta G_c^{\ddagger}$ for interconversion of the P and M helices is ≥ 104 kJ/mol (≥ 24.8 kcal/mol). Stiffening of the bridges by *meta*-phenylene units not only increases the "pitch" but also leads to conformational fixation of the helix: $\Delta G_c^{\ddagger}$ values of the same order of magnitude, which should suffice for resolution of enantiomers, are found for (7g) and (7h)[8].



It is therefore all the more surprising that the representative with the shortest bridge, (7o), displays conformational mobility at considerably lower temperatures. At 50 °C both the CH_2 and *p*-phenylene protons exhibit broadening and coalesce at 115 °C to a sharp singlet and an AB system, respectively. The value of $\Delta G_c^{\ddagger}$, *i.e.* 79.3 kJ/mol (18.9 kcal/mol), is very

[a] The structures of all compounds given have been confirmed by elemental analysis, mass spectra, and NMR spectra.
[b] Benzyl H, δ values [ppm], in $CDCl_3$.
[c] Sparingly soluble.

Although the pyrolysis of the ethano bridged disulfone (7k) also proceeds smoothly it does not conform to the pattern observed so far, which would predict formation of a cyclic system (7) having a $(CH_2)_4$ bridge: In contrast to the analogously bridged *ortho*-terphenyl system[7] the ethano bridge of (7k) is released together with SO_2 to form (7o) with a bridge shortened by four members.

(7k) (7o)

The conformational stability of the helix structure (7) depends upon the length of the bridge B. The ^{1}H-NMR spectrum of (7o) with the shortest bridge affords particularly impressive proof of fixation of the many-membered ring: at room temperature an AA'BB' system is observed for the CH_2 groups and, at remarkably high field, an AB system for the *p*-phenylene protons ($\delta_A = 5.84$, $\delta_B = 6.60$ ppm) lying in the anisotropic region of the oppositely placed benzene ring[9]. The sulfide (7b) having a longer bridge also provides some indication of a helical structure: the AA'BB' system of the $(CH_2)_2$ protons is retained at temperatures in excess of +200 °C; the free energy of activation $\Delta G_c^{\ddagger}$ for interconversion of the P and M helices is ≥ 104 kJ/mol (≥ 24.8 kcal/mol). Stiffening of the bridges by *meta*-phenylene units not only increases the "pitch" but also leads to conformational fixation of the helix: $\Delta G_c^{\ddagger}$ values of the same order of magnitude, which should suffice for resolution of enantiomers, are found for (7g) and (7h)[8].

It is therefore all the more surprising that the representative with the shortest bridge, (7o), displays conformational mobility at considerably lower temperatures. At 50 °C both the CH_2 and *p*-phenylene protons exhibit broadening and coalesce at 115 °C to a sharp singlet and an AB system, respectively. The value of $\Delta G_c^{\ddagger}$, *i.e.* 79.3 kJ/mol (18.9 kcal/mol), is very low, even in comparison with that of the stereotopically similar [4.3]paracyclophane ($\Delta G = 140.2$ kJ/mol; 33.5 kcal/mol)[10]. On the basis of model considerations and in accord with recent results obtained for the 1,8-diarylnaphthalene system[10], we interpret this value by assuming opening of the bond angles in the biphenyl system in (7o), owing to scissor-like diplacement and mutual repulsion of the *p*-phenylene rings pressed upon each other, which facilitates rotation about the central C—C bond of the 2,2'-substituted biphenyl system.

In the cyclic compounds having longer bridges the *p*-phenylene rings have more freedom to move; the bond angles of the biphenyl system should therefore not exhibit any opening in the ground state; the rotational barrier is then comparatively high.

As expected the bridging of the *o*-quaterphenyl system also has an observable effect on the UV spectrum: on going from the open-chain system (4) (shoulders at $\lambda = 233$ and 252 nm)

to the bracketed compound *(7o)* (λ_{max} = 255.5 nm) the longest wavelength absorption exhibits a 3.5 nm bathochromic shift.

Facile Synthesis of α,β-Dehydro Amino Acid Esters[**]

By *Ulrich Schmidt* and *Elisabeth Öhler*[*]

Dedicated to Professor Hans Nowotny

α,β-Dehydro amino acid esters *(4)* serve as components of antibiotic peptides and as biosynthetic intermediates[2]. One method for the preparation of the esters *(4)* starts from *tert*-butoxycarbonyl amino acid esters[3, 4]. The α-imino acid esters *(3)* tautomeric with *(4)* are accessible by *N*-chlorination/dehydrochlorination of α-amino acid esters *(1)*[4, 5]. Rearrangement of the α-imino compounds into the esters *(4)* has not hitherto been observed. However, dehydrochlorination of *N*-(chloro)phenylalanine ester gives exclusively the thermodynamically more stable ester (α-aminocinnamic ester)[4].

We have now found that the α-imino acid esters *(3)* can be rearranged into the hydrochlorides of the α,β-dehydro amino acid esters by treatment with hydrogen chloride at low temperature. The esters *(4)* can be liberated from the hydrochlorides by ammonia. In the above reaction sequence it is unnecessary to isolate the α-imino acid esters *(3)*. After dehydrochlorination of the *N*-chloro compounds *(2)* they are rearranged directly in the reaction solution. α,β-Dehydrovaline methyl ester *(4a)*, -leucine methyl ester *(4b)*, and -isoleucine methyl ester *(4c)* are readily accessible by this method.

Procedure

α,β-Dehydro amino acid methyl esters (4): tert-Butyl hypochlorite[6] (1 equiv.) is added dropwise to an ice-cooled, stirred solution of amino acid methyl ester *(1)* (10 mmol) in anhydrous ether (20 ml) with exclusion of light. After 30 min the ether is removed *in vacuo*. A solution of the residue in chloroform (50 ml) is quickly treated with 0.5 N hydrochloric acid (10 ml), washed with water (10 ml), and briefly dried over Na_2SO_4 at 0 °C. After complete removal of solvent *in vacuo* the almost pure *N*-chloroamino acid methyl ester *(2)* is obtained.

A solution of diazabicyclo[5.4.0]undecene (DBU) (1.52 g, 10 mmol) in anhydrous ether (20 ml) is quickly added dropwise to a vigorously stirred solution of *(2)* (10 mmol) in anhydrous ether (80 ml) at room temperature. After 30 min the mixture is cooled to 0 °C and DBU·HCl filtered off under suction. The ethereal solution of the crude imino acid ester *(3)* is treated at −70 °C, with vigorous stirring, with a 1 N solution of hydrogen chloride in anhydrous ether (11 ml). After 15 min the solution is stirred for another 6 h at 0 °C, then allowed to stand for 15 h at −20 °C, and subsequently evaporated to dryness *in vacuo*. Residual *(4)*·HCl is repeatedly digested with anhydrous ether and rapidly filtered off under suction. In order to liberate *(4)* the crystalline *(4)*·HCl is dissolved in anhydrous chloroform and dry NH_3 is passed through the ice-cooled solution for 10 min; ammonium chloride is filtered off and the filtrate concentrated *in vacuo*. The oily residue is distilled in a bulb tube at 11 torr and an air-bath temperature of *ca.* 110 °C.—*(4a)*[3]: yield 80 % based on *(1a)*; *(4b)*[4]: yield 63 % based on *(1b)*. ^{1}H-NMR ($CDCl_3$): no evidence for the presence of *cis-trans* isomers; δ = 1.06 (d, 6H); 2.43 (m, 1H); 3.22 (br. s, 2H); 3.76 (s, 3H): 5.41 (d, 1H) (accompanied by signals of *ca.* 10 % of *(3b)*).—*(4c)*: yield 75 % based on *(1c)*. ^{1}H-NMR ($CDCl_3$): (shows the signals of *Z*- and *E* isomer in the ratio of about 1 : 1): δ = 1.02 and 1.04 (t, 3H); 1.74 and 2.02 (s, 3H); 2.12 and 2.46 (q, 2H); 3.40 (br. s, 2H); 3.76 (s, 3H).

Activation of Double Bonds in Dehydro Amino Acids: A Model for Pyridoxal-Containing Enzymes in Elimination-Addition Reactions[**]

By *Ulrich Schmidt* and *Erhard Prantz*[*]

N-Pyridoxylideneaminoacrylic acid is frequently assumed as an intermediate of elimination and exchange reactions on pyridoxal-containing enzymes[2, 3]. Short-lived intermediates in pyridoxal-containing enzymes with an absorption region at 455—470 nm were interpreted as *N*-pyridoxylideneaminoacrylic acid[3]. It was hitherto impossible to prepare derivatives of this acid for use in biomimetic studies. Nor could simpler models such as *N*-salicylideneaminoacrylic acid derivatives be obtained by β-elimination from substituted serines and cysteines[4].

In connection with our syntheses of dehydro amino acid derivatives with free amino groups[1, 5] we have now succeeded in the direct condensation of dehydrovaline ester with benzaldehyde, salicylaldehyde, 4-nitrosalicylaldehyde, and pyridoxal to give the Schiff bases *(1)* to *(4)*. These compounds are instructive models for the pronounced reactivity of *N*-pyridoxylideneaminoacrylic acid. The extreme ease of addition to the *o*-hydroxyl compounds *(2)* to *(4)* could be demonstrated with phenylmethanethiol:

Addition of phenylmethanethiol proceeds very reluctantly in the presence of 1 mol of diazabicyclo[5.4.0]undecene (DBU) as catalyst when attempted with 0.2 M ethanolic solutions of dehydrovaline methyl ester *(5)*[5], *N*-acetyldehydrovaline methyl ester *(6)*[6], and *N*-benzylidenedehydrovaline methyl ester *(1)*. Only 10—15% conversion takes place within 1 h. In contrast, addition to the *o*-hydroxyl Schiff bases *(2)* and *(3)* is 50% complete within 10 min, and 85—90% within 1 h.

The pyridoxylidene compound *(4)* cannot be included in this series owing to its sparing solubility. However, in 0.02 M solution the salicylidene compounds *(2)* and *(3)* have reacted to the extent of 30% within 20 min and the pyridoxylidene compound *(4)* to the extent of 50%.

These facts demonstrate that the introduction of electron acceptors (nitro group) and transition to the electron-poorer pyridine system (pyridoxylidene compound) fail to accelerate the reaction markedly. The significant enhancement of the ease of addition in the aminoacryloyl system is attributable to the *o*-hydroxyl group.

Procedure

N-Salicylidenedehydrovaline methyl ester (2): The water formed on reaction of a solution of dehydrovaline methyl ester (1.29 g, 0.01 mol) *(5)* and salicylaldehyde (1.22 g) in anhydrous benzene (50 ml) is removed by azeotropic distillation (progress of reaction checked by TLC; silica gel/chloroform; R_f of *(2)* = 0.7). When no starting material can be detected by TLC the residue left on distilling off the benzene is itself subjected to high-vacuum bulb-tube distillation at a bath temperature of 140°C. Yield 1.75 g (75%) of a yellow oil which crystallizes in a refrigerator (m.p. 20—25°C). ^{1}H-NMR ($CDCl_3$): δ = 2.00 (s with doublet character, 6H); 3.80 (s, 3H); 6.78—7.44 (m, 4H); 8.06 (s, 1H); 10.26 (br. s, 1H).

(1): pale yellow oil, yield 72%. ^{1}H-NMR ($CDCl_3$): δ = 1.98 (s, 3H); 2.08 (s, 3H); 3.80 (s, 3H); 7.20—7.90 (m, 5H); 8.12 (s, 1H).

(3): m.p. 156°C from benzene/light petroleum, yield 82%. ^{1}H-NMR ($CDCl_3$): δ = 2.08 (s, 6H); 3.88 (s, 3H); 7.20—7.76 (m, 3H); 8.36 (s, 1H); 11.06 (s, 1H).

N-Pyridoxylidenedehydrovaline methyl ester (4): A solution of dehydrovaline methyl ester *(5)* (1.29 g) and pyridoxal hydrochloride (2.04 g) in methanol (150 ml) is stirred at 50°C for 2 h. After approx. ½ h the hydrochloride of *(4)* starts to precipitate. The reaction mixture is evaporated down to 50 ml, filtered, washed with anhydrous ether, and dried in a vacuum (yield 1.0 g, 32%). The suspension of the hydrochloride in dichloromethane is treated twice with saturated $NaHCO_3$ solution and twice with water, dried, and evaporated. The residue is recrystallized from benzene to give 0.87 g of yellow crystals of m.p. 148°C (dec.). ^{1}H-NMR ($CDCl_3$): δ = 2.06 (s, 3H); 2.10 (s, 3H); 2.52 (s, 4H); 3.84 (s, 3H); 7.76 (s, 2H); 7.87 (s, 1H); 8.8 (s, 1H); 13.26 (br. s, 1H). UV (C_2H_5OH): λ_{max} = 218, 295 nm; on addition of aluminum nitrate a weak maximum appears at 485 nm whose extinction increases with time.

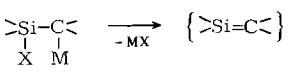
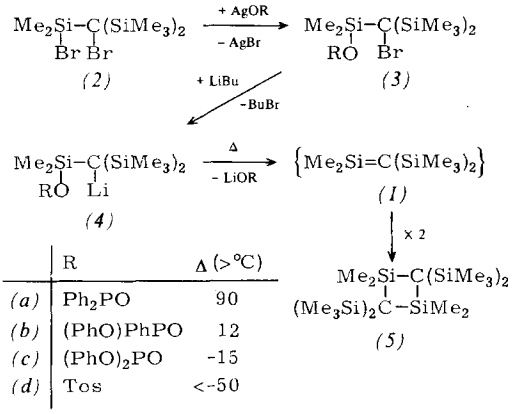
Synthesis and Some Reactions of 1,1-Dimethyl-2,2-bis-(trimethylsilyl)-1-silaethene[1]



By *Nils Wiberg* and *Gerhard Preiner*[*]

The preparation of unsaturated compounds of type >Si=E (*e.g.* E = C<, N—, O) with silicon having coordination number

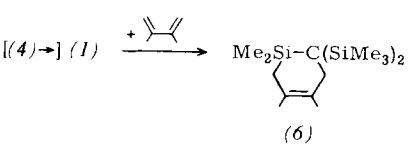
[*] Prof. Dr. N. Wiberg, Dipl.-Chem. G. Preiner
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)



3 numbered for many years among the unsolved "classical problems" of silicon chemistry[2]. The transient existence of short-lived, rapidly dimerizing silaethenes containing the characteristic >Si=C< atomic grouping was first established as late as 1966, when they were detected as secondary products in the gas-phase pyrolysis of substituted silacyclobutanes at about 600 °C[3]. Since then it has been demonstrated that silaethenes can be generated by various other routes, both thermally as well as photochemically[4a, b]. The pyrolytically generated silaethenes (in particular $Me_2Si{=}CH_2$) can be trapped by certain reagents, particularly alcohols, ketones, and dienes[4a, c]. However, owing to the high temperatures necessary for the thermolytic generation of the silaethenes the choice of trapping reagent is severely limited, thus rendering the isolation of many preparatively interesting but thermolabile products impossible.

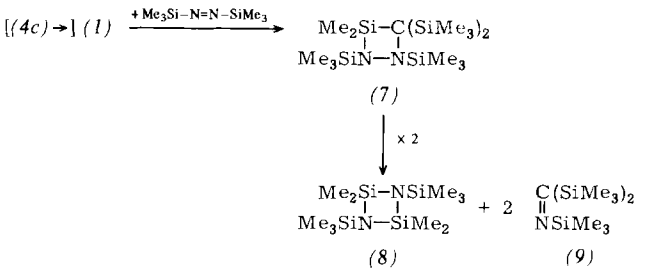
We have now found that elimination reactions according to the scheme:

(X = electronegative substituent, M = alkali metal) enable the synthesis of silaethenes under very mild conditions in organic solvents, and thus considerably extend their scope of application in synthetically useful reactions. As example we describe here the generation and a few reactions of 1,1-dimethyl-2,2-bis-(trimethylsilyl)-1-silaethenes *(1)*.



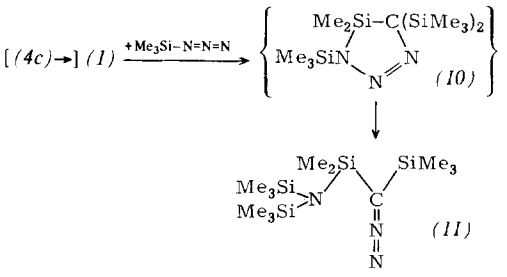
The unsaturated silicon compound *(1)*, which dimerizes to *(5)* in the absence of trapping reagents, is accessible *via* the following route using dimethylbis(trimethylsilyl)bromomethylbromosilane *(2)* as starting material:

	R	Δ (>°C)
(a)	Ph_2PO	90
(b)	(PhO)PhPO	12
(c)	$(PhO)_2PO$	−15
(d)	Tos	<−50



Thermolysis of the intermediate *(4)* in organic solvents proceeds more rapidly the more electronegative the substituent R (when R = Me, Ph, *(4)* does not decompose in the quoted way—at least up to 220 °C).

On heating *(4a—c)* in a high vacuum, the silaethene *(1)* is formed as gaseous product along with *(5)* and can be detected directly by mass spectrometry. On the other hand, product *(6)*, the formation of which by reaction of *(4)* with 2,3-dimethylbutadiene in organic media is explicable only as a Diels-Alder adduct of *(1)*, affords indirect evidence for the intermediary occurrence of *(1)* in the decomposition of *(4)*:



(6)

Apart from undergoing [2+4]cycloadditions, *(1)* obviously also undergoes other cycloadditions more rapidly than a dimerization to *(5)*. Thus *(1)*—generated from *(4c)*—reacts with blue bis(trimethylsilyl)diazene in a [2+2]cycloaddition with formation of the colorless four-membered ring compound *(7)*, which above 70 °C is converted into the colorless cyclosilazane *(8)* and the inky-blue ketimine *(9)*:

(Owing to the thermolability of the diazene[5] and *(7)* it is advantageous to use the precursor *(4c)*[9], which is reactive at low temperatures.) As a further example we might mention the reaction of *(1)* with trimethylsilylazide, which leads—most likely *via* a [2+3]cycloaddition product *(10)* containing a triazene grouping[6]—to the diazomethane derivative *(11)* in *ca.* 50 % yield[7] according to:

Experimental

To a solution of $(Me_3Si)_2CBr_2$[8] (32.46 g, 102.1 mmol) in 200 ml THF/100 ml Et_2O at −110 °C is added a solution of LiBu (103.9 mmol) in hexane (60 ml), and then 29 ml (203 mmol) $PhMe_2SiCl$. The reaction mixture is allowed to warm slowly to room temperature before removal of LiCl by filtration. Fractional distillation of the filtrate at 125 °C/high vacuum affords 36.15 g (96.9 mmol) colorless, crystalline $(Me_3Si)_2CBr{-}SiMe_2Ph$, which on treatment with 7 ml Br_2 (130 °C, 24 h) yields 34.66 g (92 mmol) *(2)* (subl. p. 100 °C/high vacuum; m.p. 152 °C) along with some PhBr.

For the synthesis of *(3)*, 10.5 mmol ROAg (prepared from $AgNO_3$ and RONa in water, dried in a high vacuum) is allowed to react with 10.0 mmol *(2)* in 10 ml THF for 6 h at room temperature. AgBr is filtered off, the filtrate evaporated down, and the remaining oily residue treated with 10 ml pentane and filtered free of insoluble material. The esters *(3)* crystallize from the pentane solution in 90 % yield; m.p. 63 °C *(3a)*, <0 °C *(3b)*, 29 °C *(3c)*, 89 °C *(3d)*.

For the synthesis of *(4)* a solution of LiBu (5 mmol) in hexane is added dropwise to a solution of *(3)* (5 mmol) in 30 ml pentane at −78 °C. Pure *(4a—c)* is recovered by filtration at −78 °C—if necessary after concentration of the solution. *(4d)* was not isolated.

Absolute Configuration of the Cancerostatic *S*(−)-Cyclophosphamide

By *Dorota A. Adamaik, Ryszard Kinas, Wolfram Saenger*, and *Wojciech J. Stec*[*]

Cyclophosphamide (Cytoxan, Endoxan, NSC 26271; *N,N*-bis(2-chloroethyl)tetrahydro-2*H*-1,3,2-oxazaphosphorin-2-amine 2-oxide) *(1)* is a clinically tested cancerostatic[1]. The observation that patients treated with racemic (±)-*(1)* preferentially excreted (−)-*(1)*[2] led to synthesis of the two enantiomers[3]. Experiments on mice showed (−)-*(1)* to have a therapeutic index LD_{50}/ID_{90} towards ADJ/PC6 plasma cell tumor that is twice as high as that of the (+)-enantiomer[4]. These findings prompted us to carry out the present crystal structure analysis in order to elucidate structure-function relations.

(−)-*(1)* crystallizes from CCl_4 as irregular stout crystals of space group P1 with $a=10.500(4)$, $b=10.490(4)$, $c=10.761(4)$ Å, $\alpha=110.0(2)$, $\beta=110.0(2)$, $\gamma=108.9(2)°$; $Z=3$. 2635 X-ray reflections were recorded with a four-circle diffractometer (Cu-K_α radiation, $2\theta/\omega$ scan) and corrected for geometric factors. The structure could be solved by direct methods after determination of the normalized structure amplitudes E_{hkl} and refined in the usual way. The coordinates and temperature factors were varied both for the model (x,y,z) and for the enantiomorph $(\bar{x},\bar{y},\bar{z})$ taking account of the anomalous scattering of P and Cl. Final weighted discrepancy indices $(R_w=[\Sigma w(|F_{obs}|-|F_{calc}|)^2/\Sigma w|F_{obs}|^2]^{1/2}$ are 7.28% for (x,y,z) and 6.77% for $(\bar{x},\bar{y},\bar{z})$. On the basis of *Hamilton*'s *R* factor test[5], the model (x,y,z) could be ruled out with a reliability index of <0.005. Figure 1 shows the structure of (−)-*(1)*: The symmetrical phosphorus atom has the *S* configuration.

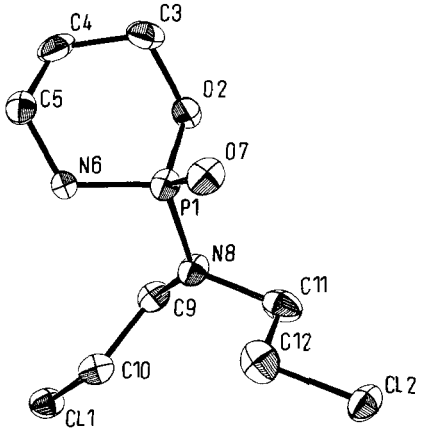

Fig. 1. Molecular structure of *S*(−)-cyclophosphamide. The thermal ellipsoids enclose the 20% probability distribution [7].

The conformation of *S*(−)-*(1)* is like that already described for the crystal structure of the racemate[6]. The oxazaphosphorin ring exists in the chair form, the substituent O(7) is axial, and the P—N bonds have partial double bond character. The C(9)—N(8)—C(11) plane is almost perpendicular to the O(2)—P(1)—N(6) plane, and the configuration of N(8) is planar (sp^2). Differences between the racemate and *S*(−)-*(1)* are seen only in orientations about the N—C bonds, thus indicating a certain degree of flexibility of the bis(2-chloroethyl)amino group while the rest of the molecule appears to be rigid.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the first synthesis of derivatives of the $C_5BH_6^+$ ion with a pentagonal-pyramidal structure.

Reaction of pentamethylcyclopentadienyltrimethylgermane *(1)*[2] with two equivalents of boron triiodide proceeds *via* extrusion of trimethyliodogermane to form the salt *(3)* having a *nido*-carbaborane structure in the cation. Although the intermediate pentamethylcyclopentadienyldiiodoborane *(2)* cannot be isolated, it can be detected by NMR spectroscopy[3].

(1) *(2)*

(3)

Compound *(3)* proves to be fairly air-stable and is readily soluble in polar aprotic solvents such as methylene chloride and acetonitrile. Its constitution and structure are confirmed by analytical and spectroscopic data.

^{1}H-NMR (in CH_2Cl_2): $\delta CH_3 = 2.32$ ppm (quartet, $^3J_{HB} = 2.2$ Hz). ^{11}B-NMR (in CH_2Cl_2 *vs.* $BF_3 \cdot OEt_2$): $\delta(CH_3)_5C_5BI^+ = 50.8$ ppm (8 of 16 lines expected theoretically, $J = 2.2$ Hz); $\delta BI_4^- = 127.6$ ppm. ^{13}C-NMR (in $CH_2Cl_2/C_2D_2Br_4$; $\{^1H\}$): $\delta CH_3 = -10.11$, δC-ring = 115.2 ppm. Mass spectrum: $m/e = 273$ $C_{10}H_{15}BI^+$ (32% int.). Conductivity (in acetonitrile, 25 °C): 173.3 Ω^{-1} cm^2 mol^{-1} ($1.933 \cdot 10^{-3}$ M) [cf. $Et_4N^+BBr_4^-$: 176.9 Ω^{-1} cm^2 mol^{-1} ($1.753 \cdot 10^{-3}$ M)[4]].

Compared to cyclopentadienylboranes of type *(2)*, the ^{11}B resonance of the cluster *(3)* shows a drastic upfield shift ($\approx$80 ppm). Hence it is concluded that the positive charge in *(3)* is not localized on the boron atom but distributed over the entire cluster. Interestingly, coupling of the CH_3 protons with the ^{11}B isotope is observed with *(3)*, but not with *(2)*.

According to MO considerations and the resulting rules[1, 5] for orbital and electron requirements, the cluster *(3)* corresponds to a minimum on the energy surface. The bonding found in *(3)* should also apply to isoelectronic systems containing neighboring elements of boron[6]. Thus an alternative mode of bonding is available for η^5-cyclopentadienyl compounds of Main Group elements instead of the hitherto discussed "centrosymmetric π-bonding".

Procedure:

A solution of *(1)* (4.0 g, 16 mmol) in CH_2Cl_2 (10 ml) is added slowly to boron triiodide (12.5 g, 32 mmol) in CH_2Cl_2 (20 ml) at -20 °C. After stirring for 1 h, all volatile components are drawn off at 0 °C. Repeated recrystallization of the residue from CH_2Cl_2 affords the product *(3)* as colorless needles, m. p. 160 °C (dec.); yield 7.8 g (62 %).

Determination of the Activation Volume $\Delta V^{\neq}$ of Simple Molecular Rearrangements by High-Resolution ^{1}H-NMR Spectroscopy at High Pressures[**]

By *Hans-Dietrich Lüdemann, Rudolf Rauchschwalbe*, and *Elmar Lang*[*]

High resolution NMR has become the most prominent method for the determination of the activation parameters $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ in simple intra- and intermolecular rearrangements. In modern monographs separate chapters are devoted to the calculation of these parameters from the temperature dependence of the proton signals[1]. An additional study of the pressure dependence of the spectra allows the determination of the activation volume from the relation:

$$\frac{d\ln k}{dp} = \frac{-\Delta V^{\neq}}{RT} \qquad (1)$$

In this communication we report the effect of pressure on two simple intramolecular rearrangements. The spectra were recorded in a recently developed high pressure NMR cell[3] fitting into the standard probe of a Varian XL 100 spectrometer. This cell can be operated at pressures up to 2000 bar and variable temperature with a resolution of 1 Hz.

1) Rotation of the dimethylamino group of N,N-dimethylacetamide around the C—N bond:

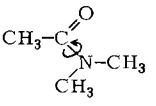

Figure 1 gives the signals of the two *N*-methyl groups in the vicinity of the coalescence temperature (T_c).

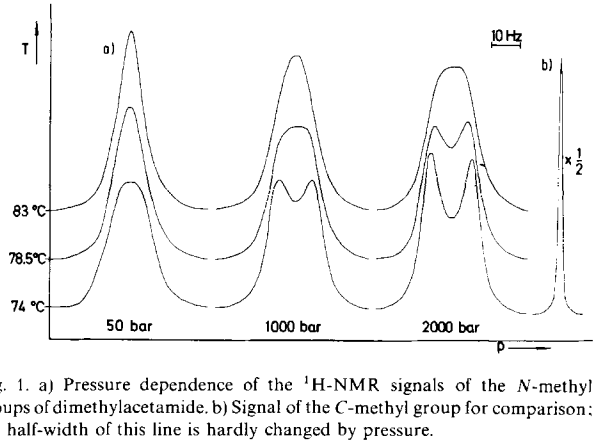

Fig. 1. a) Pressure dependence of the ^{1}H-NMR signals of the *N*-methyl groups of dimethylacetamide. b) Signal of the *C*-methyl group for comparison; the half-width of this line is hardly changed by pressure.

Institut für Biophysik und Physikalische Biochemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

Increasing pressure shifts the coalescence of the signals to higher temperatures with $\Delta T_c/\Delta p = 4.5\ \mathrm{K \cdot kbar^{-1}}$. $\Delta G^{\neq}$ and k_c were calculated at the various pressures by insertion of T_c, the low temperature values of the frequency difference, and the half-width of the signals into the standard equations[1, 2]. The inversion rates between 74 and 83 °C were calculated as a function of pressure assuming Arrhenius-type behavior. Insertion of these rates into eq. (1) yields $\Delta V^{\neq} = 10.3 \pm 1.0\ \mathrm{cm^3 \cdot mol^{-1}}$. The inversion of the dimethylamino group is thus connected with a considerable volume increase in the immediate vicinity of the molecule.

2) Ring inversion of cyclohexane:

An increase of pressure shifts T_c to lower temperatures ($\Delta T_c/\Delta p = -1.0\ \mathrm{K \cdot kbar^{-1}}$); within the limits of experimental error the difference $\Delta\nu$ between the chemical shifts is not affected by pressure. Also, the half-width b_E is only slightly changed. By application of the methods described in the first example, the inversion rates k were calculated as function of pressure. $\Delta V^{\neq}$ was found to be $-1.9 \pm 0.5\ \mathrm{cm^3 \cdot mol^{-1}}$. The data used are given in Table 1.

Table 1. Pressure dependence of the proton resonance spectra of cyclohexane in the coalescence region.

Pressure [bar]	50	1000	2000
Coalescence temperature [K]	217	216	215
Frequency difference [Hz]	48.5	48.5	48.5
Half-width [Hz]	15.5	16.5	17.0
Inversion rate (217 K) k_{217} [s^{-1}]	87	96	107

The unexpected result is that increasing pressure significantly accelerates the ring inversion. This can be qualitatively explained by assuming that the twist or boat conformations adopted by the molecule during ring inversion have slightly smaller molar volumes than the energetically more favorable chair forms. Further studies on substituted cyclohexanes and in other solvents will be necessary for a better description of this effect.

Experimental

Measuring frequency: 100.1 MHz, FT technique, 16k memory, spectral width: 1000 Hz.—*Example 1:* Solution (vol.-%) of dimethylacetamide (60), tetramethylsilane (20), and [D_6]-acetone (20).—*Example 2:* Solution (vol.-%) of cyclohexane (40), tetramethylsilane (30), [D_2]-dichloromethane (15), and [D_{14}]-methylcyclohexane (15).

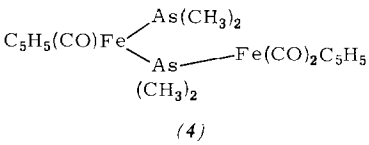
An Organometallic Five-Membered Ring with Hetero-Metal-Metal Bonding[**] [1]



By *Erika Röttinger, Rainer Müller,* and *Heinrich Vahrenkamp*[*]

As Lewis bases, organometalloarsanes such as *(1)*[2] are capable of substituting CO ligands in metal complexes, and thus of forming As-bridged dinuclear complexes. Mild reaction conditions are necessary for the preparation of hetero dinuclear complexes, whereas at high temperatures reaction of the organometalloarsanes with themselves is predominant[1]. We have now observed the first combination of these two reaction possibilities with formation of the trinuclear metal-arsenic five-membered ring *(2)*.

Reaction of *(1)* with excess $C_5H_5Co(CO)_2$ at elevated temperature affords dark-green *(2)*. The expected simple As-bridged dinuclear complex *(3)* is not formed, even under milder conditions. It must be assumed, therefore, that *(1)* initially reacts with itself to give the non-isolable dinuclear organometalloarsane *(4)*, which then reacts with the cobalt complex $C_5H_5Co(CO)_2$. This assumption is supported by the fact that the dinuclear complex $[C_5H_5(CO)Fe{-}As(CH_3)_2]_2$, which can be formed *via (4)*, is obtained as main product of the reaction.

The heterocycle *(2)* manifests itself in the IR spectrum (cyclohexane, $\mathrm{cm^{-1}}$) by three CO stretching modes (1942 s, 1928 vs, 1758 vs) and in the ^{1}H-NMR spectrum (benzene, int. TMS, ppm) by three C_5H_5 signals (3.95, 4.35, 4.69) and four CH_3 signals (1.26, 1.34, 1.43, 1.50). Its structure was determined by X-ray crystallography[3]. Figure 1 shows the approximate planarity of the novel five-membered ring system and the CO-bridged hetero metal-metal bond. Since the IR spectrum of *(2)* in solution shows only one bridging CO group, while the solid state structure shows two such groups, *(2)* must be a fluxional molecule[4].

In the case of the two previously known five-membered heterocycles with carbonylmetal moieties[5] the synthetic route precluded formation of heterobimetallic species. Complexes

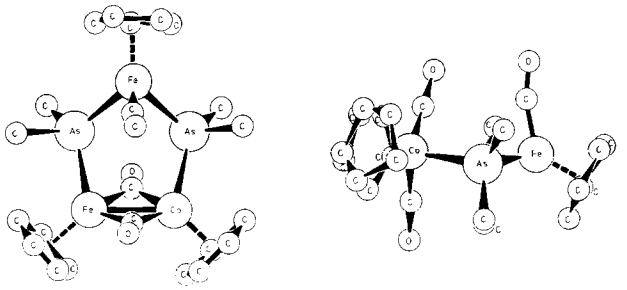

Fig. 1. Two views of the molecular structure of *(2)*. Averaged bond lengths (in clockwise direction) Co—Fe = 2.460, Fe—As = 2.363, As—Fe = 2.328, Fe—As = 2.340, As—Co = 2.348 Å.

such as *(2)*, however, appear to be accessible in a systematic way. Comparison of the stereochemistry of *(2)* with that of an open-chain M_3As_2 compound without metal-metal bonding[6] shows that the relief of steric strain is a driving force in the formation of *(2)*. Heterotrinuclear complexes with two dimethylarsenic bridges[7] should thus be capable of rearranging to metal-metal coupled heterocycles such as *(2)*, a prediction which is substantiated by preliminary findings[8].

Experimental:

Synthesis of *(2)*: A mixture of *(1)* (2.74 g, 9.7 mmol) and $C_5H_5Co(CO)_2$ (2.70 g, 15.0 mmol) in cyclohexane (50 ml) is stirred for 4 d at 85 °C. After removal of all volatile compounds *in vacuo* the reaction mixture is chromatographed on silica gel with benzene. The first, red (main) fraction contains $[C_5H_5(CO)Fe—As(CH_3)_2]_2$. The second, green fraction, after recrystallization from benzene/cyclohexane (4:1), affords 0.36 g (11 %) of *(2)*, m.p. 257 to 259 °C (dec).

μ-Thiadiborolene-bis(η-thiadiborolenecobalt)—A "Homogeneous" Triple-Decker Sandwich with Three Heterocyclic Ligands[1]

By *Walter Siebert* and *Wilfried Rothermel*[*]

The triple-decker sandwich compounds previously reported in the literature are each made up of two cyclopentadienyl metal fragments bridged by homocyclic C_5H_5-[2] or heterocyclic C_2B_3-[3], C_2B_2S-[1], and C_4B-ligands[4]. We report here on the compound *(1)*·[Co*(1)*]$_2$ *(2)*, the first representative in which three thiadiborolene rings *(1)* are present as μ- and as η-ligands. *(2)* is formed from *(1)* and $Co_2(CO)_8$ *via* the isolable dinuclear complex *(1)*$_2$·$Co_2(CO)_4$[5].

(1)

(2)

The triple-decker structure follows from the analytical and spectroscopic data of the air-stable *(2)*. Besides the molecular ion $L_3Co_2^+$ [L = *(1)*] ($I_{rel} = 100$, referred to $^{11}B_5{}^{10}B$) the mass spectrum (70 eV) contains, *inter alia*, the fragments $L_2Co_2^+$ (73), L_2Co^+ (12), LCo^+ (7), L^+ (7), $\{L—CH_3\}^+$ (11), $(C_2H_5)_2C_2BCH_3^+$ (60) and $(C_2H_5)_2C_2B^+$ (25).—In the ^{1}H-NMR spectrum [δ = 2.80 (Q, 4; $J = 7.6$ Hz), 2.1 (M, 8), 1.50 (T, 6), 0.96 (T, 12), 0.78 (S, 6) and 0.73 (S, 12) ppm (in CS_2 rel. to TMS ext.)] the quartet proves the magnetic equivalence of the bridge-ligand methylene protons and thus also the triple-decker array. As in thiadiborolene mononuclear complexes[6], a multiplet (ABX_3 system) is observed for the CH_2 groups of the two terminal ligands. Two ^{11}B-NMR signals [δ = 14 (S, 2) and 30 (br. S, 4) ppm (in CS_2 rel. to BF_3·OEt_2 ext.)] are also compatible with *(2)*: as in *(1)*·$[Mn(CO)_3]_2$ (22.5 ppm)[7] and in *(1)*·$[Fe(C_2H_5)]_2$ (12.0 ppm)[1] the B atoms of the central ring experience strong electronic shielding.

In *(2)* the electron balance can be described in terms of the construction of the 30 valence-electron triple-decker[8] from three thiadiborolene dianions and two Co-d^6 cations. Consideration of *(2)* as a seven-atom cluster requires that the bonding molecular orbitals are occupied by 16 skeletal electrons [2 × 1 (Co), 2 × 3 (C), 2 × 2 (B), 4 (S)] according to the rule for *closo* compounds[9].

μ-(3,4-Diethyl-2,5-dimethyl-1,2,5-thiadiborolene)-bis(η-3,4-diethyl-2,5-dimethyl-1,2,5-thiadiborolenecobalt) (2)

$Co_2(CO)_8$ (1.30 mmol) reacts with *(1)* (2.77 mmol) in toluene (20 ml) under N_2 to give a deep-blue solution. After addition of further *(1)* (2.7 mmol) the mixture is heated under reflux for 1.5 h and the resulting red solution filtered. The filtrate is concentrated by evaporation and treated with petroleum ether. On cooling to −10 °C black shiny crystals are deposited; m.p. 172 to 175 °C (dec.) yield 0.57 g (71 %).

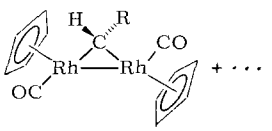
Novel Synthesis of μ-Methylene Complexes[**]



By *Wolfgang A. Herrmann, Carl Krüger, Richard Goddard,* and *Ivan Bernal*[*]

As recently reported[1], *N*-alkyl-*N*-nitrosourea derivatives are suitable for use as especially mild nitrosylation reagents in organometallic chemistry. We have now found that this class of compounds also provides a facile and productive entry to μ-methylene-transition metal complexes.

The rhodium complex *(1)* reacts with *N*-methyl-*N*-nitrosourea in boiling benzene to give a red coordination compound *(2a)* which is stable in the solid state and in solution. On the basis of total elemental analysis, osmometric molecular-weight determination, and ^{1}H-NMR, IR, and mass spectra the compound has been characterized as μ-methylenebis(carbonyl-η-cyclopentadienylrhodium) (*Rh—Rh*) (Table 1). The homologous μ-ethylidene derivative *(2b)* can be obtained in similar manner with *N*-ethyl-*N*-nitrosourea. Deuterium-labeling experiments confirm that the carbene bridge ligand originates from the alkyl groups of the organic reagent. The surprising formation of *(2a)* and *(2b)* requires ring opening of the metallacyclic system of *(1)*; mechanistic details are still unknown.

(1)

(2a), R = H
(2b), R = CH_3

The new procedure obviates use of diazoalkanes for methylene transfer[2]. A further advantage is the ready accessibility of numerous alkyl-substituted nitrosoureas.

We performed the first crystal structure determination[3] of an organometallic compound with bridging CH_2 by analyzing *(2a)* (Fig. 1): the carbene C atom, like the two Rh atoms, is located in a distorted tetrahedral environment. The *trans* orientation of the centrically bonded, almost parallel cyclopentadienyl rings leads to identical configurations at the chiral metal centers.

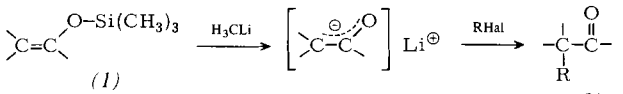
Reviews

Abstracts of selected progress reports and review articles



Applications of Mössbauer spectroscopy to the study of heterogeneous catalysis are considered by *J. A. Dumesic* and *H. Topsøe*. This technique largely satisfies the desire to study real catalysts (*i.e.* not only single crystals or films) *in situ* (*i.e.* not only in ultrahigh vacuum). Mössbauer spectroscopy is not restricted merely to catalytic systems containing iron or tin but can be applied to other systems containing "Mössbauer atoms" or "Mössbauer isotopes" such as antimony, europium, nickel, ruthenium, gold, and tungsten. The technique can also be modified so as to provide information about systems not containing any "Mössbauer atoms". [Mössbauer Spectroscopy Applications of Heterogeneous Catalysis. Adv. Catal. *26*, 121—246 (1977); 255 references]

[Rd 942 IE—F]

Toxins from marine organisms are the topic of survey compiled by *P. J. Scheuer*. Tetrodotoxin, saxitoxin, and ciguatoxin have been studied because they can occur in edible marine organisms. The structure of ciguatoxin has not yet been elucidated; it is only known to be a hydroxylated lipid. Aplysiatoxin from the midgut of a species of sea hare proved to be the bromine compound *(1)*. The extremely potent palytoxin from

(1)

a coelenterate is a truly remarkable compound: its molecular weight is about 3000, and the molecule apparently does not contain any repeating units, any amino acids, or any of the common sugars. It is hardly attacked by enzymes. [Marine Toxins. Acc. Chem. Res. *10*, 33—39 (1977); 92 references]

Trivialnamenkartei (Card File of Organic Trivial Names). 5. Ergänzungslieferung (5th Supplementary Batch). Issued by the Gesellschaft Deutscher Chemiker, Abteilung Chemie-Information und -Dokumentation Berlin. Verlag Chemie, GmbH, Weinheim 1976. 1st edit., 1024 cards, DM 208.—.

Every chemist knows that trivial names are both useful and infuriating. Useful because they are brief designations for compounds whose systematic names may be very cumbersome, and infuriating because they seldom give the least indication of the compound's structure. One is thus forced to fall back on memory when one wants to correlate the name with the structural formula, or one must turn to a good reference work. Such a reference work has been available for the last few years in the form of the Trivial Name Card File[*] which, if this new fifth batch is included, now contains more than 13000 entries. Like the previous cards, this fifth batch consists both of cards giving new names and of replacement cards that correct information given previously or bring it completely up to date. In the top left-hand corner each card bears the position number that applies on alphabetical arrangement of the cards according to the German spelling of the trivial names; in the top right-hand corner is the position number obtained by sorting arrangement according to American English spelling. Below these numbers are, respectively, the German and English trivial names. The center of the card is occupied by the structural formula with an indication of the stereochemistry, in the bottom left-hand corner is the molecular formula, and in the bottom right-hand corner are one or two references with the aid of which one can find the description of the compound in Chemischer Informationsdienst or Chemical Abstracts. The card file thus contains all that is needed for preliminary information about substances whose designations often sound truly exotic—no longer is one helpless in the face of pinseline, gentiakochianine, or colestipol; the contents do not become outdated and thus the investment is worthwhile. One might even take the presence of this card file as a criterion of the quality of a chemical library.

H. Neithard [NB 370 IE]

Strukturen der Materie und ihre Symmetrie, in Stereobildern (Structure of Matter and its Symmetry, in Stereoscopic Pictures). By *E. Egert* and *H. J. Lindner*. 3D Bildstudio R. Schmidt, 6101 Nieder-Ramstadt 1976. 1st edit., 30 pp., 42 figs. (stereoscopic pictures); in spiral binding; red-green spectacles and ruler/protractor included; DM 18.20 (from ten or more DM 16.00).

The structure of matter is three-dimensional and recognition of the spatial relationships is essential for its understanding. There are several possible ways of reproducing it. The widely used two-dimensional projection is convenient but not really satisfactory because "the ability to visualize three-dimensional structures from two-dimensional representations varies greatly between individuals". It is remarkable that a book containing structures of molecules and lattices in stereoscopic representation should appear at this time, when there are more than a dozen systems of molecular models that appear to satisfy the desire for three-dimensional viewing.

It is quite natural to see in three dimensions; why then should one not also see the larger molecules and lattices in that way, whose structures are too elaborate to be built with normal models? Although one can learn chemistry without stereoscopic pictures, it would be a pity to be denied this experience of space, which in view of the quality of the *Egert/Lindner* book becomes an esthetic pleasure.

Section a) deals with the crystal structures of metals and nonmetals, b) with ionic crystals, c) with the structures of inorganic molecules (boron and silicon compounds and metal complexes), d) with the structures of organic molecules, and e) with types of crystal lattice and symmetry elements.

The attempt to introduce stereoscopic pictures as teaching aids in the training of chemists is in itself nothing new: the materials supplied with the textbooks by *Klages*, *Holleman*, and *Wiberg*, and now by *Streitwieser* and *Heathcock*, and the book by *Bernal*, *Hamilton*, and *Ricci* use the method each within its own framework, as do Vol. A 1 of Molecular Structures and Dimensions and some Journals.

The new book attempts to show that this method of presentation has distinct advantages over models and, even if it does not replace them, it is undoubtedly a valuable extension thereof. The possibility of emphasizing the unit cell in an extended lattice is used with advantage. The transformation of the stereoformulas of D- and L-glyceraldehyde, placed in relation to one another by a mirror plane floating in space, into the Fischer projections becomes very clear. In the 14 Bravais lattices the angles drawn in can be viewed three-dimensionally. In the especially successful chapter on "Symmetry Elements" the symmetry axes and planes shown in space materially ease recognition of *e.g.* right- and left-handed screws and the understanding of symmetry operations (*e.g.* rotation-inversion). While spatial recognition requires some time and practice with the stereoscopic pictures of the older type, and even in *Bernal*'s book, it is evident as soon as one opens the present volume. The separations and angles between atoms in space can be obtained (measured off) by means of the ruler/protractor supplied; they are impressive in comparisons of enantiomers or diastereoisomers (the latter unfortunately not illustrated). The philosophy of the book—combination of stereoscopic pictures with brief but effective introductory text, is put expertly into practice. It is a pity that the diamond and graphite lattices were not arranged next to each other, that the adamantane structure was not emphasized in the diamond lattice, and that 5α-cholestane was not illustrated alongside the 5β-isomer.

An advantage of stereoscopic pictures over models is clearly that with the former numerous structures can be stored in a small space for examination and comparison. On the other hand, it can be interesting to model parts of the stereoscopic structures so as to view them from all sides.

The only "shortcoming" of the book is that it is limited largely to inorganic structures; the organic chemistry section is only three pages long and contains only two illustrative blocks, even if interesting ones. The chapter on natural products contains only 5β-cholestane; it is precisely complicated molecules that exceed the capacity of a model kit or cause much trouble, and here the advantage of stereoscopic pictures would be really evident. How impressive it would be to see in three dimensions (with symmetry relationships), for example staggered biphenyls, cumulenes and acetylenes of various lengths (with their π-electron distributions), spiro compounds, twistane enantiomers, asteranes, propellanes, triptycene, rotaxanes, catenanes, sterically strained and spatially hindered molecules, conformational changes on transition from ligands to complex, topomerization processes (inversion at nitrogen, bull-

[*] Cf. Angew. Chem. Int. Ed. Engl. 5, 326 (1966).

valene, hypostrophene, *etc.*), packing in organic crystal lattices, chiral natural products, carbohydrates, and the primary, secondary, and tertiary structures of peptides. The *meso/d,l-*, *erythro/threo-*, and *(R,S)*-notation also for chiral axes and planes could be ideally introduced. And it would be of great interest to have a section on biochemical structures, *e.g.* nucleic acid helices, hormones, and enzymes.

Since stereochemistry combines specialist areas from the whole of chemistry, there arises, on the basis of this book, a desire for a complete work with a similar title and in similar style which, based on the main types of bonding, should include both organic chemistry and biochemistry.

The book is reasonably priced and deserves wide distribution.

Fritz Vögtle [NB 367 IE]

The Hydrogen Bond. Recent Developments in Theory and Experiment. (3 volumes). Edited by *P. Schuster, G. Zundel* and *C. Sandorfy*. North-Holland Publishing Company, Amsterdam—New York 1976, 1st edit., *ca.* 1520 pp., bound, 3 vols. together $ 173.75.

The forty authors of this volume have attempted collectively to review our present state of knowledge of the hydrogen bond. After an introduction that touches on the field of H-bonding in excited molecules *(E. Lippert)*, the first volume (Theory) begins with a well-rounded treatise on energy hypersurfaces, in which the various approximation methods are carefully compared *(P. Schuster)*. Four articles are devoted to dynamics: these treat the one-dimensional motion of the proton in the double minimum potential *(J. Brockmann)*, coupling of several such tunnelling protons *(W. Weidemann)*, coupling of the proton motion to other nuclear vibrations in the strong-coupling approximation *(G. L. Hofacker et al.)*, and finally the direct solution of motions on two-dimensional energy surfaces *(P. Janoschek)*; here one misses a critical comparison of these various methods of consideration. The volume ends with treatment of the statistics of H-bonds in ice and water *(J. W. Perram)*.

Volume 2 (Structure and Spectroscopy) deals first with the geometry of the H-bond, as obtained from X-ray and neutron diffraction in solids *(I. Olovsson et al., Th. F. Kötzle* and *M. S. Lehmann)*, as well as with additional spectroscopic aspects concerning the angular dependence *(W. A. P. Luck)*. Recent information on the hydrogen stretching vibration is reviewed in detail *(D. Hadzi* and *S. Bratos)*, anharmonicity being treated separately *(C. Sandorfy)*. The peculiar continuum absorption in the infrared is discussed thoroughly *(G. Zundel)*, whereas little space is devoted to long-wave IR spectroscopy *(W. G. Rothschild)*. Two articles on nuclear resonance spectroscopy with reference to chemical shifts and quadrupole coupling complete the second volume *(E. E. Tucker* and *E. Lippert, R. Blinc)*.

The third volume (Dynamics, Thermodynamics and Special Systems) contains, in the section on dynamics, a pithy review of nuclear magnetic relaxation in liquid H-bonding systems *(H. G. Hertz* and *M. D. Zeidler)*. In addition, the less common incoherent neutron scattering is considered *(J. A. Jaik)*. The somewhat disconnected article on dielectric measurements does not contain any discussion of dielectric relaxation *(L. Sobzyk, H. Engelhardt* and *K. Bunzl)*. Treatment of matrix isolation spectroscopy *(H. E. Hallam)* and ferroelectrics *(V. H. Schmidt, H. Stiller)* is followed by a section on thermodynamics, containing a clear exposition of calorimetry and the connection between thermodynamic and spectroscopic measurements *(A. D. Sherry)* and a report on vapor pressure measurements *(H. Wolff)*. H-Bonding in adsorbates on silicon oxide and aluminum oxide is described at some length *(H. Knözinger)*. The third volume closes with a consideration of H-bonds in water *(W. A. P. Luck)* and a collection of data on the H-bonding in the various modifications of ice *(E. Whalley)*.

The individual articles vary greatly in type of presentation: some are pure literature reviews, some are detailed original work, and some are clear characterizations of a certain field. The review as a whole suffers greatly from the division into more than two dozen articles, although most of the articles are very satisfactory in their class. The work nevertheless adds up to an impressive collection of the literature up to about 1974, and one may await hopefully the planned continuation dealing with biological aspects; there, however, a better accord between fewer authors on content and presentation of both theory and experiment is desirable.

The three volumes must be commended to all who deal in any way with H-bonding, in particular to workers at Institutes where physicochemical research on hydrogen-bonding is in progress. They cannot, however, be regarded as a substitute for the 16-year old monograph by *Pimentel* and *McClellan*, and thus the reviewer hopes that one of the authors will find the courage and time to contract the contents of the collection in conherent form to a quarter of its length.

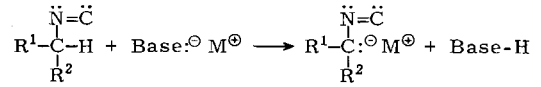
Recent Applications of α-Metalated Isocyanides in Organic Synthesis



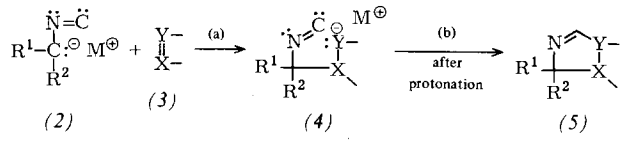
By Ulrich Schöllkopf[*]

Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

Being both nucleophilic and electrophilic, α-metalated isocyanides can add to polar double bonds, forming heterocycles. They are also synthons for α-metalated primary amines. This article describes recent or improved procedures for their use in organic synthesis: 1) In heterocyclic syntheses to give 2-oxazolines, 2-imidazolines, 2-thiazolines, oxazoles and oligooxazoles, thiazoles, triazoles, imidazolinones, pyrroles, 5,6-dihydro-1,3-oxazines and -thiazines, and (*via* cycloaddition with nitrones) 2-imidazolidinones. 2) In the field of formylaminomethylenation, for example transformation of estrone methyl ether and a keto sugar into the corresponding α-formylaminoacrylic esters, and the conversion of aldehydes and ketones by 3- and 4-pyridylmethyl isocyanides into *N*-(1-pyridyl-1-alkenyl)formamides and their hydrolysis to 3- and 4-acylpyridines. 3) In connection with the use of α-metalated isocyanides as synthons for α-metalated primary amines, the author demonstrates how they may be used for preparation of 1,2- and 1,3-amino alcohols, 1,2-diamines, 2,3-diaminoalkanoic acids and for synthesis of higher amino acids starting from simple amino acids.

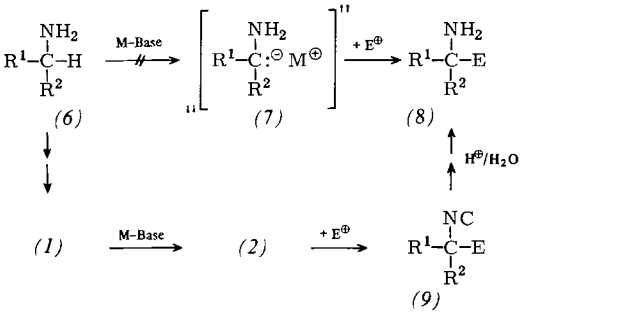
1. Introduction

The activating effect of the cyano group on neighboring C—H bonds has been known for nearly a century[1]. However, it was only in 1968 that *Schöllkopf* and *Gerhart*[2] discovered that alkyl isocyanides *(1)* can be anionized (metalated) in the α-position, albeit not quite so readily as alkyl cyanides.



(1) *(2)*

Metalation (anionization) is accomplished with the usual bases employed in carbanion chemistry such as butyllithium (with and without complexing agent), potassium *tert*-butoxide, sodium methoxide, sodium hydride, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), or triethylamine; the precise choice depends upon the substituents R^1 and/or R^2. The α-metalated isocyanides *(2)* are not isolated but immediately subjected to further reaction in the same reaction vessel. Any alkyl isocyanide *(1)* can be metalated provided that its parent hydrocarbon is as acidic or more acidic than methane. *sec*-Alkyl isocyanides without activating substituents cannot be metalated; cyclopropyl and cyclobutyl isocyanide are exceptions to this rule.



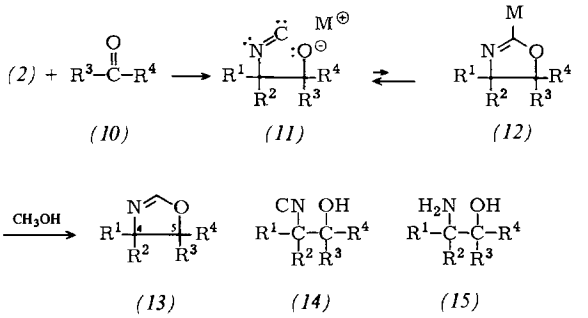
The significance of α-metalated isocyanides *(2)* in organic synthesis[3] is due, on the one hand, to the ambivalent nature of these reagents. They contain a nucleophilic center, the metalated (anionized) carbon atom, which can add to polar multiple bonds *(3)* [according to (a)], and an electrophilic center, the isocyanide carbon atom, which permits cyclization of the adducts *(4)* [according to (b)] to form heterocycles of type *(5)* (cf. Scheme 1).

[*] Prof. Dr. U. Schöllkopf
Organisch-chemisches Institut der Universität
Tammannstrasse 2, D-3400 Göttingen (Germany)

Scheme 1. Synthesis of heterocycles *(5)* from α-metalated isocyanides *(2)* and compounds with polar multiple bonds *(3)*.

On the other hand, the α-metalated isocyanides *(2)* are synthons for the (hypothetical) α-metalated primary amines "*(7)*" and permit chain extension of primary amines by electrophiles $E^{\oplus}$ [*(6)* → *(8)*]. Primary amines *(6)* have insufficient CH acidity for direct metalation and/or are preferentially metalated at the nitrogen. Thus synthetic equivalents (synthons) are required for "*(7)*", in which the amino group bears a mask which is readily introduced at the amine stage, is stable to bases, has an acidifying effect, and can be removed with ease after chain extension[4]. A mask largely fulfilling these requirements is the carbon atom of the isocyanide group. Amines *(6)* can be readily transformed into isocyanides *(1)*, either *via* the *N*-formyl derivatives[5] or directly by the Mąkosza variant of the long-known carbylamine reaction[6]. The isocyanide group is sufficiently stable towards bases and exerts an acidifying effect. After reaction of the metalated isocyanide *(2)* with $E^{\oplus}$, the adduct *(9)* can easily be converted into the amine *(8)* by acid hydrolysis (cf. Scheme 2).

Scheme 2. α-Metalated isocyanides *(2)* as synthons for α-metalated primary amines "*(7)*". Chain elongation of the amines *(6)* to *(8)*.



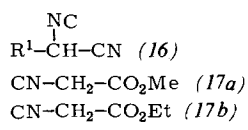
According to a toxicological study performed at Bayer AG[7], isocyanides appear to be practically non-toxic towards warm-blooded animals, with few exceptions. Nevertheless, all operations should be performed in a well-ventilated fume hood and all equipment washed with acids immediately after use. Both these measures are recommended if only because of the unpleasant odor of the lower alkyl isocyanides. Higher alkyl isocyanides, diisocyanides, or isocyanides containing a further functional group are largely or completely odorless.

Since the applications of α-metalated isocyanides *(2)* were summarized in 1974[3], the present article considers only selected examples and/or recent developments.

2. Syntheses of Heterocycles According to Scheme 1

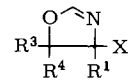
2.1. 2-Oxazolines

On reaction with aldehydes and ketones *(10)*, α-metalated isocyanides *(2)* afford 2-oxazolines *(13)*[8]. Intermediates are known to be the carbonyl adducts *(11)* and the tautomeric 2-metalated 2-oxazolines *(12)* which are transformed into 2-oxazolines *(13)* on addition of water or (preferably) methanol, *i.e.* on alkaline workup. The mobile tautomeric equilibrium *(11)* ⇄ *(12)* lies almost entirely on the left-hand side. Addition of glacial acetic acid immediately after that of the carbonyl component leads to 2-isocyano alcohols *(14)*[9]. Protonation of *(11)* is reversible in alkaline medium, explaining why 2-oxazolines *(13)* are obtained under conditions of thermodynamic product control.



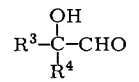
The advantage of this oxazoline synthesis consists in the linkage of the C-4—C-5 bond during the reaction. In contrast, conventional oxazoline syntheses start from 2-amino alcohols *(15)*, which are frequently difficult to obtain. Moreover, transformation of 2-amino alcohol into 2-unsubstituted 2-oxazoline is problematic[10]. Since 2-oxazolines *(13)*, as imino ethers, are easily hydrolyzed, our synthesis is recommended for the preparation of 2-amino alcohols *(15)*; this class of compounds commands interest owing to its documented or potential biological activity.

Hydrolysis of *(13)* generally proceeds readily with conc. HCl in methanol at room temperature[8]. However, some amino alcohols *(15)* eliminate water under these conditions or rearrange. In such cases it is recommended that the oxazolines *(13)* first be transformed in neutral or basic medium into the *N*-(β-hydroxyalkyl)formamides (heating in aqueous methanol, possibly in the presence of triethylamine) which are then deformylated. Warming with 2 mol of *p*-toluenesulfonic acid monohydrate in acetone or dichloromethane has proved convenient as a method for mild deformylation; *(15)* is precipitated as the ammonium toluenesulfonate—alternatively the compound may be warmed with 2 N caustic soda.



Mention should be made of some specific examples involving functionalized isocyanides. 1-Isocyanoalkyl cyanides *(16)* yield (in dichloromethane with triethylamine as base) 2-oxazoline-4-carbonitriles *(20a)*[11], and the isocyanoacetic esters *(17a)* and *(17b)* give (in ethanol with sodium cyanide as catalyst) the 2-oxazoline-4-carboxylic esters *(20b)* and *(20c)*, respectively, the precursors of serines *(15)*, $R^2 = CO_2H$[12], with diethyl isocyanomethanephosphonate *(18)* (under the same conditions) diethyl 2-oxazoline-4-phosphonate *(20d)*[13], and with *p*-toluenesulfonylmethyl isocyanide *(19)*[14] (according to the "cyanide method" or in methanol with potassium carbonate as base) 4-toluenesulfonyl-2-oxazolines *(20e)*[15,16], which can react further to give oxazoles by elimination of toluenesulfinate if $R^4 = H$[16]. Use of thallium ethoxide as base permits isolation of 4-ethoxy-2-oxazolines *(20f)*—formed by subsequent nucleophilic exchange of toluenesulfinate for ethoxide—which can be hydrolyzed to the otherwise somewhat inaccessible 2-hydroxyaldehydes

(21)[17]. The α-metalated *p*-toluenesulfonylmethyl isocyanide *(19)* is not only an ambivalent reagent but also contains a nucleofugal leaving group, thus considerably extending its scope (cf. also Sections 2.4 and 4.3).



(16)

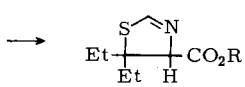
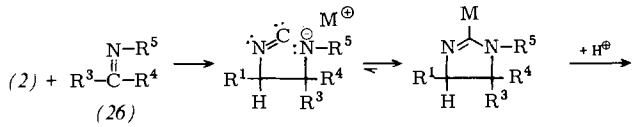
(20f), X = OEt, R^1 = H



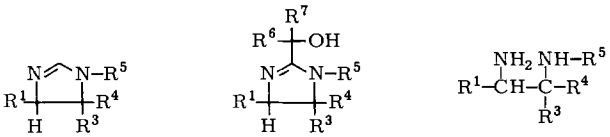
(21)

2.2. 2-Thiazolines

Diethyl thioketone *(22)* reacts with lithioisocyanoacetic esters *(23)* (in tetrahydrofuran at −60 °C) to form 3-ethyl-2-isocyano-3-mercaptopentanoic esters *(24)* which cyclize to give 5,5-diethyl-2-thiazoline-4-carboxylic esters *(25)*[18]. The synthesis should be applicable to other thioketones, the main difficulty probably lying in the preparation and manipulation of the (generally) unstable thioketones. 2-Thiazolinecarboxylic esters of type *(25)* command interest as starting compounds for the synthesis of structural variants of penicillin (cf. also Section 4.2).



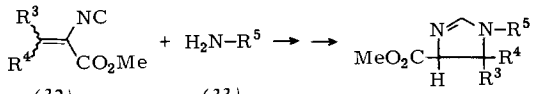
(22) *(23)* *(24)*



(25) *(a)*, R = Et
(b), R = $PhCH_2$

2.3. 2-Imidazolines

α-Metalated isocyanides *(2)* can also add to the carbonyl-analogous azomethine group. Thus lithiomethyl and lithiobenzyl isocyanide react with Schiff bases *(26)* (in tetrahydrofuran at −60 °C) to give 2-imidazolines *(29)*[19]. Methyl isocyanoacetate *(17a)* reacts (in methanol) at room temperature to form methyl 2-imidazoline-4-carboxylates *(29a)*, $R^1 = CO_2Me$, the amine present in trace amounts in azomethine presumably acting as anionizing base[19].—In contrast to the case of *(11)*, the analogous intermediate *(27)* cannot be detected in this reaction. The tautomeric equilibrium appears to lie predominantly on the side of the 2-metalated imidazoline *(28)*. This compound can be trapped—when working in aprotic media—with ketones, for example, to yield 2-hydroxymethyl derivatives *(30)*[19].

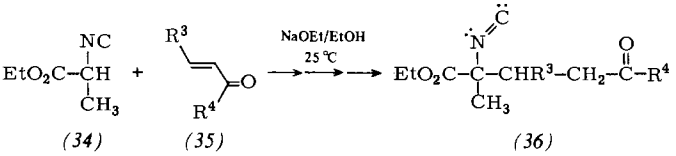


(2) + *(26)* → *(27)* ⇌ *(28)*

(29) *(30)* *(31)*

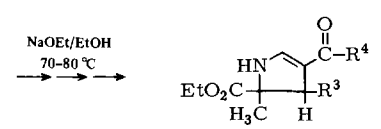
(29a), $R^1 = CO_2Me$

Alternatively, the methyl 2-imidazoline-4-carboxylates *(29a)* can be obtained from 2-isocyanoacrylic esters *(32)* (cf. Section 4.2) by addition of primary amines *(33)* or ammonia (in methanol at room temperature)[19]. The 1-unsubstituted 2-imidazole-4-carboxylic esters *(29b)* are readily accessible in this way.



(32) *(33)*

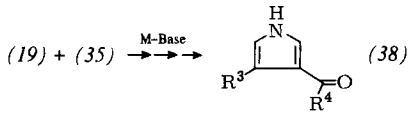
(29a), R^5 = Alkyl
(29b), R^5 = H



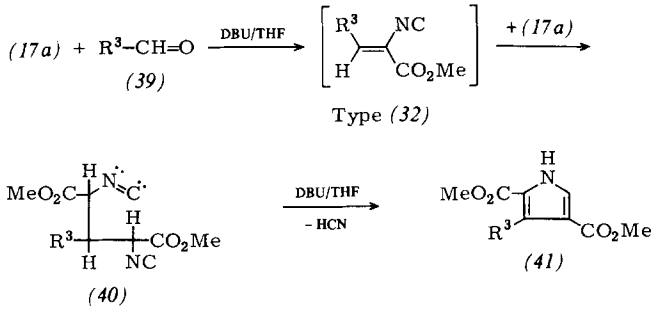
2-Imidazolines of type *(29)* warrant interest on account of their proven or potential pharmacological activity[20]. They are usually synthesized by ring closure from 1,2-diamines of type *(31)*; however, the latter are often difficult to prepare. Furthermore, ring closure to give 2-unsubstituted 2-imidazolines is problematical[20]. Since imidazolines are readily susceptible to acid hydrolysis, being cyclic amidines, this synthesis is also suitable for preparation of 1,2-diamines *(31)* or 2,3-diaminoalkanoic acids (α,β-diamino acids) *(31)*, $R^1 = CO_2H$[21], which are likewise biologically active or potentially so.

2.4. 2-Pyrrolines and Pyrroles

Reaction of, for example, ethyl isocyanopropionate *(34)* with α,β-unsaturated carbonyl compounds *(35)*, at room temperature under the conditions of the Michael addition, affords ethyl 2-isocyano-2-methyl-5-oxoalkanoates *(36)*[22], which cyclize to the pyrrolines *(37)* on heating to 70—80 °C, after abstraction of a proton from an α position to the carbonyl group[22]. Other Michael acceptors, such as acrylonitrile, react similarly[23].

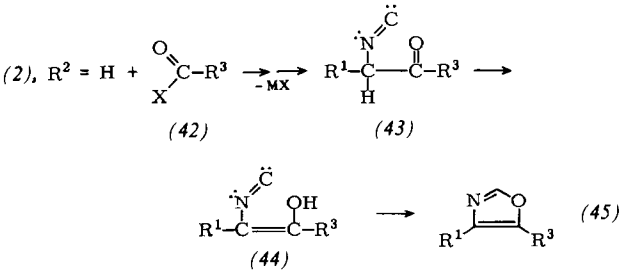


(34) *(35)* *(36)*

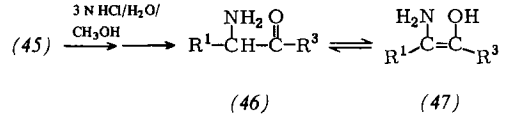


(37)

Particular preparative interest attaches to a synthesis developed by *van Leusen et al.*[24] for 3-acyl-substituted pyrroles of type *(38)* by reaction of *p*-toluenesulfonylmethyl isocyanide *(19)* with activated olefins *(35)* in glycol dimethyl ether/dimethyl sulfoxide with sodium hydride as base[24,25]. Michael addition and cyclization are followed by elimination of toluenesulfinate and tautomerization. 2-Unsubstituted 3-acylpyrroles are not readily accessible by conventional methods because Friedel-Crafts acylation occurs preferentially in position 2 of pyrroles.

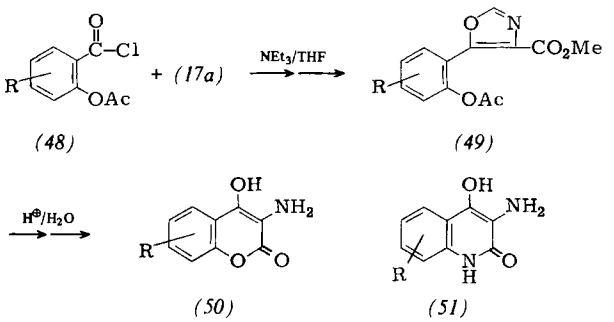


According to *Matsumoto et al.*[26], dimethyl 2,4-pyrroledicarboxylate *(41)* is formed on reaction of methyl isocyanoacetate *(17a)* (two equivalents) and an aldehyde *(39)* (one equivalent) in tetrahydrofuran in the presence of DBU. The course of this reaction, which was previously observed by *Schöllkopf* and *Schröder*[27] is still unclear in its details. Methyl α-isocyanoacrylate *(31)* is proposed as intermediate[26], and is assumed to give the pyrroledicarboxylate *(41)* *via* a Michael adduct *(40)*. The postulated methyl isocyanoacrylate *(32)* could neither be detected by spectroscopy nor trapped by addition of other nucleophiles; it would hardly be expected under these conditions (cf. Section 4.2), and yet control experiments showed that it does indeed give the esters *(41)* on reaction with methyl isocyanoacetate *(17a)* in the presence of DBU[26].

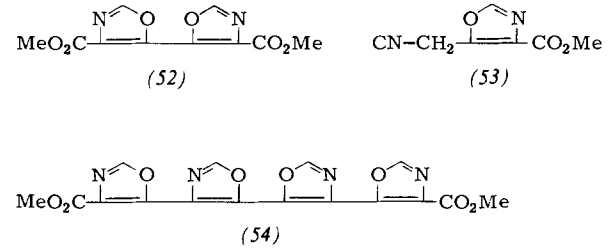


2.5. Oxazoles, Imidazoles, Thiazoles, and 2-Imidazolin-5-ones

Oxazoles *(45)* are formed on treatment of α-metalated isocyanides *(2)*, $R^2 = H$, with acylating agents *(42)* such as acyl chlorides, esters, *N*,*N*-dialkylamides, or imidazolides[28-30]. The intermediate α-isocyanoketones *(43)* are not isolable; they cyclize *via* the enols *(44)* to give oxazoles *(45)* on workup.

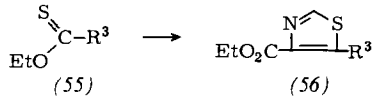


In some cases—especially with acyl chlorides—two equivalents of the metalated isocyanide *(2)* are required because the strongly acidic isocyano ketone *(43)* protonates unreacted *(2)*. However, an optimum choice of acylating agent, metalating agent, solvent, and reaction conditions also leads to good yields of oxazoles *(45)* when *(2)* and *(42)* are used in a ratio of 1 : 1[28-30].

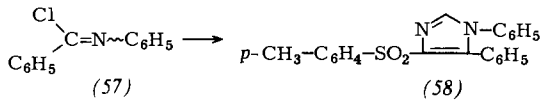


Oxazoles are valuable synthetic intermediates[31]. Their acid hydrolysis affords α-amino ketones *(46)* which are in equilibrium with α-amino enols *(47)*.

3-Amino-4-hydroxycoumarin derivatives *(50)*, which are key components for the preparation of bactericidal compounds, have been synthesized by *Matsumoto et al.*[32]. Their approach was to treat 2-chloroformylphenyl acetate *(48)* with methyl isocyanoacetate *(17a)* (in tetrahydrofuran with triethylamine as base) in order to obtain the oxazole derivatives *(49)* which yield the coumarin *(50)*[32] in a straightforward reaction on acid hydrolysis. 3-Amino-4-hydroxy-2(1*H*)-quinolinones *(51)* were synthesized in analogous fashion[33].

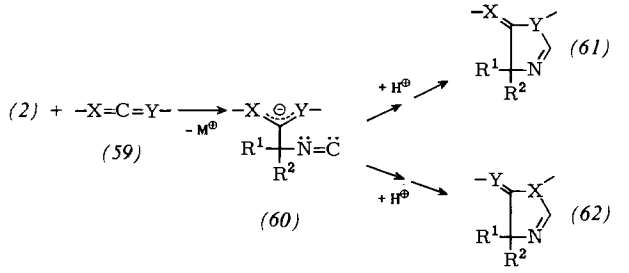


Not only monocyclic heterocycles can be synthesized with α-metalated isocyanides, but also sequences of heterocycles. Thus methyl isocyanoacetate *(17a)* and oxalyl diimidazolide—prepared *in situ* from oxalyl dichloride and imidazole[34]—react smoothly (in tetrahydrofuran with triethylamine as base) to give dimethyl 5,5′-bioxazole-4,4′-dicarboxylate *(52)*, while lithiated methyl 5-isocyanomethyl-4-oxazolecarboxylate *(53)*, the self-condensation product of methyl isocyanoacetate *(17a)*[30,35], yields dimethyl 5,4′:5′,5″:4″,5‴-quateroxazole-4,4‴-dicarboxylate *(54)* with oxalyl dichloride.

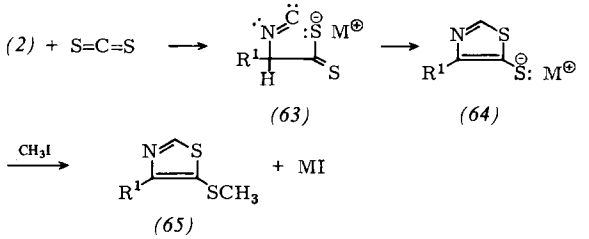


α-Metalated isocyanides *(2)* also react with hetero-analogous acylating agents. *Hartmann et al.*[36] obtained ethyl 4-thiazolecarboxylates *(56)* from thionic esters *(55)* and ethyl isocyanoacetate *(17b)* (in methanol with potassium cyanide as catalyst), and *van Leusen et al.*[37] prepared 1,5-diphenyl-4-(*p*-

toluenesulfonyl)imidazole *(58)* from α-metalated *p*-toluenesulfonylmethyl isocyanide *(19)* and the imidoyl chloride *(57)*.

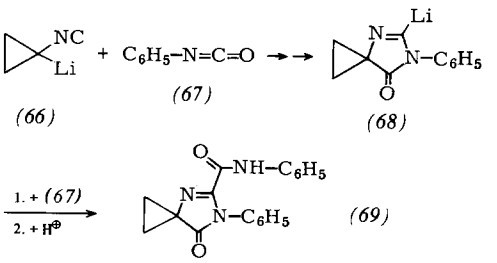


(55) *(56)*



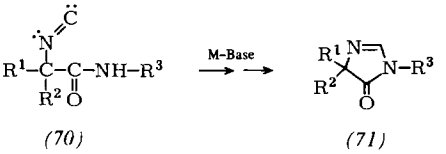
(57) *(58)*

Reactions of α-metalated isocyanides *(2)* with heteroallenes *(59)* have not yet been studied systematically. If $X \neq Y$, the intermediates *(60)* can cyclize to the heterocycles *(61)* or *(62)*.



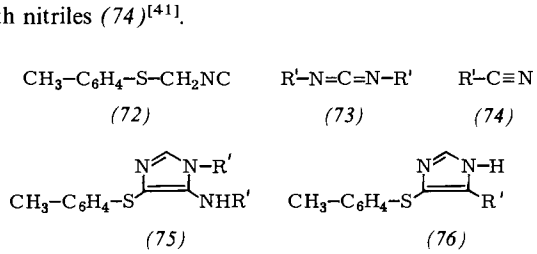
(59) *(60)* *(61)* *(62)*

α-Metalated isocyanides *(2)*, $R^2 = H$, react with carbon disulfide *via* the intermediates *(63)* to give thiazolethiolates *(64)*, which afford 5-(methylthio)thiazoles *(65)* with methyl iodide[38]. Other 5-(alkylthio)thiazoles should be accessible in analogous manner.



(63) *(64)* *(65)*

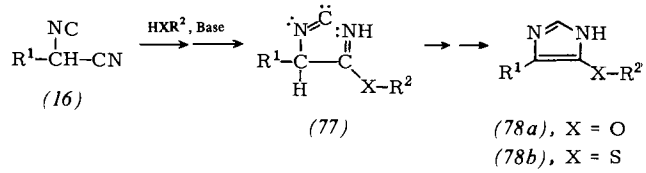
Reaction of 1-lithiocyclopropyl isocyanide *(66)* (in tetrahydrofuran at −65 °C) with phenyl isocyanate *(67)* gives mainly the bisadduct *(69)*[39] because the intermediate *(68)* quickly reacts with remaining isocyanate *(67)*.



(66) *(67)* *(68)* *(69)*

2-Unsubstituted 5-imidazolinones of type *(71)* are formed, however, when 2-isocyanoalkanamides *(70)*—prepared from methyl 2-isocyanoalkanoates and amines with *p*-toluenesulfonic acid as catalyst[40]—are subjected to base-induced cyclization[40].

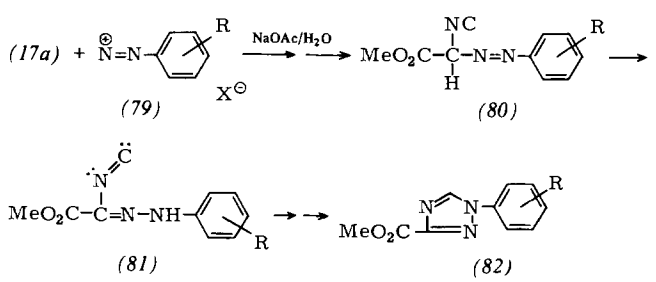
(70) *(71)*



α-Metalated (4-methylphenylthio)methyl isocyanide *(72)* gives 5-amino-4-(4-methylphenylthio)imidazoles *(75)* with carbodiimides *(73)*; and 4(5)-(4-methylphenylthio)imidazoles *(76)* with nitriles *(74)*[41].

(72) *(73)* *(74)* *(75)* *(76)*

3. Other Heterocyclic Syntheses

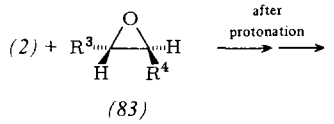


Alkyl isocyanides of type *(4)* containing a nucleophilic group Y which are able to undergo heterocyclization according to Scheme 1 (b), are not only accessible *via* Scheme 1 (a). It is self-evident that α-metalated isocyanides *(2)* are not essential for their preparation. Examples are provided by the synthesis of imidazolinones *(71)* by ring closure of the isocyano carboxamides *(70)* or cyclization of 2-iminoalkyl isocyanides *(77)*, formed by addition of alcohols or thiols (in the presence of basic catalysts) to isocyanonitriles *(16)*, to give the novel 5(4)-alkoxy- or 5(4)-(alkylthio)imidazoles *(78)*[42].

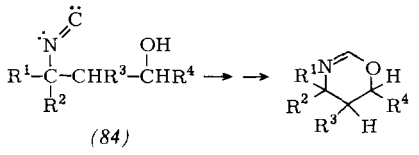
(16) *(77)* *(78a)*, X = O; *(78b)*, X = S

3.1. Triazoles

Like methyl cyanoacetate, methyl α-isocyanoacetate *(17a)* can also be coupled to arenediazonium ions *(79)* (in aqueous methanol with sodium acetate as base). The initially formed azo compounds *(80)* cyclize *via* the hydrazones *(81)* to give methyl 1-aryl-1*H*-1,2,4-triazole-3-carboxylates *(82)*[43].



(17a) *(79)* *(80)* *(81)* *(82)*

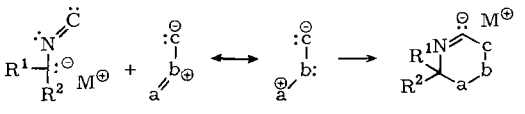


3.2. 5,6-Dihydro-4*H*-1,3-oxazines and -thiazines

Expectedly, α-metalated isocyanides *(2)* add to epoxides *(83)*, giving 3-hydroxy-alkyl isocyanides *(84)* which can be cyclized[44] to 5,6-dihydro-4*H*-1,3-oxazines *(85)*, *e.g.* by warming with cuprous oxide in benzene[44]. The additions *(2)* + *(83)* → *(84)* take place in accord with the pattern valid

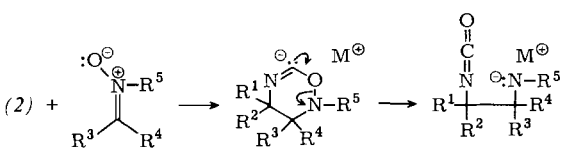
for nucleophilic epoxide cleavage; *i.e.* the sterically less hindered carbon atom is substituted with inversion[44].

(83)



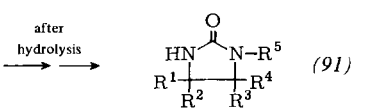
(84) *(85)*

Dihydrothiazines [S in place of O in *(85)*] are accessible analogously[45], although some episulfides [S in place of O in *(83)*] are attacked by α-metalated isocyanides *(2)* at sulfur in a reaction which is not entirely unexpected by the organometallic chemist[45].



3.3. 2-Imidazolidinones

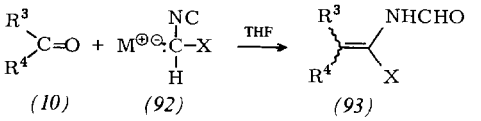
α-Metalated isocyanides *(2)* are ambivalent reagents. Consequently, they should react with the likewise ambivalent 1,3-dipoles *(86)*[46] to form metalated six-membered heterocycles of type *(87)*.



(2) *(86)* *(87)*

Among the numerous 1,3-dipoles[46] we have so far tried only nitrones *(88)*, which we found to give 1-substituted 2-imidazolidinones *(91)*[47]. This shows that cycloaddition to give *(89)* [according to *(2)* + *(86)* → *(87)*] is followed by ring opening to the metalated 2-isocyanato amines *(90)* which undergo straightforward further reaction to form the imidazolidinones *(91)*.

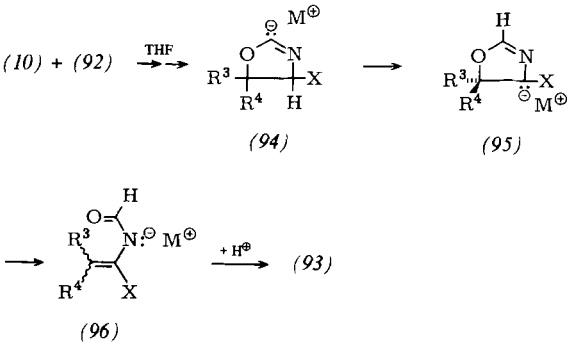
(88) *(89)* *(90)*



(91)

4. Formylaminomethylenation of Carbonyl Compounds

4.1. General

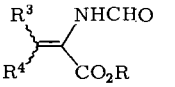


Reaction of α-metalated isocyanides of type *(92)* bearing a relatively strongly acidifying group X on the isocyano-substituted carbon atom with carbonyl compounds *(10)* in an aprotic medium gives *N*-(1-alkenyl)formamides of type *(93)* bearing the group X in the α position (Scheme 3). An oxo oxygen atom is formally replaced by the formylaminomethylene group in this reaction[27].

(10) *(92)* *(93)*

Scheme 3. Formylaminomethylenation of carbonyl compounds. X: substituent exerting a (−M) effect.

Formylaminomethylenation begins (cf. also Section 2.1) with nucleophilic carbonyl addition and formation of the 2-metalated oxazoline *(94)*. This product isomerizes by (probably intermolecular) proton shift from C-4 to C-2, to the oxazolinyl anion *(95)* in which the substituent X stabilizes the negative charge on C-4. Fast electrocyclic ring opening transforms *(95)*—at −70 to 0°C—into the "heteropentadienyl anion" *(96)* which can be isolated as the *N*-alkenylformamide *(93)* after protonation.

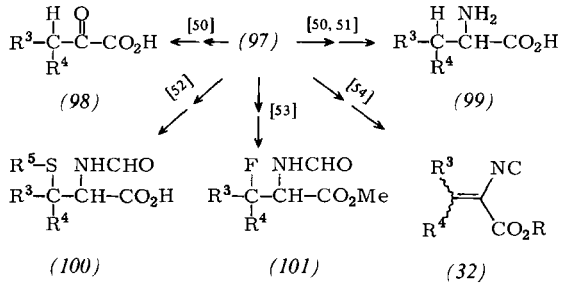


(94) *(95)* *(96)*

The following examples involving three types of α-metalated isocyanides *(92)*—*viz.* metalated isocyanoacetic esters [*(17)*, *i.e.* X = CO_2R], metalated *p*-toluenesulfonylmethyl isocyanide [*(19)*, *i.e.* X = SO_2—C_6H_4—CH_3], and metalated 3- and 4-pyridylmethyl isocyanides [X = 3- or 4-pyridyl]—should provide an indication of the scope of formylaminomethylenation.

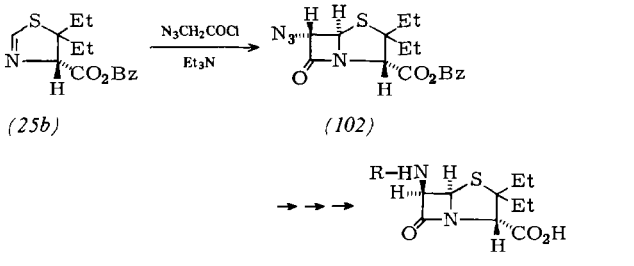
4.2. α-Formylaminoacrylic Esters

α-Formylaminoacrylic esters *(97)* are obtained by formylaminomethylenation of aldehydes and ketones *(10)* with isocyanoacetate esters *(17)*. Two procedures have proved especially valuable. In the first one, the ester *(17)* is metalated with potassium *tert*-butoxide in tetrahydrofuran at −70°C; the carbonyl compound *(10)* is added and workup is as usual after warming to room temperature[27]. However, the sterically hindered carbonyl group in 3-methoxyestrone could be formylaminomethylenated in good yield only by refluxing in THF[48]. In the second procedure, sodioisocyanoacetic ester [type *(92)*, X = CO_2R] is generated *in situ* (in tetrahydrofuran) with sodium hydride as base. *(17)* and the carbonyl compound *(10)* are simultaneously added dropwise at 20°C[27,49].



(97a), R = Me
(97b), R = Et

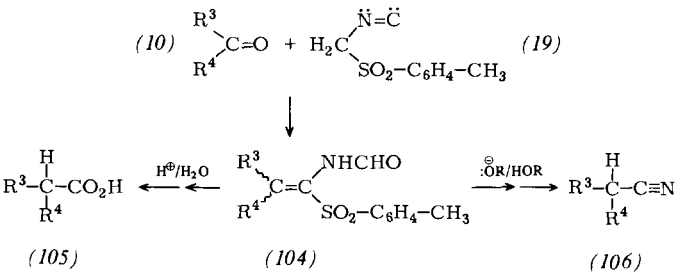
Formylaminomethylenation has several advantages over the classical azlactone procedure of *Erlenmeyer*[50] which gives



α-acylaminoacrylic acids. Less reactive carbonyl compounds can usually also be formylaminomethylenated under mild conditions and in good yields. Moreover, reaction gives not the acids but the esters which are more valuable for further reactions, and the formyl group can be removed easily and selectively.

Some of the many applications of formylaminoacrylic esters *(97)* are surveyed in Scheme 4.

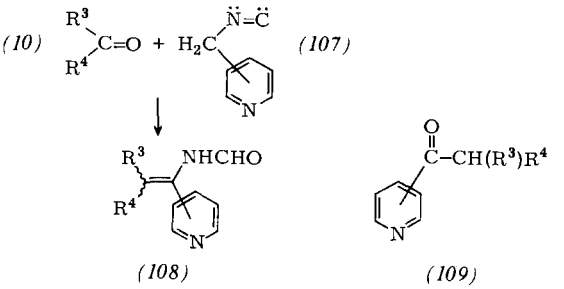
Scheme 4. Some of the derivatives accessible from α-formylaminoacrylic esters *(97)*. R = Me or Et.



α-Isocyanoacrylic esters *(32)* add nucleophiles with great avidity at their double bond[54]. The addition products can be cyclized to heterocycles with ester groups. Thus, as already mentioned (cf. Section 2.3), reaction with ammonia gives 2-imidazoline-4-carboxylic esters of type *(29b)*[19], and that with hydrogen sulfide gives 5-substituted 2-thiazoline-4-carboxylic esters of type *(25)*[55a] (cf. also Section 2.2), which are of interest as starting compounds for synthesis of modified penicillins. For example, *Claes* and *Vanderhaeghe*[55b] synthesized (±)-2,2-diethyl-6β-phenoxyacetamidopenam-3α-carboxylic acid *(103)*, a structural variant of penicillin V, *via* the 6-azido-2,2-diethylpenamic ester *(102)* from benzyl 5,5-diethyl-2-thiazoline-4-carboxylate *(25b)*.

(103), R = $C_6H_5OCH_2CO$

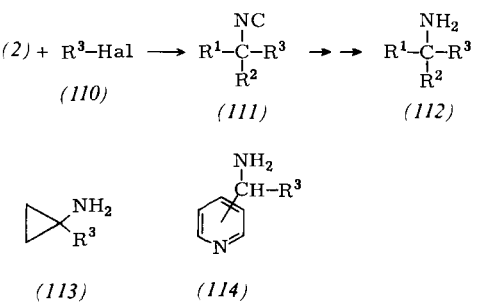
4.3. *N*-(1-Toluenesulfonyl-1-alkenyl)formamides; Chain Elongation of Ketones



Formylaminomethylenation of ketones *(10)* with *p*-toluenesulfonylmethyl isocyanide *(19)* affords *N*-(1-toluenesulfonyl-1-alkenyl)formamides *(104)*[15]. These compounds can be transformed into the carboxylic acids *(105)*[15] with aqueous acids and into the nitriles *(106)* with alkoxide[56, 57]. This means that formylaminomethylenation with *(19)* solves an important problem of preparative organic chemistry, *i.e.* the straightforward and productive transformation of a ketone *(10)* into the next-higher carboxylic acid *(105)* or the next-higher nitrile *(106)*. Mention should be made of a particularly convenient single-pot process developed by *van Leusen et al.*[56] for the transformation *(10)* → *(106)*.

4.4. *N*-(1-Pyridyl-1-alkenyl)formamides

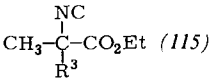
Since the pyridine ring exerts a comparatively strong electron-attracting effect—and can therefore function as X in *(92)*—aldehydes and ketones *(10)* can be formylaminomethylenated[58] with 3- or 4-pyridylmethyl isocyanides *(107)* to give *N*-(1-pyridyl-1-alkenyl)formamides of type *(108)*. Metalation is again best accomplished with (excess) potassium *tert*-butoxide (in THF as solvent). Reactions of *(107)* can also be conducted in such a way that 4-(3- and 4-(4-pyridyl)-2-oxazolines of type *(13)* are isolated[8]. On acid hydrolysis, the *N*-alkenylformamides *(108)* yield 3- and 4-acylpyridines *(109)*[58]. The procedure should also provide an entry to those pyridyl ketones which are accessible only with difficulty, if at all, by conventional methods.



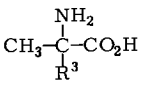
Heteroanalogs of benzyl isocyanide other than *(107)* should also react in the same way.

5. Chain Elongation of Primary Amines According to Scheme 2

5.1. Chain Elongation with Alkylating Agents; Amino Acid Synthesis



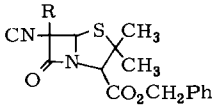
Chain elongation of common primary amines *(6)* with alkyl halides *(110)* as $E^{\oplus}$ to give higher amines *(112)*—as studied for a series of examples[59]—proceeds according to Scheme 2 *via* the metalated isocyanides *(2)*. In this way amines can also be prepared which cannot be obtained otherwise, or only with difficulty. For example, the tertiary cyclopropyl-



amines *(113)* are accessible *via* cyclopropyl isocyanide *(66)*, H in place of Li, or the 1-(pyridyl)alkylamines *(114)* *via* (pyridyl)methyl isocyanides *(107)*[59].

Reaction of α-metalated 2-isocyanopropionic ester, prepared from the ester *(34)* and potassium *tert*-butoxide or sodium hydride in THF or THF/DMSO[60, 61], with alkyl halides furnishes the higher 2-isocyano-2-methylalkanoic esters *(115)* and thence, by hydrolysis, amino acids[60, 61]. Examples are provided by the synthesis of α-methylphenylalanine *(116)*[60] or α-methylhistidine *(117)*[61b]. In attempts to synthesize optically active α-methyldopa *(118)*, alkylation of optically active menthyl and bornyl α-isocyanopropionate with 3,4-dimethoxybenzyl bromide was investigated. While the product yields were 80—85%, the enantiomeric purity was only 10%[61c].

Predictably, the reaction can also be applied to α-isocyano carboxamides. Thus benzyl 6-isocyanopenicillanate *(119a)* can be transformed, in dimethylformamide *via* the potassium derivative *(119b)* (readily obtained with potassium carbonate), into the compounds *(119c)* alkylated at C-6[62] whose isocyano group can then be converted into the amino group by *p*-toluenesulfonyl hydrate[62].

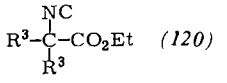


(115)

(116), $R^3 = CH_2-C_6H_5$

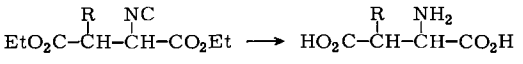
(117), R^3 = 4-Imidazolyl

(118), R^3 = 



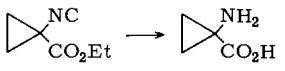
(119a), R = H

(119b), R = K

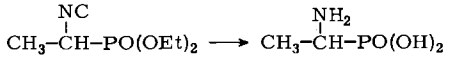


(119c), R = Alkyl

(119d), R = $CH_2-CH_2-CO_2Et$



On alkylation of ethyl isocyanoacetate *(17b)* with "small" and/or particularly reactive alkyl halides *(110)*, bisalkylation to give *(120)* predominates[60]; nevertheless, α-halo carboxylic esters give satisfactory yields (in dimethyl sulfoxide with sodium hydride as base) of isocyanosuccinic esters of type *(121)*[63], which furnish aspartic acids *(122)* on hydrolysis[63]. The tendency to undergo double alkylation can be exploited in cycloalkylation, *e.g.* with 1,2-dibromomethane to prepare



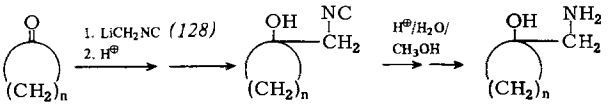
(120)

(121) *(122)*

(123) *(124)*

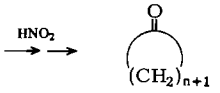
(125) *(126)*

ethyl 1-isocyano-1-cyclopropanecarboxylate *(123)*[60], the precursor of 1-amino-1-cyclopropanecarboxylic acid *(124)*.



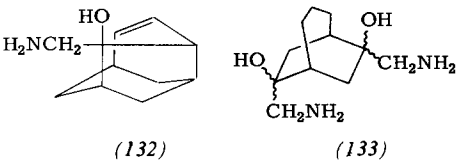
Amino acid synthesis by alkylation of 2-isocyanoalkanoic esters is comparable with the (acylamino)malonic ester method[64], and sometimes superior to it[63]. The isocyano ester procedure also permits synthesis of α-substituted amino acids.

Starting from the isocyanomethanephosphonic ester *(18)*[13], reaction of the lithium derivative with methyl iodide (in tetrahydrofuran at −70°C) gives the 1-isocyanoethanephosphonic ester *(125)*[65], whose hydrolysis should furnish 1-aminoethanephosphonic acid *(126)*. This suggests a facile synthesis of α-amino phosphonic acids—the phosphonic acid analogs of the amino acids[71].



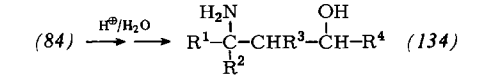
5.2. α- and β-Hydroxyalkylation of Primary Amines; Ring Expansion of Cyclic Ketones

One variant of α-hydroxyalkylation of primary amines *(6)* with carbonyl compounds *(10)* to form 2-amino alcohols *(15)* has already been mentioned in connection with 2-oxazoline syntheses (Section 2.1)[8]. Another variant consists in trapping of the adducts of type *(11)* obtained from *(2)* and *(10)* as isocyano alcohols *(14)* by addition of glacial acetic acid, and conversion of *(14)* into amino alcohols *(15)*, *e.g.* with hydrochloric acid in methanol. Which of the two methods is more favorable will have to be established from case to case.



In the isocyanomethyllithium process for ring expansion of cyclic ketones, the cyclic ketone *(127)* is treated with isocyanomethyllithium *(128)* to give 1-(isocyanomethyl)-1-cycloalkanol *(129)*, which is hydrolyzed to the aminomethyl compound *(130)* before being subjected to a Tiffeneau-Demyanov rearrangement to yield the ring-enlarged ketone *(131)*[9b]. Recent applications of this procedure lie in the synthesis (and Tiffeneau-Demyanov rearrangement) of the tricyclic 2-amino alcohol *(132)*[66] and the bis(aminomethyl) compound *(133)*[67], which is not accessible by conventional methods from the diketone.

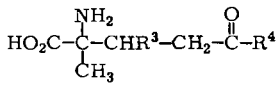
(127) *(129)* *(130)*



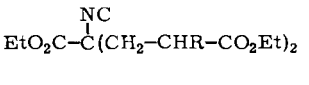
(131)

(132) *(133)*

In the β-hydroxyalkylation of primary amines *(6)* the α-metalated isocyanides *(2)* are allowed to react with epoxides



(84) *(134)*

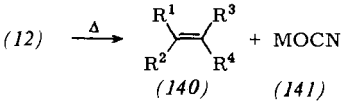


(83) (cf. Section 3.2) and the resulting 3-hydroxyalkyl isocyanides *(84)* are hydrolyzed to the 3-amino alcohols *(134)*[44].

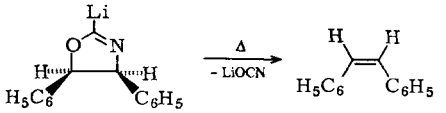
5.3. Chain Elongation by Michael Addition or Cyanoethylation

The Michael addition of 2-isocyanopropionic ester *(34)* to α,β-unsaturated carbonyl compounds *(35)*, giving the adducts *(36)*, has already been mentioned in Section 2.4. Hydrolysis of *(36)* should afford the amino acids *(135)*[22]. Ethyl isocyanoacetate *(17b)* reacts with sterically unhindered Michael acceptors to give bisadducts, such as *(136)* with ethyl acrylate, *(137)* with ethyl methacrylate[22], *(138)* with acrylonitrile, or *(139)* with methacrylonitrile[23]. Benzyl 6-isocyanopenicillanate *(119a)* gives the Michael adduct *(199d)* with ethyl acrylate[62].

(135)



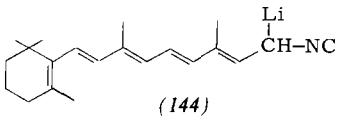
(136), R = H
(137), R = CH_3



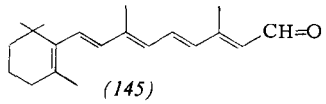
(138), R = H
(139), R = CH_3

6. Carbonyl-Olefination with α-Metalated Isocyanides

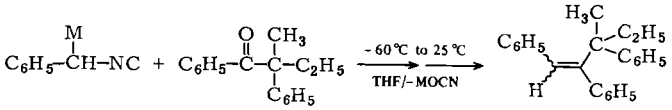
Some of the 2-metalated oxazolines *(12)* formed from α-metalated isocyanides *(2)* and carbonyl compounds *(10)* decompose to olefins *(140)* and metal cyanate *(141)* on warming (in tetrahydrofuran)[2].



(140) *(141)*



(142) *(143)*



Since cyanate elimination is stereospecific—as illustrated by *(142)* → *(143)*[68]—we formulate the reaction as a 1,3-dipolar cycloreversion. Such a process is only rarely observed, in contrast to 1,3-dipolar cycloaddition[46]. Viewed preparatively, the reaction *(2)*+*(10)*→*(140)*+*(141)* amounts to a carbonyl-olefination. However, compared with the Wittig reaction it is of minimum significance because cyanate elimination can occur only if highly conjugated or phenyl-substituted olefins are formed. For example, all-*trans*-α-lithioretinyl isocyanide *(144)* and all-*trans*-retinal *(145)* give isomer-free (all-*trans*-)β-carotene[69], while lithio- or potassiobenzyl isocyanide *(146)* and highly sterically hindered (and hence inert) 2-methyl-1,2-diphenyl-1-butanone *(147)* cleanly afford 3-methyl-1,2,3-triphenyl-1-pentene *(148)*[70]. The olefination *(147)* → *(148)* should no longer occur with the relatively inert

(144)

(145)

(146), M = Li, K *(147)* *(148)*
